Figure 3. Measured first natural frequency as a function of the bolt tension: long bolt (left) and short bolt (right). The different markers indicate the test series, the marker size denotes the impact strength (from [11], [12]).

with the bolt tension: the natural frequency of the transverse vibrations and the corresponding modal damping. The other attempted potential featues did not demonstrate the sufficient correlation with bolt tension or were not sufficiently reproducible.

2.2 Selected features

Natural frequencies

The natural frequencies obtained by zero-cross counting of the filtered signal are shown in Figure 3. As expected, there is a strong correlation between the natural frequencies and the bolt tension, observed for both long and short bolts.

Damping ratio

The effective linear damping ratio of the first mode was estimated by fitting the exponential decay to the envelope of the filtered signal a_Σ (Figure **2**c). The damping ratio decreases with increasing bolt tension, as shown in Figure **4**, [11] and [12]. In absolute values, the damping ratios

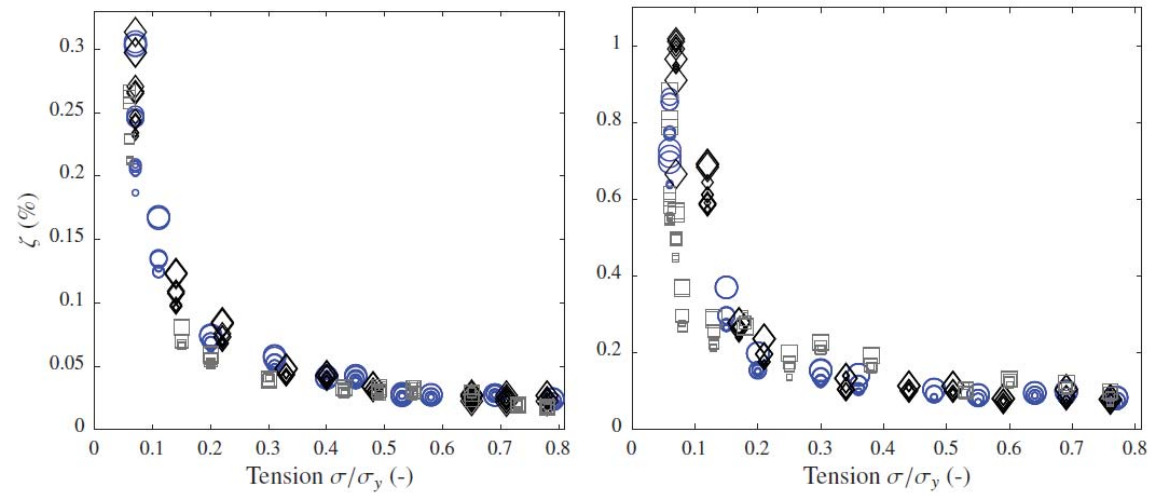

Figure 4. The damping ratio of the first mode as a function of the bolt tension for the long (left) and short (right) bolts (from [11], [12]). Legend is the same as in Figure 3.

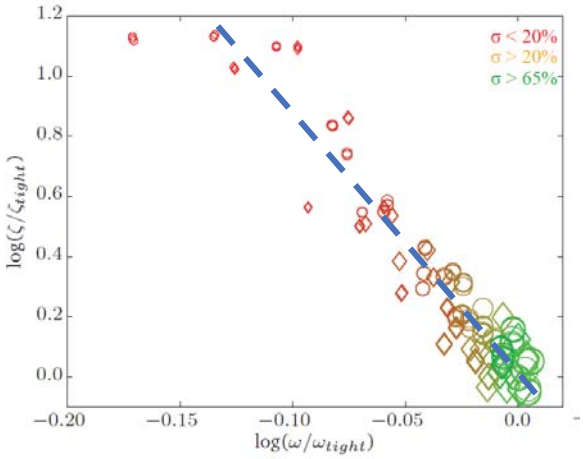

Figure 5. Distribution of the points with coordinates (normalized frequency; normalized damping) (from [12]). The markers' color and size correspond to the tension of the bolt.

differ for the long and short bolt, however, if scaled with the bolt slenderness ratio, the damping ratio becomes invariant to bolt sizes. The slenderness ratio is defined as $s = l/\sqrt{I/A}$, where l, I and A are bolt's length, the moment of inertia of bolt's section and area of bolt's section, respectively. The theoretical explanation of this interesting observation is provided in [12].

Combined frequency and damping feature

The combination of the normalized natural frequency and damping ratio into a single bolt tension feature was suggested in [12] and is shown in Figure 5 for both long and short bolts. The frequency and damping are normalized by the respective characteristics of the nominally tightened bolt. In Figure 5 the points corresponding to the well-tightened bolts are concentrated in the bottom-right corner, whilst those of the relatively loose bolts are spread along the dashed line leading towards the upper-left corner of the plot.

Discussion

During the experiments, it became clear that the frequency and damping, either separately or combined, can be considered as reliable qualitative indicators of bolt tension. The next natural step would be suggesting a model explaining the experimentally observed phenomena and providing a quantitative relation between the measured vibration properties and the unknown bolt tension.

3 MODELLING A SINGLE-BOLT JOINT

From the first glance, it is natural to model a tightened bolt as a pre-stressed clamped-clamped beam. For such a beam the dependence of the i-th transverse natural frequencies from the tension is well-known [15],

$$\omega_i = \frac{\lambda_i}{l\,s}\sqrt{\frac{E}{\rho}\left(1+\frac{\sigma}{E}\left(\frac{K_i\,s}{\lambda_i^2}\right)^2\right)}, i = 1,2\ldots \tag{1}$$

where l is the length of the beam, s is the slenderness ratio, σ is the axial stress, E and ρ are beam's material Young's modulus and density, respectively and K_i and λ_i are non-dimensional constants, depending on the i-th mode shape.

As it follows from (1), the square of the natural frequencies is directly proportional to the axial stress σ, and thus to the bolt tension. Figure 6 shows the corresponding line on top of the experimental results (adjusting the length l to fit the high values of σ). Apparently, for the long

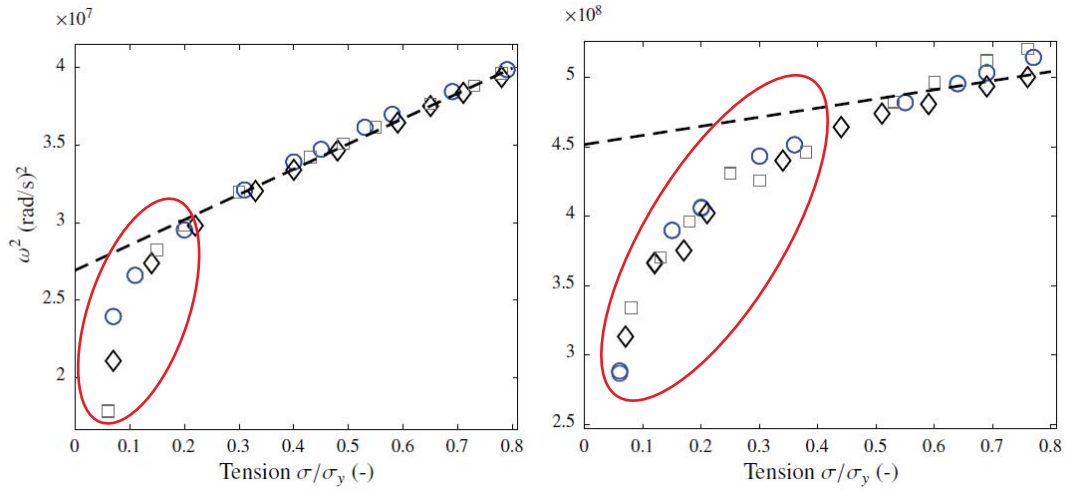

Figure 6. Square of the first natural frequency $\boldsymbol{\omega_1}$ as function of bolt tension $\boldsymbol{\sigma}$. The markers denote experimental results; dashed line is the model according to (1). Left – long bolt, right – short bolt. The red ovals indicate the region where the clamped-clamped beam model is not suitable (from [10]).

bolt, the fit is good for a wide range of σ, and less for the short bolt. Common for both cases, the fit is not good for low tension levels (circled), indicating that the clamped-clamped beam model does not reflect reality at low levels of tension.

The study [10] suggested an extended model that could explain the observed behavior at the full range of the tension levels. The model (Figure **7**) consists of a Bernoulli-Euler beam, subjected to an axial tensile force σA, and supports at both ends, which both have translational and rotational stiffnesses, k_u and k_θ, respectively. To reflect reality, where the bolt tension affects the contact stiffness, in the model, these stiffnesses are functions of the axial force. For high levels of σA, the stiffness values approach infinity, and the beam boundary conditions become clamped-clamped.

With the model in hand, the next task is to obtain the stiffness parameters and their dependence on tension. In [16] it was demonstrated that it is possible to estimate the stiffness parameters from the measured natural frequencies of the beam. Another approach was taken in [10], where the model of the contact between the mating surfaces was introduced. It was noticed that the contact surfaces in real structures are rough, which is manifested as a distribution of tiny asperities at a micro-scale level, whose interactions can be thought of as springs connecting the mating surfaces. It was observed that the normal (interfacial) stiffness increases with the increase of the contact pressure. Using the asperities-based contact model (Figure 8), it was possible to obtain the values of k_u and k_θ, which resulted in quite good agreement with the measured data, for the full range of tension (Figure 9).

The study [17] extended the model suggested in [10] (Figure 8), by the damping elements, which were added to all springs. It was shown that assuming the damping linearly proportional to the rotational and translational stiffnesses, one can get quite a good agreement with the experimental results shown in Figure **4**. Apparently contradicting though, is that the underlying

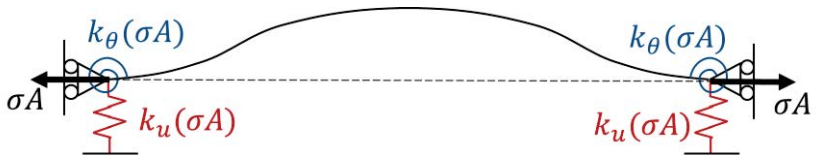

Figure 7. The model suggested in [10].

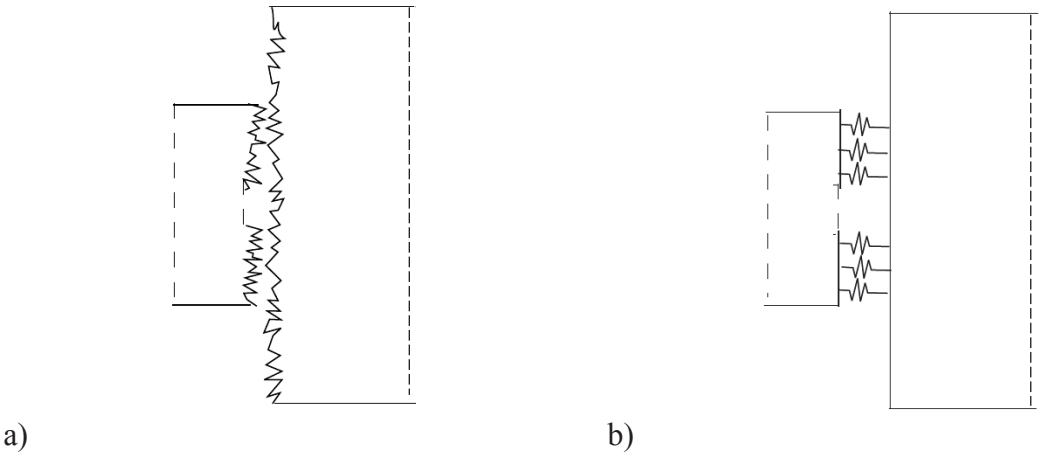

Figure 8. Modeling of the contact between the mating surfaces. a) Micro-level, with the roughness presented as asperities; b) modeling as springs connecting the surfaces (from [10]).

microscale damping mechanism is essentially nonlinear, whilst the collective macroscale behavior is linear. The study [17] suggested a model, which demonstrated that the non-linear multi-degree-of-freedom asperities-based model can be effectively converted to a single-degree-of-freedom model with a cubic nonlinearity, and further showed that the nonlinear term vanishes as the number of asperities increase, thus validating the observed effective linearity in damping.

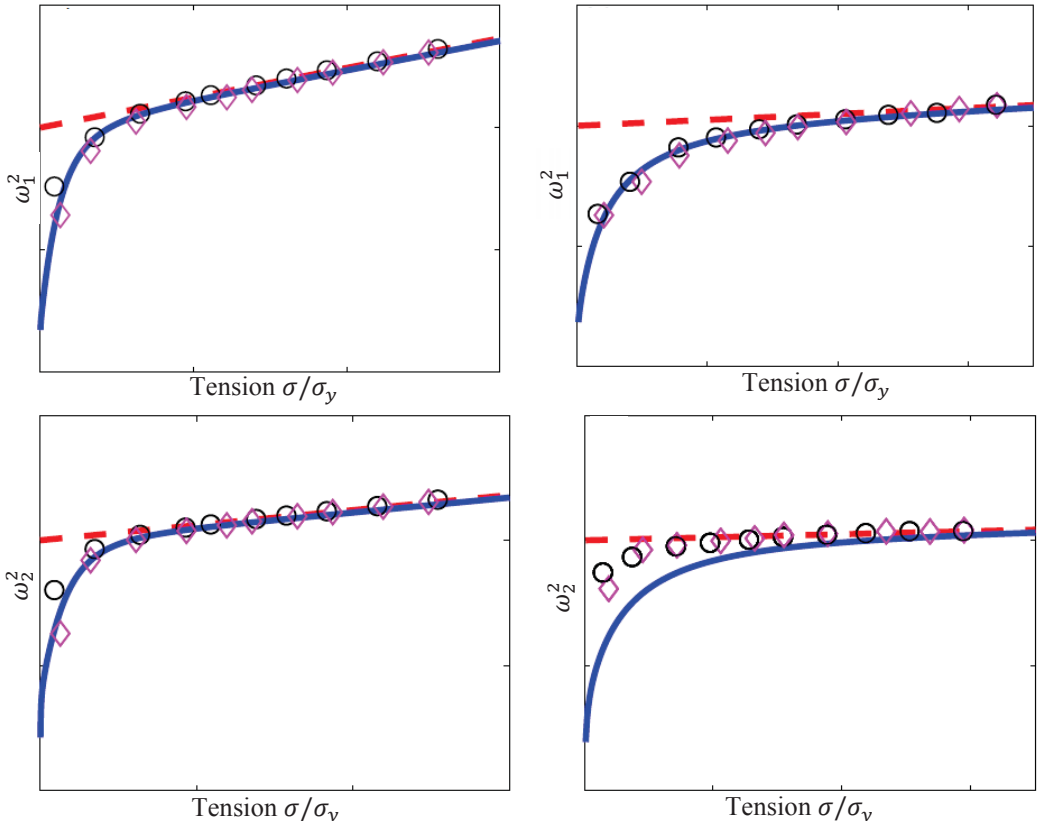

Figure 9. Qualitative comparison of the experimental results (markers), the clamped-clamped model (1) (red dashed line) and the extended model (Figure 7) (blue curve). Left / right columns – long / short bolts; Top / bottom rows – first / second natural frequencies (from [17]).

4 MODELLING MULTI-BOLT JOINT

In studies [18], [19], another aspect of the bolt tension estimation problem was investigated. As the most bolted joints consist of many nearly identical bolts tightened to almost identical levels, the bolts will have very similar boundary conditions and thus almost identical natural frequencies. In a likely case of very light damping, a frequency response measured on one bolt after an impact might include the vibrational response of other bolts. So, a question arises, if it is possible to separate which frequencies belong to which bolt. To start with, analytical, numerical and experimental models of a structure with two identical bolts were established (Figure 10).

It was found that, if the bolts have identical or very similar tension, the system behaves as a whole, and it is impossible to assign natural frequencies to a single bolt, as the global in-phase and anti-phase modes arise. However, if the bolts' tensions are different, their modes can be considered as local, the bolts can be considered separately, and the single-bolt model is fully applicable.

5 PRACTICAL CONSIDERATIONS

One of the aims of the VEBJI project was to explore feasible methods for estimating bolt tension having potential for industrial application. It is apparent (Figure 5), that the studied vibration features are suitable for distinguishing a nominally tightened bolt ($0.7\ \sigma_y$) from a very loose one ($< 0.3\ \sigma_y$). However, the ambition of the project was to be able to distinguish a nominally tightened bolt from the slightly under- and over-tightened ones, for example, to be able to find the tension within $\pm 0.1\sigma_y$ around the nominal tension $0.7\ \sigma_y$. In this region the vibration-based features have a low sensitivity to the tension (Figure 3, Figure **4**), i.e. the value of the feature changes little with the significant change of the tension level. As the vibration features are obtained from noisy measurements, it makes it challenging to develop a robust technique for estimating the tension with the desirable precision.

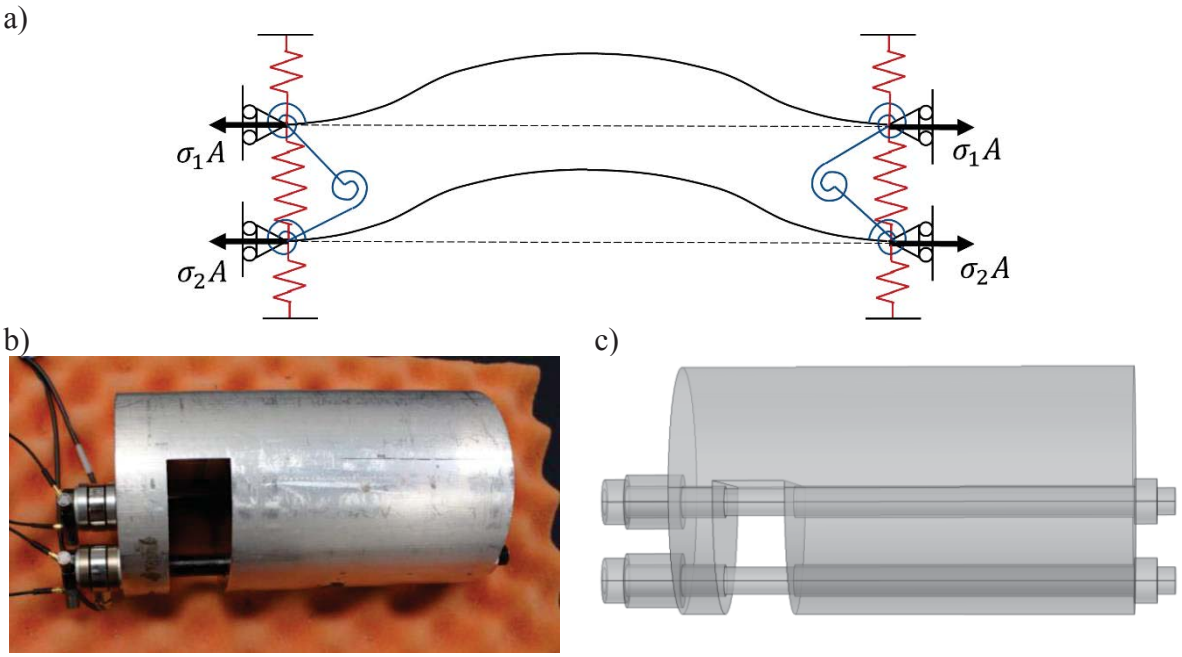

Figure 10. Two bolts structure from [19]: a) Analytical model; b) Experimental setup; c) COMSOL model

The study [20] attempted to suggest and test the algorithm that employs the first transverse natural frequency as the vibration feature, and then takes the next step towards classification, i.e. distinguishing the loose bolts from the tightened ones. The algorithm uses the gradient of the first natural frequency with respect to the tension from the clamp-clamp beam model (1). Also, the algorithm assumes that initially the bolt was tightened to the nominal tension value. The latter is used as the reference for the subsequent tension checks. The propagation of the uncertainty of the measured vibration feature to the uncertainty of the estimated bolt tension was conducted following the Delta method [21]. The variability of the vibration features was estimated by measuring the first transverse natural frequency of a big number of similar bolts holding a wind turbine blade on the test rig (Figure 11). It was concluded that the described above approach is not readily feasible, and it was suggested that the following can potentially improve the technique: 1) Improvements of the excitation/measurement/signal processing procedures; 2) Employing more sensitive features; 3) Combining several vibration features.

6 ON-GOING RESEARCH

The study [9] paved a way to another promising technology developed in the frame of VEBJI, which is currently patent pending [22]. In [9], it was analytically shown and numerically demonstrated that the boundary stiffnesses parameters (Figure 7) can be estimated from measured transverse natural frequencies. However, the method requires identification of a high number of modes, which is difficult to measure in practice (with hammer excitation only the first two transverse modes can be reliably identified). The new method suggests changing the dynamic properties of the bolt in a controllable way, by adding a known mass to the threaded end

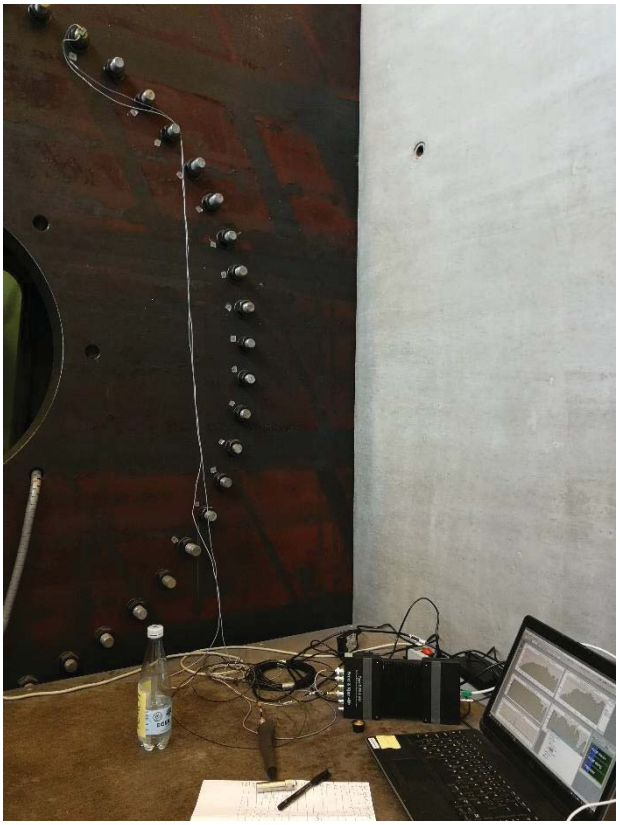

Figure 11. A test rig (wind turbine blade test bench) used to test the classification algorithm suggested in [20].

of the bolt. Thus, adding one or two masses to the bolt and measuring the first few natural frequencies, it is possible to estimate the tensional force acting in the bolt; the details of the method are presented in [23].

In the multi-bolt scenario, it is also anticipated that adding mass to the bolt end will make its dynamics different from the dynamics of the surrounding bolts; this will facilitate distinguishing the response of the tested bolt from the others (see Section 4).

As it was observed during the experiments, with hammer excitation employed, it is only possible to reliably identify the first two transverse modes, mainly due to the lack of excitation energy at the higher frequency range. The attempt to use the method in a real-life scenario, described in Section 5, also called for the improvement of the applied excitation and signal processing procedures. An approach to deal with this problem is to replace the hammer impacts with excitation by piezoelectric elements [24], which are generally more efficient at higher frequency ranges.

CONCLUSION

The paper describes the challenges, learnings, and achievements of the VEBJI project, whose aim was to generate knowledge and potentially develop a technique for estimating bolt tension using vibrations artificially excited in a bolt.

The study demonstrated that it is rather straightforward to distinguish a well-tightened bolt from a loose one, which could be done using the natural frequency and damping of the first transverse mode. However, it is more difficult to distinguish a nominally tightened bolt (characterized by axial stress σ_n) from slightly under- or overtightened ones ($< 0.9\ \sigma_n$ and $> 1.1\ \sigma_n$, respectively). Though the added mass method (Section 6) produces promising results, it still needs to be tested for multi-bolt joints scenarios.

Abstract. *Identification of nonlinear restoring force (NRF) and dynamic loadings provides useful information for structural damage prognosis (DP). Due to higher complexity of structural nonlinearities, it is difficult to establish an exact parametric mathematical model in prior to describe the nonlinear behavior of a structural member or a substructure under strong dynamic loadings in practice. Moreover, external dynamic loading applied on an engineering structure is usually unknown and only acceleration responses at limited degrees of freedom (DOFs) of the structure are monitored. In this study, a nonparametric NRF and excitation identification approach combining Legendre polynomial and extended Kalman filter with unknown input (EKF-UI) is proposed using limited acceleration measurements fused with displacement measurement for the purpose of eliminating drift problem. The performance of the proposed approach is illustrated via numerical simulation with a multi-degree-of-freedom (MDOF) frame structure equipped with an MR damper mimicking nonlinearity under different unknown loading scenarios. Partial acceleration measurement of the structure polluted by intensive measurement noises is employed for the identification. The parameter identification convergency procedure and the effect of initial estimation errors of structural parameters on the final identification results are investigated. Identified results demonstrate that the proposed approach is capable of identifying structural nonlinear behavior, excitation and dynamic response measurement in a nonparametric way with acceptable accuracy.*

1 INTRODUCTION

Structural identification for the purpose of structural health monitoring (SHM) and damage evaluation using vibration measurements has attracted extensive attentions in structural engineering field in the last decades [1, 2]. Generally speaking, structural damage usually results

in changes in structural parameters such as stiffness and damping. Because structural vibration frequencies and modal shapes extracted from dynamic response measurement depend on stiffness, lots of vibration-based structural damage detection approaches have been proposed, where structural damage is represented by a stiffness decrease identified from the extracted structural frequencies and/or modal shapes [3]. Strictly speaking, most of the identification approaches based on eigenvalues and/or modal shapes are only applicable for linear elastic systems. However, structural nonlinearity is a common phenomenon encountered in engineering structures subjected to severe dynamic loading and should be considered during the vibration analysis and the identification for structures [4-6]. Representing damages in a nonlinear dynamic system using the changes in stiffness identified with eigenvalues or modal shapes extracted from dynamic response time history of the system experiencing nonlinearity is doubtful and questionable. Structural nonlinear restoring force (NRF) is a direct director describing the initiation and development of structural nonlinearity and can be used directly to determine the energy consumption during the whole procedure of vibration, which provides more helpful information for damage prognosis (DP) compared with stiffness.

Since it is usually hard to measure structural responses at all degrees of freedom (DOFs) of a structure with lots of sensors, structural identification with only partial structural response measurements has received more attention [7]. A simultaneous NRF and mass identification approach is developed by Xu. et al. [8] for multi-degree-of-freedom (MDOF) structures using the EKF with weighted global iteration (EKF-WGI) based on limited absolute acceleration response. However, the conventional EKF approach works well when the information of external inputs to structures is available. Because all external excitations to a structure are not always available in practice, it is important to develop structural nonlinearity and excitation identification algorithms for engineering structures experiencing nonlinearity under dynamic excitations. Yang et al. [9] proposed an adaptive EKF with unknown input (AEKF-UI) approach for the identification of time-varying parameters and unknown external excitations. Lei et al. [10] proposed an algorithm based on sequential application of an extended Kalman estimator (EKE) for the extended state vector of a structure and least-squares estimation (LSE) of its unknown external excitations to detect structural damage with limited input and output measurement signals. This approach is applied for the identification of linear structures where structure damage is described as the decrease in stiffness. For the identification of non-linear structural parameters under limited input and output measurements, an algorithm based on the sequential application of EKE for the parameters of a parametric model describing nonlinearity and the LSE for the unmeasured excitation is proposed [11]. More recently, Liu et al. [12] proposed a data fusion based EKF with unknown inputs (EKF-UI) approach for simultaneously identifying structural parameters and unknown excitations. A general system and unknown inputs simultaneous estimation using EKF-UI approach was proposed by Pan et al. [13] to meet the challenges coming with the unavailability of dynamic response and excitation information. A General Extended Kalman filter with unknown inputs (GEKF-UI) is proposed to estimate the structural parameters and the unknown excitations (inputs) simultaneously to overcome the limitations of the existing EKF methods for the identification of both time-invariant and time-varying systems. In all of the above studies, the parametric models describing the nonlinearity of the structure are assumed and the parameters of the parametric models are identified.

In this paper, a nonparametric structural NRF, excitation, unmeasured dynamic response identification approach based on the Legendre polynomial model and EKF-UI is proposed for nonlinear structure composed of a linear structure and a nonlinear member of a magnetorheological (MR) damper. Data fusion is used to eliminate the drift problem in dynamic responses identification. The proposed approach was numerically validated with MDOF structures

equipped with a MR damper mimicking nonlinear behavior under different excitation forms. The parameter identification convergency procedure and the effect of initial estimation errors of structural parameters on the final identification results are investigated. Identification results show that the proposed method is effective to identify NRF and the unknown excitations when no parametric models describing the nonlinearity of the structure are employed.

2 NONPARAMETRIC NRF AND EXCITATION IDENTIFICATION APPROACH

In physical science and mathematics, the Legendre polynomial is a system of orthogonal polynomials, with a vast number of beautiful properties and innumerable applications. Any piecewise continuous function $z(x,y)$ with finitely many discontinuities in the interval of [-1, 1] can be expressed by the sequence of sums of a number of Legendre polynomials shown as follows,

$$z(x,y) \approx \sum_{n=0}^{N}\sum_{m=0}^{M} c_{nm} L_n(x) L_m(y) \tag{1}$$

where c_{nm} is the coefficient of the Legendre polynomials of $L_n(x)$ and $L_m(y)$, N and M are integrals.

The recursive relationship of Legendre polynomials is shown in the following equation,

$$L_n(x) = \sum_{m=0}^{\left[\frac{n}{2}\right]} (-1)^m \frac{(2n-2m)!}{2^n m!(n-m)!(n-2m)!} x^{n-2m} \quad (n=0,\ 1,\ 2,\ \cdots\cdots) \tag{2}$$

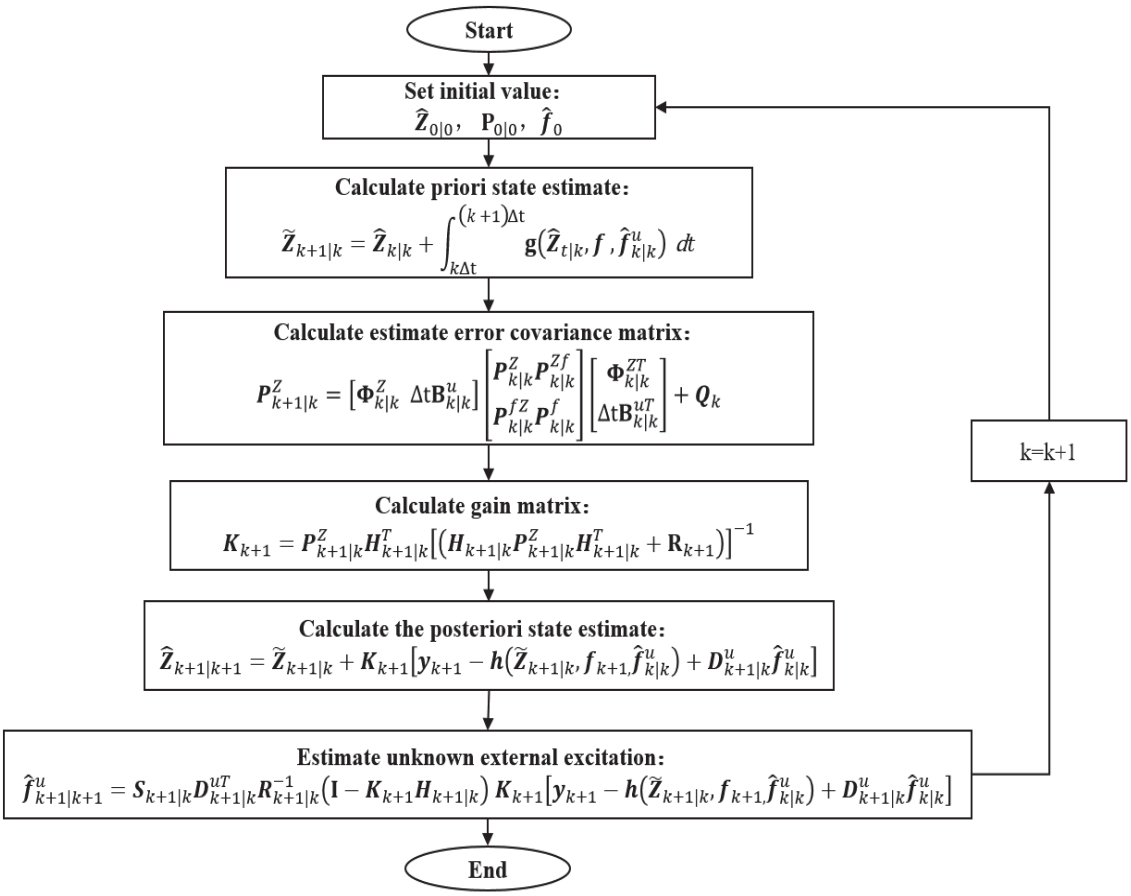

Figure 1: Flowchart of the presented algorithm for identifying structural parameters and unknown excitations

In this study, without using any parametric models describing structural nonlinear behavior, the structural NRF could be described in the form of Legendre polynomial of structural relative velocity, relative displacement as shown in the equation (3),

$$R_{i,i-1}[\dot{x}(t), x(t), \theta] \approx \sum_{h=0}^{k} \sum_{j=0}^{q} c_{i,i-1,h,j}^{non} L_h(v'_{i,i-1}) L_j(s'_{i,i-1}) \tag{3}$$

where $R_{i,i-1}[\dot{x}(t), x(t), \theta]$ is the NRF between the ith DOF and the i-1th DOF, $v_{i,\,i-1}$ and $s_{i,\,i-1}$ are relative velocity and relative displacement vectors, $c_{i,i-1,h,j}^{non}$ is the coefficient of the polynomial, k and q are integers which depend on the nature and extent of the nonlinearity. $L_h(v'_{i,i-1})$ and $L_j(s'_{i,i-1})$ are Legendre polynomial. The identification flowchart of the proposed method is shown in details in Figure 1, where $\boldsymbol{Z}$, $\boldsymbol{P}$, $\boldsymbol{f}$, $\boldsymbol{g}$, $\boldsymbol{K}$ and $\boldsymbol{y}$ are extended state vector, the covariance matrix of error, external excitation, state equation, Kalman gain matrix and observation vector, respectively.

3 NUMERICAL SIMULATION VALIDATION CONSIDERING DIFFERENT EXCITATION SCENARIOS

To verify and validate the effectiveness of the proposed approach for the state of the structure, the unknown inputs and NRF identification with only partial measurements of acceleration and displacement, numerical studies with a four-story shear frame equipped with a MR damper on the fourth floor to mimic nonlinear behavior of structure under two different excitation scenarios including the direct point excitation and earthquake excitation are carried out. The mass, inter-story stiffness and damping coefficients corresponding to each story of the four-story shear frame are $m_i = 400kg$, $k_i = 320kN/m$, and $c_i = 0.24kN \cdot s/m$ (i=1,…, 4), respectively.

In the direct analysis of the dynamic response of the nonlinear structure, a parametric model for the employed MR damper is required even it is unnecessary in the identification approach proposed in this study. Here, the modified Dahl model described in the following equation is used [14].

$$f_{non}^{MR} = K_0 s_{i,i-1} + C_0 v_{i,i-1} + F_d Z - f_0 \tag{4}$$

where f_{non}^{MR} is the NRF provided by the MR damper, K_0 and C_0 is the stiffness coefficient and damper coefficient of the MR damper, F_d represents the coulomb frictional force determined by the current intensity, $s_{i,i-1}$ and $v_{i,i-1}$ represent the displacement and velocity of the MR damper installed on the i-1th floor, f_0 is the initial force, and Z is a constant determined by the following equation:

$$\dot{Z} = \sigma v_{i,i-1}(1 - Z\,\mathrm{sgn}(v_{i,i-1})) \tag{5}$$

where σ is the hysteresis coefficient of the MR damper. Here, the parameters take the following values, $\sigma = 50s/m$, $K_0 = 0.05kN/\mathrm{m}$, $C_0 = 1.995kN \cdot \mathrm{s/m}$, $F_d = 0.035kN$, and $f_0 = 0$.

Only acceleration responses at the first, third, and fourth floors are used in identification. Simultaneously, the displacement responses on the second and fourth floors are used for data fusion. The acceleration responses are polluted with white noises with 3% noise-to-signal ratio in root mean square. In the iterative process, in order to consider the effect of the initial

values of stiffness and damping coefficients on the identification results. A -20% and a -40% initial estimation error for both stiffness and damping coefficients are considered.

A normalized root-mean-square error (NRMSE) is defined to evaluate the accuracy of the unmeasured dynamic responses as well as the unknown excitation identification results. The NRMSE is defined as follows,

$$\mathrm{NRMSE} = \sqrt{\frac{\sum_{k=1}^{np}\left(\gamma_k^i - \gamma_k^a\right)^2}{\sum_{k=1}^{np}\left(\gamma_k^a\right)^2}} \times 100\% \tag{6}$$

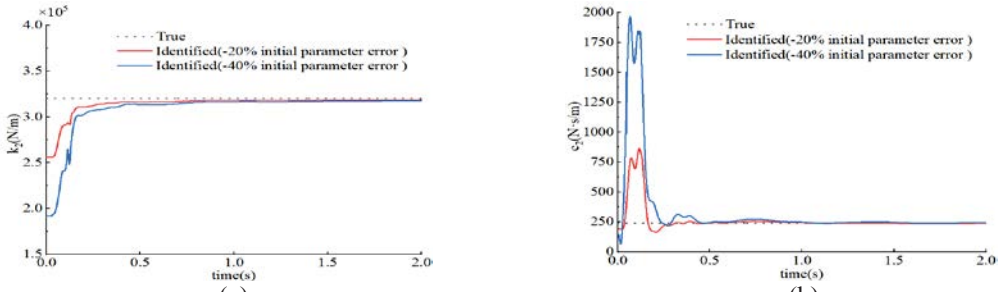
in which *np* is the number of sampling points; γ_k^i and γ_k^a are the identified unknown dynamic responses, NRF and unknown excitation and their actual value of the *k*-th sample time step.

3.1 Case1: A point excitation

The nonlinear shear frame structure is subjected to a sinusoidal excitation applied on the third floor. Based on the proposed approach, the inter-story stiffness and the damping coefficients of the corresponding linear part of the structure are identified and the identified results compared with the real values are shown in Table 1. The maximum of the relative errors corresponding to the inter-story stiffness and damping coefficients are 0.62% and 5.42%, respectively.

Structural parameters	Real value	Identified value	Error	Structural parameters	Real value	Identified value	Error
$k_1\left(kN\cdot m^{-1}\right)$	320	319	0.31%	$c_1\left(N\cdot s\cdot m^{-1}\right)$	240	227	5.42%
$k_2\left(kN\cdot m^{-1}\right)$	320	319	0.31%	$c_2\left(N\cdot s\cdot m^{-1}\right)$	240	239	0.42%
$k_3\left(kN\cdot m^{-1}\right)$	320	318	0.62%	$c_3\left(N\cdot s\cdot m^{-1}\right)$	240	242	0.83%
$k_4\left(kN\cdot m^{-1}\right)$	320	320	0.00%	$c_4\left(N\cdot s\cdot m^{-1}\right)$	240	240	0.00%

Table 1: Identified structural parameters (-20% initial parameter error)



(a) (b)

Figure 2: Iterative identification process compared with the true values: (a) stiffness on the second floor (b) damping coefficient on the second floor

Further investigation on the effect of different initial estimation errors of structural stiffness and damping coefficients on the iterative processes of the identified parameters and their identification accuracy is carried out and the corresponding results are plotted in Figure 2, whereas the dashed curves are the actual ones for comparison. It is obvious that the identified parameters are able to stably converge to their theoretical values. Figure 3 demonstrates the comparison of the identified displacement on the third floor and the acceleration response on the

second floor with their true results determined by integration. Figure 4 shows the comparison of identified excitation force on the third floor and the MR damper force on the fourth floor with their true results when the initial estimation errors for stiffness and damping coefficients are -20%. From Figures 3 and 4, it can be found the identified results have a good agreement with the true values.

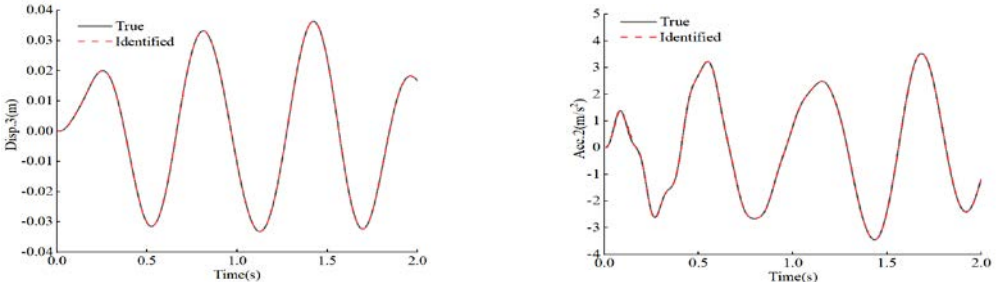


Figure 3: The comparison of identified dynamic response with their true values (-20% initial parameter error): (a) displacement on the third floor, (b) acceleration on the second floor

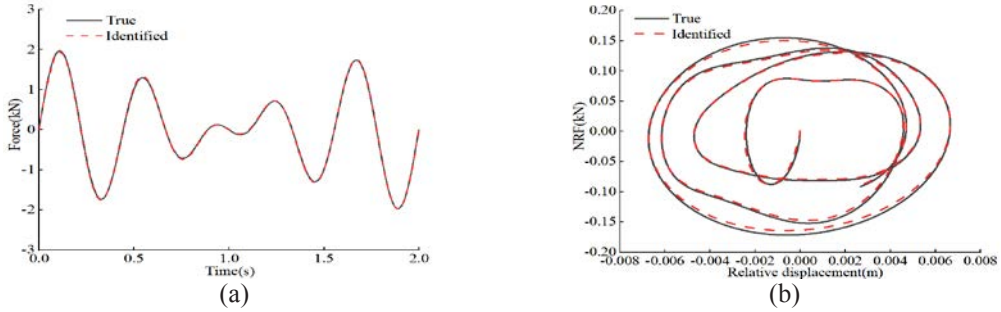

Figure 4: The comparison of identified excitation force and the MR damper force with their true results (-20% initial parameter error): (a) unknown excitation, (b) the hysteretic of MR damper on the fourth floor

Identified quantifies (-20% initial parameter error)	NRMSE(%)	Identified quantifies (-40% initial parameter error)	NRMSE(%)
Displacement on the 3rd floor	0.001	Displacement on the 3rd floor	0.001
Acceleration on the 2nd floor	0.014	Acceleration on the 2nd floor	0.099
Excitation on the 3rd floor	0.048	Excitation on the 3rd floor	0.175
NRF on the 4th floor	0.086	NRF on the 4th floor	0.817

Table 2: NRMSE results corresponding to the identified dynamic response, excitation and NRF

The NRMSE results for the identified numerical model are shown in Table 2. It can be clearly seen from Table 2 that the values of NRMSE are very small, which indicates the identified results are close to their actual ones. However, different initial parameter estimation errors have no obvious negative influence on the identified results.

3.2 Case 2: Earthquake excitation

A further case where the nonlinear shear frame model is subjected to an earthquake excitation with an acceleration peak value of 0.3g is investigated considering the fact that the nonlinear behavior identification for engineering structures after the exciting of earthquake is

critical. Based on the proposed approach, the inter-story stiffness and damping coefficients of the linear part of the nonlinear structure can be identified and compared with their true values as shown in Table 3. It can be found that the inter-story stiffness can be identified with a very high accuracy even noise-contained acceleration response is employed. The maximum relative error for damping coefficients is 3.33% but is still acceptable.

Structural parameters	Real value	Identified value	Error	Structural parameters	Real value	Identified value	Error
$k_1\left(kN\cdot m^{-1}\right)$	320	320	0.00%	$c_1\left(N\cdot s\cdot m^{-1}\right)$	240	232	3.33%
$k_2\left(kN\cdot m^{-1}\right)$	320	320	0.00%	$c_2\left(N\cdot s\cdot m^{-1}\right)$	240	231	3.75%
$k_3\left(kN\cdot m^{-1}\right)$	320	320	0.00%	$c_3\left(N\cdot s\cdot m^{-1}\right)$	240	235	2.08%
$k_4\left(kN\cdot m^{-1}\right)$	320	320	0.00%	$c_4\left(N\cdot s\cdot m^{-1}\right)$	240	239	0.42%

Table 3: Identified structural parameters (-20% initial parameter error)

Iterative process comparison of the identified parameters when different initial estimation errors are considered are shown in Figure 5. Similar to parameter identification results under sine excitation, the identified parameters can converge to their theoretical values with very small error.

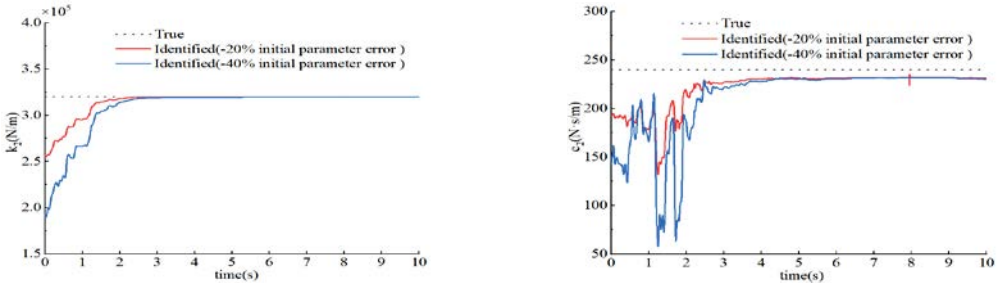

Figure 5: Iterative process comparison of the identified parameters of shear frame structure: (a) stiffness on the second floor (b) damping coefficient on the second floor

Figure 6 gives the comparison of the identified displacement response on the third floor and the acceleration response on the second floor with their corresponding actual results. Figure 7 shows the comparison of identified base excitation acceleration and the hysteretic of the MR damper on the fourth floor with their true values. It can be easily observed from Figures 6 and 7 that the identified unknown dynamic response, earthquake acceleration and the damping force of MR damper meet their true values very well.

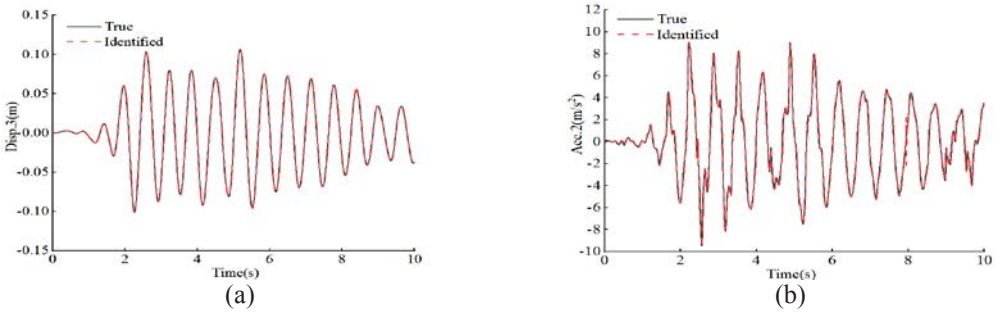

Figure 6: The comparison of identified dynamic response with their true values (-20% initial parameter error): (a) displacement on the third floor, (b) acceleration on the second floor

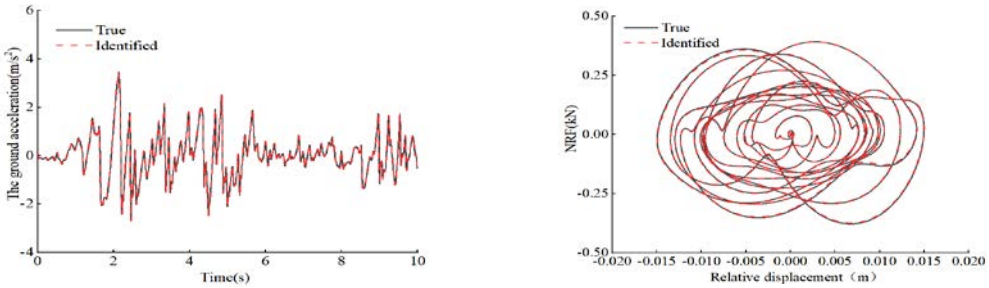

(a) (b)

Figure 7: The comparison of identified results with its true values (-20% initial parameter error): (a) unknown excitation, (b) the MR damper force on the fourth floor

The NRMSE results for the identified unknown responses are shown in Table 4. It can be seen from Table 4 that the values of NRMSE are smaller, which indicates the proposed method can accurately identify the unknown dynamic response, earthquake acceleration and NRF with high accuracy. Moreover, the initial estimation errors for stiffness and damping coefficients have no obvious negative effect on the identification results.

Identified quantifies (-20% initial parameter error)	NRMSE(%)	Identified quantifies (-40% initial parameter error)	NRMSE(%)
Displacement on the 3rd floor	0.001	Displacement on the 3rd floor	0.002
Acceleration on the 2nd floor	0.019	Acceleration on the 2nd floor	0.015
Excitation on the 3rd floor	0.028	Excitation on the 3rd floor	0.018
NRF on the 4th floor	0.021	NRF on the 4th floor	2.195

Table 4: NRMSE results corresponding to the identified dynamic response, excitation and NRF

4 CONCLUDING REMARKS

In this paper, a nonparametric MR damper force identification approach based on a Legendre polynomial and an extended EKF with unknown input is proposed. Numerical simulation results with a MDOF frame structure equipped with a MR damper under both point excitation and based earthquake excitation show that the proposed method is capable of identifying structural responses, MR damper force and unknown input with acceptable accuracy in a nonparametric way, where no parametric models for the MR damper are required.

The proposed approach is potential for structural nonlinearity identification, which plays key roles in post-event damage prognosis and remaining load-carrying capacity and remaining service life forecasting for engineering structures where structural nonlinear behavior and loading profiles should be considered.

Keywords: Virtual sensing, Bayes' rule, Quantization, Clipping, Overload error, Sensor network

Abstract. *In vibration monitoring of structures, quantization and overload errors may be significant when measuring vibrations with highly variable magnitudes. In analog-to-digital (A/D) conversion, each data value must be expressed by a finite number of bits. Therefore, a finite number of levels are available to approximate an infinite number of analog values. This A/D conversion results in a round-off error, or quantization error. The signal-to-noise ratio can be increased by setting the dynamic range so that the analog signal occupies it as much as possible. If the dynamic range is too small, it can result in overload error due to signal clipping. Both aforementioned errors can be reduced using Bayesian virtual sensing. Each data point can be estimated using the data from the whole sensor network on the structure. The variance of the quantization error is known, which can be used in the likelihood and prior estimation. The resulting posterior mean is more accurate than the quantized signal. The clipped sensors are estimated using the conditional probability of the clipped sensors given the remaining unclipped sensors. In a numerical experiment of a bridge structure with 28 accelerometers, the reduction of the quantization error and the reconstruction of the clipped sensors were studied using the response data only. The main requirement is that the number of sensors must be greater than the number of active modes to ensure redundancy of the sensor network. The signal-to-noise ratio was used as a performance measure. Virtual sensors outperformed the quantized data and an optimal dynamic range of the A/D converter was found.*

1 INTRODUCTION

In monitoring of structural vibrations, different magnitudes of vibration occur. For example, a bridge may vibrate under the excitation of different types of vehicles, variable wind levels, small ground tremor, or different magnitudes of earthquakes. In some applications, it is important to measure all vibration levels, for example in rainflow analysis for fatigue monitoring.

An issue in measuring a wide range of vibration levels is the quantization error. In analog-to-digital (A/D) conversion, each data value must be expressed by a finite number of bits. Therefore, a finite number of levels are available to approximate an infinite number of analog values. This A/D conversion results in a round-off error, quantization error. The signal-to-noise ratio can be increased by setting the dynamic range so that the analog signal occupies it as much as possible. If the dynamic range is too small, it can result in clipping due to overload. Both of these errors may be significant when measuring vibration with highly variable magnitudes.

Quantization has been studied in communication and a typical problem is how to optimally quantize analog signals [1]. In the present study, however, the objective is to reconstruct the already quantized signals in order to reduce the quantization error. A uniform quantizer is assumed with a user-defined dynamic range. The signal-to-noise ratio (SNR) is used as a performance measure, because it is also very important in the detection theory [2] used in structural health monitoring.

Noise reduction is done by applying Bayesian virtual sensing [3]. It is assumed that a sensor network with simultaneous sampling is installed on the structure. If the network is redundant, each sensor's signal can be estimated using all the signals in the network. It has been shown that the Bayesian virtual sensors are more accurate than the actual measurement [3]. It is assumed that quantization is done properly and quantization error is the only source of error. With this assumption, it is possible to concentrate on the research question whether quantization error can be reduced after digitization. The analog-to-digital converter (ADC) is, however, a nonideal device and exhibits a variety of errors, for example linearity error, gain error, and offset error [4]. It should be mentioned that with modern equipment, other measurement errors may be considerably higher than the error in the A/D conversion [5]. If at least a 12-bit ADC is used, the other sources of error in the data acquisition and processing procedures are more significant in practice [6]. However, even with modern equipment, quantization errors can be significant when different levels of magnitudes are measured with a fixed dynamic range.

The paper is organized as follows. Quantization is introduced in Section 2 with two types of errors, granular noise and overload noise. Bayesian virtual sensors are designed in Section 3 to reduce the quantization error. A numerical experiment of a bridge deck is performed in Section 4, in which three different magnitudes of vibration are measured with 28 accelerometers at different points of the structure. The measurements are quantized and then reconstructed using virtual sensing. Finally, concluding remarks are given in Section 5.

2 QUANTIZATION

Vibration data are continuous both in time and amplitude. Sampling results in time discretization. Resulting samples are still continuous in amplitude. When the samples are digitized in the analog-to-digital converter (ADC), rounding error occurs. Quantization is the process of approximating the continuous range of values with a finite number of bits. The output values are referred to as output levels, output points, or reproduction values [7]. The number of bits determines the number of levels L:

$$L = 2^R \tag{1}$$

where R is the word size, resolution, or code rate. For example, for 8-, 12-, and 16-bit ADCs, the number of levels are 256, 4096, and 65536, respectively.

The quantizer divides the real line into L cells. Figure 1 shows the quantizer characteristics of a uniform 3-bit quantizer with $L = 2^3 = 8$ possible levels. The mapping $y = Q(x)$ in Figure 1a is a staircase function and the quantization error is shown in Figure 1b. Each bounded cell is called a granular cell and a cell that is unbounded is called an overload cell. Together all of the overload cells are called the overload region [7]. The range of the quantizer is defined as the total length of the granular cells.

In a uniform quantizer, the quantized signal $\mathbf{y}(t_i)$ is obtained from the sampled continuous-amplitude data $\mathbf{x}(t_i)$ using the following.

$$\mathbf{y}(t_i) = \Delta x \cdot \mathrm{floor}\left(\frac{\mathbf{x}(t_i)}{\Delta x}\right) + \frac{1}{2} \tag{2}$$

where t_i is the sampling instant and Δx is the quantization interval. The function floor(x) rounds x to the nearest integer less than or equal to x. An analog signal and the corresponding quantized signal with a 3-bit ADC are plotted in Figure 2.

In order to study the quantization error, it is assumed that no other errors occur and quantization is done properly. It should be noted that other sources of error (noise) can be more serious than the quantization error, e.g. aperture error, jitter, and nonlinearities [6].

Uniform quantization is assumed, in which the intervals Δx are of the same length. The true value at each sampling instant is approximated by the quantized level closest to it. The quantization error

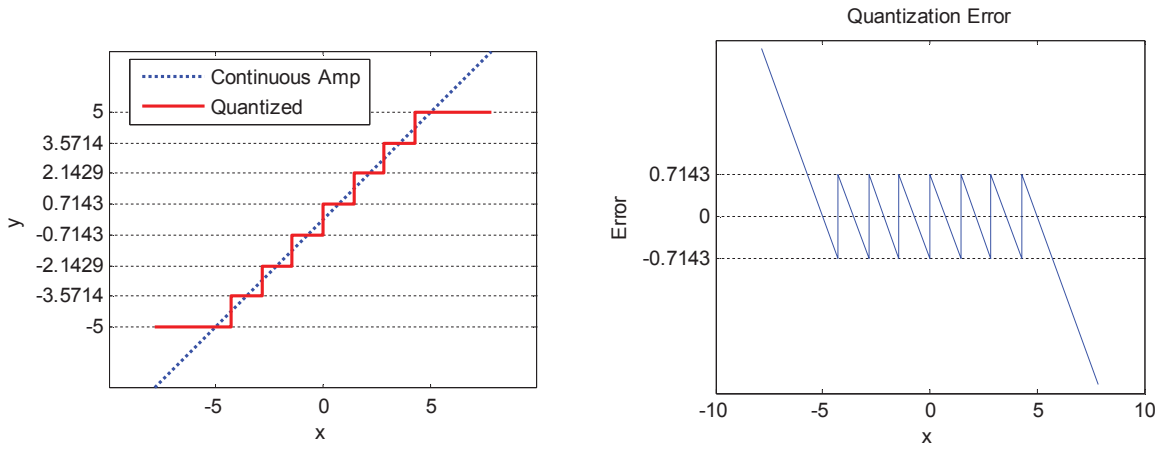
$$w(n) = \mathbf{y}(n) - \mathbf{x}(n) \tag{3}$$

thus varies between $-\Delta x/2$ and $\Delta x/2$. A uniform probability density function of the quantization error is assumed [6]:

$$p(w) = \begin{cases} \dfrac{1}{\Delta x} & -\dfrac{1}{2}\Delta x \le w \le \dfrac{1}{2}\Delta x \\ 0 & \text{otherwise} \end{cases} \tag{4}$$

The mean value of the error is zero, and the variance is

$$\sigma_w^2 = \int_{-\infty}^{\infty} w^2 p(w) dw = \frac{1}{\Delta x}\int_{-0.5\Delta x}^{0.5\Delta x} w^2 dw = \frac{\Delta x^2}{12} \tag{5}$$



(a) (b)

Figure 1: (a) Mapping of a 3-bit uniform quantizer and (b) the quantization error.

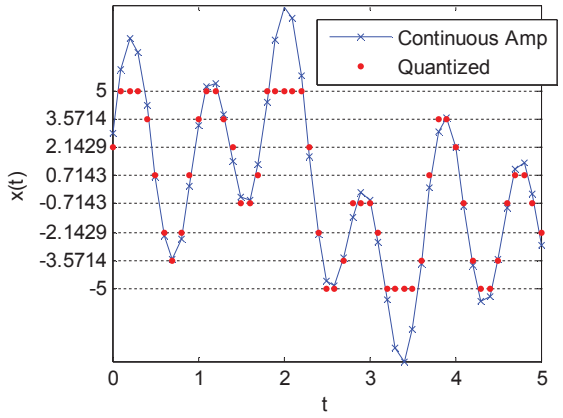


Figure 2: An example of a quantized signal with a 3-bit ADC.

2.1 Granular and overload noise

The quantization error (3) is often denoted as noise introduced by the quantizer. Granular noise occurs for an input that lies within the bounded cells of the quantizer. The overload noise is introduced if the input lies in the overload region i.e. in an unbounded cell. Therefore, granular error is relatively small while overload noise can be very large (Figure 1b and Figure 2) [7].

The performance of the quantizer is often specified in terms of a signal-to-noise ratio (SNR). It should be mentioned that the SNR is also important in the detection theory [2]. Structural health monitoring (SHM) utilizes measured vibration signals in damage detection. Therefore, a quantizer with a large SNR is advantageous [8].

The SNR is defined as [7]

$$SNR = 10\log_{10}\frac{E(X^2)}{D} \tag{6}$$

where D is the average distortion, which for a uniform quantizer is given in (5) if the input signal is bounded in the granular region.

In practice, most of the signals are unbounded, and the maximum error is infinite. Therefore, the overload region should be avoided. On the other hand, for the best signal-to-noise

ratio (SNR), the measured signal must occupy as much of the available ADC range as possible. The ADC setting is therefore a trade-off between the maximal SNR and a small probability of overload.

If the ADC range is adjusted to the extreme events, the SNR of the small events may become small. On the other hand, if the ADC range is adjusted to small amplitudes, the large vibrations can result in overload error due to signal clipping. Clipping occurs if the measured signal exceeds the ADC range. These overload errors can be unbounded. The quantizer approximates the values in the overload region to the maximum (or minimum) quantization level, which is the overload amplitude. In the signal plot, it looks like the signal peaks have been clipped (Figure 2).

The clipped channels may be useless due to a large error. Fortunately, clipping is easy to detect. It may be possible to reconstruct clipped data, if there exist unclipped channels at the same data point. The reconstruction can be done using Bayesian virtual sensing introduced in the next section and applied to both granular and overload errors.

3 BAYESIAN VIRTUAL SENSING

Bayesian virtual sensing is used to estimate sensor data that are more accurate than the quantized signals. A sensor network with simultaneous sampling is required. The objective is to reduce the quantization error of each signal using all the quantized response data in the network.

The main requirement is that the number of sensors in the network is large enough to make the system redundant. In practice, the number of sensors should be larger than the number of active modes.

There are two different quantization errors discussed in Section 2. The granular error is reduced with a different algorithm than the overload error. In order to reduce granular noise, all channels can be used in estimation excluding the clipped data. For granular error, the sensor's own quantized value can be also utilized, because its error variance is known. To reduce overload error and reconstruct the clipped data, the remaining unclipped channels should be only used for estimation. The data from the clipped sensor cannot be used, because its noise variance is unknown. Another option is to assign an infinite error variance to all clipped sensors. This would allow the development of a unified algorithm.

Notice that no mathematical model (e.g. a finite element model) is needed. The virtual sensors are estimated based on quantized measurement only. Also, the excitation is unknown.

Empirical virtual sensing is applied to the current measurement. Consider a sensor network measuring p simultaneously sampled responses $\mathbf{y} = \mathbf{y}(t_i)$ at time instant t_i. An additive noise model of quantization is assumed [7]. Each measurement $\mathbf{y}$ includes measurement error $\mathbf{w} = \mathbf{w}(t_i)$ (3):

$$\mathbf{y} = \mathbf{x} + \mathbf{w} \tag{7}$$

where $\mathbf{x} = \mathbf{x}(t_i)$ are the exact values of the measured degrees of freedom (DOF). All vectors are divided into predicted DOFs $\mathbf{u}$ and remaining DOFs $\mathbf{v}$:

$$\mathbf{y} = \begin{Bmatrix} \mathbf{y}_u \\ \mathbf{y}_v \end{Bmatrix} \qquad \mathbf{x}_m = \begin{Bmatrix} \mathbf{x}_u \\ \mathbf{x}_v \end{Bmatrix} \qquad \mathbf{w} = \begin{Bmatrix} \mathbf{w}_u \\ \mathbf{w}_v \end{Bmatrix} \tag{8}$$

For simplicity but without loss of generality, assume zero-mean variables $\mathbf{y}$. The partitioned data covariance matrix $\mathbf{\Sigma}_y$ is

$$\boldsymbol{\Sigma}_y = \mathrm{E}\left[\mathbf{y}\mathbf{y}^T\right] = \begin{bmatrix} \boldsymbol{\Sigma}_{y,uu} & \boldsymbol{\Sigma}_{y,uv} \\ \boldsymbol{\Sigma}_{y,vu} & \boldsymbol{\Sigma}_{y,vv} \end{bmatrix} = \begin{bmatrix} \boldsymbol{\Gamma}_{y,uu} & \boldsymbol{\Gamma}_{y,uv} \\ \boldsymbol{\Gamma}_{y,vu} & \boldsymbol{\Gamma}_{y,vv} \end{bmatrix}^{-1} = \boldsymbol{\Gamma}_y^{-1} \tag{9}$$

where the precision matrix $\boldsymbol{\Gamma}_y$ is defined as the inverse of the data covariance matrix $\boldsymbol{\Sigma}_y$ and is also written in partitioned form. E(·) denotes the expectation operator.

The objective is to find a linear estimator for the virtual sensors. It is well known that linear estimator is derived if the variables are normally distributed. Therefore, even if the granular error is uniformly distributed, a normal distribution is assumed in this paper with the same mean and variance as the true distribution.

A linear minimum mean square error (MMSE) estimate for $\mathbf{y}_u \mid \mathbf{y}_v$ ($\mathbf{y}_u$ given $\mathbf{y}_v$) is obtained by minimizing the mean-square error (MSE) and can be computed either using the covariance or precision matrix [9, 10]. The expected value, or the conditional mean, of the predicted variable is:

$$\hat{\mathbf{y}}_u = \mathrm{E}(\mathbf{y}_u \mid \mathbf{y}_v) = -\boldsymbol{\Gamma}_{y,uu}^{-1}\boldsymbol{\Gamma}_{y,uv}\mathbf{y}_v = \mathbf{K}\mathbf{y}_v \tag{10}$$

where $\mathbf{K} = -\boldsymbol{\Gamma}_{y,uu}^{-1}\boldsymbol{\Gamma}_{y,uv}$. The error covariance MSE is

$$\mathrm{cov}(\mathbf{y}_u \mid \mathbf{y}_v) = \boldsymbol{\Gamma}_{y,uu}^{-1} \tag{11}$$

Measurement error $\mathbf{w}$ is assumed to be granular noise only and independent of $\mathbf{x}$, with a covariance matrix (see Equation 5)

$$\boldsymbol{\Sigma}_w = E\left[\mathbf{w}\mathbf{w}^T\right] = \begin{bmatrix} \boldsymbol{\Sigma}_{w,uu} & \boldsymbol{\Sigma}_{w,uv} \\ \boldsymbol{\Sigma}_{w,vu} & \boldsymbol{\Sigma}_{w,vv} \end{bmatrix} = \frac{\Delta x^2}{12}\begin{bmatrix} \mathbf{I}_{uu} & \mathbf{0} \\ \mathbf{0} & \mathbf{I}_{vv} \end{bmatrix} \tag{12}$$

where $\mathbf{I}_{uu}$ and $\mathbf{I}_{vv}$ are unity matrices with proper dimensions.

Using Equation 7 and the assumed noise model, the conditional means of $\mathbf{y}$ and $\mathbf{x}$ are equal:

$$E(\mathbf{y}_u \mid \mathbf{y}_v) = E(\mathbf{x}_u \mid \mathbf{y}_v) + E(\mathbf{w}_u) = E(\mathbf{x}_u \mid \mathbf{y}_v) \tag{13}$$

Using Equations 7 and 12, the MMSE error covariance contains both the estimation error and noise:

$$\mathrm{cov}(\mathbf{y}_u \mid \mathbf{y}_v) = \mathrm{cov}(\mathbf{x}_u \mid \mathbf{y}_v) + \boldsymbol{\Sigma}_{w,uu} \tag{14}$$

The objective is to find a better estimate for $\mathbf{x}_u$ than the actual measurement $\mathbf{y}_u$ utilizing the noisy measurements $\mathbf{y}$ from the sensor network. From Bayes' rule,

$$p(\mathbf{x}_u \mid \mathbf{y}) = p(\mathbf{x}_u \mid \mathbf{y}_u, \mathbf{y}_v) = \frac{p(\mathbf{y}_u \mid \mathbf{x}_u, \mathbf{y}_v)\, p(\mathbf{x}_u \mid \mathbf{y}_v)}{p(\mathbf{y}_u \mid \mathbf{y}_v)} \tag{15}$$

where the likelihood is

$$p(\mathbf{y}_u \mid \mathbf{x}_u, \mathbf{y}_v) = p(\mathbf{y}_u \mid \mathbf{x}_u) = N(\mathbf{y}_u \mid \mathbf{x}_u, \boldsymbol{\Sigma}_{w,uu}) \tag{16}$$

and the prior is

$$p(\mathbf{x}_u \mid \mathbf{y}_v) = N(\mathbf{x}_u \mid \mathbf{K}\mathbf{y}_v, \boldsymbol{\Sigma}_{\text{prior}}) \tag{17}$$

and the prior covariance is obtained from (11) and (14):

$$\boldsymbol{\Sigma}_{\text{prior}} = \text{cov}(\mathbf{x}_u \mid \mathbf{y}_v) = \boldsymbol{\Gamma}_{y,uu}^{-1} - \boldsymbol{\Sigma}_{w,uu} \tag{18}$$

The denominator $p(\mathbf{y}_u \mid \mathbf{y}_v)$ in (15) is a Gaussian with mean (10) and covariance (11), and can be easily evaluated. However, it is merely a normalizing factor, which does not depend on $\mathbf{x}_u$, and its computation is not necessary.

The posterior distribution (15) is obtained by some manipulation, resulting in

$$\begin{aligned} p(\mathbf{x}_u \mid \mathbf{y}) &\propto p(\mathbf{y}_u \mid \mathbf{x}_u) p(\mathbf{x}_u \mid \mathbf{y}_v) \\ &\propto \exp\left[-\frac{1}{2}(\mathbf{y}_u - \mathbf{x}_u)^T \boldsymbol{\Sigma}_{w,uu}^{-1}(\mathbf{y}_u - \mathbf{x}_u) - \frac{1}{2}(\mathbf{x}_u - \mathbf{K}\mathbf{y}_v)^T \boldsymbol{\Sigma}_{\text{prior}}^{-1}(\mathbf{x}_u - \mathbf{K}\mathbf{y}_v) \right] \\ &= \exp\left\{ -\frac{1}{2}\left[\mathbf{x}_u - \boldsymbol{\Sigma}_{\text{post}}(\boldsymbol{\Sigma}_{w,uu}^{-1}\mathbf{y}_u + \boldsymbol{\Sigma}_{\text{prior}}^{-1}\mathbf{K}\mathbf{y}_v) \right]^T \boldsymbol{\Sigma}_{\text{post}}^{-1} \left[\mathbf{x}_u - \boldsymbol{\Sigma}_{\text{post}}(\boldsymbol{\Sigma}_{w,uu}^{-1}\mathbf{y}_u + \boldsymbol{\Sigma}_{\text{prior}}^{-1}\mathbf{K}\mathbf{y}_v) \right] \right\} \end{aligned} \tag{19}$$

where the posterior covariance $\boldsymbol{\Sigma}_{\text{post}}$ is

$$\boldsymbol{\Sigma}_{\text{post}} = \text{cov}(\mathbf{x}_u \mid \mathbf{y}) = (\boldsymbol{\Sigma}_{w,uu}^{-1} + \boldsymbol{\Sigma}_{\text{prior}}^{-1})^{-1} \tag{20}$$

and the posterior mean is

$$\hat{\mathbf{x}}_u = E(\mathbf{x}_u \mid \mathbf{y}) = \boldsymbol{\Sigma}_{\text{post}}(\boldsymbol{\Sigma}_{w,uu}^{-1}\mathbf{y}_u + \boldsymbol{\Sigma}_{\text{prior}}^{-1}\mathbf{K}\mathbf{y}_v) \tag{21}$$

Notice that the posterior mean (21) is a weighted sum of all sensor readings in the network. Equation (21) can also be written in the following matrix form.

$$\hat{\mathbf{x}}_u = \left[\boldsymbol{\Sigma}_{\text{post}}\boldsymbol{\Sigma}_{w,uu}^{-1} \quad \boldsymbol{\Sigma}_{\text{post}}\boldsymbol{\Sigma}_{\text{prior}}^{-1}\mathbf{K} \right] \begin{Bmatrix} \mathbf{y}_u \\ \mathbf{y}_v \end{Bmatrix} = \mathbf{a}_u^T \mathbf{y} \tag{22}$$

where the coefficient row vector $\mathbf{a}_u^T$ is

$$\mathbf{a}_u^T = \left[\boldsymbol{\Sigma}_{\text{post}}\boldsymbol{\Sigma}_{w,uu}^{-1} \quad \boldsymbol{\Sigma}_{\text{post}}\boldsymbol{\Sigma}_{\text{prior}}^{-1}\mathbf{K} \right] \tag{23}$$

For each single sensor u, a corresponding vector $\mathbf{a}_u^T$ is computed. All these vectors can be assembled in a coefficient matrix $\mathbf{A}$ to compute all estimates simultaneously:

$$\hat{\mathbf{x}} = \begin{bmatrix} \mathbf{a}_1^T \\ \mathbf{a}_2^T \\ \bullet \\ \mathbf{a}_p^T \end{bmatrix} \mathbf{y} = \mathbf{A}\mathbf{y} \tag{24}$$

where each row u of matrix $\mathbf{A}$ represents the corresponding sensor. Notice that both $\mathbf{u}$ and $\mathbf{v}$ represent the unclipped sensors only. Reconstruction of clipped sensors is discussed in the next section.

3.1 Reduction of overload error

A different algorithm is proposed to reduce overload error. The reconstruction of the clipped sensors in a single data point can be done simultaneously using the prior mean (17) and prior covariance matrix (18). The posterior mean is not used, because the noise variances of the clipped sensors are not known. Sensors $\mathbf{u}$ include all clipped sensors at the data point,

while sensors **v** include the remaining unclipped sensors. Clipped sensors are easy to detect; their values are equal to the overload amplitude.

It is important to have training data with granular error only. The data covariance matrix is estimated from the training data. Also the covariance matrix of the quantization error (12) is formed using the known ADC settings.

4 NUMERICAL EXPERIMENT

A numerical simulation was performed using a finite element model of a stiffened bridge deck (Figure 3). The structure was 30 m long and 11 m wide. It had four longitudinal and three lateral stiffeners. The slab was made of concrete with a Young's modulus of $E = 40$ GPa, Poisson ratio of $\nu = 0.15$, density of $\rho = 2500$ kg/m^3, and thickness of 250 mm. The stiffeners were made of steel ($E = 207$ GPa, $\nu = 0.30$, $\rho = 7850$ kg/m^3). The longitudinal stiffeners had a web with a thickness of $t = 16$ mm and a height of $h = 1.4$ m. The bottom flange had a thickness of $t = 50$ mm and a width of $b = 700$ mm. The lateral stiffeners were 1.4 m high and 30 mm thick plates.

The modelling was done using four-node discrete Kirchhoff quadrilateral shell elements with a diagonal mass matrix. The nodes of the bottom flanges were simply supported at both ends of the bridge. Longitudinal displacements were fixed only at one end of the bridge. The corners of the concrete deck were supported in the lateral and vertical directions.

Seven lowest modes were included in the analysis with natural frequencies of 3.95 Hz, 5.35 Hz, 13.7 Hz, 15.4 Hz, 18.0 Hz, 24.1 Hz, and 24.8 Hz. Modal damping was assumed with damping ratios of $\zeta_1 = \zeta_2 = 0.01$, $\zeta_3 = \zeta_4 = 0.02$, and $\zeta_5 = \zeta_6 = \zeta_7 = 0.03$.

Two independent unknown random loads were applied at nodes 774 and 872 in the vertical direction (the green squares in Figure 3). Three load cases were simulated with different standard deviations of the random excitations: (1) medium excitation with $\sigma_{F1} = 100$ N and $\sigma_{F2} = 150$ N, (2) small excitation with $\sigma_{F1} = 10$ N and $\sigma_{F2} = 15$ N, and (3) large excitation with $\sigma_{F1} = 1000$ N and $\sigma_{F2} = 1500$ N. Because ambient excitation was assumed, the steady state response was computed. For the steady state analysis, periodic pseudorandom excitations in the frequency range between 0 and 8.25 Hz with random amplitudes and phases were generated [11], and the analysis was performed in the frequency domain [12]. The excitation was not measured.

The response was computed with a modal superposition algorithm using the first seven modes. The analysis period was 20.48 s with a sampling frequency of 50 Hz. One measurement period then included 1024 samples from each sensor.

Vertical accelerations were measured at 28 points shown in Figure 3. Each channel was quantized with a 12-bit ADC, $L = 4096$. The dynamic range was the same in all channels. It was set so that a prescribed maximum number of channels overloaded simultaneously. The quantization interval Δx was thus known and the variance of the quantization error σ_w^2 was computed and used in estimating the empirical Bayesian virtual sensors from the physically measured and digitized 28 accelerations. The training data were all data points with no clipping.

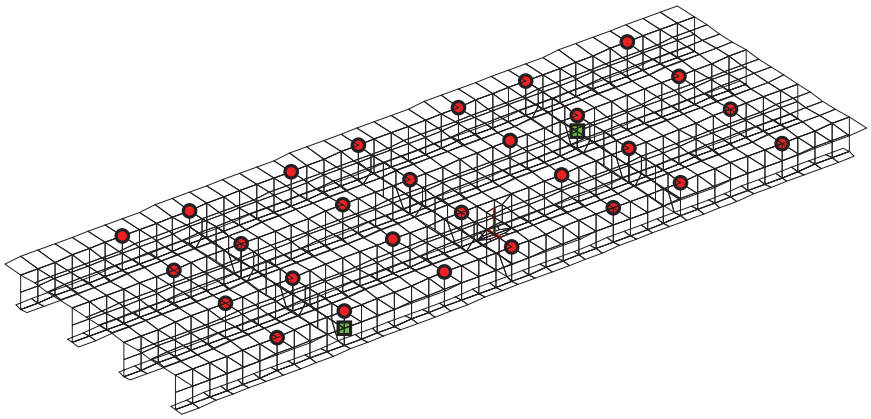

Figure 3: Finite element model of the bridge deck. The accelerometers are shown with red circles and the excitation points with green squares.

4.1 Reduction of granular noise

First, quantization error due to granular noise was only studied. Overload was not allowed, so that the only measurement error was due to granular noise. The dynamic range was set to ± 0.132 m/s^2, $\Delta x = 1.29 \cdot 10^{-4}$ m/s^2, and the standard deviation of the quantization error was $\sigma_w = 3.72 \cdot 10^{-5}$ m/s^2, which was known. Figure 4 shows that the actual quantization error was equal to the theoretical value (5), or $\sigma_w = \Delta x / \sqrt{12} \approx 0.289 \Delta x$. The theoretical value was used in Bayesian virtual sensing, which resulted in virtual sensors having less noise than the actual measurement as shown in Figure 4. It can be seen that all virtual sensors were more accurate than the actual hardware. However, the errors in the virtual sensors were no longer equal but varied between sensors.

The signal of sensor 8 is shown in Figure 5a. The three measurements with different magnitudes can be clearly distinguished. The number of quantization levels in measurement 2 with very small acceleration amplitudes was between 6 (sensor 8) and 29 (sensor 4). A detail of the signal of sensor 8 is shown in Figure 5b. It can be seen that the quantization error was significant resulting in a low SNR. Also in the same plot is the virtual sensor data, which is very close to the exact data.

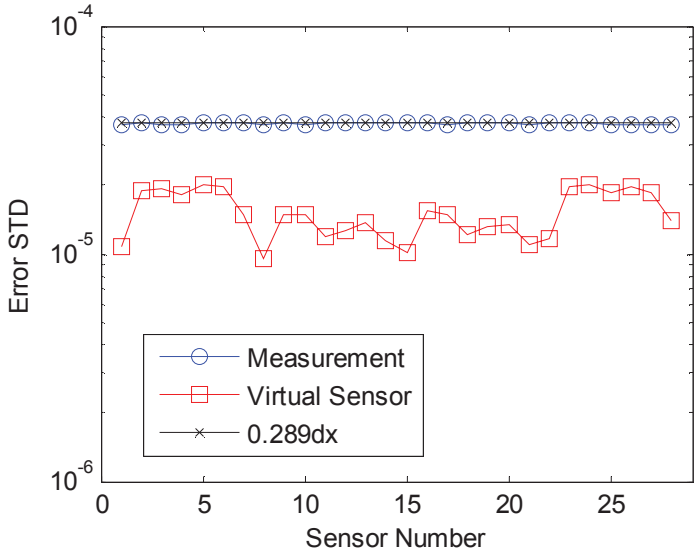

Figure 4: Standard deviation (STD) of the quantization error (actual 'O' and theoretical 'x') and STD of the error in the virtual sensors (squares).

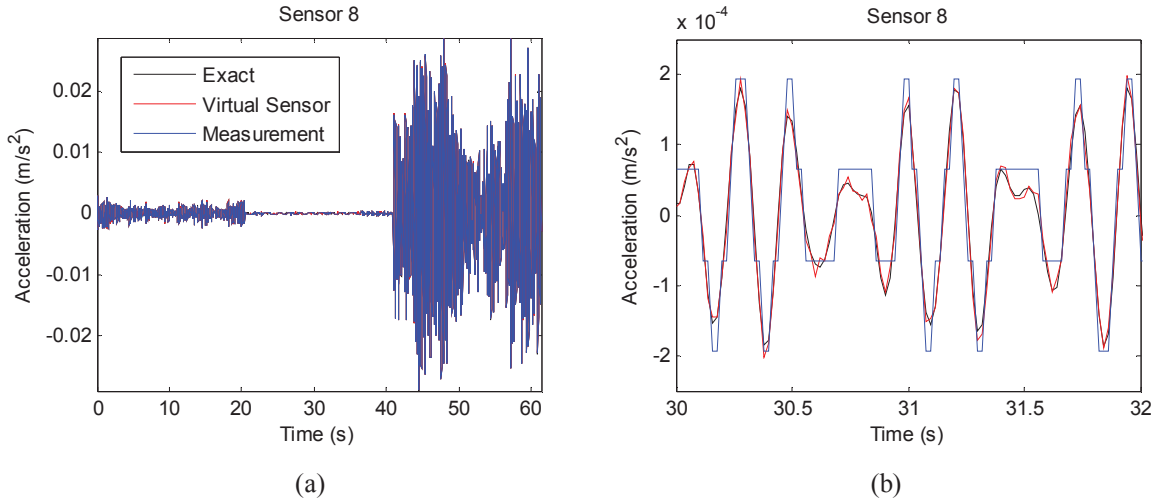

Figure 5: (a) Acceleration of sensor 8 in all three measurements with no clipping. A comparison of the quantized signal, virtual sensor, and exact values. (b) A detail of measurement 2 with only four quantization levels. The virtual sensor and the exact values are also shown.

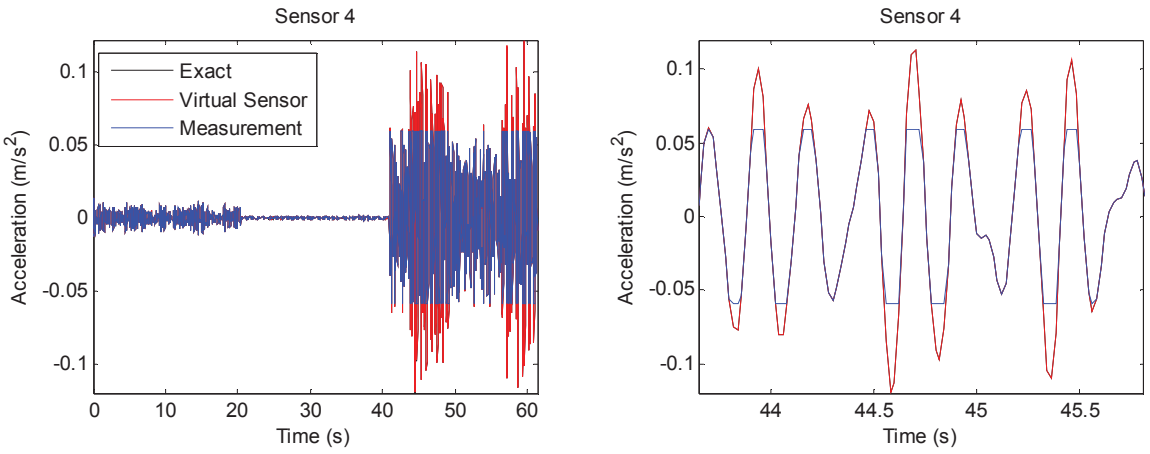
4.2 Overload error in maximum of 60% sensors

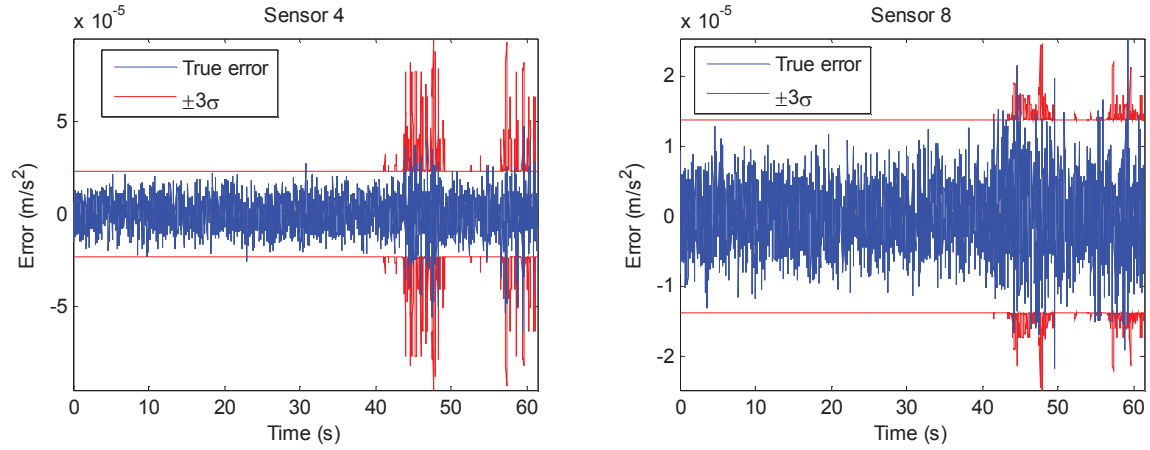
The dynamic range of the ADC was adjusted so that the maximum number of channels in the overload region was 17 (60% of the total number of sensors). The dynamic range was set to ± 0.059 m/s^2, $\Delta x = 5.75 \cdot 10^{-5}$ m/s^2, and the standard deviation of the quantization error was $\sigma_w = 1.66 \cdot 10^{-5}$ m/s^2. The signal of sensor 4 is shown in Figure 6. It can be seen that clipping occurred several times during measurement 3. However, the clipped sensors could be reconstructed using the data of the unclipped sensors.

The estimation error of the virtual sensors 4 and 8 are plotted in Figure 7 together with the estimated 3σ limits. Notice that the estimation error is larger for the data points having clipped sensors. This is because a smaller number of sensors could be used in the estimation.



(a) (b)

Figure 6: (a) Signal of sensor 4 and (b) a detail. Overload error (clipping) is clearly seen. The difference between the exact and virtual sensor signals cannot be visually distinguished.



(a) (b)

Figure 7: Estimation errors of (a) virtual sensor 4 and (b) virtual sensor 8. The estimated 3σ limits are also shown.

4.3 The effect of the dynamic range of the ADC

The objective is to maximize the SNR. This can be done by fully utilizing the dynamic range of the ADC. However, the excitation levels can vary considerably and the maximum is unknown. This can result in overload error due to clipping.

The SNRs of the three measurements were studied by varying the dynamic range of the ADC. In the first case, all measurements were within the granular regions and no clipping occurred (Section 4.1). In the next three cases, the maximum number of clipped signals in a single data point was 9, 17 (Section 4.2), and 26 corresponding to respectively 30%, 60%, and 90% of the total number of sensors in the network. The histograms showing the number of data points versus the number of overloaded channels are plotted in Figure 8.

The SNR was computed for each case and separately for each measurement. Because the noiseless signal was known, the SNR values are accurate. The SNRs of each physical and virtual sensor in all three measurements are plotted in Figure 9. First, it can be seen that the virtual sensors provided higher SNRs than the physical sensors in all cases.

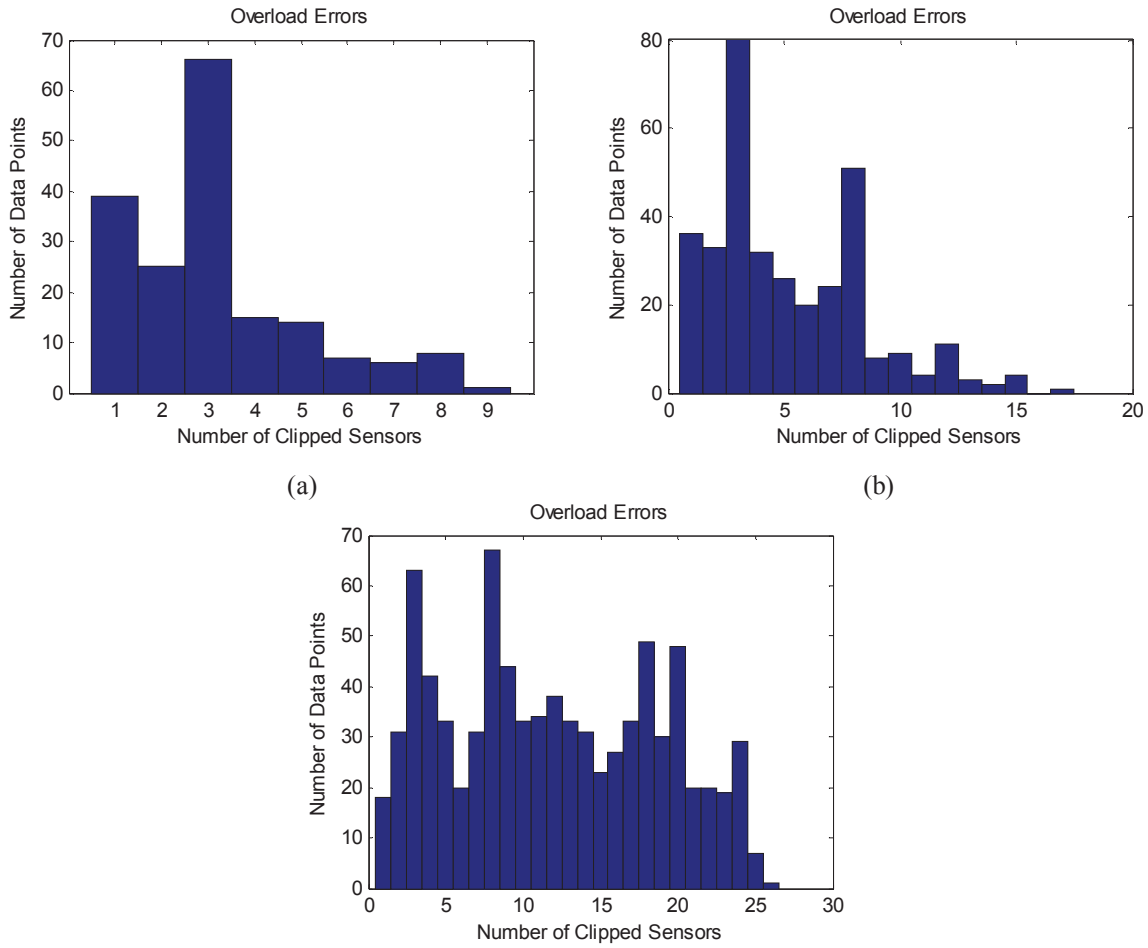


Figure 8: Histograms showing the number of data points with different number of clipped sensors. The maximum number of clipped sensors in a single data point was (a) 9 (30%), (b) 17 (60%), and (c) 26 (90%).

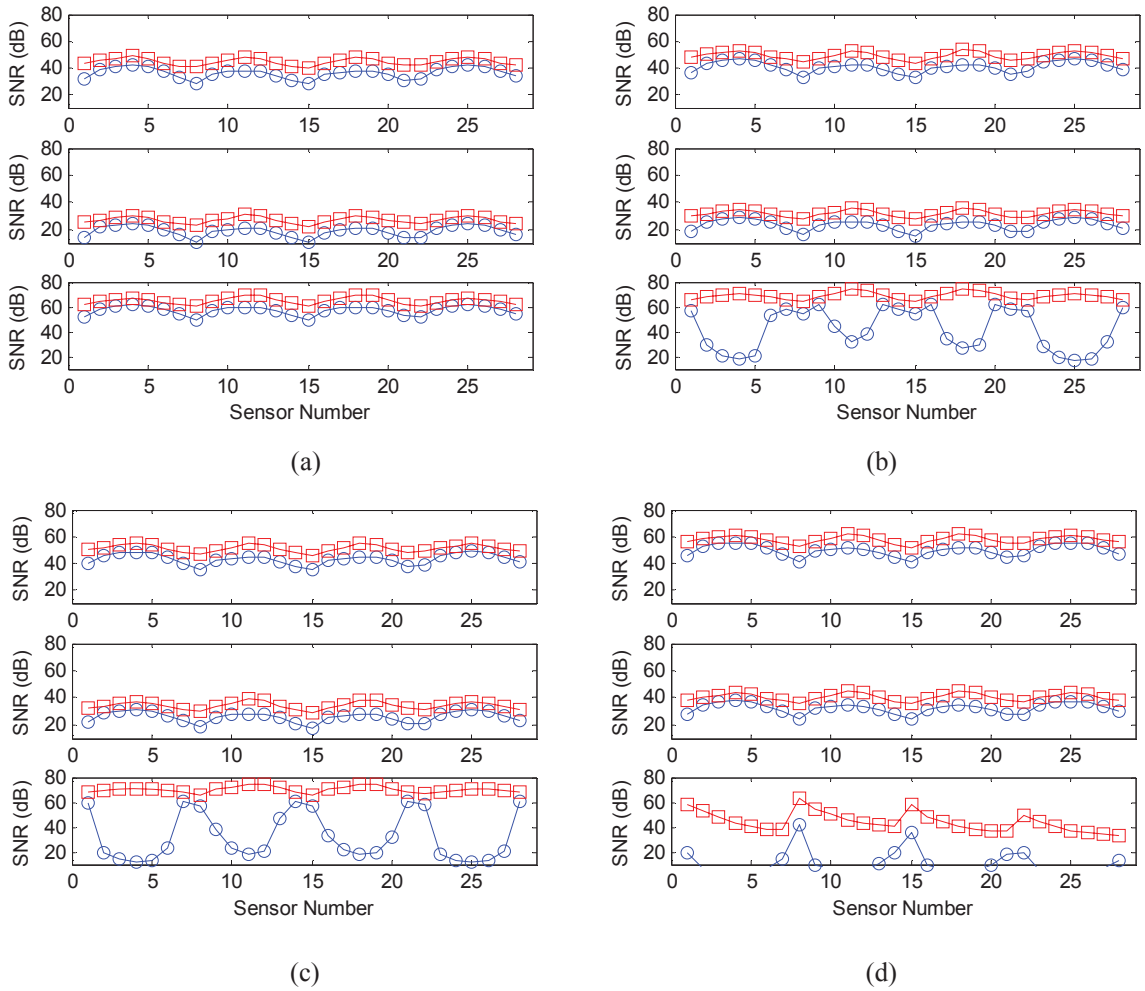

Figure 9: Signal-to-noise ratios (SNR) of physical (blue circles) and virtual (red squares) sensors in each measurement (top: measurement 1, middle: measurement 2, and bottom: measurement 3). In measurement 3, the maximum number of clipped sensors in a single data point was (a) 0 (no clipping), (b) 9 (30%), (c) 17 (60%), and (d) 26 (90%).

Second, the SNRs of measurements 1 and 2 increased when the dynamic range of the ADC was decreased. This is because the two measurements occupied a larger dynamic range of the ADC and no clipping occurred in any channels. All data points of measurements 1 and 2 could therefore been used as training data.

The most interesting is the measurement 3, in which different number of overload errors occurred. With physical sensors, the SNR decreased considerably due to overloading. However, the virtual sensors exhibited an increasing SNR up to the case with a maximum of 17 channels (60%) clipping simultaneously. Beyond that, reconstruction of the clipped signals became inaccurate.

The maximum and minimum SNR of the physical sensors in each case and separately for each measurement are listed in Table 1. Table 2 shows the corresponding data for the virtual sensors. The SNR of the physical sensors decreased considerably in measurement 3 due to clipping. On the other hand, the SNR of the virtual sensors increased with a decreasing dynamic range of the ADC up to the point in which a maximum of 17 sensors (60%) clipped simultaneously. This could be considered optimal from these four possible settings.

Meas No		Max number (%) of clipped sensors			
		0	9	17	26
		0%	30%	60%	90%
1	Max	41.7	46.3	48.5	**55.3**
	Min	27.6	32.5	34.7	**41.2**
2	Max	23.9	28.4	31.0	**37.8**
	Min	10.7	15.6	17.6	**24.6**
3	Max	61.5	**61.8**	61.1	42.3
	Min	**49.8**	16.9	11.9	4.8

Table 1: Maximum and minimum SNRs of the physical sensors. The highest values are shown bolded.

Meas No		Max number (%) of clipped sensors			
		0	9	17	26
		0%	30%	60%	90%
1	Max	48.6	53.3	55.2	**61.6**
	Min	39.7	43.7	45.5	**51.8**
2	Max	30.7	36.1	38.6	**45.2**
	Min	22.4	27.3	28.8	**35.5**

	Min	60.3	64.3	**65.4**	33.4

Table 2: Maximum and minimum SNRs of the virtual sensors. The highest values are shown bolded.

5 CONCLUSION

Quantization of measured vibration signals results in granular or overload noise. Bayesian virtual sensing can be used to reduce those errors. If quantization is the only source of error, the variance of the granular noise is known and can be used in estimation.

For a large SNR, it is recommended to adjust the dynamic range of the ADC so that the measured signal occupies the most of it. Quantization error can be an issue in monitoring applications, in which a large range of amplitudes can occur. For very small amplitudes, the SNR may be small, because the signal level is low compared to the granular error. With very large amplitudes, overload error may be large resulting in a low SNR. Both effects are issues in damage detection, because detection performance depends on the SNR.

In order to maximize the SNR of very variable vibration amplitudes, it was shown that it is possible to allow overloading in a subset of channels. It is then possible to reconstruct the clipped channels using the remaining unclipped channels. Also, the granular error can be reduced using virtual sensing.

The very same approach can be used also for a more practical case, in which there exist also other sources of error than quantization. Overload noise is nevertheless always relevant in practice, because the amplitudes are typically unbounded.

Keywords: Damage localization, Density Ratio Estimation method, Kullback–Leibler divergence, Non-parametric estimation.

Abstract. *A machine learning technique, the Density Ratio Estimation method is applied for the first time to detect structural damage, using test data from a scale model of a three-storey building structure under random excitation as a case study. The method detects damage by comparing the Probability Density Functions (PDFs) of measured vibration signals from an undamaged state and a potentially damaged state. Since the vibration signals from one sensor are not independent over time, instead of applying the vibration signals directly, the sequences of signals are used to train the model in order to account for the signal dependence, leading to multi-dimensional PDFs. To enhance model robustness, non-parametric models are applied for structural health monitoring problems. One limited way to detect damage is to estimate the non-parametric PDFs under the undamaged state and potentially damaged state separately, and then compare them. However, this method is very difficult to apply when the dataset has many dimensions, and can often be intractable. The method applied in the current study estimates the PDF change directly, without estimating individual PDFs. Moreover, the damage indices in conventional methods are generally heuristic. In contrast, the damage index in the current study is Kullback–Leibler divergence, which has a clear statistical meaning; a measure of difference between two PDFs. To demonstrate the capability of the method, it is applied to data from a laboratory test which was previously conducted by Los Alamos National Lab. It is shown that the method can detect damage locations successfully.*

1 INTRODUCTION

Structural Health Monitoring (SHM) is used to automate the assessment of damage in civil infrastructure, allowing the cost-effective management of maintenance activities. As part of the SHM problem, vibration-based damage detection has gained widespread interest as the vibration signal measurement and acquisition technology is mature and reasonably low-cost [1]. The underlying idea of vibration-based damage detection is that damage will significantly change the physical properties of a structure, which consequently change the measured vibration response of the structure [2].

Following the framework of Farrar et al. [3], the SHM process can be summarized as (a) operational evaluation, (b) data acquisition and cleansing, (c) feature extraction, and (d) statistical model development. Features are extracted from the measured data and used to develop a statistical model. Commonly used features include the first four statistical moments (mean, standard deviation, skewness, and kurtosis) [4, 5, 6], autoregressive model coefficients [7, 8, 9, 10], and modal parameters (natural frequencies [11, 12, 13], mode shapes [14, 15], and modal damping [16, 17]). Other examples of extracted features can be found in Astroza [18].

A statistical model can be developed by comparing the Probability Density Functions (PDFs) of the extracted features from the undamaged and damaged structures [3, 4]. In this paper, we apply a method which excludes any feature extraction and uses raw data directly to train the statistical model. The main idea is to detect damage by comparing PDFs of measured data from an undamaged state and potentially damaged state. To the authors' knowledge, only Figueiredo et al. [19] have used a similar method to detect damage by comparing PDFs of accelerations. In their work, the measured data from the undamaged state was assumed to be normally distributed, while the PDFs of measured data under nonlinear damaged states deviated from a normal distribution. However, because samples in vibration signals are not independent over time, they need not have specific PDFs. Instead of applying the vibration signals directly, the sequences of signal samples can be used to train the model in order to account for the time dependence of the signal samples relative to each other. This leads the PDFs to be multi-dimensional.

As the PDF type is not known beforehand, the PDF is estimated with non-parametric methods for the sake of algorithm robustness. Two most widely used non-parametric techniques are histogram analysis and kernel methods [20]. Then the damage can be detected by comparing the two PDFs, from the undamaged state and potentially damaged state respectively. However, this approach is very difficult to apply for multi-dimensional PDFs, and can often be intractable, since high dimensional non-parametric density estimation is known to be a hard problem [21]. Therefore, estimating two PDFs separately may be ineffective. Essentially, for the aim of detecting damage, what matters is only the change in the PDFs between the undamaged and damaged states, rather than the PDFs themselves; therefore it is potentially more computationally efficient to directly estimate this PDF change.

On this basis, this paper applies the method presented by Kawahara and Sugiyama [22] to detect damage in structures. Instead of separately estimating the two PDFs, of measured data from the undamaged and potentially damaged structure, this method estimates the change between the two PDFs directly, in the form of a density ratio. The method uses a sequence of signals to train the model in order to account for the time dependence of signal samples relative to each other. The density ratio is then estimated in a non-parametric form to enhance the robustness of the model.

In the remainder of the paper, the theoretical principles behind the damage detection al-

gorithm are presented (Section 2) before an explanation of its application to the case study structure and the key results (Section 3). Finally, the main conclusions and areas of future work are highlighted (Section 4).

2 DAMAGE DETECTION USING DENSITY RATIO ESTIMATION

In this section, the key theoretical principles behind the applied method [22] are briefly summarised.

2.1 Problem formulation

Let y_i be a signal at time step i, for example the acceleration signal from a sensor. Since signals of dynamic response are not independent over time, we consider sequences of them. This is a common practice in subspace identification since it allows us to implicitly take time correlation into consideration to some degree [23]. Let $\boldsymbol{y}(i)$ be the sequence of length k starting at time i:

$$\boldsymbol{y}(i) = [y_i, y_{i+1}, \cdots, y_{i+k-1}]. \tag{1}$$

$\boldsymbol{y}(i)$ is also refered as 'sequence' in the rest of this paper. Similarly, the $\boldsymbol{y}(i+1)$ is

$$\boldsymbol{y}(i+1) = [y_{i+1}, y_{i+2}, \cdots, y_{i+k}]. \tag{2}$$

In this way, a set of sequences $\boldsymbol{y}(i+1)$, $\boldsymbol{y}(i+2)$, $\cdots$, $\boldsymbol{y}(i+n)$ can be generated from the original signal. To estimate the density ratio, we need two sets of sequence samples from the undamaged state and a potentially damaged state, respectively,

$$\{\boldsymbol{y}_{\text{und}}(i+1), \boldsymbol{y}_{\text{und}}(i+2), \cdots, \boldsymbol{y}_{\text{und}}(i+n_{\text{und}})\} \sim p_{\text{und}}(\boldsymbol{y}) \tag{3}$$

$$\{\boldsymbol{y}_{\text{dam}}(i+1), \boldsymbol{y}_{\text{dam}}(i+2), \cdots, \boldsymbol{y}_{\text{dam}}(i+n_{\text{dam}})\} \sim p_{\text{dam}}(\boldsymbol{y}) \tag{4}$$

where $\boldsymbol{y}_{\text{und}}(i+1)$, $\boldsymbol{y}_{\text{und}}(i+2)$, $\cdots$, $\boldsymbol{y}_{\text{und}}(i+n_{\text{und}})$ are the sequence samples for the undamaged structure, which follow (represented by $\sim$) the PDF $p_{\text{und}}(\boldsymbol{y})$. n_{und} is the number of sequence samples. The Eq.(4) is defined likewise for the damaged structure.

The damage is detected by comparing the difference between $p_{\text{und}}(\boldsymbol{y})$ and $p_{\text{dam}}(\boldsymbol{y})$, which is quantified by the Kullback–Leibler (KL) divergence [24]:

$$\begin{aligned} \text{DI} &= \text{KL}(p_{\text{und}}(\boldsymbol{y}) \parallel p_{\text{dam}}(\boldsymbol{y})) \\ &= \int p_{\text{und}}(\boldsymbol{y}) \log\left(\frac{p_{\text{dam}}(\boldsymbol{y})}{p_{\text{und}}(\boldsymbol{y})}\right) \mathrm{d}\boldsymbol{y} \\ &\approx \frac{1}{n} \sum_{i=1}^{n_{\text{und}}} \log\left(\frac{p_{\text{dam}}(\boldsymbol{y})}{p_{\text{und}}(\boldsymbol{y})}\right) \end{aligned} \tag{5}$$

where DI is the Damage Index, and $\mathrm{d}\boldsymbol{y}$ is used as a shorthand for $\mathrm{d}y_1 \mathrm{d}y_2 \cdots \mathrm{d}y_k$ in Eq.(5). If the DI for a sensor location is larger than a predetermined threshold, the corresponding component will be believed to be damaged. Otherwise, the component is believed to be undamaged. The threshold is defined in Section 2.3.

The remaining question is how to estimate the density ratio,

$$r(\boldsymbol{y}) := \frac{p_{\text{dam}}(\boldsymbol{y})}{p_{\text{und}}(\boldsymbol{y})} \tag{6}$$

Of course, $r(\boldsymbol{y})$ can be estimated by estimating the two PDFs $p_{\text{und}}(\boldsymbol{y})$ and $p_{\text{dam}}(\boldsymbol{y})$ with non-parametric models, separately. However, non-parametric PDF estimation is known to be a hard problem, and estimating two PDFs separately may be ineffective. It is suggested that it is more efficient to directly estimate $r(\boldsymbol{y})$.

2.2 Density ratio modelling and estimation

The density ratio is assumed to be a non-parametric form:

$$\hat{r}(\boldsymbol{y}) = \sum_{l=1}^{n_{\text{dam}}} \alpha_l K_\sigma(\boldsymbol{y}; \boldsymbol{y}_{\text{dam}}(l)) \tag{7}$$

where $\{\alpha_l\}_{l=1}^{n_{\text{dam}}}$ are parameters to be learned from the data samples and $K_\sigma(\boldsymbol{y}, \boldsymbol{y}_{\text{dam}}(l))$ is a kernel function. $\hat{r}(\boldsymbol{y})$ is an estimate of the true $r(\boldsymbol{y})$. In this paper, the widely used Gaussian kernel function is applied,

$$K_\sigma(\boldsymbol{y}; \boldsymbol{y}_{\text{dam}}(l)) = \exp(-\frac{\|\boldsymbol{y} - \boldsymbol{y}_{\text{dam}}(l)\|^2}{2\sigma^2}) \tag{8}$$

where the kernel width σ is an open tuning parameter and needs to be chosen appropriately for better estimation.

Once the density ratio is modelled, our next aim is to estimate it. Using the definition of $\hat{r}(\boldsymbol{y})$, we can approximate $p_{\text{dam}}(\boldsymbol{y})$ by

$$\hat{p}_{\text{dam}}(\boldsymbol{y}) = \hat{r}(\boldsymbol{y}) p_{\text{und}}(\boldsymbol{y}) \tag{9}$$

To estimate the ratio $\hat{r}(\boldsymbol{y})$, the method fits the approximated $\hat{p}_{\text{dam}}(\boldsymbol{y})$ to the true $p_{\text{dam}}(\boldsymbol{y})$ using the parameters $\{\alpha_l\}_{l=1}^{n_{\text{dam}}}$. We use the Kullback-Leibler divergence as a goodness of fit measure and the objective is to minimize

$$\begin{aligned}
\text{KL}(p_{\text{dam}}(\boldsymbol{y}) \parallel \hat{p}_{\text{dam}}(\boldsymbol{y})) &= \text{KL}(p_{\text{dam}}(\boldsymbol{y}) \parallel \hat{r}(\boldsymbol{y}) p_{\text{und}}(\boldsymbol{y})) \\
&= \int p_{\text{dam}}(\boldsymbol{y}) \log (\frac{p_{\text{dam}}(\boldsymbol{y})}{\hat{r}(\boldsymbol{y}) p_{\text{und}}(\boldsymbol{y})}) d\boldsymbol{y} \\
&= \underbrace{\text{KL}(p_{\text{dam}}(\boldsymbol{y}) \parallel p_{\text{und}}(\boldsymbol{y}))}_{\text{constant}} - \int p_{\text{dam}}(\boldsymbol{y}) \log \hat{r}(\boldsymbol{y}) d\boldsymbol{y} \\
&= \text{constant} - \sum_{i=1}^{n_{\text{dam}}} \log(\sum_{l=1}^{n_{\text{dam}}} \alpha_l K_\sigma(\boldsymbol{y}_{\text{dam}}(i), \boldsymbol{y}_{\text{dam}}(l)))
\end{aligned} \tag{10}$$

Meanwhile, an additional constraint is introduced, since $\hat{p}_{\text{dam}}(\boldsymbol{y}) = \hat{r}(\boldsymbol{y}) p_{\text{und}}(\boldsymbol{y})$ must be a valid PDF and as such should satisfy,

$$\begin{aligned}
1 = \int \hat{p}_{\text{dam}}(\boldsymbol{y}) d\boldsymbol{y} = \int \hat{r}(\boldsymbol{y}) p_{\text{und}}(\boldsymbol{y}) d\boldsymbol{y} &\approx \frac{1}{n_{\text{und}}} \sum_{j=1}^{n_{\text{und}}} \hat{r}(\boldsymbol{y}(j)) \\
&= \frac{1}{n_{\text{und}}} \sum_{j=1}^{n_{\text{und}}} \sum_{l=1}^{n_{\text{dam}}} \alpha_l K_\sigma(\boldsymbol{y}_{\text{und}}(j), \boldsymbol{y}_{\text{dam}}(l))
\end{aligned} \tag{11}$$

Now the optimization problem is summarised as

$$\begin{cases} \underset{\{\alpha_l\}_{l=1}^{n_{\text{dam}}}}{max} & \sum_{i=1}^{n_{\text{dam}}} \log(\sum_{l=1}^{n_{\text{dam}}} \alpha_l K_\sigma(\boldsymbol{y}_{\text{dam}}(i), \boldsymbol{y}_{\text{dam}}(l))), \\ s.t. & \frac{1}{n_{\text{und}}} \sum_{j=1}^{n_{\text{und}}} \sum_{l=1}^{n_{\text{dam}}} \alpha_l K_\sigma(\boldsymbol{y}_{\text{und}}(j), \boldsymbol{y}_{\text{dam}}(l)) = 1, \\ & \text{and } \alpha_1, \ldots, \alpha_{n_{\text{dam}}} \geq 1. \end{cases} \tag{12}$$

This is a convex optimization problem and the global solution can be obtained, e.g., by simply performing gradient ascent and feasibility satisfaction iteratively. The pseudo code can be found in Kawahara and Sugiyama [22].

2.3 Damage index threshold

For different sensors, distinct DI values can be obtained. The DI is essentially a measure of the change between the undamaged and damaged structure. Therefore, the DI values from the sensors around the damage should be larger compared with those from the other sensors. To distinguish these outliers caused by local damage, a threshold needs to be set up. In previous studies, the measured data of undamaged structures are commonly assumed to be normally distributed [7, 25, 26]. Similarly, the DI of the undamaged structure is assumed to be normally distributed in this paper. The threshold is defined as the upper bound of the 95% confidence, which is calculated by

$$\xi = \bar{x} + \frac{\sigma}{\sqrt{s}} t_{95\%}(s-1) \tag{13}$$

where $\bar{x}$ and σ are the mean and standard deviation of the DI values from all sensors, s is the number of sensors. For the case of this paper, $s = 4$. Therefore, $t_{95\%}(4-1) = 2.353$ is obtained from a statistical table. If a DI value is larger than the threshold ξ, it means the DI value is larger than 95% of the DI values from a certain state, which indicates it is an outlier. Hence it is likely to indicate damage.

3 EXPERIMENTAL DATA AND DAMAGE DETECTION

In order to assess the efficacy of the proposed method for damage detection, a detailed study was carried out on an already published dataset from laboratory tests [19].

3.1 Test structure description

The tests were conducted at Los Alamos National Lab [19], on a three-storey aluminium structure (Figure 1), consisting of plates connected by columns. Different 'damage' states were induced by adding mass to plates or reducing the stiffnesses of columns. The different states are listed in Table 1. State 1 is the baseline condition, where no damage was present. The PDF for State 1 corresponds to the $p_{\text{und}}(\boldsymbol{y})$ in the algorithm. In States 2 and 3, 'damage' was simulated by adding mass on certain floors. For the States 4 - 9, damage was induced by stiffness reduction of different columns. The PDFs for States 2 - 9 correspond to the $p_{\text{dam}}(\boldsymbol{y})$ in the algorithm. The column locations are represented by storey numbers (1, 2, 3) and plates side labels (A, B, C, D), which are shown in Figure 1. For example, 1BD means the column located between the base and first floor at the intersection of plane B and D.

The structure was excited by an electro-dynamic shaker through its base. For each test, a band-limited random excitation in the range of 20 - 150 Hz was used to excite the structure,

with the excitation level approximately 20N RMS measured at Sensor 1. With accelerometers mounted on each plate, acceleration-time series under different structural states were collected. For each state, ten time-series were measured in order to consider the variability in the data. Each time-series includes 8,192 data points and was sampled with a sampling frequency of 320 Hz (the natural frequencies of the structure are approximately 30 Hz, 55 Hz and 70 Hz). The acceleration-time series of States 1, 3, 5, 7, and 9 from Sensors 2 to 5 are plotted in Figure 2. The test data and more information on the structure are accessible from Los Alamos National Lab [27].

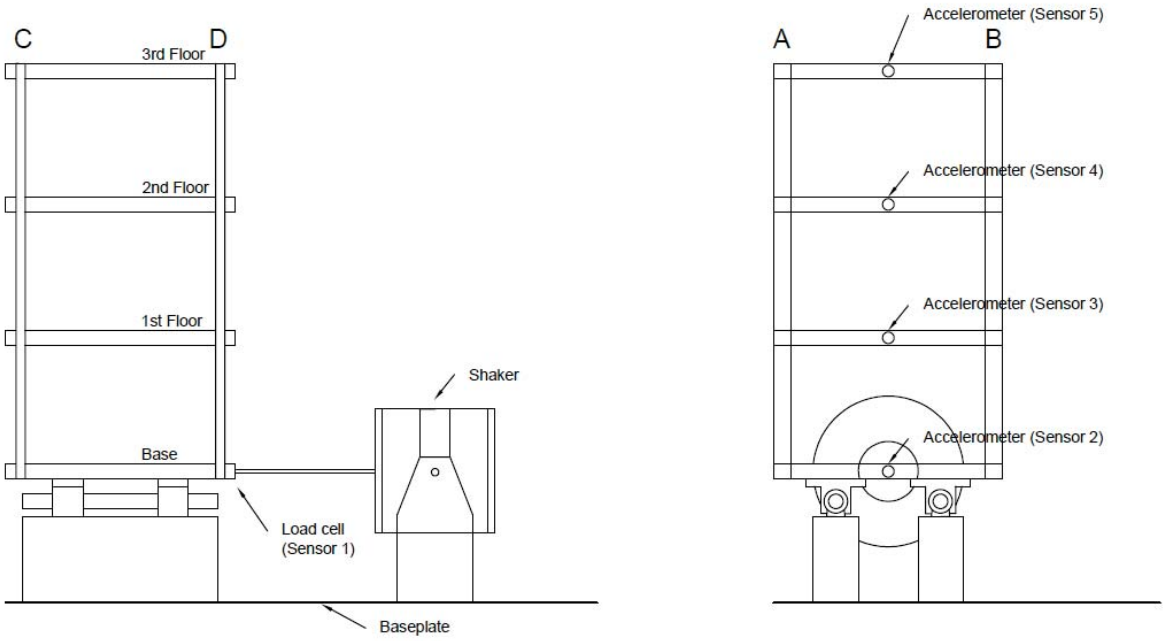

Figure 1: Diagram of laboratory structure (redrawn from [19])

Label	Description
State 1	Baseline condition
State 2	Mass = 1.2 kg at the base
State 3	Mass = 1.2 kg on the 1st floor
State 4	87.5% stiffness reduction in column 1BD
State 5	87.5% stiffness reduction in column 1AD and 1BD
State 6	87.5% stiffness reduction in column 2BD
State 7	87.5% stiffness reduction in column 2AD and 2BD
State 8	87.5% stiffness reduction in column 3BD
State 9	87.5% stiffness reduction in column 3AD and 3BD

Table 1: Structural states tested (after [19])

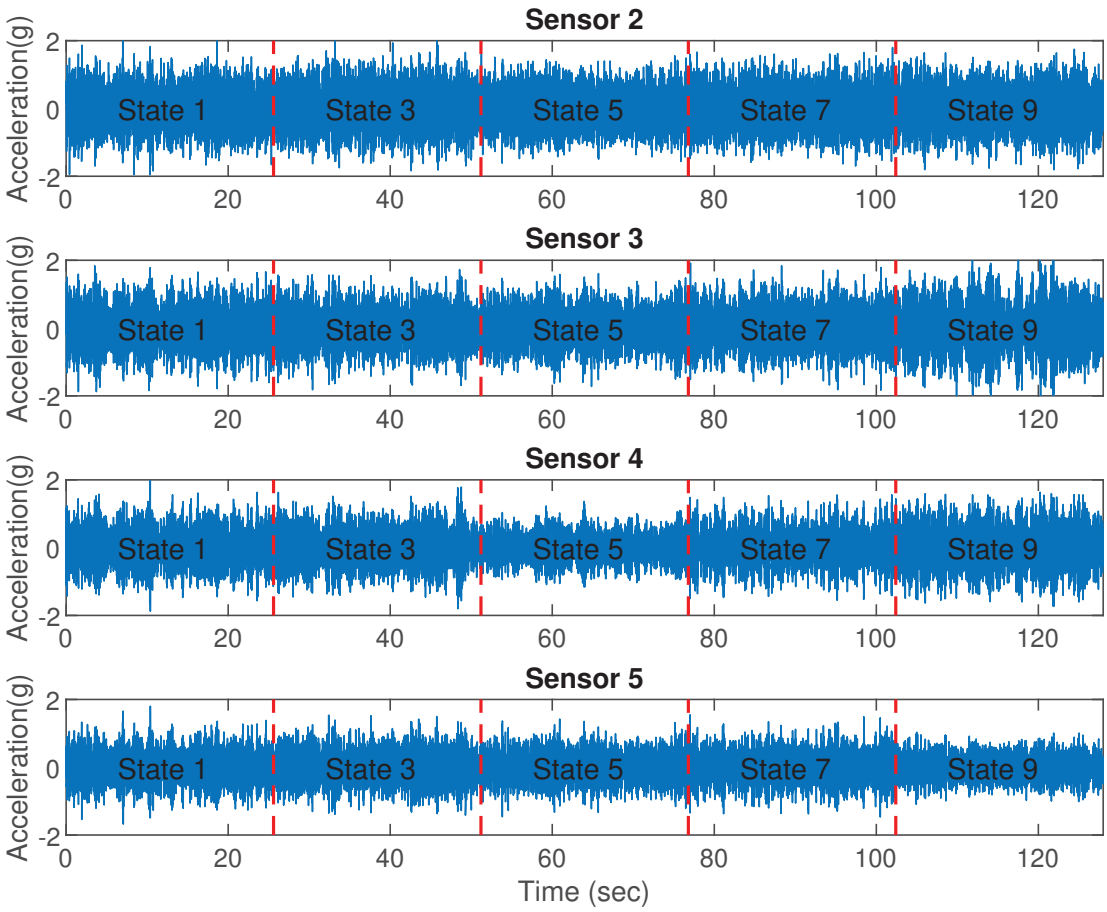

Figure 2: Acceleration-time series of various state conditions from Sensors 2 to 5 (redrawn from [19]).

3.2 Damage detection and localization

For the proposed algorithm, the sequence length is set as $k = 5$. The DI values of States 2 - 9 are obtained by feeding the data from one of the States 2 - 9 and the data from State 1 to the algorithm, respectively. However, because of the variability of the signals, the DI from any two records in State 1 are not zeros, but some small values. To account for this variability, the DI values of State 1 were deducted from the DI values of States 2 - 9. The final results are shown in Figure 3, where blue columns represent DI values for different sensors and red dot lines represent thresholds.

For damage detection, it can be seen that each state except State 4 has one DI above the corresponding threshold, which indicates the state has been identified as damaged. The reason why State 4 has not been detected may be because it contains only a relatively small amount of damage.

For damage localization, it is shown that in State 2, where a mass is added to the base floor, only Sensor 2 has a DI value larger than the threshold, indicating damage is in the base floor. Similarly, for State 3, only Sensor 3 has a larger value than the threshold. From State 4 to State 9, the damage is induced by stiffness reduction of columns at different locations. For States 4 and 5, the DI for Sensor 3 is close to or exceeds the thresholds, indicating the 1st floor is damaged. For the States 6 and 7, the detected location is the 2nd floor. The results for States

8 and 9 indicate that the 3rd floor is detected as damaged. Overall, the model has detected the damage location successfully for all 7 damage states other than State 4.

