PREFACE

This volume contains the full-length papers accepted for presentation at the XI International Conference on Structural Dynamics EURODYN 2020, streamed online from Athens, Greece on November 23-26, 2020.

EURODYN Conference Series is organized under the auspices of the European Association of Structural Dynamics (EASD). EASD was founded in 1990 as a joint European initiative of experts in Structural Dynamics, with the purpose of sponsoring and overseeing the organization of the EURODYN conferences, scheduled to take place with a three-year interval. The first EURODYN Conference was held in Bochum in 1990, organized by the founding president of EASD Prof. Wilfried Krätzig. Following Bochum, the conferences were held in Trondheim (1993), Florence (1996), Prague (1999), Munich (2002), Paris, (2005), Southampton (2008), Leuven (2011), Porto (2014), Rome in 2017 and this year in Athens, the city where the EURODYN 2020 conference would have taken place in June 2020.

In view of the first signs of the COVID-19 pandemic at the beginning of this year, we were forced to postpone the conference dates at the end of November 2020. This was expected to give the opportunity to the participants to attend the conference either physically or remotely. Unfortunately, and contrary to what we had all anticipated, the COVID-19 was still around at the end of June 2020, and hence we were left with no other choice but to abandon the idea of a physical conference and organize a fully online event. This transition was very painful and created many administration complications. Nevertheless, EASD and the organizing committee have seen this sanitary crisis as an opportunity to organize a different type of event and to propose a new approach for scientific collaboration and communication that respects both the legacy of the conference series and the health of the members of the European Community of Structural Dynamics.

EURODYN conferences have been established as the top scientific events in the area of theoretical, numerical and experimental Structural Dynamics worldwide and are highly-anticipated every three years by the international community of Structural Dynamics. For the 2020 edition of EURODYN series, more than 1000 abstracts were submitted, of which 830 were selected for presentation and among them 400 full-length papers were accepted for publication in the EASD Open Access Procedia, indexed by Scopus Database.

The editors of this volume would like to thank all authors for their contributions. Special thanks go to the 88 colleagues who were involved in the organization of 38 Minisymposia and to the reviewers who contributed to the scientific quality of this e-book with their work.

We would particularly like to thank the Members of the EASD Executive Board, and especially Álvaro Cunha, the President of EASD, Guido De Roeck, the Honorary Chairman of EURODYN 2020 and Fabrizio Vestroni the Chair of the EURODYN 2017, for their valuable advice, suggestions and interest, during the three-year preparation period of EURODYN 2020. Their contributions were significant to the successful outcome of this undertaking.

ACKNOWLEDGEMENTS

The conference organizers acknowledge the support towards the organization of the "XI International Conference on Structural Dynamics", to the following organizations: European Association for Structural Dynamics (EASD), Greek Association for Computational Mechanics (GRACM), Hellenic Society for Earthquake Engineering (HSEE), School of Civil Engineering, National University of Athens (NTUA).

Plenary, Semi-Plenary Speakers and Minisymposia Organizers

We would also like to thank the Plenary and Semi-Plenary Speakers and the Minisymposia Organizers for their help in the setting up of a high standard Scientific Programme.

Plenary Speakers: Geert Degrande, Tracy Kijewski-Correa, Yi Qing Ni

Semi-Plenary Speakers: Eleni Chatzi, Joel P. Conte, Geert Lombaert, Andrei Metrikine, Sotirios Natsiavas, Filippo Ubertini

MS Organizers: I. Antoniadis, M. Arnst, K. Bakalis, B. Balachandran, C.C. Baniotopoulos, M. Barbato, J. Beck, M. Beer, G. Bonnet, C. Borri, C. Boutin, L. Bruno, E. Caetano, F. Casciati, C.A. Keywords: liquid storage tank, seismic response, soil-structure interaction, fluid-structure interaction, shells

Abstract. *The paper establishes a computationally inexpensive method to deal with the dynamic response of liquid storage tanks subjected to seismic excitation including dynamic soil-structure interaction. The tank is modelled as a thin shell, the stored liquid is described as an inviscid and incompressible fluid and the soil medium is modelled as an elastic continuum. The dynamic response of the tank-liquid-soil system is derived in the frequency domain using dynamic substructuring and mode matching. The tank vibrations are first expressed in terms of the in-vacuo shell modes while the liquid motion is described as a superposition of linear potentials. The soil reaction to the plate of the tank is derived on the basis of a boundary integral formulation with the excitation field being the seismic free-field ground motion. Due to its high computational efficiency, the proposed method is suitable when a large number of simulations is required as is the case in seismic risk analysis. It overcomes the limitations of most mechanical analogues used nowadays, while at the same time maintains an accuracy comparable to that of finite element models within a fraction of the computation time of the latter.*

1 INTRODUCTION

The dynamic response of liquid storage tanks subjected to ground excitation has been a subject of continuous research over the past decades [1]. Despite the many modelling techniques available, most models can be classified into two broad categories: Finite Element (FE) models [2] and simplified mechanical analogues with a few degrees of freedom [3, 4].

In a simplified model, the various components of the tank-liquid system are described by point masses, springs and dashpots at certain locations [5]. Such models are useful for engineering purposes since they can prognosticate the base shear force and the overturning moment [6], however, they have certain limitations. First, they provide estimations of the design stresses at the base of the tank alone. Second, when they need to consider shells of non-uniform thickness or dynamic soil-structure interaction, they become needlessly complex, and even though procedures are described in the design codes to incorporate some of these effects [7], these procedures are approximate and cannot always guarantee accurate solutions. On the contrary, when a detailed dynamic analyis is required, FE modelling is often considered. Detailed FE models can overcome most of the limitations of the simpler models described earlier, however, they are computationally expensive and require experienced end users. In addition, the modelling of the unbounded soil domain and the proper inclusion of the seismic excitation remain always a challenge.

To overcome the disadvantages of the aforementioned modelling methods, this paper introduces an alternative method of numerical analysis of the tank-liquid-soil system. By doing so, one can overcome the main disadvantage of the FE models while, at the same time, computational accuracy stays uncompromised. The linear dynamic response of the tank-liquid-soil system is derived in the frequency domain using a mode-matching, dynamic substructuring technique. The substructuring technique, together with the Rayleigh-Ritz method, have been previously employed in [8, 9] for the solution of tank-liquid dynamic problems albeit in the absence of dynamic soil-structure interaction (SSI). In contrast to these earlier works, in this paper the eigenvalue problems are first formulated to obtain the modes of vibration of the tank and the liquid satisfying a set of predefined boundary conditions in an exact manner. Once the vibration modes of the tank and the liquid are determined to within a set of unknown complex-valued coefficients, the latter are obtained by ensuring the kinematic compatibility at the tank-liquid interface and by satisfying the equations of motion of the shell structure subjected to seismic motion. In addition to that, the dynamic reaction of the soil at the bottom side of the plate is considered through a boundary integral formulation in line with Lin et al. [10], thus coupling the tank-liquid system to the soil modelled as a three-dimensional continuum.

The main novelty of the paper lies in the establishment of a computationally inexpensive method to obtain the solution of the fully coupled tank-liquid-soil system subjected to seismic excitation. The computational efficiency stems from the adoption of the dynamic substructuring technique and the fact that for each substructure a standard eigenvalue problem is first solved before the forced response is treated. As will be shown, for low frequency seismic excitations, a few modes usually suffice to reach satisfactory convergence which adds to the computational speed. Furthermore, the solution technique proposed is very efficient and does not require the treatment of the whole coupled problem anew every time one of the substructures alters, i.e. varying liquid volume in the tank or soil composition. Given that, the authors believe that the proposed method is especially useful when a large number of simulations are required as, for example, is the case in seismic risk analyses and probabilistic assessments; cases in which the engineer is usually restricted to the use of simplistic models not capable of capturing all possible

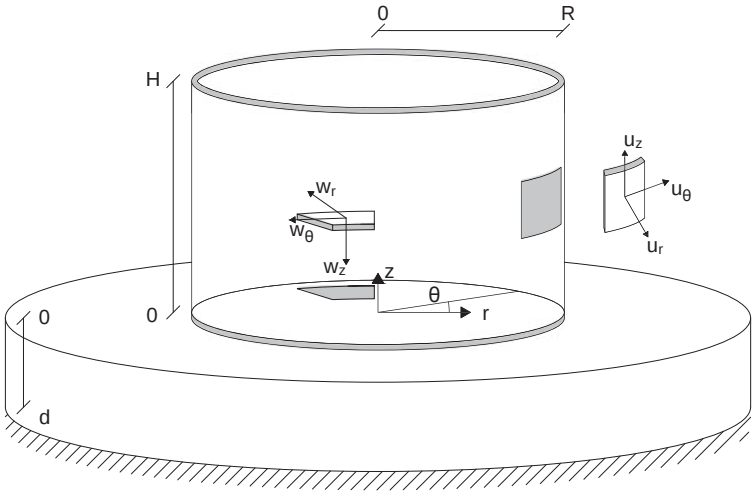

Figure 1: Definition of the displacement components and of the local coordinate system of the tank-liquid-soil system.

failure mechanisms.

In chapter 2, the model is described including the governing equations. The solution method for each subsystem is covered in detail in chapter 3, while chapter 4 establishes the algebraic system of equations that yields the solution to the coupled tank-liquid-soil problem subjected to a seismic excitation. In chapter 5, a convergence analysis is performed and model predictions are compared with FE simulations. Finally, chapter 6, summarises the main results of the paper.

2 MODEL DESCRIPTION

A typical liquid storage tank is shown in Fig.1. The shell structure consists of a circular plate and a cylindrical wall with the parameters E, ν, h and ρ corresponding to the Young's modulus, the Poisson's ratio, the thickness, and the density of the various parts of the shell, respectively. A cylindrical global coordinate system is adopted (r, θ, z) in which r is the radial coordinate, θ is the circumferential coordinate and z is the vertical coordinate. The tank is filled with liquid up to a height of $H_l \leq H$ with H being the height of the wall of the tank. The liquid is assumed inviscid and incompressible with a density ρ_l. The soil column of depth d that supports the tank is modelled as a linear elastic continuum with material parameters ρ_s, λ, μ corresponding to the density and the two Lamè constants of the elastic continuum, respectively. The seismic excitation is included through the free-field ground motion.

The governing equations describing the tank dynamic response read:

$$\boldsymbol{L}_p \boldsymbol{w}_p(r,\theta,t) + \rho_p h_p \ddot{\boldsymbol{w}}_p(r,\theta,t) = \boldsymbol{\sigma}_s(r,\theta,t) + \boldsymbol{p}_p(r,\theta,t) \tag{1}$$

$$\boldsymbol{L}_w \boldsymbol{u}_w(\theta,z,t) + \rho_w h_w \ddot{\boldsymbol{u}}_w(\theta,z,t) = \boldsymbol{p}_w(\theta,z,t) \tag{2}$$

in which $\boldsymbol{w}_p = [w_r, w_\theta, w_z]^{\mathrm{T}}$ is the displacement vector of the mid-surface of the plate, $\boldsymbol{L}_p$ is the stiffness operator of the plate [11], $\boldsymbol{\sigma}_s = [\tau_{rz}, \tau_{r\theta}, \sigma_z]^{\mathrm{T}}$ represents the boundary stress vector induced by the interaction with the soil (including the seismic excitation), and $\boldsymbol{p}_p = [0, 0, p_{liq}]^{\mathrm{T}}$ accounts for the pressure of the stored liquid. Next to that, $\boldsymbol{u}_w = [u_r, u_\theta, u_z]^{\mathrm{T}}$ denote

the displacement of the mid-surface of the wall along the radial, circumferential and vertical directions, respectively. The operator $\boldsymbol{L}_w$ accounts for the stiffness of the cylindrical shell [12] and the force vector $\boldsymbol{p}_w = [p_{liq}, 0, 0]^{\mathrm{T}}$ includes the pressure exerted by the motion of the stored liquid normal to the shell surface. In Eqs.(1–2), the overdot represents a derivative with respect to the time variable.

Supplementary to the equations of motion, a set of boundary and interface conditions need to be formulated to complete the statement of the problem shown in Fig.1:

$$\boldsymbol{u}_w|_{z=0} - \boldsymbol{u}_p|_{r=R} = \boldsymbol{0}\,,\; \phi_{w,z}|_{z=0} - \phi_{p,r}|_{r=R} = 0\,,\; \boldsymbol{f}_w|_{z=0} - \boldsymbol{f}_p|_{r=R} = \boldsymbol{0}\,,\; \boldsymbol{f}_w|_{z=H} = \boldsymbol{0} \tag{3}$$

In Eqs.(3), $\phi_{w,z} = -\partial u_r/\partial z$ and $\phi_{p,r} = -\partial w_z/\partial r$ and $\boldsymbol{f}_w = [M_{zz}, N_{zz}, V_{zr}, T_{z\theta}]^{\mathrm{T}}$ is the generalised force vector of the wall segment which includes the moment M_{zz}, the membrane force N_{zz} and the shear forces V_{zr} and $T_{z\theta}$ [12]. Similarly, $\boldsymbol{f}_p = [M_{rr}, V_r, N_{rr}, N_{r\theta}]^{\mathrm{T}}$ corresponds to the generalised force vector of the plate at the connection with the wall.

Considering a liquid that is inviscid and incompressible, and limiting the scope to linear vibrations, the governing equation for the liquid reads:

$$\nabla^2\phi(r,\theta,z,t) = 0 \tag{4}$$

in which $\phi(r,\theta,z,t)$ denotes the velocity potential. The interface and boundary conditions for the liquid region read:

$$\left.\frac{\partial\phi(r,\theta,z,t)}{\partial r}\right|_{r=R} = \dot{u}_r(\theta,z,t)\,,\; \left.\frac{\partial\phi(r,\theta,z,t)}{\partial z}\right|_{z=0} = \dot{w}_z(r,\theta,t) \tag{5}$$

$$\left.\left(\frac{1}{g}\ddot{\phi}(r,\theta,z,t) - \frac{\partial\phi(r,\theta,z,t)}{\partial z}\right)\right|_{z=H_l} = 0 \tag{6}$$

A single soil layer is considered and the local coordinate system is employed with the z-coordinate pointing downwards, such that the soil surface is at $z = 0$ and the bedrock at $z = d$. The equations of motion read [13]:

$$(\lambda+\mu)\nabla\nabla\boldsymbol{u}_s(r,\theta,z,t) + \mu\nabla\times\nabla\times\boldsymbol{u}_s(r,\theta,z,t) = \rho_s\ddot{\boldsymbol{u}}_s(r,\theta,z,t) \tag{7}$$

in which $\boldsymbol{u}_s = [u_{s,r}, u_{s,\theta}, u_{s,z}]^{\mathrm{T}}$. The boundary conditions and interface conditions of the soil domain at $z = 0$ and $z = d$ read:

$$\begin{array}{rcll} \boldsymbol{u}_s(r,\theta,d,t) & = & \boldsymbol{0} & \\ \boldsymbol{u}_s(r,\theta,0,t) & = & \boldsymbol{u_p}(r,\theta,t) & r \le R \\ \boldsymbol{\sigma}_s^s(r,\theta,0,t) & = & \left\{ \begin{array}{ll} \boldsymbol{0} & r > R \\ -\boldsymbol{K}_s(r,\theta,t) * \left(\boldsymbol{u}_s^f(r,\theta,0,t) - \boldsymbol{u}_p(r,\theta,t)\right) & r \le R \end{array} \right. & \end{array} \tag{8}$$

in which $\boldsymbol{\sigma}_s^s$ is the surface traction acting on the plate along the r-, θ- and z-coordinate at $z = 0$ and the asterisk denotes a convolution operation. The term $\boldsymbol{K}_s(r,\theta,t)$ denotes the dynamic stiffness of the soil column evaluated at the surface of the ground as explained in section 3.3 and $\boldsymbol{u}_s^f(r,\theta,0,t)$ is the free-field ground motion which defines here the excitation mechanism. Equations (1–8) govern the dynamics of the tank-soil-liquid system in the time domain.

3 SOLUTION APPROACH PER SUBSTRUCTURE

The governing equations (1–8) are first transformed to the frequency domain by introducing the Fourier transform pair with respect to time as follows:

$$\tilde{G}(\omega) = \int_{-\infty}^{\infty} g(t) \mathrm{e}^{-\mathrm{i}\omega t} \, \mathrm{d}t \;\text{ and }\; g(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \tilde{G}(\omega) \mathrm{e}^{\mathrm{i}\omega t} \mathrm{d}\omega, \tag{9}$$

in which $g(t)$ is understood here as the examined quantity. Complex-valued variables in the frequency domain are indicated with a tilde over the variable.

The resulting set of coupled partial differential equations need to be solved for each excitation frequency. The solution approach is based on the following steps: (i) Solution to the eigenvalue problem of the tank *in-vacuo* (section 3.1); (ii) Eigensolutions of the liquid domain (section 3.2); (iii) Derivation of the dynamic stiffness matrix of the soil at the interface with the tank in the frequency domain (section 3.3); (iv) Solution to the coupled tank-liquid-soil system by making use of the steps (i–iii) as described further in section 4.

3.1 Eigenvalue problem of the tank *in-vacuo*

The equations of motion, boundary and interface conditions for the plate and wall of the tank, neglecting the presence of the water and the soil, are transformed into the frequency domain by means of Eq.(9). The solution is found via separation of variables [14]. A set of algebraic equations is found for the *in-vacuo* shell modes after substituting the assumed solutions for the plate and the wall into the boundary and interface conditions.

$$\boldsymbol{G}_n \cdot \boldsymbol{a} = 0 \tag{10}$$

$\boldsymbol{G}_n$ denotes the coefficient matrix and $\boldsymbol{a}$ is a vector composed of the unknown constants. For a non-trivial solution, the determinant of the coefficient matrix $\boldsymbol{G}_n$ is set equal to zero, i.e. $\det(\boldsymbol{G}_n) = 0$. This results at a transcendental equation which yields an infinite set of eigenvalues ω_{nm} with $m = 0, 1, 2, 3, ...$ for each circumferential order n. A numerical algorithm is developed with the frequency ω (for every circumferential order n) defined as the running variable which is then iterated numerically to find the zeroes of the determinant. Once the values of ω_{nm} are obtained, the tank motion can be expressed as a summation of modes in the frequency domain:

$$\tilde{\boldsymbol{w}}_p(r, \theta, \omega) = \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} \tilde{X}_{nm} \boldsymbol{D}_n^t(\theta) \boldsymbol{W}_{nm}(r) \tag{11}$$

$$\tilde{\boldsymbol{u}}_w(\theta, z, \omega) = \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} \tilde{X}_{nm} \boldsymbol{D}_n^t(\theta) \boldsymbol{U}_{nm}(z) \tag{12}$$

$\boldsymbol{D}_n^t(\theta) = \textit{diag}\ [\cos(n\theta), \sin(n\theta), \cos(n\theta)]$ contains the circumferential dependency of the tank modes and $\boldsymbol{W}_{nm} = [W_{z,nm}, W_{\theta,nm}, W_{r,nm}]^{\mathrm{T}}$ and $\boldsymbol{U}_{nm} = [U_{z,nm}, U_{\theta,nm}, U_{r,nm}]^{\mathrm{T}}$ are the eigenvectors of the plate and the wall, respectively. The indices n, m define the circumferential and axial mode numbers, respectively. The unknown complex-valued amplitudes $\tilde{X}_{nm}$ can be obtained by satisfying the forced vibration problem. The eigenvectors satisfy the following orthogonality condition:

$$\rho_p h_p \iint_S \boldsymbol{D}_q^t \boldsymbol{U}_{ql}^{\mathrm{T}} \boldsymbol{D}_n^t \boldsymbol{U}_{nm} \mathrm{d}S + \rho_w h_w \iint_{S_0} \boldsymbol{D}_q^t \boldsymbol{W}_{ql}^{\mathrm{T}} \boldsymbol{D}_n^t \boldsymbol{W}_{nm} \mathrm{d}S_0 = a_n \Gamma_{nm} \delta_{qn} \delta_{lm} \,, \tag{13}$$

in which δ_{np} and δ_{ml} are the *Kronecker* deltas and S, S_0 denote the surface of integration for the wall and the plate of the tank, respectively. The scalar quantity a_n denotes an integration constant related to the circumference, i.e. $\int_0^{2\pi} D_q^t D_n^t d\theta = a_n \delta_{qn}$; a_n equals π for $n = 0$ and 2π otherwise.

3.2 Eigensolutions of the liquid domain

The liquid potential function is separated into three scalar functions, each one satisfying a subset of the imposed boundary and interface conditions. This allows an analytical treatment of the problem [15]. The total liquid potential is decomposed into three velocity potentials, namely: (i) $\phi^{(1)}(r, \theta, z, t)$ which satisfies the homogeneous boundary conditions at $z = 0$ and $z = H_l$ as well as the imposed kinematic constraint at the interface with the wall; (ii) $\phi^{(2)}(r, \theta, z, t)$ which satisfies the homogeneous boundary conditions at $r = R$ and $z = H_l$, and the imposed kinematic constraint at the interface with the plate; and (iii) $\phi^{(3)}(r, \theta, z, t)$ which does not alter the conditions satisfied already at $z = 0$ and $r = R$ but allows exact satisfaction of the boundary condition at $z = H_l$.

The superposition of the three scalar functions provides the total solution which can be expressed as follows [8]:

$$\tilde{\phi}(r, \theta, z) = \sum_{n=0}^{\infty} \sum_{a=1}^{\infty} \tilde{\phi}_{na}^{(1)} + \tilde{\phi}_{00}^{(2)} + \sum_{n=0}^{\infty} \sum_{b=1}^{\infty} \tilde{\phi}_{nb}^{(2)} + \tilde{\phi}_{00}^{(3)} + \sum_{n=0}^{\infty} \sum_{c=1}^{\infty} \tilde{\phi}_{nc}^{(3)}, \tag{14}$$

in which the following definitions hold:

$$\tilde{\phi}_{na}^{(1)}(r, \theta, z) = \tilde{P}_{na} \phi_{z,na}^{(1)}(z) \phi_{r,na}^{(1)}(r) \cos(n\theta) \tag{15}$$

$$\tilde{\phi}_{00}^{(2)}(r, \theta, z) = \tilde{Q}_{00}(z - H_l) \tag{16}$$

$$\tilde{\phi}_{nb}^{(2)}(r, \theta, z) = \tilde{Q}_{nb} \phi_{z,nb}^{(2)}(z) \phi_{r,nb}^{(2)}(r) \cos(n\theta) \tag{17}$$

$$\tilde{\phi}_{00}^{(3)}(r, \theta, z) = \tilde{S}_{00} \tag{18}$$

$$\tilde{\phi}_{nc}^{(3)}(r, \theta, z) = \tilde{S}_{nc} \phi_{z,nc}^{(3)}(z) \phi_{r,nc}^{(3)}(r) \cos(n\theta) \tag{19}$$

The modal amplitudes $\tilde{P}_{na}$, $\tilde{Q}_{nb}$, and $\tilde{S}_{nc}$ are the unknown complex constants for the liquid domain which will be determined together with the modal amplitudes of the structure by satisfying the forced equations of motion and the kinematic conditions at the tank-liquid interfaces described previously. The index n denotes the circumferential mode number of each potential. The indices a, b and c denote the axial mode numbers. The terms ε_{nb} and ε_{nc} are the roots obtained by setting $J_n'(\varepsilon) = 0$.

3.3 Dynamic stiffness of the soil

To obtain the dynamic stiffness of the soil, the equations are first transformed into the frequency-Hankel domain by means of a Fourier-Hankel transform. In this transformed domain, the dynamic stiffness matrix of a single soil layer reads [13]:

$$\begin{bmatrix} \bar{\boldsymbol{p}}(k, 0) \\ \bar{\boldsymbol{p}}(k, d) \end{bmatrix} = \begin{bmatrix} \bar{\boldsymbol{S}}_{11} & \bar{\boldsymbol{S}}_{12} \\ \bar{\boldsymbol{S}}_{21} & \bar{\boldsymbol{S}}_{22} \end{bmatrix} \begin{bmatrix} \bar{\boldsymbol{u}}(k, 0) \\ \bar{\boldsymbol{u}}(k, d) \end{bmatrix}, \tag{20}$$

in which $\bar{\boldsymbol{p}}(k, 0; d)$, $\bar{\boldsymbol{u}}(k, 0; d)$ correspond to the boundary stress and displacement vectors, respectively, and the bar denotes functions in the frequency-wavenumber domain. The matrix $\bar{\boldsymbol{S}}$

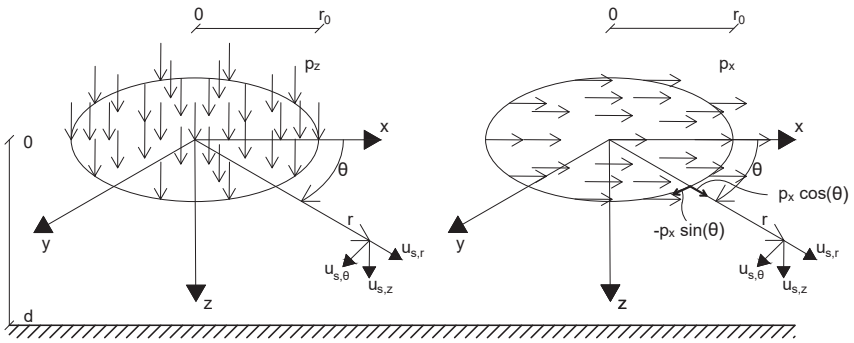

Figure 2: Vertical and horizontal loads distributed evenly over a circular subdisk.

is the dynamic stiffness matrix in the wavenumber-frequency domain. The only terms of interest in $\bar{\boldsymbol{S}}$ are $\bar{\boldsymbol{S}}_{11}$, since the stiffness is needed only at the ground surface. For the sake of brevity of the notations hereafter, we adopt $\bar{\boldsymbol{u}}(k) = \bar{\boldsymbol{u}}(k,0)$, $\bar{\boldsymbol{p}}(k) = \bar{\boldsymbol{p}}(k,0)$ and $\bar{\boldsymbol{p}}(k) = \bar{\boldsymbol{S}}_{11}\bar{\boldsymbol{u}}(k)$. The inverse of the dynamic stiffness matrix of the ground surface, i.e. the flexibility matrix, is of the form:

$$\bar{\boldsymbol{S}}_{11}^{-1} = \bar{\boldsymbol{F}} = \begin{bmatrix} \bar{F}_{11} & 0 & \bar{F}_{13} \\ 0 & \bar{F}_{22} & 0 \\ \bar{F}_{31} & 0 & \bar{F}_{33} \end{bmatrix} \tag{21}$$

Having established a relation between the stresses and displacements at the surface of the ground, one can derive the dynamic stiffness in a straightforward manner. The plate of the tank is assumed to contact the ground surface through circular areas referred to as subdiscs. The loads over a circular subdisk are expanded in Fourier series in the circumferential direction, where $n = 0$ relates to an axisymmetric load and $n = 1$ to an antisymmetric load. The complex amplitudes of the load are related by the following Fourier-Hankel transform pair [13]:

$$\begin{aligned} \bar{\boldsymbol{p}}_n(k) &= a_n \int_{r=0}^{\infty} r\boldsymbol{C}_n(kr) \int_{\theta=0}^{2\pi} \boldsymbol{D}_n(\theta)\tilde{\boldsymbol{p}}(r,\theta)\mathrm{d}\theta\mathrm{d}r \\ \tilde{\boldsymbol{p}}(r,\theta) &= \sum_{n=0}^{\infty} \boldsymbol{D}_n(\theta) \int_{k=0}^{\infty} k\boldsymbol{C}_n(kr)\bar{\boldsymbol{p}}_n(k)\mathrm{d}k \end{aligned} \tag{22}$$

In Eq.(22), a_n is a normalization factor that is equal to $1/2\pi$ or $1/\pi$ for $n = 0$ and $n \neq 0$ respectively. $\boldsymbol{D}_n$ is a diagonal matrix with trigonometric functions, describing the circumferential dependency and $\boldsymbol{C}_n$ contains Bessel functions. Three load cases are considered. A vertical load case and two horizontal load cases; one symmetric and one anti-symmetric with respect to $\theta = 0$. The derivation of the latter two cases is identical but for the trigonometric functions in $\boldsymbol{D}_n$.

The radius of each subdisk equals r_0 and the amplitudes of the vertical and horizontal loads are denoted as p_z and p_x, respectively, as shown in Fig.2. The vertical load, that is assumed uniformly distributed over the subdisc, is transformed into the wavenumber domain by means of Eq.(22):

$$\bar{\boldsymbol{p}}_0(k) = \frac{1}{2\pi} \int_{r=0}^{r_0} r\boldsymbol{C}_0(kr) \int_{\theta=0}^{2\pi} [0,0,p_z]^{\mathrm{T}}\mathrm{d}\theta\mathrm{d}r = -\frac{r_0}{k} J_1(kr_0)[0,0,p_z]^{\mathrm{T}} \tag{23}$$

$\bar{\boldsymbol{p}}_0(k)$ relates to $\bar{\boldsymbol{u}}(k)$ through the flexibility matrix Eq.(21):

$$\bar{\boldsymbol{u}}_0(k) = -\frac{p_z r_0}{k} J_1(kr_0)[\bar{F}_{13},0,\bar{F}_{33}]^{\mathrm{T}} \tag{24}$$

The displacements of the surface at any r and θ are found by:

$$\tilde{\boldsymbol{u}}_s^z(r,\theta) = -r_0 p_z \int_{k=0}^{\infty} J_1(kr_0)\boldsymbol{C}_0(kr)\left[\bar{F}_{13}, 0, \bar{F}_{33}\right]^{\mathrm{T}} \mathrm{dk} \tag{25}$$

Following a similar procedure for the horizontal load one obtains:

$$\tilde{\boldsymbol{u}}_s^x = r_0 p_x \boldsymbol{D}_1(\theta) \int_{k=0}^{\infty} J_1(kr_0)\boldsymbol{C}_1(kr)\left[\bar{F}_{11}, \bar{F}_{22}, \bar{F}_{31}\right]^{\mathrm{T}} \mathrm{dk} \tag{26}$$

Applying the load in y-direction ($\theta = \pi$), via the same steps, an expression can be found similar to Eq.(26).

The integrals in Eqs.(25–26) are evaluated by making use of contour integration. The solution derived holds both within and outside the subdisk. The resulting expressions for $r \leq r_0$ read:

$$\tilde{\boldsymbol{u}}_s^z(r,\theta) = \tilde{p}_z \left(r_0 \pi \mathrm{i} \sum_{k_r} H_1^{(2)}(k_r r_0)\boldsymbol{C}_0(k_r r) \left[\frac{\bar{F}_{13}^n}{\tilde{F}_{p,k}^d}, 0, \frac{\bar{F}_{33}^n}{\bar{F}_{p,k}^d} \right]^{\mathrm{T}} + \left[0, 0, \bar{F}_{33}(0)\right]^{\mathrm{T}} \right), \tag{27}$$

$$\tilde{\boldsymbol{u}}_s^x = -\tilde{p}_x \boldsymbol{D}_1(\theta) \left(r_0 \pi \mathrm{i} \sum_{k_r} H_1^{(2)}(k_r r_0)\boldsymbol{C}_1(k_r r) \left[\frac{\bar{F}_{11}^n}{\bar{F}_{p,k}^d}, \frac{\bar{F}_{22}^n}{\bar{F}_{s,k}^d}, \frac{\bar{F}_{31}^n}{\bar{F}_{p,k}^d} \right]^{\mathrm{T}} - \left[\bar{F}_{11}(0), \bar{F}_{11}(0), 0\right]^{\mathrm{T}} \right) \tag{28}$$

Similarly, the expressions for $r \geq r_0$ read:

$$\tilde{\boldsymbol{u}}_s^z(r,\theta) = r_0 \tilde{p}_z \pi \mathrm{i} \sum_{k_r} J_1(k_r r_0)\boldsymbol{C}_0(k_r r) \left[\frac{\bar{F}_{13}^n}{\bar{F}_{p,k}^d}, 0, \frac{\bar{F}_{33}^n}{\bar{F}_{p,k}^d} \right]^{\mathrm{T}} \tag{29}$$

$$\tilde{\boldsymbol{u}}_s^x = -r_0 \tilde{p}_x \pi \mathrm{i} \boldsymbol{D}_1(\theta) \sum_{k_r} J_1(k_r r_0)\boldsymbol{C}_1(k_r r) \left[\frac{\bar{F}_{11}^n}{\bar{F}_{p,k}^d}, \frac{\bar{F}_{22}^n}{\bar{F}_{s,k}^d}, \frac{\bar{F}_{31}^n}{\bar{F}_{p,k}^d} \right]^{\mathrm{T}} \tag{30}$$

Equations (27–30) define the frequency response functions (FRFs) for a constant distributed force over a circular area with radius r_0. The superscript n here denotes the numerator of the flexibility functions and d the denominator of those; in all cases the derivative of the denominator is taken with respect to k, indicated with subscript k. The FRFs are derived for a single subdisk around the origin. By normalizing the amplitude of the stresses (p_x, p_y, p_z), the dynamic impedance $\tilde{\boldsymbol{R}}_s(r,\theta)$ is obtained which upon inversion yields the dynamic stiffness of the soil $\tilde{\boldsymbol{K}}_s(r,\theta)$.

4 COUPLED TANK-LIQUID-SOIL SYSTEM

The motion of the liquid is described by Eqs.(14–19) and the motion of the tank by Eqs.(11–12). Upon substitution of these expressions into the interface and boundary conditions given by

Eqs.(5–6), and after the use of the orthogonality conditions, one obtains:

$$\Gamma_{na}\tilde{P}_{na} = -\mathrm{i}\omega \sum_{m=0}^{\infty} \tilde{X}_{nm} \int_0^{H_l} \phi^{(1)}_{z,na}(z) U_{r,nm}(z) \mathrm{d}z \tag{31}$$

$$\Gamma_{nb}\tilde{Q}_{nb} = -\mathrm{i}\omega \sum_{m=0}^{\infty} \tilde{X}_{nm} \int_0^{R} \phi^{(2)}_{r,nb}(r) W_{z,nm}(r) r \mathrm{d}r \tag{32}$$

$$\begin{aligned}\Gamma_{nc}\tilde{S}_{nc} = &\sum_{a=1}^{\infty} \tilde{P}_{na} \left.\frac{\partial \phi^{(1)}_{z,na}(z)}{\partial z}\right|_{z=H_l} \int_0^{R} \phi^{(3)}_{r,nc}(r)\phi^{(1)}_{r,na}(r) r \mathrm{d}r \\ &+ \sum_{b=1}^{\infty} \tilde{Q}_{nb} \left.\frac{\partial \phi^{(2)}_{z,nb}(z)}{\partial z}\right|_{z=H_l} \int_0^{R} \phi^{(3)}_{r,nc}(r)\phi^{(2)}_{r,nb}(r) r \mathrm{d}r\end{aligned} \tag{33}$$

The integration constants derived directly from the orthogonality relations are omitted here for the sake of brevity. Next to the satisfaction of the kinematic conditions at the tank-liquid interface, the forced equations of motion of the structure need to be satisfied. Considering Eqs. (11–12) and the fact that for every mode of vibration of the shell $\boldsymbol{L}_w \boldsymbol{u}_{nm} = \omega^2_{nm} \rho_w h_w \boldsymbol{u}_{nm}$ and $\boldsymbol{L}_p \boldsymbol{w}_{nm} = \omega^2_{nm} \rho_p h_p \boldsymbol{w}_{nm}$, the stiffness terms can be replaced by the inertia ones, i.e.:

$$\sum_{n=0}^{\infty}\sum_{m=0}^{\infty} \left(\left(\omega^2_{nm} - \omega^2\right) \rho_p h_p + \tilde{\boldsymbol{K}}_s \right) \tilde{X}_{nm} \boldsymbol{D}^t_n \boldsymbol{W}_{nm} - \tilde{\boldsymbol{p}}_{p,n} \cos(n\theta) = \tilde{\boldsymbol{K}}_s \tilde{\boldsymbol{u}}^f_s \tag{34}$$

$$\sum_{n=0}^{\infty}\sum_{m=0}^{\infty} \left(\omega^2_{nm} - \omega^2\right) \rho_w h_w \tilde{X}_{nm} \boldsymbol{D}^t_n \boldsymbol{U}_{nm} - \tilde{\boldsymbol{p}}_{w,n} \cos(n\theta) = 0 \tag{35}$$

in which the liquid pressures are $\tilde{\boldsymbol{p}}_{n,p} = [0, 0, \tilde{p}_{n,l}|_{z=0}]^{\mathrm{T}}$ and $\tilde{\boldsymbol{p}}_{n,w} = [\tilde{p}_{n,l}|_{r=R}, 0, 0]^{\mathrm{T}}$. $\boldsymbol{W}_{nm}$ and $\boldsymbol{U}_{nm}$ are the eigenvectors of the plate and wall respectively with respect to circumferential mode number n and axial mode number m. By substituting Eqs.(15–19) into $\tilde{\boldsymbol{p}}_{n,p}$ and $\tilde{\boldsymbol{p}}_{n,w}$ one can expand the liquid pressures in terms of the summation of the potential functions. By summing up the components of Eqs.(34–35), one can make use of Eq.(13) to eliminate part of the modal summations. By considering the above, the final set of infinite equations that needs to be solved for every n-mode number reads:

$$\begin{aligned}\sum_{m=0}^{\infty} \left(\omega^2_{nm} - \omega^2\right) \Gamma_{nm} - \int_0^{R} \boldsymbol{W}^{\mathrm{T}}_{nm} \tilde{\boldsymbol{p}}_{p,n} \mathrm{d}r - \int_0^{H} \boldsymbol{W}^{\mathrm{T}}_{nm} \tilde{\boldsymbol{p}}_{w,n} \mathrm{d}z \\ = \frac{1}{a_n} \iint_{S_0} \boldsymbol{D}^t_n \boldsymbol{W}^{\mathrm{T}}_{nm} \tilde{\boldsymbol{K}}_s \left(\tilde{\boldsymbol{u}}^f_s - \tilde{X}_{nm} \boldsymbol{D}^t_n \boldsymbol{W}_{nm} \right) \mathrm{d}S_0\end{aligned} \tag{36}$$

This approach is valid as shown in [16] for a pile foundation embedded into the soil. The final matrix equation can be represented in a condensed form as follows:

$$\boldsymbol{Q}_n \cdot \boldsymbol{c}_n = \boldsymbol{F}_n \tag{37}$$

$\boldsymbol{Q}_n$ is the modal coefficient matrix of dimensions $(a+b+c+m) \times (a+b+c+m)$ which is fully-populated, complex-valued, and gathers the multipliers of the amplitude coefficients resulting from equations (31–33) and (36). Vector $\boldsymbol{c}_n$ contains the liquid unknowns P_{na}, Q_{nb}, S_{nc} and modal amplitude coefficients of the structure X_{nm} and is of size $(a + b + c + m)$. Vector $\boldsymbol{F}_n$ represents the modal projection of the dynamic loading. By following a straightforward matrix operation, i.e. $\boldsymbol{c}_n = \boldsymbol{Q}^{-1}_n \boldsymbol{F}_n$, one can obtain both the liquid and the structure unknown constants once a proper truncation scheme of the infinite system is established.

5 MODEL VALIDATION

The tank-liquid system is validated with a FE model using a Kelvin-Voigt foundation with frequency independent springs and dashpots to represent the SSI effects. The soil domain is validated separately by comparing the results of a harmonically excited rigid massless plate [17, 18].

5.1 Convergence criteria and eigenvalues of the liquid-tank system

The base case considered for validation is a tank with $H/R = 0.71$ and $H = 22$m. The tank is composed of steel material ($\nu = 0.30$ and $\rho = 7850$ kg m^{-3}) with a plate thickness of $h_w = 19$mm and $h_w/h_p = 1.267$. The plate rests on elastic foundation with $k_v = 40$MNm^{-2} and $k_v/k_h = 16$. The stored liquid has a density of 1000kgm^{-3} and a fill level ratio $H_l/H = 1.0$. The adopted computational method involves the truncation of the infinite set of algebraic equations to obtain the unknown modal coefficients. It has been found that the results are most sensitive to the truncation limits of the liquid modes and rather insensitive to the number of structural modes considered as long as a reasonable criterion is adopted for the latter. The number of structural modes to be considered can be estimated by examining the energy spectrum of the dynamic excitation and choosing a truncation limit for the structural modes such that the eigenfrequency of the upper limit in the summation is twice as high as the highest frequency of interest-based on the energy spectrum [19]. Figure 3 depicts the average error at the shell-liquid interface for varying number of liquid modes and for a range of frequencies for two cases of circumferential mode numbers, i.e. $n = 0$ and $n = 1$. As can be seen, when the number of axial modes increases for a given circumferential order, the error decreases monotonically. For the case study considered here, about 30 modes suffice to reduce the error to below 5% for $n = 0$ and about 40 modes to stay within the same limit for $n = 1$.

The proposed model is validated against results obtained by FEM simulations in Comsol Multiphysics® COMSOL Multiphysics® [20]. The validation is performed for several key parameters; here results are shown for a varying liquid volume. As can be seen in Table 1, the differences in the computed eigenvalues between the present model and the FEM are less than 10% in all cases and in most cases below 5%. In Fig. 4, a few mode shapes obtained with the two models are shown. As can be seen, the modes are very similar which proves the validity of the developed model.

$\mathbf{n=1}$	**Present model**		**FEM [20]**		$\lvert\delta f\rvert$ **[%]**	
H_l/H	$f_{1,1}(Hz)$	$f_{1,2}(Hz)$	$f_{1,1}$	$f_{1,2}(Hz)$	$\delta f_{1,1}$	$\delta f_{1,2}$
0%	6.29	12.06	6.42	12.14	2.00	0.63
50%	2.65	6.35	2.39	6.07	9.97	4.55
100%	1.31	3.99	1.24	3.70	5.52	5.80

Table 1: Eigenvalues (in Hertz) obtained by using a FE model in COMSOL Multiphysics® [20] and the present model for the $n = 1$ family of modes and for varying fill height of the liquid.

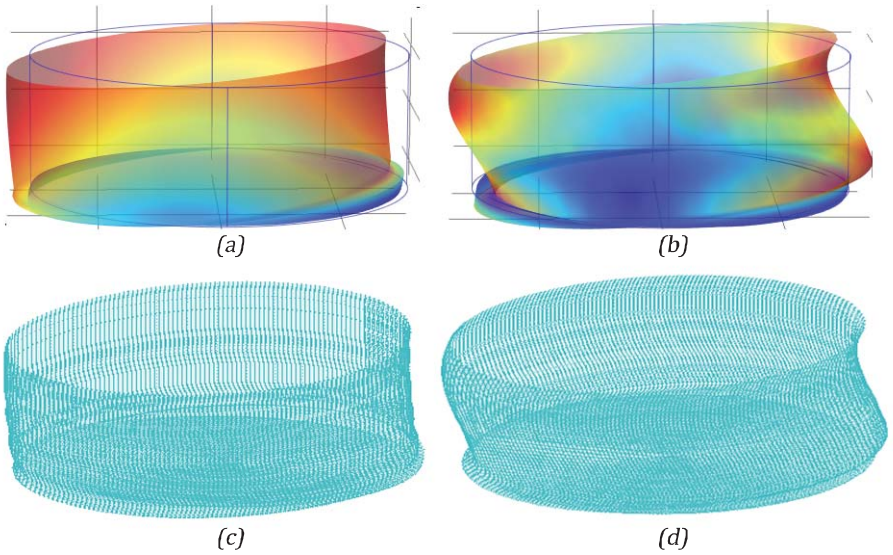

Figure 4: Comparison of the modal shapes of the tank-liquid system obtained by using the FE model in COMSOL Multiphysics® [20] and the present model for a filled tank:(a) FE mode $(1, 1)$; (b) FE mode $(1, 2)$ (c) present model mode $(1, 1)$; (d) present model mode $(1, 2)$.

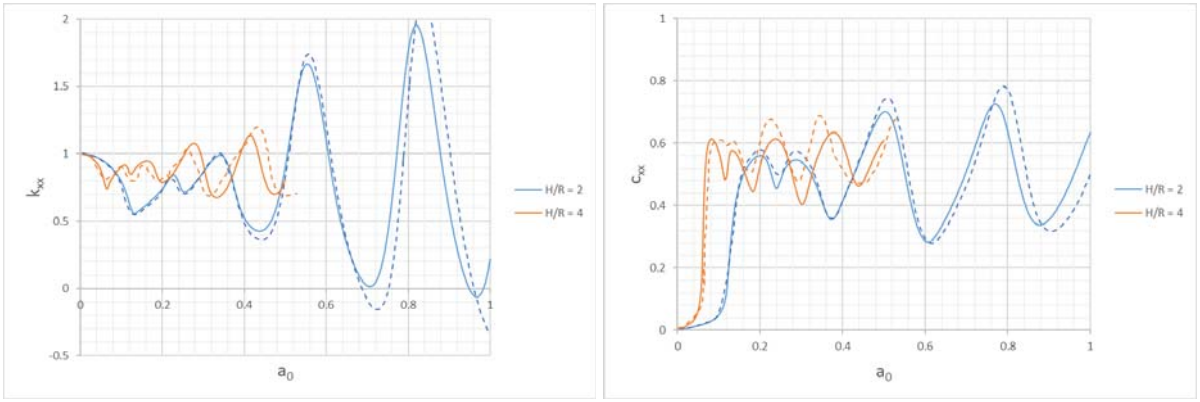
5.2 Dynamic soil stiffness

The derivation of the dynamic stiffness is benchmarked against results presented in the literature for the case of a rigid plate. To facilitate a direct comparison with literature, a normalized frequency is introduced as $a_0 = \omega R/2\pi c_s$. The dynamic stiffness and damping coefficients in the horizontal direction are defined as:

$$\tilde{K}_{xx} = K^0_{xx}\left(k_{xx} + \mathrm{i}\frac{\omega R}{c_s}c_{xx}\right)(1 + 2\mathrm{i}\beta) \tag{38}$$

in which K^0_{xx} is the static stiffness and k_{xx}, c_{xx} denote the dynamic stiffness and damping coefficients, respectively, and c_s denotes the shear wave speed in the soil.

For the validation case the following values are chosen: $d/R = 2; 4$, $\nu = 1/3$, damping ratio $\beta = 5\%$. The comparison is based on a discretisation of the plate surface in 15 rings yielding in total 709 subdisks. Figure 5 shows that the dynamic stiffness k_{xx} and damping coefficients c_{xx} are in very good agreement with literature [17, 18]. Moreover, the solution for the static case converges relatively fast as shown in Fig.6. It is expected that this is an extreme case since peak stresses are located at the edge of the plate. The subdisks have only one node; thus, the more elements included, the better the stress representation at the edge. When travelling waves with short wavelengths compared to the plate radius are excited, a higher number of elements might be required, albeit in the field of earthquake engineering this is not expected.



(a) Horizontal stiffness coefficient (b) Horizontal damping coefficient

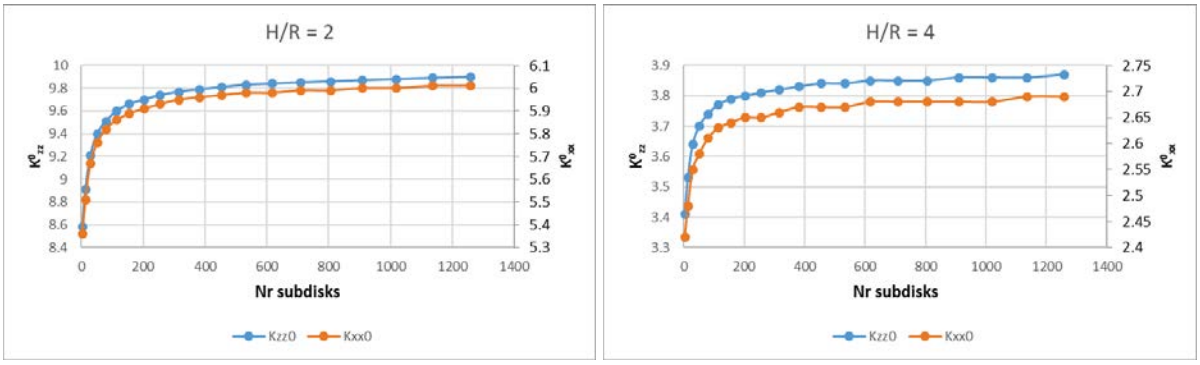

Figure 6: Convergence of the static stiffness for d/R = 2 and d/R = 4.

6 CONCLUSIONS

A computationally inexpensive method is developed for the prediction of the dynamic response of a liquid storage tank subjected to seismic excitation. The model consists of three main subsystems, namely: the shell structure representing the tank, the stored liquid and the soil domain. Emphasis is placed on the theoretical development of the model and the description of an elegant method of solution to the final system of coupled differential equations. The strength of the method is that it can cope with a full dynamic analysis of a coupled tank-liquid-soil system and it can easily be expanded in cases of non-uniform shell thickness and multi-layered soils. Next to that, due to the fact that substructuring forms the basis of the solution technique, the model is suitable for a large number of computations in which some parts of the total system are altered whereas others remain unchanged. The authors believe that the proposed model can be especially useful when a large number of simulations is required as, for example, is the case in seismic risk analyses.

Abstract. *The Wave Finite Element (WFE) method is based on wave propagation in periodic structures. Starting from a Finite Element (FE) analysis of a single period (sub-structure) we are able to derive the dynamic behaviour relative to the entire structure. Thanks to a reduction in the degrees of freedom (dofs) of the system and by decomposing the response of the structure on a wave basis, the calculation time is considerably reduced compared to the classic FEM. Numerous structures have been solved with this method but it can not deal easily on the boundary conditions. In this study, we develop a technique of WFE to deal with more general cases of structures constrained in a arbitrary manner as a multiple supported bridge. By using the WFE method, the vectors of dofs and loads will be decomposed on the wave basis in function of loads and reaction forces of the supports. Then, by substituting the boundary condition in this wave decomposition, we obtain a relation between the reaction forces and the loads which permits to calculate the structure response. The numerical applications show that the WFE and FEM agree well and the new method permits to reduce significantly the calculation time.*

1 INTRODUCTION

The Wave Finite Element (WFE) is a powerful numerical method that allows to drastically reduce the number of degrees of freedom of a structural model providing a great advantage in terms of computational time. This method has been developed for periodic structures where the geometry repeats itself in a certain direction, and is based on wave propagation. The objective is to compute the wave modes which constitute a base that, similarly to the eigen modes often used in the dynamic analysis, can be used to decompose the structural response in terms of forces and displacements at the considered degrees of freedom. The wave modes are characteristics of the elementary periodic element therefore they can be computed by solving an eigenvalues problem consistently formulated for this element. According to the approach proposed by Duhamel et al. [1, 2, 3] the periodic element can be modelled using the conventional finite element method to retrieve its mass, stiffness and damping matrices. In this approach, these matrices are then used to obtain the dynamic stiffness of the cell in the frequency domain and the theory of periodic structure is used to build the dynamic stiffness matrix of the whole structure. Once the wave base has been determined for the period of the structure and the dynamic problem formulated in terms of this base, the solution of the dynamic equation can be carried out by imposing the boundary conditions. This approach has been followed in Hoang et al. [4] that proposed the wave approach, based on the computation of the dynamic response as the sum of different wave contributions generated by the forces acting on the structure. In previous studies [4, 5], the WFE has been applied considering constrains applied only at the ends of the structure or included inside the periodic element, as for the case of railway tracks. The objective of this paper is to extend the application of the WFE to the study of the dynamic response of multi-supported periodic structures, including the possibility to account for different types of boundary conditions. The extension proposed in this paper allows to analyse structures, such as bridges, whose supports may be of different types and are not necessarily equally spaced. The paper is structured in four sections. The second is dedicated to the introduction of the WFE starting from the type of structures considered in the study and the approaches of resolution. The third section contains the original part of this paper dealing with the analytical formulation of the WFE of a periodic structure with multiple intermediate supports. Finally, in the fourth section the numerical results will be presented with reference to a number of case studies.

2 WAVE FINITE ELEMENT

2.1 Discrete formulation

A periodic system consists of a number of identical elements, in terms of geometric shape, physical properties, boundary conditions, and connections with other substructures, coupled together to form the whole system, see Figure (1). Using the FE method, the generic element is modelled and two types of nodes can be defined: *internal nodes* and *boundary nodes*. The boundary nodes are in turn divided into *left nodes* and *right nodes* with d *degrees of freedom* (dofs) for each side. The kinematic behaviour of the system is described by the column vector of nodal displacements $\mathbf{q}$ which number of components is equal to the total number of dofs of the substructure. On the other hand, the respective nodal forces are described by the column vector $\mathbf{F}$. Their relation is given by the discrete equation of motion:

$$(\mathbf{K} + i\omega\mathbf{C} - \omega^2\mathbf{M})\mathbf{q}(\omega) = \mathbf{D}(\omega)\mathbf{q}(\omega) = \mathbf{F}(\omega) \tag{1}$$

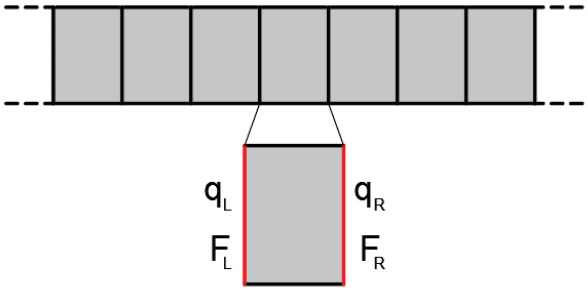

Figure 1: General substructure.

where $\mathbf{D}$ is the *dynamic stiffness matrix* (DSM), and $\mathbf{M}$, $\mathbf{C}$ and $\mathbf{K}$ are respectively the Mass, Dumping and Stiffness Matrix. The dynamic equation can be rewritten in the expanded form in order to separate the degrees of freedom into left (L), inner (I) and right (R) ones.

$$\begin{bmatrix} \mathbf{D}_{LL} & \mathbf{D}_{LI} & \mathbf{D}_{LR} \\ \mathbf{D}_{IL} & \mathbf{D}_{II} & \mathbf{D}_{IR} \\ \mathbf{D}_{RL} & \mathbf{D}_{RI} & \mathbf{D}_{RR} \end{bmatrix} \begin{bmatrix} \mathbf{q}_L \\ \mathbf{q}_I \\ \mathbf{q}_R \end{bmatrix} = \begin{bmatrix} \mathbf{F}_L \\ \mathbf{F}_I \\ \mathbf{F}_R \end{bmatrix} \tag{2}$$

Writing the inner degrees of freedom $\mathbf{q}_I$ in function of the boundary dofs $\mathbf{q}_R$ and $\mathbf{q}_L$, we can reduce the inner nodes in order to obtain a condensed form of the dynamic stiffness matrix.

$$\begin{bmatrix} \bar{\mathbf{D}}_{LI}\mathbf{F}_I \\ \bar{\mathbf{D}}_{RI}\mathbf{F}_I \end{bmatrix} + \begin{bmatrix} \bar{\mathbf{D}}_{LL} & \bar{\mathbf{D}}_{LR} \\ \bar{\mathbf{D}}_{RL} & \bar{\mathbf{D}}_{RR} \end{bmatrix} \begin{bmatrix} \mathbf{q}_L \\ \mathbf{q}_R \end{bmatrix} = \begin{bmatrix} \mathbf{F}_L \\ \mathbf{F}_R \end{bmatrix} \tag{3}$$

Where,

$$\bar{\mathbf{D}}_{LL} = \mathbf{D}_{LL} - \mathbf{D}_{LI}\mathbf{D}_{II}^{-1}\mathbf{D}_{IL},\ \bar{\mathbf{D}}_{LR} = \mathbf{D}_{LR} - \mathbf{D}_{LI}\mathbf{D}_{II}^{-1}\mathbf{D}_{IR},\ \bar{\mathbf{D}}_{RL} = \mathbf{D}_{RL} - \mathbf{D}_{RI}\mathbf{D}_{II}^{-1}\mathbf{D}_{IL}$$
$$\bar{\mathbf{D}}_{RR} = \mathbf{D}_{RR} - \mathbf{D}_{RI}\mathbf{D}_{II}^{-1}\mathbf{D}_{IR},\ \bar{\mathbf{D}}_{LI} = \mathbf{D}_{LI}\mathbf{D}_{II}^{-1},\ \bar{\mathbf{D}}_{RI} = \mathbf{D}_{RI}\mathbf{D}_{II}^{-1}$$

Considering two consecutive substructures (n) and $(n+1)$, two fundamental conditions must be always satisfied: continuity of the displacement along the junction $\mathbf{q}_R^{(n)} = \mathbf{q}_L^{(n+1)}$, equilibrium of the forces acting in the junction: $\mathbf{F}_R^{(n)} + \mathbf{F}_L^{(n+1)} = \mathbf{F}_B^{(n)}$. These equations can be manipulated in order to write the terms regarding substructure $(n+1)$ in function of those regarding the preceding substructure (n).

$$\begin{bmatrix} \mathbf{q}_L^{(n+1)} \\ -\mathbf{F}_L^{(n+1)} \end{bmatrix} = \mathbf{S} \begin{bmatrix} \mathbf{q}_L^{(n)} \\ -\mathbf{F}_L^{(n)} \end{bmatrix} + \begin{bmatrix} \bar{\mathbf{D}}_{qI}\mathbf{F}_I^{(n)} \\ \bar{\mathbf{D}}_{fI}\mathbf{F}_I^{(n)} - \mathbf{F}_B^{(n)} \end{bmatrix} \tag{4}$$

Where, $\mathbf{S}$ is the *transfer matrix* given by:

$$\mathbf{S} = \begin{bmatrix} -\bar{\mathbf{D}}_{LR}^{-1}\bar{\mathbf{D}}_{LL} & -\bar{\mathbf{D}}_{LR}^{-1} \\ \bar{\mathbf{D}}_{LR} - \bar{\mathbf{D}}_{RR}\bar{\mathbf{D}}_{LR}^{-1}\bar{\mathbf{D}}_{LL} & -\bar{\mathbf{D}}_{RR}\bar{\mathbf{D}}_{LR}^{-1} \end{bmatrix} \tag{5}$$

with $\bar{\mathbf{D}}_{qI} = -\bar{\mathbf{D}}_{LR}^{-1}\bar{\mathbf{D}}_{LI}$ and $\bar{\mathbf{D}}_{fI} = \bar{\mathbf{D}}_{RI} - \bar{\mathbf{D}}_{RR}\bar{\mathbf{D}}_{LR}^{-1}\bar{\mathbf{D}}_{LI}$.
The nodal displacements $\mathbf{q}^{(n)}$ and the nodal forces $\mathbf{F}^{(n)}$, together describe the state of the substructure. For this reason we define the *state vector* $\mathbf{u}^{(n)}$ of the substructure (n) and $\mathbf{b}^{(n)}$ the vector of external loads acting on the substructure (n) as:

$$\mathbf{u}^{(n)} = \begin{bmatrix} \mathbf{q}_L^{(n)} \\ -\mathbf{F}_L^{(n)} \end{bmatrix}, \quad \mathbf{b}^{(n)} = \begin{bmatrix} \bar{\mathbf{D}}_{qI}\mathbf{F}_I^{(n)} \\ \bar{\mathbf{D}}_{fI}\mathbf{F}_I^{(n)} - \mathbf{F}_B^{(n)} \end{bmatrix} \tag{6}$$

Equation (4) can be written in a more synthetic form:

$$\mathbf{u}^{(n+1)} = \mathbf{S}\mathbf{u}^{(n)} + \mathbf{b}^{(n)} \tag{7}$$

This last equation represents the relation between the generic substructure (n) and its next substructure $(n+1)$ by means of the transfer matrix $\mathbf{S}$. This leads to:

$$\mathbf{u}^{(n)} = \mathbf{S}^{n-1}\mathbf{u}^{(1)} + \sum_{k=1}^{n-1} \mathbf{S}^{n-k-1}\mathbf{b}^{(k)} \tag{8}$$

Equation (8) represents the relation between the state vector of the first substructure and the state vector of the substructure (n). One also has

$$\mathbf{u}^{(N+1)} = \mathbf{S}^{N-n+1}\mathbf{u}^{(n)} + \sum_{k=n}^{N} \mathbf{S}^{N-k}\mathbf{b}^{(k)} \tag{9}$$

2.2 Wave formulation

The wave modes are the eigenvectors solution of

$$\mathbf{S}\begin{bmatrix}\mathbf{q}_L \\ -\mathbf{F}_L\end{bmatrix} = \lambda \begin{bmatrix}\mathbf{q}_L \\ -\mathbf{F}_L\end{bmatrix} \tag{10}$$

Hence, each eigenvalue of the matrix $\mathbf{S}$ provides a propagation constant λ_i while the eigenvector Φ_i represents the wave shapes, namely the way in which the substructure deforms. For each eigenvalue λ_i of eigenvector Φ_i, there is an eigenvalue $1/\lambda_i$ associated to an eigenvector denoted Φ_i^*.

The matrix $\mathbf{S}$ is symplectic meaning that ${}^t\mathbf{S}\mathbf{J}\mathbf{S} = \mathbf{J}$ with $\mathbf{J} = \begin{bmatrix}\mathbf{O} & \mathbf{I} \\ -\mathbf{I} & \mathbf{O}\end{bmatrix}$. The orthogonality properties are such that ${}^t\mathbf{\Phi}^*\mathbf{J}\mathbf{\Phi} = \mathbf{I}$, ${}^t\mathbf{\Phi}^*\mathbf{J}\mathbf{\Phi}^* = {}^t\mathbf{\Phi}\mathbf{J}\mathbf{\Phi} = \mathbf{O}$ with $\mathbf{\Phi} = [\Phi_1, ..., \Phi_d]$.

We can decompose the state vector $\mathbf{u}^{(n)}$ and the load vector $\mathbf{b}^{(n)}$ in the wave base as a combination of positive and negative waves:

$$\begin{aligned} \mathbf{u}^{(n)} &= \mathbf{\Phi}\mathbf{Q}^{(n)} - \mathbf{\Phi}^*\mathbf{Q}^{*(n)} \\ \mathbf{b}^{(n)} &= \mathbf{\Phi}\mathbf{Q}_B^{(n)} - \mathbf{\Phi}^*\mathbf{Q}_B^{*(n)} \end{aligned} \tag{11}$$

Where $\mathbf{Q}^{(n)}$ and $\mathbf{Q}^{*(n)}$ represent the vectors of *wave amplitude* of the positive-going and negative-going waves. The terms $\mathbf{Q}_B^{(n)}$ and $\mathbf{Q}_B^{*(n)}$ are the vectors of wave amplitude generated by the external loads $\mathbf{F}_I^{(n)}$ and $\mathbf{F}_B^{(n)}$. The wave amplitudes of the external loads can be derived from equation (11), by multiplying both sides by $\mathbf{\Phi}^{*T}\mathbf{J}$ as follow:

$$\begin{aligned} \mathbf{\Phi}^{*T}\mathbf{J}\mathbf{b}^{(n)} &= \mathbf{\Phi}^{*T}\mathbf{J}\mathbf{\Phi}\mathbf{Q}_B^{(n)} - \mathbf{\Phi}^{*T}\mathbf{J}\mathbf{\Phi}^*\mathbf{Q}_B^{*(n)} \\ &= \mathbf{Q}_B^{(n)} \\ &= (\mathbf{\Phi}_q^{*T}\bar{\mathbf{D}}_{fI} - \mathbf{\Phi}_F^{*T}\bar{\mathbf{D}}_{qI})\mathbf{F}_I^{(n)} - \mathbf{\Phi}_q^{*T}\mathbf{F}_B^{(n)} \end{aligned} \tag{12}$$

The same thing can be done to compute the value of $\mathbf{Q}_B^{*(k)}$. Multiplying both sides by $\mathbf{\Phi}^T\mathbf{J}$:

$$\begin{aligned} \mathbf{\Phi}^{T}\mathbf{J}\mathbf{b}^{(n)} &= \mathbf{\Phi}^{T}\mathbf{J}\mathbf{\Phi}\mathbf{Q}_B^{(n)} - \mathbf{\Phi}^{T}\mathbf{J}\mathbf{\Phi}^*\mathbf{Q}_B^{*(n)} \\ &= \mathbf{Q}_B^{*(n)} \\ &= (\mathbf{\Phi}_q^{T}\bar{\mathbf{D}}_{fI} - \mathbf{\Phi}_F^{T}\bar{\mathbf{D}}_{qI})\mathbf{F}_I^{(n)} - \mathbf{\Phi}_q^{T}\mathbf{F}_B^{(n)} \end{aligned} \tag{13}$$

3 WFE FOR STRUCTURES WITH SEVERAL SUPPORTS

3.1 Derivation of the intermediate reactions

In this section, a technique of WFE will be developed to deal with more general cases of structures constrained in a arbitrary manner as a multiple supported bridge. By convention, the constrain can be placed only in the junction between two substructures. If we consider the reactions as external forces acting on the structure, from the equilibrium of external forces and internal forces we have:

$$\mathbf{F}_R^{(k)} + \mathbf{F}_L^{(k+1)} = \mathbf{F}_{ext}^{(k)} + \mathbf{R}^{(k)} \tag{14}$$

Hence this time $\mathbf{F}_B$ is given by:

$$\mathbf{F}_B^{(k)} = \mathbf{F}_{ext}^{(k)} + \mathbf{R}^{(k)} \tag{15}$$

The wave amplitudes can be expressed in function of the external loads $\mathbf{F}_{ext}^{(k)}$ and reactions $\mathbf{R}^{(k)}$ as follows from (12) and (13):

$$\mathbf{Q}_B^{(k)} = (\mathbf{\Phi}_q^{*T}\bar{\mathbf{D}}_{fI} - \mathbf{\Phi}_F^{*T}\bar{\mathbf{D}}_{qI})\mathbf{F}_I^{(k)} - \mathbf{\Phi}_q^{*T}(\mathbf{F}_{ext}^{(k)} + \mathbf{R}^{(k)}) \tag{16}$$

$$\mathbf{Q}_B^{*(k)} = (\mathbf{\Phi}_q^{T}\bar{\mathbf{D}}_{fI} - \mathbf{\Phi}_F^{T}\bar{\mathbf{D}}_{qI})\mathbf{F}_I^{(k)} - \mathbf{\Phi}_q^{T}(\mathbf{F}_{ext}^{(k)} + \mathbf{R}^{(k)}) \tag{17}$$

The sum (8) can be written as

$$\mathbf{\Phi}\mathbf{Q}^{(n)} - \mathbf{\Phi}^*\mathbf{Q}^{*(n)} = \mathbf{S}^{n-1}\left(\mathbf{\Phi}\mathbf{Q}^{(1)} - \mathbf{\Phi}^*\mathbf{Q}^{*(1)}\right) + \sum_{k=1}^{n-1}\mathbf{S}^{n-k-1}\left(\mathbf{\Phi}\mathbf{Q}_B^{(k)} - \mathbf{\Phi}^*\mathbf{Q}_B^{*(k)}\right) \tag{18}$$

Multiplying by $\mathbf{\Phi}^{*T}\mathbf{J}$, using $\boldsymbol{\mu} = [\lambda_1, ..., \lambda_d]$, this gives

$$\mathbf{Q}^{(n)} = \boldsymbol{\mu}^{n-1}\mathbf{Q}^{(1)} + \sum_{k=1}^{n-1}\boldsymbol{\mu}^{n-k-1}\mathbf{Q}_B^{(k)} \tag{19}$$

In the same way, from (9), one has

$$\mathbf{Q}^{*(N+1)} = \boldsymbol{\mu}^{*N-n+1}\mathbf{Q}^{*(n)} + \sum_{k=n}^{N}\boldsymbol{\mu}^{*N-k}\mathbf{Q}_B^{*(k)} \tag{20}$$

with $\boldsymbol{\mu}^* = \boldsymbol{\mu}^{-1}$. We get

$$\mathbf{Q}^{*(n)} = \boldsymbol{\mu}^{N+1-n}\mathbf{Q}^{*(N+1)} - \sum_{k=n}^{N}\boldsymbol{\mu}^{k+1-n}\mathbf{Q}_B^{*(k)} \tag{21}$$

If we call $\mathbf{R}^{(n_s)}$ the vector of reaction corresponding to the constrain s placed in n_s, the state vector is given as follow using (11):

$$\begin{aligned}\mathbf{u}^{(n)} = \mathbf{\Phi}\boldsymbol{\mu}^{n-1}\mathbf{Q}^{(1)} - \mathbf{\Phi}^*\boldsymbol{\mu}^{N+1-n}\mathbf{Q}^{*(N+1)} + \mathbf{T}^{(n)} + \\ - \mathbf{\Phi}\sum_{n_s<n}\boldsymbol{\mu}^{n-1-n_s}\mathbf{\Phi}_q^{*T}\mathbf{R}^{(n_s)} + \mathbf{\Phi}^*\sum_{n_s\geq n}\boldsymbol{\mu}^{n_s+1-n}\mathbf{\Phi}_q^{T}\mathbf{R}^{(n_s)}\end{aligned} \tag{22}$$

$\mathbf{T}^{(n)}$ gathers all the known terms obtained from $\mathbf{F}_{ext}^{(k)}$ and $\mathbf{F}_I^{(k)}$.

3.2 Boundary conditions

The application of the conditions can be written in a synthetic way at support s as:

$$\mathbf{L}_s \mathbf{u}^{(n_s)} = \mathbf{B}_s \tag{23}$$

The matrix $\mathbf{L}_s$ is a *logical matrix* or $(0, 1)$ *matrix*. It can assume different forms depending on the type of constrain and his position along the structure. For a one-dimensional beam and a fixed support, $\mathbf{L}_s$ is given by:

$$\mathbf{L}_s = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \end{bmatrix}$$

The index matrix $\mathbf{L}_s$ for two-dimensional and three-dimensional structures is not so easy to find. The strategy used is to construct the matrix $\mathbf{L}_s$ by means of sub-matrices that subsequently can be assembled. For multiple node junctions, the column state vector is composed by the d nodal displacements followed by the d nodal forces. The Matrix $\mathbf{L}_s$, that multiplies the state vector (see equation (23)) can be seen as the composition of two square sub-matrices $\mathbf{L}_q$ and $\mathbf{L}_F$ that apply to displacements and forces respectively:

$$\mathbf{L}_s \mathbf{u}^{(n_s)} = \left[\begin{array}{c|c} \mathbf{L}_q & \mathbf{L}_F \end{array} \right] \begin{bmatrix} \{\mathbf{q}\} \\ \\ \{\mathbf{F}\} \\ \\ \end{bmatrix} \tag{24}$$

The matrices $\mathbf{L}_q$ and $\mathbf{L}_F$, in turn, consist of sub-matrices, corresponding to each node, named $\mathbf{L}_{q,sub}$ and $\mathbf{L}_{F,sub}$. These sub-matrices are square, identical for every node and depend on the kind of support. Their dimensions correspond to the number of dof for each node.

$$\mathbf{L}_q = \begin{bmatrix} \mathbf{L}_{q,sub} & & \\ & \ddots & \\ & & \mathbf{L}_{q,sub} \end{bmatrix}, \quad \mathbf{L}_F = \begin{bmatrix} \mathbf{L}_{F,sub} & & \\ & \ddots & \\ & & \mathbf{L}_{F,sub} \end{bmatrix} \tag{25}$$

The sub-matrices $\mathbf{L}_{q,sub}$ and $\mathbf{L}_{F,sub}$ have to be constructed for every type of structure (beam, shell, plates, etc.) from whom the number of dof per node depends. The boundary conditions are denoted by the column vector $\mathbf{B}_s$, where the subscript refers to the respective constrain s. Each component represents the admitted displacement of each dof. The vector $\mathbf{B}_s$ depend on the type of constrain:

- rigid constrains: $\mathbf{B}_s = [\mathbf{0}]$
- elastic constrain: $\mathbf{B}_s \neq [\mathbf{0}]$

3.3 Solution of the problem

In order to apply the boundary conditions, equation (22) has to be multiplied for the index matrix $\mathbf{L}_s$ and equalled to the vector $\mathbf{B}_s$. For each support s, the boundary conditions can be written as $\mathbf{B}_s = \mathbf{L}_s \mathbf{u}^{(n_s)}$ so that:

$$\begin{aligned} \mathbf{L}_s \mathbf{\Phi} \boldsymbol{\mu}^{n_s - 1} \mathbf{Q}^{(1)} - \mathbf{L}_s \mathbf{\Phi}^* \boldsymbol{\mu}^{N+1-n_s} \mathbf{Q}^{*(N+1)} + \mathbf{L}_s \mathbf{T}^{(n_s)} + \\ - \mathbf{L}_s \mathbf{\Phi} \sum_{n_i < n_s} \boldsymbol{\mu}^{n_s - 1 - n_i} \mathbf{\Phi}_q^{*T} \mathbf{R}^{(n_i)} + \mathbf{L}_s \mathbf{\Phi}^* \sum_{n_i \geq n_s} \boldsymbol{\mu}^{n_i + 1 - n_s} \mathbf{\Phi}_q^{T} \mathbf{R}^{(n_i)} = \mathbf{B}_s \end{aligned} \tag{26}$$

The next step consists in replacing the vector $\mathbf{R}^{(n_i)}$ with the expression $\mathbf{L}_i^T\tilde{\mathbf{R}}^{(n_i)}$ in order to consider only the non zero components of the reaction. For a notation issue, the following assumption are made:

$$\mathbf{\Phi}_s = \mathbf{L}_s\mathbf{\Phi}; \quad \mathbf{\Phi}_s^* = \mathbf{L}_s\mathbf{\Phi}^\star \tag{27}$$

Finally:

$$\begin{aligned}\mathbf{\Phi}_s\boldsymbol{\mu}^{n_s-1}\mathbf{Q}^{(1)} - \mathbf{\Phi}_s \sum_{n_i<n_s} \boldsymbol{\mu}^{n_s-1-n_i}\mathbf{\Phi}_i^{*T}\tilde{\mathbf{R}}^{(n_i)} \\ + \mathbf{\Phi}_s^* \sum_{n_i\geq n_s} \boldsymbol{\mu}^{n_i+1-n_s}\mathbf{\Phi}_i^T\tilde{\mathbf{R}}^{(n_i)} - \mathbf{\Phi}_s^*\boldsymbol{\mu}^{N+1-n_s}\mathbf{Q}^{*(N+1)} = \mathbf{B}_s - \mathbf{L}_s\mathbf{T}^{(n_s)}\end{aligned} \tag{28}$$

Equation (28) can be written for every constrain s, leading to a system of linear equations in the form:

$$\mathbf{AX} = \mathbf{F} \tag{29}$$

The vector of the unknowns is:

$$\mathbf{X} = \begin{bmatrix} \mathbf{Q}^{(1)} \\ \tilde{\mathbf{R}}^{(n_1)} \\ \vdots \\ \tilde{\mathbf{R}}^{(n_s)} \\ \vdots \\ \tilde{\mathbf{R}}^{(n_S)} \\ \mathbf{Q}^{*(N+1)} \end{bmatrix} \tag{30}$$

Once matrix $\mathbf{A}$ and vector $\mathbf{F}$ are defined, it is possible to solve the problem:

$$\mathbf{X} = \mathbf{A}^{-1}\mathbf{F} \tag{31}$$

Replacing the reactions $\mathbf{R}$ and wave amplitudes $\mathbf{Q}^{(1)}$ and $\mathbf{Q}^{*(N+1)}$ in equation (22), the response of the entire periodic structure is obtained.

4 APPLICATIONS

In order to validate this technique, two applications have been developed. The two structures will present different dimensions and types of constraints placed in an arbitrary manner. For each application the frequency response function (FRF) of the structure will be calculated with respect to a specific point. To confirm the results, every problem will be solved both by the FE method and the WFE method. Furthermore, for both methods the calculation time will be given so that the efficiency can be compared. The general procedure consists in dividing the structure into a certain number of identical substructures. Using the software Abaqus, the substructure is modelled and the stiffness and mass matrix obtained. By importing this data, the problem can be solved by the software Matlab. In fact, from the stiffness and mass matrix it is possible to obtain the dynamic stiffness matrix and the transfer matrix $\mathbf{S}$.

4.1 1D Beam

The structure considered is the multi supported beam represented in Figure (2) with $L = 50m$. The objective of this application is to demonstrate the possibility of considering different types of constrained not necessarily equispaced.

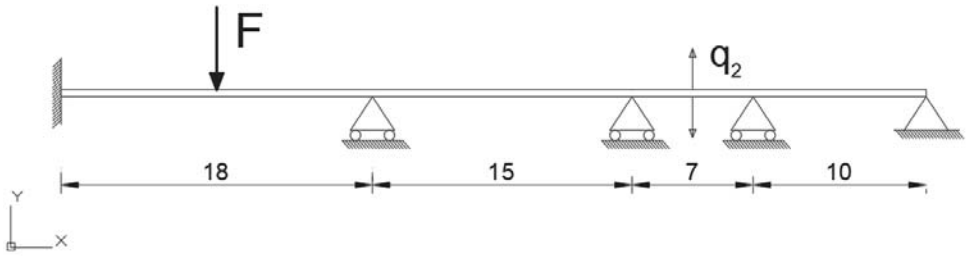

Figure 2: Multi-supported beam

The section of the beam is a IPE 400, see Figure (7) and Table (3). The external force is a vertical point force and acts to the middle of the first span. His value is $F = 5\,kN$. The material considered is steel and the mechanical properties are summarized in Table (1).

Steel	
Density	$d = 7850\,kg/m^3$
Elastic modulus	$E = 210\,GPa$
Poisson modulus	$\nu = 0.3$

Table 1: Mechanical properties of steel.

The beam is composed by 220 substructures of length $l = 0.2m$ with 33 dofs by period and 6603 dofs in the whole structure. The type of element is a 2-node linear beam in a plane. In Figure (3) are reported the results of the analysis. The results match perfectly. The computational time is drastically reduced being $49.31s$ for FEM and $5.57s$ for WFEM.

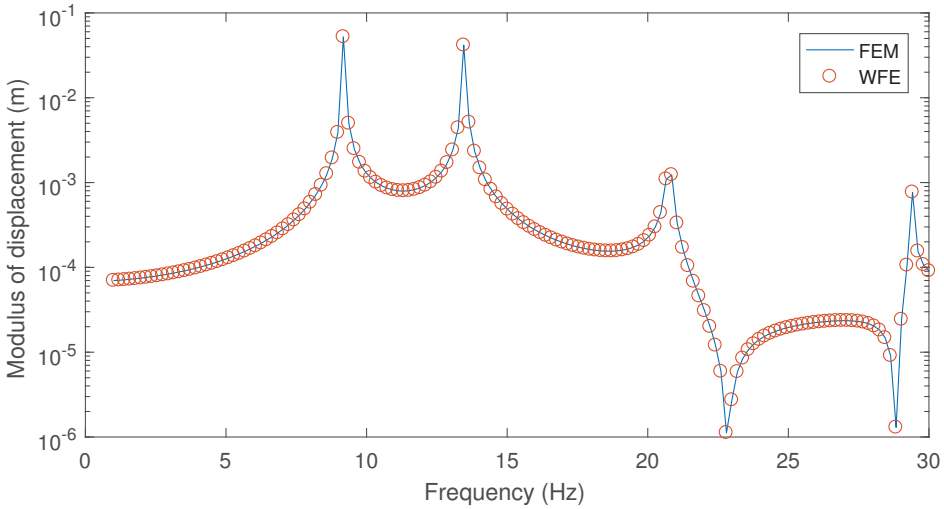

Figure 3: Frequency response function. Logarithm of the modulus of the displacement in function of the frequency.

4.2 Multi-supported bridge

In this section, the dynamic behaviour of a multi-supported bridge is studied. The total length is $L = 120m$. The bridge is fixed to the ends and supported by two equispaced roller supports.

The maximum span is $L_{span} = 40m$. The longitudinal scheme of the bridge is represented in Figure (4). The bridge presents a box-beam deck which dimensions are represented in Figure

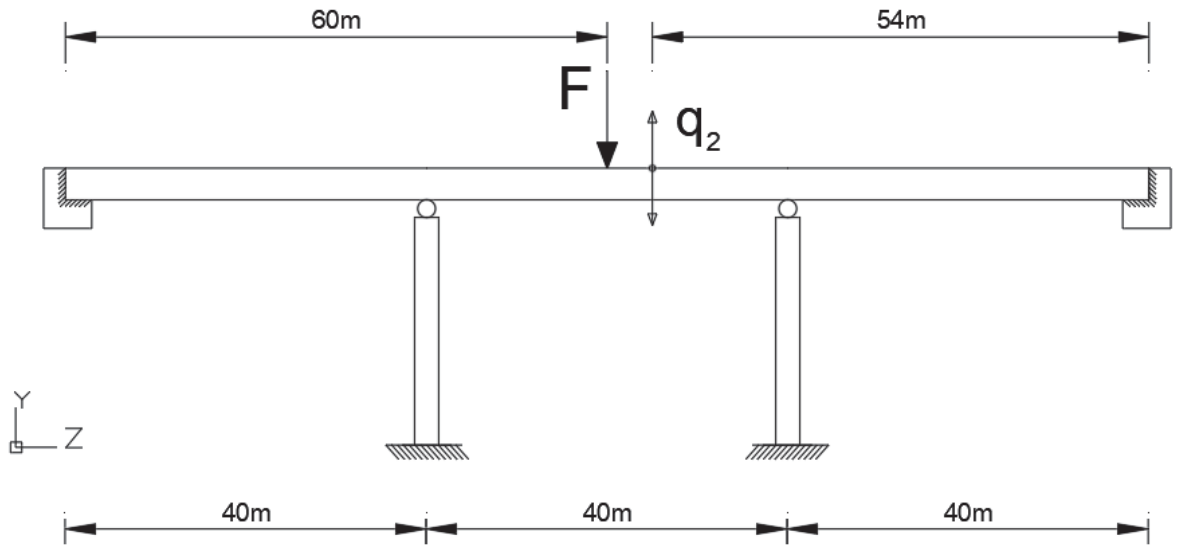

Figure 4: Multi-supported bridge

(5). The external force is a vertical point force and acts to the middle of the structure; its value

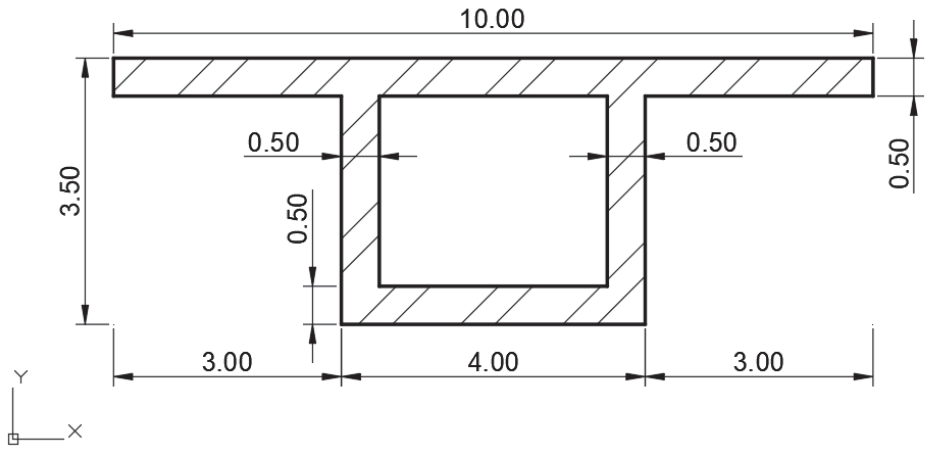

Figure 5: Section of the bridge (m).

is $F = 10\,kN$. The position is at the right upper corner of Figure (5). The response is also computed at the right upper corner. The material considered is concrete and the mechanical property are summarized in Table (2).

The bridge is composed by 480 substructures of length $l = 0.25m$ with 1368 dofs by period and 329004 dofs in the whole structure. The substructure has been modelled by a 8-node linear brick of dimensions $0.25m$. The FRF has been computed every $0.15\,Hz$ in the range of frequencies $0 - 30\,Hz$. The result obtained by applying the WFE method and showed in Figure (6) matches with the one obtained with the FEM. Moreover the computational time is halved being 204 minutes for FEM and 100 minutes for WFEM equivalent to 51% of time reduction.

HP Concrete	
Density	$d = 2500\,kg/m^3$
Elastic modulus	$E = 48\,GPa$
Poisson modulus	$\nu = 0.2$

5 CONCLUSIONS

As already mentioned, the WFE method has proved to be an excellent calculation tool to obtain results in a definitely shorter time compared to FEM. The proposed technique, that can be seen as a way to impose the boundary conditions, is simple but at the same time very effective. It is important to highlight the high efficiency in terms of time reduction and memory used during the computation. Finally, through practical applications, we have validated the method by finding results that coincide with the FEM but with the advantages of obtaining a computational time that in the worst case is halved.

Keywords: domain decomposition, time-integration, FETI, asynchronous, multirate, multi-time-step, variational

Abstract. *In this contribution we derive a nonlinear version of the BGC-macro asynchronous time-integration method and investigate the resulting spurious oscillations on the interface, resulting from the coupling on a course time-grid. The main difference to the nonlinear PH-method lies in a different coupling condition, which is only based on the coupling of velocities by Lagrange-Multipliers. We give a brief introduction to our implementation in our in-house developed open-source software AMfe and PyFETI. Afterwards we address the possibility of wave-reflections on the interfaces in certain cases. In the last part of the paper we derive a different asynchronous coupling-method from the variational principle utilizing a generalized midpoint-rule. Due to weak instabilities, when the constraint is formulated on displacment-level, we modify the arising condition such that it is enforced on velocity-level but still represents an energy with the interface-forces. As a prove of concept and for comparability to the BGC-macro method we only use a coarse discretization of the Lagrange-Multiplier-field. Then we show that spurious oscillations couldn't be eliminated in our special test-case, due to that coarse discretization, but incompatibilities in the displacements-filed were smoothed. The amplitude of energy-oscillations is kept similar compared to the BGC-macro method.*

1 INTRODUCTION

When it comes to parallelization of large structural dynamics simulations, domain decomposition methods are widely used in Finite Elements codes. One family of such domain decomposition techniques are the Finite Elements Tearing and Interconnecting (FETI)-methods, originally proposed by Farhat e.a. [2] for linear static structures. Later they've been extended to nonlinear dynamic problems and equipped with efficient preconditioning and recycling-techniques [4, 5, 9]. Things get more troublesome with local highly nonlinear phenomena, as load-balancing becomes an issue and the portion of communication increases. One approach to improve efficiency is a localization approach, where local nonlinear problems are solved [13]. A different idea is the adaptation of the time-step to the physics of each substructure and saving unnecessary computations. Originally the GC-method has been proposed, which allows subcycling on one substructure and enforces compatibility on the small time-steps [6]. Although both this method and its extension to α-integration-schemes, the BGC-micro method [1], share the characteristic that they are derived from a pseudo-energy method, they dissipate energy on the interface. This issue is resolved by non-dissipative methods, that enforce compatibility only at a coarse syncronization time-step, such as the PH- and BGC-macro-methods [14, 1]. However, these methods lead to spurious oscillations on the interface, as shown by Prakash and Hjelmstad [15]. Despite these oscillations it has been shown for a sandwitch-beam with an impact-load, that this asynchronous approach leads to less computations for a nonlinear impact-simulation compared to a completely fine time-discretization and a model, that is decomposed into two subdomains [15]. So the goal of future work is to transfer this computational efficiency to a FETI-solver while avoiding spurious oscillations and conserving energy. A different approach is to derive methods from the variational principle or Hamilton's principle. That approach is well known in structural dynamics from the derivation of differential equations of motion. In the discrete case, this approach can be used to derive time-integration-schemes, that conserve linear and angular momentum and are symplectic and have energy-oscillations bounded, such as the non-dissipative Newmark-β scheme [8]. This technique can also be extended to asynchronous or multirate cases, as it has been done by Leyendecker and Ober-Blöbaum, but instead of spacial decomposition, the separation of dynamics with respect to their speeds is used [12]. In Wenger e.a. higher order variational integrators for synchronous constrained systems have been constructed with a more generalized discretization of the displacements and Lagrange-Multipliers via polynomials in time [16]. In the following chapters we extend the BGC-macro method to nonlinear systems for a Newmark-β scheme and compare it with the nonlinear PH-method in terms of spurious oscillations. For that we start with an introduction to FETI for nonlinear structural dynamics in chapter 2. Subsequently we derive the nonlinear BGC-macro and show the possibility of wave-reflections on a disadvantageous example in chapter 3. In the third part of this article, we give an introduction to the variational principle and derive a variational coupling method for asynchronous time-integration over the generalized midpoint-rule in chapter 4.

2 FETI FOR NONLINEAR STRUCTURAL DYNAMICS

2.1 Nonlinear structural dynamics

We consider a nonlinear structural dynamics problem, which differential equation of motion can be described by d'Alembert's principle as

$$\mathbf{M}\ddot{\vec{q}} + \vec{f}_{int}(\vec{q}) - \vec{f}_{ext}(t) = \vec{0} \tag{1}$$

The system's displacements and their time-derivatives, velocities and accelerations, are represented by $\vec{q}$ and $\dot{\vec{q}}$ and $\ddot{\vec{q}}$ respectively. Moreover $\mathbf{M}$ is the mass-matrix, $\vec{f}_{int}$ the internal forces, resulting from the structure's deformation, which can be nonlinear in $\vec{q}$ and $\vec{f}_{ext}$ are the external forces, which might be time-dependent. The previously mentioned FETI-methods utilize a non-overlapping domain-decomposition approach to subdivide the whole domain of our problem or structure into smaller pieces and solve them on separate computing cores [2]. These socalled subdomains or substructures are coupled by Lagrange-Multipliers on the interfaces only. The equations of motion in (1) are therefore described locally on a substructure s

$$\mathbf{M}^{(s)}\ddot{\vec{q}}^{(s)} + \vec{f}_{int}^{(s)}(\vec{q}^{(s)}) + \mathbf{B}^{(s)^T}\vec{\lambda} - \vec{f}_{ext}^{(s)}(t) = \vec{0} \tag{2}$$

and extended by a global compatibility-condition for the accelerations on the interface Γ_λ

$$\sum_{s=1}^{N_s} \mathbf{B}^{(s)}\ddot{\vec{q}}^{(s)} = \vec{0} \tag{3}$$

where $\mathbf{B}$ is a signed Boolean matrix, that condenses the local degrees of freedom on the interface Γ_λ. It has been shown by Farhat e.a., that coupling on the accelerations doesn't cause a drift of the displacements and leads to more stable computations than in case of displacement-coupling [3, 4]. The solution procedure of both equations (2) and (3) now consists of a time-integration scheme, such as the well known Newmark-β scheme

$$\begin{aligned}
\dot{\vec{q}}_{n+1} &= \dot{\vec{q}}_n + (1-\gamma)\Delta t\ddot{\vec{q}}_n + \gamma\Delta t\ddot{\vec{q}}_{n+1} \\
\vec{q}_{n+1} &= \vec{q}_n + \Delta t\dot{\vec{q}}_n + \left(\frac{1}{2} - \beta\right)\Delta t^2\ddot{\vec{q}}_n + \beta\Delta t^2\ddot{\vec{q}}_{n+1}
\end{aligned}$$

with $\beta \in [0, \frac{1}{4}]$ and $\gamma \in [0, \frac{1}{2}]$ being parameters, that tune accuracy and numerical damping of the integration scheme. Hence we have the solutions of the next time-step $n+1$ related to the previous time-step n only. To solve the nonlinear system for the upcoming time-step $n+1$ we can use a Newton-Raphson scheme and linearize equations (2) and (3), resulting in

$$\begin{aligned}
\mathbf{M}^{(s)}\Delta\ddot{\vec{q}}^{(s)} + \frac{\partial\vec{f}_{int}^{(s)}(\vec{q}_{n+1,i}^{(s)})}{\partial\vec{q}^{(s)}}\frac{\partial\vec{q}^{(s)}}{\partial\ddot{\vec{q}}^{(s)}}\Delta\ddot{\vec{q}}^{(s)} + \mathbf{B}^{(s)^T}\Delta\vec{\lambda} + \\
+\mathbf{M}^{(s)}\ddot{\vec{q}}_{n+1,i}^{(s)} + \vec{f}_{int}^{(s)}(\vec{q}_{n+1,i}^{(s)}) + \mathbf{B}^{(s)^T}\vec{\lambda}_{n+1,i} - \vec{f}_{ext}^{(s)}(t_{n+1}) &= \vec{0} \qquad (4) \\
\sum_{s=1}^{N_s}\mathbf{B}^{(s)}\Delta\ddot{\vec{q}}^{(s)} + \mathbf{B}^{(s)}\ddot{\vec{q}}_{n+1,i}^{(s)} &= \vec{0} \qquad (5)
\end{aligned}$$

with i being the Newton-iteration's index and the Newton-updates

$$\begin{aligned}
\ddot{\vec{q}}_{n+1,i+1}^{(s)} &= \ddot{\vec{q}}_{n+1,i}^{(s)} + \Delta\ddot{\vec{q}}^{(s)} \\
\dot{\vec{q}}_{n+1,i+1}^{(s)} &= \dot{\vec{q}}_{n+1,i}^{(s)} + \gamma\Delta t\Delta\ddot{\vec{q}}^{(s)} \\
\vec{q}_{n+1,i+1}^{(s)} &= \vec{q}_{n+1,i}^{(s)} + \beta\Delta t^2\Delta\ddot{\vec{q}}^{(s)} \\
\vec{\lambda}_{n+1,i+1} &= \vec{\lambda}_{n+1,i} + \Delta\vec{\lambda}.
\end{aligned}$$

2.2 Solving the interface-problem

The solution of the linearized equations in (4) and (5) with the unknowns $\Delta\ddot{\vec{q}}^{(s)}$ and $\Delta\vec{\lambda}$ is usually obtained by an iterative procedure, such as a Conjugate Gradient in case of symmetric systems. The local solutions $\Delta\ddot{\vec{q}}^{(s)}$ depend of the global Lagrange Multipliers $\Delta\vec{\lambda}$ and are determined by

$$\Delta\ddot{\vec{q}}^{(s)}(\Delta\vec{\lambda}) = -\mathbf{J}^{(s)^{-1}}\left(r\vec{e}s^{(s)} + \mathbf{B}^{(s)^T}\Delta\vec{\lambda}\right)$$

with the local Jacobian $\mathbf{J}$ and the associated residual $r\vec{e}s$. By reinserting these local solutions into the compatibility condition (5) we get the global interface-problem

$$\underbrace{\sum_{s=1}^{N_s}\mathbf{B}^{(s)}\mathbf{J}^{(s)^{-1}}\mathbf{B}^{(s)^T}}_{\mathbf{F}}\Delta\vec{\lambda} = \underbrace{\sum_{s=1}^{N_s}\mathbf{B}^{(s)}\mathbf{J}^{(s)^{-1}}r\vec{e}s^{(s)} - \mathbf{B}^{(s)}\ddot{\vec{q}}^{(s)}_{n+1,i}}_{\vec{d}}$$

which is solved iteratively and solves the local problems in each iteration with updated $\Delta\vec{\lambda}$ as external forces. This means in a Conjugate Gradient the operation $\mathbf{F}\Delta\vec{\lambda}$ is performed once every iteration. For implementation purposes we can formulate this operation as

$$\mathbf{F}\Delta\vec{\lambda} = \sum_{s=1}^{N_s}\mathbf{B}^{(s)}\Delta\ddot{\vec{q}}^{(s)}(\Delta\vec{\lambda}) - \vec{d} \tag{6}$$

3 ASYNCHRONOUS TIME-INTEGRATION ON NONLINEAR SYSTEMS

3.1 Derivation of the nonlinear BGC-macro method

In the previous chapter 2.1 the FETI method has been applied to a nonlinear structural dynamics problem, where the same time-step-size has been used on every substructure. This is often referred to as synchronous time-integration. In certain cases different adapted time-step-sizes might come in handy. For example in cases with different dynamics in substructures, like due to different material-stiffnesses or fast nonlinear processes in a substructure, e.g. cracks. Having different time-steps on substurctures is usually referred to as *asynchronous time-integration* [7], multi-timestep [6, 14, 15] or multirate method [12]. In the following we

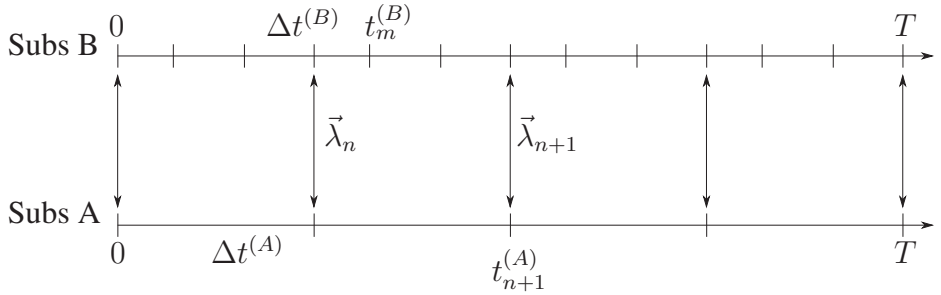

Figure 1: Page layout.

focus on a method, that couples substructures only at a syncronization time-step, as depicted in Figure 1 and proposed by Prakash e.a. [14]. Between these synchronization time-steps the Lagrange-Multipliers are interpolated linearly in time and applied locally on the substructures.

Hence we can extend the nonlinear residuals (2) and (3) by the linear interpolation on the local time-step m of the Lagrange-Multipliers

$$\vec{\lambda}_{m+1} = \vec{\lambda}_n \frac{t_{n+1} - t_{m+1}}{t_{n+1} - t_n} + \vec{\lambda}_{n+1} \frac{t_{m+1} - t_n}{t_{n+1} - t_n}$$

and apply them on the local residual

$$\mathbf{M}^{(s)} \ddot{\vec{q}}^{(s)}_{m+1} + \vec{f}^{(s)}_{int}(\vec{q}^{(s)}_{m+1}) + \mathbf{B}^{(s)^T} \vec{\lambda}_{m+1} - \vec{f}^{(s)}_{ext}(t_{m+1}) = \vec{0}.$$

As in the formulation of the GC-method we formulate the Newmark-β scheme in residual form, based on the velocities

$$\frac{1}{\gamma \Delta t}(\dot{\vec{q}}_{m+1} - \dot{\vec{q}}_m) - \frac{1-\gamma}{\gamma} \ddot{\vec{q}}_m - \ddot{\vec{q}}_{m+1} = \vec{0}$$

$$\vec{q}_m + \Delta t \dot{\vec{q}}_m + \left(\frac{1}{2} - \frac{\beta}{\gamma}\right) \Delta t^2 \ddot{\vec{q}}_m + \frac{\beta \Delta t}{\gamma}(\dot{\vec{q}}_{m+1} - \dot{\vec{q}}_m) - \vec{q}_{m+1} = \vec{0}$$

and write the local solutions and residuals in concatenated form

$$\tilde{\vec{q}}_m = \begin{bmatrix} \ddot{\vec{q}}_m \\ \dot{\vec{q}}_m \\ \vec{q}_m \end{bmatrix} \quad \tilde{\vec{r}}^{(s)} = \begin{bmatrix} \mathbf{M}^{(s)} \ddot{\vec{q}}^{(s)}_{m+1} + \vec{f}^{(s)}_{int}(\vec{q}^{(s)}_{m+1}) + \mathbf{B}^{(s)^T} \vec{\lambda}_{m+1} - \vec{f}^{(s)}_{ext}(t_{m+1}) \\ \frac{1}{\gamma \Delta t}(\dot{\vec{q}}_{m+1} - \dot{\vec{q}}_m) - \frac{1-\gamma}{\gamma} \ddot{\vec{q}}_m - \ddot{\vec{q}}_{m+1} \\ \vec{q}_m + \Delta t \dot{\vec{q}}_m + \left(\frac{1}{2} - \frac{\beta}{\gamma}\right) \Delta t^2 \ddot{\vec{q}}_m + \frac{\beta \Delta t}{\gamma}(\dot{\vec{q}}_{m+1} - \dot{\vec{q}}_m) - \vec{q}_{m+1} \end{bmatrix} = \vec{0} \quad (7)$$

$$\tilde{\vec{r}}^{I} = \sum_{s=1}^{N_s} \mathbf{B}^{(s)} \dot{\vec{q}}^{(s)}_{N_m} = \vec{0} \quad (8)$$

By linearizing residuals (7) and (8) for these local solutions $\tilde{\vec{q}}_j$, $\tilde{\vec{q}}_{j+1}$ and $\vec{\lambda}_{n+1}$, as it has been done in the nonlinear PH-method [15], we can write the full linearized system in matrix form

$$\tilde{\mathbf{M}}^{(s)} = \begin{bmatrix} \mathbf{M}^{(s)} & \mathbf{0} & \mathbf{K}^{(s)} \\ -\gamma \Delta t^{(s)} \mathbf{I} & \mathbf{I} & \mathbf{0} \\ -\beta {\Delta t^{(s)}}^2 \mathbf{I} & \mathbf{0} & \mathbf{I} \end{bmatrix} \qquad \mathbf{N}^{(s)} = \begin{bmatrix} \mathbf{0} & \mathbf{0} & \mathbf{0} \\ -\Delta t^{(s)}(1-\gamma)\mathbf{I} & -\mathbf{I} & \mathbf{0} \\ -\Delta t^{(s)}(1/2-\beta)\mathbf{I} & -\Delta t^{(s)} \mathbf{I} & -\mathbf{I} \end{bmatrix}$$

$$\tilde{\mathbf{B}}^{(s)^T} = \begin{bmatrix} \mathbf{0} \\ \mathbf{B}^{(s)^T} \\ \mathbf{0} \end{bmatrix} \qquad \tilde{\mathbf{C}}^{(s)} = \begin{bmatrix} \mathbf{B}^{(s)^T} \\ \mathbf{0} \\ \mathbf{0} \end{bmatrix}$$

$$\left[\begin{array}{cccc|c|c} \tilde{\mathbf{M}}^{(B)}_1 & & & & & \frac{1}{N_m}\tilde{\mathbf{C}}^{(B)} \\ \mathbf{N}^{(B)} & \tilde{\mathbf{M}}^{(B)}_2 & & & & \frac{2}{N_m}\tilde{\mathbf{C}}^{(B)} \\ & \ddots & \ddots & & & \vdots \\ & & \mathbf{N}^{(B)} & \tilde{\mathbf{M}}^{(B)}_{N_m} & & \frac{N_m}{N_m}\tilde{\mathbf{C}}^{(B)} \\ \hline & & & & \tilde{\mathbf{M}}^{(A)}_{n+1} & \tilde{\mathbf{C}}^{(A)} \\ \hline & & & \tilde{\mathbf{B}}^{(B)} & \tilde{\mathbf{B}}^{(A)} & \mathbf{0} \end{array}\right] \left[\begin{array}{c} \Delta\tilde{\vec{q}}^{(B)}_1 \\ \Delta\tilde{\vec{q}}^{(B)}_2 \\ \vdots \\ \Delta\tilde{\vec{q}}^{(B)}_{N_m} \\ \hline \Delta\tilde{\vec{q}}^{(A)}_{N_m} \\ \hline \Delta\vec{\lambda}_{n+1} \end{array}\right] = \left[\begin{array}{c} -\tilde{\vec{r}}^{(B)}(\tilde{\vec{q}}^{(B)}_0, \tilde{\vec{q}}^{(B)}_1, \vec{\lambda}_1) \\ -\tilde{\vec{r}}^{(B)}(\tilde{\vec{q}}^{(B)}_1, \tilde{\vec{q}}^{(B)}_2, \vec{\lambda}_2) \\ \vdots \\ -\tilde{\vec{r}}^{(B)}(\tilde{\vec{q}}^{(B)}_{N_m-1}, \tilde{\vec{q}}^{(B)}_{N_m}, \vec{\lambda}_{n+1}) \\ \hline -\tilde{\vec{r}}^{(A)}(\tilde{\vec{q}}^{(A)}_n, \tilde{\vec{q}}^{(A)}_{n+1}, \vec{\lambda}_{n+1}) \\ \hline -\tilde{\vec{r}}^{I}(\tilde{\vec{q}}^{(A)}_{n+1}, \tilde{\vec{q}}^{(B)}_{N_m}) \end{array}\right] \quad (9)$$

The main-difference between this method and the nonlinear PH-method lies in the coupling condition [15]. We didn't formulate the coupling-residual based on a force-residual, but a compatibility of end-point-velocities only. In the BGC-macro method this compatibility condition arises from the Pseudo-energy-method and therefore this method can be seen as a nonlinear version of the BGC-macro method [1].

3.2 Numerical experiments on nonlinear asynchronous time-integration

3.2.1 Implementation

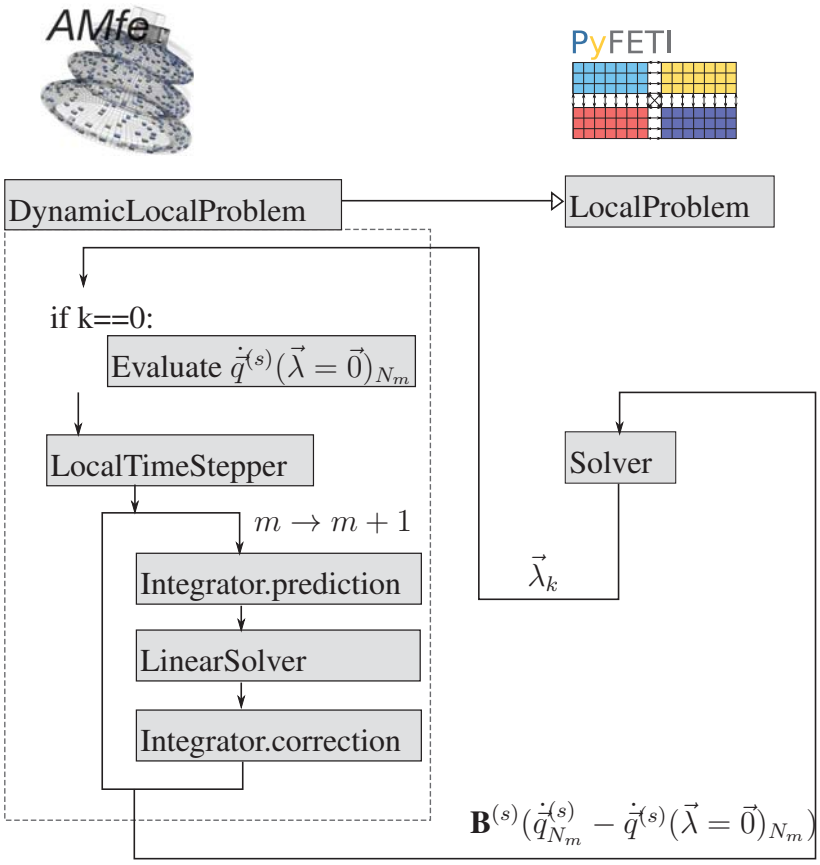

Figure 2: Implementation of the asynchronous time-integration in our FE-framework, which consists of the Python packages AMfe and PyFETI. Here k is the index of each CG-iteration.

For the following experiments we implemented the previous method (9) in a time-stepping manor and integrated it into our FE-framework as depicted in Figure 2. The general framework consists of two open-source Python-packages, the nonlinear FE-library AMfe [17] and the MPI-parallelized FETI-library PyFETI [18]. The softwares' stable master-branches are published on github. As soon as the implementation of the here presented methods is cleaned up and fully integrated in a more flexible and modular manor, they will be published there as well. PyFETI provides the FETI-solver and a local-problem class, which gets the Lagrange-Multipliers as input, does local computations and returns the results to the FETI-solver. This class is customized with local time-stepping routines to implement the method from (9). During the first FETI-iteration the constant $\vec{d}$ from (6) has to be evaluated by performing the local computations with the Lagrange-Multipliers set to a start-value, e.g. $\vec{\lambda} = \vec{0}$.

3.2.2 Spurious oscillations on the interface

As a reference we started with applying our method to the split Duffing-oscillator problem, as used by Prakash e.a.[15], which is shown in Figure 3. The springs' stiffnesses are nonlinear

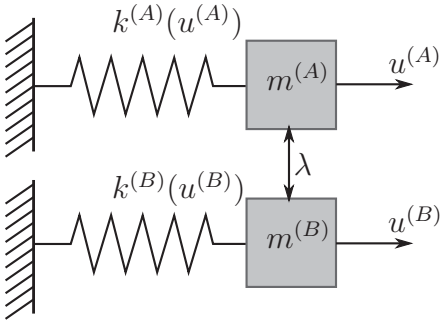

Figure 3: Split Duffing Oscillator.

in the displacements

$$k^{(s)}(q^{(s)}) = k_1 q^{(s)} + k_2 q^{(s)^3}$$

and are set with the parameters from Table 1. In case of rather fine time-discretizations we

	k_1	k_2	m
A	1	1	1
B	10	-5	1

Table 1: Material-parameters for nonlinear Split Duffing Oscillator.

experience a bit more spurious oscillations of the velocities between the synchronization-time-steps, as shown in Figure 4. In the case of a coarser time-discretization in Figure 5 the oscillations increase for both methods, which leads to incompatibilities in the displacements. Hence the force-residuals on the interface of the nonlinear PH-method seem to decrease the amplitude of such spurious oscillations slightly, but require more precomputations, while the method, which is presented here only enforces coupling by Lagrange-Multipliers.

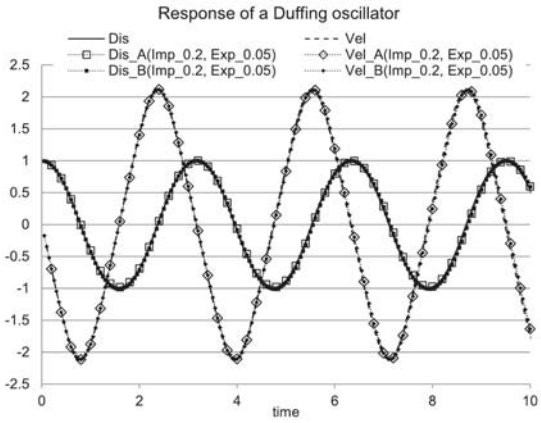
3.2.3 Unphysical reflections on the interface

After the tests on a simple split Duffing-Oscillator, we applied the method to a 2D example beam. The beam's geometry and domain decomposition can be seen in Figure 6. It is loaded with a shock from the right and clamped on the left-hand side. The shock vanishes long before the first syncronization step. The model-parameters can be found in Table 2. With this setup we get a wave in substructure B, which is visualized by the normal-stresses in Figure 7. This wave

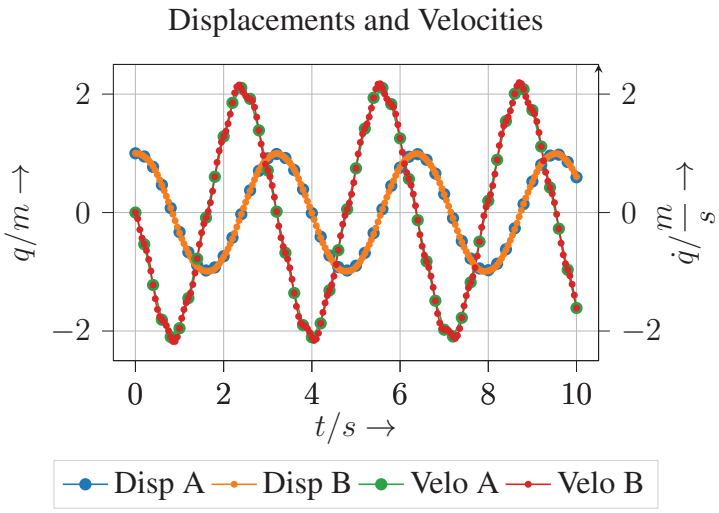
l_1	l_2	H	d	f_{max}	t_1	t_2	ΔT	Δt
$40m$	$10m$	$10m$	$2m$	$5.0 \cdot 10^4 N$	$0.00015s$	$0.0003s$	$0.001s$	$0.00001s$

Material-model	Young's-Modulus	Poisson's ratio	Density	thickness
St.Venant-Kirchhoff	$60 \cdot 10^5 N/m^2$	0.34	$2.7 \cdot 10^{-3} kg/m^3$	$0.5m$

Table 2: Model-parameters for 2D beam-example

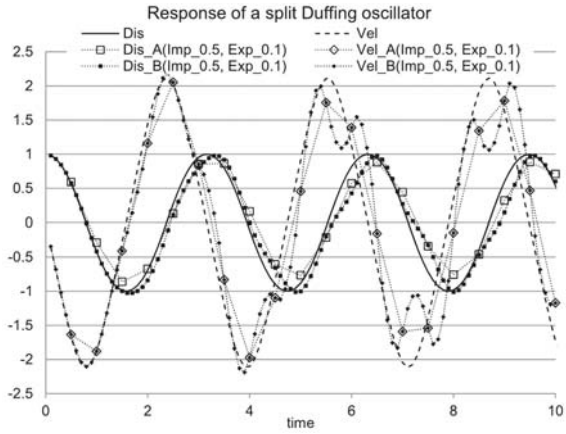


(a) Displacements and velocities of both substructures A, B with nonlinear PH-method [15]

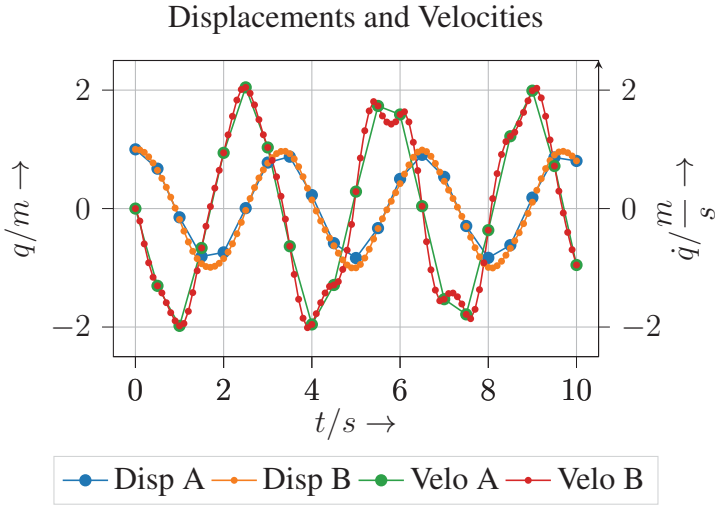


(b) Displacements and velocities of both substructures A, B with nonlinear BGC-macro

Figure 4: Solutions for the split Duffing-oscillator with a rather fine time-discretisation: $\Delta t^{(A)} = 0.2s$ and $\Delta t^{(B)} = 0.05s$



(a) Displacements and velocities of both substructures A, B with nonlinear PH-method [15]



(b) Displacements and velocities of both substructures A, B with nonlinear BGC-macro

Figure 5: Solutions for the split Duffing-oscillator with a rather coarse time-discretisation: $\Delta t^{(A)} = 0.5s$ and $\Delta t^{(B)} = 0.1s$

reaches the interface before the syncronization time-step, high-frequency parts are reflected, as can be seen at the switched sign of the normal stresses in Figure 7, and form a standing wave inside substructure B. During the intermediate time-steps substructure B can be interpreted as a single plate for those high frequencies. The coarse substructure A is not able to follow the fast dynamics of that wave and only captures slower deformations, but overall energy has to be conserved. Hence this fast dynamic stays inside substructure B.

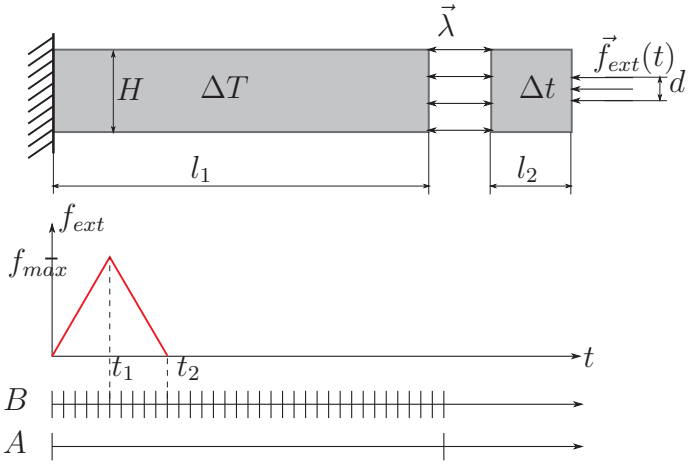


Figure 6: Geometry of the 2D beam and loading with an external shock.

4 A VARIATIONAL APPROACH TO COUPLING CONDITIONS IN TIME

4.1 Construction of a variational asynchronous coupling condition

4.1.1 Introduction to the variational principle in continuous dynamics

In Prakash e.a. it has been stated already, that the spurious oscillations in chapter 3.2.2 pollute the solution [15]. We also showed the appearance of unphysical reflections on the interface in case of inappropriate time-step-sizes and loadings in chapter 3.2.3. These reflections are not just inaccurate, but might also alter the solution by triggering nonlinear cracking events to early or destabilizing the solution with resonances. According to Gravouil e.a. such oscillations don't appear in the micro-step-based methods, such as HATI and BGC-micro, but they suffer from artificial energy-dissipation [7]. An approach, that might be able to resolve these issues is based on the variational principle. For continuous systems this principle, also known as Hamilton's principle, plays a key-role in structural dynamics. Let's consider the Lagrangian

$$\mathcal{L}(\dot{\vec{q}}, \vec{q}) = \mathcal{T}(\dot{\vec{q}}) - \mathcal{V}(\vec{q}) = \frac{1}{2}\dot{\vec{q}}^T \mathbf{M} \dot{\vec{q}} - \mathcal{V}(\vec{q})$$

of a mechanical system, consisting on the kinetic energy $\mathcal{T}$ and potential energy $\mathcal{V}$ of the system. As conservative mechanical systems, meaning systems without loading or dissipation, in nature always move such that energy within the system is kept constant, we can also require, that the Lagrangian integrated over the time-intervall and varied for the displacement $\vec{q}$ stays 0

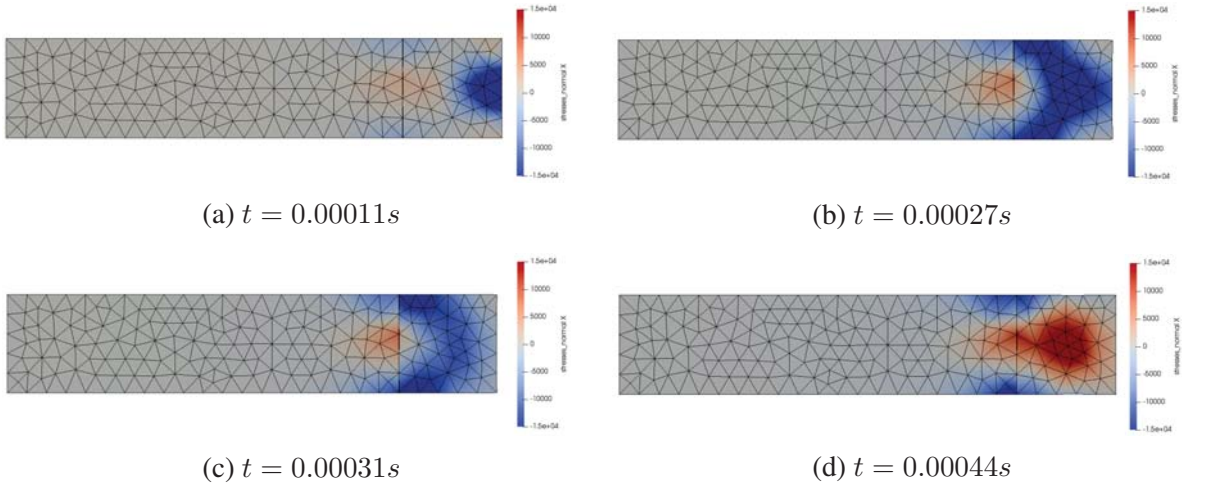
$$\delta S(\dot{\vec{q}}, \vec{q}) = \delta \int_0^T \mathcal{L}(\dot{\vec{q}}, \vec{q}) dt = \int_0^T \frac{\partial \mathcal{L}}{\partial \vec{q}} \delta \vec{q} + \frac{\partial \mathcal{L}}{\partial \dot{\vec{q}}} \delta \dot{\vec{q}} dt = 0. \tag{10}$$

Here S is called the action integral. With integration by parts we get

$$\delta S(\dot{\vec{q}}, \vec{q}) = \int_0^T \left[\frac{\partial \mathcal{L}}{\partial \vec{q}} - \frac{d}{dt} \frac{\partial \mathcal{L}}{\partial \dot{\vec{q}}} \right] \delta \vec{q} dt + \left[\frac{\partial \mathcal{L}}{\partial \dot{\vec{q}}} \delta \vec{q} \right]_0^T = 0$$

and if we require fixed end-points for $\delta\vec{q}(t=0) = \delta\vec{q}(t=T) = \vec{0}$ now and that the integral has to evaluate 0 for arbitrary variations $\delta\vec{q}$, we get the Euler-Lagrange-equation

$$-\frac{\partial \mathcal{L}}{\partial \vec{q}} + \frac{d}{dt} \frac{\partial \mathcal{L}}{\partial \dot{\vec{q}}} = \frac{d}{dt} \frac{\partial \mathcal{T}}{\partial \dot{\vec{q}}} + \frac{\partial \mathcal{V}}{\partial \vec{q}} = \vec{0}$$



(a) $t = 0.00011s$ (b) $t = 0.00027s$

(c) $t = 0.00031s$ (d) $t = 0.00044s$

Figure 7: Normal stresses in beam-length direction of the 2D-beam at several time-steps. The solution of the coarse substructure have been interpolated linearly onto the fine time-grid for visualization purposes only.

which is our equation of motion from (1) without external loads. Constraints are not taken into account here, but can be included by the interface-energy

$$\mathcal{H}(\vec{q}, \vec{\lambda}) = \vec{g}(\vec{q})^T \vec{\lambda} \tag{11}$$

with the gap-function $\vec{g}(\vec{q})$ [11]. The Lagrangian of such a constrained system is then written as

$$\mathcal{L}(\dot{\vec{q}}, \vec{q}, \vec{\lambda}) = \mathcal{T}(\dot{\vec{q}}) - \mathcal{V}(\vec{q}) - \mathcal{H}(\vec{q}, \vec{\lambda}) \tag{12}$$

4.1.2 Construction of the discrete coupling condition

This approach can be transfered to discrete systems and used for the construction of Variational Time-Integrators, which provide some built-in properties, such as Symplecticity, conservation of linear and angular momentum and bounded oscillations of energy. These properties lead to good long-time behavior of such a Variational Integrator. In fact Kane e.a. showed, that the non-dissipative Newmark-β scheme with $\gamma = \frac{1}{2}$ is variational and can be derived from a Midpoint-rule as integration-scheme [8]. Lew e.a. also developed an asynchronous integrator, based on this principle, but with updating the solutions based on the previous neighboring solution directly and therefore not suitable for a FETI-solver [10]. Leyendecker and Ober-Blöbaum proposed a variational approach for constrained systems and multirate integration, that couples slow and fast dynamics over Lagrange-Multipliers [12]. In the following we use this approach as a basis for the derivation of a new asynchronous coupling technique and domain decomposition. The starting-point of constructing an integrator is the time-discretization of the solutions. Time-dependent shape-functions $\Phi(t)$ and $\Theta(t)$, similar to Wenger [16], lead to a flexible formulation

$$\vec{q}(t) = \sum_{m=0}^{N_m} \Phi(t)_m \vec{q}_m \qquad \dot{\vec{q}}(t) = \sum_{m=0}^{N_m} \frac{d\Phi(t)_m}{dt} \vec{q}_m$$

$$\vec{\lambda}(t) = \sum_{j=0}^{N_j} \Theta(t)_j \vec{\lambda}_j$$

for the approximation of the solutions at any time t. Different indices of displacements and Lagrange-Multipliers indicate the option of different discretizations for both fields and N_m and N_j are the number of time-steps over the full trajectory. These are then inserted into the Lagrangian (12)

$$\mathcal{L}(\vec{q}_0^{(s)}, \dots, \vec{q}_{N_m}^{(s)}, \vec{\lambda}_0, \dots, \vec{\lambda}_{N_j}, t) = \sum_{s=1}^{N_s} \frac{1}{2} \left(\sum_{m=0}^{N_m^{(s)}} \frac{d\Phi(t)_m^{(s)}}{dt} \vec{q}_m^{(s)} \right)^T \mathbf{M}^{(s)} \left(\sum_{m=0}^{N_m^{(s)}} \frac{d\Phi(t)_m^{(s)}}{dt} \vec{q}_m^{(s)} \right) - \\ - \mathcal{V} \left(\sum_{m=0}^{N_m^{(s)}} \Phi(t)_m^{(s)} \vec{q}_m^{(s)} \right)^{(s)} - \mathcal{H} \left(\sum_{m=0}^{N_m^{(s)}} \Phi(t)_m^{(s)} \vec{q}_m^{(s)}, \sum_{j=0}^{N_j} \Theta(t)_j \vec{\lambda}_j)^{(s)} \right) \tag{13}$$

and extended to substructured systems by summing up all local Lagrangians. Due to the free to choose time-discretizations, we still need an appropriate formulation for the gap-function. The gap-function is supposed to measure the gap at any point in time and is written as

$$\vec{g}(\vec{q}_0^{(s)}, \dots, \vec{q}_{N_m}^{(s)}, t) = \sum_{s=1}^{N_s} \mathbf{B}^{(s)} \sum_{m=0}^{N_m^{(s)}} \Phi(t)_m^{(s)} \vec{q}_m^{(s)}$$

where the **B**-matrix is the same as in (3). The next key-point of the integrator's construction is the numerical integration over the time-intervall. The choice of the integration-scheme influences the properties of the constructed integrator. We choose the generalized midpoint-rule here, to have compatibility conditions and time-integration with the non-dissipative Newmark-β derived consistently from the same integration-scheme. One can also choose different integration-schemes for both, compatibility-condition and Lagrangian, as it has been done by Leyendecker e.a. [12]. Moreover the integration requires a segmentation-approach. In our examples here we use the same time-discretization as in chapter 3 to ensure comparability, meaning we have the same time-step-sizes for substructure A and the Lagrange-Multipliers and use a fraction of that time-step-size on the neighboring substructure B. Moreover we use linear time-shape-functions $\Phi(t)$ and $\Theta(t)$ for the solutions

$$\Theta_n(t) = \begin{cases} \frac{t_{n+1}-t}{\Delta T} & t_n \leq t \leq t_{n+1} \\ \frac{t-t_{n-1}}{\Delta T} & t_{n-1} \leq t < t_n \\ 0 & t > t_{n+1} \\ 0 & t < t_{n-1} \end{cases}$$

$$\Phi_n^{(A)}(t) = \begin{cases} \frac{t_{n+1}-t}{\Delta T} & t_n \leq t \leq t_{n+1} \\ \frac{t-t_{n-1}}{\Delta T} & t_{n-1} \leq t < t_n \\ 0 & t > t_{n+1} \\ 0 & t < t_{n-1} \end{cases}$$

$$\Phi_m^{(B)}(t) = \begin{cases} \frac{t_{m+1}-t}{\Delta t} & t_m \leq t \leq t_{m+1} \\ \frac{t-t_{m-1}}{\Delta t} & t_{m-1} \leq t < t_m \\ 0 & t > t_{m+1} \\ 0 & t < t_{m-1} \end{cases}$$

resulting in a discretization as in Figure 8. For the integration of (13) we evaluate the La-

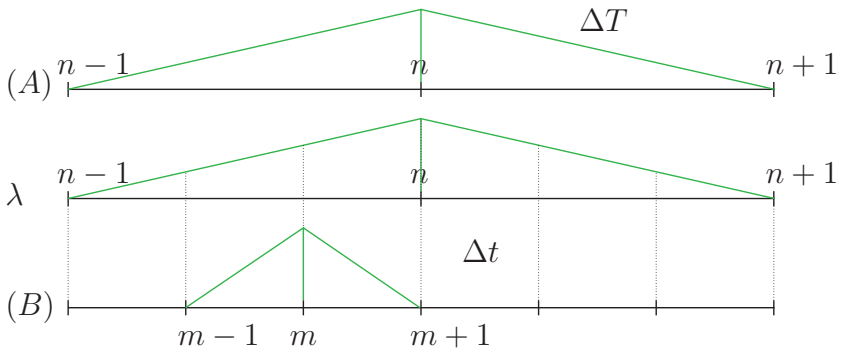


Figure 8: Time-discretization for two substructures A and B and the Lagrange-Multiplier-filed. Additionally the linear shape-function for the Lagrange-Multipliers at time-step n is shown.

grangian at intermediate timesteps

$$t_{m+\alpha/n+\alpha} = (1-\alpha)t_{m/n} + \alpha t_{m+1/n+1}, \qquad \alpha \in [0,1]$$

resulting in

$$\begin{aligned}
&S(\bar{q}_0^{(A)}, \dots, \bar{q}_{N_n}^{(A)}, \bar{q}_0^{(B)}, \dots, \bar{q}_{N_m}^{(B)}, \vec{\lambda}_0, \dots, \vec{\lambda}_{N_n}) = \\
&= \sum_{n=0}^{N_n-1} \Delta T \left[\frac{1}{2} \left(\frac{\bar{q}_{n+1}^{(A)} - \bar{q}_n^{(A)}}{\Delta T} \right)^T \mathbf{M}^{(A)} \left(\frac{\bar{q}_{n+1}^{(A)} - \bar{q}_n^{(A)}}{\Delta T} \right) - \mathcal{V}\left((1-\alpha)\bar{q}_n^{(A)} + \alpha \bar{q}_{n+1}^{(A)} \right) - \right. \\
&\left. - \left((1-\alpha)\bar{q}_n^{(A)} + \alpha \bar{q}_{n+1}^{(A)} \right)^T \mathbf{B}^{(A)^T} \left((1-\alpha)\vec{\lambda}_n + \alpha \vec{\lambda}_{n+1} \right) \right] + \\
&+ \sum_{m=0}^{N_m-1} \Delta t \left[\frac{1}{2} \left(\frac{\bar{q}_{m+1}^{(B)} - \bar{q}_m^{(B)}}{\Delta t} \right)^T \mathbf{M}^{(B)} \left(\frac{\bar{q}_{m+1}^{(B)} - \bar{q}_m^{(B)}}{\Delta t} \right) - \mathcal{V}\left((1-\alpha)\bar{q}_m^{(B)} + \alpha \bar{q}_{m+1}^{(B)} \right) - \right. \\
&\left. - \left((1-\alpha)\bar{q}_m^{(B)} + \alpha \bar{q}_{m+1}^{(B)} \right)^T \mathbf{B}^{(B)^T} \sum_{n=0}^{N_n} \Theta_n(t_{m+\alpha}) \vec{\lambda}_n \right]
\end{aligned}$$

Analogously to the continuous case in (10) the variation of this discrete action integral for its arguments

$$\begin{aligned}
&\delta S(\bar{q}_0^{(A)}, \dots, \bar{q}_{N_n}^{(A)}, \bar{q}_0^{(B)}, \dots, \bar{q}_{N_m}^{(B)}, \vec{\lambda}_0, \dots, \vec{\lambda}_{N_n}) = \\
&= \sum_{n=0}^{N_n} \frac{\partial S}{\partial \bar{q}_n^{(A)}} \delta \bar{q}_n^{(A)} + \sum_{m=0}^{N_m} \frac{\partial S}{\partial \bar{q}_m^{(B)}} \delta \bar{q}_m^{(B)} + \sum_{n=0}^{N_n} \frac{\partial S}{\partial \vec{\lambda}_n} \delta \vec{\lambda}_n = \vec{0}
\end{aligned}$$

must still evaluate as zero. We still require $\delta \bar{q}_0^{(A)} = \delta \bar{q}_{N_n}^{(A)} = 0$, $\delta \bar{q}_0^{(B)} = \delta \bar{q}_{N_m}^{(B)} = 0$, $\delta \vec{\lambda}_0 = \delta \vec{\lambda}_{N_n} = 0$ and that this equation must hold for arbitrary variations $\delta \bar{q}_n^{(A)}$, $\delta \bar{q}_n^{(B)}$, $\delta \vec{\lambda}_n$. This leads

to the equations

$$\Delta T\left[\frac{1}{\Delta T}\mathbf{M}^{(A)}\frac{\vec{q}_n^{(A)}-\vec{q}_{n-1}^{(A)}}{\Delta T}-\alpha\frac{\partial\mathcal{V}\left((1-\alpha)\vec{q}_{n-1}^{(A)}+\alpha\vec{q}_n^{(A)}\right)}{\partial\vec{q}}-\mathbf{B}^{(A)^T}\begin{bmatrix}(1-\alpha)\alpha & \alpha^2\end{bmatrix}\begin{bmatrix}\vec{\lambda}_{n-1}\\ \vec{\lambda}_n\end{bmatrix}\right]+$$
$$+\Delta T\left[-\frac{1}{\Delta T}\mathbf{M}^{(A)}\frac{\vec{q}_{n+1}^{(A)}-\vec{q}_n^{(A)}}{\Delta T}-(1-\alpha)\frac{\partial\mathcal{V}\left((1-\alpha)\vec{q}_n^{(A)}+\alpha\vec{q}_{n+1}^{(A)}\right)}{\partial\vec{q}}-\right.$$
$$\left.-\mathbf{B}^{(A)^T}\begin{bmatrix}(1-\alpha)^2 & (1-\alpha)\alpha\end{bmatrix}\begin{bmatrix}\vec{\lambda}_n\\ \vec{\lambda}_{n+1}\end{bmatrix}\right]=\vec{0}$$
$$\Delta t\left[\frac{1}{\Delta t}\mathbf{M}^{(B)}\frac{\vec{q}_m^{(B)}-\vec{q}_{m-1}^{(B)}}{\Delta t}-\alpha\frac{\partial\mathcal{V}\left((1-\alpha)\vec{q}_{m-1}^{(B)}+\alpha\vec{q}_m^{(B)}\right)}{\partial\vec{q}}-\alpha\mathbf{B}^{(B)^T}\sum_{n=0}^{N_n}\Theta_n(t_{m-1+\alpha})\vec{\lambda}_n\right]+$$
$$+\Delta t\left[-\frac{1}{\Delta t}\mathbf{M}^{(B)}\frac{\vec{q}_{m+1}^{(B)}-\vec{q}_m^{(B)}}{\Delta t}-(1-\alpha)\frac{\partial\mathcal{V}\left((1-\alpha)\vec{q}_m^{(B)}+\alpha\vec{q}_{m+1}^{(B)}\right)}{\partial\vec{q}}-\right.$$
$$\left.-(1-\alpha)\mathbf{B}^{(B)^T}\sum_{n=0}^{N_n}\Theta_n(t_{m+\alpha})\vec{\lambda}_n\right]=\vec{0}$$

for each $\vec{\lambda}_n$:

$$\sum_{m=0}^{N_m-1}\Delta t\mathbf{B}^{(B)}\begin{bmatrix}(1-\alpha)\Theta_n(t_{m+\alpha}) & \alpha\Theta_n(t_{m+\alpha})\end{bmatrix}\begin{bmatrix}\vec{q}_m^{(B)}\\ \vec{q}_{m+1}^{(B)}\end{bmatrix}+$$
$$+\Delta T\left[\mathbf{B}^{(A)}\begin{bmatrix}(1-\alpha)\alpha & \alpha^2\end{bmatrix}\begin{bmatrix}\vec{q}_{n-1}^{(A)}\\ \vec{q}_n^{(A)}\end{bmatrix}\right]+\Delta T\left[\mathbf{B}^{(A)}\begin{bmatrix}(1-\alpha)^2 & \alpha(1-\alpha)\end{bmatrix}\begin{bmatrix}\vec{q}_n^{(A)}\\ \vec{q}_{n+1}^{(A)}\end{bmatrix}\right]=\vec{0}$$

The first two equations result in the Newmark-β scheme for $\alpha=0.5$

$$\begin{aligned}\vec{q}_{m+1} &= (1-\alpha)\Delta t\dot{\vec{q}}_{m+1}+\alpha\Delta t\dot{\vec{q}}_n+\vec{q}_n\\ \ddot{\vec{q}}_{m+1} &= -\tfrac{1-\alpha}{\alpha}\ddot{\vec{q}}_m+\tfrac{1}{\alpha\Delta t}(\dot{\vec{q}}_{m+1}-\dot{\vec{q}}_m)\end{aligned}$$

and the local equilibrium of forces at generalized midpoints

$$\mathbf{M}^{(A)}\ddot{\vec{q}}_{n+\alpha}^{(A)}+\underbrace{\frac{\partial\mathcal{V}}{\partial\vec{q}}\left(\vec{q}_{n+\alpha}^{(A)}\right)}_{\vec{f}_{int}}+\mathbf{B}^{(A)^T}\begin{bmatrix}(1-\alpha) & \alpha\end{bmatrix}\begin{bmatrix}\vec{\lambda}_n\\ \vec{\lambda}_{n+1}\end{bmatrix}=\vec{0}$$
$$\mathbf{M}^{(B)}\ddot{\vec{q}}_{m+\alpha}^{(B)}+\underbrace{\frac{\partial\mathcal{V}}{\partial\vec{q}}\left(\vec{q}_{m+\alpha}^{(B)}\right)}_{\vec{f}_{int}}+\mathbf{B}^{(B)^T}\begin{bmatrix}\Theta_n(t_{m+\alpha}) & \Theta_{n+1}(t_{m+\alpha})\end{bmatrix}\begin{bmatrix}\vec{\lambda}_n\\ \vec{\lambda}_{n+1}\end{bmatrix}=\vec{0}.$$

The third equation is the new coupling condition. In this form it leads to unstable computations after a few time-steps though and if we compare it with previous coupling conditions from BGC-macro (7) and dynamic FETI (3), we notize the unfavorable displacement-coupling here. As this is just a numerics issue related to Lagrange-Multipliers without masses, we replace them by corrected velocities

$$\Delta\vec{q}^{(s)}=(1-\alpha)\Delta t^{(s)}\Delta\dot{\vec{q}}^{(s)}$$

, which result from the integration-scheme

$$\sum_{m=0}^{N_m-1} \Delta t^2(1-\alpha)\mathbf{B}^{(B)} \left[(1-\alpha)\Theta_n(t_{m+\alpha}) \quad \alpha\Theta_n(t_{m+\alpha})\right] \begin{bmatrix} \dot{\vec{q}}_m^{(B)} \\ \dot{\vec{q}}_{m+1}^{(B)} \end{bmatrix} +$$
$$+\Delta T^2(1-\alpha) \left[\mathbf{B}^{(A)} \left[(1-\alpha)\alpha \quad \alpha^2\right] \begin{bmatrix} \dot{\vec{q}}_{n-1}^{(A)} \\ \dot{\vec{q}}_n^{(A)} \end{bmatrix}\right] +$$
$$+\Delta T^2(1-\alpha) \left[\mathbf{B}^{(A)} \left[(1-\alpha)^2 \quad \alpha(1-\alpha)\right] \begin{bmatrix} \dot{\vec{q}}_n^{(A)} \\ \dot{\vec{q}}_{n+1}^{(A)} \end{bmatrix}\right] \qquad = \vec{0}$$

$$\mathbf{M}^{(A)}\ddot{\vec{q}}_{n+\alpha}^{(A)} + \underbrace{\frac{\partial \mathcal{V}}{\partial \vec{q}}\left(\vec{q}_{n+\alpha}^{(A)}\right)}_{\vec{f}_{int}} + \mathbf{B}^{(A)^T}\left[(1-\alpha) \quad \alpha\right]\begin{bmatrix}\vec{\lambda}_n \\ \vec{\lambda}_{n+1}\end{bmatrix} = \vec{0}$$

$$\mathbf{M}^{(B)}\ddot{\vec{q}}_{m+\alpha}^{(B)} + \underbrace{\frac{\partial \mathcal{V}}{\partial \vec{q}}\left(\vec{q}_{m+\alpha}^{(B)}\right)}_{\vec{f}_{int}} + \mathbf{B}^{(B)^T}\sum_{n=0}^{N_n}\Theta_n(t_{m+\alpha})\vec{\lambda}_n = \vec{0}.$$

4.2 Numerical experiments on variational coupling

In this section we apply our new variational asynchronous midpoint (VAMP) coupling condition to the Split Duffing Oscillator, known from chapter 3.2, but for now just with linear stiffnesses and $\alpha = 0.5$, which resembles the well known Newmark-β scheme. As a prove of concept we only solve the interface-problem with a direct solver here. In Figure 9 the displacements and velocities from the VAMP-coupling are compared with the BGC-macro. Both are referenced to the solutions from the synchronous coupling. The positive mainly positive energy in the BGC-macro case doesn't necessarily mean, that overall energy is growing, as the sign depends on the signs of the **B**-matrices. With the weak coupling of the VAMP-method the interface-oscillations of velocities couldn't be reduced, but incompatibilities in the displacement-field are smoothed. Hence a coarse discretization of the Lagrange-Multiplier-field always leads to such oscillations. We'ld like to point out, that the interface-energy in Figure 10 is oscillating, as expected, but bounded and the amplitude is similar for the VAMP-method compared to the strong coupling. The interface-energy is calculated by multiplying the current gap with the current Lagrang-Multiplier according to (11).

(b) Interface-energy with VMP-coupling

Figure 10: Interface-energy for the split Duffing-oscillator with a rather coarse time-discretisation: $\Delta t^{(A)} = 0.5s$ and $\Delta t^{(B)} = 0.1s$. Black curve as reference from the synchronous case with $\Delta t = 0.1s$.

5 CONCLUSIONS

Asynchronous time-integration methods with a strong end-point coupling conserve energy at these synchronization-points, but produce local oscillations between those synchronization steps. Based on the nonlinear PH- and linear BGC-macro-method, we derived a nonlinear version of the BGC-macro for Newmark-β integration schemes. It couples substructures by Lagrange-Multipliers only and doesn't require any presolution-step, but leads to slightly larger amplitudes of the spurious oscillations. Furthermore we show the risk of wave-reflections on the interface in case of adverse time-step-sizes and loadings. In order to find ways of reducing these unphysical effects while keeping the method energy-conserving, we derived a new coupling method from the variational principle. With the variational principle comes a number of inherent properties, such as bounded energy-oscillations and conservation of momentum, while in the BGC-approach the pseudo-energy method was solely used to derive a stable method. Moreover it opens up a large variety of options to create new coupling-methods. In the here presented case of a coarse Lagrange-multiplier discretization this method leads to a weak coupling of the substructures and still produces spurious oscillations in our test-example, while oscillations in the interface-energy are bounded at similar amplitudes as in the strong coupled case of the nonlinear BGC-method. Further research will be done on the velocity-oscillations and whether they can be eliminated by a more fine time-discretization of the Lagrange-Multipliers while keeping the energy bounded. Moreover we have to mention that the variational method couples Lagrange-Multipliers more along the full trajectory, which is disadvantageous in the context of High-Performance-Computing. Different integration-schemes during the construction might reduce these couplings while maintaining the variational properties. The interface-problem of the variational method has been solved with a direct solver as a prove of concept. In future work we will extend this approach to nonlinear problems and solve the interface problem with our FETI-solver, which will enable further performance studies. Moreover further work is needed on the choice of time-shape-functions.

Keywords: Multibody Dynamics, Bridge Expansion Joints, Earthquake Protection Devices.

Abstract. *Various types of devices are used to protect structures from seismic collapse, such as hydraulic or metallic hysteretic dampers or elastomeric and spherical pendulum bearings as isolators. In this paper however, a component which is already included in almost every medium to long span bridge, will be investigated and optimized to act as an earthquake protection device: the bridge expansion joints. Those structural components are placed between the abutment and the bridge superstructure or between different bridge sections to compensate relative movements, such as heat expansion elongation. Since these devices are often connected to bridge ends, the application of the expansion joints as a seismic protection device is potentially very beneficial. Also, it is expected to be economically advantageous because expansion joints are included by most bridges and under certain circumstances additional and expensive other protection devices can be replaced. The Paper demonstrates an approach of creating a precise and efficient multibody simulation model of expansion joints which will able to computationally determine their impact on seismic events.*

1 INTRODUCTION

The main purpose of the expansion joint in bridges is to cover the gap between the bridge ends and the respective abutment or between several bridge sections which is included to compensate relative movements, such as heat expansion elongation. These gaps need to be covered in order to achieve a continuous roadway for vehicles and pedestrians. In order to bridge this gaps, so called modular expansion joints come into consideration. They partition the gap into several sub-gaps, which for themselves are smaller than the allowed minimum distance. The structural elements, which fulfill this task in most configurations are the so called center beams, which are visible on the surface of the bridge roadway. The underlying support beams, which are significantly more stiff than the center beams, carry the loads induced by crossing vehicles to the gap edges. Because the gaps are not constant, the expansion joint needs to able to partition this movement equidistantly over all sub-gaps. Therefore, several control mechanisms have been developed over time. These mechanisms have in common, that they generate damping forces when the expansion joint is moved due to friction. As a result of this, it shall be investigated more deeply how much those friction forces affects the dynamic behaviour of a bridge under seismic loads.

Several papers like [2], [9] have discussed the dynamic response of bridge expansion joints due to traffic loads, which are capable of evaluating their behaviour in the vertical movement direction. Because it is expected that most of the seismic damping potential of an expansion joint arises from planar movements, those spatial directions need to be considered, too. Others like [10] investigated the pounding response of an expansion joint where the expansion joint is represented as a gap with a simplified, linear spring-damper mechanism. This is acceptable to calculate the effect of pounding towards a flexible bridge model, but is not sufficient when the nonlinear damping force of the expansion joint is of interest. For that case, a spatial multibody dynamics model will be built which is able to reproduce realistic damping forces and is suitable for targeted seismic protection behaviour. This model will be able to investigate the dynamic response of expansion joints which is expected to behave like hydraulic dampers with additional inertial forces. In contrast to that, a static response of the system is not expected, because most response forces are velocity dependent.

2 SWIVEL JOIST EXPANSION JOINTS

2.1 System description

The expansion joint which will be investigated in this paper is the Swivel Joist expansion joint. This type of expansion joint uses a control mechanism that follows the intercept theorem which describes distance relationships of intersecting lines. The task of the swivel joist is fulfilled by the support beam, which can execute rotational movements. Those rotational movement apply a control force to the elastomeric bearings, which are able to slide along the top of the support beam, as well as to the elastomeric springs at the bottom side of the support beam. These elastomeric parts are translationally fixed to the center beams, which are the visible components from the roadway, and can only rotate around the vertical axis. A very basic schematic representation of the control mechanism is displayed in Figure 1.

The elastomeric bearings and springs are preloaded to avoid a lift-off of the center beams. This force generates a significant friction force along the sliding direction of the bearings and springs which is considered as the main reason why the expansion joint is applying damping forces to the moving superstructure.

The outermost center beams of the expansion joint are called the edge beams. These beams

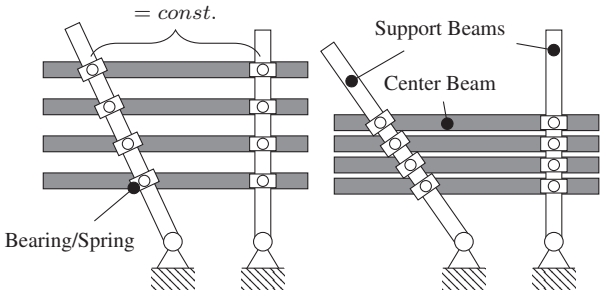

Figure 1: Schematic representation of the kinematic control mechanism of a swivel joist expansion joint

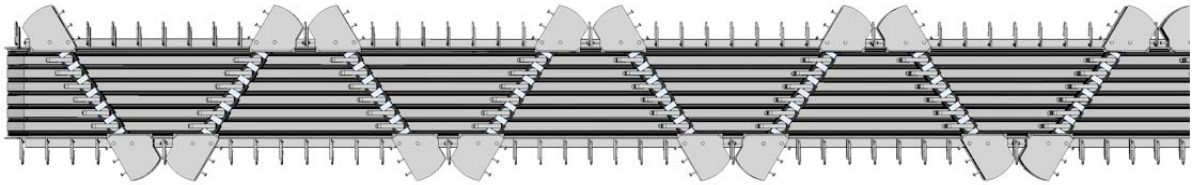

Figure 2: 3D CAD model of a swivel joist expansion joint example in bottom view

are fixed to the corresponding bridge deck and forces the support beams to swivel when one side of the bridge is moving.

3 SIMULATION MODEL

The aim of this work is to build a multibody simulation model of expansion joints which can be used to investigate their seismic retrofit potential. The fact that earthquakes are highly dynamic events which can take up to several minutes, the first requirement to the model is numerical efficiency. Because of high friction forces, it is expected that several force elements like contacts and couplings have to be extremely stiff to conserve a realistic behauviour of the model. On the other hand, such stiff force elements lead to stiff differential equations which need special solvers to gain results in a reasonable computation time.

The second requirement to the model is the possibility for easy adaption to other configurations. Because expansion joints are mostly custom made for a specific bridge, there are many possible configurations to investigate. So it needs to be possible to quickly create new simulation models by only specifying the configuration and the building process of the model itself should be automated.

The third requirement is that the model is easily extendable to other physical simulation environments for future extension possibilities as well as to custom algorithms like special friction models.

All those requirements lead to the conclusion, that it is reasonable to develop a multibody simulation environment which can be extended and automated on demand. The main parts needed to model an expansion joint are presented in the following sections.

3.1 Modeling concept

It is common to reduce the model to the essential components of interest. Parts which have less to no influence on the simulation results are ignored so that only a basic representation of the real system is left. This means for the expansion joint simulation under earthquake loads

that all parts which are affecting the control mechanism must be included. Therefore a model is built with the center beams, the support beams and the included bearings and springs. Figure 3 shows such a reduced simulation model of an example setup.

Figure 3: Reduced model for multibody simulation

The bearings at the top and the springs at the bottom side of the support beam are connected to the overlying center beams and can only rotate about the vertical axis. The contact definition between the bearings and the support beams includes the sidewall, which transmits the control force when the expansion joint is moving, and the top and bottom surface which represent the preloading and the resulting friction force.

Only one edge beam, which applies the external movement, is included because the second edge beam is assumed to be fixed for the first simulations which represent a simple opening and movement cycle. The functionality of this edge beams gets replaced by a kinematic constraint which allows a rotation of the support beams around the vertical axis only. The moving edge beam will be moved by a function of time which is coupled to a 3D force element to measure the force which is necessary to open and close the expansion joint.

3.2 Building simulation model

3.2.1 Rigid body dynamics

The system will be mathematically described by the well known Differential-Algebraic-Equations (DAE) of index 3

$$\begin{aligned} \dot{y} &= Kz \\ M\dot{z} &= F^e + J_g^T \lambda \\ 0 &= g(y) \end{aligned} \tag{1}$$

with the position vector y which containts translational positions and the Euler parameter in this setup and therefore K is the kinematic matrix, the velocity vector z, the mass matrix M, the external forces F^e and the constraint forces $J_g^T \lambda$ which are arising from the kinematic constraint

equations $g(y)$. According to [8], the index of the DAE gets reduced to 1 by two successive time derivations of $g(y)$ which can be solved by any ordinary differential equation solver

$$\dot{y} = Kz \tag{2}$$

$$M\dot{z} = F^e + J_g^T \left(J_g M^{-1} J_g^T\right)^{-1} \left(\dot{J}_g z + J_g M^{-1} F^e\right) \tag{3}$$

The external forces F^e are defined by the included contacts and the jacobian matrix J_g of all constraint equations need to be determined before the system can be solved. This steps are shown in the following sections.

3.2.2 Contacts

Contact mechanics plays an essential role in multibody dynamics and many different approaches have been published. Flores and Lankarani [4] gave a good overview of the relevant contact force models used by many multibody dynamics software. The most basic algorithm with energy dissipation is a linear Kelvin-Voigt contact model which will be implemented to simulate the contact behaviour between the bearings and support beams. It will be used as a point to surface contact where a pre-defined point P_1 represents the contact point and a corresponding surface normal vector n_2 attached to a point P_2 defines a surface. When P_1 penetrates the surface defined by n_2, a force will be applied to both bodies. A contact detection algorithm is implemented to detect whether and how much penetration is established. Therefore the scalar product of the vector between P_2 and P_1 in the local coordinate system of body 2 and the normal vector n_2 calculates the amount of penetration δ. The penetration velocity $\dot{\delta}$ gets calculated in a similar fashion. The linear Kelvin-Voigt contact model then describes the contact normal force as

$$F_n = \begin{cases} k\delta + d\dot{\delta}, & \text{if } \delta > 0 \\ 0, & \text{else} \end{cases} \tag{4}$$

with the contact stiffness k and contact damping d. For stabaility reasons and to make sure that the contact pairs do not stick permanentely, it needs to be guaranteed that

$$k\delta \overset{!}{>} d\dot{\delta} \tag{5}$$

Flores and Lankarani stated in [4] that the linear Kelvin-Voigt contact model may have several weaknesses mainly for high impact velocities. Because relatively slow velocities are considered for the first expansion joint models, this limitations are acceptable. When a more detailed contact behaviour is desired, the contact model described by Hunt and Crossley [6] might be more suitable.

The contact points get applied to the bearing bodies as shown in figure 4. Four contact points are transmitting the control forces from the support beam sidewall. The contact point for the top or bottom surface, depending on which side the bearing is mounted, generates the preloading force through geometrical positioning. These contact points are always closed and slightly overlapping with their contact surface to generate a constant force.

When two bodies get in contact with each other, a friction force tangential to the surface normal n_2 occurs. Many highly detailed models based on the friction model by Dahl [1] which are able to include stick-slip-effects have been developed. This is a common phenomenon which is observed at expansion joints, too. The disadvantage of those models is their complexity and the increasing numerical effort when solving differential equations affected by them. To

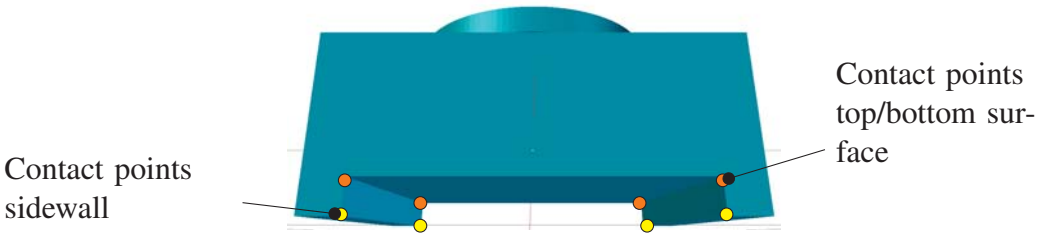

Figure 4: Distribution of the contact points on the bearings

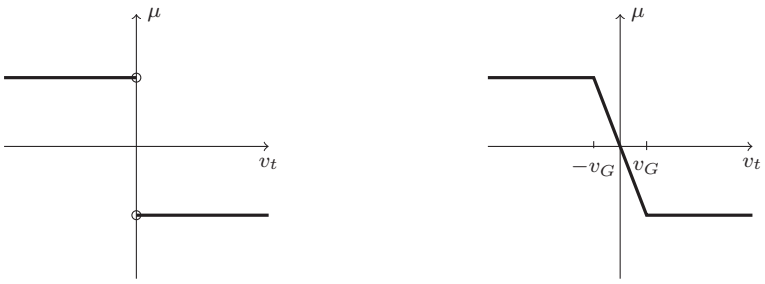
conserve an efficient simulation model of the expansion joint, two basic friction models get implemented instead. The first one represents the statical Coulomb friction model with the tangential velocity dependent friction coefficient $\mu(v_t)$ which is illustrated in figure 5a. To overcome numerical difficulties at $v_t = 0$, μ gets approximated by a linear function when $v_t \in [-v_G, v_G]$ as shown if figure 5b.



(a) with singularity (b) without singularity

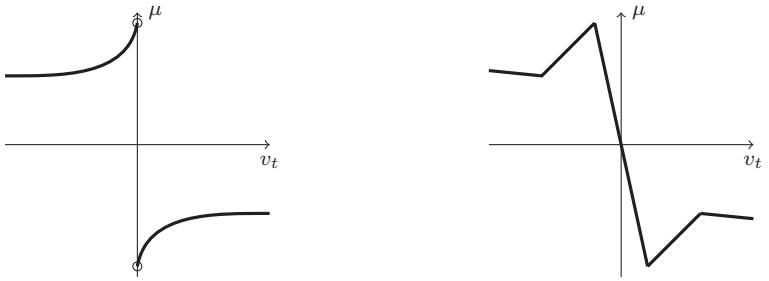
Figure 5: Coulomb friction model

A more enhanced friction model, which includes the Stribeck-effect, is presented by Marques et al. [7]. This effect, illustrated in figure 6a, includes the fact, that the friction coefficient is higher at low velocities than the kinetic friction coefficient is. To simplify the calculation of μ, the continuous function gets approximated by linear sections. It has been observed in the expansion joint simulations that a slightly increasing kinetic friction coefficient is a good approximation of the real friction behaviour, which can be seen in figure 6b. This slightly increasing friction coefficient must be limited to avoid unrealistic high friction at higher velocities. The singularity at zero velocity has to be approximated the same way as in the aforementioned model.

Both friction models are implemented and used for tests within the multibody dynamics environment. Together with the normal forces of the contacts, the friction forces define the external forces F^e from equation 3.

3.2.3 Kinematic constraints

The interaction between the bearings and the center beams could be described either by force elements like so called bushings, which are basically three dimensional springs, or by kinematic constraint equations. Because it is expected that the contacts and those bushings need to be very stiff to ensure a realistic force transmission, the differential equations describing this system will be very stiff, too. To reduce those stiff force elements and the number of degrees of freedom



(a) with singularity (b) without singularity

Figure 6: Friction model with Stribeck-effect

of the model at the same time, kinematic constraints come into consideration. The connection between the bearings and the corresponding center beams could be simplified to the effect of a hinge. This constrains two bodies in a way so there is only one rotational degree of freedom left.

To include the effect of this hinge in the dynamic differential equation of the index reduced system 3, the jacobian J_g of the constraint equation $g(y)$ need to be determined. This constraint equation could be built with the basic vector constraints presented by Flores [3] to

$$g(y) = \begin{bmatrix} r_{0P_2,0} - r_{0P_1,0} \\ m_2^T u_2 \\ n_2^T u_2 \end{bmatrix} = 0 \tag{6}$$

where $r_{0P_1,0}$ and $r_{0P_2,0}$ are the vectors from the global coordinate System 0 to the local connection points of the hinge, m_2 and n_2 are the perpendicular vectors to the rotation axis attached to body 1 but transformed to the local coordinate system of body 2 and u_2 is the rotation axis attached to body 2. This equation depicts a hinge constraint because it constrains all translational movement and two rotations by requiring that the perpendicular vectors m_2 and n_2 are always perpendicular to u_2. The first derivative in time of equation 6 delivers the jacobian for each body to

$$\dot{g}(y) = \underbrace{\begin{bmatrix} I_{3\times3} & \tilde{r}_{1P1,0} \\ 0_{1\times3} & -\tilde{m}_2^T u_2 \\ 0_{1\times3} & -\tilde{n}_2^T u_2 \end{bmatrix}}_{J_{g1}} z1 + \underbrace{\begin{bmatrix} -I_{3\times3} & -\tilde{r}_{2P2,0} \\ 0_{1\times3} & A_{12}^T \tilde{m}_2^T u_2 \\ 0_{1\times3} & A_{12}^T \tilde{n}_2^T u_2 \end{bmatrix}}_{J_{g2}} z_2 \tag{7}$$

where $\tilde{r}_{1P1,0}$ and $\tilde{r}_{2P2,0}$ are the skew-symmetric matrices of the vector from the local coordinate system to the connection points transformed to the global coordinate system, z_1 and z_2 are the velocity vectors of the corresponding bodies and A_{12} is the transformation matrix between the local coordinate systems of the bodies. The jacobians of all bodies are collected when building the model providing the global jacobian J_g from equation 3. Another time derivative of the constraint equation delivers the product $\dot{J}_g z$ to

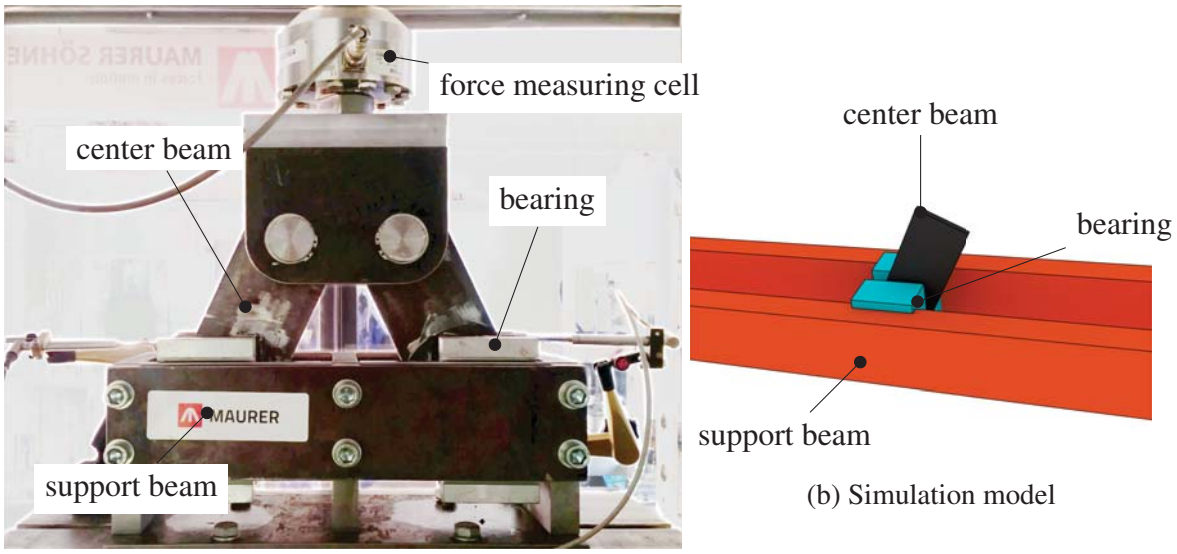
$$\dot{J}_g z = \begin{bmatrix} \dot{A}_{01} \left(\omega_{01,1} \times r_{1P1,1}\right) + \dot{A}_{02} \left(\omega_{02,2} \times r_{2P2,2}\right) \\ \left(\dot{A}_{12} u_2 \times m_2\right) \omega_{02,2} \\ \left(\dot{A}_{12} u_2 \times n_2\right) \omega_{02,2} \end{bmatrix} \tag{8}$$

with the derivatives of the transformation matrices $\dot{A}_{01}$, $\dot{A}_{02}$ and $\dot{A}_{12}$. This product will be collected into a global matrix for all bodies as well.

3.3 Friction coefficient

3.3.1 Test setup

The all determining forces generated by expansion joint are the friction forces generated between the preloaded bearings and the support beam due to the high normal force. In order to build a model which represents this behaviour, it is essential to know the friction coefficient μ. To achieve this, a simple test which should represent a realistic contact and movement scenario is set up as shown in figure 7a.



(a) Test

(b) Simulation model

Figure 7: Test setup and simulation model for a realistic friction force determination

With this setup it is intended to reproduce the angled force transmission that is occurring within the expansion joints. The bearings are preloaded with the standard preloading force and the sliding surfaces are identical to the real world contact faces. The force, which is necessary to move the system, is determined by the force measuring cell mounted between a hydraulic cylinder and the representative center beams. The hydraulic cylinder moves up and down with a frequency of $1\,\mathrm{Hz}$.

It has to be considered that friction is not the only physical phenomenon occurring in this setup influencing the time-load curve. Besides friction, there is also a noticeable amount of deformation of the elastomeric rubber bearings due to the high shear forces. This will be approximated by the linear Kelvin-Voigt contact model which allows a limited amount of penetration and represents therefore a deformation of the rubber bearings.

3.3.2 Validation with multibody simulation model

To validate the results from the friction tests, a corresponding multibody simulation model is built as shown in figure 7b. Because the test setup is symmetrical, the simulation model consists of one center beam, two bearings and two fixed support beams only. To generate the preload forces, the contact points of the main sliding surface are defined with a slight penetration of their surfaces and with a contact stiffness of $4 \times 10^7\,\mathrm{kN\,m^{-1}}$. The bearings themselves are connected

to the center beam by kinematic hinges. The results of the test and the simulation results with the basic Coulomb friction model and the Coulomb friction model with the Stribeck effect are compared in figure 8.

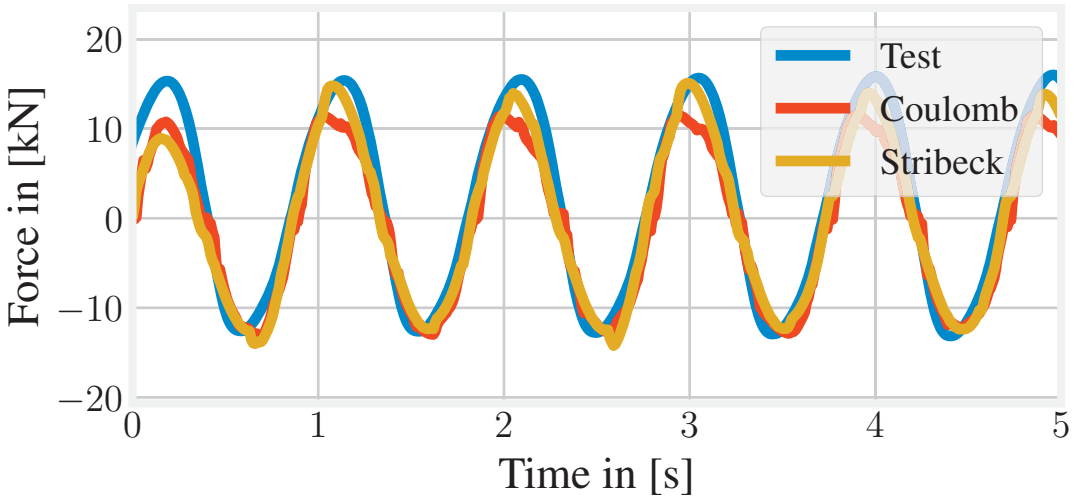


Figure 8: Force from the friction test and the simulations with different friction models

A typical effect within the swivel joist mechanism is the rising force which is needed to open the expansion joint where the angle between the center and support beams become nearly $90°$. This effect is called self-locking and first signs of this could be observed in figure 8 where the pull forces in positive direction are slightly higher than the push forces. This behaviour is represented more precisely by the friction model with the included Stribeck effect with a slightly rising kinematic friction coefficient as shown in figure 6b. This is plausible considering that the relative velocity between the bearing and the support beam increases the more the expansion joint opens and therefore the friction coefficient calculated by this model rises as well. The simulations showed that a static friction coefficient of about $7\,\%$ and a kinematic friction coefficient of $5\,\%$ producing realistic results, hence this values will be used in the follwing sections.

3.4 Numerical aspects

Before a simulation of the actual swivel joist expansion joint model could be done, several numerical aspects need to be considered. The high friction forces require very stiff contact elements to ensure realistic force transmission which leads to stiff initial value problems. Especially for large expansion joints with many bearings and therefore many contacts the simulation for simple opening/closing movements takes weeks with ordinary explicit solvers. Hairer and Wanner [5] suggested implicit methods for such problems. Therefore, the simpliest implicit solver, the backward Euler method

$$q_{k+1} = q_k + hf\left(t_{k+1}, q_{k+1}\right) \tag{9}$$

with the time step size h and

$$q = \begin{bmatrix} y \\ z \end{bmatrix} \tag{10}$$

can be used to solve the initial value problem

$$\dot{q} = f\left(t, q\right) \tag{11}$$

In order to gain the next step at $k+1$, a nonlinear equation system needs to be solved. Hairer and Wanner [5] suggested to solve this with a simplified Newton iteration. The bottleneck of this method is the computation of the jacobian

$$J = \left.\frac{\partial f_i}{\partial q_j}\right|_k \approx \frac{f\left(t, q + \epsilon q_j\right) - f(t, q)}{\epsilon} \tag{12}$$

which is done with a forward difference scheme where i are the functions and j is the number of the degrees of freedom. It has been observed that there are very small changes to the entries of the jacobian from step to step so a recomputation every time step is not necessary which speeds up the simulation tremendously.

A big advantage of the implicit Euler is that it is very efficient because only two function calls are needed per time step. According to [5], this method is also L-stable which means that uninteresting high oscillations of the true solution may be damped by the solver. This often undesired effect called numerical damping allows a reasonable time step size for the expansion joint model without instabilities in the numerical solution.

4 PLANAR OPENING AND CLOSING VALIDATION

To compare the simulation model to a real world example, a simple opening and closing scenario is used. Therefore, a relatively small expansion joint of the type MAURER DS240 is mounted on a test bench and the edge beam is moved by a hydraulic cylinder. This cylinder is equipped with a force measuring cell to determine the force which is needed to move the system. To observe a planar movement, the force is acting in a $45°$ angle, so the expansion joint executes a diagonal movement. The test bench setup is shown in figure 9.

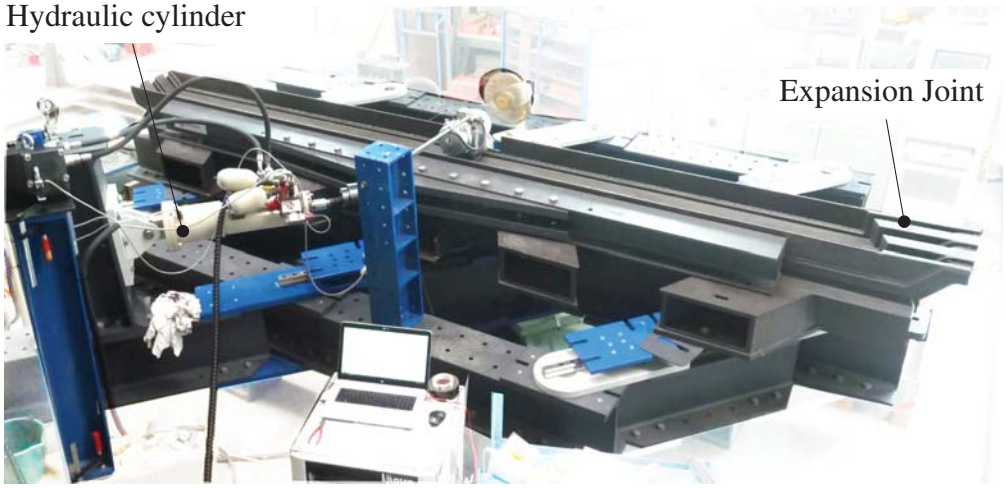

Figure 9: Test bench setup for opening and closing validation

The corresponding simulation model is shown in figure 3. The results from the test and simulations can be seen in figure 10.

Because the friction coefficients are similar, the maximum forces in both simulations are equal. The main difference between those friction models is the curvature of the force needed

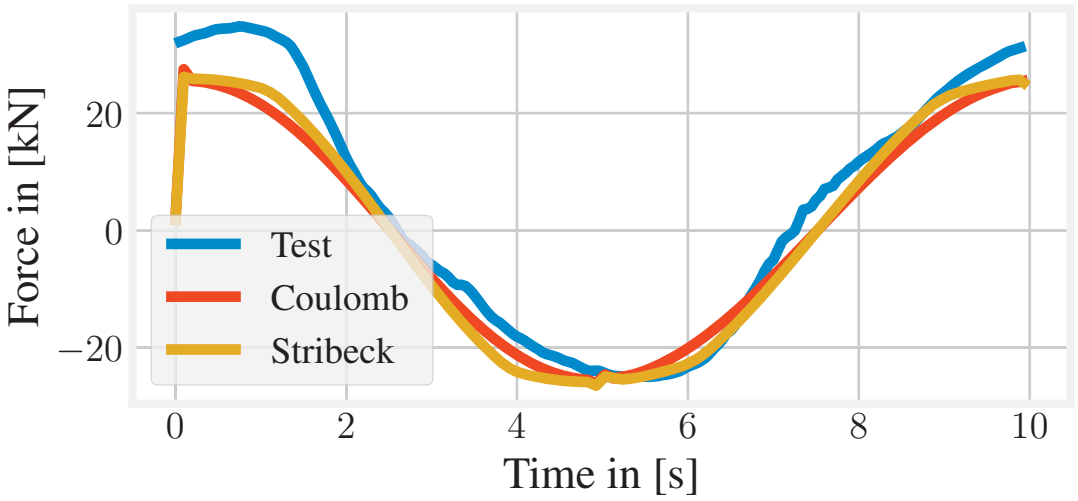

Figure 10: Force from the test and simulations with different friction models

to move the expansion joint, which is considered to be more realistic. Both models are showing a difference in the positive maxima to the measured force. This results from the fact that the test setup is not planar. Instead, the test bench is tilted forward so the hydraulic cylinder has to generate a higher push than pull force. Because of the little movement of only $10\,\mathrm{cm}$, there is not generated any noticeable amount of self-locking.

5 CONCLUSION

This research showed how a multibody dynamic model of an expansion joint for bridges could be created. Different models for the friction forces are presented, tested and compared to real world tests. The simulation model could reproduce realistic forces and movement behaviour. One big challenge is to create an efficient model which can be used in earthquake simulations with a reasonable simulation time. Therefore, stiff force elements are modeled by kinematic constraint equations and the overall stiff differential equations are solved by a simple and efficient Euler backwards method. Further test will include different configurations of the expansion joint and realistic earthquake loads applied to the models.

6 ACKNOWLEDGMENT

I would like to express my very great appreciation the company MAURER SE for the financial support to make this project possible.

Keywords: Reusing preconditioners, Frequence response, Heuristic approach.

Abstract. *In this work, a delayed frequency preconditioner (DFP) is developed and applied in structural problems for speeding-up the frequency response computation. The challenge of computing the frequency response lies in the computation of the linear system that involves the excitation forces and also the dynamic stiffness which is frequency-dependent. For each frequency, the dynamic stiffness must be updated and a new factorization must be performed, which introduces a high computational cost on the solutions of the linear systems. Alternatively, iterative solver such as GMRES can be applied to avoid the cost of factorization, however they require good preconditioners that are traditionally also frequency-dependent. In the new approach, the dynamic stiffness operator is updated with the frequency whereas the preconditioner is kept constant for a range of frequencies serving as a low-cost preconditioner for the iterative solver. This technique saves computation time because a new factorization is avoided for each frequency point. On the other hand, the effectiveness of the delayed preconditioner is destroyed when the frequency of the dynamic operator is too far away from each other. Therefore, we propose a heuristic approach to update the preconditioner when it is underperforming. The algorithm is tested on structural problems and the results show that this approach can drastically reduce the number of iterations for the computation of the frequency response.*

1 INTRODUCTION

Frequency Response (FR) is commonly computed to find the steady-state response of structures under periodic load since they have significantly less computational cost compared to the time integration methods. FR computation is essential in several aspects of design, optimization and analysis [1–6] and in various fields ranging from large aircraft components [7] to micro-electro-mechanical systems [8].

Structural components and assembly models, due to geometrical intricacies and complexity, require very fine three-dimensional discretization. The model order becomes so large that the frequency response computational cost becomes very high. The response is generally desired at more than one frequency, hence, adding extra folds to the computational burden. In such cases, one way of computing the FR is by modal superposition method which helps reduce the problem size depending on the number of mode shapes retained [9]. Another way is to use reduced order models (ROM) that condense static or dynamic information to a smaller number of degrees-of-freedom (DoF) [1]. Even for the ROM, the modal superposition method is preferred over direct solution techniques [10] that require factorization of the dynamic stiffness matrix. Since these methods are approximate, their accuracy highly depends on the selected range of frequency – usually the low frequency range. Specific methods for FR computation avoiding excessive computation burden, that are based on interpolatory model order reduction methods, are reviewed in [11]. In particular, it discusses how several Krylov sequence vectors of dynamics stiffness are computed and used as a reduction basis to find the harmonic response over the frequency range of interest. This approach is called ”Moment Matching” or ”Padé approximation”.

It is well-known that direct solvers are not feasible for very large problems. Iterative solvers, for example, Conjugate Gradient or GMRES method [12], are then employed which use an initial guess of the solution and iterate until the error has been minimized [13]. Preconditioners are used for improving their performance. Preconditioners computed using LU factorization of the matrix are very effective but they are expensive [14]. Computing good preconditioners while reducing the cost of computation is an active area of research since the cost of computing preconditioners influences largely the overall cost of the iterative solver. In [15], a new preconditioner for solving the Helmholtz equation using iterative solver is discussed. Another preconditioner for the same equation is proposed in [16]. Moreover, efficient algorithms and implementation are necessary [17]. Perconditioning also can be done using parallel algorithms [18] when parallel computers are used. Numerous other studies propose new preconditioners for specific problems since there is no ideal preconditioner for every problem [19]. Nevertheless, some examples of popular preconditioners are Incomplete Cholesky, Incomplete LU, Successive over-relaxation (SOR), Symmetric SOR and Multigrid [20] which can be found in most of the computational libraries.

In this paper, a simple method for reusing preconditioners for the FR computation is proposed to reduce the computational cost. The concept of recycling preconditioners has been investigated for other problems. For instance, [21] proposes recycling preconditioners for topology optimization problems and analyses the advantages. Authors in [22, 23] investigate recycling preconditioners for the variational Monte Carlo problem. The simulation involves the solution of a series of Monte-Carlo steps. The preconditioner from one step is updated and mapped to another step. This updated preconditioner is then reused in the next step instead of computing a new preconditioner.

Since frequency response for a structural problem is generally computed for many frequen-

cies, the preconditioner at one frequency is proposed to be reused for some frequencies until its recycling becomes costly for the iterative solver. The so-called Delayed Frequency Preconditioner (DFP) is explained in detail and demonstrated on a beam problem. The method is very simple to implement and saves a lot of preconditioner computations.

The next section presents the system of equations of a typical mechanical system. Section 3 and 4 discuss the iterative solvers and the proposed delayed frequency preconditioner, respectively. In Section 5, results in terms of computation of the DFP are discussed in detail.

2 Equation of Motion of Structural Systems

A simplified structural problem can be represented by the differential equation of motion with mass $\mathbf{M}$, stiffness $\mathbf{K}$ and a viscous damping[1] $\mathbf{C}$ matrix:

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{C}\dot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) = \mathbf{f}(t) \tag{1}$$

where $\mathbf{u}(t)$ is a time varying displacement vector due to action of linear force $\mathbf{f}(t)$. The single dot and double dot over $\mathbf{u}(t)$ denote velocity and acceleration, respectively. Assuming a periodic force $\mathbf{f}(t) = \tilde{\mathbf{f}}e^{i\omega t}$, the equation can be transformed to frequency domain

$$(-\omega^2\mathbf{M} + i\omega\mathbf{C} + \mathbf{K})\tilde{\mathbf{u}}(\omega) = \tilde{\mathbf{f}}(\omega) \tag{2}$$

The expression in parentheses is called dynamic stiffness of the system to be denoted here by

$$\mathbf{Z}(\omega) \triangleq -\omega^2\mathbf{M} + i\omega\mathbf{C} + \mathbf{K} \tag{3}$$

and substituting back in Eq. (2) gives the familiar form of linear system of equations

$$\mathbf{Z}(\omega)\tilde{\mathbf{u}}(\omega) = \tilde{\mathbf{f}}(\omega) \tag{4}$$

Note that Eq. (4) needs to be solved at every frequency $\omega = \omega_j$ in a desired bandwidth $[\omega_1, \omega_N]$ with N spectral points. Keeping in mind that the problem needs to be solved for N excitation frequencies in the frequency range of interest, the above quantities are denoted at j^{th} step for the following discussion as:

$$\tilde{\mathbf{u}}^{(j)} \triangleq \tilde{\mathbf{u}}(\omega_j), \quad \mathbf{Z}^{(j)} \triangleq \mathbf{Z}(\omega_j), \quad \tilde{\mathbf{f}}^{(j)} \triangleq \tilde{\mathbf{f}}(\omega_j) \tag{5}$$

3 Iterative Solution of the Linear System with Preconditioners

The linear system of Eq. (4) needs to be solved at each frequency point within the bandwidth. This can be computed by direct solvers which require factorization of the matrix, for example, LU factorization. It would be eminent immediately that such an operation would be extremely expensive given the size of typical discretized mechanical systems (on the order of 10^6 DoF) and that for all the spectral points. An alternate approach is to use the iterative solvers. Some of the solvers, based on Krylov Subspace, are Conjugate Gradient (CG), BiCG, MINRES, GMRES among many others. The iterative processes require good preconditioners for faster convergence. Some examples of preconditioners are Incomplete Cholesky, Incomplete LU, Successive over-relaxation (SOR), Symmetric SOR and Multigrid [20]. Eq. (4) can be written for the iterative formulation as:

$$\mathbf{Z}^{(j)}(\tilde{\mathbf{u}}_k^{(j)} + \Delta\tilde{\mathbf{u}}) = \tilde{\mathbf{f}}^{(j)} \quad \text{with} \quad \Delta\tilde{\mathbf{u}} \triangleq \tilde{\mathbf{u}}_{k+1}^{(j)} - \tilde{\mathbf{u}}_k^{(j)} \tag{6}$$

[1] The choice of damping model is arbitrary. A linear damping (Rayleigh or proportional) model is used in this work

where $k = 0, 1, , , N_k$ is the iteration index of the iterative solver. Rearranging the terms in Eq. (6)

$$\mathbf{Z}^{(j)} \Delta \tilde{\mathbf{u}} = -\mathbf{Z}^{(j)} \tilde{\mathbf{u}}_k^{(j)} + \tilde{\mathbf{f}}^{(j)} \tag{7}$$

and preconditioning the above equation with $\mathbf{P}^{(j)}$ at ω_j:

$$\begin{aligned} \mathbf{P}^{(j)} \Delta \tilde{\mathbf{u}} &= -\mathbf{Z}^{(j)} \tilde{\mathbf{u}}_k^{(j)} + \tilde{\mathbf{f}}^{(j)} \\ \mathbf{P}^{(j)} (\tilde{\mathbf{u}}_{k+1}^{(j)} - \tilde{\mathbf{u}}_k^{(j)}) &= -\mathbf{Z}^{(j)} \tilde{\mathbf{u}}_k^{(j)} + \tilde{\mathbf{f}}^{(j)} \\ \mathbf{P}^{(j)} \tilde{\mathbf{u}}_{k+1}^{(j)} &= (\mathbf{P}^{(j)} - \mathbf{Z}^{(j)}) \tilde{\mathbf{u}}_k^{(j)} + \tilde{\mathbf{f}}^{(j)} \end{aligned} \tag{8}$$

and muliplying both sides of the last of Eq. (8) with $[\mathbf{P}^{(j)}]^{-1}$ gives the equation used in the iterative solvers.

$$\tilde{\mathbf{u}}_{k+1}^{(j)} = \left(\mathbf{I} - [\mathbf{P}^{(j)}]^{-1} \, \mathbf{Z}^{(j)} \right) \tilde{\mathbf{u}}_k^{(j)} + [\mathbf{P}^{(j)}]^{-1} \, \tilde{\mathbf{f}}^{(j)} \tag{9}$$

Given an iterative solver, Eq. (9) requires that a preconditioner is computed at ω_j for which the solver would take some iterations to converge. Then for all subsequent frequency steps $\omega_{j+1}, \omega_{j+2}, \ldots, \omega_N$, new preconditioners $[\mathbf{P}^{(j+1)}]^{-1}, [\mathbf{P}^{(j+2)}]^{-1}, , \ldots, [\mathbf{P}^{(N)}]^{-1}$ will have to be computed. Since this N times repeated preconditioner computation is a costly operation for frequency response calculation, we aim to reduce it by recycling the preconditioner. This will be presented in the next section.

4 Delayed Frequency Preconditioner (DFP)

Generally, the dynamic stiffness $\mathbf{Z}^{(j)}$ is a different matrix at every ω_j, and therefore, requires a new preconditioner $\mathbf{P}^{(j)}$. The difference lies in the eigenvalues $\mathbf{\Lambda}^{(j)}$ of $\mathbf{Z}^{(j)}$. This is expounded by writing the eigen-decomposition of $\mathbf{Z}$ at two discrete frequency steps.

$$\begin{aligned} \mathbf{Z}^{(j)} &= \mathbf{\Phi} \mathbf{\Lambda}^{(j)} \mathbf{\Phi}^T \\ \mathbf{Z}^{(j+1)} &= \mathbf{\Phi} \mathbf{\Lambda}^{(j+1)} \mathbf{\Phi}^T \end{aligned} \tag{10}$$

where $\mathbf{\Phi}$ are eigenvectors of $\mathbf{Z}$ that remain unchanged at every ω. The eigenvalue matrix $\mathbf{\Lambda}^{(j)}$ and $\mathbf{\Lambda}^{(j+1)}$ have different diagonal elements which can be interpreted as the modal participation factors of the invariant modes $\mathbf{\Phi}$. In the limiting case when $\delta\omega = \omega_{j+1} - \omega_j$ is small, the change in eigenvalues of $\mathbf{Z}^{(j)}$ and $\mathbf{Z}^{(j+1)}$ is small, i.e.

$$\begin{aligned} &\mathbf{\Lambda}^{(j+1)} \approx \mathbf{\Lambda}^{(j)} \quad \text{when} \quad \delta\omega \longrightarrow 0 \\ \implies \; &\mathbf{Z}^{(j+1)} \approx \mathbf{Z}^{(j)} \end{aligned} \tag{11}$$

This property can be exploited to use $\mathbf{P}^{(j)}$ as $\mathbf{P}^{(j+1)} = \mathbf{P}^{(j)}$ at $\omega = \omega_{j+1}$. The preconditioner $[\mathbf{P}^{(j)}]^{-1}$ is thus recycled at $\omega_{j+1}, \omega_{j+2}, \ldots$ in the GMRES or CG iterative solver until a set criterion. If $[\mathbf{P}^{(j)}]^{-1}$ is a good preconditioner for the dynamic matrix $\mathbf{Z}^{(j)}$, it should make the expression $[\mathbf{P}^{(j)}]^{-1}\mathbf{Z}^{(j)}$ in Eq. (9) similar to an identity matrix. Using the same preconditioner in the successive linear system $\mathbf{Z}^{(j+1)}$ (perturbed by small $\delta\omega$ Eq. (3)), $[\mathbf{P}^{(j)}]^{-1}$ is still good enough and so is the resulting Krylov basis (upon which the GMRES or CG solvers are based on). However, the effectiveness of the preconditioner $[\mathbf{P}^{(j)}]^{-1}$ decreases slightly. The solver may take more iterations to converge. By continuing recycling the preconditioner, the solver will take more and more iterations. In order to avoid excessively high iterations, a heuristic

approach can be implemented in the algorithm. For example, as soon as a fixed number of iterations N_k of the iterative solver has been reached, a new preconditioner will be computed and reused for the next linear systems' solutions. However, it should be noted that successive increase in the number of iterations may still be cheaper than computing a new preconditioner at every step. This should be considered when choosing the fixed number of iterations N_k.

Assuming that a preconditioner was computed at frequency ω_j to solve Eq. (9). The same preconditioner was used for some τ number of frequencies. Thus, Eq. (9) can be expressed for the proposed delayed preconditioner in the following form:

$$\tilde{\mathbf{u}}_{k+1}^{(j+\tau)} = \left(\mathbf{I} - [\mathbf{P}^{(j)}]^{-1} \, \mathbf{Z}^{(j+\tau)} \right) \tilde{\mathbf{u}}_{k}^{(j+\tau)} + [\mathbf{P}^{(j)}]^{-1} \, \tilde{\mathbf{f}}^{(j+\tau)} \tag{12}$$

Comparing this equation with Eq. (9), note the change in superscripts of $\tilde{\mathbf{u}}$, $\tilde{\mathbf{f}}$ and $\mathbf{Z}$ while it remains unchanged for the recycled preconditioner $\mathbf{P}^{(j)}$. With the recycled preconditoner, it may not be known a priori the total number of preconditioner computations N_τ in the entire frequency band. However, the recycling is beneficial if $N_\tau < N$ and it scales such that $N_\tau << N$ when N is large in the same bandwidth (higher frequency resolution).

Since the preconditioner computation is delayed by τ in frequency, it is termed as *Delayed Frequency Preconditioner* or DFP. This reduces the computational burden significantly over the whole spectrum. An indicative algorithm of this method is also presented below:

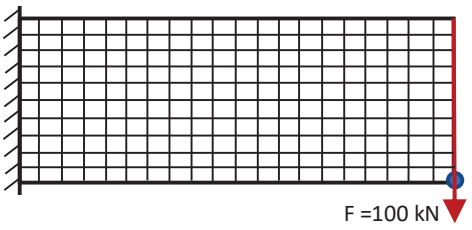
Algorithm 1 Delayed Frequency Preconditioner

$\omega = \omega_{\mathbf{1}}, \omega_{\mathbf{2}} ... \omega_{\mathbf{N}}$ ▷ frequency points
update = $True$ ▷ initialize with preconditioner at ω_1
for $j = 1,\ 2,\ 3\ to\ N$ **do**
    $Z^{(j)} = -\omega_j^2 M + i\omega_j C + K$ ▷ dynamic stiffness matrix
    if (update = $True$) **then**
        $\mathbf{P}$ = compute_preconditioner($Z^{(j)}$) ▷ e.g. iLU preconditioner
    end if
    $\tilde{\mathbf{u}},\ k$ = iterative_solver($\mathbf{Z}^{(j)}, \tilde{\mathbf{f}}^{(j)}, \mathbf{P}$) ▷ Output: solution and number of iterations k
    if ($k \geqslant N_k$) **then**
        update = $True$
    else
        update = $False$
    end if
end for

It should be evident that the DFP is only a recycled preconditioner which can be obtained by any common methods. In this paper, the choice of the preconditioner is restricted to Incomplete and Complete LU. If the system matrix is symmetric and positive definite, the LU can be replaced by Cholesky factorization.

5 Application of the Method

The proposed DFP is tested on a simple beam with a small number of DoF in order to test various parameters. A simple cantilevered steel beam of Fig. 1 is subject to a dynamic load at its free end. It has been discretized into 200 elements. The choice of number of elements arises from the fact that, generally, the reduced order models have a similar model order in many design and optimization studies to conduct parametric studies.



Young's Modulus	$210\ GPa$
Density	$7860\ kg/m^3$
Poisson's ratio	0.3
Beam Size	$8\ m \times 3\ m$
Number of DoF	462
Element Type	Plane-stress
	4-node quadrilateral
Damping Model	$\alpha\mathbf{M} + \beta\mathbf{K}$
α	1×10^{-3}
β	1×10^{-6}

Figure 1: The cantilevered beam with force applied on its unconstrained edge. The beam mechanical properties are also given on the right.

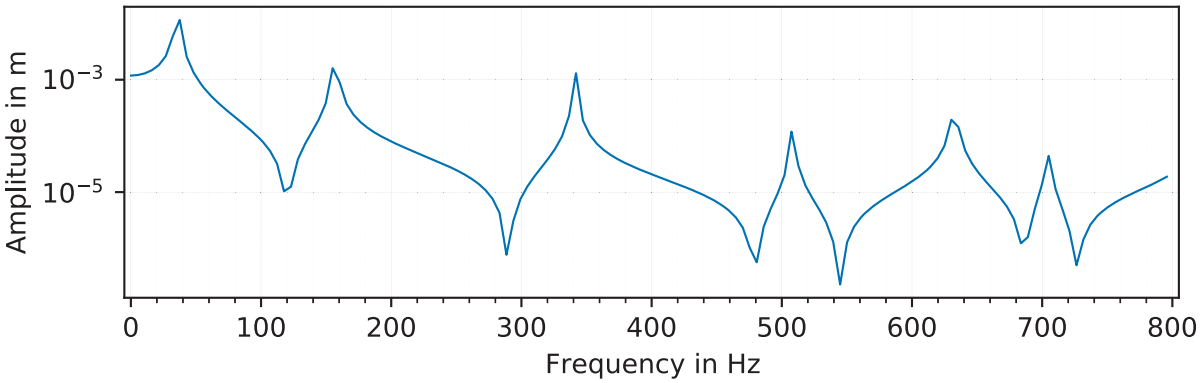


Figure 2: The forced response of the beam at the blue marked DoF in Fig. 1.

A displacement response function of the beam is shown in Fig. 2. The corresponding displacement DoF is shown in Fig. 1 with the blue marker. The frequency band is 0-800 Hz with 150 data points.

The accuracy of an iterative solver is determined by the tolerance limit. In the following analyses, the same tolerance limit is used for frequency response (FR) when a new preconditioner is computed at every frequency and when a delayed preconditioner is used. Therefore, the accuracy of the results from the solver remains the same for both the methods. Due to this reason, the comparison amongst different solvers with preconditioners and the proposed DFP is not deemed necessary. Instead, the results will be discussed only from the perspective of computational performance. The iterative solver chosen for the study is GMRES (in the *scipy* sparse linear algebra library of Python) with two preconditioners i.e. complete and incomplete LU. The two will be used as the DFP.

In Fig. 3, the number of iterations by the GMRES solver is plotted with an incomplete LU preconditioner. It can be seen that it takes mostly 4 or 5 or more iterations for the solver to converge at different frequencies. Since no DFP has been used, a new preconditioner was computed at each step. The small jumps in the number of iterations correspond to the resonance frequencies where the dynamic stiffness is ill-conditioned due to the dominance of the modes.

The DFP algorithm is implemented with the two preconditioners (complete LU and incomplete LU denoted simply by LU and iLU, respectively) in Fig. 4 which has the same axes as Fig. 3. Comparing the two figures, with only iLU preconditioner, the number of iterations is the same at the first frequency. The iterations start to increase gradually (Fig. 4) as the precon-

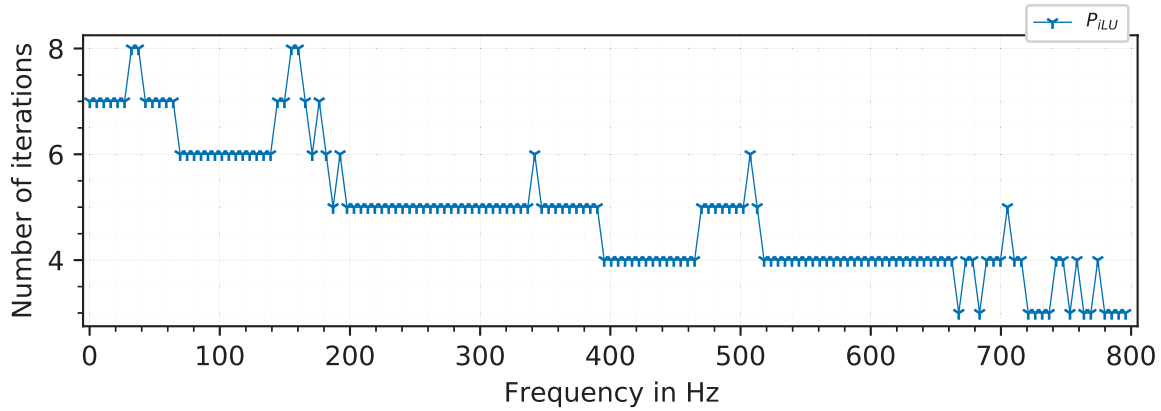

Figure 3: Number of GMRES iterations to convergence when using incomplete LU preconditioners. A new preconditioner is computed at each frequency.

ditioner at the first frequency is being reused until 135 Hz. This is where a new factorization was performed for a new preconditioner indicated by the encircled markers. The criterion for this was set to be 10 iterations $N_k = 10$. As soon as the limit is crossed, a new factorization is performed. The algorithm then continues with the new preconditioner for the next frequencies. Throughout the frequency band, only 17 factorizations were performed with iLU. Again near the resonances, the number of iterations becomes higher and the preconditioner is no longer valid for further frequency points. The complete LU preconditioner is also included in this figure. An LU factorization will be very expensive for a large system, however, in this case, only a few such factorizations are required. This can be afforded and analyzed for the given problem. At the outset of a new factorization, the solver converges in only one iteration since the solution process is direct. But it requires a few iterations as the preconditioner is recycled at the next frequencies. The number of LU factorizations are only 11 compared to 17 for iLU. It should be noted that the computational cost of iLU factorization is cheaper depending on the number of matrix entries that are dropped.

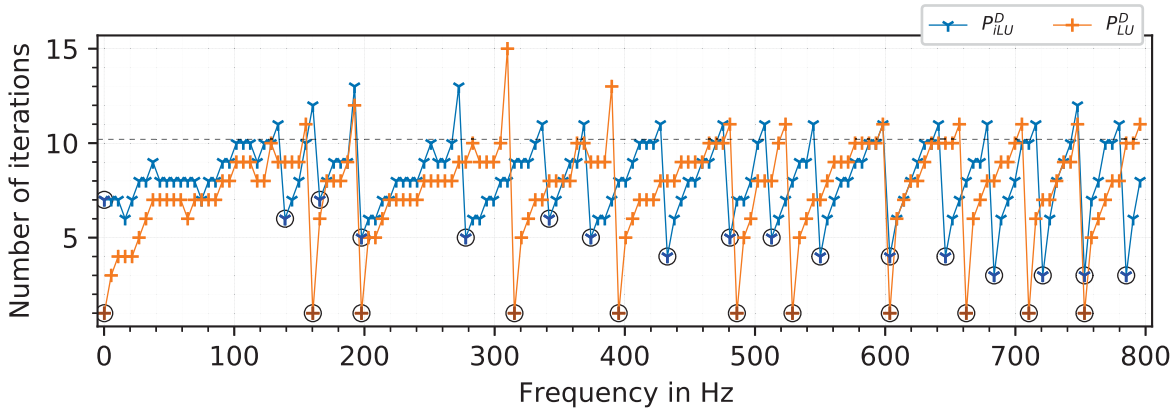

Figure 4: Number of GMRES iterations to convergence when using delayed frequency preconditioners (DFP) algorithm. The delayed preconditioners are incomplete $\mathbf{P}^D_{iLU}$ and complete $\mathbf{P}^D_{LU}$.

The new factorizations with the DFP are correlated with the condition number of the expression $[\mathbf{P}]^{-1}\mathbf{Z}^{(j)}$ which is plotted in Fig. 5 for different $\mathbf{P}$. If $\mathbf{P} = \mathbf{P}_I$ is an identity matrix, the

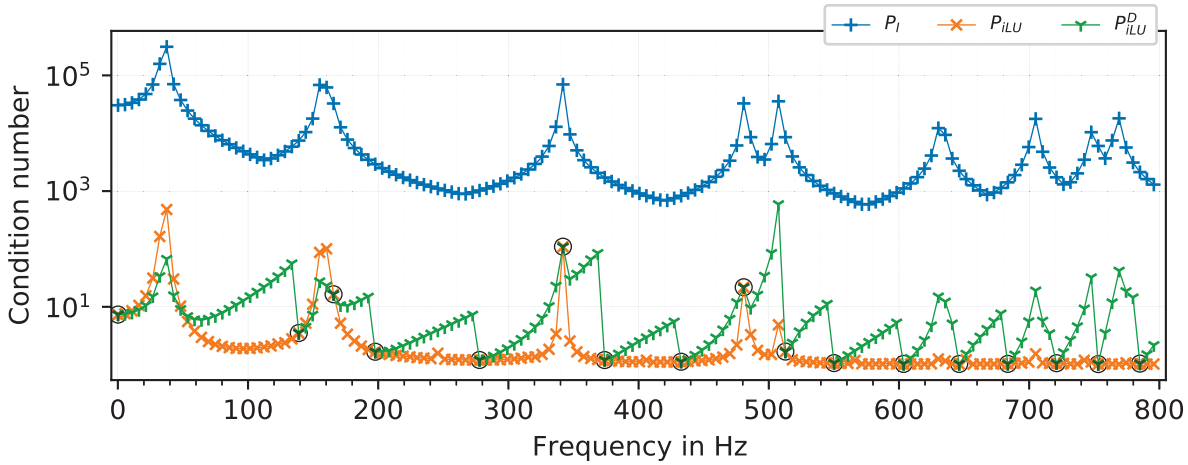

Figure 5: Comparison of condition number with no preconditioner $\mathbf{P}_I$ –an identity matrix, a simple iLU preconditioner $\mathbf{P}_{iLU}$ and the DFP iLU preconditioners $\mathbf{P}^D_{iLU}$.

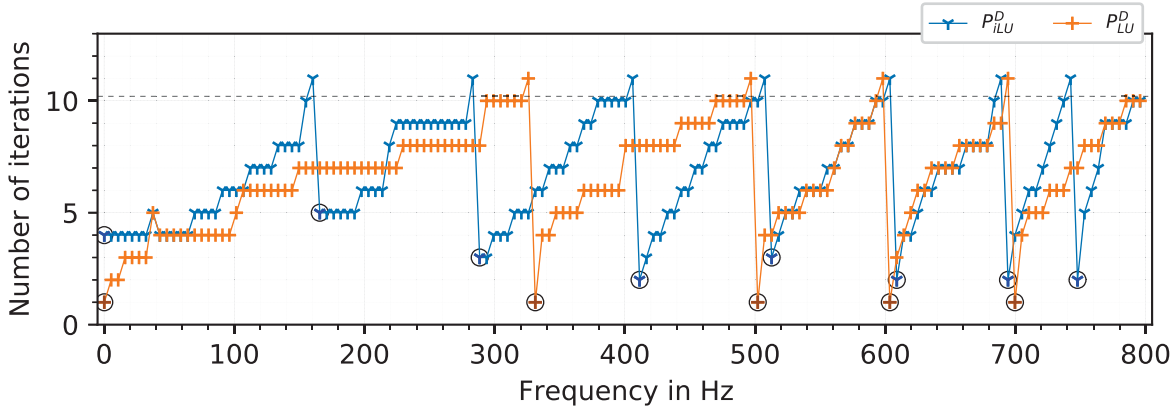

Figure 6: Number of iteration for convergence with BiCGSTAB iterative solver and using delayed preconditioners – incomplete iLU $\mathbf{P}^D_{iLU}$ and complete LU $\mathbf{P}^D_{LU}$.

condition number corresponds exactly to that of the dynamic stiffness $\mathbf{Z}$ which becomes high near the resonances. In its vicinity, the eigenvalues of $\mathbf{Z}^{(j)}$ change rapidly with ω_j. By using the conventional preconditioning technique discussed with iLU preconditioner, the condition number decreases but the behaviour remains the same. It requires more iterations for the solver to converge in the regions where the condition number is high, as was shown in Fig. 3. With the DFP algorithm, the condition number (Fig. 5) behaviour is quite different. It gradually increases and requires more iterations successively (Fig. 3). The change in eigenvalues[2] of $\mathbf{Z}^{(j)}$ renders the reused preconditioner inappropriate. Therefore, a new factorization is performed shown with an encircled marker in Fig. 5.

The method is tested for the same problem with a Bi-Conjugate Gradient Stabilized (BiCG STAB) iterative solver and the same two preconditioners for the DFP method. The number of iterations is shown in Fig. 6. The behaviour is similar to the GMRES solver, however, it

[2]The change in eigenvalues is inferred from the fact that the condition number is the ratio of the largest and smallest singular values of a matrix.

			DFP	
		$\mathbf{P}_{iLU}$	$\mathbf{P}^{D}_{iLU}$	$\mathbf{P}^{D}_{LU}$
	Number of frequencies	150	150	150
GMRES	Number of Iterations	732	1219	1140
	Number of preconditioners	150	17	11
BiCGSTAB	Number of Iterations	423	1024	1005
	Number of preconditioners	150	8	5

Table 1: Performance Comparison of GMRES and BiCGSTAB with and without Delayed Frequency Preconditioner

	Iteration limit N_k	5	10	15	20	25	30	40	50	60
$\mathbf{P}_{iLU}$	Total Iterations	2424	2424	2424	2424	2424	2424	2424	2424	2424
$\mathbf{P}^{D}_{iLU}$	Total Iterations	2424	2419	2430	2580	2749	2981	3249	3375	3661
	Number of preconditioners	150	147	80	15	4	3	2	2	1
	Percentage reduction in computation time	-0.4	1.5	22.5	41.1	41.8	39.2	37.8	33.7	28.5

Table 2: Effect of different iteration limits N_k on the performance of the DFP method. The test was done on the beam problem of Fig. 1with 8122 DoF.

requires a lower number of refactorizations. This is possibly because of the inherent difference of the objective function minimization in the solvers. The comparison of the DFP performance is tabulated in Table 1 for the two solvers. The significant observation is a great reduction in the number of preconditioners from 150 without DFP to 17 and 8 with DFP for GMRES and BiCGSTAB solvers, respectively. It should be noted that BiCGSTAB has also a lesser number of iterations to convergence along with lower refactorizations.

In the following, the computational performance of the method is analyzed. The ratio of the computational cost of computing the LU and iLU preconditioners to the cost of one iteration of the solver increases with an increase in the size of matrices. Since the beam problem considered so far has a small number of DoFs, this ratio is small. Hence, the time saved is not significant. In order to show an appreciable reduction in computation time, a similar problem with 8122 DoFs was used. The time for computing FRF with BiCGSTAB solver using iLU preconditioner with and without the delayed preconditioner was measured for various iteration limits N_k in Table 2 along with the other parameters. When the iteration limit is small, for example, $N_k = 5$, a new preconditioner is computed at all the frequencies. So, the performance of the DFP method is the same as without the DFP. As the iteration limit was increased, the number of preconditioner computations were reduced and there was an improvement in the performance of the method. It can be seen that for $N_k = 25$, the preconditioner was computed only 4 times and there was a 41.8% reduction in the computation time when the DFP algorithm is used. As the iteration limit was further increased, the performance no longer increases. This is due to the fact that the iterative solver then took more total iterations and time to converge, thereby overpowering the time saved by reducing the number of preconditioner computations. As it be seen at $N_k = 60$ that only one preconditioner needed to be computed but it is not quite effective anymore. From the above observations, it can be concluded that the computational time shows an optimum-like behaviour as the iteration limit is changed.

So far, various results were shown for 150 frequency data points in the entire band of frequency. At this point, the scalability for variation in the data points or resolution is discussed.

Table 3 lists the number of preconditioner computations as the number of frequency data points is increased. It is clearly seen that a remarkably smaller number of refactorizations are needed in comparison to the number of data points. In the absence of the DFP, many refactorizations would be needed which is quite expensive. In the limiting case, when the frequency resolution is very coarse, the DFP algorithm will behave as without a delayed preconditioner.

Number of frequencies	10	50	100	150	250	400	1000	2000
Number of $\mathbf{P}$ Computations	4	8	11	11	11	13	14	14

Table 3: Scalability of the DFP: Effect of increasing the number of frequencies in the given range (making $\delta\omega$ smaller) on number of refactorizations for the preconditioners is listed. A complete LU factorization was used and recycled for the data.

6 Conclusions and Future Work

A method for reusing information about preconditioners during frequency response computation was proposed. This method is tested on a beam problem. Two iterative solvers, GMRES and BiCG, were used for this study. The performance of the method was studied for two preconditioners, LU and iLU. The method helps to reduce the number of preconditioner computations significantly, thereby reducing the overall computation cost. The computational performance of the method depends on the iteration limit N_k and shows that an optimum value of N_k may be needed for maximum computational savings. If this limit is low, in the worst-case scenario, factorization has to be done at every other frequency. If the limit is too high, very few preconditioners are computed but it would take more iterations to converge and hence would require more time. Further, it was shown that the method is more effective when the gap between the frequency points becomes smaller.

The method can also be extended to other problems and improvements can be suggested as follows:

- Only linear problems have been considered in this paper. Nonlinearity might arise through material properties or friction contact. This method could be extended to such non-linear problems.
- In this study, only single domain geometries are considered. For very large problems, domain-decomposition method needs to be used. For such cases, the same method can be extended to reuse information from each subdomain.
- The performance of the method can be tested for other linear solvers and preconditioners.

Abstract *Contact-impact events frequently occur between solid contact interfaces in complex dynamic mechanical systems and engineering applications. Impact force models are used to determine the responses of contacting solids. The selection of the impact force model strongly affects the predictions of the dynamic behavior of the contacting bodies, mainly in sequential repeated impacts. In this work, the strong nonlinear dynamic behavior of a cantilever steel beam, repeatedly impacting a steel rigid stop is investigated applying experimental and numerical methodologies. The applicability of a nonlinear constitutive force model selection and model-updating framework at engineering problems where contact-impact phenomena happen in a sequential periodic manner is presented. First, a discrete Finite Element (FE) model of the examined beam was developed. Applying Covariance Matrix Adaptation – Evolution Strategy (CMA-ES) model updating methodology, coupled with robust, accurate and efficient Finite Element Analysis (FEA) software, the linear behavior of the cantilever beam was validated under enforced motion conditions followed by equivalent experimental trials, in order to tune the material and geometrical properties and boundary conditions parameters and develop a high-fidelity linear FE model. Next, the general viscoelastic impact force law based on the Hertz contact theory, augmented with a damping term is integrated in the updated linear FE model. Upon further experimental trials of the impacting cantilever beam under base excitation, a model selection process using Bayesian inference is carried out between nine different expressions of the viscous term at constant nonlinear power exponent, updating the inferred parameters of the most probable force model. A new model selection and updating process including the nonlinear power exponent in the inferred parameters is finally presented in order to tune and study in detail the effect of the contact stiffness, coefficient of restitution, nonlinear power exponent and clearance gap between the contacting bodies in a specific sinusoidal excitation frequency of the impacting cantilever beam, validating the experimental results.*

1 INTRODUCTION

Contact-impact events occur between two colliding bodies that belong to a multibody system or move unconstrained, at an instant of time. During an impact, elastic or plastic deformations locally developed around the contact area, effects related to vibration propagation and abrupt velocity changes and energy dissipation phenomena are detected. These phenomena are augmented and become crucial in engineering applications when involved bodies move intermittently or have clearance joints between them and especially when sequential repeated impacts take place [2-5].

The basic difficulty in order to accurately model and analyze a multibody system with impact-contact phenomena, is the selection of the most appropriate constitutive force model that adequately represents the impact events regarding aspects that include the materials of the contacting bodies and their damping characteristics, their geometry and clearance distance, along with the overall kinematics of the phenomenon involving contact point, impact direction and boundary conditions [7-9]. As the impact model depends on many parameters, coefficient of restitution (COR), c_r, has been introduced as a parameter to determine the energy dissipation during the complete impact event. In all models, the choice of the coefficient of restitution reflects the type of collision. The value of COR is in the range of $0 \le c_r \le 1$, where for a fully elastic contact, the restitution coefficient is equal to the unit, whereas for a fully plastic contact, the restitution coefficient is null. COR is highly depended on the impact speed and direction, material properties and geometry of colliding bodies and duration of contact [10, 11].

In this work, the parameters that contribute to the evaluation of the contact force, including the contact stiffness, contact viscous damping, CORs and clearance, during the strong nonlinear dynamic behavior of a cantilever steel beam, repeatedly impacting a steel rigid stop is investigated applying experimental and numerical methodologies. At first, a high-fidelity finite element (FE) model of the cantilever beam was developed and validated under enforced motion conditions (base excitation) followed by equivalent experimental trials, tuning its material properties and boundary condition parameters. Single objective optimization formulation, without the need of sub-structuring methods, is used for estimating the parameters of the finite element model. The updated FE model is then reduced in order to accommodate a viscoelastic impact force model based on the Hertz contact theory, augmented with a damping term to account for the dissipation of energy during the impact events, as a function of the coefficient of restitutions (COR) between the impacting bodies [12]. The parameters of the applied constitutive impact force model are tuned in order to match the numerical predictions and recorded experimental data. Both unreduced linear FE model and reduced numerical model updating procedures, are achieved implementing response residuals that include time-histories of accelerations [13-18]. A state-of-the-art optimization algorithm, namely, covariance matrix adaptation evolution strategy (CMA-ES) [19-22], is applied in parallel computing, to solve the single-objective optimization problem [23, 24]. The applicability and effectiveness of the methods applied, is explored and issues related to estimating unidentifiable solutions [25-28] arising in FE model updating formulations are also addressed.

The presentation in this work is organized as follows. The theoretical formulation of finite element model updating is briefly presented in section 2. Section 3 presents the viscoelastic dissipative contact force models. Section 4 presents the experimental application. Section 5 presents the updating of the linear FE model. Section 6 presents the experimental set up of the nonlinear model whereas section 7 presents the nonlinear FE model update and results. Conclusions are summarized in section 8.

2 MODEL UPDATING TO MOST PROBABLE PARAMETERS USING CMA-ES

The most probable values (MPVs) of the parameter set $\underline{\theta}$ of the non-linear model are those that maximize the posterior density function (PDF). Numerical acceleration time histories, included in the actual measure of fit, are computed. Thus, Covariance Matrix Adaptation Evolution Strategy (CMA-ES) [1-3], is applied to maximize the natural logarithm of the probability density function, $\ln\left[p(\underline{\theta},\underline{\sigma}\,|\,D,M_i)\right]$. CMA-ES is applied using an already proposed framework in previous works [4-6], to minimize the minus natural logarithm of the probability density function $-\ln\left[p(\underline{\theta},\underline{\sigma}\,|\,D,M_i)\right]$, updating model parameters to the most probable values (MPVs). The algorithm is applied in a parallel computing scheme to compensate for the computation time. Details on the formulation sequence of CMA-ES and the proposed framework can be found in [4].

The objective-function to be minimized that is passed to CMA-ES, is:

$$g\left(\underline{\theta},\underline{\sigma}\right)=-\ln\left[p\left(\underline{\theta},\sigma\,|\,D,M_i\right)\right]=$$

$$=\frac{N_s N_m}{2}\ln\left(2\pi\right)+\frac{N_s N_m}{2}\ln\left(\sigma^2\right)+\frac{1}{2\sigma^2}\sum_{j=1}^{N_s}\frac{\sum_{k=1}^{N_m}\left(\hat{y}_j(k)-y_j\left(k;\underline{\theta}\right)\right)^2}{\sum_{k=1}^{N_m}\left(\hat{y}_j(k)\right)^2}-\ln\pi\left(\underline{\theta},\sigma\,|\,M_i\right) \tag{1}$$

The process terminated when the difference of the best values of two consecutive sets of iterations was less than $\Delta g(\underline{\theta},\underline{\sigma})=10^{-3}$. A version of the CMA-ES algorithm (programmed in C), and the numerical analysis were coupled through a developed C language script, allowing the framework to be compiled and run independently in parallelization. The computer that was used, hosts two (2) Intel® Xeon® Gold Processors 6130 (22M Cache, 3.70 GHz) with 16-cores and 32-threads, resulting in a total number of sixty-four (64) logical (virtual) cores and 128GB of RAM, on Linux Ubuntu 18.04 Operating System.

3 VISCOELASTIC DISSIPATIVE CONTACT FORCE MODELS

Pure elastic contact force constitutive models have the disadvantage of neglecting forces acted upon contacting bodies during compression and restitution phases. Thus, internal damping has been introduced to augment the pure elastic laws and account for energy dissipation during an impact-contact event. A general formulation of the contact force law can be expressed combining elastic and viscous components as [7, 8]:

$$f=K\delta^n+\chi\delta^n\dot{\delta} \tag{2}$$

where K is the generalized contact stiffness depended on the material properties of the colliding bodies and geometry of the local contacting region, δ is the relative indentation between the contacting bodies, n is the nonlinear power exponents, χ represents the hysteresis damping factor and $\dot{\delta}$ is the indentation velocity. **Table 1** presents the most popular expressions of the damping factor χ adopted in the consequent model selection process, where $\dot{\delta}^{(-)}$ represents the initial value of the velocity exactly at the moment of contact-impact occurrence. In all above laws the nonlinear power exponents proposed by all researchers is $n=3/2$ and has been included as such in the implementation of the above expressions during the model selection process.

Table 1. Most popular contact-impact constitutive force models.

Model	Reference of force model	Contact-impact Constitutive force law	Damping factor χ
1	Hertz [9]	$f=K\delta^n$	0

2	Gharib and Hurmuzlu [10]	$f = K\delta^n + \chi\delta^n\dot{\delta}$	$\chi = \frac{1}{c_r}\frac{K}{\dot{\delta}^{(-)}}$
3	Herbert and McWhannel [11]		$\chi = \frac{6(1-c_r)}{(2c_r-1)^2+3}\frac{K}{\dot{\delta}^{(-)}}$

7	Lankarani and Nikravesh [15]		$\chi = \frac{3(1-c_r^2)}{4}\frac{K}{\dot{\delta}^{(-)}}$
8	Zhiying and Qishao [16]		$\chi = \frac{3(1-c_r^2)e^{2(1-c_r)}}{4}\frac{K}{\dot{\delta}^{(-)}}$
9	Gonthier et al. [17]		$\chi = \frac{1-c_r^2}{c_r}\frac{K}{\dot{\delta}^{(-)}}$

4 EXPERIMENTAL ARRANGEMENT

The experimental set up of the contact-impact cantilever beam is illustrated in **Fig. 1**. A steel beam of total length $745mm$ was tightened on one end, between two compact aluminum blocks for a length of $145mm$ in order to create a fixed support. The bottom aluminum block was mounted on an electromagnetic shaker and a linear variable differential transformer (LVDT) sensor was placed on top of the upper block in order to measure base excitation time histories of displacements, along with accelerometer B recording base excitation time histories of acceleration. Furthermore, three (3) tri-axial accelerometers A1, A2 and A3, were placed at the $2/3s$ of the length of the beam, at the point where contact-impact occurs and at the free end respectively, all in the middle of the width of the beam. Lastly, a load cell was placed below accelerometer A2 at a clearance distance, leaving a gap between the beam and the rigid stop. Load cell was recording imposed impact force during experimental trials.

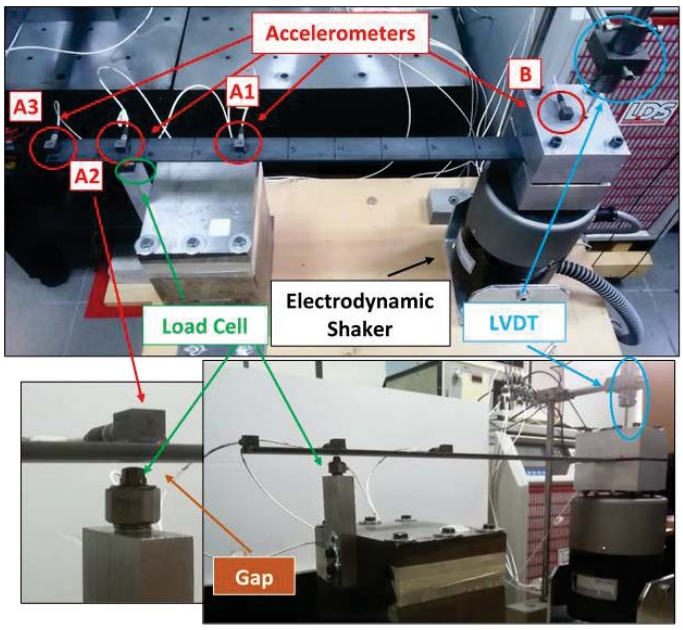

Fig. 1 Experimental arrangement of cantilever beam.

The experimental cantilever beam is a steel beam with Young's modulus $E = 210GPa$, Poisson's ratio $v = 0.3$ and density $\rho = 7850kg/m^3$. Similarly the nominal material properties of the aluminum accelerometers were $E = 69GPa$ for the Young's modulus and $\rho = 2750kg/m^3$. The cantilever steel beam is a simple structural arrangement, which is mounted from one end being free to oscillate under ground motion in the vertical direction. The length of the cantilever is $600mm$, its width is $40mm$ and its thickness is $5mm$.

At first in order to examine the linear response of the cantilever structure, the material and geometrical properties, the boundary condition parameters of the elastic properties of the support, along with the contribution of the accelerometers themselves in the overall response, an experimental arrangement without the rigid stop was introduced. A series of experimental trials were performed under three sinusoidal base motions at 4Hz, 6Hz and 8Hz excitation frequencies and various ranges, recording excitation accelerations at point B and response accelerations at locations A1, A2 and A3.

5 UPDATING OF LINEAR FE MODEL

5.1 Development of linear FE model

Strictly based on the experimental structure, the equivalent finite element model was developed as presented in **Fig. 2** with a schematic diagram of the experimental setup. The accelerometers were also included in the geometry of the structure as its was noticed that their contribution to the overall response of the structure is not negligible. The geometry of the cantilever beam along with the accelerometers themselves is discretized by shell and solid elements respectively, using appropriate pre-processing commercial software [18]. The introduced 2D plane with dimensions $600x40mm$ is modeled with 960 CQUAD shell elements with $5mm$ discretization length and $5mm$ nominal thickness.

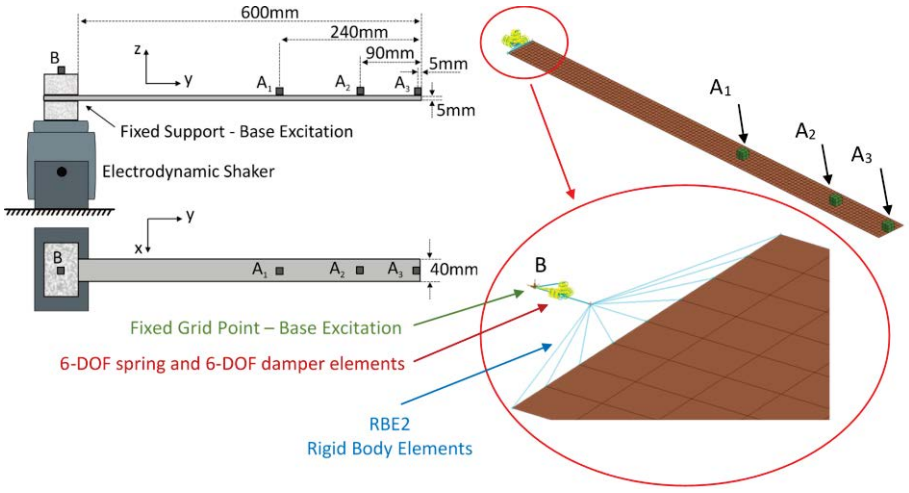

Fig. 2 Schematic diagram of the experimental setup and linear Finite Element model of the cantilever beam.

Because the fixed support (tightening of the beam between two aluminum blocks) is not in fact a rigid connection but has some flexibility, spring and damping elements are used to correctly model this fixed support at all translational and rotational degrees of freedom. In particular, the nodes of the FE model at the end support of the beam are depended and connected through rigid elements (RBE) at one independent node, which corresponds to accelerometer in location B, where the base excitation is applied. At this end of the cantilever beam the support was modeled as elastic with 6-DOF spring and 6-DOF damper elements, whereas the rest of the nodes of the FE model move freely. The total number of DOFs was approximately

3,800. Also, the accelerometers with dimensions $10x10x10mm$ were modeled with 24 CHEXA solid elements with $5mm$ discretization length. The middle node of the bottom surface of accelerometer A1 is located at $240mm$ from the free end, the equivalent node of accelerometer A2 is located at $90mm$ from the free end and the equivalent node of accelerometer A3 is located at $5mm$ from the free end.

5.2 Linear FE model parameterization and updating results

The parameterization of the finite element model of the linear cantilever beam is introduced in order to facilitate the applicability of the updating framework. The parameterized model is consisted of 4 parts, as shown in **Fig. 3**.

Part P1 corresponds to the steel beam and is modeled with shell elements whereas part P2 corresponds to the 3 accelerometers, which are modeled with solid elements. Parts P3 and P4 correspond to 1D elements representing the elasticity of the support using 6 spring and 6 damping elements in all 6 DOFs respectively. The Young's modulus and the material density are used as design variables for the material properties of the beam and accelerometers. The thickness of the shell elements of the beam P1 is also included in the design variables. 6 K_i and 6 C_i where $i=1,\ldots 6$ stiffness and damping parameters are included as design variables for parts P3 and P4. Moreover, damping ratios, using Rayleigh damping in a small and in a large frequency of the linear model were also included in the design values. The total number of design variables resulted in 19 variables.

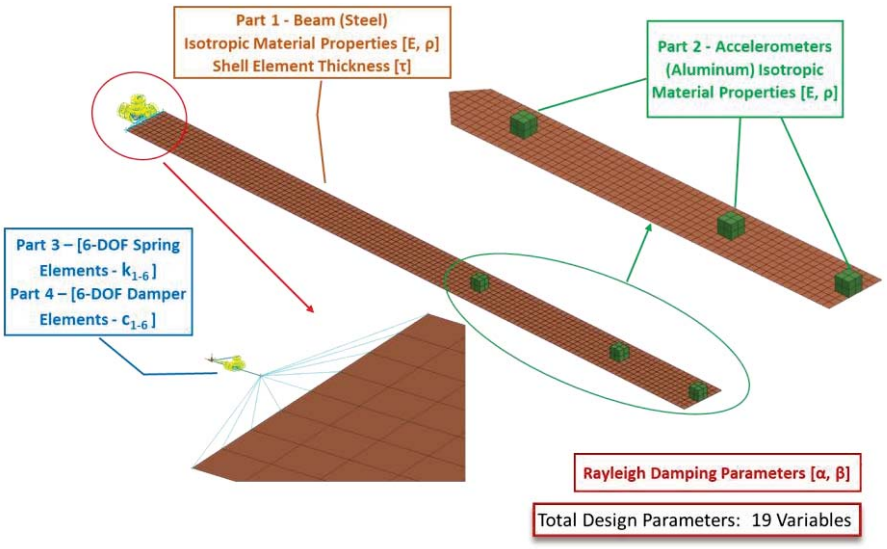

Fig. 3 Linear Finite Element Model Parameterization.

The CMA-ES algorithm is applied to update the developed linear FE model directly comparing raw measured and numerically predicted acceleration responses at all measured locations and directions. **Table 2** presents the design variables, their upper and lower boundaries (LB and UB), as well as the updated results for each parameter.

The time-histories of accelerations predicted by the optimal linear FE model (green continuous line) of the cantilever beam are compared, in **Fig. 4**, to the time-histories of accelerations coming directly from the measured data (red continuous line) at A1 and A3 indicative measurement locations at Z local component for three excitation frequencies 4Hz, 6Hz and 8Hz. Although tuning of the FE model was conducted at 6Hz excitation frequency, there is a good correlation of the experimentally obtained and numerically predicted accelerations time histories both at 4Hz and 8Hz excitation frequencies, resulting in a high fidelity linear FE model of the examined structure that could confidently be used in the subsequent nonlinear analysis incorporating the impact force model.

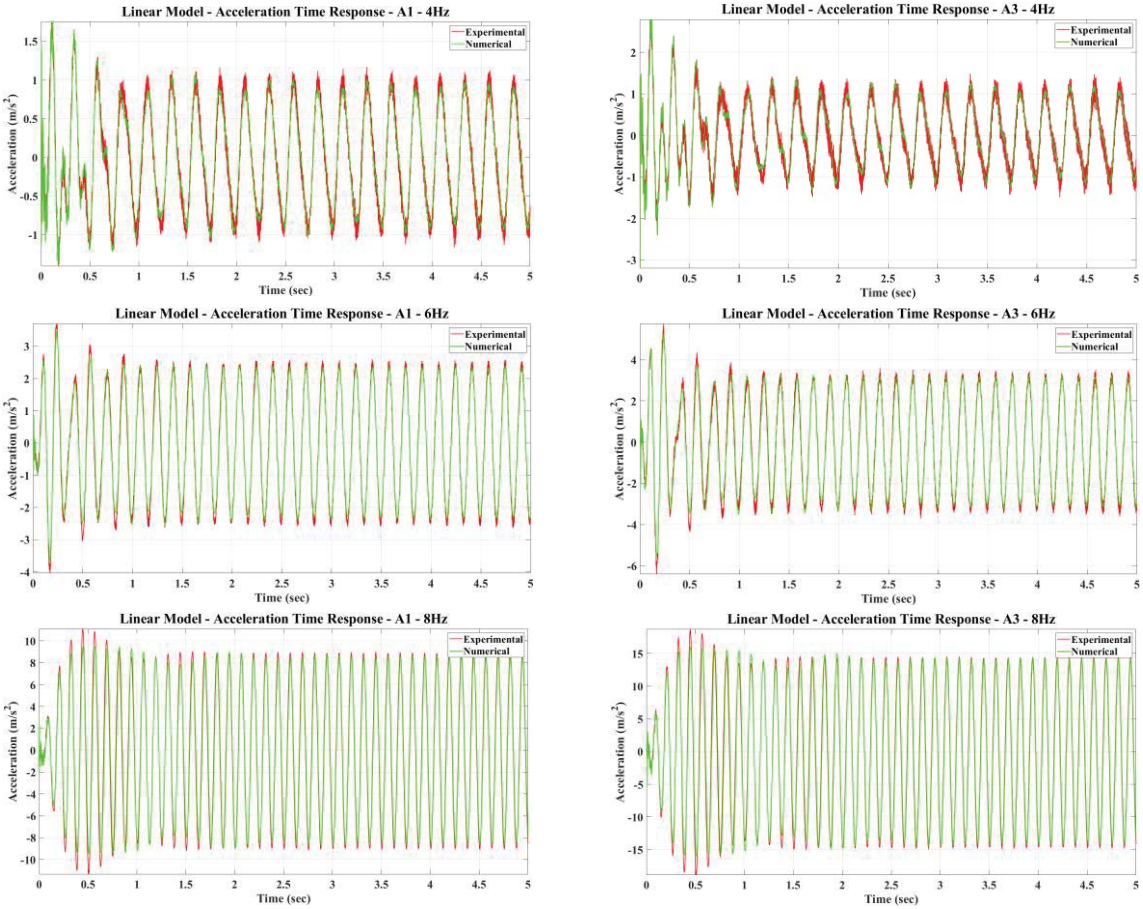

Fig. 4 Time histories of accelerations at A1 and A3 locations from 4Hz, 6Hz and 8Hz excitation frequency.

6 EXPERIMENTAL SET UP OF NONLINEAR MODEL

In this section the nonlinear behavior of the cantilever beam under repeated sequential impacts is closely examined. A schematic illustration of the experimental set up including impact-contact events is presented in **Fig. 5**, which depicts the location and component direction of acceleration measurements along with the location of the load cell that records imposed forces during impacts for comparison purposes.

Excitation and response measurements from ground motion in all direction at 6Hz excitation frequency were recorded in order to measure experimental base excitation at B location and integrate it in the nonlinear FE model at the respective node. The acceleration time histories at locations A1, A2 and A3 at all directions were also recorded in order to be included in the subsequent model selection and model updating processes. Accelerometer A2 is placed on top of the cantilever beam, above the rigid stop where the load cell is located. Thus, measurements recorded from A2 were the most informative since this is the point of contact from which elastic stress waves begin to propagate.

During experimental measurements it was noticed that the dynamic behavior of the beam is fully depended on the dissipation of induced impact energy in the form of transverse and longitudinal elastic stress waves between two consecutive impacts. The impact force and consequently the impact energy are associated to the frequency and range of base excitation. Thus, according to excitation parameters, the elastic stress waves are propagated in the deformable solid medium and do not fade out from one impact event to another, resulting in different impact parameters between impact-contact occurrences.

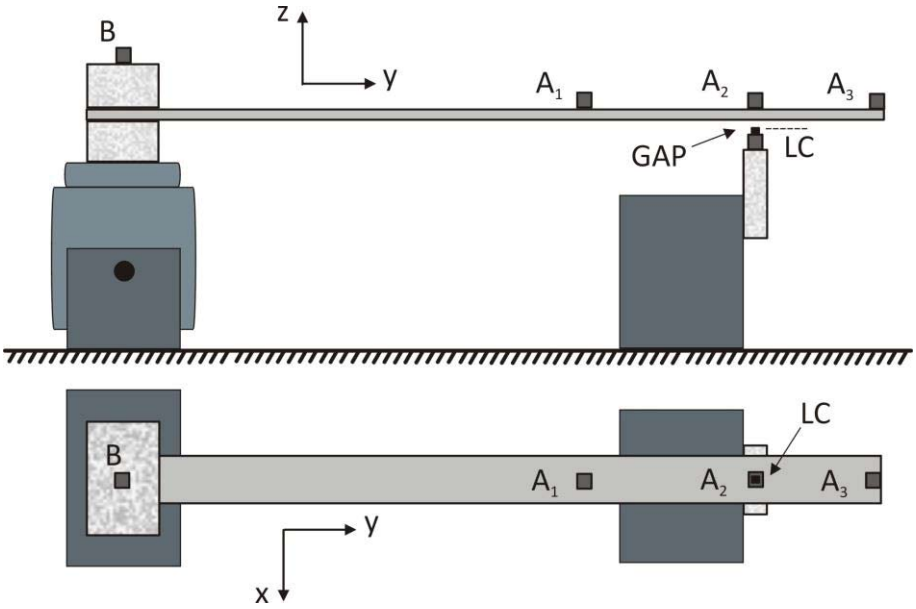

Fig. 5 Schematic illustration of the experimental set up including impact-contact events.

7 NONLINEAR FE MODEL UPDATE

The material and geometrical properties as well as the boundary condition parameters updated using the linear model of the cantilever beam in the previous section, do not depend on the integration of the constitutive force law. Thus, the updated values of modulus of elasticity, density, thickness and spring and damper of the support as presented in **Table 2** were retained constant in the analysis of the nonlinear FE model. The impact parameters are tuned i.e. the generalized contact stiffness K, the coefficient of restitution c_r that affect the imposed force

during each contact-impact event as well as the clearance gap u_g. The nonlinear power exponent was also retained constant at $n_f = 3/2$ as all examined force models proposed.

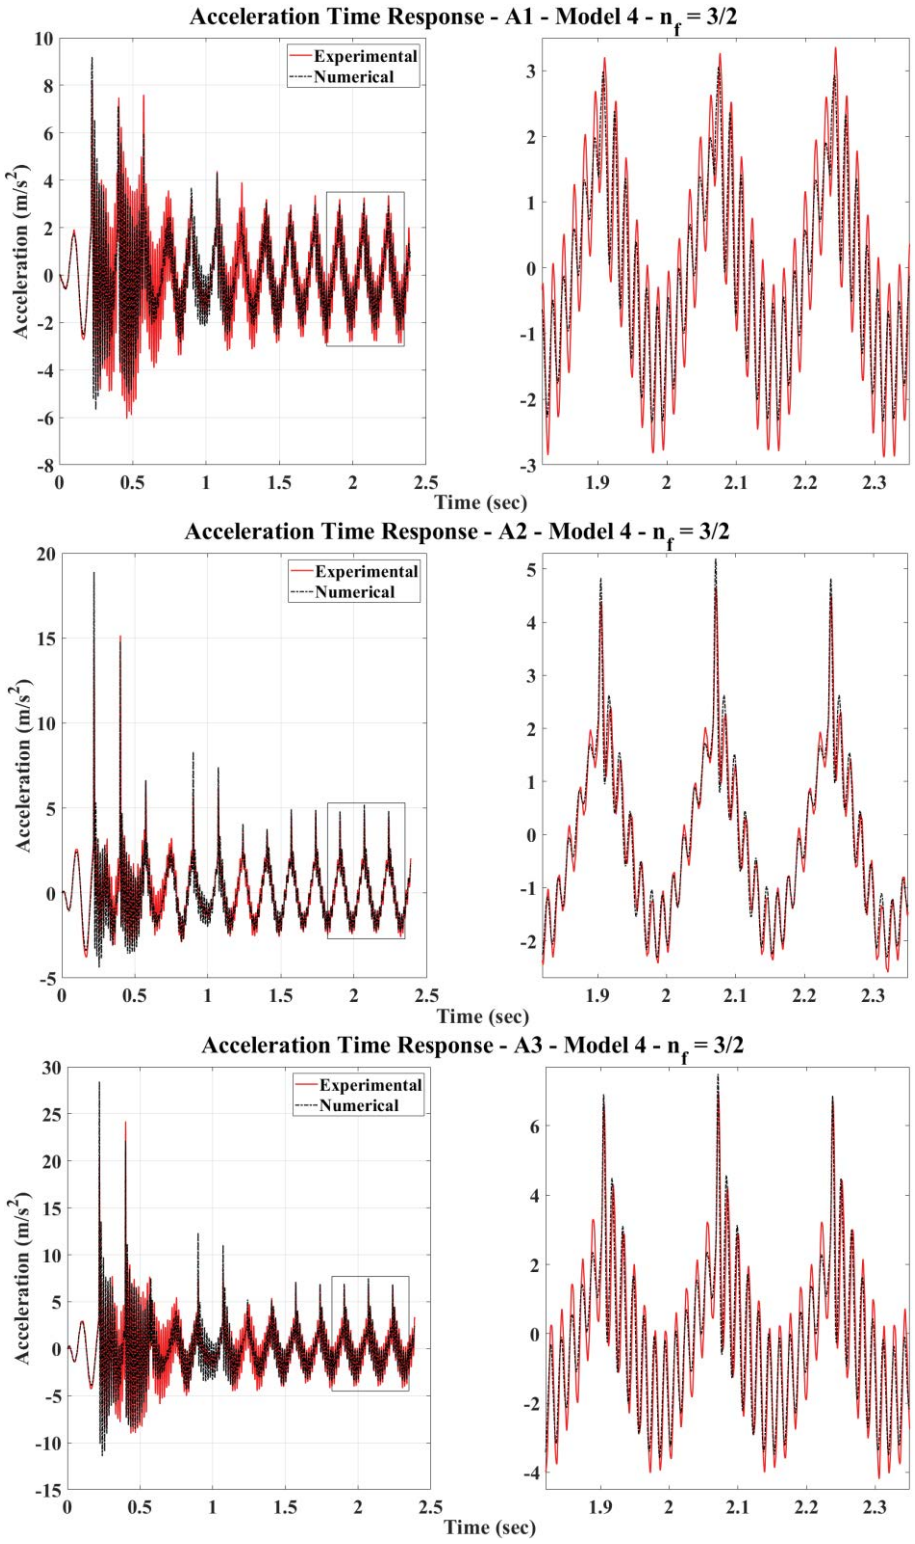

Fig. 6 Time histories of accelerations at A1, A2 and A3 locations, Z component, 6Hz excitation frequency for Model 4 with $n_f = 3/2$.

The prediction error parameters representing modeling and measurements errors at A1, A2, A3 and B sensor locations, were combined in one error parameter σ at a range of variation

$\sigma \in \left[10^{-4},1\right]$. In order to acquire deep insight of the dynamics of the problem, as well as moderate the computational effort, it was chosen to study the $N_c,\{c=1,\ldots,12\}$ first impacts, included in the first $2.5\,\text{sec}$ of the response. This time duration includes impacts both in transient $0 \le t \le 1.5\,\text{sec}$ and steady state response $1.5 < t \le 2.5\,\text{sec}$.

Parameters K^{N_c} and $c_r{}^{N_c}$, the clearance gap u_g and error parameter σ are the updated parameters at a wide enough range based in engineering knowledge and previous experience $\left(\underline{\theta} \in [100,9900]\times[0.1,0.9]\times[1.35,1.45]\times\left[10^{-4},1\right]\right)$. Additionally, as structural damping plays a key role in nonlinear response, Rayleigh damping corresponding to a small and at a large frequency were also included in the inferred parameters with wide range $(\zeta_1,\zeta_2)=[0.1\%,9.9\%]$, in order to fulfill an adequate correlation between the experimental and numerical acceleration time histories.

A comparison of the time histories of acceleration predicted by the optimal nonlinear FE model integrating force Model 4 (Flores et al. [12]) depicted with black dashed-dotted line and the experimental measurements depicted with red continuous line, are presented in **Fig. 6**, at measurement locations A1, A2 and A3 in Z direction and at 6Hz excitation frequency.

Similarly a comparison between the measured imposed impact force at each contact-impact event (red continuous line) and the numerically predicted nonlinear force (black dashed-dotted line) produced by Model 4 (Flores et al. [12]) is presented in **Fig. 7**. Both **Fig. 6** and **Fig. 7** include a zoomed boxed area of the last three impact events from approximately $1.8 \le t \le 2.3\,\text{sec}$ well after the steady state response has been met. It is worth mentioning that all impact parameters of the $N_c = 12$ impact-contact events have been taken into consideration in the nonlinear FE model update scheme, including all transient response and the beginning of the steady state response, increasing difficulty and complexity of the examined engineering problem.

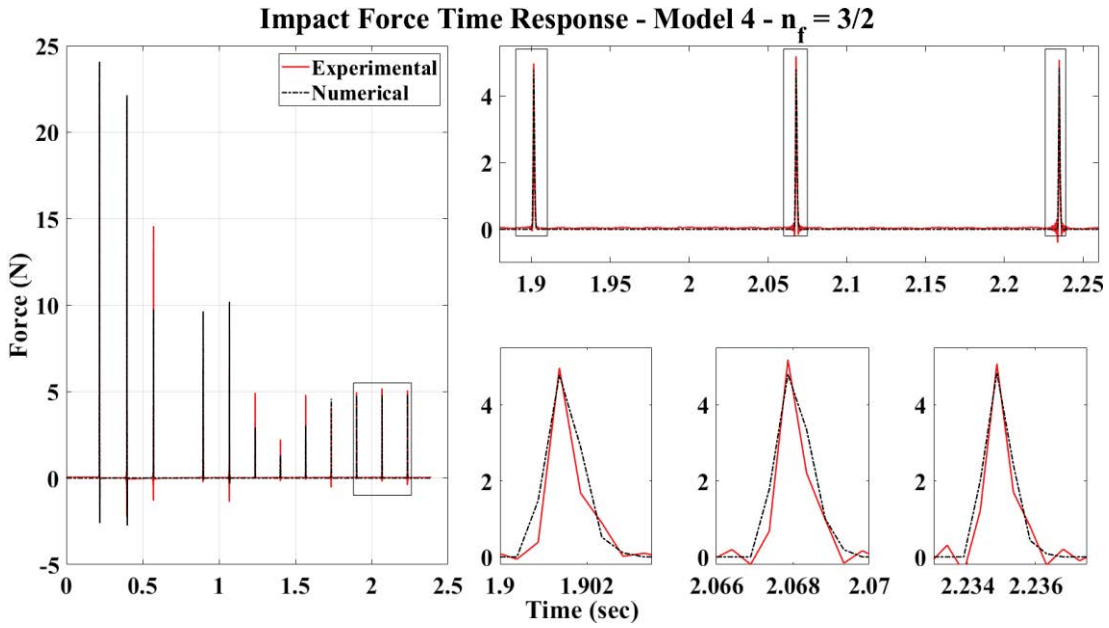

Fig. 7 Experimentally measured and numerically predicted impact force for Model 4 with $n_f = 3/2$.

It is clear that impact force model approaches with great accuracy the peaks of the measured impact force, as clearly presented in the zoomed areas. Thus it could be regarded as a high fidelity impact force model that could be used in further engineering investigation on this specific experimental arrangement and excitation loading.

8 CONCLUSIONS

In conclusion, a nonlinear constitutive force model-updating framework applied at a simple engineering problem (cantilever beam) where contact-impact events occur in a sequential periodic manner is extensively presented. At first, a high-fidelity finite element (FE) model of the experimentally examined cantilever beam was developed and validated in linear response conditions, under enforced motion, followed by equivalent experimental trials, tuning its material and geometrical properties and boundary condition parameters using deterministic single objective function, without the need of sub-structuring. The updated linear FE model is used for the nonlinear response, accommodating a viscoelastic impact force law based on the Hertz contact theory, augmented with a damping term. The impact parameters are updated to the most probable values using CMA-ES and probabilistic objective function. Finally, the updated final model validated with high accuracy the experimental results.

Keywords: Geometric Non-linear Structures, Parametric Systems, Nonlinear Model Reduction, Optimization, Hyperreduction

Abstract. *Parameter studies to design the dynamics of structures that undergo large deformations, such as wind turbine blades or MEMS, can be a tedious task. These studies are usually done with finite element models. The equations of motion provided by the finite element method are nonlinear and high-dimensional. This typically leads to high computation times, especially if the equations must be solved for each parameter variation of the design study.*

Model reduction can reduce the computation time by approximating the high dimensional parametric models. This is done in two steps: First, a Galerkin projection is done that approximates the solution by a linear combination of basis vectors. Second, the evaluation of the nonlinear force term is accelerated by a hyper-reduction. Both steps are challenging if large parameter variations are present because suitable basis vectors as well as the coefficients for the hyper-reduction are dependent on these parameters. An update of the coefficients for the hyper-reduction is very time consuming and can make the benefit of the model reduction useless.

The hyper-reduction method that is used in this contribution is the Energy Conserving Sampling and Weighting method (ECSW). This method requires training sets for computing coefficients for the hyper-reduction. This contribution shows how cost-intensive updates of the reduced order model can be avoided by computing coefficients for the ECSW that are valid for the whole parameter space of interest. We propose to generate training sets for some design parameter samples and compute coefficients that can be used for the whole parameter space. These training sets are computed without the need for expensive time integration of the full order model. Instead, Nonlinear Stochastic Krylov Training Sets (NSKTS) are used that only require static solutions to some applied training forces.

A simple case study of a shape parameterized cantilever beam illustrates the performance of the method. It is shown that computation time can be reduced for large numbers of design changes, but shows worse accuracy compared to local methods.

1 DESIGN STUDIES FOR GEOMETRIC NON-LINEAR STRUCTURES WITH MODEL REDUCTION

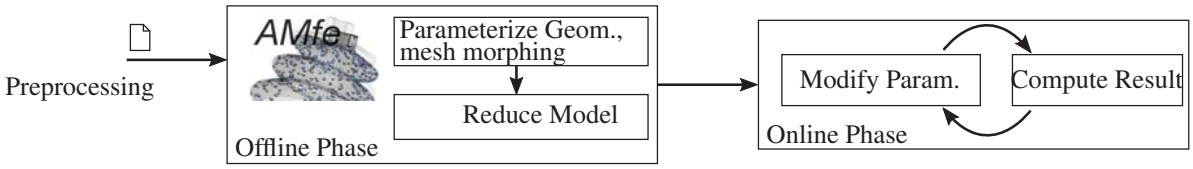

Figure 1: Workflow for faster design studies with model reduction [5]. It consists of two phases: A model is parameterized and reduced in the offline phase. Results and design changes are computed with the reduced order model in the online phase.

Design studies that analyze the dynamics of structures that undergo large deformations can be a tedious task due to high computation times. The reason for this is the nonlinear structure of the equations of motion resulting from the finite element discretization. Computation time can be reduced by applying model reduction. Model reduction reduces the full model to a smaller problem that can be solved in less time. This can be exploited to speed up design studies. A possible workflow is depicted in Figure 1. First, the finite element model is preprocessed and parameterized. Then, model reduction is carried out which results in a reduced order model. This step is called the offline phase. Afterwards, the design study can be performed on the reduced model in the online phase. The online phase consists in the iterative computation of results with the reduced order model and design changes that can be derived from these results. By using the reduced model to iteratively compute results for new designs it is expected that the computation time can be significantly diminished.

The big challenge in this workflow is to provide reduced order models such that the total computation time, that consists of the reduction process (offline costs) and the computation of results (online costs), is smaller than that of direct computations. In general, two different concepts to achieve this goal are distinguished: First, one single reduced order model can be provided, that is valid for the whole parameter space of interest. Second, a new reduced order model is calculated at each design iteration. This contribution proposes an ansatz for the first concept. We will show how a reduction basis can be generated without the need for training simulations and with validity for the whole parameter space. Furthermore, we show how a hyper-reduction with the Energy Conserving Sampling and Weighting method is carried out such that only one reduced order model is needed for the online phase.

The remainder of this contribution is organized as follows: Section 2 gives an overview over how model reduction is performed. This consists of two steps, reduction basis computation and hyper-reduction. Section 3 shows how a reduction basis for the whole parameter space is computed. The hyper-reduction method, namely the Energy Conserving Sampling and Weigthing method, that is summarized in section 2, is extended in section 4 for the parametric case. This section shows how training sets for the hyper-reduction can be computed and how a hyper-reduced order model is created for the whole parameter space. Section 5 demonstrates the performance of the proposed method on a cantilever beam case study. A conclusion is given in the last section.

2 THE TWO STEPS OF MODEL REDUCTION FOR GEOMETRIC NON-LINEAR STRUCTURES

After the finite element discretization, we get the equations of motion

$$\boldsymbol{M}(\boldsymbol{p})\ddot{\boldsymbol{u}}(t) + \boldsymbol{f}(\boldsymbol{p}, \boldsymbol{u}(t), \dot{\boldsymbol{u}}(t)) = \boldsymbol{F}(\boldsymbol{p}, t) \tag{1}$$

where $\boldsymbol{u} \in \mathbb{R}^N$ are the displacements of the finite element nodes, $\boldsymbol{M}$ is the mass matrix, $\boldsymbol{F}$ are the external loads and $\boldsymbol{f}$ is the restoring force that is nonlinear for structures undergoing large deflections. The different quantities also depend on the design parameters $\boldsymbol{p}$ of the system.

The first step to reduce the equations of motion is a Galerkin projection. The displacements $\boldsymbol{u}$ are approximated by a linear combination of n basis vectors $\boldsymbol{v}_i$. This can be written as

$$\boldsymbol{u} = \boldsymbol{V}\boldsymbol{q}, \quad \boldsymbol{V} \in \mathbb{R}^{N \times n} \tag{2}$$

where $\boldsymbol{V}$ is the so called reduction basis and contains column-wise the basis vectors $\boldsymbol{v}_i$. A Galerkin projection on the subspace spanned by these vectors results in

$$\boldsymbol{V}^\mathsf{T}\boldsymbol{M}(\boldsymbol{p})\boldsymbol{V}\ddot{\boldsymbol{q}}(t) + \boldsymbol{V}^\mathsf{T}\boldsymbol{f}(\boldsymbol{p}, \boldsymbol{V}\boldsymbol{q}(t), \boldsymbol{V}\dot{\boldsymbol{q}}(t)) = \boldsymbol{V}^\mathsf{T}\boldsymbol{F}(t)\,. \tag{3}$$

The equations of motion (3) have dimension n and thus must be solved for a reduced number of unknowns compared to equation (1). However, the nonlinear force term still must be evaluated for the full element domain that results in a poor speed-up. Thus, a second step, the hyper-reduction, must be carried out to accelerate the evaluation of the nonlinear force term $\boldsymbol{V}^\mathsf{T}\boldsymbol{f}$.

One method that is able to achieve this acceleration is the Energy Conserving Sampling and Weighting method (ECSW) [1]. It uses the fact that the nonlinear force term

$$\boldsymbol{V}^\mathsf{T}\boldsymbol{f}(\boldsymbol{V}\boldsymbol{q}, \boldsymbol{V}\dot{\boldsymbol{q}}) = \sum_{e \in E} \boldsymbol{V}^\mathsf{T}\boldsymbol{L}_e^\mathsf{T}\boldsymbol{f}_e(\boldsymbol{L}_e\boldsymbol{V}\boldsymbol{q}, \boldsymbol{L}_e\boldsymbol{V}\dot{\boldsymbol{q}}) \tag{4}$$

is an assembly of element forces $\boldsymbol{f}_e$. The matrices $\boldsymbol{L}_e$ map the local degrees of freedom of the element to the global degrees of freedom. The idea of ECSW is to assemble only a subset $\tilde{E} \in E$ of all elements and extrapolate their contribution by introducing weights ξ_e. The hyper-reduced internal storing force

$$\boldsymbol{f}_{hr,ECSW} := \sum_{e \in \tilde{E} \subset E} \xi_e \boldsymbol{V}^\mathsf{T}\boldsymbol{L}_e^\mathsf{T}\boldsymbol{f}_e(\boldsymbol{L}_e\boldsymbol{V}\boldsymbol{q}, \boldsymbol{L}_e\boldsymbol{V}\dot{\boldsymbol{q}}) \tag{5}$$

can be computed faster because much less element forces $\boldsymbol{f}_e$ must be evaluated with the approximation.

The subset $\tilde{E}$ and the weights ξ_e are chosen by forcing

$$\begin{aligned} &|\delta W_{hr}(\boldsymbol{q}_\tau, \boldsymbol{0}) - \delta W(\boldsymbol{q}_\tau, \boldsymbol{0})| \leq \varepsilon_{ECSW} \cdot \delta W(\boldsymbol{q}_\tau, \boldsymbol{0}) \\ \Leftrightarrow\ &|\delta\boldsymbol{q}^\mathsf{T}\boldsymbol{f}_{hr}(\boldsymbol{q}_\tau, \boldsymbol{0}) - \delta\boldsymbol{q}^\mathsf{T}\boldsymbol{V}^\mathsf{T}\boldsymbol{f}(\boldsymbol{V}\boldsymbol{q}_\tau, \boldsymbol{0})| \leq \varepsilon_{ECSW} \cdot \delta\boldsymbol{q}^\mathsf{T}\boldsymbol{V}^\mathsf{T}\boldsymbol{f}(\boldsymbol{V}\boldsymbol{q}_\tau, \boldsymbol{0}) \end{aligned}$$

such that the virtual work δW for a system that is deflected into the direction of training displacements $\boldsymbol{u}_\tau = \boldsymbol{V}\boldsymbol{q}_\tau$ is conserved for any virtual displacement $\delta\boldsymbol{q}$ up to a relative tolerance ε_{ECSW}.

This requirement can be translated to the minimization problem

$$\arg\min_{\xi\in\Phi} \|\boldsymbol{\xi}\|_0 \quad \text{where} \quad \Phi = \{\boldsymbol{\xi} \in \mathbb{R}^{N_e} : \|\boldsymbol{G}\boldsymbol{\xi} - \boldsymbol{b}\| \leq \varepsilon_{ECSW}\|\boldsymbol{b}\| \text{ and } \xi_e \geq 0\} \tag{6}$$

where

$$\boldsymbol{G} = \begin{bmatrix} \boldsymbol{g}_{11} & \cdots & \boldsymbol{g}_{1N_e} \\ \vdots & \ddots & \vdots \\ \boldsymbol{g}_{N_\tau 1} & \cdots & \boldsymbol{g}_{N_\tau N_e} \end{bmatrix} \in \mathbb{R}^{nN_\tau \times N_e} \qquad \text{and} \qquad \boldsymbol{b} = \begin{bmatrix} \boldsymbol{b}_1 \\ \vdots \\ \boldsymbol{b}_{N_\tau} \end{bmatrix} \in \mathbb{R}^{nN_\tau} \tag{7}$$

are built up by the entries

$$\boldsymbol{g}_{le}(\boldsymbol{q}_{\tau_l}) = \boldsymbol{V}^\mathsf{T}\boldsymbol{L}_e^\mathsf{T}\boldsymbol{f}_e(\boldsymbol{L}_e\boldsymbol{V}\boldsymbol{q}_{\tau_l}) \in \mathbb{R}^n \qquad \text{and} \qquad \boldsymbol{b}_l = \boldsymbol{f}_r(\boldsymbol{q}_{\tau_l}) = \sum_{e=1}^{N_e} \boldsymbol{g}_{le}(\boldsymbol{q}_{\tau_l})\,. \tag{8}$$

Here, N_e and N_τ describe the number of elements of the full order model and the number of training sets, respectively. An approximate solution to 6 can be computed by solving a non negative least square problem as described in [1].

3 GLOBAL REDUCTION BASIS

One challenge to reduce geometric nonlinear equations of motion is to compute a proper reduction basis $\boldsymbol{V}$. One option is to use vibration modes of the linearized system and static modal derivatives [2, 3] as basis vectors.

Vibration modes $\boldsymbol{\phi}_i$ are computed by solving the eigenvalue problem

$$(\boldsymbol{K} - \omega_i^2\boldsymbol{M})\boldsymbol{\phi}_i = \boldsymbol{0} \quad \text{with} \quad \boldsymbol{K} = \left.\frac{\partial \boldsymbol{f}(\boldsymbol{u})}{\partial \boldsymbol{u}}\right|_{\boldsymbol{u}=\boldsymbol{0}}\,. \tag{9}$$

The static modal derivatives

$$\Theta_{ij} = -\boldsymbol{K}^{-1} \cdot \nabla_{\boldsymbol{\phi}_j}(\boldsymbol{K}) \cdot \boldsymbol{\phi}_i \tag{10}$$

contain nonlinear information and are important to make the reduction basis able to represent large deflections. A reduction basis is gained by column-wise stacking vibration modes and static modal derivatives into a reduction matrix

$$\boldsymbol{R} = [\ldots, \boldsymbol{\phi}_m, \ldots | \ldots, \Theta_{ij}, \ldots]\,, \qquad m \in M, (i,j) \in T\,. \tag{11}$$

Guidelines for choosing M and T can be found e.g. in [4].

The reduction basis $\boldsymbol{R}$ depends on the mass matrix and the internal restoring force of the system. Thus, it also depends on the design parameters $\boldsymbol{p}$ of the system. If a reduction basis for the whole parameter space is desired, one can process as proposed e.g. in [5]. The parameter space of interest is sampled at some parameter values

$$P_{\text{sample}} = \{\boldsymbol{p}_1,\ \boldsymbol{p}_2, \ldots, \boldsymbol{p}_{N_S}\} \tag{12}$$

and a reduction basis $\boldsymbol{R}_i$ is computed at each sample point $\boldsymbol{p}_i \in P_{\text{sample}}$. Then these bases are concatenated into a matrix

$$\boldsymbol{S} = [\boldsymbol{R}_1\ \boldsymbol{R}_2\ \cdots\ \boldsymbol{R}_{N_S}] \tag{13}$$

which is then deflated to avoid linear dependency and bad conditioning. The deflation can be carried out by computing the singular value decomposition

$$\boldsymbol{S} = \boldsymbol{U}\,\boldsymbol{\Sigma}\,\boldsymbol{W}^{\mathsf{T}} \tag{14}$$

and taking the first n left singular vectors $\boldsymbol{V}_{\text{global}} = [\boldsymbol{u}_1, \boldsymbol{u}_2, \dots \boldsymbol{u}_n]$ whose singular values are greater than a certain tolerance.

4 GLOBAL ECSW WITH NONLINEAR STOCHASTIC KRYLOV TRAINING SETS

To compute the reduced element set $\tilde{E}$ and the corresponding weights ξ (as explained in Section 2), one must have a training set that is typically generated by simulation without hyper-reduction of a reference problem. This incurs significant offline costs. Strategies to obtain training sets without needing to perform a full simulation have been proposed in the past. One of these strategies is called nonlinear stochastic Krylov training sets (NSKTS) which was proposed by Rutzmoser in [6]. This method will be used here and is briefly summarized in the following paragraphs.

First, a force Krylov subspace

$$\boldsymbol{F}_{\text{kry,raw}} = \left[\boldsymbol{V}^{\mathsf{T}}\boldsymbol{b},\ (\bar{\boldsymbol{K}}^{-1}\bar{\boldsymbol{M}})\boldsymbol{V}^{\mathsf{T}}\boldsymbol{b},\ (\bar{\boldsymbol{K}}^{-1}\bar{\boldsymbol{M}})^2\boldsymbol{V}^{\mathsf{T}}\boldsymbol{b},\ \dots,\ (\bar{\boldsymbol{K}}^{-1}\bar{\boldsymbol{M}})^{(q-1)}\boldsymbol{V}^{\mathsf{T}}\boldsymbol{b}\right] \tag{15}$$

is computed where $\boldsymbol{b}$ is the localization vector of the external load $\boldsymbol{F}$ and

$$\bar{\boldsymbol{K}} = \boldsymbol{V}^{\mathsf{T}}\boldsymbol{K}\boldsymbol{V}, \qquad \bar{\boldsymbol{M}} = \boldsymbol{V}^{\mathsf{T}}\boldsymbol{M}\boldsymbol{V}$$

are the reduced stiffness and mass matrices, respectively. The Krylov vectors are orthogonalized such that

$$\boldsymbol{F}_{kry}^{\mathsf{T}}\boldsymbol{K}^{-1}\boldsymbol{F}_{kry} = \boldsymbol{I}\ . \tag{16}$$

Afterwards, β forces are generated by

$$\boldsymbol{f}_{rand,i} = \boldsymbol{F}_{kry} \cdot \boldsymbol{n}_i \tag{17}$$

where $\boldsymbol{n}_i$ is a random vector, such that $\boldsymbol{f}_{rand,i}$ are linear combinations of the vectors from the Krylov subspace (15). Training sets $\boldsymbol{q}_{\tau,i,l}$ are then computed by solving nonlinear static problems

$$\boldsymbol{V}^{\mathsf{T}} \cdot \boldsymbol{f}(\boldsymbol{V}\boldsymbol{q}_{\tau,i,l}) = \frac{l}{k}\boldsymbol{f}_{rand,i} \qquad \text{with } l \in \{1,2,\dots,k\} \text{ and } i \in \{1,2,\dots,\beta\}\ . \tag{18}$$

We use this procedure to compute one set of weights ξ_{global} and elements $\tilde{E}_{\text{global}}$ that is used for all parameter values of interest.

First, we compute NSKTS $\boldsymbol{q}_\tau(\boldsymbol{p}_s)$ for each sample point $\boldsymbol{p}_s \in P_{\text{sample}}$ (c.f. eq. (12)). Then, the quantities

$$\boldsymbol{G}_{\text{global}} = \begin{bmatrix} \tilde{\boldsymbol{g}}_{11} & \cdots & \tilde{\boldsymbol{g}}_{1N_e} \\ \vdots & \ddots & \vdots \\ \tilde{\boldsymbol{g}}_{N_S1} & \cdots & \tilde{\boldsymbol{g}}_{N_SN_e} \end{bmatrix} \in \mathbb{R}^{k\cdot\beta\cdot N_S \times N_e} \qquad \text{and} \qquad \boldsymbol{b}_{\text{global}} = \begin{bmatrix} \tilde{\boldsymbol{b}}_1 \\ \vdots \\ \tilde{\boldsymbol{b}}_{N_S} \end{bmatrix} \in \mathbb{R}^{k\cdot\beta\cdot N_S} \tag{19}$$

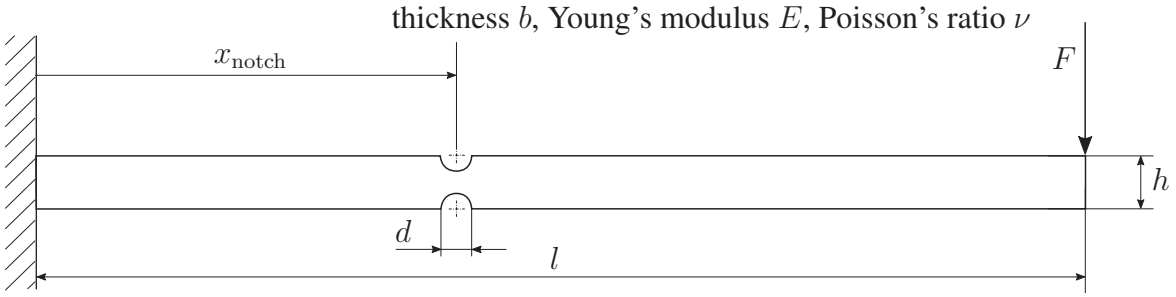

Figure 2: Notched cantilever beam. The design parameter is the position of the notch $\boldsymbol{p} = [x_{\text{notch}}/l]$. Fixed dimensionless parameters: $\frac{F}{El^2} = 3 \cdot 10^{-8} \cdot (\sin(0.0503\,\tau), \nu = 0.49, \frac{h}{l} = 0.05, \frac{d}{l} = 0.03, \frac{b}{l} = 0.1, \tau = \sqrt{\frac{E}{\rho}}\frac{t}{l}$

are built up by the entries

$$\tilde{\boldsymbol{g}}_{se} = \begin{bmatrix} \boldsymbol{V}^{\mathsf{T}}(\boldsymbol{p}_s) \cdot \boldsymbol{L}_e^{\mathsf{T}} \boldsymbol{f}_e(\boldsymbol{p}_s, \boldsymbol{L}_e \boldsymbol{V}(\boldsymbol{p}_s)\, \boldsymbol{q}_{\tau_{1,1}}(\boldsymbol{p}_s)) \\ \vdots \\ \boldsymbol{V}^{\mathsf{T}}(\boldsymbol{p}_s) \cdot \boldsymbol{L}_e^{\mathsf{T}} \boldsymbol{f}_e(\boldsymbol{p}_s, \boldsymbol{L}_e \boldsymbol{V}(\boldsymbol{p}_s)\, \boldsymbol{q}_{\tau_{1,k}}(\boldsymbol{p}_s)) \\ \boldsymbol{V}^{\mathsf{T}}(\boldsymbol{p}_s) \cdot \boldsymbol{L}_e^{\mathsf{T}} \boldsymbol{f}_e(\boldsymbol{p}_s, \boldsymbol{L}_e \boldsymbol{V}(\boldsymbol{p}_s)\, \boldsymbol{q}_{\tau_{2,1}}(\boldsymbol{p}_s)) \\ \vdots \\ \vdots \\ \boldsymbol{V}^{\mathsf{T}}(\boldsymbol{p}_s) \cdot \boldsymbol{L}_e^{\mathsf{T}} \boldsymbol{f}_e(\boldsymbol{p}_s, \boldsymbol{L}_e \boldsymbol{V}(\boldsymbol{p}_s)\, \boldsymbol{q}_{\tau_{\beta,k}}(\boldsymbol{p}_s)) \end{bmatrix} \in \mathbb{R}^{k \cdot \beta \cdot N_S} \tag{20}$$

$$\tilde{\boldsymbol{b}}_s = \sum_{e=1}^{N_e} \tilde{\boldsymbol{g}}_{se} \tag{21}$$

where $N_S = |P_{\text{sample}}|$ is the number of sample points and $\boldsymbol{V}(\boldsymbol{p}_s)$ are local reduction bases that are computed at sampling point $\boldsymbol{p}_s$. The matrix $\boldsymbol{G}_{\text{global}}$ and the vector $\boldsymbol{b}_{\text{global}}$ are used to compute a global set of weights and elements for the ECSW as described by equation (6).

By using the local reduction bases $\boldsymbol{V}(\boldsymbol{p}_s)$ in equation (20), the global hyper-reduction maintains the virtual work, that is produced by a training set $\boldsymbol{q}_\tau(\boldsymbol{p}_s)$, in the directions of its local reduction basis that is computed for the same sample point $\boldsymbol{p}_s$. It is not necessarily maintained in all directions spanned by the global reduction basis $\boldsymbol{V}_{\text{global}}$. Nevertheless, this requirement is fulfilled for all sample points simultaneously.

5 CASE STUDY

The proposed method is demonstrated by means of a case study. Figure 2 shows a drawing of the case study which is a cantilever beam. Its dimensions can be taken from the drawing. The beam is weakened by a notch at position x_{notch}. The case study uses the relative position of this notch $\boldsymbol{p} = x_{\text{notch}}/l$ as design parameter.

The mesh is shape parameterized by modifying the node positions. Thus, the mesh topology is maintained when the parameter is changed. This is illustrated in Figure 3. The mesh consists of $N_e = 1,148$ elements.

The desired parameter range of interest is set to $\boldsymbol{p} \in [0.3, 0.6]$. We have no information about optimal position of sample points a priori. For this reason, we make an attempt by choosing sampling points that are equidistantly distributed in the parameter range of interest. A reduction basis is computed at each of these sample points. The first 5 modes and all their static derivatives are included in this basis. Thus, a reduction basis' dimension is 20 at each sample point. A

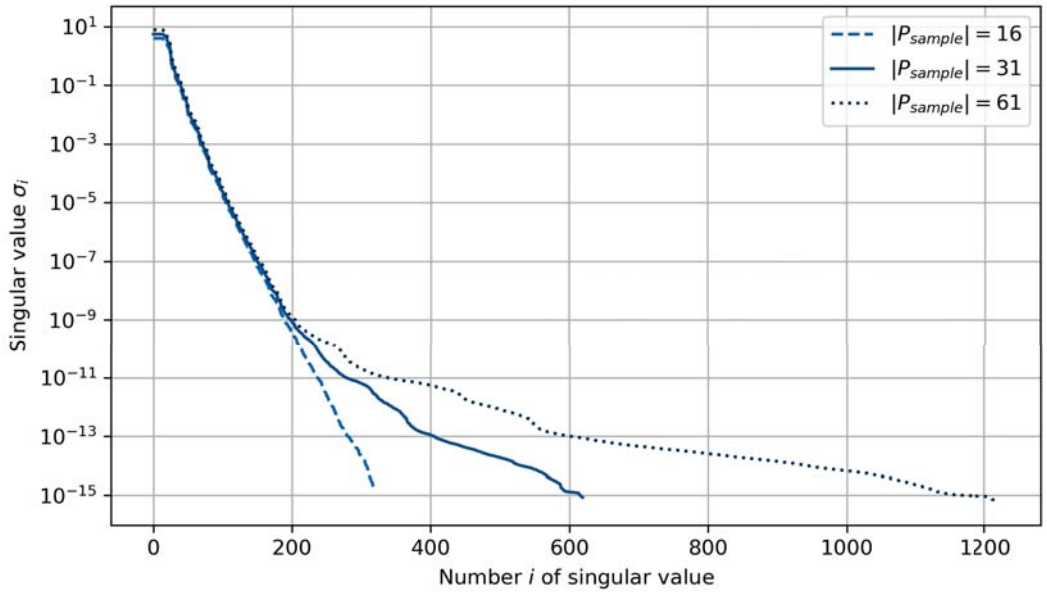

Figure 4: Singular values for deflation of global basis for three different numbers of sampling points.

singular value composition for three different numbers of sampling points is computed according to equation (14) to deflate the global basis. The singular values are shown in figure 4 and give a hint about if the number of sample points has been chosen properly. The singular values show that $|P_{\text{sample}}| = 31$ sample points seem to be a good compromise between the number of sample points and the approximation of the global reduction basis that would be spanned by the full parameter space of interest. For this reason, we present results for

$$P_{\text{sample}} = \{0.30,\ 0.31,\ 0.32,\ \ldots,\ 0.60\} \tag{22}$$

as sample points in the following.

We have $N_s = |P_{\text{sample}}| = 31$ sample points such that the global basis has a dimension of 620 before deflation. A reduction basis $\boldsymbol{V}_{\text{global}}$ is built with the first 300 left singular vectors. Nonlinear stochastic Krylov training sets (NSKTS) are computed for each sample point. The dimension of the Krylov subspace is $q = 4$. $\beta = 6$ linear combinations of Krylov vectors are built for each sample point and $k = 30$ load increments are computed for each linear combination. Figure 5 shows some examples of the computed NSKTS.

This contribution shows results for two parameter values as an example. These values are $\boldsymbol{p} = 0.41$, which is a sample point, and $\boldsymbol{p} = 0.405$, which is between two sample points.

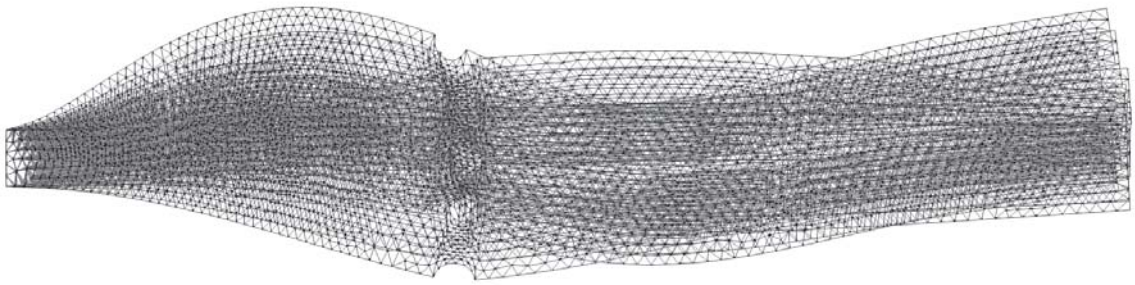

Figure 5: Overlaid examples for NSKTS that are computed for $\boldsymbol{p} = 0.41$

The graph in Figure 6 displays the tip displacement of the beam, simulated with a full order model. Figure 7 displays the absolute error for each time step for different reduced order models. The gray curves are errors for hyper-reduced models that are locally reduced. This means that reduction basis, NSKTS and ECSW-weights are computed directly (locally) for the parameter value of interest. This is the classic approach where a new reduced order model is computed for each parameter of interest. The blue graphs display errors for the global approach described in Section 4. This approach uses a global reduction basis and a global ECSW.

One can see that the error becomes smaller when smaller tolerances ε_{ECSW} are chosen. Furthermore, one can see that the local approach gives smaller errors compared to the global approach if the same tolerance ε_{ECSW} is used.

Table 1 summarizes computation times for different steps of the offline and online phase. One can conclude that much more elements in $\tilde{E}$ are needed for the global approach when the same error is desired. This also leads to higher computation times t_{online} in the online phase. However, as it is a global approach, which means that only one reduced order model must be computed for the whole parameter space of interest, there exists a break-even point where the global approach is beneficial in time compared to the local approach. This is illustrated in Figure 8.

6 CONCLUSION

Model reduction can help to reduce computation time when design studies are carried out that investigate the dynamics of geometric nonlinear structures. This contribution proposes a workflow for design studies where only one reduced order model is computed that is used to compute results for all design parameters of interest. This workflow uses nonlinear stochastic Krylov training sets that are computed for some parameter samples. They are used to gain a global set of weights and elements for the Energy Conserving Sampling and Weighting hyper-reduction method. The shape parameterized cantilever beam case study shows that a classic local approach is cheaper and needs less elements in the hyper-reduced element set $\tilde{E}$ and leads to shorter simulation times and smaller approximation errors. In contrast, the global approach only is beneficial if the number of parameter values, that need to be simulated, is very high. Then, the high offline costs for the global reduced order model pay off.

Keywords: Distributed plasticity, mesh-dependence, fiber, seismic performance

Abstract. *Currently, nonlinear analyses are widely used to evaluate the performance of special steel moment frames (Special SMF). Most of the mathematical models used in these analyses used concentrated plasticity approaches whit lumped nonlinearities at the end of beams and columns. Even when these models are highly recommended due to their simplicity and computational efficiency, they present some setbacks related to the axial-flexural interaction and the load protocol calibration dependency. In order to overcome these problems, a distributed plasticity model can be used. However, these models are not intended to capture local geometrical effects such as buckling or necking into the material constitutive law. In addition, these models present localization issues when the constitutive law includes softening, leading to variability in the global response.*

This paper proposes a distributed plasticity beam-column model that overcome these limitations. The constitutive material law proposed herein captures softening due to local buckling under compression stress using a non-symmetric strain-stress curve. The parameters are calibrated through experimental data and validated for different axial loads and loading protocols. Moreover, to solve the softening-localization issue, a method of regularization is proposed. This regularization is verified through static and dynamic analyses of an 8-story Special SMF building. The results show that the proposed model can represent the behavior of W shape sections under different load protocols and axial load demands. In addition, the model can accurately incorporate critical features as maximum flexural capacity, flexure axial interaction, and post-peak softening. The regularization method yielded negligible variations under different plastic lengths of the column for all the analyses. The proposed model is simple to implement, and the results indicate that it can be used to evaluate the seismic performance of Special SMF.

1 INTRODUCTION

Nowadays, the seismic performance of structures is commonly assessing with nonlinear analyses, due to the drastic improvement in computational storage and speed in the last 30 years. As a consequence, several codes such as the ASCE7-16 [1], ASCE-41 [2], and FEMA P-695 [3] require advanced nonlinear analyses to determine the behavior of a structure. However, in order to perform dynamic analyses, where structures are subjected to large deformations, nonlinear models need to capture two significant effects: element deterioration and nonlinear geometric effects. These effects allow the mathematical model to capture large deformations or trigger structural instability [4].

In special steel moment frames (Special SMF), the leading causes of beam-column element deterioration are related to local geometric instabilities. In beams, the deterioration is controlled by local flange buckling [5], while columns are controlled by local flange-web buckling and lateral-torsional buckling [6]. Therefore, a Special SMF model used in seismic performance assessment needs to include these phenomenological effects, as well as the structural geometrical effects (P-delta).

In literature, three main modeling approaches have been used in nonlinear Special SMF models: 1) finite element, 2) concentrated plasticity, and 3) distributed plasticity. The first one is considered the most detailed approach because these models can explicitly capture local instabilities and force interactions in any location within the structure. However, they are not recommended for complex analyses that include many structural members or several nonlinear incursions [7]. In contrast, concentrated plasticity models limit the nonlinear behavior to predefined locations (i.e., at the end of the elements where the inelasticity is expected) using calibrated constitutive curves that represent the element behavior. Even when these models are commonly used due to their simplicity and computational efficiency, they can not capture axial-flexural interaction or plasticity spreading, and they are highly dependent on the calibration load protocol [8].

Distributed plasticity is an approach that is between the other two, and it is a simplification of the finite element method that uses uniaxial materials. A common element of this approach is the fiber beam-column element, which consists of dividing the element into several nonlinear sections where the response is evaluated. This approach requires to define a material constitutive law for the section fibers and an integration method to combine the section responses [9]. Nevertheless, these models obtain the element response as an emergent property entirely related to the constitutive law. Then in order to capture local geometrical instabilities, the constitutive law should include phenomenological effects [7]. Moreover, these models present a critical setback due to strain localization when the constitutive law includes softening, which leads to a spurious mesh-dependence (i.e., non-objective global response) [10].

Even though some authors have proposed constitutive laws that include phenomenological effects, they only utilized a fixed mesh-discretization [8,11]. Therefore, the mesh-sensitivity of these results was not evaluated, consequently a procedure that ensures objective global response is necessary. In this sense, the Smeared-Crack approach is a method that modifies the constitutive law parameters depending on the mesh-discretization to reduce the effects of the localization [12]. This method has been implemented in reinforced concrete fiber models to achieve objective responses [10].

This study proposes a phenomenological calibrated constitutive law and a regularization process applicable to seismic performance assessment of Special SMF. First, the constitutive law is implemented with a non-symmetric curve that represents the section deterioration using compression softening. This curve is calibrated with experimental laboratory tests and validated under different axial load demands and load protocols. Then, the proposed regulariza-

tion method is presented in detail. The regularization process starts with a characterization of the global element response, followed with a sensitivity analysis of mesh-discretization and constitutive parameters to propose a rational set of regularization rules. Finally, the constitutive law and the regularization rules are used on an 8-story Special SMF building under static and dynamic nonlinear analyses to determine its applicability for seismic performance assessment.

2 CONSTITUTIVE LAW

in order to model the element deterioration adequately, the material constitutive law needs to capture not only the steel mechanical properties but also it requires to capture local geometric instabilities. Thus, the constitutive law proposed herein used a non-symmetric behavior with a compression softening branch that represents steel W-Sections local buckling that consequently takes into account the loss of capacity in the section. The open-source software OpenSees [13] was used to implement this behavior. The uniaxial Steel02 and Hysteretic materials were used together (into a Parallel material) to obtain the desired constitutive law. The Steel02 material presents the residual stress (Fig.1(a)) and the Hysteretic material a non-symmetric behavior (Fig.1(b)). The resulting material shows smooth stiffness transition and the compression softening branch until it reaches the residual stress (Fig.1(c-d)).

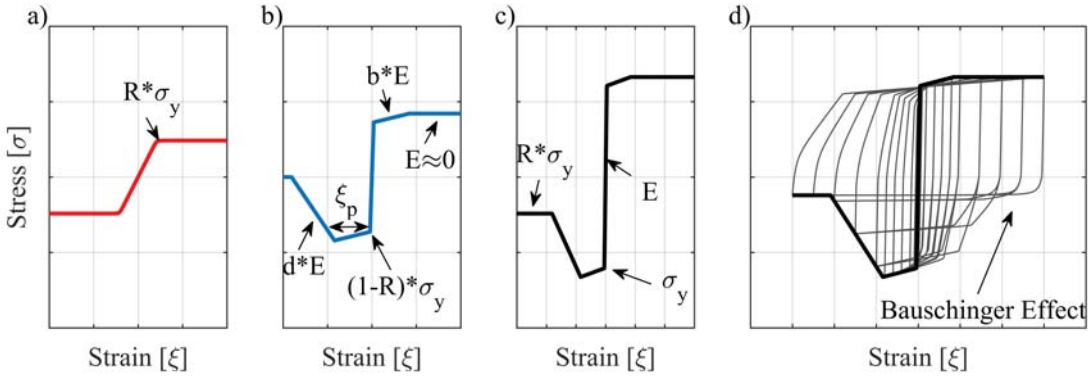

Figure 1: Constitutive law. a) Steel02, b) Hysteretic, c) Proposed material envelope, d) Proposed material cyclic.

The proposed constitutive curve has six characteristic parameters. Two of them are the steel mechanical properties: Young's modulus (E) and yielding stress (σ_y). The additional four calibrated parameters represent the local geometrical instabilities: strain hardening (b), plastic strain (ξ_p), strain softening (d), and residual stress (R).

2.1 Calibration and Validation

The laboratory experiment C4 presented in Elkady and Lignos (2018) [6] was replicated to calibrate the post yielding parameters and to capture the local geometrical effects in W-sections. The calibration test consisted of a cantilever W24x168 column subjected to a lateral collapse consistent load protocol and an axial load demand (P_g) of 0.2 the yielding axial capacity (P_y). The experimental setup is presented in Fig.2(a)), where the column model uses a single fiber-beam column element with the modified Gauss-Radau integration method (Fig.2(b)). In this integration method, the mesh-discretization depends on the plastic length assigned at the element ends, and the plastic length value for the calibration was considered equal to the column depth. The results of Fig.2(c) presents the experimental (Target) and the simulated global responses (Moment-Chord rotation).

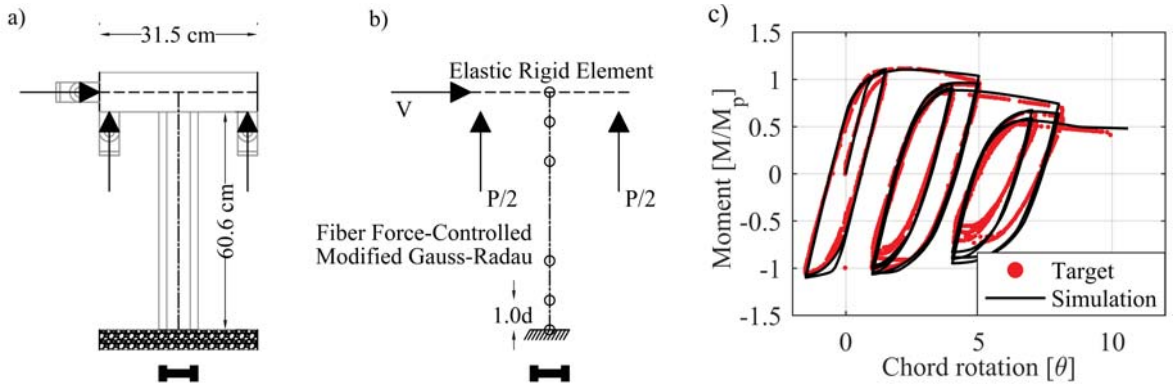

Figure 2: Calibration. a) Experimental setup, b) Numerical model, c) Experimental and simulated responses.

The four parameters related to the local geometrical instabilities were varied until the simulated moment-chord rotation response reached the best visual approximation with the experimental response. The values obtained from the calibration corresponds to 0.005, 0.015, 0.010, and 0.5 for b, ξ_p, d, and R, respectively. With these values, the proposed constitutive law captures the maximum capacity of the column, the smooth transition, the monotonic deterioration, and the cyclic strength and stiffness degradation correctly (Fig.2(c)).

After determining the six parameters, the constitutive law was validated using three additional experimental tests with different axial load demands and load protocols. The experiments correspond to the experiments C2, C3, and C6 obtained from Elkady and Lignos (2018) [6]. These models used the previously calibrated material parameters, and a plastic length equal to the column's depth. The only differences were the load protocol and the axial load demand, as presented in Fig.3(a-c). In addition, Fig.3 shows the comparison between the simulated and the experimental responses.

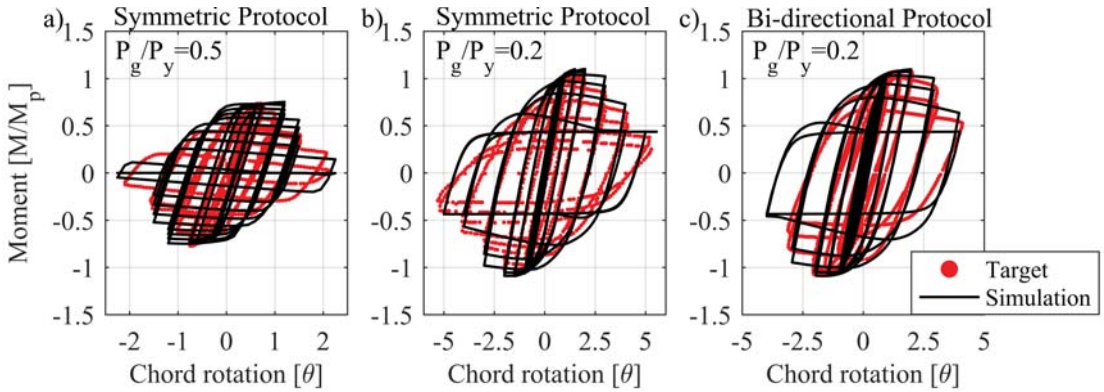

Figure 3: Validation. a) Test C2, b) Test C3, c) Test C6.

The results show that for a high axial load demand (Fig.3(a)), the response is more fragile because it reaches lower rotations than their counterpart with less axial load (Fig.3(b,c)). Fig.3(b-c) show that the simulations capture the stabilization of the moment deterioration when the fragile behavior does not control the response. Additionally, the proposed constitutive curve captures the behavior under the bi-directional symmetric load protocol, capturing the strength deterioration and cyclic degradation adequately (Fig.3(c)).

3 REGULARIZATION METHOD

The selection of an arbitrary plastic length value in the calibration section limits the proposed constitutive law to that unique mesh-discretization. As shown later, mesh-sensitive responses were obtained for different plastic lengths. Therefore, to get an objective response, a regularization method that reduces this spurious mesh-dependence is necessary. The regularization proposed uses the smeared-crack approach, which modifies the constitutive law parameters through regularization rules dependent on the mesh, to obtain an objective global response [12].

Before developing the regularization rules, three steps were necessary to understand the behavior of the global response. First, it was required to idealize the global element response to quantify the variations of the response. Second, addressing the global response differences due to mesh-discretization allowed determining trends in the global response. Finally, a sensitivity analysis of the constitutive law parameters allows determining their influence in the element's response curve. With this information, rational regularization rules can be developed to achieve an objective response.

3.1 Global response behavior.

Contrary to the concentrated plasticity models, the global element response in distributed plasticity models is not previously defined. This response is an emergent behavior that involves the constitutive law, the section geometry, and the element geometry. Therefore, to assess variations in the response curve is necessary to describe its behavior with a certain number of parameters that enable a quantitative comparison. For this purpose, the monotonic global response (moment-chord rotation) was idealized with a multilinear symmetric curve with four regions (Fig.4(a)). The first one represents the elastic element behavior, and it is limited by the yielding point, which is defined when the current stiffness becomes 20% the initial stiffness (K_{init}) (Fig.4(b)). The second region represents the element hardening capacity, and it is limited by the maximum moment and its respective chord rotation. The third region shows the element deterioration behavior, and a residual moment point defines it. Where the residual moment point is computed when the stiffness becomes 50% of the previous step stiffness (K_{curr}) (Fig.4(c)). The last region keeps constant the residual moment capacity.

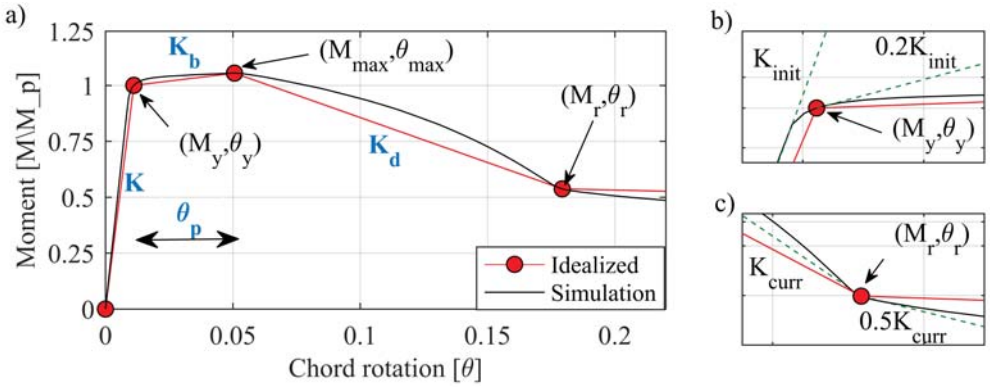

Figure 4: Response idealization. a) Moment chord-rotation, b) Yielding point, c) Residual point, d) Parameters

This idealization allows determining six global parameters presented in Fig.4(a): elastic stiffness (K), yielding moment (M_y), hardening stiffness (K_b), plastic rotation (θ_p), deterioration stiffness (K_d), and residual moment (M_r). These global parameters are coherent with the constitutive law parameters representing similar behavior on a different scale level (constitutive-material, and global-element).

The next step is to determine the mesh-sensitivity of the global response. For this purpose, monotonic static analyses were carried varying only the plastic length (L_p) of the modified Gauss-Radau integration method in the range of 0.3 to 1.8 the plastic length of the calibration (L_{pc}), while keeping the material parameters constant. These analyses illustrate the spurious mesh-dependence of the global moment-chord rotation response (Fig.5(a)). In addition, the analyses allow identifying tendencies in the global parameter values due to the plastic length variations (L_p/L_{pc}). The sub-index c denotes a calibration value or a value obtained using the calibration parameters.

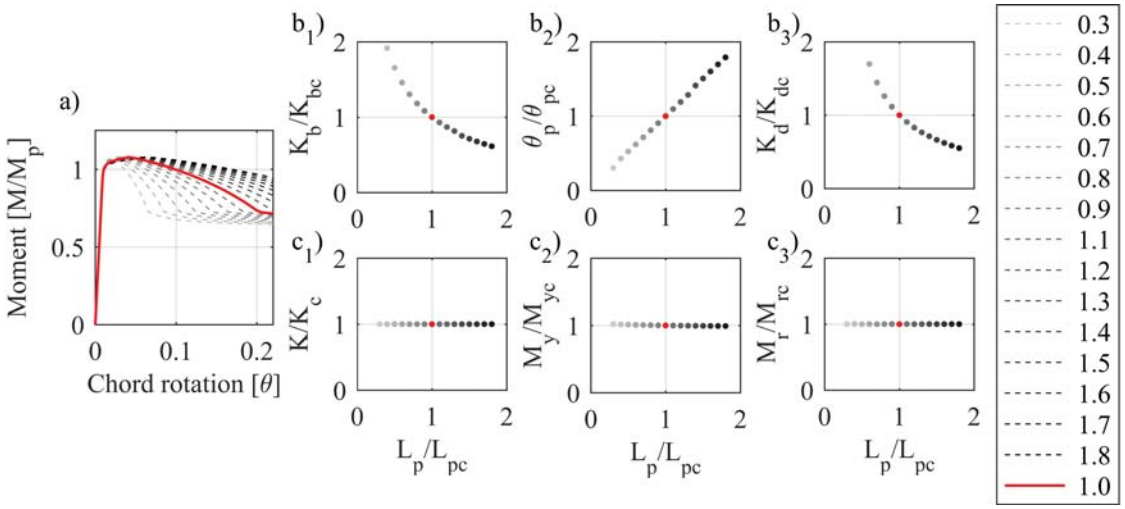

Figure 5: Sensitivity analysis. a) Moment-chord rotation response, b) Main tendencies, c) Null tendencies.

The results show that a variation in the plastic length leads to an inverse variation on hardening stiffness and deterioration stiffness (Fig.5(b_1,b_3)). Meanwhile, the plastic length leads to a direct variation on plastic rotation (Fig.5(b_2)). The other global parameters were not affected (Fig.5(c_1-c_3)), this invariability can be noticed in the moment-chord rotation curves too.

The regularization rules should affect the constitutive law parameters. Therefore, it is required to assess the global response variation due to changes in the constitutive parameters. Three sensitivity analyses were carried varying the constitutive parameters (b, ξ_p, and d) related to the plastic length sensitive global parameter (K_b, θ_p, and K_d). Only one parameter was varied at the time, while the other constitutive law parameters and the plastic length remained equal to the calibrated values. The variation range was kept the same as before from 0.3 to 1.8 the calibrated value. These results lead to determine tendencies in the variations of the global parameters that are critical to defining the regularization rules. Fig.6 shows the moment-chord rotation response of the carried monotonic static analyses varying the constitutive parameters. Also, the normalized tendencies between the constitutive law parameter and the global parameter are presented.

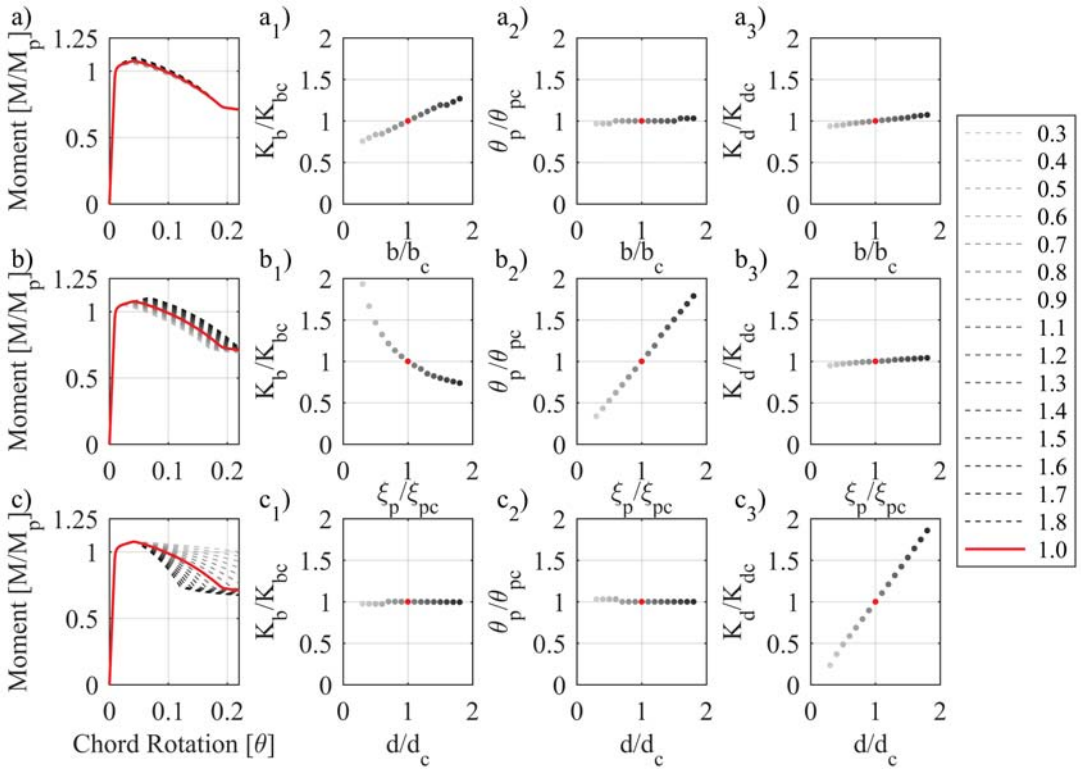

Figure 6: Sensitivity analysis. a) Strain hardening (b), b) Plastic strain (ξ_p), c) Strain deterioration (d).

The three parameters b, ξ_p, and d, show linear tendencies with their respective global parameters K_b, θ_p, and K_d (Fig.6(a_1, b_2, c_3)). Therefore, any variation applied to these parameters affects the global response in the same proportion. A secondary tendency was obtained for the plastic strain, which presents an inverse correlation with the hardening stiffness (Fig.6(b_1)).

3.2 Regularization proposal

The regularization rules should reduce the variations of the global response due to the mesh-discretization and canceling the tendencies showed in (Fig.5(b_1-b_3)). Inverse operations on the global parameter can negate these tendencies. Then, the plastic rotation divided by the plastic length ratio (L_p/L_{pc}), and hardening stiffness and deterioration stiffness multiplied by the same ratio reduces the tendencies. Even more, due to the linear dependence between global parameters and constitutive law parameters (Fig.6(a_1, b_2, c_3)), this operation can be applied to the constitutive law parameters with an equivalent effect on the global response. Consequently, the regularization rules are defined by three equations, one for each sensible constitutive law parameter.

$$b=b_c*(L_p/L_{pc}) \quad (1)$$

$$\xi_p=\xi_{pc}/(L_p/L_{pc}) \quad (2)$$

$$d=d_c*(L_p/L_{pc}) \quad (3)$$

Where L_p, b, ξ_p, and d are the values used in the analysis and L_{pc}, b_c, ξ_{pc}, and d_c are the calibration values, which are the column's depth, 0.005, 0.015, and 0.010, respectively.

With the regularized constitutive law parameters, a new sensitivity analysis varying the plastic length was performed. The element moment-chord rotation response increases its objectivity considerably (Fig.7(a)). In addition, the tendencies presented on the previous sensitivity analysis became negligible for plastic rotation and stiffness deterioration, but hardening

stiffness still presents a slight variation mainly under lower plastic length ratios (Fig.7(a_1)). This difference in stiffness hardening comes from the secondary tendency caused when the plastic strain is modified (Fig.6(b_1)). In order to cancel the variation on stiffness hardening, an alternative regularization rule on the strain hardening was determined:

$$b=b_c*(L_p/L_{pc})^{0.7} \qquad (4)$$

The alternative moment-chord rotation results (Fig.7(b)) show a similar behavior than the obtained with the initial regularization rules. However, the stiffness hardening tendency presents negligible variations to the plastic length (Fig.7(b_1)).

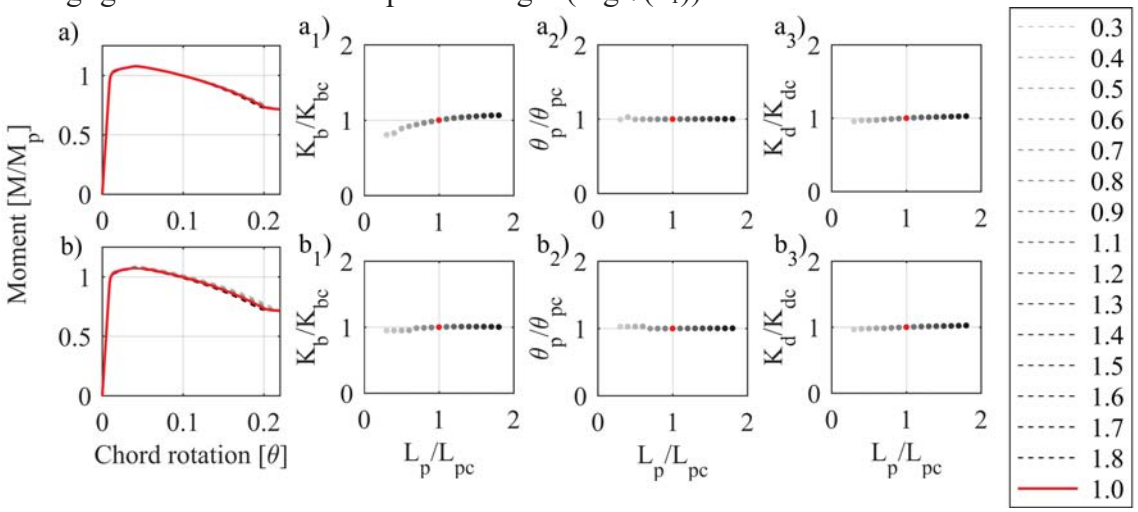

Figure 7: Regularized sensitivity. a) Initial regularization, b) Alternative Regularization.

4 SEISMIC ASSESSMENT

After developing the constitutive law and the regularization rules, these are applied to an eight-story structure with perimetral Special SMF as the lateral system (Fig. 8). The archetype was obtained from the ATC 71 project [14] and was designed for a D_{max} seismic risk category. The building present prequalified reduce beam section (RBS) on beams, and additional web thickness on column-beam connections (Panel Zone). This archetype has been used in several types of Special SMF research, and more detail is presented in [14–16]. The geometrical features of the lateral system are shown in Table 1.

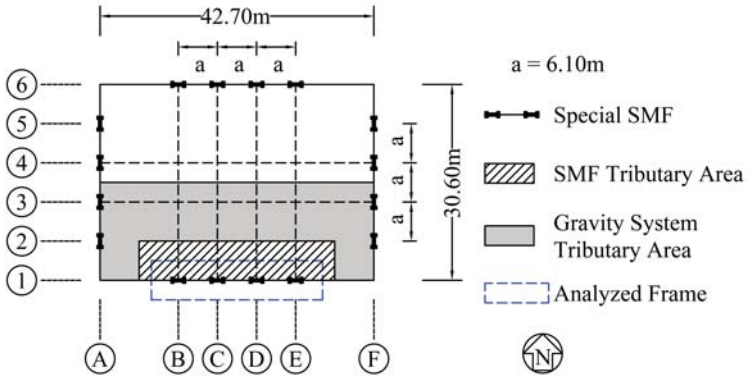

Figure 8. Archetype Plan View

Story	Elevation [m]	Beam Section	Exterior Column Section	Interior Column Section	Doubler Plate Size

Table 1: Geometrical parameters.

Determine the influence of the regularization method is the main purpose of this research. Therefore, only elements with unknown plastic lengths were modeled with a distributed plasticity approach and the corresponding regularization method. In beams, a fixed plastic length (the RBS connection's length) and the absence of coupled phenomena (i.e., axial-flexural interaction) causes that a concentrated plasticity model can accurately represent the deterioration characteristics of these elements. The constitutive law used in the model was presented by Lignos (2008) [5], and it is known as modified Ibarra-Medina-Krawinkler (mod IMK). This constitutive capture beam's strength deterioration, in addition to strength and stiffness cyclic degradation (Fig.9(c)). More detail of the calibration process and its implementation is presented in [5,16]. The Panel Zones were modeled with the parallelogram methodology proposed in [17]. This approach uses a moment-shear deformation constitutive law that captures the joint nonlinear behavior. (Fig.9(b)), which include an initial stiffness, a secondary stiffness after beam flange yielding, and a hardening slope after columns web yielding.

On the other hand, columns were modeled using a distributed plasticity model with a single force-controlled fiber beam-column element with a modified Gauss-Radau integration method (Fig.9(d)). Three sets of models were developed, varying the plastic length and the regularization method employed. The first set uses the proposed constitutive law without a regularization process, the second set presents the initial regularization rules, and the third set uses the alternative regularization rules. The plastic length was varied from 0.3 to 1.4 the column's depth in the three sets.

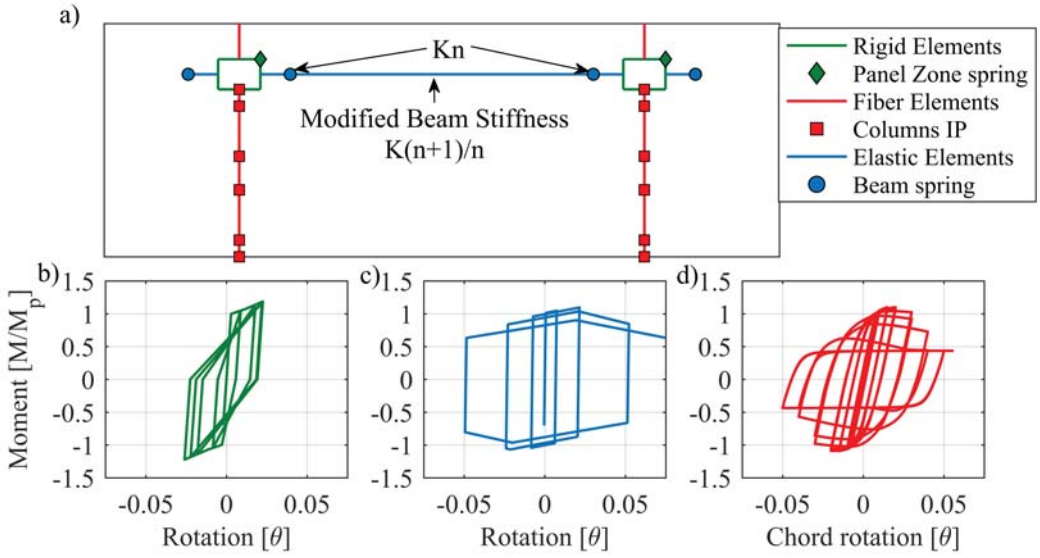

Figure 9: Modeling considerations. a) Frame model, b) Panel zone, c) RBS, d) Column.

The damping assignation considers a Rayleigh damping ratio of 2.5% applied in the first period (T_1) and on $0.2T_1$ according to the recommendations given in [14]. In addition, stiffness damping was not assigned on rotational springs to avoid unexpected damping forces due to stiffness changes after yielding [18]. Therefore, a damping modification was considered for the concentrated plasticity beam elements; the detail of this modification is presented in [19]. Moreover, the P-delta effects were considered with the leaning column approach, which consists of connecting the lateral displacement of the structure with a zero-flexural stiffness column that carries the non-tributary gravity load.

Once defined the model, a seismic performance assessment requires to determine a procedure to verify the behavior of the structure. ASCE 41 [2] establish two nonlinear procedures for seismic evaluations: 1) Nonlinear static procedure, 2) Non-linear time-history procedure. Both approaches are considered using a simplified method that enables determining the model capability of capturing structural instability with a mesh-independent global response.

4.1 Nonlinear static procedure (NSP)

This procedure uses a monotonic static analysis (Pushover) to assess the nonlinear behavior of the structure under an incremental lateral load. The analysis was performed in accordance with FEMA P-695 [3], where the load pattern was proportional to the first modal displacement and the mass distribution. In the nonlinear static procedure, the global acceptance criterion for seismic assessment is related to the maximum drift reached on a target roof displacement. Therefore, the differences showed in the capacity curve are directly related to the differences in the structure's seismic performance using this procedure. The results are presented as the capacity curve with the basal shear/weight ratio (V/W) versus the roof drift (Δ_r/H_r) (Fig.10(a, b, c)). In addition, the structure drift profile is presented at three different events: 1) at the yielding point (0.8%), maximum capacity, and the last step previous basal shear becomes negative.

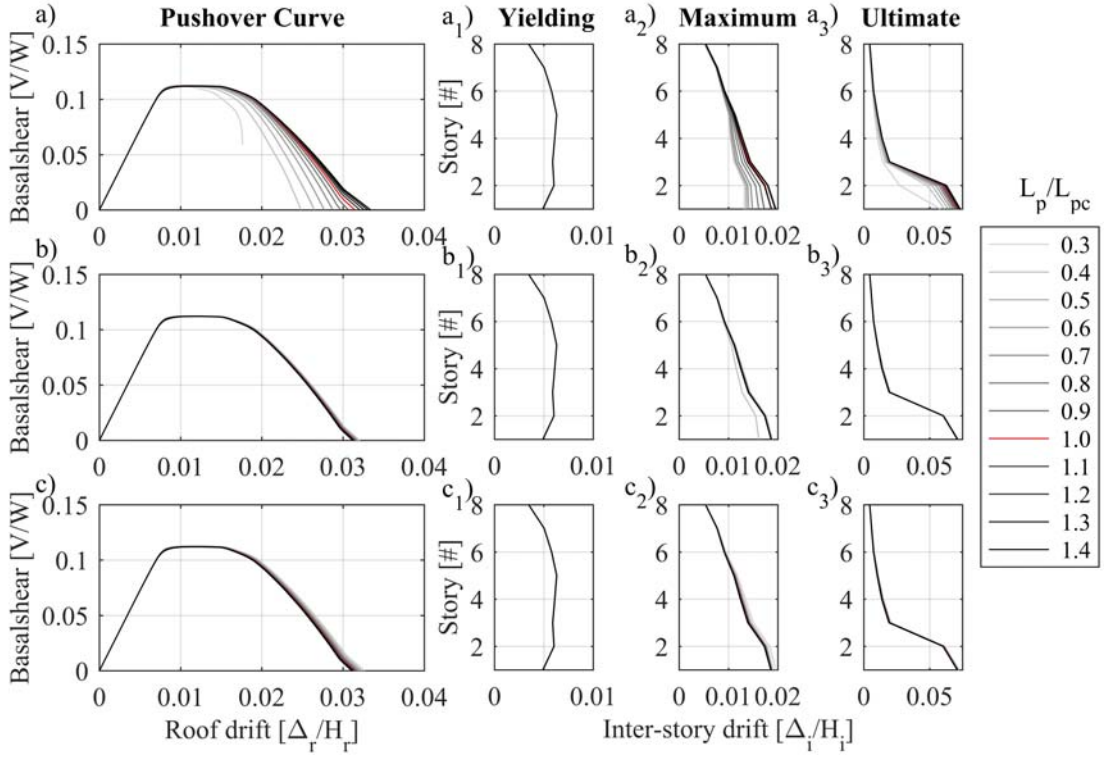

Figure 10: NSP. a) Non-regularized, b) Initial regularization, c) Alternative regularization

It is noticeable that for lower roof drifts demands (less than 0.8%), there is no need for the regularization because the columns do not present softening incursions (Fig.10(a_1, b_1, c_1)). However, on the maximum capacity and the last drift, there is a significant difference in the non-regularized models with variations of 25% and 20%, respectively. Also, it is noticeable that shorter plastic lengths lead to less ductile behavior (Fig.10(a)). In contrast, the regularized results lead to objective responses regardless of the plastic length used in the analysis (Fig.10(b, c)). There is a variation of 5% on the maximum capacity drift profile using the initial regularization rules (Fig.10(b_2)). However, despite that difference, the two regularization rules lead to an objective global response of the structure during the entire analysis.

A more detail summary of the pushover curve is presented in Table 2, where the drift at the maximum basal shear (δ_{Vmax}), the last drift reached by the model (δ_{last}), and the number of Newton-Raphson's iterations until the end of the analysis (NR_{iter}) are presented. This table shows the variations of the non-regularized models not only in the δ_{last}, but also in the δ_{Vmax} which lead to verify the importance of a regularization method even before the secondary (negative) stiffness of the pushover. These differences become negligible whit both regularization methods. These results show that on NSP, it is possible to achieve an objective response despite the weight of the most demanded IP, without increasing the Newton-Raphson iterations.

4.2 Nonlinear time history procedure (NDP)

This procedure requires to subject the structure to a set of ground motions scaled to the desired seismic intensity, and the median of the maximum responses of the structure is evaluated under specific criteria [2]. In this study, the structure was subjected to one ground motion as a simplified method to verify the constitutive law and the regularization process. The Kocaeli, Turkey ground motion of 1999 was selected and scale under three seismic intensity levels that represent a service level, design level, and maximum considered earthquake (MCE) level. The results of the time-history nonlinear analyses are presented as the 1st inter-story drift response at each intensity level (Fig.11).

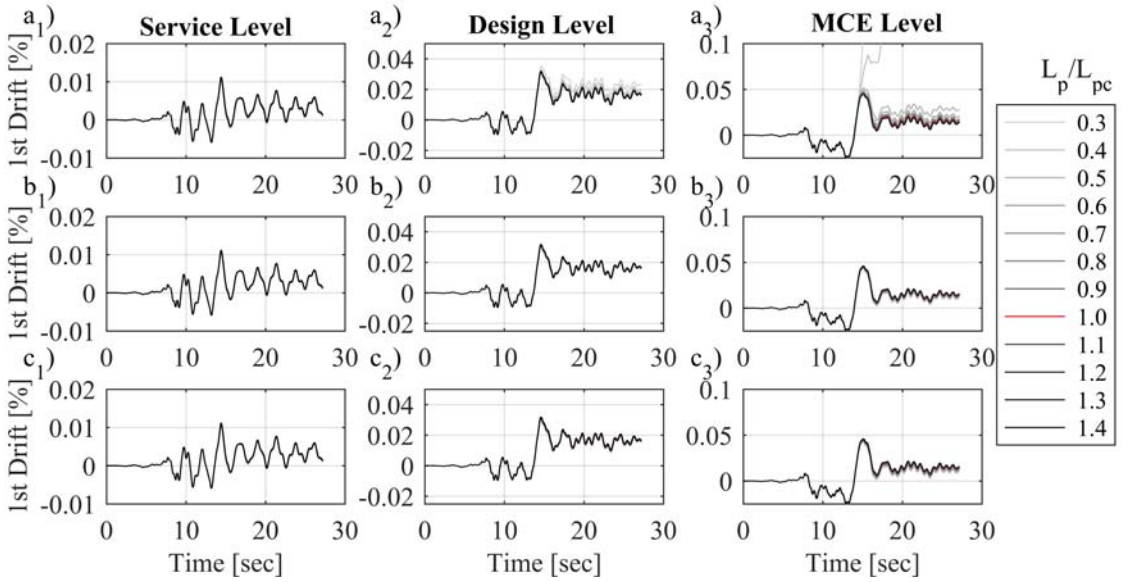

Figure 11: NDP. a) Non-regularized, b) Initial regularization, c) Alternative regularization

The results show that regularization is not necessary for lower intensity levels as the services one (Fig.11(a_1)), and for the design level, the differences are not considerable (Fig.11(a_2)). However, at the MCE level, the non-regularized models show a completely different response, and the localization caused structural instability in two models (Fig.11(a_3)). On the other hand, both regularization rules lead to an objective response (Fig.11(b_1-c_3)). The effect is mainly significative under the highest seismic intensity level, where the differences

are negligible (0.5%, on the maximum drift, and 0.2% on the residual drift). There is no significant difference between the initial and the alternative regularization method.

Similar to the NSP analysis, the maximum inter-story drift (δ_{Max}), the maximum residual inter-story drift (δ_{Res}), and the number of Newton-Raphson iterations until the end of the analysis (NR_{iter}) are presented in Table 3. For instance, the models without regularization and with plastic length lower than the calibration one (L_p/L_{pc}<1.0) present higher deformations than the base case (L_p/L_{pc}=1.0). The opposite behavior is noticeable in models with plastic lengths' higher than the calibration (L_p/L_{pc}>1.0). In contrast, both regularization proposals yield to negligible variations in the δ_{max}, and δ_{Res} with the same computational cost analysis even in a complex nonlinear time-history analysis with high seismic demand.

5 CONCLUSIONS AND RECOMMENDATIONS

This study focuses on assessing regularization rules applied on a phenomenological calibrated steel material that includes softening in the constitutive law. The regularization was tested on a monotonic cantilever test and an eight-story Special SMF building. In addition, the regularization and the constitutive law were assessed under different levels of seismic intensities to determine its applicability for seismic assessment of Special SMF. The main conclusions of this study are:

- The phenomenological calibration captured the behavior of steel W-section adequately under different conditions of load protocol and axial load demands. Also, the phenomenological calibration included the softening branch, which simulated the local geometrical instability of the experimental test.
- The process to define the regularization rules led to identifying essential tendencies of the constitutive law parameters and the mesh-discretization in the global response. Furthermore, this process established an intuitive method to develop regularization rules that reduced the spurious mesh-dependence of the model.

- The seismic assessment of Special SMF using distributed plasticity models showed that regularization was not required in lower levels of seismic intensity because the structure remained substantially elastic. However, in higher demands such as design or MCE, the regularization of the constitutive law became critical to achieving objective responses.
- The regularization rules presented in this study led to objective responses under all the tested analyses. Moreover, there was no significant difference between the two groups of regularization rules, and both of them can be used in seismic performance assessment.
- This regularization process leads to a simple method that controls the mesh-dependence of global results. Furthermore, the procedure does not require additional implementation on OpenSees (i.e., elements, materials, or analyses). Also, since the procedure does not require a fine mesh-discretization, it can be used to reduce the number of elements, or integration points per structural element without compromising the global response.

This study presented limitations regardless of the single archetype used in the seismic assessment section. The effect of the constitutive law and the regularization rules should be tested on a broader range of Special SMF. Also, the performance conditions considered in this structural seismic assessment are related to global performance criteria; a more detailed performance-based analysis is required that includes local conditions such as element rotations.

A significant improvement in considering the distributed plasticity model in columns is that it explicitly captured the axial-flexural interaction. Adding this effect enabled an axial-shortening assessment that was not taking into account in this research. Further research needs to be carried in order to determine if this phenomenon is critical in the seismic performance assessment of Special SMF.

Keywords: Model updating, Parameter estimation, Dynamic response, Damage detection, Convolutional Neural Networks, Deep Learning.

Abstract. *A critical step of building a reliable Finite Element (FE) model is closing the gap between the actual and the simulated structural behaviour by utilizing FE model updating methods. Current updating methods typically require hand-crafted features such as natural frequencies and mode shapes. As a result, limitations in identifying these features are becoming also limitations in the updating process. With the ability to utilize raw data, Deep-Learning (DL) algorithms have the potential to avoid such limitations. This paper aims to validate the efficiency of 1D Convolutional Neural Networks (CNNs) in estimating FE model parameters using synthetic acceleration data. The performance of 1D CNNs was tested on a simple FE beam model. The influence of training pair numbers, and acceleration signal duration on the algorithm performance was evaluated. The results indicate that the 1D CNNs have the ability to estimate FE model parameters with high accuracy. Final results indicate that the standard damage detection and the more novel model parameter estimation, through using 1D CNNs, can be practised synchronously with equally good results.*

1 INTRODUCTION

Finite element (FE) modelling has been in broad use for analysing structural behaviour [1], even though there are uncertainties and assumptions inherent in it (e.g. material properties, boundary conditions) [2]. These uncertainties may compromise the ability of an FE model to simulate the actual static and dynamic behaviour of a structure. To reduce the uncertainties and build a reliable FE model, a reconstruction of it can be considered by calibrating its parameters based on actual structural behaviour data, a process widely known as FE model updating.

FE model updating methods are broadly classified into non-iterative and iterative ones [2, 3]. The former are computationally efficient yet, they tend to produce physically meaningless results. For this reason, they are not widely used in practice [3–5]. On the other hand, iterative methods can overcome this limitation.

Iterative methods estimate a set of FE model parameters by using error minimization techniques; however, there are several concerns associated with their deployment. Namely, some of the methods may converge prematurely to a local optimal solution; such is the case of the Particle Swarm Optimization (PSO). Others rely on a rather complex implementations; such is the case of genetic algorithms [3]. Neural Networks (NNs), being another class of Machine learning (ML) algorithms, provide an alternative solution to avoid such concerns owing to their inherent learning-process step.

NNs can learn any non-linear/complex relationship between the structural response (as embedded for instance within natural frequencies and mode shapes) and a set of FE model parameters [6]. For this reason, several attempts have been made to update FE models using NNs. One of the first attempts was made by Levin and Lieven [7]. In their study, a numerical model of a ten-element cantilever beam was used. They updated the Young's moduli and the density of each element working only with the first five frequencies and mode shapes. They concluded that NNs can withstand the presence of noise even when there is limited data. The limitation of using modal parameters is that the ensuing modal analysis techniques used for extracting them carry assumptions and approximations. On the other hand, the Frequency Response Functions (FRFs) are directly measured in structures. For this reason, Sadr et al. [8] used FRFs to improve NNs' performance in FE model updating. However, training NNs with the large size of FRFs could be time consuming due to the algorithm shallow-learning architecture. To tackle the trade-off between computational cost and algorithm performance, they used Principal Component Analysis (PCA) as a data reduction method. This approach was verified on a numerical (ten-degrees-of-freedom lumped parameter system) and an experimental example (free-free beam). In real-life applications, Sabamehr et al. [9], applied NNs to update FE models of three different bridges. In this study, the change of stiffness of some elements was estimated using NNs and natural frequencies.

A constraint of NNs in FE model updating is that the output data (e.g. FE model parameters) need to be equal or less than the number of input data (e.g. structural responses) [10]. Furthermore, any artefact in the modal parameter identification or the FRFs' reduction would carry over on the final NNs results.

The recent advancements in ML algorithms have led to developing Deep Learning (DL) algorithms, in which the machine can learn by using only raw data [11]. DL algorithms (e.g. Convolutional Neural Networks -CNNs-) have the potential to avoid the drawbacks of traditional NNs.

For instance, modal parameter identification techniques, with their limitations and constraints on the FE model updating process, can be bypassed by utilizing raw acceleration data. As a result, the advantages of the learning process of NNs are maintained and the drawback of utilizing hand-crafted features is overcome.

1D CNNs have already been implemented successfully in vibration-based applications in civil, mechanical and aerospace engineering [12–15]. 1D CNNs can learn from vibration data arranged in the form of a vector, which is convenient for one-point response data, or a matrix, which is convenient for multi-point response data. Abdeljaber et al. [15] used the vector form to identify and locate structural damage at the joints of a laboratory steel grandstand-like frame by using 1D CNNs and acceleration data. The results of this study show that the 1D CNNs have the ability to detect damage at several structural conditions with high accuracy even though these structural conditions were not included in the training data. The limitation of this study is that the number of the structural conditions for training the 1D CNNs should equal the number of the considered joints as well as that the structural condition which represents the undamaged structure needs to exist. To overcome this limitation, Abdeljaber et al. [14] used only two structural conditions, namely, undamaged and severely damaged to assess the overall structural condition of a benchmark structure (four-story, braced steel structure). Different structural conditions, which simulate different level of overall damage, were used to evaluate the algorithm. In their study, a good estimation of the overall structural condition was reported. On the other hand, Zhang et al. [16] used a matrix of acceleration time histories as input data to detect structural damage. The method was validated on three different structures, including an in-service steel girder bridge. In their study, the structural damage was simulated by adding a mass to the structures. Several structural conditions were simulated by changing the position of this mass. The multi-points acceleration responses of each structural condition were used as training and validating data. The latter data was used to evaluate the accuracy of the 1D CNNs performance. The results show a high accuracy (97.2% - 99.5%) in detecting and locating the structural damage.

Inspired by the aforementioned achievements of the 1D CNNs in classification of structural conditions, this paper is aiming to validate the efficiency of 1D CNNs in estimating FE model parameters. A simple numerical cantilever beam model was adopted and different levels of artificial damage were considered for it through the introduction of a non-rigid rotational support. The beam was dynamically loaded for producing synthetic acceleration data. The, multi-point acceleration responses, were formed into an input matrix to estimate the parametrically varying rotational stiffness of the cantilever beam. By this approach, the FE model updating process can be performed simultaneously with detecting and evaluating structural damage.

The paper is organised as follows. The background of 1D CNNs is first reviewed. Then, the proposed method of the FE model updating technique is presented, including reference to previous relevant studies. The performance of the algorithm is then analysed as a function of the number of training data cases, and the acceleration signal duration. Finally, the trained 1D CNNs is tested to validate the proposed methodology.

2 OVERVIEW OF 1D CONVOLUTIONAL NEURAL NETWORKS (1D CNNS)

CNNs used in this study consist of two stages; the feature extractor stage and the fully connected layer stage [17] as illustrated in Figure 1.

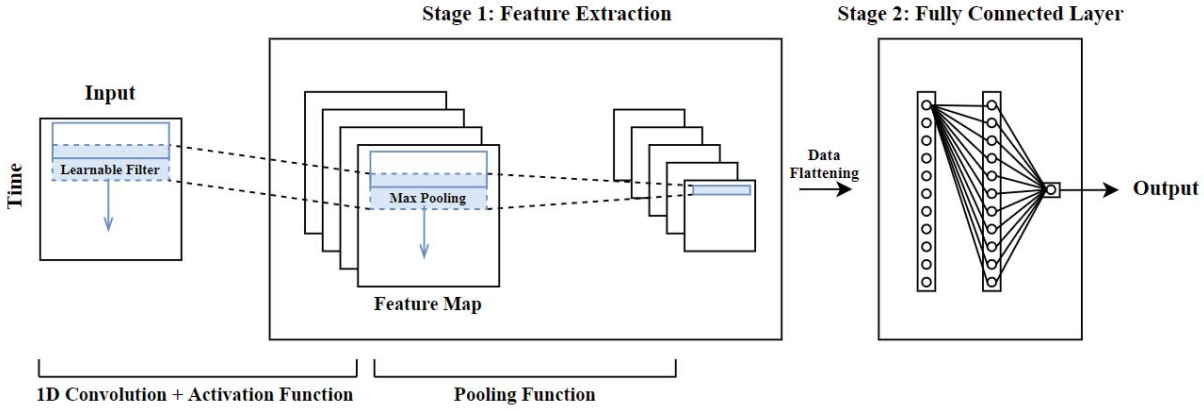

Figure 1: An architecture of 1D CNN includes feature extraction and regression stages.

Extracting features is achieved by stacking and alternating convolutional layers and pooling layers. Figure 1 shows only one convolutional layer and pooling layer for illustration purposes. In the convolutional layer, the input data are convolved by learnable filters and activation functions to generate feature maps. It is worth noting that the activation function is used to introduce nonlinearity to the algorithm, which in turn improves the algorithm learning from complex structural data. There are different types of activation functions such as Rectified Linear Unit (ReLU), sigmoid and linear activation function [18]. As a side effect of generating feature maps, the dimension of data is increasing as shown in Figure 1, where each learnable filter generates a feature map. To reduce the data dimension, pooling layers are used. The pooling layers use a pooling function to operate. The most common pooling function is "max pooling", which convolves over the feature map to select the maximum value of the covered portion. An added benefit of the max pooling function is that it performs a denoising role [19].

In the second stage of CNNs, fully connected layers perform regression based on the extracted features in the first stage. The fully connected layers are the traditional NNs. After the second stage, the prediction error is estimated by a loss function such as the Mean Square Error (MSE). To reduce the error, an optimization function (e.g. Adam as in [20]) is used to update the learnable parameters of the filters in the first stage. In the following section, the FE model updating approach using 1D CNNs is introduced besides related studies which include FE model updating applications using NNs in order to draw similarities for the proposed technique.

3 TRAINING AND VALIDATING THE 1D CNNS

FE model updating by using 1D CNNs, generally, consists of three steps: generating sufficient training data; preparing the training data to train the 1D CNNs; and training and validating the 1D CNNs performance.

Generating training data is a critical step for 1D CNNs' performance. The training data include pair vectors (hereafter called training pairs), where each consists of a vector of FE model parameters (i.e the 1D CNN output), and a vector of their corresponding structural responses (i.e. the 1D CNN input). The training pairs are aimed to cover a wide range of structural conditions. For example, the output vector of Sabamehr et al. [9] includes ± 50% variations of the stiffness of a Pre-Stressed Concrete Box (PSCB) girder bridge. In the case of a voided slab bridge, they assumed variations of ± 20%. In the Lu and Tu [21] study on a numerical model of a lumped-mass stick, which simulates a six-storey building frame, the inter-storey sway stiffness was assumed to range between 100% to 35% to represent undamaged and highly damaged frame members, respectively. After selecting the configuration of the parameter values for each

output vector, the input vectors can be numerically simulated to form the training pairs which would later be prepared for training the 1D CNNs.

Various techniques of preparing training pairs are typically used to improve the algorithm performance, such as data normalisation, data augmentation, padding, shuffling, and the mini-batch technique. Normalising training pairs allows to overcome the drawback of larger values dominating over smaller ones on the algorithm performance [22]. In the Avci et al. [23] study, the acceleration signals of the input vector were normalised in the intuitive range of (-1,1). Because their study was considering damage identification, the output vector was containing only two values, 0 and 1 for the damaged and undamaged cases, respectively. This (0,1) range was used also by Lu and Tu [21] for the output vector in their study of FE model updating using NNs.

Another technique is data augmentation which is often used to increase the number of training pairs when there is limited data [24]. For example, window slicing, which is a data augmentation technique, was introduced for time series in [25]. In this technique, the original time series data is sliced to several segments. Avci et al. [23] applied window slicing in civil engineering application. They sliced the available acceleration signals to several vectors. In this way, each training pair was divided into several training pairs. In the same manner, several acceleration signals, which form a matrix, can be divided into submatrices.

On an adverse note, the introduction of the submatrices leads to compromising the feature extraction process around the border of each submatrix. Namely, the data of the first and the last rows of these submatrices would be scanned only once by the learnable filters. To tackle this issue, the submatrices can be upsized by adding zeros around the borders (padding [26]). In this way, the first and the last rows are covered more than once by the learnable filters.

In addition to the aforementioned techniques, the shuffling of the training pairs is crucial to avoid any bias in the learning process of the algorithm. Finally, updating the learnable parameters after each mini-batch (i.e. portions of the training pairs), instead of one batch (i.e. all the training pairs), can improve the 1D CNN performance and reduce the computational cost. The algorithm requires several passes of all the mini-batches to improve, where each pass is called epoch [11, 27].

For the stage of training and validating the algorithm performance, part of the training pairs (hereafter called validating pairs) are not included in the training process. The validating pairs are utilized to validate the algorithm performance throughout the training process. The validating process is achieved by using a loss function (e.g. MSE). The algorithm can be considered as well-trained when it produces an acceptable error on training pairs as well as validating pairs. Once the algorithm is well-trained, it can be fed the measured structural response of the actual structure to estimate the FE model parameters. These values of the FE model parameters are not necessarily included in the training and validating pairs owing to the regression operation of the 1D CNNs.

Some parameters of 1D CNNs can by adjusted by the user to improve the algorithm performance; such can be the number of the convolutional and pooling layers, the size and number of the learnable filters, the type of activation functions, and the optimization function. The adjusting process of these parameters is called hyperparameter tuning [27]. The manual approach of hyperparameter tuning was adopted by many researchers in mechanical and civil engineering [14, 15, 24, 28]. In this approach, some “rules of thumb” or expert judgment is required. For example, using smaller size learnable filters in multiple convolutional layers would be better than larger size learnable filters in a single convolutional layer. Also, the number of the learnable filters in the first convolutional layers should be more than their number in the last convolutional layers. The ReLU activation function is recommended to be used in the convolutional

layers, while the linear activation function is suitable for regression output layer. Also, the MSE is suggested as a loss function for the regression task of the algorithm [27].

4 NUMERICAL EXAMPLE

A simple numerical example is used in this section for illustrating the implementation of 1D CNNs in FE model updating. The numerical example is a 3D FE model of an I-section cantilever beam which was simulated using shell elements in Abaqus [29]. The cantilever beam is made up of steel with density 7850kg/m^3, Young's modulus 210GPa, and Poisson's ratio 0.3. It has a cross section area cover of 100×100mm, with flange and web thickness of 8mm and 6mm, respectively. The cantilever length is selected as 2.5m so that any shear contributions in the output deflection can be minimised and analytical validation of the FE model can be performed by using standard Euler-Bernoulli beam theory [30], [31].

4.1 Validation of FE model

In this section, the static and dynamic behaviour of the model was validated before pursuing any FE model updating. First, the analytical value of the maximum deflection of the cantilever was calculated. For a static vertical point load of 2kN, applied at the cantilever free end, the corresponding analytical deflection compares with the numerical deflection as shown in Table 1. In a follow-up step, the natural frequencies of the first four modes were calculated analytically and were compared to their numerical counterpart, as shown in Table 2. Results show that both the static and dynamic behaviour of the FE model is in good agreement with the theoretical expectations. It should be noted that although the error in the 2nd bending mode is higher than the error in the other modes, it is not considered significant.

Table 1: Comparison of the numerical and analytical solution of the cantilever tip deflection.

	Numerical solution	Analytical solution	Error %
Vertical displacement	13.55mm	13.44mm	0.8

Table 2: Comparison of the numerical and analytical solution of the cantilever natural frequencies.

Natural frequency (Hz)		Mode type	Error %
Numerical solution	Analytical solution		
11.642	11.663	1st lateral	-0.2
19.265	19.393	1st bending	-0.7
36.441	-	1st torsional	-
72.433	73.096	2nd lateral	-0.9
115.63	121.540	2nd bending	-4.9

After validating the cantilever FE model, different states of the in-plane rotational boundary condition, considered equivalent to damage, were simulated and studied by using different values for the in-plane rotational spring stiffness. It is to be noted that the cantilever mechanism of carrying the main load is having a primarily bending behaviour [32]. The value of the rotational spring (10^{13} N.mm/rad) was selected as the case where the frequency of the 1st bending mode of the rotational spring-supported beam is matching the corresponding frequency of the fixed cantilever beam. For this task, the 1st bending mode is selected since the in-plane rotational spring stiffness is not expected to couple considerably with the lateral modes.

4.2 Generating training pairs and training the 1D CNNs

Specifying the training pairs means specifying both the output and input vectors. The output vectors consist of different values of rotational spring stiffness to simulate different states of the support. To illustrate, a 10% reduction on the initial stiffness value is considered accounting for a nominal 10% damage at the support. The input vectors consist of vertical acceleration responses at four equidistanced locations as shown in Figure 2. For the dynamic excitation of the cantilever beam, a vertical monoharmonic force of 100N amplitude and 10Hz frequency was applied at the free end of the cantilever from zero initial conditions; acceleration response signals were sampled at 200Hz. The four acceleration signals are forming a matrix with four columns, for each rotational spring case.

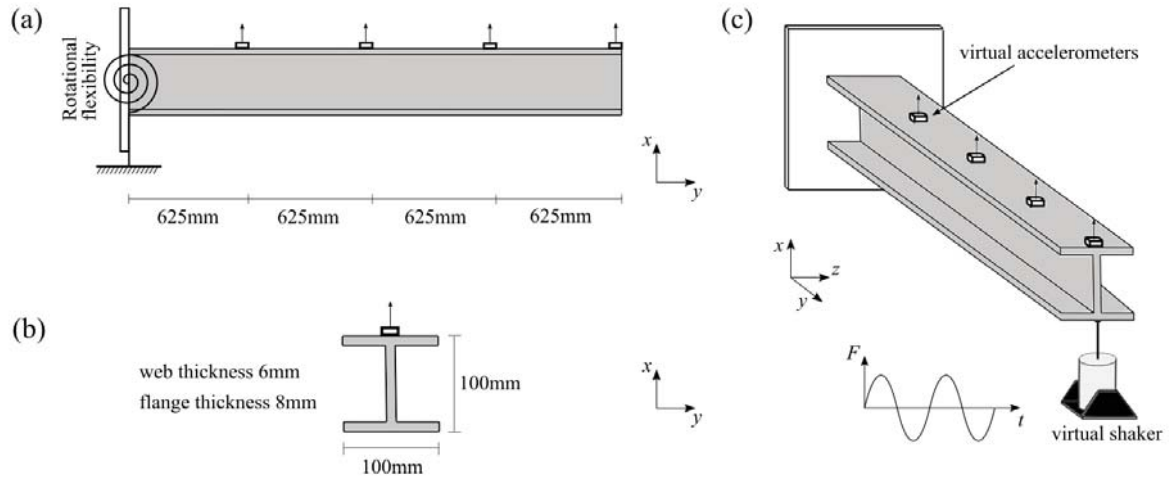

Figure 2: (a) Locations of acceleration response measurements on the spring-supported cantilever beam (not to scale), (b) beam's cross section, and (c) location of monoharmonic force.

Subsequently, the training pairs were prepared to improve the algorithm performance by data normalisation, data augmentation, and padding techniques. First, each input matrix of the training pairs was normalised in a range of (-1,1), while the output vector was normalised in a range of (0,1). Secondly, a data augmentation technique was adopted by dividing the matrices, after each 20 time steps, forming 1000 submatrices. Finally, the padding technique was applied to each submatrix. 10% of the prepared training pairs were used as validating pairs.

Thereafter, the 1D CNN was implemented using the Python library Keras [18]. The 1D CNN was developed in the cloud-based computing service provided by Google called Google Colaboratory (Colab) [33]. This cloud service provides a Graphics Processing Unit (GPU) which accelerates the training phase.

Table 3: Proposed 1D CNNs architecture

No. Layer	Layer type	Filter size	No. filter	Activation function
1	Input layer	-	-	-
2	Convolution	3	32	ReLU
3	Max pooling	2	32	-
4	Convolution	3	64	ReLU
5	Average pooling	2	64	-
6	Fully connected	-	32	ReLU
7	Fully connected	-	1	Linear

The error of the 1D CNNs was estimated by the MSE loss function, after feeding 64 submatrices (i.e. mini-batch size) a time. The MSE was reduced by the Adam optimisation method and the process was repeated for all mini-batches for 80 times (i.e. number of epochs). The algorithm architecture and parameters selected by trial and error are reported in Table 3.

Training the 1D CNN with more data would improve its performance. However, generating more data would increase the computational cost. To find a sufficient data size which yields a good performance of the algorithm, the influence of several data sizes on the algorithm's performance were evaluated. The several data sizes were realised by increasing (1) the number of training pairs, and (2) the acceleration signal duration. It is worth noting that the learnable parameters of the filters have random initial values for improving the algorithm performance. As a consequence, the MSE of a 1D CNN simulation is not a unique value [34]. Inspired by the work of Lee et al. [34], the average MSE of ten simulations was considered for evaluation purposes as shown in Table 4.

Table 4: Example of averaging MSE of ten simulations of a 1D CNN.

No.	MSE
1	0.0015
2	0.00303
3	0.00206
4	0.00358
5	0.00133
6	0.00221
7	0.00372
8	0.00099
9	0.00396
10	0.00123
Average	0.00236

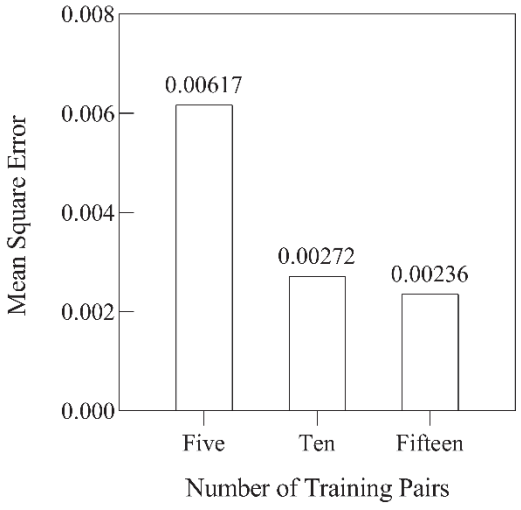

Figure 3: The influence of number of training pairs on the MSE.

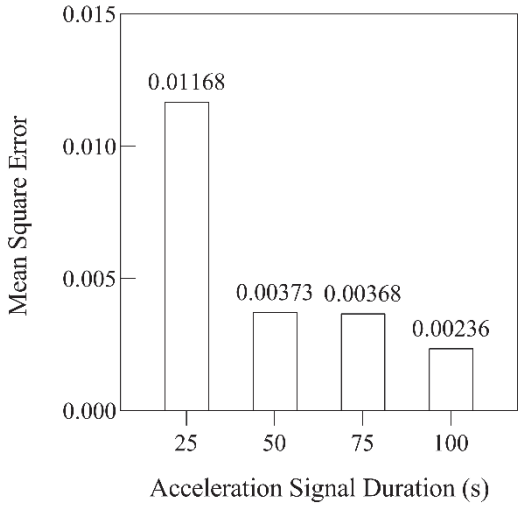

Figure 4: The influence of acceleration signal duration on the MSE.

To evaluate the influence of the number of training pairs, the 1D CNN was trained by (1) five, (2) ten, and (3) fifteen training pairs which were selected randomly within a range of rotational stiffness between 10^{13} and 10^{11} N.mm/rad (i.e. simulating undamaged and 99% damaged support respectively). In the three cases of training pairs, the maximum and minimum spring stiffness values were included. Also, the length of the acceleration response signals were 100s. Figure 3 shows that the averaged MSE in the first case is almost triple its value in the second and third cases. Also, the averaged MSE of the third case differs only marginally from the second case. Therefore, the third case is adopted, as having reached convergence, and used hereafter in this study.

The influence of the acceleration signal duration on the algorithm performance was evaluated by focusing on four different signal durations: 25s, 50s, 75s, and 100s. Figure 4 shows that longer signal duration improves the algorithm performance, as intuitively expected. It can be noticed that the difference of averaged MSE between the 25s and the 50s cases is larger than the difference between the 75s and the 100s cases. Therefore, the adopted acceleration signal duration in this study was selected as 100s.

4.3 Testing the CNN performance

After comparing the averaged MSEs for evaluation purposes, the trained 1D CNNs with the lowest MSE (0.00099) was selected for this section. Throughout the training and validating process, the MSE was calculated after each epoch as shown in Figure 5. The same figure shows good convergence between the MSE of both training and validating pairs, which means that the algorithm is categorized as a "well-trained" one.

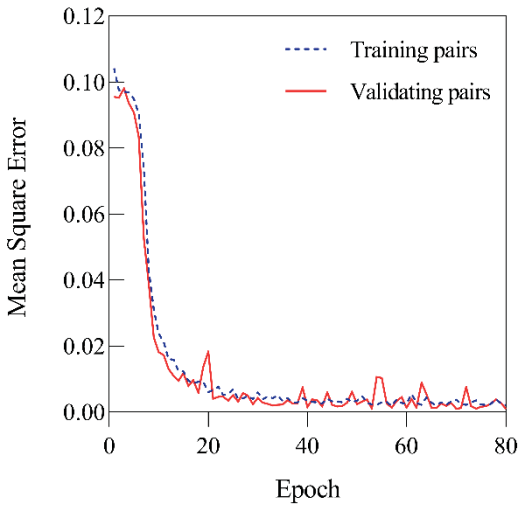

Figure 5: Training performance in term of MSE.

Then, four new cases of rotational spring stiffness (Table 5), which are within the range of stiffnesses that were used in the training pairs, were considered to test the efficiency of the 1D CNNs within an FE model updating approach. These four cases were used to generate four testing pairs. The selection of these testing pairs was done to study the effects of the availability of training pairs around each test pair. To illustrate, the number of training pairs around the first and the fourth testing pairs are more than the second and the third testing pairs.

Table 5: Rotational spring stiffness and corresponding damage for generating testing pairs.

No.	Spring stiffness (N.mm/rad)	Damage %
1	9×10^{12}	10
2	7×10^{12}	30
3	6×10^{12}	40
4	4×10^{12}	60

As mentioned earlier, the input matrix of each pair was divided into 1000 submatrices. In this way, the algorithm is producing 1000 estimations for each testing pair. Table 6 shows an example of some estimations of the algorithm in the case of the first testing pair (i.e. 9×10^{12} N.mm/rad). Subsequently, the estimations were averaged to represent the final selected spring stiffness. The remaining testing pairs were fed to the algorithm one at a time to have 1000 estimations at each time. Table 7 shows the averaged estimations of the four testing pairs compared with the actual spring stiffnesses. It is shown that the errors of the 1D CNN estimations are between -0.4% and 5.1%. From the results, it is clear that the more training pairs around and the testing pair (e.g. the second and the third cases), the higher accuracy can be achieved. The results show that the 1D CNN, in the presence of sufficient data, can not only evaluate the level of damage, but also estimate the value of associated FE model parameters.

Table 6: Example of the 1D CNNs estimations for 9×10^{12} N.mm/rad spring stiffness.

Spring stiffness (N.mm/rad)
9.052×10^{12}
8.25×10^{12}
9.038×10^{12}
..
8.036×10^{12}
9.057×10^{12}

Table 7: The accuracy of the 1D CNNs estimations for four cases of spring stiffness.

Spring stiffness (N.mm/rad)		Error %
Actual	Estimated	
9×10^{12}	8.92×10^{12}	-0.9%
7×10^{12}	7.36×10^{12}	5.1%
6×10^{12}	6.15×10^{12}	2.5%
4×10^{12}	3.98×10^{12}	-0.4%

5 CONCLUSIONS

In this paper, a 1D CNN was implemented for estimating FE model parameters. A numerical example of a 3D cantilever beam was used to validate the efficiency of the algorithm. The 1D CNN was trained to estimate a parametrically varying rotational base spring stiffness, which represented damaged states of the originally rigid support; for input acceleration data from a small number of points was used. The performance of the 1D CNN was evaluated as a function of the number of training pairs, and their actual length/size.

Results show that the benefit of increasing the training data size is significant for the algorithm performance. However, this benefit, generally, is decreasing with progressively increasing data sizes. For the application in hand, the sufficient training data size consists of fifteen training pairs and 100s duration of the acceleration signals.

The well-trained 1D CNNs, having a 0.00099 MSE, was used to estimate different rotational spring stiffness values, = not included within the training pairs. The results prove that the algorithm is capable of estimating the FE model parameter within an error band of -0.4% to 5.1%. The results also indicate that the 1D CNNs can be used in FE model updating with little modification of their more widespread equivalent damage detection version.

Keywords: Natural frequencies, Continuous Euler-Bernoulli model, Slenderness.

Abstract. *This paper presents a dynamic analysis of a single-storey frame composed by one beam and two columns in order to compare the modal analysis results of a full-continuous analytical formulation, based on the Euler-Bernoulli model, to different simplified discrete models. The four models analyzed, through* Maplesoft 2015.1, are: shear *frame model, concentrated mass model, and consistent mass model, which are discrete models, and a full-continuous analytical formulation based on the Euler-Bernoulli model. Historically, simple discrete models, such as the shear building model, have been used rather than continuous analytical formulations due to their simplicity and good accuracy in many practical situations. Nevertheless, geometric characteristics of current structures have changed and, consequently, their dynamic behaviour tends to depart from those ideal for many simplified discrete models. The results obtained illustrated the effect of the element's slenderness and the model type on the first natural frequency obtained with the four different models. The slenderness of 50 represented a benchmark for result analysis, with the concentrated and consistent mass models presenting frequencies similar to the Euler-Bernoulli model when the column slenderness was higher than 50 and the beam slenderness was lesser than 50. Also, the analysis of the first mode shape suggested that this property is not highly influenced by the model type.*

1 INTRODUCTION

Response analysis of structures subjected to dynamic loading, such as earthquakes, winds, waves, rotating machines, and vehicle traffic depends, first of all, on carrying out the modal analysis of the structure [1]. The modal analysis is performed considering only physical and geometric characteristics of the structure, from which it is possible to calculate natural frequencies and mode shapes. Natural frequencies of structure represent physically the number of cycles that each simple harmonic motion of its respective mode shape performs per second [2].

Before carrying out the modal analysis, it is necessary to discretize the structure in a reasonable amount of degrees of freedom for a preliminary assessment. From the results obtained, additional degrees of freedom may be necessary for more detailed investigations on the dynamic behaviour of the structure [3].

The precision and convergence of the results directly depend on how discretized the structure is, that is, they depend on the amount of degrees of freedom that the structural model has. However, there are many structures that can be represented only by its first natural frequencies and mode shape without impairing the accuracy of the results. In this way, the amount of degrees of freedom can be considerably reduced [2].

A full continuous model, including an infinite amount of degrees of freedom, should be used for the best possible accuracy [4]. But sometimes it is not common to use such analysis due to the high complexity equations that arise in this mathematical model [5].

Even when modelling a simple three-bar frame structure, the dynamic analysis turns into a time consuming and error prone algebraic exercise. But due to advances in computational software based on symbolic calculations, such problems can now be easily handled by computers. This turns to be very appropriate, since, in the last instance, the algebraic problem of the dynamic analysis of structures, as continuous systems, is translated in a single transcendental equation, which has only closed form solutions for very simple cases [6]. Usually, a numerical procedure, with the aid of graphical analysis, is then employed to solve this transcendental equation and, finally, the whole dynamic problem, providing the natural frequencies and mode shapes.

A couple of literatures and researches contributed to the development of natural frequencies of some types of structures. Blevins [7] presents tables and formulas for the determination of the natural frequencies and mode shapes, taking into account the effects of bending, shear, torsion and axial forces in beams modelled as continuous systems.

Clough and Penzien [8], Humar [9], and Craig and Kurdila [10] show examples of continuous system analysis of a cantilever beam coupled to a concentrated mass at its free end. Similarly, Clough and Penzien [8] present boundaries conditions, compatibility equations and equilibrium equations of a plane frame continuous model composed by one column and one beam. However, in these literatures, only the algebraic equations obtained from the boundary and equilibrium conditions are presented, without performing any further mathematical development.

Bomtempo [11] and Bomtempo and Pedroso [12] carried out studies regarding the dynamic behaviour of continuous and discrete models of an offshore structure. These models consisted of a cantilever beam coupled to the concentrated mass and mass moment of inertia in order to evaluate the effects of a deck in relation to a monoleg offshore platform.

Vu et al. [13] and Seibel and Copetti [14] developed dynamic analysis under free and forced vibrations of double-beam system. The two beams are connected through spring and damper taking into account different types of loadings and boundary conditions. From Euler-Bernoulli dynamic equation, the natural frequencies were calculated.

Morelato [15], Maiz et al. [16], Migoto [17] and Roncevic et al. [18] performed analytical solutions for natural frequencies and mode shapes of Euler-Bernoulli beams with non classical boundary conditions, for example, translational and rotational spring, inertial and attached mass, and damper.

Koplow et al. [19], Jaworski and Dowell [20], Lu et al. [21] , Giunta and Cicirello [22] and Yu et al. [23] presented closed form solutions for dynamic response for one and multiple stepped beams when there is change of material or cross section shape. The analytical solutions were compared with experimental and finite element numerical results for different boundary conditions.

Tsai [24] used the dynamic stiffness method with the intention to perform a dynamic analysis of a plane frame taking into account the effects of mass distribution in the beam elements. The Wittrick–Williams algorithm was used to identify the natural frequencies.

Failla [25] performed an exact vibration analysis of one and two storey plane frame considering generalised parameters of discrete multi-mass-multi-spring subsystems and elastic rotational joints.

To the best of knowledge of the authors, no work has presented a study about direct comparison between simplified discrete techniques and full continuous formulation based on Euler-Bernoulli theory.

In this sense, this work has the objective to compare the modal analysis results, natural frequencies and mode shapes, obtained from a set of simplified discrete models, such as shear frame, concentrated mass, and consistent mass, to those obtained from a full-continuous analytical model based on Euler Bernoulli theory. A one-storey plane frame is used in the study for the sake of brevity, but the formulations presented here can be easily extended to more complex frame structures. The influence of relevant design parameters, such as beam and columns slenderness, over the fundamental frequency of each analysis model is evaluated and discussed.

In all the results only the fundamental vibration mode was considered, since the shear frame model has only one degree of freedom.

2 MATHEMATICAL FORMULATIONS

In this chapter, mathematical formulations for the case of one-storey building for the four models studied in this work are presented, based on some literatures [6, 8]. The usual simplification of considering only flexure stiffness in the analysis of frame elements is employed. In the formulations, the sub-indexes h and v identify horizontal and vertical elements, respectively. The K, I, M, L, ρ, and ω symbols represent, respectively, the stiffness coefficient, moment of inertia, mass, length of each frame element, mass distributed per unit length and frequency.

2.1 Shear frame model

Figure 1 shows the shear frame model for one-storey building which represents the structure in a single degree of freedom with some unique characteristics.

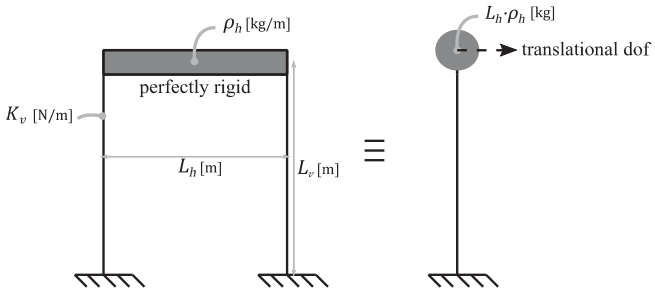

Figure 1: Shear frame model.

The horizontal elements are considered perfectly rigid, contributing only in terms of added mass. Due to its high stiffness, the horizontal element restrains any rotational degrees of freedom in the nodes to which it is connected, allowing only translational movements. The flexibility of the structure is produced just by the vertical elements, whose stiffness coefficients are the well-known flexural stiffness coefficients of bar elements obtained by using the Principle of Virtual Work [26].

The mass of vertical elements is disregarded as insignificant compared to the total mass of structure. This model tends to yield to better results when the horizontal elements have a high flexural stiffness when compared to the vertical elements, such as a slab-beam floor system supported by long columns.

The stiffness and mass matrix degenerate to scalar values, allowing the direct computation of the natural frequency as:

$$\begin{aligned} K &= 2\left(\frac{12EI_v}{L_v^3}\right) \\ M &= \rho_h L_h \\ \omega &= \sqrt{\frac{K}{M}} = \sqrt{\frac{24EI_v}{\rho_h L_h L_v^3}} \end{aligned} \tag{1}$$

2.2 Concentrated mass model

The concentrated, or lumped, mass model extends the shear frame model in two aspects: (i) it considers the flexibility of horizontal element; and (ii) considers the mass of vertical elements. In the case of one-storey frame, two extra degrees of freedom are added to the discrete model which corresponds to the rotation of the nodes.

The masses are still considered concentrated at the nodes of frame, being the mass of vertical and horizontal elements lumped all together in the nodes. The distribution of masses of an element into its nodes is proportional to the relative distance between two consecutive nodes. This model, however, does not include the rotational inertia originated by the lumped masses in the nodes, disregarding its magnitude when compared to the translational inertia.

The concentrated mass model for one-storey frame is illustrated in Figure 2, with all the relevant parameters indicated. Structures with horizontal and vertical elements of similar stiffness tend to be well represented by this model.

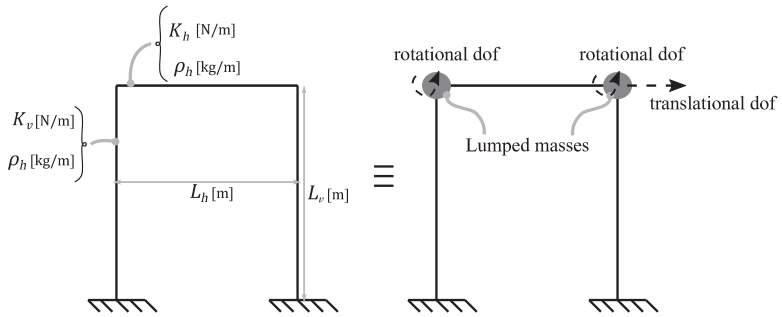

Figure 2: Concentrated mass model.

As shown above, the one-storey frame model is represented by three degrees of freedom: one related to the translational movement in the horizontal direction, and two rotations related to each of the free nodes of the structure. The stiffness and mass matrixes are, therefore, of 3x3 dimension, and are written as:

$$\mathbf{M} = \begin{bmatrix} \rho_v \cdot L_v + \rho_h \cdot L_h & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \tag{2}$$

$$\mathbf{K} = \begin{bmatrix} \frac{24 \cdot E \cdot I_v}{L_v^3} & \frac{6 \cdot E \cdot I_v}{L_v^2} & \frac{6 \cdot E \cdot I_v}{L_v^2} \\ \frac{6 \cdot E \cdot I_v}{L_v^2} & \frac{4 \cdot E \cdot I_v}{L_v} + \frac{4 \cdot E \cdot I_h}{L_h} & \frac{2 \cdot E \cdot I_h}{L_h} \\ \frac{6 \cdot E \cdot I_v}{L_v^2} & \frac{2 \cdot E \cdot I_h}{L_h} & \frac{4 \cdot E \cdot I_v}{L_v} + \frac{4 \cdot E \cdot I_h}{L_h} \end{bmatrix} \tag{3}$$

The determination of natural frequencies requires the solution of the dynamic equilibrium equation, which ultimately leads, for the case of undamped free vibration, to the following equation:

$$\det\left[-\omega^2 \cdot \mathbf{M} + \mathbf{K}\right] = 0 \tag{4}$$

By solving the previous equation, three roots for the natural frequencies ω, given in rad/s, can be found. They are related to the three vibration modes allowed by the three degrees of freedom present in the discrete model.

2.3 Consistent mass model

The consistent mass model further develops the concentrated mass model by considering the mass as a distributed parameter in the structure, not only as mere lumped masses in the nodes. This can be achieved by using the Principle of Virtual Work. This model is fitted for structures in which the mass is an important factor in the dynamic behaviour and may not be correctly represented by the concentrated mass model. Figure 3 illustrates the consistent mass model, for the case in which each element has a homogeneously distributed mass represented by its mass distributed per unit length ρ.

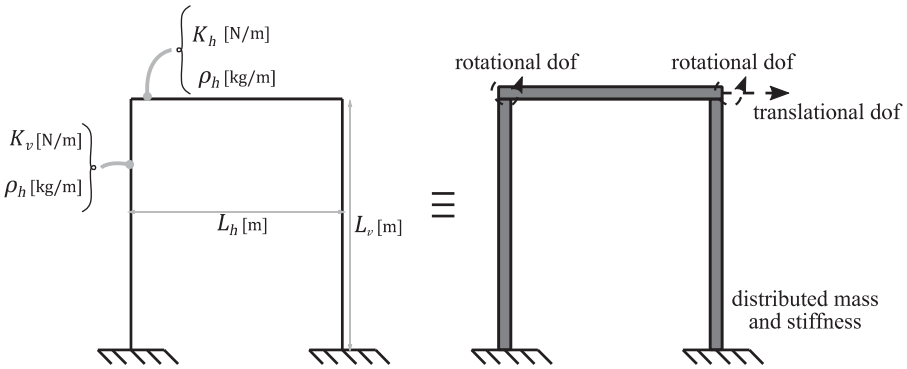

Figure 3: Consistent mass model.

Since the only change in relation to the concentrated mass model is the consideration of distributed mass along the elements, no changes in the stiffness matrix presented on Equation 3 is introduced. By considering mass as distributed along the elements, effects of rotational inertia are added in the model and the mass matrix becomes dense, which becomes:

$$\mathbf{M} = \begin{bmatrix} \frac{26}{35}\rho_v \cdot L_v + \rho_h \cdot L_h & \frac{11}{210}\rho_v \cdot L_v^{\,2} & \frac{11}{210}\rho_v \cdot L_v^{\,2} \\ \frac{11}{210}\rho_v \cdot L_v^{\,2} & \frac{\rho_v \cdot L_v^{\,3}}{105} + \frac{\rho_h \cdot L_h^{\,3}}{105} & -\frac{\rho_h \cdot L_h^{\,3}}{140} \\ \frac{11}{210}\rho_v \cdot L_v^{\,2} & -\frac{\rho_h \cdot L_h^{\,3}}{140} & \frac{\rho_v \cdot L_v^{\,3}}{105} + \frac{\rho_h \cdot L_h^{\,3}}{105} \end{bmatrix} \tag{5}$$

The solution of natural frequencies by this model is of the same type given in Equation 4, and the three roots found correspond to the natural frequencies associated to each mode shape allowed by the degrees of freedom.

The consistent mass model can usually be employed in finite element schemes, and has the following advantages: greater precision and faster convergence with increasing number discretized elements; potential energy and kinetic energy are evaluated in a consistent manner and, because of this, it is possible to determine how the computed values of natural frequencies relate to the exact values [2].

The accuracy of the results obtained through the consistent mass matrix is only slightly better than the results of the concentrated mass matrix, since the inertial forces associated with the rotation of the nodes are not generally significant in many problems of structural engineering. Because of this, the concentrated mass matrix is still widely used [2].On the other hand, Rao [26] questions that it is not obvious which of the two methods presents more accurate results for the response of the structure, since one method can present more satisfactory results than the other depending on the dynamic problem and the discretization of elements.

2.4 Full-continuous Euler-Bernoulli model

A full-continuous model for the dynamic equilibrium of a one-storey frame under free vibration can be constructed by applying the following partial differential equation (PDE) to each element *i*, properly considering the continuity of the frame in the boundary conditions:

$$EI_i \cdot \frac{\partial^4 u_i(x_i,t)}{\partial x_i^{\,4}} + \rho_i \cdot \frac{\partial^2 u_i(x_i,t)}{\partial t^2} = 0 \tag{6}$$

Considering this is a PDE involving two variables, *x* and *t*, a way to solve the problem is using the Separation of Variables for each element *i*, which is given by:

$$u_i(x_i,t) = X_i(x_i)T(t) \tag{7}$$

Substituting Equation 7 into Equation 8, and isolating each variable in a equation side, one arrives at the equation below, which holds only if each side is equal to the same constant denoted by β_i^4:

$$\frac{X_i^{(iv)}}{x_i} = -\frac{\rho_i}{EI_i}\frac{\ddot{T}}{t} = \beta_i^4 \tag{8}$$

This allows to separate the PDE into two ordinary differential equations (ODE) as shown:

$$\begin{cases} X_i^{(iv)}(x_i) - \beta_i^4 X_i(x_i) = 0 \\ \ddot{T}(t) + \dfrac{E_i I_i}{\rho_i}\beta_i^4 T(t) = 0 \end{cases} \tag{9}$$

The solution of these two ODE is given by:

$$\begin{aligned} T(t) &= \bar{A}\cos(\omega t) + \bar{B}\sin(\omega t) \\ X_i(x_i) &= A_i\cos(\beta_i x_i) + B_i\sin(\beta_i x_i) + C_i\cosh(\beta_i x_i) + D_i\sinh(\beta_i x_i) \end{aligned} \tag{10}$$

By inspection of the first equations from both Equation 9 and 10, it can be obtained the relation between the frequency ω and the parameter β_i defined for each element, as given by :

$$\omega = \beta_i^2\sqrt{\frac{EI_i}{\rho_i}} \tag{11}$$

The boundary equations and compatibility equation for each element are indicated in Figure 4, which also presents the local coordinate system for each element and their identification, as considered in the computations performed in this work.

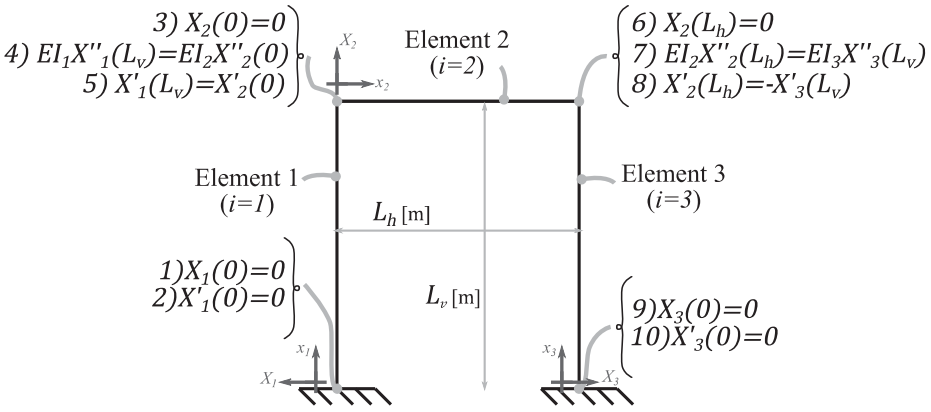

Figure 4: Euler-Bernoulli model boundary conditions.

In the Figure 4, the boundary conditions are presented by the first, second, third, sixth, ninth and tenth equation. The fourth and seventh equation are the compatibility equations for bending moments at nodes and the fifth and eighth equation are the compatibility equations for rotation at nodes.

By applying these boundary conditions to the second equation of Equation 10, considering the appropriate elements, one obtains a set of 10 equations given by:

$$\begin{gathered}
A_1 + C_1 = 0 \\
B_1 + D_1 = 0 \\
A_2 + C_2 = 0 \\
I_v\beta_1^2(-A_1\cos\beta_1 L_v - B_1\sin\beta_1 L_v + C_1\cosh\beta_1 L_v + D_1\sinh\beta_1 L_v) + I_h\beta_2^2(A_2 - C_2) = 0 \\
\beta_1(-A_1\sin\beta_1 L_v + B_1\cos\beta_1 L_v + C_1\sinh\beta_1 L_v + D_1\cosh\beta_1 L_v) - \beta_2(B_2 + D_2) = 0 \\
A_2\cos\beta_2 L_h + B_2\sin\beta_2 L_h + C_2\cosh\beta_2 L_h + D_2\sinh\beta_2 L_h = 0 \\
I_h\beta_2^2(-A_2\cos\beta_2 L_h - B_2\sin\beta_2 L_h + C_2\cosh\beta_2 L_h + D_2\sinh\beta_2 L_h) + I_v\beta_3^2(A_3\cos\beta_3 L_v + B_3\sin\beta_3 L_v - C_3\cosh\beta_3 L_v - D_3\sinh\beta_3 L_v) = 0 \\
\beta_2(-A_2\sin\beta_2 L_h + B_2\cos\beta_2 L_h + C_2\sinh\beta_2 L_h + D_2\cosh\beta_2 L_h) + \beta_3(-A_3\sin\beta_3 L_v + B_3\cos\beta_3 L_v + C_3\sinh\beta_3 L_v + D_3\cosh\beta_3 L_v) = 0 \\
A_3 + C_3 = 0 \\
B_3 + D_3 = 0
\end{gathered} \tag{12}$$

Also, it can be defined two dynamic equilibrium equations, which model the continuity of the frame and the interaction between each connected element, being given by:

$$\begin{aligned}
EI_v X_1^{(iii)}(L_v) &= -\frac{\rho_h}{2}\cdot L_h\cdot\omega^2\cdot X_1(L_v) \\
EI_v X_3^{(iii)}(L_v) &= -\frac{\rho_h}{2}\cdot L_h\cdot\omega^2\cdot X_3(L_v)
\end{aligned} \tag{13}$$

By substituting the second equation of Equation 10, these last two expressions become:

$$\begin{gathered}
EI_v\beta_1^3(A_1\sin\beta_1 L_v - B_1\cos\beta_1 L_v + C_1\sinh\beta_1 L_v + D_1\cosh\beta_1 L_v) + \frac{\rho_h L_h}{2}\omega^2(A_1\cos\beta_1 L_v - B_1\sin\beta_1 L_v + C_1\cos\beta_1 L_v + D_1\cos\beta_1 L_v) = 0 \\
EI_v\beta_3^3(A_3\sin\beta_3 L_v - B_3\cos\beta_3 L_v + C_3\sinh\beta_3 L_v + D_3\cosh\beta_3 L_v) + \frac{\rho_h L_h}{2}\omega^2(A_3\cos\beta_3 L_v - B_3\sin\beta_3 L_v + C_3\cos\beta_3 L_v + D_3\cos\beta_3 L_v) = 0
\end{gathered} \tag{14}$$

Substituting the Equation 11 in the set of equation given by Equations 12 and 14, one ends up with 12 equations involving 13 variables to be determinate: four variables A_i, B_i, C_i and D_i, for each of the three elements, and the ω variable. Since this system of equations is homogeneous, the determinant of the coefficient matrix must be equal to zero in order to the system to have a non-trivial solution.

From this condition, one draws the characteristic polynomial and the transcendental equation, which is solved numerically. The roots found are the values related to the natural frequencies ω of the system. From these values, the parameter β_i can be calculated through Equation 11, for each element and natural frequency. Setting A_1=1, the other 11 constants are calculated and then the mode shape functions for beam and columns are obtained.

3 RESULTS AND DISCUSSIONS

A routine in the software Maplesoft 2015.1 was developed to obtain the fundamental frequencies and mode shapes of a one-storey frame under undamped free vibration modelled by shear frame, concentrated mass, consistent mass, and continuous Euler-Bernoulli models. The influence of the element slenderness on the results of each model was analysed, by varying separately the columns and beam slenderness by changing its length. The slenderness of an element is defined as:

$$\lambda = \frac{L}{\sqrt{\frac{I}{A}}} = \frac{L}{\sqrt{\frac{b\cdot h^3}{12\cdot(b\cdot h)}}} = \frac{L}{h}\cdot\sqrt{12} \tag{15}$$

In which L is the element length, I is the element's cross-section moment of inertia in the axis under flexure, and A is the element's cross-section area. For rectangular cross-sections,

such as those considered in this work, the above properties may be further simplified in terms of the cross-section height, *h*, and base, *b*, defined accordingly to the axis of flexure being considered.

In the analysis presented in this work, the other parameters of the structure are: elastic modulus = 30 [GPa]; mass distributed per unit length of beam = 250 [kg/m]; mass distributed per unit length of columns = 100 [kg/m]; columns with square cross-section of width 0.2 [m]; beam with rectangular cross-section of 0.5 [m] height per 0.2 [m] width. When not subjected to variation to produce different slenderness, the length of the beam and columns are, respectively, 5.0 [m] and 3.0 [m].

Furthermore, since the shear frame model provides a single vibration mode, because it has one degree of freedom, only the first mode will be considered in the modal analysis.

3.1 Fundamental frequency

In Figure 5, it is evaluated the first natural frequency results due to the variation of column slenderness. It can be noticed that the shear frame model best approximated the Euler-Bernoulli model as the column slenderness increased. The concentrated and the consistent mass models present remarkably similar results, with negligible small differences in relation to the Euler-Bernoulli model for slendernesses higher than 50. Overall, the simplified models present a stiffer behaviour, since in all slenderness tested they produced higher natural frequencies.

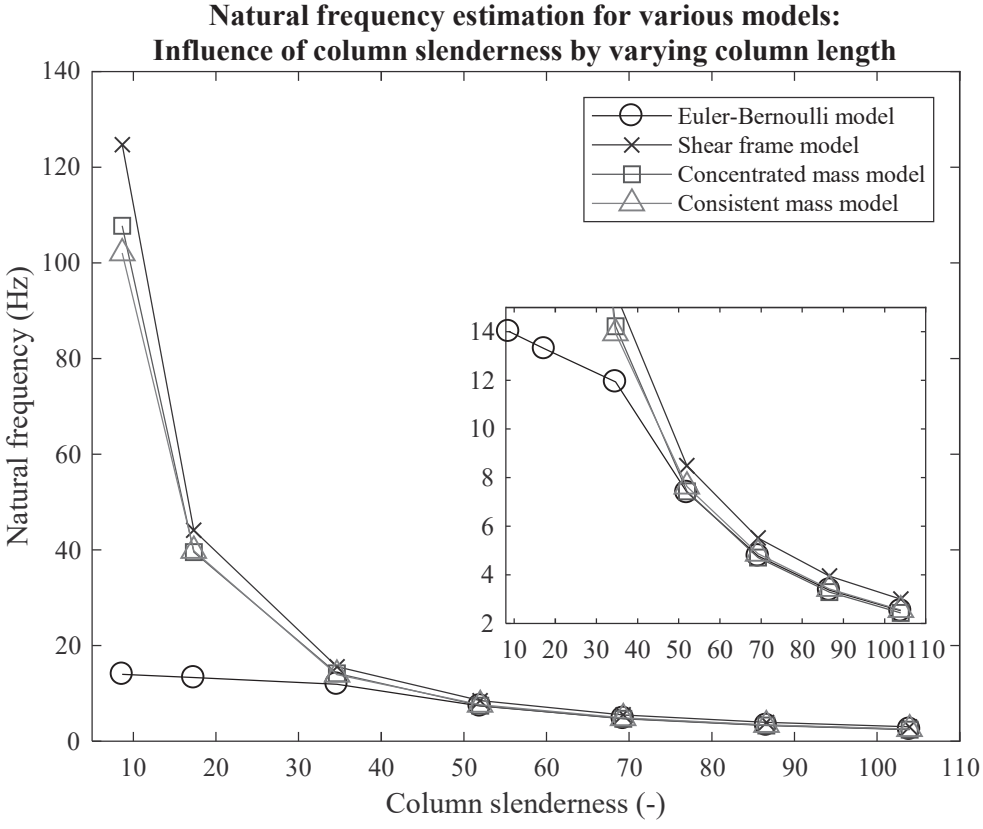

Figure 5: Influence of column slenderness on the first natural frequency, by varying column length

The Euler-Bernoulli model results diverge significantly from the other models for slendernesses lower than 50, indicating that this model still retains most of its flexible behaviour, in comparison to the other models, even when the one-storey frame has very bulk columns. It is

relevant to observe that for bulk elements the Euler-Bernoulli itself may be an inappropriate model since it disregards any flexibility related to the shear stiffness, which results in a much more stiffer model when compared to more realistic models, such as those drawn from Timoshenko Beam theory. For instance, the rule-of-thumb of L/h=10 is usually employed to define a minimum aspect ratio that defines elements slender enough to be modeled with Euler-Bernoulli theory. In the context of the prismatic cross-sections used in this work, this rule-of-thumb corresponds to a slenderness of 34.64. In this way, the observation that for small column slenderness the Euler-Bernoulli model still provided the lowest natural frequencies, i.e. resulted in the most flexible model, while it is clearly already outside the scope of its proper use, is an indicative that the simplified models shall not be used if the columns are considerably bulk.

In Figure 6, it is evaluated the first natural frequency response due to the variation of beam slenderness. Generally speaking, the variation on beam slenderness affects the models' results in a opposite trend when compared to variation of columns' slenderness. In contrast to the previous result, now the shear frame model has better approximation to the Euler-Bernoulli model with the decrease of the element. The concentrated and the consistent mass model continue presenting remarkably similar results, but now better approximated Euler-Bernoulli model when the slenderness was small, with negligible differences for slendernesses lower than 50. Furthermore, from a slenderness equal or higher than 50, the Euler-Bernoulli model diverged significantly from the other models, presenting lower frequency values and thus a more flexible behaviour. Overall, as in the previous analysis, the simplified models still present a stiffer behaviour, since, for all slenderness tested, they continued to produce higher natural frequencies.

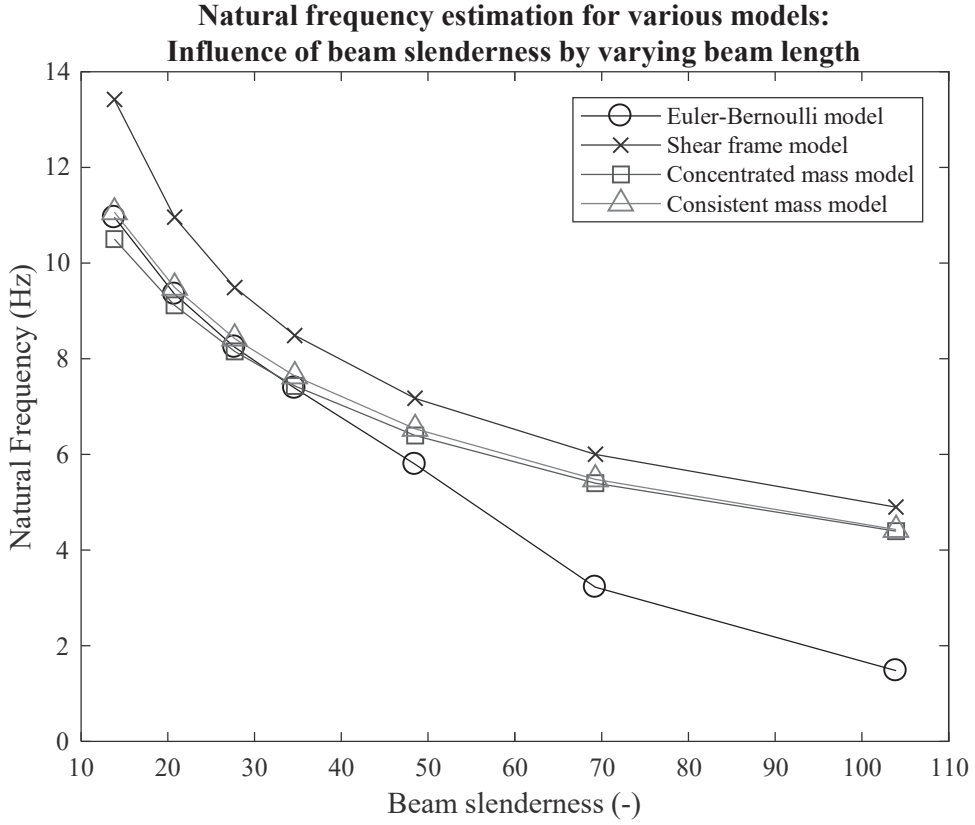

Figure 6: Influence of beam slenderness on the first natural frequency, by varying beam length.

The difference between the effects of beam slenderness and column slenderness on the natural frequencies may reside in the fact that, due to the differences in the adopted cross-section dimensions, to produce the same slenderness the beam length needed to be considerably larger than the column length. This may have led to a problem of poor discretization of elements, which showed in the beam slenderness analysis among the high slendernesses results. The simplified discrete models used in this work modeled each element as a single discrete element, which was probably insufficient to model the long beams produced on the beam slenderness analysis. The Euler model, however, properly retained its flexibility due to its continuous formulation.

For instance, considering the column and beam cross-section dimensions adopted, while a column length equal to 5.77 m leads to a column slenderness equal to 100, a beam length equal to 14.43 m is required to produce this same beam slenderness. Furthermore, while the column slenderness, which was the highest value analysed, was associated to a column length of 6.35 m, a beam slenderness equal to 45 was already associated to a longer beam length, of 6.50 m.

These examples illustrate that the divergence observed in the beam slenderness analysis for higher slenderness are related to the artificial stiffness of simplified discrete models with insufficient discretization. This problem with discrete models is, therefore, related to the discretization capability of the method used, and may be avoided if extended discrete methods, such as finite element or differences methods are employed.

Lastly, from Figures 5 and 6 it can be noticed that there is a slenderness range in both beam and column elements in with the discrete models can produce results close to the continuous model. In contrast, in some extreme cases, the models have no correlation and yield relevant discrepancy in natural frequency results.

3.2 Fundamental mode shape

In order to compare the mode shapes obtained with the different models, it was analysed a standard model with the properties described in the beginning of this section. Again, it is highlighted that only the first mode is considered, since the shear frame model only contains a single degree-of-freedom, which leads to a single mode.

Before discussing the following results, it is important to delve into the process undertook in this work of obtaining the mode shape with the continuous Euler-Bernoulli model by using a symbolic mathematics software such as Maplesoft 2015.1. As previously explained, when assembled the Euler-Bernoulli model leads to a system of trigonometric equations containing 12 equations and 13 variables, whose solution is obtained by invoking the requirement of a non-trivial solution which leads to the determinant of the coefficient's matrix, i.e. the transcendental equation of the system, being equal to zero. The process of computing the determinant of such matrix, even if performed with a symbolic mathematics software, is computed with a numerical method and, therefore, is susceptible to numerical errors and instabilities.

Considering this, Figure 7 presents the results obtained when computing and plotting the coefficient's matrix transcendental equation in terms of the natural frequency ω, which is the 13^{th} variable of the system. From this figure, it is possible to observe that the obtained transcendental equation presents two remarkably close roots, at around 45 rad/s and 48 rad/s. Such closely spaced modes are not expected in frame structures such as the one being considered, and the relatively small local minima between these two roots suggested that one of these modes might be a spurious mode originated by numerical errors.

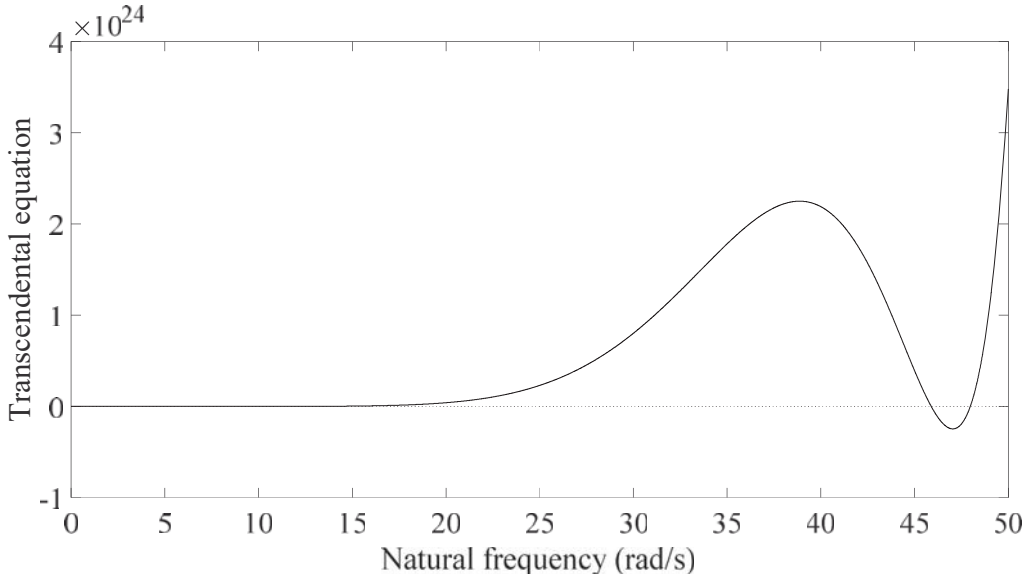

Figure 7: Transcendental equation plot.

In order to assess this possibility, the mode shapes associated to both roots were computed and compared. The results are presented in Figure 8, and the mode shapes were normalized in relation to the displacement at the top of the vertical columns.

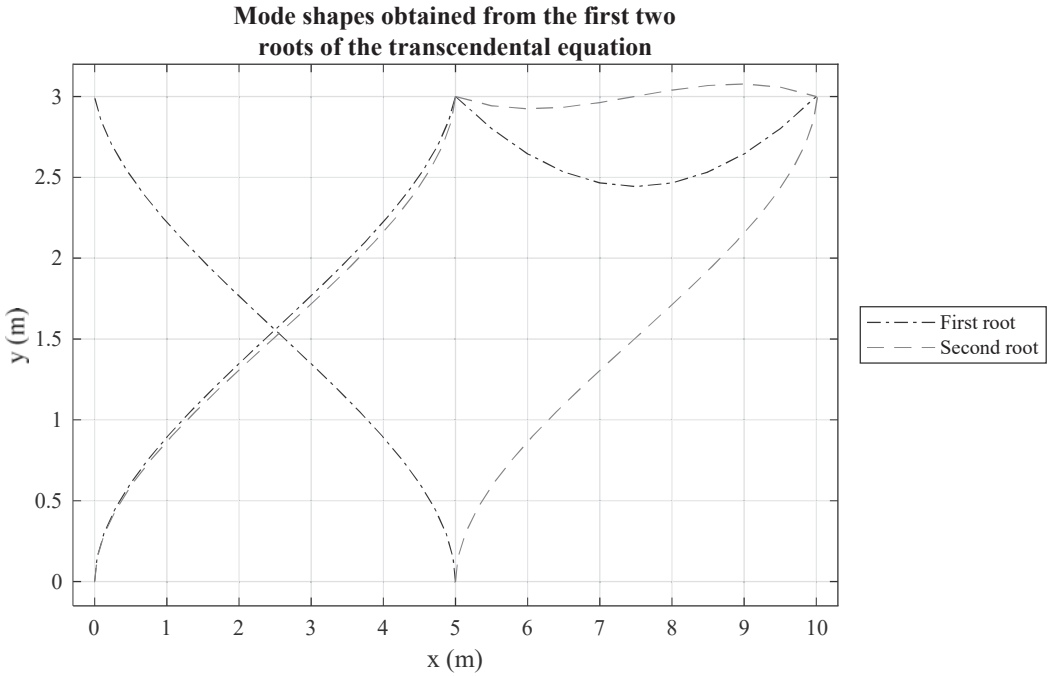

Figure 7: Comparison of the first and second roots of the transcendental equation.

As expected, one of the modes, i.e. the one associated to the first root, presented a non-real mode shape, with the columns displacing in opposite global directions. Such shape is not real, since the horizontal element is not supposed to undergo normal deformations, e.g. extension or reduction, with the structural model being considered. In this way, only modes with the columns displacing in the same global direction are related to real modes.

In this way, the Figure 8 presents the mode shapes obtained with the different models. For the concentrated and consistent models, a third-degree polynomial was assumed to interpolate the displacements between the nodes.

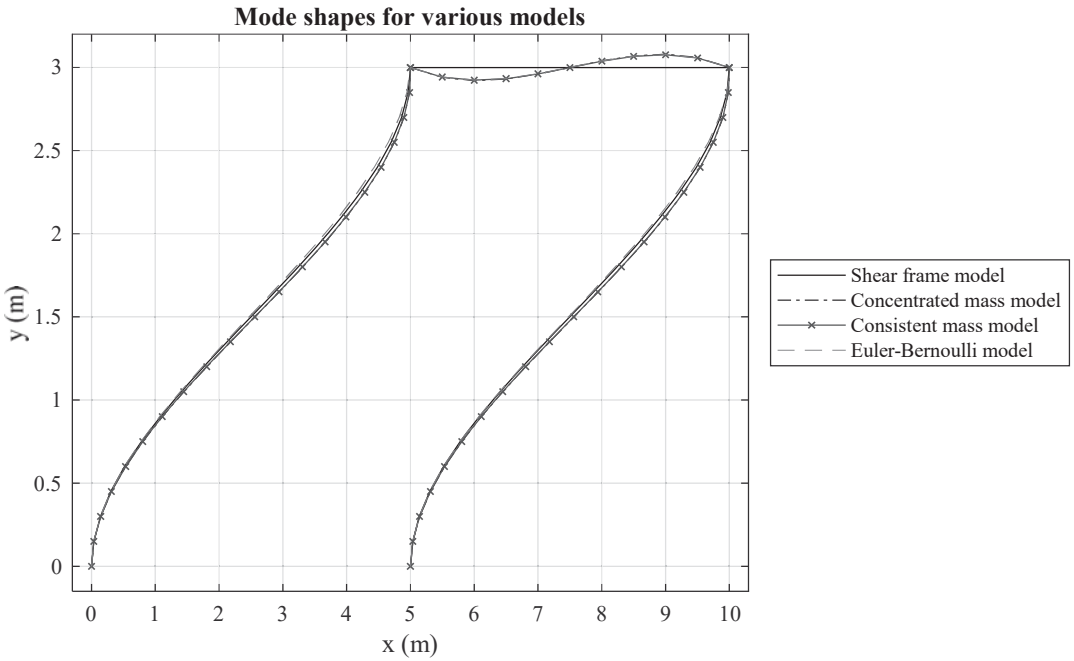

Figure 8: Comparison of mode shapes obtained with the various models.

Apart from the shear frame model, which does not possess flexibility on the horizontal element, all the models present remarkably good coherence between each other. This suggests that the mode shape, at least for the first mode, is not greatly affected by using more complex models, such as the full-continuous Euler-Bernoulli model.

4 CONCLUSIONS

This work presented a comparison of fundamental frequency and mode shape of three simplified models (shear frame, concentrated mass, and consistent mass) in relation to continuous Euler-Bernoulli model for a one-storey framed structure under free vibration. The main conclusions are:

- Both the concentrated and consistent mass models presented remarkably similar results, with accurate results when compared with the continuous model, while shear building model presented the worst results;
- The slenderness of 50 represented a benchmark for evaluating the results from the different models. Concentrated and consistent mass models presented frequencies similar to those obtained from the Euler-Bernoulli model when the column slenderness was higher than 50 and the beam slenderness was lesser than 50;
- The comparison of mode shapes suggested that this property is not highly influenced by the model type.

Keywords: Newmark integration scheme, proper generalized decomposition, proper orthogonal decomposition, modal analysis, transient excitation

Abstract. *In this contribution, we present the space-time formulations of a nonlinear quasistatic and a linear dissipative dynamic system using the proper generalized decomposition approach. Regarding the quasistatic problem, the equation of equilibrium is transformed into the space-time formulation. Regarding the linear dynamic problem, the set of equations of motion are transformed into one space-time equation, using a space-time formulation of the Newmark integration ansatz. In both cases, the space-time formulation is projected in two coupled space and time equations, which are solved by the fixed point algorithm. The results are compared to the conventional step-by-step algorithm regarding accuracy and efficiency. Solving the problem iteratively in terms of response enrichments, temporal and spatial proper generalized decomposition modes are identified and analyzed during convergence. It is shown that the set of spatial proper generalized decomposition modes of both the quasistatic and the dynamic problem are highly correlated as they can both be replaced by an uncorrelated significantly smaller orthonormal basis representation. In the quasistatic case, it is shown that the response after the first enrichment is purely elastic, while after the second enrichment plastic behavior can be detected. However, plasticity cannot be detected locally by investigation of the proper generalized decomposition modes, but by the uncorrelated orthonormal basis functions using the proper orthogonal decomposition. In the dynamic case, more than only one enrichment is required to evaluate the linear response history as the solution can be decomposed into a set of motion patterns. Nevertheless, the evaluated correlated spatial proper generalized decomposition modes differ significantly from the linear modes of vibration.*

1 Introduction

High-dimensional and finely meshed models are ubiquitous in finite element applications and structural dynamics. They generally demand significant computational efforts, especially, if nonlinearities are involved. However, the latter are inevitable in order to obtain realistic structural response predictions. This, in turn, is essential for reliable decisions about the design of structures and infrastructures and, therefore, has a significant impact on industry and society.

Various computational strategies have been developed in structural dynamics in order to deal with the issue of high-dimensionality.

As a statistical pattern technique the proper orthogonal decomposition can be used to find the dominant motion patterns for the low-order description of nonlinear systems [1]. Here, the transformation into low-order subspaces depends on the set of proper orthogonal modes obtained from structural response pattern [2]. In particular, the applicability of the proper orthogonal decomposition to transient excitations depends mainly on the choice of the observation time period used for the calculations of the proper orthogonal modes [3]. If nonlinearities are not captured in those deformation patterns, they cannot be displayed in the low-order model. However, if the nonlinear response behavior is captured, a surprisingly small number of proper orthogonal modes is sufficient to accurately describe the dynamic response behavior [4, 5].

Another approach is to divide the structure into various substructures. The main goal is to provide low-order representations of the inside areas of the substructures while keeping the number of degrees of freedom of the boundaries unaltered. The Craig-Bampton method [6] and the dual Craig-Bampton method [7] provide powerful techniques in this regard. Although these two strategies are mainly applicable to linear systems, a hierarchical formulation of the Craig-Bampton method has been presented on vibro-impact problems with linear contact formulations [8, 9] and highly nonlinear contact laws [10]. Recently, also a combination of the proper orthogonal decomposition and substructure techniques has been proposed [11].

The proper generalized decomposition (PGD), however, provides a strategy that is neither restricted by the level or type of nonlinearity nor a-priori system identifications are required. This method has firstly been introduced by Ladevéze [12] and has then been applied in many fields such as chemistry [13], thermo-mechanics [14], fluid dynamics [15, 16], geophysics [17] and solid mechanics [18, 19]. Especially, in structural mechanics, first approaches have been proposed to use the proper generalized decomposition ansatz to solve elastoplastic and viscoplastic structures subjected to quasistatic loading [20, 21]. Shirafkan et al. physically interpreted the evolution of spacial and temporal functions, which they refer to as proper generalized decomposition modes, and analyzed these modes during convergence [22]. Furthermore, the Multi-field PGD has been applied to resolve the undamped elastodynamic model and the solution was interpreted by Time Discontinuous Galerkin and Multi-field time-continuous methods [23].

In this contribution, we will develop a new family of efficient and stable algorithms to evaluate the response of linear and nonlinear structures. In particular, we will propose space-time formulations, where we will avoid the step-by-step strategies of conventional time integration schemes and will show that the response is built iteratively in the whole time domain until convergence is achieved. In Section 2, we will develop the strategy in an elastoplastic quasistatic framework. Hereby, the conventional equations of equilibrium will be extended. In Section 3, we will extend this new obtained formulation to dissipative systems in structural dynamics introducing a space-time formulation of the Newmark method. The numerical results of both the quasistatic and dynamic approach will be presented in Section 4. Finally, in Section 5, the conclusion will be given.

2 Formulation of the space-time solution for a quasistatic nonlinear problem

In static equilibrium the terms of inertia are neglected and the external force $\mathbf{F}(t)$ on the system is equal to the resulting internal force $\mathbf{F}_{\text{int}}$:

$$\mathbf{F}(t) - \mathbf{F}_{\text{int}}(\mathbf{u}) = \mathbf{0} \ . \tag{1}$$

Here, $\mathbf{u}$ denotes the unknown structural displacement. The equation is rewritten in the incremental form [24] as

$$\mathbf{K}(\mathbf{u})\Delta\mathbf{u} = \underbrace{\mathbf{F} - \mathbf{F}_{\text{int}}(\mathbf{u})}_{\mathbf{R}(\mathbf{u})} \ , \tag{2}$$

where $\mathbf{R}(\mathbf{u})$ denotes the residual, $\mathbf{K}(\mathbf{u})$ is the tangential stiffness matrix dependent on displacement and $\Delta\mathbf{u}$ is the displacement increment. After discretization of the time domain into in this contribution refered to as temporal nodes t_i $(i = 0, \dots, n_t)$, Equation (2) can be solved incrementally, where static equilibrium is found in a step-by-step manner, as shown in Figure 1a. In each time step an iterative solver, as e.g. the Newton-Raphson algorithm [24], presented in Figure 1b, must be applied.

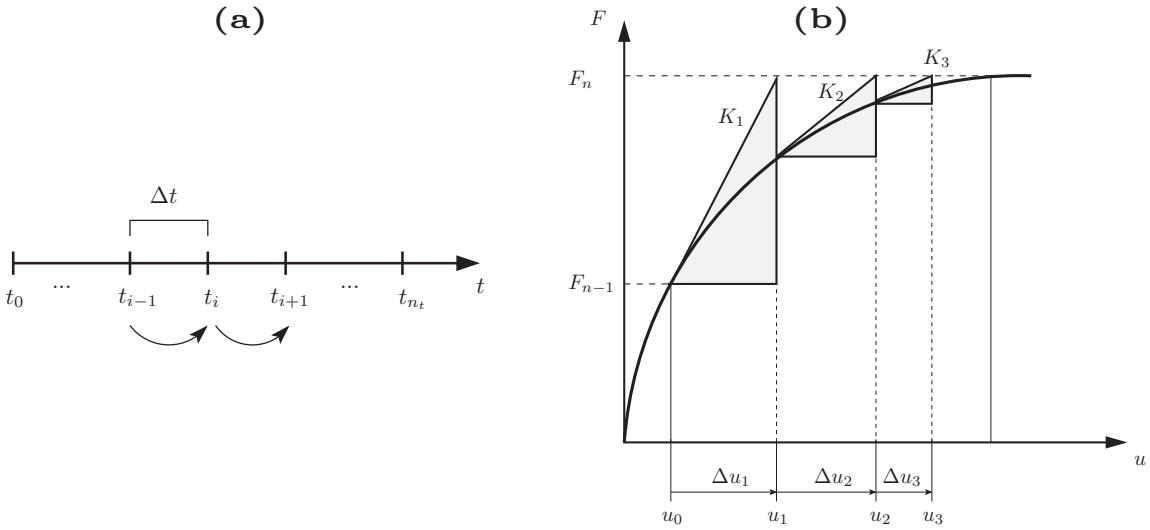

Figure 1: Conventional solution procedure; (a) step-by-step procedure in time; (b) Newton-Raphson iteration within each time step.

In this contribution, we compute the unknowns simultaneously at each temporal node, which will be realized iteratively, as illustrated in Figure 2. Hereby, the quasistatic space-time approach draws on our recently published paper [22].

The solution is then defined by a summation of M functionals, also called enrichments. The solution of a problem f dependent on space and time, can then be written as

$$f(\mathbf{x}, t) \approx \sum_{m=1}^{M} \chi^m(\mathbf{x})\theta^m(t) \ , \tag{3}$$

where $\chi^m(\mathbf{x})$ is the spatial and $\theta^m(t)$ is the temporal function in the m^{th} enrichment. Having defined the space-time solution ansatz, the incremental equation of equilibrium (2) must be

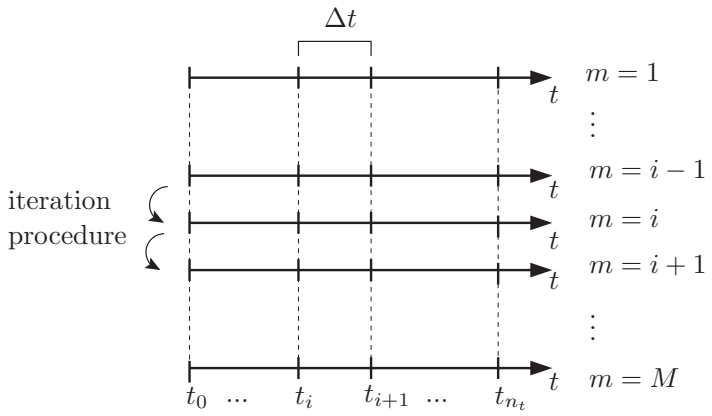

Figure 2: Space-time iteration scheme

reformulated in a space-time framework. According to the spatial discretization of the structure, we define the displacement matrix in each enrichment step in matrix form:

$$\mathbf{u}(\mathbf{x}, t) = [\mathbf{u}(t_0), \ldots, \mathbf{u}(t_{n_t})] \, . \tag{4}$$

Equivalently, the time-dependent internal and external force are expressed as:

$$\begin{aligned} \mathbf{F}_{\text{int}}(\mathbf{u}) &= [\mathbf{F}_{\text{int}}(t_0), \ldots, \mathbf{F}_{\text{int}}(t_{n_t})] \, , \\ \mathbf{F}(t) &= [\mathbf{F}(t_0), \ldots, \mathbf{F}(t_{n_t})] \, . \end{aligned} \tag{5}$$

The residual matrix is then evaluated by $\mathbf{R}(\mathbf{u}, t) = \mathbf{F} - \mathbf{F}_{\text{int}}$. The space-time residual is decomposed into a sum of dyadic products of uncorrelated space and time vectors. Therefore, the singular value decomposition (cf. [4]) is applied:

$$\mathbf{R}(\mathbf{x}, t) = \mathbf{R}_x \mathbf{S} \mathbf{R}_t^T \approx \sum_{j=1}^{n_{tr}} s^j \mathbf{R}_x^j \otimes \mathbf{R}_t^j \tag{6}$$

In this Equation, $\mathbf{R}_x^j$ are the left singular vectors extracted from the $n_x \times n_x$ matrix $\mathbf{R}_\mathbf{x}$, and $\mathbf{R}_t^j$ are the right singular vectors extracted from the $n_t \times n_t$ matrix $\mathbf{R}_\mathbf{t}$. The matrix $\mathbf{S}$ is a $n_x \times n_t$ rectangular diagonal matrix with the singular values s^j in descending order. Each value s^j defines the level of contribution of the j^{th} singular vector pair to the total energy of the space-time residual. Although all singular values must be considered to achieve an exact decomposition, in general, only a small number is necessary for an approximation with sufficiently high accuracy. The truncation number n_{tr} is defined so that the truncated sum contains at least 99.9% of the total sum of the singular values [4].

Furthermore, the space-time formulation of the stiffness matrix is defined by the dyadic product of the spatial and temporal stiffness matrices $\mathbf{K}_x$ and $\mathbf{K}_t$:

$$\mathbf{K} = \mathbf{K}_x \otimes \mathbf{K}_t, \; \mathbf{K}_x \in \mathbb{R}^{n \times n}, \; \mathbf{K}_t \in \mathbb{R}^{n_t \times n_t}. \tag{7}$$

Finally, using the proper generalized decomposition ansatz, the unknown displacement is written as a sum of enrichment functionals:

$$\mathbf{u}(\mathbf{x}, t) = \sum_{m=1}^{M} \Delta \mathbf{u}^m(\mathbf{x}, t) \, . \tag{8}$$

Here, the m^{th} enrichment is decomposed by

$$\Delta\mathbf{u}^m(\mathbf{x},t) = \Delta\mathbf{u}_x^m \otimes \Delta\mathbf{u}_t^m \ . \tag{9}$$

The vectors $\Delta\mathbf{u}_x^m$ and $\Delta\mathbf{u}_t^m$ define the modes of the m^{th} enrichment in the space and time domain.

Having defined the decomposition of the residual (6), the stiffness matrix (7) and the displacements (8), the equation of equilibrium can be reformulated into the space-time equation. For the m^{th} enrichment this yields to:

$$\Big(\mathbf{K}_x \otimes \mathbf{K}_t\Big)\Big(\Delta\mathbf{u}_x^m \otimes \Delta\mathbf{u}_t^m\Big) = \sum_{j=1}^{Tr} s^j \mathbf{R}_x^j \otimes \mathbf{R}_t^j \ . \tag{10}$$

Equation (10) is simplified to:

$$\mathbf{K}_x\Delta\mathbf{u}_x^m \otimes \mathbf{K}_t\Delta\mathbf{u}_t^m = \sum_{j=1}^{Tr} s^j \mathbf{R}_x^j \otimes \mathbf{R}_t^j \ . \tag{11}$$

In this equation, there are two unknowns: $\Delta\mathbf{u}_x^m$ and $\Delta\mathbf{u}_t^m$. However, multiplication by $\big(\Delta\mathbf{u}_t^m\big)^T$ leads to the projection into the space equation

$$\widehat{\mathbf{K}}_t\Delta\mathbf{u}_x^m = \widehat{\mathbf{R}}_x \ , \tag{12}$$

whereby $\widehat{\mathbf{K}}_t$ and $\widehat{\mathbf{R}}_x$ are defined as

$$\begin{aligned} \widehat{\mathbf{K}}_t &= \big(\Delta\mathbf{u}_t^m\big)^T \mathbf{K}_t \Delta\mathbf{u}_t^m \mathbf{K}_x \ , \\ \widehat{\mathbf{R}}_x &= \sum_{j=1}^{Tr} s^j \big(\Delta\mathbf{u}_t^m\big)^T \mathbf{R}_t^j \big(\mathbf{R}_x^j\big)^T \ . \end{aligned} \tag{13}$$

Furthermore, scalar multiplication of Equation (11) by $\big(\Delta\mathbf{u}_x^m\big)^T$ leads to the time equation

$$\widehat{\mathbf{K}}_x\Delta\mathbf{u}_t^m = \widehat{\mathbf{R}}_t, \tag{14}$$

whereby $\widehat{\mathbf{K}}_x$ and $\widehat{\mathbf{R}}_t$ are written as:

$$\begin{aligned} \widehat{\mathbf{K}}_x &= \big(\Delta\mathbf{u}_x^m\big)^T \mathbf{K}_x \Delta\mathbf{u}_x^m \mathbf{K}_t, \\ \widehat{\mathbf{R}}_t &= \sum_{j=1}^{Tr} s^j \big(\Delta\mathbf{u}_x^m\big)^T \mathbf{R}_x^j \big(\mathbf{R}_t^j\big)^T \ . \end{aligned} \tag{15}$$

These two coupled Equations (12) and (14) describe the space-time problem and must be solved simultaneously. Hereby, the fixed point algorithm is applied to iteratively evaluate $\Delta\mathbf{u}_x^m$ and $\Delta\mathbf{u}_t^m$. The spatial unknown $\Delta\mathbf{u}_x^m$ in equation (12) is evaluated while keeping $\Delta\mathbf{u}_t^m$ fixed. Subsequently, the temporal unknown $\Delta\mathbf{u}_t^m$ in equation (14) is evaluated while keeping $\Delta\mathbf{u}_x^m$ fixed. This procedure is repeated until convergence is achieved. The evaluated vectors $\Delta\mathbf{u}_x^m$ and $\Delta\mathbf{u}_t^m$ are inserted into equation (16) in order to obtain the update of the total displacement function after the m^{th} enrichment:

$$\mathbf{u}^m(\mathbf{x},t) = \mathbf{u}^{m-1}(\mathbf{x},t) + \Delta\mathbf{u}_x^m \otimes \Delta\mathbf{u}_t^m \ . \tag{16}$$

In this equation, $\Delta\mathbf{u}_x^m \otimes \Delta\mathbf{u}_t^m$ is the incremental enrichment functional after the current enrichment step and $\mathbf{u}^{m-1}(\mathbf{x},t)$ denotes the total solution of the sum of the preceding $(m-1)$ enrichment functionals. The convergence of the algorithm is examined after each enrichment by means of the Frobenius norm

$$\|\mathbf{Q}\| < \varepsilon_{(conv)} \tag{17}$$

considering

$$\mathbf{Q} = \mathbf{K}_x\Delta\mathbf{u}_x^m \otimes \mathbf{K}_t\Delta\mathbf{u}_t^m - \sum_{j=1}^{Tr} s^j\mathbf{R}_x^j \otimes \mathbf{R}_t^j \ , \tag{18}$$

with $\varepsilon_{(conv)}$ as the chosen convergence interval. Figure 3 shows the proposed space-time solution algorithm.

Enrichments:
for $m = 1 : M$ **do**
  Initialize $\Delta\mathbf{u}_t^0$;

  Fixed point algorithm:
  for $i = 1 : i_{\max}$ **do**
    Solution of space equation: $\Delta\mathbf{u}_x^i = \mathcal{D}^m\left(\Delta\mathbf{u}_t^{i-1}\right)$;
    Solution of time equation: $\Delta\mathbf{u}_t^i = \mathcal{B}^m\left(\Delta\mathbf{u}_x^i\right)$;
    Fixed point convergence check :
      $\|\Delta\mathbf{u}_t^i\|\ \|\Delta\mathbf{u}_x^i\|$ - $\|\Delta\mathbf{u}_t^{i-1}\|\ \|\Delta\mathbf{u}_x^{i-1}\| \leq \varepsilon_{(FP)}$;
  end
  $\Delta\mathbf{u}_x^i \longrightarrow \Delta\mathbf{u}_x^m$;
  $\Delta\mathbf{u}_t^i \longrightarrow \Delta\mathbf{u}_t^m$;

  Update the PGD displacement functional $\mathbf{u}(\mathbf{x},t)$
    $\mathbf{u}^m(\mathbf{x},t) = \mathbf{u}^{m-1}(\mathbf{x},t) + \Delta\mathbf{u}_x^m \otimes \Delta\mathbf{u}_t^m$

  Check convergence:
    $\|\mathbf{K}_x\Delta\mathbf{u}_x^m \otimes \mathbf{K}_t\Delta\mathbf{u}_t^m - \sum_{j=1}^{Tr} S^j\mathbf{R}_x^j \otimes \mathbf{R}_t^j\| < \varepsilon_{(conv)}$
end

Figure 3: Space-time solution algorithm using the proper generalized decomposition ansatz and the fixed point method.

3 Space-time solution of the linear damped dynamic problem

The linear damped set of equations of motion is written as:

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{C}\dot{\mathbf{u}} + \mathbf{K}\mathbf{u} = \mathbf{F}(t), \tag{19}$$

where $\mathbf{M}$, $\mathbf{C}$ and $\mathbf{K}$ denote the $n \times n$ mass-, damping- and stiffness matrix. $\mathbf{F}(t)$ denotes the vector of external force. The vectors $\ddot{\mathbf{u}}$, $\dot{\mathbf{u}}$ and $\mathbf{u}$ denote the acceleration, velocity and displacement, respectively. We introduce the Newmark procedure as a representative of implicit

integration methods in structural dynamics. In general, the set of equations of motion is then supposed to be fulfilled at fixed time instants t_i, preferably defined in equidistant time intervals $\Delta t = t_i - t_{i-1}$. Approximation of the solution functions in between those time instants leads to the implicit Newmark equations [26]:

$$\mathbf{u}_i = \mathbf{u}_{i-1} + \big[\Delta t\big]\dot{\mathbf{u}}_{i-1} + \big[(\frac{1}{2} - \beta)\Delta t^2\big]\ddot{\mathbf{u}}_{i-1} + \big[\beta\Delta t^2\big]\ddot{\mathbf{u}}_{i-1} \tag{20}$$

and

$$\dot{\mathbf{u}}_i = \dot{\mathbf{u}}_{i-1} + \big[(1-\gamma)\Delta t\big]\ddot{\mathbf{u}}_{i-1} + \big[\gamma\Delta t\big]\ddot{\mathbf{u}}_{i-1}. \tag{21}$$

The set of equations of motion (19) can be rewritten in the incremental form as:

$$\mathbf{M}\Delta\ddot{\mathbf{u}}_i + \mathbf{C}\Delta\dot{\mathbf{u}}_i + \mathbf{K}\Delta\mathbf{u}_i = \Delta\mathbf{F}_i(t), \tag{22}$$

where $\Delta\ddot{\mathbf{u}}_i$, $\Delta\dot{\mathbf{u}}_i$ and $\Delta\mathbf{u}_i$ are the displacement, velocity and acceleration increments, obtained by:

$$\begin{aligned} \Delta\ddot{\mathbf{u}}_i &= \ddot{\mathbf{u}}_i - \ddot{\mathbf{u}}_{i-1}, \\ \Delta\dot{\mathbf{u}}_i &= \dot{\mathbf{u}}_i - \dot{\mathbf{u}}_{i-1}, \\ \Delta\mathbf{u}_i &= \mathbf{u}_i - \mathbf{u}_{i-1}\ . \end{aligned} \tag{23}$$

The incremental force vector $\Delta\mathbf{F}_i(t)$ is equivalently defined as:

$$\Delta\mathbf{F}_i(t) = \mathbf{F}_i(t) - \mathbf{F}_{i-1}(t)\ . \tag{24}$$

Considering the set of equations of motion (22) and the Newmark formulations (20) and (21), the displacement, velocity and acceleration increments can be obtained step-by-step [24].

Instead of using the conventional approach, we will transform the linear damped dynamic problem into the space-time formulation. To this aim, we, firstly, have to discover a way to convert the incremental displacement vector $\Delta\mathbf{u} = \mathbf{u}_i - \mathbf{u}_{i-1}$ into a space-time matrix. Discretizing the time domain into the temporal nodes t_i $(i = 1, 2, 3, \ldots, n_t)$, we define one displacement matrix as a sequence of displacement vectors in each temporal node:

$$\mathbf{u}(\mathbf{x}, t) = [\mathbf{u}(t_0), \mathbf{u}(t_1), \ldots, \mathbf{u}(t_{n_t})]\ . \tag{25}$$

The incremental space-time displacement matrix is then defined as:

$$\Delta\mathbf{u}(\mathbf{x}, t) = [\mathbf{u}(t_1) - \mathbf{u}(t_0), \mathbf{u}(t_2) - \mathbf{u}(t_1), \ldots, \mathbf{u}(t_{n_t}) - \mathbf{u}(t_{n_{t-1}})]\ . \tag{26}$$

Using this approach, the space-time formulation of initial displacement $\mathbf{u}_0$ must be added by an additional term. The displacement increment is then reformulated as:

$$\mathbf{u}_i - \mathbf{u}_{i-1} \longrightarrow \mathbf{I}_s\mathbf{u}_s \otimes \mathbf{A}_t\mathbf{u}_t - \mathbf{u}_0 \otimes \mathbf{A}_0 \tag{27}$$

The vectors $\mathbf{u}_s$ and $\mathbf{u}_t$ denote the space and time decomposition of the displacement. The matrix $\mathbf{I}_s$ denotes the identity matrix with dimension $n_s \times n_s$, and the matrix $\mathbf{A}_t$ with the dimension $n_t \times n_t$ consists of entries 0, 1 and -1. The vector $\mathbf{A}_0$ consists of one entry equal to one, while the remaining entries are zero. Using this approach, the conventional Newmark equations (20) and (21) are reformulated to the Newmark equations in the space-time framework:

$$\mathbf{I}_s\mathbf{u}_s \otimes \mathbf{A}_1\mathbf{u}_t + \mathbf{I}_s\mathbf{u}_s \otimes \mathbf{A}_2\dot{\mathbf{u}}_t + \mathbf{I}_s\mathbf{u}_s \otimes \mathbf{A}_3\ddot{\mathbf{u}}_t = \mathbf{u}_0 \otimes \mathbf{A}_5 + \dot{\mathbf{u}}_0 \otimes \mathbf{A}_6 + \ddot{\mathbf{u}}_0 \otimes \mathbf{A}_7 \tag{28}$$

$$\mathbf{I}_s\mathbf{u}_s \otimes \mathbf{A}_1\dot{\mathbf{u}}_t + \mathbf{I}_s\mathbf{u}_s \otimes \mathbf{A}_4\ddot{\mathbf{u}}_t = \dot{\mathbf{u}}_0 \otimes \mathbf{A}_5 + \ddot{\mathbf{u}}_0 \otimes \mathbf{A}_8 \tag{29}$$

The matrices $\mathbf{A}_1$, $\mathbf{A}_2$, $\mathbf{A}_3$ and $\mathbf{A}_4$ have the dimension $n_t \times n_t$. The corresponding components are defined according to the respective coefficients of the Newmark equations (20) and (21). Furthermore, $\mathbf{A}_5$, $\mathbf{A}_6$, $\mathbf{A}_7$ and $\mathbf{A}_8$ are vectors. They are necessary to realize the space-time equivalents of the initial displacement $\mathbf{u}_0$, velocity $\dot{\mathbf{u}}_0$ and acceleration $\ddot{\mathbf{u}}_0$ in an equivalent manner to Equation (27). In the next step, the set of equations of motion (19) is transformed into space-time. Thus, we define the stiffness-, damping and mass matrix in the space-time formulation as a dyadic product of the spatial and temporal matrices, c.f. (7):

$$\begin{aligned} \mathbf{M} = \mathbf{M}_s \otimes \mathbf{M}_t,\ \mathbf{M}_s \in \mathbb{R}^{n\times n},\ \mathbf{M}_t \in \mathbb{R}^{n_t\times n_t}. \\ \mathbf{C} = \mathbf{C}_s \otimes \mathbf{C}_t,\ \mathbf{C}_s \in \mathbb{R}^{n\times n},\ \mathbf{C}_t \in \mathbb{R}^{n_t\times n_t}. \end{aligned} \tag{30}$$

Thus, the set of equations of motion can be rewritten in the space-time formulation:

$$(\mathbf{M}_s \otimes \mathbf{M}_t)(\mathbf{u}_s \otimes \ddot{\mathbf{u}}_t) + (\mathbf{C}_s \otimes \mathbf{C}_t)(\mathbf{u}_s \otimes \dot{\mathbf{u}}_t) + (\mathbf{K}_s \otimes \mathbf{K}_t)(\mathbf{u}_s \otimes \mathbf{u}_t) = \mathbf{F} \tag{31}$$

Since the mass, damping and stiffness matrices are considered to be constant during the whole computation process, we apply the simplifications $\mathbf{M}_t = \mathbf{I}_t$, $\mathbf{C}_t = \mathbf{I}_t$ and $\mathbf{K}_t = \mathbf{I}_t$. Consequently, Equation (31) can be simplified to:

$$\mathbf{M}_s\mathbf{u}_s \otimes \mathbf{I}_t\ddot{\mathbf{u}}_t + \mathbf{C}_s\mathbf{u}_s \otimes \mathbf{I}_t\dot{\mathbf{u}}_t + \mathbf{K}_s\mathbf{u}_s \otimes \mathbf{I}_t\mathbf{u}_t = \mathbf{F}. \tag{32}$$

Simplification of the decomposed set of equations of motion (32) and the space-time reformulated Newmark equations (28) and (29) leads to:

$$\begin{aligned} \mathbf{u}\mathbf{A}_1^T + \dot{\mathbf{u}}\mathbf{A}_2^T + \ddot{\mathbf{u}}\mathbf{A}_3^T = \mathbf{u}_0\mathbf{A}_5^T + \dot{\mathbf{u}}_0\mathbf{A}_6^T + \ddot{\mathbf{u}}_0\mathbf{A}_7^T, \\ \dot{\mathbf{u}}\mathbf{A}_1^T + \ddot{\mathbf{u}}\mathbf{A}_4^T = \dot{\mathbf{u}}_0\mathbf{A}_5^T + \ddot{\mathbf{u}}_0\mathbf{A}_8^T, \\ \mathbf{M}_s\ddot{\mathbf{u}} + \mathbf{C}_s\dot{\mathbf{u}} + \mathbf{K}_s\mathbf{u} = \mathbf{F}. \end{aligned} \tag{33}$$

Although the dynamic equation in the space-time has, theoretically, three unknowns, the space-time displacement matrix $\mathbf{u}$, the space-time velocity matrix $\dot{\mathbf{u}}$ and the space-time acceleration matrix $\ddot{\mathbf{u}}$, we take advantage of the fact, that in the linear case, the velocity as well as the acceleration can be written as a function of the displacement. The dynamic linear damped system in the space-time is described by one algebraic space-time equation:

$$\mathbf{K}_s\mathbf{u} - \mathbf{C}_s\mathbf{u}\mathbf{W} + \mathbf{M}_s\mathbf{u}\mathbf{Y} = \mathbf{L}. \tag{34}$$

The matrices $\mathbf{W}$, $\mathbf{Y}$ include the $\mathbf{A}_i$ coefficient matrices written as:

$$\begin{aligned} \mathbf{W} = \mathbf{A}_1^T\big(\mathbf{A}_2^T - \mathbf{A}_1^T(\mathbf{A}_4^T)^{-1}\mathbf{A}_3^T\big)^{-1}, \\ \mathbf{Y} = \mathbf{A}_1^T\big(\mathbf{A}_2^T - \mathbf{A}_1^T(\mathbf{A}_4^T)^{-1}\mathbf{A}_3^T\big)^{-1}\mathbf{A}_1^T\big(\mathbf{A}_4^T\big)^{-1}, \end{aligned} \tag{35}$$

The vector $\mathbf{L}$ contains the external force and the initial conditions, expressed in matrix form:

$$\mathbf{L}(t) = [\mathbf{L}(t_1), \mathbf{L}(t_2), \ldots, \mathbf{L}(t_{n_t})]. \tag{36}$$

In order to decompose the space-time formulation of the vector $\mathbf{L}(t)$ into a sum of dyadic products of uncorrelated space and time vectors, we employ the singular value decomposition [1]:

$$\mathbf{L} = \mathbf{L}_s\mathbf{S}\mathbf{L}_t \approx \sum_{j=1}^{Tr} s^j\mathbf{L}_s^j \otimes \mathbf{L}_t^j. \tag{37}$$

In this equation, $\mathbf{L}_s^j$ are the left singular vectors with dimension n_s and is extracted form the matrix $\mathbf{L}_s$. Analogously, the right singular vector $\mathbf{L}_t^j$ is extracted form the $n_t \times n_t$ matrix $\mathbf{L}_t$. The matrix $\mathbf{S}$ is a $n_s \times n_t$ rectangular diagonal matrix with the singular values s^j in descending order, cf. Equation (6).

Equivalent to the quasistatic approach, the solution is defined as the summation of displacement enrichments:

$$\mathbf{u}(\mathbf{x},t) = \sum_{i=1}^{m-1} \mathbf{u}_s^{(i)} \otimes \mathbf{u}_t^{(i)} + \mathbf{u}_s^{(m)} \otimes \mathbf{u}_t^{(m)}. \tag{38}$$

Having finally defined the decomposition of mass-, damping- and stiffness matrix (32), force matrix (37) and the displacement (38), the main equation of motion (34) is defined in the space-time framework:

$$\begin{aligned} \mathbf{K}_s\big[\sum_{i=1}^{m-1} \mathbf{u}_s^{(i)} \otimes \mathbf{u}_t^{(i)} + \mathbf{u}_s^{(m)} \otimes \mathbf{u}_t^{(m)}\big] - \mathbf{C}_s\big[\sum_{i=1}^{m-1} \mathbf{u}_s^{(i)} \otimes \mathbf{u}_t^{(i)} + \mathbf{u}_s^{(m)} \otimes \mathbf{u}_t^{(m)}\big]\mathbf{W} + \\ \mathbf{M}_s\big[\sum_{i=1}^{m-1} \mathbf{u}_s^{(i)} \otimes \mathbf{u}_t^{(i)} + \mathbf{u}_s^{(m)} \otimes \mathbf{u}_t^{(m)}\big]\mathbf{Y} = \sum_{j=1}^{Tr} s^j \mathbf{L}_s^j \otimes \mathbf{L}_t^j \end{aligned} \tag{39}$$

This equation has the two unknowns $\mathbf{u}_s^m$ and $\mathbf{u}_t^m$. Multiplication by $\left(\Delta \mathbf{u}_t^m\right)^T$ leads to the time equation

$$\mathbf{u}_t^{(m)} = \left(a\mathbf{I}_t - b\mathbf{W}^T + c\mathbf{Y}^T\right)^{-1}\big[\widehat{\mathbf{L}}_t - \mathbf{V}_{s1} + \mathbf{V}_{s2} - \mathbf{V}_{s3}\big]. \tag{40}$$

Analogously, multiplication by $\left(\Delta \mathbf{u}_s^m\right)^T$ leads to the space equation

$$\mathbf{u}_s^{(m)} = \left(e\mathbf{K}_s - f\mathbf{C}_s + g\mathbf{M}_s\right)^{-1}\big[\widehat{\mathbf{L}}_s - \mathbf{V}_{t1} + \mathbf{V}_{t2} - \mathbf{V}_{t3}\big]. \tag{41}$$

Equations (40) and (41) are coupled and solved simultaneously using the fixed point algorithm and describe our space-time problem. The scalars a, b, c, e, f and g are defined as:

$$\begin{aligned} a &= \left(\mathbf{u}_s^{(m)}\right)^T \mathbf{K}_s \mathbf{u}_s^{(m)}, \qquad b = \left(\mathbf{u}_s^{(m)}\right)^T \mathbf{C}_s \mathbf{u}_s^{(m)}, \qquad c = \left(\mathbf{u}_s^{(m)}\right)^T \mathbf{M}_s \mathbf{u}_s^{(m)}, \\ e &= \left(\mathbf{u}_t^{(m)}\right)^T \mathbf{I}_t \mathbf{u}_t^{(m)}, \qquad f = \left(\mathbf{u}_t^{(m)}\right)^T \mathbf{W} \mathbf{u}_t^{(m)}, \qquad g = \left(\mathbf{u}_t^{(m)}\right)^T \mathbf{Y} \mathbf{u}_t^{(m)}. \end{aligned} \tag{42}$$

The external force matrices in the current enrichment m are expressed as:

$$\widehat{\mathbf{L}}_s = \sum_{j=1}^{Tr} s^j \left(\mathbf{L}_t^j\right)^T \mathbf{u}_t^{(m)} \mathbf{L}_s^j, \qquad \widehat{\mathbf{L}}_t = \sum_{j=1}^{Tr} s^j \mathbf{L}_s^j \mathbf{u}_s^{(m)} \mathbf{L}_t^j \tag{43}$$

Furthermore the vectors $\mathbf{V}_{s1}$, $\mathbf{V}_{s2}$, $\mathbf{V}_{s3}$, $\mathbf{V}_{t1}$, $\mathbf{V}_{t2}$ and $\mathbf{V}_{t3}$ are written as:

$$\begin{aligned} \mathbf{V}_{s1} &= \sum_{i=1}^{m-1} \left(\mathbf{u}_s^{(i)}\right)^T \mathbf{K}_s \mathbf{u}_s^{(m)} \mathbf{I}_t \mathbf{u}_t^{(i)}, \qquad \mathbf{V}_{t1} = \sum_{i=1}^{m-1} \left(\mathbf{u}_t^{(i)}\right)^T \mathbf{I}_t^T \mathbf{u}_t^{(m)} \mathbf{K}_s \mathbf{u}_s^{(i)}, \\ \mathbf{V}_{s2} &= \sum_{i=1}^{m-1} \left(\mathbf{u}_s^{(i)}\right)^T \mathbf{C}_s \mathbf{u}_s^{(m)} \mathbf{W}^T \mathbf{u}_t^{(i)}, \qquad \mathbf{V}_{t2} = \sum_{i=1}^{m-1} \left(\mathbf{u}_t^{(i)}\right)^T \mathbf{W} \mathbf{u}_t^{(m)} \mathbf{C}_s \mathbf{u}_s^{(i)}, \\ \mathbf{V}_{s3} &= \sum_{i=1}^{m-1} \left(\mathbf{u}_s^{(i)}\right)^T \mathbf{M}_s \mathbf{u}_s^{(m)} \mathbf{Y}^T \mathbf{u}_t^{(i)}, \qquad \mathbf{V}_{t3} = \sum_{i=1}^{m-1} \left(\mathbf{u}_t^{(i)}\right)^T \mathbf{Y} \mathbf{u}_t^{(m)} \mathbf{M}_s \mathbf{u}_s^{(i)}. \end{aligned} \tag{44}$$

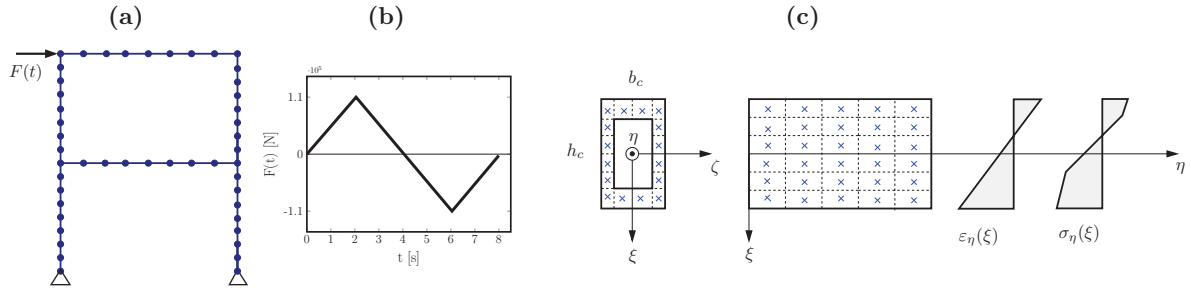

Figure 4: (a) frame structure; (b) sinusoidal quasistatic force history; (c) beam element and nonlinear stress-strain relation

After each enrichment, the evaluated vectors $\mathbf{u}_t^{(m)}$ and $\mathbf{u}_s^{(m)}$ are inserted into Equation (38) to obtain the update of the total displacement function. Equivalent to the quasistatic approach, the convergence of the algorithm is examined after each enrichment by means of the Frobenius norm

$$\|\mathbf{Q}\| < \varepsilon_{conv} \tag{45}$$

with

$$\mathbf{Q} = \mathbf{K}_s\mathbf{u}_s^{(m)} \otimes \mathbf{u}_t^{(m)} - \mathbf{C}_s\mathbf{u}_s^{(m)} \otimes \mathbf{W}^T\mathbf{u}_t^{(m)} + \mathbf{M}_s\mathbf{u}_s^{(m)} \otimes \mathbf{Y}^T\mathbf{u}_t^{(m)} - \sum_{j=1}^{Tr} s^j\mathbf{L}_s^j \otimes \mathbf{L}_t^j \tag{46}$$

and ε_{conv} as the chosen convergence interval.

4 Numerical results

4.1 Numerical results of the elastoplastic problem subjected to quasistatic excitation

As example, we introduce the geometry of a frame structure with two stories and one bay, depicted in Figure 4a (height and width are 8m). The columns and the beam of the structure are discretized by five elements, leading to a total number of 122 degrees of freedom. In Figure 4b, the force history used in this study, is depicted. The force time history is discretized choosing a constant time increment Δt of 0.05 second. An elastoplastic material model with kinematic hardening is implemented, as depicted in Figure 4c. The parameters are chosen as: initial stiffness $E_1 = 240$ GPa, yield stress $\sigma_Y = 220$ MPa, post yielding stiffness $E_2 = 0.1E_1$, Poisson's ratio 0.3. All cross sections of the columns and beam are modeled by quadratic hollow rectangular shapes. The dimensions are 0.3 m $\times$ 0.1 m. The thickness is $t = 10$ mm.

Regarding the conventional step-by-step method, the solution at time t_{i+1} is obtained iteratively based on the foregoing solution at time t_i. However, the proposed space-time procedure solves the problem in the entire time domain. Regarding the classic step-by-step reference method, in total 6237 iterations are performed within 160 time steps, whereas the convergence interval of the residual is set to 1.0 e-3. Regarding the space-time method, only 80 iterations are performed in order to reach the same level of accuracy. The enrichments are composed of a dyadic product of spatial and temporal modes, $\Delta\mathbf{u}_x$ and $\Delta\mathbf{u}_t$, as proposed in Equation (9), which are obtained during each enrichment from Equations (12) and (14). The displacements of the structure are then evaluated by the summation of all already iteratively evaluated enrichments. The results are presented in Figure 5. In particular, Figure 5a shows the evolution of the temporal modes. Figure 5b shows the evolution of the corresponding spatial modes. Additionally, Figure 5c shows the horizontal displacement of the node in the top left corner after each enrichment, and Figure 5d illustrates the corresponding hysteresis of this node.

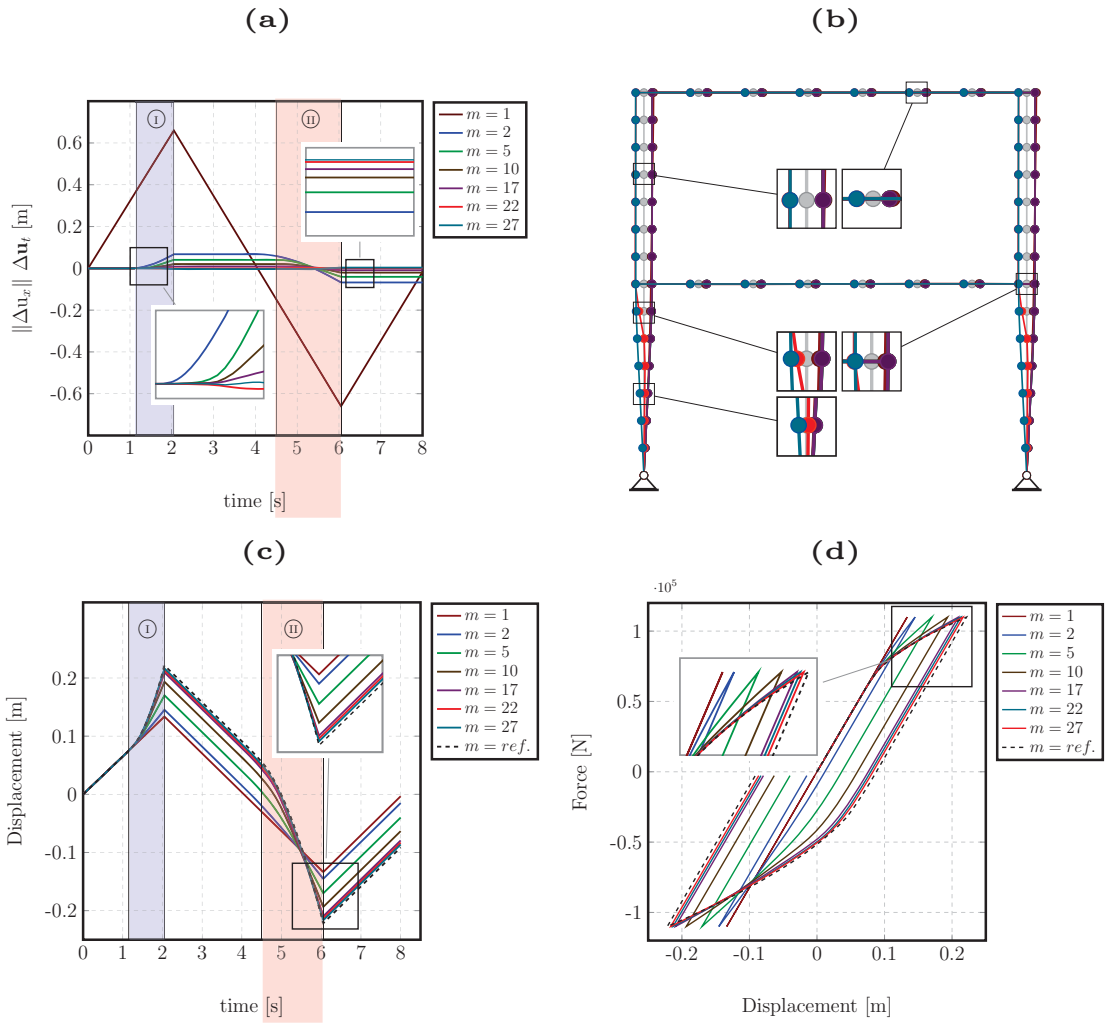

Figure 5: (a) The temporal mode multiplied by the length of the spatial mode $\|\Delta \mathbf{u}_x\| \Delta \mathbf{u}_t$;(b) the spatial mode $\frac{\Delta \mathbf{u}_x}{\|\Delta \mathbf{u}_x\|}$ at different enrichment steps m; (c) displacement response during loading time history; (d) hysteresis behavior after different enrichment steps m, reference solution (ref.). Compare qualitatively with the results in [22].

After the first enrichment step, the linear response is observed. This is seen by the first temporal mode in Figure 5a and the displacement after the first enrichment in Figure 5c. Both of these functions are linearly dependent on the excitation function. This is also verified in Figure 5d, where a linear function of the force-displacement response is observed after the first enrichment. Thus, the displacement in every time step, $\mathbf{u}^{(i)}$, is equal to the solution of the corresponding linear equation $\mathbf{K}^{\text{in}} \mathbf{u}^{(i)} = \mathbf{F}^{(i)}$. From the second enrichment on, the response of the structure evolves into the plastic range. Within the first time period, $0 \leq t \leq 1.15$ s, no plastic deformation is observed and the values of $\Delta \mathbf{u}_t$ are zero for all enrichments except the first one. This can be seen in Figure 5a. Two crucial time periods are defined for this example, in which the plastic strain rate is not equal to zero. This is time period Ⓘ in $1.15 \leq t \leq 2$ s, and time period Ⓘ Ⓘ in $4.5 \leq t \leq 6$ s, as depicted in Figure 5a. Within these time periods, the slopes of the temporal modes $\Delta \mathbf{u}_t^i$ $(i = 2, \ldots, M)$ are not equal to zero, whereas outside those time periods a constant function is observed for all of the temporal modes. With increasing number of enrichments, the amplitude of the temporal modes decreases until convergence. On the one

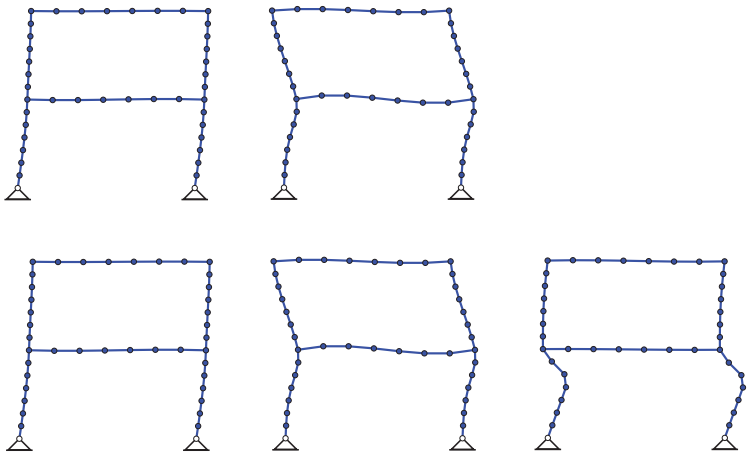

Figure 6: Uncorrelated proper orthogonal decomposition (POD) basis of the spatial modes after five (first row) and after 25 (second row) enrichments.

hand, we observe that $\Delta\mathbf{u}_t^i$ alters if plastic deformation is occurs, as shown in Figure 5a within time period Ⓘ during loading in positive x-direction and within time period Ⓘ. On the other hand, we observe that $\Delta\mathbf{u}_t^i$ remains constant if no additional plastic deformation is induced, as shown in Figure 5a in the time period $2 \leq t \leq 4.5$ s and $6 \leq t \leq 8$ s. These effects can also be observed in Figure 5c, where the solution drifts off the elastic response and converges to the reference solution. Within time periods Ⓘ and Ⓘ, the slope of the converged displacement function varies from the slope of the linear solution $(m = 1)$, whereas, within the remaining time periods, these functions are always parallel to the linear solution. In Figure 5d, it is also shown that the amount of plasticity increases with increasing number of enrichments and the hysteresis becomes broader until convergence to the reference solution.

Having revealed that the first enrichment response is purely linear, we emphasize that the spatial modes of the remaining enrichments, as depicted in Figure 5b, cannot directly be related to a spatial distribution of purely localized plastic deformation. They are rather identified as a set of modes, containing a superposition of global elastic and plastic structural deformation patterns. However, an indication that directly indicates plasticity cannot be seen by this evolution of spatial modes. Considering the horizontal force, as depicted in Figure 4, plastic zones will evolve around both corners of the frame structure. In order to investigate this local effect of the spatial evolution of the inelastic response, an observation matrix after each enrichment is defined that contains a set of correlated spatial modes $\mathbf{Q}^m = [\Delta\mathbf{u}_x^1, \Delta\mathbf{u}_x^2, \ldots, \Delta\mathbf{u}_x^m]$. Using the singular value decomposition (6), this observation matrix represents a set of orthonormal left singular basis vectors $\left[\boldsymbol{\Phi}_1^m, \boldsymbol{\Phi}_2^m, \ldots, \boldsymbol{\Phi}_{n_{tr}}^m\right]$. The singular values provide the amount of energy belonging to each corresponding mode. The number of required basis vectors n_{tr} is then evaluated by ensuring that 99.9% of the total energy of the observation matrix is stored within the set of basis vectors. In Figure 6, this truncated orthonormal basis, evaluated with regard to a varying number of enrichments, is presented. In particular, the first row in this figure shows the orthonormal uncorrelated basis after 5 enrichments, whereas the second row in this figure shows the orthonormal uncorrelated basis after 25 enrichments. The number of required basis vectors that contains almost the whole information of the set of spatial modes increases with increasing number of enrichments. Finally, a maximum number of three basis vectors contains 99.9% of the energy of the observation set obtained using 25 spatial modes. Thus, being able to reduce the number of 25 proper generalized decomposition modes to a number of three uncor-

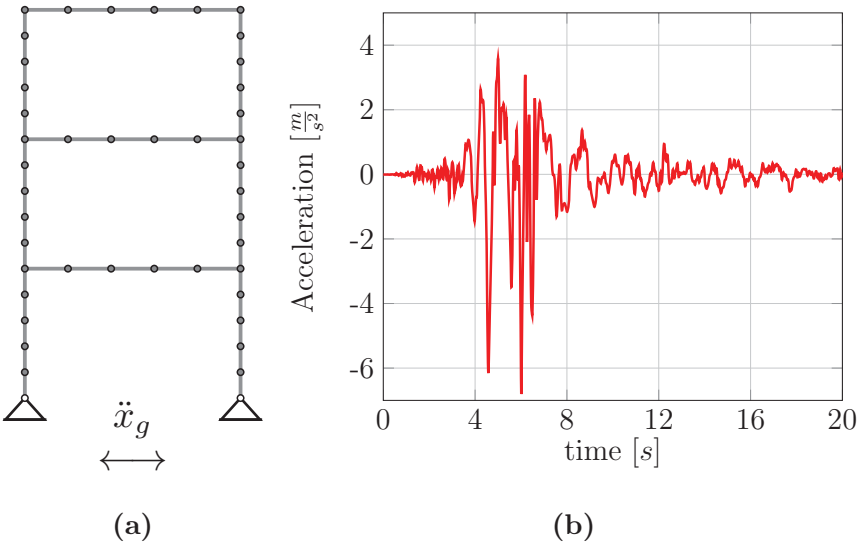

Figure 7: (a) Representative plane frame structure; (b) Horizontal acceleration of Kobe earthquake.

related basis vectors reveals that the spatial modes can be identified as highly correlated. The first uncorrelated basis mode describes the global response behavior of the structure and does not change significantly with increasing number of enrichments. After five enrichments, both basis vectors can only describe rather global response patterns, while local plastic deformations cannot be described. After 25 enrichments, the second and third basis modes clearly show local plastic response behavior around the corners of the frame structures. Consequently, the evolution of localized plastic effects with increasing number of enrichments cannot be interpreted by the set of the spatial modes of the enrichments, as they are highly correlated, but it can be well interpreted by their orthonormal basis representation.

4.2 Numerical results of the dynamic problem including damping subjected to transient excitation

In this section, a linear viscously damped system is solved using the introduced space-time formulation. The results are compared with the conventional Newmark solution. Furthermore, the proper generalized decomposition modes are investigated during convergence. As illustrative example, we investigate the response of two-dimensional frame structure, depicted in Figure 7a subjected to an earthquake record, depicted in Figure 7b. As depicted in this figure, the frame consists of three stories and one bay. Columns as well as beams of the frame structure are discretized by five elements, which leads to 128 degrees of freedom. The chosen time step Δt for the calculation is 10^{-2} s, which is equal to the time resolution of the excitation record. As for the quasistatic example, the whole structure is discretized by a 2 node truss-beam element, applying the Euler-Bernoulli beam theory [25]. The Young's modulus of the material is chosen as $E = 210$ GPa. All cross sections of the columns and beam are modeled by quadratic hollow rectangular shapes. The dimensions are 0.3 m $\times$ 0.1 m. The thickness of the cross sections is chosen as $t = 10$ mm. Rayleigh damping is introduced with a damping parameter of 0.04 for the fourth and 15^{th} mode. Figure 8 presents the horizontal displacement response of the node in the top left corner of the frame after each enrichment. In this figure, we observe convergence to the step-by-step reference solution within the first 18 enrichments. Figure 9 presents the spatial and temporal modes within the first three enrichment steps. In comparison, the first three linear

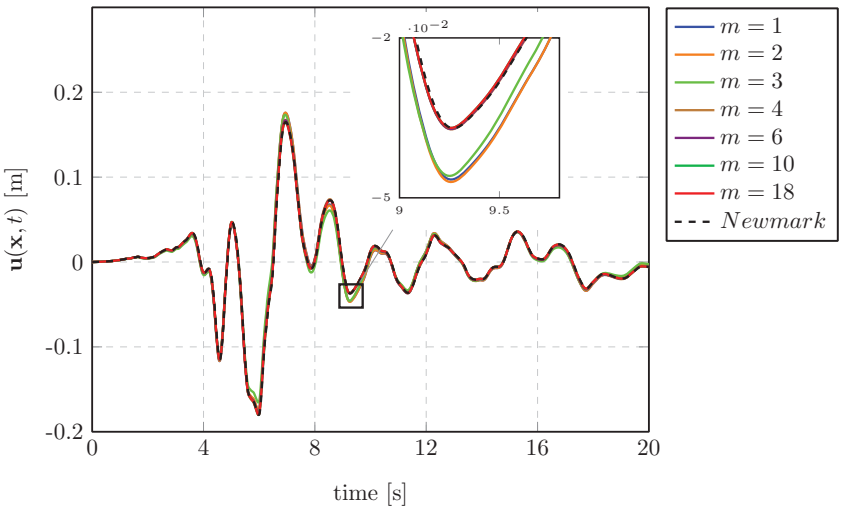

Figure 8: Displacement response during the loading time history after different enrichment.

modes of vibration are presented in red color in this figure. Looking at the patterns of the spatial PGD modes, significant differences can be observed compared to the linear modes of vibration. With increasing number of enrichments, spatial PGD modes are observed to reveal a high correlation with the depicted modes (not shown in this figure). This has also been observed for the quasistatic problem.

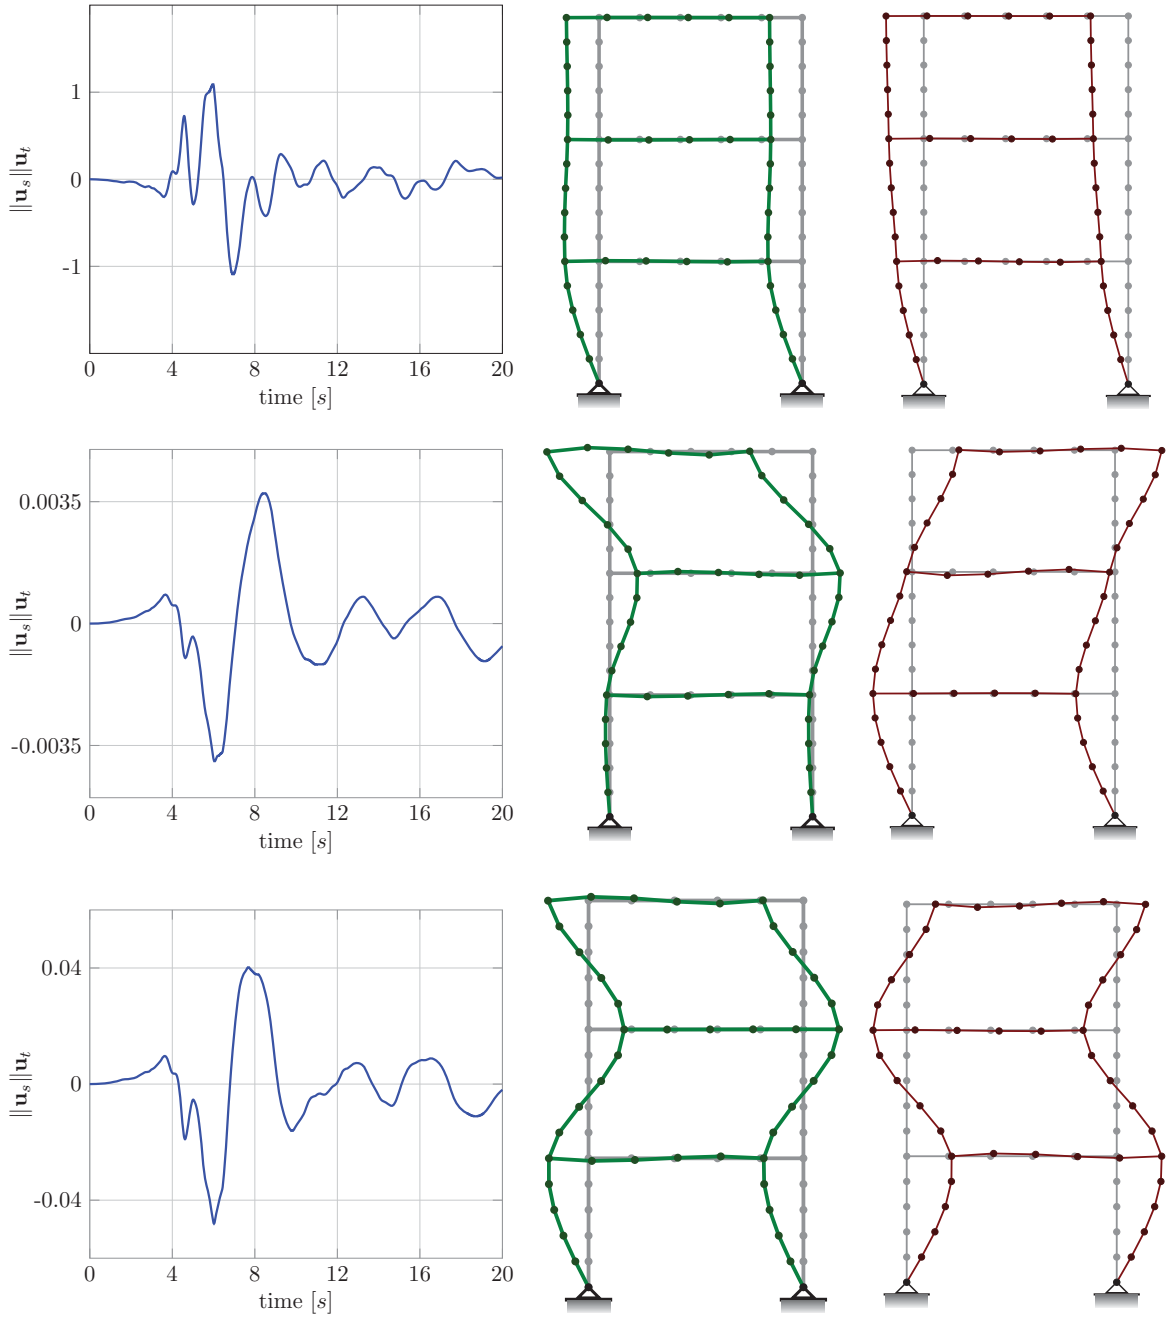

Figure 9: Left column: Expression of the temporal multiplied by the length of spatial mode $\|\mathbf{u}_s\|\mathbf{u}_t$; middle column: the spatial modes $\frac{\mathbf{u}_t}{\|\mathbf{u}_s\|}$ after the first three enrichment steps; right column: the first three modes of vibration.

5 Conclusion

In this paper, a space-time formulation of linear and nonlinear structures has been employed. Firstly, the space-time formulations in the quasistatic elastoplastic framework has been presented. Secondly, a space-time formulation of the Newmark solution for the linear damped equations of motion has been employed. Both formulations have been verified by numerical demonstrations.

Regarding the quasistatic case, the first enrichment represents the solution to the linear equation $\mathbf{K}^{\text{in}}\mathbf{u}^{(i)} = \mathbf{F}^{(i)}$ at all time steps $i = 1 \dots n_t$. However, with the second enrichment the solution starts to evolve into the nonlinear range until convergence is achieved. Regarding the dynamic case, however, a higher number of enrichments is necessary to approximate the linear response function as dynamic motion can be described by a superposition of motion patterns. The spatial proper generalized decomposition modes, however, are significantly different to the linear modes of vibration. Furthermore, the spatial proper generalized decomposition modes reveal a high correlation, so that only a small number of modes differs from each other significantly. This is observed for both, the nonlinear quasistatic and the dynamic problem.

In future studies, we will extend the proposed Newmark space-time method to elastoplastic dynamic problems. Furthermore, it is of great interest whether these types of space-time methods can be applied to vibro-impact problems, such as [27, 28], that can reveal unpredictable dynamical behavior.

Keywords: Isogeometric collocation, Nonlinear dynamics, Finite rotations, Timoshenko beams.

Abstract. *In this paper we review some of the most recent computational techniques based on the isogeometric analysis for the solution of the dynamic problem of geometrically exact beams. The kinematics of a spatial Timoshenko beam undergoing finite displacements and rotations involves the Lie group* $\mathrm{SO}(3)$*. Most of the computational complexities originate from the presence of such a non-additive and non-commutative rotation group. By employing the incremental rotation vector to describe the evolution of finite rotations, we discuss how the isogeometric collocation (IGA-C) method can be efficiently used in both explicit and implicit Newmark-based schemes.*

1 INTRODUCTION

For a wide range of engineering problems, accurate and efficient beam formulations able to reproduce large and fast three-dimensional motions are of paramount importance. The isogeometric collocation (IGA-C) method was proposed in [1, 2] with the primary objective of exploiting the higher smoothness of non-uniform rational B-Splines (NURBS) basis functions used in isogeometric analysis (IGA) [3] and the low computational cost of collocation. NURBS basis functions, used both for the geometry representation and the space discretization of the differential problem, significantly simplify the operations of mesh generation and refinement. Moreover, once the initial mesh is generated, refinements do not affect the geometric approximation. IGA has proven to achieve increased accuracy and robustness on a per degree-of-freedom basis compared with standard Finite Element Analysis (FEA) [4, 5, 6].

IGA-C seeks to achieve higher efficiency since, in contrast to Galerkin.based IGA, the need for numerical quadrature is completely removed due to the discretization of the strong form of the governing equations. IGA-C requires only one evaluation point per degree of freedom, regardless of the approximation degree, resulting in a much faster method compared to standard Galerkin-based IGA [7]. IGA-C proved excellent performances in a wide range of applications. Timoshenko beam formulations were successfully proposed in [8, 9, 10, 11, 12, 13]. Bernoulli-Euler beams and Kirchhoff plates were addressed in [14], and Reissner-Mindlin plate and shell problems in [15] and [16], respectively. Kirchhoff-Love plate and shell problems were studied in [17]. In [18, 19, 20] IGA-C was extended to geometrically nonlinear three-dimensional shear-deformable beams. Nonlinear planar Kirchhoff rods were formulated in [21]. In linear dynamics, an explicit IGA-C formulation was introduced in [2] and more recently an explicit higher-order space- and time-accurate method for elastodynamics was proposed in [22]. IGA-C methods for the nonlinear dynamics of geometrically exact beams have been investigated so far only in [23] through an implicit quaternion-based formulation, [24] through an explicit formulation based on the spatial incremental rotation vector, and in [25] through an implicit formulation based on the material incremental rotation vector.

In this work we review and compare the main features of the explicit and implicit formulations we recently proposed in [24] and [25], respectively. In the explicit formulation we adopt one of the best-performing Newmark time integration method for $\mathrm{SO}(3)$ proposed by Krysl & Endres in [26] for the rotational dynamics of rigid bodies. In the implicit formulation we adopt the $\mathrm{SO}(3)$-extended version of the classical Newmark scheme originally proposed in [27].

Both formulations are geometrically consistent, namely the main operations of linearization, variables initialization and kinematic update are made consistently with the geometric structure of the configuration manifold. High efficiency and accuracy are guaranteed by the IGA-C attributes combined with the rotation-vector parameterization for the incremental rotation.

2 THEORETICAL BACKGROUND

2.1 The configuration manifold and its tangent spaces

The motion of any material particle $\boldsymbol{p} \in \mathcal{B}$ of a shear-deformable beam is expressed as follows

$$\boldsymbol{\varphi}(t, \boldsymbol{p}) = \boldsymbol{c}(t, \boldsymbol{q}) + \mathbf{R}(t, \boldsymbol{q})(\boldsymbol{p} - \boldsymbol{q}) \,,$$

where $t \in \boldsymbol{T}$ is the time ($\boldsymbol{T} = [0, T] \subset \mathbb{R}$ being the time domain), $\boldsymbol{q} \in \mathcal{B}$ is the material position of the centroid of the beam cross section containing point $\boldsymbol{p}$. $\mathcal{S} \subset \mathcal{B}$ is the centroid line. (Figure 1).

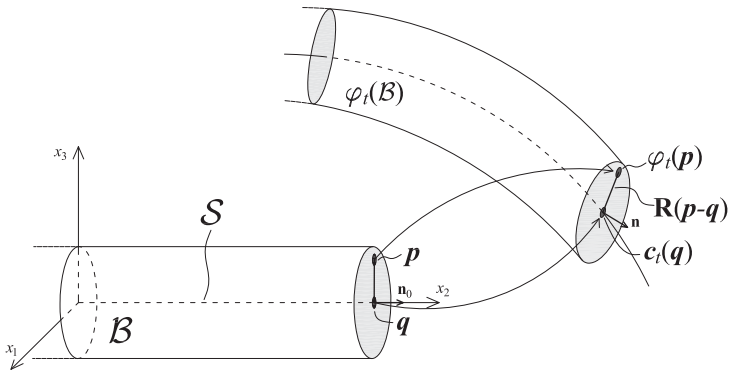

Figure 1: Motion of a three-dimensional shear deformable beam.

The configuration manifold is the set

$$\mathcal{C} = \left\{ (\boldsymbol{c}, \mathbf{R}) \,|\, \boldsymbol{c} : \boldsymbol{T} \times \mathcal{S} \to \mathbb{R}^3 \,, \mathbf{R} : \boldsymbol{T} \times \mathcal{S} \to \mathrm{SO}(3) \right\} \,,$$

where $\boldsymbol{c}(t, \boldsymbol{q})$ is the spatial location of the center of mass of the beam cross section at time t and point $\boldsymbol{q} \in \mathcal{S}$, and $\mathbf{R}(t, \boldsymbol{q})$ is the rigid rotation of the same cross section at the same time. Namely, the (finite) rotation of each beam cross section is described by a time-depending orthogonal operator $\mathbf{R}$ belonging to the non-commutative Lie group $\mathrm{SO}(3)$. On $\mathrm{SO}(3)$ rotation updates, transformations of $\mathrm{SO}(3)$ onto itself, must be consistently performed by a suitable composition of an incremental rotation with the current rotation. Such an operation is non-additive and non-commutative. The latter attribute leads to a substantial difference between spatial and material descriptions of the motion on $\mathrm{SO}(3)$. Indeed, we have that spatial and material tangent spaces to $\mathrm{SO}(3)$ at $\mathbf{R}$ are respectively defined as follows

$$T^s_{\mathbf{R}} \mathrm{SO}(3) = \left\{ \tilde{\boldsymbol{\vartheta}} \mathbf{R} \,|\, \tilde{\boldsymbol{\vartheta}} \in \mathrm{so}(3) \,, \mathbf{R} \in \mathrm{SO}(3) \right\} \,,$$
$$T^m_{\mathbf{R}} \mathrm{SO}(3) = \left\{ \mathbf{R} \widetilde{\boldsymbol{\Theta}} \,|\, \widetilde{\boldsymbol{\Theta}} \in \mathrm{so}(3) \,, \mathbf{R} \in \mathrm{SO}(3) \right\} \,,$$

where $\mathrm{so}(3)$ is the set of 3×3 skew-symmetric matrices [27, 28][1].

Configuration update is made as follows

$$\mathbf{R}_\varepsilon = \exp(\varepsilon \widetilde{\boldsymbol{\vartheta}}) \mathbf{R} = \mathbf{R} \exp(\varepsilon \widetilde{\boldsymbol{\Theta}}); \quad \boldsymbol{c}_\varepsilon = \boldsymbol{c} + \varepsilon \boldsymbol{\eta}$$

where $\widetilde{\boldsymbol{\vartheta}}$ and $\widetilde{\boldsymbol{\Theta}}$ are the spatial and material incremental rotation vectors, respectively; $\boldsymbol{\eta}$ is the incremental displacement, and $\varepsilon \in \mathbb{R}$. (Figure 2).

3 Balance equations in strong form

The displacement-based version of the balance equations is

$$\mu \mathbf{R}^{\mathsf{T}} \boldsymbol{a} = \widetilde{\boldsymbol{K}} \mathbb{C}_N \boldsymbol{\Gamma}_N + \mathbb{C}_N \boldsymbol{\Gamma}_{N,s} + \mathbf{R}^{\mathsf{T}} \bar{\boldsymbol{n}} \tag{1}$$

$$\boldsymbol{J} \boldsymbol{A} + \widetilde{\boldsymbol{W}} \boldsymbol{J} \boldsymbol{W} = \widetilde{\boldsymbol{K}} \mathbb{C}_M \boldsymbol{K}_M + \mathbb{C}_M \boldsymbol{K}_{M,s} + \widetilde{(\mathbf{R}^{\mathsf{T}} \boldsymbol{c}_{,s})} \mathbb{C}_N \boldsymbol{\Gamma}_N + \mathbf{R}^{\mathsf{T}} \bar{\boldsymbol{m}} \tag{2}$$

where μ is the mass per unit length of the beam; $\boldsymbol{a}$ is the spatial acceleration vector of the cross section centroid; $\widetilde{\boldsymbol{K}} = \mathbf{R}^{\mathsf{T}} \mathbf{R}_{,s}$ is the beam curvature in the material form; $\boldsymbol{\Gamma}_N$, $\boldsymbol{K}_M$ are the strain

[1] With the symbol $\sim$ we denote elements of $\mathrm{so}(3)$. Furthermore, for any skew-symmetric matrix $\widetilde{\boldsymbol{a}} \in \mathrm{so}(3)$, $\boldsymbol{a} = \mathrm{axial}(\widetilde{\boldsymbol{a}})$ indicates the axial vector of $\widetilde{\boldsymbol{a}}$ such that $\widetilde{\boldsymbol{a}} \boldsymbol{h} = \boldsymbol{a} \times \boldsymbol{h}$, for any $\boldsymbol{h} \in \mathbb{R}^3$.

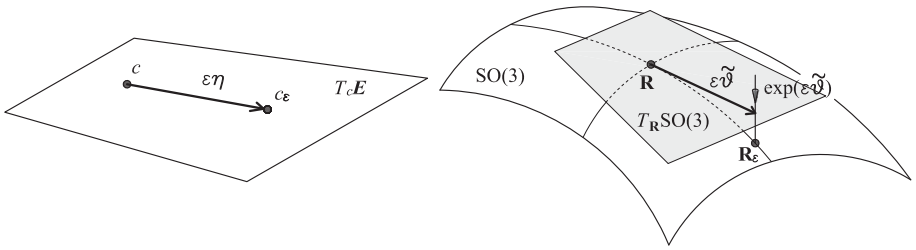

Figure 2: Tangent space to SO(3). Spatial case: $T_{\mathbf{R}}\,\mathrm{SO}(3) = T^s_{\mathbf{R}}\,\mathrm{SO}(3)$.

measure vectors in the material form; $\bar{\boldsymbol{n}}$, $\bar{\boldsymbol{m}}$ are the external forces and moments per unit length in spatial form; $\boldsymbol{J}$ is the material inertia tensor; $\widetilde{\boldsymbol{W}} = \mathbf{R}^{\mathsf{T}}\dot{\mathbf{R}}$ is the material angular velocity tensor and $\boldsymbol{W} = \text{axial}(\widetilde{\boldsymbol{W}})$ its axial vector; $\boldsymbol{A} = \dot{\boldsymbol{W}}$ is the material angular acceleration vector; $\mathbb{C}_N = \text{diag}(GA_1, EA, GA_3)$ and $\mathbb{C}_M = \text{diag}(EJ_1, GJ, EJ_3)$.

The corresponding spatial rotational inertia is given by $\boldsymbol{j}\boldsymbol{\alpha} + \widetilde{\boldsymbol{\omega}}\boldsymbol{j}\boldsymbol{\omega} = \mathbf{R}(\boldsymbol{J}\boldsymbol{A} + \widetilde{\boldsymbol{W}}\boldsymbol{J}\boldsymbol{W})$, where $\boldsymbol{\alpha}$ and $\boldsymbol{\omega}$ are the angular acceleration and velocity in the spatial form.

4 TIME AND SPACE DISCRETIZATIONS

4.1 Explicit (spatial) Newmark scheme

With $\mathcal{I}_u = [0, 1] \subset \mathbb{R}$ as the normalized one-dimensional domain of the basis functions, the spatial approximation of the incremental rotation and displacement is introduced as follows

$$\boldsymbol{\vartheta}(u) \approx \sum_{j=0}^{\mathrm{n}} R_{j,p}(u)\check{\boldsymbol{\vartheta}}_j \quad \text{with} \quad u \in \mathcal{I}_u\,, \tag{3}$$

$$\boldsymbol{\eta}(u) \approx \sum_{j=0}^{\mathrm{n}} R_{j,p}(u)\check{\boldsymbol{\eta}}_j \quad \text{with} \quad u \in \mathcal{I}_u\,, \tag{4}$$

where $\check{()}_j$ indicates the jth control value of the quantity; $R_{j,p}$ indicates the jth NURBS basis function of degree p [29]. Velocities and accelerations are discretized in a similar way through $\check{\boldsymbol{\omega}}_j$, $\check{\boldsymbol{v}}_j$, and $\check{\boldsymbol{\alpha}}_j$, $\check{\boldsymbol{a}}_j$. Note that in the explicit formulation, the latter represent the primary variables of the problem.

At time $t = t^{n-1} = h(n-1)$, h being the time step size and n the time step counter, the control values of the incremental displacement and rotation vectors are expressed as follows

$$\check{\boldsymbol{\eta}}_j^{n-1} = h\check{\boldsymbol{v}}_j^{n-1} + \frac{h^2}{2}\,\check{\boldsymbol{a}}_j^{n-1}; \quad \check{\boldsymbol{\vartheta}}_j^{n-1} = h\check{\boldsymbol{\omega}}_j^{n-1} + \frac{h^2}{2}\,\check{\boldsymbol{\alpha}}_j^{n-1}\,, \tag{5}$$

$$\check{\boldsymbol{v}}_j^{n} = \check{\boldsymbol{v}}_{pj}^{n-1} + \frac{h}{2}\,\check{\boldsymbol{a}}_j^{n}; \quad \check{\boldsymbol{\omega}}_j^{n} = \check{\boldsymbol{\omega}}_{pj}^{n-1} + \frac{h}{2}\,\check{\boldsymbol{\alpha}}_j^{n}\,. \tag{6}$$

By exploiting the above equations, consistent kinematic updates of RHSs of Eqs. (1) and (2) can be done [24] leading to the following time-discretized balance equations

$$\mu\boldsymbol{a}^n = \boldsymbol{\psi}^n; \qquad \boldsymbol{j}^n\boldsymbol{\alpha}^n + \widetilde{\boldsymbol{\omega}}^n\boldsymbol{j}^n\boldsymbol{\omega}^n = \boldsymbol{\chi}^n\,.$$

It is noted that, due to Eq. (6), a nonlinear term in $\boldsymbol{\alpha}^n$ appears in the rotational balance equation. Therefore a linearization is needed leading to the following system of equations

$$\mu\sum_{j=0}^{\mathrm{n}} R_j\check{\boldsymbol{a}}_j^n = \boldsymbol{\psi}_i^n; \quad \frac{\partial\mathbf{r}_i^n(\hat{\boldsymbol{\alpha}}_i^n)}{\partial\boldsymbol{\alpha}_i^n}\sum_{j=0}^{\mathrm{n}} R_j\delta\check{\boldsymbol{\alpha}}_j^n = -\hat{\mathbf{r}}_i^n\,.$$

The complete formulation including the discretizatin of the boundary conditions (not reported here) is available in [24].

4.2 Implicit (material) Newmark scheme

The material form of the Newmark algorithm for $\mathrm{SO}(3)$ [27] is given as follows

$$\mathbf{R}^{n+1} = \mathbf{R}^n \exp(\widetilde{\boldsymbol{\Theta}}^n)\,, \tag{7}$$

$$\boldsymbol{\Theta}^n = h\boldsymbol{W}^n + h^2\left[\left(\frac{1}{2}-\beta\right)\boldsymbol{A}^n + \beta\boldsymbol{A}^{n+1}\right]\,, \tag{8}$$

$$\boldsymbol{W}^{n+1} = \boldsymbol{W}^n + h\left[(1-\gamma)\,\boldsymbol{A}^n + \gamma\boldsymbol{A}^{n+1}\right]\,. \tag{9}$$

The algorithm used to integrate the motion of the beam centroid line is the standard Newmark for nonlinear dynamics, which, for the sake of completeness, is reported in the following

$$\boldsymbol{c}^{n+1} = \boldsymbol{c}^n + \boldsymbol{\eta}^n\,, \tag{10}$$

$$\boldsymbol{\eta}^n = h\boldsymbol{v}^n + h^2\left[\left(\frac{1}{2}-\beta\right)\boldsymbol{a}^n + \beta\boldsymbol{a}^{n+1}\right]\,, \tag{11}$$

$$\boldsymbol{v}^{n+1} = \boldsymbol{v}^n + h\left[(1-\gamma)\,\boldsymbol{v}^n + \gamma\boldsymbol{a}^{n+1}\right]\,. \tag{12}$$

In the implicit formulations the balance equations are written at t^{n+1} as follows

$$-\mu\mathbf{R}^{\mathsf{T}n+1}\boldsymbol{a}^{n+1} + \widetilde{\boldsymbol{K}}^{n+1}\mathbb{C}_N\boldsymbol{\Gamma}_N^{n+1} + \mathbb{C}_N\boldsymbol{\Gamma}_{N,s}^{n+1} + \mathbf{R}^{\mathsf{T}n+1}\bar{\boldsymbol{n}}^{n+1} = \mathbf{0}\,, \tag{13}$$

$$\begin{aligned}&-(\boldsymbol{J}\boldsymbol{A}^{n+1} + \widetilde{\boldsymbol{W}}^{n+1}\boldsymbol{J}\boldsymbol{W}^{n+1}) + \widetilde{\boldsymbol{K}}^{n+1}\mathbb{C}_M\boldsymbol{K}_M^{n+1} + \\ &\mathbb{C}_M\boldsymbol{K}_{M,s}^{n+1} + \mathbf{R}^{\mathsf{T}n+1}\boldsymbol{c}_{,s}^{n+1} \times \mathbb{C}_N\boldsymbol{\Gamma}_N^{n+1} + \mathbf{R}^{\mathsf{T}n+1}\bar{\boldsymbol{m}}^{n+1} = \mathbf{0}\,,\end{aligned} \tag{14}$$

The geometrically consistent linerization of the above equations and the boundary conditions (not reported here) is discussed in detail in [25]. Once linearized equations are obtained, space discretizaion is introduced as follows

$$\delta\boldsymbol{\Theta}^{n+1}(u) = \sum_{j=0}^{\mathrm{n}} R_{j,p}(u)\delta\check{\boldsymbol{\Theta}}_j^{n+1} \quad \text{with} \quad u \in \mathcal{I}_u\,, \tag{15}$$

$$\delta\boldsymbol{\eta}^{n+1}(u) = \sum_{j=0}^{\mathrm{n}} R_{j,p}(u)\delta\check{\boldsymbol{\eta}}_j^{n+1} \quad \text{with} \quad u \in \mathcal{I}_u\,, \tag{16}$$

where incremental rotations and displacements $\delta\check{\boldsymbol{\Theta}}_j^{n+1}$ and $\delta\check{\boldsymbol{\eta}}_j^{n+1}$ represent the primary variable of the implicit formulation. Let $\delta\check{\boldsymbol{\Theta}}_j^{n+1,k}, \delta\check{\boldsymbol{\eta}}_j^{n+1,k}$ be the solution of the linearized system at the iteration kth. Iteration updates are based on the following consistent scheme (we refer to [25] for a comprehensive discussion of the update formulas)

$$\boldsymbol{c}_i^{n+1,k+1} = \sum_{j=0}^{\mathrm{n}} R_j(\check{\boldsymbol{p}}_j^{n+1,k} + \delta\check{\boldsymbol{\eta}}_j^{n+1,k}); \quad \mathbf{R}_i^{n+1,k+1} = \mathbf{R}_i^{n+1,k}\exp(\delta\widetilde{\boldsymbol{\Theta}}_i^{n+1,k})$$

5 NUMERICAL RESULTS

5.1 Cantilever beam

The test, originally proposed in [30], consists of a beam of length $1\,\mathrm{m}$ and with a square cross section with side $0.01\,\mathrm{m}$. The Young's modulus is $E = 210 \times 10^9\,\mathrm{N/m^2}$, the Poisson's ratio is $\nu = 0.2$ and the material density is $\rho = 7800\,\mathrm{kg/m^3}$. With respect to a Cartesian reference system (x_1, x_2, x_3), initially the beam axis is placed along x_2 and the deformation occurs in the (x_2, x_3) plane due to a constant concentrated transversal tip force $\bar{n}_{c_3}$. In Figure 3 the time histories of the beam tip displacements are shown. Two load intensities: $\bar{n}_{c_3} = -10\,\mathrm{N}$ and $\bar{n}_{c_3} = -100\,\mathrm{N}$ are considered. The loads are applied with constant intensity for a duration of $0.5\,\mathrm{s}$ through a step-function without any ramp. For both cases $p = 4$ and $\mathrm{n} = 20$. An excellent agreement is found with [30] (for the small amplitude vibrations case) and between the explicit (see above and [24]) and implicit (see above and [25]) formulations for both small and large amplitude vibrations cases. The implicit formulation appears particularly efficient since it is able to reproduce very fast nonlinear dynamics with impulsive loads (no load ramp functions are applied to any of the two load intensities) with a time step 500 times larger than the explicit formulation. Note that four iterations per time step are required in the Newton-Raphson algorithm with a tolerance on the L_2 norm of the incremental vector of 10^{-10} .

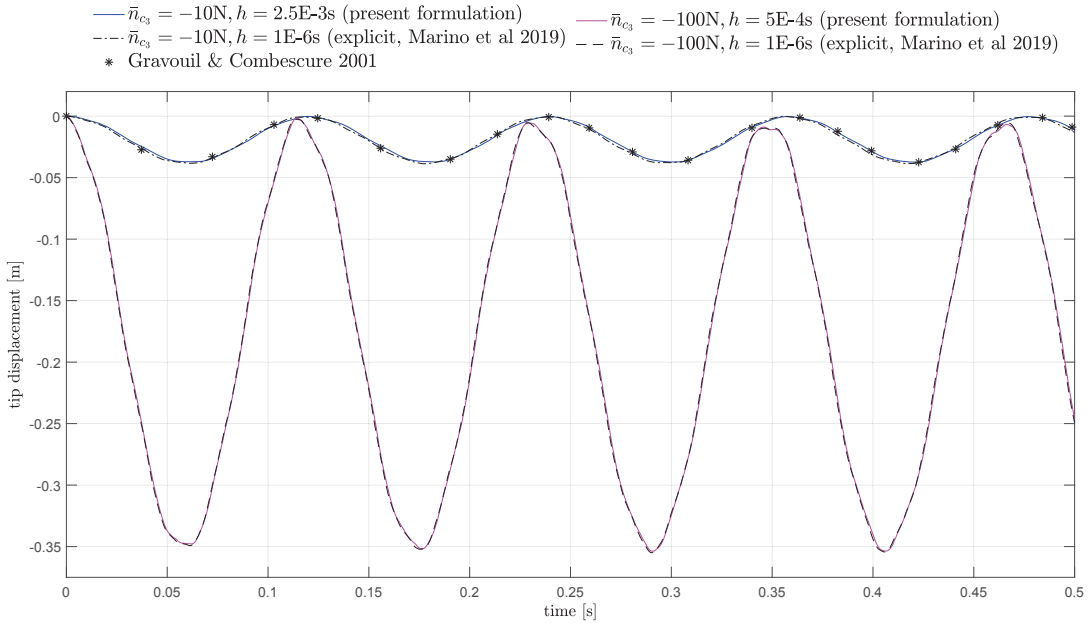

Figure 3: Tip displacement of a cantilever beam subjected to a tip transversal load F_3 with two different intensities. In both cases $p = 4$ and $\mathrm{n} = 20$. Comparisons are made with results obtained in Marino et al 2019 [24] and Gravouil & Combescure 2001 [30].

In Figure 4 four snapshots of the deformed beam are shown. To assess the higher-order space-accuracy of the method when fast and large motions occur, in Figure 5 we show the convergence curves of the L_2 norm of the error for the load case $\bar{n}_{c_3} = -100\,\mathrm{N}$. The error is calculated as $err_{L_2} = ||\boldsymbol{u}^r - \boldsymbol{u}^h||_{L_2}/||\boldsymbol{u}^r||_{L_2}$, where $\boldsymbol{u}^h$ and $\boldsymbol{u}^r$ are the approximate and reference vertical displacements, respectively, evaluated at $t = 1\,\mathrm{ms}$. The reference solution $\boldsymbol{u}^r$ is obtained with $p = 6$, $\mathrm{n} = 80$ and a time step $h = 1 \times 10^{-7}\,\mathrm{s}$.

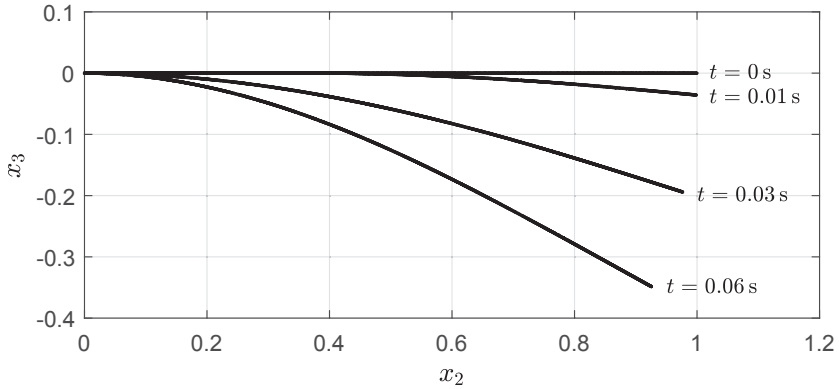

Figure 4: Explicit formulation. Snapshots of a cantilever beam subjected to a tip force $F_3 = -100\,\mathrm{N}$. $p = 4$, $n = 20$, $h = 1 \times 10^{-6}\,\mathrm{s}$. Identical results were obtained with the implicit formulation with $h = 5 \times 10^{-4}$.

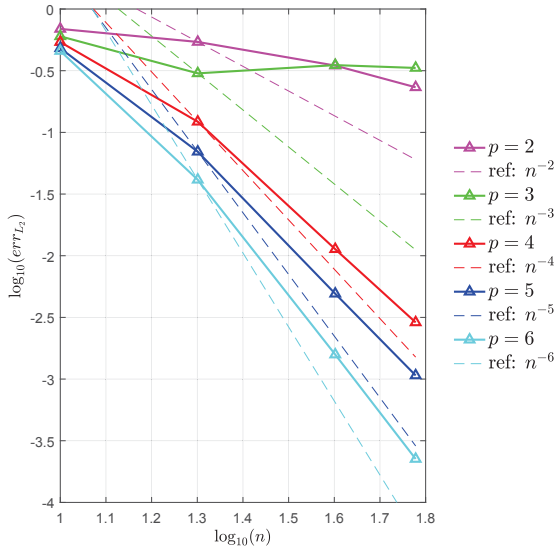

Figure 5: Explicit formulation. L_2 norm of error vs. number of collocation points for a cantilever beam under an in-plane transversal tip force with NURBS basis functions of degrees $p = 2, \ldots, 6$. Dashed lines indicate reference orders of convergence.

5.2 Swinging flexible pendulum

The test consists of an initially straight beam of length $1\,\mathrm{m}$ with a circular cross section of diameter $0.01\,\mathrm{m}$. The Young's modulus is $E = 5 \times 10^6\,\mathrm{N/m^2}$, the Poisson's ratio is $\nu = 0.5$ and the material density is $\rho = 1100\,\mathrm{kg/m^3}$. The beam, initially placed along x_2, is hinged at the end located at $(0, 0, 0)$ and is free at the other end. The motion occurs under the effect of the gravity only.

Figure 6 shows eleven snapshots taken from time 0 to $1\,\mathrm{s}$ with increments of $0.1\,\mathrm{s}$. Results associated with different combinations of basis function degrees, number of collocation points and time step sizes obtained with the implicit formulation are compared. Up to approximately $0.5\,\mathrm{s}$, the results of all cases are almost indistinguishable. After that time, the results with $p = 4$ exhibit some loss of accuracy, while the results with $p = 6$ are always very accurate, also when using a coarser mesh (red line) or when doubling the time step size (green line), indicating that the error due to the space discretization dominates and can be easily (and efficiently) reduced

by order elevation.

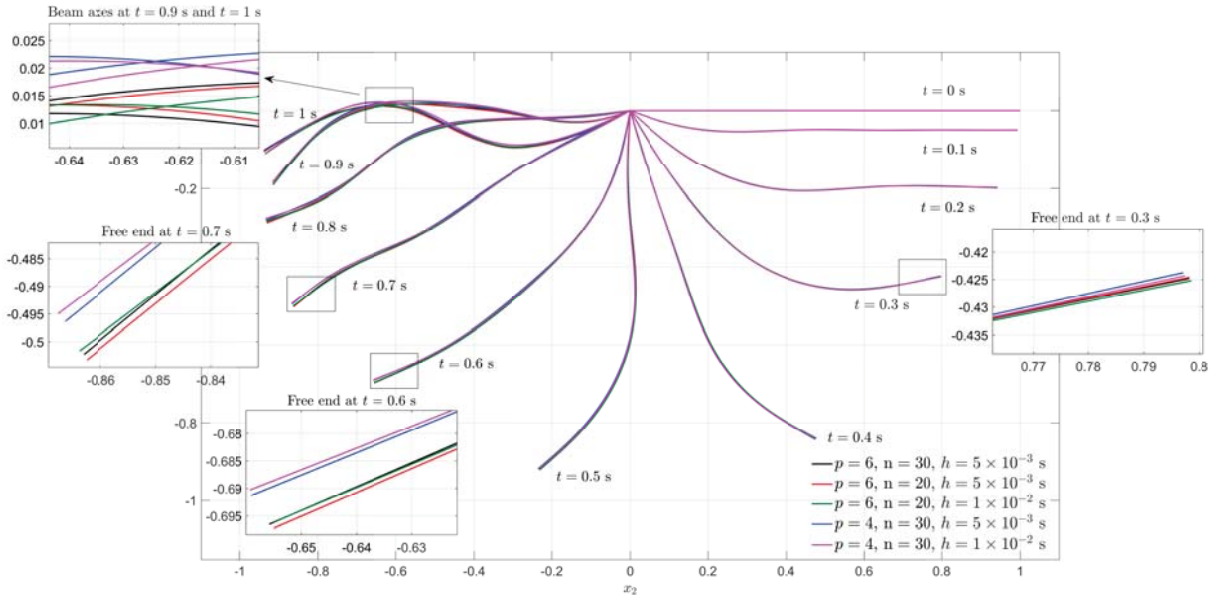

Figure 6: Implicit formulation. Snapshots of a swinging flexible pendulum subjected to gravity only from time 0 to $1\,\mathrm{s}$ with increments of $0.1\,\mathrm{s}$ for different basis function degrees, number of collocation points and time step spans [25].

Figure 7 shows the vertical tip displacement. Comparisons are made with results obtained in [24] (explicit), [25] (implicit), Lang et al 2011 [31] and Weeger et al 2017 [23].

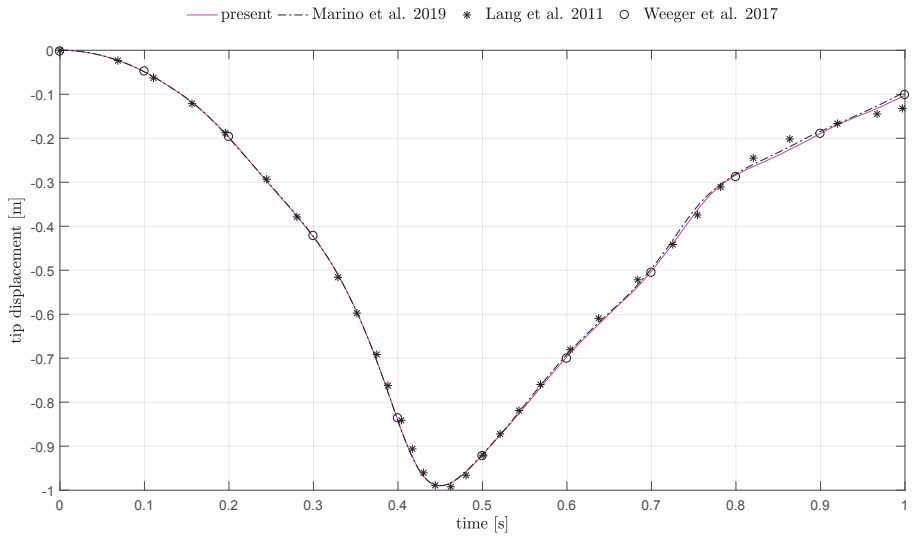

Figure 7: Vertical tip displacement of a swinging flexible pendulum. Comparisons are made with results obtained in Marino et al 2019 [24], Lang et al 2011 [31] and Weeger et al 2017 [23]. Results of the present formulation are obtained with $p = 6$, $\mathrm{n} = 30$, $h = 5 \times 10^{-3}\,\mathrm{s}$ [25].

5.3 Three-dimensional flying beam

The test, proposed originally by Simo & Vu-Quoc in [27], consists of an initially straight free flexible beam with length $L = 10$ placed in the plane (x_2, x_3) subjected at the lower end

to three different time-varying concentrated loads applied simultaneously (Figure 10). Under these loads the beam undergoes a forward translation due to $\bar{n}_{c_2}$, a forward tumbling due to $\bar{m}_{c_1}$ and an out-of-plane deformation due to $\bar{m}_{c_3}$.

The convergence curves of the L_2 norm of the error evaluated at $t = 2\,\mathrm{s}$ vs. the number of collocation points are shown in Figure 8. The error is calculated as above using a reference solution $\boldsymbol{u}^r$ obtained with $p = 8$, $\mathrm{n} = 200$ (approximately 2.3 on the abscissa of Figure 8) and $h = 0.1$. Very good convergence rates are observed up to $p = 5$. They are p for even degrees and $p - 1$ for odd degrees, which is the typical behavior in isogeometric collocation using Greville points [1, 2, 20]. For higher degrees, especially for $p = 8$, as the number of collocation points increases, the temporal error becomes dominant and slightly affects the quality of the convergence rate.

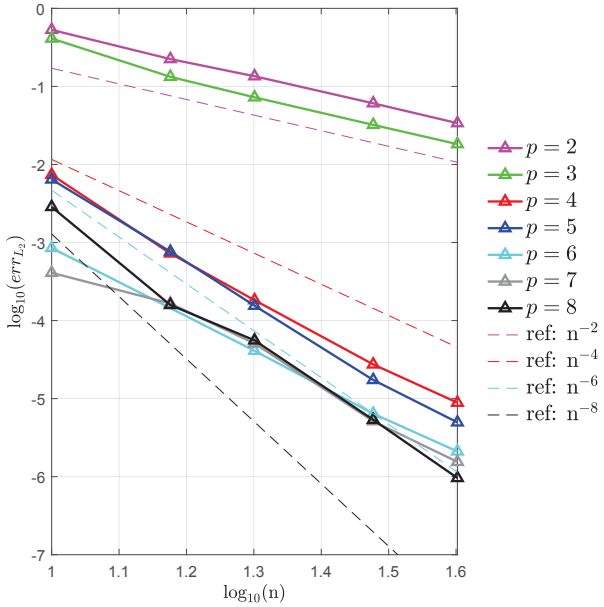

Figure 8: Implicit formulation. L_2 norm of the error evaluated at $t = 2\,\mathrm{s}$ vs. the number of collocation points for the free flying beam for NURBS basis functions of degrees $p = 2, \ldots, 8$. Dashed lines indicate reference orders of convergence. Reference solution computed with $p = 8$, $\mathrm{n} = 200$, $h = 0.1$.

For the implicit formulation, with our choice of β and γ, the standard Newmark time integration scheme is second-order accurate in time [27]. To verify that this attribute is preserved in the implicit IGA-C formulation on $\mathrm{SO}(3)$, we show in Figure 9 the error in L_2 norm associated with time step sizes of 0.05, 0.1, and 0.2. The error is evaluated by comparing the beam configuration at $t = 5$ with a reference solution obtained with $h = 0.01$. In all cases $p = 6$ and $\mathrm{n} = 60$. A perfectly quadratic rate is observed. Figure 10 (right panel) shows some snapshots of the beam centroid line. Results associated with five combinations of p, h, and n are shown. When the largest time step is considered ($h = 0.2$), as expected, the temporal error dominates the spatial one. Reducing the time step size to 0.1, which is more appropriate for this application [27], the accuracy increases significantly. Although unconditional stability is not formally proved in the present nonlinear context, it is noted the high stability of the method even with very large time step sizes. Figure 11 shows snapshots from time 0 to 11.5 with increments of 0.1 in a three-dimensional view.

Very similar results (not reported here) are obtained with the explicit formulations with $h = 1 \times 10^{-5}\,\mathrm{s}$ (see [24]).

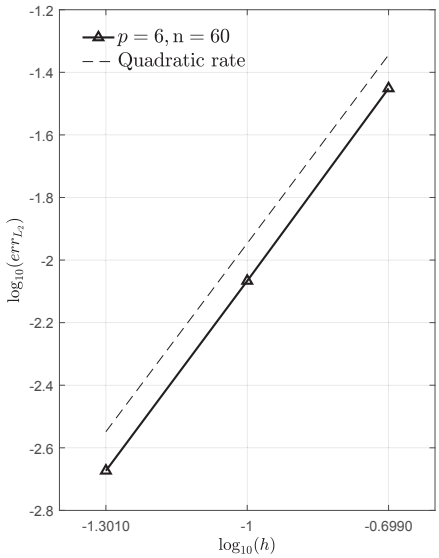

Figure 9: Implicit formulation. L_2 norm of the error vs. time step sizes of 0.05, 0.1, 0.2 for the free flying beam. The error is evaluated by comparing the beam configuration at $t = 5$ with a reference solution obtained with $h = 0.01$. In all cases $p = 6$ and $\mathrm{n} = 60$.

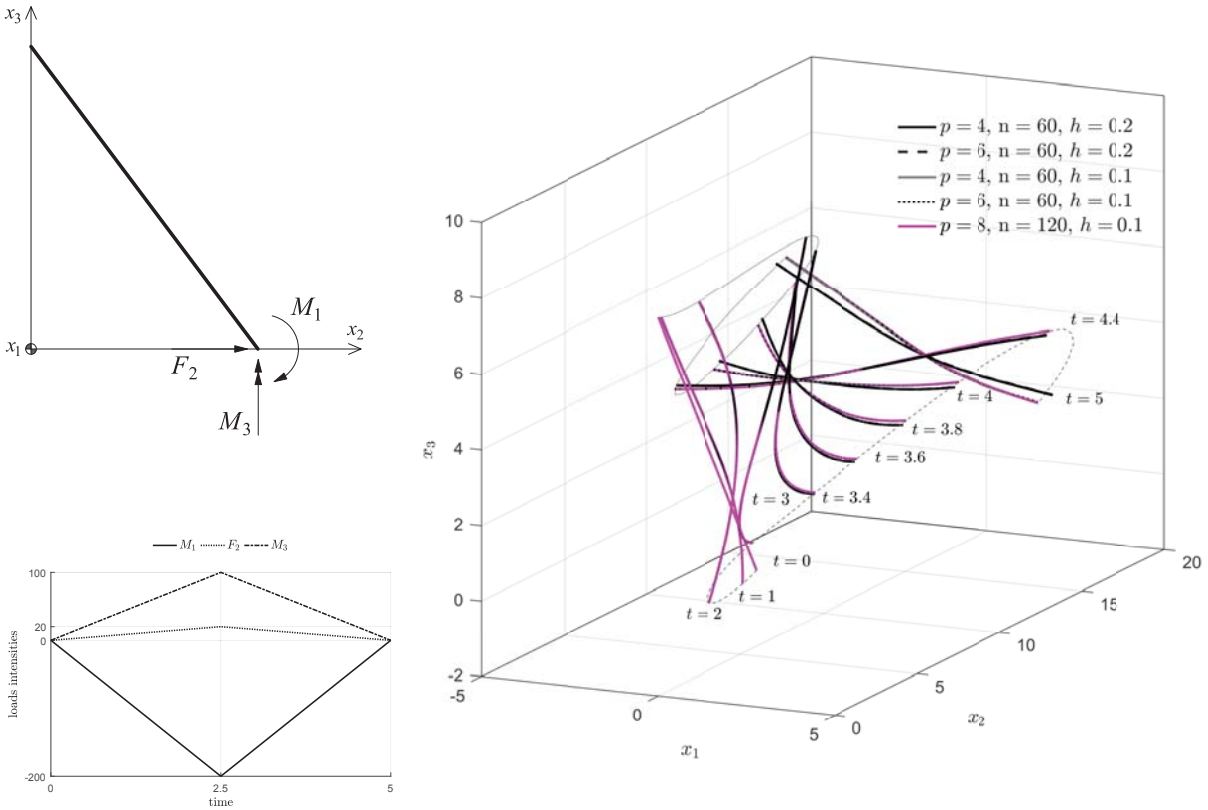

Figure 10: Implicit formulation. Flying flexible beam: initial configuration and loads (left panels). Snapshots in the early tumbling stage for different combinations of polynomial degrees and time step sizes (right panel) [25].

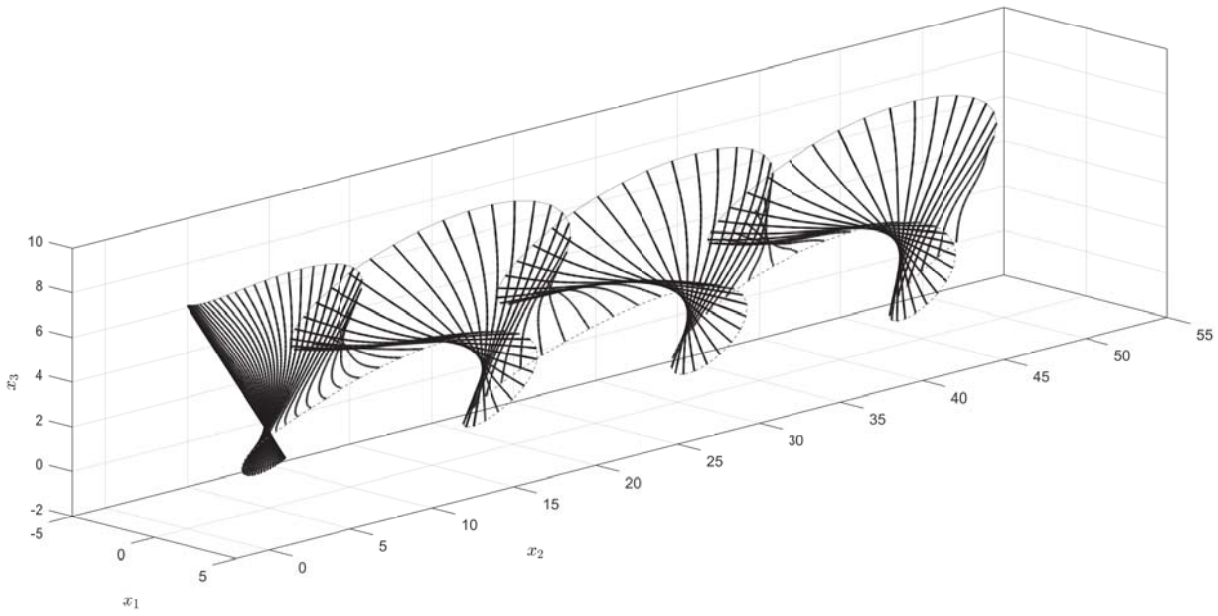

Figure 11: Implicit formulation. Three-dimensional view of the flying flexible beam. Snapshots from time 0 to 11.5 with increments of 0.1 [25].

6 CONCLUSIONS

Both explicit and implicit formulations are geometrically consistent, high-order accurate in space and very efficient. In the explicit formulation, RHSs of the balance equations are obtained by means of consistent update of the kinematic quantities at previous time step. The nonlinear term associated with the angular acceleration has a negligible effect on the overall efficiency of the method since the Newton-Raphson algorithm converges always in one iteration regardless of magnitude and rate of the rotations. The formulation we developed is meant as the basis on which a fully explicit formulation can be developed. With *fully explicit* we mean not only the time integration scheme, but also no equation solving. This can be achieved by developing a suitable mass lumping technique [22] suitable for nonlinear beams.

The implicit method is very stable, even with very large time step sizes, and is able to capture very fast nonlinear dynamics with a remarkable advantage in terms of time step size compared to the explicit version. Order elevation improves the overall accuracy significantly and, in a context where efficiency is one of the major goals, this is a remarkable attribute. Main future developments should be oriented towards energy and momentum preserving IGA-C methods.

Keywords: Pylons, Antennas, Flexible structures, Structural monitoring, Ambient vibrations, Dynamic loads, Elastic waveguides

Abstract. *The monitoring of flexible structures such towers, antennas and pylons comprising critical infrastructure for power transmission and telecommunications is necessary in order to ensure their continuous operation. This particular field of engineering comes under the umbrella of structural health monitoring, which in recent years has been given high priority in developed countries. There, the built infrastructure is both extensive, encompassing diverse groups of systems such as energy, telecommunication, utility and transportation networks, while at the same time is ageing rapidly. The goal is to set up monitoring schemes with a stand-alone configuration and a wireless transmission of data to central locations for further processing. Thus, it becomes necessary for the sensors employed to have some structural analysis capabilities that can be used in tandem with their data processing functions, all within an artificial intelligence environment. To this end, we develop analytical models for vibrations in elastic waveguides that model flexible structures of variable cross-section and demonstrate their efficiency and accuracy through comparisons with finite element models.*

1 INTRODUCTION

Broadly speaking, infrastructure can be classified as the built environment plus the necessary networks for the supply of energy, water, communications and transportation. Since network operation must remain continuous, Structural Health Monitoring (SHM) is required as a necessary step in setting up maintenance protocols [1]. The data streams generated by monitoring must be evaluated with the aid of Artificial Intelligence (AI) algorithms that will allow authorities to reach rational conclusions regarding the current state of network operation and to assess the need for maintenance, repair, retrofit and rehabilitation [2]. Within this cycle, it is necessary to use numerical models to analyze the current state of the structure as needed [3]. The usual path followed nowadays for modelling either the structure or the structural network under consideration is the Finite Element Method (FEM). This usually requires the setup of meshes for discretizing the continuum that are quite detailed and possibly cannot be accommodated within wireless sensor nodes with limited computational resources and power supply. It then becomes necessary to introduce analytical models with closed-form solutions [4] which can be programmed using computer platforms such as Java [5]. This representation is both accurate and efficient and requires small amounts of computing power. This way, the data streams generated by ambient vibrations and other external loads can be processed and compared with computed response markers [6, 7]. Then, these data streams will be either discarded or transmitted to a central processing unit for further evaluation. The final goal is to produce reliable information through SHM to decide if the structure in question is in need of repairs.

Flexible structures such as antennas and pylons used in power transmission and in telecommunications can be efficiently modelled as elastic waveguides, i.e. base-supported beams of variable cross-section with a continuous mass distribution. In general, these waveguides undergo axial, flexural and torsional vibrations, see Fig. 1. Their motion is governed by partial differential equations in a space variable x (m) and in time t (s). Invariably, a transformation to the frequency domain follows, whereby ordinary differential equations result that are parametric in the frequency ω (rad/s). The change in cross-section along the length results in dispersion phenomena that would otherwise be absent. Furthermore, it might be that the aforementioned three types of vibration patterns are coupled, but this would result in a problem that is probably intractable in terms of a closed-form-solution. Practically speaking, for a circular cylindrical cross-section only flexural vibrations might be influenced by the presence of an axial force, and this would depend on the external loading configuration and frequency content [8]. In here, we will focus on the axial vibration problem as a first step in exploring the suitability of these models to SHM.

2 MECHANICAL MODEL FOR STRUCTURES OF VARIABLE CROSS-SECTION

Figure 1 depicts a free-standing waveguide placed along the X-axis. For transverse $f(x,t)$ and longitudinal $p(x,t)$ loads distributed along the length of the waveguide, plus initial conditions, a bending moment $M(x,t)$, a shear force $Q(x,t)$ and an axial force $N(x,t)$ develop across the cross-section. Also, $u(x,t)$ and $w(x,t)$ are the axial and transverse displacements, respectively, with $\theta=\partial w/\partial x$ being the slope of the neutral axis. The following definitions for the forces and boundary conditions corresponding to a cantilevered waveguide are given below, with initial conditions assumed to be zero:

$$N = EA(x)(\partial u/\partial x), \qquad M = -EI(x)(\partial w^2/\partial x^2), \qquad Q = -EI(x)(\partial w^3/\partial x^3),$$
$$M(a,t) = Q(a,t) = w(b,t) = w'(b,t) = 0, \quad N(a,t) = u(b,t) = 0 \tag{1}$$

In the above, $EA(x)$ and $EI(x)$ are the aggregate axial and flexural stiffness that varies along the antenna length, $a \le L \le b$. Finally, the alternative notation used here involves primes ($'$) and dots ($\cdot$) to respectively denote differentiation with respect to the spatial coordinate x and time t. We will consider the following type of smooth variation for the flexural stiffness, the axial stiffness and the distributed mass of the waveguide as

$$EI(x) = (EI)_{base}(x/b)^3,\ EA(x) = (EA)_{base}(x/b),\ m(x) = (m)_{base}(x/b) \tag{2}$$

Where EI, EA, m are the reference values at the base $x = b$, with the antenna length being $L = b - a$. The type of variation assumed dictates the type of the partial differential equation that will result. When the equations of motion are transformed in the frequency domain, they become Bessel and Euler equations for the axial and flexural vibrations, respectively.

3 EQUATIONS OF DYNAMIC EQUILIBRIUM

By considering force and moment equilibrium of the differential segment dx in Fig. 1, we obtain coupled governing equations of dynamic equilibrium for axial and flexural motion as

$$\frac{\partial}{\partial x}\left(EA(x)\,\frac{\partial u(x,t)}{\partial x}\right) - \frac{\partial}{\partial x}\left(Q(x,t)\,\frac{\partial w(x,t)}{\partial x}\right) - m(x)\,\frac{\partial^2 u(x,t)}{\partial t^2} = p(x,t) \tag{3}$$

$$\frac{\partial^2}{\partial x^2}\left(EI(x)\,\frac{\partial^2 w(x,t)}{\partial x^2}\right) - \frac{\partial}{\partial x}\left(N(x,t)\,\frac{\partial w(x,t)}{\partial x}\right) + m(x)\,\frac{\partial^2 w(x,t)}{\partial t^2} = f(x,t) \tag{4}$$

3.1 The time domain

If the coupling terms $\partial/\partial x(Q\cdot\partial w/\partial x)$ in the former and $\partial/\partial x(N\cdot\partial w/\partial x)$ in the latter equation are ignored, then by differentiating the variable stiffness terms we recover the following equations:

$$EA(x)\cdot u'' + (\partial EA(x)/\partial x)\cdot u' - m(x)\cdot \ddot{u} = p(x,t) \quad (5)$$
$$EI(x)\cdot w'''' + 2(\partial EI(x)/\partial x)\cdot w''' + (\partial^2 EI(x)/\partial x^2)\cdot w'' + m(x)\cdot \ddot{w} = f(x,t) \quad (6)$$

Next, by introducing the variable stiffness representations of Eq. (2) and recover the final form for the equations of dynamic equilibrium as follows:

$$(EAx/b)\cdot u'' + (EA/b)\cdot u' - (mx/b)\cdot \ddot{u} = p(x,t) \quad (7)$$

$$(EIx^4/b)\cdot w'''' + 8(EIx^3/b)\cdot w''' + 12(EIx^2/b)\cdot w'' + (mx/b)\cdot \ddot{w} = f(x,t) \quad (8)$$

Remark 1: By examining the uncoupling assertions more carefully, we see that omission of the shear force Q in Eq. (3) implies that $\partial w^3/\partial x^3 = 0$, i.e., we recover a polynomial solution in the spatial coordinate for the transverse displacement in the form of $w(x,t) = g_1(t)x^2 + g_2(t)x + g_3(t)$. A similar state of affairs exists if we neglect the axial force N in Eq. (4), i.e., we get $\partial u/\partial x = 0$ so that $u(x,t) = (a_1 t + a_2)x + (b_1 t + b_2)$. Strictly speaking therefore, Eq. (5) and (6) are no longer mathematically consistent with the original system of Eq. (3) and (4). In essence, what we assume is that axial and flexural vibrations in the waveguide are respectively induced by upwards/downwards travelling pressure (P) and horizontally polarized shear (SH) waves, without conversion from one wave type to another.

3.2 The frequency domain

For harmonic vibrations, we have the displacements as $w(x,t) = W(x)e^{i\omega t}$ and $u(x,t) = U(x)e^{i\omega t}$, where $e^{i\omega t} = \cos(\omega t) + i\sin(\omega t)$, and likewise for the external distributed forces, i.e., $f(x,t) = F(x)e^{i\omega t}$, $p(x,t) = P(x)e^{i\omega t}$. Then,

$$xU'' + U' + a^2 xU(x) = \tilde{P}(x),\ a^2 = (m\omega^2)/EA \quad (9)$$

$$x^4 W(x)'''' + 8x^3 W''' + 12x^2 W'' - \beta^4 xW(x) = \tilde{F}(x),\ \beta^4 = (m\omega^2)/EI \quad (10)$$

Note that both $a(\omega) = \omega/c_p$, $c_p = (E/\rho)^{-1/2}$ (the P-wave speed) and $\beta(\omega)$ are the usual real-valued wavenumbers associated with vibrations of prismatic beams. Also, $\tilde{P}$, $\tilde{F}$ are the scaled spatial variations of the external forces. If the above equations are normalized with respect to the leading derivative terms, we respectively recover a Bessel equation of zero order and an incomplete Euler equation of the fourth order, i.e.,

$$U'' + (1/x)\cdot U' + a^2 \cdot U = \tilde{P} \quad (11)$$
$$W(x)'''' + (8/x)W''' + (12/x^2)W'' - (\beta^4/x^3)W(x) = \tilde{F} \quad (12)$$

Remark 2: We note here that a quadratic variation of the mean radius $D/2$ of a circular cylindrical pylon of constant thickness t yields a complete Euler equation of the fourth order. This will be communicated in future work, since the quadratic variation is a more general representation that can replace the model of Eq. (2). For the above flexural vibration case, although the eigenfrequencies can still be recovered from Eq. (12), the key substitution that will give solutions of the type $W(x) = \sum B_i |x|^{mi}$, $i = 1\ldots4$ will not work.

3.3 Solution for axial vibrations

The homogeneous solutions to the Eq. (11) is

$$U(x) = A_1 J_0(ax) + A_2 Y_0(ax) \tag{13}$$

Where J_0, Y_0 respectively are the Bessel functions of zero order, first and second kind. Next, A_i are constants of integration to be determined from the boundary conditions. For the tapered waveguide with fixity at the base, we have that $U(x = b) = 0$, while for a traction-free condition at the top, we have that $N(x = a) = 0 \rightarrow U'(x = a) = 0$. The second boundary condition requires the first derivative of the displacement solution of Eq. (13). This is accomplished by noting that the spatial derivatives of the Bessel functions are given by the following expressions: $J'_0(ax) = -aJ_1(ax)$, $Y'_0(ax) = -aY_1(ax)$. Now, for the aforementioned homogeneous conditions, constants A_i can only be determined relative to each other. This is done using the displacement derivative evaluated at $x = b$ and setting it equal to zero. Back-substitution into Eq. (13) evaluated at $x = a$ and subsequently also setting it equal to zero yields the following transcendental equation

$$J_0(ab) - \{J_1(aa)/Y_1(aa)\} \cdot Y_0(ab) = 0 \tag{14}$$

An analytical solution for wave number $a_n = \omega_n/c_p$ values which are the roots of the above equation is not possible, and therefore the Newton-Raphson method is used with starting values being the eigenfrequencies ω_n of a reference pylon with constant cross-section. More specifically, if we consider a pylon whose cross-section matches that of the tapered pylon at its base, then $A = 2\pi db$, $m = \rho A$. Closed-form solutions for the displacement vector, the wave numbers, the eigenfrequencies and the eigenfunctions are as follows (Graff, 1975):

$$U(x) = A_1 \sin(ax) + A_2 \cos(ax),\ a_n = (2n - 1)\pi/(2L) \tag{15}$$
$$\omega_n = (2n - 1)\pi c_p/(2L), \quad \varphi_n(x) = \sin(a_n x), \quad n = 1,2,\ldots,\infty$$

Once the eigenfrequencies ω_n of the tapered pylon have been determined, then the corresponding eigenfunctions $\varphi_n(x)$ are the displacements given in Eq. (13), after substitution of the corresponding wave number a_n and with $A_1 = 1$, $A_2 = -J_1(aa)/Y_1(aa)$.

3.4 Modal analysis for axial vibrations

Modal analysis commences with the transformation from the physical displacement coordinates u to the generalized (or modal) coordinates q_i, $i = 1,2,3,\ldots$ by use of the eigenfunctions φ_i as follows:

$$u(x,t) = \sum_{i=1}^{\infty} \left(\varphi_i(x) \cdot q_i(t) \right) \tag{16}$$

Substitution of this expansion into the uncoupled form of the equation of motion, Eq. (4a), pre-multiplication by eigenfunction φ_j and integration over the length of the waveguide gives

$$\sum_{i=1}^{\infty} \left\{ \int_0^L \varphi_j(x) \cdot [EA(x)\varphi'_i(x)]' dx \cdot q_i(t) - \int_0^L \varphi_j(x) \cdot m(x) \cdot \varphi_i(x) dx \cdot \ddot{q}_i(t) \right\} = \sum_{j=1}^{\infty} \int_0^L \varphi_j(x) \cdot p(x,t) dx \tag{17}$$

We note that because of the orthogonality property of the eigenfunctions with respect to the stiffness $EA(x)$ as the weight function, the only non-zero terms remaining are when the two counters coalesce, i.e. $i = j$. This is now followed with integration by parts to shift the spatial derivatives ($'$) outside the brackets to the eigenfunctions $\varphi_i(x)$. Intermediate terms arising in the integration are zero because of the homogeneous spatial boundary conditions. The final result is a system of single degree-of-freedom (SDOF) equations of the form

$$[M]_i \cdot \{\ddot{q}(t)\}_i + [K]_i \cdot \{q(t)\}_i = \{P(t)\}_i \tag{18}$$

where the system matrices involve integration over the waveguide length as

$$[M_i] = \int_0^L m(x) \cdot \varphi^2{}_i(x) dx, \quad [K_i] = \int_0^L EA(x) \{\varphi''{}_i(x)\}^2 dx$$

$$\{P(t)\}_i = \int_0^L \varphi_i(x) \cdot p(x,t) dx$$

As with standard modal analysis, the accuracy achieved in solving for the displacement $u(x,t)$ depends on the number of generalized coordinates $q_i(t)$ retained in the series expansion, which from the previous eigenvalue analysis requires no more than four terms. Finally, the integrals over the length of the waveguide are evaluated by low order Gauss quadrature.

4 NUMERICAL EXAMPLE

We consider a thin-walled steel pylon used, e.g., in supporting electric cable lines for high-speed trains, see Fig. 1. The pylon cross-section has the shape of a ring with mean radius $R=D/2$ and constant thickness t. The length $L = (b - a)$ of the pylon under consideration comprises continuously welded segments for a total length of 12 m, while the base is fixed. Table 1 lists values for the modulus of elasticity E, Poisson's ratio v and the mass density ρ. At any given station $a \le x \le b$, the cross-sectional area is $A = 2\pi Rt$, the principal moment of inertia is $I = \pi R^3 t$ and the mass per unit length is $m = A\rho$. From this information, it is possible to compute both axial $EA(x)$ and flexural $EI(x)$ stiffness, as well as the mass $m(x)$ per length of the pylon. These quantities vary linearly with height for the mass and axial stiffness and cubically for the flexural stiffness, see Eq. (2), with the base of the pylon (btm) considered as the reference point.

4.1 Eigenvalue analysis for axial vibrations

As mentioned in sub-section 3.3, we introduce a cantilevered pylon with a constant cross-section whose configuration matches that of the non-homogenous pylon at the base to serve as benchmark for comparison purposes. We now compute its first five eigenfrequencies ω_i and their respective modal masses M_i and stiffnesses K_i, see the left column in Table 2 and also Fig. 3. Similarly, for the tapered pylon, we use the Newton-Raphson method to numerically solve the characteristic polynomial resulting from imposition of the homogeneous boundary conditions to the solution given in Eq. (13). Standard procedure of back-substitution of the recovered eigenfrequencies into the normalized displacement function gives the corresponding eigenfunctions. All these values appear as the right column of Table 2 and in Fig. 3. The computations regarding the tapered pylon were carried out in a Python programming environment [9] requiring negligible running times.

We note that axial vibrations occur at high frequencies, given that the first eigenfrequency of the uniform pylon is 108 Hz and that of the non-uniform one is 146 Hz. Also, the non-uniform pylon consistently has higher values for the eigenfrequencies, because of less mass as compared to the uniform pylon, all other things being equal. Regarding the presence of structural damping in the pylons, it is possible to introduce [10] a complex elasticity modulus in the form $E(1.0+i\eta\omega)$, where the structural damping coefficient η is in the range of 0.1%. This damping is in addition to the dispersion effects for the tapered pylon and results in complex number formalism for the ensuing numerical solution.

4.2 Comparisons with FEM models

The same cantilevered pylon is now modeled using two types of FEM representations, namely a 'stick' model comprising 2-noded beam elements with 6 degrees-of freedoms (DOF) per node and a 'shell' model comprising 4-noded shell elements with also 6 DOF per node [11]. The convergence study focuses on the axial vibration eigenvalues and examines the necessary number of finite elements along the length and breadth of the pylon to achieve convergence of the results.

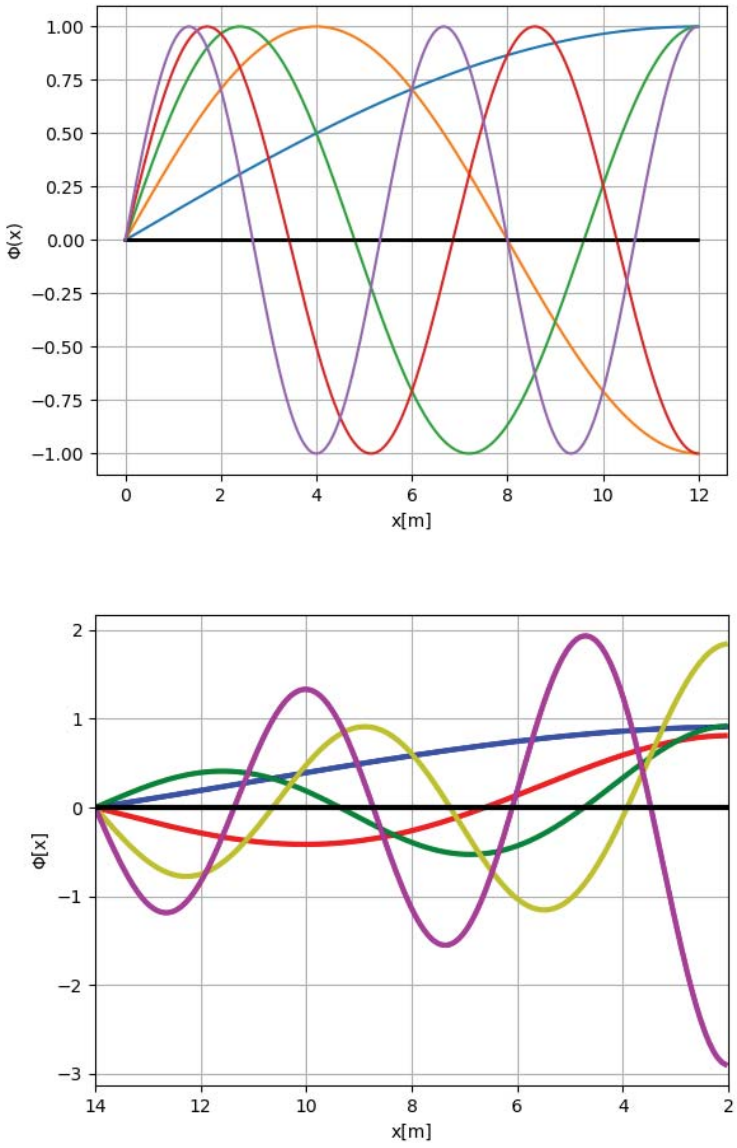

Figure 3: Steel pylon with (top) constant and (bottom) variable cross-section: The first five normalized eigenfunctions $\varphi_i(x)$. Legend: 1 = blue / 2 = red / 3 = green / 4 = yellow / 5 = purple

Starting with the 'stick' model, we begin with 10 uniformly spaced elements for the pylon yielding 60 DOF and reach a maximum of 100 elements resulting in 600 DOF. For the 'shell' model, the smallest acceptable mesh covers the circumference of the cross-section with 3 shell elements spanning 120° sectors each. Therefore, the comparable numbers for the 'shell' model start at 30 elements with 180 DOF and range up to 300 elements with 1800

DOF. Of course, the FEM 'shell' model yields vibration patterns that cannot be captured by the waveguide model, such as 'breathing' modes where the circumference's shape diverges from the original circular one. We see in Fig. 4 that roughly 20 finite elements per length are required in most cases before the eigenfrequencies start to converge, yielding a minimum finite element length of 50 cm. This holds true for both 'stick' and 'shell' models, and we observe that although both FEM models give identical results, they overshoot the analytical waveguide solution by about 2%.

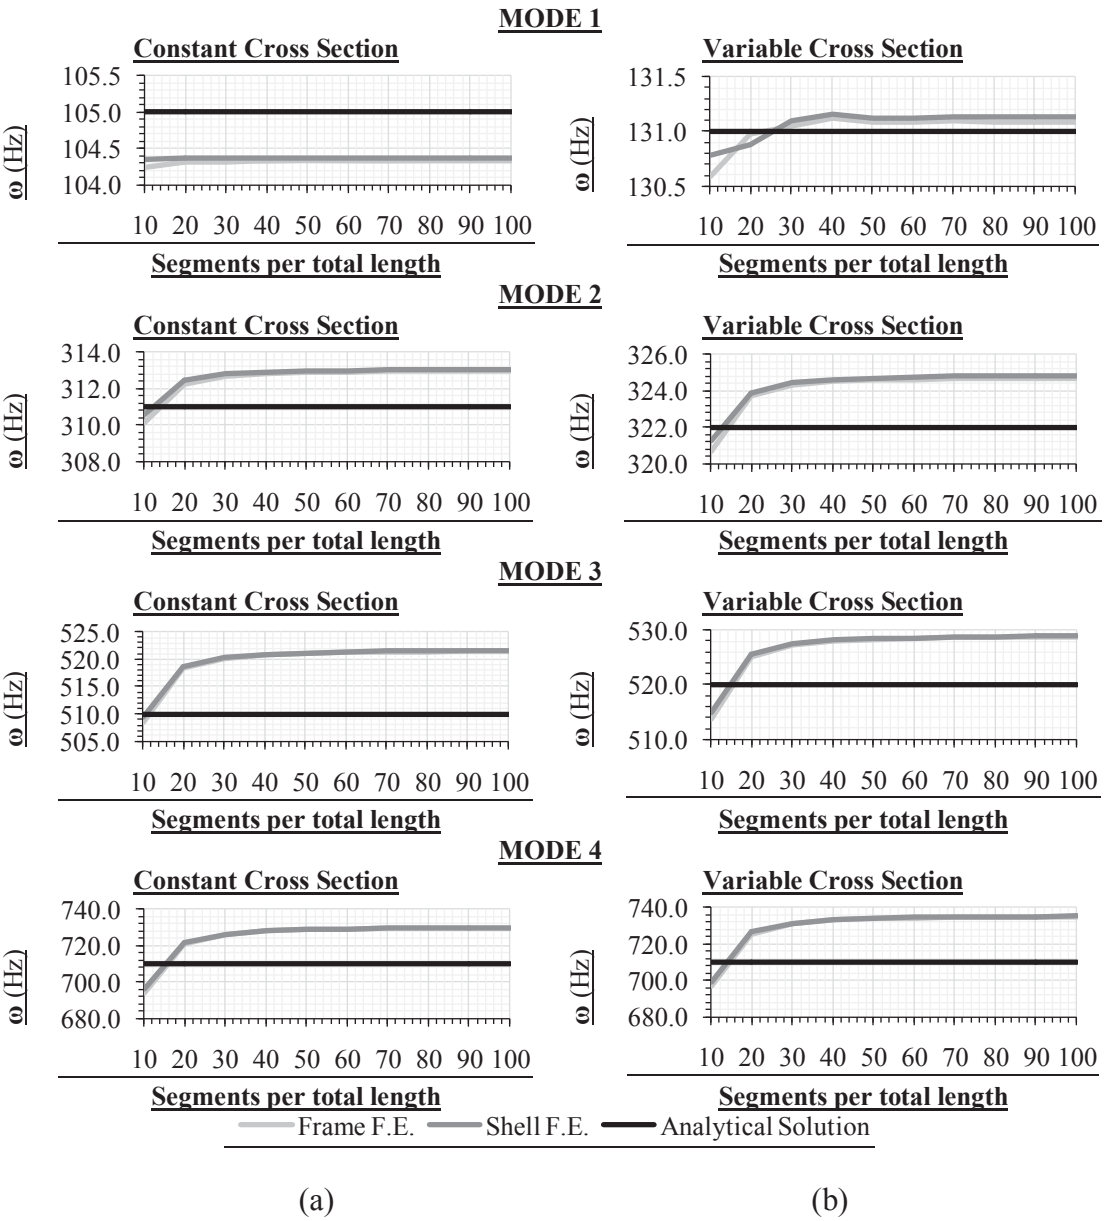

Figure 4: FEM convergence study on the first four axial eigenfrequencies for both (a) constant and (b) variable pylon cross-sections. Note: 3 shell finite elements are used to model the pylon circumference

4.3 Transient axial vibrations

We distinguish two types of quasi-harmonic external loads on pylons supporting electric lines that are generated by the passage of high speed trains: (i) High frequency base accelerations in the vertical direction (axial vibrations) in the range around 50 Hz resulting from the train's wheels running across rails that have minor imperfections; and (ii) low frequency base accelerations in the horizontal direction (flexural vibrations) in the range around 5 Hz as the train moves rapidly forward. Both cases lead to a forcing function in the form $p(x,t) = f(x,t) = -mg\sin(\Omega t)$, where g=9.81 m/s^2 is the acceleration of gravity and Ω (rad/s) is the external frequency of vibration. Focusing on axial vibrations, Fig. 5 is a parametric study summarizing the number of eigenfunctions necessary in the modal analysis to achieve convergence of the transient displacement at the top of the pylon, with the time axis ranging as $0 < t < 0.4$ s. We observe that as the external frequency of vibration increases, so does the number of eigenfunctions necessary for convergence. However, even three eigenfunctions are sufficient, provided the excitation frequency in the axial case does not exceed a value of $f = \Omega/2\pi = 300$ Hz.

5 CONCLUSIONS

An analytical model based on elastic waveguides was presented here for determining the dynamic vibrations of flexible structures such as antennas and pylons to environmentally induced loads. The stiffness of these structures may vary with height and both axial and flexural vibrations were considered, with torsional vibrations to be communicated in future work. These solutions are meant to replace large-scale FEM models for reasons of computational economy within the context of real-time data processing in wireless sensor nodes. This is a crucial step in SHM operations, whereby data streams are transmitted by the sensor nodes to a central processing unit only when calculations show that certain tolerance limits are exceed. These limits can be pre-set, but it is necessary to first quantify and then update them over the course of time. To this end, numerical models for monitored structures, which are both accurate and efficient in terms of computing power, must be introduced.

Keywords: nonlinear dynamics, negative stiffness, double-well Duffing oscillator, experimental identification, model updating.

Abstract. *Systems exhibiting a negative stiffness region are often used as vibration isolators, due to their enhanced damping properties. The device tested in this paper is part of a damping system and it acts like an asymmetric double-well Duffing oscillator, with two stable and one unstable equilibrium positions. The range of motion can either be bounded around one stable position (in-well oscillations) or include all the three positions (cross-well oscillations). Depending on the input amplitude, the oscillator can exhibit linear and nonlinear dynamics, and chaotic motion as well. Due to its asymmetrical design, the two linearized systems associated to small-amplitude oscillations around one stable equilibrium position are different. In this work, the dynamical behavior of the system is first investigated in the case of linear and nonlinear in-well oscillations and then in the case of cross-well oscillations with chaotic motion. To accomplish this task, the device is mounted on a shaking table and it is driven through several excitation levels with both harmonic and random inputs. An experimental bifurcation tracking analysis is also carried out to understand the possible response scenarios. Afterwards, the nonlinear identification is performed using nonlinear subspace algorithms to extract the restoring force of the system. Eventually, the physically-based model of the device is updated to match the identified characteristics via genetic algorithms.*

1 INTRODUCTION

Devices and materials based on a negative stiffness behavior are very often used as vibration isolators due to their amplified damping properties [1,2]. In particular, in the case of engineering structures, examples can be found in automotive suspensions [3,4] or seismic isolation [5,6].

When the negative stiffness effect is coupled to a nonlinear polynomial stiffness contribution, the so-called double-well Duffing oscillator is obtained, whose dynamical properties have been extensively studied in the literature due to the wide kind of motions it can exhibit, ranging from linear to highly nonlinear and chaotic [7]. This oscillator exhibits two stable and one unstable equilibrium positions, and the oscillations can either be bounded around one stable point (in-well or intra-well small oscillations) or include all the three positions (cross-well or infra-well large oscillations). In both cases, periodic oscillations can evolve to steady in-well or cross-well chaotic motions under external excitation [8]. The occurrence of irregular motion, consisting of random-like crossings from oscillations around the two stable equilibrium positions, was first observed experimentally in 1971 [9] and the motion was called "snap-through". A comprehensive literature review about the Duffing equation can be found in [10].

In this work, a negative stiffness oscillator is studied and tested to derive a reliable nonlinear dynamical model. The dynamical properties of the oscillator are first investigated to uncover the possible kind of motions it can exhibit (in-well, cross-well, chaotic). To accomplish this tasks, the device is mounted on a shaking table and it is driven through several excitation levels with harmonic and random inputs. The experimental bifurcation diagram is estimated, together with the attractor surface in the case of chaotic motion.

Afterward, nonlinear system identification is performed to extract the model parameters directly from the measurements. The nonlinear subspace identification (NSI) method [11–14] is adopted to identify the nonlinear restoring force of the system using just one cross-well measurement obtained with random excitation. Eventually, a model updating procedure is implemented with genetic algorithms to refine the physically-based model based on the identified restoring force.

2 NEGATIVE STIFFNESS OSCILLATOR

The device under investigation consists in a U-shaped steel frame connected through rods to a central moving mass. The frame has the purpose to keep the rods under compression during their movement, exerting a compression force $p(\theta)$ depending on the rotation angle θ. A schematic representation of the device is depicted in Figure 1.

It is assumed that the inertia of the moving parts can be concentrated into one central point with mass m, comprising the mass of the central bushing and the equivalent inertia of the rods. The vertical movement of this point is described by the coordinate $y(t)$. The lower surface of the frame is attached to a shaking table, so that displacement $b(t)$ can be imposed to the structure. The free-body-diagram of mass m is depicted in Figure 1.

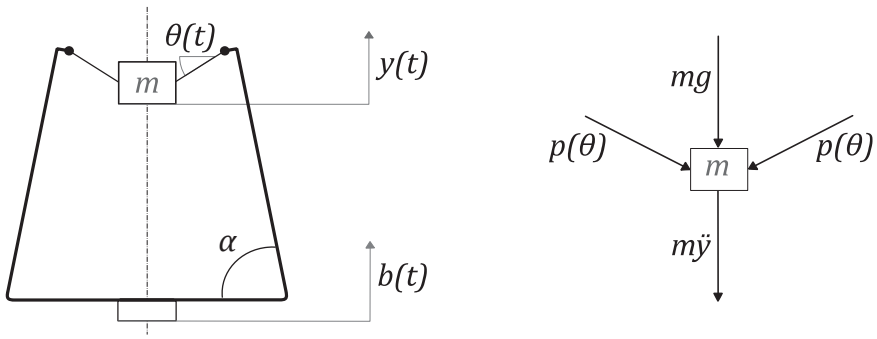

Figure 1: Schematic representation of the negative stiffness oscillator and free-body-diagram of *m*.

With $z(t) = y(t) - b(t)$, the equation of motion of the system in the variable z(t) can be written as

$$m\ddot{z} + k_3 z^3 + k_2 z^2 - k_1 z + k_0 = -m\ddot{b}, \tag{1}$$

where $k_0 = mg$ and the coefficients k_3, k_2, k_1 have to be experimentally estimated. Eq. (1) has the form of a negative-stiffness Duffing equation, and its restoring force K and elastic potential U can be defined as

$$K(z) = k_3 z^3 + k_2 z^2 - k_1 z + k_0, \tag{2}$$

$$U(z) = \frac{1}{4} k_3 z^4 + \frac{1}{3} k_2 z^3 - \frac{1}{2} k_1 z^2 + k_0 z. \tag{3}$$

A qualitative representation of the potential is shown in Figure 2, where its asymmetric double-well characteristic can be observed, together with the three equilibrium positions z^* obtained by setting $K(z^*) = 0$. Two out of three positions represent a stable equilibrium, namely z_-^* and z_+^*, while the central position z_0^* is an unstable point.

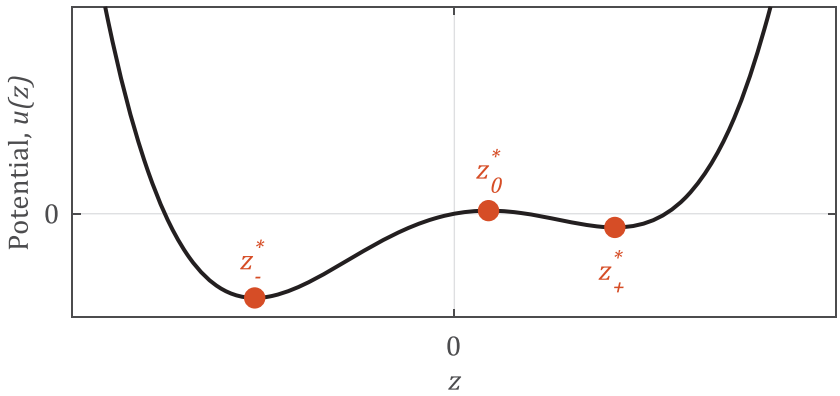

Figure 2: Potential $U(z)$. Orange dots: equilibrium positions.

The oscillations of the moving point are said to be *in-well* when the motion is bounded around one of the two stable equilibrium positions $z_{\pm}^{*}$. The associated linear natural frequency $\omega_{\pm}$ can be computed by

$$\omega_{\pm} = \sqrt{\frac{K'\left(z_{\pm}^{*}\right)}{m}}, \tag{4}$$

$K'\left(z_{\pm}^{*}\right)$ being the derivative of $K(z)$ computed in z_{-}^{*} or z_{+}^{*}.

3 EXPERIMENTAL CHARACTERIZATION

Two photos of the experimental setup corresponding to the two stable equilibrium positions are reported in Figure 3. The moving mass is instrumented with a laser vibrometer to measure its absolute displacement $y(t)$, whose zero position corresponds to the horizontal configuration of the rods ($\theta = 0$). The acceleration of the base $\ddot{b}(t)$ is also recorded through an accelerometer and the displacement $z(t)$ is computed as the difference between the laser measure $y(t)$ and the displacement of the base $b(t)$, obtained by integrating twice its measured acceleration.

The system is driven by harmonic inputs with fixed excitation frequency $\omega = 9 \cdot 2\pi$ rad/s and different amplitudes. The measured signals are sampled at 512 Hz. By applying this set of harmonic excitations, the so-called *bifurcation map* of the system can be built for a specific excitation frequency. The bifurcation map is a snapshot of the kind of steady-state solutions that can be obtained for a given excitation frequency when ranging over the excitation amplitude. Each point in the map represents the amplitude(s) of the steady-state solution for a specific value of the excitation amplitude. Indeed, the system can in principle exhibit super-harmonics of the exciting frequency (meaning frequency contents at $2\omega, 3\omega, 4\omega, \ldots$), sub-harmonics ($1/2\ \omega, 1/3\ \omega, 1/4\ \omega, \ldots$) or chaotic motion.

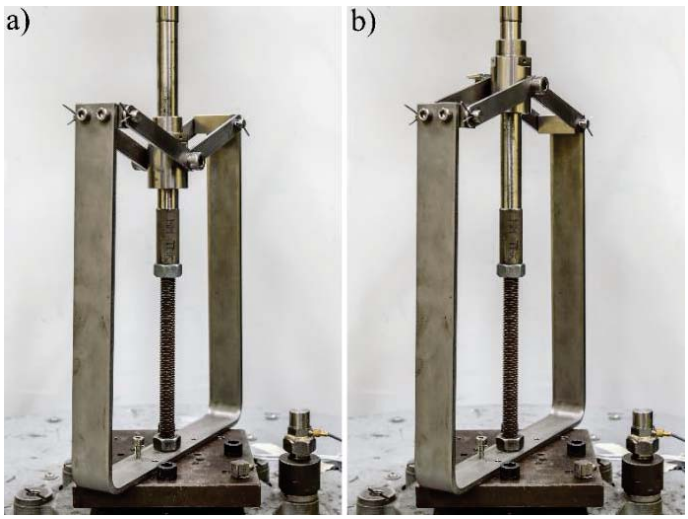

Figure 3: Photos of the experimental setup. a) Negative equilibrium position z_{-}^{*}; b) Positive equilibrium position z_{+}^{*}.

When building the bifurcation map on experimental time series, one should be able to detect the presence of super/sub-harmonics in order to correctly estimate the amplitude(s) of the response. This is done in this work automatically by performing a periodicity analysis of the measured displacement $z(t)$ over a certain number of periods of the input force. The algorithm seeks the number of periods that gives the *best* periodicity of the output signal:

- A *period-1* solution is gathered if the output is periodic with the input. The system in this case might respond with higher harmonics of the excitation frequency ω.
- A *period-2* solution is gathered if the output is periodic with twice the period of the input. The system in this case responds also with the sub-harmonic $1/2\ \omega$.
- A *period-4* solution is gathered if the output is periodic with four times the period of the input. The system in this case responds also with the sub-harmonics $1/2\ \omega, 1/4\ \omega$.
- ...

The experimental bifurcation map is depicted in Figure 4, where the cross-well region is highlighted in grey. Since the map is inferred from experimental measurements, it is not intended to be an exhaustive representation of all the possible bifurcations of the system, as it would be rather difficult to experimentally collect the huge number of points that would be required. Nevertheless, it gives useful information about the range of motions the system exhibits for different input amplitudes. In particular, a cascade of period doublings can be appreciated when the input amplitude is around $12 - 15\ \mathrm{m/s^2}$, especially when starting from the positive equilibrium position ($z_+^* = 0.023$ m).

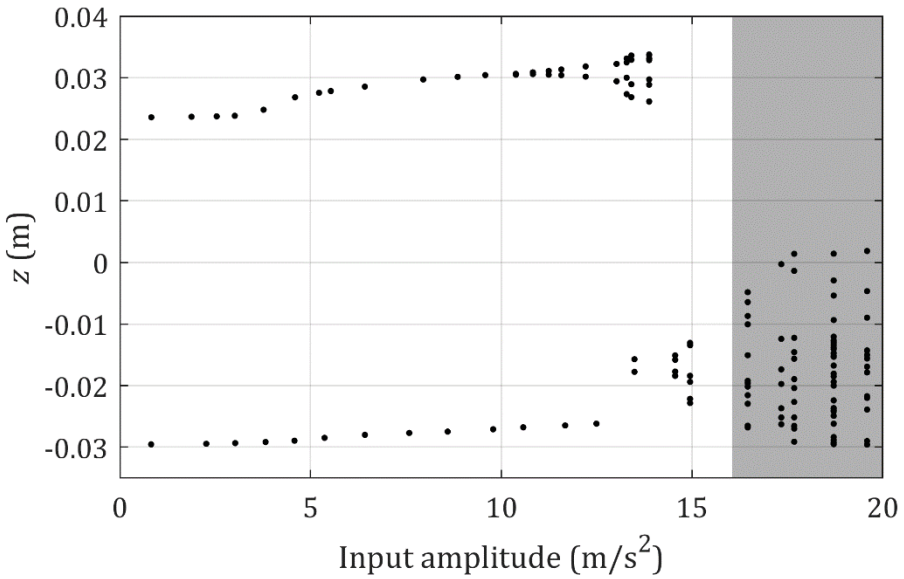

Figure 4: Experimental bifurcation map of the system. The chaotic region is highlighted in grey.

The time series and phase diagrams of some of the points of the bifurcation map are depicted in Figure 5. The selected phase diagrams correspond respectively to a period-1 solution, a period-2 solution, a period-4 solution and to a cross-well motion of the system. The latter in particular can be called *chaotic* in this context, as no periodic solution to a periodic input is retrieved, and this behavior lasts for the entire acquisition time (10 minutes).

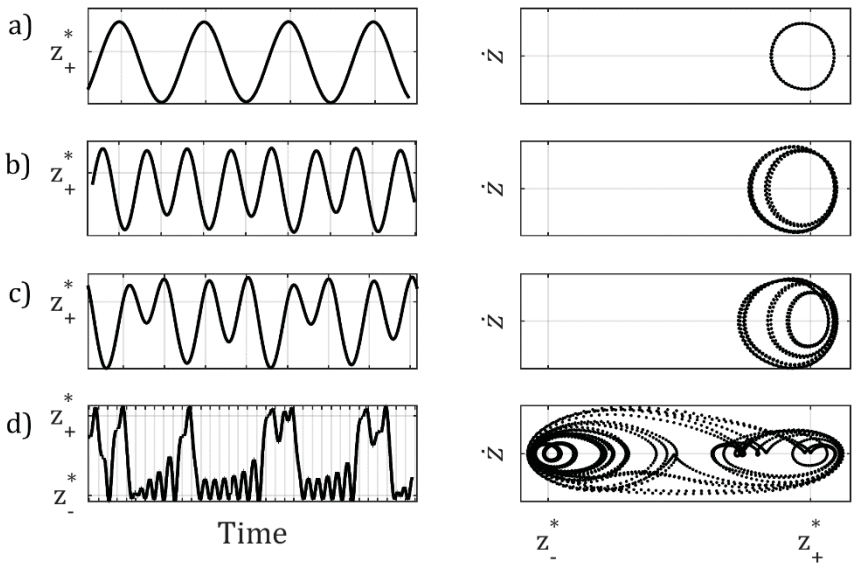

Figure 5: Time series and corresponding phase diagrams of selected measurements. a) Period-1 solution. b) Period-2 solution. c) Period-4 solution. d) Cross-well motion.

It should be recalled that no definition of *chaos* is universally accepted, and this is particularly true when experimental data is considered. The reason is that uncertainties and noise in the data acquisition may interfere with the extreme sensitivity to the initial conditions that characterizes chaotic systems.

The well-known LLE (largest Lyapunov exponent) [15] can be used to check whether the system is behaving chaotically or not: a positive sign means chaotic motion, while a negative sign is representative of a periodic orbit. Several methods exist to compute the LLE from experimental time series, and the one proposed in [16] is adopted here. Results are shown in Figure 6, where a positive sign is retrieved.

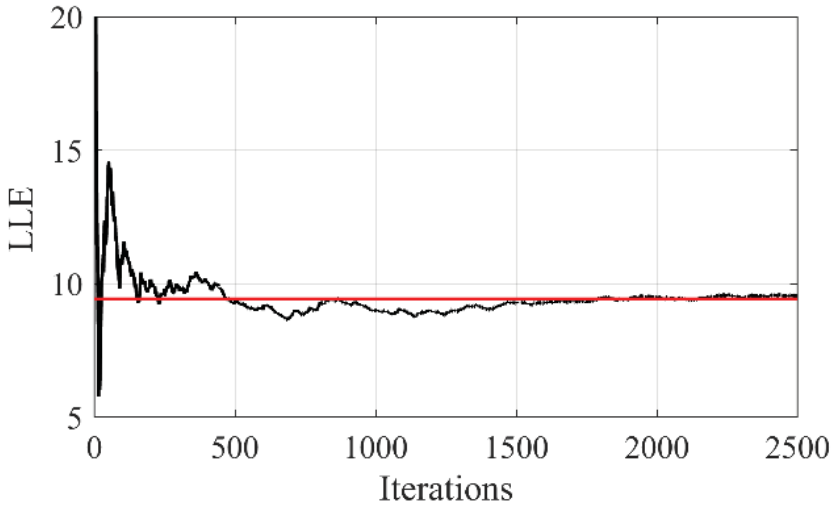

Figure 6: Estimation of the largest Lyapunov exponent. Red line: convergence mean value.

Eventually, the experimental Poincaré sections are computed for different phase synchronizations ϕ of the data with the forcing term [17]. The typical shape of a strange attractor is retrieved [8] and depicted in Figure 7a in a polar plot, while three of its sections are represented in Figure 7b,c,d.

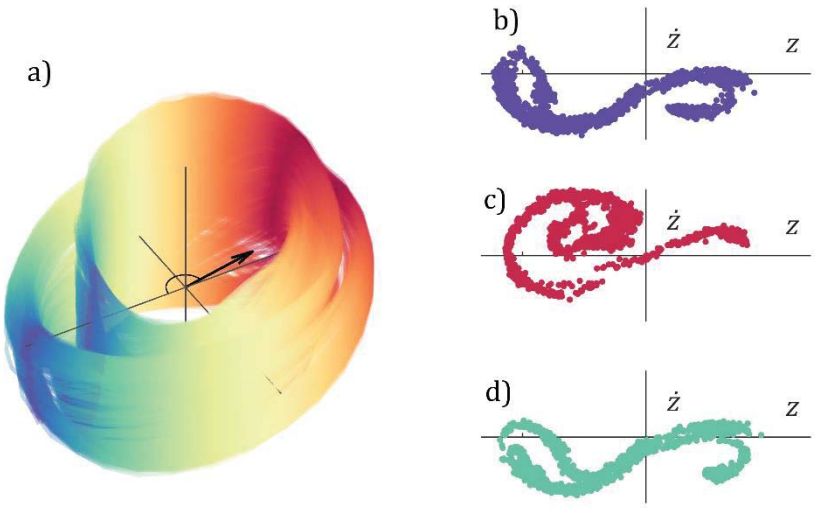

Figure 7: Experimental Poincaré sections. a) Polar representation of the attractor surface; b) Poincaré section, $\phi = 0°$; c) Poincaré section, $\phi = 170°$; d) Poincaré section, $\phi = 320°$.

4 IDENTIFICATION OF THE NONLINEAR RESTORING FORCE AND MODEL UPDATING

The nonlinear subspace identification (NSI) method is adopted in the following to identify the nonlinear state-space model of the system, with the final purpose of estimating its restoring force. NSI relies on the possibility of splitting the nonlinear equation of motion into an underlying-linear (and stable) system (ULS) and a nonlinear feedback. By looking at Eq. (1), this seems not to be possible for the considered system, as the negative linear stiffness creates an unstable ULS. Nevertheless, a workaround can be found by shifting the reference axis and considering the oscillations of the moving point around one *reference position*. This reference position is chosen as one of the two stable equilibrium points $z_{\pm}^{*}$, and it is generally referred to as z^{*}. A new variable $x(t)$ can therefore be defined as

$$x(t) = z(t) - z^{*}, \tag{5}$$

so as to write the equation of motion in the variable x

$$m\ddot{x} + K(x + z^{*}) = -m\ddot{b}, \tag{6}$$

with

$$K(x+z^*) = k_3x^3 + (k_2 + 3k_3z^*)x^2 + \left(3k_3z^{*2} + 2k_2z^* - k_1\right)x \\ = k_3x^3 + \tilde{k}_2x^2 + \tilde{k}_1x. \tag{7}$$

The new coefficients of the restoring force to be identified are therefore k_3, $\tilde{k}_2$ and $\tilde{k}_1$. Also, a nonlinear damping model of the kind $c^{nl}\dot{x}(t)|\dot{x}(t)|$ is sought by the method in addition to a linear viscous damping $c\dot{x}$, to account for the dissipation that comes with the relative motion between the moving point and the vertical steel guide.

Indeed, the ULS depends on the choice of the reference position z^*, therefore:

- When $z^* = z_-^*$ the modal parameters of the underlying-linear small oscillations around the *negative* equilibrium position can be estimated;
- When $z^* = z_+^*$ the modal parameters of the underlying-linear small oscillations around the *positive* equilibrium position can be estimated;

Consequently, two mutually exclusive ULSs can be obtained with NSI. For this reason, a single cross-well measurement under random excitation is fed to the NSI algorithm with two consecutive choices of the reference position: namely $z^* = z_-^*$ and $z^* = z_+^*$. The measurement is sampled at 512 Hz and lasts 300 s, with the last 60 s used for validation purposes.

A model order equal to 2 is chosen for the nonlinear state-space identification, the system being a single-degree-of-freedom system, and the corresponding modal parameters are listed in Table 1.

Reference position	Natural frequency (Hz)	Damping ratio (%)
z_-^*	11.41	11.2
z_+^*	9.19	20.3

Table 1: Modal parameters of the two underlying linear systems identified with NSI.

The validation of the identified model is carried out by simulating the output of the system $x^{SIM}(t)$ with the identified nonlinear state-space model, given the measured input. The simulated and the measured outputs are then compared to estimate the modeling error. Results are reported in Figure 8 in terms of simulated and measured time histories, in time and frequency domains. The statistical parameters of the residual between the measured output $x(t)$ and the simulated one $x^{SIM}(t)$ are listed in Table 2. Generally, the identified state-space model is capable of catching the cross-well motion with a very good accuracy, providing a percentage RMS deviation from the measurement of approximately 8%.