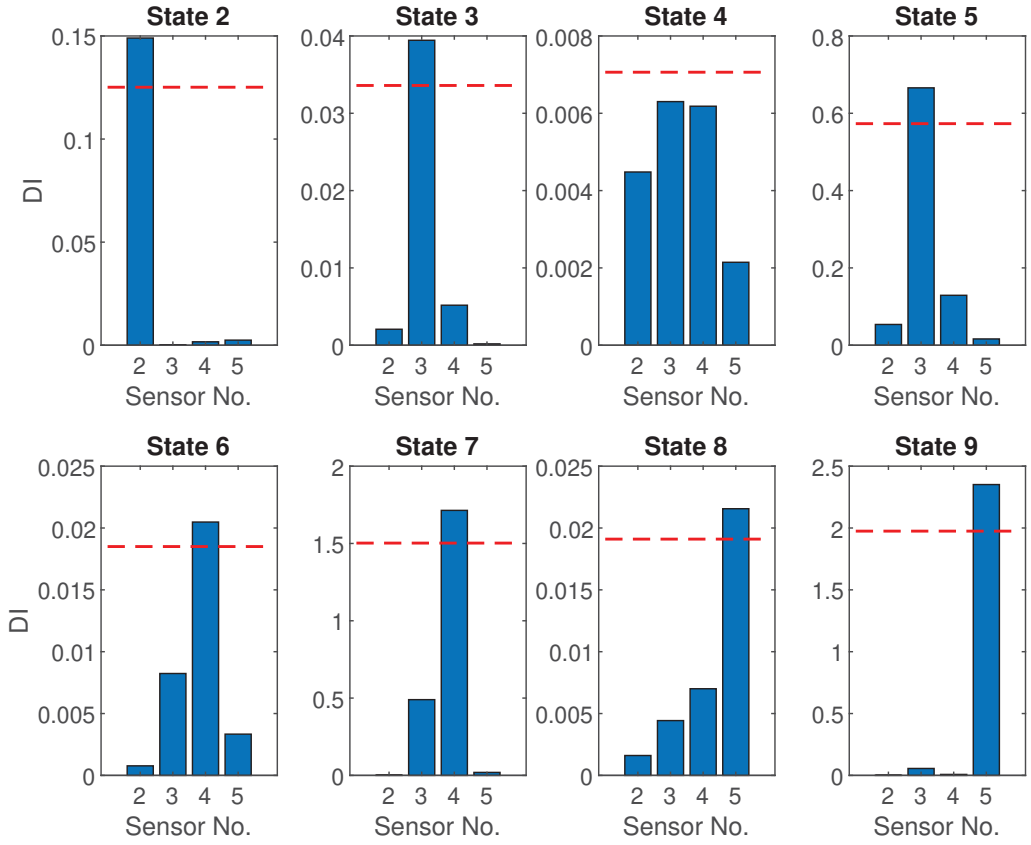

Figure 3: Damage Index for different locations for different states

4 CONCLUSIONS

In this paper, a vibration-based damage localization algorithm is presented. Sequences of acceleration signals are applied as input for model training, to account for the time dependence of samples relative to each other. The KL divergence, between the PDFs of measured vibration signals from an undamaged state and a potentially damaged state, is used as a Damage Index to indicate damage. The difficulty of estimating multi-dimensional PDFs with a non-parametric method is overcome by applying the Density Ratio Estimation method. The method has been demonstrated on experimental data from a scale model of a three-storey building structure under random excitation from Los Alamos National Lab. The results show that the algorithm is able to detect and localize damage in the model. These initial results are very encouraging, but further studies are needed to test the validity of the algorithm, such as on other structures or for less severe damage.

Keywords: Surface vehicle dynamics, wheelbase filtering, spectral estimation, dynamics identification

Abstract. *The problems of effective parametric spectral estimation for random vibration signals and dynamics identification for traveling surface vehicles are addressed. Wheelbase Filtering effects, including the induced periodic modulation, on measured random vibration signals are explored, leading to special–structure AutoRegressive Moving Average (ARMA) models which are referred to as Wheelbase Filtering ARMA (WF–ARMA) models. Compared to their conventional counterparts, the postulated models avoid potential model structure mismatch and lack of statistical parsimony, potentially leading to excellent parametric spectral estimation accuracy. Furthermore, exploring their fundamental structural relationships with the stationary (non–moving) vehicle dynamics allows for the postulation of a method for the identification of the latter through the former, thus permitting effective output–only stationary dynamics identification from in–motion random vibration signals. The high achievable accuracy of the postulated estimators is assessed via Monte Carlo numerical experiments with a basic half–vehicle vertical model. The superiority of the postulated WF–ARMA approach is also demonstrated via comparisons with classical Welch based, AR based, and conventional ARMA based spectral estimators.*

1 INTRODUCTION

Random vibration response based, also referred to as *output–only*, modeling and analysis for traveling surface vehicles is of high interest as: (a) It is practical, not requiring unavailable road or rail excitation signals, and (b) may offer valuable insights into the vehicular dynamics under actual operating and boundary conditions, precise dynamical models, and also lead to effective Health Monitoring and Condition Based Maintenance (CBM) for automobiles and rail vehicles [1–4]. Yet, the problem is challenging due to various factors affecting the response of a traveling surface vehicle, including the so–called Wheelbase Filtering (WF) effect [5, p. 168].

Wheelbase Filtering (WF) arises in all wheeled surface vehicles, as the *same* road surface or rail excitation is applied to all wheels on one side of the vehicle with time delays that depend upon the vehicular geometry (distances among axles) and the traveling speed. These delays induce a modulation on the vibration response characteristics, specifically sharp periodic troughs in its Power Spectral Density (PSD), which not only render spectral estimation challenging, but also 'mask' the fundamental (*stationary*) vehicular dynamics (such as resonances and antiresonances). Therefore, the identification of the stationary vehicular dynamics under actual traveling conditions constitutes a challenging problem [6].

Although Wheelbase Filtering is well known in the field of vehicle suspension design [7, 8], its effects on spectral estimation and vehicular dynamics identification have yet to be studied. A recent exception is reference [6], focusing on vehicular dynamics identification via subspace identification techniques under specific conditions, including measurement of the leading wheel excitation.

The present study *aims* at addressing random vibration response modeling and analysis for traveling surface vehicles in two steps: First Wheelbase Filtering is studied and, based upon it, a proper representation and corresponding parametric spectral estimation for in–operation random vibration response signals are postulated. Second, based upon the former, stationary vehicular dynamics identification is explored.

The main idea is based upon considering the effects of Wheelbase Filtering on a random vibration signal and the subsequent introduction of special–structure AutoRegressive Moving Average (ARMA) models fully capturing the induced modulation, and thus allowing for proper signal representation. These models, currently referred to as *Wheelbase Filtering ARMA (WF–ARMA) models*, are characterized by two important *structural characteristics* when compared to their conventional counterparts as employed for modeling the random vibration response on a stationary (non–traveling) vehicle or structural system [9–11]. These constraints pertain to the model's MA polynomial structure, which is shown to be characterized by: (i) Order higher than its AutoRegressive (AR) counterpart, and, (ii) a certain sparsity, due to a number of potentially missing terms. These characteristics offer further insights into the effects of Wheelbase Filtering, as they are demonstrated to lead to zeros close to the unit circle (discrete–time case) which are, in turn, responsible for the periodic troughs appearing in the modulated Power Spectral Density.

The special structure of WF–ARMA models reveals, in particular structural characteristic (i) above, the *model structure misspecification* (mismatch) problem introduced through the use of conventional ARMA models in the context of parametric spectral estimation. In addition, characteristic (ii) above is instrumental in ensuring *statistical parsimony* (model economy) which is, in turn, essential for achieving the highest possible estimation accuracy [12, pp. 491–492].

Furthermore, exploring the relationships between a WF–ARMA model with the stationary vehicular dynamics, allows for the identification of the latter through the former. While this may

be achieved in a simple manner under proper constraints on the time delay between the axles, it is shown that it may be also achieved unconditionally at the expense of employing vibration signals measured under more than one traveling speeds.

In order to effectively demonstrate the concepts, the study makes use of a basic 2 DOF (Degree Of Freedom) vehicle model, that is a two–wheeled (bi–axial) half–vehicle vertical model with front and rear suspension elements, which is capable of describing the bounce and pitch motions. Spectral estimation and vehicular dynamics identification effectiveness is then examined via Monte Carlo numerical experiments with white noise road/rail displacement profiles. Interesting comparisons with non–parametric, Welch–based [12, pp. 186–187], and parametric, conventional AR and ARMA based [13, pp. 172–188], spectral estimators are also presented.

The rest of the article is organized as follows: The Wheelbase Filtering effects on the random vibration response Power Spectral Density are briefly discussed in section 2. The special structure and estimation of Wheelbase Filtering ARMA models are discussed in section 3, and the identification of the stationary vehicular dynamics in section 4. Performance assessment for the postulated methods, along with interesting comparisons, are presented in section 5, and concluding remarks are summarized in section 6.

2 WHEELBASE FILTERING EFFECTS ON THE VIBRATION RESPONSE POWER SPECTRAL DENSITY

Consider the simple, linear (small displacement), 2 DOF, two–wheeled (bi–axial) half–vehicle vertical model of Figure 1, which includes front and rear suspension elements with massless wheels. The vehicle is assumed to travel on a straight track/road under *constant speed*, with the excitation being provided by the vertical rail/road stochastic displacement profile, which is, for simplicity, currently assumed to be uncorrelated (white).

Let the bounce and pitch chassis (center of mass) displacements be designated as $z(t)$ and $\phi(t)$, respectively, and the vertical acceleration at a certain point, say A, on the vehicle by $y(t)$. Also let $u_1(t)$ and $u_2(t)$ represent the excitation (track displacement profile) acting on the front and rear wheel, respectively. The geometrical characteristics of the model are presented in

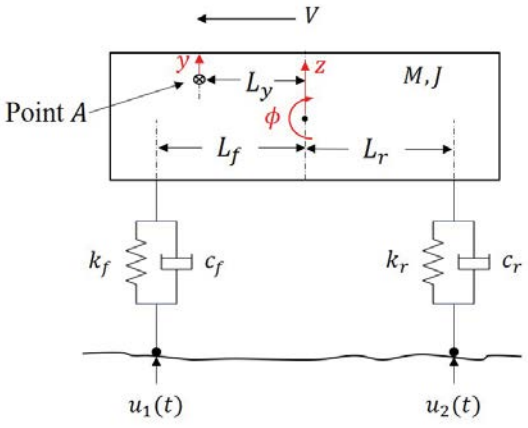

Figure 1: The 2 DOF two–wheeled half–vehicle vertical model.

Figure 1, while its mathematical representation (for small values of $\phi(t)$) is:

$$M\ddot{z}(t) + C_b\dot{z}(t) + K_b z(t) = c_f\dot{u}_1(t) + k_f u_1(t) + c_r\dot{u}_2(t) + k_r u_2(t) \tag{1a}$$

$$J\ddot{\phi}(t) + C_p\dot{\phi}(t) + K_p\phi(t) = c_f L_f\dot{u}_1(t) + k_f L_f u_1(t) - c_r L_r\dot{u}_2(t) - k_r L_r u_2(t) \tag{1b}$$

$$\ddot{y}(t) = \ddot{z}(t) + L_y\ddot{\phi}(t) \tag{1c}$$

with: $K_b := k_f + k_r \qquad C_b := c_f + c_r \qquad K_p := k_f L_f^2 + k_r L_r^2 \qquad C_p := c_f L_f^2 + c_r L_r^2$

Note that the 3rd equation above describes the vertical acceleration at Point A, while M, J stand for the car body mass and pitch moment of inertia, respectively, and k_f, c_f and k_r, c_r stand for the front and rear, respectively, suspension stiffness and viscous damping coefficients. The geometrical parameters L_f, L_r, L_y are defined in Figure 1 with respect to the body center of mass (c.m.).

Based on these equations the relationship between the excitations $u_1(t)$ and $u_2(t)$ and the response $\ddot{y}(t)$ may, in the Laplace (s) domain, be expressed as:

$$\ddot{Y}(s) = H_1(s)U_1(s) + H_2(s)U_2(s) \tag{2}$$

It should be noted that $H_1(s)$ and $H_2(s)$ designate the transfer functions between the track displacement profile acting on the 1st and 2nd wheel, respectively, and the vibration acceleration response at Point A, and as such represent the *stationary* Multiple–Input Single–Output (MISO) vehicular dynamics.

Observing that $u_2(t)$ is identical to $u_1(t)$ but delayed by time delay $\tau = (L_f + L_r)/V$ (see Figure 1; V designating the vehicle traveling speed):

$$u_2(t) = u_1(t - \tau) \tag{3}$$

Equation 2 then yields:

$$\ddot{Y}(s) = \underbrace{\left[H_1(s) + e^{-\tau s}H_2(s)\right]}_{H_{eq}(s)} U(s) \tag{4}$$

with $u(t) := u_1(t)$. Equation 4 clearly suggests that the MISO representation of Equation 2 may be expressed as a Single–Input Single–Output (SISO) system with *equivalent* ('phenomenal') transfer function $H_{eq}(s)$.

The *modulation* induced by Wheelbase Filtering [5, p. 169] may be observed in the frequency domain by examining the Power Spectral Density $S_{\ddot{y}\ddot{y}}(\omega)$ (ω designating frequency in rad/s) of the random vibration acceleration $\ddot{y}(t)$ signal at Point A as follows:

$$\begin{aligned} S_{\ddot{y}\ddot{y}}(\omega) = |H_{eq}(j\omega)|^2 S_{uu}(\omega) = |H_1(j\omega) + e^{-j\omega\tau}H_2(j\omega)|^2 \cdot S_{uu}(\omega) \implies \\ \implies S_{\ddot{y}\ddot{y}}(\omega) = \Big\{|H_1(j\omega)|^2 + |H_2(j\omega)|^2 + \\ +2\Big[\cos(\omega\tau)\,\mathrm{Re}\{H_1(j\omega)H_2^\star(j\omega)\} + \sin(\omega\tau)\,\mathrm{Im}\{H_1(j\omega)H_2^\star(j\omega)\}\Big]\Big\} \cdot S_{uu}(\omega) \end{aligned} \tag{5}$$

with $S_{uu}(\omega)$ designating the track excitation displacement Power Spectral Density, j the imaginary unit, $|\cdot|$ complex magnitude, and * complex conjugation. $\mathrm{Re}\{\cdot\}$ and $\mathrm{Im}\{\cdot\}$ designate real and imaginary part, respectively. The trigonometrical terms in the above expression indicate periodic modulation with period:

$$\Omega_{mod} = 2\pi/\tau \qquad \text{(rad/s)}$$

Parameter	Symbol	Value
Chassis mass (kg)	M	2 880
Pitch moment of inertia ($kg \cdot m^2$)	J	1 440
Front suspension stiffness (N/m)	k_f	1.7×10^6
Rear suspension stiffness (N/m)	k_r	1.7×10^6
Front suspension damping coefficient (Ns/m)	c_f	2.4×10^4
Rear suspension damping coefficient (Ns/m)	c_r	2.4×10^4
Distance between c.m. and the front suspension (m)	L_f	1.25
Distance between c.m. and the rear suspension (m)	L_r	1.25
Distance between c.m. and point $\mathcal{A}$ (m)	L_y	0.50

Table 1: The 2 DOF vehicle model parameters.

introduced by Wheelbase Filtering. It is obvious that for $L_y \neq 0$ (for $L_y = 0$ only bounce motion occurs) the extrema of $S_{\ddot{y}\ddot{y}}(\omega)$ do *not* generally coincide with those of the individual Frequency Response Function (FRF) magnitudes $|H_1(j\omega)|$ and $|H_2(j\omega)|$ which entail the resonances associated with the bounce and pitch motions.

The effects of Wheelbase Filtering on the vibration response Power Spectral Density are demonstrated in the following illustrative case study.

Illustrative Case Study: Consider the basic vehicle model of Figure 1, with parameter values as in Table 1, traveling at $V = 80\ km/h$ with resulting time delay $\tau = 0.1125\ s$. The road/rail vibration displacement excitation is independently identically distributed as normal with zero mean and unit variance. The model is discretized with sampling frequency $f_s = 80\ Hz$ via the impulse invariance method [14, pp. 206–209], with the time delay translated into $d = 9$ sampling periods (samples).

The vehicle's Frequency Response Function (FRF) H_1 and H_2 magnitudes are, along with the vibration acceleration response Power Spectral Density at Point A, $S_{\ddot{y}\ddot{y}}$, depicted in Figure 2. Two resonant frequencies are evident in the two FRF magnitudes, while the Wheelbase Filtering effect, with the introduced periodic modulation with period $F_{mod} = 1/\tau \approx 8.888\ Hz$, heavily distorting the response PSD and 'masking' the original model characteristics, including the resonant frequencies. Further insight may be gained by examining the vehicle model stationary poles and zeros (of the discretized transfer functions H_1 and H_2), along with those of the equivalent (phenomenal) transfer function, H_{eq}, as indicated in Figure 3. Evidently, Wheelbase Filtering introduces (additional) zeros into H_{eq} (hence into the PSD $S_{\ddot{y}\ddot{y}}$), yet none of the equivalent transfer function zeros coincides with those of H_1 or H_2. Furthermore, one complex zero pair (designated as r_1) introduces the first (barely observable) trough in the response PSD (Figure 2), while four additional pairs (designated as r_i for $i = 2, \ldots, 5$) are distributed closely to the unit circle and introduce four subsequent sharp troughs in the response PSD.

Based on the above, it is evident that vibration response spectra are heavily influenced by Wheelbase Filtering effects, which are 'masking' the vehicle's stationary dynamical characteristics, including resonant frequencies. This may have detrimental consequences on signal based modeling, analysis, and condition monitoring.

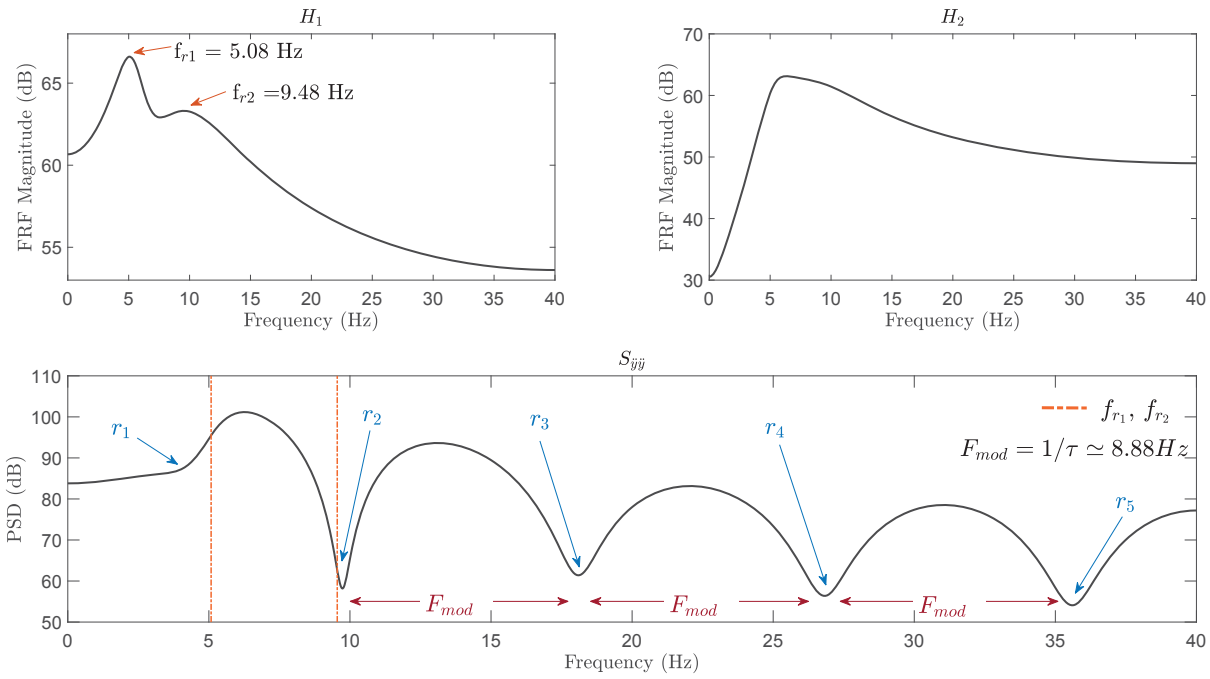

Figure 2: Stationary Frequency Response Function (FRF) magnitude curves for H_1 (a), H_2 (b), and the vertical vibration acceleration response (Point A) Power Spectral Density (c). [Illustrative case study.]

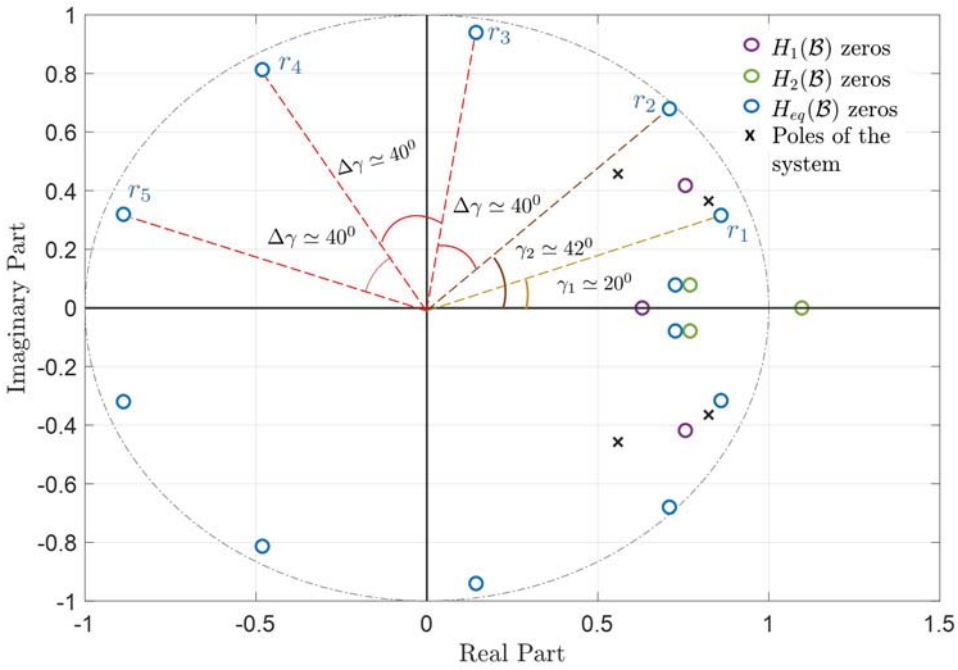

Figure 3: The poles and zeros of the discretized H_1, H_2 and H_{eq} transfer functions. [Illustrative case study.]

3 PARAMETRIC REPRESENTATION AND POWER SPECTRAL DENSITY ESTIMATION FOR THE RANDOM VIBRATION RESPONSE

3.1 The special–structure ARMA model for random vibration response signal representation

The discrete–time H_1 and H_2 stationary transfer functions (Equation 2) may be parameterized as:

$$H_1(\mathcal{B}) := \frac{C_1(\mathcal{B})}{A(\mathcal{B})} \qquad H_2(\mathcal{B}) := \frac{C_2(\mathcal{B})}{A(\mathcal{B})} \tag{6}$$

through the polynomials:

$$\begin{aligned} A(\mathcal{B}) &:= 1 + a_1\mathcal{B} + a_2\mathcal{B}^2 + \ldots + a_{na}\mathcal{B}^{na} \qquad \text{(monic)} \\ C_1(\mathcal{B}) &:= c_{1,0} + c_{1,1}\mathcal{B} + c_{1,2}\mathcal{B}^2 + \ldots + c_{1,nc}\mathcal{B}^{nc} \\ C_2(\mathcal{B}) &:= c_{2,0} + c_{2,1}\mathcal{B} + c_{2,2}\mathcal{B}^2 + \ldots + c_{2,nc}\mathcal{B}^{nc} \end{aligned}$$

with $\mathcal{B}$ (also known as q^{-1}) designating the *backshift operator* defined such that $\mathcal{B}^i u[t] := u[t-i]$ (t within brackets designating discrete time normalized by the sampling period T, that is $t = 0, 1, 2, \ldots$). na, nc designate the corresponding polynomial degrees – obviously na is also the *system order*. Substituting Equation 6 into the discretized version of Equation 2 leads to the following representation of the equivalent SISO model:

$$A(\mathcal{B})y[t] = \Big[C_1(\mathcal{B}) + C_2(\mathcal{B}) \cdot \mathcal{B}^d\Big]u[t], \quad u[t] \sim \text{i.i.d. } \mathcal{N}(0, \sigma^2) \tag{7}$$

with $d := \tau/T$ designating the *time delay* in terms of number of samples (presently assumed to be an integer) and $u[t]$, $y[t]$ standing for the discretized versions of the road/track profile displacement excitation and random vibration response, respectively. As previously stated, $u[t]$ is assumed identically independently distributed (i.i.d.) Gaussian with zero mean and variance σ^2.

Upon re–arrangement and absorption of $c_{1,0}$ into $u[t]$, the equivalent model of Equation 7 may be written as:

$$A(\mathcal{B})y[t] = \bar{C}(\mathcal{B})\bar{u}[t] \qquad \bar{u}[t] = c_{1,0} \cdot u[t] \sim \text{i.i.d. } \mathcal{N}(0, c_{1,0}^2\sigma^2) \tag{8}$$

with the *normalized* MA polynomial being (the normalization is to warrant monic polynomial):

$$\bar{C}(\mathcal{B}) := \frac{1}{c_{1,0}}\Big[C_1(\mathcal{B}) + C_2(\mathcal{B}) \cdot \mathcal{B}^d\Big] := \bar{C}_1(\mathcal{B}) + \bar{C}_2(\mathcal{B}) \cdot \mathcal{B}^d := 1 + \bar{c}_1\mathcal{B} + \cdots + \bar{c}_{nc+d}\mathcal{B}^{nc+d}$$
$$\bar{C}(\mathcal{B}) : \text{monic} \qquad \bar{C}_1(\mathcal{B}) : \text{monic} \qquad \bar{C}_2(\mathcal{B}) : \text{non–monic} \tag{9}$$

and the corresponding normalized versions of $H_1(\mathcal{B})$, $H_2(\mathcal{B})$:

$$\bar{H}_1(\mathcal{B}) := \frac{\bar{C}_1(\mathcal{B})}{A(\mathcal{B})} \qquad \bar{H}_2(\mathcal{B}) := \frac{\bar{C}_2(\mathcal{B})}{A(\mathcal{B})} \tag{10}$$

Notice that in all of the above expressions the overbar designates that the indicated polynomial (or the numerator polynomial in a transfer function) is normalized via division by $c_{1,0}$ (Equation 9).

The representation of Equation 8 is an AutoRegressive Moving Average (ARMA) model of orders $(na, nc + d)$, that is an ARMA$(na, nc + d)$ model, with two structural conditions distinguishing it from conventional ARMA models typically employed for representing the random vibration response on a stationary (non–traveling) vehicle or other structural systems [11]:

(i) The MA order $nc + d$ is, in general, *higher* than its AR counterpart na.

(ii) For $d > nc$ (typical under *low traveling speed*), the MA polynomial is characterized by a certain *sparsity* (missed intermediate terms).

Because of these, and for easy distinction, this model is subsequently referred to as a *Wheelbase Filtering ARMA model of orders* $(na, nc+d)$, with d designating the delay, or in short as a WF–ARMA$(na, nc + d)$ model. The following comments regarding the importance of structural conditions (i) and (ii) are now in order.

Comments:

(a) Structural condition (i) is instrumental for proper modeling, as potential violation (for instance by following the usual AR and MA order equality or MA order being equal to its AR counterpart minus one [11]) would imply *model structure misspecification* (mismatch), causing serious representation deficiency and model accuracy degradation.

(b) Structural condition (ii) is also instrumental because it warrants *statistical parsimony* (model economy), which is essential for achieving the highest possible estimation accuracy [12, pp. 491–492].

(c) As already indicated (illustrative case study in section 2), these structural conditions lead to the introduction of pairs of zeros close to the unit circle, which are responsible for the troughs in the vibration response Power Spectral Density.

(d) The zeros proximity to the unit circle also implies that pure AutoRegressive (AR) models, which are commonly employed in applications due to their estimation simplicity, are inappropriate (especially in the presence of very sharp troughs), as their use is expected to lead to poor approximations and/or very high model orders (see section 5).

(e) Evidently, in the 'very high' traveling speed case, $d \approx 0$ and the WF–ARMA$(na, nc+d)$ model degenerates to a conventional ARMA(na, nc) counterpart.

3.2 Remarks on WF–ARMA model estimation

Estimation of the WF–ARMA$(na, nc + d)$ model of Equation 8, that is determination of the AR/MA parameter vector $\boldsymbol{\theta} := [\ \boldsymbol{a} \vdots \bar{\boldsymbol{c}}\ ]^T$ (^{T} designating transposition) and the white noise variance ($c_{1,0}^2\sigma^2$) from a measured vibration response signal $y[t]$ ($t = 1, 2, \ldots, N$), may be based on the Prediction Error (PE) principle [12, pp. 199–201] subject to the provision that, in accordance to structural feature (ii), for $d > nc$ the pseudo–regression vector should have the form (notice the missing terms between the second and third groups):

$$\boldsymbol{\psi}[t, \boldsymbol{\theta}] := \big[y[t-1] \ldots y[t-na] \vdots e[t-1, \boldsymbol{\theta}] \ldots e[t-nc, \boldsymbol{\theta}] \vdots e[t-d, \boldsymbol{\theta}] \ldots e[t-(nc+d), \boldsymbol{\theta}]\big]^T$$

with $e[t, \boldsymbol{\theta}]$ designating the model–based one–step–ahead prediction error [12, pp. 68–70]. Of course, this is a function of the parameter vector $\boldsymbol{\theta}$, thus leading to a Nonlinear Least Squares optimization problem which may be tackled via *Gauss–Newton* and *Levenberg–Marquardt* procedures [12, pp. 326–329].

Model order estimation may be based on direct computation of d (for given traveling speed) and na, nc selection via the Bayesian Information Criterion (BIC) [12, pp. 505–507].

Once the WF–ARMA$(na, nc + d)$ model has been estimated, the random vibration response model based Power Spectral Density may be obtained as (T designates the sampling period):

$$S_{\ddot{y}\ddot{y}}(\omega) = \left|\frac{\bar{C}(e^{-j\omega T})}{A(e^{-j\omega T})}\right|^2 \cdot \left(c_{1,0}^2\sigma^2\right) \tag{11}$$

4 VEHICULAR DYNAMICS IDENTIFICATION

Vehicular dynamics identification depends upon the delay d (in samples) compared to the stationary MA order nc. As, in turn, d depends on the traveling speed, the cases of 'low' and 'high' traveling speeds are separately considered.

4.1 'Low' traveling speed ($d > nc$) case

In this case the terms of the $\bar{C}_1(\mathcal{B})$ and $\bar{C}_2(\mathcal{B})$ polynomials are, in the $\bar{C}(\mathcal{B})$ expression of Equation 9, non–interlaced and thus clearly separated (by the missing terms) among themselves, so that they may be accurately recovered from the obtained estimate of $\bar{C}(\mathcal{B})$. Using the estimate of $A(\mathcal{B})$, estimates of $\bar{H}_1(\mathcal{B})$ and $\bar{H}_2(\mathcal{B})$ may be then obtained through Equation 10.

Observe that the normalized versions, $\bar{H}_1(\mathcal{B})$ and $\bar{H}_2(\mathcal{B})$, are obtained instead of their original counterparts, or, in other words, the H_1 and H_2 transfer functions are recovered to a constant multiplier (constant multiplier uncertainty). Likewise the excitation variance is obtained as $(c_{1,0}^2 \cdot \sigma^2)$, instead of the actual σ^2 of Equation 7. Frequency Response Function (FRF) estimates may be also readily obtained from the transfer functions via the substitution $\mathcal{B} = e^{-j\omega T}$.

4.2 'High' traveling speed ($d \leq nc$) case

Unlike in the previous case, this is slightly more complex, as the terms of the polynomials $\bar{C}_1(\mathcal{B})$ and $\bar{C}_2(\mathcal{B})$ are interlaced in producing $\bar{C}(\mathcal{B})$ (Equation 9). The precise relationships between the coefficients of the three polynomials may be readily obtained as:

$$\bar{c}_i = \begin{cases} \bar{c}_{1,i} & i = 1, \cdots, d-1 \\ \bar{c}_{1,i} + \bar{c}_{2,i-d} & i = d, \cdots, nc \\ \bar{c}_{2,i-d} & i = nc+1, \cdots, nc+d \end{cases} \tag{12}$$

Evidently, the coefficients of the $\bar{C}_1(\mathcal{B})$ and $\bar{C}_2(\mathcal{B})$ polynomials cannot be uniquely recovered, implying that vehicular dynamics identification is not possible.

Yet, this may be overcome by employing *two* measured random vibration response signals, say $y^p[t]$, $y^q[t]$ $(t = 1, 2, \ldots, N)$ corresponding to *two* distinct traveling speeds V^p and V^q (and thus delays d^p and d^q), respectively. Assume, without loss of generality, that $d^q < d^p < nc$. Based on the available vibration response signals two models, a WF–ARMA$(na, nc + d^p)$ and a WF–ARMA$(na, nc + d^q)$, are estimated:

$$A^p(\mathcal{B})y^p[t] = \bar{C}^p(\mathcal{B})\bar{u}^p[t] \qquad \bar{u}^p[t] = c_{1,0}^p \cdot u^p[t] \sim \mathcal{N}(0, (c_{1,0}^p \sigma^p)^2) \tag{13a}$$

$$A^q(\mathcal{B})y^q[t] = \bar{C}^q(\mathcal{B})\bar{u}^q[t] \qquad \bar{u}^q[t] = c_{1,0}^q \cdot u^q[t] \sim \mathcal{N}(0, (c_{1,0}^q \sigma^q)^2) \tag{13b}$$

Evidently, the AR polynomials should be identical, that is $A^p(\mathcal{B}) \equiv A^q(\mathcal{B})$ (apart from estimation errors), so the AR parameters may be obtained as simple averages of the individual estimates.

On the other hand, the MA polynomials $\bar{C}^p(\mathcal{B})$, $\bar{C}^q(\mathcal{B})$ should be distinct, due to $d^p \neq d^q$, but interrelated due to their internal structure, that is common $\bar{C}_1(\mathcal{B})$ and $\bar{C}_2(\mathcal{B})$ stationary polynomials (Equation 9):

$$\bar{C}^p(\mathcal{B}) := \bar{C}_1(\mathcal{B}) + \bar{C}_2(\mathcal{B}) \cdot \mathcal{B}^{d^p} \qquad \bar{C}^q(\mathcal{B}) := \bar{C}_1(\mathcal{B}) + \bar{C}_2(\mathcal{B}) \cdot \mathcal{B}^{d^q} \tag{14}$$

These relationships lead to the following set of equations:

$$
\begin{array}{ll}
\underline{\bar{C}^p(\mathcal{B}):} & \underline{\bar{C}^q(\mathcal{B}):} \\
\left.\begin{array}{r} \bar{c}_{1,1} = \bar{c}^p_1 \\ \vdots \\ \bar{c}_{1,d^p-1} = \bar{c}^p_{d^p-1} \end{array}\right\} (d^p-1) \text{ eqs} & \left.\begin{array}{r} \bar{c}_{1,1} = \bar{c}^q_1 \\ \vdots \\ \bar{c}_{1,d^q-1} = \bar{c}^q_{d^q-1} \end{array}\right\} (d^q-1) \text{ eqs} \\
\left.\begin{array}{r} \bar{c}_{1,d^p} + \bar{c}_{2,0} = \bar{c}^p_{d^p} \\ \vdots \\ \bar{c}_{1,nc} + \bar{c}_{2,nc-d^p} = \bar{c}^p_{nc} \end{array}\right\} (nc-d^p+1) \text{ eqs} & \left.\begin{array}{r} \bar{c}_{1,d^q} + \bar{c}_{2,0} = \bar{c}^q_{d^q} \\ \vdots \\ \bar{c}_{1,nc} + \bar{c}_{2,nc-d^q} = \bar{c}^q_{nc} \end{array}\right\} (nc-d^q+1) \text{ eqs} \\
\left.\begin{array}{r} \bar{c}_{2,nc+1-d^p} = \bar{c}^p_{nc+1} \\ \vdots \\ \bar{c}_{2,nc} = \bar{c}^p_{nc+d^p} \end{array}\right\} (d^p) \text{ eqs} & \left.\begin{array}{r} \bar{c}_{2,nc+1-d^q} = \bar{c}^q_{nc+1} \\ \vdots \\ \bar{c}_{2,nc} = \bar{c}^q_{nc+d^q} \end{array}\right\} (d^q) \text{ eqs}
\end{array}
\tag{15}
$$

which may be then used to set up an overdetermined linear system of equations with the coefficients of $\bar{C}_1(\mathcal{B})$ and $\bar{C}_2(\mathcal{B})$ as unknowns ($2nc + d^p + d^q$ equations in $2nc + 1$ unknowns). This system may be solved in a Least Squares sense in order to provide estimates of the coefficients of $\bar{C}_1(\mathcal{B})$ and $\bar{C}_2(\mathcal{B})$. The identification of the stationary vehicular dynamics, in terms of the transfer functions $\bar{H}_1(\mathcal{B})$, $\bar{H}_2(\mathcal{B})$, is then complete.

5 PERFORMANCE ASSESSMENT AND COMPARISONS VIA MONTE CARLO EXPERIMENTS

Performance assessment is based on the illustrative case study of section 2. The traveling speed is $V = 80\ km/h$, resulting into a time delay $\tau = 0.1125\ s$, which for sampling frequency $f_s = 80\ Hz$ is equivalent to $d = 9$ samples long. The road/rail vibration displacement excitation is independently identically distributed with normal distribution having zero mean and unit variance, that is $u[t] \sim$ i.i.d. $\mathcal{N}(0, 1)$.

Estimation results are based on $1\ 000$ Monte Carlo runs, with the random vibration vertical acceleration signal in each run being $\Delta t = 250\ s$ ($N = 20\ 000$ samples) long. Each obtained vibration signal is pre–processed by having its sample mean removed and its sample standard deviation normalized to unity (the latter for purely numerical reasons).

Parametric spectral estimation results for the observed random vibration signal are presented first, followed by vehicular dynamics identification results.

5.1 WF–ARMA model based random vibration parametric spectral estimation

For the 2 DOF model treated, a WF–ARMA$(4, 3{+}9)$ model (that is $na = 4$, $nc = na-1 = 3$, $d = 9$) is appropriate [11]. WF–ARMA$(4, 3 + 9)$ based parametric spectral estimation is thus pursued, while interesting comparisons with the non–parametric Welch method [12, pp. 186–187], the pure AR based method, as well as ARMA$(4, 12)$ based spectral estimation [13, pp. 172–188], are also made. These comparisons are of particular interest, as the non–parametric Welch and the AR based methods are quite popular due to their implementation simplicity and low computational complexity. The comparison with ARMA$(4, 12)$ based spectral estimation – notice that this model is order–wise equivalent to its WF–ARMA$(4, 3 + 9)$ counterpart – is performed in order to isolate and assess the benefits of imposing structural condition (ii) related

Estimated Model	Estimation Method	MATLAB function
Non–parametric PSD	Welch	`pwelch.m`
AR(57)	Ordinary Least Squares (OLS)	`ar.m`
ARMA(4,12)	Nonlinear Least squares (NLS)	`armax.m`
WF–ARMA(4,3+9)		`custom function`
Random vibration signal length: $N = 20\,000$ samples		
Welch method details: Hamming window, segment length 512 samples, overlap 90%, $\delta f \simeq 0.15Hz$		

Table 2: Spectral estimation details.

to sparsity (see subsection 3.1) even when structural condition (i) is met. Estimation details are, for all cases, provided in Table 2, while Monte Carlo estimation results are presented in Figure 4.

Based on the obtained results, WF–ARMA$(4, 3 + 9)$ spectral estimation is evidently excellent, exhibiting no bias and minimal variability. Welch based spectral estimation is adequate, but characterized by significantly increased variability. AR based spectral estimation employs AR(57) models, selected via the BIC criterion [11]. This high order is expected and due to the pure AR approximation of the ARMA based dynamics, while it is aggravated by the first, sharp, spectral trough. Yet, estimation accuracy is still not very good for the specific trough, while ripples and considerable variability are observed across the bandwidth. Finally, ARMA$(4, 12)$

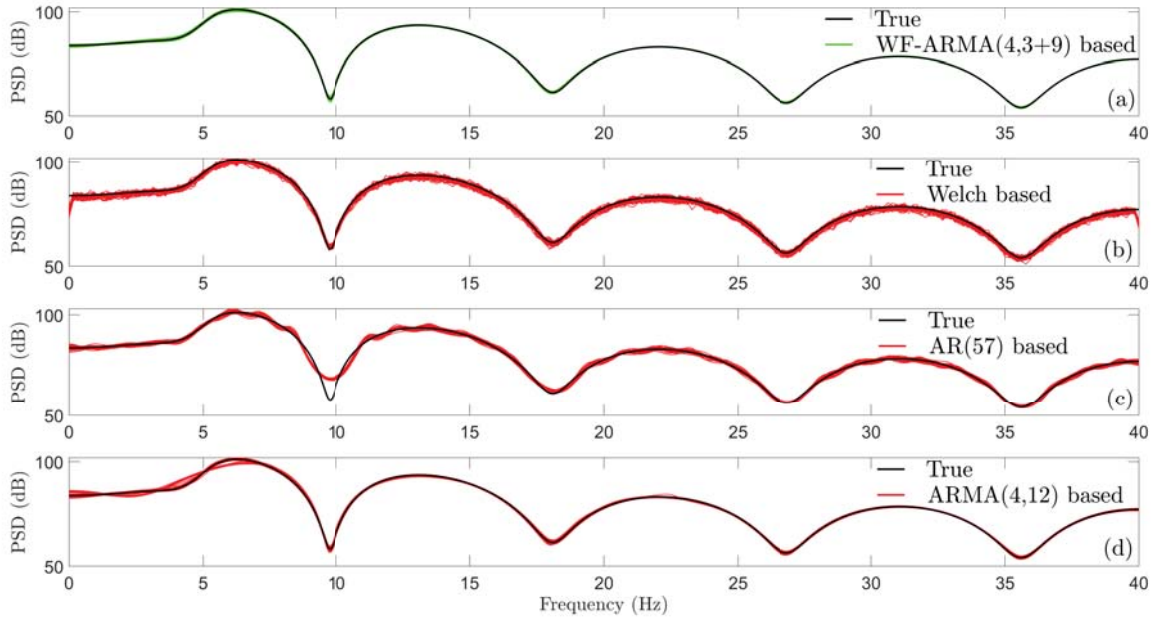

Figure 4: Spectral estimation assessment via the illustrative case study: (a) WF–ARMA based method, (b) Welch based method, (c) AR based method, and (d) ARMA based method with true orders. [In each case the true Power Spectral Density is shown in black; Traveling speed $V = 80\ km/h$; 1 000 Monte Carlo runs per method.]

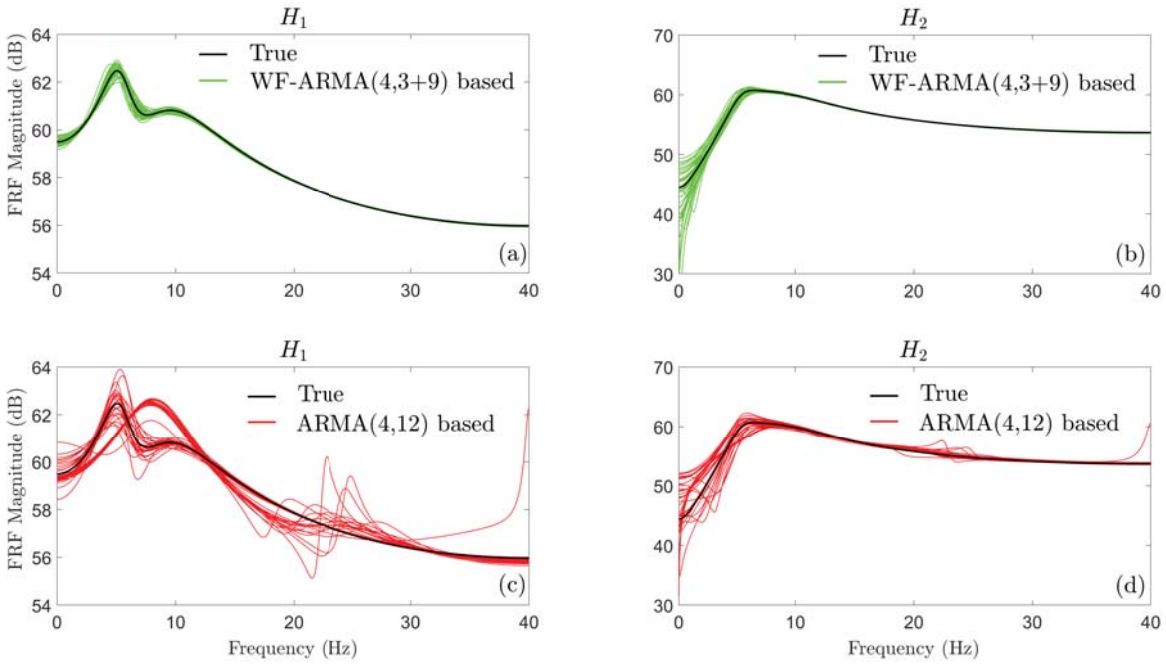

Figure 5: Vehicular dynamics estimation assessment via the illustrative case study under a single traveling speed: Stationary Frequency Response Function (FRF) H_1 and H_2 magnitude estimates obtained by the WF–ARMA (a,b) and ARMA (c,d) based methods. [The true FRF magnitudes are shown in black; Traveling speed $V = 80\ km/h$; 1 000 Monte Carlo runs per method.]

based estimation is adequate, but exhibiting certain bias at low frequencies and somewhat increased variability compared to that attained via the WF–ARMA$(4, 3 + 9)$ model.

Overall, the presented results illustrate the effectiveness and advantages of the postulated WF–ARMA model based spectral estimation approach.

5.2 WF–ARMA model based vehicular dynamics identification

'Low' traveling speed case ($V = 80\ km/h$, $d = 9 > nc = 3$) In this case the procedure of subsection 4.1 is applied based on the WF–ARMA$(4, 3 + 9)$ model. For comparison, in particular for observing the benefits of imposing structural condition (ii) related to sparsity, the procedure is also applied based on an ordinary ARMA$(4, 12)$ model. This is accomplished by a–posteriori setting to zero the parameters that ought to be omitted. Monte Carlo dynamics identification results by both methods are, in terms of stationary Frequency Response Functions (FRF) magnitudes for H_1 and H_2, presented in Figure 5, while corresponding modal parameter estimates obtained by the WF–ARMA$(4, 3 + 9)$ method are presented in Table 3.

The stationary FRF magnitudes estimated by the WF–ARMA based method (in this case without scaling uncertainty, as $\sigma^2 = 1$ so that $c_{1,0}$ is estimated) are very good, while those obtained by the ARMA based method exhibit serious problems in terms of both high variability and (in several cases) wrongly estimated modes. The benefits of imposing structural condition (ii) are thus confirmed as significant. The modal parameter estimates obtained by the WF–ARMA based method are also very good, with small standard deviations.

'High' traveling speed case ($d \leq nc = 3$) In this case the procedure of subsection 4.2 is

Mode	Natural Frequency f_n (Hz)		Resonant Frequency f_r (Hz)		Damping Ratio ζ (%)	
	True	Estimate (mean $\pm$ std)	True	Estimate (mean $\pm$ std)	True	Estimate (mean $\pm$ std)
Bounce	5.47	5.47 ± 0.18	5.08	5.09 ± 0.15	0.24	0.24 ± 0.02
Pitch	9.67	9.66 ± 0.23	9.48	9.47 ± 0.26	0.42	0.43 ± 0.01

Table 3: Vehicular modal parameter estimation for the illustrative case study: Natural frequency, resonant frequency and damping ratio estimates by the WF–ARMA method versus true counterparts. [Traveling speed $V = 80$ km/h; 1 000 Monte Carlo runs.]

applied based on two traveling speeds, $V^p = 240$ km/h and $V^q = 360$ km/h. The resulting models are WF–ARMA$(4, 3+3)$ and WF–ARMA$(4, 3+2)$, respectively.

The estimated H_1 and H_2 stationary FRF magnitudes are contrasted to their theoretical counterparts in Figure 6. The estimates are quite good, with some bias present at very low frequencies. Similarly to the 'low' traveling speed case, the stationary FRF magnitudes are estimated without scaling uncertainty, as $(\sigma^p)^2 = (\sigma^q)^2 = \sigma^2 = 1$ so that $c_{1,0}$ is obtained as a simple average of the individual $c^p_{1,0}$ and $c^q_{1,0}$ estimates [refer to Equation 13, Equation 8 and observe that $c^p_{1,0}$ and $c^q_{1,0}$ do not depend upon the delay d, thus speed, and should be both equal to $c_{1,0}$].

6 CONCLUDING REMARKS

The problems of effective parametric spectral estimation for random vibration signals and dynamics identification for traveling surface vehicles, in view of Wheelbase Filtering effects on measured random vibration signals, have been addressed. Special–structure AutoRegressive Moving Average (ARMA) models, referred to as Wheelbase Filtering ARMA (WF–ARMA) models, have been postulated for the precise representation, estimation, and spectral analysis of random vibration signals. A method for stationary vehicular dynamics identification based on in–motion random vibration signals (output–only identification) has been also developed. The main conclusions from the study may be summarized as follows:

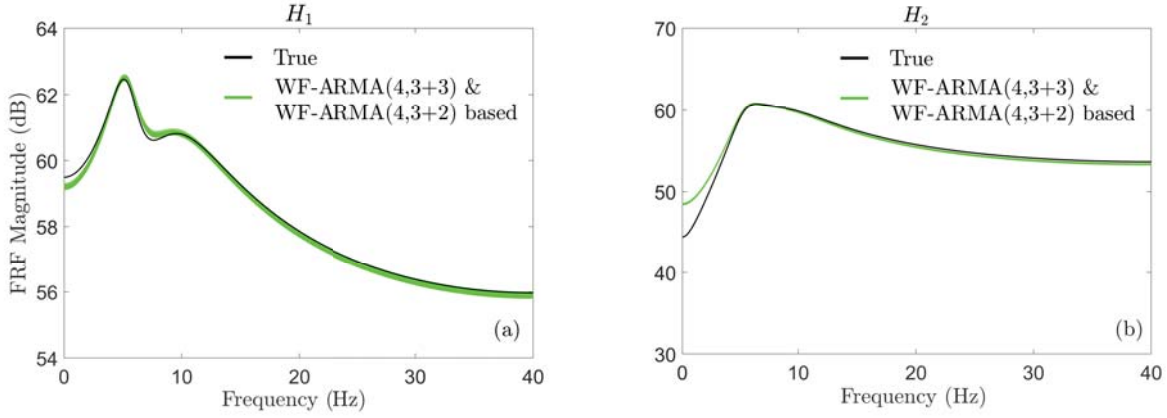

Figure 6: Vehicular dynamics estimation assessment via the illustrative case study under two traveling speeds: Stationary Frequency Response Function (FRF) H_1 and H_2 magnitude estimates obtained by the two WF–ARMA models. [The true FRF magnitudes are shown in black; Traveling speeds $V^p = 240$ km/h and $V^q = 360$ km/h; 1 000 Monte Carlo runs per speed.]

- Wheelbase Filtering effects lead to special–structure ARMA (WF–ARMA) models for the representation and parametric spectral estimation of random vibration signals for traveling surface vehicles.
- The special structure of WF–ARMA models is instrumental for achieving high accuracy. Indeed, compared to their conventional counterparts, WF–ARMA models avoid the detrimental effects of model mismatch and lack of statistical parsimony.
- The stationary vehicular dynamics may be properly identified via in–motion random vibration signals under a single or multiple nominal speeds.
- The superiority of the postulated WF–ARMA based approach has been demonstrated via Monte Carlo comparisons with classical Welch based, AR based, and conventional ARMA based spectral estimators.

Keywords: FE updating, System Identification, Structural Health Monitoring, Deep Learning, Damage Identification

Abstract. *The present study focuses on the implementation of a methodology to bridge the gap between SHM models with numerically generated data and correspondence with measurements from the real structure to provide reliable damage predictions. In the proposed novel methodology, numerically generated data from simulation models are integrated with measurements from the corresponding real structure to achieve high accuracy in identifying and predicting potential structural damages. A truss structure consisting of composite carbon fiber tubes, aluminum elements and steel bolts for the connections is used for the application of the proposed approach. The process begins with the three-dimensional finite element (FE) models of the examined cylindrical parts, developed in robust finite element analysis software simulating each carbon fiber ply and resin matrix. The real structure and FE models are analyzed in dynamic loading to identify their response. After, the complete assembly FE models are updated based on the data from experimental tests that correspond to the conducted analysis tests on composite cylindrical parts. The potential damage of the structure, set as loose bolts defining a multiclass damage identification problem, is then simulated with the optimal models through a series of stochastic FE load cases for different excitation characteristics. The simulated acceleration time series are then be fed in for the training of a supervised Convolutional Neural Network (CNN) classifier. The trained CNN is finally validated on experimentally measured structural states of the truss. Reliable results prove that optimal FE modeling may be used with machine learning techniques to synthesize a damage identification tool despite the uncertainties, which are tackled by the inherent advantage of numerical generated results to simulate arbitrary number of load cases in small amount of type and minimal effort.*

1 INTRODUCTION

Damage detection methods and Structural Health Monitoring (SHM) is increasingly attracting attention in prognosis and maintenance planning of various structural and mechanical systems. Vibration measurements for damage indexing [1] and SHM [2,3] have been the traditional way of building mathematical classification models that have as task to detect and identify potential damage in systems. More recently, the promising Machine Learning (ML) subcategory known as Artificial Neural Networks (ANN) has entered the SHM field showing great potential in damage detection tasks [4,5]. The advantages that ANNs may offer for SHM against the traditional mathematical models are highlighted as the minimal user preprocessing to input data and the automatic learning of damage features in vibration signals [6]. Usually, ANNs are applied in a multilayer form to achieve that and their architecture and training methods form the wide field of Deep Learning (DL).

Even though new models and methods have been proposed so far for SHM, such as ANNs, the problem of acquiring adequate and appropriate data still exists and is of most importance. All SHM methods go through the so called "training" or model building phase where data of different structural health states is used to "teach" the classifier how to separate a healthy from a damaged condition. The data needs to as representative as possible of the candidate structure for future damage or fault identification, therefore most training data is derived from experimentally measured sources. Experimentally measured data for damaged states could be difficult to get however in most of the cases of real structural systems, since it would require expensive or dangerous to measure damages [7]. Examples in the literature are sparse for data acquisition on damaged states of real structures [8,9].

A novel method was proposed recently with simulated experiments derived from optimal FE models for the data generation [6] in order to bypass difficulties that arise from damaged state measurements and various ambient conditions consideration. The requirement is that the candidate system for SHM to be identified properly on the healthy state and that the damaged are adequately defined to be simulated by FE. Various load cases, ambient conditions and damages may then be simulated and the extracted data can be fed directly with minimal pre-processing in a CNN classifier.

In this work, the potential of the promising system identification and damage detection framework by simulated experiments, is explored further for complex structures. A carbon fiber reinforced polymer (CFRP) truss structure is used as a benchmark. The novel damage detection framework includes a system identification and model updating for the material parameters or the structure and in turn a stochastic FE simulation for generation of labeled health statues. A CNN is trained by the simulated data and validated afterwards by measurements on the real structure. The physical benchmark structure and the imposed damages are described in Section 2, along with the workflow of the complete framework. The system identification and FE model updating is shown in Section 3. Results on the data generation, CNN training and evaluation on the health status of the real structure are shown in Section 4. The performance of the framework is finally discussed in the Conclusions section.

2 CARBON FIBER REINFORCED POLYMER BENCHMARK TRUSS STRUCTURE

Purpose of this work is to test the proposed simulated experiments framework against large and complex structures. The benchmark truss case shown in Figure 1, comprises of CFRP tubes connected on aluminum parts which are bolted on solid aluminum edges [10].

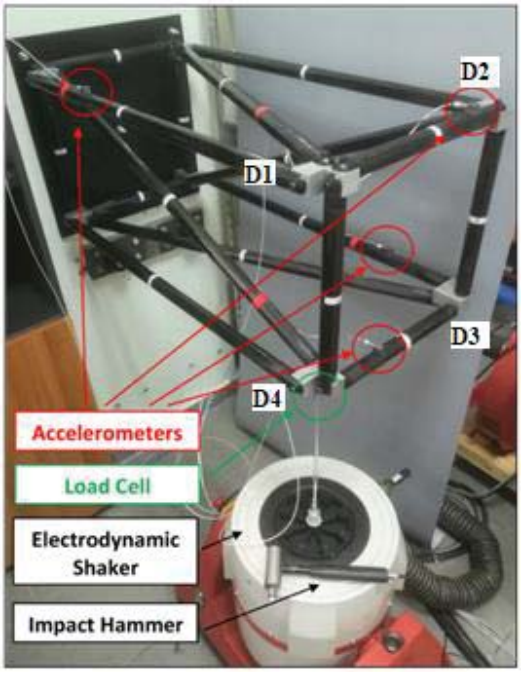

Figure 1 Experimantal setup of the CFRP pin-joined benchmark structure (left). Rubber interface for stiffness reduction of the bolted connection (right)

The benchmark structure poses challenges against the effective identification of the composite material parameters and the effective FE modeling of the bolted connections. The artificial damage to be studied is considered compromised bolts between the aluminum to carbon connection and the solid aluminum edges. Four bolts in total are the candidate damage positions every time as noted in Figure 1 as D1, D2, D3 and D4. The damaged cases bolts are left untightened in order to reduce connection stiffness. Impact loading is used for all SHM tests in this work. The proposed SHM framework proceeds as shown in Figure 2, starting with the FE model building and identification.

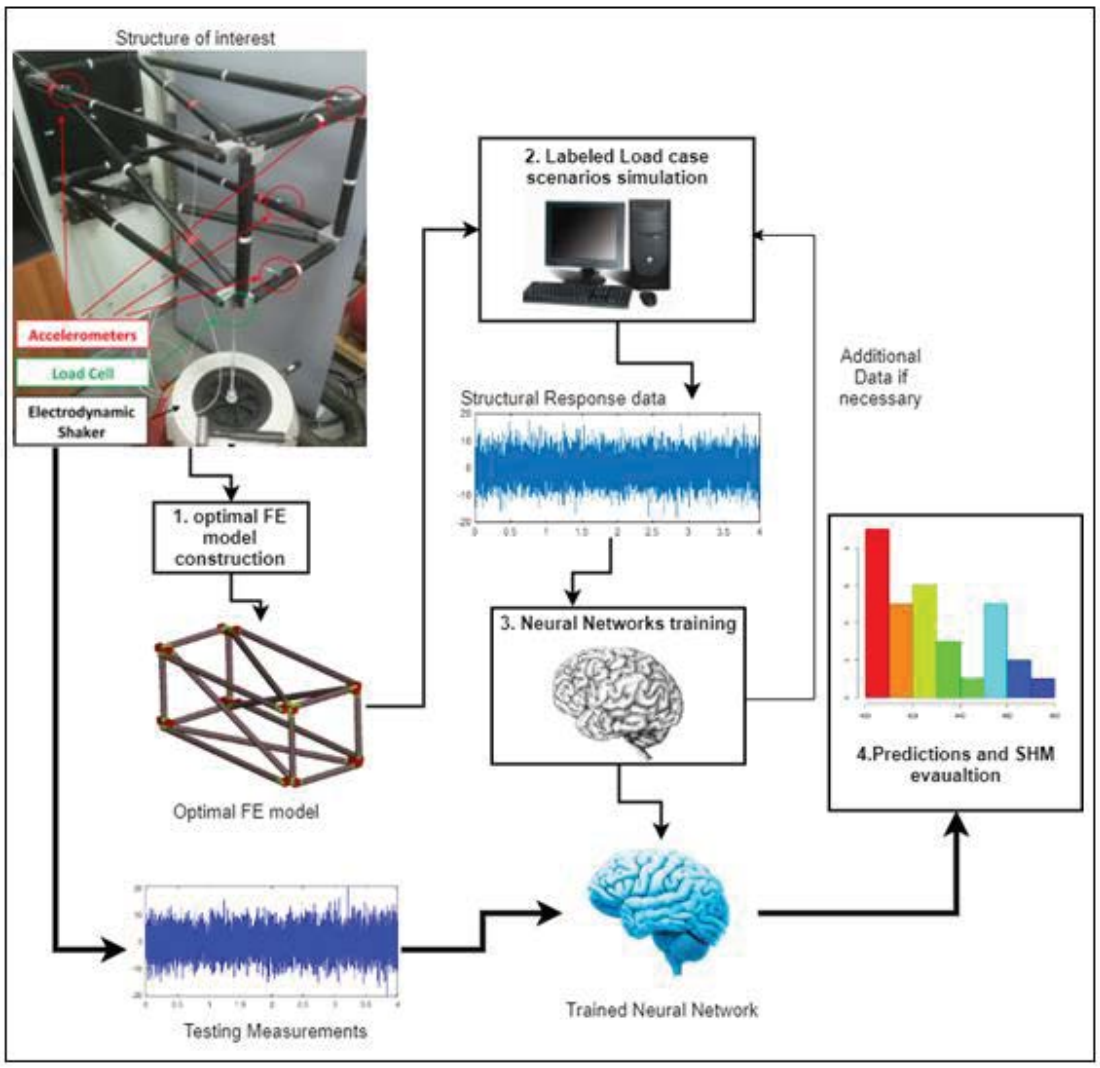

Figure 2 Workflow of the proposed SHM framework

3 SYSTEM IDENTIFICATION AND FINITE ELEMENT MODEL UPDATING OF PARAMETERS

The FE model of the truss structure is constructed using a total of 205.240 triangular shell elements for the CFRP tubes and 1.730.616 tetrahedra elements for the metallic parts and glue that connects them with the tubes. The bolts are modeled as rigid elements that connect the truss sections. In parallel, identification of the truss structure system is performed by extracting the experimental frequency response functions (FRF) with impact loading, shown in Figure 3. The CMA-ES stochastic optimization algorithm [11] is used after to update the FE model CFRP and metallic part material properties on the identified system, based on the experimental FRFs.

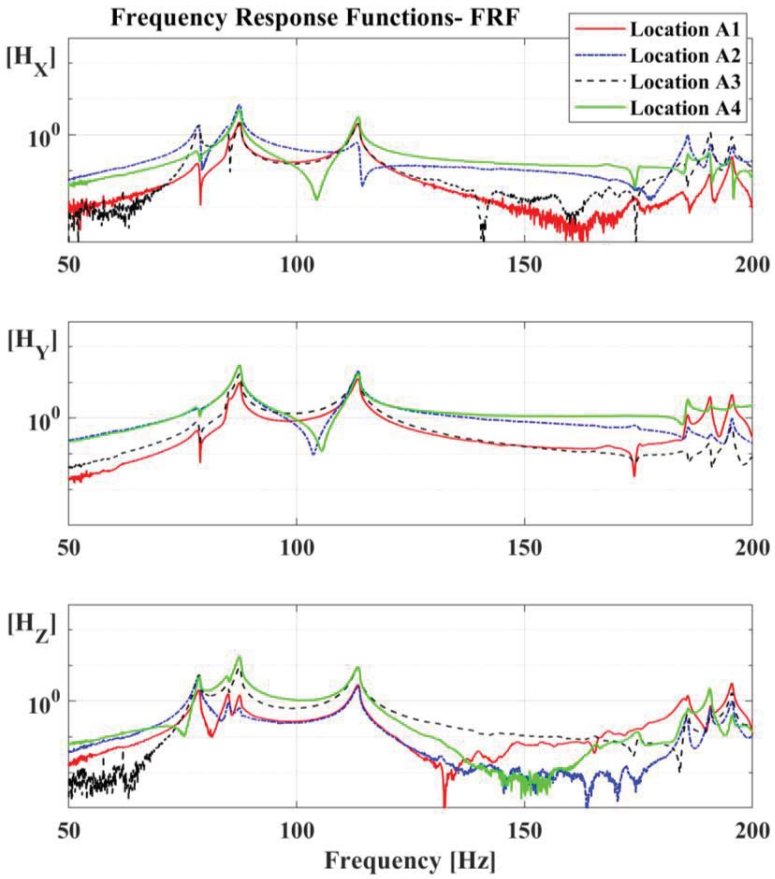

Figure 3 Frequency response functions for impact loading of the truss structure

Prior to update the FE model is divided in parts as shown in Figure 4, according to the material type of each. Results for the first 7 frequencies of the updated FE model are shown in Table 1 in comparison with the identified experimental ones

	Identified Frequency [Hz]	Frequency Updated FE [Hz]	Frequency Error (%)
1	78.456	77.2	1.6
2	84.932	82.85	2.45
3	87.651	91.7	4.619
4	113.542	114.71	1.028
5	185.584	188.91	1.79
6	190.736	189.6	0.59
7	195.502	194.66	0.43

Table 1: Comparison between identified and updated FE frequencies

For damping values, CMA-ES was used again with a starting point the previously updated material values, converging after to the values of 0.0099, 0.00989 and 0.00933 for frequency ranges between 0-100, 100-120 and 120-2000 Hz respectively. The complete updated FE model is after validated on impact excitation and the time histories of

accelerations at the node locations are compared between experimental and numerical results. The results are shown in Figure 5.

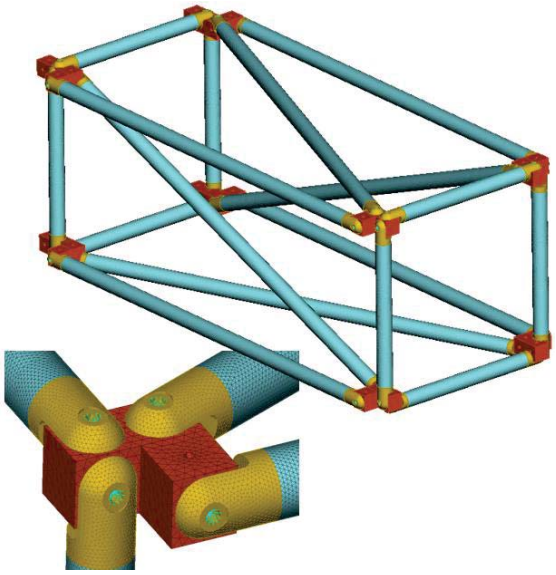

Figure 4 Grouped FE model parts (according to color) with repsect to their material properties

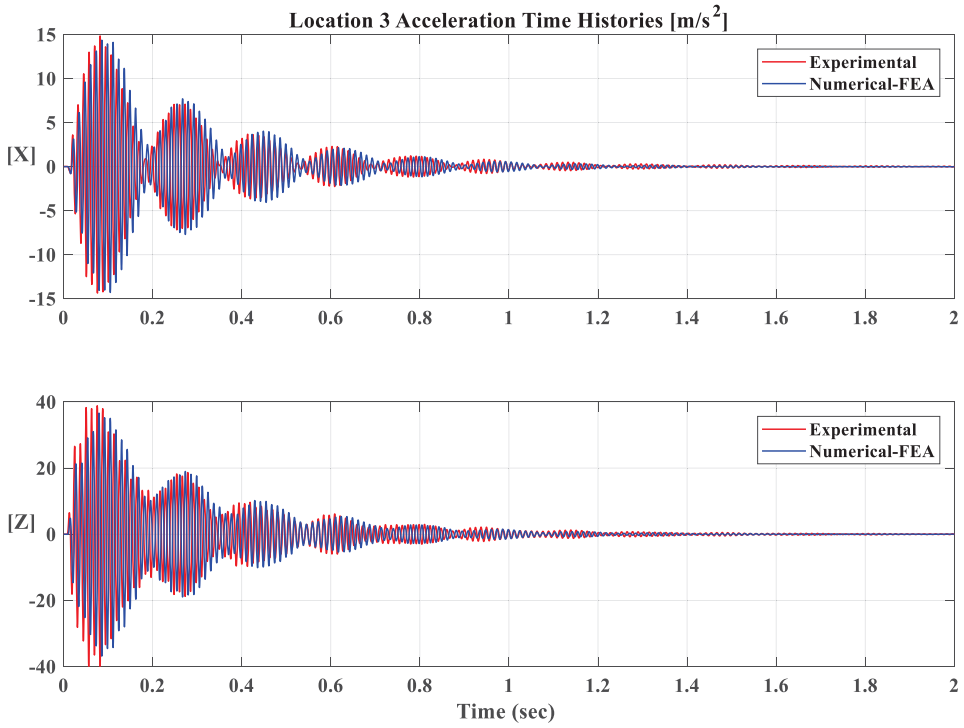

Figure 5 Identified numerical vs experimental acceleration time response for impact load

The acceleration comparison shows a good correspondance between the real and the numerical structure. With the updated FE model at hand now, the data generation step may proceed with the subsequent CNN training, described in Section 4.

4 DATA GENERATION, TRAINING AND EXPERIMENTAL VALIDATIONS

The SHM data generation is performed with the identified FE model of the truss structure which is used to simulate the Healthy the four damaged states D1, D2, D3 and D4. The bolted connections are modeled as rigid bodies for the Healthy status and removed according to the damage type. Random sampling in order to promote classifier generalization is used for the material and model parameters through a repetitive load case scheme [6] on the FE equations of motion:

$$\mathbf{M}(\rho)\mathbf{A} + \mathbf{C}(\mathbf{K},\mathbf{M},\alpha,\beta)\mathbf{V} + \mathbf{K}(E)\mathbf{U} = \mathbf{F} \tag{1}$$

Where $\mathbf{A},\mathbf{V}$ and $\mathbf{U}$ are global the acceleration, velocity and displacement vectors respectively. $\mathbf{M},\mathbf{C}$ and $\mathbf{K}$ represent the global mass, damping and stiffness matrices of the structure that depend on the model physical parameters of density ρ, damping α and β and elasticity E. The data generation algorithm is shown in Algorithm 1. Uniform random distribution is used for all values with a $\pm 10\%$ range from the identified material values. Impact loading was used as excitation.

Algorithm 1: Numerical model data generation algorithm

Input: Number of load cases n and statistical bounds for each quantity ρ, α, β, E

Output: n number of labeled acceleration vectors at preselected FE nodes

1. **for** $i = 1:n$ **do**
2. define Health status y according to FE model $\rightarrow \mathbf{Y}$
3. *sample* $E \rightarrow \mathbf{K} = \mathbf{K}(E)$
4. *sample* $\rho \rightarrow \mathbf{M} = \mathbf{M}(\rho)$
5. *sample* $\alpha, \beta \rightarrow \mathbf{C} = \mathbf{C}(\mathbf{K},\mathbf{M},a_i,\beta_i)$
6. **Solve** $\mathbf{MA} + \mathbf{CU} + \mathbf{KU} = \mathbf{F}$
7. **return A and Y**
8. **end**

The extracted accelerations and health label status after 400 load cases for each 5 statuses are completed form the SHM training data set (2):

$$Train\_set = \{(\mathbf{A}_1, \mathbf{Y}_1), (\mathbf{A}_1, \mathbf{Y}_2), ...(\mathbf{A}_n, \mathbf{Y}_n)\} \tag{2}$$

The CNN is trained after on the examples of set (2) in order to learn to identify damage. A "Deep" and "multiheaded" averaging form [6] is used that comprises of different 1D signal convolutional filters. Next 10 experimental measurements of each state are input in the trained CNN to check its predictions. Results are shown for a binary damage identification case, meaning a Healthy class and a single Damaged class containing D1, D2, D3 and D4. The predictions on the experimental Health status are shown in Figure 6. The class predictions come in values between 0 and 1, with 0.5 being the class threshold. Blue is used for the Healthy class score that the network predicts and red for the Damaged. The sum of the blue and red column is always equal to 1 in the network output. The histograms are read as follows. From 1-10 the histograms show the predictions scores for inputs from

Healthy experimental states. From 11-20, 21-30, 31-40, 41-50 the histograms show the predictions scores for inputs from D1, D2, D3 and D4 experimental states respectively which all together form the Damaged class in this binary damage identification problem. The validations scores come to 100% on the real states with only D1 and D2 predicting the state with 90% and 80% accuracy respectively. The trained CNN can be therefore regarded as reliable for the given problem.

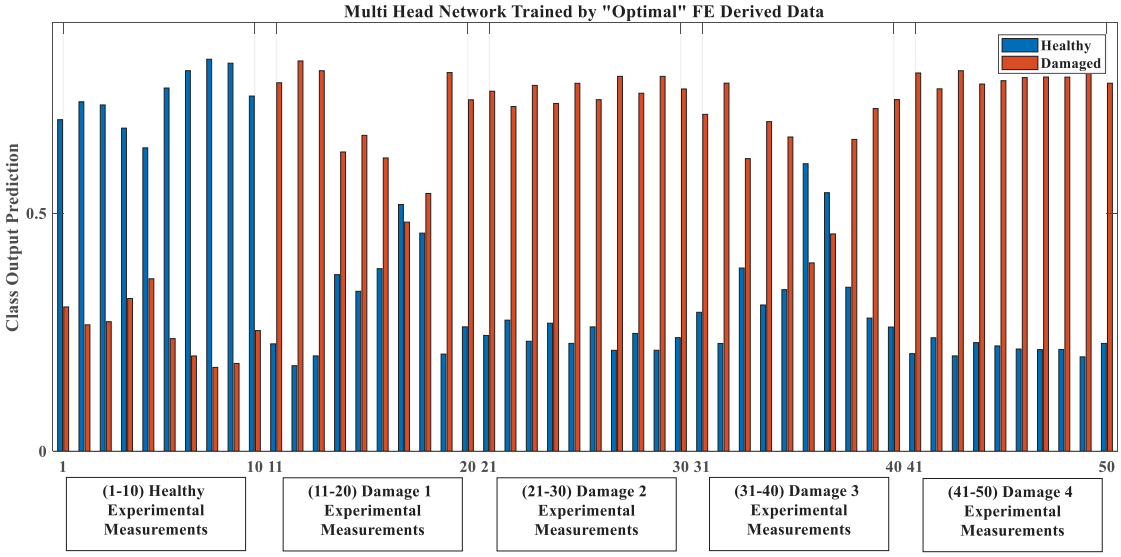

Figure 6 Predictions of the numerically trained CNN on the experimental status

5 CONCLUSIONS

In this work a system identification and damage detection framework was present for a CFRP truss structure. The damage cases for truss structure SHM benchmark test were applied as loose bolts. After the system identification of material parameters, a FE model was developed and served as the SHM training data source in order to feed in a Deep CNN classifier. The numerically trained CNN was finally validated on experimental states of the benchmark and showed close to 100% accuracy in a binary damage identification problem, meaning separating the Healthy from different Damaged conditions. The presented framework on the benchmark structure shows great potential for future SHM tools and further testing is planned such as damage cases of less magnitude and damage detection combing with damage location.

Keywords: Output-only identification, Damage localization, H-infinity estimation, Mechanical parameter estimation, Mass perturbation methods, Projection techniques in state space

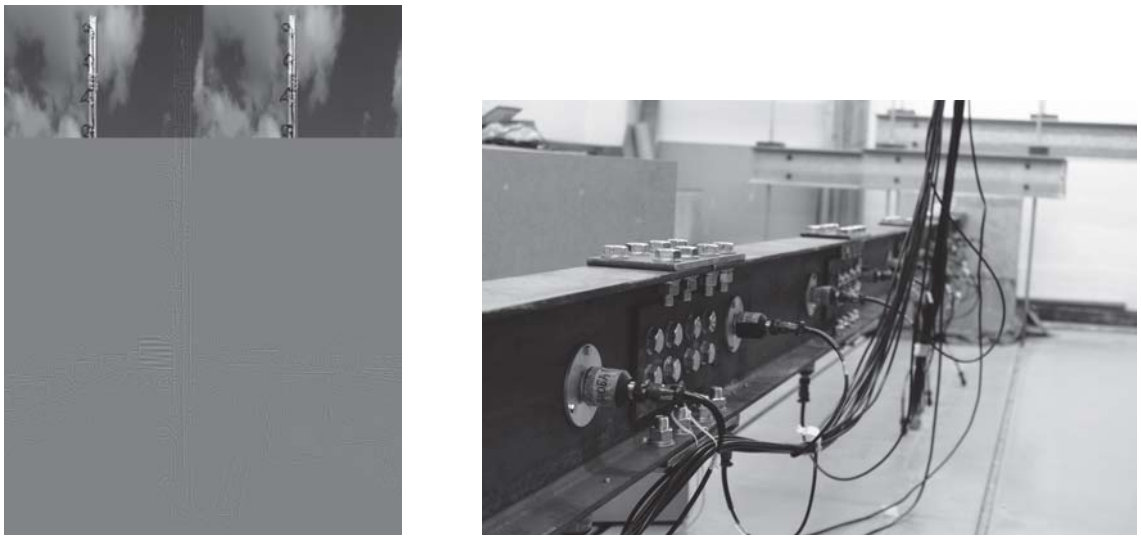
Abstract. *A new in-situ experimental setup for damage localization and mechanical parameter estimation has been built at two test fields, outdoors at a rooftop and in a laboratory at Leipzig University of Applied Sciences. Excited by wind, the structure can be identified by output-only methods. In this contribution current progress on the development of damage localization and scaling output-only systems from a general operator notation is shown. At the beginning damage localization based on $\mathcal{H}_\infty$-estimation is briefly shown. Modifying this theory, system scaling and mechanical parameter estimation is discussed afterwards. Finally, experimental results are shown and analysed.*

1 Introduction

In structural dynamics the parametrization of a mechanical model allows to analyse system properties and predict structural responses in certain load cases. To parametrize real life structures, a *linear-elastic* mechanical model is often a well-suited approximation at an operation point, which is modelled by mass, stiffness, and damping ($\bar{M}$, $\bar{K}$, and $\bar{D}$). To avoid a priori model errors and a possible huge numerical effort, *system identification* allows a straightforward alternative parametrization of a mechanical model, which the authors focus in this contribution. Directly based on measurements, the identified system has a considerably smaller model order. Here, the parametrization of a *linear, time-invariant state space system* is very advantageous, as this allows to subsequently apply identified parameters in other techniques.

Stochastic system identification. Because deterministic excitations are cost-intensive, elaborate, and sometimes impossible to apply at large-scale civil engineering structures, identification methods based on *ambient excitations* (e.g. wind, traffic, waves, microseism) should be applied instead [1]. Some stochastic system identification methods are a) stochastic realization [2], b) stochastic subspace identification (SSI) [3], c) canonical correlation analysis (CCA) [4], and so on. Because ambient excitations are in general unmeasurable, state space parameters A and C can be determined only based on structural response measurements. Hence, the physical interpretation of the identified system is an important issue. A widespread approach is the identification of modal data (free scaled mode shapes), named operational modal analysis (OMA) [5–7]. However, without the necessity of numerical computations based on (real or complex-conjugated) mode shapes, we focus on the development of a general, system theoretic identification approach.

Motivation: Mechanical parameter estimation and damage localization. A new in-situ experimental setup for damage localization and mechanical parameter estimation has been built at two test fields, outdoors at a rooftop and in a laboratory at Leipzig University of Applied Sciences (see figure 1 and section 4). Excited by wind, the structure can be identified by output-



(a) Wind-exposed structure at a rooftop (b) Laboratory structure

Figure 1: Experimental structures

only methods. The authors aim to develop and verify a damage localization method based on the *state projection estimation error* (SP2E) [8–11], which is insensitive to environmental and operational conditions (EOC). While first attempts based on principal component analysis were analysed [12], a system theoretic approach may be advantageous.

In this contribution, current progress on the development of damage localization and scaling output-only systems from a general operator notation is shown. To begin with in section 2, damage localization based on SP2E is briefly shown. Modifying this theory, the novel *state projections for system scaling* (SP2S) method and subsequent mechanical parameter estimation is discussed afterwards, which is based on output-only measurements and the mass perturbation technique (repetition of measurement with known additional mass Δ_M, section 3). Finally, experimental results are shown and analysed in section 4.

Some notes on the used nomenclature. Because structural alterations are a key element of this contribution (e.g. stiffness modifications $\Delta_{K,i}$ and/or *mass perturbations* $\Delta_{M,i}$), the definition of structural state i is introduced: $i = 0$ defines the reference and $i > 0$ the altered structural state.

We focus on the application of estimation/control approaches in structural dynamics. Hence, a more general system theoretic notation is used: The map to y from u is denoted by T_{yu}. By using a linear, time-invariant state space system, T_{yu} may be written in frequency domain as

$$\left.\begin{aligned} \sigma x(\sigma) &= Ax(\sigma) + Bu(\sigma) \\ y(\sigma) &= Cx(\sigma) + Du(\sigma) \end{aligned}\right\} \sigma = (s, z) \ .$$

Based on state space parameters A, B, C, and D, the frequency response matrix function follows:

$$T_{yu}(\sigma) = \left[\begin{array}{c|c} A & B \\ \hline C & D \end{array}\right] \overset{\sigma}{=} C\big(\sigma I - A\big)^{-1} B + D \ .$$

2 Damage localization based on $\mathcal{H}_\infty$-estimation: State projection estimation error (SP2E)

2.1 Basis: Output-only identification

As mechanical system parameters ($\bar{M}$, $\bar{K}$, and $\bar{D}$) and structural excitations are unknown for real large-scale structures, we use the SSI [3] to parametrize discrete-time state space parameters A and C. These matrices are applied to define a *discrete-time system*

$$\begin{bmatrix} x_{k+1} \\ y_k \end{bmatrix} = \left[\begin{array}{c|cc} A & I & 0 \\ \hline C & 0 & I \end{array}\right] \begin{bmatrix} x_k \\ w_k \\ v_k \end{bmatrix}, \quad n_k = \begin{bmatrix} w_k \\ v_k \end{bmatrix} \quad \text{with } \big\langle n_k, n_k \big\rangle := \begin{bmatrix} Q & S \\ S^* & R_v \end{bmatrix} \ . \tag{1}$$

2.2 $\mathcal{H}_\infty$-estimation: Worst-case analysis

$\mathcal{H}_\infty$-theory leads to estimators, which are less susceptible to *disturbance uncertainties*. A key element for that is to consider the so-called worst-case. Hence, one uses the $\mathcal{H}_\infty$-norm to bound a system $T_{\tilde{s}n}$ by γ, which is equivalent to bound the largest singular value of matrix function $T_{\tilde{s}n}$, namely

$$\|T_{\tilde{s}n}\|_{\mathcal{H}_\infty} = \sup_n \frac{\|\tilde{s}\|_2}{\|n\|_2} = \max_\omega \bar{\sigma}\Big(T_{\tilde{s}n}(e^{j\omega})\Big) \ < \gamma \ , \quad \tilde{s} = s - \hat{s} = L\big(x - \hat{x}\big) = L\tilde{x} \ . \tag{2}$$

Although $\mathcal{H}_\infty$-theory may lead to over-conservative estimators, they outperform Kalman filters ($\mathcal{H}^2$ estimators), when the disturbances are unknown [13]. An important difference to Kalman filtering is the usage of weighting parameter L, allowing different applications in $\mathcal{H}_\infty$-estimation [13]. For the case of *filtering signals in additive noise* [14] one uses $L = C$.

There are plenty $\mathcal{H}_\infty$-theory approaches [13–17]. A powerful, theoretical approach is the derivation of estimation as *a special case of control* by using the lower linear fractional transformation (LLFT, see figure 2) [18]:

$$\begin{bmatrix} x_{k+1} \\ \tilde{s}_k \\ y_k \end{bmatrix} = \underbrace{\left[\begin{array}{c|cc|c} A & I & 0 & 0 \\ \hline L & 0 & 0 & -I \\ C & 0 & I & 0 \end{array}\right]}_{P} \begin{bmatrix} x_k \\ w_k \\ v_k \\ \hat{s}_k \end{bmatrix}, \qquad \begin{bmatrix} \hat{x}_{k+1} \\ \hat{s}_k \end{bmatrix} \underbrace{\left[\begin{array}{c|c} A - K_p C & K_p \\ \hline L & 0 \end{array}\right]}_{K} \begin{bmatrix} \hat{x}_k \\ y_k \end{bmatrix} . \tag{3}$$

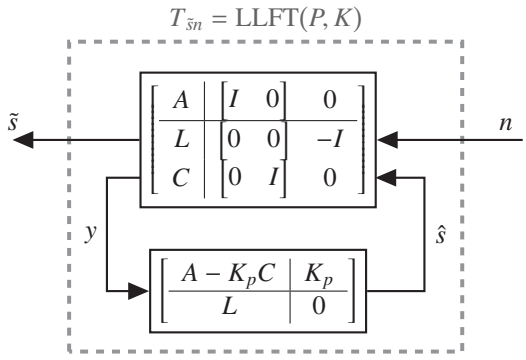


Figure 2: Estimation as a special case of control

LMI based $\mathcal{H}_\infty$-estimation. Linear matrix inequality (LMI) methods are widespread to determine $\mathcal{H}_\infty$-controllers [19, 20]. Based on the bounded real lemma, a γ-optimal controller K exists in discrete-time (see equation (2)) in both equivalent expressions

$$\left\| T_{\tilde{s}n}\big(\mathcal{A}_{cl}, \mathcal{B}_{cl}, \mathcal{C}_{cl}, \mathcal{D}_{cl}\big) \right\|_{\mathcal{H}_\infty} < \gamma, \quad \mathcal{H} = \begin{bmatrix} -\mathcal{X}^{-1} & \mathcal{A}_{cl} & \mathcal{B}_{cl} & 0 \\ \mathcal{A}_{cl}^T & -\mathcal{X} & 0 & \mathcal{C}_{cl}^T \\ \mathcal{B}_{cl}^T & 0 & -\gamma^2 I & \mathcal{D}_{cl}^T \\ 0 & \mathcal{C}_{cl} & \mathcal{D}_{cl} & -I \end{bmatrix} < 0 , \tag{4}$$

if the above inequality is feasible for $\mathcal{X} > 0$. Hence, an *optimization problem* follows, namely the minimization of γ under the above constraints, which may be solved numerically (see [21, 22]). A numerical minimum for γ^2 can be found by *semidefinite programming* (SDP), which may lead to the strictly proper form

$$\begin{bmatrix} \hat{x}_{k+1} \\ \hat{y}_k \end{bmatrix} = \underbrace{\left[\begin{array}{c|c} A_f & K_f \\ \hline C & 0 \end{array}\right]}_{K_{\text{LMI}}} \begin{bmatrix} \hat{x}_k \\ y_k \end{bmatrix} . \tag{5}$$

Riccati recursion/equation based $\mathcal{H}_\infty$-estimation. Besides the LMI solution, the application of indefinite metric spaces for $\mathcal{H}_\infty$-estimation [14] is a remarkable theory. Based on the

minimization of an indefinite quadratic form [23], this theory leads to a Riccati recursion

$$P_{k+1} = AP_k\left(I - \begin{bmatrix}L\\C\end{bmatrix}^*\left(\begin{bmatrix}L\\C\end{bmatrix}P_k\begin{bmatrix}L\\C\end{bmatrix}^* + \begin{bmatrix}-\gamma^2 I & 0\\0 & I\end{bmatrix}\right)^{-1}\begin{bmatrix}L\\C\end{bmatrix}P_k\right)A^* + Q \tag{6a}$$

$$= A\Big(P_k^{-1} - \gamma^{-2}L^*L + C^*C\Big)^{-1}A^* + Q\ . \tag{6b}$$

To determine an $\mathcal{H}_\infty$-estimator, a convergent solution $P = P_{k+1} = P_k$ must be computed and important existence conditions are taken into account

$$\forall k: \quad \tilde{P}_k^{-1} = P_k^{-1} - \gamma^{-2}L^*L > 0, \quad P_k^{-1} - \gamma^{-2}L^*L + C^*C > 0\ . \tag{7}$$

Because a direct recursive computation is numerically imprecise [24], one can solve a *discrete-time algebraic Riccati equation* (DARE) instead. To get a solution, the eigenvectors of an extended symplectic pencil are used to numerically determine matrix P [25], which leads to the *a priori* $\mathcal{H}_\infty$-estimator

$$\begin{bmatrix}\hat{x}_{k+1}\\ \hat{y}_k\end{bmatrix} = \underbrace{\left[\begin{array}{c|c}A_p & K_p\\ \hline C & 0\end{array}\right]}_{K_{\text{DARE}}}\begin{bmatrix}\hat{x}_k\\ y_k\end{bmatrix} \quad \text{with } K_p = A\tilde{P}C^*\big(C\tilde{P}C^* + I\big)^{-1}, \quad A_p = A - K_pC\ . \tag{8}$$

As $\gamma \to \infty$, the estimator in equation (8) becomes the well-known Kalman filter (an $\mathcal{H}_2$-optimal estimator) [13].

2.3 Damage localization by state projection estimation error (SP2E) method

A difference process has been proposed for damage localization by the authors [9–11]. Process d follows the introduced system in discrete-time

$$\begin{bmatrix}\hat{x}_{0,k+1}\\ \hat{x}_{i,k+1}\\ x_{i,k+1}\\ d_k\end{bmatrix} = \underbrace{\left[\begin{array}{ccc|cc}A_{p,0} & 0 & K_{p,0}C_i & 0 & K_{p,0}\\ 0 & A_{p,i} & K_{p,i}C_i & 0 & K_{p,i}\\ 0 & 0 & A_i & I & 0\\ \hline -C_0 & C_i & 0 & 0 & 0\end{array}\right]}_{T_{dn}}\begin{bmatrix}\hat{x}_{0,k}\\ \hat{x}_{i,k}\\ x_{i,k}\\ w_k\\ v_k\end{bmatrix}\ . \tag{9}$$

Using state projections, a Sylvester equation must be solved, which leads to the following:

$$\begin{bmatrix}A_{p,0} & 0\\ 0 & A_{p,i}\end{bmatrix}\bar{\Theta} - \bar{\Theta}A_i = -\begin{bmatrix}K_{p,0}\\ K_{p,i}\end{bmatrix}C_i\ , \quad \bar{\Theta} = \begin{bmatrix}Y\\ Z\end{bmatrix} \tag{10a}$$

$$\begin{bmatrix}\hat{x}_{0,k+1}\\ \hat{x}_{i,k+1}\\ x_{i,k+1}\\ d_{V,k}\end{bmatrix} = \underbrace{\left[\begin{array}{ccc|cc}A_{p,0} & 0 & 0 & -Y & K_{p,0}\\ 0 & A_{p,i} & 0 & -Z & K_{p,i}\\ 0 & 0 & A_i & I & 0\\ \hline -C_0 & C_i & C_iZ - C_0Y & 0 & 0\end{array}\right]}_{T_{dVn}}\begin{bmatrix}\hat{x}_{0,k}\\ \hat{x}_{i,k}\\ x_{i,k}\\ w_k\\ v_k\end{bmatrix}\ . \tag{10b}$$

The SP2E difference process approach is a form of *model reduction*, namely the truncation of estimator poles. This has been discussed by the authors [9–11] and allows to define

$$\begin{bmatrix}x_{k+1}\\ d_{V,k}\end{bmatrix} = \underbrace{\left[\begin{array}{c|cc}A_i & I & 0\\ \hline C_T & 0 & 0\end{array}\right]}_{T_{dVn}}\begin{bmatrix}x_k\\ w_k\\ v_k\end{bmatrix}\ , \quad C_T = \begin{bmatrix}-C_0 & C_i\end{bmatrix}\begin{bmatrix}Y\\ Z\end{bmatrix} = C_iZ - C_0Y\ . \tag{11}$$

As a result one determines the difference process d_V taking state projections into account. The average process power of d_V can be analysed for damage localization:

$$\bar{P}_{dV} = \operatorname{diag}\big(R_{dV}\big) \quad \text{with} \quad R_{dV} = \big\langle d_{V,k}, d_{V,k} \big\rangle \ . \tag{12}$$

The SP2E method has been verified based on experimental data and the study of damage localization results can be found in [9–11].

3 System scaling and mechanical parameter estimation based on output-only identification and mass perturbations

3.1 Relation of structural states in general operator notation

In this section some brief notes on the novel *state projections for system scaling* (SP2S) method and mechanical parameter estimation are given (for details see [26]). To find a relation for that, the constitutive equation of motion in structural dynamics is reordered to

$$a_i \stackrel{s}{=} T_{af,i} f : \qquad \bar{M} a_i(t) + \bar{D} v_i(t) + \bar{K} d_i(t) = f(t) - \Delta_{M,i} a_i(t) \ . \tag{13}$$

The mechanical system in reference structural state $T_{af,0}$ has the response of state i due to input $f - \Delta_{M,i} a_i(t)$ after a settling time (steady state vibrations). Omitting initial values, this may be expressed in Laplace domain by

$$a_i(s) = T_{af,0}(s)\Big(f(s) - \Delta_{M,i} a_i(s)\Big), \qquad T_{af,i} \stackrel{s}{=} T_{af,0}\big(I_p - \Delta_{M,i} T_{af,i}\big) \ . \tag{14}$$

In equation (14) we presuppose the same average excitation spectrum (in a stochastic sense) for both structural states $T_{af,0}$ and $T_{af,i}$. Equation (14) is very important to relate *reference and altered structural states in one framework* and a system description for the structural states is necessary to apply the found relation, which is shown below.

3.2 State projections for system scaling method (SP2S)

A state space approach is focused below, because this allows to apply standard system analysis techniques afterwards. Hence, by applying state space parameters A_i, B_i, C_i, and D_i in equation (14), one concludes the following in continuous-time:

$$\left[\begin{array}{c|c} A_i & B_i \\ \hline C_i & D_i \end{array}\right] \stackrel{s}{=} \left[\begin{array}{c|c} A_0 & B_0 \\ \hline C_0 & D_0 \end{array}\right] \left[\begin{array}{c|c} A_i & B_i \\ \hline -\Delta_{M,i} C_i & I_p - \Delta_{M,i} D_i \end{array}\right] \tag{15a}$$

$$\stackrel{s}{=} \left[\begin{array}{cc|c} A_0 & -B_0 \Delta_{M,i} C_i & B_0 (I_p - \Delta_{M,i} D_i) \\ 0 & A_i & B_i \\ \hline C_0 & -D_0 \Delta_{M,i} C_i & D_0 (I_p - \Delta_{M,i} D_i) \end{array}\right] \tag{15b}$$

$$a_i \stackrel{s}{=} T_{af,i} f : \qquad \begin{bmatrix} \dot{x}_0 \\ \dot{x}_i \\ a_i \end{bmatrix} = \left[\begin{array}{cc|c} A_0 & -B_0 \Delta_{M,i} C_i & B_0 (I_p - \Delta_{M,i} D_i) \\ 0 & A_i & B_i \\ \hline C_0 & -D_0 \Delta_{M,i} C_i & D_0 (I_p - \Delta_{M,i} D_i) \end{array}\right] \begin{bmatrix} x_0 \\ x_i \\ f \end{bmatrix} \ . \tag{15c}$$

In equation (15b) the state space system on the right-hand side has a considerably larger model order than the left-hand side. Applying the state projection technique of equation (10), a block diagonal form is determined:

$$A_0 \Theta_i - \Theta_i A_i = B_0 \Delta_{M,i} C_i \tag{16a}$$

$$\left[\begin{array}{c|c} A_i & B_i \\ \hline C_i & D_i \end{array}\right] \stackrel{s}{=} \left[\begin{array}{cc|c} A_0 & 0 & B_0 (I_p - \Delta_{M,i} D_i) - \Theta_i B_i \\ 0 & A_i & B_i \\ \hline C_0 & C_0 \Theta_i - D_0 \Delta_{M,i} C_i & D_0 (I_p - \Delta_{M,i} D_i) \end{array}\right] \ . \tag{16b}$$

Therefore, constraints are introduced to find a solution in accordance to state projection results:

$$-B_0\Delta_{M,i}C_i = \Theta_i A_i - A_0\Theta_i \tag{17a}$$
$$C_i = C_0\Theta_i - D_0\Delta_{M,i}C_i \tag{17b}$$
$$0 = B_0(I_p - \Delta_{M,i}D_i) - \Theta_i B_i \tag{17c}$$
$$D_i = D_0(I_p - \Delta_{M,i}D_i)\ . \tag{17d}$$

Using above, this leads to a solution to the model order problem of equation (15). A numerical efficient algorithm to solve the described problem is unknown to the authors so far. Hence, a rather theoretical approach based on the Kronecker product $\otimes$ is applied instead:

$$\mathcal{A}\mathcal{X}\mathcal{B} = \mathcal{C} \quad \longrightarrow \quad \Big(\mathcal{B}^T \otimes \mathcal{A}\Big)\mathrm{vec}\big(\mathcal{X}\big) = \mathrm{vec}\big(\mathcal{C}\big)\ . \tag{18}$$

The first two constraints of equation (17) are applied above, while the third and fourth are not used in the following. Using the Kronecker product approach, the set of constraints is reordered:

1. Constraint $-B_0\Delta_{M,i}C_i + A_0\Theta_i - \Theta_i A_i = 0$:

$$-\Big(C_i^T\Delta_{M,i}^T \otimes I_{n_0}\Big)\mathrm{vec}\big(B_0\big) + \Big((I_{n_i}\otimes A_0) - (A_i^T \otimes I_{n_0})\Big)\mathrm{vec}\big(\Theta_i\big) = 0\ . \tag{19}$$

2. Constraint $-D_0\Delta_{M,i}C_i + C_0\Theta_i = C_i$:

$$-\Big(C_i^T\Delta_{M,i}^T \otimes I_p\Big)\mathrm{vec}\big(D_0\big) + \Big(I_{n_i}\otimes C_0\Big)\mathrm{vec}\big(\Theta_i\big) = \mathrm{vec}\big(C_i\big)\ . \tag{20}$$

Because equations (19) and (20) are defined for i, both constraints can be used multiple times. Using A_i, C_i, and $\Delta_{M,i}$ ($i = 0,\ 1,\ \ldots$), both constraints are stacked together in a *system of linear equations*

$$\begin{bmatrix} \mathrm{vec}\big(B_0\big) \\ \mathrm{vec}\big(D_0\big) \\ \mathrm{vec}\big(\Theta_1\big) \\ \mathrm{vec}\big(\Theta_2\big) \\ \vdots \end{bmatrix} = \begin{bmatrix} -C_1^T\Delta_{M,1}^T\otimes I_{n_0} & 0 & (I_{n_1}\otimes A_0)-(A_1^T\otimes I_{n_0}) & 0 & \cdots \\ -C_2^T\Delta_{M,2}^T\otimes I_{n_0} & 0 & 0 & (I_{n_2}\otimes A_0)-(A_2^T\otimes I_{n_0}) & \\ \vdots & \vdots & \vdots & \vdots & \ddots \\ 0 & -C_1^T\Delta_{M,1}^T\otimes I_p & I_{n_1}\otimes C_0 & 0 & \cdots \\ 0 & -C_2^T\Delta_{M,2}^T\otimes I_p & 0 & I_{n_2}\otimes C_0 & \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix}^{\dagger} \begin{bmatrix} 0 \\ 0 \\ \vdots \\ \mathrm{vec}\big(C_1\big) \\ \mathrm{vec}\big(C_2\big) \\ \vdots \end{bmatrix}\ . \tag{21}$$

This system of linear equations can be solved to estimate B and D of the structural reference state (e.g. by Tikhonov regularization). The described method is called *state projections for system scaling* (SP2S) and details can be found in [26].

3.3 Mechanical parameter estimation based on identified state space parameters

Using a Markov parameter approach, one may estimate mechanical properties based on continuous-time state space parameters A, B, and C [27]:

$$\hat{M} = \Big(C_0A_0^{1-m}B_0\Big)^{-1}\ , \quad \hat{K} = -\Big(C_0A_0^{-1-m}B_0\Big)^{-1}\ , \quad \hat{D} = -\hat{M}\Big(C_0A_0^{2-m}B_0\Big)\hat{M}\ . \tag{22}$$

Parameter m refers to the measurement type: Displacements $m = 0$, velocities $m = 1$, and accelerations $m = 2$.

3.4 Comparison to the mode shape based approach

Two important eigenvalue problems arise from the equation of motion in structural dynamics [28], which are briefly discussed below. To understand the real mode shape based mechanical parameter estimation problem, the eigenvalue problem

$$\big(- \bar{M}_i \omega_{i,l}^2 + \bar{K} \big) \phi_{i,l} = 0 \tag{23}$$

is shown first, which leads to real mode shapes $\Phi_i = [\phi_{i,1} \quad \phi_{i,2} \quad \ldots]$, $\Phi_i \in \mathbb{R}^{N_{dof} \times N_{dof}}$. A scaling factor α can be used to compute mass-normalized mode shapes $\bar{\phi}_l = \phi_l \alpha_l$. Based on identified real eigenvectors (e.g. by frequency domain decomposition), one needs scaled mode shapes to estimate mechanical parameters by

$$\hat{M}_i = \left[\sum_{l=1}^{n} \bar{\phi}_{i,l} \bar{\phi}_{i,l}^T \right]^{-1}, \quad \hat{K} = \left[\sum_{l=1}^{n} \frac{\bar{\phi}_{i,l} \bar{\phi}_{i,l}^T}{\omega_{i,l}^2} \right]^{-1}, \quad \hat{D} = \left[\sum_{l=1}^{n} \frac{\bar{\phi}_{i,l} \bar{\phi}_{i,l}^T}{2 \zeta_{i,l} \omega_{i,l}} \right]^{-1} . \tag{24}$$

Because real structures always have damping $\bar{D} > 0$, the eigenvalue problem in equation (23) may be generalized to

$$\begin{bmatrix} \bar{D} & \bar{M}_i \\ \bar{M}_i & 0 \end{bmatrix} \begin{bmatrix} \psi_{i,l} \\ \psi_{i,l} \lambda_{i,l} \end{bmatrix} \lambda_{i,l} + \begin{bmatrix} \bar{K} & 0 \\ 0 & -\bar{M}_i \end{bmatrix} \begin{bmatrix} \psi_{i,l} \\ \psi_{i,l} \lambda_{i,l} \end{bmatrix} = 0 \, . \tag{25}$$

The theoretical necessary number of mode shapes is doubled, hence $\Psi_i = [\psi_{i,1} \quad \psi_{i,2} \quad \ldots]$, $\Psi_i \in \mathbb{C}^{N_{dof} \times 2N_{dof}}$. This leads to *complex conjugated* eigenvalues, for i denoted by $\Lambda_i = \mathrm{diag}(\lambda_{i,1}, \lambda_{i,1}, \ldots)$ with $\lambda_{l,l+1} = -\zeta_l \omega_l \pm j \omega_l (1 - \zeta_l^2)^{0.5}$. Again a factor β may be used, which allows to determine scaled mode shapes $\bar{\psi}_l = \psi_l \beta_l$. In contrary to the mass-scaling approach, complex mode shapes can be scaled to $-45°$. Then, mechanical parameters are estimated by analysing the sum of outer products (e.g. based on SSI):

$$\hat{M}_i = \left[\sum_{l=1}^{n} \bar{\psi}_{i,l} \lambda_{i,l} \bar{\psi}_{i,l}^T \right]^{-1}, \quad \hat{K} = \left[- \sum_{l=1}^{n} \frac{\bar{\psi}_{i,l} \bar{\psi}_{i,l}^T}{\lambda_{i,l}} \right]^{-1}, \quad \hat{D} = - \sum_{l=1}^{n} \hat{M} \bar{\psi}_{i,l} \lambda_{i,l}^2 \bar{\psi}_{i,l}^T \hat{M} \, . \tag{26}$$

Several methods have been developed to scale mode shapes based on the mass perturbation technique [29–34]. To estimate mechanical parameters, an important rank problem must be considered: If $\hat{F}$ is full-rank with $n \geq p$, the inverse $\hat{F} \hat{K} = I_p$ exists. Very importantly, the rank deficient case $\hat{K} = \hat{F}^\dagger$ with $n < p$ leads to $\hat{F} \hat{F}^\dagger \neq I_p$.

4 Experimental results of a real structure

4.1 The experimental study

This section covers experimental results of mechanical parameter estimation of the laboratory structure (see figure 1b). The proof of damage localization by SP2E has been given before (see [10]). In this contribution the authors discussed several methods to estimate corresponding mechanical parameters (table 1), which will be applied below. All three methods are based on output-only measurements and mass perturbations (repetition of measurement with known additional mass Δ_M).

Abbreviation	Approach	Equation
<Kronecker>	Kronecker product based method applying state projections.	(22)
<Mode I>	Modal approach based on real eigenvectors.	(24)
<Mode II>	Modal approach employing complex eigenvectors.	(26)

Table 1: Discussed methods to estimate corresponding mechanical parameters

The experimental structure. To apply techniques described above, a cantilever arm (length $6.15\,\mathrm{m}$) in a laboratory at Leipzig University of Applied Sciences was analysed. The modular structure consists of six beam elements with $1\,\mathrm{m}$ length each (cross section IPE200, DIN EN 10 034) and were connected by bolted steel plates. Therefore, stiffness and mass alterations can be applied using additional steel plates. Using a wind excitation by wind machines (random, stationary ambient excitation), structural acceleration responses were measured in lateral direction by twelve uniaxial, piezoelectric accelerometers (equally spaced $100\,\mathrm{cm}$, measurement position $\mathrm{M}_1 \ldots \mathrm{M}_6$, see figure 3).

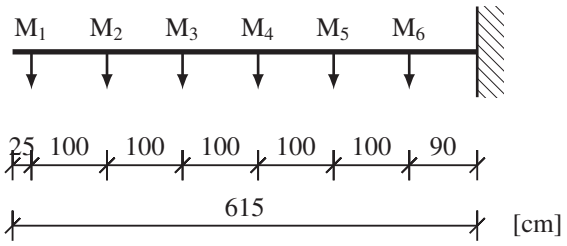

Figure 3: Mechanical system: Cantilever arm

Data processing Measured accelerations had a duration of $30\,\mathrm{min}$ ($f_s = 2\,\mathrm{kHz}$) and were analysed by Welch's method first. For a sufficient statistical population we applied approximately 215 averages by Hanning window ($L = 2^{15}$). The estimated spectrum was used to identify the output-only system: An inverse Fourier transform of spectrum S_y led to covariance matrix function R_y, which was applied in the stochastic subspace identification method. SSI results A and C eventually identified noise poles, which had been suppressed by model reduction techniques afterwards. This led to the identification of six natural frequencies (bending modes in lateral direction).

4.2 Results: Corresponding mechanical parameter estimates

4.2.1 Corresponding mass estimate

In this study all discussed methods led to a mass estimate $\hat{M}$ with a dominant main diagonal, which corresponds to the laboratory structure. Because, corresponding mass estimates are elaborate to analyze (e.g. interpretation of off-diagonal elements), the trace of $\hat{M}$ is used below.

Simulated mass [kg]

17	0	0	0	0	0
0	32	0	0	0	0
0	0	32	0	0	0

6	0.6	-0.3	-0	0.1	1.3	29
	1	2	3	4	5	6

Figure 4: Estimated corresponding mass $\hat{M}$, for abbreviations see table 1

The results of corresponding mass estimates is given in figure 4. The Kronecker product based method leads to trace$(\hat{M}) = 168.7\,\mathrm{kg}$. Besides that, both modal approaches lead by definition to symmetric parameter matrices with a similar trace of $\hat{M}$, trace$(\hat{M}) = 166.8\,\mathrm{kg}$. The experiments have been repeated two times and structural mass of the laboratory set-up has been repeatedly estimated.

4.2.2 Corresponding stiffness estimate

Stiffness $\bar{K}$ is a central parameter to describe mechanical systems (e.g. relation between external static forces and measured displacements). Corresponding stiffness estimates are given in figure 5. Although all three methods lead to a similar result in comparison to the simulated, analytical stiffness parameters, differences between simulation and real laboratory structure must be emphasized. Possible explanations may be: a) The real stiffness of laboratory clamping end is not infinite, which was presupposed in the Euler-Bernoulli beam simulation, and b) the used Euler-Bernoulli beam equation assumes a constant flexural rigidity EI, which is not exact considering the bolted steel plate connections (figure 1b).

Essentially, the corresponding mass and stiffness estimates can be evaluated similarly. In the results of all methods one may recognize a band parameter matrix. However, the Kronecker

product based method leads to a non-symmetric parameter matrix. In summary, the estimation of corresponding stiffness has been estimated successfully.

5 Conclusions

In this contribution the current progress on the development of damage localization and scaling output-only systems from a general operator notation is shown. At first damage localization based on the *state projection estimation error* (SP2E) method is briefly presented. Modifying this theory, system scaling and mechanical parameter estimation is discussed afterwards. Based on output-only measurements and a mass perturbation technique, this allows to define a mechanical parameter estimation method, which is afterwards compared to two well-known modal approaches using real and complex eigenvectors. Finally, experimental results are shown and analysed. Identifying a real mechanical system, the applicability of the novel *state projections for system scaling* (SP2S) method is confirmed. More results can be found in [9–11, 26]. Some theoretical and practical issues are still open, which should be analysed in the future. These studies may focus on an application at large-scale structures taking varying environmental and operational conditions into account.

Keywords: Piecewise periodic, guided wave, meta-structure, damage detection, unit-cell modeling, vibroacoustics

Abstract. *In this work, we develop a numerical framework for analyzing Bloch waves and their interactions with localized damages. A reduced Bloch expansion technique is first used to sub-structure the waveguide's healthy part, while a detailed finite element description of the damaged regions can be applied. A remarkable strength of this modelling technique lies in the possibility to compute the dynamic response of the overall structure (finite or infinite) subjected to harmonic or transient loads. The damage model and its location on the waveguide can both be updated with almost negligible additional computational effort. The performances compared with standard finite element analysis of a similar problem are outstanding (i.e. faster by at least 3 orders of magnitude). Two types of indicators can therefore be computed over a large number of possible waveguide-damage configurations: (i) the local transmission, reflection and conversions of Bloch waves at the interfaces of the damaged region, and (ii) the global harmonic or transient response of a loaded waveguide. This approach is used to extend the detectability of small-scaled damages in large-scaled periodic waveguides by exploiting the frequency-conversions of the Bloch scattering coefficients. These so-called 'diffusion features' are eventually used to improve sub-wavelength damage quantification and localization.*

1 INTRODUCTION

Guided wave testing (GWT) is a reliable, long-range and highly sensitive damage inspection technique. It is already well documented and extensively used for structural health assessment of various transportation, aerospace and offshore components. Although embedded GWT solutions are still seldom in the transportation industry, the upcoming IoT revolution will undoubtedly stimulate this field and replace many periodic maintenance inspections by embedded monitoring devices. On the other hand, many structural parts are becoming increasingly complex in this industry, to tackle combined needs for lightweight structures and enhanced vibroacoustic performances. Despite their many advantages, these lightweight structures exhibit various scattering behaviors (e.g. local resonances, Bragg effects, frequency-conversion) which considerably alter the broadband dispersion features and overall applicability of GWT strategies. The question addressed in this work states as follows: how can advanced waveguide modelling techniques be used to detect small damages in large-scaled periodic assemblies?

If the structure has a canonical form, explicit homogenized models can be used to describe the local dynamics (for stiffened plates, see Fossat et al. [1]). In more complex assemblies such as typical lightweight structures, numerical methods (or semi-analytical [2]) are needed, generally involving a refined finite element description of the structure and associated with model order reduction schemes [3–5] to reduce the computational cost involved. Since it was shown that that high-order guided resonances tend to have a superior sensitivity to small scaled damages [6], the selective generation of guided resonances (or any form of Floquet solutions [7, 8]) can be seen as a possible way to perform multi-modal pre-assessment of a damage's scattering properties. These indicators have already been used in axisymmetric structures (see for ex. [9–11]), however such analyses require extensive computation efforts and wave-based methodologies. This paper presents a computationally efficient modeling scheme able to predict both the wave dispersion characteristics, the finite or semi-infinite dynamic response and local damage scattering properties.

2 METHOD

2.1 Wave Finite Element Method

Consider a waveguide made of identical consecutive sub-structures of length d. Denoting $\mathbb{M}$, $\mathbb{C}$, $\mathbb{K}$ the generalized finite element mass, damping and stiffness matrices of the structure and $\mathbf{u}$ the displacements, the governing equation of the free waveguide writes:

$$(\mathbb{K} + j\omega\mathbb{C} - \omega^2\mathbb{M})\mathbf{u} = \mathbf{0}. \tag{1}$$

The Floquet theory gives the form of the solutions $U(x)$ of a linear differential equation $H(x)U(x) = 0$ where H is a periodic operator such as $H(x + d) = H(x)$. The solution can therefore be written as a superposition of Floquet vectors using a d-periodic invertible matrix $\mathbb{V}$ and a constant matrix κ as:

$$U(x) = \mathbb{V}(x)e^{\kappa x} \tag{2}$$

Defining the complex propagation constants $\lambda = e^{\kappa d}$, the Floquet theory gives the relation between the displacements of two consecutive unit-cells as $u_{i+1} = \lambda u_i$. In the direct WFEM form, the generalized dynamic stiffness matrix is decomposed into its left and right-sided DOFs located at the junction between the unit-cells, while the inner DOFs can be condensed. Introducing the Floquet theory in the force equilibrium equation yields the direct form of the dispersion

relation as the following quadratic eigenvalue problem:

$$\left(\lambda\mathbb{D}_{LR} + (\mathbb{D}_{LL} + \mathbb{D}_{RR}) + \frac{1}{\lambda}\mathbb{D}_{RL}\right)\phi = \mathbf{0}.$$

Alternatively, the dispersion relation can be written without dynamic condensation with the form:

$$\mathbf{D}(\lambda)\begin{Bmatrix}\mathbf{u}_L\\ \mathbf{u}_I\end{Bmatrix} = \begin{Bmatrix}\mathbf{0}\\ \mathbf{0}\end{Bmatrix},$$

where:

$$\mathbf{D}(\lambda)\ :\ \mathbf{D} \longrightarrow \begin{bmatrix}\mathbf{D}_{RL} & \mathbf{D}_{RI}\\ \mathbf{0} & \mathbf{0}\end{bmatrix}\frac{1}{\lambda} + \begin{bmatrix}\mathbf{D}_{RR}+\mathbf{D}_{LL} & \mathbf{D}_{LI}\\ \mathbf{D}_{IL} & \mathbf{D}_{II}\end{bmatrix} + \begin{bmatrix}\mathbf{D}_{LR} & \mathbf{0}\\ \mathbf{D}_{IR} & \mathbf{0}\end{bmatrix}\lambda.$$

The wave-mode WFEM reduction was used to reduce the computational effort (e.g. [4, 5] for details). The propagating solutions are selected among the complex solutions $\lambda = e^{-jkd}$. Solutions are discriminated into positive Ψ^+ and negative Ψ^- wave amplitudes. A wavematching procedure is used to track frequency-dependent waves and plot the dispersion curves.

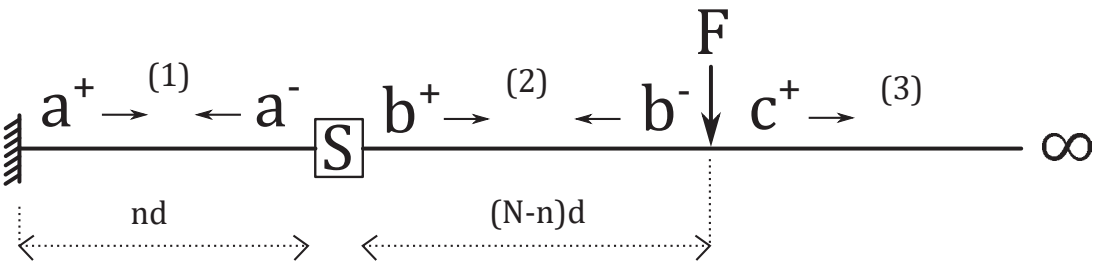

Figure 1: Semi-infinite piece-wise periodic waveguide configuration.

2.2 Diffusion properties

The presence of a coupling region, defined by the scattering matrix $\mathbb{S}$ in the waveguide results in the introduction of two coupling conditions at both sides of the coupling element. Using the above mentioned Floquet expansion gives, for any incident wave source terms (α^+, β^+) [12], the reflection and transmission coefficients as:

$$\begin{Bmatrix} R\\ T\end{Bmatrix} = -\begin{bmatrix}\mathbb{D}_{RL}\Psi^-\Lambda + (\mathbb{D}_{RR}+\mathbb{S}_{LL})\Psi^- & \mathbb{S}_{LR}\Psi^+\\ \mathbb{S}_{RL}\Psi^- & (\mathbb{S}_{RR}+\mathbb{D}_{LL})\Psi^+ + \mathbb{D}_{LR}\Psi^+\Lambda\end{bmatrix}^{-1}\begin{Bmatrix}\alpha^+\\ \beta^+\end{Bmatrix}$$

The above relation allows the computation of diffusion coefficients from a single incident wavetype for any given scattering section $\mathbb{S}$.

2.3 Forced response of the piecewise periodic structure

The following configuration is considered: the piecewise waveguide is composed of three sections as shown in Figure 1. Section 1 contains N_1 cells. It is clamped on the left side and connected to section 2 by a scattering region described by matrix $\mathbb{S}$. An external load is applied at a distance N_2 from the coupling region and defines the semi-infinite section 3. Using

the Floquet expansion, the generalized governing equation can be rewritten under the reduced form:

$$\mathcal{H} \begin{Bmatrix} \mathbf{a}^+ \\ \mathbf{a}^- \\ \mathbf{b}^+ \\ \mathbf{b}^- \\ \mathbf{c}^+ \end{Bmatrix} = \begin{Bmatrix} 0 \\ 0 \\ 0 \\ F \\ 0 \end{Bmatrix},$$

where $\mathcal{H} = \mathcal{H}(\mathbb{D}, \mathbb{S}, \Psi^+, \Psi^-, \{\Lambda^k\}_{k=[0..N]})$ is a Floquet decomposition of the dynamic stiffness matrix projected on the extremities of each waveguide section (interested readers are refered to [13] for detailed methodology). Note that the maximal dimension of this sparse linear problem is equal to the number of DOFs in a single unit-cell's edge. In general, a reduction to a few propagating and evanescent waves can provide an additional reduction of the dimension by several orders of magnitude. In the example below, the total number of DOFs in sections (1) and (2) is 100k DOFs including the scattering element. The Floquet expansion yields a reduced system of size 250.

3 APPLICATION

The methodology is then used to compute the diffusion indicators, displayed as a set of three frequency-dependent coefficients: the Transmission (T) and Reflection (R), as well as a Diffusion (D) term defined as in [12].

3.1 Description of the model

The considered waveguide is an aluminium framed structure of unit-cel's length l_x=5 cm meshed using 3D block elements and involving three different internal damages as described in fig. 2. The loading and boundary conditions are the ones of an attempted inspection of the region between the actuated region and the clamped end, considering a semi-infinite part on the other side (no reflected waves). The configuration therefore corresponds the one shown in fig. 1. The damage model is parametrized and consists in a local reduction of the stiffness on the walls of the damaged unit-cell along three possible direction (see fig. 2).

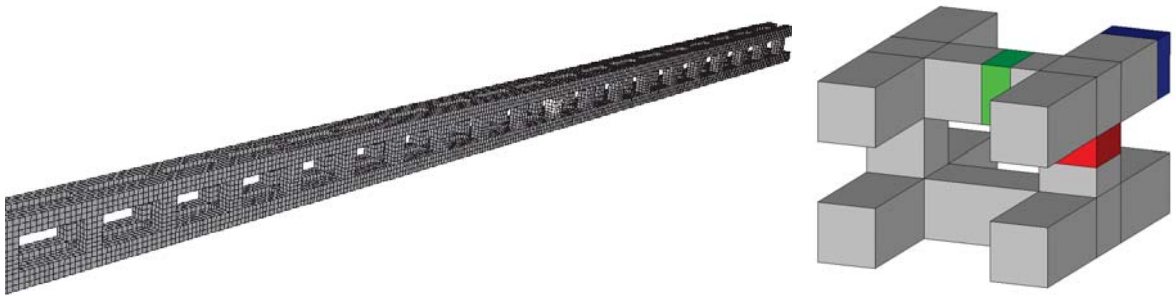

Figure 2: (a) FEM of a finite section of the framed structure. (b) Example of damage scenario along x (blue), y (green) and z (red).

3.2 Diffusion features

The diffusion of all propagating waves produced by a x-oriented damage are computed using Eq. 2.2. The dispersion curves of the first 9 propagating waves is shown in fig. 4. One

can identify the Bragg bandgap affecting most transverse waves between 8-13 kHz. The three coefficients displayed in fig. 3 over frequency for each wave indicate the expected sensitivity of the wave to a given damage. It can be assumed that the more sensitive the wave to the damage is, the more altered the overall dynamic response will be once subjected to this wavetype's loading. For a sake of clarity, the non-propagative regions (e.g. bandgaps) are hidden, based on the wave's spatial attenuation criterion (i.e. above 5% amplitude decay per unit-cell).

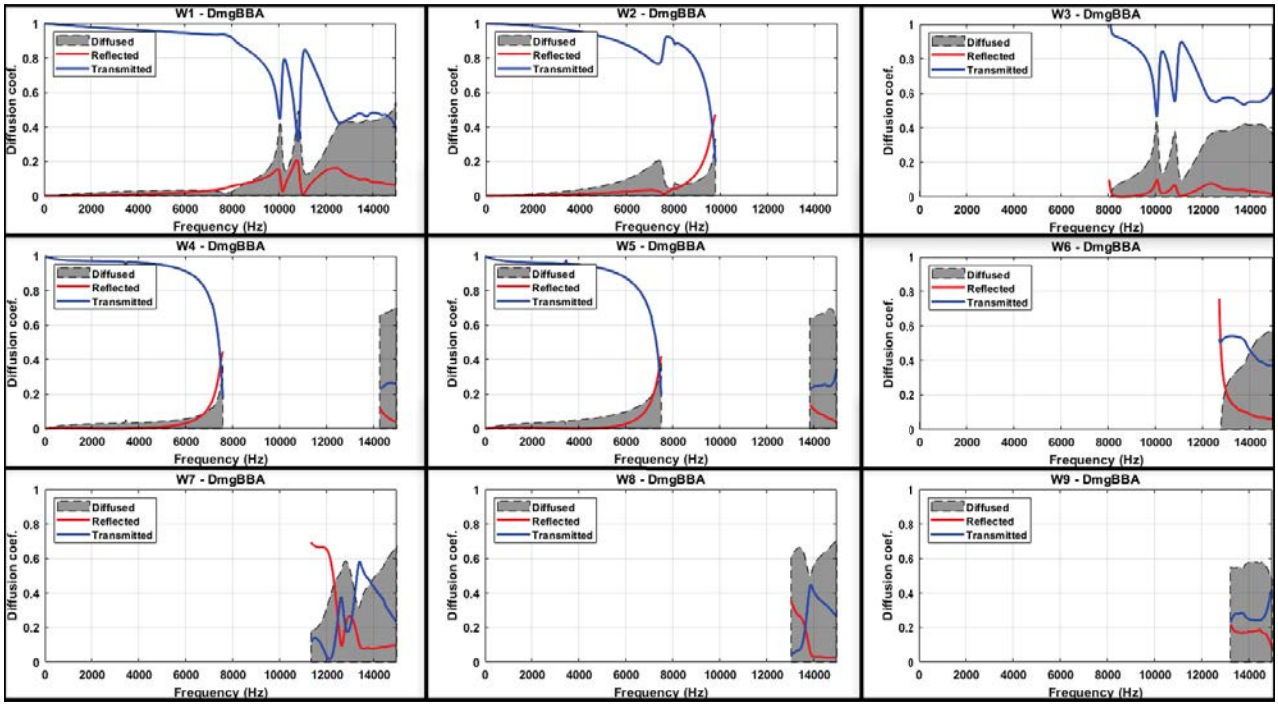

Figure 3: Transmission, Reflection, and Diffusion coefficients of all propagating waves in the considered bandwidth, for a damage of type 'longitudinal'.