Once the identified model is validated, the coefficients of the nonlinear restoring force can be extracted [11–14], obtaining:

$$K(x+z^*) = k_3x^3 + \tilde{k}_2x^2 + \tilde{k}_1x \\ = 7.35 \cdot 10^5\, x^3 - 6.45 \cdot 10^3\, x^2 + 1.34 \cdot 10^3\, x. \tag{8}$$

The identified restoring force K and the corresponding potential U are depicted in Figure 9a,b. As for the nonlinear damping coefficient c^{nl}, a value of $-5\ \mathrm{Ns^2/m^2}$ is obtained. The total damping force $D(\dot{z}) = c\dot{z} + c^{nl}\dot{z}|\dot{z}|$ is depicted in Figure 9c.

Residual mean (mm)	Residual standard deviation (mm)

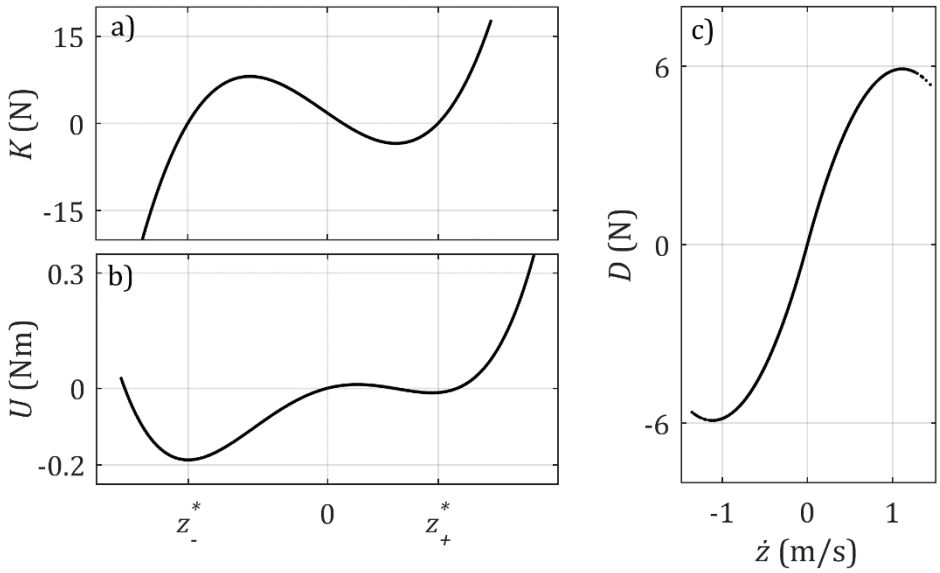

Figure 9: Estimation of the restoring force K (a), the corresponding potential U (b) and the damping force D (c).

4.1 Model updating

Once the parameters of the restoring force have been estimated from the experimental measurements, a comparison with the originally designed values is carried out to validate the model. A model updating procedure is implemented to adjust the physical parameters of the model and minimize the difference between simulated and identified behaviors. A genetic algorithm (GA) [18] is adopted to find the global optimum set of parameters. Genetic algorithms offer the chance to effectively update the model parameters, by exploring the range of feasible values in a smart and fast way. Also, crossover and mutation operators reduce the risk of falling into local minima [18]. The selected fitness function ϵ to be minimized is defined as the sum of two relative error functions ϵ_ω and ϵ_{z^*}. The function ϵ_ω is associated to the residuals on the positive and negative natural frequencies $\omega_\pm$, while ϵ_{z^*} is related to the residuals on the positive and negative equilibrium positions:

$$\epsilon_\omega = \mathrm{RMS}\left\{100\left|\frac{(\omega_-^{MOD} - \omega_-^{EST})}{\omega_-^{EST}}\right|, 100\left|\frac{(\omega_+^{MOD} - \omega_+^{EST})}{\omega_+^{EST}}\right|\right\}$$
$$\epsilon_{z^*} = \mathrm{RMS}\left\{100\left|\frac{(z_-^{*MOD} - z_-^{*EST})}{z_-^{*EST}}\right|, 100\left|\frac{(z_+^{*MOD} - z_+^{*EST})}{z_+^{*EST}}\right|\right\} \tag{9}$$
$$\epsilon = \epsilon_\omega + \epsilon_{z^*}$$

The superscripts *MOD* and *EST* stand respectively for "model" and "estimation". In particular, the estimated natural frequencies $\omega_\pm^{EST}$ are the ones listed in Table 1. The parameters to be optimized are the Young's modulus E of the frame, the frame angle α and the moving mass m. The values of the fitness function across the generations of GA are shown in Figure 10, while the final result is depicted in Figure 11.

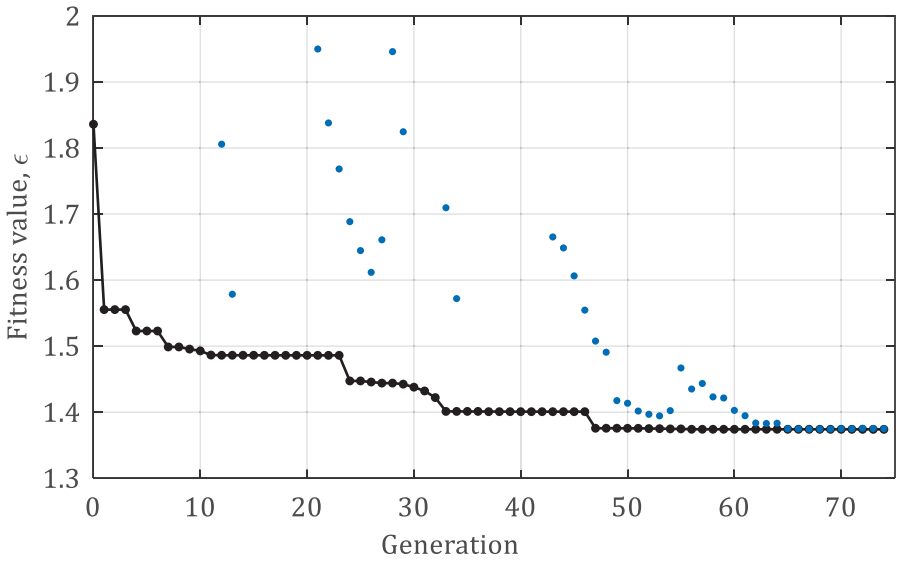

Figure 10: Values of the fitness function across the generations of GA. Black line: best fitness; blue dots: mean fitness values.

The optimization reduces the residual between the experimental characteristics and the model prediction, providing a good match between the final restoring force and potential curves, with a residual ϵ equal to 1.38%.

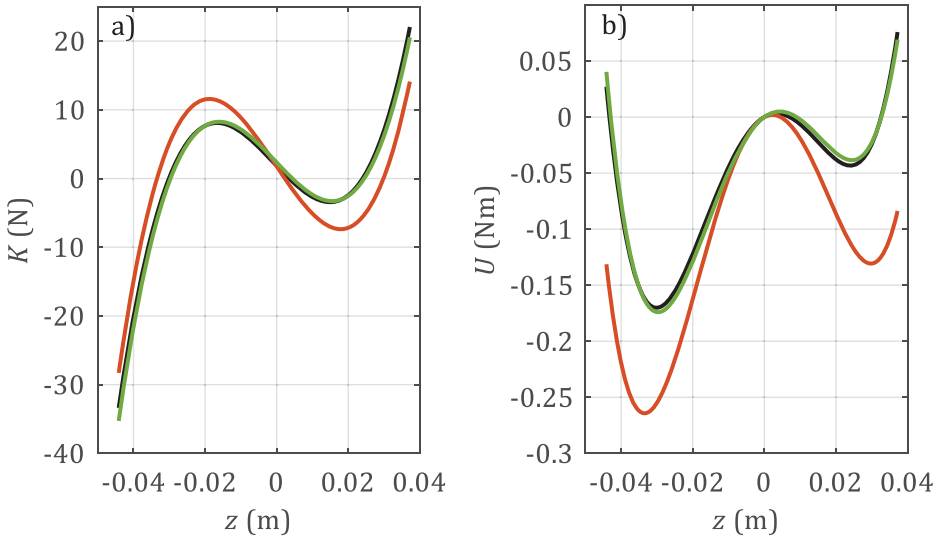

Figure 11: Results of the optimization in terms of restoring force in (a) and potential in (b). Black line: identified curves; orange line: starting values; green line: final values.

5 CONCLUSIONS

A negative stiffness oscillator has been characterized experimentally to exploit its dynamical behavior. A variety of different kind of motions can be obtained because of the bi-stable nature of the device, from in-well to cross-well oscillations, including chaotic motion. These dynamical behaviors have been confirmed by the experimental observations, obtained with harmonic inputs. The bifurcation map of the system has been estimated, together with the attractor surface in the case of chaotic motion. Eventually, the nonlinear restoring force of the system has been identified from the measured time series by applying the nonlinear subspace identification method, and the physically-based model of the device updated via genetic algorithm to match the experimental results.

Keywords: stepped beam, transvers vibration, nonlinear vibration, forced vibration

Abstract. *Stepped beams like structures are extensively used in several mechanical and civil engineering fields, such as for high-rise buildings, robot arms, etc. The objective of the current study is to analyse the geometrically non-linear behaviour of free and forced multi-stepped Euler-Bernouilli beams. The first part consists on determining the multi-stepped beam natural frequencies and associated mode shapes, which constitute the basic functions used afterwards in the non-linear theory. The effect of geometrical non-linearity is based on the Von Karman's assumptions. By deriving the discretized expressions of linear and nonlinear strain and kinetic energies, Hamilton's principle is used to reduce the problem to a non-linear algebraic system solved by means of approximate methods. This leads to the determination of the non-linear modes and their corresponding curvatures, illustrated by application examples showing the effect of geometrical non-linearity on the dynamic behaviour of multi-stepped beams. The effect of the variation of the cross section area and second moment of inertia is also examined. Considering forced vibrations, the single mode approach is used to obtain the non-linear frequency response function in the vicinity of the predominant mode. The effects of the variation in the type of the stepped beam cross section and corresponding parameter ratios are investigated and illustrated by specific application cases.*

1 INTRODUCTION

In many structures encountred in aeronautical, civil or mechanical engineering, stepped beams are used to support loads, transmit motion or to reinforce the entire system. Often in their operation, these types of beams are subjected to vibrations, either free or forced, which require a study in order to be able and predict their dynamic behaviour. Many works have examined the behaviour of this type of beams under various end conditions and under different types of loads.

A review of the literature goes back to N. J. TALEB and E. W. SUPPIGER who applied the Cauchy function method to obtain an approximation of the fundamental frequency and modal configuration of the free transverse vibration of the beams [1]. Balasubramanian and Subramanian studied the performance of a four-degree-of-freedom-per-node element for the vibration analysis of uniform and multi-step beams [2]. S. Naguleswaran gave a brief overview of the work on stepped and multi-stepped beams in [3]. He also examined different cases of vibration of stepped beams in [4,5,6]. In [7,8], MAO used the Adomian Decomposition Method (ADM) to study the free vibration of a stepped beam with two and more uniform sections. Suddoung, Charoensuk and Wattanasakulpong studied the free vibration response of stepped beams made of a functionally graded material (FGM), supported by various types of elastic elements at the ends. In order to obtain the natural frequencies and mode shapes, the solution of the differential equation of motion was performed by the differential transformation method denoted as DTM [9]. R.M. Lin and T.Y. Ng presented in [10] a new method for the calculation of the natural frequencies and mode shapes for the case of free vibration, which is ideally suited for forced vibration applications according to the author.

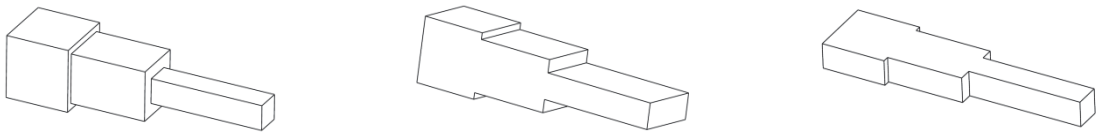
While most studies on stepped beams have focused on linear vibration analysis, only two works have been found which considered the effect of non-linearity. Sato [11] analysed the non-linear free vibration of stepped beams using the transfer matrix method. Nuttawit Wattanasakulpong and Arisara Chaikittiratana used the Adomian modified decomposition method to study the problems of linear and nonlinear free vibration of stepped beams [12].

None of the works cited above has examined the nonlinear forced response of multi-stepped beams. The purpose of this paper is to present a contribution to the analysis of geometrically nonlinear free and forced vibration of multi-stepped beams assuming Euler-Bernoulli's and Von Karman's hypotheses. The first part consists on determining the stepped beam natural frequencies and associated mode shapes, which are used as basic functions in the non-linear theory. Discretized expressions of the nonlinear and linear strain and kinetic energies are derived, and Hamilton principle is used to reduce the problem to a non-linear algebraic system solved by an approximate method. This leads to determination of the non-linear modes and their corresponding curvatures, which are then illustrated to show the effect of non-linearity on the dynamic behaviour of beams examined. The effect of cross-sectional variation is also examined. Forced vibrations are then examined using the single mode approach to obtain the non-linear frequency response functions are obtained in the neghborhood of the predominant mode. The impact of the variation in the cross section area and second moment of inertia at each step is then illustrated in the forced case.

2 GENERAL FORMULATION

2.1 Linear formulation

The present study concerns three homogeneous Euler-Bernoulli beams shown in Figure 1, characterized by a double change in the rectangulair cross-section. In the first beam (a), the width varies; in the second (b), the height varies, and in the third beam (c), both dimensions vary. For the rest of the study, the beams are suupposed to be fully clamped and are subjected to transverse vibrations.



Beam (a) Beam (b) Beam (c)

Figure 1: Three representative cases of the stepped beams examined.

The figure below shows that each of the multi-stepped beams is clamped at both ends and partitioned to three uniform rectangular cross-section subbeams.

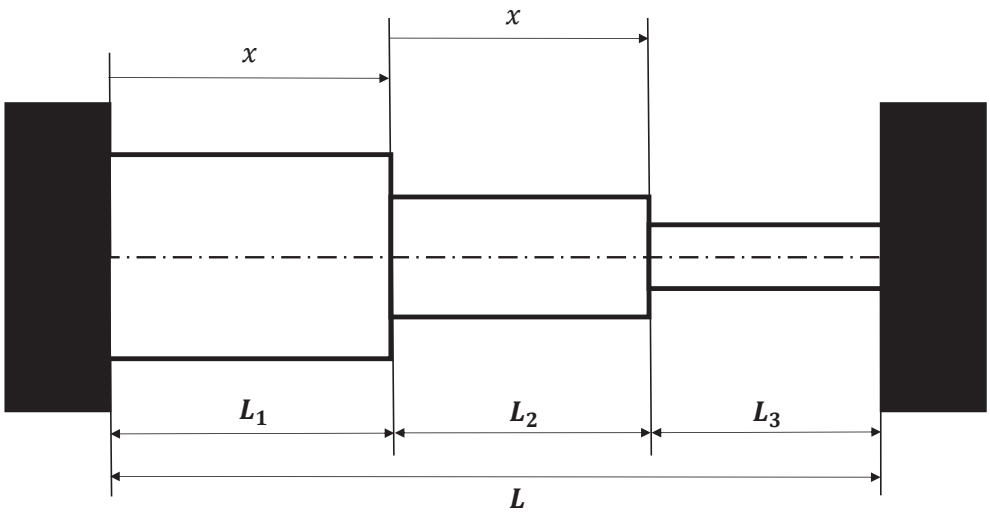


Figure 2: The coordinate system for a stepped beam.

The mechanical and geometrical characteristics of the beams are given in Table1.

	1st subbeam	2nd subbeam	3th subbeam
The length	L_1	L_2	L_3
The young's modulus	E_1	E_2	E_3
The area of cross-section	S_1	S_2	S_3
The second moment of inertia of cross-section	I_1	I_2	I_3
The mass per unit length	ρ_1	ρ_2	ρ_3
The thickness	H_1	H_2	H_3
The eigenvalue parameters	β_1	β_2	β_3
Radius of gyration	$\mathscr{R}_1$	$\mathscr{R}_2$	$\mathscr{R}_3$

Table 1: Characteristics of the three subbeams

The free transverse vibration in each subbeam is governed by the following equation:

$$\frac{d^4 W_i(x)}{dx^4} - \beta_i^4 W_i(x) = 0 \qquad ; x \epsilon [0\ L] \qquad \text{(For i=1,2…, 12)} \tag{1}$$

Where

$$\beta_{ij}^4 = \omega_i^2 \frac{\rho_j S_j}{E_j I_j} \qquad \text{(For j=1 to 3)} \tag{2}$$

Substituting the non-dimensional parameters in eq (2), one obtains the following equation:

$$\frac{d^4 W_i(x^*)}{dx^{*4}} - \beta_i^4 W_i(x^*) = 0 \qquad ; x^* \epsilon [0\ 1] \tag{3}$$

Where

$$x_j^* = \frac{x_j}{L}; R_j^* = \frac{L_j}{L} \quad ; z_j = \frac{\beta_{ij}}{\beta_{i1}}; u_j = \frac{S_j}{S_1}; v_j = \frac{I_j}{I_1} \tag{4}$$

Each step of the beam is defined by the ratio of the cross-section area, the ratio of the second moment of inertia and the eigenvalue parameters (u_j, v_j and z_j). The general solution of eq. (2) may be expressed in each span as:

$$W_i(x^*) = \left\{ \begin{array}{c} W_{ij}(x^*) \rightarrow \{ x_{j-1}^* \le x^* \le x_j^* \} \\ \cdots \\ \cdots \end{array} \right\}$$

$$W_{ij}(x^*) = A_j \cosh\left(\beta_{ij} L\left(x^* - x_{j-1}^*\right)\right) + B_j \sinh\left(\beta_{ij} L\left(x^* - x_{j-1}^*\right)\right) + C_j \cos\left(\beta_{ij} L\left(x^* - x_{j-1}^*\right)\right) + D_j \sin\left(\beta_{ij} L\left(x^* - x_{j-1}^*\right)\right) \tag{5}$$

The satisfaction of the compatibility conditions, at each change of cross-section, as well as the end conditions leads to a homogeneous system.

The end conditions at the left side:

$$W_{i1}(x^*)\Big|_{x^*=0} = 0 \quad ; \frac{dW_{i1}(x^*)}{dx^*}\Big|_{x^*=0} = 0 \tag{6, 7}$$

The end conditions at the right side:

$$W_{i3}(x^*)\Big|_{x^*=0} = 0 \quad ; \frac{dW_{i3}(x^*)}{dx^*}\Big|_{x^*=1} = 0 \tag{8, 9}$$

The compatibility conditions at a change of cross-section are given by:

$$W_{ij}(x^*)\Big|_{x^*=x_j^*} = W_{ij+1}(x^*)\Big|_{x^*=x_j^*} \tag{10}$$

$$\left.\frac{dW_{ij}\left(x^*\right)}{dx^*}\right|_{x^*=x_j^*} = \left.\frac{dW_{ij+1}\left(x^*\right)}{dx^*}\right|_{x^*=x_j^*} \tag{11}$$

$$EI_j \left.\frac{d^2W_{ij}\left(x^*\right)}{dx^{*2}}\right|_{x^*=x_j^*} = EI_{j+1} \left.\frac{d^2W_{ij+1}\left(x^*\right)}{dx^{*2}}\right|_{x^*=x_j^*} \tag{12}$$

$$EI_j \left.\frac{d^2W_{ij}\left(x^*\right)}{dx^{*2}}\right|_{x^*=x_j^*} = EI_{j+1} \left.\frac{d^2W_{ij+1}\left(x^*\right)}{dx^{*2}}\right|_{x^*=x_j^*} \tag{13}$$

The homogeneous system, obtained by satisfying the compatibility and end conditions, is solved by means of the Newton-Raphson algorithm and gives the non-trivial solutions that constitute the natural frequencies beam.

2.2 Nonlinear formulation

2.2.1 Free vibration

The total strain energy V of the beam can be written as:

$$\boldsymbol{V} = \boldsymbol{V_a} + \boldsymbol{V_f} \tag{14}$$

Where $\boldsymbol{V_a}$ is the axial strain energy due to the nonlinear axial forces induced by the large vibration amplitudes and $\boldsymbol{V_f}$ is the strain energy due to bending, expressed as:

$$V_f = \frac{1}{2}\int_0^L E\ I(x)\left(\frac{\delta^2 w}{\delta x^2}\right)^2 dx;\ V_a = \frac{E}{8L}\cdot\left(\int_0^L S(x)\left(\frac{\delta w}{\delta x}\right)^2\right)^2 dx \tag{15, 16}$$

The kinetic energy, denoted by T can be expressed as:

$$T = \frac{1}{2}\rho \int_0^L S(x)\left(\frac{\delta w}{\delta t}\right)^2 dx \tag{17}$$

Assuming harmonic motion and expanding the transverse displacement(w) in the form of a finite series of basic spatial functions, one may write:

$$w(x,t) = a_i W_i(x)\sin(\omega t) \tag{18}$$

Where the a_i are the basic functions contribution coefficients, which vary from [0.1 to 2] with a step of (0.1) . Using the form of w in equation (18), the expressions for total strain and kinetic energy can be written as follows:

$$T = \frac{1}{2}\ \omega^2\, a_i a_i \left(\ \cos(\omega t)\right)^2 M_{ij} \tag{19}$$

$$V = \frac{1}{2}\, a_i a_j\, a_k\, a_l\, (\sin(\omega t))^4 B_{ijkl} + \frac{1}{2}\, a_i a_i \left(\sin(\omega t)\right)^2 K_{ij} \tag{20}$$

In which M_{ij} , K_{ij} and B_{ijkl} are the mass matrix, the rigidity matrix and the nonlinearity tensor. It is well known that the dynamic behaviour of a conservative system can be expressed using Hamilton's principle as:

$$\delta \int_0^{\frac{2\omega}{t}} (V - T)\, dt = 0 \tag{21}$$

After substitution of equations (19 and 20) in equation (21), the mathematical development leads to:

$$2[K]\{A\} + 3\left[B\left(\{A\}\right)\right]\{A\} - 2\omega^2\, [M]\{A\} = 0 \tag{22}$$

Before determining the column vector of the contribution coefficients {A} and the frequency (ω) which are unknowns, equation (22) is put in its dimensionless form by replacing the dimensional parameters with the following parameters.

$$\frac{W_i(x^*)}{W_i^*(x^*)} = \mathscr{R}_{/}; \frac{\omega^2}{\omega^{*2}} = \frac{E I_1}{\rho S_1 L^4}\ ; \frac{M_{ij}}{M_{ij}^*} = \rho S_1 H_1^{\,2} \tag{23, 24, 25}$$

$$K_{ij} = \frac{E I_1 H_1^{\,2}}{L^3} K_{ij}^*; B_{ijkl} = \frac{E I_1 H_1^{\,2}}{L^3} B_{ijkl}^{\,*} \tag{26, 27}$$

The substitution of the above equations equation (22) gives:

$$\left[K^*\right]\{A\} + \frac{3}{2}\left[B^*\left(\{A\}\right)\right]\{A\} - \omega^{*2}\, [M^*]\{A\} = 0 \tag{28}$$

If geometrically nonlinear free vibration is examined, equation (28) is solved by the so-called second formulation, previously developed by M. EL KADIRI AND R. BENAMAR in reference [13].

2.2.2 Forced vibration

To study non-linear forced vibrations, the multi-step beam is supposed to be excited by a concentrated harmonic force, located at the point x0. The concentrated harmonic force can be expressed as in ref [14] by:

$$\mathrm{F}_i^c = F^c \cos(\omega t)\, w_i(x_0) = \mathrm{f}_i^c \cos(\omega t) \tag{29}$$

In order to study of the system dynamic behaviour, Hamilton's principle is applied, with additioN of the term due to the concentrated force, which gives, as in ref[15] :

$$\delta \int_0^{\frac{2\omega}{t}} (V - T + F)\, dt = 0 \tag{30}$$

Substituting equations (19, 20 and 29) in equation (30), leads to the following equation:

$$2[K]\{A\} + 3\left[B\left(\{A\}\right)\right]\{A\} - 2\omega^2\, [M]\{A\} = \left\{F^c\right\} \tag{31}$$

Equation (31) is made dimensionless by putting the dimensionless parameters (23, 24, 25, 26 and 27) in equation (31) to get:

$$\left[K^*\right]\{A\}+\frac{3}{2}\left[B^*\left(\{A\}\right)\right]\{A\}-\omega^{*2}\,[M^*]\{A\}=\left\{F^{c*}\right\} \tag{32}$$

Where f_i^{c*} is the dimensionless force that can be written as:

$$f_i^{c*}=\frac{L^3}{E\,I_1}F^c w_i^*\left(x_0\right) \tag{33}$$

Equation (32) was solved by a method called the single mode approach, presented by M.EL KADIRI AND R. BENAMAR in reference [13]. This approach consists on considering only the predominant mode and neglecting all of the others. In the present case, the predominant mode and the contribution coefficients are denoted by "i" and"a_i", which leads to an equation as follows:

$$1+3\,a_i^{\,2}\frac{B_{iiii}^{\,*}}{K_{ii}^{\,*}}-\frac{f_i^{c*}}{a_i\,K_{ii}^{\,*}}=\left(\frac{\omega_{nl}^*}{\omega_1^*}\right)^2 \tag{34}$$

Where $\omega_1^*=\dfrac{K_{ii}^{\,*}}{M_{ii}^{\,*}}$.

3 NUMERICAL RESULTS AND DISCUSSION

3.1 Free vibration

The cases shown in table (2) and all figures below are for beams with two stepped cross-section changes. The cross-section ratios of the 1st and 2nd step are designated by "u1" and u2 with u1= 0.8 and u2= 0.25. The three beams keep the same ratio u1 and u2. Each of the latter two are expressed differently. The representation of the ratios is as follows:
-Beam 1 is of variable height and width.
-Beam 2 is of a constant width and a variable height.
-Beam 3 is of a constant height and a variable width.

Table 2: The first four eigenvalues for clamped–clamped beams with [(u_2=0.8 u_3=0.25) and (R_1=0.25; R_2=0.3; R_3=0.45)]

The first four eigenvalues of beam (a, b and c) in this study are represented in table 2, and a comparison is made between beam (c) and the two beams of ref[8,3] , and between beam (b) and that of ref[3] .

The figure below shows the effect of the variation in the cross-sections on the frequency ratio dependence on the maximum vibration amplitude.

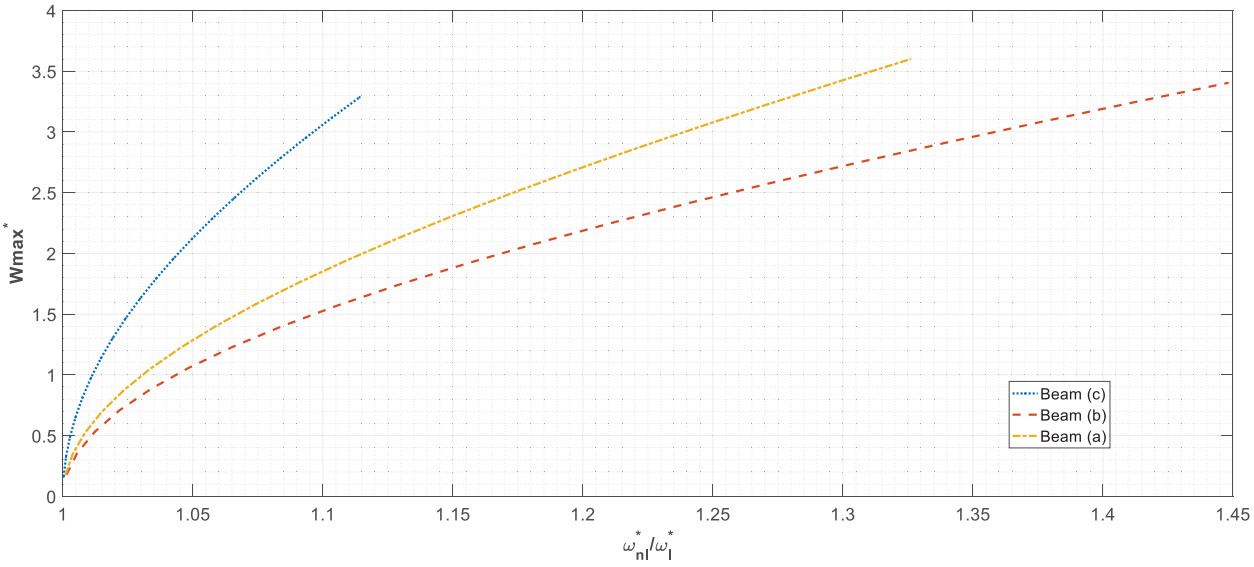

Figure (3) Backbone curves of the three types of beams studied, corresponding to the fundamental nonlinear mode.

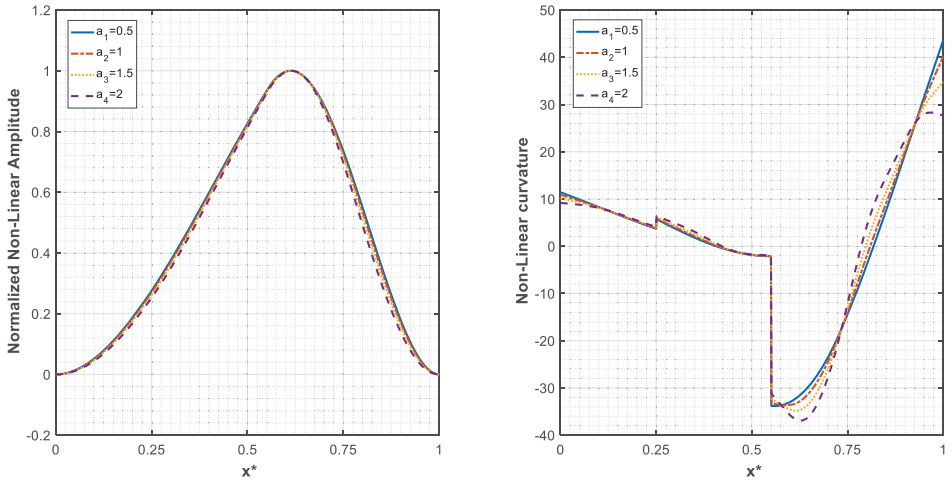

Figure (4): The normalized first non-linear mode and the associated curvature distribution of beam (a) for different values of amplitudes

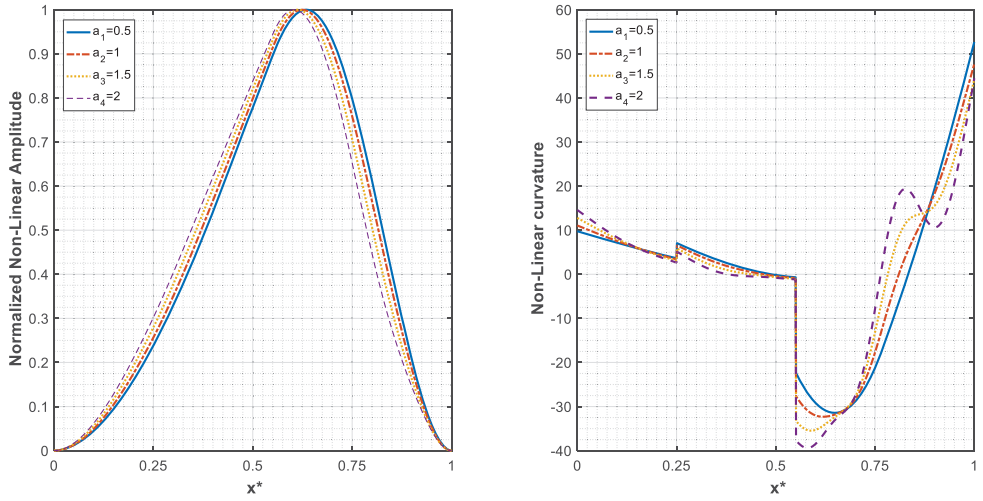

Figure (5): The normalized first non-linear mode and the associated curvature distribution of beam (b) for different values of amplitudes

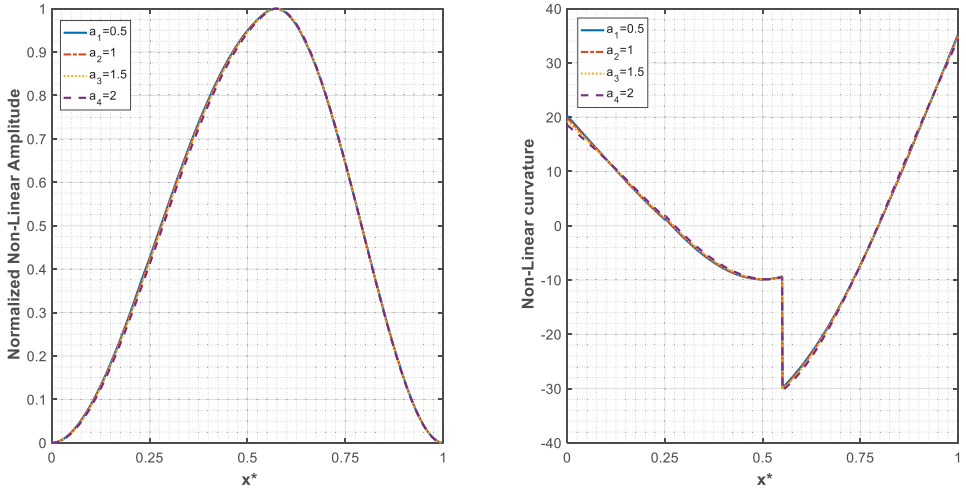

Figure (6): The normalized first non-linear mode and the associated curvature distribution of beam (c) for different values of amplitudes

As shown in the figures above, the non-linearity is highest in beam (b) compared to the other 2 beams. In addition, beam (a) has a higher non-linearity than beam (c). It is also noticed that the geometric non-linearity is not only correlated with the ratio of the cross-section areas, but also with the way it varies.

Moreover, the bending moment results show that for the same beam, the hypothesis of neglecting geometric non-linearity induces an error. For example, the result obtained of the bending moment of the beam (a) at x^*=0.6 with a contribution coefficient a_1= 0.1 is 5.7178629838255, when the contribution coefficient a_1= 2 the result equal to 127.9047642462426, which lead to an error of 13.547% between the linear and non-linear result. The same thing for beam (b) where the bending moment at the same point and with a contribution coefficient a_1= 0.1 equal to 4.9691227579006, when the contribution coefficient a_1= 2 the result equal to 131.27, which lead to an error of 31.88%. Also for beam (b) where the bending moment at the same point and with a contribution coefficient a_1= 0.1 equal to 4.201562264286194, when the contribution coefficient a_1= 2 the result equal to

87.938783062186658, which lead to an error of 3.9075377764628%, hence the interest of the present study.

3.2 Forced vibration

The figures below show the non-linear dynamic behaviour of the forced beam.
The case of the non-linear dynamic behaviour of the forced beam has been studied, using the single-mode approach, in which all modelled beams were excited by a concentrated force, located at the middle of the beam. The study was repeated for three different values of concentrated forces, which were increased according to the following formula [$F^c=10^n$](for n=0,1,2 and 3).

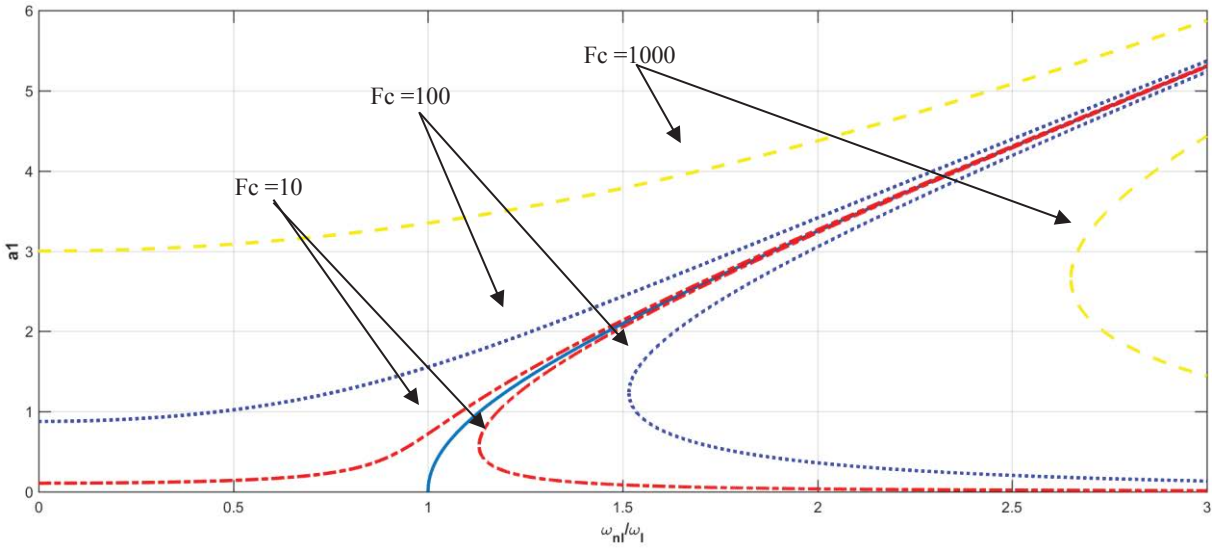

Figure (7) :Nonlinear frequency response functions, based on the single mode approach, for the first beam, subjected to three levels of excitation

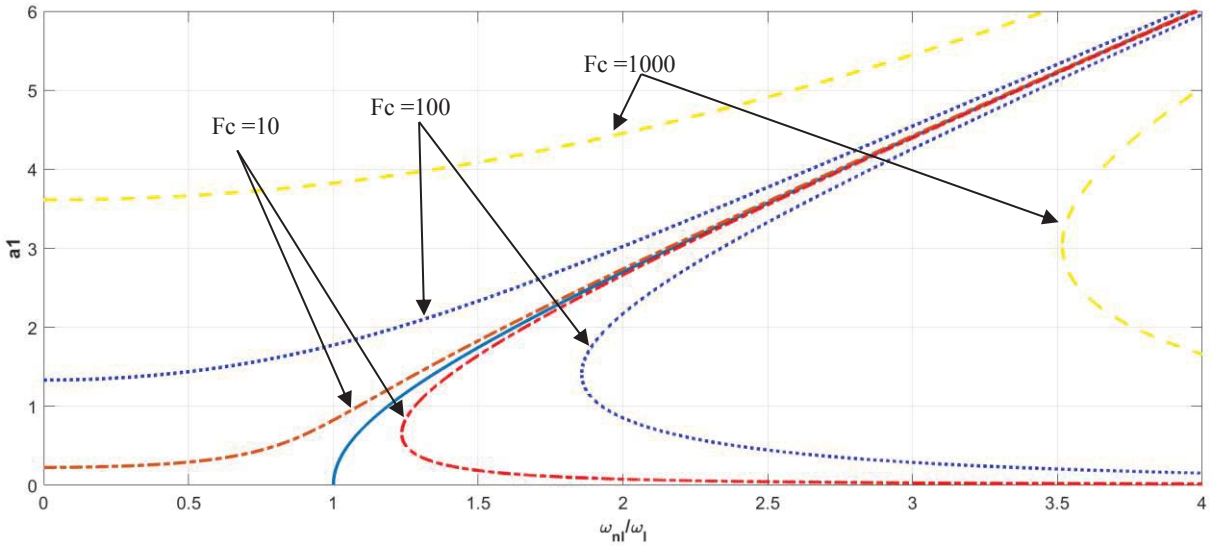

Figure (8): Nonlinear frequency response functions, based on the single mode approach, for the second beam subjected to three levels of excitation

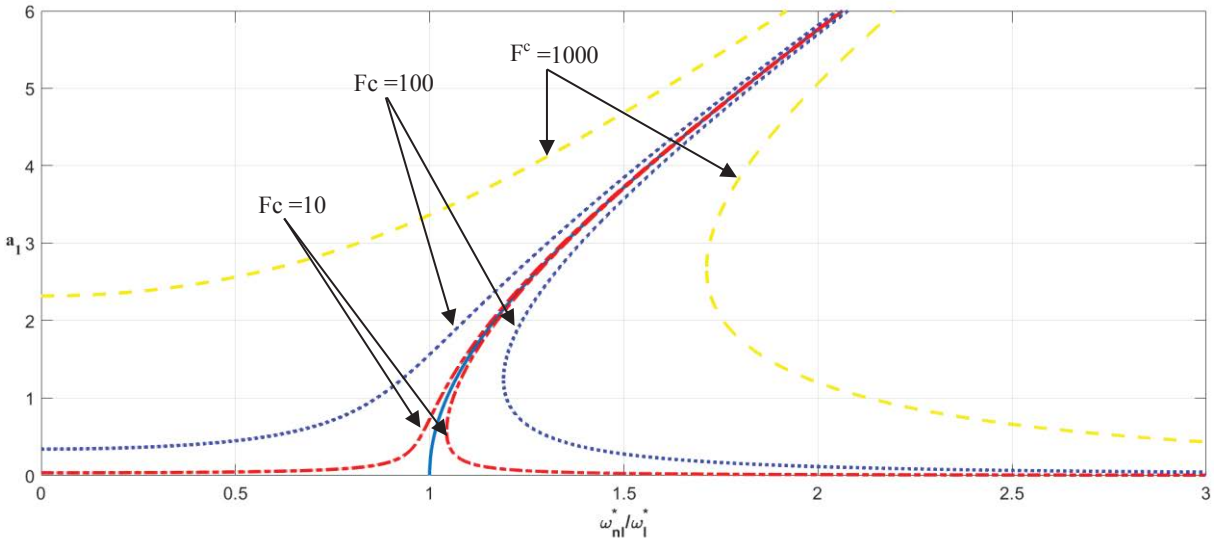

Figure (9): Nonlinear frequency response functions, based on the single mode approach, for the third beam subjected to three levesl of excitation

By assuming the single mode approach, an analysis of the dynamic behaviour of stepped beams was done in the vicinity of the predominant mode. The response curves have been exhibited for the three beams shown in figure (1), which were excited by a concentric harmonic force.

The figures (7, 8 and 9) clearly represent the particular behaviour of non-linear systems, like the jump phenomenon where for the same frequency range, diverse results are possible, also the unproportional progression of the frequency response to the intensity of excitation.

4 CONCLUSION

The analysis of geometrically non-linear, free and forced transverse vibrations of a multi-step beam was examined analytically using Euler-Bernoulli's beams theory and the Von Karman's nonlinearity assumptions. The solution of the linear problem was obtained for three types of beams with different cross-sections, leading to the calculation of frequencies and determination of the mode shapes. The latter were then used as basic functions for the analysis of the non-linear problem. The non-linear algebraic system was subsequently reduced using Hamilton's principle and spectral analysis, and solved using an approximate method called second formulation. This led to examination of the effect of the cross-section variation on the non-linear dynamic behaviour of the beams, illustrated by the backbone curves. The non-linear dynamic behaviour of a beam subjected to a concentric force was also studied using the single-mode approach in the neighbourhood of the predominant mode. The effect of the force level was examined and then illustrated for the three cases.

Abstract. *Numerical schemes based on the Boundary Element Method are proposed to perform Nonsmooth Modal Analysis. The latter aims at finding continuous families of periodic orbits of mechanical systems featuring unilateral contact constraints. In this contribution, a simple one-dimensional rod system is targeted. The frequency response, in the form of backbone-curve diagrams, and displacement field are presented. The proposed results compare well with existing studies on this topic.*

1 INTRODUCTION

Within the framework of structural dynamics, linear modal analysis is a daily used tool in industry, aiming at predicting vibratory resonances of periodically forced mechanical systems by searching for continuous families of periodic solutions exhibited by the underlying autonomous (i.e. unforced) system. However, various challenges arise when possibly large-scale *nonlinear* dynamical systems are targeted and for which *nonlinear modal analysis* is needed instead [7]. Nonlinearity has commonly two forms: smooth or nonsmooth function of the state. The nonlinearity is said to be smooth when the governing equation involves a function of the state which is differentiable. Such functions are commonly polynomial. The nonlinearity is said to be nonsmooth otherwise, as for instance, unilateral contact conditions. *Nonsmooth Modal Analysis* (NSM) is a version of modal analysis dedicated to such systems. A few numerical schemes exist to perform NSM, with inherent limitations [11, 12]. In the present work, it is proposed to explore the numerical capabilities of two numerical schemes grounded on the Boundary Element Method (BEM) to perform NSM.

2 SYSTEM OF INTEREST

The system of interest, shown in Figure 1, is a one-dimensional bar of length L with a unilateral contact condition at its right tip. The unknown displacement field is $u(x,t)$, where

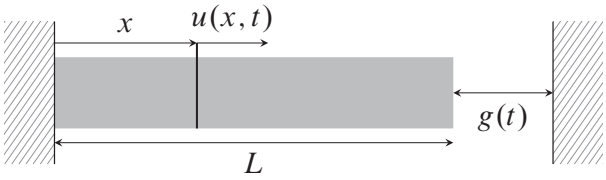

Figure 1: System of interest

x is the space coordinate and t is time. Wave speed c is space-independent and the classical one-dimensional wave equation governs the dynamics, that is

$$u_{,tt} - c^2 u_{,xx} = 0, \quad \forall x \in]0\,;L[. \tag{1}$$

Unilateral contact on the right tip is expressed as a Signorini boundary condition

$$g(t) \geq 0, \quad u_{,x}(L,t) \leq 0, \quad g(L,t)u_{,x}(L,t) = 0. \tag{2}$$

where $g(t) = g_0 - u(L,t)$. Also, since the bar is clamped on the left, $u(0,t) = 0$ applies.

In context of nonlinear modal analysis [7], families of periodic solution forming modal manifolds are computed through a numerical scheme which assumes that no impact law is required as the contact interface but instead, a switch between free-flight and sticking phases occurs.

3 METHODOLOGY

In this paper, two numerical schemes based on the Boundary Element Method are implemented. The BEM forms a family of methods for which the boundary of the domain of interest is the main ingredient of the formulation and full domain discretization is not required when initial condition and body force vanish [6]. It has the notable benefit of reducing the dimension of the formulation. Among the various incarnations of BEM, the Time Domain BEM (TD-BEM)

and Frequency Domain BEM (FD-BEM) are selected to perform nonsmooth modal analysis. The first strategy combines TD-BEM and a simplified shooting method, while the second one combines FD-BEM to Harmonic Balanced Method (HBM).

3.1 Time Domain Boundary Element Method and Shooting Method

TD-BEM is a version of BEM which requires the discretization of both time and space. By pre-multiplying the governing equation (1) with its fundamental solution [4] and performing integration in time and space and then integration by parts, the formulation can be transformed into Boundary Integral Equation (BIE), which here reads [3]

$$\begin{aligned} u(x,t) = &\int_0^t p^*(x,t,\xi,\tau)u(\xi,\tau)\,\mathrm{d}\tau\Big|_{\xi=L} + \int_0^t p^*(x,t,\xi,\tau)u(\xi,\tau)\,\mathrm{d}\tau\Big|_{\xi=0} \\ &- \int_0^t u^*(x,t,\xi,\tau)\,p(\xi,\tau)\,\mathrm{d}\tau\Big|_{\xi=L} - \int_0^t u^*(x,t,\xi,\tau)\,p(\xi,\tau)\,\mathrm{d}\tau\Big|_{\xi=0} \\ &- \frac{1}{c^2}\int_0^L u^*(x,t,\xi,0)v(\xi,0)\,\mathrm{d}\xi + \frac{1}{c^2}\int_0^L \frac{\partial u^*(x,t,\xi,0)}{\partial\tau}\Big|_{\tau=0} u(\xi,0)\,\mathrm{d}\xi \end{aligned} \tag{3}$$

where p represents traction on the boundary ; $u^*(x,t,\xi,\tau)$ and $p^*(x,t,\xi,\tau)$ are the displacement and stress fundamental solutions. Any internal state for $x \in]0\,;L[$ at time t is dependent on the boundary displacement and traction at past times as well as initial states. In order to use TD-BEM, space and time are first discretized. Space integration of the initial states (last two terms in (3)) is performed by discretizing space into n elements and $n+1$ nodes with $\Delta x = L/n$ such that $x_k = k\Delta x$ for $k = 0,\ldots,n$. Time step is set to $\Delta t = \Delta x/c$ to guarantee stability of TD-BEM, such that $t^i = i\,\Delta t$ for $i = 0,\ldots,n$. Equation (3) is discretized by reading it on the boundary, that is $x = 0$ and then $x = L$ for all t^i for all $i = 0,\ldots,n$; it now becomes

$$\mathbf{H}^{ii}\mathbf{u}^i = \mathbf{G}^{ii}\mathbf{p}^i + \sum_{j=0}^{i-1}(\mathbf{G}^{ij}\mathbf{p}^j - \mathbf{H}^{ij}\mathbf{u}^j) + \mathbf{U}^i\mathbf{u}_0 + \mathbf{V}^i\mathbf{v}_0, \quad i = 1,\ldots,n \tag{4}$$

where $\mathbf{u}^i \approx [u(0,t^i), u(L,t^i)]^\top$ and $\mathbf{p}^i \approx [p(0,t^i), p(L,t^i)]^\top$ are displacement and traction vectors on boundary, with size of 2×1. The quantities $\mathbf{H}^{ii}$, $\mathbf{G}^{ii}$, $\mathbf{H}^{ij}$, and $\mathbf{G}^{ij}$ are 2×2 coefficients matrices, evaluated from time-domain integration in (3) of fundamental solutions u^* and p^*. Vectors $\mathbf{u}_0 = [u(x_k,0)_{k=0\ldots,n}]$ and $\mathbf{v}_0 = [v(x_k,0)_{k=0\ldots,n}]$ are the discretized initial displacement and velocity fields, with size $n+1$. The corresponding coefficient matrices of size $2\times(n+1)$ are $\mathbf{U}^i$ and $\mathbf{V}^i$ stemming from space integration of fundamental solutions in (3). For systems without Signorini boundary conditions, Equation (4) can be solved at every time step starting at $i = 1$ where half of the quantities in $\mathbf{u}^i$ and $\mathbf{p}^i$ are unknown, that is $(u(0,t^i), u(L,t^i))$ or $(u(0,t^i), p(L,t^i))$ or $(u(L,t^i), p(0,t^i))$ or $(p(0,t^i), p(L,t^i))$.

In order to account for unilateral contact conditions, TD-BEM is coupled with the floating boundary method [8]. It sees Signorini boundary condition as a switch between non-homogeneous Dirichlet and homogeneous Neumann boundary conditions. This technique does not require an impact law in the BEM format, thus avoiding the chattering or energy dissipation that might exist in other methods [1].

To perform NSM, a shooting method is used. It calculates, here in the discretized framework, the difference between the initial state $\mathbf{q}_0 = (\mathbf{u}_0, \mathbf{v}_0)$ and the corresponding final state $\mathbf{q}(\mathbf{q}_0, T)$ after a yet unknown period T assumed to exist. For a periodic motion, the equality $\mathbf{q}(\mathbf{q}_0, T) = \mathbf{q}_0$

holds. In this work, $\mathbf{v}_0 = \mathbf{0}$ is assumed [11], and the problem to be solved thus reduces to: Find vector $\mathbf{u}_0$ and strictly positive integer m, where $T = m\Delta t$, such that

$$\mathbf{u}_m = \hat{\mathbf{G}}\mathbf{p} - \hat{\mathbf{H}}\mathbf{u} + \hat{\mathbf{U}}^m\mathbf{u}_0 = \mathbf{u}_0 \tag{5}$$

with the notations

$$\hat{\mathbf{G}} = [\hat{\mathbf{G}}^{m1}\ \hat{\mathbf{G}}^{m2}\ \cdots\ \hat{\mathbf{G}}^{mm}],\quad \mathbf{p} = \begin{bmatrix}\mathbf{p}^1\\ \mathbf{p}^2\\ \vdots\\ \mathbf{p}^m\end{bmatrix},\quad \hat{\mathbf{H}} = [\hat{\mathbf{H}}^{m1}\ \hat{\mathbf{H}}^{m2}\ \cdots\ \hat{\mathbf{H}}^{mm}],\quad \mathbf{u} = \begin{bmatrix}\mathbf{u}^1\\ \mathbf{u}^2\\ \vdots\\ \mathbf{u}^m\end{bmatrix}$$

where $\hat{\mathbf{G}}^{mj}$ and $\hat{\mathbf{H}}^{mj}$ are $(n+1)\times 2$ coefficient matrices and $\hat{\mathbf{U}}^m$ is a $(n+1)\times(n+1)$ coefficient matrix. Also, $\mathbf{u}_m = [u(x_k, m\Delta t)_{k=0\ldots,n}]$. Since some $\mathbf{p}^j$ and $\mathbf{u}^j$ in (5) are unknown, Equation (4) is invoked, that is:

$$\mathbf{H}\mathbf{u} = \mathbf{G}\mathbf{p} + \mathbf{U}\mathbf{u}_0 \tag{6}$$

with the notations

$$\mathbf{H} = \begin{bmatrix}\mathbf{H}^{11} & \mathbf{0} & \mathbf{0} & \ldots & \mathbf{0}\\ \mathbf{H}^{21} & \mathbf{H}^{22} & \mathbf{0} & \ldots & \mathbf{0}\\ \mathbf{H}^{31} & \mathbf{H}^{32} & \mathbf{H}^{33} & \ldots & \mathbf{0}\\ \vdots & \vdots & \vdots & \ddots & \vdots\\ \mathbf{H}^{m1} & \mathbf{H}^{m2} & \mathbf{H}^{m3} & \ldots & \mathbf{H}^{mm}\end{bmatrix}, \mathbf{G} = \begin{bmatrix}\mathbf{G}^{11} & \mathbf{0} & \mathbf{0} & \ldots & \mathbf{0}\\ \mathbf{G}^{21} & \mathbf{G}^{22} & \mathbf{0} & \ldots & \mathbf{0}\\ \mathbf{G}^{31} & \mathbf{G}^{32} & \mathbf{G}^{33} & \ldots & \mathbf{0}\\ \vdots & \vdots & \vdots & \ddots & \vdots\\ \mathbf{G}^{m1} & \mathbf{G}^{m2} & \mathbf{G}^{m3} & \ldots & \mathbf{G}^{mm}\end{bmatrix}, \mathbf{U} = \begin{bmatrix}\mathbf{U}^1\\ \mathbf{U}^2\\ \mathbf{U}^3\\ \vdots\\ \mathbf{U}^m\end{bmatrix}.$$

Combining linear systems (5) and (6) yields

$$\begin{bmatrix}\mathbf{H} & -\mathbf{U}\\ \hat{\mathbf{H}} & \mathbf{I}-\hat{\mathbf{U}}\end{bmatrix}\begin{bmatrix}\mathbf{u}\\ \mathbf{u}^0\end{bmatrix} = \begin{bmatrix}\mathbf{G}\\ \hat{\mathbf{G}}\end{bmatrix}\mathbf{p} \tag{7}$$

where $\mathbf{I}$ is a $(n+1)\times(n+1)$ identity matrix. In the floating boundary method, the Signorini condition is considered as a switch between Dirichlet and Neumann conditions. As soon as the contact duration T_c is set, the time step at which the switch happens is known, so does the boundary condition (Dirichlet or Neumann) at each time step at $x = L$. Thus Equation (7) can be solved by reorganizing the known and unknown entries in $\mathbf{u}$ and $\mathbf{p}$, according to the boundary condition at $x = L$ at each time step. Accordingly, by first assuming only one contact switch per period, such a strategy systematically skim through given intervals of values on period T and contact duration T_c (for a chosen Δt). However, physically unacceptable solutions can be found. Accordingly, admissibility is systematically checked to ensure complementary conditions (2) are satisfied. Non-admissible solutions with non-admissible penetration or contact forces are discarded. Such way of Signorini boundary condition enforcement is similar in spirit with a precedent scheme [12], but also shows differences in detail.

3.2 Frequency Domain Boundary Element Method

Frequency Domain Boundary Element Method (FD-BEM) is a frequency-domain form of BEM which targets periodic solutions. Via a Fourier transform in time at frequency ω

$$\tilde{u}(x) = \frac{1}{2\pi}\int_{-\infty}^{\infty} u(x,t)\exp(-i\omega t)\,\mathrm{d}t \tag{8}$$

the wave equation (1) becomes the well-known one-dimensional Helmholtz equation

$$\frac{\mathrm{d}^2\tilde{u}(x)}{\mathrm{d}x^2} + \kappa^2\tilde{u}(x) = 0 \tag{9}$$

where $\kappa = \omega/c$ is the frequency number. Similar to TD-BEM, FD-BEM is based on a weighted residual form of (9), where the weight function is the fundamental solution to the Helmholtz equation [2] with the corresponding BIE

$$2\tilde{u}(x) = \tilde{u}(0)\cos\kappa x + \tilde{u}(L)\cos(\kappa(L-x)) - \frac{1}{\kappa}(\tilde{p}(0)\sin\kappa x - \tilde{p}(L)\sin(\kappa(L-x))) \tag{10}$$

where $\tilde{p}$ is the Fourier Transform of p. Reading (10) on the boundary leads to

$$\begin{bmatrix} \kappa & 0 & -\kappa\cos\kappa L & \sin\kappa L \\ -\kappa\cos\kappa L & \sin\kappa L & \kappa & 0 \end{bmatrix} \begin{bmatrix} \tilde{u}(0) \\ \tilde{p}(0) \\ \tilde{u}(L) \\ \tilde{p}(L) \end{bmatrix} = 0, \quad \kappa \neq 0 \tag{11}$$

Through (11), $\tilde{u}$ at frequency ω can be solved for a combination of Dirichlet and/or Neumann boundary conditions. The time domain solution is then recovered through an inverse Fourier Transform. However, such a formulation is not well adapted when $u(L,t)$ and $p(L,t)$ are both constrained by the complementary condition (2) expressed in time domain. This complementarity condition can be equivalently recast into the equality [9]

$$r(t) \equiv p(L,t) + \max(0, \rho(u(L,t) - g_0) - p(L,t)) = 0, \quad \forall t \tag{12}$$

where $\rho \in \mathbb{R}^+$. In the remainder, the residual $r(t)$ will be made to vanish in an integral sense only. To insert (12) into FD-BEM with the aim of finding periodic solutions, Fourier expansions are considered, that is

$$p(L,t) = \frac{1}{2}a_0 + \sum_{n=1}^{\infty} a_n\cos n\omega_0 t + b_n\sin n\omega_0 t \tag{13}$$

where $\omega_0 = 2\pi/T$ is the base frequency. The corresponding base frequency number is $\kappa_0 = \omega_0/c$. Knowing that $u(0,t) = 0$, it follows from (11) that

$$u(L,t) = \frac{L}{2}a_0 + \sum_{n=1}^{\infty} \frac{\tan n\kappa_0 L}{n\kappa_0}(a_n\cos n\omega_0 t + b_n\sin n\omega_0 t) \tag{14}$$

Since initial velocity is assumed to be zero [11], all sin terms vanishes. Only constant and cos terms remain in equation (13) and equation (14).

The truncated Fourier series of $u(L,t)$ and $p(L,t)$ with m harmonics only is then substituted into (12). The Harmonic Balance Method (HBM) [5] is used to solve for the unknown coefficients $(a_0, a_1, a_2, \ldots, a_m)$. As a special case of Galerkin techniques, HBM reads

$$\int_0^T {}_i(t)r(t)\,\mathrm{d}t = 0, \quad \forall i \tag{15}$$

where the following family of functions is selected: $(1, \cos\omega_0 t, \cos 2\omega_0 t, \ldots, \cos m\omega_0 t)$. With $m+1$ equations, $m+1$ unknown coefficients can be solved for by the (Non-Smooth) Newton method. The function $p(L,t)$ is then reconstructed through (13) and so are other needed functions used to build the Nonsmooth Modes of Vibration. Basic continuation is implemented [7] in order to construct the desired backbone curves, by increasing ω_0 by a small value and solve again, with previous solution as initial guess.

4 RESULTS

In this section, the following is considered: $L = 1$, $c = 1$ and $g_0 = 0.5$. For TD-BEM, the bar is discretized into $n = 50$ elements in space with element length $\Delta x = L/n$ and time step is set accordingly. For FD-BEM, $m = 15$ is used.

The corresponding backbone curves are shown in figure 2. The backbone curve shows the

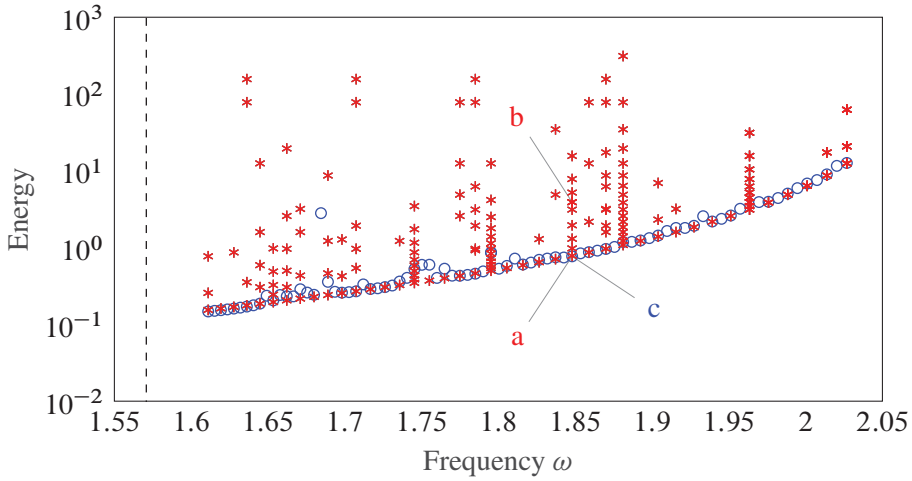

Figure 2: Backbone curve of the first mode. Red stars: TD-BEM/Shooting; blue circles: FD-BEM/HBM. Dashed line: linear mode

frequency-dependence of the total energy, and compares well with existing solutions [11], except for backbone curve near linear mode. Since contact period length decreases as frequency ω decreases [11], short period of contact cannot be evaluated precisely with $m = 15$ harmonics. Due to inaccurate Fourier expansion and residual function, HBM struggles converging to useful periodic solutions. Thus this part of solution is skipped.

It can be observed that TD-BEM captures more than one possible solution for a given frequency of vibration, which shows similar pattern of nonsmooth modes distribution with existing results [10]. Two such solutions feature the same frequency but distinct contact durations, as shown in figure 3 (see points a and b). This is induced by the full internal resonance in the investigated system [12]. Although solution b shows a low-frequency pattern similar to solution a, extra energy is introduced due to higher frequency mode. Comparatively FD-BEM/HBM currently cannot guarantee convergence to internal resonance solutions. More advanced continuation technique might be required to find internal resonance branches.

Displacement solved by FD-BEM/HBM at point c on backbone curve is depicted in Figure 4. Overall, the displacement field is similar to solution at point a in Figure 3. It is worth noting that Signorini conditions in FD-BEM/HBM is enforced in integral sense through (15), unlike in TD-BEM the complementary condition is met pointwise, ie for every time step. Accordingly, residual pointwise penetration occurs as shown in figure 5.

In terms of computational efficiency, FD-BEM/HBM is much superior to TD-BEM/Shooting. With the suggested discretization settings, TD-BEM is about 700 times slower than FD-BEM/HBM to find the whole backbone curve. When n increases, such difference is expected to increase, since the total number of combination between T and T_c to be skimmed increases in $O(n^2)$, while for FD-BEM/HBM the step size of continuation can be arbitrarily controlled.

5 CONCLUSIONS

In this paper, two methods have been introduced to perform nonsmooth modal analysis on a simple academic system. Both methods have shown capability to converge to admissible solutions.

The TD-BEM/shooting methodology has shown good capability of capturing highly-detailed step-wise admissible solutions. However, its challenging implementation leads to high computational costs. Although it has shown no numerical energy dissipation in this one-dimensional case, this might be untrue for higher dimensional systems, in which case it would become ineligible for such modal investigations.

Comparatively, FD-BEM/HBM features a much lower computational cost, at the cost of solving Signorini conditions in an integral sense only. This formulation is also energy preserving by construction and could be extended to problems in two or three dimensions. More advanced continuation techniques, such as pseudo-arclength [7], are expected to be coupled into existing FD-BEM/HBM scheme.

Keywords: Stall flutter, Aeroelasticity, Boundary element method (BEM), Discrete vortex particle method (DVM), Panel method, Blade cascade, Viscous-inviscid coupling.

Abstract. *In this paper study of subsonic stall flutter in the steam turbine blades is carried out. Subsonic stall flutter is one of the dominating and frequently occurring aeroelastic phenomena in large power turbines. The study is carried out by both experimentally and numerically to understand the fundamental physics behind it. Aerodynamics damping (AD) is one of the parameter to analyze the aeroelastic stability of stall flutter in 2D blade cascade. To numerically model the stall flutter in steam turbine a medium fidelity numerical tool is developed. In this research project computationally less expensive potential flow based hybrid boundary element method e.g. panel method, flow model is developed to model the unsteady flow in low pressure turbine blade cascade and to estimate the aeroelastic stability (stall flutter) parameters. A modified version panel method using viscous-inviscid coupling including discrete vortex particle (DVM) free wake model can be used for the separated flow conditions as it is in stall flutter case. These methods are widely adopted for aeroelastic modeling of wind turbines, helicopter rotors, and aircraft aeroelasticity problem . The AD for different Inter blade phase angle (IBPA) is estimated using newly developed hybrid BEM based flow model. The estimated AD will be compared with experimental data and CFD results to evaluate the efficiency and the accuracy of the model.*

1 INTRODUCTION

To meet the exponential growth in electrical power demand world wide the efficiency improvement of the existing power plants and the development of high energy output power plants are being considered in the world. Most of these power plant uses fossil fuel or nuclear material as a heat source to generate electricity with help of power turbines e.g. gas turbine, steam turbines. Therefore, power turbine are key component of whole energy generation system. In the quest to generate more power in the nuclear power plants or coal fired power plants giant steam turbines are being installed fully and efficiently utilize the large volume steam produced in it and this can achieved by increasing the physical dimension of the power turbine, but if one hand increasing the size of power turbine are the solution it poses other type engineering challenges which directly effect the safety and the life cycle of these large power turbines. One of such problem engineer or designer need to address is flow induced vibration. The larger low pressure steam turbine blades are more prone to mechanical vibration due to longer size and less stiffness, which leads to high-cycle fatigue failure and in worse case blade loss and damaging the whole system. The aeroelasticity of low-pressure turbine blade has been the subject of much attention in the past and recent years, [1, 2]

In this paper study of subsonic stall flutter in the steam turbine is carried out. Subsonic stall flutter is one of the dominating and frequently occurring aeroelastic phenomena in large power turbines. Subsonic stall flutter in steam turbine LP stage is very complex physic phenomena and remains a very active topic of research. However, very less work has been done in the subsonic dynamic stall flutter in steam turbine cases in past. The majority of work on subsonic dynamic stall flutter is carried out either on gas turbine or jet engine compressors and fan blades [3, 4]. The problem of dynamic stall flutter in LP turbine blades are getting more important because of ever increasing size of blading to produce more electricity. Therefore, in this research the issue of dynamic stall flutter is studied in details. The study will be carried out by both experimentally, numerically to understand the fundamental physics behind it. Aerodynamics damping (AD) is one of the parameter to study the aeroelastic stability of stall flutter in 2D blade cascade.

Reduced order flow solver: To numerical study the stall flutter in steam turbine there are well developed computational fluid dynamics (CFD) and computational structural dynamics (CSD) based aeroelastic models available for this purpose, however, theses CDF-CSD based models are computationally very expensive. In CFD-CSD based aeroelastic models flow computation is responsible for majority of computational time. Therefore, in this research project computationally less expensive potential flow based hybrid boundary element method (BEM) flow model will be developed to model the unsteady flow in low pressure (LP) turbine blade cascade and to estimate the aeroelastic stability (stall flutter). The panel method (PM) is one of such methods and first proposed by Hess and Smith [5] to model the lifting and non-lifting potential flow around slender bodies. These methods are good compromise of speed and accuracy and can be used for complex geometry until the flow fulfills the criteria of potential flow and free from flow separation. However, for subsonic stall flutter modified PM using viscous-inviscid coupling including discrete vortex particle (DVM) wake model can be used for the separated flow case [6, 7, 8] as it is in stall flutter. These methods are widely adopted for aeroelastic modeling of wind turbines, helicopter rotors, and aircraft aeroelasticity problem [6, 8, 9]. The AD for different Inter blade phase angle (IBPA) is estimated using newly developed hybrid BEM based flow model. The estimated AD will be compared with experimental data and CFD results to evaluate the efficiency and the accuracy of the model. The successful implementation of the proposed aeroelastic model for subsonic stall flutter in 2D cascade will have significant impact

on the computational time reduction and will give researcher and engineering freedom to iterate different blade profile in very short time period at preliminary LP turbine design stage for blade design optimization and to understand the subsonic stall flutter in more details in steam turbine application.

2 Hybrid boundary element method for flow modeling

2.1 Panel method

The panel method is a family of boundary element methods and it is often employed to simulate the aerodynamic flow over lifting and non lifting bodies in attached flow conditions. In the PM flow field is assume to be inviscid and irrotational and it gives the solution of of Laplace's potential flow equation and 2D version can be given by Eq. 1

$$\nabla^2\Phi(x,y) = \frac{\partial^2\Phi}{\partial^2 x} + \frac{\partial^2\Phi}{\partial^2 y} = 0 \tag{1}$$

where $\Phi(x,y)$ is the scalar velocity potential and it is function of position vector $r(x,y)$ .The surface panel method discretization and solution strategy over lifting airfoil is given in the Fig 1. In the PM to construct the flow field and find the solution of the field variables, singularity

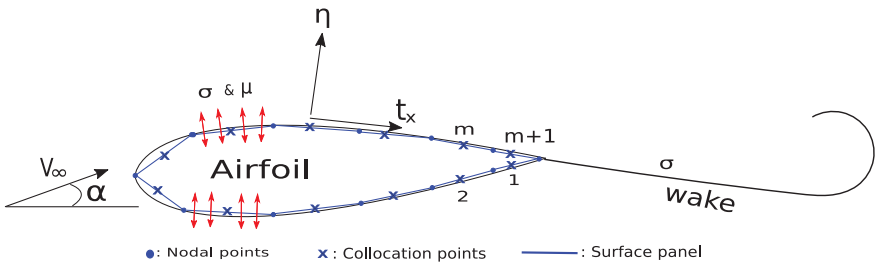

Figure 1: Panel method discretization of airfoil using source and doublet singularities panel

panel elements are placed over the airfoil surface and in the wake. In this work each surface panel elements include a combination of constant strength source (σ) and a doublet (μ) distribution while the wake panels feature only doublet panels because the wake do not carry any aerodynamic load. Notice that in these formulation, the integration is to be carried out along the complete surface of the airfoil. Using the superposition principle, any such distribution of sources and doublet satisfies Laplace's equation, but we will need to find the conditions for (σ) and a doublet (μ) such that the flow tangency boundary condition and the Kutta condition are satisfied. Therefore, boundary conditions (BC) are imposed on control points lying on the centroid of each surface panel as shown in Fig 1.The required BCs are, (1) enforcing the impermeability flow at solid or a fixed normal flow condition ($\nabla\Phi \cdot n = V_n = 0$), (2) Far field: The disturbance created by the singularities on the body and wake must disappear at infinity ($\lim_{|\mathbf{r}|\to\infty} \nabla(\Phi - \Phi_\infty) = 0$). (3) the Kutta condition and Kelvin's theorem, are imposed in order to obtain a complete description of the flow field and the resulting aerodynamic loads. The pressure field (p) is then obtained solving the unsteady Bernoulli equation 6 .

$$\frac{\partial\Phi}{\partial t} + \frac{p}{\rho} + \frac{V^2}{2} = const \tag{2}$$

Furthermore, the surface panels are arranged so as to represent the actual airfoil's geometry. More details about required BC, numerical implementation and determining field variables using unsteady PM can be find in Katz [10]. Apart from many advantages of PM over CFD in terms of speed an accuracy, it suffers from one main disadvantage that is PM can not be employed for separated flow regimes and also it ignores the viscous effect of the fluid. Therefore, in this present paper a modified version of panel method will be used to simulated flow separation including viscous effect close to the body surface in boundary layer (BL) region Fig.2, BL is thin layer of fluid close vicinity of the solid boundary where the fluid viscous effects are dominant. Therefore, in the modified version of the panel method two way viscous-inviscid loose coupling strategy will be adopted to simulate the flow separation and take the account of the viscous effect of the fluid. In this research work BL parameters are estimated with the help of 2D integral boundary layer method.

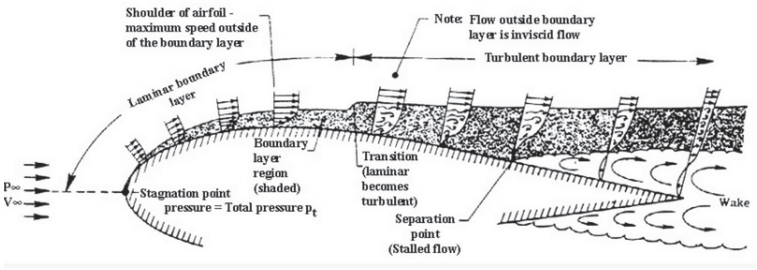

Figure 2: Concept of boundary layer over wing surface [10]

2.2 Integral Boundary layer method :

The integral form of 2D BL equations which relies on the *Von kármán momentum integral equation* can be given by Eq. 3

$$\frac{d\theta}{dx} + \frac{\theta}{U_e}(2+H)\frac{dU_e}{dx} = \frac{1}{2}c_f \tag{3}$$

in which

$$H = \frac{\delta^*}{\theta} \quad and \quad c_f = \frac{2\tau_w}{\rho U_e} \tag{4}$$

Here U_e is the edge velocity, H is the shape factor of the BL velocity profile, θ is momentum thickness of BL, δ^* displacement thickness, τ_w wall shear stress and c_f is the skin friction coefficient of the body surface. The BL equation are solved over airfoil surface along the streamwise direction to determine the separation points. Once the separation points are estimated on the surface a second share layer is shed from the point.

In modified version of PM which is used here, the viscous effect is modeled using integral form of BL equation and the inviscid part with classical PM. A similar modified version of PM with one way viscous-inviscid coupling with double wake technique is adopted by Prasad et al.[9] to simulate the separated flow around wind turbine blades. However, this type of modified PM can successfully simulated steady separated flow cases till the separation occurs only in the suction side of the wing, furthermore, in the Prasad's model static separation points are assumed which means once the separation point is estimated by solving the BL equation it remains unchanged. This is one of the drawback for the model to be employed in dynamic

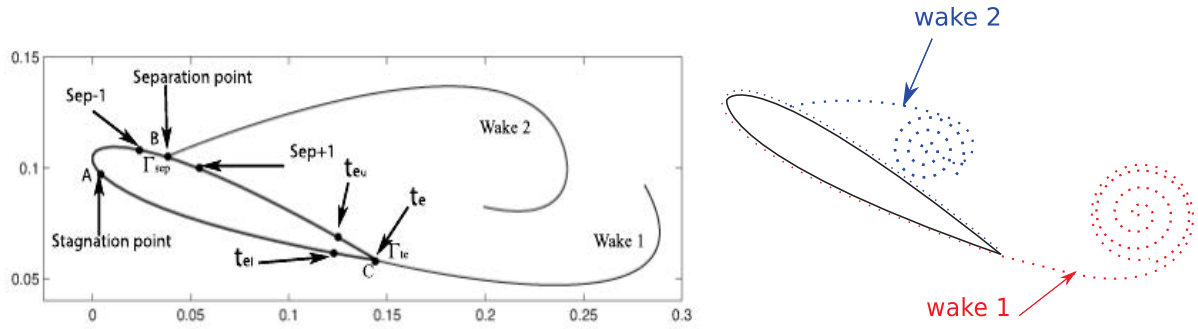

Figure 3: Double wake model using modified PM [9]

stall flow simulation where separation point changes in time, moreover, it is also challenging to model the unsteady wake using continuous doublet vortex sheet due to numerical instability issue. Therefore, a more sophisticated strategy is adopted to model unsteady wake shape in this research with help of discrete vortex particle method (DVM).

2.3 Discrete vortex particle method

Unlike the Prasad et. al. model in the this paper separation points are calculated at each time step not only once for the oscillating airfoil. Moreover, 2D discrete vortex particle method (DVM) will is used to simulate the unsteady wakes using 'vortex blob'. In the DVM the motion and evolution of the vortex blobs are governed by the vorticity transport equation and for the incompressible flow it can be given by Eq. 7

$$\frac{D\omega}{Dt} = (\omega.\nabla)u + \nu\nabla^2\omega \tag{5}$$

where ω is vorticity vector, u velocity vector, ν is kinematic viscosity, and ∇^2 is Laplace's operator respectively. Similar technique to model the unsteady wake is adopted by [7, 8].

2.4 Vortex blob wake conversion

Once the separation point is known a doublet panel is shed from the separation point and second one from the trailing edge.These first panel is nascent wake panel as shown in the Fig. 4. In the next time step these nascent panel converted into vortex blob and a new nascent wake panel is shed again from new separation point. The conversion of doublet wake panel into

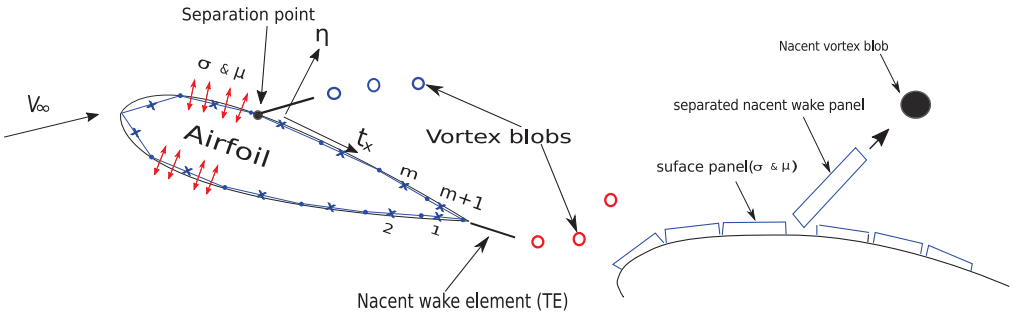

Figure 4: Vortex blob wake conversion model in hybrid PM flow solver

equivalent vortex blob is carried out by similar approach as proposed by [7, 8] to model unsteady wake .The process continue till the edn of the time step or preset convergence criteria of the aerodynamic forces.

3 Flutter analysis Method

The balance between the structure and aerodynamic forces in the system is represented by the aeroelastic Eq. 6

$$[M]\{\ddot{X}\} + [G]\{\dot{X}\} + [K]\{X\} = \{F_{ab}(t)\} \tag{6}$$

where $[M]$, $[G]$, and $[K]$ are the model mass, model damping and model stiffness matrices respectively,$\{X\}$ represents the modal coordinate vector and finally $\{F_{ab}(t)\}$ is the modal unsteady aerodynamic force vector which contains two terms: $F_{disturbance}(t)$ that includes the aerodynamic disturbances upstream and downstream the blade and $F_{damping}(t)$ which represents the aerodynamic damping resulting from the interaction between the blade itself and the flow. For flutter analysis, only the aerodynamic forces due to the vibration of the blade are considered resulting in $F_{disturbance}(t) = 0$ and simplifying the above equation to: Eq. 6

$$[M]\{\ddot{X}\} + [G]\{\dot{X}\} + [K]\{X\} = \{F_{disturbance}(t) + F_{damping}(t)\} \tag{7}$$

The solution of the above equation Eq. 7 allows the determination of the aerodynamic damping and thus the aeroelastic stability of the system.

There are different numerical methods can be used to approximate the aerodynamics characteristics of the system. One of them is “Time Linearized Method” assumes that the unsteady perturbations in the flow are small compared with the mean flow. Then the unsteady flow can be approximated by small harmonic perturbations around a mean value.

In the present research work potential flow based hybrid PM method is used with linearized flow equations assuming the small unsteady perturbation. TWM method with principle of linear superimposition is used to estimate the aerodynamic damping [11, 12] . In the cascade aerodynamic influence of main blade on which the damping is evaluated and the influence other blades on it is superimposed to get the total aerodynamic damping.

Figure 5: Indexing of blades in cascade [13]

Therefore, in TWM the total unsteady response on a blade (here blade “0” in Fig.5) composed of the individual responses from itself and from the other blades lagged by the respective multiple of the IBPA and can be given by Eq. 8

$$\hat{c}^{m,\sigma}_{P,A,twm}(x,y) = \sum_{n=-N/2}^{n=+N/2} \hat{c}^{n,m}_{P,A,ic}(x,y).e^{-i\sigma.n} \tag{8}$$

where $\hat{c}^{m,\sigma}_{P,A,twm}(x,y)$ is the complex pressure coefficient at point (x,y,z) , acting on blade m with the cascade oscillating in traveling wave mode with interblade phase angle σ and

$\hat{c}^{n,m}_{P,A,ic}(x,y)$ is the pressure coefficient of the vibrating blade n , acting on the non-vibrating reference blade m at point (x,y,z) . The coefficients $\hat{c}^{n,m}_{P,A,ic}(x,y)$ are , commonly referred to as local aerodynamic influence coefficients and it is normalized by dynamics pressure "q" and amplitude of oscillation "A". The pressure coefficient is integrated over the surface to get the unsteady force and for the work done for each cycle is obtained by multiplying the total force by respective oscillating displacement. Therefore, aerodynamic damping parameter is given by work done per cycle and normalized by π and amplitude of oscillation "A" and is given in Eq. 9

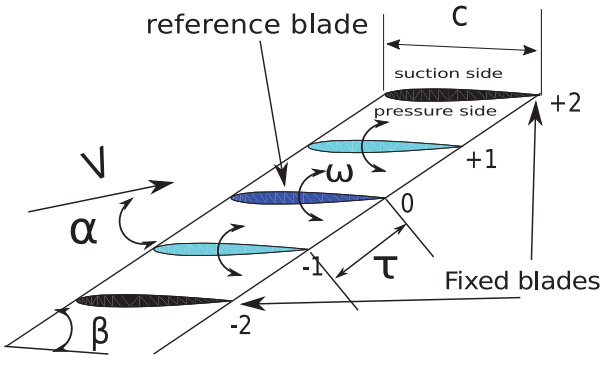
$$Aerodynamic\ damping(\Xi) = -\frac{c_w}{\pi A^2} \tag{9}$$

where c_w is the aerodynamic work done per cycle. The $positive$ value of Ξ indicates the flow acting in stabilizing manner whereas $negative$ value can cause flutter, therefore, unstable.

3.1 Cascade flutter analysis with unsteady PM

To construct the flow field around oscillating cascade as shown in the Fig.6 using hybrid PM solver each cascade is discretized into small number of panels. Constant strength source and doublet singularity element are distributed over the discretized airfoils, and free wake is modeled using DVM, . In order to evaluate the aerodynamic damping at reference airfoil ("0") the velocity potential (Φ) induced by source and doublet singularity element of the airfoil and the all the other airfoils oscillating in the respective phase lag is superimposed linearly along with the effect of free wakes . This is arranged in matrix form and called aerodynamics influence coefficient matrix (AICM) . With AICM along with zero normal normal flow on the body wall, system of equation $[A]\{x\} = \{y\}$ can be solved to estimate the unknown strength of perturbation potential. More details about the this numerical calculation is given in Katz [10] and the same formulation is adopted here. Once the perturbation potential is known the unsteady pressure coefficient can easily be estimated, hence the aerodynamic force and the work for each time step, the summation of all the time step in one complete cycle gives the total aerodynamic work done in one period.

The experimental test is carried out on 5 blade cascade with NACA0010 series airfoil and flow condition are, constant inlet velocities , 10m to30 m/sec, mean camber line incidence angles ($\alpha_0 = 5°to15°$), pitching amplitudes ($\bar{\alpha} = 2°to5°$), reduced frequencies $k = 0.015\ to\ 0.3$ based on semi chord, and 8 IBPA (φ) = 0, $\pm45°$, $\pm90°$,$\pm135°$, $\pm180°$. This kind of superimposed velocity potential can be obtained for any airfoil in the cascade. The oscillatory motion



Parameter	Value
Chord (C)	70mm
Flow angle (α)	$+5°to+15°$
Stagger angle (β)	$+15to+25°$
Slant height (τ)	18mm
Oscillating feq.(ω)	10hz to 30hz
Oscillating Amp.($\bar{\alpha}$)	$\pm2mmto\pm$ 5mm

Figure 6: Schematic diagram of and nomenclature of 2D cascade

of the cascade blade can be given in complex form by

$$\alpha(t) = \bar{\alpha} e^{i(\omega t \pm n\varphi)} \tag{10}$$

where n is blade number Fig.5 and the ω is the frequency of oscillation in rad/sec and $\omega = \frac{2.k.U_\infty}{chord}$. Hence the effective angle of attack (α_{eff}) at any time instance is given by Eq. 11

$$\begin{aligned} \alpha_{eff}(t) &= \alpha_0 + \alpha(t) \\ &= \alpha_0 + \bar{\alpha} e^{i(\omega t \pm n\varphi)} = \alpha_0 + \bar{\alpha} sin(\omega t \pm n\varphi) \end{aligned} \tag{11}$$

The blade cascade and geometry and the related parameter values are given in the Fig.6. The wake shape and flow flied around the cascade simulated using hybrid PM is presented in the Fig.7 and Fig.9 for two different time steps. In the Fig.7 the evaluation of the flow field is

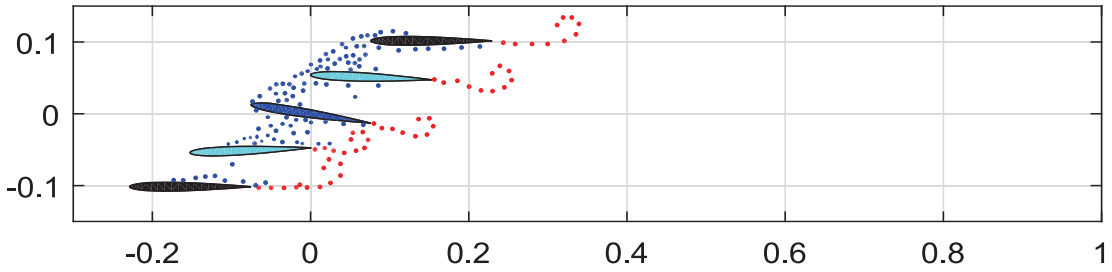


Figure 7: Vortex blob wake shapes at time step T= 15 using hybrid PM at $\alpha_0 = 11°$ and $\bar{\alpha} = 5°$ at reduce frequency $k = 0.115$ and wind speed $Q_\infty = 30.0m/s$

depicted at the first 15 time step the time step size is $\delta t = 0.023$ sec. and oscillating frequency is 15 Hz with amplitude of oscillation is 3 degree and inflow angle 11 degree and k=0.05. The flow start to separate from the suction side of the all airfoils, but the separation position varies in the three oscillating airfoils depending upon the oscillation cycle. In the Fig.9 the wake shapes

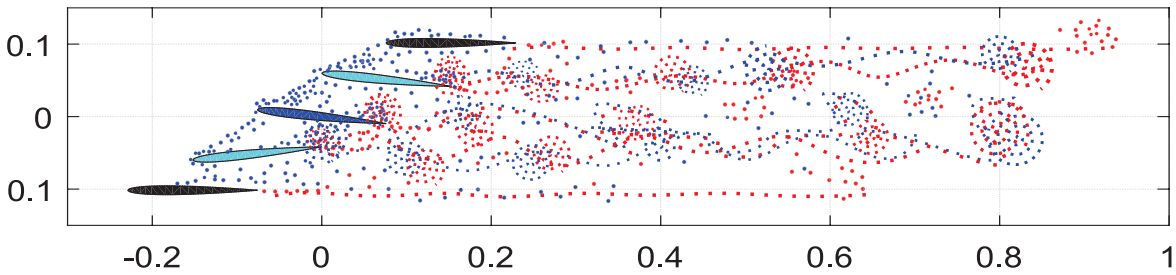

Figure 8: Vortex blob wake shapes at time step T= 150 using hybrid PM at $\alpha_0 = 11°$ and $\bar{\alpha} = 5°$ at reduce frequency $k = 0.115$ and wind speed $Q_\infty = 30.0m/s$

and flow at 150th time step is presented. It can noticed that the leading edge separated shear layer from the lower blade influencing the blade above it strongly, which is complies with the real case. However, there in not significant separation observed in the two fixed airfoils (blade no. -2 and +2 in the Fig.6). Furthermore, in the convergence point of view the proposed hybrid

PM performs very well and starts to converge after 50 time steps for both test cases. Also the fast convergence is due to the fact that PM is based on Laplace's potential flow equation which itself second order linear differential equation, therefore, solution start to converge as soon as starting vortices moves away from the body in unsteady hybrid PM model. For the present tests cases it starts to to happens around 50th time step.

4 Experimental setup for 5 Blade cascade

The physical model of the blade cascade is given in the Fig.9. Five 3D printed blade with NACA0010 profile and 70mm chord length and 100 mm span is attached with base plate. The base plate can be rotate to set the desire angle of attack (α), each blade can also be slide horizontally to set the stagger angle of the cascade. Each of the five blades are attached in the base plate with a mechanism which allows it feed with individual excitation. The experiment is performed in two different configurations. In one configuration the two ends blades (-2 and +2 blade number) in Fig.6 are fixed and the three blades 0, -1 and +1 are excited with the help of shaker, the potion of there shaker are shown in the top right in the Fig.9. All the blades are placed inside rectangular channel with one flow inlet from wind tunnel and the exist as shown in the Fig.9. There gap between channel walls and the blade tip is negligible to ensure the 2D flow field over the cascade and minimize the tip vortex effects. In the second configuration all the blades hang with and free to move in pitching motion, and they are suspended with the help of torsional springs. The experimental test campaign is carried out for wide at different flow speed from 10 m/sec till 50 m/s, different flow angle (from $0°$ till $15°$ and stagger angles (from $10°$ to $25°$). The aerodynamic damping is estimated by multiplying the total force by total pitching displacement in one cycle of oscillation.

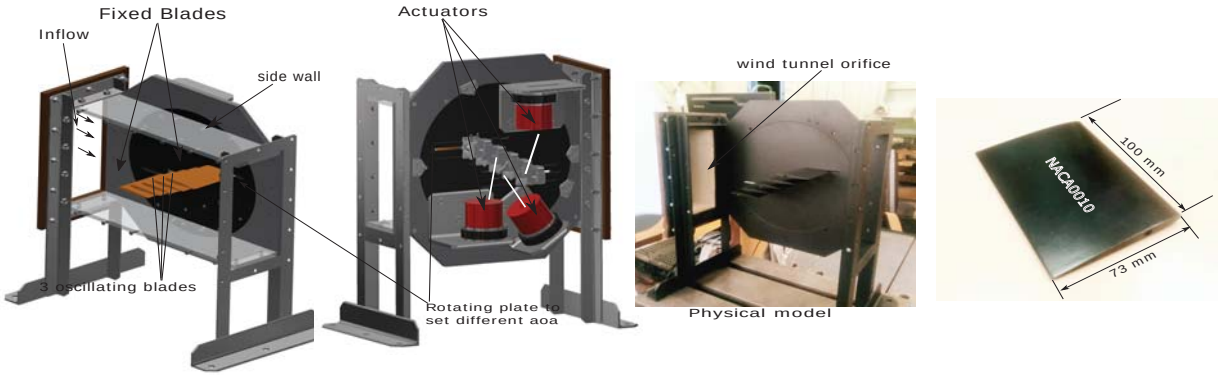

Figure 9: Experimental setup and physical model of the 5 blade cascade

5 Results

At first the the isolated pitching airfoil test is selected for the comparison purpose. The experimental results are obtain from the Galbraith et al. [14]. A cyclic lift coefficient of NACA0015 test results which corresponds the stall flow condition, are compared with simulated results using hybrid PM and presented in the Fig.10. In the Fig.10 results of the present model are in good agreement with the experimental data, although they exhibit a slight overestimation of the lift for high angle of attack (above $15°$). A small deviation in the shape of the C_L loop can be

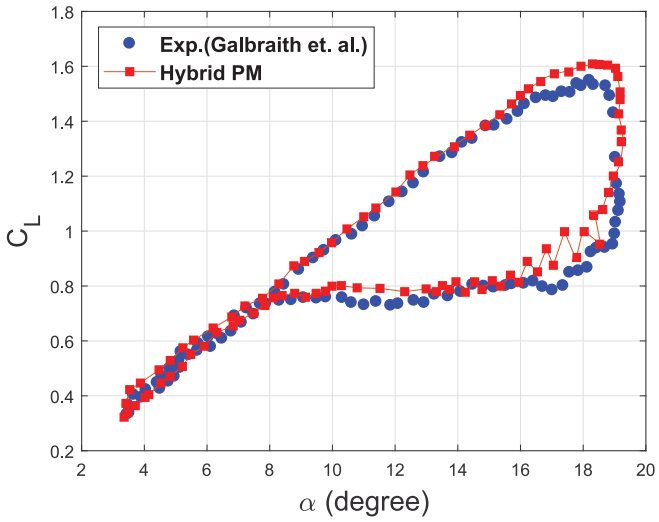

Figure 10: Lift coefficient vs. angle of attack for pitching aerofoil NACA 0015 at Re =1.5×10^{06}, reduce frequency (k) = 0.05

detected in the region close to the maximum pitching angle during the downstroke. This can be caused by strong separated vortex originated due to downstrok motion of the airfoil at the peak maximum angle. Furthermore, the present numerical results exhibit some oscillations when the stall occurs (between 13° to 18°) which is caused by the accumulation of the vortex blob at one point of time which may induce strong velocity potential on the airfoil surface. The problem can be solved by using more sophisticated diffusion method or eliminating the some blobs during the this period. Furthermore, it is worth mentioning that the time computation time taken to achived the converge result for pitching airfoil is approximately 2.5 CPU mins on single core Intel i7, which can be significantly lower then CFD based model, if adopted for the same test case.

The hybrid PM is then employed to estimate the aerodynamic damping for the 5 blade cascade model and the estimated AD vs. IBPA is presented in the Fig.11. the estimated AD curve shows that the present solver managed to predict stable and unstable IBPA region and for the 0 IBPA the cascade is stable for the used flow condition. However, due to lack of experimental result at this moment the accuracy of the results can not be verified. However, a similar linear cascade test case is presented by Prasad et al.[15], but for classical flutter cases. In his study Prasad et al. used CFD model for 11 blade 2D cascade to estimate the AD s-curve, and computational time taken is 13 CPU hrs on 4-core, Intel i7 processor, which is significantly higher compared to present proposed method which takes approximately 12 CPU mins to estimate the AD s-curve as shown in the Fig.11. Hence, the present method can be computationally more efficient than the CFD based model for the stall flutter test condition, if CFD is used, however, the CFD model estimation can be more accurate compared to the hybrid PM, because flow separation effects can be better represented by turbulence models in CFD based numerical models.

6 Conclusion

The paper present the development and implementation of a medium fidelity flow solver based on boundary element panel method to simulate the subsonic stall flutter in the 2D cas-

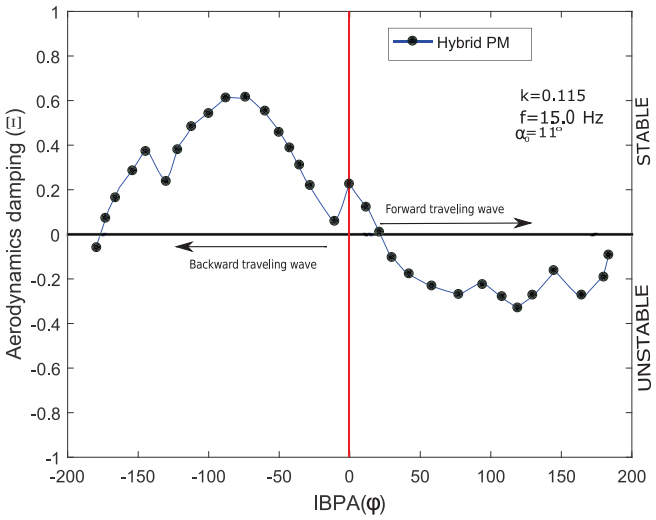

Figure 11: The AD (Ξ) vs IBPA, at $\alpha_0 = 11°$ and $\bar{\alpha} = 5°$ at reduce frequency $k = 0.115$ and wind speed $Q_\infty = 30.0m/s$ using hybrid PM

cades. To model separated flow the classical panel method is modified using viscous-inviscid coupling technique and the free wake is modeled using discrete vortex particles. The hybrid PM is tested for isolated pitching airfoil test case where the estimated cyclic lift coefficient vs angle of attack results shows good agreement with simulated one in Fig.10.Furthermore, the AD for the 5 blade cascade is estimated using the similar method for the subsonic stall flow condition in Fig.11. However, the experimental results were not ready by the time of submission of this paper, therefore, accuracy of the results can not be verified. However, the simulated AD looks reasonable for the similar test case in other literature. Moreover, the present method show significant reduction in the execution compared to CFD based numerical model. Therefore, the proposed method is good compromised of speed and accuracy over CFD based solvers and it has great potential to be used industrial application.The successful implementation of the proposed aeroelastic model for subsonic stall flutter in 2D cascade will have significant impact on the computational time reduction and will give researcher and engineering freedom to iterate different blade profile in very short time period at preliminary LP turbine design stage for blade design optimization and to understand the subsonic stall flutter in more details in steam turbine application.

Future work: In future the experimental results for the 5 blade cascade will be compared with the simulated results for AD and the wake shapes and also unsteady pressure field over the blade surface at different flow conditions.

Keywords: Rectangular plate, Geometrically non-linear, Lagrange's equations, Non-linear transverse vibration.

Abstract. *The main purpose of the paper is to investigate the effect of geometrically non-linear first mode shape free and force transverse vibration of "Clamped-Free-Clamped-Free rectangular plate", denoted as 'C-F-C-F RP', at large vibration amplitudes. Lagrange's equations and the harmonic balance method are used in order to formulate the problem that lead to obtain a non-linear algebraic equations. These later can be used to determine the dependency of displacement amplitudes, excitation frequencies, and the deflection associated to the first mode shape. In addition, it exhibits the contribution coefficients of higher mode shapes that contribute on the first mode shape. The obtain equations are solved via explicit solution which is an approximate method and which is used and compared previously in the case of free and forced vibration. The numerical obtain results can be used to predict the influence of the excitation frequencies and the level of applied forces on the dynamic response of thin C-F-C-F flat isotropic structures.*

Nomenclature

(x, y)	Point co-ordinates of RP.	a, b	Length, width of the plate.
$*$	The star exponent indicates non-dimensional parameters.	a_i	Basic function contribution.
α	The plate aspect ratio $\alpha = b/a$.	D	Bending stiffness.
$\mathrm{W}(x, y)$	Transverse displacement at point (x, y) on the plate.	E	Young's modulus.
$\mathrm{w}_{ij}(x, y)$	Basic function obtained as product of the i^{th} Clamped–Clamped and j^{th} Free–Free beam functions in the x and y directions.	F^c	Concentrated harmonic force.
		f_i^c	Generalized force corresponding to concentrated force F^c.
		H	Thickness of the plate.
ρ	Mass density per unit volume of the plate.	q_i	Teneralized co-ordinate.
		S	Dimensional surfaces of RP.
ϑ	Poisson ratio.	T	Knitecs energy.
		V_f, V_a	Bending and axial strain respectively.

1 INTRODUCTION

The thin structures encounter a large amplitude of deflections when they are subject to large external loads; in other words, these structures present geometrically non-linear vibrations. In aircraft skin panels, geometric non-linearity often occurs when the aircraft is subject to high aerodynamic forces [1]. This non-linearity is usually produced by the membrane stresses in the structure and results in an increase of resonance frequencies (hardening or softening resonance) and mode shape changes with regard to level of applied forces on the structure at large vibration amplitudes [2].

The literature on isotropic plate shows a variety of configurations and approaches which are listed and presented in the references [3, 4, 5, 6]. These configurations were numbered at 21 boundary conditions cases and created by Clamped, Free and Simply supported at the plate's edges that were investigated previously. These configurations have been changed from 21 to 55 cases by adding the fourth boundary condition named as Guided. Referring again, to the literature, it could be observed that there is a broad use of plates in various engineering fields and in different structural components because of their flexibility [7].

In the context of non-linear vibrations of thin plates at large deflections, many researchers have studied this type of non-linearity by using different methods [8, 9, 10, 11]. In the last few years, there has been a growing interest in geometrically non-linear using a model that was applied in beams [8] and plates [12] which has known an experimental validation in reference [13]. This model was based on Hamilton's equations and spectral analysis that aim to illustrate the dynamic response of system in order to determine the contribution coefficients of the mode non-concerned on the given mode shape. Furthermore, the model led to prove the dependency of displacement amplitudes, frequency, mode shape and associated bending stress, and is was used and applied in different continue (plates, beams, shell, etc.) ([14, 15, 16, 17]) and discrete (mass and spring) ([18, 19, 20]) structures.

The purpose of this paper is to investigate numerically free and forced vibration of C-F-C-F[1] RP[2] (see Figure 1) with a ratio equals to 0.66 (α=0.66) at large vibration amplitudes. The adopted model is an extend of the model presented in [12]. The non-linear algebraic equations are obtained using Lagrange's equations and the harmonic balance method, in order to illustrate the effect of large deflection on thin mechanical structures (C-F-C-F RP).

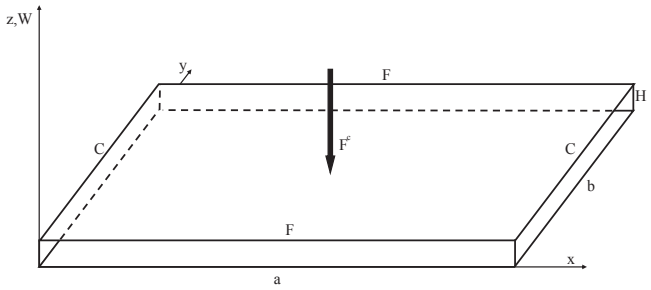

Figure 1: Rectangular plate notations of C-F-C-F

2 Theoretical formulation based on Lagrange's equations and the harmonic balance method

The isotropic thin RPs figured in Figure 1 have the bending stiffness D:

$$D = \frac{EH^3}{12\left(1-\vartheta^2\right)} \tag{1}$$

For such plates, the total strain energy denoted V is given as the sum of the strain energy due to the bending V_f and the membrane strain energy V_a induced by large deflections of structure ($V = V_a + V_f$). These terms can be written as follow without taking into account the in-plane displacements:

$$\mathrm{V_f} = \frac{1}{2}D\int_S \left[\left(\frac{\delta^2 W}{\delta x^2}\right)^2 + \left(\frac{\delta^2 W}{\delta y^2}\right)^2 + 2(1-\vartheta)\left(\frac{\delta^2 W}{\delta x \delta y}\right)^2 + 2\vartheta\left(\frac{\delta^2 W}{\delta x^2}\frac{\delta^2 W}{\delta y^2}\right)\right] dS \tag{2}$$

$$V_a = \frac{3D}{2H^2}\int_S \left[\left(\frac{\delta W}{\delta x}\right)^2 + \left(\frac{\delta W}{\delta y}\right)^2\right]^2 dS \tag{3}$$

And T is the kinetic energy of plate as given by:

$$T = \frac{1}{2}\rho H\int_S \left(\frac{\delta W}{\delta t}\right)^2 dS \tag{4}$$

Where the S is the surface of RP and W is the deflection function.

In the three later equations, terms involving the in-plane displacements and their derivatives have been omitted. This assumption, which simplifies considerably the theory and leads to obtain good results for reasonable ranges of vibration amplitudes, has been adopted and justified in many previous papers.

[1]Clamped-Free-Clamped-Free

[2]Rectangular Plate

The C-F-C-F RP have been discretized from i^{th} C-C and j^{th} F-F beam mode shapes in the x and y directions, respectively. Furthermore, the deflection function is assumed harmonic, which is extended as a series of n basic spatial functions $\mathrm{w}_k(x,y)$:

$$\begin{aligned} W(x,y,t) &= q_k(t)\mathrm{w}_k(x,y) \\ &= a_k\mathrm{w}_k(x,y)\sin(\omega t) \\ &= \alpha_{ij}\mathrm{w}_{ij}(x,y)\sin(\omega t) \end{aligned} \tag{5}$$

with $k = n(i-1)+j$

The rearranging and substitution of the equation (5) into the equations (2), (3) and (4), respectively, leads to obtain the following equations:

$$V_f = \frac{1}{2}q_i q_j k_{ij} \tag{6}$$

$$V_a = \frac{1}{2}q_i q_j q_k q_l b_{ijkl} \tag{7}$$

$$T = \frac{1}{2}\dot{q}_i \dot{q}_j m_{ij} \tag{8}$$

where m_{ij}, k_{ij} and b_{ijkl} are the mass, the linear and non-linear rigidity tensors, respectively. With the indices i, j, k and l are varying from 1 to n. The expressions for these tensors are given by:

$$m_{ij} = \rho H \int_S \mathrm{w}_i \mathrm{w}_j dS \tag{9}$$

$$k_{ij} = D\int_S \left[\frac{\partial^2 \mathrm{w}_i}{\partial x^2}\frac{\partial^2 \mathrm{w}_j}{\partial x^2} + \frac{\partial^2 \mathrm{w}_i}{\partial y^2}\frac{\partial^2 \mathrm{w}_j}{\partial y^2} + 2(1-\vartheta)\frac{\delta^2 \mathrm{w}_i}{\delta x \delta y}\frac{\delta^2 \mathrm{w}_j}{\delta x \delta y} + 2\vartheta\frac{\delta^2 \mathrm{w}_i}{\delta x^2}\frac{\delta^2 \mathrm{w}_i}{\delta y^2}\right] dS \tag{10}$$

$$b_{ijkl} = \frac{3D}{2H^2}\int_S \left[\left(\frac{\partial \mathrm{w}_i}{\partial x}\frac{\partial \mathrm{w}_j}{\partial x} + \frac{\partial \mathrm{w}_i}{\partial y}\frac{\partial \mathrm{w}_j}{\partial y}\right)\left(\frac{\partial \mathrm{w}_k}{\partial x}\frac{\partial \mathrm{w}_l}{\partial x} + \frac{\partial \mathrm{w}_k}{\partial y}\frac{\partial \mathrm{w}_l}{\partial y}\right)\right] dS \tag{11}$$

The dimensionless parameters were used in this paper to simplify the interpretation of the obtained results as used in [14, 16], and we can put:

$$\begin{aligned} \mathrm{w}_i(x,y) = H\mathrm{w}_i^*\left(\frac{x}{a},\frac{y}{b}\right) = H\mathrm{w}_i^*\left(x^*,y^*\right), \quad \frac{\omega^2}{\omega^{*2}} = \frac{D}{\rho H b^4}, \\ \frac{k_{ij}}{k_{ij}^*} = \frac{DaH^2}{b^3}, \quad \frac{m_{ij}}{m_{ij}^*} = \rho H^3 ab, \quad \frac{bijkl}{b_{ijkl}^*} = \frac{DaH^2}{b^3} \end{aligned} \tag{12}$$

2.1 Application to free vibration of C-F-C-F RP

Lagrange's equations have been employed to describe the non-linear dynamic behavior for a conservative system (C-F-C-F RP), that can be written as follow:

$$-\frac{\partial}{\partial t}\left(\frac{\partial T}{\partial \dot{q}_r}\right) + \frac{\partial T}{\partial q_r} - \frac{\partial V}{\partial q_r} = 0, \qquad r = 1-n \tag{13}$$

The q_i is assumed to be harmonic, as used in equation (5) we get:

$$q_i(t) = a_i \sin \omega t, \qquad i = 1 - n$$

In the equation (13), V and T are replaced by their expressions given above in (6), (7), and (8), and their derivatives are calculated with respect to the $a_i's$. The following set of non-linear algebraic equations are obtained by applying the harmonic balance method and non-dimensional parameters:

$$\frac{3}{2} a_i a_j a_k b^*_{ijkr} + a_i k^*_{ir} - a_i \omega^{*2} m^*_{ir} = 0, \qquad i, j, k, r = 1 - n \tag{14}$$

The later can be written in matrix form as following:

$$\left([K^*] - \omega^{*2} [\mathbf{M}^*] \right) \{\mathbf{A}\} + \frac{3}{2} [\mathbf{B}^*(\mathbf{A})] \{\mathbf{A}\} = \{\mathbf{0}\} \tag{15}$$

The column vector of basic function (contribution coefficients) $\{\mathbf{A}\}$, which can be written as $\{\mathbf{A}\}^{\mathrm{T}} = [a_1 a_2 \dots a_n]$.

In addition ω^* is the non-dimensional non-linear frequency response that can be obtained through (14) as:

$$\omega^{*2} = \frac{a_i a_j k^*_{ij} + \frac{3}{2} a_i a_j a_k a_l b^*_{ijkl}}{a_i a_j m^*_{ij}} = \frac{k_{ij}}{m_{ij}} + \frac{3}{2} \frac{a_k a_l b_{ijkl}}{m_{ij}} \tag{16}$$

In order to obtain the numerical solution for the non-linear problem in the neighborhood of the first mode shape, the contribution of this mode is chosen and others of higher modes are calculated numerically via explicit method (first formulation) of the remaining $(n-1)$ non-linear algebraic equations. Furthermore, the dynamic response free vibration can bee obtained the following equations:

$$3 a_i a_j a_k b^*_{ijkr} + 2 a_i k^*_{ir} - 2 a_i \frac{a_i a_j k^*_{ij} + a_i a_j a_k a_l b^*_{ijkl}}{a_i a_j m^*_{ij}} m^*_{ir} = 0, \qquad r = 1 - n \tag{17}$$

2.2 Forced vibration application in C-F-C-F RP

Considering the RP exhibited in Figure 1 which is excited harmonically with a concentrated forces applied at the plate's center (x_0, y_0), In this way we can write:

$$F(x_0, y_0) = F^c \delta(x - x_0) \delta(y - y_0) \sin(\omega t) \tag{18}$$

The corresponding generalized force F^c is given by:

$$F^c_i(t) = F^c \mathrm{w}_i (x_0, y_0) \sin \omega t = f^c_i \sin(\omega t) \qquad i = 1 - n \tag{19}$$

The dimensionless of generalized forces f^{c*}_i that is applied on the RP can be obtained from the following equation:

$$f^{c*}_i = \frac{b^3 F^c}{aDH} \mathrm{w}^*_i(x^*_0, y^*_0), \qquad i = 1 - n \tag{20}$$

Assuming that equation (5) holds for q_i which is supposed to be harmonic, we get:

$$q_i(t) = a_i \sin \omega t, \qquad i = 1 - n \tag{21}$$

The problem of forced vibration was reduced to a non-linear algebraic equation of C-F-C-F RP by applying Lagrange's equations and harmonic balance method as used in the previous subsection:

$$-\frac{\partial}{\partial t}\left(\frac{\partial T}{\partial \dot{q}_r}\right)+\frac{\partial T}{\partial q_r}-\frac{\partial V}{\partial q_r}=F_r, \qquad r=1-n \tag{22}$$

The non-linear algebraic equations have been obtained by substituting the terms of V_f, V_a, T into the later equation and by applying the harmonic balance method that yield to:

$$\frac{3}{2}a_i a_j a_k b^*_{ijkr}+a_i k^*_{ir}-a_i\omega^2 m^*_{ir}=f^*_r, \qquad i,j,k,r=1-n \tag{23}$$

where ω^* is the dimensionless excitation frequency. Hence, the equation (23) can be written in matrix form as:

$$\left([K^*]-\omega^{*2}\left[\mathbf{M}^*\right]\right)\{\mathbf{A}\}+\frac{3}{2}\left[\mathbf{B}^*(\mathbf{A})\right]\{\mathbf{A}\}=\{\mathbf{F}^*\} \tag{24}$$

3 Explicit procedure of solution

3.1 Free vibration

The explicit method or the first formulation as used in [14], leads to obtain the solution in the neighborhood of the first non-linear mode shape, and the basic functions vector $\{\mathbf{A}\}$ can be written as: $\{\mathbf{A}\}^{\mathrm{T}}=[a_1\varepsilon_2\ldots\varepsilon_6]$, with the contribution coefficients indice is varying from 2 to 6. Indeed, $\varepsilon_2\ldots\varepsilon_6$ can be considered small compared to a_1.

This method is based on an approximation that leads to neglect the second and third terms in the expression $a_i a_j a_k b^*_{ijkr}$. With respect to ε_i, the remaining term can be reduced to $a_1^3 b^*_{111i}$.

$$\frac{3}{2}a_1^3 b^*_{1111}+a_1 k^*_{11}-a_1\omega^2 m^*_{11}=0 \tag{25}$$

which gives :

$$\omega^2=\frac{k_{11}}{m_{11}}+\frac{3}{2}a_1^2\frac{b_{1111}}{m_{11}} \tag{26}$$

The i^{th} basic functions of the contributions (ε_i) is explicitly calculated from the i^{th} approximate equation of system (14):

$$\frac{3}{2}a_1^3 b^*_{111i}+\left(k^*_{ii}-\omega^2 m^*_{ii}\right)\varepsilon_i=0 \qquad i=2-6 \tag{27}$$

Then, the last equation allows to the following analytical expression for i^{th} contributions that contribute to the first mode shape:

$$\varepsilon_i=\frac{-\frac{3}{2}a_1^3\overline{b}^*_{111i}}{\overline{k}^*_{ii}-\omega^{*2}_{nl}\overline{m}^*_{ii}}=\frac{-\frac{3}{2}a_1^3\overline{b}^*_{111i}}{\overline{k}^*_{ii}-\left[\frac{\overline{k}_{11}}{\overline{m}_{11}}+\frac{3}{2}\frac{a_1^2\overline{b}_{1111}}{\overline{m}_{11}}\right]\overline{m}^*_{ii}} \qquad i=2-6 \tag{28}$$

The non-linear dynamic response free vibration is described in the equation below:

$$\mathrm{W}^*_{nl}(x^*,y^*)=\frac{-\frac{3}{2}a_1^3 b^*_{1111}}{(k^*_{11}-\omega^{*2}m^*_{11})}\mathrm{w}^*_{11}(x^*,y^*)+\frac{-\frac{3}{2}a_1^3 b^*_{1112}}{(k^*_{22}-\omega^{*2}m^*_{22})}\mathrm{w}^*_{12}(x^*,y^*)+\cdots+\frac{-\frac{3}{2}a_1^3 b^*_{1116}}{(k^*_{66}-\omega^{*2}m^*_{66})}\mathrm{w}^*_{16}(x^*,y^*)) \tag{29}$$

3.2 Forced vibration

The non-linear algebraic equations obtained from (23) were solved using the explicit method. In order to obtain a multi-dimensional non-linear frequency response, this structure has been subjected to high levels of applied forces amplitudes and harmonic excitation. The C-F-C-F RP is excited harmonically in the neighbourhood of the first mode shape, which is generated only by the first basic function w_{11} and that is the predominant in the dynamic response, then the equation (23) is reduced to:

$$\frac{3}{2}a_1^3 b_{1111}^* + \left(k_{11}^* - \omega^2 m_{11}^*\right) a_1 = f_1^* \tag{30}$$

where b_{1111}^*, k_{11}^*, and m_{11}^* are respectively the non-dimension terms of the non-linear, the linear rigidity, and the mass tensor corresponding to the first mode shape of C-F-C-F RP. After rearranging the above equation, we obtain:

$$\left(\frac{\omega^*}{\omega_{1L}^*}\right)^2 = 1 + \frac{3}{2}\overline{a}_1^2 \frac{\overline{b}_{1111}^*}{\overline{k}_{11}^*} - \frac{\overline{f}_1^*}{a_1 k_{11}^*} \tag{31}$$

As mentioned above, the explicit method and harmonic balance method have been applied to deduce ε_i:

$$\frac{3}{2}a_1^3 b_{111i}^* + \left(k_{ii}^* - \omega^2 m_{ii}^*\right) \varepsilon_i = f_i^* \qquad\qquad i = 2 - 6 \tag{32}$$

The last equation allows to the following analytical expression for i^{th} contributions that contribute on the first mode shape:

$$\varepsilon_i = \frac{f_i^* - \frac{3}{2}a_1^3 b_{111i}^*}{k_{ii}^* - \omega^{*2} m_{ii}^*}, \qquad\qquad i = 2 - 6 \tag{33}$$

Then, the first mode of the non-linear steady state periodic forced response function of C-F-C-F RP can be expressed as following:

$$\mathrm{W}_{nl}^*(x^*, y^*) = \frac{f_1^* - \frac{3}{2}a_1^3 b_{1111}^*}{(k_{11}^* - \omega^{*2} m_{11}^*)} \mathrm{w}_{11}^*(x^*, y^*) + \frac{f_2^* - \frac{3}{2}a_1^3 b_{1112}^*}{(k_{22}^* - \omega^{*2} m_{22}^*)} \mathrm{w}_{12}^*(x^*, y^*) + \cdots + \frac{f_6^* - \frac{3}{2}a_1^3 b_{1116}^*}{(k_{66}^* - \omega^{*2} m_{66}^*)} \mathrm{w}_{16}^*(x^*, y^*)) \tag{34}$$

4 Results and discussions

In this section, we will discuss the results obtained in the numerical simulations of free and forced vibration, in order to show the effect of geometrically non-linear on C-F-C-F RP at large vibration amplitudes with the plate's ratio equals to 0.66 ($\alpha = 0.66$). These simulations were carried out on RP made from aluminium alloy with a thickness of 0.6 mm. The dimensions of this plate are 240 x 360 mm (width x length), that gives 0.66 in the ratio. According to the commercial catalog, the density, Young modulus, and the Poisson's ratio of this plate are $2140 Kg/m^3$, 7x$10^{10} N/m^2$, and 0.34, respectively.

Dynamic response of a C-F-C-F rectangular plate is calculated using the first, six, and nine first linear modes shape ($\mathrm{w}_{11}, \mathrm{w}_{12}, \mathrm{w}_{13}, \ldots, \mathrm{w}_{19}$) in equation 29 and 34.

4.1 Free vibration

The non-dimensional terms of mass, linear and non-linear rigidity tensors were computed numerically by using the software "MATLAB".

The linear analysis was obtained by neglecting the term of geometrical nonlinearity; this assumption leads us to obtain the values of the fundamental frequency parameter of various plate's ratio which are included in Table 1. Furthermore, the later linear frequencies have been determined by Leissa in [3] using Symmetric-Antisymmetric Modes of C-F-C-F rectangular plates and are compared with those obtained by our present study which shown a good convergence of solutions. The backbone curves forced vibration in the case of C-F-C-F RP were not found in the literature.

Table 1: Comparison of the first fundamental frequency parameters of a C-F-C-F RP, with various α.

Aspect ratio α	Present study	Leissa[3]	Percentage error (%)
1	25.54	26.40	3.26
0.9	22.70	22.10	-2.71
0.66	13.32	-	-

The values of contribution coefficients corresponding to the first mode shape was calculated by explicit solution from the equation (28) with a given assignment contribution (a_1), and the results are listed in Table (2). From this table, the five contributions show their contribution on the first mode shape and these values become important when the (a_1) increase.

Figure 5 represents the corresponding curve of fundamental resonance (F = 0 N) obtained by plotting the equation (29). The first non-linear mode shape of C-F-C-F RP with $\alpha = 0.66$ is depicted in Figure 5 and the dependence of the non-linear frequency on the non-dimensional vibration amplitudes is shown. As may expected, a hardening type of non-linearity of C-F-C-F RP is observed.

The amplitudes mode shape dependence are investigated, which allow to illustrate the effect of large transverse vibration amplitudes on the first mode shape. The normalized sections along the x an y directions, corresponding to $y^* = 0.5$ and $x^* = 0.5$ of the non-linear fundamental mode shape were obtained from equation (29) are plotted in Figure 2 (a) and (b). The later, show respectively the increase of all curvatures near the free edges and decrease for the clamped edges. These curves obtained for the large, medium, and low displacement amplitudes which are corresponding to 4.91, 0.98, and 0.4 at the plate's center, respectively.

4.2 Forced vibration

The present subsection aims to treat the transverse steady state periodic forced response of thin C-F-C-F isotropic RP with the $\alpha = 0.66$, which the geometric and mechanical characteristics were presented above.

The equation (32) holds to obtain (33), which allows to an analytical expression for ε_i with $i = 2 - 6$ to be derived in terms of a_1, and the results are listed in Table 3. These results are obtained with a given typical values of a_1 in order to calculate the first six basic functions varying from 0.3 to 2.

The thin C-F-C-F isotropic RP was excited with a concentrated harmonic forces at the plate's center. The non-linear algebraic equations (23) have been reduced to single-mode approach, that assumed to neglect all co-ordinates except a single resonant co-ordinate as obtained in equation (30) and (31). The convergence of the solution was studied using the first mode shape which is the predominant (single mode approach), the first six and nine mode shapes (multimode solution) in the two equations (31) and (34), respectively, with 1 N of forcing vibration amplitude.

These latter are plotted in Figure 3 and showed the convergence of the results that can be reached for six modes shape via multimode solution. In addition, these curves show a slight difference for the dimensionless displacements less than 1.5 and the difference becomes clearer for the remains results.

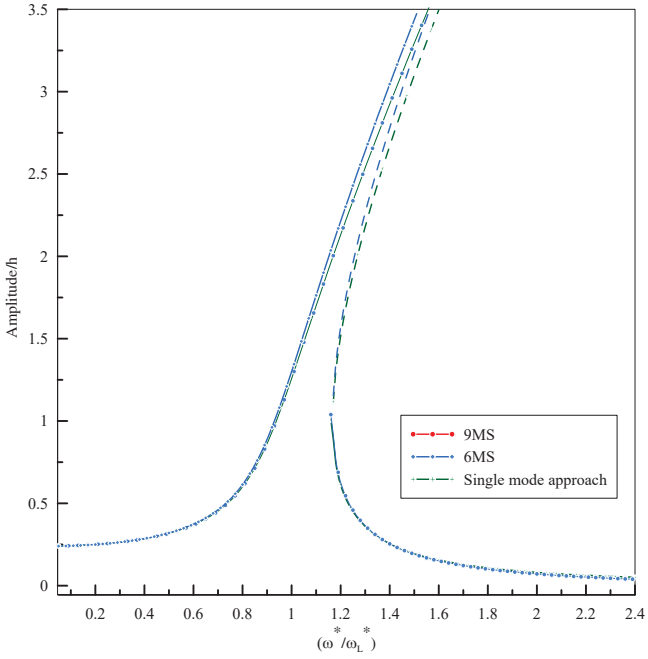

Figure 3: Backbone curve corresponding to the single mode approach and multi-mode solution.

In Figure 4 the linear and nonlinear frequency response curves are given in term of the

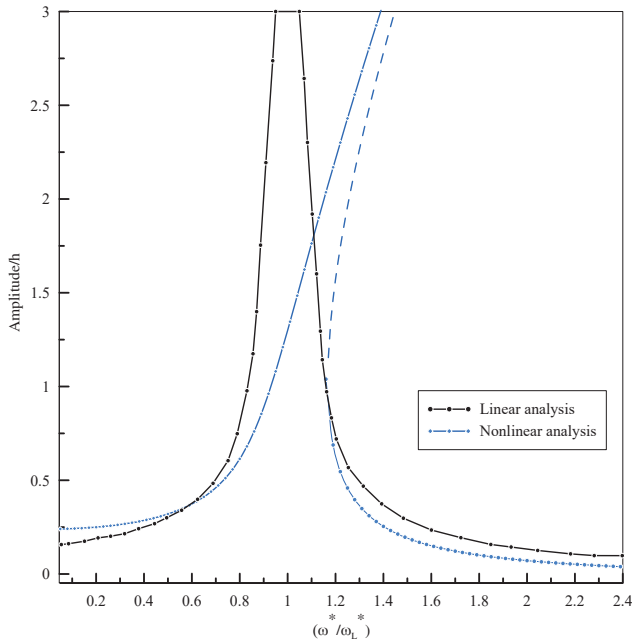

Figure 4: Linear and nonlinear analysis forced vibration response of C-F-C-F RP.

amplitudes and the frequency parameter. The results corresponding to this excitation correspond to the classical response in the forced linear model that obtained by neglecting the nonlinear term (b_{ijkl}) in equation (34).

Furthermore, forced responses of RP under different concentrated amplitude forces (F^c= 0, 0.25, 0.5, and 1 N) are shown in Figure 5 using first six modes shape. These three curves show the hardening type resonance for all considered excitation levels and the jump phenomena was observed near 0.6, 0.8, and 1.1 dimensionless displacements, respectively.

5 Conclusion

The geometrically non-linear dynamic free and steady state periodic forced response of thin and isotropic C-F-C-F RP were investigated via a theoretical model which was developed in this paper. The effect of large vibration amplitudes was studied in order to determine the amplitudes frequency dependence and associated first mode shape free and forced vibrations.

The model used is based on Lagrange's equations and the harmonic balance method that were used to reduce the problem to non-linear algebraic equations without tacking into account the in-plane displacements and their derivatives. These later, gave the terms of mass tensor, linear and non-linear rigidity due to the geometrical non-linearity which were computed numerically. In addition, the non-linear dynamic, response in free and forced vibration, were investigated by using the first six plate functions. These functions were obtained as products of the first six beam functions in the x and y directions that were used to discretize the C-F-C-F RP.

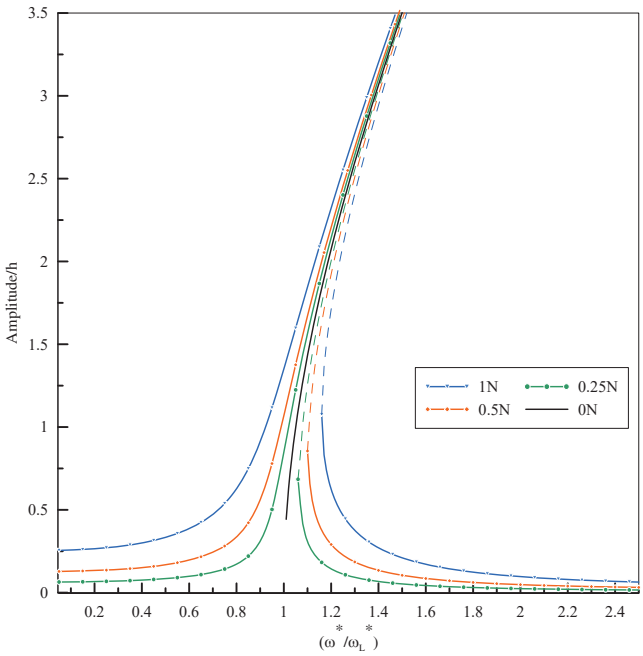

Figure 5: Resonance curves for 0, 0.25, 0.5 and 1 N of forcing vibration.

The RP's α=0.66 was chosen, the amplitudes frequency dependence were studied and presented for free vibration case. The results obtained showed that the frequency response increases with the increase of the amplitude, which led as to exhibit the hardening type of resonance as expected. In addition, when the amplitude increases, the deflection of the first mode shape increases at the Free-Free edges and decreases in the vicinity of plate's center, and an increase of the mode shape of C-C edges when the amplitudes increase.

The steady state periodic forced response was studied and the hardening non-linearity was obtained as in the free case using the same structure. Furthermore, the single-mode approach and the multi-mode solution were studied and plotted, illustrating a correlation between them for 1.5 in dimensionless displacements. The effect of applied harmonic forces (0, 0.25, 0.5 and 1N) and the excitation frequency on the dynamic response of C-F-C-F RP were illustrated. These results show the jump phenomena near 0.6, 0.8, and 1.1 dimensionless displacements, respectively for 0.25 , 0.5 and 1 N, forcing vibration.

Based on the obtained results, it can be concluded that the research into geometrically non-linear dynamic on thin and isotropic C-F-C-F RP has been very successful. Furthermore, these investigation are require to taking into account of the in-plane displacements. Thus, the future works will concerning to carry out an experimental studies to compare with the obtained numerical results.

Keywords: Non-Linear Longitudinal Vibration, Lagrange's equations, Linearized Approach, Harmonic Balance Method, Geometrically Non-linear.

Abstract. *The present study aims to investigate the problem of linear and non-linear longitudinal free vibration of uniform rods and rods with sections varying exponentially. This problem is reduced to a non-linear algebraic equation which is based on the Lagrange's equations and the harmonic balance method. In fact, these methods were applied previously to study the non-linear transverse vibration of the different continuous structures (beams, plates, and shells) and discrete structures (2-dof and multi-dof systems). However, the present model leads to obtain a solution of a non-linear algebraic system using numerical method. The non-linear frequencies corresponding to the first, second and third non-linear mode shapes of Clamped-Free uniform and non-uniform rods are treated via the Linearized Approach. Therefore, the obtained numerical results exhibit the geometrically non-linear effect. The dependencies of the amplitude on the slope of exponential function coefficient, the frequency and on the non-linear mode shape are applied for the first, second and third mode shapes, in order to examine the used method in the case of Clamped-Free non-uniform rods longitudinal free vibration at large amplitudes.*

Nomenclature

δ	Slope of exponential function coefficient	k_i	linear rigidity of spring i
ω	frequency parameters	k_{ij}	General terms for the linear rigidity tensor
*	the asterisk indicates non-dimensional parameters	L	Length of the rod
ρ	Mass per unit volume	m_i	i^{th} mass of 2-dof system
A	Mode amplitude	m_{ij}	General terms for the mass tensor
A_i	Amplitude of the displacement u_i	S	Area of the cross section
a_i	Contribution coefficient of i^{th} linear mode shape	S_0	Maximum section of rods
a_i	contribution coefficient	T	kinetic energy
b_{ijkl}	General terms for the nonlinearity tensor	$U(x,t)$	The longitudinal displacement
C	Velocity of propagation	u_i	Displacement of mass m_i
E	Young's modulus	U_l	Linear potential energy
		U_{nl}	non-linear potential energy
		x	Axial position coordinate

1 Introduction

The longitudinal vibration analysis of rods is an important issue in structural engineering applications, such as high-rise buildings, long-span bridges, aerospace machines and many other industrial usages. Longitudinal and torsional vibrations are significant in these structures and their natural frequencies have to be considered in the design process. The determination of both linear and nonlinear natural frequencies, with associated mode shapes and bending stress, are essential in structural dynamic analysis in order to design efficient machines. The external vibrations loading and services condition may cause large displacements and rotations that lead to considerable pre-stress states in the structure. Consequently, the modal behavior of structures is evidently a property of the equilibrium state and natural frequencies are subject to change.
The exact solutions and the numerical techniques for linear longitudinal vibration of homogeneous rods can be found in literature [16, 13], while analytical studies on inhomogeneous rods are scarce. Eisenberger [11], Matsuda and al [15], Bapat [4], Abrate [1], Kumar and Sujith [12], Anil Raj , Sujith [18] and Xu and al [19] studied the linear longitudinal vibration of rods with variable sectional area and they obtained the exact solutions for certain functional forms of an involved parameter.
The present work devotes to the non-linear longitudinal vibration of rods using a model based on Lagrange's formulation and harmonic balance method. This structure is reduced to a non-linear algebraic system, which can be solved by numerical procedures (iterative, linearized or explicit). These methods have been developed and used to examine the non-linear behavior of continuous structures and discrete systems [8, 7, 9, 10, 17, 2], longitudinal, transverse vibration of 2-dof systems [6]. In our case, an application is made using the linearized procedure [8]

leading to the fundamental non-linear longitudinal mode shape of C-F[1] rods.

2 Theoretical formulation

Actually, the main objective of the present paper is to determinate the dynamic response of C-F rods with section varying exponentially at large vibration amplitudes, in order to illustrate the non-linear longitudinal mode shapes and natural frequencies of C-F rods with section varying exponentially. We start by presenting in the first subsection the formulas for the natural frequencies, mode shapes and displacements of linear C-F rods. Then in the second one the formulation of the basic theory of geometrically non-linear longitudinal free vibration of rods are presented.

2.1 Linear Model

The uniform rods having the following characteristics: E: Young's modulus, ρ: mass per unit volume, L: length of the rod, S: area of the cross section, $U(x,t)$: the longitudinal displacement which is assumed to be harmonic, i.e. $U(x,t) = u(x)\sin(\omega t)$, and are well-known by the equation of longitudinal vibrations of rods, this can be written by:

$$\frac{\partial}{\partial x}\left(S\frac{\partial u}{\partial x}\right) = \frac{S}{C^2}\frac{\partial^2 u}{\partial t^2} \tag{1}$$

where C is the velocity of propagation of the displacement or stress waves in the rod, and it is given by:

$$C = \sqrt{\frac{E}{\rho}} \tag{2}$$

Considering now the longitudinal vibrations of the rods with exponential sections which are illustrated in Figure 1, taking into account the same geometrical characteristics presented earlier. These sections can be written as below and S_0 is the maximum section of rods:

$$S(x) = S_0 \exp(\delta x) \tag{3}$$

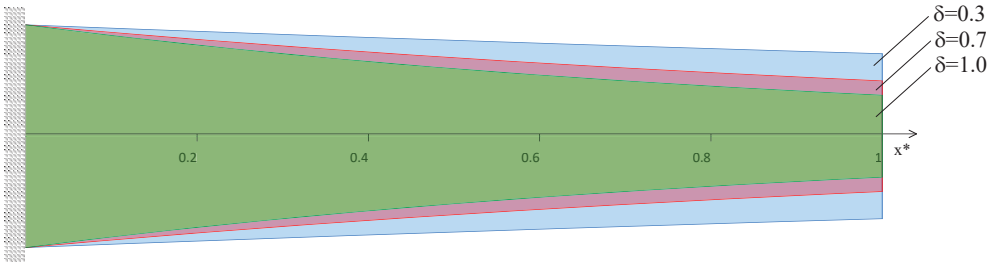

Figure 1: Notation of rods with sections varying exponentially (blue: $\delta = 0.3$, red: $\delta = 0.7$, green: $\delta = 1.0$)

[1]Clamped-Free

By substituting the equation (3) into (1) and by using the classical method of separation of variables, we obtain a differential equation we the solution gives the following mode:

$$u_n(x) = \left(\sin \frac{n\pi}{L} x\right) e^{-\frac{\delta}{2}x} \tag{4}$$

with the frequencies expression written as:

$$\omega_n = \frac{1}{2}\sqrt{\frac{E}{\rho}}\sqrt{\left(\frac{4\pi^2 n^2}{L^2} + \delta^2\right)} \tag{5}$$

2.2 Non-Linear Model

The method presented in this subsection is based on a semi-analytical approach. The dynamic behavior is obtained by using Lagrange's equations for a conservative system, which leads to:

$$-\frac{\partial}{\partial t}\left(\frac{\partial T}{\partial \dot{q}_r}\right) + \frac{\partial T}{\partial q_r} - \frac{\partial V}{\partial q_r} = 0, \quad r = 1, \ldots, n \tag{6}$$

In the above equation, T is the kinetic energy of the rod given by:

$$T = \frac{1}{2}\int_0^L \rho S \left(\frac{\partial u}{\partial t}\right)^2 dx \tag{7}$$

V is the total strain energy, which can be written as the sum of the linear strain energy V_l and the non linear strain energyV_{nl}:

$$V = V_l + V_{nl} = \frac{1}{2}\int_0^L ES\left(\frac{\partial u}{\partial x}\right)^2 dx + \frac{1}{2}\left[\int_0^L ES\left(\frac{\partial u}{\partial x}\right)^3 dx + \frac{1}{4}\int_0^L ES\left(\frac{\partial u}{\partial x}\right)^4 dx\right] \tag{8}$$

The large displacement U is assumed to be harmonic which is expanded in the form of a finite series, one obtains:

$$U(x,t) = q_i(t)u_i(x) = a_i u_i(x)\sin \omega t \tag{9}$$

where the usual summation convention for the repeated index i varies from 1 to n. After substituting the expression given in equation (9) ,for the displacement function U, in the energy expressions (7) and (8) and performing the discretization,we obtain the following expressions for the potential and kinetic energies that can be written as:

$$T = \frac{1}{2}\dot{q}_i \dot{q}_j m_{ij} \tag{10}$$

$$V_l = \frac{1}{2} q_i q_j k_{ij} \tag{11}$$

$$V_{nl} = \frac{1}{2} q_i q_j q_k q_l b_{ijkl} + \frac{1}{2} q_i q_j q_k c_{ijk} \tag{12}$$

where k_{ij} denotes the classical rigidity tensor due to V_l; b_{ijkl} and c_{ijk} represent the nonlinearity tensors due to V_{nl} and m_{ij} stands for the mass tensor attributable to T. The expressions for the general terms of these tensors are given by :

$$m_{ij} = \int_0^L \rho S u_i u_j dx \tag{13}$$

$$k_{ij} = \int_0^L ES \frac{\partial u_i}{\partial x} \frac{\partial u_j}{\partial x} dx \tag{14}$$

$$b_{ijkl} = \int_0^L \frac{ES}{4} \left(\frac{\partial u_i}{\partial x} \frac{\partial u_j}{\partial x} \frac{\partial u_k}{\partial x} \frac{\partial u_l}{\partial x} \right) dx \tag{15}$$

$$c_{ijk} = \int_0^L ES \left(\frac{\partial u_i}{\partial x} \frac{\partial u_j}{\partial x} \frac{\partial u_k}{\partial x} \right) dx \tag{16}$$

Referring to [7], we put The non-dimensional parameters as follow:

$$u_i(x) = L u_i^* \left(\frac{x}{L} \right) = L u_i^* \left(x^* \right); \frac{\omega^2}{\omega^{*2}} = \frac{E}{\rho L^2}; \frac{m_{ij}}{m_{ij}^*} = \rho S L^3; \frac{k_{ij}}{k_{ij}^*} = ESL; \frac{b_{ijkl}}{b_{ijkl}^*} = ESL \tag{17}$$

The amplitudes a_i are the unknown parameter that should to be determined as well as the frequency ω. Replacing T and V into equation (6) by their expressions given above, and applying the harmonic balance method we obtain:

$$2 a_i k_{ir}^* + 3 a_i a_j a_k b_{ijkr}^* - 2 \omega^{*2} a_i m_{ir}^* = 0; \qquad r = 1, \ldots, n \tag{18}$$

the later can be written in matrix form as:

$$2 \left[K^* \right] \{A\} + 3 \left[B^* (\{A\}) \right] \{A\} - 2 \omega^{*2} \left[M^* \right] \{A\} = 0 \tag{19}$$

where ω^* is the non-dimensional non-linear frequency parameter. The expression of the later can be obtained by pre-multiplying equation (19) by $\{A\}^T$ from the left hand side, and written as:

$$\omega^{*2} = \frac{\{A\}^T [K^*] \{A\} + \frac{3}{2} \{A\}^T [B^* (\{A\})] \{A\}}{\{A\}^T [M^*] \{A\}} \tag{20}$$

By substituting and rearranging the equation (20) into (18), we obtain:

$$3 a_i a_j a_k b_{ijkr}^* + 2 a_i k_{ir}^* - 2 \left(\frac{a_i a_j k_{ij}^* + \frac{3}{2} a_i a_j a_k a_1 b_{ijkl}^*}{a_i a_j m_{ij}^*} \right) a_i m_{ir}^* = 0; \quad r = 1, \ldots, N \tag{21}$$

This obtained equation is a non-linear algebraic system that can be solved using an iterative, explicit and linearized procedure. This later is used in the present work in order to study the amplitude frequency dependence and associated first, second and third nonlinear longitudinal mode shapes of C-F uniform rods and non-uniform rods, respectively.

3 Numerical Details

Various non-linear vibration problems are solved due to the non-linear algebraic system formally similar to equation (19) and having the following form:

$$\left([K_l] + \frac{3}{2}[B(A)]\right)\{A\} - \omega^2[M]\{A\} = \{0\} \tag{22}$$

in which $\{A\}^T$ is the column matrix of the basic function or the linear mode shape contribution coefficients $\{A\}^T = [a_1 a_2 \dots a_N]$.$[M]$, $[K_l]$ and $[B]$ are respectively the mass matrix, the linear rigidity matrix and the non-linear rigidity matrix. Equation (22) can be also written as:

$$\left([K_l] + \frac{3}{2}[K_{nl}]\right)\{A\} = \omega^2[M]\{A\} \tag{23}$$

Each term of the matrix $[K_{nl}]$ is a quadratic function of the column matrix of coefficients $\{A\}$, and is given by $(K_{nl})_{ij} = (3/2)a_k a_l b_{ijlk}$. When the later term is neglected, the non-linear eigenvalue problem (23) is reduced to the classical linear eigenvalue problem as written below:

$$[K_l]\{A\} = \omega^2[M]\{A\} \tag{24}$$

which is the Rayleigh-Ritz formulation of the linear vibration problem. In the linear case, the eigenvalue of the equation (24) leads to a series of eigenvalues and corresponding eigenvectors. In the non-linear case, the solution of the equation (23) should lead to a set of amplitude dependent eigenvectors, with their associated amplitude dependent eigenvalues. The non-linear problem (23) could be solved using incremental-iterative, linearized or approximate solution known as the explicit method that was used previously in [14].

In this paper the linearized method [5] is adopted to solve the equation (23). The purpose is to replace the iterative method of of the non-linear eigenvalue problem (23) solution, by a direct solution of a modified linear eigenvalue problem. The numerical results obtained, generally in similar problems, have shown that the contribution coefficient a_c of the assigned basic function

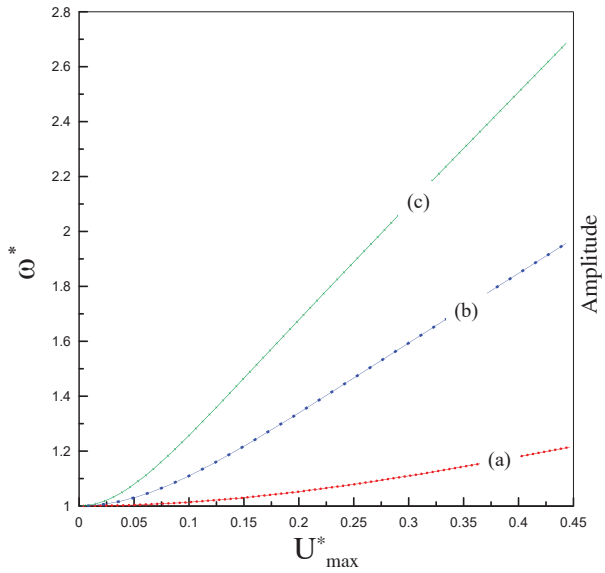

Figure 3: The backbone curves correspond- ing to the first (a), second (b) and third (c) non linear longitudinal mode shapes of a C- F uniform rods.

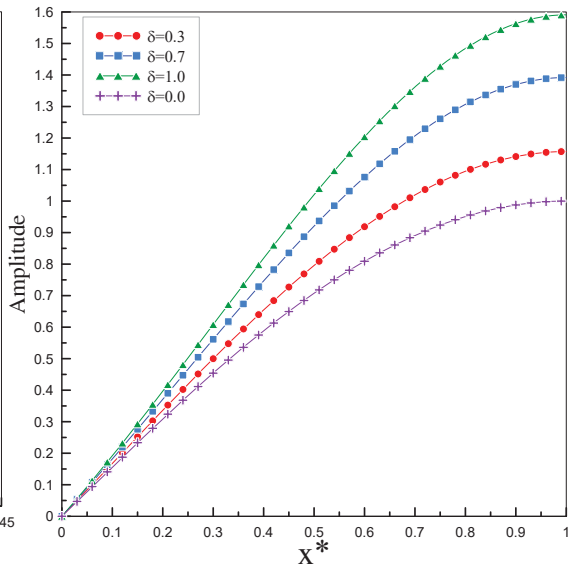

Figure 4: The first linear mode shape of a C- F rods with a section varying exponentially for various values of δ.

remains predominant for a wide range of amplitudes, compared to the other basic functions or linear mode shape contribution coefficients. Based on this result, an assumption is made in the neighborhood of the considered resonance, by writing the general term of the non-linear geometrical stiffness matrix in a simplified form:

$$(K_{nl})_{ij} = \frac{3}{2} a_c^2 b_{ccij} \tag{25}$$

The non-linear eigenvalue problem (23) becomes:

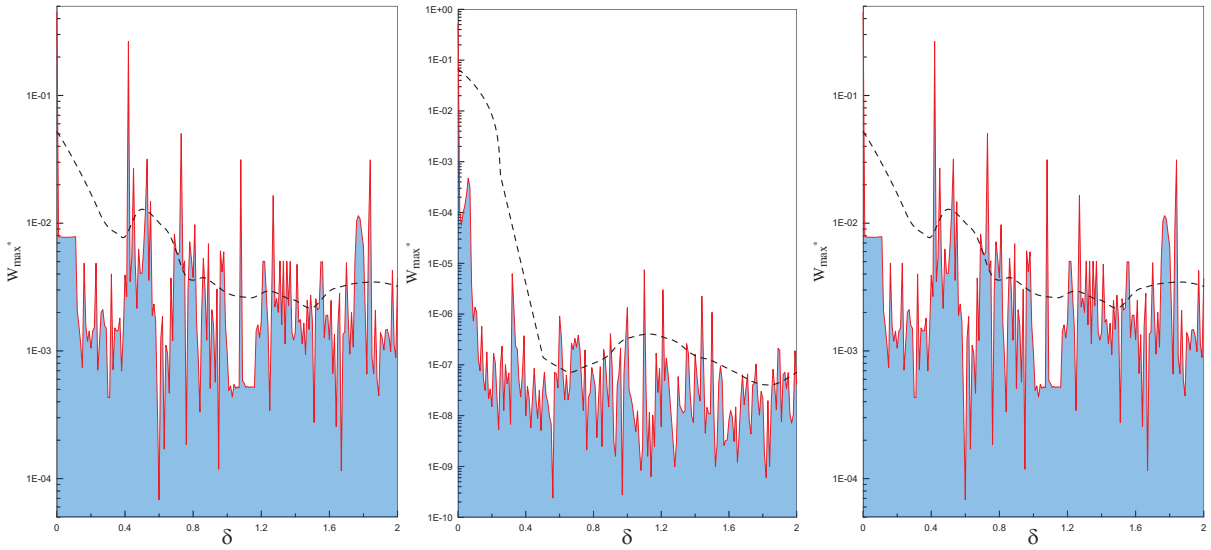
$$[K]\{A\} = \omega^2 [M]\{A\} \tag{26}$$

in which $[K]$ is the modified global stiffness matrix of the structure given by:

$$K_{ij} = (K_l)_{ij} + \frac{3}{2} a_c^2 b_{ccij} \tag{27}$$

Thus, for a given value of the predominant contribution a_c of the mode under consideration, the modified rigidity matrix $[K]$ is constant, and the eigenvalue problem (26) is a classical one. The direct solution of the linear eigenvalue problem (26), for a specified value of a_c and corresponding to a fixed amplitude of vibration of a chosen point, leads to the value of the eigenvalue ω^2 and the corresponding eigenvector $\{A\}$.

The choice of the number of the basic functions was based on the contribution coefficients value a_i assigned of other mode shapes which allow the convergence of the calculation and the time compilation optimization. For this purpose we calculated the contribution coefficients value on the first, second and third mode shapes to determinate the number of the contribution



(a) First mode shape (b) Second mode shape (c) Third mode shape

Figure 5: (——) Maximum amplitude versus the slope of exponential function coefficient, (- - -): Locally Estimated Scatterplot Smoothing (LOESS).

coefficients value that contribute significantly. Figure 2 illustrates the value of contribution coefficients for the first, second and third mode shapes for each δ value that increases with the increase of the contribution coefficients. This figure leads us to deduce the choice of the numbers of the basic functions which are 5, 13 and 19, that contribute significantly on the first, second and third mode shapes ,respectively, and which can not be neglected in the process of simulation.

4 Results and Interpretations

To verify the method used in the current paper, non-dimensional frequency is compared with the differential quadrature method employed in the reference [3]. This later consists in approximating the derivative of a function at a sample point to a weighted linear summation of the value of the function at all of the sample points in the domain. The calculations were made using 15 points Differential Quadrature Method for both uniform and non-uniform clamped-free rods. Table 1 shows a clear concordance value of non-dimensional frequency for uniform C-F rods. In order to compare non-uniform rods for $S(x) = (x+1)^2$, presented in the reference [3], with sections varying exponentially, the slope of exponential function coefficient was fixed at a value equals to 1.386 as plotted in Figure 8. Table 2 shows that the method gives acceptable results due to the section difference.

4.1 Uniform rods

Numerical results are obtained for C-F uniform rods. The backbone curves, corresponding to the uniform case for the first three nonlinear longitudinal mode shapes, shows a hardening type of nonlinear dynamic behavior with an increase of the nonlinear frequencies parameters by 12%, 46% and 88%, respectively for the first three nonlinear mode shapes with the maximum non dimensional vibration amplitude equals to 0.16. This can be depicted in Figure 3.

Uniform [3]	Uniform [present]
1.5708	1.570796327
4.7124	4.71238898
7.8540	7.853981634

4.6042	4.408039122
7.7899	7.373738343
10.9499	10.34303691

Table 2: Non-dimensional frequency comparison for non-uniform C-F rods

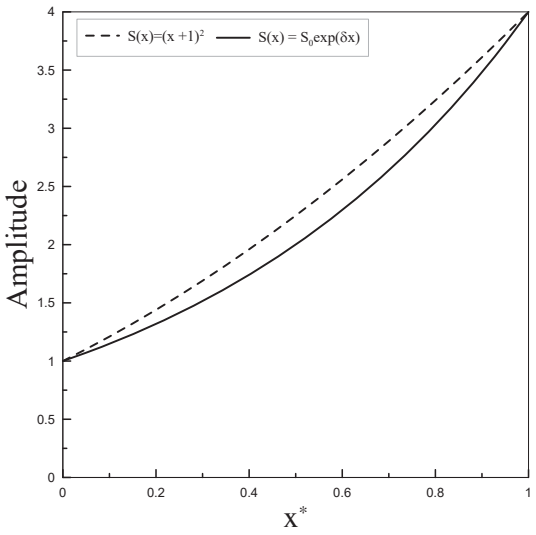

Figure 8: Comparaison of non-uniform rods.

4.2 Rods with section varying exponentially

The first three linear mode shapes of C-F rods with section varying exponentially $S = S_0 e^{\delta x}$ are plotted for various values of δ and shown in Figure 4. These linear modes correspond to the basic functions used in each case within the nonlinear theory.

Figure 5 illustrates the displacement amplitude versus the slope of exponential function coefficient and shows that the amplitude decreases with the increase of exponential slope (δ) due to the decrease of the section at the Free boundary condition.

The backbone curves of a C-F rods with a section varying exponentially for the first three nonlinear longitudinal mode shapes and their geometric non-linearity effect are represented in Figure 6.

Thus, for the first nonlinear mode shape corresponding to the maximum non dimensional vibration amplitude is equal to 0.2, the nonlinear frequencies increase with 5%, 6% and 6.2% respectively for delta equals to 0.3, 0.7 and 1.0. In addition, the second nonlinear mode shape corresponding to the maximum non dimensional vibration amplitude is equal to 0.3, the increase of the nonlinear frequencies is equal to 61.8%, 65% and 67.5% respectively for delta equals to 0.3, 0.7 and 1.0. And finally, the third nonlinear mode shape corresponding to the maximum non dimensional vibration amplitude is equal to 0.4, the nonlinear frequencies increase by 80%, 92% and 128% respectively for delta equals to 1, 0.7 and 0.3.

Figure 7 depicts the amplitude longitudinal mode shapes dependence that can be clearly seen, and shows the importance of the nonlinear effect on our structure which should be taken into account in the calculation. It can be also seen in Table 3 and 4 the difference between the geometrical nonlinearities and the linear case for first and second mode shapes with δ equals to 1.0 , with a relative difference up to 15.092% for the first mode shape and 245.171% for the second mode shape.

5 Conclusion

The model, based on Lagrange's formulation and Harmonic Balance Method, was developed to determine the nonlinear mode shapes of transverse vibration of beams, circular and rectangular plates. The numerical formulation of this model was presented and the expressions of the linear and nonlinear rigidity tensors were developed. The linearized procedure was used to solve the nonlinear algebraic equation obtained by reducing the problem of C-F uniform and non-uniform rods. The numerical results corresponding to the fundamental, the second and the third nonlinear modes shape were presented showing qualitative consistence of the model used. Furthermore, the obtained results showed a nonlinear behavior of the hardening type resonance response.

Keywords: Pile Dynamics, Normal modes, Regularized Coulomb friction

Abstract. *In this paper, a new model is developed to describe the nonlinear dynamics of two axially deformable bars sliding relative to each other in which the interaction is governed by friction. The first bar is fixed at one end and is subjected to a distributed normal force perpendicular to its axis to activate friction at the common interface, while the second bar is allowed to slide relative to the fixed one. A semi-analytical solution method is developed in which only the nonlinear interaction is addressed numerically. The dynamic behaviour of the bars is expressed as a summation of vibration modes including the necessary rigid body mode to allow for the permanent sliding of one bar relative to the other. This results in a computationally efficient scheme without compromising the accuracy of the solutions. The developed model can be used in pile driveability studies. In this case the fixed bar resembles the soil column while the second bar describes the dynamics of the driven pile.*

1 INTRODUCTION

In many engineering fields, including the field of pile driving, friction plays an important role. For example, accurate prediction of underwater noise generated in the seawater during the process of pile driving with vibratory devices requires the simultaneous prediction of the pile progression into the soil and, thus, the incorporation of a proper frictional model to describe the pile-soil slip behaviour. State of the art models in underwater noise prediction for impact pile driving all assume perfect contact between pile and soil [1, 2]. Problems including high frequency bands solved with a fixed FE-mesh, need both a fine spatial and time discretization to describe the propagating waves. This results in enormous computational efforts upto insolvable problems [2]. As a first step towards the development of a computational efficient model that predicts noise during vibratory pile driving including slippage of the pile, the dynamics of two elastic bars in frictional contact is studied in this paper.

The inclusion of friction complicates the problem, as it introduces a strong nonlinearity. To describe the forces at a frictional interface an appropriate frictional law should be chosen [3]. Since the focus herein is on noise generated during the driving process of piles with vibratory devices, the interest is in a straightforward frictional model that can describe the sliding between pile and soil. The most common frictional model is based on the Coulomb friction law. Coulomb's friction can be applied in many fields such as in a simplified model for belt driving mechanics, in which the Coulomb's friction law represents the dry friction between belt and support [4]. Variations on Coulomb's friction for multi-body mechanicals systems are described for example by Marques et al. [5]. The Coulomb friction, which is multivalued at zero velocity, can be approximated by alternative methods which deviate from Coulomb's friction below a certain velocity threshold and have a finite slope at zero velocity, e.g. linear velocity-dependent friction at low velocities and an approximation by a hyperbolic tangent [5]. Another alternative is introduced by Threlfall, the method avoids the discontinuity in the transition between positive and negative and it has a higher resemblance with the Coulomb friction law at velocities below a certain threshold [6]. This last friction law fits the problem of vibratory pile driving since it is smooth and the pile is assumed to slide continuously to the soil, while sticking can be neglected.

The model discussed in this work can be seen as a predecessor of a three-dimensional model to be used in pile driving noise prediction including the effect of pile-soil slip. In section 2, the problem statement is explained, including the equations of motions, boundary conditions and Threlfall's friction law. Hereafter, the solution method is described. The solution approach is largely analytical; a numerical scheme is used only to evaluate standard integrals. Section 3 describes the limitations of the method in terms of convergence, including criteria for the truncation of the number of modes that are used in this work. Section 4 shows results for the case of an impact load represented by a block function and a harmonic load. Finally, section 5 contains conclusions regarding the model performance.

2 MATHEMATICAL FORMULATION

2.1 Governing equations

The model under consideration is schematized in Fig. 1. It consists of two bars, which can deform in the axial direction and interact through a frictional interface. The equations of motion

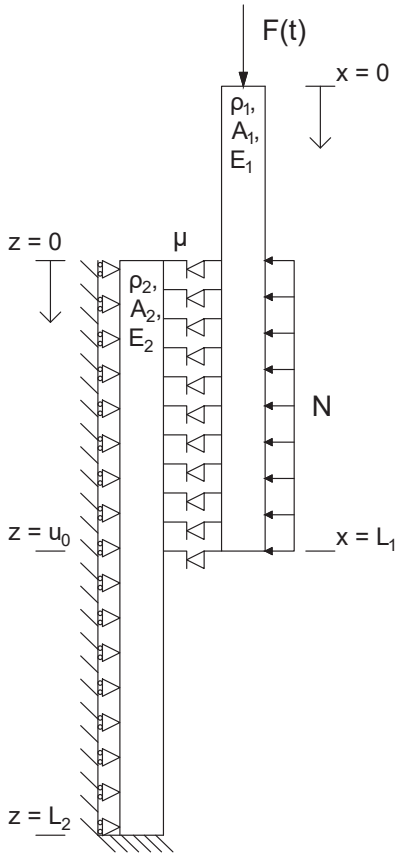

Figure 1: Schematization of the problem statement

describing the dynamics of the two bars read:

$$\rho_1 A_1 \ddot{u}_1(x,t) = E_1 A_1 u_1''(x,t) - T_1(x,t) + F(t)\delta(x) \tag{1}$$

$$\rho_2 A_2 \ddot{u}_2(z,t) = E_2 A_2 u_2''(z,t) - T_2(z,t) \tag{2}$$

in which subscript 1 refers to the forced bar and subscript 2 to the constrained bar, hereafter called bar 1 and 2. The constants ρ, A and E define the density, area and elasticity of the bars respectively. $T_{1,2}(x,t)$ represents the friction that acts on either bar. The driving force $F(t)$ can alternatively be included in a time-dependent boundary [7], however, the interest here lies not in the precise description of the top boundary stresses. A local coordinate system is adopted for bar 1. The progression of the lower end of bar 1 with respect to the upper end of bar 2 is characterized by $u_0(t)$ as shown in Fig. 1. The prime and dot indicate derivatives with respect to spatial coordinates and time, respectively. Threlfall's friction law is adopted, i.e. the signum function that is smoothed around zero velocity:

$$T_1(x,t) = \mu N \operatorname{sgn}(\Delta v_1(x,t)) \left(1 - e^{-k\frac{\Delta v_1(x,t)}{v_{95}}}\right) H(x - L_1 + u_0(t)) \tag{3}$$

$$T_2(z,t) = \mu N \operatorname{sgn}(-\Delta v_2(z,t)) \left(1 - e^{-k\frac{\Delta v_2(z,t)}{v_{95}}}\right) H(u_0(t) - z) \tag{4}$$

with:

$$\Delta v_1(x,t) = \dot{u}_1(x,t) - \dot{u}_2(x - L_1 + u_0(t), t) \tag{5}$$

$$\Delta v_2(z,t) = \dot{u}_2(z,t) - \dot{u}_1(z + L_1 - u_0(t), t) \tag{6}$$

where H is the Heaviside function and v_{95} is a velocity threshold above which the friction behaves almost velocity independent, i.e. at $\Delta v = v_{95}$: $T \approx 0.95 T_{max}$ for $k = 3$. The velocity threshold is based on the maximum modal change of velocity amplitude per time step, derived based on the results of section 2.2 of this paper as:

$$v_{95} = \frac{4\mu N \Delta t}{\pi \rho_1 A_1} \tag{7}$$

The boundary conditions read:

$$u_1'(0,t) = u_1'(L_1,t) = u_2'(0,t) = u_2(L_2,t) = 0 \tag{8}$$

The initial conditions are:

$$u_1(x,t_0) = u_{t_0}, \quad \dot{u}_1(x,t_0) = \dot{u}_{t_0}, \quad u_2(x,t_0) = w_{t_0}, \quad \dot{u}_2(x,t_0) = \dot{w}_{t_0} \tag{9}$$

Eqs. (1) to (9) govern the dynamics of the coupled system in the time domain.

2.2 Solution method

A modal solution approach is adopted, therefore, the displacements are expressed as a summation of modes:

$$u_1(x,t) = \sum_{n=1}^{\infty} \phi_n(x)\eta_n(t), \qquad u_2(z,t) = \sum_{m=1}^{\infty} \psi_m(z)\zeta_m(t) \tag{10}$$

Bar 1 is allowed to slide with respect to bar 2; the relative motion is governed by the rigid body motion of bar 1; relative displacement due to deformation of either bar is neglected. Substitution of Eq. (10) into Eqs. (1) and (2) yields:

$$\sum_{n=1}^{\infty} \phi_n(x)\ddot{\eta}_n(t) + \omega_n^2 \phi_n(x)\eta_n(t) = \frac{F(t)\delta(x) - T_1(x,t)}{\rho_1 A_1} \tag{11}$$

$$\sum_{m=1}^{\infty} \psi_m(z)\ddot{\xi}_m(t) + \omega_m^2 \psi_m(z)\xi_m(t) = -\frac{T_2(z,t)}{\rho_2 A_2} \tag{12}$$

with:

$$\phi_n(x) = \cos\left(\frac{\omega_n x}{c_1}\right), \qquad \omega_n = \frac{n\pi c_1}{L_1} \qquad n = 0,1,2,... \tag{13}$$

$$\xi_m(z) = \cos\left(\frac{\omega_m z}{c_2}\right), \qquad \omega_m = \frac{(2m-1)\pi c_2}{2L_2} \qquad m = 1,2,3,... \tag{14}$$

being the spatial eigenfunctions satisfying Eqs. (8). Eqs. (11) and (12) are multiplied by another mode and integrated over the length of each bar, making use of the orthogonality relation of the modes. After substituting Eqs. (3) and (4) into Eqs. (11) and (12), one obtains:

$$\ddot{\eta}_n(t) + \omega_n^2 \eta_n(t) = \frac{1}{\rho_1 A_1 a_n}\left(F(t) - \mu N \int_{L_1 - u_0(t)}^{L_1} \phi_n(x)\,\mathrm{sgn}(\Delta v_1(x,t)) \times \left(1 - e^{-k\frac{\Delta v_1(x,t)}{v_{95}}}\right)\mathrm{d}x\right) \tag{15}$$

$$\ddot{\xi}_m(t) + \omega_m^2 \xi_m(t) = -\frac{\mu N}{\rho_1 A_1 a_m}\int_0^{u_0(t)} \psi_m(z)\,\mathrm{sgn}(\Delta v_2(z,t))\left(1 - e^{-k\frac{\Delta v_2(z,t)}{v_{95}}}\right)\mathrm{d}z \tag{16}$$

with:

$$a_n = \int_0^{L_1} \phi_n(x)^2 \mathrm{d}x = \begin{cases} L_1 & n = 0 \\ \frac{1}{2} L_1 & n \neq 0 \end{cases}, \quad a_m = \int_0^{L_2} \psi_m(z)^2 \mathrm{d}z = \frac{1}{2} L_2 \tag{17}$$

To facilitate a computationally efficient solution of Eqs. (15) and (16), a straightforward time-stepping scheme is chosen, assuming that the relative velocity, $\Delta v_{1,2}(z,t)$, and the progression $u_0(t)$ are constant during a time step. Under the stated assumptions, Eqs. (15) and (16) act linear during a time step and the modal amplitudes η_n and ξ_m can be found using the Duhamel's integral for each time step. The closed-form solution to Eq. (15) reads:

$$\begin{aligned} \eta_n(t_{i+1}) = {} & A_n \sin(\omega_n t_{i+1}) + B_n \cos(\omega_n t_{i+1}) \\ & + \frac{1}{\omega_n a_n \rho_1 A_1} \int_{t_i}^{t_{i+1}} F(\tau) \sin(\omega_n (t_{i+1} - \tau)) \mathrm{d}\tau - \frac{\mu N \left(1 - \cos(\omega_n \Delta t)\right)}{\omega_n^2 a_n \rho_1 A_1} \\ & \times \int_{L_1 - u_0(t_i)}^{L_1} \phi_n(x) \operatorname{sgn}(\Delta v_1(x,t_i)) \left(1 - e^{-k \frac{\Delta v_1(x,t_i)}{v_{95}}}\right) \mathrm{d}x \end{aligned} \tag{18}$$

in which A_n and B_n are found by the previous time step:

$$\begin{aligned} A_n &= \frac{\sin\left(\omega_n t_i\right) \omega_n \eta_n(t_i) + \cos\left(\omega_n t_i\right) \dot{\eta}_n(t_i)}{\omega_n} \\ B_n &= \frac{\cos\left(\omega_n t_i\right) \omega_n \eta_n(t_i) - \sin\left(\omega_n t_i\right) \dot{\eta}_n(t_i)}{\omega_n} \end{aligned} \tag{19}$$

and in the special case of the initial time step:

$$\eta_n(t_0) = \frac{\int_0^{L_1} u_{t_0} dx}{a_n}, \qquad \dot{\eta}_n(t_0) = \frac{\int_0^{L_1} \dot{u}_{t_0} dx}{a_n} \tag{20}$$

The time derivative of $\eta_n(t)$ is given as:

$$\begin{aligned} \dot{\eta}_n(t_{i+1}) = {} & A_n(t_i) \omega_n \cos(\omega_n t_{i+1}) - B_n(t_i) \omega_n \sin(\omega_n t_{i+1}) \\ & + \frac{1}{a_n \rho_1 A_1} \int_{t_i}^{t_{i+1}} F(\tau) \cos(\omega_n (t_{i+1} - \tau)) \mathrm{d}\tau - \frac{\mu N \sin(\omega_n \Delta t)}{\omega_n a_n \rho_1 A_1} \\ & \times \int_{L_1 - u_0(t_i)}^{L_1} \phi_n(x) \operatorname{sgn}(\Delta v_1(x,t_i)) \left(1 - e^{-k \frac{\Delta v_1(x,t_i)}{v_{95}}}\right) \mathrm{d}x \end{aligned} \tag{21}$$

with $\Delta t = t_{i+1} - t_i$. Similar procedure for ξ_m results in:

$$\begin{aligned} \xi_m(t_{i+1}) = {} & C_m(t_i) \sin(\omega_m t_{i+1}) + D_m(t_i) \cos(\omega_m t_{i+1}) \\ & - \frac{\mu N \left(1 - \cos(\omega_m \Delta t)\right)}{\omega_m^2 a_m \rho_2 A_2} \int_0^{u_0(t_0)} \psi_m(z) \operatorname{sgn}(\Delta v_2(z,t_i)) \left(1 - e^{-k \frac{\Delta v_2(z,t_i)}{v_{95}}}\right) \mathrm{d}z \end{aligned} \tag{22}$$

$$\begin{aligned} \dot{\xi}_m(t_{i+1}) = {} & C_m(t_i) \omega_m \cos(\omega_m t_{i+1}) - D_m(t_i) \omega_m \sin(\omega_m t_{i+1}) \\ & - \frac{\mu N \sin(\omega_m \Delta t)}{\omega_m a_m \rho_2 A_2} \int_0^{u_0(t_i)} \psi_m(z) \operatorname{sgn}(\Delta v_2(z,t_i)) \left(1 - e^{-k \frac{\Delta v_2(z,t_i)}{v_{95}}}\right) \mathrm{d}z \end{aligned} \tag{23}$$

Where C_m and D_m are found similar to A_n and B_n. As mentioned earlier, the spatial integrals including the friction terms need numerical evaluation. The time step needs to be chosen such that it is smaller than a tenth of the smallest period in the system: $\Delta t < 2\pi / \max(\omega_i)/10$.

2.3 Linear equivalent model

The model is compared to a fully linear model that is valid for the case of no sliding. The

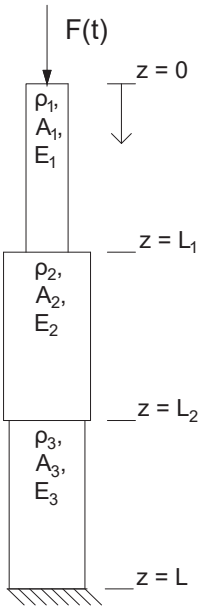

Figure 2: Schematization of the linear equivalent model

linear equivalent problem is composed of three bars as shown in Fig. 2, where the material properties of the second bar are based on the weighted averages of bar 1 and 3. The equation of motion of the whole system for each bar reads:

$$\begin{aligned} \rho_1 A_1 \ddot{u}_1 - E_1 A_1 u_1''(z,t) &= F(t)\delta(z) \qquad 0 < z < L_1 \\ \rho_2 A_2 \ddot{u}_2 - E_2 A_2 u_2''(z,t) &= 0 \qquad\qquad L_1 < z < L_2 \\ \rho_3 A_3 \ddot{u}_3 - E_3 A_3 u_3''(z,t) &= 0 \qquad\qquad L_2 < z < L \end{aligned} \tag{24}$$

The top boundary is stress-free since the applied force is accounted for in the equation of motion and the bottom boundary is fixed, furthermore, the interface conditions describe the continuity of displacements and stresses. The modes of the system can be found by solving the eigenvalue problem that is formed after substituting the general solution for each of the bars in the boundary and interface conditions. The modes are orthogonal with respect to the density and area [8]:

$$\int_0^{L_1} \rho_1 A_1 \phi_m(z)\phi_n(z)dz + \int_{L_1}^{L_2} \rho_2 A_2 \phi_m(z)\phi_n(z)dz + \int_{L_2}^{L} \rho_3 A_3 \phi_m(z)\phi_n(z)dz = a_n \delta_{nm} \tag{25}$$

The modal amplitudes are found analytically by making use of the orthogonality of the modes:

$$\eta_n(t) = A_n \sin(\omega_n t) + B_n \cos(\omega_n t) + \frac{1}{\omega_n a_n} \int_0^t F(\tau) \sin(\omega_n (t-\tau)) \mathrm{d}\tau \tag{26}$$

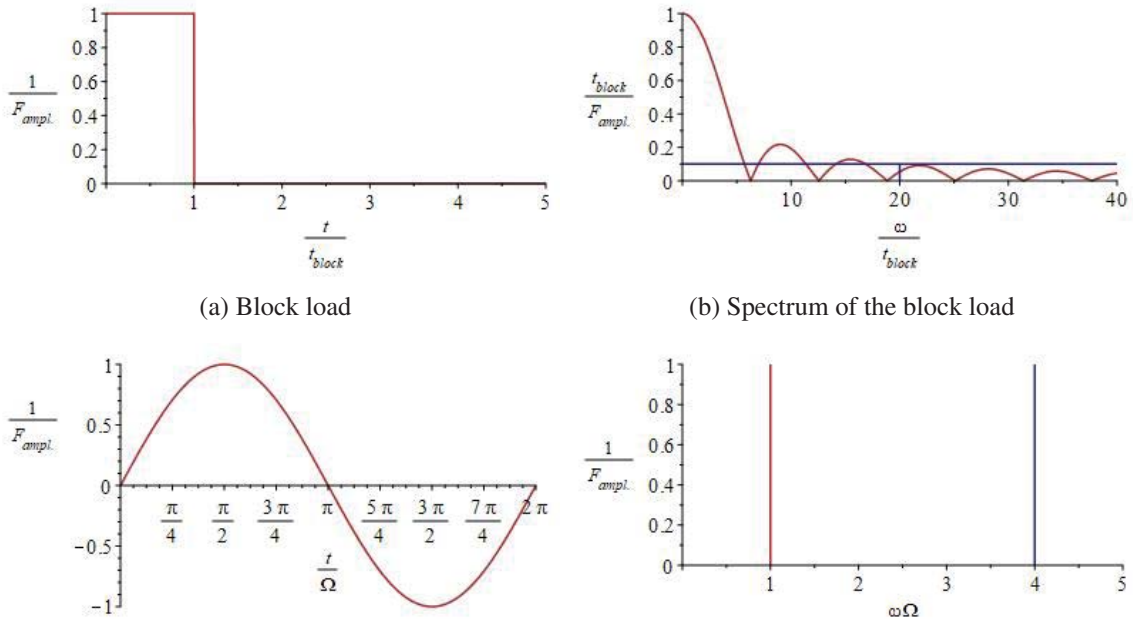
A_n and B_n are found by the initial conditions at $t = 0$:

$$A_n = \frac{1}{a_n \omega_n} \sum_{i=1}^{3} \int_{L_i} \rho_i A_i \phi_n(z) \dot{u}_i(z,0) dz \tag{27}$$

$$B_n = \frac{1}{a_n} \sum_{i=1}^{3} \int_{L_i} \rho_i A_i \phi_n(z) u_i(z,0) \mathrm{d}z \tag{28}$$

3 RESULTS

Two cases will be examined; the case of a block function load and the case of a high-frequency harmonic excitation. The two load cases are visualized in both time and frequency domain in Fig. 3. The material properties are chosen such that the wave speeds in both bars are



(a) Block load

(b) Spectrum of the block load

(c) Harmonic load

(d) Spectrum of the harmonic load

Figure 3: Load in time and frequency domain (red), and the minimum of frequencies included in the results (blue)

representative for steel and sandy soil. For bar 1 the properties are: $\rho_1 A_1 = 1$, $E_1 A_1 = 5000^2$, $c_1 = 5000$ and $L_1 = 20$, for bar 2: $\rho_2 A_2 = 5$, $E_2 A_2 = 500^2$ $c_2 = 500$ and $L_2 = 20$. In the initial state, the friction interface is half of bar 1, i.e. $u_0(0) = 10$. The duration of the applied block load is $t_{block} = 0.001$. The harmonic load starts at $t = 0$ with $\Omega = 1000$. The amplitude of both loads is 10. The influence of the friction coefficient μN is shown in the graphs, where μN varies from 0.1 to $100 \mu N$. $\mu N = 100$ is chosen sufficient high to approximate the linear case, where both bars move together and no sliding occurs. This case serves as validation of the description of the model with friction. The number of modes that are considered is based on the eigenfrequencies of the modes. At least frequencies excited by the block load, with an amplitude higher than 10% of the maximum amplitude or frequencies up to four times the excitation frequency of the harmonic load are included, as indicated with the blue lines in Figures 3b and 3d. For the block load and harmonic load this result in $\omega_{max} = 20.000$ and $\omega_{max} = 4.000$ respectively. This relates to about 25 and 5 flexible modes of bar 1 and about 250 and 50 modes

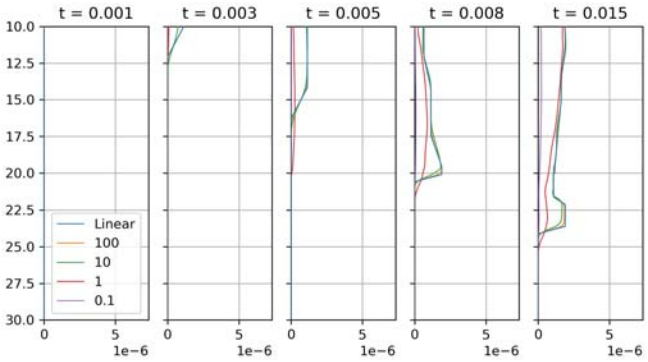
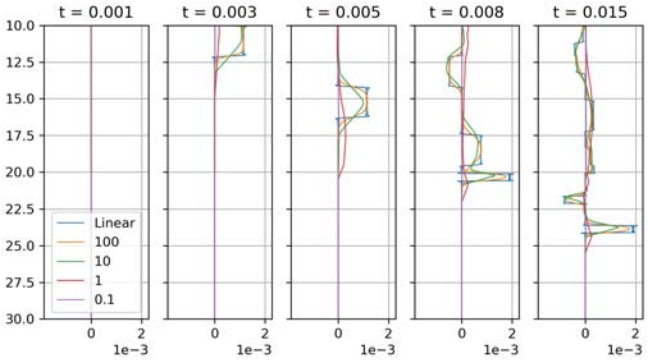
(b) Velocity of bar 1



(c) Displacement of bar 2



(d) Velocity of bar 2

Figure 5: The dynamic response of the bars when bar 1 is subjected to a sinusoidal load for different values of μN

for bar 2. While the friction force is based on the relative velocity of the bars, the velocities are preferably described with the same accuracy, i.e. the smallest wavelength of both bars is of the same order. Since both bars have the same length, the same number of modes are included in both bars, governed by the highest number required.

Fig. 4 shows the displacement and velocity of both bars due to a block load, representing impact pile driving. It can be seen that the block function is well represented by the summation of modes. Therefore also higher modes are activated along the whole bar. This can be seen in the amplification of higher modes, ahead of the wave-front in Fig. 4a, especially in case of high friction forces. Although present, over time these vibrations cancel out and they do not excite the system. For low friction coefficients, almost no energy dissipates into bar 1. Therefore, the wave reflects back and forth almost undisturbed.

In case of the response to a harmonic load, shown in Fig. 5, higher frequencies are not excited from the beginning, therefore, the results are more smooth. In all cases, the highest friction $\mu N = 100$ is in good agreement with the linear results. Both bars converge to the same displacement and velocity for $\mu N = 100$. Contrary, for low friction amplitudes, the unconstrained bar slides over the constrained bar. Due to that, final displacements are bigger at $t = 0.015$, best shown in Fig. 4a. Generally, the model behaves as expected, e.g. the wave-fronts align for all waves in the first bar upon the moment it starts interacting with the second bar, then for high friction amplitudes, the wave speed of both bars is based on a weighted average, whereas for low-frequency amplitudes, the wave-speed is less affected by the second bar. This is best shown in Figures 4c and 4d, where at $t = 0.004$, the three different wave-fronts are visible.

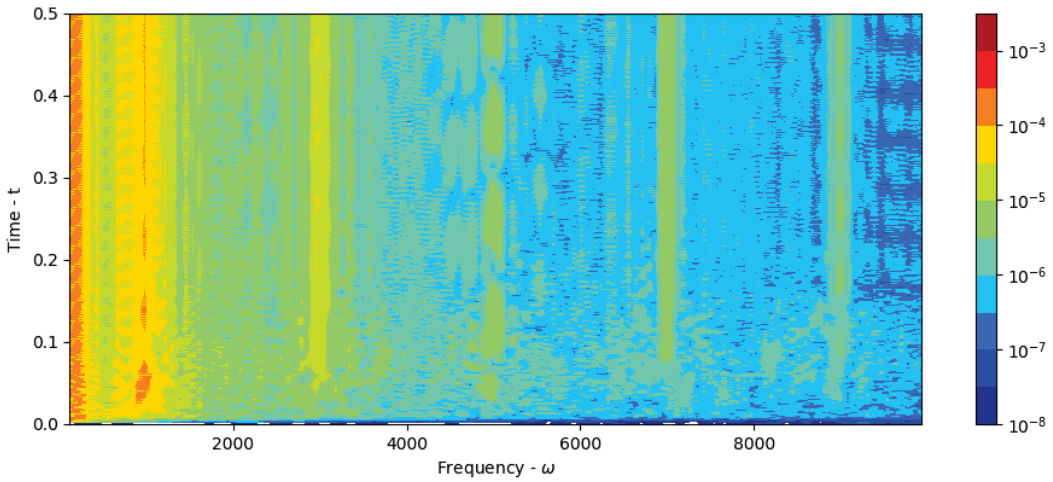

Figure 6: Time-frequency response of bar 2 for μN = 1

Fig. 6 points the importance of including the frictional interface in noise generating models for vibratory pile driving. The time-frequency plot clearly identifies the presence of the odd higher order harmonics that are excited in the system due to the presence of the frictional surface.

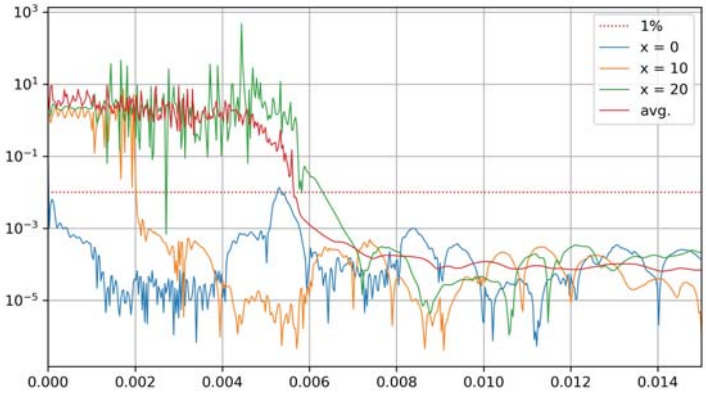
4 CONVERGENCE

The convergence of the model is satisfied based on displacements and velocities. The model is not able to describe the stress at the top boundary correctly due to the delta function, but the exact boundary stress at the top is not of interest, with an increasing number of modes, a

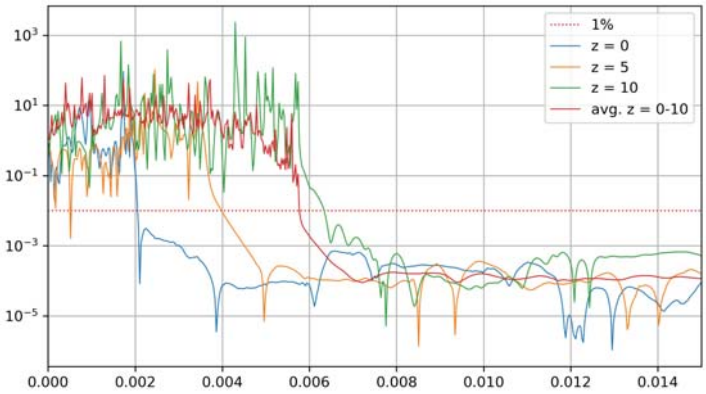
good approximation of the stress close to the boundary can be obtained. Since the time step is chosen sufficiently small: $\Delta t < 2\pi/\max(\omega_i)/10$, and depends on the number of modes in the system, the convergence of the solution depends on the truncation of the modes. The truncation criterion is based on the displacement of the bar at the final time step:

$$\delta(x, t_{i_{max}}) = \frac{\left|\sum_{n=1}^{0.9N} u_n(x,t) - \sum_{m=1}^{N} u_m(x,t)\right|}{\left|\sum_{m=1}^{N} u_m(x,t)\right|} < 1\% \tag{29}$$

where N is the number of modes. It needs to be mentioned that the convergence criterion only holds at each point from the time moment onwards when the first wave reaches the point, while before that, the denominator is zero. The convergence over time for the block load case from section 3 and $\mu N = 10$ is studied for both bars. Since the final wavefront just passed half of bar 2, only the upper half of bar 2 is taken into account. The convergence is checked between $N = 225$ and $N = 250$ modes. Fig. 7 shows that the displacements converge directly after the



(a) $\delta(x, t_i)$ of bar 1



(b) $\delta(z, t_i)$ of bar 2

Figure 7: Relative error between 225 and 250 modes for $t = 0 \rightarrow 0.015$

first wavefront arrives to $\delta < 0.1\%$. It confirms that the number of modes chosen in section 3 is more than sufficient for the convergence of the displacements.

5 CONCLUSIONS

The modelling technique presented in this paper is suitable for describing the interaction of two flexible bars in frictional contact. Although stick is not included in the model, high friction forces approximate the linear model that corresponds to bars under stick condition. The accuracy of the solution increases with the number of modes included. The number of modes included is a trade-off between computational efficiency and accuracy, whereas the length of the time signal is linearly related to the computation time. More modes need to be included to approximate sudden jumps in stress or velocity. This is of major importance in impact excitations but since the work focuses on harmonic excitations, sudden jumps are not expected. Conclusively, the modelling approach seems suitable for the field of application since the excitation is mainly harmonic, the non-linear behaviour of the interface can be included without compromising the computational time compared to linear models.

Abstract: *Impact protection systems are currently constructed from several layers of materials with different mechanical properties. The purpose of such a system is to stop the projectile after hitting and also to minimize the damage to the inner layers of the shield caused by the impact. The frontal layer plays a significant role in the deceleration of the impact mass. This layer must be made of a material with appropriate elastic properties. It is necessary to create a suitable theoretical model (mechanical model) and analyze it to design an effective material system. In this test a theoretical dynamic model of the protective structure is adopted for the elastic-damping dynamic system. The model assumes that two parameters are responsible for the projectile braking efficiency in the frontal layer. These are such coefficients as dry friction (h) and viscous friction (η), which occur in a function describing the braking force of an appropriate form. Their values were estimated using a numerical method, where the limiting time of projectile braking in the frontal layer of the analyzed material and the braking distance were determined. These two values obtained by means of numerical simulation methods with the use of ABAQUS program allowed verifying the usefulness of the proposed identification method. The range of calculations was performed on the composite material samples made of rubber material - SBS rubber waste combined with polyurethane resin. The penetration of samples was simulated with M43 7.62 mm projectile core.*

1 INTRODUCTION

Current solutions of anti-impact systems (butts) are based on the search for such solutions that the frontal layer provides safe protection against projectiles ricocheting. A projectile fired from a gun poses two primary threats. The first one is the possibility of piercing the shield behind the target butt, which, in consequence, allows the bullet to continue its flight beyond the designated area. The second threat is a ricochet phenomenon [1]. It consists in that the projectile falling at an appropriate angle to the shield bounces off it and causes a return towards the shooter [2, 3]. Such a shield is to prevent the further flight of the projectile without changing direction and protect against further movement of the reflected projectiles.

The front protective layer of the impact shield (the so-called "front layer") is designed to reduce to the maximum extent possible the velocity of the bullet hitting the specific shield, which is traditionally made of e.g., armored sheet [4]. The design of such a system relates to the development of an appropriate puncture model and its analysis. The authors have presented many works related to the models of the process of piercing the composite shields [5–7]. This issue is frequently solved by employing numerical tools [8–10].

Therefore, this work aims to present an identification method used to determine specific values of constants describing mechanical properties of the frontal layer under conditions of fast velocity that we are dealing with during the piercing of a small-arms projectile. Experimental verification of the model constants was carried out in the ABAQUS program. The obtained results are guidelines for working on useful materials of the frontal layer of anti-ricochet plates.

2 THEORY

2.1 Model and assumptions

In this work, a theoretical dynamic model of the anti-impact construction with the diagram shown in Figure 1 has been adopted.

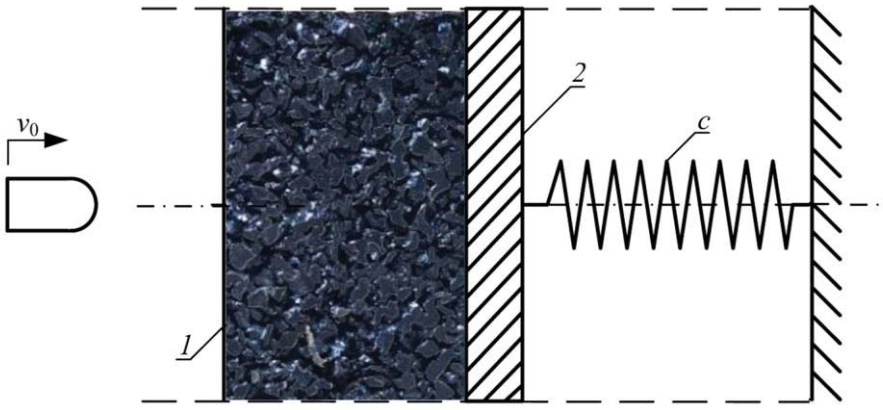

Figure 1: Diagram of the adopted dynamic model: 1 – visco-plastic front layer, 2 – energy-absorbing layer, v_0 – initial velocity of the projectile, c – rigidity of the system.

This model assumes that the central ballistic shield (2) is preceded by a specific frontal layer (1) made of a material capable of absorbing the projectile's kinetic energy as much as possible. Determining the necessary thickness of this protective layer is one of the objectives of this study. In order for this layer to be indestructible, it is envisaged that it is made of a material with viscous-plastic properties (e.g., granulates, dense liquids, gels, sands, muddy soils, etc.). For mechanical properties, such materials give resistance to a body moving in it (e.g., a

projectile). It takes the form of a force dependent on the projectile's speed. It is assumed that the model of such a force is the $S(v)$ function of the form:

$$S(v) = h\,sign(v) + \eta v \tag{1}$$

where h is the constant that determines the so-called dry friction, while η is the constant that defines viscous friction.

2.2 Identification of dynamic properties of the front layer

The model assumes two parameters responsible for the projectile braking efficiency in the front layer. These are constant coefficients h and η, which appear in the function of the form (1).

The method using the angular momentum principle was proposed to determine those values. Assuming two moments of time: t_1 and t_2 (with $t_2 > t_1$), the difference of momentum in these moments, under the principle that the difference of momentum is equal to the force impulse, is calculated from the dependence:

$$p(t_2) - p(t_1) = \int_{t_1}^{t_2} -S(v)dt \tag{2}$$

Provided that in this case the moment $t_1 = 0$ means the time when the projectile of the mass m falls into the material of the protective layer and has an initial velocity of $v(0) = v_0$ and at t_2 the projectile stops (that is $t_2 = t_z$), where $v(t_z) = 0$ and the force $S(v)$ takes the form (1), the above equation will take form:

$$-mv_0 = -\int_0^{t_z} h dt - \int_0^{t_z} \eta v dt \tag{3}$$

hence:

$$mv_0 = ht_z + \eta \int_0^{x(t_z)} dx = ht_z + \eta b \tag{4}$$

where x is the projectile path in the material ($v = dx/dt$), and $b = x(t_z)$ is the braking distance of the projectile in the material. Hence the relationship $t_z(b)$ of the form:

$$t_z = \frac{m}{h} v_0 - \frac{\eta}{h} b \tag{5}$$

Constants:

$$A_1 = \frac{m}{h}, \quad A_2 = \frac{\eta}{h} \tag{6}$$

which can be estimated from the relation (5) if for several different initial velocity values v_0 the corresponding values t_z and t_z are measured and then a known method of regression analysis is used. Once the values A_1 and A_2 have been determined, the parameters of the constants of the function model (1) are of the following form:

$$h = \frac{m}{A_1}, \quad \eta = A_2 h \tag{7}$$

Therefore, the identification should be based on the measurement of the penetration time of the projectile until it stops in the material under investigation for different initial velocities and determining the length of the braking distance of the projectile in the examined material.

3 EXPERIMENTAL VERIFICATION

Simulation tests were carried out in the ABAQUS program. For this purpose, geometric elements of the samples and the projectile were made as volumetric ones. The hybrid method combining the standard finite element method (FEM) [11] with smoothed particle hydrodynamics (SPH) [12] was used as a limiting parameter of the strain ε_{li}.

3.1 Material description

The material accepted for testing, which constituted the surface layer, was a polymer composite obtained from the rubber waste from used car tires. This composite was made up of styrene butadiene rubber (SBR) in combination with polyurethane resin (PUR3), in the 1:1 mixing ratio.

Figure 2 displays an example of basic material characteristics from piercing on a testing machine at the speed of 30 mm/sec.

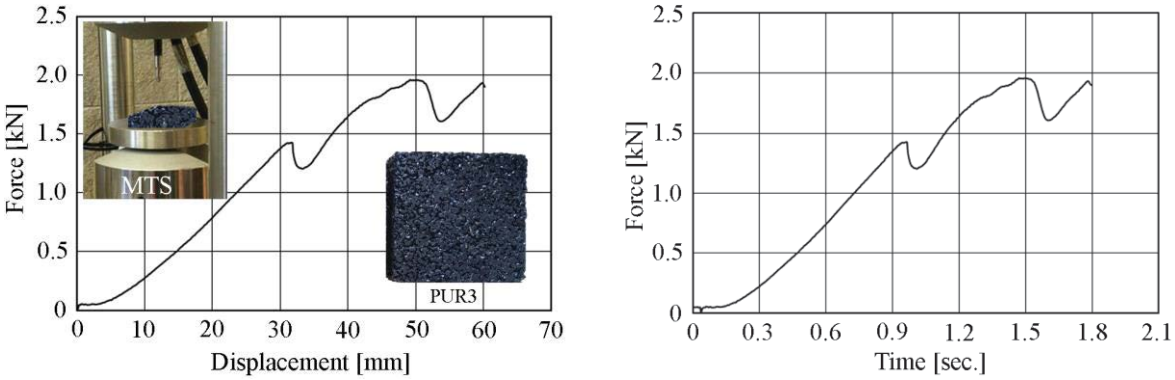

Figure 2: Selected piercing characteristics of the PUR3 sample: (a) displacement, (b) time.

3.2 Assumptions for modeling

In numerical analysis, the system was simplified to one 200 × 200 × 100 mm block and a projectile core. The analysis considered the M43 PS 7.62 mm projectile, the exact characteristics of which are given in the paper [13]. The simplification was made in the projectile model by modeling only its core since the jacket and lead jacket have hardly any effect on the analysis result and could be omitted. The core was volume-modeled with the 0.5 mm Hex-type discretization. The material of the polymer layer (anti-ballistic top layer) was described with 0.8 mm Hex-type elements (Fig. 3).

The Johnson-Cook (J-C) constitutive model was employed to describe the projectile material. This model correctly reproduces the material behavior under high-speed deformation conditions in the elastic-plastic range with the account taken of the material reinforcement and thermal weakening [13, 14]. The shielding material was described using the elastic-plastic model. The boundary conditions were set in such a way that the numerical model reproduces the features of the system during experimental studies to the utmost possible level. The initial velocity v_{0_1} = 715 m/s, v_{0_2} = 665 m/s, v_{0_3} = 615 m/s and v_{0_4} = 565 m/s was assigned to the projectile. The rotational speed was omitted, and its influence on kinetic energy dissipation was assumed to be negligible. The elastic layer of the ballistic shield was fixed on the perimeter. The restraint of the shield was blocked as translations and rotations in the three X, Y and Z axes. The analysis used the default contact model based on the "punishment function" method [15]

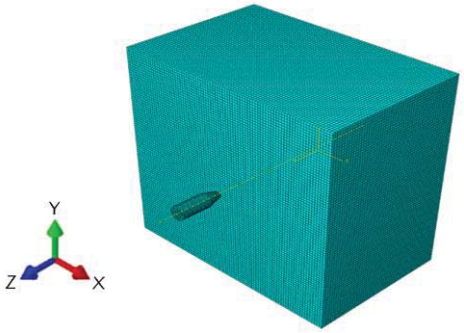

Figure 3: Numerical model of the projectile core and shield material.

Material parameters of the PUR3 composite were specified based on own research (Appendix A), and Table 1 presents the remaining.

	ρ [kg/m^3]	E [GPa]	ν [-]	A [MPa]	B [MPa]	C [-]	n [-]	m [-]
Core	7800	210	0.32	430	820	0.002	0.3	1.03
PUR3	1100	3.7	0.48	-	-	-	-	-

where: ρ – density, E – Young's modulus, ν – Poisson's ratio, A – yield at zero plastic strain, B – hardening constant, C – the strengthening coefficient of strain rate, n – hardening exponent, m – temperature softening constant.

Table 1: Material constants [13, 14].

4 RESULTS AND DISCUSSION

The numerical analysis aimed at determining such parameters as the projectile braking distance in the material (b) and the limiting time (t_z) at which the projectile is decelerated in the material.

The numerical analyses found that the system of 4 PUR3 blocks brakes the projectile, which was also confirmed in preliminary studies on the ballistic track. When the verification had been completed, several series of calculations were carried out. Figure 4 displays the example results.

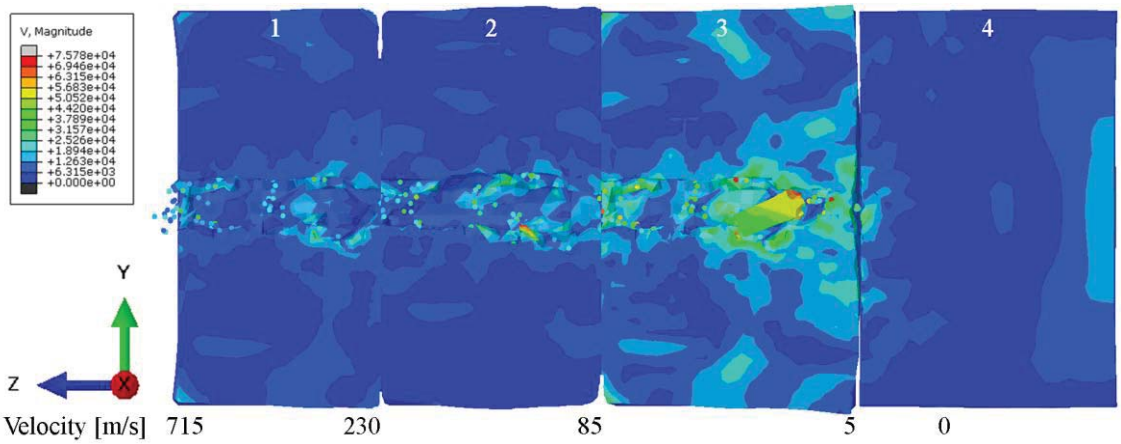

Figure 4: Example of velocity distribution of the impactor in the PUR3 material.

The impactor velocity steps shown in the analyzed system of the anti-ballistic shield front layer made up of four 200 × 200 × 100 mm blocks allow the determination of the projectile path (x) in the material as well as its braking distance $x(t_z)$. The latter was easy to estimate

from the analysis of time steps of the projectile position in the material. Parameters were estimated based on equation (5) for four initial velocities of the projectile. The results are summarized in Figure 5 only for v_{0_1} = 715 m/s.

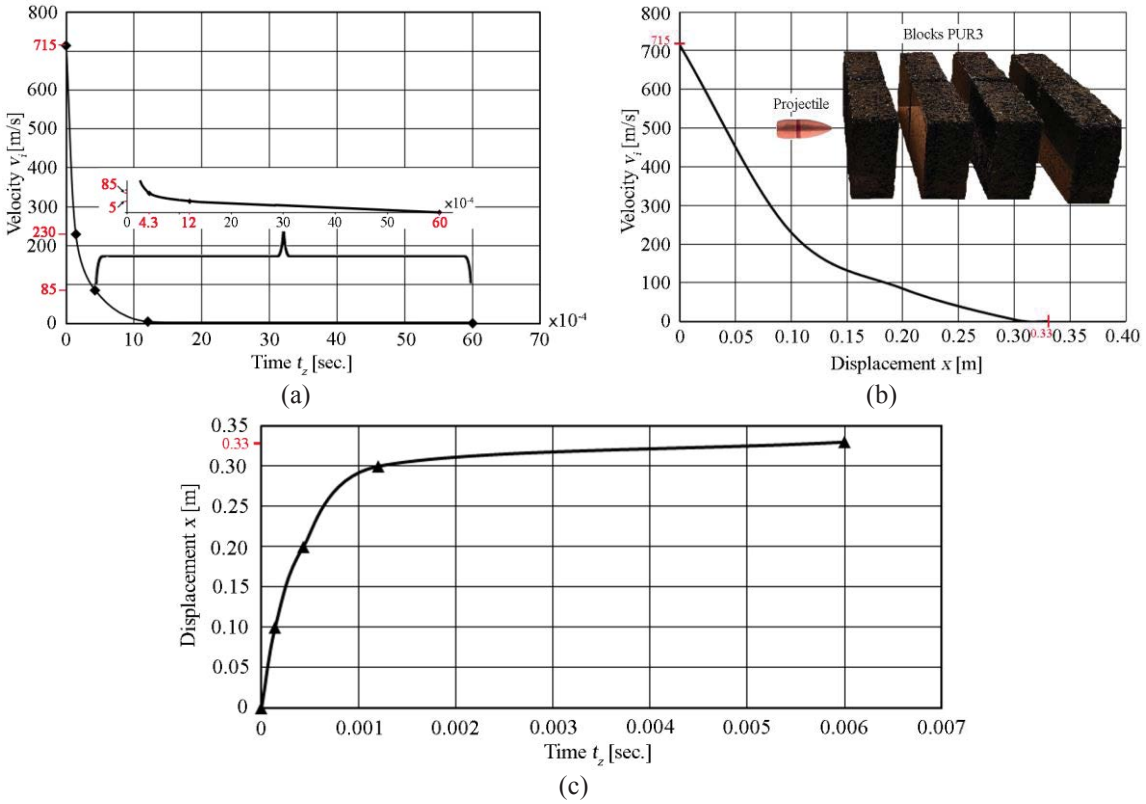

Figure 5: Diagrams of numerical analyses: (a) velocity v_i – time t_z dependence (b) velocity v_i – displacement x dependence, (c) displacement x – time t_z dependence.

After the estimation of the unknowns t_z and b, values A_1 i A_2 were calculated using the regression analysis method. Ultimately, it was possible to estimate the model parameters, i.e., the constant determining the so-called dry friction (h) and viscous friction (η). Example results are presented in Table 2.

Parameter	v_0 [m/s]	t_z [s]	b [m]	A_1 [s²/m]	A_2 [s/m²]	h [kgm/s²]	η [kg/ms]
Value	715	$6.0 \cdot 10^{-3}$	0.330	$1.4 \cdot 10^{-5}$	$1.2 \cdot 10^{-2}$	565.512	6.815
	665	$5.6 \cdot 10^{-3}$	0.290				
	615	$5.2 \cdot 10^{-3}$	0.270				
	565	$4.9 \cdot 10^{-3}$	0.245				

Table 2: Example searched values of the analyzed model.

During the analysis, it could be clearly seen that the higher the dry friction value, the greater was the error in estimating the values of h and η.

5 CONCLUSIONS

The analysis of the proposed model of dynamic estimation of parameters responsible for its effectiveness proved the right direction of work. The proposed method of identification based

on the momentum principle, and then the use of numerical tools in the form of the ABAQUS program can be successfully employed. The method is burdened with some errors resulting from simplifications applied in numerical analysis. However, it enables the adoption of certain conclusions for designing the anti-impact shield layers. Based on the findings obtained, it can be stated that the dry friction value has an impact on the final result. The application of the hybrid methods of the adopted model parameterization can be presumed as promising directions of conducting works on identifying the type of impact resistance systems. The authors intend to perform similar experimental studies, including tests of real systems.

Keywords: Nonlinear Dynamics. Experiments. Correlated Multipoints Excitation. Numerical Simulation. Harmonic Balance Method for random excitations.

Abstract. *This paper presents experiments of a nonlinear system subjected to two broadband correlated random excitations. The system studied is a steel beam bonded on both sides to a heavy steel block. First of all, correlation between two broadband random excitations is studied. This study analyses and compares the effects of the correlation choice into the apparition and/or attenuation of some symmetric or anti-symmetric modes of the beam. Two different types of correlation are experimentally introduced: in phase and opposite phase. Secondly, nonlinear effects are identified according to the presence of secondary peaks corresponding to the appearance of harmonic components of the first three natural modes (i.e. two symmetric and one anti-symmetric) of the clamped-clamped beam. Then, from experimental output data, the correlation effects added to the nonlinear effects open the discussion about the observation of some combinations of different harmonics from different modes of the nonlinear system under study. Finally, an extension of the classical Harmonic Balance Method (HBM) is proposed for the numerical prediction of the nonlinear dynamic behavior of a mechanical system subjected to two broadband correlated random excitations. Comparison between experiments and numerical simulations validate the numerical strategy for the prediction of the global nonlinear response as well as the contribution of harmonics for a mechanical system subjected to multipoints correlated random excitations.*

1 INTRODUCTION

Nonlinear vibrations in many mechanical systems may have different origins. For instance, nonlinearities can be explained by the constitutive law of the material used in a dynamical structure or by the geometry of the structure itself (such as for example the case of large displacements). Nonlinearities effects are numerous [1]: discontinuities in the frequency response, dependency of eigenfrequencies with input amplitude [2], presence of secondary peaks resulting from the harmonics generated by the primary resonance [3], *etc*. Correlated multipoints excitations and its effects on the linear (or nonlinear) response of a dynamical system have already been studied in the literature [4, 5]. This paper illustrates correlation effects as the amplification and/or the attenuation of some symmetric or anti-symmetric vibrations modes. Numerical methods have been developed to compute the nonlinear response of such structures. Among them, an extension of the classical Harmonic Balance Method (HBM) enables to compute the multi-harmonic frequency response of the clamped-clamped beam with non-ideal boundary conditions and subjected to two broadband random excitations.

This paper is organized as follows: firstly experimental set-up of the clamped-clamped beam is presented with observations of correlation on temporal input data for two different types of correlation (in phase and opposite phase). Correlation effects are experimentally observed on the first three natural modes of the clamped-clamped beam. Then, the presence of secondary peaks corresponding to the harmonics generated by the primary resonance of each mode are studied to point out nonlinear behavior. Finally, numerical simulations based on an extension of the Harmonic Balance Method are performed for the prediction of the nonlinear response of a mechanical system subjected to two broadband correlated random excitations.

2 EXPERIMENTS

2.1 Experimental set-up

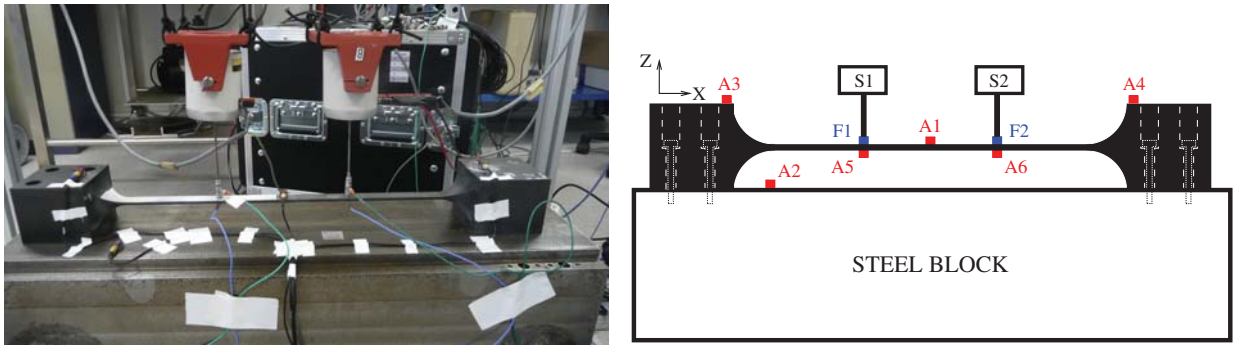
The experimental clamped-clamped beam studied in this paper is the same as the one presented in [2, 3]. A new experiment set-up is presented in figure 1a, the structure (beam + blocks) is screwed to a heavy steel block and the whole system has been instrumented with four three-dimensional accelerometers (A1 to A4), two one-dimensional accelerometers (A5, A6) and two cell forces (F1, F2) as depicted in figure 1b. Accelerometers A2, A3 and A4 are present to assure the correct embedding of the whole structure during experiments. The beam is subjected to a bipoints random correlated excitation by two electrodynamic shakers referenced in figure 1b using Multi-Input-Multi-Output (MIMO) control technology [8]. The shakers configuration is designed to excite the modes of the beam within a chosen bandwidth of frequencies. The first correlation is therefore spatial since the position of each shaker is fixed for all the experiments, and symmetrical about the center of the beam.

2.2 Temporal input data

Each shaker is piloted with a Power Spectral Density (PSD) and the correlation between both excitations is defined in the Cross Spectral Density (CSD) with the notions of coherence and phase, according to the equation (1):

$$S_{12}(f) = \sqrt{\gamma_{12}^2(f) S_{11}(f) S_{22}(f)}\, \exp\left(j\phi_{12}(f)\right) \tag{1}$$

where $S_{11}(f)$ and $S_{22}(f)$ are the PSD of temporal excitations $F_1(t)$ and $F_2(t)$, f is the frequency. $\gamma_{12}(f)$ is the coherence between both PSD $S_{11}(f)$ and $S_{22}(f)$, its value experimentally



(a) (b)

Figure 1: (a) A picture of the experimental set-up. (b) A schematic of the experimental set-up which includes six accelerometers (A1 to A6) and two cell forces (F1, F2) related to the two electrodynamic shakers S1 and S2.

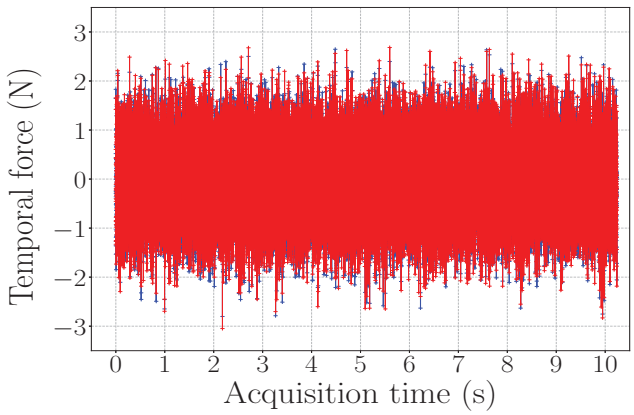


Figure 2: Two experimental random temporal forces F1 (blue) and F2 (red) generated with the MIMO control technology [8], the "in phase" correlation is the one created with a coherence equal to 0.98 and a phase equal to 0° along the whole bandwidth.

varies between 0.05 and 0.98: it is impossible to get two perfectly correlated or uncorrelated multipoints excitations with the electronic devices of this experimental set-up. $\phi_{12}(f)$ is the phase between both temporal excitations $F_1(t)$ and $F_2(t)$. The phases corresponding to the two correlation types studied in this paper are respectively 0° (in phase) and 180° (opposite phase), with a coherence set at 0.98. Other configurations of coherence and phases have been tested, but are not presented is in this paper for the sake of clarity.

The shape of each PSD is a band-limited white noise, *i.e.* the level of excitation is constant along the whole bandwidth, for all experiments. The sampling frequency is 3200 Hz with a desired resolution frequency of 0.098 Hz. The total duration of one experiment is 307.2 s. The output signal is decomposed into 30 temporal blocks of 10.24 s each. A periodogram estimate computes an approximation of the PSD for each of the 30 blocks. Then, the PSD of the output signal is calculated by averaging all the estimates [9]. The input PSD is constant over time to ensure that the response is stationary. Both experimental temporal random inputs of one of the temporal blocks of 10.24 s for two different correlation types (in phase and opposite phase) are plotted in figures 2 and 3. The generation of a bipoints correlated random excitation with the MIMO control technology is validated.

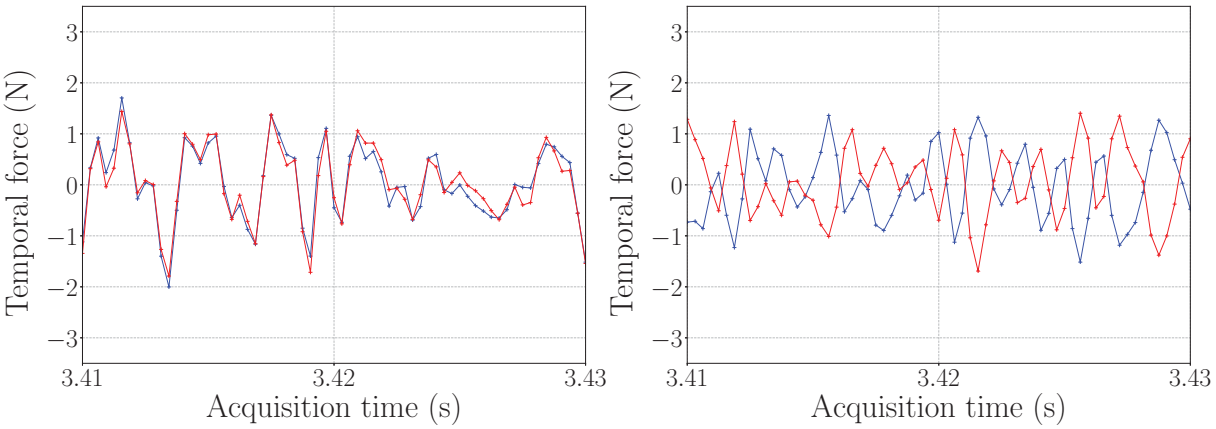

Figure 3: Zoom on two types of correlation (a) in phase (b) opposite phase for two experimental random temporal forces F1 (blue) and F2 (red).

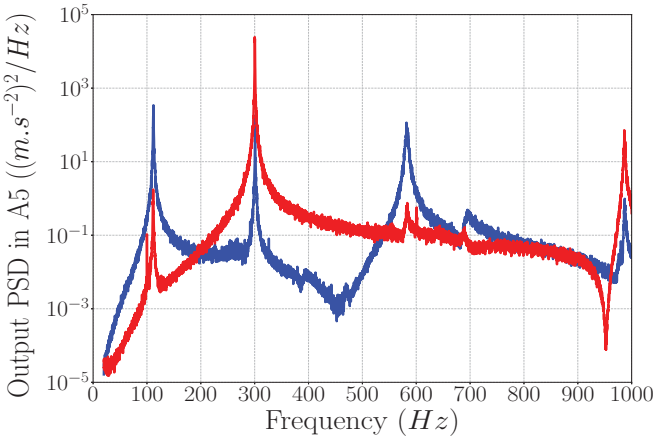

Figure 4: Experimental output PSD of accelerometer A5 with a RMS level of 0.5 N for two different correlation types along the bandwidth $[20 - 1000\,\text{Hz}]$. The correlation types are in phase (blue) and opposite phase (red).

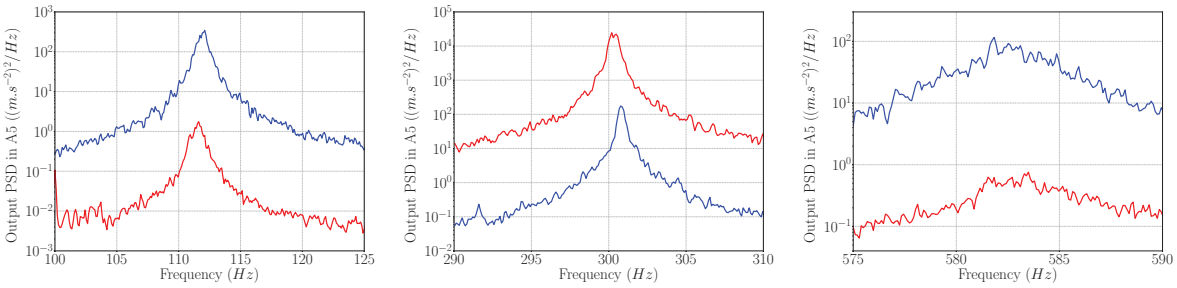
2.3 Results

2.3.1 Correlation effects

Experimental results for one level of excitation (0.5 N RMS) along the bandwidth $[20 - 1000\,\text{Hz}]$ for two different correlation types (in phase and opposite phase) are plotted in figure 4. Correlation effects are observed as the amplification and/or the attenuation of some symmetric or anti-symmetric vibrations modes in the vicinity or their primary resonance. For the "in phase" correlation, as shown in figure 5, symmetric modes are amplified and anti-symmetric modes are attenuated whereas for the "opposite phase" correlation, symmetric modes are attenuated and anti-symmetric modes are amplified.



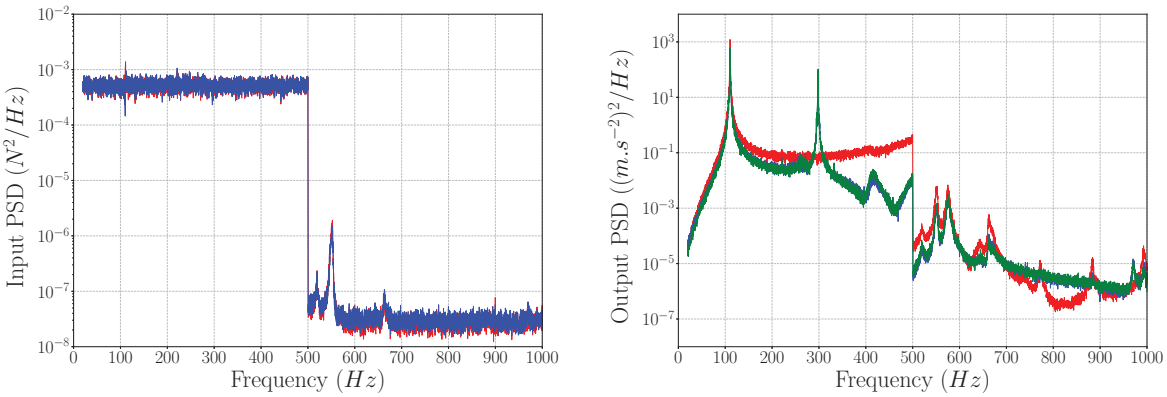
(a) (b) (c)

Figure 5: Zoom on the resonance of each mode: (a) first mode (symmetric) (b) second mode (anti-symmetric) (c) third mode (symmetric). The correlation types are in phase (blue) and opposite phase (red).

2.3.2 Nonlinear effects

As described in [3], an input PSD centered around the frequency of the primary resonance of one mode induces nonlinear effects. This nonlinear behavior is generally characterized by the appearance of secondary peaks corresponding to the harmonics generated by the primary resonance of this mode. Then, in order to study the combination of correlation effects and nonlinear effects, an approach similar to that of [3] is followed and experimental measurements have been realized for one level of excitation (0.5 N RMS) along the bandwidth $[20 - 500$ Hz$]$ *i.e.* where only the first symmetric mode and the first anti-symmetric mode of the clamped-clamped beam are solicited.

Both experimental input and output for one ideal level of excitation (0.5 N RMS) along the bandwidth $[20 - 500$ Hz$]$ for the in phase correlation are plotted in figure 6. The control of the input PSD shows its limitations, as in [3], with the presence of unexpected resonance peaks in the bandwidth $[500 - 1000$ Hz$]$. The output is rich in information. In the bandwidth $[20 - 500$ Hz$]$, the same effects of correlation choice are foreseen in the vicinity of the primary resonance of the first mode and the second mode of the clamped-clamped beam. In the bandwidth $[500 - 1000$ Hz$]$, several peaks of resonance which are not present in the experimental input signal are observed. They reveal a nonlinear dynamic behavior. Moreover some of these peaks are harmonics generated by the primary resonance of the amplified mode (first mode). Figure 7 illustrates closer the nonlinear effects depicted along the bandwidth $[500 - 1000$ Hz$]$. Harmonics of the primary resonance of the first mode situated at approximately $f_1 = 110.28$ Hz are highlighted with vertical lines from $5f_1$ to $9f_1$. Most of the peaks in the figure 7 correspond to an harmonic of f_1, nevertheless other peaks are observed.



(a) (b)

Figure 6: Experimental input (a) and output (b) PSD for the experiment with a RMS level of 0.5 N along the bandwidth $[20 - 500\,\text{Hz}]$ for the "in phase" correlation. The input PSD are the ones from the two shakers S1 (blue) and S2 (red). The output PSD are the ones from accelerometers A1 (red), A5 (blue) and A6 (green).

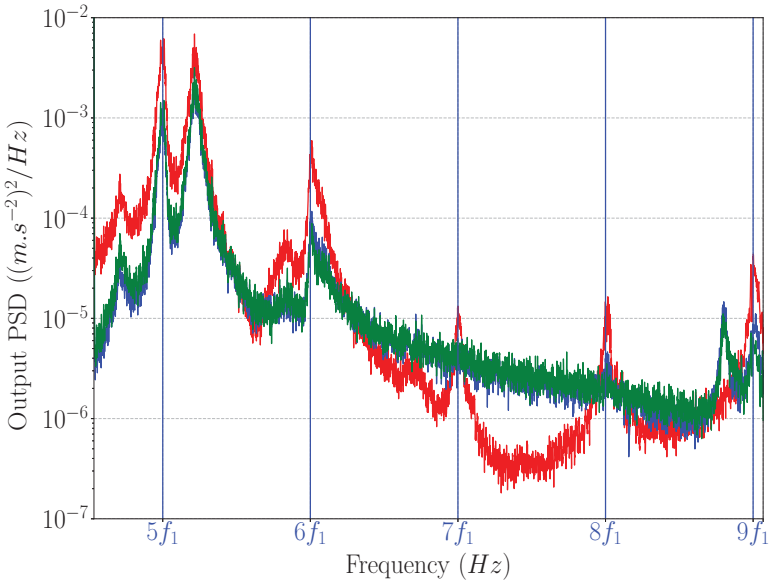


Figure 7: Zoom on the experimental output PSD on the bandwidth $[500 - 1000\,\text{Hz}]$ for the experiment with a RMS level of 0.5 N along the bandwidth $[20 - 500\,\text{Hz}]$ for the "in phase" correlation. The output PSD are the ones from accelerometers A1 (red), A5 (blue) and A6 (green). Vertical lines (blue) represent harmonics of the primary resonance of the first mode situated at $f_1 = 110.28$Hz.

3 HARMONIC BALANCE METHOD (HBM) FOR RANDOM EXCITATIONS

The Harmonic Balance Method enables to solve numerically a discrete problem described as [6] :

$$\mathbf{M\ddot{W}} + \mathbf{D\dot{W}} + \mathbf{KW} = \mathbf{F_1} + \mathbf{F_2} + \mathbf{F_{nl}}(\mathbf{W}) \tag{2}$$

where $\mathbf{M}$, $\mathbf{D}$ and $\mathbf{K}$ are mass, damping and stiffness matrices of a mechanical system.

In the case of a nonlinear system subjected to random excitations, the steady state nonlinear response $\mathbf{W}$, the stochastic excitations $\mathbf{F_j}(t)$ ($j = 1, 2$) and the nonlinear force $\mathbf{F_{nl}}(t)$ are defined as:

$$\begin{aligned}
\mathbf{W}(t) &= \mathbf{B_0} + \sum_{i=1}^{N} \left(\mathbf{A_i} \sin\left(i\Delta f t\right) + \mathbf{B_i} \cos\left(i\Delta f t\right)\right) \\
\mathbf{F_j}(t) &= \mathbf{C_{0,j}} + \sum_{i=1}^{N} \left(\mathbf{S_{i,j}} \sin\left(i\Delta f t\right) + \mathbf{C_{i,j}} \cos\left(i\Delta f t\right)\right) \\
\mathbf{F_{nl}}(t) &= \mathbf{C_0} + \sum_{i=1}^{N} \left(\mathbf{S_i} \sin\left(i\Delta f t\right) + \mathbf{C_i} \cos\left(i\Delta f t\right)\right)
\end{aligned} \tag{3}$$

where Δf is the resolution frequency and N defines the number of harmonic components in order to describe the entire frequency band of interest.

We define $F_1(a_1, t)$ and $F_2(a_2, t)$ as two correlated random forces applied to the structure respectively at abscissas a_1 and a_2 and initiated with the cross-spectral density matrix:

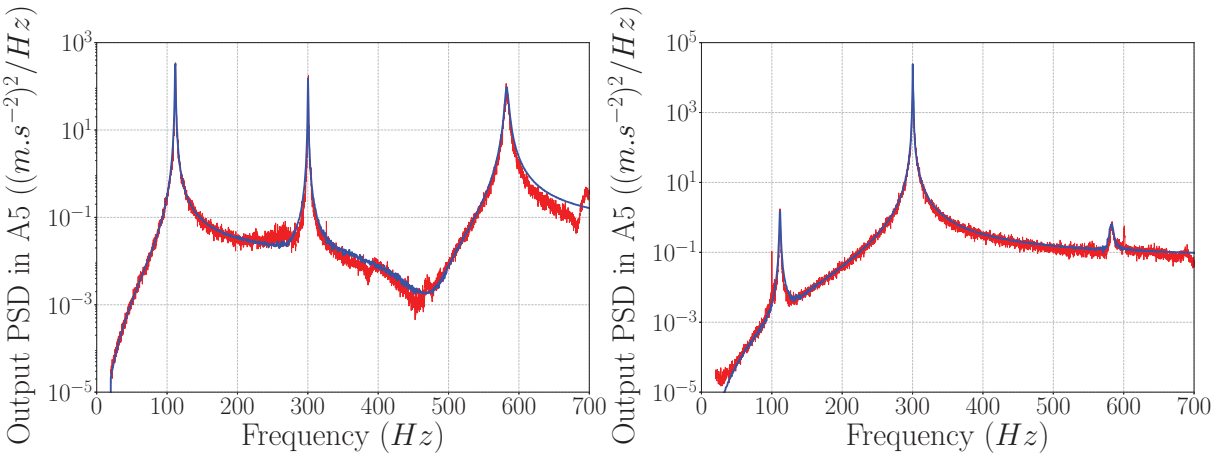
$$\mathbf{S}(f) = \begin{bmatrix} S_{11}(f) & \rho(f)\sqrt{S_{11}(f)S_{22}(f)} \\ \bar{\rho}(f)\sqrt{S_{11}(f)S_{22}(f)} & S_{22}(f) \end{bmatrix} \tag{4}$$

where $S_{11}(f)$ and $S_{22}(f)$ represent PSD of excitations 1 and 2. We define correlation in the off-diagonal term $S_{12}(f)$ as $\rho(f)\sqrt{S_{11}(f)S_{22}(f)}$ where $\rho(f)$ is the spectral correlation coefficient. It can be real or complex and enables to introduce a phase between the two temporal excitations. Equations developed by Shinozuka [11] are used to define two correlated random forces in the time domain. Thanks to Cholesky decomposition, $\mathbf{S}(f)$ can be written as the product $\mathbf{H}(f)\mathbf{H}^*(f)$ where $H_{ij}(f)$ terms are defined as functions of the $S_{mn}(f)$ terms. Finally, $F_1(a_1, t)$ and $F_2(a_2, t)$ can be expressed by:

$$F_1(a_1, t) = \delta(a_1, x)\sqrt{2\Delta f}\ \Re\left[\sum_{i=1}^{N} H_{11}(f_i) \exp\left[j2\pi f_i t + i\phi_{1i}\right]\right] \tag{5}$$

$$\begin{aligned}
F_2(a_2, t) \;=\; & \delta(a_2, x)\ \sqrt{2\Delta f}\ \Re\left[\sum_{i=1}^{N} H_{21}(f_i) \exp\left[j2\pi f_i t + i\phi_{1i}\right]\right] \\
& + \delta(a_2, x)\ \sqrt{2\Delta f}\ \Re\left[\sum_{i=1}^{N} H_{22}(f_i) \exp\left[j2\pi f_i t + i\phi_{2i}\right]\right]
\end{aligned} \tag{6}$$

where $\delta(a_j, x)$ is the Dirac function defined at abscissa a_j. Δf is the resolution frequency. $\Re$ is the real part number. $H_{ij}(f)$ terms are known from Cholesky decomposition of matrix $\mathbf{S}(f)$. f_i is the ith frequency of the frequency domain. The ϕ_{ji} random variables uniformly distributed between 0 and 2π are defined for all the frequencies $i \in [\![1, N]\!]$ and for the two excitations $j \in$



(a) (b)

Figure 8: Experimental output (red) and numerical simulation (blue) based on the extended Harmonic Balance Method for in phase (a) and opposite phase (b) random excitations.

$[\![1, 2]\!]$, they are independent one from each other. It can be noted that the HBM seeks the steady state solution in the form of a truncated Fourier series for nonlinear systems subjected to a deterministic excitation with one fundamental frequency or evenly spaced frequencies [3]. In order to fulfill this objective with two broadband correlated random excitations, the key is to define the parameter Δf in equations (5) and (6) as the fundamental frequency. That choice leads to the fact that the random excitation is now seen as an equivalent deterministic excitation with one fundamental frequency and multiple harmonics. Yet, the method remains random since the numerical output PSD is obtained by averaging the estimates from the individual responses to one multipoints correlated random excitation.

One of the originality of the proposed methodology is to be able to consider the random excitation as a series of cosine functions with weighted amplitudes, evenly spaced frequencies and random phase angles. This new formulation will allow to use the HBM for the prediction of the nonlinear response of a mechanical system subjected to two broadband correlated random excitations. For the interested reader, different versions of HBM adapted to single-point random excitation have been previously studied and compared to a shooting method (based on time integration) in terms of robustness and computional efficiency [3].

As described in [3], if an expression of the nonlinear force $f_{nl}(t)$ is known, Alternate Frequency Time-method is used to determine coefficients $\mathbf{C_i}$ and $\mathbf{S_i}$ as functions of unknowns $\mathbf{A_i}$ and $\mathbf{B_i}$. The final set of equations which needs to be minimized with a continuation technique is given by:

$$\mathbf{H}\left(\mathbf{X}, \mathbf{F1}, \mathbf{F2}\right) = \mathbf{AX} - \mathbf{B}\left(\mathbf{F_1}, \mathbf{F_2}\right) - \mathbf{B_{nl}}\left(\mathbf{X}\right) \tag{7}$$

Figure 8 shows the comparison of simulation and experiments for the in phase and the opposite phase correlations. For each simulation, an ideal input PSD along the bandwidth $[20 - 1000$ Hz$]$ has been created based on the RMS value of each effort (0.5 N RMS) and 100 estimates have been performed in order to reduce the variance of the estimated output PSD. Comparison between experiments and simulation enables to validate the mechanical model of the beam.

4 CONCLUSION

Experiments for a clamped-clamped beam have been performed in order to study the effects of a multipoints correlated random excitation to a nonlinear system. Correlation effects have been observed with the amplification and/or the attenuation of some symmetric or anti-symmetric vibrations modes. Nonlinear effects, as previously observed in [3] for a random excitation centered around the frequency of the primary resonance of one mode, have been pointed out with the presence of secondary peaks corresponding to the harmonics of this mode. In the current study, combination of both correlation and nonlinear effects have been observed.

Once the mechanical model of the beam validated, on going work is focusing on the simulation, using the proposed Harmonic Balance Method for random excitations, of the secondary peaks in the bandwidth $[500 - 1000\,\text{Hz}]$. It will help the understanding of these nonlinear effects and their dependency to the correlation of the random excitations.

Keywords: power flow analysis, vibrational energy transfer, nonlinear interface, double external forces

Abstract. *This paper investigates the vibration power flow transmission between nonlinearly coupled oscillators, each subjected to a harmonic excitation force with different phase angles. The harmonic balance method is used for analytical formulations of frequency-response relationship and time-averaged power flows. Numerical integrations are also conducted for validation of the analytical results and for comparison. Time-averaged transmitted power between the oscillators is used as an index to quantify the level of vibration transmission. The effects of the stiffness nonlinearity of the coupling interface on vibration power transmission are studied and revealed. It is found that when the excitation forces are of certain phase difference, the dynamic response of the oscillators and power flow between then may be reduced in the low-frequency range. The relative displacement amplitude between two oscillators may increase with the relative phase angle. It is also found that when the system is excited near resonances, the relative phase angle has little effects on the response amplitudes and time-average input power. It is also shown that time-averaged transmitted power is more sensitive than time-averaged input power to the relative phase angle. These findings lead to better understanding of vibration transmission mechanisms of coupled systems with different excitation forces and thus can facilitate enhanced designs of vibration suppression systems.*

1 INTRODUCTION

There is a growing interest in the vibration behaviour of nonlinear mechanical systems for enhanced understanding and also for better use of nonlinear elements to improve the dynamic performance. Whilst many previous investigations have focused on the response characteristic in terms of the displacement or velocity responses, limited work has been reported on the corresponding vibration energy transmission within nonlinear systems. Correspondingly it is necessary to examine the vibration power flow input, transmission and dissipation mechanisms in nonlinear systems.

The power flow analysis (PFA) is a widely accepted tool for dynamic analysis of vibration systems. Vibration power flow combines the force and velocity amplitudes as well as their phase angle into one quantity, and hence provides a better indication of vibration transmission in oscillating systems. The PFA method is well-established for the linear systems [1-4]. In recent years, the PFA is developed to investigate vibration transmission within nonlinear dynamic systems. Xiong et al. [5] investigated the power flow performance of a nonlinear isolator mounted on a travelling flexible ship. The PFA approach has also been employed to investigate the power flow characteristics of the Duffing oscillator [6], a nonlinear vibration isolation system with negative stiffness mechanism [7], coupled oscillators with a nonlinear interface [8] and power flow between coupled nonlinear oscillators [9]. Work has also been reported on power flow and vibration transmission characteristics of non-smooth oscillating system with bilinear elements [10] and impact oscillators with linear and nonlinear constraints [11]. Most of these investigations consider a single external force, the vibration transmission and power flow behaviour of coupled systems subjected to multiple external excitation forces is not clear and needs investigations.

In this paper, vibration power flow characteristics of nonlinearly coupled oscillators excited by two harmonic forces with the same frequency but different phase angles are investigated. Both analytical harmonic balance method and numerical results are presented to reveal the effects of the relative phage angle between the two forces on the steady-state response amplitudes and on the time-averaged power flows. The remaining content of paper is organised as follows. The modelling and formulation parts are presented in section 2 and section 3, respectively. Section 4 examines the influence of phase angle lag on the vibration power flow transmission. Conclusions are drawn at the end of paper.

2 MODELLING

Figure 1 shows a schematic representation of the system comprising two linear subsystems with a nonlinear interface. Subsystem one consists of a mass m_1 with a linear spring with stiffness coefficient k_1 and a viscous damper with damping coefficient c_1 subjected to an external harmonic force $f_1 \cos \omega t$. Subsystem two comprises a mass m_2 attached to a linear spring with coefficient k_2 and a viscous damper with damping c_2 with another external force $f_2 \cos(\omega t + \varphi)$, where φ is the relative phase angle between the two harmonic forces. The masses oscillate horizontally without friction and their static equilibrium positions, where $x_1 = x_2 = 0$, are taken as the reference. The two subsystems are connected by a nonlinear interface with restoring force $g(\delta) = k_3\delta + k_4\delta^3$, where k_3 and k_4 are the linear and nonlinear spring coefficients at the interface, respectively, $\delta = x_2 - x_1$ is the relative displacement between the two masses.

The governing equations of the coupled system are

$$m_1\ddot{x}_1 + k_1x_1 + c_1\dot{x}_1 - g(\delta) = f_1 \cos \omega t, \tag{1a}$$

$$m_2\ddot{x}_2 + k_2x_2 + c_2\dot{x}_2 + g(\delta) = f_2 \cos(\omega t + \varphi). \tag{1b}$$

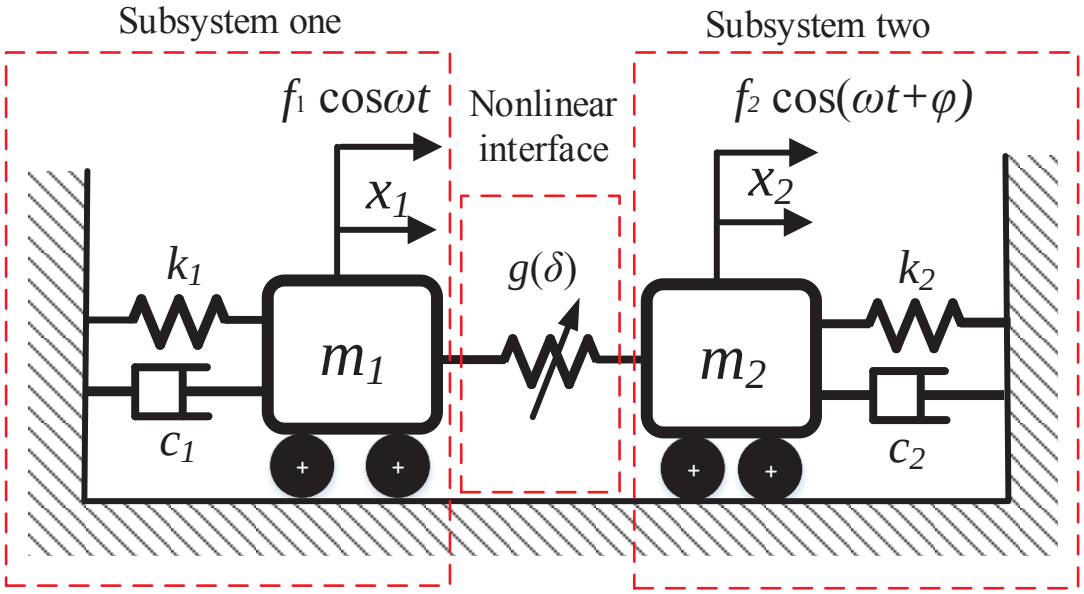

Figure 1: A schematic representation of nonlinearly coupled oscillators excited by two different external forces

Non-dimensional parameters and variables are introduced below to facilitate later calculations,

$$\omega_1 = \sqrt{\frac{k_1}{m_1}}, \omega_2 = \sqrt{\frac{k_2}{m_2}}, \mu = \frac{m_2}{m_1}, \lambda = \frac{k_3}{k_1}, \beta = \frac{k_4 l_0^2}{k_1}, \gamma = \frac{\omega_2}{\omega_1}, X_1 = \frac{x_1}{l_0}, X_2 = \frac{x_2}{l_0},$$

$$Y = X_2 - X_1, \zeta_1 = \frac{c_1}{2m_1\omega_1}, \zeta_2 = \frac{c_2}{2m_2\omega_2}, F_1 = \frac{f_1}{k_1 l_0}, F_2 = \frac{f_2}{k_1 l_0}, \Omega = \frac{\omega}{\omega_1}, \tau = \omega_1 t.$$

where ω_1 and ω_2 are the natural frequencies of subsystems one and two, respectively, μ is the mass ratio, λ and β are the non-dimensional stiffness ratios of the spring at the interface, γ is the natural frequency ratio, l_0 is the un-stretched length of the spring k_1 on the left, X_1 and X_2 are the non-dimensional displacements of masses m_1 and m_2, respectively, Y is the non-dimensional relative displacement of the masses, ζ_1 and ζ_2 are the non-dimensional damping coefficients, F_1 and F_2 are the non-dimensional forcing amplitudes, Ω is the non-dimensional excitation frequency, τ is the non-dimensional time. Using these non-dimensional parameters, the governing equations (1a) and (1b) can be written into a non-dimensional form

$$X_1'' + X_1 + 2\zeta_1 X_1' - \lambda Y - \beta Y^3 = F_1 \cos\Omega\tau, \tag{2a}$$

$$\mu(X_1 + Y)'' + 2\mu\zeta_2\gamma(X_1 + Y)' + \mu\gamma^2(X_1 + Y) + \lambda Y + \beta Y^3 = F_2 \cos(\Omega\tau + \varphi), \tag{2b}$$

where the primes denote differentiation operations with respect to the non-dimensional time τ. Eqs. (2a) and (2b) can be further transformed into first-order ordinary differential equations and solved using a fourth-order Runge-Kutta numerical integration method. Although this method can provide accurate predictions of the response, the computational cost is relatively high. In comparison, the harmonic balance method can be used to obtain he steady-state response at lower computation cost.

Here, a first-order harmonic balance method is used to predict the steady-state response of the system. The displacement, velocity and acceleration of the mass m_1 and the relative displacement between the two masses are assumed to be

$$X_1 = a\cos(\Omega\tau + \phi), X_1' = -a\Omega\sin(\Omega\tau + \phi), X_1'' = -a\Omega^2\cos(\Omega\tau + \phi), \tag{3a-3c}$$

$$Y = b\cos(\Omega\tau + \theta), \quad Y' = -b\Omega\sin(\Omega\tau + \theta), Y'' = -b\Omega^2\cos(\Omega\tau + \theta). \tag{3d-3f}$$

Using Eq. (3) to replace the corresponding terms in Eq. (2a) and (2b) and balancing the coefficients of terms $\cos(\Omega\tau)$ and $\sin(\Omega\tau)$, it follows that

$$-a\Omega^2\cos\phi + a\cos\phi - 2\zeta_1 a\Omega\sin\phi - \lambda b\cos\theta - \frac{3\beta b^3}{4}\cos\theta = F_1, \tag{4a}$$

$$a\Omega^2\sin\phi - a\sin\phi - 2\zeta_1 a\Omega\cos\phi + \lambda b\sin\theta + \frac{3\beta b^3}{4}\sin\theta = 0, \tag{4b}$$

$$\mu(-a\Omega^2\cos\phi - b\Omega^2\cos\theta) + 2\mu\zeta_2\gamma(-a\Omega\sin\phi - b\Omega\sin\theta) + \mu\gamma^2(a\cos\phi + b\cos\theta) + \lambda b\cos\theta + \frac{3\beta b^3}{4}\cos\theta = F_2\cos\varphi, \tag{4c}$$

$$\mu(a\Omega^2\sin\phi + b\Omega^2\sin\theta) + 2\mu\zeta_2\gamma(-a\Omega\cos\phi - b\Omega\cos\theta) + \mu\gamma^2(-a\sin\phi - b\sin\theta) - \lambda b\sin\theta - \frac{3\beta b^3}{4}\sin\theta = -F_2\sin\varphi. \tag{4d}$$

Note that Eq. (4) provides four nonlinear algebraic equations with four unknowns a, b, ϕ and θ. The Newton-Raphson based numerical continuation could be employed to obtain the corresponding solutions for dynamics responses, phase angles and associated vibration power flow variables as formulated in the section below.

3 VIBRATION POWER FLOW ANALYSIS

3.1 Time-averaged input power

The non-dimensional instantaneous power input into the integrated system is the product of external forces and corresponding velocities

$$p_{\text{in}} = X_1' F_1\cos\Omega\tau + X_2' F_2\cos(\Omega\tau + \varphi), \tag{5}$$

where X_1' is the non-dimensional velocity of mass m_1 and X_2' is the non-dimensional velocity of mass m_2. The steady-state time-averaged input power over an excitation cycle is

$$\bar{p}_{\text{in}} = \frac{1}{\tau_s}\int_{\tau_0}^{\tau_0+\tau_s} p_{\text{in}}\ \mathrm{d}\tau \approx -\frac{aF_1\Omega}{2}\sin\phi - \frac{aF_2\Omega}{2}\sin(\phi-\varphi) - \frac{bF_2\Omega}{2}\sin(\theta-\varphi). \tag{6}$$

where τ_0 is the starting time for the averaging and τ_s is the averaging time. The approximation made in Eq. (6) was based on a first-order analytical approximation of the steady state velocities, i.e., $X_1' = -a\Omega\sin(\Omega\tau+\phi)$ and $X_2' = X_1' + Y' = -a\Omega\sin(\Omega\tau+\phi) - b\Omega\sin(\Omega\tau+\theta)$, and an averaging time of one excitation cycle, i. e., $\tau_s = 2\pi/\Omega$.

3.2 Time-averaged transmitted power

The non-dimensional transmitted power transferred from subsystem one to subsystem two through the nonlinear interface is product of transmitted force and non-dimensional velocity $X_2{}'$ of the mass of subsystem two:

$$p_{\text{t}} = F_t X_2' = F_t(X_1{}' + Y'), \tag{7}$$

where $F_t = -\lambda Y - \beta Y^3$ is the non-dimensional transmitted force. The steady-state time-averaged transmitted power from $\tau = \tau_0$ to $\tau = \tau_0 + \tau_s$ is

$$\bar{p}_{\text{t}} = \frac{1}{\tau_s}\int_{\tau_0}^{\tau_0+\tau_s} p_{\text{t}}\,\mathrm{d}\tau \approx -ab\Omega\sin(\theta-\phi)\left(\frac{\lambda}{2} + \frac{3b^2\beta}{8}\right), \tag{8}$$

where first-order approximations of the steady-state displacements and velocities were used as in Eq. (6). In the approximation in Eq. (8), the averaging time τ_s is set to be one excitation period, i.e., $\tau_s = 2\pi/\Omega$.

4 RESULTS AND DISCUSSIONS

The effects of the relative phase angle φ between two external forces on the level of vibration transmission of coupled system is investigated herein. The phase angle φ changes from 0 to $\pi/2$ and then to π with the corresponding analytical results denoted by solid, dashed and dotted lines in Figs. 2 and 3. The squares, circles and triangles represent the direct numerical integration results obtained by the fourth-order Runge-Kutta method for the cases with φ being $0, \pi/2$ and π, respectivley. The other parameters of the system are $\mu = 0.5, \lambda = \gamma = 1, \zeta_1 = \zeta_2 = 0.01, \beta = 0.5, F_1 = F_2 = 0.1$.

Figure 2 examines the effects of phase angle φ on the response amplitude of mass m_1 and relative displacement amplitude under dual forces excitations. Fig. 2 shows that there are two peaks in each displacement amplitude curve of mass m_1 but only one peak in the curve of relative displacement amplitude. It could be explained by modal analysis theory that the masses experience in-phase motion at the first resonance and out-of-phase motion at the second resonant frequency. When the relative phase angle equals π, i.e., two external forces acting in different directions, the first resonant peak of oscillator m_1 disappears. Fig. 2(a) also shows that the response amplitude of mass m_1 decreases as the increase of the relative phase angle φ at a prescribed excitation frequency in the low-frequency range. In contrast, the relative displacement amplitude b between the masses is the largest when $\varphi = \pi$ at a prescribed value of Ω in the low-frequency range. As the excitation frequency Ω becomes large in the high-frequency range, the effects of phase angle on the response amplitude a becomes weak. Fig. 2(b) shows that at a specific value of Ω in the high-frequency range, the relative displacement amplitude b is the largest when $\varphi = \pi$, compared with the other two cases. It is also noted that the relative phase angle φ between two excitation forces has very small effects on the resonant peak frequencies as the resonant peaks of the three considered cases merge.

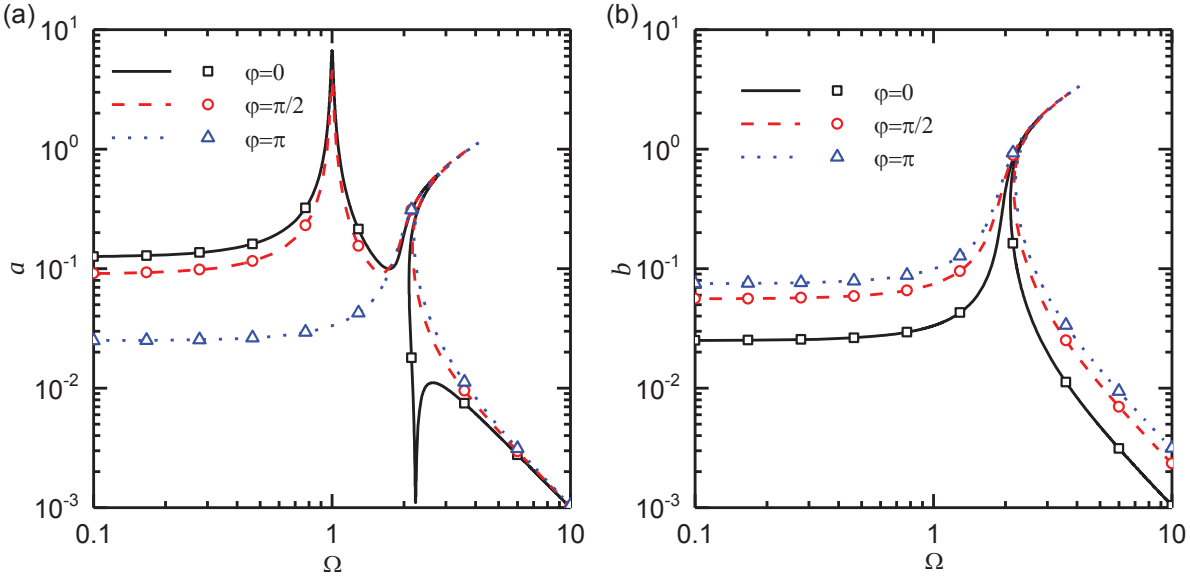

Figure 2: Effects of phase angle lag φ on the response amplitude a and b. Other system parameters are $\mu = 0.5, \lambda = \gamma = 1, \zeta_1 = \zeta_2 = 0.01, \beta = 0.5, F_1 = F_2 = 0.1$.

Figure 3 presents the influence of the relative phase angle φ on the power flow transmission. Two resonant peaks are observed in each curve of both the time-averaged input power $\bar{p}_{\text{in}}$ and the time-averaged transmitted power $\bar{p}_{\text{t}}$, as shown in Fig. 3(a) and 3(b), respectively. Fig. 3(a) shows that there is a larger amount of input power into the coupled system for the $\varphi = 0$ case

when Ω is small, as compared with the other two cases with different values of φ. As the increase of excitation frequencies, the effects of different values of phase angle φ on $\bar{p}_{\mathrm{in}}$ is observed to be small. Fig. 3(b) shows that the phase angle has a significant influence on the time-averaged transmitted power $\bar{p}_{\mathrm{t}}$. Compared with the other two cases, the case with $\varphi = \pi$ (i.e., the forces act in opposite directions) can result in lower power transmission level. It also demonstrated the relative phase angle between the two excitations may significantly change the peak values of the transmitted power behaviour. The results indicate that the phase angle of the excitation forces may have large influence on vibration transmission in nonlinear systems.

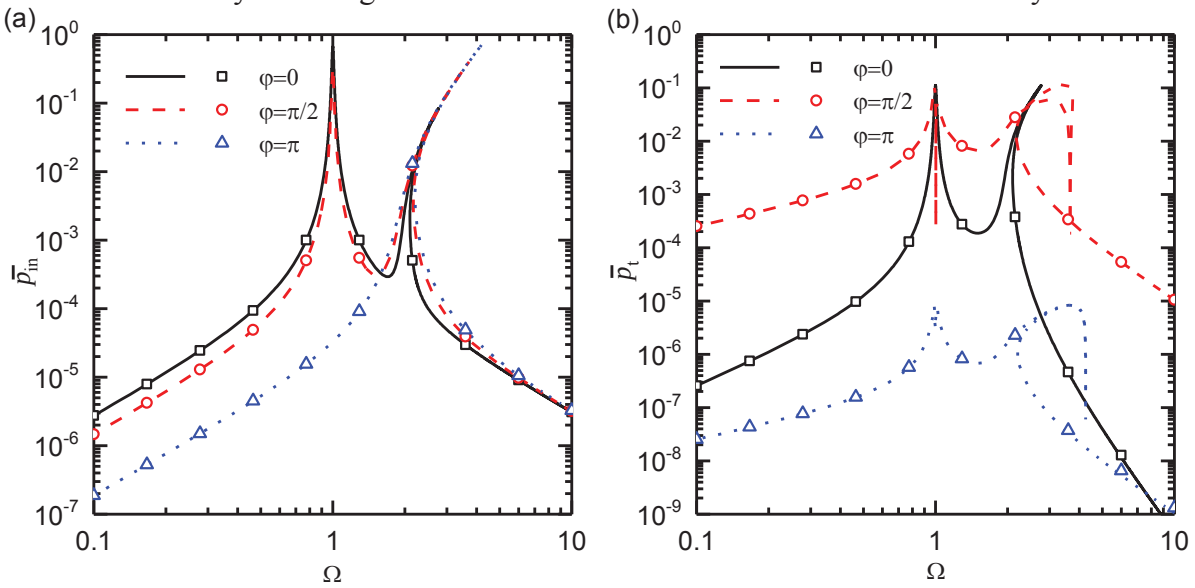

Figure 3: Effects of phase angle lag φ on the time-averaged power flow $\bar{p}_{\mathrm{in}}$ and $\bar{p}_{\mathrm{t}}$. System parameters are $\mu = 0.5, \lambda = \gamma = 1, \zeta_1 = \zeta_2 = 0.01, \beta = 0.5, F_1 = F_2 = 0.1$.

5 CONCLUSIONS

The dynamic response and the time-averaged power flow characteristics of nonlinearly coupled oscillators subject to dual forces excitations with different phase angles are investigated. Both analytical harmonic balance method and numerical Runge-Kutta method are used to explore the effects of the relative phase angle on steady-state response amplitudes and vibration power flow variables. It is found dynamic response and power transmission in the system excited at low frequencies could be reduced by adjusting phase angle difference in dual excitations systems. The relative displacement amplitude between the masses may increase with the relative phage angle when away from the resonance. It is also found that the phase angle of the excitation forces may have small effects on the peaks of dynamic response and the time-averaged input power. It is also shown that the vibration transmission in terms of the time-averaged transmitted power between the two oscillators may be sensitive to the variations of the relative phase angle. The results provide some new insight into vibration transmission and power flow in nonlinear systems with more than one excitation forces. The PFA method may also be used for vibration transmission analysis of more complex nonlinear systems for enhanced design of vibration mitigation devices exploiting nonlinearity.

Keywords: Gear model, Stochastic dynamics, Path integration, Filtered noise

Abstract. *The stochastic dynamic response of a spur gear pair model under filtered noise excitation is investigated. The spur gear pair is modeled as a single degree of freedom (SDOF) system in which nonlinear backlash and time-varying mesh stiffness as well as stochastic excitation are considered. Four cases are addressed, based on how the noise is incorporated in the loading terms. A first order filter is employed to generate various filtered noises with the same energy but different power spectrum. The combination of the SDOF gear model and the shaping filter leads to a three dimensional (3D) Markov model. The numerical path integration (PI) technique is adopted to obtain the probabilistic response of the gear model using an adaptive time-stepping method in order to increase the accuracy of the time integration. To model a narrow band noise excitation, a second order filter is applied to model the excitation, leading to a four dimensional (4D) Markov model. The results are verified by comparing with Monte Carlo simulations. The effect of the noise spectrum on the probabilistic response is evaluated for different loading cases.*

1 INTRODUCTION

Gears are widely used in a variety of different industrial applications. Investigation on the dynamical behavior of gears is important for other fields of related research such as design, tribology, reliability assessment, etc. The first studies of the dynamics of gear systems are from the early 20th century and the topic has continued to be an active research area until now. Early gear models were linear, excluding or neglecting nonlinearities such as backlash [1]. Nonlinear, time-varying (NTV) gear models were developed and investigated in the 90's [2–5]. More recently, researches have focused on multi-degrees of freedom (DOF) modeling of the gear mesh system, which lead to more realistic and complicated models as well [6,7]. All those studies belong to the category of deterministic dynamics.

Stochastic excitation may be prevalent in gear systems due to randomness in the external loading or within internal parameters. In some applications, such as wind turbine drivetrains, ship propulsions and automobile gearboxes, the effect of randomness is significant, which implies the necessity to conduct a stochastic analysis to obtain accurate and realistic results. Moreover, knowledge about the probability density function (PDF) of the response is of key importance for the purpose of reliability assessment and reliability-based design in such systems. This latter can be achieved by considering a stochastic component as part of the excitation. Under suitable modelling assumptions, this would typically lead to a stochastic differential equation (SDE). Although the simplest stochastic excitation is the Gaussian white noise (GWN), which is characterized by a uniform power across the frequency band, real stochastic loadings will invariably have varying spectral distributions. For instance, some wind loadings has a descending power spectral density (PSD) which can be approximated by a first order linear filter [8]. In this work, the random excitation is assumed to be a filtered Gaussian white noise, which leads to an n-dimensional SDE in the state space. The response of such systems is a Markov vector process and its transitional PDF is governed by the Fokker-Planck (FP) equation. However, the analytical solution of the FP equation is restricted to linear systems and a limited class of nonlinear models [9].

Tobe et al. [10,11] considered random excitation in gear systems using a statistical linearization technique. They also experimentally verified their theoretical results. Using statistical linearization leads to inaccurate results for systems with discontinuous nonlinearities. This led Kumar et al. [12] to adopt a direct integration technique to study the dynamic response of a gear pair. Similarly, Neriya et al. [13] investigated a helical gear system which included both backlash and time-varying mesh stiffness, and was also subjected to a random transmission error. The mean value and variance of the response were calculated by the piecewise linearization method. Pfeiffer and Kunert [14] evaluated the rattling problem for a gear system. Wang and Zhang [15] considered the effect of speed-dependent random errors on the stochastic vibration of the gear model.

The path integration (PI) method provides a numerical approach to approximate the solution of FP equations. A basic version is used by Wehner and Wolfer [16] to solve nonlinear FP equations. Subsequently, Naess and Moe [17], Lin and Yu [18], Zhu [19], and others have applied and further developed the PI technique in order to evaluate several engineering problems. An efficient and accurate approach was applied by Naess et al. [20] for solving a SDOF gear model with a non-smooth restoring mechanism under stochastic excitation caused by Gaussian white noise. It is a unique feature of the PI method to deal with non-smooth stochastic dynamics. The dynamical model in [20] was assumed as nonlinear time-invariant (NTI), neglecting the variation of mesh stiffness with contact status. A short time Gaussian approximation (STGA) was adopted to approximate the conditional PDF [21] and captured the evolution of the response PDF using a stepwise solution technique. Later, Mo and Naess [22] showed that for chaotic

response of a gear system, the stochastic and deterministic attractors are very similar by comparing the response PDF with the Poincaré map of the deterministic system in [2]. In both papers, a fixed time step was used in general. However, in order to reduce numerical errors due to non-smooth dynamical behavior, a backward Runge-Kutta time-stepping algorithm combined with a Newton iteration method was used to split the fixed step into two sub-steps. This permits to accurately find out when the deterministic trajectory crosses the boundary between two regimes of nonlinearity. Another similar approach to account for the non-smooth backlash function was proposed by Wen et al. [23], who dealt with a linear dynamic model for each part of the state space. Although an important interaction between time-varying mesh stiffness and backlash nonlinearity in gear meshing systems was reported, a constant averaged stiffness was used in their model. Considering the stochasticity of the system, establishing the exact switching time between different regimes of the dynamical system is not meaningful since there is no deterministic trajectory. Therefore, the aforementioned approach may fail to be sufficiently accurate and efficient, a fact confirmed by the results obtained with Monte Carlo simulations. In order to decrease the calculation error, Hasnijeh et al. [24] applied a novel adaptive time-stepping method. The main idea of this method is to determine the time-step length based on the amount of marginal probability at non-smooth boundaries. They proved the efficiency of the adaptive method relative to the fixed time-stepping for non-smooth systems.

The simplest and usually the most reliable approach to determine the response PDF of SDEs is provided by the Monte Carlo simulation (MCS) method. In this approach, the response statistics are extracted from a large number of response realizations, which are generated using a stochastic integration method. Feng et al. [25] used MCS to investigate a stochastic spur gear model including the effects of sliding friction. MCS is useful as a verification tool for checking results obtained by other more efficient methods. However, it is a rather time-consuming method if highly accurate results are needed, especially for low probability events.

In the present paper, the response PDF of an SDOF nonlinear, time-varying gear model under the excitation of a filtered noise is obtained. The NTV gear model includes both backlash nonlinearity and time-varying mesh stiffness (TVMS). Three main sub-problems are addressed herein. The first assignment consists in proving the capability of the adaptive path integration (API) method to investigate non-smooth dynamical gear systems under the excitation of filtered white noise. A first order filter is used to generate the filtered white noise, extending the Markov property of this second-order system to the 3D state space. The second goal pursued here is to evaluate the effect of uncertain loading parameters on the response PDF. For this purpose, the applied additive noise of the problem is categorized into two different stochastic loading models. Finally, a parametric study is carried out to show the effect of the loading spectrum on different aspects of the response PDF. Three filtered versions of noises are applied with equal energies but different spectrum distributions. To assess the capability of the path integration method in dealing of systems with higher dimensions, a 4D system is also considered by using a second-order filter to generate a narrow-band noise. Results are verified by Monte Carlo simulations for all cases. To the best of the authors' knowledge, the response PDF of a gear model under filtered noise has not been investigated before. The response PDF contains a lot of raw information which can be utilized in different ways depending on the purpose of the analysis, such as mechanical design and reliability analysis. In addition, the effect of the input frequency spectrum on the response PDF is studied for each stochastic excitation case.

2 STOCHASTIC DYNAMICAL MODEL

Fig. 1 depicts the spur gear pair model considered here. The equation of motion for this model is given in dimensionless form in Eq. (1), and its derivation is discussed in [1, 24].

$$\ddot{q}(t) + 2\zeta\dot{q}(t) + k_h(t)f\big(q(t)\big) = F_m + F_{ah}\cos(\Omega t) \tag{1}$$

$$f\big(q(t)\big) = \begin{cases} q(t) - 1 & q(t) > 1 \\ 0 & -1 < q(t) < 1 \\ q(t) + 1 & q(t) < -1 \end{cases} \tag{2}$$

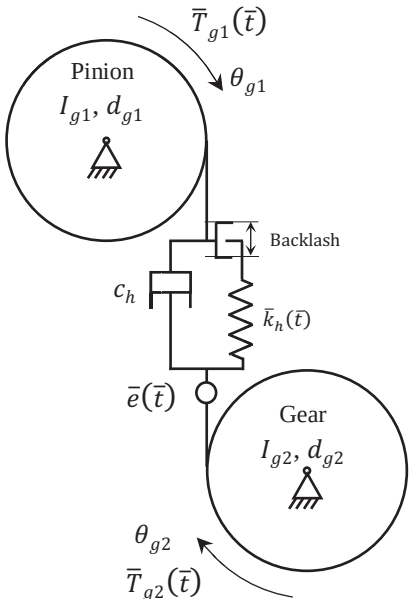

Figure 1: Gear pair model [24]

In Eq. (1), q is the difference between the dynamic transmission error and the static transmission error, ζ denotes damping ratio, k_h is the time-varying mesh stiffness, f represents the nonlinear backlash function, Ω is the excitation frequency, and F_m and F_{ah} are the mean and alternating components of the loading, respectively.

Eq. (1) is a two-dimensional state space NTV problem and may have multi-solutions, depending on the parameter values. The deterministic solution of this system can include no-impact, single-sided or double-sided impact cases, maybe with several subharmonics [2]. In the case of a multi-solution problem, the initial conditions will determine which deterministic solution would occur. As opposed to deterministic dynamics, the probabilistic response of the system may include both solution types simultaneously because of the stochastic essence of the excitation and also due to uncertain initial conditions [3]. In order to evaluate the effect of uncertainty in loading components on the dynamical behavior of the gear system, two separate cases are defined in the following based on an additive noise F_s and intensity parameter λ.

Case A: Uncertainty in the mean component of the loading which may arise from external torque fluctuation

$$\ddot{q}(t) + 2\zeta\dot{q}(t) + k_h(t)f\big(q(t)\big) = (F_m + \lambda F_s) + F_{ah}{\Omega_h}^2\cos(\Omega_h t) \tag{3}$$

Case B: Uncertainty in the alternating component of the loading that may be caused by manufacturing errors [4–6]

$$\ddot{q}(t) + 2\zeta\dot{q}(t) + k_h(t)f\big(q(t)\big) = F_m + (F_{ah} + \lambda F_s){\Omega_h}^2\cos(\Omega_h t) \tag{4}$$

3 FILTERED WHITE NOISE

3.1 First order linear filter

The noise component is assumed to be a stationary process, allowing the use of the shaping filter techniques in order to generate it from a Gaussian white noise [7]. In this study, the stochastic excitation is considered to have a particular power spectral density (PSD) function which can be modeled as follows

$$\dot{F}_s = -\alpha F_s + \gamma N_t \tag{5}$$

where N_t is the standard Gaussian white noise process and, α and γ are filter parameters. Knowing that $N_t dt = dW(t)$ [8] and defining $x_1 = q(t)$, $x_2 = \dot{q}(t)$ and $x_3 = F_s(t)$, the state space form of Eq. (3) can be rewritten as

$$\begin{cases} \mathrm{d}x_1 = x_2 \mathrm{d}t \\ \mathrm{d}x_2 = \left[F_m + F_{ah}{\Omega_h}^2 \cos(\Omega_h t) - 2\zeta x_2 - k_h(t) f(x_1) + \lambda x_3\right] \mathrm{d}t \\ \mathrm{d}x_3 = -\alpha x_3 \mathrm{d}t + \gamma \, \mathrm{d}W(t) \end{cases} \tag{6}$$

where $W(t)$ now denotes a standard Wiener process with stationary and independent increments. Similar forms will be obtained for Eq. (4). The power spectral density function for F_s is,

$$S(\omega) = \frac{\gamma^2}{2\pi(\omega^2 + \alpha^2)} \tag{7}$$

3.2 Second order linear filter

To evaluate the capability of the path integration method in dealing with non-smooth systems of higher dimensions, the gear model in combination with a second order linear filter is also considered. The filter equations are as follows [7]

$$\begin{cases} \dot{G}_s = -\alpha F_s \\ \dot{F}_s = G_s - \beta F_s + \gamma N_t \end{cases} \tag{8}$$

α, β and γ are filter parameters. In the current study, the second order filter is only used for case A. Defining $x_3 = G_s$ and $x_4 = F_s$, the 4D state space model for Eq. (3) can be written as

$$\begin{cases} \mathrm{d}x_1 = x_2 \mathrm{d}t \\ \mathrm{d}x_2 = \left[F_m + F_{ah}{\Omega_h}^2 \cos(\Omega_h t) - 2\zeta x_2 - k_h(t) f(x_1) + \lambda x_4\right] \mathrm{d}t \\ \mathrm{d}x_3 = -\alpha x_4 \mathrm{d}t \\ \mathrm{d}x_4 = (x_3 - \beta x_4) \mathrm{d}t + \gamma \, \mathrm{d}W(t) \end{cases} \tag{9}$$

The power spectral density function for F_s is obtained as follows,

$$S(\omega) = \frac{1}{2\pi} \frac{\gamma^2 \omega^2}{(\alpha - \omega^2)^2 + (\beta\omega)^2} \tag{10}$$

The advantage of being able to use a second order filter is that it allows a study of the effect of narrow band excitation processes on the response of the gear system.

4 THE PATH INTEGRATION METHOD

Eq. (6) can be expressed by the standard Itô SDE form as follows,

$$\mathrm{d}\mathbf{x}(t) = \boldsymbol{\alpha}(\boldsymbol{x}, t)\mathrm{d}t + \boldsymbol{\beta}(t)\mathrm{d}\mathbf{W}(t) \tag{11}$$

Since the main goal of the current study is to investigate 3D problems, the formulation is developed for a 3D state space model. The formulation can be easily generalized to higher dimensions. Therefore, $\mathbf{x}(t) = (x_1, x_2, x_3)^{\mathrm{T}}$ is a 3D state space vector process, $\boldsymbol{\alpha}(\mathbf{x}, t)$ is the drift vector and $\boldsymbol{\beta}(t)$ is the diffusion matrix and the vector $\mathrm{d}\mathbf{W}(t) = \mathbf{W}(t + dt) - \mathbf{W}(t)$ denotes the independent increments of a standard Wiener vector process. The SDE (11) has a unique solution in the strong sense for every set of parameter values [9]. This solution has a joint probability distribution of states for a specific time that can be calculated through application of the numerical PI method.

The response of the dynamical system (11) is a Markov process and the transition probability density function (TPDF), $p(\mathbf{x}, t|\mathbf{x}', t')$, satisfies the Fokker-Planck (FP) equation, which is written as follows

$$\frac{\partial}{\partial x} p(\mathbf{x}, t|\mathbf{x}', t') = -\sum_{i=1}^{3} \frac{\partial}{\partial x_i} \alpha_i(\mathbf{x}, t) p(\mathbf{x}, t|\mathbf{x}', t') + \frac{1}{2} \sum_{i=1}^{3} \sum_{j=1}^{3} \frac{\partial^2}{\partial x_i \partial x_j} \left(\boldsymbol{\beta}(t).\boldsymbol{\beta}^{\mathrm{T}}(t)\right)_{i,j} p(\mathbf{x}, t|\mathbf{x}', t') \quad (12)$$

In addition to several numerical methods presented for solving the FP equation directly, the probabilistic evolution of the state space vector process $\mathbf{x}(t)$ can be captured based on the Markov property of the response using the basic equation of the PI method

$$p(\boldsymbol{x}, t) = \int_{\boldsymbol{\Gamma}} p(\boldsymbol{x}, t|\boldsymbol{x}', t') p(\boldsymbol{x}', t') d\boldsymbol{x}' \quad (13)$$

where $\boldsymbol{\Gamma}$ is the state space and $d\mathbf{x}' = \prod_{i=1}^{3} dx_i'$. In fact, the method consists of evaluating the TPDF core thence determining the PDF $p(\mathbf{x}, t)$ of the state space vector $\mathbf{x}$ at time t from the previous PDF $p(\mathbf{x}', t')$ at time t' through Eq. (13). To implement the PI method, a discrete time approximation is needed. Naess and Moe [17] proposed a fourth-order Runge-Kutta-Maruyama (RKM) for the numerical solution of (11) as follows

$$\mathbf{x}(t) = \mathbf{x}(t') + \mathbf{r}(\mathbf{x}(t'), t', \Delta t) + \beta(t')\Delta\mathbf{W}(t') \quad (14)$$

The deterministic part of Eq. (14) is the explicit fourth-order Runge–Kutta (RK4) approximation $\mathbf{x}(t) = \mathbf{x}(t') + \mathbf{r}(\mathbf{x}(t'), t', \Delta t)$, which represents the time evolution of the deterministic part of (11) with a global error of order $O(\Delta t^5)$, where $\Delta t = t - t'$. Numerical experiments predict that the approximation to the deterministic part outweighs other residues in terms of accuracy in the solution of Eq. (11) [8]. Thus, a fourth-order RKM is applied in the form of $\mathbf{r}(\mathbf{x}(t'), t', \Delta t)$ for the deterministic part of Eq. (11). The Wiener process $\mathbf{W}(t)$ has independent increments, hence $\Delta\mathbf{W}(t') = \mathbf{W}(t) - \mathbf{W}(t')$ is a Gaussian variable and the TPD $p(\mathbf{x}, t|\mathbf{x}', t')$ is a Gaussian PDF for every t'. For sufficiently small Δt, the time sequence $\{\mathbf{x}(t_i)\}_{i=0}^{\infty}$ becomes a Markov chain which can approximate the time-continuous Markov solution of the SDE (11). For the model given by Eq. (6), the conditional PDF $p(\mathbf{x}, t|\mathbf{x}', t')$ follows a degenerate multi-dimensional Gaussian PDF [11],

$$p(\mathbf{x}, t|\mathbf{x}', t') = \delta\left(x_1 - x_1' - r_1(\mathbf{x}(t'), t', \Delta t)\right) \delta(x_2 - x_2' - r_2(\mathbf{x}(t'), t', \Delta t)) \tilde{p}(x_3, t|\mathbf{x}', t') \quad (15)$$

where $\delta(.)$ denotes the Dirac delta function and

$$\tilde{p}(x_3, t|\mathbf{x}', t') = \frac{1}{\sqrt{2\pi\gamma^2\Delta t}} \exp\left\{-\frac{\left(x_3 - x_3' - r_3(\mathbf{x}(t'), t', \Delta t)\right)^2}{2\gamma^2\Delta t}\right\} \quad (16)$$

in which $r_{\mathrm{i}}(\mathbf{x}', t', \Delta t)$ $i = 1,2,3$ are Runge-Kutta increments corresponding to each state. If the initial PDF $p_0(\mathbf{x}^{(0)}) = p(\mathbf{x}, t_0)$ is specified, Eq. (13) can be written in a stepwise format as follows

$$p\left(\mathbf{x}^{(n)}, t_n\right) = \int_{\mathrm{R}^3} \dots \int_{\mathrm{R}^3} \prod_{i=1}^{n} p\left(\mathbf{x}^{(i)}, t_i \middle| \mathbf{x}^{(i-1)}, t_{i-1}\right) p_0\left(\mathbf{x}^{(0)}\right) \mathrm{d}\mathbf{x}^{(0)} \dots \mathrm{d}\mathbf{x}^{(n-1)} \tag{17}$$

Eq. (17) expresses the mathematical formulation of the PI technique as used in this study. A finite region of integration that covers almost the whole probability range of the response should be introduced for evaluating Eq. (17), with consideration that the computational time is dramatically influenced by the state space discretization resolution. If the region of integration is determined appropriately, the probability loss that arises would be negligible. The initial PDF can, in principle, be chosen quite arbitrarily as long as there is nonzero variance in all spatial dimensions. This is necessary for the numerical algorithms to work properly. What determines the choice of the initial PDF depends on the specific problem investigated. For the purpose of this paper, the initial PDF is assumed to be Gaussian, as follows:

$$p_0\left(\mathbf{x}^{(0)}\right) = p\left(\mathbf{x}^{(0)}, t_0\right) = \prod_{i=1}^{n} \frac{1}{\sqrt{2\pi}\sigma_{x_i}^{(0)}} \exp\left(-\frac{1}{2}\left(\frac{x_i - \mu_{x_i}^{(0)}}{\sigma_{x_i}^{(0)}}\right)^2\right) \tag{18}$$

where $\mu_{x_i}^{(0)}, i = 1,2,3$ denote initial mean values and $\sigma_{x_i}^{(0)}$ $(> 0), i = 1,2,3$ represent standard deviations.

A challenging issue in the numerical calculations of non-smooth dynamics is the abrupt change in their behavior. In the deterministic problems, it can be overcome by identifying the transition point between two different dynamical regimes within a time step and splitting it into two sub-steps with different dynamics. However, in the corresponding stochastic dynamic analysis, there is no specific trajectory that would allow the transition points to be identified. In this study, a new adaptive time-stepping scheme is used in order to reduce both the numerical error and calculation runtime in comparison with the fixed time-step method [1]. The main idea behind this adaptive time-stepping method is to decrease the time step proportionally to the magnitude of the marginal probability density at the non-smooth boundaries. In the considered gear system, there are two boundaries $x_1 = -1$ and $x_1 = 1$ that separate three different dynamical zones. The mathematical formulation behind this approach can be written as follows

$$\Delta t_i = t_i - t_{i-1} = \max\left[\left(\left(1 - \frac{\max\left\{p_{x_1}(-1, t_{i-1}), p_{x_1}(1, t_{i-1})\right\}}{p_{x_1}^{(\max)}}\right)\Delta t_{\max}\right), (\Delta t_{\min})\right] \tag{19}$$

where p_{x_1} is the marginal PDF for the state variable x_1 and $p_{x_1}^{(\max)}$ is its maximum value. $\Delta t_{\max}$ is the maximum time step, and a minimum time increment $\Delta t_{\min}$ is introduced in order to avoid a zero length step when the marginal PDF approaches its maximum at the specified boundaries.

5 RESULTS AND DISCUSSION

5.1 Deterministic dynamical behavior

The deterministic dynamics of the model is investigated in order to compare probabilistic response with the deterministic results. A square-wave is considered as follows

$$k_h(t) = \begin{cases} 0.8 & (n-1)t_p \le t < (n-1)t_p + t_p/2. \;\; n = 1.2.3 \cdots \\ 1.2 & (n-1)t_p + t_p/2 \le t < nt_p. \;\; n = 1.2.3 \cdots \end{cases} \tag{20}$$

where t_p is the gear mesh period. It has been reported that the interaction between time-varying mesh stiffness and backlash nonlinearity becomes more pronounced in the multi-solution zone and especially for heavily loaded systems [12]. As a dimensionless case of study, parameters $\zeta = 0.05$, $F_m = 0.3$ and $F_{ah} = 0.1$ are borrowed from references [2,3,12]. This is a heavily loaded gear pair system, since $\hat{F} = F_m/F_{ah} = 3$ [2]. For $\Omega_h = 0.65$ there are two coexisting

solutions, which are named by Kahraman [2] as the no impact and the single-sided impact solutions (Fig. 2-a). The deterministic domain of attraction is shown in (Fig 2-b). The deterministic system will adopt one of the solutions depending on the initial condition. The initial distribution parameters in this paper are chosen as $\mu_{x_1}^{(0)} = \mu_{x_2}^{(0)} = 0$, $\sigma_{x_1}^{(0)} = 0.5$ and $\sigma_{x_2}^{(0)} = 0.25$ which covers both basins of attraction, but mostly the single-sided impact solution. The difference between applying deterministic versus stochastic initial condition is illustrated schematically in Fig. 2-b.

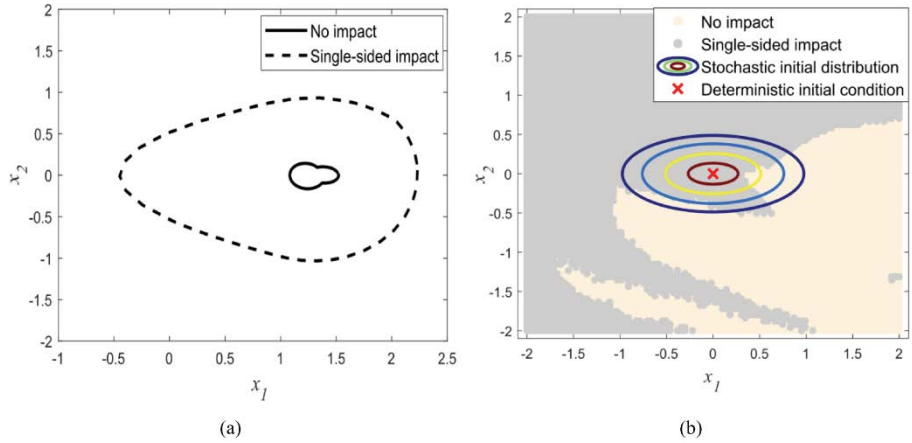

Figure 2: a) Multi-solution system with limit cycles in phase plane. b) Stochastic initial distribution versus deterministic initial condition in the domain of attraction of the system.

5.2 Stochastic dynamics of 3D Problems

In order to investigate the effect of introducing noise spectrum on the probabilistic response of the gear model, three different stochastic excitations are considered here. The filter parameters for the three cases illustrated in Fig. 3 are specified in such a manner that the energy of the noise is kept constant. The intensity of noise for all cases of study is λ=0.05.

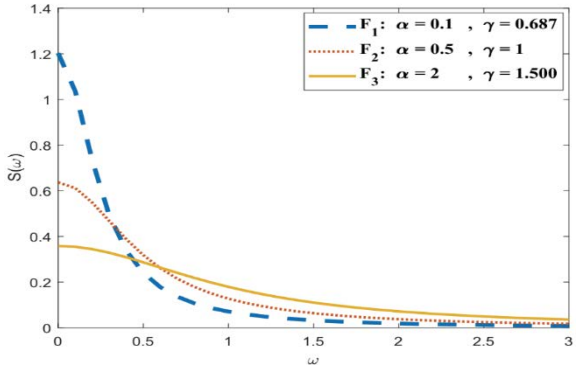

Figure 3: Frequency spectrum for different noises

The first goal of the current study is to show the capability of the adaptive path integration method to obtain accurate response PDF of a non-smooth random dynamical system under filtered noise. The evolution of the response PDF is captured via the PI technique with an adaptive time-stepping approach. Comparisons of the marginal PDFs for t = 10 t_p obtained by Monte Carlo simulations are shown in Figs. 4 and 5 for cases A, B, respectively. The accuracy and precision of the method are confirmed qualitatively for all cases due to good agreement between the PI and MCS results.

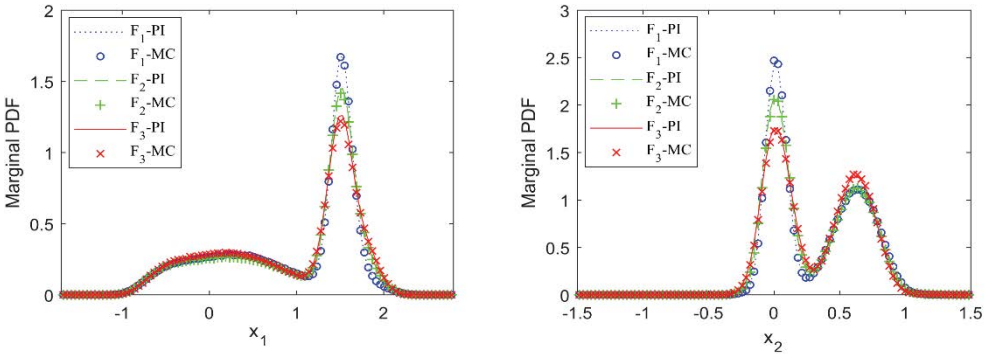

Figure 4: Marginal PDFs of the response for case A after $10t_p$ obtained by the PI method and MC simulation

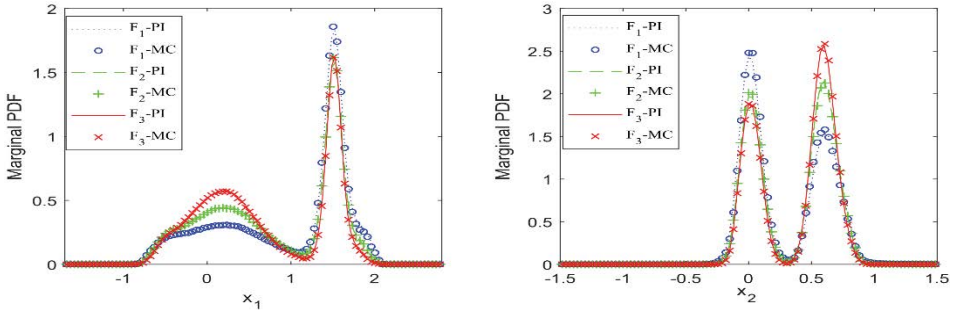

Figure 5: Marginal PDFs of the response for case B after $10t_p$ obtained by the PI method and MC simulation

In order to better illustrate both the effects of noise spectrum and loading uncertainty, the joint PDFs for cases A and B are also plotted in Figs. 6 and 7. In contrast to deterministic dynamic systems which assume a unique solution, the stochastic system response will be characterized by a probability distribution influenced by a nondeterministic distribution of initial conditions as well as an additive stochastic excitation. In this study, the initial distribution covers both basins of attraction of each solution. According to similar studies [18,23], it is expected that both no-impact solutions and single-sided impact solutions coexist. As the effect of uncertainty in these two categories reveals quite different results, the necessity of investigating the source of stochastic excitation in such nonlinear dynamical systems becomes obvious. It is also seen that the spectrum shape of the additive noise partly affects the probabilistic response in cases A and B.

The uncertainty in each component of the loading is basically due to external torque perturbations or manufacturing errors in the real system [26–28], but this matter is not pursued in the context of the current paper. The methodology and results that are presented in this study can have important implications in engineering applications of gear systems under uncertain excitation. The probability distribution function of the gear system response contains subtle information about the system, which is essential for the purpose of reliability-based design of such systems.

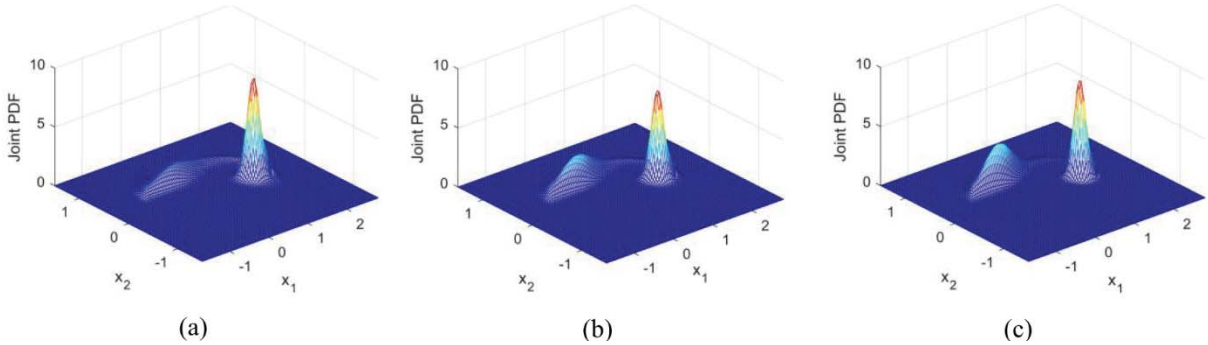

Figure 7: Stationary response Joint PDF of the problem case B under filtered noise excitation of a) F_1, b) F_2 and c) F_3

5.3 Stochastic dynamics of the 4D Problem

Considering parameter values $\alpha = 1.5, \beta = 0.5$ and $\gamma = 1$, the frequency spectrum of the filtered noise is illustrated in Fig. 10. This spectrum can be considered as an approximation of a narrow-band noise. The intensity of the noise for all cases of study is set to λ=0.05.

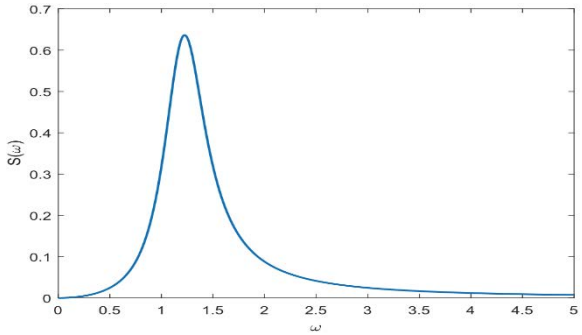

Figure 8: Frequency spectrum of second order filter

The response PDF is calculated by the path integration method and compared with Monte Carlo simulations. Fig. 9 indicates marginal PDFs and Fig. 10 shows joint PDFs for $t = 10t_p$. Although increasing the dimensions of the problem raised the computational cost, the accuracy and precision of the results are satisfactory for the solution of this non-smooth 4D problem. This shows the capability of the path integration method in dealing with higher dimensional problems.

6 CONCLUSIONS

In the current study, the probabilistic response of a spur gear pair under uncertain loading is investigated. The single degree of freedom gear model contains both backlash nonlinearity and time-varying mesh stiffness. Based on which component of the loading contains uncertainty, two different sub-problems are defined. The uncertainty is assumed to be represented by a first order filtered white noise, resulting in a 3D state space problem. An efficient numerical path integration technique in combination with a novel adaptive time-stepping scheme is applied in order to capture accurately the evolution of the response PDF. Marginal PDFs calculated via the PI method are compared with those obtained by Monte Carlo simulations for each of the cases that are studied. The comparisons confirm the accuracy and precision of the methodology. The effect of uncertain loading on the stationary response is quite different depending on its origin. This demonstrates the importance of identifying the stochastic source in investigating the dynamics of gear systems. The effect of spectra on the dynamic behavior is also studied by considering three noise representations with equal energies but different frequency spectrum in each case. In addition, an extension of the problem to 4D, combining the gear model with a second order filter is investigated to show the capability of path integration method in dealing with higher dimensional problems. The response PDF contains raw but qualitatively important information that needs further interpretations according to the application.

A NEW TIME INTEGRATION SCHEME IN MULTIBODY DYNAMICS INVOLVING FRICTIONAL IMPACT BASED ON A RETURN MAP TO NON-FLAT CONFIGURATION MANIFOLDS

E. Paraskevopoulos, P. Passas and S. Natsiavas

Department of Mechanical Engineering, Aristotle University

Keywords: Multibody dynamics, impact and friction, return map, augmented Lagrangian, geometric cubic splines.

Abstract. *This work presents a new numerical integration method for determining dynamics of a class of multibody systems with impact and friction. The method is based on the development of a novel return mapping and its proper incorporation into an augmented Lagrangian formulation. Namely, when an impact is detected during a time step, this map is applied at the end of the step to bring the system position back to the configuration manifold of the allowable motions. The novelty of this map is related to the fact that it is performed within a non-flat manifold. Moreover, once an impact is detected, the post-impact state is determined by analytical means. This is achieved by first performing a proper coordinate transformation, bringing the system into a new set of coordinates, which are suitable for describing the impact dynamics. In this coordinate set, the dominant dynamics is governed by a system of three equations of motion only, which are valid during the short contact interval. In this way, the inherent numerical stiffness of the class of systems examined is properly addressed. Finally, the accuracy and efficiency of the new method is demonstrated by applying it to a several mechanical examples.*

1 INTRODUCTION - OBJECTIVES

A new numerical scheme is developed, leading to an accurate and efficient determination of the dynamics of a class of multibody mechanical systems subjected to a single unilateral and a set of bilateral motion constraints. The existing methods can be classified in two categories, known as event-driven or time-stepping methods. When an event-driven method is applied, a standard integrator is employed during an impact free phase of the system up until a contact is detected. The state of the system at the beginning of the next impact free part of the motion is then determined by applying a complementarity formulation or an augmented Lagrangian method [1,2]. When a time-stepping method is used, a temporal discretization of the generalized displacements and velocities is performed by selecting a time step regardless of the presence or absence of switching points [2,3]. These methods evaluate the impulse of both the impulsive and non-impulsive forces over the time step. Eventually, they yield the position and velocity at the end of the time step by solving a complementarity problem or applying an augmented Lagrangian method. Consequently, the time-stepping methods are more efficient for large scale systems, exhibiting a large number of closely spaced events. Their main drawback is that they have a low order of accuracy due to the discontinuities induced by the impacts [4,5].

The main objective of this work is to present a new method for the direct integration of the equations of motion for multibody systems with frictional impacts. For systems with bilateral constraints only, a suitable numerical integration methodology was developed recently, based on an augmented Lagrangian formulation [6]. That methodology is now extended to systems involving a unilateral constraint as well. This task is achieved by developing a suitable return map, which is activated any time an impact event is detected when using a time-stepping integration method. The idea of a return map is similar to that applied earlier to other problems of mechanics, including friction or plasticity effects [7,8]. However, these methods were applied to Euclidean manifolds and were based on a projection to the closest point on the restricting surface. Here, a significant modification is necessary since the configuration space is non-Euclidean. In addition, following the detection of an impact event, the equations of motion are transformed into a set of three equations only, evolving over a much smaller time scale than the others, which are solved separately, until the end of the impact event [9]. This is a key to overcoming numerical stiffness problems in an efficient manner. These advantages are demonstrated in the second part of this study by using some typical mechanical examples.

The material of this paper is organized as follows. First, the essential dynamic characteristics of the class of constrained multibody mechanical systems examined are presented briefly in the following section. Next, the main idea of the return map is introduced. Namely, the basic ingredients of the new numerical algorithm, leading to development of a suitable return mapping process, are presented. Then, selected numerical results are presented for several mechanical examples. Finally, a summary of the main results, together with possible future extensions are included in the last section.

2 CLASS OF SYSTEMS EXAMINED - NUMERICAL INTEGRATION

This work focuses on dynamics of a class of multibody mechanical systems, subject to a set of bilateral constraints and a single frictional contact constraint. The equations of motion were obtained in earlier studies of the authors within the general framework of Analytical Dynamics [6,9]. In brief, the motion is described by a set of generalized coordinates $q = (q^1 \dots q^n)$, locating the position of a point p along a curve of the configuration manifold M for any time t [10,11]. The tangent vector $\underline{v}$ to this curve represents the generalized ve-

locity and belongs to an n-dimensional vector space T_pM, the tangent space of manifold M at p. Consequently, if $\mathfrak{B}_e = \{\underset{\sim}{e}_1 \quad \dots \quad \underset{\sim}{e}_n\}$ is a basis of T_pM, then $\underset{\sim}{v} = v^i \underset{\sim}{e}_i$, by using the common summation convention on repeated indices. Also, each vector is related directly to a covector, by employing the duality pairing $\underset{\sim}{u}^*(\underset{\sim}{w}) \equiv \langle \underset{\sim}{u}, \underset{\sim}{w} \rangle$, $\forall \underset{\sim}{w} \in T_pM$, where $\langle \cdot, \cdot \rangle$ is the inner product of T_pM [12]. Moreover, the elements of the dual (cotangent) space T_p^*M represent generalized momenta with components

$$p_i = g_{ij} v^j, \quad (i, j = 1, \dots, n), \tag{1}$$

where g_{ij} are the components of the metric tensor at point p.

When there are no motion constraints, the solution path on manifold M is determined by Newton's second law

$$\nabla_{\underset{\sim}{v}} \underset{\sim}{p}_M^* - \underset{\sim}{f}_M^* = \underset{\sim}{0}. \tag{2}$$

Covectors $\underset{\sim}{p}_M^* = p_i \underset{\sim}{e}^i$ and $\underset{\sim}{f}_M^* = f_i \underset{\sim}{e}^i$ represent generalized momenta and applied forces, respectively. The covariant differential of covector $\underset{\sim}{p}_M^*$ along a curve with tangent vector $\underset{\sim}{v}$ takes the form

$$\nabla_{\underset{\sim}{v}} \underset{\sim}{p}^*(t) = (\dot{p}_i - \Lambda_{ji}^m p_m v^j) \underset{\sim}{e}^i, \tag{3}$$

where the quantities Λ_{ij}^k are known as affinities [12].

The presence of a contact event is modeled by an inequality of the form

$$\rho(p) \geq 0. \tag{4}$$

Then, the motion of point p is restricted to lie on one side of a hypersurface in M. In this way, the function ρ establishes a new manifold

$$X = \{p \in M \mid \ \rho(p) \geq 0\}, \tag{5}$$

with dimension n. Apart from the boundary ∂X, defined by the equality in expression (4), this manifold possesses an interior $X^o = X \setminus \partial X$. This theoretical setting makes possible the direct application of results from the theory of manifolds with a boundary [13]. Also, the impulse occurs along the direction defined by the convector

$$d\rho = (\partial \bar{\rho} / \partial x^i) \underset{\sim}{e}^i, \tag{6}$$

where $\bar{\rho} = \rho(\varphi^{-1}(x))$ and $x = \varphi(p)$ is a special coordinate set of the manifold employed in the vicinity of a boundary point.

The presence of bilateral motion constraints is signaled by equalities, with general form

$$\dot{\psi}^R \equiv a_I^R(q) v^I = 0, \ (I = 1, \dots, n \ \text{and} \ R = 1, \dots, k). \tag{9}$$

For a holonomic constraint, the corresponding equation can be integrated and put in the form

$$\phi^R(q) = 0. \tag{10}$$

If the constraints are given by Eq. (9), the equations of motion on manifold M are obtained by

$$\underset{\sim}{h}^{*} \equiv \underset{\sim}{h}_{M}^{*} - \underset{\sim}{h}_{C}^{*} = \underset{\sim}{0}, \tag{13}$$

in place of Eq. (2), where

$$\underset{\sim}{h}_{M}^{*} = h_I \underset{\sim}{e}^{I} \text{ with } h_I = (g_{IJ} v^J)^{\cdot} - \Lambda_{LI}^{K} g_{KJ} v^J v^L - f_I \tag{14}$$

and

$$\underset{\sim}{h}_{C}^{*} = \sum_{R=1}^{k} h_R a_I^R \underset{\sim}{e}^{I} \text{ with } h_R = (\bar{m}_{RR} \dot{\lambda}^R)^{\cdot} + \bar{c}_{RR} \dot{\lambda}^R + \bar{k}_{RR} \lambda^R - \bar{f}_R . \tag{15}$$

The convention on repeated indices does not apply to index R. Also, the quantities $\bar{m}_{RR}$ and $\bar{f}_R$ are determined completely by the constraints, while the coefficients $\bar{c}_{RR}$ and $\bar{k}_{RR}$ are also selected in an appropriate manner [14]. Finally, substitution of Eqs. (14) and (15) into Eq. (13) leads to a set of n second order ODEs in the $n+k$ unknowns q^I and λ^R. A complete mathematical formulation is obtained after including the k equations of the constraints, which are expressed originally by Eq. (9) and put eventually in the following second order ODE form

$$g_R = (\bar{m}_{RR} \dot{\psi}^R)^{\cdot} + \bar{c}_{RR} \dot{\psi}^R = 0 \text{ or } g_R = (\bar{m}_{RR} \dot{\phi}^R)^{\cdot} + \bar{c}_{RR} \dot{\phi}^R + \bar{k}_{RR} \phi^R = 0, \tag{16}$$

for a non-holonomic and a holonomic constraint, respectively.

The picture becomes more involved in the presence of friction [9,15]. In general, the complexity of the resulting set of equations of motion precludes application of procedures leading to analytical solutions and makes difficult even the selection and application of appropriate numerical techniques. Consequently, the focus of the present study is to initiate the establishment of a theoretically sound and numerically efficient process for solving these equations. This process involves several challenging tasks. One of them is to set up a suitable algorithm, which leads first to detection of a contact event and then to prediction of a pre-impact state of the system in a sufficiently accurate and efficient manner. This is the main objective of the present study.

3 RETURN MAP

To facilitate the discussion, Fig. 1 is provided. First, at time t_m the system configuration is represented by a point p_m, with coordinates q_m, which lies in the interior X^0 of the corresponding constrained manifold X. However, at the next discrete time t_{m+1}, the new configuration point $p_{m+1}^{(k,1)}$, with $k=1$, is found to lie outside X, indicating that an impact event may have occured. In practice, this is verified by using an appropriate contact detection algorithm [16,17]. The next step is to return to a point on the boundary ∂X, representing the configuration of the system where the impact took place. This is achieved through development and application of a suitable return mapping. In the present work, this step is performed with extra care, since the configuration manifold M is non-Euclidean. First, due to the non-flatness of the configuration space, a special type of curves is employed in performing a spatial discretization. Specifically, these are selected to be the straightest curves, known as autoparallels [12]. In addition, the boundary ∂X is locally convex (i.e., it is a half-space or a corner for a single or multiple contact, respectively [9,18]). Based on the above, the task of returning from $p_{m+1}^{(k,1)}$ back to a point $p_{m+1}^{(j+1,2)}$ on the boundary ∂X in a unique way is reduced to finding the auto-

parallel joining these points, having the shortest length among a family of autoparallels. This leads naturally to construction of suitable Jacobi fields along these curves [19].

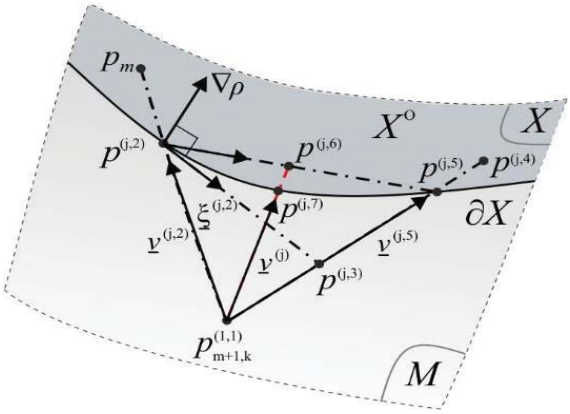

Figure 1: Illustration of the basic steps of the return map.

A complete description of the steps of the return map developed can be found in [18]. With this map, some significant theoretical gains were achieved by exploiting the Lie group nature of the configuration manifolds arising for the class of systems examined. Specifically, the special curve selected by this map to return a point from the outside to the boundary of the constrained manifold, defined by a unilateral constraint, has the shortest length among a special set of curves emanating from the outer point. The length was defined in terms of the kinetic energy of the system. In particular, the kinetic energy associated with the motion of the figurative particle along a natural curve $\gamma(r)$ on the configuration manifold is related to the length of this curve by

$$T(t) = \tfrac{1}{2}\int_0^t \langle \underline{v}(r), \underline{v}(r)\rangle dr\,, \tag{17}$$

where $\underline{v}(r)$ is the tangent vector of $\gamma(r)$ [11,12]. Using this definition as a basis, the energy function

$$L(s) = \tfrac{1}{2}\int_0^1 \langle \underline{v}(r,s), \underline{v}(r,s)\rangle dr \tag{18}$$

is introduced next for each γ^s curve of the two-dimensional surface created around a Jacobi field, parameterized so that $r=0$ at the pole p and $r=1$ at its other end and having tangent vector $\underline{v}(r,s)$ (see Fig. 2). Then, the special value of s, at which this function possesses an extreme value is found by imposing the condition

$$\varphi(s) \equiv L'(s) = \underline{\xi}(L) = 0\,, \tag{19}$$

where $\underline{\xi}(L)$ represents the derivative of L along the direction defined by vector $\underline{\xi}$. In order to check whether this extremum corresponds to a minimum or a maximum value of the energy function $L(s)$, its Hessian should be constructed in an appropriate manner on the configuration manifold [20], according to the following definition

$$H(s) \equiv L''(s) = \underline{\xi}(L'(s))\,. \tag{20}$$

It can be shown that the Hessian function is at least locally positive, rendering the energy function $L(s)$ locally convex [18].

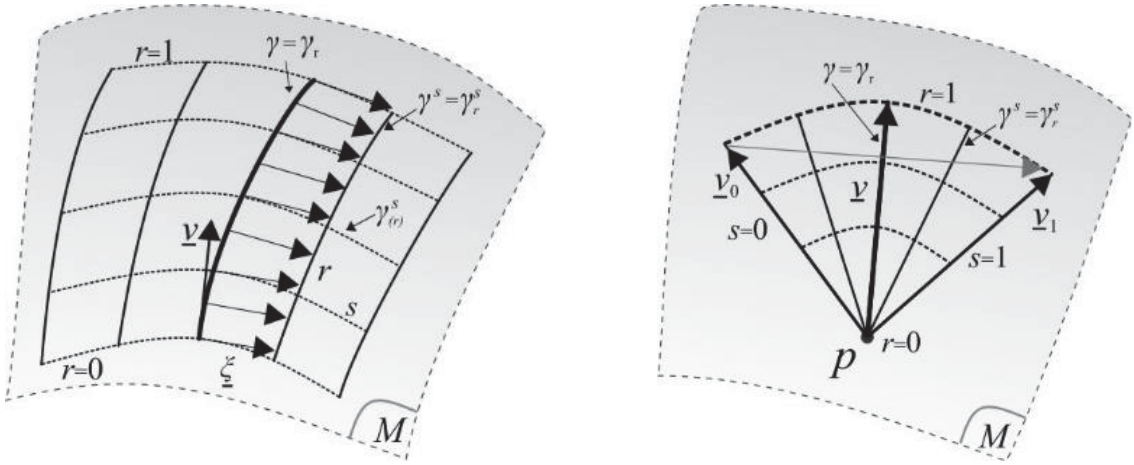

Figure 2: Jacobi fields: (a) without and (b) with a pole p.

In addition, the curve selected crosses the boundary of the allowable motions in a normal way, while the corresponding Jacobi field has no component normal to this autoparallel. In this way, the new return map can be considered as a generalization of the classical orthogonal projection operation performed in Euclidean spaces [8,21,22]. Based on this theoretical foundation, a complete numerical algorithm was set up, providing the means to project points escaping from the constrained configuration manifold during the numerical integration, back to the set of allowable motions [18]. Once this process converges to a point near ∂X, the equations of motion are transformed into a special set of coordinates, where the dominant dynamics is governed by three differential equations only [9]. These equations are then solved until the end of the impact event, where they are transformed back to the original coordinates. In this way, the inherent numerical stiffness problem is treated in an efficient manner.

4 NUMERICAL RESULTS

The set of numerical results presented next focuses on performance of the return map, which plays a central role in the integration scheme developed. This procedure was developed in a way that can fit within any of the available methodologies for the integration of the equations of motion of constrained systems. Here, the equations of motion employed in producing the numerical results form a set of second order ODEs in both the generalized coordinates and the Lagrange multipliers related to the constraint action [14]. For systems with bilateral constraints, these equations were solved by developing a suitable numerical integration methodology, based on an augmented Lagrangian formulation [6].

In all the examples studied next, knowledge of the function ρ, defined as in Eq. (6), permits evaluation of its differential $d\rho$. This is a covector related to vector $\nabla\rho$, the gradient vector of ρ, through Eq. (1). In matrix form,

$$d\rho^T = G\nabla\rho \quad \Rightarrow \quad \nabla\rho = G^{-1}d\rho^T \tag{21}$$

where the (invertible) matrix $G=[g_{ij}]$ includes the components of the metric tensor in the selected basis. In addition, covector $d\rho$ is related to a covector $d\hat{\rho}$ of the physical space by a linear mapping [15], as follows

$$d\rho = d\hat{\rho} D \,. \tag{22}$$

In general, the matrix D in this mapping is established by relating the relative velocity $\underline{V}$ at the contact point in the physical space with the generalized velocities, by

$$\underline{V} = D\,\underline{\dot{q}} \tag{23}$$

Then, combination of Eqs (21) and (22) yields eventually

$$\nabla\rho = G^{-1}(d\hat{\rho} D)^T \,. \tag{24}$$

The gradient vector $\nabla\rho$ is normal to the boundary hypersurface ∂X . In this case, the representative vector of $d\hat{\rho}$ is normal to the local contact surface in the physical space.

4.1 Impact of a particle within a circular ring

The first mechanical system examined is a particle with mass m , moving in the interior of a rigid circular ring of radius R , as shown in Fig. 3a. This example involves a planar translation only, so that the particle position can be determined by two Cartesian coordinates, q^1 and q^2 , while the original configuration space is $M = \mathbb{R}^2$. In this case, the inward normal to the boundary ∂X , consisting of the perimeter of the ring, is

$$\underline{n} \equiv \nabla\rho = \tfrac{1}{m} d\rho^T \tag{25}$$

Moreover, if (q_b^1, q_b^2) are the coordinates of the bisection point $p_{m+1,k}^{(j,2)}$, the normal vector to the boundary ∂X is

$$\underline{n} = -\frac{1}{m\sqrt{(q_b^1)^2+(q_b^2)^2}} \begin{pmatrix} q_b^1 & q_b^2 \end{pmatrix}^T \tag{26}$$

Then, the tangent vector to ∂X at that point is given by

$$\underline{\xi} = \underline{v} - \frac{\underline{v}\,\underline{n}^T}{\underline{n}^T\underline{n}}\,\underline{n} \tag{27}$$

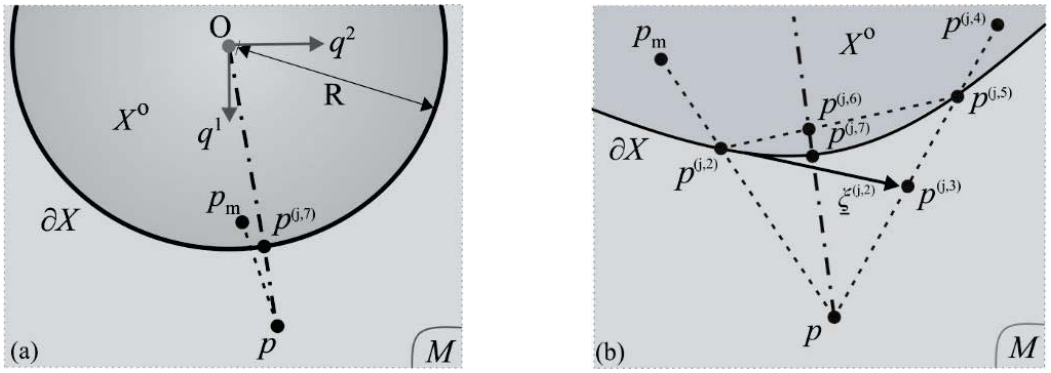

Figure 3: (a) Particle in a circular ring and (b) details of the projection from pole p to boundary ∂X .

The second term in the right hand side of Eq. (27) corresponds to the classical orthogonal projection of vector $\underline{v}$ on vector $\underline{n}$, arising in a flat manifold [21,22].

First, in Fig. 3b are shown details of the projection from the pole p back to ∂X . Next, in Fig. 4 are shown selected numerical results for the example considered, for a particle of unit mass and a ring of radius R=0.74m. The initial position of the particle was at (0.1m, -0.5m),

while its initial velocity was (10m/s, -2m/s). The results presented were obtained for $k=1$, by choosing different initial length steps $s_{m+1,1}^{(j,2)}$ along the direction defined by the tangent vector $\underline{\xi}_{m+1,1}^{(j,2)}$, in order to locate point $p_{m+1,1}^{(j,3)}$, according to the process described earlier. Specifically, the reference length step was selected to coincide with the length of the straight line (autoparallel) joining points $p_{m+1,1}^{(1,1)}$ and $p_{m+1,1}^{(j,2)}$. First, in Fig. 4a are depicted results illustrating the number of iterations needed in order to locate the correct value of coordinate q^1 at impact, for the same pole $p_{m+1,1}^{(1,1)}$. Qualitatively similar results were also obtained for coordinate q^2. Likewise, in Fig. 4b are presented results for the norm of vector $\underline{\xi}_{m+1,1}^{(j,2)}$, normalized by the norm of the velocity vector of the autoparallel joining points $p_{m+1,1}^{(1,1)}$ and $p_{m+1,1}^{(j,2)}$. Obviously, selecting an initial step value close to the characteristic length step s_0 leads to a rapid convergence.

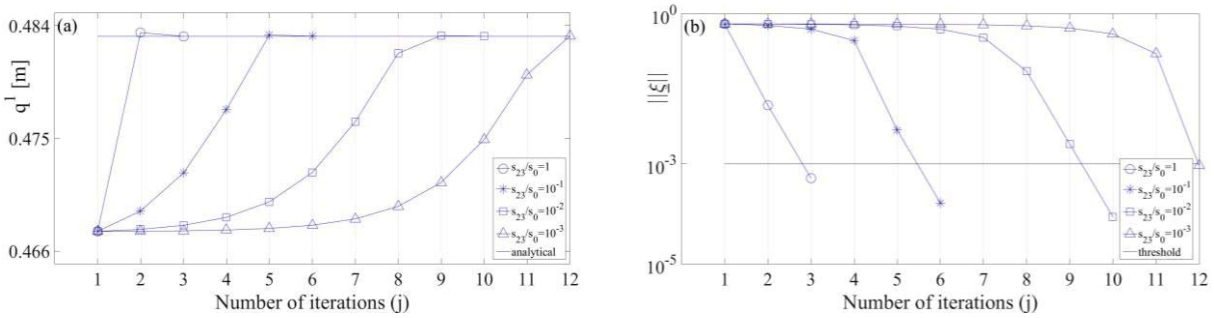

Figure 4: Collision of a particle with a rigid circular ring: (a) convergence in coordinate q^1 and (b) norm of vector $\underline{\xi}$ at the point where the shortest autoparallel crosses the boundary ∂X.

The above numerical results indicate that the smaller the value of s_{23} (compared to s_0) the larger the number of iterations needed for convergence. In such a case, the two-dimensional smooth surface created between the two end autoparallels emanating from the pole and ending at points $p_{m+1,1}^{(j,2)}$ and $p_{m+1,1}^{(j,5)}$ (see Fig. 1) does not include the minimizing autoparallel during the initial iterations. On the other hand, convergence difficulties were also encountered for $s_{23} > s_0$, due to several reasons. The most frequent was the non-intersection of the autoparallel passing through the pole $p_{m+1,1}^{(1,1)}$ and point $p_{m+1,1}^{(j,3)}$ with the boundary ∂X. Cases where point $p_{m+1,1}^{(j,3)}$ was found in the interior X^o or point $p_{m+1,1}^{(j,6)}$ was located out of the constrained manifold X, due to loss of convexity of the boundary ∂X or failure of the contact detection algorithm, were also encountered. In all these cases, the successful remedy to achieve convergence was to reduce the value of s_{23}.

4.2 Impact of a rigid body with a rigid wall

Next, a rigid body hitting a rigid wall is considered, as depicted in Fig. 5. As configuration space of the free body is selected the six-dimensional product $M \equiv \mathbb{R}^3 \times M(3)$ [23]. Then, the position and orientation of the body with respect to an inertial reference frame $\mathbb{F}$ (or $O\chi^1\chi^2\chi^3$) in the physical space is represented by a point on this manifold, with generalized coordinates $\underline{q}(t) = (\underline{q}_C^T \quad \underline{q}_R^T)^T$. Part $\underline{q}_C$ specifies the position of the body center of mass C,

while $\underline{q}_R$ describes the body orientation in the physical space. The tangent vector to the autoparallel curves is also split in a similar form. The first part leads to curves corresponding to segments of straight lines, while the rotational part leads to special curves on the manifold, with each point on these curves related to a 3×3 rotation matrix R, providing the orientation of the body with respect to $\mathbb{F}$. Moreover, for two points along such a curve, located at a distance Δs,

$$R(s+\Delta s) = R(s)\exp(\Delta s\,\tilde{v}_R) \tag{28}$$

where the entity $R(s+\Delta s) = R(s)\exp(\Delta s\,\tilde{v}_R)$ represents a 3×3 skew-symmetric matrix having $\underline{v}_R$ as axial vector [24].

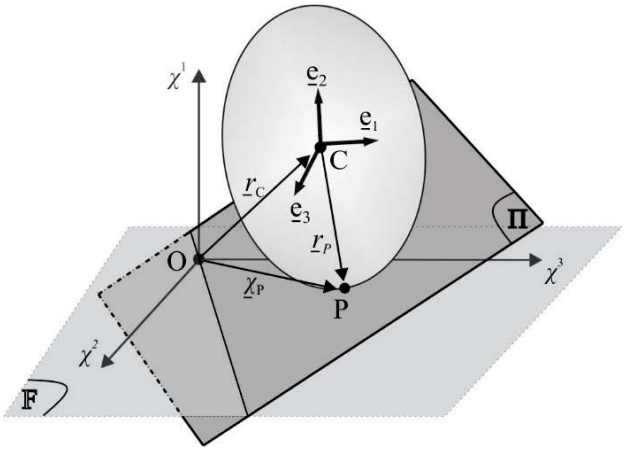

Figure 5: A rigid body hitting a plane rigid wall.

Next, in Fig. 6 are shown numerical results corresponding to impact of a homogeneous solid ellipsoid with a rigid ground. The ellipsoid has a unit mass and principal semi-axes equal to 0.1m, 0.3m and 0.15m, while the position of the rigid plane is determined by selecting $(s_1 \quad s_2 \quad s_3)$=(-0.2 0.1 1.0). Moreover, the initial position of the ellipsoid center of mass is at point (0.3m, 0.4m, 0.2m), while the components of the initial angular velocity of the ellipsoid in the body frame are $\underline{\Omega}$=(0.3 0.1 0.2) rad/sec. Finally, the set of results presented next were obtained for different length steps s_{23} along vector $\underline{\xi}^{(j,2)}_{m+1,k}$, locating point $p^{(j,3)}_{m+1,k}$, as shown in Fig. 1. Also, the reference length step s_0 was selected as in the previous example. Again, all the results presented next were obtained for $k=1$, while similar behaviour was also encountered for $k>1$, when needed.

In the set of results shown in Fig. 6, the motion of the ellipsoid center of mass is restricted by a spherical joint, so that only rotation of the ellipsoid is possible to occur. First, in Fig. 6a is illustrated the convergence obtained in the value of one of the Euler angles for a given pole ($k=1$) and variable j. Similar results were also obtained for the other two Euler angles of the ellipsoid and for other poles. Likewise, in Fig. 6b are presented results for the norm of vector $\underline{\xi}$ obtained at the point where the shortest autoparallel crosses the boundary ∂X. Again, selecting a value of the initial length step along vector $\underline{\xi}^{(j,2)}_{m+1,1}$ close to the characteristic length step s_0 leads to a rapid convergence. In addition, similar convergence difficulties with

those mentioned in the previous example were also encountered for $s_{23} > s_0$, which were overcome by decreasing the value of s_{23}.

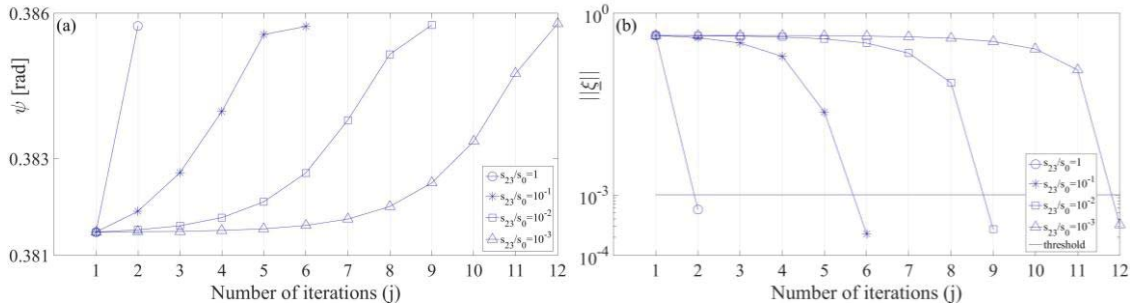

Figure 6: Collision of a rigid ellipsoid (with a pinned center of mass) with a rigid ground: (a) convergence in an Euler angle and (b) norm of vector $\underline{\xi}$ at the point where the shortest autoparallel crosses the boundary ∂X.

4.3 Impact of two solid bodies

The algorithm developed can be applied to general single point collisions, with any combination of solid bodies. For instance, in Fig. 7a is illustrated the convergence obtained in one of the Euler angles of the ellipsoid, while a similar diagram for a translational coordinate of its mass center is shown in Fig. 7b. Then, in Fig. 7c are shown results for one of the box Euler angles. Finally, in Fig. 7d are presented results for the norm of vector $\underline{\xi}$ obtained at the point where the shortest autoparallel crosses ∂X. Once again, selecting a value close to the reference length step s_0 leads to a rapid convergence. Also, convergence was achieved eventually in all cases, by properly adjusting the length step.

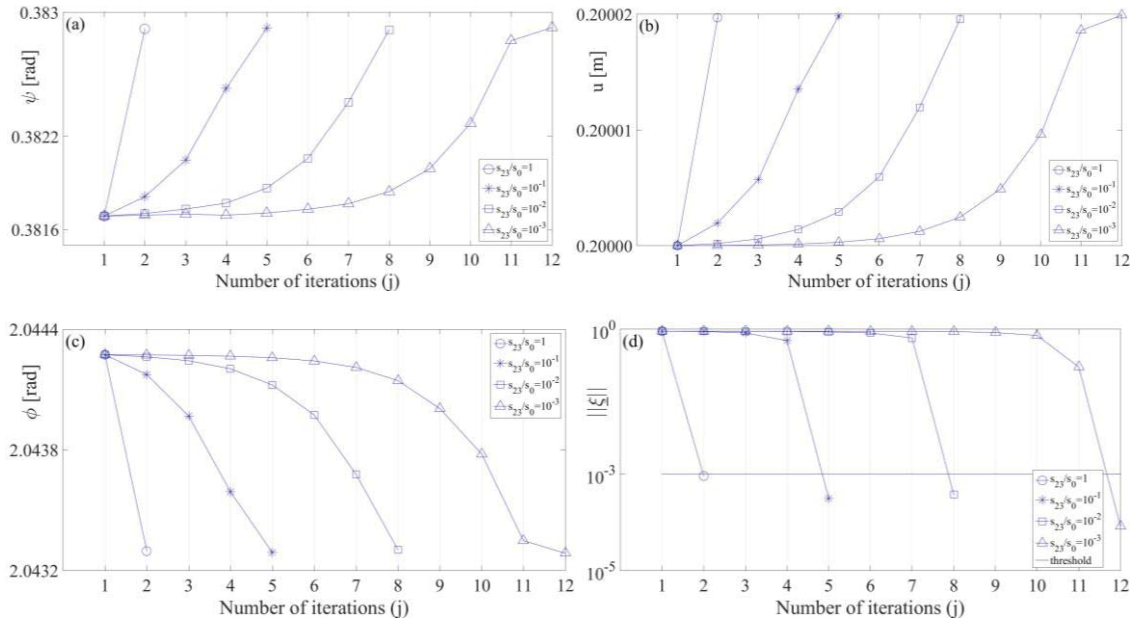

Figure 7: Collision of an ellipsoid with a box: (a) convergence of one Euler angle of the ellipsoid, (b) convergence of one translational coordinate of the ellipsoid, (c) convergence of one Euler angle of the box and (d) norm of vector $\underline{\xi}$ at the point where the shortest autoparallel crosses the boundary ∂X.

Finally, it is noted that the same analysis is also applicable to mechanical systems involving deformable bodies, as well, by assuming that they have been discretized geometrically before. For instance, if the dominant flexibility effects of a free solid body are described by n elastic modes, included in a $3\times n$ matrix Φ, the configuration manifold is represented by an $(n+6)$-dimensional product space, $M \equiv \mathbb{R}^3 \times M(3) \times \mathbb{R}^n$ [24,25]. This implies that the array with the generalized coordinates $\underline{q}(t)$ is now split in parts $\underline{q}_C$, $\underline{q}_R$ and $\underline{q}_F$, with the last part representing the flexibility effects.

4.4 Dice tossing

The time integration method developed can be applied to general single point collisions, with any combination of solid bodies and any geometric shape. For instance, a set of numerical results is presented next, obtained for motion of a die thrown over a rigid ground. This motion is viewed from a coordinate system $Oxyz$, which is fixed on the ground. It is affected by gravity, acting along the negative z-axis and involves frictional impacts. The die considered is a homogeneous rigid cube, with a mass of 0.016 kg and edge length 0.02 m. It starts from a position above the ground, with the cube edges parallel to the axes of the $Oxyz$ coordinate system. Moreover, the initial position and (linear and angular) velocity are chosen to satisfy two scenarios. In the first, the cube executes a planar motion, taking place in the vertical plane Ozx. Namely, it hits the ground with one of four of its eight edges only, so that the motion is equivalent to a square hitting the horizontal line Ox. In the second scenario, the initial conditions are modified so that the cube exhibits a spatial motion and hits the ground with one of its vertices. In all cases, the value of the kinematic restitution parameter was selected as $e = 0.5$. In addition, the value of the coefficient of friction between the die and the ground was chosen as $\mu = 0.05$ or 0.20, while the maximum penetration ratio was selected as $\delta = 0.20$.

The first set of numerical results is presented in Fig. 8. Here, the initial position of the cube center is at (0, 0, 0.3) m, while its initial velocity is (0.5, 0, -0.5) m/s. Moreover, the initial angular velocity of the cube is (0, 10, 0) rad/s. These initial conditions lead to a subsequent plane motion of the cube, which is continued even after the bouncings on the ground due to the symmetry of the cube geometry. First, in Fig. 8a is shown the projection of the trajectory executed by the cube center of mass on the vertical plane Ozx for the two values selected for μ. Likewise, in Fig. 8b is shown the projection of the same trajectory on the horizontal plane Oxy. Then, the histories of the two non-zero velocity components of the mass center are shown in Fig. 8c. Finally, the history of angular velocity of the cube is presented in Fig. 8d. A remarkable result is that, for the case with $\mu = 0.20$, the cube starts moving in the opposite direction than it was thrown after the first impact, as it becomes clear by Figs. 8a and 8c.

Next, in the set of results presented in Fig. 9, the initial position of the cube center and its initial velocity are kept the same as in the previous case. However, an angular velocity component about the x-axis is added, so that the initial cube angular velocity is (10, 10, 0) rad/s. These initial conditions lead to a general spatial motion of the cube. First, in Fig. 9a is shown the projection of the trajectory executed by the cube center of mass on plane Ozx for the two values selected for the coefficient of friction. Likewise, in Fig. 9b is depicted the projection of the same trajectory on plane Oxy.

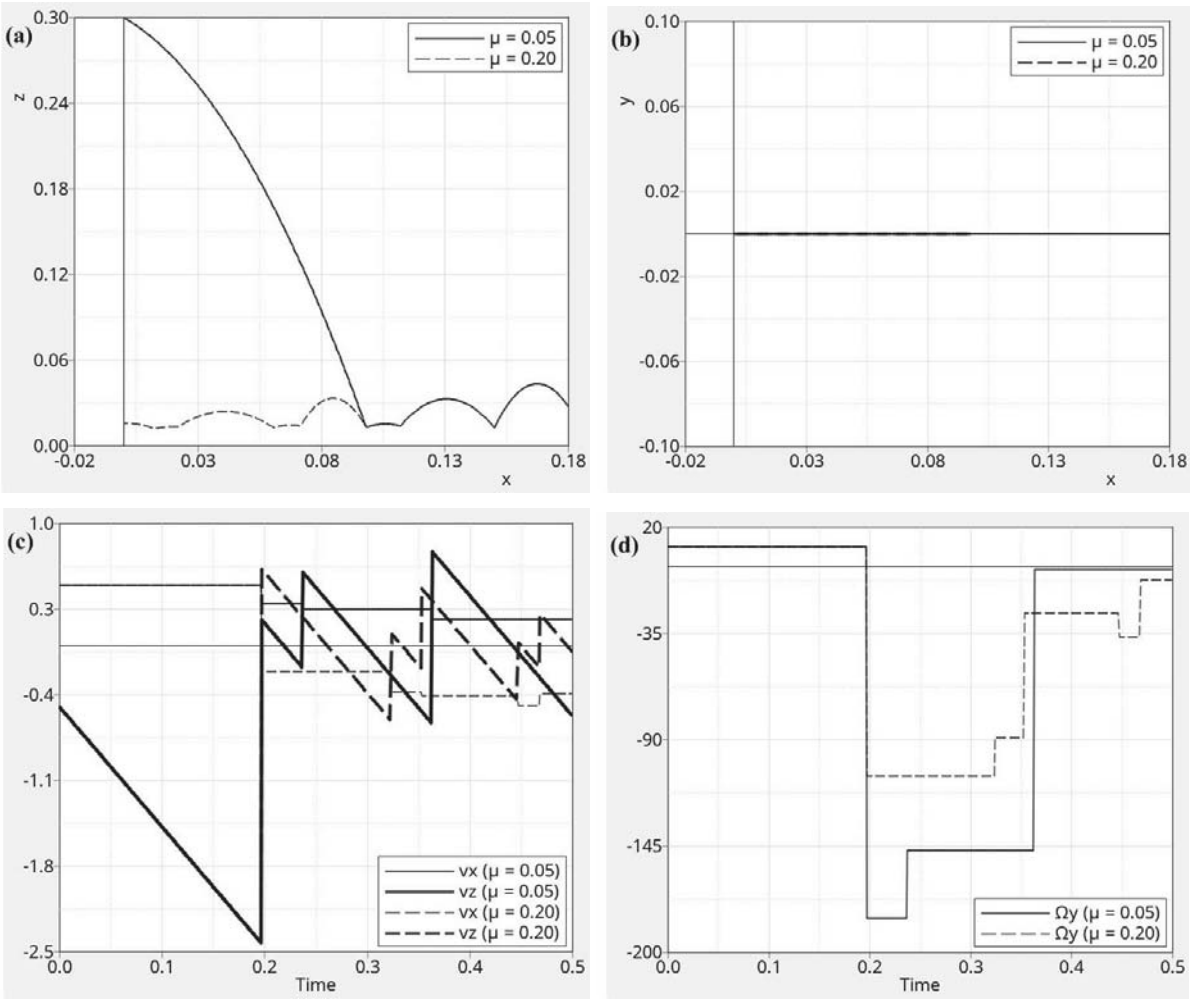

Figure 8: Plane die tossing. Projection of the trajectory of the cube center on: (a) the vertical plane Ozx and (b) the horizontal plane Oxy. Histories of: (c) the velocity components of the mass center and (d) the angular velocity of the cube.

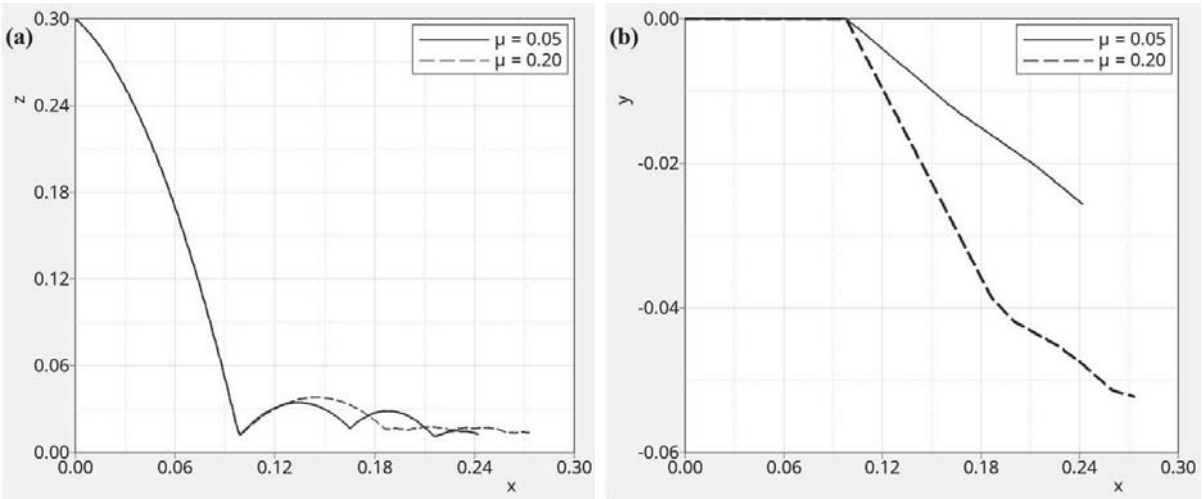

Figure 9: Spatial die tossing. Projection of the trajectory of the cube center on: (a) the vertical plane Ozx and (b) the horizontal plane Oxy.

Finally, the emphasis was placed on the dynamics of the cube during the first impact phase. For this, the velocity components of the cube contact point are shown in Fig. 10. First, the tangential velocity V_x is presented in Fig. 10a, while the corresponding tangential velocity V_y and normal velocity V_z are included Fig. 10b, for the plane motion of the die. Similar results are also included in Figs. 10c and 10d, for the spatial cube motion. In all cases examined, a smooth change is observed to occur in the velocity components throughout the impact phase.

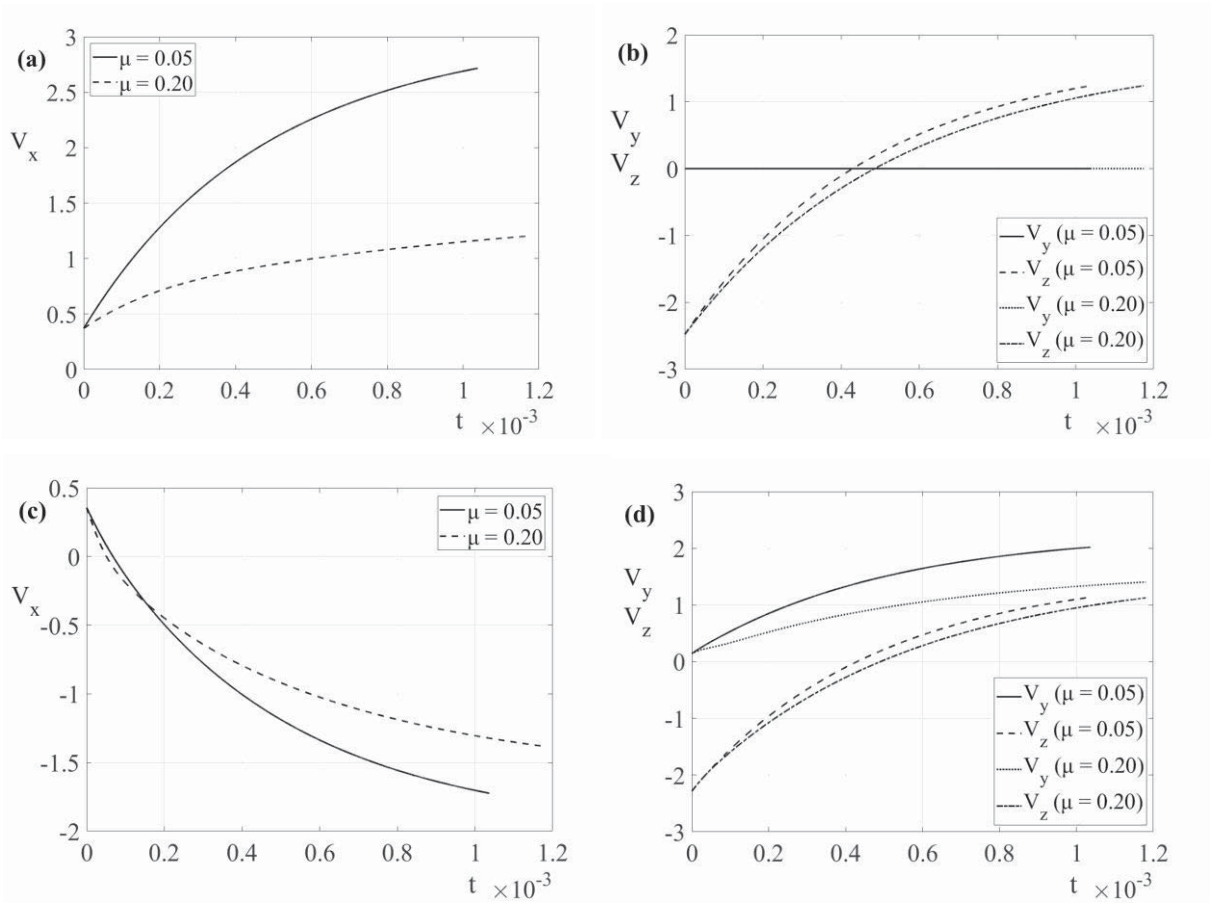

Figure 10: Velocity components of the cube contact point during the first impact phase: (a) tangential component V_x (plane motion), (b) tangential component V_y and normal component V_z (plane motion), (c) tangential component V_x (spatial motion), (d) tangential component V_y and normal velocity component V_z (spatial motion).

5 SUMMARY AND EXTENSIONS

In the first part of this study, the basic steps of a return map, which can be a vital part of any time stepping scheme for capturing dynamics of multibody systems involving impacts, were presented. A theoretical basis for this map was built using concepts of differential geometry, referring to Jacobi fields on manifolds. This need arises from the fact that the configuration space of the class of systems examined is non-Euclidean. Specifically, application of this map in order to return a point from the outside to the boundary of the constrained manifold, defined by a unilateral constraint, leads to a curve with the shortest length among a special set of curves emanating from the outer point. These curves represent the straightest curves on a manifold and are known as autoparallels. In addition, the final curve selected crosses the boundary of the allowable motions in a normal way. In this way, the new return map is a gen-

eralization of the classical orthogonal projection operation performed in Euclidean spaces. Based on these ideas, a complete numerical algorithm was set up, providing the means to project points escaping from the constrained configuration manifold during the numerical integration, back to the set of allowable motions. Finally, these ideas were verified in the second part of this work, by presenting numerical results for a selected set of mechanical examples.

The return map developed can be applied to any discrete mechanical system subject to a set of bilateral motion constraints and a single unilateral constraint. A first possible step is to extend this map for handling cases with multiple impacts. This is a theoretically challenging subject, involving consideration of configuration manifolds with corners, having a large engineering importance [1,3,26]. Another useful extension is to embed this map into a complete time-stepping methodology, employed for the direct integration of the equations of motion of multibody systems with impacts. In particular, violation of a unilateral constraint during time integration is associated with interpenetration, which may occur during the numerical process but is not physically acceptable. In such cases, application of this map can provide appropriate values of the position and velocity, which can then be used as the pre-impact state of the class of dynamical systems examined. This, in turn, is a necessary step for the evaluation of the post-impact state and the subsequent return to a new smooth part of the motion.

Abstract. *Single-degree-of-freedom (SDOF) nonlinear oscillators are widely used for modelling systems with just one degree-of-freedom in addition to single mode approximations to structural elements such as beams and cables, as well as other multi-degree-of-freedom (MDOF) applications. In this work, an investigation of the behavior of SDOF nonlinear oscillators is carried out using the method of direct normal forms. So far, this method has only been considered as a theoretical technique used for solving limited nonlinear dynamical systems in which low orders of nonlinearities appear, involving quadratic and cubic nonlinearities. In this work, thanks to the implementation of symbolic computations, the method of direct normal forms is generalized for solving nonlinear SDOF systems with any order of polynomial (or geometric) weak nonlinearities. Using this new approach, the effect of any higher order nonlinear term, or any combination of nonlinear terms can be investigated. Backbone curve relations are obtained for a selection of example systems representing both hardening and softening systems, and the results are verified by comparing the approximate analytical solutions to numerical solutions generated using COCO numerical continuation toolbox in Matlab.*

1 INTRODUCTION

Nonlinear normal forms method is a well-established technique for obtaining approximate solutions for nonlinear oscillators with various types of weak (typically smooth) nonlinearities. In principle, it can be used for either SDOF or MDOF problems; although for systems with more than a few degrees-of-freedom the algebraic complexity quickly escalates. It is also possible for the analyst to select certain resonant (or non-resonant) cases to study, by making one (or sometimes more) near-identity transforms [3]. The analytical basis of the technique is to use matrix algebra via a series of analytical steps that finally detect the desired resonances and can be used to find approximate solutions, such as so-called backbone curves, for the SDOF or MDOF system being considered.

While this method has the potential to be applied for a wide range of applications, it can generate large and complicated mathematical terms. As a result, it could be helpful to use symbolic packages, which can deal with such complex mathematical expressions and also offer the possibility of enhancing the accuracy of solution by increasing the number of terms truncated in the solution.

Another way to simplify such computations is to reduce the system order prior to computation. This is a pragmatic way to decrease the matrix sizes involved, however the size of the residual terms (i.e. those excluded by the reduction) should be estimated in order to ensure the accuracy of the final solution. Using a computation package, such as Maple software, makes it possible to build a highly structured code that can, in principle, solve for any order of nonlinearity and potentially a large number of nonlinear terms. In this work, the number of terms is limited to two.

The origin of the idea of normal form transformations is attributed to the work of Poincaré. Following this, the application of normal forms method for SDOF and MDOF is discussed widely in the literature. Notably the Hamiltonian normal form (and Birkhoff normal forms) were introduced for conservative dynamical systems [21], and are typically used to model undamped unforced applications in physics and engineering. The work of Arnold [22] did much to extend and promote the idea of normal form transformation in engineering mechanics. The normal form approach was extended to problems of forced and damped systems of coupled nonlinear oscillators by Jezequel and Lamarque, [24], and given recast in a perturbation framework by Nayfeh [25].

Because most mechanical vibration problems are naturally described by sets of second-order differential equations, a variant of the normal forms method applied directly to second order dynamical problems was first introduced by Neild and Wagg in [3]. The authors originally referred to this modified technique as ‘second order normal forms’. This approach will be used during the formulation and discussion in this work.

Compared with other techniques, the primary advantage of the direct normal forms is the ability of inherently computing the harmonics without pre-assuming any specific harmonic components included in trial solutions. Thus, no prior knowledge of the harmonic components in the response of the system is required and no additional complexity is needed when considering the harmonics. Furthermore, the process of direct normal forms can be formulated in a matrix-based manner, which makes its application more appropriate for the computer automation.

The direct normal form technique has been used in a number of conducted research works, investigating nonlinear dynamics of mechanical systems. Xin et al., [9], considered the SDOF nonlinear oscillators of polynomial-type nonlinearities using the direct normal form technique, their work involved investigation of velocities and displacements, whilst illustrating the contributions of the different polynomial nonlinearities in different forms to the system response by the resulting resonance response functions (RRFs).

Shaw et al. [23], studied the performance of the nonlinear vibration isolator using the direct normal form technique. The system was modelled as a SDOF oscillator with cubic and quintic nonlinear terms. The authors estimated a group of backbone curves of the nonlinear vibration isolator by considering its equivalent conservative system. Cammarano et al. [9] investigated the optimal load for the nonlinear energy harvester in the case of purely resistive loads. Their work was carried out both analytically and numerically, and the results showed that analytical solutions obtained using direct normal forms were in very close agreement with the numerical results within the frequency range of interest. The direct normal form technique was also applied to study the nonlinear dynamic behaviors of MDOF systems, see for example [9] and references therein.

However, in order to generalise the applications of direct normal forms, thanks to the implementation of Maple symbolic computations, this work focuses on studying SDOF nonlinear systems with higher orders of geometric nonlinearities. One reason for taking this approach is that, when attempting the direct normal forms analysis of such systems, usual hand calculations, can be extremely difficult as the number of terms included increases.

Due to the inherent nature of nonlinearities, the use of direct normal forms is not limited to nonlinear oscillators; many real-life engineering applications exhibit geometric, or even damping nonlinearities quite naturally. Therefore, the direct normal form technique has been used to study nonlinear beams, cables, shells, plates and multi-storey buildings - see [3] for detailed description of many of these applications. In this work, the direct normal forms method is used to analyse some SDOF oscillators with one, or two, geometric nonlinear terms. The application of this method, with the aid of symbolic computation algorithm, enables a robust computational method for the investigation of the dynamics exhibited by these types of oscillators using backbone curves.

2 DIRECT NORMAL FORMS METHODOLOGY

For the case of unforced vibrating systems, the technique is applied using four main consecutive steps:

Step 1: Linear modal transformation in order to decouple the linear terms.
Step 2: Derivation of the equation of motion for the nonlinear transformation.
Step 3: Applying the near-identity transform.
Step 4: Solving the resulting normal forms equation (or equations).

In addition, studying systems that are externally forced usually requires one further transformation, in which, any non-resonant forcing terms are to be excluded. Finally, damping term (usually viscous damping) is normally included within the nonlinear vector.

2.1 Computation of backbone curves using direct normal forms

Consider the case of nonlinear forced-damped SDOF oscillator, whose equation of motion may be written as

$$M\,\ddot{x}(t)+C\,\dot{x}(t)+K\,x(t)+N_x(x,\dot{x},r)=P_x\mathbf{r},, \tag{1}$$

where the over dots represent derivation with respect to time, x represents the physical displacements, M, C and K denote the mass, damping coefficient and linear stiffness respectively, $N_x(x)$ is the nonlinear restoring force, ε is used to denote smallness of the nonlinear terms, the amplitude of the forcing term is denoted by P_x, and $\mathbf{r}$ is the forcing vector which can be written as $\mathbf{r}=\left\{r_p, r_m\right\}^T=\left\{e^{i\Omega t}, e^{-i\Omega t}\right\}^T$ where the forcing frequency is denoted a by Ω.

As mentioned earlier, direct normal forms analysis is applied using four main steps, for convenience, only key parts of the analysis are to be discussed in this work while the complete detailed analysis of this type of systems is extensively discussed in [3]. Moreover, for the application of the direct normal form technique, the nonlinear terms are assumed to be expressed in a polynomial form in terms of x.

From Eq. (1) all nonlinear terms are gathered in one term, $\overline{N}_x(x)$. Herein, both damping and nonlinear terms are assumed to be efficiently small compared to the linear stiffness and the forcing term, hence, more conveniently Eq. (2) can be rewritten as

$$M\,\ddot{x}(t)+K\,x(t)+\overline{N}_x(x,\dot{x},r)=\mathbf{P_x}\mathbf{r}, \tag{2}$$

where $\overline{N}_x(x,\dot{x},r)=N_x(x,\dot{x},r)+C\,\dot{x}(t)$

Now, the application of direct normal forms begins, by writing Eq. (2) in its *linear modal normal form*, using the transformation $x \to q$, simply by applying $x = \Phi q$, where Φ is the matrix containing the mode shapes, then, Eq. (2) becomes

$$\ddot{q} + \Lambda q + \overline{N}_q(q, \dot{q}, \mathbf{r}) = \mathbf{P_q r}, \tag{3}$$

where $\overline{N}_q(q, \dot{q}, \mathbf{r}) = \left(\Phi^T M \Phi\right)^{-1} \Phi^T \overline{N}_x(\Phi q, \Phi \dot{q}, \mathbf{r})$, $\mathbf{P_q} = \left(\Phi^T M \Phi\right)^{-1} \Phi^T \mathbf{P_x}$

Herein, $q = u + \varepsilon H(u)$ where u and $H(u)$ are the fundamental and harmonic components of q respectively.

The assumed solution has the form

$$u = u_p + u_m = \left(\frac{U}{2} e^{-i\phi}\right) e^{i\omega_r t} + \left(\frac{U}{2} e^{i\phi}\right) e^{-i\omega_r t}, \tag{4}$$

Where U, ϕ and ω_n are the displacement amplitude, phase lag, and response frequency, respectively.

In order to complete the analysis, $\overline{N}_q$, in view of Eq. (4), should be decomposed into two vector $\mathbf{n}^*$ and $\mathbf{u}^*$ where $\mathbf{n}^*$ is a row vector contains the coefficients part and $\mathbf{u}^*$ is a column vector represents the nonlinear functions of u.

For the case of polynomial nonlinear terms (as appears in Eq. 2), the ℓ^{th} element of $\mathbf{u}^*$ may be written as

$$u_\ell^* = u_{pn}^{s_{p,\ell}} u_{mn}^{s_{m,\ell}} \tag{5}$$

Where $s_{p,l}$ and $s_{m,l}$ are exponents of u_p and u_m in the ℓ^{th} element of $\mathbf{u}_{(j)}^*$ respectively. This step is symbolically done in the proposed algorithm for every term in $\mathbf{u}^*$. In order to identify the resonant nonlinear terms retained in $\mathbf{n}_{u(j)}$ from $\mathbf{n}_{(j)}$, a vector $\beta_{(j)}$, is introduced, i.e.

$$\beta_{(j)n,\ell} = \left[\sum_{n=1}^{N} \left(s_{pj,\ell,n} - s_{mj,\ell,n}\right) \omega_{rn}\right]^2 - \omega_{rn}^2 \tag{6}$$

Finding $\boldsymbol{\beta}^*$ matrix is crucially important to complete the analysis, and it is performed symbolically with a series of iterative loops that capture the power indices in Eq. (5) and then substitute the result in Eq. (6).

The procedure discussed above is a short summary of the direct normal forms technique. In the following subsection, two examples of SDOF nonlinear oscillators are studied; the first example represents a SDOF conservative (unforced and undamped) oscillator with two different orders of geometric nonlinearities, whereas the second example is a SDOF oscillator with

viscous damping and harmonic forcing applied away from resonance. Lastly, the frequency response of a general system of a forced damped nonlinear oscillator with two types of geometric nonlinearities is studied. It is important to mention that all manipulations and solutions to be shown are computed using Maple symbolic computation packages with the aid of the COCO toolbox in Matlab for numerical comparisons and verifications.

2.2 SDOF conservative oscillator with various nonlinearities

Considering the following general formula for unforced, un-damped SDOF oscillator,

$$\ddot{x}(t) + \omega_n^2 x(t) + \alpha_1 x^{\mu}(t) + \alpha_2 x^{\nu}(t) = 0, \tag{7}$$

where ω_n is the natural frequency of the system, α_1 and α_2 are arbitrary small coefficients for the nonlinear terms, μ and ν are the lower and higher orders of the nonlinear terms, respectively. Furthermore, in order to achieve stable energy levels, at least one of the nonlinear orders (i.e. μ and ν) should be an odd number, for detailed discussion of the potential functions and how they are used to study the stability level of the system refer to [3].

Using this approach it is possible to compare the results for different configurations of μ and ν. Such systems with different parameters and orders of nonlinearities can be theoretically used for modelling some engineering applications. In principle, the symbolic computations method introduced in this work has the potential to be applied to general SDOF systems with any number of nonlinear terms. In order to test this method we start with two nonlinear terms described by Eq. (7) and increase the order, accordingly, it is possible to understand the capabilities and limitations of this method.

The following procedure illustrates the use of symbolic computations of a normal form method in order to solve Eq. (7) for $\mu = 2$ and $\nu = 7$, nevertheless, following the same procedure, it is possible to solve the equation for any other values, as long as at least one exponent is odd.

Direct normal forms analysis of such systems undergoes a series of transformations that involve complex mathematical manipulations, in this work the most important results are shown, focusing on the utilization of symbolic computation software, i.e. Maple. Rewriting Eq. (7) with $\mu = 2$ and $\nu = 7$, leads to

$$\ddot{x}(t) + \omega_n^2 x(t) + \alpha_1 x^2(t) + \alpha_2 x^7(t) = 0, \tag{8}$$

The first step is using Eq. (3) in view of Eq. (2) to make the linear modal transformation, in this step it should be noticed that for SDOF systems the transform is unity and $x = q$, then

$$\ddot{q} + \Lambda q + N_q(q) = 0, \text{ where } \Lambda = \omega_n^2 \text{ and } N_q(\mathbf{q}) = \alpha_1 q^2 + \alpha_2 q^2 \tag{9}$$

The second step is the near-identity transform, and for $\varepsilon = 1$, rewriting the nonlinear terms using $\mathbf{u}$, one should obtain $N_q(u) = \alpha_1 u_1^2 + \alpha_2 u_1^7$ and $\mathbf{u}_1 = \mathbf{u}_{p1} + \mathbf{u}_{m1}$, thus

$$\mathbf{n}_{(1)}(\mathbf{u}) = \mathbf{n}^* \mathbf{u}^*(\mathbf{u}_p, \mathbf{u}_m) = \alpha_1 \left(u_{p1} + u_{m1}\right)^2 + \alpha_2 \left(u_{p1} + u_{m1}\right)^7 \tag{10}$$

Expanding Eq. (10), $\mathbf{n}_{(1)}(\mathbf{u})$ will contain many terms (11 term in this case), these terms have to be primarily decomposed into coefficients and nonlinear functions vectors $\mathbf{n}^*$ and $\mathbf{u}^*$, respectively.

$$\mathbf{n}^* = \begin{bmatrix} \alpha_1 & \alpha_1 & \alpha_2 & \alpha_2 & 2\alpha_1 & 7\alpha_2 & 21\alpha_2 & 35\alpha_2 & 35\alpha_2 & 21\alpha_2 & 7\alpha_2 \end{bmatrix} \tag{11a}$$

$$\mathbf{u}^* = \begin{bmatrix} u_{m1}^2 & u_{p1}^2 & u_{m1}^7 & u_{p1}^7 & u_{p1}u_{m1} & u_{p1}u_{m1}^6 & u_{p1}^2 u_{m1}^5 & u_{p1}^3 u_{m1}^4 & u_{p1}^4 u_{m1}^3 & u_{p1}^5 u_{m1}^2 & u_{p1}^6 u_{m1} \end{bmatrix}^T \tag{11b}$$

As the number of nonlinear terms and their corresponding orders increase, or when considering higher order accuracy (i.e. ε_2, ε_3, ...) this initial step becomes harder to be manipulated by usual hand calculations. Symbolically, the proposed algorithm can be efficiently completed to do this step and produce $\mathbf{n}^*$ and $\mathbf{u}^*$ matrices.

Using the proposed symbolic algorithm, we have been able to study several SDOF oscillators with two weak nonlinearities of variable orders. The key point in applying direct normal forms, especially for SDOF problems, is the number of terms involved in the matrices. Table 1 shows the number of terms for cases of conservative nonlinear oscillators of various orders of nonlinearities, i.e. for different configurations of μ and ν. Values in the highlighted cells represents the case when only one nonlinear term appears in the EOM.

Table (1): Number of terms involved in matrices for selected values of ν and μ

μ \ ν	3	5	7	9	11	13
2	7	9	11	13	15	17
3	**4**	10	12	14	16	18
4	9	11	13	15	17	19
5	10	**6**	14	16	18	20
6	11	13	15	17	19	21
7	12	14	**8**	18	20	22
8	13	15	17	19	21	23
9	14	16	18	**10**	22	24
10	15	17	19	21	23	25
11	16	18	20	22	**12**	26
12	17	19	21	23	25	27
13	18	20	22	24	25	**14**

The increasing number of terms appearing in Table 1 leads to additional difficulties for hand calculations to be performed. Importantly, more complex systems will lead to a higher number of terms; some examples of more complex cases include:

- the EOM involves viscous damping (in this case two additional terms are to be added to those in Table 1),
- the system contains more than two types of polynomial nonlinearities,
- solving the EOM for a higher order accuracy (i.e. ε_2)
- and when using the direct normal forms technique for MDOF systems,

all of the aforementioned cases can yield to a dramatic increase in the size of the matrices, thus, the mathematical complexity is also increased, these causes can justify turning to symbolic computation method.

In order to complete the analysis, by applying Eq. (6), $\boldsymbol{\beta}^*$ can be written as

$$\boldsymbol{\beta}^* = \begin{bmatrix} 3\omega_{r1}^2 & 48\omega_{r1}^2 & 3\omega_{r1}^2 & 48\omega_{r1}^2 & -\omega_{r1}^2 & 24\omega_{r1}^2 & 8\omega_{r1}^2 & 0 & 0 & 8\omega_{r1}^2 & 24\omega_{r1}^2 \end{bmatrix} \tag{12}$$

It should be emphasized that, according to direct normal forms analysis, any *zero* value in $\boldsymbol{\beta}^*$ matrix indicates the presence of a resonant term; while any *nonzero* value indicates a non-resonant or harmonic term.

The next step, illustrates the resulting coefficients of resonant terms $\mathbf{n}_{\mathbf{u}}^*$ and of harmonic terms $\mathbf{h}^*$ for both resonant and non-resonant cases (refer to [3] for detailed analysis). In symbolic programming, this step is based on conditional loop manipulation for each element in $\boldsymbol{\beta}^*$ with respect to $\mathbf{n}^*$. The results are

$$\mathbf{n}_{\mathbf{u}}^* = \alpha_2 \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 35 & 35 & 0 & 0 \end{bmatrix} \tag{13a}$$

$$\mathbf{h}^* = \frac{1}{\omega_{r1}^2} \begin{bmatrix} \frac{\alpha_1}{3} & \frac{\alpha_1}{48} & \frac{\alpha_2}{3} & \frac{\alpha_2}{48} & -2\alpha_1 & \frac{7\alpha_2}{24} & \frac{21\alpha_2}{8} & 0 & 0 & \frac{21\alpha_2}{8} & \frac{7\alpha_2}{24} \end{bmatrix} \tag{13b}$$

If the analysis is only truncated to ε_1 accuracy, which regularly leads to acceptable inspection of the nonlinear effects of small nonlinearities, the final step is rewriting the transformed equation of motion. For the non-resonant case, Eq. (9) in u-transformed coordinate system becomes

$$\ddot{\mathbf{u}} + \Lambda \mathbf{u} + \mathbf{n}_{\mathbf{u}}^* \mathbf{u}^* = 0,$$

$$\ddot{\mathbf{u}} + \omega_n^2 \mathbf{u} + 35\left(u_{p1}^3 u_{m1}^4 + u_{p1}^4 u_{m1}^3\right) = 0, \tag{14}$$

and the near identity transform is written as

$$\mathbf{q} = \mathbf{u} + \mathbf{h}^{*}\mathbf{u}^{*},$$

$$\mathbf{q} = \mathbf{u} + \frac{1}{3\omega_{r1}^{2}}\left(\begin{array}{l}\alpha_1 u_{m1}^{2} + \dfrac{\alpha_1 u_{p1}^{2}}{16} + \alpha_2 u_{m1}^{7} + \dfrac{\alpha_2 u_{p1}^{7}}{16} - 6\alpha_1 u_{p1}u_{m1} + \dfrac{7\alpha_2 u_{p1}u_{m1}^{6}}{8} + \\ \dfrac{63\alpha_2 u_{p1}^{2}u_{m1}^{5}}{8} + \dfrac{63\alpha_2 u_{p1}^{5}u_{m1}^{2}}{8} + \dfrac{7\alpha_2 u_{p1}^{6}u_{m1}}{8}\end{array}\right) \tag{15}$$

Substituting in the assumed solution Eq. (4), and solving the positive (or negative) complex exponential terms by exact balancing, one can get the equation of the backbone curve for this system, which is

$$\omega_{r1}^{2} = \omega_n^{2} + \frac{35}{64}\alpha_2 U^{6} \tag{16}$$

Following the same aforementioned procedure, one should be able of finding the backbone curve for any values of ν and μ in Eq. (7). One advantage of having a computer pattern in such case is the ability of doing several runs with different conditions. Table 2 shows the backbone curve obtained for the first four values of ν when $\mu = 2$ for the ε_1 expansion. It is clear that a general pattern is repeated for the backbone equation found, so if $\mu = 2$ it could be generalized for any value of ν that

$$\omega_{r1}^{2} = \omega_n^{2} + \eta_i \alpha_2 U^{\nu-1}, \quad \nu = 3, 5, 7, \ldots \tag{17}$$

Where η_i is a constant.

Table (2): Backbone curve equations of ε_1 accuracy for different values of ν while $\mu = 2$

Value of ν	Equation of motion	Backbone curve equation
3	$\ddot{x}(t) + \omega_n^{2}x(t) + \alpha_1 x^{2}(t) + \alpha_2 x^{3}(t) = 0$	$\omega_{r1}^{2} = \omega_n^{2} + \frac{3}{4}\alpha_2 U^{2}$
5	$\ddot{x}(t) + \omega_n^{2}x(t) + \alpha_1 x^{2}(t) + \alpha_2 x^{5}(t) = 0$	$\omega_{r1}^{2} = \omega_n^{2} + \frac{5}{8}\alpha_2 U^{4}$
7	$\ddot{x}(t) + \omega_n^{2}x(t) + \alpha_1 x^{2}(t) + \alpha_2 x^{7}(t) = 0$	$\omega_{r1}^{2} = \omega_n^{2} + \frac{35}{64}\alpha_2 U^{6}$
9	$\ddot{x}(t) + \omega_n^{2}x(t) + \alpha_1 x^{2}(t) + \alpha_2 x^{9}(t) = 0$	$\omega_{r1}^{2} = \omega_n^{2} + \frac{63}{128}\alpha_2 U^{8}$

Practically, for weak nonlinear case, the values of α_1 and α_2 should be small, typically less than unity, Fig. (1) shows the backbone curves for the conservative oscillators appearing in Table 2, using the following numerical values; $\alpha_1 = 0.2$, $\alpha_2 = 0.1$ and $\omega_n = \pi$ rad/s.

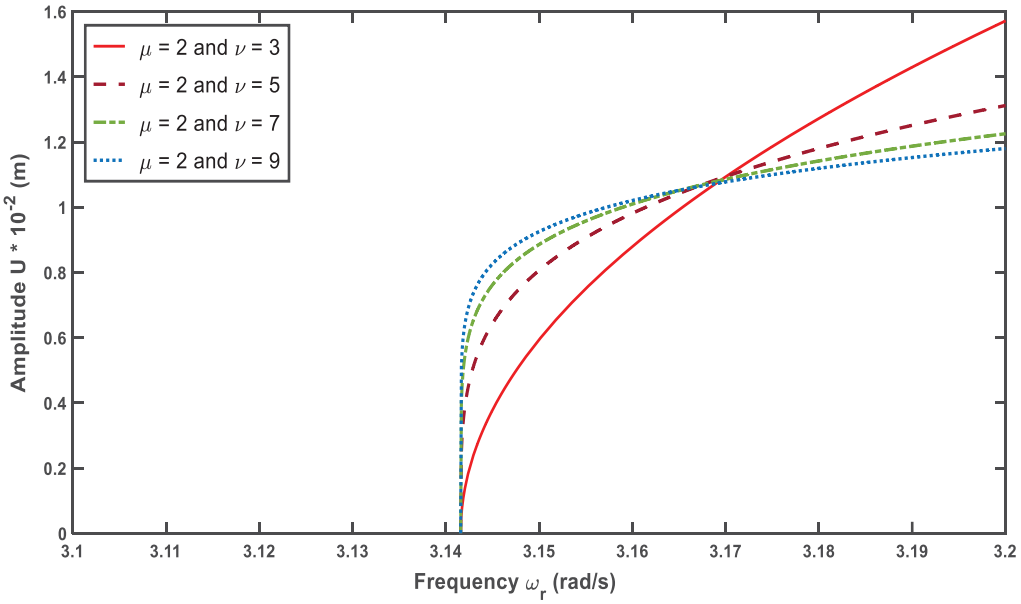

Fig. (1): Conservative backbone curves for different values of ν while $\mu = 2$

Furthermore, we could obtain the backbone curve relation truncated to ε_1 accuracy for any values of ν and μ in Eq. (7). Table 3 shows some examples of these results.

Table (3): Backbone curve equations of ε_1 accuracy for different values of ν and μ

Value of ν	Value of μ	Equation of motion	Backbone curve equation
3	5	$\ddot{x}(t) + \omega_n^2 x(t) + \alpha_1 x^3(t) + \alpha_2 x^5(t) = 0$	$\omega_{r1}^2 = \omega_n^2 + \frac{3}{4}\alpha_1 U^2 + \frac{5}{8}\alpha_2 U^4$
4	7	$\ddot{x}(t) + \omega_n^2 x(t) + \alpha_1 x^4(t) + \alpha_2 x^7(t) = 0$	$\omega_{r1}^2 = \omega_n^2 + \frac{35}{64}\alpha_2 U^6$
5	9	$\ddot{x}(t) + \omega_n^2 x(t) + \alpha_1 x^5(t) + \alpha_2 x^9(t) = 0$	$\omega_{r1}^2 = \omega_n^2 + \frac{5}{8}\alpha_1 U^4 + \frac{63}{128}\alpha_2 U^8$
6	9	$\ddot{x}(t) + \omega_n^2 x(t) + \alpha_1 x^6(t) + \alpha_2 x^9(t) = 0$	$\omega_{r1}^2 = \omega_n^2 + \frac{63}{128}\alpha_2 U^8$
7	11	$\ddot{x}(t) + \omega_n^2 x(t) + \alpha_1 x^7(t) + \alpha_2 x^{11}(t) = 0$	$\omega_{r1}^2 = \omega_n^2 + \frac{35}{64}\alpha_2 U^6 + \frac{231}{512}\alpha_2 U^{10}$

The following findings are noted:

- Any even nonlinearity found in the EOM is removed by the normal form transformation and does not appear in the backbone curve. This phenomenon is found in literature in terms of quadratic nonlinearity, here we generalise this finding for any even nonlinearity.

- Referring to Table 3 and comparing with Table 2, it is clear that the frequency detuning accompanied with direct normal forms resulted in, at least for ε_1 accuracy, a behavior similar to superposition regarding the final backbone curve expression.

- Some of these results are numerically verified using COCO numerical continuation toolbox in Matlab (see Fig. (3)), and acceptable agreement between analytical backbone curves and numerical backbone manifolds is seen.

In conclusion, in order to generalise the ε_1 backbone curve relation for any SDOF nonlinear oscillator with two types of nonlinearities, Eq. (7), in view of Table 1 and Table 2, provided that ν and μ are odd, the following relation can be obtained

$$\omega_{r1}^2 = \omega_n^2 + \eta_1 \alpha_1 U^{\nu-1} + \eta_2 \alpha_2 U^{\mu-1} \tag{18}$$

Where η_1 and η_2 are constants directly related to the order of the nonlinearity, Table 4 shows the values of this constant for several orders of the nonlinear terms. Finally, as mentioned earlier, any even nonlinearity in the EOM will be removed by the normal form and will not appear in Eq. (18).

Table (4): Values of the constant η_i appearing in the backbone curve relation, Eq. (18)

Order of nonlinearity	3	5	7	9	11	13	15	17
η_i	$\frac{3}{4}$	$\frac{5}{8}$	$\frac{35}{64}$	$\frac{63}{128}$	$\frac{231}{512}$	$\frac{429}{1024}$	$\frac{6435}{16384}$	$\frac{12155}{32768}$

Using Eq. (18) and Table 4 it is possible to get the conservative backbone curve relation for any nonlinear oscillator with two different types of polynomial nonlinearities. As an example, if the EOM contains both cubic and quintic nonlinearities, i.e.

$$\ddot{x}(t) + \omega_n^2 x(t) + \alpha_1 x^3(t) + \alpha_2 x^5(t) = 0,$$

then, the conservative backbone curve of ε_1 accuracy will be

$$\omega_{r1}^2 = \omega_n^2 + \frac{3}{4}\alpha_1 U^2 + \frac{5}{8}\alpha_2 U^4$$

2.3 Non-resonant Duffing oscillator with cubic nonlinearity

As an example of a more complex system, we now consider the system of a Duffing oscillator with cubic nonlinearity, viscous damping and forcing away from resonance where the ratio between the driving frequency and the natural frequency is 1/3 (i.e. $a = 1/3$),

$$\ddot{x}(t) + 2\zeta\omega_n \dot{x}(t) + \omega_n^2 x(t) + \alpha\, x^3(t) = R\cos(\Omega t) \tag{19}$$

Using the proposed direct normal forms technique applied symbolically, it is required to generate analytical conservative backbone curve equations for ε_1 accuracy, and compare with forced (and lightly damped) response curves. The step by step procedure involves large matrices and algebraic terms, hence, only the key results are to be shown, while further results for matrix algebra manipulations can be found in Appendix 1. After applying direct normal forms analysis we get

$$\frac{1}{4}\left[3\alpha U_1^3 + \left(24\alpha e^2 + 4\left(\omega_n^2 - \omega_{r1}^2\right)\right)\right]\cos\left(\omega_{r1}t - \phi_1\right) + 2\alpha e^3\cos\left(\omega_{r1}t\right) - 2\zeta\omega_n\omega_{r1}U_1\sin\left(\omega_{r1}t - \phi_1\right) = 0 \tag{20}$$

Where $e = \dfrac{R}{2(\omega_n^2 - \Omega^2)}$.

Applying the suitable trigonometric identities, and then balancing the sines and cosines terms in Eq. (20) we get

$$\zeta\omega_n\omega_{r1}U = -\alpha e^3\sin\left(\phi_1\right) \tag{21a}$$

$$3\alpha e^2 + \frac{3}{8}\alpha U_1^3 + \frac{1}{2}\left(\omega_n^2 - \omega_{r1}^2\right) = -\alpha e^3\cos\left(\phi_1\right) \tag{21b}$$

Hence, it is possible to use Eq. (21) to get an expression for U as a function of ω_{r1}, therefore, computing the forced response curve analytically, this has been previously done in [3] by applying traditional hand calculations. In order to compare with our proposed symbolic computation method, the same problem has been solved in conservative case (unforced-undamped case), and the conservative backbone curve is computed using Eq. (18) and Table (4) and plotted in Fig. (2), along with the analytically computed forced-damped response curves for several values of R using Eq. (21). The numerical values chosen for this figure are $\omega_n = 2$ rad/s, $\zeta = 0.01$ and $\alpha = 0.2$.

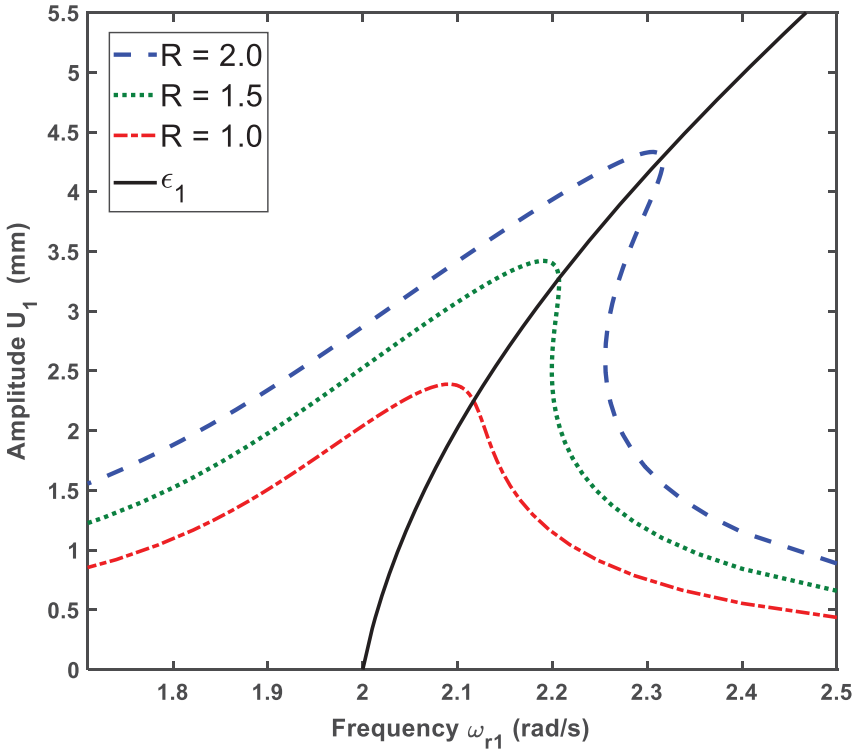

Fig. (2): Backbone curve of damped forced Duffing oscillator with cubic nonlinearity

Figure (2) represents a typical backbone curve and response curves for any forced damped nonlinear system. From this figure, several important observations can be noticed; first of all, as the value of α is positive, hardening behavior is clearly seen, in contrary, if α is negative softening behavior will be noticed. Furthermore, as the figure shows the relation between natural frequency and amplitude, the backbone curves do not perfectly coincide with the manifolds, and this is due to the presence of damping. Finally, as the forcing amplitude *R* becomes higher, more matching between the backbone curves and their manifolds occurs.

Finally, in order to compare the frequency response of several nonlinear terms in combination, recall Eq. (5) in its forced damped case, that is

$$\ddot{x}(t) + 2\zeta\omega_n\dot{x}(t) + \omega_n^2 x(t) + \alpha_1 x^{\nu}(t) + \alpha_2 x^{\mu}(t) = R\cos(\Omega t) \tag{22}$$

Various values of ν and μ can be considered, the corresponding EOM can be studied using direct normal forms and analytical backbone curve relations are then obtained. Three cases are studied, linear oscillator and cubic-quintic oscillator in both hardening and softening cases (3-5 Hardening, 3-5 Softening). Figure 3 represents backbone equation for all previous cases along with their forcing manifolds obtained numerically using COCO. Figure 3 is generated using the numerical data: general parameters for all cases $\omega_n = 2$ Hz, $\zeta = 0.05$ and $R = 1$. In the case of hardening cubic-quintic oscillator $\alpha_1 = 0.2$ and $\alpha_2 = 0.3$. Finally, for softening cubic-quintic oscillator $\alpha_1 = -0.2$ and $\alpha_2 = -0.3$.

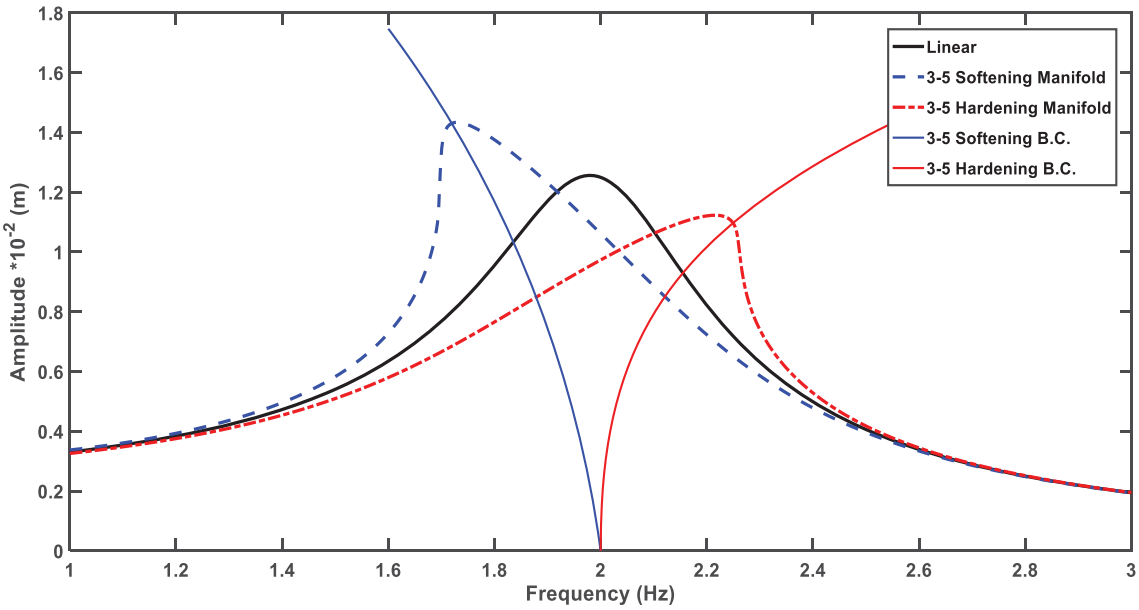

Fig. (3): Frequency response of various types of nonlinearities

Figure 3 illustrates the effect of both hardening and softening nonlinear terms on the frequency response of the system; firstly, compared to the linear case, hardening polynomial nonlinearities the shift the peak to the right whilst minimizing the maximum vibration amplitude of the system. On the other hand, softening nonlinear terms cause shifting to the left and maximizing the vibration amplitude. However, using Eq. (18) along with Table 4 it is possible to obtain the conservative backbone curves for SDOF oscillator with two nonlinear terms, and compare with the forced-damped frequency response computed numerically using COCO toolbox in Matlab.

3 CONCLUSION

In this work, the direct normal forms method is used to study the dynamical behavior of SDOF oscillators with higher orders of polynomial nonlinearities. Symbolic computations using Maple were implemented for the analytical solutions, where backbone curves expressions of ε_1 order were obtained and the results were verified using COCO numerical continuation toolbox in Matlab. A general formula for any SDOF nonlinear oscillator with two polynomial nonlinearities are obtained by computing high number of terms in the solution (refer to Table 1).

The overall truncated analytical results show good agreement with the numerical results, accordingly, extending the direct normal forms using symbolic computations can yield to some desired findings regarding the dynamics of the system. Although the proposed technique overcomes the mathematical complexities and enables fast analysis of SDOF nonlinear oscillators, its limited to weakly nonlinear systems were the nonlinear terms are modelled by polynomial terms in the EOM, so that the direct normal forms technique is applicable.

Overall, the work shows good insight regarding the implementation of symbolic computations when studying SDOF nonlinear oscillators, were we have been able to analytically compute the conservative backbone curves for any SDOF oscillator with two nonlinear terms.

Keywords: Non-intrusive reduced order modeling, Nonlinear geometric vibration, Basis construction

Abstract. *Reduced order modeling for nonlinear geometric vibrations of thin-walled structures has been an active research subject in the last two decades due, in particular, to its advantage in significantly reducing the computational cost of determining the dynamic response. Two key issues of this modeling are the construction of the basis and the identification of nonlinear stiffness coefficients. The present study focuses on the basis construction and a systematic strategy is proposed to achieve it using data derived from the linear modes of the structure with some general information about the dynamic loading, e.g., cut-off frequency. Thus, the basis is applicable to a broad range of such dynamic loadings. A clamped-clamped straight beam is used to demonstrate the construction of bases according to the proposed strategy. A force distribution mapped from measured aerodynamic pressure distribution is used as loading for which both static and dynamic nonlinear responses are obtained at various levels, from weakly to very strong nonlinear, and from both finite element and reduced order models. This data is used to assess the constructed bases and validate the predictions of the ensuing reduced order models. It is shown that the constructed bases provide a very good representation of the finite element nonlinear structural responses and that the corresponding reduced order model lead to accurate predictions of these responses. The importance of adding out-of-band linear modes in the basis is also demonstrated.*

1 INTRODUCTION

In the last two decades, reduced order modeling methods have been developed for the prediction of the nonlinear geometric vibrations of thin-walled structures [1-14]. As seen below, these methods require a notable number of nonlinear static solutions to be performed as part of the reduced order model (ROM) construction. Thus, they are not computationally efficient for determining the static response of the structure to a few different loads. Rather, the ROMs become valuable when there is a large number of nonlinear solutions needed, either when there are many different static loadings or more likely when determining long duration dynamic computations, e.g., for fatigue life prediction. The ROMs are also very desirable in multi-physics problems, see [15-17] for examples, both because many iterations may be needed between different physics solvers but also because of the ease of implementing the ROM governing equations in a non-structural solver. Reduced order models are also very valuable in uncertainty analyses, see [18-20] for example not only because of their computational efficiency but also because they provide a framework to globally introduce uncertainty which is challenging to do at the finite element level.

Of interest here are non-intrusive nonlinear reduced order models (ROMs), i.e., those built from data extracted from commercial finite element software, e.g., Nastran, Abaqus, etc., see [21] for a recent review. One advantage of non-intrusive reduced order models is the capability to handle complex geometry and boundary conditions of structures in engineering practice. Such reduced order models have been built for a large number of structures and their potential has been demonstrated, e.g., see [13, 22-25].

In the present nonlinear reduced order models, the nonlinear structural displacemens of the finite element model $\underline{u}(t)$ are represented as

$$\underline{u}(t) = \sum_{n=1}^{N} q_n(t)\,\underline{\phi}^{(n)} \,. \tag{1}$$

where $q_n(t)$ are the time-dependent generalized coordinates and $\underline{\phi}^{(n)}$ are the basis functions. Assuming the material is linearly elastic following a Kirchhoff – Saint Venant constitutive equation, the governing equation of the nonlinear reduced order model can be obtained using the Galerkin approach, see [7] for details, as (summation over repeated indices implied)

$$M_{ij}\ddot{q}_j(t) + D_{ij}\dot{q}_j(t) + K_{ij}^{(1)} q_j(t) + K_{ijl}^{(2)} q_j(t) q_l(t) + K_{ijlp}^{(3)} q_j(t) q_l(t) q_p(t) = F_i(t), \qquad i = 1, 2, \ldots, N, \tag{2}$$

where M_{ij} denotes the elements of the mass matrix, $K_{ij}^{(1)}$, $K_{ijl}^{(2)}$, and $K_{ijlp}^{(3)}$ are the linear, quadratic, and cubic stiffness coefficients, and $F_i = \underline{\phi}^{(i)T}\,\underline{F}$ is the modal force associated with mode i. The damping matrix D_{ij} is added to collectively represent various energy dissipation mechanisms. One commonly used damping model, as adopted in the present paper, is the Rayleigh damping model, defined as

$$D_{ij} = \alpha M_{ij} + \beta K_{ij}^{(1)} \,, \tag{3}$$

where α and β are the Rayleigh damping coefficients.

In non-intrusive reduced order models, the ROM matrices in Eq. (2) are identified using data from commercial finite element software. The computation of the linear matrices, i.e., the mass and the stiffness, is straightforward once their finite element counterparts are extracted from the finite element software. Specifically, the matrices M and $K^{(1)}$ are obtained as the projection on the basis $\Phi = \left\{ \underline{\phi}^{(1)}, \underline{\phi}^{(2)}, \ldots, \underline{\phi}^{(N)} \right\}$ of the finite element mass ($M^{(FE)}$) and linear stiffness ($K^{(FE)}$), i.e.,

$$M = \Phi^T M^{(FE)} \Phi \quad \text{and} \quad K^{(1)} = \Phi^T K^{(FE)} \Phi \,. \tag{4}$$

The damping matrix can then be computed using the Rayleigh damping model.

The evaluation of the nonlinear stiffness coefficients has to proceed differently since the global nonlinear stiffness operator is typically not computed/not available in a commercial finite element code. In one proposed approach, the displacement-force method [6,7], a set of designed static displacements are imposed to the structure and the corresponding nonlinear forces are obtained from the finite element code. They are then used to compute the corresponding modal forces F_i. Finally, imposing the same modal displacements and modal forces to the ROM governing equation, Eq. (2), leads to the conditions

$$K_{ij}^{(1)} q_j + K_{ijl}^{(2)} q_j q_l + K_{ijlp}^{(3)} q_j q_l q_p = F_i \tag{5}$$

which can be used to determine the stiffness coefficients $K_{ijl}^{(2)}$ and $K_{ijlp}^{(3)}$. By an appropriate selection of imposed displacements, the coefficients to be identified can be divided into a number of smaller (including up to three modes) groups and identified separately, see [6,7] for details.

When the basis of a ROM is large, this displacement-force method requires a large number of static solutions, i.e., $O(N^3/6)$. To resolve this issue, a method using the tangent stiffness matrix, denoted as $K^{(T)}$, instead of the force in the identification has been developed [13]. This displacement-$K^{(T)}$ method relies on the availability of the tangent stiffness matrix for each imposed displacement. Once this matrix has been obtained, it is projected on the basis, as in Eq. (4), and then matched to its ROM counterpart of *iu* element given by

$$K_{iu}^{(T)} = \frac{\partial F_i}{\partial q_u} = K_{iu}^{(1)} + \left[K_{iju}^{(2)} + K_{iuj}^{(2)} \right] q_j + \left[K_{ijlu}^{(3)} + K_{ijul}^{(3)} + K_{iujl}^{(3)} \right] q_j q_l \,. \tag{6}$$

The advantage of this approach is that an $N \times N$ matrix (the tangent stiffness matrix) is obtained for each solution, thereby leading to a reduction of the computational effort to $O(N^2/2)$.

In principle, the nonlinear stiffness coefficients should be independent of the imposed displacements used to identify them. However, due to difference the nonlinear formulation between the ROM and most commercial finite element software, it is observed that the identified stiffness coefficients exhibit variations with respect to the amplitude of the displacements used. To counteract this dependence, a multi-level identification method has been developed to find the optimal displacement level for each nonlinear stiffness coefficient [26].

The above discussion has focused on the identification of the nonlinear stiffness coefficients but another key issue is the selection of the basis. The basis determines how well the ROM represents nonlinear responses of the structure, while the nonlinear stiffness coefficients dictate

the nonlinear geometric effects due to the large deformation of the structure. Together they determine the accuracy of the ROM predictions.

A significant feature of the nonlinear geometric response of thin-walled structures is the in plane displacements due to the large transverse deformations associated with the "membrane stretching" effect. These in plane displacements, which are typically higher frequency/higher strain than their transverse counterparts, play an important role in the nonlinear stiffening and thus must be properly accounted for by the nonlinear ROM. In this discussion, the transverse direction is formally defined as the direction normal to the thin-wall surface, and the two in plane directions in general are defined as two orthogonal directions on the surface perpendicular to the transverse direction. Thus, the transverse and in plane directions would then change with location on the structure when curvature is present. To avoid this situation, the transverse and in plane directions will here be defined for panels with shallow curvature as those associated with the fixed, flat, mean surface.

In previous non-intrusive nonlinear ROM investigations, two types of approaches have been used to construct the ROM basis, see [21] for discussion. One approach, termed the implicit condensation and expansion method [5], uses a basis composed of linear modes that captures well the transverse component of the displacements. The in plane displacements are not directly modeled, they are assumed statically condensed on the linear modes and thus their effects are accounted for through changes of the nonlinear stiffness coefficients. If desired, e.g., to estimate the stresses, the in plane displacements can be recovered in the expansion component of the method.

The second strategy to construct the ROM basis seeks to represent all components, transverse and in plane, of the displacement field. Such a basis is formed by enriching the linear modes that would be used in the absence of nonlinear effects with a set of additional basis functions, such as dual modes [7], higher order linear modes (see [21]), other modal derivatives [27]. The dual modes, used in the sequel, are extracted from a set of nonlinear static solutions corresponding to loadings that would induce in the linear case displacements that are along one or two of the selected linear modes. The corresponding forces on the finite element mesh are thus of the form

$$\underline{F}_{ij,s}^{(FE)} = K^{(FE)}\left[\pm\alpha_{ij,s}(\underline{\phi}_i + \underline{\phi}_j)\ /\ 2\right], \tag{7}$$

where i and j are the indices of the two modes (the case $i = j$ emulates the single mode case). In this equation, $\alpha_{ij,s}$ are a set of scaling factors selected so that the corresponding structural response spans a given range of levels. Once these responses have all been determined, the transverse components of this data are first removed by making the displacements orthogonal to the linear modes selected. Next, a proper orthogonal decomposition (POD) analysis is carried out and POD eigenvectors with desired features (see section 2) are retained as dual modes.

While the final measure of the appropriateness of a basis is the accuracy in the matching of predictions from the ROM and from the underlying finite element model, this measure is also affected by the estimation of the nonlinear stiffness coefficients, which may be inaccurate, see [28]. An intermediate validation of the basis can be performed by quantifying how well the basis represents the displacement field obtained from the finite element model. This task can be achieved through the representation error defined as

$$\varepsilon_{re} = \frac{\left\|\underline{u}_{basis} - \underline{u}_{FE}\right\|}{\left\|\underline{u}_{FE}\right\|} \times 100\%, \tag{8}$$

where $\underline{u}_{FE}$ is a nonlinear structural displacement predicted by the finite element software, and $\underline{u}_{basis}$ is its best approximation given the basis in the least squares sense, i.e.,

$$\underline{u}_{basis} = \Phi \cdot \underline{q}_{proj}, \tag{9}$$

where $\underline{q}_{proj}$ is the vector of projection coefficients of the finite element displacement on the basis. It should be noted that the representation error can be evaluated for the entire displacement field or any subset thereof. In fact, it will be convenient in the sequel to determine separately representation errors of the transverse and in plane displacement. For such computations, the projection is still performed overall displacements but the computation of ε_{re} is limited to the displacements chosen.

2 SYSTEMATIC PROCEDURE FOR DUAL MODES BASIS CONSTRUCTION

Since its introduction[3], the dual modes methodology has been used to form the ROM basis for 35 different structural models, see [3,4,7,11-13,15-17, 21-26] and references therein, ranging from simple structures to rather complex ones (e.g., the 9-bay panel of [13]. Over the years the methodology has slightly evolved and has been refined. This section presents an up-to-date, detailed nonlinear ROM basis construction procedure, starting with the selection of the linear modes and the determination of the associated duals.

As stated in the introduction, nonlinear ROMs are most valuable for dynamic analyses, multi-physics problems, and/or uncertainty quantification and propagation efforts owing to their overhead in nonlinear static solutions. The latter two situations may require specific considerations on the basis construction and thus are not covered here where the focus is on the dynamic response to a persistent loading in the frequency band [0, f_{cutoff}] where f_{cutoff} is a frequency low enough that (i) the natural frequencies of the linear system are reasonably well separated (this requirement is also applicable for linear ROMs) and (ii) the modes excited are primarily transverse.

As is well known and will be further shown in Section 3, the nonlinear response of structures evolves, and not just by a scaling, as the loading level increases. It is thus desirable to set a limit on what level of displacements the basis will be expected to represent well. If there is no problem specific limit, it is suggested here that the maximum displacement be set from first failure of the structure. Higher levels could be set if the desired application of the ROM is to crack initiation and propagation till ultimate collapse. First failure for clamped thin walled structures that we have considered occurs often when the peak displacement is of the order of a few (say 3-5) thickness.

With the above conditions, the construction of the ROM basis proceeds as follows.

(A) Selection of the Linear Modes

The selection of the relevant linear modes is the first step of the basis construction. At the very least, this set should include the linear modes that would be used in the linear case, i.e., those in the band [0, f_{cutoff}]. This set may not be sufficient however. Energy transfer between in-band and out-of-band modes is well known to exist and can occur in particular "statically" through modal interactions rooted in the nonlinear stiffness coefficients as well as "dynamically", e.g., internal resonances, see section 3 and [29] for ROM-based examples. The former interaction is detectable in particular in the construction of the duals, see step C below, but the latter is more difficult to predict a priori. A safer approach for the latter would then be to include modes in a broader band [0, $p\ f_{cutoff}$] where p is a factor larger than 1. Given the cubic nature of the nonlinearity, the value $p = 3$ is used in section 3. In this regard, note that "strong nonlinear

events", e.g., local buckling, global buckling, snap-through, may necessitate a finer mode selection to be well captured.

(B) Generation of Data for Dual Modes Determination

As discussed in section 2, the dual modes are extracted from static finite element solutions in which the loading is of the form of Eq. (7). In principle, all (non repeating) combinations of *i* and *j* should be considered, including *i* = *j*. Proceeding in this manner will lead to $O(N_t^2/2)$ combinations and sets of static solutions where N_t denotes the number of linear modes selected in step A above. For complex structures/large models, this number of combinations may be excessively large, especially assuming that some dual modes will be taken for each combination.

In seeking a reduction of this effort, it is noted that not all combinations are as important. From the derivation in [7], it is concluded that the combinations that involve the largest responding modes are those producing the most important dual modes. Assuming that such information is available or can be estimated, one could split the linear modes into three groups: group 1 of which all combinations are taken (i.e., "dominant modes"), group 2 which are considered in combination each with a group 1 mode, and group 3 which are not included in any combination.

In the past, the split between these 3 groups has been made based on the linear response and this has worked well except for the beam of [23] and the 9-bay panel of [13] in which a linear mode with very little linear response has a much larger one in the nonlinear case. Such cases could be detected from the set of nonlinear stiffness coefficients of the linear modes only which can already be identified. Such a detection is currently investigated. Another strategy is to check as the dynamic response is computed that the split of modes is indeed correct and to modify the basis if it is found that the assumed split is not appropriate.

In the above spirit, the example of section 3 will consider all modes in-band to belong to group 1 and those out-of-band to belong to group 3 based on the expectation that the in-band modes will contribute notably more than the out-of-band ones. Should an internal resonance involving an out-of-band mode be suspected, this mode should be included in group 1 (see discussion of [29]).

In closing this discussion, it is worthwhile to comment on the factor of 1/2 appearing in Eq. (7). As written, the linear responses induced by the forces of Eq. (7) are

$$\underline{u} = \pm\alpha_{ij,s}(\underline{\phi}_i + \underline{\phi}_j) \ / 2 \tag{10}$$

and thus these displacements involve both significantly (equally) the 2 modes. As time progresses, the ratio of the responses of modes *i* and *j* will vary and thus no fixed number is likely to characterize their relative importance. Assuming them equal, as in Eq. (10), is thus meant as inducing a representative interaction. In fact, an earlier version of Eq. (7) [7] used the finite element mass matrix instead of the stiffness one. This gives rise to static linear displacements

$$\underline{u} = \pm\frac{\alpha_{ij,s}}{2}\left[\frac{\underline{\phi}_i}{\omega_i^2} + \frac{\underline{\phi}_j}{\omega_j^2}\right] \tag{11}$$

which differ from Eq. (10) by the relative scaling of the two modes involved which involves the two linear natural frequencies ω_i^2 and ω_j^2. Very good bases were also constructed from the corresponding nonlinear static responses.

(C) Selection of the Dual Modes

The dual modes are constructed using the above nonlinear displacement data from each combination, one after another in a loop over all combinations. The default order of the

combinations in the loop is determined by sorting the summations of the squares of the natural frequencies of the two modes in each of the combinations, which is an indication of the combined stiffness of the two modes, from the smallest to the largest. The smaller the summation is, the larger the effect of that combination of two modes on the in plane deformation may be expected.

Overall, the dual modes will be selected as eigenvectors of POD analyses of the data generated in step B, each combination in turn, but not necessarily the eigenvectors with largest eigenvalues. Rather the necessary eigenvectors are those that lead to a good capturing of especially the in plane displacements which are significantly larger for nonlinear responses than they are for linear ones owing to the membrane stretching effect. In the past, see for example [7,13,21], this selection was performed based on a strain energy measure associated with each eigenvector based on the expectation that in plane motions are stiffer, typically much stiffer than their transverse components. Then, as many of the large strain POD eigenvectors would be taken for each combination as necessary to capture well each of the responses generated for that combination. A slightly different strategy is described below that effectively leads to the same dual mode selection but is more systematic. It relies on prescribed representation error thresholds for the transverse and in plane displacements, $\varepsilon_{re,thr}^{T}$ and $\varepsilon_{re,thr}^{I}$. In our past investigations, as well as in section 3, these thresholds were set to 1%.

Then, the dual construction is divided in the following sub-steps.

(a) The first sub-step focuses on confirming or completing the linear mode basis. At the beginning of the loop, the basis consists of linear modes only. Then, the response data for each combination is projected on the current set of linear modes and the corresponding representation errors of the transverse displacements, ε_{re}^{T} are computed. If these errors are below the threshold $\varepsilon_{re,thr}^{T}$, then no action is taken. If one or more is above this threshold, then two options are possible. The first one is to add more linear modes to be basis, specifically those that are most present in the transverse components of $\underline{u}_{basis} - \underline{u}_{FE}$. The second option is to enrich the basis during step (c).

(b) For each combination in the loop starting with the first, the set of nonlinear displacements are made orthogonal to the set of linear modes, including those obtained in sub-step (a) if applicable. Then, a proper orthogonal decomposition (POD) of this set of displacement residuals is carried out and step (c) follows.

(c) For all quantities of interest, e.g., total displacement, individual displacement components, the representation error of the set of nonlinear responses for the current combination by the current basis - including transverse modes and dual modes constructed from previous combinations if any - is computed. If any of these errors is larger than its pre-defined threshold, then one or more POD eigenvector will be added to the current basis. To select which one is most appropriate, each POD eigenvector is added to the current basis individually and the representation error of the set of displacements by this temporary new basis is computed. The POD eigenvector which gives the largest reduction of representation error is taken as a dual mode and added to the current basis, which is then updated. This is repeated for the current combination with the rest of the POD eigenvectors until all representation errors are below their respective thresholds. Note that if a threshold is set for the representation error of the transverse displacement, adding appropriate POD eigenvectors to satisfy this threshold is the alternate option to the addition of linear modes discussed in sub-step (a). A comparison of these two options for a beam example is presented in Section 3.

The basis is updated, then sub-steps (b) and (c) are carried out for the next combination. After going through all the combinations, the construction of the basis is finished, and the ROM basis is obtained.

3 BEAM EXAMPLE

3.1 ROM of a clamped-clamped beam

An isotropic straight beam is used to exemplify the systematic procedure described above for the basis construction. Note that the flat character of the beam and its uniform properties through the thickness imply that transverse and in plane set of modes are decoupled from each other which will allow sharper conclusions to be drawn. The beam is of rectangular cross section and clamped at both ends, and its geometric and material properties are listed in Table 1.

Properties	Value
Length	0.2286 m
Width	1.2696e-2 m
Thickness	7.8765e-4 m
Density	7867.3 kg/m^3
Young's modulus	2.05e+11 Pa
Shear modulus	8.00e+10 Pa

Table 1: Properties of the clamped-clamped straight beam.

A finite element model of this beam was constructed in Nastran using 40 beam ("CBEAM") elements. The beam span is along the x-direction, and the transverse direction is the z-direction which is along the thickness of the beam.

For the basis construction, it is assumed that the cut-off frequency of the loading is f_{cutoff} = 500 Hz. For this clamped-clamped beam, the nonlinearity can be measured by its maximum transverse displacement in terms of the beam thickness, h, and the target for the basis is to represent the nonlinear displacements up to $u_{max} = 3h$, which is the failure level for the load defined below, with an error less than or equal to 1% in both transverse and in plane directions.

Following the proposed procedure, the six linear transverse modes within the band of $[0,3\,f_{cutoff}]$ were taken as the initial transverse modes of the basis. Their natural frequencies are listed in Table 2.

Mode	1	2	3	4	5	6
Natural frequency (Hz)	79.1	218.0	427.3	706.2	1054.8	1472.9

Table 2: Properties of the clamped-clamped straight beam.

For the dual modes, the combinations of the first three transverse modes in the excitation band are considered (i.e., they are part of group 1) while the out-of-band modes are not considered at all (they form group 3). Thus, the number of combinations is 6. For each combination, a set of 14 pairs (positive and negative) of forces are generated by Eq. (7), and the corresponding nonlinear static displacements are computed with Nastran. The values of the coefficients $\alpha_{ij,s}$ were selected so that the corresponding displacement fields span the domain $u_{max} \in [-3h,-0.1h] \cup [0.1h,3h]$ as uniformly as possible. The dual modes were constructed by

proceeding through the 6 combinations in the order stated in section 2, i.e., [1-1, 1-2, 2-2, 1-3, 2-3, 3-3], where the numbers are the indices of the transverse modes in Table 2.

From step (1) of the procedure, it is found that the six linear transverse modes are not enough to satisfy the 1% criterion for the representation error in the transverse direction, and the two options as described in sub-steps (Ca) and (Cc) are implemented. With the option of adding more linear transverse modes (Ca), a 20-mode basis is constructed which consists of the initial 6 linear modes, additional 4 linear modes, and 10 duals (Basis 10L10D). With the option of adding POD eigenvectors (Cc), a 18-mode basis is constructed which consists of the initial 6 linear modes and 12 dual modes (Basis 6L12D) where two of the dual modes are accounting for the transverse error. Owing to the decoupling of in plane and transverse basis functions, the 10 in plane duals of the two bases are essentially the same.

Two more bases will be considered which are reductions of ones above. In the first, the 2 transverse dual modes of the 6L12D basis or the 4 additional linear modes of the 10L10D are moved leading to a 6L10D basis. For the final basis, the 3 out-of-band linear modes are removed resulting in a 3L10D basis.

3.2 Load case for basis assessment and ROM validation

The aerodynamic pressure distribution measured on a panel [30], as shown in Fig. 1(a), is mapped on the beam yielding the normalized pressure distribution of Fig. 1(b) and (1c). This spatial distribution was multiplied by a bandlimited white noise of cut-off frequency of 500 Hz scaled to different sound pressure levels to produce the dynamic loading to assess the adequacy of the basis and to validate the ROM predictions.

The modal forces along the six transverse modes selected corresponding to this load are listed in Table 3. All the modes have non-zero modal forces; the first mode has the largest value but modes (in decreasing order) 3, 5, and 2 have large/non-negligible values as well.

Mode	**1**	**2**	**3**	**4**	**5**	**6**
Modal force	127.31	-20.31	-53.08	-3.37	31.16	-0.84

Table 3: Modal forces of the transverse modes.

3.3 Basis assessment

Nonlinear static and dynamic response data was generated from Nastran with the above loading for the assessment of the four bases constructed. For the static data, the force was scaled at 14 different levels to achieve maximum displacements from very small to 4.3 thicknesses. For the dynamic data, three overall sound pressure levels (OASPLs) of 110dB, 125dB, and 130dB, were considered and 5-second response time histories were obtained at the time step of 5×10^{-5} second for a total of 100,000 time steps. The standard deviation of the steady-state response of transverse displacement at the center point of the beam, where the maximum displacement is observed, is about 0.50, 0.88, and 1.85 thicknesses for the three load levels, with corresponding maximum values of 1.34, 3.57, and 5.30 thicknesses, respectively.

For the assessment of the two constructed bases, the representation error of the transverse (ε_{re}^{T}) and in plane (ε_{re}^{I}) displacement components were computed using the static and the dynamic response data.

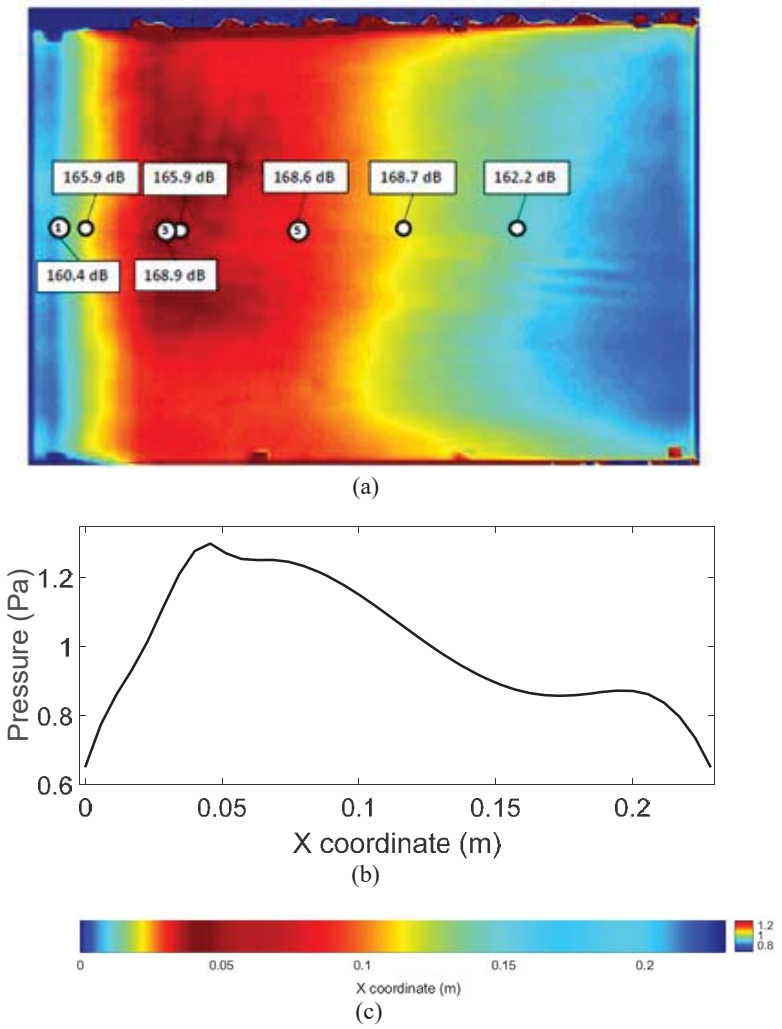

Figure 1. Spatial distribution of the force on the beam, mapped from experimental measurement of aerodynamic pressure distribution on a flexible panel. (a) measured pressure distribution on a panel [24]); (b), (c) mapped force distribution on the beam.

In addition, for the static data, the error in recovering the first eigenvalue of the tangent stiffness matrix of the beam at a deformed position is also computed as

$$\varepsilon^{K_t} = \frac{\left|\lambda_{basis}^{K_t} - \lambda_{FE}^{K_t}\right|}{\lambda_{FE}^{K_t}} \times 100\%, \tag{12}$$

where λ_{FE}^{Kt} and λ_{basis}^{Kt} are the first eigenvalues of the tangent stiffness matrix of the finite element model (directly computed in Nastran) and that of the basis which is obtained by projecting the finite element tangent stiffness matrix on the basis, respectively.

The values of the errors ε_{re}^{T}, ε_{re}^{I}, and ε^{K_t} are shown in Table 4 for all 4 bases described in section 3.1 for static displacement levels of 2.0, 3.0, and 4.1 thicknesses. For each basis, two reduced bases are generated, the first one removing the dual modes or the higher-order linear modes and the second one further removing the three linear modes out of the excitation band

which are common to the two bases. The three error for the reduced bases is then computed and listed in Table 4 as well.

From this data, it is seen that the two "full" bases, 6L12D and 10L10D, both have very good (small) representation errors, even at the displacement level of 4.1 thicknesses which is beyond the 3 thicknesses used as maximum displacement for the basis construction. All errors are below 1%, consistently with the 1% threshold set for the basis construction. This suggests the displacement data used in the basis construction is sufficient.

Consider next the 6L10D basis which has the same in plane basis as the 6L12D and 10L10D models Accordingly, it has the same in plane error ε_{re}^{I} but higher transverse representation and eigenvalue errors exceeding in fact the 1% threshold level for the highest loading. Reducing the number of linear modes to 3, i.e., the 3L10D basis yields further increases in the transverse and eigenvalue errors. This finding is not surprising given the notable modal force on linear mode 5.

	ε_{re}^{T}			ε_{re}^{I}			ε^{Kt}		
$u_{\max}$	*2.0h*	*3.0h*	*4.1h*	*2.0h*	*3.0h*	*4.1h*	*2.0h*	*3.0h*	*4.1h*
6L12D	0.04%	0.05%	0.02%	0.03%	0.04%	0.04%	0.010%	0.001%	0.031%
10L10D	0.03%	0.08%	0.15%	0.03%	0.04%	0.04%	0.059%	0.215%	0.485%
6L10D	0.38%	0.79%	1.27%	0.03%	0.04%	0.04%	0.676%	0.560%	2.315%
3L10D	1.39%	2.51%	3.55%	0.03%	0.04%	0.04%	1.932%	3.345%	4.057%

Table 4: Representation errors of the nonlinear static displacements at various levels by the various bases

Listed in Tables 5 and 6 are listed the comparison of the means and standard deviations of the transverse and in plane representation errors computed from the dynamic data. From this standpoint, both of the full bases perform very well, except for the standard deviation of the in plane displacement at 130dB. However, it should be noted that at this load level the maximum displacement is 5.30 thicknesses, far above the level which the constructed bases are expected to perform well.

The reduced bases have similar behavior to the static data which is actually surprising because one would expect that the out-of-band modes, be it modes 4, 5, 6, or the extra 4 linear modes in the 10L10D model or finally the 2 transverse duals of the 6L12D, would have only a very small effect on the response which is dominated by its in-band behavior. This finding already suggests that the out-of-band modes will play an important role in the dynamic predictions discussed in the ensuing section.

3.4 ROM validations

The stiffness coefficients of the two full bases (6L12D and 10L10D) were identified using the multi-level displacement-$K^{(T)}$ method [26]. This effort also provides the stiffness coefficients of the 6L10D and 3L10D by eliminating the coefficients relating to deleted modes. The static and dynamic prediction from these four ROMs were then compared to the corresponding Nastran predictions.

The ROM-Nastran comparisons for the static case are shown in Figs 2 and 3. Shown in Fig. 2 are the transverse displacements at the center of the panel and the in plane displacements at the left and right quarter points. Moreover, shown in Fig. 3 are the entire displacement field at three load levels. Clearly, the matching between the 6L12D or 10L10D ROM predictions and their Nastran counterpart is excellent.

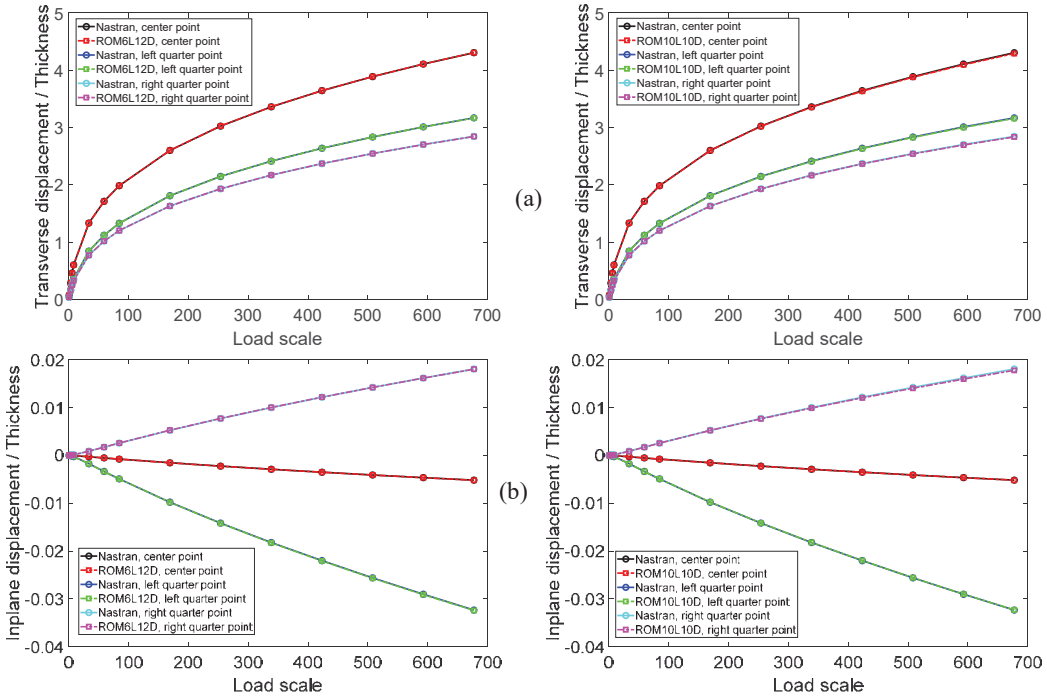

Figure 2. Static displacements at the center and the two quarter points as function of load scale. ROM6L12D (left column), ROM10L10D (right column) vs. Nastran. (a) Transverse and (b) in plane displacement.

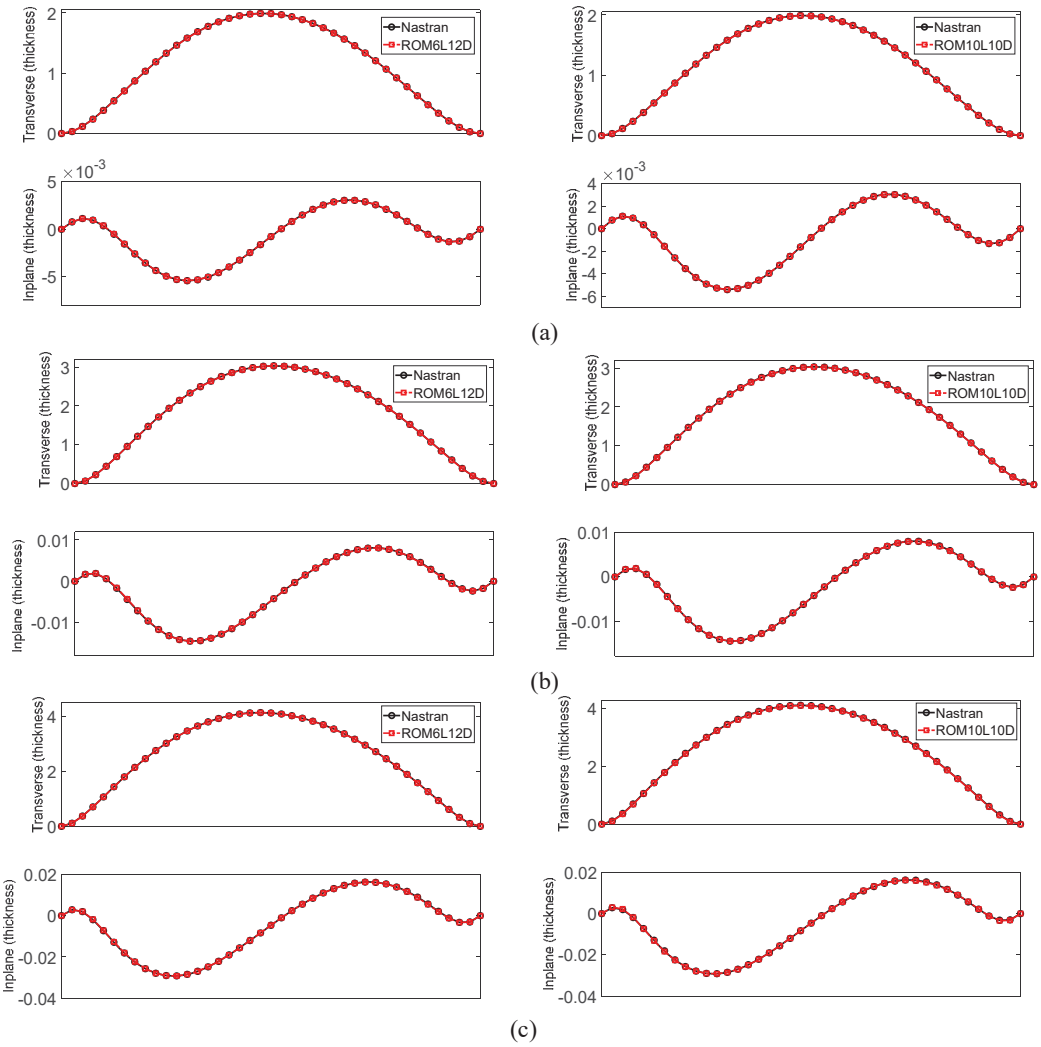

Figure 3. Static validation: whole-field displacements at three displacement levels. ROM6L12D (left column), ROM10L10D (right column) versus Nastran. (a) Displacement level of 2 thicknesses; (b) Displacement level of 3 thicknesses; and (c) Displacement level of 4 thicknesses.

The validation of the ROMs in the dynamic case started with an assessment of the bases to represent the Nastran data. This was done by projecting this data at each time step on the 6L12D and 10L10D bases at the three OASPLs, then summing the modal contributions as in Eq. (9) to reconstruct the full displacement fields. As shown in Figs 4-6, the power spectral densities (PSDs) of the reconstructed displacements labeled as "Basis" in these figures matched nearly identically their Nastran counterparts. These results demonstrate that the bases are very good.

While computing the ROM dynamic responses at the three different sound pressure levels, it was observed that these predictions are sensitive to the identified nonlinear stiffness coefficients, especially those which are known to be usually poorly identified (see [28] for discussion). To minimize, but not eliminate, this sensitivity the ROMs were "cleaned" [28] zeroing out most of the poorly identified coefficients, many of which are expected to be zero by symmetry. This operation allows a good comparison between different bases and, as will be seen below, still leads to an excellent match with the Nastran predictions.

The dynamic responses of the four ROMs were then computed at the three OASPLs of

110dB, 125dB, and 130dB using a Newmark solver with the same time step as Nastran, initially set to 5 10^{-5}s. The corresponding power spectral densities (PSDs) of the transverse displacement at the center point and the in plane displacement at the left quarter point for both the 6L12D and 10L10D bases are first compared to those of the Nastran results in Figs. 4-6.

It is seen that these ROM predictions match their Nastran counterparts very well at the 110dB and 125dB levels but differences are clearly visible at the 130dB level. This trend seems consistent with the representation errors of Tables 5 and 6 but the differences in spectra, e.g., on Fig. 6 appear much more significant that the representation errors which are still barely larger

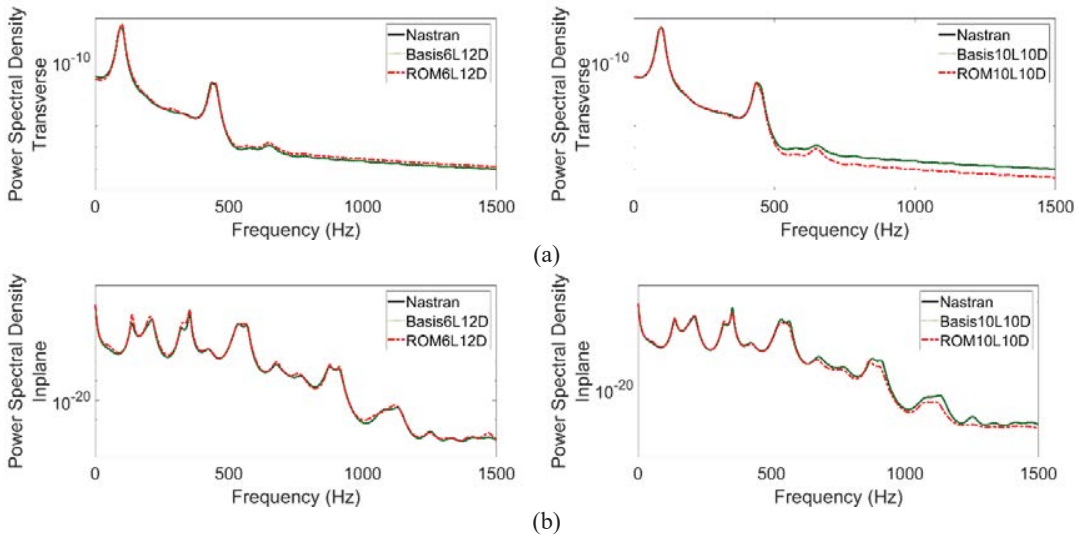

Figure 4. Dynamic validation: power spectral densities (PSD) of displacement at 110dB OASPL (maximum standard deviation of transverse displacement is 0.5 thicknesses). Cleaned ROM6L12D (left column) and ROM10L10D (right column) versus Nastran. (a) Transverse displacement at center point; and (b) In plane displacement at left quarter point.

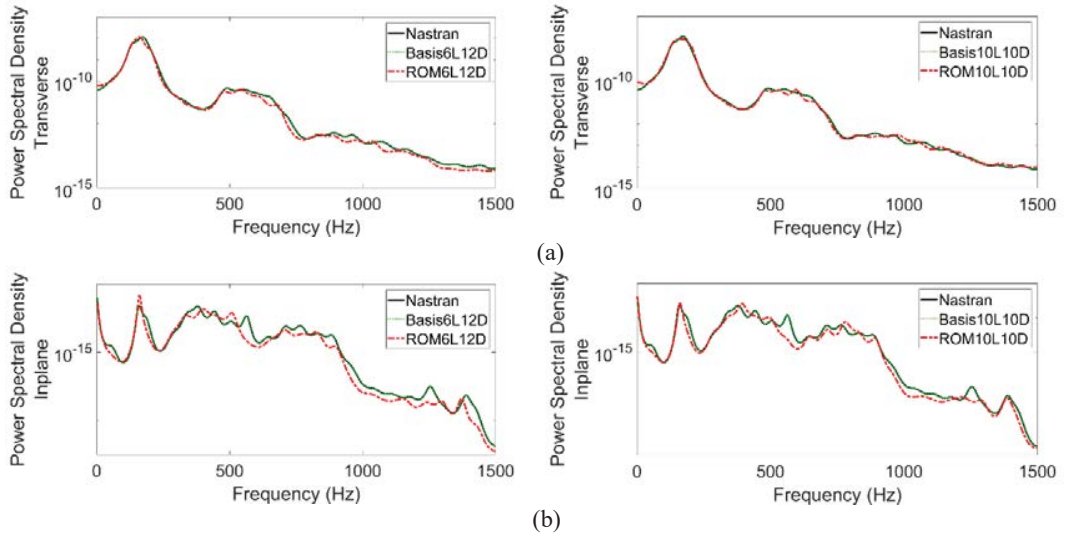

Figure 5. Dynamic validation: power spectral density (PSD) of displacement. Load level 125dB (maximum standard deviation of transverse displacement is 1.5 thicknesses). Cleaned ROM6L12D (left column) and ROM10L10D (right column) versus Nastran. (a) Transverse displacement at center point; and (b) In plane displacement at left quarter point.

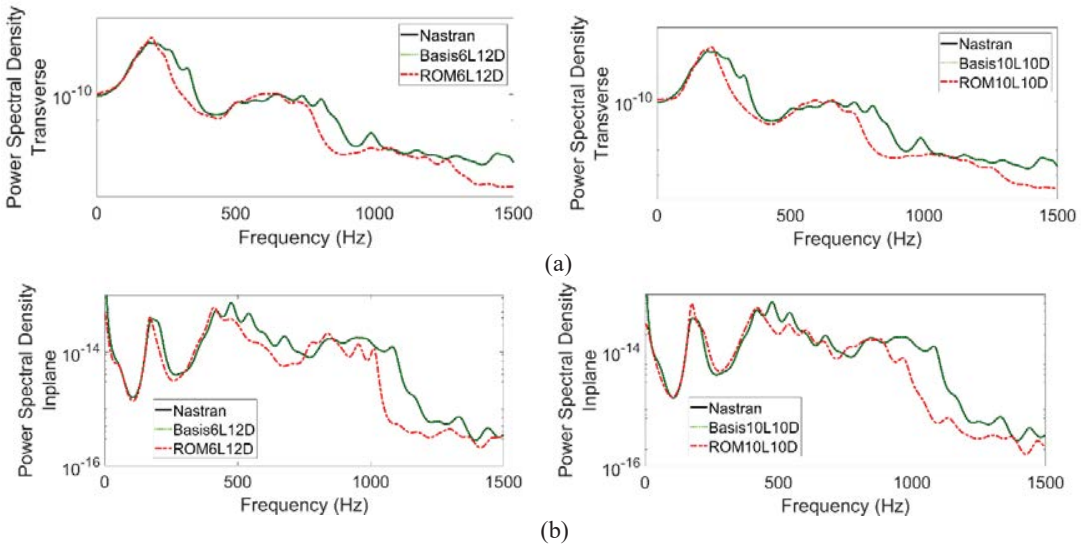

Figure 6. Dynamic validation: power spectral density (PSD) of displacement. Load level 130dB (maximum standard deviation of transverse displacement is 1.9 thicknesses). Cleaned ROM6L12D (left column) and ROM10L10D (right column) versus Nastran. (a) Transverse displacement at center point; and (b) In plane displacement at left quarter point.

than the 1% threshold. An investigation of the 130dB response was carried out and it was found that the time step of $5\ 10^{-5}$s. is not sufficiently small to capture the in plane dynamics. Accordingly, it was reduced to $1\ 10^{-5}$s for both Nastran and ROMs and shown in Fig. 7 are the resulting power spectral densities of the displacements. An excellent matching is observed for both ROMs and in both directions

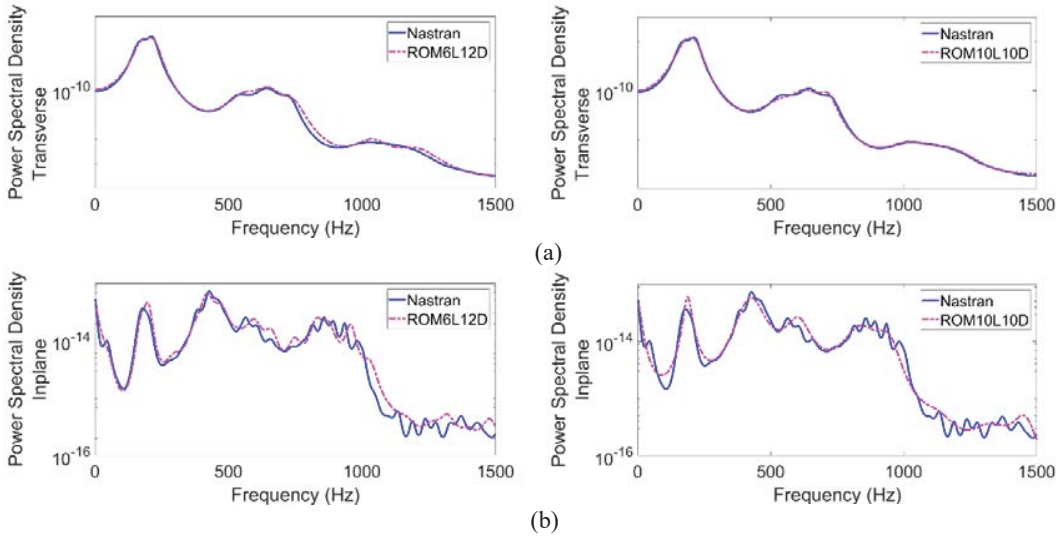

Figure 7. Dynamic validation: power spectral density (PSD) of displacement computed at a smaller time step then resampled back to the original. Load level 130dB (maximum standard deviation of transverse displacement is 1.9 thicknesses). Cleaned ROM6L12D (left column) and ROM10L10D (right column) versus Nastran. (a) Transverse displacement at center point; and (b) In plane displacement at left quarter point.

The final aspect of the present effort focused on assessing the effect of including transverse / linear modes whose natural frequencies are out of the excitation band. To this end, starting from the ROM6L12D the two dual modes which are basically transverse modes were first removed, leading to a ROM6L10D, then three linear modes were also removed, giving rise to a ROM3L10D. Note that all the modes removed have natural frequencies out of the excitation band. Then, the predictions of these two reduced ROMs (cleaned similarly to ROM6L12D) are shown in Figs 8-10 at the same three sound pressure levels of 110dB, 125dB, and 130dB and with time steps of 5 10^{-5}s at the lowest two levels and 1 10^{-5}s at the highest one. While the matching between the ROM and Nastran predictions is still very good at the 110dB level, some differences become visible at 125dB but the predictions can still be considered good. The comparison worsens further at the 130dB level in both transverse and in plane directions, the latter particularly. It is not very easy to assess which of the two models is better. Regardless, the key conclusion drawn from these results is that out-of-band transverse modes play an increasingly important role as the excitation level is increased. Thus, the inclusion of some of these modes in the model is necessary for the accurate prediction of the response especially at high response levels.

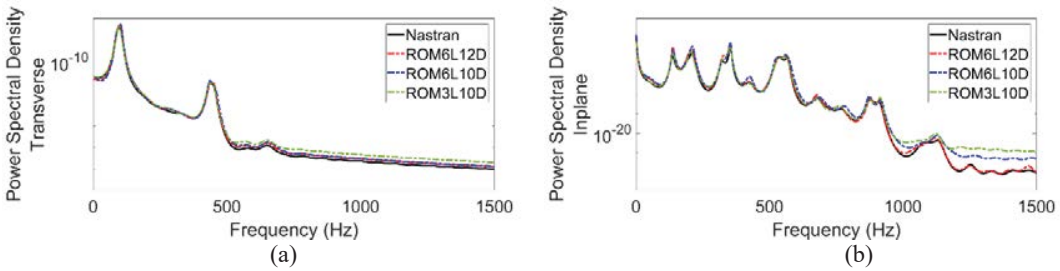

Figure 8. Comparison of the power spectral density (PSD) of displacement predicted by ROM6L12D, ROM6L10D and ROM3L10D, all cleaned, against Nastran. Load level 110dB (maximum standard deviation of transverse displacement is 0.5 thicknesses). (a) Transverse displacement at center point; and (b) In plane displacement at left quarter point.

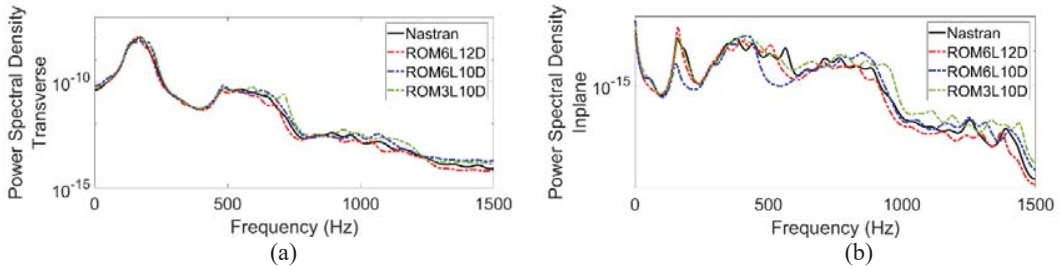

Figure 9. Comparison of the power spectral density (PSD) of displacement predicted by ROM6L12D, ROM6L10D and ROM3L10D, all cleaned, against Nastran. Load level 125dB (maximum standard deviation of transverse displacement is 1.5 thicknesses). (a) Transverse displacement at center point; and (b) In plane displacement at left quarter point.

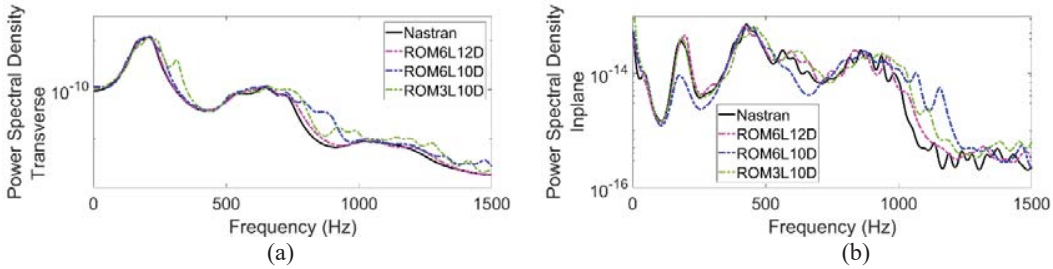

Figure 10. Comparison of the power spectral density (PSD) of displacement predicted by ROM6L12D, ROM6L10D and ROM3L10D, all cleaned, against Nastran. The same smaller time step resampled back to the original as in Figure 7 is used. Load level 130dB (maximum standard deviation of transverse displacement is 1.9 thicknesses). (a) Transverse displacement at center point; and (b) In plane displacement at left quarter point.

4 CONCLUSIONS

A systematic strategy is developed for the construction of a "general" basis for reduced order models of the nonlinear geometric vibration of thin-walled structures. This strategy is an extension/more detailed version of the existing one where some linear modes are selected to represent large transverse displacements and the associated "dual" modes are derived to account for the "in plane" membrane stretching deformations due to the nonlinear geometric effects. Central to this basis construction process is the selection of linear modes of the basis according to the cut-off frequency, f_{cutoff}, of the loading, and the derivation of the dual modes using static nonlinear responses related to the selected linear modes.

Formalizing some recent, limited observations, it is proposed here that the set of linear modes selected at the start of the basis construction includes not only those in the band of excitation but also some out-of-band modes ones. Tentatively, it is suggested that the linear modes selected span the band $[0,3\, f_{cutoff}]$. As in prior investigations, dual modes are added to this basis which are derived from proper orthogonal decompositions (POD) of residuals of projection of specific static nonlinear finite element responses on the linear basis. The process by which POD eigenvectors are selected as dual modes is however fully formalized and is based on the representation error of the data generated by the current basis. The step-by-step implementation procedure of the proposed strategy is presented.

A clamped-clamped straight beam is used to exemplify the approach and two bases are constructed following the implementation procedure. A distributed force mapped from a measured aerodynamic pressure distribution on a panel is used as a good example of loading. For this load, nonlinear static and dynamic response data are obtained from the commercial finite element software Nastran and used to assess the constructed bases. It is shown that the proposed procedure is appropriate, and the constructed bases are excellent in terms of representation errors.

The nonlinear stiffness coefficients of these bases are next identified to permit predictions and their comparisons with the corresponding static and dynamic finite element data. The predictions from the two bases are found to be essentially identical but do not match well the Nastran data at the highest dynamic load. It is argued that these differences are in fact rooted in errors in the identified ROM coefficients, not in shortcomings of the basis. Finally, two reduced bases are obtained from the previous two by removing the out-of-band linear modes/transverse basis functions. It is found that the predictions from these bases is still very good at low response levels but worsens as the peak displacements increase clearly demonstrating the importance of

including out-of-band linear modes/transverse basis functions in sharp contrast with linear problems.

Keywords: nonlinear vibrations, fractional derivative, viscoelastic foundation, standard linear solid model

Abstract. *The interaction between a loaded plate and the soil foundation is a typical problem in civil engineering. To solve the plate-foundation interaction problem, different viscoelastic models of foundations are used, among them fractional derivative Winkler-type or Pasternak-type models [1], since during last decades the fractional calculus plays an important role in dynamic problems of structural mechanics [2]. In the present paper, the dynamic response of a rectangular simply supported nonlinear plate resting on a viscoelastic Winkler-type foundation, the damping features of which are described by the fractional derivative standard linear solid model, is studied using the fractional derivative expansion method [3,4].*

1 INTRODUCTION

Over the last few decades the problems of the interaction between various building structures and soil foundation have been of great interest among researchers. In order to calculate the reaction force of the foundation in dynamic problems, several models were proposed. The first attempt to describe the reaction of foundation was the Winkler model, according to which the foundation is considered to be elastic. The main disadvantage of a linear elastic model is its inconsistency in the representation of the viscoelastic behavior of materials. In this regard, a viscoelastic element was added to the Winkler model. There are many combinations of elastic and viscous elements connected in series or in parallel, therefore, based on the Winkler elastic model, several viscoelastic models of foundation were proposed, such as the Kelvin-Voigt, Maxwell, Zener, Poynting-Thomson and Burgers models, which are reviewed in [5].

Later, the Winkler model was developed and supplemented by several scientists, such as Filonenko-Borodich (1940), Hetényi (1950), Pasternak (1954), Vlasov (1966) and Reissner (1958), as a result of which the so-called two-parameter foundation models appeared [6]. Two-parameter models are known as models, wherein the top layer connects the elements of foundation to each other, therefore, in addition to the vertical component of the foundation reaction force, shear stresses are also taken into account. The Pasternak model was also generalized for a viscoelastic case [5,6]. The dynamic behavior of plates on a viscoelastic foundation was considered in [7] and [8], where the response of a viscoelastic plate and thick plate on viscoelastic foundation was studied, respectively.

Nowadays, fractional derivative Winkler-type or Pasternak-type models of viscoelastic foundations are becoming increasingly widespread [1, 9-14], since during last decades the fractional calculus plays an important role in dynamic problems of structural mechanics [2]. Thus, the Kelvin – Voigt fractional model is used in [9] to describe the time-dependent behavior of the soil foundation under the vertical load. The behavior of a rectangular viscoelastic plate on a viscoelastic foundation, which is described by a two-parameter model with a fractional derivative, is analyzed in [10]. The interaction between a rectangular linear elastic plate and the viscoelastic foundation defined by the fractional derivative standard linear solid model with four parameters, which is the combination the Kelvin-Voigt element and a spring connected in series, was studied in [11]. A rectangular plate subjected to a moving load was considered in [12], in so doing the viscoelastic properties of the foundation were defined by the Winkler-type model. Graphs of the stress on the plate surfaces were numerically constructed for the cases of free (after the termination of the action of a movable load on the plate) and forced vibrations. The fractional derivative Kelvin-Voigt model for a Pasternak-type viscoelastic foundation was utilized in [13], and the equations of motion were derived for an elastic and viscoelastic rectangular loaded plate. Forced vibrations of completely free rectangular orthotropic nanoplate were studied in [14], where the viscoelastic foundation was described via the Kelvin-Voigt model.

In the present paper, the dynamic response of a rectangular simply supported nonlinear plate resting on a viscoelastic Winkler-type foundation, the damping features of which are described by the fractional derivative standard linear solid model, is studied for the case of the one-to-one internal resonance using the fractional derivative expansion method [3,4].

2 PROBLEM FORMULATION

Let us consider nonlinear vibrations of a simply supported elastic plate in a viscoelastic medium, based on a viscoelastic foundation (Fig.1), the dynamic response of which is described by the von Karman equation in terms of the plate's lateral deflection $w = w(x, y, t)$ and the Airy's stress function ϕ:

$$D\nabla^4 w+\rho h\frac{\partial^2 w}{\partial t^2}-\frac{\partial^2 w}{\partial x^2}\frac{\partial^2 \phi}{\partial y^2}-\frac{\partial^2 w}{\partial y^2}\frac{\partial^2 \phi}{\partial x^2}+2\frac{\partial^2 w}{\partial x\partial y}\frac{\partial^2 \phi}{\partial x\partial y}=q-F_1-F_2, \tag{1}$$

$$\nabla^4\phi=Eh\left[\left(\frac{\partial w}{\partial x\partial y}\right)^2-\frac{\partial^2 w}{\partial x^2}\frac{\partial^2 w}{\partial y^2}\right], \tag{2}$$

where $\nabla^4=\partial^4/\partial x^4+2\partial^4/\partial x^2\partial y^2+\partial^4/\partial y^4$ is the biharmonic operator, q is the external load, $D=Eh^3/12(1-\nu^2)$ is the plate's cylindrical rigidity, E and ν are the elastic modulus and Poisson's ratio of the plate's material, respectively, h and ρ are its thickness and density, t is the time, $F_2=\tilde{\lambda}w$ is the reaction force of the viscoelastic foundation, $F_1=æ_1\tau_1^{\gamma_1}D_{0+}^{\gamma_1}w$ is the damping force of the viscoelastic medium possessing the retardation time τ_1 and damping coefficient $æ_1$, which is modeled by the viscoelastic Kelvin-Voigt model with the Riemann-Liouville derivative $D_{0+}^{\gamma_1}$ of the fractional order γ_1 $(0<\gamma_1\le 1)$ [2,15]:

$$D_{0+}^{\gamma}x(t)=\frac{d}{dt}\int_0^t\frac{x(t-t')dt'}{\Gamma(1-\gamma)t'^{\gamma}}\quad(0<\gamma=\gamma_1\le 1), \tag{3}$$

and $\Gamma(1-\gamma)$ is the Gamma function.

Let us assume, following [16], that the compliance operator of a viscoelastic foundation is described by the standard linear solid model with the Riemann-Liouville fractional derivative D_{0+}^{γ} (3) when $\gamma=\gamma_2$:

$$\tilde{\lambda}=\lambda_\infty\left[1-æ_2\nu_\varepsilon\frac{1}{1+\tau_2^{\gamma}D_{0+}^{\gamma_2}}\right], \tag{4}$$

where λ_∞ is the coefficient of instantaneous compliance of the foundation, $\nu_\varepsilon=\Delta\lambda\lambda_\infty^{-1}$, $\Delta\lambda=\lambda_\infty-\lambda_0$ is the defect of the compliance, i.e., the value characterizing the decrease in the compliance operator from its non-relaxed value to its relaxed value, and τ_2 and $æ_2$ are the retardation time and damping coefficient of the viscoelastic foundation, respectively.

Considering a simply supported plate, the following boundary conditions should be added to the set of equations (1) and (2) at each edge:

$$\text{at}\quad x=0\ \text{and}\ a,\quad w=\frac{\partial^2 w}{\partial x^2}=0;\qquad \text{at}\ y=0\ \text{and}\ b,\quad w=\frac{\partial^2 w}{\partial y^2}=0. \tag{5}$$

In order to identify the possibility of the occurrence of the internal resonance during nonlinear vibrations of a plate based on a viscoelastic foundation and to carry out its subsequent analysis, suppose that only two natural modes of vibrations with numbers m_1n_1 и m_2n_2 are excited. Then the deflection of the plate could be represented in the following form:

$$\begin{aligned}w(x,y,t)&=x_1(t)\sin\frac{\pi m_1 x}{a}\sin\frac{\pi n_1 y}{b}+x_2(t)\sin\frac{\pi m_2 x}{a}\sin\frac{\pi n_2 y}{b}\\&=x_1(t)W_{m_1n_1}(x,y)+x_2(t)W_{m_2n_2}(x,y),\end{aligned} \tag{6}$$

where $x_i(t)$ $(i=1,2)$ are generalized displacements, and $W_{m_in_i}(x,y)$ are the eigen functions.

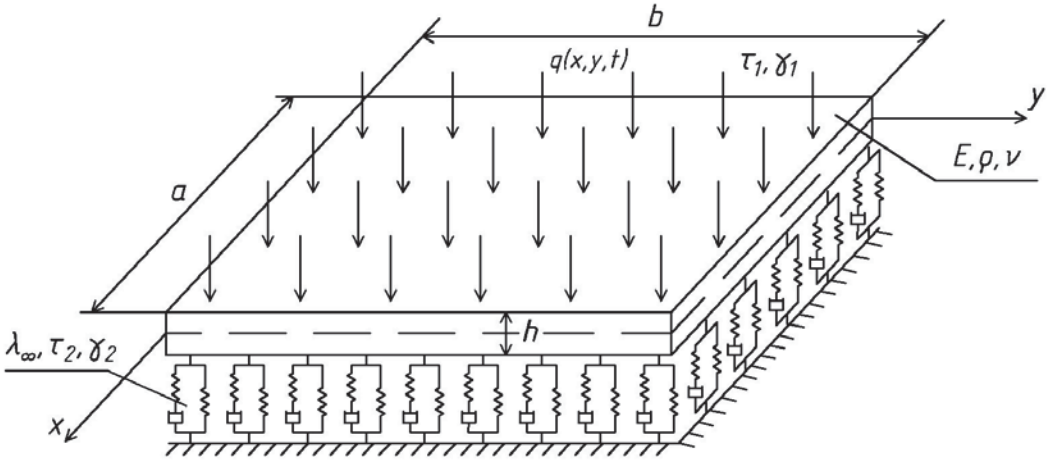

Figure 1: Plate on a viscoelastic foundation modelled by the fractional derivative standard linear solid model

Substituting the proposed solution (6) in (2), taking into account the boundary conditions (5) and integrating with account for the orthogonality conditions of sines, we obtain the stress function in the following form:

$$\begin{aligned}\phi(x,y,t) &= \frac{1}{32\xi^2}\left(\frac{n_1^2}{m_1^2}\cos\frac{2\pi m_1 x}{a}+\xi^4\frac{m_1^2}{n_1^2}\cos\frac{2\pi n_1 y}{b}\right)x_1(t)^2\\ &+\frac{1}{32\xi^2}\left(\frac{n_2^2}{m_2^2}\cos\frac{2\pi m_2 x}{a}+\xi^4\frac{m_2^2}{n_2^2}\cos\frac{2\pi n_2 y}{b}\right)x_2(t)^2\\ &+\frac{1}{4}\left[\left(B^2\cos\frac{\pi(m_1+m_2)x}{a}\cos\frac{\pi(n_1-n_2)y}{b}\right.\right.\\ &\left.+C^2\cos\frac{\pi(m_1-m_2)x}{a}\cos\frac{\pi(n_1+n_2)y}{b}\right)\beta_1^2\\ &-\left(A^2\cos\frac{\pi(m_1+m_2)x}{a}\cos\frac{\pi(n_1+n_2)y}{b}\right.\\ &\left.\left.+D^2\cos\frac{\pi(m_1-m_2)x}{a}\cos\frac{\pi(n_1-n_2)y}{b}\right)\beta_2^2\right]x_1(t)x_2(t),\end{aligned} \tag{7}$$

where $\xi=\frac{b}{a}$, $\beta_1=(m_1n_2+m_2n_1)$, $\beta_2=(m_1n_2-m_2n_1)$,

$$A^2=\frac{\xi^2}{\left[(m_1+m_2)^2\xi^2+(n_1+n_2)^2\right]^2},\qquad B^2=\frac{\xi^2}{\left[(m_1+m_2)^2\xi^2+(n_1-n_2)^2\right]^2},$$

$$C^2=\frac{\xi^2}{\left[(m_1-m_2)^2\xi^2+(n_1+n_2)^2\right]^2},\qquad D^2=\frac{\xi^2}{\left[(m_1-m_2)^2\xi^2+(n_1-n_2)^2\right]^2}.$$

Substituting the assumed two-term expansion for the deflection function of the plate (6) and the stress function (7) in the equation of motion of the plate (1) resting on the viscoelastic

foundation yields the following set of nonlinear differential equations with respect to the generalized displacements:

$$\ddot{x}_1 + \Omega_1^2 x_1 + \frac{\lambda_\infty}{\rho h}\left[1 - æ_2 \nu_\varepsilon \, э_\gamma^* (\tau_2^{\gamma_2})\right] x_1 + \alpha_1 x_1^3 + \alpha_2 x_1 x_2^2 + \frac{æ_1 \tau_1^{\gamma_1}}{\rho h} D_{0+}^{\gamma_1} x_1 = P_1(t), \tag{8}$$

$$\ddot{x}_2 + \Omega_2^2 x_2 + \frac{\lambda_\infty}{\rho h}\left[1 - æ_2 \nu_\varepsilon \, э_\gamma^* (\tau_2^{\gamma_2})\right] x_2 + \alpha_3 x_2^3 + \alpha_4 x_2 x_1^2 + \frac{æ_1 \tau_1^{\gamma_1}}{\rho h} D_{0+}^{\gamma_1} x_2 = P_2(t), \tag{9}$$

where $P_i(t) = \dfrac{\int_0^a \int_0^b q(x,y,t) W_{m_i n_i}(x,y)\, dxdy}{\rho h \int_0^a \int_0^b \left[W_{m_i n_i}(x,y)\right]^2 dxdy}$, α_i are the coefficients depending on the vibration mode numbers which are given in Appendix, Ω_i^2 are the natural frequencies of the linear vibration of the plate defined as

$$\Omega_i^2 = \frac{Eh^2}{12\rho(1-\nu^2)} \nabla^4 W_{m_i n_i}(x,y) = \frac{E\pi^4 h^2}{12\rho(1-\nu^2)b^4}\left(\xi^2 m_i^2 + n_i^2\right)^2, \tag{10}$$

and $э_\gamma^* (\tau_2^{\gamma_2})$ is the Rabotnov dimensionless fractional operator defined as follows [17]

$$э_\gamma^* (\tau_2^{\gamma_2}) = \frac{1}{1 + \tau_2^{\gamma_2} D_{0+}^{\gamma_2}}. \tag{11}$$

Note that in the case of free damped vibrations $P_i(t) = 0$.

3 METHOD OF SOLUTION

In order to solve a set of two nonlinear equations, (8) и (9), the method of multiple time scales [18,19] could be utilized assuming damping coefficients $æ_i$ to be small values of order of ε^2

$$æ_i = \varepsilon^2 \mu_i, \tag{12}$$

where μ_i are finite values.

Then the generalized displacements $x_i(t)$ could be represented via the following expansion in two time scales T_0 and T_2:

$$x_i(t) = \varepsilon X_{i1}(T_0, T_2) + \varepsilon^2 X_{i2}(T_0, T_2) + \varepsilon^3 X_{i3}(T_0, T_2) + \ldots, \tag{13}$$

where $T_n = \varepsilon^n t$ are new independent variables, among them: $T_0 = t$ is a fast scale characterizing motions with the natural frequencies, and $T_2 = \varepsilon t^2$ is a slow scale characterizing the modulation of the amplitudes and phases of the modes with nonlinearity.

Recall that the first and the second time derivatives, as well as fractional derivative could be expanded in terms of the new time scales, respectively, as follows [4, 19]:

$$\frac{d}{dt} = D_0 + \varepsilon^2 D_2 + \ldots, \quad \frac{d^2}{dt^2} = D_0^2 + 2\varepsilon^2 D_0 D_2 + \ldots \tag{14}$$

$$D_+^\gamma = \left(\frac{d}{dt}\right)^\gamma = \left(D_0 + \varepsilon^2 D_2 + ...\right)^\gamma = D_0^\gamma + \varepsilon^2 \gamma D_0^{\gamma-1} D_2 + ..., \tag{15}$$

where $D_0 = \partial / \partial T_0$, and $D_2 = \partial / \partial T_2$.

Note that [15]

$$\left(\frac{d}{dt}\right)^\gamma \varphi = D_+^\gamma \varphi = \frac{d}{dt} \int_{-\infty}^{t} \frac{\varphi(t')dt'}{(t-t')^\gamma \Gamma(1-\gamma)}. \tag{16}$$

But in the present case the process of vibrations starts at the time $t = 0$. Thus, the fractional derivative $D_{0+}^\gamma \varphi$ in the form of (3) should be adopted.

Fractional derivatives (16) and (3) act in a different way on the exponential function $e^{\lambda t}$, which is utilized in further treatment, i.e. [20]

$$D_+^\gamma e^{\lambda t} = \lambda^\gamma e^{\lambda t}, \tag{17}$$

and

$$D_{0+}^\gamma e^{\lambda t} = \lambda^\gamma e^{\lambda t} + \frac{\sin \pi x}{\pi} \int_0^\infty \frac{u^\gamma}{u+\lambda} e^{-ut} du\,. \tag{18}$$

However, as it has been shown in [20], if when utilizing the generalized method of multiple time scales only the zero and first order approximations are considered, then the second term in (18) could be neglected.

Expansion of the Rabotnov dimensionless fractional operator in a Taylor series in terms of a small parameter has the form [21]:

$$\begin{aligned} \text{э}_\gamma^* (\tau^\gamma) &= \frac{1}{1+\tau^\gamma D_{0+}^\gamma} = (1+\tau^\gamma D_{0+}^\gamma)^{-1} = \left[1+\tau^\gamma (D_0^\gamma + \varepsilon^2 \gamma D_0^{\gamma-1} D_2)\right]^{-1} \\ &= (1+\tau^\gamma D_0{}^\gamma)^{-1} - \varepsilon^2 (1+\tau^\gamma D_0{}^\gamma)^{-2} \tau^\gamma \gamma D_0{}^{\gamma-1} D_2 + ... \end{aligned} \tag{19}$$

Substituting expansion (13) with account for relationships (14), (15), and (19), after equating the coefficients at like powers of ε to zero, we are led for the case of free damped vibrations to the following set of recurrence equations to various orders:

to order ε

$$D_0^2 X_{11} + \omega_1^2 X_{11} = 0\,, \tag{20}$$

$$D_0^2 X_{21} + \omega_2^2 X_{21} = 0\,, \tag{21}$$

to order ε^3

$$\begin{aligned} D_0^2 X_{13} + \omega_1^2 X_{13} = &-2D_0 D_2 X_{11} - \left(\overline{\mu}_1 \tau_1^{\gamma_1} D_0^{\gamma_1} - \lambda_\infty \nu_\varepsilon \overline{\mu}_2 (1+\tau_2^{\gamma_2} D_0^{\gamma_2})^{-1}\right) X_{11} \\ &- \alpha_1 X_{11}^3 - \alpha_2 X_{11} X_{21}^2\,, \end{aligned} \tag{22}$$

$$\begin{aligned} D_0^2 X_{23} + \omega_2^2 X_{23} = &-2D_0 D_2 X_{21} - \left(\overline{\mu}_1 \tau_1^{\gamma_1} D_0^{\gamma_1} - \lambda_\infty \nu_\varepsilon \overline{\mu}_2 (1+\tau_2^{\gamma_2} D_0^{\gamma_2})^{-1}\right) X_{21} \\ &- \alpha_3 X_{21}^3 - \alpha_4 X_{21} X_{11}^2\,, \end{aligned} \tag{23}$$

where ω_1 and ω_2 are vibration frequencies of the mechanical system "plate + viscoelastic foundation"

$$\omega_i^2 = \Omega_i^2 + \frac{\lambda_\infty}{\rho h}, \tag{24}$$

and $\overline{\mu}_i = \dfrac{\mu_i}{\rho h}$ $(i = 1, 2)$.

The solution of linear equations (20) and (21) has the form

$$X_{j1} = A_j(T_2)\exp\left(i\omega_j T_0\right) + \overline{A}_j(T_2)\exp\left(-i\omega_j T_0\right), \tag{25}$$

where $A_j(T_2)$ $(j = 1, 2)$ are yet unknown functions and $\overline{A}_j(T_2)$ are conjugate functions with $A_j(T_2)$.

In order to solve the set of equations (22) and (23), it is necessary to define the action of the fractional derivative $D_{0+}^{\gamma_i}$ (3) and the Rabotnov dimensionless fractional operator $э_\gamma^*(\tau_2^{\gamma_2})$ (11) on the functions X_{j1}, i.e., to calculate $D_{0+}^{\gamma_i} e^{i\omega_j t}$ and $\dfrac{1}{1+\tau_2^{\gamma_2} D_{0+}^{\gamma_2}} e^{i\omega_j t}$. It was shown in [2, 21] that these expressions are reduced to the following form:

$$D_{0+}^{\gamma} e^{i\omega_j t} \simeq \left(i\omega_j\right)^{\gamma} e^{i\omega_j t}, \tag{26}$$

$$\frac{1}{1+\tau_2^{\gamma_2} D_{0+}^{\gamma_2}} e^{i\omega_j t} \simeq \frac{1}{1+(i\omega_j \tau_2)^{\gamma_2}} e^{i\omega_j t}. \tag{27}$$

Substituting relationships (25) in equations (22) and (23) with due account for formulas (26) and (27) yields

$$\begin{aligned}
&D_0^2 X_{13} + \omega_1^2 X_{13} = -2i\omega_1 D_2 A_1 \exp\left(i\omega_1 T_0\right) \\
&-\left[\overline{\mu}_1 \tau_1^{\gamma_1} \left(i\omega_1\right)^{\gamma_1} - \lambda_\infty \nu_\varepsilon \overline{\mu}_2 (1 + \tau_2^{\gamma_2} \left(i\omega_1\right)^{\gamma_2})^{-1}\right] A_1 \exp\left(i\omega_1 T_0\right) \\
&-\alpha_1\left[A_1 \exp\left(3i\omega_1 T_0\right) + 3\overline{A}_1 \exp\left(i\omega_1 T_0\right)\right] A_1^2 \\
&-\alpha_2\left\{A_2^2 \exp\left[\left(\omega_1 + 2\omega_2\right) T_0\right] + 2A_2\overline{A}_2 \exp\left(i\omega_1 T_0\right) + \overline{A}_2^2 \exp\left[i\left(\omega_1 - 2\omega_2\right) T_0\right]\right\} A_1 + cc,
\end{aligned} \tag{28}$$

$$\begin{aligned}
&D_0^2 X_{23} + \omega_2^2 X_{23} = -2i\omega_2 D_2 A_2 \exp\left(i\omega_2 T_0\right) \\
&-\left[\overline{\mu}_1 \tau_1^{\gamma_1} \left(i\omega_2\right)^{\gamma_1} - \lambda_\infty \nu_\varepsilon \overline{\mu}_2 (1 + \tau_2^{\gamma_2} \left(i\omega_2\right)^{\gamma_2})^{-1}\right] A_2 \exp\left(i\omega_2 T_0\right) \\
&-\alpha_3\left[A_2 \exp\left(3i\omega_2 T_0\right) + 3\overline{A}_2 \exp\left(i\omega_2 T_0\right)\right] A_2^2 \\
&-\alpha_4\left\{A_1^2 \exp\left[\left(2\omega_1 + \omega_2\right) T_0\right] + 2A_1\overline{A}_1 \exp\left(i\omega_2 T_0\right) + \overline{A}_1^2 \exp\left[i\left(\omega_2 - 2\omega_1\right) T_0\right]\right\} A_2 + cc.
\end{aligned} \tag{29}$$

The analysis of equations (28) and (29) shows that the one-to-one internal resonance is possible in the case when

$$\omega_1 = \omega_2, \quad \text{and therefore,} \quad \Omega_1 = \Omega_2. \tag{30}$$

The condition for eliminating secular terms in equations (28) and (29) with account for equation (30) leads to a set of two governing equations:

$$2i\omega_1 D_2 A_1 + \left[\overline{\mu}_1 \tau_1^{\gamma_1} \left(i\omega_1\right)^{\gamma_1} - \lambda_\infty \nu_\varepsilon \overline{\mu}_2 (1 + \tau_2^{\gamma_2} \left(i\omega_1\right)^{\gamma_2})^{-1} \right] A_1 + 3\alpha_1 A_1^2 \overline{A}_1 + \alpha_2 \overline{A}_1 A_2^2 + 2\alpha_2 A_1 A_2 \overline{A}_2 = 0, \tag{31}$$

$$2i\omega_2 D_2 A_2 + \left[\overline{\mu}_1 \tau_1^{\gamma_1} \left(i\omega_2\right)^{\gamma_1} - \lambda_\infty \nu_\varepsilon \overline{\mu}_2 (1 + \tau_2^{\gamma_2} \left(i\omega_2\right)^{\gamma_2})^{-1} \right] A_2 + 3\alpha_3 A_2^2 \overline{A}_2 + \alpha_4 \overline{A}_2 A_1^2 + 2\alpha_4 A_2 A_1 \overline{A}_1 = 0. \tag{32}$$

Multiplying (31) by $\overline{A}_1$ and (32) by $\overline{A}_2$, adding and subtracting the equations conjugate to them, and also representing functions A_1 and A_2 in their polar form

$$A_i = a_i e^{i\varphi_i} \quad (i = 1, 2), \tag{33}$$

where $a_i = a_i(T_2)$ and $\varphi_i = \varphi_i(T_2)$ are the functions of amplitudes and phases of vibrations, yield the following set of equations:

$$\left(a_1^2\right)^{\cdot} + s_1 a_1^2 = -\omega_1^{-1} \alpha_2 a_1^2 a_2^2 \sin\delta, \tag{34}$$

$$\left(a_2^2\right)^{\cdot} + s_2 a_2^2 = \omega_2^{-1} \alpha_4 a_1^2 a_2^2 \sin\delta, \tag{35}$$

$$\dot{\varphi}_1 = \frac{1}{2}\lambda_1 + \frac{3}{2}\alpha_1 \omega_1^{-1} a_1^2 + \alpha_2 \omega_1^{-1} a_2^2 + \frac{1}{2}\alpha_2 \omega_1^{-1} a_2^2 \cos\delta, \tag{36}$$

$$\dot{\varphi}_2 = \frac{1}{2}\lambda_2 + \frac{3}{2}\alpha_3 \omega_2^{-1} a_2^2 + \alpha_4 \omega_2^{-1} a_1^2 + \frac{1}{2}\alpha_4 \omega_2^{-1} a_1^2 \cos\delta, \tag{37}$$

where $\delta = \varphi_2 - \varphi_1$ is the phase difference,

$$s_i = \overline{\mu}_1 \tau_1^{\gamma_1} \omega_i^{\gamma_1 - 1} \sin\psi_1 + \lambda_\infty \nu_\varepsilon \overline{\mu}_2 \omega_i^{-1} R_i \sin\Phi_i, \quad \lambda_i = \overline{\mu}_1 \tau_1^{\gamma_1} \omega_i^{\gamma_1 - 1} \cos\psi_1 - \lambda_\infty \nu_\varepsilon \overline{\mu}_2 \omega_i^{-1} R_i \cos\Phi_i,$$
$$\psi_i = \frac{1}{2}\pi\gamma_i, \quad R_i = \sqrt{1 + 2(\tau_2\omega_i)^{\gamma_2} \cos\psi_2 + (\tau_2\omega_i)^{2\gamma_2}}, \quad \tan\Phi_i = \frac{(\tau_2\omega_i)^{\gamma_2} \sin\psi_2}{1 + (\tau_2\omega_i)^{\gamma_2} \cos\psi_2} \quad (i = 1, 2). \tag{38}$$

The set of equations (34)-(37) is the determining one for the amplitudes and phases of nonlinear free vibrations of a simply supported elastic plate on a viscoelastic foundation, damping features of which are defined by the fractional derivative standard linear solid model (4), when vibrations occur in a viscoelastic surrounding medium, properties of which are described by the fractional derivative Kelvin-Voigt model (3).

Reference to the governing equations (34)-(37) shows that nonlinear damped vibrations of the mechanical system "elastic plate on a viscoelastic foundation" in a viscoelastic surrounding medium are defined by the damping coefficients s_i (38), which depend on natural frequencies of two coupled modes Ω_i and rheological parameters of the supporting foundation and surrounding medium, involving two fractional parameters γ_1 and γ_2.

4 NUMERICAL ANALYSIS

The resulting set of equations (34)-(37) is solved numerically by using the fourth-order Runge-Kutta method in the «GNU Octave» system. The results of a numerical experiment are shown in Fig. 2 for free vibrations at different magnitudes of fractional parameters γ_1 and γ_2.

A rectangular plate with an aspect ratio $a/b=3$ was considered as an example for the case of $m_1=3, n_1=2, m_2=6, n_2=1$, for which $\Omega_{32}=\Omega_{61}$.

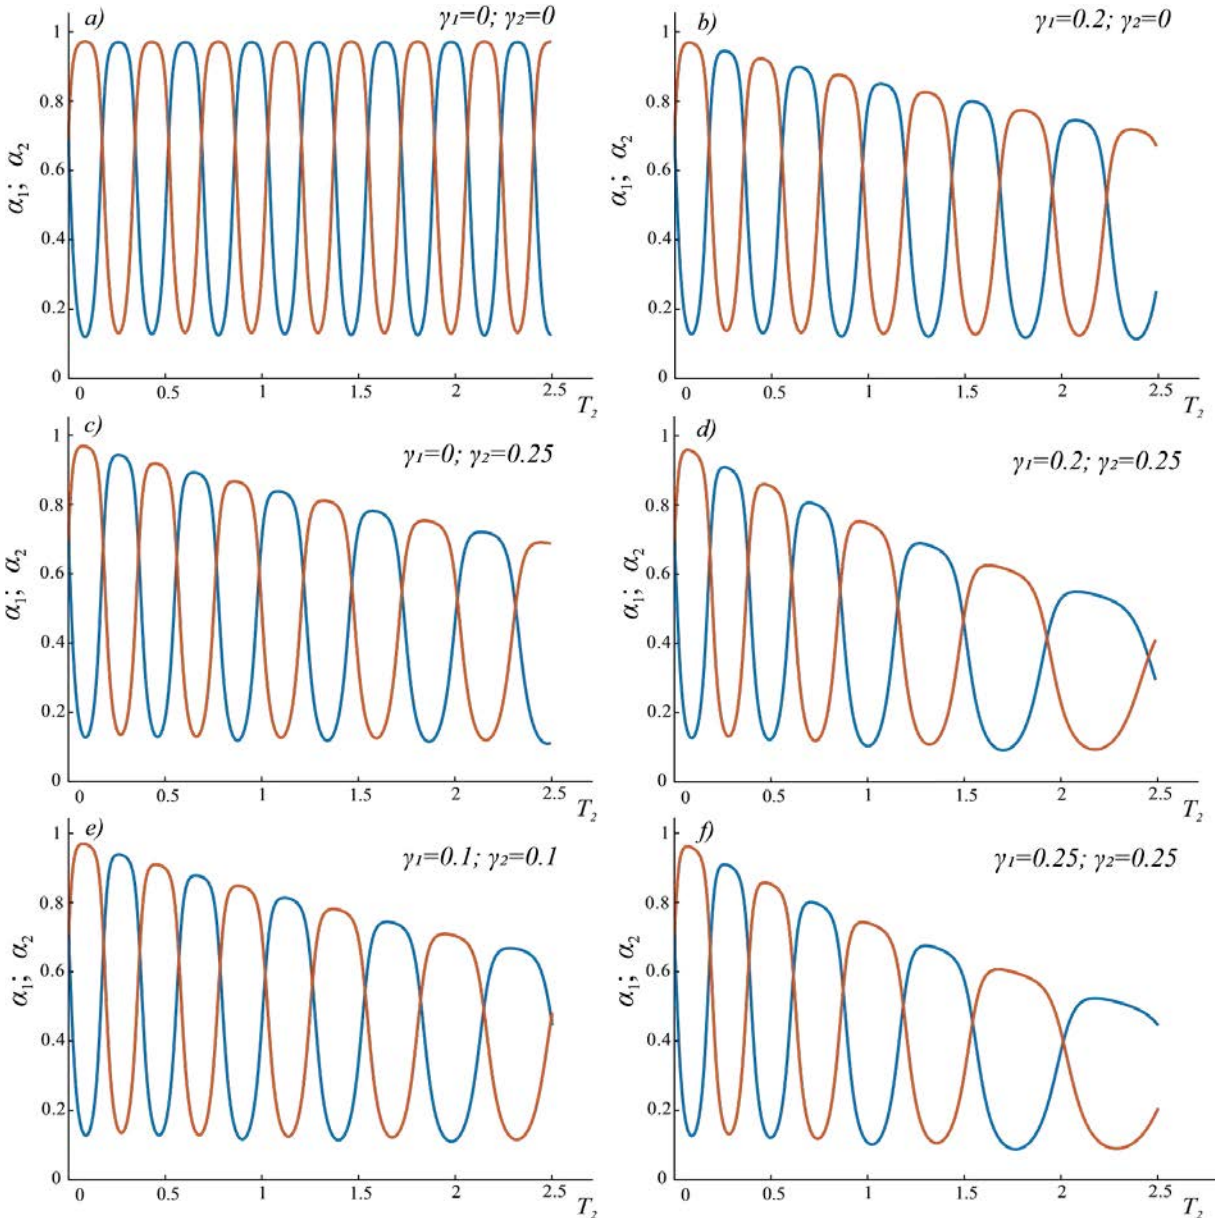

Figure 2: The dimensionless time T_2 dependence of the dimensionless amplitudes of free vibrations in the case of the 1:1 internal resonance for a plate on a viscoelastic viscoelastic foundation, blue line – a_1, orange line - a_2

Reference to Fig. 2 clearly shows the energy exchange between interacting vibration modes for all considered cases: undamped and damped vibrations of an elastic plate on an elastic foundation, respectively, at $\gamma_1=\gamma_2=0$ (Fig. 2a) and $\gamma_1=0.2$, $\gamma_2=0$ (Fig. 2b); vibrations of an elastic plate on a viscoelastic foundation ($\gamma_2\neq 0$) surrounded by an elastic ($\gamma_1=0$) and viscoelastic ($\gamma_1\neq 0$) medium, in Fig. 2c and Figs. 2d-f, respectively. The increase in the fractional parameter of the viscoelastic foundation results in a significant decrease in dimensionless amplitudes of nonlinear vibrations (Fig. 2c). With the appearance of the damping

properties of the environment (Fig. 2d-f), in which the plate vibrates, the damping of vibrations increases.

Figure 3 shows the calculated results of vibration amplitudes of the plate in the elastic medium ($\gamma_1 = 0$) when damping features of the viscoelastic foundation are described by the fractional derivative standard linear solid model (solid lines) and fractional derivative Kelvin-Voigt model (dashed lines) at $\gamma_2 = 0.25$. From Fig. 3 it is seen that the period of vibrations described by the KV-model is more than that described by the SLS-model.

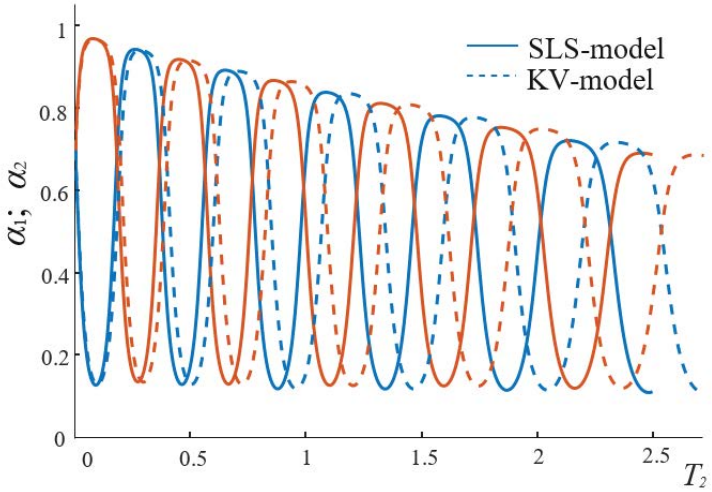

Figure 3: The time T_2 dependence of the dimensionless amplitudes of free vibrations in the case of the 1:1 internal resonance for a plate on a viscoelastic foundation at $\gamma_1 = 0,\ \gamma_2 = 0.25$; blue line – a_1, orange line - a_2

5 CONCLUSION

In the present paper, the problem of nonlinear vibrations of a von Karman simply supported elastic plate based on a viscoelastic foundation is solved. The damping features of the viscoelastic foundation are described by the fractional derivative standard linear solid model, while the damping properties of the environment in which the vibrations occur are described by the Kelvin-Voigt viscoelastic model with the Riemann-Liouville fractional derivative. The governing equations are obtained for determining nonlinear amplitudes and phases in the case of free vibrations, when the natural frequencies of the two dominant vibration modes are close to each other. The resulting set of equations allows one to control the damping properties of the external environment and the foundation by changing the fractional parameters from zero, what corresponds to an elastic medium and/or elastic foundation, to unit, what conforms to the traditional standard linear solid model, resulting in the expansion of the range of applicability of the solution obtained.

The derived set of equations has been solved numerically and could be also generalized for the case of force driven vibrations [22]. The results of numerical investigation have been compared with the case of viscoelastic foundation, the damping features of which are described by the fractional derivative Kelvin-Voigt model. The proposed standard linear solid model is preferable over other models, because it is able to describe both creep and relaxation properties of the viscoelastic materials (soil), while the Kelvin-Voigt model is unsuitable for describing the relaxation of materials and the Maxwell model could not describe the creep of materials. Thus, the obtained results are more accurate in comparison with those based on more simple models of viscoelasticity.

Keywords: Helmoltz resonator, hardening behavior, time multiple scales, subharmonic resonance.

Abstract. *Nonlinear amplitude-frequency response of a Helmholtz resonator is investigated by taking into account nonlinear restoring and damping forces [1]. Method of multiple time scales [2] applied to complexified form [3] of system equations are used for detection of different system dynamics. Several developments are done to obtain hardening behavior allowing targeted energy transfer from an acoustical mode to the nonlinear absorber [4]. Modified geometries of the neck are first considered to decrease the damping and activate cubic nonlinearities. Obtained results for large amplitudes show accelerated amplitude dependency of resonant frequencies of nonlinear geometry resonators compared to classical ones. This nonlinear response can be used as a passive controller system with nonlinear restoring forcing function for having broadband frequency absorption. The time multiple scale method around the 1:1 resonance allows to detect Slow Invariant Manifold (SIM) of the system, its equilibrium and singular points. Analytical predictions are compared with those obtained by direct numerical integration of system equations. Experimental verifications are performed and presented. Then, a two frequency driving (subharmonic resonance) is considered and we show that the phase difference of the driving can modify the classical softening behavior of an Helmholtz resonator. By choosing a phase difference into a certain range we show that it is possible to obtain hardening behavior and an improvement of the nonlinear response with generation of higher amplitude oscillations. The proposed results are mainly obtained by using method of multiple time scales [2] which has been used in thousands of papers and has been proved to be very accurate and very computational efficient. The results have been validated numerically with Runge-Kutta schemes of order four: the errors are less than 1% and the computational time is drastically reduced owing to analytical approximations.*

1 INTRODUCTION

In acoustics, Helmholtz Resonators (HR) [5] are often used to absorb sound, specifically for low frequencies where the classical porous materials are not efficient anymore. A lot of applications are done in buildings [6], aeronautics, industries. However, they are only efficient for a specific frequency. To broadband the frequency range of efficiency of classical mecanical resonators, it is possible to use a nonlinear restoring force [7, 8, 9, 10]. Some authors [11, 12] applied this concept in vibro-acoustics by using a cubic nonlinearity (a viscoelastic membrane). They have shown that it is possible to transfer acoustical energy irreversibly. In the present work, we are interested to use a pure acoustical resonator.

In [1], it was shown that it is possible to obtain nonlinear behavior of HR. Indeed nonlinear damping (due to jet loss) [13] and also nonlinear restoring force with quadratic and cubic term (due to the nonlinear elasticity of the cavity air for high amplitudes excitations) [14] can be taken into account. In [14] they show that it is theoretically possible to obtain a softening behavior.

Moreover, [15] mentioned the frequency dependency of the resonator on the flow velocity and on the resonator geometry. That is why, as underlined by [16], tayloring the neck of the resonator can influence the vortex apparition and dissipation around the neck. This fact allows to go further in the nonlinear domain, in terms of the nonlinear restoring force, if the vortex and dissipation around the neck are minimized. This point has been underlined in [1] and is also shown in the present paper with different neck geometries. By reducing vortex shedding by nonlinear tailoring of the HR neck, it is then possible to obtain hardening behavior for high amplitudes and not only softening behavior as performed by previous papers [14, 17]. Experimental verifications are also provided.

With this hardening behavior of the HR, it has been shown in [4] that it possible and feasible to activate targeted energy transfer. The case of the passive control of an coustical mode (created by a system composed of a tube with coupling boxes) by using a HR having a nonlinear hardening behavior has been treated analytically using method of multiple time scales [2] applied to complexified form [3] of system equations for detection of different system dynamics. In the present paper main results are given. Experimental verification has also been perfomed.

In [1, 4], it was shown that for very high amplitudes it is possible to obtain hardening behavior under certain conditions (neck geometry, decreasing of vortex phenomenon...). So it is not obvious to obtain hardening behavior for classical HR. That is why we propose in the present paper to study the two frequency driving (subharmonic resonance) case for a classical HR. The aim is to show that the phase difference of the driving can modify the classical softening behavior of an HR. By choosing a phase difference into a certain range we show that it is possible to obtain hardening behavior and an improvement of the nonlinear response with generation of higher amplitude oscillations. The proposed results are mainly obtained by using method of multiple time scales [2] which has been used in thousands of papers and has been proved to be very accurate and very computational efficient.

This paper is structured as follows: First, in Section 2, results about hardening behavior of HR with modified neck geometry are shown with experimental verifications of the targeted energy transfer. Then, in Section 3, the response of the two-frequency driving is studied. Finally, in Section 4, we conclude about the results of this work.

2 ONE-FREQUENCY DRIVING WITH MODIFIED GEOMETRY OF HR

In the following we consider HR excited by sound wave as shown in Figure 1. HR consists

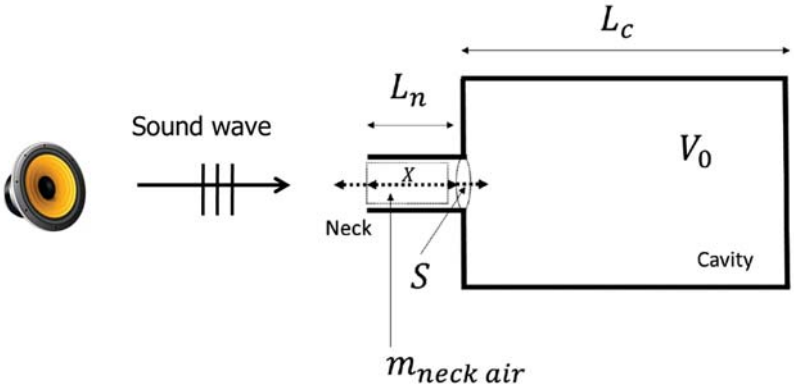

Figure 1: Helmholtz resonator excited by sound wave.

in an air column neck considered as incompressible mass and compressible air in the cavity. For HR physics, following hypothesis are considered: the transformations inside the acoustic resonator are adiabatic; the neck length L_n is considered much smaller than cavity length L_c and the neck air mass $m_{neck\ air}$ is considered as incompressible [18]. The friction due to the air high velocity in the neck will produce damping [13, 14] and the compression of the air in the cavity produces a restoring force. The displacement X of the air in the neck will cause the change of pressure Δp [17, 14]:

$$\Delta p = -\rho L_e \omega_0^2 \left[X - \frac{(\hat{\gamma}+1)\, S}{2V_0} X^2 + \frac{(\hat{\gamma}+1)\,(\hat{\gamma}+2)\, S^2}{6V_0^2} X^3 \right] \tag{1}$$

where ρ is the air density, L_e is the effective length of the neck ($L_e = L_n + (16r/3\pi)$, with r the radius of the cylindrical neck as mentioned in [14]), S is the cross section of the neck, V_0 is the volume in the cavity, $\hat{\gamma}$ is the specific heat ratio and ω_0 is the linear resonance frequency of the resonator.

2.1 Nonlinear behavior of modified HR

In [1] and [19] , different geometries of the neck of HR (as illustrated in Figure 2) have been considred to decrease the vortex phenomenon to be able to activate nonlinear terms of the nonlinear restoring force. Indeed, usually, the cubic term in Equation (1) is not taken into account [17]. However, incorporating here the cubic nonlinearity allows to balance damping term, which is usually of third order. Because of the attenuation of vortex shedding (by tailoring the neck) the nonlinear term will be dominant and the cubic nonlinearity can be activated.
In Figure 2, configurations H_1 and H_2 correspond to cylindrical and conical necks respectively, while configurations H_5 corresponds to quadratic neck with different radius of inlets and outlets. Characteristics of these configurations are given in Table 1.

To measure different acoustic properties of the HR, the test set-up is a classical Kundt tube (described for example in [1]) with different microphone positions to be able to measure the incident pressure on the HR (the HR is inserted as the end of the Kundt tube) and the pressure inside the cavity of the resonator. The used Kundt tube has a diameter of 46 mm. The length of the cavity has been taken as 25mm and the systems are excited by different sinusoidal forces: pressures inside the cavity during resonances are measured and corresponding amplitudes are evaluated. Obtained results are shown in Figure 3. In Figure 3 the behavior of the resonator with cylindrical neck remains almost linear until a high pressure level, i.e. the frequency does

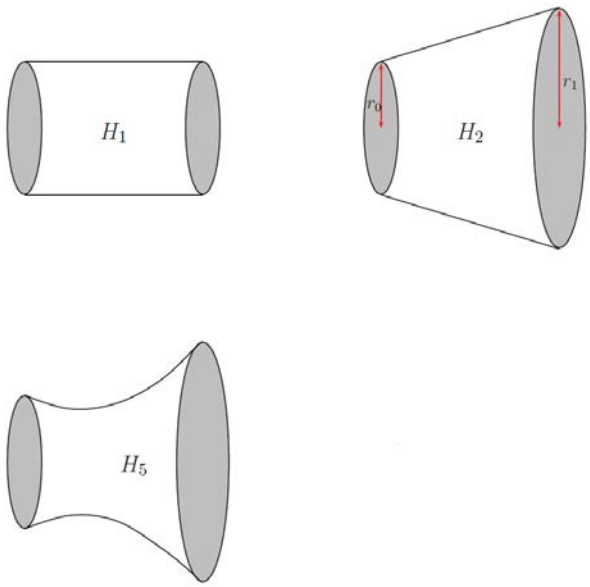

Figure 2: Different geometries of the neck of HR considered in [19].

	H_1	H_2	H_5
$L_n(mm)$	8.5	8.5	8.5
$r_0(mm)$	1.5	1.5	1.7
$r_1(mm)$	1.5	2	3.25

Table 1: Characteristics of different configurations of necks .

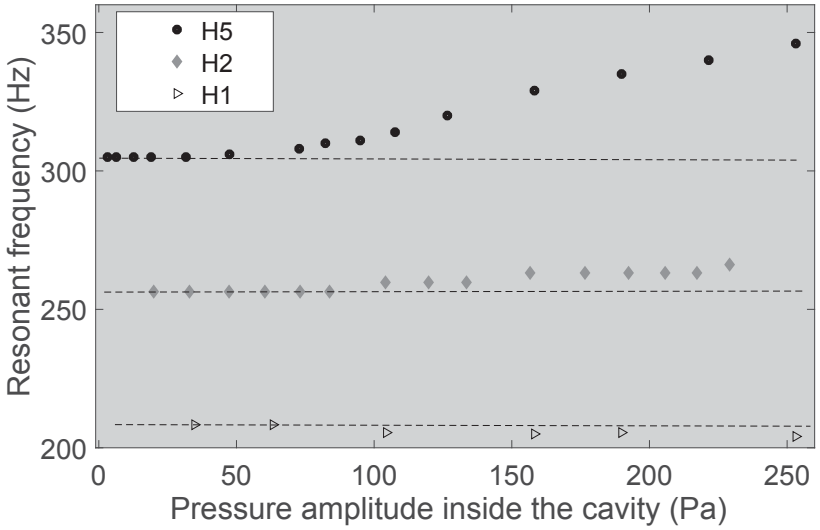

Figure 3: Dependency of the resonant frequency on the pressure amplitude (sinusoidal excitation, different resonators with length of the cavity of 25mm): resonant frequency vs. pressure amplitude inside the cavity.

not vary much in function of amplitude. We can also see a slightly softening behavior already

seen in previous publications [14, 17].
Moreover, Figure 3 shows that geometrical nonlinearity of the neck H_5 makes the resonator experiences a nonlinear behavior that starts at lower pressure level compared to the cylindrical case, i.e. after $P = 31.6Pa$ (with conical neck H_2 the nonlinear behavior starts at $P = 100Pa$). This means that frequency increases in a nonlinear manner with the increase of the amplitude, i.e. hardening behavior. These experimental results show that nonlinear tailored neck of the resonator accelerates considerably the start of the nonlinear response of the system compared to the resonators with cylindrical necks.

Combining all damping, restoring terms and the external pressure increment p^*, we can obtain the governing equation (see for example [1] for more details):

$$\frac{d^2X}{dt^{*2}} + \frac{\xi}{2L_e}\frac{dX}{dt^*}\left|\frac{dX}{dt^*}\right| + 2\delta^*\frac{dX}{dt^*} + \omega_0^2 X\left(1 - \alpha\frac{SX}{V_0} + \beta\left(\frac{SX}{V_0}\right)^2\right) = -\frac{p^*}{\rho L_e} \tag{2}$$

where t^* is the real time,
$\delta^* = (S/2\rho L_e)\, Re\,(Z_{in} + Z_{vis})$, $\alpha = (\hat{\gamma}+1)/2$, $\beta = ((\hat{\gamma}+1)(\hat{\gamma}+2))/6$ and ξ is the total hydraulic-resistance coefficient of the neck. Z_{in} is the acoustic impedance at inlet of HR, Z_{vis} is the friction acoustic impedance. We introduce dimensionless variables, $t = \omega_0 t^*$, $x = \frac{SX}{V_0}$, $\delta = 2\delta^*/\omega_0$, $\sigma = (\xi/2)(V_0/L_e S)$, $p = p^*/\rho c^2$ (c is the sound velocity) we get:

$$\frac{d^2x}{dt^2} + \sigma\frac{dx}{dt}\left|\frac{dx}{dt}\right| + \delta\frac{dx}{dt} + \left(x - \alpha x^2 + \beta x^3\right) = -p \tag{3}$$

In [1], in function of the order of magnitude of the displacement x, small parameter ε was introduced (for example $x = \varepsilon y$, with y of order 1 when x is small) and all parameters have been estimated in function of this ε. It was found that two regimes have to be considered to perfectly modelised the behavior of such HR, i.e. to obtain softening behavior first (for low levels) and then hardening behavior (for high levels).
Classical development by using multiple scales method developped by Nayfeh [2] can be performed to obtain fixed points of the system. This allows to obtain the skeleton curve of the amplitude-frequency (see [1] for more details). Example of results are shown in Figure 4. This nonlinear behavior of the resonator can be used as the nonlinear geometrical restoring forcing function of an oscillator to be coupled to a medium for passively controlling the acoustical energy of that medium via the same principles as in mechanical systems [20]. In the following we present results on the energy transfer from a linear system to modified HR.

2.2 Nonlinear targeted energy transfer by using modified HR

In [4], it has been shown that it is possible to obtain a targeted energy transfer from one acoustical mode to an HR with nonlinear behaviors. For the HR, nonlinear restoring forces and nonlinear damping have been taken into account with modified geometry of the neck. The considered system is represented in Figure 5. A time multiple scale method around a 1:1 resonance has been used to detect slow invariant manifold of the system, its equilibrium and singular points. We denote X_1 the displacement of the air mass in the small diameter tube (acoustical mode created owing to coupling box) and X_2 the displacement of the neck air mass of the modified HR. We can deduce different orders of magnitude of each parameter by taking their realistic values for possible practical applications in acoustics. Some parameters are fixed (for example air properties) and others are adjusted for the experiment within a realistic range. So

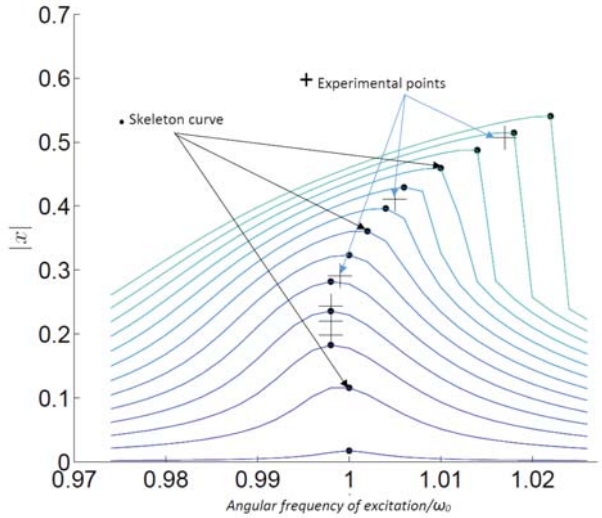

Figure 4: Softening and hardening behavior in function of amplitude of excitation (data taken from [1]).

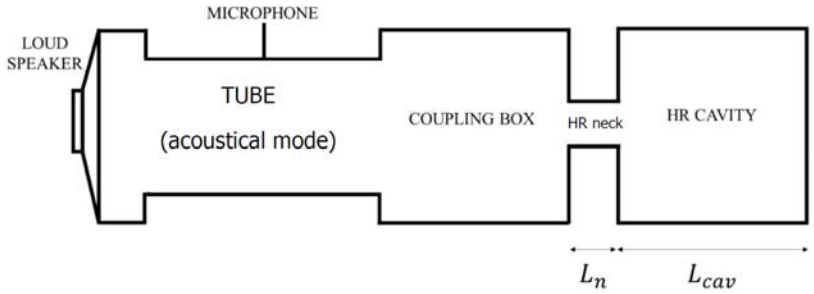

Figure 5: Considered system to obtain targeted energy transfer from one acousticla mode to HR.

we are able to express the govering equations in different orders of magnitudes, using a small parameter, $\varepsilon \ll 1$, considered as the ratio of the secondary system mass to the main system mass and we can also normalize equations with respect to time by considering the following changes of variable: $\tau = \Omega t$, where Ω is the natural angular frequency of the main acoustical mode.
Complex variables of Manevitch [3] can also be used:

$$\begin{aligned} \varphi_1 e^{j\omega_n \tau} &= \frac{dX_1}{d\tau} + j\omega_n X_1 \\ \varphi_2 e^{j\omega_n \tau} &= \frac{dX_2}{d\tau} + j\omega_n X_2 \end{aligned} \tag{4}$$

with $j^2 = -1$ and ω_n is the ratio of the angular frequency of excitation divided by Ω.
A multiple scale method [2] can be performed, where we consider a new scales of time $\tau_k = \varepsilon^k \tau$, $k = 0, 1, ...0$, where τ_0 is the fast time scale and τ_1 and so on are slow time scales.
We study the system around the 1:1 resonance and we replace expressions of X_1 and X_2 as functions of φ_1 and φ_2 in the system of governing equations and we use a Galerkin's technique by keeping first harmonics of the system [21]. As shown in [4], by solving the system of equations at different orders of ε and by using polar expressions

$$\varphi_1 = N_1 e^{j\delta_1} \tag{5}$$

$$\varphi_2 \quad = \quad N_2 e^{j\delta_2}$$

it is possible to find the Slow Invariant Manifold (SIM), that give the relations of N_1 in function of N_2. It is also possible to analyze the behavior of the system at τ_1 time scale around the SIM. This allows to find ordinary fixed points and fold singularities [21]. Stability borders of the SIM as presented in [21] can be provided. When the system possesses fold singularities, in fact equilibrium and singular points coincide on the fold line of the system. In this case, the system presents persisting bifurcations between its stable zones which correspond to extreme energy exchanges between two oscillators [22]. It has been shown in [4] that existence and positions of fold singularities and equilibrium points, for fixed parameters of the HR, depends on characteristics of excitation.

In order to activate nonlinear absorber, the absorber should be designed in a manner that the SIM can present two peaks for given physical parameters. This means that the parameters of HR relevant to nonlinear terms should be tuned. Via setting $\dfrac{\partial N_1}{\partial N_2} = 0$, we impose that the SIM possesses two local maxima which leads to find possible parameters of HR for having two peaks. This gives us a mathematical inequality that some parameters must be satisfied. Results for possible realistic values satisfying this condition are shown in Figure 6 where we can see the superposition of SIM compared to the numerical simulation in terms of N_1 vs N_2 curve (a good analytical prediction is obtained) for a given set of parameters (details are given in [4]). In the Figure 6 we also show the numerical simulation of N_1 versus τ where one can see a better decreasing of N_1 when the HR is coupled. First, after starting from the initial conditions there are nonlinear interactions between energies of the acoustical mode and HR in terms of N_1, N_2, which is accompanied by reduction of N_1 in a nonlinear manner. Then when the system reaches to the stability border of SIM, it faces a bifurcation which corresponds to abrupt energy decrease of N_2 with almost constant level of N_1. Finally, after bifurcation the energy of acoustical mode, N_1 decreases until it reaches to zero. In [4] experimental verifications have also been done. An example of experimental result is given in Figure 7 with the evolutions of energies of the main system, i.e. N_1 with and without coupled HR. We can see that the energy transfer to the HR allows to have faster absorption i.e. sharper slop of the energy decreament of the main system. An energy reduction is shown in a sharp and faster manner followed by a classical exponential decrease. This scenario is typical behavior for targeted energy transfer and has already been underlined by [11].

So, it was shown that for very high amplitudes it is possible to obtain hardening behavior under certain conditions (neck geometry, decresaing of vortex phenomenon...) allowing to activate targeted energy transfer. However it is not obvious to obtain hardening behavior for classical HR. That is why we propose in the next section to study the two frequency driving (subharmonic resonance) case for a classical HR.

3 SUBHARMONIC RESONANCE OF CLASSICAL HR

In this section we consider that the external excitation p of a classical resonator in Equation (3) is a two-frequency driving.

By assuming that displacement x is small, we introduce small parameters to solve this equation. Indeed, we introduce ε such that $x = \varepsilon y$, with y of order 1. So, in function of the orders of magnitude (by looking at physics), we can write $\delta = \varepsilon^2 r_2$, $\sigma = \varepsilon r_1$. For the two frequency driving we choose $p = \varepsilon^3 f_0 \cos(\Omega t) + \varepsilon^2 f_2 \cos(2\Omega t + \phi)$. The linear frequency is expressed

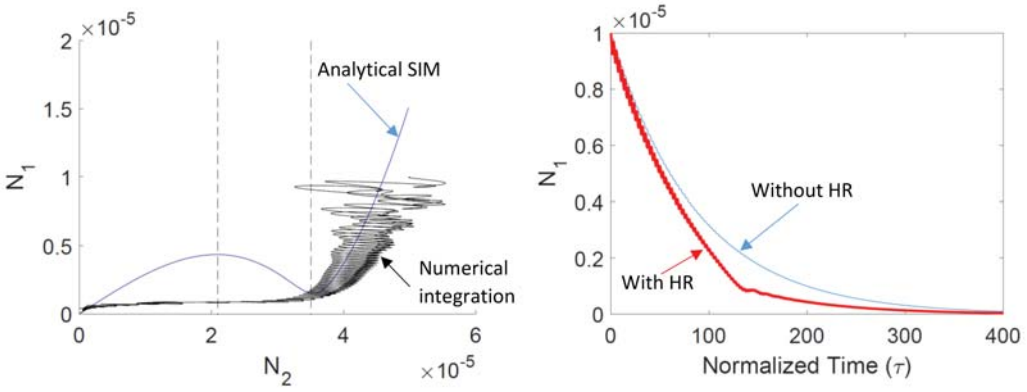

Figure 6: N_1 vs N_2 analytical and numerical for initials conditions ($\tau = 0$) $X_1 = X_2 = 0$, $\frac{dX_1}{d\tau} = 1 \times 10^{-5}$, $\frac{dX_2}{d\tau} = 5 \times 10^{-5}$ (data taken from [4]).

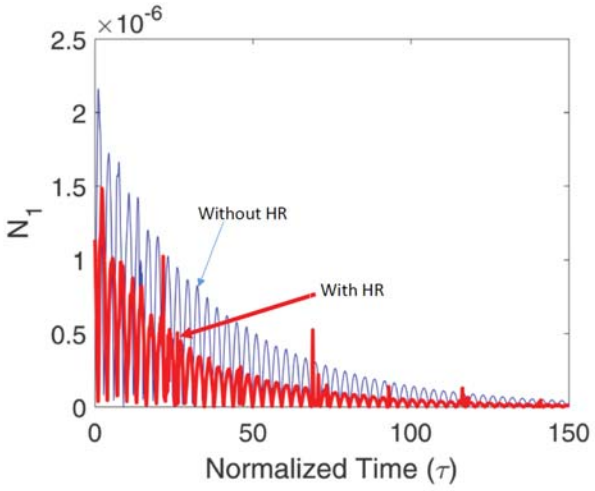

Figure 7: Experimental results showing targeted energy transfer from one acoustical mode to HR (data taken from [4]).

by $\Omega = 1 + \varepsilon^2\mu$ where μ is the frequency detuning.

$$\frac{d^2y}{dt^2} + \varepsilon^2 r_1 \frac{dy}{dt}\left|\frac{dy}{dt}\right| + \varepsilon^2 r_2 \frac{dy}{dt} + y - \varepsilon\alpha y^2 + \varepsilon^2\beta y^3 = -\varepsilon^2 f_0 \cos(\Omega t) - \varepsilon f_2 \cos(2\Omega t + \phi) \quad (6)$$

Then, we apply the multiple time scale method with the expansion of y in the form of: $y = y_0 + \varepsilon y_1 + \varepsilon^2 y_2 + O(\varepsilon^3)$. We develop the time in fast and slow scales: $T_0 = \varepsilon^0 t$, $T_1 = \varepsilon^1 t$ and $T_2 = \varepsilon^2 t$. When we replace these developments in the principal equation (6), we obtain :

$$\varepsilon^0 : \qquad \frac{\partial^2 y_0}{\partial T_0^2} + y_0 = 0 \quad (7)$$

$$\varepsilon^1 : \quad 2\frac{\partial^2 y_0}{\partial T_0 \partial T_1} + \frac{\partial^2 y_1}{\partial T_0^2} + y_1 - \alpha y_0^2 = -\frac{f_2}{2}\left[e^{i(2T_0 + 2\mu T_2 + \phi)} + e^{-i(2T_0 + 2\mu T_2 + \phi)}\right] \quad (8)$$

ε^2 :

$$2\frac{\partial^2 y_0}{\partial T_0 \partial T_2} + \frac{\partial^2 y_0}{\partial T_1^2} + 2\frac{\partial^2 y_1}{\partial T_0 \partial T_1} + \frac{\partial^2 y_2}{\partial T_0^2} + r_1 \frac{\partial y_0}{\partial T_0}\left|\frac{\partial y_0}{\partial T_0}\right| + r_2 \frac{\partial y_0}{\partial T_0} + y_2 - 2\alpha y_0 y_1 + \beta y_0^3 \quad (9)$$

$$= -\frac{f_0}{2}\left[e^{i(T_0+\mu T_2)} + e^{-i(T_0+\mu T_2)}\right]$$

When we follow the development in multiple scales used by Nayfeh [2], we continue eliminating secular terms of the precedent equations (7, 8, 9).
The equation (7) has a solution with the following form:

$$y_0 = A\left(T_1, T_2, T_3, ...\right) e^{iT_0} + A^*\left(T_1, T_2, T_3, ...\right) e^{-iT_0} \tag{10}$$

where .* stands for conjugate of a complex variable.
For the first equation coming from (8):

$$A = A\left(T_2, T_3, ...\right) \tag{11}$$

For the second equation coming from (8):

$$y_1 = -\frac{1}{3}\alpha A^2 e^{2iT_0} + 2\alpha A A^* - \frac{1}{3}\alpha A^{*2} e^{-2iT_0} + \frac{f_2}{6}\left[e^{i(2T_0+2\mu T_2+\phi)} + e^{-i(2T_0+2\mu T_2+\phi)}\right] \tag{12}$$

We introduce (10) and (12) in the expression (9), and we replace A with the complex form: $A = \hat{y}e^{i\gamma}$. The expression is separated in the real part and the imaginary part. After simplifying, using $\Delta = \gamma - \mu T_2$, we obtain the system of two equations:

$$\begin{aligned} \hat{y}\frac{\partial \Delta}{\partial T_2} &= -\ \hat{y}\mu + \frac{f_0}{4}\cos\left(\Delta\right) + \hat{y}^3\left[\frac{3}{2}\beta - \frac{5}{3}\alpha^2\right] - \frac{f_2}{6}\alpha\hat{y}\cos\left(\phi - 2\Delta\right) \\ \frac{\partial \hat{y}}{\partial T_2} &= \frac{f_0}{4}\sin\left(\Delta\right) - \frac{r_2}{2}\hat{y} - r_1\hat{y}^2\left(\frac{8}{3\pi}\right) + \frac{f_2}{6}\alpha\hat{y}\sin\left(\phi - 2\Delta\right) \end{aligned} \tag{13}$$

Fixed points of the system (13) can be obtained by setting $\frac{\partial \Delta}{\partial T_2} = 0$ and $\frac{\partial \hat{y}}{\partial T_2} = 0$. This will allow to obtain the skeleton curve of the amplitude-frequency curve.
It should be underlined that for the special case $f_0 = 0$ and no non linear damping ($r_1 = 0$), we obtain directly from the second equation of System (13) that $\sin\left(\phi - 2\Delta\right) = 3\frac{r_2}{\alpha f_2}$. It means that this is possible only if this value is inferior to 1. So it means that subharmonic resonance, for the case of excitation by just the second harmonic ($f_0 = 0$), is possible only as $3\frac{r_2}{\alpha f_2} < 1$. Physically, this implies that the coefficient of the double frequency term must overcome the coefficient of the damping term, which is a well known result for subharmonic resonance. However, if the two terms (f_0 and f_2) are taken in account, then it is possible to obtain subharmonic resonance even if $3\frac{r_2}{\alpha f_2} > 1$ and very different behaviors can occur.
Indeed, it is then possible to obtain different nonlinear behaviors in function of the phase difference ϕ. For example, we can calculate the amplitude-frequency curve in function of ϕ as shown in Figure 8 by taking the following physical realistic parameters: $\hat{\gamma} = 1.4$ (specific air ratio of air), $r_1 = 0.8$ and $r_2 = 2$ (values very close to litterature values by assuming $\varepsilon = 0.1$), $f_0 = 0.25$ (the case $f_2 = 0$ and $f_0 = 0.25$ corresponds to 122dB by considering sound velocity $c = 343\text{m.s}^{-1}$ and $\rho = 1.2\text{kg.m}^{-3}$) and $f_2 = 0.6$ (this corresponds to 150dB).
In Figure 8, we can clearly see that for a certain range of ϕ it is possible to obtain hardening behavior instead of classical softening behavior when ϕ equals to 0 (softening for $\mu < 0$ and hardening for $\mu > 0$). The dots represent the maximum of amplitude for each curve (one curve for each fixed ϕ) so at the resonance frequency.

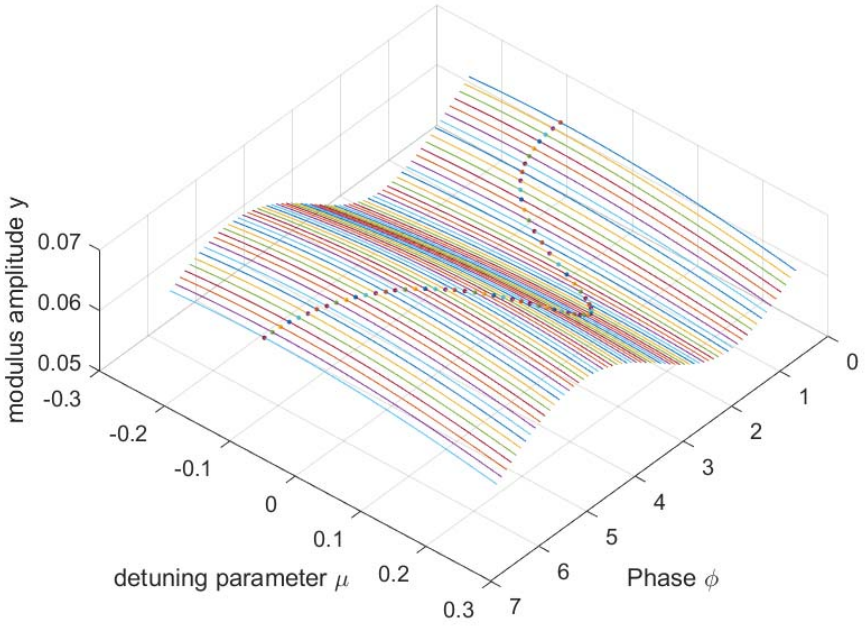

Figure 8: Example of amplitude-frequency curve in function of the phase lag ϕ. The dots represent the maximum of amplitude for each curve (one curve for each fixed ϕ) so at the resonance frequency.

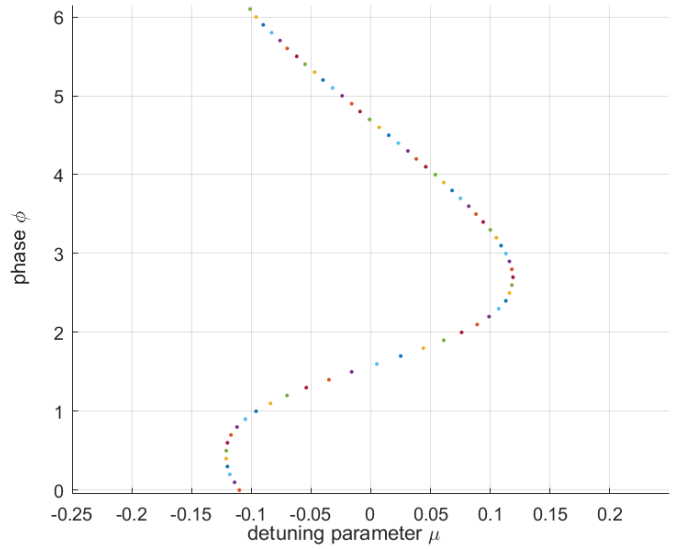

Figure 9: Nonlinear response of ϕ as function of μ (softening for $\mu < 0$ and hardening for $\mu > 0$). The dots represent the maximum of the amplitude-frequency curve (so at the frequency of resonance).

The Figure 9 allows to see that the intervals where the behavior becomes hardening is around $\phi \in [\pi/2; 3\pi/2]$.

Moreover, as shown in Figure 10, the phase ϕ allows to obtain higher amplitudes at resonance, which can be very interesting for some applications. With the given parameters for this figure the case with only the first harmonic (case $f_0 = 0.25$ and $f_2 = 0$) gives an amplitude of

0.06. By considering the two-frequency driving excitation and owing to the phase difference the amplitude can increase at almost 0.0675 for a phase difference near $3\pi/2$. It means that amplitude can increase approximately 12.5% as compared with the single frequency driving. All the results have been validated numerically with Runge-Kutta schemes of order four: the errors are less than 1% and the computational time is drastically reduced owing to analytical approximations.

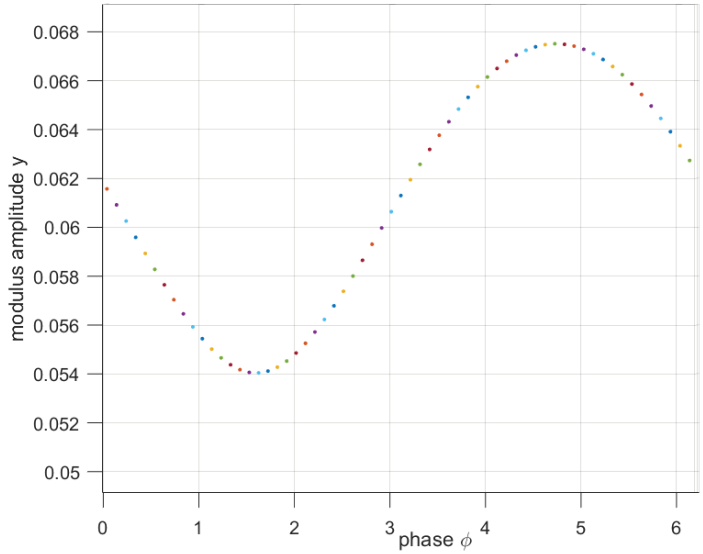

Figure 10: The variation of amplitude at resonance frequency in function of ϕ .The dots represent the maximum of the amplitude-frequency curve (so at the frequency of resonance).

4 CONCLUSIONS

Nonlinear amplitude-frequency responses of an acoustic Helmholtz resonator have been investigated by taking into account nonlinear restoring and damping forces. The objective of the present paper is to show that it is possible to obtain nonlinear hardening behavior of HR either by modifying the geometry of the neck either by using a two-frequency driving with a phase difference. This nonlinear hardening behavior is necessary to active targeted energy transfer phenomenon from an acoustical mode to a pure acoustical resonator. Analytical treatment of governing system equations has been carried on by using time multiple scale method and complexification method to detect slow invariant manifold of the system, its equilibrium and singular points. Owing to the obtained analytical developments, we have shown that it is possible to use all nonlinear characteristics of the HR, including bifurcations and not just its classical damping capacity. Analytical predictions have been compared with those obtained by direct numerical integration of system equations showing good agreement. Experimental verification has also been perfomed for some configurations. The nonlinear response can be increased by using a two-frequency driving for certain phase difference and taking into account the two first harmonics can change the characteristic responses even for situation where the double frequency component does not overcome the damping effect. We have shown that the phase difference has a crucial role to obtain different nonlinear behaviors. It remains to verify

experimentally this last point and apply those last results in practical engineering applications.

EMPIRICAL EXPRESSION PREDICTING SEISMIC DISPLACEMENT OF SANDY SLOPES IN GREECE IN TERMS OF SOIL PROFILE TYPE USING NON-LINEAR DYNAMIC STICK-SLIP ANALYSIS

Abstract

In earthquake analyses, usually the seismic displacement of slopes along slip surfaces is estimated by the sliding-block model, where a rigid block rests on an inclined plane and every time that the applied horizontal acceleration is larger than the critical horizontal acceleration value for relative motion, the block slides. Empirical expressions giving the distance moved by the sliding-block model have been proposed and recently these equations are based on relevant data bases of specific regions. However, level of accuracy of the sliding-block model is limited primarily because of the dynamic response of the soil both above and below the slip surface. Recently a coupled numerical code which predicts the seismic response along slip surfaces by considering the dynamic response both above and below the slip surface has been developed (Katsenis et al, 2019). The code is used to propose empirical expressions relating the seismic displacement along slip surfaces, not only on the predictions of the sliding block model, but also on the soil type category according to Eurocode and the depth of the slip surface. For this purpose, extensive parametric analyses were performed. Different acceleration histories recorded in Greece were applied below the soil layers with a slip surface with varying horizontal critical acceleration value for relative motion and depth. Soil behaves linearly only at very small shear strains, well below the typical shear strains exerted in soil profiles near severe earthquakes. The present work extends previous work for non-linear soils. It was observed that the non-linear effect is more important on loose deposits and the previously developed equations were extended to simulate this effect.

Keywords: slopes, sliding-block model, dynamic response, seismic displacement, constitutive modeling, slip surface, coupled analyses, slopes.

1 INTRODUCTION

Engineers usually assess the seismic safety of slopes using the dynamic factor of safety calculated along slip surfaces by comparing the applied forces to the soil strength [1]. However, evaluations based on the dynamic factor of safety have the serious drawback that they do not consider the seismic displacement, which is directly related to damage [2]. The "conventional" sliding-block model [3] is the most commonly used simplified model predicting the seismic displacement of slopes for given earthquake motions [4]. A rigid block rests on an inclined plane (Fig. 1). The resistance along the block-inclined plane boundary follows the Mohr-Coulomb law. Critical acceleration is defined as the minimum horizontal acceleration which causes movement of the block. Every time where the applied horizontal acceleration is larger than the critical acceleration, the block slides. The total displacement is obtained by the addition of the partial slips. This model is used for the prediction of permanent seismic movement of slopes along a predefined slip surface, by appropriately selecting the equivalent critical and applied acceleration values of the "conventional" sliding-block model [2, 3, 4]. Different empirical expressions have been proposed predicting the seismic displacement of the sliding-block model, in terms, primarily, of the ratio of the maximum acceleration of the applied seismic motion divided by the critical horizontal acceleration for sliding [4-9]. Some of these expressions use other than the maximum acceleration parameters of the seismic motion, such as the maximum velocity or the Arias Intensity, or parameters of the earthquake that produced the seismic motion, such as its earthquake magnitude or its earthquake fault distance [5, 9]. In addition, region-specific empirical expressions have been proposed predicting the seismic displacement of the sliding-block model, as different regions have different earthquake faults and geological profiles conditions, and thus potentially different applied seismic motions characteristics. Region-specific empirical expressions predicting the seismic displacement with the "conventional" sliding-block model for seismic motions in Greece have been proposed by [9].

The conventional sliding-block model described above assumes rigid motion and thus it does not consider the dynamic response of the soil both above and below the slip surface, which affects the seismic displacement along the slip surface. Based on results of simplified dynamic models, expressions have been proposed predicting the seismic displacement along the slip surface in terms of not only the critical acceleration for sliding and characteristics of the applied seismic motion described above, but also characteristics affecting the dynamic response of the sliding mass such as its height and shear wave velocity [10-12]. However, the seismic displacement along a slip surfaces depends not only on the dynamic characteristics of the sliding mass, but also on the dynamic characteristics of the soil profile below the slip surface and above the underlying bedrock [13, 14]. Recently, a new cost-effective method, is proposed predicting the seismic sliding movement of dry slopes in soil profiles along slip surfaces with resistance following the Mohr-Coulomb law. The method models the coupled dynamic response of soils both above and below the slip surface [13]. An advantage of this method is simplicity, which makes it ideal in performing dynamic parametric analyses.

Depending on the geographical locations, National Codes specify the characteristics of the design typical seismic motion, such as the maximum seismic acceleration [15]. This seismic motion typically corresponds at bedrock sites. Furthermore, Eurocode [1] classifies the soil profiles into distinct categories, presumably exhibiting similar dynamic response. Based on the above, it is of interest for practicing engineers, to relate the seismic displacement along slip surfaces, not only to characteristics of the seismic motion and the critical horizontal acceleration for sliding, but also to the soil type category according to Eurocode, as well as, possibly, the depth of the slip surface.

Katsenis et al. [16, 17] proposed empirical expressions relating the seismic displacement along slip surfaces in Greece, in terms of not only characteristics of the acceleration history and the critical horizontal acceleration for sliding, but also to the soil type category according to Eurocode, as well as, the depth and length of the slip surface. In particular, they proposed and validated equations correcting the predictions of the conventional sliding-block model for typical seismic motions of Greece in terms of the soil profile type according to Eurocode and the depth and length of the slip surface. Katsenis et al. [16, 17] assumed a linear soil profile. However, soil behaves linearly only at very small shear strains, well below the typical shear strains exerted in soil profiles near severe earthquakes. It is inferred that for accurate predictions, the linear methods described in the previous chapter must be extended with constitutive equations simulating the non-linear soil response.

The purpose of the present work is to extend the empirical expressions proposed by Katsenis et al. [16, 17] for dry sandy layers considering the non-linear soil response. For this purpose, the following are performed below: (a) ground profile types are selected according to Eurocode, (b) a data base of seismic motions in Greece is collected, (c) numerical analyses are performed using the recently developed numerical code by [13], (d) based on the analyses performed and statistical analysis an empirical equation correcting the seismic displacement predictions of the sliding-block model based on the soil type category according to Eurocode, as well as the depth of the slip surface is derived and validated, (e) the results are discussed and an example practical application of the proposed expression for the prediction of the seismic displacement of an actual slope in Greece is given.

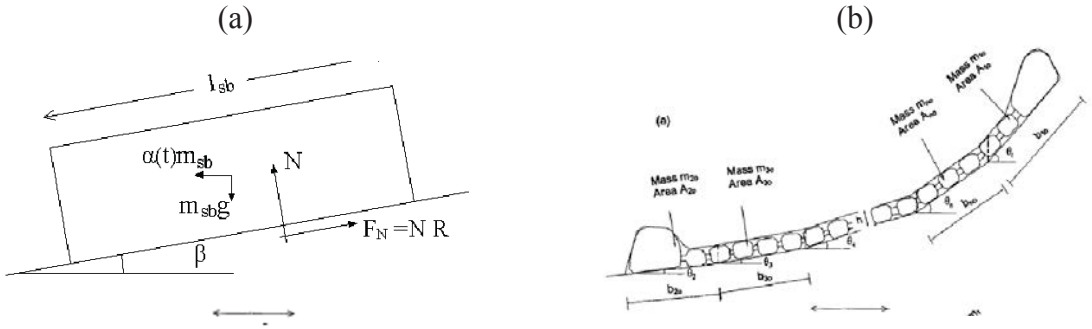

Fig. 1: (a) The conventional sliding block model, (b) the sliding chain model used to derive equation (3b).

2 MODEL SIMULATING THE NON-LINEAR SLIDING DYNAMIC RESPONSE OF SLOPES [13]

2.1 Simulation of sliding dynamic response

As shown in Fig. 2a, the present work models a slope with a slip surface as a continuous dynamic system of height (h_1+h_2) separated by a horizontal slip element at height h_2 above its base. Only horizontal acceleration is applied at the base of the lower body and above and below the slip element different properties exist. Thus, the system is divided in two non-linear elastic bodies. The index "1" is used for the upper body and the index "2" is used for the lower body. The upper body and lower bodies have mass m_i, tangent shear modulus $G_{t\text{-}i}$, viscous material damping ratio λ_i, and density ρ_i where i takes the values 1 and 2 for bodies 1 and 2 respectively. The two bodies move a horizontal distance x_i, velocity x'_i and acceleration x''_i, where i takes the values 1 and 2 for bodies 1 and 2 respectively

(a) (b)

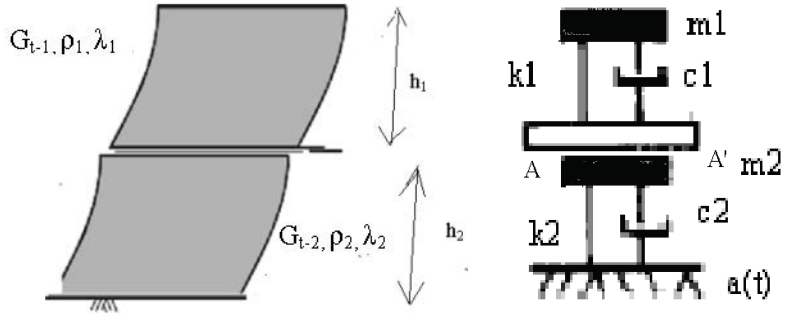

Figure 2: (a) Continuous system dynamic system considered in the present work, (c) the assumed discrete dynamic system approximation.

Fig. 2b gives the assumed equivalent discrete 2-body dynamic system with slip element approximation of the continuous system of Fig. 2a. If no slippage at the slip surface occurs, the equation of motion of the 2-body system of Fig 2b is:

$$\begin{bmatrix} m_1 & 0 \\ 0 & m_2 \end{bmatrix} \begin{bmatrix} x''_1 \\ x''_2 \end{bmatrix} = \begin{bmatrix} k_1(t) & -k_1(t) \\ -k_1(t) & k_1(t)+k_2(t) \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} c_1(t) & -c_1(t) \\ -c_1(t) & c_1(t)+c_2(t) \end{bmatrix} \begin{bmatrix} x'_1 \\ x'_2 \end{bmatrix} - a(t) \begin{bmatrix} m_{ef-1} \\ m_{ef-2} \end{bmatrix} \quad (1a)$$

where

$$m_i = \frac{\rho_i \times h_i}{2} \quad (1b)$$

$$m_{ef-i} = \frac{2 \times \rho_t \times h_i}{\pi}$$

$$k_i(t) = \frac{\pi^2 \times m_i \times G_{t-i}(t)}{4 \times h_i^2 \times \rho_t}$$

$$c_i(t) = \frac{\pi \times m_i \times \lambda_i}{h_i} \sqrt{\frac{G_{t-i}(t)}{\rho_t}}$$

where a(t) is the applied acceleration in the base of the system in terms of time t, $k_i(t)$ and $c_i(t)$ are the viscous damping and spring stiffness coefficients of bodies 1 and 2, in terms of time t, m_i are the masses of bodies 1 and 2 and m_i are the equivalent masses of bodies 1 and 2 where the inertia acceleration is applied.

Also, non-linear elasticity and the geometry of Fig. 2b predicts that for any incremental change in horizontal displacement of the two bodies (dx_1, dx_2) the corresponding incremental change in shear stress at time t ($d\tau_1$, $d\tau_2$) at the two bodies equals

$$d\tau_1 = G_{t-1}(t) \frac{dx_1 - dx_2}{h_1} \quad (2a)$$

$$d\tau_2 = G_{t-2}(t) \frac{dx_2}{h_2} \quad (2b)$$

Sliding at the slip element of Fig. 2b occurs when

$$-a_c(t)-\frac{m_{ef-1}}{m_1}x_1''-a(t)>0 \tag{3a}$$

$$-m_1a_c(t)-m_1x_1''-m_1a(t)>0$$

where $a_c(t)$ is the horizontal acceleration for relative displacement of the slip element, in terms of time. In particular, the effect of rotation of the sliding mass above the slip surface is simulated by increasing the critical acceleration of the slip element with the distance moved along the slip element (u) as:

$$a_c(t)=a_{co}+11\frac{u}{L} \tag{3b}$$

where a_{co} is the critical acceleration at u=0 and L is the slip length.

Sliding in only one direction is assumed and the governing equation of motion at the slip element is

$$u''=-a_c(t)-\frac{m_{ef-1}}{m_1}x_1''-a(t)=-a_c(t)-0.64x_1''-a(t) \qquad \text{for} \quad u'>0 \tag{4}$$

where u'' and u' is the relative acceleration and velocity along the slip element.

During sliding, the two bodies move separately. The equations of motion for the upper and lower masses become:

$$m_1x_1''+c_1(t)x_1'+k_1(t)x_1=-m_{ef-1}[a(t)+u''(t)] \tag{5a}$$

$$m_2x_2''+c_2(t)x_2'+k_2(t)x_2=-m_{ef-2}a(t)-u''(t)m_{ef-1} \tag{5b}$$

Sliding stops when the relative velocity of the slip element (u') becomes zero. Then, again equations (1) hold.

The above solution is, according to the terminology used by [4,5], is "coupled". On the other hand, in the approximate "decoupled" case, separation of the two bodies is not simulated and equations (5) are not applied. Furthermore, for the rigid conventional sliding-block case, the above equations do not hold: sliding occurs when

$$-a_c(t)-a(t)>0 \tag{6a}$$

and the governing equation of motion at the slip element is

$$u''=-a_c(t)-a(t) \qquad \text{for} \quad u'>0 \tag{6b}$$

It should be noted that in equations (5) the critical acceleration for relative motion is expressed in terms of $a_c(t)$, and thus the effect of rotation of the sliding mass above the slip surface is simulated by equation (3b).

2.2 Constitutive modeling of the soil profile in the non-linear case

For the non-linear case, at the soil profile bodies i (i=1,2), the tangent shear modulus G_{t-i} is estimated as:

$$G_{t-i}(t) = \frac{G_{o-i}}{T_i(t)} \tag{7a}$$

where

$$G_{o-i} = Vs_i^{\,2}\rho_t \tag{7b}$$

$$T_i(t) = 1 + \left(\frac{1}{\eta a_i} - 1\right)\left|\frac{\tau_t(t) - \tau_{o-t}(t)}{\eta b_i}\right| \tag{7c}$$

where G_{o-i} and Vs_i are the shear modulus and shear wave velocity respectively at very small shear strain, $\tau_i(t)$ and $\tau_{o-i}(t)$ is the shear stress and the shear stress of the last stress reversal at time t of body i and a_i and b_i are model parameters which equal to

$$\eta a_i = 0.5 \tag{8a}$$

for $PI_i(\%) \le 15\%$ $$\eta b_i = 6.4 \cdot 10^{-5}\left(\frac{Go_i}{\sigma'_i}\right) \tag{8b}$$

for $PI_i(\%) > 15\%$ $$\eta b_i = (1.29 \cdot PI_i(\%) - 8.00) \cdot 10^{-5}\left(\frac{Go_i}{\sigma'_i}\right)$$

where PI_i is the plasticity index of body i. Fig. 3b illustrates that equation (8b) fits well the factor $\{\eta b / [Go/\sigma']\}$ in terms of PI.

2.3 Discussion of the proposed equations

Equations (1b), (4a), (5) are identical to those used by Rathje and Bray [5] and the form of equations (1a), (6) and (7) is similar to those used by Lin and Whitman [4]. In addition, equation (4b) has been used by Jafarian and Lashgari [7] based on the sliding chain model of figure 1b [20].

The constitutive model equations (8) predicting shear modulus degradation along of the body above and below the slip element are similar to those proposed by Papadimitriou et al. [19], but adjusted for the dry simpler case. The state-of-art work by Vucetic and Dobry [23], indicates that the decrease of the shear modulus with the shear strain depends as a first approximation only on the Plastisity Index (PI) of the soil, as illustrated in Fig. 3a. In equations (8), the model parameters ηa_i specify the Gs/Gmax ratio where the shear stress-degradation response is fitted, and the model parameter ηb_i fits the value of the actual response at a_i. A typical value of a_i for the problem considered is 0.5. Assuming ηa=0.5, for the simulation of Fig. 3a, $\eta\beta_i$ varies in terms of only Go and PI, as illustrated in equations (8).

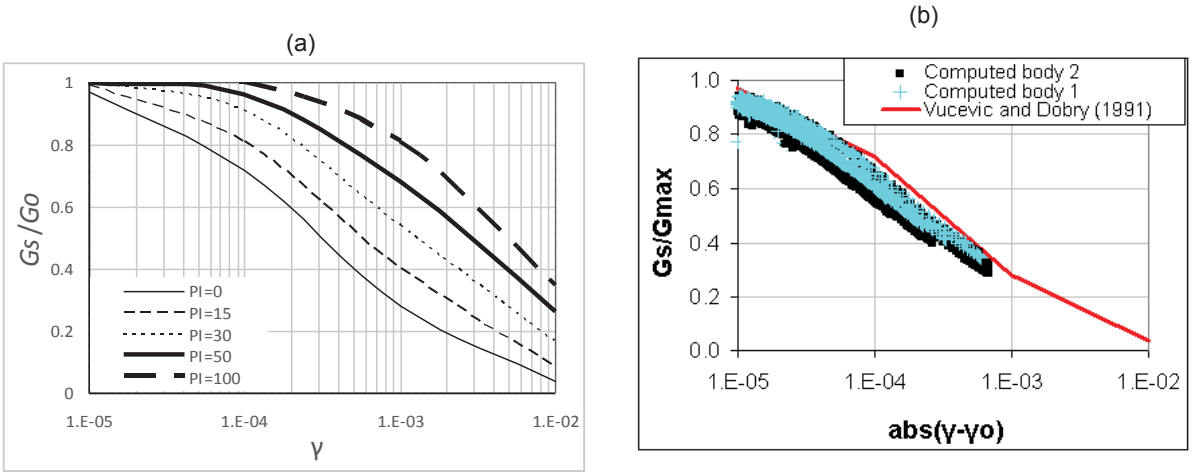

Figure 3: (a) State-of the art shear modulus degradation in terms of shear strain (γ) and Plasticity Index (PI) [23]. (b) simulation for this degradation for the case studied in section 2.4.

2.4 Numerical implementation

Equations (1)-(5), (7) and (8) simulating the non-linear dynamic response of a 2-body system with a slip element with constant strength were solved numerically using the Newmark method with its parameters β and γ taking the values of 0.25 and 0.50 respectively. For the linear case, input at the numerical code is the seismic acceleration history, the critical acceleration a_{co} and the variables h_i, Vs_i, ρ_i, λ_i. Output includes the acceleration time history of the two bodies for the coupled and decoupled cases and the acceleration, velocity and displacement history along the slip element for the coupled, decoupled and rigid cases. For the non-linear dry case, additionally, the value of the Plasticity Index (PI_i) is needed. Additional output of the program in this case is (a) the tangent shear moduli of bodies 1 and 2 versus time, (b) the shear stress-strain response of the two bodies and the (c) the secant modulus degradation with shear strain of the two bodies.

Figures 4 and 3b give typical output results of the proposed method. The case of non-linear sandy soil with $h_1=h_2=15$m, $Vs_1=200$m/s, $Vs_2=300$m/s, $\rho_1=\rho_2=2$t/m^3, $\lambda_1=\lambda_2=0.15$, under the Aegion 1995 earthquake input motion and slip surface with $a_{c0}=0.5$m/s^2 and, L=100m and model parameters $a_1=\alpha_2=0.5$, $\beta_1=\beta_2=1$ is presented. Fig. 3b illustrates that equation (8b) fits well the Vucetic and Dobry [23] curves.

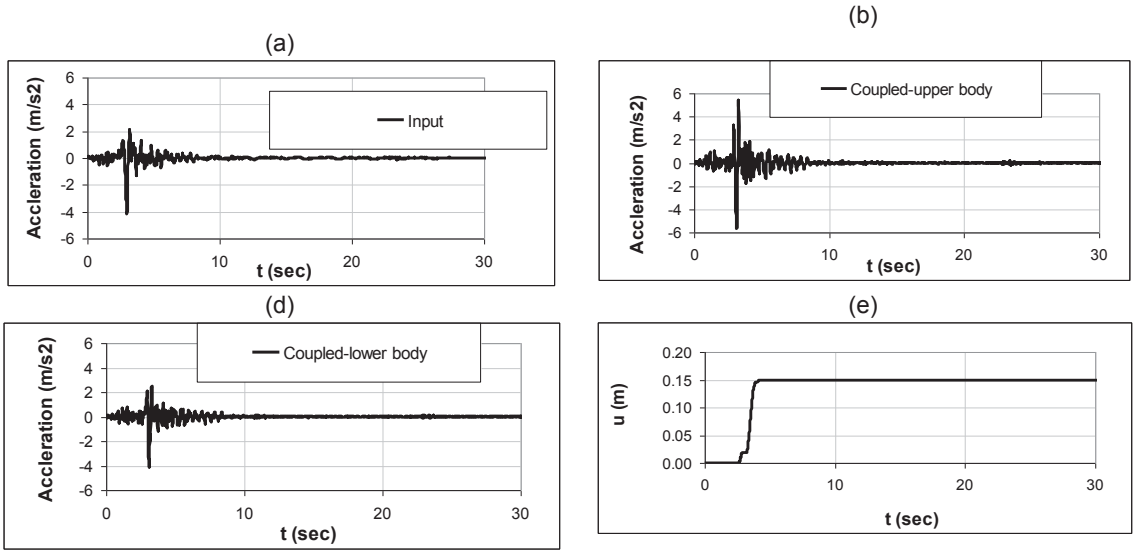

Figure 4: Typical results of the proposed method. The case of non-linear sandy soil with $h_1=h_2=15$m, $Vs_1=200$m/s, $Vs_2=300$m/s, $\rho_1=\rho_2=2$t/m^3, $\lambda_1=\lambda_2=0.15$, under the Aegion 1995 earthquake input motion and slip surface with $a_{c0}=0.5$m/s^2, L=100m and model parameters $a_1=\alpha_2=0.5$, $\beta_1=\beta_2=1$. (a) input acceleration history, (b),(c) acceleration histories of bodies 1 and 2, (d) seismic displacement along the slip surface versus time.

3 GROUND TYPES ACCORDING TO EUROCODE

Eurocode [1] defines ground types A-E, as given in table 1, based on observations by the earthquake engineering community that (a) only the first 30m depth of a soil profile play an important role in the dynamic response, (b) for given soil type, the only soil property that affects considerably the dynamic response is the shear wave velocity and (c) for similar dynamic response, a non-uniform soil profile with n layers may be simplified by an uniform one, with shear velocity Vs_{30}, defined as

$$Vs_{30} = \frac{30\text{m}}{\sum_{i=1}^{n} \frac{h_i}{Vs_i}} \tag{9}$$

where h_i and Vs_i is the thickness in m and elastic shear wave velocity of layer i of the n layers of the soil profile.

Ground type	Description	Vs_{30} (m/s)
A	Rock or other rock-like geological formation	>800
B	Deposits of very dense or medium-dense sand, gravel or stiff clay	360-800
C	Deep deposits of dense or medium-dense sand, gravel or stiff clay	180-360
D	Deposits of loose-to-medium cohesionless soil or of soft-to-firm cohesive soil	<180
E	Soil profile consisting of a surface alluvium layer with Vs values of type C or D and thickness varying between 5-20m, underlain by type A soil	

Table 1: Ground type according to Eurocode [1].

4 DATA BASE OF SEISMIC MOTIONS IN GREECE

In the present work real-time acceleration histories from the most significant recorded seismic events that took place in Greece between 1970 and 2014 were used as a database. Data were obtained from the Internet Site for European Strong-Motion Data (www.isesd.hi.is/). In addition, the seismic recording from the more recent earthquake that occurred in Kefalonia on 03/02/2014 of size M≥6.10 [Argostoli, Lixuri, Chavriata], which were is included until recently in the European Strong-Motion Database (ESD) was used. In particular, the filtered acceleration time histories for the horizontal seismic component xx were obtained. The criteria used to select the Database are the magnitude of the earthquake Mw>5 and the maximum acceleration α max≥0.04g. A total of 50 seismic motions were selected in this manner. Table A1 of the Appendix presents the number of the seismic motion, its name, its station, its date, and its magnitude (Mw). The time histories were analyzed with the seismosignal program [16] the to extract the spectral and temporal parameters. Table A2 of the Appendix presents for each seismic motion, its mean period, its predominant period, its peak acceleration and velocity value (a_{max} and V_{max}), its Arias intensity and its Epicentral distance.

5 PREVIOUS EMPIRICAL EXPRESSION

5.1 Cases considered

The elastic soil profile option of the model [13] was used. and thus equations (7) and (8) were not applied. In addition a very long slip length (L=1000m) was used initially and thus the rotation of the sliding mass effect was not simulated. Then, in order to assess the effect of the rotation of the sliding mass, the above cases were repeated for L=10m, 30m, 100m, 300m. According to Eurocode ground types of table 1, the soil profiles of table 2 were selected. The Vs_1,Vs_2 values correspond to the average ones of each soil profile of table 1, while for the density value, which does not affect considerably the dynamic soil response, the typical value of $\rho=2t/m^3$ was selected. The damping was taken as $\lambda_1=\lambda_2=15\%$, similarly to analyses by [5, 7, 13]. The critical acceleration value a_c was selected in such a way that computed final seismic displacement of the conventional sliding-block case ($u_{f\text{-}sl}$) varies from about 0.05m to about 0.5m. The reason is these are tolerable displacement values for typical structures.

At least five (5) a_c values were applied for each seismic motion and Vs_1,Vs_2 soil profile. For all these cases of soil profiles and a_c values, the 50 seismic motions described in section 2 above were applied and the seismic displacement (u_f) was computed. For comparison reasons, the seismic displacement for a rigid block for the same applied motion and critical acceleration value ($u_{f\text{-}sb}$) was also estimated.

Ground type	Vs (m/s)	h_1	h_1+h_2	$\rho_1=\rho_2$	$\lambda_1=\lambda_2$	a_{co}
S-B	$Vs_1=Vs_2=580$	5, 10, 20m	30m	2t/m3	0.15	In such a way that computed final seismic displacement along the slip surface (uf) varied from a few mm to tens of cm
S-C	$Vs_1=Vs_2=270$					
S-D	$Vs_1=Vs_2=100$					
S-E	Vs_1=200m/s, Vs_2=1000m/s					

Table 2. Soil profiles assumed in the analysis

5.2 Form of equation

As described above, as different regions have unique earthquake faults and geological profiles characteristic conditions, they have seismic motions of different characteristics and thus different empirical expressions predicting seismic dis-placement. Region-specific empirical expressions predicting (uf-rigid) in Greece has been proposed by [9]. For this reason, in order, possibly to omit predicting the effect of factor such as a_c, a_{max}, Arias intensity, earthquake magnitude etc on u_f, we propose just to relate u_f on $u_{f\text{-}rigid\text{-}L=1000m}$, where $u_{f\text{-}rigid\text{-}L=1000m}$ is predicted with previously proposed equations and the u_f incorporates, additional the dynamic effects of the soil profile both above and below the slip surface. Based on the above, we can write

$$u_f = Ra\ R\ u_{f\text{-}rigid\text{-}L=1000m} \tag{10}$$

where the factor RA simulates the dynamic effect for L=1000m and Ra simulates the effect of the rotation of the sliding mass on the rigid case.

Furthermore, preliminary inspections of the obtained results illustrated that RA increases or decreases as a_c decreases, and at small a_c value it tends to 1. However, a_c for the design seismic displacement value varies a lot for different seismic motions: for the typical results for a seismic motion of high and low a_{max} value, a_c varies between 0.01-0.09g and 0.002-0.05g respectively. This variation is eliminated if the factor R is related to $u_{f\text{-}rigid\text{-}L=1000.}$. Fig. 5 gives the ratio RA in terms of ($u_{f\text{-}rigid\text{-}L=1000}$) of soil profiles (a) S-B, (b) S-C, (c) S-D, (d) S-E in terms of ($u_{f\text{-}rigid}$) for seismic motion (i) S3 and (b) S29 of Appendix A. It can be observed that: RA increases or decreases as $u_{f\text{-}rigid\text{-}L=1000}$ increases, and at large $u_{f\text{-}rigid\text{-}L=1000}$ value it tends to 1. Based on the above we propose the following equation:

$$RA = 1 + a1\ (0.1/\ u_{f\text{-}rigid\text{-}L=1000})^{a2} \tag{11a}$$

where a1, a2 are model parameters. In particular, a1 gives the factor (R-1) at $u_{f\text{-}rigid}$=0.1m and a2 gives the manner that the factor R changes in terms of $u_{f\text{-}sb,}$ Further parametric analysis illustrated that as a first approximation a1 depends on both the soil profile and h1, while a2 depends only on the soil profile (Fig. 6). Thus, equation (4) can be adjusted as

$$RA = 1 + [n1 - n2\ (h1\text{-}10m)]\ (0.1/\ u_{f\text{-}rigid\text{-}L=1000}\ )^{a2} \tag{11b}$$

where the parameters n1, n2, a2 depend on the soil type.

After having obtained the effect of soil type and slip surface depth, the effect of slip length is investigated in the present work. We propose the following equation predicting R1:

$$Ra=0.5\ \{1+\tanh\ [\ln(c_2/(\ u_{f\text{-}rigid\text{-}L=1000}\ /L)^{c1}\ )]\ \} \tag{12}$$

where c1, c2 may depend on the seismic motion.

Equation (12) is a modified version of an equation used by Ishibashi and Zhang [12] to simulate a similar effect: the decrease from 1 to zero the ratio of the secant shear modulus to the small strain shear modulus as the shear strain increases. Equation (6) predicts that Ra equals to one when ($u_{f\text{-}rigid\text{-}L=1000}$ /L) takes a very small value and Ra decreases from one to zero as ($u_{f\text{-}rigid\text{-}L=1000}$ /L) increases.

Further analysis illustrated that it was sufficient to keep the c1 factor constant, taking the value 0.8, and varying the factor c_2, which takes a very small value when Ar is very small and then increases as Ar increases (Fig. 7).

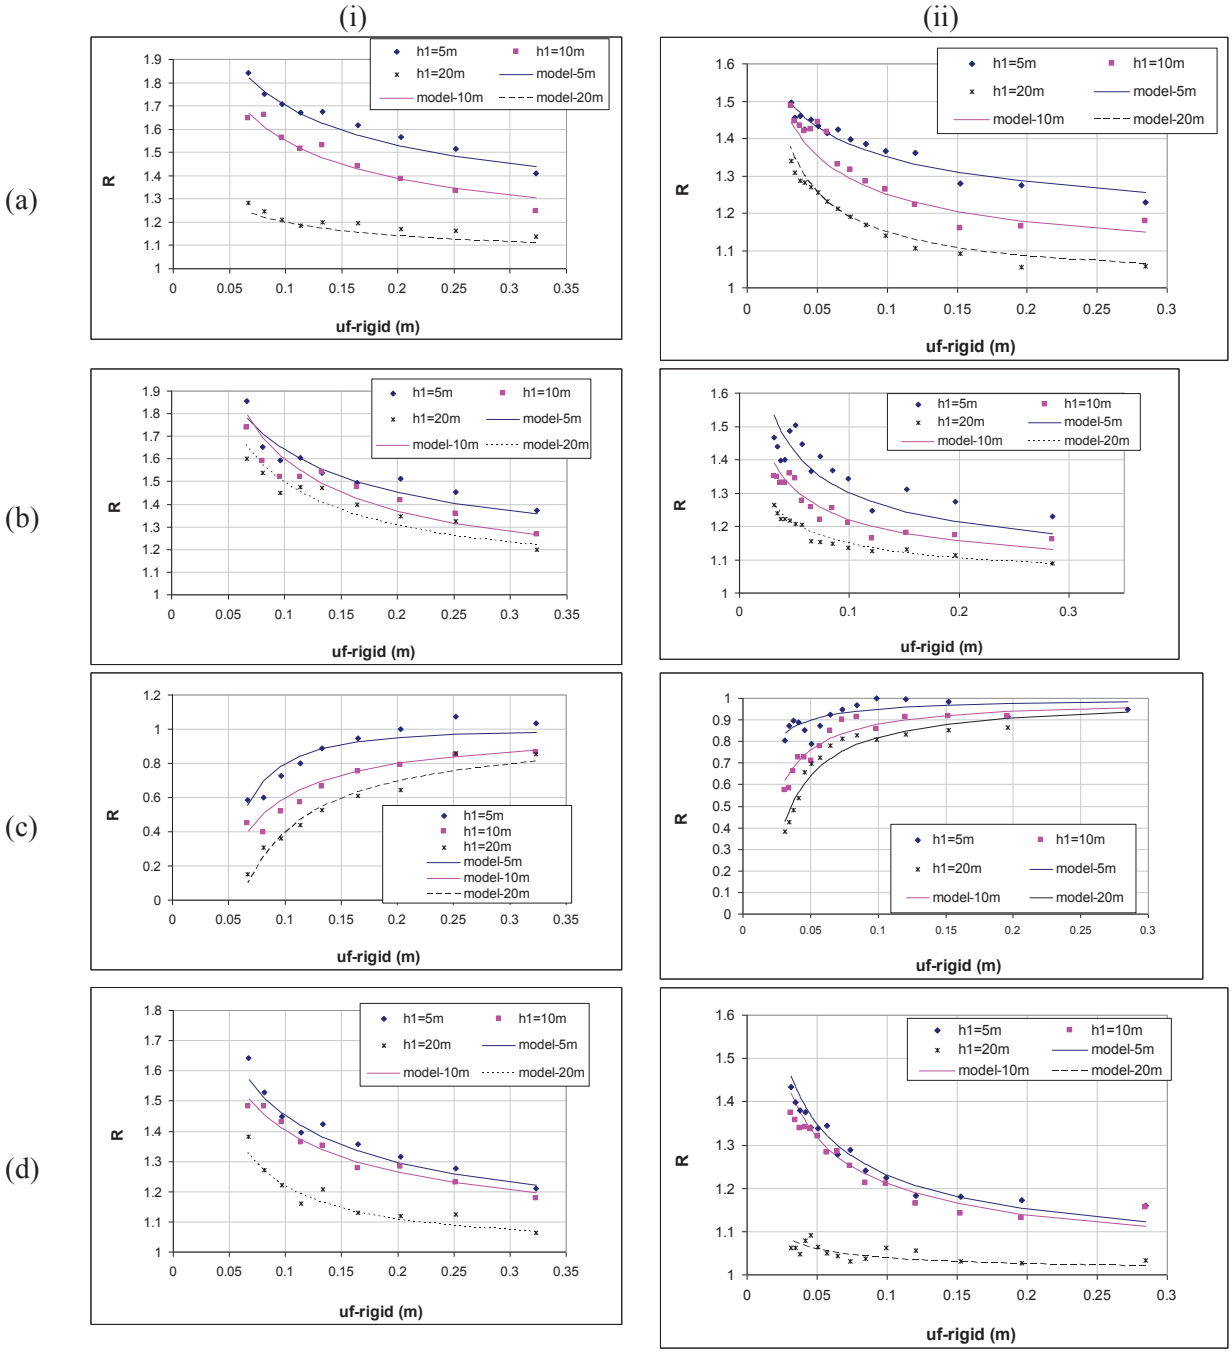

Fig. 5. Ratio RA in terms of ($u_{f\text{-}rigid}$) of soil profiles (a) S-B, (b) S-C, (c) S-D, (d) S-E for seismic motion (i) S3 and (b) S29 of table A1

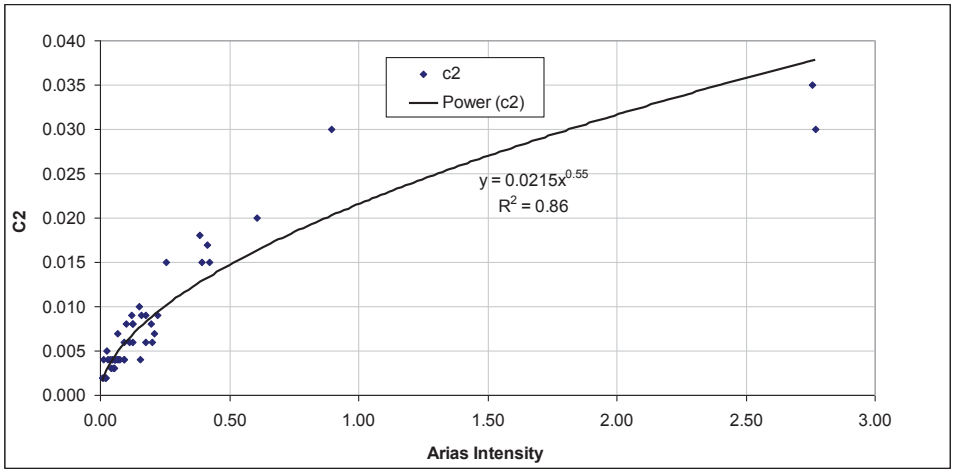

Fig. 7: The factor c2 in terms of Arias intensity and best-`fit trend for all seismic motion cases

5.3 Proposed equation

Based on the previous section results, Katsenis et al. [17] give the following equation predicting the seismic displacement along slip surfaces in terms of (a) the conventional sliding-block predictions **($u_{f\text{-}rigid\text{-}1000m}$)**, (b) soil type category according to Eurocode, (c) the depth (h1) and length (L) of the slip surface:

$$u_f = Ra\ u_{f\text{-}rigid\text{-}1000m}\ \{1+ [n1 - n2\ (h1\text{-}10m)]\ (0.1/\ u_{f\text{-}rigid\text{-}1000m}\ )^{a2}\} \quad (13a)$$

where

$$Ra = 0.5\ \{1+\tanh[\ln((([0.0215Ar^{0.55}]/(u_f/L))^{0.8})]\ \} \quad (13b)$$

and n_1, n_2, a_2 are model parameters given in table 3.

Soil type	n1	n2	a2	n1'
S-B	0.19	0.0093	0.6	0.05
S-C	0.26	0.0101	0.6	-0.63
S-D	-0.15	0.0111	1.0	-0.88
S-E	0.14	0.0118	0.4	0.02

Table 3. Parameters of equations (13) and (15) in terms of soil type

6 EFFECT OF NON-LINEAR RESPONSE

Katsenis et al [13] studied in detail the effect of non-linear response for a particular case: the Aegion 1995 seismic motion with a_{co}=0.5m/s^2, Vs_1= 20 to 5000m/s, Vs_2=Vs_1, h_1=h_2=15m, ρ_1=ρ_2=2t/m3, λ_1=λ_2=0.15, L=1000m, PI_i=0. Fig 8a presents the computed effect of non-linearity: u_f for the linear and nonlinear (coupled) cases versus Ts_1/Tm, where Tm is the mean period of the applied seismic motion and

$$Ts_1 = \frac{4h_1}{Vs_1} \tag{14}$$

Fig 8b gives the corresponding maximum shear strain for the non-linear analyses.

Fig 8a illustrates that the effects of non-linearity on u_f are significant. They can be interpreted by the effect of non-linearity on the representative shear modulus value of the analysis. In particular, as a result of non-linearity, the shear modulus value decreases and therefore, the "equivalent" Ts_1/Tm value is larger than the "elastic one". It is inferred that the u_f versus Ts_1/Tm curves are shifted to the left in the non-linear analyses. More specifically, fig. 8b illustrates that in the non-linear analyses the maximum shear strain takes a very small value at Ts_1/Tm=0 and then gradually increases as Ts_1/Tm increases. The reason is that as Ts_1/Tm increases, Vs_1=Vs_2 decreases and thus the soil becomes softer. Consistently to the above, Fig 8a illustrates that u_f in the non-linear analyses is more-or-less the same at Ts_1/Tm=0, but as Ts_1/Tm increases the u_f versus Ts1/Tm curve is shifted to the left and the shift is more pronounced as Ts_1/Tm increases.

To demonstrate quantitatively the effect of nonlinearity described above, we consider the example case of Fig. 8a and Ts_1/Tm=0.5. According to Fig. 8a, in this case in the linear response u_f=0.25m and according to Fig. 8b in the non-linear dry response the maximum γ_{cyc} value for bodies 1 and 2 equals 0.2 and 1% respectively, or 0.6% in average. Thus, according to Fig. 3a the maximum shear modulus decrease is by about 10 times and thus the average decrease is 5 times. As in these analyses Vs_1=Vs_2, it is inferred that in the nonlinear dry case Ts-av/Tm increases about 2.2 times and thus the "equivalent linear" Ts_1/Tm =Ts-av/Tm value equals 0.5*2.2=1.1 and the corresponding u_f value according to fig 8a is 0.14m. It is inferred that for Ts_1/Tm=0.5, u_f decreases from 0.25m in the linear case to 0.14m in the non-linear dry case. This agrees completely with the numerical results given in Fig. 8a for Ts_1/Tm=0.5.

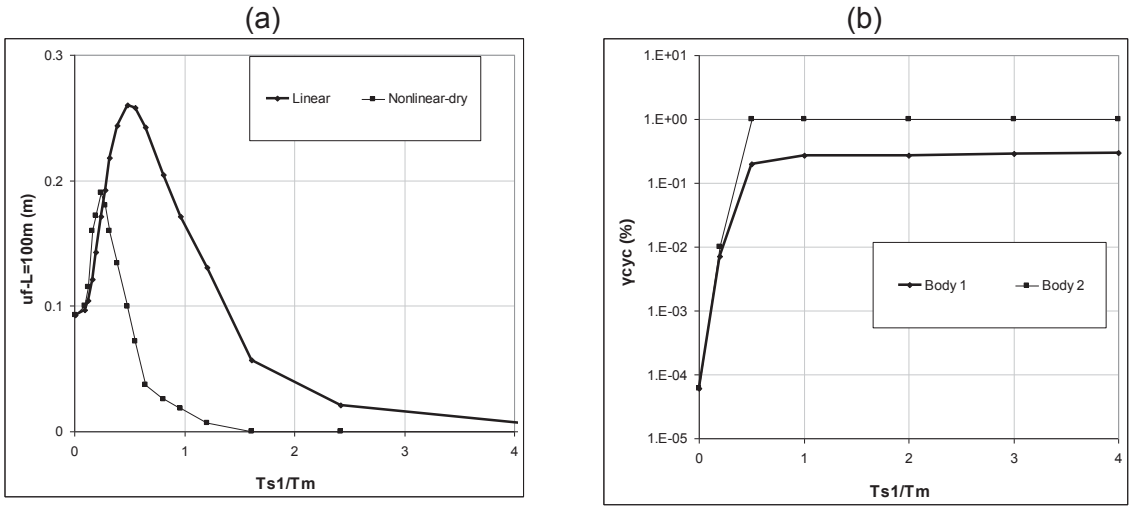

Fig. 8. (a) The computed permanent seismic displacement (u_f) for the linear, nonlinear dry (fa_i= 0) and nonlinear saturated (fa_1=0.3, fa_2=1) coupled analyses versus Ts_1/Tm and (b) the corresponding maximum shear strain for the non-linear analyses. The case of the Aegion 1995 seismic motion with a_{co}=0.5m/s^2, Vs_2=Vs_1, h_1=h_2=15m, ρ_1=ρ_2=2Mg/m^3, λ_1=λ_2=0.15. L=1000m, PI_i=0 is presented.