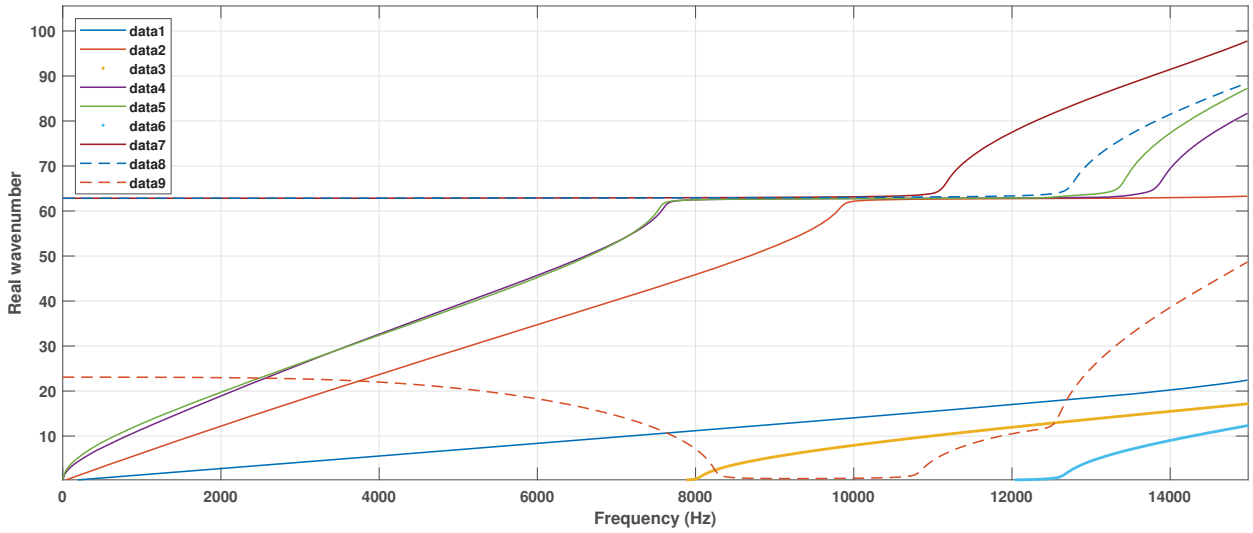

Figure 4: Dispersion curves in the framed structure.

Note that the sensitivities tend to increase close to the non-propagating regions (cut-on, Bragg, local resonances etc.). For illustration purpose, one can compare the diffusion plots of waves 5 (middle) and 7 (bottom left). It is clearly visible that wave 5 is almost insensitive to the damage, except near the bandgap, and is mainly diffused above 14 kHz. On the other hand, wave 7 cuts-on at 12 kHz but exhibits a higher reflection (above 60%) between 12 and 13 kHz.

3.3 Forced response

The hypothesis that the overall dynamic response of the semi-infinite structure will be more sensitive by applying wave 7 than wave 5 is tested in the below. In the loading region, a guided mode actuation is assumed to produce a frequency-dependent edge unit-cell forced appropriation of a selected wave. The co-localized forced response is calculated in fig. 5 for both wavetype actuations, each comparing the healthy and damaged cases. It shows that the diffusion analysis gave a fair prediction, as the dynamic response is more sensitive under normalized load to wave 7 than wave 5, despite its reduced propagative bandwidth. In addition, the reduced wave model described above gives the full dynamic response solution to a given loading case in less than a second.

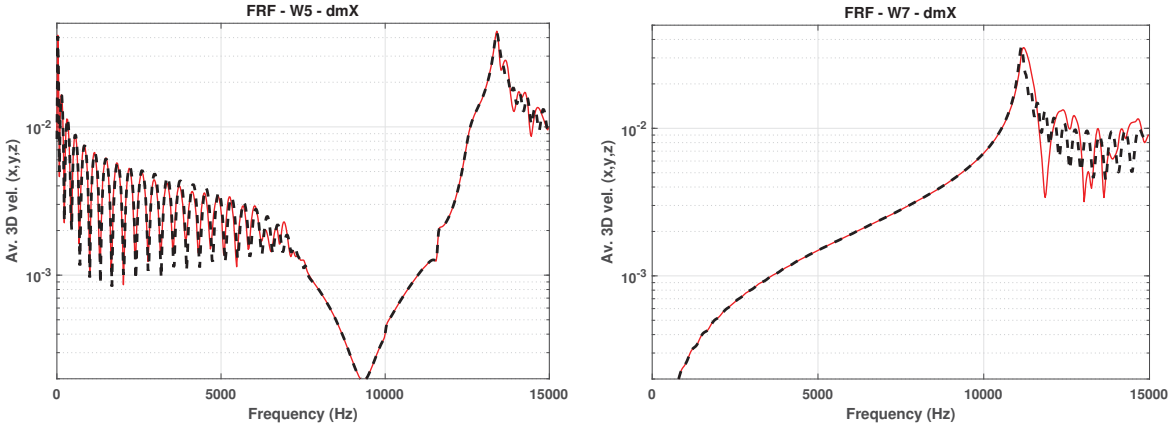

Figure 5: Forced response of the semi-infinite structure under wave-mode appropriation index 5 (a) and (7). The co-localized response is computed considering an healthy (dashed) and damaged (continuous) region with a longitudinal damage type.

4 CONCLUSIONS

The conclusions of this work can be stated as follows:

- A generalized Floquet decomposition was used to derive the dispersion characteristics, the damage scattering information and the forced response from a single unified numerical framework.
- The method was coupled with a model order reduction scheme, providing outstanding computation performances.
- These methodologies were proved of remarkable efficiency to model and predict the detectability of small-scaled damages in a framed structure using both dynamic response and diffusion analysis.

Abstract.

On April 25, 2015, a Mw 7.8 earthquake struck the Gorkha district of Kathmandu, Nepal. Several masonry structures such as temples and monuments collapsed in Patan Durbar Square. A 300-year-old two-story masonry building in Patan that is the subject of this study is about a 5-minute walk from Patan Durbar Square. Although the building did not collapse, cracks were confirmed in several places. Since the vibrational characteristics of the building had been measured prior to the Gorkha earthquake, the vibrational characteristics of the building were measured again after the Gorkha earthquake.

Since the building is two stories high, it was modelled using a two degree-of-freedom (DOF) system and structural damage was modelled as stiffness reduction of each story. Two damage identification techniques for the two DOF system were proposed which identifies stiffness reduction of each story using modal data. The first method utilises the natural frequencies of the first and second modes and mode shapes of the first mode before and after the earthquake. The second method utilises the natural frequencies and mode shapes of the first and second modes before the earthquake and the natural frequencies of the first and second mode after the earthquake. The mode shape after the earthquake is not utilised in the second technique.

Using the proposed techniques, the stiffness reduction ratio for each story was identified. A comparison of the results of the first and second techniques was conducted and the results of the second technique were superior. During the microtremor observation after the earthquake, the accelerometers were unexpectedly plated at a different location from that before the earthquake. The first technique utilises the mode shapes before and after the earthquake and the mode shapes at the different locations are different. Therefore, the second technique possibly showed better results. Based on the results of the second technique, it was estimated that the stiffness of each story was reduced about 11.5% to 15.5% due to the earthquake.

1 INTRODUCTION

In the Kathmandu Valley, there are seven World Heritage Sites, including dozens of monuments and hundreds of historic private and public buildings that were constructed in the seventeenth and eighteenth centuries. Given that the region lies within the Himalayan orogenic belt, earthquake activity is frequent. Therefore, many historic buildings have been damaged by or collapsed because of earthquakes over the centuries [1),2)]. For example, in 1934, the Bihar earthquake with a magnitude of 8 or more struck Kathmandu, destroying temples, shrines and monuments of significant cultural heritage[3),4)].

The Kathmandu Valley was designated a World Heritage Site by UNESCO in 1979. However, as industrialisation and commercialisation proceeded in this region, numerous historic masonry structures with tiled roofs and composite buildings of masonry and timber were demolished, and low-quality concrete buildings were constructed. Therefore, the Kathmandu Valley was registered in a list of endangered Cultural Heritage sites in 2003. Due to the subsequent efforts of the World Heritage Committee and associated Nepalese ministries, it was unlisted in 2007[5)]. However, efforts to protect these sites from earthquake disasters have been severely lacking.

Against this background, we conducted research to understand the seismic safety of existing historic masonry buildings in Kathmandu [6),7),8),9)]. A 300-year-old, two-story masonry building located in Jhatapol within the Patan district was selected as a target building, and its vibrational characteristics were investigated through microtremor observations in 2009[8)]. Following these researches, the M_w 7.8 Gorkha earthquake struck the region of Kathmandu on April 25, 2015. The earthquake was the most disastrous to strike Nepal since the 1934 Bihar earthquake[10),11),12)]. The total number of completely damaged buildings was determined to be 498,852, with the number of partially damaged buildings being 256,697. Among them, low-strength masonry buildings accounted for 95% of the completely damaged building (474,025) and 67.7% of the partially damaged buildings (173,867)[12)].

After the Gorkha earthquake, we visited Kathmandu to investigate structural damage in the target building, which was categorised as a low-strength masonry building. Even though several monuments and buildings in Patan Durbar Square had been damaged and some had collapsed, the target building survived the earthquake. It was difficult to evaluate the severity of damage to this building by visual inspection alone. Therefore, microtremor observations of the building were conducted in 2016 to search for changes in vibrational characteristics.

The results of this work are presented here as follows. First, the vibrational characteristics, especially the first- and second-mode natural frequencies, the shape of the first mode and the damping ratios of the first mode of the translational motion in the longitudinal and transverse directions, are evaluated for the buildings before and after the earthquake. Second, structural parameters are modelled with a two degree-of-freedom (DOF) system and an identification method for the structural parameters from these vibrational characteristics is proposed. Then, structural parameters are identified from the vibrational characteristics of the buildings before and after the earthquake. Assuming that the mass is unchanged, the structural damage due to the earthquake is estimated as the stiffness reduction of the first and second floors.

2 TARGET BUILDING

The target building is a 300-year-old, two-story brick masonry building located in Jhatapol in the Patan district. It is a public building located near Patan Durbar Square, a World Heritage Site. The distance between the epicentre and the target building is about 78 km. The distance between the target building and the United States Geological Survey (USGS) strong-motion

station (KATNP) is about 4.3 km. The peak ground accelerations at KATNP for the NS, EW and UD components are 162 gal, 155 gal and 184 gal, respectively.

Photos of the building before and after the earthquake are shown in Fig. 1. A plan view of the building is shown in Fig. 2. The building has two stories and lateral dimensions of 16.5 × 5.6 m. The heights of the lower and upper stories are 2.4 and 2.1 m, respectively. The maximum height of the building is 6.5 m. Each wall has openings, with the western wall having the largest openings. The walls are composed of mortared bricks. The roof consists of corrugated galvanised iron sheets resting on wooden beams and battens.

Figure 2: Plan view of the target building with numbered measurement locations

3 NATURAL FREQUENCIES AND MODE SHAPES BEFORE AND AFTER EARTHQUAKE

3.1 Microtremor Observation

Figure 2(a) shows the orientation of the structures and measurement locations where the accelerometers were placed. The acceleration responses were measured at Point 1 before the earthquake and at Point 2 after the earthquake as shown in Fig. 2(b). The measurements at the same locations were not possible due to human error. One accelerometer was placed on the first floor and the other accelerometer was placed on the second floor (roof floor), denoted by F1 and F2, respectively. The sampling interval of measurement data was 0.01 s. From the measured data, 10 sets of 4096 data points were extracted, and the average of their Fourier amplitudes was computed. For smoothing, the Parzen window with a frequency band of 0.4 Hz was applied.

3.2 Natural frequencies and mode shape

Figure 3 compares the Fourier amplitudes of the responses on the first and second floors in the longitudinal (x, NS) and transverse (y, EW) directions before and after the earthquake. Clear peaks can be seen at 6.87 Hz and 10.2 Hz before the earthquake and 6.43 Hz and around 9.56 Hz after the earthquake in the longitudinal direction. Clear peaks can be seen at 4.33 Hz

and 7.13 Hz before and 4.02 Hz and 6.68 Hz after the earthquake in the transverse direction. Peaks at 5.78 Hz in the transverse direction before the earthquake are torsional motion, so these were disregarded.

The mode shape is defined as the ratio of the amplitude of the first floor to the amplitude of the second floor around natural frequencies considering the shapes of the Fourier amplitudes around the natural frequencies. The shape of the first mode in the longitudinal direction then is estimated as 0.368 before and 0.367 after the earthquake. The shape of the first mode in the transverse direction is estimated as 0.269 before and 0.324 after the earthquake. The shape of the second mode before the earthquake was also read.

Comparisons of the natural frequencies of the first and second translational modes, the shape of the first translational mode and the damping ratio of the first translational mode are shown in Table 1. The natural frequencies decreased because of the earthquake by about 6.27% to 7.16%. The reduction ratio in the transverse direction was larger than that in the longitudinal direction. Assuming that the mass of the structure was unchanged by the earthquake, the decrease in the natural frequencies indicates a reduction in stiffness, i.e., the occurrence of structural damage.

4 IDENTIFICATION OF STIFFNESS REDUCTION USING FIRST AND SECOND NATURAL FREQUENCIES AND FIRST MODE SHAPE BEFORE AND AFTER EARTHQUAKE

4.1 Identification of stiffness-to-mass ratio using first and second natural frequencies and first mode shape

Since the target building has two stories, the building is modeled with a two degree-of-freedom (DOF) system as shown in Fig.4.

In this section, an identification technique of the stiffness-to-mass ratio used natural frequencies of the first and second modes and the mode shape of the first mode. This method directly identifies the stiffness-to-mass ratio of the building before and after an earthquake. By comparing the stiffness-to-mass ratio before and after the earthquake assuming that the mass is constant before and after the earthquake, structural damage is identified as stiffness reduction.

Let us assume that ω_j is the natural circular frequency and $\phi_j = \{\phi^j{}_1 \ \phi^j{}_2\}^T$ is the shape of the j-th mode. The natural circular frequency can then be obtained from the frequency f_j of the j-th mode by $\omega_j=2\pi f_j$.

ω_j and ϕ_j are the solutions of the eigenvalue problem as follows,

$$\begin{bmatrix} -m_1\omega_j^2 + k_1 + k_2 & -k_2 \\ -k_2 & -m_2\omega_j^2 + k_2 \end{bmatrix} \begin{Bmatrix} \phi_1^j \\ \phi_2^j \end{Bmatrix} = \begin{Bmatrix} 0 \\ 0 \end{Bmatrix}. \tag{1}$$

where m_i and k_i are mass and stiffness of the i-th floor. From the second equation of Eq. (1), the ratio of structural parameters can be correlated with the natural circular frequency and mode shape,

$$\frac{k_2}{m_2} = \frac{\omega_j^2}{1-(\phi_1^j/\phi_2^j)}. \tag{2}$$

In this study, the structural parameter k_2/m_1 is obtained by the natural circular frequency and mode shape of the first mode since the mode shape of the second mode is not estimated in the previous section,

$$\frac{k_2}{m_2} = \frac{\omega_1^2}{1-(\phi_1^1/\phi_2^1)}. \tag{3}$$

Next, to obtain the solution $\phi_j \neq 0$, the determinant of the matrix should be 0 in Eq. (1). Therefore,

$$m_1m_2\omega_j^4 - (m_1k_2 + m_2k_1 + m_2k_2)\omega_j^2 + k_1k_2 = 0. \tag{4}$$

Since ω_1 and ω_2 are the solutions of Eq. (4),

$$\omega_1^2 + \omega_2^2 = \frac{m_1 k_2 + m_2 k_1 + m_2 k_2}{m_1 m_2} = \frac{k_2}{m_2} + \frac{k_1}{m_1} + \frac{k_2}{m_1}, \tag{5}$$

$$\omega_1^2 \omega_2^2 = \frac{k_1 k_2}{m_1 m_2}. \tag{6}$$

By substituting Eq. (3) with Eq. (6), the structural parameter k_1/m_1 is obtained as

$$\frac{k_1}{m_1} = \omega_2^2 \{1 - (\phi_1^1 / \phi_2^1)\}. \tag{7}$$

By substituting Eqs. (3) and (7) with Eq. (5), the structural parameter k_2/m_1 is obtained as

$$\frac{k_2}{m_1} = \omega_1^2 + \omega_2^2 - \frac{\omega_1^2}{1 - (\varphi_1^1 / \varphi_2^1)} - \omega_2^2 \{1 - (\varphi_1^1 / \varphi_2^1)\} = \left\{ - \frac{\omega_1^2}{1 - (\varphi_1^1 / \varphi_2^1)} + \omega_2^2 \right\} (\varphi_1^1 / \varphi_2^1). \tag{8}$$

By taking the ratio of Eqs. (7) and (8), structural parameter m_2/m_1 is obtained as

$$\frac{m_2}{m_1} = \left[-1 + (\omega_2^2 / \omega_1^2) \{1 - (\phi_1^1 / \phi_2^1)\} \right] (\phi_1^1 / \phi_2^1). \tag{9}$$

Therefore, three independent parameters are obtained as shown in Eqs. (7), (8) and (9).

4.2 Results

By substituting the natural frequencies of the first and second translational modes and the mode shape of the first translational mode before and after damage, structural parameters were estimated as shown in Table 2.

The stiffness of the second floor, k_2, is much smaller than that of the first floor, k_1. The mass of the second floor, m_2, is also smaller than that of the first floor, m_1. This is because the ceiling of the upper floor consists of a small number of light timber beams, while the ceiling of the lower floor consists of dense timber beams and heavy bricks.

The mass ratio, m_2/m_1, remains unchanged at 0.146 for the longitudinal direction which supports the assumption that the mass was unchanged by the earthquake. However, the mass ratio was changed from 0.264 to 0.281 for the transverse direction. This is because the measurement location is different before and after the earthquake as shown in Fig.2. The measurement location for the longitudinal direction is almost the middle for both the pre- and post-earthquake conditions and this is why the mass ratio is unchanged before and after the earthquake. On the contrary, the measurement location for the transverse direction is different and this is why the mass ratio changed before and after the earthquake.

Hence, it is possible to assume that the mass is unchanged by the earthquake for the longitudinal direction. Then the reduction of stiffness, k_1 and k_2, can be obtained as the reduction of k_1/m_1 and k_2/m_1, as shown in Table 2 (a). The stiffness reduction ratios of the first and second stories were 12.0% and 12.1% for the longitudinal direction.

As stated before, the mass ratio was different before and after the earthquake for the transverse direction. However, we obtained the reduction of k_1/m_1 and k_2/m_1, as shown in Table 2 (b). The stiffness reduction ratios of the first and second stories were 18.9% and 0.856% for the transverse direction which is different from those for the longitudinal direction. One of the reasons is the different measurement location before and after the earthquake and comparing the mode shapes of the first mode at the different measurement locations is inappropriate.

Table 2 Comparison of structural parameters before and after the 2015 Gorkha earthquake

(a) Longitudinal (x, NS) direction

	Before earthquake	After earthquake	Change ratio
m_2/m_1 [-]	0.146	0.146	0.237%
k_1/m_1 [1/s^2]	2595.4	2283.6	-12.0%
k_2/m_1 [1/s^2]	429.7	377.8	-12.1%

(b) Transverse (y, EW) direction

	Before earthquake	After earthquake	Change ratio
m_2/m_1 [-]	0.264	0.281	6.31%
k_1/m_1 [1/s^2]	1467.7	1190.7	-18.9%
k_2/m_1 [1/s^2]	267.3	265.0	-0.856%

5 IDENTIFICATION OF STIFFNESS REDUCTION USING FIRST AND SECOND NATURAL FREQUENCIES MODE SHAPES BEFORE EARTHQUAKE AND FIRST AND SECOND NATURAL FREQUENCIES AFTER EARTHQUAKE

5.1 Identification of stiffness-to-mass ratio reduction using first and second natural frequencies and mode shapes before earthquake and first and second natural frequencies after earthquake

Since the measurement locations before and after the earthquake are different due to human error, it is better not to compare the mode shapes before and after the earthquake observed at different locations. Therefore, in this section, we propose a different technique. We use the natural frequencies of the first and second modes for both the pre- and post-earthquake conditions, but only use the mode shapes of the first and second modes in the pre-earthquake conditions. We do not use the mode shape in the post-earthquake conditions.

The eigenvalue problem of the model before the earthquake is written as follows.

$$(-\lambda_j[M]+[K])\{\varphi_j\}=0 \tag{10}$$

where $[M]$ is the mass matrix, $[K]$ is the stiffness matrix, λ_j and $\{\phi_j\}$ are the j-th eigenvalue and eigenvector, respectively, of the model before the earthquake. The j-th eigenvector λ_j is the square of the natural frequency ω_j.

The eigenvalue problem of the model after the earthquake is expressed as

$$\left\{(-\lambda_j-\delta\lambda_j)[M]+([K]-[\delta K])\right\}\left(\{\varphi_j\}+\{\delta\varphi_j\}\right)=0 \tag{11}$$

where $[K]$-$[\delta K]$ is the stiffness matrix before the earthquake. The j-th eigenvalue and eigenvector of the model after the earthquake are λ_j -$\delta\lambda_j$ and $\{\phi_j\}$+$\{\delta\phi_j\}$, respectively. $[\delta K]$ is the reduction of the stiffness matrix due to the earthquake, $\delta\lambda_j$ is the reduction of the j-th eigenvalue and $\{\delta\phi_j\}$ is the increment of the j-th eigenvector due to the reduction of the stiffness matrix.

Expanding Eq. (11) and disregarding higher terms yields

$$(-\lambda_j[M]+[K])\{\varphi_j\}+(\delta\lambda_j[M]-[\delta K])\{\varphi_j\}+(-\lambda_j[M]+[K])\{\delta\varphi_j\}=0 \tag{12}$$

Since the first term of Eq. (12) becomes 0 from Eq. (10), Eq. (12) becomes

$$(\delta\lambda_j[M]-[\delta K])\{\varphi_j\}+(-\lambda_j[M]+[K])\{\delta\varphi_j\}=0 \tag{13}$$

After multiplication of each term from the left by $\{\phi_j\}^T$, Eq. (13) becomes

$$\{\varphi_j\}^T(\delta\lambda_j[M]-[\delta K])\{\varphi_j\}+\{\varphi_j\}^T(-\lambda_j[M]+[K])\{\delta\varphi_j\}=0 \tag{14}$$

Since the mass and stiffness matrices are symmetric, the second term of Eq. (14) becomes

$$\begin{aligned}&\{\varphi_j\}^T(-\lambda_j[M]+[K])\{\delta\varphi_j\}=\{\varphi_j\}^T(-\lambda_j[M]^T+[K]^T)\{\delta\varphi_j\}\\&=\left\{(-\lambda_j[M]+[K])\{\varphi_j\}\right\}^T\{\delta\varphi_j\}=0^T\{\delta\varphi_j\}=0\end{aligned} \tag{15}$$

Therefore, Eq. (14) becomes

$$\{\varphi_j\}^T(\delta\lambda_j[M]-[\delta K])\{\varphi_j\}=0 \tag{16}$$

The difference of the eigenvalues can be obtained as

$$\delta\lambda_j=\frac{\{\varphi_j\}^T[\delta K]\{\varphi_j\}}{\{\varphi_j\}^T[M]\{\varphi_j\}} \tag{17}$$

The equation of motion of free vibration of the two DOF system is written as follows,

$$\begin{bmatrix}m_1 & 0\\ 0 & m_2\end{bmatrix}\begin{Bmatrix}\ddot{x}_1(t)\\ \ddot{x}_2(t)\end{Bmatrix}+\begin{bmatrix}k_1+k_2 & -k_2\\ -k_2 & k_2\end{bmatrix}\begin{Bmatrix}x_1(t)\\ x_2(t)\end{Bmatrix}=\begin{Bmatrix}0\\ 0\end{Bmatrix} \tag{18}$$

where $x_i(t)$ is the displacement response of the i-th floor. By dividing the first and second equations by m_1, Eq. (18) is rewritten as,

$$\begin{bmatrix}1 & 0\\ 0 & m_2/m_1\end{bmatrix}\begin{Bmatrix}\ddot{x}_1(t)\\ \ddot{x}_2(t)\end{Bmatrix}+\begin{bmatrix}k_1/m_1+k_2/m_1 & -k_2/m_1\\ -k_2/m_1 & k_2/m_1\end{bmatrix}\begin{Bmatrix}x_1(t)\\ x_2(t)\end{Bmatrix}=\begin{Bmatrix}0\\ 0\end{Bmatrix}. \tag{19}$$

From Eq. (19), we substitute Eq. (20) with Eq. (17)

$$[M]=\begin{bmatrix}1 & 0\\ 0 & m_2/m_1\end{bmatrix}\quad\{\varphi_i\}=\begin{Bmatrix}\varphi_1^j/\varphi_2^j\\ 1\end{Bmatrix}\quad[\delta K]=\begin{bmatrix}1 & 0\\ 0 & 0\end{bmatrix}(\delta k_1/m_1)+\begin{bmatrix}1 & -1\\ -1 & 1\end{bmatrix}(\delta k_2/m_1). \tag{20}$$

Then we obtain

$$\delta\lambda_j=\frac{\{\varphi_1^j/\varphi_2^j\quad 1\}\begin{bmatrix}1 & 0\\ 0 & 0\end{bmatrix}\begin{Bmatrix}\varphi_1^j/\varphi_2^j\\ 1\end{Bmatrix}}{\{\varphi_1^j/\varphi_2^j\quad 1\}\begin{bmatrix}1 & 0\\ 0 & m_2/m_1\end{bmatrix}\begin{Bmatrix}\varphi_1^j/\varphi_2^j\\ 1\end{Bmatrix}}(\delta k_1/m_1)+\frac{\{\varphi_1^j/\varphi_2^j\quad 1\}\begin{bmatrix}1 & -1\\ -1 & 1\end{bmatrix}\begin{Bmatrix}\varphi_1^j/\varphi_2^j\\ 1\end{Bmatrix}}{\{\varphi_1^j/\varphi_2^j\quad 1\}\begin{bmatrix}1 & 0\\ 0 & m_2/m_1\end{bmatrix}\begin{Bmatrix}\varphi_1^j/\varphi_2^j\\ 1\end{Bmatrix}}(\delta k_2/m_1) \tag{21}$$

where δk_i is the reduction in the stiffness of the i-th floors.

$$\delta\lambda_j=\frac{(\varphi_1^j/\varphi_2^j)^2}{(\varphi_1^j/\varphi_2^j)^2+m_2/m_1}(\delta k_1/m_1)+\frac{(\varphi_1^j/\varphi_2^j)^2-2(\varphi_1^j/\varphi_2^j)+1}{(\varphi_1^j/\varphi_2^j)^2+m_2/m_1}(\delta k_2/m_1) \tag{22}$$

By using the first and second eigenvalues and eigenvectors of the model before the earthquake, we obtain the correlation between the reduction of eigenvalues and the reduction of the stiffness.

$$\begin{Bmatrix}\delta\lambda_1\\ \delta\lambda_2\end{Bmatrix}=\begin{bmatrix}\dfrac{(\varphi_1^1/\varphi_2^1)^2}{(\varphi_1^1/\varphi_2^1)^2+m_2/m_1} & \dfrac{(\varphi_1^1/\varphi_2^1)^2-2(\varphi_1^1/\varphi_2^1)+1}{(\varphi_1^1/\varphi_2^1)^2+m_2/m_1}\\ \dfrac{(\varphi_1^2/\varphi_2^2)^2}{(\varphi_1^2/\varphi_2^2)^2+m_2/m_1} & \dfrac{(\varphi_1^2/\varphi_2^2)^2-2(\varphi_1^2/\varphi_2^2)+1}{(\varphi_1^2/\varphi_2^2)^2+m_2/m_1}\end{bmatrix}\begin{Bmatrix}\delta k_1/m_1\\ \delta k_2/m_1\end{Bmatrix} \tag{23}$$

By solving Eq. (23), we finally get the stiffness reduction of each floor.

$$\begin{Bmatrix} \delta k_1 / m_1 \\ \delta k_2 / m_1 \end{Bmatrix} = \begin{bmatrix} \dfrac{(\varphi_1^1 / \varphi_2^1)^2}{(\varphi_1^1 / \varphi_2^1)^2 + m_2 / m_1} & \dfrac{(\varphi_1^1 / \varphi_2^1)^2 - 2(\varphi_1^1 / \varphi_2^1) + 1}{(\varphi_1^1 / \varphi_2^1)^2 + m_2 / m_1} \\ \dfrac{(\varphi_1^2 / \varphi_2^2)^2}{(\varphi_1^2 / \varphi_2^2)^2 + m_2 / m_1} & \dfrac{(\varphi_1^2 / \varphi_2^2)^2 - 2(\varphi_1^2 / \varphi_2^2) + 1}{(\varphi_1^2 / \varphi_2^2)^2 + m_2 / m_1} \end{bmatrix}^{-1} \begin{Bmatrix} \delta\lambda_1 \\ \delta\lambda_2 \end{Bmatrix} \tag{24}$$

The necessary parameters in this technique are the mode shapes of the first and second modes before the earthquake ($\varphi_1^1 / \varphi_2^1$, $\varphi_1^2 / \varphi_2^2$), mass ratio before the earthquake (m_2 / m_1), and reduction of eigenvalues due to the earthquake ($\delta\lambda_1$, $\delta\lambda_2$). The mass ratio is estimated using the technique in the previous section and the reduction of the eigenvalue is computed from the natural frequencies before and after the earthquake.

5.2 Results

The results are shown in Table 3. The stiffness reduction of the first and second stories for the longitudinal direction is about 12.6% and 13.0%, which is almost the same as the results in the previous section. The stiffness reduction of the first and second stories for the transverse direction is about 11.5% and 15.5%, which is different from the results in the previous section. In the previous section, the stiffness reduction ratio for the longitudinal and transverse directions differs significantly which is perplexing. Therefore, the result of this section provides a better solution.

Table 3 Comparison of structural parameters before and after the 2015 Gorkha earthquake

(a) Longitudinal (*x*, NS) direction

	Before earthquake	Reduction after earthquake	Change ratio
k_1/m_1 [1/s^2]	2595.4	327.8	−12.6%
k_2/m_1 [1/s^2]	429.7	55.7	−13.0%

(b) Transverse (*y*, EW) direction

	Before earthquake	Reduction after earthquake	Change ratio
k_1/m_1 [1/s^2]	1467.7	169.3	−11.5%
k_2/m_1 [1/s^2]	267.3	41.4	−15.5%

6 CONCLUSIONS

This paper presented a study of a two-story historic masonry building in the Patan district of Kathmandu that survived the 2015 Gorkha earthquake. Since the vibrational characteristics of the building had been measured before the earthquake (in 2009), microtremor observations were conducted after the earthquake (in 2016), then vibrational characteristics such as natural frequencies and mode shape could be compared before and after the earthquake.

The natural frequencies of the first and second translational modes decreased by 6.27% and 6.28% in the longitudinal direction and by 7.16% and 6.31% in the transverse direction, indicating that damage had occurred.

The translational motion of the building was modeled by a two degree-of-freedom system, and an identification method for the stiffness-to-mass ratio based on the first and second natural frequencies and first mode shape was proposed. Through the application of the proposed identification method, structural parameters were identified, and the stiffness of the first and second stories decreased by 12.0% and 12.1% in the longitudinal direction and by 18.9% and 0.856% in the transverse direction. The stiffness reduction in the transverse direction is differ-

ent from that in the longitudinal direction because of the use the mode shapes observed at the different measurement locations before and after the earthquake.

Therefore, the technique using only mode shapes before the earthquake was proposed. Through the application of the second proposed identification method, the stiffness reduction of the first and second stories for the longitudinal direction is about 12.6% and 13.0% which is almost the same as the results in the first proposed method. The stiffness reduction of the first and second stories for the transverse direction is about 11.5% and 15.5%.

Although the target building did not collapse during the M_w 7.8 Gorkha earthquake, one should not assume that the building could survive another earthquake of the same magnitude. The stiffness of the building was reduced about 11.5% to 15.5% which is quite a large reduction.

ACKNOWLEDGEMENTS

The authors deeply thank the late Prof. Hitoshi Taniguchi for his kind encouragement and warming support during the research.

Abstract. *This work has the ambition generate an algorithm able to clearly identify buried antipersonnel mines from GPR data acquisitions. The algorithm is generated as a combination of a convolutional neural network (CNN) and a symbolic data analysis (SDA) process. The CNN is a powerful tool to automatically detect buried objects with even small metal content; the SDA reduces the probability of false positives, i.e. objects identified as mines, even though they are not and has the great advantage of not requiring a predefined dataset. Experimental campaign, conducted on real terrain, has proven the validity of the presented algorithm.*

1 INTRODUCTION

With more than 90 million mines spread in more than 10 countries all over the world, the demining problem is far to be solved. Despite the ban produced by the Ottawa Treaty in 1997, mines still contaminate several countries. The number of victims overcomes 6000 per year including children. More than human lives also the agricultural sector and the economic development of those countries are at stake. Public health costs, psychological effects as post-traumatic stress disorder and depression represent the major example of the produced social impact. Military forces and humanitarian volunteers devote their efforts to mine detection, and to demining. Trained animals, metal detectors and mechanical devices are the most employed strategies. However, they can be excessively time-consuming and expensive, and, as they might fail at detecting all the mines, they can be dangerous. Advanced sensors have been introduced as possible solutions to this problem, as Ground Penetrating Radar (GPR) [1], tomography [2, 3] and X-rays [4], in addition to the more conventional infrared [5], metal detector [6], acoustic waves [7, 8], ultrasounds [9, 10]. Among these technologies, the GPR has often been introduced in subsoil investigations, given its enhanced ability to discriminate even small metal fragments [11]; besides, its least invasiveness, safety and speed mark it as a rather perfect tool for mine clearance exploration and UXOs (unexploded ordnance) detection [12]. Despite the practical advantages, mine detection via GPR is often affected by clutter contamination due to antenna coupling, ground reflection, and other possibly hidden objects [13], which harm the easy implementation of an automatic detection procedure. The clutter phenomenon is here mainly related to the ground reflections: the magnitude of the ground reflections depending upon the surface roughness [14], the small metal content of antipersonnel mines and the modest depth of burial generate a signature of the target hardly discernible, unless clutter mitigation methods are introduced [15].

This work, based on GPR data acquisition, is part of a larger research project, named MINOR, MINe Overall Recognition, aimed at providing the exact real-time location of antipersonnel mines. It introduces a two-step strategy combining algorithms to accurately detect the presence of a mine and tell the difference between a mine and other hidden objects. Eventually, an experimental campaign has been carried out as first attempt to validate the strategy.

2 MINE DETECTION ALGRITHMS

An offline algorithm auto-generates data to train and tune a deep learning neural network able to select those windows identified by characteristic mine reflection signature; a second algorithm based on Symbolic Data Analysis (SDA) is employed to automatically cluster the data and classify the mines from other objects. A convolutional neural network is theoretically able by itself to appropriately cluster the signals in the radargrams; however, a high accuracy level can be achieved only through an extremely broad and various database. Such database can be considered reliable only if the elements of the dataset are produced by experimental acquisitions, implying a time consuming and costly experimental campaign. SDA, being an unsupervised process, does not require a pre-established database and represents one of the most powerful tools for the reduction of false positive detection, namely objects which are not mines but identified as if they were.

2.1 Numerical data generation

Convolutional neural networks (CNN) are regularized versions of multilayer perceptrons, namely a fully connected networks where each neuron in one layer is connected to all neurons

of the following layer. The "fully-connectedness" of these networks results in a data overfitting. A CNN takes advantage of the hierarchical patterns in data and assembles more complex patterns using smaller and simpler ones; a description of the aforementioned techniques is found in [16-19].

AlexNet is an already existing CNN trained on over a million of images, able to recognize 1000 different objects. The reason of employing an existing network stands in the large amount of time and data set needed to train from scratch a new CNN. AlexNet has an input layer and an output layer constituted of 1000 output neurons for the classification and 23 hidden layers that compute convolutional processes. The application of this CNN to this context considers a first training aimed at distinguishing possible targets from free areas, clean by any buried object; indeed, the CNN has been modified so that the last layer returns only two classification outputs. For this purpose, the network has been trained so to recognize the hyperbolic shape, typical of buried objects, inside a radargram. Hence, two kind of radargrams, shown in Figure 1, have been used: one “Target”, namely a hyperbola produced by defining a detailed model of the mine in terms of geometry, dimensions and density of the composing materials, and one “Free area”, which only contains the terrain interface signal. The aspect ratio of the images is such that the dimensions of the image are proportional to the spatial grid of the experimental radargram.

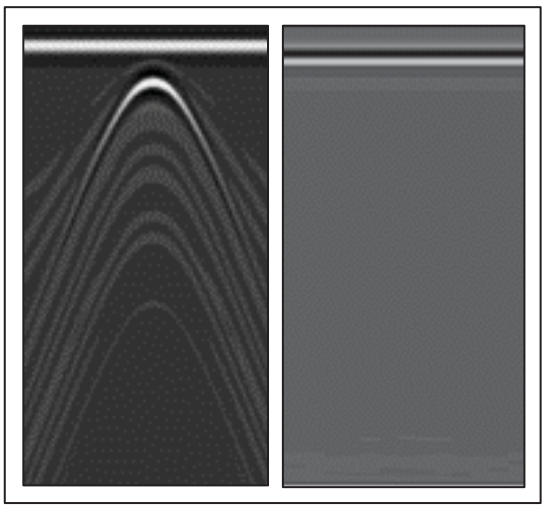

Figure 1: Simulated radargram frames for the neural network training: target on the left and free area on the right.

The training radargrams have been obtained using a Georadar simulation software, GprMax [20], a Finite-Difference Time-Domain software that emulates the propagation of an electromagnetic wave inside a medium. The medium is discretized in a grid of points and every point has assigned physical parameters of the medium (dielectric constant, magnetic permeability). The trend of the electromagnetic field is computed in time in correspondence of the grid points. A total of 2400 radargrams have been generated: 1200 with a target buried in various positions and depths, and 1200 without target, namely free area.

Once the convolutional neural network has been trained, it can be used on the radargrams referred to experimental data. The algorithm generates a window translating along the radargram; each selected frame is compared with the simulated radargram frames in Figure 1, and according to the level of match, the network returns the probability the selected portion of the radargram is actually a mine: low values of probability are related to “Free areas”, encircled in green, high values correspond to “Targets”, even though the possibility of false positive is not cancelled yet.

2.2 Symbolic Data Analysis (SDA)

Symbolic analysis belongs to the larger group of data mining techniques, and in particular of data clustering methods. In data clustering, related data are divided into homogeneous groups even with no a priori information about the groups' characteristics [21]. Clusters are generated by gathering in the same group objects with high level of similarity and separating in different groups those objects with the lowest similarity. This approach allows the identification of structures in an unlabelled dataset by organizing data into similar groups. The data can be presented as time-series or, equivalently in the space domain, as space-series. Space series, as well as time-series, are dynamic data, since each value varies with the space coordinate and time coordinate, respectively. By assuming each point of the space-series as an observation sequentially made, it is apparent how a space-series data is high dimensional.

The importance of clustering space-series datasets stands in: i) the chance to unveil the hidden information buried into space-series database; ii) space-series cluster structures are usually displayed as images; this simplifies the understanding of data clusters, the outliers and the structures.

The idea behind space-series clustering is rather straightforward [22]: in the present context of mine identification, assume D a space-series data, namely $D = \{h(x_1), \dots, h(x_s)\}$ is the set of depths at which a buried object is detected, corresponding to the set of space points $\{x_1, \dots, x_s\}$; consider a set of n space-series data $S = \{D_1, \dots, D_n\}$. Space-series clustering is an unsupervised process that redistributes the set S into a new set $G = \{G_1, \dots, G_p\}$, where similar space-series are assembled together into the *i-th* cluster G_i in respect to a suitable similarity measure. G_i is called cluster, and the original dataset S is the union of p- non overlapping clusters $S = \bigcup_{i=1}^{p} G_i$, being $G_i \cap G_k = 0 \; \forall i \neq k$.

There are several clustering algorithms [16,22], such as: hierarchical, partitioning clustering and multi-step clustering algorithm. in the present context, only hierarchical and partitioning clustering are be employed. Hierarchal clustering creates a hierarchy of clusters by adopting either agglomerative or divisive algorithms. The agglomerative algorithm, here used, considers each symbolic element of the data as a cluster and progressively combines the clusters; as a result, nested hierarchy of similar groups is created. A dendrogram, a tree-like diagram that records the sequences of merges [17], exhibits the generated groups. Despite the strong advantage of hierarchal clustering, which does not require any initial information regarding the number of clusters to be generated, this approach unveils limitations because of its quadratic computational complexity, preventing its application to large datasets. Besides, the accuracy of hierarchical algorithms is limited since they cannot adapt the clusters after merging in agglomerative method.

3 EXPERIMENTAL CAMPAIGN

The experimental campaign is devoted to the identification of objects buried in a field through the mean of a GPR sensor. The aim is the validation of the proposed algorithm. For this reason, mine prototypes have been used as well as metallic objects and other objects, to test the capability of the algorithm to find an object buried underground, and to classify the objects in two classes, namely mine and non-mine objects.

3.1 General description of the phases

Prior the GPR survey, few steps are required to prepare the terrain. At first, a metal detector has been used to check the presence of unwanted buried objects. The following decontamination ensures the GPR would acquire only the on-purpose hidden objects. The hidden objects,

targets of the GPR antenna, consists of three types of mine prototype, different in shape and dimensions, and two additional disturbances: a metal container and a brick. The targets have been set on a grid, as in Figure 2, which also shows the origin of the GPR data acquisition reference system and the axes along which data are collected. The dimensions of the grid are reported in Figure 3, together with the different depths at which the objects are buried so to estimate their influence on detection by GPR: h_1, h_2, h_3 range from 15 cm, up to 7 cm.

Figure 2: Experimental grid.

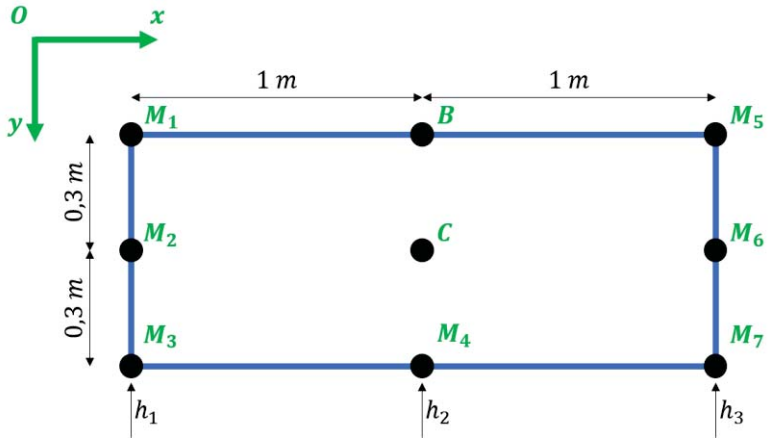

Figure 3: Grid dimensions.

The grid dimensions ensure a wide enough space for the GPR antenna to cross the area in between targets without detecting them. Accordingly, the resulting radargrams should be able to evidently display clear of targets regions and contaminated portions.

3.2 GPR Survey

After the terrain has been left at rest for few days to recreate a semi-undisturbed state, a GPR survey has started. A commercial 1.6-GHz GPR antenna, RIS MF Hi-Mod model, is used to acquire data over a clay mixed with topsoil terrain that simulates woods conditions.

Figure 4 and Figure 5 are examples of the obtained radargrams, related to the longitudinal acquisitions along the y-axis, displayed in Figure 2, of the objects buried at a depth h_1 and h_2, respectively. The green line represents the external boundary of the grid, where the origin of the reference system is set; each red line pinpoints the a priori known position of the targets and, for a resolute acquisition, should correspond to the position identified by the GPR. In

Figure 4, the three red lines correspond to the objects set at h_1 and, accordingly, denote the mines; it is worth to mention the simulated signature in Figure 1 well mimics the experimental ones. There is a clear difference, mainly due to the dimensions of the objects, between the first recorded signal, shown in Figure 4 corresponding to $Y = 0.2m$ and reerring to the largest mine in Figure 2, and the other two, which refer to mines of similar dimensions.

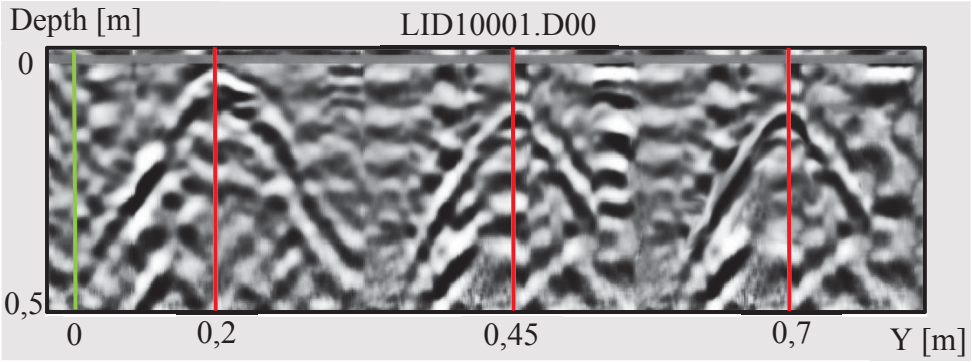

Figure 4: Radargram of the acquisition at $\boldsymbol{h_1}$.

The signatures in Figure 5 are related to the disturbance objects, except for the last one, which refers to the mine M_4 in Figure 3. The first signal is related to the brick and does not show an evident mark because of the type of material; the second identifies the metal can, and given the large amount of metal content, its hyperbola is the most clear one; eventually, the last hyperbola correspond to the mine M_4, and has a rather similar trend with respect to the last hyperbola in Figure 4, which indeed resembles the same type of mine.

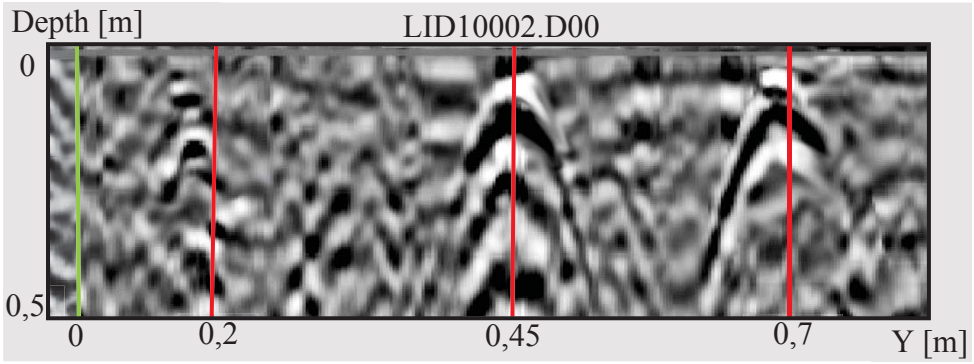

Figure 5: Radargram of the acquisition at $\boldsymbol{h_2}$.

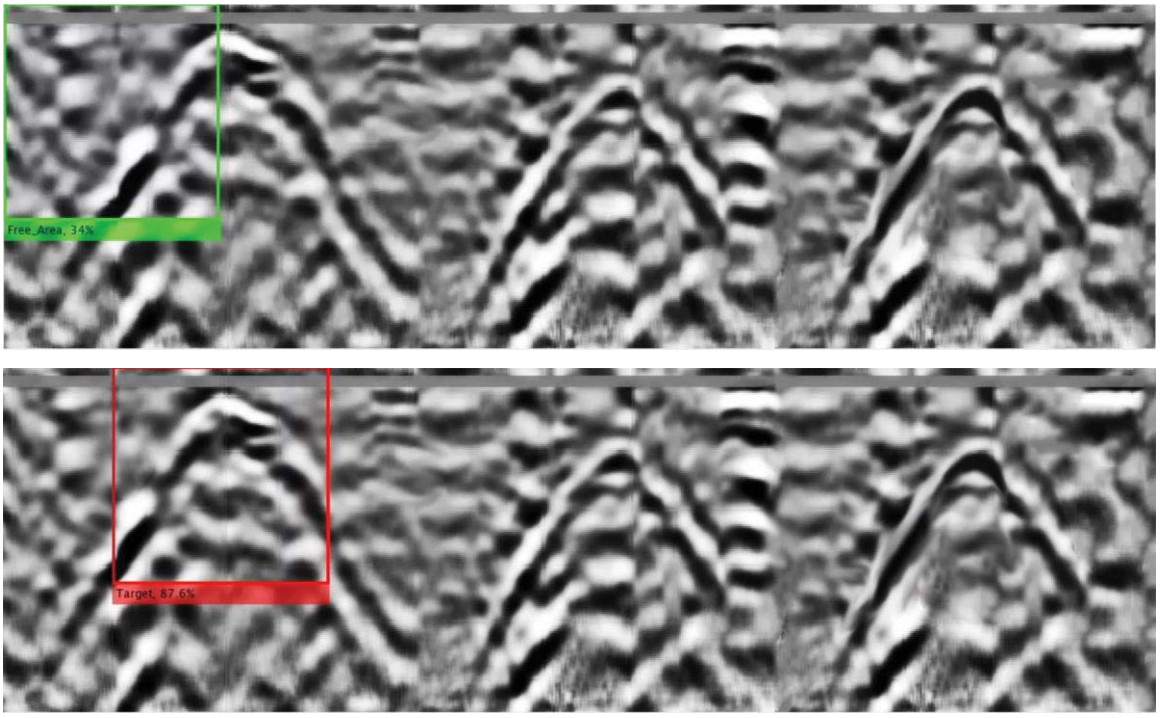
Along the first direction of acquisition, the y axis mines are well detected and provide a rather clear hyperbola, probably due to the good compromise between the dimensions of the mines, the number of metallic pieces and the depth of burial; indeed, the higher the metal content, the clearer the signature, whilst the depth depends upon the frequency of the antenna. Despite the good quality of the acquisition, the signals still appear affected by clutter noise due to the ground reflections. Such a noisy acquisition, which shows a much worse scenario than the several examples present in literature [24,25], can be easily justified. A first reason is related to the terrain composition. Most of the performed experimental campaign have been conducted in different terrains, such as sandy soil; since the resolutions is highly affected by the level of moisture [25], it is apparent how a clayish terrain has less chances to complete dry out with respect to sandy soils, especially during winter days and morning day acquisitions. This

investigation is one of the rarest examples in which a 1.6 GHz antenna is employed in real terrain conditions and, even though the terrain is closer to more realistic situations, it inevitably produces a less defined radargrams with respect to sandy soil, which represents a quite considerable simplification. Eventually, this aspect compromises the neural network training, which should rely on a vast image dataset, hardly acquirable in these conditions. A second issue refers to the employed antenna. 1.6 GHz antenna does not provide an accuracy such that shallow buried objects can be distinctly identified. Indeed, it has high resolution for an, at least, 10 cm depth. This explains the reason why the radargram in Figure 4 is more readable that the one in Figure 5, related to shallow buried objects.

4 RESULTS AND DISCUSSION

The obtained experimental radargram have been used as input for the trained CNN, which should be able to cluster contaminated areas from free areas in a realistic scenario. CNN returns, indeed, the probability the detected object is a mine: the higher the value of the probability, the more likely the target is a mine, and free area should correspond to an almost zero probability. Figure 6 shows the real time application of the proposed algorithm, which is continuously applied to the radargram h_1 in Figure 4 by the use of a suitable sliding window. Starting from the first subplot, the first part of the radargram is framed in a window and processed by CNN, which returns a low probability, of about 34%, of finding a mine. When the window slides rightwards and its position corresponds to the mine position, the probability increases, up to a value of 88 % as in the second subplot; then, when the window progressively overcomes the mine, the probability decreases again.



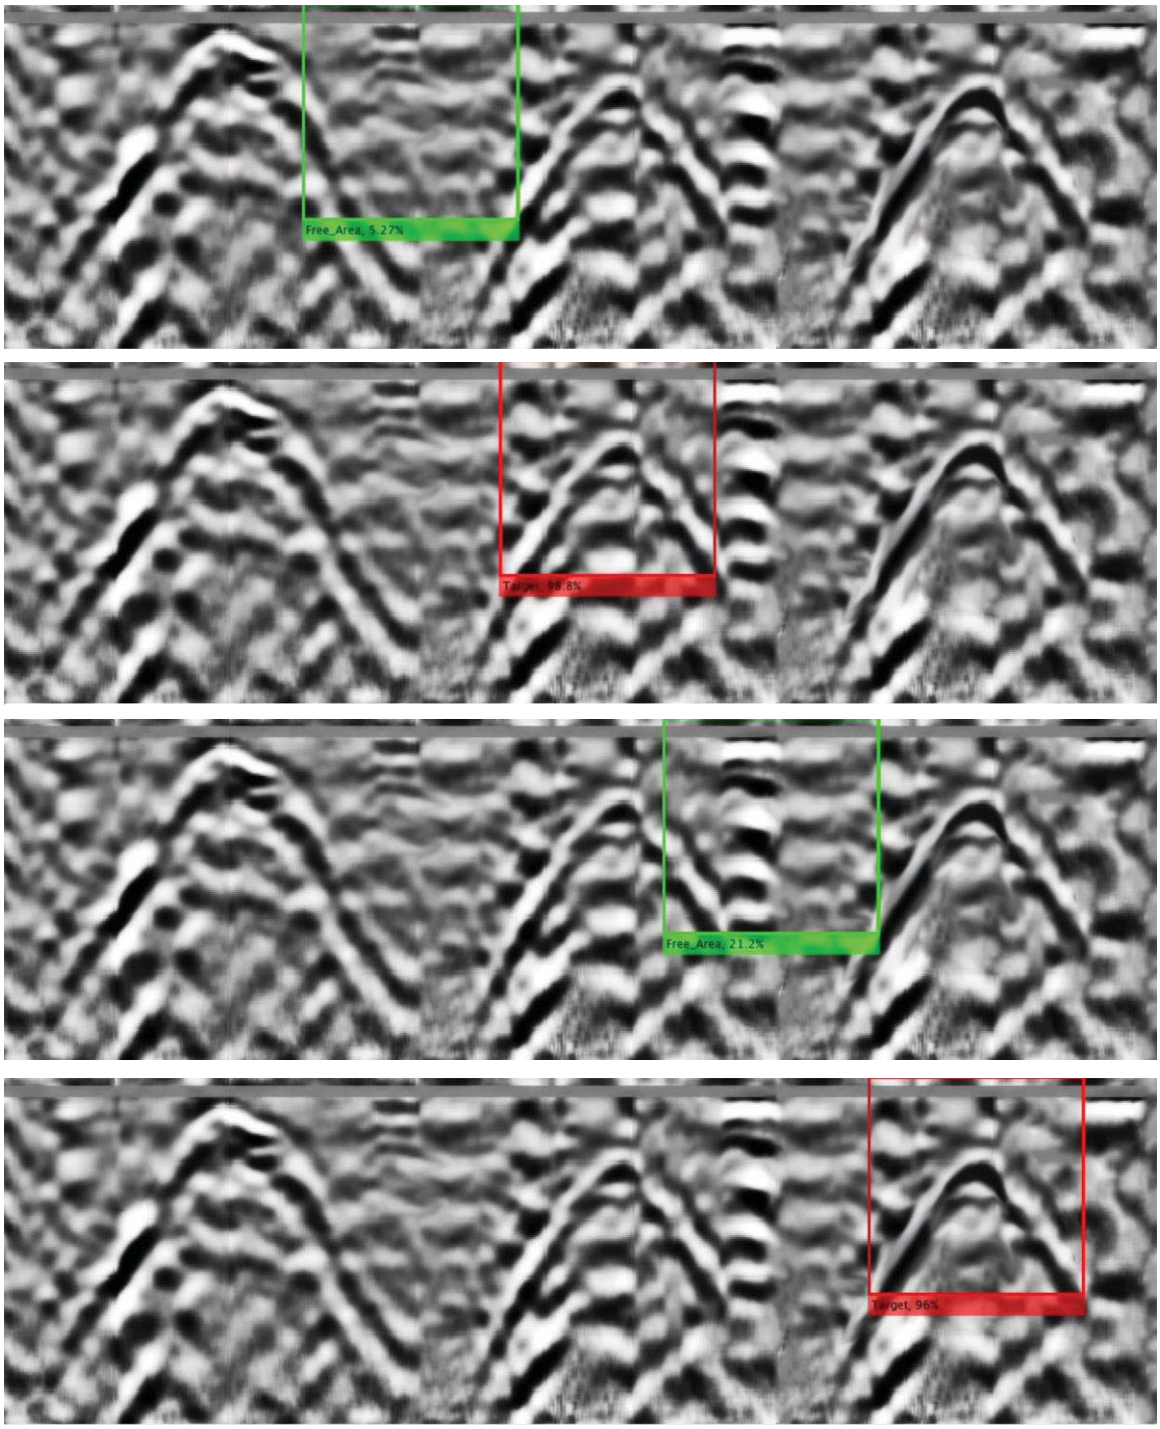


Figure 6: Target estimation of $\boldsymbol{h_1}$ radargram resulting from the neural network clustering.

Figure 7 shows the probability curve generated in output by CNN corresponding to the acquisition h_1 and confirms the reliability of the presented identification procedure.

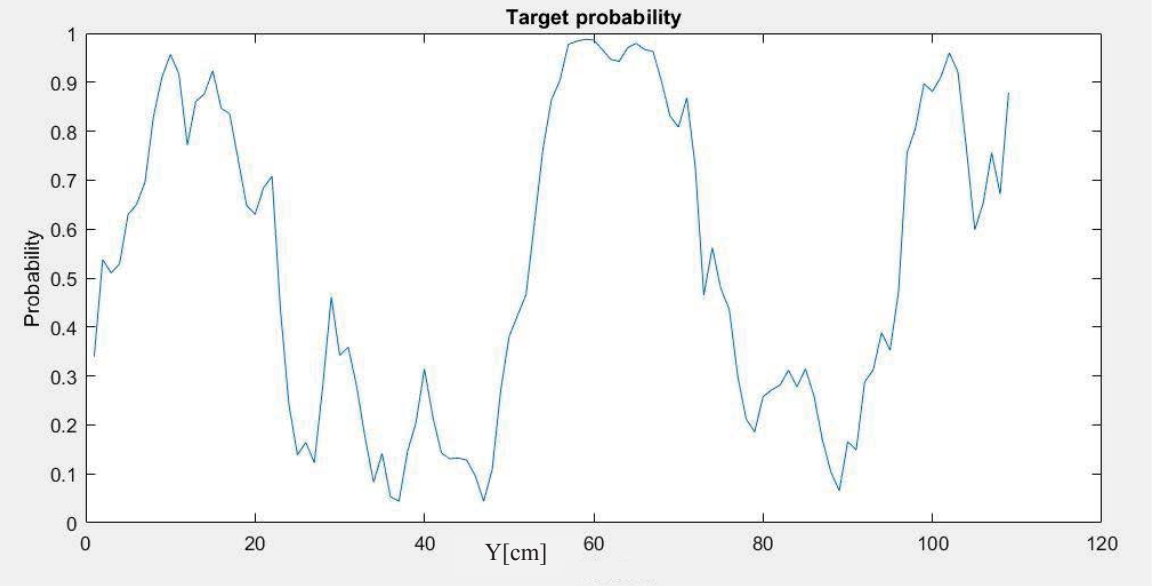

Figure 7: Probability trend corresponding to the $\boldsymbol{h_1}$ acquisition.

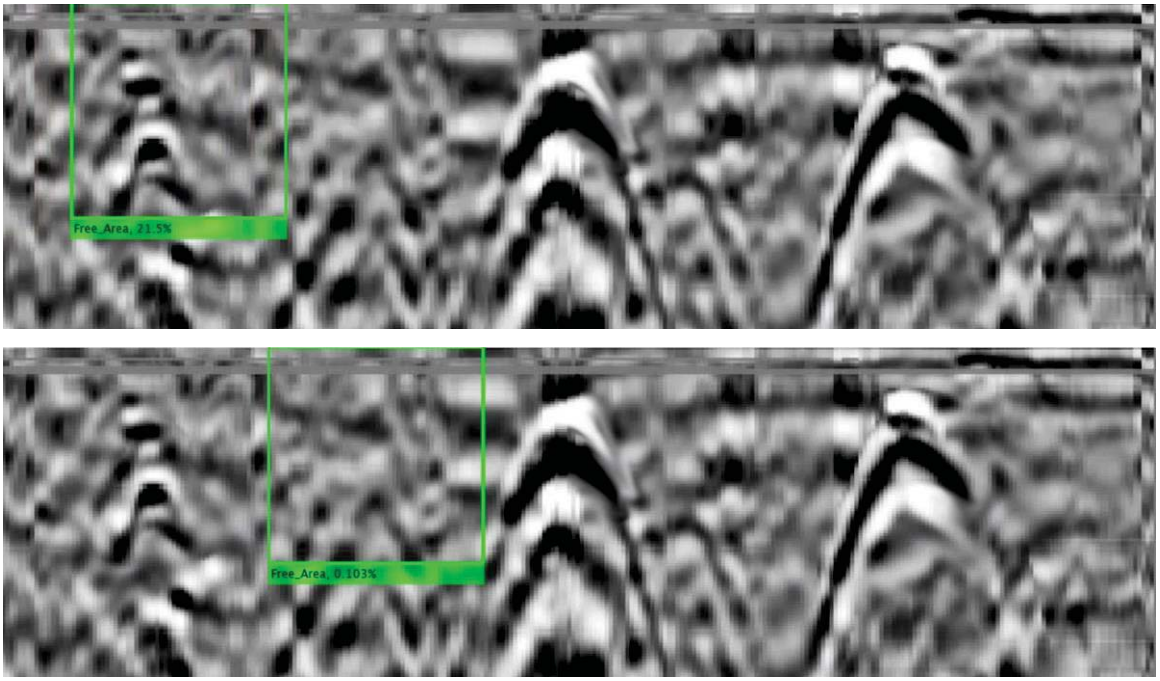
Figure 8, analogously to Figure 6, presents the result of the identification algorithm, regarding the acquisition at the depth h_2. Two main aspects are highlighted: i) as shown by the first subplot, the signal related to the brick is not associate to a target and the region is considered as "Free area", with a probability of mine detection of only 21%; ii) on the other hand, the can, given the large amount of metallic parts, is classified as mine, with an extremely high probability of more than 98%, as in the third subplot. This implies the identification algorithm is properly able to cluster "Free areas" and non-metallic objects; however, it is not sufficiently trained to distinguish, among metallic objects, those that are mines. For this purpose, the SDA algorithm must be introduced, even though it is still under test.



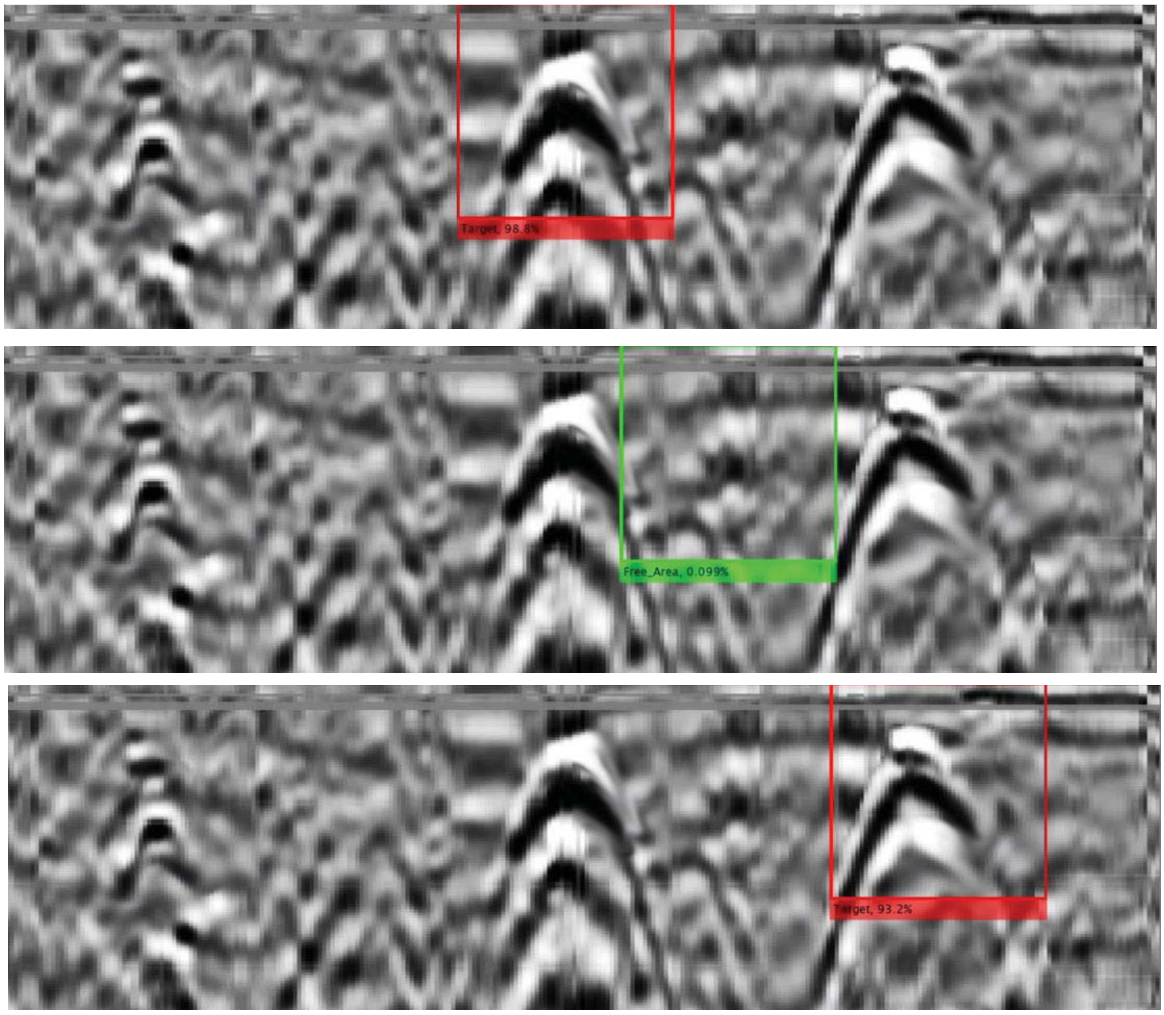


Figure 8: Target estimation of $\boldsymbol{h_2}$ radargram resulting from the neural network clustering.

5 CONCLUSIONS AND FUTURE PERSPECTIVES

The presented work has the ambition generate an algorithm able to clearly identify buried antipersonnel mines from GPR data acquisitions. The algorithm is generated as a combination of a convolutional neural network and a symbolic data analysis process. Despite the experimental measurements are affected by a high level of clutter noise, the two-step algorithm well distinguishes "Free areas" and non-metal objects from mine-like targets. The chance to reduce the probability of false positives, i.e. objects identified as mines, even though they are not, is handled through the SDA, which has the great advantage of not requiring a predefined dataset, but that is still under test.

Part of a larger research project, named MINOR, MINe Overall Recognition, aimed at providing the exact real-time location of antipersonnel mines, the algorithm has shown to be a powerful tool to automatically detect buried objects with even small metal content.

Keywords: Nonlinear systems, System identification, Lie symmetries, Observability, Structural Health Monitoring.

Abstract. *This work investigates the use of Lie symmetries for assessing and improving the observability of dynamical systems under examined sensor setups. The framework of Lie symmetry is extended to account for unmeasured and hence unknown inputs. An efficient algorithm is developed to calculate the translation and scaling symmetries of nonlinear systems with unknown inputs. The use of the algorithm to assess the observability of a given nonlinear system is demonstrated, i.e. in theory whether it would be successful to identify the dynamic states, the parameters and the unknown inputs of the system from given measurements. The work further shows the potential application of the calculated symmetries for transforming the model of an unobservable system to an equivalent model with a minimum number of unobservable states and unknown inputs. The proposed method and algorithm are illustrated on the observability properties of a dynamical system with a Bouc-Wen nonlinearity.*

1 Introduction

During a system identification campaign, a priori observability analysis of a dynamical system [1, 2] is used to predict whether it is feasible to infer the state variables and parameters of the system from a given set of input-output measurements [3, 4, 5]. Recent developments of novel identification methods such as [6, 7, 8, 9] allow for estimating the unmeasured and hence unknown inputs of a system reliably as well as its state variables and parameters. To meet the demand of observability analysis when invoking such identification methods, the Observability Rank Condition (ORC) [3] was extended to alleviate the constraint that all inputs need to be measured [10, 11]. Recently the authors achieved efficient automated observability testing of large linear systems with unknown parameters [12], relaxing the significant computational constraints of the default implementations of the ORC.

It has been found in [4, 5, 13, 14] that the observability properties of a system are closely associated with the existence of Lie symmetries in the system. Symmetry was first introduced by Lie [15, 16] to define a way of variable transformations that leaves differential equations invariant. Sedoglavic [4, 5] used the concept of Lie symmetry for dynamical systems with fully known inputs and output measurements, and demonstrated the connections between symmetry and observability. The computational framework of Lie symmetry was explored in [4, 17, 18, 14], resulting in methods for the efficient calculations of certain types of Lie symmetries for a given system.

In this work, the concept of Lie symmetry and the corresponding computational framework are further used and extended for nonlinear systems with partially measured inputs, i.e. where some or potentially all of the inputs are unmeasured. The occurring method, and consequently algorithm, can be used as an alternative tool to assess the observability of such systems. Furthermore, the work illustrates that, relying on the results of symmetries, an unobservable dynamical model can be transformed to an equivalent model with a minimum number of unobservable states and unknown inputs. Such a model, either through the use of a minimal set of assumptions or through re-defining a new state vector of reduced length, can lead to a fully observable model. The proposed method of model transformation will potentially find useful applications in improving the observability and identifiability of dynamical systems under examined sensor setups. In the end of the paper, the proposed algorithm and the idea of model transformation are illustrated through a carefully chosen example.

2 Lie symmetries of nonlinear systems with unknown inputs

This work focuses on nonlinear systems with unknown inputs that can be generally written in the following state space representation:

$$\begin{aligned} \dot{\mathbf{x}} &= \mathbf{f}(\mathbf{x}, \mathbf{u}, \mathbf{w}) \\ \mathbf{y} &= \mathbf{h}(\mathbf{x}, \mathbf{u}, \mathbf{w}) \end{aligned} \tag{1}$$

where $\mathbf{x} = [x_1, x_2, ..., x_n]$ denotes the augmented state vector [1] containing both the dynamic states and the time-invariant parameters of the underlying system. $\mathbf{w} = [w_1, w_2, ..., w_m]$ denotes the unmeasured and hence unknown inputs, $\mathbf{u} \in \mathbb{R}^l$ the vector of measured inputs and $\mathbf{y} \in \mathbb{R}^p$ the vector of output measurements. Assume system (1) contains r groups of Lie symmetries. The $i^{th}(1 \leq i \leq r)$ group of Lie symmetries of system (1) is a one-parameter, $\epsilon_i \in \mathbb{R}$, group of transformations:

$$\begin{aligned} {}^i\boldsymbol{\phi}_{\mathbf{x}}(\mathbf{x}, \mathbf{w}, \epsilon_i) &= [{}^i\phi_{x,1}, {}^i\phi_{x,2}, ..., {}^i\phi_{x,n}] \\ {}^i\boldsymbol{\phi}_{\mathbf{w}}(\mathbf{x}, \mathbf{w}, \epsilon_i) &= [{}^i\phi_{w,1}, {}^i\phi_{w,2}, ..., {}^i\phi_{w,m}] \end{aligned} \tag{2}$$

where the $j^{th}(1 \leq j \leq n)$ component of ${}^i\boldsymbol{\phi}_{\mathbf{x}}$, i.e. ${}^i\phi_{x,j}$, is a Lie symmetry of the j^{th} component of $\mathbf{x}$, i.e. x_j, and it is an analytic funtion of $\mathbf{x}$, $\mathbf{w}$ and the real constant parameter ϵ_i. Similarly, ${}^i\phi_{w,j}(1 \leq j \leq m)$ is a Lie symmetry of w_j and it is also an analytic funtion of $\mathbf{x}$, $\mathbf{w}$ and ϵ_i. A fundamental property of Lie symmetries is that such group of transformations of $\mathbf{x}$ and $\mathbf{w}$ fulfills the equations of system (1) leaving the measured inputs and the output measurements unchanged, i.e.:

$$\begin{aligned} {}^i\dot{\boldsymbol{\phi}}_{\mathbf{x}} &= \mathbf{f}({}^i\boldsymbol{\phi}_{\mathbf{x}}, \mathbf{u}, {}^i\boldsymbol{\phi}_{\mathbf{w}}) \\ \mathbf{y} &= \mathbf{h}({}^i\boldsymbol{\phi}_{\mathbf{x}}, \mathbf{u}, {}^i\boldsymbol{\phi}_{\mathbf{w}}) \end{aligned} \tag{3}$$

where it should be noted that the functions $\mathbf{f}$ and $\mathbf{h}$ between equations (1) and (3) remain the same. Further based on Lie's First Fundamental Theorem [15, 16], the following differential equations hold with known initial conditions of ${}^i\boldsymbol{\phi}_{\mathbf{x}}$ and ${}^i\boldsymbol{\phi}_{\mathbf{w}}$:

$$\begin{aligned} \frac{\partial {}^i\boldsymbol{\phi}_{\mathbf{x}}}{\partial \epsilon_i} &= {}^i\boldsymbol{\xi}_{\mathbf{x}}({}^i\boldsymbol{\phi}_{\mathbf{x}}, {}^i\boldsymbol{\phi}_{\mathbf{w}}), \quad {}^i\boldsymbol{\phi}_{\mathbf{x}}(\mathbf{x}, \mathbf{w}, 0) = \mathbf{x} \\ \frac{\partial {}^i\boldsymbol{\phi}_{\mathbf{w}}}{\partial \epsilon_i} &= {}^i\boldsymbol{\xi}_{\mathbf{w}}({}^i\boldsymbol{\phi}_{\mathbf{x}}, {}^i\boldsymbol{\phi}_{\mathbf{w}}), \quad {}^i\boldsymbol{\phi}_{\mathbf{w}}(\mathbf{x}, \mathbf{w}, 0) = \mathbf{w} \end{aligned} \tag{4}$$

where ${}^i\boldsymbol{\xi}_{\mathbf{x}}$ and ${}^i\boldsymbol{\xi}_{\mathbf{w}}$ are analytic functions. $\frac{\partial {}^i\boldsymbol{\phi}_{\mathbf{x}}}{\partial \epsilon_i}\big|_{\epsilon_i=0} = {}^i\boldsymbol{\xi}_{\mathbf{x}}(\mathbf{x}, \mathbf{w})$ and $\frac{\partial {}^i\boldsymbol{\phi}_{\mathbf{w}}}{\partial \epsilon_i}\big|_{\epsilon_i=0} = {}^i\boldsymbol{\xi}_{\mathbf{w}}(\mathbf{x}, \mathbf{w})$ are called the infinitesimals of the Lie group of transformations.

3 Computations of translation and scaling Lie symmetries

In this section, the computational framework of Lie symmetries of system (1) is derived by extending the works in [18, 13] to account for the existence of the unmeasured inputs. The symmetry computation relies on setting up a system of differential equations whose solution provides the information of ${}^i\boldsymbol{\xi}_{\mathbf{x}}$ and ${}^i\boldsymbol{\xi}_{\mathbf{w}}$ appearing in equations (4). The first differential equation of the system is derived starting from the equation:

$$\frac{\partial(\frac{d^i\boldsymbol{\phi}_{\mathbf{x}}(\mathbf{x},\mathbf{w},\epsilon_i)}{dt})}{\partial \epsilon_i} = \frac{d(\frac{\partial^i\boldsymbol{\phi}_{\mathbf{x}}(\mathbf{x},\mathbf{w},\epsilon_i)}{\partial \epsilon_i})}{dt} \tag{5}$$

Equation (5) is proved to hold for all realizations of $\mathbf{x}$, $\mathbf{w}$ and ϵ_i in Appendix A. The second differential equation is derived based on the property that the measurements remain unchanged with respect to any realization of the value of ϵ_i, and therefore:

$$\frac{d\mathbf{y}}{d\epsilon_i} = \mathbf{0} \tag{6}$$

Applying the chain rule to equations (5) and (6) yields:

$$\begin{cases} \frac{\partial \mathbf{f}}{\partial {}^i\boldsymbol{\phi}_{\mathbf{x}}} {}^i\boldsymbol{\xi}_{\mathbf{x}} + \frac{\partial \mathbf{f}}{\partial {}^i\boldsymbol{\phi}_{\mathbf{w}}} {}^i\boldsymbol{\xi}_{\mathbf{w}} = \frac{\partial {}^i\boldsymbol{\xi}_{\mathbf{x}}}{\partial {}^i\boldsymbol{\phi}_{\mathbf{x}}}\mathbf{f} + \frac{\partial {}^i\boldsymbol{\xi}_{\mathbf{x}}}{\partial {}^i\boldsymbol{\phi}_{\mathbf{w}}}\frac{d^i\boldsymbol{\phi}_{\mathbf{w}}}{dt} \\ \frac{\partial \mathbf{h}}{\partial {}^i\boldsymbol{\phi}_{\mathbf{x}}} {}^i\boldsymbol{\xi}_{\mathbf{x}} + \frac{\partial \mathbf{h}}{\partial {}^i\boldsymbol{\phi}_{\mathbf{w}}} {}^i\boldsymbol{\xi}_{\mathbf{w}} = \mathbf{0} \end{cases} \tag{7}$$

where $\mathbf{f}$ and $\mathbf{h}$ correspond to the functions in (3). It is noted that equations (7) hold for any realization of ϵ_i including $\epsilon_i = 0$. Evaluating equations (7) at $\epsilon_i = 0$ leads to:

$$\begin{cases} \frac{\partial \mathbf{f}}{\partial \mathbf{x}} {}^i\boldsymbol{\xi}_{\mathbf{x}} + \frac{\partial \mathbf{f}}{\partial \mathbf{w}} {}^i\boldsymbol{\xi}_{\mathbf{w}} = \frac{\partial {}^i\boldsymbol{\xi}_{\mathbf{x}}}{\partial \mathbf{x}}\mathbf{f} + \frac{\partial {}^i\boldsymbol{\xi}_{\mathbf{x}}}{\partial \mathbf{w}}\frac{d\mathbf{w}}{dt} \\ \frac{\partial \mathbf{h}}{\partial \mathbf{x}} {}^i\boldsymbol{\xi}_{\mathbf{x}} + \frac{\partial \mathbf{h}}{\partial \mathbf{w}} {}^i\boldsymbol{\xi}_{\mathbf{w}} = \mathbf{0} \end{cases} \tag{8}$$

where $\mathbf{f}$ and $\mathbf{h}$ correspond to the functions in (1). Analytically solving the system of equations (8) yields ${}^{i}\boldsymbol{\xi}_{\mathbf{x}}(\mathbf{x},\mathbf{w})$ and ${}^{i}\boldsymbol{\xi}_{\mathbf{w}}(\mathbf{x},\mathbf{w})$, and the Lie's First Fundamental Theorem ensures ${}^{i}\boldsymbol{\xi}_{\mathbf{x}}(\mathbf{x},\mathbf{w})$ and ${}^{i}\boldsymbol{\xi}_{\mathbf{w}}(\mathbf{x},\mathbf{w})$ contain the essential information for characterizing ${}^{i}\boldsymbol{\xi}_{\mathbf{x}}({}^{i}\boldsymbol{\phi}_{\mathbf{x}},{}^{i}\boldsymbol{\phi}_{\mathbf{w}})$ and ${}^{i}\boldsymbol{\xi}_{\mathbf{w}}({}^{i}\boldsymbol{\phi}_{\mathbf{x}},{}^{i}\boldsymbol{\phi}_{\mathbf{w}})$. Subsequently solving equations (4) allow for obtaining the group of Lie symmetries ${}^{i}\boldsymbol{\phi}_{\mathbf{x}}$ and ${}^{i}\boldsymbol{\phi}_{\mathbf{w}}$.

In general, obtaining the analytical solution of the above system of differential equations is challenging if no assumptions are made for the symmetries [18]. However, if ${}^{i}\boldsymbol{\phi}_{\mathbf{x}}$ and ${}^{i}\boldsymbol{\phi}_{\mathbf{w}}$ are assumed to be certain types of symmetries, such as translations and scalings, the system of differential equations can be solved automatically and efficiently. Section 3.1 and 3.2 discuss in detail the efficient computations of one-parameter translation and scaling types of symmetries of system (1). It is further assumed in the following sections that all the symmetries occuring in the system are related to translation and scaling symmetries and their combinations. This simplifying assumption is often satisfied for a wide range of real world engineering systems. Other types of Lie transformations not studied in this work include affine, quadratic, Mobius and some more general higher-order polynomial symmetries investigated in [18, 14] for systems with fully measured inputs. Efficient computations of those types of symmetries are potentially also available for the system described in (1) and will be the focus of future extensions of this work.

3.1 Translation symmetries

If the i^{th} group of Lie symmetries are translation symmetries then:

$$\begin{aligned}
{}^{i}\phi_{x,1} &= x_1 + \alpha_{i,1}\epsilon_i \\
&\vdots \\
{}^{i}\phi_{x,n} &= x_n + \alpha_{i,n}\epsilon_i \\
{}^{i}\phi_{w,1} &= w_1 + \alpha_{i,n+1}\epsilon_i \\
&\vdots \\
{}^{i}\phi_{w,m} &= w_m + \alpha_{i,n+m}\epsilon_i
\end{aligned} \tag{9}$$

where $\alpha_{i,1},...,\alpha_{i,n+m}$ are constant coefficients to be determined. If the expressions of ${}^{i}\boldsymbol{\phi}_{\mathbf{x}}$ and ${}^{i}\boldsymbol{\phi}_{\mathbf{w}}$ from equations (9) are used in equations (7), consequently equations (8) are simplified to:

$$\begin{cases}
\begin{bmatrix} \frac{\partial f_1}{\partial x_1} & \cdots & \frac{\partial f_1}{\partial x_n} \\ \vdots & \ddots & \vdots \\ \frac{\partial f_n}{\partial x_1} & \cdots & \frac{\partial f_n}{\partial x_n} \end{bmatrix} \begin{bmatrix} \alpha_{i,1} \\ \vdots \\ \alpha_{i,n} \end{bmatrix} + \begin{bmatrix} \frac{\partial f_1}{\partial w_1} & \cdots & \frac{\partial f_1}{\partial w_m} \\ \vdots & \ddots & \vdots \\ \frac{\partial f_n}{\partial w_1} & \cdots & \frac{\partial f_n}{\partial w_m} \end{bmatrix} \begin{bmatrix} \alpha_{i,n+1} \\ \vdots \\ \alpha_{i,n+m} \end{bmatrix} = \mathbf{0} \\
\begin{bmatrix} \frac{\partial h_1}{\partial x_1} & \cdots & \frac{\partial h_1}{\partial x_n} \\ \vdots & \ddots & \vdots \\ \frac{\partial h_p}{\partial x_1} & \cdots & \frac{\partial h_p}{\partial x_n} \end{bmatrix} \begin{bmatrix} \alpha_{i,1} \\ \vdots \\ \alpha_{i,n} \end{bmatrix} + \begin{bmatrix} \frac{\partial h_1}{\partial w_1} & \cdots & \frac{\partial h_1}{\partial w_m} \\ \vdots & \ddots & \vdots \\ \frac{\partial h_p}{\partial w_1} & \cdots & \frac{\partial h_p}{\partial w_m} \end{bmatrix} \begin{bmatrix} \alpha_{i,n+1} \\ \vdots \\ \alpha_{i,n+m} \end{bmatrix} = \mathbf{0}
\end{cases} \tag{10}$$

3.2 Scaling symmetries

If the i^{th} group of Lie symmetries are scaling symmetries then:

$$\begin{aligned} {}^{i}\phi_{x,1} &= e^{\alpha_{i,1}\epsilon_i} x_1 \\ &\vdots \\ {}^{i}\phi_{x,n} &= e^{\alpha_{i,n}\epsilon_i} x_n \\ {}^{i}\phi_{w,1} &= e^{\alpha_{i,n+1}\epsilon_i} w_1 \\ &\vdots \\ {}^{i}\phi_{w,m} &= e^{\alpha_{i,n+m}\epsilon_i} w_m \end{aligned} \tag{11}$$

where $\alpha_{i,1}, ..., \alpha_{i,n+m}$ are constant coefficients to be determined. If the expressions of ${}^{i}\boldsymbol{\phi}_{\mathbf{x}}$ and ${}^{i}\boldsymbol{\phi}_{\mathbf{w}}$ from equations (11) are used in equations (7), consequently equations (8) are simplified to:

$$\begin{cases} \begin{bmatrix} \frac{\partial f_1}{\partial x_1} & \dots & \frac{\partial f_1}{\partial x_n} \\ \vdots & \ddots & \vdots \\ \frac{\partial f_n}{\partial x_1} & \dots & \frac{\partial f_n}{\partial x_n} \end{bmatrix} \begin{bmatrix} \alpha_{i,1} x_1 \\ \vdots \\ \alpha_{i,n} x_n \end{bmatrix} + \begin{bmatrix} \frac{\partial f_1}{\partial w_1} & \dots & \frac{\partial f_1}{\partial w_m} \\ \vdots & \ddots & \vdots \\ \frac{\partial f_n}{\partial w_1} & \dots & \frac{\partial f_n}{\partial w_m} \end{bmatrix} \begin{bmatrix} \alpha_{i,n+1} w_1 \\ \vdots \\ \alpha_{i,n+m} w_m \end{bmatrix} \\ - \begin{bmatrix} \alpha_{i,1} & \dots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \dots & \alpha_{i,n} \end{bmatrix} \begin{bmatrix} f_1 \\ \vdots \\ f_n \end{bmatrix} = \mathbf{0} \\ \begin{bmatrix} \frac{\partial h_1}{\partial x_1} & \dots & \frac{\partial h_1}{\partial x_n} \\ \vdots & \ddots & \vdots \\ \frac{\partial h_p}{\partial x_1} & \dots & \frac{\partial h_p}{\partial x_n} \end{bmatrix} \begin{bmatrix} \alpha_{i,1} x_1 \\ \vdots \\ \alpha_{i,n} x_n \end{bmatrix} + \begin{bmatrix} \frac{\partial h_1}{\partial w_1} & \dots & \frac{\partial h_1}{\partial w_m} \\ \vdots & \ddots & \vdots \\ \frac{\partial h_p}{\partial w_1} & \dots & \frac{\partial h_p}{\partial w_m} \end{bmatrix} \begin{bmatrix} \alpha_{i,n+1} w_1 \\ \vdots \\ \alpha_{i,n+m} w_m \end{bmatrix} = \mathbf{0} \end{cases} \tag{12}$$

Both systems of equations (10) and (12) can be converted to a linear in the coefficients system:

$$\mathbf{M}\boldsymbol{\alpha}_i = \mathbf{0} \tag{13}$$

where $\boldsymbol{\alpha}_i = [\alpha_{i,1}, ..., \alpha_{i,n+m}]$ and $\mathbf{M}$ is a matrix of functions of $\mathbf{x}$, $\mathbf{w}$ and $\mathbf{u}$. $\mathbf{M}$ can be calculated symbolically by:

$$\mathbf{M} = \frac{\partial \mathbf{P}}{\partial \boldsymbol{\alpha}_i} \tag{14}$$

where $\mathbf{P}$ is a vector of the left hand side of equations (10) and (12) that can be commonly expressed in terms of equations (8):

$$\mathbf{P} = \begin{bmatrix} \frac{\partial \mathbf{f}}{\partial \mathbf{x}} {}^{i}\boldsymbol{\xi}_{\mathbf{x}} + \frac{\partial \mathbf{f}}{\partial \mathbf{w}} {}^{i}\boldsymbol{\xi}_{\mathbf{w}} - \frac{\partial {}^{i}\boldsymbol{\xi}_{\mathbf{x}}}{\partial \mathbf{x}} \mathbf{f} \\ \frac{\partial \mathbf{h}}{\partial \mathbf{x}} {}^{i}\boldsymbol{\xi}_{\mathbf{x}} + \frac{\partial \mathbf{h}}{\partial \mathbf{w}} {}^{i}\boldsymbol{\xi}_{\mathbf{w}} \end{bmatrix} \tag{15}$$

The vector of coefficients $\boldsymbol{\alpha}_i$ can then be determined by calculating the kernel of $\mathbf{M}$ symbolically, i.e. $\boldsymbol{\alpha}_i = ker(\mathbf{M})$ giving rise to different bases as groups of realizations of $\boldsymbol{\alpha}_i$. Each basis corresponds to a different parameter ϵ_i. An algorithm was presented in [18] to calculate $\boldsymbol{\alpha_i}$ efficiently for rational nonlinear systems by specializing symbolic variables in $\mathbf{M}$ to random values and performing computations over a finite field.

4 r-parameter group of Lie symmetries, observability and model transformation

4.1 Combination of translation and scaling symmetries

It is often the case that a dynamical system contains multiple one-parameter groups of Lie symmetries. Multiple translation and scaling symmetries of system (1) can be obtained by calculating the kernel of $\mathbf{M}$ for multiple solutions of bases with each basis corresponding to the coefficients of an independent group of translation or scaling symmetries. These obtained groups of translations and scalings can be treated separately, or alternatively they can be combined into a single multi-parameter group of Lie symmetries. The principle behind the way of combination is based on the property that Lie transformations of ${}^i\boldsymbol{\phi}_{\mathbf{x}}$ and ${}^i\boldsymbol{\phi}_{\mathbf{w}}$ are themselves Lie transformations of $\mathbf{x}$ and $\mathbf{w}$ that satisfy the equations of the original system [16]. Assume there exists r one-parameter groups of symmetries including r_t groups of translations and r_s groups of scalings. If one successively applies the translations and scalings in spite of their sequence to transform $\mathbf{x}$ and $\mathbf{w}$ iteratively, the result gives an r-parameter group of Lie symmtries of system (1).

Without loss of generality, it is assumed that all the translation symmetries are combined first. Let $\boldsymbol{\alpha}_1, ..., \boldsymbol{\alpha}_{r_t}$ be the coefficients of the translations, and the j^{th} component of the combination is given by:

$$x_j + \alpha_{1,j}\epsilon_1 + ... + \alpha_{r_t,j}\epsilon_{r_t} \tag{16}$$

Next all the scaling symmtries are combined. Let $\boldsymbol{\alpha}_{r_t+1}, ..., \boldsymbol{\alpha}_r$ be the coefficients of the scalings, and the j^{th} component of the combination is given by:

$$e^{\alpha_{r_t+1,j}\epsilon_{r_t+1}+...+\alpha_{r,j}\epsilon_r} x_j \tag{17}$$

Combining all the one-parameter groups of symmetries using equations (16) and (17) gives:

$$\phi_{x,j} = e^{\alpha_{r_t+1,j}\epsilon_{r_t+1}+...+\alpha_{r,j}\epsilon_r}(x_j + \alpha_{1,j}\epsilon_1 + ... + \alpha_{r_t,j}\epsilon_{r_t}) \tag{18}$$

where $\phi_{x,j}$ is the j^{th} component of $\boldsymbol{\phi}_{\mathbf{x}}$. $\boldsymbol{\phi}_{\mathbf{x}}(\mathbf{x}, \mathbf{w}, \boldsymbol{\epsilon})$ is used to denote the r-parameter group of Lie symmetries with $\boldsymbol{\epsilon} = [\epsilon_1, ..., \epsilon_r]$. $\boldsymbol{\phi}_{\mathbf{w}}(\mathbf{x}, \mathbf{w}, \boldsymbol{\epsilon})$ can be obtained in a similar fashion.

4.2 From Lie symmetries to observability

Same as their one-parameter sub-groups of Lie symmetries, $\boldsymbol{\phi}_{\mathbf{x}}$ and $\boldsymbol{\phi}_{\mathbf{w}}$ as the transformations of $\mathbf{x}$ and $\mathbf{w}$ satisfy the equations of system (1) leaving $\mathbf{u}$ and $\mathbf{y}$ unchanged, i.e.:

$$\begin{aligned} \dot{\boldsymbol{\phi}}_{\mathbf{x}} &= \mathbf{f}(\boldsymbol{\phi}_{\mathbf{x}}, \mathbf{u}, \boldsymbol{\phi}_{\mathbf{w}}) \\ \mathbf{y} &= \mathbf{h}(\boldsymbol{\phi}_{\mathbf{x}}, \mathbf{u}, \boldsymbol{\phi}_{\mathbf{w}}) \end{aligned} \tag{19}$$

This foundamental property builds the relationship between the r-parameter group of Lie symmetries and the observability of system (1). If $\phi_{x,j} \not\equiv x_j$, then x_j is unobservable given the measurements of $\mathbf{u}$ and $\mathbf{y}$. Similarly, if $\phi_{w,j} \not\equiv w_j$, then w_j is unobservable given the measurements of $\mathbf{u}$ and $\mathbf{y}$. On the contrary, if $[\boldsymbol{\phi}_{\mathbf{x}}, \boldsymbol{\phi}_{\mathbf{w}}] \equiv [\mathbf{x}, \mathbf{w}]$, then all the states and unmeasured inputs are observable resulting in a fully observable underlying system.

4.3 Model transformation

The model of an unobservable system can be transformed to an equivalent model with a minimum number of unobservable states and unmeasured inputs utilizing the results of Lie

symmetries. If system (1) was found to contain an r-parameter group of Lie symmetries, then at least a total of r states and unmeasured inputs are unobservable whose symmetries are functions of $\boldsymbol{\epsilon}$. There exist however a set of transformations of the states and unmeasured inputs, $\mathbf{x_T}$, with respect to which the system model can be re-written or transformed such that the transformed model contains up to $n+m-r$ observable states and unmeasured inputs and a minimum number of unobservable variables. In the case where all the unobservable variables could vanish, the model transformation would lead to a fully observable model.

To obtain $\mathbf{x_T}$ in the case of transforming an unobservable model to be observable, if possible, a transformation $\mathbf{S}$ is first sought by combining the components of $\boldsymbol{\phi}_\mathbf{x}$ and $\boldsymbol{\phi}_\mathbf{w}$, i.e. $\mathbf{S}(\boldsymbol{\phi}_\mathbf{x}, \boldsymbol{\phi}_\mathbf{w})$, where the goal is to eliminate all the parameters $\boldsymbol{\epsilon}$. $\mathbf{x_T}$ is then introduced to be identically equal to $\mathbf{S}(\boldsymbol{\phi}_\mathbf{x}, \boldsymbol{\phi}_\mathbf{w})$. This process will be demonstrated through the example where some added properties of this transformation allow for obtaining an observable reduced model.

5 Algorithm

An algorithm is presented as follows to summarize the procedure of computing translation and scaling symmetries of system (1). All the computations involved are symbolic, and the resulting multi-parameter group of Lie symmetries from the algorithm is a combination of all the translations and scalings computed using the methods described in Section 3.1, 3.2 and 4.1.

Algorithm I

Input: state-space and measurement equations of system (1)

Output: an r-parameter group of translation and scaling Lie symmetries

1. Compute $\frac{\partial \mathbf{f}}{\partial \mathbf{x}}$, $\frac{\partial \mathbf{f}}{\partial \mathbf{w}}$, $\frac{\partial \mathbf{h}}{\partial \mathbf{x}}$ and $\frac{\partial \mathbf{h}}{\partial \mathbf{w}}$
2. First compute the translation symmetries. Let ${}^1\boldsymbol{\alpha} = [\alpha_1, ..., \alpha_n]$ and ${}^2\boldsymbol{\alpha} = [\alpha_{n+1}, ..., \alpha_{n+m}]$. Compute $\mathbf{P_1} = \frac{\partial \mathbf{f}}{\partial \mathbf{x}}({}^1\boldsymbol{\alpha})^T + \frac{\partial \mathbf{f}}{\partial \mathbf{w}}({}^2\boldsymbol{\alpha})^T$ and $\mathbf{P_2} = \frac{\partial \mathbf{h}}{\partial \mathbf{x}}({}^1\boldsymbol{\alpha})^T + \frac{\partial \mathbf{h}}{\partial \mathbf{w}}({}^2\boldsymbol{\alpha})^T$
3. Let $\mathbf{P} = [\mathbf{P_1}^T, \mathbf{P_2}^T]^T$, and compute $\mathbf{M} = \frac{\partial \mathbf{P}}{\partial \boldsymbol{\alpha}}$
4. Compute $\boldsymbol{\alpha} = ker(\mathbf{M})$ and obtain r_t bases of $\boldsymbol{\alpha}$
5. Substitute the coefficients to equations (9) to obtain the translations $[{}^1\boldsymbol{\phi}_\mathbf{x}, {}^1\boldsymbol{\phi}_\mathbf{w}]$, ..., $[{}^{r_t}\boldsymbol{\phi}_\mathbf{x}, {}^{r_t}\boldsymbol{\phi}_\mathbf{w}]$
6. Now compute the scaling symmetries. Compute $\mathbf{P_1} = \frac{\partial \mathbf{f}}{\partial \mathbf{x}} diag(\mathbf{x})({}^1\boldsymbol{\alpha})^T + \frac{\partial \mathbf{f}}{\partial \mathbf{w}} diag(\mathbf{w})({}^2\boldsymbol{\alpha})^T - diag({}^1\boldsymbol{\alpha})\mathbf{f}$ and $\mathbf{P_2} = \frac{\partial \mathbf{h}}{\partial \mathbf{x}} diag(\mathbf{x})({}^1\boldsymbol{\alpha})^T + \frac{\partial \mathbf{h}}{\partial \mathbf{w}} diag(\mathbf{w})({}^2\boldsymbol{\alpha})^T$
7. Let $\mathbf{P} = [\mathbf{P_1}^T, \mathbf{P_2}^T]^T$, and compute $\mathbf{M} = \frac{\partial \mathbf{P}}{\partial \boldsymbol{\alpha}}$
8. Compute $\boldsymbol{\alpha} = ker(\mathbf{M})$ and obtain r_s bases of $\boldsymbol{\alpha}$
9. Substitute the coefficients to equations (11) to obtain the scalings $[{}^{r_t+1}\boldsymbol{\phi}_\mathbf{x}, {}^{r_t+1}\boldsymbol{\phi}_\mathbf{w}]$, ..., $[{}^{r}\boldsymbol{\phi}_\mathbf{x}, {}^{r}\boldsymbol{\phi}_\mathbf{w}]$
10. Combine $[{}^1\boldsymbol{\phi}_\mathbf{x}, {}^1\boldsymbol{\phi}_\mathbf{w}]$, ..., $[{}^{r}\boldsymbol{\phi}_\mathbf{x}, {}^{r}\boldsymbol{\phi}_\mathbf{w}]$ to obtain $\boldsymbol{\phi}_\mathbf{x}$ and $\boldsymbol{\phi}_\mathbf{w}$ following equations (16), (17) and (18)

6 Example: a 2 degrees of freedom (DOFs) mass-spring system with a Bouc-Wen element

Consider a 2 DOFs mass-spring system as showin in Figure 1. The displacements of the two masses m are denoted as x_1 and x_2 respectively, and the corresponding velocities are denoted as v_1 and v_2. k_1 and k_1 are the effective stiffness of the springs. The first spring is assumed to be a Bouc-Wen element with the elastic displacement r. The 2 DOFs system is driven by an unmeasured force $F(t)$ applied at the second mass. The state-space equations of the underlying

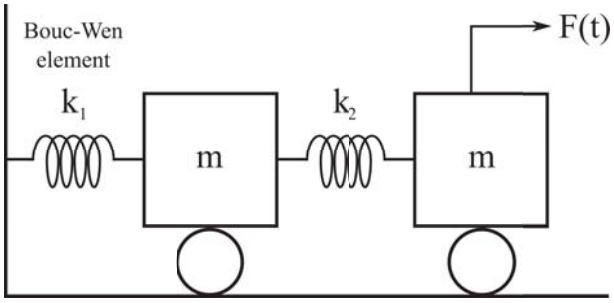

Figure 1: a 2 DOFs mass-spring system with a Bouc-Wen element

system are given by:

$$\frac{d}{dt}\begin{bmatrix} x_1 \\ x_2 \\ v_1 \\ v_2 \\ r \\ k_1 \\ k_2 \\ m \\ \beta \\ \gamma \end{bmatrix} = \begin{bmatrix} v_1 \\ v_2 \\ \big(-k_1 r + k_2(x_2 - x_1)\big)/m \\ \big(k_2(x_1 - x_2) + F\big)/m \\ v_1 - \beta|v_1||r|r - \gamma v_1|r|^2 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} \tag{20}$$

where β and γ are the Bouc-Wen hysteretic parameters. The parameters k_1, k_2, m, β and γ are unknown and thus are to be identified given measurements. It should be noted that the exponent of the Bouc-Wen model is assumed to be known and equal to 2. This is not due to the limitations of the method suggested in this work which would allow for studying non-rational systems, but for presenting the results within a more concise way. The displacements x_1 and x_2 are measured, and therefore the measurement equations of the system are given by:

$$\mathbf{y} = \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} \tag{21}$$

The proposed method in this work cannot be applied directly to the underlying system because the system is not smooth due to the existence of the absolute value operators. However, as discussed in [1], it can be divided into several smooth branches under different conditions of the states, and these smooth branches are then allowed to be examined separately. The function of $\dot{r}$ for each branch is formulated in the following while the equations of the other states remain the same.

$$\begin{aligned} A &: \dot{r} = v_1 - \beta v_1 r^2 - \gamma v_1 r^2, \quad when \quad v_1 > 0 \quad and \quad r > 0 \\ B &: \dot{r} = v_1 + \beta v_1 r^2 - \gamma v_1 r^2, \quad when \quad v_1 < 0 \quad and \quad r > 0 \\ C &: \dot{r} = v_1 + \beta v_1 r^2 - \gamma v_1 r^2, \quad when \quad v_1 > 0 \quad and \quad r < 0 \\ D &: \dot{r} = v_1 - \beta v_1 r^2 - \gamma v_1 r^2, \quad when \quad v_1 < 0 \quad and \quad r < 0 \end{aligned} \tag{22}$$

For the sake of brevity, only Lie symmetries of branch A are studied, while the detailed discussions on the observability properties of the complete non-smooth system can be referred

in the works [1, 11]. For branch A, Algorithm I gives a 2-parameter group of Lie symmetries that is a combination of a group of translations and a group of scalings:

$$[\boldsymbol{\phi}_{\mathbf{x}}, \boldsymbol{\phi}_{\mathbf{w}}] = [x_1, x_2, v_1, v_2, r, e^{\epsilon_1} k_1, e^{\epsilon_1} k_2, e^{\epsilon_1} m, \beta + \epsilon_2, \gamma - \epsilon_2, e^{\epsilon_1} F] \tag{23}$$

As can be seen from the results of symmetries, the symmetries of x_1, x_2, v_1, v_2 and r are identically equal to themselves, which indicates that those states are observable within branch A. On the contrary, the parameters k_1, k_2, m, β and γ are unidentifiable and the unmeasured excitation F is unobservable. The observability results suggested by the symmetries are in agreement with the results output from the observability algorithm ORC-DF [11].

In the following, a transformation $\mathbf{S}$ is determined for combining the resulting Lie symmetries so as to eliminate all ϵ_1 and ϵ_2:

$$\mathbf{S}(\boldsymbol{\phi}_{\mathbf{x}}, \boldsymbol{\phi}_{\mathbf{w}}) = \begin{bmatrix} x_1 \\ x_2 \\ v_1 \\ v_2 \\ r \\ \frac{e^{\epsilon_1} k_1}{e^{\epsilon_1} m} \\ \frac{e^{\epsilon_1} k_2}{e^{\epsilon_1} m} \\ \beta + \epsilon_2 + \gamma - \epsilon_2 \\ \frac{e^{\epsilon_1} F}{e^{\epsilon_1} m} \end{bmatrix}^T = \begin{bmatrix} x_1 \\ x_2 \\ v_1 \\ v_2 \\ r \\ \frac{k_1}{m} \\ \frac{k_2}{m} \\ \beta + \gamma \\ \frac{F}{m} \end{bmatrix}^T \tag{24}$$

A set of new variables, f_1, f_2, δ and F_m, are then introduced such that:

$$\mathbf{x_T} = \begin{bmatrix} x_1 \\ x_2 \\ v_1 \\ v_2 \\ r \\ f_1 \\ f_2 \\ \delta \\ F_m \end{bmatrix}^T \equiv \begin{bmatrix} x_1 \\ x_2 \\ v_1 \\ v_2 \\ r \\ \frac{k_1}{m} \\ \frac{k_2}{m} \\ \beta + \gamma \\ \frac{F}{m} \end{bmatrix}^T \tag{25}$$

and the model of branch A can be re-written with respect to $\mathbf{x_T}$ as follows:

$$\frac{d}{dt} \begin{bmatrix} x_1 \\ x_2 \\ v_1 \\ v_2 \\ r \\ f_1 \\ f_2 \\ \delta \end{bmatrix} = \begin{bmatrix} v_1 \\ v_2 \\ -f_1 r + f_2(x_2 - x_1) \\ f_2(x_1 - x_2) + F_m \\ v_1 - \delta v_1 r^2 \\ 0 \\ 0 \\ 0 \end{bmatrix} \tag{26}$$

Note in the transformed model (26), $f_1 = \frac{k_1}{m}$ and $f_2 = \frac{k_2}{m}$ are related to the natural frequencies of the system, δ is the new Bouc-Wen parameter and $F_m = \frac{F}{m}$ is a new unmeasured input to the system. Given the same measurements model (26) is observable with all its state variables and parameters as well as the unmeasured input observable, which can be verified by the observability algorithm ORC-DF.

7 Conclusions

This work derives the computational framework of Lie symmetries of nonlinear systems with unmeasured inputs, and proposes an efficient algorithm used to calculate the translation and scaling symmetries of such systems. The computed Lie symmetries find applications in predicting and improving the observability of dynamical systems under examined sensor setups. Furture works will be devoted to extending the algorithm to compute more general forms of Lie symmetries as well as to introducing a systematic methodology of model transformation. Other applications of Lie symmetries in improving models and identification results of engineering systems will be explored.

8 Appendix A: a proof of equation (5)

Applying the chain rule to the left hand side of equation (5), one obtains:

$$\frac{\partial(\frac{d^i\boldsymbol{\phi}_{\mathbf{x}}(\mathbf{x},\mathbf{w},\epsilon_i)}{dt})}{\partial\epsilon_i} = \frac{\partial(\frac{\partial^i\boldsymbol{\phi}_{\mathbf{x}}}{\partial\mathbf{x}}\frac{d\mathbf{x}}{dt} + \frac{\partial^i\boldsymbol{\phi}_{\mathbf{x}}}{\partial\mathbf{w}}\frac{d\mathbf{w}}{dt})}{\partial\epsilon_i} \tag{27}$$

Using the product rule equation (27) is equivalent to:

$$\frac{\partial(\frac{d^i\boldsymbol{\phi}_{\mathbf{x}}(\mathbf{x},\mathbf{w},\epsilon_i)}{dt})}{\partial\epsilon_i} = \frac{\partial^{2i}\boldsymbol{\phi}_{\mathbf{x}}}{\partial\mathbf{x}\partial\epsilon_i}\frac{d\mathbf{x}}{dt} + \frac{\partial^i\boldsymbol{\phi}_{\mathbf{x}}}{\partial\mathbf{x}}\frac{\partial(\frac{d\mathbf{x}}{dt})}{\partial\epsilon_i} + \frac{\partial^{2i}\boldsymbol{\phi}_{\mathbf{x}}}{\partial\mathbf{w}\partial\epsilon_i}\frac{d\mathbf{w}}{dt} + \frac{\partial^i\boldsymbol{\phi}_{\mathbf{x}}}{\partial\mathbf{w}}\frac{\partial(\frac{d\mathbf{w}}{dt})}{\partial\epsilon_i} \tag{28}$$

Since $\dot{\mathbf{x}}$ and $\dot{\mathbf{w}}$ are independent of ϵ_i, $\frac{\partial(\frac{d\mathbf{x}}{dt})}{\partial\epsilon_i}$ and $\frac{\partial(\frac{d\mathbf{w}}{dt})}{\partial\epsilon_i}$ vanish and equation (28) simplifies to:

$$\frac{\partial(\frac{d^i\boldsymbol{\phi}_{\mathbf{x}}(\mathbf{x},\mathbf{w},\epsilon_i)}{dt})}{\partial\epsilon_i} = \frac{\partial^{2i}\boldsymbol{\phi}_{\mathbf{x}}}{\partial\mathbf{x}\partial\epsilon_i}\frac{d\mathbf{x}}{dt} + \frac{\partial^{2i}\boldsymbol{\phi}_{\mathbf{x}}}{\partial\mathbf{w}\partial\epsilon_i}\frac{d\mathbf{w}}{dt} \tag{29}$$

Similarly applying the chain rule to the right hand side of equation (5), one obtains:

$$\frac{d(\frac{\partial^i\boldsymbol{\phi}_{\mathbf{x}}(\mathbf{x},\mathbf{w},\epsilon_i)}{\partial\epsilon_i})}{dt} = \frac{\partial(\frac{\partial^i\boldsymbol{\phi}_{\mathbf{x}}}{\partial\epsilon_i})}{\partial\mathbf{x}}\frac{d\mathbf{x}}{dt} + \frac{\partial(\frac{\partial^i\boldsymbol{\phi}_{\mathbf{x}}}{\partial\epsilon_i})}{\partial\mathbf{w}}\frac{d\mathbf{w}}{dt} \tag{30}$$

Equation (30) simplifies to:

$$\frac{d(\frac{\partial^i\boldsymbol{\phi}_{\mathbf{x}}(\mathbf{x},\mathbf{w},\epsilon_i)}{\partial\epsilon_i})}{dt} = \frac{\partial^{2i}\boldsymbol{\phi}_{\mathbf{x}}}{\partial\epsilon_i\partial\mathbf{x}}\frac{d\mathbf{x}}{dt} + \frac{\partial^{2i}\boldsymbol{\phi}_{\mathbf{x}}}{\partial\epsilon_i\partial\mathbf{w}}\frac{d\mathbf{w}}{dt} \tag{31}$$

Comparing equations (29) and (31), the left and right hand sides of equation (5) coincide and therefore equation (5) is proved to hold.

Keywords: Damage detection, Structural health, Evolutionary algorithm, Glulam, Optimization.

Abstract. Damage Detection and Structural Health Monitoring use different techniques to diagnose the threat of failure in structures. Vibration-based approaches have demonstrated to be a useful tools in testing and monitoring structures. They use the intrinsic correlation between structural damage and vibration response. Thus, the information provided by vibration sensors defines the health status of the structure allowing to identify the potential cause of failure. Model tuning or updating based methods use an ideal theoretical model (FEM) of the structure and try to minimize the difference with respect to the real system. This difference provides not only a measure of location of the damage but also the intensity. Model updating is performed by means of Evolutionary Algorithms (EA) and other techniques. In this work, Differential Evolution (DE) is used to solve the residual optimization. DE algorithms are the most popular technique within Evolutionary Algorithms. This technique uses an adaptive probabilistic method to mimic the Darwinian evolution in order to find the optimal numerical values of the design variables. This approach uses natural selection, random mutations and crossover to change the values of the variables defining the solution toward the optimal solution. The main goal of the paper is focused on the detection of failures in Glued Laminated Timber (Glulam). To this end, both theoretical and experimental vibrational data are measured and used to perform model updating.

1 INTRODUCTION

The origin of glued laminated timber (Glulam) as a structural element is not new, however, in recent years the use of this material in constructions has experienced a huge increase. Since the 1970s, the evolution of new manufacturing techniques for this material have allowed the construction of curved beams and improved the quality of their performances. Furthermore, due to the capacity to produce large beams Glulam can be used for modern high-volume buildings. Nowadays the manufacturing techniques allow the manufacturing of beams for large spaces, greater than 100 meters, and adopt varied shapes making this material a valuable element in structural applications but also of great aesthetic value. Indeed, Glulam is particularly suitable in situations where a pleasant aesthetic appearance is required, which gives it a very important advantage over other materials commonly used in construction. There are many applications in large spaces such as the construction of auditoriums, sport centers, religious spaces, shopping centers, airports, walkways, etc., which frequently use this material due to the aforementioned properties.

However, it is necessary to highlight an aspect of this material that makes its potential even greater in the future. It is an obvious fact that an ecological and sustainable construction is a growing trend and these facts have an important future in the industrial and economic development of the countries. The use of environmentally responsible and sustainable materials is a fundamental part of this process. The use of wooden structures in construction is one of the best ways to achieve an environmentally friendly activity, since wood is one of the most sustainable resources provided by nature.

Obviously, compared to other traditional materials used in construction the main disadvantage of Glulam is that its mechanical and resistant properties are lower. In addition, a non-homogeneous and anisotropic material, making difficult its numerical modelling and analysis. The safety of wooden structures is controlled and the quality of the wood used and its manufacturing process is certified by means of standards. Technical Building Codes [1] consider timber as a structural material and allows the determination of limit states based on mechanical properties. It is true that these procedures are focused primarily on solid timber and not on Glulam, and fundamentally with laboratory tests in the pre-execution phase [2]. This information allows to know the behavior of the material in a reliable way and to guarantee the safety of the Glulam structures in their calculation and numerical simulation [3]. However, as an organic material, it is exposed to multiple factors that can cause its deterioration and reduce its structural capacity [4].

On the other hand, the analysis of the current situation reveals that there are no general and sufficiently proven techniques for the in-situ structural evaluation of this type of structures [5]–[7]. In fact, until recently the diagnosis of the structural state of this type of construction has been carried out almost exclusively by visual inspections, measurement of humidity and surface density or hardness [8], [9]. The lack of methods for inspection and diagnosis applied over large areas of the structural elements makes necessary the research of the behavior of this material [5]. Despite the preventive treatments to which Glulam is summited, it is exposed to numerous degradation processes that do not have other traditional materials in construction. The causes that could deteriorate the material are abiotic origin (e.g. water, solar radiation, etc.), biotic (e.g. xylophagus fungi, insects, etc.) and mechanical (e.g. wood singularities, deformations, breaks, mechanical overloads, etc,). Due to these peculiarities, the Non-Destructive Testing (NDT) techniques used in other materials cannot be used directly in Glulam, since the possible defects due to the deterioration of the material have particular and generally different characteristics and properties.

In both solid timber and Glulam, these inspection techniques remain an important field of research today[8], [10]. In the case of solid timber, there is a large literature where NDTs and semi-destructive tests (SDT) are investigated [10]–[12]. In the case of laminated wood, the problem is still greater, since there is very little work on this type of test. The problem is accentuated if it is considered that the responsibility of laminated wood structures is greater than those built with solid timber, since these structures are usually of a larger size, which also entails a greater risk and responsibility

As it has been reflected in numerous publications, the dynamic response of the structures provides a rich source of information on the mechanical properties of the structural elements and the defects or degree of deterioration [13]–[16]. Indeed, the vibrational response of a structural component to dynamic excitation depends on its intrinsic characteristics and boundary conditions. In the literature, approaches based on modal analysis have been highlighted above other NDT due to several characteristics that make them very attractive in defining the health status and identifying possible causes of failure. The so-called adjustment by updating EF models uses an intact theoretical model of the system or structural component as a reference[14], [16]–[18]. That is, it takes as reference the theoretical model of finite elements called healthy state. Through experimental measurements on the real system, these tests are compared with the theoretical model. In this way, it is about finding out what modifications have to be made in the theoretical (healthy) model so that the experimental and theoretical response become the same. Modifications in the theoretical model provide information about the defects of the structure under test.

2 MATHEMATICAL BACKGROUND

In this work, modal properties are used for updating finite element model. To this end, modal properties and methods are described in this section. The base of the method is that modal properties are related to the mechanical properties of the structural element. Dynamic behavior of the structures can be described in terms of their distributed stiffness, damping and mass properties. Thus, the modal properties can be related with mass and stiffness matrices. FRF function may be expressed as the summation of the different contribution of each mode. That is,

$$H_{mn}(\omega j) = \sum_{i=1}^{N} \frac{-\omega^2 \varphi_m^i \varphi_n^i}{-\omega^2 + 2\xi_i \omega_i \omega j + \omega_i^2} \tag{1}$$

This equation provides the FRF due to the excitation in position *m* and the response at position *n*. *N* is the number of the mode, ω_i, ξ_i are the i^{th} natural frequency and damping ratio, respectively. The variation of the frequency is considered by means of the parameter ω. The modal properties of the structure depend on the stiffness and mass matrices, therefore, the measured modal parameters can be provided by the finite element model if the correct stiffness and mass are obtained. Thus, the model updating process need to identify the correct dynamic matrices from the measured data. Therefore, it is possible to obtain the correct Young's modulus at different sections of the structural element. The variation of the Young's modulus is related with the presence of defect in the structures. Consequently, the determination of the variation of this modulus in different sections of the structure may help us to find out where a deterioration is produced. In this work, the determination of the correct Young's Modulus is obtained by the following residual function.

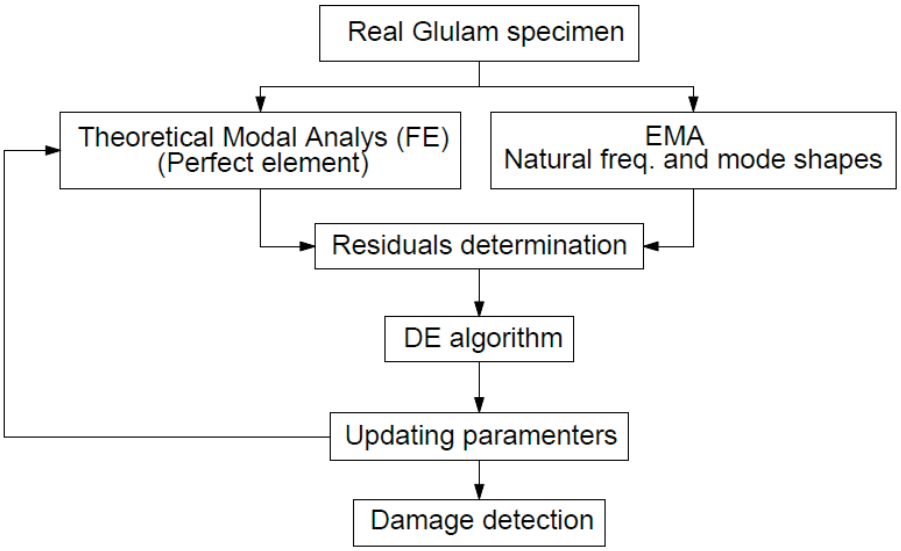

Figure 1: Flowchart of the updating methodology using the Differential Evolution algorithm.

$$\Pi = \sum_{i=1}^{N} \upsilon_i \left(\frac{\omega_i^e - \omega_i^t}{\omega_i^e}\right) + \sum_{i=1}^{N} \tau_i \left[1 - MAC_i\left(\varphi_m^i, \varphi_n^i\right)\right] \quad (2)$$

where the parameter e is for measured and t for theoretical (or calculated). Parameters ν_i and τ_i are the weighting parameters that measures the relative contribution of modes and natural frequencies. The MAC is the Modal Assurance Criterion, which achieves the value of 1 when the evaluated modes are equal and zero when they are completely different. Thus, the first part of Eq.(2) ensures that the natural frequencies obtained by the finite element model are close to those measures experimentally. The second part of this equation measures the correlation between both, theoretical and experimental modes. In this way, by comparing the results the updating method evaluates the changes in the model allowing the evolutionary algorithm to predict the values of the stiffness in each section of the structural element. Thus, the goal of the algorithm is to minimize the Eq.(2). Fig. 1 shows the general procedure where the DE algorithm is included. The basics of this algorithm is described in the following section.

3 DIFFERENTIAL EVOLUTION ALGORITHM

The denomination Evolutionary Algorithms refers to several algorithms that mimic the natural phenomena to optimize a goal function [19], [20]. In this work, Differential evolution is selected because it has been demonstrated in many works that is robust, effective and reliable [21], [22]. This section describes this evolutionary algorithm applied to model updating. The strategy of this algorithm involves the evolution of a population with a size S_{max}. This parameter represents the maximum number of individuals in one generation. It can be formulated as follows,

$$\mathbf{E}_l^g = \mathrm{E}_{l,k}^g; \quad k = 1,2,\ldots, k_{max} \quad (3)$$

where **E** represents the vector of the Young's Modulus parameters at each section. Superscript g stands for the generation number, and l is the index for the individual. Parameter k stands for the dimension of the vector. The size of the population (i.e. k_{max}) does not change during the optimization process. The maximum number of generations is g_{max}, which is established as the convergence criterion of the algorithm. The fitness function is given by Eq.(2) and the

initial vector of the population is chosen to cover a wide range of the space of the variables. A uniform probability function is used to provide the value of the variables in the initial population. However, DE algorithm does not admit the formulation of constraint as local optimization does. Thus, the fitness function should be adapted to include constraints. The method used in this work is Static Penalty. It requires the introduction of the penalty term as follows,

$$\Phi(\mathbf{E}_k^g) = \Pi(\mathbf{E}_k^g) + \sum_{c=1}^{nc} R_c \, max\left[0, g_c\left(\mathbf{w}\mathbf{E}_k^g\right)\right] \tag{4}$$

Where R_c is the penalty coefficient and nc is the number of constraints. In this work, the constraints represent the lowest and highest value of the stiffness.
The mutation operator used in this work is given by the following equation,

$$E_{l,k}^{g+1} = E_{l1,k}^{g} + F\left(E_{l2,k}^{g} - E_{l3,k}^{g}\right); \quad l = 1,2, \ldots, l_{max} \tag{5}$$

where subscripts l_1, l_2 and l_3 refer to three individuals of the actual generation randomly selected. Parameter F is the mutation factor selected by the analyst between 0 and 2. The next operator is Crossover, which is defined as follows,

$$E_{l,m}^{g+1} = \begin{cases} E_{l,m}^{g+1} & if\, A(k) \le Cr \\ E_{l1,m}^{g} & if\, A(k) > Cr \end{cases}; \; k = 1,2, \ldots, k_{max} \tag{6}$$

where Cr is the crossover constant selected by the analyst between 0 and 1. $A(k)$ is a random number. Next, selection operator is applied, which is given by,

$$\boldsymbol{E}_l^{g+1} = \begin{cases} \mathbf{E}_l^{g+1} & if\ \Phi\left(\mathbf{E}_l^{g+1}\right) < \Phi\left(\mathbf{E}_l^{g}\right) \\ \mathbf{E}_l^{g} & if\ \Phi\left(\mathbf{E}_l^{g+1}\right) \ge \Phi\left(\mathbf{E}_l^{g}\right) \end{cases} \tag{7}$$

This equation is repeated for each generation until the maximum number of generations is achieved. Thus, the algorithm requires five parameters defined by the analyst, i.e. population size, l_{max}, constant factor, F, crossover constant, C_r, constraint factor, R_c, and maximum number of generations, g_{max}.

4 EXAMPLE: APPLICATION TO GLULAM BEAMS

Two kind of experiments were carried out in this work. The first test one was done on elements without defects. The main goal of these tests was to obtain the dynamic mechanical properties, obtaining the modal parameters without damage. In order to assess the algorithm in the second kind of experiments, damages were introduced in the elements.

Figure 2: Glulam specimens with two laminas (a and b) and five laminas (c).