7 EMPIRICAL EQUATION: PROPOSED MODEL: FORM AND DERIVATION AND VALIDATION PROCEDURE

Based on section above, it is inferred that in non-linear analyses, the shear velocity of the soil layer is modified. As described in section 5, the shear wave velocity in the existing empirical model (13) enters thru the parameters n1, n2, a2. According to table 3, from these three parameters, only the parameter n1 varies dramatically with soil type, taking values ranging from 0.26 to -0.15. It is inferred that, as a first approximation, only this parameter may be modified for the non-linear case. Furthermore, as Vs increases, the shear strain which develops during seismic loading is less and thus the modification needed in the parameter n1 will be less.

Thus, we propose the following equation to estimate the seismic displacement for the non-linear case:

$$u_f = Ra\ u_{f\text{-}rigid\text{-}1000m}\ [1+ [n1 + n1' - n2\ (h1\text{-}10m)]\ (0.1/\ u_{f\text{-}rigid\text{-}1000m}\ )^{a2'}] \quad (15a)$$

where

$$Ra =0.5\ \{1+\tanh[\ln(([0.0215Ar^{0.55}]/(u_f/L))^{0.8})]\ \} \quad (15b)$$

and n_1, n_2, a_2 are the model parameters of the previous equation (13), given in table 3, while the model parameter n1', which simulates the effects of nonlinearity in sandy soils depends on soil type.

In addition, the following procedure is used to evaluate the model parameter n1', defined as

$$n1'= n1_{non\text{-}linear\text{-}PI=0} - n1_{linear} \quad (16)$$

- (a) First, the data base described in section 5.1 is divided in two parts, one to determine the model parameters (DB1), and the other to validate it (DB2). The data base DB1 is the odd number earthquakes and DB2 is the even number of earthquakes.

- (b) Then, for the non-linear case for sands (PI=0), perform parametric analyses identical to those described in section 5.1 for L=1000m.
- (c) Estimate the model parameter n1' by analyzing the results for h1=10m per soil type and taking the average value. In this respect, it can be observed that, as L=1000m, Ra=1 and thus for h1=10m

$$n1' = [u_{f\text{-non-linear}} / u_{f\text{-rigid-1000m}} - 1] / [0.1 / (u_{f\text{-rigid-1000m}})^{a2'}] - n1 \quad (17)$$

- (d) Analyze the error in the estimation of n1' for h1=5m and 20m in terms of soil type. The error of the predictions is defined in the present work as

$$Er = 1 - Predicted/Computed \quad (18)$$

- (e) Once these empirical expressions is derived, use the database DB2 described above to validate the proposed equation. Measure the error (Er) in all 12 cases of the 25 input motions, thus in 12*25=300 cases in total and confirm that the mean and standard deviation of the error are close to zero. Furthermore, analyze the obtained error for all earthquakes in terms of soil type and h_1 (for 12 cases) in order to establish if the accuracy depends on soil type and h_1.

8 EMPIRICAL EQUATION: PROPOSAL AND VALIDATION

Based on the procedure described in section 7, table 3 gives the n1' obtained value per soil type. The standard deviation per soil type and h1 of the error (equation (18)) was in the range of 0.06-0.09, reasonably close to zero. Furthermore, in table 3 it can be observed that the estimated n1' values are larger for the cases of soil types S-C and S-D, consistently to the fact that these two soil types have much lower Vs values and thus the effects of nonlinearity in these soils are greater. Thus, for the non-linear case, equation (15) is proposed with the model parameters of table 3.

Once the empirical equation (15) with the model parameters of table 3 was established using the database DB1, its error in the predictions of this equation was established using DB2. Considering all the data of DB2, the absolute value mean and standard deviation of the error (equation (18)) were estimated as 0.05 and 0.05 respectively. As these values are close to zero, the error is small and acceptable. Furthermore, the obtained error for all earthquakes was obtained in terms of soil type and h_1 as given in table 4. It can be observed that in all cases the error has mean value less than 0.10 and standard deviation less than 0.12.

	Mean Value (Absolute value)			Standard Deviation		
Soil type	h1=5m	h1=10m	h1=20m	h1=5m	h1=10m	h1=20m
S-B	0.08	0.08	0.08	0.07	0.05	0.09
S-C	0.07	0.07	0.09	0.08	0.10	0.11
S-D	0.08	0.08	0.07	0.07	0.08	0.09
S-E	0.09	0.09	0.10	0.06	0.06	0.12

Table 4. Statistical analysis of the error in the predictions of equation (17) with the parameters of table 3 in terms of soil type and h_1

9 EXAMPLE APPLICATION

As an example application, we consider a site in Greece of soil category S-C where the slip surface is at average depth 5m and geotechnical and seismic analysis for bedrock seismic mo-

tion characteristics of the site gave ac=0.01g, and design earthquake of magnitude Mw=7.0 at distance R=1km. Equation (13) by [9] predicts an Arias Intensity Ia=22.0m/s and equation (21) by [9] predicts a corresponding maximum value of seismic displacement with "conventional" sliding-block model $u_{f\text{-}rigid\text{-}L=1000m}$=9.5cm. Application of the empirical expressions (6) with the parameters of table 3 would predict that when considering dynamic effects, Ra=0.98 and u_f=6.3cm. For the elastic case, u_f would equal 12.3cm. Thus, the seismic displacement u_f would increase by about 50% as a result of non-linear response.

10 CONCLUSIONS

- The present work proposes the empirical expression (15) with the parameters of table 3 predicting the seismic displacement of sandy slopes along slip surfaces in Greece, in terms of (a) the conventional sliding-block model predictions, (b) the soil type category according to Eurocode and (c) the depth and length of the slip surface.
- These equations were obtained by extensive parametric analyses using a recently developed dynamic coupled numerical code which predicts the seismic displacement of a ninlinear soil profile along a slip surface at some depth. An extensive data base of seismic motions recorded in Greece was applied below typical soil layers according to Eurocode category type with slip surface at different depths and varying the resistance (as defined by the critical acceleration value) in such a way that computed final seismic displacement of the conventional sliding-block case varies from about 0.05m to 0.5m. The results were analyzed statistically.
- The effects of non-linearity are simulated thru the factor n1', which affects considerably the results for the soft/loose soil profiles S-C and S-D.

Keywords: blade, flutter, travelling wave, Van der Pol model

Abstract. *Inner material damping effect for reduction of self-excited vibrations due to aero-elastic instability is studied on a numerical reduced model of a rotating turbine wheel with 66 blades. The aerodynamic nozzle excitation of the rotating wheel arises from the spatially periodical flow of steam through the stator blade cascade. This excitation causes travelling deformation waves in the wheel. The analysis of forced vibration of the wheel under self-excitation is oriented on the narrow frequency range and therefore the bladed wheel is modelled by a modal synthesis method. The self-excited aero-elastic forces are described by Van der Pol model acting herein independently to the 1th axial flexural mode of each blade of the wheel. Numerical simulations showed a very fast entry of amplitudes increase due to self-excitation. The initial forced vibration mode by nozzle excitation was decisive for the vibration pattern of self-excitation. Its suppression depended on the ratio between the intensity factor of self-excitation and the size of proportional damping describing the inner damping.*

1 INTRODUCTION

Since traditional computational fluid and structural tools are computationally very expensive and required large computational power to simulate fluid-structure problems in machines where the large fluid domain and complex solid bodies need to be discretized, we aim at development and application of reduced-order modeling order modeling (ROM) of flutter oscillations in turbine bladed wheel dynamics. Although such ROM approaches are medium fidelity models yet, they can bring interesting knowledge of their dynamic behavior of a bladed wheel system.

Beside the forced nozzle excitation, the gas flowing through a blade cascade can cause instability and/or increase of self-excited oscillations [1-3]. For determination of critical behavior of self-excited vibration in the blade cascade, the boundary element based panel method as ROAM method is developed to model a flow field around bodies [4]. For description of post-critical dynamic behavior of the bladed wheels, a semi-analytical approach based on the Van der Pol model was proposed [5-7]. For case studies, the different blade systems modeled by mass-spring discretized models with viscous-elastic or dry-friction damping in the blades shroud were analyzed. Van der Pol model advantage is a conversion of negative damping into positive one after the amplitude of self-excited oscillations exceeds prescribed limits.

This contribution is continuation of our study of self-excitation in bladed wheels. In this approach, however, we choose the modal synthesis ROM method for the bladed wheel reduction [8-10]. It shows that the vibration of the turbine wheels occurs in narrow frequency ranges when dominant resonant vibration occurs. In literature Van der Pol model of self-excitation is used in connection with stator blade vortex shedding excitations and “lock-in” phenomena. As the vortex shedding frequency approaches the natural frequency of the body, both frequencies lock-in [11-13]. In our approach, however, we deal with classical flutter phenomena [1] in bladed wheels that is linked with travelling deformation waves and inter-blade-phase-angle (IBPA) initiated by nozzle excitation. If the material and structural damping of the wheel is low, the flutter can cause rapid increase of vibration amplitudes that can lead to high cycle fatigue of the blade. Resonant frequencies and vibration mode shapes does not change significantly due to higher vibration amplitudes in the flutter state. Therefore, if we correctly asses the frequency range for modal reduction, this method could precisely describe the bladed wheel dynamics because the modal properties of the reduced system are properly approximated. The aero-elastic forces are described again by Van der Pol model related to selected eigenmode. As example of possible suppression of this dangerous phenomenon, we introduced a simple proportional damping term which describes inner material damping into the equation of motion.

2 GENERAL SPECIFICATIONS

The homogeneous equation of motion of the undamped original mechanical system can be written in the matrix form as

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{K}\mathbf{u} = \mathbf{0}\,, \tag{1}$$

where $\mathbf{M}$ and $\mathbf{K} \in R^{n\times n} \in R^{n\times n}$ are mass and stiffness square matrices of dimension n, $\ddot{\mathbf{u}}$, $\mathbf{u}$ are acceleration, displacement vectors of the DOFs.

That leads to the eigenvalue problem

$$(\mathbf{K} - \Lambda\mathbf{M})\mathbf{X} = \mathbf{0}\,, \tag{2}$$

The solution of (2) yields the matrices of eigenvalues Λ and of eigenvectors $\mathbf{X}$

$$Diag(\mathbf{\Lambda}) = [\lambda_1, \lambda_2, \ \dots \ , \lambda_n], \mathbf{X} = [\mathbf{x}_1, \mathbf{x}_2, \ \dots \ , \mathbf{x}_n] . \tag{3}$$

If the eigenvector matrix satisfies the orthonormal condition then

$$^T\mathbf{XMX} = \mathbf{I}, \mathbf{XKX} = \mathbf{\Lambda} . \tag{4}$$

For simplicity of modal synthesis explanation, let us assume assembly just two identical blade segments (n_r=2). The homogenous equation of motion of uncoupled subsystems is

$$\mathbf{M}_c\ddot{\mathbf{u}}_c + \mathbf{K}_c\mathbf{u}_c = \mathbf{0} , \tag{5}$$

where

$$\mathbf{M}_c = \begin{bmatrix} \mathbf{M} & 0 \\ 0 & \mathbf{M} \end{bmatrix}, \ \mathbf{K}_c = \begin{bmatrix} \mathbf{K} & 0 \\ 0 & \mathbf{K} \end{bmatrix}, \ \mathbf{u}_c = \begin{bmatrix} \mathbf{u}_1 \\ \mathbf{u}_2 \end{bmatrix},$$

with eigenvalue characteristics

$$\mathbf{\Lambda}_c = \begin{bmatrix} \mathbf{\Lambda} & 0 \\ 0 & \mathbf{\Lambda} \end{bmatrix}, \ \mathbf{X}_c = \begin{bmatrix} \mathbf{X} & 0 \\ 0 & \mathbf{X} \end{bmatrix}, \tag{6}$$

where $\mathbf{K}_c, \mathbf{M}_c, \mathbf{X}_c, \mathbf{\Lambda}_c \in R^{nn_r xnn_r}$ (n is number of DOFs of the segment, n_r is number of segments).

Each connection between the blade subsystems can be described by a constraint vector $\mathbf{T}_v$. For example, let $\mathbf{K}$ is a matrix of R^{4x4} and 4th DOF u_{14} of the 1th blade and the 3rd DOF u_{23} of the 2nd blade are connected by spring with stiffness c_1. The constrain is governed by the expression

$$c_1(u_{14} - u_{23}) = F_1 . \tag{7}$$

To create the full modification stiffness matrix in original DOFs, the constrain can be expressed by a constraint vector $\mathbf{T}_v$

$$c_1 \, ^T\mathbf{T}_v\mathbf{u}_c = F_1 , \tag{8}$$

where $^T\mathbf{T}_v = \begin{bmatrix} 0 & 0 & 0 & 1 & 0 & 0 & -1 & 0 \end{bmatrix}$. Then the modification stiffness is constituted as

$$\Delta\mathbf{K} = \mathbf{T}_v \, ^T\mathbf{T}_v c_1 . \tag{9}$$

The full synthesized system can be described by the equation of motion

$$\mathbf{M}_c\ddot{\mathbf{u}}_{cN} + \left(\mathbf{K}_c + \Delta\mathbf{K}\right)\mathbf{u}_{cN} = \mathbf{f}_{cE} , \tag{10}$$

which leads to eigenvalue problem

$$\left(-\mathbf{\Lambda}_{cN}\mathbf{M}_c + \left(\mathbf{K}_c + \Delta\mathbf{K}\right)\right)\mathbf{X}_{cN} = \mathbf{0} . \tag{11}$$

To reduce the full DOF space of the synthesized structure (10) we choose the modal subspace

$$\bar{\mathbf{X}}_c = \begin{bmatrix} \bar{\mathbf{X}} & 0 \\ 0 & \bar{\mathbf{X}} \end{bmatrix},$$

where $\bar{\mathbf{X}} \in R^{n\times m}$ is matrix of arbitrarily chosen m eigenvectors of $\mathbf{X} \in R^{n\times n}$ of the original one-blade subsystem. Introducing the transformation $\mathbf{u}_{cN} = \bar{\mathbf{X}}_c \mathbf{Q}_{cNR}$ and $\ddot{\mathbf{u}}_{cN} = -\bar{\mathbf{X}}_c \mathbf{\Lambda}_{cNR} \mathbf{Q}_{cNR}$ and pre-multiplying by ${}^T\bar{\mathbf{X}}_c$ in (11), when the eigenvector matrix $\bar{\mathbf{X}}_c$ satisfies the orthonormal condition (4) then we get

$$[-\mathbf{\Lambda}_{cNR} + (\mathbf{\Lambda}_{cR} + \Delta\mathbf{K}_{cNR})]\mathbf{Q}_{cNR} = \mathbf{0}, \tag{12}$$

where $\mathbf{Q}_{cNR}$ is reduced synthesized modal matrix, $\Delta\mathbf{K}_{cNR} = {}^T\bar{\mathbf{X}}_c \Delta\mathbf{K} \bar{\mathbf{X}}_c$ is reduced modification matrix of $R^{mn_r \times mn_r}$.

Remark: To avoid the calculations of the eigenvalue problem of the full synthesized system (10) the modal subspace $\mathbf{X}_{cN}$ is approximated by $\mathbf{X}_c$ for expression of $\mathbf{u}_{cN}, \ddot{\mathbf{u}}_{cN}$. Therefore it is necessary to use the same boundary conditions of the uncoupled and synthesized models.

To preserve the solution in modal space, then the external and self-excitation forces has to be expressed in reduced space and equation of motion of synthezised reduced wheel system can be expressed as

$$\mathbf{M}_{cR}\ddot{\mathbf{u}}_R + \beta(\mathbf{K}_{cR} + \Delta\mathbf{K}_{cNR})\dot{\mathbf{u}}_R + \mathbf{G}(\mathbf{u}_{RB}, \dot{\mathbf{u}}_{RB}) + (\mathbf{K}_{cR} + \Delta\mathbf{K}_{cNR})\mathbf{u}_R = \mathbf{f}_{cRE}(t), \tag{13}$$

where $\mathbf{K}_{cR} = {}^T\bar{\mathbf{X}}_c \mathbf{K}_c \bar{\mathbf{X}}_c$, $\mathbf{M}_{cR} = {}^T\bar{\mathbf{X}}_c \mathbf{M}_c \bar{\mathbf{X}}_c$, β is coefficient of proportional damping and $\mathbf{u}_{RB}$ is defined bellow..

In steam turbines the stator blades create so-called nozzle excitation, i.e. spatially periodical flow that acts on the rotor blades with periodic force which frequency is dependent on angular velocity of the rotor and number of stator blades. Number of stator blades is usually chosen lower than number of rotor blades and their difference gives number of NDs which is excited by the nozzle excitation. The excitation force can be described by

$$F_{Ei} = F_b \cos\left[n_s \omega_r t - 2\pi \left(1 - \frac{n_s}{n_r}\right) i \right], \quad i = 1, \ldots, n_r, \tag{14}$$

where F_b is the force amplitude, ω_r the angular velocity of the rotor and n_r and n_s are the numbers of rotor and stator blades. So force vector ${}^T\mathbf{f}_{cRE} = \left[{}^T\mathbf{f}_{cRE1} \quad {}^T\mathbf{f}_{cRE2} \quad . \quad {}^T\mathbf{f}_{cREn} \right]$ is composed of reduced external excitation vectors $\mathbf{f}_{cREi} = \mathbf{p}_{Ei} F_{Ei}$ of each blade (i=1, n_r), where $\mathbf{p}_{Ei} = {}^T\bar{\mathbf{X}}\mathbf{d}_{cEi}$ is participation factor of i-blade. Distribution excitation vector $\mathbf{d}_{cEi}$ of the blade is zeros vector with ones only on positions corresponding to DOFs of the blade where forces act.

In addition to the nozzle excitation, we assumed the self-excitation aerodynamic forces $\mathbf{G}$ that uniformly act on one selected mode of each blade. To study the effect of the self-excited vibrations, Van der Pol model was used as

$$G_i = -\mu\left[1-\left(\frac{u_{RBi}}{r}\right)^2\right]\dot{u}_{RBi}, \quad i=1,\ldots,n_r, \tag{15}$$

where μ is intensity of self-excitation and r is a value of amplitude at which the negative damping changes into positive. This property allows us to study the behavior in this unstable regions because it prevents the amplitude to grow to infinity and stopping the simulations. Displacements u_{RBi} and their velocities $\dot{u}_{RBi}$ are linked with absolute values of selected modal coordinates calculated for each blade at each step of time integration. The construction of vector $\mathbf{G}$ is analogical to $\mathbf{f}_{cRE}$ Due to uniformity distribution assumption its vectors $\mathbf{d}_{ci}$ are unity vector and arising participation vectors of blades are multiplied by function (15). Therefore, the unstable behavior of each blade in selected vibration modes is enabled.

3 STUDY CASE

For demonstration of the blade assembly by modal synthesis and calculations of its dynamic behavior under nozzle excitation and self-excitation, the modified turbine bladed wheel was chosen as a study case (Fig.1). In addition to the modified model, the real structure of the wheel (n_r =66 blades) has interconnections in shrouds and tie-bosses of blades.

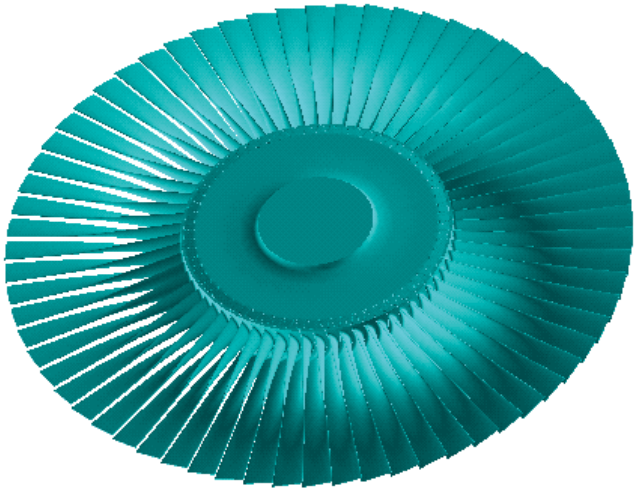

Figure 1: Model of bladed wheel.

The numerical models of the whole wheel with mesh of 1946303 nodes and the one-blade segment used for modal synthesis of 30383 nodes (91149 DOFs) were built in the program ANSYS 19.3. The node topology of one-blade segment including a blade and disk partition is shown in figure 2.

The bottom nodes (light blue marks) of the model (shaft area) were clamped in all DOFs. The nodes (N25201 and N25467) of y-axis nozzle excitation and nodes of ten couplings' pairs between left and right sides of neighboring segments, i.e. pairs N3696-N3185, N3475-N1875, N3546-N1587, N3405-N1980, N3427-N2077, N1109-N3154, N3602-N2408, N3673-N2690, N3273-N1840, N3561-N2515, are depicted in the figure too. All DOFs of the paired nodes were connected by springs with stiffness $c_1 = 1e8 Nm^{-1}$. Then the constrain expressions (9) were used to create modification matrix $\Delta\mathbf{K}_{cR}$. Since the modal matrix $\bar{\mathbf{X}} \in R^{91149\times 3}$ consisted

of flexural (one tangential and two axial) eigenmodes of the first three eigenfrequencies (Tab.1) of the segment, the final dimensions of the global matrices of equation (13) were reduced (198x198).

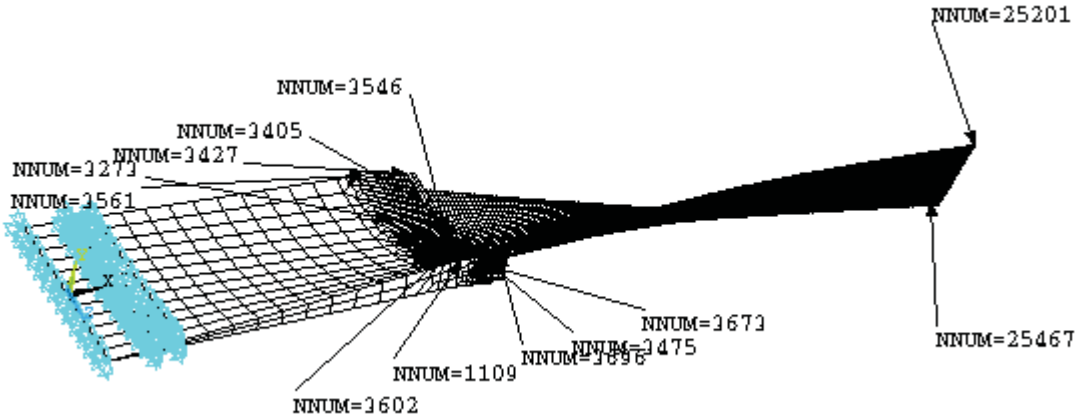

Figure 2 FE model of one-blade segment

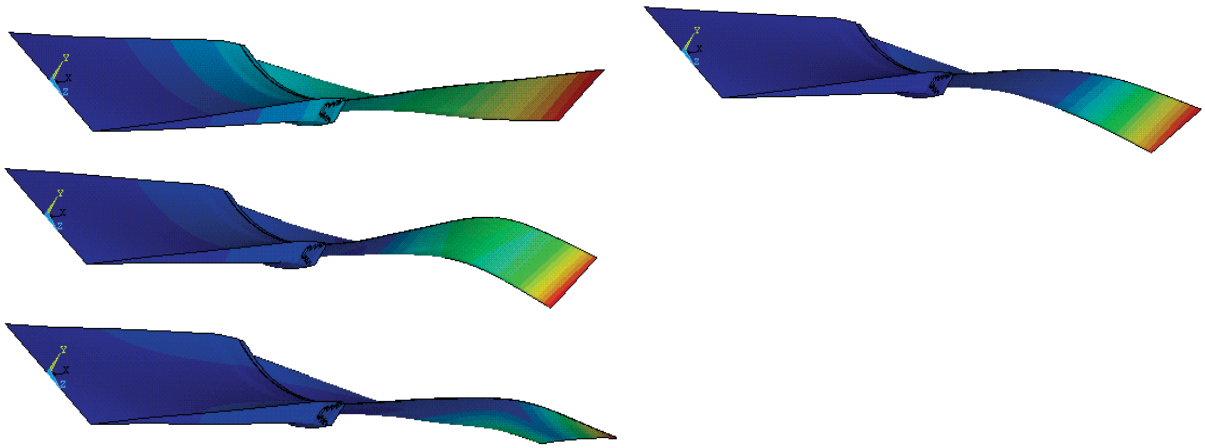

Figure 3: First four eigenmodes: a) 1. Tangential bending, b) 1. Axial bending c), 2. Axial bending, d) 1. Torsional.

By couplings between the 1th and the last 66th blade we create a rotational periodicity of the assembly. These structures are characteristic by double eigenfrequencies of the eigenvalue problem. To assess accuracy of the mode approximation the results of eigenfrequencies ω_{ci} of uncoupled assembly, ω_{cFi} of full unreduced model (as reference) and ω_{cNRi} of modified reduced system are presented in Tab. 2. It can be seen a good agreement between full model and synthesized model results. Small differences between modes with different number of nodal diameters show that the disk is relatively stiff compared to the blades that is demonstrated by small disk displacements of all eigenmodes in Fig. 4. Selected shapes of eigenmodes (2ND and 4ND) associated with their double eigenfrequencies computed by the full wheel FE model are depicted in the figure 4.

Selection of modes, modal reduction of one-blade segment and modal synthesis of the wheel were calculated in Matlab after importing full matrices from ANSYS.

4 SIMULATIONS OF WHEEL DYNAMIC BEHAVIOUR - NOZZLE EXCITATION AND SELF-EXCITATION

The simulations of self-excited vibrations on reduced-order model of bladed wheel were realised in Simulink block scheme environment. Simulation time-step was chosen 1e-4 s and the used solver was "ode3". The mode sensitive to self-excitation was selelected the 1th axial flexural mode (Fig. 3). To analyse dynamical response of the wheel with combined nozzle excitation and self-excitation we assumed 62 stator blades (n_s). At this case the vibration mode with 4ND is dominantly excited. When we assume that the revolution speed is 300rpm, the excitation frequency of rotor blades is 5x62 = 310Hz and therefore very far away from resonant vibration of the 4ND mode (cca 35Hz). The force amplitude F_b was 10N. At this

case, the wheel is out of forced resonant vibration and amplitudes are small. However, the vibration level can get to high amplitudes in some conditions due to self-excitation caused by the stator blade wakes. Therefore, we aimed at this study on evolution of vibration amplitudes in time for different values of the intensity of Van der Pol self-excitation (Fig.5).

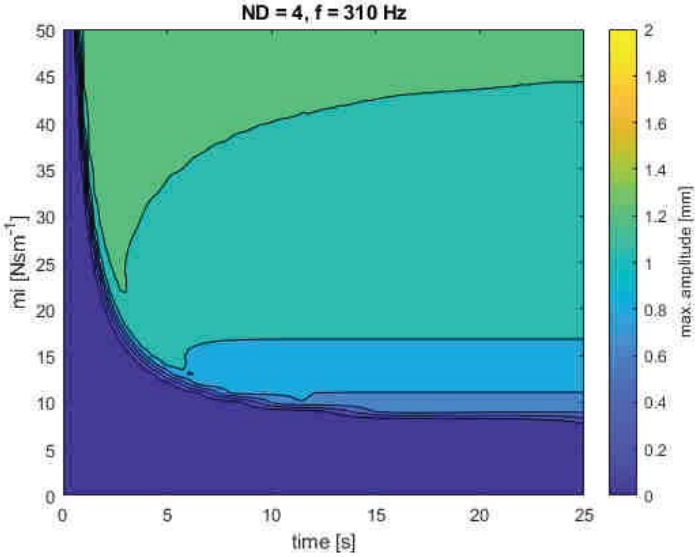

Figure 5: Contour picture of maximal amplitude time dependence versus size of intensity of Van der Pol excitation.

The figure shows evolution of maximal amplitude in time with change of the intensity of Van der Pol self-excitation μ. For small self-excitation intensity, the self-excitation is not able to overcome structural damping and the amplitude of vibration excited by nozzle excitation remains at very small level. When the intensity gets higher, the self-excitation starts to dominate after certain period of time. The higher the intensity is, the shorter time is needed for the self-excitation to start and the higher the final vibration amplitude is. As to the excited vibration mode number of nodal diameters of the running wave it was found out that 4 nodal diameters initially excited stay even when the vibration is dominated by the self-excitation. Therefore, self-excitation does not change the vibration mode determined by number of stator blades.

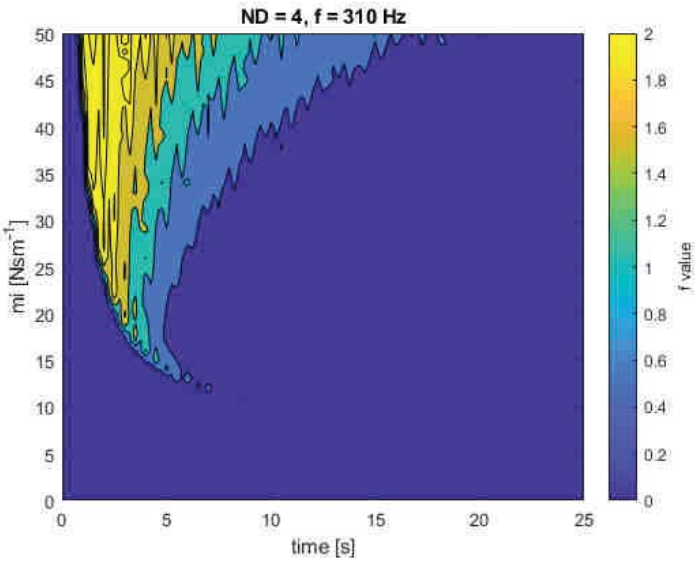

Figure 6: Contour picture of ND's identification error function time dependence versus size of intensity of Van der Pol excitation.

Number of nodal diameters was evaluated in certain time-steps of the simulation by fitting sine function on ordered amplitudes of all blades by minimizing the target function. Amplitude of "f value" is reached minimum of that function (Fig.6). From this figure we can see that when self-excitation starts, a combination of vibration modes is excited before it stabilises during time. Because of the combination a higher error in ND identification occurs.

5 SUPPRESSION OF SELF-EXCITATION BY INNER DAMPING

To study the effect of additional structural damping which could suppress or diminish danger of self-excited vibrations we introduced to our numerical model for self-excitation also proportional damping as described in equation (13). The proportional damping models mainly inner material damping. For describing the effect we chose intensity of self-excitation $\mu = 25$ and calculated dynamic responses of the wheel for different values of coefficient β. The similar graphs (Fig. 7-8) are shown as in the previous paragraph. Instead of intensity μ dependence, however, time development of vibration amplitudes is evaluated for different values of coefficient β.

We can see that due to higher values of β we can suppress effect of self-excitation. For lower values, however, the self-excitation is suppressed just at the beginning and pronounces in few seconds. Again the vibration mode with 4ND prevails, except of short time period and lower values of β, in both forced and self-excited vibration states.

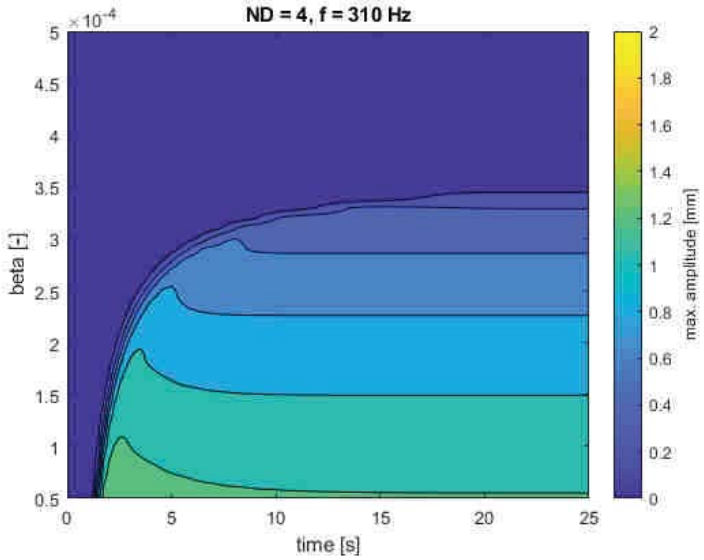

Figure 7: Contour picture of maximal amplitude time dependence (case $\mu = 25$) versus size of coefficient of proportional damping.

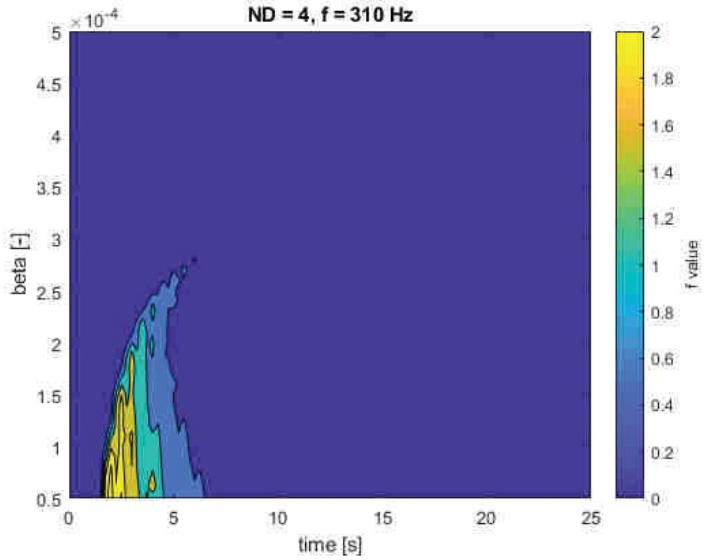

Figure 8: Contour picture of ND's identification error function time dependence (case $\mu = 25$) versus size of coefficient of proportional damping.

6 CONCLUSION

The paper introduced the method of modal synthesis as ROM method for the turbine bladed wheel modelling. It was shown that this approach can lead to efficient DOF reduction with very good approximation of modal characteristics. It brings possibility to calculate fast more realistic deformation patterns of the blades and whole turbine wheels for study of flutter phenomena. Due to high DOF reduction (from tens of thousands to several DOFs), a computational time of time integration of the motion equations decreases from days to minutes and this ratio increases with complexity of non-linearities (e.g. dry-friction contacts) included in the wheel model.

The ascertained results of numerical simulations showed that due to self-excitation the very fast entry of amplitude increase can arise. The slope depends on the ratio between intensity factor of self-excitation and coefficient of proportional damping. At this first study the Van der Pol model was related to the 1th axial flexural mode of vibration. The result leads to logical conclusion since the self-excitation forces and viscous damping forces are dependent both on absolute velocity of blades. On contrary to vortex shedding excitations and "lock-in" effect, the simulations of classical flutter showed that the effect of self-excitation can arise out of resonant frequency and low vibration amplitudes. If it occurs, it is dependent on ratios between damping factor and intensity of self-excitation. In the study case, four nodal diameters mode initiated by nozzle excitation remained even if the vibration was dominated by the self-excitation. So, the initial forced structural mode was decisive for the vibration pattern of self-excitation. The achieved results are in accord qualitatively with our previous studies [5-7] performed on the simplified numerical models.

Next, these simulations will be extent to different types of Van der Pol model, e.g. dependent on relative blade motions, and to suppression of self-excitation by dry-friction damping. Possibilities of more complex distribution of Van der Pol model based on experimental results would be considered, too.

In this study we modelled self-excitation by Van der Pol model, however, this approach can be used for other FSI approaches such as loose coupling structural solver with a ROAM panel method, too.

ACKNOWLEDGEMENT: This research is supported by the research project of Czech science foundation GA19-02288J: Robust reduced-order modelling of fluid-structure interaction problems. The authors are also grateful to Doosan Škoda Power, s.r.o. for providing bladed wheel geometry.

Keywords: Theory of collision, Rolling balls, Billiards.

Abstract. *The elements of geometry, kinematics and dynamics of rolling homogeneous balls along curvilinear lines are defined. The complete theory of the impact and collision of heavy rolling balls, through geometry, kinematics and dynamics of rolling balls, is defined. A new definition of the coefficient of restitution (collision) was introduced, starting from the hypothesis of the conservation of the sum of angular momentum of the balls in rolling, for instantaneous rolling axes, after the collision in relation to the before collision of the bodies. The expressions for the outgoing angular velocities of the ball rolling after the collision have been derived and their rolling paths after the impact or collision have been determined and various possible anchors have been shown. The difference between the content of the term billiards used in mathematical works of many mathematicians, as well as the research that remains in the field of geometry is pointed out. Our theory of ball rolling and collision is based on the examples of the abstraction of real systems of rolling heavy homogeneous billiard balls to a mechanical model.*

1 INTRODUCTION. A BRIEF OVERVIEW OF THE HISTORY OF CLASSICAL IMPACT AND COLLISION THEORY

In 1668, the Royal Scientific Society in London launched a call for a solution to the problem of impact and collision dynamics, and for that call, the well-known scientists Wallis (John Wallis, 1616-1703, Mechanica sive de mote-1688) and Huygens (Christiaan Huygens - De motu corporum ex percusione) submitted their papers. Using the results of the collision, which they submitted to the Royal Scientific Society of Wallis, and the Huygens, and adding their generalizations, Isaac Newton laid down the fundamental foundations of the Theory of Impact, which are still unsurpassed today. Even before Newton, Wallis and Huygens, there was research into the dynamics of impact. Thus, for example, collision problems were addressed by Galileo Galilee, who came to the realization that the impact force was infinitely large in relation to the pressure forces, but did not reach and learn about the relation of the impact impulses and the impact forves of movement. Today's knowledge of collision dynamics has not, in fact, been much advanced than this collision theory, which was founded

by Newton, Wallis, and Huygens. In connection with this competition of the Royal Scientific Society, are submitted Papers which contained the first set of basic eelements of collision theory. The name also mentions Sir Christopher Michael Wren (20 October 1632 - 25 February 1723), who was also the president of the Royal Scientific Society**.**

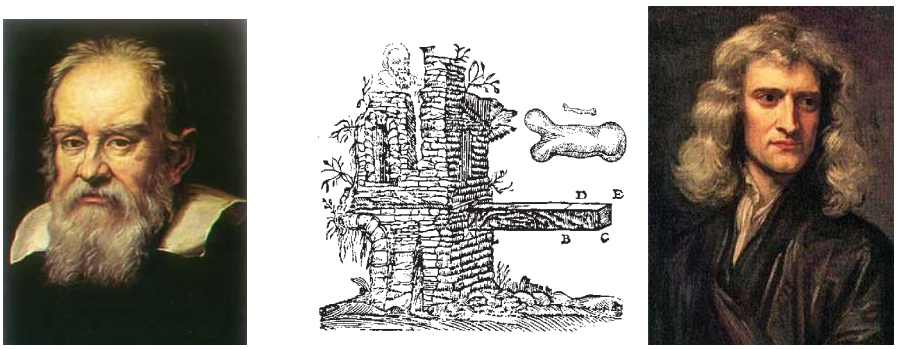

Figure 2. Scientists: author of the original ideas Theoretical and Applied Mechanics: Galileo Galilei (Paris, February 15, 1564 - Florence, January 8, 1642) and author of an authentic and significant work: *"Discorsi e dimostrazioni matematche intorno a due nuove scienze attenti alla mecanica e i movimenti locali" 1638* (left) and Sir Isaac Newton, (Lincolnshire, December 25, 1642 - London, March 20, 1726/7) (right) author of Basic Collision Theory and Works: Mathematical Principles of Natural Philosophy (Lat. Philosophiae Naturalis Principia Mathematica), published in 1687.

The dynamics of collisions between rolling balls occur in many engineering systems, and especially in the dynamics of roller bearings. Even today, no general theory of collisions between rolling balls has been given. Some recent results by the author of this paper present new and original results in support of the classical theory of collisions between rolling balls. These results are presented in the next parts of this article.

In the game of billiards, collisions of rolling equal balls occur. The complexities of billiard dynamics and billiard models and the possibility of observing and noting the complex phenomena and phenomena of collision dynamics were pointed out by Coriolis (fr. Gaspard-Gustave de Coriolis; Paris, May 21, 1792). - Paris, September 19, 1843) and to illustrate this we quote the following quotation (see References [1, 2, 3]):

"In connection with the game of billiards ..... different dynamic tasks occur, the solutions of which are contained in this event. I think that people, who know theoretical mechanics, and even students of the Polytechnic Schools, are interested in learning about the explanations of all the original phenomena, which can be observed with the movement of billiard balls. "

2 AN ELEMENTARY LOGICAL ANALOGY

In the examples of the simplest dynamics of rigid bodies with one degree of freedom of movement, we will present an elementary logical analogy, which should be understandable and easily understood.

Why do we begin with this article, which should be popular but at the same time contain the results of a high scientific domain?

It is well known that the most fundamental breakthroughs in science, which have become a lasting scientific heritage, are in fact elementary learning, which, in the integration of knowledge and conceptual processes, grows into complex scientific disciplines. The aim and answer of the question posed is to show that starting from the simplest dynamics of rigid bodies, translation and rolling, and then determining the elementary logical analogy among these dynamics and abstraction to the model of these dynamics, one can move to qualitative and mathematical analogies.

Then, by abstracting the disparate parameters of the dynamics of two real systems, one can come up with one theoretical model, meaning described by a unique mathematical model with the same elements of mathematical phenomenology, we can use the knowledge of the properties of one to convey it in the knowledge of the properties of the other, logically analogous.

Using logical, structural, qualitative and mathematical analogies, in both directions, we aim to obtain new original results of the theory of collision between bodies in rolling. We base the new results on the well-known theory of collision between bodies in translation. Here, and today the unsurpassed theory of collision between bodies in translational moving, has been formulated by world-renowned scientists Isaac Newton, John Wallis, and Christiaan Huygens.

So, let's start with a logical analogy between the dynamics of the body systems shown in Figure 3. a * and b *.

Figure 3.a* shows two rigid bodies that can move along an ideally smooth horizontal surface in one direction, so that their median plane is always vertical, so it is a planar, translational motion of a rigid body with one degree of freedom of movement, so we can consider it as a material point of concentrated mass in the center of mass. Such a body is exposed to the effect of five constraints (links): two translations are prevented (one in the vertical direction and one in the direction perpendicular to the plane of plane motion) and three rotations about three orthogonal directions (about the direction of the body translation, about the vertical direction and about the direction perpendicular to the previous two).

The kinetic parameters of the motion translation of the rigid body model from Figure 3. a* are: m_k, $k=1,2$, masses,, the velocities of body translation, $\vec{v}_{C1}$ and $\vec{v}_{C2}$, which are the connected vectors for the centers of mass of these bodies C_1 and C_1. Suppose that each of the bodies is loaded by one external force with intensity F_k, $k=1,2$, with a direction collinear with velocity and an attack point at the center of mass of the corresponding body affected.

On the basis of the theorem on the change of the linear momentum of motion (or quantity of motion), we construct the differential equation of translational dynamics of one and the other body, in translator motion, in the form:

$$m_k \dot{v}_{Ck} = F_k \,,\ k = 1,2 \tag{1}$$

The change in the linear momentum of body motion theorem states that this change in time equals the sum of active and reactive forces. The linear momentum of motion in the translation of a rigid body or the impulse of the translational motion of a body is the product between the mass of the body and the velocity $\vec{v}_{Ck}$, $k = 1,2$ of the center of mass: $\vec{\mathbf{K}}_k = m_k \vec{v}_{Ck}$, $k = 1,2$.

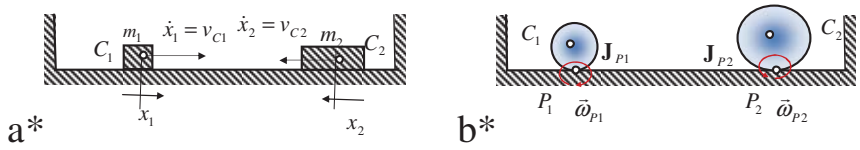

Figure 3. Models of the two simplest dynamics of material bodies, each with one degree of freedom of movement: a * transition dynamics of a rigid body and b* rolling without sliding of a rigid body (with form of homogeneous disk, homogeneous sphere or homogeneous with one axis and one plane of symmetry).

Figure 3 b * shows two bodies, which roll, without sliding, straight along a linear path (guide, trace) through a circular plane contour of the body, a circular shape with a corresponding center at a point, C_1 , and C_2, respectively. These rolling bodies may be spherical balls, cylinders, or disks, but also of other shapes, having one axis of symmetry and one plane of symmetry in which there is a contour of the shape of a circle, by which the legs are to roll.

Such bodies, which roll without sliding, have one degree of freedom of movement. Since each free body has six degrees of freedom of movement, this means that five motion constraints, three translation constraints and two rotations are imposed on the motion of these bodies from Figure 1. b *, that is, five bonds are imposed on each of the bodies. The first limitation is that the median plane of symmetry of the body, in which the center of mass of the body, is at all times in the plane of contour of rolling. This produces the constraints of one translation perpendicular to that rolling plane, and of two rotations about two orthogonal axes in that plane of rolling. The connection with the non-slip rolling route prevented one translation in the direction of the rolling route and one translation directly on the rolling route. All these together represent five links and constraints, leaving only one degree of freedom of movement, which is rolling around the current instantaneous axis of rolling.

Therefore, we direct our further consideration to that class of bodies, which roll without slipping. Figure 3 b * shows two rigid bodies, which roll without sliding at angular velocities $\vec{\omega}_{P1}$ and $\vec{\omega}_{P2}$, at the corresponding instantaneous axes of rolling, passing through the points, P_1 or P_2 respectively, of the contact of the bodies in rolling and the track on which they are rolling, which are directed orthogonal to the plane of the rolling. The axial moments of inertia of the masses of the body in rolling for the instantaneous axes of rolling are $\mathbf{J}_{P1}$ and $\mathbf{J}_{P2}$. As kinetic parameters of the rolling dynamics of each body are the instantaneous angular velocities of rolling $\vec{\omega}_{P1}$ and $\vec{\omega}_{P2}$, which are related to the instantaneous axes of rolling. These axes move translation ally along the rolling path, and the axial moments of inertia of the mass of the body and for the corresponding instantaneous oscillations, for the observed body class, $\mathbf{J}_{P1}$ and $\mathbf{J}_{P2}$ do not change during the rolling dynamics.

Based on the theorem on the change of angular momentum (or kinetic moment) for the instantaneous axis of rolling without sliding, we construct the differential equation of the dynamics of rolling of one and the other body, in the form:

$$\mathbf{J}_{Pk}\dot{\omega}_{Pk} = \mathfrak{M}_{Pk}, \quad k = 1,2 \tag{2}$$

By comparing two analyzes of the dynamics of the bodies on two systems, one in translation and other in rolling, without sliding, from Figure 3. a * and b *, we establish a logical, and at the same time, qualitative analogy and phenomenological mapping of the kinetic parameters of these models of two different dynamics, each with one degree of freedom. The mathematical analogy follows.

3 DYNAMICS OF COLLISION BETWEEB TWO ROLLING BODIES IN NON-SLIP ROLLING

3.1 Basic settings for collision dynamics between two bodies in non-slip rolling

From the previous kinetic analysis, and the conclusions, we have drawn and proved, it follows that to consider the dynamics of collisions of axial symmetric rigid bodies with one plane of symmetry, which are in non-slip rolling, we must start with incoming angular velocities and rolling paths. Then, the axial moment of inertia of rolling body masses for the instantaneous axes of rolling should be included by introducing analogous assumptions, as well as for the case of analogous dynamics of impact and collisions of bodies in translational motions determined by the translational velocities and corresponding masses.

The theory of collision dynamics (and in the special case of impact) is based on the following assumptions:

1* The contact time τ of two bodies in a collision is very short;

2* The impact forces $\vec{F}^{ud}$ and the corresponding impact moments $\vec{\mathfrak{M}}^{ud}$ of the forces are variable and of high intensity, of the order of magnitude $\frac{1}{\tau}$, and of short duration during the contact time τ of two bodies in the collision and during the collision they have attack points at the contact points in the collision;

3* The change of angular momentum of motion of the material two bodies in rolling for the corresponding rolling axes, during the collision is finite.

4* The impulse (linear momentum) and angular momentum of "ordinary forces" compared to the impulse (linear momentum) and angular momentum of instantaneous collision forces, are much much smaller and can be neglected.

3.2 Intensity of outgoing angular velocities in the centrally centric collision of two bodies in the rolling, without sliding, immediately after the collision

We look at two axial symmetric rigid bodies, with one central plane of symmetry, centrally colliding, and making contact at one point of collision, or two balls of different radii, or two disks of different radii, axial moments of inertia of masses of bodies for the corresponding instantaneous axes of rolling $\mathbf{J}_{P1}$ and $\mathbf{J}_{P2}$. These axial moments of inertia of masses do not change for the axial rolling axes in motion.

The bodies are in a non-slip rolling position at the moment t_0 and have angular velocities $\vec{\omega}_{P1}(t_0)$ and $\vec{\omega}_{P2}(t_0)$at an instant t_0 before entering the collision configuration and are referred to as incoming (inlet or impact) angular velocities. At the moment t_0 of collision starting, the two bodies will touch at one point P where both bodies have a tangential plane

in common. We assume that a collision lasts briefly over an interval $(t_0, t_0+\tau)$ of time, which lasts for a short time τ (and realistically tends to zero). After this collision of short-term contact, the bodies are separated and separated by angular velocities $\vec{\omega}_{P1}(t_0+\tau)$ and $\vec{\omega}_{P2}(t_0+\tau)$, which we call the outgoing angular velocities. That it is necessary to determine the intensities of these outgoing angular velocities, $\vec{\omega}_{P1}(t_0+\tau)$ and $\vec{\omega}_{P2}(t_0+\tau)$, and that we have already determined the paths of outgoing rolling velocities and the directions of rolling and directions of those outgoing velocity velocities immediately after the collision.

Imagine that, at the point P of contact of two bodies in a state (configuration) of collision, we have drawn a tangential plane and it's normal $\vec{n}$. This tangential plane is called the touch plane, and the direction of that normal to the touch plane determines the direction of the collision. Since the centers C_1 , and C_2 of mass of the bodies in collision are at this normal, and if the incoming rolling traces of the bodies are at that normal, the collision is called a centric (central) collision, and if not the collision is skew or oblique eccentric. When the incoming angular velocities $\vec{\omega}_{P1}(t_0)$ and $\vec{\omega}_{P2}(t_0)$ of both bodies in the collision are collinear with the tangent plane, that is, direct with the direction of the collision, then it is a true (directional) collision of the rolling bodies, otherwise it is an skew collision of two rolling bodies.

3.3 Hypothesis of conservation of sum of angular momentum for instantaneous axes of rolling of two bodies in rolling before and after collision of two axial symmetric bodies

At the time of the collision, both bodies, which roll immediately before the collision, come into contact at one point, or line-derivatives. In the collision event, although we have made the assumption of models of rigid, axisymmetric bodies with a central plane of symmetry, during the collision they deform locally, in the local contact area. If the contact of the bodies in the collision is at the point of contact (for example, the contact of the spherical surfaces of the balls in the collision, or the rotation ellipsoids), deformation occurs in the immediate vicinity of the contact point. And this deformation lasts until the projections of the angular velocities of rotation of the body in the collision in the direction of the collision (the normal on the tangent equal to both bodies in the contact point of the collision) are equal. Then also the projections of the relative angular velocities of the rolling motion around the instantaneous axes of rolling of the body in the collision, one relative to the other, towards the collision direction became zero. From that moment, zero projections of relative angular velocities in the direction of the collision, begin to restore the state of the body as it was before the collision until the moment when the bodies separate from each other. During this time the projection of the relative velocities of the bodies in the collision of one relative to the other begins to increase and continues until the bodies have, in the part in contact, their original shape. Then there is a moment when we consider that the bodies have practically separated and that there is a period of time after the collision. Therefore, the collision period can be divided into two parts: τ' the compression period in the tangential direction to the body at the point of contact, and τ'' the restitution period in the tangential direction to the body at the point of contact in the collision, with the total short-time duration $\tau = \tau' + \tau''$ of the collision.

Since external active forces and moments of forces of finite intensities have impulses of forces equal to zero, and couplings have kinetic moments equal to zero and, at infinitesimal intervals of time, we consider that two material rigid bodies, which roll with the incoming angular velocities and in collision, are considered as one system. Therefore, the hypothesis of

the conservation of the sum of angular momentum (kinetic momentum) for the instantaneous axes of rolling of the body - the movement before and after the collision, can be applied to the dynamics of the same to in the form:

$$\mathbf{J}_{P1}\vec{\omega}_{P1}(t_0)+\mathbf{J}_{P2}\vec{\omega}_{P2}(t_0)=\mathbf{J}_{P1}\vec{\omega}_{P1}(t_0+\tau)+\mathbf{J}_{P2}\vec{\omega}_{P2}(t_0+\tau). \quad (3)$$

This hypothesis about the conservation of the sum of the angular momentum of motion by rolling in a collision of two bodies, which is analogous to the hypothesis of the conservation of the sum of the linear momentum of motion of two bodies in a collision and in translational motion (see References [4-8, 11-15[).

3.4 Coefficient of restitution or collision of two axisymmetric rolling bodies with one central plane of symmetry

When the incoming angular velocities $\vec{\omega}_{P1}(t_0)$ and $\vec{\omega}_{P2}(t_0)$ of rolling and the axial moments of inertia of mass $\mathbf{J}_{P1}$ and $\mathbf{J}_{P2}$ for the instantaneous axes of rolling of the bodies in a collision, are known, the previous hypothesis relation (3) of conservation of the sum of the angular momentum of motion for the instantaneous axes of rolling bodies, before and after the collision, is not sufficient to determine two unknown outgoing angular velocities $\vec{\omega}_{P1}(t_0+\tau)$ and $\vec{\omega}_{P2}(t_0+\tau)$, after the collision of two bodies, which roll just before and after the collision. We need another relation, an equation, which we will set from the very properties of the body in a collision. As we have already described the collision and contact process of two bodies, in the period of solid body compression, the angular velocity $\vec{\omega}_{P1}(t_0)$ of the first body will decrease by $\vec{\omega}_{P1}(t_0)-\vec{\omega}_{CP}$, and the second increases by $\vec{\omega}_{CP}-\vec{\omega}_{P2}(t_0)$, where $\vec{\omega}_{CP}$ the angular velocity of both bodies in the collision is at the end of the compression at the local environment of the contact point of the bodies in the collision. As both bodies are deformed in the local area around the point of joint contact in the collision, it is apparent that, during the restitution period, the deformations of the body will not be immediately lost and that the angular velocity $\vec{\omega}_{P1}(t_0)$ of the first body will decrease by $k(\vec{\omega}_{CP}-\vec{\omega}_{P2}(t_0))$ another angular velocity and the angular velocity $\vec{\omega}_{P2}(t_0)$ of the second body will increase for size $k(\vec{\omega}_{CP}-\vec{\omega}_{P2}(t_0))$, where k is some coefficient. Based on this analysis we can write that the angular velocities $\vec{\omega}_{P1}(t_0+\tau)$ and $\vec{\omega}_{P2}(t_0+\tau)$ of the bodies that were in the collision are outgoing

$$\vec{\omega}_{P1}(t_0+\tau)=\vec{\omega}_{P1}(t_0)-(1+k)(\vec{\omega}_{P1}(t_0)-\vec{\omega}_{CP})=(1+k)\vec{\omega}_{CP}-k\vec{\omega}_{P1}(t_0), \quad (4)$$

$$\vec{\omega}_{P2}(t_0+\tau)=\vec{\omega}_{P2}(t_2)+(1+k)(\vec{\omega}_{CP}-\vec{\omega}_{P2}(t_0))=(1+k)\vec{\omega}_{CP}-k\vec{\omega}_{P2}(t_0). \quad (5)$$

Subtracting these previous relations (4) - (5) we obtain

$$\vec{\omega}_{P2}(t_0+\tau)-\vec{\omega}_{P1}(t_0+\tau)=k(\vec{\omega}_{P2}(t_0)+\vec{\omega}_{P1}(t_0)). \quad (6)$$

The ratio k of the relative angular velocities of rolling of the axisymmetric bodies after and before the collision is

$$k=\frac{\omega_r(t_0+\tau)}{\omega_r(t_0)}=\frac{\omega_{P2}(t_0+\tau)-\omega_{P1}(t_0+\tau)}{\omega_{P1}(t_0)-\omega_{P2}(t_0)} \quad (7)$$

and *is called the collision coefficient, or the coefficient of restitution, or the coefficient of establishment of rolling bodies in a collision.*

This coefficient k is also newly introduced and represents a new definition of the collision coefficient, or the coefficient of restitution or the coefficient of establishment of rolling bodies in a collision. This new definition (7) is derived by author of this paper.

With the introduction of this new refinement of collision coefficient, we have generalized Newton's definition from the theory of collision between rigid bodies in translator motion to the theory of collision between rigid bodies in rolling motion without sliding by use difference of rolling angular velocities both after and before the collision. If a kinetic state can be defined by one angular velocity about the instantaneous axis of rolling for each of the bodies, in arriving to define the dynamics of the collision, we inject our definition of the coefficient k of restitution over the ratio of the relative angular velocities of the rolling bodies after and before the collision.

3.5 Intensity of outgoing angular velocities of rolling two bodies after a collision

In order to determine the intensities of the outgoing angular velocities of rolling of two bodies after a collision, $\vec{\omega}_{P1}(t_0+\tau)$ and $\vec{\omega}_{P2}(t_0+\tau)$, it is sufficient to eliminate from the previous relations (4) - (5) the unknown angular velocities of both bodies, $\vec{\omega}_{CP}$, in the collision at the end of the compression at the local environment of the point of contact of the bodies in the collision. Then solve the relations by unknown outgoing angular velocities and, which is not difficult to do, so for the outgoing angular velocities, $\vec{\omega}_{P1}(t_0+\tau)$ and $\vec{\omega}_{P2}(t_0+\tau)$, after the collision of the balls, we get the following expressions:

$$\vec{\omega}_{P1}(t_0+\tau)=\vec{\omega}_{P1}(t_0)-\frac{1+k}{1+\frac{\mathbf{J}_{P1}}{\mathbf{J}_{P2}}}(\vec{\omega}_{P1}(t_0)-\omega_{P2}(t_0)) \tag{8}$$

$$\vec{\omega}_{P2}(t_0+\tau)=\omega_{\mathbf{P1}}(t_0)+\frac{1+k}{1+\frac{\mathbf{J}_{P2}}{\mathbf{J}_{P1}}}(\omega_{\mathbf{P1}}(t_0)-\omega_{\mathbf{P2}}(t_0)) \tag{9}$$

By determining these intensities of the outgoing angular velocities $\vec{\omega}_{P1}(t_0+\tau)$ and $\vec{\omega}_{P2}(t_0+\tau)$ of rolling of the balls (axial symmetric bodies each with central plane of symmetry) after the collision, we have solved the complete problem of the theory of collision of axisymmetric bodies in rolling without slipping (see References [4-15[)..

These expressions (3), (7), (8) and (9) can be reached by a logical, qualitative and mathematical analogy, starting from the theory of collisions of bodies in translational motion.

4 MECHANICS OF BILLIARDS I – GEOMETRY AND KINEMATICS

"In connection with the game of billiards .... various dynamic tasks occur, the solutions of which are contained in that event.

I think that people, who know theoretical mechanics, and even students of the Polytechnic School, are interested in explaining all the original phenomena, which can be observed with the movement of billiard balls".

Gaspar-Gustav de Coriolis (1990). *Théorie mathématique des effets du jeu de billard ; suivi des deux celebres memoires publiés en 1832 et 1835 dans le* Journal de l'École Polytechnique*: Sur le principe des forces vives dans les mouvements relatifs des machines & Sur les équations du mouvement relatif des systèmes de corps* (Originally published by Carilian-Goeury, 1835 ed.). Éditions Jacques Gabay. ISBN 2-87647-081-0.

For an introduction to the content of billiard mechanics, which includes content on the geometry, kinematics and dynamics of billiard games, it is most illustrative to rely on a few Coriolis sentences, which we have adopted as the motto of this paper. Obviously, many authors believe that these few sentences point to the complexity of geometry, kinematics and dynamics of billiard games; because the analysis, which we will expose here, reveals that the dynamics of billiards includes many phenomena of dynamics of real systems. Our presentation will be based on our results, but also on the constant, from comparisons with the results achieved today by other authors, both mechanics and mathematicians, and it is evident that our results are original.

Multiple keywords and concepts of kinematics and dynamics, such as: ball dynamics as a rigid body, non-slip rolling, collision, alternation of velocity direction, impact velocity, outgoing velocity, ball rolling path, center of gravity trajectory, central and scew (oblique) collision, force impulse, kinetic energy, impact and collision, collision of two spheres, collision of three spheres, impulse forces, linear momentum of motion, angular momentum of motion, speak about their complexity of dynamics of the system of billiard game elements. This is even when looking at only the movement of one billiard ball, but when more balls are involved, and then we have a really complex system, hybrid structures and dynamic configurations of billiard play.

Figure 4. a * Gaspar-Gustave de Coriolis or Gistav Coriolis (fr. Gaspard-Gustave de Coriolis) (Paris, May 21, 1792 - Paris, September 19, 1843) and b * Jean Victor Ponsele (fr. Jean-Victor Poncelet) (July 1, 1788 - December 22, 1867)

But first let's start with the names of famous scientists who have contributed to the knowledge of certain aspects of the dynamics of billiards.

As we were quoting a few sentences from Gaspar-Gustavo de Coriolis or Gustavo Coriolis at the outset, here is some biographical information about this important scientist, especially in the field of mechanics. He was a mathematician, a mechanical engineer, and a scientist. He is best known for his work on the Coriolis acceleration and Coriolis force. Coriolis was the first to coin the term "work" for the product of force and distance. In 1829, Coriolis published a textbook, *Calcul de l'Effet des Machines*, which presented mechanics in a way that could easily be applied in industry. During this period, the true term for kinetic energy $\mathbf{E_k} = \frac{1}{2}mv^2$ was established, as well as its relation to mechanical work (see References [1, 2,3]).

Coriolis explored the possibilities of generalizing kinetic energy and work on rotating systems and, as a result, produced the work *Sur les équations du mouvement relatif des*

systèmes de corps, presented at the French Academy of Sciences (1832). Coriolis wrote the work *Sur les équations du mouvement relatif des systèmes de corps*,1835. In the 20th century, the terms "*Coriolis acceleration*" and "*Coriolis force*" appeared on systems with coupled transverse rotational motion and relative curvilinear motion.

Beginning with the works of George Birkoff, billiard systems have become a popular topic of study, drawing on a variety of fundamentals, beginning with ergodic Mors theory, KAM theory, and others. Also, the dynamics of billiard systems is interesting because it occurs quite naturally in a number of tasks of mechanics and physics: in the dynamics of vibro-impact systems, diffraction of short waves, dynamics of ball bearings, etc.

The basis of the dynamics of billiards is the theory of dynamics of systems with one-sided constraints. There are essentially various models of theory of impact. The one-sided bond imposed on the system can be replaced by the field of conservative and dissipative forces. Then, the coefficients of elasticity and dissipation by some assumption are introduced to the aspirations of infinity, as Kozlov writes in Reference [10]. It can then be shown that the movement of such a "released" system with fixed initial data, at each finite interval of time, tends to move with an impact (see Reference [10])..

Finally, it is necessary to emphasize again that in the approach to investigating the properties of the billiard game phenomenon, it is necessary to establish the basic models of billiards. These models, under the same keyword "*billiards*", distinguish between defined tasks: geometry, kinematics, and dynamics of billiards, or the totality of all these tasks. For example, starting tasks are about the properties of mathematical billiards. When approached by mathematicians, then it remains in the domain of billiard geometry and the elements are the geometric point and its possible open or closed polygonal paths, that is, polygons inscribed in a certain area by a unilaterally bounded closed contour line. Periodic trajectories are possible, depending on the initial position and the initial direction of the trajectory of the geometric point. Then, the basic determinations are the lengths and angles that determine the directions of the path of the geometric point. Then it works with lengths and angles, and the units of measurement are meters and degrees or radians. This is a rough approximation of the real billiards system and does not take into account the time at which the geometric point is moved along the trajectory. If the basic determination of time in addition to lengths and angles is included, then it moves into the field of kinematics, kinetics, so kinetic parameters, elements of translation velocity and angular velocity of rolling are included.

If we stay only on the mathematical model that we enrich with basic determination over time, with a unit in seconds, then only the kinematic element of the geometric point translation rate, with the unit of meter per second, is included. A mass associated with a geometric point can be added to this model, so we have a model of gross abstraction of a real billiard by a material point that has mass, velocity, and its motion in time is observed. The mass has a unit in pounds. We have already included this in the model in addition to geometry and kinematics and dynamics, and with that we open the questions of determining the impulses of motion, kinetic energy and forces under which the dynamics are realized, including impacts at unilateral holding bonds and collisions between material points. However, for better abstraction of the billiard system to the model of billiard dynamics, it is not a satisfactory model not with a geometric point or with a material point, but with a rolling ball, which has its mass, a certain mass distribution, defined by the axial moment of inertia of the masses for the axis of rolling of the ball, and has a certain the instantaneous angular velocity of rolling about the instantaneous axis of rolling, measured in units of radian per second, or the velocity of translation of the center of mass in units of meters per second, and the angular velocity of rotation about the central eigen axis of self-rotation measured in units of radians per second. It means that if a billiards model is formed as an abstraction of a real

model of billiards with one or more balls rolling, then the elements of the billiard events are studied elements of geometry, kinematics and dynamics of billiards.

Then we have a body of a certain shape and a line along which it rolls, so the definitions of length are used, so we are in the domain of geometry, and when we include the analysis of translational velocities of the center of mass and the angular velocity of rotation of central self rotation axis, then we are in the domain of kinematics, and if we now include masses and moment of inertia of masses, and with it impulses of motion and kinetic moment (angular momentum), kinetic energy and impulse forces, we completed the task of kinetics of billiards or dynamics of the system of billiards. In the following chapters, we will first define the models of billiards and then analyze the elements of geometry, kinematics and dynamics of billiards within the limits of contemporary knowledge of the scientific literature in this field, as well as the original results of the authors of this chapter.

4.1 Billiard geometry in a nutshell

In this section, we also highlight the contributions of the French scientist, engineer and mathematician, Jean-Victor Poncelet (July 1, 1788 - December 22, 1867), who is known for the following works: ''*Traité des propriétés projectives des figures''* (1822) and ''*Introduction à la mécanique industrielle* (1829)''. And here, we will point out a number of his theorems in geometry, which are of importance for investigation of the geometry of billiards and for determining the periodic paths of the rolling of billiard balls in elliptic billiards, as well as in billiards other forms of contours (see References [9,10]).

It is certainly important to find out the properties of ideal mathematical billiards. Today, many researches on this topic are based on a series of basic theorems of Jean-Victor Poncelet, so here we will list the definitions of some of them (see References [9,10])..

Theorem 1. (Poncelet Theorem): Consider two conical sections (conics) C and D, which lie in the plane. Suppose that a polygon is inscribed in a conical section C, and described around a conical section (conics) D. Then there are an infinite number of such polygons inscribed in one conical section, and described around the other conical section, all of which have an equal number of sides. Even more than that, every point of the conical intersection C is the subject of such a broken line.

Theorem 2. (Poncelet Theorem): Suppose that there is such a point on the conical section (conic) Γ that the polygon $\mathbf{T}_0\mathbf{T}_1\mathbf{T}_2\mathbf{T}_3\mathbf{T}_4...\mathbf{T}_{n-2}\mathbf{T}_0\mathbf{T}_{n-1}\mathbf{T}_0$ with the number of sides $n \geq 3$ is inscribed in the conic section (conic) Γ and described around the conic section Γ_u and that the right Γ_u does not tangent the conic section (conic) Γ_u for $i = 2,3,3,...,n-2,n-1$. Then for arbitrary $n \geq 3$ there is some polygon $\mathbf{N}_0\mathbf{N}_1\mathbf{N}_2\mathbf{N}_3\mathbf{N}_4...\mathbf{N}_{n-2}\mathbf{N}_0\mathbf{N}_{n-1}\mathbf{N}_0$ with sides inscribed in a conical section Γ and described around a conical section Γ_u.

Theorem 3. (Poncelet theorem for an area): Suppose that C and D, are two areas in space (on the surface). If there is some closed polygon, inscribed in the area C and described around the area D, it means that there are infinitely many such polygons. In addition, each point of the area C appears as the theme of such a polygon and all polygons have an equal number of sides.

One of the numerous Poncelet theorems is Comprehensive Generalized Poncelet Theorem, but we don't preset it, because in our opinion previous three listed theorems are

good illustration of the content and aims of these series of Poncelet theorems for applications in the geometry of models of billiards as abstraction of real billiards into mathematical billiards, as pre geometrical objects without reality (for more details see mathematical references [9]).

Figure 5 shows the mechanical model as a good abstraction of a real elliptical billiard: Track of the ball rolling along the horizontal plane of the elliptical billiard with the plan of horizontal components of the incoming impact velocities and outgoing velocities after the impact of the ball into a contour elliptical cylindrical surface with vertical derivatives, as well as a detail plan of the velocity of one ball skew impacts.

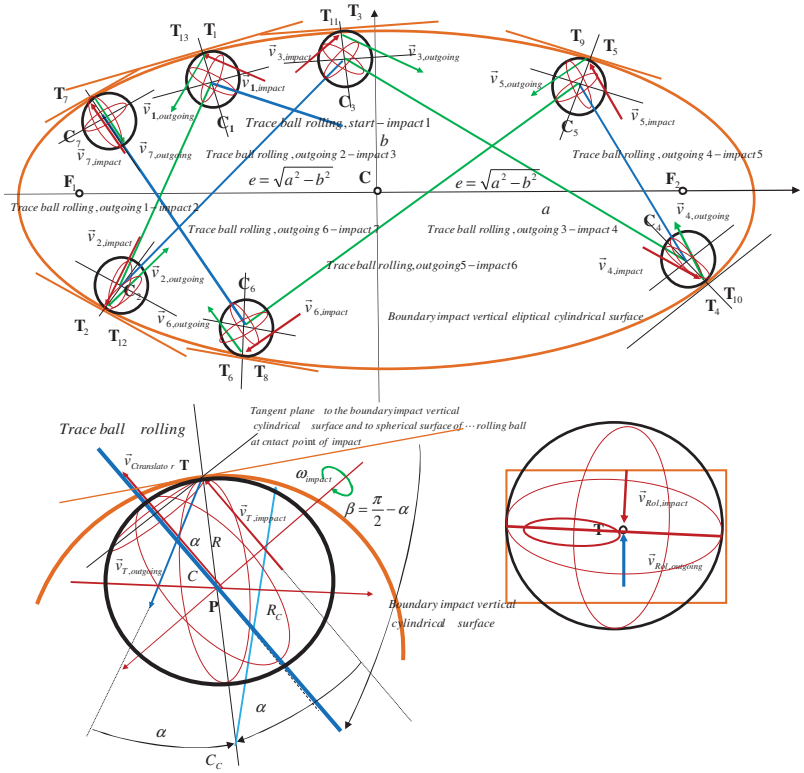

Figure 5. Line-trace of the rolling motion of the ball along the horizontal plane of the elliptical billiards with the plan of horizontal components of the incoming impact velocities and the outgoing velocities of the contact point after the impact of the ball into a contour elliptical cylindrical surface with vertical derivatives (up). Detail of the plan of the velocity of one ball in the configuration of the skew impact (down).

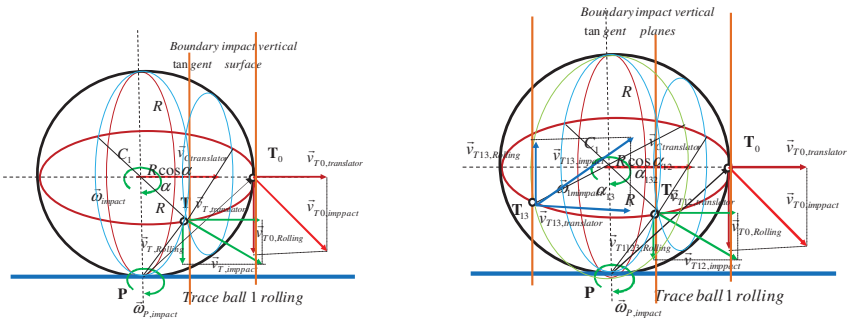
4.2 Elements of billiards kinematics

In the Figure 5, we have presented a model of an elliptical billiard with a rolling one ball, which rolls on a horizontal surface bounded by a single-size contour elliptical-cylindrical surface with vertical derivatives. The billiard balls are of the same dimensions and radius R, which is not negligible with respect to the semiaxis ellipses in the horizontal flat base of the elliptical billiards, which we denote by and a and b, which, according to the semi-axes, has an eccentricity of focus $e = \sqrt{a^2 - b^2}$. With this in mind, the model of elliptical billiards in

Fig. 5 cannot be reduced to mathematical billiards by reducing the billiard sphere to a material or geometric point. Her line-trace of billiard ball rolling, which is a broken polygonal line, open or closed, is a polygon, and its path can be determined purely geometrically using Poncelet theorems, or other results in the field of mathematical billiard models known from the literature, which remain in the domain of pure geometry. It is necessary to first determine the geometric location of the points of centers of ball of the impacts in relation to the contour of the elliptic area of billiards, and in the new contour to determine the paths of rolling the ball centers.

In the observed model of the elliptical billiard from case in Figure 5, we can see that the parts of the track of the roll of the billiard ball in arriving at the point of impact, ball and contour, and leaving it after being hit by the contour elliptical-cylindrical surface are parallel to the corresponding horizontal velocity component just before the impact and by the corresponding horizontal component of the outgoing velocity of the point of impact of the ball after impact. The translational velocities of the center of mass of the sphere, before and after impact in the contour surface, are equal to the horizontal components of the incoming velocity before impact and the outgoing velocity after the collision, the point at which the sphere impact to the contour elliptical-cylindrical surface.



Picture 6. Plan of the velocity of impact of a point on a large circle of a sphere, which rolls along a straight line in a horizontal plane

We will, now, turn to the representation of the kinematic elements of each of the possible impacts of a ball in rolling, to the contour surface, as well as to the kinematic elements of different cases of mutual collision of two balls.

4.2.1. Component velocities of points of impact of billiard balls in rolling. In the picture 6 has shown several points, $\mathbf{T}_0$, $\mathbf{T}$ and $\mathbf{T}_{13}$ which all lie on a large circle in a horizontal plane parallel to the horizontal plane of the billiards, in which lie the lines-traces of rolling the sphere.

At these points, vertical lines corresponding to the vertical derivatives of the contour elliptical-cylindrical surface of the impact of the ball on it are drawn. There are infinitely many such possible points of impact of a ball, as well as collisions with another ball, and we denote them by $\mathbf{T}_k$, $k = 0,1,2,3,4,.....$, and all of them also lie on a large circle in a horizontal plane. The rolling path without sliding the ball is parallel to that plane. The point $\mathbf{P}$ is the point of contact between the ball and the ball rolling path. The axis of instantaneous rotation-rolling of the ball along the track passes through the point $\mathbf{P}$ of the contract. That axis is perpendicular to the route of rolling at all times and moves along that route. With point $\mathbf{P}$, we have indicated the angular velocity of the training rolling when the ball is rolling, without sliding, along the incoming route before impact the ball in the contour cylindrical surface.

From Figure 6 it can be observed that the point at the greatest normal distance from the central instantaneous axis of rotation when rotating the ball along the line-trace and that it is equal to the radius R of the ball, while all other points from the large circle of the sphere, in the horizontal central plane, is at a smaller normal distance, and that this distance equals zero points on the diameter of that circle parallel to the current axis of rotation of the ball rolling along the track. If we denote the angle α_k that the radius of a large circle drawn from the center of that circle to a point $\mathbf{T}_k$, $k=0,1,2,3,4,.....$ on it coincides with the direction of the radius of that circle with the direction of the impact, then the normal distance of a point on the large circle of a billiard ball sphere is $h_{\mathbf{T}_k}=R\cos\alpha_k$ in the range from zero to R.

The incoming velocity by which a billiard ball impacts to a contour cylindrical (polygonal-cylindrical, elliptical-cylindrical or curvilinear-cylindrical) surface with vertical derivatives, corresponding to a point, $\mathbf{T}_k$, $k=0,1,2,3,4,.....$ of impact, has two components: one horizontal parallel to the incoming line of rolling of the ball-sphere surface, equal to the velocity $\vec{v}_{\mathbf{T}_k,impact}=\vec{v}_{\mathbf{C}_k,impact}$ of the center of mass of the ball and one vertical due to the rotation - the ball about the current central axis

$$\vec{v}_{\mathbf{T}_k,Roling,impact}=-\omega_{\mathbf{P}_k,impact}R\cos\alpha_k\vec{k}=-\frac{v_{\mathbf{C}_k,impact}}{R}R\cos\alpha_k\vec{k}=-v_{\mathbf{C}_k,impact}\cos\alpha_k\vec{k} \quad (10)$$

After impacting the ball in a cylindrical (polygonal-cylindrical, elliptical-cylindrical or curvilinear-cylindrical) surface with a vertical derivative, a point $\mathbf{T}_k$, $k=0,1,2,3,4,.....$, by which the ball struck and bounced, has an outgoing velocity with two components: one horizontal parallel to the outgoing track of the ball equal to the outgoing translational velocity $\vec{v}_{\mathbf{T}_k,outgoing}=\vec{v}_{\mathbf{C}_k,outgoing}$ of the center of mass of the ball and one vertical component $\vec{v}_{\mathbf{T}_k,Roling,outgoing}$ due to the outgoing rotation-rolling of the ball:

$$\vec{v}_{\mathbf{T}_k,Roling,outgoing}=\omega_{\mathbf{P}_k,outgoing}R\cos\alpha_k\vec{k}=\frac{v_{\mathbf{C}_k,outgoing}}{R}R\cos\alpha_k\vec{k}=v_{\mathbf{C}_k,outgoing}\cos\alpha_k\vec{k}. \quad (11)$$

The directions of trace rolling and directions of these velocities are determined purely kinematically by the rule that the angles, which are the directions of the horizontal component of the incoming and outgoing velocities of the observed possible contact points $\mathbf{T}_k$, $k=0,1,2,3,4,.....$, are closed with the normal on the contour cylindrical surface of the impact. The same rule applies to the vertical components of the ball rolling, which, with the direction of normal to the contour cylindrical surface into which the ball hits, close the right angles.

A complete prior analysis of the velocity components before and after the impact of a point on a rolling ball by which a ball strikes or collides is valid in the event of a collision, but the specifics of determining the direction of outgoing velocities are shown in each specific case of impact or collision. Therefore, in the following Figures 5 we will show a number of special cases of configuration of a rolling ball and a cylindrical shock, respectively, of two balls in a collision, or of striking a ball on different contour surfaces of the impact. From the previous kinematic analysis of the component incoming and outgoing velocities of the contact-impact points $\mathbf{T}_k$, $k=0,1,2,3,4,.....$ of the individual rolls of the ball in the rolling, before and after the collision, we conclude that it is *sufficient to consider the incoming and outgoing angular rolling velocity* before and after the collision, as well as the corresponding rolling routes. With kinematic elements we can completely define the kinematics of the ball's impact in rolling. We will show this in other cases of billiard ball strikes and collisions.

The answer to the question what are the values of the intensity of the outgoing component angular velocities belongs to the field of impact dynamics and collisions, so we

will answer this question in the chapter dynamics of billiards, taking into account the type and type of impact, ie collision. Although, from the forms (8) and (9), we can obtain that the outgoing angular velocity $\vec{\omega}_{P1}(t_0+\tau)=-k\vec{\omega}_{P1}(t_0)$ of the ball rolling after impact into a fixed contour, in which the coefficient k of restitution. In ideally elastic impact coefficient k of restitution is equal to one, and depending on the type of impact, that is, the properties of the sphere and the contour, it is in the interval $k\in[0,1]$, where we have adopted for the contour, in which the sphere of ball strikes, that the axial moment of inertia of mass is infinite $\mathbf{J}_{P2}\to\infty$ and its incoming angular the rolling velocity $\omega_{P2}(t_0)=0$ "is equal to zero", and it follows that its "outgoing angular rolling velocity" is zero, $\vec{\omega}_{21}(t_0+\tau)=0$, just as it was before the ball struck it, into the boundary surface.

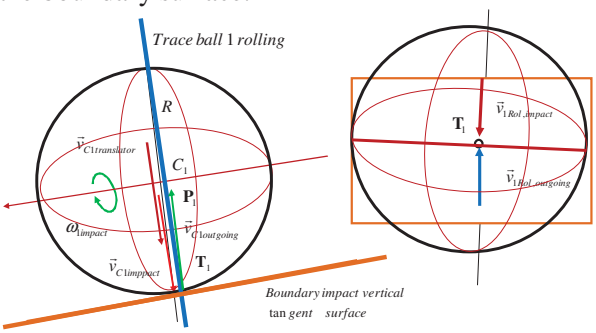


Figure 7. Plan for the incoming and outgoing velocities of the point of impact of a ball at the central impact of a billiard ball, which rolls along a horizontal plane and an impact perpendicular to the vertical contour plane of impact

4.2.2. The central impact of the ball in rolling into a contour vertical plane, as well as into a convex and concave surface.

In the Figure 7 shows a plan of the incoming and outgoing velocities of the contact point of the central impact of a billiard ball in rolling, which rolls along a horizontal plane and a track perpendicular to the vertical contour surface in which it strikes. The horizontal component of the incoming velocity of the ball impact point is equal to the translational velocity of the center of mass of the ball, while the vertical component of the incoming velocity of that ball impact point is equal

$$\vec{v}_{\mathbf{T},Roling,impact}=\vec{v}_{1,Roling,impact}=-\omega_{\mathbf{P},impact}R\vec{k}=-\frac{v_{\mathbf{C},impact}}{R}R\vec{k}=-v_{\mathbf{C},impact}\vec{k} \tag{12}$$

and it has the highest intensity because it is $\alpha=0$, also the point of impact, in this case it is farthest from the current axis of rotation of the ball and equals R, that is, the ball rolling line closes the angle $\alpha=0$, because it is directional to the contour radius of the ball. The angular velocity $\vec{\omega}_{1,impact}$ of rotation of the ball when rolling is parallel to the contour plane, that is, to the direction of rotation of the ball and is denoted by:

$$\vec{\omega}_{P,impact}=\vec{\omega}_{1,impact}=-\frac{v_{\mathbf{C},impact}}{R}\vec{i}\,, \tag{13}$$

if we have adopted the coordinate axis x in the contour plane, the axis y in the normal direction to that plane. So that $\vec{v}_{\mathbf{T},impact} = \vec{v}_{\mathbf{C},impact} = -v_{\mathbf{C},impact}\vec{j}$. The direction and direction of the incoming roll path of a billiard ball before impact is determined by a unit vector $-\vec{j}$, while the outgoing roll path after a impact is determined by a unit vector $\vec{j}$. Immediately after the central impact on the contour vertical plane, the components $\vec{v}_{\mathbf{T},outgoing}$ and $\vec{v}_{\mathbf{T},Roling,outgoing}$ of the outgoing velocity of the point of impact of the ball and the center of mass of the rolling ball, as the angular velocity $\vec{\omega}_{P,outgoing}$ of the outgoing rolling of the ball along the outgoing route are:

$$\vec{v}_{\mathbf{T},outgoing} = \vec{v}_{\mathbf{C},outgoing} = v_{\mathbf{C},outgoing}\vec{j} \tag{14}$$

$$\vec{v}_{\mathbf{T},Roling,outgoing} = \omega_{\mathbf{P},outgoing}R\vec{k} = \frac{v_{\mathbf{T},outgoing}}{R}R\vec{k} = v_{\mathbf{C},outgoing}\vec{k} \tag{15}$$

$$\vec{\omega}_{P,outgoing} = -\vec{\omega}_{P,impact} = -\vec{\omega}_{1,impact} = \frac{v_{\mathbf{T},outgoing}}{R}\vec{i} = \frac{v_{\mathbf{C},outgoing}}{R}\vec{i} \tag{16}$$

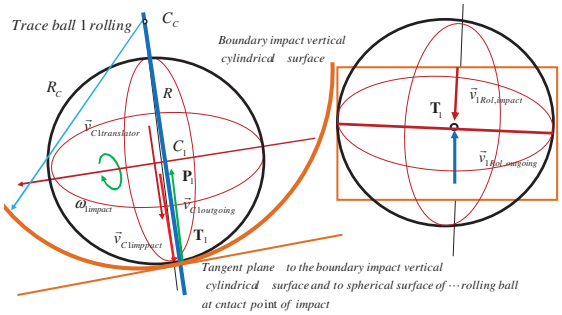

Figure 8. Plan of the incoming and outgoing velocities of the point of impact of a ball at the central impact of a billiard ball, which rolls along a horizontal plane and a track perpendicular to the vertical contour of a curvilinear cylindrical concave surface

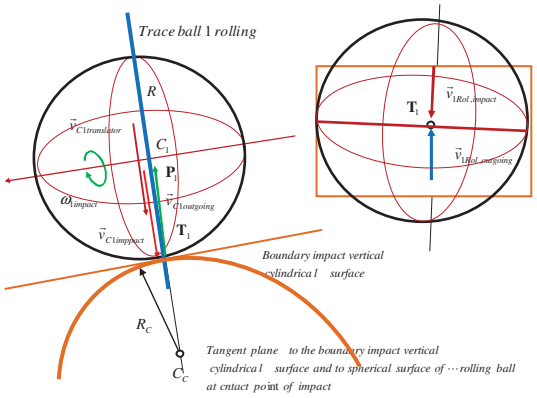

Figyre 9. Plan of the incoming and outgoing velocities of the point of impact of the ball at the central impact of the billiard ball, which rolls along the horizontal plane and the route perpendicular to the vertical contour curved cylindrical convex surface of impact

The central impact of a ball in rolling into a contour concave curvilinear surface with a vertical derivative is presented in Figure 8. In this Figure 8 shows a plan of the incoming and

outgoing velocities of a billiard ball point in the case of a central impact in a tangent plane to a contour concave curvilinear surface with vertical derivatives. This line of incoming ball rolling passes through the center of the curve of the concave line along which the vertical derivative describes that curvilinear cylindrical surface. In order for such an impact, it is necessary that the radius of curvature in the part of the concave curve along the line of the curvilinear contour surface be greater than the radius of the billiard sphere. This is shown in Figure 8. Position the coordinate system so that the coordinate axis x is in a tangent plane to the contour curved cylindrical surface, and the axis y in the normal direction to that plane, so that it passes through the center of the curve of the contour surface, while the axis z is in the direction of its vertical derivative is drawn through the point contact (impacts, strikes) billiard balls into the contour surface. Now, by defining the tangent surface through the point of impact of the billiard ball into the contour surface, for this case we have reduced the central impact of the billiard ball to a plane.

The central impact of a ball in rolling into a contour convex curvilinear surface with a vertical derivative is presented in Figure 9. In the Figure 9 shows a plan of the incoming and outgoing velocities of a ball point in the event of a central impact of a billiard ball in rolling, which rolls on a horizontal plane and a track perpendicular to a vertical tangent plane drawn to a contour convex curvilinear surface with a vertical derivative in which it strikes. This line of incoming rolling trace of the sphere passes through the center of the curve of the convex curve along which the vertical derivative describes that curvilinear surface. In order for such a collision, the ratio of the radius of curvature in the part of the curve to the line of the curvilinear contour surface and the radius of the billiard sphere is irrelevant. This is shown in Figure 9. Position the coordinate system such that the coordinate axis x is in a tangent plane to the contour convex curvilinear cylindrical surface, and the axis y in the normal direction to that plane, so that it passes through the center of the contour surface curvature, while the axis z in the direction of its vertical derivative is drawn through the point strikes billiard ball into a contour convex surface. Now, by defining the tangent surface through the point of impact of the billiard ball into the contour surface, we have reduced the task to the central impact of the billiard ball on a plane.

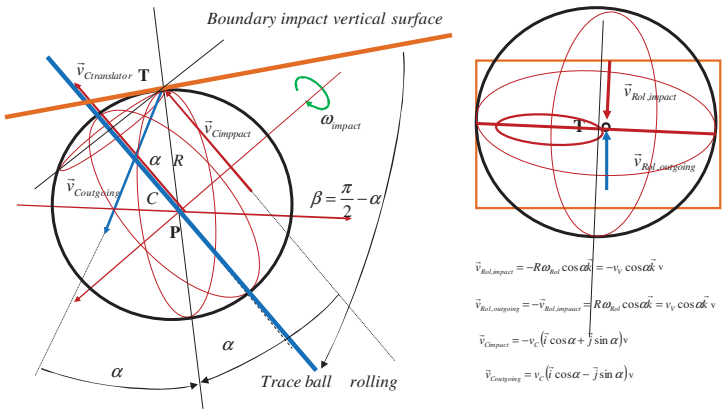

Figure 10. Plan of the incoming and outgoing velocities of the point of impact of a ball at a skew (oblique) impact of a billiard ball, which rolls along a horizontal plane and a track directed at an angle in relation to the normal to the vertical contour plane of the impact

4.2.3. Oblique (skew) impact of a ball in rolling into a contour vertical plane. In the Figyre 10 shows a plan of the incoming and outgoing velocities of a billiard ball point in

the event of an oblique (skew) roll of a billiard ball in rolling, before and after it strikes a vertical plane. The ball rolls along a horizontal plane and slopes obliquely at a sharp angle to the vertical contour plane of impact. We set up the coordinate system so that the coordinate axis x is in the contour plane of impact, and the axis y in the normal direction to that plane, while the axis z in the direction of its vertical derivative is drawn through the point of impact of the billiard ball into the contour plane. The unit vector orientation of the direction and direction of the ball rolling path before impact is: $\vec{n}_{impact} = -\left(\vec{i}\sin\alpha + \vec{j}\cos\alpha\right)$. The incoming velocity components are:

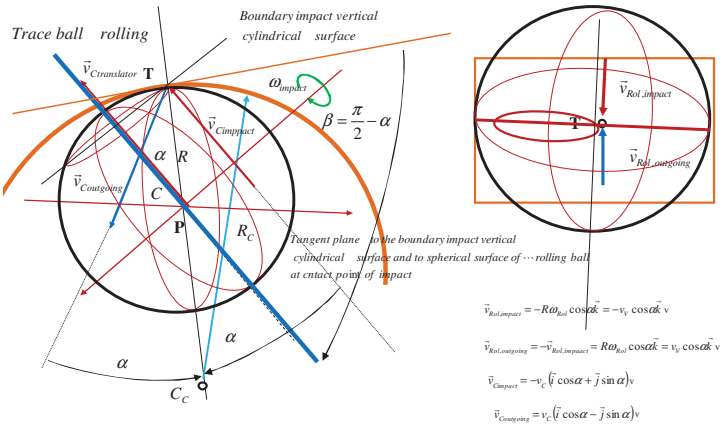

Figure 11. Plan of the incoming and outgoing velocities of the contact point of impact of a ball at an oblique impact of a billiard ball, which rolls along a horizontal plane and a line directed at an angle relative to the normal to a vertical contour curved cylindrical concave surface

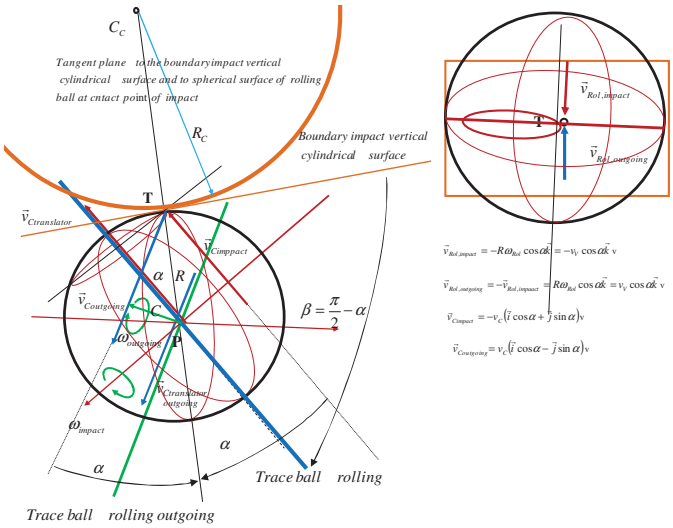

Figure 12. Plan of the incoming and outgoing velocities of the contact point of impact of a ball at an oblique impact of a billiard ball, which rolls along a horizontal plane and a line directed at an angle in relation to the normal to the vertical contour curved cylindrical concave impact surface

The translational velocity of the center **C** of mass of the ball just before impact is:

$$\vec{v}_{C,impact} = -v_C\left(\vec{i}\sin\alpha + \vec{j}\cos\alpha\right) \tag{17}$$

The instantaneous angular velocity $\vec{\omega}_{P,impact}$ of rotation due to the ball rolling along the route immediately before impact is:

$$\vec{\omega}_{impact} = \vec{\omega}_{P,impact} = \omega_{P,impact}\left(-\vec{i}\cos\alpha + \vec{j}\sin\alpha\right) = \frac{v_{C,impact}}{R}\left(-\vec{i}\cos\alpha + \vec{j}\sin\alpha\right) \tag{18}$$

The horizontal component $\vec{v}_{\mathbf{T},hor,impact}$ of the velocity of the ball point $\mathbf{T}$ by which the ball strikes the vertical contour plane is equal to the translational velocity $\vec{v}_{C,impact}$ of the center $\mathbf{C}$ of mass of the ball:

$$\vec{v}_{\mathbf{T},hir,impact} = \vec{v}_{C,impact} = -v_C\left(\vec{i}\sin\alpha + \vec{j}\cos\alpha\right) \tag{19}$$

The vertical component $\vec{v}_{\mathbf{T},Rol,impact}$ of the velocity $\vec{v}_{\mathbf{T},impact}$ of the ball point $\mathbf{T}$, by which the ball hits the vertical contour, is planar due to the rolling of the ball along the horizontal line-trace by the angular velocity $\vec{\omega}_{P,impact}$ of rolling about momentary avis and is equal to:

$$\vec{v}_{\mathbf{T},Rol,impact} = -R\omega_{\mathbf{P},Rol}\cos\alpha\vec{k} = -v_{\mathbf{C},impact}\cos\alpha\vec{k} \tag{20}$$

The horizontal component $\vec{v}_{\mathbf{T},hor,outgoing}$ of the velocity $\vec{v}_{\mathbf{T},outgoing}$ of the ball point $\mathbf{T}$ with which the ball leaves after hitting the vertical contour plane is equal to:

$$\vec{v}_{\mathbf{T},hor,outgoing} = v_{\mathbf{T},hormoutgoing}\left(-\vec{i}\sin\alpha + \vec{j}\cos\alpha\right) \tag{21}$$

The velocity $\vec{v}_{C,outgoing}$ of translation of the center $\mathbf{C}$ of mass of the ball immediately after impact is a horizontal component $\vec{v}_{\mathbf{T},hor,outgoing}$ of the departure velocity $\vec{v}_{\mathbf{T},outgoing}$ of the ball point $\mathbf{T}$ after the impact of the ball into the contour plane:

$$\vec{v}_{C,outgoing} = v_{C,outgoing}\left(-\vec{i}\sin\alpha + \vec{j}\cos\alpha\right) = \vec{v}_{\mathbf{T},hor,outgoing} = v_{\mathbf{T},hor,outgoing}\left(-\vec{i}\sin\alpha + \vec{j}\cos\alpha\right) \tag{22}$$

The instantaneous angular velocity $\vec{\omega}_{\mathbf{P},outgoing}$ of rotation due to the ball rolling along the track immediately after impact is:

$$\vec{\omega}_{outgoing} = \vec{\omega}_{\mathbf{P},outgoing} = \omega_{P,outgoing}\left(\vec{i}\cos\alpha + \vec{j}\sin\alpha\right) = \frac{v_{\mathbf{T},hor,outgoing}}{R}\left(\vec{i}\cos\alpha + \vec{j}\sin\alpha\right) \tag{23}$$

The vertical component $\vec{v}_{\mathbf{T},Rol,outgoing}$ of the velocity of the ball point $\mathbf{T}$, by which the ball leaves after striking the vertical contour plane, is the cause of the continuous rolling of the ball along the horizontal line at angular velocity $\vec{\omega}_{\mathbf{P},outgoing}$ and is equal to:

$$\vec{v}_{\mathbf{T},Rol,outgoing} = R\omega_{\mathbf{P},outgoing}\cos\alpha\vec{k} = -v_{\mathbf{T},Rol,impact}\vec{k} \tag{24}$$

The unit vector orientation of the direction and direction of the ball rolling path after impact is: $\vec{n}_{outgoing} = \left(-\vec{i}\sin\alpha + \vec{j}\cos\alpha\right)$.

4.2.4. An oblique (skew) impact of a ball in rolling into a contour concave or convex curvilinear surface with a vertical derivative. In Figures 11 and 12 show the plans of the incoming and outgoing velocities of the contact point $\mathbf{T}$ of a billiard ball in the case of an oblique impact, before and after the impact of the contour concave or the convex curvilinear surface with vertical derivatives. The ball rolls on a horizontal plane and slants obliquely at a sharp angle with respect to the tangent plane to the contour convex or concave curvilinear surface at the contact point $\mathbf{T}$ of impact of the sphere into it. Then, the incoming ball rolling path does not collinear with normal to the tangent plane through contact point $\mathbf{T}$ and do not cross the center $\mathbf{C}_0$ of its curve before the impact. Position the coordinate system so that the coordinate axis x is in a tangent plane to the contour surface of the impact, and the axis y in the normal direction to that tangent plane, so that it passes through the center of its curve $\mathbf{C}_0$, as well as into centre of ball $\mathbf{C}$, while the axis z in the direction

of its vertical derivative is drawn through the contact point $\mathbf{T}$ of impact of the billiard ball in the contour surface. The snow velocities for both of these cases are as analogous as in the case of an oblique impact in the plane contour-boundary, where in the tangent plane is analogous to the occupational impact from the previous example of an oblique collision into the plane.

4.2.5. Central collision between two billiard balls in rolling. If the rolling paths of the stock exchange slides of the two billiard balls are in one rolling line and are directed towards each other or the first one roll at a slower velocity so that the second one can catch up, a central collision between two balls can be realized. The configuration of the between two billiards balls is shown in Figure 13.

Now, at the point $\mathbf{T}_1 \equiv \mathbf{T}_2 \equiv \mathbf{T}_{12}$ of collision of the two balls, we place an imaginary common tangent plane, which are tangent to both and the other sphere at the contact point $\mathbf{T}_1 \equiv \mathbf{T}_2 \equiv \mathbf{T}_{12}$ of their collision. We set up a coordinate system such that the coordinate axis x is in their common tangent plane through the collision-contact point $\mathbf{T}_1 \equiv \mathbf{T}_2 \equiv \mathbf{T}_{12}$, and the axis y in the normal direction to that tangent plane, while the axis z in the vertical direction lies in the tangent plane in which the paths of the balls rolling are drawn through the collision point of the billiards balls.

The unit vectors of orientation of the direction $\vec{n}_{1,impact} = -\vec{j}$ and $\vec{n}_{2,impact} = \vec{j}$ direction of the paths of the ball rolling before the collision are in the opposite directions, respectively. The components of the incoming velocities of the rolling balls before the collision are $\vec{v}_{C1,impact} = -v_{C1}\vec{j}$ or $\vec{v}_{C2,impact} = v_{C2}\vec{j}$: The translation velocities of the centers of mass, $\mathbf{C}_1$, or $\mathbf{C}_2$ the balls immediately before their collision, are $\vec{v}_{C1,impact} = -v_{C1}\vec{j}$ and $\vec{v}_{C2,impact} = v_{C2}\vec{j}$: respectively. The angular velocities of the rolling billiard balls without slipping immediately before their collision, are $\vec{\omega}_{P1,impact}$ and $\vec{\omega}_{P2,impact}$: respectively are:.

$$\vec{\omega}_{1,impact} = \vec{\omega}_{P1,impact} = -\vec{i}\,\omega_{P1,impact} = -\frac{v_{C1,impact}}{R}\vec{i}$$

$$\vec{\omega}_{2,impact} = \vec{\omega}_{P2,impact} = \vec{i}\,\omega_{P2,impact} = \frac{v_{C2,impact}}{R}\vec{i} \tag{25}$$

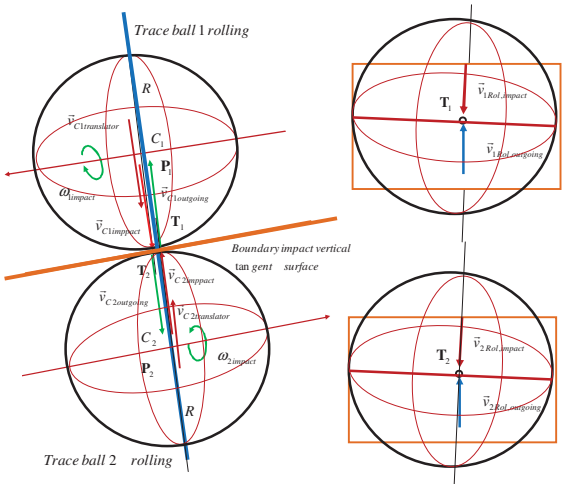

Figure 13. Plan the incoming and outgoing velocities of the collision points of two balls at their central collision

The horizontal components $\vec{v}_{\mathbf{T}1,hor,impact}$ and $\vec{v}_{\mathbf{T}2,hor,impact}$ of the velocities $\vec{v}_{\mathbf{T}1,impact}$ and $\vec{v}_{\mathbf{T}2,impact}$ of the points $\mathbf{T}_1$ and $\mathbf{T}_2$ the balls that the balls collide with are equal to the velocities $\vec{v}_{C1,impact}$ or $\vec{v}_{C2,impact}$ of the corresponding centers of mass, $\mathbf{C}_1$, or $\mathbf{C}_2$ the corresponding balls:

$$\vec{v}_{\mathbf{T}1,hor,impact} = \vec{v}_{C1,impact} = -v_{C1}\vec{j}\text{, respectively } \vec{v}_{\mathbf{T}2,hor,impact} = \vec{v}_{C2,impact} = v_{C2}\vec{j}\ , \quad (26)$$

Vertical components $\vec{v}_{\mathbf{T}1,Rol,impact}$ and $\vec{v}_{\mathbf{T}2,Rol,impact}$ of velocities of points $\mathbf{T}_1$ and $\mathbf{T}_2$ of the balls that collide with the balls are velocities due to the rolling of the balls along the horizontal track by the incoming angular velocities $\vec{\omega}_{P1,impact}$ and $\vec{\omega}_{P2,impact}$ are defined as:

$$\vec{v}_{\mathbf{T}1,Rol,impact} = -R\omega_{\mathbf{P}1,Rol}\vec{k} = -v_{\mathbf{C}1,impact}\vec{k} \quad (27)$$

respectively

$$\vec{v}_{\mathbf{T}2,Rol,impact} = -R\omega_{\mathbf{P}2,Rol}\vec{k} = -v_{\mathbf{C}2,impact}\vec{k} \quad (28)$$

The horizontal components $\vec{v}_{\mathbf{T}1,hor,outgoing}$ and $\vec{v}_{\mathbf{T}1,hor,outgoing}$ of the velocities of the points $\mathbf{T}_1$ and $\mathbf{T}_2$ of the balls with which the balls leave after the collision are:

$$\vec{v}_{\mathbf{T}1,hor,outgoing} = v_{\mathbf{T}1,hor,outgoing}\vec{i}\ \text{, respectively } \vec{v}_{\mathbf{T}2,hor,outgoing} = -v_{\mathbf{T}2,hpr,outgoing}\vec{i} \quad (29)$$

The velocities $\vec{v}_{C1,outgoing}$ and $\vec{v}_{C2,outgoing}$ of translation of the centers of mass, $\mathbf{C}_1$, or $\mathbf{C}_2$ the corresponding sphere immediately after the mutual collision, is equal to the corresponding horizontal components $\vec{v}_{\mathbf{T}1,hor,outgoing}$ and $\vec{v}_{\mathbf{T}1,hor,outgoing}$ of the departure velocities of the corresponding contact point $\mathbf{T}_1$ and $\mathbf{T}_2$ sphere after the collision:

$$\vec{v}_{C1,outgoing} = v_{C1,outgoing}\vec{j} = \vec{v}_{\mathbf{T}1,hor,outgoing} = v_{\mathbf{T}1,hoe,outgoing}\vec{j}$$
$$\vec{v}_{C2,outgoing} = -v_{C2,outgoing}\vec{j} = -\vec{v}_{\mathbf{T}2,hoe,outgoing} = -v_{\mathbf{T}2,hor,outgoing}\vec{j} \quad (30)$$

The instantaneous angular velocities $\vec{\omega}_{\mathbf{P}1,outgoing}$ and $\vec{\omega}_{\mathbf{P}2,outgoing}$ of ball rolling due to the outgoing rolling of each of the balls per track immediately after the collision are:

$$\vec{\omega}_{1,outgoing} = \vec{\omega}_{\mathbf{P}1,outgoing} = \omega_{P1,outgoing}\vec{i} = \frac{v_{\mathbf{T}1,hor,outgoing}}{R}\vec{i}$$

$$\vec{\omega}_{2,outgoing} = \vec{\omega}_{\mathbf{P}2,outgoing} = \omega_{P2,outgoing}\vec{i} = -\frac{v_{\mathbf{T}2,hor,outgoing}}{R}\vec{i} \quad (31)$$

The vertical component $\vec{v}_{\mathbf{T}1,Rol,outgoing}$ and $\vec{v}_{\mathbf{T}2,Rol,outgoing}$ of the departure velocities of contact points $\mathbf{T}_1$ and $\mathbf{T}_2$ of the balls, by which each of the balls leaves after each other's central collision, is the cause of the outgoing rolling of each of the balls along the horizontal track at angular velocity, respectively, and is determined by the following expressions:

$$\vec{v}_{\mathbf{T}1,Rol,outgoing} = R\omega_{\mathbf{P}1,outgoing}\vec{k} = v_{\mathbf{T}1,Rol,impact}\vec{k}$$
$$\vec{v}_{\mathbf{T}2,Rol,outgoing} = R\omega_{\mathbf{P}2,outgoing}\vec{k} = v_{\mathbf{T}2,Roll,impact}\vec{k} \quad (32)$$

The unit vectors of orientation of the direction and orientation of the outgoing lanes of the outgoing roll of the balls in the outlet after the collision are: $\vec{j}$ and $-\vec{j}$, respectively.

4.2.6. An oblique collision of two billiard balls in a non-slip roll. If the rolling traces of two billiard balls on rolling without slipping intersect, and the balls simultaneously reach the position that they can collide, then such a collision is said to be an oblique collision of two balls. Figures 14 and 15 shown the plans of the component incoming $\vec{v}_{C1,impact}$ and $\vec{v}_{C2,impact}$ and outgoing $\vec{v}_{C1,outgoing}$ and $\vec{v}_{C2,outgoing}$ velocities of ball center mass $\mathbf{C}_1$ and $\mathbf{C}_2$ of

an oblique collision of two billiard balls rotating horizontally relative to a common vertical tangent plane at a common point of collision.

Their velocities $\vec{v}_{C1,impact}$ and $\vec{v}_{C2,impact}$ of the centers of mass $\mathbf{C}_1$ and $\mathbf{C}_2$, are non-collinear and we are using the collision model decomposition to subsystems presented in Figure14. In the following Figure 15 shows a plan of the component of incoming $\vec{v}_{C1,impact}$ and $\vec{v}_{C2,impact}$, and outgoing $\vec{v}_{C1,outgoing}$ and $\vec{v}_{C2,outgoing}$ velocities of an oblique collision of two billiard balls, rolling along a horizontal plane, relative to a common vertical tangent plane at a common impact point of oblique collision when their translational velocities of their centers $\mathbf{C}_1$ and $\mathbf{C}_2$ of ball mass are no collinear, using a complex system model.

When asked how many such positions in the collision configuration can be insulated, how to define using the distance of the centers of mass of the two balls. Here is the conclusion of the theorem.

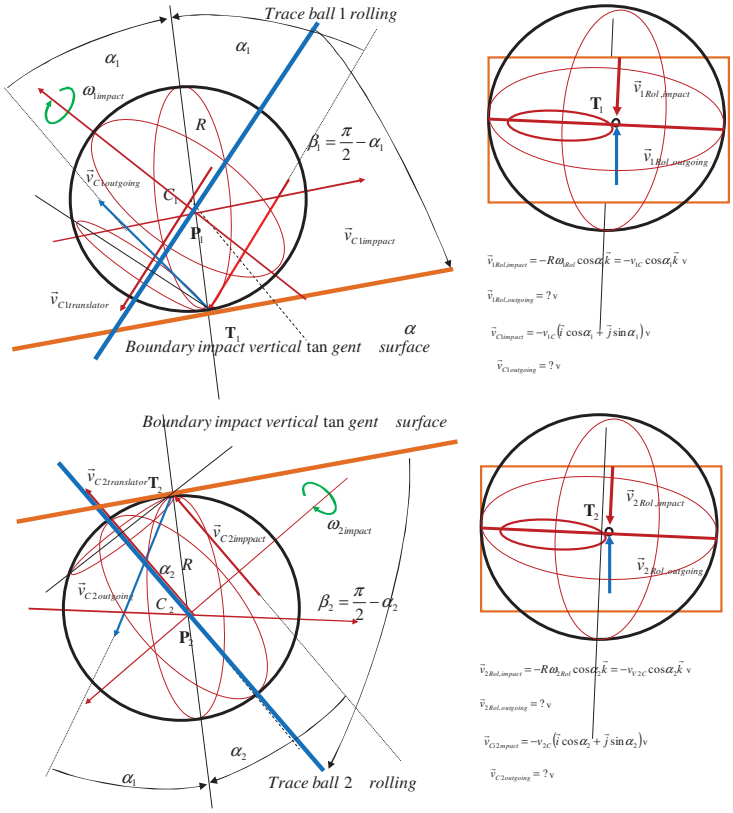

Figure 14. Decomposed system of two equal billiard balls in configuration of a oblique (skew) collision. Plan of the incoming and outgoing velocities of the collision contact points of each of the two balls at their oblique collision.

4.2.7. The theorem of the feasibility of the collision of two billiard balls. *Two billiard balls, of equal radius, in rolling without slipping, and rolling along the intersecting tracks, can reach the configuration of the collision, and the realization of the same, only if only if their centers* $\mathbf{C}_1$ *and* $\mathbf{C}_2$ *of mass are located at the corresponding distance* $\overline{\mathbf{C}_1\mathbf{C}_2} = 2R$ *at points, which are at the translational velocities of their centers of mass* $\mathbf{C}_1$ *and* $\mathbf{C}_2$ *, and*

are directed and oriented to the point of intersection of their rolling paths. There are infinitely many such configurations of the collision feasibility of two balls. A collision is possible before both balls pass the point of intersection of the tracks, and also in the condition that one has not reached the position of the section of the tracks and that the other ball has passed through that section of the tracks, but so that the intensities of the velocities allow the first round to cross the position of cross sections of the tracks.

We shall now give one analysis and explanation of the plan of the component velocities $\vec{v}_{\mathbf{T}1,hor,outgoing}$ and $\vec{v}_{\mathbf{T}1,hor,outgoing}$, as well as $\vec{v}_{\mathbf{T}1,Rol,outgoing}$ and $\vec{v}_{\mathbf{T}2,Rol,outgoing}$ of the points $\mathbf{T}_1$ and $\mathbf{T}_2$ of balls in which the balls collide, using quoted Figures 14 and 15 respectively. If there was a collision through the points $\mathbf{T}_1$ and $\mathbf{T}_2$ at the collision point $\mathbf{T}_1 \equiv \mathbf{T}_2 \equiv \mathbf{T}_{12}$, then the two balls, set up an imaginary common tangent plane, which is tangent to both sphere surface at the point of their collision $\mathbf{T}_1 \equiv \mathbf{T}_2 \equiv \mathbf{T}_{12}$. Let us set the coordinate system so that the coordinate axis x is in their common tangent plane through the collision point, and the axis y in the normal direction to that tangent plane and passes through both cents of the mass $\mathbf{C}_1$ *and* $\mathbf{C}_2$ of billiard balls in the collision configuration, while the axis z is in the tangent plane and in the vertical direction in the plane in which the tracks of rolling balls lie and are pulled through the collision point of billiard balls.

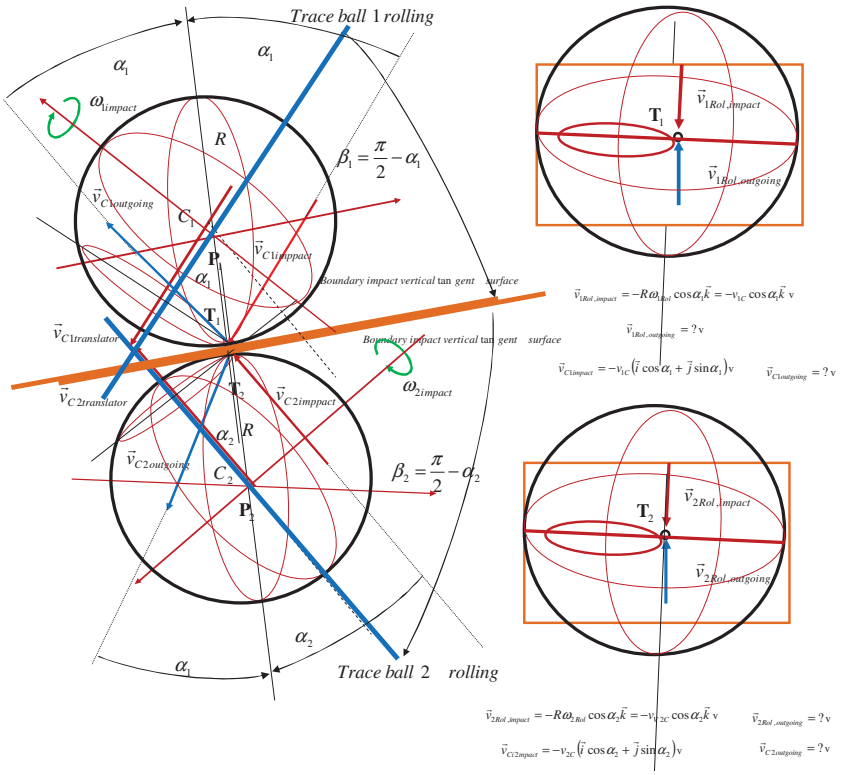

Figure 15. A system of two equal billiard balls that roll on rolling tracks in a oblique (skew) collision configuration. Plan the incoming and outgoing velocities of the collision points of each of the two balls at their oblique collision

The unit vectors of orientation of the direction and focusing of the incoming ball rolling paths, just before the oblique collision, are defined by the unit orientation vectors:

$$\vec{n}_{1,impact}=-\left(\vec{i}\sin\alpha_1+\vec{j}\cos\alpha_1\right),\ \text{and}\ \ \vec{n}_{2,impact}=-\vec{i}\sin\alpha_2+\vec{j}\cos\alpha_2. \tag{33}$$

in which the angles α_1 and α_2 of the rolling path of each of the balls are locked by the direction of the normal to the tangent plane to the sphere surfaces of the balls at the contact point of their collision, that is, by the direction of the line passing through the centers $\mathbf{C}_1$ and $\mathbf{C}_2$ of mass and both balls.

The components of the incoming velocities of the balls in rolling before the collision are:

The translation velocities $\vec{v}_{C1,impact}$ and $\vec{v}_{C2,impact}$ of the centers of mass $\mathbf{C}_1$ and $\mathbf{C}_2$, or of the balls just before their collision, are:

$$\vec{v}_{C1,impact}=v_{C1}\vec{n}_{1,impact}=-v_{C1}\left(\vec{i}\sin\alpha_1+\vec{j}\cos\alpha_1\right),$$

and

$$\vec{v}_{C2,impact}=v_{C2}\vec{n}_{2,impact}=v_{C2}\left(-\vec{i}\sin\alpha_2+\vec{j}\cos\alpha_2\right) \tag{34}$$

The instantaneous angular velocities $\vec{\omega}_{P1,impact}$ and $\vec{\omega}_{P2,impact}$ of rolling due to the rolling of balls on the corresponding incoming traces immediately before their collision are:

$$\vec{\omega}_{1,impact}=\vec{\omega}_{P1,impact}=\omega_{P1,impact}\left(\vec{i}\cos\alpha_1+\vec{j}\sin\alpha_1\right)=\frac{v_{C1,impact}}{R}\left(\vec{i}\cos\alpha_1+\vec{j}\sin\alpha_1\right)$$

$$\vec{\omega}_{2,impact}=\vec{\omega}_{P2,impact}=\omega_{P2,impact}\left(\vec{i}\cos\alpha_2-\vec{j}\sin\alpha_2\right)=\frac{v_{C2,impact}}{R}\left(\vec{i}\cos\alpha_2-\vec{j}\sin\alpha_2\right) \tag{35}$$

The horizontal components $\vec{v}_{\mathbf{T}1,hor,impact}$ and $\vec{v}_{\mathbf{T}2,hor,impact}$ of the velocities of the points $\mathbf{T}_1$ and $\mathbf{T}_2$ the balls that the balls collide with are equal to the velocities of the corresponding centers $\mathbf{C}_1$, and $\mathbf{C}_2$ of mass, of the corresponding balls:

$$\vec{v}_{\mathbf{T}1,hor,impact}=\vec{v}_{C1,impact}=v_{C1}\vec{n}_{1,impact}=-v_{C1}\left(\vec{i}\sin\alpha_1+\vec{j}\cos\alpha_1\right)$$

and

$$\vec{v}_{\mathbf{T}2,hor,impact}=\vec{v}_{C2,impact}=v_{C2}\vec{n}_{2,impact}=v_{C2}\left(-\vec{i}\sin\alpha_2+\vec{j}\cos\alpha_2\right) \tag{36}$$

Vertical components $\vec{v}_{\mathbf{T}1,Rol,impact}$ and $\vec{v}_{\mathbf{T}2,Rol,impact}$ of velocities of the contact points $\mathbf{T}_1$ and $\mathbf{T}_2$ balls that collide with the balls are velocities due to the rotation of the balls along the horizontal track by the incoming angular velocities and are defined as:

$$\vec{v}_{\mathbf{T}1,Rol,impact}=-R\omega_{\mathbf{P}1,Rol}\vec{k}=-v_{\mathbf{C}1,impact}\vec{k}$$

and

$$\vec{v}_{\mathbf{T}2,Rol,impact}=-R\omega_{\mathbf{P}2,Rol}\vec{k}=-v_{\mathbf{C}2,impact}\vec{k} \tag{37}$$

The horizontal components $\vec{v}_{\mathbf{T}1,hor,ougoing}$ and $\vec{v}_{\mathbf{T}2,hor,outgoing}$ of the velocities of contact points $\mathbf{T}_1$ and $\mathbf{T}_2$ balls, with which each of the balls leaves after the mutual collision are:

$$\vec{v}_{\mathbf{T}1,hor,ougoing}=\vec{v}_{C1,outgoing}=v_{C1}\vec{n}_{1,outgoing}=v_{C1}\left(-\vec{i}\sin\alpha_1+\vec{j}\cos\alpha_1\right)$$

and

$$\vec{v}_{\mathbf{T}2,hor,outgoing}=\vec{v}_{C2,outgoing}=v_{C2}\vec{n}_{2,outgoing}=-v_{C2}\left(\vec{i}\sin\alpha_2+\vec{j}\cos\alpha_2\right) \tag{38}$$

The outgoing velocities $\vec{v}_{C1,outgoing}$ and $\vec{v}_{C2,outgoing}$ of translation of the centers $\mathbf{C}_1$ and $\mathbf{C}_2$ of mass, or the corresponding sphere, immediately after the mutual collision of the billiard balls are equal to the corresponding horizontal component $\vec{v}_{\mathbf{T}1,hor,ougoing}$ and $\vec{v}_{\mathbf{T}2,hor,outgoing}$ of the outgoing velocity of the corresponding contact points $\mathbf{T}_1$ and $\mathbf{T}_2$ sphere after the collision:

$$\vec{v}_{C1,outgoing} = v_{C1}\vec{n}_{1,outgoing} = \vec{v}_{\mathbf{T}1,hor,ougoing} = v_{\mathbf{T}1,hor,ougoing}\left(-\vec{i}\sin\alpha_1 + \vec{j}\cos\alpha_1\right)$$

and

$$\vec{v}_{C2,outgoing} = v_{C2}\vec{n}_{2,outgoing} = \vec{v}_{\mathbf{T}2,hor,outgoing} = -v_{\mathbf{T}2,hor,outgoing}\left(\vec{i}\sin\alpha_2 + \vec{j}\cos\alpha_2\right) \quad (39)$$

The instantaneous angular velocities $\vec{\omega}_{\mathbf{P}1,outgoing}$ and $\vec{\omega}_{\mathbf{P}1o,utgoing}$ of the rolling and due to the outgoing rolling of each of the balls per track immediately after the collision are:

$$\vec{\omega}_{1,outgoing} = \vec{\omega}_{\mathbf{P}1,outgoing} = \omega_{P1,outgoing}\left(\vec{i}\cos\alpha_1 + \vec{j}\sin\alpha_1\right) = \frac{v_{\mathbf{T}1,hor,outgoing}}{R}\left(\vec{i}\cos\alpha_1 + \vec{j}\sin\alpha_1\right)$$

$$\vec{\omega}_{2,outgoing} = \vec{\omega}_{\mathbf{P}2,outgoing} = \omega_{P2,outgoing}\left(-\vec{i}\cos\alpha_2 + \vec{j}\sin\alpha_2\right) = \frac{v_{\mathbf{T}2,hor,outgoing}}{R}\left(-\vec{i}\cos\alpha_2 + \vec{j}\sin\alpha_2\right) \quad (40)$$

The vertical components $\vec{v}_{\mathbf{T}1,Rol,outgoig}$ and $\vec{v}_{\mathbf{T}2,Rol,outgoig}$ of the departure velocities of contact points $\mathbf{T}_1$ and $\mathbf{T}_2$ of balls, by which each of the balls leaves after each other's oblique collision, are the cause of the outgoing rolling of each of the balls along the horizontal track at angular velocities, $\vec{\omega}_{P1,outgoing}$ respectively $\vec{\omega}_{P2,outgoing}$, and are determined by the following expressions:

$$\vec{v}_{\mathbf{T}1,Rol,outgoing} = R\omega_{\mathbf{P}1,outgoing}\cos\alpha_1\vec{k} = v_{\mathbf{T}1,impact}\cos\alpha_1\vec{k}$$

$$\vec{v}_{\mathbf{T}2,Rol,outgoing} = R\omega_{\mathbf{P}2,outgoing}\cos\alpha_2\vec{k} = v_{\mathbf{T}2,impact}\cos\alpha_2\vec{k} \quad (41)$$

The unit vectors of orientation of the direction and focusing of the outgoing traces of the outgoing roll of each ball of the balls in the outlet after the collision are:

$$\vec{n}_{1,outgoing} = -\vec{i}\sin\alpha_1 + \vec{j}\cos\alpha_1 ,$$

respectively

$$\vec{n}_{2,outgoing} = -\vec{i}\sin\alpha_2 + \vec{j}\cos\alpha_2 \quad (42)$$

Conclusion-Theorem: *If the incoming paths of the balls in the rolling block equal angles with the common tangent plane to the balls at the contact points of collision of the balls, then the horizontal components of the outgoing velocities of those points close the same angles with that tangent plane. Also, the outgoing paths of one or the other ball, as well as the translational velocities of the centers of mass of the ball, close the same angles with this common tangent plane of collision.*

4.2.8. A special case of an oblique collision of two billiard balls in rolling along parallel rolling tracks. In Figures 16 and 17 shown the plan of incoming and outgoing velocities of an oblique collision of two billiard balls, rolling along parallel tracks in one horizontal plane, relative to the common vertical tangent plane when their velocities are collinear – decomposition, in Figure16, of the system into subsystems at the time of the collision. This is a special case of the previous general case of the configuration of an oblique collision of two billiard balls. Figure 17 shows that velocity plan on a complex, unrecompensed system. For such a collision to be possible, the necessary condition is that the maximum normal distance between the incoming traces of rolling of the balls before the collision is less than the diameter of the balls, respectively $h_{\max} \le 2R$.

Here, we will not list the expressions for the component velocities of the contact point of the balls in the collision configuration, since it is only obvious how to determine them according to the velocity plans from Figures 16, 17 and 17, and the order from the pre-description in the general case of the oblique collisin.

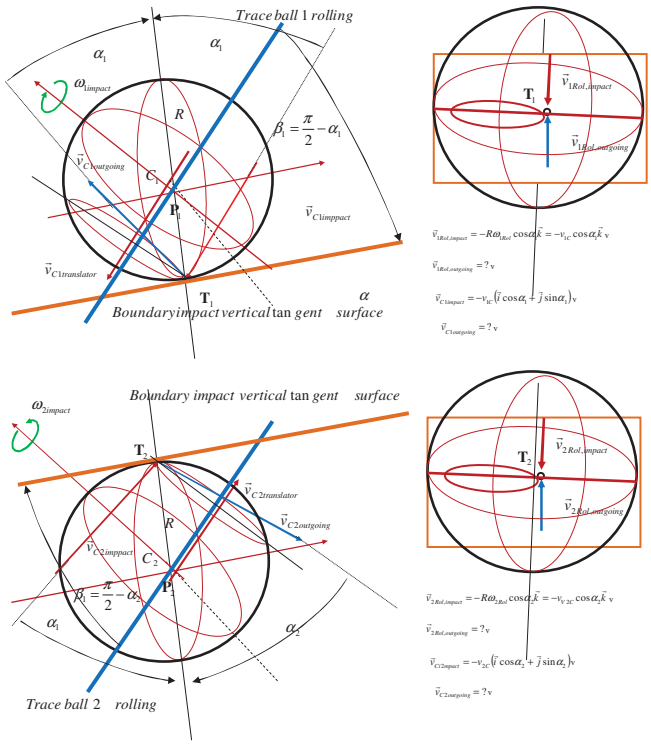

Figure 16. Decomposed system of two equal billiard balls rolling along parallel tracks in a collision configuration - Plan for the incoming and outgoing velocities of the collision points of each of the two balls, at their oblique collision and parallel incoming tracks, but parallel and outgoing treks

We, only, give the expressions for the instantaneous angular velocities $\bar{\omega}_{\mathbf{P}1,outgoing}$ and $\bar{\omega}_{\mathbf{P}1o,utgoing}$ of rolling and due to the outgoing rolling of each of the balls on the track immediately after the collision, which are:

$$\bar{\omega}_{1,outgoing} = \bar{\omega}_{\mathbf{P}1,outgoing} = \omega_{P1,outgoing}\left(\vec{i}\cos\alpha_1 + \vec{j}\sin\alpha_1\right) = \frac{v_{\mathbf{T}1,hor,outgoing}}{R}\left(\vec{i}\cos\alpha_1 + \vec{j}\sin\alpha_1\right)$$

respectively

$$\bar{\omega}_{2,outgoing} = \bar{\omega}_{\mathbf{P}2,outgoing} = -\omega_{P2,outgoing}\left(-\vec{i}\cos\alpha_1 + \vec{j}\sin\alpha_1\right) = -\frac{v_{\mathbf{T}2,hor,outgoing}}{R}\left(-\vec{i}\cos\alpha_1 + \vec{j}\sin\alpha_1\right) \quad (43)$$

The unit vectors of orientation of the direction and focusing of the outgoing traces of the outgoing rolling of the balls in departure immediately after the collision are:

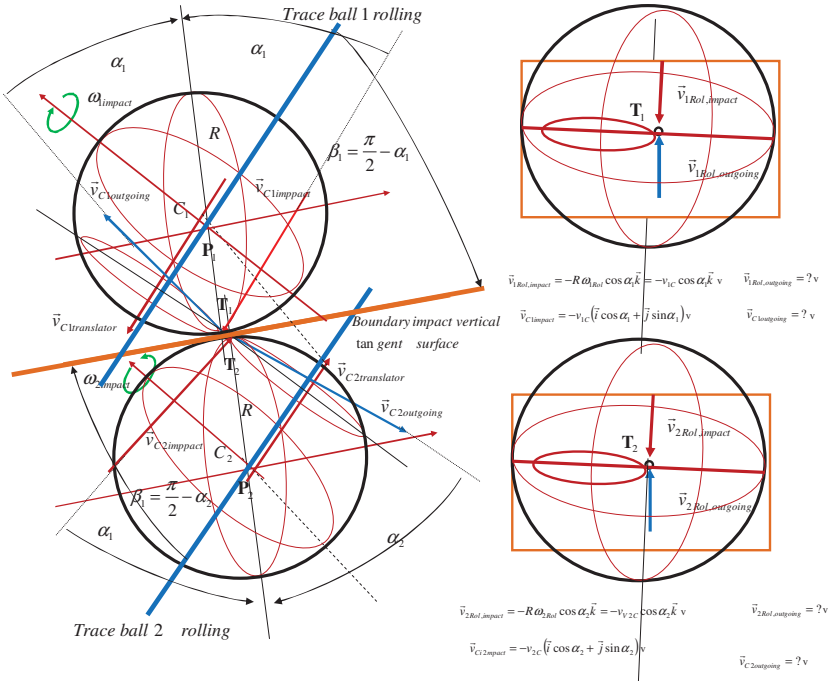
$$\vec{n}_{1,outgoing} = -\vec{i}\sin\alpha_1 + \vec{j}\cos\alpha_1 ,$$

respectively

$$\vec{n}_{2,outgoing} = -\left(-\vec{i}\sin\alpha_1 + \vec{j}\cos\alpha_1\right) \quad (44)$$

Conclusion-Theorem: *In the case of an oblique collision of balls with parallel incoming rolling paths, the outgoing rolling paths of the balls following the collision are also parallel, and the horizontal components of the incoming velocities of the collision points are in a straight line, while the horizontal components of the outgoing velocities of the collision points after the collision are at to another real one. These rights are crossed at the collision*

point in the collision configuration. The departure velocities of the center of mass after the collision are also parallel.



Picture 17. A system of two equal billiard balls rolling along parallel tracks in a collision configuration-Plan the incoming and outgoing velocities of the collision points of each of the two balls at their oblique collisions and parallel incoming traces, but parallel and outgoing traces of rolling

Main conclusion-Main Theorem: *The complete analysis of the component velocities of the collision points - the contact points of the balls in rolling was aimed to show that in the collision theory there is a ball of billiards in rolling, and more generally in the theory of collisions of axisymmetric bodies with one central plane of symmetry in which there is a circular contour by which the body can be rolled, it is sufficient to use only the angular velocity of rolling of the body around the instantaneous rolling axis, to describe the complete geometry, kinematics, and dynamics of the collision of the body in rolling.*

5 MECHANICS OF BILLIARDS II - THE DYNAMICS OF BILLIARDS

5.1 Basic elements of the dynamics of collision and impact of the rolling homogeneous rigid material balls

In order to describe the basic phenomena of the dynamics of billiards, we start from some basic definitions and definitions in the dynamics of the rolling of a material homogeneous rigid billiard ball with sphere surface, which we have presented at the beginning of this article, in the section on logical, qualitative and mathematical analogies.

Moving to the dynamics of billiards, in addition to the lengths and times, we also introduce the materiality of billiard balls. When rolling a ball, which is performed by rolling about the current axis of rotation or by translating at the velocity of the center of mass and rotating about its own central axis at some instantaneous angular velocity, we have two

approaches for description billiard ball dynamics. To describe such motion, materiality is calculated using the mass M of the ball and the axial moments of inertia of the mass of the ball for the instantaneous axis of rotation or for the central axis of rotation. For a material ball of mass M and radius R, the mass of the ball is: $M = \rho\frac{4}{8}R^3\pi$, ρ is the mass density of the ball or the mass per unit volume of the ball, the axial moment of inertia of the mass of the billiard ball for the center axis is $\mathbf{J}_C=\frac{2}{5}MR^2$, and the axial moment of inertia of the mass of the billiard ball for the axis tangent to the ball in any the point of its surface corresponding to the instantaneous axis of rolling of the ball when rolling is $\mathbf{J}_P=\mathbf{J}_C+MR^2=\frac{2}{5}MR^2+MR^2=\frac{7}{5}MR^2$, and is equal to the sum of the axial moment of mass inertia for the parallel central axis and the position moment of inertia of mass (which is equal to the product of mass of the ball and the square of the distance of the instantaneous axis of rolling from its parallel center axis of rotation of the sphere). These axial moments of inertia of the mass of a material sphere represent the inertial coefficients of the dynamics of the ball, which is rolling, and as the mass of the ball is the inertial coefficient for the case of translational motion of the ball, so the axial moments of inertia of the mass of the ball for rotation or rolling are its corresponding inertial coefficients! *Billiard balls with equal radiuses can be with different axial moments of inertia of their masses depending of the mass density of ball's material.*

When the paths of two material points meets at some point and if they reach the same point of their paths at different velocities and accelerations, then the dynamics of the collision of those two material points is achieved. The reciprocal dynamic effect of one material point on another material point is called a collision, and their dynamics in that short time interval are *the dynamics of a collision*.

If one material sphere (ball) is stationary and the other is moving, and in the movement of the rolls, it encounters a sphere in speace, one, moving, material sphere strikes (impacts) another, immobile material sphere. Since rest is a special case of the dynamics of a material sphere (ball), then we can say that the *concept of collision is more general than the concept of impact.*

An impact and collision can occur between one material sphere (ball) and a system of material balls, a collision with one of the material balls of a system of material balls, which is transmitted instantaneously to the other material balls of the system or body. Likewise, a collision of a material sphere-ball can be achieved by collision with a material rigid or deformable body. Collision is also possible in various combinations between material balls, material ball systems, and rigid and or deformable bodies. According to the properties and character of the material systems - participants in the collision event, collisions can be divided into several different types or groups: ideally elastic collision, ideally plastic collision and collision with a coefficient of restitution between zero and one.

It is very important to be aware of the phenomenon and the inherent elements of the collision, in other words the dynamics of the collision and its *vector and scalar invariants.* In the dynamics of billiards, as we can conclude from the preceding chapters, there is an impact of a billiard ball into a contour cylindrical surface, as well as a collision between two balls or a number of billiard balls in rolling.

Characteristic of a collision is that two solid spheres-balls come into contact at one common point at which one point of the spherical surfaces of the spheres in the collision reach simultaneously.

That point is the contact point of the collision of the masses of both balls, in which their dynamics interact, and thus the instantaneous, short-term duration, dynamic effect of one

rolling ball on the other at the contact of the current (very short interval) time is observed whereby the occurrence of a jump (discontinuous) changes in the kinetic parameters of the dynamics of both in the arrival of both rolling balls. This is primarily manifested in the change of direction and intensity of the velocity of motion of both material balls, which collided with respect to the intensities and directions of their velocities before their collision. In the collision of two material balls, *instantaneous forces of high intensity* and *short-time-action* occur in a short time interval in which the material balls are in contact during the dynamics of the collision, which disappear upon the separation of the system immediately after the collision.

The forces created by the collision of two material balls and in the state of contact of these two balls are also called *high-intensity impact forces*, of *short duration* and of final impulse. It should be emphasized that, by moving to the study of the dynamics of collisions, we have introduced, in addition to the length and time, the mass, or materiality, of billiard balls.

When studying collisions, and even material balls, some basic assumptions are made, which allow the model of collision dynamics of two rolling billiard balls to be assembled, and the task is simplified, but satisfactory models of real dynamics of collision of two balls are obtained. In the first part of this article we have presented the latest results of the authors of this article, which contribute to the extension of the theory of collision, geometry, kinematics and dynamics of collisions of the body in the rolling, which we will not repeat here but only to determine the outgoing angular velocities of the roll of billiard balls immediately after the collision.

5.2 Impact forces $\vec{F}(t)$ and impact moments $\vec{\mathfrak{M}}(t)$ in the collision of two material balls in rolling. Instantaneous impulse and momentum of motion of a ball in rolling before and after a collision

When it comes to systems of two bodies moving by rolling without sliding and in the dynamics of billiards, we have two or more balls, which are in rolling around the corresponding instantaneous axis of rolling, so the angular momentum difference of motion of the balls for the instantaneous axis of rotation is:

$$d\vec{\boldsymbol{p}}(t) = \vec{\mathfrak{M}}(t)dt = d\vec{\mathfrak{L}}_{\mathfrak{M}}(t) \tag{45}$$

where by $\vec{\mathfrak{L}}_{\mathfrak{M}}$ is denoted the impulse angular momentum and $\vec{\mathfrak{M}}(t)$ is the moment of impact impulse forces. If we integrate the previous differential relation, we obtain the following expression for the coupling angular momentum $\vec{\mathfrak{L}}_{\mathfrak{M}}$ of the body in rolling:

$$\vec{\mathfrak{L}}_{\mathfrak{M}} = \vec{\mathfrak{L}}(t) - \vec{\mathfrak{L}}(0) = \int_0^t \vec{\mathfrak{M}}(t)dt = \mathbf{J}_{\mathbf{P}}\vec{\omega}_{\mathbf{P}}(t) - \mathbf{J}_{\mathbf{P}}\vec{\omega}_{\mathbf{P}}(0) = \mathbf{J}_{\mathbf{P}}\vec{\omega}_{\mathbf{P}} - \mathbf{J}_{\mathbf{P}}\vec{\omega}_{\mathbf{P}0} \tag{46}$$

This previous vector expression should be considered conditionally, taking into account the discontinuity of the velocity direction in the impact configuration, as well as the discontinuity of the direction of movement occurring between the configuration immediately before and after the collision of two balls, as well as the interaction of rolling traces of the balls at the moment of impact. Also, it should be taken into account that the moment of the oscillating impact force, that is, the angular momentum of motion for the rolling axis, is also scalar, as opposed to the angular momentum of the moment for the point, which will be discussed in the case of rolling without sliding along the track, where the current the axis moves translation.

The increment $\Delta\vec{\mathfrak{L}}(t)$ of kinetic momentum or angular momentum $\vec{\mathfrak{L}}_{\mathfrak{M}}(t)$ of the motion for a finite time interval is equal to the momentum of an impulse impact force $\vec{\mathfrak{M}}(t)$ or coupling acting on a rolling ball, along its rolling path, at that short time.

Since both the linear momentum $\vec{K}_F(t)$ of the impulse impact force and the angular momentum $\vec{\mathfrak{L}}_{\mathfrak{M}}$ of the coupling are vector integrals, these in the general case do not coincide with the direction of the force $\vec{F}(t)$ or coupling $\vec{\mathfrak{M}}(t)$.

The mean value of the instantaneous coupling $\vec{\mathfrak{M}}_{sr}(t)$ can be determined from the previous relation (46) as:

$$\vec{\mathfrak{M}}_{sr}(\tau)=\frac{\vec{\mathfrak{L}}_{\mathfrak{M}}(\tau)}{\tau}=\frac{1}{\tau}\int_{t_0}^{t_0+\tau}\vec{\mathfrak{M}}(t)_{ud}\,dt \tag{47}$$

In the event that the coupling $\vec{\mathfrak{M}}(t)$ or moment of constant forces $\pm\vec{F}(t)=\vec{const}$, the angular momentum $\vec{\mathfrak{L}}_{\mathfrak{M}}(t)$ of coupling or moment of forces, though a vector integral, is collinear with coupling:

$$\vec{\mathfrak{L}}_{\mathfrak{M}}(t)=\vec{\mathfrak{L}}(t)-\vec{\mathfrak{L}}(t_0)=\int_{t_0}^{t}\vec{\mathfrak{M}}dt=\vec{\mathfrak{M}}(t-t_0)=\mathbf{J}_{\mathbf{P}}\vec{\omega}_{\mathbf{P}}(t)-\mathbf{J}_{\mathbf{P}}\vec{\omega}_{\mathbf{P}}(0)=\mathbf{J}_{\mathbf{P}}\vec{\omega}_{\mathbf{P}}-\mathbf{J}_{\mathbf{P}}\vec{\omega}_{\mathbf{P}0} \tag{48}$$

It means that the impulse $\vec{\mathfrak{L}}_{\mathfrak{M}}(t)$ of the coupling $\vec{\mathfrak{M}}(t)$ or moment of force, acting on the material ball via the point of impact, along its trajectory of motion when rolling the ball, at a finite time interval $\Delta t=t-t_9=\tau$, is equal to the increment of the angular momentum $\Delta\vec{\mathfrak{L}}(t)$ of the motion (kinetic moment) for that finite time interval.

When the coupling $\vec{\mathfrak{M}}(t)$ or moment of force is finite, the impulse $\vec{\mathfrak{L}}_{\mathfrak{M}}(t)$ of that coupling or torque in a small time interval, when $\Delta t=t-t_9=\tau\to 0$, equals zero. If the change in angular velocity $\Delta\vec{\omega}=\vec{\omega}(t)-\vec{\omega}(t_0)=\vec{\omega}-\vec{\omega}_0$ is finite in magnitude and occurs in a very short time $\Delta t=t-t_0=\tau\to 0$, then the impulse $\vec{\mathfrak{L}}_{\mathfrak{M}}(t)$, of the coupling $\vec{\mathfrak{M}}(t)$, ie the moment of forces must be finite, but that coupling $\vec{\mathfrak{M}}(t)$, or moment of the forces $\vec{F}(t)$, must be infinitely large. Such couplings $\vec{\mathfrak{M}}(t)$ or moments of forces $\vec{F}_{ud}(t)$ that occur in the short time and give a finite impulse $\vec{\mathfrak{L}}_{\mathfrak{M}}(t)$ (angular momentum) of the coupling are called the instant coupling or the momentary impact moment of the momentary impact forces of the finite impulse.

From the relation of the theorem on the change of kinetic energy and its relation to the coupling power, that is, the moment of forces, which performs work along the trajectory of motion of a material sphere-ball in rolling, it is valid:

$$\frac{dE_k}{dt}=P=\left(\vec{\mathfrak{M}}(t),\vec{\omega}(t)\right) \tag{49}$$

we can write:

$$dE_k=Pdt=\left(\vec{\mathfrak{M}}(t),\vec{\omega}(t)\right)dt \tag{50}$$

Upon approximate integration of the last relation we obtain:

$$E_k-E_{k0}=\int_{t_0}^{t}\left(\vec{\mathfrak{M}}(t),\vec{\omega}(t)dt\right)=\int_{t_0}^{t}\left(\vec{\mathfrak{M}}(t)dt,\vec{\omega}(t)\right)=\int_{t_0}^{t}\left(\vec{\omega}(t),d\vec{\mathfrak{L}}_{\mathfrak{M}}(t)\right)$$

$$E_k - E_{k0} \approx \frac{1}{2}\left(\vec{\omega}(t) + \vec{\omega}(t_0), \vec{\mathfrak{L}}_{\mathfrak{M}}(t - t_0)\right) \tag{51}$$

whereby we assumed that the approximate value of the integral could be determined assuming the mean value of the instantaneous angular velocity $\vec{\omega}_{sr} = \frac{1}{2}[\vec{\omega}(t) + \vec{\omega}(t_0)]$ during the impact process in a short time interval.

Based on the foregoing approximate relation (51), we can conclude that for infinitely short intervals the increments of the "*live force*" (*kinetic energy*) of the material sphere-ball in the rolling and in the collision dynamics, as well as the operation of the instantaneous impact forces, have finite values.

Moving by rotating about the current axis of rolling by an angle $\vec{\vartheta}_{\mathbf{P}} = \vec{\vartheta}$, or around the current pole, on a track of rolling a material ball, which by rolling has reached the collision configuration, is infinitesimal $\Delta t = t - t_0 = \tau \to 0$ and tending to zero during a small increment of time $\Delta t = t - t_0 = \tau \to 0$. Since the angular velocity $\vec{\omega} = \dot{\vec{\vartheta}}$ of rolling around the current axis of rolling, the angular momentum of the rolling pulse is the same:

$$\vec{\mathfrak{L}}_{\mathfrak{M}}(t_0 + \tau) = \vec{\mathfrak{L}}(t_0 + \tau) - \vec{\mathfrak{L}}(t_0) = \int_{t_0}^{t_0+\tau} \vec{\mathfrak{M}} dt = \vec{\mathfrak{M}}(t_0 + \tau - t_0) \tag{52}$$

$$\vec{\mathfrak{L}}_{\mathfrak{M}}(t_0 + \tau) = \mathbf{J}_{\mathbf{P}} \vec{\omega}_{\mathbf{P}}(t_0 + \tau) - \mathbf{J}_{\mathbf{P}} \vec{\omega}_{\mathbf{P}}(t_0) = \mathbf{J}_{\mathbf{P}} \dot{\vec{\vartheta}}_{\mathbf{P}} - \mathbf{J}_{\mathbf{P}} \dot{\vec{\vartheta}}_{\mathbf{P}0} \tag{53}$$

respectively

$$\mathbf{J}_{\mathbf{P}} \dot{\vec{\vartheta}}_{\mathbf{P}} = \vec{\mathfrak{L}}_{\mathfrak{M}}(t_0 + \tau) + \mathbf{J}_{\mathbf{P}} \dot{\vec{\vartheta}}_{\mathbf{P}0} \tag{54}$$

which after integration gives:

$$\mathbf{J}_{\mathbf{P}}\left[\vec{\vartheta}_{\mathbf{P}}(t_0 + \tau) - \vec{\vartheta}_{\mathbf{P}}(t_0)\right] = \int_{t_0}^{t_0+\tau} \vec{\mathfrak{L}}_{\mathfrak{M}}(t) dt + \mathbf{J}_{\mathbf{P}} \dot{\vec{\vartheta}}_{\mathbf{P}0}(t_0 + \tau - t_0) = \int_{t_0}^{t_0+\tau} \vec{\mathfrak{L}}_{\mathfrak{M}}(t) dt + \mathbf{J}_{\mathbf{P}} \dot{\vec{\vartheta}}_{\mathbf{P}0}(t_0)$$

$$\mathbf{J}_{\mathbf{P}}\left[\vec{\vartheta}_{\mathbf{P}}(t_0 + \tau) - \vec{\vartheta}_{\mathbf{P}}(t_0)\right] = \int_{t_0}^{t_0+\tau} \vec{\mathfrak{L}}_{\mathfrak{M}}(t) dt + \mathbf{J}_{\mathbf{P}} \dot{\vec{\vartheta}}_{\mathbf{P}0}(t_0) \tag{55}$$

where the mean value $\vec{\mathfrak{L}}_{\mathfrak{M},sr}$ of the angular momentum of the instantaneous coupling or moment of force in a short time interval $\Delta t = t - t_0 = \tau \to 0$.

As $t \to t_0$ there will be an increase in the angle of rolling, that is $\Delta \vec{\vartheta}_{\mathbf{P}} = \left[\vec{\vartheta}_{\mathbf{P}}(t_0 + \tau) - \vec{\vartheta}_{\mathbf{P}}(t_0)\right]_0 \approx 0$, the rolling of the ball during the impact or the collision, on the basis of which, we can conclude that the material sphere during the short-lived effect of the instantaneous coupling, or the moment of the instantaneous force in the dynamics of the collision is immobile.

We can, now also, define the term impact in terms of action.

The action which gives to a body the instantaneous forces $\vec{F}_{impact}$ and instantaneous couplings $\vec{\mathfrak{M}}_{impact}$ of a finite impulse, that is, angular momentum of moment short-lived action in the interval $\Delta t = t - t_0 = \tau \to 0$ is called a *stroke-impact*.

The vector invariants $\vec{\omega}_{\mathbf{P}}(t_0 + \tau)$ and $\vec{\omega}_{\mathbf{P}}(t_0)$, the instantaneous angular velocities before and after the impact always refer to the same material ball that rolls, $\vec{\omega}_{\mathbf{P}}(t_0)$, and $\vec{\omega}_{\mathbf{P}}(t_0 + \tau)$ are called the instantaneous angular velocities of the observed material sphere-ball to impact, before and, after, the collision (or impact). If the material ball at the moment of

impact on the motionless material of another system has an instantaneous angular velocity $\vec{\omega}_{\mathbf{P}}(t_0)=\vec{\omega}_{\mathbf{P},impact}$ then we say that it is the *incoming angular velocity of the rolling ball* or *the angular velocity of impact.* This currently produced angular velocity during a collision by which a material ball rolls out of contact with another system with $\vec{\omega}_{\mathbf{P}}(t_0+\tau)=\vec{\omega}_{\mathbf{P},outgoing}$ which it collided is called *the outgoing angular velocity.*

As we have shown in the previous analysis, we must bear in mind that in the short time of collision contact, the positions of the material balls in collision contact, when the impact forces or shocks are acting, change very little and slowly. These infinitesimal changes in the position of the material balls by rolling, or by changing the rolling angle, are in the order of magnitude of the small interval of time during which the collision takes place. Therefore, it is justified that changes in position during a short interval in which a collision occurs are neglected.

In the case of impact of a material ball into a fixed material or a limiter or a unilaterally restraining bond, the following relation can be written:

$$\vec{\omega}_{\mathbf{P},outgoing}-\vec{\omega}_{\mathbf{P},impact}=\Delta\vec{\omega}_{\mathbf{P}}=\frac{1}{\mathbf{J}_{\mathbf{P}}}\vec{\mathfrak{L}}_{\mathfrak{M}}(t_0+\tau)=\frac{1}{\mathbf{J}_{\mathbf{P}}}\int_{t_0}^{t_0+\tau}\vec{\mathfrak{M}}_{impact}(t)dt \tag{56}$$

5.3 Outgoing angular velocities, translational velocities, momentum of coupling impulses, and motion of rolling balls after an oblique ideally elastic collision of two balls

In Figures 15 and 18 show the configuration of the balls and the plan of the incoming and outgoing translational velocities and the angular rolling velocities of both balls in the case of an oblique (skew) collision of two equal balls, moving in opposite directions along the intersecting tracks. In order to determine the intensities of the outgoing angular velocities of the balls after the oblique collision, we will make an analogy with the central centric collision of two balls moving towards each other known angular velocities, for which the relations between the incoming and outgoing angular velocities are known.

In the case of ideally elastic oblique collision between balls, which we consider, the intensities of the component outgoing velocities after their collision, and in accordance with the previous decomposition analyzes of the kinematics of the balls in the collision into simple motions, when we consider that the masses of the balls are $m_1=m_2=M$ equal and the coefficient of restitution $k=1$, for ideal elastic collision, are:

1* The intensities of the horizontal components $v_{T1,trabslator,outgoing}$ and $v_{T2,translator,outgoing}$ of the outgoing velocities of the ball points due to translation after an oblique collision are:

$$v_{T1,trabslator,outgoing}=v_{T1,translator,impact}-\frac{2}{1+\dfrac{\mathbf{J}_{P1}}{\mathbf{J}_{P2}}}\left(v_{T1,translator,impact}-v_{T2,translator,i,pact}\right) \tag{57}$$

$$v_{T1,trabslator,outgoing}=v_{T2,translator,impact}=v_{T1,hor,outgoing}$$

$$v_{T2,translator,outgoing}=v_{T2,translator,impact}+\frac{2}{1+\dfrac{\mathbf{J}_{P2}}{\mathbf{J}_{P1}}}\left(v_{T1,translator,impact}-v_{T2,translator,impact}\right) \tag{58}$$

$$v_{T2,translator,outgoing}=v_{T1,translator,impact}=v_{T2,hor,outgoing}$$

The directions of these outgoing velocities are shown in figures 15 and 18, as in Figure 20. In the Figure 20 shows a complete plan of the incoming and outgoing angular velocities of rolling both balls with their rolling paths before and after an oblique collision.

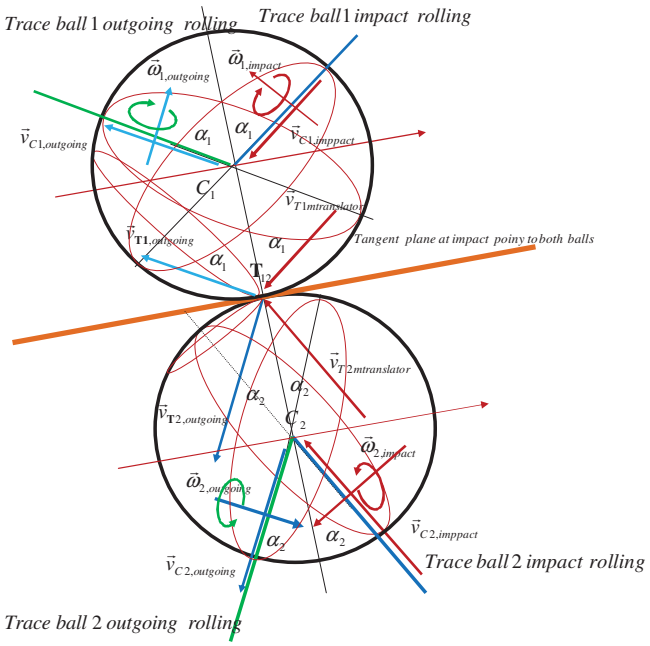


Figure 18. Collision of two rolling balls: Plan of incoming and outgoing angular velocities of rolling balls with their rolling paths before and after an oblique collision

2* The intensities of the outgoing angular velocities $\omega_{\mathbf{P}1,,outgoing}$ and $\omega_{\mathbf{P}2,outgoing}$ of rolling of the balls after a collision are determined by the following expressions:

$$\omega_{\mathbf{P}1,,outgoing} = \omega_{\mathbf{P}1,impact} - \frac{1+k}{1+\frac{\mathbf{J}_{P1}}{\mathbf{J}_{P2}}}\left(\omega_{\mathbf{P}1,impact} - \omega_{\mathbf{P}2,impact}\right) = \omega_{\mathbf{P}2,impact} = \frac{v_{\mathbf{C}2,impact}}{R} \tag{59}$$

$$\omega_{\mathbf{P}2,outgoing} = \omega_{\mathbf{P}2,impact} + \frac{1+k}{1+\frac{\mathbf{J}_{P2}}{\mathbf{J}_{P1}}}\left(\omega_{\mathbf{P}1,impact} - \omega_{\mathbf{P}2,impact}\right) = \omega_{\mathbf{P}1,impact} = \frac{v_{\mathbf{C}1,impact}}{R} \tag{60}$$

which are identical to expressions (8) and (9) for the case of a central collision of balls, in which this applies only to the intensities of the outgoing angular velocities, but whose directions of traces are different and depend on the type of collision and the configuration of the incoming angular velocities of the balls in with respect to their tangent plane at the point of impact, tangent to both balls at their common point of contact in the collision configuration.

Intensity of vertical components $v_{T1,Rolling,outgoing}$ and $v_{T2,Rolling,outgoing}$ of the velocity of the point of impact on the spherical surface of the sphere after impact due to the rolling of the balls in a horizontal plane, for ideal elastic collision, are:

$$v_{T1,Rolling,outgoing} = v_{T1,Rolling,impact} - \frac{2}{1+\frac{\mathbf{J}_{P1}}{\mathbf{J}_{P2}}}\left(v_{T1,Rolling,impact} - v_{T2,Rolling,impact}\right) = v_{T2,Rolling,impact} \tag{61}$$

$$v_{T2,Rolling,outgoing} = v_{T2,Rolling,impact} + \frac{2}{1+\frac{\mathbf{J}_{P2}}{\mathbf{J}_{P1}}}\left(v_{T1,Rolling,impact} - v_{T2,Rolling,impact}\right) = v_{T1,Rollin,impactg} \tag{62}$$

For an oblique impact of a collision of two balls, we cannot use a vector relation to change the angular momentum of the motion of one or the other sphere-ball in rolling because these are moments of impulses for different axes directions, but we must go to scalars, since the moments of the impulse of motion for axes are scalars. So now, to change the angular momentum intensity of the rolling motion of the first rolling ball, from the kinetic state just before the collision to the kinetic rolling state of the first ball after the oblique collision and the angular momentum of the coupling momentum as a result of the interaction of the collision of the second ball with the first due to the oblique collision, we can write the forces:

$$\left|\vec{\mathfrak{L}}_{\mathfrak{M},12}\right| = \left|\vec{\mathfrak{L}}_1(t)\right| - \left|\vec{\mathfrak{L}}_1(0)\right| = \left|\int_0^t \vec{\mathfrak{M}}_{12}(t)dt\right| = \mathbf{J}_{\mathbf{P},1}\left[\left|\vec{\omega}_{\mathbf{P}1}(t)\right| - \left|\vec{\omega}_{\mathbf{P}1}(0)\right|\right]$$

$$\left|\vec{\mathfrak{L}}_{\mathfrak{M},12}\right| = \left|\vec{\mathfrak{L}}_1(t)\right| - \left|\vec{\mathfrak{L}}_1(0)\right| = \mathbf{J}_{\mathbf{P}1}\left[\left|\vec{\omega}_{P1,outgoing}\right| - \left|\vec{\omega}_{P1,impact}\right|\right] \tag{63}$$

$$\left|\vec{\mathfrak{L}}_{\mathfrak{M},12}\right| = \left|\vec{\mathfrak{L}}_1(t)\right| - \left|\vec{\mathfrak{L}}_1(0)\right| = \left|\int_0^t \vec{\mathfrak{M}}_{12}(t)dt\right| = \frac{\mathbf{J}_{\mathbf{P}1}}{R}\left(v_{\mathbf{T}1,outgoing} - v_{C1,impact}\right)$$

$$\left|\vec{\mathfrak{L}}_{\mathfrak{M},12}\right| = \left|\vec{\mathfrak{L}}_1(t)\right| - \left|\vec{\mathfrak{L}}_1(0)\right| = \frac{7}{5}MR\left(v_{C2,outgoing} - v_{C1,impact}\right) \tag{64}$$

Then, now, to change the angular momentum intensity of the motion of the second rolling ball, from the kinetic state just before the collision to the kinetic rolling state of the second ball after the oblique collision and the momentum coupling resulting from the interaction of the collision of the first ball with the second due to the oblique collision, we can write the forces as:

$$\left|\vec{\mathfrak{L}}_{\mathfrak{M},21}\right| = \left|\vec{\mathfrak{L}}_2(t)\right| - \left|\vec{\mathfrak{L}}_2(0)\right| = \left|\int_0^t \vec{\mathfrak{M}}_{21}(t)dt\right| = \mathbf{J}_{\mathbf{P},2}\left[\left|\vec{\omega}_{\mathbf{P}2}(t)\right| - \left|\vec{\omega}_{\mathbf{P}2}(0)\right|\right]$$

$$\left|\vec{\mathfrak{L}}_{\mathfrak{M},21}\right| = \left|\vec{\mathfrak{L}}_2(t)\right| - \left|\vec{\mathfrak{L}}_2(0)\right| = \mathbf{J}_{\mathbf{P}2}\left[\left|\vec{\omega}_{P2,outgoing}\right| - \left|\vec{\omega}_{P2,impact}\right|\right] \tag{65}$$

$$\left|\vec{\mathfrak{L}}_{\mathfrak{M},21}\right| = \left|\vec{\mathfrak{L}}_2(t)\right| - \left|\vec{\mathfrak{L}}_2(0)\right| = \left|\int_0^t \vec{\mathfrak{M}}_{21}(t)dt\right| = \frac{\mathbf{J}_{\mathbf{P}2}}{R}\left(v_{\mathbf{T}2,outgoing} - v_{C2,impact}\right)$$

$$\left|\vec{\mathfrak{L}}_{\mathfrak{M},21}\right| = \left|\vec{\mathfrak{L}}_2(t)\right| - \left|\vec{\mathfrak{L}}_2(0)\right| = \frac{7}{5}MR\left(v_{C1,outgoing} - v_{C2,impact}\right) \tag{66}$$

The sum of these changes is the angular momentum intensity of motion of the first and second balls by rolling from the kinetic state just before the oblique collision to the kinetic state of rolling the balls after the oblique collision relative to the kinetic state before the oblique collision is:

$$\left|\vec{\mathfrak{L}}_{\mathfrak{M},21}\right| - \left|\vec{\mathfrak{L}}_{\mathfrak{M},21}\right| = 0 \tag{67}$$

which gives *the condition of conservation of the sum of the angular momentum intensity of* the angular momentum of motion during the oblique collision of the balls in rolling, and which was introduced by hypothesis (3) in the first part of this paper:

$$\left|\vec{\mathfrak{L}}_{\mathfrak{M},1}(0)\right| + \left|\vec{\mathfrak{L}}_{\mathfrak{M},2}(0)\right| = \left|\vec{\mathfrak{L}}_{\mathfrak{M},1}(t)\right| + \left|\vec{\mathfrak{L}}_{\mathfrak{M},2}(t)\right| \tag{68}$$

$$\mathbf{J}_{\mathbf{P},1}\left|\vec{\omega}_{\mathbf{P}1}(0)\right| + \mathbf{J}_{\mathbf{P},2}\left|\vec{\omega}_{\mathbf{P}2}(0)\right| = -\left(\mathbf{J}_{\mathbf{P},1}\left|\vec{\omega}_{\mathbf{P}1}(t)\right| + \mathbf{J}_{\mathbf{P},2}\left|\vec{\omega}_{\mathbf{P}2}(t)\right|\right) \tag{69}$$

This means that the sum of the angular momentum magnitudes of the two balls rolling at the moment just before the ideally elastic oblique collision is equal to the sum of the angular momentum intensities of their motion immediately after the ideally elastic and central and oblique collision.

The kinetic energy of the system, consisting of the first and second balls, which roll to each other, in the kinetic state and moment just before the ideally elastic of their oblique collision, is:

$$\mathbf{E}_{Kin,impact} = \mathbf{E}_{1,Kin,impact} + \mathbf{E}_{2,Kin,impact} = \frac{1}{2}\left[\mathbf{J}_{\mathbf{P}1}\omega^2_{\mathbf{P}1,impact} + \mathbf{J}_{\mathbf{P}2}\omega^2_{\mathbf{P}2,impact}\right] \tag{70}$$

$$\mathbf{E}_{Kin,impact} = \frac{1}{2}\left[\mathbf{J}_{C1}\omega^2_{1impact} + M_1 v^2_{C1impact}\right] + \frac{1}{2}\left[\mathbf{J}_{C2}\omega^2_{2,impact} + M_2 v^2_{C2impact}\right]$$

$$\mathbf{E}_{Kin,impact} = \frac{M}{2}\left(\mathbf{i}^2_C + 1\right)\left(v^2_{C2,impact} + v^2_{C1,impact}\right) \tag{71}$$

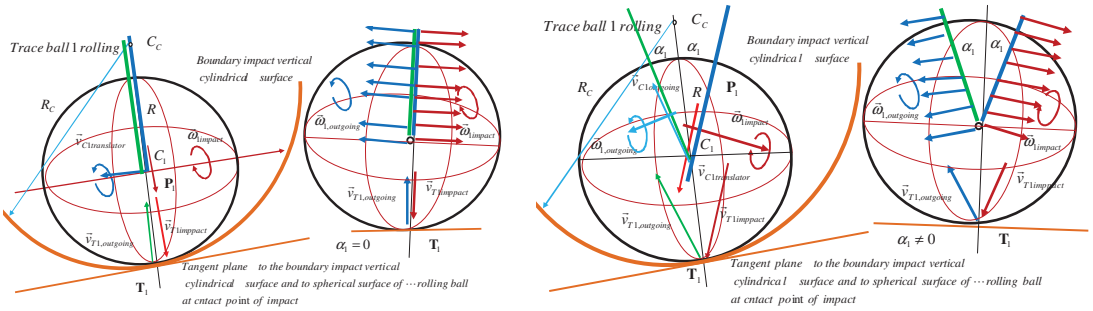
where the coefficient $\kappa = \left(\mathbf{i}^2_C + 1\right) = \frac{7}{5}$ of rolling without sliding the balls along the track.

The kinetic energy of the system, consisting of first and second balls, which rolls away from each other, in the kinetic state and the moment immediately after their ideally elastic skew collision is:

$$\mathbf{E}_{Kin,outgoing} = \mathbf{E}_{1,Kin,outgoing} + \mathbf{E}_{1,Kin,outgoing} = \frac{1}{2}\left[\mathbf{J}_{\mathbf{P}1}\omega^2_{\mathbf{P}1,outgoing} + \mathbf{J}_{\mathbf{P}2}\omega^2_{\mathbf{P}2,outgoing}\right] \tag{72}$$

$$\mathbf{E}_{Kin,outgoing} = \frac{1}{2}\left[\mathbf{J}_{C1}\omega^2_{1,outgoing} + M_1 v^2_{C1outgoing}\right] + \frac{1}{2}\left[\mathbf{J}_{C2}\omega^2_{2,outgoing} + M_2 v^2_{C2outgoing}\right] \tag{73}$$

$$\mathbf{E}_{Kin,impact} = \frac{M}{2}\left(\mathbf{i}^2_C + 1\right)\left(v^2_{C2,impact} + v^2_{C1,impact}\right) \tag{74}$$



a* b*

Figure 19. Partial analogies between central and oblique collisions of a rolling ball into a cylindrical curvilinear surface with vertical derivatives: opening of the trace od a rolling ball for an oblique collision (b *) with respect to the central impact (a *)

So it is

$$\mathbf{E}_{Kin,outgoing} = \mathbf{E}_{Kin,impact}$$

$$\mathbf{E}_{1,Kin,outgoing} + \mathbf{E}_{2,Kin,outgoing} = \mathbf{E}_{1,Kin,impact} + \mathbf{E}_{2,Kin,impact} \tag{75}$$

and that *there is no loss of kinetic energy* in an *obliquely elastic collision of two equal balls.*

In Fig. 19 shows the configuration of the ball and the plan of incoming and outgoing velocities of translation of the point of impact and angular velocities of rolling with incoming and outgoing rolling paths for different cases of impact of the ball into fixed cylindrical concave or convex surfaces, and for cases of central and oblique-skew collisions respectively.

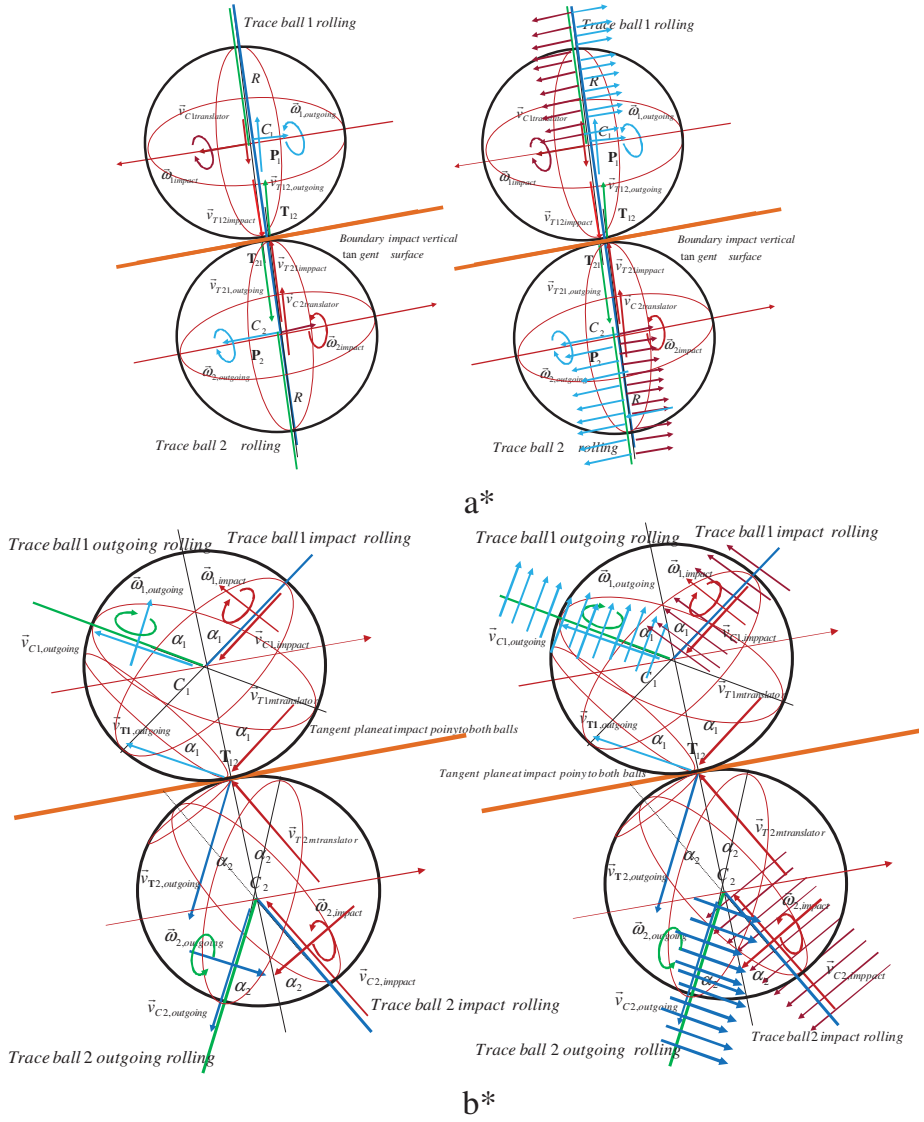


Figure 20. Partial analogies between the central and oblique collisions of two rolling balls: the opening of the traces of ball rolling in oblique (skew) collision (b *) with respect to the central collision of the balls (a *).

In the Figure 20 shows the configuration of two balls with corresponding plans of the incoming and outgoing translation velocities of the point of their contact and angular rolling velocities with incoming and outgoing rolling paths for different cases of mutual collision of these balls, and for cases of centric central as well as oblique collisions.

In this, as in the previous cases of different types of ball collision configurations, when ideally elastic collisions occur, there is no loss of kinetic energy, and the expressions for kinetic energy before and after collision will not be cited because they are identical to the terms written in the previous first section.

6 CONCLUDING CONSIDERATIONS

Using the analysis of the elements of geometry, kinematics and dynamics of impact (see Figure 19) and collision of balls (see Figure 20), which we have given in the previous parts of this paper, it is possible to draw some conclusions and generalizations.

Here we can imagine that the route-traces of rolling both balls, by which the balls are rolling "*corrected*" into straight lines and that each ball is rolling along the corresponding "*corrected straight route*" until the configuration is impact by an appropriate incoming angular velocity, and from the configuration of the collision by the outgoing angular velocities along *"broken traces with break",* as if a central collision had occurred, but we should take into account that at the point of collision on the route "a fracture" of the route occurs and that the angular velocity discontinuity occurs with the alternations of the angular velocity direction and orientation. The same goes for the other ball. This practically means that there is *a jump in the intensity of the angular velocity of rolling in the kinetic state of the collision*, and that the "*breaking*" *of the rolling path changes and the direction of the instantaneous angular velocity of the roll-out after the collision changes*. The "fracture of the rolling path" depends on the angle at which the rolling path comes from the normal tangent plane to the balls at the point of impact.

This consideration returns us to the central collision of two balls. So the task comes down to a central collision of two balls from which to determine the intensities of the translational outgoing velocities and the outgoing angular velocities of rolling about the current axis, or around it parallel to its own central axis of each of the balls, and then the "*track legs expand*" as corner angles with the apex in the point of collision configuration and set at angles with respect to the normal of the tangent plane at the collision-contact points of the rolling traces of the balls, depending on the angles that the incoming balls rolling paths close to that normal. This leads us to the conclusion that it is, also, possible to use a central collision to determine the intensities of the angular velocity of rolling and to change the angular momentum of motion, and in the case of oblique collision of rolling balls of different radii and masses, and to use appropriate analogies. It should be emphasized that it is necessary to determine the outgoing rolling routes after a collision taking into account the incoming routes.

In the dynamics of billiards, there is a simultaneous collision of several balls, so the problem of determining the directions of the components of the outgoing velocities after the collision is not difficult to determine, but even today the question of determining the intensity of the individual components of the outgoing angular velocities of rolling formed in the collision of several balls is open.

Keywords: Building contents, RC building, Fragility assessment, Asymmetric rigid blocks.

Abstract. *The seismic response of freestanding building contents that are hosted in different stories of a structure has not received yet the appropriate attention in the literature, despite the fact that the possible damage of the contents may result to excessive losses. Considering that valuable objects, e.g. artefacts, hospital equipment, computer servers, among others, are hosted in multistorey buildings and are freestanding on a rigid base, there is urgent need for seismic fragility and risk assessment methods in order to prioritize seismic protection measures. The paper discusses, a performance-based fragility assessment framework using either acceleration or velocity-based demand parameters. The structure's capacity is assessed using the Multiple Stripe Analysis (MSA) method. The fragility curves of the building contents are obtained using appropriate Engineering Demand Parameters (EDPs) and Intensity Measures (IMs) for the problem at hand. The paper aims to shed light on the fragility assessment of freestanding rigid blocks investigating how the behavior of the structure affects the block's response. A second goal is the comparison of the seismic response of symmetric and asymmetric freestanding contents hosted in a multistorey shear RC building.*

1 INTRODUCTION

Earthquake losses may be due to structural damage, damage of non-structural components and also due to the damage of the structure's contents. Recent guidelines, e.g. FEMA P-58 [1], FEMA E-74 [2], ATC-120 [3], address the problem of the seismic response of building contents, acknowledging that the losses are comparable, or may exceed, those of structural damage. Non-structural damage can be due to damage of components attached, or anchored, to the hosting building, or due to damage on the freestanding inventory of the building. In the latter case, there is a huge variability of systems and configurations hampering the systematic study of the problem and the recommendation of generally-applicable guidelines. The risk assessment of building contents is a complicated task since the response of the contents depends also on the behaviour of the hosting structure. As a result, there may be cases where a strong earthquake does not overturn an object but strongly damages the structure, while more benign ground motions may leave the structure intact causing losses due to damage on the building's contents. The paper focuses on the seismic performance, fragility and risk assessment of freestanding building contents that can be assumed rigid and are either symmetric or asymmetric. Freestanding building contents are usually treated as rocking rigid blocks and thus are modelled using Housner's theory [4]. The Multiple Stripe Analysis (MSA) method is adopted in order to assess the structure and its contents considering that the structural collapse implies also collapse/overturning of the contents. The latter observation was first implemented and discussed in detail by Fragiadakis and Diamantopoulos [5] by only for symmetric rectangular blocks. A second point of interest is the derivation of fragility curves and the calculation of the Mean Annual Frequency (MAF) of the rocking building contents.

Despite the significance of the problem at hand, there are relatively few past studies on the seismic response assessment of freestanding contents. Recent research examines, for example, the seismic behaviour of artefacts or hospital equipment. Spyrakos *et al.* [6] proposed predictive models for artefacts assuming that they form systems of one, or two, rocking blocks, while Di Sarno *et al.* [7] performed shake table tests on hospital equipment. In this direction, Wittich and Hutchinson [8, 9] studied the seismic response of human-formed artefacts that are either standing on a pedestal [8] or are asymmetric [9]. Both configurations are common for freestanding building contents and therefore the numerical tools developed are quite useful for their seismic performance assessment.

One of the first studies that focus on the fragility of rocking systems is the work of Purvance *et al.* [10]. They showed that objects with multiple rocking points are more fragile than predicted. Konstantinidis and Makris [11] studied the seismic response of laboratory equipment using analytical solutions and experimental results, while Konstantinidis and Nikfar [12] studied the sliding motion of stocky freestanding equipment and contents located at base-isolated buildings. Dimitrakopoulos and Paraskeya [13] proposed dimensionless fragility curves for the rocking response of rectangular blocks under near-fault excitations of their base. Their work was the first that proposed dimensionless Intensity Measures (IMs) for rocking blocks, while Giouvanidis *et al.* [14] discussed the fragility assessment of rocking frames. Petrone *et al.* [15] focused on the efficiency of different intensity measures in predicting the damage states of the rigid block, while alternative intensity measures for rocking systems were also investigated by Pappas *et al.* [16] and Kavvadias *et al.* [17]. Furthermore, Fragiadakis and Diamantopoulos [5] examined the fragility assessment of building contents that are hosted in a four-storey RC building proposing an early-stage risk framework for non-anchored contents. The main interest of the paper focuses on the probabilistic response assessment of the contents without neglecting

the structure's response. Some years earlier Fragiadakis *et al.* [18] and Fragiadakis and Diamantopoulos [19] had presented preliminary results on handling building contents assuming either elastic response of the structure or omitting the effect of structure's collapse on the fragility assessment. Recently, Fragiadakis *et al.* [20] completed an extensive experimental campaign on the seismic response of artefacts, with emphasis on statues and busts, which are asymmetric, Vlachos *et al.* [21] proposed compact solutions for handling asymmetric museum exhibits that are freestanding on a pedestal and Masi *et al.* [22] examined the resistance of museum artefacts against blast loading.

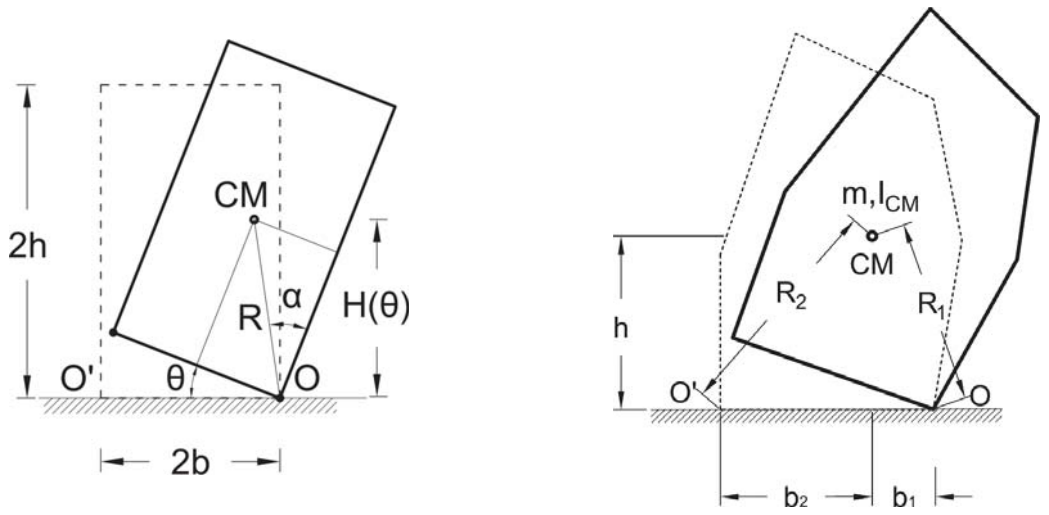
The paper presents a performance-based seismic fragility and risk assessment framework for freestanding building contents which has been discussed in Fragiadakis and Diamantopoulos [5] for symmetric rectangular blocks only. An extension of the methodology in case of asymmetric building contents is presented here concerning blocks whose distance of the center of mass is different from the two pivot points. Contrary to previous works on the seismic fragility assessment of rocking contents, the proposed methodology discusses how the response of the hosting building and that of the contents are coupled and also the effect of different stories. In order to consistently study the effect of increasing seismic intensity in a performance-based setting, a modified version of the Multiple Stripe Analysis method is adopted. It is shown that the EDP that should "drive" the MSA simulations is that of the building rather than that of the contents and also that the collapse of the building should not be neglected. Moreover, the calculation of fragility and risk are discussed. Existing fragility assessment methodologies are adopted showing that the IM of the building should be adopted (instead of that of the contents), while a procedure that uses the total probability theorem in order to calculate the MAFs combining fragilities that were separately generated for the structure and for the contents is investigated. Overall it is shown that the problem is not as simple, as it may initially seem, and that various tools should be appropriately combined in order to accurate and efficiently calculate the risk of freestanding contents. Essentially, the paper is based on the work of Fragiadakis and Diamantopoulos [5] extending the fragility and risk assessment of symmetric building contents to the planar investigation of non-symmetric cases, which is usual for museum artefacts.

2 THE DYNAMICS OF A ROCKING BLOCK

2.1 Symmetric freestanding rocking block

In order to study the seismic response of freestanding building contents that are subjected to an earthquake ground motion, it is firstly assumed that the bodies are orthogonal (i.e. symmetric) rocking blocks. Following the pioneering work of Housner [4], the problem of rocking and overturning of freestanding blocks has been the subject of intense analytical and experimental research. Despite its apparent simplicity, the rocking problem has been proven difficult, since the blocks behave nonlinearly and also due to the occurrence of many impacts between the rocking bodies and their base. Previous studies have revealed the complex response, including certain counter-intuitive trends [23]. Planar models are adopted in this work. This is an often made approximation, which may leads to unconservative results when applied to three-dimensional objects. Nevertheless, the two-dimensional, planar modelling, which is adopted here, offers some simplicity and was found adequate for the purpose of this work.

The fundamentals of rocking theory are briefly summarized in order to allow studying the seismic behaviour of freestanding rocking blocks and also the transition to the asymmetric case to be straightforward for the reader. Figure 1a shows a rigid block of dimensions $2b \times 2h$ that oscillates about point O (or O'). The block has weight W and moment of inertia I_0 about point



(a) (b)

Figure 1: Geometry of: (a) the symmetric rocking block and (b) the asymmetric rocking block.

O. Assuming that the block is homogeneous and thus the center of gravity is located at height h, the block's slenderness angle is equal to $\alpha = atan(b/h)$. The slenderness angle α together with the size parameter $R = \sqrt{b^2 + h^2}$ define fully the geometry of the block. Consequently, the equation of motion of the rocking block as first proposed by Housner[4] is:

$$I_o\ddot{\theta}(t) + mgR\sin\left[\alpha\text{sgn}\theta(t) - \theta(t)\right] = -m\ddot{u}_g(t)\,R\cos\left[\alpha\text{sgn}\theta(t) - \theta(t)\right] \tag{1}$$

where the rotation θ is the only degree of freedom. The sign function is used to define the pivot point (O or O'), i.e. when O' is the pivot point, the angle θ is negative. The fact that the equation of motion changes when the rotation changes sign makes the behaviour of the system nonlinear. For rectangular blocks, the moment of inertia is $I_0 = (4/3)mR^2$ and Eq. 1 can be written:

$$\ddot{\theta}(t) = p^2\left[-\sin\left(\alpha\,\text{sgn}\left(\theta(t)\right) - \theta(t)\right) - \frac{\ddot{u}_g(t)}{g}\cos\left(\alpha\,\text{sgn}\left(\theta(t)\right) - \theta(t)\right)\right] \tag{2}$$

where p denotes the characteristic frequency parameter of the rocking block, defined as:

$$p = \sqrt{\frac{WR}{I_0}} = \sqrt{\frac{3g}{4R}} \tag{3}$$

Following Figure 1a, in the static case, when $\theta \geq \alpha$ the block will overturn since the self-weight becomes an overturning force instead of a restoring force. Under dynamic loading, this is not strictly true since there may be cases where the block does not overturn for θ/α values that slightly exceed one. Therefore, the rotation is normalized with the slenderness angle in order to obtain the metric θ/α that provides an estimate of how close to overturning is the block. Moreover, when the block is at rest ($\theta = 0$), omitting the inertia term in Eq. 1, we find that it will start rocking motion if the ground acceleration $\ddot{u}_g$ exceeds a threshold value, i.e. when:

$$|\ddot{u}_g| \geq (b/h)g \Leftrightarrow |\ddot{u}_g| \geq g\tan\alpha \tag{4}$$

On the other hand, a body will slide if the seismic force $F_{eq} = m\ddot{u}_g$ exceeds the static friction:

$$F_{eq} \geq \mu_{st}W \Leftrightarrow |\ddot{u}_g| \geq \mu_{st}g \tag{5}$$

where μ_{st} is the static coefficient of friction. Therefore, the inequality of Eq. 5 implies that typically an acceleration above $0.60g$ is required for sliding to occur if the $\mu_{st} = 0.60$. Comparing Eq. 4 with Eq. 5, sliding will precede rocking only if $tan\alpha$ is less than μ_{st}. This is possible for small friction conditions, or for stocky blocks, i.e. for small μ_{st} or for large $tan\alpha$ values. When neither conditions of Eq. 4 or Eq. 5 are met, the body will remain at rest in its initial position. Assuming that μ_{st} are large and that the buildings contents considered here are slender, the effect of sliding is omitted. Therefore, the freestanding building contents are examined considering that their response concerns pure rocking motion.

The seismic response assessment of rocking structures is a complicated task. Various alternative ways to model and solve rocking systems that are subjected to real ground motion records are discussed in Diamantopoulos and Fragiadakis[24]. Furthermore, damping is event-based, meaning that energy is lost only when the angle of rotation θ reverses, indicating an impact of the block at a non-deformable base. The conservation of angular momentum just before and right after each impact defines the coefficient of restitution η, which is calculated with the formula proposed by Housner[4]:

$$\eta = \frac{\dot{\theta}_2}{\dot{\theta}_1} = 1 - \frac{3}{2}\sin^2\alpha \tag{6}$$

where $\dot{\theta}_1$ and $\dot{\theta}_2$ are the angular velocities before and after the impact, respectively.

2.2 Asymmetric freestanding rocking block

Considering the dynamics of a symmetric freestanding block, that have been discussed in the previous subsection, the extension of the theory to asymmetric cases is presented here. Thus, the asymmetric rocking block of Figure 1b is assumed. The block's width is $b = b_1 + b_2$, the center's of mass height is h while the total mass and the rotational moment of inertia with respect to the center of mass are m and I_{CM}, respectively.

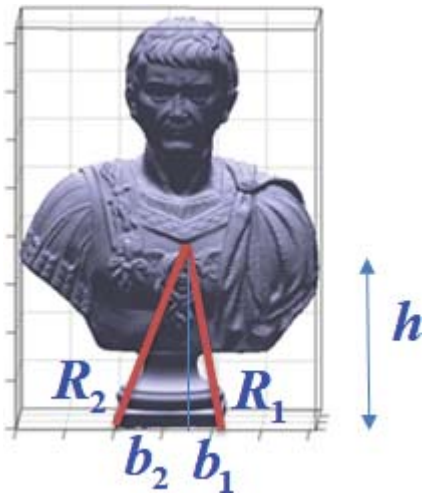


Figure 2: Implementation of the asymmetric rocking block theory to a freestanding bust.

.

The rocking motion of an asymmetric rocking block (e.g. the bust of Fig. 2), that can be assumed as rigid, is described by a modified equation of motion that has been introduced by

Wittich and Hutchinson [9]:

$$\left(I_{CM}+mR_i^2\right)\ddot{\theta}\left(t\right)+mgR_i\sin\left[\alpha_i\text{sgn}\theta\left(t\right)-\theta\left(t\right)\right]=-m\ddot{u}_g\left(t\right)R_i\cos\left[\alpha_i\text{sgn}\theta\left(t\right)-\theta\left(t\right)\right] \tag{7}$$

where the subscript i denotes the positive or negative rotation of the block and $sgn(\theta)$ is the signum function that corresponds to rocking motion with respect to the critical or the noncritical side. It is assumed that $i=1$ when the block rotates with respect to O and $i=2$ when the pivot point is the O'.

When an impact occurs, the kinetic energy is reduced and this reduction is derived through conservation of momentum with reference to the rocking point immediately before and just after the impact. This yields to a velocity ratio, known as the coefficient of restitution, which for the rigid block of interest is given by the following formulas for the positive to negative rotation (η^{+-}) and the negative to positive transition (η^{-+}), respectively:

$$\eta^{+-}=\frac{1}{I_{CM}+mR_1^2}\left[I_{CM}+mR_2^2-m(b_1+b_2)R_2sin\alpha_2\right] \tag{8}$$

$$\eta^{-+}=\frac{1}{I_{CM}+mR_2^2}\left[I_{CM}+mR_1^2-m(b_1+b_2)R_1sin\alpha_1\right] \tag{9}$$

3 FRAGILITY AND RISK ASSESSMENT

3.1 Fragility analysis

The seismic risk assessment of building contents requires the prior knowledge of the fragility of both the building and the contents. For building contents, the fragility provides the probability of overturning as a function of the seismic excitation (i.e. seismic intensity). Past research on fragility assessment focuses on the risk assessment of the structure itself [25], while the contents are examined separately and, usually, neglecting the effect of the hosting structure. Usually, fragility curves of building contents are empirical and are targeted to specific component types (e.g. cladding panels, masonry parapets). The direct fragility calculation that is here adopted through simulations allows to consider additional sources of uncertainty (e.g. related to the shape of the object, its mass distribution) and has been discussed in detail by Fragiadakis and Diamantopoulos [5]. A brief summary of the methodology is presented in the lines below.

The fragility function is the conditional limit-state exceedance probability, given by the expression:

$$F_R=P(EDP>edp|IM) \tag{10}$$

The structure is first examined. There will be simulations that the building collapses (denoted as "C") and simulations where no collapse occurs (denoted as "NC"). Making this separation and dropping the conditioning term in order to simplify the notation, i.e.: $P(EDP)=P(EDP>edp|IM)$, the probability of Eq. 10 is calculated using the total probability theorem (TPT):

$$F_R^{(s)}=P(EDP^{(s)}|NC)(1-P_C)+P_C \tag{11}$$

Focusing on the rocking body, when an object is subjected to a seismic ground motion there are three possible types of response: (i) the object may not rock and remain at rest, (ii) it may rock, or (iii) it may overturn. Using the TPT for the block, the fragility function becomes:

$$F_R^{(b)}=P(EDP^{(b)}|NoRock)P_{NoRock}+P(EDP^{(b)}|Rocking)P_{Rocking}+P(EDP^{(b)}|Ovtn)P_{Ovtn} \tag{12}$$

where $P(EDP^{(b)}|NoRock)$, $P(EDP^{(b)}|Rocking)$ and $P(EDP^{(b)}|Ovtn)$ are the probabilities that $EDP^{(b)} = \theta/\alpha$ exceeds a threshold value $edp^{(b)}$ and P_{NoRock}, $P_{Rocking}$ and P_{Ovtn} are the corresponding probabilities of no rocking, rocking and overturning, respectively. The superscripts "s" and "b" are used in order to distinguish the quantities that refer to the structure and the block, respectively. Blocks that will not rock, will not exceed any $edp^{(b)}$ value and thus $P(EDP|NoRock) = 0$, while the overturning blocks always exceed the limit-state threshold and consequently $P(EDP|Ovtn) = 1$. The conditional limit-state probability (fragility) is further simplified to:

$$F_R^{(b)} = P(EDP^{(b)} \geq edp|Rocking)(1 - P_{Ovtn} - P_{NoRock}) + P_{Ovtn} \tag{13}$$

The calculation of Eq. 13 is discussed in the sections that follow. A fundamental assumption of our derivation is that: "the simulations that collapse the building also overturn/collapse the freestanding contents".

3.2 Risk assessment

The risk is expressed as the mean annual frequency (MAF) of a limit-state being exceeded. Adopting the PEER's formula, the limit-state MAF for the structure and for a rigid block are calculated with the aid of the following expressions:

$$\lambda_{EDP}^{(s)} = \int_{IM^{(s)}} P(EDP^{(s)}|IM^{(s)}) \, |d\lambda_{IM^{(s)}}| \tag{14}$$

$$\lambda_{EDP}^{(b)} = \int_{IM^{(b)}} P(EDP^{(b)}|IM^{(b)}) \, |d\lambda_{IM^{(b)}}| \tag{15}$$

where $\lambda_{EDP}^{(s)}$, $\lambda_{EDP}^{(b)}$ is the mean annual frequency of the engineering demand parameter ($EDP^{(s)}$ or $EDP^{(b)}$) exceeding threshold level and $d\lambda_{IM}^{(s)}$, $d\lambda_{IM}^{(b)}$ is the slope of the seismic hazard curve. The limit-state MAFs are easily obtained convolving the site hazard curve, expressed as function of the IM, with the fragility curve obtained with respect to the EDP of interest. For the structure, the IM of interest is always available, e.g. spectral acceleration $S_a(T_1, 5\%)$, but for the block this information is available only at the ground floor. For assets located at a storey, the calculation of $d\lambda_{IM}^{(b)}$ has no meaning and thus their fragility should be calculated as function of $IM^{(s)}$ instead of $IM^{(b)}$:

$$\lambda_{EDP}^{(b)} = \int_{IM^{(s)}} P(EDP^{(b)}|IM^{(s)}) \, |d\lambda_{IM}| \tag{16}$$

Conditioning the block's fragility to $IM^{(s)}$, i.e. using Eq. 16 instead of Eq. 15, is also conceptually preferable since the MAF is directly calculated from the site's hazard. The superscript "s" has been dropped from $d\lambda_{IM^{(s)}}$, since $d\lambda_{IM}$ always refers to the site and thus the structure.

A simplified and more generic methodology for the seismic risk of structure's contents is possible if we apply the TPT, using the block's intensity measure $IM^{(b)}$ as an intermediate variable. This allows to expand Eq. 16 and obtain the MAF using the expression:

$$\lambda_{EDP}^{(b)} = \int_{IM^{(s)}} \int_{IM^{(b)}} P(EDP^{(b)}|IM^{(b)}) \, dP(IM^{(b)}|IM^{(s)}) \, |d\lambda_{IM}| \tag{17}$$

where $P(IM^{(b)}|IM^{(s)}) = P(EDP^{(s)}|IM^{(s)})$ is the building's fragility curve. Eq. 17 can be used in order to calculate separately the fragilities using Eqs. 14 and 15, thus bypassing the need for performing building simulations and storing the response acceleration histories for the stories of interest. This approach has been examined by Fragiadakis and Diamantopoulos [5] and is not adopted in the current work.

4 MULTIPLE STRIPE ANALYSIS

The Multiple Stripe Analysis (MSA) method can be used for calculating the limit-state fragilities for both the structure and its contents. Multiple Stripe Analysis (MSA) method [26, 27] has conceptual similarities to the IDA method. In MSA instead of scaling separately all ground motions, every record is scaled to the same IM level. IDA involves subjecting the structure, or the block, to a suite of ground motion records, each scaled to multiple levels of intensity. After incrementally scaling every ground motion, single record capacity curves are produced in terms of demand versus seismic intensity [5].

Since for every scaling level the ground motions have the same IM value, the EDP values form a "stripe" which allows to directly calculate the median (50% percentile) and the 16% and 84% percentile capacity curves conditional on the IM. In IDA the scaling factors will be different, but stripped data can be easily obtained with interpolation. Below we first discuss how the MSA method is applied for the cascading problem at hand. We first examine the structure and in the subsection that follows we discuss how the fragilities of the freestanding contents are obtained from the floor response histories.

The four-storey RC building (Fig. 3), that adopted in Fragiadakis and Diamantopoulos [5], is also considered here. For the building every MSA curve can be plotted in the EDP-IM plane. The median curve (50% percentile) provides an estimate of the expected value and the fractile curves can be used to measure the dispersion as it is discussed in Vamvatsikos and Fragiadakis[28]. The MSA capacity curves plot the $S_a(T, 5\%)$ vs the $EDP^{(s)}$ [5]. In the most common form of MSA $EDP^{(s)}$ is the maximum interstorey drift ratio. However, a different EDP has to be adopted for studying building contents. The $EDP^{(s)}$ is either the normalised peak floor acceleration (PFA), or the peak floor velocity (PFV). Summarizing the data to EDP-IM plots [5] allow to directly calculate $P(EDP_j^{(s)}|NC)$ and P_C (Eq. 11) for every IM stripe. If the $EDP_j^{(s)}$ values are lognormally distributed, the buildings fragility for the j^{th} storey is calculated as follows:

$$P(EDP^{(s)} \geq edp^{(s)}) = 1 - P(EDP^{(s)} < edp^{(s)}) = \Phi\left(\frac{\mu_{logEDP} - edp^{(s)}}{\sigma_{logEDP}}\right) \tag{18}$$

where μ_{logEDP} and σ_{logEDP} are the mean and the standard deviation of the logarithm of the demand, always conditional on the $IM^{(s)}$. Regardless the IM, the fragility of the building should be obtained combing Eq. 18 with Eq. 11:

$$F_R^{(s)} = \Phi\left(\frac{\mu_{logEDP} - edp^{(s)}}{\sigma_{logEDP}}\right)(1 - P_C) + P_C \tag{19}$$

where P_C is the percentage of collapsed simulations. Obviously different fragilities will be obtained depending on the EDP of interest.

A very efficient alternative for calculating the fragilities using MSA, is to fit the CDF (cumulative distribution function) of a lognormal distribution on the striped EDP-IM data as discussed by Baker [27]. The fragility function can be simply seen as the lognormal CDF:

$$F_R^{(s)} = P(EDP^{(s)} \geq edp) = \Phi\left(\frac{log(EDP^{(s)}/\theta_a)}{\beta_a}\right) \tag{20}$$

where θ_a and β_a are the parameters that we need to determine. θ_a is the "median" of the fragility function, i.e. the IM value corresponding to limit-state probability equal to 0.5 and β_a is the

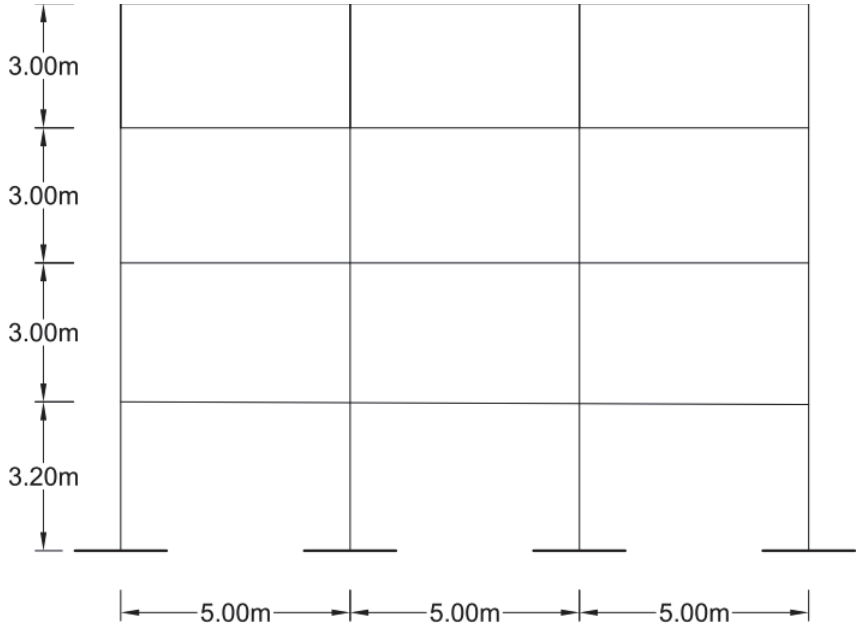

Figure 3: Four storey RC building.

dispersion (standard deviation of $\log(IM)$). The values of θ_a and β_a are obtained from the whole data using a Maximum Likelihood Estimation (MLE) approach [27] that is briefly summarized in the lines below. Eq. 20 should not be confused with Eq. 19; the latter concerns a single stripe and thus provides a single point of the fragility curve, while the former is the lognormal CDF that represents the whole fragility curve.

MSA provides at discrete IM levels (stripes), the number of successes n_{suc}, i.e. the number of simulations that the limit-state has been exceeded after n_{tot} simulations. Using the binomial distribution on the data of a single stripe, the probability of having exactly n_{suc} successes after n_{tot} simulations, will be:

$$P(Success = n_{suc}) = \left(\begin{array}{c} n_{tot} \\ n_{suc} \end{array} \right) P(EDP^{(s)})^{n_{suc}} (1 - P(EDP^{(s)}))^{n_{tot} - n_{suc}} \tag{21}$$

If there are k stripes, substituting Eq. 20 to Eq. 21, we obtain the MLE function as:

$$\mathcal{L} = \prod_{i=1}^{k} \left(\begin{array}{c} n_{tot,i} \\ n_{suc,i} \end{array} \right) \Phi \left(\frac{log(EDP^{(s)}/\theta_a)}{\beta_a} \right)^{n_{suc,i}} \left(1 - \Phi \frac{log(EDP^{(s)}/\theta_a)}{\beta_a} \right)^{n_{tot,i} - n_{suc,i}} \tag{22}$$

The only unknowns are θ_a and β_a which are found as the values that maximise the likelihood function $\mathcal{L}$ of Eq. 21, or preferably its natural logarithm. This can be achieved easily with a spreadsheet or with a simple computer script. The MLE approach uses the whole EDP-IM data of the stripe and thus it is not necessary to separate them according to Eq. 12. This approach produces always smooth fragility curves.

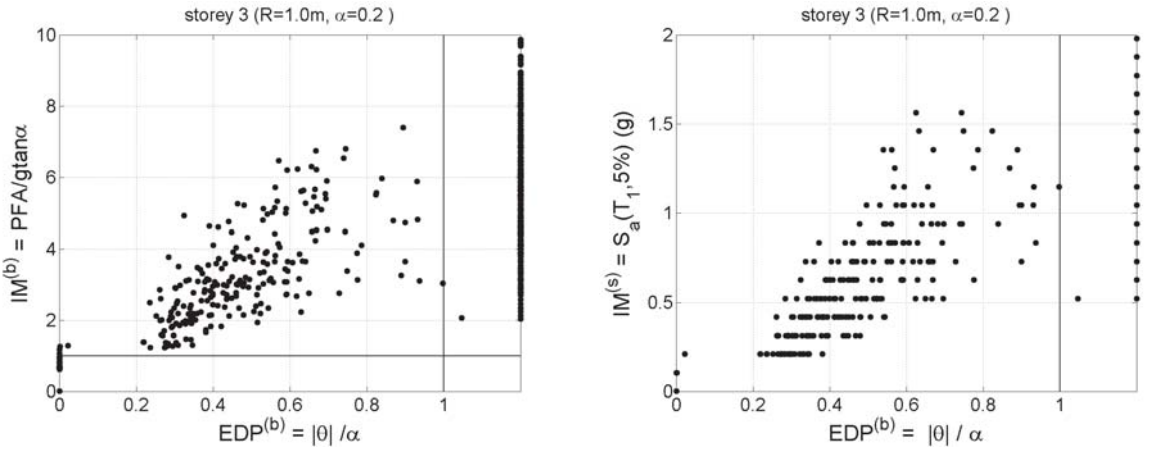
Figure 4 shows the EDP-IM plots of a freestanding block with $R = 1.0m$ and $\alpha = 0.2$. The hosting structure was subjected to the MSA simulations as it has been discussed in Fragiadakis and Diamantopoulos [5] and then the simulations are transferred to the $EDP^{(b)} - IM^{(b)}$ (Fig. 4a), or the $EDP^{(b)} - IM^{(s)}$ plane (Fig. 4b). In both plots the collapsed simulations appear as dots just right to the vertical line at $EDP^{(b)} = 1$. The dots below the horizontal line at

$IM^{(b)} = 1$ (Fig. 4a) correspond to the no rocking simulations. As already discussed in Section 3.1, the $EDP^{(b)} - IM^{(b)}$ is the natural EDP-IM representation, but is not the easiest choice when it comes to the calculation of MAF $\lambda_{EDP}^{(b)}$. Moreover, as shown in Figure 4a, the data in the $EDP^{(b)} - IM^{(b)}$ form a cloud, while if they are plotted in the $EDP^{(b)} - IM^{(s)}$ plane they are already conditional on the $IM^{(s)}$.

Both EDP-IM representations allow to calculate the fragility of the blocks, but with respect to a different IM. Defining the fragility conditional on the IM of the structure, i.e. $F_R^{(b)} = P(EDP^{(b)}|IM^{(s)})$ can be used for directly calculating the MAF using Eq. 16. On the other hand, the intuitive definition $F_R^{(b)} = P(EDP^{(b)}|IM^{(b)})$ provides the storey fragilities with respect to the block's IM and for the storey of interest. Another major difference is that when $IM^{(b)}$ is adopted, the EDP-IM data appear as a "cloud" (Fig. 4a), while when $IM^{(s)}$ is adopted instead, they appear in stripes (Fig. 4b). The MSA method can be directly applied to the striped data, while the cloud data require a different post-processing in order to derive the fragility curve. In the case of Figure 4b, the data form stripes and hence they can be post processed as was already shown for the building:

$$F_R^{(b)} = \Phi\left(\frac{\mu_{logEDPb} - edp^{(b)}}{\sigma_{logEDPb}}\right)(1 - P_{Ovtn} - P_{NoRock}) + P_{Ovtn} \tag{23}$$

Since the $F_R^{(b)}$ is calculated at every stripe P_{NoRock}, P_{Ovtn} are simply obtained as the percentage of simulations where no-rocking and overturning was observed, respectively. The fitting of Eqs.20-22 is also very efficient in the case of the freestanding contents. If the data are not stripped, as in Figure 4a, the cloud analysis method, discussed in the next section, should be used instead.



(a) (b)

Figure 4: Seismic response of a freestanding building content with $R = 1.0m$ and $\alpha = 0.2$: (a) plotting $EDP^{(b)} - IM^{(b)}$ results to cloud data, (b) plotting $EDP^{(b)} - IM^{(s)}$ results to data in stripes.

Cloud analysis is a common method when the data are scattered in the EDP-IM plane (e.g. Fig. 4a). This occurs when the ground motions are left unscaled, or when they have all been scaled with the same factor. In cloud analysis a least-squares straight line is usually fitted on the $log(EDP^{(b)})$ - $log(IM^{(b)})$ data [5]. The linear fit provides the mean of the logarithms (μ_{logEDP}) and a single constant value for the dispersion σ_{logEDP}. Knowing μ_{logEDP} and σ_{logEDP}, it is

possible to calculate the fragility of the rocking simulations using Eq. 23. This requires the knowledge of the no-rocking P_{NoRock} and overturning P_{Ovtn} probabilities over the whole IM range. These probabilities are calculated using a logistic regression model (logit) which yields a probability estimate that is function of the $IM^{(b)}$ [29]. Therefore, for the overturning case:

$$P_{Ovtn} = \frac{1}{1 + e^{-(b_1 + b_2 log(IM^{(b)}))}} \tag{24}$$

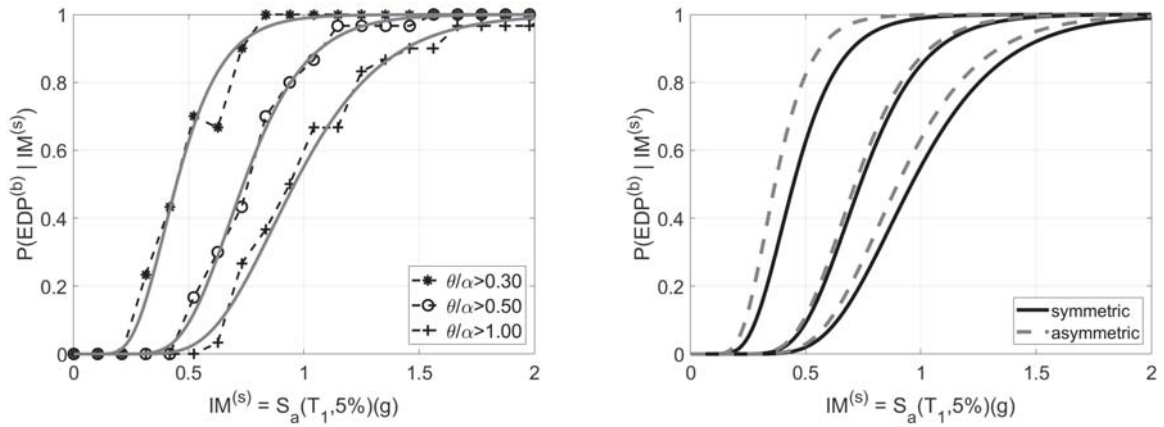
where the constants b_1, b_2 are the parameters of the logistic regression model, obtained with binomial-based, generalized linear model (GLM) regression.

The fitting of Eqs.20-22 is a robust method also for cloud analysis. The fitting is possible assuming stripes with a single simulation. Thus, in Eq. 22, k is equal to the total number of simulations of the cloud and in Eq. 21, n_{suc} is either 0 or 1 and always $n_{tot} = 1$. Attention should be paid on applying the MLE formula on the complete set of simulations that consists of no-rocking, rocking and overturning simulations. The fragility curves produced by the rocking data will considerably differ from the curves of the full dataset giving unsafe results [5]. The problem can be amended applying the MLE fitting to the rocking data only and combining the resulting fragilities with the no-rocking and the overturning fragilities P_{NoRock} and P_{Ovtn} of the logistic regression model (Eq. 24). The combination is achieved with the total probability theorem (TPT) (Eq. 13) and, as shown in Fragiadakis and Diamantopoulos [5], it gives exactly the same curve with that obtained from all the data.

5 NUMERICAL INVESTIGATION

The case study building adopted is the four-storey RC building that has been discussed in detail by Fragiadakis and Diamantopoulos [5]. This planar building is considered as a simplification and is used as a case study. The building is subjected to a suite of thirty far-field ground motion records and the response time-histories are used as input for the response assessment of the contents. The work aims to shed light on the fragility and risk assessment of building contents that are hosted in different stories of a structure and are considered as symmetric or asymmetric. The asymmetry of a rocking block leads to different equation of motion and the energy dissipation depends on the pivot point. Also, it has been shown in Vlachos *et al.* [21] that the sign of the ground motion also affects the response.

Considering the fragility and risk assessment two blocks, a symmetric and an asymmetric, are assumed. The symmetric block has slenderness angle $\alpha = 0.20$ and size parameter $R = 1.0m$ and the asymmetric slenderness angles $\alpha_1 = 0.212$, $\alpha_2 = 0.182$ and size parameters $R_1 = 1.003m$, $R_2 = 0.997m$. Three limit-states are identified for each block. The corresponding $EDP^{(b)} = \theta/\alpha$ threshold values are assumed as 0.3, 0.5 and 1, respectively. Figure 5a shows the fragility curves of a rectangular block on the 2^{nd} storey of the RC building considered and Figure 5b compares the fragility curves of the symmetric and the asymmetric block in each limit-state. The curves were produced with respect to $IM^{(s)} = S_a(T_1, 5\%)$, a practice that allows convolving the fragility curve with the hazard curve in order to obtain the mean annual frequency (MAF) (Eq. 16). As shown in Figure 5, both chainsaw-like and smooth fragilities can be obtained depending on the post-processing method. Both curve types are acceptable, although intuitively the reader will be more comfortable with the smooth curves offered by the MLE fitting of Eq. 20. The smooth fragility curves are shown in rest of the manuscript. Figure 6 shows the block overturning fragilities using PFA as the intensity measure $IM^{(b)}$ of the block. The solid lines refer to the block subjected to the storey response time-history and assuming that the structure's collapse means overturning of the blocks, while the dashed



(a) (b)

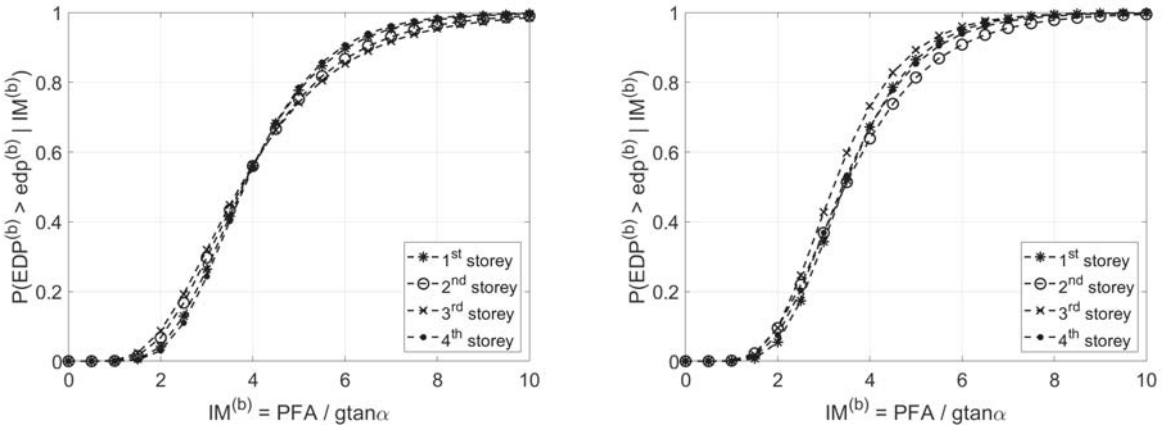
Figure 6: Overturning fragility curves of a slender block assuming it as symmetric or asymmetric: (a) the block is considered at the 1^{st} storey of the structure, (b) the block is considered at the 4^{th} storey of the structure.

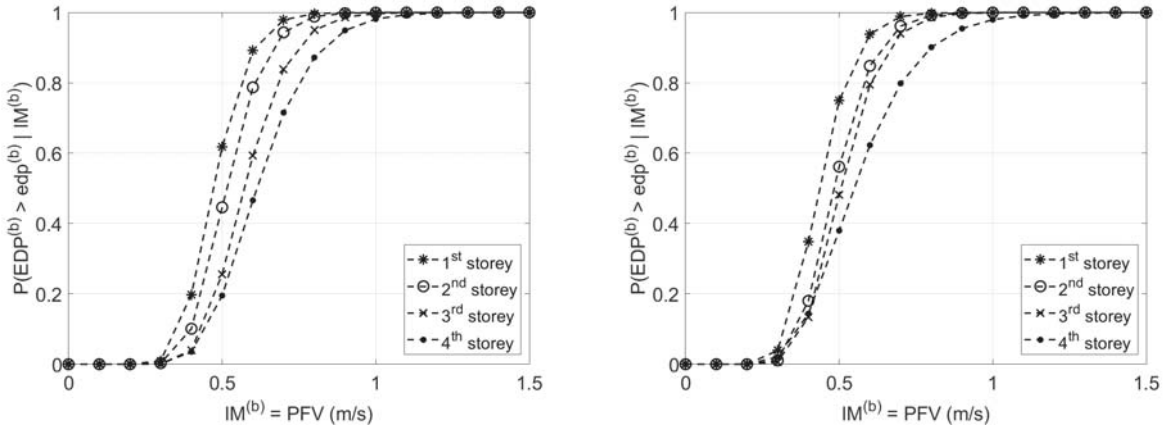
lines were obtained omitting the structure's collapse. Also, the dark lines correspond to the symmetric block and the grey to the asymmetric. As expected, the asymmetric block is always more vulnerable, while the building affects the fragilities especially when the block is hosted in the lower storeys of the building (Fig. 6a vs Fig. 6b). Figure 7 presents for all stories of the structure the block overturning fragilities assuming $IM^{(b)} = PFA/gtan\alpha$. For both blocks, the storey fragilities practically coincide. In principle, the fragility curves should coincide since they provide a property of the system that should not be sensitive to the ground motion set. However, due to the substantially different frequency content of the ground motions this in not always the rule. Of interest is also to show the fragilities obtained using as $IM^{(b)}$ the PFV instead of the PFA (Fig. 8). Adopting the PFV, the storey fragilities appear more dispersed compared to the $PFA/gtan\alpha$, which is more profound for the symmetric block. It is noted that the value of $tan\alpha$ is obtained from the symmetric block. As a general conclusion, although qualitatively our conclusions are not affected by the $IM^{(b)}$, the fragility curves will differ and



(a) (b)

Figure 7: Storey overturning fragility curves: (a) slender symmetric block ($R = 1.0m, \alpha = 0.2$), (b) slender asymmetric block. The structure's collapse has been adopted in both cases.

their interpretation requires attention.



(a) (b)

Figure 8: Storey overturning fragility curves using PFV as the IM of the block: (a) slender symmetric block ($R = 1.0m, \alpha = 0.2$), (b) slender asymmetric block. The structure's collapse has been adopted in both cases.

In order to calculate the limit-state mean annual frequencies (MAF) of the block, we adopt the hazard curve that has been adopted in Fragiadakis and Diamantopoulos [5] and corresponds to a site in the island of Crete, Greece. As discussed in Section 3.2, the limit-state MAFs are "exactly" calculated with Eq. 16. Alternatively, the MAFs can be calculated with Eq. 17 finding separately the fragility of the block and of the structure. The calculation of Eq. 17 requires the derivative of the block's fragility, which essentially is the probability density function (PDF) for a number of discrete limit-states. This alternative has been discussed in Fragiadakis and Diamantopoulos [5] showing that the PFV leads to more stable solutions in comparison with the PFA. For the blocks considered, the MAFs of Eq. 16 are shown in Table 1 for the first and the fourth storey of the RC building considered. From the values of the MAFs it is obvious that a symmetric block is more stable than an asymmetric is all storeys of the structure. Especially, in the fourth storey the differences become important while the values of the MAFs in the first

storey are close comparing the symmetric and asymmetric case.

storey	$(\theta/\alpha \leq 0.3)$	$(\theta/\alpha \leq 0.5)$	$(\theta/\alpha \leq 1.0)$
$1^{st} symmetric$	1353 years	3427 years	5280 years
$1^{st} asymmetric$	1230 years	2838 years	4933 years
$4^{th} symmetric$	170 years	808 years	2478 years
$4^{th} asymmetric$	105 years	538 years	1226 years

Table 1: Limit-state MAFs obtained for a rocking block using the exact (Eq. 16) approach.

6 CONCLUSIONS

A fragility assessment framework for freestanding building contents has been discussed. The building contents were modelled as rigid, symmetric or asymmetric, blocks and it was assumed that they are hosted in a four-storey RC building [5]. It has been shown that the problem addressed is complicated since the response of the structure and the contents are coupled. The problem becomes more complicated when the contents are asymmetric because the response depends also on the sign of the record and the side of the asymmetry. The findings of the study have been obtained using a two-dimensional, four-storey building and two-dimensional simulations for the contents. Hence, the reults cannot be always generalized. Further research is required in order to fully understand the effect of the structure on the fragility of freestanding contents. In conclusion, the authors would like to mention that the work presented should be considered as an attempt to offer some first guidelines on how the rocking problem can be handled for freestanding objects that can be assumed asymmetric and are hosted in a building. Some of the major conclusions of the paper are briefly summarized as follows:

- An MSA-based (Multiple Stripe Analysis) fragility-assessment methodology, tailored to freestanding building contents, is presented. The vulnerability of the contents depends on their geometry and the dynamic characteristics of the structure. Moreover, the fragility of the blocks should not be calculated independently of the collapse, or damage, of the building.

- Depending on the post-processing of the results, cloud or multiple-stripe data are obtained. The proper post-processing in order to consistently handle rocking, non-rocking and overturned blocks should be considered; otherwise the fragilities will be underestimated.

- A symmetric and an asymmetric block have been considered, showing that the geometry of the block is critical. It is found that symmetric blocks are more safe because the asymmetry affects the response. Of course this observations refers to the four-storey structure considered, but it clearly shows the importance of both building and block properties and also the fact that the fragility of freestanding contents is very different from that of anchored contents that are expected to behave as elastically deforming structures.

Keywords: Parametric instability, Thin-walled column, Local buckling, FRP column

Abstract. *The parametric instability of pultrude fiber-reinforced polymer columns with a channel section under harmonic axial load is investigated in this paper. The three plates of channel section (web and two flanges) are modelled using von Kármán nonlinear plate theory. The Ritz method is used to discretize the continuous structure resulting in coupled nonlinear equations of motion, which are solved numerically. Bifurcation diagrams obtained by continuation methods and Floquet theory are used to obtain the transition curves between trivial and nontrivial solutions and to study the nonlinear oscillations of the column in the unstable regions.*

1 INTRODUCTION

The use of structural elements made of fiber reinforced polymers (FRP) has significantly increased in recent years. The increased interest lies in the advantages over traditional construction materials, such as high strength-to-weight ratio, corrosion resistance and the ease of transportation and erection. Structural elements with thin-walled and open sections are commonly found in metal structures and, more and more often, in structures designed with new materials such as FRP profiles and other composite materials. FRP structural shapes have shown to provide efficient and economical applications in buildings, bridge decks, retaining walls, airport facilities, storage structures exposed to salts and chemicals, reinforcing members of casings or fuselages as, salt storage sheds, bridge superstructures, among others. Short thin-walled bars under compressive loads may fail due to a local instability buckling mode with the critical load controlling their design [1, 2]. Under dynamic loads the column may buckle due to parametric instability at load levels much lower than the static critical load and exhibit a complex nonlinear behavior. Parametric resonances are often encountered in mechanics (e.g., dynamic buckling of columns, plates and shells, water waves in vertically forced containers, stability of general motions) and in various areas of physics. However, little is known on their behavior and stability under dynamic loads. In the present work a short column with a channel cross-section under harmonic forcing is analyzed. The channel section is discretized as three thin-walled plates described by the von Kármán nonlinear plate theory and appropriate continuity conditions are prescribed at the web-flange intersections [3]. A consistent modal solution is used together with the Ritz method to obtain the coupled nonlinear equation of motions, which are solved by the Runge-Kutta method and bifurcation diagrams are obtained by the brute-force method and continuation techniques. A parametric analysis, considering different materials, shows the influence of the column length, section geometric dimensions and elastic constants of the material on the parametric instability boundaries in the force control space and bifurcation scenario of the structure.

2 PROBLEM FORMULATION

The present work considers a thin-walled column of length L having a channel cross-section with web width b_w, web thickness t_w, flange width b_f and flange thickness t_f, as illustrated in Fig. 1(a). Since many commercially-available pultruded shapes have constant thickness, it is hereafter assumed that $t_w = t_f = h$. For the local buckling analysis, the flanges and web are modelled using the von Kármán nonlinear plate theory [4].

The displacement field is given by,

$$\bar{u} = u + z\beta_x; \quad \bar{v} = v + z\beta_y; \quad \bar{w} = w; \quad \beta_x = -w_{,x}; \quad \beta_y = -w_{,y} \tag{1}$$

where $\bar{u}$ and $\bar{v}$ are the in-plane displacement components in the x and y directions, respectively, $\bar{w}$ is the transversal displacement in the z direction of an arbitrary point (x, y, z) of the plate, u, v and w are the corresponding displacements at a point $(x, y, z = 0)$ situated in the middle surface of the plate (see Fig. 1(b)) and β_x and β_y are the rotations around the x and y axes, respectively.

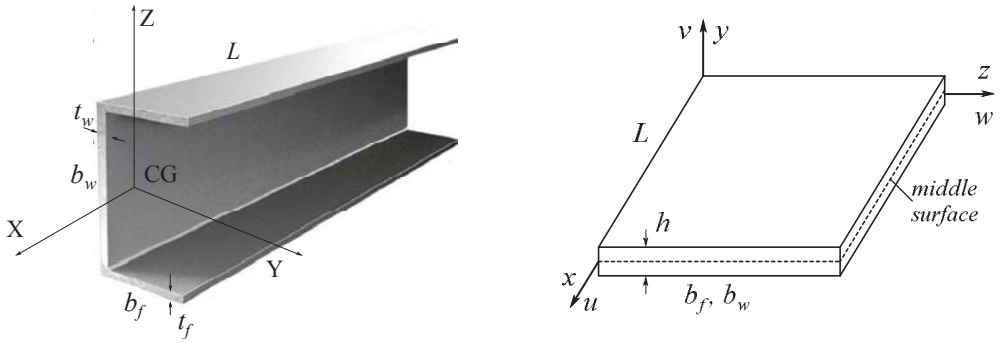

Figure 1: (a) C-profile geometry and global coordinate system. (b) Plate element (web and flange), local coordinate system and displacement field (the global and local *x* axes have the same direction).

The strain–displacement relations and changes of curvature of the middle-surface are given by:

$$\begin{gathered}\varepsilon_x = u_{,x} + \frac{1}{2}w_{,x}^2;\ \varepsilon_y = v_{,y} + \frac{1}{2}w_{,y}^2; \\ \gamma_{xy} = \left(u_{,y} + v_{,x} + w_{,x}w_{,y}\right);\ k_x = \beta_{x,x}; \\ k_x = \beta_{y,y};\ k_{xy} = (\beta_{x,y} + \beta_{y,x})/2\end{gathered} \tag{2}$$

Considering the constitutive equations of a typical orthotropic elastic material obeying Hooke's law, with the principal directions coinciding with the direction of the fibers and its transversal direction in the *x*-*y* plane, and the strain-displacement relations, the expression relating internal forces and moments to the strains of the FRP profile can be written as [5]:

$$\begin{Bmatrix} N_x \\ N_y \\ N_{xy} \\ M_x \\ M_y \\ M_{xy} \end{Bmatrix} = \begin{bmatrix} A_{11} & A_{12} & 0 & 0 & 0 & 0 \\ A_{12} & A_{22} & 0 & 0 & 0 & 0 \\ 0 & 0 & A_{66} & 0 & 0 & 0 \\ 0 & 0 & 0 & D_{11} & D_{12} & 0 \\ 0 & 0 & 0 & D_{12} & D_{22} & 0 \\ 0 & 0 & 0 & 0 & 0 & D_{66} \end{bmatrix} \begin{Bmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \\ \kappa_x \\ \kappa_y \\ \kappa_{xy} \end{Bmatrix} \tag{3}$$

where N_x, N_y and N_{xy} are the normal and shear in-plane stress resultants per unit length, M_x, M_y and M_{xy} are the flexural and torsional moment resultants per unit length, as illustrated in Fig. 2, and:

$$A_{ij} = \int_{-\frac{h}{2}}^{\frac{h}{2}} Q_{ij}\, dz; \qquad D_{ij} = \int_{-\frac{h}{2}}^{\frac{h}{2}} Q_{ij}\, z^2\, dz \quad (i,j = 1,2,6) \tag{4}$$

where

$$\begin{gathered}Q_{11} = \frac{E_{11}}{(1-v_{12}v_{21})}; \\ Q_{22} = \frac{E_{22}}{(1-v_{12}v_{21})}; \\ Q_{12} = \frac{v_{21}E_{11}}{(1-v_{12}v_{21})};\ Q_{66} = G_{12}\end{gathered} \tag{5}$$

The x direction coincides with the main direction of the material parallel to the fibers, direction 1, the y direction coincides with the main direction of the material perpendicular to the fibers, direction 2, and the z direction coincides with the direction perpendicular to the thickness.

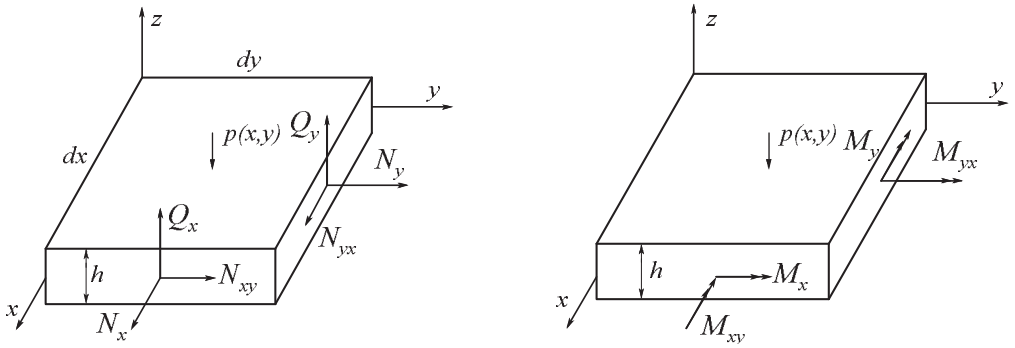

Figure 2: Plate element and internal force resultants per unit length in the local coordinate system (positive directions [6]).

The strain energy, U, is given by [4-6]:

$$U = \frac{1}{2}\iint \left(A_{11}\varepsilon_x^2 + 2A_{12}\varepsilon_x\varepsilon_y + A_{22}\varepsilon_y^2 + A_{66}\gamma_{xy}^2\right) dx\, dy + \frac{1}{2}\iint \left(D_{11}\kappa_x^2 + 2D_{12}\kappa_x\kappa_y + D_{22}\kappa_y^2 + D_{66}\kappa_{xy}^2\right) dx\, dy \tag{6}$$

For the axially compressed plate the potential energy of the applied loads is given by:

$$\Omega = -\frac{\bar{N}_x}{2}\int_0^b \int_0^L w_{,x}^2 dxdy \tag{7}$$

where $\bar{N}_x$ is the applied axial load per unit length at $x = 0$ and $x = L$.

The kinetic energy T of the plate, considering only the transversal inertia, is:

$$T = \frac{\rho h}{2}\int\int \dot{w}^2\, dxdy \tag{8}$$

where $\left(\dot{}\right)$ denotes the derivative with respect to time and ρ is the density of the material.

The Lagrangian of the three plates of the C profile is given by:

$$L = \sum_{i=1}^{3} T_i - \mathrm{U}_i - \Omega_i \tag{9}$$

To use the Ritz method, appropriate shape functions taking into account the boundary and continuity conditions for the displacements need to be prescribed. The following expressions are adopted for the web:

$$\begin{aligned} (x,y,t) &= U(t)sin\left(2\frac{m\pi x}{L}\right)cos\left(2\frac{\pi y}{b_w}\right); \\ v(x,y,t) &= V(t)cos\left(2\frac{m\pi x}{L}\right)sin\left(2\frac{\pi y}{b_w}\right) \\ w(x,y,t) &= W(t)sin\left(\frac{m\pi x}{L}\right)sin\left(\frac{\pi y}{b_w}\right) \end{aligned} \tag{10}$$

where $U(t)$, $V(t)$, $W(t)$, $X(t)$ and $Y(t)$ are the time dependent modal amplitudes and m is the number of axial half-waves. By imposing the compatibility conditions along the web-flange connection the displacements for the flange are given by (connection at $y = 0$)

$$u(x,y,t) = U(t)sin\left(2\frac{m\pi x}{L}\right)\left[1-\left(\frac{y}{b_w}\right)^2\right];$$
$$v(x,y,t) = V(t)cos\left(2\frac{m\pi x}{L}\right)\frac{y}{b_w} + y^3 \quad (11)$$
$$w(x,y,t) = W(t)sin\left(\frac{m\pi x}{L}\right)\frac{\pi y}{b_w}$$

They satisfy the simply-supported boundary conditions at $x = 0$ and $x = L$ and the continuity conditions along the web-flange interface.

3 RESULTS

In the present numerical analysis, a thin-walled column of length L having a channel cross-section with web width $b_w = 200\text{mm}$, flange width $b_f = 100\text{mm}$ and uniform thickness $t_w = t_f = 5\text{mm}$ is considered. As a reference an isotropic material (ISO) with Young's modulus $E_1 = E_2 = 28\text{kN/mm}^2$, in-plane shear modulus $G_{12} = 11.38\text{kN/mm}^2$ and Poisson ratio $v_{12} = v_{21} = 0.23$ is assumed. A FRP profile´s with Young's modulus in the longitudinal direction $E_1 = 28\text{kN/mm}^2$, Young's modulus in transverse direction $E_2 = 19.3\text{kN/mm}^2$, in-plane shear modulus $G_{12} = 2.6\text{kN/mm}^2$, major Poisson's ratio $v_{12} = 0.23$ and minor Poisson's ratio $v_{21} = 0.1585$, based on catalog values, is adopted. For the mass density is equal to $\rho = 1850\text{kg/m}^3$ and the viscous damping ratio is $\xi = 1.45\%$. Similar to a plate [6], the channel profile buckle with m half-waves in the longitudinal direction, with m increasing with L. For each value of m, the load reaches a minimum value which is usually taken as the critical load of the structure [6]. The minimum static critical load for the isotropic material is 239.3kN/m, while for the pultruded column it is equal to 115.5kN/m, a decrease of 52% in the load capacity. Also, the fundamental frequency is highly dependent on the material constants decreasing from 1982rad/s to 1255rad/s. This affects the parametric instability boundaries in the forcing frequency versus forcing magnitude plane, as illustrated in Fig. 3, decreasing the parametric instability transition boundary and moving the resonant regions to the lower frequency range. These boundaries are obtained by solving the nonlinear equation of motion of the damped system by continuation techniques in conjunction with Floquet theory for a large number of forcing frequencies [7] and by increasing slowly the forcing magnitude while holding the frequency constant. The dashed horizontal black lines correspond to the static critical load. Again, there is a palpable decrease in the dynamic critical load compared with the isotropic material. The principal parametric resonance region occurs in the neighborhood of $\Omega_f = 2\omega_o$, while second instability region to the left corresponds to $\Omega_f = \omega_o$, and is referred to as fundamental resonance region. These two regions are the most significant in structural dynamics, since in these two regions the critical dynamic buckling load can be considerably lower than the static buckling load. These results evidence the dangerous consequences of parametric instability in lightly damped structural systems.

Figure 4 compare the nonlinear frequency-amplitude relations of the two materials. They are obtained by the shooting method starting at $2\omega_o$ [8]. Here ω_{nl} is the amplitude-dependent nonlinear frequency. Both structures exhibit a hardening behavior with the FRP column exhibiting a higher degree of nonlinearity. This influences the bifurcations connected with each tongue in the force control space. The principal parametric resonance region is bounded on the left by a supercritical period-doubling bifurcation, as illustrated for the bifurcation diagrams of the two materials for $\Omega_f = 2\omega_o$ in Fig. 5(a), and on the right by a subcritical period-doubling bifurcation, while fundamental resonance region is bounded on the left by a supercritical pitchfork bifurcation and on the right by a subcritical pitchfork bifurcation.

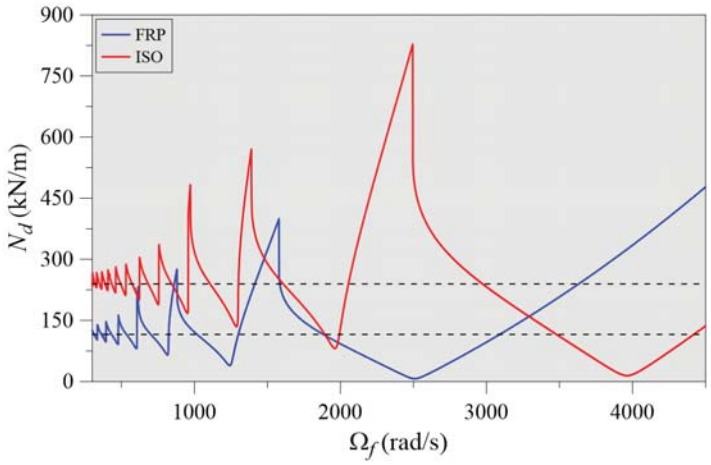

Figure 3: Parametric instability boundaries of the isotropic and pultrude profiles in the force control space.

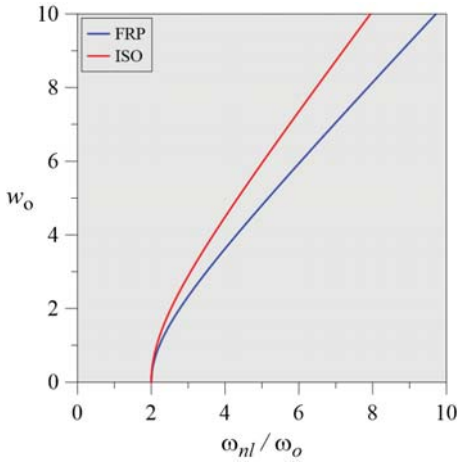

Figure 4: Nonlinear frequency-amplitude relation.

The effect of a static pre-load is to decrease the fundamental frequency and the dynamic buckling mode. Additionally, it leads to an increasing number of bifurcations at low load levels, leading to various coexisting solutions. Figure 5(b) shows the bifurcation diagram obtained considering a static load level equal to 75% of the static critical load ($Q_s = N_s/N_{cr} = 0.75$, compare with Fig. 5(a)). For this static load level, Fig. 6(a) shows the basin of attraction, while Fig. 6(b) shows the associated four coexisting solutions for $\Omega_f = 2\omega_o$ and $Q_d = 0.76$ (the dots are the fixed points of the Poincaré map of each solution). There are two large amplitude period-one attractors and two medium amplitude period-two attractors, but most initial conditions converge to one of the two large amplitude attractors. Fig. 6(c) shows the Poincaré map of the chaotic attractor obtained for $\Omega_f = 2\omega_o$ and $Q_d = 1.50$.

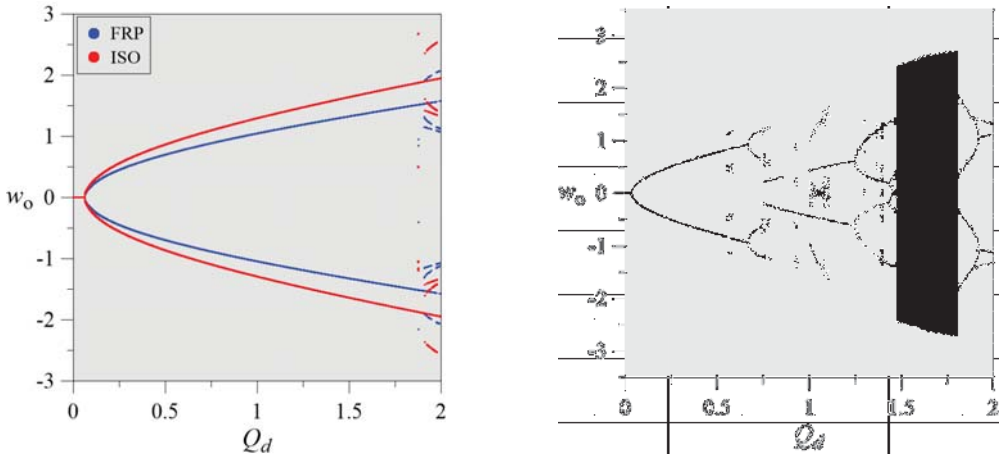

Figure 5: (a) Bifurcation diagram of the Poincaré map for the two material considering $\Omega_f = 2\omega_o$. $Q_d = N_d/N_{cr}$. (b) The effect of a static preload $Q_s = N_s/N_{cr} = 0.75$ on the bifurcation diagram of the FRP profile considering $\Omega_f = 2\omega_o$.

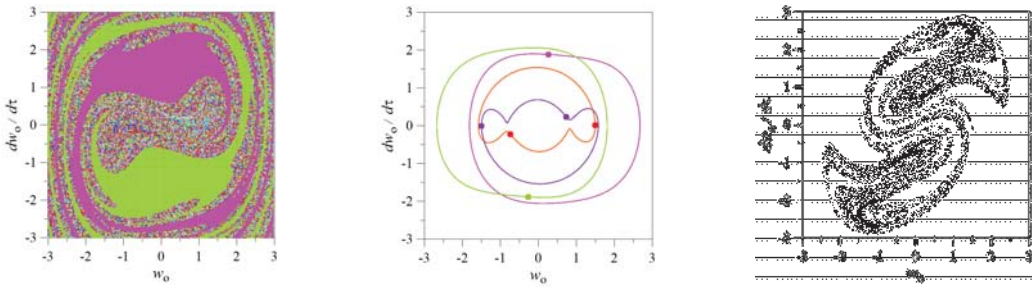

Figure 6: (a-b) Basin of attraction and associated attractors for $\Omega_f = 2\omega_o$ and $Q_d = 0.76$. (c) Poincaré map for $\Omega_f = 2\omega_o$ and $Q_d = 1.50$.

4 CONCLUSIONS

The results evidence that the static buckling loads, natural frequencies and parametric instability load are highly dependent on the orthotropy of the FRP material. There is a palpable decrease in static and dynamic the critical load and fundamental frequency when compared with the isotropic material. This decrease is due to the FRP low resistance in the transversal direction and low shear modulus. Within the parametric instability tongues, the nonlinearity leads to a qualitatively rich dynamics with several coexisting periodic and chaotic solutions, leading to basins of attraction with a complex topology. The parametric instability of the pultruded column is important because it causes the stable vertical equilibrium position to bifurcate into large-amplitude solutions and initiates a process that may lead the failure and the loss of load carrying capacity.

Keywords: geometrical imperfection, cylindrical panel, internal resonances.

Abstract. *This work evaluates the influence of initial geometric imperfections on a slender cylindrical panel nonlinear response, considering the three following cases of internal resonances: 1:1, 1:3 or 1:1:2. Nonlinear Donnell shallow shell theory is used to obtain the nonlinear equations of motion. Based on previous works, a consistent modal solution for the transverse displacement field is derived from a perturbation technique, considering the modal coupling and interaction in a simply supported cylindrical panel. Then, the standard Galerkin method is applied to reduce the problem to a system of differential equations in time domain. The backbone curves, resonance curves, phase-portraits and basin of attraction are obtained to evaluate the influence of the initial geometrical imperfection on the stability of transversally excited circular cylindrical panels. The numerical results indicate that the presence of an initial geometrical imperfection changes strongly the resonance curves, creating news stable paths and dynamic jumps and increases the nonlinearity and complexity of the panel response for each case of internal resonance, leading to fractal basins of attraction in the main resonance region.*

1 INTRODUCTION

Thin-walled cylindrical panels are used in several engineering areas, with emphasis in naval, aeronautical and civil engineering applications. They are circular sectors of cylindrical shells and are usually described by the shallow shell theory. Despite a simple geometry, the slenderness of this element makes it susceptible to loss of stability and excessive vibrations when subjected to static and dynamic loads, which can lead the structure to collapse. For these reasons, efforts should be employed to understand the nonlinear phenomena and instabilities of these structures. Among the non-linear phenomena, due to the geometric nonlinearities, strong modal coupling and interaction are inherent phenomena of slender shell structures. Another phenomenon is the modal interaction that occurs when different buckling or vibration modes have same critical load or some natural frequencies are commensurate (internal resonance) [1-3]. Therefore, this study aims to contribute to the understanding of the phenomena: modal coupling and modal interaction in simply supported cylindrical panels. To consider both phenomena, the transverse displacement field is deduced from a perturbation technique [4-6], leading a reduced order model that converges for vibration amplitudes up to the order of the thickness of the panel.

2 PROBLEM FORMULATION

Consider a simply supported cylindrical panel subjected to a time-dependent transversal load made by a linear, homogeneous and isotropic material. The transversal equation of motion and the compatibility equation, based on Donnell's non-linear shallow shell theory, are given in terms of the transversal displacement w and Airy stress function f respectively by:

$$\begin{aligned}\rho h\ddot{w}+2\eta_1\rho h\Omega_0\,\dot{w}+D(w_{,xxxx}+\frac{2}{R^2}w_{,\theta\theta xx}+\frac{1}{R^4}w_{x\theta\theta\theta})-f_{,\theta\theta}(w_{,x}+w_{0,x})_{,x}\\ +R\,f_{,xx}-f_{,xx}(w_{,\theta}+w_{0,\theta})_{,\theta}-2\,f_{x\theta}(w_{,\theta x}+w_{0,\theta x})-p(t)=0\end{aligned} \tag{1}$$

$$\frac{\nabla^4 f}{E\,h}=\frac{1}{R^4}\left(w_{,x\theta}{}^2-w_{,xx}w_{,\theta\theta}+R\,w_{,xx}+2\,w_{,x\theta}w_{0,x\theta}-w_{,xx}w_{0,\theta\theta}-w_{,\theta\theta}w_{0,xx}\right) \tag{2}$$

where D [$=Eh^3/12(1-\nu^2)$] is the flexural stiffness, R is the radius of curvature, h is the cylindrical panel thickness, ρ is the mass density, $p(t)$ is the transversal load distributed along the domain, η_1 is the viscous damping parameter, E is the Young's modulus, ν is the Poisson ratio and Ω_0 is the natural frequency of the perfect cylindrical panel.

The transversal harmonic pressure load, distributed along the domain, is given by:

$$p(t)=pl\sin(n\,r)\sin(m\,q)\cos(\Omega t) \tag{3}$$

where $r=\pi\theta/\Theta$, $q=\pi x/L$, pl is load magnitude, Ω is the excitation frequency, Θ is the angle width of the cylindrical panel and m and n are the number of axial and circumferential half-wave, respectively.

The initial geometrical imperfection is described by a pre-defined function w_0 in the shape of the fundamental vibration modes [6]:

$$w_{01}=C_1\sin(q)\sin(r) \tag{4}$$

where C_1 is the imperfection magnitude.

3 NUMERICAL RESULTS

Based on the analytical results of the vibration frequencies of a simply supported perfect panel, obtained by the use their classical vibration modes of a simply supported cylindrical panel [5, 6], three different geometries displaying different types of internal resonance are selected. Table 1 presents the basic geometric dimensions of the selected cylindrical panels that exhibits 1:1, 1:3 and 1:1:2 internal resonance as well as the natural frequencies and modes involved in the internal resonances. From Table 1, it is observed that small changes in the angle the panel's length or opening angle lead to different types of internal resonances.

Θ (rad)	L (m)	Internal resonance	Axial half-wave	Circumferential half-wave	Natural frequency (Hz)
0.1658	0.1	1:1	$m = 1$	$n = 1$	686.29
			$m = 1$	$n = 2$	686.29
0.0577	0.1	1:3	$m = 1$	$n = 1$	992.05
			$m = 3$	$n = 2$	2976.16
0.1658	0.091	1:1:2	$m = 1$	$n = 1$	741.88
			$m = 1$	$n = 2$	741.88
			$m = 2$	$n = 1$	1483.75

Table 1: Geometries of cylindrical panel with internal resonance and their natural frequencies and vibration modes (R = 1m, h = 0.001m, $E = 2.06\text{x}10^{11}$ N/m², ρ = 7800kg/m³ and $\nu = 0.3$).

For the nonlinear analysis, the transversal displacement field is obtained by applying the perturbation technique described in [2-6]. To start the perturbation procedure, it is necessary to consider a seed solution, which in this work is the sum of the linear vibration modes involved in the internal resonance (Table 1) [2-3, 6]. The perturbation procedure leads to a modal solution that considers naturally all modal coupling and interaction concerning these modes. However the obtained general modal solution is extremely long and for easy understanding only the considered modes are shown here.

The modal solution for the cylindrical panel with 1:1 internal resonance is given by:

$$\begin{aligned} w=&\left[A1_{11}(t)\,\sin(r)+A1_{13}(t)\,\sin(3r)+A2_{11}(t)\,\sin(2r)+A2_{13}(t)\,\sin(6r)\right]\sin(q)\\ &+\left\{A3_{22}(t)\left[3/4-\cos(2r)+1/4\cos(4r)\right]+A4_{22}(t)\left[3/4-\cos(4r)+1/4\cos(8r)\right]\right\}\\ &\left[3/4-\cos(2q)+1/4\cos(4q)\right] \end{aligned} \tag{5}$$

while for the cylindrical panel with 1:3 internal resonance the obtained modal solution is given by:

$$\begin{aligned} w=&\left[A1_{11}(t)\,\sin(q)+A1_{13}(t)\,\sin(3q)+A1_{15}(t)\,\sin(5q)+A1_{17}(t)\,\sin(7q)\right]\sin(r)\\ &+\left\{A1_{22}(t)\left[3/4-\cos(2q)+1/4\cos(4q)\right]+A2_{22}(t)\left[3/4-\cos(6q)+1/4\cos(12q)\right]\right\}\\ &\left[3/4-\cos(2r)+1/4\cos(4r)\right] \end{aligned} \tag{6}$$

and for the case with 1:1:2 internal resonance the considered modal solution is:

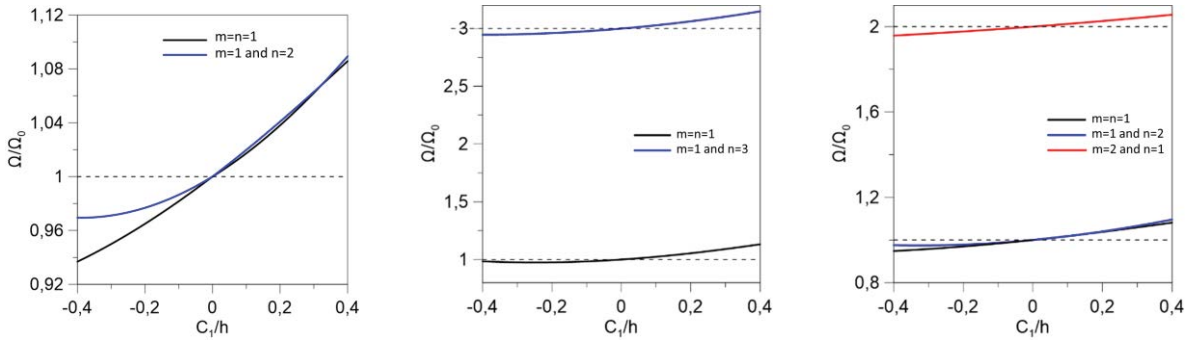
$$
\begin{aligned}
w=&\left[A1_{11}(t)\sin(r)+A2_{11}(t)\sin(2r)+A2_{13}(t)\sin(6r)+A3_{13}(t)\sin(3r)\right]\sin(q)+\\
&\left[A3_{11}(t)\,\sin(r)+A3_{13}(t)\,\sin(3r)\right]\sin(2q)+\left\{A4_{22}(t)\left[3/4-\cos(2r)+1/4\cos(4r)\right]\right.\\
&\left.+A5_{22}(t)\left[3/4-\cos(4r)+1/4\cos(8r)\right]\right\}\left[3/4-\cos(2q)+1/4\cos(4q)\right]\\
&+A6_{22}(t)\left[3/4-\cos(2r)+1/4\cos(4r)\right]\left[3/4-\cos(4q)+1/4\cos(8q)\right]
\end{aligned}
\tag{7}
$$

These modal solutions, Eqs. (6)-(7), ensure the convergence of the backbone and resonance curves up to vibration amplitudes of the same order as the shell thickness [6]. These expressions satisfy the following transversal boundary conditions:

$$
\begin{aligned}
&w(0,\theta)=w(L,\theta)=w(x,0)=w(x,\Theta)=0\\
&M_x(0,\theta)=M_x(L,\theta)=M_\theta(x,0)=M_\theta(x,\Theta)=0
\end{aligned}
\tag{8}
$$

To obtain the Airy stress function f, the modal expansion in Eq. (5-7), depending on the case, is substituted into Eq. (2), together with the geometrical imperfection, Eq. (4), and the compatibility equation is solved analytically. The obtained stress function and the chosen modal expansion are then substituted into equation of motion, Eq. (1), and discretized by using the standard Galerkin method.

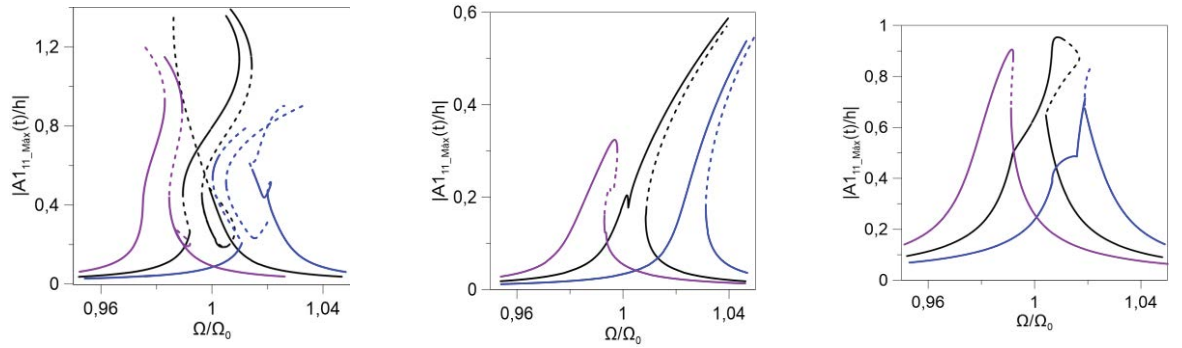
Figure 1 shows the variation of the natural frequency of imperfect cylindrical panel, normalized with respect the natural frequency of perfect cylindrical panel, with the magnitude of geometrical imperfection. It is observed from Fig. 1a that for negative values of C_1/h the natural frequency of both vibration modes diverge and the 1:1 internal resonance is destroyed. On the other hand, for positive values of C_1/h the 1:1 the two frequencies remain sufficiently close to ensure the 1:1 internal resonance. In the 1:3 and 1:1:2 internal resonances cases, the amplitude of the geometrical imperfection in the analyzed range maintain the natural frequencies remains nearly commensurate, so that the influence of the internal resonance is always observed.



(a) 1:1 internal resonance (b) 1:3 internal resonance (c) 1:1:2 internal resonance

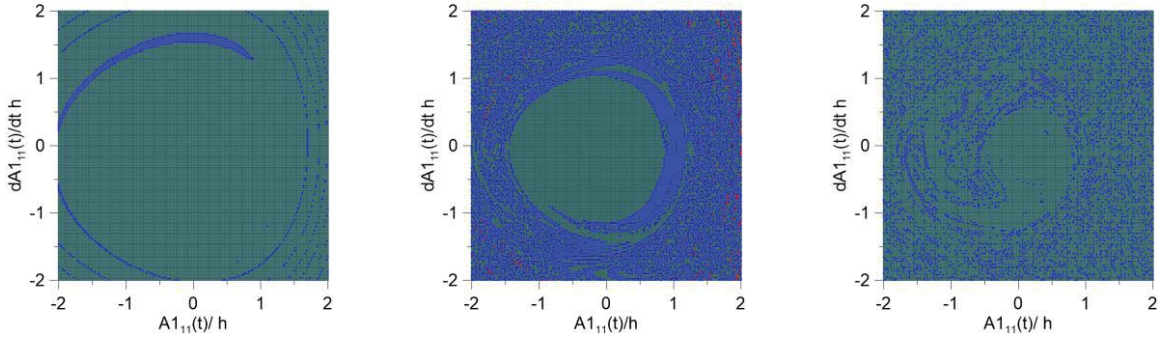
Figure 1: Variation of the normalized natural frequency with the amplitude of initial geometric imperfection for the different cases of internal resonance.

When an initial geometrical imperfection in the shape of fundamental vibration mode with amplitude C_1/h is considered, it is observed in Fig. 2 that the resonance curves are dependent of magnitude and sign of the geometric imperfection. For a positive value of imperfection (blue curve), the resonance curve moves to the right compared with the perfect case (black curve) due to the increase of the natural frequency of imperfect panel (see Fig. 1). On the other hand, for negative value of imperfection (purple curve) the resonance curve moves to the left due to the decreasing value of the natural frequency according with Fig 1.



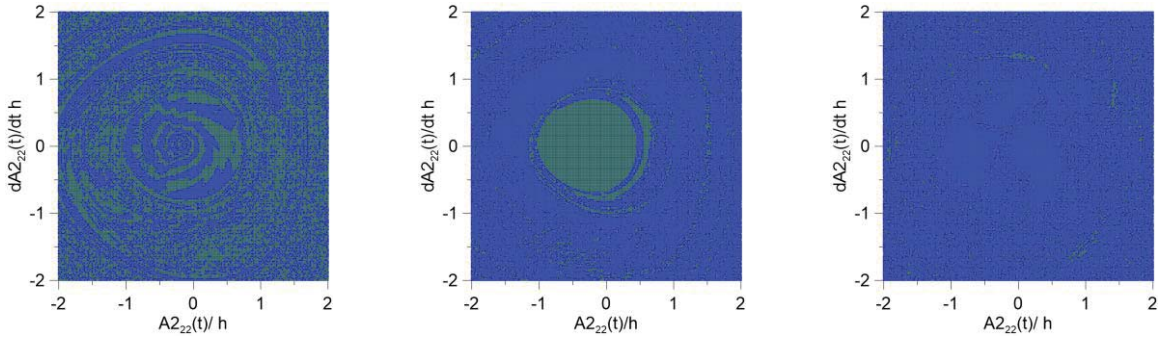
(a) 1:1 internal resonance (b) 1:3 internal resonance (c) 1:1:2 internal resonance

Figure 2: Resonance curves of perfect and imperfect panel – amplitude of driven mode and imperfection in the shape of driven mode. (pl = 0.5 kN/m²; η_1 = 0.001; —— C_1/h = -0.10; ---- C_1/h = 0.0; —— C_1/h = 0.10).



(a) C_1/h = -0.10 - Ω/Ω_0 = 0.98 (b) perfect panel - Ω/Ω_0 = 1.005 (c) C_1/h = 0.10 - Ω/Ω_0 = 1.005

Figure 3: Basin of attraction for 1:1 internal resonance case considering selected values of frequency of excitation. (pl = 0.5 kN/m²; η_1 = 0.001)



(a) C_1/h = -0.10 - Ω/Ω_0 = 0.98 (b) perfect panel - Ω/Ω_0 = 1.005 (c) C_1/h = 0.10 - Ω/Ω_0 = 1.021

Figure 4: Basin of attraction for 1:1:2 internal resonance case considering selected values of frequency of excitation. (pl = 0.5 kN/m²; η_1 = 0.001)

The presence of an initial geometrical imperfection changes strongly the resonance curves, creating news stable paths and dynamic jumps and increases the nonlinearity and complexity of the panel response for each evaluated internal resonance as illustrated by, for example, the basins of attraction given by Figs. 3 and 4 for the 1:1 and 1:1:2 internal resonance cases, respectively. The competition between the resonant and non-resonant attractors lead to large fractal regions and sensitivity to initial conditions. The presented basins of attractions in Figs.

3 and 4 agree with the resonance curves in Fig. 2 with respect the number of detected attractors for the chosen values of excitation frequency.

4 CONCLUDING REMARKS

A new consistent modal solution, that takes into account the modal interaction between two, or three, different vibration modes, previously developed by the authors, is applied in this work to investigate the influence of an initial geometrical imperfections on the resonance curves of a cylindrical panel displaying three distinct cases of internal resonance. It is verified in free vibration analysis that positive geometric imperfection in the form of the fundamental mode increases the stiffness of the cylindrical panel, and, consequently its natural frequencies, while negative imperfections causes a decrease in the natural frequencies involved in the internal resonance. The forced vibrations of the cylindrical panel with an initial geometrical imperfection in the shape of fundamental mode modifies the vibration amplitudes, the dynamic stability and bifurcation scenario of the resonance curves, leading to strong competition between the resonant and the non-resonant attractors which in its turn leads to highly intertwined fractal basins of attraction in the main region of resonance.

Abstract. *This work deals with the design, the mechanical modeling and the experimental testing of microscale lattice structures tessellating bistable tensegrity prisms. The analyzed units have only one internal mechanism and one self-stress state, and can be transformed into bistable structures, by replacing the cables with bars, and suitably adjusting the members' lengths. We experimentally validate the theoretical prediction of the response of spatial assemblies of such units, through mechanical tests on physical models fabricated by multiphoton lithography. We also numerically show that the examined structures support the propagation of compact compression waves under impact loading, which paves the way to their use for the fabrication of novel acoustic lenses with tensegrity architecture.*

1 INTRODUCTION

In the past several years, the advancement in additive manufacturing (AM), and especially in nano and micro scale printing, has taken a big leap, opening a new era for futuristic materials and material sciences. Research on metamaterials is one of the most focused area because of their unprecedent properties arising from the physical structure of the lattices. Generally, materials in their original and/or traditional form do not show better properties as compared to those shown by the same material but in a designed architected shape. Due to their particular architecture, which can confer them high strength to weight ratio, frequency bandgaps, negative overall moduli and negative mass density, they possess highly stable physical characters [**?**, **?**]. Success in producing metamaterials with extraordinary properties has been achieved at the macroscale level. However, due to their usually complex geometry, it is quite difficult to produce micro- and nanoscale metamaterials with AM techniques [**?**]. Tensegrity architectures represent some of the most complex forms, making them difficult to produce as well. Nevertheless, due to their nonlinear properties they are one of the most suitable candidates for morphing structures [**?**]. Tensegrities have originally been used for producing free-standing prestressed systems with cables in tension and bars in compression. In addition, since they exhibit various non-linear static and dynamic properties, arising from their connectivity, geometry and internal mechanisms, tensegrity systems have become more popular and subject of research [**?**]- [**?**]. Various stable configurations are possible only with change in stress levels and in the lengths of cables and bars. In this way it becomes possible to have bi-stable tensegrity structures, and some of the recent studies have found bi-stable tensegrities at macroscopic scale. This commendable property can be highly inspirational in producing reconfigurable metamaterials and structures based on tunable tensegrity structures [**?**]. One paradigmatic example presented by Calladine [**?**] can be examined to understand the behavior of tensegrity structures, this is shown in Figure **??**. In

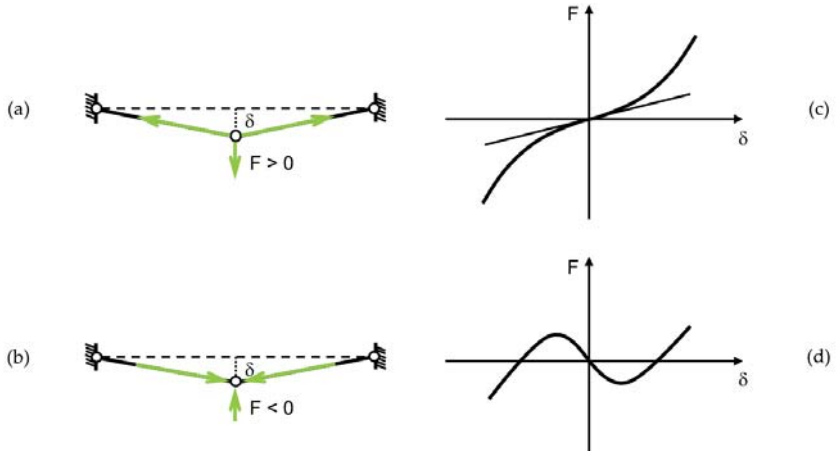

Figure 1: Behavior of the two-element system in various prestress states.

Figure **??** (a) two pre-stressed elements are hinged at three points placing the mechanism in equilibrium state when the pre-stress is positive (cables in tension). The same configuration can be turned into an unstable equilibrium one if the sign of the stress is changed as shown in the Figure **??** (b). The resulting nonlinear behaviour under load is related to the sign of pre-stress is as shown in Figure **??** (c, d). It has been observed that if the rest length of the elements is increased slightly with respect to the lengths in the equilibrium state, then system becomes

bi-stable by showing the two different stable configurations. It is worth noticing that, the AM of cables poses a challenge because present day technologies are not yet capable of manufacturing such elements, while the manufacturing of bars are feasible with various AM processess. One option to overcome this challenge is to manufacture corresponding lattice structures by keeping nodal positions the same, allowing for bending stresses to be present in the structure. Bending stresses can be mitigated by manufacturing the ends of the bars in a tapered way or by introducing flexible hinges. The limitation of this procedure is that hinges does not behave in a perfect manner. However, lattice structures obtained from tensegrity systems can still inherit some of their nonlinear properties, included the bistable behavior.

2 Materials and methods

2.1 Bi-stable configuration from monostable tensegrity structures

A method to obtain bi-stable system based on tensegrity systems can be devised by following the analogy with the system shown in Figure **??**. When the system has only one stable configuration, then it is termed as monostable and if it has two stable configurations, it is termed as bi-stable system. It is possible for such a system to have a stable self-stress state when the two elements are in tension, introducing first-order stiffness to internal mechanism. In a system consisting of two linearly elastic member, the load-displacement relationship can be approximated by a cubic-polyomial equation. In such a system, the slope of the curve in the origin is always directly proportional to the self-stressing forces. By changing the sign of the self-stress the system can be turned into an unstable one. In addition, when the elements are unstressed, the systems is placed in either one of two stable configurations. The load-displacement curve in this case is similar to that shown in Figure **??** (d). Two example in three dimensions are

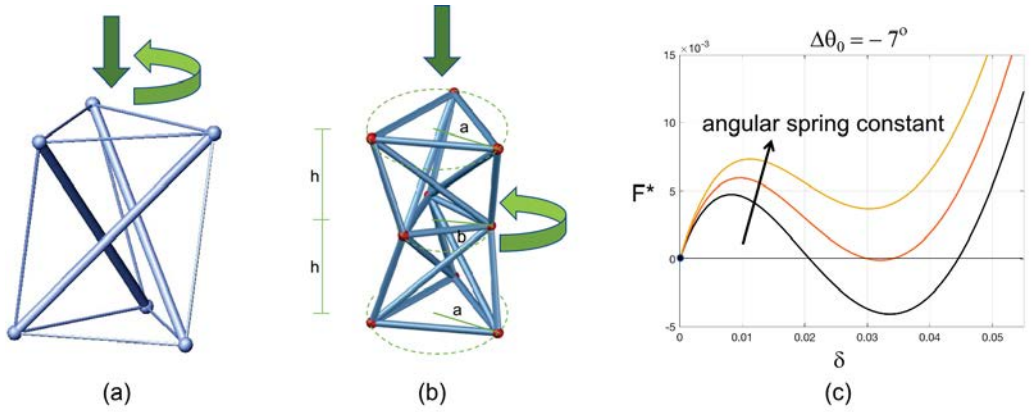

Figure 2: Tensegrity prism (a). Dual tensegrity prism (b). Examples of force-displacement diagrams for the dual tensegrity prism subjected to a vertical load (c). The three $F^* \, vs \, \delta$ curves correspond to increasing values of the angular spring constant k_s, with the black curve corresponding to $k_s = 0$, the orange (dark grey) curve corresponding to $k_s = 0.8 \mu N \mu m$, and the yellow (light grey) curve corresponding to $k_s = 1.6 \mu N \mu m$ (see the other model parameters in the text). The force parameter $F^* = F/(dk_a)$ is given by the applied vertical force F divided by the bars' diameter d and by an axial spring constant equal to $k_a = 99.07 \mu N/\mu m$, while the displacement parameter δ is the ratio between the vertical displacement and $2h$.

presented in Figure **??** (a) and (b). The first one is the classical-tensegrity triangular prism (See Figure **??** (a)), while the second one is a dual tensegrity prism, realized with bars only, obtained by superposition of two mirror copies of a same tensegrity prisms. When a verti-

cal load is applied to the tensegrity prims, it causes a roto-translation of the top triangle with respect to the bottom triangle (see green arrows in Figure **??**, a). When a vertical load is applied on the dual tensegrity prism, it causes a roto-translation of the middle triangle, and just a relative translation of the top triangle, with respect to the bottom one. Bi-stable structures can be obtained by following these steps: (i) a pre-stressed stable tensegrity structure should be found with one independent self-stress state and one internal mechanism, (ii) a slightly displaced, unstressed configuration of the same structure should be considered, (iii) a numerical model should be adopted to obtain bi-stable response under static loading, (iv) the geometry and material properties cab be adjusted according to the available fabrication methods and experimentation conditions, (v) fabricated structures should be subjected to the experimental tests in order to confirm the designed behaviour the model. To this purpose, a dual bistable lattice have been considered, as shown in Figure **??** (b), and corresponding force-displacement diagrams have been computed (see Figure **??** (c)). A Stick-and-Spring model has been adopted in such computation [**?**, **?**], where the elements of the structure are considered as axial springs, and angular springs responds to change in angles between certain pairs of adjacent bars. While the stable configuration of a tensegrity prism corresponds to a relative rotation between top and bottom triangles of $\theta_0 = 150$ degrees, in the dual tensegrity prism the initial relative rotation between bases in each prism is $\theta_0 = 150 + \Delta\theta_0$. The plots in Figure **??** (c) are obtained considering an elastic material of Young's modulus $E = 1.2GPa$ (typical of polymers used in multiphoton lithography), members' diameter $d = 0.75\mu m$, top and bottom base radius $a = 5\mu m$, middle base radius $b = 3.5\mu m$, prism height $h = 10\mu m$. The three $F^* \, vs \, \delta$ curves correspond to increasing values of the angular spring constant k_s, with the black curve corresponding to $k_s = 0$, the orange (dark grey) curve corresponding to $k_s = 0.8\mu N\mu m$, and the yellow (light grey) curve corresponding to $k_s = 1.6\mu N\mu m$. The force parameter $F^* = F/(dk_a)$ is given by the applied vertical force F divided by the bars' diameter d and by an axial spring constant equal to $k_a = 99.07\mu N/\mu m$ (obtained considering a nominal member length of $5.35\mu m$). The displacement parameter δ is the ratio between vertical displacement and $2h$.

2.2 Fabrication by multiphoton lithography (MPL) technology

The structure in Figures **??** (a), composed of three dual prisms, has been considered for fabrication. The specimen shown in Figures **??** (b) has been fabricated with the help of the multiphoton lithography (MPL) technology. The material used was obtained by mixing of several organic-inorganic constituents: Zr-DMAEMA consisting of 70 wt % zirconium propoxide, 10 wt% (2-dimethylaminoethyl) methacrylate (DMAEMA) (Sigma-Aldrich), and 20 wt% ASTM type II deionized, distilled water. First, 1.4 ml of 3-(trimethoxysilyl)propyl methacrylate (MAPTMS) (Sigma-Aldrich) were mixed with 0.14 gr of hydrochloric acid into a vial. Afterwards, 137.7 μl of DMAEMA were mixed with 0.66 ml of zirconium (IV) propoxide solution containing 70 wt% 1-propanol in another vial. Then the two mixtures have been added together and diluted with 0.2 ml of distilled water and 0.016 gr of photoinitiator consisting of 4,4-bis(diethylamino)benzophenone (Sigma-Aldrich). Fabrication was performed 24 hour after placing it on glass substrate in vacuum. Multi-level experimentation was performed to ensure the least experimental error. After preparation of samples as shown in Figure **??** (b), samples were subjected to the multiple tests by nano-indentation.

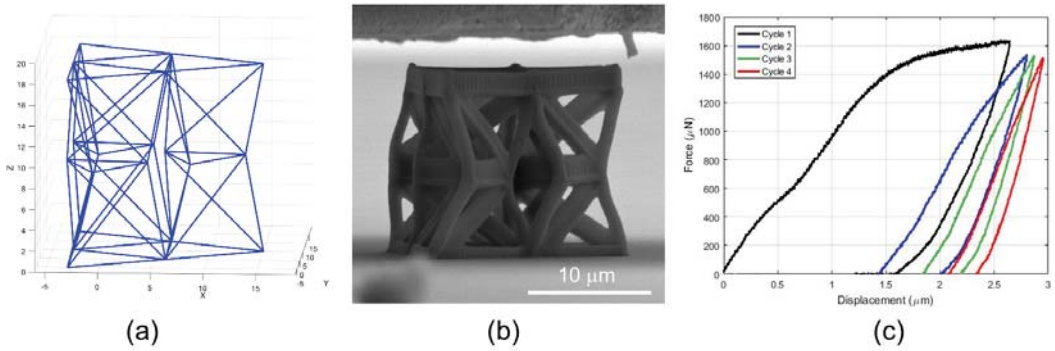

Figure 3: Model of fabricated structure (a). Sample fabricated by MPL and subjected to a compression test (b). Force-displacement curve for a cyclic loading-unloading compression test (c).

3 Compression test

After fabrication of the samples with the help of MPL, multi unit array compression tests were performed at the minuscule scale shown in Figure **??** (b) to analyze the behaviour of the fabricated samples in order to understand the major effects and experimental accuracy of MPL fabrication technology. The obtained force-displacement relationship are shown in Figure **??** (c). Twisting of the middle triangle during testing has been observed. In the force-displacement graph the softening behavior of the system has been seen and at the same time residual deformation has been seen after unloading. The elastic model developed earlier shows a behavior consistent with that depicted in Figure **??** (c). In addition, material behaves in slight viscoelastic manner when loading-unloading cycles were applied. An estimate of the critical damping factor that can be associated to our force-displacement curves in Fig. **??**(c) gives a damping ratio greater than 10% in the first cycle, reducing to few percents in the fourth cycle.

4 Wave dynamic applications

A major application of the nano lattice structures is in wave dynamics. The response of the bistable structure exhibiting the single soft mode can also be used in carrying mechanical energy through compact solitary waves. Figure **??** shows the design of a chain of tensegrity-based

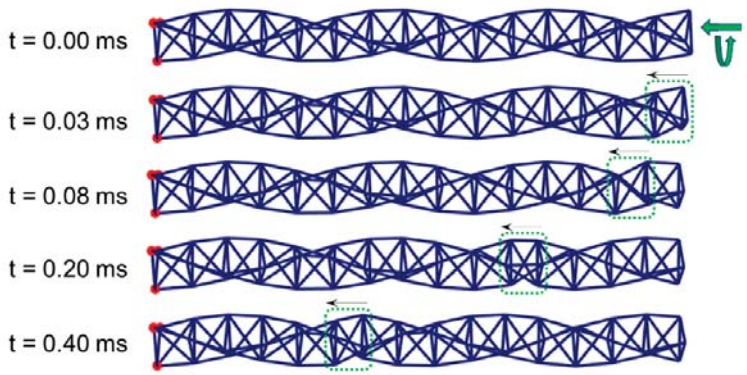

Figure 4: Various stages of motion of a column of fifteen bistable prisms.

units, fixed at the one end, which can be useful in wave dynamic applications and in the area of

non-linear mechancal metamaterials. The concept design of the bistable tensegrity architecture shown in Figure **??** can be very helpful to formulate the mechanical metamaterials. This design, which is fixed at one end and free at other end, can be tested for wave dynamic applications according to the procedure given in refs. [**?**,**?**], which shows that the design is capable of forming compression waves when impulsive load is applied at the free end. The Figure **??** shows the behavior of such system at discrete times, after being impacted with initial horizontal speed of v_0 and angular speed ω of the end triangle so that the bistable mechanism get activated. The dimensions of such system comprises of *a/h* = 0.5, $\Delta\theta_0$ = -3, $v_0(\mathrm{E}/\rho)^{0.5}$= 0.3609, $v_0/\omega_0 = a^2/h$, $k_s/(a^2 k_a)$= 0.0041, with a the circumscribed radius of the base triangle, h the height of a prism, E the Young's modulus, k_a and k_s the axial and angular spring constant respectively, and ρ denoting the mass density of the material. In this system localization of compression waves was observed at one unit in the chain, while almost no movement in rest of the system has been observed. This 'localized' behavior of such system can be highly useful in designing the revolutionary acoustic lenses, which can be used in non-invasive scalpel to accurately locate the defects in various biological or engineering materials. In addition, the highly non-linear structures can be used to generate compact solitary waves in tensegrity acoustic lenses. Further studies will be focused on the generation of such bistable unit cells.

5 Concluding remarks

In this research work the bistable mechanical response of microlattice structures with nanoscale features and tensegrity architecture has been studied. The MPL technology has been employed to additively manufacture physical models of the investigated structures.These models have been tested under compression loading, and their bistable response, combined with viscoelastic behavior, has been experimentally verified. Numerical simulations have shown that the examined lattices support the propagation of compression compact waves under the application of compression forces and twisting moments at one end. Such a behavior can be profitably employed to fabricate novel acoustic lenses that are able to focus the mechanical energy in very narrow regions of space within a host body.

Keywords: Periodic media; Dispersion curve; modulation; high frequency; multi-scale method

Abstract. *Dynamics at low frequencies of periodic heterogeneous media is conventionally described by the method of homogenization of periodic media, when it exists a scale separation between displacements and the characteristic size of a cell irreducible from the media. At higher frequency, this separation of scales is lost and the homogenization method becomes obsolete. In order to cross this barrier, we propose to consider periodic modes over a period composed of several irreducible cells. Around the eigenfrequencies of these multicells periods with periodic boundary conditions, large evolution situations emerge. A new separation of scales is therefore defined between the amplitude of the mode and the characteristic size of the period. The equations governing the modulation are thus obtained, and their nature differs if the mode considered is single or multiple.*

From the macroscopic modulation equations we can extract an approximation of the fundamental dispersion curve, in the vicinity of the periodic eigenmodes of the multi-cells period. Consequently, a construction by parts of the fundamental dispersion curve is provided.

1 Introduction

This paper falls within the study of macroscopic dynamic behaviour of periodic media. In most cases, analytic description is not reachable and the problem is solved via a numeric computation of the dispersion curves, which carry all the dynamic properties of the system. We propose in this paper an analytic method for reaching parts of the dispersion curves via an asymptotic multi-scale method. This method is first full described on a periodic network of spring-mass, for which the dispersion curve is well-known. In a second time, we evidence the power of this methodology to periodic reticulated beams, which present a more complex behaviour.

At low frequency, when there is a large scale separation between the length of the cell and the characteristic size of the vibrations, the classical homogenization method allows efficiently to establish the continuous equivalent description. This scale separation is lost for frequencies higher than the diffraction frequency. However, instead of considering the amplitude of the mean displacement in a unit cell, it appears that the concept of scale separation may still be used when considering the amplitude of periodic eigenmodes defined on (multi-)cells. Thus, the same principle of asymptotic multi-scale method enables to describe the large scale modulations around the eigenfrequencies of the mono- and/or multi-cells period. Finally, the properties of the modulation are straightforwardly related to the dispersion curves at the considered frequencies.

2 Exact dispersion relations in 1D spring-mass chains.

Exact wave dynamics of a spring-mass chain is well known for harmonic waves at any frequency in such systems. However a new point of view is provided by the modulation analysis as initially proposed in Daya *et al.* (2002), Craster *et al.* (2010), or in (Boutin *et al.*, 2012) using a multi-cells approach.

2.1 Classical analysis

Consider a periodic 1D spring-mass system whose irreducible period Ω is constituted by a massless spring of stiffness k, length ℓ, and a rigid mass m. Studying harmonic wave propagation at the angular frequency ω, the balance of forces on the n^{th} mass (i.e. on the n^{th} cell Ω), reads

$$(v_{n+1} - 2\,v_n + v_{n-1}) + \chi_\omega\, v_n = 0, \quad \chi_\omega = (\omega/\omega_0)^2, \quad \text{and} \quad \omega_0 = \sqrt{\frac{k}{\mathrm{m}}} \tag{1}$$

Then the motion v_n of n^{th} mass is on the form : $v_n = V_0 e^{i(\omega\, t - \mathrm{k}_\omega\, n\, \ell)}$ where k_ω is the wave number. Thus (1) leads to the dispersion relation:

$$4\sin^2\left(\frac{\mathrm{k}_\omega\,\ell}{2}\right) = \chi_\omega = \left(\frac{\omega}{\omega_0}\right)^2 \tag{2}$$

Consequently $2\omega_0$ corresponds to the absolute cut-off angular frequency, separating propagating and non propagating waves. That is in the angular frequency range $\omega \leq 2\omega_0$, the waves can propagate with the wave number k_ω defined by the dispersion relation (2). Long wavelengths correspond to $\mathrm{k}_\omega\ell \to 0$ so that successive masses follow almost the same motion. From the dispersion relation (2), this situation is reached at low angular frequency, $\omega \ll \omega_0$. Furthermore, expanding (2) near zero gives :

$$|\mathrm{k}_\omega|\ell \simeq \frac{\omega}{\omega_0}$$

thus $|\mathrm{k}_\omega| \simeq \omega/\sqrt{k\ell^2/\mathrm{m}}$ when $\omega \ll \omega_0$, i.e the dispersion relation matches the usual description of long wave propagation in a 1D medium of lineic elastic modulus $k\ell$ and lineic mass m/ℓ.

2.2 Multi-cells analysis

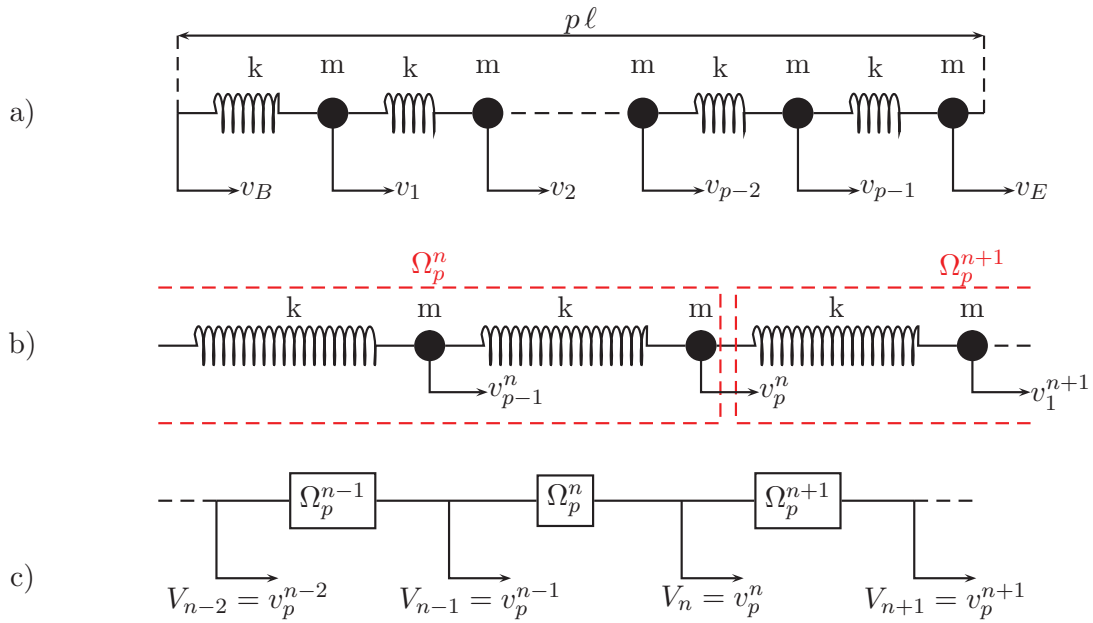

Figure 1: Multi-cells approach. a) A multi-cells period Ω_p made of p spring-mass (length ℓ, stiffness k, mass m) with extremity motions v_B and v_E as limit conditions. b) The two last masses of n^{th} multi-cells Ω_p and the first mass of $(n+1)^{th}$ Ω_p. c) Macroscopic viewpoint : the displacement of the p^{th} mass of the n^{th} multi-cells Ω_p defines the leading displacement $V(x_n)$ of this period.

Dispersion equation (2) shows that the only situation presenting an evolution at large scale is found in the vicinity of $\omega \simeq 0$. In order to find other situations, we now investigate the same spring-mass chain, but with a period Ω_p made of p irreducible cell Ω, that is $\Omega_p = \bigcup_p \Omega$. We denote $V_n = v_{np}$ the motion of an edge the n^{th} period Ω_p, and $v_{np+m}, 0 < m < p$ the motion of inner masses of Ω_p, which can be liked to V_n and V_{n+1} by the following expression :

$$v_{np+m} = \frac{(\beta_\omega^{p-m} - \beta_\omega^{m-p})\, V_n + (\beta_\omega^m - \beta_\omega^{-m})\, V_{n+1}}{\beta_\omega^p - \beta_\omega^{-p}} \quad ; \quad 0 \leq m \leq p \tag{3}$$

By construction, expression (3) insures that the dynamic balance is satisfied for the inner masses of Ω_p, with $\beta_\omega^p + \beta_\omega^{-p} = 2 - \chi_\omega$

$$V_{n-1} - \left(\beta_\omega^p + \beta_\omega^{-p}\right)\, V_n + V_{n+1} = 0 \tag{4}$$

When $\beta_\omega^p = 1$ then $V_n = V_{n+1}$ which means that motions are Ω_p-periodic. In other words the p^{th} roots of the unity lead to large scale evolution. The expression of these roots are (Int(.) stands for the Integer part)

$$\left\{ \beta_{\omega\,\frac{q}{p}} = \exp(\pm i \frac{q}{p} 2\pi) \qquad \forall q \in [\![0; \mathrm{Int}(\frac{p}{2})]\!] \right\}$$

Moreover, as $\beta_\omega = \exp(i\mathrm{k}_\omega \ell)$ we can express the wavenumbers and angular frequencies corresponding to the latter expression of $\beta_{\omega_{\frac{q}{p}}}$, see (2) :

$$\left\{ \mathrm{k}_{\omega_{\frac{q}{p}}} = \frac{q}{p}\frac{2\pi}{\ell} \quad ; \quad \omega_{\frac{q}{p}} = 2\omega_0 \sin(\frac{q}{p}\pi) \qquad \forall q \in [\![0; \mathrm{Int}(\frac{p}{2})]\!] \right\} \tag{5}$$

We can now rewrite (3) as :

$$v_{np+m} = a\Phi_m^{\frac{q}{p}} + b\Psi_m^{\frac{q}{p}} \quad \forall 0 \leq m < p\,;\, 0 \leq q \leq \mathrm{Int}(\frac{p}{2}) \text{ with } \begin{cases} \Phi_m^{\frac{q}{p}} = \cos(\mathrm{k}_{\omega_{\frac{q}{p}}} m\ell) \\ \Psi_m^{\frac{q}{p}} = \sin(\mathrm{k}_{\omega_{\frac{q}{p}}} m\ell) \end{cases}$$

where the set of eigenmodes $\{\Phi^{\frac{q}{p}}, \Psi^{\frac{q}{p}}\}$ respects the periodic boundary conditions of Ω_p. Moreover, since Ω_p owns p degrees of freedom, there are p modes. Note that $\Psi^0 = 0$ and, for p even, $\Psi^{\frac{1}{2}} = 0$. Hence the only single modes are Φ^0 and $\Phi^{\frac{1}{2}}$ (for p even) which are respectively associated with the zero frequency and the cut-off angular frequency $2\,\omega_0$, and lead to an identical (respectively opposite) motion of consecutive masses, independently of Ω_p. For $\frac{q}{p} \neq \{0, 1/2\}$, $\Phi^{\frac{q}{p}}$ and $\Psi^{\frac{q}{p}}$ are double modes associated with the angular eigenfrequency $\omega_{\frac{q}{p}}$ given by (5).

3 Wave dispersion curves derived through asymptotic multi-scale method

3.1 Large modulation of high frequency waves in a periodic network of resonators

The motions of a period Ω_p are periodic exactly at the periodic angular eigenfrequencies $\omega_{\frac{q}{p}}$ and, despite these motions vary at a scale ℓ, the amplitudes of the modes are constant over the whole Ω_p. Hence, in the vicinity of these angular frequencies, the mode amplitudes are no longer constant but present a large-scale evolution, compared to the size of the period. This allows to introduce the scale ratio $\varepsilon_p = \ell_p/L = p\,\ell/L$ where L reprents the modulation length. The macroscopic description is derived using the homogenization of discrete periodic media Caillerie *et al.* (1989), Hans et Boutin (2008), Sanchez-Palencia (1980) adapted to multi-cells period and high frequencies Rallu *et al.* (2018) :

- The first step is to introduce a continuous variable $V(x)$, as $V(x_n = n\ell_p) = V_n$. This variable represents the mode amplitude;
- Then, because of the small variation of $V(x)$ between x_n and x_{n+1}, a Taylor expansion is performed for the consecutive reference masses :

$$V_{n\pm1} = V\left(x_n \pm \ell_p\right) = V\left(x_n\right) \pm \ell_p \partial_x V\left(x_n\right) + \frac{\ell_p^2}{2}\partial_x^2 V\left(x_n\right) + \ldots$$

- The spatial and frequency variables are assymptotically exanded in powers of ε_p, for example

$$V(x) = V^{(0)}(x) + \varepsilon_p\, V^{(1)}(x) + \mathcal{O}(\varepsilon_p^2) \quad ; \quad \omega = \omega^{(0)} + \varepsilon_p\, \omega^{(1)} + \mathcal{O}(\varepsilon_p^2) \text{ with } \omega^{(0)} = \omega_{\frac{q}{p}}$$

  Note that the angular frequency is expanded around the periodic angular eigenfrequencies $\omega_{\frac{q}{p}}$;

- These three developments are then introduced in the balance equation (4);
- Finally, sort and collect the differents terms in ε_p powers. The dominant terms yield a non trivial equation that provides the macroscopic description at the leading order.

Applying this process leads to the following macroscopic descriptions at the leading order:

Low-frequency range i.e $q = 0, \omega \approx 0 + \varepsilon_p\, \omega^{(1)}$.

$$k\, \ell\, \partial_x^2 V + \frac{\mathrm{m}}{\ell}\, \omega^2\, V = \mathcal{O}\left(\varepsilon_p\right) \tag{6}$$

This case corresponds to the usual assumption of scale seration, where the variation of motion of two consecutive masses is very small. Note that in this case the mode amplitude matches the motion of the masses. This macroscopic equation describes the modulation the (simple) static mode.

Frequencies close to the cut-off frequency for p even, that is, $q = p/2$ and $\omega \approx 2\,\omega_0 + \varepsilon_p^2\, \omega^{(2)}$.

$$k\, \ell\ \partial_x^2 V + \frac{\mathrm{m}}{\ell}\left(-\omega^2 + \left(2\,\omega_0\right)^2\right)\, V = \mathcal{O}(\varepsilon_p) \tag{7}$$

This equation describes the modulation of a simple mode where two consecutive masses have opposite motions.

Frequencies close to the double eigenmodes frequencies i.e. $0 < q < \mathrm{Int}(p/2)$ and $\omega \approx \omega_{\frac{q}{p}} + \varepsilon_p\, \omega^{(1)}$

$$k\, \ell\, \partial_x^2 V + \frac{\mathrm{m}}{\ell}\, \frac{\left(\omega - \omega_{\frac{q}{p}}\right)^2}{\cos^2(\frac{q}{p}\pi)}\, V = \mathcal{O}\left(\varepsilon_p\right) \tag{8}$$

Note that contrary to (7), (i) this case correspond to the modulation of a *double* mode, (ii) the frequency term is always positive and (iii) this macroscopic description depends on p. Morevover, the modulation frequency is not an edge of the Brillouin zone, and could not be derived with antiperiodic conditions used in Craster *et al.* (2010).

3.2 Approximation of the dispersion equations

Drawing a parallel with the wavenumber $\pm\mathrm{k}_\omega$ describing wave propagation in the spring-mass system, we can introduce the *modulation number* κ_ω in order to describe the harmonic modulation :

$$V(x) = V_0\, \exp(\pm i\, \kappa_\omega\, x) \tag{9}$$

In the vicinity of the periodic angular eigenfrequencies, an approximation of the fundamental dispersion curve can be built as a perturbation of the periodic mode. Consequently the modulation number is the angular frequency increment divided by the group velocity :

$$\mathrm{k}_\omega = \mathrm{k}_{\omega_{\frac{q}{p}}} + \kappa_\omega + \mathcal{O}\left(\varepsilon\right) \quad ; \quad \kappa_\omega = \frac{\omega - \omega_{\frac{q}{p}}}{C_{\omega_{\frac{q}{p}}}} \quad ; \quad C_\omega = \frac{d\omega}{dk_\omega}$$

Introducing (9) in the three modulation equations at the leading order (6), (8), (7) yields the dispersion relation for modulation. Moreover, modulation numbers are straightforwardly linked to the scale ratio ε_p

$$\varepsilon_p = |\kappa_\omega| \ell_p$$

Consequently, at a given ε_p, an estimation of the validity frequency range around the periodic angular eigenfrequency is possible.

Low frequency range $\omega \approx 0$ $(q = 0)$:

$$|\kappa_\omega| = \frac{1}{\ell}\frac{\omega}{\omega_0} + \mathcal{O}(\varepsilon) = k_\omega + \mathcal{O}(\varepsilon)$$

Thus in low-frequency range, the modulation number κ_ω matches the wavenumber k_ω at the leading order. An estimation of the validity frequency range is :

$$\frac{|\Delta\omega|}{\omega_0} = \frac{|\omega - 0|}{\omega_0} \approx \frac{\varepsilon_p}{p} \tag{10}$$

Frequencies close to the cut-off frequency ($\omega \approx 2\,\omega_0$ and p even), the dispersion relation of modulation is determined from (7) as:

$$|\kappa_\omega| = \frac{1}{\ell}\sqrt{4 - \left(\frac{\omega}{\omega_0}\right)^2} + \mathcal{O}(\varepsilon) = \frac{2}{\ell}\sqrt{\frac{2\omega_0 - \omega}{\omega_0}} + \mathcal{O}(\varepsilon)$$

Then the frequency range of validity is given by

$$\frac{|\Delta\omega|}{\omega_0} = \frac{|2\omega_0 - \omega|}{\omega_0} \approx \left(\frac{\varepsilon_p}{2p}\right)^2 \text{ if } \omega < 2\omega_0 \tag{11}$$

Frequencies close to the double eigenmode eigenfrequencies $\omega \approx \omega_{\frac{q}{p}}$, $0 < q < \mathrm{Int}(p/2)$) the modulation number given by (8) reads

$$|\kappa_\omega| = \frac{1}{\omega_0\,\ell}\frac{|\omega - \omega_{\frac{q}{p}}|}{\cos\left(\frac{q\,\pi}{p}\right)} + \mathcal{O}(\varepsilon)$$

corresponding to a frequency range of :

$$\frac{|\Delta\omega|}{\omega_0} = \frac{|\omega - \omega_{\frac{q}{p}}|}{\omega_0} \approx \frac{\varepsilon_p}{p\cos(\frac{q}{p}\pi)} \tag{12}$$

Note that when $\omega > \omega_{\frac{q}{p}}$ (respectively $\omega < \omega_{\frac{q}{p}}$) then k_ω and κ_ω have identical (respectively opposite) signs. Consequently, the wave and the modulation propagate in the same (respectively opposite) direction, see Figure 2.

In the Figure 3, we build (a) the fundamental dispersion curve in the first half of the Brillouin area, and then piecewise parts of the dispersion curve, near the periodic eigenfrequencies of :

- (b) the specific periodic modes of Ω ($\omega \approx 0$, dashed blue lines), Ω_2 ($\omega \approx 2\omega_0$, dashed red lines) and Ω_3 ($\omega \approx \sqrt{3}\omega_0$, dashed cyan lines)
- (c) in adding the specific modes of Ω_4 ($\omega \approx \sqrt{2}\omega_0$, dashed magenta lines) and Ω_5 ($\omega \approx 2\sin(\frac{\pi}{5})\omega_0$ and $\omega \approx 2\sin(\frac{2\pi}{5})\omega_0$, dashed green lines).

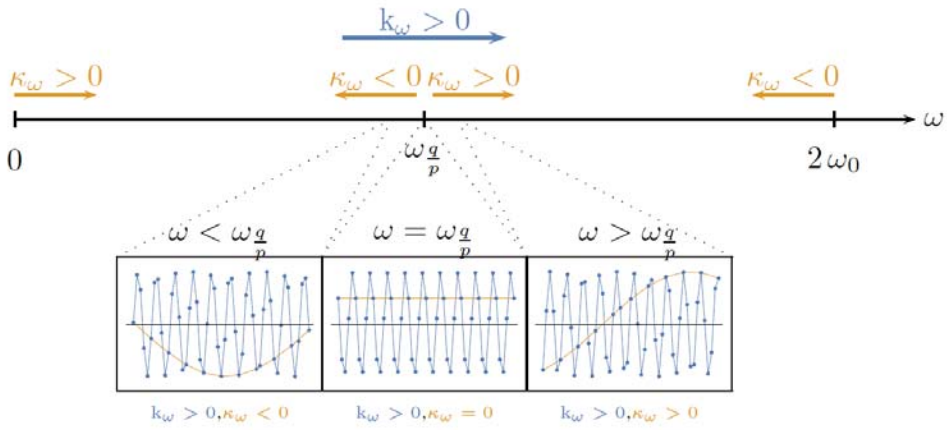

Figure 2: Direction of propagation of the wave (in blue) versus the direction of propagation of the modulation of the wave (in orange). As an illustration, a period Ω_5 is considered and both the wave and modulation direction of propagation are indicated for frequencies around the first angular eigenfrequency $\omega_{\frac{1}{5}}$.

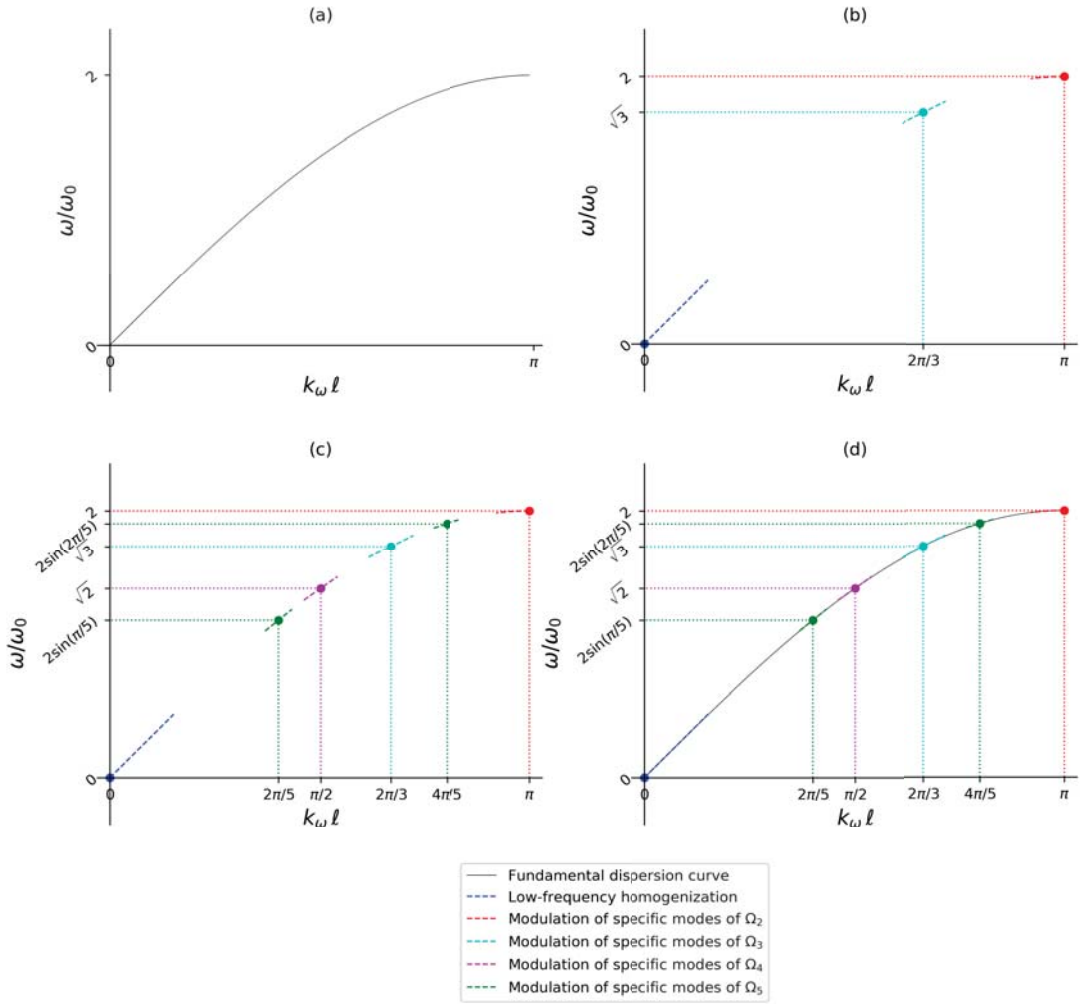

Figure 3: (a) Fundamental dispersion curve in the first half of the Brillouin zone. This dispersion curve can be rebuilt in part from the modulation number: (b) with the specific modes of $\{\Omega_p\}_{0<p\leq 3}$ and (c) with the specific modes of $\{\Omega_p\}_{0<p\leq 5}$. (d) an overlay of fundalental and piecewise parts of the dispersion curve.

The frequency ranges of validity of the macroscopic descriptions have been taken with a value of $\varepsilon_p = 0.5$. Because of the term ε_p^2, the frequency validity range (11) is much less wide than (10) and (12). In the Figure (d), the fundamental dispersion curve is overlayed on its piecewise approximations. In the Figure 4, the dispersion curve of the spring-mass system is built piecewise in varying the value of ε_p : (a) $\varepsilon_p = 0.5$, (b) $\varepsilon_p = 1$, (c) $\varepsilon_p = 1.5$ and (d) $\varepsilon_p = 2.5$. These great values of ε_p are not mathematically justifiable, because the homogenization process requires that $\varepsilon_p \to 0$. Nevertheless, we can see this as an extrapolation of the osculated curves around the Bloch modes : hence, the more the value of ε_p is great and the more the fundamentable dispersion curve is accuratly built thanks to piecewise approximations around the Bloch modes. Moreover, in the case where $\varepsilon_p = 2.5$, the successive approximations pass from their origin almost to the next Bloch mode, allowing a rebuilt by successive secant osculation curves.

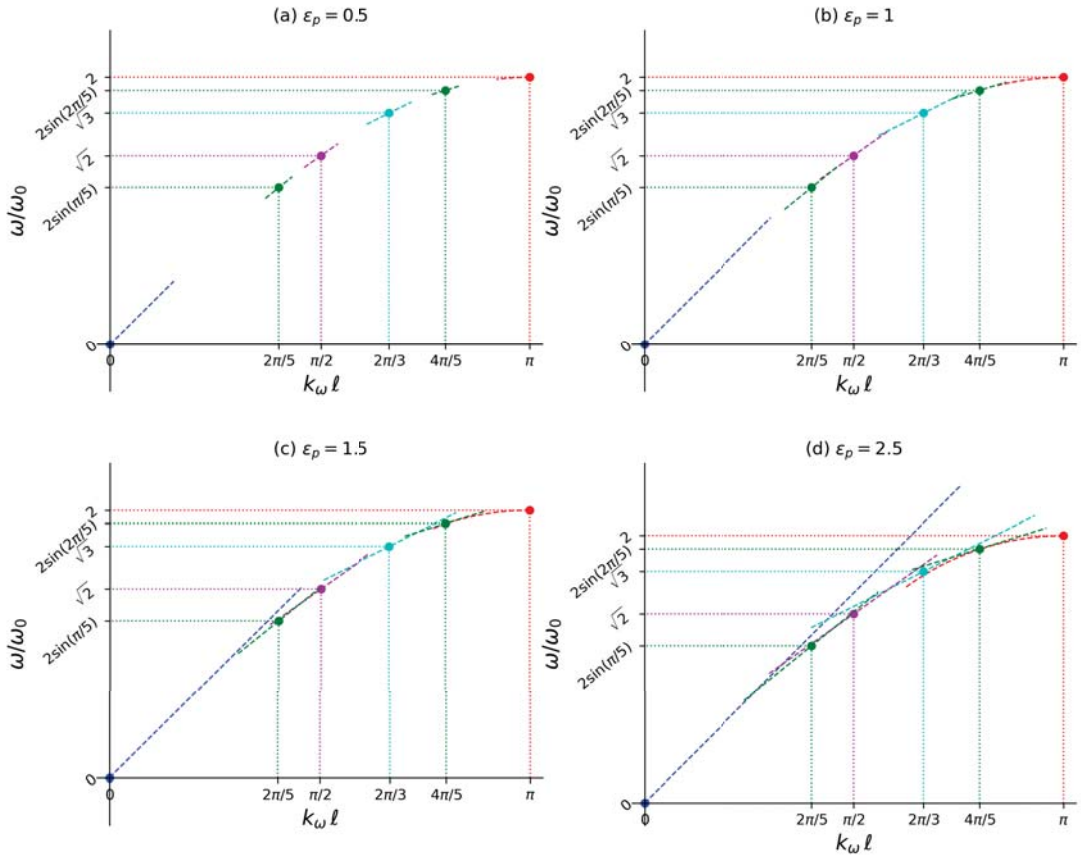

Figure 4: Dispersion curve build piecewise thanks to modulation curves as in the Figure 3, but in varying the value of ε_p from 0.5 to 2.5.

4 Application to discrete lattices

The latter methodology, developped on a well-known spring-mass system, is now applied to a network made of a stack of symetric elastic frames (see Figure 5) constituted by three identical rigidly and mass-less connected bending beams. This structure departs from the spring-mass system because in the reticulated beams (i) stiffness and mass are continuously distributed in the local beams, therefore an irreducible cell Ω owns an infinite number of periodic eigenmodes, and (ii) the 2D nature of the structure involves an enriched kinematics. Each cell owns two

nodes then six degrees of freedom. Each local beam is characterized by (i) its geometrical parameters : length ℓ, width a, depth h, cross section A and inertia regarding its longitudinal axis $I = a^3 h/12$, and (ii) its mechanical elastic parameters : elastic modulus E, mass density ρ.

Due to the symmetry of the considered structures, the local variables can be reorganized in two sets of uncoupled variables linked to (i) the transversal kinematic of the reticulated beam (namely V_n the average transversal displacement, θ_n the average rotation of the nodes and α_n the rotation of the n^{th} cell) and (ii) to the longitudinal kinematic of the reticulated beam (U_n the average longitudinal displacement, Δ_n the transversal dilatation and Φ_n the differential rotation of the nodes). In this paper we illustrate the piecewise building of dispersion curve only on

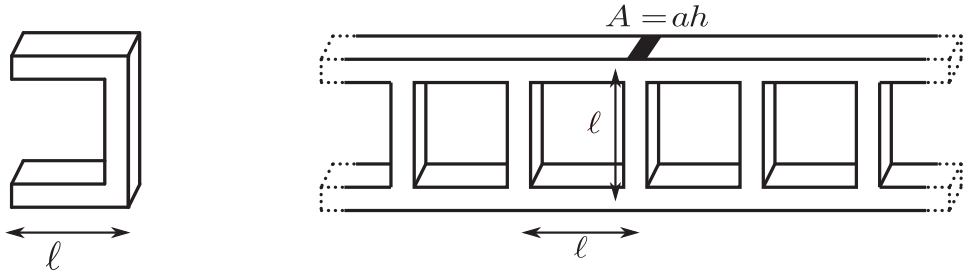

Figure 5: Left : Cell Ω of the reticulated beam. Right : periodic framed beam.

transversal kinematics. The chosen geometrical and mechanical parameters of local frames are:

$$E = 210\text{GPa}\,;\ \nu = 0.2\,;\ \rho = 7800\text{kg/m}^3\,;\ \ell = 1\text{cm}\,;\ a = 0.5\text{mm} \tag{13}$$

which corresponds to a slenderness of a local beam : $\ell/a = 20$.

Denoting by $\underline{\mathcal{V}}_n =^T \left(\frac{1}{2}\,\alpha_n\,\ell, V_n, \theta_n,\right)$ the transversal generalized displacements of the n^{th} cell, the force and momentum balances of the n^{th} cell involves the generalized displacements of the neighboring cell $n-1$ and $n+1$ and take the matrix form:

$$\underline{\underline{H}}.\,\underline{\mathcal{V}}_{n-1} + \underline{\underline{\mathcal{H}}}_T.\,\underline{\mathcal{V}}_n +^T \underline{\underline{H}}.\,\underline{\mathcal{V}}_{n+1} = \underline{0} \tag{14}$$

$$\underline{\underline{H}} = \begin{bmatrix} \frac{EA}{\ell} g_2(\chi) & 0 & 0 \\ 0 & \frac{12\,EI}{\ell^3} f_4(\gamma) & \frac{6\,EI}{\ell^2} f_6(\gamma) \\ 0 & -\frac{6\,EI}{\ell^2} f_6(\gamma) & -\frac{2\,EI}{\ell} f_5(\gamma) \end{bmatrix}$$

$$\underline{\underline{\mathcal{H}}}_{\mathrm{T}} = \begin{bmatrix} a_{\mathrm{T}} & 0 & b_{\mathrm{T}} \\ 0 & c_{\mathrm{T}} & 0 \\ b_{\mathrm{T}} & 0 & d_{\mathrm{T}} \end{bmatrix} \text{ with } \begin{cases} a_{\mathrm{T}} = -\dfrac{12\,EI}{\ell^3}\left(f_1(\gamma) + f_4(\gamma)\right) - \dfrac{2\,EA}{\ell} g_1(\chi) \\ b_{\mathrm{T}} = \dfrac{6\,EI}{\ell^2}\left(f_3(\gamma) + f_6(\gamma)\right) \\ c_{\mathrm{T}} = \dfrac{EA}{\ell}\left(g_2(\chi) - g_1(\chi)\right) - \dfrac{24\,EI}{\ell^3} f_1(\gamma) \\ d_{\mathrm{T}} = -\dfrac{2\,EI}{\ell}\left(f_5(\gamma) + 2\,f_2(\gamma)\right) - \dfrac{8\,EI}{\ell_{\mathrm{w}}} f_2(\gamma) \end{cases}$$

where $\chi = \sqrt{\frac{\rho\,\omega^2}{E}}\,\ell$ and $\gamma = \sqrt[4]{\frac{\rho\,A\,\omega^2}{E\,I}}\,\ell$ are two dimensionless parameters describing the local regime of the beam respectively in compression and in bending. The elasto-inertial functions f_i

and g_i are defined by :

$$\begin{cases} g_1(x) = x\cot(x) \\ g_2(x) = \dfrac{x}{\sin(x)} \\ f_1(x) = \dfrac{\cosh(x)\,\sin(x)+\sinh(x)\,\cos(x)}{1-\cos(x)\,\cosh(x)}\,\dfrac{x^3}{12} \\ f_2(x) = \dfrac{\cosh(x)\,\sin(x)-\sinh(x)\,\cos(x)}{1-\cos(x)\,\cosh(x)}\,\dfrac{x}{4} \end{cases} \qquad \begin{cases} f_3(x) = \dfrac{\sinh(x)\,\sin(x)}{1-\cos(x)\,\cosh(x)}\,\dfrac{x^2}{6} \\ f_4(x) = \dfrac{\sinh(x)+\sin(x)}{1-\cos(x)\,\cosh(x)}\,\dfrac{x^3}{12} \\ f_5(x) = \dfrac{\sinh(x)-\sin(x)}{1-\cos(x)\,\cosh(x)}\,\dfrac{x}{2} \\ f_6(x) = \dfrac{\cosh(x)-\cos(x)}{1-\cos(x)\,\cosh(x)}\,\dfrac{x^2}{6} \end{cases}$$

4.1 Dispersion equations

The dispersion relation $\mathcal{E}\,(\omega, \mathrm{k}_\omega) = 0$ of harmonic transversal waves can be found considering $\underline{\mathcal{V}}_n =^T \left(\frac{1}{2}\,\alpha_n\,\ell, V_n, \theta_n, \right)$ in the form (the time dependence $e^{i\omega t}$ is omitted) :

$$\underline{\mathcal{V}}_n = \underline{\mathcal{V}}_0\, e^{i\,\mathrm{k}_\omega\, n\,\ell} \qquad k_\omega \in [0, \frac{\pi}{\ell}[\tag{15}$$

Introducing (15) in (14) yields :

$$\underline{\underline{\mathbb{D}}}_{\mathrm{T}}.\underline{\mathcal{V}}_0 = \begin{bmatrix} \tilde{a}_{\mathrm{T}} & 0 & b_{\mathrm{T}} \\ 0 & \tilde{c}_{\mathrm{T}} & \tilde{e}_{\mathrm{T}} \\ b_{\mathrm{T}} & -\tilde{e}_{\mathrm{T}} & \tilde{d}_{\mathrm{T}} \end{bmatrix}.\underline{\mathcal{V}}_0 = \underline{0} \text{ where } \begin{cases} \tilde{a}_{\mathrm{T}} = a_{\mathrm{T}} + \dfrac{2\,EA}{\ell_{\mathrm{w}}}\,g_2(\chi)\,\cos\left(\mathrm{k}_\omega\,\ell\right) \\ \tilde{c}_{\mathrm{T}} = c_{\mathrm{T}} + \dfrac{24\,EI}{\ell^3}\,f_4(\gamma)\,\cos\left(\mathrm{k}_\omega\,\ell\right) \\ \tilde{d}_{\mathrm{T}} = d_{\mathrm{T}} - \dfrac{4\,EI}{\ell}\,f_5(\gamma)\,\cos\left(\mathrm{k}_\omega\,\ell\right) \\ \tilde{e}_{\mathrm{T}} = \dfrac{12\,EI}{\ell^2}\,f_6(\gamma)\,i\sin\left(\mathrm{k}_\omega\,\ell\right) \end{cases}$$

The roots of the determinant of $\underline{\underline{\mathbb{D}}}_{\mathrm{T}}$ yield the dispersion equation of the transversal waves in the reticulated structure :

$$\det\left(\underline{\underline{\mathbb{D}}}_{\mathrm{T}}\right) = \left(\tilde{a}_{\mathrm{T}}\,\tilde{d}_{\mathrm{T}} - \tilde{b}_{\mathrm{T}}^2\right)\,\tilde{c}_{\mathrm{T}} + \tilde{a}_{\mathrm{T}}\,\tilde{e}_{\mathrm{T}}^2 = \mathcal{E}_{\mathrm{T}}\,(\omega, \mathrm{k}_\omega) = 0$$

Then, the corresponding kernel of $\underline{\underline{\mathbb{D}}}_{\mathrm{T}}$ provides the kinematics associated to set $\{\omega_I, \mathrm{k}_{\omega I}\}_I$ solutions of $\mathcal{E}_{\mathrm{T}}\,(\omega, \mathrm{k}_\omega) = 0$. Application of this method is illustrated on Figure 6:

The first quasi-linear branch clearly shows that at low frequencies the transversal dynamics is driven by the average transversal displacement V. The second branch, strongly non-linear corresponds at low wavenumbers to the gyration mode. The latter, driven by the rotation of the section $\alpha\,\ell$, is activated after a cut-off frequency (around 4,4 kHz). Note however that for wavenumbers greater than $\mathrm{k}_\omega = 0.2\pi/\ell$ the dynamics activated in this branch, moves from $\alpha\,\ell$ to the average rotation of the nodes $\theta\,\ell$. As for the third branch, that appears at higher frequencies (around 37kHz), the kinematics is firstly driven by V, and by θ at larger wavenumbers. The two next branches are dominated by nodes rotation θ, the rigid body motion of the two nodes being negligible, consistently with the inner resonance mechanism within the framed beams. This shows that a given branch is not associated with a specific kinematics.

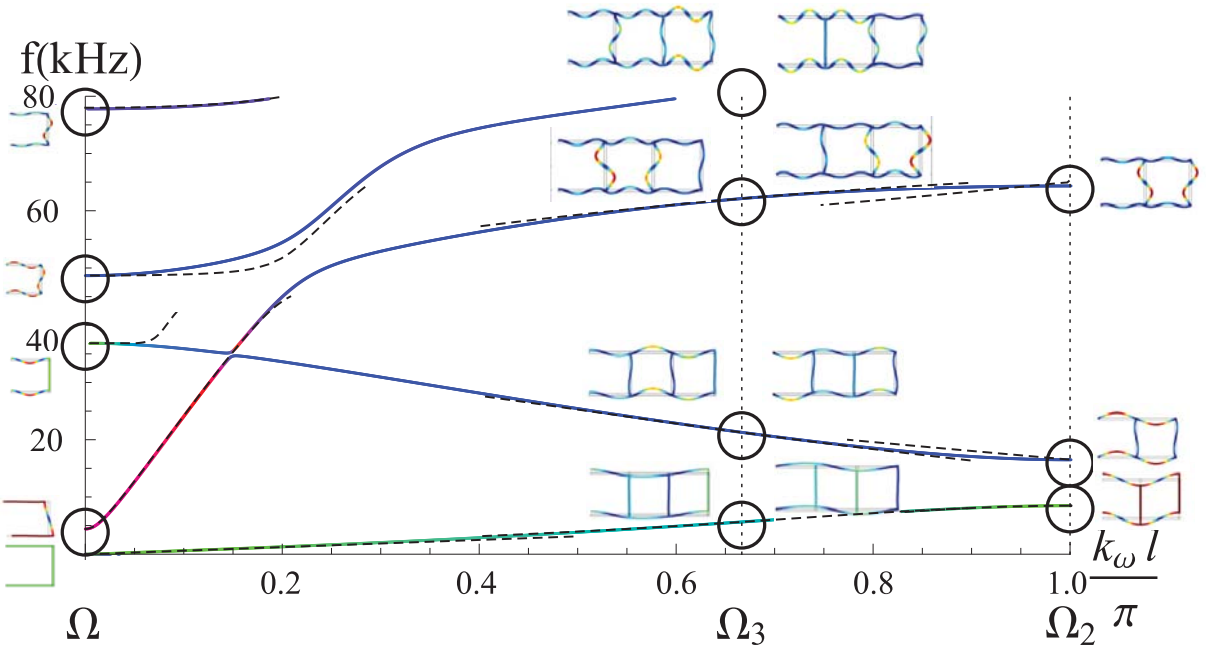

Figure 6: Dispersion curve in the half on the first Brillouin zone for the transversal kinematics : $\alpha\,\ell$,V,$\theta\,\ell$. Black circles correspond to the Bloch modes for periods made of one cell (Ω), two cells (Ω_2) and three cells (Ω_3). In dashed lines the asymptotic description of the dispersion curves derived by modulation analysis.

4.2 Bloch modes

Let a period $\Omega_p = \bigcup_p \Omega$, constituted by a stack of p irreducible cells Ω. When $\mathrm{k}_\omega \ell/2\pi = q/p \in [0, 1/2[$, then the eigenmodes of Ω_p with periodic boundary conditions are emerging. This leads to the associated periodic angular eigenfrequencies thanks to the dispersion relation :

$$\mathcal{E}\left(\omega, \frac{q2\pi}{p\ell}\right) = 0 \quad \text{where} \quad q = 0, ..., \mathrm{Int}(p/2) \tag{16}$$

Finally, the Bloch mode is given by the kernel of $\underline{\underline{\mathbb{D}}}_T$, given at the couple $(\omega, \frac{q2\pi}{p\ell})$ solutions of (16).

On the figure 6, the first solutions corresponding to periods Ω, Ω_2 and Ω_3 are depicted by black circles. The corresponding modal shapes (taking account of their multiplicity) are calculated by finite element on these three periods with periodic boundary conditions.

4.3 Modulation approach

This asymptotic approach is closely related to the HPDM method Caillerie *et al.* (1989) and the asymptotic method for modulation analysis of framed beams is full described in Rallu *et al.* (2018). The procedure is splitted into the following key steps. 1. Reduce the studied structure to an equivalent discrete model. This is obtained by condensing the balance equations of the beam elements within the period at the nodes of the period. 2. Establish an exact recurrence equation by expressing the balance of the edges nodes of the considered (multi-)cells period. 3. Identify the periodic eigenmodes and eigenfrequencies of the (multi-)cell. 4. Consider frequencies close to a given eigenfrequency and assume a large scale modulation. Then rewrite the recurrence equation in terms of Taylor expansions of the continuous variables that describe the amplitude of the eigenmode. 5. Introduce the asymptotic expansions of the variables and rescale the physical parameters of the element constituting the period. Here, all the local frames

are identical, and we consider a slenderness contrast of the local fram as $\ell/a = O(\varepsilon^{-1})$. The geometrical values chosen in (13) are consistent with this contrast. 6. Deduce the various envelope models that apply close to the eigenfrequencies of the considered (multi-)cells.

This approach applied on the transversal kinematics allows to extract the approximation of dispersion curve around the periodic eigenmodes of periods made of one, two and three irreducible cells. All the equations are detailed in Rallu *et al.* (2019). These approximations are given in dashed lines on Figure 6.

In the figure 6 are represented in parallel of the dispersion curves determined from a direct calculus and the asymptotic dispersion curves derived from the analytical expressions given by the modulation analysis. This figure clearly shows that the asymptotic model for quasi-static "V"-mode fits the exact dispersion curve related to the bending of the reticulated beam in a large wave number range, namely up $k_\omega = 0.5\pi/\ell_{\rm w}$, which is much larger than its theoretical validity domain $k_\omega \ell_{\rm w} \ll 1$.
On the contrary the asymptotic model for the dynamic "V"-mode fits the exact solution in a limited range of wavenumbers. This relies on the fact that the dominant kinematic variable of this branch change from variable V for $k_\omega \leq 0.05\,\pi/\ell_{\rm w}$, to θ for $k_\omega \geq 0.05\,\pi/\ell_{\rm w}$. As for the asymptotic dispersion curves identified considering Ω_2 and Ω_3, one notices a large range of good matching between the asymptotic and exact results.

5 Conclusion

The goal of this paper is to describe the methodology of construction of parts of the dispersion curve of periodic elastic networks. This process is full and clearly described on a a periodic network of elastic resonators : First, a multi-cells approach is presented in order to identify the situation of large scale evolutions, which correspond to the frequency ranges around the eigenfrequencise of the multi-cells period Ω_p with periodic boundary conditions. Then, in these situations, the framekork of asymptotic analysis of high-frequency modulation in periodic systems is a applied and yields the equations governing the large scale modulations. At low frequencies, the modulation approach matches the classical homogenization method. But at higher frequencies, the nature of the descriptions departs from the usual macroscopic formulation : (i) the macroscopic operator is applied on the amplitude of the periodic eigenmodes, (ii) instead of an unique equivalent model, a family of descriptions is derived for modulation phenomena; this family is associated to the modes of the irreducible or the multiple cells, (iii) the nature of the modulation equations is different whether the mode is simple or multiple. Thanks to these macroscopic descriptions, a piecewise built of the dispersion curve is possible in the vicinity of the periodic eigenfrequencies of Ω_p. Finally, compared to Floquet-Bloch theory, the specificity of the modulation approach is to extract the frequency bands where the large scale modulations are allowed and to determine their governing equations.

As an illustration, we applied this methodology to reticulated beams, whose the enriched kinematics and the continuous distribution of mass and stiffness involve wave dispersion curves with several branches. The main outcomes are (i) a given dispersion branch may involves different kinematics, (ii) the modulation analysis performed on multi-cell around rational Bloch number allows to build by parts the dispersion curves and to relate them to an effective analytical description, (iii) these approximations are reliable in a range such that the kinematics do not significantly changed. These results established on a particular beam lattices may be extended to more complexe periodic structures and clarify the physics behind the dispersion curves.

Keywords: Cross-laminated timber, Dynamic stiffness method, Floor, Natural frequency

Abstract. *Cross-laminated timber (CLT) panels have an increasing market share and extensive application in civil engineering practice, as full size walls or floor structures. CLT provides a compelling alternative to the concrete and steel (as conventional building materials), providing a low carbon footprint and comfortable living conditions. However, the orthotropic elastic material behavior of wood and the crosswise lay-up yield a relatively complex kinematics of CLT, characterized by high shear deformation across the thickness. This complicates the appropriate and accurate kinematic description of CLT and further prolongs the design phase of the real engineering structure.*

Due to the relatively low weight, CLT floors are particularly prone to human-induced vibrations, causing vibration serviceability issues such as annoyance to human occupants and dysfunction of vibration sensitive equipment. Therefore, for the accurate response prediction of CLT under dynamic loading, its fundamental dynamic properties should be derived first.

In the paper, dynamic stiffness-based FREEVIB software, previously developed by the authors, has been used for modeling and prediction of the free vibration characteristics of CLT floor structures. Frequency curves taking into account: (i) span-to-thickness (a/h) ratio, (ii) plate aspect (a/b) ratio and (iii) different combinations of end constraints, have been developed using FREEVIB and systematized to be easy for use in engineering practice, especially in the conceptual design phase of CLT-based buildings. The results have been compared against the current CLT design recommendations.

1 INTRODUCTION

Recent technological advances and new construction techniques have led to the development of new natural composite material called cross-laminated timber (CLT) - a multilayer composite made of several thin wooden layers bonded together in a crosswise manner. It has outstanding structural strength, stiffness and aesthetic properties, a high level of prefabrication, fire resistance and construction speed. Finally, it is highly sustainable material that represents a compelling alternative to the traditional concrete, steel and masonry structures [1].

Due to the relatively low weight, CLT floors are prone to human-induced vibrations, causing vibration serviceability issues such as annoyance to human occupants and dysfunction of vibration sensitive equipment. Therefore, for the accurate response prediction of CLT under dynamic loading, its fundamental dynamic properties should be derived first.

The aim of this paper is to provide the practical guidelines for design of CLT floors by means of their dynamic properties. FREEVIB [2] software developed by the authors, based on the dynamic stiffness method (DSM) [3] in conjunction with the higher-order shear deformation theory (HSDT) [4], has been used for modeling and prediction of the free vibration characteristics of CLT floors. Key feature of the DSM is the dynamic stiffness element and the corresponding dynamic stiffness matrix derived from the exact (strong form) solution of the governing equations of motion. So far, the FREEVIB's library includes several rectangular dynamic stiffness element formulations, capable to describe the complex kinematics of laminar composites. It allows for the application of arbitrary combinations of edge conditions and, like in the conventional FEM, implies the effective assembly procedure.

By using FREEVIB, frequency curves taking into account: (i) span-to-thickness (*a/h*) ratio, (ii) plate aspect (*a/b*) ratio and (iii) different combinations of end conditions, have been developed and systematized to be easy for use in engineering practice. The results have been compared against the current CLT design recommendations from CLT Handbook Canada [5], CLT Structural design – proHolz Austria [6], or the exact solution based on classical laminated plate theory (CLPT) [7], in order to highlight the influence of transverse shear deformation on dynamic properties of the panel.

2 DYNAMIC STIFFNESS METHOD FORMULATION

The dynamic stiffness matrix of the considered HSDT-based plate element is obtained through several steps. The first one is derivation of Euler-Lagrange equations of motion for the HSDT, by using the Hamilton's principle in terms of the displacements. After that, the equations of motion are transformed into the frequency domain by assuming a harmonic representation of the displacement/rotation field:

$$u(x,y,t) = \hat{u}(x,y,\omega)e^{i\omega t} \tag{1}$$

In. Eq. (1), $\hat{u}(x,y,\omega)$ are the amplitudes of the displacement or rotation $\hat{u}(x,y,t)$ in the frequency domain. Having in mind that Eq. (1) is valid for all angular frequencies ω in the considered frequency range, the argument ω will be omitted in further representations. After the substitution of the above transformation into the governing equations of motion, they are transformed into the following set of partial differential equations:

$$\mathbf{L}\hat{u}(x,y) = 0, \tag{2}$$

where **L** is the matrix of the differential operators [8, 9] defined in terms of the plate stiffness coefficients, the mass moments of inertia and the angular frequency ω. Displacement or rotation amplitudes of a rectangular plate element are then represented as a superposition of four symmetry contributions: both symmetric (SS), symmetric - anti-symmetric (SA), anti-

symmetric - symmetric (AS) and both anti-symmetric (AA). It is now possible to analyze only one quarter of a rectangular plate, which significantly reduces the size of the corresponding dynamic stiffness matrix. By using the method of separation of variables, the general solution for each symmetry contribution can be represented in the Fourier series form as:

$$\tilde{u}^{ij}(x,y) = \sum_{m}^{\infty} {}^{1}U_m^{ij}(x)\, {}^{1}f_m^{ij}(y) + \sum_{m}^{\infty} {}^{2}U_m^{ij}(y)\, {}^{2}f_m^{ij}(x) \tag{3}$$

In Eq. (3), $\tilde{u}^{ij}(x,y)$ is the corresponding displacement or rotation function, ${}^{1}U_m^{ij}(x)$ and ${}^{2}U_m^{ij}(y)$ (ij = SS, SA, AS or AA) are the unknown displacement or rotation functions, while $f_m^{ij}(y)$ and $f_m^{ij}(x)$ are the base trigonometric functions, depending on the symmetry case. In practical calculations, the infinite Fourier series must be truncated. Thus, the accuracy of solution depends on the number of terms in the general solution.

With the aid of the projection method [10], the following relation is obtained:

$$\tilde{\mathbf{Q}}^{ij} = \tilde{\mathbf{F}}_D^{ij} \left(\tilde{\mathbf{D}}_D^{ij} \right)^{-1} \tilde{\mathbf{q}}^{ij} = \tilde{\mathbf{K}}_D^{ij} \tilde{\mathbf{q}}^{ij}, \tag{4}$$

where $\tilde{\mathbf{q}}^{ij}$ is the vector of projections of displacement components $\hat{u}^{ij}$ along plate boundaries, $\tilde{\mathbf{Q}}^{ij}$ is the corresponding force projection vector, and $\tilde{\mathbf{K}}_D^{ij}$ is the dynamic stiffness matrix for the ij symmetry contribution. The dynamic stiffness matrix for a completely free dynamic stiffness element is obtained by using the transformation matrix $\mathbf{T}$ (for details see [8, 9, 11]).

The size of the dynamic stiffness matrix $\tilde{\mathbf{K}}_D$ depends on the number of terms in the general solution M, the type of the vibration problem (in plane or transverse) and applied plate theory (CPT, FSDT, HSDT).

Considering that transverse and in-plane vibrations of a single plate represent two independent states, the dynamic stiffness matrix of the single plate is derived by combining the dynamic stiffness matrices for the transverse and in-plane vibration, respectively. The assembly procedure is then performed as in the conventional FEM.

In the analysis, arbitrary combinations of boundary conditions can be applied by removing the rows and columns of the global dynamic stiffness matrix that correspond to the components of the constrained displacement projections. After that, the natural frequencies can be computed from the assembled global dynamic stiffness sub-matrix (related to the unknown generalized displacement projections), using some of the search methods. Finally, after the natural frequencies have been computed, the i^{th} mode shape corresponding to the natural frequency ω_i is obtained in the usual manner.

Formulated dynamic stiffness elements served as basis for the development of object-oriented computational framework FREEVIB [2] for free vibration analysis of plate-like structures. FREEVIB is written in Python [12]. For input parameters related to the geometry, material and number of terms in trigonometric series (M), simple text file may be created in the prescribed format, or generated using the existing graphical pre-processors. Using the procedure described in the previous sections, a variety of plate-like structural problems can be analyzed.

3 CALCULATION OF FUNDAMENTAL DYNAMIC PROPERTIES OF CLT PANELS AND DEVELOPMENT OF FREQUENCY CURVES

In this section, fundamental frequencies of different CLT panels have been calculated using FREEVIB, taking into account: (i) span-to-thickness (*a/h*) ratio, (ii) plate aspect (*a/b*) ratio and (iii) different combinations of boundary conditions (BC). They are then systematized to be easy for use in engineering practice (this is of special importance in the conceptual design phase of CLT-based buildings).

Current models for design of CLT panels mainly emerged from the long tradition of using only simple beam-like elements in timber structures. Gamma method is based on the procedure for design of mechanically jointed beams according to Eurocode 5, Annex B [13]. The stiffness properties are defined using the effective moment of inertia $I_{0,ef}$, and the connection efficiency factors γ_i which account for the shear flexibility of the cross layers. The Gamma method accounts for the influence of transverse load-bearing effect and different static systems using the $k_{transverse}$ and k_e coefficients, respectively. The above method is based on the Bernoulli's hypothesis and linear stress-strain relationship, without accounting for the transverse shear deformation.

However, this approach is not able to accurately account for the 2D load transfer and, therefore, cannot reflect the load carrying mechanism of a plate. To overcome this, classical exact solutions for composite laminates could be successfully applied for thin CLT panels, simply supported along all sides. However, this limits the possible area of application by means of edge conditions.

FREEVIB tends to overcome the above issues, by: (i) accurately accounting for the transverse shear deformation, (ii) taking into account the cross-lamination of layers and, (iii) considering arbitrary combinations of boundary conditions.

3.1 Frequency curves for rectangular simply supported CLT panels

To validate the model and highlight the influence of transverse shear deformation on fundamental dynamic properties of CLT panel, the study of simply supported (SSSS) 3- and 5-layers rectangular CLT panels is performed by using the HSDT-based dynamic stiffness elements using FREEVIB. All layers are of equal thickness. C24 strength class according to [6] is used (see Table 1), which is common in the production of CLT. The outer layers are oriented in the *a*-direction (longitudinal), while the cross layers are oriented in the *b*-direction (lateral).

Different plate side to thickness ratios have been considered, varying from thick ($a/h = 5$) to thin ($a/h = 30$) plate situation. The calculations have been performed by using M=9 terms in the series expansion. Plates were discretized using only one dynamic stiffness element.

In the first phase, the model is validated against the results based on the following CLT design recommendations:

- CLT Handbook Canada [5], based on the Bernoulli-Euler beam theory, without accounting for the transverse shear deformation and neglecting the transverse load-bearing effect,
- CLT Structural design – proHolz Austria [6], based on the Gamma method [13],
- the exact (2D) solution based on classical laminated plate theory (CLPT) [7]).

E_0	E_{90}	G_0	G_r	ν_{12}	ρ
11000 N/mm^2	370 N/mm^2	690 N/mm^2	50 N/mm^2	0.44	420 kg/m^3

Table 1: Mechanical properties for C24 timber class of CLT panels

The results for dimensionless frequencies $\Omega = \omega\left(a^2 / h\right)\left(\rho / E_{90}\right)^{1/2}$ are plotted in Figure 1.

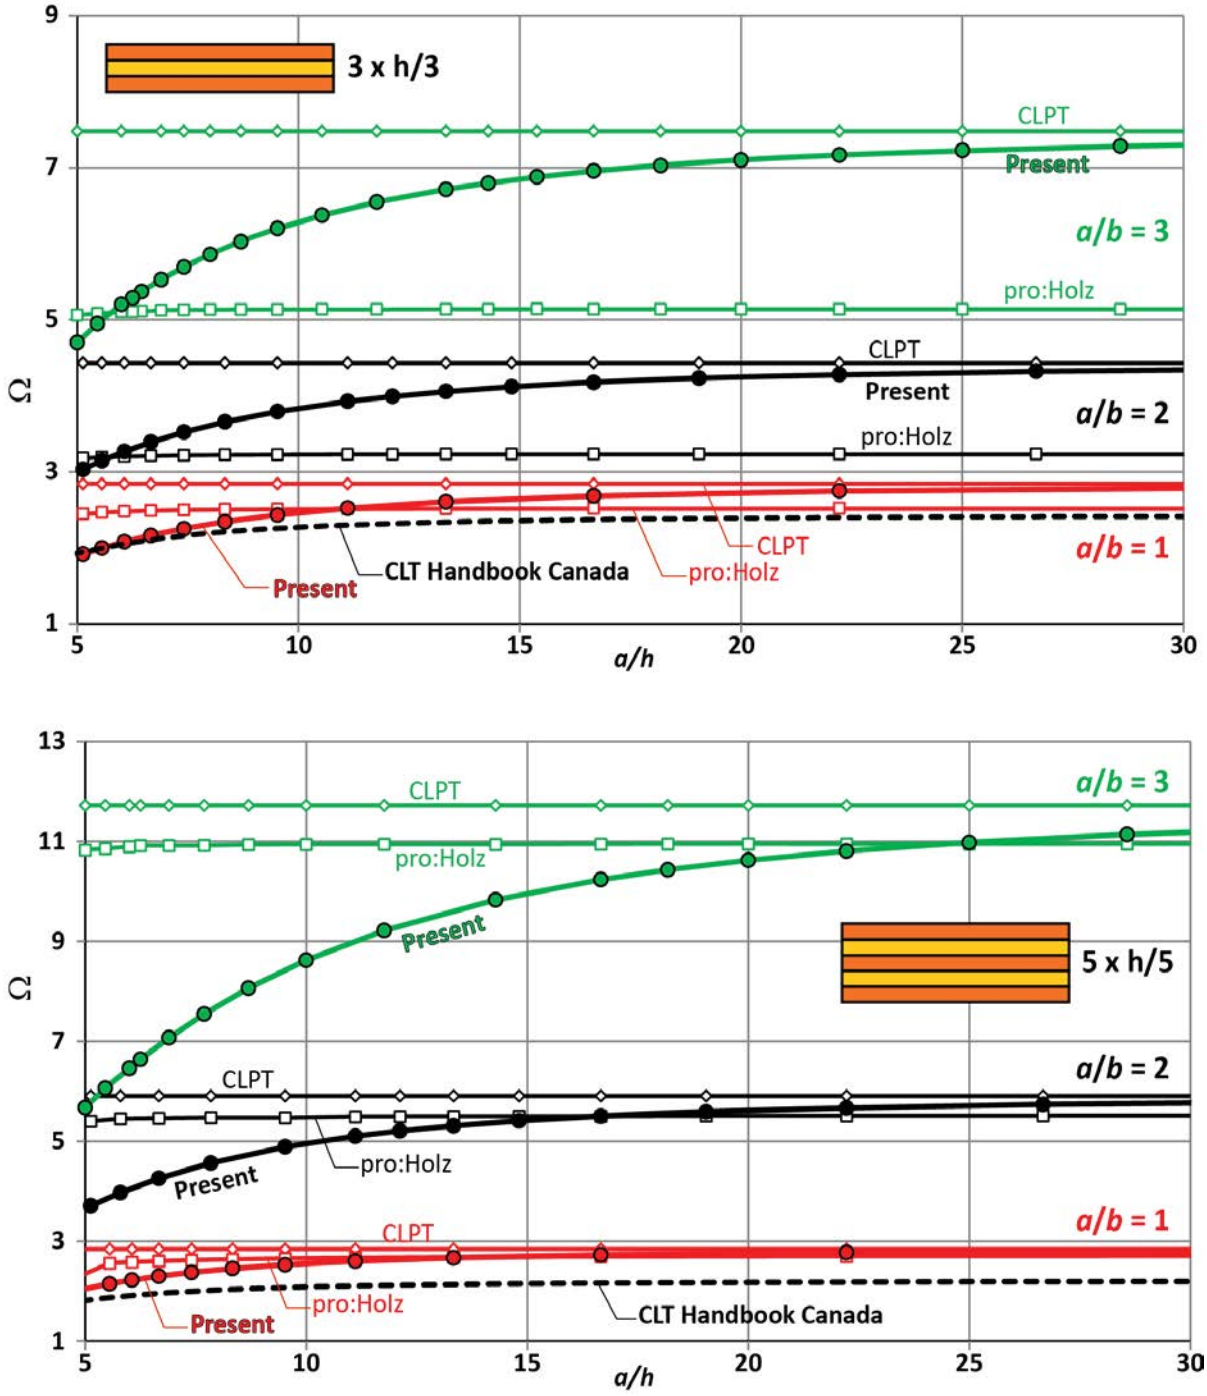

Figure 1: Frequency curves for rectangular simply supported (SSSS) CLT panels (C24), considering different numerical models, stacking sequences, span-to-thickness (*a*/*h*) and plate aspect (*a*/*b*) ratios

The dimensionless natural frequencies presented in Figure 1 are not completely practical for the application in engineering practice. Having in mind that the HSDT-based models accounts for the transverse shear deformation, cross-lamination and arbitrary boundary conditions, the frequency curves will be systematized in a more logical way, to be applicable in preliminary engineering design of CLT floors.

The results are shown in Figure 2, for the simply supported (SSSS) 3- and 5-layers panels.

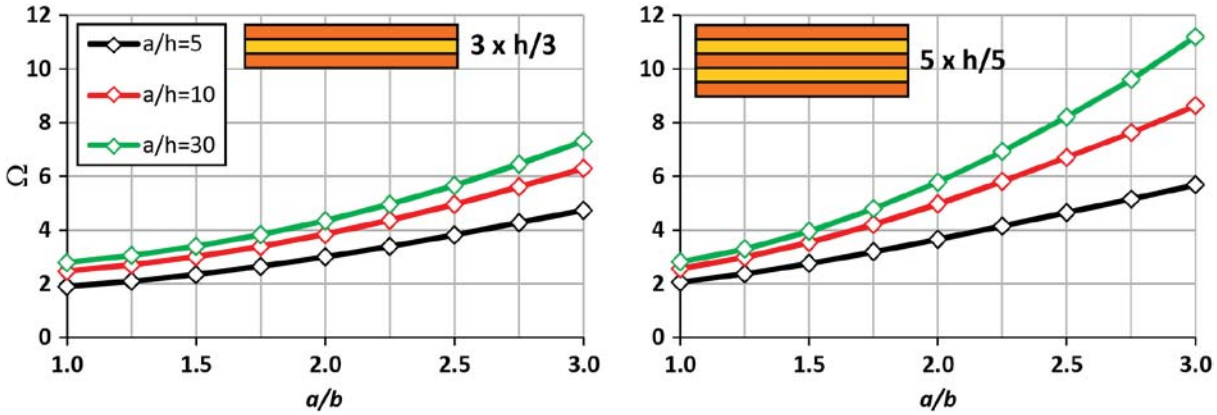

Figure 2: Frequency curves from FREEVIB for rectangular simply supported (SSSS) CLT panels (C24)

3.2 Frequency curves for rectangular CLT panels with different combinations of BC

In this section, we provide the frequency curves for CLT panels with non-classical boundary conditions. This is applicable in engineering practice, where different combinations of boundary conditions may occur. The panels with SSSF and SFSF boundary conditions (see Figure 3 for details) are considered.

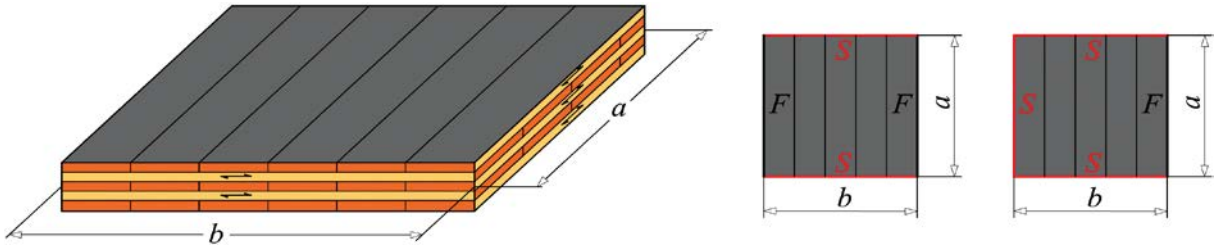

Figure 3: SFSF and SSSF CLT panels with marked grain orientation of the layers

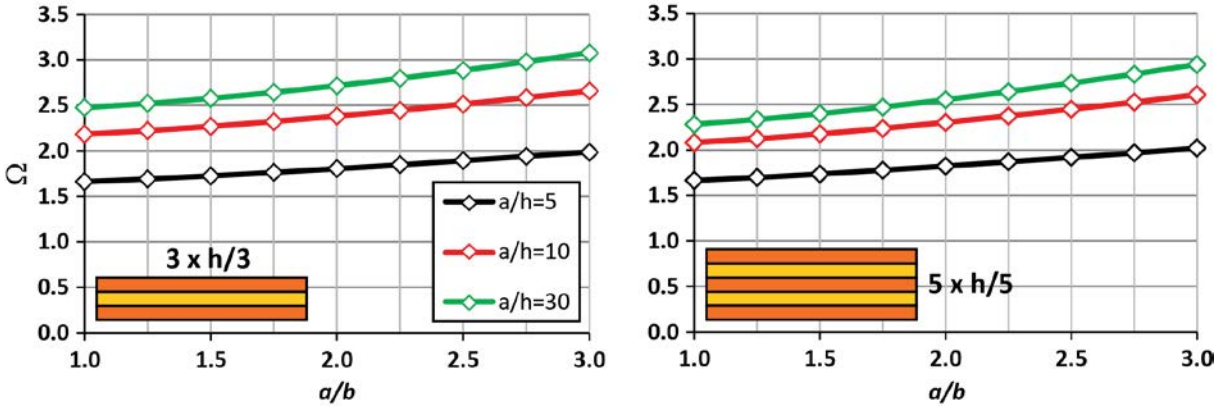

Figure 4: Frequency curves from FREEVIB for rectangular SSSF CLT panels (C24)

For both considered boundary conditions (Figures 4 and 5), the lower *a/h* ratio expectedly yields the lower values of dimensionless frequencies. With increasing *a*/*b* for the fixed *a*/*h*, dimensionless frequencies are slightly increased for the SSSF boundary conditions. This is due to the influence of constraints along the *a*-side (Figure 4), which is more pronounced for lower values of length *b*.

Finally, the SFSF model (Figure 5), which is in fact the beam-like structure, the influence of *a*/*b* does not exist, because only single (longitudinal) load-bearing direction is activated.

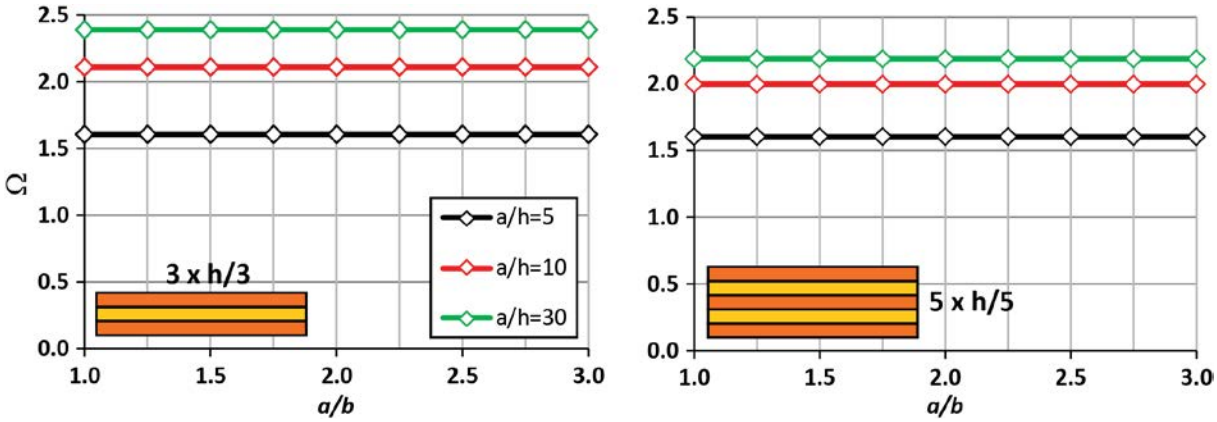

Figure 5: Frequency curves from FREEVIB for rectangular beam-like SFSF CLT panels (C24)

4 CONCLUSIONS

From the performed analyses and constructed frequency curves, some conclusions are derived:

- When calculating the fundamental frequencies of the SSSS panels, both the CLPT-based model [7] and the one based on proHolz recommendations [6] are insensitive to the change of *a/h* ratio, due to the simplifications of transverse shear deformation.
- The difference in Ω between these two models is higher for the 3- than for the 5-layers panels, because the influence of the cross layers is higher for the 3-layers case, which cannot be completely accounted for by using the relatively simple model from [6].
- On the contrary, FREEVIB results are accurately accounting for the transverse shear deformation. Therefore, the fundamental frequency expectedly decreases with the lower values of *a*/*h* (thick plate situation). When the *a*/*h* ratio approaches the slender panel limit, the obtained results from the FREEVIB converge to the CLPT solution.
- The increasing of the *a*/*b* ratio for the fixed *a*/*h*, results in the increased dimensionless frequency Ω for the SSSS panel. This scenario means that value for *b* is decreasing for the fixed values of *a* and *h*, which yields the higher frequency because of the fact that all sides are simply supported.
- The results from the CLT Handbook Canada [5] are not taking into account the *a/b* ratio, because they treat the panel as a 1m wide beam, simply supported on two sides, without any additional treatment of the transverse load-bearing mechanism.
- The FREEVIB also accurately predicts the fundamental frequencies of the CLT panels with non-classical boundary conditions. The lower *a/h* ratio expectedly yields the lower values of dimensionless frequencies. With increasing *a*/*b* for the fixed *a*/*h*, dimensionless frequencies are slightly increased.

Beside the presented analyses, FREEVIB [2] could be successfully applied for the 7-layers panels, as well as for the prediction of fundamental frequencies of panels with openings.

Abstract. *To study the dynamic performance of the composite box-girders with corrugated steel webs (CBGCSWs), three CBGCSWs with different cross-sections (single-cell, double-cell, and triple-cell cross-sections) were taken as the research objects respectively to study their dynamic characters. Considering the shear lag effect and the shear deformation of the corrugated steel webs, the governing differential equations and boundary conditions of the natural vibration were derived based on the energy variation principle and Hamilton principle. The theoretical natural flexural vibration frequencies of the CBGCSWs were obtained and compared with the numerical results by ANSYS software. A parametric analysis was conducted including the wave shape and the thickness of the corrugated steel web, the ratio of the section width to the calculating span B/L, and the ratio of the section height to the calculating span H/L. The results show that the shear lag effect and the shear deformation of the web have a great influence on the vertical flexural vibration of the CBGCSWs. The vertical flexural frequencies increase slightly with the increasing of B/L, the increasing of the web thickness, and the decreasing of the corrugated angle of the steel web, but apparently with the increasing of the height of the girder.*

1 INTRODUCTION

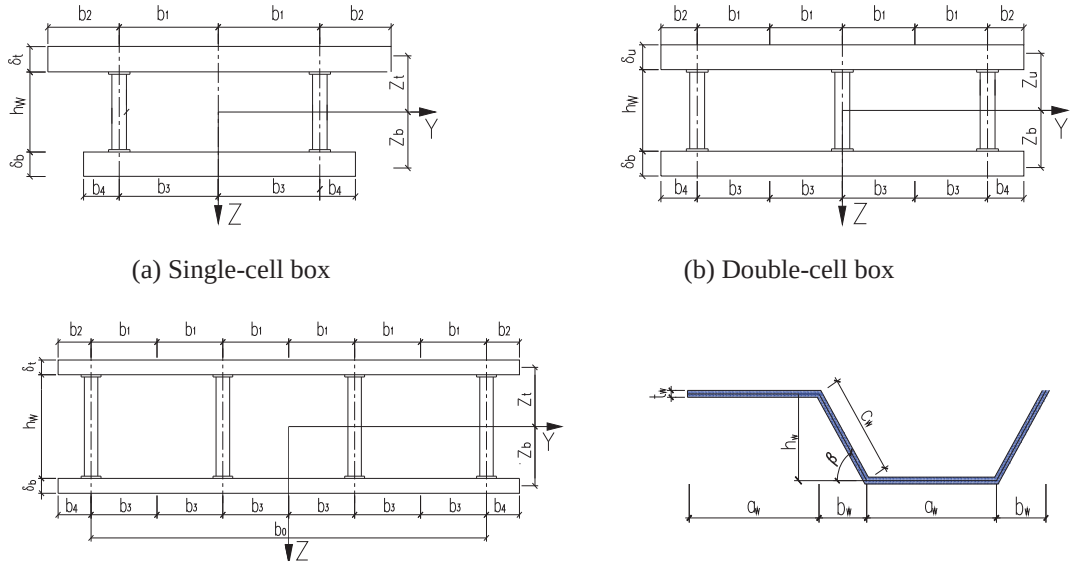
The composite box-girders with corrugated steel webs (CBGCSWs) have been used widely due to their great advantages such as lighter structural self-weight, faster construction speed, higher efficiency of prestressing, better solution for avoiding the problem of web cracking, and so on [1,2]. The static properties of the CBGCSWs including bending, shear, and torsional behaviors have been researched rather deeply at present [3-6]. There are also some studies on the dynamic performance of the CBGCSWs by using theoretical, numerical and experimental methods, but most of them were about the single-cell box section [7-11].

In this paper, a theoretical derivation about the vertical flexural vibration characters was performed on single-cell, double-cell, and triple-cell CBGCSWs respectively. The analytical solutions were compared with the numerical results by ANSYS software, and some key parameters were analyzed by using the theoretical model.

2 THEORETICAL ANALYSIS

2.1 Assumptions

The cross-sections and ordinate used in this paper are shown in figure.1, where b_1, b_3 are the half width of the top and bottom inner flanges, respectively; b_2, b_4 are the width of the top and bottom cantilever flanges, respectively; t_t, t_b are the thickness of the top and bottom flanges, respectively; h_w is the height of the steel girder; z_t, z_b are the distance from the top and bottom flanges to the gravity axis of the section, respectively.



(a) Single-cell box

(b) Double-cell box

(c) Triple-cell box

(d) Wave shape of the corrugated steel web

Figure 1: Cross-sections and ordinate.

The assumptions in the subsequent derivation are as follows:

(1) Both the corrugated steel web and the concrete flange are in the elastic stage and there is no relative slip between them.

(2) The section remains quasi-plane under flexural deformation.

(3) The flexural rigidity of the corrugated steel web is neglected. The bending moment is only resisted by the top and bottom concrete flanges, while the shear force is only resisted by the corrugated steel webs.

(4) Only the in-plane shear strain and the longitudinal normal strain of the concrete flanges are considered, the vertical and lateral normal strain in the concrete flanges and all of the out-plane shear strain are neglected, namely, $\varepsilon_x \neq 0$, $\varepsilon_y = \varepsilon_z = 0$, $\gamma_{xy} \neq 0$, $\gamma_{yz} = \gamma_{xz} = 0$.

2.2 Warp shape function of the shear lag

In the flexural vibration of the CBGCSWs, the longitudinal displacement in the cross-section is induced not only by the bending deformation which obeys the plane-section law, but also by the shear lag effect, so the generalized longitudinal dynamic displacement in the flexural vibration $U(x,y,t)$ can be expressed as follows,

$$U_{\mathrm{t(b)}}(x,y,t) = -z_{\mathrm{t(b)}} \cdot \varphi(x,t) + g(y)u(x,t) \tag{1}$$

Where the subscript t and b represent the top and bottom flanges respectively; $\varphi(x,t)$ is the dynamic slope in the bending deformation; $g(y)$ is the warp shape function of the shear lag; $u(x,t)$ is the dynamic displacement function of the maximum difference of the shear deformation in the concrete slab.

The cosine function is used for the warp function of the shear lag in this paper as follows,

$$g_i(y)=\begin{cases} -\alpha_1\left|\cos\dfrac{\pi y}{2b_1}\right| + D & \text{Top inner flange} \\ -\alpha_2 \cos\dfrac{\pi(|y|-ib_1-b_2)}{2b_2} + D & \text{Top cantilever} \\ -\alpha_3\left|\cos\dfrac{\pi y}{2b_3}\right| + D & \text{Bottom inner flange} \\ -\alpha_4 \cos\dfrac{\pi(|y|-ib_3-b_4)}{2b_4} + D & \text{Bottom cantilever} \end{cases} \tag{2}$$

Where i is the number of the cells, i=1,2,3⋯, and when i is an even number, the variable y in the top and bottom flanges should be replaced by $\bar{y}=|y|-b_1$; α_j (j=1,2,3,4) is the coefficient to consider the warp difference between the top and bottom flanges and can be given by,

$$\alpha_j = \frac{\left[l^2 + 8b_1^2(1+\nu)\right]}{\left[l^2 + 8b_j^2(1+\nu)\right]} \cdot \frac{b_j^2}{b_1^2} \cdot \beta \quad (j=1,2,3,4) \tag{3}$$

Where l is the calculating span; μ is the Poisson ratio; β is a coefficient, when j=1,2, β=1; and when j=3,4, $\beta=z_b/z_t$.

To satisfy the self-equilibrium condition of the axial force in the overall section, let $\int g(y)dA = 0$, then,

$$D=\left(\alpha_1 A_1 + \alpha_2 A_2 + \alpha_3 A_3 + \alpha_4 A_4\right) \Big/ \left(2\pi A_f\right) \tag{4}$$

Where A_f is the total area of the top and bottom flanges; A_1, A_3 are the areas of the top and bottom inner flanges, respectively; A_2, A_4 are areas of the top and bottom cantilevers.

2.3 Vibration equations

In the following derivation, the first, second and third-order partial derivatives of an arbitrary function $F(x,t)$ will be written as $F'(x,t)$, $F''(x,t)$ and $F'''(x,t)$ on the variable x, and $\dot{F}(x,t)$, $\ddot{F}(x,t)$ and $\dddot{F}(x,t)$ on the variable t.

(1) The dynamic flexural strain energy of the concrete flanges

From equation (1), the longitudinal dynamic normal strain of the flanges should be,

$$\varepsilon_{xt(b)}(x,y,t)=\frac{\partial U_{t(b)}(x,y,t)}{\partial x}=-z_{t(b)}\varphi'(x,t)+g(y)u'(x,t) \tag{5}$$

Then the total flexural dynamic strain energy of the top and bottom flanges can be given by,

$$\begin{aligned} V_{fb}(t)&=\frac{1}{2}\int_A t_t E_c \varepsilon_{xt}{}^2(x,y,t)dA+\frac{1}{2}\int_A t_b E_c \varepsilon_{xb}{}^2(x,y,t)dA \\ &=\frac{1}{2}E_c\int_0^l\left\{I_y[\varphi'(x,t)]^2+A_y[u'(x,t)]^2-2S_y\varphi'(x,t)u'(x,t)\right\}dx \end{aligned} \tag{6}$$

Where t_t, t_b are the thickness of the top and bottom flanges, respectively; E_c is the elastic module of concrete; I_y is the total inertia moments of the top and bottom flanges about the axis y, $I_y=\int_A z^2dA=z_t^2(A_1+A_2)+z_b^2(A_3+A_4)$; A_y is the total warp area of the shear lag of the top and bottom flanges, $A_y=\int_A g^2(y)\,dA=\sum_{j=1}^{4}\left(\alpha_j^2/2-4\alpha_j D/\pi+D^2\right)A_j$; S_y is the warp area moment of the shear lag, $S_y=\int_A zg(y)dA=z_t\sum_{j=1}^{2}A_j(D-2\alpha_i/\pi)+z_b\sum_{j=3}^{4}A_j(D-2\alpha_i/\pi)$.

(2) The dynamic shear strain energy of the concrete flanges induced by the shear lag

From equation (1), the dynamic shear strains of the flanges induced by the shear lag are,

$$\gamma_{ft(b)}(x,y,t)=\frac{\partial U_{t(b)}(x,y,t)}{\partial y}=g'(y)u(x,t) \tag{7}$$

Then the total dynamic shear strain energy of the top and bottom flanges can be given by,

$$V_{fs}(t)=\frac{1}{2}\int_A t_t G_c\gamma_{ft}(x,y,t)^2dA+\frac{1}{2}\int_A t_b G_c\gamma_{fb}(x,y,t)^2dA=\frac{1}{2}\int_0^l G_c k_u u^2(x,t)dx \tag{8}$$

Where G_c is the shear module of concrete, $G_c=E_c/[2(1+\nu_c)]$, ν_c is the Poisson ratio of concrete; k_u is the warp coefficient of the shear lag, $k_u=\int_A[g'(y)]^2dA$.

(3) The dynamic shear strain energy of the corrugated steel webs

The dynamic shear strain of the steel web is the difference between the first-order derivative of the vertical dynamic deflection $W(x,t)$ and the dynamic slope $\varphi(x,t)$ of the girder, namely, $\gamma_w(x,t)=W'(x,t)-\varphi(x,t)$, so the dynamic shear strain energy of the corrugated steel web can be given by,

$$V_w(t)=\int_0^l\frac{G_e A_s}{2}\gamma_w^2(x,t)dx=\frac{1}{2}\int_0^l G_e A_s\left[W'(x,t)-\varphi(x,t)\right]^2dx \tag{9}$$

Where G_e is the equivalent shear module of corrugated steel web due to the corrugation effect, $G_e=G_s(a_w+c_w)/(a_w+b_w)$, a_w, b_w, c_w are shown in figure 1; G_s the shear module of steel, $G_s=E_s/[2(1+\nu_s)]$, ν_s is the Poisson ratio of steel; A_s is the total shear area of the steel web.

(4) The total dynamic strain energy of the CBGCSWs

The total dynamic strain energy of the CBGCSWs $\Pi(t)$ is the summation of the $V_{fb}(x,t)$, $V_{fs}(x,t)$, and $V_w(x,t)$, namely,

$$\begin{aligned} \Pi(t)&=V_{fb}(t)+V_{fs}(t)+V_w(t)=\frac{1}{2}E_c\int_0^l\left\{I_y[\varphi'(x,t)]^2+A_y[u'(x,t)]^2-2S_y\varphi'(x,t)u'(x,t)\right\}dx \\ &+\frac{1}{2}\int_0^l G_c k_u u^2(x,t)dx+\frac{1}{2}\int_0^l G_e A_s\left[W'(x,t)-\varphi(x,t)\right]^2dx \end{aligned} \tag{10}$$

(5) The kinetic energy of the CBGCSWs

In the vertical flexural vibration, the kinetic energy of the CBGCSWs can be expressed as,

$$T(t)=\frac{1}{2}\int_0^l \dot{W}(x,t)^2\bar{m}dx \tag{11}$$

Where $\bar{m}$ is the mass of the girder per unit length, $\bar{m}=\rho_c A_f+\rho_s A_s$, ρ_c, ρ_s are the density of the concrete and the steel, respectively.

2.4 The solution of the vibration equations

According to the Hamilton principle, for a structure in elastic and small deformation state, in the time interval t_1 to t_2, only the real movement can make the first-order variation of the total energy function be zero, namely, $\delta\int_{t_1}^{t_2}\left[\Pi(t)-T(t)\right]dt=0$. Substitute equations (10) and (11) into it, the flexural vibration controlling differential equations and boundary conditions of the CBGCSWs can be obtained as follows,

$$\bar{m}\ddot{W}(x,t)+G_e A_s\left[\varphi'(x,t)-W''(x,t)\right]=0 \tag{12}$$

$$G_e A_s\left[\varphi(x,t)-W'(x,t)\right]+E_c S_y u''(x,t)-E_c I_y\varphi''(x,t)=0 \tag{13}$$

$$G_c k_u u(x,t)-E_c A_y u''(x,t)+E_c S_y\varphi''(x,t)=0 \tag{14}$$

$$E_c\left[I_y\varphi'(x,t)-S_y u'(x,t)\right]\delta\varphi\Big|_0^l=0 \tag{15}$$

$$\left[E_c A_y u'(x,t)-E_c S_y\varphi'(x,t)\right]\delta u\Big|_0^l=0 \tag{16}$$

$$G_e A_s\left[W'(x,t)-\varphi(x,t)\right]\delta W\Big|_0^l=0 \tag{17}$$

The vertical dynamic deflection $W(x,t)$ in flexural vibration of a simply supported girder can be expressed by,

$$W(x,t)=\sum_{n=1}^{\infty}W_n(x)\sin(\omega_n t+\alpha_n) \tag{18}$$

Where $W_n(x)$ is the vibration function of a simply supported girder, $W_n(x)=A_n\sin(n\pi x/l)$ [9], $(n=1、2、3、4.....\infty)$; ω_n is the circular frequency of the flexural vibration; α_n is the initial phase angle.

Substitute equation (18) into equation (12), (13), and (14), and consider $\sin(\omega_n t+\alpha_n)$ will not always be zero, therefor,

$$\begin{aligned}&\bar{m}\omega_n^2\left[G_e G_c A_s k_u W_n(x)-E_c\left(G_c k_u I_y+G_e A_s A_y\right)W_n''(x)+E_c^{\,2}\left(I_y A_y-S_y^2\right)W_n^{(4)}(x)\right]\\&=G_e G_c A_s k_u E_c I_y W_n^{(4)}(x)+E_c^{\,2}G_e A_s\left(I_y A_y-S_y^2\right)W_n^{(6)}(x)\end{aligned} \tag{19}$$

From equation (19), the circular frequency of the flexural vibration can be obtained as,

$$\omega_n=\beta_n\left(\frac{n\pi}{l}\right)^2\sqrt{\frac{E_c I_y}{\bar{m}}} \tag{20}$$

$$\beta_n=\frac{\sqrt{1+\left(\frac{n\pi}{l}\right)^2\frac{E_c\left(S_y^2-I_y A_y\right)}{G_c k_u I_y}}}{\sqrt{1+\left(\frac{n\pi}{l}\right)^2\frac{E_c I_y}{G_e A_s}+\left(\frac{n\pi}{l}\right)^2\frac{E_c A_y}{G_c k_u}+\left(\frac{n\pi}{l}\right)^4\frac{E_c^{\,2}\left(I_y A_y-S_y^2\right)}{G_e G_c A_s k_u}}} \tag{21}$$

$$f_n=\omega_n/2\pi \tag{22}$$

From equation (21) it can be seen, when the shear lag effect and the shear deformation of the web are neglected, the coefficient β_n=1, and ω_n, f_n will be the solutions of a Euler-Bernoulli beam.

3 EXAMPLES

3.1 Analytical Solutions

The flexural natural frequencies of three 4.4m-span simply-supported CBGCSWs with single-cell, double-cell, and triple-cell cross-sections respectively are calculated herein. The sections of each girder are shown in figure 1, and the dimensions and some sectional characters are shown in table 1. For each girder, the concrete is C40 with an elastic modular of E_c=3.25×10^{4}MPa, a Poisson ratio of v_c=0.1667, and a shear modular of G_c=1.39×10^{4}MPa; the steel web is Q235 with an elastic modular of E_s=2.06×10^{5}MPa, a Poisson ratio of v_s=0.3, a shear modular of G_s=7.92×10^{4}MPa and an equivalent shear modular of G_e=9.81×10^{4}MPa. The wave shape of the corrugated steel web shown in figure 1 is same for each girder, with a h_w of 200mm, a a_w of 64mm, a b_w of 24mm, and a c_w of 45mm.

Section	b_1	b_2	b_3	b_4	t_t	t_b	I_y	A_y	S_y	k_u	$\bar{m}$
	(mm)						(10^9mm^4)	(10^4mm^2)	(10^7mm^3)		(g/mm)
Single-cell	400	200	400	100	80	80	2.15	6.23	0.90	3.90	332.38
Double-cell	400	100	400	100	80	80	3.14	6.50	1.14	4.20	493.68
Triple-cell	400	100	400	100	80	80	4.39	9.70	1.71	6.17	696.57

Table 1: Dimensions and some sectional characters of the examples.

From equations (20)-(22), the flexural natural frequencies can be obtained in table 2.

Section	f_{1E}(Hz)	ω_1	f_1(Hz)	error	f_{2E}(Hz)	ω_2	f_2(Hz)	error
Single-cell	38.32	208	33.18	13.4%	153.30	632	100.67	34.3%
Double-cell	37.97	207	32.99	13.1%	151.90	631	100.52	33.8%
Triple-cell	37.83	205	32.69	13.6%	151.31	622	99.02	34.6%

Note: f_{1E} and f_{2E} are the frequencies of a Euler beam with the same section and dimensions with the CBGCSWs.

Table 2: Flexural natural frequencies of the examples.

From table 2 it can be seen,

- There is little difference among the vertical flexural frequencies of the three girders, which is because the vertical flexural frequency is mainly influenced by the flexural rigidity and the mass of the girder by increasing with the former and decreasing with the latter. With the larger of the cell number, the increasing magnitude of the mass is a little higher than that of the flexural rigidity, so the vertical flexural frequencies have no increase but a little decrease.
- There are great errors between the solutions of the Euler-Bernoulli beam and the results of equation (22), which means the shear lag effect and the shear deformation of the web have a great influence on the vertical flexural vibration of the CBGCSWs.

3.2 Comparison with numerical results

The FE models of the three examples were built by using ANSYS software. The concrete flanges were simulated by element solid65, and the steel webs were simulated by element shell63. The Multipoint Constrain function was employed to realize the connection between the concrete flanges and the steel webs. The natural vertical flexural frequencies and the comparison between the theoretical and numerical results are shown in table 3.

Section	The first-order			The second-order		
	$f_{theoretical}$(Hz)	$f_{numerical}$(Hz)	error(%)	$f_{theoreticla}$(Hz)	$f_{numerical}$(Hz)	error(%)
Single-cell	33.18	30.66	-7.59	100.67	92.03	-8.58
Double-cell	32.99	30.2	-8.45	100.52	90.19	-10.27
Triple-cell	32.69	29.14	-10.8	99.02	87.14	11.99

Table 3: Comparison between the theoretical and numerical results.

From table 3 it can be seen that the numerical results are satisfied well with the theoretical solutions with the errors all below 5%, which can prove the correction of the analytical derivation process and the FE model.

4 PARAMETRIC ANALYSIS

Based on the theoretical and FE model, a parametric analysis including the wave shape and the thickness of the corrugated steel web, the ratio of the section width to the calculating span *B*/*L*, and the ratio of the section height to the calculating span *H*/*L* were performed.

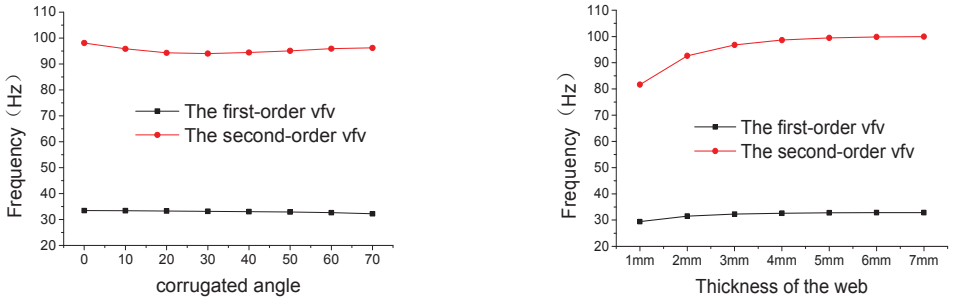
4.1 The wave shape and the thickness of the corrugated steel web

Based on the section and dimension of the double-cell CBGCSWs, remain a_w=64mm and b_w=24mm in figure 1(d) and change c_w and d_w of the corrugated steel web to the values shown in table 4, then the first and second-order vertical flexural frequencies are shown in figure 2(a).

Based on the double-cell CBGCSWs, change the web thickness to 1mm, 2mm, 3mm, 4mm, 5mm, 6mm and 7mm, then the results can be obtained and shown in figure 2(b).

Corrugated angle β（°）	0	10	20	30	40	50	60	70
c_w（mm）	24.0	24.3	25.7	27.3	31.2	36.9	48.4	69.3
d_w（mm）	0	4	9	13	20	28	42	65

Table 4: Dimensions of the corrugated steel web.



(a) Wave shape (b) Thickness

Figure 2: Effect of the wave shape and the thickness of the corrugated web.

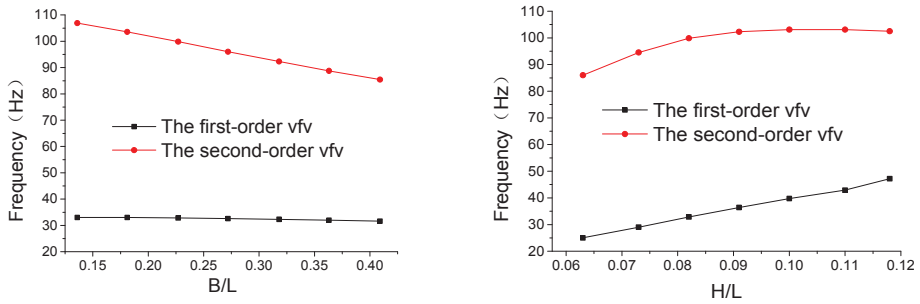
From figure 2 it can be seen that,

- The largest vertical flexural frequency appears when the corrugated angle β=0 (namely, straight web), and then with the increase of β, the frequencies decrease slightly, which means the larger of the β, the smaller of the axial rigidity of the steel webs and subsequently the flexural rigidity of the CBGCSWs.
- The vertical flexural frequencies increase with the web thickness, but the increasing magnitude is small, especially for the first-order one, which means that the vertical flexural rigidity is mainly supplied by the top and bottom concrete flanges, and only increasing the web thickness cannot improve the vertical flexural rigidity apparently.

4.2 The ratio of the section width to the calculating span *B*/*L* and the ratio of the section height to the calculating span *H*/*L*

Based on the section and dimension of the double-cell CBGCSWs, change the width of the flange to 0.6m, 0.8m, 1.0m, 1.2m, 1.4m, 1.6m and 1.8m (*W*/*L*=0.136, 0.181, 0.227, 0.272, 0.318, 0.363, and 0.409, respectively), then the results are shown in figure 3(a).

Also based on the double-cell CBGCSWs, change the height of the section to 0.28m, 0.32m, 0.36m, 0.40m, 0.44m, 0.48m and 0.52m (*H*/*L*=0.063, 0.073, 0.082, 0.091, 0.100, 0.110, and 0.118, respectively), then the results are shown in figure 3(b).



(a) *B*/*L* (b) *H*/*L*

Figure 3: Effect of *B*/*L* and *H*/*L* on the natural frequencies of the CBGCSWs.

From figure 3 it can be seen that,

- The vertical flexural frequencies decrease with the increasing of *B*/*L* due to the increasing magnitude of the mass exceeding that of the vertical flexural rigidity;
- The flexural frequencies increase with the increasing of *H*/*L* in a linear tendency for the first-order one and a curved tendency for the second-order one, which means the height of the section is a predominant factor to enlarge the vertical flexural rigidity of the girder.

5 CONCLUSIONS

- The shear lag effect and the shear deformation of the web have a great influence on the vertical flexural vibration of the CBGCSWs.
- There is little difference among the vertical flexural frequencies of the single-cell, double-cell, and triple-cell CBGCSWs due to the increasing magnitude of the mass exceed-

ing that of the vertical flexural rigidity, and for the same reason, the vertical flexural frequencies decrease with the increasing of *B*/*L*.

- The vertical flexural rigidity is mainly supplied by the top and bottom concrete flanges, and only increasing the web thickness or reducing the corrugated angle cannot improve the vertical flexural rigidity apparently.
- The height of the section is a predominant factor to enlarge the vertical flexural rigidity of the girder.

Keywords: Composite, Metamaterial, Elastodynamics, Elliptic fibers.

Abstract. *The paper presents the study of elastic composites acting as resonant metamaterials. The composites are made of long fibers of elliptic cross section. The condition for obtaining resonant metamaterials is presented in the context of homogenization by using asymptotic expansion. It is shown that inner resonance occurs in the case of soft inclusions embedded within a stiffer matrix, both components having mass densities of the same order of magnitude. The localization problem coming from the asymptotic expansion is solved in the case of fibers with elliptic cross sections, leading to the dynamic density of the material. The dynamic density is characterized by resonance frequencies and the related eigenfunctions of the inclusions, that are obtained by using an expansion along Mathieu functions. The method allows us to obtain the (orthotropic) dynamic density related to various cases of elliptic cross section, recovering the extreme cases of circular cross-sections and nearly plate inclusions.*

1 INTRODUCTION

Numerous works were performed during the last decades on metamaterials, firstly in the field of electromagnetism and more recently in the field of acoustics. This field of research can be traced back to 1968 paper of Veselago [1] on electromagnetism, as explained in [2]. There are different ways to produce acoustic metamaterials and this work is restricted to inclusion-matrix elastic composites.

This work rests on results obtained by asymptotic homogenization in elastodynamics. Homogenization methods extending the ones used in elastostatics have been indeed used since a few decades[3]. These methods produce two kinds of effective behaviours:

- When the elastic properties of constituents are of the same order within the composite, the effective behaviour is essentially non local in space: this is characterized by effective parameters expressed with the use of wave vectors and this type of behaviour is often studied by using Bloch waves.

- For composites containing soft and massive inclusions, the dynamic behaviour is characterized by inner resonance. The effective properties are local in space, but some effective physical parameters, the components of the "effective dynamic density" are frequency dependent: the behaviour is non-local in time[4, 5].

This work produces results on a locally resonant fiber-matrix composite containing fibers of elliptic cross section. In a first step, we recall the results of homogenization theory showing the conditions to produce locally resonant inclusion matrix composites and the general expression of the dynamic density induced by the inner resonators. This expression uses the resonance frequencies of the inclusions and the participation factors of each resonance frequency. In a second step, a fiber-matrix composite containing elastic fibers is studied. The resonance frequencies within the elastic fibers are produced for different components of the motion at the macroscopic scale. Finally, it is shown that the metamaterial is in fact an acoustic polarizer: it allows us to cancel preferentially some components of the dynamic motion around specific frequencies.

2 CONDITIONS FOR INNER RESONANCE

One considers a periodic composite containing two species: matrix ($s = m$) and inclusions ($s = i$), each phase being characterized by Lamé coefficients $\lambda_{(s)}, \mu_s, s = m, i$ and densities $\rho_{(s)}$. The dynamic equation in each phase is given for an harmonic motion by

$$\mathbf{div}(\boldsymbol{\sigma}_{(s)}) + \rho_{(s)}\omega^2\mathbf{u}_{(s)} = 0, \tag{1}$$

where $\boldsymbol{\sigma}_{(s)}$ is the stress tensor, $\mathbf{u}_{(s)}$ the displacement field and ω the radial frequency. The components $\sigma_{ij(s)}$ of the stress tensor are related to the components of linearized strain tensor $\epsilon_{ij(s)}$ by

$$\sigma_{ij(s)} = 2\mu_{(s)}\epsilon_{ij(s)} + \lambda_{(s)}\epsilon_{kk(s)}\delta_{ij}. \tag{2}$$

Homogenization theory can be used if the size of the periodic cell l is small compared with the size L of the composite volume under consideration, allowing us to introduce the scaling factor $\varepsilon = l/L$. As shown in [4], the inner resonance occurs when the elasticity parameters comply with the following condition:

$$\frac{\lambda_{(i)} + 2\mu_{(i)}}{\lambda_{(m)} + 2\mu_{(m)}} = O(\varepsilon^2), \tag{3}$$

$\rho_{(m)}$ and $\rho_{(i)}$ being of the same order.

Under these conditions and if the radial frequency leads to a wavelength within the matrix being of order of L, the material has an effective behaviour characterized by a (static) effective elasticity tensor obtained by considering that the inclusions are void (negligible elasticity tensor of the inclusions) and a dynamic density $\rho_{eff}(\omega)$ obtained by studying the displacement within the inclusion.

The relative displacement $\mathbf{w} = \mathbf{u}_{(i)} - \mathbf{u}_{(m)}$ within the inclusion is obtained from the solution of

$$\begin{aligned} \mu_{(i)}\mathbf{\Delta w} + (\lambda_{(i)} + \mu_{(i)})\mathbf{grad}(div(\mathbf{w})) + \rho_{(i)}\omega^2\mathbf{w} \\ = -\rho_{(i)}\omega^2\mathbf{u}_{(m)}, \end{aligned} \tag{4}$$

its value being null at the boundary between matrix and inclusion. The displacement $\mathbf{u}_{(m)}$ of the matrix around the inclusion is considered as nearly constant, its fluctuations being negligible due to the large stiffness of the matrix.

Due to the homogeneous boundary condition, the solution of this problem can be obtained from the related eigenfunctions and eigenvalues. For a periodic cell with three planes of symmetry, the dynamic density is a second order diagonal tensor in the axes of symmetry and its components are given by :

$$\rho_{jj(eff)} =< \rho > +n_{(i)}\rho_{(i)}h_{jj}, \tag{5}$$

where the components h_{jj} are given from the radial eigenfrequencies $\omega_p, p = 1..\infty$ by:

$$h_{jj}(\omega) = \sum_{p=1}^{\infty} K_{jj}^p \frac{\omega^2}{\omega_p^2 - \omega^2}, \tag{6}$$

K_{jj}^p being the participation factors obtained from the eigenfunctions $\mathbf{u}^p$ by:

$$K_{jj}^p = \frac{(< \mathbf{u}^p >_{(i)} .\mathbf{e}_j)^2}{< ||\mathbf{u}^p||^2 >_{(i)}}, \tag{7}$$

$\mathbf{e}_j$ being the unit coordinate vectors.

In theory, the sum in the previous expression is infinite. However, the only acceptable frequency contents of the waves crossing the composite are those complying with the condition for the wavelength in the matrix to be large compared with the size of the cell. Therefore, the sum must be restricted to the eigenfrequencies meeting this condition. The eigenfunctions are obtained for the three directions $j = 1, 2, 3$ of the macroscopic acceleration. For each direction of $\mathbf{e}_j$, one obtains a set of eigenfunctions and eigenvectors characterized by a specific symmetry, the three sets being independent.

3 SOLUTION BY SEPARATION OF VARIABLES FOR ELLIPTIC FIBERS

The solution by separation of variables is used to obtain the eigenfrequencies and eigenfunctions in cylinders of elliptic cross section, as shown in Fig. 1.

3.1 LONGITUDINAL MOTION

For a longitudinal motion, the motion is antiplane with $\mathbf{w} = w_3\mathbf{e}_3$, where w_3 is solution of

$$\mu\Delta w_3 + \rho\omega^2 w_3 + f_3 = 0, \tag{8}$$

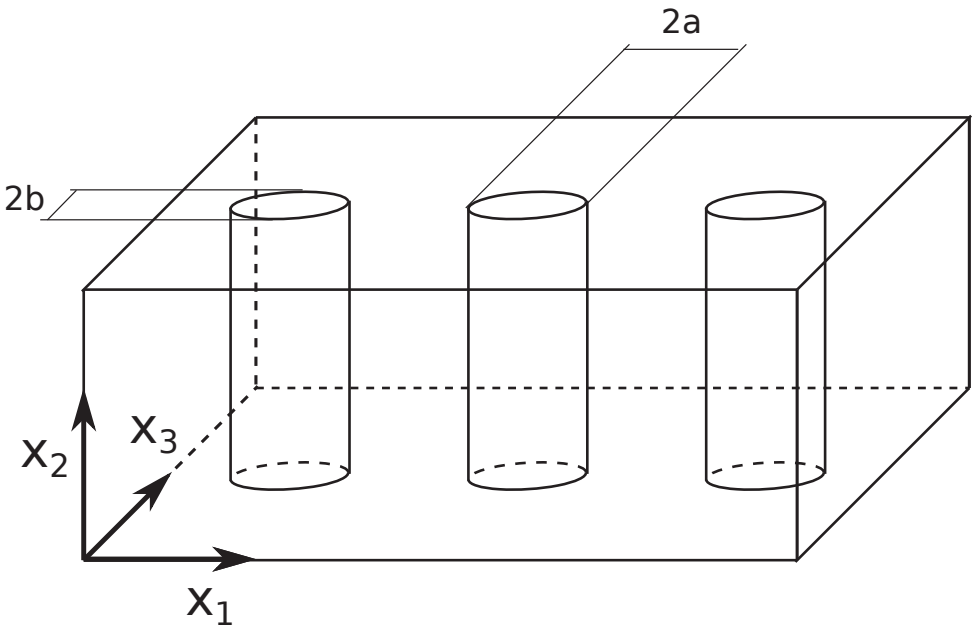

Figure 1: Geometry of the composite: fibers with elliptic cross section characterized by radii a and b.

where $\mu = \mu_{(i)}, \rho = \rho_{(i)}, f_3 = \rho_{(i)}\omega^2 u_{3(m)}$. The motion is characterized by the celerity of shear waves $v_s = \sqrt{\mu/\rho}$ within the inclusions. For an elliptic cross-section, the separation of variables is achieved by using $x_1 = c\cosh\xi\cos\eta, x_2 = c\sinh\xi\sin\eta$. ξ is the radial coordinate ($0 \leq \xi < \infty$) and η is the angular coordinate ($0 \leq \eta < 2\pi$), $2c$ being the focal length of the ellipse. For the interior of the ellipse, ξ is restricted to $\xi \leq \xi_e$, where ξ_e corresponds to points located on the elliptic contour. Taking into account that w_3 must be symmetric with respect to $0x_1$ and $0x_2$, the solution in elliptic coordinates is given by:

$$w_3(\eta,\xi) = \sum_{p=0}^{\infty} D_p ce_{2p}(\eta, q_s) Mc_{2p}(\xi, q_s) \tag{9}$$

where D_p are constant, ce_{2p} are Mathieu functions characterized by the previously defined symmetry, Mc_{2p} are the related radial Mathieu functions. q_s is function of the wave number $k_s = \omega/v_s$ given by: $q_s = \frac{1}{4}c^2k_s^2$. Mathieu functions are obtained under the form of Fourier series

$$ce_{2m}(\eta, q_s) \quad = \quad \sum_{r=0}^{\infty} A_{2r}^{(2m)}(q_s)\cos 2r\eta$$

where the Fourier coefficients $A_{2r}^{(2m)}(q_s)$ are functions of q_s. Obtaining these coefficients has been the subject of numerous works. A finite set of these coeffficients can be obtained by computing the eigenvalues and eigenvectors of a matrix function of q_s[6]. Then, the radial Mathieu functions Mc_{2p} are also expressed by using the set of Fourier coefficients. A recent work [7] gives the best way to obtain the set of Fourier coefficients. Using the orthogonality property of Mathieu functions and the boundary condition allows us to compute the eigenfunctions by solving: $Mc_{2p}(\xi_e, q_s) = 0$ for different values of p. This gives a set of values of q_s which provide the set of eigenfrequencies. Then, the eigenfunction related to each eigenfrequency is $ce_{2p}Mc_{2p}$, which provides the related participation factor.

3.2 TRANSVERSAL MOTION

For a transversal motion, the solution is given by a plane displacement in plane x_1, x_2. It is obtained by decomposition into scalar and vector potentials φ, $\mathbf{\Psi}$ by $\mathbf{u} = \mathbf{grad}\varphi + \mathbf{curl}\mathbf{\Psi}$, with $\mathbf{\Psi} = \psi.\mathbf{e}_3$. Both potentials φ, ψ can be again expanded along Mathieu functions, using q_p for φ and q_s for ψ. This leads to an expression of the displacement from Mathieu functions and their derivatives. The eigenfunctions are again obtained by the homogeneous boundary condition along the elliptic contour and the participation factors are given by a suitable integration within the contour.

4 NUMERICAL RESULTS

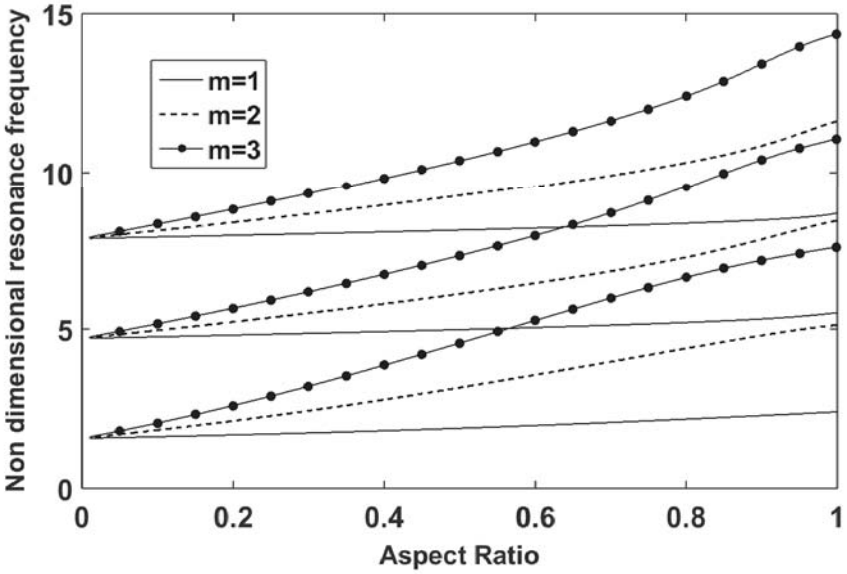

Figure 2: Resonance frequencies for a longitudinal motion as a function of the aspect ratio: modes related to the first three eigenfrequencies for Mathieu functions of first three orders ($m = 1, 2, 3$).

For the longitudinal motion, the solution does not involve compressional waves. As a consequence, the eigenfrequencies are functions of the shear modulus μ and of the radii a and b of the fibers. All results can be expressed by looking for the non-dimensional resonance frequency $\omega^{(p)*} = b\omega/v_s$ as a function of the aspect ratio $f = b/a$. The length introduced into the non dimensional frequency is the smaller radius b of the ellipse. The aspect ratios related to decreasing values of f correspond to ellipses of the same smaller radius and increasing values of the larger radius.

As explained previously, the modes related to Mathieu functions of different orders are decoupled. So, for each value of order m, one can find a set of eigenfrequencies which cancel the value of the radial Mathieu function at the surface of the fiber.

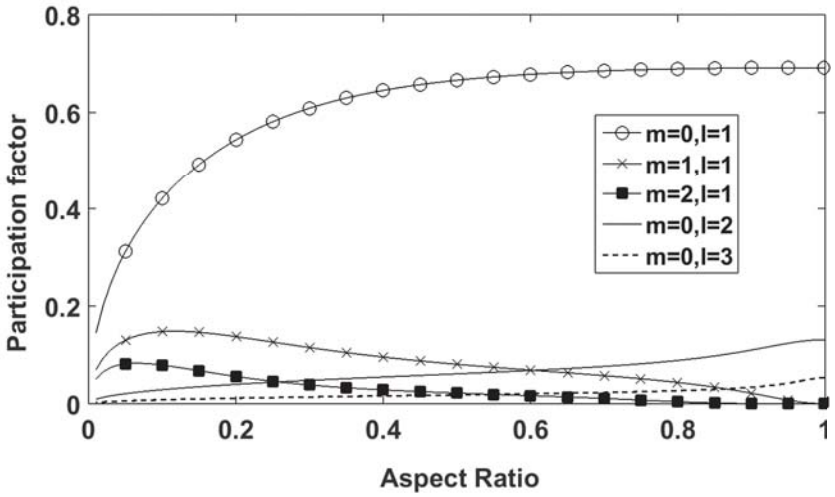

Figure 3: Participation factors for a longitudinal motion as a function of the aspect ratio: modes related to the 9 cases of Fig. 2 which have a significant contribution.

Fig. 2 presents the first three eigenfrequencies related to the first three values of m. It has been checked that, for the limit case of circular cross sections ($f = 1$), the results recover the values of eigenfrequencies for $m = 1$ obtained in [8]. In the case of circular fibers, the solution is expressed by using Bessel functions J_{2m}. The values for $m > 1, f = 1$ recover also the ones obtained for circular fibers and higher indices of Bessel functions. The limit case of small aspect ratio is also of interest. It can be seen that the first eigenfrequencies for $m = 0, 1, 2$ tend to $\pi/2$ while the second (resp. third) eigenfrequencies tend to $3\pi/2$ (resp.$5\pi/2$), these limit values correspond to the case of very flat fibers, whose eigenfunctions can be obtained explicitly. All eigenfrequencies increase with f, due to the fact that the section of the ellipse decreases with f when b is constant.

The participation factors that have a significant contribution related to the eigenfrequencies of Fig. 2 are reported in Fig. 3. It can be seen for almost circular sections that the participation factors are null for $m > 0$ and are not null for $m = 0$, which corresponds to the results obtained in [8]. However, the curves show that the participation factors increase for smaller aspect ratios, the contribution for the first eigenfrequencies related to $m > 0$ becoming significative. In the case of transversal motion, along x_1 or x_2, the results (not reported here) are functions of compressional and shear waves, v_p and v_s and therefore functions of the Poisson's ratio.

As explained in the previous section, the components of the dynamic density are negative near the resonance frequencies. As an example, the three components of dynamic density are reported in Fig. 4 for a composite containing fibers of plastified PVC ($E_i = 112MPa, \nu_i = 0.38, \rho_i = 1500kg/m^3$) within an aluminium matrix ($E_m = 72GPa, \nu_m = 0.34, \rho_m = 2500$). The three stopping bands sb_i corresponding to the first

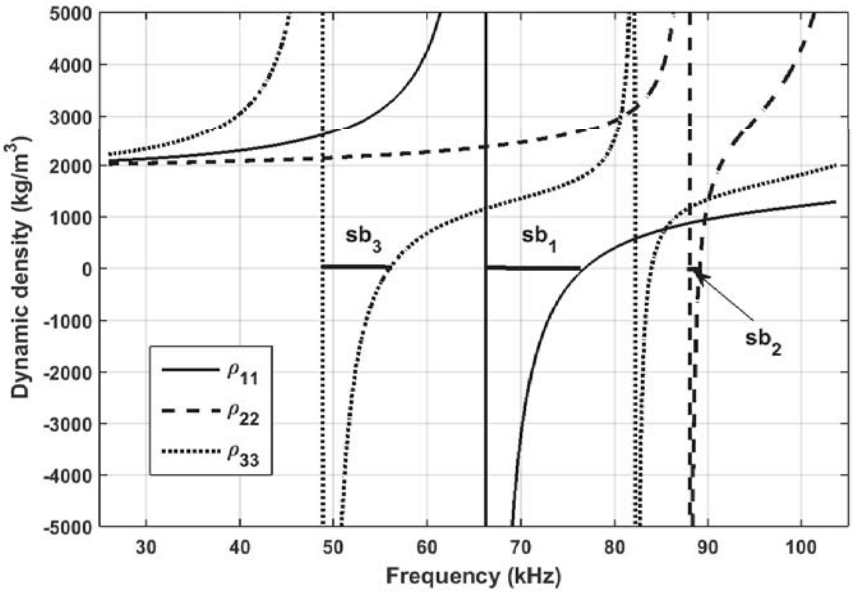

Figure 4: The three components of dynamic density for a composite of aluminium matrix and PVC fibers with an aspect ratio of 0.5. The first stop band for each direction i is reported by sb_i

eigenfrequencies along the three directions are distinct contrarily to the case of cylindrical fibers (2 identical stopping bands) or spherical inclsions (3 identical stopping bands. It means that one of the components of motion for plane waves crossing the composite is cancelled: the composite acts as a full polarizer, as do the well known linear optical polarizers.

5 CONCLUSIONS

The conditions for inclusion matrix composites to produce inner resonance have been recalled: the elasticity constants of inclusions must be significantly smaller than the ones of the matrix, the densities of both components being of the same order. In this case, the dynamic density is a function of the resonance frequency of the inner inclusions and of the eigenfunctions obtained at resonance. The dynamic density becomes negative near each eigenfrequency and the effect of the related eigenfunction on the dynamic density is characterized by a participation factor. A composite containing soft elliptic fibers embedded within a significantly stiffer matrix has been studied. The dynamic motion within the fiber is studied by using Mathieu functions and the eigenfrequencies and eigenfunctions were computed. For this configuration, the dynamic density is orthotropic, the motion along the three axes being characterized by components of the dynamic densities that are

all different, which is not the case for spherical inclusions or circular cylindrical fibers. As a consequence, the composite acts as a polarizer, which can extinct one component of the motion near the related eigenfrequency.

A TWO MODE NON-UNIFORM APPROXIMATION FOR AN ELASTIC ASYMMETRIC SANDWICH

Mohammed Alkinidri, Julius Kaplunov, and Ludmila Prikazchikova

Keele University
Staffordshire, UK, ST5 5BG
e-mail: m.o.s.alkinidri@keele.ac.uk, j.kaplunov@keele.ac.uk, l.prikazchikova@keele.ac.uk

Keywords: Asymptotic, contrast, laminate, two-mode, wave, non-uniform.

Abstract. *An elastic asymmetric sandwich is considered under the assumption that the stiffness and density of thin skin layers are much greater than those of a core layer. It is shown that for typical values of problem parameters the lowest shear resonance frequency appears to be asymptotically small, while the rest of thickness resonances do not belong to a low-frequency range. As an example, a scalar antiplane problem in linear elasticity is studied. A polynomial long-wave low-frequency approximation of the full dispersion relation is derived. It governs two vibration modes including the fundamental one and the lowest harmonic. Without asymmetry the dispersion relation splits into two parts corresponding to symmetric and antisymmetric modes [1], simplifying analysis drastically. It is remarkable that for the chosen set of problem parameters the derived approximation is not asymptotically uniform and is only valid over narrow non-overlapping vicinities of zero and the lowest shear thickness resonance frequencies. This is in contrast to the earlier considered setup of a similar laminate with the thick skin layers, for which the associated asymptotic behaviour is uniform [2]. The same observation is also true for in-plane motion of a symmetric laminate, see [3] for further detail.*

1 Introduction

Asymmetric sandwich plates become increasingly important as components of ultra-light multifunctional structures in various fields of engineering, see for example [4, 5, 6] and references therein. Many of these structures might also demonstrate high contrast in material and geometric properties of the layers, for example lightweight photovoltaic panels [7] and new models of windscreens [8].

Asymptotic analysis of an asymmetric sandwich structure with a light core and stiff skin layers is conducted in [2] for anti-plane shear motion. As shown in this paper, an additional small cut-off frequency might arise depending on the choice of the contrast material parameters of the layers. A two-mode long-wave asymptotic approximation, constructed in [2] is uniform, i.e. valid for the whole low-frequency range. At the same time, despite the presence of a small cut-off frequency, it might not always be the case. There are some setups of contrasting problem parameters resulting in non-uniform asymptotic behaviour, e.g. see [3] considering a plane problem for a symmetric sandwich plate. In this case, the associated asymptotic behaviour appears to be composite, i.e. it is valid only over narrow non-intersecting vicinities of zero and lowest cut-off frequencies. The concept of composite expansions is based on tackling limiting cases only without a special care of the less important intermediate region, e.g. see [10] and [11]. Recently, composite wave models have been constructed for thin and periodic structures in [12, 13, 14]. An asymptotic methodology for three-layered plates with contrast parameters of the layers was earlier adapted in [15] mainly concerned with static deformation. Among the publications on the subject, we also mention [16, 17, 18, 19, 20].

In this paper we investigate the anti-plane problem for a three-layered asymmetric plate with very light core layer and stiff thin skin layers of different thickness. A two-mode long-wave low-frequency approximation of the exact dispersion relation is constructed and shown to be non-uniform. The asymptotic results are compared with the exact solution.

2 Statement of the problem

Consider a three-layered asymmetric elastic laminate, comprised of isotropic layers of thickness h_l, $l = 1, 2, 3$, see Figure 1. The axis x_1 of the Cartesian coordinate system passes through the mid-plane of the core layer, while the axis x_2 is orthogonal to the mid-plane. For the sake of simplicity we assume that the two outer layers have the same material parameters.

Consider antiplane shear motion, for which the only non-zero displacement component is orthogonal to the plane x_1x_2. The equations of motion for each of the layers is then given by

$$\Delta u_l - \frac{1}{c_{2l}^2}\frac{\partial^2 u_l}{\partial t^2} = 0, \qquad l = 1, 2, 3, \tag{1}$$

where $\Delta = \partial^2/\partial x_1^2 + \partial^2/\partial x_2^2$ is the Laplace operator, $u_l = u_l(x_1, x_2, t)$ are out of plane displacements, t is time, and

$$c_{2l} = \sqrt{\frac{\mu_l}{\rho_l}},$$

are the shear wave speeds, with μ_l and ρ_l standing for the Lamé elastic moduli and volume mass densities, respectively. As mentioned above, $\mu_1 = \mu_3$ and $\rho_1 = \rho_3$.

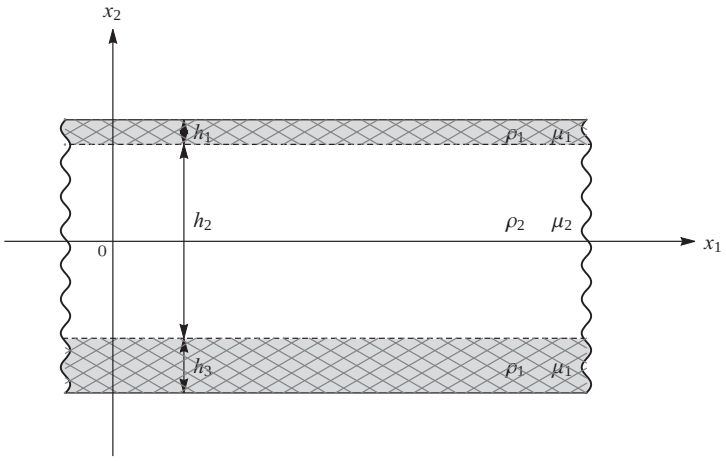

Figure 1: A three-layered asymmetric laminate

For traction-free faces and perfect bonding between the layers, the dispersion relation may be derived in the form

$$\mu\alpha_1\alpha_2\big(\tanh(h_{12}\alpha_1)+\tanh(h_{32}\alpha_1)\big)+\mu^2{\alpha_2}^2\tanh(\alpha_2)+ \\ +{\alpha_1}^2\tanh(h_{12}\alpha_1)\tanh(h_{32}\alpha_1)\tanh(\alpha_2)=0 \tag{2}$$

where

$$\alpha_1=\sqrt{K^2-\frac{\mu}{\rho}\Omega^2},\qquad \alpha_2=\sqrt{K^2-\Omega^2}$$

and

$$K=kh_2,\quad \Omega=\frac{\omega h_2}{c_{22}},\quad \mu=\frac{\mu_2}{\mu_1},\quad \rho=\frac{\rho_2}{\rho_1},\quad h_{12}=\frac{h_1}{h_2},\quad h_{32}=\frac{h_3}{h_2}.$$

3 Asymptotic approach

Consider an asymmetric laminate of a sandwich type, with the outer layers being stiff, thin and very heavy compared to the inner core layer. Hence, the ratio of parameters in the layers are taken as

$$\mu\ll 1,\quad \rho\sim\mu^2,\quad h_{12}\sim\mu,\quad h_{32}\sim\mu. \tag{3}$$

Setting K = 0 in (2) we obtain as expected $\Omega=0$, and also a small non-zero cut-off frequency given by

$$\Omega_{sh}\approx\sqrt{\frac{(h_{12}+h_{32})\rho}{h_{12}h_{32}}}\sim\sqrt{\mu}\ll 1. \tag{4}$$

Next, expanding the trigonometric functions in (2) in Taylor series about $\Omega=K=0$ and assuming (3), an approximate polynomial dispersion relation may be obtained in the form

$$\gamma_1K^2+\gamma_2\Omega^2+\gamma_3K^4+\gamma_4K^2\Omega^2+\gamma_5\Omega^4+\gamma_6K^6 \\ +\gamma_7K^4\Omega^2+\gamma_8K^2\Omega^4+\gamma_9\Omega^6+\cdots=0, \tag{5}$$

where the coefficients γ_i, $i=1,2,\ldots 9$ have been presented in [2] (cf. formula [14] in the cited paper).

Now, in view of (3), leading order coefficients γ_i become

$$\begin{aligned}
\gamma_1 &= \gamma_1^0\mu^2, \qquad & \gamma_1^0 &= 1 + h_{12}^0 + h_{32}^0,\\
\gamma_2 &= \gamma_2^0\mu + O\left(\mu^2\right), \qquad & \gamma_2^0 &= -\frac{h_{12}^0 + h_{32}^0}{\rho_0},\\
\gamma_3 &= \gamma_3^0\mu^2 + O\left(\mu^4\right), \qquad & \gamma_3^0 &= h_{12}^0 h_{32}^0 - \frac{1}{3},\\
\gamma_4 &= \gamma_4^0\mu + O\left(\mu^2\right), \qquad & \gamma_4^0 &= -\frac{2h_{12}^0 h_{32}^0}{\rho_0},\\
\gamma_5 &= \gamma_5^0 + O\left(\mu^2\right), \qquad & \gamma_5^0 &= \frac{h_{12}^0 h_{32}^0}{\rho_0^2},\\
\gamma_6 &= \gamma_6^0\mu^2 + O\left(\mu^4\right), \qquad & \gamma_6^0 &= \frac{2}{15} - \frac{h_{12}^0 h_{32}^0}{3},\\
\gamma_7 &= \gamma_7^0\mu + O\left(\mu^2\right), \qquad & \gamma_7^0 &= \frac{2h_{12}^0 h_{32}^0}{3\rho_0},\\
\gamma_8 &= \gamma_8^0 + O\left(\mu\right), \qquad & \gamma_8^0 &= -\frac{h_{12}^0 h_{32}^0}{3\rho_0^2},\\
\gamma_9 &= \gamma_9^0 + O\left(\mu\right), \qquad & \gamma_9^0 &= \frac{h_{12}^0 h_{32}^0}{3\rho_0^2},
\end{aligned} \tag{6}$$

where $\rho_0 = \rho/\mu^2$, $h_{12}^0 = h_{12}/\mu$ and $h_{32}^0 = h_{32}/\mu$. These results are summarised in Table 1, allowing comparison of asymptotic orders of the terms in approximation (5) both in the vicinity of zero and the lowest cut-off frequency (4).

Order of γ_i	Terms	Fundamental mode $\Omega^2 \sim \mu K^2$	First harmonic $\Omega_{sh}^2 \sim \mu$
$\gamma_1 \sim \mu^2$	$\gamma_1 K^2$	$\mu^2 K^2$	$\mu^2 K^2$
$\gamma_2 \sim \mu$	$\gamma_2 \Omega^2$	$\mu^2 K^2$	μ^2
$\gamma_3 \sim \mu^2$	$\gamma_3 K^4$	$\mu^2 K^4$	$\mu^2 K^4$
$\gamma_4 \sim \mu$	$\gamma_4 K^2\Omega^2$	$\mu^2 K^4$	$\mu^2 K^2$
$\gamma_5 \sim 1$	$\gamma_5 \Omega^4$	$\mu^2 K^4$	μ^2
$\gamma_6 \sim \mu^2$	$\gamma_6 K^6$	$\mu^2 K^6$	$\mu^2 K^6$
$\gamma_7 \sim \mu$	$\gamma_7 K^4\Omega^2$	$\mu^2 K^6$	$\mu^2 K^4$
$\gamma_8 \sim 1$	$\gamma_8 K^2\Omega^4$	$\mu^2 K^6$	$\mu^2 K^2$
$\gamma_9 \sim 1$	$\gamma_9 \Omega^6$	$\mu^3 K^6$	μ^3

Table 1: Asymptotic behaviour at $\mu \ll 1, \quad \rho \sim \mu^2, \quad h_{12} \sim h_{32} \sim \mu$

Using this Table, the leading order shortened approximate dispersion relation may be constructed, incorporating the fundamental mode along with the lowest harmonic with the asymptotically small cut-off frequency (4). It may be expressed as

$$\mu^2\gamma_1^0 K^2 + \left(\mu\gamma_2^0 + \gamma_5^0\Omega^2\right)\Omega^2 + \mu\gamma_4^0 K^2\Omega^2 + \gamma_8^0 K^2\Omega^4 + \gamma_9^0\Omega^6 = 0. \tag{7}$$

In this formula all the terms are of the same order μ^3 at $\Omega - \Omega_{sh} \sim \mu^{3/2}$, $K \sim \sqrt{\mu}$. The local asymptotic approximation for the fundamental mode is given by

$$\mu\gamma_1^0 K^2 + \gamma_2^0 \Omega^2 = 0. \tag{8}$$

At the same time, the local expansion for the first harmonic becomes

$$\mu^2\gamma_1^0 K^2 + \left(\mu\gamma_2^0 + \gamma_5^0\Omega^2\right)\Omega_{sh}^2 + \mu\gamma_4^0 K^2\Omega_{sh}^2 + \gamma_8^0 K^2\Omega_{sh}^4 + \gamma_9^0\Omega_{sh}^6 = 0, \tag{9}$$

where Ω_{sh} is given by (4). The associated typical near cut-off expansion, e.g. see [21, 22] for further details, is

$$\Omega^2 - \Omega_{sh}^2 = -K^2\frac{1}{\gamma_5^0}\left(\mu^2\frac{\gamma_1^0}{\Omega_{sh}^2} + \mu\gamma_4^0 + \gamma_8^0\Omega_{sh}^2\right) - \frac{\gamma_9^0\Omega_{sh}^4}{\gamma_5^0}. \tag{10}$$

Note that the long-wave assumption $K \ll 1$ dictates that the approximation (8) for the fundamental mode is valid only for $\Omega \ll \sqrt{\mu}$, whereas (10) is associated with $\Omega \sim \sqrt{\mu}$. Thus, the approximation (7) is non-uniform, in line with previous considerations in [3].

Numerical illustrations of the derived approximations are given in Figures 2-3. In Figure 2 two-mode approximation (7) (dotted lines) is compared numerically with the exact solution of the dispersion relation (2) (solid lines). A characteristic gap where the asymptotic formula (7) is not applicable is shown in Figure 2.

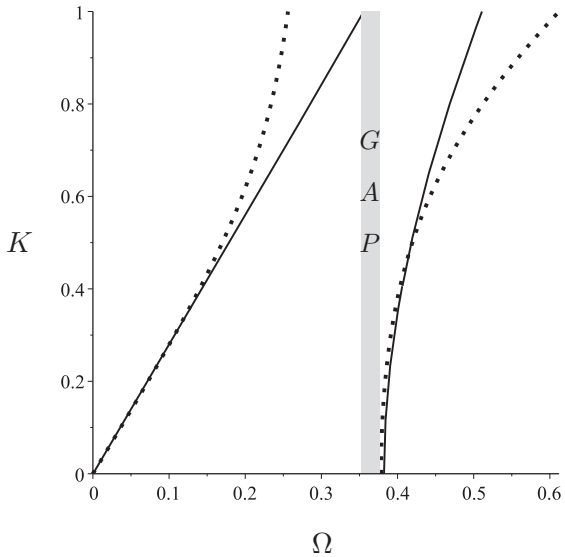

Figure 2: Dispersion curves (2) (solid lines) together with approximation (7) (dotted lines) for $h_{12} = 0.1$, $h_{32} = 0.2$, $\mu = 0.1$, and $\rho = 0.01$.

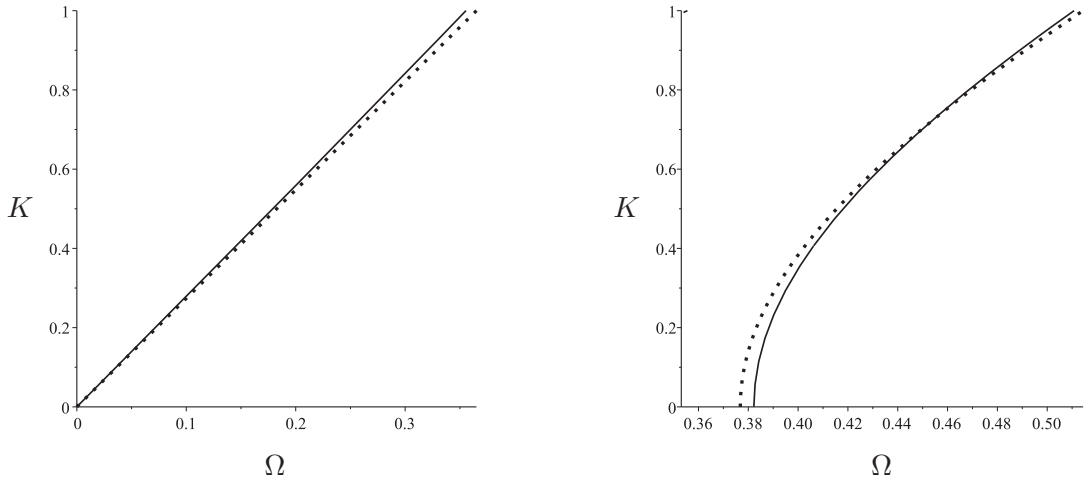
In Figure 3 exact dispersion curves (2) (solid lines) are shown together with approximations for the fundamental mode (8) and for the lowest harmonic (10) (dotted lines), demonstrating high accuracy of asymptotic predictions.



(a) Fundamental mode (b) First harmonic

Figure 3: Dispersion curves (2) (solid lines) together with approximations for a) the fundamental mode (8) and b) the lowest harmonic (10) (dotted lines) for $h_{12} = 0.1$, $h_{32} = 0.2$, $\mu = 0.1$ and $\rho = 0.01$

4 Conclusion

The present analysis complements the previous results for an asymmetric layered plate in [2]. Two-mode approximate dispersion relation has been derived for a chosen scenario for which the outer layers are relatively stiff, thin and very heavy compared to the inner layer. In contrast to [2], in which the two-mode long-wave low-frequency approximation was asymptotically uniform, the approximation obtained in the paper is of composite nature, being only valid over non-overlapping vicinities of the origin and the first cut-off frequency. Thus, the effect of high contrast does not always result in a uniform two-mode approximation as might be expected. The proposed research may be expanded to the derivation of the related two-mode differential equations of motion, based on the same scaling.

Keywords: Structural Dynamics, Model Updating, Optimal Modeling, Winded Carbon Fibers

Abstract. *An optimal computational modeling approach of CFRP (Carbon Fiber Reinforced Composite) structures is presented using cylindrical tubes parts produced on a spinning axis by winded carbon fibers in various angles and directions. First, appropriate specimens and experimental structures are being produced for testing procedures under static and dynamic load conditions for the examination of the mechanical material properties and comparison with numerical models. Discreet FE models of the specimens and the examined structures are developed consisting of mainly shell elements, simulating each carbon fiber ply and resin matrix, and solid elements for other parts such as connectors and glue that interacting with the composite. Due to the two-phase heterogeneous nature of the composite material appropriate micromechanical modeling is being applied to extract the mechanical properties parameters under the homogenization process of one layer of carbon-fiber composite of the FE model. To minimize the error between the physical structure and the FE model due the original assumptions of the homogenizations, in combination with commercial finite element analysis software an update methodology framework is being developed and used to acquire the optimal FE model. This is achieved through combining measured and numerical time-histories of strains. Single objective structural identification strategies without the need of sub-structuring methods, are used for estimating the parameters (material properties in each deformation plane) of the finite element model, based on minimizing the deviations between the experimental and analytical characteristics. A stochastic optimization evolution strategy is applied in parallel computing, to solve the single-objective optimization problem. The effect of model error and finite element model parameterization on the optimal models along with and their variability, are examined.*

1 INTRODUCTION

Carbon fiber reinforced polymer (CFRP) composites have gained much attention in recent years through their industrialized implementation and use, as a structural material for static and dynamic load bearing as well as resistance to accidental excitations and actions. Due to its low-density, low thermal expansion and high strength, stiffness and corrosion resistance, applications from aerospace and automotive industry to building reinforcement and retrofit, as well as cryogenic fuel storage tanks are emerging rapidly [1–6]. Plain-woven CFRPs are the most popular carbon fiber-reinforced composites and have been extensively investigated by researchers and are widely used in numerous applications. However, composite materials produced by filament winding manufacturing technique despite disadvantages, such as geometry limitation and need of a mandrel, has been extensively used for its low cost and speed of production with applications on pressure vessels, natural gas vehicle tanks, power transmission shafts and sporting equipment [7]. Being inherently sensitive to manufacturing treatment and due to its material variability, filament winded CFRPs strongly require certification results through numerical verification and hybrid (numerical - experimental) validation [8].

The mechanical properties of long-fiber composites show large variations [9,10] their prediction for unidirectional or woven laminated composites has been extensively discussed in the literature [11–15], but due to the complexity of the fiber paths in the layers of filament winding, these properties cannot accurately describe the behavior of filament wound pipes. The lamina properties can vary between different positions of a single filament wound tube. Thus, not only the behavior of the structure cannot be modeled efficiently, but also the failure may start prior, at an unexpected point at the weakest areas of the pattern that is being produced by the winding.

From the engineer's perspective, in order to successfully and accurately design a Carbon Fiber Reinforced Polymer (CFRP) structure, the lamina mechanical properties need to be used in combination with robust Finite Element Analysis (FEA) approaches. Other common isotropic materials might have small deviations from their nominal values in terms of mechanical properties, thus a great percentage of error at the response of a structure can be accredited at the CFRP components.

The main goal of this work is to acquire the optimal lamina mechanical properties of a CFRP composite with an efficient procedure minimizing the time-consuming experimental tests that usually required. More specifically, a simple tension test is executed first to acquire the experimental strain data. Next, a homogenization method at the fiber-matrix level using a micromechanical model is applied in order to acquire the nominal mechanical properties of the lamina. From the wide variety of micromechanical models that have being proposed [11], [13], [16], Huang's model [17] will be used as it has also being applied in similar tubes made of Glass Fiber Reinforced Polymer composites [18]. Next, the nominal values of layer properties are tuned taking full advantage of a state-of-the-art stochastic single objective optimization algorithm, alongside with experimental strain measurements of the tension test and a high-fidelity numerical finite element model (FEM). For the updating process, Covariance Matrix Adaptation – Evolution Strategy (CMA-ES) coupled with MSC Nastran Finite Element Analysis (FEA) software is applied. CMA-ES stochastic optimization algorithm is a general purpose method, that has demonstrated rapid convergence capabilities, particularly when searching for a single global optimum and has been successfully applied to linear and non-linear FE updating problems, involving large and complex models and cases [19–23]. The results are validated in different experimental tests with different types of loading and different specimen thickness, fiber orientation angles and diameter size.

The present work has the following organization. First the theoretical formulation of the

materials homogenization (Section 2.1) and the finite element model update (Section 2.2) are briefly presented. At Section 3 the experimental test to characterize the material and the application of the finite element model update procedure is presented. Section 4 presents the experimental validation on static and dynamic loads and at last Section 5 the conclusions are summarized.

2 LAMINA PROPERTIES AND FINITE ELEMENT MODEL UPDATING STRATEGIES

2.1 Nominal Lamina Properties

To acquire the nominal lamina mechanical properties from the variety of micromechanical models that have been proposed [11], [13], [16], Huang's [17] model is used, which shows acceptable results [14] for unidirectional composites and has being applied ta similar tubes formed by Glass Fiber Reinforces Polymer composite [18]. Most of the fiber and matrix properties are being provided by the manufacturer and the remaining can be found from material databases such as [24,25].

The major equations needed to calculate the nominal lamina mechanical properties are listed below:

$$E_1 = V^f E_1^f + V^m E^m \tag{1}$$

$$E_2 = \frac{(V^f + V^m a_{11})(V^f + V^m a_{22})}{(V^f + V^m a_{11})(V^f S_{22}^f + a_{22} V^m S_{22}^m) + V^f V^m (S_{21}^m - S_{21}^f) a_{12}} \tag{2}$$

$$v_{12} = V^f v_{12}^f + V^m v^m \tag{3}$$

$$G_{12} = G^m \frac{(G_{12}^f + G^m) + V^f (G_{12}^f - G^m)}{(G_{12}^f + G^m) - V_f (G_{12}^f - G^m)} \tag{4}$$

$$G_{23} = \frac{0.5(V^f + V^m a_{22})}{V^f (S_{22}^f - S_{23}^f) + V^m a_{22} (S_{22}^m - S_{23}^m)} \tag{5}$$

With: $a_{11} = \frac{E^m}{E_1^f}$ $a_{22} = a_{33} = a_{44} = 0.5(1 + \frac{E^m}{E_2^f})$ $a_{55} = a_{66} = 0.5(1 + \frac{G^m}{G^f})$

$$S_{22}^f = \frac{1}{E_2^f} \quad S_{21}^f = \frac{-v_{12}^f}{E_1^f} \quad S_{23}^f = \frac{-v_{23}^f}{E_2^f} \quad S_{22}^m = \frac{1}{E^m} \quad S_{21}^m = \frac{-v^m}{E^m} \quad S_{23}^m = \frac{-v^m}{E^m}$$

The variables E, ν, and G are the Youngs modulus, Poisson's ratio and shear modulus respectively expressed for the additional material and direction, with f, m to represent the fiber and matrix properties and direction 1 to be parallel to the fiber direction, 2 in-plane perpendicular to 1 and 3 perpendicular to both 1,2. While α_{ij} and S_{ij} correspond at elements of row i and column j of the bridging matrix and elastic-plastic compliance matrix respectively of the Huang's model [17].

2.2 Model Updating Framework

The Covariance Matrix Adaptation – Evolution Strategy (CMA-ES) is a general-purpose stochastic algorithm and together with a simple experiment is used to acquire the optimal lamina mechanical properties.

Let M be a parameterized class of structural dynamic models, that simulates the structural system and will be used to estimate desired quantities of interest. Consider $\underline{\theta}_m \in R^{N_\theta}$ be the set

of free structural model parameters to be adjusted using the measured data and let $g(\underline{\theta}_m \mid M_m)$ be the model predictions given the values of the parameter set $\underline{\theta}_m$. In this work, parameter estimation is based on response time history measurements of strains. This formulation has the advantage of applicability over both linear and non-linear systems; it compares the measured raw data of the experimental arrangement to the equivalent predictions of the numerical model. In this way, all available information is preserved, and systematic errors of the identification procedure are alleviated.

The difference between the measured response time histories and the model predicted response time histories, take the form [26]:

$$J(\underline{\theta};M)=\frac{1}{m}\sum_{i=1}^{n}\frac{\sum_{j=1}^{m}\left(\underline{g}_{ij}(\underline{\theta}_m \mid M)-\hat{y}_{ij}\right)^2}{\sum_{j=1}^{m}\left(\hat{y}_{ij}\right)^2} \tag{6}$$

where $\underline{g}_{ij}(\underline{\theta}_m \mid M)$ is the numerical time-history of the introduced FE model and $\hat{y}_{ij}$ is the respective experimental signal. Subscripts i correspond to the sensor location and measurement direction, and j corresponds to the time-step instant. n is the total number of measured sensor locations and directions, whereas m is the total number of measured time-steps (number of observations).

The measure of fit as introduced in equation (6) is consisted for strains equally weighted, expanding to the following equation (7), where $s\left(\underline{\theta}_m \mid M\right)_{ij}$ are the numerical time-histories of strains of the introduced FE model and $\widehat{s_{ij}}$ are the respective experimental strain signal. At the present experimental setup only one sensor is present resulting in equation (7).

$$J(\underline{\theta};M)=\frac{1}{m}\frac{\sum_{j=1}^{m}\left(s(\underline{\theta}_m \mid M)_{ij}-\hat{s}_{ij}\right)^2}{\sum_{j=1}^{m}\left(\hat{s}_{ij}\right)^2} \tag{7}$$

CMA-ES is applied to update the developed FE model minimizing the objective function of equation (7). The flow chart of the complete framework is presented at Figure 1 presents the flow chart of the applied framework. The flow of the framework is distinguished in two separate parts the homogenization of the material parameters and the FE model updating. The homogenization of the material parameters takes place once and considers the carbon fiber and matrix properties in order to produce the lamina properties introduced to the FE model. Independently the experimental strain response time histories are collected. The model-updating framework utilizes experimental data and the developed numerical FE model. It begins by sampling a set of material parameters from a Multivariate Normal Distribution using given means and variances based on initial lower and upper bounds. Then the FEA solver is invoked in order to compute strain response time histories at matching excitation – response locations regarding the experimental measurements. The objective function of equation (7) is calculated and the upon completion of a set of function evaluations (iteration) CAM-ES collects the minimum values in order to create new means and variances and begin a new iteration until convergence criterion is fulfilled. In this work convergence was set the difference of the best values of two consecutive iterations to be less than $\Delta J(\underline{\theta})<10^{-3}$. CMA-ES ends when convergence is met and the material parameters that correspond to the minimum objective function value pertain to the optimal updated values.

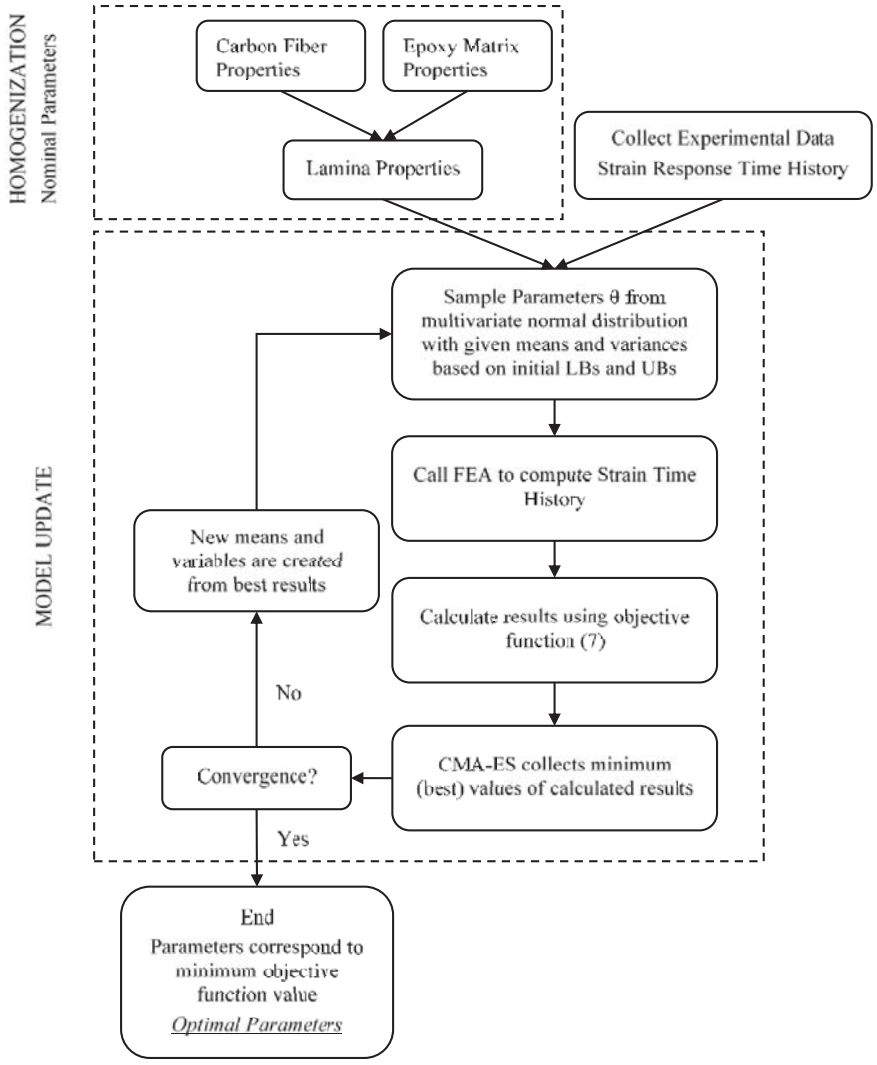

Figure 1. Flow chart of the applied CMA-ES framework based on the linear FE model updating scheme.

3 EXPERIMENTAL APPLICATION-MATERIAL CHARACTERIZATION TEST

3.3 Optimal lamina mechanical properties

A uniaxial tension experiment per ASTM 3039 [27] standard is selected for the CFRP tube with lamina properties presented in Table 1. Single-axis strain gauges were placed at the middle of each specimen and appropriate 3D printed PLA patches were glued at the edges to match the curvature of the specimen so the testing machine would not damage the specimen on installation as presented in Figure 2.

Table 1. Tensile Test Specifications.

Specimen properties				
Layer Orientation	(+/-55º)/(+/-55º)/(+85º)/(+/-55º)/(+/-55º)/(+/-55º)			
Tube Internal Diameter	220 mm			
Layer Thickness	+/- 55º	0.35 mm	**Free Height**	122 mm
	85º	0.16 mm	**Width**	22 mm

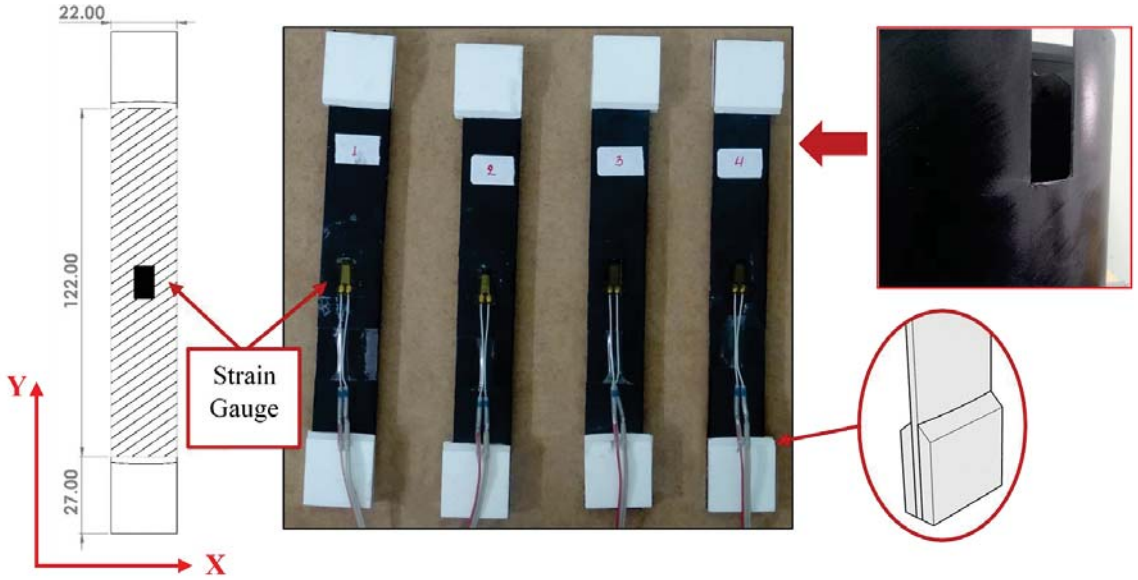

Figure 2. Tensile specimens and test setup for uniaxial tensile.

Figure 3. Experimental uniaxial tensile setup with the corresponding finite element model.

All the specimens were manufactured with the same raw materials, Toray T700S fiber and Epikote 828LVEL matrix.

The model updating methodology is conducted by parameterizing the FE model resulting in six parameters that correspond to the material lamina properties. As the material can be characterized as transversally isotropic the shear modulus at directions 1-2 and 1-3 are equal thus limiting the parameters to E_1, E_2, ν_{12}, $G_{12}=G_{13}$, G_{23}. At Table 3 the nominal values from the micromechanical model are presented along with the model update procedure results, the lower (LB) and upper (UB) bounds selected and the difference between optimal and nominal values.

A direct comparison of the strain along the Y direction is presented at Figure 4a between the nominal model and the measured experimental strain until the moment of first ply failure. The blue continuous line (labeled as Experimental) in Figure 4a represents the average of all experimentally measured tensile specimens, while the red-dotted line (labeled as ST2) and purple dash-dotted line (labeled as ST4) corresponds to the upper and lower outlines respectively, in means of strain time response, enveloping all specimens tested. The dashed line although corresponds to the numerical predictions from the nominal FE model.

Table 2. Updated design variables and updated design bounds (Lower Bound and Upper Bound) of Lamina Mechanical Properties.

	Parameters	Lower Bound	Nominal Value	Upper Bound	Updated Optimal Value	Difference (%)
1	$E_1\ [MPa]$	120000	161900	165000	138945	14.17
2	$E_2\ [MPa]$	5000	9456	12000	6615.4	30.03
3	ν_{12}	0.22	0.272	0.35	0.278	2.20
4	$G_{12}, G_{13}\ [MPa]$	3000	5908.7	6500	3387	42.67
5	$G_{23}\ [MPa]$	2000	3308.4	4500	2286.41	30.89

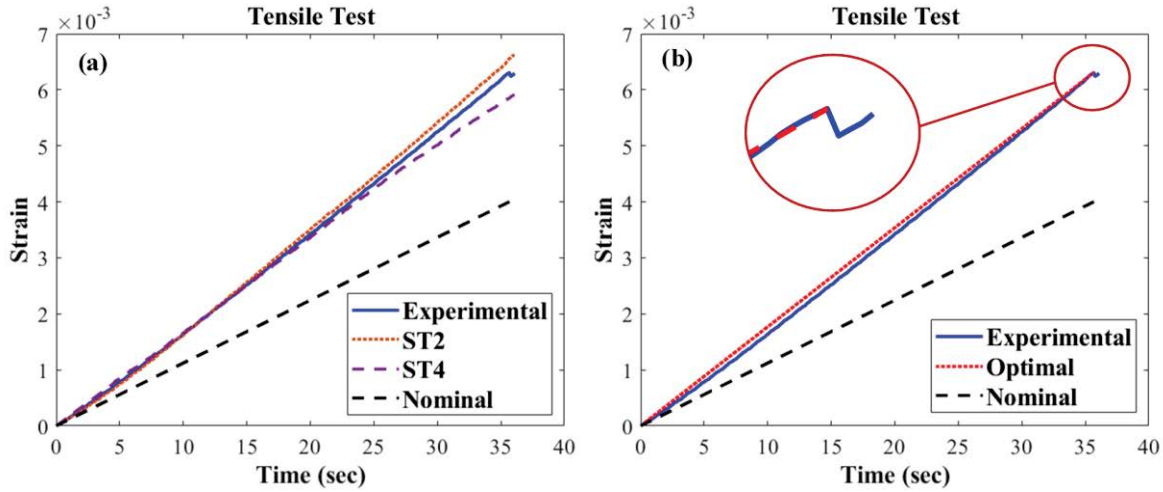

Figure 4. (a) Comparison of experimental strain with nominal FE model (b) Comparison of experimental strain with FE optimal and FE nominal models.

At last on Figure 4b the strain time response by the optimal FE model (red dotted line) is compared to the nominal predictions (black dashed line) and to the averaged experimental data, while the magnified area presents the response at the time of failure.

4 VALIDATION

In order to validate the previous results further experimental test were executed in more complex loading conditions and structures.

4.1 Three Point Bending

A straight strip with 220 mm length (180mm free length) and 36 mm width was removed from the same tube used to collect the specimens in the previous tensile test described in section **Error! Reference source not found.**. In a three-point bending test, the strip is placed at the testing machine as presented in Figure 5a, with a force control motion of the machine's head. Two strain gauges, SG1 in the transverse direction (X-axis) and SG2 in the longitudinal direction of the specimen (Y-axis) were placed to measure the induced deformations. During the experiment the machine's head was moving against the middle of the simply supported strip, up to a maximum displacement measuring time histories of head's displacement and strains developed as presented in Figure 5b.

Figure 5c presents the corresponding non-linear contact model developed in MSC Marc in the initiation state while Figure 5d presents the numerical results at the state of maximum

bending of the strip.

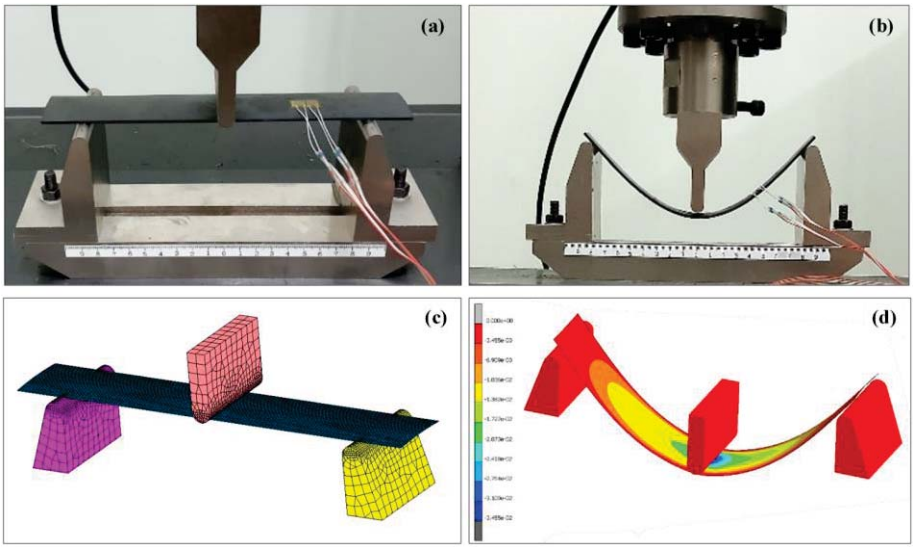

Figure 5. Three-point bending experimental set up and numerical model, (a), experimental initial state, (b) experimental max bending, (c) Non-linear FE model initial state, (d) Numerical strains along Y direction at t=335sec - max bending.

Figure 6a and Figure 7b present a comparison of the strain time responses for the strain gauge locations SG1 and SG2 respectively, between optimal FE model (red dotted line), nominal FE model (black dashed line) and experimentally measured data (blue continuous line). It is clear that the optimal model gives a far better approximation of the physical specimen. The magnified areas on Figure 8b correspond at first ply failure and a random ply failure during the experiment accordingly. While at the end of the experiment no visible damage could be detected, a plastic deformation occurred at the specimen by delamination phenomena or fault lines within the matrix of the CFRP specimen.

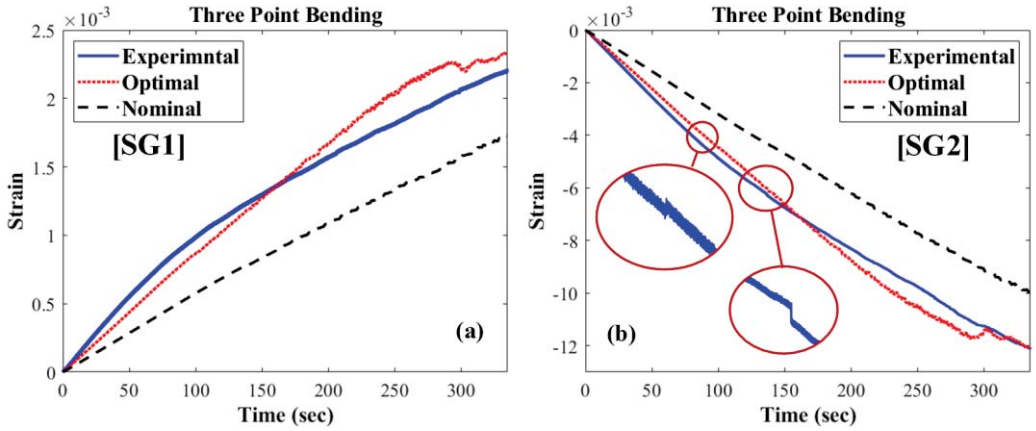

Figure 9. Comparison of experimental, FE optimal and FE nominal models for (a) SG1 (X-transverse axis) and (b) SG2 (Y-longitudinal axis).

4.2 Cylinder on Radial Deformation

The second validation test introduces a CRFP cylindrical specimen under radial deformation. The specimen's material properties are presented in Table 3. The experimental set-up was comprised of a cylindrical CFRP tube and two internal steel cylinders, properly connected to two hook-like heads and accordingly placed at the Universal Testing Machine (UTM) as presented in Figure 10.

Two cases were examined, Case 1 limited only at the linear elastic area of the material and

Case 2 until total material failure occurred. In both cases two strain gauge sensors are placed on the specimen, at an angle of 90 degrees with the axis passing through the center of the machine's grips, i.e. SG1 in the transverse direction (direction along the X-axis of the cylinder) and SG2 in the longitudinal direction of the specimen (direction in the tube perimeter, Y-axis).

The corresponding non-linear numerical model was developed using shell composite elements for the CFRP specimen, while the steel cylinders were modeled with solid elements as shown in Figure 10b.

Table 3. CFRP Specimen Properties

Specimen properties				
Layer Orientation	(+/-55º)/ (+/-55º)/(+86º) /(+/-55º) (+/-55º)/ (+/-55º)			
Tube Internal Diameter	150mm		**Width**	50mm
Layer Thickness	+/- 55º	0.35 mm		
	85º	0.16 mm		

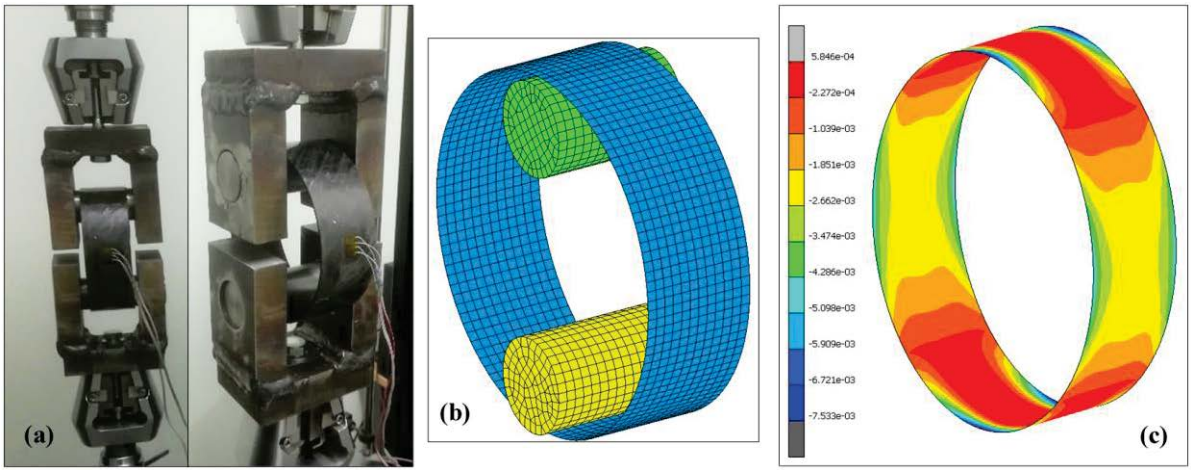

Figure 10. (a) Experimental set-up, (b) Numerical model at MSC Marc, (c) Strain at Y direction for t=23sec.

Figure 10c presents the Y-axis strain distribution on the optimal FE model of the cylindrical CFRP specimen at the point in time of maximum displacement (t=23sec) for Case 1. Regarding this Case limited at the linear area of the material, Figure 11a and Figure 11b present a comparison of the strain time responses at the strain gauge locations SG1 and SG2, between the optimal FE model (red dotted line), the nominal FE model (black dashed line) and the experimental measured data (blue continuous line).

Regarding the Case 2, until the total failure of the material, Figure 12a and Figure 12b presents a comparison of strain time responses at the strain gauge locations SG1 and SG2, between the optimal FE model (red dotted line) and the experimental measured data (blue continuous line). The magnified area of Figure 12b corresponds at the first ply failure of the experimental test. Furthermore, the three highlighted areas as the same figure represent a different state at the specimen condition. The first represent the state just before the material fail all across the width of the specimen at the contact areas for the FE optimal model. While the second state represent the state after the failure across the width of the specimen and the third the moment just before the total failure of the material and separation of the specimen.

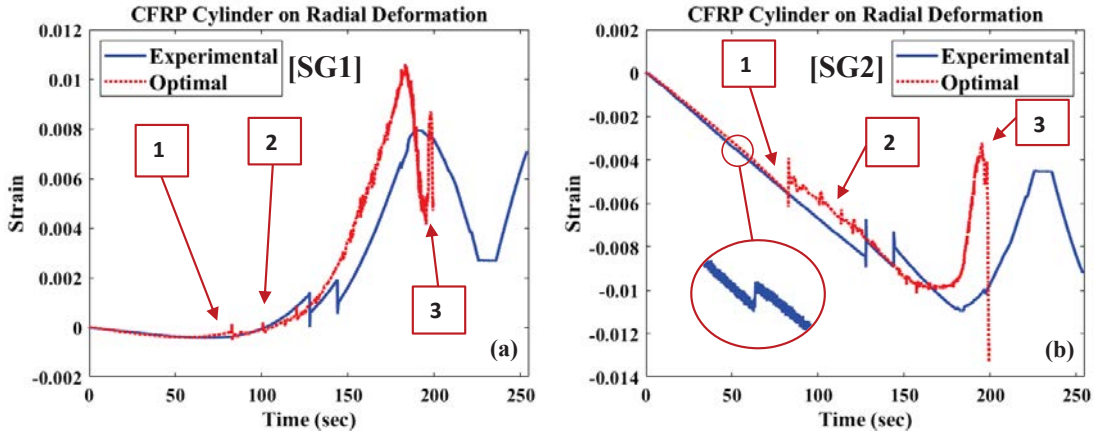

Figure 12. Comparison of experimental and FE optimal model for Case 2, (a) SG1 (X-transverse axis) and (b) SG2 (Y-longitudinal axis).

4.3 Cantilever CFRP tube

Dynamically induced excitation tests were conducted at a cantilever CFRP tubular beam as presented in Figure 13. A small radius CFRP tube along with two tri-axial accelerometers, a strain gauge sensor and a load cell at the free end of the cantilever beam, where an electromagnetic shaker device is mounted. The tubes properties are presented at Table 4 while aluminum joints were glued at the tube's edges which can be seen at Figure 14 along with the corresponding FE model in MSC Nastran.

Table 4. CFRP tube properties

CFRP properties				
Layer Orientation	(+/-8º)/ (+/-8º)/(+86º) /(+/-8º) (+/-8º)			
Tube Internal Diameter	25mm		**Length**	1m
Layer Thickness	+/- 8º	0.26 mm		
	86º	0.16 mm		

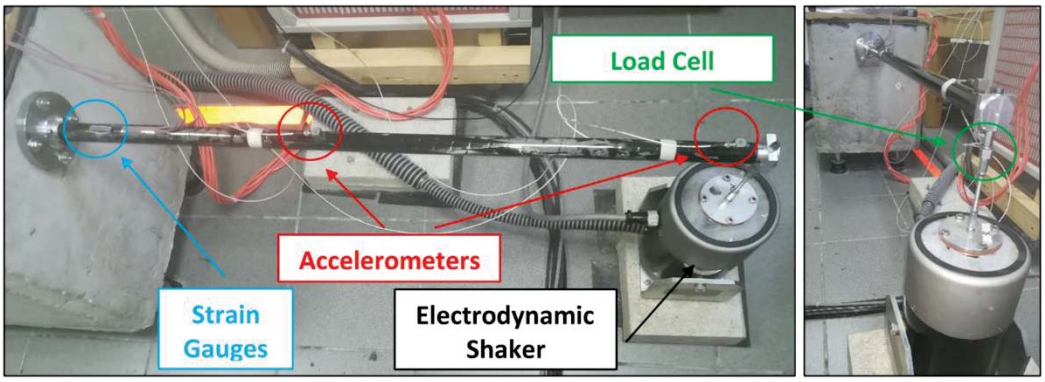

Figure 13. Experimental setup of cantilever CFRP tube under dynamic load excitation.

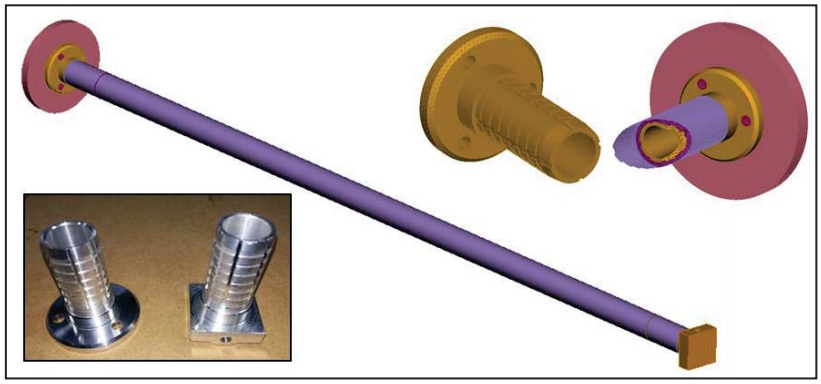

Figure 14. FE model of cantilever CFRP tube along with aluminum drop-outs.

An experimental modal analysis procedure of the CFRP cantilever beam was performed in order to quantify the dynamic characteristics of the examined structure. The measured frequency range of the test was 0-600 Hz. An initial investigation indicated that the beam has seven (7) natural frequencies in this frequency range. At Table 5 the comparison of experimentally identified natural frequencies with the numerical natural frequencies of the nominal and optimal FE model.

Table 5. Comparison between identified, nominal and optimal FE predicted modal frequencies

Mode	Identified Experimental	Nominal Numerical		Optimal Numerical	
	Frequency (Hz)	Frequency (Hz)	Error (%)	Frequency (Hz)	Error (%)
1	18.16	15.54	16.86	18.48	1.73
2	18.18	16.62	11.79	19.12	2.82
3	149.45	137.23	8.9	147.53	1.3
4	167.51	144.22	16.15	168.8	0.76
5	414.32	408.12	1.52	415.34	0.25
6	436.14	428.12	1.87	435.54	0.14
7	531.36	472.35	12.49	524.87	1.24

4.4 Small-scale pin-jointed CFRP structure

At last a complex structure (Figure 15) is presented. CFRP tubes similar to the one of Section 4.3 glued and mounted with aluminum joints were used. Four tri-axial accelerometers were placed on the pin-joined CFRP frame structure, which was anchored on flat plate parallel to the ground, on a vertical concrete column. An electromagnetic shaker was mounted on a free end of the frame where a load cell sensor was placed to record imposed forces under dynamic

excitation load.

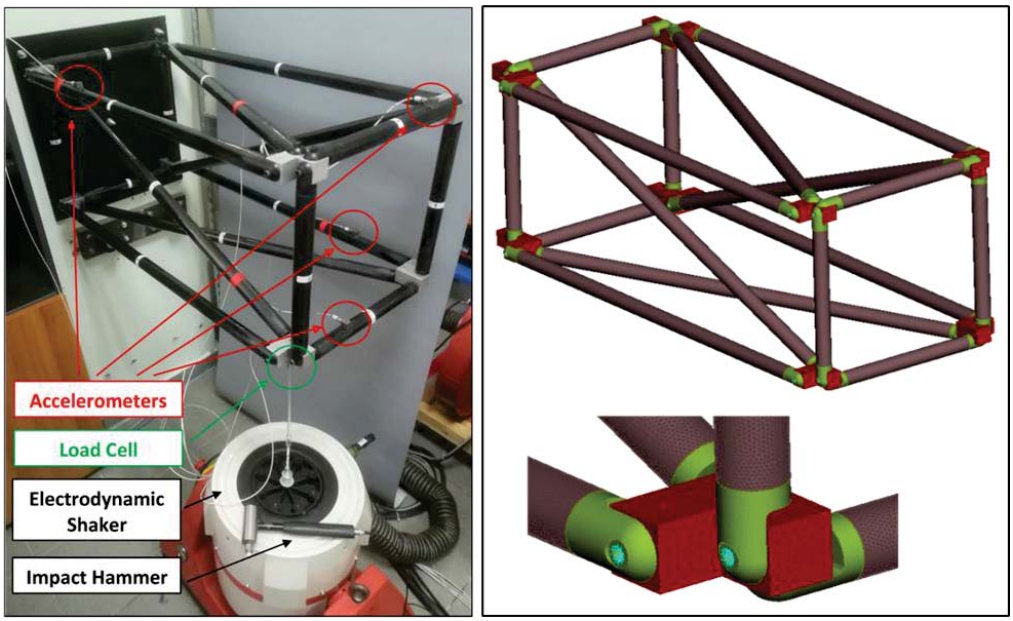

Figure 15. Experimental setup and FE model of small-scale CFRP pin-joined structure.

The corresponding optimal FE model was created in MSC Nastran (Figure 15), the geometry of the structure is discretized with composite shell and solid elements. For a harmonic excitation a comparison between the experimental and numerical acceleration time histories of two measured locations is presented at Figure 16 . The experimental acceleration is represented with black continuous line while with red continuous line is the equivalent response of the optimal FE model. As it is obvious the optimal model can predict the response of the physical structure.

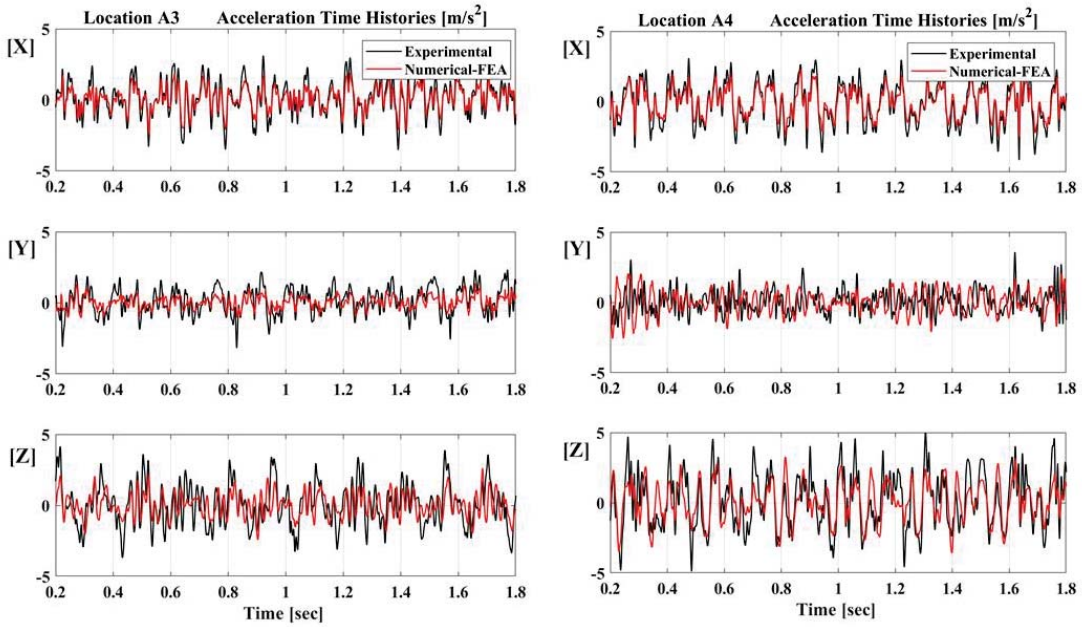

Figure 16. Comparison between experimental and numerical acceleration time histories in X, Y and Z local directions at a random force excitation.

As it is obvious the optimal model can predict the response of the physical structure. The remaining error can be addressed at the mechanical properties and uncertainties during the manufacturing of the other parts of the assembly.

5 CONCLUSIONS

In this work a modeling procedure of structures that include filament wound CFRP tubes parts is presented. From a simple tensile experiment and with the use and a stochastic single objective optimization algorithm (CMA-ES) coupled with a commercial finite element software the optimal lamina mechanical properties can be acquired with precision. These properties show a great range between different raw materials and manufacturing methods and are crucial for the prediction of material failure but also at the dynamic response of a structure. The presented methodology has been experimentally validated with different loading types and in simple and more complex structures at the linear area of the material but also until the material's failure. It is able to predict with the structure's response and the materials behavior until failure thus reducing the error that a micromechanical model produces.

Keywords: laminated composite, cylindrical shells, natural frequencies, vibration analysis.

Abstract. *This paper investigates the vibration behaviour of simply-supported laminated composite cylindrical shells with various fibre orientations. For some specific fibre orientations, theoretical wave propagation approach based on Love's theory is used for free vibration analysis of the laminated orthotropic composite cylindrical shells. The circumferential natural frequencies have been obtained and compared with numerical finite element results for validation and comparison. The finite element method is employed for the forced vibration analysis of laminated composite cylindrical shells with various fibre orientations subjected to harmonic loading. The results show that natural frequencies, mode shapes and the steady-state response at prescribed points can be tailored by properly designing fibre orientations for vibration mitigation. It is found that fibre orientations may have significant influence on the circumferential natural frequencies of the first few circumferential modes. For the first two circumferential modes, the associated natural frequencies may increase with fibre orientation angle. In comparison, the natural frequencies of larger circumferential modes may decrease with fibre orientation angle. The steady-state responses of cylindrical shells under a harmonic concentrated force are obtained. The variations of the resonance frequencies and corresponding peak value of steady-state response with fibre orientations have been investigated. The findings could improve the understanding of dynamic behaviour of the laminated composite cylindrical shells, and benefits optimisation of the fibre orientations for vibration suppression purpose.*

1 INTRODUCTION

There has been much research interest in the vibration transmission behaviour of mechanical systems and engineering structures for possible vibration suppression [1-6]. Laminated composite structures are increasingly used in various engineering applications including aircrafts, rockets, submarines and pipes due to their superior performance such as high stiffness-to-weight and strength-to-weight ratios, and flexibility in design, compared to traditional metallic structures. The circular cylindrical shells have been one of the most important and basic structural elements in engineering structures [7-8]. In the practical applications, those engineering components may exhibit severe vibrations when the frequencies of the external force are close to one of the natural frequencies. As a result, vibration problems of this type of structures have been a subject of great interest. Various laminated shell theories have been proposed and developed through different assumptions and simplifications such as Reissner-Naghdi's linear shell theory, Donnell-Mushtari-Vlasov's theory, Sanders' theory and Flugge's theory [9]. Among the numerous theories, the classical shell theory based on the Kirchhoff-love hypothesis is widely used. The detailed comparison studies can be found in monographs on vibration of shells, which has been done by Leissa [9], Qatu [10] and Reddy [11]. To conclude, vibration analysis of this type of structures has been of great significance, from which insight may be gained into dynamic characteristics and optimal design of such laminated composite structures.

There have been some methods developed and used to study the vibration behaviour of cylindrical shells [12-17]. For example, Lam and Loy [12-13] compared the natural frequencies of rotating laminated cylindrical shells with different shell theories, namely Donnell's, Flugge's, Love's and Sanders' and then employed the Ritz method to study the effects of boundary conditions and fibre orientation on the natural frequencies of thin orthotropic laminated cylindrical shells based on Love's theory. The free vibration of laminated cylindrical shells using differential quadrature method was conducted by Shu and Du [14]. Zhang [15] developed wave propagation approach for vibration analysis of cross-ply laminated composite shells base on Love's shell theory. Liu et al. [16] derived exact characteristic equations for free vibration of thin orthotropic circular cylindrical shells based on Donnell-Mushtari shell theory. Jin et al. [17] employed Rayleigh-Ritz method based on Reissner-Naghdi's theory to obtain the exact solution based on the energy functions of the shell, which is applicable to a variety of boundary conditions.

Most of the previous studies have focused on the development of analytical methods to investigate the free vibration analysis of cross-ply laminated composite cylindrical shells according to different shell theories in confined boundary conditions and exact solutions for the shells with a variety of boundary conditions. There is much less research work on the detailed vibration characteristics of laminated composite cylindrical shells with arbitrary lamination schemes. The free and force vibration characteristics of submerged finite elliptic cylindrical shell has been investigated [8]. The vibration analysis of the laminated composite plates has been conducted and the influence of the lamination schemes on the vibration characteristics has been investigated [18-19]. It is of great significance to develop an accurate and efficient method that can be used to investigate the vibration characteristics of laminated composite cylindrical shells with complex lamination schemes. It has been revealed that the wave propagation method based on Love's theory is feasible and of high accuracy for cross-ply laminated composite cylindrical shell. For the cylindrical shell with complex lamination schemes, the FEA method may be used for the vibration analysis of composite structures and it also can be employed to verify the analytical results. In this study, the natural frequencies and mode shapes of the laminated composite cylindrical shells with different lamination schemes and geometric parameters are obtained by using both the wave propagation method and the FEA for comparison. The dynamic

responses of the cylindrical shells under harmonic excitation are investigated and obtained. The effects of fibre orientations on the vibration behaviour are examined.

2 METHMATICAL MODELLING

2.1 Model description

Figure 1 shows the schematic diagram of a thin laminated composite cylindrical shell having length L, thinckness h and radius R, and arbitrary number of layers. The cylindrical coordinate system (x, θ, z) is fixed at the middle surface of the cylindrical shell. The components of the displacement field (u, v, w) in this coordinate system are defined such that u is the displacement in the axial direction of x, v in the circumferential direction of θ and w in the radial direction of z. The fibres of laminates in each layer follows helix lines on the cylindrical shell, and the helix angle for the i-th layer is denoted by θ_i. A harmonic force is applied to the point (x_e, θ_e, R) on the cylindrical shell. The circumferential modal shapes with different circumferential modal numbers have been shown in Fig. 1(b) [15]. Fig. 1(c) shows the geometry of the cylindrical shells composed of N layers.

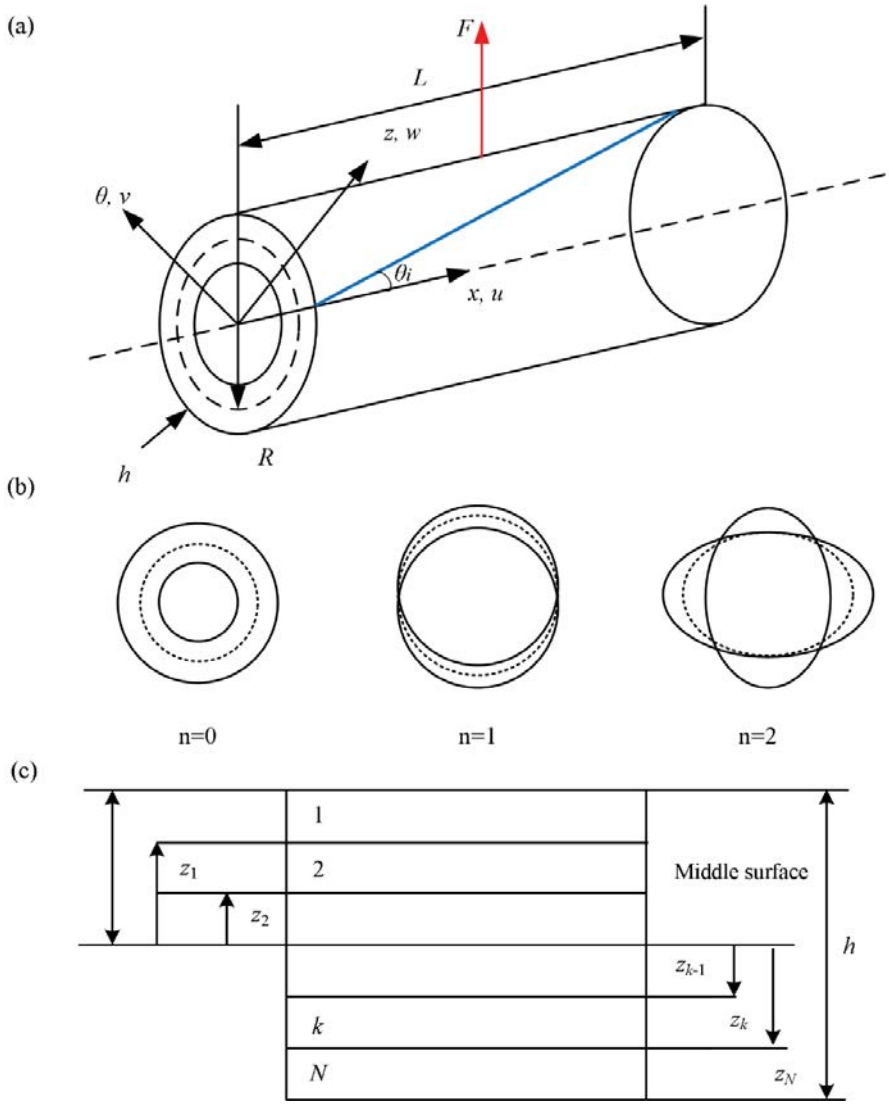

Figure 1: (a) The geometry of a laminated composite cylindrical shell; (b) circumferential modal shapes and (c) Geometry of an N-layered laminated composite cylindrical shell.

2.2 Theoretical solution of free vibration analysis

The classical shell theory is employed to establish the theoretical model. The displacement field for the shell is described by

$$u(x,\theta,z,t) = u_0(x,\theta,t) - z\frac{\partial w_0(x,\theta,t)}{\partial x},$$
$$v(x,\theta,z,t) = v_0(x,\theta,t) - z\frac{\partial w_0(x,\theta,t)}{R\partial\theta},$$
$$w(x,\theta,z,t) = w_0(x,\theta,t), \tag{1}$$

where u_0, v_0 and w_0 represent the middle surface displacement of the laminated composite cylindrical shell in axial, circumferential and radial directions, respectively.

The cylindrical shell under consideration is with constant thickness h, mean radius R, axial length L. here the respective displacements in the axial, circumferential and radial directions are denoted by $u(x,\theta,t)$, $v(x,\theta,t)$ and $w(x,\theta,t)$. The strain-displacement relations for thin circular cylindrical shells are

$$\varepsilon_x = \frac{\partial u}{\partial x}, \quad \varepsilon_\theta = \frac{\partial v}{R\partial\theta} + \frac{w}{R}, \quad \varepsilon_{x\theta} = \frac{\partial u}{R\partial\theta} + \frac{\partial v}{\partial x},$$
$$\chi_x = -\frac{\partial^2 w}{\partial x^2}, \quad \chi_\theta = \frac{1}{R^2}\left(\frac{\partial v}{\partial\theta} - \frac{\partial^2 w}{\partial\theta^2}\right), \quad \chi_{x\theta} = \frac{2}{R}\left(\frac{\partial v}{\partial x} - \frac{\partial^2 w}{\partial x\partial\theta}\right).$$

The relationship between the stress resultants and the internal forces and moments is

$$\begin{bmatrix} N_x \\ N_\theta \\ N_{x\theta} \\ M_x \\ M_\theta \\ M_{x\theta} \end{bmatrix} = \begin{bmatrix} A_{11} & A_{12} & A_{16} & B_{11} & B_{12} & B_{16} \\ A_{12} & A_{22} & A_{26} & B_{12} & B_{22} & B_{26} \\ A_{16} & A_{26} & A_{66} & B_{16} & B_{26} & B_{66} \\ B_{11} & B_{12} & B_{16} & D_{11} & D_{12} & D_{16} \\ B_{12} & B_{22} & B_{26} & D_{12} & D_{22} & D_{26} \\ B_{16} & B_{26} & B_{66} & D_{16} & D_{26} & D_{66} \end{bmatrix} \begin{bmatrix} \varepsilon_x \\ \varepsilon_\theta \\ \varepsilon_{x\theta} \\ \chi_x \\ \chi_\theta \\ \chi_{x\theta} \end{bmatrix}, \tag{2}$$

where N_x, N_θ and $N_{x\theta}$ are membrane forces, M_x,,M_θ and $M_{x\theta}$ are bending and torsion moments, and A_{ij} , B_{ij} and D_{ij} denotes the stiffnesses expressed by $A_{ij} = \sum_{k=1}^{N} \bar{Q}_{ij}\,(z_{k+1} - z_k)$, $B_{ij} = \frac{1}{2}\sum_{k=1}^{N} \bar{Q}_{ij}\,(z^2{}_{k+1} - z^2{}_k)$ and $D_{ij} = \frac{1}{3}\sum_{k=1}^{N} \bar{Q}_{ij}\,(z^3{}_{k+1} - z^3{}_k)$,where $i,j = 1,2$ or 6. For a specially orthotropic laminated composite shell, some stress stiffness coefficients are zero, i.e. $B_{ij} = 0$ and $A_{16} = A_{26} = D_{16} = D_{26} = 0$.

The governing equations of motion for thin cylindrical shells according to the love's theory in terms of the force and moment resultants are expressed as,

$$\frac{\partial N_x}{\partial x} + \frac{\partial N_{x\theta}}{R\partial\theta} = \rho h\frac{\partial^2 u}{\partial t^2},$$
$$\frac{\partial N_{x\theta}}{\partial x} + \frac{\partial N_\theta}{R\partial\theta} + \frac{\partial M_{x\theta}}{R\partial x} + \frac{\partial M_\theta}{R^2\partial\theta} = \rho h\frac{\partial^2 v}{\partial t^2},$$
$$\frac{\partial^2 M_x}{\partial x^2} + \frac{2\partial^2 M_{x\theta}}{R\partial x\partial\theta} + \frac{\partial^2 M_\theta}{R^2\partial\theta^2} - \frac{N_\theta}{R} = \rho h\frac{\partial^2 w}{\partial t^2}. \tag{3}$$

The governing equations can be rewritten in the matrix form,

$$\begin{bmatrix} L_{11} & L_{12} & L_{13} \\ L_{21} & L_{22} & L_{23} \\ L_{31} & L_{32} & L_{33} \end{bmatrix} \begin{Bmatrix} u(x,\theta,t) \\ v(x,\theta,t) \\ w(x,\theta,t) \end{Bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}. \tag{4}$$

where the coefficients are defined as follows,

$$L_{11} = A_{11}\frac{\partial^2}{\partial x^2} + \frac{A_{66}}{R^2}\frac{\partial^2}{\partial\theta^2}\ , \qquad L_{12} = \left(\frac{A_{12}}{R} + \frac{A_{66}}{R}\right)\frac{\partial^2}{\partial x\partial\theta}\ , \qquad L_{21} = \left(\frac{A_{12}}{R} + \frac{A_{66}}{R}\right)\frac{\partial^2}{\partial x\partial\theta}\ ,$$

$$L_{13}=\frac{A_{12}}{R}\frac{\partial}{\partial x},\quad L_{22}=\left(A_{66}+\frac{2D_{66}}{R^2}\right)\frac{\partial^2}{\partial x^2}+\left(\frac{A_{22}}{R^2}+\frac{D_{22}}{R^4}\right)\frac{\partial^2}{\partial\theta^2},$$
$$L_{23}=\left(\frac{A_{22}}{R^2}\frac{\partial}{\partial\theta}-\left(\frac{D_{12}+2D_{66}}{R^2}\right)\frac{\partial^2}{\partial x^2\partial\theta}-\frac{D_{22}}{R^4}\frac{\partial^3}{\partial\theta^3}\right),\ L_{31}=-\frac{A_{12}}{R}\frac{\partial}{\partial x},$$
$$L_{32}=\left(\frac{D_{12}+4D_{66}}{R^2}\right)\frac{\partial^3}{\partial\theta\partial x^2}+\frac{D_{22}}{R^4}\frac{\partial^3}{\partial\theta^3}-\frac{A_{22}}{R^2}\frac{\partial}{\partial\theta},$$
$$L_{33}=-D_{11}\frac{\partial^4}{\partial x^4}-2\left(\frac{D_{12}+2D_{66}}{R^2}\right)\frac{\partial^4}{\partial x^2\partial\theta^2}-\frac{D_{22}}{R^4}\frac{\partial^4}{\partial\theta^4}-\frac{A_{22}}{R^2}.$$

Based on the wave propagation approach [15], for the case of the shell simply supported at both ends, the explicit form of the solution can be assumed as

$$u(x,\theta,t)=\sum_{n=1}^{\infty}U_{mn}\cos(\beta\theta)\,e^{\mathrm{i}\omega t-\mathrm{i}k_m x},$$
$$v(x,\theta,t)=\sum_{n=1}^{\infty}V_{mn}\sin(\beta\theta)\,e^{\mathrm{i}\omega t-\mathrm{i}k_m x},$$
$$w(x,\theta,t)=\sum_{n=1}^{\infty}W_{mn}\cos(\beta\theta)\,e^{\mathrm{i}\omega t-\mathrm{i}k_m x},\tag{5}$$

where U_{mn}, V_{mn}, W_{mn} are the maximum amplitudes in the axial, circumferential and radial directions, respectively, $k_m=m\pi/L$, $\beta=n/R$ and, m and n are the axial and circumferential wavenumbers, respectively. Substituting Eq. (5) into Eq. (4) leads to

$$\begin{bmatrix}L_{11}-\Omega & L_{12} & L_{13}\\ L_{21} & L_{22}-\Omega & L_{23}\\ L_{31} & L_{32} & L_{33}-\Omega\end{bmatrix}\begin{Bmatrix}U_n\\V_n\\W_n\end{Bmatrix}=0.\tag{6}$$

Expansion of the determinant for the coefficient matrix of Eq. (6) in terms of $\rho h\omega^2=\Omega$ leads to a cubic equation for Ω:

$$\Omega^3+C_1\Omega^2+C_2\Omega+C_3=0,\tag{7}$$

which can be used to obtain the natural frequencies of the laminated composite shell. It has been demonstrated that the three positive roots are the angular natural frequencies of the cylindrical shell in the axial, circumferential and radial directions. The lowest value of the three positive roots is for the flexural vibration, and the other two represent in-plane vibrations.

3 RESULSTS AND DISCUSSSIONS

The theoretical formulations that were presented in the previous section is used firstly to obtain the free vibration behaviour. The structure considered are three-layered composite laminates cylindrical shells. The thickness of each layer is one third of the shell thickness. The cylindrical shell is constructed of different layers of orthotropic materials with different fibre orientations and the relevant properties are as the same as that given in literature [15] for verification of results. The geometrical and material properties parameters are set as $h/R=0.002$, $L/R=20$, $E_{22}=7.6\mathrm{GN/m^2}$, $E_{11}/E_{22}=2.5$, $G_{12}=4.1\mathrm{GN/m^2}$, $\nu_{12}=0.26$ and $\rho_0=1643\mathrm{kg/m^2}$. According to the Love's theory, it is assumed that layers are perfectly bonded. There is no flaw or gap between the layers, and no slipping between the layers. For the cylindrical shells with orthotropic laminates, different cases with the fibre orientation reducing from 90° to 0° at the interval of 15°.

The natural frequencies of laminated composite cylindrical shell with fibre orientation of $[90^\circ/0^\circ/90^\circ]$, $[90^\circ]_3$ and $[0^\circ]_3$ can be obtained based on theoretical approach as presented previously. For the other cases, the FEA are used to obtain the results. In ANSYS FEA modelling, the element 281 is employed to model the cylindrical composite laminated shell. The whole model contains 24080 nodes and 8000 elements. Each element has 8 nodes, each with six degrees of freedom. The number of integration points for each layer is set as three. There is one point located on the top surface, one on the bottom surface, and the third point is located at the

midpoint between the previous two points. The ANSYS Shell281 element is based on the first order shear deformation theory. The calculations have been carried out for the axial wavenumber *m*=1. A comparison of the natural frequencies of laminated composite cylindrical shells with various fibre orientations with different circumferential mode numbers *n* has been presented in the Table 1. For the composite laminate cylindrical shell with cross-ply $[90^\circ/0^\circ/90^\circ]$ lamination scheme, Table 1 shows that the theoretical results from wave propagation approach have great agreement with the those obtained from the FEA method and those are obtained by the Newton-Raphson procedure theoretically in the literature [12]. It is also found that theoretical results of the natural frequencies of laminated composite shells in $[90^\circ]_3$ and $[0^\circ]_3$ are close to those obtained from numerical FEA method. The FEA is therefore verified and employed for free vibration analysis of the cylindrical shells with other fibre orientations.

Table 1: Comparison of non-dimensional frequency parameter $\bar{\omega} = \omega\sqrt{\rho R^2/E_{22}}$ for three-layered cylindrical shells with different lamination sequences with simply supported-simply supported boundary conditions (h/R=0.002 and L/R=20).

Fig. 2 presents the circumferential mode shapes of the three-layered cross-ply cylindrical shells in $[\theta]_3$ with different fibre orientations while the axial wavenumber is kept to be *m*=1 and circumferential number is *n*=2. It is found that when the circumferential number is 2, the natural frequencies increase with the increase of the fibre orientations. It is observed that the circumferential modal shapes vary significantly with the change of fibre orientations. The position on the circumferential mode with the maximum displacement rotates with the change the fibre orientations. When the fibre orientation is changed from 0° to 90°, the maximum position for modal displacement changes from left side to right side, as shown in Fig. 2. It reveals that excited mode can be changed by tailoring fibre orientations.

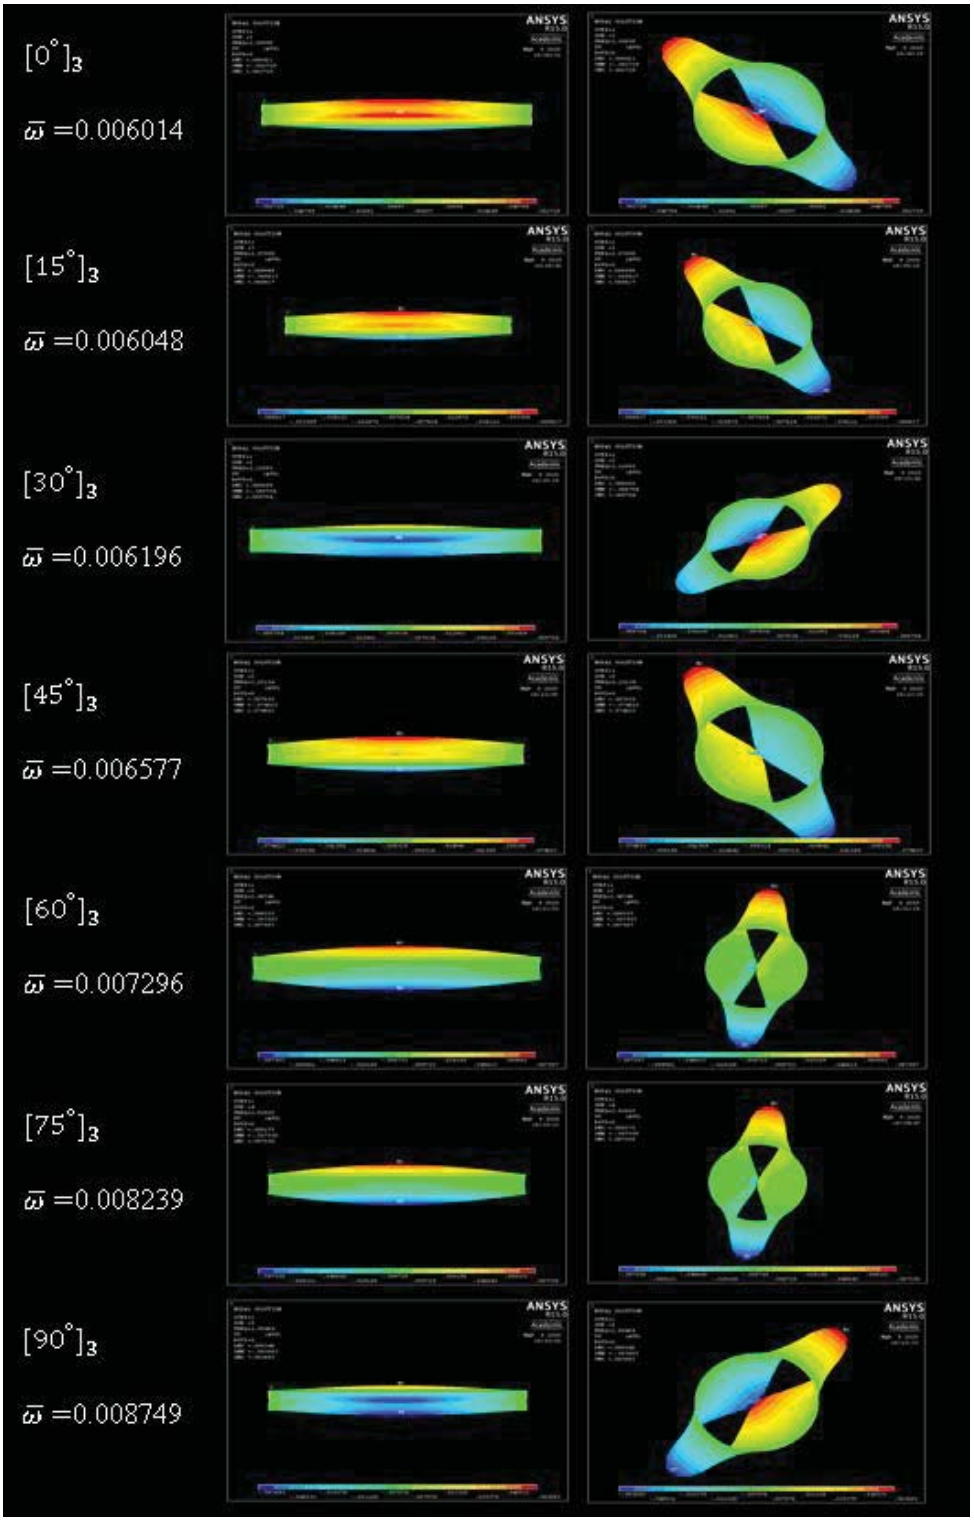

Figure 2: Mode shape of three-layered cross-ply cylindrical shells in $[\theta]_3$ with different fibre orientations with mode shape circumference number of n=2.

Fig. 3 shows the effects of fibre orientation on the circumferential natural frequencies with the mode sequence number n changing from 1 to 5. It is found that the influence of fibre orientations on circumferential natural frequencies is more significant at small circumferential mode n. The circumferential natural frequencies increase with the increase of fibre orientation angle when n=1 and 2. When $n = 1$, the principal mode shape is described as the bending mode. The

main reason can be that when the fibre orientation is increased to 90°, the stiffness along the circumferential directions reaches the maximum, leading to the increase of natural frequencies. In comparison, when n=3, 4 and 5, the natural frequencies decrease with fibre orientation. When the fibre orientation angle is larger than 30°, the circumferential natural frequencies corresponding to n=1 for each case are larger than those associated with large circumferential modes.

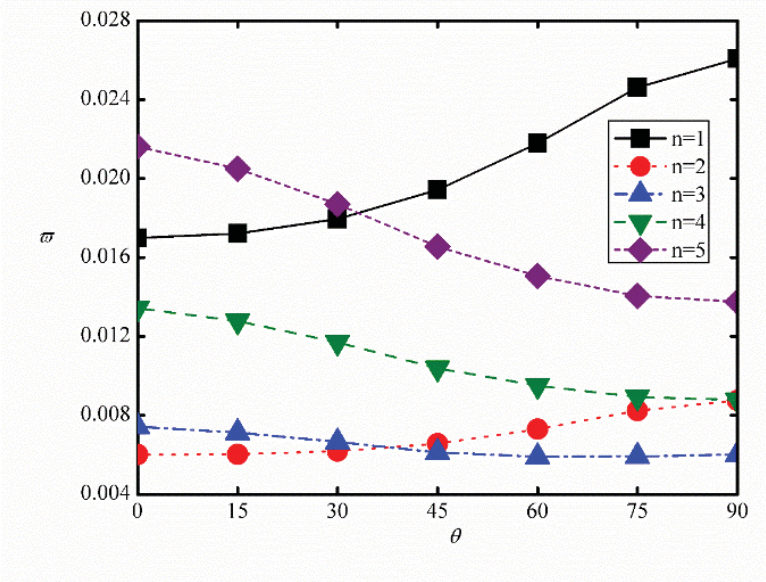

Figure 3: Variations of the non-dimensional frequencies of the shells in $[\theta]_3$ against the fibre orientations.

The theoretical wave propagation method can be employed for the free vibration of the composite laminate cylindrical shells in $[0^{\circ}]_3$ and $[90^{\circ}]_3$ to investigate the effects of the geometric ratios L/R on the natural frequencies, respectively. Four cases with different values of L/R being 1, 5, 10 and 20 are considered. Table 2 shows that for the case of L/R=1, the natural frequencies generally decrease with the increase of n. For other cases, the natural frequencies decrease first and then increase with the increase of n. It is found that natural frequency of the composite laminate cylindrical shells in $[0^{\circ}]_3$ with n=1 is the largest. It is found that when the stacking sequence is changed to the $[90^{\circ}]_3$, the natural frequencies with different circumferential number n are reduced but changing the stacking sequence from $[90^{\circ}]_3$ into $[0^{\circ}]_3$ could effectively increase the natural frequencies associated with n=1 and 2.

Table 2 has showed that the natural frequencies for the case L/R=1 decrease with the increase of n from 1 to 7. In the current case study, the forced vibration analysis of the cylindrical composite laminate shell with length L of 1m, thickness h of 0.002m and radius R of 1m is conducted. A harmonic excitation force is applied to the middle point $(0.5m, 0^{\circ}, 1m)$ of the shell structure. The fibre orientation of the cylindrical shells is set as 0°, 45° and 90°, respectively. Fig. 4. presents the dynamic response on the middle point of the cylindrical shells of different lamination schemes with the variation of the excitation frequencies. It is found that due to the superposition of the modal responses, there are a large number of the resonant peaks in a narrow frequency band. It is found that the change of the fibre orientation could effectively change the resonance frequencies and the corresponding amplitudes of the dynamic response. At specific excitation frequencies such as $\bar{\omega}$ =0.2, there is resonance peak of the shell in $[45^{\circ}]_3$ but a trough for the shell in $[0^{\circ}]_3$. At some resonance frequencies, the displacement may increase with the fibre orientation angle. These findings provide some evidence that the dynamic response could be reduced at some specific frequencies by changing the fibre orientations. More

detailed study of the vibration characteristics and effects of the fibre orientation on the dynamic behaviour may then be done for the optimization of the cylindrical shells to achieve reduced vibration level.

4 CONCLUSIONS

The vibration behaviour of laminated composite cylindrical shells simply-supported at both ends with various fibre orientations has been investigated. For specific fibre orientations, theoretical wave propagation approach based on Love's theory has been used for free vibration analysis of the laminated orthotropic composite cylindrical shells. The circumferential natural frequencies were obtained and compared with numerical finite element results for validation. The FEA was also employed for the forced vibration analysis of laminated composite cylindrical shells with various fibre orientations subjected to harmonic loading. The results showed that natural frequencies, mode shapes and the steady-state response at prescribed points can be tailored by properly designing fibre orientations for vibration mitigation. It was found that fibre orientation angle of the shell structure has significant influence on the natural frequencies associated with the first few circumferential modes. It was shown that for different circumferential modes, the fibre angles have distinctly different effects on the corresponding natural frequencies associated. The steady-state responses of cylindrical shells under a harmonic concentrated force were obtained for comparison. It was shown that the fibre angle can effectively vary the resonance frequencies and corresponding peak value of steady-state response.

Abstract. *Acoustic waves in a poroelastic medium with periodic structure are studied with respect to permanent seepage flow which modifies the wave propagation. The homogenization method provides the macroscopic equations governing the dynamic response of an effective medium. whose the properties are determined by the characteristic responses. We consider a Newtonian slightly compressible fluid under the barotropic acoustic approximation. In contrast with usual simplifications, the advection phenomenon of the Navier-Stokes equations is accounted for. The homogenization results are based on the periodic unfolding method combined with the asymptotic expansion technique. The dynamic permeability depends on the fluid flow properties including the advection effects associated with an assumed stationary perfusion of the porous structure. Numerical results show influence of the advection velocity on the strong dispersion of the quasi-shear modes*

1 INTRODUCTION

We consider acoustic wave propagation in periodic elastic, or viscoelastic scaffolds saturated by Newtonian slightly compressible fluids under the barotropic acoustic approxiamtion. The aim is to derive and analyze an effective medium model of acoustic waves superimposed to a permanent steady seepage flow through the porous material. To analyze the wave dispersion, the homogenization has been employed to upscale the Navier-Stokes equations in the context of deforming pores. This procedure leads to an effective porous medium model which captures the wave propagation for wave lengths significantly larger than the characteristic porosity size corresponding to the one period of the lattice.

The model equations were obtained in [9] using the periodic unfolding method [3], *cf.* [1] combined with the asymptotic expansion technique. Local problems for corrector functions provide the effective model parameters of the macroscopic wave propagation model which is coherent with the Biot model, yielding the two pressure modes referred to as P1 and P2. The local characteristic responses of the solid and fluid parts are decoupled even in the dynamic interactions including the wall shear stress on the periodic interfaces. A modified Darcy law is obtained; the frequency-dependent dynamic permeability tensor consisting of two parts one of which is associated with the steady advection at the pore level heterogeneity. The model has been implemented using the finite-element method and dispersion curves were obtained for different flow parameters, scaffold geometries and frequencies. Also extension for viscoelastic solid materials was elaborated [9]. The homogenized poroviscoelastic model involves the time convolutions related to the skeleton viscoelasticity and the fluid viscosity. While the macroscopic fading memory phenomena associated with the skeleton viscoelasticity are determined by the relaxation and creep functions of the pure solid phase, the seepage-associated memory effects depend on the fluid, the micropore geometry and the permanent flow perfusion.

In this paper, we record the homogenization result obtained recently in [9] and explore the dispersion properties of plane waves propagating in the homogenized medium. The aim is to illustrate the influence of the advection on the effective permeability and on the wave speed.

Basic notations

Through the paper, we shall adhere to the following notation. A point position in a Cartesian frame is specified by $x = (x_1, x_2, x_3) \in \mathbb{R}^3$, where $\mathbb{R}$ is the set of real numbers. The boldface notation for vectors $\boldsymbol{a} = (a_i)$ and second-order tensors $\boldsymbol{b} = (b_{ij})$ is used. The second-order identity tensor is denoted by $\boldsymbol{I} = (\delta_{ij})$. The fourth-order elasticity tensor is denoted by $\mathbb{D} = (D_{ijkl})$. The superposed dot denotes a derivative with respect to time. The gradient, divergence and Laplace operators are denoted by $\nabla, \nabla\cdot$ and ∇^2, respectively. When these operators have a subscript referring to the space variable, it is for indicating that the operator acts relatively at this space variable, for instance $\nabla_y = (\partial_i^y) = (\partial/\partial y_i)$. The symbol dot '$\cdot$' denotes the scalar product between two vectors and the symbol colon ':' stands for scalar (inner) product of two second-order tensors, *e.g.* $\boldsymbol{A} : \boldsymbol{B} = A_{ij}B_{ij} = \mathtt{tr}[\boldsymbol{A}^T\boldsymbol{B}] = A_{ki}B_{kj}\delta_{ij}$, where $\mathtt{tr}[\star]$ is the trace of a tensor and superscript T in $\star^T$ is the transposition operator. Operator $\otimes$ designates the tensor product between two vectors, *e.g.* $\boldsymbol{a} \otimes \boldsymbol{v} = (a_i v_j)$. Standard notations for functional spaces are adhered. Throughout the paper, x denotes the global ("macroscopic") coordinates, while the "local" coordinates y describe positions within the representative unit cell $Y \subset \mathbb{R}^3$. The normal vectors on a boundary of domains Ω_α (or Y_α) are denoted by $\boldsymbol{n}^\alpha$, $\alpha = s, f$, to distinguish their orientation outward to Ω_α (or Y_α) when dealing with the solid-fluid interfaces. By $\boldsymbol{e}(\boldsymbol{w}) = 1/2(\nabla\boldsymbol{w} + (\nabla\boldsymbol{w})^T)$ we denote the strain of a vector field $\boldsymbol{w}$ (displacements, or

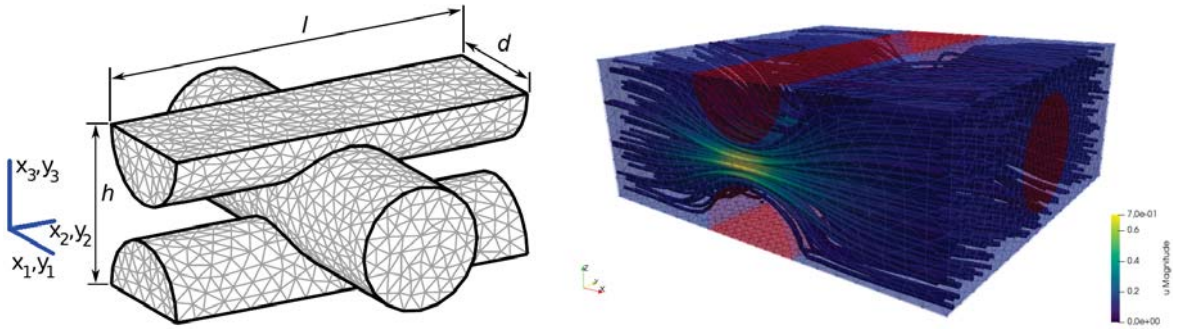

Figure 1: The periodic cell of solid fibres (left, from [4]) and the 3D periodic cell (right) consisting of the deformable solid scaffolds (red) and the fluid domain, where the flow streamlines for the mean advection velocity $\bar{w}^0 = 0.1$ m/s are shown.

velocities). The "tilde"-notation can have various meanings which are explained through the text and are clear within the particular context. The following standard functional spaces are used: by $L^2(\Omega)$ we refer to square integrable functions defined in an open bounded domain Ω; by $H^1(\Omega)$ we mean the Sobolev space $W^{1,2}(\Omega) \subset L^2(\Omega)$ formed by square integrable functions including their first generalized derivatives.Bold notation is used to denote spaces of vector-valued functions, e.g. $\mathbf{H}^1(\Omega)$; by subscript $_\#$ we refer to the Y-periodic functions.

2 Formulation of the acoustic problem

2.1 Periodic microstructure

The microstructure size is expressed by the scale parameter $\varepsilon = \ell/L$ defined by the ratio of the micro- and macroscopic characteristic lengths, denoted by ℓ and L, respectively. We consider a periodic structure of channels Ω_f^ε saturated by one homogeneous fluid. Due to the assumed periodicity of Ω_f^ε, a representative periodic cell $\mathcal{Z}_f^\varepsilon$ can be defined, which generates the fluid domain, see Fig. 1.

A periodic cell $\mathcal{Z}^\varepsilon = \prod_{i=1}^3]0, \varepsilon \ell^i[$ can be introduced, such that $\mathcal{Z}^\varepsilon = \mathcal{Z}_f^\varepsilon \cup \mathcal{Z}_s^\varepsilon \cup \partial_s \mathcal{Z}_f^\varepsilon$, where $\mathcal{Z}_s^\varepsilon \subset \mathcal{Z}^\varepsilon$ is the solid skeleton and $\partial_s \mathcal{Z}_f^\varepsilon$ is the fluid-solid interface. By $\partial_\# \mathcal{Z}_f^\varepsilon = \partial \mathcal{Z}_f^\varepsilon \setminus \partial_s \mathcal{Z}_f^\varepsilon$ we denote the "periodic part" of the boundary. For the purpose of the homogenization we consider the "unit periodic cell" $Y = \varepsilon^{-1} \mathcal{Z}^\varepsilon$ which consists of the fluid and solid parts accordingly the decomposition of $\mathcal{Z}^\varepsilon$, thus, $Y = Y_f \cup Y_s \cup \Gamma$.

The stress tensors of fluid and solid phases are respectively denoted by $\tilde{\boldsymbol{\sigma}}_f^\varepsilon$ and $\tilde{\boldsymbol{\sigma}}_s^\varepsilon$. The fluid phase is characterized by its mass density ρ_0, the bulk modulus k_f and the viscosity tensor $\mathbb{D}^{f,\varepsilon}$, see (5), whilst the solid phase is characterized by its density ρ_s and elasticity tensor $\mathbb{D}^{s,\varepsilon}$.

2.2 Acoustic wave decomposition

To treat the nonlinearity associated with fluid advection, we introduce a decomposition of the model responses into the steady part and the acoustic fluctuations, The total fields $\boldsymbol{w}$, p and the mass density of the fluid, ρ, are split into the "flow" parts $\bar{\boldsymbol{w}}$, $\bar{\rho}$ and $\bar{p}$ and the "acoustic fluctuation" parts $\tilde{\boldsymbol{w}}$, $\tilde{\rho}$ and $\tilde{p}$, so that

$$\boldsymbol{w} = \bar{\boldsymbol{w}} + \tilde{\boldsymbol{w}} \,, \quad p = \bar{p} + \tilde{p} \,, \quad \rho = \bar{\rho} + \tilde{\rho} \,. \tag{1}$$

Since the stationary fluid flow is assumed incompressible, $\bar{\rho} = \rho_0$ is a constant. Below, we assume that the steady-state flow is periodic in terms of the velocity $\tilde{\boldsymbol{w}}$. Essentially, because of the dissipation, pressure $\bar{p}$ cannot be described by a periodic function.

Concerning the solid displacement filed $\boldsymbol{u}$, the deformed configuration for the steady-state is taken as the reference one, so that $\boldsymbol{u}$ will only be associated with acoustic fluctuations (one can put $\bar{\boldsymbol{u}} \equiv \boldsymbol{0}$).

2.3 Acoustic problem formulation

The weak formulation of the acoustic problem at the pore level relies on the acoustic decomposition (1), so that the steady state response $(\bar{\boldsymbol{w}}^\varepsilon, \bar{p}^\varepsilon, \bar{\boldsymbol{u}}^\varepsilon)$ is assumed to be known.

Let $\hat{V}^\varepsilon(\Omega_f^\varepsilon), Q^1(\Omega_f^\varepsilon)$ and $\hat{U}^\varepsilon(\Omega_s^\varepsilon)$ be three admissible function spaces of the unknown fields $(\widetilde{\boldsymbol{w}}^\varepsilon, \widetilde{p}^\varepsilon, \widetilde{\boldsymbol{u}}^\varepsilon)$ of the problem constituted by the sufficiently differentiable complex-valued functions.

For almost all $t > 0$, the three fields $(\widetilde{\boldsymbol{w}}^\varepsilon, \widetilde{p}^\varepsilon, \widetilde{\boldsymbol{u}}^\varepsilon)$ such that $\widetilde{\boldsymbol{w}}^\varepsilon(t,\cdot) \in \hat{V}^\varepsilon(\Omega_f^\varepsilon)$, $\widetilde{p}^\varepsilon(t,\cdot) \in Q^1(\Omega_f^\varepsilon)$, and $\widetilde{\boldsymbol{u}}^\varepsilon(t,\cdot) \in \hat{U}^\varepsilon(\Omega_s^\varepsilon)$ satisfy

$$
\begin{aligned}
&\rho_0 \int_{\Omega_f^\varepsilon} \boldsymbol{\theta}^\varepsilon \cdot \Big(\dot{\widetilde{\boldsymbol{w}}}^\varepsilon + \ddot{\widetilde{\boldsymbol{u}}}^\varepsilon + \bar{\boldsymbol{w}}^\varepsilon \cdot \nabla(\widetilde{\boldsymbol{w}}^\varepsilon + \dot{\widetilde{\boldsymbol{u}}}^\varepsilon) + (\widetilde{\boldsymbol{w}}^\varepsilon + \dot{\widetilde{\boldsymbol{u}}}^\varepsilon) \cdot \nabla \bar{\boldsymbol{w}}^\varepsilon \Big) \\
&- \int_{\Omega_f^\varepsilon} \widetilde{p}^\varepsilon \nabla \cdot \boldsymbol{\theta}^\varepsilon + \int_{\Omega_f^\varepsilon} \mathbb{D}^{f,\varepsilon} \boldsymbol{e}(\widetilde{\boldsymbol{w}}^\varepsilon + \dot{\widetilde{\boldsymbol{u}}}^\varepsilon) : \boldsymbol{e}(\boldsymbol{\theta}^\varepsilon) = \int_{\Omega_f^\varepsilon} \tilde{\boldsymbol{f}}^f \cdot \boldsymbol{\theta}^\varepsilon + \int_{\partial_\sigma \Omega_f^\varepsilon} \tilde{\boldsymbol{g}}^{f,\varepsilon} \cdot \boldsymbol{\theta}^\varepsilon \,, \\
&\int_{\Omega_f^\varepsilon} q^\varepsilon \Big(\dot{\widetilde{p}}^\varepsilon + \bar{\boldsymbol{w}}^\varepsilon \cdot \nabla \widetilde{p}^\varepsilon + k_f \nabla \cdot (\widetilde{\boldsymbol{w}}^\varepsilon + \dot{\widetilde{\boldsymbol{u}}}^\varepsilon) \Big) = 0 \,,
\end{aligned}
\tag{2}
$$

for all $\boldsymbol{\theta}^\varepsilon \in V_0^\varepsilon(\Omega_f^\varepsilon)$ and $q^\varepsilon \in Q^0(\Omega_f^\varepsilon)$, and

$$
\int_{\Omega_s^\varepsilon} \rho_s \ddot{\widetilde{\boldsymbol{u}}}^\varepsilon \cdot \boldsymbol{v}^\varepsilon + \int_{\Omega_s^\varepsilon} \mathbb{D}^{s,\varepsilon} \boldsymbol{e}(\tilde{\boldsymbol{u}}^\varepsilon) : \boldsymbol{e}(\boldsymbol{v}^\varepsilon) - \tilde{\mathcal{I}}^\varepsilon(\tilde{\boldsymbol{\sigma}}_f^\varepsilon, \boldsymbol{v}^\varepsilon) = \int_{\Omega_s^\varepsilon} \tilde{\boldsymbol{f}}^s \cdot \boldsymbol{v}^\varepsilon + \int_{\partial_\sigma \Omega_s^\varepsilon} \tilde{\boldsymbol{g}}^{s,\varepsilon} \cdot \boldsymbol{v}^\varepsilon \,,
\tag{3}
$$

for all $\boldsymbol{v}^\varepsilon \in U_0^\varepsilon(\Omega_s^\varepsilon)$, where $\tilde{\mathcal{I}}^\varepsilon$ represents the fluid stress virtual power on interface Γ_{fs}^ε,

$$
\begin{aligned}
\tilde{\mathcal{I}}^\varepsilon(\tilde{\boldsymbol{\sigma}}_f^\varepsilon, \boldsymbol{v}^\varepsilon) &= \int_{\Gamma_{fs}^\varepsilon} \boldsymbol{n}^s \cdot \tilde{\boldsymbol{\sigma}}_f^\varepsilon \cdot \boldsymbol{v}^\varepsilon \,, \\
\tilde{\boldsymbol{\sigma}}_f^\varepsilon(\tilde{p}^\varepsilon, \boldsymbol{w}^\varepsilon + \dot{\tilde{\boldsymbol{u}}}^\varepsilon) &= -\boldsymbol{I}\tilde{p}^\varepsilon + \mathbb{D}^{f,\varepsilon} \boldsymbol{e}(\boldsymbol{w}^\varepsilon + \dot{\tilde{\boldsymbol{u}}}^\varepsilon) \,.
\end{aligned}
\tag{4}
$$

3 Homogenized model

An effective model of the two-phase medium was derived using in the asymptotic analysis $\varepsilon \to 0$ of the micro-model (2) and (4). The following scaling by powers of ε is used for the fluid viscosity μ^ε and the steady flow advection $\bar{\boldsymbol{w}}^\varepsilon$ to adjust them to the microstructure, namely to the pore size proportional to ε,

$$
\begin{aligned}
\text{viscosity:} \quad & \mu^\varepsilon = \varepsilon^2 \bar{\mu} \,, \quad \mathbb{D}^{f,\varepsilon} = \varepsilon^2 2\bar{\mu}(\mathbb{I} - \frac{1}{3}\boldsymbol{I} \otimes \boldsymbol{I}) \,, \\
\text{advection velocity:} \quad & \bar{\boldsymbol{w}}^\varepsilon(x) = \varepsilon \bar{\boldsymbol{w}}(y) \,,
\end{aligned}
\tag{5}
$$

where $\mathbb{I}$ is the fourth-order identity tensor and $\bar{\boldsymbol{w}}(y)$ with $y = x/\varepsilon$ is the Y-periodic advection velocity field, as represented in Y_f. It is worth noting that the periodic structure is retained if all the material parameters constituting the microstructure and also the advection velocity $\bar{\boldsymbol{w}}$ are constant with respect to the macroscopic position in the medium. In a general situation, the velocity field describing the steady flow in the microstructure can be established for a given macroscopic velocity $\boldsymbol{w}^0$ by means of the Forchheimer law, see *e.g.* [2], *cf.* [9], so that $\bar{\boldsymbol{w}}(x,y)$ is a two-scale function satisfying the incompressibility constraint $\nabla_y \cdot \bar{\boldsymbol{w}}(x,y) = 0$.

3.1 Characteristic responses

The asymptotic analysis (2) and (4) yields the limit equations involving macroscopic fields and two-scale fields. Due to the linearity, the latter fields can be expressed using multiplicative split into the macroscopic and the characteristic responses. However, to do so, the Laplace transformation, $\mathcal{L}\{f\} \mapsto \underset{\sim}{f}(\lambda)$, where λ is a complex variable representing the angular frequency, must be employed, since the two-scale functions are coupled with the macroscopic functions in time. In what follows, we employ the following bilinear and trilinear forms, defined in terms of the inner product and and the averaging integral,

$$\begin{aligned} \langle \boldsymbol{u},\, \boldsymbol{v}\rangle_{Y_f} &= \fint_{Y_f} \boldsymbol{u}\cdot\boldsymbol{v}\ , \\ \fint_D \star &= \frac{1}{|Y|}\int_D \star\ , \qquad \text{for any } D\subset Y\ , \\ a_f\left(\boldsymbol{w},\, \boldsymbol{v}\right) &= \langle \nabla_y \boldsymbol{w},\, \nabla_y \boldsymbol{v}\rangle_{Y_f}\ , \\ b_f\left(\bar{\boldsymbol{w}},\, \boldsymbol{w},\, \boldsymbol{v}\right) &= 2\,\langle \bar{\boldsymbol{w}}\otimes\boldsymbol{w},\, \boldsymbol{e}_y(\boldsymbol{v})\rangle_{Y_f}\ , \end{aligned} \tag{6}$$

where D can be a subdomain, or a manifold in Y. We employ the spaces of Y-periodic functions: we define $H^1_{\#}(Y)\subset W^{1,2}(Y)$ and $\mathbf{H}^1_{\#}(Y)\subset \boldsymbol{W}^{1,2}(Y)$ for scalar and vectorial fields, respectively; space $\widetilde{\mathbf{H}}^1_{\#}(Y_s)\subset \mathbf{H}^1_{\#}(Y_s)$ is restricted to functions with zero mean values in Y_s; admissible flow velocities belong to the space

$$\mathbf{H}^1_{\#0}(Y_f) = \{\boldsymbol{v}\in \mathbf{H}^1_{\#}(Y_f)|\ \boldsymbol{v}=\boldsymbol{0} \text{ on } \partial Y_f\setminus\partial Y\}\ . \tag{7}$$

In order to introduce the local autonomous problems for characteristic flow responses, we establish the following tensor operator attaining two alternative forms,

$$\boldsymbol{A} = (A_{ij})\ , \quad A_{ij} = \left\{ \begin{array}{l} \delta_{ij}\ , \\ G_{ij} = \partial^y_j \bar{w}_i \end{array}\right. . \tag{8}$$

Note that $(\boldsymbol{A}\mathbf{1}_k)_i = A_{ik}$, whereby $(\mathbf{1}_k)_j = \delta_{jk}$, thus, $(\boldsymbol{G}\mathbf{1}_k)_i = (\nabla_y \bar{\boldsymbol{w}}\mathbf{1}_k)_i = \partial^y_k \bar{w}_i$.

The characteristic responses $(\boldsymbol{w}^{\boldsymbol{A},k}, \pi^{\boldsymbol{A},k})$, where $\underset{\sim}{\boldsymbol{w}}^{\boldsymbol{A},k}\in \mathbf{H}^1_{\#0}(Y_f)$ and $\underset{\sim}{\pi}^{\boldsymbol{A},k}\in L^2(Y_f)$, satisfy

$$\begin{aligned} \lambda\left\langle \underset{\sim}{\boldsymbol{w}}^{\boldsymbol{A},k},\, \boldsymbol{v}\right\rangle_{Y_f} - b_f\left(\bar{\boldsymbol{w}},\, \underset{\sim}{\boldsymbol{w}}^{\boldsymbol{A},k},\, \boldsymbol{v}\right) \\ +\frac{1}{\bar{\nu}} a_f\left(\underset{\sim}{\boldsymbol{w}}^{\boldsymbol{A},k},\, \boldsymbol{v}\right) - \left\langle \underset{\sim}{\pi}^{\boldsymbol{A},k},\, \nabla_y\cdot\boldsymbol{v}\right\rangle_{Y_f} = \frac{1}{\lambda}\left\langle \boldsymbol{A}\mathbf{1}_k,\, \boldsymbol{v}\right\rangle_{Y_f}\ , \\ \left\langle q,\, \nabla_y\cdot \underset{\sim}{\boldsymbol{w}}^{\boldsymbol{A},k}\right\rangle_{Y_f} = 0\ , \end{aligned} \tag{9}$$

for all $\boldsymbol{v}\in\mathbf{H}^1_{\#0}(Y_f)$ and $q\in L^2(Y_f)$, where $\bar{\nu}=\rho_0/\bar{\mu}$ is the rescaled kinematic viscosity.

The poroelastic coefficients of the Biot model are expressed in terms of time-independent characteristic responses $\boldsymbol{\omega}^{ij}$ and $\boldsymbol{\omega}^*(y)$. Using the elastic bilinear form,

$$a_s\left(\boldsymbol{u},\, \boldsymbol{v}\right) = \fint_{Y_s} \mathbb{D}_s \boldsymbol{e}_y(\boldsymbol{u}) : \boldsymbol{e}_y(\boldsymbol{v})\ , \tag{10}$$

two standard autonomous problems are introduced.

(i) Find $\boldsymbol{\omega}^{ij} \in \widetilde{\mathbf{H}}^1_{\#}(Y_s)$, such that

$$a_s\left(\boldsymbol{\omega}^{ij}, \boldsymbol{v}\right) = -a_s\left(\boldsymbol{\Pi}^{ij}, \boldsymbol{v}\right) \ , \quad \forall \boldsymbol{v} \in \mathbf{H}^1_{\#}(Y_s) \ , \tag{11}$$

where $\boldsymbol{\Pi}^{ij} = (\Pi^{ij}_k)$ with $\Pi^{ij}_k = y_j \delta_{ik}$.

(ii) Find $\boldsymbol{\omega}^* \in \widetilde{\mathbf{H}}^1_{\#}(Y_s)$, such that

$$a_s\left(\boldsymbol{\omega}^*, \boldsymbol{v}\right) = -\oint_{\Gamma} \boldsymbol{v} \cdot \boldsymbol{n}^s \ , \quad \forall \boldsymbol{v} \in \mathbf{H}^1_{\#}(Y_s) \ . \tag{12}$$

3.2 Effective material parameters

Two homogenized tensors $\widehat{\underset{\sim}{\mathcal{K}}} = (\widehat{\underset{\sim}{\mathcal{K}}}_{ij})$ and $\widehat{\underset{\sim}{\mathcal{G}}} = (\widehat{\underset{\sim}{\mathcal{G}}}_{ij})$ constituting the effective Darcy law are determined by the characteristic responses $\underset{\sim}{\boldsymbol{w}}^{\boldsymbol{I},i}$ and $\underset{\sim}{\boldsymbol{w}}^{\boldsymbol{G},i}$,

$$\widehat{\underset{\sim}{\mathcal{K}}}_{ij}(\lambda) = \lambda \oint_{Y_f} \underset{\sim}{w}^{\boldsymbol{I},j}_i \ , \quad \widehat{\underset{\sim}{\mathcal{G}}}_{ij}(\lambda) = \lambda \oint_{Y_f} \underset{\sim}{w}^{\boldsymbol{G},j}_i \text{ for } i,j = 1,\dots,3. \tag{13}$$

Using the $\boldsymbol{\omega}^{ij}$ and $\boldsymbol{\omega}^*(y)$, the effective poroelastic coefficients of the Biot model are computed,

$$\begin{aligned} D^H_{ijkl} &:= a_s\left(\boldsymbol{\omega}^{ij} + \boldsymbol{\Pi}^{ij}, \boldsymbol{\omega}^{kl} + \boldsymbol{\Pi}^{kl}\right) \ , \\ B^H_{ij} &:= -a_s\left(\boldsymbol{\omega}^*, \boldsymbol{\Pi}^{ij}\right) = a_s\left(\boldsymbol{\omega}^*, \boldsymbol{\omega}^{ij}\right) = -\oint_{\Gamma} \boldsymbol{\omega}^{ij} \cdot \boldsymbol{n}^s \ , \\ N^H &:= \oint_{Y_f} \nabla_y \cdot \widetilde{\boldsymbol{\omega}}^* = a_s\left(\boldsymbol{\omega}^*, \boldsymbol{\omega}^*\right) \ , \end{aligned} \tag{14}$$

recalling that $\widetilde{\boldsymbol{\omega}}$ is a smooth extension of $\boldsymbol{\omega}$ to entire Y. Above, the alternative expressions can be derived due to the local problems (11) and (12). The following properties of the homogenized poroelastic coefficients hold: the Biot compressibility modulus $M^H > 0$, the elasticity coefficients are symmetric, $D^H_{ijkl} = D^H_{klij} = D^H_{jikl}$, and positive definite, *i.e.* $D^H_{ijkl}\xi_{ij}\xi_{kl} > 0$ for any $\xi_{ij} \in \mathbb{R}$, and the analogous properties hold also for Biot stress-coupling coefficients $B^H_{ij} = B^H_{ji}$ satisfying $\widehat{B}^H_{ij}\zeta_i\zeta_j > 0$ for any $\zeta_i \in \mathbb{R}$.

Upon introducing coefficients involving the porosity ϕ_f,

$$\widehat{\boldsymbol{B}}^H := \boldsymbol{B}^H + \phi_f \boldsymbol{I} \ , \quad M^H := N^H + \frac{\phi_f}{k_f} \ , \quad \text{with } \phi_f = \oint_{Y_f} \ , \tag{15}$$

we recover the Biot model of the poroelastic material; the total effective stress $\boldsymbol{\sigma}^{\text{eff}}$,the local pore fluid content increase $\dot{\mathcal{J}}_f = -\nabla_x \cdot (\phi_f \boldsymbol{w}^0)$, and the effective seepage velocity $\phi_f \underset{\sim}{\boldsymbol{w}}^0$ are given by

$$\begin{aligned} \boldsymbol{\sigma}^{\text{eff}} &= \mathbb{D}^H \boldsymbol{e}_x(\boldsymbol{u}^0) - p^0 \widehat{\boldsymbol{B}}^H \ , \quad \dot{\mathcal{J}}_f = \widehat{\boldsymbol{C}}^H : \boldsymbol{e}_x(\boldsymbol{u}^0) + M^H \dot{p}^0 \ , \\ \phi_f \underset{\sim}{\boldsymbol{w}}^0 &= -\widehat{\underset{\sim}{\mathcal{K}}} \frac{1}{\rho_0} (\nabla_x \underset{\sim}{p}^0 + \rho_0 \lambda^2 \underset{\sim}{\boldsymbol{u}}^0 - \underset{\sim}{\widehat{\boldsymbol{f}}}^f) + \widehat{\underset{\sim}{\mathcal{G}}} \lambda \underset{\sim}{\boldsymbol{u}}^0 \ . \end{aligned} \tag{16}$$

While the dynamic permeability $\widehat{\underset{\sim}{\mathcal{K}}}$ constitutes the Darcy law (16), as in the case of a rigid porous medium, tensor $\widehat{\underset{\sim}{\mathcal{G}}}$ presents a coupled effect of the advection $\bar{\boldsymbol{w}}$ and the macroscopic skeletom velocity $\lambda \underset{\sim}{\boldsymbol{u}}^0$.

3.3 Permeability and the visco-dynamic operator

In many works (see *e.g.* [6] and [5]) the dynamic permeability is introduced using the second-order tensor $\eta[\boldsymbol{k}(\lambda)]^{-1} := \lambda\boldsymbol{\rho} + \eta\boldsymbol{K}^{-1}$ which presents the "low-frequency approximation" (*i.e.* for small $\lambda := \mathrm{i}\omega$, given by the frequency ω and $\mathrm{i} = \sqrt{-1}$) of the visco-dynamic operator, defined by the static permeability $\boldsymbol{K}$, the dynamic fluid viscosity, η, and the tortuosity $a_\tau \geq 1$: $\boldsymbol{\rho} \approx \boldsymbol{I}\rho_a$ with $\rho_a = \rho_f a_\tau/\phi_f$. We consider $\widetilde{\boldsymbol{\mathcal{K}}}(\lambda) := [\lambda\boldsymbol{\rho} + \boldsymbol{K}^{-1}]^{-1}$ and compare it with the permeability $\widehat{\boldsymbol{\mathcal{K}}}(\lambda)$ just introduced above.

Let $\boldsymbol{\Lambda} = \mathrm{diag}_k(\Lambda_k)$ is the diagonal tensor formed by the eigenvalues Λ_k, $k = 1, 2, 3$ of the static permeability $\boldsymbol{K}$, thus, $\boldsymbol{K}\boldsymbol{X} = \boldsymbol{\Lambda}\boldsymbol{X}$. The following holds:

$$\widetilde{\boldsymbol{\mathcal{K}}}(\lambda) = \boldsymbol{X}\mathrm{diag}_k(\xi_k)\boldsymbol{X}^T\ , \quad \xi_k = \frac{\Lambda_k}{1+\lambda\Lambda_k\rho_a} = \frac{\Lambda_k(1+\lambda^*\Lambda_k)}{1+(|\lambda|\Lambda_k\rho_a)^2}\ , \tag{17}$$

where λ^* is the complex conjugate of λ and $|\lambda| = \sqrt{\lambda\lambda^*}$. The obvious asymptotics yields $\xi_k \to \Lambda_k$ for $|\lambda| \to 0_+$ and $\xi_k \to 0$ for $|\lambda| \to \infty$. It is easy to see that

$$\widetilde{\boldsymbol{\mathcal{K}}}^{-1}(\lambda) = \boldsymbol{X}\mathrm{diag}_k\left(\lambda\rho_a + \Lambda_k^{-1}\right)\boldsymbol{X}^T\ , \tag{18}$$

noting that eigenvalues Λ_k are independent of λ. By virtue of the approximation $\widehat{\boldsymbol{\mathcal{K}}}(\lambda) \approx \widetilde{\boldsymbol{\mathcal{K}}}(\lambda)$ the above asymptotics and (17),(18) reveal also the variation of $(\widehat{\boldsymbol{\mathcal{K}}}(\lambda))^{-1}$ with frequency λ.

4 Poroelastic model in the frequency domain

To study the wave propagation in the homogenized medium, the Biot model with the dynamic Darcy law will be presented in the frequency domain. We shall consider monochromatic harmonic waves of a given circular frequency ω. Further, we employ $\mathrm{i}^2 = -1$; note the relationship with the preceding section by putting $\lambda = \mathrm{i}\omega$. The Fourier transform $\mathcal{F}(\omega) : u(t,x) \mapsto \mathring{u}(\omega,x)$ is applied, replacing formally the Laplace transformation employed above. In what follows, for the sake of simplicity, we keep unchanged notation for the unknown fields, just dropping the superscript ^{0}. Since the reference fluid density ρ^0 is a constant, it is useful to introduce the following notation:

$$\begin{aligned}
\boldsymbol{u} &:= \mathring{\boldsymbol{u}}\ , & \widehat{\mathbb{D}}^H &:= \mathbb{D}^H/\rho^0\ ,\\
p &:= \mathring{p}/\rho^0\ , & \widehat{M}^H &:= \rho^0 M^H\ ,\\
\boldsymbol{w} &:= \phi_f\mathring{\boldsymbol{w}}\ , & \widehat{\mathring{\boldsymbol{\mathcal{K}}}} &:= \rho^0\mathring{\boldsymbol{\mathcal{K}}}\ ,\\
\widehat{\mathring{\boldsymbol{f}}} &:= \widehat{\mathring{\boldsymbol{f}}}/\rho^0\ , & \widehat{\mathring{\boldsymbol{\mathcal{G}}}} &:= \rho^0\mathring{\boldsymbol{\mathcal{G}}}\ ,\\
\widehat{\mathring{\boldsymbol{f}}}^f &:= \widehat{\mathring{\boldsymbol{f}}}^f/\rho^0\ , & \mathring{\boldsymbol{g}}^s &:= \mathring{\boldsymbol{g}}^s/\rho^0\ ,\\
\hat{r} &= \bar{\rho}/\rho_0\ , & \text{where } \bar{\rho} &= \bar{\rho}_s + \phi_f\rho_0 = \fint_{Y_s}\rho_s + \phi_f\rho_0\ ,
\end{aligned} \tag{19}$$

thus, $\bar{\rho}$ is the mean density. The visco-dynamic operator, *cf.* [6] and [5], is represented by the inverse dynamic permeability $\widehat{\mathring{\boldsymbol{\mathcal{K}}}}^{-1}$. Within assumptions of the acoustic fluctuations, the dynamic response of the homogenized poroelastic medium is governed by the following set of

differential equations

$$
\begin{aligned}
-\omega^2 \hat{r}\boldsymbol{u} + \mathrm{i}\omega\boldsymbol{w} - \nabla\cdot\left(\widehat{\mathbb{D}}^H \boldsymbol{e}_x(\boldsymbol{u}) - p\widehat{\boldsymbol{B}}^H\right) &= \widehat{\underset{\circ}{\boldsymbol{f}}}\,, \\
\mathrm{i}\omega\widehat{\boldsymbol{B}}^H : \boldsymbol{e}_x(\boldsymbol{u}) + \nabla\cdot\boldsymbol{w} + \mathrm{i}\omega\widehat{M}^H p &= 0\,, \\
\widehat{\underset{\circ}{\boldsymbol{\mathcal{K}}}}^{-1}(\boldsymbol{w} + \mathrm{i}\omega\widehat{\underset{\circ}{\boldsymbol{\mathcal{G}}}}\boldsymbol{u}) - \omega^2\boldsymbol{u} + \nabla_x p &= \widehat{\underset{\circ}{\boldsymbol{f}}}^f\,,
\end{aligned}
\tag{20}
$$

where $\widehat{\underset{\circ}{\boldsymbol{f}}}^f$ and $\widehat{\underset{\circ}{\boldsymbol{f}}}$ are the effective volume forces in the fluid phase and in the bulk mixture material; however, these forces are not involved in the dispersion analysis studied below. It is worth to note that the extra term $\mathrm{i}\omega\widehat{\underset{\circ}{\boldsymbol{\mathcal{K}}}}^{-1}\widehat{\underset{\circ}{\boldsymbol{\mathcal{G}}}}\boldsymbol{u}$ in the last equation emerges due to the advection phenomenon of the permanent fluid flow given by the advection Y-periodic velocity field $\bar{\boldsymbol{w}}$.

Remark 1. It is worth noting that the computed permeability $\widehat{\underset{\circ}{\boldsymbol{\mathcal{K}}}}$ is usually represented by the visco-dynamic operator $[\boldsymbol{k}(\omega)]/\eta$, see *e.g.* [6], such that $\widehat{\underset{\circ}{\boldsymbol{\mathcal{K}}}}^{-1} \approx \eta[\boldsymbol{k}(\omega)]^{-1} := \mathrm{i}\omega\boldsymbol{\rho} + \eta\boldsymbol{K}^{-1}$ presents the low-frequency Biot's approximation of the visco-dynamic operator, where $\boldsymbol{K}/\eta$ is the static permeability.

4.1 Wave dispersion analysis

The wave propagation in the heterogeneous two-phase medium is analyzed using the model of the homogenized medium. In what follows, the volume forces are disregarded, since we are interested in the free wave propagation, thus $\widehat{\underset{\circ}{\boldsymbol{f}}} = \widehat{\underset{\circ}{\boldsymbol{f}}}^f \equiv \boldsymbol{0}$.

4.2 Plane waves in homogenized medium

We look for a monochromatic harmonic plane wave propagating in direction $\boldsymbol{n}$, such that it can be written in the form

$$
\begin{aligned}
\tilde{\boldsymbol{u}}(x,t) &= \boldsymbol{u}\exp\left(-\mathrm{i}\boldsymbol{\kappa}\cdot\boldsymbol{x}\right)\exp\left(\mathrm{i}\omega t\right)\,, \\
\tilde{p}(x,t) &= p\exp\left(-\mathrm{i}\boldsymbol{\kappa}\cdot\boldsymbol{x}\right)\exp\left(\mathrm{i}\omega t\right)\,, \\
\tilde{\boldsymbol{w}}(x,t) &= \boldsymbol{w}\exp\left(-\mathrm{i}\boldsymbol{\kappa}\cdot\boldsymbol{x}\right)\exp\left(\mathrm{i}\omega t\right)\,,
\end{aligned}
\tag{21}
$$

where the triplet $(\boldsymbol{u}, p, \boldsymbol{w})$ denotes the plane wave amplitudes, ω is the circular frequency and $\boldsymbol{\kappa} = \varkappa\boldsymbol{n}$ is the wave vector. In the Fourier space, transformed (21) substituted in (20) yields

$$
\begin{aligned}
-\omega^2\hat{r}\boldsymbol{u} + \mathrm{i}\omega\boldsymbol{w} + \varkappa^2\boldsymbol{n}\cdot\widehat{\mathbb{D}}^H : \boldsymbol{n}\otimes\boldsymbol{u} - \mathrm{i}\varkappa\widehat{\boldsymbol{B}}^H\boldsymbol{n}p &= \boldsymbol{0}\,, \\
\varkappa\omega\widehat{\boldsymbol{B}}^H : \boldsymbol{n}\otimes\boldsymbol{u} - \mathrm{i}\varkappa\boldsymbol{n}\cdot\boldsymbol{w} + \mathrm{i}\omega\widehat{M}^H p &= 0\,, \\
\widehat{\underset{\circ}{\boldsymbol{\mathcal{K}}}}^{-1}(\boldsymbol{w} + \mathrm{i}\omega\widehat{\underset{\circ}{\boldsymbol{\mathcal{G}}}}\boldsymbol{u}) - \omega^2\boldsymbol{u} - \mathrm{i}\varkappa\boldsymbol{n}p &= \boldsymbol{0}\,.
\end{aligned}
\tag{22}
$$

Let us recall the approximate expression (18) of $(\widehat{\boldsymbol{\mathcal{K}}}(\mathrm{i}\omega))^{-1}$ which reveals that $(22)_3$ is well defined.

The dispersion analysis yields an implicit mapping $\omega \mapsto \varkappa$ within an interval of frequencies, $\underline{\omega} \le \omega \le \overline{\omega}$, $\underline{\omega}, \overline{\omega} \in \mathbb{R}$ for a specified direction $\boldsymbol{n}$. To compute $\varkappa$ for a given $\omega \in \mathbb{R}$, an eigenvalue problem (EVP) must be solved. The straightforward formulation (22) involving all the three variables $(\boldsymbol{u}, p, \boldsymbol{w})$, as well as the reduced formulation in $(\boldsymbol{u}, p)$, both lead to a quadratic EVP, cf. [10]. By eliminating the pressure from (22), the formulation in $(\boldsymbol{u}, \boldsymbol{w})$ is obtained, which leads to a linear EVP. Therefore, we pursue this approach of performing the dispersion analysis.

4.3 Formulation $(\boldsymbol{u}, \boldsymbol{w})$

The pressure can be eliminated from (22),

$$\begin{aligned} p &= \frac{-1}{\mathrm{i}\omega\widehat{M}^H}\left(\varkappa\omega\widehat{\boldsymbol{B}}^H : \boldsymbol{n}\otimes\boldsymbol{u} - \mathrm{i}\omega\boldsymbol{n}\cdot\boldsymbol{w}\right) \\ &= \frac{\mathrm{i}\varkappa}{\widehat{M}^H}\widehat{\boldsymbol{B}}^H : \boldsymbol{n}\otimes\boldsymbol{u} + \frac{\varkappa}{\omega\widehat{M}^H}\boldsymbol{n}\cdot\boldsymbol{w}\ , \end{aligned} \tag{23}$$

Upon substituting (23) in (22), we get

$$\begin{aligned} \varkappa^2\left(\boldsymbol{n}\cdot\widehat{\mathbb{D}}^H : \boldsymbol{n}\otimes\boldsymbol{u} + (\widehat{M}^H)^{-1}(\widehat{\boldsymbol{B}}^H\boldsymbol{n})\otimes(\widehat{\boldsymbol{B}}^H\boldsymbol{n})\boldsymbol{u}\right) - \omega^2\hat{r}\boldsymbol{u} \\ + \left(\mathrm{i}\omega\boldsymbol{I} - \varkappa^2\mathrm{i}(\omega\widehat{M}^H)^{-1}\widehat{\boldsymbol{B}}^H\boldsymbol{n}\otimes\boldsymbol{n}\right)\boldsymbol{w} = 0\ , \\ \left(\mathrm{i}\omega\widehat{\mathcal{K}}^{-1}\widehat{\mathcal{G}} - \omega^2\boldsymbol{I} + \varkappa^2(\widehat{M}^H)^{-1}(\boldsymbol{n}\otimes\boldsymbol{n})\widehat{\boldsymbol{B}}^H\right)\boldsymbol{u} + \left(\widehat{\mathcal{K}}^{-1} - \varkappa^2\mathrm{i}(\omega\widehat{M}^H)^{-1}\boldsymbol{n}\otimes\boldsymbol{n}\right)\boldsymbol{w} = 0\ , \end{aligned} \tag{24}$$

where the following substitutions (abbreviations) can be applied:

$$\begin{aligned} \widehat{\mathbb{D}}^U &= \widehat{\mathbb{D}}^H + \widehat{\boldsymbol{B}}^H\otimes\widehat{\boldsymbol{B}}^H/\widehat{M}^H\ , \\ \mathcal{A}^{U,n}_{ij} &= \widehat{D}^U_{ikjl}n_kn_l\ , \\ \boldsymbol{\mathcal{N}}^n &= \boldsymbol{n}\otimes\boldsymbol{n}\ , \end{aligned} \tag{25}$$

To proceed, (25) is substituted in (24) which then yields

$$\begin{aligned} \varkappa^2\left(\boldsymbol{\mathcal{A}}^{U,n}\boldsymbol{u} - \mathrm{i}(\omega\widehat{M}^H)^{-1}\widehat{\boldsymbol{B}}^H\boldsymbol{\mathcal{N}}^n\boldsymbol{w}\right) - \omega^2\hat{r}\boldsymbol{u} + \mathrm{i}\omega\boldsymbol{w} = 0\ , \\ \varkappa^2\left((\widehat{M}^H)^{-1}\boldsymbol{\mathcal{N}}^n\widehat{\boldsymbol{B}}^H\boldsymbol{u} - \mathrm{i}(\omega\widehat{M}^H)^{-1}\boldsymbol{\mathcal{N}}^n\boldsymbol{w}\right) + \left(\mathrm{i}\omega\widehat{\mathcal{K}}^{-1}\widehat{\mathcal{G}} - \omega^2\boldsymbol{I}\right)\boldsymbol{u} + \widehat{\mathcal{K}}^{-1}\boldsymbol{w} = 0\ . \end{aligned} \tag{26}$$

Now, $(26)_1$ and $(26)_2$ are multiplied by $1/\omega^2$ and i/ω^3, respectively. The modified equations can be expressed upon introducing matrices $\mathbb{M}(\omega)$ and $\mathbb{K}(\omega)$, where

$$\begin{aligned} \mathbb{M}(\omega) &= \begin{pmatrix} \hat{r}\boldsymbol{I}\ , & -\frac{\mathrm{i}}{\omega}\boldsymbol{I} \\ \frac{\mathrm{i}}{\omega}\boldsymbol{I} + \frac{1}{\omega^2}\widehat{\mathcal{K}}^{-1}\widehat{\mathcal{G}}\ , & -\frac{\mathrm{i}}{\omega^3}\widehat{\mathcal{K}}^{-1} \end{pmatrix}\ , \\ \mathbb{K}(\omega) &= \begin{pmatrix} \boldsymbol{\mathcal{A}}^{U,n}\ , & -\frac{\mathrm{i}}{\omega\widehat{M}^H}\widehat{\boldsymbol{B}}^H\boldsymbol{\mathcal{N}}^n \\ \frac{\mathrm{i}}{\omega\widehat{M}^H}\boldsymbol{\mathcal{N}}^n\widehat{\boldsymbol{B}}^H\ , & \frac{1}{\omega^2\widehat{M}^H}\boldsymbol{\mathcal{N}}^n \end{pmatrix}\ , \end{aligned} \tag{27}$$

The dispersion analysis consists in solving the following eigenvalue problem: Given $\omega\in\mathbb{R}$, find $\gamma = \varkappa/\omega\in\mathbb{C}$, such that a nontrivial $\mathbf{q} = [\boldsymbol{u};\boldsymbol{w}] \not\equiv \boldsymbol{0}$ satisfies

$$\mathbb{M}(\omega)\mathbf{q} = \lambda\mathbb{K}(\omega)\mathbf{q}\ , \qquad \text{where } \lambda := \gamma^2\ . \tag{28}$$

Recall that both $\mathcal{K}$ and $\mathcal{G}$ depend of the frequency $\omega > 0$.

In 3D, (28) provides 6 eigenvalues $\lambda = \gamma^2$. It is clear that $\mathrm{Ker}\,(\mathbb{K}) \neq \emptyset$; Let $\boldsymbol{n}_\perp$ is any unit vector, such that $\boldsymbol{n}_\perp\cdot\boldsymbol{n} = 0$. Then $\mathbf{q}_\perp = [\boldsymbol{0};\boldsymbol{n}_\perp]\in\mathrm{Ker}\,(\mathbb{K})$, noting that $\boldsymbol{\mathcal{N}}^n\boldsymbol{n}_\perp = \boldsymbol{0}$. Hence $\mathrm{card}\,(\mathrm{Ker}\,(\mathbb{K})) = 2$. As the consequence, there are two $\lambda_5 = \lambda_6 = \infty$. The remaining eigenvalues $\lambda_1,\ldots,\lambda_4$ represent four modes which can be identified as the quasi-shear (qS) and quasi-compressional, usually called quasi-pressure modes (qP), depending on the cosinus $\approx \boldsymbol{u}\cdot\boldsymbol{n}$ of the angle between the solid displacement polarization.

5 Numerical illustrations

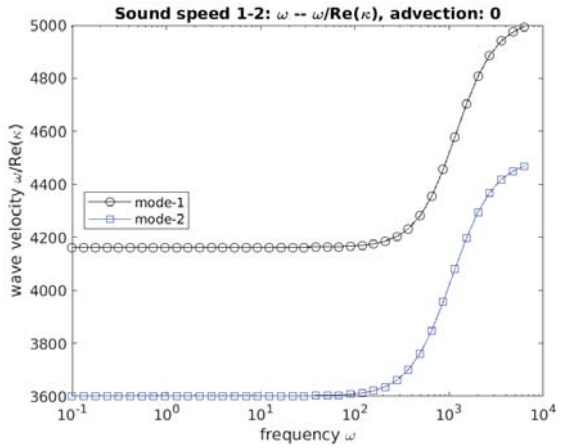
We shall illustrate the wave dispersion using a 3D geometry shown in Fig. 1, representing the periodic elastic scaffolds saturated by viscous fluid. Acoustic waves propagating in an inviscid fluid saturating this particular structure, but considered as rigid, were analyzed in [7, 8]. In Fig. 1, right, the elastic skeleton Y_s is indicated by the red color, while the flow streamlines of the advection flow $\bar{\boldsymbol{w}}$ are depicted in the fluid domain Y_f. Note that the mean velocity $\bar{w}^0 = 0.1$ m/s represents the microscopic advection field $\bar{\boldsymbol{w}}(y)$ defined in Y_f, such that $\bar{\boldsymbol{w}}^0 = \boldsymbol{\nu}\bar{w}^0 = \fint_{Y_f} \bar{\boldsymbol{w}}$ is the mean advection vector with $\bar{w}^0 = |\bar{\boldsymbol{w}}^0|$.

We aim to demonstrate the influence of the permanent fluid flow given by the macroscopic velocity $\bar{\boldsymbol{w}}^0$ on the wave dispersion. For this, compute the permeability, analyze the wave numbers obtained by solving the eigenvalue problem (28) which yiled phase velocities and attenuations of the four propagating modes. We consider two values of the advections velocity: a) $\bar{w}^0 = 0$ m/s (zero advection), b) $\bar{w}^0 = 0.1$ m/s, whereby the overall flow direction is $\boldsymbol{\nu} = \boldsymbol{e}^1 = [1,0,0]^T$. The incident wave direction $\boldsymbol{n} = \frac{1}{\sqrt{2}}[1,1,0]^T$ is not aligned with the permanent flow direction $\boldsymbol{\nu}$. The dimensions of the periodic cell shown in Fig. 1 (right) were 7.5×10^{-4} m (x_1 axis), 6.5×10^{-4} m (x_2 axis), 2.75×10^{-4} m (x_3 axis), with the fibre diameters 2×10^{-4} m. The solid fibres domain had the Al_2O_3 material parameters ($E = 300$ GPa, $\nu = 0.27$, and $\rho = 3900$ kg/m^3) while the fluid domain was filled with water ($\mu = 1.02 \times 10^{-3}$ Pa·s, $k_f = 2.25$ GPa, and $\rho_0 = 1000$ kg/m^3).

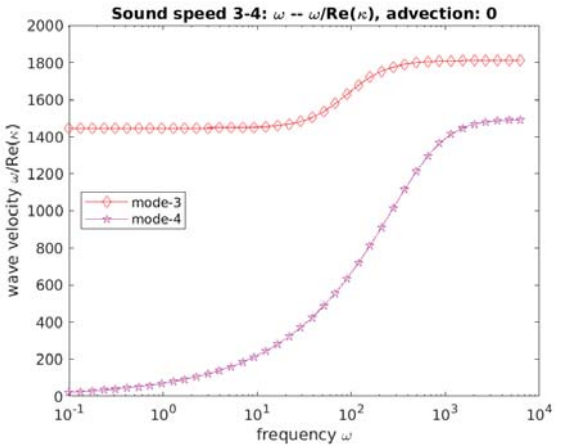
In response to the varying frequency ω, we compute eigenvalues of the dynamic permeability tensors, *i.e.* $\widehat{\boldsymbol{\mathcal{K}}}(\omega)$ and its approximation $\widetilde{\boldsymbol{\mathcal{K}}}(\omega)$, see Section 3.3. To characterize the wave propagation in such porous media, for a given direction $\boldsymbol{n}$, the classical dispersion curves $\omega \mapsto \varkappa$ are computed which yield phase velocities $\omega \mapsto c(\varkappa)$, where $c = \omega/\Re\varkappa$. It is worth noting, that the four modes can be classified as the quasi-pressure and quasi-pressure modes. For this, however, computing the projections of the complex polarization vectors $\boldsymbol{u}$ to $\boldsymbol{n}$ may yield ambiguous interpretations. Therefore, we prefer to use mode indices 1,2,3, and 4 which are assigned according to the speed of sound ordering, *i.e.* $c_1 \geq c_2 \geq c_3 \geq c_4$. Obviously, on one hand, mode switching may appear, so that this classification is not universally relevant. On the other hand, there is a correlation between prevailing model polarization and the sound speed value. In our example, modes 1 and 4 and the fast (qP1) and the slow (qP2) modes, whereas modes 2,3 describe the qS modes.

To illustrate the dynamic permeability and the advection phenomenon influence, the eigenvalues of the dynamic permeability tensors are displayed in Fig. 2; there the curves labelled by $h1, h2, h3$ represent the eigenvalues of $\widehat{\boldsymbol{\mathcal{K}}}(\omega)$ given by $(13)_1$ as the result of the homogenization of problem (2). The curves labelled by $a1, a2, a3$ are the eigenvalues of the Biot's visco-dynamic operator approximation determined using the static permeability $\boldsymbol{K} = \widehat{\boldsymbol{\mathcal{K}}}(0)$ and the isotropic tensor $\boldsymbol{\rho}$ with the tortuosity $a_\tau = 1$. The influence of the steady advection velocity $\bar{\boldsymbol{w}}^0$ is manifested both in the eigenvalue magnitudes and in differences between the eigenvalues 1, 2 for the nonzero velocity. The components of the tensors $\widehat{\boldsymbol{\mathcal{G}}}(\omega)$ are shown in Fig. 3. Since $\widehat{\boldsymbol{\mathcal{G}}}(\omega) \equiv 0$ for $\bar{w}^0 = 0.0$, only the curves for $\bar{w}^0 = 0.1$ are depicted.

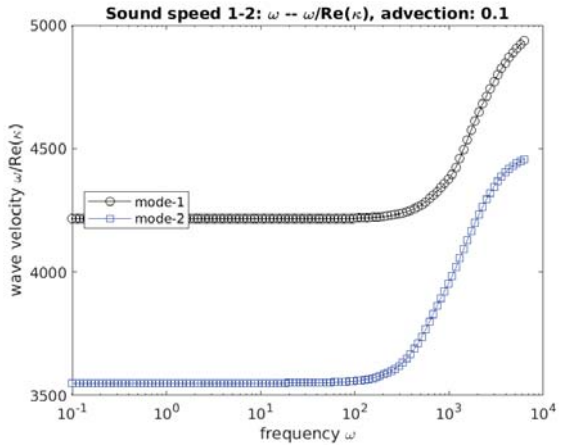
The dispersion curves are $\omega \mapsto \Re(\varkappa)$ and attenuation $\omega \mapsto \Im(\varkappa)$ curves are presented in Fig. 4 (modes 1-2) and Fig. 5 (modes 3-4). The flow advection influences more the attenuation properties expressed by $\Im(\varkappa)$, rather than the wave propagation speed corresponding to $\Re(\varkappa)$. This phenomenon is even more pronounced when the phase velocities $\omega/\Re(\varkappa_k)$ of the four modes are inspected in Fig. 6. Namely the oscillations of the shear mode $qS2$ in the interval $500 \div 1500$ Hz induced by the advection are remarkable.



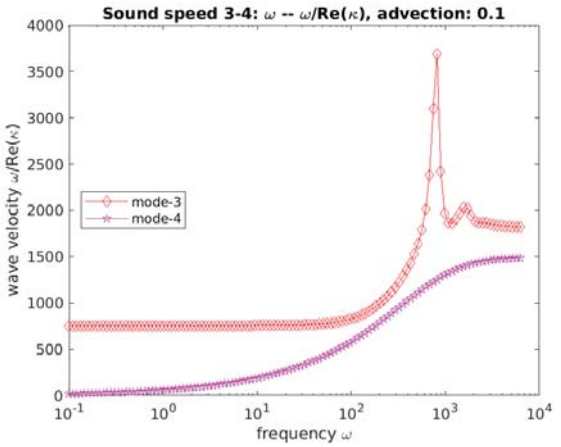
phase velocity $c_{1,2}$ (modes 1,2) for $\bar{w}^0 = 0$



phase velocity $c_{3,4}$ (modes 3,4) for $\bar{w}^0 = 0$



phase velocity $c_{1,2}$ (modes 1,2) for $\bar{w}^0 = 0.1$



phase velocity $c_{3,4}$ (modes 3,4) for $\bar{w}^0 = 0.1$

Figure 6: Phase velocity $c_k = \omega/\Re(\varkappa_k)$, $k = 1, \ldots, 4$ of the compressional qP1 and qP2 modes (labelled by indeces 1 and 4, respectively), and the shear modes qS1, qS2 (labelled by indeces 2 and 3, respectively). Steady advection: $\bar{w}^0 = 0$ (top figures), $\bar{w}^0 = 0.1$ (bottom figures).

6 Conclusion

In this paper, we presented the effective model of the acoustic wave propagation in a periodic poroelastic medium perfused by a viscous fluid. To respect an influence of the permanent flow component on the acoustic fields, the model was derived using the asymptotic homogenization applied to a linearized problem relying on the acoustic perturbations of all the involved fields. This approach enables to retain the advection phenomenon manifested by the macroscopic steady flow velocity $\bar{\boldsymbol{w}}^0$ in the limit homogenized model. As a consequence, a new generalized Darcy law governing the macroscopic seepage velocity of the acoustic waves is constituted by a modified dynamic permeability and another new tensor which introduces a coupling effect between macroscopic fluctuations of the seepage velocity and the skeleton velocity. Both these tensors are nonsymmetric when $\bar{\boldsymbol{w}}^0 \neq \boldsymbol{0}$ and depend on the advection associated with the permanent flow. This is a new ingredient in the model. The reported numerical example illustrates the strong influence of the advection phenomenon on the wave dispersion and namely the attenuation properties in specific frequency intervals in which possible oscillations of the dispersion curves are encountered. Further numerical results and a deeper analysis of the dispersion phenomenon influenced by the permanent flow in porous media will be reported in a forthcoming paper.

Keywords: Sandwich beam, Zig-Zag model, Analytical method.

Abstract. *This work provides a bending free vibration analysis of sandwich beams with three layered, using a proposed new analytical method based on energy approach and spectral analysis. Zig-zag displacement model is used to define the face and core layers displacements. The upper and lower layers are assumed to be Euler-Bernoulli beams, while the central layer is considered to be a Timoshenko beam. Two boundary conditions (Simply supported and clamped ends) are assumed. Assuming a harmonic motion, the governing equations of the sandwich beam are derived by applying Hamilton's principle. Two differential equations coupled in axial and transverse deformations are obtained. The present model is validated by comparing the obtained results with those available in the literature. A parametric study is done to show the effects of some parameters such as face/core thickness ratio and face/core density ratio on the natural frequencies of sandwich beams.*

1 INTRODUCTION

Sandwich structures have spread in automotive, aerospace and marine industries due to their lightness, excellent acoustic absorption and their im-pact and heat resistance. Heavy use of this type of structure in several industries required the research of new theories adapted to the study of their behavior in bending, buckling and vibrations.

Numerous of publications concerning sandwich beams, plates and shells are cited by Vinson [1] who presented characteristics and advantages of sandwich structures. Grigolyuk and Chulkov [2] provided the first hypotheses on the deformations of sandwich structures. Wang et al. [3] provided the higher-order hypotheses which include shearing of beams and plates. Zigzag hypotheses for multilayered plates were formulated by Carrera [4].