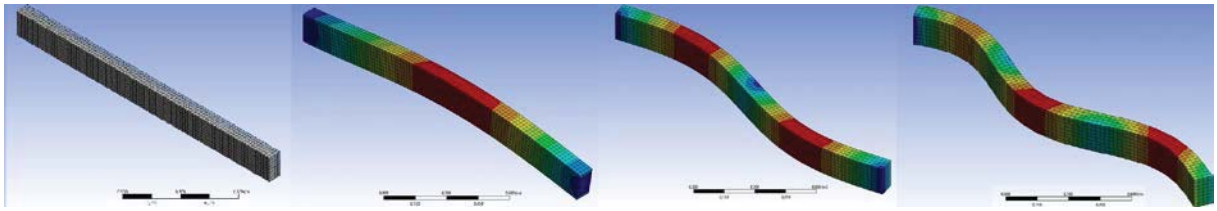

Figure 3: Theoretical model of the glued laminated beam formed by two laminas.

Pinus radiata (GL-24) was the wood specie used for these experiments. The nominal mechanical properties were: MOE = 9.1GPa and Possion ratio = 0.38. The density considered was 336.0 kg/m^3. The adhesive used was melamine-uera 1247 with hardener 2526. The nominal mechanical properties of the adhesive is: MOE = 3.5GPa and Poisson ratio = 0.34.
Three uniform clear beams with any defects were used to determine the dynamic properties of the wood used in Glulam. The dimensions of these elements were L=1.85m (length), d=0.15m (wide) and e=0.04m (thick). These experiments were used to determine the empiric modulus of elasticity (MOE) and Poisson ration of pure wood. After that, three uniform simple Glulam beams formed by two laminas were used to determine the influence of the adhesive between the elements of wood (see Fig. 2a and 2b). Each lamina has a thickness of 0.04m. Finally, Glulam beams formed by five laminas were considered as a general case (see Fig. 2c).
The measurement system consisted of four capacitive accelerometers (Measurement Specialties, model 4610), an impact hammer (Kistler, model 9724A), an acquisition system (HBM, model QuantumX MX1601B, 16 channels). Catman® Software and Matlab® were used to processing the signal and ARTeMIS® software was used to obtain the modal shapes and modal parameters. Each beam was supported at both ends and the accelerometers were located uniformly distributed along its length. The hammer impacted in one point of the beam and the signal was picked up by the four accelerometers to obtain the modal parameters after processing the signal. Commercial finite element package (ANSYS®) was used to generate a 3D-model of the beams. Figure 3 shows the FE model and modes for the model formed by two laminas in a simple beam used in this work. Each lamination was modelled as a separate entity. This modelization allows introducing the material characteristics of each element in order to be modeled individually. A perfect bonded connection was assumed between laminas. The induced damage considered in all cases was a loss of stiffness in some part of the structural element. This effect responds to most of the causes of failures in this type of structures. To modelize the imperfections, the beams were divided in five parts. The stiffness was considered constant in one of each part (see Fig. 3), but they could vary independently in the updating process.

5 RESULTS

Each individual in the DE algorithm is defined by the five variables, which are the Young's Modulus in each section. A damage was induced in the second section of the beams (Section 2 in Fig. 4). The measurement of the FRF provided the natural frequencies and modes of the real system. This information was introduced in the algorithm for updating the finite element model. Therefore, the parameters of the algorithm are the following: size of the population, l_{max}=50, F=2, crossover constant, C_r=1, constraint factor, R_c=1, and maximum number of generations, g_{max}=25.

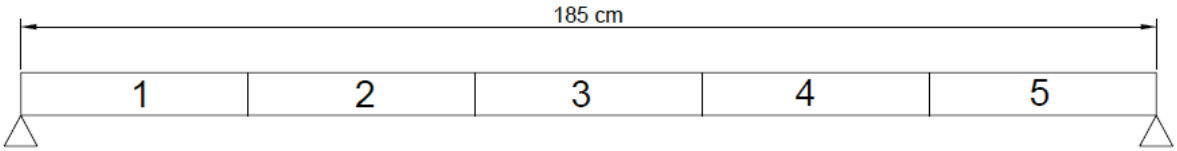

Figure 4: Scheme of the numerical beam with the five part were the stiffness is constant.

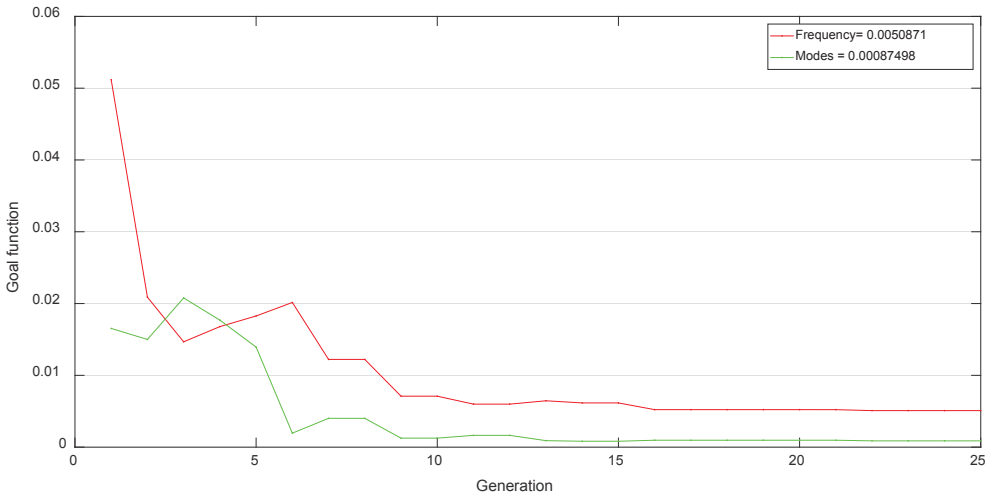

Figure 5: Evolution of the fitness during the updating process.

Fig. 5 shows the evolution of the goal function, i.e. Eq.(2), during the optimization process. In this graph, the two terms of both parts of the formula have been represented (i.e. red = frequency term and green = modes term). It is clear that the trend in the evolution during the 25 generations is good enough. The differences between the two curves is mainly due to the weighting parameters considered in the example. Fig. 6 shows the evolution of the Young's Modulus in each generation. The values of the variables in sections 1, 3, 4 and 5 are very close to the nominal value of the Young's Modulus. However, the value of section 2 is clearly lower due to the damage induced in the beam. Fig. 7 shows the comparison of the theoretical and experimental results with the porcentage of accuracy.

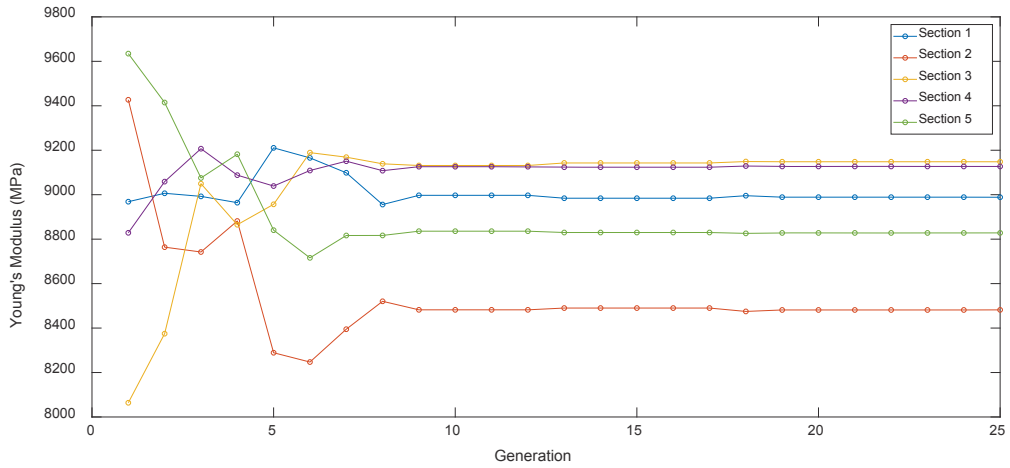

Figure 6: Evolution of the Young's Modulus in each section during the updating process.

6 CONCLUSIONS

The use of glued laminated timber is increasing in developed countries due to the several advantages that this material provides. The structural members are used with different size and shapes, which makes this material attractive for architects and users. However, many types of defects that are exclusive to this material have influence on the mechanical properties. This fact makes the evolution of the mechanical properties of this material over time unknown. For this reason, it is necessary to develop methods for the evaluation of the health status of Glulam structural elements. In this study, FE model updating methodology is proposed for the evaluation of damage in structural elements of glued laminated timber. The proposed method was implemented using a DE algorithm for the minimization of the residual function. Experimental and theoretical simulations were compared by means of this residual function. The method demonstrate that it is capable of finding the damage when it is produced by a loss of stiffness. Thus, the algorithm is reliable for the detection of local damage in structural elements made of Glulam.

Keywords: Decision Trees, Mahalanobis Distance, Damage Detection, Pseudo-Damage Localization.

Abstract. *Vibration-based Structural Health Monitoring (VSHM) systems continuously gather data from an array of sensors mounted on a structure. Features are constructed from the data measured. The aim is to monitor the vibration responses in the search for changes that may hint to damage. The continuous data acquisition generates high-dimensional feature spaces that require Data-Driven approaches to make inferences concerning the integrity of the structure. In recent years, machine learning has played an increasingly important role in VSHM. Data-driven algorithms have been successfully used to construct models capable of detecting anomalies such as damage in the features derived from the vibration signals. Mahalanobis Distance based novelty detection is a common used method to detect damage. Yet, the resulting models have been labelled "black box models" given that they lack interpretability. This becomes a relevant challenge in the presence of high-dimensional feature spaces. Using machine learning algorithms that can be interpreted would enable a more reliable novelty detection process, building trust in these methods and easing the decision-making process. Decision Trees (DT) is a widely used interpretable machine learning algorithm. The hierarchical structure of this algorithm enables the prioritisation of features that are used as predictors in the damage detection models. Furthermore, the nature of the algorithm enables the user to track the decisions and understand the classification process in detail. In this paper, we introduce the complementary use of so-called "black box models" and DT for novelty detection. The proposed damage detection approach is tested on an experimental setup with a 14.3m wind turbine blade (WTB) equipped with 24 accelerometers. A pseudo-damage was simulated by adding masses to several locations of the WTB. The pseudo-damage was detected by means of a semi-supervised novelty-detection. The novelties were later studied in detail with decision-trees to make inferences on their potential causes.*

1 Introduction

Methods to monitor the integrity of a structure have been intensely studied in the past decades [1–5]. Traditionally, researchers have had robust experimental setups and performed reliable measurements to successfully compare the modal parameters of a structure and identify damage [6–8]. However, these methods have limitations given that the confidence interval of features can be exceeded due to environmental factors as shown in [9]. Additionally, such physics-based methods are often impractical due to the high complexity of the structure and the level of expertise that is required for their development [10, 11]. This is where data-driven techniques, and especially machine learning approaches, may become a powerful alternative. In recent years, machine learning techniques have been implemented in research and applied to multiple structures, thus proving their capability to detect damage [12–14]. Semi-supervised algorithms have been of particular interest for damage detection when only the healthy condition of the structure is known. Initially proposed by [15], the use of the Mahalanobis Distance (MD) for novelty detection became a popular method to cluster extracted features from the structure or system response. In [16, 17], the authors used the MD to identify the deviations from a reference state defined from observations from a pristine structure and detect potential damage in a structure or system. Often, this one-dimensional clustering method contains false alarms, i.e., the novelty index is outside the ”healthy” reference cluster but does not correspond to damage. Studies have shown that environmental and operational conditions are one of possible reasons for these false alarms [18, 19].

Decision Trees (DT) are not new to the field of VSHM. For example, [20] localized a point mass on a CFRP plate employing k-nearest neighbors and linear discriminant algorithms such as DTs using strain response data. Similarly, in [21], a problem of localizing an added mass on a plate structure was approached using a modified DT algorithm that also output probabilities of each class. The plate was divided into grids where each zone was assigned to a number. The output of a classifier contained zone numbers as class labels with a probability of point mass being placed in that particular zone. Nevertheless, DTs have been underutilized in VSHM applications by exploding only their classification capability and not its high interpretability and transparency. Therefore, this paper proposes the use of DTs to identify the features and their values responsible for false alarms when identifying novelties while monitoring the condition of a structure. Features related to novelties identified by the semi-supervised MD method proposed by [15] are clustered by means of DTs. Once the novelties are classified, the DTs are used to understand their occurrence. The technique was tested on data gathered from a 14.3m wind turbine blade (WTB) mounted on a test rig. The WTB was equipped with 24 accelerometers and excited by an impulse force of a electromagnetic actuator to force vibration responses. Initially, the vibration response was measured from a pristine WTB. Later, mass was added in different locations to simulate novelties. This is a well-known approach to emulate the local structural changes that are caused by damage. The relevance of each individual feature and the transparent reasons for classification are related to the position and the amount of mass added. By looking into the structure of DTs, it was possible to locate the sensors positioned closer to the mass added.

2 Methodology

The methodology proposed in this study combines the use of MD-based novelty detection and DTs to better understand the occurrence of the novelties.

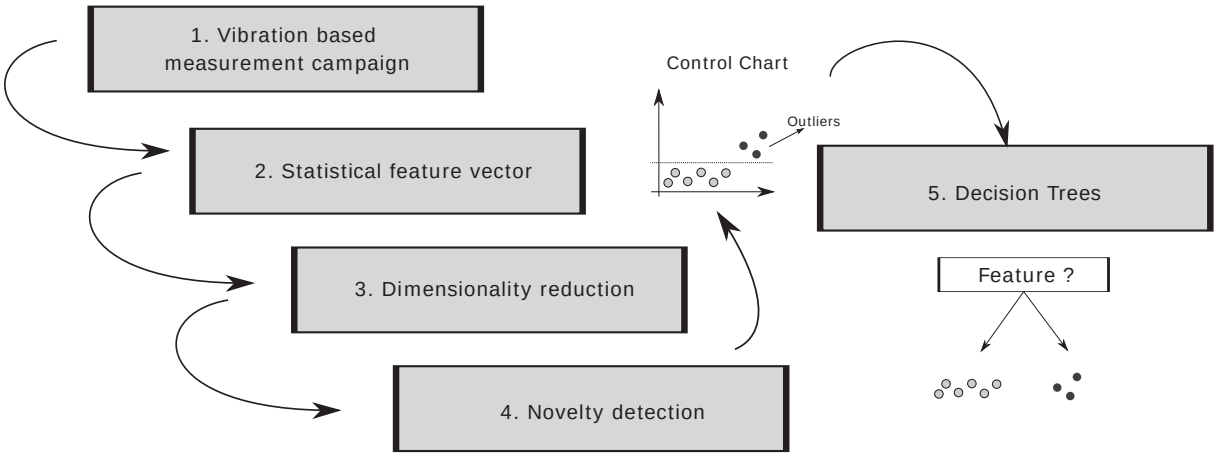

Figure 1: Graphical summary of the methodology followed in this paper

The procedure of DT bases its classification on the best possible split. This allows to understand which features and their values are responsible for the classification of novelties. Fig. 1 summarizes the main steps followed in the methodology suggested in this paper for pseudo-damage detection and interpretation.

2.1 Vibration-based measurement campaign

Vibration responses are measured from a structure when excited by an electromechanical actuator and organised in a matrix as follows,

$$\boldsymbol{V}^k = \begin{pmatrix} v_{11} & v_{12} & \dots & v_{1n} \\ v_{21} & v_{22} & \dots & v_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ v_{m1} & v_{m2} & \dots & v_{mn} \end{pmatrix} = (v_{ij}) \in \mathbb{R}^{m \times n} \tag{1}$$

where v_{ij} is the i^{th} vibration measurement with the length m of the accelerometer j^{th} for the k^{th} observation, i.e, the vibration responses of all the n accelerometers due to an electromechanical actuator on the structure. The details of the measurement campaign are provided later in section 3

2.2 Statistical feature vector

The covariance of the vibration response is used to measure the direct relationship between accelerometers positioned on the WTB. In the context of novelty detection, the covariance is used as a damage sensitive feature (DSF) where a change would enable the identification of

novelties due to changes in vibration response resulting in changes in the covariance feature.

$$\boldsymbol{S}^k = \begin{pmatrix} s_{11} & s_{12} & \cdots & s_{1n} \\ s_{21} & s_{22} & \cdots & s_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ s_{n1} & s_{n2} & \cdots & s_{nn} \end{pmatrix} = (s_{jq}) \in \mathbb{R}^{n \times n} \tag{2}$$

In Eq. 2, $\boldsymbol{S}^k$ is the covariance matrix for the k^{th} observation and stores the covariance s_{jq} between accelerometers j and q and, for $j = q$, s_{jq} represents the variance. Due to the symmetric properties of the covariance matrix, only the upper triangle is used as a feature vector as in Eq. 3.

$$\boldsymbol{f}^k = \begin{bmatrix} s_{11} & s_{12} & \cdots & s_{1n} & \cdots & s_{22} & \cdots & \cdots & s_{nn} \end{bmatrix}^T \tag{3}$$

All feature vectors $\boldsymbol{f}^k$ are arranged in one feature matrix $\boldsymbol{F}$ shown in Eq. (4)

$$\boldsymbol{F} = \begin{bmatrix} \boldsymbol{f}^1 & \boldsymbol{f}^2 & \cdots & \boldsymbol{f}^R \end{bmatrix} \tag{4}$$

where R is the total amount of observations.

2.3 Dimensionality reduction

Prinicipal Component Analysis (PCA) is an orthogonal transformation applied to a set of potentially correlated values into linearly uncorrelated values which are known as the principal components (PC) [22]. The first PCs contain most of the variability from the original dataset leaving each succeeding component with the remaining variability. This procedure allows to reduce the dimension of a dataset while allowing to keep most of the information possible expressed in variability of the data. In this analysis, PCA is applied to reduce the dimension of the feature matrix and account for collinearity between the feature vectors.

2.4 Mahalanobis distance-based novelty detection

The distance between a point and a distribution in a multivariate space can be described by the the Mahalanobis Distance (MD) [23]. Unlike the Euclidean distance, the MD normalizes the features by the inverse covariance matrix taking into account the features trend. A common use for the MD is to cluster multivariate data and detect outliers. In this paper, the MD is used as a novelty detection index. The novelties identified are later correlated to the introduced pseudo-damage created by adding mass in several locations of the blade. The MD is calculated using the following equation:

$$d(\boldsymbol{f}^k, \boldsymbol{Y}) = \sqrt{(\boldsymbol{f}^k - \boldsymbol{\mu_Y})^T \boldsymbol{\Sigma}_{\mathbf{Y}}^{-1} (\boldsymbol{f}^k - \boldsymbol{\mu_Y})} \tag{5}$$

where $d(\boldsymbol{f}_r, \boldsymbol{Y})$ is the MD between the feature vector $\boldsymbol{f}^k$ and the reference state $\boldsymbol{Y} \subseteq \boldsymbol{F}$, $\boldsymbol{\mu_Y}$ is the mean of the samples in $\boldsymbol{Y}$ and $\boldsymbol{\Sigma_Y}$ is the covariance between samples in feature vector $\mathbf{Y}$. To avoid confusion, note that the covariance $\boldsymbol{\Sigma_Y}$ is different from covariance $\boldsymbol{S}^k$. The threshold of the reference state during the training stage is represented by T, consequently $d(\boldsymbol{f}^k, \boldsymbol{Y}) > T$ are considered novelties. In this study, the choice of T is based on the cumulative distribution function of the MD and n^{th} percentile of the data in the training set is allowed to exceed the threshold. For this analysis 2% of training data was allowed to exceed T.

To avoid numerical error by computing the inverse of $\mathbf{\Sigma_Y}$ for the MD, the condition number of $\mathbf{\Sigma_Y}$ are examined and the influence of dimensional reduction by PCA in section 4.1 .

2.5 Decision trees

Decision Trees (DTs) belong to a class of "white box" type supervised learning algorithms [24, p. 1]. DTs make data classification an interpretable and visual process by explicitly representing each decision taken to split the data into their labeled classes. This paper uses DTs mainly to classify the novelties identified by the semi-supervised novelty detection method described in subsection 2.4.

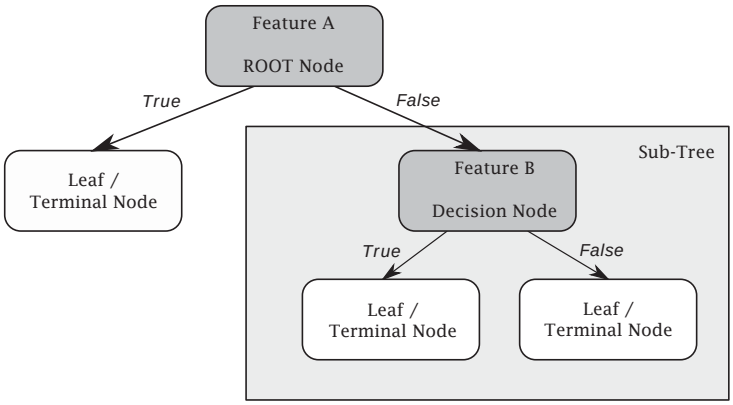

Figure 2: Decision trees principals

DTs are flowchart-like structures, such as the one shown in Fig. 2, that start from a single node, known as the root node and branch into possible outcomes. The algorithm learns to partition and this occurs recursively until no more splits are possible, therefore reaching a terminal node (or leaf node). The aim of the partition is to separate the data-set into its labeled classes.

The key task performed by the DT is the partition. The most effective split of the data-set is based on the selection of appropriate features and characteristics of the feature for comparison and decision-making. There are several attribute selection measures (ASM) that can be used for partitioning such as the information gain, gain ratio, and gini index. The decision as to which ASM to implement is discretionary. As shown in [25], the results from different ASM only differ in 2% of the cases, therefore the choice of ASM does not significantly impact the results. The DTs constructed in this paper use the information gain measure which is based on Shannon's concept of entropy [26], a measurement of the impurity of labeled input-set calculated as per Eq. 6 where p_+ is the proportion of positive examples and p_- the proportion of negative examples. The entropy H of a labeled data-set $\mathbf{S}$ in a decision node describes how well the data is currently split. If the entropy of a node is 0, then the data from this node belongs to its labeled class, i.e., no further partitioning is possible and a terminal node has been reached.

$$H(\mathbf{S}) = -p_+ log_2 p_+ - p_- log_2 p_- \tag{6}$$

Once the data-set is split, e.g., by feature A, the corresponding entropy of the resulting nodes is calculated as in Eq. 7, where $\mathbf{v}$ is a subset corresponding to a class of feature A, $\mathbf{S_v}$ is the size of the subset, and $\mathbf{S}$ the overall number of labeled data in $\mathbf{v}$. That is to say, the entropy of each

of the resulting nodes after the partition are added into a weighted average.

$$H_A(\mathbf{S}) = \sum_{\mathbf{v} \in Values(A)} \frac{|\mathbf{S_v}|}{|\mathbf{S}|} H(\mathbf{S_v}) \tag{7}$$

Since the objective of the information gain measure is to decrease the entropy after the partition, $H(\mathbf{S})$ and $H_A(\mathbf{S})$ are compared by calculating the information gain as per Eq. 8. An iterative process identifies the features that results in a maximum $Gain(\mathbf{S}, A)$.

$$Gain(\mathbf{S}, A) = H(\mathbf{S}) - H_A(\mathbf{S}) \tag{8}$$

Ultimately, the algorithm provides a hierarchical structure, where the root node corresponds to the feature within the data-set with the highest relevance for the classification.

3 Experimental data collection campaign

The proposed method is tested on a 14.3m WTB manufactured by Olsen Wings [27] shown in Fig. 3. The blade is mounted on a test rig and equipped with an electromagnetic actuator such as the one in Fig. 4a and placed close to the root of the blade.

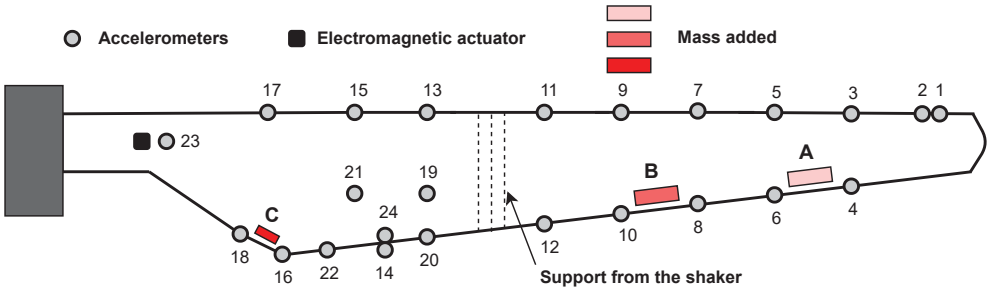

Figure 3: Schematic representation of the experimental set up of the 14.3m wind turbine blade. The WTB is mounted to an additional shaker which is not used for this experiments.

To measure the vibration response of the blade excited by the actuator hit, a total amount of 24 mono-axial accelerometers, Brüel & Kjær Type 4507, were mounted along the blade as shown in Fig. 3. The accelerometers 2 to 22 measure the vibration response in flap-wise direction, accelerometer 1 in edgewise direction.

The measured vibration response was recorded by a data acquisition system with a sampling frequency of 16,384Hz. Using the actuator as a trigger signal, the vibration responses from all accelerometers were aligned and trimmed to 200 samples around the maximum amplitude of accelerometer 23. This sample range was identified as the most sensitive to changes in dynamic response as shown in [19]. An example of the vibration response from accelerometer 8 is shown in Fig 5a and 5b

To simulate novelties, mass in form of heavy bolts, shown in Fig 4b, were placed in different locations marked in red in Fig. 3. The blade was excited 2000 times without mass to create a baseline for novelty detection. Then, in location A, five bolts (each with an approx. weight of 1kg) were place on the blade and the blade was excited ten times. Next, the amount of bolts was increased to 10 and 20 bolts repeating the procedure for each variation of mass and for locations B and C. Masses for each location we placed and measured separately. Table 1 summarizes the damage scenarios simulated with the corresponding mass added and locations.

4 Results and discussion

4.1 Novelty detection

The control charts in Fig 6 and 7 illustrate the MD-based novelty index and the necessity to transform the features by dimensional reduction. To highlight the limitations of applying the MD-based novelty index on a large features space of a redundant experiment, the covariance was calculated from the first 22 vibration responses measured in the accelerometers 1 to 22 resulting in a total amount of 253 features per observation. When calculating the MD directly from the features without a transformation, the novelty index strongly deviate from the created reference as shown in Fig. 6.

Comparing the results to Fig. 7, it can be seen that significant deviations occur after the training limit of the first 1500 samples. As shown in Eq. 5, the MD uses the inverse covariance matrix $\mathbf{\Sigma_Y^{-1}}$. To understand the deviations and avoid numerical errors, the condition number of the covariance matrix $\mathbf{\Sigma_Y}$ is calculated after reducing the amount of principal components one by one.

If the condition number is not much larger than 100, the matrix can be considered as well conditioned and non-singular. Given the fact that the blade was excited by the electromechan-

Table 1: Simulated novelties according to location and mass added

Scenario	Mass	Location	Number of Excitations
Blade without mass			
Training		-	1500
Testing		-	500
Blade with mass	5kg	A	10
	10kg	A	10
	20kg	A	10
	5kg	B	10
	10kg	B	10
	20kg	B	10
	5kg	C	10
	10kg	C	10
	20kg	C	10
Total			2090

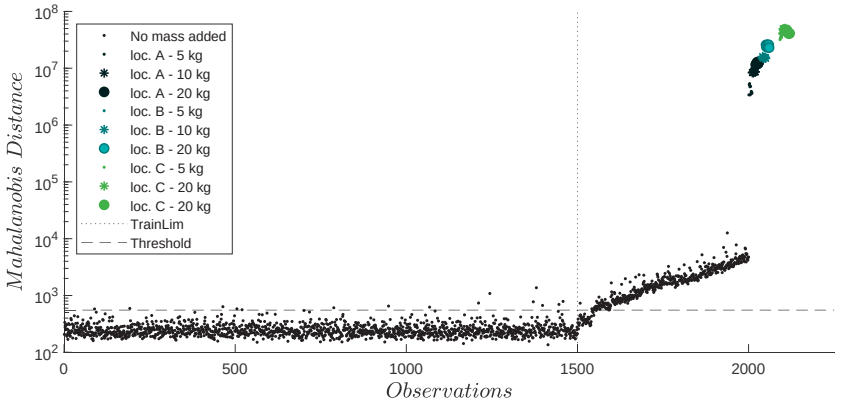

Figure 6: MD-based novelty index without dimensional reduction

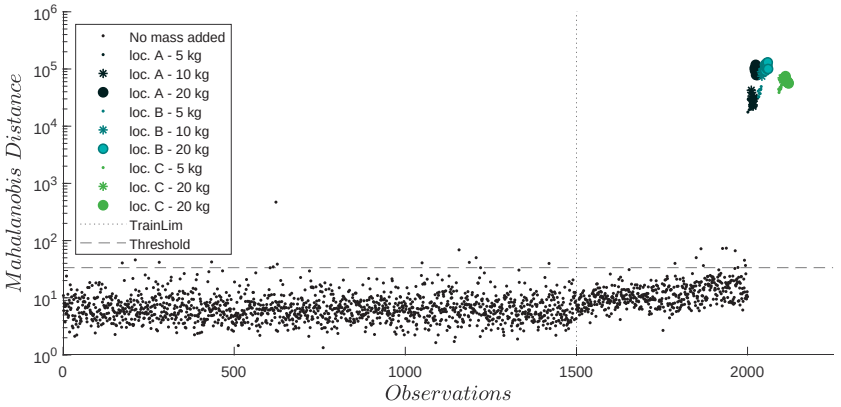

Figure 7: MD-based novelty index with dimensional reduction

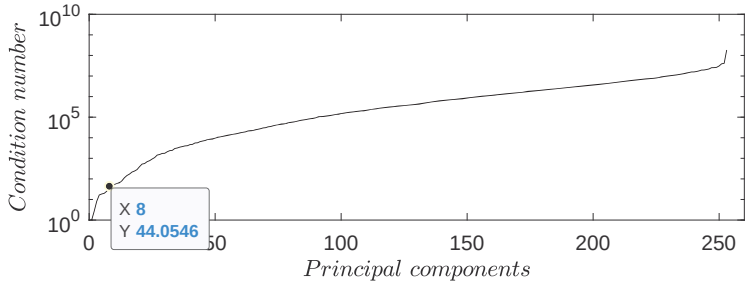
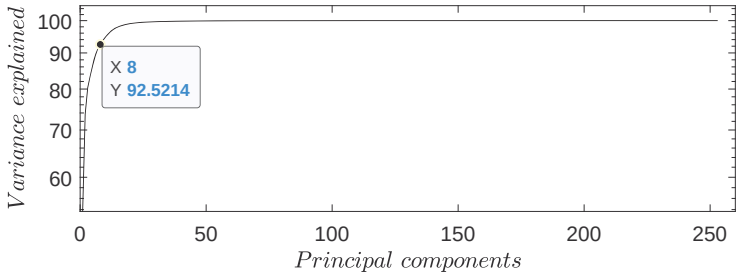
ical actuator for 2000 times under the same conditions, small deviation in the excitation or measurement noise will amplify noise in the test data by the factor of the condition number. Therefore, it was crucial for this analysis to avoid high condition numbers. Keeping more then 90% of the explained variance allowed to lower the condition number to 44 and a total amount of 8 components were left.



(a)



(b)

Figure 8: (a) Condition number. (b) Accumulative variance by principal components

As shown in Fig. 8a, by using a large amount of principal components, the condition number of covariance matrix $\mathbf{\Sigma_Y}$ is over 10^5. Collinearity in the feature matrix can be avoided by reducing the number of principal components. There is no clear answer of how many components to use; nevertheless, the principal components needed can be narrowed down by observing the condition number and variance explained.

4.2 Novelties explained by decision trees

To be able to interpret the DTs, the features used for classification have to be interpretable. Therefore, for analyzing the novelties, the covariance matrix is first reduced to its diagonal using only the variance associated with each accelerometer response. This will simplify the interpretation of the DTs and its complexity. The dimensional reduction by PCA reduced the false alarm rate for novelty detection. Once novelties are detected, features can be used without the dimensional reduction for supervised learning with DT, thereby maintaining the interpretability of the features. Three classification trees were constructed, one for each location of the masses. Locations only along the trailing edge of the WTB were considered. As shown in Table 1, each location has 3 cases (or classes) referring to 3 different masses added. The DT for mass location A is visualized in Fig. 9. The feature in the root of the tree is the variance of sensor 6, which is located right before the added mass. To split the case 1 from the remaining 2, 3 and 4, the variance of the feature had to be below 31.05, i.e., an increase in variance should have occurred

in the vibration signal after the masses were added. To separate the case with 20kg from the ones where 5 and 10kg were added, the variance of accelerometer 6 had to be above 37.02. Data from 5kg and 10kg cases were split by the variance from sensor 4, showing that adding 10kg of mass would increase the variance compared to 5kg. The features chosen by the DT algorithm to separate data recorded from a WTB with mass on it from the ones without mass were those corresponding to the accelerometers positioned next to the mass, thereby pointing the location of the mass placed.

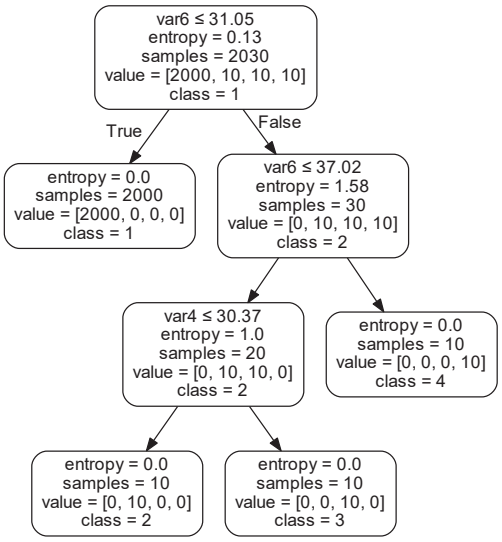


Figure 9: DT for mass location A

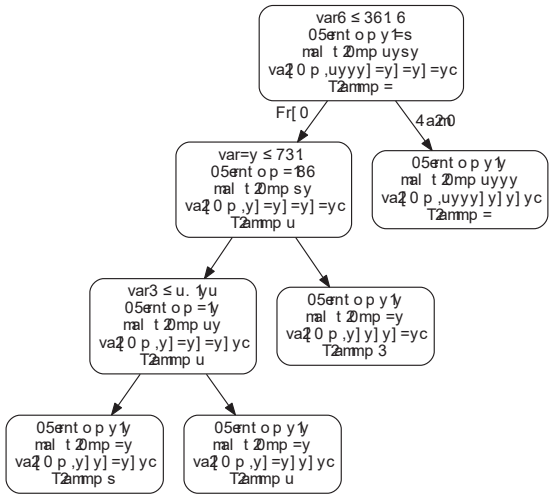

Figure 10: DT for mass location B

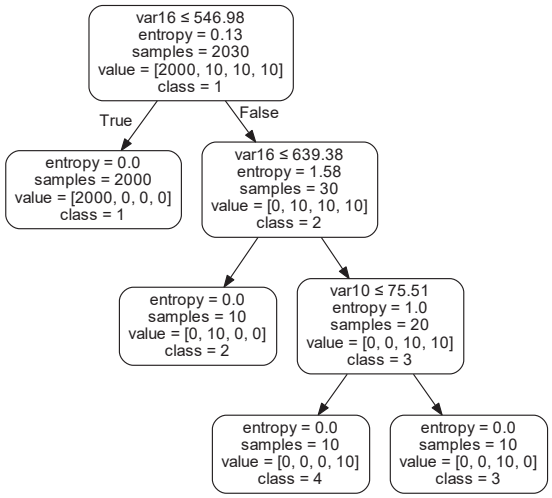

Figure 11: DT for mass location C

For mass location B and C in Fig. 10 and 11, the root nodes of the DTs were able to separate

data from a WTB with and without mass by a single sensor which is located right next to the mass. Nevertheless, by separating the 5kg from 10kg of mass added for location B, the affected sensors were not near the the location of the mass but towards the tip of the blade. The same can be observed for mass location C, where the added mass between sensor 16 and 18 had a significant effect on sensor 10 which is located further down the trailing edge. Detailed information on hyperparameters for the decision trees can be found in Appendix A

5 Conclusions

The work presented in this paper introduces DT as a tool for interpreting and understanding the causes of novelties identified by the MD-based novelty index. The technique was implemented in a large scale WTB with added mass to simulate damage in different locations. The consequences of separating observations from non-added mass and added mass has been studied. Particularly the impact of a collinearity in the feature matrix and its influence on the MD-based novelty index. This was investigated by reducing the dimension of the feature matrix while monitoring the condition number. By avoiding high condition numbers, strong deviations after the training in the control chart were reduced. Once the novelties are identified, DT have been used to understand which features were responsible to cause the novelties in the control chart. The relation of features and accelerometers locations was evaluated. It was found that the accelerometers closer to the location of added mass were at the root of the DT and therefore identifying the importance of a particular feature. Limitations were identified by exploring the separation of different amount of masses. It was observed that the accelerometers further away from the locations were responsible to classify between different amounts of added mass.

This study demonstrated that the occurrence of novelties can be interpreted with the use of DTs. Additional the DTs and their hierarchical structure correlated the location of the mass to the sensor which features were at the root of the tree. Therefore, this could narrow down the location of where the added mass was added and open a further directions to pseudo-locate added masses or in other words damage.

Acknowledgements

The experiments were performed in collaboration with DTU Large Scale Facility, which is a DTU Wind Energy test facility and part of CASMaT - Villum Center for Advanced Structural and Material Testing. The contribution by DTU is partly supported by two projects funded by the Danish Energy Agency through the Energy Technology Development and Demonstration Program (EUDP). The supported projects are BLATIGUE: Fast and Efficient Fatigue Test of Large Wind Turbine Blade (Grant No. 64016-0023) and RELIABLADE: Improving Blade Reliability through Application of Digital Twins over Entire Life Cycle (Grant No. 64018-0068). The financial support is greatly appreciated.

A Decision Trees and Hyperparameters

This appendix is meant to give some insight on the hyperparameter which were used to train the DTs. The selected values for hyperparameters are shown in 2. The DTs were developed and trained by using the scikit-learn library in Python. Hyperparameters for the DT are selected in a way which does not limit the DTs. The aim is to over-fit the classification in order to understand the novelties. Detailed information about the Hyperparameters can be found in [28].

Table 2: Hyperparameters for Decision Tree IP3 algorithm

Hyper-parameter	Selected value
Split criterion	Entropy
Max depth	None
Max features	None
Max leaf nodes	None
Min impurity decrease	0
Min impurity split	None
Min. samples leaf	1
Min samples split	2
Min weight fraction leaf	0
Presort	False
Splitter	best

For training the DTs the complete labeled dataset was used with the aim to over-fit the data from where interpretation of each class can take place.

Keywords: Damage Sensitive Features, Optimal Sensor Networks, Structural Health Monitoring

Abstract. *Structural health monitoring (SHM) includes a wide range of methods focusing on the improvement of structural reliability and life cycle management of engineered systems. In the past decades, smart maintenance procedures have been proposed and implemented for a large number of civil structures with strategic and monumental relevance. Nowadays, rapid advances in signal processing and sensor technology allow for the implementation of smart maintenance schemes for conventional buildings and infrastructure. Vibration-based SHM techniques are among the most applied in the structural engineering field and become increasingly popular due to their interdisciplinary nature. In this framework, the establishment of reliable damage-sensitive features (DSF) is crucial for the efficient evaluation of structural health. This work comprises an investigation on the effectiveness of data-driven DSFs for the case of a large scale reinforced concrete benchmark under shaking table excitation. Different damage identification techniques are applied to expose the propagation of structural damage during strong ground motions. A discussion on the hardware and algorithmic requirements for reliable wireless smart sensor networks (WSSNs), capable of capturing the desired DSFs, is also included.*

1 INTRODUCTION

Despite the unavoidable costs for installation and supervision, the information obtained through monitoring proves to be invaluable in the aftermath of catastrophic events. The recent disaster of the Morandi bridge exposed the unexploited potential of measurements for the maintenance of aging structures. Considerations regarding the life cycle management consist today a prime part of the design of major infrastructure facilities. Structural health monitoring (SHM) provides the tools and the methodologies that allow for the optimization of the maintenance activities along the operational life of structures with substantial impact on the life cycle costs and the safety of the public.

Rapid advances in hardware and software capabilities allow for the widespread diffusion of SHM techniques in the conventional building stock [1, 2]. In particular, Wireless Smart Sensor Network (WSSNs) are the most promising systems for SHM applications because they don't require long cables leading a significant cost reduction and an easier installation procedure. Moreover, WSSNs are characterized by low cost and feature edge-computing capabilities enabling the decentralization of the monitoring process, by reducing the amount of data transferred and improving the energy efficiency of the monitoring configuration [3]. The energy consumption of a wireless network dictates the maintenance intervals and thus consists the bottleneck for the optimal design of WSSNs. Given that energy consumption is highly related to the network architecture, the choice of a suitable network topology for the studied application is of major importance. Shrestha and Xing [4] discussed the performance of various WSSNs topologies by comparing the reliability, energy–efficiency, network life, scalability, self-organizing capability and data latency. Other parameters that constrain further the design of optimal WSSNs stem from cost and size restrictions.

The recent paradigm of Internet of Things (IoT) [5] allows researchers to vision the Internet of STructures (IoST), where proper indexes could provide information regarding structural health at an urban scale, almost in real time. This information could support substantially both the vulnerability assessment as well as the post earthquake damage estimation, which is currently based on time consuming and inevitably subjective inspections. Despite extensive research in this field, the extraction of robust damage sensitive features (DSFs) from vibrational response still poses challenges, particularly related to damage characterization (location, severity) [6, 7]. A large category of DSFs focuses on changes of the modal properties due to structural damage. Noh and coworkers [8] proposed a DSF criterion, which relies on the ratio of the energy allocated on the first mode over the total energy of the response signal. Other candidate methodologies rely on changes in coherence between different nodes, the wavelet decomposition, Hilbert-Huang transform [9], higher order moments or entropy. Recently, Hwang and Lignos [10] described a framework for estimating story-based engineering demand parameters in instrumented steel frame buildings with steel moment-resisting frames. The proposed framework utilizes wavelet-based damage sensitive features and basic building geometric information to infer the building damage state at a given seismic intensity.

This work comprises the implementation of a wide palette of DSFs for the damage detection of full scale recordings. In section 2, the selected features are presented and the key parameters are described. In section 3, the selected features are applied for the evaluation of the recordings of a 7-storey shear wall benchmark experiment. In section 4 are summarized the results and the comparison of the performance of the studied DSFs. Finally, section 5 includes a discussion on the key issues for the design of a decentralised wireless sensor network in a SHM framework.

2 VIBRATION-BASED DAMAGE IDENTIFICATION

In this section, a brief description and some implementation examples of the selected DSFs are reported. Both modal– and non–modal–based features have been selected. In particular, autoregressive (AR) parameters and principal component analysis (PCA) of the covariance of raw acceleration data are usually referred as non–modal–based methods, as the identified parameters cannot be directly interpreted into a modal or physical domain. On the other hand, the curvature of uniform load lines (ULLs) obtained through the flexibility matrix and the transmissibility function belong to the family of modal–based DSFs. Relevant notions for novelty detection as well as damage indices (DIs) implemented in this study are also reported.

2.1 Autoregressive parameters

Autoregressive (AR) models are among the most popular non–modal–based structural identification tools. It has been shown that, despite the non–intuitive physical interpretation of AR parameters, the features captured by AR models, directly fitted to raw acceleration data, are representative of the structural behavior and can be analyzed to detect changes due to damage or changing environmental conditions [11]. AR parameters are computed following the assumption that each sample of a time series depends linearly on the previous samples and can be reconstructed by adding a residual term, which is usually assumed as Gaussian white noise. After selecting a model order (*i.e.*, how many samples are considered in the description of each element of the time series), the identification of AR parameters can be achieved through solving an ordinary least square problem. The simplicity of this method allowed for various implementation in SHM algorithms, involving different usage of AR parameters for the estimation of structural damage [12, 13].

2.2 Covariance–based DSF

Covariance is a common statistical feature that describes the relationship between two signals in time domain. Assessing the covariance of the vibrational responses of sensors placed in different position along a structure has been established as a valid statistical metric for capturing novelties in the dynamic response [14]. These changes, however, can be attributed not only to structural degradation, but also to changing environmental conditions [15]. Principal component analysis (PCA) [16] has been widely applied to enhance the novelty detection by a consequent algorithm. PCA is a linear transformation which is applied to a potentially correlated feature-set. The principal components (PCs) are sorted by their eigenvalues in a decreasing order, where the first PC has the highest explained variance after the transformation. This procedure can reduce the dimension of the feature-set while maintaining a high remaining variance explained.

2.3 Curvature of the uniform load line

Changes in modal curvature is the basis of various modal-based DSFs in the field of damage identification, as it is proven to be particularly effective to localize structural degradation related to stiffness reduction [17]. Major drawbacks of this this feature include its rather approximate computational scheme (i.e., the central difference method), starting from displacement lines, and the fact that at least three data points are required to evaluate each curvature value. As a result, modal curvature based DSFs tend to be too sensitive to inaccuracies in the identification of modal shapes and require a considerable amount of sensors, placed at equidistant locations.

In this paper, the curvature of the uniform load line (ULL) has been applied. This approach describes the structural behavior in the physical space and is less sensitive to identification errors

for higher modal shapes [18]. In particular, the ULL of a structure represents the deflection shape under the application of a uniform load vector, the entries of which are unitary forces applied at each sensor location. The ULL is generally evaluated through the flexibility matrix of the structure **F**, which can be estimated by the first r vibration modes, as following:

$$\mathbf{F} \cong \sum_{j=1}^{r} \frac{1}{\omega_j^2} \mathbf{\Phi}_j \mathbf{\Phi}_j^T \tag{1}$$

where ω_j and $\mathbf{\Phi_j}$ indicate the j–th natural circular frequency and modal shape, respectively. The ULL can thus be computed as:

$$\mathbf{u} = \mathbf{F}\mathbf{p} \tag{2}$$

where $\mathbf{p} = [1, 1, \ldots, 1]^T$ has the same size as $\mathbf{\Phi}_j$.

It should be noted that, in order to compute the real flexibility matrix, modal shapes must be mass-normalized. In this case, a variation of **u** registered during a monitoring process could also be related to a physical quantification of damage in terms of flexibility increment (*i.e.*, stiffness decrement). In real case studies, however, there is often no precise information regarding the mass distribution, especially for complex structures. As a result, the evaluation of **F** becomes particularly challenging. For the purposes of the present work, a uniform distribution of masses along the height of the building is considered. This assumption coincides with the regular geometry of the studied benchmark experiment. Therefore, modal shapes are normalized with respect to an identity matrix, and **F** is considered as proportional to the real flexibility matrix. In this case, a quantification of damage in absolute terms is not possible, but the method still allows for the localization of damage [19].

2.4 Transmissibility based criteria

Transmissibility based criteria have been recently proposed in an attempt to detect and localize damage based on output-only data [20]. The transmissibility function between points *a* and *b* of an elastic system can be defined as the ratio of the complex amplitude of the system responses in frequency domain, which can be expressed as a fraction of power spectral densities:

$$T_{a,b}(\omega) = \frac{X_a(\omega) \times X_b(\omega)}{X_b(\omega) \times X_b(\omega)} = \frac{G_{a,b}(\omega)}{G_{b,b}(\omega)} \tag{3}$$

By implementing Pearson's correlation coefficient for the transmissibility vectors in different damage states, researchers defined a correlation-based damage indicator (CDI):

$$CDI_{a,b} = |\frac{Cov(T^d, T^u)}{\sigma_{T^d}\sigma_{T^d}}| \tag{4}$$

An additional feature based on the modal assurance criterion was also defined as transmissibility assurance criterion (TAC):

$$TAC_{a,b} = \frac{[(T^d)^T(T^u)]^2}{[(T^d)^T(T^d)][(T^u)^T(T^u)]} \tag{5}$$

where T^d and T^u represent the transmissibility vectors under damaged and healthy conditions. Considering the points *a* and *b* as the recording points along subsequent storeys of a building,

transmissibility based criteria provide information for structural changes between the measuring points. For shear wall concrete buildings with rigid slabs, the earthquake induced damage is expected to concentrate in the lower floor levels. For such cases, transmissibility based criteria for damage detection and localisation are well defined. However, such criteria cannot provide robust estimation for the level of damage since they rely exclusively on low amplitude measurements, where the system is expected to respond in the equivalent elastic regime.

2.5 Mahalanobis Distance

The Mahalanobis distance (MD) is a widely applied multivariate distance metric to highlight novelties or outliers in a feature-set [21]. The MD measures the distance between a point and a distribution. The distribution is commonly calculated for a reference feature-set which is also called the training-set. The MD is described as follows:

$$d(\mathbf{x}^k, \mathbf{Y}) = \sqrt{(\mathbf{x}^k - \boldsymbol{\mu}_\mathbf{Y})^T \boldsymbol{\Sigma}_\mathbf{Y}^{-1} (\mathbf{x}^k - \boldsymbol{\mu}_\mathbf{Y})} \tag{6}$$

where $d(\mathbf{x}^k, \mathbf{Y})$ is the distance between a feature vector $\mathbf{x}^k$ and a reference $\mathbf{Y}$, with k being the k^{th} feature vector in a feature-set. $\boldsymbol{\mu}$ is the mean of features in $\mathbf{Y}$ and $\boldsymbol{\Sigma}$ the covariance of the reference feature-set. This metric is used as DI for the modal-based DSFs investigated in this work.

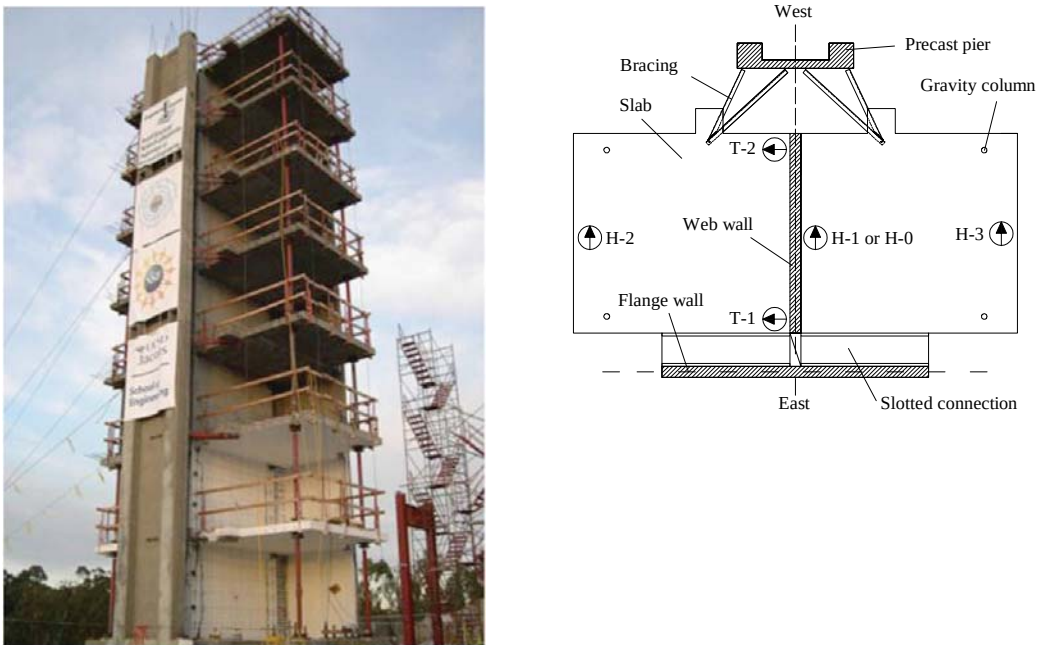
2.6 Damage indices and novelty detection

For most of the damage identification algorithms the identified parameters are compared to baseline information obtained right after the installation of the monitoring system. This baseline information is considered to represent the undamaged condition. To quantify this comparison, a proper DI has to be selected and a threshold between "damaged" and "healthy" state has to be defined. For the AR and covariance based DSFs the MD has been used as a DI since a statistically significant set of results were evaluated. For the former case, a different set of AR parameters can be identified for each data array (i.e., considering data intervals of user-defined length at each sensor location). In general, damage localization cannot be directly achieved by analyzing local modifications in AR parameters [13]. For this reason, the mean of MDs computed over the set of all recording nodes has been selected as the final DI for the purposes of damage detection. Similarly, the MD-based damage index is evaluated for the covariance and PCA based DSF. A threshold is selected for the reference state and is represented by T_{th}. The choice of T_{th} is based on a cumulative distribution of the damage index where the k^{th} percentile of the data is allowed to exceed the threshold. Consequently, $d(\mathbf{x}^k, \mathbf{Y}) > T_{th}$ are considered as novelties and are potentially correlated to damage.

For the modal-based DSFs longer datasets are required and thus only deterministic DIs can be defined through the analyzed data. For the curvature of the ULL, the percentage variation between local estimates of the DSF in different damage scenarios is considered. For the transmissibility based DSF the identified CDI and TAC metrics are evaluated.

3 DAMAGE DETECTION ON REAL-SCALE RECORDINGS

The DSFs described in Section 2 are evaluated using the data collected during a benchmark experiment on a full-scale RC structure tested on a shaking table at the University of California, San Diego [22, 23]. After a brief description of the case study, the results are reported and discussed.



(a) (b)

Figure 1: Picture of the tested structure (a) and ground floor plan of typical storey (b)

3.1 Description of the case study

The specimen, shown in Figure 1a, consists of two perpendicular walls (web and flange wall) and a concrete slab at each storey–level, supported by four gravity columns and an auxiliary post–tensioned column that provides torsional stability to the system (Figure 1b). Shaking table tests were designed to progressively damage the building through the simulation of four historic earthquakes recorded in California, with increasing intensity. Before and after each shaking test, the response of the building was recorded under white noise (WN) excitation, with a root mean square (RMS) amplitude equal to $0.03\,\mathrm{g}$, and low amplitude ambient vibration (AV), as described in detail in [22, 23] and in Table 1. In particular, between tests S3.1 and S3.2, the bracing system between the slabs and the post–tensioned column was stiffened. The present work focuses exclusively on the acceleration response during the white noise excitation before and after the strong shaking events.

The instrumentation of the tested structure includes 45 uniaxial accelerometers: 29 measuring the longitudinal direction (three on each floor slab, one on the web wall at mid-height of each story, and one on the pedestal base), 14 measuring the transversal direction (2 on each floor slab), and 2 nodes measuring the vertical direction (at the base, on the pedestal). In this paper seven different sensor configurations are considered, as described in Table 2, with reference to Figure 1b. The original data are sampled at $240\,\mathrm{Hz}$ and are here downsampled at $100\,\mathrm{Hz}$. More details about the geometry and the instrumentation can be found in [22, 23].

Test	Description
S0	8min WN (0.03%g RMS) + 3min AV

(a) AR Model

(b) Covariance based DSF

Figure 2: Control charts for non-modal-based DSFs

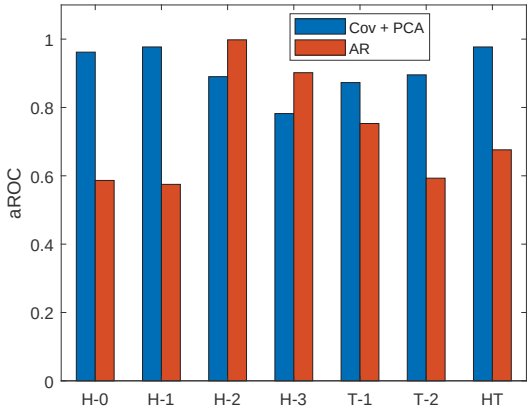

Figure 3: aROC and false alarm rates obtained for the non-modal-based approaches

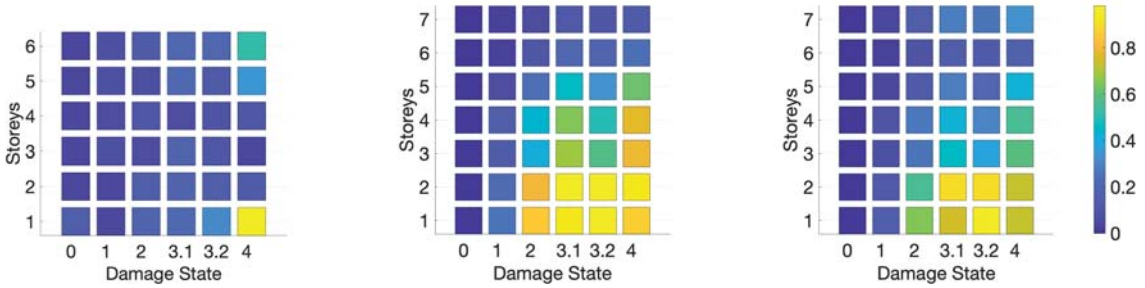
3.2 Discussion of the results

For non-modal-based DSFs, a control chart approach demonstrates clearly the online novelty detection procedure for damage identification. Response windows of seven minutes, divided into sets of 1000-samples, are considered as separate inspection intervals. The DSF is computed for each inspection interval and compared to the baseline estimation, which is evaluated based on the first 55 intervals for condition S0. In Figure 2, the MD between the feature evaluation on each interval and the baseline is presented. For brevity, only the results for the sensor deployment layout T-1 are reported. The threshold for novelty detection is set in the training set and allows 1% of outliers. A comparison between the control charts of the AR based DSF (Figure 2a) and the covariance based DSF (Figure 2b) demonstrates that, the AR model captures adequately the transition from the healthy state to the first damaged state, while it fails to provide clear boundaries between the subsequent damage states. On the other hand, the covariance based DSF differentiates better significant damage (S4 and S5) from the initial damage states, while indicates minor variations from conditions S1 to S3.1.

Summary results obtained from the evaluation of these DSFs using all the deployment layouts of Table 2 are reported in Figure 3. It can be noticed that, although the false alarm rate of the covariance-based method is generally higher, the area under the ROC curve (indicated



(a) Curvature (b) TAC (c) CDI

Figure 4: Transmissibility-based and curvature-based damage indices evaluated for each damage condition

here as aROC) is greater in most cases, denoting a better discrimination between healthy and damaged conditions. Moreover, it is worthy to note that the AR-based method works better in the transversal direction, showing higher aROC values, while the covariance-based approach performs well in all the deployment layouts.

Figures 4a, 4b and 4c illustrate the damage indices calculate by the curvature-based and the transmissibility based approaches, by considering the sensor deployments H-1. In this work, a deterministic comparison between healthy and damaged conditions is considered. In order to compute curvature, the central difference method is employed, assuming that the base displacement is 0, obtaining 6 curvature values.

While the curvature-based approach is less sensitive to small damages, the transmissibility function appears to detect also small variations in the dynamic behavior, showing an accurate estimation of the damage position and consistent representation of the identified damage degradation due to increasing the excitation amplitude. Moreover, the TAC criterion proves to be more sensitive to damage in comparison to the CDI criterion.

4 CONSIDERATIONS ON WIRELESS SENSOR NETWORK IMPLEMENTATIONS

The considerations reported in this section refer to a star-topology network. This is one of the most commonly used topology due to its simplicity, although Cluster Head and mesh topologies provide a better flexibility, *i.e* network scalability, communication reliability or energy management [4]. In particular, the network was designed to collect n samples of acceleration data at each node location at user-defined inspection intervals. Depending on the feature, DSFs are then partially or fully computed in the central monitoring station (*i.e.*, the sink node), where damage identification takes place. Table 3 summarizes the main characteristics of interest for the implementation of DSFs on a WSSN. While univariate AR parameters and covariance can only identify structural changes due to modifications of the dynamic response in time domain, modal-based parameters can provide information about the position and, under certain assumptions, the extent of damage. The number of channels needed to calculate each DSF reflects the possibility to compute it in a decentralized manner, by performing part of the processing on the nodes. The minimum number of samples to be transferred to the central monitoring station for the evaluation of the DSFs is also considered as a performance index.

AR parameters are identified on single data series, such as the raw acceleration signals recorded by each node. In this case, AR parameters could be identified onboard and the transmission could be reduced to the selected order of the AR model (p). Covariance and trans-

DSF	Id level	Num. of channels	Num. of samples	Complexity
AR parameters	Detection	$\geqslant 1$	p	O(p^2n)
Covariance	Detection	$\geqslant 2$	n	-
Curvature	Loc./Quant.	$\geqslant 3$	n	-
Transmissibility	Localization	$\geqslant 2$	s	O($slog(s)$)

Table 3: Characteristics of the considered DSFs

missibility functions require couples of acceleration channels for their evaluation in time and frequency domain respectively. Truncated spectra can thus be employed to estimate the transmissibility in the band of interest. The number of samples required at the level of central node is therefore equal to the number of points of the truncated frequency spectrum (s), which can be computed on each node before transmission. The curvature based DSF requires recordings of at least three subsequent nodes to be computed. Hence, the identification of this feature has to be performed in a centralized fashion with complete data series, in order to preserve phase information.

Computational complexity is an aspect of utmost importance when decentralized processes are implemented on low-cost smart nodes, since they are generally characterized by small computational capabilities and limited battery life. The identification of AR parameters can be obtained through several algorithms with varying complexity. The ordinary least squares problem yields an asymptotical complexity of O(p^2n), with p denoting the order of AR model and n the number of training samples. Alternatively, through the Yule-Walker method, the complexity becomes O($p^2 + np$), still being strongly dependent on the selected order, which increases with the structural complexity. Among the different Yule-Walker solvers, Dushin and Frolov [24] exploited the Levinson–Dusrbin recursion for extrapolating AR coefficients and monitoring environmental phenomena such as humidity and light. Lynch [25] exploited the Burg's method to solve the Yule-Walker equations which avoids complex matrix inversion operations. In such a case, considering 4000–time samples and the identification of 30 AR coefficients, the WSSN needed $8\,\mathrm{s}$ of computational time with $3\,\mathrm{J}$ of energy consumption.

Covariance and curvature based DSFs are not suitable for decentralization in a simple star-topology network. Hence, the computational complexity at the central node is high, involving the evaluation of all couples of covariance functions for the former feature, and a complete automated modal identification for the latter. The computation of the frequency spectrum for the identification of transmissibility functions can be conducted on the nodes with a complexity of O($slog(s)$), by implementing fast Fourier transform (FFT) with s frequency points. It is worth mentioning that Goertzel's algorithm [26] can also be utilized for frequency analysis with a computational complexity of O(s) for a single bin of the spectrum and exploiting recursion [27].

5 CONCLUSIONS

Despite recent advances in algorithms and hardware related to damage identification, SHM remains an unexploited potential in civil engineering practice. The substantial costs related to the instrumentation and the management of the recorded data undermine the widespread implementation of sensors networks that could provide valuable insights into the structural behaviour of infrastructure and buildings during and after catastrophic events. This work explores the efficiency of various modal-based and data-driven DSFs, implemented on real scale recordings. The applicability of the studied DSFs in low cost WSSNs, in terms of computational complex-

ity, energy efficiency and data transmission, is also discussed.

In the present case, data-driven DSFs estimated by short data series detect accurately damage and could be computed almost in real time in permanent SHM applications. While the AR-based approach proves to be more robust in sensing the transition from healthy to damaged state, the covariance–based approach is more suitable to identify severe structural degradation. The possibility to compute the AR parameters on smart nodes allows for the decentralization of the processing, reducing substantially the volume of the data to be transmitted. For distributed sensor networks, modal–based DSFs can provide information related to both the location and the severity of damage. In the present study, transmissibility–based approaches perform very well in both tasks. Although these indexes can only be assessed in the central node, the required information reduces to truncated spectral coordinates. Finally, the curvature-based approach proves to be sensitive only to severe damage and is not suitable for decentralized configurations.

Keywords: direct stiffness calculation, iterative model updating, modal curvature, interpolation error, strain energy, composite beam, comparison

Abstract. *This paper reports results relevant to the experimental comparison of a number of vibration-based methods for damage localization applied using responses recorded during forced vibration tests on a composite beam. Damage is intended herein as a stiffness change. Four methods from the literature were compared: two model-based methods, namely the direct stiffness determination method and the model updating method and two response-driven methods, namely the modal interpolation error method and the modal strain energy method. The tested specimen is a composite beam made of timber and plaster boards, with a total span of 4.0 m and simply supported at the ends. During the forced vibration tests responses in terms of acceleration were measured at 24 points along the beam axis. Responses were recorded in both the reference states and in several modified states in which local variations of bending and shear stiffness were simulated adding a stiffener or unscrewing a number of bolts. Using the accelerometric responses the comparison of the four considered methods was performed in terms of the accuracy of damage localization.*

1 INTRODUCTION

Vibration-based non-destructive testing as part of Structural Health Monitoring (SHM) has become a growing interest of the civil engineering research community due to the increased need of an informed support to decision related to the request for higher safety standards [1], to the large number of structures approaching the end of design life and to the changing of loading conditions due to the increase of traffic [2]. The goal of SHM is to optimize structural management through the identification of structural damage at the earliest stage or the acquisition of data enabling a prognosis of the remaining service life. This can reduce both long-term and emergency management costs [3]–[6]. According to [7], it is expected that in the future SHM will take an important part in the administration of transport infrastructure due to the lack of effectiveness and scarce reliability of visual inspections which are highly dependent on the subjectivity of the operator and do not provide real-time information about the structural state.

Several SHM methods exist in the literature, allowing different levels of damage identification, i.e. damage detection, damage localization, damage quantification and damage prognosis [8]. In this paper the focus in on vibration-based damage localization methods, which uses vibration data, e.g. velocities and accelerations, recorded on instrumented locations of the structure to identify changes in stiffness. In general, they can be classified in model-based methods and response-based methods. Model-based methods need a numerical model of the structure, e.g. Finite Element (FE) model, whereas response-based methods use only data recorded on the structure. Model-based methods are more time consuming and require higher computational effort with respect to response-based methods. However, they usually allow also to quantify the severity of damage beside its existence and location. A comparison of several response-based methods for damage localization applied on a real bridge is provided in the reference [9].

In this paper, four well-known vibration-based methods for damage localization are compared: two model-based methods, namely the direct stiffness determination method and the model updating method and two response-based methods, namely the modal interpolation method and the modal strain energy method. Damage is intended in general as a change in stiffness. The methods are applied to a bridge-like lab specimen using modal parameters provided by experimental modal analysis. The comparison is performed in terms of accuracy of the damage localization. Different scenarios are considered, namely an increase of bending stiffness and two shear damages.

The paper consists of several sections. Section 2 introduces the considered methods; Section 3 describes the experimental specimen and the damage scenarios; Section 4 reports the results of the damage assessment and the comparison of results; conclusions are given in Section 5.

2 THEORETICAL BACKROUND OF USED METHODS

2.1 Model-based methods

2.1.1. Finite Element Model Updating

The Finite Element Model Updating (FEMU) method uses a numerical model of the investigated structure whose parameters are updated minimizing the residual between the model and the structure experimental characteristics. Herein the values of the modal parameters, estimated by means of operational or experimental modal analysis, are used to update the stiffness matrix of the FE model. The stiffness matrix is modelled as a function of the model parameters according to the equation:

$$\mathbf{K}(\theta_{\mathrm{M}}) = \mathbf{K_0} + \sum_{j=1}^{N_M} \theta_{M,j}\mathbf{K_j} \tag{1}$$

where $\mathbf{K_0}$ represents an initial stiffness matrix, $\mathbf{K}(\theta_{\mathrm{M}})$ is the updated stiffness matrix which depends on the parameter vector θ_{M}, $\mathbf{K_j}$ is the contribution of the substructure $j = 1, \dots, N_M$ to the global stiffness matrix and $\theta_{M,j}$ is a scaling parameters representative of its effective stiffness.

The optimal parameters are found by minimizing a cost function [10]. As mentioned in [11], in most practical applications, the cost function is formulated as a sum of squared residuals, as follows:

$$F(\theta_M) = \frac{1}{2}\sum_{k=1}^{m} a_k \frac{\left(\bar{d}_k - y_k(\theta_{\mathrm{M}})\right)^2}{\bar{d}_k^2} \tag{2}$$

where $\bar{d}_k$ is the $k = 1, \dots, m$ experimental data, $y_k(\theta_{\mathrm{M}})$ is the output response of the model and the factor a_k reflects the weight appointed to the normalized residuals. In this paper the components of the modal shapes are used as output model y_{k}.

By minimizing the cost function $F(\theta_M)$, it is possible to find values of the optimal parameter θ^*_{M} that the best match between the model and the experimental data is achieved.

2.1.2. Direct stiffness calculation

The direct stiffness calculation (DSC) method uses the experimental natural frequencies and their corresponding mode-shapes to derive the dynamic stiffness. The method is based on the relation, valid at each section *x* of the beam, between the dynamic bending stiffness *EI*, the bending moment M_b and the corresponding curvature (second derivative of modal shape ϕ_b) [12], [13]:

$$EI(x) = \frac{M_b(x)}{\phi_b''(x)} \tag{3}$$

The bending moments M_b are caused by the inertial forces F_I corresponding to the considered modal shape and can be computed at each section as:

$$F_I(x) = \omega^2 m(x)\phi_b(x) \tag{4}$$

where $m(x)$ represents a mass at each section, ω is the natural frequency and $\phi_b(x)$ is the value at each section of the modal shape connected to the natural frequency ω. In the case of undamped system, the relation between internal forces and inertial forces is:

$$\mathbf{K}\boldsymbol{\phi}_b = \omega^2 \mathbf{M_a}\boldsymbol{\phi}_b \tag{5}$$

where $\mathbf{K}$ is stiffness matrix, $\mathbf{M_a}$ represents a mass matrix (analytically determined) and $\boldsymbol{\phi}_b$ is the vector of the bending modal shape. It represents a pseudo static system. Therefore, the accelerations recorded during the forced vibration tests can be directly multiplied by mass matrix in order to calculate the inertial forces. These pseudo static forces are used in static analysis

(e.g. with a finite element package) in order to calculate modal bending moments M_b. The next step represents calculation of curvature, e.g. using the Finite Difference Method. Because of the occurred inaccuracies, it is recommended to use smoothing function. Therefore, residual penalty-based method is applied and is very similar to FE approach mentioned before. The references [12], [13] describe the method in more detail.

2.2 Response-based methods

2.2.1. Modal strain energy method

The damage index proposed in reference [14] is based on the assumption that damage does not change the fraction of modal strain energy, defined as the ratio between the modal strain energy stored in the *i*-th element and the modal strain energy stored in the structure. In this way, the ratio between the bending stiffness of the *i*-th element in the Undamaged (U) and in the Damaged (D) states can be computed as a function of the modal curvatures retrieved by the SHM system in the two states. Summing up the contributions of all the identified modes, the following expression is obtained for the damage index at the *i*-th location, i.e. one of the $i = 1, \dots, N$ locations where the components of the modal shapes are known that is where sensors are located:

$$\beta_i = \sum_{k=1}^{n_{modes}} \frac{\phi''_{k,i,D}{}^2}{\sum_{i=1}^{N} \phi''_{k,i,D}{}^2} \Big/ \sum_{k=1}^{n_{modes}} \frac{\phi''_{k,i,U}{}^2}{\sum_{i=1}^{N} \phi''_{k,i,U}{}^2} \tag{6}$$

The damage index β_i assumes values higher than one at locations where a reduction of the bending stiffness occurs in the state D.

2.2.2. Modal interpolation error method

The interpolation error method proposed in reference [15] takes advantage of the properties of the cubic spline interpolation of mode-shapes to localize damage on structures. In particular, due to the so-called "Gibbs phenomenon for splines", a sudden increase of the interpolation error is observed at the locations with a curvature discontinuity. Therefore, this property can be used to identify the locations where a change of stiffness occurs. At the i-th ($i = 1, .., N$) instrumented location, the performance of the interpolation is computed for the k-th mode through the interpolation error $E_{k,i}$, defined as the absolute difference between the measured component of the k-th mode-shape at that location $\phi_{k,i}$ and the interpolated value $\hat{\phi}_{k,i}$, i.e. $E_{k,i} = \left|\phi_{k,i} - \hat{\phi}_{k,i}\right|$. The interpolation error at the i-th location is obtained by combining the contributions of all the identified modes as follows:

$$E_i = \sqrt{\sum\nolimits_{k=1}^{n_{modes}} E_{k,i}^2} = \sqrt{\sum\nolimits_{k=1}^{n_{modes}} \left|\phi_{k,i} - \hat{\phi}_{k,i}\right|^2} \tag{7}$$

The interpolation error can be computed in the reference state, E_i^U, and in a possibly damaged state, E_i^D. The increase of the interpolation error at the i-th location with respect to the reference state, $\Delta E_i = E_i^D - E_i^U$, indicates a loss of stiffness at that location and it is assumed as damage indicator. The main advantage of this method is that it does not require the direct computation of modal shapes' curvature. Additional information on the interpolation error method can be found in the references [16], [17].

3 EXPERIMENTAL MODEL

3.1 Description of the lab specimen

The tested lab specimen consisted in a simple bridge-like structure made by a main timber beam coupled with plaster boards, see Figure 1. Three timber boards (each with dimensions of 4000 x 100 x 20 mm) were used to build the main beam. The upper part of the specimen, the "deck", was made of three overlapped plasterboard layers with thickness 12.5mm each. The deck was 300 mm wide and 37.5 mm high. The plasterboard layers were connected by pairs of screws tightened every 170 mm into the main timber beam. The supports are located 50 mm from both ends.

Figure 1: The lab specimen.

Three scenarios have been considered, namely the simulation of a repair and two shear damages. They are displayed in Figure 2. The repair, referred in the following as Scenario 1, was simulated by fixing a timber board (dimensions of 200 x 100 x 20 mm) to the main beam at 1.4 m from the left end of the beam, see Figure 2 (a). The two shear damage scenarios, named Scenarios 2 and 3, were modelled by unscrewing a number of bolts connecting the plaster boards and the main beam: the screws were removed in two stages, four screws for each stage. In Scenario 2, four bolts were removed in the area 0-200 mm from the left support. In Scenario 3, the remain four bolts were removed in the area 200-400 mm from the left support, see Figure 2 (b).

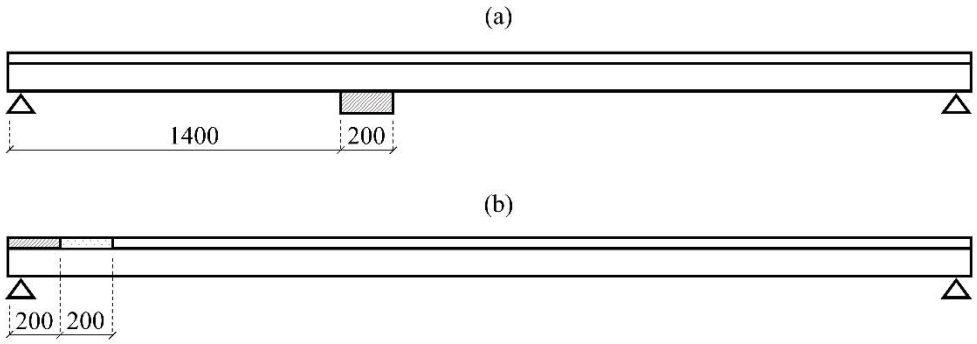

Figure 2: (a) Scenario 1 – the addition of a stiffener; (b) Scenarios 2 and 3 – the shear damage (quotes in mm).

Dynamic tests (forced vibrations test) were carried out using 24 high-sensitivity accelerometers (PCB Piezotronics 393B31) shown in Figure 3 (a). Two electromagnetic exciters were placed 500 mm from both ends of the beam see Figure 3 (b) and synchronized [18] to apply the excitation force as a sine wave. Responses were recorded with a sampling rate of 2048 samples

per second and later down sampled to 100 samples per second. The peak-picking method [19] was applied to perform dynamic identification. Tests were carried out in all scenarios under similar environmental conditions (20°C temperature - 60% humidity). Therefore, the effect of environmental conditions was not taken into account.

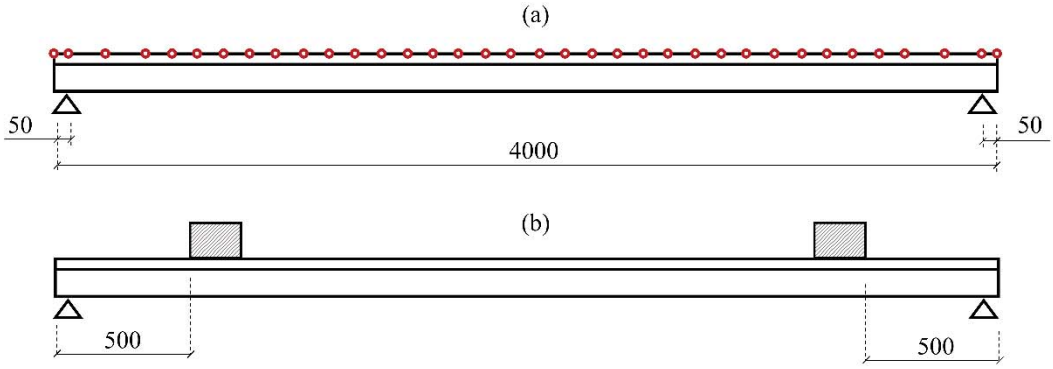

Figure 3: (a) Lateral view of the lab specimen and location of sensors; (b) Location of the exciters (quotes in mm).

4 APPLICATION OF DAMAGE LOCALIZATION MEHTODS

For each scenario, accelerations were measured at 24 locations along the test specimen. The components of the modal shapes were calculated at the same locations and later interpolated using a smooth function according to the method described in [20]. Only the first identified modal shape, reported in Figure 4 for the different scenarios, is used to apply the damage localization methods. It can be observed that in Scenario 1 and Scenario 3 the reference modal shape differs from the modified configuration. Regarding Scenario 2, the modal shapes in the reference and damaged configurations look very similar.

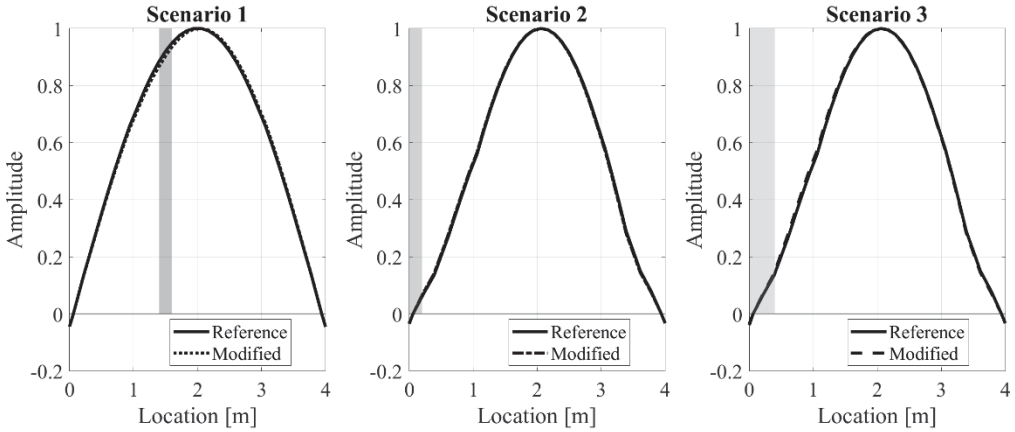

Figure 4: Identified first modal shapes for the considered scenarios

4.1 Results of the model-based methods

The results obtained using the FEMU and the DSC method for Scenario 1, the simulated repair, are displayed in Figure 5. The black line shows the identified values of *EI*. The reference values of this parameter computed from the geometry of the section, are reported with the grey line: EI=274 kNm^2 at the section with the stiffener and EI=145 kNm^2 at all the other sections.

Only the first bending modal shape (shown in Figure 4) was used as input for the two methods. The reason is that the performance of the DSC method decreases when it is applied using higher modal shapes which present multiple nodes, leading to zero by zero division in Equation 3. The bending moments (caused by inertial forces from the first modal shape) at each section were also determined numerically using the FE model. In the application of the DSC method, the curvature was calculated numerically using the Finite Difference Method. According to that, it was possible to calculate the bending stiffness of each section using Equation 3.

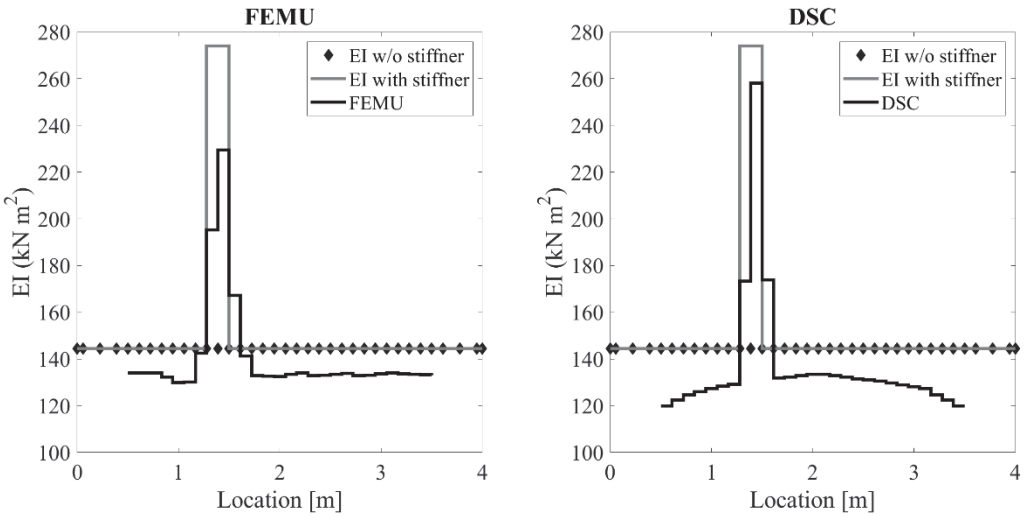

Figure 5: Model based methods: Scenario 1 – repair simulation.

The results of the DSC method are presented only for Scenario 1, since for Scenarios 2 and 3 the method was not able to identify the damage possibly due to its location very close to the boundary where the computation of curvatures is always tricky.

Figure 6 reports the results obtained applying the FEMU method to Scenarios 2 and 3. The reference value computed for the intact beam from its geometry is EI_0=145 kNm^2 marked with a dotted line in Figure 6. The solid line with squares shows the *EI* values identified for the intact structure: the higher values identified in the region close to the left end side of the beam are due to the presence of a higher number of screws with respect to the rest of the beam. The first stage of damage (Scenario 2) was simulated by unscrewing four bolts; additional four bolts were loosened in the second damaged stage (Scenario 3). The values identified for *EI* in the two damage scenarios are reported in Figure 6 and show a decrease around the damaged region with respect to the reference value.

A variation of *EI* (an increase in scenario 2 and a decrease in scenario 3) is mistakenly estimated in the region close to the right end side of the beam, around the section at 3.4 m, from the left end side. This variation is likely to depend on the presence of the shaker at this location that was not modelled as a concentrated mass in the FE model.

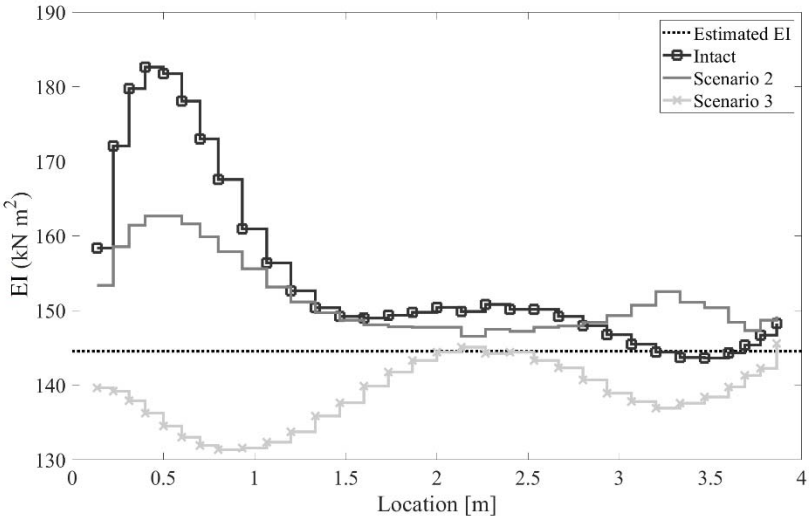

Figure 6: FEMU method: Scenario 2 and 3 – shear damage.

4.2 Response-based methods

The damage indices related to the two response-based damage localization indices are computed according to the formulation described Section 2.2. The curvature, needed to apply the modal strain energy method, is estimated by the Central Difference method. The modal interpolation error method does not require the computation of the curvature. The results are displayed in Figure 7, Figure 8 and Figure 9. The damage indicators in the different positions have been normalized to have the maximum value equal to one. It is observed that both the modal strain energy method and the modal interpolation error method are able to correctly localize changes of stiffness in Scenario 1 and the shear damage simulated in Scenario 2. Note that in the case of the modal strain energy method, the damage indicator reaches the minimum values in correspondence of the added timber board (grey region). In fact, the damage indicator represents the ratio between the bending stiffness between the reference and the "damaged" scenarios. In cases of loss of stiffness, the damage location is associated with a positive peak of the damage indicator.

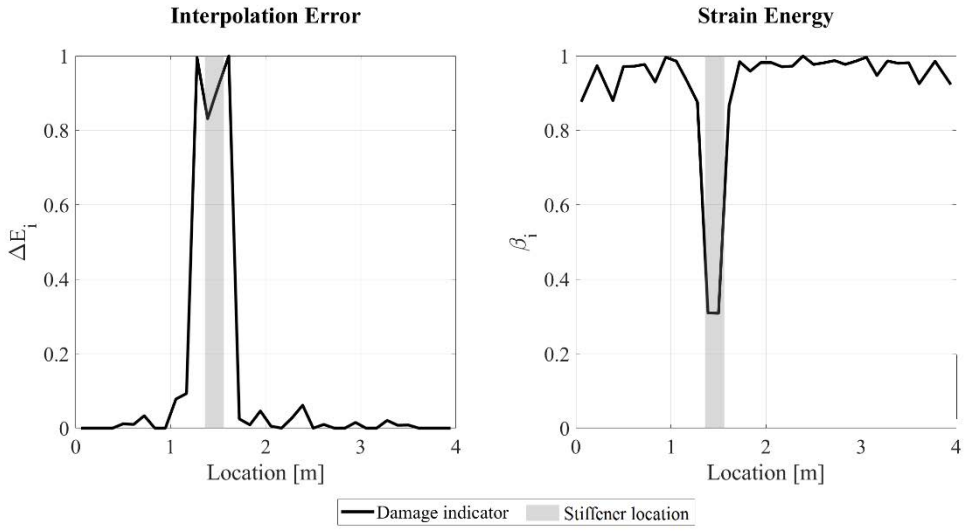

Figure 7 Data-driven methods: Scenario 1 – repair simulation.

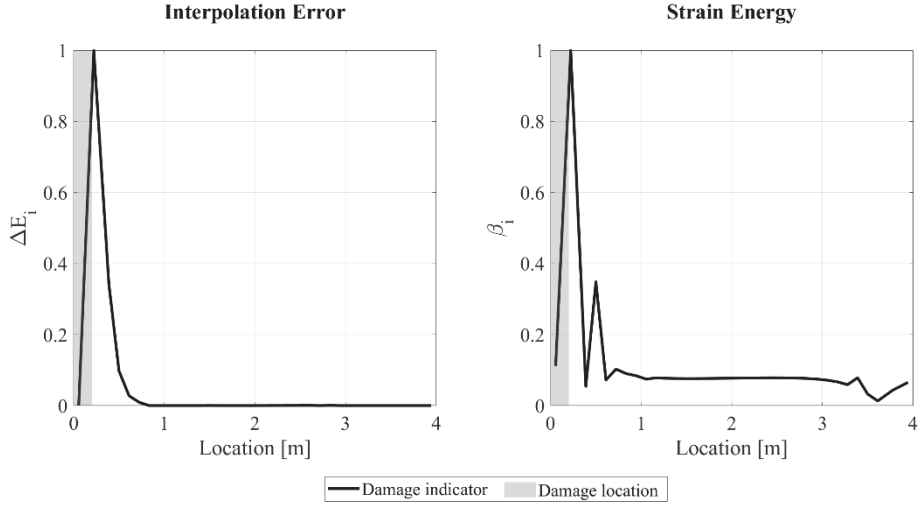

Figure 8: Response-based methods: Scenario 2 – shear damage.

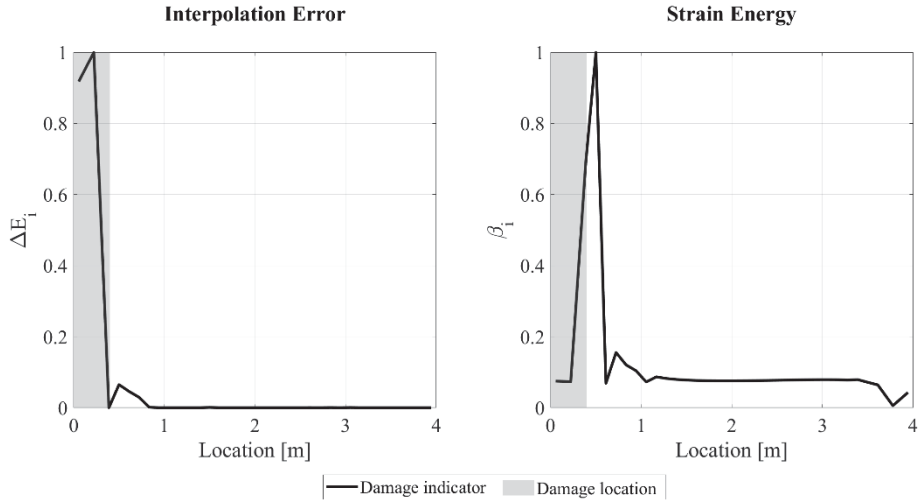

Figure 9: Response-based methods: Scenario 3 – shear damage.

4.3 Comparison of methods

The comparison of the results obtained using the considered methods is performed in terms of the relative error e_L, expressed in percentage, defined in reference [21] as follows:

$$e_L = \frac{x_R - x_I}{L} \times 100 \tag{8}$$

where x_R and x_I are the real and the identified locations, respectively, in which the change of stiffness has occurred and $L = 4\ m$ is the length of the specimen. The relative error can be positive or negative according to the relative locations of x_R and x_I, and it is equal to zero if $x_R = x_I$. The values assigned to x_R are 1. 5 m in Scenario 1, 0.10 m in Scenario 2 and 0.2 m in Scenario 3. The values of the relative errors are displayed in Table 1.

Since a quantification of damage can be achieved by the two model-based methods, a comparison of the two model-based methods is performed in Table 2 in terms of difference of identified and real stiffness achieved in Scenario 1.

Method	Scenario 1	Scenario 2	Scenario 3
DSC	2.78	-	-
FEMU	2.78	-7.23	-4.73
Modal interpolation error	-2.75	-3.05	-0.56
Modal strain energy	0.00	-3.05	-7.50

Table 1: Values of the relative error e_L, in %.

Method	Identified EI [kNm^2]	Reference EI [kNm^2]	Difference [%]
DSC	258	274	-6
FEMU	229	274	-16

Table 2: Comparison of results for Scenario 1.

5 CONCLUSIONS

Four methods for damage localization, two model-based and two response-based are compared in this paper using an experimental case study. Two different damage scenarios were simulated by a) locally changing the bending stiffness of the specimen and b) reducing the shear stiffness gradually in two steps.

The comparison shows that:

- The response-based methods provide the correct identification of damage for the variation of both the bending and the shear stiffness. They are particularly straightforward to apply and do not require a numerical model of the structure. However, these methods do not provide information about damage severity.
- The FEMU - model-based - method provides accurate location and severity of damage for both bending and shear damage scenarios. The DSC while successfully identifies, with higher accuracy with respect to the FEMU, the variation of the bending stiffness, fails to identify a shear damage close to the support of the beam.

ACKNOWLEDGEMENTS

This paper has been supported by the grant No. 1/0749/19 provided by the VEGA Agency of Ministry of Education, Science, Research and Sport of the Slovak Republic and of the Ministry of Education, Science, Research and Sport of the Slovak Republic within the Research and Development Operational Program for the project 'University Science Park of STU Bratislava', ITMS 26240220084. Further support was provided by a grant from the research program of Slovak University of Technology – Excellent teams of young researchers 2018. Part of this work was performed during the stay of Dr Venglar at Politecnico di Milano in the framework of an Erasmus + agreement.

Keywords: Railway suspension, Fault detection, Health monitoring, Vibration–based methods, Robust methods, Statistical Time Series.

Abstract. *The feasibility of on–board random vibration–based fault detection in railway suspension systems based on a single, car body mounted, vibration sensor and variable nominal traveling speeds (Operating Conditions, OCs) is explored via robust Statistical Time Series (STS) type detection methods. The study is based on field tests performed on an Athens Metro vehicle traveling at* $60, 70, or\ 80\ km/h$*, while two fault scenarios are considered: Air Spring (AS) pressure reduction by* 25% *and Lateral Damper (LD) subject to lubricant loss. The problem is shown to be challenging due to the use of a single sensor, the considerable influence of the OCs (varying nominal speed) on the dynamics, and the minor nature of the LD fault. The study focuses on two Multiple Model type methods: A non–parametric Power Spectral Density based method and a parametric AutoRegressive model based method. The results of the study, based on thousands of test cases, demonstrate perfect detection performance of both methods for the AS fault, but, expectedly, degraded performance (especially by the non–parametric method) for the LD fault. Preliminary comparisons with an alternative method, employing the Multiscale Permutation Entropy (MPE) and Linear Local Tangent Space Alignment (LLTSA), have indicated significant degradation in performance for both fault scenarios.*

1 INTRODUCTION

Health Monitoring for railway vehicle components is important for purposes related to ride comfort and safety, as potential deterioration and faults may have severe implications, including increased derailment risk. Health Monitoring also plays a central role in Condition Based Maintenance (CBM), leading to reduced cost while increasing availability and reliability for railway vehicles [1].

As a result, considerable attention has been devoted to the first important aspect of a Health Monitoring system, which is *detection of faults*, including early–stage faults in railway suspensions which constitute an important part of the vehicles [2].

In this context *on–board vibration–based* methods are particularly important because of a number of advantages, which include the capability of continuous operation without interrupting service, the potential for reliable operation, high detection performance, full automation, operation with a minimal number of sensors (due to the methods' "global" nature), and also the abundant availability of low cost sensors and related equipment [2].

The available methods for this purpose may be divided into two broad categories: *Physics–model–based* and *data–model–based* [1] (broadly referred to as model–based and data–based, respectively). As the name implies, methods in the first category rely on physics–based models of the vehicular suspension dynamics [3]. Fault detection is based on a "consistency" (defined in various ways) check of the measured vibration signals and the model, with the suspension system declared as healthy as long as "consistency" is confirmed [4, 5, 6]. Such methods require the detailed and accurate physics–based modeling of the suspension dynamics, including accurate determination of model parameters, which may be cumbersome or difficult in practice. Moreover, the measurement of a considerable number of signals is also required for parameter determination (estimation) in the "*baseline*" or "*learning phase*"; this may be also needed in the method's normal operation in the "*inspection phase*".

On the other hand, methods within the data–model–based category rely on dynamical models obtained from measured signals via system identification and related techniques [1]. Such approaches are more common and offer various advantages including more realistic and accurate modeling, the use of *partial* models of the dynamics based on only few measured signals (even a single signal may sometimes suffice), and modeling simplicity. The methods typically operate on a proper *feature vector* (or *characteristic quantity*) [7], which conveys information on the dynamics; such feature vectors may consist of time–domain [8, 9], correlation–domain [10, 11], or frequency–domain quantities [12].

For all categories of methods, careful and exhaustive assessment of the achievable detection performance, in particular through field tests, are still limited. Performance assessment with early–stage and incipient faults is also scarce, while the detrimental effects on performance of varying *Operating Conditions (OCs)*, such as traveling speed, payload, track irregularities and so on, have been barely addressed — the reader is referred to [4] for track irregularity effects on performance and to [13] for a method designed to account for varying payload. The issue with varying OCs is particularly serious, as the OCs may have significant effects on the feature vector (representing the suspension dynamics), which may even completely "mask" the effects due to a fault and which need to be captured for effective fault detection [13, 14]. *Robust* methods, aiming at effectively overcoming such issues are thus necessary.

The present study *aims* at examining the feasibility of robust data–model–based vibration methods for overcoming some of the aforementioned critical problems. The following questions are specifically addressed:

- Is it feasible to achieve fault detection for *minor*, early–stage, faults in suspension elements? In particular a Lateral Damper (LD) fault consisting of minor oil leakage is considered, along with a more significant Air Spring (AS) fault consisting of pressure reduction by 25%.

- Is it feasible to achieve *effective* detection with a *single* vibration sensor mounted on the car body (implying a very *partial* model of the dynamics) and under *unsupervised* operation? (Implying use of only healthy system signals in the "*baseline phase*".)

- Is it feasible to maintain high detection performance (that is high correct detection rate combined with a minimal false alarm rate) under *varying nominal speeds* (Operating Conditions)?

In this study these questions are addressed via field measurements on an instrumented Athens Metro rail vehicle under three distinct nominal speeds ($60, 70, 80\ km/h$). Two robust Statistical Time Series (STS) type methods of the Multiple Model (MM) type are employed: A *non-parametric* Unsupervised Multiple Model Power Spectral Density (U-MM-PSD) based method, and a *parametric* Unsupervised Multiple Model AutoRegressive (U-MM-AR) based method. Comprehensive and statistically reliable detection performance assessment results are presented via Receiver Operating Characteristics (ROC) curves using thousands of inspection test cases. Interesting comparisons with an alternative method are also provided.

The rest of this article is organized as follows: The vehicle, the fault scenarios and the field measurements are presented in section 2. Preliminary analysis on the effects of the nominal traveling speed and the faults on the random vibration signals are presented in section 3. The robust Multiple Model (MM) based fault detection methods are outlined in section 4, and fault detection performance assessment is presented in section 5. Concluding remarks are finally summarized in section 6.

2 THE VEHICLE, THE FAULT SCENARIOS, AND THE FIELD MEASUREMENTS

2.1 The railway vehicle, the operating conditions, and the measurement set–up

A typical (locally referred to as "third generation") Athens Metro passenger vehicle, manufactured by Hyundai-–Rotem-–Hanwha and consisting of two motorcars with driver cab ($32.609\ tn$ each), two motorcars ($31.379\ tn$ each) without driver cab, and two trailing cars ($26.788\ tn$ each), is employed (total length $106\ m$, mass $181.551\ tn$). Each car body is supported by two bogies, at its front and rear ends, through secondary suspensions. On the other hand, each bogie is connected to two wheelsets through primary suspensions (Figure 1).

In–operation random vibration acceleration signals are measured during field tests (no passengers on board) on a regular straight track, at one of three nominal traveling speeds ($60, 70, 80\ km/h$; permissible deviations of $\pm 3\ km/h$) which constitute the problem's Operating Conditions (OCs). Signal acquisition is based on a single lightweight accelerometer (PCB $356B21$) mounted on one of the trailing cars, at the car body close to the air spring (Figure 1) and measuring in the lateral (y) direction, and a portable data acquisition unit (NI PXIe-1082 chassis and NI PXIe-4492 module). The total numbers of measured signals and related details are presented in Table 1.

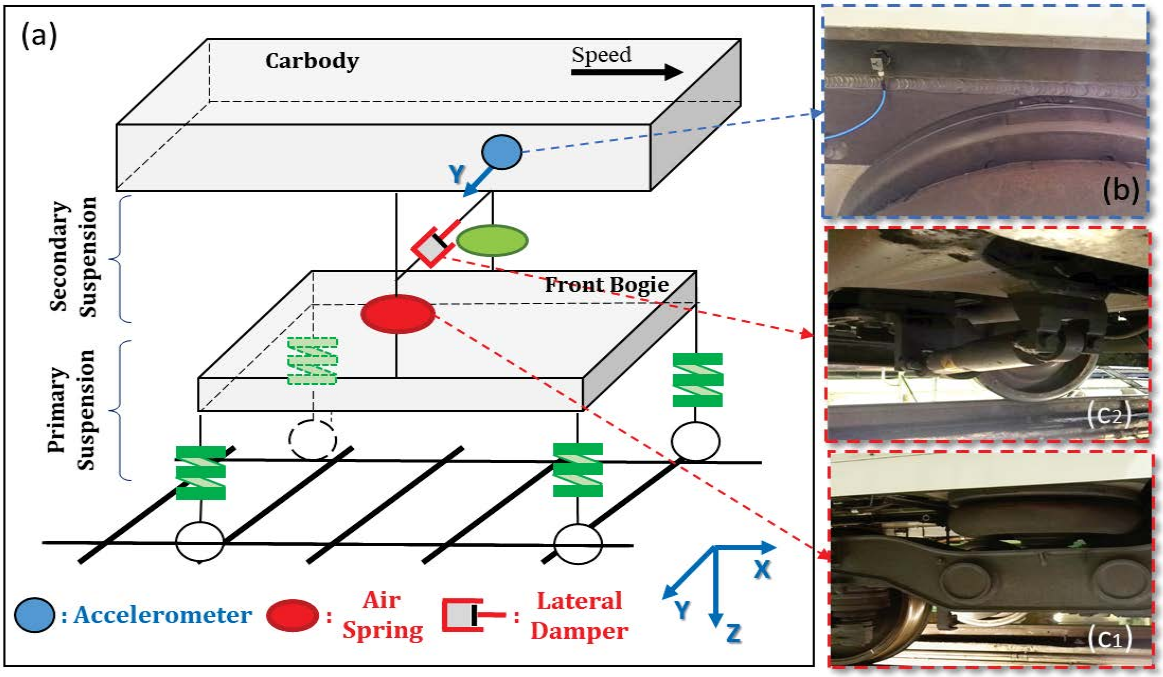

Figure 1: Measurement set–up: (a) Half vehicle schematic, (b) accelerometer position, (c) fault scenarios [(c_1) Air Spring, (c_2) Lateral Damper].

Vehicular health state	# of signals (per speed)	# of signals (all speeds)
Healthy	37	111
Lateral Damper (LD) fault	15	45
Air Spring (AS) fault	12	36
Signal bandwidth $2-490$ Hz; sampling frequency $f_s = 980$ Hz; signal length $N = 8\,000$ samples (8.16 s).		
Nominal vehicular speeds 60, 70, 80 km/h (Operating Conditions).		

Table 1: Numbers of employed signals and their characteristics.

2.2 The fault scenarios and the vibration signals

Two fault scenarios are considered: The 1st corresponds to Air Spring (AS) pressure reduction by 25%, and the 2nd to Lateral Damper (LD) deterioration due to lubricant loss (Figure 1). The measured random vibration signals are pre—processed via Chebyshev Type II high pass filtering (filter order 18, cutoff frequency $f_c = 2\ Hz$) and subsequent normalization by each signal's standard deviation.

3 PRELIMINARY ANALYSIS: EFFECTS OF THE NOMINAL TRAVELING SPEED AND THE FAULTS ON THE RANDOM VIBRATION SIGNALS

The changes in the dynamics induced by a fault are reflected in the measured random vibration signal characteristics, through which fault detection is to be accomplished. Yet, the vibration characteristics (and the corresponding *partial dynamics*) are also influenced by the traveling speed [14]; this is due to the "wheelbase filtering" phenomenon [15] associated with

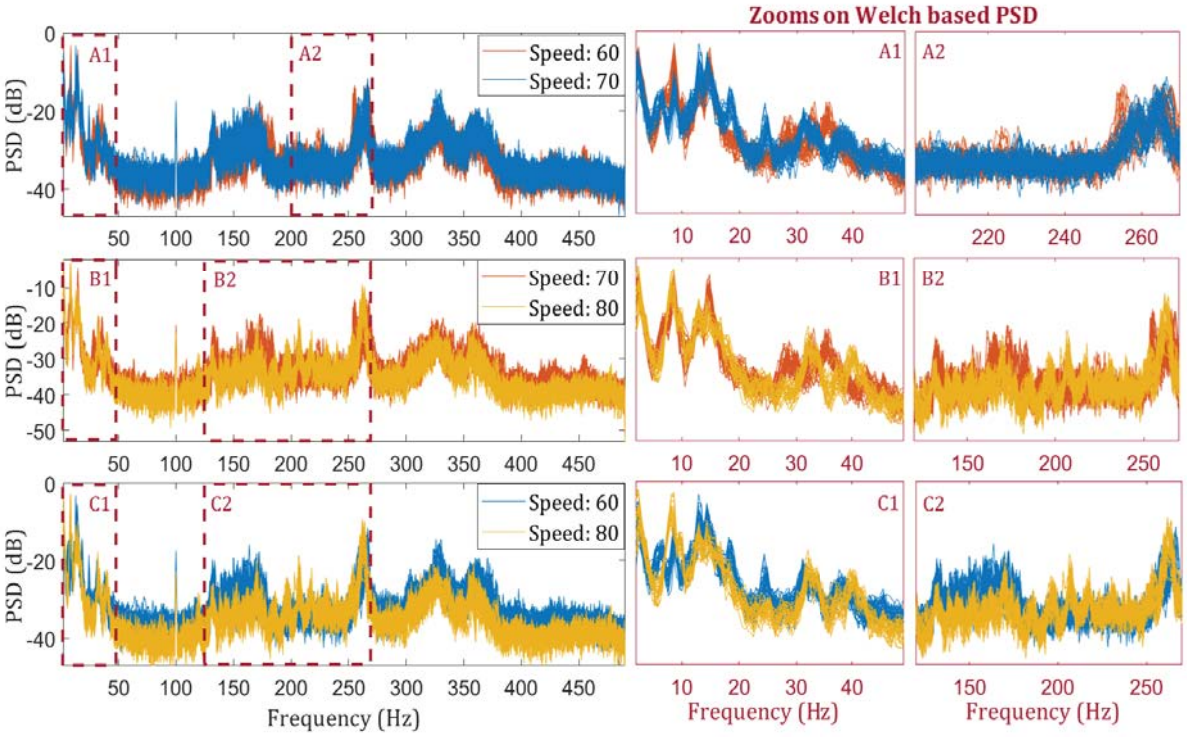

Figure 2: Effects of nominal traveling speed (Operating Condition) on the random vibration PSD for the healthy vehicle. [All 3 nominal speeds; 37 healthy signals per nominal speed; Welch based PSD estimates.]

time delays between any two pairs of wheelsets. The dependence of the random vibration Power Spectral Density (PSD) on the nominal traveling speed ($60, 70, 80\ km/h$) of the healthy vehicle is examined in Figure 2 (Welch PSD estimates [16, pp. 186-187] with Hamming window, segment length of 2048 samples, 85% overlap, frequency resolution $\delta f = 0.47\ Hz$, MATLAB function *pwelch.m*). Based on this, it is evident that the nominal speed has significant effects on the vibration PSD; a fact inevitably challenging fault detection performance.

The effects of faults on the corresponding ("observable") dynamics are, for all three nominal speeds, examined via random vibration PSD comparisons between the healthy and each fault (LD or AS) scenario in Figure 3. Evidently, the Air Spring (AS) fault induces considerable changes in the partial dynamics, which are subsequently reflected on the random vibration PSD, with the healthy and faulty envelopes exhibiting considerable discrepancies at certain frequency ranges. Yet, this is not the case for the Lateral Damper (LD) fault, for which the healthy and faulty envelopes seem to almost coincide. As vibration–based fault detection methods rely on fault–induced changes on the measured signal characteristics (reflecting changes in the corresponding dynamics), the detection of the LD fault is expected to be challenging.

4 THE ROBUST MULTIPLE MODEL BASED FAULT DETECTION METHODS

Fault detection is explored via two *robust* and *unsupervised Multiple Model* (MM) type Statistical Time Series (STS) methods: The first is a *non–parametric* Unsupervised Multiple Model Power Spectral Density (U–MM–PSD) based method and the second a *parametric* Unsupervised Multiple Model AutoRegressive model (U–MM–AR) based method.

At the heart of each method lies a *partial* (based on a single vibration response signal) repre-

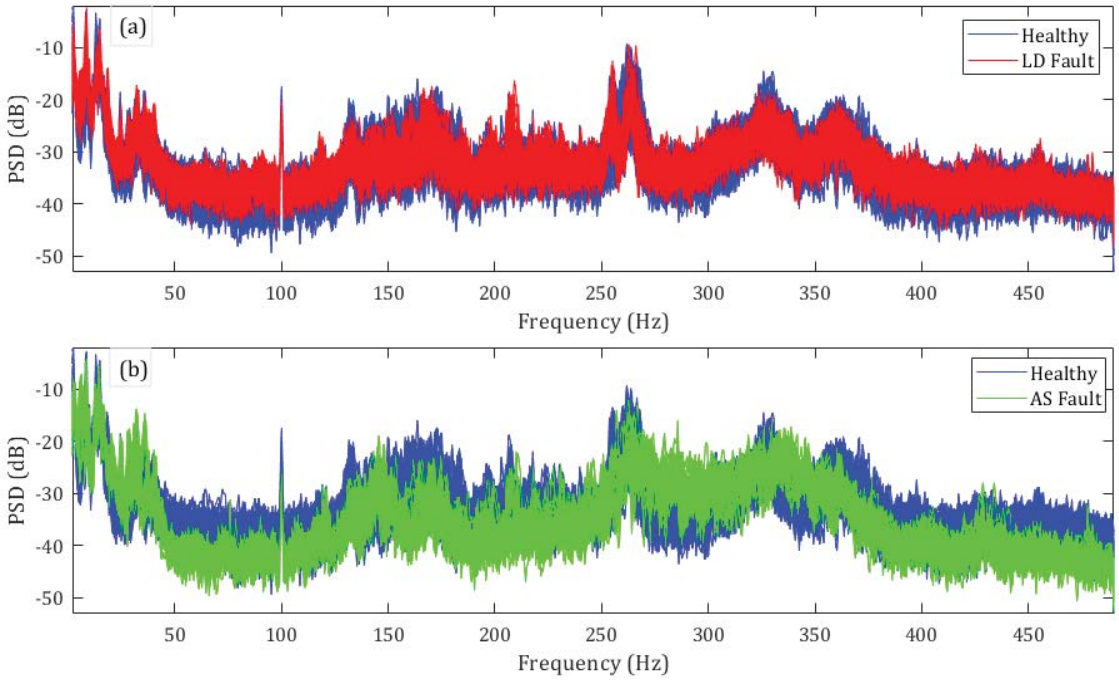

Figure 3: Effects of faults on the vibration PSD under all three nominal speeds: (a) Healthy versus Lateral Damper (LD) fault; (b) Healthy versus Air Spring (AS) fault. [Healthy state 111 signals; LD faulty state 45 signals; AS faulty state 36 signals.]

sentation (*elementary model*) of the vehicular dynamics via the Power Spectral Density (PSD) in the first (U–MM–PSD) method and AutoRegressive (AR) modeling in the second (U–MM–AR). The non–parametric PSD, estimated via the Welch method, and the AR parameter vector thus constitute the *feature* (characteristic quantity) of each method, respectively. AR modeling is based on Linear Least Squares [16, pp. 81-83] (MATLAB function *arx.m*), while model order selection is based on the Bayesian Information Criterion (BIC) and the Residual Sum of Squares normalized by the Signal Sum of Squares (RSS/SSS) [16, pp. 505-507].

Both robust fault detection methods operate within a Multiple Model framework [17], which implies that a multitude of elementary (nominal) models, say $M_{o,i}, i = 1, 2, \ldots, n$ (n designating the MM dimensionality) are used; these collectively constitute the *Multiple Model (MM) representation*, say M_o, of the *healthy* vehicular dynamics under *varying* Operating Conditions and uncertainty (note that the subscript "o" is used for representing the healthy vehicular state). Such a MM representation may be also viewed as a non–parametric description of the "*Healthy Subspace*" within the *Feature Space* (which is the space spanned by the scalar feature components) of a specific method (Figure 4). The Multiple Model representation is built in an *initial baseline (learning)* phase using signals obtained from the healthy vehicular state. In the normal operation of the method (*inspection phase*), a fresh signal is obtained with the vehicle in unknown health state. Based on it, a corresponding elementary (current nominal) model, say M_u (the subscript "u" designates unknown health state), is built, and detection is based on determining whether or not the current nominal model M_u belongs to the healthy subspace M_o. In the positive case the vehicle is declared as "healthy", else as "faulty".

The decision–making mechanism employs a *distance metric* D between the current nominal model M_u and the healthy subspace M_o. This is currently defined as the minimum of individual

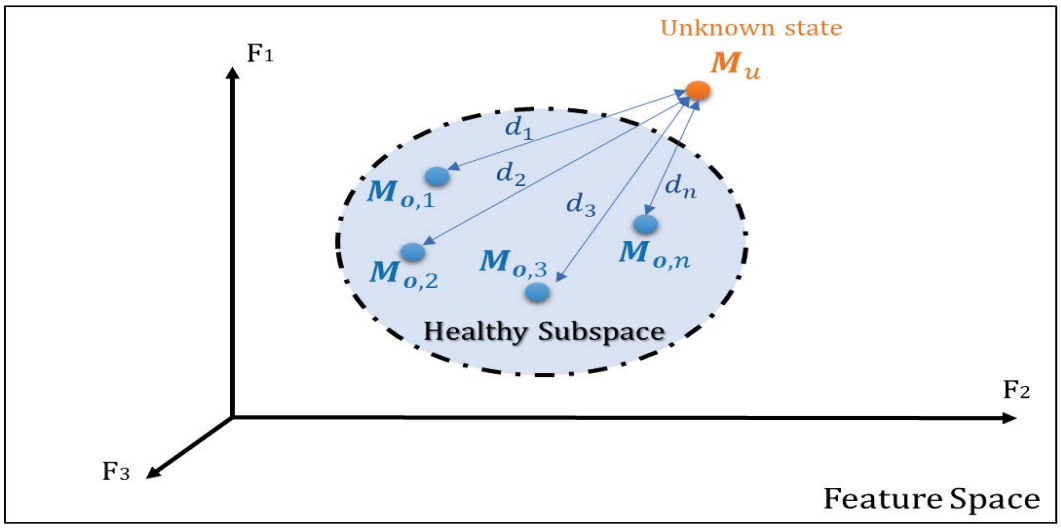

Figure 4: Schematic representation of the MM concept: Within the Feature Space, the Healthy Subspace is non–parametrically modeled via elementary nominal models $M_{o,i}(i = 1, 2, ..., n)$. A model M_u represents the current, unknown, vehicular health state. The current state is then declared as healthy if and only if M_u belongs to the Healthy Subspace.

distances between M_u and all elements of M_o, that is:

$$D := \min_i(d(M_{o,i}, M_u)) \qquad (i = 1, 2, ..., n) \tag{1}$$

with $d(M_{o,i}, M_u)$ designating either the Euclidean distance (U–MM–PSD method) or the Kullback–Leibler (KL) divergence (pseudo-–distance) [18, pp. 756-758] (U-MM-AR method). Fault detection is then declared if and only if D is greater than a user specified threshold l_{lim}, that is:

$$\begin{aligned} D \leq l_{lim} &\rightarrow \textit{Healthy Vehicle} \\ \textit{otherwise} &\rightarrow \textit{Faulty Vehicle} \end{aligned} \tag{2}$$

5 DETECTION PERFORMANCE ASSESSMENT

5.1 Preliminaries and the performance assessment procedure

Based on preliminary analysis, the selections of Table 2 have been made for each method.

The methods' detection performance assessment is then based on a systematic procedure which uses "rotations" in order to warrant consistency and validity of the results by eliminating the dependence of performance on the sample vibration signals selected for use within the baseline phase.

The healthy vehicular state is represented in three "healthy" signal pools, each one corresponding to a different nominal speed $(60, 70, 80\ km/h)$. The vehicle's faulty states are represented in an "AS" and an "LD" signal pool, each one including vibration signals under the Air Spring fault or the Lateral Damper fault and all three nominal speeds. The assessment then consists of the following steps:

Step 1: In the baseline phase, equal numbers of vibration signals are randomly selected from the three "healthy" signal pools. The selected signals form the baseline signal set. The remaining healthy sample signals (from all "healthy" pools) along with the total number of signals

Method	Feature	Feature dimensionality	Distance type
U-MM-PSD	(non-parametric) PSD	1 025	Euclidean
U-MM-AR	AR parameter vector	101	Kullback–Leibler
Multiple Model (MM) dimensionality (# of nominal models) $n = 60$.			
PSD Welch estimation: segment length of 2048 samples; overlap 85%; frequency resolution (δf) 0.47 Hz.			
AR modeling: selected model AR(101); BIC -1.52; RSS/SSS 19%; SPP 79.			
BIC: Bayesian Information Criterion			
RSS/SSS: Residual Sum of Squares normalized by the Signal Sum of Squares			
SPP: (Scalar) Samples Per (estimated scalar) Parameter			

Table 2: Detection method details.

# rotations	# healthy inspection signals	# LD fault inspection signals	# AS fault inspection signals
1	51	45	36
60	3 060	2 760	2 160
No of baseline signals per rotation $n = 60$.			

Table 3: Inspection test cases.

from the "AS" and "LD" signal pools are part of the inspection signal set and reserved for the methods' assessment in the inspection (fault detection) phase.
Step 2: The selection procedure presented in Step 1, which produces the baseline signal set and the inspection signal set respectively, is repeated until all healthy sample signals are selected in at least one baseline signal set. Each such repetition is designated as a "rotation".
Step 3: The fault detection procedure is carried out for all employed sets of baseline signals and the corresponding inspection sets. This leads to a high number of inspection test cases on which fault detection performance is assessed.

The numbers of rotations and baseline and inspection signals are summarized in Table 3.

5.2 Performance assessment

The performance of the fault detection methods is assessed via Receiver Operating Characteristic (ROC) curves, each representing the True Positive Rate (TPR, that is the correct damage detection rate) versus the False Positive Rate (FPR, that is the false alarm rate) for varying decision threshold [19, pp. 34-35]. The obtained results are, for all 7 980 inspection test cases (Table 3), presented in Figure 5 (notice that the distance metric D, normalized in the range $0 - 1$, is also shown for each inspection test case).

Based on these results, it is evident that both methods achieve ideal performance (TPR 100% for FPR 0%) for the Air Spring (AS) fault scenario, despite the variation in the nominal traveling speed. Yet, as expected (see section 3), the performance is less impressive for the Lateral Damper (LD) fault scenario, as the effects of this fault on the partial (single sensor) dynamics presently employed are minimal and "masked" by nominal speed variation and other underlying uncertainties (Figure 3). Indeed, for this scenario the U–MM–PSD method achieves a TPR of 60% for a low ($\approx 5\%$) FPR. The U–MM–AR method is clearly better, achieving a remarkably

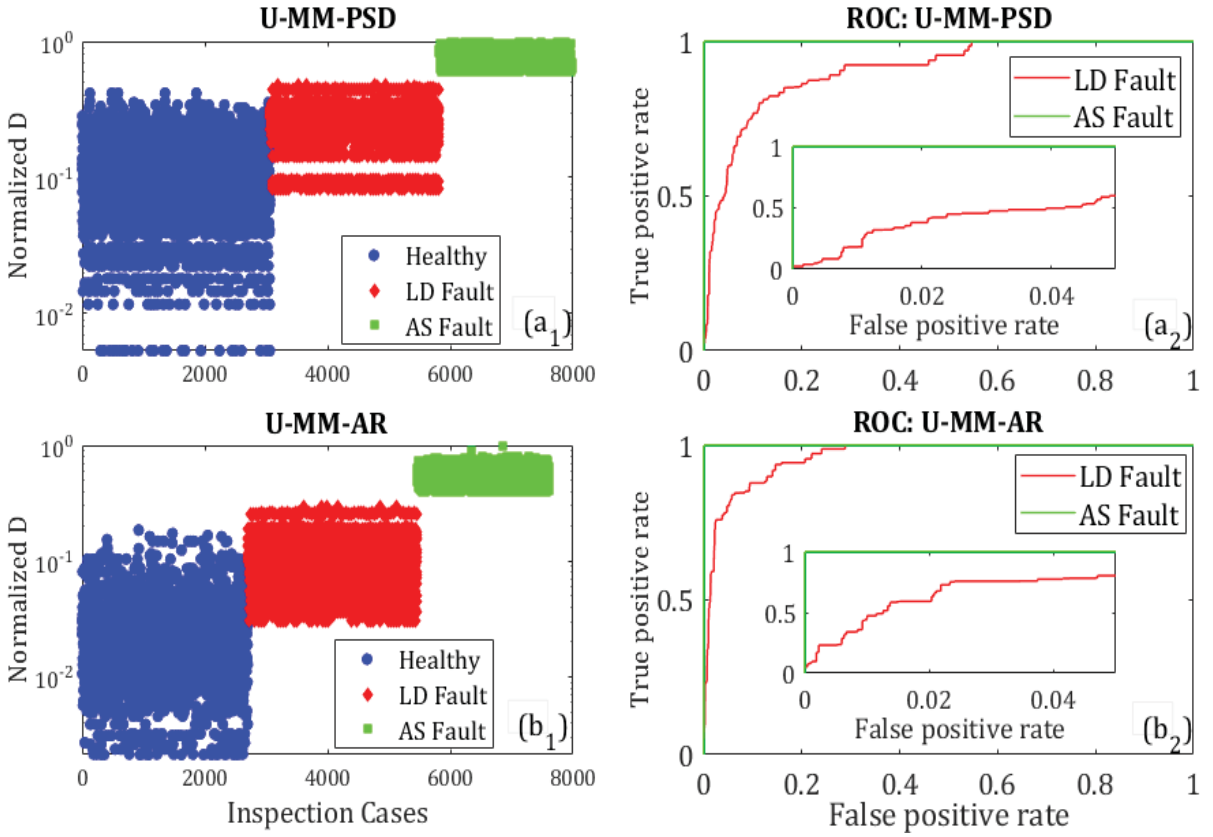

Figure 5: Fault detection performance assessment via the normalized distance metric D and ROC curves: (a_1,a_2) U–MM–PSD method, (b_1,b_2) U–MM–AR method. [All 3 nominal travelling speeds; 7 980 inspection test cases in total for each method.]

higher TPR of 81% for FPR of 5%. This is in line with the results of other studies [17, 20] and may be attributed to the advantages offered by parametric AR models over non–parametric counterparts.

Finally, an interesting, yet preliminary, comparison with an alternative method is presented. This is motivated by a recent study on railway suspension fault detection, employing the Multiscale Permutation Entropy (MPE) as feature and Linear Local Tangent Space Alignment (LLTSA) for feature dimensionality reduction [21]. For the MPE feature, the embedding dimension m, time delay τ, and scale factor s are set to $m = 4$, $\tau = 1$ and $s = 12$ (see [21, pp. 4-5] for definitions and details), respectively. Additionally, for the LLTSA feature dimensionality reduction method, the neighbor number k and intrinsic dimension d are set to $k = 7$ and $d = 3$ (see [21, pp. 5-6] for definitions and details), respectively. These selections are currently embedded into the presented MM framework, giving rise to a U–MM–MPE–LLTSA approach which operates on the raw (no pre–processing) random vibration signal. Details are presented in Table 4 and comparative assessment results are, for all three methods, presented via ROC curves in Figure 6. Based on them, the alternative U–MM–MPE–LLTSA approach offers no improvement in detection performance, as it significantly lags behind the U–MM–PSD and U–MM–AR methods.

Method	Feature	Feature dimensionality	Distance type
U–MM–MPE–LLTSA	Vector of MPE–LLTSA values	3	Euclidean

Table 4: U–MM–MPE–LLTSA detection method details.

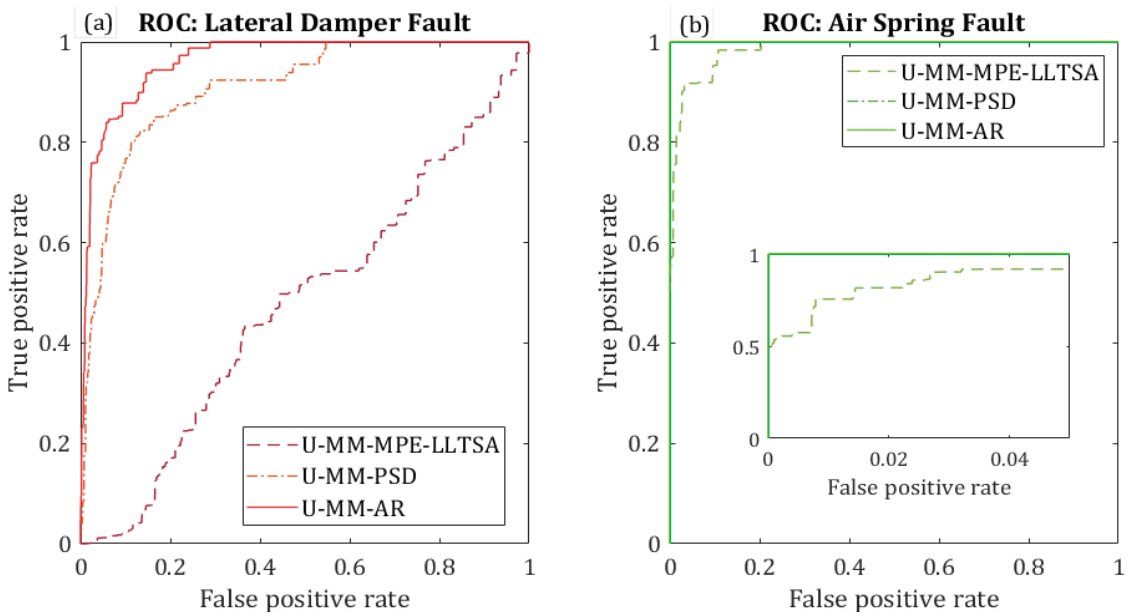

Figure 6: Comparative fault detection performance assessment with an alternative U–MM–MPE–LLTSA method via ROC curves for the: (a) LD fault, and the (b) AS fault. [All 3 nominal traveling speeds; 7 980 inspection test cases in total for each method.]

6 CONCLUDING REMARKS

The feasibility of a *single* random vibration signal based on–board fault detection for railway suspension systems under *varying* nominal traveling speeds (Operating Conditions) has been considered via two Multiple Model (MM) type robust methods: The first is based on *non–parametric* Power Spectral Density (U–MM–PSD method) and the second on *parametric* AutoRegressive modeling (U–MM–AR method). Comparisons with an alternative method have been also presented. All methods are unsupervised, so that only healthy signals are used in the baseline (learning) phase. The study has been based on signals obtained during field tests on an Athens Metro vehicle using a single, laterally–measuring, car body mounted accelerometer. Two fault scenarios have been considered: An Air Spring (AS) fault and an *early–stage* Lateral Damper (LD) fault. The main conclusions from the study may be summarized as follows:

- The use of a *single* vibration sensor (and thus only *partial* system dynamics) has been shown to lead to a challenging detection problem. Yet, it is desirable for reasons of simplicity, as well as reduced maintenance and installation cost.
- The problem is further aggravated by the considerable influence of the *varying* nominal traveling speed (Operating Condition) on the *partial* dynamics.
- While the AS fault is considerable (25% pressure reduction), the LD fault (oil leakage) is minor, with corresponding effects on the *partial* dynamics.

- In spite of the above difficulties, the two *robust* MM methods (U–MM–PSD and U–MM–AR) have achieved perfect performance for the AS fault, but, expectedly, degraded performance for the LD fault.
- Preliminary comparisons with an alternative method employing the Multiscale Permutation Entropy (MPE) and Linear Local Tangent Space Alignment (LLTSA) have indicated significant degradation in performance for both fault scenarios.
- Overall, the study has demonstrated – in a statistically reliable way using thousands of inspection test cases and ROC curves – the potential of single–sensor–based *robust* and *unsupervised* random vibration methods for effective fault detection in railway suspension systems. Work is ongoing on various aspects and will be reported elsewhere.

ACKNOWLEDGEMENTS

This research has been co–financed by the European Union and Greek national funds through the Operational Program Competitiveness, Entrepreneurship and Innovation, under the call RESEARCH–CREATE–INNOVATE (project code: T1EDK - 01440). The authors are grateful to the technicians and volunteers who helped with the field tests.

Keywords: System identification, N4SID, ambient vibration measurement, RC building, brick infill.

Abstract. *System identification of a code conforming low-rise reinforced concrete frame building in Kathmandu, Nepal is reported in this paper. The fundamental vibration period and damping ratio of the building were determined using ambient vibration records taken in three floors of the building. Ambient vibration measurements were taken using three triaxial accelerometers. Two methods of system identification, Welch spectral method and N4SID method, are used to estimate the modal properties. Fundamental vibration periods of the four-storied building estimated from non-parametric Welch spectral method are 0.292s and 0.289s in the two orthogonal directions. The corresponding results from the parametric state-space N4SID method are 0.266s and 0.264s in the orthogonal directions. The corresponding damping ratios are estimated to be 6.3% and 6.9%. These periods are longer than that of a simplified finite element model of the building assumed to be fixed at the supports. This indicates that the flexibility of the soil under the building foundation, plays an important role in the vibration frequencies of the structure.*

1 INTRODUCTION

Civil engineering structures are frequently exposed to dynamic loads in their service lives. Dynamic actions such as earthquake and strong winds can cause severe damage to such structure, or in case of milder actions, impart damages that are not visible immediately, but can accumulate over time. . Also, repeated actions on the structure leads to fatigue of structural elements. These phenomenon cause softening of the structure, which can mean degradation of stiffness and/or strength of its force resisting elements. As a result, the structure becomes more vulnerable to future environmental actions. Identification of such damages, especially those that are not visible on the surface, is important for timely remedial actions so that damage aggravation and accumulation over time can be avoided. Structural system identification and health monitoring is therefore a very important and growing research field in civil engineering.

System identification or an experimental modal analysis is a mathematical framework to identify dynamic properties of a structure from measured vibration and potentially excitation forces. System identification using vibration measurement at different times can reveal potential damage and its accumulation in the structure manifested in the form of change in its dynamic properties. This method has specific advantage over the other methods; they are non-destructive and able to identify damage that is not visible on the surface. Moreover, the structure can remain operational during testing, which can be a continuous process. Also, artificial excitation is often not needed , and ambient vibration induced by traffic or wind actions can be used There are two main genres of mathematical methods for system identification, parametric methods [3] and non-parametric methods [6]. In this study, both methods are used for system identification of a code conforming RC building located in Kathmandu, Nepal.

Finite element modeling based on mechanical properties and geometry of the structural systems can also be used to estimate their modal parameters. Reliability of the numerical results depends on assumption made to create model. There are several uncertainties involved in such modeling, for example in material properties, rigidity of connections, conditions of the soil supporting the foundation, etc., which introduce simplifying assumptions and engineering judgements in finite element modeling. These uncertainties translate to uncertainties in the estimated dynamic behavior of the structure. In addition, as the structure ages, its dynamic properties change. If the structure is subjected to strong loading or repeated moderate loading, it can lose part of its stiffness, which results in change of its dynamic behavior. System identification can be used to identify such changes and calibrate/update finite element models, which can then be used for analyzing its safety and/or designing retrofitting schemes. As dynamic characterization studies are limited in Nepal [9], this study considers a code conforming four-storied residential building located in Lalitpur metropolitan city, Nepal. Sawaki et al. [9] performed system identification of a four-storied residential building using aftershocks and ambient vibration records and concluded that the non-parametric method results in unrealistic damping ratios. To this end, this study incorporates both non-parametric and parametric methods to perform system identification.

2 CASE STUDY BUILDING

The studied residential building is situated in a densely populated area of Kathmandu Valley nearby the Bagmati River. The building is a four-story residential building constructed in 2013. The structural configuration of the building is a reinforced concrete frame with brick infill walls. The moment resisting frame structure consists of concrete columns, beams, and floor slabs. Locally made brick with cement-sand mortar is used as infill walls on the building. The infill walls contribute significantly to the overall stiffness of the building [8].

Figure 1 shows the structural layout of the building showing location of beams and columns. The building is asymmetrical in plan with off grid columns and beams. All the rectangular columns have section size of 300×230mm except the circular columns that have diameter of 230mm. All the beams have section size of 230×355mm including uniform slab thickness of 100mm. Concrete used in the building for casting of primary structural elements is ordinary concrete with mix proportion of 1:2:4 (cement: sand: aggregate) equivalent to M15 grade concrete. The specified characteristics compressive strength of a cube [150mm] in 28days for M15 concrete is 15MPa with modulus of elasticity 19365MPa (IS 456:2000 [2], modulus of elasticity, $E_c = 5000\sqrt{f_{ck}} \approx 19365$MPa). Structural reinforcement used in the building are deformed steel bars of Fe415 grade. The specified minimum 0.2% proof stress or yield strength of corresponding grade steel is 415MPa. The estimated strength of the infill walls is 2.5 MPa with modulus of elasticity 1750 MPa.

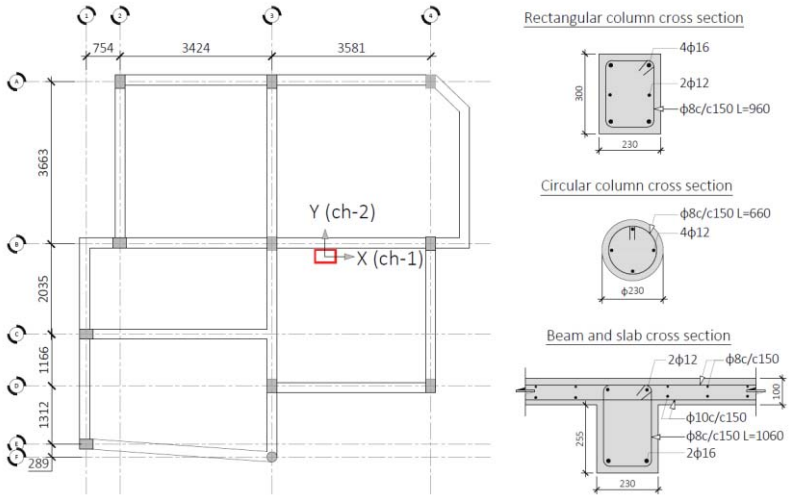

Figure 1: Structural layout of the building showing beams and columns and their cross sections. The red rectangle shows the location of accelerometer and orientation of the instrument sensor axis are indicaed with the arrows.

3 SYSTEM IDENTIFICATION

3.1 Ambient vibration measurement

Three digital accelerometers were installed on three different floors to record ambient vibration of the building. The instruments were located on the first second and third floor. Figure 1 shows the location of instruments (red rectangle) on plan view of the building. All three instruments on different floors were aligned vertically. The accelerometers used are ETNA2 units manufactured by Kinemetrics Inc. Direction of the measurement with respect to accelerometer sensors is indicated by co-ordinate axis shown in Figure 1.

3.2 Welch spectral method

This is a non-parametric method of system identification. This method estimates the frequency response function of the structure based on frequency-domain representations of its excitation and response. Using the Fourier transforms of measured input and output, an empirical estimate of the complex frequency response function, $\hat{H}(\Omega)$, can be obtained. Alternatively, estimates of power spectral densities of the excitation and response can be used as

$$\left|\hat{H}(\Omega)\right|^2 = \frac{\left|S_{yy}(\Omega)\right|}{\left|S_{uu}(\Omega)\right|} \tag{1}$$

where $S_{uu}(\Omega)$ and $S_{yy}(\Omega)$ are the power spectral densities (psd) of excitation and response, respectively, and Ω is the circular frequency.

Because of the inherent variability of Fourier Amplitude Spectra (see, for example, Rupakhety and Sigbjörnsson, 2012 [10]), some form of smoothing needs to be performed on periodogram estimates of psds. The Welch spectra reduces the variation in the psds by dividing the signals into different segments and averaging their spectral estimates. For a stationary signal, the Welch spectra provides an estimate of the true spectra of the random process. In case of ambient vibrations, the excitation can be assumed to be a white noise, and from Equation 1, an estimate of the system transfer function normalized by the variance of the excitation is obtained directly from $S_{yy}(\Omega)$. The natural frequencies can be obtained from the plot of squared amplitude of the complex frequency response function by picking the peaks. For system with small damping values, up to 10% of the critical damping, the peak of the plot occurs close to the natural frequency of the system. The frequencies and most of the power of the response gets concentrated in a narrow band of frequencies around the peak. If the damping ratio of the system is higher, the peak lies away from the natural frequency of the system and the power spectrum becomes wider. Response of a lightly damped structure excited with white noise process can be modelled as a narrow band process. The damping ratio of the structure can be estimated from the half power bandwidth method, which is based on the following equations [4]:

$$\xi = \frac{f_2 - f_1}{2f_n} \tag{2}$$

$$\Delta f = f_2 - f_1 = 2\xi f_n$$

Where, Δf is the half-power bandwidth defined in the frequency band where the power density of the response reduces to half its value at the peak; f_1 and f_2 are linear frequencies at corners of half power and f_n is the linear frequency of the peak which is approximately equal to the undamped natural frequency of lightly damped systems. This method is straightforward when power spectral density function contains one dominant peak, which is the case for damped single degree of freedom systems. For multiple degrees of freedom systems, multiple peaks corresponding to different vibration modes can often be observed. Identification of higher modes can sometimes be difficult due to noise in the measured signal. Identification of higher modes is more difficult when signal to noise ratio is large, which is often the case with ambient vibration measurements.

To apply this method to the case study building, recorded time series data from all the floors channel 1 (ch-1 Figure 1) and channel 2 (ch-2 in Figure 1) were divided into twenty equal segments. Then the signals were filtered using fourth order Butterworth filter to remove noise. The frequency band chosen for the filter was 0.5Hz to 20Hz. Each segment of time series was windowed and tapered with a Tukey window. Power spectral density (PSD) of the filtered signals was estimated using Welch´s algorithm. Figure 2 shows the plot of estimated PSD of the twenty segments with mean PSD for both channels. Figures 2a, 2c, and 2e show plots of PSD from first floor to third floor in the direction of channel 1 with estimated mean PSD. Similarly, Figures 2b, 2d, and 2f show plots of PSD from first floor to third floor in the direction of channel 2. All plots show clear peaks which represents the fundamental frequency of the system in the corresponding direction.

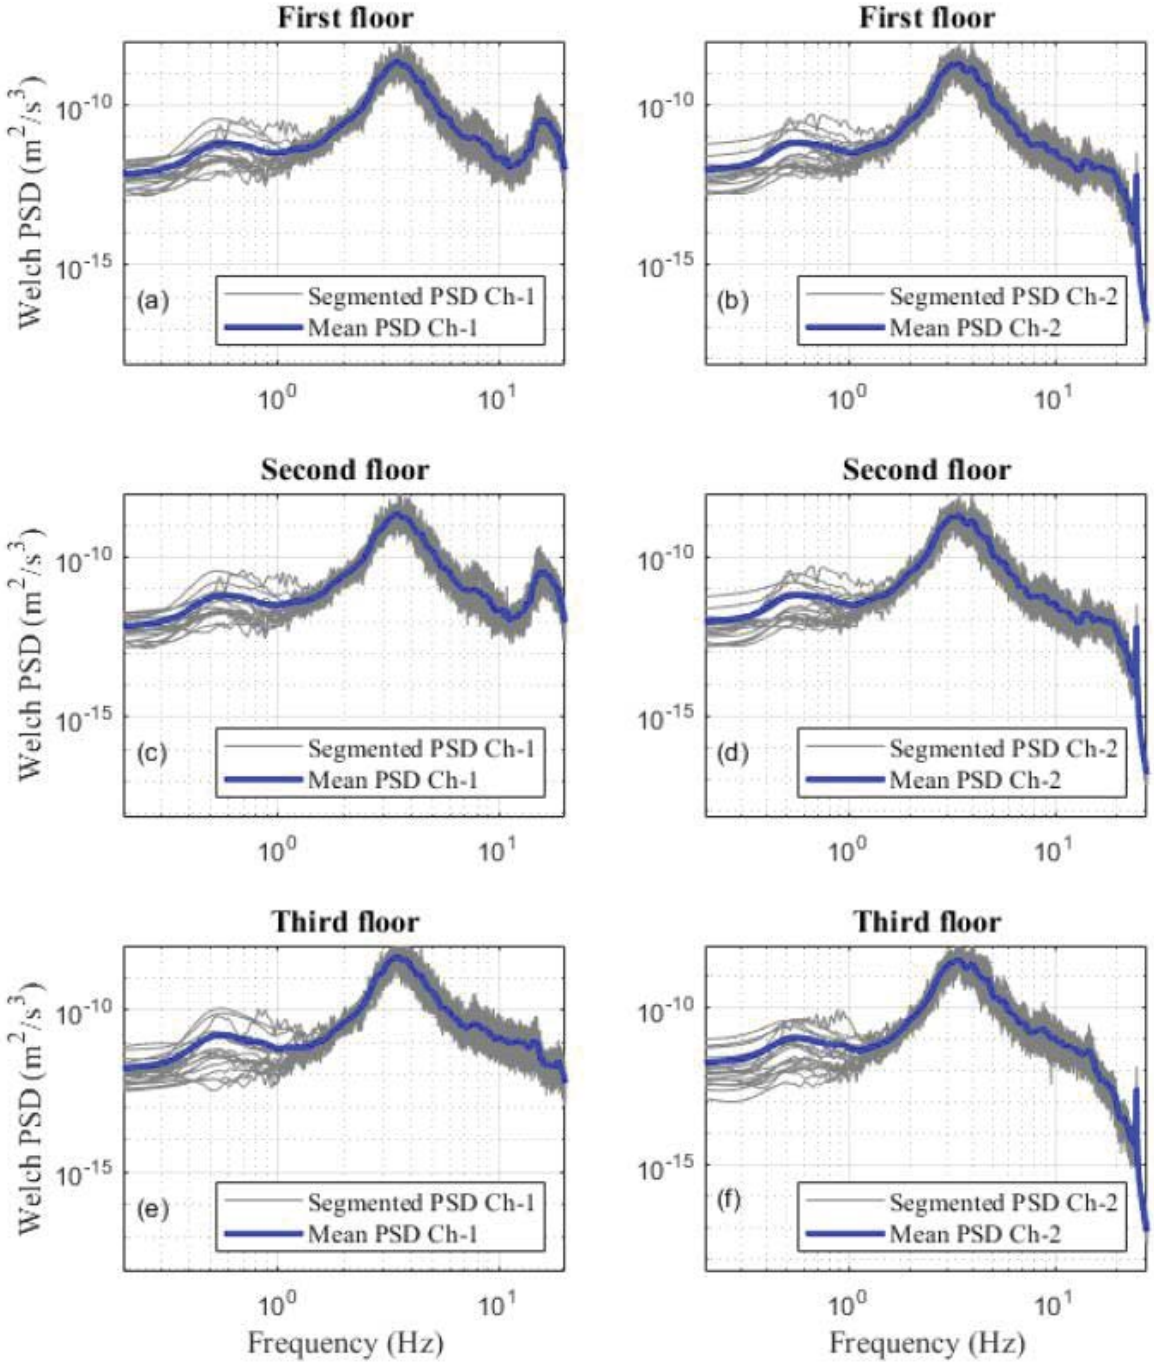

Figure 2: Plot of Welch´s PSD from recorded ambient vibration. The gray lines represent 20 segments of measured acceleration, and the blue lines represent the mean.

Estimated fundamental vibration period and damping ratios from three different floors are tabulated in Table 1. For example, mean vibration period estimated from channel 1 of the first-floor data is 0.290s with standard deviation 0.017s. Similarly, fundamental vibration period obtained from channel 2 is 0.289s with standard deviation 0.028s. Mean natural periods obtained from the second floor and third floor along channel 1 are 0.288s and 0.289s respectively. Mean natural periods obtained from second floor and third floor along channel 2 are 0.296s and 0.291s, respectively. Estimated vibration periods on both principal directions show consistently similar results for different floors. Mean of estimated vibration period along each direction

represents fundamental vibration period of the building along corresponding principal direction. Therefore, it can be concluded that the mean estimated fundamental period of the building along channel 1 is 0.289s and along channel 2 is 0.292s. This concludes that the fundamental periods of the building on both the directions are almost similar. However, mean damping ratios estimated for both the channels from different floors shows more variability with higher standard deviations (range of variation 3 - 6%). Such variation on damping ratio is directly related to the smoothing, window selection and overlap of data during PSD estimation. For example, Smoothing of PSD leads to flattening of the peaks which results in inaccurate estimates of damping ratios [5].

Data	Damping Ratio Ch-1 (%)	Fundamental Period Ch-1 (s)	Damping Ratio Ch-2 (%)	Fundamental Period Ch-2 (s)
First floor	8.126 (3.681)	0.290 (0.017)	11.435 (4.939)	0.289 (0.028)
Second floor	8.389 (3.901)	0.288 (0.017)	9.165 (4.713)	0.296 (0.023)
Third floor	9.148 (4.303)	0.289 (0.016)	11.655 (6.211)	0.291 (0.027)

Table 1: Mean fundamental vibration period and damping ratio with standard deviation estimated from three different floors using Welch spectral analysis.

3.3 N4SID method

N4SID stands for Numerical algorithms for subspace state space system identification and is described in detail in [7]. This method is based on parametric mathematical model called state-space model which consist of a set of input, output and state variables linked together by first order differential equations. The following equations represent a state-space model in continuous time:

$$\left\{\dot{x}(t)\right\} = [A]\{x(t)\} + \{B\}u(t)$$
$$\{y(t)\} = \{C\}\{x(t)\} \tag{3}$$

Where [A] is parametric system matrix, {B} and {C} are parametric vectors. The vector {x(t)} is called the state of the structure. The number of elements of x(t), n, is called the model order. The state space model ([A], {B} and {C}) can be calibrated from measured excitation and response. The model can then be used to estimate vibration periods and damping ratios of the structure. The results are generally sensitive to the selected model order. Selection of suitable model number helps to remove spurious modes and bias of the modes. Spurious modes are either noise modes, that arise due to physical reasons, e.g., excitation and noise or mathematical modes that arise due to over-estimation of the model order. Similarly, bias of the modes can be defined as the combination of different modes (true mode and noise mode) on identified mode which is due to under estimation of model order. The selection of suitable model order is facilitated by stabilization diagrams. A stabilization diagram is made by selecting a wide range of model orders and by plotting all identified modes in a frequency versus model order diagram. Figure 2 shows the stabilization diagram for data segment 5 for channel 1. The plot shows the estimated natural frequencies and damping ratios for model orders 1 to 20. The parameters are estimated by the least squares rational function (LSRF) algorithm. The

figure helps to identify stable and unstable peaks in the frequency response function. The results show that some of the true modes only appear after model order 4. A model order of 6 seems sufficient to identify the two modes of vibration of the structure, and is therefore selected for further analysis.

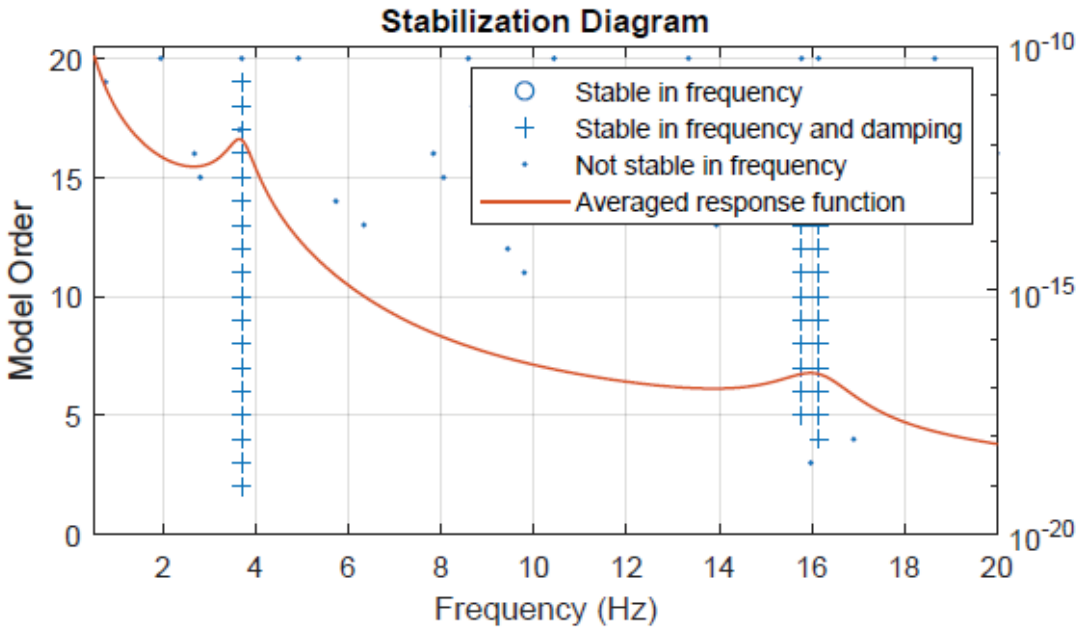

Figure 2: Stabilization diagram showing stable modes and averaged frequency response function for data segment 5 channel -1.

Measured signals from all three floors were aligned in time and divided into twenty segments. Signals were filtered using fourth order Butterworth filter The frequency band chosen for the filter was 0.5Hz to 20Hz. Then N4SID algorithm in MATLAB was used to estimate state-space model with model order of six. No exogeneous input was used in calibrating the model as the excitation is assumed to be a white noise process. Estimated mean fundamental vibration period and damping ratios are presented in Table 2. The mean vibration period for first and second mode obtained from channel 1 data is 0.266s and 0.078s with standard deviation of 0.009s and 0.031s. Similarly, the mean vibration period for first and second mode obtained from channel 2 data is 0.264s and 0.143s with standard deviation of 0.012s and 0.035s respectively. This shows that the variance of period obtained for second mode is higher than that for the first mode. Mean damping ratio obtained from channel 1 data is about 6.3% with standard deviation of 1.3%. Similarly, mean damping ratio obtained from channel 2 data is about 6.9% and standard deviation of 1.1%. Variation in damping ratio estimated from this method is lower than that estimated from the non-parametric method.

Data	Fundamental Period (s)		Damping Ratio (%)
	Mode 1	Mode 2	
Channel 1	0.266 (0.009)	0.078 (0.031)	6.340 (1.265)
Channel 2	0.264 (0.012)	0.143 (0.035)	6.968 (1.140)

Table 2: Mean fundamental vibration period and damping ratio with standard deviation estimated from ambient vibration measurement using N4SID method.

4 DISCUSSION AND CONCLUSIONS

The estimated fundamental period of vibration of the building is around 0.26s. The empirical equation proposed by Guler et al. [1] estimates the fundamental period of reinforced concrete moment resisting frames with brick infill walls with the following equation.

$$T_0 = 0.026H^{0.9} \tag{4}$$

For the building being studied here, this equation results in fundamental vibration period of 0.24s, which is fairly close to the results obtained from system identification. The building being studied is constructed on a site with alluvial deposits, which might affect the vibration frequencies of the structure. Dhakal, 2020 [11] presents finite element models of the building with fixed base and flexible base to account for the effects of soft soils at the site. The finite element models show that the vibration frequencies estimated from the flexible base model matches the results of system identification better. This indicates that system identification using ambient vibration measurement can be used to detect and calibrate the effects of underlying soil in vibration properties of buildings. This is valuable in calibrating and updating finite element models which can be used for detailed seismic analysis. For example, mechanical elements used to model soil in the finite element model of the building can be tuned to match the modal frequencies estimated from ambient vibration measurements.

The results of this study show that system identification using ambient vibrations is a reliable method of estimating the fundamental period of vibration of buildings. The estimated periods are consistent with results presented in the literature and mechanical models of the building. The parametric method seems to be superior to the non-parametric method and is found to be more reliable in identifying higher modes of vibration. In addition, damping ratios estimated from the non-parametric method showed larger variability than those estimated from the parametric method. The degree if smoothing used in the former method is subjective to the analyst and introduces such variability. There is no quantitative guideline on what degree of smoothing is optimal. In the parametric method, some level of subjectivity is introduced by the selection of model order. But unlike in the non-parametric method, the analyst can make use of the stabilization diagram to select a proper model order. In this aspect, the parametric method is found to be more suitable for system identification.

Since ambient vibration measurements are inexpensive and can be performed rapidly, it will be useful to perform similar tests on several buildings in Nepal. By sampling buildings of different construction quality, site conditions, heights, infill walls and opening ratios, effects of these parameters on vibration frequencies of typical reinforced buildings in Nepal can be studied. Furthermore, empirical equations relating these frequencies to parameters such as building height, site conditions, and opening ratios can be calibrated. Such equations will be useful in updating seismic design codes in Nepal.

Abstract. *The assessment of the structural integrity of bridge cables through the identification of axial force has a long tradition in engineering practice. Vibration-based methodologies usually involve fitting a set of measured natural frequencies to a force-frequency relationship, which may take into account the effects of sag-extensibility and non-negligible bending stiffness. However, the accuracy of the results is largely dependent on an adequate characterization of the boundary conditions, namely the effective length of vibration and the rotational restraints at the supports. Moreover, the identification of high-order modes (essential for attaining good estimates of the bending stiffness) may be hampered by the attenuation of small wavelength disturbances before reaching the cable ends, preventing the definition of standing waves.*

This paper presents a novel methodology for the identification of mechanical properties in bridge cables, which does not require any assumption about boundary conditions. Assuming that cables behave as Euler-Bernoulli or Timoshenko beams with a tensile force, analytical expressions for the dispersion relation of transverse waves are derived. As for experimental dispersion relations, they can be obtained by the computation of time-frequency distributions of the response at two different sections of the cable, permitting the identification of arrival times for each frequency component, and of the respective propagation velocities.

The validation of this methodology is conducted on a stay cable from a footbridge, recording the response to an impact hammer excitation with two accelerometers. Mechanical properties are then identified through the fitting of the analytical expressions derived to the experimental dispersion curves. The obtained results for bending stiffness are consistent within a large diversity of experimental setups, regarding the location and type of the external excitation, and the distance between the sensors. This approach can thus provide in situ estimates of the flexural rigidity in bridge cables, unaffected by errors in the characterization of boundary conditions, which will prove useful in the local assessment of damage.

1 INTRODUCTION

The increasing use of cables as load-carrying members in civil engineering structures has generated a need for accurate and reliable methods to evaluate their integrity and identify the installed axial force. Among these, vibration-based techniques are very popular and usually involve fitting a set of measured natural frequencies to force-frequency relationships, which may be exact or approximate, and explicit or implicit. Apart from the simpler taut string model, existing formulations can include the effects of sag-extensibility [1], non-negligible bending stiffness [2], or both [3]. Considering the need to work with large-diameter cables, models that account for flexural rigidity have been the subject of various investigations in recent years, and simultaneous identification of this property and the axial force is now becoming a common practice. Nevertheless, the accuracy of the results depends on the characterization of boundary conditions, particularly the effective length of vibration and the rotational restraints at the edges [4]. Some techniques can already address the problem of non-ideal supports (i.e., besides hinges or clamps) [5] [6] [7], but they require obtaining the cable mode shapes through denser instrumentation, which hampers most in situ applications. In addition to the uncertain boundary conditions, many cables reveal a progression of natural frequencies that is insensitive to the bending stiffness, at least for mode orders typically identified. In fact, small wavelength disturbances (susceptible to the effects of flexural rigidity) are prone to attenuation before reaching the cable ends, preventing the definition of standing waves.

In such a context, this study proposes an identification approach based on the characteristics of transient waves propagating along a cable medium, rather than vibration modes. Dispersion relations for group velocities are derived, assuming that cables behave as Euler-Bernoulli or Timoshenko tensioned beams, and fitted to the ones obtained in situ.

The outline of this paper is as follows: section 2 gathers the theoretical contributions of the study, namely the relevant dispersion characteristics associated with Euler-Bernoulli and Timoshenko models. The methodology for experimental assessment of dispersion relations is described in section 3, and results from an actual scale case study are presented and discussed in section 4. Finally, section 5 synthetizes the main conclusions, pointing out some relevant observations for future work.

2 DISPERSION RELATIONS

2.1 Euler-Bernoulli Model

Assuming that plane sections remain plane after deformation and orthogonal to the neutral axis, the behavior of a cable with constant bending stiffness EI and mass per unit length μ, subject to a tensile force T, is governed by the equation of motion:

$$-c_f^2 \frac{\partial^4 u}{\partial s^4} + c_t^2 \frac{\partial^2 u}{\partial s^2} = \frac{\partial^2 u}{\partial t^2} \tag{1}$$

in which u represents the transverse displacement (as a function of position s and time t), c_t designates the velocity $\sqrt{T/\mu}$ and c_f stands for the quantity $\sqrt{EI/\mu}$.

Harmonic and non-trivial solutions $u(s,t) = Ae^{i(\gamma s - \omega t)}$ for equation (1), with frequency ω and wavenumber γ, exist only if the following characteristic condition is verified:

$$c_f^2 \gamma^4 + c_t^2 \gamma^2 - \omega^2 = 0 \tag{2}$$

Since the group velocity c_g is defined by $d\omega/d\gamma$ [8], one can differentiate implicitly the equation above to obtain:

$$c'_{gt}(\omega) = \sqrt{\frac{2c_t^4 + 8c_f^2\omega^2}{c_t^2 + \sqrt{c_t^4 + 4c_f^2\omega^2}}} \tag{3}$$

This expression corresponds to the dispersion relation for the group velocity of transverse waves in a tensioned Euler-Bernoulli beam and shreds evidence that each frequency component of the response propagates with a distinct velocity. Conversely, if $c_f = 0$ in equations (1) to (3), the non-dispersive model of a taut string is derived, with a constant dispersion relation $c'_{gt}(\omega) = c_t$.

In order to illustrate the previous result, expression (3) is computed for a cable with a cross-sectional area A of 0.015 m^2 and moment of inertia I of 1.25335×10^{-5} m^4, under an axial loading of 7500 kN. As for material parameters, the elastic modulus E and the mass density ρ are assumed equal to 200 GPa and 7.8 ton m^{-3}, respectively. Figure 1(a) reveals that the group velocity approaches c_t when $\omega \to 0$, as anticipated by expression (3); on the other hand, Figure 1(b) illustrates an improper result in a high frequency range, since c'_{gt} grows without limit and, therefore, infinite group velocities are attained.

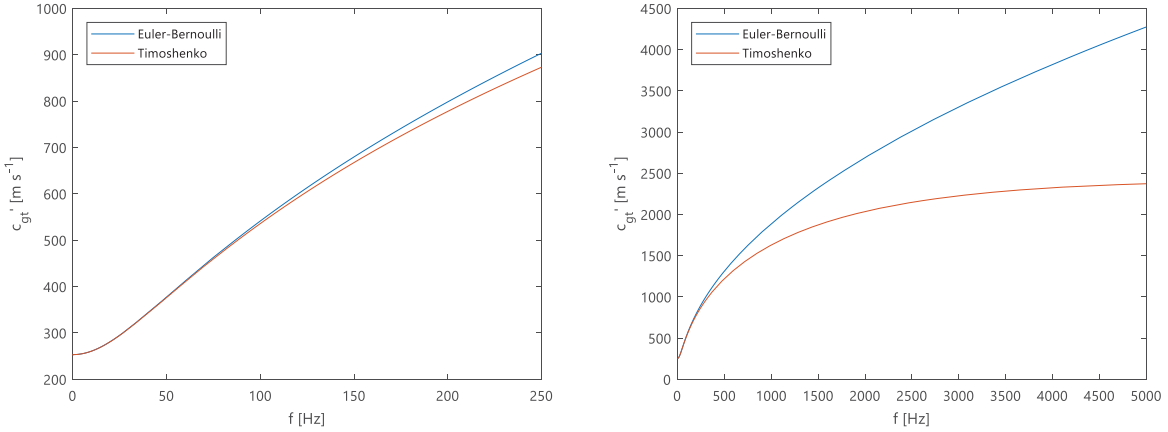

Figure 1: Dispersion relations for c'_{gt} (Euler-Bernoulli and Timoshenko models), up to: (a) 250 Hz; (b) 5000 Hz.

2.2 Timoshenko Model

The correction of the previously obtained result requires introducing the effects of shear deformation and rotary inertia [9]. If φ designates the cross-section rotation, the cable behavior is now expressed by the system of equations:

$$\begin{aligned} \frac{GAK}{\mu}\left(\frac{\partial^2 u}{\partial s^2} - \frac{d\varphi}{ds}\right) + c_t^2\frac{\partial^2 u}{\partial s^2} &= \frac{\partial^2 u}{\partial t^2} \\ \frac{GAK}{\mu}\left(\frac{\partial u}{\partial s} - \varphi\right) + c_f^2\frac{\partial^2 \varphi}{\partial s^2} &= \frac{I}{A}\frac{\partial^2 \varphi}{\partial t^2} \end{aligned} \tag{4}$$

which represents the equilibrium of a tensioned Timoshenko beam [10]; G and K denote the distortion modulus and the shear coefficient, respectively.

The propagation of harmonic waves $u(s,t) = A_1 e^{i(\gamma s - \omega t)}$ and $\varphi(s,t) = A_2 e^{i(\gamma s - \omega t)}$ leads to the characteristic equation:

$$\tau_3\gamma^4 + c_t^2\gamma^2 - (\tau_2\gamma^2 + 1)\omega^2 + \tau_1\omega^4 = 0 \tag{5}$$

where auxiliary parameters τ_1, τ_2 and τ_3 are defined by:

$$\tau_1 = \frac{\mu I}{GA^2K} \tag{6}$$

$$\tau_2 = \frac{I}{A}\left(1 + \frac{T}{GAK} + \frac{E}{GK}\right) \tag{7}$$

$$\tau_3 = \left(1 + \frac{T}{GAK}\right)c_f^2 \tag{8}$$

From equation (5), two dispersion relations for group velocities arise, in accordance with the degrees of freedom of the Timoshenko model. Focusing only on transverse-dominant waves, one can obtain:

$$c'_{gt}(\gamma_t) = \frac{\tau_2\gamma_t + \frac{2\tau_1(2\tau_3\gamma_t^3 + c_t^2\gamma_t) - \tau_2\gamma_t(\tau_2\gamma_t^2 + 1)}{\sqrt{(\tau_2\gamma_t^2 + 1)^2 - 4\tau_1\gamma_t^2(\tau_3\gamma_t^2 + c_t^2)}}}{\sqrt{2\tau_1\left(\tau_2\gamma_t^2 + 1 - \sqrt{(\tau_2\gamma_t^2 + 1)^2 - 4\tau_1\gamma_t^2(\tau_3\gamma_t^2 + c_t^2)}\right)}} \tag{9}$$

with:

$$\gamma_t(\omega) = \sqrt{\frac{\tau_2\omega^2 - c_t^2 + \sqrt{(\tau_2\omega^2 - c_t^2)^2 - 4\tau_3\omega^2(\tau_1\omega^2 - 1)}}{2\tau_3}} \tag{10}$$

Returning to the previous example (and assuming that the material is isotropic, with a Poisson ratio of 0.3), Figure 1 evidences that both models agree in a low frequency range and deviate largely when $\omega \to \infty$; in particular, the new dispersion relation has a horizontal asymptote, of value $\sqrt{c_t^2 + GAK/\mu}$. The validity domain of the Euler-Bernoulli hypothesis is a function of the cable properties; therefore, only the Timoshenko model will be regarded hereinafter.

In order to assess the sensitivity of c'_{gt} to T, EI and GAK, 10% variations in the value of these parameters are now considered and represented in Figure 2. This figure illustrates that group velocity is generally independent of the axial force, except in the low frequency range. On the contrary, shear rigidity controls the value of the horizontal asymptote, while bending stiffness determines the rapidness in the increase of c'_{gt}.

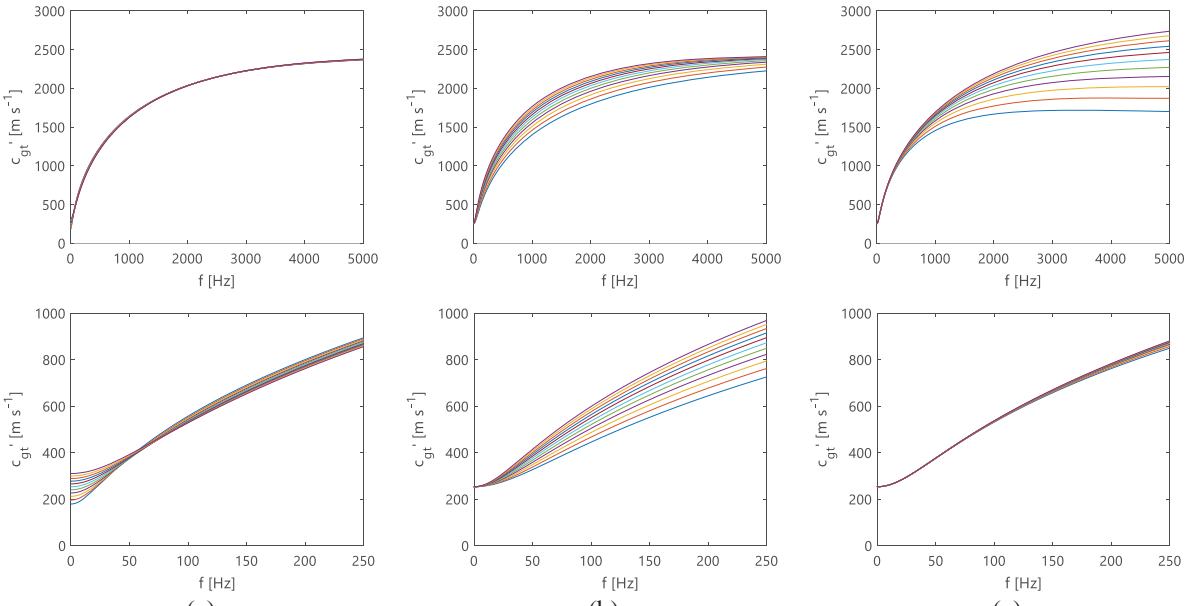

Figure 2: Dispersion relations for c'_{gt} (Timoshenko model), considering 10% variations in the value of: (a) axial force T; (b) bending stiffness EI; (c) shear rigidity GAK.

3 METHODOLOGY

The methodology for the experimental assessment of dispersion relations requires obtaining time-frequency distributions at two sections of a cable. The wavelet transform of the response u is a function $\{\mathcal{W}u\}$, defined by:

$$\{\mathcal{W}u\}(a,b) = \frac{1}{\sqrt{|a|}}\int_{-\infty}^{+\infty} u(t)\psi^*\left(\frac{t-b}{a}\right)dt \tag{11}$$

in which ψ^* denotes the complex conjugate of the mother wavelet ψ, that has an oscillatory nature [11]. Following Apostoloudia *et al.* [12], this study will employ the mother wavelet of Morlet. The scale parameter $a \neq 0$ is responsible for dilating (i.e., stretching or compressing) the function ψ, while b corresponds to a translation parameter. If $\psi(t)$ is localized around $t = 0$ and its Fourier transform around $\omega = \omega_0$, then $\psi((t-b)/a)$ is centered at $t = b$ in the time domain and $\omega = \omega_0/a$ in frequency domain. As such, $\{\mathcal{W}u\}(a,b)$ provides time-frequency information of u around a point $(b, \omega_0/a)$.

Kishimoto *et al.* [13] proved that, for a fixed location s, the peaks in the magnitude of $\{\mathcal{W}u\}$ indicate the arrival time of a frequency component ω that propagates with a group velocity c_g. Accordingly, introducing an external excitation at a section S0 and recording the cable response at S1 and S2, one can identify arrival times t_{S1} and t_{S2} of each frequency ω, by the relative maxima of both time-frequency distributions. Referring to Figure 3(a), the group velocity c'_{gt} is then given by:

$$c'_{gt}(\omega) = \frac{d_{S1,S2}}{t_{S2}(\omega) - t_{S1}(\omega)} \tag{12}$$

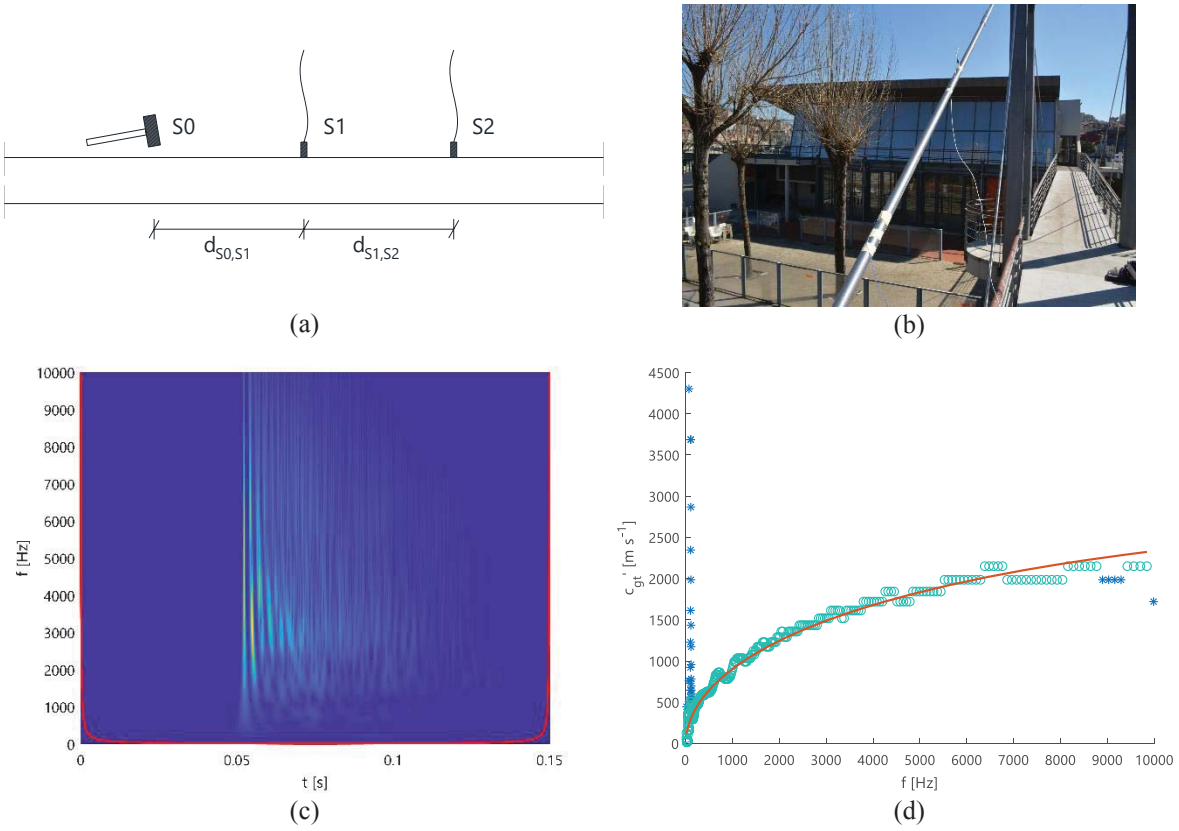

Figure 3: Assessment of dispersion relations in cables: (a) experimental setup; (b) application to the case study; (c) scalogram of the response at S1; (d) experimental and fitted dispersion relation.

The validation of the proposed methodology is performed on a cable from a footbridge, represented in Figure 3(b), using two piezoelectric accelerometers and an impact hammer.

Figure 3(c) illustrates the scalogram of transverse accelerations at S1 (i.e., the magnitude of the respective wavelet transform). This representation reveals that the spectral content is distributed along ridges in the time-frequency plane: the first ridge corresponds to the direct propagation from S0, while the subsequent ones arise from reflections at the cable ends.

In most applications, the sensor position relative to each cable end (and hence the distance covered by the reflected waves) is difficult to assess. As a result, t_{S1} and t_{S2} are here identified by the first ridge in the respective scalograms and the methodology becomes independent of any assumption concerning boundary conditions. Figure 3(d) represents the experimental dispersion curve, calculated according to expression (12); blue markers symbolize outliers, identified through the DBSCAN algorithm [14].

The stay under analysis consists of a solid, stainless steel bar, with a diameter of 28.6 mm and shear coefficient K equal to 0.925 [15]. Assuming that the material is isotropic, only the axial force T and the elastic modulus E remain unknown. These parameters are then estimated by fitting the analytical relation (9) to the experimental curve.

4 RESULTS AND DISCUSSION

Based on the previous methodology, different experimental setups were defined, concerning the impact location and the distance between accelerometers. Red (R), blue (B) and steel (S) hammer tips were used, with increasing hardness of the contact surface and a consequent rise on the excitation's frequency content.

In addition to these experiments, natural frequencies were obtained through an ambient vibration test, which enabled the simultaneous identification of $T = 48.1$ kN and $E = 188.9$ GPa. Table 1 presents the errors in the dispersion-based estimates of E relative to the latter value, and evidences that the obtained results are accurate and consistent within setups, especially for blue and red hammer tips. This methodology appears, however, to be less suitable for extracting adequate estimates of the axial force, since very significant errors are attained in this parameter. In fact, as shown in Figure 2(a), group velocities are generally insensitive to the value of T, except in a low frequency range where arrival times are difficult to identify, because the transient response is concealed in the stationary vibration of the cable.

Setup	S1	S2	S3	B1	B2	B3	R1	R2	R3
$d_{S0,S1}$ [m]	0.564	0.564	0.219	0.564	0.564	0.219	1.120	0.564	0.219
$d_{S1,S2}$ [m]	1.008	1.008	0.487	1.008	0.487	0.487	1.008	1.008	0.487

5 CONCLUSIONS

In this paper, cables were assumed as Euler-Bernoulli or Timoshenko tensioned beams and sag-extensibility effects were neglected. In comparison with the taut string hypothesis, the first model allowed highlighting the dispersive behavior introduced by the bending stiffness, since each frequency component now traveled with a distinct group velocity. The formulation is, however, inadequate for applications involving a wide frequency domain of interest, such as those considered in this study, motivating the corrections for shear deformation and rotary inertia. The Timoshenko model thus derived evidenced that the dynamic behavior of cables is roughly divided into three domains, the first (low frequencies) being governed by the axial force,

the second (increase of c'_{gt}) controlled by the bending stiffness and the last (asymptotic behavior for $\omega \to \infty$) defined by the shear rigidity.

The proposed methodology for experimental assessment of dispersion relations is conceptually independent of boundary conditions and applicable to any cable, regardless of the nature of the progression of natural frequencies. Unlike strategies relying on the characterization of mode shapes, this approach requires only two sensors, from which time-frequency distributions of the transient response are computed. The relative maxima of the scalograms enable the identification of arrival times for each frequency component, and of the respective group velocity.

The results obtained from in situ tests reveal that this dispersion-based methodology provides adequate estimates of the bending stiffness, which will prove useful in the local assessment of damage. In contrast, whether a similar accuracy is attainable for axial force is a subject of ongoing research.

Keywords: System identification; structural dynamics; experimental modal analysis

Abstract. *The real dynamic response of any structure, assuming linear behaviour, can be accurately reproduced by means of a modal model issued from an Experimental Modal Analysis (EMA). Natural frequencies, mode shapes and damping ratios, together with some information about the modal masses of the structure, form a complete set of valid information to carry out simulations. However, using that sort of model, no direct information about the physical properties of the structure is available and it may be challenging to try to reproduce the effect of a structural modification like a mass addition, stiffness modification or changes in the boundary conditions. To overcome this, Model Updating techniques have been developed together with the evolution of the Finite Element Method (FEM) paradigm as a way to adapt the computational models to some experimentally estimated properties of a real structure. As a result, the models behave quite similarly to the real structure and, indirectly, some of its physical properties can be estimated and eventually modified according to any simulation requirement. However, the proper application of a Model Updating technique often leads to an iterative and time consuming process which usually rely on accurate enough FEM models and the understanding of relatively sophisticated optimization algorithms to provide meaningful results; otherwise, unrealistic updated properties could be obtained as the best options to reproduce the real structural dynamics and the physical properties estimation or modification is no longer trustworthy.*

In this work, an alternative methodology is proposed to estimate the physical matrices of a structure. We assume that the structure behaves linearly and that a modal model has been previously identified. Then, by using a set of equations like the eigenproblem relationships, the orthogonality equations and symmetry assumptions, the physical matrices elements are calculated by means of the Moore-Penrose pseudo-inverse. This approach provides an exact accomplishment of the equations when there are more unknowns than equations, and an optimal solution in the least squares sense in the opposite situation.

1 INTRODUCTION

During the last decade, advances in the field of microcontrollers and processors have led to the active development of permanent monitoring systems for structures and infrastructures. These systems enable, with a relatively small investment, to continuously track some basic parameters of the structure, like its natural frequencies and damping ratios among others, without the need to deploy large temporary sensor networks for carrying out experimental tests, which usually are more expensive.

This sort of systems is usually associated to structure health monitoring systems (SHM) capable of postprocessing the great amount of measured data with the main aim of assessing the structural integrity. To do so, it is very useful to know the spatial distribution of the structural properties and their relationship with the measured modal parameters. One way to do this requires a Finite Element Method (FEM) model, conveniently updated to represent the same measured structural parameters. However, this presents the problem of having built a detailed enough FEM model, for which the updating process may be very time consuming and lead to unrealistic estimated physical properties, as it can be inferred from [1].

Another way to deal with the modelling problem consists in directly estimating a mathematical reduced model from the measured data, which can be a modal model or a physical model, among others. The modal model is usually easier to estimate, and it enables to simulate different loading scenarios, but it does not directly provide the spatial distribution of the properties, making it difficult to perform potential structural modifications.

Physical models have been estimated since several decades ago, like in [2], where the author proposed a simple orthogonality principle inversion, or [3], who proposed a pseudo-inverse approach for incomplete estimated modal models. Since then, several approaches to this problem have been addressed assuming different types of damping models and various considerations, like [4], [5], [6], [7], [8] or [9]. In this work, a methodology to estimate a physical reduced-order model from experimental data is developed. The procedure is presented as a common framework to deal with both general viscous and general structural damping models, which do not make any proportionality assumption. It is conceived to be programmed in a structural health monitoring system to help with the damage detection and predict the response of the damaged structure to decide if the structure can remain in this way or if maintenance works should be carried out. The model estimation is based on the modal properties, so the proposed procedure happens in two well separated stages: during the first stage, the modal properties are estimated from experimental Frequency Response Functions (FRFs); the second stage is devoted to estimate the physical model from the modal one.

The article first presents the theoretical background needed to settle a nomenclature in Section 2. Section 3 is entirely devoted to developing the methodology and Section 4 shows an example of application. Section 5 is centred on a discussion about the advantages and drawbacks of the proposed methodology finishing the article with a set of conclusions.

2 THEORETICAL BACKGROUND

Every linear system can be described with the system of differential equations of Eq. 1, characterized by the real-valued and symmetric mass (M), damping (D) and stiffness (K) matrices, where q represents the N degrees of freedom of the structure and f stands for the dynamic forces acting on them. According to the chosen damping model, the system of differential equations changes [10]: Eq. 1a represents the system of equations for viscous damping model and Eq. 1b, for structural damping model.

$$M\ddot{q}(t) + D\dot{q}(t) + Kq(t) = f(t) \quad (1a)$$
$$M\ddot{q}(t) + (K + jD)q(t) = f(t) \quad (1b)$$

After transforming Eq. 1 to the frequency domain, Eq. 2 is obtained from which the dynamic stiffness can be defined for each damping model (Eq. 3a for viscous damping and Eq. 3b for structural damping). The inverse of the dynamic stiffness is the commonly known as Frequency Response Functions (FRFs) matrix H(w), whose rows or columns are usually estimated separately by means of experimental tests and it can be demonstrated that only one, well selected, of this rows or columns provides enough information to estimate the modal properties of the tested structure.

$$G(\omega)\, Q(\omega) \;=\; F(\omega) \quad (2)$$

$$G(\omega) = -\omega^2 M + j\omega D + K \quad (3a)$$
$$G(\omega) = -\omega^2 M + K + jD \quad (3b)$$

The modal properties of a structure are defined as a way to solve Eq. 1. Assuming a complex exponential response, the solution to the homogeneous system can be obtained by solving first the eigenproblem of Eq. 4a, for viscous damping, and Eq. 4b, for structural damping, which must be verified for all the *m* pairs of eigenvalues and eigenvectors of the structure. The complex-valued eigenvectors ϕ_r are called mode shapes of the structure and the eigenvalues s_r contain the natural frequency ω_r and damping ratio, ζ_r or η_r, depending on the damping model (see Eq. 5a, viscous damping, and Eq. 5b, structural damping). When the modal information is calculated analytically, the number of obtained modes is equal to the number of degrees of freedom ($m = N$). However, if they are estimated through an experimental modal analysis (EMA), this number is usually lower ($m <= N$) and the model is said to be incomplete.

$$(s_r^2\, M + s_r D + K)\phi_r = 0 \quad (4a)$$
$$(s_r^2\, M + K + jD)\phi_r \;=\; 0 \quad (4a)$$

$$s_r = -\omega_r \zeta_r + j\omega_r \sqrt{1 - \zeta_r^2} \quad (5a)$$
$$s_r^2 = \omega_r^2 (1 + \eta_r) \quad (5b)$$

The mode shapes verify some orthogonality equations respect to the physical matrices. These equations can be divided into two groups, one associated to the mass matrix and another to the stiffness one, as shown in Eqs. 6 (for viscous damping model) and Eqs. 7 (for structural damping model), where $\Phi = [\phi_1 \quad ... \quad \phi_m]$ is the mode shape matrix whose columns contain the mode shapes, S stands for the eigenvalue matrix, a diagonal matrix containing the *m* eigenvalues, and I_m is the $m \times m$ identity matrix. Note that, by definition, mode shapes are not uniquely defined, and they can be scaled arbitrarily. It is common, however, to scale them to make the orthogonality properties have the right sides shown in Eqs. 6 and 7.

$$\Phi^{\mathrm{t}}\, C\, \Phi + S\, \Phi^{\mathrm{t}}\, M\, \Phi + \Phi^{t}\, M\, \Phi\, S = I_m \quad (6a)$$
$$\Phi^{\mathrm{t}}\, K\, \Phi - S\, \Phi^{\mathrm{t}}\, M\, \Phi\, S = -S \quad (6b)$$

$$\Phi^{\mathrm{t}}\, M\, \Phi = I_m \quad (7a)$$
$$\Phi^{\mathrm{t}}\, (K + jD)\, \Phi = S^2 \quad (7b)$$

Thanks to the modal properties, the calculation of FRFs can be simplified to the expressions shown in Eq. 8a, for viscous damping, and Eq. 8b, for structural damping. This represent a huge advantage in terms of computation efficiency in relation with inverting Eq. 3 and makes possible identification techniques like the curve fitting method proposed in the next section.

$$H(\omega) = \Phi \left[diag\left(\frac{1}{j\omega - s_r}\right)\right] \Phi^{\mathrm{t}} \tag{8a}$$

$$H(\omega) = \Phi \left[diag\left(\frac{1}{s_r^2 - \omega^2}\right)\right] \Phi^{\mathrm{t}} \tag{8b}$$

Eq. 8 represent the starting point of the methodology presented in this article and detailed in the next section.

3 METHODOLOGY

The methodology starts by performing a complete modal test to the structure. It is necessary to distribute a set of sensors on the structure and measure both inputs and outputs in *N* well selected degrees of freedom. Then, by means of an estimator like H_1, H_2 or H_v, among others, the FRFs have to be calculated. As stated before, only a well selected row or column of the FRFs matrix H(ω) is needed to completely extract the modal information of the *m* modes inside the measured frequency range.

There are several ways to estimate the modal properties from the FRFs, but the curve fitting method is proposed in this work to estimate at the same time all the required modal information. Also, to make the procedure slightly more independent from the user, a varying order procedure is applied. In this way, the order of the modal model is varied from a minimum value to a maximum, sequentially performing a curve fitting to the expressions in Eq. 8 and enabling to draw a sort of stability diagram like the ones shown in Figure 4. In other words, several modal models are estimated assuming different numbers of modes inside the measured frequency band, each of which differently fits the experimental FRFs. The goodness of fit is evaluated through the sum of squared error between the experimental and the calculated real and imaginary parts of the FRFs, an indicator which should monotonously decrease with the model order. Finally, since the upper bound for the model order can be potentially high, leading to a model with an order unnecessarily high, it can be useful to define an error threshold under which a certain modal model can be "acceptable" for engineering purposes. The value of this threshold should be adapted according to the engineer expertise, the aim of the structure and the kind of the subsequent analysis to be performed with the model. The first order whose modal model meets the error threshold is retained as the identified modal model for the structure.

Once the modal properties have been identified, they are used as inputs to the physical matrix estimation. This technique aims to calculate the full set of physical matrices, M, K and D, that satisfies all the relationships and conditions presented in Section 2. For doing it in the most general way, in this work rewriting Eqs. 4 and 6, for viscous damping, or 7, for structural damping, as a linear system of equations is proposed. The unknowns of such a system are the elements of the physical matrices, as stated in Eq. 9. In this simple equation, x_M contains all the terms of the mass matrix, x_K the terms of the stiffness matrix and x_D the ones corresponding to the damping matrix. Note that the terms in x_M, x_K and x_D can be arranged as desired as long as the columns of A are arranged accordingly.

$$A \begin{bmatrix} x_M \\ x_K \\ x_D \end{bmatrix} = b \tag{9}$$

In the following sections, the different kind of equations are summed up for clarity.

3.1 Eigenproblem equations

Presented in Eq. 4 for each damping model, these equations represent the basic relationship between the modal information and the physical matrices. Since every pair of eigenvalue and eigenvector leads to a column vector of N zeroes, and m pairs have been identified, there are a total of mN eigenproblem equations, shown in Eq. 10. The terms in matrix A_{eig}, of size $mN \times 3N^2$, are composed of eigenvector elements, some of them multiplied by their corresponding eigenvalues. The associated mN terms in vector b_{eig} are equal to 0.

$$A_{eig} \begin{bmatrix} x_M \\ x_K \\ x_D \end{bmatrix} = b_{eig} = 0 \tag{10}$$

3.2 Orthogonality equations

Although derived from the eigenproblem relationship, the orthogonality equations (Eqs. 6 and 7) are linearly independent of them. The corresponding terms in A_{ort} matrix (Eq. 11) are calculated by products of different eigenvectors elements and, in the viscous damping case, some of them are also multiplied by their corresponding eigenvalues. The terms in vector b are not all null, being some of them equal to 1 and other equal to the eigenvalues, according to Eqs. 6 and 7. A priori, there are $2m^2$ orthogonality equations, but thanks to the inherent symmetry of modal matrices this number can be reduced to $2m\,(m+1)/2$.

$$A_{ort} \begin{bmatrix} x_M \\ x_K \\ x_D \end{bmatrix} = b_{ort} \tag{11}$$

3.3 Symmetry equations

Physical matrices are typically symmetric. This means that some of the $3N^2$ variables are equal to some others. This fact can be expressed in a set of $3N\,(N-1)/2$ equations (Eq. 12) containing pairs of 1 and –1 correctly placed in the matrix A_{sym} to take account for this. The corresponding elements in the vector b_{sym} are 0.

$$A_{sym} \begin{bmatrix} x_M \\ x_K \\ x_D \end{bmatrix} = b_{sym} = 0 \tag{12}$$

3.4 Real-valued system of equations

Since matrices A_{eig} and A_{ort} and vectors b_{eig} and b_{ort} are complex valued, the general solution of the system of equations will also be complex. To avoid this and obtain real-valued physical matrices, first split the matrices A_i, vector b_i and variables vector x in real and imaginary parts, obtaining Eq. 13, where i can stand for 'eig' or 'ort' and subscripts 're' and 'im' stand for real and imaginary parts respectively. This expression can be expanded and reorganized to separate real and imaginary parts. Since two complex numbers are equal if, and only if, their real parts are equal and imaginary parts are equal as well, the expression in Eq. 14 must be satisfied, which has been simplified assuming that $x_{im} = 0$, which is the case here.

$$(A_{i,re} + jA_{i,im})(x_{re} + jx_{im}) = b_{i,re} + jb_{i,im} \tag{13}$$

$$\begin{bmatrix} A_{i,re} \\ A_{i,im} \end{bmatrix} x_{re} = \begin{bmatrix} b_{i,re} \\ b_{i,im} \end{bmatrix} \tag{14}$$

This strategy can be applied to the eigenproblem and orthogonality equations before assembly the system of equations (the symmetry equations are real-valued), doubling their number of equations.

3.5 Assembly and solution

Once the different parts of matrix A and column vector b have been built as explained in the previous sections, the complete matrix A can be assembled into one single system of equations of Eq. 15 to be solved for the physical unknowns.

$$\begin{bmatrix} A_{eig,re} \\ A_{eig,im} \\ A_{ort,re} \\ A_{ort,im} \\ A_{sym} \end{bmatrix} \begin{bmatrix} x_M \\ x_K \\ x_D \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ b_{ort,re} \\ b_{ort,im} \\ 0 \end{bmatrix} \tag{15}$$

Eq. 15 represents a system of linear equations with $N_{VA} = 3N^2$ variables and a total of $N_{EQ} = 2Nm + 2m\,(m + 1) + 3N\,(N - 1)/2$ independent equations. By comparing N_{VA} and N_{EQ}, three different situations can be found:

- $N_{EQ} = N_{VA}$. The system can be directly solved by traditional means.
- $N_{EQ} > N_{VA}$. The system can be solved using a pseudo-inverse approach, like the Moore-Penrose pseudo-inverse matrix, which provides the best fitting to all equations, minimizing the error in a least squares sense.
- $N_{EQ} < N_{VA}$. The system can be also solved using the Moore-Penrose pseudo-inverse. The obtained solution exactly satisfies all the equations, but it may not be adequate and more equations (restraints) must be imposed.

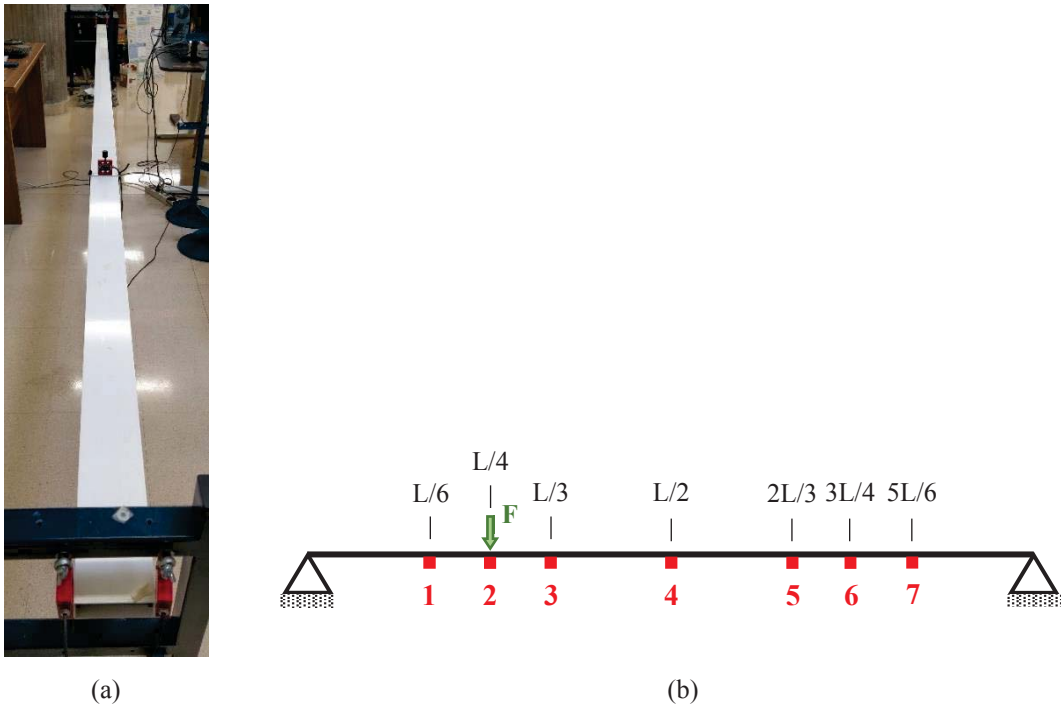
Although the most desirable situation is the first one, it is quite uncommon to have the same amount of linearly independent equations and variables. Having more equations than variables is a far more common situation if the number of identified modes approaches the number of monitored degrees of freedom. In this case, all the equations should be satisfied at the same time and the closest solution to that situation should be a convenient physical model.

However, the most typical scenario occurs when the number of identified modes is quite lower than the number of monitored degrees of freedom, $N_{EQ} < N_{VA}$. In that case, although all equations are exactly satisfied, they may not be enough for the resulting model to be convenient for further applications and some additional equations should be added to the system. Amongst all the practical options, only the total mass equation is considered in this work. This equation accounts for the total mass of the structure, which can be calculated as the sum of the diagonal terms in the mass matrix and its value should be estimated previously by means of other techniques. The authors have constated that it is only needed a rough estimation of the mass for the methodology to work and the consequences of a bad estimation have not been investigated yet, but it may have important drawbacks when applying any structural modification. Also note that other kind of equations could be also considered, like the nullity of some terms, but they are not covered in this work.

4 CASE STUDY

4.1 Structure and test description

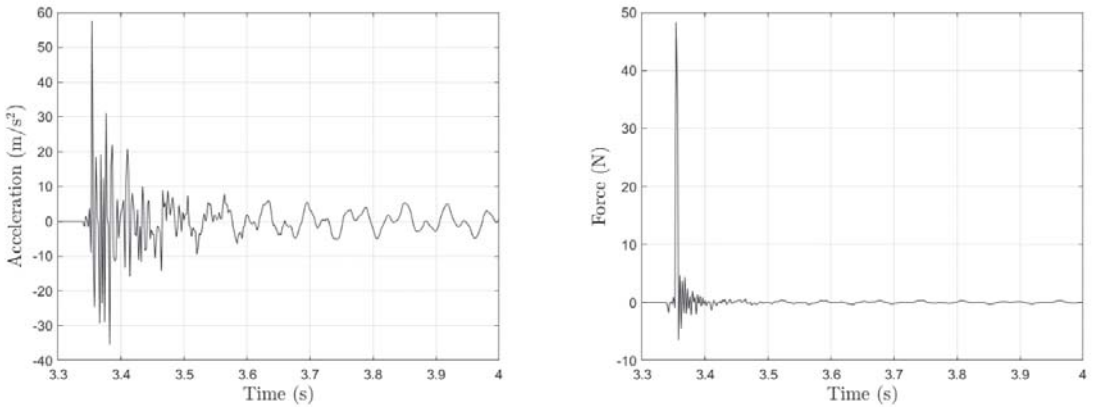
A laboratory-scaled simple-supported beam has been tested for illustrating the methodology described above. It is a 6-meter long aluminium profile with a rectangular hollow section of 100 mm width, 40 mm height and a thickness of 1.5 mm. The supports are conceived in such a way that they can be approximated to perfectly pinned supports and any friction effect can be neglected.



(a) (b)

Figure 1. Experimental set up showing (a) the picture of the beam with the load cell; and (b) the scheme with the position of the sensors, where L is the total length of the beam.

The structure, shown in Figure 1a, is monitored by means of seven accelerometers, some of them being placed on the maxima of the modal shapes for the first three modes, which are expected to be similar to $sin(k\,\pi x/L)$, with k = 1, 2 and 3, and L the total length of the beam. The accelerometers have a sensitivity of 100 mV/g and a measurement range of ±60g. The excitation is induced by means of a hammer, whose force is quantified by using a 2 mV/V, 10 kg load cell attached to the beam at $L/4$ as shown in Figure 1b. For not losing the symmetry caused by the load cell, an equivalent amount of rigid mass has been added at $3L/4$. All the sensors are connected to the acquisition system, a 16 channel SIRIUS® STGS datalogger of the brand Dewesoft. Figure 2 shows an example of recorded force and the corresponding acceleration measurement of the collocated accelerometer.



(a) (b)

Figure 2. Example of recording between 3.3 and 4 s: (a) Acceleration at $L/4$; (b) Measured force

4.2 Frequency Response Functions and modal identification

Frequency Response Functions (FRFs) are estimated using the H_v estimator which is defined as the geometric mean of H_1 and H_2 estimators, very common in literature [11]. The magnitude and phase plots of the measured FRFs are shown in Figure 3. The seven FRFs are used as inputs to the modal identification procedure. Both general viscous and structural damping are considered in parallel in this work. Also, the system to be identified corresponds to the beam containing the sensors and their cables and no effort will be devoted in this work to remove their contribution to the modal properties or to the physical matrices.

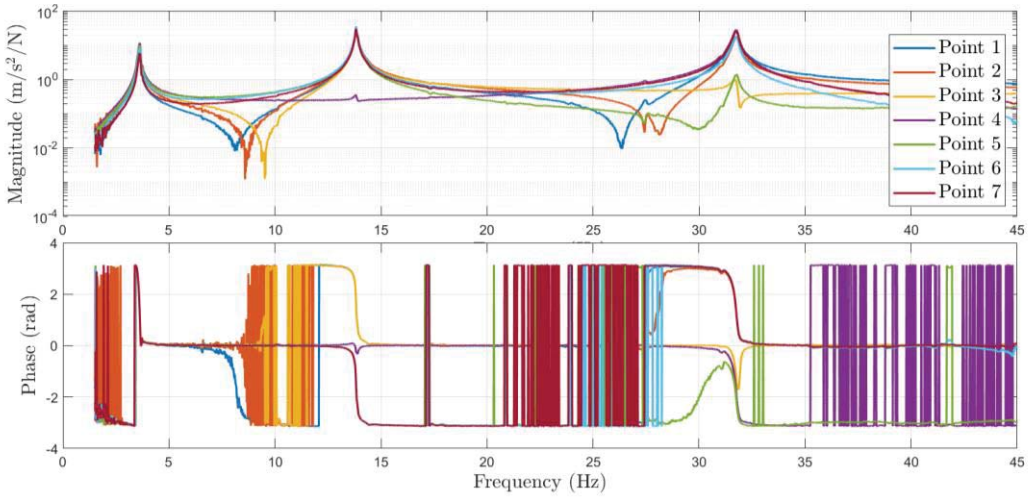


Figure 3. Experimental FRFs

Performing the curve fitting of the FRFs to the expressions in Eq. 8 at the same time applying the variable order technique described in Section 3, leads to the stability diagrams shown in Figure 4, where it can be shown the goodness of the methodology to identify the most evident modes (corresponding to the local maxima). Since there are three evident peaks in the FRFs, the order is set to vary between 1 and 5 modes. As can be seen, the three main peaks are easily identified and, if more modes are considered (4 or 5 in this case), the algorithm places them where it can but very low mode shape amplitudes and high values of damping ratios. In both cases, three modes are enough to represent the dynamic behaviour of the beam. This can be stated also in Figure 5, where the error evolution is shown for every tested model order. From

order three and above, the error remains well under two magnitude orders below the initial error value.

The final modal properties are summed up in Table 1 and the associated mode shapes are depicted in Figure 5. It can be shown that the identified natural frequencies are the same and the viscous damping factors are approximately the half of the structural ones, a relationship that van be assumed for low damped structures. This modal information is now used in the next section to estimate the physical matrices of the beam.

	Viscous damping model		Structural damping model	
	ω_r (Hz)	ζ_r	ω_r (Hz)	η_r
Mode 1	3.61	0.0063	3.61	0.0126
Mode 2	13.84	0.0036	13.83	0.0070
Mode 3	31.72	0.0033	31.72	0.0068

4.3 Physical matrices estimation

Using the modal parameters estimated in the previous section it is possible to assemble the system of equations of Eq. 9. For this case, with seven monitored degrees of freedom and three identified modes, the system contains 147 unknowns and a total of 129 equations: 24 orthogonality equations, 42 eigenproblem equations and 63 symmetry equations. Since there are more unknowns than equations, it may be useful to add the mass equation, which is estimated to be 6.5 kg. Solving for that system, matrices in Eq. 16 are obtained for the viscous damping model and in Eq. 17 for the structural damping model. Figure 6 shows an FRF comparison between the experimental one at $L/4$ and the calculated using both obtained physical models.

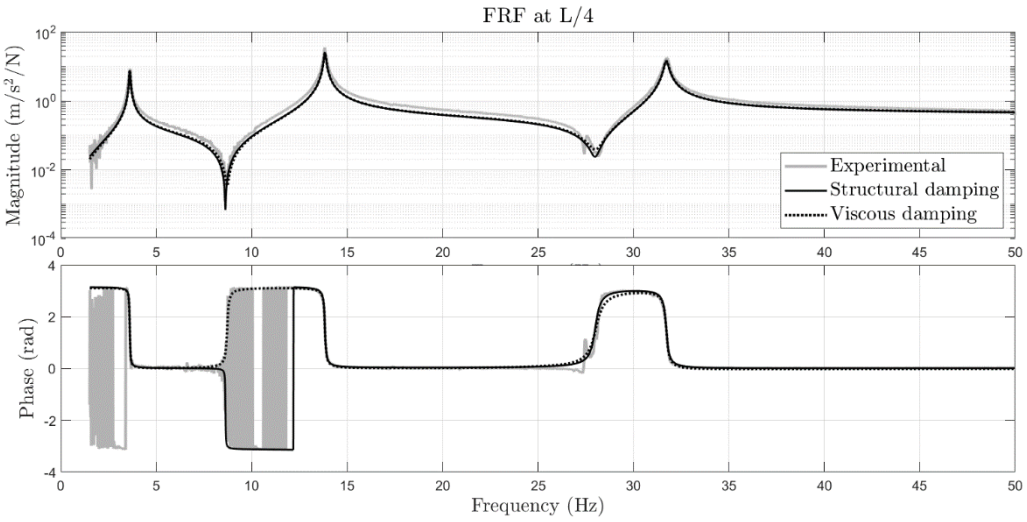

Figure 6. Comparison of FRFs at point L/4

The six presented matrices are full, and no elements can be supposed to be zero as it could be expected for a matrix issued from a finite element assemble. This may be due to several reasons, like the fact that it is a reduced model (a sort of dynamic condensed model) and the effect of the non-measured degrees of freedom have been inherently applied on the measured ones. It is also remarkable the presence of negative terms in the principal diagonals of all matrices. Moreover, it is equally remarkable the difference of magnitude order between both models, specially concerning the mass matrices, being in general the matrices corresponding to the viscous model some magnitude orders above the structural one. Although both facts seem to be counter-intuitive and hard to explain, both combinations of physical matrices lead to the dynamic behaviour represented by the FRFs in Figure 6 and so both models are expected to respond in the same way as the real structure when subjected to actions in the measured frequency band.

5 RESULTS DISCUSSION AND CONCLUSIONS

The proposed methodology is entirely based on the equations that define the modal properties and their relations with the physical matrices. No new equations or results have been extracted in this work and, however, an easy, powerful and fast to apply methodology has been developed. Unlike other methodologies based on optimization and linear programming techniques, that require their time to converge, the pseudo-inverse approach to a rectangular system of equations provides reasonably good results in a very short time lapse, something desirable when it is to be implemented in an automated SHM system.

Although not fully understandable, the two sets of matrices exactly satisfy all the equations presented in Section 3, even the one concerning the total mass of the beam. The systems of equations were, however, under-determined in both cases and the obtained solution via the Moore-Penrose inversion only provided one of the infinite possible solutions. It looks necessary to implement other kind of equations and restrictions for the variables to change this.

Unlike other methodologies based on the pseudo-inversion of some matrices, this procedure does not provide rank-deficient physical matrices. In those cases, this deficiency was caused by the difference between the number of measured degrees of freedom and the number of identified modes. Here, even if that difference exists, its effect is compensated by adding more equations and imposing, for example, the physical terms to be real.

Keywords: structural dynamics; experimental modal analysis, solid or liquid live loads.

Abstract. *Structures such as floors or bridges are usually tested, according to some standards, in order to check some of their properties. Stiffness and modal parameters can be obtained through static and dynamic testing. Usually, static testing consists in adding mass to the structure and measuring the additional deflection. For convenience reasons, the added mass is usually implemented with tanks of water. However, if the static testing scenario is used to conclude modal parameters or dynamic serviceability assessment, it is necessary to ensure that the added load is representative of the structure conditions during its life span. Although for static load testing the results do not depend on the nature of the gravitational load, the same does not occur when modal parameters are of interest. Whether the mass is solid (sandbags or concrete blocks), liquid (water in tanks) or other types (as vehicles or people, etc.) greatly affects the damping due to interaction phenomena. These interaction effects appeared in an attempt to evaluate the damping on a wooden floor through traditional techniques (modal analysis using a shaker and some accelerometers). With the floor without any load, the different modes of their girders (one-way slab floor) could be easily identified and their frequencies and damping ratios well quantified. However, when supporting water tanks, the identification procedure was a challenging task. Trying to understand how the nature (solid or liquid) of the added mass affects, six case studies based on a lab-scale structure are presented.*

1 INTRODUCTION

Figure 1 shows a load test on a pedestrian timber bridge. It consists of distributing several water-filled tanks along its length and measuring the increase in deflection to obtain the stiffness of the structure. Taking advantage of the instrumentation carried out, could a modal analysis be made to obtain the modal properties (frequency and damping ratios) of the footbridge in crowded conditions? In the same way, figure 2 shows a full-scale laboratory timber floor. For the same load, the modal properties are very different if the load is just water in a pool (left) or people. Even if people are sitting (center) or standing (right) the results are also very different.

Figure 1. Loading test in a timber footbridge.

Figure 2. Different loading conditions in a timber floor.

Trying to understand how the nature of the added mass affects, figure 3 shows two scale models (a "bridge" and a "2-storey building") on which tests are being carried out by loading these models with water balloons and inducing vertical vibrations (for the bridge) or horizontal vibrations (for the 2-storey building). In both cases, tests can be carried out by means of the standard instrumentation consisting on an impact (over a load cell) and several accelerometers, all the signals been recorded by a proper data-logger. Processing all the data (experimental modal analysis methodology, EMA, [1, 2]), mode shapes, modal damping and natural frequencies can be obtained by identification techniques [3, 4, 5).

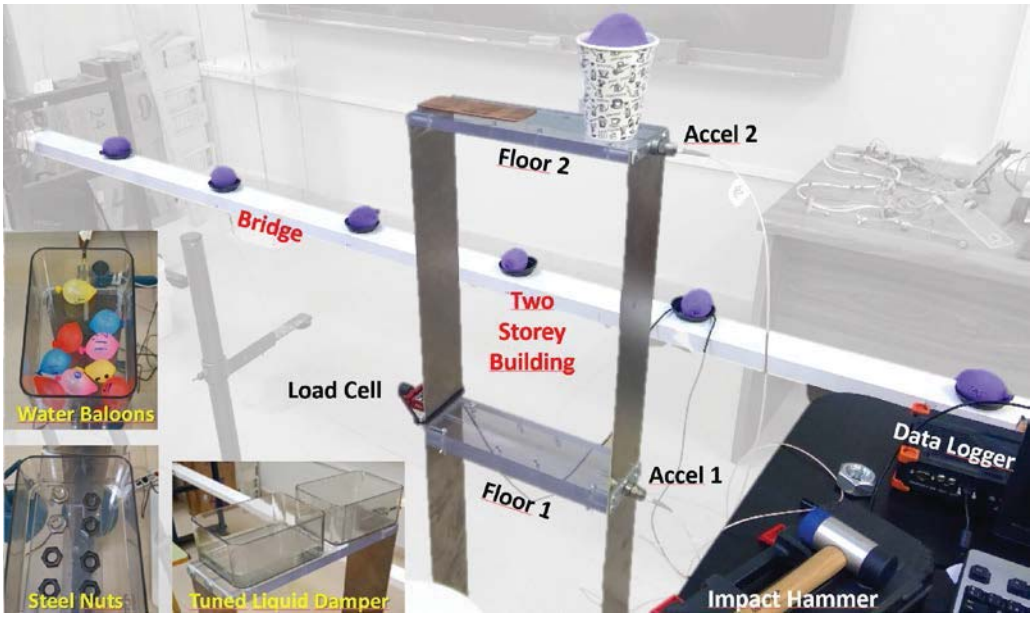

Figure 3. Lab layout.

2 CASE STUDIES DESCRIPTION

In order to design a controlled lab test and to identify the interaction effects, the model of a 2-storey building (figure 3) is used. Each floor consists of a methacrylate plate rigid enough to suppose them to be rigid bodies for the purposes of this work. They are connected to each other and to the ground *via* two aluminium plates. These plates, very stiff in one bending direction with respect to the other, limit the movement of the building model to one horizontal direction.

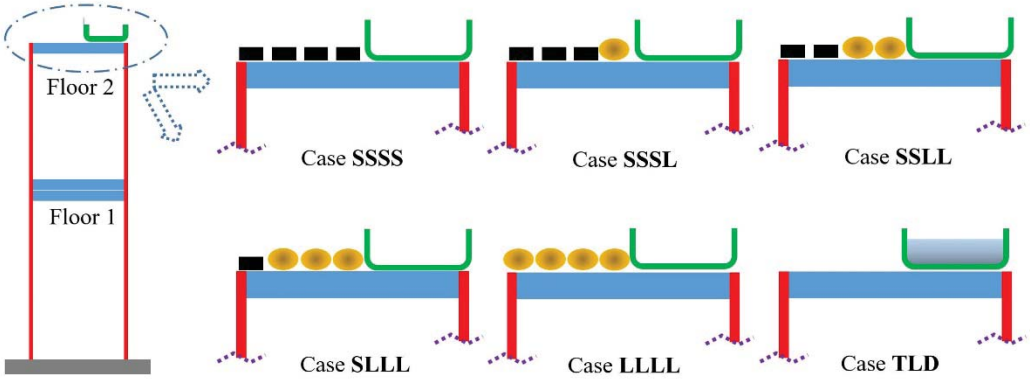

Figure 4. Scenarios under study.

Six case studies are presented (figure 4). As a reference or blank scenario, 16 steel nuts of 0.010 kg each were added on the second floor (accounting for 18% of the total mass of the floor, the first floor weighs twice as much). After that, 4 of the nuts were replaced by 4 balloons

containing the same mass in water. Later, the same with another 4 nuts and so on until the solid masses were all replaced. In the last scenario, nuts and balloons are replaced by a tank containing the same mass in water, constituting a tuned liquid damper (TLD). In figure 3, at left, nuts, balloons and the TLD can be seen. Case SSSS corresponds to the case where all the added mass is solid (nuts). In the SSSL case one quarter of the solid mass is replaced by the equivalent in water (confined in balloons). In the SSLL case half of the added mass is solid and half is liquid. Finally, in the SLLL case the added mass is one-quarter solid and three-quarters liquid and in the case LLLL case all the added mass is liquid.

3 METHODOLOGY

As can be guessed in figure 5, left, two IEPE accelerometers (100 mV/g) are installed on each floor (blue ring), both oriented to measure horizontal accelerations. The excitation consists of an impact applied to the load cell (100 N max.), also installed in floor 1 (red ring). The accelerometers and the load cell are wired to an acquisition system (SIRIUS model of the brand Dewesoft), and data are registered at 400 samples per second. In figure 5 right, FRF (H_1 estimator) are obtained after each impact and several averages (3 or 4) are carried out in order to remove some of noise.

Figure 5. Modal analysis on air.

Both FRFs (the one corresponding to the first floor or auto-FRF and the one of the second floor) (are fitted in magnitude and in phase) to a theoretical system of 2 degrees of freedom (eq. 1), in which a general viscous damping model has been assumed.

$$H_{jk}(\omega) = \sum_{r=1}^{m} \left(\frac{\theta_{rj}\theta_{rk}}{i\omega - s_r} + \frac{\theta_{rj}^{*}\theta_{rk}^{*}}{i\omega - s_r^{*}} \right) \tag{1}$$

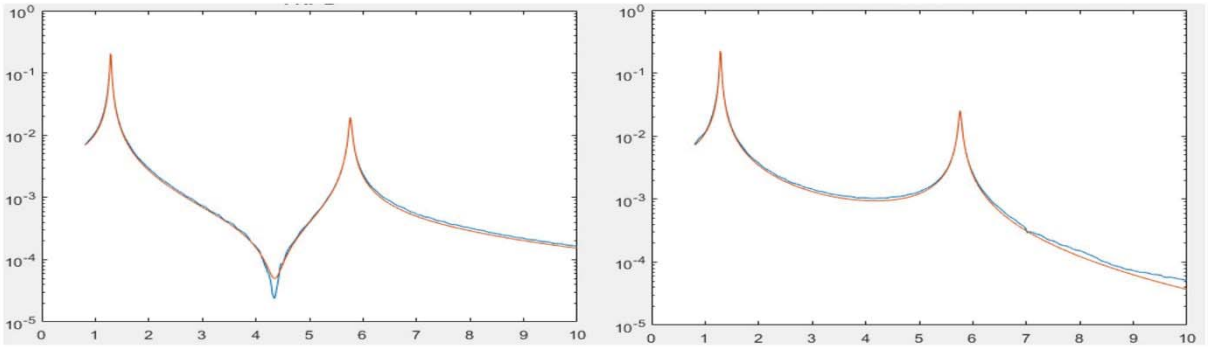

Figure 6. Case SSSS: FRF of the first floor (left) and of the second floor (right)

For the reference case (SSSS), figure 6 shows the experimental FRFs (in blue) and their corresponding fitted curves (in red) when m=2. As can be seen, the system fits perfectly with a two-dof, as intended. After the curve-fitting process, table 1 shows the modal parameters, including the modal coordinates of the two modes, that are plotted in figure 7.

	Frequency **(Hz)**	Damping **(%)**	Modal coordinates **floor1**	**floor2**

4 RESULTS

Following a similar procedure for the rest of the cases, results of table 2 and table 3 are obtained. Figure 8 shows the adjusted curves for the SSLL case and figure 9 for the LLLL case. In both cases, the adjusted curves for the SSSS case are shown in grey. Table 2 also shows the values of the accelerance of both FRFs (floor 1 and floor 2) for the peaks corresponding to mode 1 and mode 2. All these values are drawn in the graphs in figure 11.

Table 3. Modal coordinates.

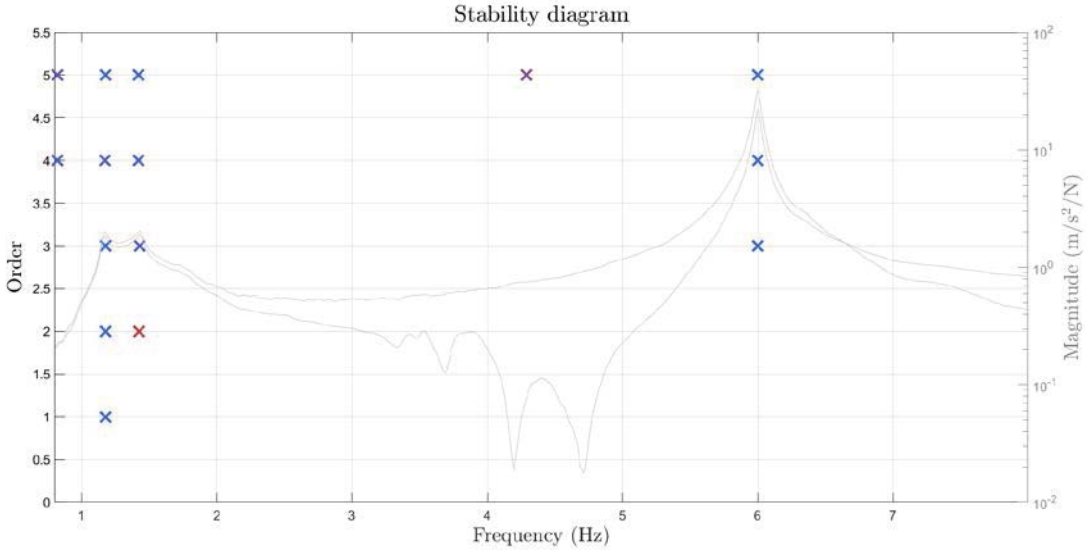

Figure 10a. Case TLD: Stability diagram.

Actually, the adjustment to the TLD case is more complicated. Precisely because of the splitting that occurs in mode 1, a setting of order 3 (m=3 in eq. 1) is necessary. Figure 10a shows the stability diagram together with the fitted FRFs (10b) for this case. The values for the split mode 1 are also shown in the corresponding tables.

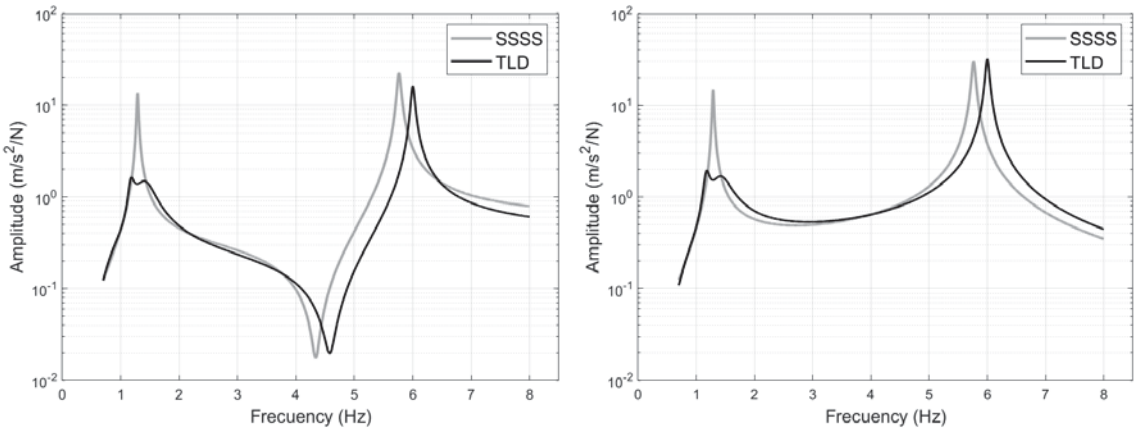

Figure 10b. Case TLD: FRF of the first floor (left) and of the second floor (right)

In order to better observe how the modal parameters evolve through the different cases, Figure 11 shows the accelerances of the first peak (in floor 1 and floor 2) together with the corresponding value of the frequency of the first mode (figure 11 a) and also the modal damping ratio (figure 11b). Similarly, figures 11c and 11d refer to the second mode.

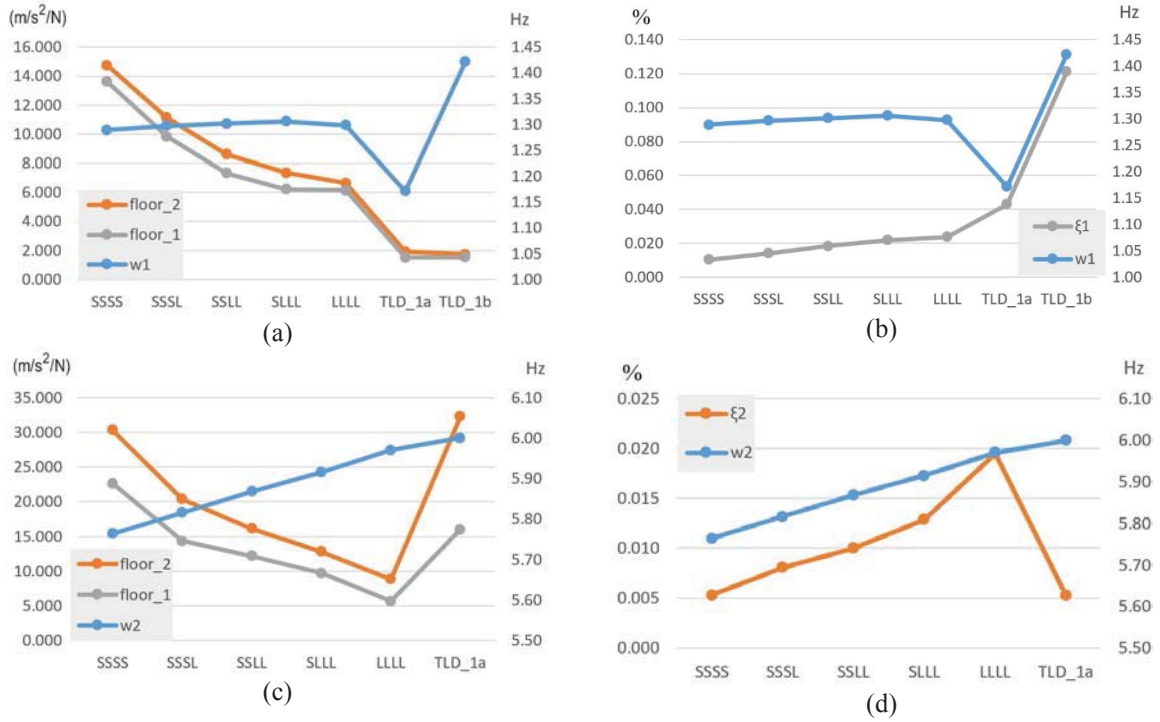

Figure 11. Trends for frequencies, accelerances and dampings

Once known the scaled modal coordinates (table 3) it is also possible to estimate the modal masses of each mode, which is shown in table 4 and plotted in figure 12.

	modal mass 1	modal mass 2
SSSS	3.007	2.323
SSSL	2.828	2.132
SSLL	2.690	2.323
SLLL	2.620	2.281
LLLL	2.936	1.819
TLD	2.867	1.479

Table 4. Modal masses for each case

Figure 12. Trends for modal masses.

5 CONCLUSIONS

As the load changes from solid to liquid, the frequency of the mode 1 remains sensibly constant (except in the split, TMD case) while the frequency of the mode 2 slightly increases (4%). Similarly, the accelerances decrease (55% on average, not counting on the TLD case) and the damping increases (up to 130% for mode 1 and 270% for mode 2, not counting on the TLD case). Modal masses do not have a defined trend.

All these interesting results must be carefully analysed. Similar experiments are proposed for vertical vibrations on the bridge scale model (figure 3). Full scale tests are also pending.

After the analysis of the estimated FRFs for all the scenarios, it will be concluded that the nature (solid or liquid) of the added mass affect the modal properties. It is known that the liquid mass can provide new natural modes. In the case the new modes are close to the ones of the

original model, relevant changes could appear because of the interaction effects, being these phenomena similar to the working principle of the tuned liquid damper (case TLD, included).

Note that more cumbersome scenarios can appear when crowds occupy the floor structure [6, 7]. From the experiments carried out, it should be concluded that the typical static load test scenarios present some limitations when used to perform modal identifications or dynamic tests, since they may not describe the actual conditions of the structure during its normal use (live loading).

Abstract. *The paper deals with structural damage identification in steel trusses. Classical procedure based on dynamic measurements able to detect flexibility changes are complemented with data predicting cracks and their evaluating by image processing. The procedure proposes first a damage index, the Stiffness Reduction Factor (SRF), evaluated on the basis of the error between the predictive truss model and the experimental modal model. Then, a nonlinear FEM model is used to determine fatigue cracks in the truss nodes which are compared with the observed ones determined by image processing. A real case study, the Quisi bridge located in Spain, is used to show the potentiality of the procedure.*

1 INTRODUCTION

Steel truss railway bridges are subject to potential damage, mainly due to fatigue phenomena and corrosion. The monitoring of infrastructures' condition becomes a very important issue to our society for detecting their damage. In last years, vibration-based damage identification methods have been proposed in conjunction with other techniques. Even though the matter has strongly exploited in the scientific community, the raising of innovative technologies in mechatronics, robotics and Information and Communication Technology (ICT) opens up new perspectives in facing the classical problems in the management of infrastructures [9]. Related to this topic, two main research fields could have impact in the inspection and monitoring of infrastructures: automated machine vision-based inspection and the classical structural vibration monitoring. In the first area the use of mobile robots and UAV have strongly increased the acquisition of images to sense the spatial characteristics of the environment, permitting the creation of "cloud" of 3D points. The second area consists in a structural health monitoring system to permit visualization and management of sensor data, data interpretation and analysis and interaction with classical finite element model for structural behavior simulation and model updating. Classical vibration-based monitoring acquires the structural dynamic response, and the corresponding analysis obtains knowledge about the actual mechanical behavior of a structure.

To assess the presence of damage in a steel truss railway bridge, a procedure that links information derived by the vibrations of the bridge with image acquisition by means of long-term monitoring system, has been developed. The paper focuses first on the effects of damage on the static and dynamical response of a nominal model of steel truss. For this purpose, damage is described as a reduction of cross section area of one element of the truss. The direct problem is addressed by FEM and the global modes are identified. The procedure for linear damage detection is tested using pseudo-experimental data, that are generated from the model under white noise. The main modal parameters of the dynamic system are evaluated, before and after damage, using Stochastic Subspace Identification (SSI) method [6-8], based on the assumption that the input is a realization of a stochastic process. The damage identification problem is solved by minimizing an objective function.

A global model of the Quisi Bridge case study is made. The aim of the global analysis is the investigation of the bridge structural behavior to evaluate the structural response due to train crossing. Numerical simulations were conducted before and after damage to study the changes in frequencies and mode shapes due to the presence of damage. In order to perform automatic identification of structural modal parameters based on structural response (output) and to calibrate the numerical global model on experimental data by model updating procedures, an Operational Modal Analysis (OMA) procedure is applied with the purpose of achieve an accurate estimation of natural frequencies. Results obtained from numerical analysis and experimental dynamic tests are mixed together to identify critical details most subjected to fatigue-induced cracks.

In particular, this work aimed at obtaining a better and more accurate comprehension of fatigue phenomena which determine fatigue cracks under the application of a large number of cycles. Thus, a local analysis of critical details is performed to assess the local stress induced by load cycles and the resistance of principal elements.

Preliminary studies performed on the Quisi Bridge, are reported.

2 A PROCEDURE FOR DAMAGE DETECTION IN A TRUSS SYSTEM

In order to assess the presence of damage in a truss structure based on vibration measurements, a sensitivity analysis is performed on a planar truss model (Figure 1) to study the defect-induced reduction of stiffness, (combination of damage intensity and extension).

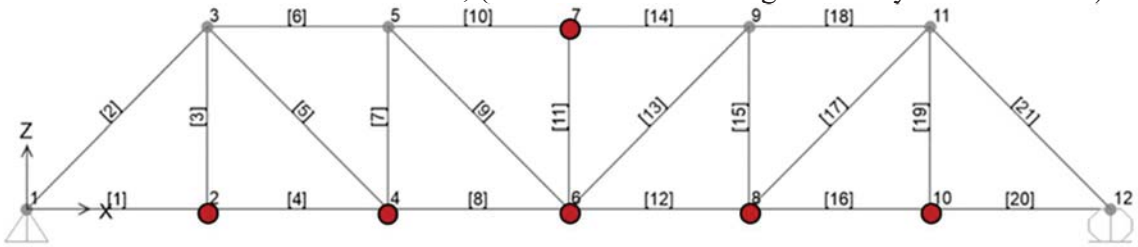

Figure 1: Sketch along with sensor layout in the 2D numerical model.

The damaged truss element is defined and implemented through a classical FEM procedure in which damage is described as a cross-section area reduction and the local stiffness matrix has the following expression:

$$\boldsymbol{K_d^e} = \frac{EA}{L} \cdot \frac{(1-\zeta)(1+\delta\zeta-\zeta)}{[(1-\zeta)(1-\delta)+\delta]^2} \begin{bmatrix} 1 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 \\ -1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} = \frac{EA}{L}(SRF)\boldsymbol{K^e} \tag{1}$$

where the damage intensity ζ and extent δ have been represented in non-dimensional form as:

$$\zeta = \frac{EA-EA_d}{EA},\ \delta = \frac{L_d}{L},\ 0 \le \zeta \le 1, 0 \le \delta \le 1 \tag{2}$$

SRF is the Stiffness Reduction Factor which is a combination of these two parameters affecting the stiffness and consequently the frequencies [10-11]. Several damage scenarios were considered: the damage parameters were applied consecutively to truss element n. 2, 5 and 6 (Figure 1).

The dependence of the frequencies on the SRF is described by numerical evaluation FEM. The procedure uses pseudo-experimental response, generated from the numerical model under white noise. Vertical accelerations of the bridge were evaluated in several nodes of the model, (indicated in red in Figure 1), and based on these measurements a dynamic identification of the modal parameters was made by SSI in time domain. The inverse problem of damage identification is addressed minimizing an objective function $\mathcal{L}(\zeta, \delta)$ based on frequency measurements, that represents the comparison between the numerical and the experimental dynamical response of the truss. The objective function $\mathcal{L}(\zeta, \delta)$ is defined as follows:

$$\mathcal{L}(\zeta, \delta) = \sum_{i=1}^{k} \left| \frac{\omega_{d,i}^{EX} - \omega_{d,i}^{NM}(\zeta,\delta)}{\omega_{u,i}^{EX}} \right|^2 \tag{3}$$

Where $\omega_{d,i}^{EX}$ and $\omega_{d,i}^{NM}(\zeta, \delta)$ are the *i*-th experimental and numerical frequencies of the damaged element respectively, while $\omega_{u,i}^{EX}$ represents the corresponding frequency in the undamaged state. Only an optimum number of modes k are needed to be considered to univocally determine the SRF(δ, ζ) curve in the damage parameter plane (δ, ζ). The number of modes that are necessary to achieve a unique solution in the optimization problem depends on the position of the damaged element in the truss. Figure 2 shows results of the performance of index $\mathcal{L}$ in the detection of curve SRF(δ, ζ) varying the number of modes k. The target point T is indicated with red circle, and the corresponding Γ- curve, in red in Figure 2, is Γ (0.3;0.5) = 0.76923.

Table 1 shows the performance of index $\mathcal{L}$ in the detection of the stiffness reduction factor Γ. The number of modes depends on which damaged truss element is considered and on the effects of the vibrational modes. Considering the first three mode of vibration is enough to determine the stiffness reduction factor for this example.
The sensitivity-based strategy can use different type of objective functions and not only frequencies: a modal assurance criterion (MAC and CoMAC); modal flexibility [5] or a combination of the first options [2]. As reported below, a damage identification based on changes in mode shapes is performed for the Quisi Bridge case study.

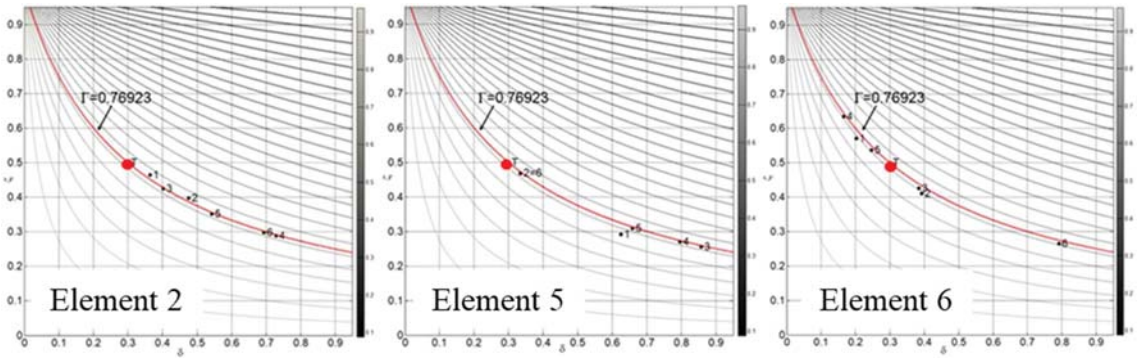

Figure 2: Effects of number of modes in the detection of SRF(δ, ζ) curve respectively in element 2, 5 and 6.

3 GLOBAL MODEL: QUISI BRIDGE CASE STUDY

The Quisi Bridge located in Benissa (Alicante) is an historic steel truss railway bridge, which is investigated with different techniques to assess the presence of fatigue damages. It is a XX century steel Bridge and it is part of the 9th FGV Railway Line. The structure consists in a top-bearing Pratt type truss. It is 170 m long with six spans of different length (Figure 3).

Figure 3: Quisi Bridge.

A 3D FE model of the main span permits to evaluate frequencies variation due to damage. Two different damage scenarios (DS) are considered: the first one (DS1) affecting one element of the main span with a stiffness reduction factor of 0.3, the second one (DS2) affecting a group of elements of the truss.
The frequency variation for the first four modes in percentage are reported in the Table 2. The frequency variation produced by damage appears to be quite low evidencing the needs of introducing also other type of damage index based on mode shapes.
The changes of mode shape can be evaluated quantitatively using a well-known correlation measure, the modal assurance criteria (MAC) between two modes shape ϕ_i e ϕ_j, as defined as:

$$\boldsymbol{MAC}_{ij} = \frac{\left|\phi_i^d \cdot \phi_j^u\right|^2}{\left|\phi_i^d\right|^2 \left|\phi_j^u\right|^2} \tag{4}$$

Mode	DS 1	DS 2
	$(f_{iu}-f_{id})/f_{iu}$ [%]	$(f_{iu}-f_{id})/f_{iu}$ [%]

Table 3: MAC comparing modes from numerical model for damaged and undamaged scenarios. Bold indicates a value calculated with the same mode from the scenario pair.

Table 3 presents MAC values comparing modes obtained by numerical FE model for DS1 and DS2 with the undamaged scenario (UN). The calculated MAC values indicate little change in mode shape for the first damage scenario, with MAC value larger than 0.98 for the first two modes. Marked change in mode shape attributable to the second damage scenario are observed. The most remarkable change occurs in the sixth mode with MAC decreasing to 0.82. A second major change occurs in the first and seventh modes (MAC=0.83). However, in some cases,

MAC fails to reflect the change in mode shape. Another well-known mode shape-derived correlation measure, the coordinate modal assurance criteria (CoMAC), is examined herein. It can be regarded as a point-wise measure of the correlation between two sets of mode shapes and be defined for a measurement point (or degree of freedom) *i* as:

$$\boldsymbol{CoMAC}_i = \frac{\left(\sum_{j=1}^{nm}\left|\phi_{ij}^{d}\phi_{ij}^{u}\right|\right)^2}{\sum_{j=1}^{nm}\left(\phi_{ij}^{d}\right)^2\sum_{j=1}^{nm}\left(\phi_{ij}^{u}\right)^2} \tag{5}$$

The CoMAC between the mode shapes of the damaged and corresponding undamaged scenarios, can be calculated as presented in Figure 4. Although CoMAC is often taken as damage locator for its space information, it might sometimes be affected by its low sensitivity to damage, (as in DS2), and from confusing localization, (as in DS1).

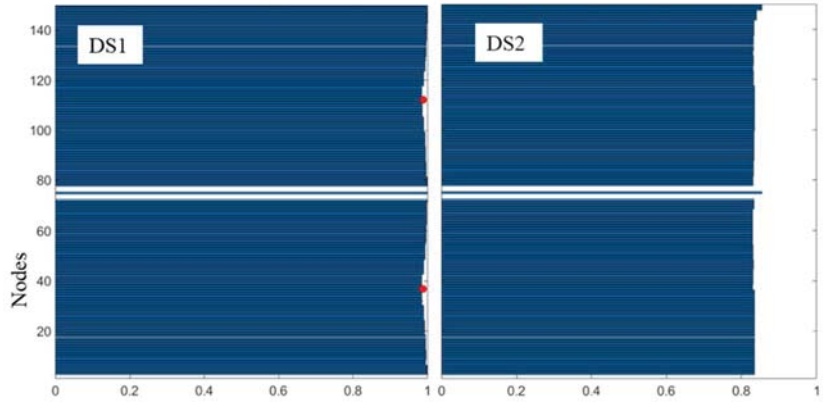

Figure 4: CoMAC comparing modes obtained by numerical model of the main span.

4 EXPERIMENTAL TEST ON THE QUISI BRIDGE

For the Quisi Bridge an experimental dynamic identification of the main features characterizing the dynamic behaviour of the structure, has be performed in order to calibrate the numerical global model on experimental data by updating procedures. Experimental tests constitute a reliable and effective tool for the evaluation of structural dynamic properties. They are composed of experimental acquisitions, obtained recording vibrations of suitable key points of the structure subjected to environmental excitations, and following numerical elaboration of data. Three uniaxial accelerometers were placed on the bridge, one in each mid-span on the right side of the bridge for the first test and on the left side for the second test. Starting from the recorded data, the global modes are identified by Operative Modal Analysis technique (OMA) [4], using the Stochastic Subspace Identification (*SSI*) in the time domain [1]. Data processing, system identification and modal analysis were performed using MACEC, which is a MATLAB toolbox developed for Experimental and Operational Modal Analysis by the Structural Mechanics division of K.U. Leuven [7].
Figure 5 shows the stabilization diagram and the PSD for the main span of the Quisi bridge in the first OMA test. The identified modal frequencies are reported in Table 4. A total of 4 frequencies for the first test, and 3 frequencies for the second test were identified based on measured response only. In general, a very good accordance is achieved. Due to the low number of accelerometers is not possible to also identified mode shapes.

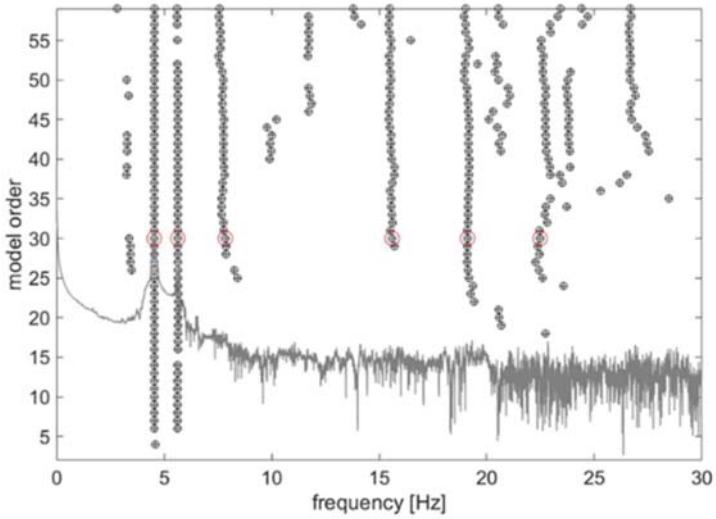

Figure 5: Stabilization diagram and PSD obtained by SSI.

Mode	f_{nm} [Hz]	OMA-test 1		OMA-test 2	
		f_{id} [Hz]	Δ[%]	f_{id} [Hz]	Δ[%]

5 LOCAL MODEL

The global analysis of the Bridge aimed at the investigation of bridge actual structural performance under train passage, including the assessment of internal forces induced by train into the critical details most subjected to vibration effects. The development of a numerical global model is essential for the identification of the key points that permitting the proper modelling also of critical details. Thus, using forces from the global FE model, it is possible to perform an analysis of the steel connection. There are a lot of benefits of a detailed simulation, first of all the possibility to study system with complex stress distribution, to reproduce correctly local dynamic behaviors, the estimation of action and contact forces, the design of retrofitting for steel connection damaged by corrosion or fatigue cracks. The correct evaluation of local effects generally neglected or simply not consider by standard mechanical modelling is one of the main issues of damage identification. The main effort is the identification of critical details most exposed to damage phenomena, these details can be successful identified by a preliminary analysis of bridge structural behaviour, by means of standard analysis properly refined in order to catch a qualitative indication of local fatigue behaviour.
Once critical details are identified, a nonlinear static analysis can be obtained by means of numerical local models able to represent properly the vibration/distortion phenomena that influence intensity and distribution of stresses. The detailed model using shell FE and links system, is developed by MIDAS-FEA software. The approach to model riveted connection in detailed shell model is made through beam between two surfaces and a system of rigid links between the master node, in the center of the hole, and the slave nodes lying on the circumference of the hole (Figure 6).

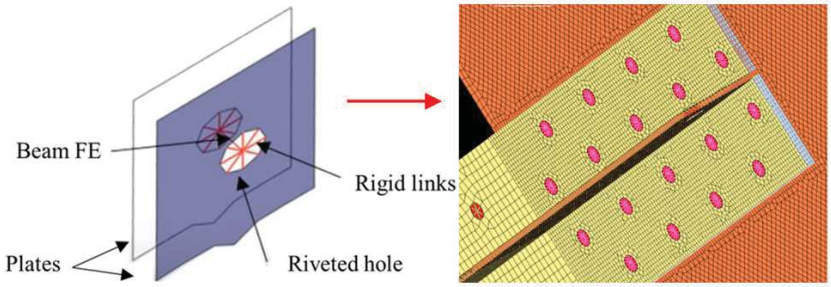

Figure 6: Details of local model.

5.1 Nonlinear static analysis

In this chapter a nonlinear static analysis is carried out. A nonlinear static analysis is a procedure in which the magnitude of the structural loading is incrementally increased in accordance with a certain predefined pattern. With the increase of the magnitude of loading failure mode of the structure are found. Beam element stresses were extracted from the FE global model (Figure 7). For each load step the nonlinear static response of the local model was computed. The stress-strain relation is expressed by an elastic-linear strain hardening law. The elastic-linear strain hardening model supposes that the continuous curve is approximated with two straight lines, the first line has a slope of Young's modulus, while the second straight line presents an idealization for the strain hardening range and has a slope which corresponds to the tangent modulus (E_t), where $E_t < E$. Figure 8 (a-l) shows the distribution of the maximum principal stresses at ten different steps of the incremental static analysis, that are reported in Table 5. The analysis of the figure reveals maximum stress levels in the order of 673 MPa, which represents high values. These maximum stresses are observed on the top of the diagonal member, in the connection plate with the upper chord.

In the Figure 9 (a), the plasticity status obtained by nonlinear static analysis: (a-1) the blue colour indicates the plastic zones that are potential crack locations, (i.e. the connection plate is a plastic region). Figure 9 (a-2) shows a detail of the double strap joint with two rows of rivets in the plate: from a static point of view both rows carry the same load which implies the same stress on the rivets, but from a fatigue point of view the two rows are in a different position, the holes in row B of the plate are loaded by P_B only and in row A the same load P_A is present on the holes but the load already introduced in row B is also passing these holes. The latter load is called a bypass load. Nevertheless, for this case study the holes in row A are more severely loaded than holes in row B and thus will be more fatigue critical. Fatigue cracks will occur in the row A cause of plastic deformation around the holes under static load. In the Figure 9 (b), the flux of the principal stresses is highlighted by blue colour (compression) and red colour (tension) lines with lengths proportional to the stress intensity.

5.2 Fatigue analysis

Fatigue failure is defined as the tendency of a material to fracture by means of progressive brittle cracking under repeated alternating or cyclic stresses of an intensity considerably below the normal strength. Although the fracture is of a brittle type, it may take some time to propagate, depending on both the intensity and frequency of the stress cycles. All structures and mechanical components that are cyclically loaded can fail by fatigue. Fatigue failure in structures frequently occurs in joints. Understanding the fatigue mechanism is essential to considering various technical conditions which affect fatigue life and fatigue crack growth.
Fundamental requirements during design and manufacturing to avoid fatigue failure are different for each different case and should be considered during the design phase. Fracture specifically describe the growth or propagation of a crack once it has been initiated and has given rise to many so-called crack growth methodologies. Fatigue analysis can be performed based on stress (stress-life method) and strain (strain-life method).
The stress-life method is mainly used for fatigue analysis under the condition of a low stress level relative to the yield stress. The stress-life method predicts the extent of fatigue under a given loading history using the relationship between the number of loading cycles (N) and stress amplitude (S) at the time when failure occurs from a cyclically applied constant load. The S-N curve shows the relationship between the stress amplitude (S) occurring from a cyclic loading of constant amplitude applied to the structure and the number of cycles to failure (N) when the stress of the corresponding amplitude is repeated. For a fatigue analysis using the stress-life method, a linear elastic analysis on the structure is performed first, and then equivalent stresses (such as principal stresses) are obtained. These stresses are then applied to an S-N curve to predict the number of loading cycles required to reach the fatigue failure in conjunction with detail category tables, to obtain a good estimation of the safety level of each detail on the bridge.
In Eurocode 3 [3], 14 S-N curves, which are equally spaced in log scale, as shown in Figure 10 (a), are defined. Each curve is characterized by the detail category $\Delta\sigma_C$. The slope coefficient m is equal to 3 for stress range above the constant amplitude fatigue limit (CAFL), $\Delta\sigma_D$, at 5 million cycles, and equal to 5 for stress range between the CAFL and the cut-off limit, $\Delta\sigma_L$, at 10 million cycles.
For riveted connections, Italian railways company imposed a value of 71 MPa, corresponding to the detail category 71, see Figure 11 (b), where the nominal stress $\Delta\sigma$ has to be calculated on the net cross-section (gross cross-section minus section of rivet holes in the critical section).

According to Eurocode 3 part 1-9, the fatigue strength value $\Delta\sigma_C$ is divided by γ_{MF}, so obtaining $\Delta\sigma_D = \Delta\sigma_C / \gamma_{MF} = 71/1.35$ MPa = 52 MPa. The fatigue strength curve is defined as follows:

$$(\Delta\sigma_R)^m N_R = (\Delta\sigma_C)^m 2 \cdot 10^6, \quad m = 3 \; for \; N \leq 5 \cdot 10^6 \tag{6}$$

$$(\Delta\sigma_R)^m N_R = (\Delta\sigma_C)^m 2 \cdot 10^6, \quad m = 5 \; for \; 5 \cdot 10^6 \leq N \leq 1 \cdot 10^8 \tag{7}$$

$$\Delta\sigma_L = (5/100)^{1/5} \Delta\sigma_D, \quad (cut - off \; limit) \tag{8}$$

When several stress amplitudes exist, the degree of damage of a material is calculated by accumulating individual damages from each of the stress amplitudes. Using the number of cycles corresponding to a specific stress amplitude, n_i, and fatigue life, N_i, the cumulative damage is calculated using Equation (9). The fatigue life of a structure is the reciprocal of the damage according to Equation (10).

$$Damage = \sum_i \frac{n_i}{N_i} \tag{9}$$

$$Fatigue \; Life = \frac{1}{Damage} \tag{10}$$

The riveted single-track railway Bridge was built in 1917 and was in use until a few years ago. After over 90 years of service, there is a motivation for assessment since the bridge has reached the end of its design working life. Therefore, an assessment is carried out to determine the residual service life of the bridge. Since the bridge has been in use for 94 years, there is a higher probability of failure due to fatigue than due to static overloading.

Data on traffic was collected from the railway's archives. A single type of locomotive has transited this line, (Locomotive series 1000), as sketched in Figure 11.

Results of fatigue analysis performed using MIDAS-FEA are reported in Figures 12 and 13. From the second fatigue result, it is noticed that there is no remaining fatigue life for elements in blue colour, it had expired 4 years before the year in which this assessment was undertaken. The member chosen for the analysis cannot be considered safe anymore. It should be noted that each specific structural element has a different fatigue life.