The earliest to provide the basic theory of sandwich structures were Plantema [5] and Allen [6]. Free vibration analysis of Sandwich beams has been performed by many scientists. Some references which are directly related to this work are briefly reviewed as follows. The first studies on the free vibrations of sandwich beams were carried out by Di Taranto [7] Mead and Marcus [8] using classical theory. Mead [9] developed a model which supposes that the upper and lower faces of a sandwich beam are deformed according to the theory of the Bernoulli-Euler beam, while the core deforms only in shear and shear. This model has been validated by comparing it to the different models adopted in several studies to analyze the free vibration of sandwich beams. Iaccarino et al. [10] investigated the core geometry effect on bending behavior of sandwich beam.

Solutions based on the finite elements used to analyse the vibrations of the sandwich beams are available in the Refs [11, 12]. This model based on a higher order theory using zigzag displacement field has been developed by Chakrabarti et al. [13] for static analysis of laminated soft-core sandwich beams. Sakiyama et al. [14] presented free vibration analysis of sandwich beam with both elastic and viscoelactic core for arbitrary conditions. They introduced a green function to obtain the characteristic equation which allows to computing modes and natural frequencies. It is a discrete solution to the differential equation governing the bending behavior of a sandwich beam.

Dynamic Stiffness Method (DSM) allows better results with a minimum number of elements. This has prompted scientists in recent years to use this method to study the free vibrations of sandwich beams. For example, Banerjee [15] used DSM to investigate the free vibrations of symmetrical sandwich beams. In this study, the governing motion equations are derived by ignoring mass of the nucleus with respect to those of the both faces. Howson and Zare [16] studied the vibratory behavior of the sandwich beam by taking into account the acceleration of flexion of the beam with the nucleus and ignoring the axial acceleration of the beam by deriving the equations of motion governing. They used DSM for various boundary conditions and elastic supports. Khalili et al. [17] investigated the free vibration of three-layered symmetric sandwich beam consists of sprung masses using the finite element formulation and DSM. Numerical examples are used for discussing the finite element formulation and dynamic stiffness matrix. Frostig and Baruch [18] investigated the free vibrations of sandwich beams with flexible core based on higher order theory. They presented different model for sandwich beams analysis. Amirani et al. [19] investigated the bending vibration of a sandwich beam with a core layer made in FGM. They used the Galerkin method to derive equations of motion. Natural frequencies are obtained by using the finite element analysis. A quasi-two-dimensional finite element formulation was developed by Bekuit et al [20] to analyze dynamic and static behavior of sandwich beams. The assumed model is three-layered and the longitudinal and transverse displacements are considered. In this study the formulations were independent of the flexibility of the central layer.

The main purpose of this research is to validate the new approach proposed here to analyze vibrational responses of a sandwich beam. Then, a parametric study is carried out to show the effects of some parameters such as face/core thickness ratio and face/core density ratio. First, the displacement field at face and core layers, is defined by using Zig-zag model. Then, assuming a harmonic motion, the both displacements are extended as finite series of basic functions, and kinetic and total strain energies are expressed in discretized forms. Finally, Hamilton's principle is applied to obtain the motion equations for both boundary conditions. Differential equations system is reduced to an eigenvalue problem, which is solved by the Rayleigh-Ritz formulation. Natural frequencies are therefore easy to determine.

2 GENERAL FORMULATION

2.1 Problem definition

The structure studied here is shown in Fig 1. It is a sandwich beam of length "*l*" l and width "*b*" b. "h_f" and "h_c" are the face sheet and core thickness respectively h_c. As shown in this figure, the beam deformations are considered to be in (x, z) plane.

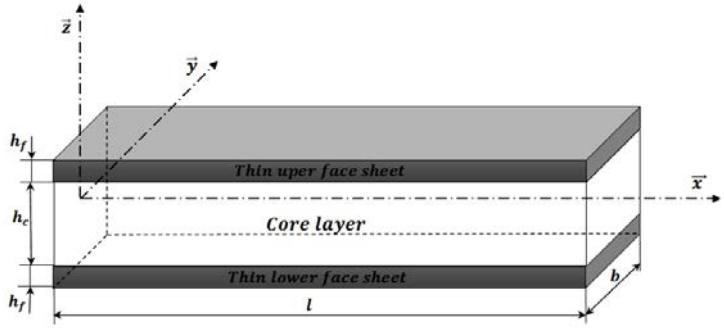

Figure 1: Geometry and coordinate system of the sandwich beam.

2.2 Displacement field

The proposal of the zig-zag model is explained by the fact that the core and sheets are made of different materials and have different thickness. This leads to a discontinuity of mechanical properties through the thickness of the beam. This does not allow to use the same theory for the core and sheets, and to treat them independently.

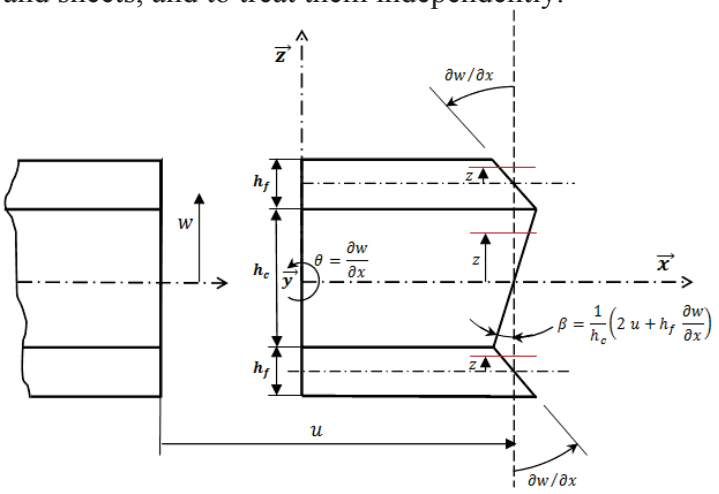

Figure 2: Geometry and coordinate system of the sandwich beam.

Motion equations of a sandwich beam elementare are derived on the basis of the following assumptions:

- Sandwich beam elementare behavior is assumed in the linear elasticity case;
- Normal deformations in z-axis direction are negligible on the core and faces $\varepsilon_z = 0$.
- No slippage and no delamination between core and sheets.
- Uper and lower thin face sheets are assumed to be deformed according to the Euler-Bernoulli beam theory, and the core is assumed to be deformed only in shear.
- Transverse displacement $w(x,t)$ is considered the same for the three layers.
- Axial displacements of the median lines of the uper and lower face sheets are $u_u(x,t)$ and $u_l(x,t)$ respectively.
- Symmetric deformation$\rightarrow u_u(x,t) = -u_l(x,t)$. $u_u(x,t) = -u_l(x,t)$ are axial displacements of the median lines of the uper and lower face sheets respectively. Therefore, $u_u = -u_l = u$

The beam displacement field is derived from the compatibility conditions for deformations.

$$U(x,t) = \begin{cases} u - z\dfrac{\partial w}{\partial x} & \textit{Uper layer} \quad -\dfrac{h_f}{2} \le z \le \dfrac{h_f}{2} \\ \left(2u + h_f \dfrac{\partial w}{\partial x}\right)\dfrac{z}{h_c} & \textit{Core layer} \quad -\dfrac{h_c}{2} \le z \le \dfrac{h_c}{2} \\ -u - z\dfrac{\partial w}{\partial x} & \textit{Lower layer} \quad -\dfrac{h_f}{2} \le z \le \dfrac{h_f}{2} \end{cases} \tag{1}$$

$$W(x,t) = w \qquad \textit{All layer} \qquad \forall\, z$$

2.3 Governing equation

To obtain the sandwich beam motion equation, Hamilton's principle Hamilton principle is applied. It is symbolically written for a period 0 to $\pi/2\omega$ as:

$$\partial \int_0^{\pi/2\omega} (T - \mathrm{U})\, dt = 0 \tag{2}$$

where, U and T are strain and kinetic energy respectively.

o Kinetic and strain energy calculation

By neglecting the axial motion, the beam kinetic energy is expressed as follows:

$$\begin{aligned} T &= \frac{1}{2}\iiint_{d\mathrm{V}} \rho \left(\left(\frac{\partial U}{\partial t}\right)^2 + \left(\frac{\partial W}{\partial t}\right)^2 \right) d\mathrm{V} = \\ &= \frac{1}{2}\iiint_{d\mathrm{V_f}} \rho_f \left[\left(\left(\frac{\partial u}{\partial t}\right) - z\left(\frac{\partial^2 w}{\partial t \partial x}\right)\right)^2 - \left(\left(\frac{\partial u}{\partial t}\right) + z\left(\frac{\partial^2 w}{\partial t \partial x}\right) + 2\left(\frac{\partial w}{\partial t}\right)^2 \right)^2 \right] d\mathrm{V_f} = \\ &+ \frac{1}{2}\iiint_{d\mathrm{Vc}} \rho_c \left[\frac{z^2}{h_c{}^2} \left(2\left(\frac{\partial u}{\partial t}\right) + h_f \left(\frac{\partial^2 w}{\partial t \partial x}\right)\right)^2 + \left(\frac{\partial w}{\partial t}\right)^2 \right] d\mathrm{V_c} = \end{aligned} \tag{3}$$

ρ_f, ρ_c are mass density of sheet-face and core respectively, with $m_f = \rho_f \mathrm{A}_f$; $m_c = \rho_c \mathrm{A}_c$.

Calculation of the integrals of Eq (3), leads to the following kinetic energy expression:

$$T=\frac{1}{2}\int_0^l\left(2m_f\left(\frac{\partial u}{\partial t}\right)^2+\left(2m_f+m_c\right)\left(\frac{\partial w}{\partial t}\right)^2+\frac{m_c}{12}\left(2\left(\frac{\partial u}{\partial t}\right)+h_f\left(\frac{\partial^2 w}{\partial t\partial x}\right)\right)^2\right)dx \tag{4}$$

Taking into account the previous assumptions, the beam strain energy is given by:

$$\mathrm{U}=\frac{1}{2}\left[\iiint_{d\mathrm{V}_f}\sigma_x\varepsilon_x d\mathrm{V}_f+\iiint_{d\mathrm{V}_c}\tau_{xz}\gamma_{xz}d\mathrm{V}_c+\iiint_{d\mathrm{V}_f}\sigma_x\varepsilon_x d\mathrm{V}_f\right] \tag{5}$$

$$\sigma_x=E\varepsilon_x \quad ; \quad \tau_{xz}=G\gamma_{xz} \tag{6}$$

$$\mathrm{U}=\frac{1}{2}\left[\iiint_{d\mathrm{V}_f}E_f\varepsilon_x^2 d\mathrm{V}_f+\iiint_{d\mathrm{V}_c}G_c\gamma_{xz}^2 d\mathrm{V}_c+\iiint_{d\mathrm{V}_f}E_f\varepsilon_x^2 d\mathrm{V}_f\right] \tag{7}$$

The integrals in the Eq. (7) are calculated by substituting the values of the strains, to obtain the following expression of the strain-energy:

$$\mathrm{U}=\frac{1}{2}\int_0^l\left(2E_fA_f\left(\frac{\partial u}{\partial x}\right)^2+2E_fB_f\left(\frac{\partial^2 w}{\partial x^2}\right)^2+G_cA_c\left[\frac{4}{h_c}u^2+\left(\left(1+\frac{h_f}{h_c}\right)\frac{\partial w}{\partial x}\right)^2+\frac{4}{h_c}\left(1+\frac{h_f}{h_c}\right)u\frac{\partial w}{\partial x}\right]\right)dx \tag{8}$$

$$d\mathrm{V}_f=\mathrm{A}_f\,dx \;;\; \mathrm{A}_f=bdz \tag{9}$$

$$\left(A_f,B_f\right)=\frac{1}{2}\int_{-h_f/2}^{+h_f/2}\left(z,z^2\right)bdz \quad ; \quad A_c=\frac{1}{2}\int_{-h_c/2}^{+h_c/2}d\mathrm{A}_c \tag{10}$$

- **Kinetic and Strain energy discretization.**

Assumptions:

- The motion is assumed to be harmonic;
- The space-functions and time are assumed to be separable.

With these assumptions, the transverse and in-plane displacements can be written respectively as:

$$\begin{cases}w(x,t)=w(x)\cos(\omega t)\\ u(x,t)=u(x)\cos^2(\omega t)\end{cases} \tag{11}$$

Space-functions $w(x)$ and $u(x)$ are expanded in the form of finite series of n basic functions $w_i(x)$ and $u_i(x)$ respectively as:

$$\begin{cases}w(x)=a_iw_i & i=1,2,3.....p\\ u(x)=b_iu_i & i=1,2,3.....q\end{cases} \tag{12}$$

It can be demonstrated by a convergence study of spectral expansions used for this model that $p=q=6$ are sufficient to obtain precise results concerning frequencies and stresses.

Discretization of the strain and kinetic energy expressions is made by substituting the expression given in Eqs. (11) into Eqs. (4) and (8), and rearranging. This leads to the following expressions:

$$\mathrm{U}=\frac{1}{2}\left[a_ia_jK_{ij}^w\cos^2(\omega t)+b_ib_jK_{ij}^u\cos^4(\omega t)+a_ib_jC_{ij}^{uw}\cos^3(\omega t)\right] \tag{13}$$

$$T=\frac{1}{2}\left[a_ia_j\omega^2M_{ij}^w\sin^2(\omega t)M_{ij}^w+b_ib_j\omega^2M_{ij}^u\sin^2(\omega t)+a_ib_j\omega^2M_{ij}^{uw}\sin(\omega t)\sin(2\omega t)\right] \tag{14}$$

where,

K_{ij}^u, K_{ij}^w : Rigidity tensors associated with u and w respectively.

M_{ij}^u, M_{ij}^w : Mass tensors associated with u and w respectively.

C_{ij}^{uw}, M_{ij}^{uw} : Coupling tensors.

$$
\begin{aligned}
K_{ij}^{w} &= \int_0^l \left[G_c A_c \left(1+\frac{h_f}{h_c}\right)^2 \frac{\partial w_i}{\partial x}\frac{\partial w_j}{\partial x} + 2E_f B_f \frac{\partial^2 w_i}{\partial x^2}\frac{\partial^2 w_j}{\partial x^2} \right] dx \\
K_{ij}^{u} &= \int_0^l \left[\frac{4G_c A_c}{hc^2} u_i u_j + 2E_f A_f \frac{\partial u_i}{\partial x}\frac{\partial u_j}{\partial x} \right] dx \\
C_{ij}^{uw} &= 4G_c \frac{A_c}{h_c}\left(1+\frac{h_f}{h_c}\right)\int_0^l u_i \frac{\partial w_j}{\partial x} dx \\
M_{ij}^{w} &= \int_0^l \left(2m_f + m_c\right) w_i w_j + \frac{m_c h_f^2}{12}\frac{\partial w_i}{\partial x}\frac{\partial w_j}{\partial x} dx \\
M_{ij}^{u} &= \int_0^l u_i u_j dx, \quad M_{ij}^{uw} = \frac{m_c h_f}{3}\int_0^l u_i \frac{\partial w_j}{\partial x} dx
\end{aligned}
\tag{15}
$$

Replacing U and T by their discretized expressions and integrating the time functions with respect to a_i's and b_i's, leads to the following coupled system of linear algebraic equations:

$$
\begin{cases}
2a_i K_{ir}^{w} + \dfrac{8}{3\pi} b_i K_{ir}^{uw} - 2\omega^2 \left(a_i M_{ir}^{w} + \dfrac{4}{3\pi} b_i M_{ir}^{uw} \right) = 0 \ , \qquad r = 1.....p \\
\dfrac{3}{2} b_i K_{is}^{u} + \dfrac{8}{3\pi} a_i K_{is}^{uw} - 2\omega^2 \left(b_i M_{is}^{u} + \dfrac{4}{3\pi} a_i M_{is}^{uw} \right) = 0 \ , \qquad s = 1.....q
\end{cases}
\tag{16}
$$

To simplify the analysis and the numerical treatment of the linear equations system, non-dimensional formulation has been considered by putting the spatial displacement functions as:

$$
x^* = x/l, \quad w_i(x) = H w_i^*(x^*), \quad u_i(x) = \lambda H u_i^*(x^*), \quad \lambda = H/l \tag{17}
$$

Eqs (16) can be written in a dimensionless form as:

$$
\begin{cases}
2a_i K_{ir}^{w*} + \dfrac{8}{3\pi} b_i K_{ir}^{uw*} - 2\omega^{*2} \left(a_i M_{ir}^{w*} + \dfrac{4}{3\pi} b_i M_{ir}^{u*} \right) = 0 \quad (1) \ , \quad r = 1.....p \\
\dfrac{3}{2} b_i K_{is}^{u*} - 2\lambda^2 \omega^2 b_i M_{is}^{u*} + \dfrac{8}{3\pi} a_i \left(K_{is}^{uw*} - \omega^{*2} M_{is}^{uw*} \right) = 0 \quad (2) \ , \quad s = 1.....q
\end{cases}
\tag{18}
$$

Axial inertia designated by the term λ^2 and coupling mass tensor M_{ir}^{uw*} can be neglected. The second set of Eq (18) can be then solved for b_i's leading to:

$$
b_i = a_j D_{ji}^*, \qquad D_{ij}^* = -\frac{16}{9\pi} K_{jl}^{u*-1} K_{il}^{uw*} \tag{19}
$$

And, $K_{ij}^{w*}, K_{ij}^{u*}, M_{ij}^{w*}, M_{ij}^{u*}, K_{ij}^{uw*}$ are non-dimensional tensors expressed as:

$$
\begin{aligned}
K_{ij}^{w*} &= \int_0^1 \alpha \frac{\partial w_i^*}{\partial x^*}\frac{\partial w_j^*}{\partial x^*} + \frac{\partial^2 w_i^*}{\partial x^{*2}}\frac{\partial^2 w_j^*}{\partial x^{*2}} dx^*, \qquad K_{ij}^{u*} = \gamma \int_0^1 \lambda u_i^* u_j^* + \frac{\partial u_i^*}{\partial x^*}\frac{\partial u_j^*}{\partial x^*} dx^* \\
M_{ij}^{w*} &= \int_0^1 w_i^* w_j^* + \eta \frac{\partial w_i^*}{\partial x^*}\frac{\partial w_j^*}{\partial x^*} dx^*, \ M_{ij}^{u*} = \int_0^1 u_i^* u_j^* dx^*, \ K_{ij}^{uw*} = \zeta \int_0^1 u_i^* \frac{\partial w_j^*}{\partial x^*} dx^*
\end{aligned}
\tag{20}
$$

$$
\begin{aligned}
\alpha &= \frac{G_c A_c l^2}{2E_f B_f}\left(1+\frac{h_f}{h_c}\right)^2, \ \gamma = \frac{A_f}{B_f} H^2, \ \lambda = 2\left(\frac{G_c A_c}{E_f A_f}\right)\left(\frac{l}{h_c}\right)^2 \\
\eta &= \frac{m_c}{12\left(m_c + 2m_f\right)}\left(\frac{h_f}{l}\right)^2, \ \zeta = 2\left(\frac{G_c A_c H l^2}{E_f B_f h_c}\right)\left(1+\frac{h_f}{h_c}\right)
\end{aligned}
\tag{21}
$$

Replacing expressions in Eq (19) into the first set of Eqs (16) leads to a decoupled set of linear algebraic equation in terms of a_i 's coefficients only:

$$a_i\left(K_{ir}^{w*}+\frac{4}{3\pi}D_{il}^{*}K_{lr}^{uw*}\right)-a_i\omega^{*2}M_{ir}^{w*}=0 \tag{22}$$

The linear algebraic Eq (22) also called the amplitude equation, can be written in the matrix form as:

$$\left[K^*\right]\{A\}-\omega^{*2}\left[M^*\right]\{A\}=\{0\} \tag{23}$$

where,

$\left[M^*\right]$ and $\left[K^*\right]$ are the dimensionless mass and stiffness matrixes respectively.

$\{A\}=\left[a_1,a_2,a_3,.....a_p\right]^T$ is the column matrix of coefficients a_i

ω^* is dimensionless natural frequency of beam defined as:

$$\omega^{*2}=\frac{\left(2m_f+m_c\right)l^4}{2E_fB_f}\omega^2 \tag{24}$$

By assuming harmonic variation, the transverse $w_i\left(x^*\right)$ and in-plane $u_i\left(x^*\right)$ basic functions are expressed as follows:

- For a simply supported sandwich beam

$$\begin{cases}w_i\left(x^*\right)=\sin\left(p_i\pi x^*\right)\\ u_i\left(x^*\right)=\cos\left(q_i\pi x^*\right)\end{cases},\quad i=1,2,3,.....,6 \tag{25}$$

- For a sandwich beam with clamped ends

$$\begin{cases}w_i\left(x^*\right)=\dfrac{ch(p_ix^*)-\cos(p_ix^*)}{ch(p_i)-\cos(p_i)}-\dfrac{sh(p_ix^*)-\sin(p_ix^*)}{sh(p_i)-\sin(p_i)}\\ u_i\left(x^*\right)=\sin\left(q_i\pi x^*\right)\end{cases},\quad i=1,2,3,.....,6 \tag{26}$$

The first six modes of transversal displacements are plotted in figure 3 for simply supported sandwich beam and sandwich beam with clamped ends.

3 RESULTS AND ANALYSIS

Validation of the approach used in this work and the impact of some parameters such as density and thickness for various boundary conditions on sandwich beam natural frequency, are presented in this paragraph. To validate the present theory, two models are considered: Sakiyama et al. [6] and Howson and Zare [8]. The characteristics of the sandwich beams used here are shown in Table 1.

	E_f (MPa)	G_c (MPa)	ρ_f (Kgm^{-3})	ρ_c (Kgm^{-3})	h_f (mm)	h_c (mm)	b (mm)	L (mm)
Sandwich beam N°1	68900	82.68	2680	32.8	0.4572	12.7	25.4	914.4
Sandwich beam N°2	68900	68.9	2687.3	119.7	0.4062	6.35	25.4	1218.7

Table 1: Characteristics of sandwich beam.

Results obtained here in the first case, concerning three natural frequencies are summarized in Table 2. These results are compared with those found by the authors [8, 6], who used different methods for simply supported sandwich beam N°1. Howson and Zare [8] studied flexural vibration behavior of sandwich beams by applying DSM (Dynamic stiffness Method), while Sakiyama et al. [6] used the Green's function as solution to analyse free vibration of sandwich beams.

It can be confirmed from this table, that the obtained results are in good agreement with the results of DSM used by Howson and Zare [8], with an acceptable accuracy.

Methods	Ω_1 (Hz)	Ω_2 (Hz)	Ω_3 (Hz)
Green's function [14]	56,159	215,820	457,220
DSM [16]	57,135	219,585	465,172
Present method	57,132	219,522	465,015

Table 2: Natural frequencies of simply supported sandwich beam.

Results obtained in the second case concerning three natural frequencies of sandwich beams N°2 with clamped ends are summarized in Table 3. These results are compared with those found by Sakiyama et al. [6] and Howson and Zare [8], who used different methods to derive motion equations. Results of these works, here again, agree perfectly with the obtained results in this study. The little differences in the results are due to approximations made and the assumptions assumed here.

Methods	Ω_1 (Hz)	Ω_2 (Hz)	Ω_3 (Hz)
Green's function [14]	33.5630	90.3640	172.0700
DSM [16]	34.5965	93.1000	177.1550
Present method	34.6055	93.1102	177.1561

Table 3: Natural frequencies of sandwich beam with clamped ends.

The plot in Fig.4 represented fundamental natural frequency variation versus thickness ratio (h_f /h_c) for two boundary conditions. This figure shows that, increase the thickness ratio leads to an increase of fundamental natural frequency in the simply supported sandwich

beams case, whereas in the case of sandwich beam with fixed ends, this frequency increases at first then decreases gradually.

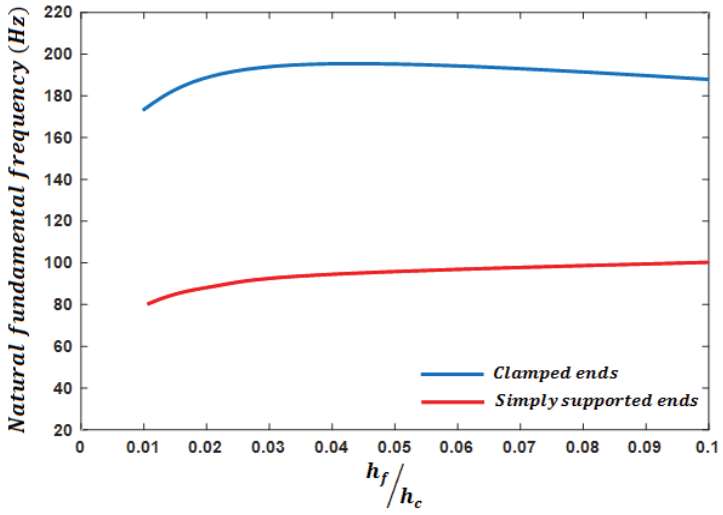

Figure 4: Effect of the thickness ratio on fundamental frequency of a sandwich beam.

The fundamental natural frequency variation versus core/face density ratio (ρ_c / ρ_f) is plotted in Fig.5. The smallest value of density ratio is corresponded the low core density. As shown in this figure, the increase of density ratio leads to a decrease of fundamental natural frequencies, whatever the boundary conditions.

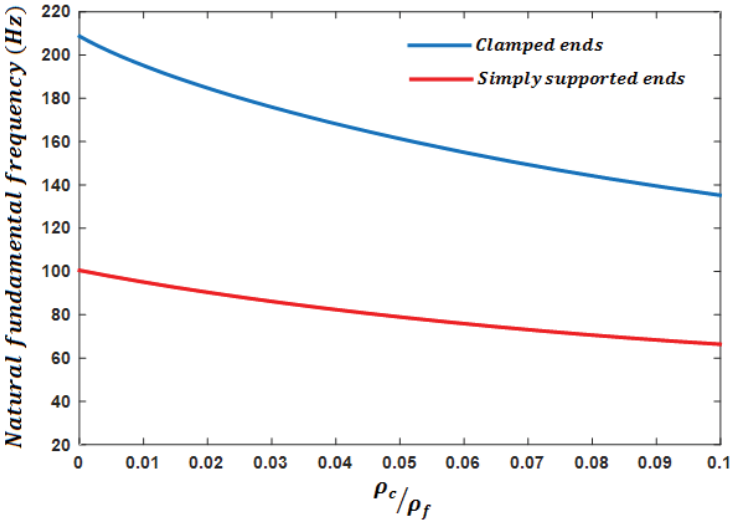

Figure 5: Effect of the density ratio on fundamental natural frequency of a sandwich beam.

4 CONCLUSION

The subject of this work is studying and analysing the bending behavior of a sandwich beam by a model based on energy approach and a spectral analysis. Various boundary conditions are assumed. Motion equations are derived by applying Hamilton's principle. Two differential equations coupled in axial and transverse deformations are obtained. These equations are decoupled by neglecting the axial inertia of the beam, and a single differential equation is formed. Natural frequencies are then computed and validated. The results obtained in present work using the new method are in good agreement with obtained results by the published theories.

The effects of thickness and density of sandwich beam are analyzed by a parametric study. This revealed that regardless of boundary conditions, the natural frequencies of the sandwich beam increase with the increase of the face/core thickness ratio, but it decrease when the core/face density ratio increases.

Keywords: asymptotic homogenization, ribbed plates, inner resonance media, Inhomogeneous Wave Correlation

Abstract. *This paper deals with the dynamic behavior of periodic orthogonally ribbed plates. Theoretical results describing the out-of-plane behavior of cellular plates involving inner resonance phenomena are derived using the periodic homogenization approach. These theoretical results are successfully compared to Wave Finite Element computations together with a mock-up of orthogonally ribbed plate with aluminium stiffeners and polycarbonate plate. The good agreement between analytical predictions and experimental measurements over the whole frequency range in terms of frequency and amplitude confirms the ability of the homogenized model to capture the locally resonant nature of the plate.*

1 INTRODUCTION

The classical plates models are well suited for homogeneous or moderately heterogeneous plates. However, difficulties appear when attempting to extend classical theories to composite structures with significantly contrasted properties. When considering ribbed plates with stiffeners of similar flexural rigidity than that of the plate, then the global behavior is that of a classical but anisotropic plate. If the stiffeners are much stiffer than the plate, the global behavior will be that of a beam lattice. In-between situations with specific beam grid/plate coupled behavior should exist. The present paper focuses on this specific situation in dynamic regime, in which the stiffener/plate contrasts induces inner resonance phenomena.

In dynamics, numerical approaches as finite elements method formulated in the framework of Floquet-Bloch theory has been developed to determine the wave dispersion of periodic media. As for ribbed plates, such a WFEM (Wave Finite Element Method) [14] has been used to determine, the free-wave propagation in plate stiffened by a grid of orthogonal beams. This method can be improved with modal reduction techniques as demonstrated by [8] in the case of orthogonally ribbed plates. Advanced numerical procedure have also been applied to the identification of propagation parameters in composite structures from experimental measurements. For example, the IWC (Inhomogeneous Wave Correlation) method introduced by [4] allows extracting the wavenumber from the experimental data and yields the empirical dispersion curve(s), as presented in [11] for several applications to ribbed panels and plates. These different numerical approaches provide accurate numerical results provided that he micro-structure is given, but fail to identify the underlying model that arises from the physics involved within the cell.

Among the theoretical approaches, the homogenization of periodic media [15, 3] is a rigorous asymptotic method for up-scaling the physics at micro-scale into a macroscopic model. This method has been extensively applied to develop advanced plate theories, and one may refer to [13, 12] for reviews on composite plates, structured plates, corrugated plates, heterogeneous shells, etc. Recently, the asymptotic approach have been applied to highly contrasted mono directionally ribbed plates [9]. This study explains theoretically that the unconventional behavior with singular dispersion and possible band-gap are straightforwardly related to inner resonance phenomena. The latter corresponds to situations where dynamic regimes co-exist at both the micro-scale of the period and the macro-scale of the structure [1, 2] that may results into negative effective mass over bands centered around the inner resonance frequencies [1, 5, 7].

The purpose of the present work is to extend the previous analysis of unidirectional ribbed plate [9] to periodic bidirectional ribbed plates.The main outcomes of this study are an analytical formulation of the equivalent model of orthogonally ribbed plates involving inner resonance phenomena, and the experimental validation of these new theoretical results.

The paper is structured as follows. The Section 2 focuses on the flexural behavior of 2D-ribbed plates. The out-of-plane model of beam grids accounting for local bending and torsion is first established through the method of asymptotic homogenization of periodic discrete media, initiated by [17], and applied to in-plane behavior in [6], [7]. Then, the coupling between the beam grid and the internal plates is detailed. From this, the equivalent plate model is established, and the unconventional features of the flexural wave dispersion is presented. Section 3 is devoted to the numerical and experimental validations of the homogenized model. The theoretical results are successfully compared to numerical calculations conducted using WFEM. Finally, the experiments performed on a prototype of ribbed plate evidences the ability of the homogenized model to describe their complex dynamic behavior.

2 Homogenization of the flexural behavior of 2D-ribbed plates

2.1 Investigated structures

The periodic orthogonally ribbed plate (hereafter called 2D-ribbed plates for simplicity and denoted $\mathcal{RP}$) under study is depicted in Fig. 1. It comprises identical "micro"-plate elements (denoted $\mathcal{P}$) connected to an orthogonal beam grid (denoted $\mathcal{G}$), both made of isotropic elastic materials. The beams of the grid are assumed significantly stiffer than the "micro"-plate (in a sense precised latter on). We focus on the dynamic range such that the size of the cell (or the width of $\mathcal{P}$) is small in regards to the wavelength in the beam grid. The referential frame of unit vectors $(\underline{e}_x, \underline{e}_y, \underline{e}_z)$ is such that $\underline{e}_x$ and $\underline{e}_y$ are the in-plane vectors along the orthogonal ribs, while $\underline{e}_z$ is the out-of-plane vector.

The two families of perpendicular beams (or stiffeners) define the ortho-beam grid $\mathcal{G}$. The stiffeners oriented along x (resp. y) are identical and spaced periodically by the length ℓ_y (resp. ℓ_x). However, the two families may differ from one another. These stiffeners intersect on perfectly stiff and mass-less nodes. This defines the rectangular periodic mesh, which is constituted by the portions of the two orthogonal stiffeners that join at a node. The period of surface $S = \ell_x \ell_y$ is characterized by the length $\ell = \sqrt{\ell_x \ell_y}$, and $O(\ell_x) = O(\ell_y) = \ell$. We will also use in the sequel the dimensionless quantities $\ell_x^\star = \ell_x/\ell$; $\ell_y^\star = \ell_y/\ell$ so that $\ell_x^\star \ell_y^\star = 1$ and $O(\ell_x^\star) = O(\ell_y^\star) = O(1)$.

Each segment of stiffeners between two consecutive nodes is modeled as an Euler-Bernoulli

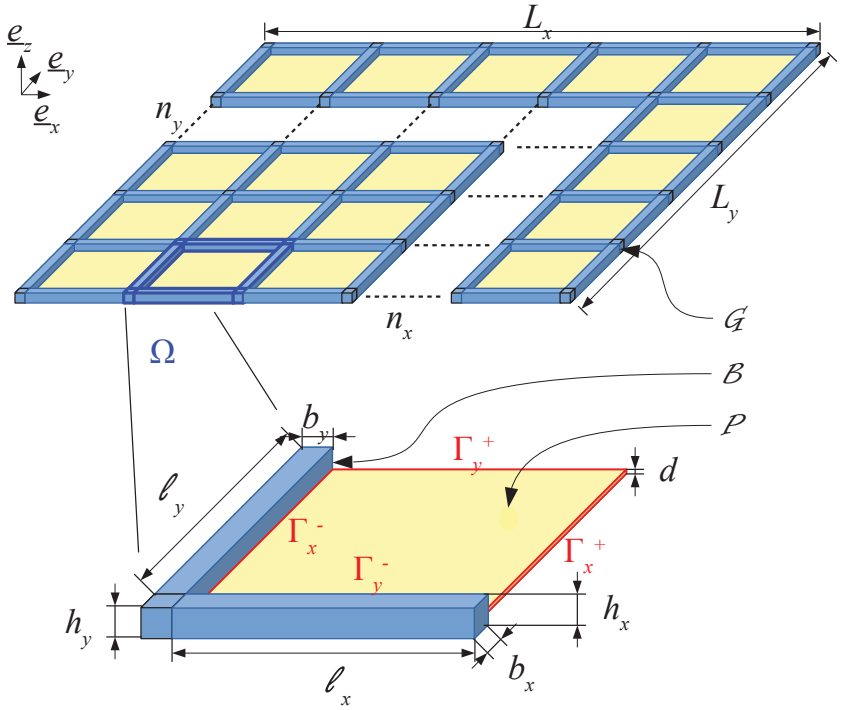

Figure 1: Orthogonally ribbed plate $\mathcal{RP}$ under study with notations associated with macro-beams constituting the beam grid $\mathcal{G}$, and focus on the unit cell Ω made of micro-beams $\mathcal{B}$ and internal micro-$\mathcal{P}$-plate

"micro"-beam (denoted $\mathcal{B}_x$, $\mathcal{B}_y$). The geometrical parameters of $\mathcal{B}_j$, with $j = x, y$, are (ℓ_j, h_j, b_j, A_j)

which stand respectively for their length, $\underline{e}_z$-thickness, width with $b_j = O(h_j)$ and section area $A_j = h_j b_j$. The mechanical parameters $(E_j, I_j = b_j h_j^3/12, G_j, \mathcal{I}_j, \rho_j, \Lambda_j = \rho_j A_j, \rho_j J_j)$ denote respectively the Young Modulus, the bending inertia, the torsional modulus and torsional inertia, the density, the linear mass, and the polar moment. The dimensions of the sections $\sqrt{A_j}$ are assumed small with respect to the lengths ℓ_j so that the behavior of the inter-node elements can be effectively modeled as Euler-Bernoulli beams. It is further assumed that the geometrical and the mechanical parameters of both types of beams $\mathcal{B}_j$ are of the same order of magnitude.

The material of the micro-plates $\mathcal{P}$ of area $\ell_x \ell_y$ and thickness d, have a Young's modulus E_p, a Poisson's ratio ν_p (the "plate modulus" is $E'_p = E_p/(1-\nu_p^2)$) and a density ρ_p. The plate bending inertia is denoted $I'_p = d^3/12$ and the surface mass $\Lambda'_p = \rho_p d$.

2.2 Homogenization of the ortho-beam grid

We aim at building a model for large transverse flexural vibrations in small deformations. The up-scaling process of the out-of plane dynamics of the ortho-grid is performed through the HPDM method (namely Homogenization of Periodic Discrete Media) [17, 10]. The developments follow the same guidelines as for the in-plane behavior studied in [7] and proceed into three steps, namely (i) the discretization of the dynamic balance, then (ii) the homogenization procedure itself through scale separation assumption and normalization, leading (iii) to the equivalent continuous model. This method applies under the key assumption of scale separation. This means that the wavelength $O(L)$ is much larger than the period size $O(l)$ and consequently $\epsilon = l/L << 1$. The macroscopic description of the grid, valid at the dominant order, is the limit behavior reached for $\varepsilon = \ell/L \to 0$. After these few steps, we are left with the following macroscopic description of the grid at the leading order :

$$\frac{E_x I_x}{\ell_y}\frac{\partial^4 U}{\partial x^4} + \frac{E_y I_y}{\ell_x}\frac{\partial^4 U}{\partial y^4} + \left(\frac{G_x \mathcal{I}_x}{\ell_y} + \frac{G_y \mathcal{I}_y}{\ell_x}\right)\frac{\partial^4 U}{\partial x^2 \partial y^2} + \omega^2\left(\frac{\rho_y J_y}{\ell_x}\frac{\partial^2 U}{\partial x^2} + \frac{\rho_x J_x}{\ell_y}\frac{\partial^2 U}{\partial y^2}\right) = \omega^2\left(\frac{\Lambda_x}{\ell_y} + \frac{\Lambda_y}{\ell_x}\right)U \quad (1)$$

The governing equation (1) is expressed with the properties of the micro-beams constituting the cell. This equation can be recast in the classical form of orthotropic plate equations, by defining

- the transverse forces $T_x^{\mathcal{G}}\underline{e}_z$, $T_y^{\mathcal{G}}\underline{e}_z$ exerted on the faces of normal $\underline{e}_x$, $\underline{e}_y$ and the in-plane vector $\underline{T}^{\mathcal{G}} = T_x^{\mathcal{G}}\underline{e}_x + T_y^{\mathcal{G}}\underline{e}_y$
- the momentum matrix $\underline{\underline{M}}^{\mathcal{G}}$ that involves the bending and torsion effects

Thus (1) is rewritten equivalently as (the differential operators operates in the (x, y) plane):

$$\begin{cases} \mathrm{div}(\underline{T}^{\mathcal{G}}) + \omega^2 \Lambda_{\mathcal{G}} U = 0 \quad ; \quad \Lambda_{\mathcal{G}} = \dfrac{\Lambda_x}{\ell_y} + \dfrac{\Lambda_y}{\ell_x} \\ \underline{\mathrm{div}}(\underline{\underline{M}}^{\mathcal{G}}) - \underline{T}^{\mathcal{G}} - \omega^2 \underline{\underline{J}}^{\mathcal{G}}.\underline{\mathrm{grad}}(U) = 0 \\ \underline{\underline{M}}^{\mathcal{G}} = \begin{pmatrix} M_{xx} = -\frac{E_x I_x}{\ell_y}\partial_x^2 U & M_{xy} = -\frac{G_y J_y}{\ell_x}\partial_x\partial_y U \\ M_{yx} = -\frac{G_x J_x}{\ell_y}\partial_y\partial_x U & M_{yy} = -\frac{E_y I_y}{\ell_x}\partial_y^2 U \end{pmatrix} \quad ; \quad \underline{\underline{J}}^{\mathcal{G}} = \begin{pmatrix} \rho_y J_y & 0 \\ 0 & \rho_x J_x \end{pmatrix} \end{cases} \quad (2)$$

The grid model (2) explicitly shows the coupling between the flexural and torsional behaviors. Note that in statics, i.e. $\omega \to 0$, (2) is identical to the grid model of [16]. Remind also that

the inertial terms containing the polar moments $\underline{\underline{J}}^{\mathcal{G}}$ may be neglected in regards to those related to the linear masses Λ. Note also that the description could be improved by considering the correctors constituted by the higher order terms of the expansions. They will not be explored here but their contribution could be appreciable when dealing with poor scale separation.

At this stage, (2) applies to the beam grid only free of external loading. The following section aims at introducing the contribution of the internal plates.

2.3 Conditions for inner dynamics of 2D-ribbed plates

We investigate 2D-ribbed plates presenting inner resonance phenomena, i.e., the stiff ortho-beam grid conveys the large wavelength, while the soft internal plate experiences a local resonance. Such a mixed regime within the cell results into (i) an inhomogeneous kinematics where the plate and grid displacements differ at the leading order and (ii) an asymmetrical coupling where the grid is forcing the soft plate. Let us specify the conditions for the occurrence of such a co-dynamic regime.

2.3.1 The co-dynamic condition

In inner resonance regime, the grid $\mathcal{G}$ and $\mathcal{P}$-plate fundamental resonances are of same order i.e., $O(\omega_{\mathcal{G}}) = O(\omega_p)$, so that :

$$O\left(\frac{E'_p I'_p}{\Lambda'_p \ell^4}\right) = O\left(\frac{EI}{\Lambda L^4}\right) \qquad \text{i.e.} \qquad \frac{E'_p}{E}\frac{\rho}{\rho_p} = O\left(\frac{h^2}{d^2}\frac{\ell^4}{L^4}\right) = O\left(\varepsilon^4 \frac{h^2}{d^2}\right) \tag{3}$$

This relation highlights the significant contrasts of mechanical properties of the constituting materials of the beam grid $\mathcal{G}$ and $\mathcal{P}$-plate.

2.3.2 Asymmetric coupling

As above stated, in presence of inner resonance, the grid acts as the forcing system that imposes its displacement to the forced $\mathcal{P}$-plate, in turn, the latter exerted forces on the grid. Considering the transverse balance of the grid loaded by the internal plates, such an asymmetric coupling requires :

$$\mathrm{div}(\underline{T}_{\mathcal{G}}) = O(T_p) \tag{4}$$

where $\underline{T}_{\mathcal{G}}$ relates to the transverse shear force (unit kN) in the grid $\mathcal{G}$ and T_p is the transverse linear shear force in the internal $\mathcal{P}$-plate (unit kN/m). The plate and beam displacements are identical at their junction, and consequently we have $w = O(U)$. Thus, from (4) and recalling that $b_k = O(h_k)$ one deduces the following requirement

$$O\left(E\frac{bh^3}{L^4}\right) = O\left(E'_p \frac{d^3}{\ell^3}\right) \qquad \text{i.e.} \qquad \frac{E'_p}{E} = O\left(\frac{\ell^3}{d^3}\frac{\ell^4}{L^4}\right) = O\left(\varepsilon^4 \frac{h^2}{d^2}\right) \tag{5}$$

In practice, $\rho/\rho_p = O(1)$ and the two conditions (3)-(5) reduces to $\frac{E'_p}{E} = O\left(\varepsilon^4 \frac{h^2}{d^2}\right)$. For ribbed plate made of a single material $E'_p = E$, and the inner-resonance arises when $d/h = O(\ell^2/L^2)$, i.e. for plates $\mathcal{P}$ significantly thinner than the beams of the grid $\mathcal{G}$. If the $\mathcal{P}$-material is much softer that the $\mathcal{G}$-material, namely $E'_p = O(\varepsilon^4 E)$ then $d/h = O(\ell/L)$ enables the inner-resonance to occur. Note that in these realistic cases, the bending stiffness of the plate is much smaller than that of the grid, in accordance with the asymmetry of the coupling. The case of inverted material properties so that the plate exhibits stiff properties and beam grid soft properties is not assessed here.

2.3.3 Beam grid loaded by internal plates

From the above analysis, provided that the conditions (3)-(5) are fulfilled, the action of internal plates is introduced in the beam grid model (2) in the form an external loading constituted by a shear force $\mathcal{F}\underline{e}_z$ and a couple $\underline{\mathcal{C}}$ resulting from the contact forces. This yield :

$$\begin{cases} \mathrm{div}(\underline{\underline{T}}^{\mathcal{G}}) + \Lambda_{\mathcal{G}}\omega^2 U + \mathcal{F} = 0 \\ \underline{\mathrm{div}}(\underline{\underline{M}}^{\mathcal{G}}) - \underline{T}^{\mathcal{G}} + \underline{\underline{J}}^{\mathcal{G}}\omega^2 \underline{\mathrm{grad}}(U) + \underline{\mathcal{C}} = 0 \end{cases} \tag{6}$$

where the coupling terms $\mathcal{F}$ and $\underline{\mathcal{C}}$ averaged on the cell are given either in terms or contact stresses on the grid or of efforts in the plate, by

$$\mathcal{F} = \frac{1}{\mathcal{S}} \int_\Gamma \underline{\underline{\sigma}}.\underline{n}\,\mathrm{ds} = -\frac{1}{\mathcal{S}} \int_{\partial\mathcal{P}} \underline{T}^{\mathcal{P}}.\underline{n}^{\mathcal{P}}\,\mathrm{dl} \tag{7}$$

$$\underline{\mathcal{C}} = \frac{1}{S} \int_\Gamma \underline{x} \times \underline{\underline{\sigma}}.\underline{n}\,\mathrm{ds} = -\frac{1}{\mathcal{S}} \int_{\partial\mathcal{P}} \underline{\underline{M}}^{\mathcal{P}}.\underline{n}^{\mathcal{P}}\,\mathrm{dl} + \frac{1}{\mathcal{S}} \int_{\partial\mathcal{P}} \frac{1}{2}(b_n^\perp \underline{n}^{\mathcal{P}})(\underline{T}^{\mathcal{P}}.\underline{n}^{\mathcal{P}})\,\mathrm{dl} \tag{8}$$

(where $b_n^\perp$ stands for the "oriented micro-beam width", i.e., $\pm b_y$, resp. $\pm b_x$, when $\underline{n}^{\mathcal{P}} = \pm\underline{e}_x$ resp. $\pm\underline{e}_y$). It remains now to express explicitly these coupling terms induced by the resonating internal plates. This is the aim of the next section.

2.4 Dynamics of the internal plates fully or partially connected to the beam grid

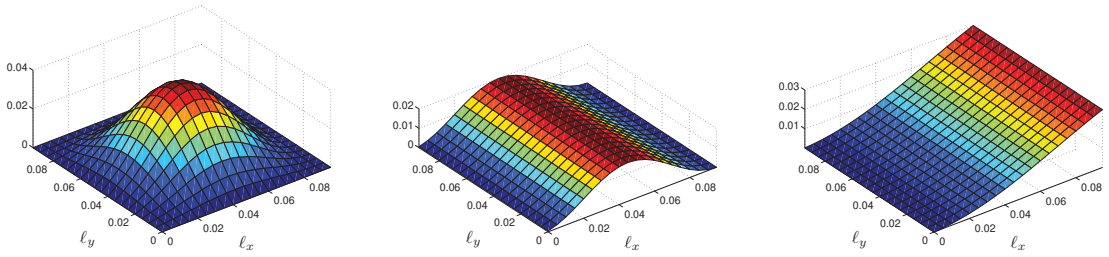
The out-of-plane motion w of the internal plates will be modeled as a Kirchhoff plate. Furthermore, the dynamic of the plate depends on the nature of its connections with the grid. We will consider the following configurations illustrated in Fig. 2 :

- $CCCC$ (Clamped-Clamped-Clamped-Clamped) i.e., the plate is clamped along its four edges,
- $CFCF$ (Clamped-Free-Clamped-Free) i.e., the plate is clamped along two opposite edges and free on the two others opposite edges, that implies a cylindrical bending as in a bi-clamped beam,
- $CFFF$ (Clamped-Free-Free-Free) i.e., the plate is clamped along one edge and free on its three others edges as a cantilever plate,
- In addition, we will also consider the case of additional masses attached on $\mathcal{P}$. To maximize its effect the mass is located at the center of the plate in the $CCCC$ and $CFCF$ configurations, whereas for $CFFF$ configuration, it is located at the outboard side of the clamped edge,

Independently of the specific type of the above listed boundary conditions, the elasto-dynamic plate problem is a 2D ($CCCC$ configuration) or 1D ($CFCF$ and $CFFF$ configurations) linear problem where the deflection $U(x,y)$ of the beam grid is the forcing term, which is *uniform* at the $\mathcal{P}$-plate scale. It results that the plate deflection takes the form

$$w(x,y,\underline{\xi}) = U(x,y)\phi_\omega^{bc}(\underline{\xi}) \tag{9}$$

where $\underline{\xi} = \xi_x\underline{e}_x + \xi_y\underline{e}_y$ stands for the local position within each $\mathcal{P}$-plate and $\phi_\omega^{bc}(\underline{\xi})$ is the frequency dependent deflection, for a unitary displacement of the grid. Hence, $\phi_\omega^{bc}(\underline{\xi})$ is the solution of the $\mathcal{P}$-problem in the configuration specified by the boundary conditions (^{bc}).



(a) (b) (c)

Figure 2: Shape of the fundamental mode associated with boundary conditions considered for the internal plates $\mathcal{P}$: (a) $C_xC_yC_xC_y$, (b) $C_xF_yC_xF_y$, (c) $C_xF_yF_xF_y$.

2.5 Homogenized flexural behavior of 2D-ribbed plate

The effect of internal plates on the grid is contained in the force $\mathcal{F}$, (7), and couple $\underline{\mathcal{C}}$, (8) and can be deduced from the knowledge of deflection in the plate $\phi_\omega^{bc}(\underline{\xi})$.

Regarding the force $\mathcal{F}$: Using the transverse force balance of $\mathcal{P}$, $\mathcal{F}$ can be re-expressed as

$$\mathcal{S}\mathcal{F}(x,y) = -\int_{\partial\mathcal{P}} \underline{T}^{\mathcal{P}}.\underline{n}^{\mathcal{P}}\,\mathrm{dl} = -\int_{\mathcal{P}} \mathrm{div}(\underline{T}^{\mathcal{P}})\,\mathrm{ds} = \omega^2\Lambda_p'\int_{\mathcal{P}} w\,\mathrm{ds}$$

i.e., introducing the following notation $\langle - \rangle = \frac{1}{\mathcal{S}}\int_{\mathcal{P}} -\mathrm{ds}$ for the mean value on the plate

$$\mathcal{F}(x,y) = \Lambda_p' \left\langle \phi_\omega^{bc} \right\rangle \omega^2 U(x,y) \tag{10}$$

Regarding the couple $\underline{\mathcal{C}}$: After integrating the transverse force balance of $\mathcal{P}$ multiplied by the local coordinate $\underline{\xi}$, one derives that

$$\mathcal{S}\underline{\mathcal{C}} = \omega^2\Lambda_p'\int_{\mathcal{P}} \underline{\xi} w\,\mathrm{ds} + \int_{\partial\mathcal{P}} \frac{1}{2}(\ell_n + b_n)\underline{n}^{\mathcal{P}}(\underline{T}^{\mathcal{P}}.\underline{n}^{\mathcal{P}})\,\mathrm{dl}$$

Furthermore, since $\underline{T}^{\mathcal{P}} = T_x^{\mathcal{P}}\underline{e}_x + T_y^{\mathcal{P}}\underline{e}_y$ we are left with

$$\underline{\mathcal{C}}(x,y) = \underline{K_\omega^{bc}} U(x,y) \qquad ; \qquad \underline{K_\omega^{bc}} = \omega^2\Lambda_p'\underline{H_\omega^{bc}} - \frac{E'I_p'}{\mathcal{S}}\underline{C_\omega^{bc}} \tag{11}$$

where $\underline{K_\omega}^{bc}$ is an elasto-inertial effective parameter that involves the frequency dependent dimensionless vectors $\underline{H_\omega^*}$ and $\underline{C_\omega^*}$. The components of the latter read explicitly

$$H_{\omega_x}^{bc} = \langle \xi_x \phi_\omega^{bc}(\underline{\xi}) \rangle \quad ; \quad C_{\omega_x}^{bc} = \frac{\ell_x + b_y}{2}\int_{-\frac{\ell_y}{2}}^{\frac{\ell_y}{2}} \left(\partial_{\xi_x}^3 \phi_\omega^{bc}|_{-\frac{\ell_x}{2},\xi_y} + \partial_{\xi_x}^3 \phi_\omega^{bc}|_{\frac{\ell_x}{2},\xi_y} \right) \mathrm{d}\xi_y \tag{12}$$

with similar expressions of the y-components by switching x and y.

Reporting expressions (7) and (8) into (6) yield the effective model of the 2-D ribbed plate that describes the grid behavior enriched by for the locally resonant internal plates.

$$\begin{cases} \mathrm{div}(\underline{T}) + \omega^2(\Lambda_{\mathcal{G}} + \Lambda_p'\langle\phi_\omega^{bc}\rangle)U = 0 \qquad ; \qquad \Lambda_{\mathcal{G}} = \dfrac{\Lambda_x}{\ell_y} + \dfrac{\Lambda_y}{\ell_x} \\ \underline{\mathrm{div}}(\underline{\underline{M}}) - \underline{T} - \omega^2\underline{\underline{J}}.\underline{\mathrm{grad}}(U) + \underline{K_\omega^{bc}}U = 0 \\ \underline{\underline{M}} = -\begin{pmatrix} \frac{E_xI_x}{\ell_y}\partial_x^2 U & \frac{G_yJ_y}{\ell_x}\partial_x\partial_y U \\ \frac{G_xJ_x}{\ell_y}\partial_y\partial_x U & \frac{E_yI_y}{\ell_x}\partial_y^2 U \end{pmatrix} \qquad ; \qquad \underline{\underline{J}} = \begin{pmatrix} \rho_y J_y & 0 \\ 0 & \rho_x J_x \end{pmatrix} \end{cases} \tag{13}$$

The inner resonance effect appears through the frequency dependent effective parameters $\langle \phi_\omega^{bc} \rangle$, and $\underline{K_\omega}^{bc}$ both associated with the dynamic motion of the internal plate. Let us first estimate the relative order of magnitude of the two non-conventional terms. From the expression (12) of $\underline{K_\omega^{bc}}$ it appears that

$$\frac{|K_\omega^{bc}||\nabla U|}{\Lambda'_p \langle \phi_\omega^{bc} \rangle U} = O\left(\frac{|K_\omega^{bc}|}{L\Lambda'_p \langle \phi_\omega^{bc} \rangle}\right) = O(\ell/L) \ll 1$$

Consequently, the effect of the non conventional torque is of one order smaller than the effect of non conventional inertia. Let us now explicit the effective mass term according to different boundary conditions :

CFCF plates : In that case the local plate problem and the corresponding field is identical to that of a clamped-clamped beam. Thus one has, when the $\mathcal{P}$-plates are clamped on the y-oriented micro beams, as in Fig.2-b (and similar expression switching x and y if the clamping is on $\mathcal{B}_x$)

$$\langle \phi_\omega^{C_x F_y C_x F_y} \rangle = \frac{2}{\delta \ell_x} \frac{1}{\coth(\delta \ell_x) + \cot(\delta \ell_x)} \qquad \delta = \sqrt[4]{\frac{\Lambda'_p \omega^2}{E'_p I'_p}} \tag{14}$$

Note that according to the above analysis $\langle \phi_\omega^{C_x F_y C_x F_y} \rangle \to \pm\infty$ when $\coth(\delta \ell_x) + \cot(\delta \ell_x) = 0$, i.e., at the eigenfrequencies of the y-bi-clamped $\mathcal{P}$-plate symmetric modes. These frequencies are accurately approximated by $(2n - \frac{1}{2})^2 \left(\frac{\pi}{\ell_x}\right)^2 \sqrt{\frac{E_p I_p}{\Lambda_p}}$, $n = 1, 2, 3, \ldots$.

$$\langle \phi_\omega^{C_x F_y F_x F_y} \rangle = \frac{1}{\delta \ell_x} \frac{\cosh(\delta \ell_x)\sin(\delta \ell_x) + \cos(\delta \ell_x)\sinh(\delta \ell_x)}{\cos(\delta \ell_x)\cosh(\delta \ell_x) + 1} \tag{15}$$

As expected, $\langle \phi_\omega^{C_x F_y F_x F_y} \rangle \to \pm\infty$ when $\cos(\delta \ell_x)\cosh(\delta \ell_x) + 1 = 0$ which corresponds to the eigenfrequencies of the y-clamped cantilever $\mathcal{P}$-plate, which are accurately approximated by $(n + \frac{1}{2})^2 \left(\frac{\pi}{\ell_x}\right)^2 \sqrt{\frac{E_p I_p}{\Lambda'_p}}$, $n = 1, 2, 3, \ldots$.

CCCC plates : For a plate clamped on its four sides there is no explicit expression of the local field. However, an analytical solution is available for circular clamped plate. This provides an approximated value for a square plates of side ℓ by matching its first eigenfrequency with that of a circular plate of radius a. The corresponding approximation reads where J_k and I_k are the Bessel and modified Bessel functions of the first kind.

$$\langle \phi_\omega^{Csquare} \rangle \approx \langle \phi_\omega^{Ccircle} \rangle = \frac{4}{\delta a}\left(\frac{J_0(\delta a)}{J_1(\delta a)} + \frac{I_0(\delta a)}{I_1(\delta a)}\right)^{-1} \qquad \text{where} \qquad a \approx 0.53\ell \tag{16}$$

2.5.1 Dispersion features in the orthogonally ribbed plate

Consider a flexural harmonic wave $U(\underline{x}) = \exp(i(k_\theta \underline{n}_\theta . \underline{x})$ propagating in the direction $\underline{n}_\theta = \cos(\theta)\underline{e}_x + \sin(\theta)\underline{e}_y$. Taking into account the facts that (i) the terms associated with polar moments are of weak magnitude compared to the translational inertia, and (ii) the terms of non conventional torque are of one order smaller that those associated with the non conventional inertia, these two terms can be disregarded at the leading order. Consequently, the flexural

$n_x = n_y = 5$	E [Pa]	ρ [kg.m^{-3}]	dimensions [m]	weight [kg]
Beam grid	69×10^9	2700	$h_y = h_x = b_y = b_x = 0.01,$	1.78
Plate	3×10^9	1200	$\ell_y = \ell_x = 0.1,\ d = 0.001$	0.363
Global structure			$L_x = L_y = 0.56$	2.14

Table 1: Geometrical and mechanical parameters of the 2D-ribbed plate $\mathcal{RP}_1$ considered for the numerical validation.

wavenumber $k_\theta(\omega)$ is given by :

$$k_\theta^4 \left(\frac{E_x I_x}{\ell_y} \cos^4(\theta) + \frac{E_y I_y}{\ell_x} \sin^4(\theta) + \left(\frac{G_x \mathcal{I}_x}{\ell_y} + \frac{G_y \mathcal{I}_y}{\ell_x} \right) \cos^2(\theta) \sin^2(\theta) \right) - \omega^2 \left(\frac{\Lambda_x}{\ell_y} + \frac{\Lambda_y}{\ell_x} + \Lambda'_p \langle \phi_\omega^{cb} \rangle \right) = 0 \quad (17)$$

The inner resonance of $\mathcal{P}$-plate accounted by $\langle \phi_\omega \rangle$, lead to dispersion features that differs notably from the classical bending case in which $k \sim \sqrt{\omega}$ in the whole frequency range. Significant changes are expected in the neighborhood of the internal plate's eigenmodes.

3 Numerical and experimental validation

We perform direct WFEM simulations of a 2D-ribbed plate designed so that resonance frequencies of the inner plate matches with that of the beam grid. The considered system denoted hereafter by $\mathcal{RP}_1$ is a square panel made up of 5×5 cells whose the stiffeners are in aluminium and internal plates in perspex, much softer than aluminium. With the geometric and mechanical parameters given on Table 1 the co-dynamic condition (3) $\omega_b = \omega_p$ is satisfied. Typical structural damping coefficients for aluminium and perspex are respectively $\eta_k = 5/1000$ and $\eta_i = 1/100$ and are included into the model as an imaginary part of the Young's modulus. Then, the effective parameters previously defined analytically and the wavenumbers are calculated for different boundary conditions on the internal plates, and compared to the results obtained by WFEM simulations.

Grid without internal plates. A first validation is achieved on the beam grid model itself. On Fig. 3-a one notices an excellent agreement between the wavenumbers along the x direction ($\theta = 0$), and along the oblique direction $\theta = \pi/4$ predicted by the homogenized model and those computed.

Grid with $CCCC$, $CFCF$ and $CFFF$ internal plates. The fundamental frequency of a $CCCC$ plate can be estimated using by Galin's formula. For a square plate : $\omega_p = (36/\ell^2)\sqrt{EI/\rho d}$, that gives here 277 Hz (the three first eigenfrequencies calculated by 3D finite element are 275 Hz, 562 Hz, 1009 Hz). The Fig. 3-b shows that the theoretical and numerical approaches provide very close results. The classical flexural dispersion is notably modified by the singularity induced by the resonance of the symmetric modes of the inner plates.

Further, the first resonance frequencies for the $CFCF$ plate are 170 Hz, 470 Hz, 921 Hz (respectively 27 Hz, 168 Hz for the $CFFF$ plate). The comparison between numerical and theoretical dispersion presented on Fig. 3-c, -d are also very satisfactory on those cases.
On Fig.3-c the singularity in the numerical results that are not predicted by the theoretical results arises at the antisymmetric resonance of the $\mathcal{P}$-plate. The latter are associated with torsional kinematics that are inhibited at the leading order in 2D-ribbed plate. Nevertheless, a slight torsion exists and the singularity generated numerically by the antisymmetric resonance

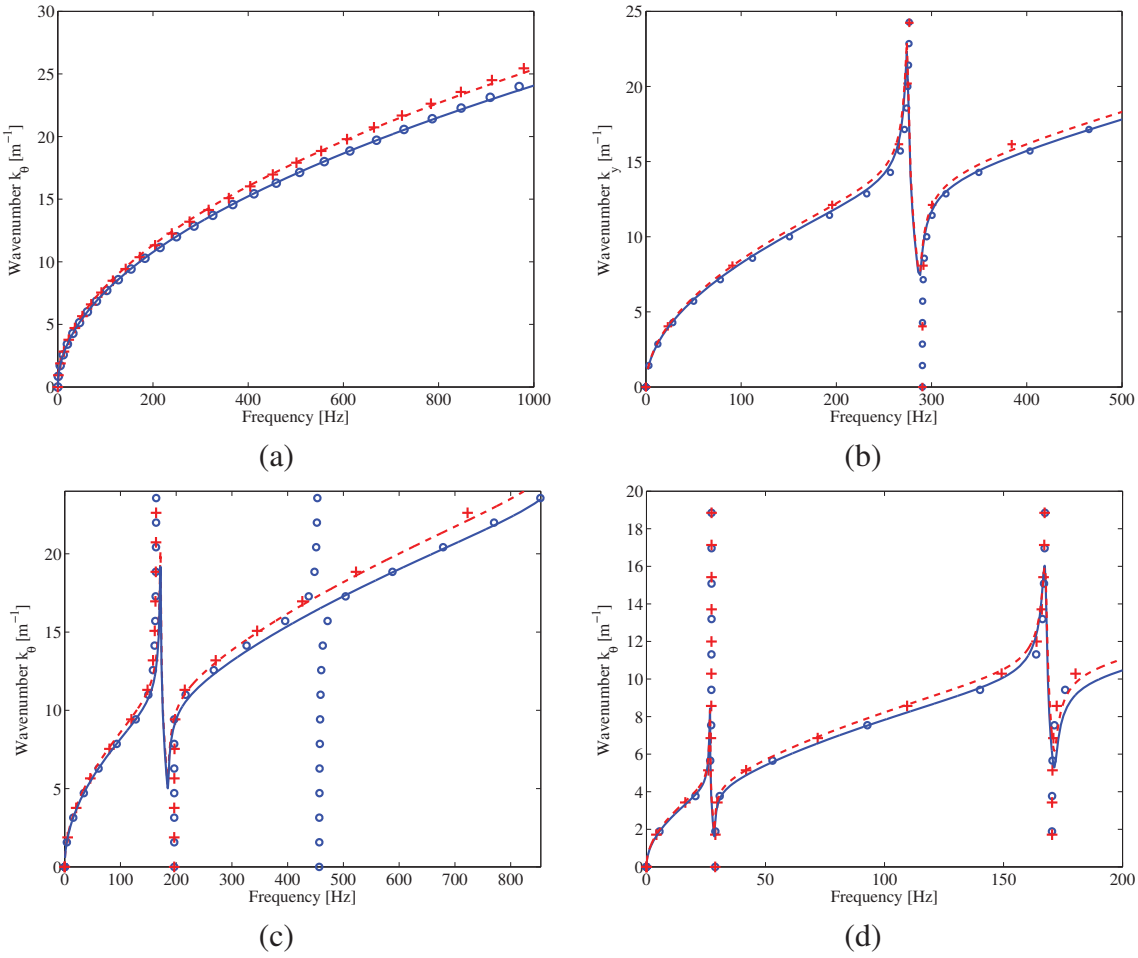


Figure 3: Wavenumbers predicted by the homogenized model in the directions $\theta = 0$ ($-$), $\theta = \pi/4$ ($--$), and by WFEM computation , $\theta = 0$ ($\circ$), and $\theta = \pi/4$ ($+$). a) Top left : Grid without internal plates, b) Top right : Grid with $CCCC$, plates. c) Bottom left : Grid with $CFCF$ plates, d) Bottom right : Grid with $CFFF$ plates.

magnifies the effects and results in a sharp and very tight singularity in the calculated wave numbers.

3.1 Experiments on 1D and 2D-ribbed plates

The panels are freely suspended and excited by a shaker that delivers a wide band random noise, The excitation point is located on the central stiffener and an impedance head gives the input force and acceleration. The velocity field is measured by a scanning Laser vibrometer. The scan is performed on a line along the excited stiffener. Measurements are performed in the frequency range 0-2kHz.

The IWC method is used to extract the wavenumber from the experimental data. For each scanned point, the frequency response function is recorded with its coherence functions. Hereafter, the flexural dispersion curves recovered from the experiments are compared to the analytical and/or the numerical ones.

The Fig. 5 shows that the experimental flexural dispersion of the grid compares satisfactorily with that given by the homogenized model of the grid. The damping results presented in Fig.5 are not investigated in more details in this paper. However they will be compared to that of Fig. 6, 7, 8 where it is clear that the local resonance introduces significant damping on the wave propagation.

4 ACKNOWLEDGEMENTS

This work was supported by the LabEx CeLyA (Centre Lyonnais d'Acoustique, ANR-10-LABX-0060) of Université de Lyon, within the program "Investissements d'Avenir" (ANR-11-IDEX-0007) operated by the French National Research Agency (ANR).

5 CONCLUSIONS

The homogenization method applied to periodic orthogonally ribbed plates with contrasted geometrical and/or mechanical parameters allowed to determine their unconventional macroscopic behavior. The model is established within the scale separation assumption, and its effective parameters are explicitly determined from the geometrical and mechanical properties of the plate and stiffeners. The complex dynamic behavior encompasses the atypical flexural dispersion associated with the enriched local kinematics induced by the inner resonance. As a consequence, the flexural waves are affected by the frequency dependent positive or negative effective mass of the moving inner plates. Hence, around the inner plate's eigenfrequencies (that depends on the boundary conditions as $CCCC$, $CFCF$, $CFFF$ or added masses) the wave dispersion presents singularities, namely strong velocity variations together with frequency bands of strong attenuation. These outcomes are successfully compared with WFEM computations for realistic examples of contrasted cellular plates and with experiments performed on two prototypes in different configurations. This shows that the homogenized model correctly captures the phenomena, that the study yields reliable design rules to tailor cellular panels.

Keywords: Discrete-to-continuum, frequency bandgaps, lattice metamaterials, tensegrity structures.

Abstract. *We formulate a discrete-to-continuum approach to the dispersion relation of one-dimensional lattice metamaterials. With reference to a generic lattice structure that can be described as a biatomic mass-spring chain, we formulate a higher order gradient continuum theory of the competent dynamical problem using a homogenization approach. The proposed theory allows us to obtain an analytic description of the bandgap-type response of the homogenized chain, and to estimate the frequency boundary region that is affected by the full transmission of mechanical waves. Numerical applications of the proposed discrete-to-continuum approach are given with reference to tensegrity metamaterials, which exhibit a prestress-tunable bandgap response over a wide range of frequencies.*

1 Introduction

Recently, researchers have focused on exploring the bandgap-type response of lattice metamaterials, e.g. [1–4]. These materials are artificial periodic structures with potential variations in density and/or geometry (refer, e.g., to [4], [5], [6] and references therein). They are characterized by unusual mechanical properties. It has been shown that such systems support phononic bandgaps, and have frequency ranges with inhibited wave propagation.
This study refers to mass-spring tensegrity lattices for which it has been demonstrated that the dispersion relation can be tuned by varying the applied internal self-stress induced by prestretching the cables forming the tensegrity units, and/or the global prestress induced by the application of compression forces to the terminal bases [7]. This paper addresses the bandgap-type response of the homogenized chain. Previous homogenization methods have been illustrated for both low and high frequency regimes, e.g. in [8], [9], in [10] and [11]. In contrast to these studies, the present work approaches the problem from the point of view of the theory of mixtures. The sense is that, for thermodynamic reason, the existence of bandgap in elastic continuum materials, at least two kinematical descriptors are necessary. The first is that on which it is evident the attenuation in the prohibited frequency band. The second is that on which the energy is stored. Thus, in a bi-atomic chain the kinematical descriptors correspond to the position of those masses and one side of the stiffer spring and on the same side of the softer spring. It is a matter of facts that if the springs have the same rigidity, no band gap is possibile.

In the first part of the paper, we develop a discrete-to-continuum approach to the dispersion relation of 1D periodic arrays, both for monoatomic and biatomic chains. Then, we apply the developed theory to tensegrity metamaterials, and we compare the results with those obtained using the discrete approach [7]. Our key findings are summarized in Sect. 4, where we also propose future research lines for the manufacturing and testing of bandgap metamaterials with tensegrity architecture.

2 Discrete-to-continuum models of bandgap systems

The present section studies continuous mathematical models able to describe the behavior of both monoatomic and biatomic systems. It is a matter of facts that a standard continuous model is not sufficient to represent an intrinsically discrete system. The reason is inside the continuous approximation, that is however attenuated by the use of non standard models. In order to provide a well-posed system of Partial Differential Equations for such models, the use of variational procedure is suggested, see e.g. [12]. Thus, an Action functional $\mathcal{A}$ is defined in terms of kinetic $\mathcal{K}$, internal $\mathcal{U}_{int}$ and external $\mathcal{U}_{ext}$ energies,

$$\mathcal{A} = \int_{t_1}^{t_2} \mathcal{K} - \mathcal{U}_{int} + \mathcal{U}_{ext}, \tag{1}$$

where t_1 and t_2 are two instants of time and where the action $\mathcal{A}$ is a functional of the fundamental kinematical fields of the continuum. We will see in Subsection 2.1 that for the continuous model of monoatomic chain we need only a single placement field χ and in Subsection 2.2 that for the continuous model of biatomic chain we need two placement fields χ_1 and χ_2. For the sake of simplicity, we consider for both cases a one dimensional continuous body of length L and an abscissa X, in the straight reference configuration, such that $X \in [0, L]$.

Once the set of kinematical fields and their admissible variation have been defined, the equation of motion are achieved by imposing that the variation of the action, among all the admissible variation of the kinematical fields, is null, i.e., $\delta\mathcal{A} = 0$

2.1 Monoatomic systems

Kinetic energy of the microstructural continuum representing the monoatomic chain contains not only the standard contribution in terms of the mass density ρ but also a non standard one in terms of the microinertia η,

$$\mathcal{K} = \int_0^L \frac{1}{2}\rho\dot{\chi}^2 + \frac{1}{2}\eta\dot{\chi}'^2, \tag{2}$$

where dot $\dot{a}$ and prime a' represents, respectively, the derivatives with respect to time t and position X.

Analogously, the internal energy contains not only the standard contribution in terms of the strain $\epsilon = u'$ but also in terms of the strain gradient $\epsilon' = u''$, where $u = \chi - X$ is the displacement field,

$$\mathcal{U}_{int} = \int_0^L \frac{1}{2}k_{el1}u'^2 + \frac{1}{2}k_{el2}u''^2, \tag{3}$$

and where k_{el1} is the standard axial stiffness and k_{el2} is the non-standard strain gradient axial stiffness.

The definition of an external energy should provide the necessary ingredients for solving boundary value problems. For the sake of simplicity, here we assume no external energy, i.e. $\mathcal{U}_{ext} = 0$.

Both standard arguments for the derivation of the variation of the action and imposing that its variation among all the admissible variation $\delta\chi$ of the fundamental kinematical field χ is null, i.e. $\delta\mathcal{A} = 0$, yields the Partial Differential Equation of the problem,

$$\rho\ddot{u} - \eta\ddot{u}'' = k_{el1}u'' - k_{el2}u''''. \tag{4}$$

By assuming a plane wave solution for the displacement field u in terms of the real part (i.e. Re) of complex exponential form,

$$u = Re\left(u_0 \exp i\left(\omega t - kX\right)\right), \tag{5}$$

where u_0, ω and k are, respectively, the complex amplitude, the angular frequency and the wave number, we obtain the following dispersion relation

$$\omega = \omega_c\left(k\right) = k\sqrt{\frac{k_{el1} + k_{el2}k^2}{\rho + \eta k^2}}, \tag{6}$$

where the function $\omega_c\left(k\right)$ has been introduced for the present continuous system. A comparison between the dispersion relations for discrete [7] and and for continuous (18) systems can be done only for large wave length $\lambda = 2\pi/k$, that means for small wave number k. Thus, it is reasonable to perform a Taylor's series expansion of both functions $\omega_d\left(k\right)$ and $\omega_c\left(k\right)$,

$$\omega_d\left(k\right) = ka\sqrt{\frac{K_{el}}{M}}\left(1 - \frac{\left(ka\right)^2}{24}\right) + o\left(k^3\right). \tag{7}$$

$$\omega_c\left(k\right) = k\sqrt{\frac{k_{el1}}{\rho}} + k^3\sqrt{\frac{k_{el1}}{\rho}}\frac{k_{el1}\eta - k_{el2}\rho}{2k_{el1}\rho} + o\left(k^3\right), \tag{8}$$

An identification of the two dispersion relations (7) and (8) yields

$$\rho = \frac{M}{a}, \quad k_{el1} = aK_{el}, \quad \eta = \rho\left(\frac{a^2}{12} + \frac{k_{el2}}{k_{el1}}\right) = \frac{M}{a}\left(\frac{a^2}{12} + \frac{k_{el2}}{aK_{el}}\right) \tag{9}$$

Eqns. $(27)_1$ and $(27)_2$ are the standard and intuitive identifications of both continuous mass density ρ and standard axial rigidity k_{el1} in term of the constitutive parameters of the discrete model M, K_{el} and a. Eq. $(27)_3$ gives a relation between the two strain gradient parameters η and k_{el2}. It is worth to be noted that the identification of null microinertia $\eta = 0$ is forbidden by the thermodynamic assumption $k_{el2} \geq 0$, that is implied by positive definiteness of the internal energy (3).

2.2 Biatomic systems

We now examine a continuous model for biatomic chains. As we have already pointed out, the fundamental kinematical fields of the continuum model of biatomic systems are the two placements χ_1 and χ_2.

Kinetic energy of such a continuum is not only the standard contribution in terms of a quadratic form of the two velocity fields $\dot{\chi}_1$ and $\dot{\chi}_2$ but also a non standard one in terms of a quadratic form of the two velocity gradient fields $\dot{\chi}'_1$ and $\dot{\chi}'_2$,

$$\mathcal{K} = \int_0^L \frac{1}{2} \begin{pmatrix} \dot{\chi}_1 & \dot{\chi}_2 \end{pmatrix} A \begin{pmatrix} \dot{\chi}_1 \\ \dot{\chi}_2 \end{pmatrix} + \frac{1}{2} \begin{pmatrix} \dot{\chi}'_1 & \dot{\chi}'_2 \end{pmatrix} B \begin{pmatrix} \dot{\chi}'_1 \\ \dot{\chi}'_2 \end{pmatrix}, \tag{10}$$

where the two matrixes A and B,

$$A = \begin{pmatrix} \rho_1 & \rho_{12} \\ \rho_{12} & \rho_2 \end{pmatrix}, \qquad B = \begin{pmatrix} \eta_1 & \eta_{12} \\ \eta_{12} & \eta_2 \end{pmatrix}, \tag{11}$$

are positive defined.

Analogously, the internal energy contains not only the standard contribution in terms of a quadratic form of the two axial strains $\epsilon_1 = u'_1$ and $\epsilon_2 = u'_2$ but also in terms of the two axial strain gradient $\epsilon'_1 = u''_1$ and $\epsilon'_2 = u''_2$, where the two displacements $u_1 = \chi_1 - X$ and $u_2 = \chi_2 - X$ are defined. Besides, a contribution in terms of the square of the difference between the two displacements u_1 and u_2 is objective and is conceived as follows,

$$\mathcal{U}_{int} = \int_0^L \frac{1}{2} k_{el0} \left(u_1 - u_2\right)^2 + \frac{1}{2} \begin{pmatrix} u'_1 & u'_2 \end{pmatrix} C \begin{pmatrix} u'_1 \\ u'_2 \end{pmatrix} + \frac{1}{2} \begin{pmatrix} u''_1 & u''_2 \end{pmatrix} D \begin{pmatrix} u''_1 \\ u''_2 \end{pmatrix}, \tag{12}$$

where the two matrixes C and D,

$$C = \begin{pmatrix} k_{el1} & k_{el12} \\ k_{el12} & k_{el2} \end{pmatrix}, \qquad D = \begin{pmatrix} k_{2el1} & k_{2el12} \\ k_{2el12} & k_{2el2} \end{pmatrix}, \tag{13}$$

are positive defined. For the sake of simplicity we assume $D = 0$. Besides, we assume no external energy, i.e. $\mathcal{U}_{ext} = 0$.

Both standard arguments for the derivation of the variation of the action and imposing that its variation among all the admissible variation $\delta\chi_1$ and $\delta\chi_2$ of the fundamental kinematical fields χ_1 and χ_2 are null, i.e. $\delta\mathcal{A} = 0$, yields the following system of Partial Differential Equations of the problem,

$$\rho_1 \ddot{u}_1 + \rho_{12} \ddot{u}_2 - \eta_1 \ddot{u}''_1 - \eta_{12} \ddot{u}''_2 = k_{el1} u''_1 + k_{el12} u''_2 - k_{el0}(u_1 - u_2) = 0 \tag{14}$$

$$\rho_2 \ddot{u}_2 + \rho_{12} \ddot{u}_1 - \eta_2 \ddot{u}''_2 - \eta_{12} \ddot{u}''_1 = k_{el2} u''_2 + k_{el12} u''_1 + k_{el0}(u_1 - u_2) = 0 \tag{15}$$

By assuming plane wave solutions for the displacement fields u_1 and u_2 in terms of the real part of complex exponential form,

$$u_1 = Re\left(u_{10} \exp i\left(\omega t - kX\right)\right), \quad u_2 = Re\left(u_{20} \exp i\left(\omega t - kX\right)\right), \tag{16}$$

where u_{10} and u_{20} are the complex amplitudes, we obtain the following dispersion relation

$$\det\begin{pmatrix} \rho_1\omega^2+\eta_1k^2\omega^2-k_{el1}k^2-k_{el0} & \rho_{12}\omega^2+\eta_{12}k^2\omega^2-k_{el12}k^2+k_{el0} \\ \rho_{12}\omega^2+\eta_{12}k^2\omega^2-k_{el12}k^2+k_{el0} & \rho_2\omega^2+\eta_2k^2\omega^2-k_{el2}k^2-k_{el0} \end{pmatrix}=0, \tag{17}$$

that in the explicit form is

$$\omega=\omega_{cc}\left(k\right)=\frac{E\left(k\right)\pm\sqrt{E\left(k\right)^2-4F\left(k\right)}}{2G\left(k\right)}, \tag{18}$$

where

$$\begin{aligned} E\left(k\right) &= k^4\left(k_{el1}\eta_2+k_{el2}\eta_1-2k_{el12}\eta_{12}\right)+ \\ &\quad k^2\left(k_{el1}\rho_2+k_{el2}\rho_1-2k_{el12}\rho_{12}+k_{el0}\left(\eta_1+\eta_2+2\eta_{12}\right)\right)+ \\ &\quad k_{el0}\left(\rho_1+\rho_2+2\rho_{12}\right) \end{aligned} \tag{19}$$

$$F\left(k\right) = k^2\left(k_{el0}\left(k_{el1}+k_{el2}+2k_{el12}\right)+k^2\left(k_{el1}k_{el2}-k_{el12}^2\right)\right)G\left(k\right) \tag{20}$$

$$G\left(k\right) = k^4\left(\eta_1\eta_2-\eta_{12}^2\right)+k^2\left(\rho_1\eta_2+\rho_2\eta_1-2\eta_{12}\rho_{12}\right)+\rho_1\rho_2-\rho_{12}^2 \tag{21}$$

and the function $\omega_{cc}\left(k\right)$ has been introduced for the present continuous system. A comparison between the dispersion relations for discrete and for continuous systems can be done only for large wave length $\lambda=2\pi/k$, that means for small wave number k. Thus, it is reasonable to perform a Taylor's series expansion of both functions $\omega_{dd}\left(k\right)$ and $\omega_{cc}\left(k\right)$, that we perform with the assumption

$$\rho_1=\rho,\quad \rho_2=\rho,\quad \eta_1=\eta,\quad \eta_2=\eta, \tag{22}$$

that yields,

$$\omega_{dd1}\left(k\right)^2 = \left(ka\right)^2\frac{K_1K_2}{2M\left(K_1+K_2\right)} \tag{23}$$

$$\omega_{dd2}\left(k\right)^2 = 2\frac{K_1+K_2}{M}-\left(ka\right)^2\frac{K_1K_2}{2M\left(K_1+K_2\right)} \tag{24}$$

$$\omega_{cc1}\left(k\right)^2 = k^2\frac{k_{el1}+k_{el2}+2k_{el12}}{2\left(\rho+\rho_{12}\right)}, \tag{25}$$

$$\omega_{cc2}\left(k\right)^2 = 2\frac{k_{el0}}{\rho-\rho_{12}}+k^2\left[\frac{k_{el1}+k_{el2}-2k_{el12}}{2\left(\rho-\rho_{12}\right)}-2\frac{k_{el0}\left(\eta-\eta_{12}\right)}{\left(\rho-\rho_{12}\right)^2}\right] \tag{26}$$

An identification of the four dispersion relations (23), (24), (25) and (26) yields

$$\rho=\frac{M}{a},\quad k_{el0}=\frac{K_1+K_2}{a},\quad k_{el1}+k_{el2}=a\frac{K_1K_2}{K_1+K_2},\quad \eta=\frac{MaK_1K_2}{2\left(K_1+K_2\right)^2} \tag{27}$$

with the assumption

$$\rho_{12}=\eta_{12}=k_{el12}=0 \tag{28}$$

3 Numerical results

We shall now apply the theory outlined above to a biatomic tensegrity chain modeled as a mass-spring chain and featuring linear springs with two alternating stiffness constants K_1 and K_2 (where $K_1<K_2$) [7]. This section includes a numerical validation of the approach

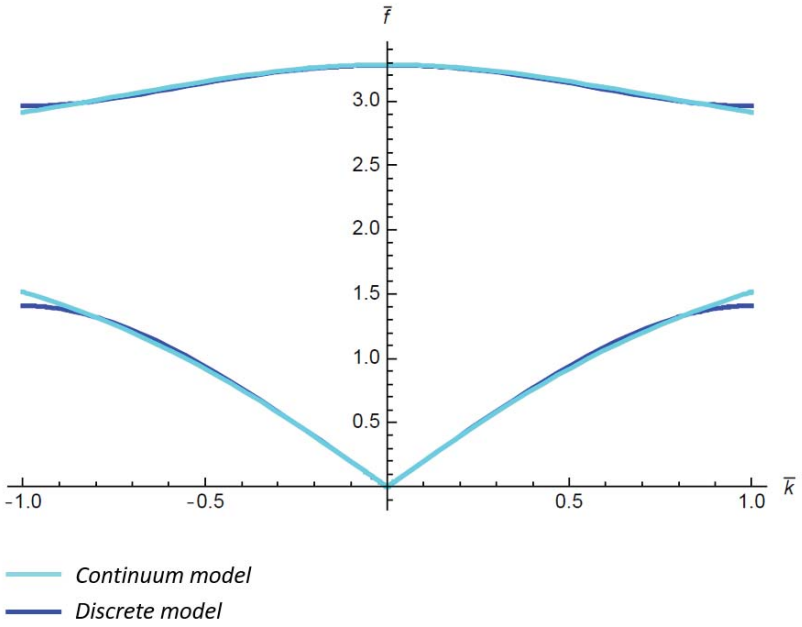

Figure 1: Dispersion relation in the first Brillouin zone for a biatomic chain under $F_0 = 4.21$ N and $\bar{p} = 0.00$, obtained by applying the discrete and continuous models.

presented in Section 2. Our results are compared with those obtained by applying Bloch-Floquet theory to a biatomic tensegrity chain, as illustrated in [7], Subsection 2.2.
We focus on a chain that is uniformly axially loaded with an initial static precompression force $F_0 = 4.21$ N applied to the terminal bases of the structure. Each unit presents an initial self-stress (internal prestress) $\bar{p} = 0.00$.

Fig. 1 compares the dispersion relation of a biatomic tensegrity chain obtained via the discrete model [7] and the continuous model (Section 2), highlighting a good overall agreement between the two approaches.
Here, $\bar{f}$ denotes the normalized frequency $\bar{f} = f\sqrt{\frac{M}{K^*}}$ where K^* is the tangent stiffness of Unit 1 (taken as a reference) in the globally prestressed configuration and M is the total mass of a unit cell. Meanwhile, $\bar{\kappa}$ denotes the normalized wavenumber $\kappa\, \pi/a$ where a is the unit cell size.

It is worth noticing that the identification of the constitutive paramenters of the continuum model in (27-28) has been done assuming small values of the wave number κ and therefore for large wave length $\lambda = 2\pi/\kappa$. Thus, from one hand this is the range in which the continuum approximation is possibile and the comparison that is done in Fig. 1 is relaiable. From the other hand, an investigation in other ranges of wave length for the continuum model still need to be done.

4 Concluding remarks

In this paper, we have analyzed the frequency band structure of a 1D monoatomic and biatomic mass-spring chain. The study led us to formulate a continuum model for these structures based on a higher order gradient continuum theory. In contrast to standard continuous models, this theory allows us to efficiently describe intrinsic discrete systems.

A numerical application of the proposed discrete-to-continuum approach has been presented with reference to tensegrity metamaterials, which exhibit a prestress-tunable bandgap response

over a wide range of frequencies while the material properties of the unit cells remain unchanged. A comparison was made between the dispersion relations for discrete and continuous systems in order to validate the mathematical homogenization theory presented.

Possible engineering applications of tensegrity metamaterials may include bandgap systems [13, 14], waveguiding [15, 16], impact protection gear [6, 17], and/or acoustic lenses [18, 19].

This study paves the way for a number of relevant extensions and generalizations that we will address in future work. These may include, for example, the 3D printing [20] and experimental dynamic analysis of tensegrity metamaterial structures at different scales.

Abstract. *In this paper, we report about the effect of the application of a state of prestress on the band structure of a periodic phononic crystal characterized by an inertial amplification mechanism. Through a numerical example, we show the possibility of inducing negative group velocity in an isolated branch of the dispersion diagram.*
A 2-step Updated Lagrangian scheme is adopted to calculate the dispersion diagram of the structure. The proposed method include (i) the static geometrically nonlinear analysis of a representative unit cell undergoing the action of an applied external load and (ii) the Bloch-Floquet decomposition applied to the linearized equations of the acousto-elasticity for the unit cell in the deformed configuration. The dispersion analysis is performed in terms of small amplitude motions superimposed on a deformed state, once the desired load has been applied.

1 Introduction

Controlling the propagation of elastic waves in solids has always attracted the interest of physicists and engineers. Considerable progress has been made in this area thanks to the introduction in the last decades of the so called *phononic crystals* and *elastic metamaterials*, i.e., artificial periodic structures with variations in density / stiffness / geometry, exhibiting unconventional dynamic properties, such as for instance frequency regions where the propagation of waves is inhibited, referred to as phononic bandgaps, or negative group velocity of their branches [1], allowing for negative refraction [2].
Since their introduction, a plethora of innovative applications relying on frequency filtering [3], topological protection [4, 5] and wave splitting [6] have been proposed in the most disparate fields ranging from the infrasonic to the ultrasonic frequency regime [7–11].
However, one of the main limitations of these structures is represented by the fact that once designed, their unusual dynamic properties are fixed in terms of operational frequency. For example, a metamaterial designed and manufactured to attain specific unconventional properties in a certain frequency range (for instance attenuating the propagation of elastic waves or exhibiting negative group velocity) cannot be modified to operate in a different frequency range. This implies poor versatility and adaptability to external variations, often essential for various practical applications.
In this context, periodic systems with adaptive elastic properties have been proposed tuning the dispersion diagrams through the piezoelectric effect [12, 13], inducing temperature variation [14], or exployting magneto- and light-based approaches [15, 17], as well as applying external mechanical loads [18–22].
The majority of the aforementioned investigations focused their attention on the bandgap shift / widening / reduction, whereas here, we report about the possibility of inducing negative group velocity in an isolated branch of the dispersion diagram of an inertially amplified phononic crystals. This is achieved through the application of an external state of prestress. A phononic crystal exhibiting inertial amplification mechanism has been chosen because it has been shown that the large inertial forces generated by amplifying the motion of a mass increases the inertia of the overall system and lowers its resonance frequency, allowing thus for sub-wavelength phenomena, while keeping the structure lightweight [25, 26]. As a consequence of this, the inertial amplification allows for a more remarkable curve shifts, if compared to the cases of Bragg scattering [21, 22] and / or ordinary local resonant metamaterials.
We consider the static deformation induced by the prestress to be in the linear elastic regime so to have a complete reversibility of the phenomena (tunability). The analysis is performed in terms of small amplitude motions superimposed on a deformed state once the desired load has been applied.
The paper is organized as follows: in section 2, the calculation method (referred to as a *2-step Updated Lagrangian scheme*) is briefly recalled. Both the static geometrically nonlinear analysis of a representative unit cell undergoing the action of an applied external load and the Bloch-Floquet decomposition applied to the linearized equations of the acousto-elasticity for the unit cell in the deformed configuration, are recalled. Section 3 provides a numerical example showing the concrete possibility of altering the dispersion band diagram through the application of an external state of prestress in a periodic structure exhibiting inertial amplification mechanism. Finally, section 4 synthesizes the principal results and provides future perspectives.

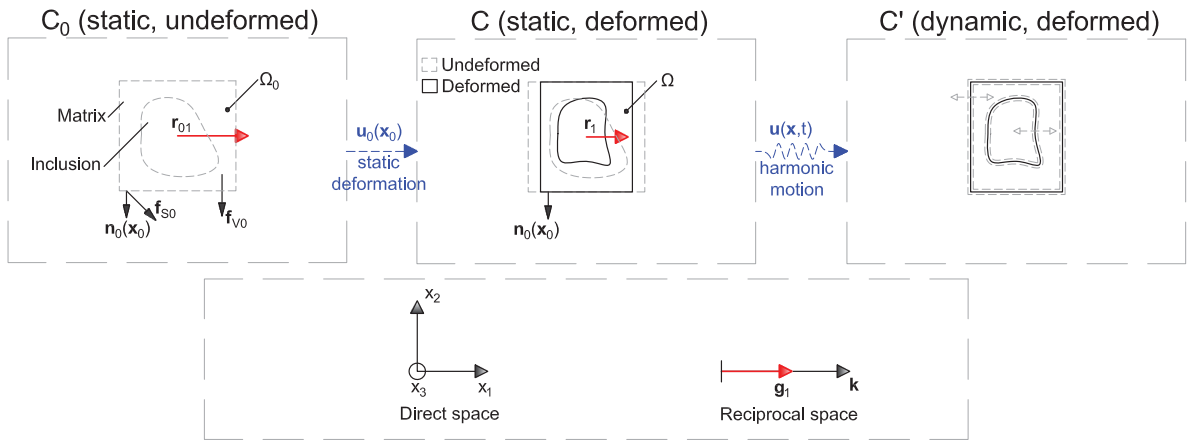

Figure 1: On the top panel, the undeformed configuration C_0, i.e. the initial unit cell (delimited by dashed lines) used to calculate the displacement and stress fields introduced by the external mechanical load (left panel), the static deformed configuration C, resulting from the application of the external mechanical load (middle panel) and the dynamic configuration C' undergoing a harmonic motion (right panel) are reported, respectively. In the bottom panel, the reference systems in the direct and reciprocal spaces are reported as well, for the sake of completeness.

2 Numerical formulation: a brief recall of the 2-step Updated Lagrangian scheme

We here recall the main steps for the band diagram calculation adopting a Bloch-Floquet finite element method which takes into account the effect of the prestress in a formulation called 2-step Updated Lagrangian scheme. Refer to [21, 22] for the full description of the approach. Synthesizing, the numerical procedure includes two principal computational steps:

1) a nonlinear static analysis involving large strains and displacements;

2) a *small-on-large* dynamic analysis, in which small vibrations are superimposed to the statically deformed unit cell.

2.1 Static analysis

Let's consider the unit cell Ω_0 represented on the top left panel of Fig. 1 by the gray dashed line. The unit cell is identified by the position vector $\mathbf{x}$ and represented by the lattice vector $\mathbf{r}_0 = \{r_{01}, 0\}^{\mathrm{T}}$ (periodicity only in the x direction is considered) and its reciprocal vector $\mathbf{g}_0 = \{g_{01}, 0\}^{\mathrm{T}} = \{r_{01}/2\pi, 0\}^{\mathrm{T}}$. If the unit cell is subjected to the application of a static volume load $\mathbf{f}_{V0}$, or surface load $\mathbf{f}_{S0}$, it undergoes a displacement $\mathbf{u}_0$, which causes a change of configuration from the undeformed state C_0 to the static deformed state C.
It is possible to write the relation between $\mathbf{r}_0$ and $\mathbf{r}$ as $\mathbf{r} = \mathbf{F}_L\mathbf{r}_0$, where $\mathbf{F}_L$ defines the affine component of the deformation gradient. Making use of the variational statement, it is possible to derive the equilibrium equations with respect to the undeformed configuration C_0:

$$\int_{\Omega} \left(\mathbf{S}(\mathbf{x}) : \delta\mathbf{E}(\mathbf{x}) - \mathbf{f}_{V0} \cdot \delta\mathbf{u}_0\right) da = \int_{\partial\Omega} \mathbf{f}_{s0} \cdot \delta\mathbf{u}_0 ds, \tag{1}$$

subjected to the Dirichlet boundary conditions:

$$\mathbf{u}_0(\mathbf{x} + \mathbf{r}_0) = \mathbf{u}_0(\mathbf{x}). \tag{2}$$

Assuming a hyperelastic material according to the Murnaghans model [27–29] and specifying the density of the unit cell as ρ_0, the elastic energy density can be defined as:

$$\psi = \frac{1}{2}\left(\lambda + 2\mu\right) I_1^2(\mathbf{E}) - 2\mu I_2(\mathbf{E}) + \frac{1}{3}\left(l + 2m\right) I_1^3(\mathbf{E}) - 2m I_1(\mathbf{E}) I_2(\mathbf{E}) + n I_3(\mathbf{E}), \tag{3}$$

in which λ and μ denote the first and second Lamé parameters, respectively, (l, m, n) the third order Murnaghan parameters, and $I_1(\mathbf{E})$, $I_2(\mathbf{E})$ and $I_3(\mathbf{E})$ the first, second and third invariants of the Green-Lagrange strain tensor, respectively.
The application of a standard Galerkin approach to Eq. (1) leads to the generalized system of equations:

$$\left[\mathbf{\Gamma}_0^{\mathrm{T}} \mathbf{K}(\mathbf{Q}_0) \mathbf{\Gamma}_0\right] \mathbf{Q}_0(\mathbf{X}) = \mathbf{P}_0(\mathbf{X}), \tag{4}$$

where $\mathbf{K}(\mathbf{Q}_0)$ is the static stiffness matrix, $\mathbf{P}_0$ the global vector of nodal forces, $\mathbf{Q}_0$ the global vector of independent nodal displacements and $\mathbf{\Gamma}_0$ the mapping operator resulting from Eq. (2) and realizing the condition $\mathbf{U}_0 = \mathbf{\Gamma}_0 \mathbf{Q}_0$. This will allow us to update the reference configuration from C_0 to C, which will be used, once properly re-meshed, as the basis unit cell for the dispersion curve calculation.

2.2 Floquet-Bloch Analysis

Under the assumption of *small-on-large analysis approach* [28, 30–32], the small harmonic perturbation $\mathbf{u}(\mathbf{x})$ can be expressed as [33]:

$$\mathbf{u}(\mathbf{x}) = \tilde{\mathbf{u}}(\mathbf{x}) \exp(\mathrm{i}kx) \exp(-\mathrm{i}\omega t), \tag{5}$$

in which the Ω-periodic displacement amplitude is taken into account (t denotes the time, ω the angular frequency, and $k \in \Lambda$ the Bloch wavenumber, being Λ the reciprocal unit cell defined in C by the reciprocal lattice vector.
The solution of the elastodynamic problem for free vibrations of the unit cell in C subjected to an initial stress $\boldsymbol{\sigma}_0$ and subjected to the Dirichlet boundary condition proceeds by first generating a new mesh for the deformed geometry of the unit cell in C and then applying a Galerkin approach [34]. The band diagrams of the phononic structure can be computed from the eigenvalue problem (the mathematical expressions of the mapping operator implementing the Dirichlet boundary condition, $\mathbf{K}_3$, $\mathbf{K}_2$, $\mathbf{K}_1$ and $\mathbf{M}$ are not reported in the present paper for the sake of brevity and can be found in Refs. [21, 22]):

$$\left\{\mathbf{\Gamma}^{\mathrm{T}} \left[k^2 \mathbf{K}_3 + \mathrm{i}k \left(\mathbf{K}_2 - \mathbf{K}_2^{\mathrm{T}}\right) + \mathbf{K}_1 - \omega^2 \mathbf{M}\right] \mathbf{\Gamma}\right\} \tilde{\mathbf{Q}}(\omega) = \mathbf{0}. \tag{6}$$

3 Numerical results

In this section, the potential of an applied external mechanical load to alter the dispersion diagram of a periodic structure characterized by an inertial amplification mechanism is shown. Specifically, the switching from positive to negative group velocity of an isolated dispersion curve is reported.
To this aim, the band diagram is calculated for the unit cell reported in Fig. 2A (proposed for the first time by Acar and Yilmaz [26]) through the numerical procedure recalled in section 2. The structure is supposed to be in epoxy with the following material parameters: $\rho = 1540$ kg/m^3, $\lambda = 2.59$ GPa, $\mu = 1.34$ GPa, $l = -18.94$, GPa, $m = -13.36$ GPa and $n = -9.81$ GPa. The geometrical dimensions can be derived from Fig. 2A knowing that $t_2 = 0.4$ mm has been assumed.

Once the deformation induced in the unit cell by an initial state of stress / strain applied to the structure has been calculated according to the steps reported in section 2.1, the band structures are computed considering the unit cell to infinitely duplicate in a periodic linear array, and assuming the epoxy in its linear elastic regime and under the hypothesis of small displacements (see section 2.2). Both a compression and a traction condition of load are considered by applying a displacement $\mathbf{u}_0(\mathbf{x}_0) \cdot \mathbf{n}_0(\mathbf{x}_0)$ normal to the external vertical faces of the unit cell (highlighted in blue in Fig. 2A).
Figure 2B reports the plots of the the reduced wavenumber k^* along the $\Gamma - X$ irreducible path as a function of the frequency ([$0 - 900$ Hz range]) for $+130$ μm (left panel), 0 μm (central panel) and -360 μm (right panel) assigned prestrains. We focus our attention on the dispersion branch highlighted in purple, which, in contrast to the other branches reported in gray, besides a general shift, undergoes a group velocity inversion for some values of the reduced wavenumber k^*. Specifically, if inducing a pre-solicitation state of traction, the inflexion point is achieved around $k^* \simeq 0.5\pi/a$, whereas, when inducing a state of pre-compression, the transition occurs for $k^* \simeq 0.65\pi/a$ (black arrows in Fig. 2B). To gain further insight on this phenomenon, the corresponding mode shape evaluated at the high symmetry points Γ and X are inspected and reported in Fig. 2C. From the comparison it emerges that while the vibration pattern is practically the same for low values of k^* (the 3 mode shapes denoted by the star symbol deform comparably), as the k^* increases, the deformation induced by the states of prestress alter the overall deformation mechanism with respect to the non-prestressed case (compare the 3 modes denoted by the circular dot). This change in the deformation mode happens only for this branch. As a consequence, for the other branches reported in gray in the diagram the effect of the prestress is to solely shift their frequencies. This allows us to infer that the prestress is differently felt from the deformation modes of the phononic crystal.
Finally, it is worth noticing that in the first pre-solicitation case (traction), a region in which solely the negative group velocity part of the dispersion branch can be isolated in frequency (see the orange dashed line and the orange arrow in Fig. 2B) from 525 to 550 Hz.
These results suggest that a deformation of the unit cell geometry induced by a compressive / tensile prestress state, already in the elastic regime, can lead to significant changes in the dynamic behaviour of a periodic structure, especially if the structure is dominated by an inertial amplification mechanism.

4 Concluding remarks

In this paper, we have reported about the effect of the application of a state of prestress on the band structure of a periodic phononic crystal characterized by an inertial amplification mechanism. Specifically, through a numerical example, we have shown the possibility of inducing negative group velocity in an isolated branch of the dispersion diagram.
The dispersion curves are calculated through a *2-step Updated Lagrangian scheme* within the which both the static geometrically nonlinear analysis of a representative unit cell undergoing the action of an applied external load and the Bloch-Floquet decomposition applied to the linearized equations of the acousto-elasticity for the unit cell in the deformed configuration, are implemented. The dispersion analysis is performed in terms of small amplitude motions superimposed on a deformed state, once the desired load has been applied. It is worth mentioning that we have considered the static deformation induced by the prestress to be in the linear elastic regime, so to guarantee a complete reversibility of the phenomena, once the load removed.
This study may represent a practical solution for reducing one of the limitations of phononic crystals / metamaterials, represented by the fact that once designed, their unusual dynamic prop-

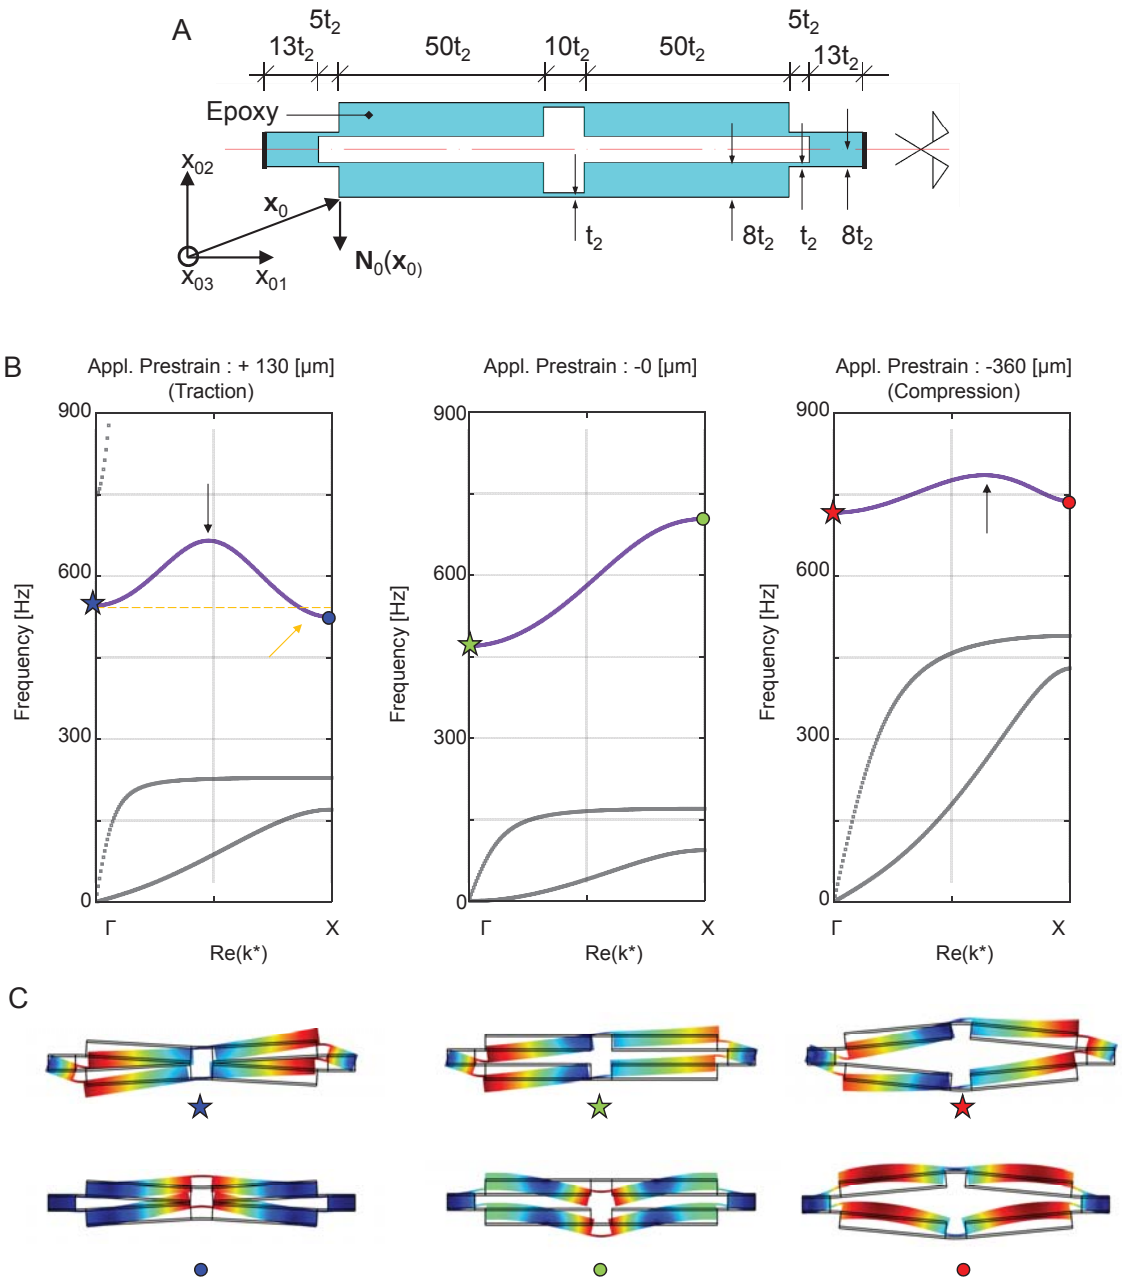

Figure 2: (A) Schematic representation of the considered unit cell along with its position $\mathbf{x}_0$ with respect to the original reference systems x_{0i}, with i = 1,2,3. Keywords: U-profile, aeroelastic instability, galloping, wind tunnel test, rectangular cylinder

Abstract. *The proposed paper deals with the experimental investigation of the susceptibility of the set of slender beams having different U-shaped cross-sections typical, e.g., for footbridges and bridge decks with railings or with wind barriers, to the classical galloping. In particular, the influence of the depth of U-shaped profiles having constant side ratio equal to 2 onto aerodynamic drag and lift coefficients was tested in the wind tunnel. Moreover, the effect of the porosity of the vertical sides of U-shaped cross-sections on these coefficients and galloping stability was also studied. The analysis of the proneness of investigated non-porous U-beams to galloping based on the classical quasi-steady theory indicates that the influence of the depth is minimal. On the other hand, when the vertical sides of U-profiles are porous, the depth represents an important factor influencing the size and angular range of positive slope of the transversal force coefficient. The comparison with the outcomes from the tests of the prisms with rectangular cross-sections is also presented and the differences are discussed in detail.*

1 INTRODUCTION

The long slender structures with bluff cross-section, that are exposed to the wind, e.g. the power line cables, towers, tall buildings, can be prone to self-excited motion classified as transverse galloping [1]. The transverse galloping is characterized as almost harmonic oscillation of the structure with high amplitudes and low frequency, which is normal to the wind direction and emerges after reaching the critical wind velocity. The amplitudes of the vibration steadily grow by increasing the flow speed above the critical value due to negative damping, thus the system is instable and the motion is divergent. The susceptibility to the galloping is usually assessed using the quasi-steady theory [2]. The necessary condition is given by the positive slope of the transverse force [3], i.e. when the negative slope of lift coefficient is higher than the drag coefficient. Both lift and drag coefficients are obtained from the static force measurements of the analyzed body in the wind tunnel. The galloping onset wind velocity estimated on basis of the quasi-steady approach is inversely proportional to the slope of transversal force coefficient and proportional to Scruton number, which characterizes mass and damping properties of the structure or structural element [4].

The loss of aerodynamic stability of prismatic bodies with orthogonal cross-section was extensively studied in the last decades, especially with the focus on rectangular and square cross-sections. For the smooth flow conditions, Parkinson [5] observed the proneness to galloping for rectangular bodies with side ratio, *SR*, between 0.75 and 3. Using force oscillation experiment Washizu et. al. [6] found out, that transverse galloping can occur for prismatic bars with the rectangular section with side ratio, *SR*, smaller than 2.5. The stability parameter related to galloping of rectangular cylinders were also investigated by Ruscheweyh et. al [7]. The authors recommended to use more precise aero-elastic model and indicated the sensitivity to galloping for rectangular with $SR < 3$. Furthermore, the analysis of the sensitivity of other bluff cross-sections such as triangular section [8], L-shaped, T-shaped and cross-shaped sections [9] and D – shaped section [10, 11] typical for ice-coated conductors were also recently published.

This article presents the analysis of the susceptibility of a set of cylinders with various U- shaped cross-sections to galloping based on the results of static wind tunnel tests and quasi-steady hypothesis. In particular, the prisms with various U-shaped cross sections associated with side ratio, $SR = 2$, were tested in detail under the smooth flow conditions. The individual U-profiles have identical outer basic geometry and differ only by their inner depth. For zero depth the U-profile transforms to the rectangle with $SR = 2$, which is prone to galloping. The differences between the aerodynamic coefficients and their trends with varying angle of wind attack related to this rectangle and individual U-profiles are presented and discussed in detail. In addition, the influence of porosity of the vertical sides onto the coefficients and the proneness to galloping instability is also studied.

2 WIND TUNNEL TEST DESCRIPTION

The experimental testing of a set of cylinders with various U-shaped cross-sections was carried out in the wind tunnel of Institute of Theoretical and Applied Mechanics of the Czech Academy of Sciences. All tested specimens were made from wood and were 160 cm long. All have identical $SR = 2$ and identical main along and across wind dimensions $B = 30$ cm and $D = 15$ cm, respectively see Figure 1. The individual U-shaped profiles differ only by their depth, *Db*. The influence of the depth upon the values of the aerodynamic drag and lift coefficient were investigated in detail in terms of dimensionless ratio, *B/Dr*. In particular, the U-profiles with ratios $B/Dr = 2.5$, 3, 4 and 6 were analyzed. In addition, also the effect of the relatively high porosity of the vertical sides (barriers), $p = 75\%$, was studied. Each barrier was built from two plastic nets with a thickness of 1 mm having an axial 5 mm square grid with a

specific degree of fill. The nets were glued onto the frontal and rear sides of a tiny plastic frame in order to secure a sufficient stiffness of the barrier. In particular, the frame consisted from columns with rectangular cross-section of 4 mm × 2 mm and axial distance equal to 5 cm connected together at the top with a horizontal bar having also the rectangular cross-section of 4 mm × 1 mm. The total thickness of the complete barriers, t_b, was 6 mm.

Moreover, the models of prisms with rectangular cross-sections given by all side ratios *B/Dr* were also built and tested for comparison with individual U-profiles.

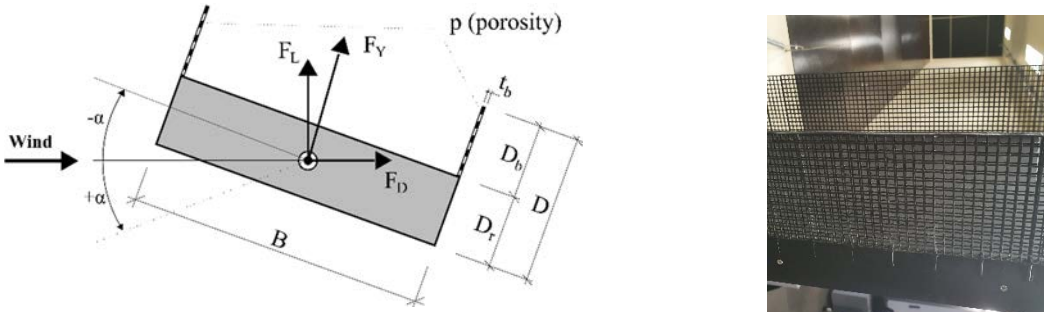

Figure 1: U-profile layout (left) and a snapshot of the vertical barrier with porosity p = 75% (right).

The models were placed vertically into the measuring part of the aerodynamic section of the wind tunnel and were enclosed between wooden and plastic end-plates, that eliminate the 3D influences and assure the homogenous flow conditions. The aerodynamic forces for the angle of attack, α, in the range from -15° to +15° were measured using two load cells ATI Industrial Automation sensors Mini 40, one at each end of the model. Each force/torque sensor was placed between the individual end of the wooden model and a specially designed rotation mechanism, which was fully fixed to metallic frame of a ceiling at the top and to a table of the floor of the wind tunnel at the bottom. The synchronized rotation of both upper and lower mechanisms enables to swivel the model with the very small angle step, $\Delta\alpha$ = 0.2°. Thus, the alternation of aerodynamic coefficients character with the changing angle, α, can be described very precisely. In our case, this small step was used for α in the range from -2.5°to 2.5°. The larger step $\Delta\alpha$ = 0.5° was used for α up to ±5° and finally for even higher α > 5° the step $\Delta\alpha$ = 1° was adopted. The data from the sensors were recorded with a sampling frequency fs = 1000 Hz for 60 seconds, which is sufficient with respect of the ergodicity and stationarity of the process.

All of the tests were performed under smooth flow conditions, i.e. with minimum turbulence intensity around 1%. Wind speed was measured by the Prandtl-Pitot tube at 400 mm above the floor before the model in place of the undisturbed stream, see the photo in Figure 2. At first, the models were loaded with the speeds in the range of 10 % - 70 % of the fan power, which is 3,0 m/s to 20 m/s, in order to determine the interval of independence of the aerodynamic coefficients on the Reynolds number, *Re*. The tests were finally carried out at a velocity of about 14 m/s corresponding to $Re = 2.8e^5$ normalized using along-wind dimension *B*.

3 PROCEDURE FOR EVALUATION OF PRONENESS TO GALLOPING FROM WIND TUNNEL DATA

In order to assess the susceptibility of the individual tested profiles to the transversal galloping according to quasi-steady theory the coefficient of the static drag and lift forces have to be determined for a various angle of attack, α. The drag and lift coefficients, C_D and C_L, respectively were calculated from the measured forces according to their definitions in the forms

$$C_D(\alpha) = \frac{2 \cdot F_D(\alpha)}{\rho \cdot U^2 \cdot D \cdot L} \quad , \qquad C_L(\alpha) = \frac{2 \cdot F_L(\alpha)}{\rho \cdot U^2 \cdot D \cdot L} \quad , \tag{1}$$

where F_D and F_L are measured drag and lift forces, respectively, ρ is air density, U is the mean wind speed, D is the cross-wind dimension and L represents the length of the model.

The proneness to galloping of the particular cross-section was subsequently assessed based on the Glauert-den Hartog instability criterion [3]

$$\frac{dC_L}{d\alpha} + C_D < 0 \quad , \tag{2}$$

for a neighborhood of the zero angle of attack, i.e., $\alpha = 0°$. Den Hartog criterion was derived from a solution of one degree of freedom system loaded by transverse force *Fy*, see Figure 1, given by the transverse force coefficient [4]

$$C_{FY}(\alpha) = -C_D(\alpha) \cdot \sin(\alpha) - C_L(\alpha) \cdot \cos(\alpha). \tag{3}$$

The course of C_{FY} against the angle of attack is also presented in this paper, since it could serve for, e.g. numerical evaluation of the expected level and character of the response. It must be noted, that the approximate solution of the first derivative of C_{FY} with respect to α for $\alpha = 0°$ gives the galloping stability parameter a_g

$$a_g = \left.\frac{dC_{FY}}{d\alpha}\right|_{(\alpha=0°)} = -\left.\left(\frac{dC_L}{d\alpha} + C_D\right)\right|_{(\alpha=0°)}, \quad (4)$$

which is provided in Eurocode [12] for determination of the critical wind velocity of unstable profiles. This stability parameter was calculated for each of the tested U-profiles for a comparison with the data in existing databases or their extensions. Measurement of the static forces was expected to be slightly distorted by the effect of the higher blockage around 8.5 %. The correction based on a comparison of the results of CFD simulations carried out for a profile placed in almost unbounded space and in the confined space simulating the actual cross-section of the wind tunnel was incorporated.

4 RESULTS OF WIND TUNNEL TESTS

4.1 Beams with rectangular cross-sections

The initial static tests were aimed to determine the drag and lift coefficients for prism with the rectangular cross-section with $SR = 2$, which represents a reference case for all other measurements. The drag coefficient $C_D = 1.48$ for $\alpha = 0°$ and the slope of lift coefficient $dC_L/d\alpha = -11.29$ around the zero angle were calculated from the mean values of measured aerodynamic forces in accord to Eq. (1). The slope of C_L was obtained from a linear regression of values related to angles α from -1° to +1°. The stability parameter $a_g = 9.81$ corresponding to the above mentioned C_D and slope of C_L is significantly higher than $a_g = 2$ provided by Eurocode [12]. Nevertheless, it was confirmed by the tests of many authors, that this value does not appear as conservative at all [13]. The most similar values to the present case can be found e.g., in [6] or [14], where the stability parameter $a_g = 8.8$ and $a_g = 8.6$, respectively were stated.

The results of subsequent measurements of rectangular prisms with higher side ratio revealed, that only for $SR = 2.5$ the slope of C_L is negative and this cylinder is prone accord to Eq.(2) to galloping. The rest of prisms with $SR = 3$, 4 and 6 was determined as stable in relation to this type of instability. The drag coefficient, C_D, and slope of C_L for zero angle of attack together with the stability parameter a_g for all rectangular prisms are summarized in Table 1. In Table 1, also the angular interval, $\Delta\alpha$, where the coefficient C_{FY} has positive slope, is presented. The boundaries of interval $\Delta\alpha$, i.e., angles α_{IP}^- and α_{IP}^+ are presented in the last column of Table 1 and their two illustrative examples are graphically shown in Figure 4.

Cross section	SR [/]	C_D [/]	$dC_L/d\alpha$ [/]	a_g [/]	$\Delta\alpha$ [°]	$\langle\alpha_{IP}^-; \alpha_{IP}^+\rangle$ [°]
	2.0	1.48	-11.29	9.81	12.4	⟨-6.2; 6.2⟩
	2.5	1.32	-17.17	15.85	9.2	⟨-4.6; 4.6⟩
	3	1.14	6.63	-	-	-
	4	1.09	39.22	-	-	-
	6	0.98	67.07	-	-	-

Table 1: The drag coefficient, C_D, and the slope of the lift coefficient, $dC_L/d\alpha$, for zero angle of attack, the stability parameter, a_g, and angular interval, $\Delta\alpha$, of the positive slope of C_{FY} of the tested rectangular prims

The tests indicated higher a_g for $SR = 2.5$ than for $SR = 2$, however, the angular range $\Delta\alpha$ of the positive slope of C_{FY} is smaller. The aerodynamic coefficients and transverse force coefficient against the angle of attack is also graphically presented in Figures 3 and 4, respectively. It must be noted, that in these figures the curves related to the coefficients of rectangular cross-sections are normalized to the height $D = 150$ mm in order to be better comparable with U - beams, while in Table 1 they are normalized with respect to their real across-wind dimensions.

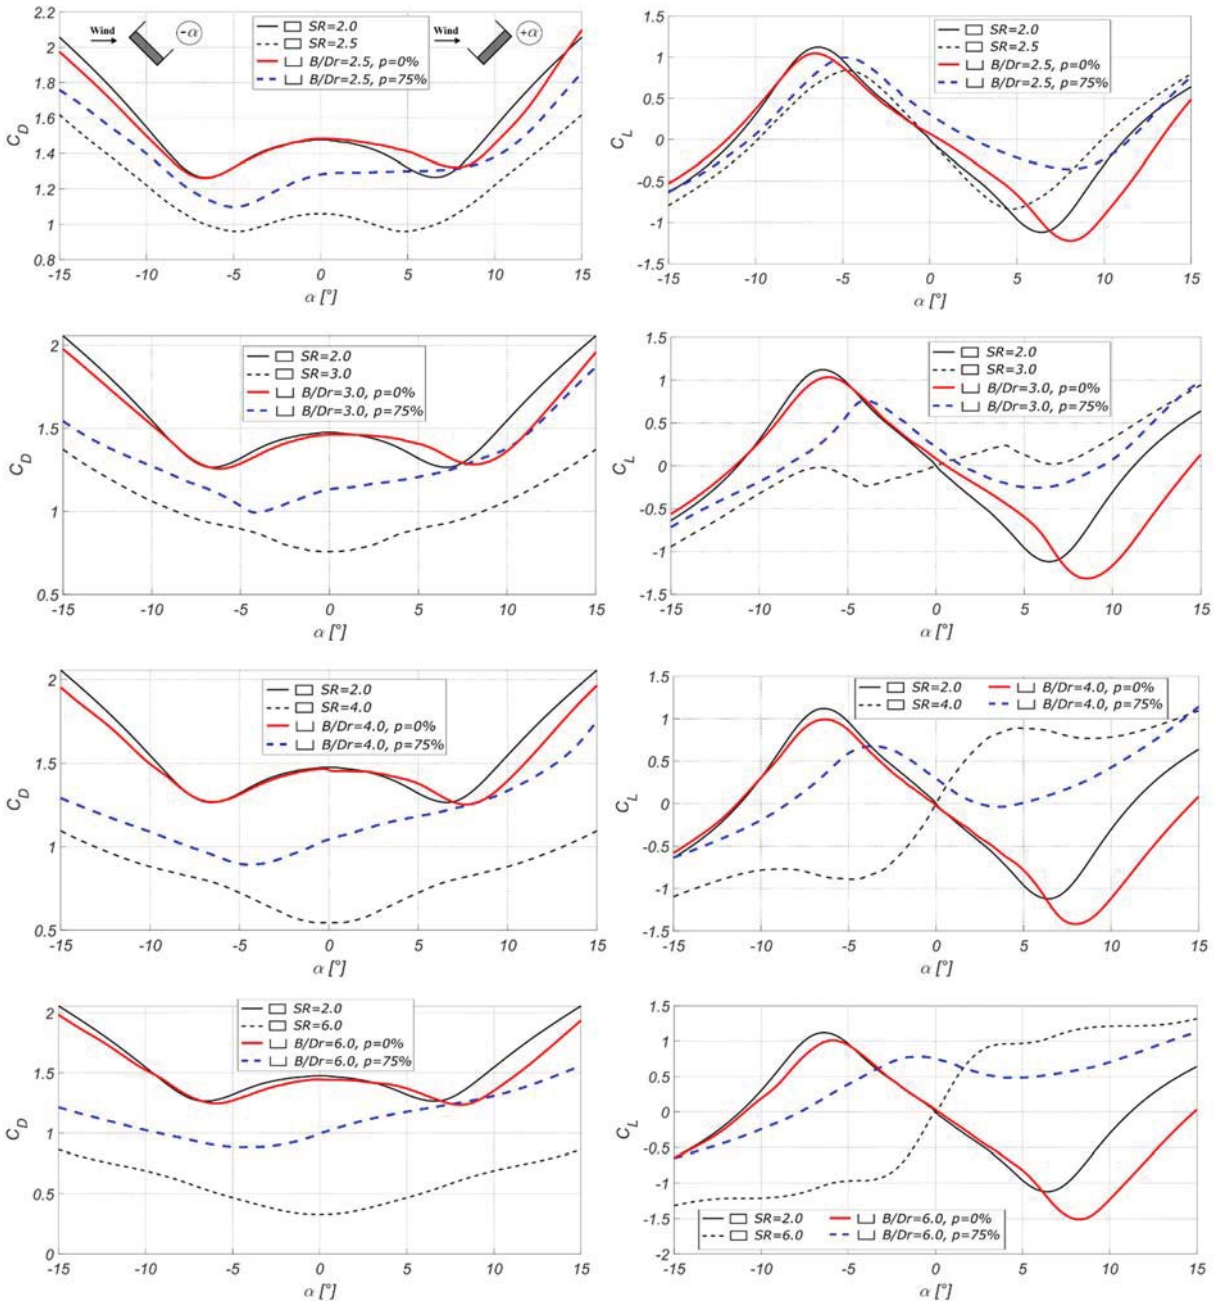

Figure 3: The drag coefficient (left column) and lift coefficient (right column) of the cylinders with rectangular and U-shaped cross sections given by side ratio *B/Dr*

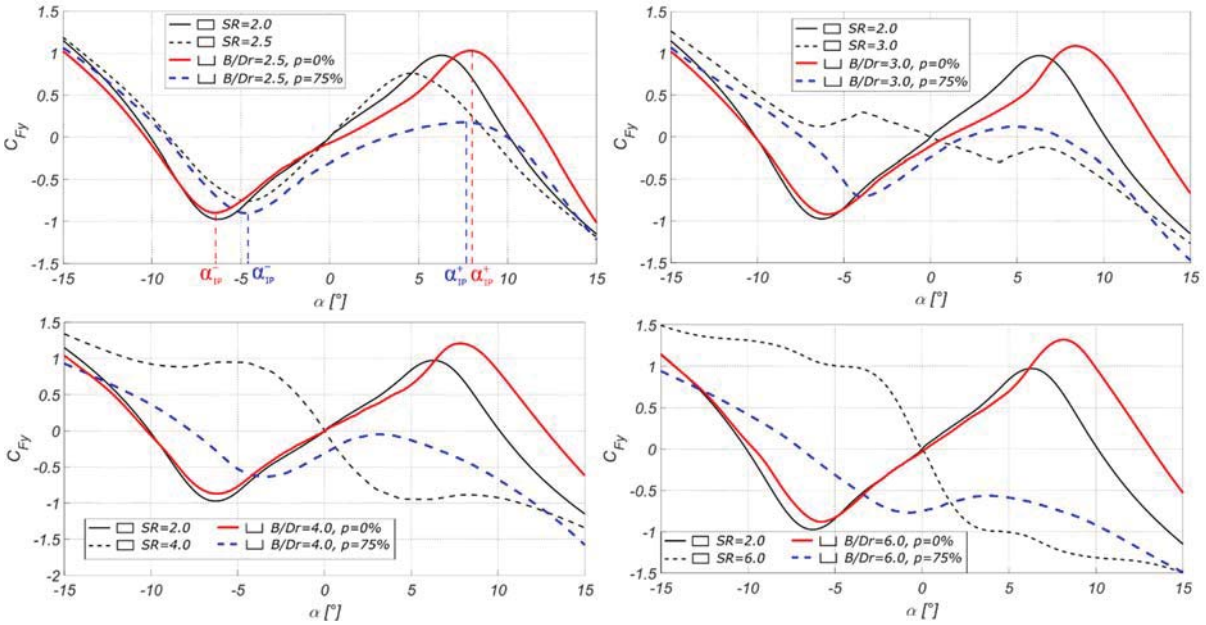

Figure 4: The transverse force coefficient of the tested cylinders with rectangular and U-shaped cross-sections

4.2 Beams with U-shaped cross-sections having non-porous vertical sides

All U-shaped prisms with zero porosity of the front and rear vertical sides (barriers) were identified as unstable. Table 2 presents the relevant aerodynamic parameters for various ratio *B/Dr*, i.e., various inner depth of the U-profile for the vicinity of zero angle of attack. The drag coefficient C_D for all *B/Dr* is almost identical to C_D of the rectangular cross-section with *SR* = 2. The slope of C_L for all *B/Dr* is negative and decreasing with the increasing inner depth, *Db*. On the other hand, the stability parameter a_g is increasing with the increase in *B/Dr*. However, a_g is in all cases smaller than a_g of the reference rectangular prism with *SR* = 2.

Cross section	B/Dr [/]	Porosity [%]	C_D [/]	$dC_L/d\alpha$ [/]	a_g [/]	$\Delta\alpha$ [°]	$\langle\alpha_{IP}^-; \alpha_{IP}^+\rangle$ [°]
⌴	2.5	0	1.48	-7.02	5.54	14.4	⟨-6.3; 8.1⟩
⌴	3	0	1.45	-8.52	7.06	14.4	⟨-6.0; 8.4⟩
⌴	4	0	1.46	-8.99	7.53	14.1	⟨-6.2; 7.9⟩
⌴	6	0	1.45	-9.59	8.14	14.0	⟨-5.7; 8.3⟩

Table 2: The aerodynamic parameters related to U-beams with zero porosity of the vertical sides

The global character of coefficients C_D, C_L and C_{FY} related to U-beams with zero porosity is illustrated in Figures 3 and 4, where they are reported against the angle of attack, α.

For negative angles up to approx. α = -8°, the minima and courses of C_D for all *B/Dr* are very similar to the minimum and the course corresponding to the reference rectangle. The same conclusion can be stated for the lift coefficient, where the coincidence is almost in the whole investigated interval of negative angles. Only the maxima of C_L are a bit lower than maximum of the reference prism.

On the contrary, the differences for positive angles exist for both C_D and C_L. In particular, the minima of C_D and C_L for all *B/Dr* lie at higher angles around α = 8.2°, which is about 2° greater value than for the rectangular prism with SR = 2. The value of the minimum of C_D is increasing with an increase in depth, D_b. On the other hand, with increasing D_b the value of the

minimum of C_L is decreasing and the slope of C_L is approaching to the slope of the reference case.

The character of the course, slope and magnitudes and positions of minima of transversal force coefficient, C_{FY}, is very similar to identical parameters of C_L. This fact holds for all tested ratios *B/Dr* and in the whole interval of investigated angles of attack. Special attention should be paid to the extension of interval Δα of the positive slope of C_{FY}, which is almost independent on depth D_b, see and compare values of $\Delta\alpha$ in Tables 1 and 2.

4.3 Beams with U-shaped cross-sections having highly porous vertical sides

The tests of U-beams with 75% porosity of vertical barriers revealed their different susceptibility to galloping. For ratios *B/Dr* = 2.5, 3 and 4 the values of stability parameter a_g indicate a comparable susceptibility, which is also very similar to non-porous U-beams, see Tables 2 and 3. Nevertheless, the angular ranges $\Delta\alpha$ of the positive slope of C_{FY} are in comparison with the non-porous prisms significantly narrowed. This reduction of $\Delta\alpha$ is increasing with the increase in the inner depth of the U-profile, i.e., in the increase in *B/Dr*.

For the highest ratio *B/Dr* = 6, not only expected decrease in C_D similar to the rest *B/Dr* due to the effect of the higher porosity occurs, but also a substantial decrease in the a_g in comparison with the same non-porous profile was determined. The interval Δα is in this case narrowed down most of all *B/Dr*. The range Δα was shifted toward the positive angles of attack, and thus the slope of C_L was in this case evaluated from data corresponding to angles from -0.4° to 0.4°. Due to the above mentioned facts, this U-beam with the highest *B/Dr* is expected to behave only weakly unstable profile when considering galloping.

Cross section	B/Dr [/]	Porosity [%]	C_D [/]	$dC_L/d\alpha$ [/]	a_g [/]	Δα [°]	$\langle\alpha_{IP}^-; \alpha_{IP}^+\rangle$ [°]
⌊⌋	2.5	75	1.28	-7.93	6.65	12.2	⟨-4.5; 7.7⟩
⌊⌋	3	75	1.10	-8.70	7.60	8.8	⟨-4.0; 4.8⟩
⌊⌋	4	75	1.00	-8.64	7.64	6.6	⟨-3.5; 3.1⟩
⌊⌋	6	75	1.00	-3.25	2.25	4.4	⟨-0.5; 3.9⟩

Table 3: The aerodynamic parameters related to U-beam with the porosity of the vertical sides p = 75%.

From Figure 3 it is evident, that curves of C_D of all prisms with vertical barriers of higher porosity have in the investigated interval of angles of attack only one minimum close to α = - 5°. The results also indicated, that at around α = 8°, there exists the angle for which the equality of C_D of both porosities related to the same ratio *B/Dr* is reached. The negative slopes of C_L around zero angle are almost identical with the corresponding slopes of C_L for zero porosity. The only exception represents the highest ratio *B/Dr*, for which the slope is significantly smaller. The angular range of negative slope of C_L is significantly reduced similarly to C_{FY} and is narrowing with the increasing *B/Dr*.

5 CONCLUSIONS

The paper presents an analysis of a proneness of a set of U-beams with constant side ratio equal to 2 to the transverse galloping. The assessment of the susceptibility of these beams that differ in the inner depth and porosity of their vertical sides was based on the quasi-steady theory and experimentally obtained drag and lift coefficients. These aerodynamic coefficients were determined for a wide range of angles of wind attack by static wind tunnel testing.

The results of analysis indicate, that the depth of the non-porous U profile has only a minor effect on the increase in the observed susceptibility to galloping. The slopes of the transversal

force coefficient related to all depths and zero angle of attack do not differ substantially. All these slopes are smaller but very close to the slope of the rectangular cross-section with identical side ratio. On the other hand, the ranges of angles of attack for which the slope of this coefficient is positive were found wider than range of the rectangular case for all depths.

The influence of the high porosity of the vertical sides of U-profile onto the aerodynamic coefficients and overall proneness to galloping was also investigated in detail. The tests for the porosity of about 75 % revealed, that in this case the depth plays an important role affecting the magnitude and the range of positive values of transversal force coefficient. In our case, especially the significant reduction of this angular range with increasing depth was observed.

Keywords: Aeroelasticity, gust load alleviation, folding wingtip, passive control

Abstract. *In recent years, the development of lighter and more efficient transport aircraft has led to an increased focus on gust load alleviation. A recent strategy is based on the use of folding wingtip devices that increase the aspect ratio and therefore improves the aircraft performance. Moreover, numerical studies have suggested such a folding wingtip solution may incorporate spring devices in order to provide additional gust load alleviation ability in flight. It has been shown that wingtip mass, stiffness connection and hinge orientation are key parameters to avoid flutter and achieve load alleviation during gusts.*

In this paper, after defining a simplified aeroelastic model representative of an symmetric aircraft, considers the case of adding movable wingtips. The effects of hinge position, orientation and spring stiffness will be considered in order to evaluate the potential of this technique for gust load alleviation. Moreover, is studied the longitudinal flight dynamics of a rigid aircraft with elastic wing and folding wingtips.

1 Introduction

Atmospheric gusts and turbulence can significantly affect aircraft ride quality and increase airframe loads. The turbulence is caused by the movement of the air through which the aircraft passes. The gust velocity is the velocity of the air perpendicular to the flight path. The calculation of the responses to gusts and turbulence is important in the design and development of aircraft because they determine the most extreme levels of stress [1]. For this purpose, loads corresponding to gusts and manoeuvres are applied to detailed linear aeroelastic models to determine the worst-case values for various quantities of interest (e.g., bending moments, shear forces, torques, and load factors) [1] [2][3].

In aircraft design a fundamental aspect is the performance optimization, and nowadays many efforts have been made to find techniques that reduce aerodynamic drag. A considerable contribution, usually 30%-40% of the overall drag, is lift induced drag, which could be reduced by increasing the wingspan. However, such a design solution has some limitations related to the increase in bending moments along the wing and also to the maximum aircraft dimensions allowed at airports. A possible solution to the second problem is to use a folding wing that can be employed on the ground. An example of this technique is the latest version of the B-777, which has a folding wing capability. Recent work has shown the possibility to use a flexible wingtip device for load alleviation. This technique is based on a hinge that allows the wingtip to rotate. A key parameter to enable successful load alleviation is the presence of a relative angle between the hinge line and the airflow [4] [5][6].

In this work two aeroelastic models of a simplified symmetric aircraft have been developed. In the first model a classical straight wing is considered, while the second model is straight wing with a folding wingtip. Dimensions and total mass between the two models is maintained constant. The main goal of this work is to analyse the effect of folding wingtip's parameters on the longitudinal flight dynamics and gust load alleviation of the aircraft [7].

2 Aeroelastic model

In this section the aeroelastic model of the aircraft with a straight wing will be presented (model one) and subsequently the wingtip will be introduced (model two). In the two aeroelastic models the following degrees of freedoms are considered: heave (z_c) and pitch (α) of the aircraft centre of gravity and the torsional (q_t) and the bending (q_b) modes of the wing [3]. The wingtip's span is assumed to be 20% of the half span and there is a relative angle (γ) between the hinge axis and the free stream velocity. The two aeroelastic models of the symmetric aircraft have been obtained through the Lagrange formulation and considering strip theory as the aerodynamic model. Figure 1 shows model one and Figure 2 shows model two.

2.1 Structural and aerodynamic model of model one

The simplified flexible aircraft consists of a uniform, untapered, unswept flexible wing of chord c and semi-span s, plus a rigid fuselage and tailplane, as shown in Figure 1. The wing is assumed to have a uniform mass distribution and the wing mass axis (WM) lies at distance l_{WM} ahead of the aircraft centre of mass. The wing elastic axis (WE) is assumed to lie at distance l_E ahead of the wing mass axis (WM). The wing aerodynamic axis (WA) is at the wing quarter chord and is at distance l_W ahead of the center of mass and at distance l_A ahead of the elastic axis. In order to minimize any coupling between the rigid body modes and the flexible mode equations, the mean axis reference frame has been used [3].

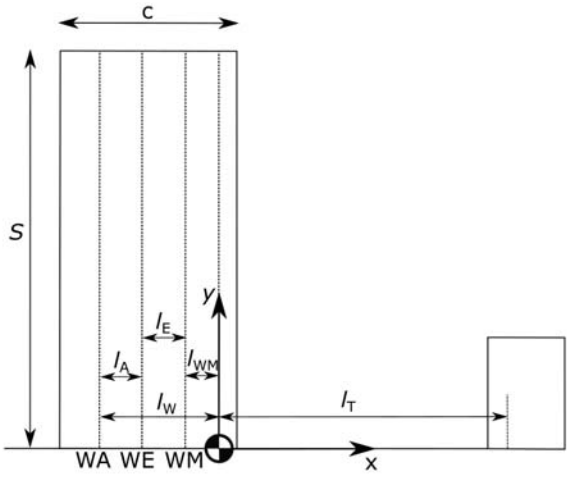

Figure 1: *Model one*

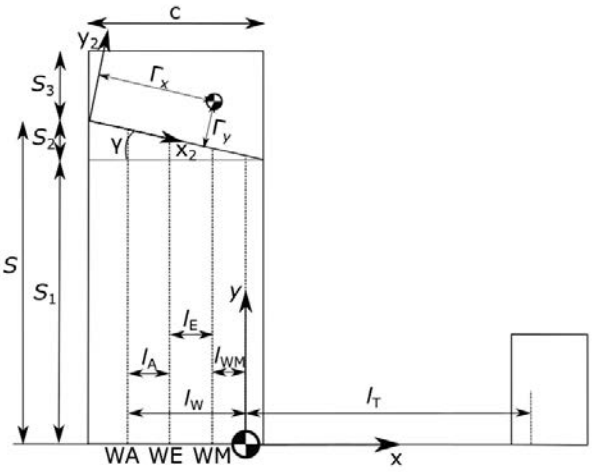

Figure 2: *Model two*

The displacement $z_{WA}(y,t)$ (downwards positive) of the wing aerodynamic axis is

$$z_{WA}(y,t) = z_c(t) - l_W\alpha(t) + k_{e_0}\left(1 + A\left(\frac{y}{s}\right)^2\right)q_b(t) - l_A\gamma_{e_0}\left(1 + B\left(\frac{y}{s}\right)\right)q_t(t) \tag{1}$$

where A and B are unknown constants defining the amount of bending and twist present along the wing span and k_{e_0} and γ_{e_0} are constants defining the wing root displacement and twist deformation. The displacement $z_T(t)$ (downwards positive) of the tailplane aerodynamic center is

$$z_T(t) = z_c(t) + l_T\alpha(t) \tag{2}$$

The aerodynamic terms due to the wing and the tailplane have to be determined. To this aim the tailplane is considered has as a rigid part, while the wing contribution involves integration using a strip dy because of the flexibility. The lift of a strip dy at the position y along the wing span is

$$dL = \frac{1}{2}\rho V^2 c dy a_w\left[\alpha - \alpha_0 + \gamma_{e_0}\left(1 + B\left(\frac{y}{s}\right)\right)q_t + k_{e_0}\left(1 + A\left(\frac{y}{s}\right)^2\right)\frac{\dot{q}_b}{V} + \frac{\dot{z}_c}{V}\right] \tag{3}$$

where a_W is the sectional wing lift curve slope. There is also a zero lift pitching moment for the wing

$$M_{0W} = \frac{1}{2}\rho V^2 S_W c C_{M_{0W}} \tag{4}$$

The tailplane lift considering the contribution of the downwash k_ϵ, the effective incidence due to the nose up pitch rate and the increment of lift due to a rigid vertical displacement, is

$$L_T = \frac{1}{2}\rho V^2 S_T\left\{a_T\left[k_\epsilon\alpha_0 + (1-k_\epsilon)\alpha + \frac{\dot{\alpha}l_T}{V} + \frac{\dot{z}_c}{V}\right] + a_E\eta\right\} \tag{5}$$

where η is the elevator angle and has been included to provide trim.

The effect of the vertical gust on the aerodynamics is a change of angle of attack. Thus on the elastic wing the increment of lift on a strip dy is given by

$$dL_{W_g} = \frac{1}{2}\rho V^2 c dy a_w\frac{w_g(t)}{V} \tag{6}$$

while on the tailplane the gust will act with a delay given by the ratio between the distance between the wing aerodynamic centre and the tailplane aerodynamic centre and the free stream velocity. Hence

$$L_{T_g} = \frac{1}{2}\rho V^2 S_T a_T \frac{w_g(t - \frac{l_W + l_T}{V})}{V} \tag{7}$$

The kinetic energy due to the rigid motion and the dynamic motion is

$$T = \frac{1}{2}m\dot{z}_c + \frac{1}{2}I_y\dot{\alpha} + \frac{1}{2}m_b\dot{q}_b + \frac{1}{2}m_t\dot{q}_t \tag{8}$$

The elastic potential energy corresponds to the strain energy in bending and torsion, such that

$$U = \frac{1}{2}k_b q_b^2 + \frac{1}{2}k_t q_t^2 \tag{9}$$

Finally, the virtual work done by lift forces and moment and gravitational field force

$$\delta W_A = \int_0^s -dL\delta z_{AC} - L_T\delta z_T + \int_0^s -dL_{W_g}\delta z_{AC} - L_{T_g}\delta z_T + M_{0W}\delta\alpha + mg\delta z_c \tag{10}$$

Exploiting the Lagrange formulation the full aeroelastic equation in the classical second order form is obtained as

$$\mathbf{A}\begin{Bmatrix}\ddot{q}_b\\ \ddot{q}_t\\ \ddot{\alpha}\\ \ddot{z}_c\end{Bmatrix} + \Big(\rho V\mathbf{B} + \mathbf{D}\Big)\begin{Bmatrix}\dot{q}_b\\ \dot{q}_t\\ \dot{\alpha}\\ \dot{z}_c\end{Bmatrix} + \Big(\rho V^2\mathbf{C} + \mathbf{E}\Big)\begin{Bmatrix}q_b\\ q_t\\ \alpha\\ z_c\end{Bmatrix} = \mathbf{f}_\eta\eta + \mathbf{f}_0 + \mathbf{f}_g + \mathbf{f}_{W_g}w_g(t) + \mathbf{f}_{T_g}w_g(t - \frac{l_W + l_T}{V}) \tag{11}$$

where **A**, **D** and **E** are the structural inertia, damping and stiffness matrices, **B** and **C** are the aerodynamic damping and stiffness matrices, **q** are the generalised coordinates and the force vector **f** on the right hand side of the equation has contributions due to the elevator, zero incidence, gravitational field, gust on the wing and gust on the tailplane.

2.2 Structural and aerodynamic model of model two

As mentioned above the difference between the two models is the presence of the movable wingtip. The model of the aircraft with the folding wingtip can be obtained from the equations of model one considering the additional contributions coming from the wingtip and taking into account that the elastic wing is composed of two contributions from wingspan s_1 and wingspan s_2, as shown in Figure 2. It is important to note that in the region of s_2 the chord is not constant, but it is function of the flare angle γ and of the span position y. The geometric relation is

$$c(y) = \frac{s_1 + s_2 - y}{\tan(\gamma)} \tag{12}$$

The wingtip is considered as a rigid body with a centre of mass at $\mathbf{\Gamma} = (\Gamma_x, \Gamma_y)$ defined in a reference system with the origin at the leading edge of the elastic wing tip and with the x-axis parallel to the hinge axis, as shown in Figure 2. θ is the degree of freedom related to the wingtip rotation and it is defined such that a positive angle variation produces a downwards displacement.

Assuming the aerodynamic centre of the wingtip is at the quarter chord and halfway along the wingspan its vertical displacement is

$$z_{AC_{wt}} = k_{e_0}\Big(1+A\Big)q_b - l_A\gamma_{e_0}\Big(1+B\Big)q_t - l_w\alpha + z_c + \frac{s_3}{2}\theta \tag{13}$$

The wingtip centre of mass is at position $\mathbf{\Gamma} = (\Gamma_x, \Gamma_y)$, and so its vertical displacement is

$$z_\Gamma = k_{e_0}\Big(1+A\Big)q_b - \Big(x_f - \frac{\Gamma_x}{\cos(\gamma)}\Big)\gamma_{e_0}\Big(1+B\Big)q_t - \Big(l_W + \frac{c}{4} - \frac{\Gamma_x}{\cos(\gamma)}\Big)\alpha + z_c + \Gamma_y\theta \tag{14}$$

where x_f is the longitudinal position of the elastic axis measured from the wing leading edge. The wingtip lift is given by

$$L_{wt} = \frac{1}{2}\rho V^2 S_{WT} a_w \left[k_{e_0}\Big(1+A\Big)\frac{\dot{q}_b}{V} + \gamma_{e_0}\Big(1+B\Big)q_t + \alpha - \alpha_0 + \frac{\dot{z}}{V} + \theta\cos(\gamma) + \frac{S_{wt}}{2}\frac{\dot{\theta}}{V} + \frac{w_g(t)}{V}\right] \tag{15}$$

The kinetic energy due to the rigid and dynamic motion is

$$T_{wt} = \frac{1}{2}m_{wt}|\dot{z}_\Gamma|^2 \tag{16}$$

and the potential energy corresponding to the strain energy of the spring at the hinge between the elastic wing and the wingtip is

$$U_{wt} = \frac{1}{2}k_{wt}\theta^2 \tag{17}$$

The total work done by the external force of the wingtip is

$$\delta W_{wt} = -dL\delta z_{ac}(y) + m_{wt}g\delta z_\Gamma \tag{18}$$

The Lagrange formulation is used to obtain the aeroelastic equation of motion as

$$\mathbf{A}\begin{Bmatrix}\ddot{q}_b\\ \ddot{q}_t\\ \ddot{\alpha}\\ \ddot{z}_c\\ \ddot{\theta}\end{Bmatrix} + \Big(\rho V\mathbf{B} + \mathbf{D}\Big)\begin{Bmatrix}\dot{q}_b\\ \dot{q}_t\\ \dot{\alpha}\\ \dot{z}_c\\ \dot{\theta}\end{Bmatrix} + \Big(\rho V^2\mathbf{C} + \mathbf{E}\Big)\begin{Bmatrix}q_b\\ q_t\\ \alpha\\ z_c\\ \theta\end{Bmatrix} = \mathbf{f}_\eta\eta + \mathbf{f}_0\alpha_0 + \mathbf{f}_g + \mathbf{f}_{W_g}w_g(t) + \mathbf{f}_{T_g}w_g(t - \frac{l_W + l_T}{V}) \tag{19}$$

In contrast to the previous case, Eq.11, an extra degree of freedom related to the wingtip rotation has been introduced.

2.3 Excitation gust

A '1 - cosine' gust disturbance is introduced at different frequencies and a constant amplitude of 5 m/s. A gust length (l_g) is considered in the range of 20-200 m in order to have a wide spectrum of excitation. The results will show that a short gust length will excite mostly the elastic modes while a long gust length will excite the rigid body modes.

3 Results

In order to analyse the models a numerical example found in literature for the gust analysis of a flexible aircraft is considered [3]. The airplane and wingtip main parameters are reported in Tables 1 and 2. All the analysis considers an equivalent airspeed of 150 m/s. The coefficients A, B, γ_{e0}, k_{e0}, the bending and the torsion modal masses have been obtained through a minimization process exploiting the orthogonality condition between the elastic modes and the rigid modes. The bending and torsional modal stiffnesses are determined to obtain the respective modal frequencies [3]. Due to the linearity of the model the analysis have been done without considering the static contribution due the initial trim in order to analyse only the dynamic response to the gust.

γ	20 deg
Γ_x	$\cos(\gamma)(c/4 + l_A + l_E)$
Γ_y	$\cos(\gamma)s_3/2$

Table 2: *Wingtip parameters*

3.1 Validation

The model validation compares the results of the model outline in this paper with the one obtained using a reference model with three degrees of freedoms, the vertical displacement and the pitch angle of the aircraft centre of gravity and the torsional mode of the wing [3]. In order to have a proper comparison, the natural frequencies of the elastic modes not considered in the reference model have been set to a high value and the torsional frequency is the same as the reference model.

The gust response in terms of vertical displacement of the trailing edge of the tip of the wing (z_{TE}), angle of incidence (α) and vertical displacement of the center of gravity (z_c) are simulated for gusts of different lengths. Figures 3 and 4 compare the results of, respectively, model one (coloured lines) and the reference model (black dash lines) and model two (coloured lines) and the reference model (black dash lines). In both models the torsional mode frequency is set at 8.5 Hz, the bending mode at 56 Hz and the flapping mode at 61 Hz in model two. The results show that the models give similar results.

3.2 Model two gust response

This section presents the dynamic response of model two for different gust lengths and for various wingtip parameters. The modal stiffness has been set in order to obtain the frequency of the bending mode at 5 Hz and the frequency of the torsional mode at 8.5 Hz when an high value of the wingtip stiffness connection is considered.

Figures 5, 6, 7 and 8 show the gust response in the case of low and high value of the stiffness connections between the wing and the wingtip. These two extreme cases represent the cases when the wingtip is free to rotate at the hinge ($k_\theta = 0$ Nm/rad) and wingtip is rigidly attached to the wing ($k_\theta = 10^8$ Nm/rad). When the wingtip is free to rotate at the hinge, the heave mode is less exited and the pitch mode is more exited with respect to the case when the wingtip

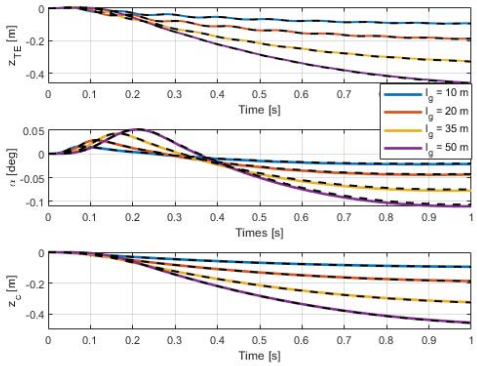

Figure 3: *Comparison between model one (continuous line) and the reference model (dash lines)*

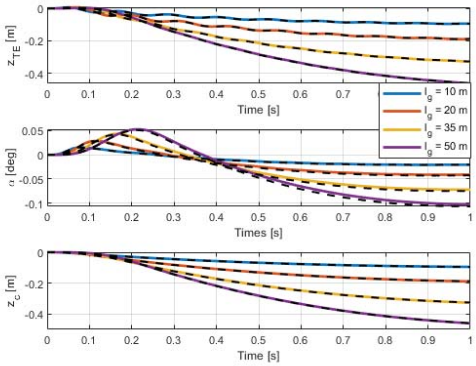

Figure 4: *Comparison between model two (continuous line) and the reference model (dash lines)*

is rigidly attached to the wing. It is also possible to see that the zero value of the stiffness connection reduces the torsional and bending mode responses.

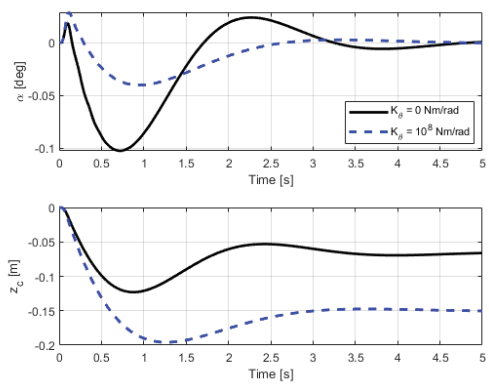

Figure 5: *Gust response of the fuselage degrees of freedom (gust length 20 m)*

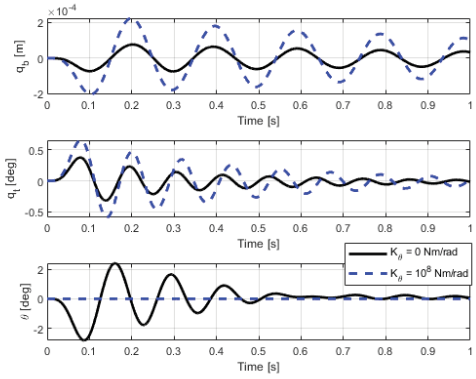

Figure 6: *Gust response of the elastic degrees of freedom (gust length 20 m)*

Figures 9, 10 and 11 show the maximum and minimum values of the wing bending and torsional modes for values of the gust length between 20 m to 200 m. Figure 9 considers different cases of wingtip stiffness connection, Figure 10 considers different cases of the flare angle (γ) and Figure 11 considers different positions, along the chordwise direction, of the wingtip centre of mass (Γ_x).

The hinge with zero torsional stiffness and the introduction of a larger flare angle are able to reduce the wing bending and the wing torsional mode response for all gust lengths. Furthermore for gusts at high frequency, if the centre of mass position is towards the trailing edge of the wingtip the torsional mode has larger positive and negative peaks, but for gusts at low frequency the torsional mode response has smaller peaks.

4 Conclusions

Two aeroelastic models representative of a symmetric aircraft have been developed, considering a straight wing and a straight wing with a folding wingtip. The validation, with respect to a similar model, has shown that the introduction of a wingtip rigidly connected to the wing gives, in terms of gust response, negligible difference with respect to the classical wing. The gust re-

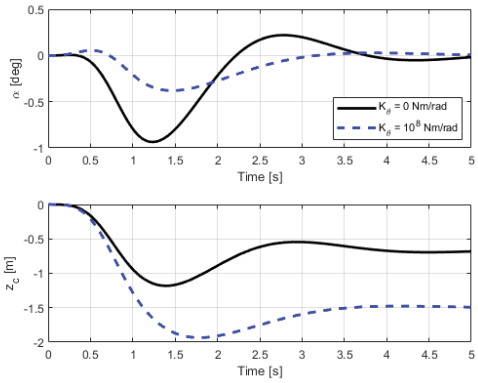

Figure 7: *Gust response of the fuselage degrees of freedom (gust length 200 m)*

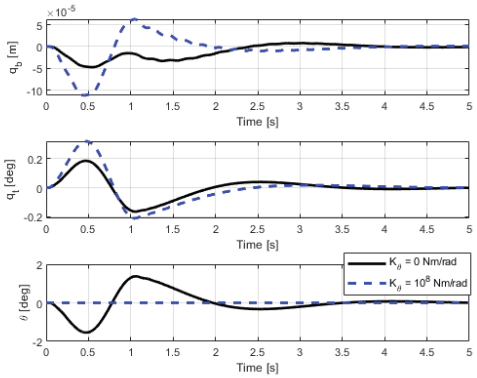

Figure 8: *Gust response of the elastic degrees of freedom (gust length 200 m)*

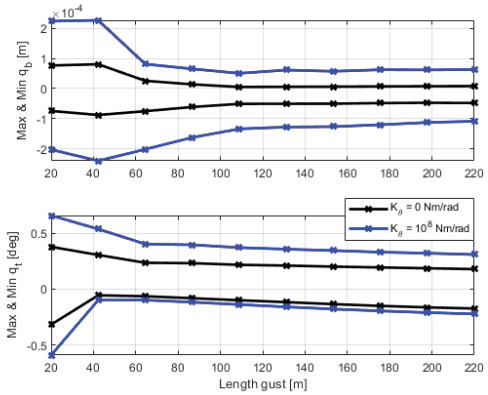

Figure 9: *Gust response for different gust lengths and values of stiffness connection*

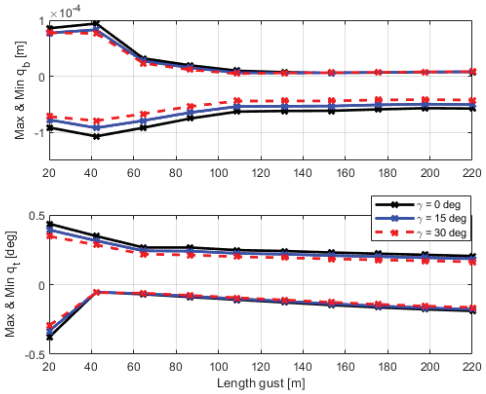

Figure 10: *Gust response for different gust lengths and flare angle ($k_\theta = 0$ Nm/rad)*

sponse analysis considering different stiffness connections of the folding wing have shown that if the wingtip is free to rotate at the hinge it is possible to reduce the bending and torsional deflection and consequently reduce the moment transmitted from the wing to the fuselage. Moreover in this configuration the aircraft will be subjected to a smaller vertical displacement during and after the gust. Finally the flare angle and wingtip centre of mass have shown to be sensitive parameters of the model.

The results have shown that, by a proper selection of the parameters, a folding wingtip could reduce the loads due to gusts with respect to a rigid wingtip. Further investigations are needed in order to better understand, in the case of large span aircraft, the effect of the geometrical nonlinearity related to the large deflections of the wingtip. Moreover experimental tests will be necessary in order to validate the models.

Acknowledgments

The research leading to these results has received funding from the Engineering Physical Science Research Council (EPSRC) through a programme grant EP/R006768/1.

Keywords: Arch dams stability, Interaction fluid-structure, Concrete Cracking, Alto Lindoso Dam.

Abstract. *The present work deals with the analysis of the structural behaviour of the Alto Lindoso arch dam under static and dynamic loads, considering fluid-structure interaction with the evaluation of service and ultimate capacity. The analysis of the maximum stresses in the super structure is obtained with undeformable foundation, since the development of the nonlinear model to evaluate these stresses, seems not to be influenced by the boundary conditions in the case of the ultimate load capacity.*

The fluid-structure interaction is formulated by the discretisation of the reservoir with infinite elements that gives a simple accommodation to complex geometries and reduced computing time in the case of concrete large dams.

The nonlinearity of the material becomes from the concrete cracking. Under tensile stresses the cracking behaviour is approximated by the smeared crack model within a small band. The width of the band may coincide with the dimension of the element. After cracking a softening behaviour control the release of the tensile stresses and the crack opening dependent on the fracture energy according to the softening behaviour. Since the dimension of the mesh affects the results of the structural analysis the independence of the mesh is obtained in this case considering linear elastic fracture mechanics.

The Alto Lindoso double curvature dam, constructed in 1992 and owned by EDP (Eletricidade de Portugal), is used as an example of the application of the model and compared to other results.

1 INTRODUCTION

A double-curvature arch dam is a very efficient structure with total volume of concrete significantly less than the conventional gravity dams. However, their geometrical complexity hinders the preliminary and final designs. Software to support the decision, to advance with a project in a specific place, giving a preliminary geometrical design with stochastic calculation performance has developed by D. J. Vicente et al [1]. The accuracy and quickness of the analysis are relevant either in the preliminary design as in final verification of the stress and strain states under static or dynamic loads. As pointed out by Chopra [2], to analyse the stress/strain state of an arch dam the structure must be correctly described, with the surrounding foundation, the concrete nonlinearities, the interaction structure-rock foundation-compressible fluid and selecting a low time step for the integration of the dynamic response. To analyse the Morrow Point Dam, Chopra [2] used 20,000 brick elements to model the body dam, 100,000 to the rock foundation, 20,000 to the fluid, and an integration time step of the order of 10−6 s for dynamic analysis. Considering the same factors, J. T. Wang [3] proceeded the analysis of Pacoima Dam, and Hariri [4, 5, 6] add the elastoplastic behaviour of the foundation, also with a large nonlinear finite-element system. These computer solutions are very time consuming, both in data preparation and computer implementation. Other authors [7-12] investigate the behaviour and stability of dams using large finite-element systems, including the relevant factors pointed out by the previous authors [2-6]. One of these factors is the concrete cracking.

The cracking of the concrete is very relevant in the design and analysis of dams in general and particularly in arch dams. The discrete crack models show advantages in the simulation of joint dams interface, as demonstrated by Zhou et al [13], with experiments in more than 20 models of high arch dams, namely under earthquakes where the joints affect the dynamic response. The models based in continuum are convenient because the dissemination and crack orientation are not known in advance. Considering the two models of this category, the damage and the smeared crack models, the smeared crack models do not involve re-meshing, the material degradation is modelled in average way and it is the option in this work by analysing the cracking formation and propagation under both static and dynamic loads. Espandar et al [7] uses a fixed smeared crack with non-orthogonal cracking in the analysis of arch dams, Mirzabozorg et al [9], Calayr et al [8] and Zhong at al [14] resort a rotating smeared crack model with, respectively a linear, exponential and bi-linear strain softening after crack starting. The stability of the smeared crack model was achieved by Li [10] increasing the mesh density and adjusting the elastic modulus according the Weibull distribution in cracking zones. The objectivity of the finite element mesh can be achieved localising the microcracking in the finite element within a small band [15, 16], keeping constant the density of fracture energy [4, 15-17].

As it was referred by Vicente [1], the procedure for the establishment of a dam includes the preliminary design, the structural performance for simplified load cases, followed by good fulfilment for the loading scenarios prescribed by regulations. A suitable solution usual requires the absence of tensile stress in the concrete. This requires to perform numerical computations from the begin to the final design procedure. Moreover, dams constructed before 1990s were designed with a pseudo-static analysis method and the actual seismic safety criteria [18] may not be satisfied. As pointed out by Wieland [19], it is needed a systematic earthquake analysis to evaluate the safety of the dams which have not been designed against earthquakes.

The authors of the present paper believe that a less time consuming model than the founded in the literature, either in data preparation and computer implementation, without loss of quality results, is relevant. This is the objective of the present work - to present a light finite element model that: discretises the structure in a few Ahmad [20] finite elements divided in

thickness layers [21]; discretises the reservoir in infinite elements to consider the fluid-structure interaction [22]; the nonlinearity of the concrete approximated by the smeared crack band model with constant energy density [15]; for dynamic analysis the displacements, velocities or accelerations are directly introduced at the borders and the Newmark-β method is used for direct integration of the equation of motion.

The model was applied to analyse the seismic behaviour of the Alto Lindoso arch dam. The results are compared with other authors. This application shows the good performance of the model.

2 CONSTITUTIVE MODEL FOR CONCRETE DAM

2.1 Title Compressed concrete

The finite element software is fit to approximate the behaviour of concrete through the elastoplastic law with the Ottosen [25] yield function and Von Mises plastic potential. However, in the study of the behaviour of arch dams the values of the compressed stresses are very low and the effect of the plasticity can be neglected.

2.2 Smeared crack band under tensile stresses

In concrete arch dams, the object of the present study, the relevant nonlinearity is due to the concrete cracking. The model used was developed and presented in [15] and it was formulated in terms of global stresses and strains. It is resumed here because it is the most relevant material nonlinearity in the dam analysis and it can highly influence the results.

The microcraking appears in a surface normal to the principal maximum tensile stress σ_t, when their value attains the concrete tensile strength f_{ct}, with the strain ε_{ct}. Being h_t the length of the element in t direction, the damage zone occurs in a length w, within the total length h_t of the element orthogonal to the crack.

In an element of volume V, there are an intact volume V_i and a damage V_d. At direction n, with no cracks, the compatibility condition imposes, $\varepsilon_n = \varepsilon_n^i = \varepsilon_n^d$, and the equilibrium gives the following integration:

$$\sigma_n = \frac{1}{V}\int_{V_i} \sigma_n^i \, dv + \frac{1}{V}\int_{V_d} \sigma_n^d \, dv \tag{1}$$

As the stresses are constant within the element at each Gauss point, the previous equation establishes the stress σ_n by

$$\sigma_n = v^i \, \sigma_n^i + v^d \, \sigma_n^d \tag{2}$$

with $v^i = V_i/V$ and $v^d = V_d/V = w/h_t$, meaning that $v^i + v^d = 1$. It can be asserted that an element has an intact volume v^i, with a strain ε_t^i given by Hook law, and a damage volume v^d, with a strain ε_t^d given by strain softening concrete behaviour.

In the t direction, normal to the crack, the axial equilibrium condition is $\sigma_t = \sigma_t^i = \sigma_t^d$ and the compatibility one is $\varepsilon_t = v^i \, \varepsilon_t^i + v^d \, \varepsilon_t^d$. For tangential stress and angular strain it is also considered $\tau_{nt} = \tau_{nt}^i = \tau_{nt}^d$ for equilibrium equation and $\gamma_t = v^i \, \gamma_{nt}^i + v^d \gamma_{nt}^d$ for deformation compatibility condition.

When the value of ε_t exceed the strain ε_{ct} ($\varepsilon_t \geq \varepsilon_{ct}$) the constitutive relation σ-ε, in terms of local coordinates n and t, can be described by:

$$\begin{Bmatrix} \varepsilon_n \\ \varepsilon_t \\ \gamma_{nt} \end{Bmatrix} = \begin{bmatrix} 1/E & 0 & 0 \\ 0 & 1/E_r & 0 \\ 0 & 0 & 1/G_r \end{bmatrix} \begin{Bmatrix} \sigma_n \\ \sigma_t \\ \tau_{nt} \end{Bmatrix} \tag{3}$$

In the previous expression, E is the Young modulus, E_r, the reduced Young modulus, and G_r the shear reduced modulus, are given by:

$$E_r = \left[\frac{1-v^d}{E} + v^d \frac{de(\sigma_t)}{d\sigma_t}\right]^{-1} ; \quad G_r = \frac{\beta G}{(1-v^d)\beta + v^d}, \tag{4}$$

where β is the decrease in tangential stiffness, varying linearly between 1, when the crack starts, to zero when the crack is opened without tensile stress.
The most common expressions for $e(\sigma_t)$ are linear, multilinear or exponential. In the present model for application to arch dams, the linear softening law is considered with the unidimensional constitutive law $\sigma - \varepsilon$, represented figure 1, and it is written by the following:

$$\sigma = \frac{f_{ct}}{\varepsilon_{ct} - \varepsilon_{tu}}(\varepsilon - \varepsilon_{tu}) \tag{5}$$

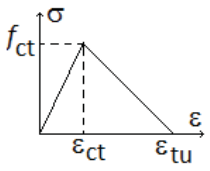

Figure 1: Stress-strain relation for concrete under tension.

The area defined by the diagram (see figure 1) is the energy deformation per unit volume G_f. According to the fracture mechanics concepts, the energy for crack propagation per unit of crack area, G_F, is a property of the concrete that can be defined using the damage length w by $G_F = w f_{ct} \varepsilon_{tu}/2$. The ultimate strain ε_{tu} can be computed and the descending branch of the stress written in function of the material parameter G_F:

$$\sigma = \frac{f_{ct} E}{w f_{ct}^{\ 2} - 2EG_F}(w f_{ct} \varepsilon - 2G_F), \tag{6}$$

that gives

$$\frac{d\sigma}{d\varepsilon} = \left[\frac{1}{E} - \frac{2G_F}{w f_{ct}^{\ 2}}\right]^{-1} \tag{7}$$

The reduced Young modulus, E_r, is obtained substituting $de(\sigma_t)/d\sigma_t$ by the inverse of the previous expression. The band width, w, is function of maximum dimension of the aggregates. In particular case it can be equal to the width of the element $w = h_t$, as suggested by Ozbalt and Bazant [23] the energy density is given by $G_f = G_F/w = G_F/h_t$ and E_r by:

$$E_r = \left[\frac{1}{E} - \frac{2G_f}{f_{ct}^{\ 2}}\right] \tag{8}$$

The material parameters, G_F and w, were evaluated experimentally by Wender et al [24] in order to be used in the numerical simulations.

The model can be extended to more than one crack, as in references [4-7,11, 16,17] but in the arch dam studied by the authors there was no case of two principal tensile stresses at the same Gauss point.

3 INTERACTION FOUNDATION-DAM-RESERVOIR

The foundation was modelled by Hariri [5] using infinite elements and he found that the results are more conservative in term of dam stresses when compared to a solution considering rigid foundation. Similar conclusion is given by Chopra [2] that to neglect the foundation mass, the stresses may be overestimated by a factor of 2 to 3. Since the objective is to develop a model less time consuming allowing a reliable behaviour of the dam under seismic loads, the rock mass foundation is neglected. It must be noted that considering the flexibility of the rock mass the period of vibration increases and influences the results.

Pressure-based infinite elements are used for simulating the reservoir domain with the same number of elements employed in dam discretization. The mid-points of the infinite elements are located at a distance from the dam equal to the height. According to Chopra [2], to neglect water compressibility may underestimated the stresses in some cases and overestimated in other cases. In the present model the water is considered incompressible by the infinite elements.

4 APPLICATION TO THE DAM-RESERVOIR SYSTEM OF ALTO LINDOSO

4.1 Geometrical characteristics of the dam

The model is applied to the Alto Lindoso dam and results are compared to other references. The dam is founded in a granite bedrock, located at the Lima river, with the following main characteristics: 309000 m^3 concrete volume; reservoir capacity of 347,8 hm^3; maximum height above foundation of 110 m; crest length of 298 m. Figure 2 represents the hydroelectric power plant [27] and figures 3 a), b), c) establish the geometrical characteristics [26] given by the planned projection of the dam, horizontal arch at depth z and the crown cantilever that has a five degree polynomial thickness variation with 4 m at the top and 21 m at the base. The arch guideline at depth z comply the equation

$$y = \frac{x^2}{2P_z} - a_z \tag{9}$$

where a_z and P_z are given by:

$a_z = 0.1867834\ z + 0.00223080\ z^2 - 0.00009865876\ z^3 + 0.000001102495\ z^4 - 0.000000004727742\ z^5$

$P_Z = 113 - 0.5703572\ z + 0.003874011\ z^2 - 0.0001736113\ z^3 + 0.000001624506\ z^4 - 0.000000004216277\ z^5$ (10)

The thickness at depth z and ordinate x is given by

$$e = e_f\left[1 + A\left(\frac{x}{100}\right)^2\right] \tag{11}$$

with e_f and A computed by:

$$e_f = 4 + 0.2081566\ z - 0.002679505\ z^2 + 0.00008034516\ z^3 - 0.0000009022521\ z^4 + \\ +0000000003209177\ z^5\ ;$$

$$A = 0.03573173\ z - 0.0008548716\ z^2 + 0.000008962299\ z^3 - 0.00000001278656\ z^4 + \\ 0.000000000005023905\ z^5\ . \tag{12}$$

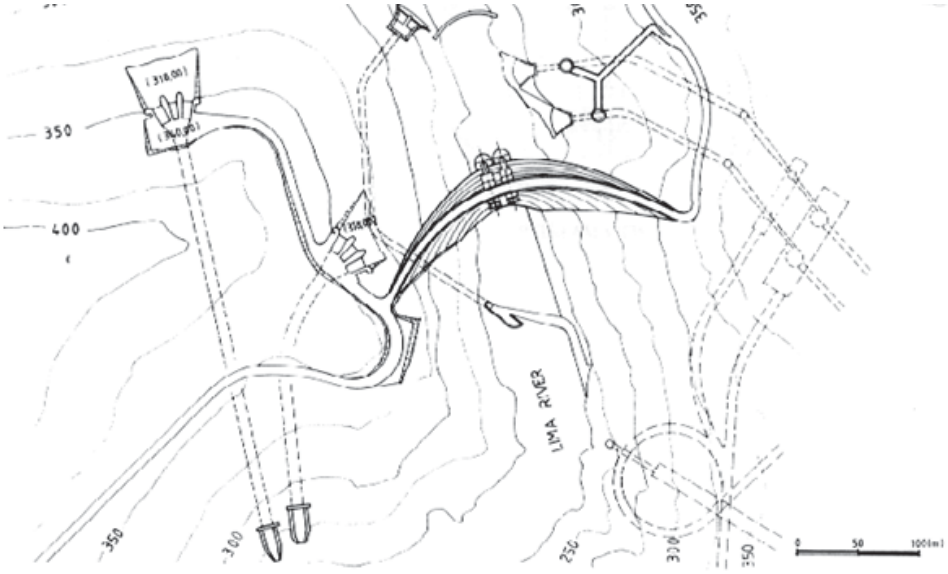

Figure 2: Hydroelectric power plant.

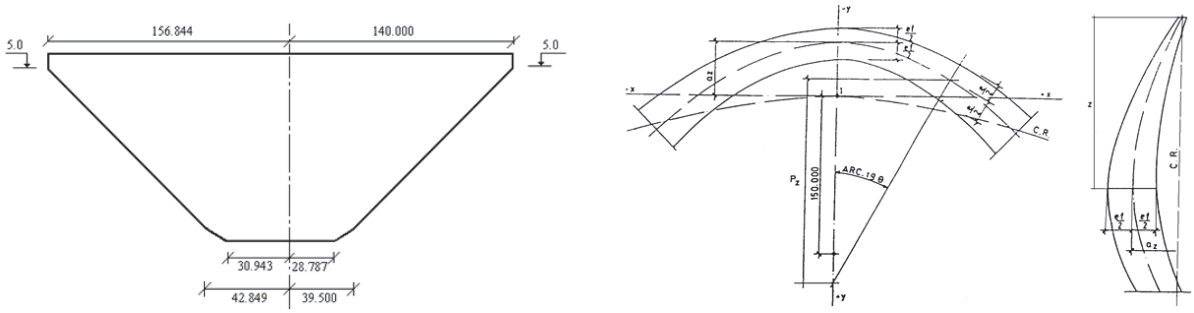

a) planned projection b) arch at depth z c) crown cantilever

Figure 3: Geometrical characteristics of Alto Lindoso arch dam.

4.2 Material parameters

The material parameters used in the analysis are summarized in table 1.

Modulus of elasticity, E	Coeficient of Poisson, ν	Conc. specific weight, γ_g	Water specific weight, γ_a	Conc. tensile strength, f_{ct}	Fracture energy $G_f=f^2_{ct}/2E$
20 GPa	0.22	24.5 kN/m^3	10 kN/m^3	1.8 / 3.65MPa	0/2/20 kN/m^2

Table 1: Material parameters.

The concrete tensile strength of f_{ct}=1.8MPa is the usual value in this kind of structure, but the value of f_{ct}=3.65MPa was also used. Values of twice or triple of the characteristic tensile strength of the concrete are usual to employ in dynamic analysis [26] and, in this case, both are used in order to compare its influence in the behaviour of the structure.

The zero value considered of the fracture energy density G_f corresponds to the σ-ε diagram without tensile retention. The other values are used to define the linear strain softening laws. The values of the fracture energy density G_f are function of the fracture energy G_F and the crack band width w. For dams usual values of G_F= 100 - 200 N/m and w=3 - 5 times the maximum aggregate dimension are generally accepted. To avoid limitations in the finite element mesh dimensions and to ensure objectivity of the analysis, an adjustment of the σ-ε diagram is made, as described above.

4.3 Analysis of the dam under static loads

In the analysis of the behaviour of the structure, in order to compute the stress distribution, the deformed shape and the maximum displacements under static and dynamic loads are relevant issue to test the model. The reliability of the model was proved using a set of analysis whose results were compared with those of the literature. Table 2 resumes the different analysis performed, all of them considering the dead load and the hydrostatic pressure in the upper stream. The foundation was considered with infinite stiffness.

		Linear elastic	Non linear – band crack model		
			G_f=0	G_f=2 kN/m^2	G_f=20 kN/m^2
Mesh A (see fig.3)	f_{ct} = 3.65MPa	ST1	-	ST2	-
	f_{ct} = 1.80MPa		-	ST3	-
Mesh B (see fig.3)	f_{ct} = 3.65MPa	ST4	ST7	ST5	ST9
	f_{ct} = 1.80MPa		ST8	ST6	ST10

Table 2: Static analysis.

The two finite element discretizations for the body dam, used in the analysis related in table 2 are represented in figure 4. The thickness of the Ahmad element is discretized in ten layers.

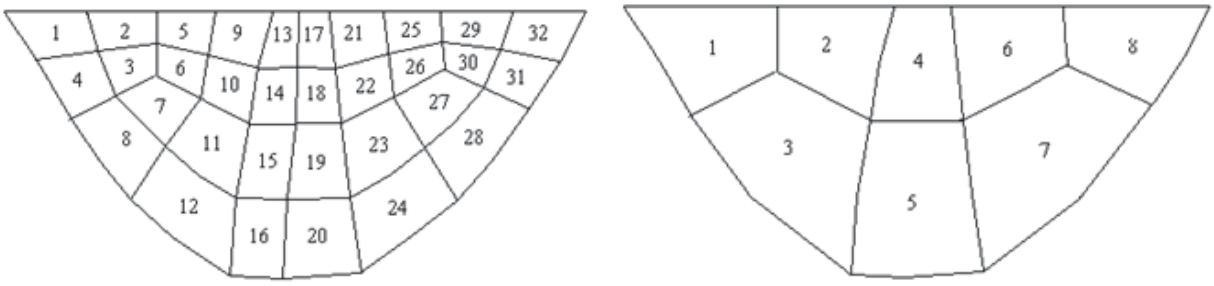

Figure 4. Discretization into 32 (mesh A) and 8 elements (mesh B) used in the analysis.

The dam reservoir was discretized in infinite elements with the intermediate nodes located at 110 m far from the medium surface of the dam, corresponding to a global of 336.9 MN of water. Figures 5 and 6 represent respectively the arch stress, σ_x, and vertical stress σ_y, along the upstream and downstream of the central cantilever, obtained with the analysis ST1e, ST2e and ST3e. The results of EDP and R. Delgado [26] are also plotted.

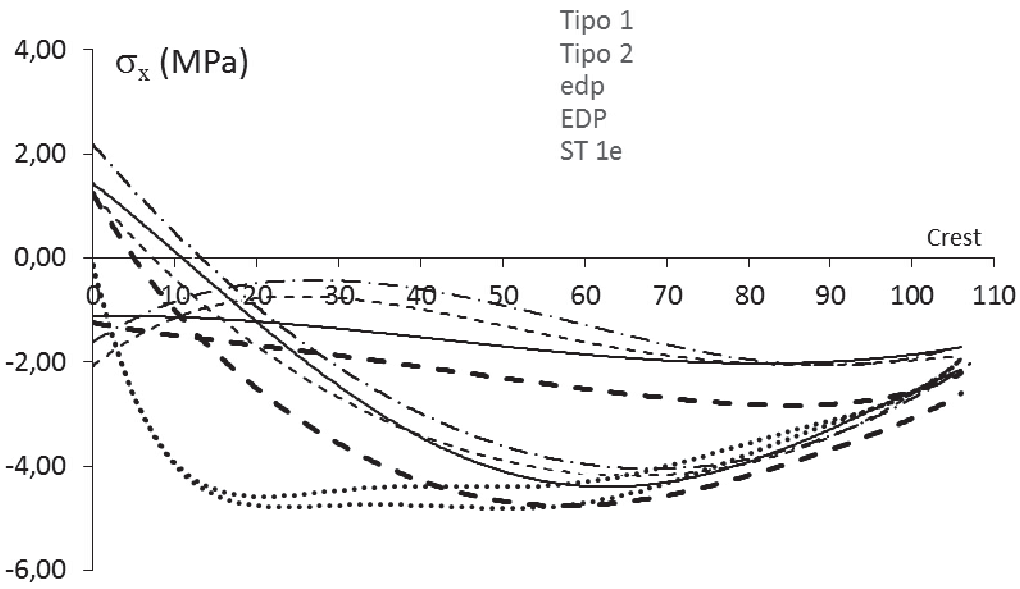

Figure 5. Arch stress σ_x, through the central cantilever.

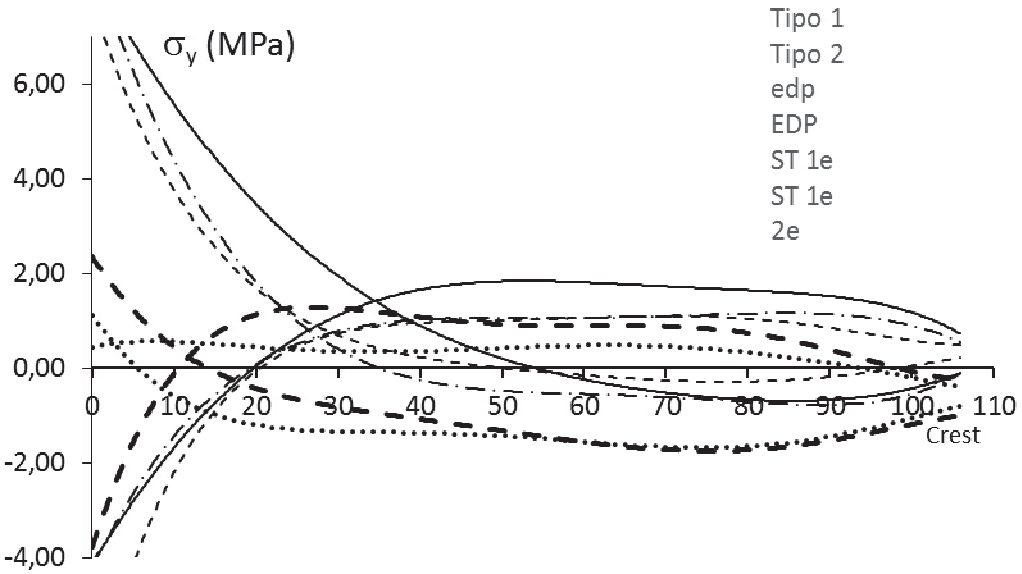

Figure 6. Arch stress σ_y, through the central cantilever.

The results of EDP were computed with a fine mesh of triangular elements and Vogt coefficients to simulate the flexibility of the foundation and R. Delgado uses 18 shell elements appealing to the symmetry of the structure [26]. Table 3 resumes maximum stresses and displacements and figure 7 shows the deformed shape of the crest.

Analysis	Maximum principal stresses (MPa)				Displacements of the midpoint of the crowning (cm)		
	Upstream		Downstream		δ_x	δ_z	δ_y
ST 1e	4.46	-6.15	1.50	-3.57	-0.39	0.98	2.71
ST 2e (f_{ct}=3.65MPa)	2.85	-4.90	1.93	-2.80	-0.40	1.06	3.02
ST 3e (f_{ct}=1.8MPa)	0.32	-2.06	0.30	-2.51	-1.04	2.11	3.29

Table 3. Maximum principal stresses and displacements.

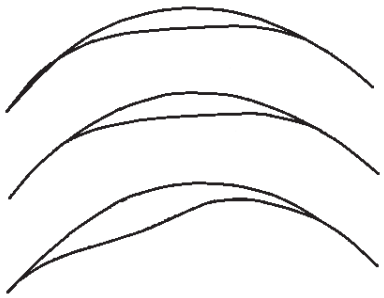

Figure 7. Deformation of the crest.

Figures 8 and 9 show the location of the cracks with the number of layers cracked at each location. In analysis ST 2e the cracks appear only at upstream (figure 8) and considering f_{ct}=1.8MPa both surfaces are cracked (see figure 9).

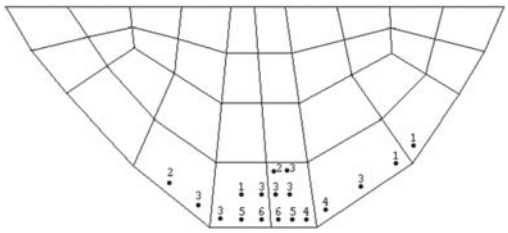

Figure 8. Crack´s location for ST 2e analysis at the upstream (f_{ct}=3.65MPa).

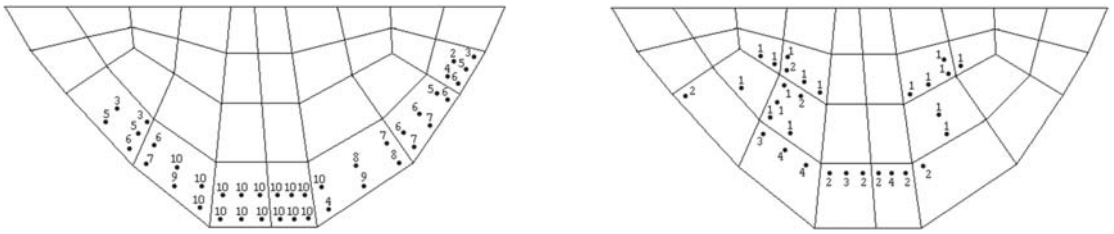


a) Upstream b) Downstream

Figure 9. Crack´s location for ST 3e analysis (f_{ct}=1.8 MPa).

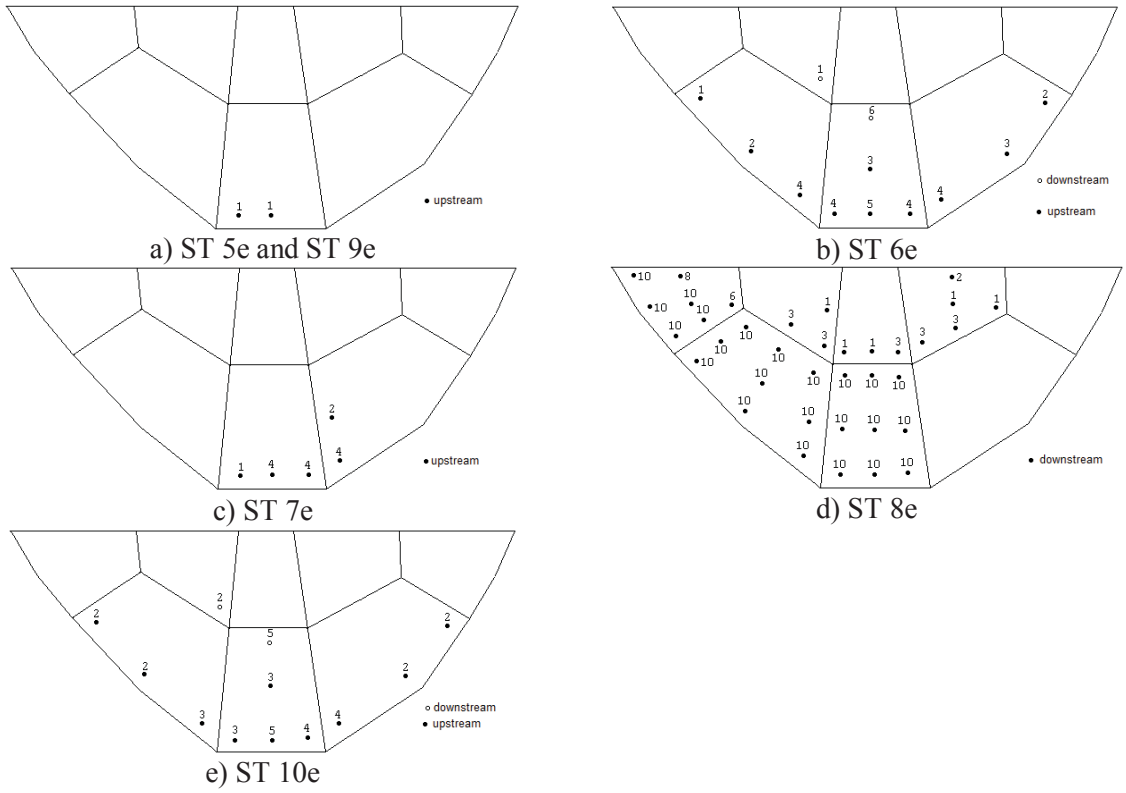
The three analysis performed show: the cracking induces a stress redistribution with relevance only for the tractions at the upstream surface near de foundation; the stress distribution, the values and directions of the principal stresses and the maximum displacements are not significantly changed when the concrete tensile strength is reduced to a half; the concrete tensile strength influences the shape of the deformation and it is not convenient to consider half of the structure even in this case of slight asymmetry of the valley.

The maximum compressive (-) and tensile (+) stresses and corresponding locations, with the number of the element in parentheses, as well the displacements of the midpoint of the crowning are resumed for the analysis ST 4e to 10e in table 4.

Analysis	Maximum principal stresses (MPa)				Displacements of the midpoint of the crowning (cm)		
	Upstream		Downstream		δ_x	δ_z	δ_y
ST 4e	4.03 (5)	-3.23 (6)	2.58 (5)	-2.62 (6)	-0.38	0.97	2.57
ST 5e	1.72 (6)	-1.45 (6)	1.78 (5)	-2.80 (6)	-0.38	0.97	2.64
ST 6e	1.76 (5)	-4.80 (3)	1.79 (5)	-3.60 (6)	-0.34	0.08	2.59
ST 7e	3.44 (4)	-6.03 (6)	3.64 (5)	-6.94 (3)	-0.65	1.10	2.85
ST 8e	1.08 (1)	-8.76 (6)	1.06 (2)	-8.56 (3)	-1.85	6.50	1.60
ST 9e	2.99 (5)	-4.66 (6)	2.03 (5)	-2.93 (4)	-0.38	0.96	2.62
ST 10e	1.76 (5)	-3.01 (4)	1.80 (5)	-3.90 (4)	-0.84	1.87	2.59

Table 4. Maximum principal stresses and displacements for ST 4e to 10e analysis.

Figure 10 shows the location of the cracks with the number of layers cracked at each location.



a) ST 5e and ST 9e

b) ST 6e

c) ST 7e

d) ST 8e

e) ST 10e

Figure 10. Crack´s location for ST 5e to 10e analysis.

It is clear the increment in the cracking in ST 6e, 8e and 10e relatively to ST 5e, 7e e 9e, because of the decrease of the tensile strength. The increasing in tensile retention related to the increase of G_f reduces the depth of the cracks (analysis 6e and 10e). The absence of tensile retention with, simultaneously, the tensile strength of f_{ct}=1.8MPa, induces a generalized cracking.

4.4 Analysis of the dam under constant acceleration, a=0.1g

Two groups of analysis are presented. The first group has the objective to compare the results of the present study with those of the existent literature and the second group analyses

the nonlinear behaviour of the dam under seismic loads.
Figure 11 compares the displacement increasing, relatively to the static analysis, of the crest midpoint obtained in linear analysis with mesh A and B and the results obtained by R. Delgado [26] that takes the fluid compressible and meshes of 10 and 18 finite elements for the half body dam. In these analysis the integration time is T/10, where T is the vibration period of 0.4s. The dynamic load is a constant acceleration of 0.1g applied from downstream to upstream and corresponds to the action of a moderate earthquake, traditionally considered in Portugal.

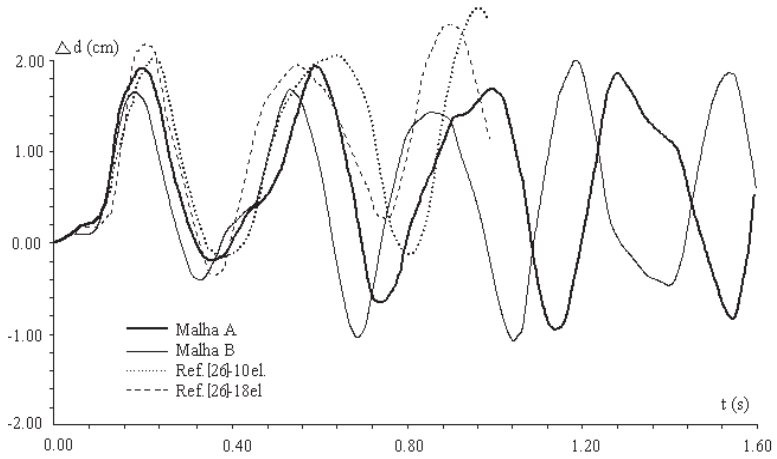


Figure 11. Horizontal displacement variation of the top of the central cantilever for a=0.1g.

The good approximation between all results in figure 11 reveals that: it is enough to consider the hydrodynamic pressures by the infinite element reservoir discretization instead of the use of 3D finite elements in a length equal to 3 times the dam height as in reference [26]; it is not relevant to consider the compressibility of the water as in reference [26]. The differences in the results can be attributed to the differences in the discretization.

The analysis were also performed for both meshes A and B considering the concrete cracking, with the tensile concrete strength of f_{ct}=3.65MPa and a density of energy G_f=2 kN/m^2. The maximum displacements of the midpoint of the crest obtained in both linear and nonlinear analysis are all in the downstream direction movements and they are resumed in table 5.

Total maximum displacements	Mesh A		Mesh B	
	t = 0.21 s		t = 0.19 s	
	Linear	Nonlinear	Linear	Nonlinear
δ_x (cm)	-0.38	-0.05	-0.50	-0.49
δ_y (cm)	4.61	5.03	4.28	4.55
δ_z (cm)	0.88	1.18	0.83	0.82

Table 5. Maximum displacements of the top of the central cantilever for a=0.1g.

At time t=0.21s, all cracks are concentrated upstream, near the support, as it can be seen in figure 12, where the number of layers cracked are indicated.

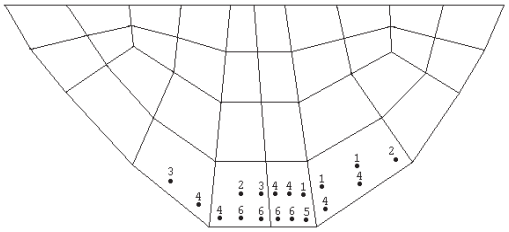

Figure 12. Crack´s location at t=0.21s for a=0.1g.

The stress variation over time can be analysed through the stress variation of two representative points located at the upstream surface of the central cantilever. One of them, placed on half height of the dam, representing the maximum compression σ_x in the arch direction. The other is the Gauss point nearest the support representing the maximum tensile stresses σ_y in the cantilever direction. In figures 13 and 14 are plotted the stresses over time, respectively, σ_x and σ_y, for the two representative points.

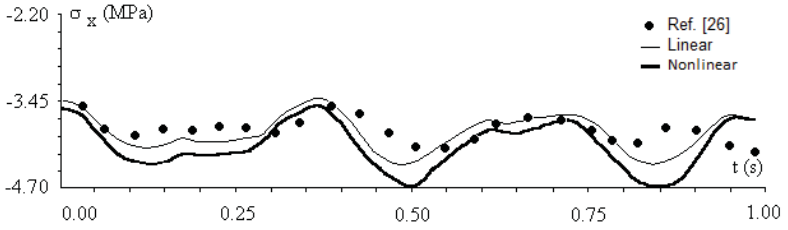

Figure 13. Stress σ_x over time at upstream half height point, for a=0.1g.

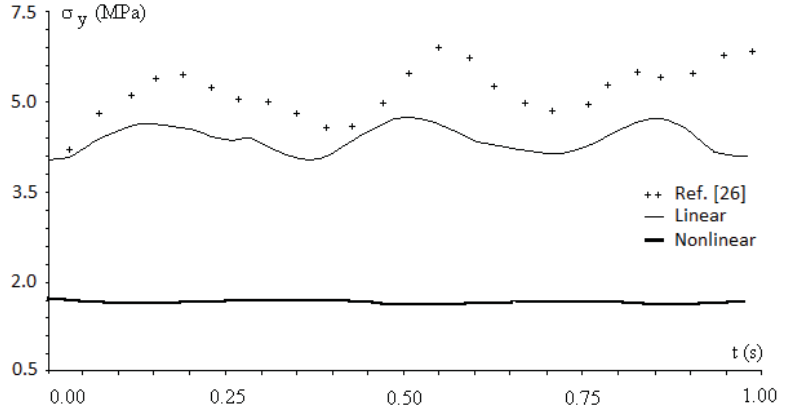

Figure 14. Stress σ_y over time at upstream near the support, for a=0.1g.

For this load case, the nonlinearity due to the cracking does not induce a relevant variation of the displacements because the cracked zone is limited to the vicinity of the support at the base (see figure 12) and simultaneously with the decrease of tensile stresses (see figure 14) the compressed stresses in the arches rise (see figure 13).

4.5 Analysis of the dam under an allowable earthquake

Due to the absence of real seismic registration close to the dam placement, an artificial ac-

celerogram generated from the ground acceleration response spectrum Se(w), as predicted in reference [28] is used. The response spectrum used is plotted in figure 15. It represents an earthquake acting during 10 s with high frequencies. This kind of earthquake is being used in the security check of arch dams and it is usually more conditioning, for typical frequencies of concrete arch dams, than other kind of long duration and low frequencies earthquake [29]. The accelerogram corresponding to the response spectrum is indicated in figure 16.

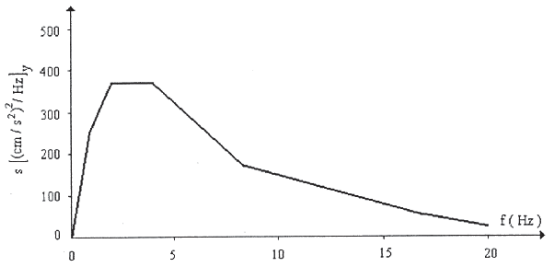

Figure 15. Response spectrum used in the generation of the accelerogram.

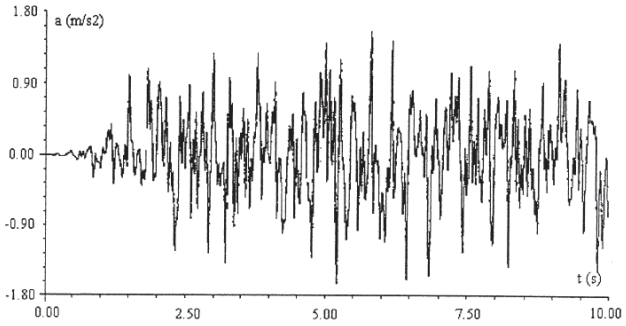

Figure 16. Accelerogram of the earthquake.

It was previously demonstrated, for dynamic load of a constant acceleration a=0.1g, that mesh B represents with good approximation the strain configuration, revealing interest for intensive simulations under seismic loads. The previous material characteristics are used in this application, with concrete strength of f_{ct}=3.65MPa and a density of energy G_f=2 kN/m^2 in nonlinear analysis with mesh B.

The displacements over the time of the midpoint of the crest are plotted in figure 17. The nonlinear analysis is represented in red and the linear in black. The upstream and downstream maximum displacements and occurring time are indicated in table 6. The figure 17 and table 6 indicate that as the effect cracking is to decrease the horizontal displacements, but it is observed an increase in the vertical displacement.

Total maximum displacements	Linear		Nonlinear	
	Upstream	Downstream	Upstream	Downstream
	t = 9.91 s	t = 7.79 s	t = 5.58 s	t = 8.20 s
δ_y (cm)	7.3	13.4	4.7	10.0

Table 6. Maximum displacements of the top of the central cantilever the earthquake.

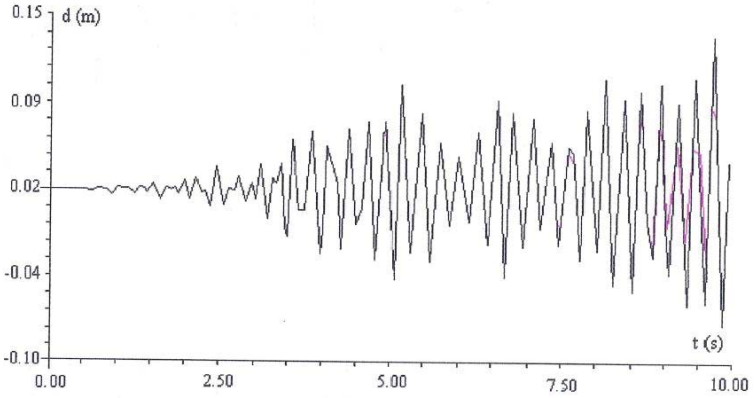

Figure 17. Horizontal displacement of the top of the central cantilever for the earthquake.

The stress variation over time can be analysed through the stress variation of two representative points located at the upstream surface of the central cantilever. One for the arch stresses, indicated in figure 18, and stresses in the cantilever direction in figure 19.

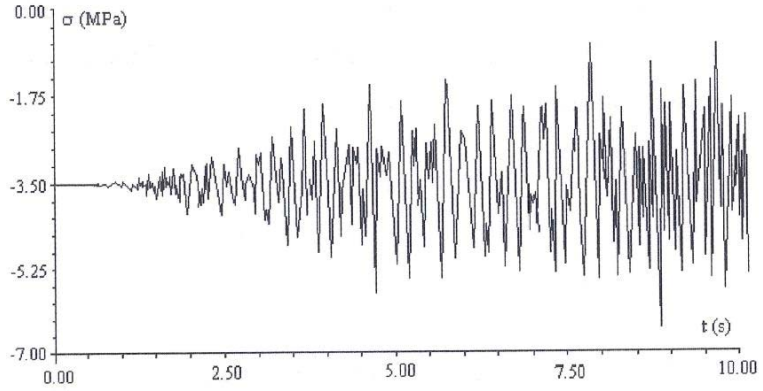

Figure 18. Arch stress, σ_x, variation over time at upstream half height point for the earthquake.

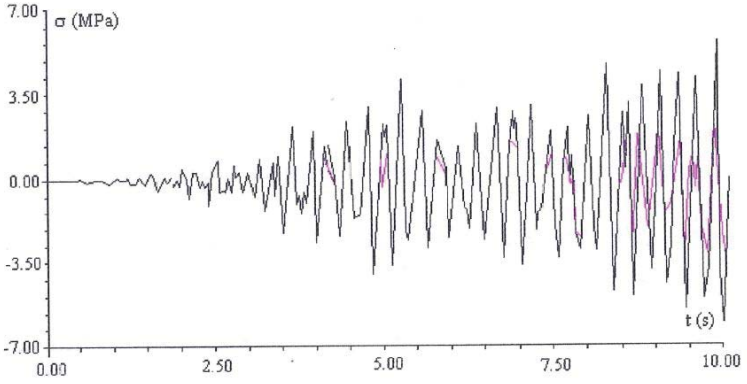

Figure 19. Stress variation, σ_y, over time at upstream near the support, for the earthquake.

The maximum stresses σ_y in the cantilever, at the upstream, vary from 6.44MPa to -4.92MPa, if cracking is disregarded, and from 2.60MPa to -3.67MPa if cracking is considered. The maximum arch stresses σ_x, downstream, vary from 5.80MPa to -0.90MPa, if cracking is disregarded, and from -6.50MPa to -0.92MPa if cracking is considered. Cracking results in a reduction of the stresses σ_y and increase in the compression stresses σ_x downstream.

5 CONCLUSIONS

The The following conclusions can be indicated:

- The present model spends little computer time, either in data preparation and computer implementation, without losing quality in the results;
- The model uses a discretisation of the structure into few finite elements with layers in the thickness;
- The model discretises the reservoir into infinite elements considering the fluid-structure interaction;
- The nonlinearity of the concrete is approximated by the smeared crack band model with constant energy density to obtain the objectivity of the finite element mesh;
- The model consider dynamic analysis of the displacements, stresses and cracking with direct integration of the equation of motion.
- The model is applied to the analysis of the seismic behaviour of an arch dam.
- The results are compared to other analysis showing the good performance of the model.

Keywords: wave energy converter, numerical modelling, SPH, DualSPHysics, point absorber, efficiency

Abstract. *In this work, the capabilities of the open source code DualSPHysics coupled with the multiphysics library Project Chrono are shown. The framework is validated through an experimental campaign performed on a wave energy converter, which consists of a cylindrical heaving-buoy and a power take-off unit. The numerical model proves to correctly reproduce the hydrodynamic response of the wave energy converter under regular waves, and with three different damping coefficients of the power take-off. With this validated setup, the sensitivity of a wave energy converter to the lateral stiffness of the anchoring system is investigated. The outcomes of this numerical campaign show that the correct design of the anchoring structure should develop along with the design of the system. Enough lateral stiffness is able to avoid excessive displacements to limit the loss of efficiency. DualSPHysics is a toolbox ready to manage complex simulations, including mechanical constraints, high energetic sea states. Various scenarios along the lifespan of a floating structure can be investigated. More importantly, the model supports the preliminary studies that are of vital importance to design a test campaign.*

1 INTRODUCTION

The process of shifting our primary energy source from fossil fuel to renewable energy seems to be driven by the increased worldwide awareness about climate change. However, many other driving forces are behind the events of the past decades, such as the economic benefit. Along with solar and wind energy, a more energy-dense source with comparable availability is represented by ocean wave energy [1]. Wave energy converters (WECs) are devices that can capture the wave energy and turn it into electricity using a power take-off (PTO) system. The movement of a floating body is often the input for any system that turns mechanical energy into electric one. Point-absorbers are representative of the most widely applied class of WECs. The floating bodies of such devices are smaller than others, and easier to produce and install [2]. On top of this, they can harvest energy irregardless of the wave directionality.

Along with physical tests, the design and optimisation of such devices can be approached via numerical modelling. A range of models is available to face this problem, such as potential flow based, boundary element method, and computational fluid dynamic (CFD) models. The first two methods—to name some implementations, WAMIT [3] and WEC-Sim [4]—are well suited to tackle the design of WECs, with a particular focus on energy efficiency. However, these approaches ground on over-relaxed conditions when it comes to model fluid, waves, and the buoy mechanics. On this account, such models cannot be used when the device is under operational sea states, where the ability of simulating nonlinearities is strictly advised to obtain reliable predictions. Very energetic sea states may represent more stressing scenarios for both buoys and structures used to restrain their movement [5]. On the other hand, CFD methods can guarantee a wider field of application.

Some meshless methods have appeared over the last decade and grown in popularity as they can be applied to highly nonlinear problems in arbitrarily complex geometries — difficult to be solved by mesh-based methods instead [6]. Among the others, Smoothed Particle Hydrodynamics (SPH) meshless technique is the most popular, having attained the required level of maturity to be used for engineering purposes [7]. Being Lagrangian, SPH can be conveniently adopted to simulate free-surface flows and for capturing highly nonlinear behaviour of wave-structure interactions, or fluid-driven objects. DualSPHysics has been already used, with outstanding outcomes, to simulate WECs [8], such as an oscillating water column [9, 10], an oscillating wave surge converter [11], and a point-absorber device [12], based on the device shown in [13].

In this work, the DualSPHysics code is used to simulate a WEC under regular sea states and with different PTO systems. The energy efficiency dependence on the anchoring-structure stiffness is investigated accounting for different configurations. A simplified model is used to mimic the effect of the structure on the buoy's dynamics.

2 DUALSPHYSICS CODE

2.1 SPH Method

This section introduces the SPH formulation implemented in DualSPHysics code, and important functionalities that are required to simulate the interaction between regular waves and a heaving cylinder.

Smoothed Particle Hydrodynamics (SPH) is a mesh-less method that discretises a volume of fluid into *particles*, whose motion is given by the governing dynamics. These *particles* represent the nodal points where physical quantities (e.g. position, velocity, density, pressure) are approximated with an interpolation of the values of the neighbouring particles on a short-ranged compact support [14, 15]. It is recognised that for free surface flows, the Lagrangian

nature of the SPH method allows multiple connections among the particles, without special treatments of any surface, for the definition itself of free surface loses all meanings. Hence, the technique is ideal for studying irregular and violent flows. SPH has been used to describe a variety of free-surface flows (wave propagation over a beach, plunging breakers, impact on structures and dam breaks [16, 17]).

The mathematical fundamental of SPH is based on the approximation of any quantities by convolution integrals. Any function F can be computed by:

$$F(\boldsymbol{r}) = \int F(\boldsymbol{r'})W(\boldsymbol{r} - \boldsymbol{r'})d\boldsymbol{r'} \tag{1}$$

where W is the kernel function [18], $\boldsymbol{r'}$ is the position of a generic computational point. This function F can approximated by interpolating particle contributions; the summation is performed over all the particles within an influence region of the compact support of the kernel:

$$F(\boldsymbol{r_a}) \approx \sum_b F(\boldsymbol{r_b})W(\boldsymbol{r_a} - \boldsymbol{r_b}, h)\frac{m_b}{\rho_b} \tag{2}$$

where a is the interpolated particle, b is a neighbouring particle, m and ρ being the mass and the density, respectively, m_b/ρ_b the volume associated to the neighbouring particle b. The kernel functions W fulfils several properties, such as positivity inside the area of interaction, compact support, normalisation and monotonically decreasing with distance [19]. One option is the piecewise polynomial Quintic Wendland kernel [20]:

$$W(q) = \alpha_D(1 - \frac{q}{2})^4(2q + 1) \qquad 0 \leq q \leq 2 \tag{3}$$

where α_D is a real number that accounts for the nature of the formulation, r is the distance, and h is the smoothing length.

The code used in this work uses the weakly compressible SPH (WCSPH) for modelling fluid. The Navier-Stokes (NS) equations are solved on account of that assumption. Hence, the differential form of the NS equations are written in a discrete version using the kernel function.

$$\frac{d\boldsymbol{v_a}}{dt} = -\sum_b m_b(\frac{P_a + P_b}{\rho_a\rho_b} + \Pi_{ab})\nabla_a W_{ab} + \boldsymbol{g} \tag{4}$$

$$\frac{d\boldsymbol{\rho_a}}{dt} = \rho_a \sum_b \frac{m_b}{\rho_b}\boldsymbol{v_{ab}}\nabla_a W_{ab} + 2\delta hc\sum_b(\rho_b - \rho_a)\frac{\boldsymbol{v_{ab}}\nabla_a W_{ab}}{\boldsymbol{r_{ab}^2}}\frac{m_b}{\rho_b} \tag{5}$$

where t is the time, $\boldsymbol{v}$ is the velocity, P pressure, Π_{ab} is the artificial viscosity [19], $\boldsymbol{g}$ is the gravitational acceleration, and W_{ab} the kernel function, whose value depends on the distance $a - b$. The system of equations is bonded by a relationship between density and pressure. For the WCSPH formulation, Tait's equation of state is used to determine fluid pressure based on particle density.

$$P = \frac{c^2\rho_0}{\gamma}\left(\left(\frac{\rho}{\rho_0}\right)^\gamma - 1\right) \tag{6}$$

where c is the speed of sound, ρ_0 is the reference fluid density, γ is the politropic constant. The fluid compressibility is adjusted so that the c can be artificially lowered to assure reasonable values for the timesteps. The Symplectic time integration algorithm [21] is used in the present work and a variable time step is calculated, involving the CFL (Courant-Friedrich-Lewy) condition, the force terms and the viscous diffusion term.

2.2 Rigid body dynamics and Coupling with Project Chrono

Fluid-driven body can be easily implemented into a SPH domain. The movement of objects interacting with fluid particles in DualSPHysics is handled with different techniques. A full SPH model can deal with a rigid body by summing the total force contributions of the surrounding fluid. By assuming that a body is rigid, the net force on each boundary particle is computed according to the designated kernel function and smoothing length. Each boundary particle k experiences a force per unit mass given by:

$$\boldsymbol{f_k} = \sum_{b \in fluid} \boldsymbol{f_{kb}} \tag{7}$$

where f_{kb} is the force per unit mass exerted by the fluid particle b on the boundary particle k. For the motion of a rigid body, the basic equations of rigid body dynamics can then be used:

$$\boldsymbol{M}\frac{d\boldsymbol{V}}{dt} = \sum_k m_k \boldsymbol{f_k} \tag{8}$$

$$\boldsymbol{I}\frac{d\boldsymbol{\Omega}}{dt} = \sum_k m_k(\boldsymbol{r_k} - \boldsymbol{r_0}) \wedge \boldsymbol{f_k} \tag{9}$$

where $\boldsymbol{M}$ is the mass of the object, $\boldsymbol{I}$ is the moment of inertia, $\boldsymbol{V}$ is the velocity, $\boldsymbol{\Omega}$ the angular velocity, and $\boldsymbol{r_0}$ the centre of mass. Equations 8 and 9 are integrated in time in order to predict the values of $\boldsymbol{V}$ and $\boldsymbol{\Omega}$ at the beginning of the next time step. Each boundary particle within the body has a velocity given by:

$$\boldsymbol{v_k} = \boldsymbol{V} + \boldsymbol{\Omega} \wedge (\boldsymbol{r_k} - \boldsymbol{r_0}) \tag{10}$$

Finally, the boundary particles within the rigid body are moved by integrating 10 in time. This approach has been checked out by Monaghan et al. (2003) [22], which shows that linear and angular momentum are conservative properties. Validations about buoyancy-driven motion are performed in Dominguez et al. (2019) [23], where DualSPHysics is tested for solid objects larger than the smallest flow scales and with various densities.

Mechanical restrictions among rigid bodies, within the DualSPHysics framework, can be handled by the solvers provided by Project Chrono [24]. The Chrono-Engine library has been implemented into the original framework, creating an integrated interface for simulating structure-structure interaction as well. In fact, the library is primarily developed to handle very large systems of 3D rigid bodies [25]. The coupling allows for arbitrarily shaped bodies to be considered, and the solver is capable of integrating externally applied forces and torques, and the effects of kinematic-type restrictions, dynamic-type restrictions and internal collisions [26]. The problem is described using a Differential Variational Inequality (DVI), cast in Cone Complementary Problem (CCP) form and solved with a novel fixed point iterative method [27]. To mimic the PTO system under study, a spring-damper system is employed (see also [28]). Such element is able to apply a force according to:

$$F(t) = b\dot{z} + kz \tag{11}$$

where b is the viscous damping, k is the stiffness, and z is the displacement.

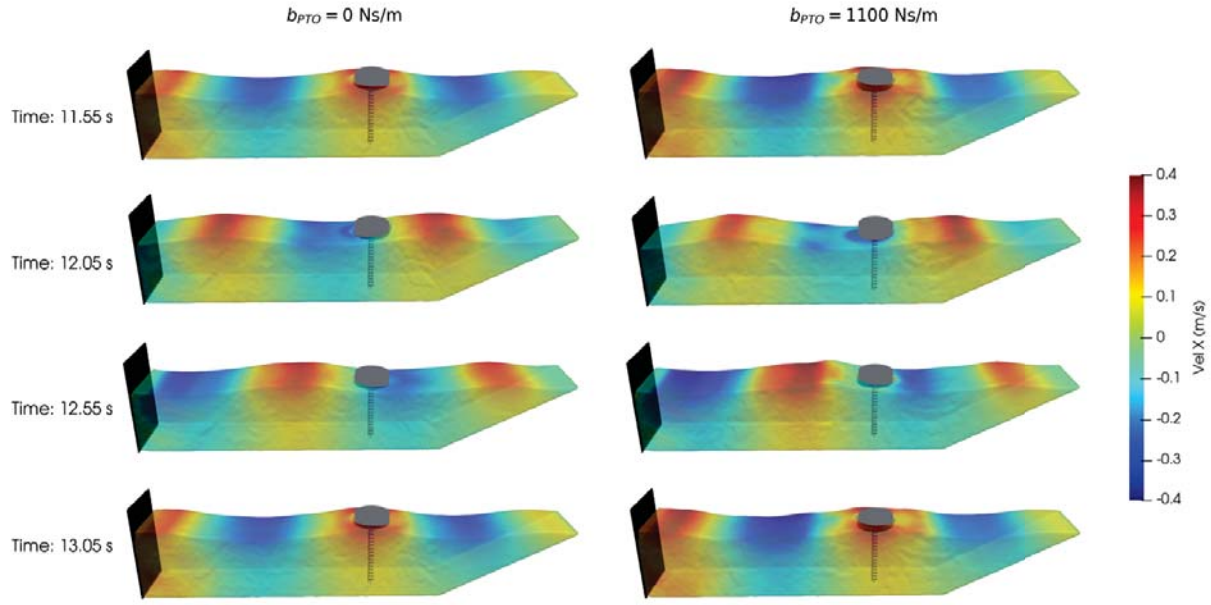

Figure 1: Snapshots of the simulations of the point-absorber for different values of the damping coefficient of the PTO.

3 VALIDATION

The specimen used for validation purposes is the wave energy converter studied by Zang et al.(2018) [29], which consists of a cylindrical heaving-buoy ($D = 0.50$m, $m = 21.6$kg, and $draft = 0.11$m) attached to a PTO system at its bottom. Rather than relying on a real device, a linear air-damper is put in its stead. This is advantageous since it allows to tune the damping coefficient and it guarantees a small variability of its value with velocity. The validation is performed by comparing the hydrodynamic response of the WEC under regular waves ($H = 0.16$m and $T = 1.50$s), and with three different damping coefficients of the PTO (b_{PTO} [Nsm^{-1}]). Different instants of the simulations can be observed in Figure 1 for two different values of b_{PTO}.

The numerical domain is modelled in the same fashion of the experimental geometries involved in (Figure 3). The flume is replicated into its exact geometries but the length. This is necessary to reduce the computational effort needed to perform the numerical analyses. A length proportional to the wave length L is used, specifically $1.50L$, and the centre of the buoy is located at 1L from the piston. This distance guarantees an optimum location, for it is far enough to allow local effects from the wave paddle, and, at the same time, close enough to avoid disturbances in the wave profile. To avoid excessive drag due to the lateral walls, periodic boundary conditions are used in place of solid boundaries. The anti-reflective structure is replaced with a dissipative beach, whose effectiveness is boosted by an additional numerical damping. Figure 1 proposes several snapshots of the numerical model, with the buoy heaving under regular waves.

Figure 2 compares the times series of the experimental and numerical vertical velocities. Each test is repeated with two different inter-particle distances, namely $dp = 0.01$m and $dp = 0.02$m, which represent the resolution of the model. As shown in past research with SPH method [30], a value of dp of around $H/10$, being H the wave height, provides accurate results. However, for a 3D environment, this may pose a limitation to the physical time to be simulated. The two investigated resolutions are respectively representative of $H/16$ and $H/8$.

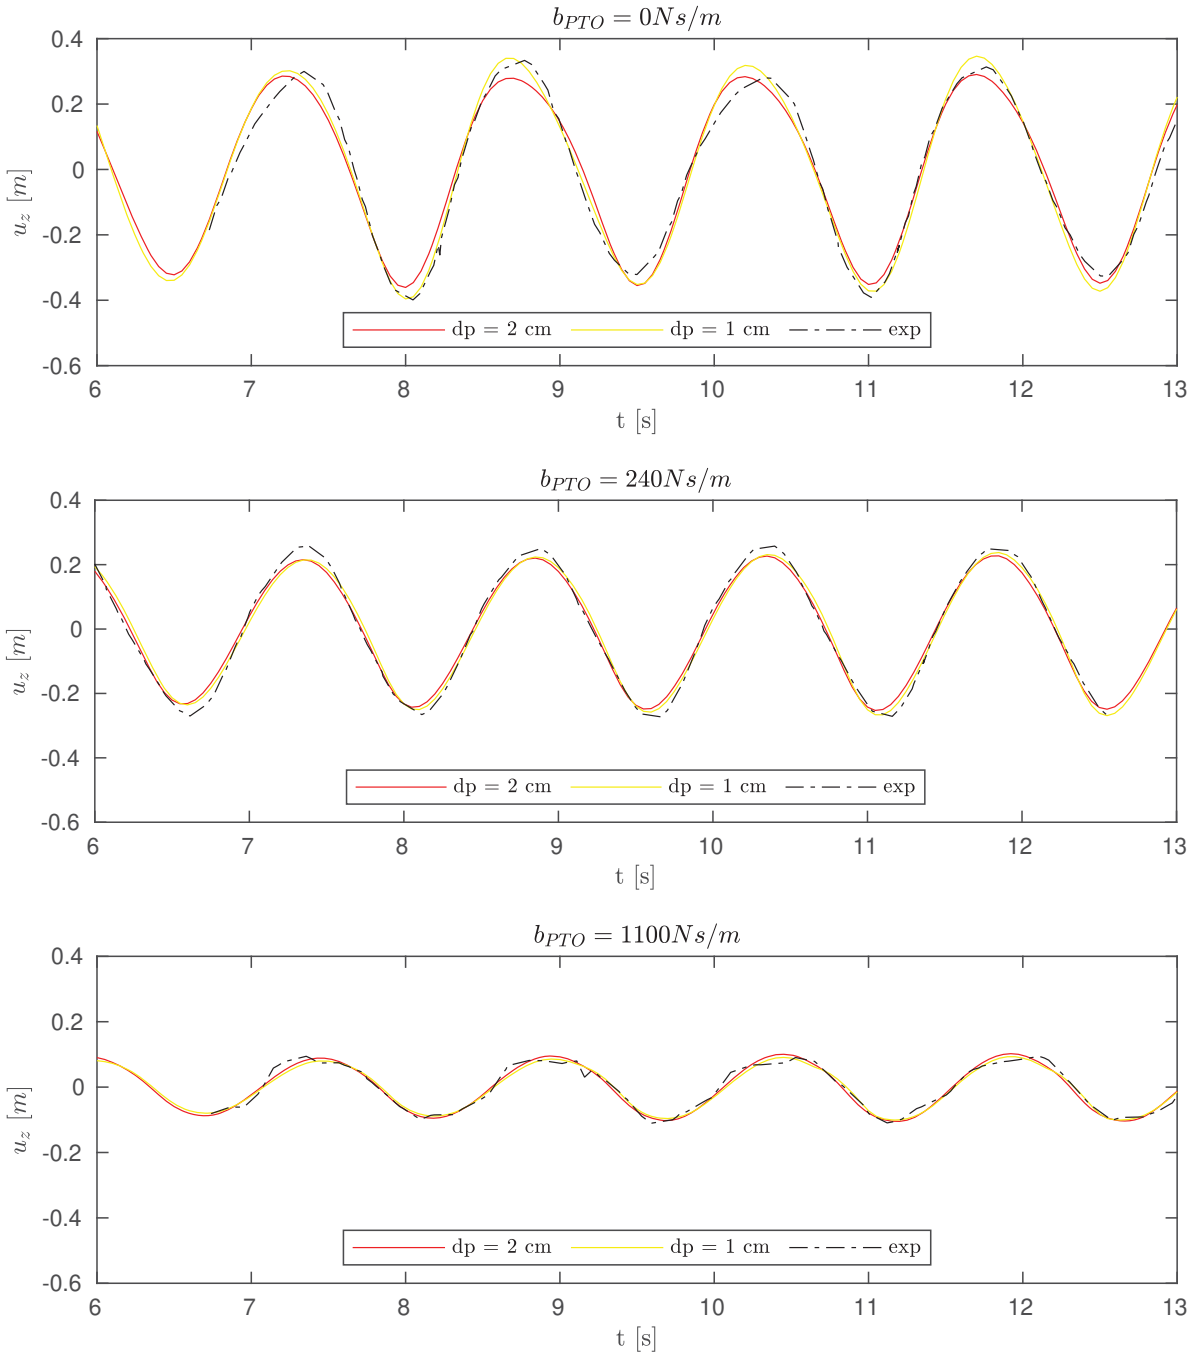

Figure 2: Comparison of the numerical and experimental time series for the vertical velocity with three different values of the damping coefficient of the PTO.

The agreement shown in Figure 2 is rather satisfying for both resolutions. For validation purposes, the time required to perform 15.00s of physical time is of around 20h for $dp = 0.01$m, and 2h for $dp = 0.02$m. These short runtimes are achieved thanks to a GTX2080 GPU card. Even though the finer mesh adheres more closely to the reference solution, the improvement is not as noticeable as the increment of runtime. Overall, the results collected in this section prove the capability of the SPH method to reproduce accurately the fluid dynamics and as well as the wave-structure interaction, which result in a correct prediction of the buoy's motion.

4 EFFICIENCY SENSITIVITY TO STRUCTURAL STIFFNESS

Test models provide researchers with a tool to investigate the physics of a natural phenomena. More than often, the model is a *scaled* reproduction of the specimen to be studied, and the scaling procedure has to be skilfully set up, taking in mind the trade off between feasibility and unavoidable scale effects. Tests in the range 1:10 and 1:20, whose parameters are given by Froude similarity, are deemed to be reliable on account of hydrodynamics. The tests presented by [29] are performed at 1:10 scale. The structure that takes in place the buoy, as it can be observed in Figure 3, may be assumed stiff enough to assume that the dynamics of the buoy develops only along the z-axis (Figure 3a)). However, the same structure can hardly be put in place just by solely scaling the model up. It is necessary to design a proper structure, which should guarantee the same degree of constraint.

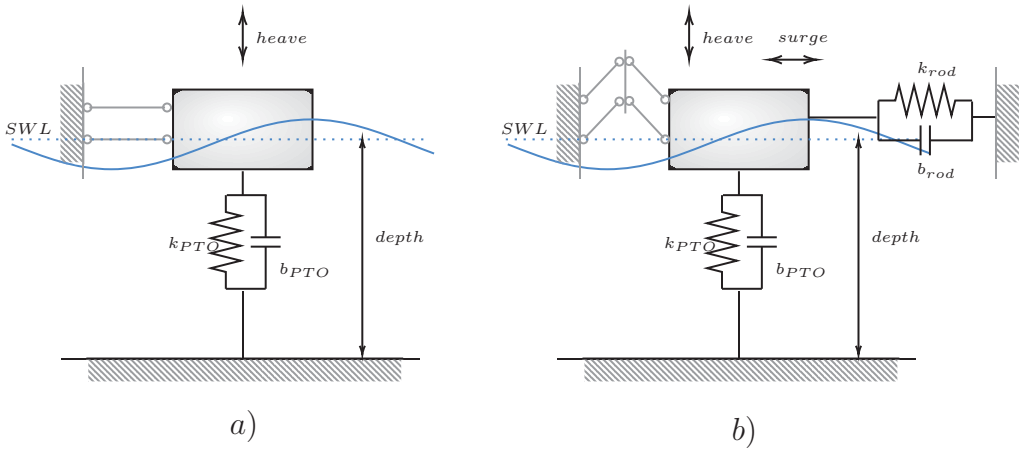

Figure 3: Structural models for the validation case *a)* and the modified one *b)*

Herein, along with the vertical spring-damper element, the submerged structure is modelled as a spring-damper element able to mimic its *lateral* damping and stiffness (Figure 3b)). It is assumed that the structure is clamped at the sea-bottom level and a hollow circular steel cross section makes up the beam. Its properties are given by:

$$k_{rod} = \frac{E\frac{\pi t_n d^3}{8}}{L} \quad \& \quad b_{rod} = 2m_{rod}\xi\sqrt{\frac{k_{rod}}{m_{rod}}} \tag{12}$$

where E is the elastic modulus, t_n is the thickness, d is the diameter, L is the length (0.890m), ξ is the damping ratio that is associated to the beam ($\xi = 0.10$), and m_{rod} is the mass of the beam. Note that the mass of the beam is considered lumped at its top. Additionally, the mass could be neglected due to its low impact on the overall kinematic.

Table 1: Geometric and mechanical properties of the profiles used for the anchoring structure.

	$d\ [mm]$	$t\ [mm]$	m	$k_{rod}\ [N/m]$	$b_{rod}\ [Ns/m]$
flexible	30	2.5	1.1	6 185	14
quasi flexible	40	3.2	1.4	18 766	32
quasi rigid	40	4.0	1.7	23 457	40
rigid	60	5.0	3.2	98 960	112

The dependence on the structural stiffness of the PTO's efficiency is investigated comparing the results obtained for the stiff structure (*rigid* in Table 1) with the results for the remaining

cases presented in Table 1. The wave height is the same used before, $H = 0.16$m, with wave periods ranging in $0.97 - 3.30$s, for a grand total of fourteen cases. In accordance with the tests presented for validation scope, the setup of the numerical domain is consistent: the length of the flume is $1L$, the width is twice the width of the device, the depth is the same. The four different viscous damping coefficients are used $[60,\ 240,\ 480,\ 720]$Ns/m.

The average power absorbed P is the quantity used as a proxy of the performance of the system. It is given by:

$$P = \frac{1}{T}\int_{t_0}^{t_0+T} b_{PTO}\, \dot{v}^2 dt \tag{13}$$

In general, heaving-buoy dynamics is highly affected by the wave conditions. This can be easily understood from the following equation:

$$\omega_0 = \sqrt{\frac{\rho g S}{m_a(\omega) + m}} \tag{14}$$

where ω_0 is the natural frequency of vibration, ρ is the buoy density, g is the gravity acceleration, S is the cross section of the heaving buoy, m_a is the added mass. For a heaving cylinder the excitation force and thus the added mass are given in an analytic form in Ref. [31]. The complex amplitude of the excitation force acting on a generic device is made up of two contributions: the Froude-Krylov force and the diffraction force. Under the assumption that the dimensions of the buoy are small in comparison with the wave length, the following holds:

$$F_e^* \approx (1 - khA^*)e^{-kh} \tag{15}$$

where F_e^* is the dimensionless amplitude of the excitation force, $k = 2\pi/L$ is the wave number, and h is the height of the cylinder. A numerical solution for the added mass, which can by found in [31], is given by:

$$m_a(\omega) = \frac{\rho S}{k}\left(1 - \frac{1.089 e^{-(0.669 k\frac{d}{2})^{0.604}} e^{-kh}}{e^{-kh}}\right) \tag{16}$$

Figure 4 collects the results of the analyses as performed on the model as described in Figure 3b). Each chart depicts the results for a value of the damping in the range above mentioned, while the four values of stiffness are compared (Table 1). Please note the dynamics of the *rigid* structure perfectly match the dynamics of the structure as shown in Figure 3a). The trend displayed by the charts is quite apparent: the less the stiffness of the system, the less the efficiency. Comparing the optimum points, the point at which the maximum power is harvested, it can be seen that there are no substantial differences between stiff and flexible structures. Though there is no difference in frequencies where the maxima are achieved, the average harvested power is sensibly lower, up to 40% in the case of the flexible structure. This trend appears to be quite consistent moving from *rigid* to *flexible* structures. The overall loss of efficiency shown in the four charts can be explained considering that the floating buoy, when free to surge, is prone to exhibit lateral displacements, according to the development of the free surface. However, for the way this PTO system works, this movement is not converted into harvested power.

5 CONCLUSIONS

This piece of research has shown that an SPH framework can presently deal with multi-physics phenomena effectively. The coupling DualSPHysics - Project Chrono library has sky-rocketed the engineering applications that can be studied with this code. Many relevant features

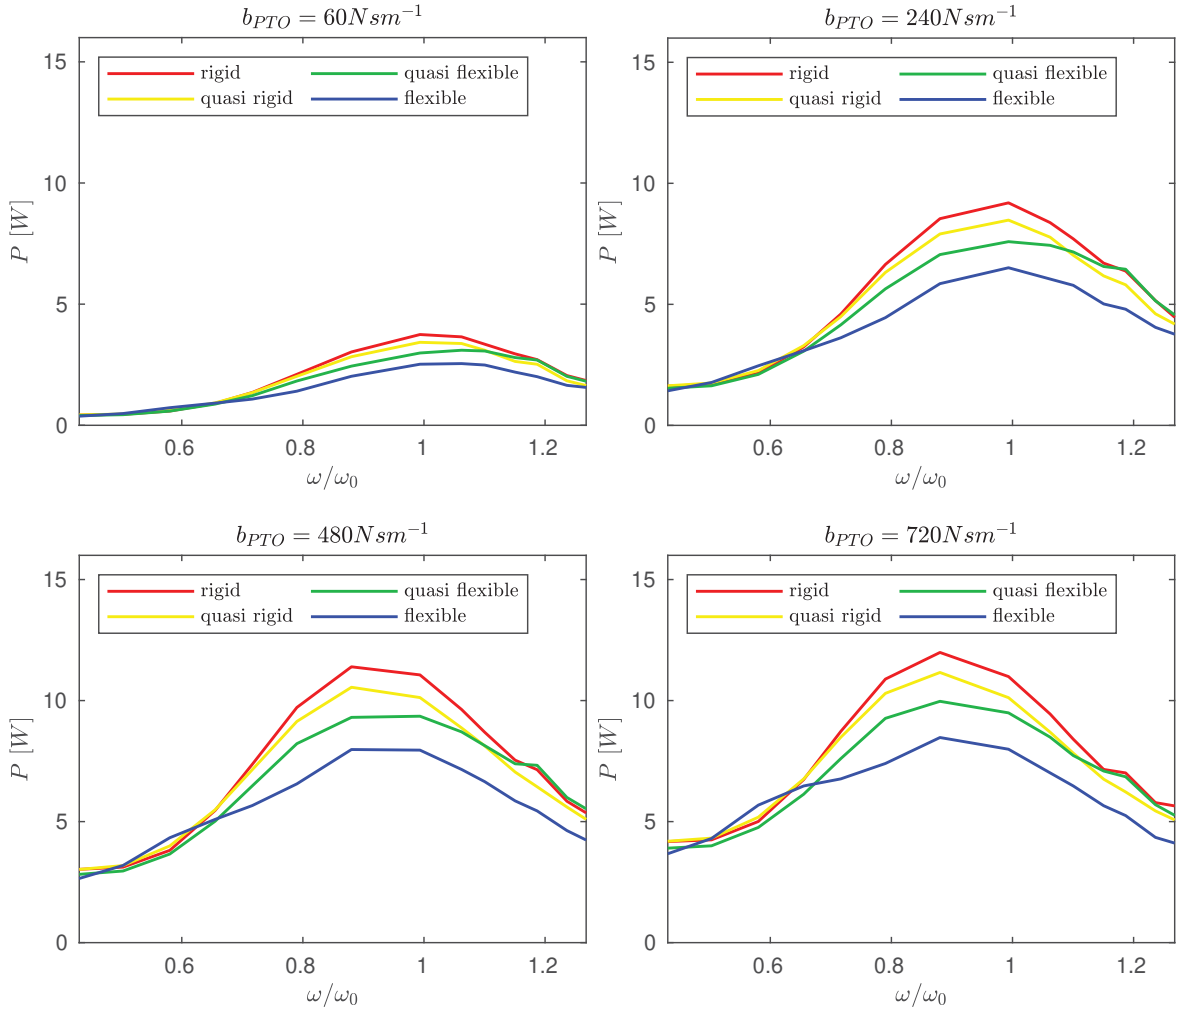

Figure 4: Absorbed power with the relative period of the buoy. Different values of the damping are presented. Each panel presents the results for a different lateral stiffness.

of a complex system can be modelled, allowing to account for the fully nonlinearities that are inherent in any natural phenomena. However, the importance of introducing flexible elements for simulating fluid-structure is not negligible. The structure can be indeed directly model into the simulation, hence considering its interaction with fluid without further assumptions on its behaviour. Indeed this feature would allow for more comprehensive survivability analyses of wave energy converters.

The validation of the numerical model has shown that, for this specific case, it is possible to achieve a high degree of reliability. The model indeed predicts the response of the fluid-driven buoy with accuracy and the runtime is reasonable for a fully 3D simulation. Therefore, the sensitivity to the structural stiffness shows that it is important to include the anchoring structure, even in a simplified way, from the preliminary phases of the design process.

Further implementations are needed to still widen the field of application of the code. It is already ongoing the implementation of Euler-Bernoulli elements, and isogeometric analyses (IGA), which a quite novel approach for finite elments analyses (FEAs).

SPEED DISTRIBUTION ON ROAD TEST SECTIONS FOR THE NEED OF PROFILE GROUND TESTING OF SPECIAL WHEELED VEHICLES

Mariusz Kosobudzki

Keywords: high mobility wheeled vehicle, speed distribution, road test sections

Abstract. *The required mobility of military sub-units (including logistics sub-units) is achieved due to the widespread use of appropriate means of transport. This is especially important in land forces. The basic means of transport there are high mobility wheeled vehicles with low (up to 4 tons), medium (up to 7 tons) and high (over 7 tons) payload. Often the chassis of these vehicles are designed taking into account some additional requirements for base chassis for military equipment (e.g. as mobile radar stations, mobile rocket launchers, recovery vehicles, etc.). Before taking a decision about accepting a new vehicle to equip army sub-units, a number of studies and tests are conducted, including qualification tests [1,2,3,4]. Their goal is to collect the required data characterizing the vehicle and check to what extent it meets the initial requirements[5]. Such tests are conducted in laboratory and operational conditions (profile ground tests). To model the laboratory and operation conditions, it is necessary to know their Life Cycle Profile [4]. The simplified Life Cycle Profile (containing basic data in the form of predicted road conditions, mileage, maximum and average speeds) is specified at the beginning of the design and construction process. However, more detailed data are required for qualifying tests on a new vehicle, including distribution of speed characteristic in given road conditions and the required test duration. The paper presents the method of determining the speed distribution over mileage and driving time to assumed road conditions using statistical tools. As a result, detailed preliminary data is obtained for planning experiments, selection of measurement equipment, or indication of appropriate road test sections [6]. In addition, an analysis was made of how the determined traffic parameters correlate with the possible driving speeds of a 4x4 military vehicle.*

1 INTRODUCTION

Military vehicles, including non-combat vehicles, are constructed in such a way as to best meet the requirements in the concept of operations (CONOPS). This paper compares all relevant requirements and characterizes the future operating environment of the vehicle, including minimum requirements for the logistics security system as well as user competence and capability. Vehicles such as these end up in the system for utilization for an extended period of time (even 30 years), therefore complex and long-term qualifying tests (Environmental Tests) are carried out before a decision is made about their ultimate acceptance [1,2,3,4]. The aforementioned tests should model future operating conditions correctly. Tests that are too stringent can cause problems such as oversizing of vehicle components (increase in total mass). Relaxing testing conditions can lead to future rapid wear of the vehicle and an increase in its failure rate. In the testing concept presented in [1], scenarios for the operational use of the vehicle are constructed using individual and distinct operational events. These scenarios are repeated until, based on the data collected, it is possible to characterize the trends of changes in critical vehicle parameters describing its durability, reliability, repairability, etc. [2]. The relevant operational events used in the respective scenarios must be modeled so that the collected data are reliable and unambiguous, and the conclusions drawn on their basis apply to the veritable future conditions of vehicle use. To that end, for test drives including, but not limited to normalized road sections, representing road surfaces on which the vehicle will operate (the length of test roads are proportional to their share in the given test run), while traveling speeds and the load carried are determined based on the postulates included in the concept of operational use (maximum and average speed). An alternative to conducting this research is used in a situation where the aforementioned standardized road test sections are not available [6,7]. Testing being conducted on selected sections of public roads is anticipated. This is a great simplification, however, when compared to the use of test sections, because the selected road sections are not standardized, causing recorded loads to be difficult to consider as a statistical representation of the operating conditions for the entire collection of vehicles. In such a case, proper modeling of the vehicle's crucial driving parameter, in this situation its speed, is of particular importance. Establishing exemplificatory statistical distributions of vehicle speed on selected sections of test roads improves the reliability of collected measurement data, and using comparative indicators in the form of pseudo damage as an example, [8] allows for modeling the required test scenarios based on other (but those of the same class) road measuring sections.

2 MODELLING THE ENVIRONMENTAL PROFILE OF VEHICLE USAGE

The choice of road section types for vehicle testing should meet the general guidelines contained in the relevant standards [6]. The basic types of roads for testing vehicles are presented there, along with the percentage of distance of these sections in the total vehicle mileage over its life cycle. From the concept of the vehicle's operational use, conclusions can be drawn regarding the expected vehicle speed (maximum and average speed). This is the basis for the compilation of statistical distributions of vehicle operation speed to the identified types of roads. For an example scenario of vehicle use, the case of a technical support vehicle was chosen when it was created from the combination of a universal high-mobility wheeled chassis with a container body complete with appropriate tools and equipment that would provide technical assistance to combat vehicles [9]. It is assumed that in such a situation the vehicle can cover a distance of approximately 60 km over 24 hours in cross-country conditions with speeds equaling V_{max}= 10 km/h and V_{avg}= 5 km/h. If the vehicle is used in tactical displace-

ment, it will travel about 20-25 km per day at speeds of V_{max}= 40 km/h and V_{avg}= 20÷25 km/h for off-road and secondary roads. If the vehicle is used for technical closing of the marching column, it can travel at speeds of V_{max}= 80 km/h and V_{avg}= 50 km/h on asphalt and paved roads which are in average and poor technical condition. However, during an individual vehicle drive as part of an operational march, operating speeds may have a value of V_{max}= 90 km/h and V_{avg}= 60 km/h on main and secondary roads. A summary of the anticipated speeds for selected vehicle use scenarios is presented in Table 1.

No.	Surface type	Estimated average speed [km/h]	Estimated maximum speed [km/h]
1	asphalt, concrete (e.g. motorways, expressways) - good surface quality	60	90
2	asphalt, concrete, cobblestone (e.g. district roads, commune roads) - medium and low surface quality	50	80
3	off-roads	25	40
4	cross-country	5	10

Table 1. Properties of Vehicle Traffic Conditions

3 STATISTICAL DISTRIBUTION OF VEHICLE'S SPEED

To prepare representative speed distributions for the indicated vehicle use scenarios, a beta statistical distribution was used, as seen in [10]:

$$f(x) = \frac{\Gamma(\alpha+\beta)}{\Gamma(\alpha)\Gamma(\beta)} x^{\alpha-1}(1-x)^{\beta-1} \tag{1}$$

where: Γ - gamma function, α, β - parameters of shape of distribution, x - width of accepted sub-range speed.

If the entire speed range is divided into a finite number of equal subranges, the formula (1) can be simplified and presented as:

$$f(x) = \frac{(\alpha+\beta-1)!}{(\alpha-1)!(\beta-1)!} x^{\alpha-1}(1-x)^{\beta-1} \tag{2}$$

where: α, β - parameters of shape of distribution, x - width of accepted sub-range speed.
For the initial determination of the value of the parameter α, the data presented in Table 2 [2] can be used.

V_{avg}/V_{max} [%]	10	20	30	40	50	60	70	80	90
α	0,2	0,5	0,75	1,25	2	3	4	6	13

Table 2. The value of α parameter.

The following equations can be used to determine the value of parameter β [10]:

$$\beta = \frac{\alpha \cdot \vartheta_{max}}{\vartheta_{avg}} - \alpha \tag{3}$$

The width of the sub-range can be posited to make it possible to maintain a set speed during tests, e.g. for cross-country driving ΔV=1.5÷4 km/h, and for main roads ΔV=5÷10 km/h. The final selection of ΔV depends on the technical capabilities of the tested vehicle. Examples of the speed distribution of the analyzed vehicle driving on a main road and driving off-road are presented in Tables 3 and 4 and in Figures 1 and 2. Table 3 presents the vehicle speed distribution (V_{max}= 90 km/h and V_{avg}= 60 km/h) where these roads represent 20% of the total test run (200km for every 1000km test).

Represented speed V_{rep} [km/h]	V_{min} [km/h]	V_{max} [km/h]	V_{avg} [km/h]	Driving time [%]	Driving time [min]	Sectional mileage [%]	Sectional mileage [km]
-	0	10	5	0,05	0,1	0,004	0,01
10	5	15	10	0,3	0,6	0,05	0,1
20	15	25	20	1,7	3,3	0,6	1,1
30	25	35	30	4,4	8,9	2,2	4,4
40	35	45	40	8,5	17,0	5,7	11,4
50	45	55	50	13,4	26,7	11,1	22,3

70	65	75	70	21,2	42,4	24,7	49,5
80	75	85	80	20,6	41,2	27,5	55,0
90	85	95	90	12,3	24,6	18,4	36,9
				100,0	**200,9**	**108,0**	**216,7**

Table 3. The beta distribution of speed (V_{max}= 90 km/ h i V_{avg}=60 km/h, distance 200 km).

The proportions of compositional speeds in the test is shown in Figure 1.

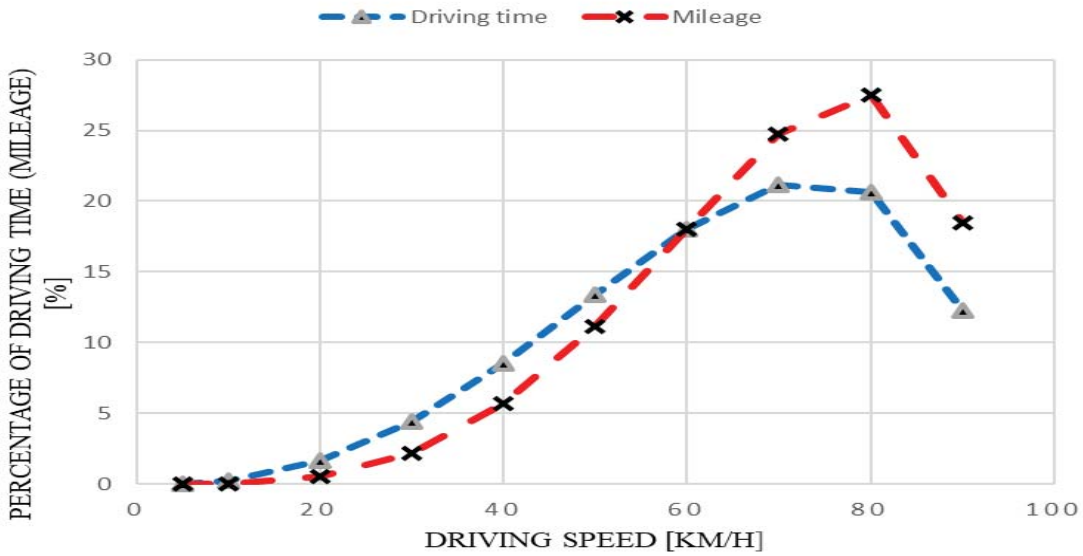

Figure 1. The beta distribution of speed (V_{max}= 90 km/ h i V_{avg}=60 km/h, distance 200 km).

Figure 1 shows that, e.g. speed V= 40 km/h, 8.5% of the driving time (17 minutes in total) should be maintained over a 5.7% distance of 200 km (11.4 km in total). Another case is presented in Table 4 concerning the distribution of vehicle speed in cross-country conditions

(V_{max}= 10 km/h and V_{avg}= 5 km/h), when these roads constitute 20% of the total mileage in the test (200km for every 1000km test).

Represented speed V_{rep} [km/h]	V_{min} [km/h]	V_{max} [km/h]	V_{avg} [km/h]	Driving time [%]	Driving time [min]	Sectional mileage [%]	Sectional mileage [km]
-	0	2	1	8,3	200,0	1,7	3,3
2	1	3	2	15,0	360,0	6,0	12,0
4	3	5	4	23,3	560,0	18,7	37,3
6	5	7	6	25,0	600,0	30,0	60,0
8	7	9	8	20,0	480,0	32,0	64,0
10	9	11	10	8,3	200,0	16,7	33,3
				100,0	**1200,0**	**105,0**	**210,0**

Table 4. The beta distribution of speed (V_{max}= 10 km/ h i V_{avg}=5 km/h, distance 200 km).

The proportions of compositional speeds in the test is shown in Figure 2.

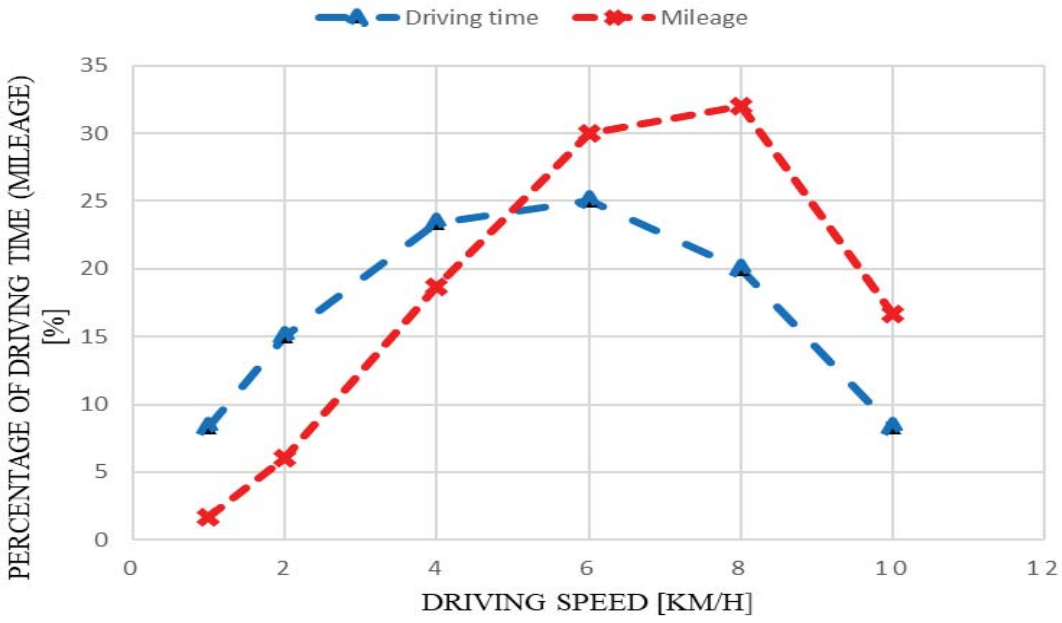

Figure 2. The beta distribution of speed (V_{max}= 10 km/ h i V_{avg}=5 km/h, distance 200 km).

The figure shows that given a speed of V= 4 km/h as an example, it is necessary to maintain 23.3% of the driving time (for a total of 560 minutes) on the 18.7% section of 200 km (37.3km in total).

4 TECHNICAL LIMITATION OF VEHICLE'S SPEED

The determined compositional speeds in vehicle tests should be achievable by the vehicle. In order to check these possibilities, a preliminary analysis of the vehicle speed resulting from the properties of the propulsion system should be carried out. Detailed information for an example of a 4x4 vehicle with a 5000kg payload is provided in Table 5. It was assumed that during the test the engine crankshaft revolutions per minute were to be kept between maxi-

mum torque and maximum power. High mobility wheeled vehicles are equipped with tires adapted for driving with variable air pressure. This causes a change in tire deflection U and a change in the vehicle speed, as shown in Table 5. Deflection U can be calculated as follows:

$$U = \frac{H'}{H} \tag{4}$$

where: H' – height of a loaded tire by reduced air pressure, H – height of loaded tire by nominal air pressure.

Max. engine torque:			Nominal engine power:			Tire:	**14.00R20 164/160J**			
1300 [Nm]	**1200÷1600** [1/min]		**240** [kW]	**2200** [1/min]		Cross-country speed correction based on tire deflection:				
Road speed [km/h]			**Cross-country** speed [km/h]			U=0,86 (nominal deflection)	U=0,8	U=0,7	U=0,6	U=0,5
Gear	**V** (n=1700 [1/min])	**ΔV** (Δn=±500 [1/min])	Gear	**V** (n=1700 [1/min])	**ΔV** (Δn=±500 [1/min])	$\Delta V_{0,86}$	$\Delta V_{0,8}$	$\Delta V_{0,7}$	$\Delta V_{0,6}$	$\Delta V_{0,5}$
C	6,9	2,0	C	3,4	1,0	0,0	-0,1	-0,2	-0,3	-0,4
1	9,9	2,9	1	4,9	1,5	0,0	-0,1	-0,3	-0,4	-0,6
2	13,9	4,1	2	6,9	2,0	0,0	-0,2	-0,4	-0,6	-0,8
3	18,7	5,5	3	9,3	2,7	0,0	-0,3	-0,5	-0,8	-1,1
4	24,8	7,3	4	12,4	3,6	0,0	-0,4	-0,7	-1,1	-1,5
5	34,4	10,1	5	17,2	5,1	0,0	-0,5	-1,0	-1,6	-2,1

7	65,0	19,1	7	32,5	9,6	0,0	-0,9	-1,9	-2,9	-3,9
8	86,7	25,5	8	43,4	12,8	0,0	-1,2	-2,6	-3,9	-5,3
R	7,2	2,1	R	3,6	1,1	0,0	-0,1	-0,2	-0,3	-0,4

Table 5. Technical characteristic of 4x4 high mobility special wheeled vehicle with payload 5000 kg (example).

The data presented in Table 5 show that low speeds (see Table 4) are achievable and maintainable if a central tire inflation system is used and the tire pressure is lowered.

5 SUMMARY

The speed distributions presented to established road sections within the adopted scenarios of vehicle utilization can be used directly (during tests, maintaining the set speeds for a specified driving time or distance) or can be used as a benchmark to compare the speed properties of the tests. This approach should provide a statistical representation of the speed of vehicles of a given category in the anticipated scenarios for their use on different roads (belonging to a certain group of roads). The error in determining the compositional speed values (approximately 5%) results from the simplifying assumptions that were made, which seems to be acceptable for this type of research.

TMEASY 6.0 – A HANDLING TIRE MODEL THAT INCORPORATES THE FIRST TWO BELT EIGENMODES

Georg Rill

OTH Regensburg
Galgenbergstr. 30, 93053 Regensburg, Germany
e-mail: georg.rill@oth-regensburg.de

Keywords: TMeasy Tire Model, Tire Force Dynamics, Virtual Test Rig, Real-time Simulation, Frequency Analysis.

Abstract. *TMeasy 6.0, an extension to the standard TMeasy tire model of version 5.3, takes the relevant first two rigid body eigenmodes of the belt into consideration. These modes represent the in plane longitudinal and rotational movements of the belt relative to the rim. The dynamics of the longitudinal force is of higher order then and reproduces the tire wheel vibrations, required for indirect tire-pressure monitoring systems (iTPMS), sufficiently well. A tailored implicit solver, which takes the stiff coupling between the longitudinal force and the belt motions into account, still provides real-time performance in addition. Simulation examples show that a rigid body vehicle model equipped with TMeasy 6.0 makes it possible to investigate second generation indirect tire-pressure monitoring systems.*

1 INTRODUCTION

Passenger car models consisting of rigid bodies are usually supplemented by handling tire models, which include a first order dynamics. This kind of vehicle models are valid up to approximately 20 Hz and provide sufficient accuracy with comparatively low computational effort. They are used to study the handling performance up to the limit range and the basics of ride comfort in offline and online simulations. In addition, modern control systems, which improve safety and comfort in general, assist the driver, or even provide automated driving, can be tested, enhanced or developed from the scratch [1]. However, indirect tire-pressure monitoring systems (iTPMS) of second generation analyze a wheel tire vibration of more than 100 Hz, which is sensitive to the tire inflation pressure, [2]. Structural tire models, like CDTire or FTire, as well the three-dimensional rigid belt approach, realized in the SWIFT tire model, incorporate the corresponding eigenmodes of course. Yet, these models are rather complex, require measurements for parameterization, and are not entirely suitable for real-time applications. That is why, the TMeasy handling tire model [3] was supplemented by the first two rigid body eigenmodes of the belt. This version is capable to reproduce rim and tire belt eigen-modes which occur in the range of 100 to 200 Hz for typical passenger car tires.

2 TMEASY TIRE MODEL

2.1 Standard Approach

TMeasy represents a handling tire model based on a semi-physical model. A smooth transition from stand still to normal driving situations is provided by a three-dimensional slip approach which includes a rather simple but very effective dynamic parking torque model in addition, [3]. In a sophisticated but quite simple contact calculation the geometric contact point is shifted at first to the static contact point and then to the dynamic contact point, [4]. These shifts take the shape of the tire cross section, the camber angle, and the tire compliance into account. TMeasy enables a skilled engineer to estimate appropriate parameter by just knowing or estimating the size, the payload of the tire, as well as the friction property of the tire road combination, [5]. Of course, the TMeasy parameter can be adjusted to tire or vehicle dynamics measurements by curve fits or just by inspection, [6].

The standard model incorporates a first order tire dynamics, which is based on the tire deflections, Figure 1. Due to this deflections the sliding velocities v_x and v_y as well as the bore angular velocity ω_n change to

$$v_x \longrightarrow v_x + \dot{x}_e, \quad v_y \longrightarrow v_y + \dot{y}_e, \quad \omega_n \longrightarrow \omega_n + \dot{\psi}_e \tag{1}$$

where $\dot{x}_e$, $\dot{y}_e$, and $\dot{\psi}_e$ describe the time derivatives of the tire deflections in the longitudinal, lateral, and torsional directions. As a consequence the normalized longitudinal slip for example is then provided as

$$s_x^N = \frac{-(v_x + \dot{x}_e - r_D\,\Omega)}{r_D\,|\Omega|\,\hat{s}_x + v_N} \tag{2}$$

where r_D names the dynamic rolling radius and Ω the angular velocity of the wheel or the rim respectively. The terms $\hat{s}_x$ and v_N denote a slip normalization factor and a small fictitious velocity which are part of the TMeasy model approach discussed in [7]. TMeasy generates the dynamic tire force in the longitudinal direction by

$$F_x^D = f_G\,\frac{-(v_x + \dot{x}_e - r_D\,\Omega)}{r_D\,|\Omega|\,\hat{s}_x + v_N} \tag{3}$$

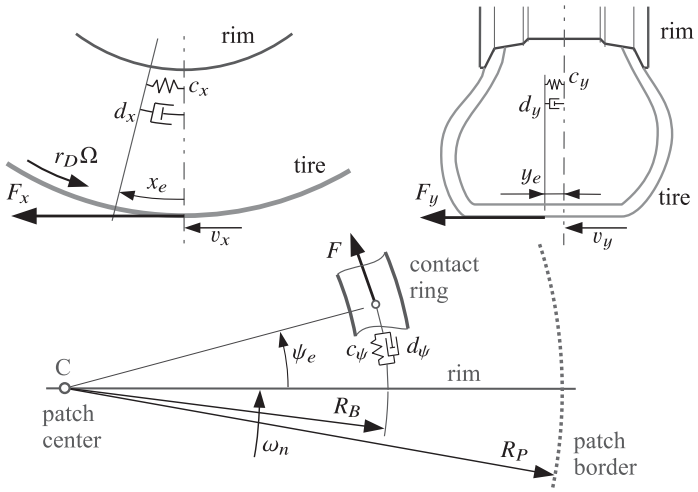

Figure 1: Tire deflections in the longitudinal, lateral, and torsional directions

where f_G represents the global derivative of the generalized force characteristics, which depends on the generalized and three-dimensional slip and processes the steady-state tire characteristics in longitudinal and lateral directions. On the other hand, the tire compliance provides the dynamic force in the longitudinal direction as

$$F_x^D = c_x\, x_e + d_x\, \dot{x}_e, \tag{4}$$

where c_x, and d_x represent the overall stiffness and damping properties of the sidewall and the tread particles in the longitudinal direction. Combining Equations (3) and (4) finally results in a first order differential equation

$$((r_D\,|\Omega|\,\hat{s}_x + v_N)\,d_x \;+\; f_G\,)\;\dot{x}_e \;=\; -\,(r_D\,|\Omega|\,\hat{s}_x + v_N)\,c_x\,x_e \;-\; f_G\,(v_x - r_D\,\Omega) \tag{5}$$

defining the dynamics of the tire deflection x_e in the longitudinal direction and via Equation (4) the first order dynamics of the longitudinal force F_x^D in addition. Similar approaches deliver the first order dynamics of the lateral force and the first order dynamics of the bore or turn torque.

The experimental validation of the lateral tire dynamics showed that in this case the first order approach realized in TMeasy already results in a quite good performance, [8]. However, braking scenarios or just rides on rough roads invoke eigen-modes of the belt that will result into a higher order dynamics of the longitudinal tire force.

2.2 In-Plane Belt Dynamics

Complex structural tire models, also provide the eigen-modes of an unloaded tire with a fixed rim, Fig. 2. The eigen-modes 1 and 2 of a freely vibrating tire correspond quite well to motions, where the rigid belt performs a rotation about the wheel rotation axis and a translation into the longitudinal direction. These two modes remain nearly unchanged if the tire is in contact with the road, which in vehicle dynamics is the most common and important case. All other modes incorporate already belt deformations or rigid belt like modes of a freely vibrating tire, like the modes 3 and 4 in Fig. 2, will be distorted significantly by the contact forces and torques.

That is why TMeasy 6.0 just takes mode 1 and 2 into account, because these first two eigen-modes influence the sliding velocity at the contact point into the longitudinal direction and hence strongly affect the longitudinal tire force. A model extension, where the wheel is split into a rigid rim and a rigid belt, takes the corresponding belt motions into account, Fig. 3.

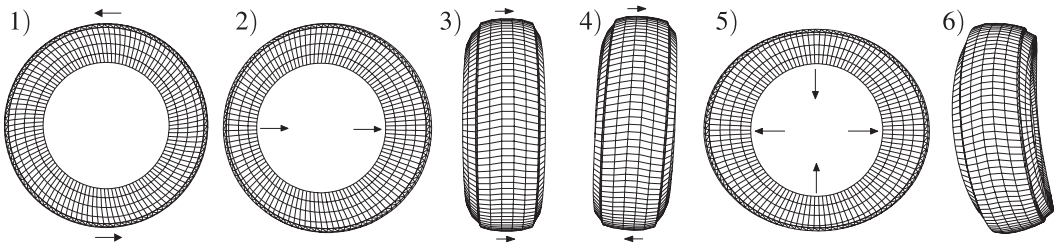

Figure 2: First six eigen-modes from left to right of a standard passenger car tire taken from [9]

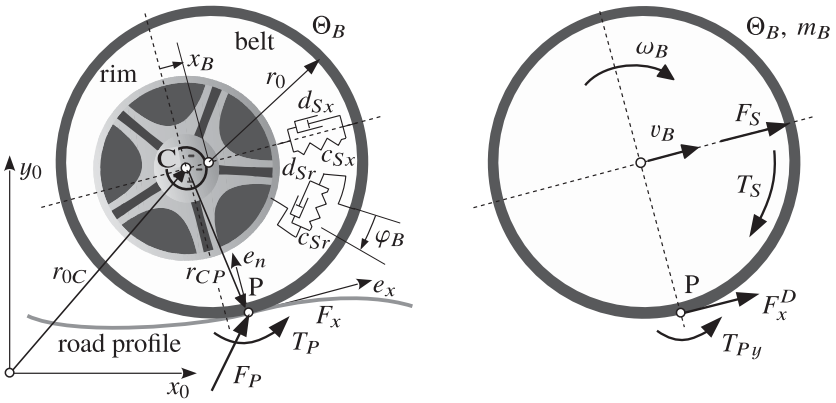

Figure 3: Rotating wheel split into rim and belt and free body diagram of the belt

The belt performs relative to the rim the rotation φ_B about the wheel rotation axis and the motion x_B into the longitudinal direction defined by the unit vector e_x, which is perpendicular to the local road normal e_n. The corresponding absolute belt velocity v_B and the absolute belt angular velocity ω_B together with the deflection of the tread particles x_T and the tire deflection y_e into the lateral direction, as well as the tire torsional deflection γ_e about the road normal e_n accomplish the internal tire states of the extended model. Whereas the standard model of version 5.3 just gets along with $n = 3$ internal states, Table 2.2.

TMeasy standard version 5.3 ($\mathbf{n = 3}$)		**TMeasy extendend version 6.0** ($\mathbf{n = 7}$)	
x_e	longitudinal tire deflection (tire sidewall + tread particles)	x_T	tread particle deflection in longitudinal direction
y_e	lateral tire deflection (tire sidewall + tread particles)	y_e	lateral tire deflection (tire sidewall + tread particles)

Table 1: Internal tire states of the TMeasy tire models of version 5.3 and version 6.0

The natural frequencies f_0^x and f_0^r of the first two tire eigen-modes provide the stiffness of the tire sidewall in longitudinal and torsional directions

$$c_{Sx} = m_B \left(2\pi f_0^x\right)^2 \quad \text{and} \quad c_{Sr} = \Theta_B \left(2\pi f_0^r\right)^2 \tag{6}$$

where Θ_B defines the belt inertia and the fictitious belt mass is simple provided by

$$m_B = \Theta_B / r_0^2 \tag{7}$$

because the belt is simply considered as a thin ring with the radius r_0 which corresponds to the unloaded tire radius. The corresponding damping parameter are computed via

$$d_{Sx} = 2\,\zeta_{Sx}\,\sqrt{m_B\,c_{Sx}} \quad \text{and} \quad d_{Sr} = 2\,\zeta_{Sr}\,\sqrt{\Theta_B\,c_{Sr}} \tag{8}$$

where ζ_{Sx} and ζ_{Sr} specify the viscous damping parameter for the tire sidewall in longitudinal and torsional directions.

In extension to Equation (3) the dynamic longitudinal tire force is now provided by

$$F_x^D \;=\; f_G\,\frac{-\left(v_x + \dot{x}_T + \dot{x}_B - r_D\dot{\varphi}_B - r_D\,\Omega\right)}{r_D\,\left|\Omega + \dot{\varphi}_B\right|\,\hat{s}_x + v_N} \tag{9}$$

The time derivative of the overall displacement $\dot{x}_e$ is replaced here by the time derivative of the displacement of the tread particles $\dot{x}_T$ and the rigid belt motions relative to the rim contribute to the transport velocity $r_D\,|\Omega| \;\rightarrow\; r_D\,|\Omega + \dot{\varphi}_B|$ and with the term $\dot{x}_B - r_D\dot{\varphi}_B$ to the contact point sliding velocity in longitudinal direction. By approximating the compliance of the tire tread particles by the stiffness c_{TP} and the damping parameter d_{TP} the dynamic tire force in longitudinal direction is also defined by

$$F_x^D \;=\; c_{TP}\,x_T \;+\; d_{TP}\,\dot{x}_T \tag{10}$$

Combining these Equations finally results in the first order differential equation

$$\left(d_{TP}\,v_{tnx} + f_G\right)\dot{x}_T \;=\; -v_{tnx}\,c_{TP}\,x_T \;-\; f_G\left(v_x + \dot{x}_B - r_D\dot{\varphi}_B - r_D\,\Omega\right) \tag{11}$$

where the abbreviation $v_{tnx} = r_D\,\left|\Omega + \dot{\varphi}_B\right|\,\hat{s}_x + v_N$ shortens the result. Now, the time derivatives $\dot{x}_B$ and $\dot{\varphi}_B$ of the translational and rotational belt motions are required in addition.

The belt equations of motion read as

$$m_B\,\dot{v}_B \;=\; F_x^D + F_S \quad \text{and} \quad \Theta_B, \dot{\omega}_B \;=\; T_y + T_S \tag{12}$$

where v_B describes the absolute velocity of the belt center into the longitudinal direction defined by the unit vector e_x and ω_B denotes the absolute angular velocity of the belt about the wheel or respectively rim rotation axis defined by the unit vector e_{yR}.

Equation (10) delivers the the dynamic longitudinal tire force F_x^D and the tire sidewall compliance provides the corresponding force and torque

$$F_S = -\left(c_{Sx}\,x_B + d_{Sx}\,\dot{x}_B\right) \quad \text{and} \quad T_S = -\left(c_{Sr}\,\varphi_B + d_{Sr}\,\dot{\varphi}_B\right) \tag{13}$$

Finally, the component of the resulting tire torque about the wheel rotation axis is provided by

$$T_y \;=\; e_{yR}^T\left(\,T_P + r_{CP} \times F_P\,\right) \;=\; e_{yR}^T\,T_T \tag{14}$$

The vectors F_P and T_P collect the tire forces and torques acting at the contact point P on the wheel (rim and belt) and the vector r_{CP} points from the rim center C to the contact point P. Then, the vector T_T represents the resulting torque which is applied to the wheel center C.

The time derivatives of the translational and rotational belt motions required in Equation (11) are defined by the kinematic differential equations

$$\dot{x}_B = v_B - e_x^T v_{0C} = v_B - v_x \quad \text{and} \quad \dot{\varphi}_B = \omega_B - e_{yR}^T \omega_{0C} = \omega_B - \Omega \tag{15}$$

where v_{0C} and ω_{0C} are vectors describing the absolute velocity of the rim center and the angular velocity of the rim and v_x and Ω denote the corresponding components into the longitudinal direction and about the wheel rotation axis.

The forces and torques applied to the rim are then given by

$$F_R \;=\; F_T - e_x^T \left(F_x^D + F_S\right) \quad \text{and} \quad T_R \;=\; T_T - e_{yR}^T \left(T_y + T_S\right) \tag{16}$$

where the torque vector T_T and the torque about the wheel rotation axis T_y are defined in Equation (14).

The TMeasy tire model of version 6.0 incorporates the unconstrained rotation of the rigid belt about the wheel or respectively rim rotation axis e_{yR}. That is why, the belt inertia Θ_B must be split off from the wheel body inertia tensor according to

$$\Theta_W \;\rightarrow\; \Theta_W - e_{yR}\,\Theta_B\,e_{yR}^T \tag{17}$$

The movements of the belt mass relative to the rim is restricted to a motion into the longitudinal direction defined by the unit vector e_x which is perpendicular to the local road normal e_n. The main motions of the wheel center, made possible by the suspension system of a vehicle, are in general performed nearly perpendicular to the road surface. Hence, the contribution of the belt mass inertia forces to the overall wheel motions is negligible within the TMeasy 6.0 model approach. The belt mass m_B is therefor considered just as a fictitious modal mass, which is used to describe the higher order dynamics of the longitudinal tire force, but will have no significant impact to the translational wheel motions.