6 LONG-TERM MONITORING

An image acquisition by means of long-term monitoring system on the Quisi Bridge, permits on one hand to improve the procedure and, on the other hand, to obtain the description of current fatigue cracks on the bridge. On-site inspections were carried out by means of non-destructive testing of the connections of the bridge. Gamma radiation radiographs, (gammagraphy), were performed. The tests were performed by the TÜV SÜD ATISAE Laboratory and the test

standard procedure UNE EN ISO 5579 was used. The gammagraphy was carried out in a total of 160 connection geometry of the viaduct. The existence of cracks, cavities, inclusions, fusion and penetration defects, imperfections in shape and dimensions and other types of imperfections have been analyzed. In general, the state of the connections is very acceptable. However, small fissures have been identified in four zones of the bridge, shown in Figure 14, 15 and 16. It is worth noting that the first crack on the first isostatic span (Figure 14) and also the second crack on the iperstatic span (Figure 15) are located down the rivet cap or in the interior of the plate inside the union of several steel sheets. Through visual inspection it is not possible to detect these cracks. The third crack, (Figure 16 (b)), could be an original failure dating back to the stage of fabrication process of the rivet on the bridge; the fourth crack (Figure 16 (c)) is of the same type as the first two. On the isostatic spans the cracks are in a similar position this could be due to the loop effect generated by the train passage. No crack was observed in the position subjected to local modeling. Thus, a second detailed local model is under realization.

The image processing of the crack images has been carried out through segmentation by thresholding. Segmentation in a digital processing is a process of partitioning an image into significant regions and it is used to extract objects from the image. As in Figure 17 the first step is the thresholding that from a grayscale image returns a binary image, subsequently the noise removal, in the third step the assessment of the boundaries of the identified regions, the regions associated with the crack are the regions 3 and 4, and these will be therefore measurable (parameter estimation of the crack). The same procedure is in progress for other crack images, it is requiring pre-processing to highlight the crack from the background (Figure 18).
Based on the information extracted from the images acquisition and the newer local model behavior, it will be possible to update the global model considering the presence of fatigue crack.

7 CONCLUSIONS

A procedure to identify damage in a steel truss bridge has been proposed. The results obtained through pseudo-dynamic testing and FEM analysis for a simple truss evidences the obtainable resolutions in damage indicator with the increase of a number of modes. For the main span of the Quisi Bridge the damage changes, affected both one single element and then a group of elements, do not affect to the main frequencies of the bridge so, a mode shape based method is performed. Natural frequency changes alone may not be sufficient for a unique identification of the location of structural damage.

From the results of stress intensity obtained in the global model, the critical point is selected to analyze the fatigue phenomena in the local model.

Fatigue damage appears in the form of fatigue cracks and can occur in primary loaded or secondary elements. Since fatigue failure is depending on the load spectra over the service life, consequently, existing steel structures suffer more from fatigue and accumulate more damage the older the bridges are.

Fatigue crack initiation in structural details is generally expected where stress concentrations may occur, such as holes as showed by the presented detailed FEM model of a joint of the Quisi Bridge. These results are comparable with the crack identified by Gammagraphy. More data are expected for the Quisi Bridge in which a permanent monitoring system will be install even with image acquisition. Figure 19 shows the experimental setup with an important number of channels, the data acquisition is done under environmental condition.

Concerning the image-based detection of fatigue cracks, the general architecture of the method is shown in Figure 20 and it includes: an initially collect the image of the structure which will be subjected to the crack detection process (image acquisition), the pre-processing of the images with segmentation, the crack detection using the result of the processed image and finally the crack feature extraction that is the step in which the detected cracks are separated based on the width, depth, area or length of the crack.

The available data will permit to perform a nonlinear model updating through an error criterion based on crack pattern and frequency and modal shape variations.

Keywords: Operational Modal Analysis, Frequency Domain Decomposition, Damping Ratios, Maximum Likelihood, EM algorithm.

Abstract. *The Frequency Domain Decomposition (FDD) method consists on identifying natural frequencies and mode shapes of structural and mechanical system as the peaks of a frequency plot. However, the damping ratio is not an output of FDD, but it is calculated in secondary step. In this work a new method is proposed to estimate the damping ratios. The idea is to use maximum likelihood estimation, where the likelihood function is defined in terms of the innovations of the state space model. This is a highly nonlinear and complicated function of the unknown parameters, so a numerical method must be used to find the maximum. In this work, the BFGS algorithm has been chosen. This method also allows quantifying the uncertainty of the parameters using the Hessian matrix. Due to the nature of the method, there are not problems with closely spaced or repeated modes.*

1 INTRODUCTION

The Frequency Domain Decomposition (FDD) algorithm is maybe the most known and used method to estimate modal parameters in Operational Modal Analysis. FDD was introduced as an extension of the classical frequency domain Peak Picking approach [1]. The main advantage of this approach is the fact that engineers and researchers can identify the modes of vibration of their system as the peaks of a frequency plot. On the contrary, other sophisticated techniques like Subspace methods are usually viewed as black boxes where the user looses the physical meaning of the parameters.

Apart from the user-friendlinees of the method, FDD gives reasonable estimates of natural frequencies and mode shapes. However, the damping ratio is not an output of FDD, but it is calculated in secondary step [2]: once the natural frequency and mode shape are computed, the contribution of this mode to the spectral density matrix is isolated and transformed back to the time domain. Then, the damping ratio is computed from the corresponding free decay. This two step method is called Enhanced Frequency Domain Decomposition (EFDD). Reference [3] is an updated review of the most relevant works for damping estimation in the FDD context.

In this work a new method for the estimation of the damping ratio is proposed. Instead of using free decays, the method proposes to estimate the damping ratios using the maximum likelihood method. The likelihood function is defined in terms of the innovations of the state space model. This is a highly nonlinear and complicated function of the unknown parameters, and among all the available numerical algorithms, the BFGS algorithm has been chosen to find the maximum of this function. This method also allows quantifying the uncertainty of the parameters, specifically, the confidence intervals of the estimates can be computed using the Hessian matrix.

2 The FDD method

The vibrations of a mechanical/structural system, $\mathbf{q}(t) \in \mathbb{R}^{n_q}$, are given by the equation:

$$\mathbf{M}\ddot{\mathbf{q}}(t) + \mathbf{C}\dot{\mathbf{q}}(t) + \mathbf{K}\mathbf{q}(t) = \mathbf{F}(t) \tag{1}$$

We can change the coordinate system to modal coordinates by mean of the linear transformation:

$$\mathbf{q}(t) = \mathbf{\Phi}\mathbf{q}_\mathbf{m}(t) \tag{2}$$

where $\mathbf{q}_\mathbf{m}(t)$ is the vibration in modal coordinates and $\mathbf{\Phi}$ is the matrix of modal vectors. Let us assume we are measuring the acceleration of n_y selected points:

$$\mathbf{y}(t) = \mathbf{L}_\mathbf{y}\ddot{\mathbf{q}}(t) \tag{3}$$

We consider the contribution of only n_m modes of vibration:

$$\mathbf{z}_\mathbf{m}(t) = \mathbf{L}_\mathbf{m}\mathbf{q}_\mathbf{m}(t) \tag{4}$$

where $\mathbf{L}_\mathbf{y} \in \mathbb{R}^{n_y \times n_q}$ and $\mathbf{L}_\mathbf{m} \in \mathbb{R}^{n_m \times n_q}$ are selection matrices. Combining these equations we have:

$$\mathbf{y}(t) = \mathbf{L}_\mathbf{y}\ddot{\mathbf{q}}(t) = \mathbf{L}_\mathbf{y}\mathbf{\Phi}\ddot{\mathbf{q}}_\mathbf{m}(t) = \mathbf{L}_\mathbf{y}\mathbf{\Phi}\mathbf{L}_\mathbf{m}^\mathbf{T}\ddot{\mathbf{z}}_\mathbf{m}(t) = \mathbf{\Phi}_\mathbf{e}\ddot{\mathbf{z}}_\mathbf{m}(t) \tag{5}$$

where $\mathbf{\Phi}_\mathbf{e} = \mathbf{L}_\mathbf{y}\mathbf{\Phi}\mathbf{L}_\mathbf{m}^\mathbf{T} \in \mathbb{R}^{n_y \times n_m}$. The auto-correlation matrix of the responses is:

$$\mathbf{C}_\mathbf{y}(\tau) = E[\mathbf{y}(t+\tau)\mathbf{y}(t)^T] = \mathbf{\Phi}_\mathbf{e}E[\ddot{\mathbf{z}}_\mathbf{m}(t+\tau)\ddot{\mathbf{z}}_\mathbf{m}(t)^T]\mathbf{\Phi}_\mathbf{e}{}^T = \mathbf{\Phi}_\mathbf{e}\mathbf{C}_\mathbf{m}(\tau)\mathbf{\Phi}_\mathbf{e}{}^T \tag{6}$$

Applying the Fourier Transform we obtain:

$$\mathbf{G_y}(\omega) = \mathbf{\Phi G_m}(\omega)\mathbf{\Phi}^T \tag{7}$$

where $\mathbf{G_m}(\omega)$ is the matrix of spectral densities in modal coordinates at a given frequency ω. On the other hand, the singular value decomposition of matrix $\mathbf{G_y}(\omega)$ is given by:

$$\mathbf{G_y}(\omega) = \mathbf{UDU}^T \tag{8}$$

where $\mathbf{D}$ is a diagonal matrix and $\mathbf{UU}^T = \mathbf{I}$. The FDD method consists in taking $\mathbf{G_m}(\omega_i) = \mathbf{D}$ and $\mathbf{\Phi} = \mathbf{U}$, where ω_i are the peaks of the spectral densities. Therefore:

- The modal frequencies are the peaks of the spectral densities, $\omega = \omega_i$.
- The modal vectors are the column of the eigenvector matrix $\mathbf{U}$ computed at $\omega = \omega_i$.

The method does not return the damping values. The most known and used approach for computing the damping is the Enhanced FDD [2]. In this work we propose a maximum likelihood approach.

3 PROPOSED METHOD

3.1 The state space model and the likelihood function

Given the acceleration recorded in the structural/mechanical system, $\mathbf{y_{1:n}} = \{\mathbf{y_1}, \mathbf{y_2}, \ldots, \mathbf{y_n}\}$, we model these data using the state space model:

$$\mathbf{x_{t+1}} = \mathbf{A x_t} + \mathbf{w_t} \tag{9}$$

$$\mathbf{y_t} = \mathbf{C x_t} + \mathbf{v_t} \tag{10}$$

where $\mathbf{w_t} \sim N(\mathbf{0}, \mathbf{Q})$ and $\mathbf{v_t} \sim N(\mathbf{0}, \mathbf{R})$. The model parameters are $\boldsymbol{\theta} = \{\mathbf{A}, \mathbf{C}, \mathbf{Q}, \mathbf{R}\}$. Using the Kalman filter, this model can be written in the *innovation form*:

$$\mathbf{x_{t+1|t}} = \mathbf{A x_{t|t-1}} + \mathbf{K e_t} \tag{11}$$

$$\mathbf{y_t} = \mathbf{C x_{t|t-1}} + \mathbf{e_t} \tag{12}$$

where $\mathbf{x_{t|t-1}} = E[\mathbf{x_t}|\mathbf{y_{1:t-1}}]$ are the predicted states, $\mathbf{K} \in \mathbb{R}^{n_s \times n_y}$ is the Kalman gain and $\mathbf{e_t} \in \mathbb{R}^{n_y}$ are the innovations, with distribution $\mathbf{e_t} \sim N(\mathbf{0}, \mathbf{\Sigma})$. Therefore, the likelihood can be written:

$$l_{\mathbf{y}}(\boldsymbol{\theta}) = -\frac{1}{2}\sum_{k=1}^{n}\left[\ln|\mathbf{\Sigma}(\boldsymbol{\theta})| + \mathbf{e_k^T}(\boldsymbol{\theta})\mathbf{\Sigma}(\boldsymbol{\theta})^{-1}\mathbf{e_k}(\boldsymbol{\theta})\right] \tag{13}$$

3.2 Maximum likelihood estimation

Let us consider m natural frequencies $\Omega = \{\omega_1, \omega_2, \ldots, \omega_m\}$ and modal vectors $\mathbf{\Phi} = \{\boldsymbol{\phi_1}, \boldsymbol{\phi_2}, \ldots, \boldsymbol{\phi_m}\}$ computed with the FDD method. The corresponding unknown damping ratios will be called $\mathbf{Z} = \{\varphi_1, \varphi_2, \ldots, \varphi_m\}$. The state space matrices can be defined from them (see [5] for details):

$$\mathbf{A} = \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ -\mathbf{\Omega}^2 & -2\mathbf{Z\Omega} \end{bmatrix}, \quad \mathbf{C} = \mathbf{\Phi}\begin{bmatrix} -\mathbf{\Omega}^2 & -2\mathbf{Z\Omega} \end{bmatrix}. \tag{14}$$

We need to define the matrices $\mathbf{Q}$ and $\mathbf{R}$ for that modal frequencies, damping ratios and modal vectors. We have not found closed formulas for that, so we have used the EM algorithm to estimate them numerically ([6]).

The system matrices, and therefore the likelihood function, are functions of the unknown damping ratios, $\boldsymbol{\theta} = \boldsymbol{\theta}(\mathbf{Z})$. Equation (13) can be written as:

$$l_{\mathbf{y}}(\mathbf{Z}) = -\frac{1}{2}\sum_{k=1}^{n}\left[\ln|\boldsymbol{\Sigma}(\mathbf{Z})| + \mathbf{e}_{\mathbf{k}}^{\mathbf{T}}(\boldsymbol{Z})\boldsymbol{\Sigma}(\mathbf{Z})^{-1}\mathbf{e}_{\mathbf{k}}(\mathbf{Z})\right] \tag{15}$$

This is a highly nonlinear and complicated function of the unknown damping ratios, $\mathbf{Z}$. We have chosen the BFGS algorithm to find the maximum of this function.

4 RESULTS

We have simulated a 4DOF structural/mechanical system defined by the following modal properties:

$$\boldsymbol{\Omega} = \begin{bmatrix} 1.52 & 3.09 & 4.42 & 5.21 \end{bmatrix} \; Hz, \tag{16}$$

$$\mathbf{Z} = \begin{bmatrix} 2.00 & 1.43 & 1.44 & 1.50 \end{bmatrix} \; \%, \tag{17}$$

$$\boldsymbol{\Phi} = \begin{bmatrix} 0.164 & 0.300 & 0.251 & -0.484 \\ 0.357 & 0.353 & -0.050 & 0.608 \\ 0.581 & -0.209 & -0.460 & -0.473 \\ 0.711 & -0.860 & 0.849 & 0.412 \end{bmatrix}. \tag{18}$$

The response of this system to a simulated random force is given in Figure 1.

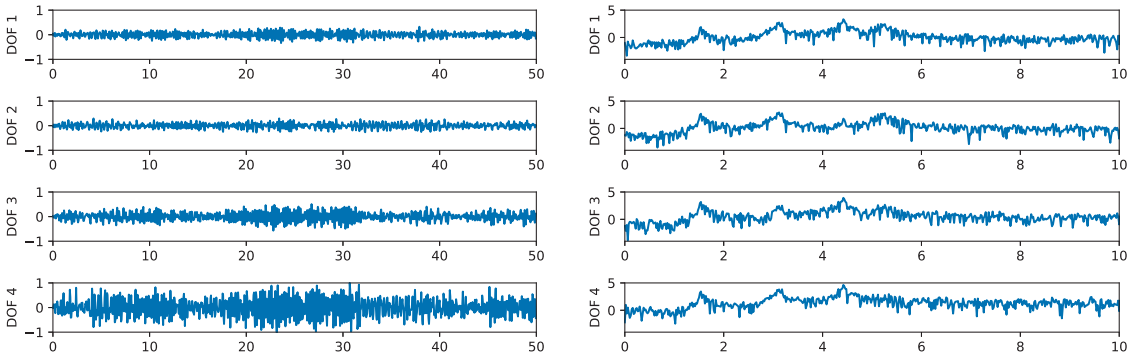

Figure 1: Simulated data.

First, we estimate the modal frequencies and modal vectors using the FDD method, see Figure 2. The results are:

$$\hat{\boldsymbol{\Omega}} = \begin{bmatrix} 1.56 & 3.16 & 4.41 & 5.23 \end{bmatrix} \tag{19}$$

$$\hat{\boldsymbol{\Phi}} = \begin{bmatrix} -0.161 & -0.276 & -0.240 & -0.462 \\ -0.347 & -0.320 & 0.049 & 0.614 \\ -0.580 & 0.221 & 0.434 & -0.465 \\ -0.718 & 0.878 & -0.866 & 0.437 \end{bmatrix} \tag{20}$$

We can check that results obtained with the FDD method are quite good.

The starting point for the BFGS algorithm was a damping ratio of 0.01 for the four modes. We have used the BFGS algorithm included in Scipy 1.4.1. The estimated damping ratios can be found in Table 1. The Table also include a 95% confidence interval computed from the Hessian matrix at the maximum.

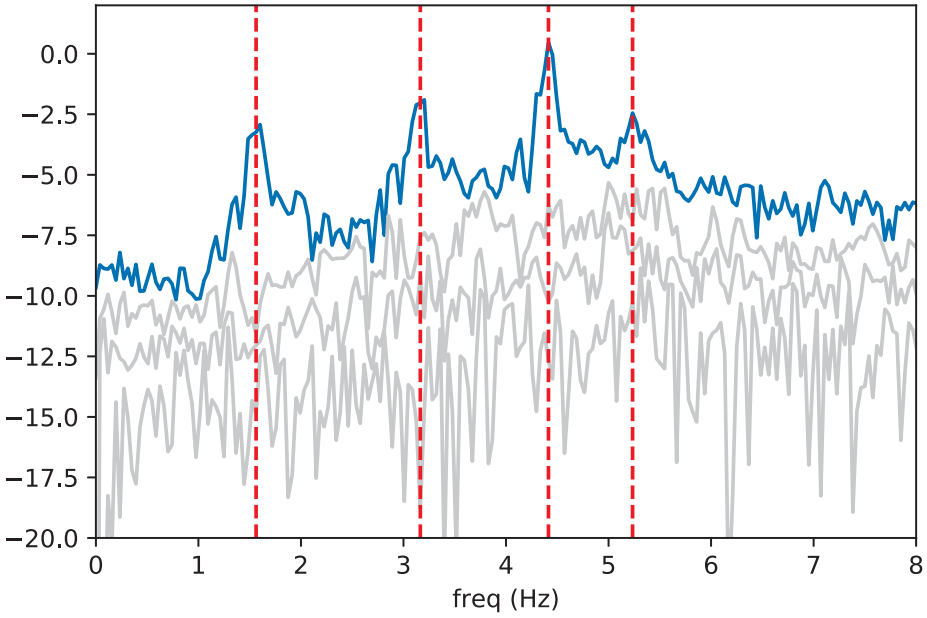

Figure 2: Estimation of modal frequencies using the FDD method.

Theoretical values	2.00	1.43	1.44	1.50
Estimated values	2.20	2.25	1.33	2.06
Standard error	0.66	0.38	0.05	0.07

Lower limit	0.86	1.48	1.22	1.90
Upper limit	3.54	3.02	1.45	2.22

Table 1: Results using the proposed method.

5 CONCLUSIONS

- We have introduced the maximum likelihood estimation of damping in a FDD context.
- First, we have shown the likelihood function.
- The likelihood function is highly nonlinear, so a good algorithm for its maximization is the BFGS.
- In the last section, we have shown the performance of the method with simulated data.

Abstract. *Railway Infrastructure Manager increasingly demand for new and effective method for the monitoring of infrastructure health, so that a relevant effort is being placed in the development of condition based monitoring and maintenance techniques for railway infrastructure. This includes track geometry, overhead contact line and the structural health of railway bridges. This paper proposes an algorithm for the bridge monitoring of railway bridges, based on accelerations measured on board train (drive-by method). The diagnostic algorithm is developed and validated based on the results of a 3D numerical model simulating the dynamic interaction of the bridge/track/train structure. The analysis is focused on steel truss bridges, on which the degradation of the connection of one diagonal element is simulated (e.g. lose bolts, deteriorated welding). In comparison with previous research works, this paper tries to overcome the need of comparison to a reference signal corresponding to the healthy bridge, which is the technique on which most of literature papers rely on. This is achieved by exploiting the roll component of the train (difference between right and left acceleration), excited as a consequence of the presence of the defect which generates an asymmetry in the bridge behavior. The numerical results show good accuracy in damage identification and location, good robustness to vehicle speed, to the presence of electrical noise and, in the case of a relevant damage, to track irregularity.*

1 INTRODUCTION

Condition based monitoring and maintenance techniques for railway infrastructure are hot research topics for academies and railway industries, regarding track geometry, overhead contact line, and the structural health of railway bridges [1],[2],[3]. Most of railway bridges were designed several decades ago, in the middle of the last century or even before, when loading conditions and traffic volumes were much different and lighter than today [4],[5]. Some of these bridges may also have undergone deterioration and corrosion during time, and they could now be structurally deficient.

The direct monitoring of a single bridge with dedicated instrumentation [6], which is a common practice in the case of main or high-speed lines, is not a feasible prospective for the entire regional and inter-regional railway lines of a country, due the huge number of bridges and the high costs related. Current bridge maintenance relying on visual inspections can be effective if clear protocols are followed, according to the typology of bridge. The obvious drawback of visual inspection is the dependence on to the experience of the inspector and also on the position of the damage, which often happens to be on a hidden member. Moreover, the time interval between inspections may also depend on the availability of personnel. For these reasons, in the last years, indirect methods have been looked for, relying on measurements acquired on the vehicle which crosses the structure. They are commonly named as drive-by methods [1]. The fundamental concept behind this approach is that a structural damage causes a change in the physical and mechanical properties of the bridge, and the bridge can be directly excited by the train passage. As a consequence, a change in the dynamic behavior of the vehicle interacting with the structure can be observed too. The advantage is that, fitting simple measurement set-up on a normal operating train, it is possible to acquire data in an almost continuous way, so that a proper trend of bridge condition could be in principle obtained for building a data base.

Drive-by methods have been mainly developed for road applications (highway bridges), but in fewer cases to railways too. They can be divided in the following two main categories [1]: *modal parameters* and *non-modal parameters*. The former, consisting in the identification of natural frequencies [7], [8], [9], [10], damping estimation methods [11] and identification of bridge mode shapes [12], [13], are demonstrated to be effective up to limited speeds (maximum 60 km/h) and, in the first two cases, they are not able to identify the exact location of a defects. These techniques are not trivial to be put in practise, and most of them were only demonstrated through numerical simulations. Moreover, their outcome can be affected by environmental conditions like temperature, especially in the case of damping and natural frequencies [14],[15],[16].

Non modal damage detection methods do not explicitly require the computation of bridge dynamic properties, but focuses on the bridge deflection under passing loads (e.g. apparent profile [17], [18] or change of curvature[19],[20]) or on the dynamic response of the vehicle crossing the bridge [21],[22],[3]. This paper focuses on the latter method, which is thought to be more promising and easy-to-implement, even if at the time being it is mostly investigated by numerical analysis. Most of the cases presented in the literature rely on the comparison of accelerations signals, gathered from the train crossing the bridge, to a reference acceleration signal corresponding to the healthy case. Accelerations are low pass filtered to cancel the vehicle and bridge natural frequencies and to isolate the quasi-static component of the signals. The current open points and drawbacks of these methods are related to the small magnitudes of the signals involved, and the need to know the precise position of the train on the bridge to perform the difference against the reference signal [23],[24]. This position may be achieved through balises or transpoder able to identify and transmit on-board train the position of the

bridge. On the other hand, this method seems to be effective even for vehicle speeds close to the common commercial speeds of commuter trains, and not too sensitive to track irregularities [3].
Another possibility to exploit the dynamic response of the vehicle crossing the bridge consists in the comparison of signals measured in the same train's run on different bogies (i.e. leading or trailing), or on different side of the vehicle if the type of defect mainly induces variation on one side of the bridge.
Following the above mentioned research line, and in particular the use of Continuous Wavelet Transform [25], this paper investigates the possibility to overcome the need of comparison to a reference signal corresponding to the healthy bridge. This result is achieved by exploiting the roll component of the bogie (difference between right and left accelerations), excited as a consequence of the presence of a defect which generates an asymmetry in the bridge behavior. The results try to put a step forward with respect to previous research work, all relying on the comparison with a baseline of the healthy bridge [2],[3]. The analysis is performed through numerical simulations carried out with a 3D numerical model for the train/track/bridge interaction [26] of a single span bridge and on a multi-span bridge.

The paper is organized as follows: Section 2 describes the 3D model for the simulation of the bridge/track/train interaction, and the simulation plan. Section 3 describes the proposed algorithm and the results achieved for a single span bridge. Section 4 summarizes the results in the case of a multi-span bridge. Finally, conclusions are drawn in Section 5.

2 NUMERICAL MODEL AND PLAN OF SIMULATIONS

The dynamic simulations of the bridge/track/train interaction are carried out with the software developed at the Department of Mechanical Engineering of Politecnico di Milano [26]. The bridge models considered are steel Warren open truss bridges with medium-span, non-ballasted track, with timber sleepers directly fastened to the girder. This configuration is selected as a first example, since it has more probability to show differences related to the loss of symmetry in the structure. As a first step of the work, a single line bridge is considered, with the track in the middle of the bridge structure. Two cases are analyzed: a single span-bridge (properties in Figure 1), and a multi-span bridge composed of 4 spans with the same properties of the single span model. This second case is investigated to evaluate the possibility of detecting defects on a damaged span by comparison with the records taken on the other spans.

Span length	21.42 [m]

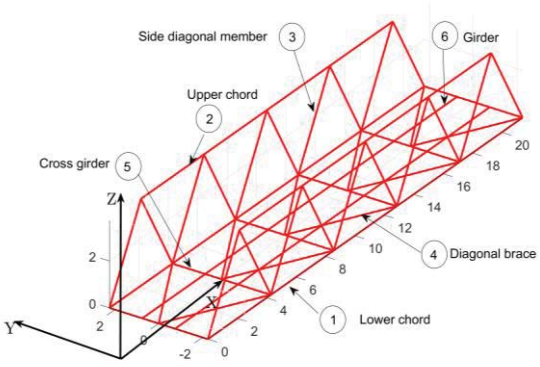

Figure 1: Single span bridge.

Two ballasted modules of length 29.4 m are added before and after the bridge (track properties as in reference [3]), to represent more realistic transients when the train enters and exits the bridge. The damage introduced in the bridge model represents a full or partial degradation of the fastenings in correspondence of the connection between the diagonal member (labelled with 3 in Figure 1) and the lower chord (labelled with 1 in Figure 1). The full damage is modeled by removing the diagonal element from the finite element model and applying a concentrated mass at the connection of the damaged element with the upper chord, to maintain its weight. The partial damage, which represents a more realistic damage condition in practice, is modeled through a reduction of the Young modulus of the damaged diagonal member. This is equivalent to considering a spring at the location of the fastening, in series with the involved diagonal element. Three different defect conditions have been studied, with a reduction of the Young Modulus equal to 30%, 50% and 70% in the damaged diagonal member. Different damage positions along the span are considered, to study whether and how damage location affects the accuracy of its detection.

Simulations of two different commuter trains have been considered, namely CSA and TSR model. They are respectively built with bogies shared between adjacent carbodies (CSA), and with the standard two-bogies configuration for each carbody, double-deck type (TSR). Their properties are described in reference [3], and not repeated here for sake of conciseness. Simulations for each train type are carried out with the train crossing the bridge at four different constant velocities, in the range of 80 km/h-140 km/h. These speeds are near to the maximum commercial speeds of these kind of trains (respectively 140 for TSR and 160 km/h for CSA), so that if satisfactory results are achieved, the desirable result of no traffic delays would result in the line.

The dynamic response of the train is measured at the bogie frame level, on the right and left side, in correspondence of the wheelset. The position of the accelerometer is of primary importance: location on axle box increases the sensitivity to defect, but involves a higher level of acceleration. This higher level of acceleration, requiring a larger full-scale value of the transducer, implies a lower sensitivity [3]. On the other hand, the location of the sensors on the bogie frame takes advantage of the effect of mechanical filtering from the primary suspension, attenuating high frequency components in the acceleration and enabling the use of more sensitive accelerometers. The drawback consists in the fact that sensors on the bogie frame are more distant from the location of the defect, so that the vibration path associated to the defect might be detected with more difficulties. Location on the bogie frame is investigated in the present paper, also considering the advantages in terms of maintenance operation of the train and the measurement set-up itself.

Since the proposed method for damage identification is based on the difference between the right and left hand side accelerations, a different irregularity profile is adopted on left and right rails, so as to simulate a more realistic case. Both vertical and roll track irregularities are considered, the total track profile being a composition of the two contributions. Profiles are obtained starting from the power spectral density functions provided by the standard ORE B176, and obtaining different level of irregularities (the highest level is reported in Figure 2). The level of irregularity is considered to be higher in the ballasted modules before and after the bridge, and it is attenuated along the bridge extension, where a non-ballasted track is present. This is a reasonable assumption considering that on the bridge the only permanent displacement is due to the dimension variation of the timber sleepers.

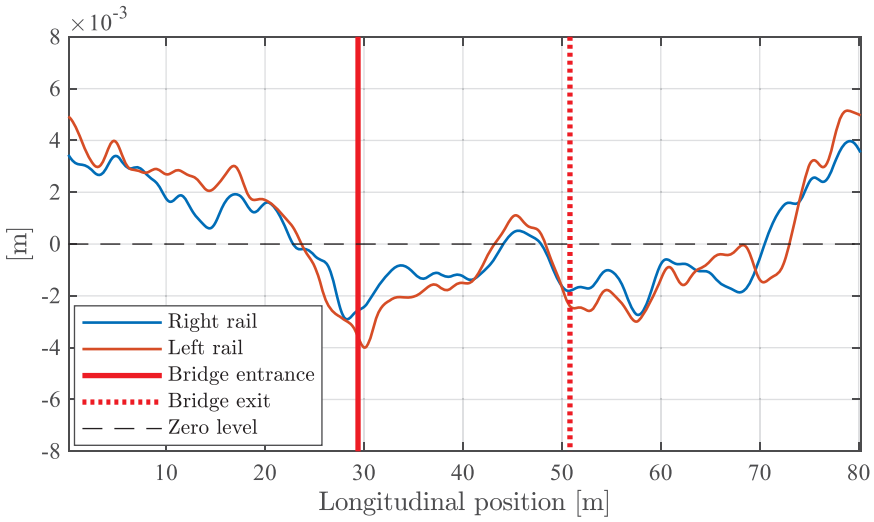

Figure 2: Vertical irregularities on left and right rails.

All the above mentioned parameters are changed individually during the simulations, varying only one parameter at once to investigate its effect on the outcomes of the proposed algorithm.

3 RESULTS FOR THE SINGLE SPAN BRIDGE

The presence of a defect on the bridge side generates an asymmetry in its behavior under the loads of the passing train. Figure 3 shows the deflection of the healthy (Figure 3a) and damaged (Figure 3b) bridges under the train load, with the black arrows highlighting the positions of the two axles of the leading bogie of the CSA train at a specific frame. In Figure 3b the damage is placed on the sixth diagonal member of the right side wall, right in the middle of the two arrows: due to the damage presence, the bridge deflection loses the symmetry characterizing the healthy structure. This asymmetry can be exploited to detect the presence of a defect, by analyzing the difference between the right and left hand side accelerations of the leading bogie.

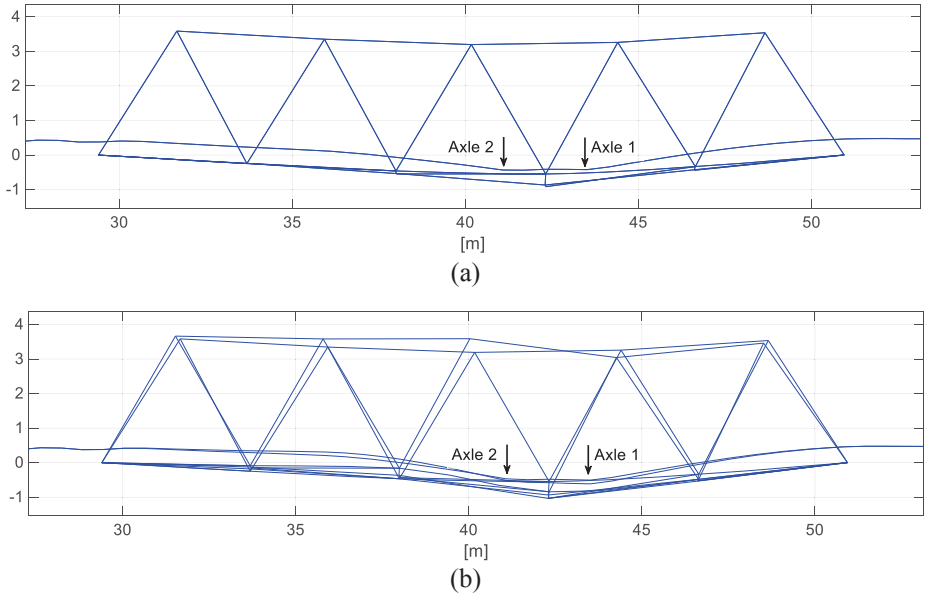

Figure 3: Bridge deflection under the train load (a) Healthy bridge. (b) Damaged bridge.

The processing algorithm consists in the application of the Continuous Wavelet Transform (CWT) to the difference of accelerations measured on the front side of the leading bogie, in correspondence of the right and left axle-boxes. The Huang-Hilbert transform was tested too on the same signal, obtaining consistent results between the two methods. Accelerations on the leading bogie are among the most suitable for diagnostic purposes, for the reason reported in [3]: the leading bogie interacts with an unperturbed bridge, so that differences in accelerations generated by a defect can be identified more precisely; bogie accelerations benefit from the filtering action provided by the primary suspension, which removes disturbances in the higher frequency range, mainly generated by track irregularities.
The possibility to detect a damage on the bridge based on the difference of right and left acceleration can be potentially affected by longitudinal and roll irregularity of the track, which may hide the presence of a damage. In order to assess the robustness of the proposed method in regard to this aspect, a different irregularity profile is adopted for left and right rails, as already described in Figure 2.
Figure 4 reports, as an example, the difference of the right and left side accelerations on the leading bogie of the CSA train at 100 km/h, corresponding to the case of total damage. A random disturbance is added to represent an electric noise, obtained from a Gaussian distribution with standard deviation equal to 10% of the RMS of the original acceleration signal. In the figure, the outer lines represent the start (continuous line) and end (dotted line) of the bridge, whereas the dashed vertical lines in the middle represent the location of the defect. The maximum magnitude of the raw signal is out of the damaged zone, and cannot be of course used as a diagnostic indicator. Wavelet coefficients are therefore computed on this signal, adopting a real-valued Morlet Wavelet.

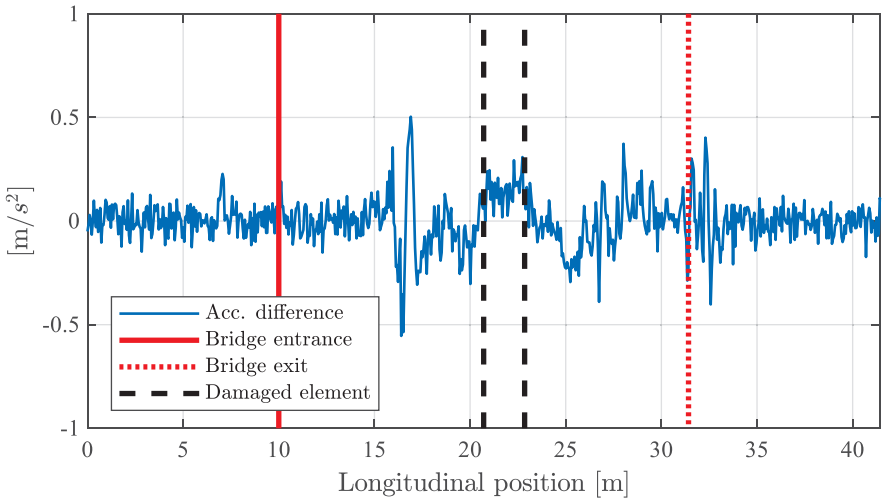

Figure 4: Difference between right and left accelerations on the leading bogie. Train speed 100 km/h.

Figure 5 reports the comparison of the module (absolute value) of the CWT coefficients in the case of the damaged bridge (Figure 5a) and of the healthy bridge (Figure 5b). The presence of the defect can be identified around the pseudo-frequency of 3.85 Hz, which corresponds to the frequency of the first peak obtained by applying a Fast Fourier Transform on the signal of Figure 4. The presence of the defect can be identified in a relatively low frequency range, where the CWT coefficients show peak values which are not present in the case of the healthy bridge. The reported results correspond to the highest level of irregularity adopted, which is the reason why several peaks in the CWT coefficients are visible at higher frequencies. With a reduction of -70% of the Young modulus of the diagonal element the damage is still clearly

identified, whereas for lower entity of the damage (e.g. reduction of 50% of the Young modulus), the presence of irregularity tends to hide the presence of a defect. The exploitability of this method is therefore a compromise between the effect induced by the defect, depending on the defect entity, and the presence of track irregularity.

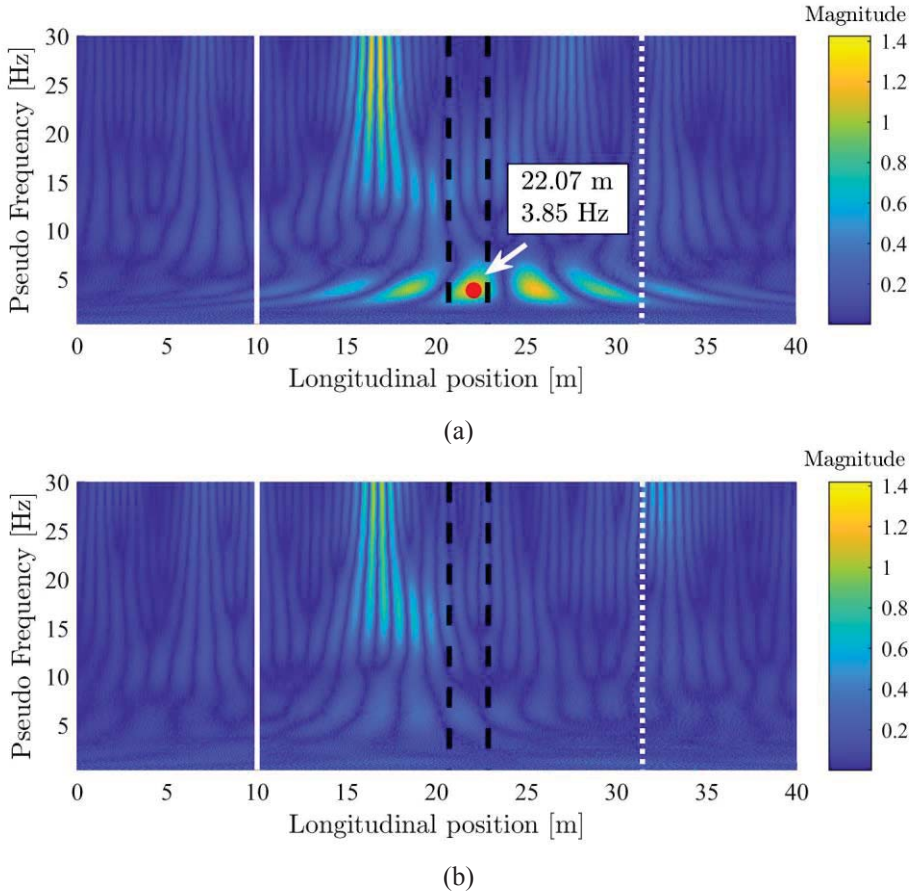

Figure 5: Module of the CWT coefficients, difference between the right and left side bogie accelerations (a) Damaged bridge, total damage. (b) Healthy bridge.

4 SIMULATION RESULTS OF MULTI-SPAN BRIDGE

The previous paragraph described the possibility to detect the presence of a relevant defect by exploiting the asymmetry in the bridge/train behavior. As a further step the case of a multi-span bridge is used to investigate the possibility of identifying a defect through the comparison of indices computed with reference to different spans. Figure 6 represents the scheme of the FEM model developed. The damaged span is highlighted by the black dashed box, whereas the remaining spans are assumed to be healthy. The damage element on span 3 is around the middle span (i.e. from 10.71 m to 12.85 m on a span length of 21.42 m).

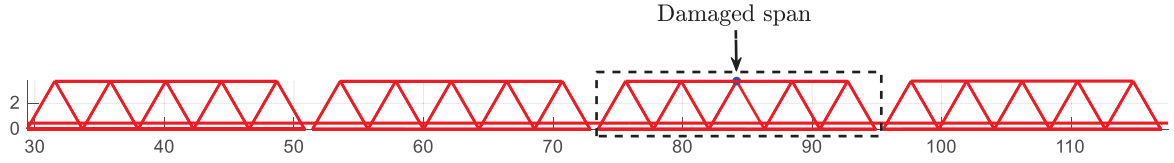

Figure 6: Lateral view of the multi-span bridge simulated.

The irregularity profile adopted is different for each span and for the left and right rails. Figure 7 represents the total irregularity profile on left and right rail, both outside and inside of the bridge area.

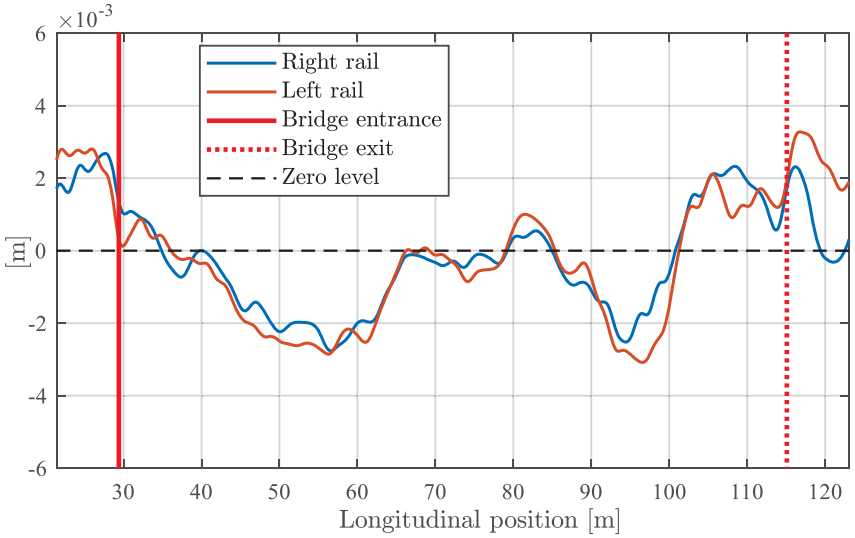

Figure 7: Total irregularity profile for left and right rail.

The acceleration data corresponding to each span can be analyzed separately, assuming to be able to separate the time histories of the four spans by the adoption of a precise GPS signal (e.g. EGNOSS). The difference between right and left bogie accelerations corresponding to each span are reported in Figure 8 for the simulation case with train speed set to 100 km/h and a total damage on the bridge. In the case of the damaged 3rd span it is possible to identify an oscillating shape, which is related to the difference between right and left side accelerations generated by the presence of the defect. The peculiarity of this signal shape can be caught by CWT.

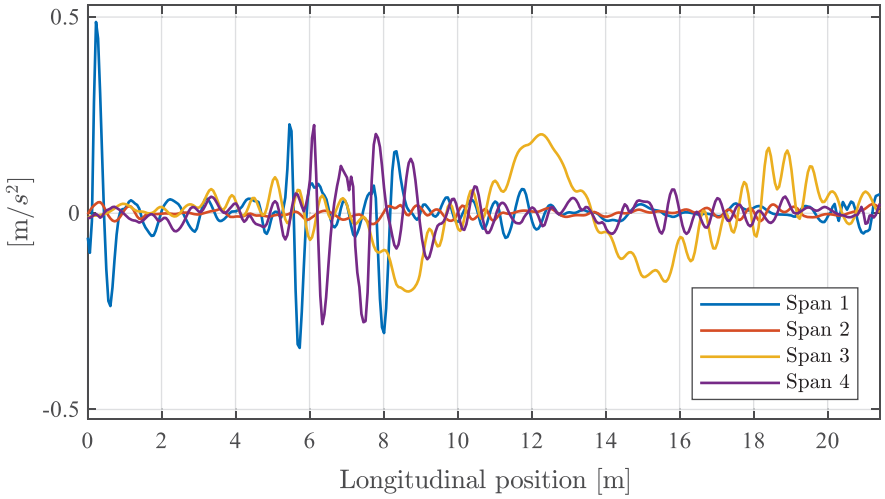

Figure 8: Front bogie accelerations difference, span from 1 to 4.

Figure 9 shows the CWT coefficients obtained with a Morlet wavelet for each single span. Once again it is possible to observe that the defect on the third span is properly caught, also by comparison with the analysis of the other spans. The defect can be properly identified for the total damage, or partial damage with a relevant reduction of the Young modulus in the diagonal element, whereas in the case of small damages it is hidden by track irregularity.

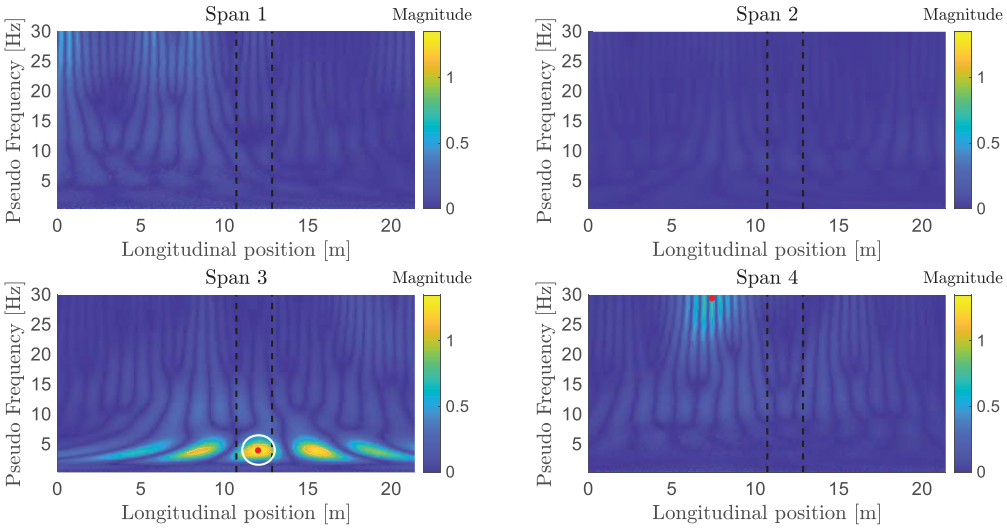

Figure 9: Module of the CWT coefficients evaluated on the difference of right and left hand side bogie accelerations (leading bogie, in correspondence of the front axle-boxes).

5 CONCLUSIONS

The paper focuses on a drive-by method for the diagnostics of railway bridges in commuter lines. It puts forward the idea that the presence of a defect on the bridge may introduce an asymmetry in the structure, which may consequently cause an asymmetry in the dynamic behavior of the train. This asymmetry can be caught by analyzing the difference between the right and left side accelerations measured on the frame of the first bogie of the train, and without the need of comparison with a baseline signal referring to the bridge in healthy condition.

The analysis is carried out through a full 3D model for the simulation of the dynamic behavior of the bridge/track/train system, in the presence of both vertical and roll track irregularity to represent a scenario close to reality. A different profile of the left and right rails may hide indeed the presence of a defect. The defect is inserted by considering the failure, or a percentage ineffectiveness, of the connection of one diagonal member of the side frame in a Warren, open type, medium-span bridge.

The difference between right and left side accelerations corresponding to the leading bogie of the train at the leading axle are analyzed through Continuous Wavelet Transform. The results show that when the simulated defect is relevant (i.e. detachment of one diagonal member in the truss bridge, or strong reduction of its Young modulus) the defect can be properly identified even with a high level of irregularity, but, for lower entities of the damage, the difference of irregularity between right and left track can hide the presence of the defect. The exploitability of this method is therefore dependent on the entity of the defect and on the severity of track irregularity.

Keywords: Structural health monitoring, Lamb wave, Damage feature, Damage identification.

Abstract. *Owing to the superiority of lamb waves in the field of Structural Health Monitoring, the Lamb wave-based damage detection and identification technology are widely used. To determine the degree of damage, two damage feature recognitions are proposed in this paper. One is extracted from the time domain, where the lamb wave signals are processed by Hilbert Transform (HT) with the time-domain analysis. According to the law of signal attenuation, the differential signal envelope amplitude procced by the Hilbert Transform is regarded as a damage feature parameter relating to the damage size. The other one is extracted by Fast Fourier transform (FFT) in frequency domain analysis. Two characteristic parameters, the amplitude and probability density in the time domain and the signal roughness parameters in the frequency domain, are defined to characterize the damage size.*

1 INTRODUCTION

With the increase of service time, the plate structure is prone to subject all kinds of damages, such as cracks, delaminations, via holes, corrosion, inclusions, and so on[1]. The Structural Health Monitoring (SHM)[2,3] technology is commonly used in predicting and monitoring structural health conditions. Researchers have been keen to improve the accuracy of determining the damage location[4,5]. Besides the location, the damage size is another important indicator, depending on which different maintenance methods are required. For example, small damage which has little impact on the structure security can be repaired as needed; and the large damage usually needs to be repaired or replaced as soon as possible. Therefore, after confirming the damage location, the relevant characteristic parameters of the damage signal can be extracted and the type/size of the damage can be identified. It will be more beneficial to the long-term use and maintenance of the structure.

Cawley[6,7] studied the effects of notch damage in metals and delamination damage and Lamb waves in composite laminates. In 1992, Wu[8] began to use the Artificial neural network (ANN) to detect structural damage. They explored the application of neural network's self-organization and learning ability in structural damage assessment and trained neural networks to identify damage. Then ANN is widely used to judge the degree of structural damage[9,10]. To accurately identify damage characteristics, it is necessary to select the appropriate damage feature parameters for ANN training and learning. Mares[11] introduced a genetic algorithm into the damage identification and used the residual force method to realize the damage location and quantitative identification. Law[12] selected the sensitivity of wavelet packet transform component energy as damage feature parameter. Li[13] reported a damage identification method based on Lamb wave multi-feature fusion, and determined the damage type by ANN. Sun[14] used energy distribution to identify damage in the structure by ANN. It can be concluded that finding suitable damage feature parameters is the key to improve the success rate of damage recognition.

This work will extract the damage features by analyzing the data based on numerical simulation. The damage size characteristics of the time/frequency domain are analyzed and summarized.

2 ANALYSIS OF ALUMINUM ALLOY PLATE DAMAGE IDENTIFICATION

2.1. Aluminum Alloy Plate Model

The 3D finite element model of the aluminum alloy plate is built with a dimension of 800 mm in length, 800 mm in width and 1 mm in height. The material parameters of the aluminum alloy plate are shown in Table 1, eight PZT sensors are arranged as circular and uniformly distributed with a square damage on the plate. The coordinates of the damage and sensors are as shown in Table 2.错误!未找到引用源。.

Table 1. The material parameters of the aluminum alloy plate

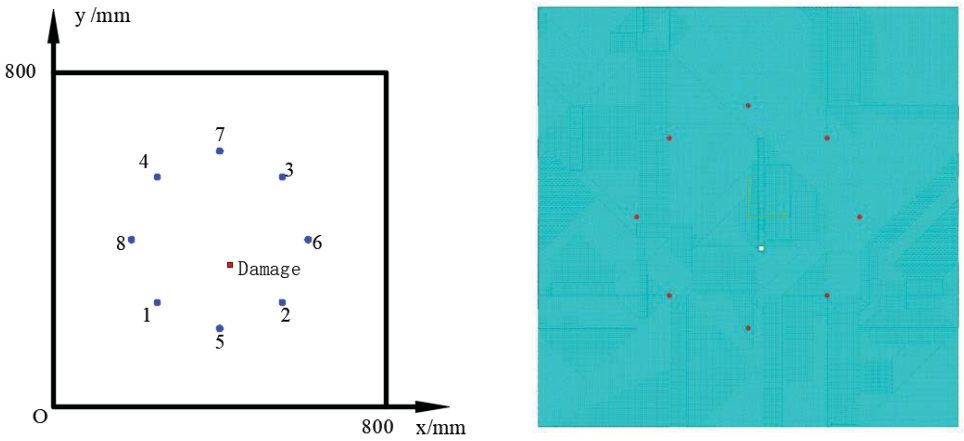
Parameter	Unit	Value
density	kg/m^3	2750
Young's modulus	Gpa	69
Poisson's ratio	--	0.33

Table 2. The coordinate of damage and sensors

	Coordinate		Coordinate
Sensor1	(250，250)	**Sensor2**	(550，250)

Sensor3	(550, 550)	**Sensor4**	(250, 550)
Sensor5	(400, 188)	**Sensor6**	(612, 400)
Sensor7	(400, 612)	**Sensor8**	(188, 400)
Square damage	(425, 340)		

The locations of PZT sensors and damage are shown in Figure 1. Eight sensors served as an actuator to excite Lamb waves in turns while the other PZT sensors act as receivers to collect the Lamb wave signals.



(a) (b)

Figure 1. Finite Element Model of The Aluminum Alloy Plate. (a) Sensor and damage location; (b) Simulation model

2.2. Damage Feature Extraction Based on Time Domain

As shown in Figure 2, when there is a damage in the aluminum plate, the lamb wave signal goes along with the route "exciter 1-damage-receiver 2". The reflection wave can be obtained by subtracting the non-damage signal from the damage signal.

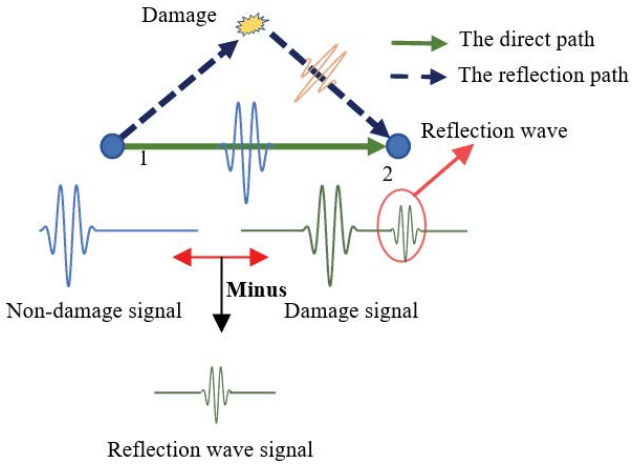


Figure 2. The propagation of damage reflection signal

Taking the square damage as an example, PZT sensor 1 excites a Lamb wave of 200KHz, and PZT sensor 2 receives that signal. The signal is shown in Figure 3.

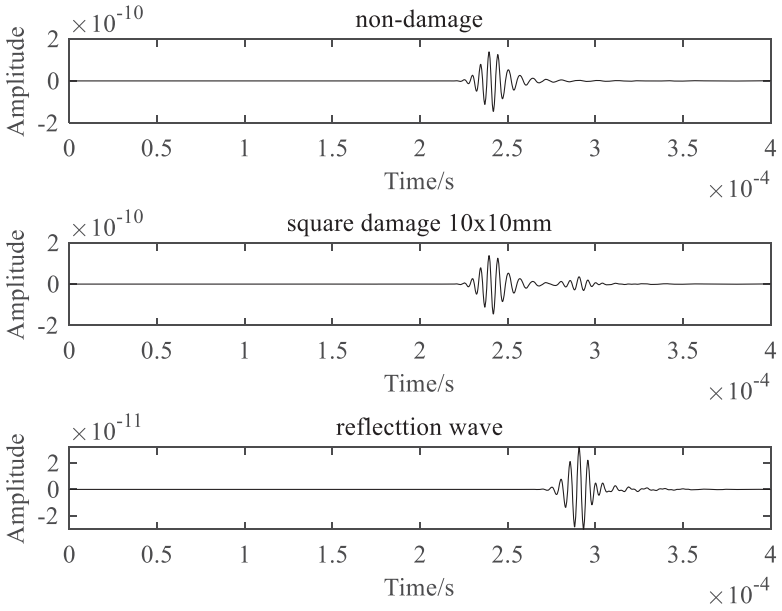

Figure 3. The damage reflection and differential signal

When a wave propagates in medium, its amplitude will gradually decrease with the increase of distance. Generally, the relationship between wave amplitude and propagation distance is

$$A = A_0 e^{\alpha D} \tag{1}$$

where, A_0 denotes the amplitude of excitation, α denotes the attenuation coefficient, and D denotes the propagation distance. To determine the coefficient of the lamb wave, the wave amplitudes in different lengths are collected in the aluminum plate, and the results are shown in Figure 4.

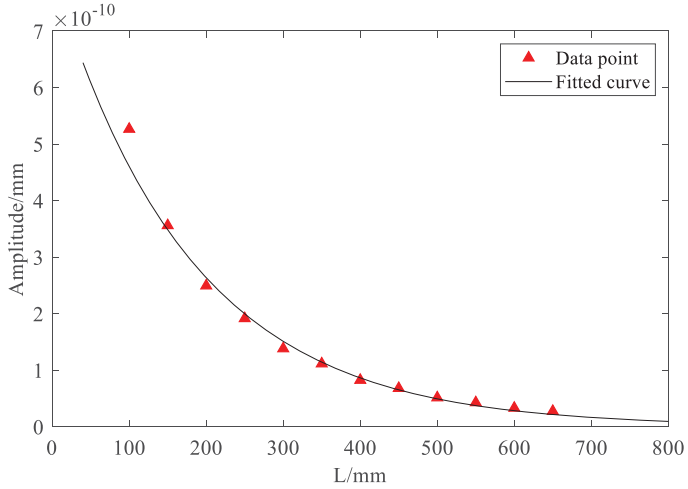

Figure 4. The attenuation of Lamb wave

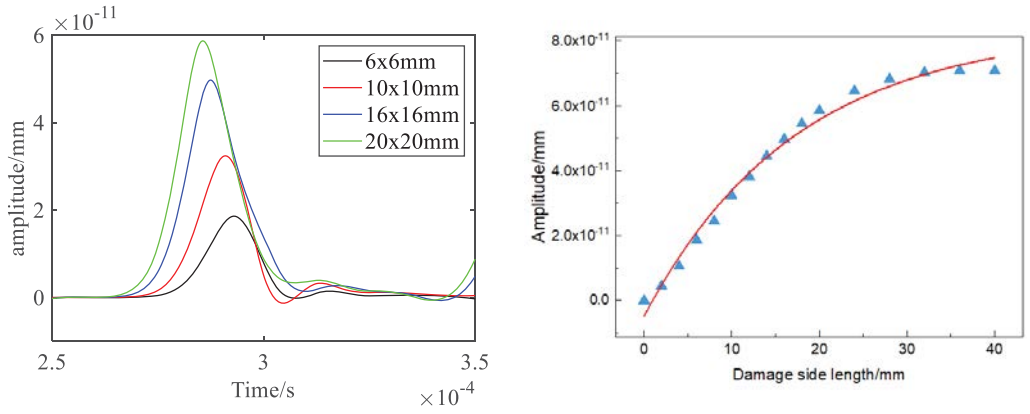
By use of curve fitting, the attenuation coefficient is obtained as $\alpha = -179.1$. Then the amplitude attenuation function of the lamb wave in the aluminum plate is shown as

$$A = 8.05 \times 10^{-10} e^{\frac{-D}{179.1}} \tag{2}$$

In order to analyze the dynamic regularity of the reflected wave signal with the degree of damage, the envelope processings are performed on the difference signals of various damage size based on Hilbert Transform(HT), as shown in Figure 5-(a). It is easy to observe that the reflection wave gradually stronger as the size of the damage increases. The energy distribution feature of the signal in the time domain is represented by the HT envelope, and the damage characteristic of size is reflected by extracting the amplitude magnitude. The different sizes of damage are simulated, and the amplitude of the reflected wave signal is plotted in Figure 5-(b).



(a) (b)

Figure 5. Lamb wave feature in time domain. (a) The upper envelope of different damage size; (b) The amplitude of the envelope with different damage size

In Figure 5 (b), it can be seen that as the degree of damage increases, the amplitude of the envelope gradually increases to the upper limit value. As the spread of lamb wave energy has limits, the strength of the reflected wave also has a limit and will not increase unlimitedly. Through curve fitting, the functional relationship of the envelope amplitude along with different damage size is

$$y = 8.36\times10^{-11} - 8.83\times10^{-11} e^{\frac{-x}{17.34}} \tag{3}$$

2.3. Damage Feature Extraction Based on Frequency Domain

Based on the frequency domain analysis, the Fast Fourier transform (FFT) is used to extract the frequency domain features from the Lamb waves signal. Frequency components and amplitude characteristics of lamb wave signals are obtained to identify the damage features of an aluminum plate. The amplitude-frequency curve with different damage size are shown in Figure 6.

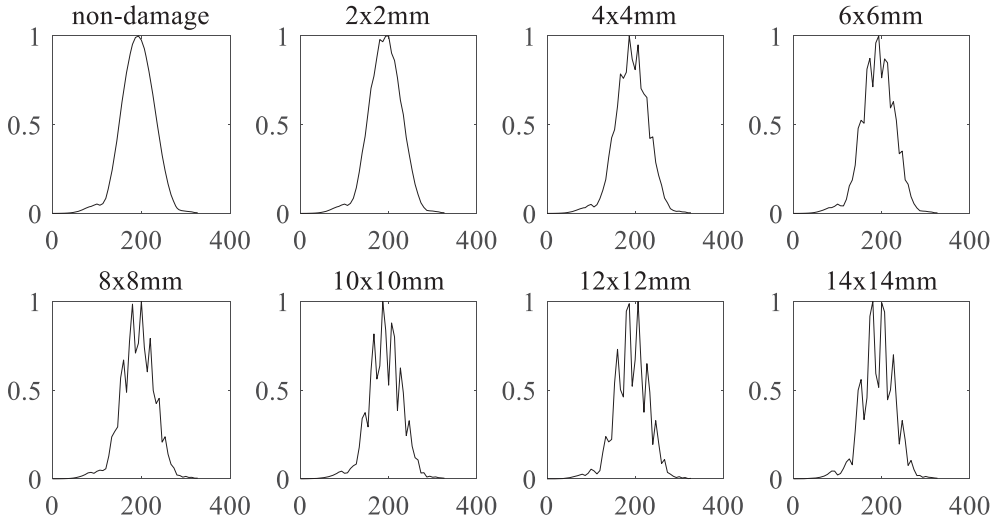


Figure 6. The frequency-domain image of different damage size

In Figure 6, as the damage size increases, the frequency range of the signal becomes decentralized. The larger the damage, the more uneven the frequency distribution. The reason is that when Lamb wave propagates to the position of damage, waveform reflection and modal conversion occur due to the sudden change of structure, which causes the waveform frequency domain signal to fluctuate. The larger the size of the damage, the higher the fluctuation, so the signal concentration level of the frequency-domain image can be used as one of the damage features for determining the damage size.

When there is no damage, the signal received by the receiving sensor is only a 200 KHz Lamb wave signal modulated by the Hanning window. The frequency-domain image of non-damage is similar to the frequency-domain figure of the excitation Lamb wave, and the frequency-domain model conforms to the law of the Hanning window rising first and then falling. Due to the existence of damage, the - reflected wave causes fluctuations in the frequency domain of the received signal. The fluctuations are closely related to the damage size. The above results in multiple frequency peaks in the signal spectrum, as shown in Figure. 5.

In order to characterize the degree of signal decentralization, the signal roughness is introduced in this paper to describe the degree of influence of impairments on frequency-domain signals. The equation of signal roughness is defined as

$$R=\sum_{i=1}^{i=n-2}\left|\frac{y_{(i+2)}-y_{(i+1)}}{\Delta x}-\frac{y_{(i+1)}-y_{(i)}}{\Delta x}\right| \tag{4}$$

where, R denotes the signal roughness and Δx represents a single increment of the frequency-domain signal, y denotes the corresponding amplitude. When the peak value or the sudden change in the graph increases, the signal roughness increases; when the signal gradually concentrates and the sudden change coefficient decreases, the signal roughness decreases.

As shown in Figure 7, the signal roughness of the frequency-domain figure increase with the expansion of damage. Therefore, the signal roughness of the frequency-domain image is a an effective damage feature indicator.

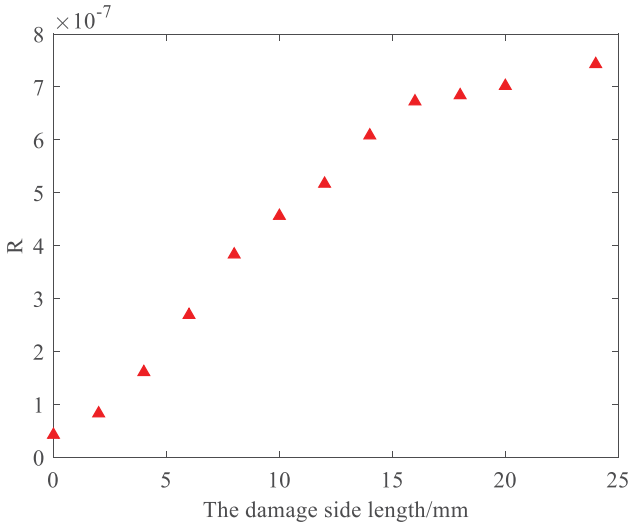

Figure 7. The signal roughness of different damage size

3 THE VERIFICATION OF THE DAMAGE FEATURE PARAMETER

To further verify the damage feature parameters' usabilities, the location of the damage changed while the transmitter and the receiver changed at the same time. As shown in Figure 8, the Lamb signal is excited by the sensor 2 and received by the sensor 3.

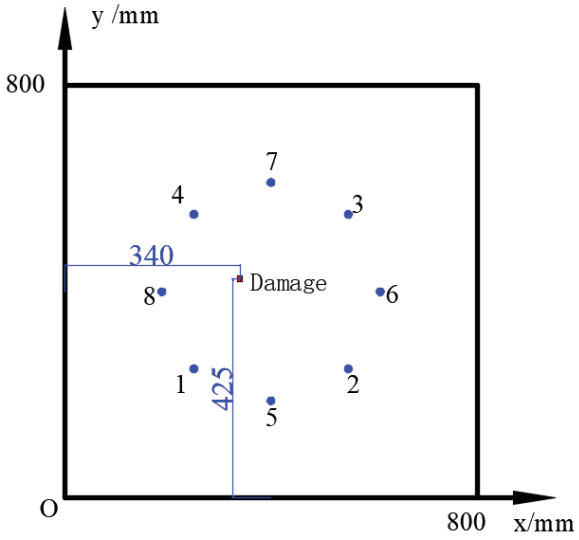

Figure 8. Change the location of the damage

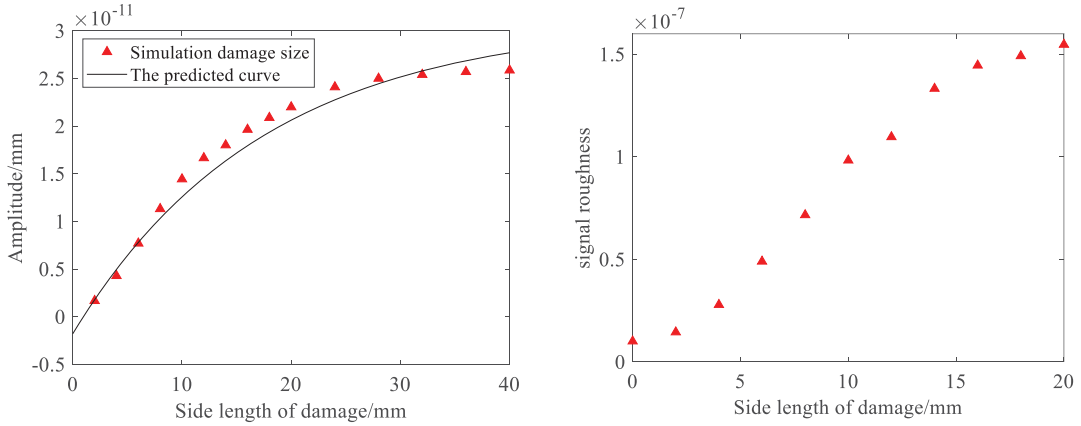
When the lamb wave arrives at the damage location, according to the Huygens-Fresnel principle, the damage will become a new wave source, and the amplitude of the new wave will be lower than the arrival amplitude. The new vibration source wave amplitude is linearly related to the arrival amplitude.

The damage location is shown in Figure 1-(a) and the propagation path length of the reflected wave $L_{1\text{-}D\text{-}2}$ is 322 mm. Another damage location is shown in Figure 8 and the propagation path length of the reflected wave $L_{2\text{-}D\text{-}3}$ is 517 mm. By substituting 322 and 517 into eq. (3), the theoretical amplitude of path $L_{2\text{-}D\text{-}3}$ is 2.9 times that of path $L_{1\text{-}D\text{-}2}$. In Figure 8, the curve-fitting function in Figure 5-(b) is divided by 2.9 so we can get the relationship between the amplitude and the size of the damage as folllows:

$$A_1 = \frac{\left(8.05\times10^{-10}e^{\frac{-L}{179.1}}\right)}{2.9} \tag{5}$$

The relationship between the actual damage size and amplitude is shown in the Figure 9-(a), the simulation damage size coincides with the theoretical predictive value calculated by the eq. (5). Therefore, the amplitude of the reflected wave can be used as a parameter to characterise damagesand the damage size can be successfully predicted.



(a) (b)

Figure 9. Simulation verification results. (a) The amplitude of the envelope with different damage size by sensor 2 sensor 3; (b) The signal roughness of different damage size by sensor 2 sensor 3

In Figure 5-(b) and Figure 9-(a), it is clear that the trends of the damage size and the envelope amplitude in the two figures are consistent, which can predict the damage size through simulations. From Figure 7 and Figure 9-(b), it can be concluded that the signal roughness is an important parameter to describe the damage size.

4 CONCLUSIONS

The characteristics of the Lamb wave signal corresponding to the degree of damage are studied in this work. Two parameters are defined to describe the damage degree both in the time-domain and frequency-domain. In the time-domain analysis, the differential signal envelope amplitude extracted from the Hilbert Transform is applied as the damage feature parameter related to the damage size. In the frequency domain analysis, the signal roughness is proposed. It is used as the damage size characteristic parameter. The feasibilities of the envelope amplitude and the signal roughness are verified by numerical simulation. The identification of multiple damages using the proposed approaches is under further investigation.

Keywords: Damage analysis, Parametric study, Composite structures, Steel-concrete composite beams, Static measurements

Abstract. *This paper presents a study of the static behavior of steel-concrete composite beams with different types of damage. Since the behavior of a composite beam under load is governed by the shear connection, it is important to investigate the overall structural response due to different levels of damage in the interface and composite layers. A finite element (FE) model of a steel-concrete composite beam is developed based on two Euler-Bernoulli beams as the composite layers coupled with a deformable shear connection. Three different damage indices are defined for the concrete slab, the steel girder, and the distributed shear connection and then embedded into the stiffness matrix of the composite beam. This model is validated by comparing its load-displacement behavior with an equivalent FE model developed using the commercial FE software ABAQUS. The impact that the loading location has on the results is then investigated. A convergence study is also carried out in terms of the displacements and strains to determine the number of composite beam FEs. The maximum displacements and strains of composite beams with different types and levels of damage are then investigated. The numerical analysis showed that after an initial reduction when the number of FEs increase, the changes in displacement and strain at each location are very small. Moreover, the bonding slip has almost no effect on the measurements, and the changes in maximum displacement and strain from undamaged to maximum damage are almost the same.*

1 INTRODUCTION

Assessing structural damage through dynamic and static analysis has become increasingly popular because the dynamic and static response of a structure are functions of its physical parameters and therefore any changes in these parameters can be reflected in the structural responses. This is why attempts have been made to evaluate the structural integrity by developing approaches based on dynamic and static measured data. Although few studies can be found in static-based methods, dynamic-based methods have been studied more widely because they are easier to implement [1, 2]. Static-based methods are based on equilibrium equations where the only significant parameter is the stiffness of a structure, which is why any reduction in stiffness due to damage is a significant parameter for damage analysis in terms of the static responses. A large number of measurements are needed to accurately analyse structural damage, which is not practical, however this problem can be solved by changing the loading locations and increasing the number of tests rather than the measurement sensors [3]. There are a number of researches into static-based methods which considered beam structures, and trusses or frames as case studies. For example, Liu and Chian [4] proposed a method to identify the elemental properties of a truss using strain values, Sanayei et al [5] used the deflection and strain data of a steel frame to estimate stiffness parameters, and Laory et al [6] used static measurements to determine the number of sensors. Wang et al [7] examined how partial shear interaction affected the static and dynamic response of steel-concrete composite structures, and found that bond slip and changes to the mode shapes are the effective parameters for identifying damage.

Different models have been developed to investigate the behaviour of steel-concrete composite structures, especially the effect of bond slip. Nie et al [8] studied the effects of bond slip on the deformation of steel-concrete composite beams using its equivalent rigidity, and found that bond slip is an effective contributor to beam deformation. Kumar et al [9] used push out test to determine how the thickness of the adhesive layer affects the capacity of composite connections. Chen et al [10] studied the static and fatigue behaviour of steel-concrete composite beams where the shear connectors had been corroded and found that the corroded studs had reduced the stiffness and load bearing capacity of the beams. Ayoub and Filippou [11] used an inelastic beam element to analyse a steel-concrete composite beam with partial interaction under cyclic loading and considered a shear connection with a distributed force as the interface model. Nguyen et al [12] used an FE model to carry out a linear static analysis of a steel-concrete composite beam with discrete shear bonding. Since no extreme loading conditions had been considered in most of the abovementioned studies, the displacements were very small and therefore the uplift effects were omitted, however, the bonding slip affects the behaviour of two-layer composite beams and must be included [12-14]. Whereas in static-based methods the displacements and/or strains are utilized to analyse structural damage, it is necessary to investigate how these parameters change in terms of different damage types.

In this paper we have developed a steel-concrete composite element with a bonding interface where the layers of concrete and steel are independently interpolated into a displacement based finite element (FE) formulation. Cases with different types of damage are introduced to describe the reduction in stiffness of a concrete slab, a steel girder, and the bonding interface. This model is verified by comparing it with the results obtained from a similar model built using the commercial FE software ABAQUS [15], where the optimal number of FEs are determined through a convergence study. A parametric study is also carried out using displacement and strain measurements. The effects that different levels of damage, and the measurements and loading locations have on the identified results are also discussed.

2 DISPLACEMENT BASED FINITE ELEMENT FORMULATION

2.1 Equilibrium and compatibility

In this section a composite beam with two layers and a deformable shear connection is formulated such that the composite beam element consists of a concrete slab on top of a steel girder with bonding interfaces (Figure 1). The equilibrium equations for each layer are formulated by considering bond slip and the effects of uplift [16]. In Figure 1 the subscripts c and s denote the concrete and steel, N, V, M and h are the axial force, shear force, bending moment, and the distance between the interface and reference axes of each layer, respectively, and D_{sc} and D_t are the shear force (bonding slip) and transverse force (uplift) per unit length. An external distributed load P is applied vertically to the concrete slab. The equilibrium equation for the composite beam section is introduced as [11]

$$\partial^T \boldsymbol{F}(x) - \partial_b^T \boldsymbol{F}_b(x) - \boldsymbol{P}(\boldsymbol{x}) = 0 \tag{1}$$

where $\boldsymbol{F}(x)$, $\boldsymbol{F}_b(x)$ and $\boldsymbol{P}(x)$ are the internal force vectors acting on the cross section, the interface bonding force, and the external load vector, respectively, and ∂ and ∂_b are the differential operators. Although any section of this composite beam has four unknown forces N_c, N_s, M and D_{sc}, there are only three equations of equilibrium for each section, so the compatibility equations should be merged to avoid any indeterminacy with the composite beam.

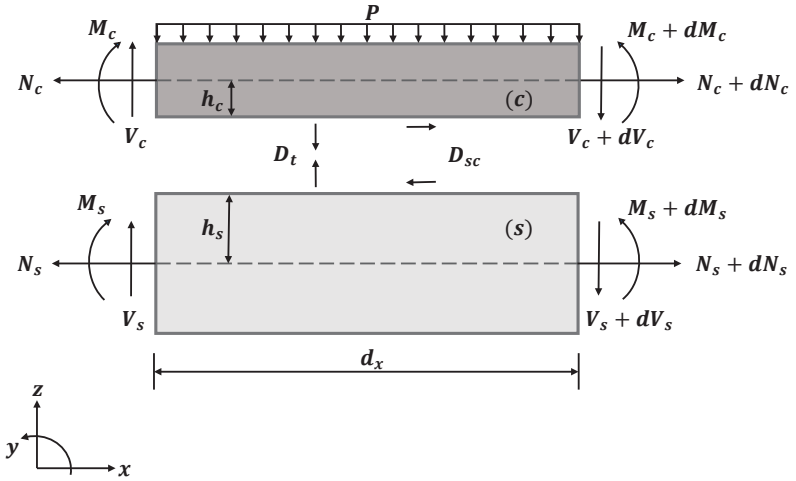

Figure 1: Diagram of a two layered composite beam element where (c) and (s) are the concrete slab and steel girder, respectively.

Since the same transverse displacement (no uplift) is considered for both layers of the composite beam, the curvature and rotation will be the same, even though different axial deformation can occur in the steel and concrete sections. The axial and transverse deformations of the composite beam are handled by the compatibility conditions based on Euler-Bernoulli beam theory. The compatibility conditions define deformation and displacement at the interface between the concrete slab and steel girder [11]. This relative displacement at the interface is known as the bond slip g and can be defined as:

$$g = u_c(x) - u_s(x) + h\partial_x v(x) \tag{2}$$

where $u_c(x)$ and $u_s(x)$ are the axial displacements of the layers of concrete and steel, and $v(x)$ is the transverse displacement. The response of the composite beam subjected to external loads can be obtained with proper boundary conditions.

2.2 Stiffness matrix

The stiffness matrices for the concrete slab, steel girder, and bonding interface are used to define the local and global stiffness matrices of the composite beam element. A continuous spring element is considered as the interface element. The axial displacements of the composite beam are estimated using quadratic polynomial functions, while the transverse displacements are obtained by cubic Hermitian polynomials [17]. Two extra nodes have been added to the middle of the concrete slab and steel girder to provide a continuous bond slip condition along the interface. The vector of elemental nodal displacement is introduced as $\boldsymbol{U} = [u_{c1} \quad u_{c2} \quad u_{c3} \quad u_{s1} \quad u_{s2} \quad u_{s3} \quad v_1 \quad \theta_1 \quad v_2 \quad \theta_2]^T$ where each component represents a degree of freedom (DOF). The composite beam element with bond slip in the interface is handled by ten DOFs including a transverse and rotation in each node, and six axial displacements (Figure 2).

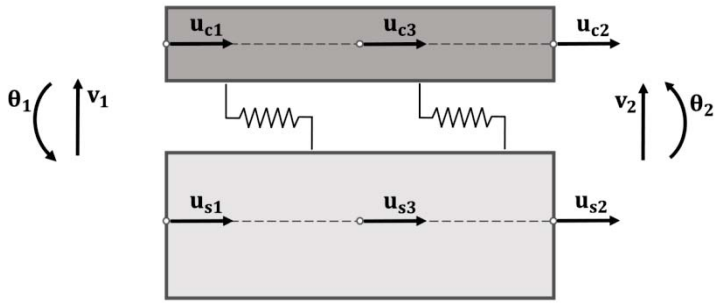

Figure 2: Nodal displacements of a steel-concrete composite element with 10 DOFs

To obtain the stiffness matrices, a small displacement due to an external load is presumed to occur and the amount of work is equal to the amount of residual internal strain energy. Therefore, the elemental stiffness matrices $\boldsymbol{k}_{ec}$ for the concrete, $\boldsymbol{k}_{es}$ for the steel sections, and $\boldsymbol{k}_{eb}$ for the bonding interface are defined as:

$$\boldsymbol{K}_e = \boldsymbol{K}_{ec} + \boldsymbol{K}_{es} + \boldsymbol{K}_{eb} = \begin{bmatrix} [\boldsymbol{K}_{e1}]_{3\times3} & [\boldsymbol{K}_{e2}]_{3\times3} & [\boldsymbol{K}_{e3}]_{3\times4} \\ [\boldsymbol{K}_{e4}]_{3\times3} & [\boldsymbol{K}_{e5}]_{3\times3} & [\boldsymbol{K}_{e6}]_{3\times4} \\ [\boldsymbol{K}_{e7}]_{4\times3} & [\boldsymbol{K}_{e8}]_{4\times3} & [\boldsymbol{K}_{e9}]_{4\times4} \end{bmatrix}_{10\times10} \tag{3}$$

where $\boldsymbol{K}_e$ is the stiffness matrix for the steel-concrete composite element.

2.3 Definition of damage

A damage index is defined as the reduction in elemental stiffness of the composite beam layers where:

$$\alpha = 1 - \frac{E}{\hat{E}} \tag{4}$$

where α is the damage index, and E and $\hat{E}$ are the equivalent Elastic modulus with and without damage, respectively. When damage index is zero, there is no damage in that element ($0 \ll \alpha \ll 1$). While the composite layers are assumed to be damaged, Eq (3) can be updated using the damage indicators as

$$\boldsymbol{K}_e = \boldsymbol{K}_{ec} + \boldsymbol{K}_{es} + \boldsymbol{K}_{eb} = (1 - \alpha_c)\widehat{\boldsymbol{K}}_{ec} + (1 - \alpha_s)\widehat{\boldsymbol{K}}_{es} + (1 - \alpha_b)\widehat{\boldsymbol{K}}_{eb} \tag{5}$$

where $\widehat{\boldsymbol{K}}_{ec}$ and $\widehat{\boldsymbol{K}}_{es}$ are the stiffness matrices of the intact concrete and steel elements, and the subscripts c, s and b denote the damage indices for the concrete, steel, and bonding interfaces. These damage indices are considered individually as scalar values embedded in the elemental damage indices zero vectors with a size that is equal to the composite element FE numbers. A transformation matrix $\boldsymbol{T}$ is used to assemble the global stiffness matrix from the local stiffness matrix presented in Eq (5) as

$$\begin{aligned} \boldsymbol{K} = \boldsymbol{K}_c + \boldsymbol{K}_s + \boldsymbol{K}_b &= \sum_{i=1}^{n} \boldsymbol{T}^T K_{ei} \boldsymbol{T} \\ &= \sum_{i=1}^{n} \boldsymbol{T}^T \boldsymbol{K}_{eci} \boldsymbol{T} + \sum_{i=1}^{n} \boldsymbol{T}^T \boldsymbol{K}_{esi} \boldsymbol{T} + \sum_{i=1}^{n} T^T \boldsymbol{K}_{ebi} \boldsymbol{T} \\ = \sum_{i=1}^{n} \boldsymbol{T}^T (1 - \alpha_{ci}) \widehat{\boldsymbol{K}}_{eci} \boldsymbol{T} + \sum_{i=1}^{n} \boldsymbol{T}^T (1 - \alpha_{si}) \widehat{\boldsymbol{K}}_{esi} \boldsymbol{T} + \sum_{i=1}^{n} \boldsymbol{T}^T (1 - \alpha_{bi}) \widehat{\boldsymbol{K}}_{ebi} \boldsymbol{T} \end{aligned} \tag{6}$$

where n is the number of FEs. $\boldsymbol{K}$, $\boldsymbol{K}_c$, $\boldsymbol{K}_s$ and $\boldsymbol{K}_b$ are the global stiffness matrices of the damaged composite beam, concrete, steel and interface elements, and α_{ci}, α_{si} and α_{bi} are the ith element damage indices of damaged concrete, steel and bonding interfaces, respectively.

3 RESULTS AND DISCUSSION

3.1 Validation of the finite element model

The structural model used in this study is a simply supported 6m long steel-concrete composite beam with a concrete slab sitting on top of an I-shape steel girder with shear connectors. The Young's modulus and density of the concrete and steel are $E_c = 3200\,MPa$, $\rho_c = 2700\ kg/m^3$, $E_s = 210000\,MPa$ and $\rho_s = 7800\ kg/m^3$, respectively. The geometrical characteristics of the beam are shown in Figure 3.

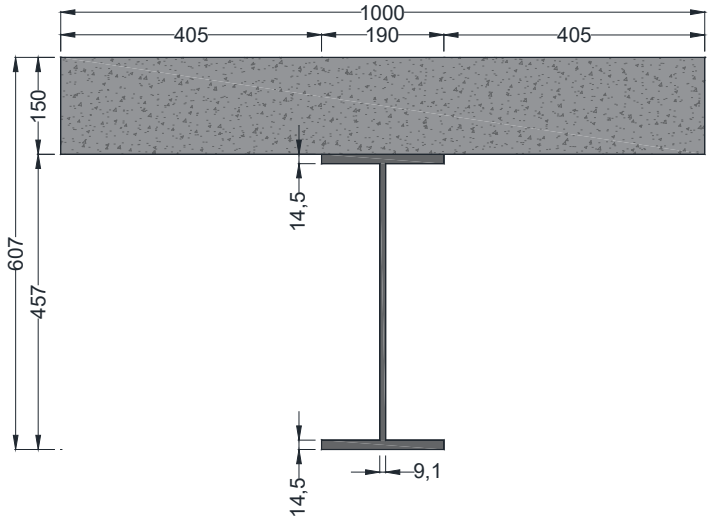

Figure 3: The geometrical characteristics of steel-concrete composite beam cross-section (length in mm)

To develop a reliable baseline FE model that could represent the real structure of interest, two equivalent FE models are constructed and their static response are compared. To this end an FE model of the steel-concrete composite beam is modelled by FE programming in MATLAB. This model is used for the damage identification in terms of different static loading locations, bond interactions, and damage cases. However, to obtain the baseline model, no damage and bond slip are considered in the analysis. Besides, another FE model with the same material and geometrical properties is built using the FE software ABAQUS, as shown in Figure 4.

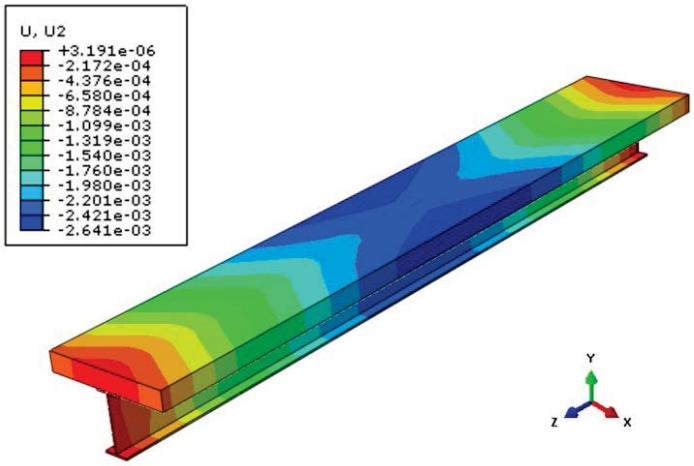

Figure 4: The FE model of steel-concrete composite beam showing displacements along the beam subjected to mid-span point loads

In each case the structure is subjected to a static load where $P = 10000\ N$ at the middle of the beam, and then at $L/3$ from the left support; the analytical displacements are measured from 60 points located equally along the composite beam. The validity of this analysis is enhanced by analysing five models with 12, 24, 36, 48 and 60 FEs for each case and then the displacements due to static loadings are used to compare the two FE models. Table 1 shows the maximum displacements of the steel-concrete composite beam obtained from the FE models developed in MATLAB (FE-M) and ABAQUS (FE-A). These displacements are almost the same for both models, showing how precise the FE model developed is by being programmed in MATLAB.

Measurement		Maximum Displacements				
Number of FEs		12	24	36	48	60
Load applied at L/2	FE-M	$2.89\text{x}10^{-3}$	$2.64\text{x}10^{-3}$	$2.60\text{x}10^{-3}$	$2.58\text{x}10^{-3}$	$2.57\text{x}10^{-3}$
	FE-A	$2.65\text{x}10^{-3}$	$2.64\text{x}10^{-3}$	$2.63\text{x}10^{-3}$	$2.62\text{x}10^{-3}$	$2.61\text{x}10^{-3}$
Load applied at L/3	FE-M	$2.46\text{x}10^{-3}$	$2.27\text{x}10^{-3}$	$2.23\text{x}10^{-3}$	$2.22\text{x}10^{-3}$	$2.21\text{x}10^{-3}$
	FE-A	$2.45\text{x}10^{-3}$	$2.26\text{x}10^{-3}$	$2.24\text{x}10^{-3}$	$2.21\text{x}10^{-3}$	$2.21\text{x}10^{-3}$

Table 1: Maximum displacements (in m) measured from the numerical models in MATLAB (FE-M) and ABAQUS (FE-A)

The differences between the maximum displacements for the model with 12 FEs are greater than those with smaller sized mesh. A convergence study has been carried out using the FE-M in terms of different numbers of FEs, where the FEs are changed from 6 to 60 and the displacement and strain values are measured.

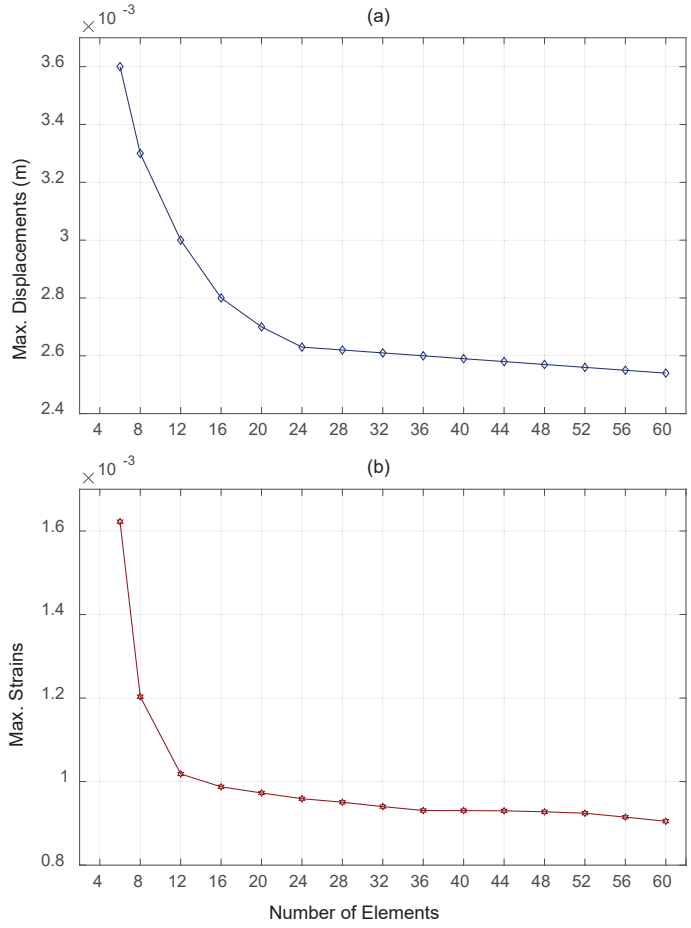

Figure 5: Convergence of maximum (a) displacement, and (b) strain in terms of the number of FEs

Figure 5 shows the convergence of maximum displacement and strain in terms of the number of FEs. While these maximum displacements and strains gradually improve by increments with the number of FEs, in both cases there is an immediate reduction in the models with FE numbers from 6 to 20. Furthermore, since the discrepancies of the model with 24 FEs are very small, 24 elements are used in the following studies.

3.2 Parametric study

A series of parametric studies based on the static responses of the beam have been carried out, and the behavior of the composite beam has been investigated for potential damages in terms of variations in static parameters such as displacement and strain. The parameter that best identifies damage is then selected. The parametric analysis is based on the displacements and strains of the composite beam for six different cases. This consists of three cases of single damage in concrete, steel and interface, two cases of double damage in the concrete-interface, and steel-interface, and one case of triple damage in the concrete-steel-interface. These cases are introduced as a reduction in the stiffness of an element in the composite beam.

Figure 6 shows the changes of maximum displacement and strain of the composite beam with 24 FEs in terms of different cases of damage and reductions in stiffness. Elements number 4 from the support on the left hand side of the composite beam have been considered as the damaged ones and a range of reduction in stiffness is applied from 0% to 90%. The static responses of the composite beam have been obtained for six different cases of damage in ten steps

of the stiffness reductions (intact to maximum damage). Although the maximum displacements increase when the stiffness decrease, these values are very small, particularly in the case of bonding loss. The discrepancies in the strains are almost zero for cases with a loss of bonding. Since the main objective is to analyse the damage on the bonding interface, the case with a single damage on the interface (Case 3 in Figure 6) is used to select the proper parameter. It is found that the loss of bonding interface results a minimum change in the maximum displacement (Figure 6.a) and strain (Figure 6.b) from undamaged to maximum damaged states. Therefore, in order to a reliable damage identification, both parameters could be used because their changes are almost the same.

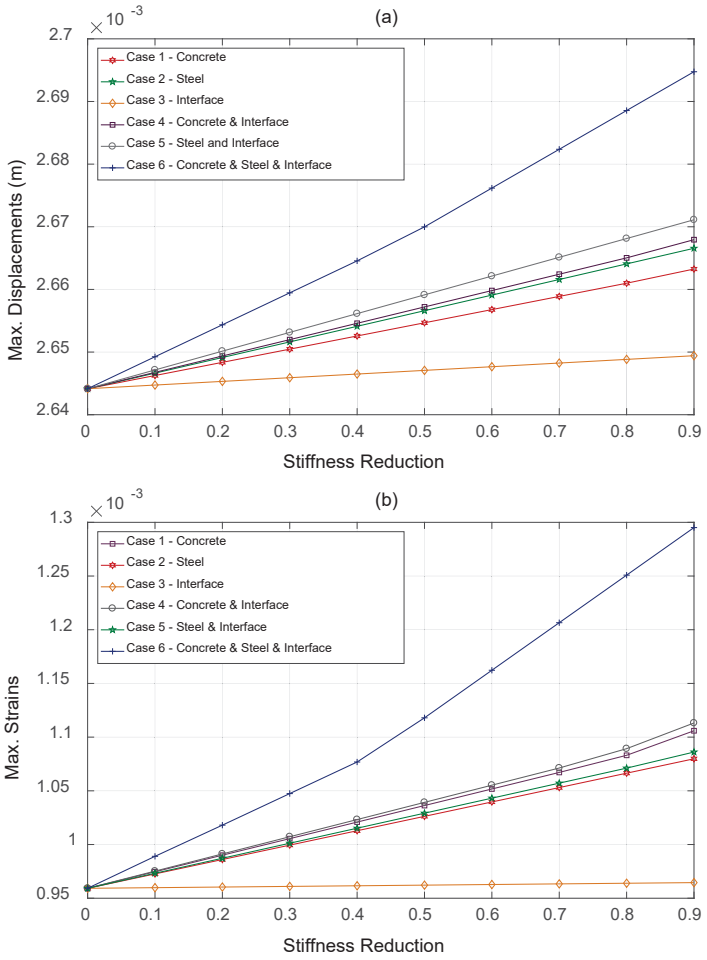

Figure 6: The changes of maximum (a) displacements and (b) strains of the beam with 24 FEs due to reductions in stiffness (from 0% to 90%) in Elements 4 for single damage (cases 1, 2 and 3), double damage (cases 4 and 5), and triple damage (case 6)

4 REVIEW

Peer review under the responsibility of the Scientific committee of Eurodyn 2020.

5 CONCLUSION

In this paper, a numerical analysis of various cases of structural damage has been carried out on a steel-concrete composite beam subjected to static loadings. An FE model of the composite beam is developed by incorporating a distributed shear connection, and then different damage

indices have been embedded into the stiffness matrix of the beam. The results indicate that the model is reliable because the displacements are acceptable in terms of different load locations with a similar FE model built from the commercial FE package ABAQUS. The convergence study established to determine the optimal number of FEs for the composite beam indicates that the discrepancies in the displacements and strains after the model with 24 FEs are very small, and therefore 24 elements are used in the numerical analysis. The maximum displacements and strains in the beam in various cases are also investigated and compared. It is found that the maximum displacements and strains at each loading location remain constant after an initial reduction when the number of FEs increase. Moreover, the bonding slip does not impact the measurements very much, and the change of maximum displacements and strains from undamaged to maximum damage are almost the same.

Keywords: Seismic structural health monitoring, life-cycle cost analysis, seismic hazard curve, sensitivity analysis.

Abstract. *Recent dramatic bridge collapses worldwide have drawn a significant attention on the problem of ageing infrastructural network and highlighted the main failure causes of bridge structures, namely: decay of the mechanical properties due to ageing, increase of traffic loads, subsidence of the soil, earthquakes, and more. Road managers have the great need of acquiring the largest possible information regarding the current health state of the transportation networks that are typically dated and huge in terms of number of bridges. Nowadays, this knowledge is gained through planned inspections to be performed on individual bridges. However, in countries where the seismic risk is high, a special attention must be paid to the seismic response of bridges, as they often constitute the most sensitive and strategic structures for the management of post-earthquake emergencies. Visual inspections are still the most used class of tools to assess the health state of structures after an earthquake. Several efforts have been made to carry out surveys and obtain updated databases on the conditions and the seismic performances of bridges; other efforts have been made to develop automatic procedures for the classification of intervention priorities after seismic events, based on rapid analysis and simplified evaluation forms. The use of seismic structural health monitoring (S^2HM) systems installed on the structure can be an excellent solution to these problems. S^2HM systems allow reducing the uncertainties affecting the assessment of the planned maintenance and allow important economic savings. The present paper proposes a novel methodology for calculating the life cycle costs of road bridges equipped with S^2HM systems. Cost analyses are carried out considering seismic scenarios of the same duration as the life span of the structure, generated through Monte Carlo simulations, based on the mean annual rate values obtained by sampling the seismic hazard curves. The procedure allows to quantify the benefits in terms of structural reliability offered by the S^2HM system, and provides knowledge on the economic advantages of the use of S^2HM that allows avoiding unnecessary traffic closures and interruptions. The cost model allows to investigate the influence of the seismic monitoring systems on life-cycle cost of bridges and to highlight the most sensitive aspects in order to obtain a significant economic return, such as site seismic hazard and lifetime.*

1 INTRODUCTION

The life cycle management of the roadway bridges network is organized with long term plannings of scheduled inspection and maintenance (I&M) that may be defined as ordinary ones. Since these operations are forseen by the design phase of the structure, their execution costs are computable. Ordinary inspections consist of control activities of the global and/or local structural safety made at fixed ranges of time [1, 2]. An Italian regulation from the ministry of public works regarding bridges inspections [3] imposes the obligation to carry out quarterly visual inspections by technicians and more detailed annual visual inspections by engineers. The scopes are to monitor and to update the knowledge of the current health state of the bridges over time in order to perform different levels of ordinary maintenance in time [4]. Ordinary I&M allows proper safety levels regarding the degradation phenomena. Therefore, the maintenance costs can be defined in terms of excpected values, namely as function of a probability of failure [5]. Moreover, to ordinary I&M costs, post-event inspection and maintenance operations (extraordinary I&M) costs must be added. The main Italian road network manager, Anas S.p.A., adds in-depth inspections through the use of special means, such as using an inspection platform, and the execution of non-destructive tests, to be carried out after extraordinary events and, in particular, after earthquakes of sufficiently large intensity. On one hand, extraordinary I&M can produce significant inconvenience to drivers, as disruption and/or diversion of traffic for the time necessary to carry out the operations. On the other hand, post events operations are the most expensive ones due to the uncertainties regarding the damage detection and localization.

Recently, several strategies of post-seismic emergency management were proposed in order to provide priority I&M operations classification methods. O'Reilly [6] and Borzi [7] proposed upadated databases and seismic risk maps for the bridges based on fragility curves to support decision making. Limongelli [8] provided a method based on the value of information of the visual inspections.

In this paper, the use of the results provided by the monitoring system during an earthquake as tool to manage the inspection operations of the monitored bridges is proposed. A life cycle cost model able i) to compute the cost of the post-event operantions when the S^{2}HM data are available [9] and ii) to quantify the obtained gain in comparison to traditional post-seismic emergency strategies is introduced. The results of the cost model application to a case study bridge by Monte Carlo simulations of the seismic scenarios and structural responses are shown. The simulation process allows to compare the total cost values for different strategies by quantitative assessments, in order to quantify the economic benefits and to highlight the most sensitive parameters. In the paper, the effects on the results of seismic hazard and lifetime are investigated.

2 S^{2}HM AND POST-EVENT INSPECTION STRATEGY

The process of implementing the damage detection strategy regarding the structural seismic risk can be defined as Seismic Structural Health Monitoring [10]. The S^{2}HM system operating principle can be different according to the monitored seismic phase [11]: i) before the event, the system processes and stores a huge quantity of data, ii) during the event, the system must be able to record the typical phenomena as exceedence drift, and, finally, iii) after the event, the system must highlight potential behavior anomalies. Each phase requires different architecture features of the system according to the specific purpose.

In this paper, S^{2}HM refers to threshold monitoring systems able to control the structural response during an earthquake and to report it to bridge managers in terms of values above or

below a performance threshold. These values can be used as health state markers of the monitored bridge components. Indeed, each threshold parameter is related to a specific limit state and, hence, to different emergency management activities, such as disruption and/or diversion of traffic, inspections and maintenances. The threshold selection is a prerogative of managers and experts on the basis of i) accuracy of the theoretical/experimental evaluation of the monitored parameters, ii) safety level to ensure, and iii) reliability of the monitoring system result.

In this work, only the ispections operations are managed by seismic monitoring results. Therefore, a condition-based post-event inspection strategy can be defined, and, according to it, the control operations on the bridge components for which an alert is supplied by S^{2}HM are carried out. The strategy is outlined by the following steps:

1) Select the limit states of the bridge to monitor (bearing failure, pier bending, etc.);

2) Identify the level of each limit state (flexural, concrete spalling, bar yelding, ultimate strength, etc.), hereinafter referred to as Damage State DS;

3) Choose and compute the values of damage parameters (pier drift, pier tilt, etc.) and the threshold values referred to the selected DS;

4) Set up the suitable S^{2}HM system to monitor the damage parameter during the eartquake;

5) Outline the extraordinary inspections referred to the exceedance of the DS.

3 LCCA FOR S^{2}HM

The life cycle cost analysis (LCCA) evaluates the total economic benefit of a structure by analyzing initial and discounted future costs [12]. Therefore, the total life cycle cost of a bridge can be defined as the sum of three cost groups: initial, management and final costs. The proposed classification follows the common practice to carry out cost analyses in terms of equivalent present value [12, 13] and, on the other hand, the need to separate the terms supposed as deterministic to the terms affected by uncertaintes and, therefore, described as expected values.

The initial costs, $C_{0,\mathrm{b}}$, include all cost items performed within the year "zero" and, hence, considered as current values. The management costs involve the activities to preserve the performance of the work and all its components. For bridges, the inspection costs, C_{I}, and the maintenance costs, C_{M}, represent the main contributions and, moreover, they must be expressed in terms of expected value, time cumulative and discounted at current value. The last group is the cost of disposal, C_{D}, of the structure at the end of its lifetime to be expressed in terms of present value.

The presence of the monitoring system affects the cost terms at the different stages of the life cycle. First, the initial purchase and installation cost, $C_{0,\mathrm{SHM}}$, and the SHM system management cost, C_{SHM}, must be added to the initial costs and to the discounted future costs, respectively. Hence, the expected total life-cycle cost of a bridge equipped with a seismic monitoring system can be expressed as follows [14]:

$$E[C(t_{\mathrm{L}})]|_{\mathrm{SHM}} = C_{0,\mathrm{b}} + C_{0,\mathrm{SHM}} + \sum_{t=1}^{t_{\mathrm{L}}} \frac{E[C_{\mathrm{SHM}}(t)] + E[C_{\mathrm{I}}(t)]|_{\mathrm{SHM}} + E[C_{\mathrm{M}}(t)]|_{\mathrm{SHM}}}{(1+r)^t} + \\ + \frac{C_{\mathrm{D}}(t_{\mathrm{L}})}{(1+r)^{t_{\mathrm{L}}}} \quad (1)$$

where t_{L} is the lifetime of the bridge expressed in years, $E[.]$ is the expected value of the considered entity, and r is the discount rate.

In a condition-based post-event inspection strategy, the inspection costs at time t can be defined as:

$$E[C_{\mathrm{I}}(t)]|_{\mathrm{SHM}} = \sum_{l=1}^{L(t)} n_{\mathrm{I},l}(t) c_{\mathrm{I},l}^{\mathrm{ord}} + \sum_{n=1}^{N} p_{\mathrm{I},n}^{\mathrm{SHM}}(t) c_{\mathrm{I},n}^{\mathrm{extra}} \tag{2}$$

where L is the total number of ordinary inspection operation types; $n_{\mathrm{I},l}$ the number per year of l-type ordinary inspection; $c_{\mathrm{I},l}^{\mathrm{ord}}$ the l-type ordinary operation, N is the total number of possible extraordinary inspection types (equal to the number of limit states that the monitoring system can detect), $p_{\mathrm{I},n}^{\mathrm{SHM}}$ is the probability that the monitoring system detects the n-th type of damage, $c_{\mathrm{I},n}^{\mathrm{SHM}}$ is the respective inspection cost.

The probability term in Eq. (2), $p_{\mathrm{I},n}^{\mathrm{SHM}}$, is the product of the probability of exceedance of the n-type of Damage State DS_n conditional on the occurrence of an earthquake, IM, and the probability of exceedance of the earthquake in one year:

$$p_{\mathrm{I},n}^{\mathrm{SHM}} = P(DS_n \cap IM) = P(DS_n|IM) \cdot P(IM) \tag{3}$$

When in the design phase, seismic monitoring system data are not available, the expected value of the inspection cost at time t, $E[C_{\mathrm{I}}(t)]$, is again the sum of the costs of ordinary and extraordinary operations, but the probability term corresponds to the probability of occurrence of a seismic event in one year [15]:

$$p_{\mathrm{I}} = P(IM) = 1 - e^{-\lambda} \tag{4}$$

where λ is the annual frequency of exceedance of the event IM, taken from the hazard curve and according to the Poisson distribution.

In order to evaluate the economic gain of the novel post-event inspection strategy compared to the traditional approach, the following cost formulas are considered in the simulation process, for the cases with and without SHM system respectively:

$$E[C(t_{\mathrm{L}})]|_{\mathrm{SHM}} = C_{0,\mathrm{b}} + C_{0,\mathrm{SHM}} + \sum_{t=1}^{t_{\mathrm{L}}} \frac{E[C_{\mathrm{SHM}}(t)] + E[C_{\mathrm{I}}(t)]|_{\mathrm{SHM}}}{(1+r)^t} \tag{5}$$

$$E[C(t_{\mathrm{L}})] = C_{0,\mathrm{b}} + \sum_{t=1}^{t_{\mathrm{L}}} \frac{E[C_{\mathrm{I}}(t)]}{(1+r)^t} \tag{6}$$

The comparison is performed in terms of economic gain, G, defined as the difference of the cumulative cost at t_{L} year between the condition-based and the traditional strategies:

$$G = E[C(t_{\mathrm{L}})] - E[C(t_{\mathrm{L}})]|_{\mathrm{SHM}} \tag{7}$$

and in terms of economically viable cases, n_{evc}, defined as the of number cases for which G is positive, over the total number of simulations, n_{tot}:

$$n_{\mathrm{evc}} = \frac{n_{\mathrm{G>0}}}{n_{\mathrm{tot}}} \tag{8}$$

All inspection costs, ordinary and extraordinary, include both operations direct costs and indirect costs [5] associated with the cost of fatalities and accidents [16], and the traffic delay [13], caused by the operations.

4 SIMULATION METHODOLOGY

In order to apply the described cost model to a case study, a multi-step simulation process is developed. The gaol is to quantify in *occurred*, equal to 1, or *not occurred*, equal to 0, the probability terms of Eqs. (3) and (4) by Monte Carlo simulations.

The starting point of the simulation methodology consists in the realization of seismic scenarios, namely the time distributions of seismic significant intensity events, consistently with the site seismic hazard [4]. The procedure consists of:

1.a) Seismic site hazard curve (PGA-λ) sampling: selection of the number I and PGA_i intensity of the seismic events of interest and evaluation of the corresponding annual frequency of exceedance, λ_i;

1.b) Generation of a sample, of statistically significant size N_{I}, of the random vector $\bar{\mathbf{T}}$ of the I uncorrelated random Earthquakes, IM_i, with Poisson distribution, mean λ_i and intensity PGA_i respectively. Thus, a matrix $I \times N_{\mathrm{I}}$ is the genereted sample where the i-th row represents the distribution on N_{I} years of the arrival times t_{PGA_i} of the i-th earthquake;

1.c) Random extraction of t_{L}-long time windows (seismic scenarios) from the previous matrix. The overlapping of the rows of the resulting $I \times t_{\mathrm{L}}$ matrices represents the time distribution of the seismic events in the interval t_{L}.

The other phases of the multi-step simulation process are:

2) Realization of a Finite Element (FE) model of the case study bridge;

3) Application to the model of accelerograms with PGA_i consistent with the analyzed seismic scenario;

4) Seismic system response relative to each seismic event, namely accelerograms, and comparison with the thresholds DS_n, as described in Sections 2 and 3.

5 CASE STUDY APPLICATION

The results of the life cycle cost analysis according to the proposed cost model in Section 3 are necessarily influenced by the initial parameters, such as input data (examined bridge and site, etc.) and design features (thresholds and inspection operations definition, etc.).

5.1 Case study bridge and S^{2}HM system

The investigated bridge is a continuous steel-concrete composite bridge. It consists of 10 different size spans for a total length of 574 m; the cross-section is made by two I-shaped steel girders and a 32 cm thick concrete slab, and the RC piers have different heights with a bi-hollow rectangular cross-section.

Regarding the condition-based post-event inspection strategy described in Section 2, the following assumptions are made:

1) Limit states: bending of the 10 piers of the bridge;

2) Damage States: cracking and bar yelding of the bottom section of each pier;

Table 1: Comparison of inspection strategies

Strategy	**Type**	**Frequency**
Condition-based post-event inspection	Ordinary level-1 $C_{\text{I-O. level-1}}$	3 months [3], Post-earthquake when $\%\delta_{\text{y},i} \leq \delta_i \leq 0.8\delta_{\text{y},i}$
	Ordinary level-2 $C_{\text{I-O. level-2}}$	Annual [3]
	Extraordinary $C_{\text{I-Extra}}$	Post-earthquake when $\delta_i \geq \%\delta_{\text{y},i}$
Traditional	Ordinary level-1 $C_{\text{I-O. level-1}}$	3 months [3]
	Ordinary level-2 $C_{\text{I-O. level-2}}$	Annual [3]
	Extraordinary $C_{\text{I-Extra}}$	Post-earthquake for each pier

Table 2: Cost items and values for LCCA

Cost item	Cost		
$C_{0,\text{b}}$	2097600 €[design documents]		
$C_{0,\text{SHM}}$	3000 €		
C_{SHM}	10% $C_{0,\text{SHM}}$		
Cost item	**Direct cost**	**Indirect cost**	**Total cost**
$C_{\text{I-O. level-1}}$	297 €/pier [17, 18]	–	297 €/pier
$C_{\text{I-O. level-2}}$	553 €/pier [17, 18]	–	553 €/pier
$C_{\text{I-Extra}}$	975 €/pier [17, 18]	343 €/pier [13, 16, 19, 20, 21]	1318 €/pier

3) Damage parameter and threshold values: relative displacements at the top of the i-th pier, equal to a percentage of the values corresponding to the cracking, $\%\delta_{\text{cr},i}$, and a percentage of the values corresponding to the elastic limit for reinforcement yielding, $\%\delta_{\text{y},i}$;

4) S^{2}HM system: bidirectional low-cost accelerometers placed at the top and at the base sections of each pier (20 accelerometers in total) that record absolute accelerations in the two main directions; relative displacements are evaluated by double integration of the recorded accelerations, with assumed zero initial displacements and velocity;

5) Extraordinary inspections strategy: Table 1 summarizes the implemented inspection strategy with S^{2}HM system; for clarity, also the traditional inspection approach is reported in the same table.

5.2 Cost analysis

Regarding the cost model illustrated at Section 3, Table 2 summarizes the adopted cost items in order to apply the simulation procedure to the case study.

The cost value of the SHM system management, C_{SHM}, is defined as annual cost that has to be discounted; the $C_{\text{I-O. level-1}}$, $C_{\text{I-O. level-2}}$, and $C_{\text{I-Extra}}$ values are reported as unit costs for a single operation and a single pier, to discount and multiply by the occurrence number.

6 SENSITIVITY ANALYSES

The application of the cost model through the simulation process allows to quantify the influence of the initial parameters on the results in terms of economic gain, G, and economically viable cases, n_{evc}.

In this work, the effects of i) the lifetime in which the comparison is performed (t_{L} value) and ii) the site seismic hazard (sampled hazard curve) are investigated. Therefore:

- Variation of lifetime in the range [10, 200] years is analyzed with 2-year step increments;
- Three seismic hazard curves are implemented in the analyses, as shown in Fig. 1.

Any time a seismic scenario is applied to the case study, the corresponding value of the economic gain G is computed. Since the random factors are involved, it is necessary to perform the simulation process a large number of times in order to statistically process the obtained results. Therefore, a first analysis has been performed in order to evaluate the number of simulations, taking into account the computational effort. The following analyses refer to a sample of 2000 scenarios (n_{tot}=2000 in Eq. 8).

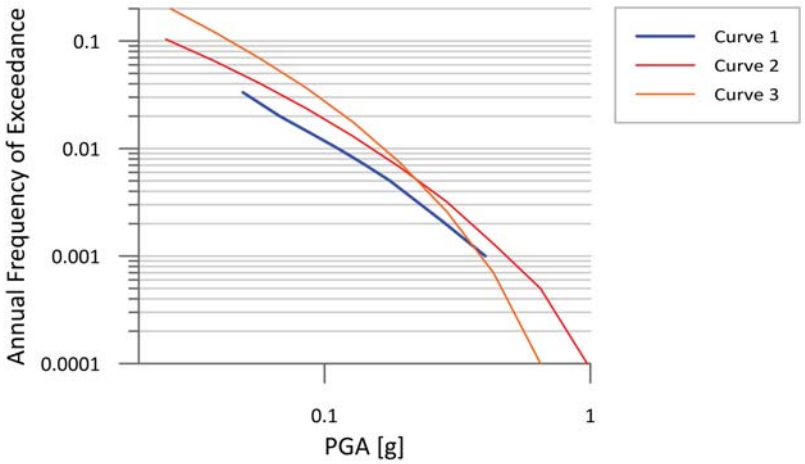

Figure 1: Seismic hazard curve: Curve 1 relative to LAT= 37.1254 LONG= 14.9275 available from [22], Curve 2 relative to LAT= 34.028 LONG= -118.251 available from [23], Curve 3 relative to LAT= 57.048 LONG= -157.236 available from [23].

6.1 Effects of the lifetime

In accordance with a condition-based post-event inspection strategy, the economic gain offered by the monitoring system can be triggered only when a seismic event occurs. Extending the analysis period allows to increase the probability that a higher number of earthquakes may happen in a scenario and, consequently, to raise the probability to obtain greater G values. On the other hand, all future cost items are reduced in terms of the present worth of the investment by the discount rate r and, in accordance with Eq. (1), the reductive effect of r increases exponentially over time. Hence, the added seismic events, as t_{L} increases, cause a progressively lower gain. Therefore, the influence of lifetime in terms of the expected benefits must be assessed in accordance with the adopted value of r.

Sensitivity analyses are performed assuming Curve 1, percentage equal to 80% and r equal to 0.01, 0.03 and 0.05. Table 3 shows the peak ground accelerations and the annual frequencies

PGA [g]	λ
0.0545	0.0284
0.0775	0.0167
0.1350	0.0076
0.2213	0.0032
0.2789	0.0021
0.3364	0.0014
0.4227	0.0009
0.5090	0.0006
0.5666	0.0005
0.6247	0.0004

Table 3: Peak ground accelerations, PGA, and annual frequencies of exceedance, λ, of Curve 1

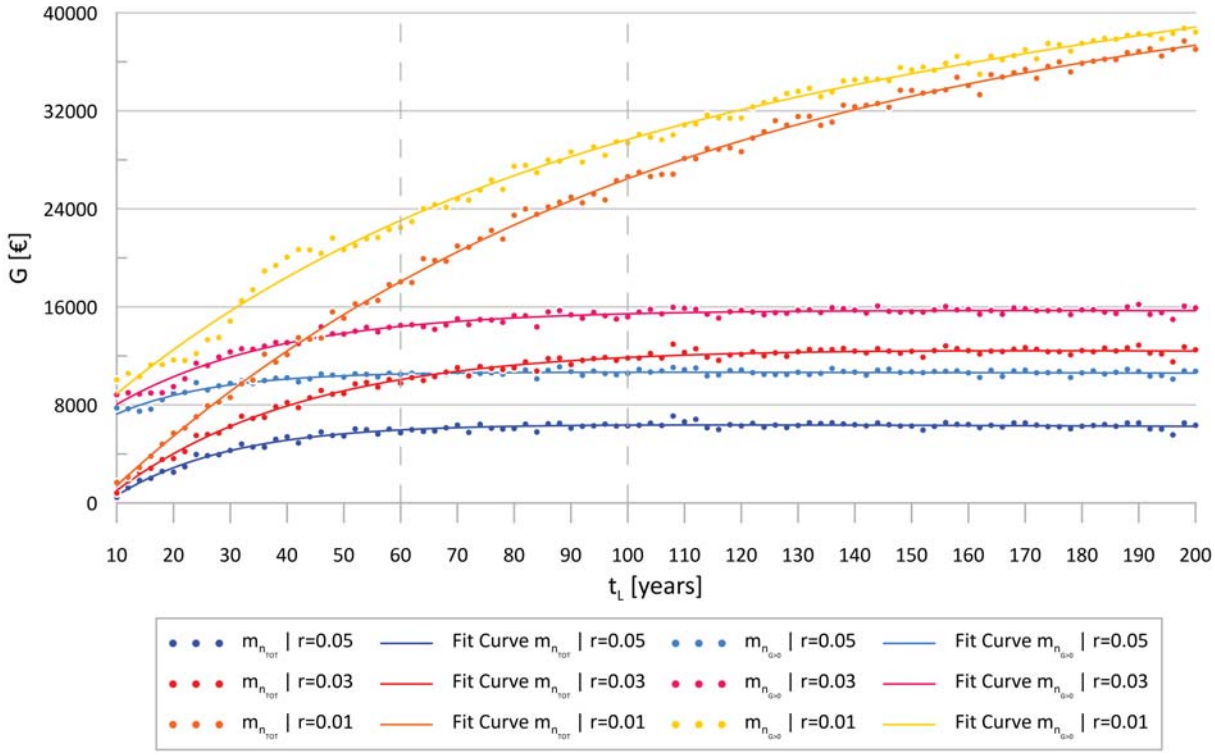

Figure 2: Comparison of $m_{n_{\text{tot}}}$ and $m_{n_{\text{G}>0}}$ function of t_{L} for r = 0.05, r = 0.03, and r = 0.01

of exceedance considered by the sampling of Curve 1 and used for the definition of seismic scenarios. The value of n_{evc}, the mean of the n_{tot} G values, $m_{n_{\text{tot}}}$, and the mean of the $n_{\text{G}>0}$ positive G values, $m_{n_{\text{G}>0}}$, are calculated for each t_{L} of the analysis range. The values of $m_{n_{\text{tot}}}$ and $m_{n_{\text{G}>0}}$ are shown and compared in Fig. 2 and the values of n_{evc} in Fig. 3, as functions of t_{L} for r equal to 0.05, 0.03 and 0.01.

The S^{2}HM benefit increases with the period of analysis with a higher growth rate for minor value of r. For high values of the discount rate, it is possible to identify a limit value of t_{L}, beyond which the gain becomes asymptotic, therefore, the comparison on larger t_{L} provides no further useful information. In the case study, the limit values equal to 60 and 100 years are

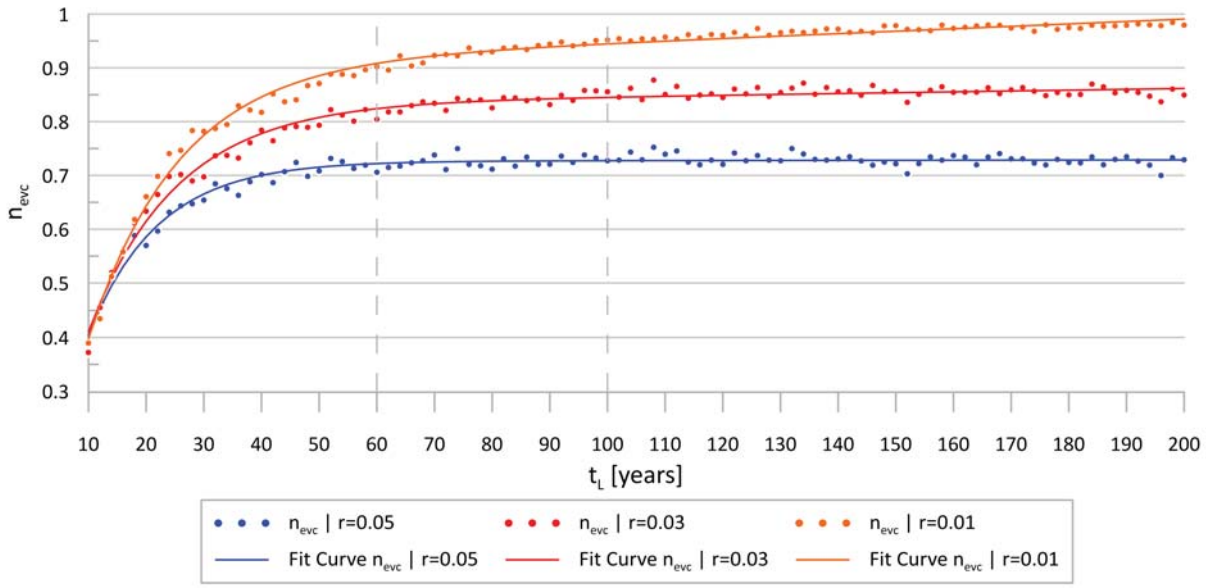

Figure 3: n_{evc} function of t_{L} for r = 0.05, r = 0.03, and r = 0.01

obtained for r=0.05 and r=0.03, respectively. For the initial value of t_{L}, the difference between the values of the pairs $m_{n_{\text{tot}}}$-$m_{n_{\text{G}>0}}$ is maximun and is greater for lower r, because the possible gain provided by single seismic events is more effective, then, it decreases with r and with an increasing t_{L}, because n_{evc} increases with t_{L} and with decreasing r.

6.2 Effects of the seismic hazard

An input parameter determining the number of seismic events that may occur during the lifetime of the bridge is the seismic hazard. A worst site hazard is characterized by bigger annual frequency of exceedance values for the same seismic intensity, therefore, over an equal analyzed lifetime, the number of events of a specific earthquake, obtained by Monte Carlo simulation, may be higher. However, a more severe seismic hazard leads to a higher probability that high intensity seismic events may occur. Severe earthquakes increase the damage probability and, therefore, the probability that more inspections are triggered, reducing the economic benefit of the monitoring system. The selected seismic hazard curves have the following features: Curve 2 is always harder than Curve 1, Curve 3 is harder than the other curves for smaller PGA values, while larger PGA values have lower probabilities.

Sensitivity analyses are performed assuming the same sampling values of PGA. Table 4 compares the annual frequencies of exceedance relative to Curve 1, Curve 2, and Curve3. Moreover, taking into account that the lifetime of a bridge is usually 100 years, the analyses are performed assuming t_{L} equal to 100 years and r equal to 0.03. The adopted percentage value is 80%.

The results are reported in terms of the relative frequency distributions of the n_{tot} G values, Fig. 4, and in terms of n_{evc}, Table 5.

The relative frequency distribution of G relative to Curve 3 is characterized by higher values of G, preceded by the results of Curve 2 and, finally, by Curve 1. The same relationship occurs for n_{evc}.

PGA [g]	λ (Curve 1)	λ (Curve 2)	λ (Curve 3)
0.0545	0.0284	0.0427	0.0737

7 CONCLUSIONS

The paper proposes a life-cycle cost model of bridges equipped with seismic monitoring systems that allow to implemet post-event inspection strategies alternative to traditional ones. The simulation methodology used in order to compare the expected value of the total cost in cases with and without a monitoring system is illustrated, highlighting the dependence of the results on the most influential parameters.

For a defined discount rate value, the procedure allows to evaluate the most suitable analysis

period, beyond which no additional benefits of the monitoring system can be demonstrated in terms of the present value of the inspection cost. Moreover, it is demonstrated that seismic structural health monitoring systems may produce important economic benefits when site hazard is characterized by high annual frequency of excedance for low PGA.

Keywords: resonance, metastrcutures, free vibration.

Abstract. *One of the most significantly deteriorated causes of bridge bearing failure is the resonance under various vibration conditions. It is important for bridge engineers to prevent the phenomenon, also called resonance, occurs to provide large amplitude vibrations when the bridge is being forced to vibrate at its natural frequency. This may lead to failure of the bridge structure under resonant vibrations. Common bridge bearings cannot well perform when vibrated large for example elastomeric bearings. This is because they do not have adequate mechanical properties to resist extremely various loads. Therefore, the concept of using metastrcutures to gain superior mechanical properties inspired us to generate a novel bridge bearing model. Because of the nature of dynamic forces on bridge structure, the vibration characteristics of a novel bridge bearing are crucial in analysis and design processes. This paper is the world's first to focus on the comprehension of vibration characteristics of a novel bridge bearing under free vibration. Through finite element method using Fusion 360 software, the numerical investigation of the modal parameters under dynamic condition was carried out for the novel bridge bearing. Also, there is a comparison of the free vibration results between the free-free and fixed boundary condition, in order to observe the influence of various boundary conditions responding to fundamental frequencies and mode shapes of a bridge structure. Additionally, to verify and develop a numerical model of bridge element, the free oscillation characteristics of the novel bridge bearing in different loads and boundary conditions are required. It is confirmed that vibration response measurements and parameters of a novel bridge bearing will be useful for bridge engineers to determine the vibration-based deterioration or to remotely monitor the bridge bearing health, since it is obvious that typical bridge bearing damage appears nearly at resonant frequencies of the bearings.*

1 INTRODUCTION

Bridge bearings also called isolators are extensively utilised in bridge engineering. Since 1950s, they have been employed as thermal expansion isolators for highway bridges and seismic base isolation bearings for building applications, especially extreme acoustic environments. Bridge bearings are critical part of the bridge elements in a bridge system. According to a review in [1, 2], the isolation system using these bearings are able to provide an element with high stiffness in one direction and high flexibility in one or more perpendicular directions. Also, the key functions of bearings for building and bridge applications are not only to transmit and accommodate loads and lateral deformations between the superstructure and the superstructure of a bridge, but also they support the weight of the superstructure [3]. Besides, bearings used for bridge application purposes should be more considered in design than those used for building application, due to additionally rotational deformations induced by girders [4].

The concept of combining horizontal flexibility and vertical stiffness is strongly suggested to be used in design of typical bridge bearings [2]. For example, these common bearings consist of rubber pads laminated with reinforcement materials (i.e. steel plates). Over decades, the development of a novel design of bridge bearings with fibre reinforcement has been widely researched. Compared to bridge bearings reinforced by steel-reinforced bearings are relatively heavy because of the steel reinforcement plates [5]. Additionally, the cost of these bearings is high due to the labour severe fabrication process [5]. Therefore, the benefits of utilising fibre reinforcement in bridge bearings are simplicity of installation, lightweight, better damping properties, high base isolation performance and lower stresses in rubber and fibre layers [6].

A main element of a rubber bearing is the rubber pads, based on an investigation in [7]. They can be employed straight without being reinforced (e.g. plain rubber isolators), or the pads can be laminated with reinforcing materials, providing a high tensile capacity for rising the vertical stiffness of the bearing by dominating buckling of the rubber [3]. A review in [8], Caltrans stated that for the entire structure, the selection of seismic rubber isolators with reinforced materials is dependent on the preferred type of an isolator.

According to [2], a rubber bridge isolator can be sensitive to a buckling type of instability identical to that of a common column, but controlled by the low-shear stiffness of an isolator. Reviews in [9, 10], bridge bearings should have adequately vertical stiffness to transfer service loads and besides be capable to facilitate the horizontal or rotational movements occurred in the girders. The bearings having adequate stiffness in vertical direction can well perform to limit the buckling behaviour and also can reduce the risk of leading to accelerated bridge failure to the bridge structure [11]. For instance, damage is not allowed in bridge bearing under any expected actions [3].

One of the most common causes of bridge failure is the resonance phenomenon under highly various vibrations. It is vital to comprehend the modal characteristics of structural bridge elements for designing and to predict the vibrated behaviours of the bridge elements. In terms of general bridge bearings, they should be developed for preventing possibly the resonance by using complex structures to reduce vibration. More recently, the use of metamaterials consisting of metastructures has a great momentum for many applications. Based on studies in [12, 13] a common material having positive Poisson's ratio, PR shows a special situation of swelling in perpendicular to compressive loading. On the other hand, a metamaterial with negative PR exhibits shrink behaviour in a direction transverse to the direction of compression [14, 15]. Negative PR metamaterials express better mechanical properties and appli-

cation prospects regarding lightweight [16], indentation resistance [17], vibration attenuation [18, 19], impact resistance [20, 21], and energy absorption [22, 23].

Our simulation shown in the following chapter was inspired by the development of typical bridge bearings using metastructures under dynamic condition which obtain superior modal properties. Nevertheless, there is no study in the comprehensively numerical modal analysis of novel bridge bearings in free oscillation. This study highlights the outcomes of a sensitivity investigation of free oscillation characteristics of a novel bridge bearing. The simulation of the bearing was investigated dependent on the finite elements, employing Fusion 360 software. The insight into dynamic will be useful for the study on non-destructive testing (NDT) and health monitoring of bridge bearings.

2 THEORETICAL BACKGROUND OF MODAL ANALYSIS

One of the most approaches to determine the dynamic properties of systems in the frequency domain is the modal analysis. In this study, the main objective is to identify the dynamic properties of novel bridge bearing components in terms of fundamental frequencies and mode shapes through the finite element method. The formulas of motion for free vibrations of a bridge bearing can be shown as follows [24-26].

In a dynamic network, the formula of motion of the network can commonly be denoted by:

$$[M]\{\ddot{y}\} + [D]\{\dot{y}\} + [S]\{y\} = \{q\} \tag{1}$$

Where [M] expresses the mass matrix, [D] represents the damping matrix, and [S] denotes the stiffness matrix. The harmonic load applied to the network with magnitude, Q and loading frequency ω is indicated by:

$$\{Q\} = Qsin(\omega t) = Qe^{j\omega t} \tag{2}$$

To be noted, a non-trivial solution to Formula (1) is $\{y\} = \{Y\}e^{j\omega t}$. Substituting the previous solution to Formula (1) and manipulating it with Formula (2), the formula of vibration is obtained as follows:

$$(-\omega^2[M] + j\omega[D] + [S])\{Y\} = \{Q\} \tag{3}$$

With some manipulations, converting Formula (3) employing modal coordinates by employing $\{Y\} = [\Phi]\{W\}$ and the orthogonality principle, and it later yields

$$W_i = \frac{\{\phi_i{}^T\}}{\omega_i^2 - \omega^2 + 2\zeta_i\omega_i\omega j})\{Q\} \tag{4}$$

Recalling $\{Y\} = [\Phi]\{\mathrm{W}\} = W_1\emptyset_1 + \cdots + W_n\emptyset_n$, Formula (4) can be re-written as presented by:

$$\{Y\} = \left(\sum_{i=1}^{n} \frac{\emptyset_i\emptyset_i^T}{\omega_i^2 - \omega^2 + 2\zeta_i\omega_i\omega j}\right)\{Q\} \tag{5}$$

Later, the reacceptance of the network can be determined by:

$$V_{ij}(\omega) = \frac{Y(\omega)}{Q_i(\omega)} = \sum_{i=1}^{n} \frac{\emptyset_i \emptyset_i^T}{\omega_i^2 - \omega^2 + 2\zeta_i \omega_i \omega j} \quad (6)$$

Therefore, ω_i is the resonant frequency, $\emptyset_i$ denotes the mass-normalized mode shape, and ζ_i denotes the modal damping ratio.

In terms of viscous damping (with critical damping c_r), $\zeta_i = \frac{d_i}{d_r}$; for proportional damping $([D] = z[M] + x[S]), \zeta_i = \frac{z}{2\omega_i} + \frac{x\omega_i}{2}$; and for hysteretic damping (η_i), $\zeta_i = \frac{\eta_{ii}}{2}$

3 A FINITE-ELEMENT SIMULATION OF NOVEL BRIDGE BEARING

The dynamic finite element (FE) simulation of a novel bridge bearing in free vibration was developed to investigate its dynamic response (i.e. natural frequency and mode shape). The FE model was generated in Fusion 360 software, using 3.72E+06 linear tetrahedral components with 5.71E+06 nodes. In this paper, we also focus on the free vibration of our model both free-free and fixed boundary condition. In terms of free-free boundary conditions, no excitation force was applied to the model, whilst the upper and lower surface of the model are not fixed because of free-free condition. For fixed condition, it is similar to the free-free condition, but the lower surface of the model is fixed.

Figure 1 demonstrates the three-dimensional finite element model for a novel bridge bearing. The honeycomb structure inspired us to create the engineered model. This is because a honeycomb structure gives a material with a very low density and relatively extreme out-of-plane compressive and out-of-plane shear performance [27-31]. The material and dimensions of the model geometry are based on the STANDARD DRAWINGS for Thai highway design and construction [32]. As given in Table 1, it indicates the material and geometrical properties of the FE model. A range of natural frequency investigations was carried out to evaluate the standard of the FE simulation. It is significant to note that the material utilised in this simulation is merely nitrile rubber, thus it is strongly suggested to use composite materials for this model, in order to acquire superior mechanical properties. Obviously, these components acting a bridge bearing can provide an expected estimation of bridge bearing's vibration in free-free and fixed condition. However, this model should be verified with experimental data in further research for public use in the near future.

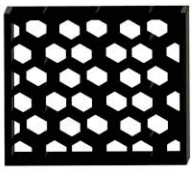

Figure 1: Finite element model of a novel bridge bearing in the free-free and fixed condition.

Parameters		
Material	Rubber	-
Elastic modulus	2	MPa
Poisson's ratio	0.49	-
Density	1.2E-06	kg/mm3
Model weight	5.12	kg
Model volume	4.26E+06	mm3
Model length	300.00	mm

Model width	300.00	mm
Model height	250.00	mm

4 RESULTS

The outcomes of numerical modal analysis for the novel bridge bearing are shown in Table 2 and Table 3 for free-free condition and fixed condition, respectively. For the two bridge bearing models under free vibration with different boundary conditions, it was observed that the fist twisting mode in vertical plane certainly controlled the first resonant mode of oscillation in free-free condition. Whilst appearing the first rolling mode for fixed conditions. For a free-free condition, the first five modes of free vibrations are shown in Table 2. Surprisingly, the minimum harmonic corresponded to the fundamental twisting mode, the second harmonic to the first rolling mode, the third harmonic to the second rolling mode, the fourth harmonic to the first shrinking mode, and lastly the fifth mode to the first buckling mode.

However, it is different to the modes of vibration which were obtained for the bearing model in the fixed condition. Table 3 exhibits the first five modes of free vibration in fixed condition. Surprisingly, the minimum harmonic corresponded to the fundamental rolling mode, the second harmonic to the first torsional mode, the third harmonic to the first shrinking mode, the fourth harmonic to the second shrinking mode, and finally the fifth mode to the third shrinking mode. The most dramatic change in fundamental harmonic between the free-free and fixed condition was the second rolling mode in free-free condition, but the first rolling mode in fixed condition, respectively. The highest frequency decrease was approximately 47.36 percent. It is clear that the fixed support played an important role in decreasing the frequency values of all vibration modes, except the twisting mode due to the increase in the frequency values. In addition, it resulted in all the different mode shapes, especially for the lowest fundamental frequency when compared to free-free condition.

According to a mention in [33], the effect of free vibration, there are several factors affecting the natural harmonics and mode shapes, which are the mass, shape, constraint, stiffness, and applied tensile or compressive loads of material and structure.

On the other hand, the validation of this simulation should be conducted by a comparison between experimental data and numerical results, in order to obtain the improved model and to be safely used in public. It is significant to note that these results are highlighted the dynamic properties because of a development in health monitoring of bridge bearing elements which one typically measures the dynamic behaviours in the bridge system by accelerometers on the bridge bearing surface [34].

Mode no.	Mode shape	Natural frequency (Hz)	Behaviour

5 CONCLUSION

Vibration characteristics of a novel bridge bearing play a major role in developing the realistic dynamic simulation of the bearing able to predict its dynamic response. The modal parameters of a novel bridge bearing in bridge system were investigated for modal analysis under free vibration with two different boundary conditions, through the finite element method using 360 Fusion software. The three-dimensional model using a honeycomb structure provides good mechanical properties and lightweight. Obviously, the resonant frequencies connected with the lower mode of oscillation of novel bridge bearing were dramatically influenced by the support boundary condition. Additionally, the mode shapes, which can behave the damaged condition of the novel bridge bearing, were affected by the fixed condition. To sum up, the fixed boundary condition had a particular effect on the vibration mode shapes and natural frequencies of a novel bridge bearing, particularly in the low frequency range. It is suggested that the determined modal parameters of the novel bridge bearing components were utilised to model bridge bearings where the influence of the boundary condition will be calculated. Nevertheless, the model should be created from composite materials that can provide superior mechanical properties. Furthermore, additional research for experiments of the novel bridge bearing fabricated by an additive manufacturing approach should be performed to compare the results between simulation and experiment.

Keywords: Robust Detection, Damage Detection, Structural Health Monitoring, Uncertainty

Abstract. *The problem of unsupervised robust vibration based damage detection under assembly–induced uncertainty is considered with a focus on the non–measurable excitation (output–only) case. The study employs a composite aerostructure and damage scenarios based on bolt loosening and characterized by 'minor' effects on the dynamics which are appreciably 'masked' by those of assembly–induced uncertainty. Detection is based on two Statistical Time Series type methods: a Multiple Model (MM) based and a Principal Component Analysis (PCA) based. The results, based on hundreds of test cases, indicate that both methods achieve very good detection performance, with the PCA–based one exhibiting an edge over its MM–based counterpart (99.5% versus 96% correct detection at a 5% false alarm rate). Although the non–measurable nature of the excitation unquestionably increases the problem difficulty, the degradation in performance is quite small, especially for the PCA–based method (from 100% to 99% at 4% false alarm).*

1 INTRODUCTION

Vibration based Structural Health Monitoring (SHM) has received significant attention in recent years as vibration signals are often naturally available and may be measured in a cost effective way and without interrupting the structure's normal operation [1, 2]. Yet, a main difficulty with this technology is related to the fact that most structures operate under varying Environmental and Operating Conditions (EOCs) and uncertainty, factors often inducing significant changes in the dynamics which may appreciably 'mask' those due to damage, thus rendering vibration based Structural Health Monitoring challenging.

Various classes of vibration based SHM methods aiming at overcoming this difficulty by exhibiting *robustness* to varying EOCs and uncertainty have been developed over the past several years. These attempt to 'separate' the effects of minor or incipient damage from those of EOCs and uncertainty, and may be classified as either 'implicit' or 'explicit'. *'Implicit'* methods attempt modeling that portion of the structural dynamics that is not significantly influenced by varying EOCs and uncertainty; they include Principal Component Analysis (PCA) [3, 4] and Factor Analysis (FA) [5] based approaches for damage detection. On the other hand, *'explicit'* methods attempt modeling the complete structural dynamics, explicitly including the effects of varying EOCs and uncertainty, via deterministic or stochastic relations; these include Functional Model (FM) based methods [6, 7], Gaussian or non-Gaussian Random Coefficient (RC) model based methods [8, 9], and Multiple Model (MM) based methods [10, 11].

Robust methods have been assessed in various experimental studies under varying Environmental (usually temperature and humidity) or Operating (such as payload) Conditions [12]. Yet, systematic and statistically reliable performance assessments based on sufficiently high numbers of experiments are relatively scarce. Moreover, damage detection under the practically important assembly–induced uncertainty has been barely considered, with the exception of a recent companion paper by the authors [13]. This has been based on hundreds of laboratory test cases involving re–assembly with a simple composite aerostructure and three distinct bolt loosening damage scenarios. Based on single–excitation trivariate–response signals, it has served to demonstrate that: (i) Detection is challenging, as the effects of damage may be indeed largely 'masked' by those of assembly–induced uncertainty, (ii) the use of robust Statistical Time Series (STS) methods may still lead to high detection performance reaching 100% correct detection at a false alarm rate of 3.5% or higher.

The *aim* of the present study is on addressing the problem of robust damage detection under assembly–induced uncertainty and *non–measurable* random (white noise) excitation (the *output–only* case). This is a case of high practical importance as the excitation is often non–measurable, for instance in flying aircraft, sea vessels, surface vehicles, wind turbines and many more structures under normal operation. Evidently, dropping the excitation signal information renders the damage detection problem more challenging, with the main question thus being on assessing the extent of the resulting degradation in detection performance.

For achieving this goal the present study employs the set–up, damage scenarios, and signals of our companion paper [13], in conjunction with two, properly adjusted, robust Statistical Time Series damage detection methods based on Vector AutoRegressive (VAR) modeling of the trivariate vibration response signal: (a) An Unsupervised Multiple Model VAR (U–MM–VAR) method, and (b) an Unsupervised Principal Component Analysis (PCA) VAR (U–PCA–VAR) method [14]. It is important to note that the *unsupervised* nature of both methods is of high practical importance as well, implying the use of vibration response signals exclusively from the healthy structure in the baseline (training) phase.

The rest of this article is organized as follows: The experimental set–up and the damage scenarios are briefly presented in section 2. The robust output–only damage detection methods are briefly outlined in section 3, while damage detection performance assessment and comparison with the measurable excitation case are presented in section 4. The conclusions drawn are finally summarized in section 5.

2 THE EXPERIMENTAL SET-UP AND THE DAMAGE SCENARIOS

2.1 The structure, the damage scenarios, and the experiments

The experiments are based on the composite aerostructure of our companion paper [13], representing the boom of a Unmanned Aerial Vehicle (UAV). The structure is clamped at its right end simulating the connection to the UAV fuselage, while its left free end is attached to an aluminum mass representing the aircraft tail (Figure 1). Both connections are bolted, with the nominal (corresponding to the healthy state) tightening torques being equal to 2 *Nm* and 4 *Nm*, respectively. The exciting random (white) force is applied at Point X, while the resulting vibration acceleration response signals are measured, at points Y1, Y2 and Y3, via lightweight accelerometers. Further details are provided in [13].

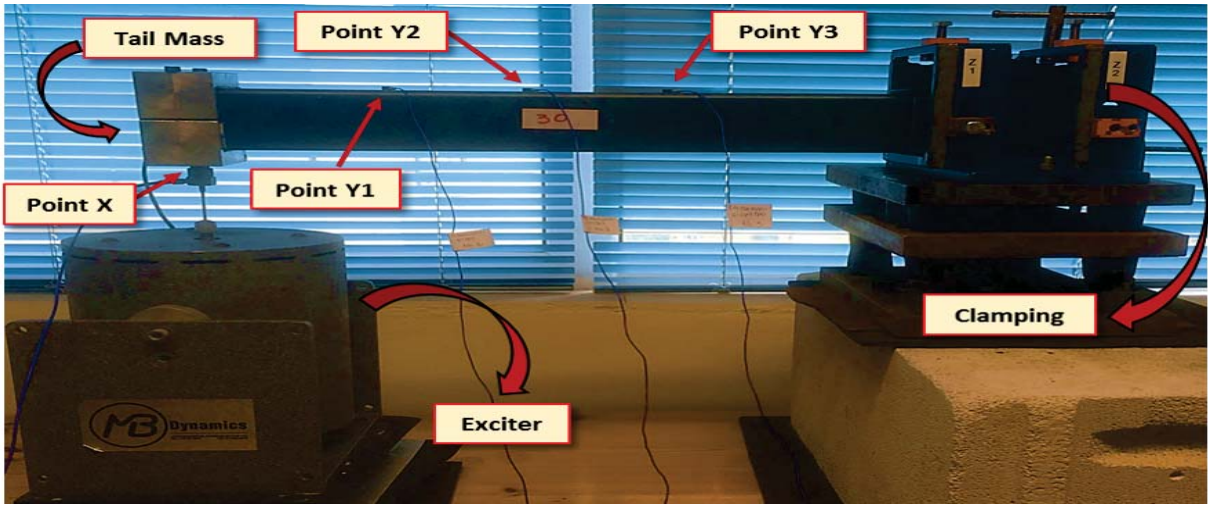

Figure 1: Experimental set–up: A random excitation is vertically applied at Point X and the resulting vertical vibration acceleration is measured at Points Y1, Y2, Y3 [13].

Three distinct damage scenarios are considered, each one characterized by a specific reduction (10%, 30% or 50%) in the tightening torque of its clamped end (fuselage connection). Details and the total number of experiments per health state are provided in Table 1.

Structural Health State	Clamping Torque [N·m]	Tail Mass Torque [N·m]	# of Experiments
Healthy	2	4	600
Damage 1	1.8	4	70
Damage 2	1.4	4	70
Damage 3	1	4	70

Table 1: The three health states and the corresponding numbers of experiments [13].

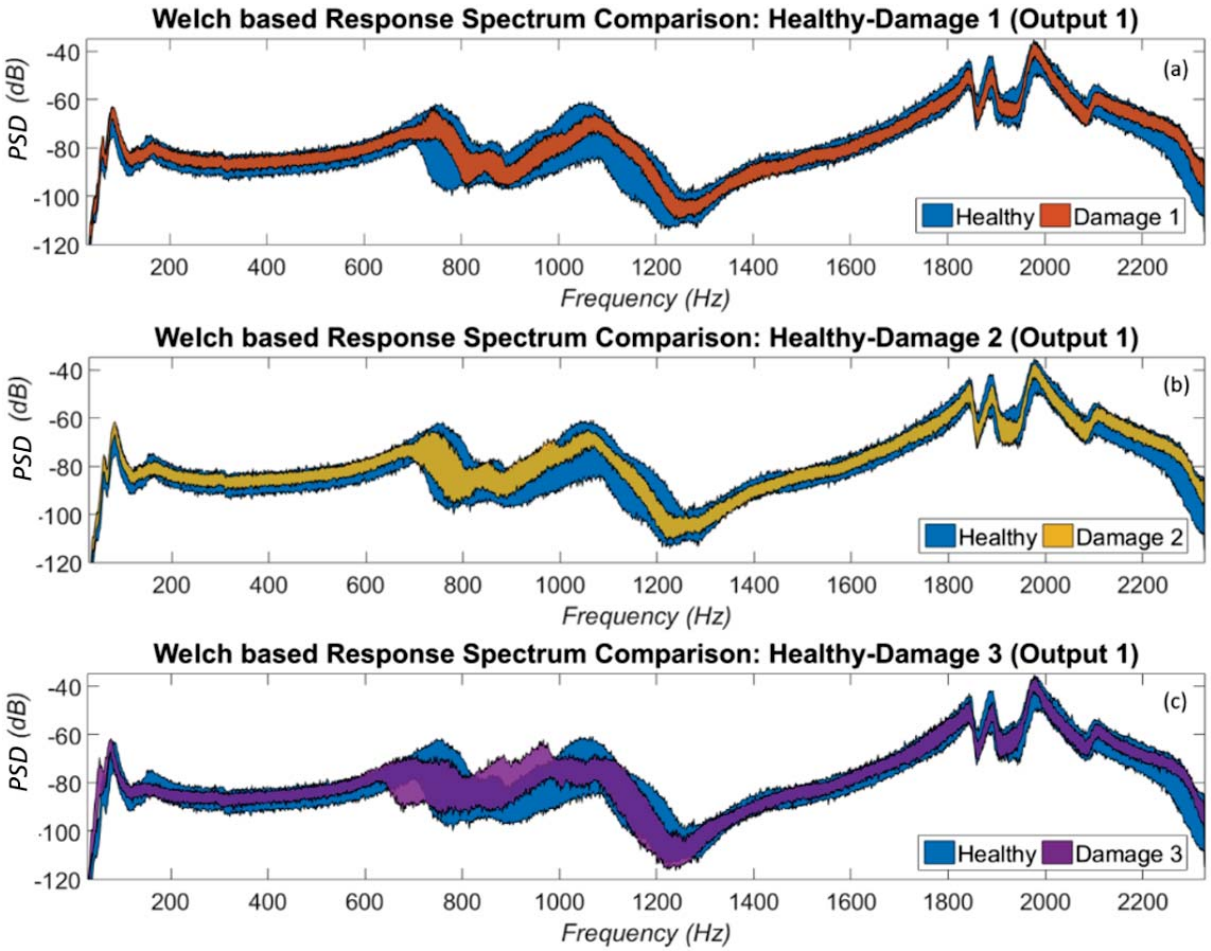

Figure 2: Assessment of the effects of damage and assembly–induced uncertainty on the dynamics: Welch–based vibration response PSD for the healthy structure versus Damage 1 (a), Damage 2 (b), and Damage 3 (c). [Measurement Point Y1; 600 PSDs for the healthy structure, 70 PSDs for each damage scenario; Welch estimation details in Table 2.]

2.2 Assessment of the effects of damage and assembly–induced uncertainty on the dynamics

The effects of each damage scenario, along with those of assembly–induced uncertainty, on the dynamics are demonstrated in Figure 2 via Welch–based Power Spectral Density (PSD) estimates [15, pp. 173-187] for signals measured at Point Y1. Evidently, the assembly–induced variability in the healthy dynamics (blue zone) is quite significant, and, to a very considerable extent, 'masking' that due to each damage scenario (especially for scenarios 1 and 2). These results imply a challenging damage detection problem, especially for the aforementioned two damage scenarios.

3 THE ROBUST OUTPUT–ONLY DAMAGE DETECTION METHODS

3.1 VAR modeling

For uncorrelated (white) force excitation the observed s-dimensional vibration acceleration signal, say $\boldsymbol{y}[t]$ ($t = 1,\ldots,N$ indicating discrete time, with the corresponding analog time being $t \cdot T_s$ with T_s designating the sampling period), may be modeled as an s-variate (presently s=3)

Vector AutoRegressive model of order n, that is a VAR(n) model, of the form [16, 17] (notice that bold face lower/upper case characters indicate vector/matrix quantities, respectively):

$$\begin{aligned} \boldsymbol{y}[t] + \sum_{i=1}^{n} \boldsymbol{A}_i \cdot \boldsymbol{y}[t-i] &= \boldsymbol{e}[t] \\ E\left\{\boldsymbol{e}[t] \cdot \boldsymbol{e}^T[t-\tau]\right\} &= \boldsymbol{\Sigma} \end{aligned} \tag{1}$$

with $\boldsymbol{A}_i\,(s \times s)$ designating the i-th AR matrix, $\boldsymbol{e}[t]\,(s \times 1)$ the model residual (one–step-ahead prediction error) signal characterized by the non–singular (and generally non–diagonal) covariance matrix $\boldsymbol{\Sigma}$, and $E\{\cdot\}$ statistical expectation. Given the vibration signal measurements $\boldsymbol{y}[t]\,(t = 1,\ldots,N)$, the estimation of the VAR parameter vector $\boldsymbol{\theta}$ comprising all AR matrix elements $\boldsymbol{\theta} = \text{vec}([\boldsymbol{A}_1 \ldots \boldsymbol{A}_n]^T)_{(n \times s^2) \times 1}$ and the residual covariance matrix $\boldsymbol{\Sigma}$ is accomplished via linear regression schemes based on minimization of the Ordinary Least Squares (OLS) or the Weighted Least Squares (WLS criterion) [15, p. 206].

3.2 The U–MM–VAR method

This method is based on a MM representation of the *healthy* structural dynamics under uncertainty [18]. This representation consists of a set of VAR(n) models along with their estimated parameters vectors $\boldsymbol{\theta}$. The method operates under two distinct phases: A baseline (training) phase and an inspection (operational) phase.

Baseline phase. $(s \times p)$ (presently $s = 3$) vibration response signals from p different experiments under healthy structural state are obtained. Based on them, a set of p VAR(n) models $m_o = \{m_{o,1},\ldots,m_{o,p}\}$ is estimated, constituting the MM representation of the healthy dynamics.

Inspection phase. Whenever a new set of vibration response signals, obtained under unknown structural state, is obtained, a new VAR(n) model m_u, of the same order as those in m_o, is estimated. A proper pseudo–distance metric, say $D(m_u, m_o)$, between the current model m_u and the MM representation m_o, is then computed.

The unknown health state is then declared as healthy if and only if the pseudo–distance metric $D(m_u, m_o)$ is lower than a user specified threshold l_{lim}, which is taken to imply that m_u belongs to the m_o MM representation; otherwise it is declared as damaged.

In the present study the pseudo–distance metric $D(m_o, m_u)$ employed is defined as:

$$D(m_u, m_o) := \min_k d(m_u, m_{o,k}) \qquad (k = 1,\ldots,p) \tag{2}$$

with $d(m_u, m_{o,k})$ designating the Kullback–Leibler (KL) divergence (pseudo–distance) [19] between two individual VAR(n) models.

3.3 The U-PCA-VAR method

This method employs the centered PCA [20, 21] for defining an n'-dimensional orthogonal coordinate system (where $n' = n \times s^2$, due to the dimension of the estimated VAR(n) parameter vector $\boldsymbol{\theta}$), on which the VAR parameters vector estimates corresponding to the healthy structural state may be projected, forming a set of mutually uncorrelated random variables [14].

Baseline phase. $(s \times p)$ (presently $s = 3$) vibration response signals from p different experiments of the healthy state are initially obtained and then a set of p VAR(n) models $m_o = \{m_{o,1},\ldots,m_{o,p}\}$ and their parameter vectors are obtained. These parameter vectors are sample

mean corrected [22], leading to the parameter vectors $\{\boldsymbol{\theta}_o\} = \{\boldsymbol{\theta}_{o,1}, \ldots, \boldsymbol{\theta}_{o,p}\}$. The sample covariance matrix $\boldsymbol{P} = \frac{1}{p-1}\sum_{k=1}^{p} \boldsymbol{\theta}_{o,k}^T \boldsymbol{\theta}_{o,k}$ $(n' \times n')$ (^{T} designating matrix transposition) is then computed and, via PCA transformation, it is decomposed into $\boldsymbol{P} = \boldsymbol{U}\boldsymbol{S}^2\boldsymbol{U}$, where $\boldsymbol{S}^2$ $(n' \times n')$ is a matrix which includes the squared singular values (positive eigenvalues) of $\boldsymbol{P}$ (arranged in decreasing order) and $\boldsymbol{U}(n' \times n')$ a real unitary matrix containing the corresponding eigenvectors of $\boldsymbol{P}$. The first $q(< n')$ columns (principal components) of the eigenvector matrix $\boldsymbol{U}$ – corresponding to the largest eigenvalues that explain a certain fraction $\gamma(\%)$ of the total parameter vector variability – are then associated with uncertainty, while the remaining m principal components are considered sensitive to damage.

Inspection phase. Whenever a new set of vibration response signals, obtained under unknown structural state, is obtained, a new VAR(n) model m_u and its parameter vector is estimated. Each estimated parameter is then centered by subtracting its sample mean (as obtained in the baseline phase), thus giving rise to the parameter vector $\boldsymbol{\theta}_u$. This is then transformed into the m-dimensional space as $(\bar{\boldsymbol{\theta}}_m)_u = \boldsymbol{U}_m^T \boldsymbol{\theta}_u$. Damage detection may be then based on the Euclidean norm of the transformed parameter vector $(\bar{\boldsymbol{\theta}}_m)_u$, following the decision making mechanism:

$$\begin{array}{rl} D = \|(\bar{\boldsymbol{\theta}}_m)_u\|_{l_2} \leq l_{lim} & \rightarrow \text{ Healthy structure} \\ \text{otherwise} & \rightarrow \text{ Damaged structure} \end{array} \tag{3}$$

where D designating the method's test pseudo–statistic and l_{lim} a user–specified limit.

4 DAMAGE DETECTION RESULTS

4.1 VAR modeling of the vibration response

Based on each set of vibration response signals measured at points Y1, Y2 and Y3 (Figure 1), each one being N=12 000 samples long, the modeling procedure involves the successive fitting of VAR(n) models for increasing AR order n, until an adequate model is reached. Model adequacy is judged via the trace of the estimated residual covariance matrix $\widehat{\boldsymbol{\Sigma}}$ and the Bayesian Information Criterion (BIC) [15, pp. 505-507]. The ratio of the number of signal scalar samples to the number of model parameters (Samples Per Parameter – SPP) should be maintained at sufficient levels (for instance above 20). Final model acceptance is based upon formal verification of the model residual uncorrelatedness (whiteness) hypothesis. This procedure leads to a VAR(55) model for the healthy structural dynamics (details in Table 2).

4.2 Comparative assessment of the methods

Damage detection performance is assessed via Receiver Operating Characteristics, ROC, curves, each representing the True Positive Rate (TPR, that is correct detection rate) versus the False Positive Rate (FPR, that is false alarm rate) for varying decision threshold [23].

$p = 300$ randomly selected experiments with the healthy structure are included in the baseline (learning) phase, while the remaining 300 healthy and 210 damaged (70 per each damage scenario) are reserved for inspection (testing). As p should be greater than the total number n' (presently $n' = 495$) of the estimated model parameters for the PCA (see subsection 3.3), a reduced number of VAR(55) scalar parameters should be employed. Indeed, the first 150 scalar parameters from the diagonals of the VAR(55) model AR matrices are selected, while γ is selected at 99.6% (U–PCA–VAR method). On the other hand 300 conventional VAR(55) models are included in the MM representation (U–MM–VAR method). Details are summarized in Table 3.

Non–Parametric Analysis						
Sampling Frequency (Hz)	Signal Length (samples)	Estimation Method	Window Type / length	Overlap (%)	δf (Hz) / # Segments	Bandwidth (Hz)

Scalar signal length N=12 000 samples.

†The first diagonal AR parameters (U–PCA–VAR).

Table 3: Detection method parameters and numbers of baseline and inspection experiments.

Performance assessment results for both methods are presented in Figure 3, in terms of pseudo–distance metric D and ROC curves, distinctly for each damage scenario. The U–MM–VAR method achieves correct detection rates that, for damage scenarios 1 and 2, approach 91% and 98%, respectively, for 5% or higher false alarm rate. The performance is even better for damage scenario 3, with 100% correct detection achieved for false alarm rate 1.5% or higher. This performance is quite impressive in view of the effects of the damage scenarios and uncertainty on the dynamics! The U–PCA–VAR method achieves even higher performance, as the correct detection rates for damage scenarios 1 and 2 approach 98.6% and 100%, respectively, for 5% or higher false alarm rate, while it achieves 100% correct detection rate for false rates of 0.4% or higher!

4.3 Comparison with the case of measurable excitation

The performance achieved by each method is now compared to that of its counterpart additionally employing the excitation signal (measurable excitation case); the latter methods are based on VAR models with Exogenous excitation (VARX models) and are thus referred to as U–MM–VARX and U–PCA–VARX methods [13]. As expected, the inclusion of excitation signal information leads to somewhat improved performance (Figure 4). This improvement is more evident for the MM–based methods (Figure 4(a)) where the correct detection rate improves from 94% to 100% for false alarm rate of 3.6%. On the other hand, the improvement is less significant for the PCA–based methods, as the correct detection rate improves from 99% to

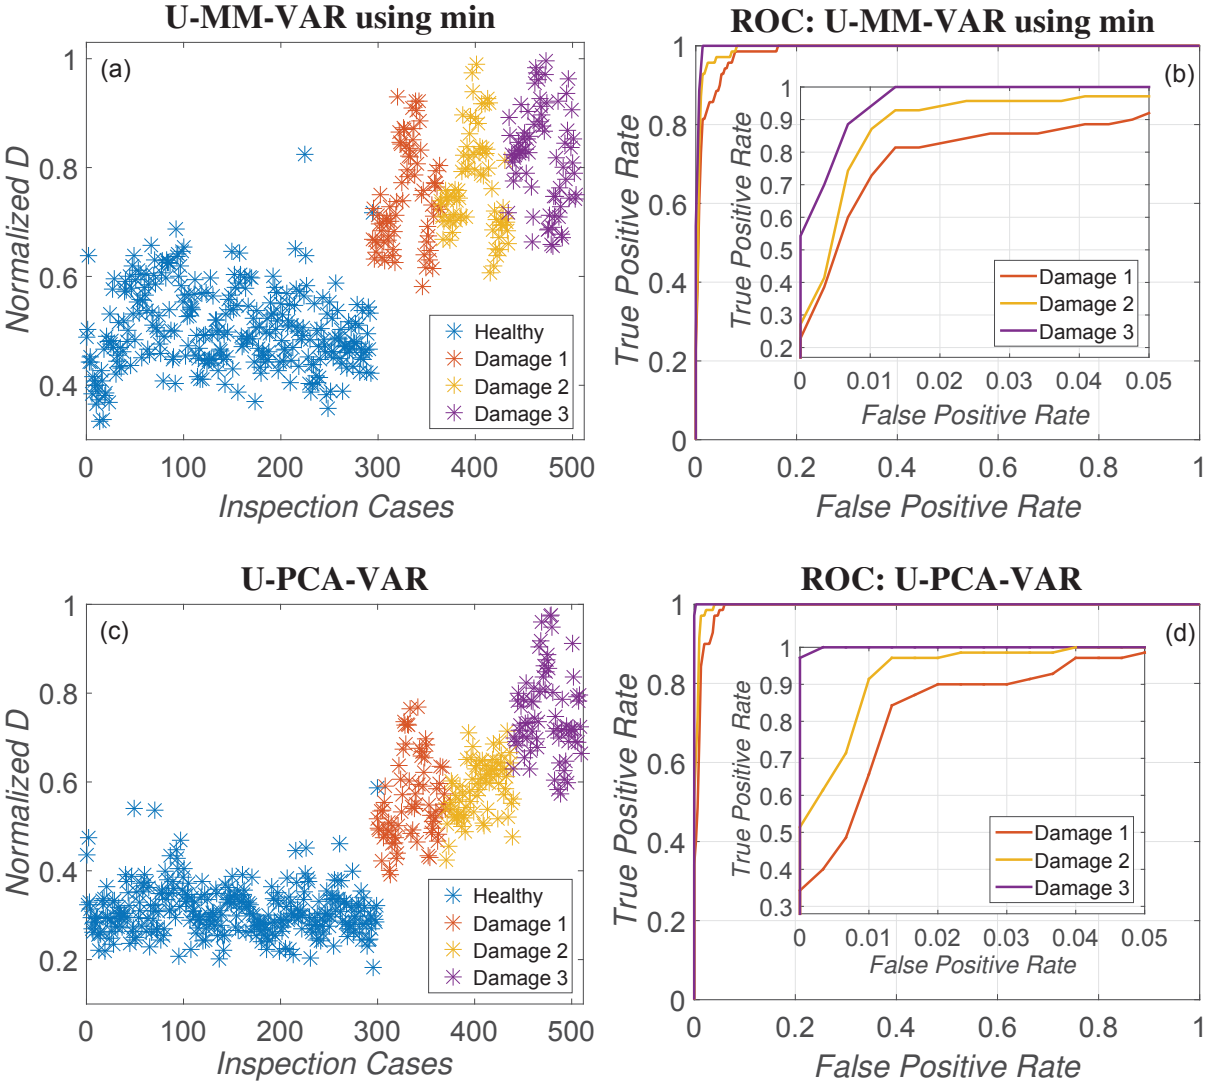

Figure 3: Damage detection performance assessment for each method and each damage scenario: Pseudo–distance metric (left column) and ROC curve (right column) for the U–MM–VAR (a,b) and U–PCA–VAR (c,d) methods (510 inspection experiments).

100% for false alarm rate of 4% (Figure 4(b)).

In general, the results indicate that the deterioration in damage detection performance due to dropping the measurement in the excitation signal is rather small, especially within the context of the PCA–based methods.

5 CONCLUSIONS

The problem of robust vibration damage detection under assembly–induced uncertainty has been considered with the focus set on the practically important non–measurable excitation (output–only) case. For this purpose experiments with a composite aerostructure under repeated assembly operations have been employed under three damage scenarios corresponding to 10%, 30%, or 50% reduction in a clamping bolt tightening torque. The problem has been tackled via two unsupervised and robust Statistical Time Series methods employing Vector AutoRegressive (VAR) modeling: The first is based on Multiple Model (MM) representations (U–MM–VAR

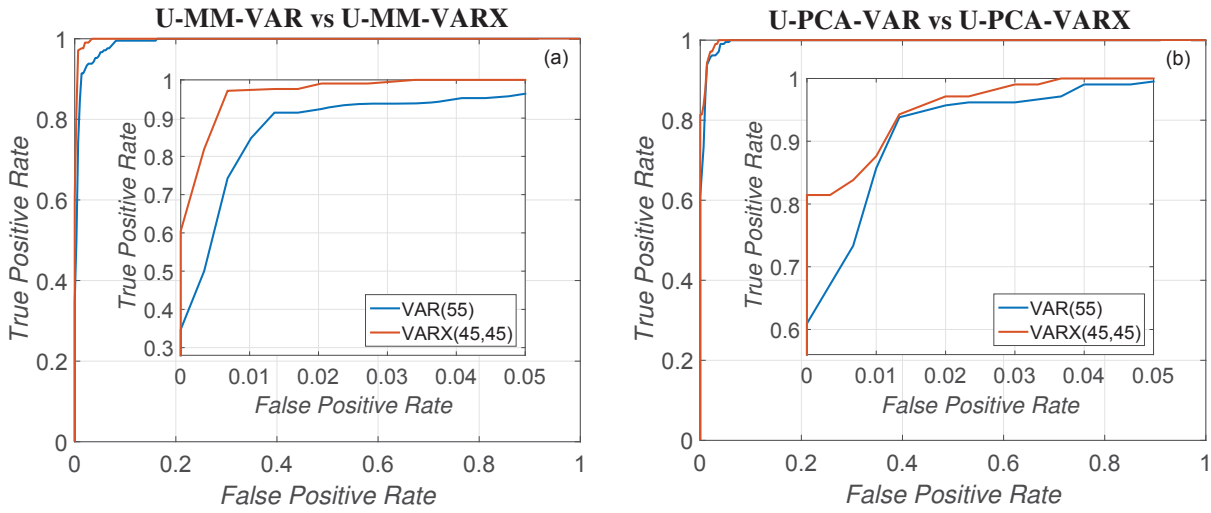

Figure 4: Damage detection performance comparison of the output–only and input–output methods via ROC curves: (a) MM–based methods, (b) PCA–based methods (cumulative curves including all damage scenarios; 510 inspection experiments per damage scenario).

method) and the second on Principal Component Analysis (U–PCA–VAR). Performance assessment has been based on 510 inspection experiments. The main conclusions drawn may be summarized as follows:

1. Despite the relatively 'minor' effects of each damage scenario on the structural dynamics and their appreciable 'masking' by those of assembly–induced uncertainty, both output–only methods lead to very good detection performance.

2. Although the performance characteristics of the two methods are largely similar, the PCA–based method offers an edge over its MM–based counterpart (correct detection rate of 99.5% versus 96% for 5% false alarm when all three damage scenarios are included).

3. As expected, the 1st damage scenario (10% torque reduction) is the most challenging, with scenarios 2 (30% torque reduction) and 3 (50% torque reduction) following in that order.

4. Although excluding the excitation signal from the damage detection procedure unquestionably increases the problem difficulty, the resulting performance degradation is relatively small, that is from 100% to 94% correct detection for the MM–based method (at 3.6% false alarm rate) and from 100% to 99% for the PCA–based method (at 4% false alarm rate).

Overall, the results of the study indicate that the use of proper robust random vibration based methods may effectively overcome the effects of assembly–induced uncertainty and achieve high detection performance even for relatively 'minor' damages and in the absence of measurable excitation.

Abstract. *Vibration-Based Monitoring (VBM) can constitute a successful approach for Structural Health Monitoring (SHM) of civil structures, but natural frequencies and displacement mode shapes can exhibit a low sensitivity to certain types of damage when compared to their sensitivity to environmental influences such as temperature. Modal strains are more sensitive to local damage and laboratory experiments have shown that they can also be insensitive to temperature changes. The direct monitoring of modal strains from very small strain levels occurring during ambient, or operational excitation has also become possible thanks to two recently developed optical interrogation techniques. The present work demonstrates for the first time the use of modal strains for VBM purposes through the monitoring a full-size civil structure. A steel railway arch bridge is monitored for a period of more than a year with eighty Fiber-optic Bragg Grating (FBG) strain sensors, multiplexed in four fibers. Thanks to a highly accurate optical interrogation technique, the ambient dynamic sub-microstrains of the monitored bridge are continuously measured with high accuracy and precision. Subsequently, the identification of its modal characteristics (modal strains and natural frequencies) is conducted on hourly basis and in a fully automated manner with the use of hierarchical clustering for the automated interpretation of the obtained stabilization diagrams. Ten modes are systematically identified from dynamic strains with a typical measured root mean square (RMS) strain value of the order of 0.01 micro-strains. The modes are tracked over time as new data are acquired. The influence of the temperature fluctuations on the modal characteristics of the bridge is extensively investigated. The results confirm that, for the achieved temperature range and temperature distribution, the modal strains of the bridge are not influenced by the temperature.*

1 INTRODUCTION

Vibration-Based Monitoring or VBM is a valuable tool for non-destructive damage identification and condition assessment of civil structures [1, 2]. The idea behind VBM is to identify changes in modal characteristics of a structure that are directly related to damage [1, 2]. The main challenge for VBM is to identify characteristics that are as sensitive as possible to structural damage and at the same time as insensitive as possible to measurement noise, loading, and environmental factors such as temperature [3, 4].

Natural frequencies are probably the most commonly used modal characteristics for damage identification [4]. Natural frequencies can be easily obtained with only a few sensors that are placed at proper locations. However, natural frequencies are influenced by environmental factors, such as temperature, and that influence can be high enough to completely mask the presence of even severe damage, necessitating data normalization [1].

Mode shapes consist another modal characteristic that is used for VBM [4]. The advantage of mode shapes over natural frequencies is that they contain local information, facilitating in this way the localization of damage. Mode shapes are also less sensitive to temperature variations, when compared to natural frequencies [4]. However, an array of sensors is required to obtain the mode shapes, which can be difficult and/or uneconomic to install in many civil structures.

Modal strains consist a modal characteristic that can be obtained from strain-based modal analyses, where dynamic strains are used as input [5, 6, 7]. Thanks to two recently developed methods for dynamic sub-microstrain measurements, the dynamic strains that occur on civil structures during ambient or operational excitation can be measured with high accuracy and precision with the use of Fiber Bragg Grating (FBG) sensors [5, 6]. Consequently, the modal strains can be identified from the measured dynamic strains with the use of subspace identification [8, 9]. Several experiments on laboratory tested concrete beams have illustrated that modal strains are highly sensitive to local damage of even moderate severity, while insensitive to temperature changes [6, 10]. Furthermore, modal strains can be obtained in a very dense grid with the use of FBGs. The advantage of FBGs is that multiple sensors can be multiplexed on a single optical fiber, offering valuable local information that facilitates the localization of damage.

The present work demonstrates the use of modal strains for VBM purposes through the long-term monitoring of a steel railway bridge. The monitoring campaign has three main goals. First, to investigate the ability of the strain monitoring method [6] to accurately measure dynamic strains and consequently identify the modal strains of a full-size civil structure under operational excitation. Second, to study the influence that environmental factors and more specifically temperature might have on the modal characteristics of a structure with complex boundary conditions and non-uniform temperature distribution. Third, to use this case study as a proof of concept of the methodology for potential end-users.

2 THE KW51 BRIDGE

The KW51 is an 117 m long railway bridge, located close to the city of Leuven in the Flemish region of Belgium. The bridge is part of the 100 km Line 36 that runs from Brussels to Liége and enables the crossing of two roads and the Leuven-Dijle channel. Line 36 is operated exclusively by passenger Thalys, ICE, Intercity, Suburbain and Omnibus trainsets.

The KW51 is a steel single-span arch bridge with a two-track deck that is suspended from the arch with thirty-two inclined braces (figure 1). The deck consists of two main girders that are stiffened by thirty-three transverse beams. The bridge is supported on four neoprene bearings at its ends, which directly sit on two concrete abutments.

(a) (b)

Figure 1: The KW51 bridge.

3 STRAIN MONITORING

The bridge is monitored with four chains of FBG sensors for more than a year, since 14 February 2019. The temperature of the bridge is also measured with one thermocouple. In the current paper, the results form the first three months of monitoring, up to 15 May 2019 are presented.

3.1 Experimental setup

The four chains of FBG sensors are located at the top surface of the bottom flange of the main girders of the bridge (figures 2 - 4). The fibers are attached to the flanges via a custom clamping system [6], to measure axial dynamic strains (figure 4a). The bottom part or ”base” of a clamping block is directly glued on a strong magnet, which is then placed on its designated location on the flange (figure 4a). Then, the fibers are firmly fixed at the discrete clamping blocks (figure 4b) to ensure the proper transfer of strains from the span to the sensors. The distance between two consecutive clamping blocks varies from 2.3 m to 2.5 m. One sensor exists between two blocks, measuring the average macro-strain between both blocks. Each fiber contains 20 FBGs, except from the northwest one that contains 19 (figure 3b). The fibers are prestressed to ensure that they remain in tension when the corresponding bridge part is being compressed. The gap that exists between the bottom flange of the transverse beams and the bottom flange of the girders (figure 4f), allows the fibers to pass below the transverse beams and get stretched along the girders.

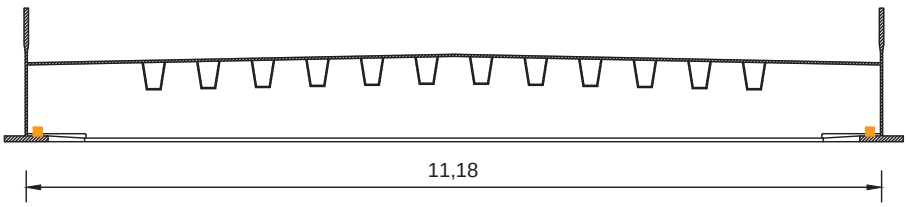

Figure 2: Typical cross-section of the deck of the KW51 bridge. The small cubes represent the clamping blocks (dimensions in m).

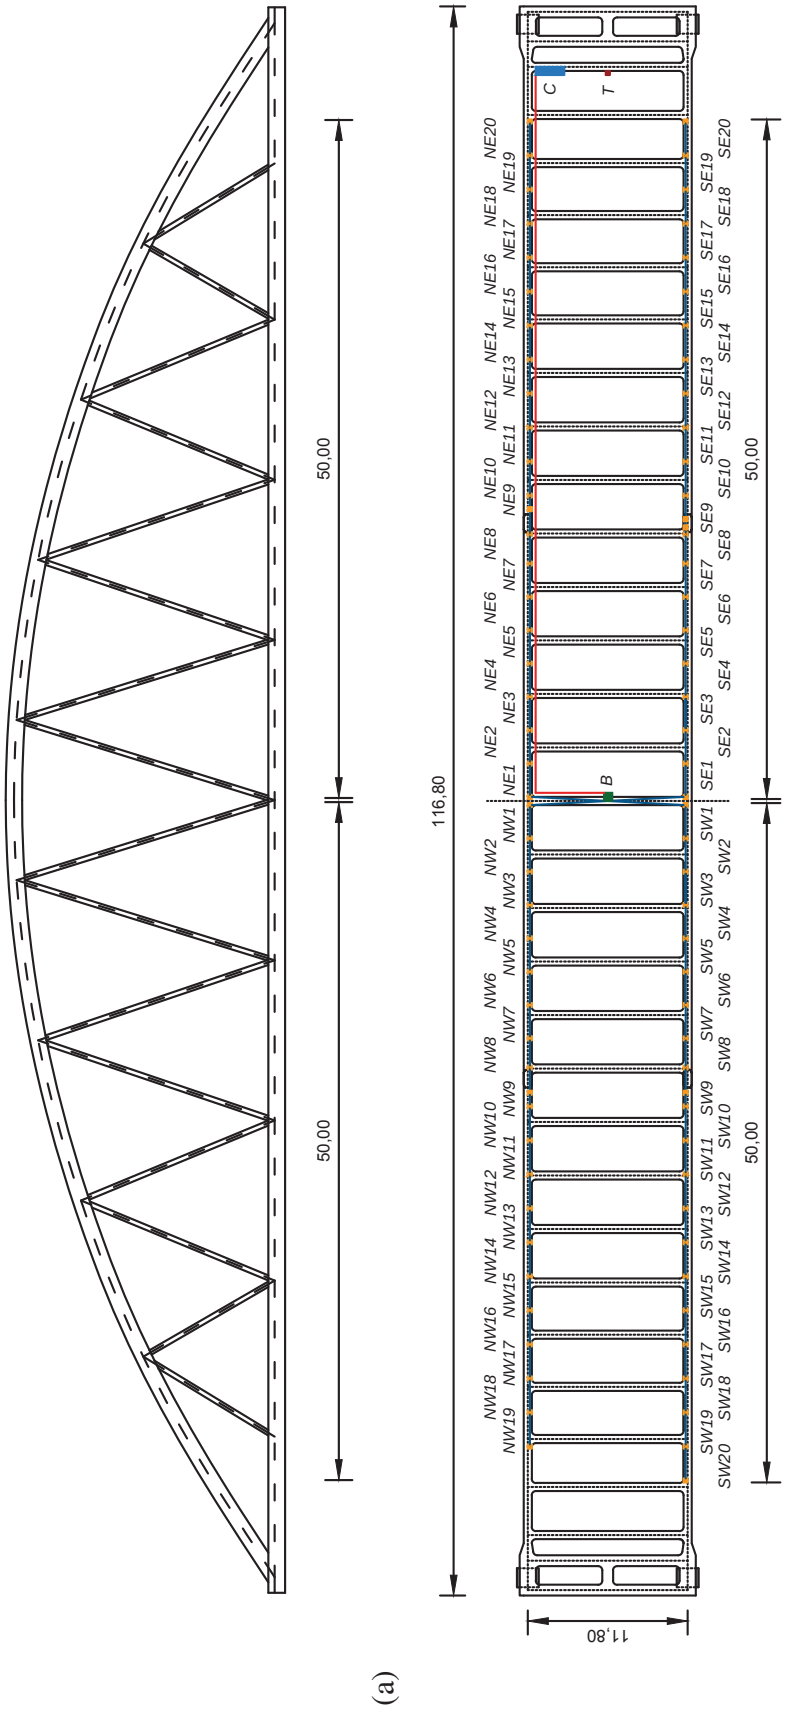

Figure 3: (a) South view of the KW51. (b) Schematic representation of the attachment of the optical fibers. The small cubes represent the clamping blocks and the rectangles the FBGs in between the clamping blocks. All FBGs are labeled; NE stands for northeast, NW for northwest, SE for southeast and SW for southwest. B denotes the box where all fibers are connected to the telecom fiber. C denotes the cabinet that contains the laptop and the acquisition system. T denotes the thermocouple. The telecom fiber is represented with a line connecting B and C (dimensions in m).

Since FBGs are sensitive to both strain and temperature, the fibers are covered with thermal insulation (figure 4c), to ensure that fast temperature fluctuations would not affect the dynamic measurements. Furthermore, the thermal insulation is covered with plastic foils to protect it against the environment. The plastic foils are secured with magnets (figure 4d).

Figure 4: (a) and (b) Photo of mounted clamping blocks and glass fiber. (c) The thermal insulation, covering the clamping box and the fiber. (d) The plastic foil, covering the thermal insulation. (e) One of the steel connection plates. (f) The gap between a transverse beam and a girder.

The strain acquisition is conducted with an interrogator that offers the required high accuracy and precision in dynamic sub-microstrain measurements [5, 6], the FAZ Technologies FAZT-I4. The sampling frequency is f_s = 1000 Hz. The acquisition system and the laptop that is required to operate the acquisition system, perform the measurements and save the data, are placed inside a cabinet that is located close to one end of the bridge and is attached on a transverse beam via magnets. The FBG fibers are connected to the acquisition system through a telecom fiber that spans the distance (≈60 m) between the cabinet and the midspan of the bridge, where all four fibers are connected to the telecom fiber in a wall mount box (figure 3).

The temperature of the bridge is measured throughout the monitoring period with a thermocouple that is used for this purpose [11]. The thermocouple is attached on the same transverse beam as the cabinet that contains the acquisition system (figure 3). The maximum recorded temperature during the first three months of the monitoring is $26°$C and the minimum $4°$C.

4 STRAIN-BASED MODAL ANALYSIS

Dynamic strain data are used for the identification of the modal characteristics of the bridge, i.e. natural frequencies and strain mode shapes. The strain data are obtained from operational excitation tests that were conducted on an hourly basis and had a duration of 900 s each. The strain data are used in strain-based Operational Modal Analyses (OMA), to identify the modal

characteristics of the span under changing temperature conditions and in a repetitive way. In total, 2139 operational excitation tests were conducted during the first three months (table 1).

Period	Tests	Period	Tests	Period	Tests	Period	Tests
14-28/2/19	316	1-31/3/19	743	1-30/4/19	720	1-15/5/19	360
Total 2139							

Table 1: Monthly amount of operational excitation tests recorded during the monitoring period of the KW51 bridge.

4.1 System identification

The data processing and the system identification is conducted with MACEC [12]. First, the static or DC offset is removed from all measured strain signals. Second, the data are low-pass filtered with an 8^{th} order Chebyshev Type I low-pass filter with a cut-off frequency of 16 Hz and then re-sampled at a lower frequency, resulting in a new sampling frequency f_s=40 Hz. Then, a fourth-order Butterworth filter with a high-pass frequency of 0.35 Hz is applied to all channels, in order to remove the influence of temperature fluctuations on the FBGs. The position-averaged RMS strain values among all sensors is in the range of 0.01 $\mu\varepsilon$. The output-only, data-driven stochastic subspace identification (SSI-data) method [8] is employed for identifying a range of state-space models from the strain data. When the time signals include one or more train passages, the data Hankel matrix [8] is modified to exclude them from the identification process, i.e. the columns of the Hankel matrix that contain data from times when a train is on the bridge, are removed. The train passages are automatically identified by an algorithm that tracks peaks in the data with amplitude larger than $1\mu\varepsilon$, which correspond to train bogies. The computed modal characteristics are used for constructing stabilization diagrams (figure 5).

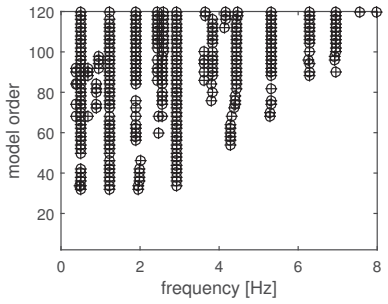

Figure 5: Typical stabilization diagram, as obtained from an ambient excitation test.

4.2 Automatic identification of modal characteristics

Modal analysis consists of four different stages: data collection, data processing, system identification and determination of a validated set of modal characteristics [13, 14]. The first three stages can be easily automated, e.g. with the use of MACEC. The user needs to make some initial choices, e.g. maximum system order, which can be used then for all data sets. The fourth stage, i.e. the determination of the modal characteristics, is also automated here by using the principles of hierarchical clustering, which is a method of cluster analysis [15] and allows to automatically select modes from the constructed stabilization diagrams.

The hierarchical agglomerative clustering is considered as a suitable procedure for clustering the estimated modes of a clear stabilization diagram and automatically obtain the psychical modes of the structure. This procedure has been successfully implemented on the ”Infante D. Henrique” bridge in Porto and it was proved to be very efficient in the identification of the bridge’s first 12 natural frequencies [16]. The implementation of the hierarchical agglomerative clustering for automatically identifying the modal characteristics of KW51 is thoroughly explained in [17]. Ten modes are consistently identified during the considered period. In figure 6, the natural frequencies of these modes are displayed for the period 14/2/19 - 15/5/19.

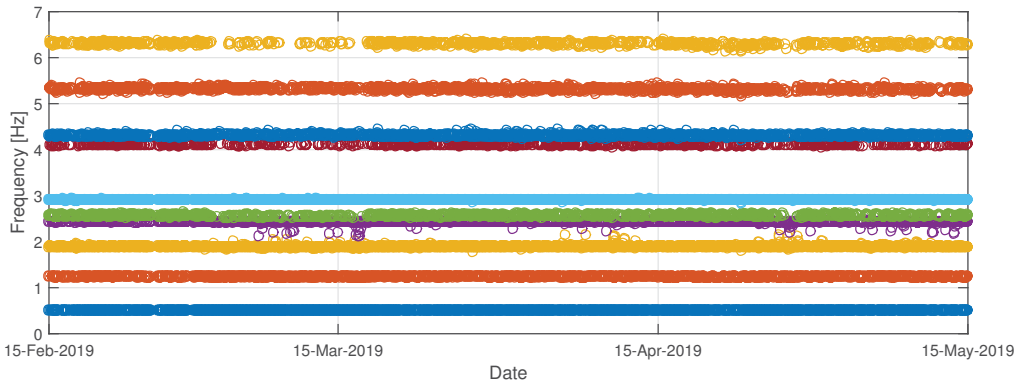

Figure 6: Automatically identified natural frequencies of the modes of KW51, during the period 14/2/19-15/5/19.

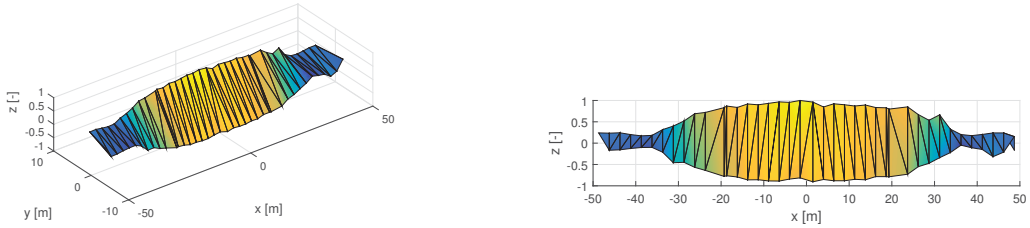
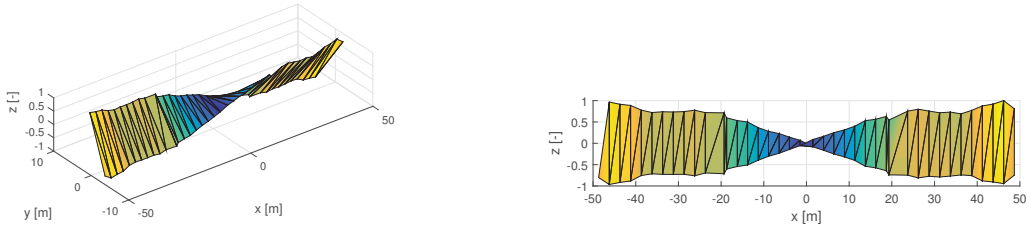
The strain mode shapes, natural frequencies and modal damping ratios of the first six modes are displayed in figures 7 and 8. The physical interpretation of the mode shapes is possible thanks to a separate acceleration-based OMA [11]. The modes can be classified as deck or arch modes, depending on which part of the bridge is predominantly excited for every mode.

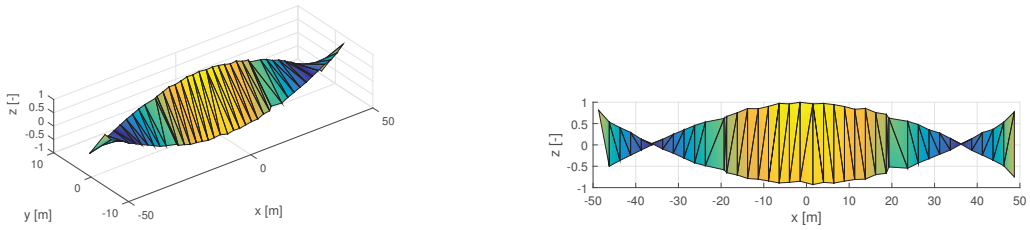


(a) Mode 1 - 1$^{\text{st}}$ lateral mode of the arch ($f_1^{\text{ssi}} = 0.51$ Hz, $\xi_1^{\text{ssi}} = 0.2\%$)

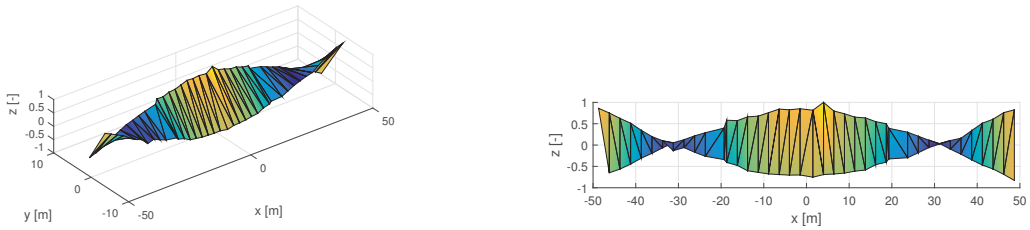


(b) Mode 2 - 2$^{\text{nd}}$ lateral mode of the arch ($f_2^{\text{ssi}} = 1.24$ Hz, $\xi_2^{\text{ssi}} = 0.1\%$)

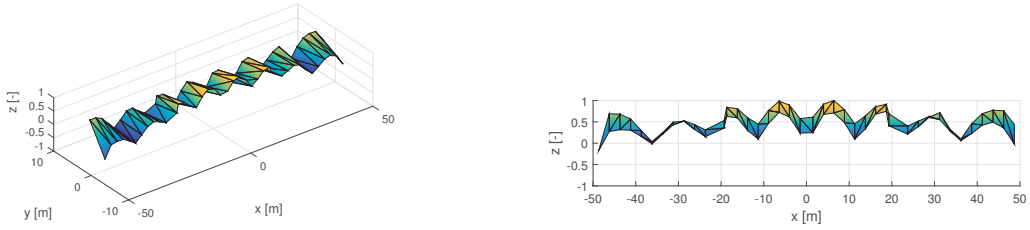
Figure 7: Strain mode shape, natural frequency and damping ratio of modes 1 and 2 of the KW51 bridge, as identified from strain-based OMA using SSI-data. The left subplots illustrate the 3D view and the right subplots the front (x-z) view of the strain mode shapes.



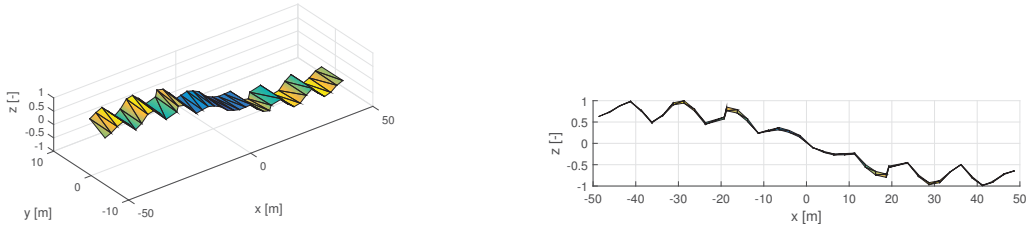
(a) Mode 3 - 1st lateral mode of the deck (f_3^{ssi} = 1.89 Hz, ξ_3^{ssi} = 0.9%)



(b) Mode 4 - 3rd lateral mode of the arch (f_4^{ssi} = 2.45 Hz, ξ_4^{ssi} = 0.1%)



(c) Mode 5 - 1st bending mode of the deck (f_5^{ssi} = 2.54 Hz, ξ_5^{ssi} = 1.8%)



(d) Mode 6 - 2nd bending mode of the deck (f_6^{ssi} = 2.92 Hz, ξ_6^{ssi} = 0.3%)

Figure 8: Strain mode shape, natural frequency and damping ratio of modes 3, 4, 5 and 6 of the KW51 bridge, as identified from strain-based OMA using SSI-data. The left subplots illustrate the 3D view and the right subplots the front (*x*-*z*) view of the strain mode shapes.

4.3 Influence of temperature on modal characteristics

The influence of temperature on the modal characteristics of the bridge, i.e. natural frequencies and strain mode shapes is investigated in the following sections.

4.3.1 Influence of temperature on natural frequencies

The time evolution of the natural frequencies of the ten systematically identified modes of KW51 is displayed in figure 6. In order to investigate the influence of temperature on natural frequencies, the natural frequencies of these modes are plotted as a function of temperature in figure 9. The natural frequencies in figure 9 are plotted within y-axis limits that are defined

based on their mean value $\mu[f_j^{\text{ssi}}]$, to provide with a common relative scaling for all modes. The limits of the y-axis in these figures are defined as $\pm 3\%$ of the mean value $\mu[f_j^{\text{ssi}}]$. The linear regression and the coefficient of determination (R^2) between temperature T and natural frequency f is also computed. Based on the linear regression, the relative change of the natural frequency of each mode $\Delta f[\%]$, for a temperature change of $\Delta T = +10°\text{C}$ can be obtained [17]. The coefficient of determination (R^2) and the relative change of the natural frequency $\Delta f_{10}[\%]$ of each mode are provided in figure 9.

It can be observed in figure 9 that temperature has an insignificant influence on the natural frequency of most of the modes of the deck (modes 3 and 5), while the modes of the arch (modes 1, 2 and 4) and the second bending mode of the deck (mode 6) appear to be more influenced from the temperature changes, for the given temperature range of about $24°\text{C}$ that was achieved during the monitoring period. An increase of $\Delta T = 10°\text{C}$ in temperature results in a relative decrease of about $\Delta f_{10} = 0.2 - 0.25\%$ for the natural frequencies of the arch modes and mode 6. The relationship appears to be relatively consistent among these modes, for the temperature range of $24°\text{C}$. The scattering of natural frequency values for some of the modes, e.g. mode 5 in figure 9e, can be as large as $\pm 2\%$ from the mean value $\mu[f_j^{\text{ssi}}]$, which creates a data "cloud", as it is proved also by their low coefficient of determination (R^2). This data "cloud" poses no correlation with the temperature changes. Such large scattering can be attributed to several factors, such as: influence of other environmental factors than temperature (e.g. solar radiation), the loading amplitude (e.g. wind intensity), the thermal inertia of the structure, identification errors, and others. Similar conclusions are drawn from the rest of the identified modes [17] and thus they are not displayed here.

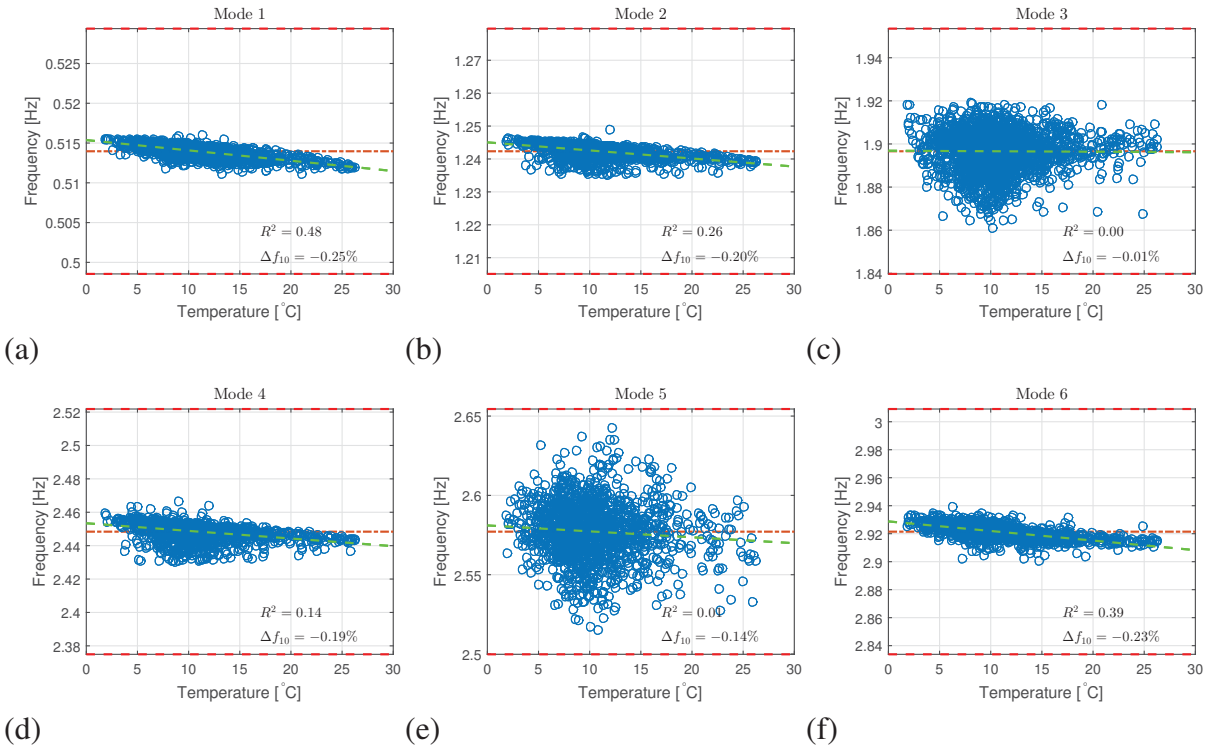


Figure 9: Evolution of the natural frequencies of modes 1 to 6 of the KW51 bridge as a function of temperature, as identified from SSI-data (f_j^{ssi}) and during the period before the retrofitting. The dash-dotted line denotes the mean natural frequency $\mu[f_j^{\text{ssi}}]$, while the dashed line denotes the linear regression of the data $f(T)$. The y-axis limits of the plots, which correspond to $\pm 3\%$ of $\mu[f_j^{\text{ssi}}]$, are also denoted with dashed lines.

4.3.2 Influence of temperature on strain mode shapes

The influence of the temperature fluctuations on the strain mode shapes $\boldsymbol{\psi}_j^{\text{ssi}}$ is investigated. The strain mode shapes obtained from all modal tests are used. First, a normalization scheme [9] is applied which allows for a direct comparison of the strain mode shapes that have been determined at different temperatures [10]. Second, the strain mode shapes are clustered in temperature groups that each have a non-overlapping range of 2°C. Third, for each temperature group k, the sample mean $\mu[\boldsymbol{\psi}_j^{\text{ssi},(k)}]$ of all strain mode shapes in the group is computed, as well as the sample standard deviation $\sigma[\boldsymbol{\psi}_j^{\text{ssi},(k)}]$ and the related $\pm 2\sigma$ confidence interval $\text{CI}[\boldsymbol{\psi}_j^{\text{ssi},(k)}]$, which boils down to a 95% confidence interval when the samples are normally distributed [9, 10]. The mean strain mode shape with its 95% confidence interval for the different temperature groups of the second bending mode of the deck (mode 6) are displayed in figure 10b. It can be clearly observed that the confidence intervals for the different temperature groups overlap completely, and they all have nearly the same width. It can therefore be concluded that, in the present experiment, there is no statistically significant influence of the temperature on the strain mode shapes, for the given temperature range of 24°C. Similar conclusions are drawn from the rest of the strain mode shapes [17] and thus they are not displayed here.

Since temperature does not influence the strain mode shapes, the statistical uncertainty must relate to other causes of variability in the strain mode shapes at a given temperature group, such as identification errors. The fact that the confidence intervals in figure 10b all fall on top of each other, indicates that the identification errors have low bias. This implies that the uncertainty on the identified strain mode shapes can be reduced by averaging. Indeed, the standard deviation *of the sample mean* of the entire set of N_k samples (i.e., identified strain mode shapes) obtained at a given temperature group *k* is related to the standard deviation of the set as:

$$\sigma[\mu[\boldsymbol{\psi}_j^{\text{ssi},(k)}]] = \frac{\sigma[\boldsymbol{\psi}_j^{\text{ssi},(k)}]}{\sqrt{N_k}} \tag{1}$$

and the related $95\,\%$ confidence interval reads:

$$\text{CI}[\mu[\boldsymbol{\psi}_j^{\text{ssi},(k)}]] = [-2\sigma[\mu[\boldsymbol{\psi}_j^{\text{ssi},(k)}]], 2\sigma[\mu[\boldsymbol{\psi}_j^{\text{ssi},(k)}]]] \tag{2}$$

Figure 10c displays, for the second bending mode, the sample mean of the complete set of all the repeatedly identified strain mode shapes $\mu[\boldsymbol{\psi}_j^{\text{ssi},(k)}]$ that are obtained at a given temperature group *k*, together with the 95% confidence interval of *the sample mean of* each set. Note that the sample mean values of figure 10b and figure 10c are identical, but that the width of the confidence intervals in figure 10c are a factor $1/\sqrt{N_k}$ narrower than in figure 10b, because in figure 10c the uncertainty of the averaged, sample mean values is considered. It can be clearly observed that the narrow confidence intervals of *the sample mean of* the different temperature groups overlap completely, and they all have nearly the same width, increasing the confidence that there is no statistically significant influence of the temperature on the strain mode shapes, for the temperature range of 24°C.

5 CONCLUSIONS

The KW51 railway bridge is monitored with four chains of FBGs for a period of more than a year. Modal tests, using ambient excitation as well as the free response of the bridge after train passages are conducted every hour throughout this period. The dynamic strain data from

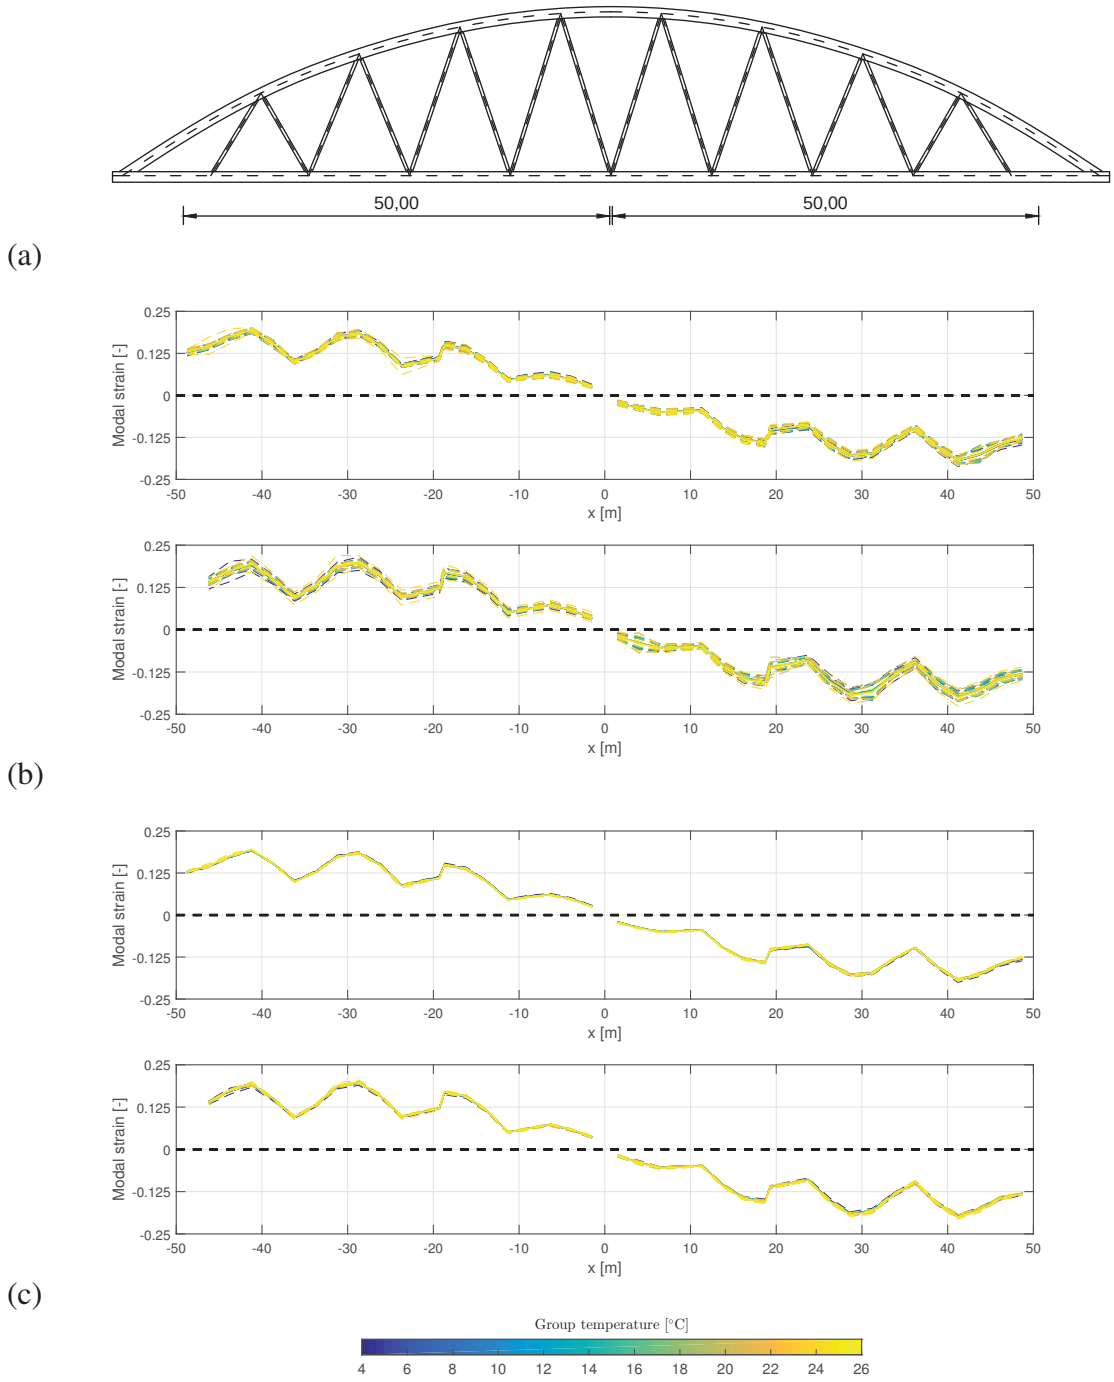

Figure 10: (a) South view of the KW51. (b) Sample mean $\mu[\boldsymbol{\psi}_j^{\mathrm{ssi},(k)}]$ and 95 % CI$[\boldsymbol{\psi}_j^{\mathrm{ssi},(k)}]$ of the strain mode shapes that have been identified in each temperature group k for mode 6. (c) Sample mean $\mu[\boldsymbol{\psi}_j^{\mathrm{ssi},(k)}]$ and 95 % CI$[\mu[\boldsymbol{\psi}_j^{\mathrm{ssi},(k)}]]$ *of the sample mean*, of the strain mode shapes that have been identified in each temperature group k for mode 6. The top and bottom subplots contain the strains at the north and south sides of the bridge, respectively.

these tests are used in operational modal analyses. Results from the first three months of the monitoring are presented in this paper.

The modal characteristics of the bridge are identified in a repetitive and automated way with the implementation of a hierarchical agglomerative clustering algorithm. Ten modes are

successfully and continuously identified throughout the monitoring period. The influence of temperature on the natural frequencies and the strain mode shapes of the bridge is investigated.

A small influence of the temperature on the natural frequency of the arch's modes is identified, while the natural frequency of the deck's modes appears not to be influenced by temperature, for the given temperature ranges.

The strain mode shapes of all identified modes are found to be insensitive to temperature changes, for the given temperature ranges, confirming the observations from past experiments in laboratory tested beams [10]. This is an important conclusion, since a temperature-insensitive dynamic characteristic can be directly used for damage identification, without requiring data normalization.

Keywords: Operational modal analysis, FE model updating, Multilevel optimization, Damage assessment.

Abstract. *For vibration-based structural health monitoring, a multilevel optimization scheme is applied to damage assessment of a prestressed concrete bridge. As a linear elastic problem to be addressed, damage was represented by reduction of structural stiffness of the reference model for the elements where the damage occurred. The Finite Element (FE) model updating problem is formulated as a nonlinear least-squares problem, which tries to minimize the differences between the reference model and the real (or simulated) structure with respect to the modal data. Due to the specific structure of the bridge, damage parametrization was introduced both using substructuring and a damage function. Consequently, the optimization variables were divided into global ones and local ones, which leads to the implementation of an iterative multilevel updating scheme. Satisfactory results were obtained for two numerical simulated damage scenarios: one with a single damage and one with multiple damage.*

1 INTRODUCTION

FE model updating has been widely applied to vibration-based structural health monitoring for damage assessment using operational modal data [1, 2, 3]. The damage assessment procedure requires solving an inverse problem based on experimental data to detect, locate, and quantify damage. The model updating technique is generally formulated into a numerical optimization problem, which tries to minimize the differences between the reference model and the real structure with respect to the modal data, such as natural frequencies and mode shapes. The solution procedure often involves a large number of unknown parameters, especially when the structure being investigated is complicate. As a result, the associated numerical problem is usually ill-posed. It might not have an unique solution, or the numerical solution is highly sensitive to small changes of the input data.[4, 5]. For a civil structure, not only the experimental results are effected by noise, but also the numerical models can be inaccurate to reproduce the behaviour of the real structure due to modelling errors. Therefore, several important issues related to FE model updating need to be carefully addressed, such as pramaterization of damage [6], modelling errors [7], objective function [8], regularization [9], environmental effects [10], and numerical optimization algorithms [11, 12, 13].

In practice, the most time consuming part is numerical modal analysis in the model updating process. Modal analysis of the reference model has to be repeated, since the objective function needs to re-evaluated with the updated parameters at every iteration step. Therefore, a simplified model of the bridge or structure is usually preferable as the reference model for the benefits of its computational efficiency [14]. Another practical problem often encountered for a civil structure is the lack of the baseline measurements for the undamaged state. Even though modal properties of the healthy structure can be estimated with a refined FE model [15, 16], the material properties and boundary conditions are influenced by environmental conditions like temperature, which increases the uncertainty of the estimation of damage parameters. In this paper, damage assessment is performed for a prestressed concrete girder bridge. It is a part of a long multispan viaduct, which consisted of a series of simply supported girder bridges. Extensive operational modal analysis was conducted by the Structural Mechanics section of KUL on the viaduct that was associated with corrosion-induced damage. It provided rich information for investigation and evaluation of the aforementioned engineering problems in a very realistic context. When an optimization problem can be divided into a series of smaller problems, an iterative multilevel solution scheme is of specific interest concerning the simplification and robustness of the numerical procedure. The multilevel optimization is a decomposition technique in which the problem is reformulated as several smaller subproblems (local problems) and a coordination problem (global problem) to preserve the coupling among the subproblems. Each span of the viaduct consisted of several main girders connected with transverse trusses. By taking into account the characteristics of the current structure, the multilevel approach described in [17] is adapted to the damage assessment of the bridge.

The paper is organized as follows. In Section 2, the context of the case study is presented regarding the bridge and the operational modal analysis. In Section 3, two different kinds of FE models were built with model calibration. The refined volume model serves as the baseline model. And the simplified plate model is used as the reference model to be updated. Two damage scenarios were simulated by the first model. In Section 4, the solution scheme is described, with the application to the two simulated damage cases. Discussion, conclusions and future perspectives are set forth at the last two sections.

2 BRIDGE DESCRIPTION AND OPERATIONAL MODAL ANALYSIS

2.1 The Boirs viaduct

The Boirs viaduct is a prestressed concrete bridge, which is composed of multiple simply supported spans at around twenty-five meters. The viaduct is a part of the roadway linking Antwerp and Liège in Belgium. There are two parallel bridges to accommodate the transportation in the opposite directions. The viaduct was designed and completed in the 1960s. In 2009, severe corrosion caused damage was found on the viaduct for several spans. Damage was mainly located on the main girders, with cracks, opening of the concrete surface, and exposure of the steel tendons (or even rupture). Humidity and leakage of the rainwater from the bridge deck was found to be the main cause of the damage.

(a) (b)

Figure 1: The Boirs viaduct, pictures taken during the tests: a) top view; b) bottom view.

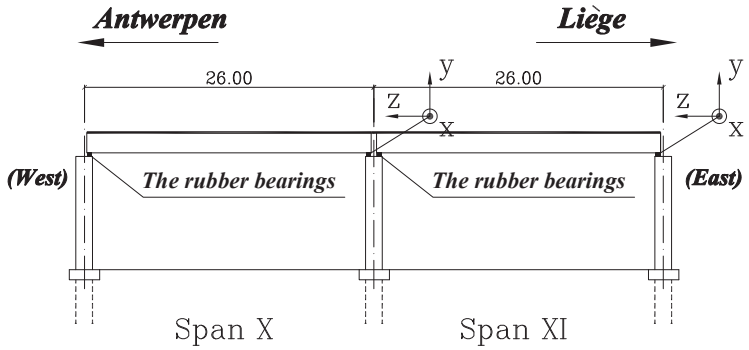

Figure 2: Elevation view of Span X and Span XI (units in meter). Note: the two adjacent Spans were of identical design.

As shown in Fig. 1, there were seven prestressed concrete main girders, simply supported on top of the piers by rubber bearings. The main girders were connected by five transverse trusses. They were assembled by triangle truss components with post-tensioning applied on-site. Extensive ambient vibration tests were performed on one of the mostly damaged spans, labelled as Span X, and the adjacent Span XI, in 2009 and early 2010 before the whole structure was demolished. See Fig. 2. As shown in Fig. 3, each span of the viaduct has similar dimensions

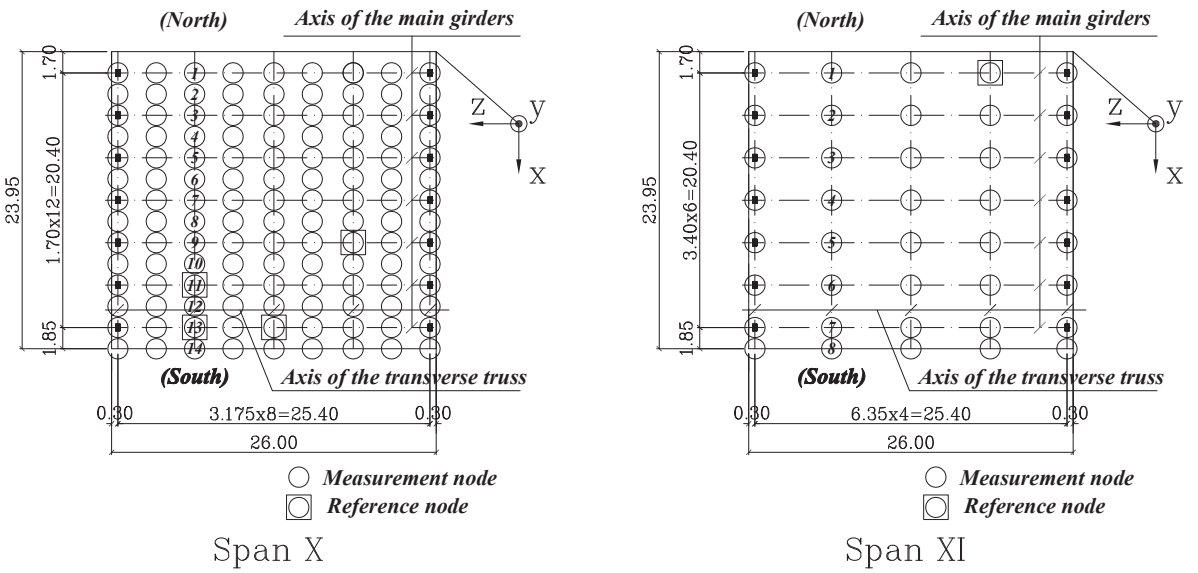

Figure 3: Plan view of Span X and Span XI, with the measurement nodes indicated by circles (units in meter).

in its longitudinal and transverse directions. Hence, the vibration characteristics of the bridge were more close to those of a plate, rather than a simply supported beam.

2.2 Operational modal analysis

Vibration tests of the Boirs viaduct were performed by using either operational modal analysis (OMA) or OMA with eXogenous inputs (OMAX) [18, 19]. Both traditional cabled sensors and latest wireless acquisition system were used to measure the acceleration responses of the deck, while the bridge was under the ambient excitation (e.g., wind and vehicles passing by on the neighbouring viaduct). See, for instance, Fig. 1. Highly reliable experimental modal results were obtained for the Span X, with the very dense sensor grid (9 by 14, equals to 126 nodes) [20]. In detail, nine cross sections of bridge, including those over the supports, were instrumented with fourteen measurement nodes on each. On the adjacent Span XI, operational modal analysis was performed with the less dense sensor grid (5 by 8, equals to 40 nodes) [21]. In detail, five cross sections were instrumented with eight measurement nodes of each. See Fig. 3 for the measurement plan. Both Span X and Span XI were of identical structure. No evident damage was found of Span XI by visual inspection, which was therefore considered almost undamaged. Accordingly, the operational modal data of Span XI could serve as the baseline data for the undamaged state of one span of the viaduct.

The experimental natural frequencies of Span X and Span XI are presented in Table 1. In total, five modes are identified. The corresponding mode shapes are plotted in Fig. 4 for Span X. And those of Span XI were however similar in appearance. Especially, m1 and m5 are not identified for Span XI. It was believed to related to the differences in the testing scheme. Since the number of the measurement nodes exceeds the number of the acquisition channels, the vibration tests had to be divided into several experimental setups concerning the measurement nodes. The incomplete mode shapes identified from each setups were combined lately by considering the predefined reference nodes or the fixed nodes as the basis for linear combination of vectors. For Span X, there were four reference nodes, which were located both at the south side and the middle of the deck, whereas for Span XI there was only one reference node located at

the north edge of the deck. As a result, the experimental modes with the modal displacements mainly on the south side of the deck could not be obtained by the latter scheme, including m1 and m5.

Mode	Span X	Span XI	Vol.(0)	Vol.(d1)	Vol.(d2)	Plate(0)	Plate(d1)	Plate(d2)
m1	5.13	n/a	5.40	5.22	5.13	5.38	5.23	5.16
m2	5.53	5.64	5.64	5.64	5.51	5.65	5.64	5.49
m3	7.83	7.99	7.69	7.65	7.59	7.67	7.62	7.56
m4	12.76	12.99	13.38	13.34	13.32	13.39	13.32	13.25
m5	15.52	n/a	16.99	16.33	16.33	17.04	16.28	16.22

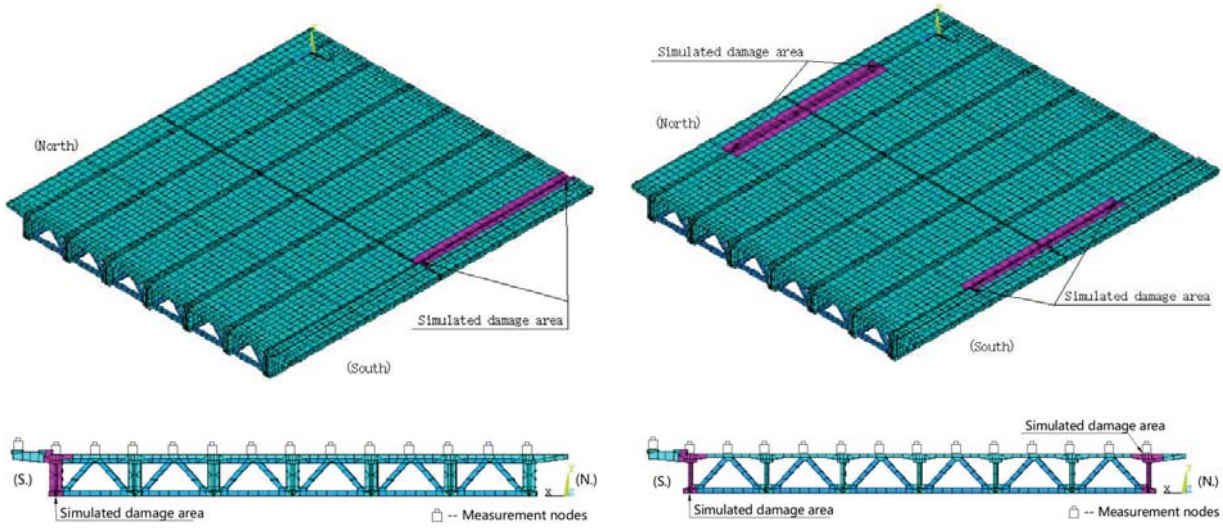
3 NUMERICAL MODEL OF THE BOIRS VIADUCT

3.1 The refined FE volume model

A refined FE volume model of the viaduct was built in ANSYS mainly with eight-node solid elements, known as Solid45. The geometry of the model strictly follows the design drawings. Even the cantilever part of the deck that served as the side walk had been carefully modelled. See Fig. 5. The rubber bearing supports were modelled with 3-D spring elements, known as Link180. The stiffness of the elements was calculated according to the size of the bearing and its material. Linear elastic properties of the materials are assumed in the FE model. See Table 2. There are in total 91,647 nodes, 71,240 elements and 274,899 DoFs in the refined model.

The intention to build the refined FE volume model is to create an accurate baseline model of the structure, in addition to generate simulated damage scenarios. Operational modal data of the undamaged Span XI were taken as the reference for calibration of the refined FE model.



(a) (b)

Figure 5: The refined FE volume model: a) single damage scenario; b) multiple damage scenario. Note: the sensor locations for the measurements on Span X are denoted with symbols on the deck.

Components	E_0(MPa)	E(MPa)	ν	G(MPa)	q(kg/m^3)
Main girder/ Slab	35,000	45,284	0.33	17,024	2,400
Transverse truss	35,000	26,723	0.33	10,046	2,400
	k_x(kN/m)	k_y(kN/m)	k_z(kN/m)		
Boundary spring	5,733	700,000	4,410		

Table 2: Material properties of the refined FE volume model. Note: E for modulus of elasticity, ν for Poisson's ratio, G for shear modulus, q for density and k for equivalent stiffness of springs.

By engineering judgement, the main uncertainties of the FE volume model were the stiffness of the main girders and the transverse trusses. FE model updating was conducted with the Young's modulus E1 and E2 of the main girders (including the slab), and the transverse trusses, respectively, as the updating parameters. Both the residuals of the eigenfrequencies and the mode shapes were included to build the objective function (see the equations below). The three modes, i.e., m2, m3 and m4, identified from Span XI were considered. In a greater detail, the residuals were defined by:

$$\begin{aligned} \varepsilon_{\lambda,i} &= (\lambda_i - \tilde{\lambda}_i)/\tilde{\lambda}_i, \text{ for } i \in \{1,2,...,n_\lambda\} \\ \boldsymbol{\varepsilon}_{\boldsymbol{\phi},i} &= (\boldsymbol{\phi}_i - \tilde{\boldsymbol{\phi}}_i)/\|\tilde{\boldsymbol{\phi}}_i\|_1, \text{ for } i \in \{1,2,...,n_\phi\} \end{aligned} \tag{1}$$

with $\lambda_i = (2\pi f_i)^2$, $\boldsymbol{\phi}_i$ the mode shape vectors, n_λ the number of eigenfrequencies to be considered and n_ϕ the number of mode shape vectors to be considered. Herein, the upper tilde denotes the experimental results and the bold Greek letter denotes a vector. The mode shapes are normalized to the maximum unity with only the real parts being considered. In order to obtain the equivalent magnitude between $\varepsilon_{\lambda,i}$ and $\boldsymbol{\varepsilon}_{\boldsymbol{\phi},i}$, the 1-norm, i.e., the sum of the absolute values of $\tilde{\boldsymbol{\phi}}_i$, had been introduced into the residuals of mode shape. On the basis of the residuals defined

by Eq.(1), the following nonlinear least-squares problem was solved.

$$\min_{\theta} \sum w_{\varepsilon_i}(\varepsilon_i)^2 = \min_{\theta} \boldsymbol{\varepsilon}^T \boldsymbol{W}_{\boldsymbol{\varepsilon}} \boldsymbol{\varepsilon} \tag{2}$$

The initial values of E1 and E2 were taken as 35 GPa and $w_{\varepsilon_i} = 1.$. The problem was solved by the Trust-Region-Reflective Algorithm (lsqnonlin) in MATLAB. The updated values were 45.3 GPa for E1 and 26.7 GPa for E2. Since the trusses were assembled by components with post-tensioning, the updating results were considered to be physically acceptable. The natural frequencies of the updated model Vol.(0) were listed in Table 1.

A single-damage scenario and a multiple-damage scenario were simulated with the calibrated FE volume model. For the single damage scenario, 25% reduction of the Young's modulus was applied to the part of the side main girder at the south edge (Fig. 5(a)). For the multiple damage scenario, the reduction of the Young's modulus was applied to both the middle parts of the side main girders at the north and south edge, but with different amplitudes. In particular, 15% reduction of the north and 25% reduction of the south. See Fig. 5(b). Natural frequencies of the damaged volume models Vol.(d1) and Vol.(d2) are listed in Table 1. The simulated modal data, including also the mode shapes will be used for damage assessment in the later section.

3.2 The simplified FE plate model

A simplified FE plate model of the viaduct was also built by ANSYS mainly with eight-node shell elements (Shell281). The plate model had the same geometry as the bridge deck on the horizontal plane. Each main girder and the adjacent slab was represented with 4 by 19, in total 76 shell elements. See Fig. 6. It was assumed that the plate model had a fixed boundary condition in translational DoFs at the supports. In addition, rotational springs were introduced at the supports to simulate the real constraints of the rubber bearings. Moreover, linear elastic properties were assumed for all the materials in the model.

As the reference model to be updated for damage assessment, the simplified FE plate model should be updated first in order to closely represent the real structure. Since the damage scenarios to be analysed were simulated by the FE volume model, the updating of the plate model took the modal data of Vol.(0) as the target. The model updating procedure followed the same rules as defined in the previous section, except that the dense measurement grid of the five mode shapes as was identified on Span X was considered. In detail, $n_\lambda = 5$, $n_\phi = 5$ in Eq.(1) and $w_{\varepsilon_i} = 1$ in Eq.(2), for which the five modes m1 to m5 as listed in Table 1 were considered. The updating parameters included flexural rigidities D11 and D22, the twisting rigidity D33 and the Poisson's ratio ν of the shell elements. For the cantilever parts of the slab at the north and the south edge, different values of elemental rigidities D should respectively be applied, since the corresponding elements were obviously much more flexible than the others. They were indicated as substructure 1a and 7b in Fig. 6. In addition, the rotational stiffness of the boundary springs was chosen to be updated. In summary, seven parameters were updated for the plate model. The natural frequencies of the updated plate model, which is denoted by Plate(0), can be found in Table 1.

4 ITERATIVE MULTILEVEL UPDATING SCHEME FOR DAMAGE ASSESSMENT

Assessment of the simulated damage scenarios was performed by updating the Plate(0) model as the reference model. As a linear elastic problem to be solved, the structural damage was considered as the reduction of the Young's modulus E in the plate model for the shell

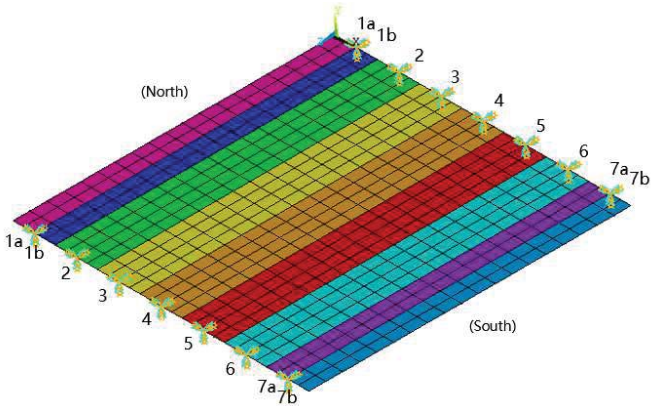


Figure 6: The simplified FE plate model. Note: substructures nr. 1 to 7 correspond to the seven main girders of the bridge.

elements where the damage occurred. The optimization problem as stated in Eq.(2) was solved in order to match the modal data of the plate model as closely as possible to those of the damage scenarios simulated by the volume model.

Modelling errors of the reference model must be addressed carefully, because the optimization method itself could not distinguish the effects of inadequate modelling and the changes of the modal characteristics due to damage. Two approaches have been proposed by the precedent researchers: 1) to update the reference model with respect to the baseline measurement, in order to produce a reliable model (see the previous section); 2) to use the difference between the damage and undamaged modal data in the formulation of the residuals [5]. Herein, the following residuals were considered in FE updating for the damage assessment:

$$\varepsilon_{\lambda,i} = \frac{\lambda_i}{\lambda_{0,i}} - \frac{\tilde{\lambda}_i}{\tilde{\lambda}_{0,i}}, \text{ for } i \in \{1,2,...,n_\lambda\} \tag{3}$$

$$\boldsymbol{\varepsilon}_{\boldsymbol{\phi},i} = \frac{(\boldsymbol{\phi}_i - \boldsymbol{\phi}_{0,i}) - (\tilde{\boldsymbol{\phi}}_i - \tilde{\boldsymbol{\phi}}_{0,i})}{\|\tilde{\boldsymbol{\phi}}_{0,i}\|_1}, \text{ for } i \in \{1,2,...,n_\phi\}$$

where the subscript 0 denotes the undamaged state and again tilde denotes the experimental values or those simulated by the volume model. In order to have the equal amplitude between $\varepsilon_{\lambda,i}$ and $\boldsymbol{\varepsilon}_{\boldsymbol{\phi},i}$, the weighting factors were introduced according to:

$$w_{\varepsilon_\lambda,i} = 1/\sum_i (\varepsilon^0_{\lambda,i})^2, \text{ for } i \in \{1,2,...,n_\lambda\} \tag{4}$$

$$w_{\boldsymbol{\varepsilon}_{\boldsymbol{\phi}},i} = 1/\sum_j (\varepsilon^0_{\boldsymbol{\phi},j})^2, \text{ for } i \in \{1,2,...,n_{\boldsymbol{\phi}}\},\ j \in \{1,2,...,n_{\boldsymbol{\phi}} \times n_{DoF}\}$$

where $\varepsilon^0_{\lambda,i}$ and $\varepsilon^0_{\boldsymbol{\phi},j}$ were obtained from Eq.(3) by replacing λ_i and $\boldsymbol{\phi}_i$ with $\lambda_{0,i}$ and $\boldsymbol{\phi}_{0,i}$, respectively. And n_{DoF} denotes the length of the mode shape vector.

Parametrization of the potential damage was another key issues to be addressed. As an inverse problem, solution of the unknown parameters, e.g., the Young's modulus of the shell elements, through the FE updating procedure was prone to be ill-posed. Modification in stiffness

of two adjacent elements in a FE model has nearly the same influence on the modal characteristics of the structure. As a result, the sensitivity matrix that was calculated between the residuals and the updating parameters was likely to be ill-conditioned, especially when a large number of updating parameters was involved. As a solution, the number of candidate parameters should be reduced by including only those that were more likely to be changed due to damage. Mathematically, it suggests to introduce extract constraints to the optimization problem in order to guarantee an unique, stable and physically acceptable solution. Understanding of the damage mechanism and engineering judgement will play a very important role in this regard.

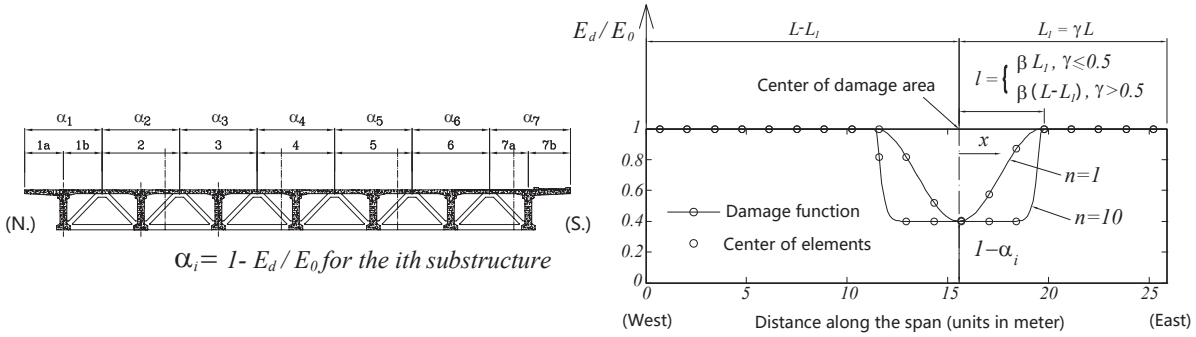

Figure 7: Damage parameterization: the global parameters α_i, and the local parameters β, γ and n for the damaged main girder.

For the current problem, damage parametrization was considered as shown in Fig.7. The reference plate model was divided into seven substructures, labelled from nr. 1 to 7. Each substructure corresponds to one of the main girders. An unique reduction factor α_i of the substructural stiffness, i.e., of the Young's modulus E was applied. This defined the first-level problem, or the global problem to be addressed. Damage localization and quantification of the possibly damaged main girder was the second problem to be solved. Three local parameters β, γ and n were used by following the damage function defined in [6], which helps to characterize a typical damage pattern of a concrete beam. Fig 7 permits the partitioning of the updating parameters into two sets: the global parameters α_i, associated with the global structure and the local parameters β_j, γ_j and n_j, associated with the jth substructure with damage. The optimization problem to be solved however remains unchanged. In detail, the following two-level approach is applied.

First-level (global) Problem. Assuming that the damage area spans across the whole substructure, Eq.(2) is to be solved with the global parameters α_i. It is somehow equivalent to set the local parameters $\beta = 1$, $\gamma = 0.5$ and $n = 100$, or a relatively large number. The damaged main girder is identified by checking $\alpha_i^* > \Delta_d$. Herein, the superscript * denotes the solution and Δ_d is the threshold value.

Second-level (local) Problem. In this stage, Eq.(2) is solved with the local parameters β_j, γ_j and n_j, together with α_j for $j = 1, 2, ..., n_d$, if there were totally n_d substructures identified with damage. Meanwhile, the global parameters α_i, except of α_j for the damaged main girders, remain unchanged. Once the local parameters are found, one proceeds to solve the first-level problem. This process is to be continued until convergence is reached. The iteration can be summarized as follows:

1. Start with an initial local parameter sets such as $\beta = 1$, $\gamma = 0.5$ and $n = 100$ for all the

substructures.

2. Solve the first-level optimization problem by Eq.(2) for the global parameters α_i and find α_i^* and n_d.

3. Solve the second-level optimization problem for α_j and the local parameters β_j, γ_j and n_j, for $j = 1, 2, ..., n_d$ by Eq.(2).

4. Check for the convergence on α_i by $|\alpha_{i,n+1} - \alpha_{i,n}| < \Delta_\alpha(1 + |\alpha_{i,n}|)$ (n for the iteration steps and Δ_α for the step size tolerance).

5. If the process has not converged, go to step 2 but with the newly updated β_j, γ_j and n_j ($j = 1, 2, ..., n_d$) and repeat the process until convergence.

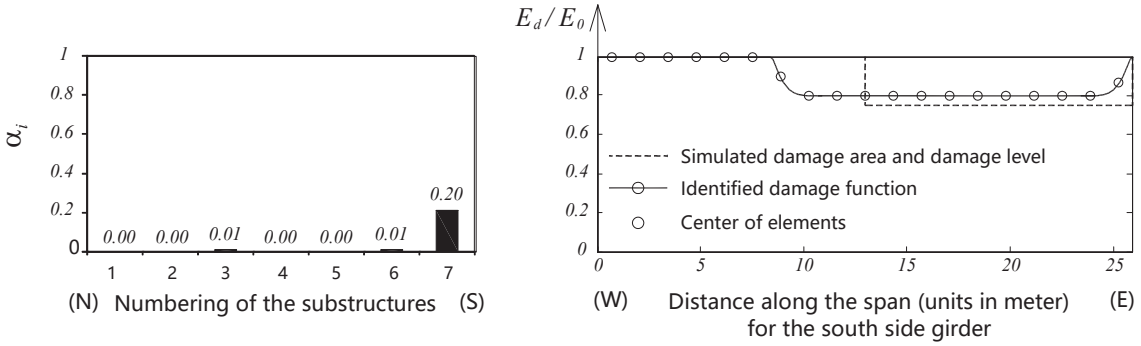

Figure 8: Final solution of the global problem and the identified damage function (the local problem) for the single damage scenario.

The aforementioned multilevel updating scheme was applied to the simulated damage scenario Vol.(d1). The numerical optimization of both the First- and Second-level problems was solved by using the Trust-Region-Reflective Algorithm (lsqnonlin) in MATLAB. Generally, multiple initial points shall be considered in order to obtain the global minimum, instead of the local minimum. Nevertheless, multiple runs could be avoided or at least reduced by choosing appropriate initial points, which should be located in a physically feasible region. In the current case study, use of $\alpha_{i,0} = 0.01$ for the First-level problem leads to the satisfactory result without multiple runs. Similarly, $\beta_{j,0} = 1.0$, $\gamma_{j,0} = 0.5$ and $n_0 = 10$ were considered as the initial values for the Second-level problem. For the substructure identified with damage ($\Delta_d = 1\%$), $\alpha_{j,0}$ took the corresponding solution of α_i^* of the First-level problem. The convergence criteria is on the relative step size with the tolerance $\Delta = 0.1\%$ for lsqnonlin and $\Delta_\alpha = 1\%$ for the multilevel scheme. The modal data of the five modes, m1 to m5 (see Table 1) were used to formulate the objective function of Eq.(2) with the residuals of Eq.(3) and the weighting factors of Eq.(4). Their mode shapes are similar in appearance to the experimental results in Fig. 4. The dense measurement gird of Span X was considered. The updating scheme stopped after three iterations, i.e., First-level, Second-level and then First-level. The respective iteration numbers of the individual problems were 10, 8 and 5. The natural frequencies of the updated plate model are listed in Table 1, denoted by Plate(d1). The final solution of the problem is shown in Fig. 8. The damage function for the south side girder was plotted with the simulated damage area and

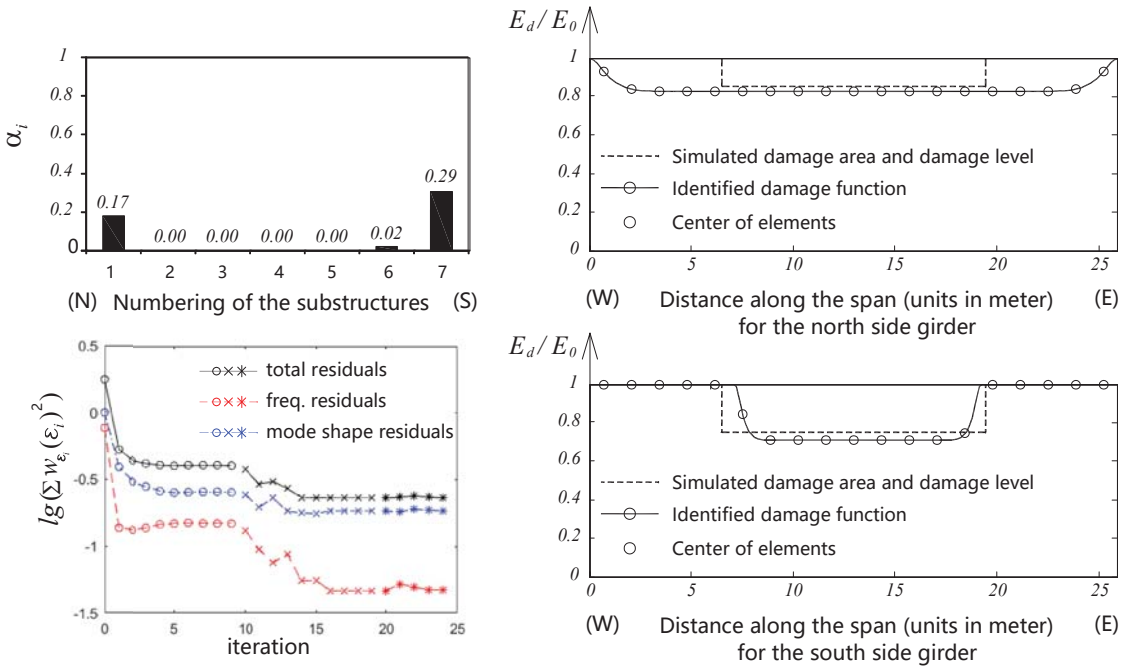

Figure 9: Final solution of the global problem and the identified damage function (the local problem) for the multiple damage scenario, with the convergence plot of the squared norm of the residuals (left below).

damage level. Evidently, the damage location has been identified almost correctly, even though the damage level was a little underestimated.

While applied to the multiple damage scenario Vol.(d2), the multilevel updating scheme used the same settings as previously, except that the threshold of damage $\Delta_d = 2\%$. The natural frequencies of the updated plate model can be found in Table 1, denoted by Plate(d2). The solution of the global and local problems are shown in Fig. 9. The two side girders were correctly identified as the damaged ones. On the south side girder, the damage location was almost properly characterized by the damage function. In comparison, on the north side girder the damage location was overestimated. On both sides, the damage levels were slightly overestimated. It may be explained by the inadequacy of the measurement nodes and the inaccuracy of the reference model. As shown in Fig. 5, the additional sensor array was placed on the cantilever part of the south side (on the side walk). Accordingly, more information about mode shape changes were available on the south side girder, as the objective function was more sensitive to damage on the south side than the north side. In Fig. 9, the convergence plot was also presented. The final solution was achieved after the First-level problem with 10 iterations, the Second-level problem with 10 iterations and the First-level problem with 5 iterations. Both the frequency residuals and the mode shape residuals were mostly smoothly reduced by iterations before the final solution.

5 DISCUSSION

On the basis of the presented case study, several issues related to FE model updating for vibration-based damage assessment of the bridge could be addressed. First, evaluation of the objective function was the most time consuming part during the computation. Since the solution used a gradient-based method, numerical modal calculation by ANSYS had to be repeated with multiple times in order to return the Jacobian matrix. It was found that use of the simplified

plate model greatly improved the computational efficiency. For instance, for each iteration the time consumed for modal analysis of the plate model was around 11 seconds from a Laptop with Intel-Core i5 and 4G Ram. In comparison, that of the volume model was more than ten times on the same device.

Secondly, to formulate the residuals directly on the mode shapes as Eq.(3) rather than the calculated MAC values significantly improved the sensitivity of the objective function to damage. In the current case study, the mode shape residuals have the length of $126 \times 5 = 625$, equals the number of the measurement nodes multiplied by the number of the modes. It is found that the MAC values calculated between the Vol.(d2) and Plate(0) were mostly greater than 0.95 for the five modes. After the updating, they were slightly improved by only around 0.01.

Thirdly, the condition numbers were calculated for the Jacobian matrix $\mathbf{J}$ at the solution points for both the First- and Second-level problems. It is defined as the ratio of the maximum singular value to the minimum singular value of the matrix. For the multiple damage scenario, in the global problem the maximum and the minimum singular values were, respectively, 11.58 and 2.05, of which the ratio was 5.64. In comparison, in the local problem the maximum and the minimum singular value were, respectively, 9.45 and 0.10, of which the ratio was 90.77. The lower the value, the better the conditioning of the Jacobian matrix. Therefore, the local problem is much poorly conditioned than the global problem. It suggests the benefits of the multilevel scheme. By considering the specific structure of the current optimization problem, the division of the variables into global and local variables will improve the robustness of the numerical optimization by solving them separately.

6 CONCLUSIONS AND FUTURE PERSPECTIVES

Based on extensive vibration measurements of the Boirs viaduct, a realistic case study for vibration-based damage assessment using FE model updating is presented. Two damage scenarios were simulated by a refined FE volume model which had been calibrated according to the baseline measurement of an undamaged span. A simplified plate model was taken as the reference model for updating. The multilevel updating scheme leads to the satisfactory results for both the single-damage and multiple-damage scenarios. Further improvement and future work however remain to be done. The influence of the measurement errors has not been investigated in the case study. Moreover, application of the algorithms has to be extended for the real damage on Span X of the Boirs viaduct.

Abstract. *Structural health monitoring is a vastly manual process that is both costly and time intensive. Implementation of distributed Internet of Things (IoT) sensor networks posits a robust alternative to current discrete-time monitoring techniques. Furthermore, IoT systems allow for long-term analysis to occur in real-time. However, existing IoT solutions for structural health monitoring do not account for remote sensing and often operate under the constraint of a readily available wireless connection. Thus, Wi-Fi-based solutions may not be conducive to remote applications. This study proposes an OpenThread mobile LTE Mesh Network using the Particle IoT development environment. The proposed development platform, in combination with a suite of distributed sensors, allows for the identification of structural degradation in critical infrastructure. In the study carried out herein, piezoelectric sensors are used to determine key salient factors contributing to the decline of overall structural health, particularly that of Canadian bridges and can be adapted for use with MEMS accelerometers or embedded Fiber Bragg gratings. The presented framework is validated through experiments on elastomeric bridge bearings, and is expected to demonstrate real-time, high-fidelity monitoring of critical structural components through a robust mesh network, especially for infrastructure located in remote areas.*

1 INTRODUCTION

Over the past several decades, Canada has experienced accelerated aging of public infrastructure, particularly of crucial transportation arteries, bridges, and trade routes. Of these transportation assets, 40% have been estimated to be in poor condition in comparison to Canadian infrastructure developed over the last 20 years [15]. Specifically, the Gardiner Expressway – a large commuter road connecting the Greater Toronto Area (GTA) with Metropolitan Toronto – is responsible for immeasurable disruptions to commuter vehicles due to persistent retrofitting and repairs [5]. As Canadian transportation infrastructure continues to age and become a hazard on the Canadian public, on-going monitoring and inspection requirements are expected to become more substantial and stringent.

Robust analysis of Canadian infrastructure is – at present – constrained by the periodicity of on-site inspections, and the quantity of aggregate sensor data. Furthermore, the hindrance on the Canadian public is two-fold; as Canadian bridges continue to age, the material consequences manifest as financial and service disruptions to Canadians. Over the next 10 to 11 years, the Canadian government endeavours to mitigate the risk associated with the decline in the condition of its roads and bridges, through the investment of over $180 billion dollars towards advancing Canadian transportation infrastructure [10].