3 PARTLY IMPLICIT SOLVER

The differential equations (11) and (12) are strongly coupled and stiff. Hence, a real time solution requires an appropriate implicit approach. At first, the differential equations (11) and (12) are combined with the kinematic differential equations (15) and grouped to a system

$$\underbrace{\begin{bmatrix} \dot{x}_T \\ \dot{v}_B \\ \dot{\omega}_B \\ \dot{x}_B \\ \dot{\varphi}_B \end{bmatrix}}_{\dot{x}} = \underbrace{\begin{bmatrix} -\left(v_{tnx}\,c_{TP}\,x_T \;+\; f_G\left(v_B - r_D\,\omega_B\right)\right) / \left(d_{TP}\,v_{tnx} + f_G\right) \\ \left(F_x^D + F_S\right)/m_B \\ \left(T_y + T_S\right)/\Theta_B \\ v_B - v_x \\ \omega_B - \Omega \end{bmatrix}}_{f(x)} \tag{18}$$

where $v_{tnx} = r_D\,|\omega_B|\,\hat{s}_x + v_N$ holds in addition. A trapezoid like integration step of size h delivers at first

$$x^{k+1} = x^k + \frac{h}{2}\left(f(x^k) + f(x^{k+1})\right) \tag{19}$$

where $x^k = x(t)$ and $x^{k+1} = x(t+h)$ denote the state vectors at time t and $t+h$. A truncated Taylor-expansion delivers

$$f(x^{k+1}) \approx f(x^k) + \frac{df}{dx}\left(x^{k+1} - x^k\right) \tag{20}$$

and Equation (19) yields

$$x^{k+1} = x^k + h\, f(x^k) + \frac{h}{2}\frac{df}{dx}\left(x^{k+1} - x^k\right) \tag{21}$$

which finally results in

$$x^{k+1} = x^k + \left(I - \frac{h}{2}\frac{df}{dx}\right)^{-1} h\, f(x^k) \tag{22}$$

where I is the identity matrix which fits to the Jacobian df/dx. If the step size h is not too large, the global derivative of the generalized tire characteristic f_G, the longitudinal velocity of the wheel center v_x, and the angular velocity of the rim Ω can be considered as nearly constant in the interval $t \rightarrow t+h$. Then, the last two equations in (22) can be solved straight away

$$x_B^{k+1} = x_B^k + \frac{h}{2}\left(v_B^k - v_x \;+\; v_B^{k+1} - v_x\right) = x_B^k - h\, v_x - \frac{h}{2}\left(v_B^{k-1} - v_B^k\right) \tag{23}$$

$$\varphi_B^{k+1} = \varphi_B^k + \frac{h}{2}\left(\omega_B^k - \Omega \;+\; \omega_B^{k+1} - \Omega\right) = \varphi_B^k - h\,\Omega - \frac{h}{2}\left(\omega_B^{k-1} - \omega_B^k\right) \tag{24}$$

In addition, the elements of the remaining 3×3 Jacobian can be calculated analytically, which speeds up the computation significantly. The partly implicit solver provided in Equation (22) produces rather accurate and stable results up to step sizes of $h = 1$ ms which corresponds to the sampling rate applied in common vehicle control systems.

4 A VIRTUAL TEST RIG

The virtual tire test rig represents a quarter car model, Figure 4. It consists of the corresponding chassis mass and the wheel. The latter is suspended at the chassis mass such that it can perform an up and down motion as well as steer and camber movements. The chassis mass

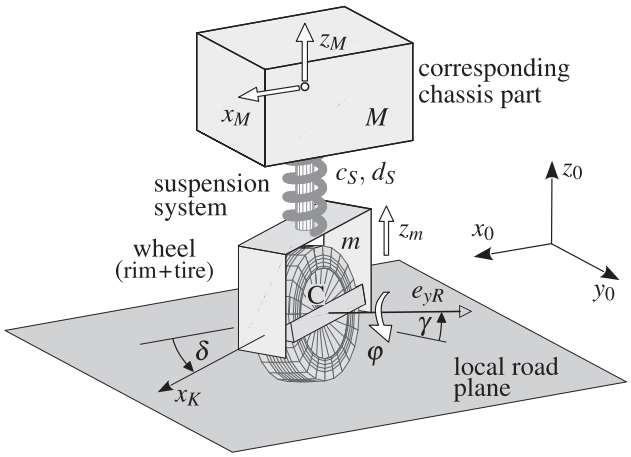

Figure 4: A virtual tire test rig represented by a quarter car model

M is supposed to move in longitudinal and vertical directions only. The generalized coordinates x_M and z_M characterizes these movements. The vector

$$r_{0M,0} \begin{bmatrix} x_M \\ 0 \\ r_0 + h_0 + z_M \end{bmatrix} \quad \text{and} \quad v_{0M,0} = \dot{r}_{0C,0} = \begin{bmatrix} \dot{x}_M \\ 0 \\ \dot{z}_M \end{bmatrix} \tag{25}$$

describes the momentary position of the chassis center with respect to the earth-fixed reference frame 0 and its velocity. The comma separated index 0 indicates that the vectors are expressed in the earth-fixed frame 0, the parameter h_0 represents the height of the chassis center above the wheel center in design position, and r_0 names the unloaded wheel radius.

The suspension system allows the wheel to perform the hub motion z_m, the steer motion δ about the vertical z_0-axis, the camber motion γ about the knuckle fixed x_K-axis, and the rotation φ about the rim fixed y_R-axis. In this model approach the wheel center C is located on the steering axis. Then, its momentary position and its velocity are provided by

$$r_{0C,0} = \begin{bmatrix} x_M \\ 0 \\ r_0 + z_m \end{bmatrix} \quad \text{and} \quad v_{0C,0} = \dot{r}_{0C,0} = \begin{bmatrix} \dot{x}_M \\ 0 \\ \dot{z}_m \end{bmatrix} \tag{26}$$

The momentary position of the wheel rotation axis and the angular velocity of the wheel or rim respectively are defined by

$$e_{yR,0} = \begin{bmatrix} -\sin\delta\cos\gamma \\ \cos\delta\cos\gamma \\ \sin\gamma \end{bmatrix} \quad \text{and} \quad \omega_{0R,0} = \begin{bmatrix} \dot{\gamma}\cos\delta - \dot{\varphi}\sin\delta\cos\gamma \\ \dot{\gamma}\sin\delta + \dot{\varphi}\cos\delta\cos\gamma \\ \dot{\delta} + \dot{\varphi}\sin\gamma \end{bmatrix} \tag{27}$$

Then

$$\Omega \;=\; e_{yR,0}^T\,\omega_{0R,0} \;=\; \dot{\varphi} + \dot{\delta}\sin\gamma \tag{28}$$

describes the absolute angular velocity of the wheel/rim about the wheel rotation axis.

The equations of motion for the virtual test rig are provided by

$$M\,\ddot{x}_M = F_D + e_{x,0}^T\,F_{T,0} \tag{29}$$

$$M\,\ddot{z}_M = F_S - M\,g \tag{30}$$

$$m\,\ddot{z}_m = -F_S - m\,g + e_{z,0}^T\,F_{T,0} \tag{31}$$

$$\Theta_W\,\dot{\Omega} = T_{D/B} + e_{yR,0}^T\,T_{T,0} \tag{32}$$

The fictitious force F_D applied to the chassis mass and provided by an appropriate controller makes it possible to accelerate or decelerate the vehicle without driving or braking the wheel. The TMeasy tire model delivers the contact forces and torques collected in the force vector $F_{T,0}$ and the torque vector $T_{T,0}$ which is related to the wheel center. The suspension force

$$F_S \;=\; F_0 - c_S\,(z_M - z_m) - d_S\,(\dot{z}_M - \dot{z}_m) \tag{33}$$

is modeled by a linear spring-damper-element, where c_S, d_S characterize its stiffness and damping properties and $z_M - z_m$ represents the suspension travel. The preload $F_0 = M\,g$ compensates the chassis weight. The torque $T_{D/B}$ makes it possible to apply a driving or braking torque to the wheel.

The maneuver driving straight ahead on a random road is characterized by vanishing steer and camber angles $\delta = 0$ and $\gamma = 0$ when potential steer and camber changes due to the suspension kinematics are neglected in this basic study. A nearly constant driving velocity is maintained either by a controlled drive force F_D acting at the chassis mass or a controlled drive torque $T_{D/B} = T_D$ applied via the half-shaft to the wheel. The former models a not driven the latter a driven wheel.

5 RESULTS

5.1 Model Parameter

The TMeasy tire model is characterized by 58 parameter in the standard version 5.3. The extended version 6.0 requires six more parameter which specify the belt inertia, the natural eigen-frequencies and viscous damping rates of the belt, as well as the stiffness of the tread particles. Table 2 collects the main parameter of the virtual test rig which characterize a standard midsize passenger car in a quarter car model approach.

Vehicle/Tire				Tire/Belt			
chassis mass	M =	312.2	kg	tire unloaded radius	r_0 =	0.2930	m
wheel mass	m =	44.6	kg	tire dynamic radius$^{(*)}$	r_D =	0.2815	m
susp. stiffn.	c_S =	17 750	N/m	belt inertia	Θ_B =	0.6868	kgm^2
susp. damp.	d_S =	2354	N/(m/s)	nat. freq. belt long.	f_{0x} =	120	Hz
rim inertia	Θ_R =	0.462	kgm^2	nat. freq. belt rad.	f_{0r} =	90	Hz
tire vert. stiffn.	c_T =	190 000	N/m	tread part. stiffn.$^{(*)}$	c_{TP} =	10	kN/mm
tire vert. damp.	d_T =	500	N/(m/s)	tread part. damp.$^{(*)}$	d_{TP} =	9 000	N/(m/s)

Table 2: Main parameter of virtual test rig and TMeasy tire model where $(*)$ holds at the tire payload of 3500 N

Equation (7) delivers a fictitious modal belt mass of

$$m_B = 8 \text{ kg} \tag{34}$$

and Equation (6) produce the stiffness properties of the sidewall as

$$c_{Sx} = 4\,500\,000 \text{ N/m} \quad \text{and} \quad c_{Sr} = 220\,000 \text{ Nm/rad} \tag{35}$$

A pressure loss in the tire is modeled by reducing the sidewall and the vertical tire stiffness to

$$c_{Sx}^{red} = 3\,000\,000 \text{ N/m} \quad \text{and} \quad c_{Sr}^{red} = 150\,000 \text{ Nm/rad} \quad \text{as well as} \quad c_T^{red} = 155\,000 \text{ N/m} \tag{36}$$

The corresponding damping parameters were kept unchanged. The reduced vertical tire stiffness lowers the dynamic rolling radius of the tire at steady-state to $r_D^{red} = 0.2789$ m as a consequence.

5.2 Driving straight ahead on random road

At first, the vehicle model is driven with a constant velocity of $v = 120$ km/h $= 33.3$ m/s on a horizontal and nearly flat road which just contains small randomly distributed irregularities. Hence, a distance of $s = 33.3$ m is covered in the interval $0 \leq t \leq 1$ s of the time histories plotted in Figure 5. The TMeasy contact model processes the road profile by an effective local road plane, which results in a slightly smoother time history of the effective contact point compared to the road roughness, Figure 5 top graph.

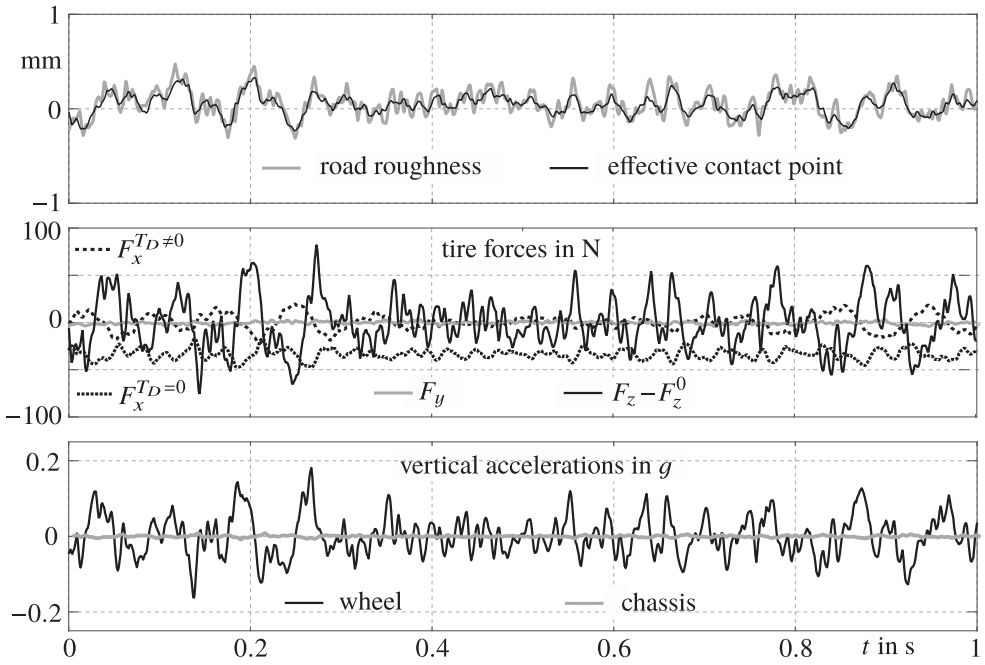

Figure 5: Virtual tire test driven straight ahead with constant velocity on random road

The spatial road profile induces small tire force fluctuations not only in the vertical but also in the longitudinal and the lateral directions, Figure 5 center graph. The longitudinal force $F_x = F_x(t)$ oscillates about zero if the wheel is driven ($T_D \neq 0$) and about a small negative value if the wheel is not driven ($T_D = 0$). In the former case the drive torque compensates the rolling resistance at the wheel and just very small longitudinal forces are required to keep the wheel rotating. In the latter case a drive force $F_D \neq 0$ applied to the chassis mass maintains the constant velocity and a certain amount of negative longitudinal tire forces is required to counteract the rolling resistance of the wheel.

The vertical tire forces F_z deviates from the steady-state value F_z^0 and generates rapidly oscillating vertical accelerations of the wheel mass, black line in bottom graph of Figure 5. The suspension system filters these excitation and results in a very smooth and comfort ride, because the vertical accelerations of the chassis mass, gray line in bottom graph of Figure 5, are hardly noticeable.

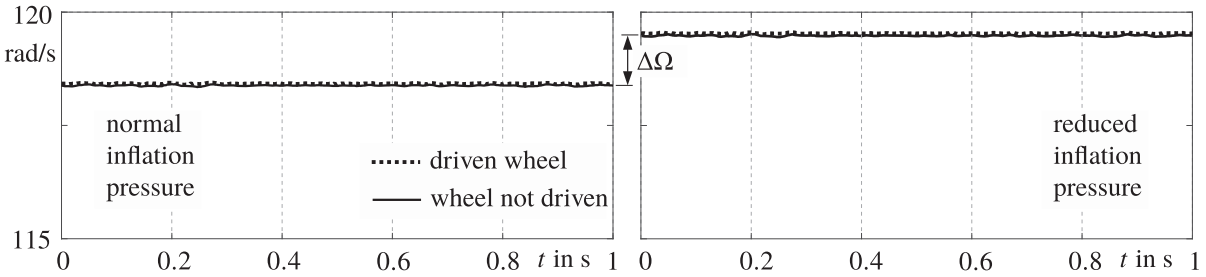

Figure 6: Rim angular velocity with normal and reduced inflation pressure

The mean value of the wheel or rim angular velocity Ω increases when the tire inflation pressure is reduced, Figure 6. Some indirect tire-pressure monitoring systems (iTPMS) take advantage of this effect. A pressure loss is detected if one wheel angular velocity deviates

significantly from the others. However, no detection is possible if all tires loose pressure at the same time.

Sophisticated iTPMS perform a frequency analysis of the angular wheel or respectively rim velocities. Induced by the road irregularities the rotating rim performs oscillations. Inspecting the angular velocity $\Omega(t)$ in the interval $0 \leq t \leq T$ a corresponding, but shifted and normalized signal is obtained by

$$y(t) = \Omega(t) - \text{mean}(\Omega(t)) \quad \text{and} \quad s(t) = \frac{2\,y(t)}{\max(y(t)) - \min(y(t))} \tag{37}$$

where $T = 1$ s was used in this basic study. This signal $s(t)$ is then transformed into the frequency domain. To eliminate any FFT processing errors, it is approximated by

$$\sigma(t) = p + q\,t + \sum_{i=1}^{i=N} A_i \,\sin\left(2\pi f_i\,t + \phi_i\right) \tag{38}$$

where $N = 200$ frequencies are predefined by $f_i = 1(1)201$ Hz and the $2 + 2N$ parameter p, q, A_i, and ϕ_i are obtained by a least square curve fit. The signal $s(t)$, its approximation $\sigma(t)$, as well as the absolute values of the amplitudes A_i are plotted in Figure 7 for different tire inflation pressures. In both cases (normal pressure and reduced pressure) the approximation

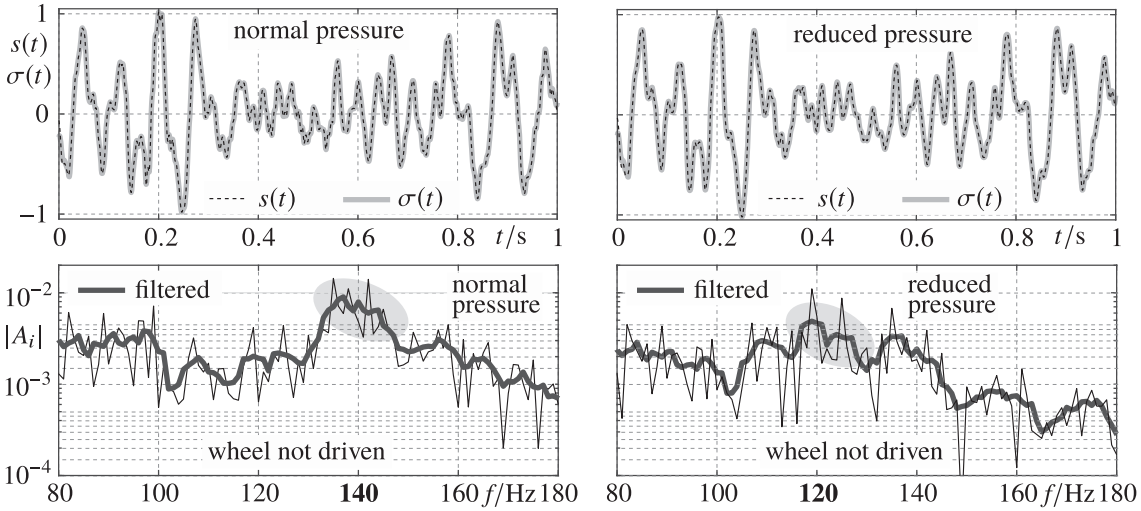

Figure 7: Frequency analysis of shifted and normalized rim angular velocity with normal and reduced inflation pressure for a not driven wheel of the virtual test rig

$\sigma(t)$ matches the signal $s(t)$ perfectly, which confirms the quality of this approach.

For a more convenient comparison the frequency responses are smoothed by a moving-average filter which operates as

$$\begin{aligned}
&\left|\hat{A}_1\right| = |A_1|\,, \quad \left|\hat{A}_2\right| = \tfrac{1}{3}\left(|A_1| + |A_2| + |A_3|\right) \\
&\left|\hat{A}_j\right| = \tfrac{1}{5}\sum_{k=j-2}^{k=j+2} |A_k| \quad \text{for} \quad 2 \leq j \leq N-2 \\
&\left|\hat{A}_{N-1}\right| = \tfrac{1}{3}\left(|A_{N-2}| + |A_{N-1}| + |A_N|\right), \quad \left|\hat{A}_N\right| = |A_N|
\end{aligned} \tag{39}$$

Practically no difference is noticeable between the time histories of the signals at normal and reduced pressure. But, the corresponding frequency responses differ in a characteristic manner. Rim and belt incorporate an eigen-mode where the rotational motion of the belt is in phase with its translational motion and out of phase with the rim rotation.

At normal pressure this eigen-mode is excited at a frequency of approximately 140 Hz which results in the resonance phenomena indicated by a grey ellipse in the lower left plot of Figure 7. This resonance frequency is slightly larger than the natural eigen-frequencies specified in Table 2, because the former occurs when the tire is in contact with the road whereas the latter hold for free tire vibrations.

A reduced inflation pressure lowers these eigen-frequencies. In this particular case, the natural eigen-frequencies of the free vibrating tire were reduced by the factor $\sqrt{2/3}$ which results in an adjustment factor of $2/3$ for the corresponding stiffness parameter. As a consequence, the resonance phenomena in the frequency response is shifted accordingly, lower right plot of Figure 7.

Figure 8 demonstrates that the characteristic shift of the resonance phenomena is also present when the wheel is driven.

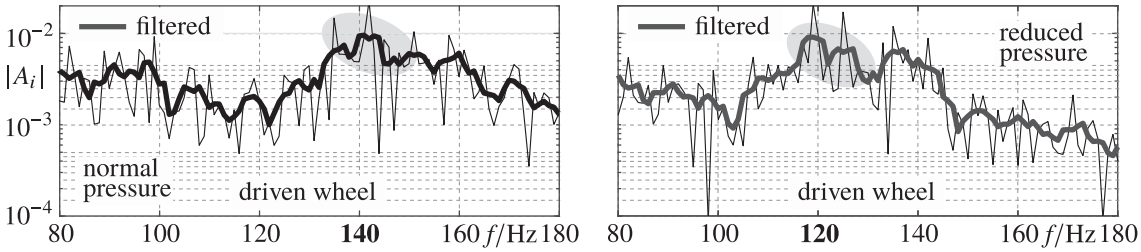

Figure 8: Frequency analysis of shifted and normalized rim angular velocity with normal and reduced inflation pressure for a driven wheel of the virtual test rig

The shift of the resonance phenomena is also observed at low ($v = 60$ km/h) and high ($v = 180$ km/h) vehicle velocities, Figure 9. The maximum resonance magnification may be

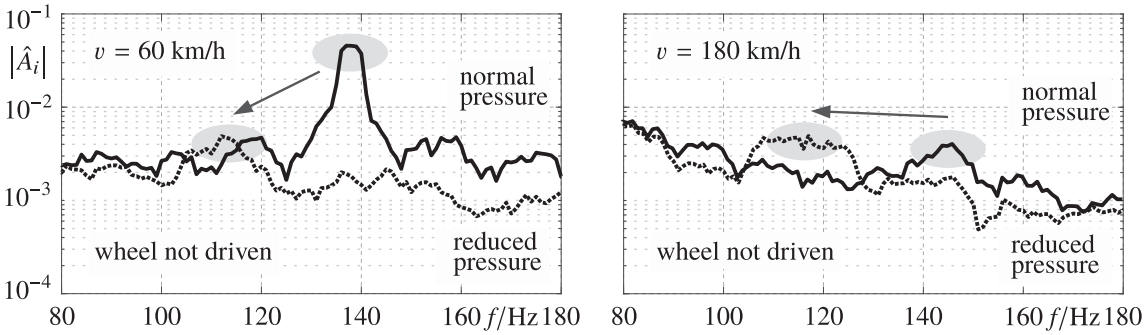

Figure 9: Frequency analysis of shifted and normalized rim angular velocity with normal and reduced inflation pressure for a driven wheel of the virtual test rig at different driving velocities

different because of specific stochastic properties of the road irregularities. But in both cases the maximum is shifted significantly to lower frequencies when the tire inflation pressure is lowered. In this particular case, it is reduced by the factor $\sqrt{2/3}$ and the shift takes place from $f \approx 140$ Hz to $f \approx 120$ Hz.

Hence, the frequency response of the angular wheel or respectively rim angular velocity, which is automatically measured in any modern passenger car, clearly indicates a pressure loss. Indirect tire-pressure monitoring systems (iTPMS) based on this concept are able to detect a simultaneous pressure loss at all tires in addition.

5.3 TMeasy standard versus TMeasy extended

The first order tire dynamics applied in the standard TMeasy 5.3 just holds in the lower frequency range. This model is suitable for all kind of driving situations but does not cover the higher frequencies of the rim and tire belt eigen-modes which are modeled in addition in the extended TMeasy version 6.0.

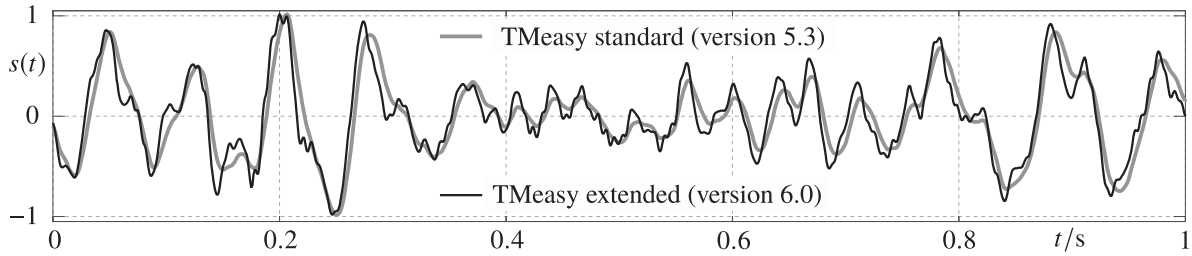

Figure 10: Time histories of shifted and normalized rim angular velocity computed for a not driven wheel of the virtual test rig with TMeasy standard and extended

Figure 10 illustrates the difference between TMeasy 5.3 and Tmeasy 6.0 by the computed time histories of the shifted and normalized rim angular velocity. The time history of the extended TMeasy version 6.0 clearly shows high-frequency components which are responsible for the resonance phenomena in the corresponding frequency range.

6 CONCLUSIONS

Some indirect tire-pressure monitoring systems (iTPMS) process higher frequent vibrations of the rim and the tire belt which are excited by road irregularities and which are sensitive to the tire inflation pressure. The extended tire model TMeasy 6.0 takes the corresponding vibration modes oft the belt into account and makes it possible to investigate such kind of iTPMS. Just the first two belt eigen-modes have to be considered which keeps the tire model TMeasy as simple as possible. A tailored partly implicit solver, which takes the coupling between the longitudinal force and the belt motions into account, provides a fast and stable numerical solution which is required in real-time applications.

Keywords: Quarter car, Suspension, Optimal seat design, Car-driver model, Genetic algorithm, PID controller.

Abstract. *This paper investigates the optimal active/passive system parameters of a nonlinear quarter car suspension-driver seat model. The mathematical model of the system has four degrees of freedom (4-DoF), with quadratic and cubic stiffness nonlinearities in suspension springs and tires, respectively. The comfort, the stability and the behavior of the suspension system are simulated using Matlab Simulink. Multi-objective genetic algorithms (GA) are used to tune the PID controller and to optimize the head acceleration, the crest factor, and the suspension and tire deflection. The numerical results show that the proposed GA-tuned parameters of the PID controller, as well as GA-tuned design parameters in the quarter car model are more efficient than those of Ziegler-Nicholas and Matlab auto-tuner techniques. The numerical results also demonstrate that active suspension systems are more efficient compared to passive systems.*

1 INTRODUCTION

The main component responsible for the dynamic behavior of a vehicle is its suspension system. The suspension system isolates the vehicle's occupants from strong vibrations induced by road surface irregularities, and enables wheels to maintain contact with the road, which provides the vehicle's stability and control. This paper investigates both passive and active vehicle suspensions. A passive suspension system uses conventional springs and dampers with no feedback action to absorb the road disturbances, while an active suspension system uses force actuator elements in a closed loop control, to provide adequate control force to the system, as a response to the input from the various sensors associated with the vehicle's vertical dynamics. Suspension systems, vehicle handling and stability as well as driver comfort and safety have been extensively studied in the literature. A wide range of global optimization techniques have been investigated to determine the optimum design and control parameters that enhance vehicle stability and passengers' safety. Wael Abbas et al [5] presented a 4-DoF human-body model, with linear seat suspension, for half car model. In this model, the seated human-body was constructed as four separate mass segments interconnected by five sets of springs and dampers, with a total human mass of 60.67 kg. O. Gundogdu [1] solved an optimization problem of a 4-DoF quarter car seat and suspension system model using genetic algorithm, to determine parameters that achieve best comfort. The quarter car and the seat, with the driver's body were modeled as a 4-DoF damped spring-mass system. Du et al [2] presented an integrated vehicle seat and suspension control strategy for a quarter car model, to improve suspension impact on ride comfort. A 4-DoF lumped parameter human model is suggested by Boileau and Rakheja [3]. The selection of the design parameters defines the constitutive relationship for nonlinear stiffness and damping while the 4-DoF driver model is linear. The reported data on biodynamic responses of the seated and standing human body exposed to whole-body vibration along different directions and the associated experimental conditions are reviewed by Rakheja et al. [4], in an attempt to identify datasets that are likely to represent comparable and practical postural and exposure conditions. A 7-DoF vehicle and seat suspension design was presented by Abbas el al. [5]. A genetic algorithm is applied to search for the optimal parameters of the seat, in order to minimize seat suspension deflection, driver's body acceleration, and achieve the best ride comfort. The simulation results were compared with the ones of the passive suspensions, subject to different road profiles. A generalized nonlinear model is formulated by Bouazara et al. [6], for the dynamic analysis of the seat suspension system with passive, semi-active and active dampers. It was concluded that the comfort performance of a seat suspension with semi-active and active dampers was enhanced by 20 to 30%. The spring and damper settings that ensure optimal ride comfort, on different road profiles and at different speeds, have been investigated by Uys et al. [7]. It is found that combining driver and rear passenger's seats weighted root mean square (RMS) and vertical acceleration, as the objective function of the optimization problem returns better results compared to the case when only one seat value is used. Genetic algorithm is employed to search for the parameters, such as damping ratio and springs constants that achieve an optimum trade-off between ride comfort and handling quality, under random road input. Genetic algorithm is also used to obtain the seat suspension system controller parameters. The results showed that an active suspension using genetic algorithm improved the dynamic performance parameters of the seat with minimum actuator force. Baumal et al. [8] also investigated both active control and passive mechanical parameters of a vehicle suspension system, that minimize the passenger's seat acceleration, under the required road-holding ability and suspension working space constraints. An analytical study along with experimental

validation, on lumped parameter models for seated human subjects, without backrest support, under vertical vibration excitation, have been carried out by Liang and Chiang [9]. Kuznetsov et al. [10] investigated a quarter car design, as a 3-DoF seat suspension system, with the driver represented by 1-DoF. Ride comfort criteria as per ISO 2631-1 were used as constraints in the algorithm for global optimization problems. Badran et al. [11] optimized a quarter car system using genetic algorithm. A weighted average of seat acceleration and head acceleration was used as a single objective function, and suspension working space as constraints.

Control of active suspension systems has been extensively covered in the literature, and span a wide range of techniques such as PID, linear quadratic regulator, adaptive sliding control, H control, sliding mode control, fuzzy logic, preview control, optimal control and neural network. However, these methods need refined mechanisms and some are difficult to implement in applications. PID and linear quadratic regulator controllers were investigated by Nagarkar et al [14] to control a nonlinear quarter car along with a human model. The quarter car model includes quadratic tire stiffness and cubic stiffness in suspension springs. The active system gives minimum head acceleration, crest factor, amplitude ratio at head and upper torso, thus providing comfort and meeting health criteria. Mahesh et al [14] ,[13] investigated a multi-objective genetic algorithm to optimize an active nonlinear quarter car suspension system, with PID and fuzzy logic control. Simulation results show that GA-based fuzzy logic and PID controller give better ride comfort.

In this paper a 4-DoF quarter car seat and suspension system model for both passive and active suspension systems subject to an excitation from a road profile is investigated. Genetic algorithm is used to determine the optimal design and control parameters that maximize ride comfort and vehicle stability. Enhanced suspension parameter values are extracted from multiple genetic algorithm runs. Dynamics of the system is simulated using Matlab/Simulink. A PID controller is tuned using Ziegler-Nicholas method to identify parameter boundaries, then tuned again using genetic algorithm, to select the best gains. These values are fed into genetic algorithm to compute enhanced design parameters. Results show an improvement in comfort. Further details will be discussed in the following sections.

2 MODEL DEVELOPMENT

The vehicle model investigated in this paper is an improvement of the linear model in [1]. It is a 4-DoF quarter car model in which the driver is represented by the upper 2-DoF lumped mass system. In this study, both linear and nonlinear models are considered. The quarter car model is set using interconnections of masses, springs and dampers, as illustrated in (Fig. 1), where M_s is the sprung mass, M_u is the un-sprung mass, K_s is the spring stiffness constant, C_s denotes dashpot. Z_r is the road or step input to the tire, Z_s and Z_u are the displacements of masses M_s and M_u respectively. The nonlinearities consist of quadratic and cubic tire stiffness and spring stiffness. The lower springs and damper represent the tire stiffness, with coefficients K_y for linear model and K_{y_1}, K_{y_2} and K_{y_3} for nonlinear model. Similarly C_s is the damping coefficient for linear model and C_{s_1}, C_{s_2} for non-linear model. The un-sprung mass is impacted by the road surface data Z_r through the tires' contact. Elastic properties of the cushion are also modeled as a spring and a dashpot with respective constants of K_c and C_c. The driver is represented by a 2-DoF lumped mass system. The upper body is also connected to the lower part through a spring and a dashpot combination with constants K_t and C_t respectively. The variables Z_t and Z_p are displacements of the thorax and pelvis from their static equilibrium positions [1]. It is assumed that the system does not vibrate in lateral and longitudinal directions, only oscillates in vertical direction (vertical to road surface). Furthermore, the tires are assumed

not losing the contact with the road surface. The motion in other directions is assumed small and hence neglected.

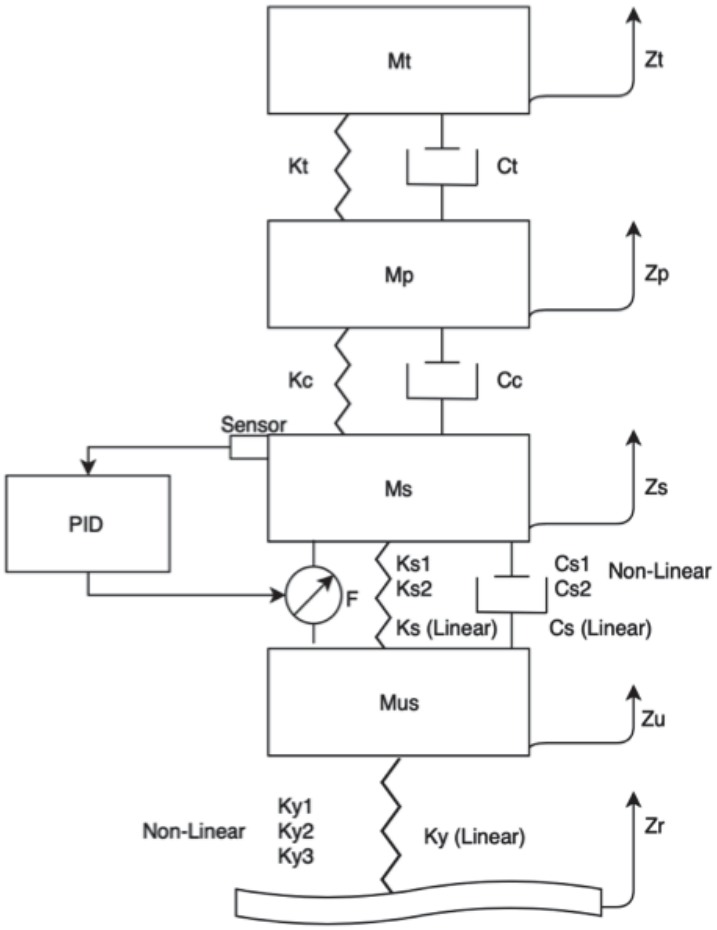

Figure 1: Model Development

The mathematical model of the quarter car model is described by the following set of equations of motions from their static equilibrium positions. The systems are solved for four state variables Z_t, Z_p, Z_s and Z_u given the road excitation Z_r.

Equations of motions for linear model

$$\begin{aligned} M_t Z_t^{''} &= -K_c \,.\, (Z_t - Z_p) - C_t \,.\, (Z_t^{'} - Z_p^{'}) \\ M_p Z_p^{''} &= K_t \,.\, (Z_t - Z_p) + C_t \,.\, (Z_t^{'} - Z_p^{'}) - K_c \,.\, (Z_p - Z_s) - C_c \,.\, (Z_p^{'} - Z_s^{'}) \\ M_s Z_s^{''} &= K_c \,.\, (Z_p - Z_s) + C_c \,.\, (Z_p^{'} - Z_s^{'}) - K_s \,.\, (Z_s - Z_u) - C_s \,.\, (Z_s^{'} - Z_u^{'}) + F \\ M_u Z_u^{''} &= K_s \,.\, (Z_s - Z_u) + C_s \,.\, (Z_s^{'} - Z_u^{'}) - K_y \,.\, (Z_u - Z_r) - F \end{aligned} \tag{1}$$

Equations of motions for non-linear model

$$
\begin{aligned}
M_t Z_t^{''} &= -K_t \,.\, (Z_t - Z_p) - C_t \,.\, (Z_t^{'} - Z_p^{'}) \\
M_p Z_p^{''} &= K_t \,.\, (Z_t - Z_p) + C_c \,.\, (Z_t^{'} - Z_p^{'}) - K_c \,.\, (Z_p - Z_s) - C_c \,.\, (Z_p^{'} - Z_s^{'}) \\
M_s Z_s^{''} &= K_c \,.\, (Z_p - Z_s) + C_c \,.\, (Z_p^{'} - Z_s^{'}) - K_{s_1} \,.\, (Z_s - Z_u) - K_{s_2} \,.\, (Z_s^{'} - Z_u^{'}) \\
&\quad -C_{s_2} \,.\, (Z_s^{'} - Z_u^{'})^2 + F \\
M_u Z_u^{''} &= K_{s_1} \,.\, (Z_s - Z_u) + K_{s_2} \,.\, (Z_s - Z_u)^3 + C_{s_1} \,.\, (Z_s^{'} - Z_u^{'}) + C_{s_2} \,.\, (Z_s^{'} - Z_u^{'})^2 \\
&\quad -K_{y_1} \,.\, (Z_u - Z_r) - K_{y_2} \,.\, (Z_u - Z_r)^2 + K_{y_3} \,.\, (Z_u - Z_r)^3 - F
\end{aligned}
\tag{2}
$$

The above models are simulated in Matlab-Simulink, with the following values for the equations' coefficients:

Suspension Parameter	**Symbol**	**Value**
Linear Spring Stiffness Coefficient	K_{s_1}	15302
Non-Linear Spring Stiffness Coefficient	K_{s_2}	2728
Linear Spring Damping Coefficient	C_{s_1}	3482
Non-Linear Spring Damping Coefficient	C_{s_2}	580
Linear Tire Stiffness Coefficient	K_{y_1}	60063
Non-Linear Square Tire Stiffness Coefficient	K_{y_2}	42509
Non-Linear Cube Tire Stiffness Coefficient	K_{y_3}	22875
Sprung Mass	M_s	295
Un-sprung Mass	M_u	39
Upper Body Mass	M_t	18.6
Lower Body Mass	M_p	46.4
Spring Stiffness Coefficient	K_s	9015
Spring Damping Coefficient	C_s	2031
tire Stiffness Coefficient	K_y	41815
Thorax Stiffness Coefficient	K_t	45005.3
Thorax Damping Coefficient	C_t	1360
Cushion Stiffness Coefficient	K_c	2500
Cushion Damping Coefficient	C_c	131.59

Table 1: Suspension parameters' values

The aim is to analyze the dynamic behavior of the active car-driver system, and determine the seat and the suspension system design parameters (coefficients in the equations of motion above) that maximize rider's comfort. This is done by minimizing the vertical displacements and acceleration of the driver's head and upper body, while maximizing the vehicle's stability and control.

A Proportional, Integral and Derivative PID controller has been used for the active suspension system (Fig.1):

PID controller design

PID control is a feedback control design. The three terms operate on the error signal to produce a control signal. If $u(t)$ is the control signal which is sent to the system, $y(t)$ the actual output, $r(t)$ the desired output, and $e(t)$ the tracking error then a PID control law is expressed as

$$u(t) = k_p\, e(t) + k_i \int_0^t e(\tau)\, d\tau + k_d\, e'(t).$$

The desired closed loop dynamics can be obtained by adjusting the three parameters k_p, k_i and k_d. Model's stability can often be obtained using only the proportional term. The integral term permits the rejection of a step disturbance. The derivative term provides damping or shaping of the response. Both the suspension system design parameters and PID controller parameters were tuned using genetic algorithm, in the next sections.

3 METHODOLOGY AND SIMULATION

3.1 Objective functions

The optimization problem is stated as a multi-objective minimization problem, solved using multi-objective genetic algorithm from Matlab toolbox. The objective function to be minimized **J** is defined as a vector function with four components, head acceleration (J_{HA}), crest factor (J_{CF}), suspension deflection (J_{S}), and tire Deflection (J_{TD}), as follows:

$$\mathbf{J} = \begin{bmatrix} J_{\text{HA}} & J_{\text{CF}} & J_{\text{S}} & J_{\text{TD}} \end{bmatrix}^t \tag{3}$$

The function J_{HA} is the root mean square of head acceleration (RMS_h) , (with $T = 5$ sec, in simulations), given by:

$$J_{\text{HA}} = \text{RMS}_h = \left\{ \frac{1}{T} \int_0^T [Z_t'']^2\, dt \right\}^{\frac{1}{2}} = \left\{ \frac{1}{T} \int_0^T \left[-\frac{k_t}{m_t} (Z_t - Z_p) - \frac{c_t}{m_t} (Z_t' - Z_p') \right]^2 dt \right\}^{\frac{1}{2}}$$

The function CF_h is the crest factor of the head acceleration and it is a ratio of the maximum acceleration to J_{HA}.

$$J_{\text{CF}} = \frac{\max Z_t''}{\text{RMS}_h}$$

The function J_{S} is the RMS value of the suspension deflection.

$$J_{\text{S}} = \left\{ \frac{1}{T} \int_0^T (Z_s - Z_u)^2\, dt \right\}^{\frac{1}{2}}$$

The function J_{TD} is the RMS value of the tire deflection.

$$J_{\text{TD}} = \left\{ \frac{1}{T} \int_0^T (Z_u - Z_r)^2\, dt \right\}^{\frac{1}{2}}$$

3.2 Genetic algorithm for suspension system

Multi-objective genetic algorithm is used to optimize the suspension parameters C_c, K_c, K_s, C_s in the linear model and C_c, K_c, K_{s_1}, K_{s_2}, C_{s_1}, C_{s_2} in the nonlinear model. In simulation,

boundary conditions are imposed on the parameters, as per the industry standards and from the literature. The Genetic algorithm minimizes the objective function given by (3), subject to equations of motion (1), (2), as nonlinear constraints and boundary conditions on the parameters. The genetic algorithm settings were selected as follows: The population size $= 30$, crossover probability, $P_c = 0.001$, and mutation probability rate, $P_m = 0.002$.
Graphs representing the state variables are generated using Simulink. Optimized parameters are given in Table 2 for linear model and Table 3 for nonlinear model.

Suspension Parameters	Symbol	Value
Cushion Damping Coefficient	C_c	128.006
Cushion Stiffness Coefficient	K_c	1414.24
Spring Stiffness Coefficient	K_s	6033.23
Spring Damping Coefficient	C_s	1750.68

Table 2: Optimized parameters (Linear case)

Suspension Parameters	Symbol	Value
Cushion Damping Coefficient	C_c	194.82
Cushion Stiffness Coefficient	K_c	1314.22
Linear Spring Stiffness Coefficient	K_{s_1}	9374.97
Non-Linear Spring Stiffness Coefficient	K_{s_2}	2338.56
Linear Spring Damping Coefficient	C_{s_1}	3459.68
Non-Linear Spring Damping Coefficient	C_{s_2}	700.07

Table 3: Optimized parameters (Nonlinear case)

3.3 Tuning PID control using genetic algorithm

PID controller was designed to ensure the displacement of the system can be controlled and minimized when the road disturbance occurs. PID parameters are randomly initialized and objective functions are determined using Ziegler-Nicholas Method and Auto-Tuner Methods in order to set the bounds for the Genetic Algorithm. GA parameters were chosen according to trial and error method. Genetic algorithm parameters are as follows: Population size $=$ 50; Crossover Fraction $= 0.8$; Mutation rate $= 0.2$; Maximum generation $= 100$; Crossover Function is arithmetic; Mutation Function is Adaptive feasible; Bounds of Parameters From 0 to 5000. In active nonlinear suspension system, the PID tuning was done using genetic algorithm, after linearizing the nonlinear system using Linearization in Simulink.

k_p	k_i	k_d

4 RESULTS and ANALYSIS

In this section, simulation results of different displacements and accelerations are presented in Tables and graphs for both linear and nonlinear models. The resulting head acceleration, head displacement, sprung accelerations and displacements of the system with the optimized parameters, the classical ones and the controlled ones are compared in figures 2-5 for linear model, and in figures 6-9 for nonlinear system. In the simulations, a step height of 0.02 m is used. The color-coded legend is as follows: classical parameters are in blue, optimized parameters are in red, and GA-tuned PID controller in green.

4.1 Linear Model

System	Passive	Optimized	Optimized PID	Variation (Passive-Optimized)	Variation (Passive-PID Optimized)
Settling Time	4.71	4.6	2.32	2.34%	50.1%
Overshoot	0.0254	0.0243	0.024	4.33%	5.51%

Table 6: Results for Sprung Displacement

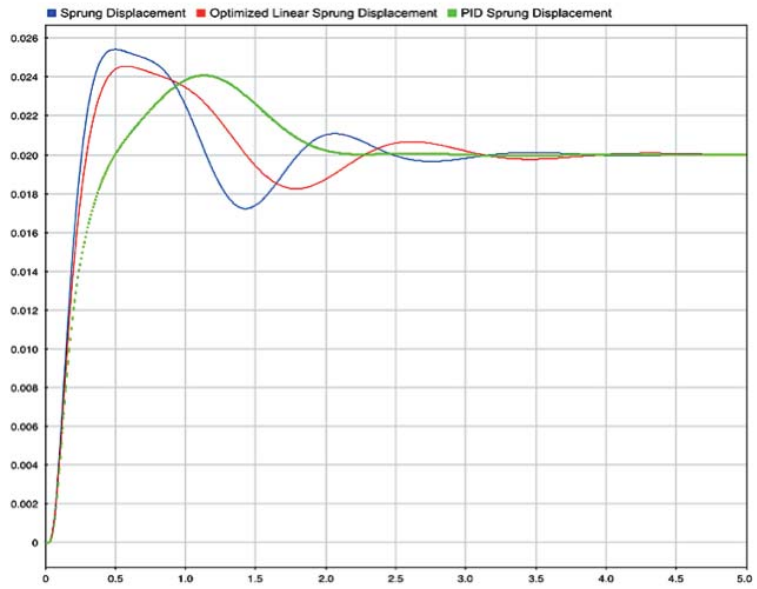

Figure 2: Linear Sprung Displacement

Figure 2 shows the sprung displacement versus time for the passive, optimized-passive and

the active suspension systems. Overshoots and settling times are extracted from the plots to show the variation between the three systems. The response of the passive suspension system is compared with both the optimized-passive and active suspension systems, which shows a variation of 2.34% in settling time values and 4.33% in overshoot values for (Passive-Optimized). While, a variation of 50.1% in settling time values and 5.51% in overshoot values are shown for (Passive-PID Optimized).

System	Passive	Optimized	Optimized PID	Variation (Passive-Optimized)	Variation (Passive-PID Optimized)
Settling Time	5+ (6.1)	4.8	4.5	21.31%	26.22%
Overshoot	0.0388	0.0365	0.0319	5.92%	17.78%

Table 7: Results for Head Displacement

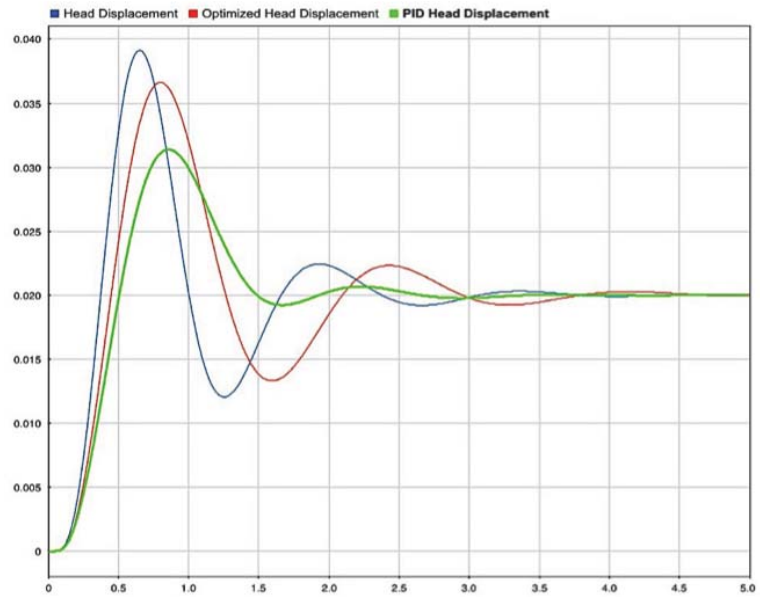

Figure 3: Head Displacement

Figure 3 shows the head displacement versus time for the passive, optimized-passive and the active suspension systems. There is a variation of 21.31% in settling time values and 5.92% in overshoot values for (Passive-Optimized) while a variation of 26.22% in settling time values and 17.78% in overshoot values are shown for (Passive-PID Optimized).

Figure 4 shows the head acceleration versus time for the passive, optimized-passive and the active suspension systems. There is almost no variation in settling time values and 40% in overshoot values for (Passive-Optimized). While, a variation of 14.15% in settling time values and 46.29% in overshoot values are shown for (Passive-PID Optimized).

Figure 5 shows the linear sprung acceleration vs time for the passive, optimized-passive and the active suspension systems. There is a variation of 13.57% in settling time values and

System	Passive	Optimized	Optimized PID	Variation (Passive-Optimized)	Variation (Passive-PID Optimized)
Settling Time	4.31	4.32	3.7	0%	14.15%
Overshoot	0.54	0.324	0.29	40%	46.29%

5 CONCLUSIONS

In this paper, a nonlinear quarter car model with a driver seat and driver, as a 4-DoF system with PID controller is investigated and compared with the passive linear system version. The model is designed to have four masses that are attached with linear and nonlinear springs and dampers. The methodology was developed to design and compare passive and active suspension systems using a classical PID controller and GA-tuned PID controller. Genetic algorithm is used to determine optimum values for the suspension design parameters and PID controller, to achieve the best performance of the system in terms of driver's comfort and vehicle's stabil-

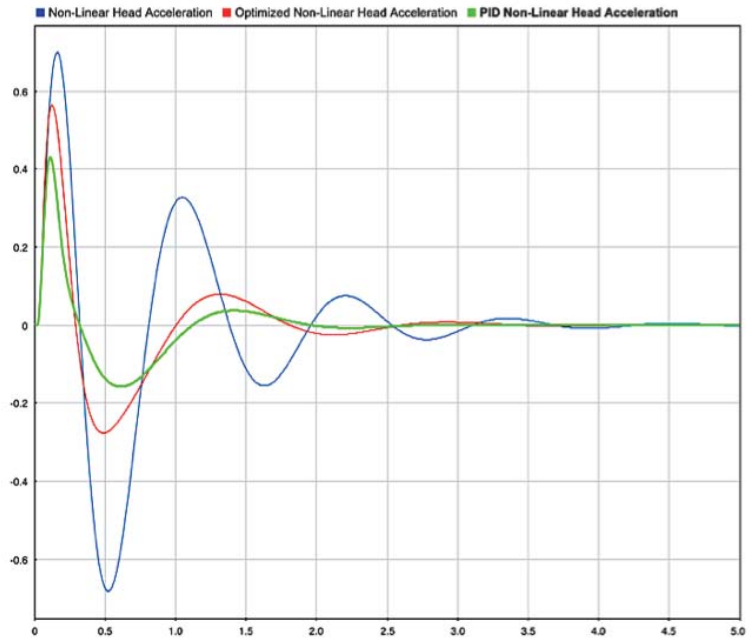

Figure 9: non-linear head acceleration

ity. Genetic algorithms showed optimum results. The optimal solutions are less oscillatory and have lower values of maximum overshoots and settling times, which results in lower HA and CF, that are directly proportional to the driver's health and comfort. Both linear and non-linear active suspension models with PID Controller were tuned by using different methods of tuning such as GA, Ziegler-Nicholas Method, and the Auto Tuner in Matlab-Simulink Toolbox. Simulation results show that implementing a GA-tuned PID controller gives better ride comfort and health criterion. The study shows a significant improvement for the active suspension system compared to the passive suspension system.

Keywords- Half-Car Model, Active Driver-Seat, Ground Hook Control

Abstract- *This paper investigates the worthiness of implementing an active PID control on the driver seat alongside with semi-active ground-hook control on the suspension system in order to compensate the down side of the ground-hook control in terms of driving comfort. The suspension - driver seat model is derived using half car model with five degrees of freedom and Matlab Simulink is utilized to simulate the Active/Semi-active stability and comfort of the different proposed setups of the suspension system. Binary and continuous ground-hook control are attempted separately while the optimum combination between them is presented using the Matlab optimization toolbox. Finally, it was deduced that implementing semi-active controlled car seat doesn't provide any significant improvement, in terms of comfort, when combined with semi-active controlled suspension system. It is also found that implementing an active controlled car seat could significantly restore or even improve the deteriorated comfort caused by ground hook controlled suspension while maintaining its superior performance in terms of stability.*

1. INTRODUCTION

The dynamic behavior of a car can be evaluated in many different ways; one of which, is its suspension system behavior. The main components of a conventional suspension system are springs, shock absorbers (or dampers), control arm, steering knuckle, ball joints and control arm brushing. The interest of the current study is to focus on the role of the springs and dampers, in the suspension system which absorbs the noise and shock, induced by the road irregularities or bumps, and isolates the wheel-suspension assembly from the rest of the vehicle. Drivers are usually subjective in judging their vehicles and their evaluation is manly dominated by the vehicle dynamic characteristics including ride and handling. Therefore, the vehicle's subjective evaluation originates from its perceived comfort level and ride stability which are considered two of the most important performance features. The design process of a conventional suspension system boils down to a tradeoff between ride comfort and vehicle handling which are conflicting processes in nature. When suspension system is designed to optimize the handling and stability of the vehicle, the passenger often perceives the ride to be rough and uncomfortable. On the other hand, when it is designed to optimize the comfort level, the vehicle is less stable during maneuvers. Car manufacturers always strive to design suspension systems of acceptable level of both stability and comfort.

Various chassis control systems have been developed, to enhance vehicle dynamic performance and driving safety. Vehicle dynamics are characterized by three motions, namely roll, pitch, and yaw, which are strongly coupled and thus affect the vehicle dynamics and control in a very complex manner. Skreekar [1] worked on reducing the vibrations transmitted to the passenger in order to improve the ride comfort. An experimental design was used to obtain the modeling equations and a genetic algorithm was then introduced to optimize the model's parameters. Crolla [2] presented a comprehensive review of vehicle dynamics theories and their contributions to practical vehicle design. In particular, the review focused on actively controlled components, like active suspension and four wheel steering and their impact on vehicle performance and safety. Rauh [3] introduced the recent advances in simulation technologies, explaining their available potentials and limitations. It was highlighted that advanced simulation technologies enabled the development of complex mechatronic chassis systems, like active suspensions, in relatively short periods of time. Gordon [4] provided a new dual model methodology of steering, throttle and braking near-optimal control inputs to simulate the closed-loop linear and nonlinear vehicle handling dynamics. Tener [5] introduced a cockpit adjustable air suspension system to either improve handling or to increase ground clearance. In addition, the spring rate can be either decreased to enhance isolation or increased to promote handling performance. Zhang [6] used a linear switched reluctance actuator (LSRA) in his active suspension and took into consideration multiple force dependent variables like the force ripple minimization and adaptive force distribution function. Funde [7] implemented sky-hook semi active control which helped increase the comfort and reduce the suspension working space and implemented ground-hook control which increased the stability on a quarter car. Darus [8] developed a mathematical model to simulate the passive and active suspension systems using full car model. A linear quadratic control technique is selected to represent the active suspension system. Florin et al. [9] utilized a quarter car model, of two degrees of freedom, to simulate the handling and ride performance of a vehicle with passive suspension system. A scheme, using Matlab Simulink, was developed and was compared to the state space model. Hassan and Mohammed [10] developed a mathematical model, using Lagrange's equation, for a full vehicle

dynamic system of ten degrees of freedom. Vassal et.al [11] Introduced design stability requirement that have been used as guidelines in this paper. Sammier et.al [12] compared between H-infinity and skyhook control for semi-active suspension systems, H-infinity performed better than the skyhook control but skyhook control required less parameters and was easier to implement. Geweda [13] also used the genetic algorithm on a seven degrees on freedom system and compared his results to the PID controlled model.
The current work implements a different combinations of active/semi-active controls, applied to the sprung mass and the driver seat, in attempt to promote comfort without compromising the stability.

2. Formulation

In the current study, a half-car model with car seat is implemented using five degrees of freedom. These degrees of freedom are represented as two unsprung mass vertical displacement, sprung mass vertical displacement, pitching rotation and driver-seat displacement. Figure 1 presents a schematic for the implemented model.

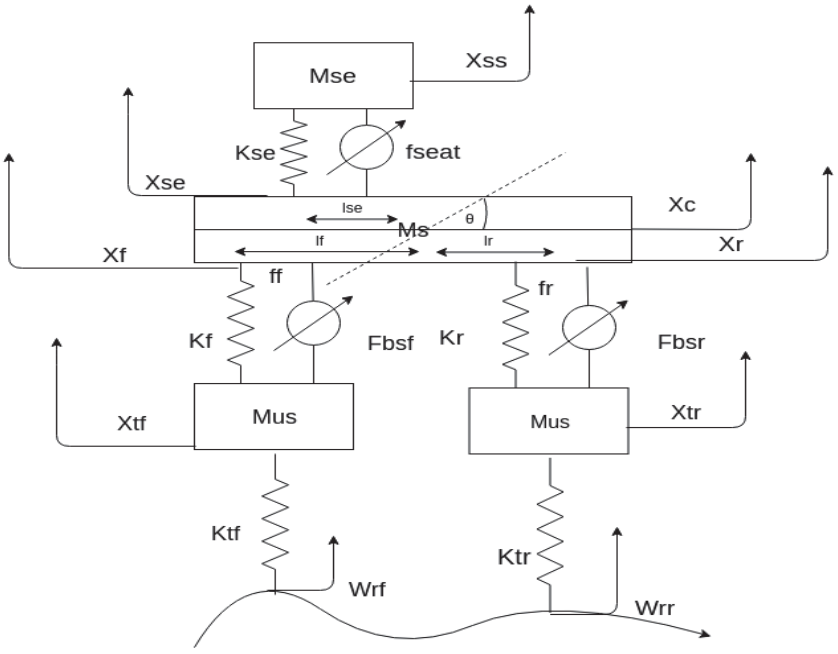

Figure 1: Half-car Model Schematic

Parameter	Symbol
Spring force	F_{ksi}
Damper force	F_{bsi}
Force quarter car	f_i
Sprung mass	M_{se}
Sprung mass moment of inertia	I_{se}
Unsprung mass front and rear	M_{us}
Stiffness tire front and rear	K_{tf} , K_{tr}
Stiffness spring front	K_f
Stiffness spring rear	K_r
Stiffness spring seat	K_{se}
Passive damping front	F_{bsf}
Passive damping rear	F_{bsr}
Passive damping seat	F_{seat}
Semi-active damper	$C_{(I)}$
Length between sprung mass center of mass and front	L_f
Length between sprung mass center of mass and rear	L_r
Length between sprung mass center of mass and car seat	L_{se}

Table 1: Car parameters abbreviation i ∈ {f,r}.

The current model was built as two independent quarter car models which were coupled together to simulate the dynamic behavior of a half-car. The following equations represent the modelling equations used in Matlab. For i ∈ {f,r}

Quarter car force:

$$f_i = F_{ksi} + F_{bsi} \tag{1}$$

Tire spring force:

$$F_{kti} = K_{ti} \times [x_{ti} - w_i] \tag{2}$$

Tire damping force:

Passive damper: $$F_{bti} = C_{ti} \times [\dot{x}_{ti} - \dot{w}_i] \tag{3}$$

Sprung mass spring force:

$$F_{\mathrm{ki}}=\mathrm{K}_i \times [x_{\mathrm{ti}} - x_i] \tag{4}$$

Sprung damping force:

Passive damper: $$F_{\mathrm{bsi}}=\mathrm{C}_i \times [\dot{x}_{\mathrm{ti}} - \dot{x}_i] \tag{5}$$

Semi-active damper: $$F_{\mathrm{bsi}}=\mathrm{C}(I)_i \times [\dot{x}_{\mathrm{ti}} - \dot{x}_i] \tag{6}$$

Active PID actuator: $$F_{\mathrm{bsi}}=\mathrm{k}_p \mathrm{e(t)}+\mathrm{k}_i \int \mathrm{e(t)}\,\mathrm{dt}+\mathrm{k}_d \frac{\mathrm{de(t)}}{\mathrm{dt}} \tag{7}$$

Car seat force:

$$f_{\mathrm{seat}} = (x_{\mathrm{ss}} - x_{\mathrm{se}}) \times K_{\mathrm{se}} + (\dot{x}_{\mathrm{ss}} - \dot{x}_{\mathrm{se}}) \times C_{\mathrm{se}} \tag{8}$$

Half car coupling equations:

$$x_f=\mathrm{x}_c - l_f \sin(\theta) \tag{9}$$

$$\dot{x}_f = \dot{x}_c - l_f \dot{\theta} \cos(\theta) \tag{10}$$

$$x_r=\mathrm{x}_c+\mathrm{l}_r \sin(\theta) \tag{11}$$

$$\dot{x}_r = \dot{x}_c+\mathrm{l}_r \dot{\theta} \cos(\theta) \tag{12}$$

$$x_{\mathrm{se}}=\mathrm{x}_C - l_{\mathrm{se}} \sin(\theta) \tag{13}$$

$$\dot{x}_{\mathrm{se}} = \dot{x}_C - l_{\mathrm{se}} \dot{\theta} \cos(\theta) \tag{14}$$

Three control methods were used to improve the passive performance of the suspension system, namely Sky-hook control, Ground-hook control as a semi-active technique, and PID active control. The Ground-hook is a control method that hooks the tires of the car to the ground to add more stability that is achieved by adjusting the damping coefficient.
Ground-hook semi-active control is given as follows:

$$C(i) = \begin{cases} C_{min}, & -\dot{x}_{ti}\dot{x}_{def} \le 0 \\ C_{max}, & -\dot{x}_{ti}\dot{x}_{def} > 0 \end{cases} \quad \text{for } i \in \{\mathrm{f,r}\}. \tag{15}$$

The second control type used is PID active control. This control was used due to the limitations of the semi-active suspension system. When semi-active suspension was implemented and didn't provide good results, active PID control was implemented as it can deliver pure force output on demand and it isn't constrained by states of the system (displacement, velocity, and acceleration). It is true that the active actuator consumes higher energy to provide such forces but when the control is applied only on one seat, we can safely assume lower energy consumption compared to fully active suspension system.

3. RESULTS AND DISCUSSION

Table.2 presents the car parameters used in the simulations as acquired from [14].

Parameter	Value
Sprung Mass (M_{se})	580 Kg
Sprung mass moment of inertia (I_{se})	1100 Kg.m^2
Unsprung Mass front and rear (M_{us})	40 Kg
Stiffness tire front and rear (K_{tf},K_{tr})	190 kN/m
Stiffness spring front (K_f)	23500
Stiffness spring rear (K_r)	23500
Stiffness spring seat (K_{se})	15 kN/m
Passive damping front (F_{bsf})	1500 N/m.s
Passive damping rear (F_{bsr})	1500 N/m.s
Passive damping seat (F_{seat})	500 N/m.s
Semi-active damper ($C_{(I)}$)	$C_{(I)} \in$ [900,3000]N/m.s
Length between sprung mass center of mass and front (L_f)	1 m
Length between sprung mass center of mass and rear (L_r)	1.5 m
Length between sprung mass center of mass and car seat (L_{se})	0.5 m

Table 2: Suspension system parameters.

In the following sections, several control configurations in suspension systems will be presented and compared to the passive system performance, in an attempt to analyze the improvement in terms of stability and comfort.

3.1 Passive car seat and semi-active ground-hooked car suspension

This section analyzes the semi-active ground-hook control (GH) suspension system performance compared to the passive suspension system performance. In the following, the two systems are denoted by “GH-Passive System” and “Passive system” in Figure 2. GH-Passive system stands for the system as described in Figure 1, with GH controlled applied to the unsprung mass while both the seat and the sprung mass are represented using a passive system. The other system denoted by Passive System stands for the system without any control applied to it.

Figure 2 presents the car seat and sprung mass displacements and accelerations and car tire displacement graphs in response to a step input of 0.05 meter, car speed is 60km/h. Step input was chosen as it excites multiple frequencies in the system, thus gives a complete picture of the system. The seat acceleration, depicted in Figure 2. (A), shows higher peak acceleration of the car seat in GH-Passive system compared to passive system due to the presence of GH controller on the unsprung mass.

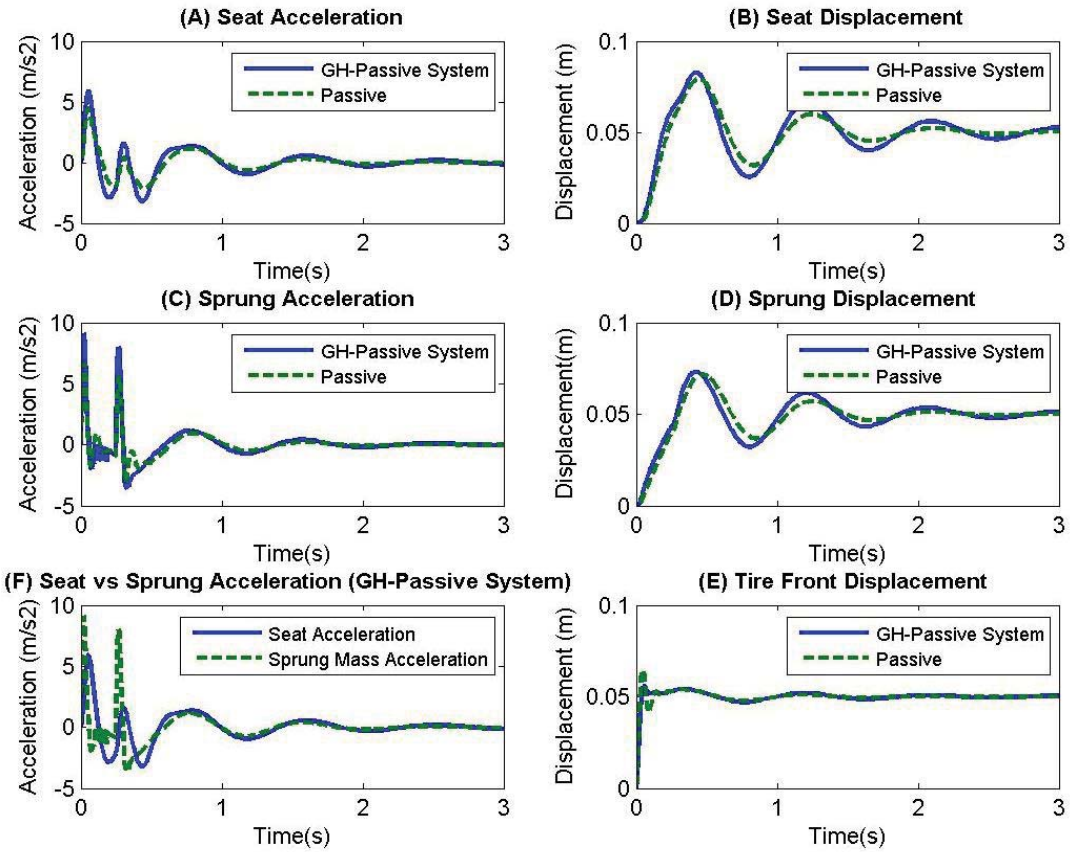

Figure 2: Ground Hook suspension/ Passive Seat.

The front tire displacement, depicted in Figure 2. (E), shows a 62.5% improvement in the overshoot value and a 47.5% less settling time compared to the passive system, note that the system starts oscillating again at 0.25s as this is the time when the back wheel hits the step input. The sprung acceleration, depicted in Figure 2. (C), shows higher peak and higher RMS acceleration in the GH system relative to the passive system. Figure 2. (F) shows that the implementation of a passive system on the car seat improves the comfort with 45% lower peek than the one of the sprung mass acceleration, and an improvement of 15% in the RMS value with respect to the sprung mass.

The implementation of GH-Passive system gives a seat RMS acceleration of 0.608, and a sprung mass RMS acceleration of 0.72. The passive system seat RMS acceleration is 0.49 and the passive

system Sprung mass RMS acceleration is 0.45. The values presented in this section will be used as a reference to compare to, in the following sections, where other combinations of different controls are applied.

3.2 Semi-active Ground-hook binary suspension and Sky-Hook Controlled seat

This section present the dynamic behavior of Sky-hooked seat (SH) alongside with the ground-hook control compared to the performance of the passive system. Figure 3 presents the car seat and sprung mass displacements and accelerations and car tire displacement, in response to a step input of 0.05 meter, car speed is 60km/h. Figure 3. (A) shows higher peak acceleration than the passive system, while Figure 3. (C) shows performance similar to that of Figure 2. (C). Figure 3. (F) shows a decline in performance as the improvement of seat peak acceleration in the first peak was reduced to 25.3% only relative to 45% in the passive system.

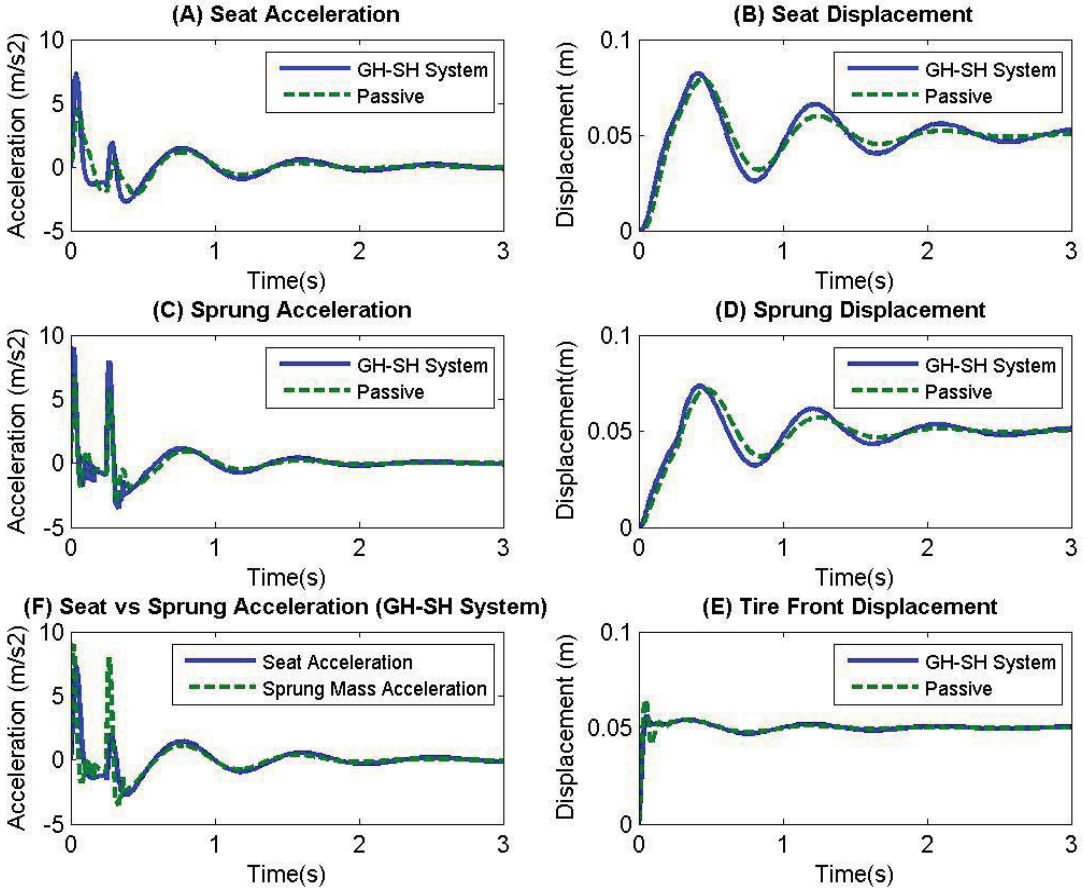

Figure 3: Ground Hook suspension/ Passive Seat.

This system resulted in seat RMS acceleration of 0.607 and sprung mass RMS acceleration of

0.6805. The RMS accelerations and the performance of the sky-hooked seat doesn't encourage the usage of a SH seat when GH is implemented and suggests that the implementation of a passive system on the car seat would be enough.

3.3 Semi-active Ground-hook binary suspension and active PID Controlled seat

In the following, the response of a system denoted by "GH-PID System" is depicted in Figure 3, which stands for GH controlled unsprung mass while a PID control is applied to the driver seat. This system is compared to the Passive System. PID controller parameters were optimized to minimize the following error expressed in terms of sprung mass displacement ant seat acceleration:

$$e(t) = \ddot{x}_{se} + (x_{ss} - x_{se}) \quad (16)$$

The auto-tuner of the PID controller in Matlab resulted in an integral controller without any proportional nor differential parameters, as shown in Table 3: PID controller parameters.

It is suggested to use a conditional parameter so that the deflection doesn't cross a certain value but that wasn't implemented here.

Parameter	Value
Kp	0
Ki	3124.23
Kd	0

Table 3: PID controller parameters.

Figure 4 presents the car seat and sprung mass displacements and accelerations in addition to car tire displacement in response to a step input of 0.05 meter and a vehicle speed of 60km/h.
The car seat acceleration Figure 4. (A) shows an improvement of 70% relative to the passive system seat. The car seat displacement of graph Figure 4. (B) shows a better displacement graph on the active seat compared to the passive seat. Figure 4. (F) shows the accelerations of both the sprung mass and the car seat, in which car seat acceleration is found to be smoother and with a lower peak; while the peak acceleration of the sprung mass is 8.6 m/s^2 while the one of the car seat is 1.86 m/s^2, this is an improvement in peak accelerations of 78.37%. This indicates that the active system managed to suppress most of the acceleration peaks applied to the sprung mass.

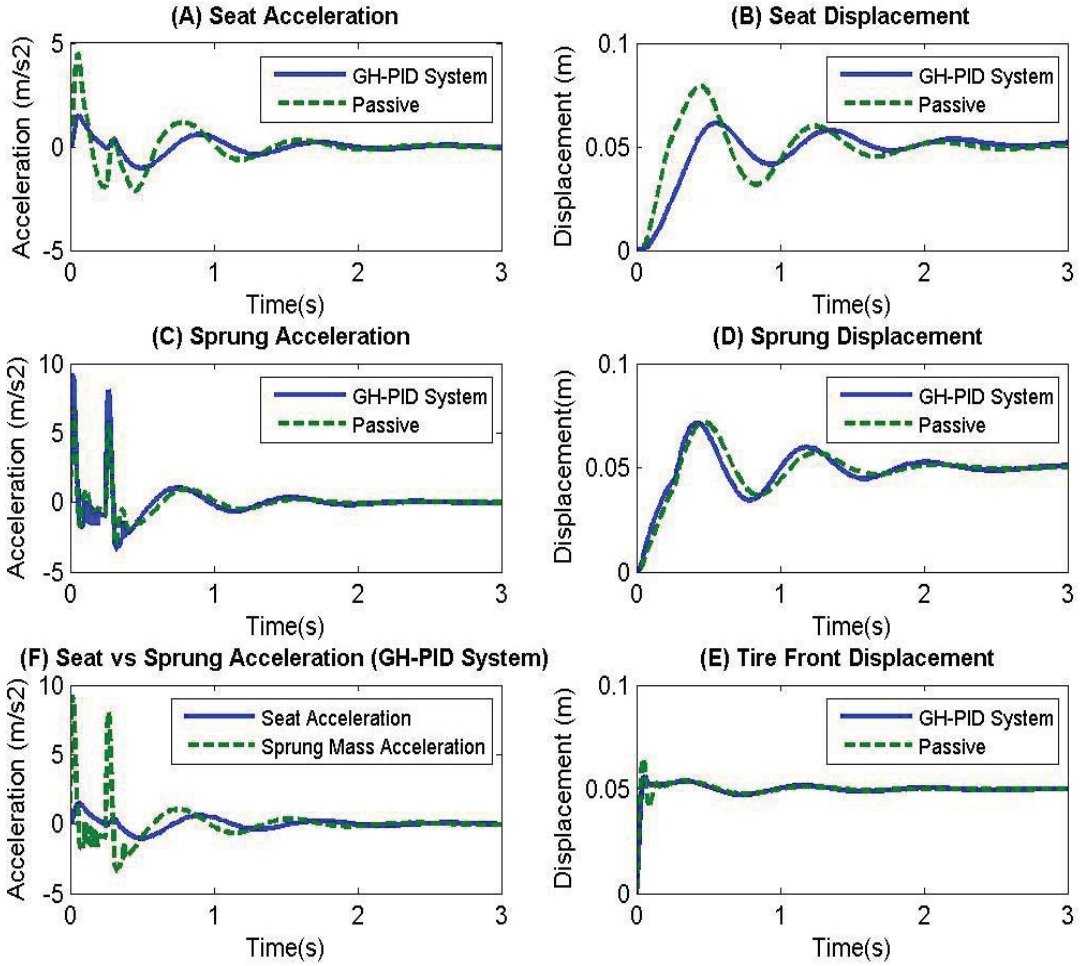

Figure 4: GH Suspension system/Active PID seat

The tire displacement shown in Figure 4. (E) is found to be similar to the tire displacement of the GH-Passive system displayed in Figure 2. (E), which means that the active seat didn't adversely affect the Ground-hook performance. Therefore, the stability using the ground-hook control was maintained while providing much better comfort performance using the active control seat. This setup resulted in a seat RMS acceleration of 0.26 and sprung RMS acceleration of 0.608, which reflects an improvement of 54.3% using the setup of active seat and semi-active ground-hook suspension system over the semi-active ground-hook suspension and passive seat setup. This is a good improvement considering that the active seat will use much less power to achieve such comfort, relative to applying PID control on the whole system. The semi-active GH system also uses very low power achieving both low power consumption and high comfort and stability performance. Both of Figure 4. (A) and Figure 4. (B) show smoother and lower peaks in displacement and acceleration respectively in the implemented hybrid system.

3.4 Semi-active Ground-hook continuous suspension and active PID Controlled seat

An attempt to improve the GH-PID binary system was to implement a GH-PID continuous system to improve the system performance and to check the overall effect of the GH continuous system.

$$C(I) = \begin{cases} C_{min}, & -\dot{x}_{ti}\dot{x}_{def} \leq 0 \\ \dfrac{\propto * C_{max} * (\dot{X}\imath - X\dot{r}\imath) + (1-\propto)Cmax * \dot{W}r\imath}{(\dot{X}\imath - X\dot{r}\imath)}, & -\dot{x}_{ti}\dot{x}_{def} > 0 \end{cases} \quad (17)$$

The factor $\propto$ determines the percentage of continuous system versus the percentage of the binary system. When $\propto = 1$ the system is reduced to a binary system and when $\propto = 0$ the system is continuous only. Genetic algorithm was implemented to find the optimum value for the parameter $\propto$ that minimizes the seat RMS acceleration and the tire max displacement. The optimum value obtained using genetic algorithm is $\propto = 0.75$.

Figure 5 presents the car seat and sprung mass displacements and accelerations and car tire displacement graphs response to a step input of 0.05 meter (5 cm), car speed is 60km/h.

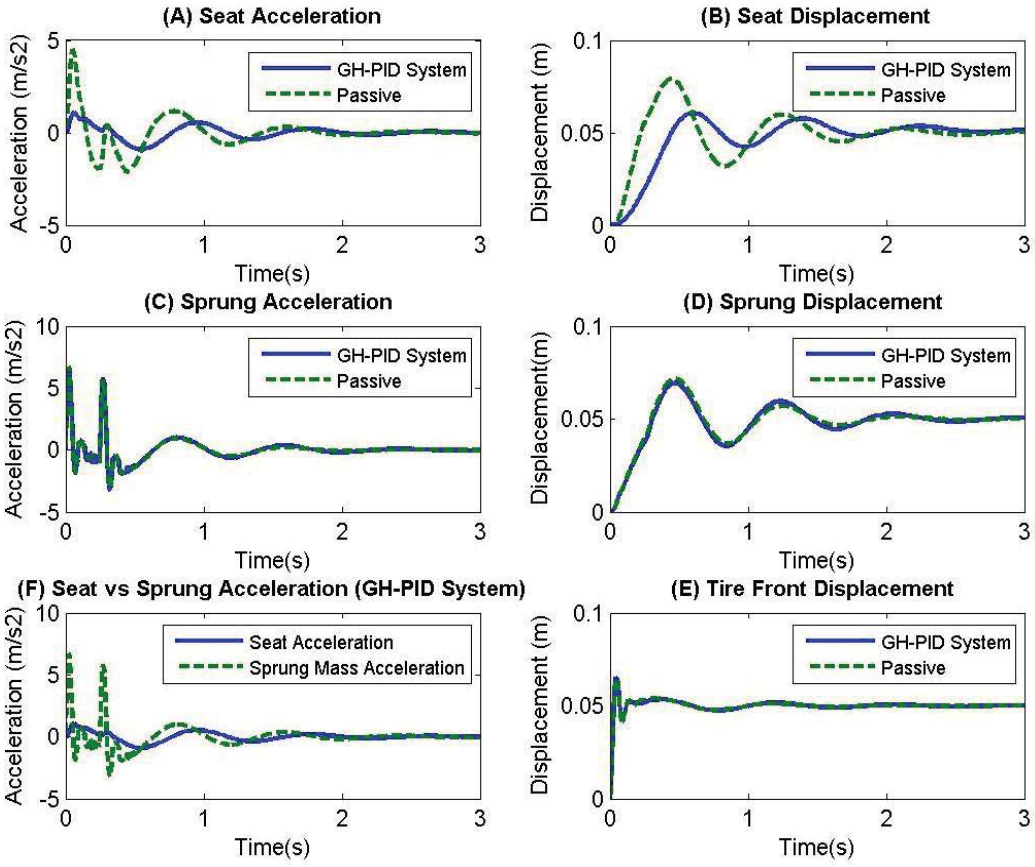

Figure 5: Continuous GH Suspension / Active PID Seat.

As shown in Figure 5. (A), the peak acceleration improved 7% compared to the GH-PID binary system presented in Figure 4. (A) and the seat displacement in Figure 5. (B) is slightly better than the seat displacement shown in Figure 4. (B). However Figure 5. (E) shows that the stability is reduced compared to that of the passive system. In addition, the performance displayed in Figure 5. (C, D) are almost identical to those of the passive system. The seat RMS acceleration is 0.24 and the sprung RMS acceleration is 0.5. The RMS acceleration was reduced, but this came at the cost of losing the improvement of the stability previously achieved in the GH binary system.

4. Conclusion

This paper investigated the worthiness of implementing an active PID control on the driver seat alongside with semi-active ground-hook control on the suspension system in order to compensate the downside of the ground-hook control in terms of driving comfort. The suspension driver seat model was derived using half car model with five degrees of freedom and Matlab Simulink is utilized to simulate the Active/Semi-active stability and comfort of the different proposed setups of the suspension system. It was found that applying semi-active ground hook control could significantly promote vehicle stability on the expense of deteriorated riding comfort. The implementation of sky-hook control of the driver-seat alongside with ground-hook control was investigated in an attempt to compensate the loss of comfort, but this type of control was of no added value. However, active PID control, when implemented in the driver-seat model has successfully fixed the downside of the ground-hook control and this set up has noticeable enhancement in both of stability and comfort.

Keywords: Autonomous car, Collision avoidance, Optimal feedback control, Nonlinear control

Abstract. *This paper presents self-driving control experiments applied to a standard vehicle equipped with an autonomous driving kit. The Auto Sapiens project is an experimental platform to test different control strategies and develop new obstacle avoidance algorithms. The Smart Fortwo vehicle is equipped with steering, thrust and brake actuators, and proprioceptive and exteroceptive sensors to identify both real-time vehicle attitude and obstacles on the track. The vehicle is controlled by a hardware in the loop system, in which innovative nonlinear control logics, called Feedback Local Optimality Principle FLOP, are implemented to achieve high performance in maintaining the stability of the vehicle during avoidance abrupt maneuvers. Tests were carried out through an ad-hoc vehicle-to-vehicle (V2V) communication system to share location, speed, heading and size information between the obstacle and the controlled vehicle. Eventually, a performance analysis of the system is made in terms of crash probability.*

1 INTRODUCTION

One of the interesting tasks of control theories is to develop new strategies devoted to the vehicle control in complex scenarios. The present investigation is in the context of safe autonomous driving in presence of obstacles [1-4]. The Society of Automotive Engineers – SAE defined different levels of automation in self-driving vehicles [5], describing systems ranging from an auxiliary assistance to the driving operations, up to a complete exclusion of the human driver. This paper is devoted to the development of level 3-4 automated driving systems, in which even if the driver is careless or absent-minded, the vehicle manages to avoid obstacles. The achievement of this goal needs to overcome several intrinsic problems, such as the management of high-speed maneuvers, which requires nonlinearities in the vehicle's model, and fast response control logics.

The standard predictive controls are one the most used strategies in the field of autonomous driving. Despite the many advantages of being able to include nonlinearities, of using general forms for constraints and cost functions, they have as negative counterpart a high computational cost, not feasible for many online processing [6], unless explicit laws [7-9] and fast approximated optimization algorithms [10] are introduced.

A new control strategy, based on the optimal control theory, is under the name of *Feedback Local Optimality Principle – FLOP*. The great advantage of this algorithm relies on its capabilities of dealing with strong nonlinearity that are the cases to which the LQR does not apply. FLOP allows feedback control laws, under general cost function, at low computational cost [11-13]. As a further result, FLOP is able to deal with obstacle avoidance strategies, as the ones developed by the authors based on the Velocity Obstacle approach [14, 15], further improved for including environmental constraints, such as the road boundaries for lane keeping. The enhanced performances achieved through FLOP control logic are demonstrated, for instance, in terms of ability to handle different and simultaneous tasks, thanks to a proper choice of a nonlinear cost function [12] and in terms of identification of a more effective optimal trajectory, obtained via a nonlinear dynamic model [11].

Auto-Sapiens is an experimental platform of the Mechatronics and Vehicle Dynamics Lab of Sapienza University of Rome, a car equipped with exteroceptive and proprioceptive sensors, steering wheel, throttle and braking actuators. Results show the avoidance maneuver performed under high-speed conditions against a virtual obstacle.

After a brief presentation of the FLOP control logic, and the related nonlinear vehicle models, Section 2 shows how to implement lane keeping and obstacle avoidance. The Auto-Sapiens platform described in Section 3 is detailed and tested is Section 4. Eventually, in Section 5, the conclusions are drawn.

2 AUTO-SAPIENS CONTROL SYSTEM

The Auto-Sapiens driving system consists of two nested control blocks. The first is the main trajectory planner to maintain or change lanes or avoid potential obstacles, compatibly with the free space available. The second is the actuators management controller, which manages the thermal engine, braking and acceleration operations to achieve the trajectory objectives stated by the planner block. The general scheme is in Figure 1 where, after the identification of the vehicle state through sensors and environmental identification, the guidance control returns a control vector in terms of desired wheel torque and steering angle. Traction and braking control The torque of the wheels is processed by the traction and braking control. If an increase of the engine torque is required, the control reads the engine speed and the gear engaged and computes the equivalent percentage of the accelerator and/or shifting to lower gears. In case of a braking

torque, the braking control comes into play. Eventually, the steering angle transforms into a wheel steering angle, according to the linear relations resulting from the kinematic steering linkage (rack and pinion steering).

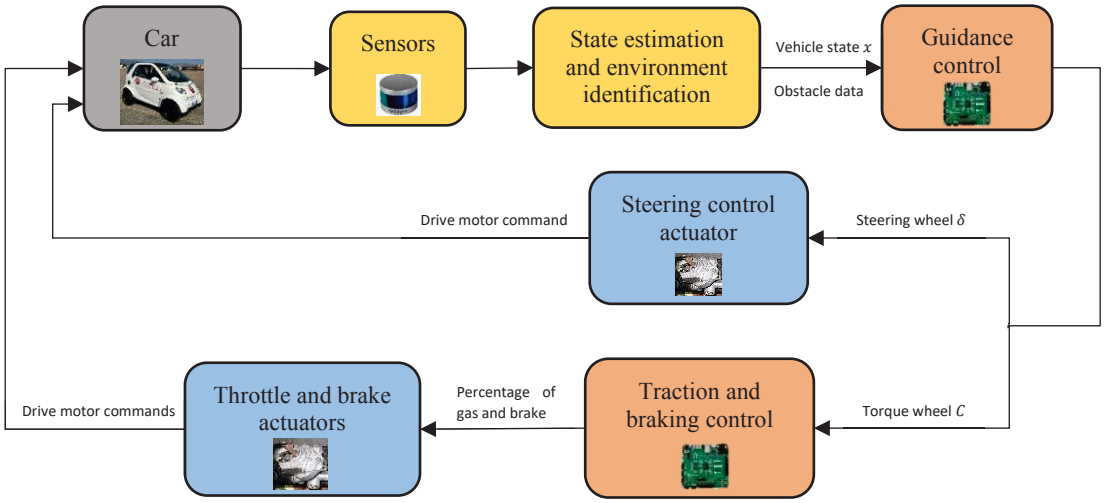

Figure 1: Auto-Sapiens control system scheme.

The control algorithms driving the guidance and traction-braking control are part of a recently developed method by the authors, called Feedback Local Optimality Principle, FLOP [11-16]. FLOP uses the classical variational approach, based on minimization of a performance index J under nonlinear constraints. Unlike excellent predictive controllers, often used to drive autonomous vehicles, the FLOP is a purely feedback control that, by incorporating nonlinear constraints and assigning custom objective functions, works in real-time at low computational costs compared to predictive controls.

The FLOP is aimed at minimizing J, a functional depending on the function $E(\boldsymbol{x},\boldsymbol{u})$, that is non-quadratic in the state variable $\boldsymbol{x}$ and quadratic in the control variable $\boldsymbol{u}$, subjected to an affine differential equation, a constraint introduced into the functional by using the Lagrangian multiplier $\boldsymbol{\lambda}$:

$$J = \int_0^T E(\boldsymbol{x},\boldsymbol{u}) + \boldsymbol{\lambda}^T\left(\dot{\boldsymbol{x}} - (\boldsymbol{\phi}(\boldsymbol{x}) + \boldsymbol{B}\boldsymbol{u})\right) dt \qquad (1)$$

$$E(\boldsymbol{x},\boldsymbol{u}) = \frac{1}{2}\boldsymbol{u}^T\boldsymbol{R}\boldsymbol{u} + g(\boldsymbol{x})$$

where $g(\boldsymbol{x})$ is any differentiable function, $\boldsymbol{\phi}(\boldsymbol{x})$ is a generic nonlinear function, $\boldsymbol{B}$ depends on the available actuators, and $\boldsymbol{R}$ is a tuning matrix. The FLOP decomposes integral (1) into $N = T/\Delta h$ sub-integrals, where Δh is the time horizon of each integral:

$$J \approx \sum_{i=1}^{N} J_i = \sum_{i=1}^{N} \int_{LB_i}^{UB_i} E(\boldsymbol{x},\boldsymbol{u}) + \boldsymbol{\lambda}^T\left(\dot{\boldsymbol{x}} - (\boldsymbol{\phi}(\boldsymbol{x}) + \boldsymbol{B}\boldsymbol{u})\right) dt \qquad (2)$$

$$\min(J_i)\ \forall\ i$$

where UB_i and LB_i limits are the upper bound and lower bound for each time interval, respectively. Moreover, for each integral, the transversality conditions hold:

$$\boldsymbol{x}_{LB_i} = \boldsymbol{x}_{UB_{i-1}} \quad ; \quad \boldsymbol{\lambda}_{UB_i} = \boldsymbol{0} \tag{3}$$

Applying the optimality principle through a finite difference technique with a time step equal to the integration step Δh, leads to the explicit control law [13]:

$$\boldsymbol{u}_{LB_i} = \boldsymbol{R}^{-T}\boldsymbol{B}^T \left[\nabla_{\boldsymbol{x}}\boldsymbol{\phi}^T|_{LB_i} - \frac{1}{\Delta h}\boldsymbol{I}\right]^{-1} \nabla_{\boldsymbol{x}} g|_{LB_i} \tag{4}$$

where $\boldsymbol{I}$ is the identity matrix. Equation (4) represents the basis of the two driving system controllers, described in detail below.

2.1 Guidance control system

Driving safely through the road traffic requires two main capabilities: being able to identify a feasible trajectory to reach a given target, and avoid any obstacle during the motion. The guidance control system, illustrated in Figure 2, consists of a decision-making logic that, analyzing external information such as lanes and obstacle position, proprioceptive data, defines a target trajectory $\boldsymbol{x}_t$ and the penalty function $g(\boldsymbol{x})$.

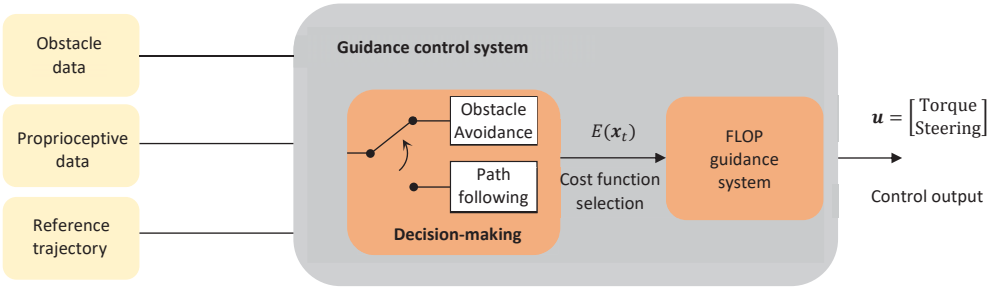

Figure 2: Auto-Sapiens guidance control system.

When detecting an obstacle, the system introduces the penalty function $g_{Obst}(\psi, \omega, V)$ to avoid the crash. For example:

$$g_{Obst}(\psi, \omega, V) = \frac{1}{2}k_1(\psi - \psi_t)^2 + \frac{1}{2}k_2\omega^2 + \frac{1}{2}k_3(V - V_t)^2 \tag{5}$$

The penalty function drives the speed of the vehicle, in terms of the its modulus V and direction ψ towards the target vector $P_t(\psi_t, V_t)$ using the penalty terms $\frac{1}{2}k_1(\psi - \psi_t)^2 + \frac{1}{2}k_3(V - V_t)^2$. They allow the safest avoidance maneuver in term of distance between the obstacle and the road boundaries (see Figure 3, a). The heading rate ω, through the penalty term $\frac{1}{2}k_2\omega^2$, slows down the steering wheel maneuvers, and the $k_i s$ are tuning parameters.

The strategy uses the Velocity Obstacle approach [14, 15], identifying a set of safe (green) and unsafe regions (red) in the velocity field.

Instead, if the road is obstacle-free, assuming a pre-assigned lane, the algorithm uses the penalty function g_{Path} (Figure 3, b):

$$g_{Path}(\psi, \omega, V, d) = \frac{1}{2}k_1(\psi - \psi_t)^2 + \frac{1}{2}k_2\omega^2 + \frac{1}{2}k_3(V - V_t)^2 + \frac{1}{2}k_4 d^2 \tag{6}$$

The vehicle trajectory to follow minimizes the distance d between the CoG (centre of gravity) and the nearest point P on the target trajectory. Then, the point P_h defines a target for the vehicle heading ψ, considering a time horizon h_t that allows to anticipate the maneuver to better chase the trajectory due to the delay of the actuators. A control for the heading rate ω is still present, and for the $k_i s$ different settings are used.

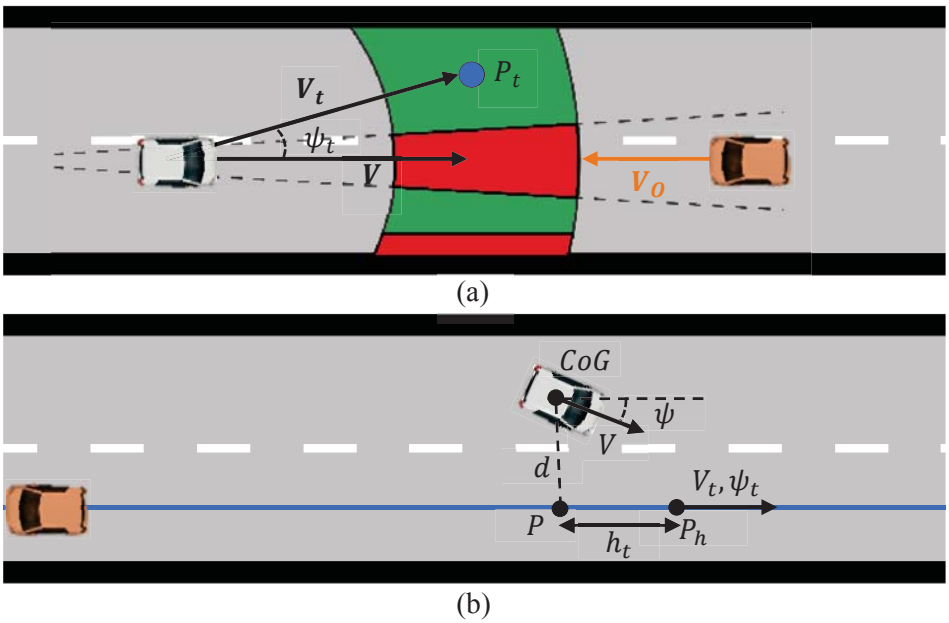

Figure 3: Autonomous driving strategies: (a) Obstacle Avoidance, (b) Lane keeping

The chosen dynamic model $\dot{\boldsymbol{x}} = \boldsymbol{\phi}(\boldsymbol{x}) + \boldsymbol{B}\boldsymbol{u}$ to control the car is based on the classical bike model [14] with rotating wheels (see Figure 4). The state $\boldsymbol{x} = [\boldsymbol{\nu}, \boldsymbol{\eta}]$ of the system is arranged as: (i) the speed field $\boldsymbol{\nu} = [u, v, \omega, \omega_r, \omega_f]$, with u, v the longitudinal and the lateral velocity in the mobile reference frame, ω is the yaw rate, ω_f and ω_r are rotational speed of frontal and rear wheel; (ii) the position and heading in the fixed frame $\boldsymbol{\eta} = [X, Y, \psi]$. The control vector $\boldsymbol{u} = [\delta, C]$ is composed by the steering angle δ and the rear wheel torque C. The $\boldsymbol{M}$, $\boldsymbol{C}(\boldsymbol{\nu}), \boldsymbol{J}$ are the inertia, Coriolis and rotational matrixes while $\boldsymbol{T}_{Pac}(\boldsymbol{\nu}, \delta), \boldsymbol{T}_{roll}(\boldsymbol{\nu}), \boldsymbol{T}_{aer}(\boldsymbol{\nu})$ and $\boldsymbol{T}_{wheel}(C)$ are forces and moment of Pacejka contact action, rolling, aerodynamic and the internal actions.

$$\begin{aligned} \boldsymbol{M}\dot{\boldsymbol{\nu}} + \boldsymbol{C}(\boldsymbol{\nu})\boldsymbol{\nu} &= \boldsymbol{T}_{Pac}(\boldsymbol{\nu}, \delta) + \boldsymbol{T}_{roll}(\boldsymbol{\nu}) + \boldsymbol{T}_{aer}(\boldsymbol{\nu}) + \boldsymbol{T}_{wheel}(C) \\ \dot{\boldsymbol{\eta}} &= \boldsymbol{J}(\psi)\boldsymbol{\nu} \end{aligned} \tag{7}$$

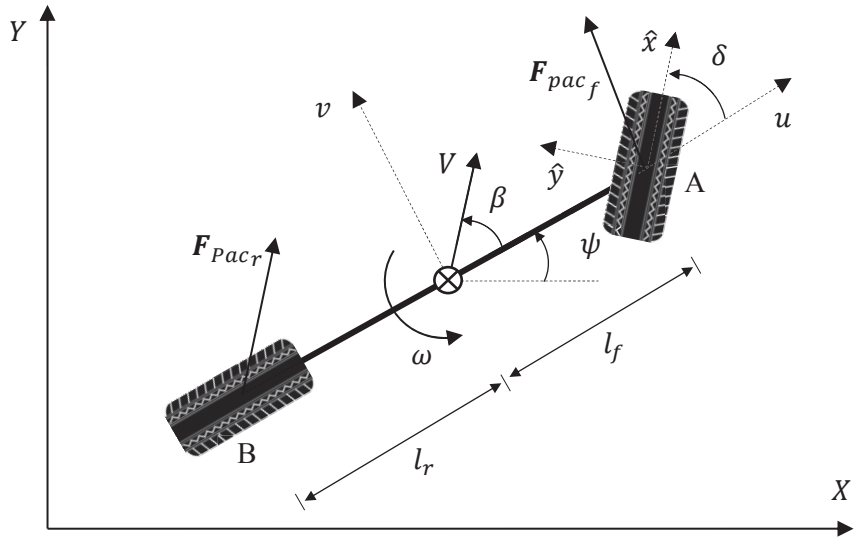

Figure 4: Bike model.

The Pacejka contact actions $\boldsymbol{T}_{Pac}$ are forces compositions $\boldsymbol{F}_{Pac}(k, \beta, F_z)$ based on the Magic Formula [17] widely used to describe the dynamic characteristics of tires. The forces depend on longitudinal and lateral slip, k and β, and the vertical load of each wheel F_z (Figure 5).

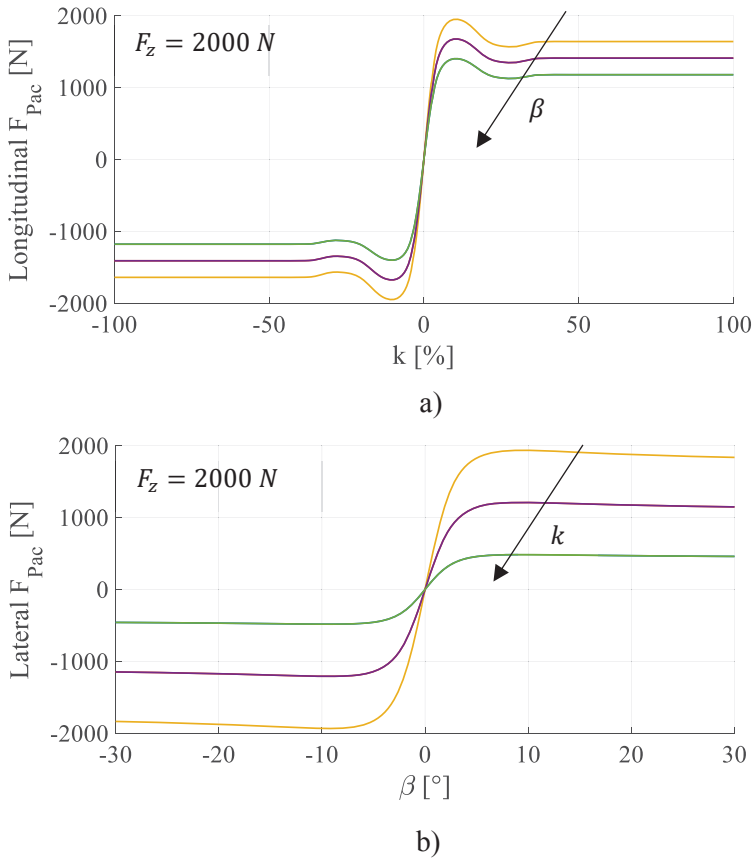

Figure 5: Longitudinal and lateral Pacejka forces.

Finally, in order for the system (7) to be included into the FLOP control, equations transform to a first order differential system, linearizing the part relating to the control actions, i.e. steering and torque. The linearization is updated to the step close to the previous conditions, such that the FLOP can consider all the nonlinearities of the bike model in terms of $\boldsymbol{v}$ and $\boldsymbol{\eta}$, ensuring a good control even of sudden maneuvers typical of obstacle avoidance. Pacejka coefficients were estimated performing empirical tests according to [18].

2.2 Traction and braking control

The traction and braking control aims at defining the percentage of throttle u_{gas} and brake u_{brake} commands to convey to the actuators. When the guidance control system returns a driving torque, $C > 0$, a second FLOP provides the control u_{gas}, considering the entire vehicle driveline up to the thermal engine (Figure 6). On the other hand, in case of a braking torque $C < 0$, the brake pedal is pressed proportionally to the value of C, up to a maximum empirical value that the braking system can provide.

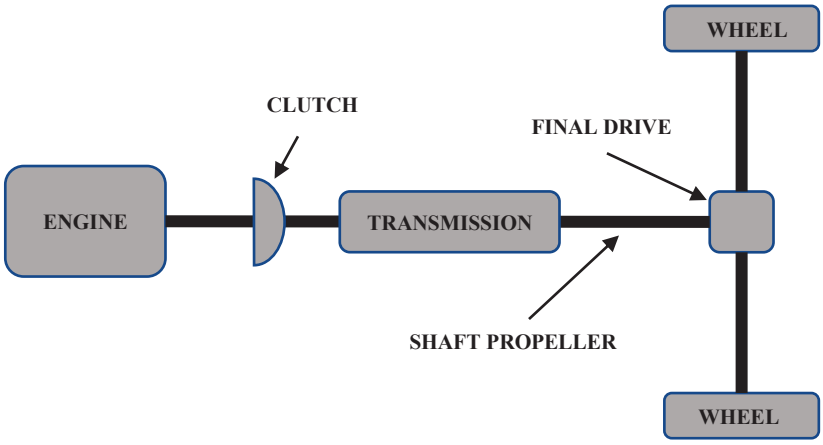

Figure 6: Driveline scheme.

The considered driveline consists by the engine, characterized by its torque curve, the flying wheel with its equivalent moment of inertia, the gearbox with its transmission ratio, the clutch, the wheels and the mass of the vehicle as shown in (Figure 6). The FLOP objective function is defined to meet two requirements: maintaining the target speed V_t, defined a priori by the guidance control system, and defining a target throttle u_t that is as much as possible close to the target control that we are going to describe below:

$$E(\omega_e, u_{gas}) = \frac{1}{2} k_1 \left(\omega_e - \tau(i) \frac{V_t}{R_{wheel}} \right)^2 + \frac{1}{2} k_2 \left(u_{gas} - u_t \right)^2 \tag{8}$$

where $\tau(i)$ is the transmission ratio between the engine and the wheel as a function of the engaged gear pair (denoted by i), coming from the on-board control unit; the R_{wheel} is the radius of the wheel; ω_e the engine revolution rate and the $k_i s$ tuning parameters.
The engine torque $C_e\left(u_{gas}, C_{e_{max}}, C_{e_{min}}\right)$ is a linear function of the u_{gas} command percentage between the maximum and minimum engine torque, as depicted in Figure 7. Therefore, the control target u_t is defined by assigning the desired torque C and the V_t:

$$u_t = \frac{\frac{\tau(i)C}{\eta} - C_{e_{min}}\left(\tau(i)\frac{V_t}{R_{wheel}}\right)}{C_{e_{max}}\left(\tau(i)\frac{V_t}{R_{wheel}}\right) - C_{e_{min}}\left(\tau(i)\frac{V_t}{R_{wheel}}\right)} \tag{9}$$

where η is the efficiency of the driveline.

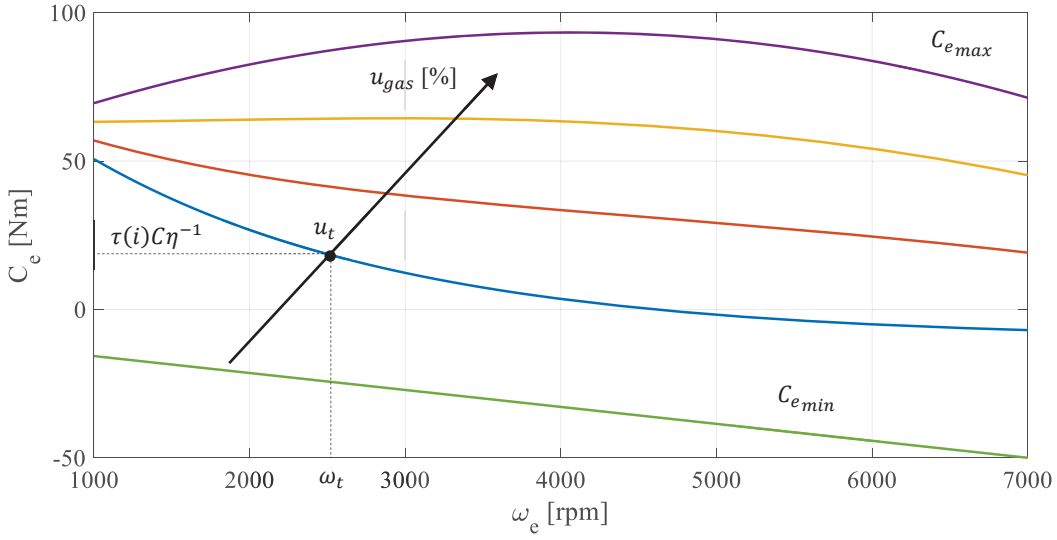

Figure 7: Engine torque curve.

The FLOP's dynamic function $\dot{\boldsymbol{x}} = \boldsymbol{\phi}(\boldsymbol{x}) + \boldsymbol{Bu}$ models the driveline of Figure 6:

$$\dot{\omega}_e = \frac{1}{I_{tot}(i)}\Big(\big(C_{e_{max}}(\omega_e) - C_{e_{min}}(\omega_e)\big)u_{gas} + C_{e_{min}}(\omega_e) - C_{res}(i)\Big) \tag{10}$$

where I_{tot} is the driveline inertia depending on the –*th* gear pair engaged, and on the efficiency η, and C_{res} is the total resistance torque related to rolling resistance, the gravity force, etc.

Also in this case, according to the FLOP formulation, it is necessary to linearize the term related to the control variable u_{gas}. When the required torque is negative and the motor is no longer able to deliver enough braking torque, the brake actuator comes into action.

3 AUTO-SAPIENS EQUIPMENT

The autonomous vehicle of the Mechatronics and Vehicle Dynamics Lab, at Sapienza University of Rome, named Auto-Sapiens is a Smart ForTwo City-Coupe, suitably modified for scientific autonomous driving experiments (Figure 8). This section describes the overall architecture of the vehicle and the hardware changes to transform it into an autonomous platform. The car has been equipped with: (*i*) proprioceptive sensors as 9DOF inertial measurement unit, GPS SKYTRAQ with 50Hz frequency, four wheels encoders; (*ii*) exteroceptive sensors as a LIDAR Velodyne, long-range radar AWR1243, short-range radar AWR1642, and ultrasonic sensors MB7040-200 Maxbotix. A central control unit manages all the data from sensors and sends the inputs from the control system to the actuators through different digital IO physical connections as I2C, P-MOD, USB 2.0, Gigabit Ethernet and Can-Bus as shown in Figure 9.

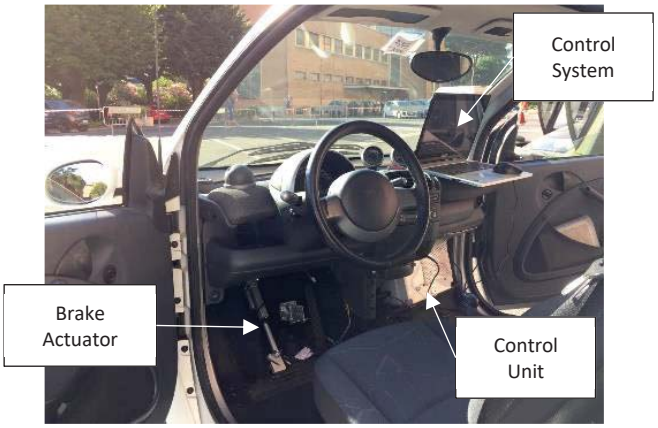

Figure 8: Autonomous kit on the *Auto-Sapiens* platform

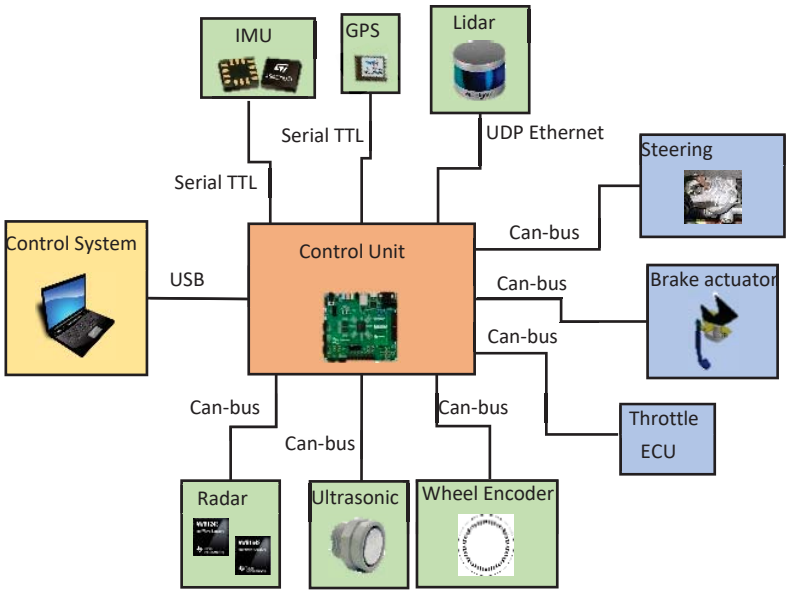

Figure 9: Hardware connection scheme

The actuators handle the steering, brake and throttle systems. The wheels are steered by the electric power unit, the same equipping the power steering of the car. A sensor to evaluate the rotation angle of the steering wheel has been set directly to the steering wheel. An ECU-Electronic Control Unit manages the throttle valve, with two potentiometers to evaluate the position of the pedal. An electrodynamic linear actuator controls the brakes applying a direct force to the pedal linkage acting on the brake pump. The Table 1 shows the most important characteristics of the vehicle.

The tests are aimed at analyzing the behavior of the car with respect to the control inputs, so the obstacle recognition is performed via V2V (Vehicle-To-Vehicle) communication, in which a virtual obstacle sends his position and attitude to the controlled vehicle (Figure 10). A local network, 30 Hz, receives the data through an UDP protocol, thanks to which the control system manages the control inputs connected to the central unit via USB with an update frequency of 20 Hz.

Parameters	Values
Mass	950 Kg
Yaw Inertia (supposed)	2000 Kg*m^2
Wheelbase	1.83 m
Distance between front wheel and CoG	1.03 m
Distance between rear wheel and CoG	0.8 m
Track	1.24 m
Wheel radius	0.2 m
Wheel inertia (supposed)	1 Kg*m^2
Max torque	92 Nm at 4500 rpm
Max Power	52 kW at 5800 rpm
0 - 100 km/h	15.5 s
Steering ratio	22:1

Table 1: Car parameters.

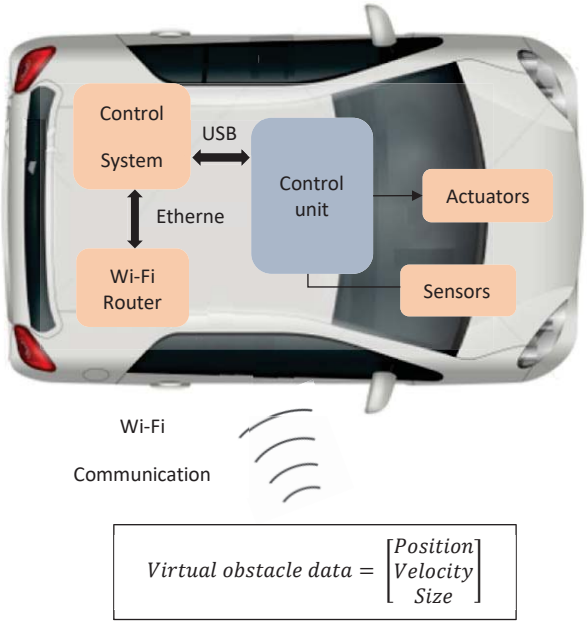

Figure 10: Auto-Sapiens communication system

4 STATE ESTIMATION

Vehicle system dynamic state estimation is a widely subject of investigation in automotive technology [19-22]. A well-known approach is the model-based estimation, which consists of two categories: kinematic and dynamic. In this framework, the Auto-Sapiens use the well-known EKF-Extended Kalman Filter applied to nonlinear dynamic models.

Writing in a compact form equation (7), the Extended Kalman filter is applied to the equations:

$$\begin{aligned} \dot{\boldsymbol{x}}(t) &= \boldsymbol{f}(\boldsymbol{x},\boldsymbol{u}) + \boldsymbol{w}(t) \\ \boldsymbol{z} &= \boldsymbol{h}(\boldsymbol{x}) + \boldsymbol{v}(t) \end{aligned} \tag{11}$$

where $\boldsymbol{w}(t)$ and $\boldsymbol{v}(t)$ represent process and measurement noise respectively and $\boldsymbol{z}$ is the observed state:

$$h = \begin{bmatrix} X \\ Y \\ \psi + \beta \\ V_X(\psi) \\ V_Y(\psi) \\ \omega \\ \omega_r \\ \omega_f \end{bmatrix} \qquad z = \begin{bmatrix} X_{Odo} \\ Y_{Odo} \\ \psi_{GPS} \\ V_{X_{GPS}} \\ V_{Y_{GPS}} \\ \omega_{IMU} \\ \omega_{r_{Odo}} \\ \omega_{f_{Odo}} \end{bmatrix} \tag{12}$$

The estimation of the position of the vehicle is possible via different methods, like simultaneous localization and mapping (SLAM), visual odometry etc. In the present case, the position $[X_{Odo}, Y_{Odo}]$ is estimated through the odometry technique which makes use of a kinematic bike-model with the velocity of the wheels, coming from the ABS, to compute the trajectory covered [22]. This approach is quite reliable if the distance and the velocities involved are not large. Vehicle heading ψ_{GPS} information coming from GPS sensor, can be used to correct the yaw prediction ψ, since the heading is the sum of the yaw and slip angle β. Moreover, from the GPS we get the speed information in the fixed reference $[V_{X_{GPS}}, V_{Y_{GPS}}]$. The yaw rate ω_{IMU} is measured by the IMU and, as mentioned before, the speed of the wheels $[\omega_{r_{Odo}}, \omega_{f_{Odo}}]$ is taken from the ABS.

5 RESULTS

The several tests performed in a controlled environment, involve the analysis of a frontal crash scenario, in which the controlled vehicle has to maintain its pre-assigned lane. Figure 11 shows that a virtual obstacle performs random generated trajectories that pass through a specific region A at a specific time, such that it will crash against the controlled vehicle.

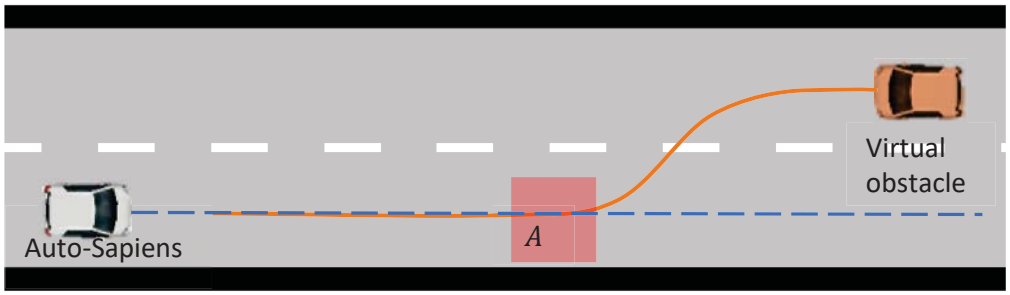

Figure 11: Crash scenario for experimental tests

The tests velocities belong to the range of 40-60 Km/h. Figure 12 shows the trajectory of the vehicle in blue, and the one in red is the obstacle: the controlled vehicle manages to evade the virtual obstacle and return to the assigned trajectory. The maneuver of obstacle avoidance starts at t_{start} with the switch-on of the penalty (5), followed by the switch-off of (5) and activation of penalty (6) till to the end, at t_{end}.

Along this time interval, the evolution of the actuators commands and that of the longitudinal velocity u are investigated. In Figure 13, the longitudinal velocity has a small decrease while the obstacle avoidance strategy is engaged, then the velocity is increasing to the target value which is the speed before the obstacle avoidance intervention.

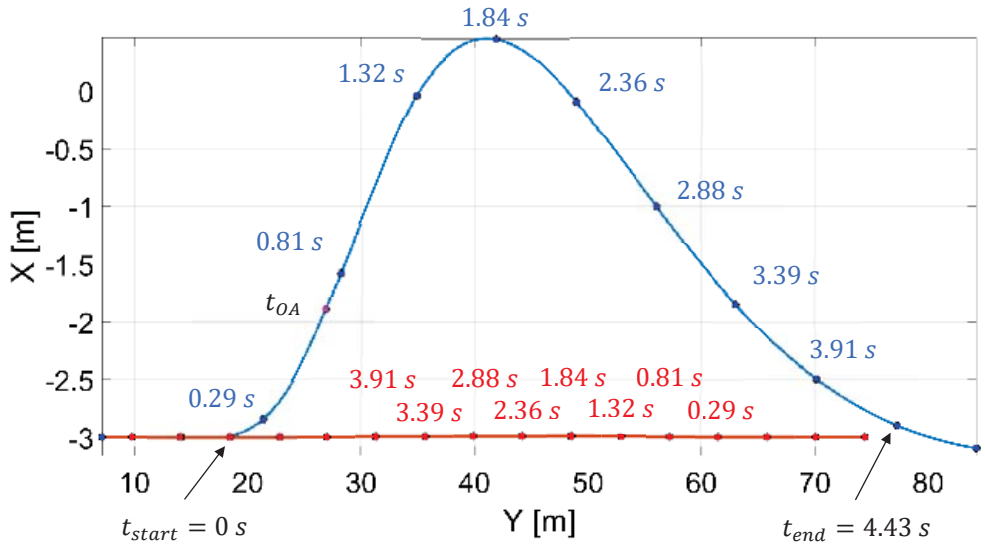

Figure 12: Trajectory of the vehicle in blue and obstacle in red with time

Alongside this, the throttle shown in Figure 14 is zero when the obstacle is engaged. This happens because the intervention threshold for the obstacle avoidance strategy to intervene is chosen for safety purposes and has a value of 2s. The control, having enough time, prefers to do a stable maneuver without braking and steering at the same time. Finally, the steering wheel of Figure 15 behaves according to the maneuver depicted in Figure 12.

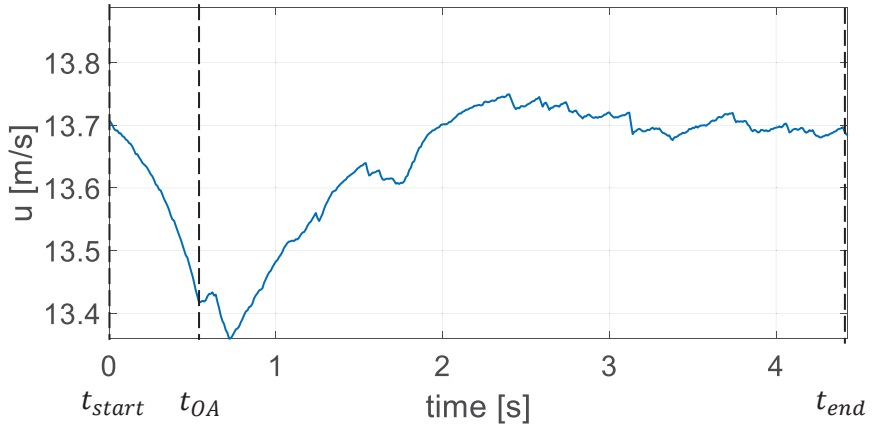

Figure 13: Longitudinal speed between t_{start} and t_{end}

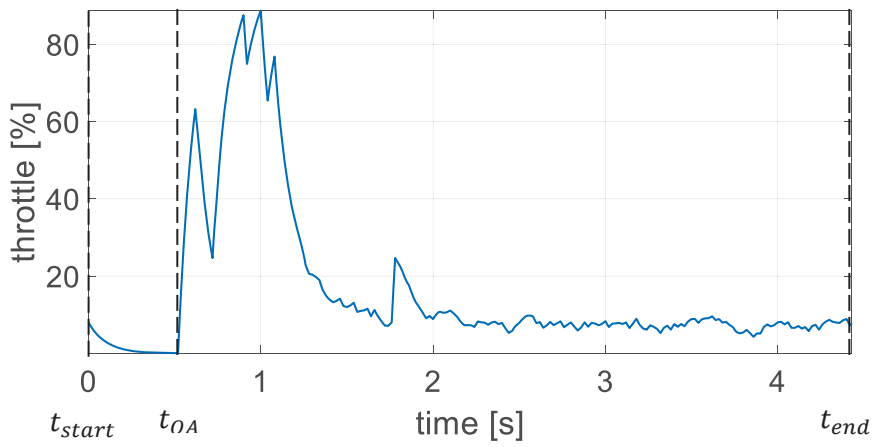

Figure 14: Throttle between t_{start} and t_{end}

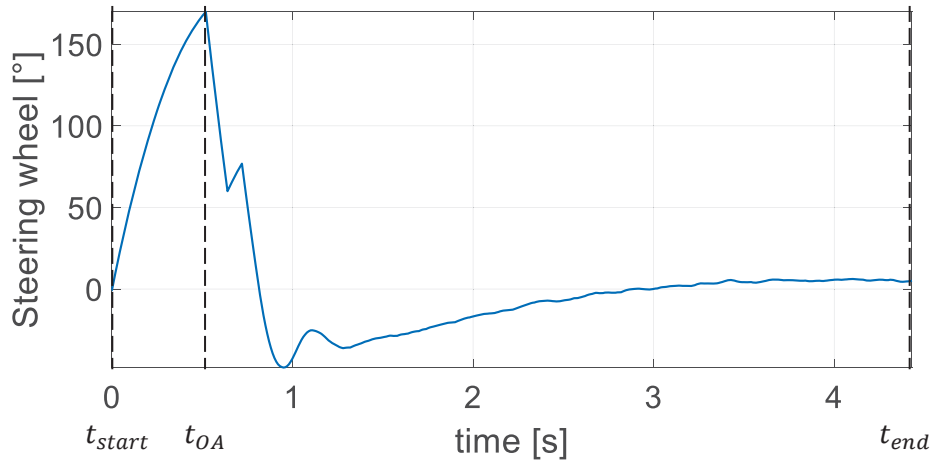

Figure 15: Steering wheel angle between t_{start} and t_{end}

An interesting analysis investigates the performance of the car in terms of accident probability. Figure 16 shows the number of successful crash-avoidance maneuvers compared to the failed maneuvers leading to the crash, classified according to a quality parameter ρ (within the range 0 to 1). In the range between 0 to 0.5, the quality of the successful avoidance maneuver is assessed through the measure of the minimum distance between the road boundaries and the virtual obstacle: at 0 the vehicle is equally distant between the boundaries and the obstacle, while at 0.5 the vehicle brushes against them. Between 0.5 and 1, the quality of the crash maneuver are assessed in terms of kinetic energy released in the collision: at 0.5 the kinetic energy involved is very low, due to the vehicle brushing against the road boundaries or obstacle, while at 1 the kinetic energy is at his maximum value between all the tests. Figure 16 shows all the experimental tests and can be noted that most of them resulted in successful maneuvers with a peak at $\rho = 0.3$, while few scenarios resulted in a crash.

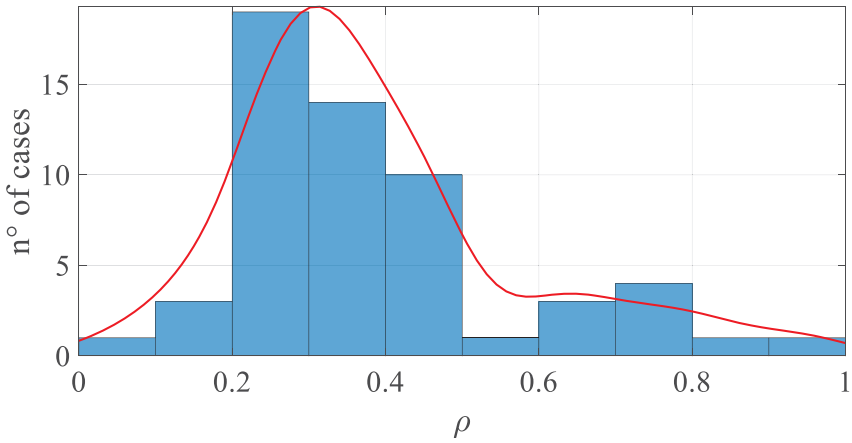

Figure 16: Performance of the system in different frontal crash scenarios: number of successful cases ($0 < \rho < 0.5$) and which ended with a crash ($0.5 < \rho < 1$).

6 CONCLUSIONS

The authors presented the first experimental tests on the *Auto-Sapiens* platform of a new autonomous driving system. The use of a new nonlinear feedback control, named *FLOP* and a new obstacle avoidance strategy, developed by the authors, shows good results in terms of performance with random scenarios under high-speed conditions. Further tests will be the subject of further investigation performed to check the robustness against more challenging scenarios, i.e. multiple obstacles, crossroads, including models of sensors to keep the environment reconstruction and obstacle detection, such as Lidar, Camera and Radar.

Keywords: Full car model, Autoregressive System, Active suspension

Abstract. *This work presents an identification technique for the suspension dynamics of a nonlinear full car model by implementing an autoregressive system with exogenous input (ARX). The ARX model was proposed as a simple and powerful tool, in terms of accuracy and computational time, compared to the complexity and significant computational cost involved with the neural networks approach which is commonly used. Firstly, the training data is provided through a full car model simulated by Matlab/Simulink. Then the training data is fed into the autoregressive algorithm, which in turn provided an autoregressive model for the suspension dynamic behavior, while this model was calibrated using another data set grabbed from the same Simulink model. Several RMS values of noise were added to different types of road excitation in order to assess the efficiency of the proposed ARX system in terms of noise filtration. Finally, the active response the autoregressive system is simulated, using a PID controller, and compared with those of the Simulink model. The proposed system identification technique proved it's efficiency in terms of accuracy in the light of its very fast computational speed.*

1 INTRODUCTION

A suspension system plays a crucial role in maintaining an automobile's stability and passenger comfort during the drive. The suspension system can be divided into three types, passive, semi-active and active suspension. The passive model is an open-loop control system that is not acted upon by any control system. It only contains springs and dampers, allowing the system to passively store energy by the springs and dissipate energy through the dampers. Changing the damper on the existing passive suspension into variable damper, transforms the system into a semi-active suspension, adapting to changing road conditions. The addition of an actuator to the system transforms the system into active suspension, adding external controlling energy that is presented as a closed-loop system. This allows the system to take action against road change, it calculates and adds the required energy to keep the tires intact on the road, improving the overall driving stability and passenger comfort.

M. Savaresi et $al.$ [1] have created a black box Non-linear autoregressive with exogenous input (NARX) model for a magneto-rheological (MR) damper for vehicle control. A. Suebsomran [2] has developed an approximate linear model for a non-linear electromagnetic suspension system as well as Linear state feedback control, adaptive neural network control and a hybrid of linear state feedback and adaptive neural network control on the plant system. I.Ö. Bucak et $al.$ [3] have done vibration control on a non-linear quarter-car suspension system by reinforcement learning method . D. Hanafi et $al.$ [4] have developed a NARX model for quarter-car suspension system using neural network technique, data used were real data obtained by automobile driving on a special road. D. Hanafi. [5] implemented a PID controller on NARX model for a semi-active quarter car suspension system. M.N.Howell et $al.$ [6], developed a reward-intaction based reinforcement learning algorithm to minimize the RMS of four-wheel car body acceleration. Z. Saad et $al.$ [7], have developed a NARX model and RLS learning algorithm as a black box model for car speed forecasting. B. C. Ng et $al.$ [8], have developed a NARX model to model the dynamic behavior of an automobile air conditioning system. S. Inagaki et $al.$ [9], have developed a SS-ARX model in the purpose of human driving behavior recognition. H. Luo et $al.$ [10], have developed a Dual-Tree Complex Wavelet enhanced Convolutional Long Short- Term Memory neural network (DTCWT-CLSTM), a method aimed to be a structural health monitoring tool for an automotive suspension. Y. Mao et $al.$ [11], have proposed two estimation algorithms for Hammerstein controlled autoregressive systems. V. Krishnaswami et $al.$ [12], presented a NARMAX model to detect a failure in actuators of an internal combustion engine. W. Pawlus et $al.$ [13], proposed a NAR model parameters estimated by feed-forward neural networks the NAR model is derived from a more general NARMA model, NAR model was proposed for calculating vehicle crashworthiness. S. Barone et $al.$ [14], have developed a CAR model as a statistical tool for improving the reliability of a pre-equipped OBD system in a passenger car. C. Debes et $al.$ [15], proposed an autoregressive algorithm to process the signal with added non-Gaussian noise. C. A. Aliza et $al.$ [16], proposed a prototype model for a passive quarter car suspension. C. Kim et $al.$, Y. Qin et $al.$ [17], proposed a classification method for a semi-active suspension system based on deep neural networks, evaluation done through computer simulation. X. Q. Sun et $al.$ [18], have used hybrid system theory to model the continuous and discrete dynamics of the height adjustment process of a vehicle. X. Xu et $al.$ [19], developed a non-linear parallel interlinked air half-car suspension system, then the model was linearized by Taylor expansion. E. Ilkonen et $al.$ [20], proposed a non-linear dynamic model for a MacPherson active suspension system as well as state control and estimation using Makrov models. E. Asadi et $al.$ [21], proposed a model for an adaptive electromagnetic hybrid damper.

M. F. Aly et $al.$ [22], have carried out a design and optimization for a vehicle suspension system with passive variable stiffness and active damping, using a genetic algorithm. A. H. Tesfay et $al.$ [23], designed and modeled a variable stiffness air spring semi-active suspension system.

ARX is an abbreviation for autoregressive system with exogenous input. Unlike any system identification method, ARX models aim to find direct relation between the systems' degrees of freedom, system inputs, and output. The current work presents an attempt to generate an autoregressive model for a full-car suspension system. Training data will be given in the form of time domain data for the displacement of each sprung and unsprung masses of each wheel as well as the road input all given as learning data. All of the training data were generated by a model for a full car suspension developed on Simulink and the same Simulink model will be used afterwards for validation purposes.

2 The Full Car Mathematical Model

2.1 Full Car Suspension Parameters

The current full car suspension system has seven degrees of freedom, as shown in the illustrative figure (1) below, which represents the vertical displacement of each wheel, the vertical displacement of the unsprung mass, the pitch of the unsprung mass and the roll of the unsprung mass. The current study implements the same car model presented by Darus et $al.$ [24], and table (1) presents the definitions of the model's notations.

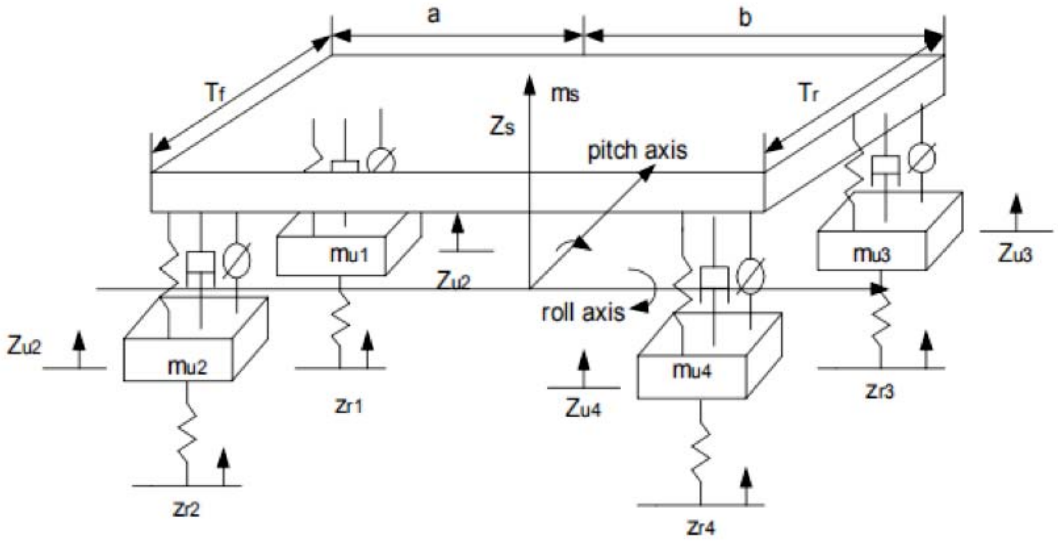

Figure 1: Full car mathematical model

Table 1: Table of notations.

Variables	Definitions
Z_s	Vertical displacement of the center of mass of the sprung mass
Z_{u1}	Vertical displacement of the front right wheel
Z_{u2}	Vertical displacement of the front left wheel
Z_{u3}	Vertical displacement of the rear right wheel
Z_{u4}	Vertical displacement of the rear left wheel
θ_s	Sprung mass of the pitch angle
ϕ_s	Sprung mass of the roll angle
f_i	Force due to actuation on wheel i
i	Index reference to each wheel (1,2,3,4)

From the above model the equations of motion for the sprung mass parts connecting with each unsprung mass $(Z_{s1}, Z_{s2}, Z_{s3}, Z_{s4})$ can be stated as follows

$$Z_{s1} = T_f\phi_s + a\theta_s + Z_s \tag{1}$$

$$Z_{s2} = -T_f\phi_s + a\theta_s + Z_s \tag{2}$$

$$Z_{s3} = -T_r\phi_s - b\theta_s + Z_s \tag{3}$$

$$Z_{s4} = -T_r\phi_s - b\theta_s + Z_s \tag{4}$$

3 Autoregressive Full Car Model

The autoregressive process aims to predict the following states Z_{si}, Z_{ui}, Z_{ri} by using the data extracted from the Simulink model as an input training data. Once Z_{si} is acquired from each wheel. θ_s, ϕ_s, Z_s can be computed from the relations mentioned before.

$$Z_{St+\delta t} = \begin{pmatrix} Z_{S2} \\ Z_{S3} \\ \vdots \\ Z_{S999} \end{pmatrix}, Z_{St} = \begin{pmatrix} Z_{S1} \\ Z_{S2} \\ \vdots \\ Z_{S998} \end{pmatrix}, Z_{St-\delta t} = \begin{pmatrix} Z_{S0} \\ Z_{S1} \\ \vdots \\ Z_{S997} \end{pmatrix} \tag{5}$$

Similarly, for Z_u and Z_r, the above procedure was implemented to get their corresponding time vectors.
The solution of the system was assumed to be as follows:

$$Z_{si(t+\delta t)} = a_0 Z_{si(t)} + a_1 Z_{si(t-\delta t)} + a_2 Z_{ui(t)} + a_3 Z_{ui(t-\delta t)} + a_4 Z_{ri(t)} + a_5 Z_{ri(t-\delta t)} + b_0 f_{i(t)} + b_1 f_{i(t-\delta t)} \tag{6}$$

In order to calculate Z_s, a matrix "A" is formulated as shown in equation (7). The "A" matrix was formulated using the same order of the terms in equation (6) where $b_0, b_1 = zero$ in case of the passive suspension system.

$$A = \left[Z_{s(t)} \left| Z_{s(t-\delta t)} \right| Z_{u(t)} \left| Z_{u(t-\delta t)} \right| Z_{r(t)} | Z_{r(t-\delta t)} \right] \tag{7}$$

$$\{a\} = \left([A]^T [A]^{-1} \right) [A]^T \left\{ Z_{s(t+\delta t)} \right\} \tag{8}$$

By solving for the vector a gives the coefficients $a_0, a_1, a_2, a_3, a_4, a_5$ which are used later in the formulation of the polynomial representing the displacement of the sprung mass Z_s as in equation (6).

Similarly for Z_u, the same procedures were implemented as follows:

$$A = \left[Z_{u(t)} \left| Z_{u(t-\delta t)} \right| Z_{s(t)} \left| Z_{s(t-\delta t)} \right| Z_{r(t)} | Z_{r(t-\delta t)} \right] \tag{9}$$

$$\{a\} = \left([A]^T [A]^{-1} \right) [A]^T \left\{ Z_{u(t+\delta t)} \right\} \tag{10}$$

$$Z_{ui(t+\delta t)} = a_0 Z_{ui(t)} + a_1 Z_{ui(t-\delta t)} + a_2 Z_{si(t)} + a_3 Z_{si(t-\delta t)} + a_4 Z_{ri(t)} + a_5 Z_{ri(t-\delta t)} + b_0 f_{i(t)} + b_1 f_{i(t-\delta t)} \tag{11}$$

By solving equations (1), (2), (3), and (4) simultaneously, we can get the following: θ_s, ϕ_s, Z_s:

$$\phi_s = \frac{Z_{s1} - Z_{s2} + Z_{s3} - Z_{s4}}{2T_f + 2T_r} \tag{12}$$

$$\theta_s = \frac{Z_{s1} + Z_{s2} - Z_{s3} - Z_{s4}}{2a + 2b} \tag{13}$$

$$Z_s = Z_{s1} + Z_{s2} + Z_{s3} + Z_{s4} + \frac{(2b - 2a)\theta_s}{4} \tag{14}$$

It can be seen that these three degrees of freedom are functions of the other four ones, thus, the first four degrees of freedom $(Z_{s1}, Z_{s2}, Z_{s3}, Z_{s4})$ can be used to calculate the other three which will save computational time spent on applying regression techniques to model them.

In order to improve the accuracy and to account for the coupling between the four wheels, some difference and product terms were added as follows:

$$(Z_{u1} \cdot Z_{u2}, Z_{u3} \cdot Z_{u4}, Z_{u1} \cdot Z_{u3}, Z_{u2} \cdot Z_{u4}, Z_{u1} \cdot Z_{u4}, Z_{u2} \cdot Z_{u3})$$

and the difference terms added were:

$$(Z_{u1} - Z_{u2}, Z_{u3} - Z_{u4}, Z_{u1} - Z_{u3}, Z_{u2} - Z_{u4}, Z_{u1} - Z_{u4}, Z_{u2} - Z_{u3})$$

where:

$$Z_{u1} \cdot Z_{u2} = Z_{u1}(t_i)\, Z_{u2}(t_i) \; and \; Z_{u1} - Z_{u2} = Z_{u1}(t_i) - Z_{u2}(t_i)$$

The choice of the non-linear terms was biased to symmetrical terms and was subject to trial and error. Each vector that represents its corresponding non-linear term is concatenated in each $[A]$ matrix, and each corresponding term is included in the regression polynomial in equations (6) and (11).

The approach used in the addition of a PID controller to the autoregressive model generated was by solving the system in two steps, the first step was by applying the autoregressive technique on a passive model, then by using this model generated to predict the effect of the force outputted from the PID controlled actuator in the following manner; in the same manner in equation (10), the passive model was generated, then the same regression technique will again be applied but with as follows:

$$Z_s(t + \delta t) - \{a\}[A] = b_0 f(t) + b_1 f(t - \delta t) \tag{15}$$

$$\{b\} = \left([B]^T [B]^{-1} \right) [B]^T \left\{ Z_{s(t+\delta t)} - \{a\}[A] \right\} \tag{16}$$

where B is a matrix containing the time steps of the generated PID force as illustrated in figure (2). By substituting the values of b_0 and b_1, extracted from equation (16), into equation (6).

4 Results and Discussion

In order to test the predicted model, several road input types were introduced to the system and the response calculated from the auto-regressive system polynomial was compared to that extracted from the Simulink model. The types of input introduced to the system were sinusoidal input, step input, road bumps, and random excitation.

4.1 Sinusoidal input

A sinusoidal input, of 0.06 m amplitude and 10 $\frac{rad}{sec}$ frequency, has been applied to all wheels, while those applied to wheels 1 and 4 have a phase shift of $\frac{\pi}{2}$ which can be expressed as [24]:

$$Z_{r1}(t), Z_{r4}(t) = 0.06sin(10t + \frac{\pi}{2}) \tag{17}$$

$$Z_{r2}(t), Z_{r3}(t) = 0.06sin(10t) \tag{18}$$

The same road input excitation applied to the predicted model was applied to the Simulink model and the results were compared and shown as follows in figures (3), (4), and (5).

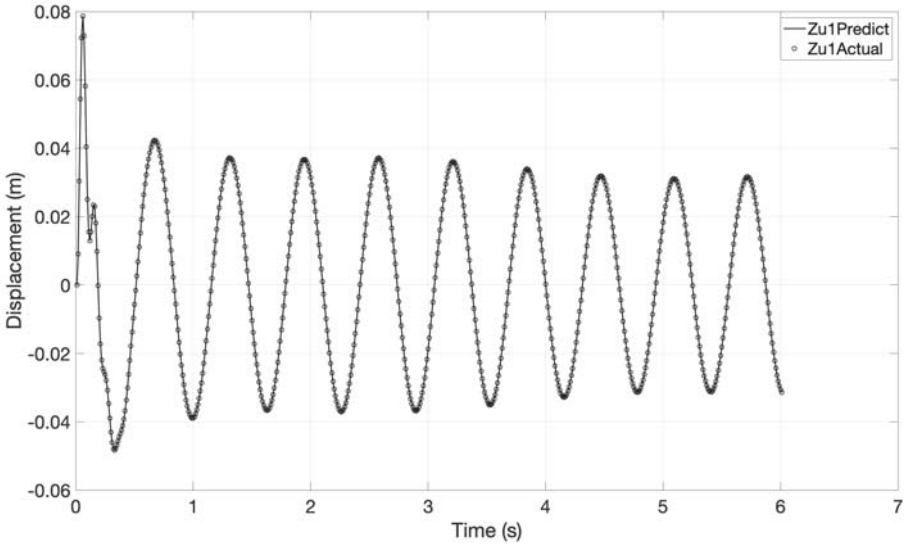

Figure 3: Unsprung mass Zu1 response

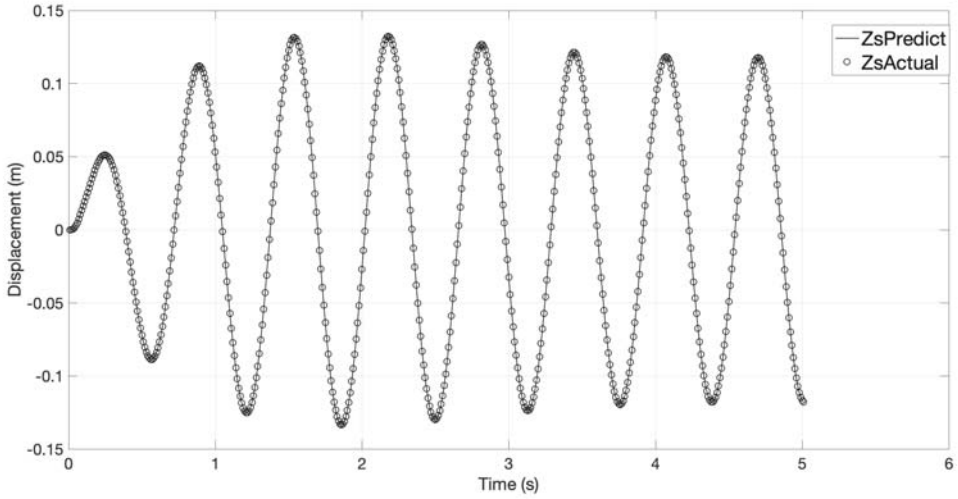

Figure 4: Center of mass Zs response

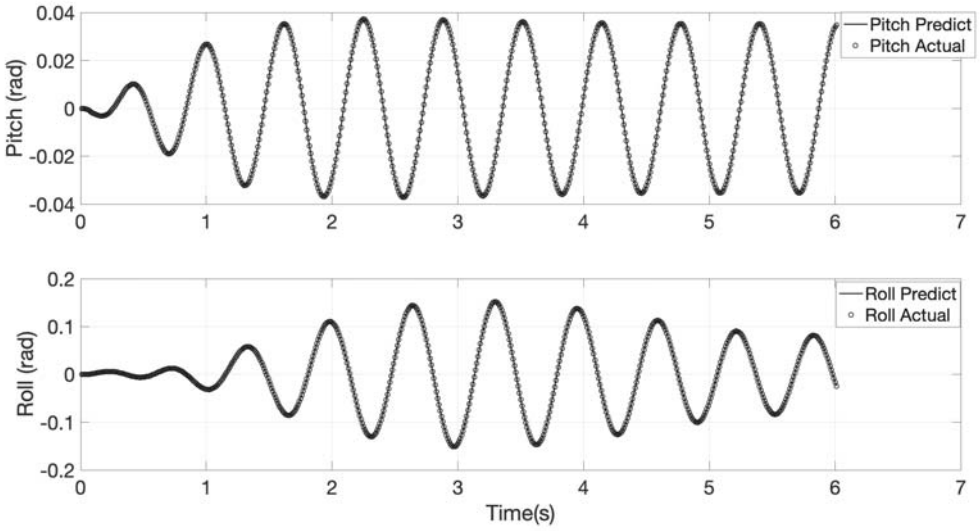

Figure 5: Sprung mass Pitch and Roll

It is shown in the above figures (3), (4), and (5) that the results of Z_{u1},Z_s, $Pitch$, and $Roll$ show that the predicted model responses are in a very good agreement with their corresponding states obtained from the Simulink model.

4.2 Model Robustness

While building the model, the assessment of the model robustness was a crucial issue. Therefore, in order to test the robustness of the model, two different types of data sets were implemented in training the autoregressive model. The first one was an input with a training data set of monotonic nature like, for example, step input or sinusoidal, applied seperately as shown in figure. The second one was a mixed type of input presented as a combination of two different road excitations, for example, sinusoidal and step applied in sequence.

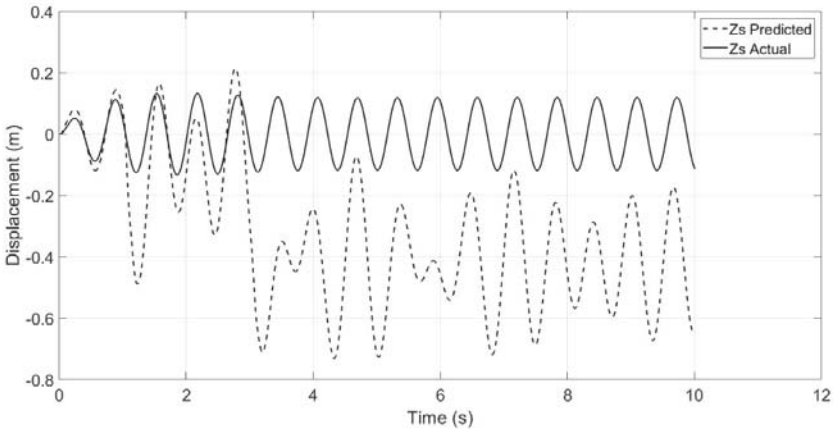

Figure 6: Sprung mass response, subjected to sinusoidal input and trained by step input

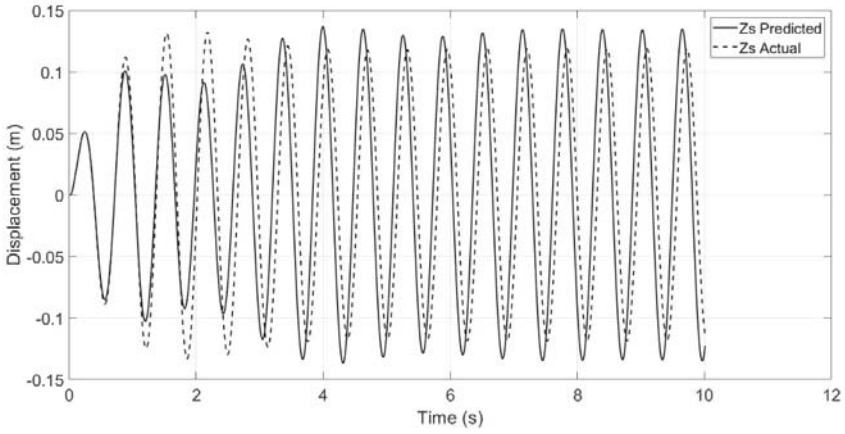

Figure 7: Sprung mass response, subjected to sinusoidal input and trained by mixed input

Figure (6) represents the sprung mass repsonse, subjected to sinusoidal input when it was trained by only step input, while figure (7) represents the sprung mass reponse, subjected to the same sinusoidal input when it was trained by a multiple inputs, which was simulated as a step input followed by a random excitaion. It's found that using single-type input, utilised in training data sets, fell short in training the autoregressive model which was reflected by a very poor prediction of the sprung mass displacement in response to sinusoidal input as depicted in figure (6), while, the usage of multi-type input proved efficient in training the autoregressive model as depicted in figure (7).

4.3 PID controller implementation

In order to test the active performance, of the trained autoregressive model, compared to it's passive response to the same sinusoidal input mentioned above in equations (17) and (18). The active response of the sprung mass, using a PID controller following the procedure detailed equations (15) and (16), is presented in figures (8) and (9).

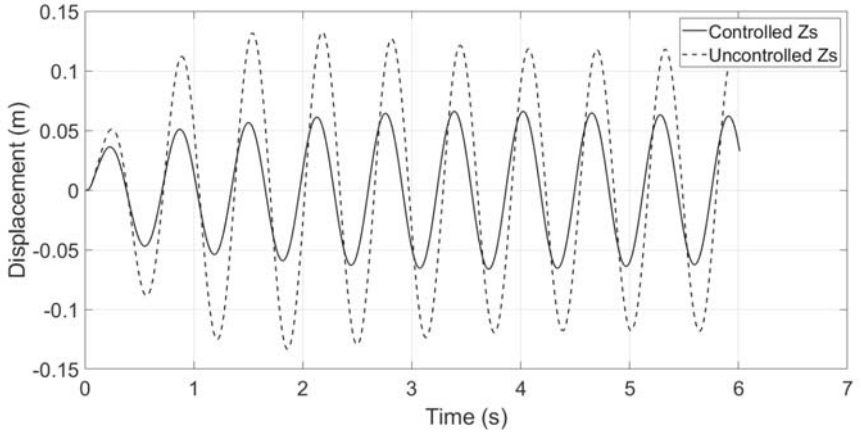

Figure 8: Sprung mass response after adding PID controller

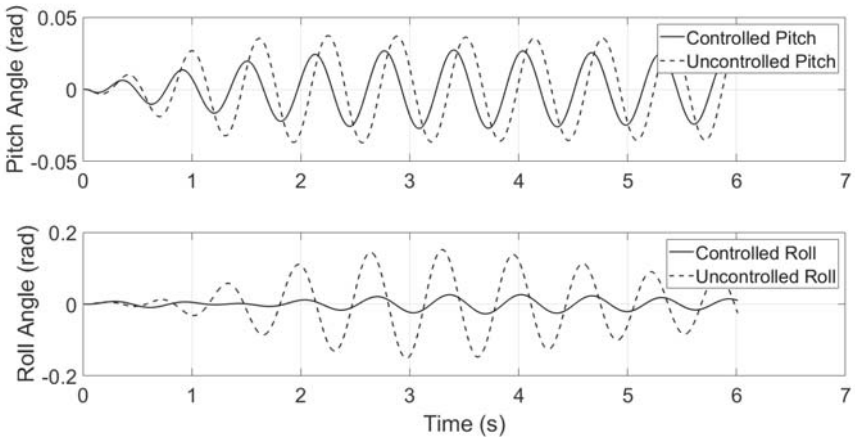

Figure 9: Sprung mass Pitch and Roll after adding PID controller

It's found in the figures 8 and 9, as expected that the PID control can add significant effect in mitigating the vertical displacement, pitch, and roll amplitudes.

4.4 Noise Filtration Capacity of Autoregressive systems

In order to test the ability of the autoregressive model to generate a stable model in spite of being in a noisy environment, the approach used was adding noise to the inputs used to build the autoregressive model through adding a random signal to the signals from Unsprung and Sprung masses of each wheel. Firstly, a noise of Variance of *0.0005 m* and the mean value of *zero* was added to the sinusoidal input mentioned above in equations (17) and (18). The results of the wheel number 1 "Z_{u1}" and Sprung mass "Z_s" are shown below in Figures (10) and (11) respectively.

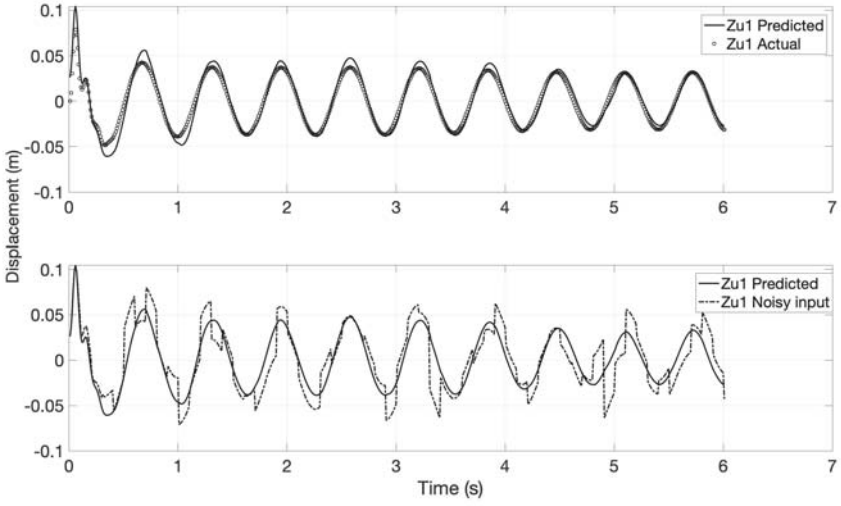

Figure 10: Wheel number 1 displacement in response to noisy sinusoidal excitation

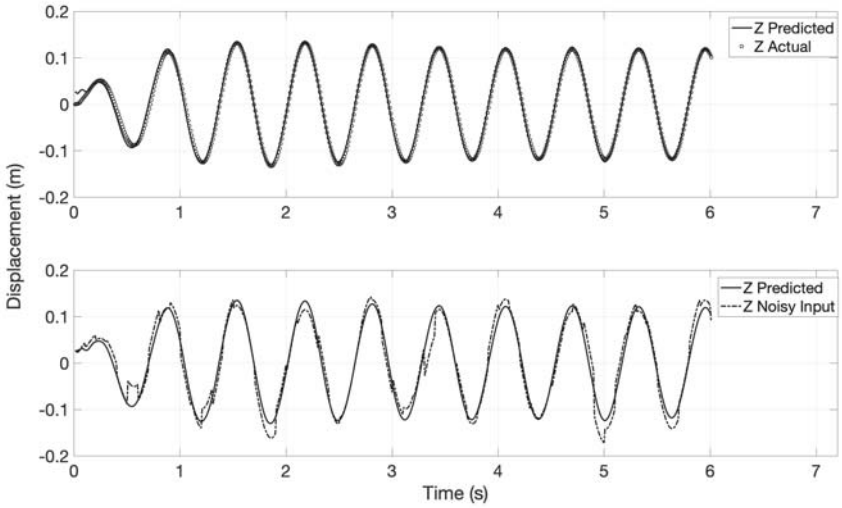

Figure 11: Sprung mass displacement in response to noisy sinusoidal excitation

The above figures (10), and (11) show the predicted model responses of different degrees of freedom Z_{u1}, and Z_s compared to the training data with and without the inclusion of noise to the training set. This shows the model's capability to filter the noise. For further testing of the model, it was tested with no inputs and only with an initial excitation, the initial conditions applied to the system were:

$$Z_{u1}(0) = Z_{u2}(0) = Z_{u3}(0) = Z_{u4}(0) = Z_s(0) = 0.1, \text{ and } \dot{Z}_s(0) = 1$$

The response for the Unsprung and sprung masses to the above initial excitation is shown below in figures (12) and (13) respectively.

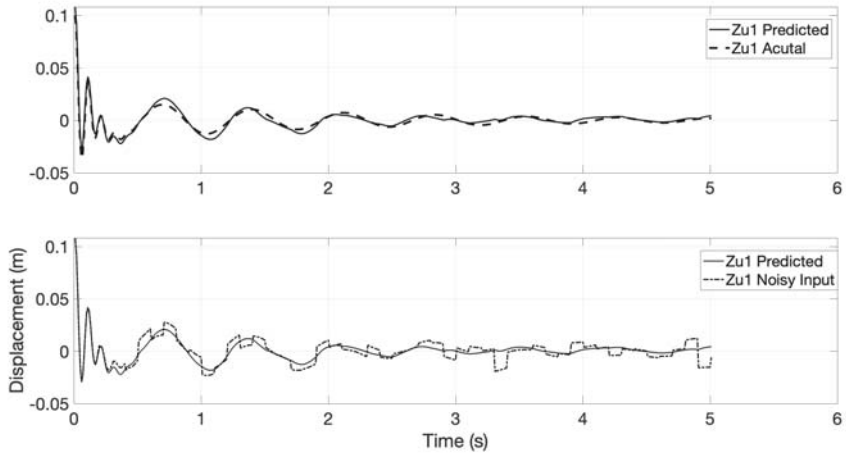

Figure 12: Wheel number 1 displacement in response to noisy initial condition

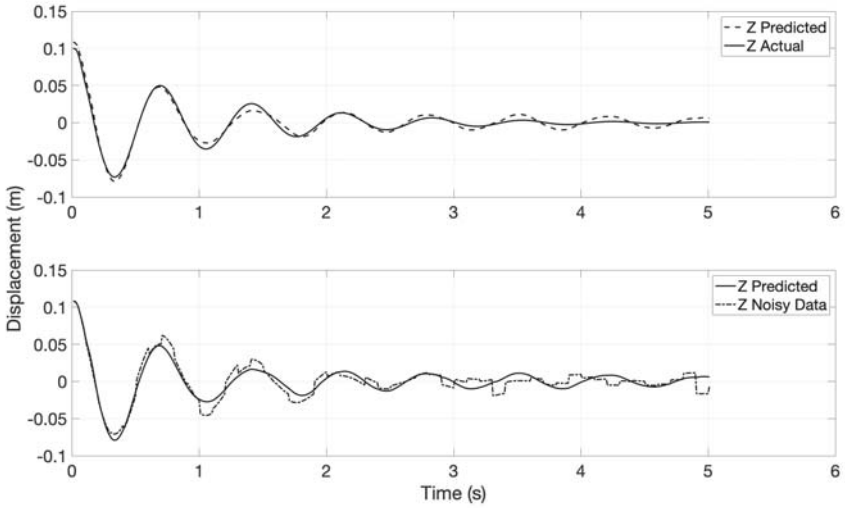

Figure 13: Sprung mass displacement in response to the noisy initial condition

Figures 12 and 13 show that the autoregressive model was able to be trained with noise added to the data sets and to give accurate predictions of the data excluding the effect of the noise.

4.5 Conclusion

- While testing the generated autoregressive model, it was noticed that the model has a higher capability of capturing the actual system dynamics when various types of inputs were used in the training phase. It was found that the predictions can be improved significantly if the system is trained with two types of inputs, for example, sinusoidal and random, it can provide much better predictions to the step response rather than when it was built only using single input; sinusoidal or random.

- The autoregressive model was able to be trained with noise added to the data sets and to give accurate predictions of the data excluding the effect of the noise.

- Autoregressive models could come up with unacceptable results once being trained, using a training data set which contains a constant value for a relatively long duration.

Keywords: String stability, Automated driving, Co-simulation, Platooning control.

Abstract. *This work proposes a set of methods and tools to analyse and quantify key performance aspects of controlled automotive platoons. These methods assess classical stability and string stability properties in both analytical and empirical settings. An automotive platoon consists of multiple tightly spaced vehicles which aim to follow a desired velocity or distance profile safely, autonomously, and efficiently. Cooperative vehicular platooning can greatly improve traffic efficiency and safety, while increasing traffic throughput and fuel efficiency. One difficulty for establishing a stable platoon, besides classical stability of individual vehicles, is known as "string stability". Essentially, in a string stable platoon, disturbances of any individual vehicle are not amplified along the platoon. In addition to stability, the performance of a platoon control structure must be quantified, for example by measuring disturbance rejection bandwidth / control error decay rate. Most of the proposed platoon control architectures developed in the past guarantee platoon stability/string stability only under restrictive assumptions. In this work tools and methods are proposed to analyse classical stability, error signal measures, as well as analytical and empirical string stability. This allows the user to evaluate platoon safety and performance for given control structures and conduct parameter studies at various levels of system complexity. To investigate platoon behaviour under realistic conditions, test scenarios are empirically evaluated in a co-simulation of multiple instances of the commercial simulation software IPG TruckMaker.*

1 INTRODUCTION

As heavy duty vehicle (HDV) road traffic is rising steadily through growing freight transportation, increasing road capacity is gaining importance. One way to address this issue is to reduce the distance between consecutive vehicles, as shown in [1]. For safety reasons, however, safe driving by human drivers requires a time-headway of about 2 seconds as typically laid down in legal regulations. Driving at small inter-vehicular distances also comes with benefits in fuel efficiency due to reduction of air resistance [2]. To safely reduce the distance, longitudinal control architectures are added. To further improve performance of a string of longitudinal controlled semi-autonomous vehicles following each other, thereby forming a platoon, vehicle-to-vehicle (V2V) communication is added. This allows the platoon to react cooperatively according to desired trajectories in a situation-aware manner [3].

To achieve this goal, each individual vehicle must show stable dynamics with respect to injected disturbances. Essentially, a desired time headway policy must be reliable. Single-vehicle control structures, for example adaptive cruise control (ACC) systems, were developed in the past. However, these did not consider error propagation along a platoon of vehicles. It has been shown that in many commercially available ACC systems, errors are actually amplified from one vehicle to its follower [4]. To assess this problem, the concept of string stability is introduced. In a string stable platoon, disturbance propagation does not increase along the platoon. Multiple definitions for string stability were proposed in the past as surveyed in [5].

Intensive research has been done before on linear platoon dynamics. Due to high expenses of testing platoon dynamics in real world settings though, only few experiments were executed. To allow an efficient assessment and analysis of platoon behaviour in arbitrary simulation settings, this work provides the following main contributions:

- methods formulated to assess
  - stability properties,
  - string stability analysis and
  - performance indicators,
- implemented into tools to evaluate these aspects in
  - linear dynamics,
  - non-linear high-fidelity co-simulation settings.

Using the proposed methods and tools allows to evaluate platoon performance in realistic settings in an efficient and reproducible way.

2 LINEAR AND NON-LINEAR MODELS

In this first section, the chosen platoon model, classical linear stability as well as string stability are described.

2.1 Linear platoon dynamics model

The position of each vehicle is denoted as x_i wherein the index $i \in \mathbb{Z}$ refers to the i-th vehicle. Hence, x_{i-1} denotes the predecessor's position, and x_{i+1} as the follower's as depicted in Fig. 1. The distance between one vehicle and its predecessor is given by

$$d_i = x_{i-1} - x_i - L_{i-1}, \tag{1}$$

where L_i denotes the length of the i-th vehicle. Starting from x (index i dropped in the following when referring to the ego vehicle i only), the velocity v and the acceleration a are given by the differential equations $v = \dot{x}$ and $a = \dot{v}$. For simplicity (to measure error propagation) homogeneous vehicle platoons are assumed below. With the controller input $u := a_{desired}$ and by approximating the vehicle behaviour with the simplified linear time invariant (LTI) dynamics

$$\dot{a} = -\frac{1}{\tau}a + \frac{1}{\tau}u, \tag{2}$$

as well as using the state vector $\mathbf{x} = \begin{bmatrix} x & v & a \end{bmatrix}^T$, the general vehicular system in discrete state-space form can be written as

$$\mathbf{x}_{k+1} = \mathbf{A}_d \mathbf{x}_k + \mathbf{b}_d u_k \tag{3}$$

where $\mathbf{A}_d$ and $\mathbf{b}_d$ are the corresponding discrete equivalents of $\mathbf{A}$ and $\mathbf{b}$ with T_s as sampling time. The time constant $\tau = \tau(v)$ represents the engine dynamics, which depends on the current vehicle's velocity. Due to this dependence, a constant value of τ can only be assumed for a specific operating point at velocity v_0. Furthermore, to focus on control parameter studies, wireless communication is assumed flawless.

2.2 Non-linear platoon dynamics

With knowledge of linear vehicle dynamics behaviour, more sophisticated results are obtained using the non-linear high fidelity simulation software IPG TruckMaker®[7]. The co-simulation structure is depicted in Fig. 2, taken from [3].

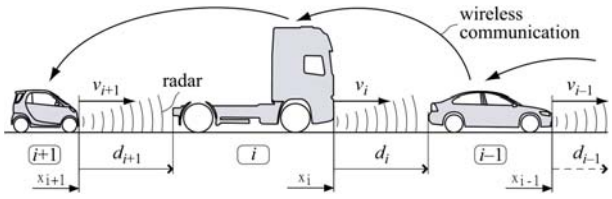

Figure 1: CACC-equipped string of vehicles, adopted from [6]

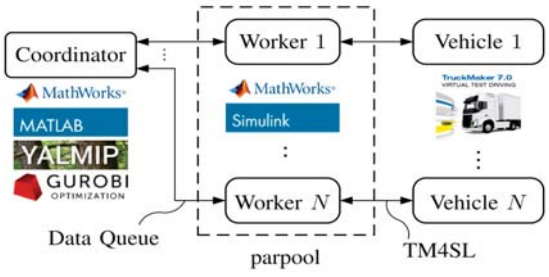

Figure 2: Structure of the co-simulation setup taken from [3]

3 STABILITY PROPERTIES

In general two aspects of stability are considered. First one to be addressed is individual vehicle stability. On one hand, direct evaluation of classical stability exists in linear time-invariant systems, in which one vehicle is linearly modelled as mentioned in Sec. 2.1. In this work absolute and relative stability criteria are used to assess linear dynamics stability.

3.1 Combined criterion of absolute and relative stability

The absolute stability criterion of the Laplace transformed system $G(s)$ is given by

$$\max(\Re(s_j)) < -\alpha, \qquad \forall j = 1, ..., n, \quad \alpha \geq 0, \tag{4}$$

where $\max(\Re(s_j))$ denotes the real part of the slowest pole, α is the value which corresponds to the desired absolute stability (decay rate of envelope) and n is the order of the denominator polynomial of $G(s)$. With (4) fulfilled, any error response in the system decays faster than $\exp(-\alpha t)$. Classical stability corresponds to fulfilling (4) with $\alpha = 0$. Relative stability is fulfilled if all poles at least show damping ratio ζ_{min}, that is, they lie to the left of the rays

$$\mathrm{s} = \omega_n \left(-\zeta_{\min} + j\sqrt{1 - \zeta_{\min}^2} \right) \qquad \omega_n \in \mathbb{R}^+ \cup \{0\} \tag{5}$$

with $\zeta_{\min}$ as the desired damping factor and ω_n as the natural frequency of the oscillation.

If both criteria (4) and (5) are met, the system is considered as stable under the stability requirements α and ζ_{min}.

3.2 String stability criteria

String stability, on the other hand, is one special problem in autonomous platoon control. For example, the fact that adaptive cruise control (ACC) systems as they are implemented in modern autonomous vehicles are stable and robust, does not imply a damping effect on error propagation between vehicles. Such controllers are thus generally not string stable for an autonomous platoon as shown in [4]. There are numerous definitions for string stability as surveyed in [5]. The original verbal definition from [8] reads

Def. *A string of vehicle is stable if, for any set of bounded initial disturbances to all the vehicles, the position fluctuations of all the vehicles remain bounded and these fluctuations approach zeros as* $t \to \infty$

However, to assess string stability mathematically, one common criterion for string stability, taken from [5], is given by the system p-norm

$$\|G_i(s)\|_p \leq \|G_{i-1}(s)\|_p \qquad p = 1, 2, \infty, \tag{6}$$

where $G_i(s)$ is a chosen closed-loop error transfer function in the case of linear platoon dynamics. An empirical formulation based on error signal $\mathcal{L}_p$-norms, also from [5], reads

$$\text{a)} \quad \frac{\|e_i\|_p}{\|e_{i-1}\|_p} \leq 1 \qquad \text{b)} \quad \frac{\|e_i\|_p}{\|e_2\|_p} \leq 1 \qquad i = 3, ..., m \qquad p = 1, 2, \infty, \tag{7}$$

where e_i denotes the spatial error signal, see Sec. 4.1, and m is the number of vehicles in the platoon. Essentially, equation (7, a) requires that the selected error signal norm decays along the platoon. A weaker formulation is formulated by (7, b) which means that the error signal norm is bounded behind the second vehicle.

Note that even in a string stable platoon, collisions can happen if the spatial error exceeds the required distance d_i. Therefore the $\mathcal{L}_\infty$-norm of the spatial error needs to be bounded as

$$\|e_i\|_\infty \leq r + hv_i \qquad i = 2, \ldots, m, \tag{8}$$

to assure string stability and collision avoidance. In turn, the $\mathcal{L}_1$ or $\mathcal{L}_2$-norms are less relevant if they are not strictly decaying along the platoon, however, further investigation is required in this case. Furthermore a performance indicator can be defined for each vehicle by quantifying the ratio of eqn. (7, a). Taking the average ratio across the platoon (9, b) is one possible measure of the performance of the platoon.

$$\text{a)} \quad PI_{p,i}^{string} = \frac{\|e_i\|_p}{\|e_{i-1}\|_p} \qquad \text{a)} \quad PI_{p,avg}^{string} = \frac{1}{m-1}\sum_{i=2}^{m} \frac{\|e_i\|_p}{\|e_{i-1}\|_p}. \tag{9}$$

4 PLATOON CONTROL STRUCTURES

In this work, close attention is paid to the cooperative adaptive cruise controller (CACC) derived in [6] as well as the model predictive controller (MPC) used in [3].

4.1 Cooperative adaptive cruise control (CACC)

Starting from a constant time headway spacing policy the position error is given by

$$e_i(t) = (x_{i-1}(t) - x_i(t) - L_{i-1}) - (r + hv_i(t)) \tag{10}$$

with the time headway h and the desired standstill distance r. The control law is designed for the error dynamics as

$$\dot{u}_i = -\frac{1}{h}u_i + \frac{1}{h}(k_p e_i + k_d \dot{e}_i + k_{dd}\ddot{e}_i) + \frac{1}{h}u_{i-1}, \qquad i = 2, \ldots, m,$$

with the adjustable controller parameters $\mathbf{K} = \begin{bmatrix} k_p & k_d & k_{dd} \end{bmatrix}^T$ and the desired acceleration u_i of vehicle i. Note that the leader vehicle in position $i = 1$ is controlled differently. The block diagram of the controlled system is depicted in Fig. 3 with the controller parameter vector $K(s)$ and the vehicle actuation transfer function $G(s)$

$$K(s) = k_p + k_d s + k_{dd} s^2, \qquad G(s) = \frac{1}{\tau s + 1} \tag{11}$$

4.2 Model predictive controller (MPC)

A more sophisticated controller is given by the distributed platooning MPC with safety guarantees as detailed [3]. In that concept, predicted ego vehicle trajectories are being communicated to the follower in order to inform the follower's predictive control problem. This communication is done event-triggered based on a predefined tolerance which is a key design parameter.

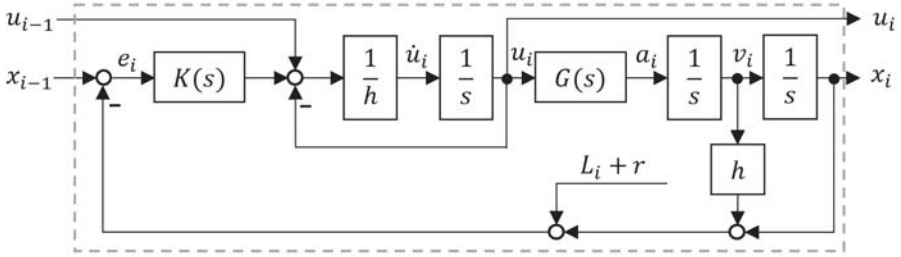

Figure 3: Block diagram of a CACC controlled vehicle adopted from [6].

5 METHODS AND TOOLS

In this section, the developed methods and tools are presented. With the listed mathematical criteria, a platoon can be tested for classical stability as well as string stability.

5.1 Parametrization of the controller

For the CACC control structure of Sec. 4.1, the platoon closed loop dynamics is parametrized via the parameter vector $\mathbf{K}$ given by

$$\mathbf{K} \in \mathcal{K}_p \times \mathcal{K}_d \times \mathcal{K}_{dd} \tag{12}$$

wherein $\mathcal{K}_p = \{k_{p,\min}, \ldots, k_{p,\max}\}$ (with $\mathcal{K}_d$ and $\mathcal{K}_{dd}$ defined analogously) are sets which contain all investigated parameter values. The platoon analyses are carried out on the whole cartesian parameter space. Depending on which values are tested, the parameter vector $\mathbf{K}$ can be defined analogously for any control architecture.

5.2 Stability analysis of individual vehicles

Starting out, a linear model has to be checked if the required classical stability criteria are met. This is achieved by calculating the poles of the resulting discrete system which correspond to the eigenvalues of $\mathbf{A}_d$, see equation (3). As these poles are in the discrete z-domain they are converted back to the continuous time s-domain by $s = \frac{1}{T_s}\ln(z)$, with the sampling time T_s. Absolute and relative stability are then checked with equations (4) and (5). Thus irrelevant parameter combinations are sorted out rapidly.

5.3 Platoon string stability

With knowledge about linear individual vehicle stability, string stability can be assessed via simulation of the platoon with predetermined manoeuvres (see Sec. 5.6). The resulting error signal norms are then used in criteria (7, a or b) to assess string stability. As linear analysis requires only small effort, a large range of parameter combinations can be tested efficiently.

The non-linear co-simulation setup is then used to compare with linear analysis on a subset of the parameter combinations and receive high-fidelity results via the software IPG TruckMaker®.

5.4 Performance indicator

To further investigate non-linear platoon behaviour a performance indicator (PI) is evaluated via eqn. (9), which is the averaged quantification of the error decay along vehicles $2, \ldots, m$ along the platoon.

Note: Although these methods are described with the CACC architecture, they can readily be used for other control architectures (such as the distributed MPC from [3]) as well.

5.5 Implementation of analysis methods and tools

The developed set of methods and tools have been implemented in MATLAB as described in the following section. First, the goal is to obtain knowledge of relevant parameter ranges in which basic individual vehicle stability is present. Then, string stability has to be assessed only if each individual vehicle is stable. The second part is responsible to test one specific combination of parameters with either the linear or non-linear dynamics (TruckMaker co-simulation). To run the second part for all relevant configurations from part 1, the third code part is developed. Finally the simulation results are assessed for performance properties. A summarized overview is given in Fig. 4.

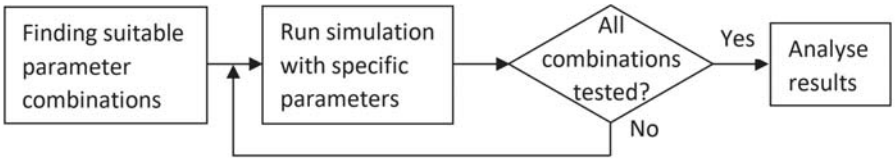

Figure 4: Flow-chart of the algorithm

5.6 Platoon simulation

Starting out, a suitable value for the time constant τ, used in the linear model, has to be set. By simulating an acceleration step of $a = 0.2\,\mathrm{m/s^2}$ starting from $v = 50\,\mathrm{km/h}$, a time constant of $\tau = 0.3\,\mathrm{s}$ is chosen as an appropriate approximation the drivetrain dynamics by comparing against the detailed TruckMaker co-simulation.

It shows that the linear model can produce too large control signals which is not directly comparable to the non-linear situation, where the maximum acceleration is significantly limited by the power of the vehicle's engine. Thus, for the linear simulation, maximum acceleration bounds $a_{\max}(v)$ are implemented as a lookup table, clipping acceleration and deceleration with respect to the current velocity v. The used data for the clipping bounds are typical values of realistic HDVs.

To efficiently obtain the desired information, three different test manoeuvres are implemented. First, an acceleration step response is tested for one individual vehicle, which allows to estimate the time constant τ used in the linear model. The second manoeuvre is set up to assess string stability. The platoon is required to drive at a constant velocity while at time t_M the leader performs a short sudden braking action followed by acceleration to the desired velocity again. This allows to examine error propagation empirically. Finally, a velocity reference step is investigated to further understand the behaviour of the platoon.

As all relevant parameter combinations need to be tested, a result matrix $\mathcal{M}^{string}(PI^{string}_{p,i})$ is defined to store the results with parametrization $\mathbf{K}$ as mentioned in section 5.1. To keep the result memory requirements small, only the number of decaying p-norms is stored.

In this study, 3 different error signal p-norms ($\|\cdot\|_1,\ \|\cdot\|_2,\ \|\cdot\|_\infty$) are evaluated. These are then normalized by the value of the second vehicle. Thus an direct evaluation of string stability can be done as given by equation (7, left).

6 RESULTS

As mentioned above, special attention is given to the selected CACC and MPC architectures. Results obtained via the above derived methods and tools are presented in this section.

6.1 Cooperative adaptive cruise control

Three parameters are tested for the CACC architecture as mentioned in Sec. 5.1. The comparison of string stable and string unstable behaviour is depicted in Fig. 5. 2D-slices of the resulting matrix $\mathcal{M}^{string}$ are depicted in Fig. 6. Although the majority of the linear system configurations meet the stability requirements, only a few parameter configurations of the non-linear system lead to all three error signal norms decaying.The performance indicator shows decaying $\mathcal{L}_\infty$ error norms for a string stable system as depicted in Fig. 7.

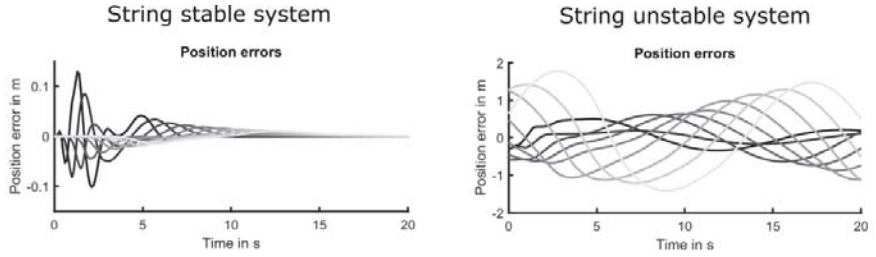

Figure 5: Example of a string stable and a string unstable parameter configuration. Starting from the second vehicle in black, following vehicles getting brighter in colour.

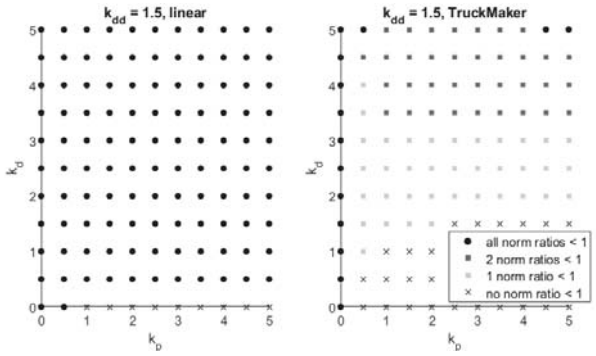

Figure 6: String stability map for parametrization $\mathbf{K}$ with linear simulation results left and non-linear co-simulation results right.

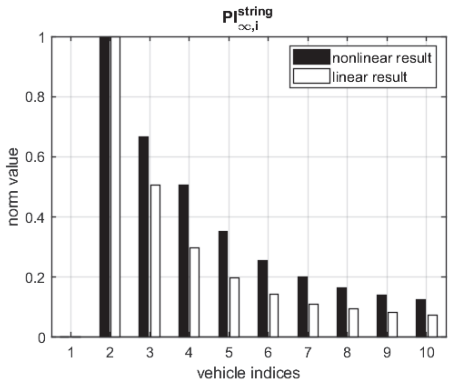

Figure 7: $PI_{\infty,i}^{string}$ (eqn. (9)) resulting from CACC parameters: $k_p = 5$, $k_d = 5$ and $k_{dd} = 1.5$.

6.2 Model predictive control

For the MPC architecture the varied parameters are the corridor width r (defining the event trigger tolerance to send predictive information along the platoon) and the tolerance time samples n_{tol} (affecting control robustness) (see [3] for details). The chosen manoeuvre consists of a platoon of 10 vehicles driving at a speed of $v = 50\,\mathrm{km/h}$ which approach a slower car driving at $v = 30\,\mathrm{km/h}$. The controlled platoon slows down to avoid a collision. Fig. 8 shows the parameter result map (left) as well as the performance indicator for a string stable system (middle) and a string unstable system (right).

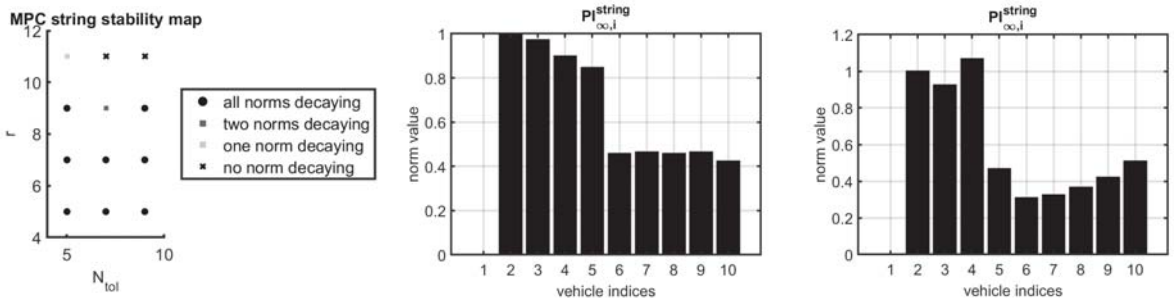

Figure 8: Results from the MPC with the string stability map (left) and $PI_{p,i}^{string}$ for a stable system ($r = 9, N_{tol} = 5$, middle) as well as for an unstable system ($r = 11, N_{tol} = 7$, right) with $p = \infty$

7 CONCLUSIONS

In this work, methods and tools are proposed to efficiently assess and quantify stability and performance aspects of semi-autonomous vehicular platoons. These allow to compare results from linear investigations with results gained from a high-fidelity co-simulation, here based on detail simulations with the commercial software IPG TruckMaker®. A short overview of investigated aspects is given in Table 1. These proposed tools can directly be applied to assess the performance of other control architectures.

Evaluated Aspect	CACC	MPC
Individual stability	✓	
Linear string stability	✓	
Non-linear string stability	✓	✓
Performance	✓	✓

Table 1: Overview of investigated aspects of CACC and MPC architectures.

Keywords: Creep groan, Disk brake, Test rig, Transient simulation, Vibration analysis

Abstract. *Vibro-acoustic brake emissions impair a vehicle's comfort and quality. In this context, self-excited brake creep groan phenomena gain in relevance. The non-linear low-frequency vibrations of creep groan potentially appear during an overlap of moderate brake pressures with slow velocities near standstill. Electrified cars with semi-autonomous driving functionalities are especially prone. To treat creep groan already at early stages of the brake development process, reliable investigation and evaluation methods must be available. On that account, this paper deals with test rig experiments and equivalent transient simulations. Both approaches are considered at vehicle corner level which involves axle and suspension components, brake assembly and wheel of one front side of a passenger car. The observed creep groan phenomena have fundamental stick-slip intervals at approximately 90 or 20 Hz. To analyse measured and/or computed time series data in a deterministic way, different rating criteria are specified. These relate to physically reasonable, purely synthetic or statistical metrics. Thereby obtained abstract number values allow the identification, categorisation and validation of brake creep groan vibrations in experiment and/or simulation.*

1 INTRODUCTION

1.1 Vibro-acoustic brake emissions

Noise, vibration and harshness (NVH) phenomena of technical products have a long-term relevance, see trend curves in Figure 1. As discussed by Barden [1], haptical characteristics and audible properties evolve into the most important subconscious criteria after a few month after purchase.

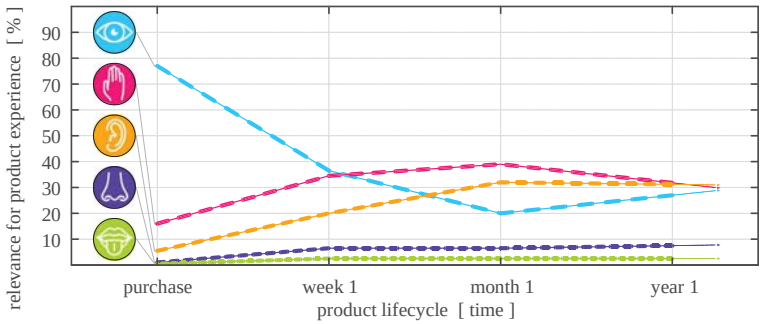

Figure 1: Product experience over time, adapted from [1].

Vibro-acoustic phenomena are critical in automotive fields. Abendroth et al. [2] discussed this issue with respect to friction brake systems. Haptical and audible brake NVH problems impair a vehicle's comfort and quality. Moreover, vibro-acoustic brake emissions pretend a brake system malfunction.

North American market studies from 2011 [3] and 2014 [4] indicated brake NVH phenomena as a top-three complaint reason about passenger cars newer than six months and as a top-five complaint reason about passenger cars newer than three years. A survey from 2017 [5] revealed vibro-acoustic brake emissions as major inconvenience for roughly 2 % of Japanese customers.

Warranty claims against the manufacturers are caused by multiple possible brake NVH problems, see terminology in Figure 2 and remarks in [6].

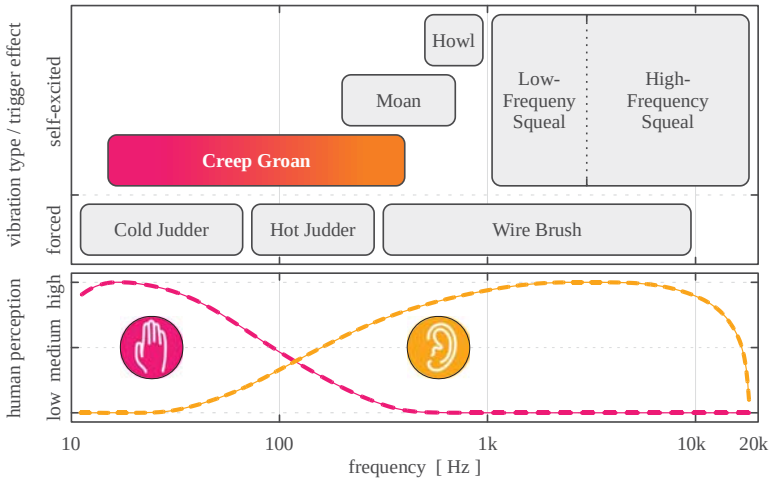

Figure 2: Typical classification and human perception of disk brake NVH phenomena.

1.2 Brake creep groan

According to literature [7 - 21] and the authors' works [22 - 26], disk brake creep groan can be described as follows:

Creep groan refers to periodic non-linear brake and chassis vibrations which are relevant in a low-frequency range from approximately 15 to 400 Hz.

Creep groan phenomena mainly occur at brake pressures below 30 bar in conjunction with vehicle velocities below 0.3 km/h.

It occurs if drive torque and brake torque are at similar levels. The friction contacts between linings and disk potentially have two alternating tribological states, namely stick or slip. The macroscopic stick causes a system pretension with large elastic deflections. The macroscopic slip leads to a relaxation of the system. Alternating stick-slip is enabled by different coefficients of static and dynamic friction. Depending on the situation, self-excited stick-slip persists up to some seconds.

Each abrupt transition from stick to slip excites resonances of the auxiliary vehicle corner components. These inherent oscillations significantly contribute to the impulsive non-linear vibrations.

Creep groan mainly appears for cars with automated gearboxes or electrified automobiles if the service brake is released for a slow move-off. Creep groan also appears for vehicles with any powertrain architecture if the service brake is released for a slow roll-off at inclines or if the service brake is activated during steering at standstill. Moreover, semi-autonomous driving functionalities such as remote-controlled-parking often lead to creep groan, see Figure 3.

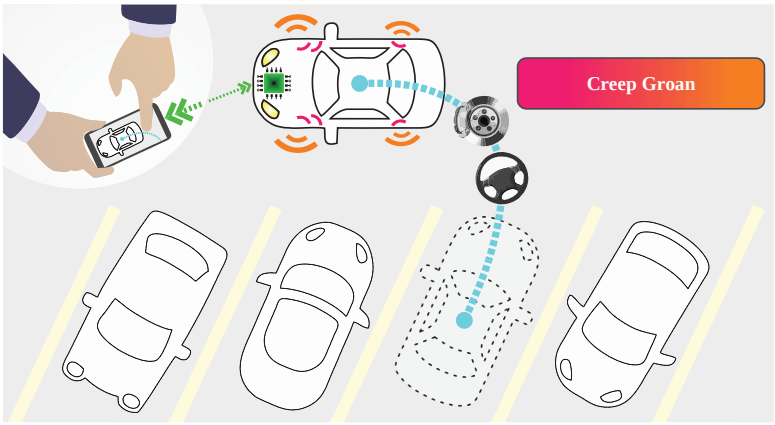

Figure 3: Remote-controlled-parking with creep groan during slow move-off or during steering at standstill.

To avoid further expensive warranty claims against the manufacturers, creep groan robust brake systems must be designed based on improved brake NVH development processes. As outlined by Abendroth et al. [2] and Abdelhamid [6], the manufacturers require more standardised investigation methods as well as more homogenous data analysis techniques.

1.3 Existing investigation (data generation) methods for brake creep groan

Early industrial publications, e.g. the work of Schwartz et al. [7], rather focussed on basic road tests. Papers of the 1990s, e.g. [8 - 10], comprised more detailed full vehicle measurements and/or simple dynamometer test bench investigations. These studies also included a 1-d rigid body model [8] and a 2-d finite element (FE) model [9]. Then, a 3-d multi-body system (MBS) model [11] and a sophisticated lumped torsional model [12] of the vehicle driveline were presented.

More recent publications from industry and academia often involve road tests, test rig experiments at different subsystem levels and/or friction pair benchmarks, e.g. [13 - 21]. Simulative investigations of diversified complexity can also be found, compare with [15, 16, 20, 21].

Several previous works of the authors have dealt with subsystem test procedures and equivalent simulative methods. An experimental creep groan screening approach is discussed in [22]. It is performed on a drum driven suspension and brake test rig. A transient simulation strategy for the computation of creep groan vibrations is discussed in [24, 26]. It relates to a 3-d corner FE model.

In current brake NVH development processes, full vehicle road tests such as the recommendation VDA 314 [27] are state-of-the-art. No creep groan experiments at component level are performed by the manufacturers. No approach for a reliable simulative prediction of creep groan is established.

1.4 Remarks on established data evaluation techniques for brake squeal

To evaluate brake squeal at component level, experimental and simulative techniques are widely applied in current brake NVH development processes.

On the experimental side, one can find the recommendation SAE J2521 APR2013 [28], see discussion in [2, 6]. This established dynamometer test matrix procedure involves more than thousand operational parameter combinations. A spectral algorithm analyses the A-weighted sound pressure level (SPL). If a certain deciBel (dB) threshold is exceeded within two given frequency limits, any acoustic event is quantitatively rated as squeal noise. All measurements can be cumulated to one objective noise index (ONI) according to directives of an acceptance chart. This chart has adaptable rating scales, e.g. values from 1 to 9 with 1 as worst case. The ONI correlates with the subjective human perception.

On the simulative side, one can find the complex eigenvalue analysis (CEA), see mathematical description in [23]. This established quasi-static linear FE approach calculates the natural mid- to high-frequency oscillation behaviour of the operated brake system. The complex eigenvalues calculated by the CEA are analysed. Negatively damped eigenmodes appear if the real parts of the complex eigenvalues have positive signs. This case refers to dynamically unstable modal coupling and squeal noise respectively.

1.5 Existing data evaluation techniques for brake creep groan

The full vehicle road test procedure VDA 314 [27] consists of separated creep groan test sessions. Subjective annoyance ratings from 1 to 10 are determined by the test driver. Averaged and maximum A-weighted SPL of at least one cabin microphone are documented as well. Accelerometers at each brake calliper are optional. Exemplary raw data is shown in Figure 4.

The measured sound pressure next to the driver’s ear is an incoherent superposition of 85 Hz creep groan at both front brakes of the tested car. However, there is also significant background noise from the internal combustion engine of the passenger car.

In general, sound pressure analyses are more challenging for creep groan than for squeal due to reasons such as reduced low-frequency microphone sensitivity and harsh noise composition of creep groan including super-harmonics. Bader [13] applied a discrete wavelet transformation including its inverse equivalent. His method relates to the kurtosis which describes the fourth moment of the signal. It is increased during creep groan. Abdelhamid and Bray [14] used a signal whitening filter to improve the results. Moreover, they applied tonality and loudness to obtain psycho-acoustic evaluations. Augsburg et al. [19] calculated the radiated sound power based on microphone data, but the outcome of this method was not discussed.

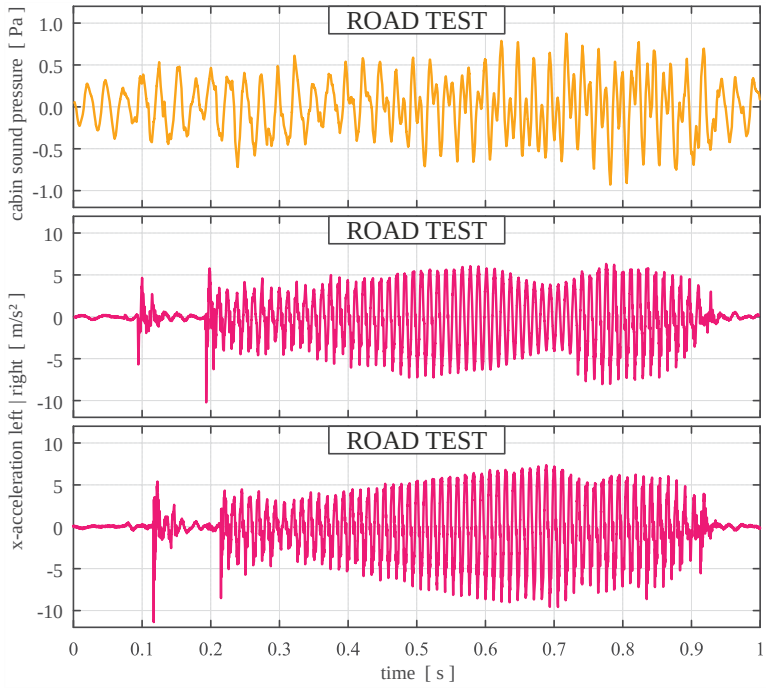

Figure 4: Cabin microphone signal and both front brake calliper x-acceleration signals of exemplary 85 Hz creep groan during road tests.

In general, acceleration analyses regarding creep groan are challenging as well. To detect creep groan, Crowther and Singh [12] examined time domain metrics such as duration of creep groan, dynamic acceleration range and two different quadratic sum definitions. Neis et al. [17] used a root mean square (RMS) expression akin to these quadratic sums. A similar method was presented by Augsburg et al. [19]. This group calculated an averaged overall vibration emission by the RMS in the frequency domain. Rösner and Özdil [18] applied modulation principles, e.g. a low-pass filter or a peak hold algorithm. They found correlations between cumulative energy as well as time domain peak hold areas with purely subjective ratings. Zhao et al. [21] used the acceleration's kurtosis to detect creep groan.

The authors elaborated two techniques to analyse and classify creep groan based on acceleration signals, see [22, 25]. A spectral algorithm is described in [22]. If an adjustable dB threshold is exceeded by several equidistant peaks within two adaptable frequency limits, any brake NVH event is quantitatively rated as creep groan. Moreover, the fundamental stick-slip frequency is identified by logical inquiries. An artificial neural network (ANN) framework is treated in [25]. It rests on millions of emulated acceleration spectra. Inputs and outputs during training of the ANN framework were created according to the spectral algorithm's logic. Based on both techniques, the systematic test matrix measurements lead to a creep groan map (CGM) and a cumulated creep groan index (CGI), see [22]. The CGI indicates excellent to poor creep groan performance with values from 0 to 1000. Certainly, these analyses can be applied to simulative data alike.

Transient simulation offers great potentials to gain deeper insight to the mechanisms of creep groan vibrations. To evaluate simulative data, time series of disk to linings relative motions are often used, compare with [11, 20, 23, 24, 26]. System energy quantities, e.g. dissipative energy [11, 20], or friction contacts associated quantities, e.g. local coefficient of friction [9, 20], are also suitable to evaluate creep groan vibrations.

1.6 Outline of this paper

Firstly, experiments and simulations at vehicle corner level are discussed. Then, comparison metrics are introduced. These are used for the identification, categorisation and validation of typical brake creep groan vibrations. Lastly, conclusions are drawn.

2 TEST RIG EXPERIMENTS

A vehicle corner including its wheel is according to Augsburg et al. [19] a suitable subsystem to perform creep groan experiments. In terms of complexity, corner test rigs are situated in between inertia type brake dynamometers and roller type chassis dynamometers, see differentiations in [2, 18].

The authors have access to a drum driven suspension and brake test rig. It is placed in an air-conditioned chamber. A hydraulically adjusted loading unit maintains a defined in-situ height of the test setup to guarantee the correct vertical pretension of axle and suspension components. The wheel is driven against a brake torque exclusively by the drum. Therefore, brake pressure and drum velocity are under control. Further information on the corner test rig is provided in [22 - 26].

The relevant test setup is a MacPherson suspension strut assembly of the left front side including its 17” wheel. It has a front-mounted single-piston floating calliper brake system. The friction couple consists of a ventilated 330 mm cast iron monobloc disk and pad linings which are designed for the European market. This test setup, which has a mass of roughly 55 kg, is mounted to the test rig’s attachment plate, see photograph in Figure 5.

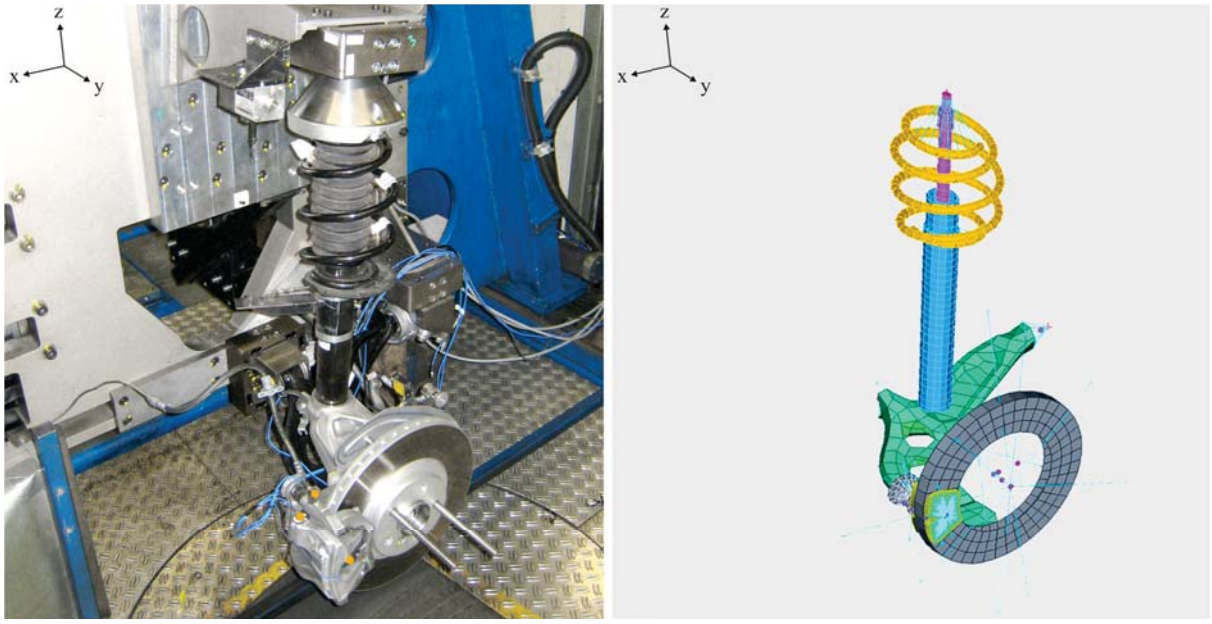

Figure 5: Left: Drum driven corner test rig including lifted MacPherson setup (wheel removed) with front-mounted floating calliper brake system. Right: Pre-processor representation of corner FE model (wheel included) at in-situ height.

The installed sensor equipment is listed in Table 1. Signals were sampled at 10 kHz. In particular, two axis directions from the triaxial accelerometer at the calliper anchor as well as the y-force from the load cell behind the hydro bushing are relevant in this paper.

subject	component; location	sensor type
acceleration	floating calliper; top middle	triaxial accelerometer ‘PCB 356A01-HT’
-‖-	calliper anchor; top middle	triaxial accelerometer ‘PCB 356A02’

Table 1: Sensor equipment in corner test rig experiments.

Systematic test matrix measurements were carried out for brake pressures from 4 to 40 bar and drum velocities from 0.04 to 0.40 km/h. A cooling airstream stabilised the friction pair temperature between 20 and 35°C.

The analysis of calliper acceleration signals leads to a CGM, see Figure 6. Regions with creep groan are clearly separated from rather uncritical vibration-free sections. Large coloured circles indicate creep groan as well as its fundamental stick-slip frequency. Note that regions with multiple possible creep groan phenomena can be identified, e.g. for 15 bar at 0.14 km/h. Basic explanations on these vibration bifurcations are provided in [21].

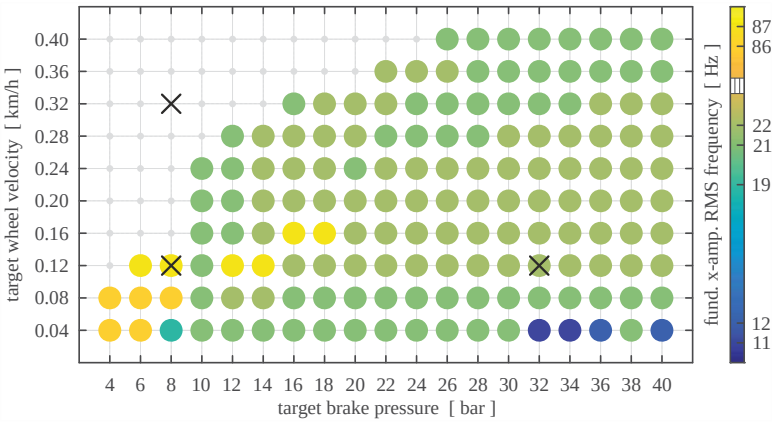

Figure 6: Exemplary CGM of fundamental creep groan frequencies.

Three representative experimental examples, which are marked with a cross in Figure 6, are chosen to apply different comparison metrics:

- **no creep groan for 8 bar at 0.32 km/h**
- **87 Hz creep groan for 8 bar at 0.12 km/h**
- **22 Hz creep groan for 32 bar at 0.12 km/h**

3 FE SIMULATIONS

A 3-d FE model was presented in [24]. It was used in [26] as well. An improved version of this initial 3-d FE model is relevant here. The improvements relate to the contact stiffness definition, the suspension strut discretisation, the coordinate system alignment and the system's velocity excitation as well as its longitudinal pretension. A pre-processor snapshot of this improved corner FE model is shown in Figure 5. Vehicle corner parts and FE model implementations are listed in Table 2. An overview of topology, elements, constraints as well as other descriptive subjects is given in Table 4 (Appendix).

vehicle corner part	FE model implementation
tyre 17"	linear spring-damper elements + point inertia
5-spoke rim	kinematic couplings + point inertia
monobloc disk	rigid shells + point inertia
pad lining	solid continuum elements
pad backing plate	kinematic couplings + point inertia
hydraulic piston	rigid shells + kinematic couplings + point inertia
floating calliper	rigid shells + kinematic couplings + point inertia
calliper anchor	kinematic couplings + point inertia
knuckle with hub	kinematic couplings + point inertia
control arm	shell continuum elements
track rod	rigid elements + point inertia
hydro bushing (y)	non-linear spring-damper element
other bushings (xyz)	linear spring-damper elements
strut damper tube	Timoshenko beams
strut damper rod	Timoshenko beams
strut coil spring	Timoshenko beams

Table 2: MacPherson setup with floating calliper brake system versus FE model.

The corner FE model has a mass of almost 53 kg. It involves 3438 nodes and 2449 elements which have a minimum length of 1.50 mm. Each lining consists of 792 first-order solid elements which have an averaged length of 4.39 mm. The disk is considered by rigid shells. The two structural components of the floating calliper subsystem are simplified by lumped masses in kinematic relations. More attention was paid to the suspension strut assembly including coil spring because this subsystem strongly participates in the non-linear vibration patterns during creep groan. Rubber bushings and hydro bushings also strongly contribute to quasi-static displacements and dynamic deflections of the vehicle corner, see [24, 26].

Four boundary nodes provide fixed positions similar to the attachment points at the corner test rig. Since the FE model is positioned at in-situ height, no loading according to the car's mass is applied. Longitudinal and rotational pretension of the axle and suspension components is achieved by imposing brake pressure as well as ground velocity. Further information on the application of both operational parameters is provided in [24, 26].

The exponential expression according to Equation 1 is relevant for the tangential friction interaction of disk to linings, compare with [15, 16, 20]. The specific coefficient of friction μ at any lining node depends on the local relative speed $\dot{c}_r$. Two exemplary curves were defined, see [24, 26]. The coefficient of static friction μ_s was set to 0.5 respectively. The coefficient of dynamic friction μ_k was set to 0.45 for 8 bar and it was set to 0.42 for 32 bar. The decay factor d_c was set to 0.1609 for 8 bar and it was set to 0.0208 for 32 bar.

$$\mu = \mu_k + (\mu_s - \mu_k) e^{-d_c \dot{c}_r} \tag{1}$$

ABAQUS was used for transient FE simulations. Two solution schemes of direct time integration were considered, namely explicit and implicit. Initial and minimum time increment of the implicit algorithm were manually set to 1e-3 and 1e-12 s. Based on the FE model's properties, e.g. size, density and stiffness of each element, the stable time increment for the explicit scheme was automatically set to 3.612e-7 s. Computations were performed on four cores of a 2 GHz processor with access to 96 GByte main memory.

The result correlation of both solution schemes appeared quite well, but the calculation effort was clearly different. In case of macroscopic stick-slip, the ratio between computation time and simulation time was at least 58e3 for the best-performing implicit scheme, but it was always roughly 19e3 for the explicit algorithm. These ratios are valid for 2 s simulation time and output data sampled at 10 kHz. Results calculated by the explicit scheme are presented in this paper.

In analogy to the three representative experimental examples, comparable simulative examples are chosen to apply different comparison metrics:

- **no creep groan for 8 bar at 0.32 km/h**
- **89 Hz creep groan for 8 bar at 0.12 km/h**
- **23 Hz creep groan for 32 bar at 0.12 km/h**

4 DEFINITION OF COMPARISON METRICS

4.1 Spectral contents - various signals

The overall RMS value y_{RMS} for n values of a digitised field quantity signal y_i reads as Equation 2. This physically reasonable definition reflects the original signal's energy equivalent. The overall dB level $\mathrm{L}_{y_{\mathrm{RMS}}}$ in reference to a predefined or standardised value y_0 reads as Equation 3.

$$y_{\mathrm{RMS}} = \sqrt{\frac{1}{n}\sum_{i=1}^{n}|y_i|^2} \tag{2}$$

$$\mathrm{L}_{y_{\mathrm{RMS}}} = 10\lg\frac{y_{\mathrm{RMS}}^2}{y_0^2} \tag{3}$$

Time series data sampled at 10 kHz is relevant. Frequency spectra are calculated from 1 Hz to 2.5 kHz in a constant 1 Hz interval. Therefore, a Hanning window Fast Fourier Transform (FFT) algorithm is used. It splits any digitised signal into a finite number of sine functions with corresponding frequency, amplitude and phase. If this is done for n values of y_i, a separate $y_{\mathrm{RMS}}(f_j)$ is available for each discrete frequency f_j. The incoherent spectral dB level sum $\mathrm{L}_{y[f_a, f_b]}$, which includes each $y_{\mathrm{RMS}}(f_j)$ within two frequencies $[f_a, f_b]$, is for a constant interval Δf as written in Equation 4. It represents an incoherent superposition of certain spectral components of the original signal. Two identical incoherent summands would achieve a 3 dB increase.

$$\mathrm{L}_{y[f_a, f_b]} = 10\lg\frac{y_{\mathrm{RMS}}^2(f_a) + y_{\mathrm{RMS}}^2(f_a+\Delta f) + \cdots + y_{\mathrm{RMS}}^2(f_b)}{y_0^2} \tag{4}$$

If an energy size signal Y_i is analysed, the overall arithmetic mean value $\mathrm{Y}_{\mathrm{amv}}$ according to Equation 5 is used instead of Equation 2. Nevertheless, it also reflects the original signal's energy equivalent. The overall dB level $\mathrm{L}_{\mathrm{Y}_{\mathrm{amv}}}$ in reference to Y_0 reads as Equation 6.

$$\mathrm{Y_{amv}} = \frac{1}{n}\sum_{i=1}^{n} Y_i \tag{5}$$

$$\mathrm{L_{Y_{amv}}} = 10\lg\frac{\mathrm{Y_{amv}}}{Y_0} \tag{6}$$

After the Hanning window FFT is performed, the spectral dB level sum $\mathbf{L_{Y[f_a, f_b]}}$ includes each relevant $\mathbf{Y_{amv}}(f_j)$. It is calculated according to Equation 7. Again, a superposition of two equally valued spectral summands would achieve a 3 dB increase.

$$\mathrm{L_{Y[f_a, f_b]}} = 10\lg\frac{\mathrm{Y_{amv}}(f_a) + \mathrm{Y_{amv}}(f_a + \Delta f) + \cdots + \mathrm{Y_{amv}}(f_b)}{Y_0} \tag{7}$$

4.2 Orbital indices - motion signals

In the following, the estimation of the border area $\mathbf{A_{P_v|Q_h}}$ of an exemplary 2-d orbit face is explained, see Figure 7. This synthetic metric is shaped by two digitised signals which are denoted as P_v and Q_h here. The signals' subscripts indicate vertical and horizontal axis assignments. To estimate $\mathbf{A_{P_v|Q_h}}$, two synchronous calculation threads are executed.

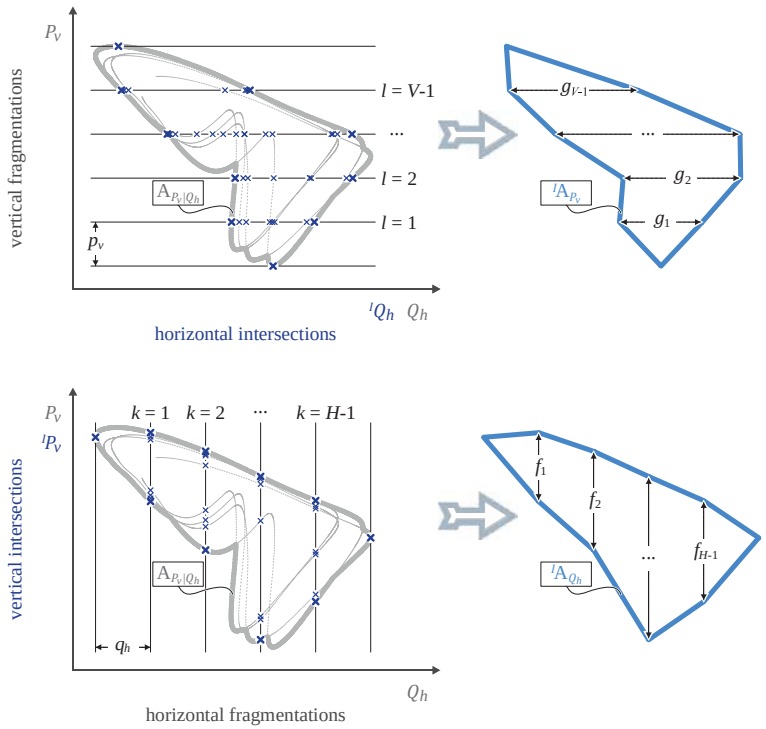

Figure 7: Synchronous calculation threads for the border area of an exemplary 2-d orbit face.

Firstly, a number of V equidistant fragments of height p_v and a number of H equidistant fragments of width q_h are used to discretise the 2-d orbit face. Height p_v and width q_h are defined by Equation 8 and Equation 9 with respect to 50 equidistant fragments respectively.

$$p_v = \frac{\max(P_v) - \min(P_v)}{V} \tag{8}$$

$$q_h = \frac{\max(Q_h) - \min(Q_h)}{H} \tag{9}$$

Secondly, P_v and Q_h are replaced by coarser signal equivalents ${}^{I}P_v$ and ${}^{I}Q_h$ which have data points exclusively at grid line intersections. Local vertical and horizontal spreadings f_k and g_l at each grid line are obtained by Equation 10 and Equation 11.

$$f_k = \max\left({}^{I}P_{v_k}\right) - \min\left({}^{I}P_{v_k}\right) \quad \text{for } k = 1, \cdots, H-1 \tag{10}$$

$$g_l = \max\left({}^{I}Q_{h_l}\right) - \min\left({}^{I}Q_{h_l}\right) \quad \text{for } l = 1, \cdots, V-1 \tag{11}$$

Thirdly, two border areas ${}^{I}\mathbf{A}_{P_v}$ and ${}^{I}\mathbf{A}_{Q_h}$ of the 2-d orbit face are calculated. Triangles at the outer fragments lead to simplified trapezoidal formulas as written in Equation 12 and Equation 13.

$${}^{I}\mathrm{A}_{P_v} = q_h \sum_{k=1}^{H-1} f_k \tag{12}$$

$${}^{I}\mathrm{A}_{Q_h} = p_v \sum_{l=1}^{V-1} g_l \tag{13}$$

Lastly, Equation 14 is applied to estimate $\mathbf{A}_{P_v|Q_h}$ of the exemplary 2-d orbit face, see Figure 7.

$$\mathrm{A}_{P_v|Q_h} \approx \frac{{}^{I}\mathrm{A}_{P_v} + {}^{I}\mathrm{A}_{Q_h}}{2} \tag{14}$$

4.3 Statistical characteristics - various signals

The arithmetic mean value is calculated according to Equation 5. The range is defined similar to Equation 10 or Equation 11. The sample standard deviation reads as Equation 15.

$$\mathrm{Y}_{\mathrm{std}} = \sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(Y_i - \mathrm{Y}_{\mathrm{amv}})^2} \tag{15}$$

Based on an empirical approach, two additional customised statistical metrics $\mathbf{Y}_{\mathbf{mtr1}}$ and $\mathbf{Y}_{\mathbf{mtr2}}$ are considered. These are defined by Equation 16 and Equation 17.

$$\mathrm{Y}_{\mathrm{mtr1}} = 2 \times \mathrm{Y}_{\mathrm{std}} + \mathrm{Y}_{\mathrm{rng}} \tag{16}$$

$$\mathrm{Y}_{\mathrm{mtr2}} = \frac{2 \times \mathrm{Y}_{\mathrm{std}} + \mathrm{Y}_{\mathrm{rng}}}{\mathrm{Y}_{\mathrm{amv}}} \tag{17}$$

5 DISCUSSION OF RESULTS

5.1 Comparison of spectral contents

- **component acceleration (experiment / simulation)**

Two combined FFT spectra are shown in Figure 8, Figure 9 and Figure 10 respectively. These xz-acceleration spectra relate to the sensor at the calliper anchor or its equivalent mesh node in the corner FE model. To combine x- and z-direction, the incoherent sum is calculated separately for each frequency. This is done based on Equation 4. Spectral contents from 50 to 500 Hz and 5 to 1000 Hz are summed alike.

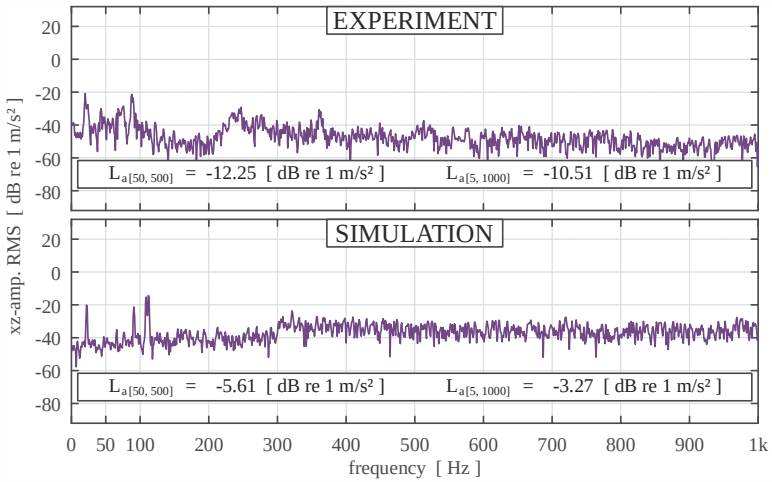

Figure 8: Both no creep groan / summed spectrum of calliper anchor xz-acceleration signals for 1 s.

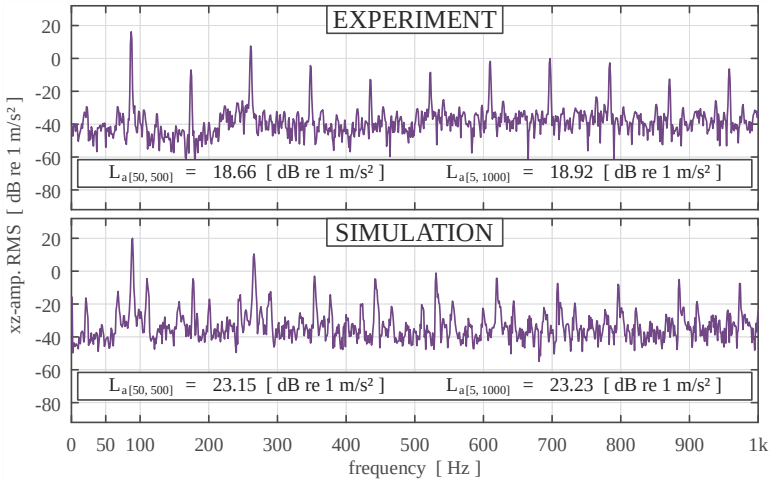

Figure 9: 87|89 Hz creep groan / summed spectrum of calliper anchor xz-acceleration signals for 1 s.

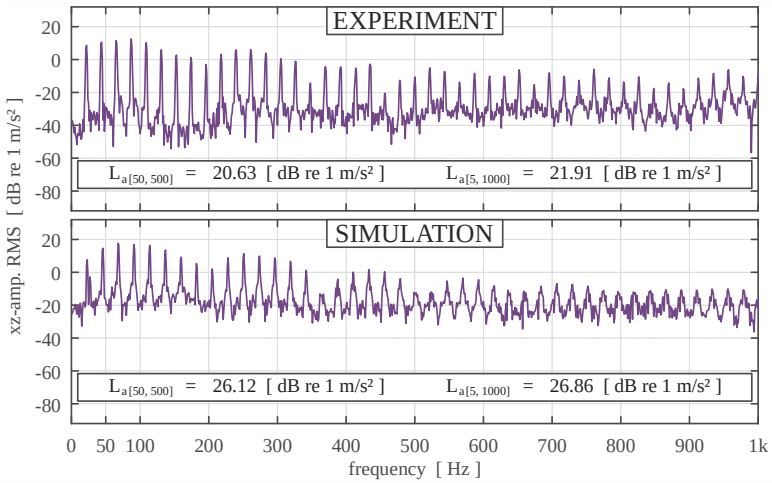

Figure 10: 22|23 Hz creep groan / summed spectrum of calliper anchor xz-acceleration signals for 1 s.

Both xz-acceleration spectra in Figure 8 reflect low and flat broadband vibration characteristics. This is expectable for any almost vibration-free example. All four spectra in Figure 9 and Figure 10 show typical patterns of creep groan vibrations, compare with [7, 10, 11, 12, 17,

19, 20]. The fundamental peak indicates the major stick-slip interval. Its super-harmonics reflect non-linear vibration characteristics.

In case of creep groan, the spectral acceleration dB level sum is approximately 30 dB increased, see Table 5 (Appendix). Hence, this physically reasonable acceleration metric enables a recognition of creep groan vibrations and an assessment of the general low-frequency NVH criticality. However, the differences between the creep groan phenomena with fundamental stick-slip intervals around 90 or 20 Hz are just roughly 3 dB. Thus, a distinction between the two types is uncertain.

- **system energy (simulation)**

Purely simulative results are shown in Figure 11, Figure 12 and Figure 13. These FFT spectra relate to the overall kinetic energy of the corner FE model. Spectral contents from 50 to 500 Hz and 5 to 1000 Hz are calculated based on Equation 7.

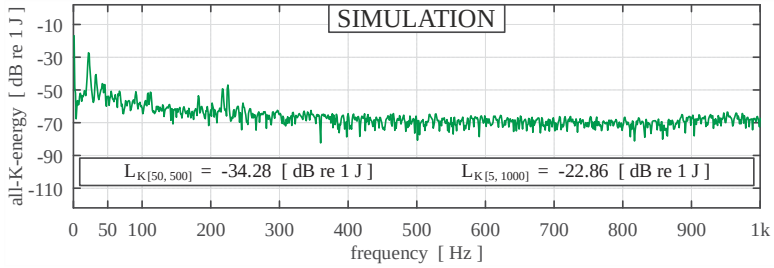

Figure 11: No creep groan / spectrum of computed overall kinetic energy signal for 1 s.

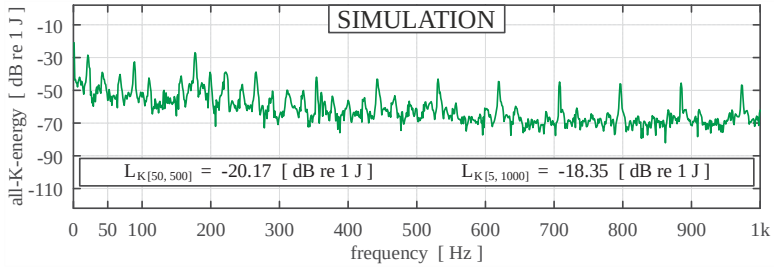

Figure 12: 89 Hz creep groan / spectrum of computed overall kinetic energy signal for 1 s.

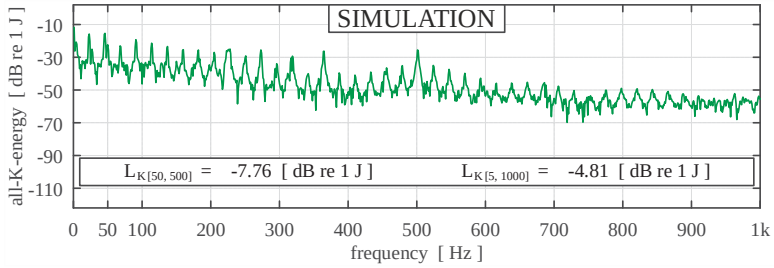

Figure 13: 23 Hz creep groan / spectrum of computed overall kinetic energy signal for 1 s.

These kinetic energy spectra show characteristics akin to the three simulative xz-acceleration spectra, but the amplitudes at higher frequencies are lower due to the velocity dependency of the kinetic energy. Note that a constant rotation of the wheel assembly including disk contributes to the 0 Hz amplitude.

Both energy dB level sums enable a detection of macroscopic stick-slip, see Table 5 (Appendix). In particular, spectral contents from 50 to 500 Hz are suitable for a reliable distinction between the two types. The 23 Hz stick-slip vibration achieves at least a 10 dB higher

spectral dB level sum than the 89 Hz stick-slip vibration. A disadvantage of this physically reasonable energy metric is its purely simulative applicability.

5.2 Comparison of orbital indices

- **time integral of component acceleration (experiment / simulation)**

To estimate velocity and displacement from experimental or simulative acceleration data, a trapezoidal time integral formula is used. Concerning 0.18 s time segments, operating deflection shape (ODS) patterns, 2-d orbit faces and phase portraits are shown in Figure 14, Figure 15 and Figure 16. Border area indices are calculated for x- and z-direction of the sensor at the calliper anchor or its equivalent mesh node in the corner FE model, see Table 5 (Appendix).

Each example contains four quadrants. The brake ODS graph on the bottom right indicates substantial vibration patterns of the floating calliper subsystem including disk, compare with [9, 10]. The graph on the top left shows the clockwise-rotating displacement-displacement orbit face concerning x- and z-direction. A coloured bar indicates the absolute xz-velocity. The graphs on lower left and upper right show clockwise-rotating phase portraits which are shaped by different displacement-velocity combinations.

Figure 14 refers to 8 bar at 0.32 km/h. This combination does not cause creep groan in experiment and simulation. Based on marginal motions and low surface velocities, border areas and orbital indices are very small.

Figure 15 refers to 8 bar at 0.12 km/h. Creep groan appears with a fundamental stick-slip interval around 90 Hz respectively. Thus, both examples show roughly 16 repetitive cycles with comparable signatures. The border areas lead to similar orbital indices of medium size. Distinctive rotational motions of the calliper subsystem about the disk's axis occur with high surface velocities. These vibration patterns are enabled by a first-order bending deflection of the MacPherson suspension strut assembly, see [24, 26]. Maximum surface velocities are reached shortly after a macroscopic transition from stick to slip.

Figure 16 refers to 32 bar at 0.12 km/h. Creep groan appears with a fundamental stick-slip interval around 20 Hz respectively. Thus, both examples show roughly four repetitive cycles. The orbital indices are relatively high. The vibration patterns involve two relevant contributors, see [24, 26]. Firstly, large longitudinal displacements of the wheel assembly including disk. These motions, which relate to the fundamental stick-slip interval, are mainly enabled by elastic deformations of the lower control arm bushings. Secondly, fast rotational deflections of the floating calliper subsystem. These motions, which relate to superposed natural eigenmodes of higher frequency, occur similar in Figure 15. The highest surface velocities appear shortly after a macroscopic transition from stick to slip.

Since the orbital indices depend on the observed vibration patterns, a recognition and distinction of creep groan is possible. Moreover, the general low-frequency NVH criticality can be determined.

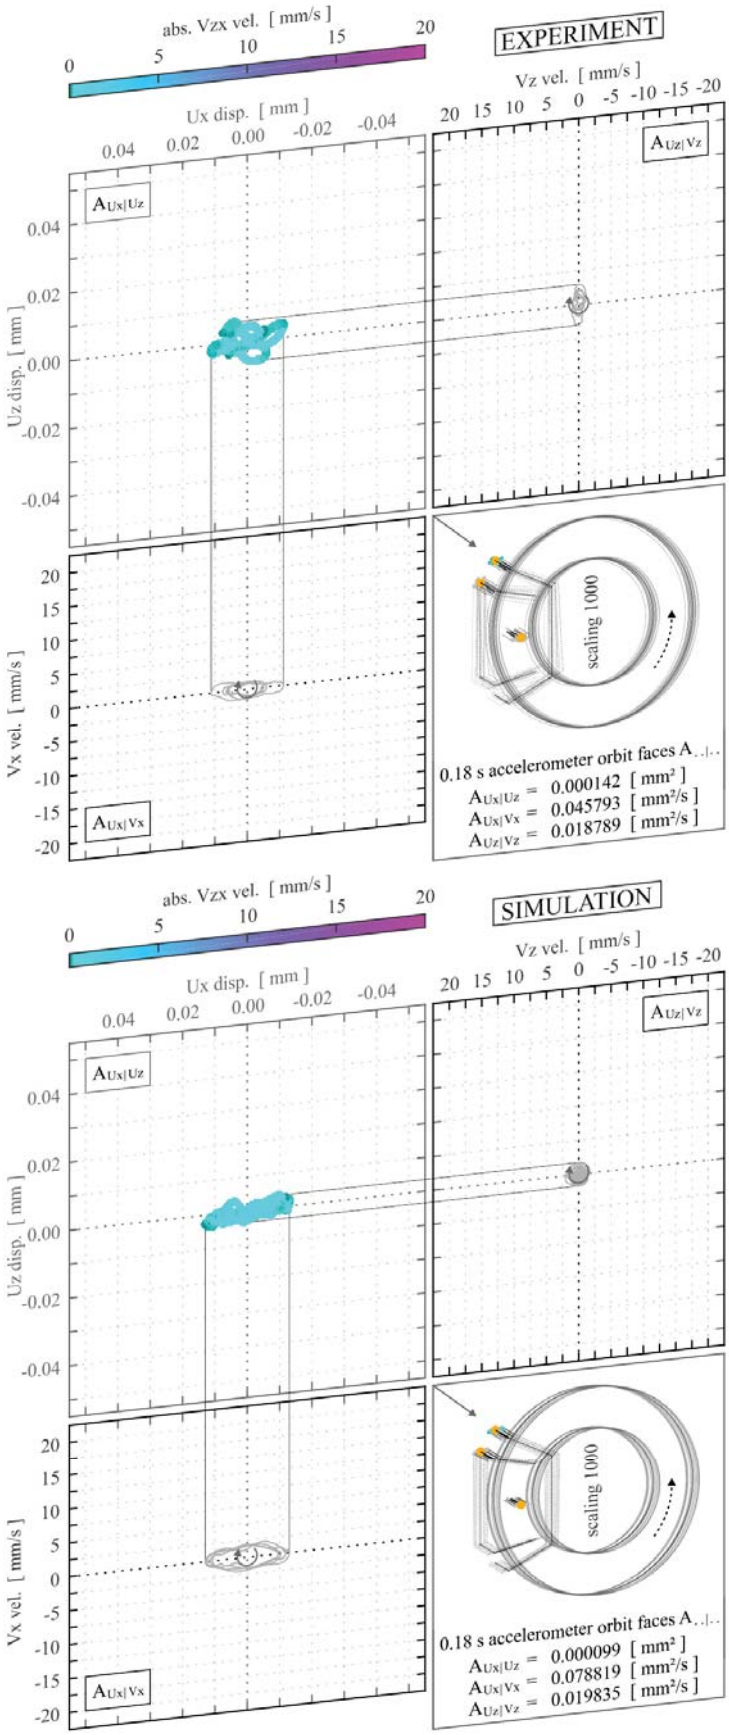

Figure 14: Both no creep groan / disp.-disp. and disp.-vel. patterns of calliper anchor x- and z-acceleration signal time integrals for 0.18 s.

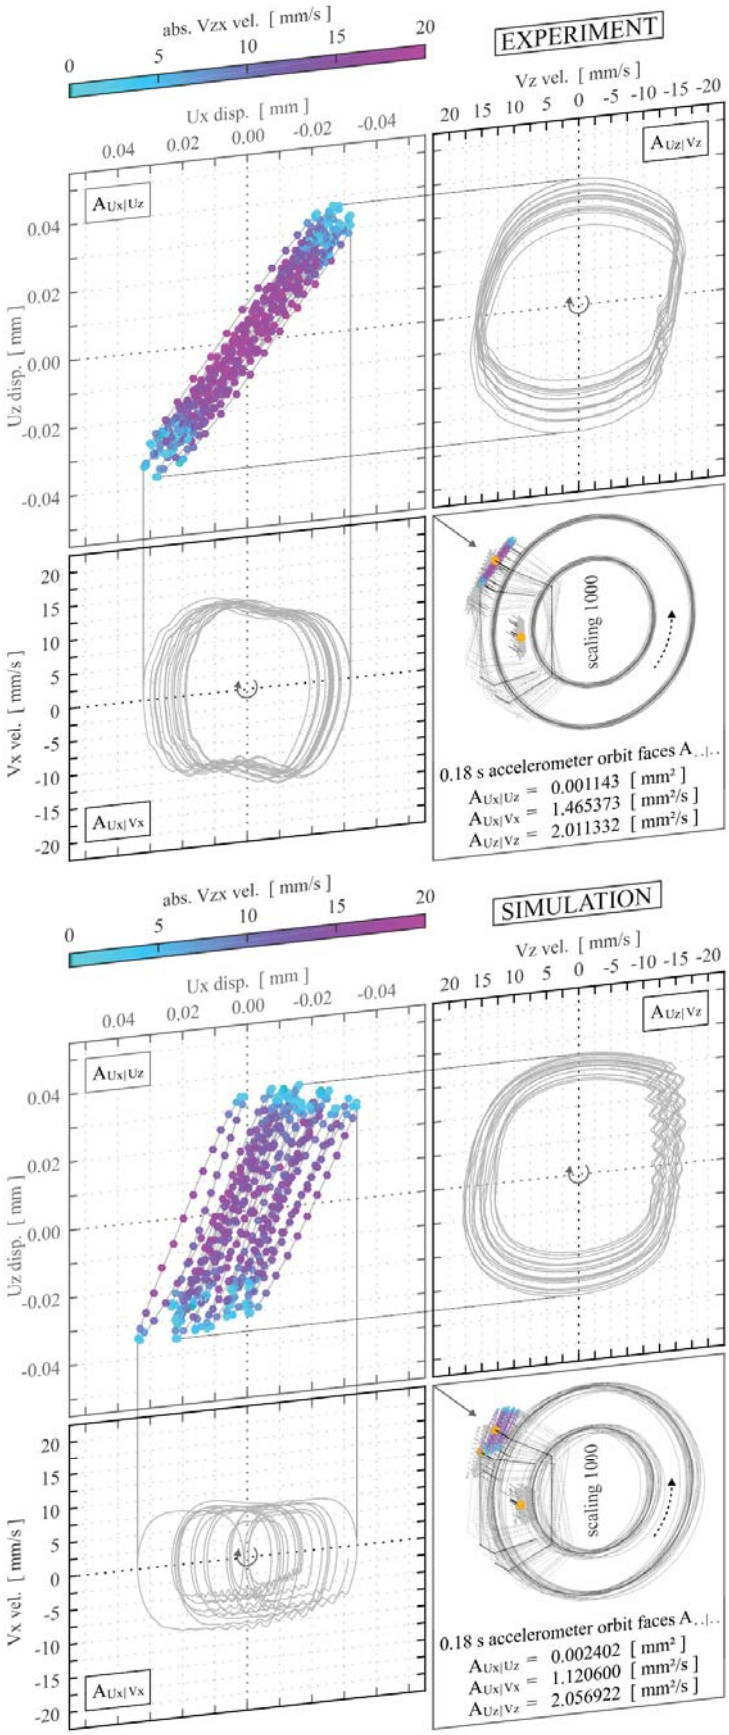

Figure 15: 87|89 Hz creep groan / disp.-disp. and disp.-vel. patterns of calliper anchor x- and z-acceleration signal time integrals for 0.18 s.

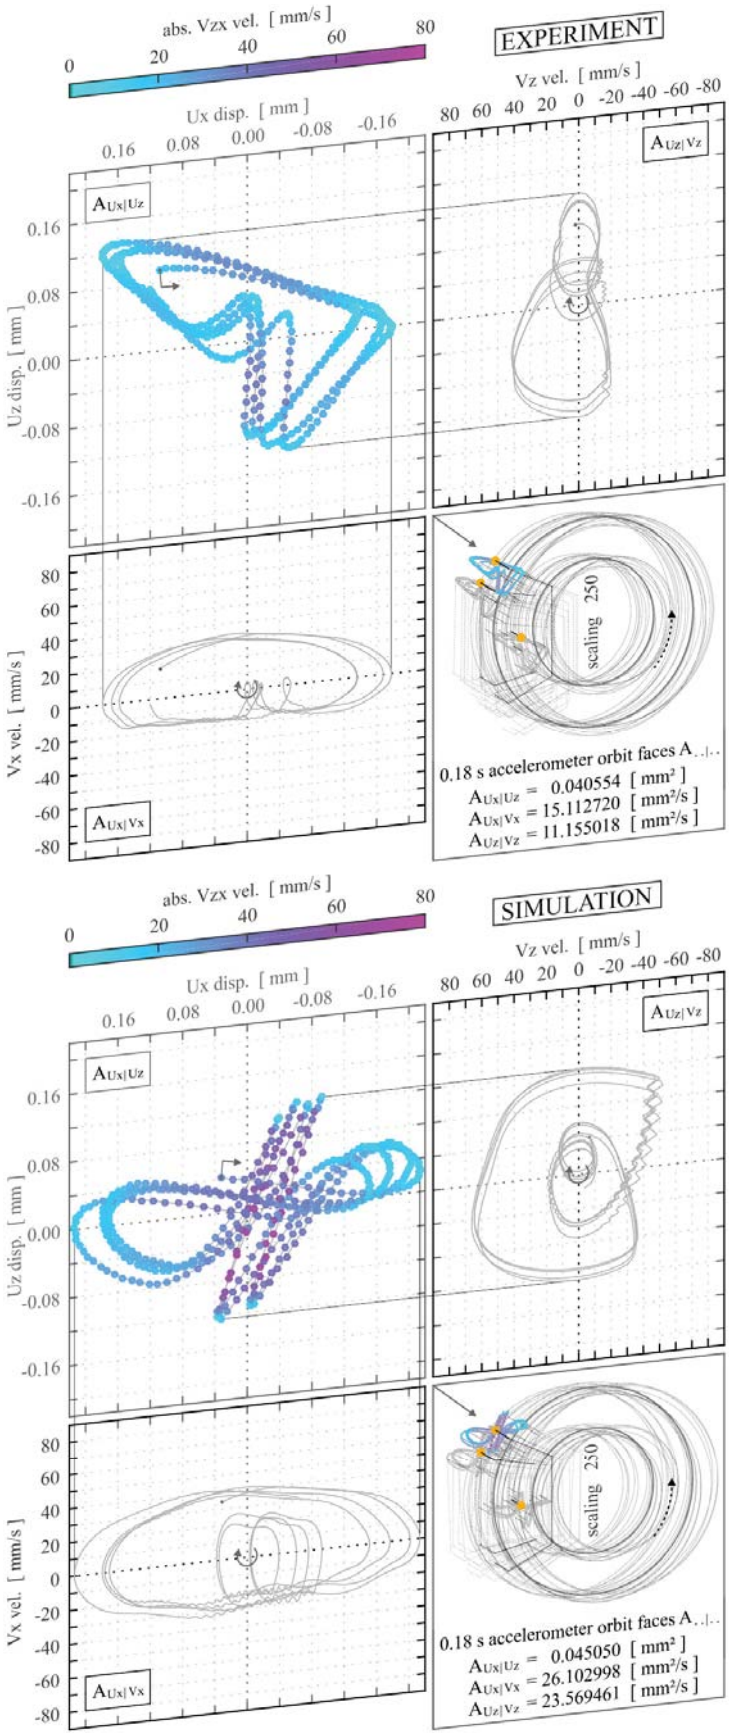

Figure 16: 22|23 Hz creep groan / disp.-disp. and disp.-vel. patterns of calliper anchor x- and z-acceleration signal time integrals for 0.18 s.

5.3 Comparison of statistical characteristics

- **interface force (experiment / simulation)**

Different creep groan phenomena favour different characteristics of the dynamic forces between lower control arm bushings and vehicle body, see [24, 26]. In the following, the y-force at the hydro bushing is analysed. Its quasi-static proportion relates to the system pretension which depends on brake pressure and coefficient of friction. The dynamic proportion of this y-force relates to the vibration behaviour.

Figure 17, Figure 18 and Figure 19 show results for 0.18 s time segments. The y-force associated values of arithmetic mean, range and sample standard deviation as well as the values of both empirical metrics are listed in Table 5 (Appendix).

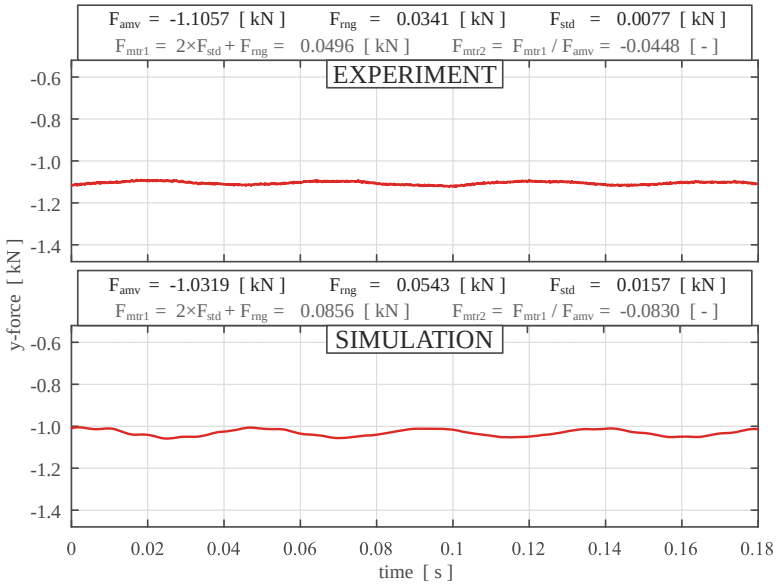

Figure 17: Both no creep groan / hydro bushing y-force signal for 0.18 s.

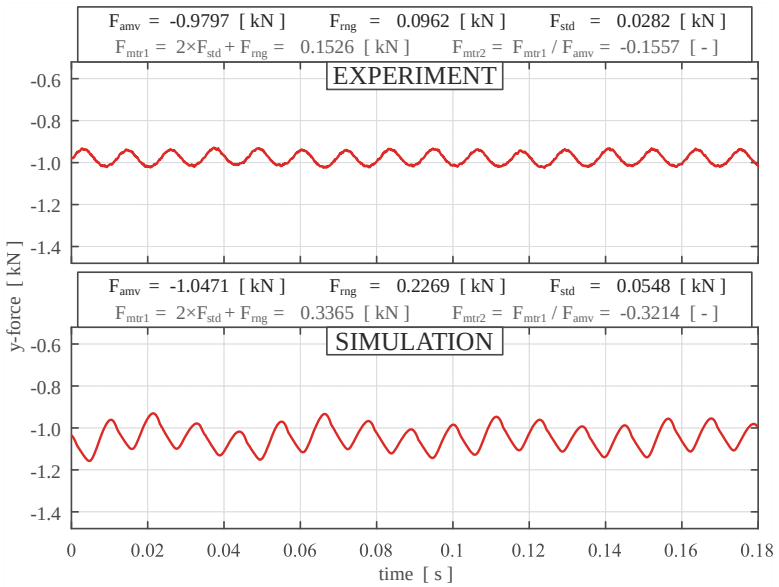

Figure 18: 87|89 Hz creep groan / hydro bushing y-force signal for 0.18 s.

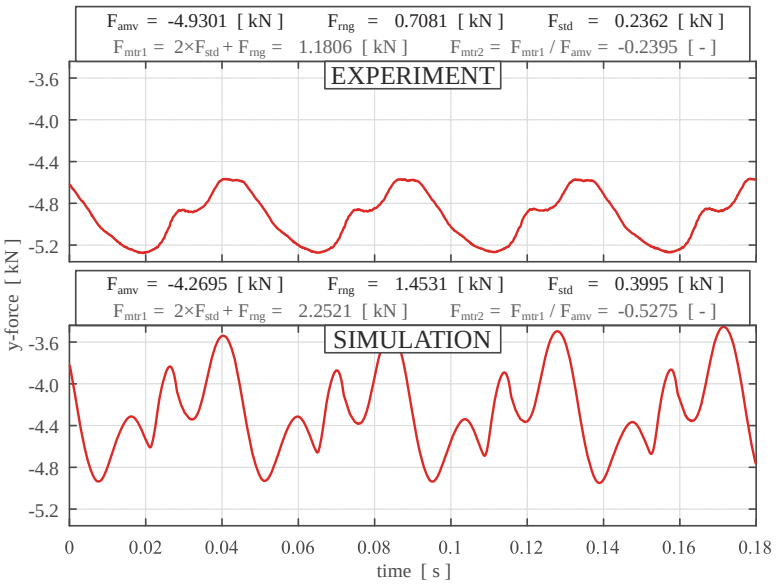

Figure 19: 22|23 Hz creep groan / hydro bushing y-force signal for 0.18 s.

Both almost vibration-free examples in Figure 17 reveal a sinusoidal oscillation of low amplitude. In case of creep groan, the y-force signal reflects the first-order bending deflection of the suspension strut assembly. This elastic deformation is mainly involved in the 87 and 89 Hz examples, see Figure 18. However, it also appears for the 22 and 23 Hz examples which are dominated by elastic hydro bushing deformations, see Figure 19. Either way, the highest absolute y-force appears shortly prior to each macroscopic transition from stick to slip. Different y-force characteristics in experiment and simulation most likely indicate weaknesses of the hydro bushing's FE model implementation.

Creep groan leads to an increased y-force range and an increased y-force sample standard deviation. A distinction between the two types in Figure 18 and Figure 19 is probably possible. The y-force arithmetic mean depends on brake pressure and coefficient of friction. It is used to normalise one of the empirical metrics. Based on this normalised value, a recognition and distinction of creep groan can be achieved if integer numbers of stick-slip vibration cycles or sufficiently long time series data are considered.

- **averaged friction pair condition (simulation)**

The contact status is relevant for 231 mesh nodes per lining. The optional specific states are defined as gap, slip and stick. These have freely chosen number values of 0, 1 and 2, compare with [20]. All additional mesh nodes at the lining chamfer are always in specific gap status.

An exemplary post-processor snapshot of continuous macroscopic slip is shown in Figure 20. Accordingly, mesh nodes in specific stick status and mesh nodes in specific slip status appear simultaneously.

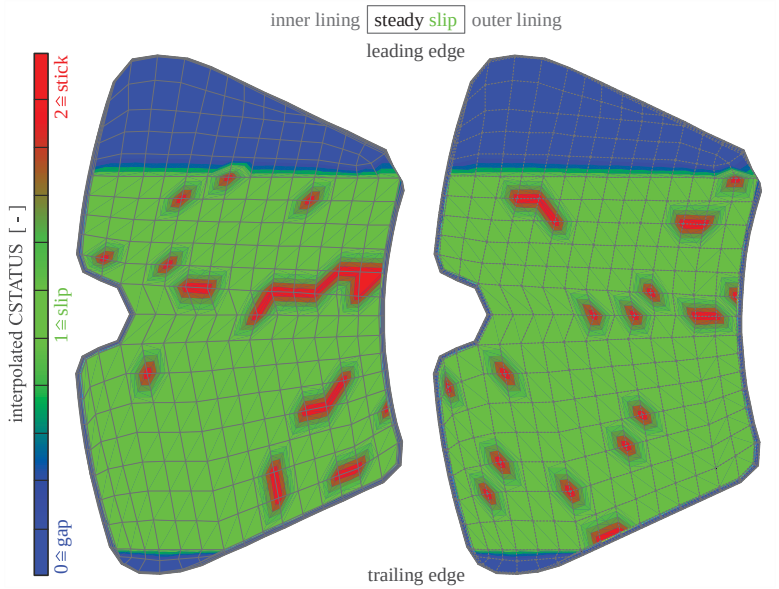

Figure 20: No creep groan / contact status (gap / slip / stick) specific node assignment example of continuous macroscopic slip.

In the following, the averaged contact status is analysed. It is shown for 0.18 s time segments in Figure 21, Figure 22 and Figure 23. Again, each calculated value is listed in Table 5 (Appendix).

The upper part of Figure 21 confirms the absence of macroscopic stick-slip. The lower part of Figure 21 represents Figure 20. Note that mesh nodes in specific stick status at this arbitrary point in time also change to specific slip status during the 0.18 s time segment. Certainly, these changes appear vice versa as well.

The averaged contact status in Figure 22 clearly indicates the 89 Hz stick-slip vibration. The four exemplary node assignments show typical transitions. These transitions have no detectable macroscopic pattern. A comparable random transition behaviour of all mesh nodes also occurs for the 23 Hz stick-slip vibration, see Figure 23.

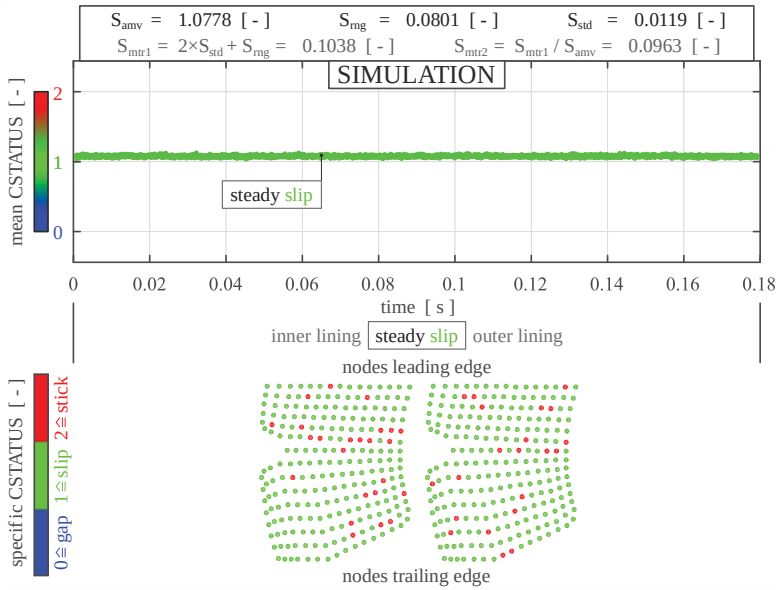

Figure 21: No creep groan / averaged friction pair contact status signal for 0.18 s and specific node assignment example.

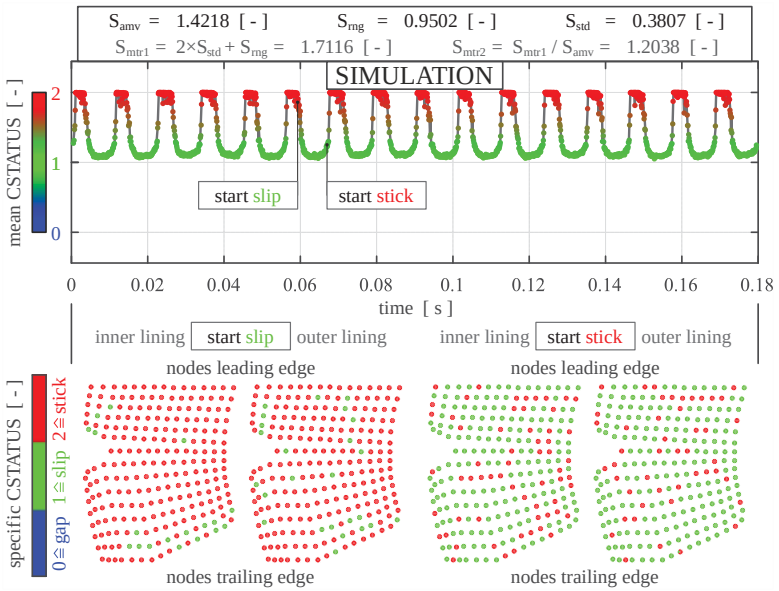

Figure 22: 89 Hz creep groan / averaged friction pair contact status signal for 0.18 s and specific node assignment example.

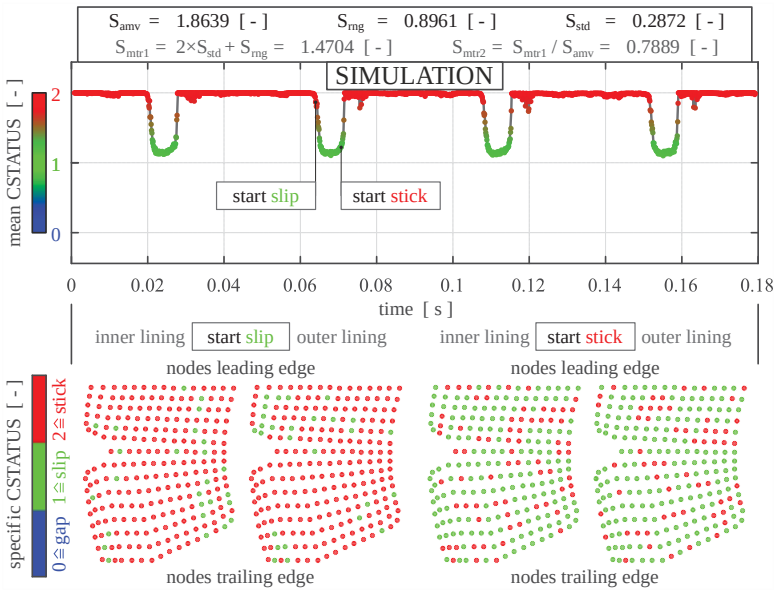

Figure 23: 23 Hz creep groan / averaged friction pair contact status signal for 0.18 s and specific node assignment example.

Based on the freely chosen number values of 0, 1 and 2 for the averaged friction pair contact status, macroscopic stick-slip leads to an increase of arithmetic mean, range and sample standard deviation. The empirical metric according to Equation 17 can be used for a simulative distinction between the two most relevant types of stick-slip vibrations. Again, integer numbers of stick-slip vibration cycles or sufficiently long time series data have to be considered.

6 CONCLUSIONS

Suitable subsystem investigation methods and efficient data analysis techniques are necessary to reveal problematic creep groan already at early stages of the brake development pro-

cess. For this purpose, experimental and simulative approaches at vehicle corner level as well as different rating criteria are discussed in this paper.

Concerning an exemplary MacPherson setup with floating calliper brake system, two different creep groan phenomena were identified. Depending on the applied operational parameter combinations in experiment and simulation, fundamental stick-slip intervals were at roughly 90 or 20 Hz. Certainly, vibration-free conditions were identified as well.

To objectively compare experiments and/or simulations in terms of creep groan, three kinds of metrics were calculated in MATLAB based on time series data. These are physically reasonable, purely synthetic and statistical metrics. Thereby obtained absolute quantities are listed in Table 5 (Appendix). These abstract number values are helpful for efficient data evaluations and large-scale result validations.

A normalised summary of the most promising rating criteria is given in Table 3. Concerning each comparison metric, the smallest value relates to 0 % and the largest value represents 100 %. This normalisation is done separately for experiment and simulation. Similar creep groan phenomena lead to comparable percentage spans. Thus, the identification, categorisation and validation of typical brake creep groan vibrations is possible.

Table 3: Summary of relativised quantities of suitable comparison metrics in experimental and/or simulative validation.

To confirm or improve the proposed comparison metrics, a next step might be an extended operational parameter study. Attention might be given to situational weighting factors depending on the most common real-world operational parameter combinations. Modified psycho-acoustic evaluation metrics might be applicable as well.

Abstract. *Bolted joints are one of the oldest and widely-used means of connecting parts of technical installations. For mission-critical and expensive assets, periodic inspection of bolted joints is the conventional way of ensuring the assets' structural integrity, and hence their safe operation. Currently, the inspections require hours of physically demanding and monotonic work, as in practice it often means re-tightening the bolts. Thus, the asset maintenance units will benefit from a simpler and less demanding technique, which would allow checking the correct bolt tightening and notifying if a bolt is loose.*

For the last three years, a joint research team led by the Technical University of Denmark in collaboration with Brüel & Kjær and Karlsruhe Institute of Technology was conducting a project, where vibrations, artificially induced in a bolted joint, were utilized for estimation of the static axial force acting in the bolt. The presented paper provides an overview of the project, lists the numerous challenges the project had to deal with and describes what was learned and achieved.

1 INTRODUCTION

Bolted joints are one of the most used means of connecting parts of technical installations. For mission-critical assets, held together by bolted joints, regular inspections of proper bolt tightness are mandatory for certification and safe operation. As the bolt tension is impossible to measure and check in-situ, most of such inspections today are performed using a torque wrench. This procedure could potentially lead to the overtightening of bolts, which is undesirable. With large structures and heavy bolts, using a torque wrench, the bolt inspection procedure becomes a monotonous and physically demanding work, often conducted in tough environments. That is why a simpler and less demanding technique of checking bolt tightness is on high demand in many industries.

The abovementioned became a motivation for establishing the VEBJI project, a collaborative work between Technical University of Denmark (DTU), Brüel & Kjær and Karlsruhe Institute of Technology. VEBJI stands for Vibration for Estimating Bolted Joints Integrity. As it follows from the title, the project aims in utilizing vibrations, artificially induced in a bolt, as the source of information regarding its tension. As a starting point, we used an observation that, when impacted, a well-tightened bolt sounds differently from a loose one [1]. An impact excites different types of vibrations in the bolt, and some of them cause acoustic waves in the audible range, which a human being can perceive and judge. Thus, it was suggested to study how the bolt tension affects its vibrations, and possibly propose a technique for detecting loose bolts, based on the analysis of bolt transient vibrations, excited, for example, by impacting the bolt with a hammer.

There are alternative methods for bolt tightening check, a review can be found in [2]. Besides torque wrench and hydraulic tensioners, which are used for controllable bolt tightening, the most developed technique for controlling bolt tension is by check bolt elongation utilizing ultrasonic transducers. Commercial solutions employing this technology exist, for example, i-Bolt® by ERREKA [3] can be named as one of them. The drawbacks of the technique are the sensitivity to temperature and special requirement to machining of the bolts' butt-ends.

Two pilot studies, conducted by DTU students as master projects [4], [5], demonstrated that indeed the vibration patterns of tightened and loose bolts are different. Comparing a tightened / loose bolt with a differently tightened guitar string, it is natural to expect the difference in the pitch of the radiated sound. However, in the bolt case, audibly, the difference in pitch is hardly distinguishable. But in contrast, the tightened bolt produces a clear ringing sound, whilst the sound from a loose bolt is rather dull, i.e. decaying faster and containing less high-frequency content. The idea of the pilot projects was to find some properties in the measured vibration signal that can be utilized to characterized bolt tension. In structural health monitoring literature, these properties are often called *features*. Farrar and Worden in [6] provide the following definition: "A damage sensitive feature is some quantity extracted from the measured system response data that indicates the presence (or not) of damage in a structure". Alongside with the abovementioned natural frequencies and damping, other vibration features and / or their combinations are possible, for example, the ratio of natural frequencies, modal interaction, attack time, amplitudes of nonlinear harmonics, etc.

However, it was not straightforward to find the features of the measured vibration signals that could in a robust way indicate if the bolt is well-tightened or not. As bolt tightening features, [4] attempted the natural frequencies and damping of the lowest transverse modes, and in [5] the authors attempted psychoacoustic metrics, the vibration energy decay rate, and spectral centroids. Generally, the results of the two projects were not satisfactory, however, the projects indicated that the experimental work needs to be promoted to a much higher quality level to ensure the experiments being more controllable and reproducible. Alongside that, it became

clear that a better understanding of bolt vibrations is required to explain what was observed during the experiments. These altogether became the groundwork for the VEBJI project.

The paper is built as follows: Section 2 describes the extensive measurement campaign, followed by Section 3, which introduces a model of a single-bolt joint. Section 4 concerns multi-bolt joints. Section 5 touches practical considerations for real-life scenarios. Finally, section 6 introduces the on-going research.

2 EXPERIMENTAL WORK

It was decided to start the project with an extensive measurement campaign, in an attempt to experimentally study the vibration patterns of differently tightened bolts in well-controlled environments and examine the vibration features that are correlated with the bolt tension. The results of the test campaign were thought to initiate the theoretical studies aimed to understand and explain what was observed during the experiments, and theoretically check the applicability of the found vibration features to different bolt sizes and bolted joint configurations.

During the pilot projects, the bolts were tightened using a torque wrench. It was suspected that the torque wrench was the main source of the observed variability. Indeed, applying the wrench in numerous tightening/untightening circles deforms the threads of the bolt and the nut, and damages the mating surfaces of the bolt, washers and the test rig. To retain the geometric and material properties of the test setup, it was decided to replace the torque wrench with a hydraulic tensioner. During the tightening process, the tensioner is pressurized using a hand pump, causing the bolt elongation. Then the nut is finger tightened. After the pressure release, the bolt contracts and compresses the test rig [7].

It is known that a torque wrench is a highly inaccurate tool with the variation of torque-to-tension up to 30% [8]. In the initial experiments conducted in the frame of the pilot studies, a strain gauge mounted on the bolt body was used to estimate its tension. This arrangement was proved to be impractical as the strain gauge is a very delicate sensor, and it requires a special test rig design to allow cabling. Subsequently, the strain gauge was replaced by a force washer directly measuring the compressing force, which is proportional to the bolt's tension.

Considering bolt excitation, it was decided to employ impact excitation as the most practical one. The pilot studies demonstrated that transverse vibrations can be easily excited by impacting the bolt at any point and in any direction. Even an impact in axial direction could excite transverse vibrations (this was later investigated in [9]). For the experiments, the excitation in the transverse direction was chosen.

To catch a possible nonlinear behavior of the bolt, it is necessary to excite the bolt by a well-controllable excitation force with increasing strength. To achieve this, a special pendulum-hammer was designed, where the impact strength was controllable by the initial inclination of the pendulum, and the impact force was measured by a force transducer.

In contrast to the pilot studies, in the VEBJI test campaign, the vibration signal was measured by two miniature accelerometers mounted on the bolt head. One accelerometer was aligned to measure in the direction of the impact, and another in the direction perpendicularly to the first one. This improvement allowed measuring bolt vibration in both transverse directions.

The experiment (the setup is shown in Figure 1), is described in full detail in [10], [11], [12], here a brief overview is given. It was a rather extensive test campaign, two types of bolts were tested, M12x260 and M12x140; the bolt was tightened in 10 load steps, in the range from approximately 0.07 of the yield stress σ_y to approximately 0.8 σ_y (the nominal bolt tension for this class of bolts is 0.7 σ_y). At each tension level, the bolt was impacted with four increasing impact strengths, and each measurement was conducted three times. To ensure repeatability, the experiment was repeated three times, including the full disassembly of the test rig. During

the experiments, 720 time-histories were acquired with a high sampling rate, each time history consisted of two acceleration signals and the impact force signal.

2.1 Overview of the measurement campaign results

A typical acceleration signal is shown in Figure **2**a. As the bolt is a nearly symmetrical structure, one can expect the pairs of transverse modes of vibration with almost identical natural frequencies. The spectra in Figure **2**b show the peaks corresponding to the first pair of modes (just below 1 kHz) and the second pair of modes (above 2.5 kHz). The double peaks are (sometimes) distinguishable in the zoomed view (as shown). Applying a narrow band-pass filter (BPF) around the natural frequencies of the modes' pairs, it was possible to separate the pairs in the time domain; the resulting filtered signals $a_1(t)$ and $a_2(t)$ measured in the direction of the impact and the perpendicular direction, respectively, are shown in Figure **2**c, together with their envelopes and the envelope of $a_\Sigma(t) = \sqrt{a_1(t)^2 + a_2(t)^2}$.

The amplitudes of the measured signals in Figure **2**c is slowly modulated, which is a characteristic of a beating, the phenomenon which appears when two sinusoidal signals with slightly different frequencies are added together. The frequency of the modulation is then equal to the difference between the frequencies of the sinusoids. In [13], the likely explanation is provided: both modes of the first pair are excited by the hammer impact, and the modal response is the exponentially decaying sinusoidal oscillation at the damped natural frequencies of the mode. The system is effectively linear, and the two modes do not interact but the accelerometers pick up the mixture of both sinusoids, resulting in the observed beating. Another plausible

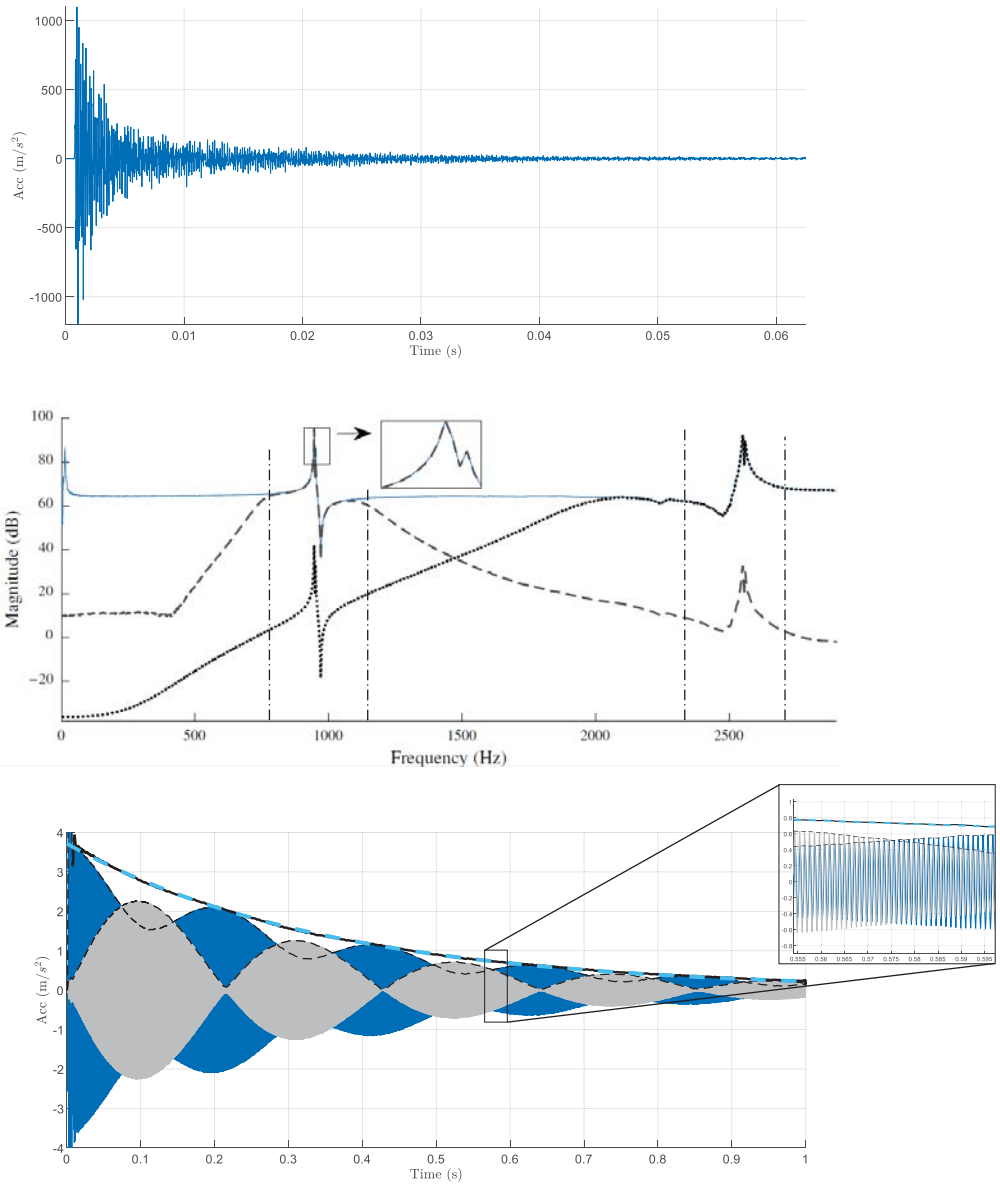

Figure 2. Measure signal and signal processing (from [11]). a) Raw acceleration signal measured in the impact direction. b) Spectra: blue - the spectrum of the raw signal, dash line – after applied BPF around the first natural frequency, dot-line – after applying BPF around the second natural frequency. Vertical dot-dash lines – the cut-off frequencies of the applied BPF. c) Two transverse acceleration signals $a_1(t)$ and $a_2(t)$, after applying BPF around the first transverse resonant frequency. Thin dash lines – their envelopes. Thick dash line – the envelope of $a_\Sigma(t) = \sqrt{a_1(t)^2 + a_2(t)^2}$.

explanation involves a non-linear interaction (i.e. energy exchange) between the two transverse modes, as explained in [14].

Based on the observations during the experiment, numerous vibration characteristics were considered as potential features [12], including natural frequencies, modal damping, modes interaction inside and outside the pairs, variation in time of the instantaneous natural frequencies and damping, input/output linearity, impact duration, etc. These characteristics were correlated with bolt's tension and their reproducibility was checked using available time histories. Based on the analysis, two characteristics were studied in detail, as they demonstrated solid correlation