Innovation in real-time Structural Health Monitoring technologies in Canada is stagnant due to constraints pertaining to cost, scalability, and communication protocols (i.e. Wi-Fi, RF, WLAN, or Bluetooth) [1][3][6][11]. Furthermore, innovations in Structural Health Monitoring may benefit from a holistic approach to its design; as such, many existing SHM systems are suited for specific applications and are seldom universally applicable. The study carried-out herein provides a high-level framework for autonomous, real-time monitoring of critical bridge components (i.e. elastomeric bearings). The system architecture is validated experimentally through the instrumentation of elastomeric bridge bearings but can be adapted to suit the needs of alternative applications. The SHM system identified in this study endeavours to address the following objectives through its development:

1. Autonomous, real-time monitoring of critical bridge components through an LTE-based OpenThread Mesh Network;
2. Implementation of real-time Convolutional Neural Networks for robust classification and feature identification of sensor data;
3. Design of a real-time Human-Machine Interface (HMI) for data visualization at an end-user level.

This study addresses the first objective and provides a framework for the overall approach employed in this project; a path for which future developments can be made.

2 THE INTERNET OF THINGS

2.1 Overview

The Internet-of-Things (IoT) comprises all systems composed of autonomous, interrelated devices that communicate via a wireless network. IoT-devices seldom require much human or third-party input, and hence pose promising implications for developments in real-time SHM technologies. At a high-level, IoT systems are defined as the interconnection of wireless sensor nodes with a network gateway (i.e. Wi-Fi, RF, WLAN, Bluetooth, 4G LTE, LTE-M, 5G, etc..), and a network gateway with a cloud service (Figure 1) [3]. IoT systems are typically designed to carry-out tasks that may otherwise *not* occur in real-time. Current monitoring and inspection processes of critical transportation infrastructure is vastly manual, time-intensive, and expensive. The implementation of IoT systems in the context of SHM may alleviate the financial

burden associated with outdated approaches in infrastructure monitoring and is a robust tool for use in risk and hazard mitigation.

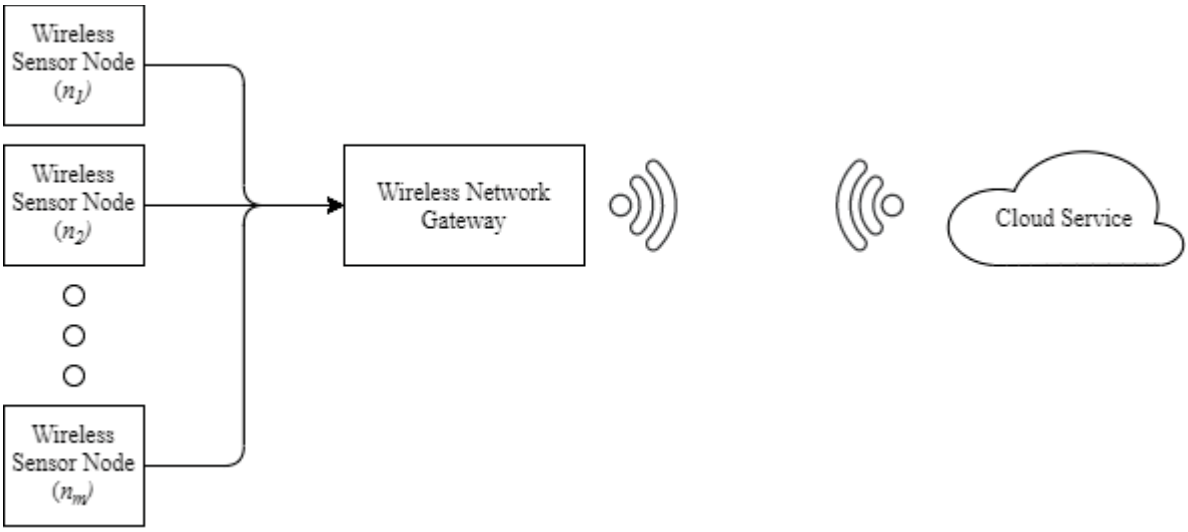

Figure 1: General IoT Architecture

2.2 Shortcomings in Existing SHM Systems

There exists a paradigm-shift in the development of Structural Health Monitoring technologies that is largely driven by the emergence of robust IoT systems. Modern SHM subscribes to a divergence from manual monitoring and inspection processes, and places emphasis on an investment in autonomous, real-time, and wireless replacements.

Network Type

To their detriment, existing solutions in real-time SHM are widely dependent on Wi-Fi or WLAN communication protocols. These networks require substantially more power than their modern counterparts and can provide far less coverage in remote locations where a high-fidelity network may not be readily available. With bandwidth discrepancies becoming narrower between communication protocols, Wi-Fi is no longer as advantageous for use in SHM systems as it may have been in previous decades. LTE networks provide a low-power alternative to Wi-Fi/WLAN with similar bandwidth capabilities, and thus are a compelling alternative for use in SHM systems [2].

Sensor Node Communication

Intercommunication between wireless sensor nodes is *not* ubiquitous among existing IoT systems due to the nature of their network topologies. Star network topologies have substantial penetration in the field of SHM due to their ease of implementation, but are limited by their range of operability, and power requirements. Furthermore, in many applications where star topologies are used, there exists a single point of communication between sensor nodes and the network gateway. This poses limitations not only on the operating range of the SHM system, but on applications where redundancy between sensor nodes is required [8].

Until recently, mesh topologies remained somewhat esoteric in their design and implementation in SHM applications. Mesh networks are an emerging topology in the realm of IoT, that have yet to see extensive application-driven realizations in structural health monitoring. Mesh topologies provide a favorable alternative to traditional SHM systems, most of which are constrained by their security, operating range, and scalability. The mesh network framework

identified herein provides a scalable alternative to existing SHM technologies and aims to address emerging nuances in the field of real-time infrastructure monitoring.

3 MESH NETWORK ARCHITECTURE

3.1 Advantages of a Mesh Network

Mesh network topologies have comparatively less market penetration in the realm of structural health monitoring on account of their once nebulous implementation. The emergence of cost-efficient, high-fidelity mesh development platforms is particularly advantageous for use in industrial structural health monitoring systems. An industrial mesh network poses promising solutions to nuances arising in real-time SHM, particularly in the context of network security, range of operability, and scalability. The framework identified herein was validated through instrumentation of elastomeric bridge bearings.

Network Resilience: Self-Healing and Self-Formation

In traditional wireless sensor network topologies, a single point of communication is established between a sensor node and a network router or gateway. If the connection between a sensor node and the network gateway or router is interrupted, the node may remain offline until human intervention is established. Self-healing capabilities of mesh topologies are two-fold; (1) the network may re-establish the connection to offline nodes, and (2) the network may re-route or reconfigure itself through another router or node in the network so-as-to establish the most reliable connection [11][16]. The ability of a mesh topology to redirect network traffic and data streams is crucial for remote SHM applications, where routine maintenance is infeasible. In general, self-healing algorithms are comprised of three stages:

1. Disconnection – a node is disconnected or removed from the network due to an interrupted connection.
2. Detection – neighbouring nodes in the mesh detect the removal of the node from the network.
3. Reconnection – neighbouring nodes reconnect to the nearest stable nodes in the mesh.

If a node is inserted into the mesh, the network may re-establish its connections in a similar fashion known as self-formation.

Range of Operability and Signal Strength

In mesh topologies, sensor nodes may be configured to behave as repeaters; furthermore, sensor nodes may establish and share a connection between each other to improve the range of operability within a network. Infrastructure monitoring systems have a tendency to span large distances. Specifically, structural health monitoring in the context of bridges necessitates a system with a broad range of operability; hence, such systems may benefit from a network that can operate reliably across long distances. Figure 2 identifies a four node, one gateway mesh network. The four sensor nodes reside within the signal range of the network gateway. In traditional non-mesh wireless sensor networks, if a node is inserted outside of the gateway's range of operability, a connection will not be established. In the case of a mesh network, an inserted node may establish a connection with other sensor nodes, so long as it is in range of a sensor node's shared connection. The inserted node may join the mesh and extend the signal range for subsequent nodes to join the network [9][13].

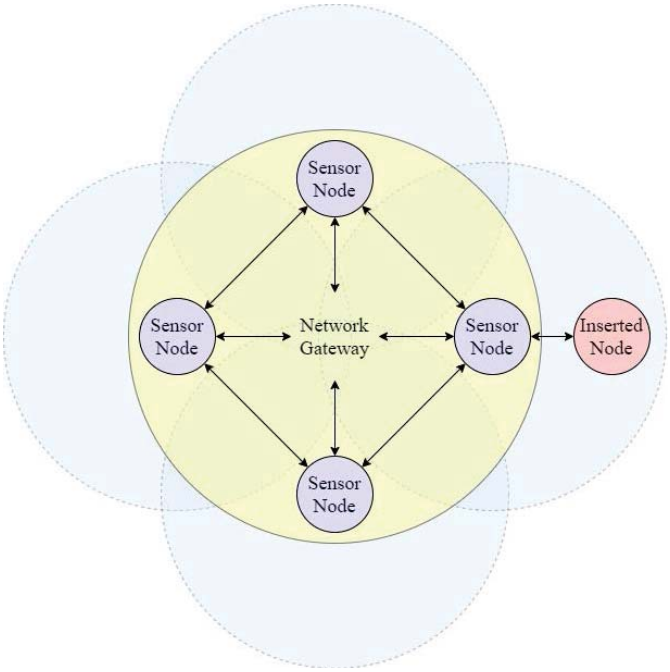

Figure 2: Signal Repeating in Mesh Topologies

3.2 Mesh Framework

The mesh framework identified in this study was founded on the open-source implementation of Thread®, a mesh protocol that facilitates intercommunication between IoT-enabled devices. OpenThread implements all network layers of the Thread protocol (identified in Figure 3), and provides a portable, low-power alternative to traditional non-mesh systems. OpenThread mesh networks support MAC-secure IEEE 802.15.4, a radio frequency communication protocol that enables low-power, short-range interactions between devices. The IEEE 802.15.4 protocol forms the basis for communication between sensor nodes in the overall mesh framework illustrated in Figure 4 [17][18].

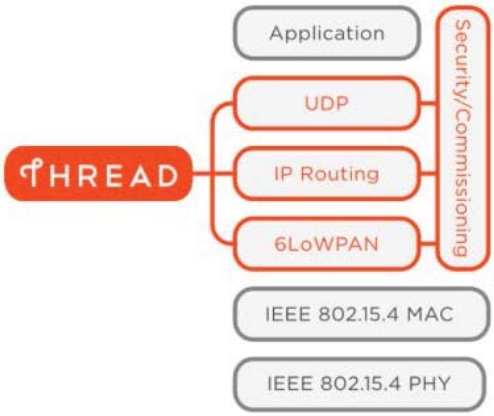

Figure 3: Thread Mesh Framework

The system identified in this study was developed on the LTE-M enabled Particle development platform. The network gateway device utilizes a multi-band LTE Cat M1 modem that enables the mesh to communicate data streams on the nearest cellular network. This is

particularly advantageous in remote applications, where access to a reliable wireless connection may not be readily available. The particle development platform comprises a suite of nodes, routers, and gateways that establish connections with each other via System-on-Chip (SoC) Bluetooth, and proprietary RF communication protocols. The system designed for use in this study is illustrated – in its totality – in Figure 4.

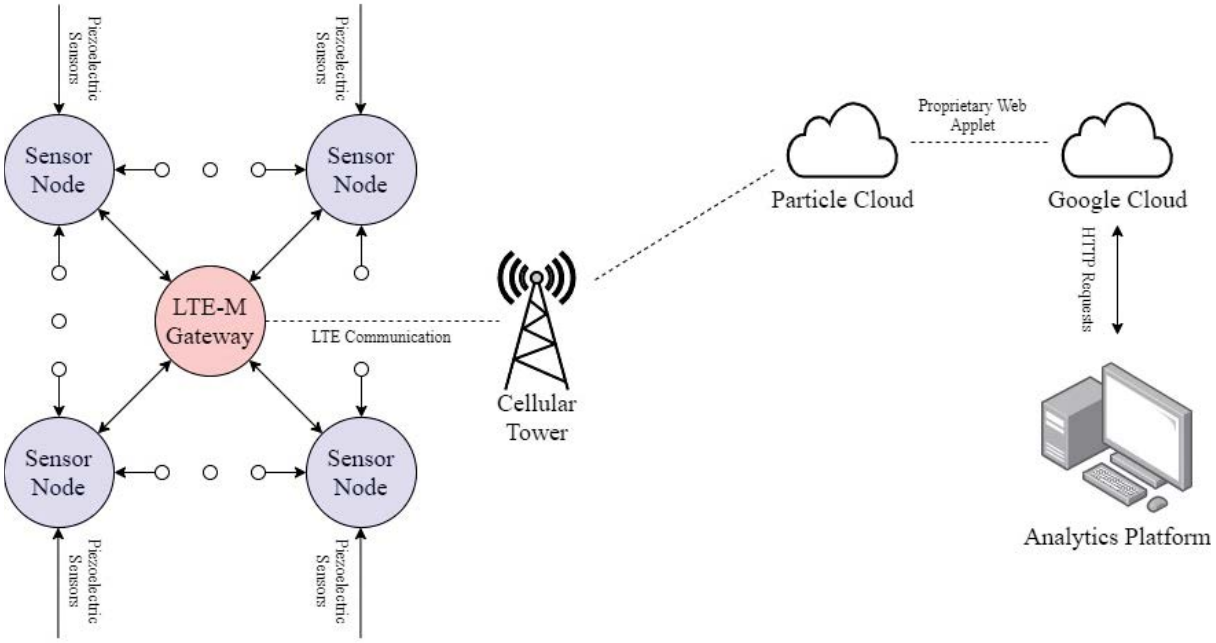

Figure 4: System Architecture

4 EXPERIMENTAL VALIDATION

4.1 Experimental Setup

For demonstrative purposes, a single node single gateway mesh network was established. An elastomeric bridge bearing was instrumented with four Polyvinylidene Fluoride (PVDF) membrane piezoelectric (PZT) sensors. When compressed, the PZT sensors produce a small voltage. To be provided as analog input to the sensor node, a conditioning and level shifting circuit was required. The top-level interconnection between PZT sensors, conditioning circuitry, and sensor node is identified in Figure 5. Per the setup identified in Figure 6, four piezoelectric sensors were placed along the surface of the elastomeric bridge bearing to measure the force (in kN) applied. For demonstrative purposes, a linearly increasing force of up to 20 kN was applied to the elastomeric bearing. It should be noted that these forces are *not* representative; the force applied was limited so-as-to not inflict deliberate damage on the bearing.

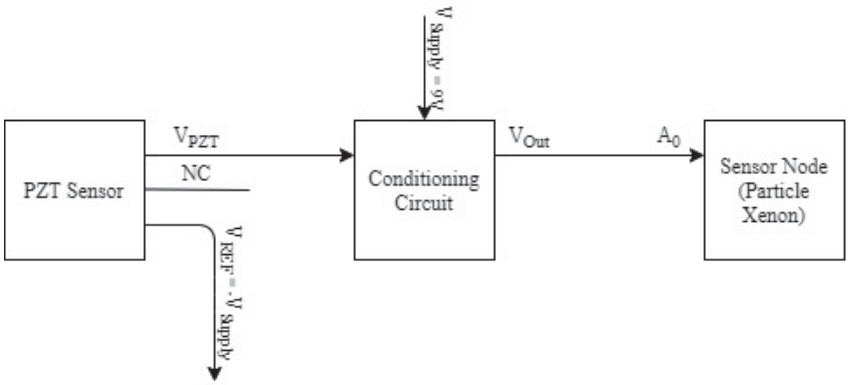

Figure 5: Top-level Sensor Conditioning Block Diagram

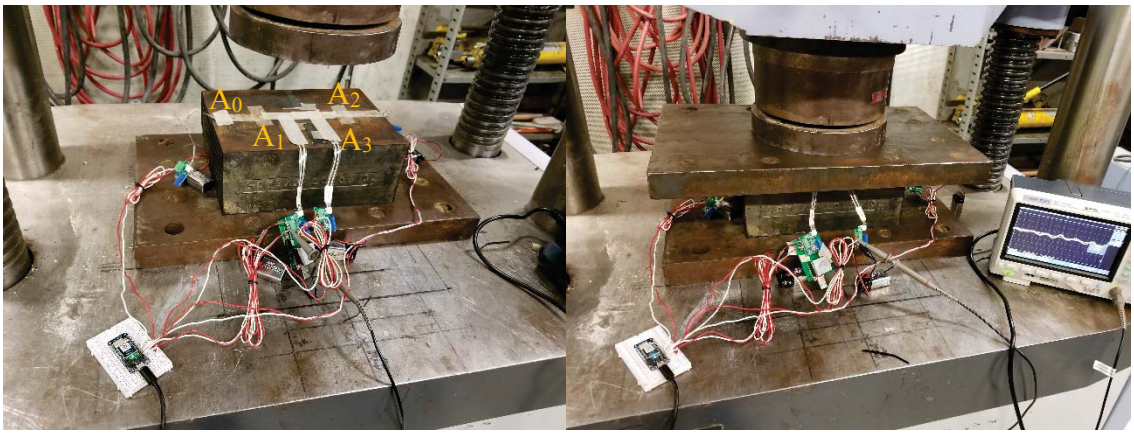

Figure 6: Experimental Setup

4.2 Analysis Methodology

Calibration and Level Shifting

Each sensor was subjected to a 20-point calibration prior to testing. A linear regression was performed to identify the relationship between the response of the sensors (post analog-to-digital conversion) and the applied force in newtons. Due to uneven compression of the sensors from inaccuracies in the distribution of the force applied, sensor pairs A_0 and A_1, and A_2 and A_3 were averaged. An analysis of the high frequency noise intrinsic to the raw signal was performed as a means to identify a model for real-time filtering.

Due to the nature of the SHM system described herein, the convolution of a linear time-invariant (LTI) filter was not sufficient. Data shall not be subjected to analysis at discrete intervals; rather, the data shall undergo real-time analysis. The analysis described herein provides the framework for the design of a linear time-varying filtering model, for use in pre-processing sensor data.

Outlier Identification

Outliers were identified and replaced in the raw data to improve linearity in the response of the sensor data. Outliers were determined through application of a 35-point moving window. Data points that were outside 3 standard deviations of the 35-point moving average were identified as outliers (i.e. datapoints that do not reside within a 99.7% confidence interval).

Preliminary outlier identification was validated through comparison of the Mahalanobis distance with a critical value determined by the chi-square distribution, with 0.3% significance. The Mahalanobis distance is defined as:

$$D_M(x) = \sqrt{(x - \mu)^T S^{-1} (x - \mu)} \tag{1}$$

Where D_M is the computed distance for observations in the dataset, x is the array of observations, μ is the sample mean within the set of observations, and S^{-1} is the inverse of the covariance matrix. Outliers were subsequently determined by computing the cumulative probabilities of the Mahalanobis distances using the chi-square distribution:

$$1 - \varphi(D_M(x), k) \leq 0.03 \tag{2}$$

Where φ is the cumulative distribution function of the chi-square distribution, evaluated for the Mahalobis distances with k degrees of freedom (equal to the number of variates examined in the dataset) [8].

Pre-filtering

An 11-point moving average filter was applied to the dataset to separate the high-frequency noise components from the signal. The moving average filter was defined by:

$$S_{out}[n] = \frac{1}{N} \sum_{i=0}^{N} S_{in}[n - i] \tag{3}$$

Where N is the size of the filter's window, n is sample size, and i is the current data point within the moving window [14]. Note that as the magnitude of the noise intrinsic to the piezoelectric sensor response is increased, the size of the window applied may vary; furthermore, this method is employed for preliminary noise separation only.

High-Frequency Noise Separation

High-frequency noise components of the input signal were separated from the filtered data, by subtracting the filtered data from the raw signal, i.e.:

$$Noise[n] = S_{in}[n] - S_{out}[n] \tag{4}$$

Distribution of Noise

Probability plots were generated to estimate the distribution of high-frequency noise present in the raw sensor data and goodness-of-fit statistics were determined through application of a chi-square test, i.e.:

$$\sum_{i=1}^{k} \frac{(n_i - e_i)^2}{e_i} < C_{1-\alpha,f} \tag{5}$$

k is the number of intervals in the data, n is the observed frequency for k intervals, e is the theoretical frequency of the assumed distribution, and C is the critical value in the chi-square distribution [4].

4.3 Results

Descriptive Statistics

An observation of 1709 data points were sampled from the piezoelectric sensors and were compiled for analysis. No statistical outliers were determined and thus all data points were retained. Descriptive statistics were generated for each of the sensors and are identified in Table 1.

Sensor	Sample Mean (N)	Standard Deviation (N)	Skewness	Kurtosis
Avg (A_0, A_1)	$1.28x10^4$	$4.18x10^3$	-0.1370	1.8644
Avg (A_2, A_3)	$1.27x10^4$	$4.20x10^3$	0.0617	1.8031

Table 1: Raw Data Descriptive Statistics

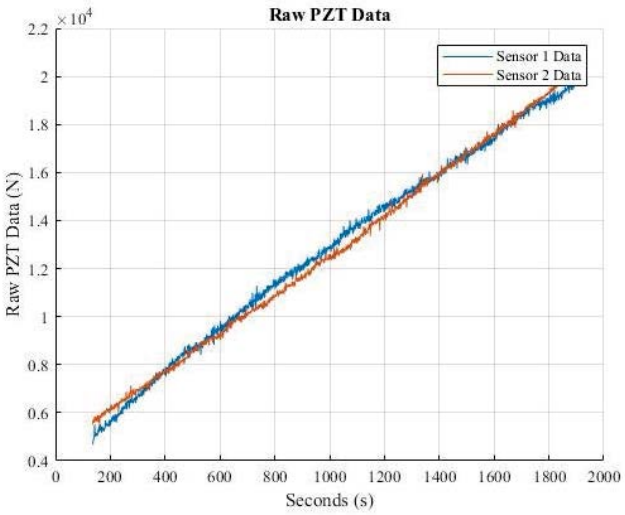

Figure 7: Raw Piezoelectric Sensor Data

Moving Average Filter

Post-application of the moving average filter, descriptive statistics of the filtered data remained within a margin of error of the raw data. The noise-filtered data is identified in Figure 8.

Sensor	Sample Mean (N)	Standard Deviation (N)	Skewness	Kurtosis
Avg (A_0, A_1)	$1.30x10^4$	$4.04x10^3$	-0.1283	1.8600
Avg (A_2, A_3)	$1.29x10^4$	$4.09x10^3$	0.0619	1.8000

Table 2: Filtered Data Descriptive Statistics

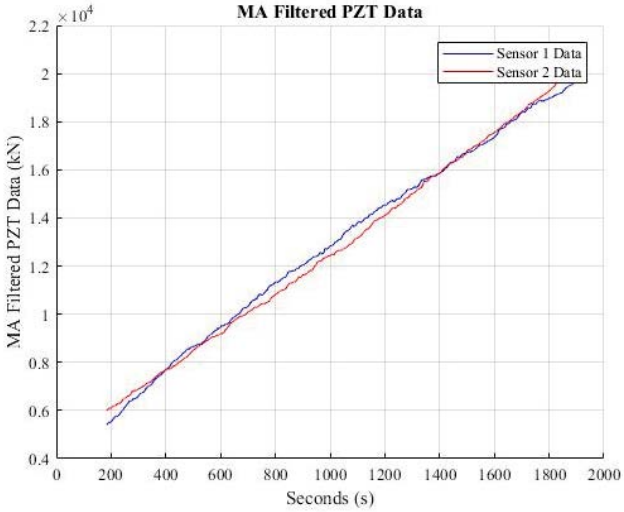

Figure 8: Filtered Piezoelectric Sensor Data

Distribution of Noise

Per the chi-square goodness-of-fit statistics, the null hypothesis is accepted for normally distributed noise, with a significance level of $\alpha = 5\%$. Values within the distribution of high-frequency noise are both positive and negative. For this reason, Rayleigh and lognormal distributions were not tested, as the characteristics of the noise intrinsic to the PZT sensors violates the non-zero, positive nature of these distribution types. The null hypothesis is accepted; the distribution of high-frequency noise is consistent with that of a normal distribution with 95% certainty. The results of the chi-square goodness-of-fit test for an assumed normal distribution are shown in Table 3:

Sensor	DOF	α	$C_{1-\alpha, f}$	X^2
Avg (A_0, A_1)	7	0.05	14.0671	13.2504
Avg (A_2, A_3)	7	0.05	14.0671	12.5474

Table 3: X^2 Goodness-of-Fit Statistics

The chi-square goodness-of-fit statistics for each sensor are below the threshold point indicated by $C_{1-\alpha, f}$, and hence, the null hypothesis is accepted.

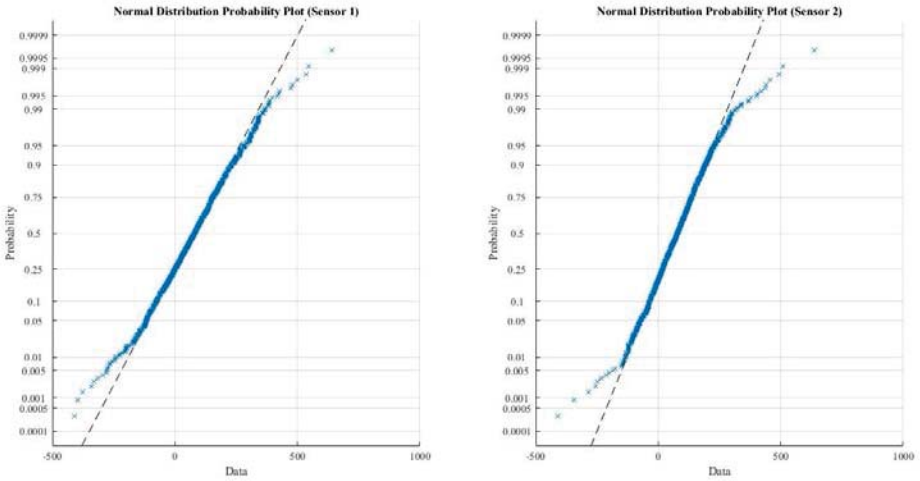

Figure 9: Normal Distribution Probability Plots

Wiener Filtering

Due to the Gaussian nature of the high-frequency noise present in the raw piezoelectric sensor signal, a 1-D linear time-varying Wiener filter was selected for use in this application [7]. The descriptive statistics of the resulting signal are similar to those computed for the moving average filter; furthermore, the difference in signal quality is indiscernible. For the purposes of real-time analysis, a Wiener or moving average filter can be applied in data pre-processing.

Sensor	Sample Mean (N)	Standard Deviation (N)	Skewness	Kurtosis
Avg (A_0, A_1)	1.30×10^4	4.04×10^3	-0.1276	1.8600

Monte Carlo Simulations

The signal conditioning methodology described in this study was validated through the iteration of ten thousand Monte Carlo Simulations. These simulations were performed for the addition of programmatically generated Gaussian noise to the original Wiener-filtered signal. A sample of a single iteration of the Monte Carlo simulation, with programmatically generated noise added to the original Wiener-filtered data, is shown in Figure 11. The signal was subsequently subjected to Wiener filtering, the results of which are identified in Figure 12. It was noted that the Wiener filtering algorithm is consistent for gaussian additive noise across all iterations of the Monte Carlo simulation; thus, the chosen filtration methodology is efficient in the removal of gaussian intrinsic to the piezoelectric sensors and is suitable for use in data pre-processing in preparation for deep learning. The mean error across all simulations was 41.3 Newtons or 0.21% of the maximum value in the target signal.

Frequency Spectra Analysis

The efficacy of the chosen filtration methodology was further validated through analysis of the power spectral density (PSD) of each sensor signal. A comparison of each signal's PSD is performed pre and post filtration to determine the extent by which the chosen methodology eliminates high-frequency components from the target signal. It is noted in Figure 13 and Figure 14, the high-frequency n^{th} order harmonics are successfully eliminated from the target signal.

5 CONCLUSION AND FUTURE WORKS

The study described herein explores the capabilities and efficacy of OpenThread mesh networks for real-time Structural Health Monitoring (SHM). Through experimental validation on elastomeric bridge bearings, it proposes a linear-time varying filtration model that is applied for pre-processing data for deep learning. The applicability of the proposed approach is investigated experimentally, through the instrumentation of elastomeric bridge bearings subjected to compressive loads. Probability plots and chi-square goodness-of-fit statistics were generated for raw piezoelectric sensor data to estimate the distribution of high-frequency noise intrinsic to the signal of interest. The chosen filtration and signal conditioning methodology was validated through 10000 Monte Carlo Simulations. The simulations were used to identify the efficacy of the chosen filter design for signals with random samples of gaussian noise superimposed on the signal of interest. The results suggest that the LTE-M mesh network identified in this study is a robust tool for long-term and real-time monitoring of elastomeric bridge bearings and provides an alternative for bridge infrastructure located in remote areas, where the use of Wi-Fi/WLAN networks is infeasible.

The proposed network design identified in this study provides a foundation for future developments, including the development of deep learning models for feature identification and classification of real-time data. Future work will examine the efficacy of Convolutional Neural Networks – an emerging deep learning architecture in the field of SHM – for use in pattern recognition, feature identification, and predictive modelling, with the aim to advance infrastructure monitoring capabilities in Canada. Furthermore, with Canada's increasing interest in structural health monitoring and the revitalization of its aging infrastructure, the framework identified in this study poses a compelling solution to intermittent, manual, and time-intensive inspection processes that are currently available.

Keywords: On-board measurement, High-speed railway, bridge resonance, track irregularity

Abstract. *The resonance occurring when the excitation frequency of a running train coincides with the frequency of a bridge may considerably affect the safety and comfort of high-speed railway bridges. In Japan, train speed limits have been introduced in bridges operating for over 20 years because the resonance with their frequency has deteriorated. Their detection and monitoring by comprehensive and high-frequency measurements without the need to install sensors are important on many railway bridges. This study proposes a novel and efficient drive-by resonant bridge detection method using two track irregularity measurement devices that are already installed on some commercial high-speed trains. The proposed method enables the estimation of the resonance-induced bridge amplified response by comparing the two track irregularities measured on the first and last train vehicles. The simulation results confirm that the amplified bridge vibration between the passage of the last and first vehicles is accurately detected by the proposed method. In the field tests, the proposed method is applied to two track irregularities measured on the first and last vehicles of a train. The amplified bridge vibration of the resonant bridges validated by in-situ measurements is then detected using the proposed drive-by method.*

1 INTRODUCTION

Resonance inducing a large amplitude vibration of a railway bridge is an inevitable issue in modern high-speed railways [1]. Resonance occurs when the excitation frequency of a running train matches the bridge frequency [2]. The excitation frequency of a running train is determined by the regular wheelset arrangement of its vehicles and the traveling speed. Therefore, resonance is an important issue when the increase of excitation frequency with the acceleration of a high-speed train coincides with the bridge frequency [3]. Moreover, resonance may become an important issue when the bridge frequency decreases because of deterioration and crack propagation associated with aging [4].

Detecting the resonant bridge and measuring the displacement and/or acceleration from the ground are important to confirm the bridge safety and usability at resonance [5]. However, bridges requiring inspection are numerous and involve high human and economic burden for individual ground measurements.

Therefore, efficiently and comprehensively inspecting many railway bridges in one run becomes possible if the condition of high-speed railway bridges can be estimated through on-board data measured by running trains. Moreover, implementing inspections at a high frequency is achievable if using a commercial train is feasible. Therefore, developing a method for evaluating the resonant state of bridges using on-board measurement data for efficient detection and management of resonant bridges is important.

This study introduces a novel drive-by detection method for resonant bridges using the track irregularity data measured on the first and last vehicles in a commercial train on a high-speed railway.

Hester and Gonzales [6] indicated that almost no drive-by bridge performance evaluation method is available for high-speed railways with the train passing through bridges at stages. The fact that a resonant bridge [1–4] in a high-speed railway, which is indirectly but closely related to the bridge performance, is detected by on-board measurements represents the novel and unique engineering contribution of this study. Although many studies involved numerical simulations only, the effectiveness of the proposed method is demonstrated herein by detecting a resonant bridge based on the measured track displacement of a high-speed railway and on-site bridge measurements. This also is another original contribution of this study.

2 DETECTION METHOD

We propose a method for detecting resonant bridges based on the track irregularities measured on the first and last vehicles of a running train. This method assumes that a track irregularity measurement system [7] for commercial trains is present in some high-speed railways in Japan. Details of the instrument and the measurement accuracy are provided in [7]. The track irregularity mentioned herein refers to the track displacement or rail profile, including the bridge's static and dynamic displacement response.

The track irregularity measured at different points in time (two points in a train) includes the bridge's dynamic response, rail irregularities other than the bridge's response, and track structure displacement. Assuming that the track irregularities are unchanged when measured at two points in time, these components are offset by the difference in the two track irregularities measured at different positions, with these converted into functions of the positions. Conversely, when the dynamic response component of a bridge changes (amplifies) as the train passes, only the dynamic response component of the bridge is extracted by the processing difference even if the track irregularity is at the same position.

2.1 Dynamic response of a resonant bridge observed from a moving point

Now, let us consider a case where a concentrated load series at a fixed interval corresponding to a vehicle length L_c runs on a bridge with a span length L_b at a resonance speed v_{res}. Sufficient concentrated loads are assumed to have passed, and a steady state is assumed to have been attained. Here, if the position x_p is a concentrated load and the fundamental frequency of the bridge is f_1, Eq. (1) is satisfied.

$$f_1 = \frac{v_{res}}{L_c} = \frac{x_p}{L_c t} \tag{1}$$

The dynamic response component $z_{b,d}(x,t)$ of the bridge at a position x $(0 \le x \le L_b)$ and time t on the bridge is given by Eq. (2).

$$z_{b,d}(x,t) \approx \xi_{1,d}(t)\sin\left(\frac{\pi x}{L_b}\right) \tag{2}$$

Based on the steady-state assumption, the modal displacement $\xi_{1,d}$ satisfies Eq. (3).

$$\xi_{1,d}(t) = A_{res}\sin(2\pi f_1 t + \theta_{res}) \tag{3}$$

The term A_{res} represents the dynamic response amplitude under the steady state of the resonance. From the resonance condition, $\theta_{res} = \pi(1 - L_b/L_c)$. Equation (4) is obtained by substituting Eq. (3) in Eq. (2) and focusing on the dynamic response $z_{b,d}(x_p)$ of the bridge at the moving concentrated load's position x_p.

$$z_{b,d}(x) \approx A_{res}\sin\left(2\pi\frac{x}{L_c} + \theta_{res}\right)\sin\left(2\pi\frac{x}{2L_b}\right) \tag{4}$$

Equation (4) shows that the track irregularity waveform caused by the resonant bridge's dynamic response component observed at a moving load position during the passage of the resonant bridge can be expressed by multiplying the two waves with the wavelengths representing the vehicle length L_c and twice the bridge length $2L_b$. Figure 1 shows an example when the span length is 50 m. Note that $A_{res} = 1$.

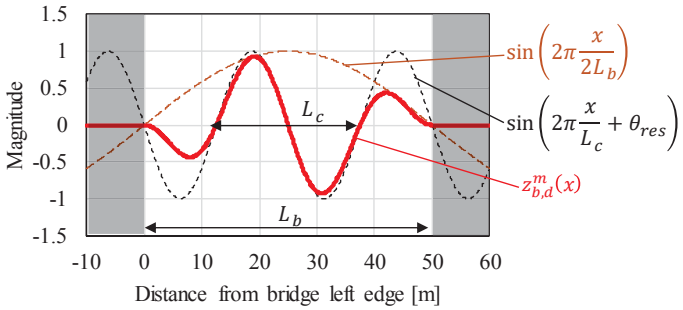

Figure 1: Dynamic response component of a bridge observed at a moving load position during the bridge passage (vehicle length: 25 m; bridge length: 50 m).

2.2 Extraction method for the resonant bridge response

First, a vibration component with a wavelength corresponding to a vehicle length L_c was extracted. A bandpass filter with a passing frequency band equivalent to the vehicle length L_c was used, with bandpass filtering performed on the measured track irregularities. The track irregularities that underwent this processing are termed herein as vehicle length irregularities. Consequently, the track irregularity component, excluding the bridge vibration and the bridge static deflection component, was reduced.

Next, envelope processing, that is, estimating $\sin(\pi x/L_b)$ in Eq. (4), was performed for the vehicle length irregularity. The amplitude of the vibration component with a wavelength equal to the vehicle length L_c was estimated by envelope processing. The track irregularity after this processing is referred to herein as the vehicle length irregularity amplitude. In the resonant bridge, a dominant sinusoidal component corresponding to the bridge span was formed based on the relationship in Eq. (4). By contrast, no dynamic response caused by the resonance existed in non-resonant bridges. The vehicle length irregularity amplitude lacked a dominant component.

Finally, the difference between the vehicle length irregularity amplitudes measured for the first and last vehicles was calculated. The measured track irregularities were assumed to be converted from time to position functions prior to the processing. Determining whether the dominant cause of the vehicle length irregularity in the last vehicle was resonance, static deflection component of the bridge, or irregular component corresponding to the vehicle length by the bandpass filter processing and the envelope processing alone was impossible. The dynamic response of the bridge at resonance gradually increased as the train passes, indicating that the bridge's dynamic component, which was caused by the resonance predominating during the passage of the last vehicle, was hardly generated when the first vehicle passed. Conversely, the static deflection component of the bridge and the track irregularity component corresponding to the vehicle length were almost identical for the first and last vehicles. Common components, such as static deflection and track irregularity, can be removed by subtracting the vehicle length irregularity amplitude of the first vehicle from that of the last. Therefore, if the predominant component corresponding to the bridge length is observed in the irregularities subjected to difference processing, the bridge is said to be resonating.

3 VERIFICATION RESULTS ON THE NUMERICAL SIMULATION

The train speed effect on the proposed method was verified by a numerical simulation for a simply supported bridge. We calculated the bridge displacement component by using a general simulation model [6,8] involving a two-dimensional vehicle with six degrees of freedom (DOF) and a bridge with a three-DOF system. Vehicles are usually based on the multibody system, whereas bridges are based on the beam theory. The train was modeled herein by connecting 12 vehicle models. The vehicle length L_c was 25 m, with a bogie center interval of 17.5 m, an axle interval of 2.5 m, and an axle load of 120 kN. For other parameters and details, please see Ref. [6].

For the actual resonant bridge [4], the span length was 30 m with a unit length mass of 25 t, a natural frequency of 2.8 Hz at which the resonance speed was approximately 250 km/h, and a 2% modal damping ratio.

Considering the track irregularity measurement system, the displacements just below the first/second bogie centers of the last/first vehicle were extracted from the simulation results. When converting the time series response to distance, resampling was performed at 250 mm intervals in accordance with the actual track displacement measurement.

The train speeds were 200, 230, 250, 270, and 300 km/h, which corresponded to ±10% and ±25% of a resonance speed of 250 km/h. Figure 2(a) shows the bridge displacement response at each train speed. Figure 2(b) depicts the bridge displacement responses just below the first/second bogie centers at the last/first vehicle at each train speed. These displacements were assumed to originate from the irregular track measurements. The dynamic response of the bridge was greatly amplified at a resonance speed of 250 km/h, although the track irregularity (bridge displacement) when traversing the bridge, as measured by the first vehicle, was unchanged.

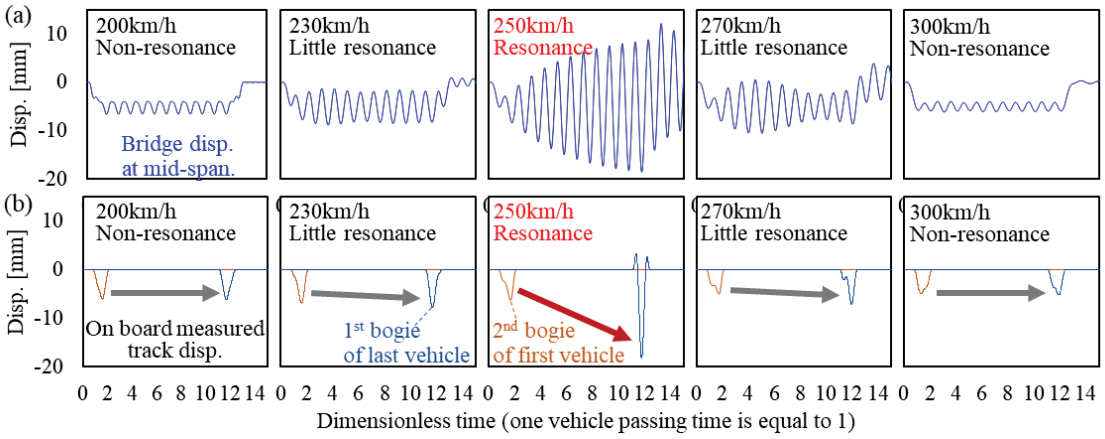

Figure 2: (a) Bridge displacement response at each train speed and (b) bridge displacement response just below the first/second bogie centers at the last/first vehicle at each train speed (vehicle length = 25 m; bridge length = 30 m).

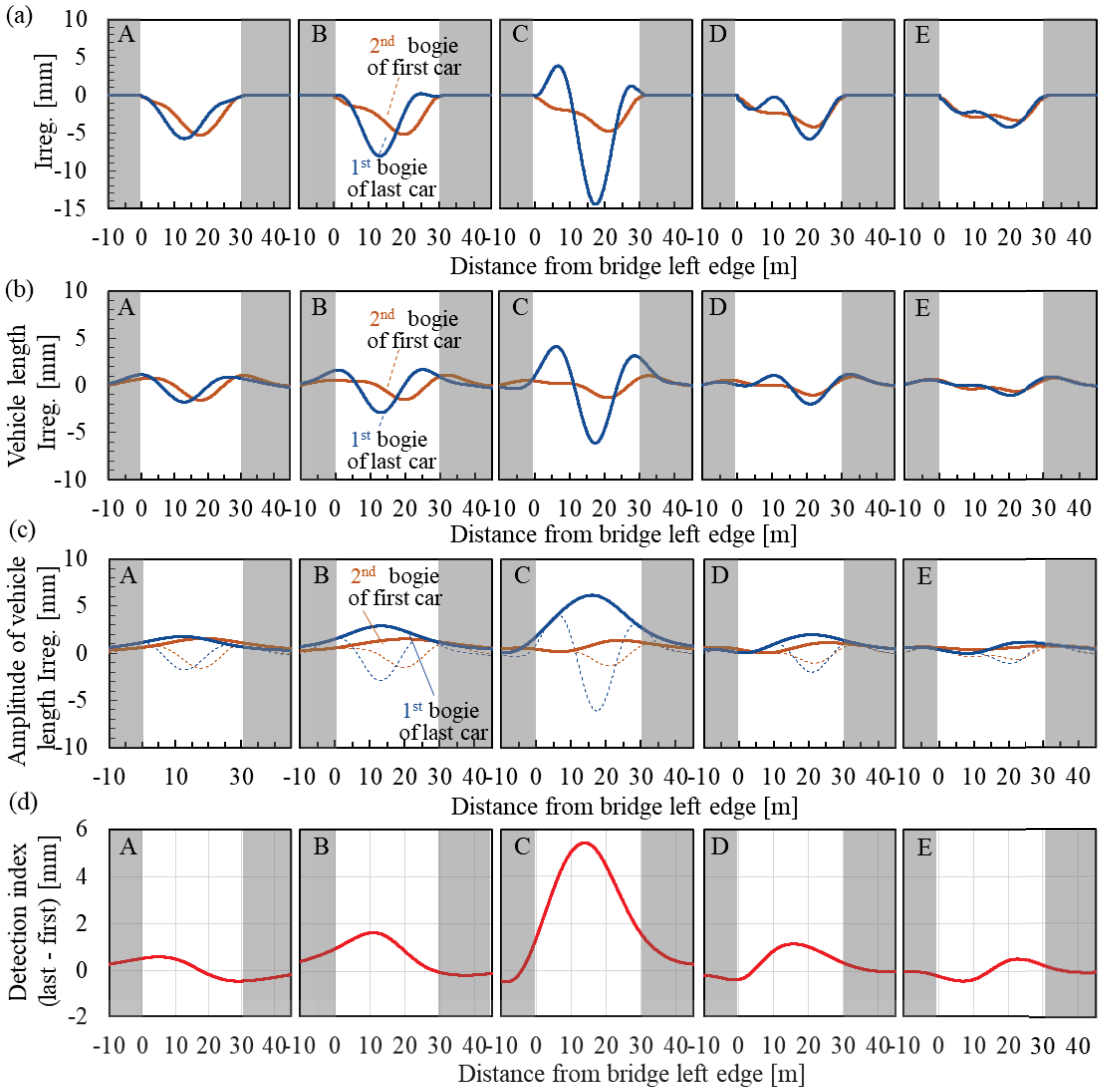

Figure 3: (a) Track irregularity (Irreg) composed of the bridge displacement, (b) vehicle length irregularities, (c) vehicle length irregularity amplitudes, and (d) resonance detection index (A, B, C, D, and E are 200, 230, 250, 270, and 300 km/h, respectively).

Figure 3 illustrates the results of applying the proposed method to the bridge displacement components observed by the first and last vehicles. Figure 3(a) presents the track displacement consisting only of the bridge displacement component obtained by converting Figure 2 into a distance sequence. Figure 3(b) shows the vehicle length irregularities after bandpass filtering. Figure 3(c) displays the vehicle length irregular amplitudes after the envelope processing. Figure 3(d) exhibits the detection indices after the difference processing.

Figures 3(c) and (d) denote that in the resonance state, the vehicle length irregularity amplitude of the last vehicle is higher than that of the first vehicle. Therefore, the detection index forms a convex dominant component in the resonant bridge section.

4 VALIDATION RESULTS ON ACTUAL VEHICLE AND BRIDGE

4.1 Target high-speed railway

A resonant bridge was detected, and the resonance state was verified by an on-site measurement by applying the proposed method to a real high-speed railway. The method was applied to high-speed railway lines, where the first and last vehicles hosting the track displacement measurement devices, including the inertia measurement mounted on a bogie, were run. The train includes eight cars measuring 25 m, a bogie center interval of 17.5 m, an axle interval of 2.5 m, and an axle load of approximately 120 kN when empty. The running speed of the target section was approximately 230–250 km/h. The track irregularity measuring devices were installed at the second and first bogie centers of the first and last vehicles, respectively. The position detection devices were also installed on the first and last vehicles and converted from time to distance function by recording the communication with the ground terminal every 3 km. Furthermore, the relative position of the last vehicle was finely corrected by the cross-correlation based on the measured data of the first vehicle [9]. In this study, the time series response of the track irregularity measured from the vehicle at 2 kHz sampling was converted to a distance series response at 250 mm intervals.

4.2 Detection results of the resonant bridge

Figure 4 shows an example of the application result of the method. From the top, this involves the structure type; structure span; train speed; track irregularities, including the bridge displacement measured at the first and last vehicles; vehicle length irregularities; vehicle length irregularity amplitudes; and resonance detection index (RDI). The train speed was approximately 230 km/h, with six bridges from A1 to A6 in the section. Others frequently involved rigid frame viaducts instead of the embankments on Japanese high-speed railways.

The difference between the first and last vehicles for the measured track irregularities and the vehicle length irregularities is usually very small. However, the vehicle length irregularity of the last vehicle was confirmed to increase in the A3 section of the bridge. Consequently, the vehicle length irregularity amplitude of the last vehicle in the A3 section of the bridge was higher than that of the first vehicle. The RDI of the A3 section of the bridge displayed a dominant convex shape with a primary length almost equal to the bridge span length. This is consistent with the numerical calculation results. Therefore, resonance was determined for bridge A3 at a train speed of 230 km/h. The RDIs of the other bridge sections and the ramen viaduct section were generally less than 1 mm, and the train was not in resonance when running at a speed of 230 km/h.

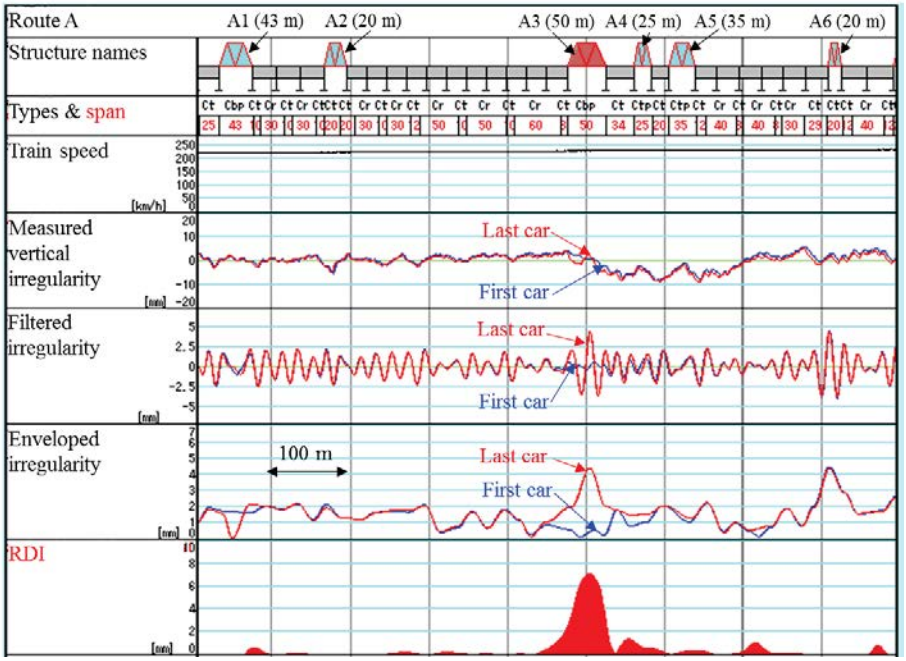

Figure 4: Example of the measured track displacement and application results of the proposed method

4.3 *In-situ* measurement result of the detected bridge

The vertical displacement of bridge A3 during the train passage was measured by using a laser Doppler velocimeter with a self-vibration correction (U-Doppler II, sampling 2 kHz [10]). The details of U-Doppler II are provided in Ref. [10]. The measurement target position was the bridge's mid-span. Figure 5 depicts the field measurements and the equipment used.

Figure 6 shows the time series response of bridge A3 from the *in-situ* field measurements. The dynamic response amplitude of bridge A3 increased as the train passes, with a large free vibration confirmed even after the train has passed. These responses are typical primary resonance waveforms; therefore, the resonance of the bridge detected by the proposed method was proven.

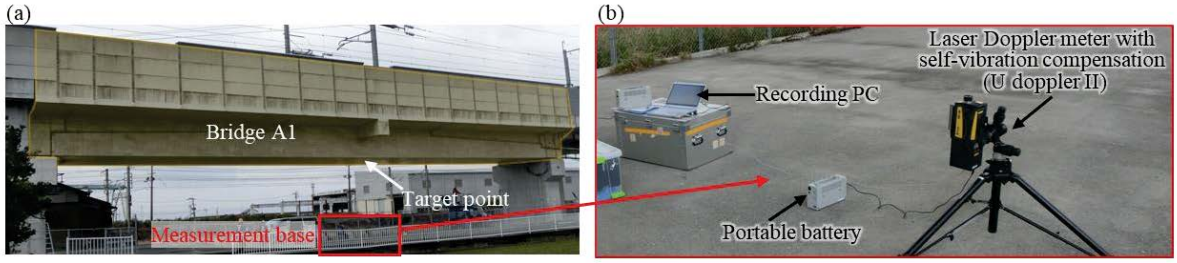

Figure 5: (a) Field test bridge and measurement environment. (b) U-Doppler II and its setup.

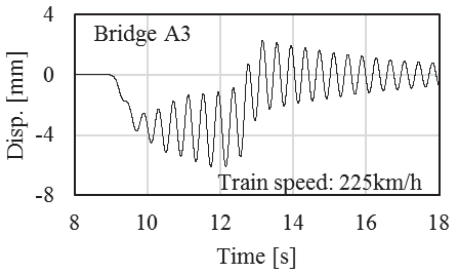

Figure 6: *In-situ* measured time series displacement response of bridge A3 detected by on-board measurement track irregularity data.

5 CONCLUSIONS

In this study, we developed a drive-by system for detecting resonant bridges from the data measured using high-speed railway vehicles. We proposed a novel methodology for detecting a resonant bridge by focusing on the track irregularity differences, including the bridge displacement components measured using the first and last vehicles. After a numerical verification, we applied the proposed method to the measurement data for the track irregularities from high-speed railways of Japan. We proved that resonant bridges were detectable on the track maintenance management system used daily by Japan's railway companies. Our findings are summarized as follows:

- We proposed a bandpass filter and an envelope processing method for estimating the vehicle track length irregularity amplitudes that highlighted unique components of the resonant bridge. The difference between the filtered and enveloped track irregularities measured in the first and last vehicles was used as the resonant bridge detection index. We also proposed a methodology for detecting resonant bridges based on their peaks.
- Through a numerical simulation at different train speeds, the RDI was confirmed to form a convex dominant component, with the dominant length almost identical to the bridge span length only at resonance.
- We applied the proposed method to the track irregularities at the positions of the first and last vehicles measured by the bogie-mounted track irregularity devices installed in Japan's high-speed railway trains. In fact, we detected a resonant bridge based on the RDI. Moreover, the *in-situ* bridge displacement measurements for a detected bridge demonstrated that the detected bridges actually resonated.

Despite these findings, problems associated with the construction of a generalized on-board measurement and diagnosis system still exist. We performed only limited numerical simulations and minimal verification. Therefore, the applications of the proposed method, such as the effects of the track irregularities, excluding the bridge displacement component, effects of the position synchronization errors, and effects of the measurement errors, require detailed studies in the future, especially in terms of the effects of the bridge span length.

Keywords: Building vibrations, vibration sources, monitoring network, signal characteristics

Abstract.

A study was undertaken to define which set of signal characteristics can be used to differentiate between various vibration sources in a built environment. Several datasets of vibration measurements on known sources are obtained and analyzed. A set of 11 signal characteristics were determined for all signals. Based on the correlation between these characteristics, 6 signal characteristics (a_{max}, v_{max}, $f_{d,f,a}$, D_s, N_{peak}) were selected for a detailed analysis. This analysis showed that differentiation between vibration sources based on signal characteristics is feasible. Further research should investigate the possibilities and limitations of the dataset and determined whether identification of vibration sources based on the obtained signal characteristics is attainable.

1 INTRODUCTION

Since 2014, a large building vibration monitoring network is in place in the province of Groningen in the North of the Netherlands [1]. The primary objective of this network is to monitor vibrations caused by shallow earthquakes, induced by natural gas production in this region. In approximately 350 buildings vibrations are measured in three orthogonal directions at foundation level in a stiff point near the corner of the building.

After an earthquake with a magnitude M $\geqslant$ 2.5, building inspections are executed for those buildings that experienced a trigger event, i.e. a vibration velocity exceeding a threshold of 1 mm/s [2]. These inspections are performed to obtain information on the occurrence and progression of damage. Besides earthquake vibrations, the threshold is frequently exceeded due to vibrations from other internal and external causes (e.g. traffic, construction work, slamming doors, jumping). To obtain information on the cause of these triggers, building owners are asked to fill in a website-form and specify a reason for the threshold exceedance. The large amount of data collected on all these different types of vibration sources provide for a unique opportunity to obtain a better understanding of their characteristics and the possible influence these sources have on the occurrence of damage to buildings.

The ultimate aim of this research is to develop a method to identify vibration sources in the monitoring network. The goal of this study is to establish a set of signal characteristics and determine to what extent these characteristics can be used to differentiate between various vibration sources in a built environment. To that end, several datasets of vibration measurements on known sources are obtained and analyzed. The following datasets are used to study the set of vibration characteristics:

- Time traces measured in the monitoring network from verified events, i.e. the Garrelsweer earthquake of 9/6/2019 [3] and F16 sonic booms on 6/6/2016 [4].
- A test campaign in the monitoring network with various vibration sources, see report TNO 2019 R11872 [5 for a detailed explanation.
- Data from measurement projects performed in the past by TNO on several external vibration sources (mass pile driving, vibratory pile driving, railway traffic and blasting).

This paper describes the setup of these datasets and discusses the findings of this research. Chapter 2 gives some background information on the monitoring network and discusses the state-of-the-art in vibration source analysis, with a focus on vibration research in the built environment. The datasets used in this research are detailed in Chapter 3; Chapter 4 explains the applied analysis techniques and the determined vibration characteristics. Chapter 5 presents and discusses the results and findings obtained from the various datasets. Chapter 6 gives the conclusions and recommendations of this research.

2 BACKGROUND

2.1 Seismic monitoring networks and seismic noise

Seismic monitoring networks can roughly be grouped in country-scale, urban-scale, and building-scale monitoring networks. Each network has different tasks, but all have a common objective of earthquake risk reduction. According to D'Alessandro et al. [6] the different scale monitoring networks generally have the following purposes:

- National seismic networks are intended for earthquake observation and seismological studies.
- Urban networks are used to map the earthquake intensity and as early-warning system.
- Building networks are applied for structural health monitoring purposes and also as on-site warning systems.

An increasing trend is observed in urban seismic monitoring networks around the world, which are mainly used to characterize the subsurface structure and improve seismic risk management in populated areas [6]. The introduction of low-cost MEMS sensor systems has further contributed to this development [7-9]. Although the original intention of most of these networks was for seismological purposes e.g. [10-13 (see [13] for an extensive reference overview), the data measured for non-natural vibration sources is being studied more thoroughly over the last decades.

Riahi and Gerstoft [14] studied the traffic-generated noise measured by 5200 geophones that covered a 7x10 km area in Long Beach (California, USA). From the seismic noise they were able to extract metro activity, departing and landing aircraft, and traffic movement along the highway at night.

Boese et al. [15] have investigated anthropogenic and natural noise recorded by borehole seismometers installed beneath the Eden Park stadium in Auckland, New Zealand. They observed elevated noise levels (10-15 dB) in records obtained during the 2011 Rugby World Cup matches.

Green et al.[16] studied the recordings of five broadband seismometers, deployed in central London during the summer of 2015. A comparison of power spectra with observatory stations in much less populated areas showed most of the spectrum is dominated by anthropogenic noise. For short periods ($T < 0.4$ s) road traffic was found to have the largest effect. In close proximity to the tracks, railways also generated observable signals for $T < 0.3$ s. At very long periods ($T > 20$ s) the influence of trains was observed across the city. The air movement through the subway also resulted in increased noise levels for periods $T > 30$ s.

Similar observations were made by Diaz et al. [17] through an analysis of the seismic records obtained from a broad-band seismic station located near the center of Barcelona. A spectrogram of the vertical seismic acceleration measured between 1/9/2016 and 13/9/2016 showed the frequency ranges dominated by traffic, ocean activity and subway activity. A decimated timeseries of the same period clearly showed the night/day and working day/weekend variations. Diaz et al. [17] could also relate some peaks in the time series to traffic increases before and after FC Barcelona football games.

Particular relevant for the current study is a statistical analysis performed by Groos and Ritter [18] on 4 hr timeseries for classification purposes. Their classification scheme is based on deviations from the Gaussian distribution. The parameters used in the classification are different ratios of percentile intervals of the vibration signal histogram. Based on these parameters Groos and Ritter [18] defined 10 noise classes, which account for non-corrupt (NC1 – NC6) and corrupt (NC10 – NC13) time series.

The current study investigates the characteristics of signals from vibration sources with frequency content between 1 and 100 Hz (T between 0.01 and 1 second). The studies by for example Green et al. [16] and Diaz et al. [17] show that in this frequency range, the largest contribution generally comes from man-made vibrations. Studies on man-made vibrations have mainly researched the effects on damage, e.g. [19-22], and comfort, e.g. [23-26]. Characteristics that have been extensively studied are the amplitude and frequency of the vibrations, mainly with the purpose of predicting and assessing the risk on damage or nuisance. A detailed discussion of studies into man-made vibrations is provided in chapter 5, where a comparison is made with the results of the current study.

2.2 The monitoring network building vibrations

The monitoring network building vibrations was designed and built with the goal to obtain more insight into the effects of earthquakes on buildings in Groningen. This chapter gives general background on the sensor network; a more detailed description of the monitoring network is provided in report TNO 2015 R10501 [1]. Figure 1 illustrates the approximately 350 locations in the monitoring network where vibrations are measured.

The vibration measurement systems were supplied by GeoSig and consist of a recorder (GMSplus measuring system) and a tri-axial sensor (AC-73 force balance accelerometer). The GeoSig sensors are located near a stiff corner of a building (~0.5 m) on the inside or outside, as illustrated in Figure 2(a) and (b). De X- and Y-direction of each sensor are respectively parallel and perpendicular to the façade, the Z-direction is pointing upwards. The GeoSig sensors continuously sample accelerations at 250 Hz, which are automatically integrated to velocities.

The sensor transmits full resolution (250 Hz) data when a velocity threshold is exceeded. After the exceedance of the threshold level of 1 mm/s in X, Y, or Z-direction, the trigger event is logged with a pre-trigger time of 10 s until 20 s after the last threshold exceedance.

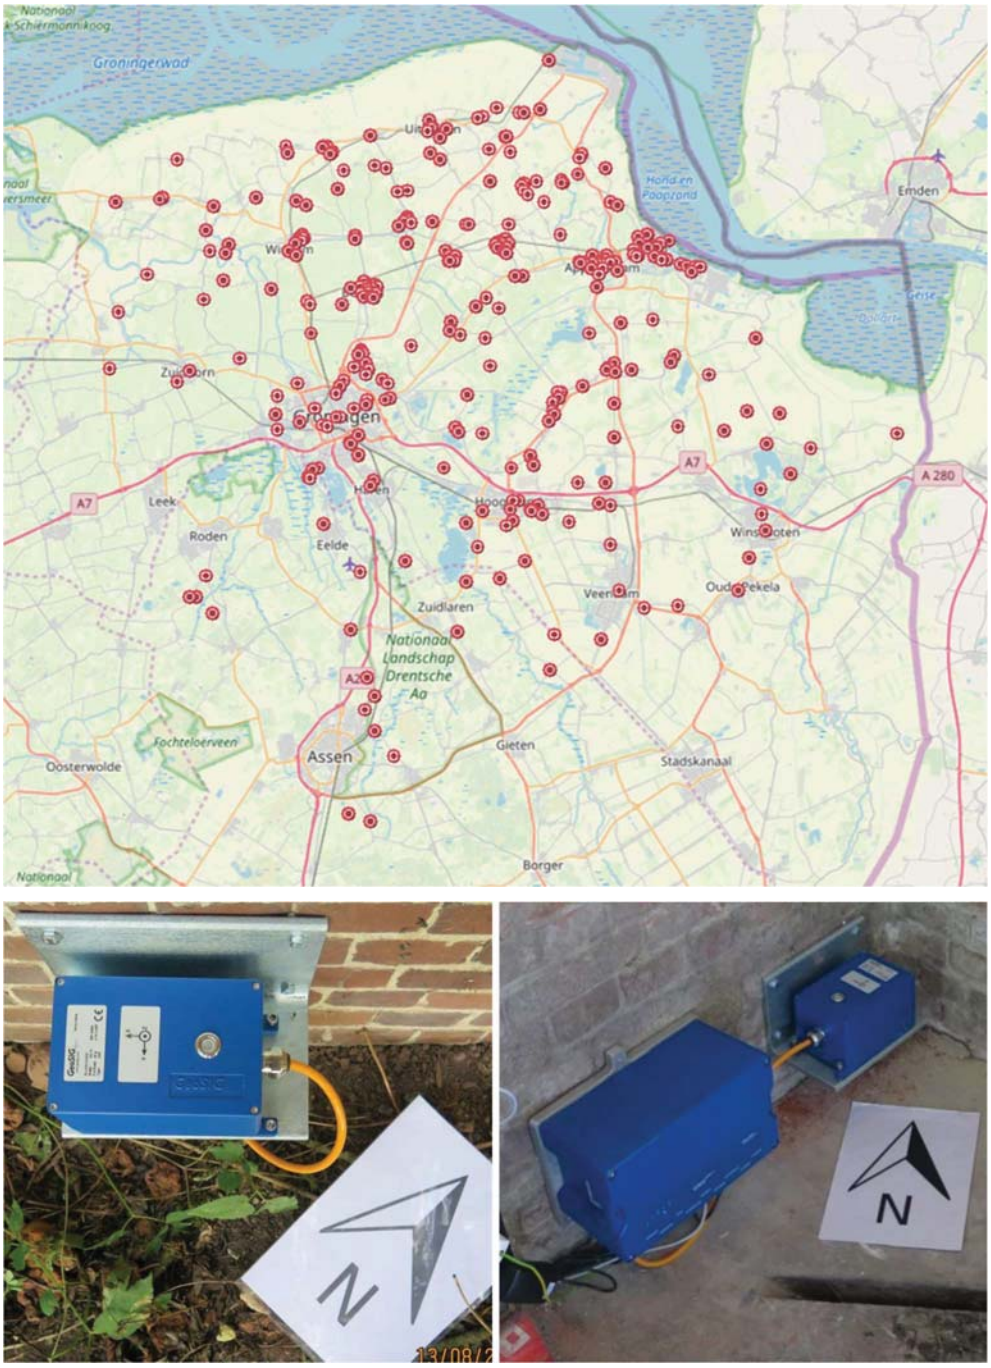

Figure 1: (top) Sensor locations in the building sensor network in Groningen, (bottom left) Geosig sensor near a stiff corner on the outside of a building, and (bottom right) a Geosig sensor near the stiff corner inside, the large box to the left is the recorder, the small box to the right is the sensor.

3 DATA DESCRIPTION

3.1 Earthquake Garrelsweer

On June 9, 2019 an earthquake was measured near Garrelsweer with a magnitude M = 2.5, located at 3 km depth. Figure 2 shows the location of the epicenter as defined by the KNMI [27], and the locations of the triggered and non-triggered sensors.

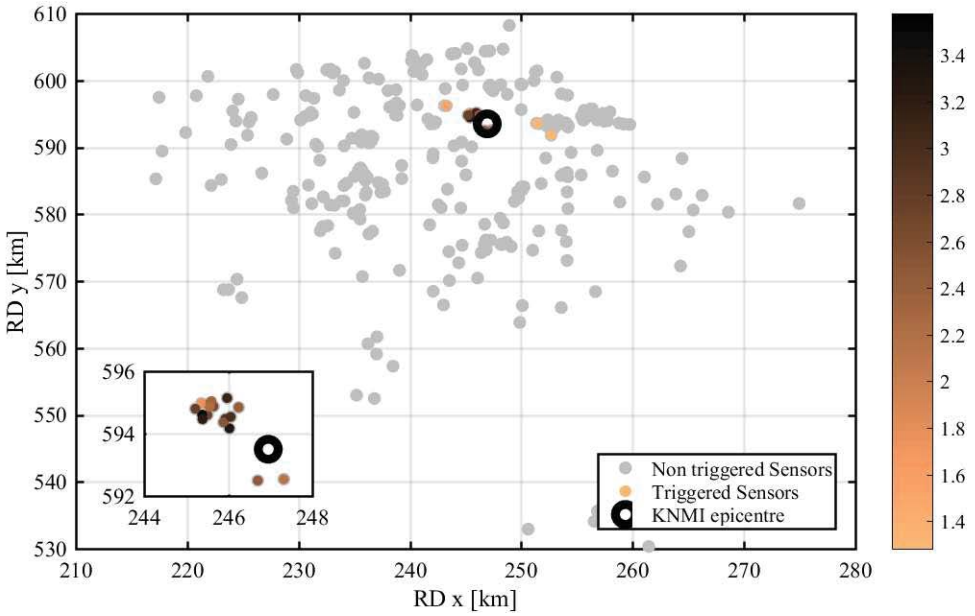

Figure 2: Triggered and non-triggered sensors in the monitoring network during the Garrelsweer earthquake (9-6-2019), taken from [3].

A detailed analysis of the data from the monitoring network can be found in [3]. A total of 257 signals were applied in the current study. The majority of these signals did not result in a trigger, i.e. the maximum observed vibration velocity is lower than 1 mm/s.

3.2 Sonic booms of F16 aircrafts

On the 6th of June 2016 at 15.30 (local time), two F16's crossed the sound barrier above the province of Groningen. The vibrations due to the low-frequency pressure waves were recorded by the monitoring network. Figure 3 shows two snapshots of a movie of the pressure waves due to sonic booms by the F16 aircrafts. These pressure waves were derived from the vibration signals measured by the monitoring network. A total of 271 signals measured in the monitoring network are used in this study to determine the characteristics of building vibrations due to sonic booms caused by supersonic aircrafts.

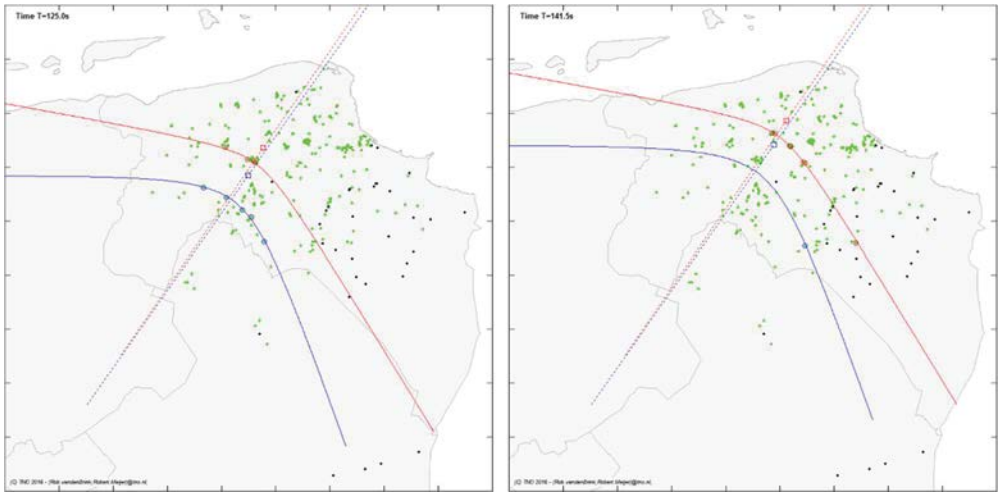

Figure 3: Two snapshots of a movie which shows the movement of the two pressure waves due to the two F16, based on the vibration signals measured in the monitoring network. Taken from [4].

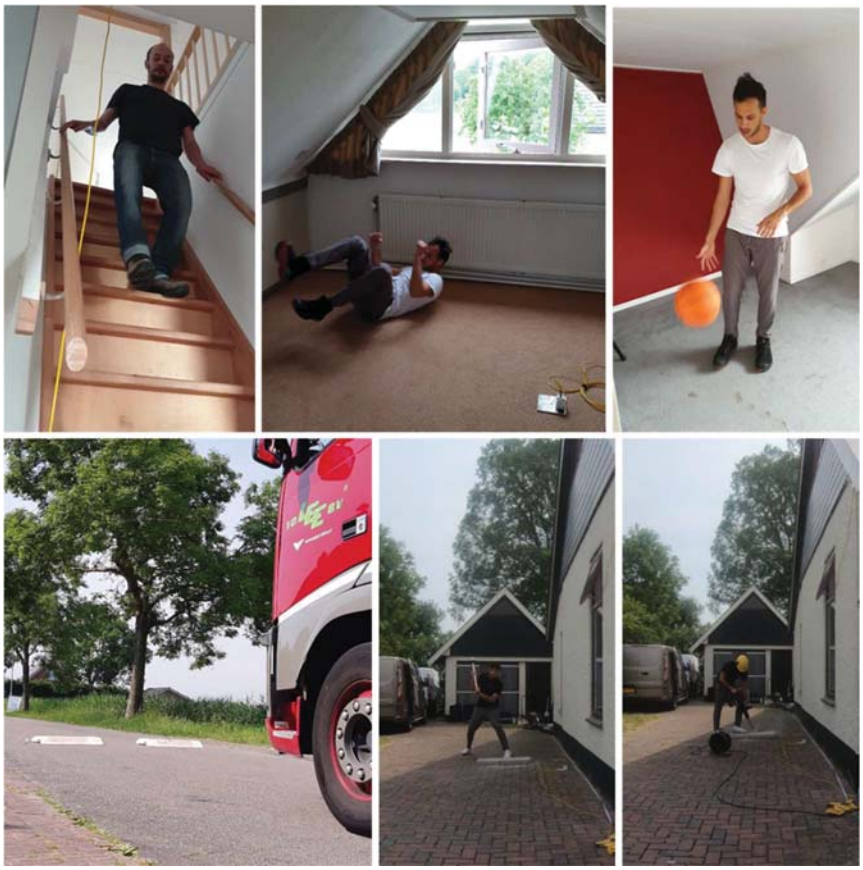

Figure 4: Internal and external vibration sources applied in the test campaign in the monitoring network.

3.3 Test campaign in the building monitoring network

To develop a database with measured vibration signals of internal and external sources, a test campaign was organized and executed, in which known vibrations sources were applied near sensors in the monitoring network. In this campaign two tests were performed:

1. Various internal and external vibration sources were applied in a house in Groningen, while vibrations were measured at various positions in the building.
2. A truck drove twice a predefined route along 17 sensors in the monitoring network.

Figure 4 shows some of the internal and external sources that were tested during this campaign. A detailed description of the tests and the results is given in [5].

3.4 Blasting

A measurement campaign was performed by TNO to assess the influence of blast induced vibrations in buildings around a defense exercise area in the Netherlands. Exercises with 8 different types of explosions were performed in the exercise area, while vibrations were measured at 4 different buildings in the surroundings at distances ranging between 3 and 7.5 km. Measurements were performed with Sundstrand QA-700. The sensors were sampled simultaneously with 2000 Hz. The data of some of these sensors were applied in the current study.

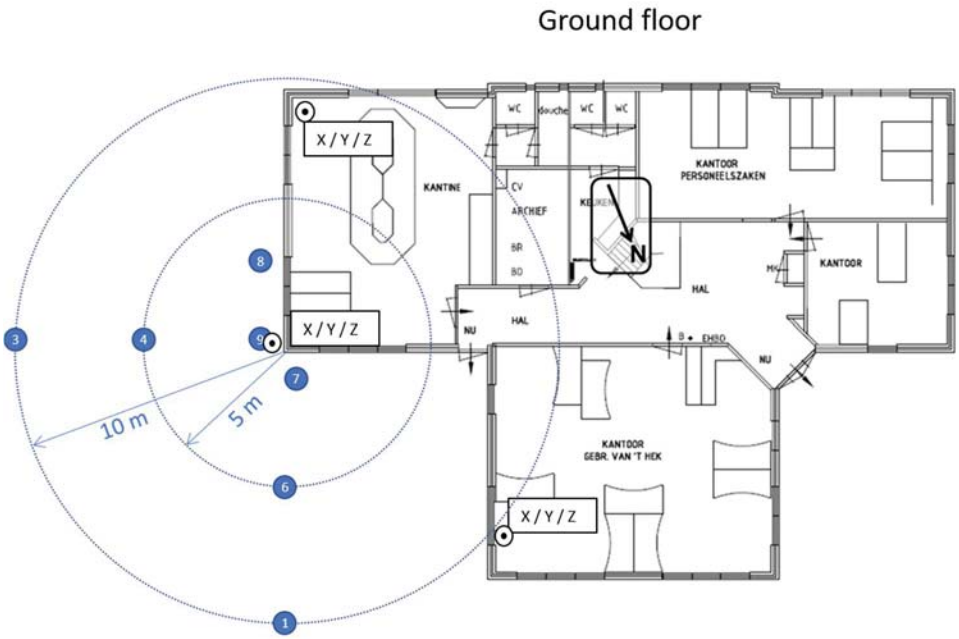

Figure 5: Sensor positions (black circles) and mass pile driving and vibratory sheet pile driving locations (blue circles).

3.5 Mass pile driving and vibratory sheet pile driving

A series of tests were performed with mass pile driving and vibratory sheet pile driving near an office building in the province of North-Holland. Locations of the pile driving and the sensore locations used are specified in Figure 5. Since the building was about to be replaced by a new building, high vibration levels could be induced, and damage initiation was also monitored.

Measurements at these locations were performed with Sundstrand QA-700 sensors; the sensors were sampled at 2000 Hz. The data of the indicated sensors in Figure 5 were used in the current study.

3.6 Railway traffic

Between September and November 2012 measurements were performed by TNO at 3 buildings along the HSL-south track between Amsterdam and Rotterdam. The buildings were located at 125 m, 150 m, and 450 m from the railway track. Only the data of the buildings at 125 m and 150 m that exceeded the background noise were used in this study. The data from the building at 450 m was not clearly distinguishable from background vibration levels.

Accelerations were measured at the foundation, the ground floor, the first floor and outside near the building and 50 m from the track. The accelerations measured at the foundation are used in the current study. The measurements were performed with Sundstrand QA-700 sensors. The data were sampled with 500 Hz. Measurements were performed on Thalys and V250 trains with passage speeds ranging between 160 and 300 km/h.

4 ANALYSIS

Before computation of the various characteristics, some preprocessing is performed on the measured acceleration signals. This preprocessing consists of the following steps:

i. Offsets are removed, such that the acceleration signals have a zero mean value;
ii. A 4th order Butterworth high-pass filter with cut-off frequency of 0.8 Hz is applied to remove trends which might affect the integration to velocities;
iii. The acceleration signals are integrated to obtain velocity signals;
iv. The absolute maximum velocity is determined for the X, Y, and Z-direction;
v. The acceleration and velocity signal of the direction with the largest absolute maximum velocity is selected for further analysis, these are from here on referred to as a(t) and v(t);
vi. The time instance at which the absolute maximum or peak velocity occurs is determined and used to trim the signal;
vii. The acceleration and velocity signal a(t) and v(t) are trimmed from -10 s to +20 s of the peak velocity.

The processed acceleration and velocity signals were analyzed with the Fast Fourier Transform (FFT) and the Short Time Fourier Transform (STFT), and the Arias intensity function of all signals was determined. Finally, the number of peaks in the signals was analyzed through the derivative of the Arias intensity function. The following signal characteristics were determined from the acceleration and velocity signals, a(t) and v(t):

- The absolute maximum acceleration and velocity levels, a_{max} and v_{max};
- The acceleration and velocity peak factor, g_a and g_v;
- The dominant frequencies of the acceleration and velocity FFT spectra, $f_{d,f,a}$ and $f_{d,f,v}$;
- The dominant frequencies of the acceleration and velocity STFT spectra, $f_{d,s,a}$ and $f_{d,s,v}$;
- The Arias intensity, I_a;
- The significant duration, D_s;
- The number of peaks, N_{peak}.

A detailed explanation of the performed analysis is provided in [28].

5 RESULTS AND DISCUSSION

This chapter presents the results of the analysis on the datasets described in chapter 3. Section 5.1 presents and discusses the correlation of the characteristics computed for all vibration signals. Based on these results a set of characteristics is selected, for which detailed results are shown in section 5.2 to 5.6.

5.1 Correlation between determined signal characteristics

Each of the computed characteristics provide some information on the features of the measured signals. However, some characteristics can provide similar information. To filter the characteristics that provide new information, the correlation between each of the characteristics has been computed using the absolute value of the Pearson correlation coefficient, $|\rho_{x,y}|$. If 2 variables are highly correlated then $|\rho_{x,y}|$ tends to 1; if they are poorly correlated, $|\rho_{x,y}|$ tends to 0.

The complete correlation matrix for all the signal characteristics is shown in Figure 6 . This figure shows that the characteristics determined with the acceleration timeseries are highly correlated with those obtained from the velocity timeseries.

The interest of this study is on the signal characteristics that provide new information on a vibration signal, i.e. those signal characteristics that have relatively little correlation with each other (i.e. $|\rho_{x,y}| < 0.6$). The results of the following signal characteristics will be discussed in the next paragraphs:

the maximum acceleration and maximum velocity, a_{max} and v_{max}
the dominant frequency of the acceleration signal, $f_{d,f,a}$
the acceleration peak factor, g_a
the significant duration, D_s
the number of peaks, N_{peak}

Because a relatively large amount of literature can be found on the peak acceleration and velocity these are both discussed in detail in the next paragraph. The results of the other signal characteristics can be found in [28].

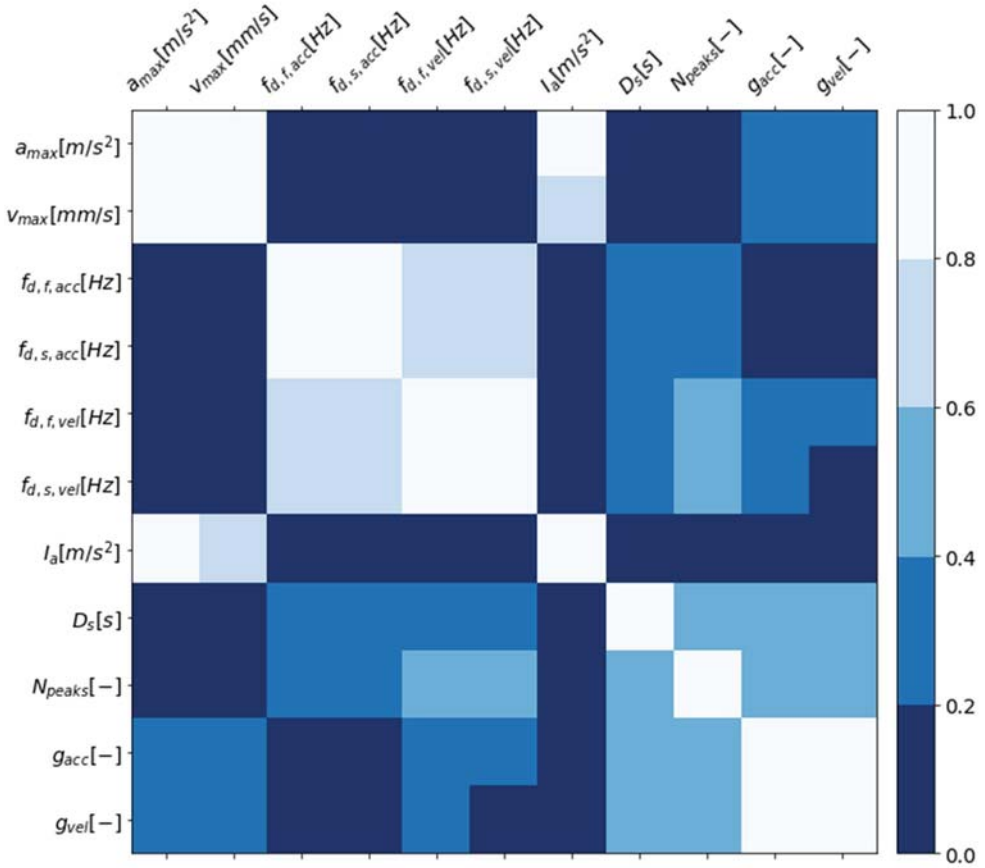

Figure 6: Correlation matrix of all computed signal characteristics. Note that the matrix is symmetric, i.e. the upper half gives the same information as the lower half

5.2 Absolute maximum vibration levels, a_{max} and v_{max}

Figure 6 and Figure 7 show box plots and individual samples of the absolute maximum acceleration and velocity determined per source type. The vibration sources are ranked in order of increasing median value of the boxplots. The background vibration results are placed at the top as reference.

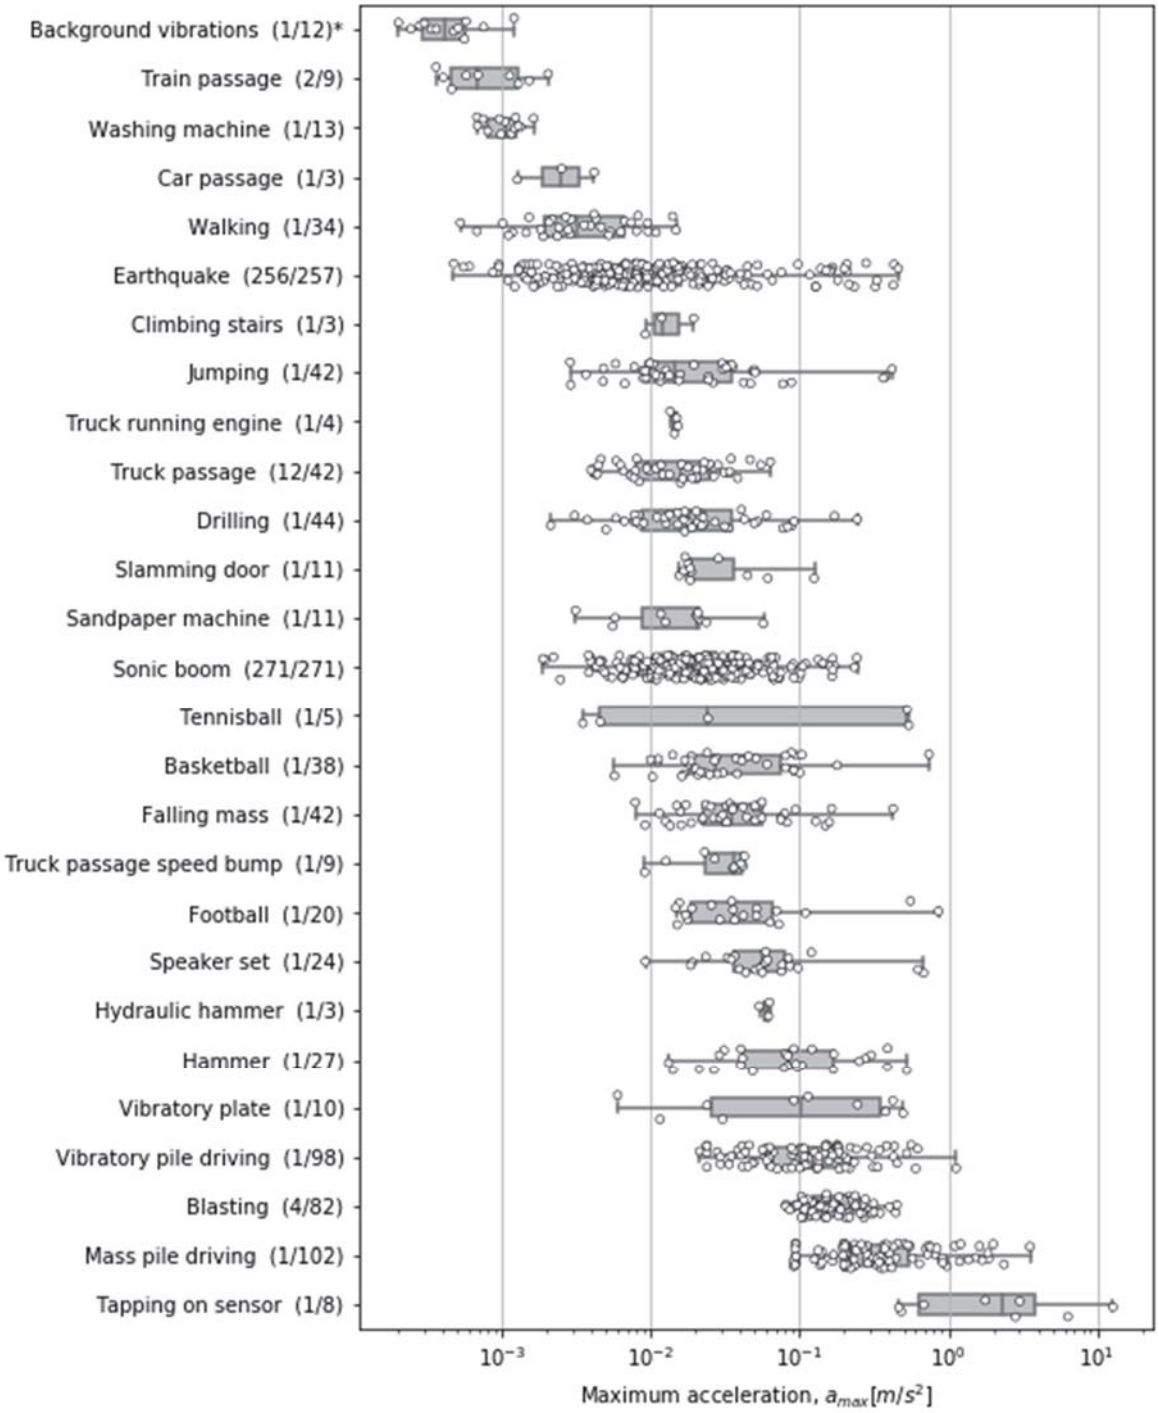

Figure 6: Boxplots and samples for the absolute maximum acceleration a_{max} obtained in all tests.
*(number of buildings/number of measured signals)

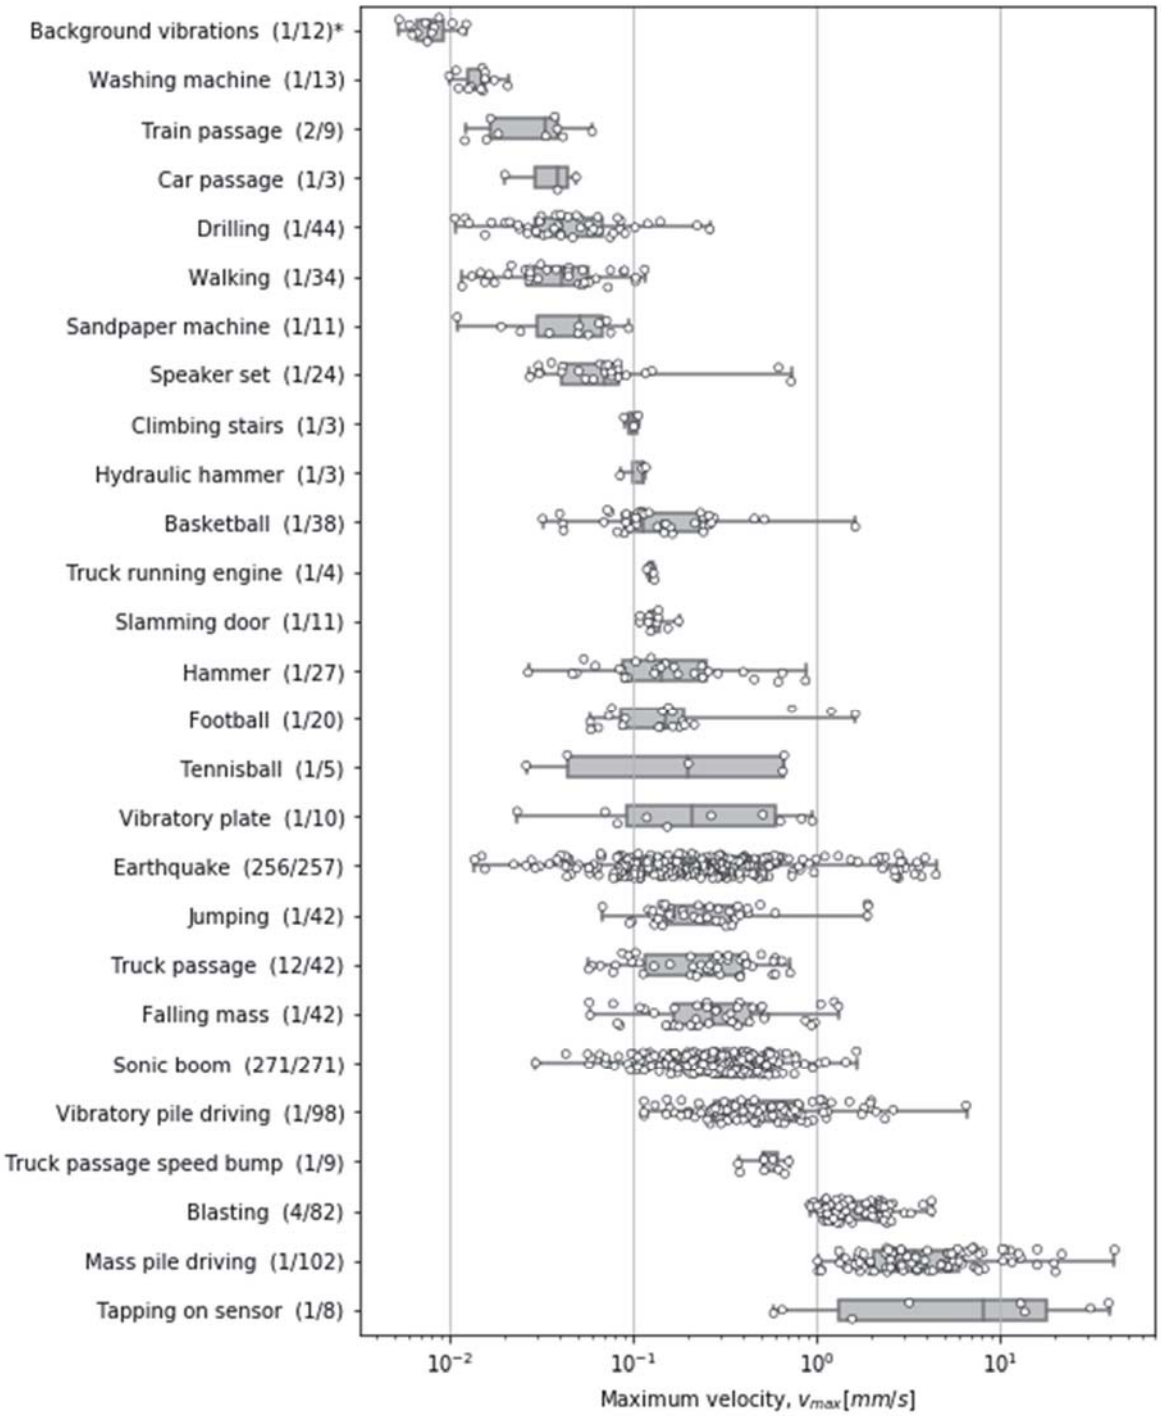

Figure 7: Boxplots and samples for the absolute maximum velocity v_{max} obtained in all tests.
*(number of buildings/number of measured signals)

The smallest maximum vibration levels are observed for the train passages, the washing machine and the car with running engine. In the tests with these sources the vibration levels only just exceeded the measured background vibration levels. The main reason for the low values of the train passages is the large distance between the track and the buildings at which measurements were performed.

Connolly et al. [29] and Kouroussis et al. [30] found peak velocities of 0.1 mm/s and smaller for measurements on vibrations induced by high-speed trains at a distance of 100 m. This matches with the vibration velocities found here for high-speed train passages at distances of 125 m and 150 m. For distances down to 2 m from the track, maximum velocities up to 4 mm/s were measured by Connolly et al. [29].

The vibration levels observed for road traffic, particularly the truck passage, also match well with values found in literature for the range of distances studied here (i.e. between 10 and 30 m). Hao et al [26] observed maximum accelerations of 0.006 – 0.015 m/s^2 for truck passages at a distance of 20 m. Hajek et al. [31] specify that for clay soils the maximum vibration velocities at 10 to 30 m are typically between 0.1 and 2 mm/s. For distances down to 3 m Hajek et al. [31] specify maximum vibrations velocities up to 3 mm/s. Staalduinen and Smits [32] describe maximum velocities ranging between 0.3 and 3 mm/s, based on 12 experimental studies performed by TNO (e.g. [33-36]).

The largest maximum vibration levels are determined for tapping the sensor and mass pile driving. The range of vibration velocities determined for mass pile driving (~1 – 40 mm/s) are similar to those specified by Staalduinen et al. [37] and Jongmans et al. [38]; these studies determined vibration velocities between 3 and 20 mm/s. For the tests performed at 10 m distance, lower values (around 1 mm/s) were found in the current study than in [37] and [38].

For vibratory pile driving Staalduinen et al. [37] found vibrations velocities up to 10 mm/s for distances between 10 and 20 m. Athanasopoulos and Pelekis [39] describe similar vibration levels for these distances. For distances between 1 and 10 m they found vibration velocities up to 25 mm/s. Lower vibration levels are observed for the vibratory pile driving data analyzed in the current study. A possible reason is that these pile driving tests were performed to depths of approximately 16 meter, while the stiff soil layer was at a larger depth.

The maximum accelerations and maximum velocities measured for the 2019 Garrelsweer earthquake range between 5x10-4 and 0.4 m/s^2 and 0.01 and 5 mm/s (see Figure 6.4 and Figure 6.5). During other earthquakes in the Groningen area (see [40]-[45]) vibration velocities up to 27 mm/s and accelerations up to 1.5 m/s^2 were measured by the monitoring network.

The vibrations induced by the air overpressure due to the sonic boom and the blasting exercises had acceleration levels between 0.002 and 0.5 m/s^2 and velocity levels between 0.03 and 4 mm/s. Much larger vibration levels (up to 500-600 mm/s) are described in other studies on blasting induced vibrations [46-48]. The main reason is these data were obtained for much shorter distances between the explosion and the sensor. Not only is the air overpressure larger at shorter distance, but there is also a large contribution of vibrations through the ground.

Few studies describe results of normal household vibrations such as presented in Figure 6.4 and Figure 6.5. Some velocity levels measured of typical building activities are given by Nicholls et al. [46], unfortunately it is not clear at which position in the building these levels were measured. Vibration levels measured by Nicholls et al. [46] for a door closing ranged between 0.1 and 1.4 mm/s. Considering the velocity levels measured in the slamming door tests presented in the current study, a better description is probably closing door tests. For jumping, Nicholls et al. [46] describe velocity levels between 1 and 125 mm/s. The large differences with the levels observed in the current study are probably due to the sensor location, and maybe to some extent due to the intensity of jumping.

In conclusion, the vibration levels observed for the various vibration sources in this dataset fit well with the ranges mentioned in literature. However, they do not give a good representation of the complete range of levels that can occur in the built environment. For most vibration sources the dataset is at the low end of these ranges. Therefore the ranges for a_{max} and v_{max} in Figure 6.4 and Figure 6.5 might not be very useful for differentiation between the studied vibration sources.

5.3 Acceleration dominant frequency, $f_{d,f,a}$

Figure 7 shows the box plots for the dominant frequencies $f_{d,f,a}$ of the acceleration FFT per studied vibration source. The vibration sources are ranked in order of increasing median dominant frequency. The dominant frequencies determined for the background vibrations are placed at the top as reference for the vibration sources.

Figure 7 shows that most signals with dominant frequencies $f_{d,f,a} < 35$ Hz are due to sources producing (repeated) transient vibrations, such as a truck or train passage, mass pile driving, or an earthquake. Sources which generate continuous vibrations, such as drilling, vibratory pile driving, a vibratory plate or a speaker set playing loud music typically have dominant frequencies $f_{d,f,a} > 25$ Hz.

According to Muller [49] the dominant frequency of mass pile driving signals is between 5 and 25 Hz, which is also observed in Figure 7. The dominant frequency $f_{d,f,a}$ determined for vibratory pile driving is concentrated around 37 Hz, which was the driving frequency of the vibratory machine. This frequency is within the range (30 – 40 Hz) for high-frequency pile-driving described by Deckner [22].

In Figure 7 dominant frequencies between 2 and 6 Hz are observed for the train passages. These low values are most likely related to the relative large distances (125 and 150 m) between the buildings and the track. Similar low frequencies were found by Ditzel [50] in measurements at two locations in the Netherlands. Ditzel [50] attributes the relative low dominant frequencies to a low-pass filter behavior of a ditch alongside the track. From measurements on passages of various types of trains, Suhairy [51] found dominant frequencies between 5 and 12.5 Hz. Measurements performed by the Dutch Railways [52] show that the dominant frequencies are generally smaller than 10 Hz.

Based on the previously mentioned studies on the effects of road traffic by TNO, Staalduinen and Smits [32] conclude that the dominant frequency is typically observed around 10 Hz, but can range between 5 and 15 Hz. The dominant frequencies for the car passages in Figure 7 are concentrated at 4-5 Hz, while the dominant frequencies observed for the truck passages are mainly observed between 5 and 15 Hz.

The dominant frequencies for the Garrelsweer earthquake are between 1 and 20 Hz (with one outlier at almost 30 Hz), this corresponds with the dominant frequencies determined for other earthquakes measured in the monitoring network [40-45]. This range is also very similar to that found for truck passages (see Figure 7).

The dominant frequencies for the sonic boom are generally observed between 1 and 25 Hz, which matches well with the range observed for earthquakes and truck passages. However, much larger dominant frequencies were also measured for the sonic boom (up to 95 Hz). For blasting the dominant frequencies were observed between 10 and 25 Hz. Nicholls et al [46] and New [47] found dominant frequencies mainly between 20 and 70 Hz, although they encountered values up to 500 Hz. Aloui et al [48] measured dominant frequencies between 1.5 and 11 Hz. These differences are mainly related to the applied explosion charge and the distances between the source and the sensor. The results of blasting in the current study were obtained for similar distances as applied in Aloui et al [48].

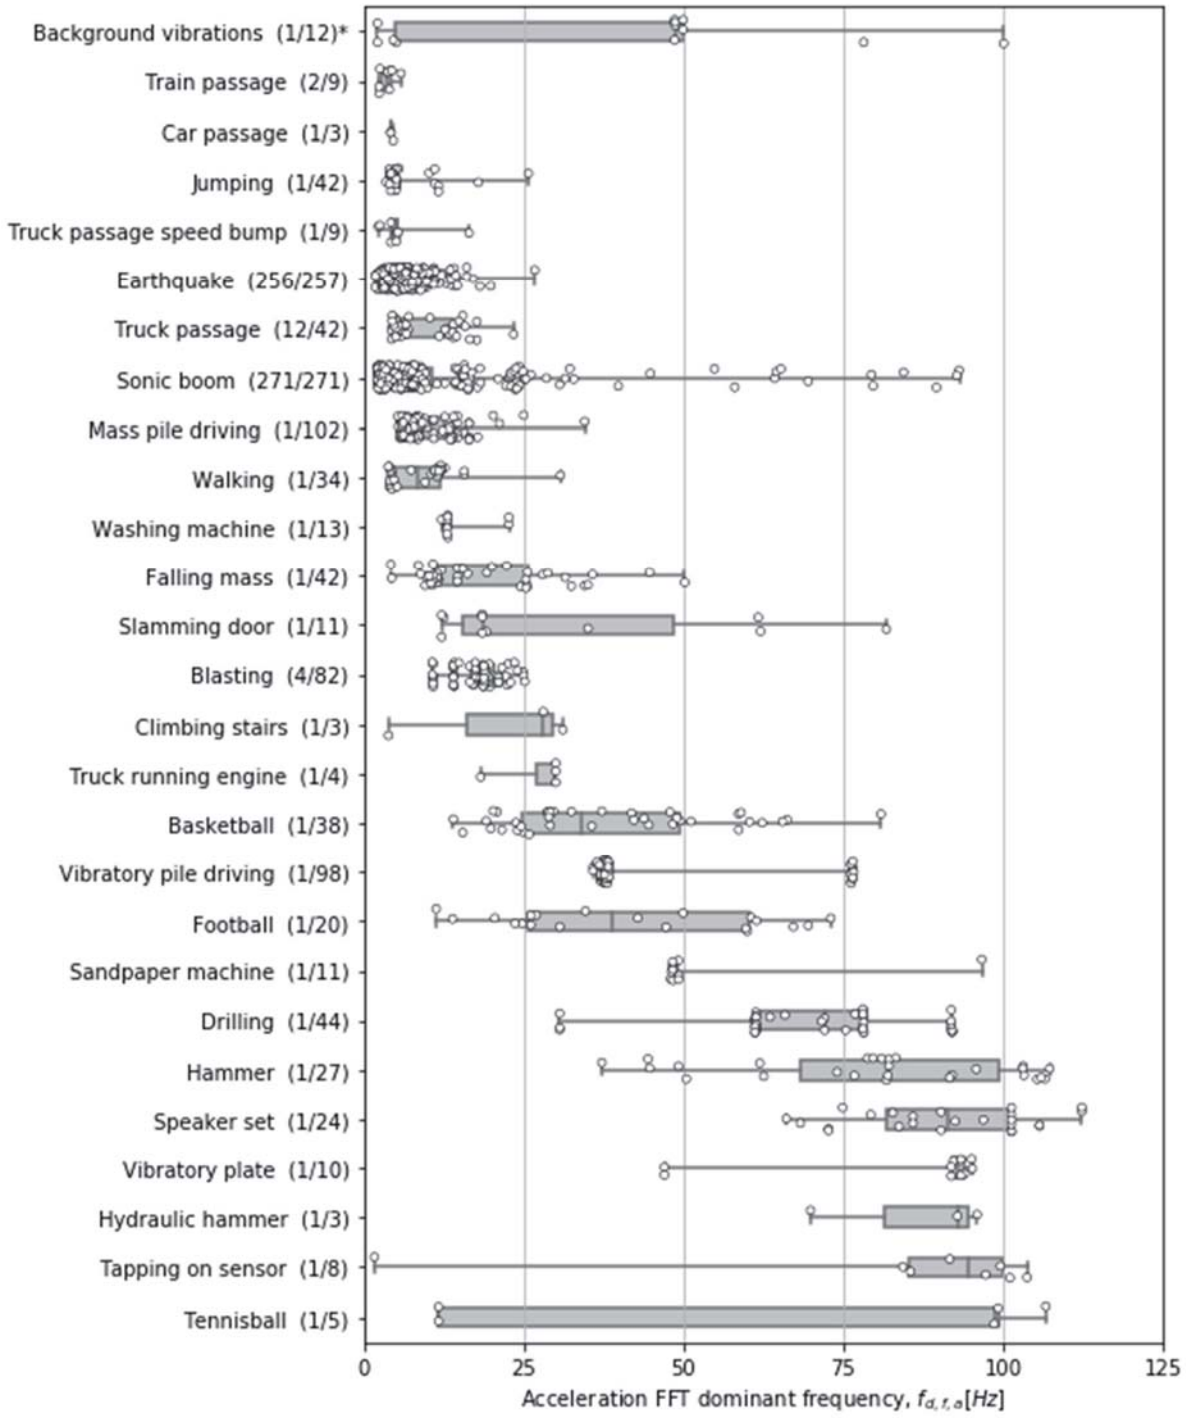

Figure 7: Boxplots and samples for the dominant frequency $f_{d,f,a}$ obtained in all tests.
*(number of buildings/number of measured signals)

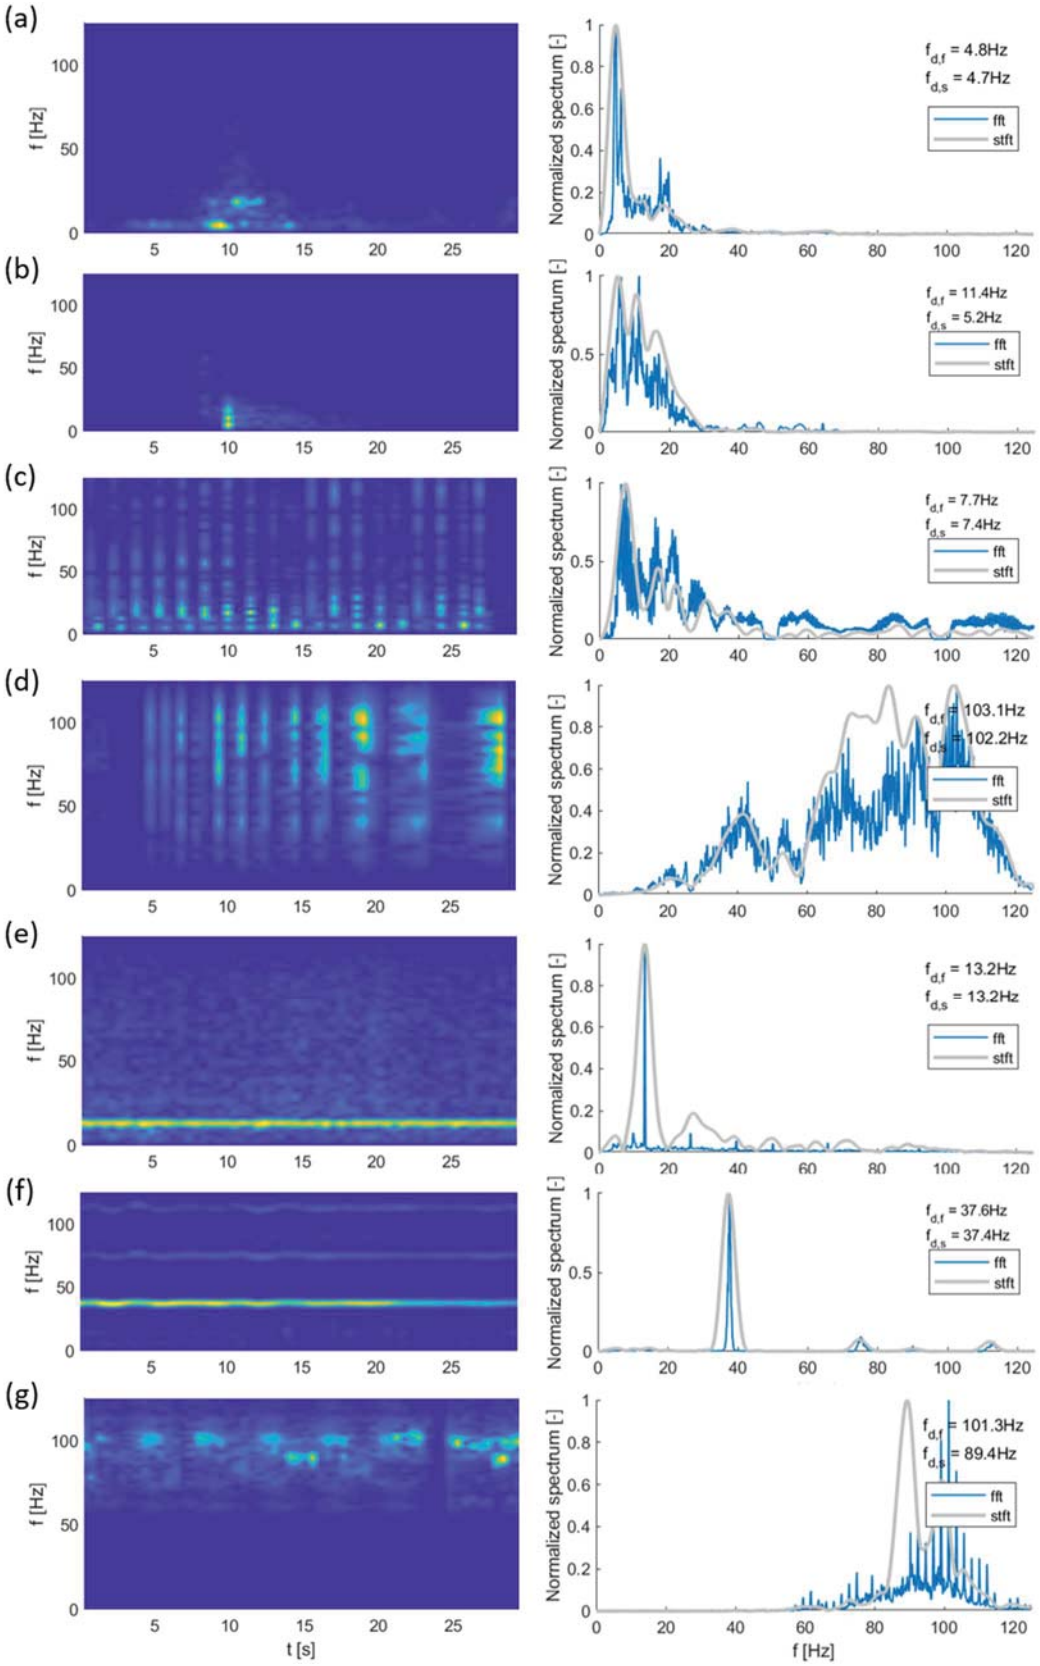

Figure 8: Acceleration spectrograms and spectra of several vibration sources: (a) truck passage, (b) earthquake, (c) mass pile driving, (d) hammer, (e) washing machine, (f) vibratory pile driv-ing, and (g) speaker music.

Figure 8 shows examples of the spectrograms (STFT) and spectra (FFT) of some of the measured acceleration signals. The spectrum of an earthquake and truck passage, Figure 8(a) and (b), are both concentrated in the low frequency range, with most energy content between 0 and 25 Hz. Similar spectra can be observed for a train passage, a sonic boom or blasting.

Similar to the earthquake and truck passage in Figure 8(a) and (b), mass pile driving shown in Figure 8(c), also has a large energy content in the low frequency range. However, for mass pile driving energy content is also found at higher frequencies. The spectral content of the hammer example shown in Figure 8(d) is mainly found above 30 Hz. Another distinguishing feature is the relatively broad spectrum compared to the earthquake, truck passage and mass pile driving.

Figure 8(e), (f), and (g) show STFT and FFT spectra of continuous vibration sources. Both the washing machine and vibratory pile driving have narrow band spectra with harmonic frequencies of the dominant frequency. Similar features are observed in the spectra of other types of machinery, such as the vibratory plate or drilling. The spectrum of the speaker playing music is more broadband, with large peaks at some distinct frequencies.

Based on these FFT and STFT spectra, other spectral features that could prove useful to allow for more differentiation between vibration sources the bandwidth of the spectrum (e.g. the 3 dB bandwidth) or harmonic frequencies (cepstrum analysis).

5.4 Acceleration peak factor, g_a

Figure 9 shows box plots of the acceleration peak factor g_a per studied vibration source. The vibration sources are ranked in order of increasing peak factor; the background vibration results are placed at the top as reference. Figure 10 shows examples of the acceleration signals of some of the tested vibration sources.

The smallest peak factors are observed for signals of sources which produce a (monotonic) continuous vibration, such as a sanding machine or a vibratory hammer used in (sheet) pile driving. The peak factors for these continuous signals are generally even smaller than the peak factors determined for the background vibrations. Vibration signals with peak factors $g_a < 6$ are likely to have been caused by a continuous vibration source, and are unlikely to contain large pulses.

Examples of a monotonic continuous vibration signal from a sanding machine and a background vibration signal are shown in Figure 10(a) and (b). The signal of the sanding machine is much denser due to the high-frequency continuous signal produced by this source, while no large peaks are present. Due to the high-frequency content the standard deviation is larger, which results in a smaller peak factor.

The largest peak factors are observed for signals with a single pulse or small number of pulses or a single short-duration transient. These type of signals are for example caused by hitting the sensor (e.g. by hand or hammer), dropping a hard heavy object (e.g. a stone) or an air pressure wave (e.g. caused by a sonic boom or blasting).

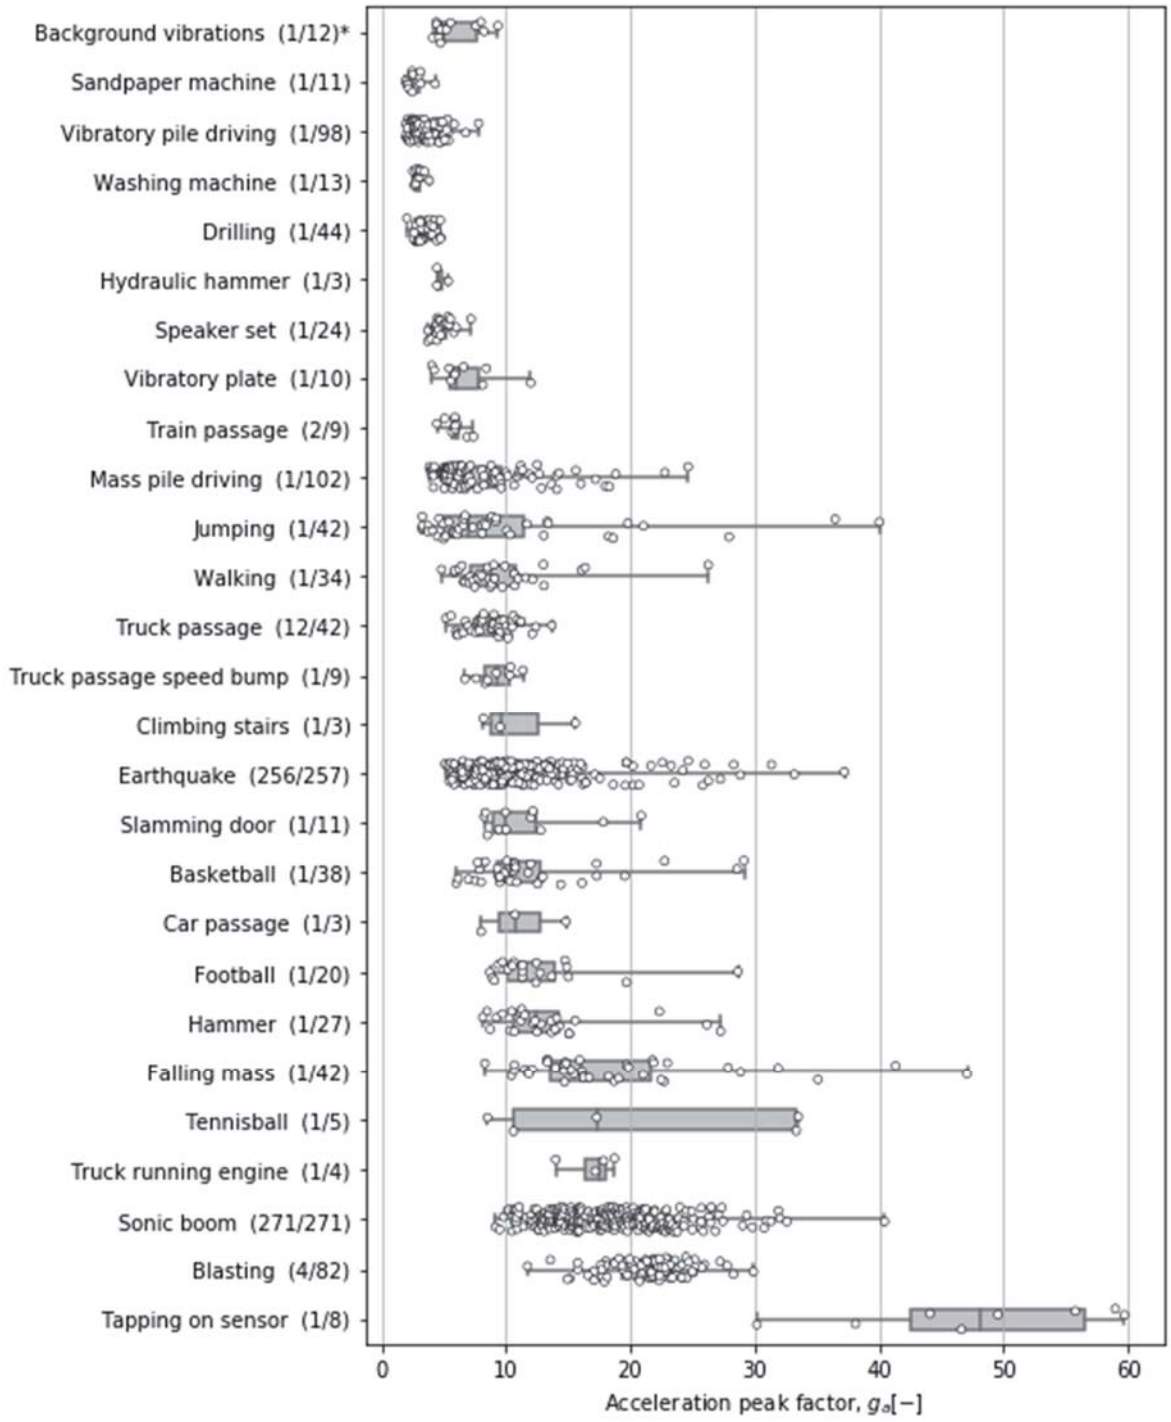

Figure 9: Boxplots and samples for the acceleration peak factor g_a obtained in all tests.
*(number of buildings/number of measured signals)

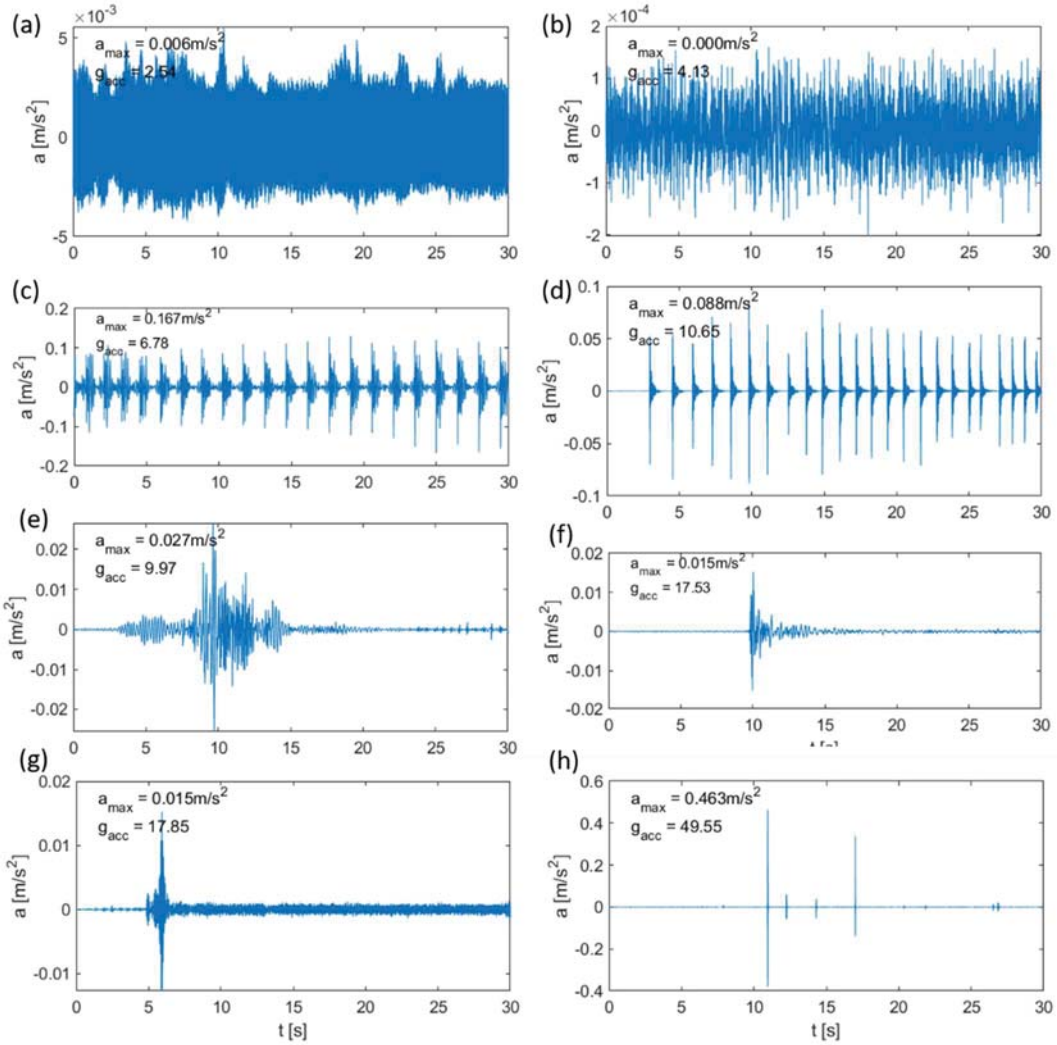

Figure 10: Acceleration signals of vibration sources with varying peak factors: (a) sandpaper machine, (b) background noise, (c) pile driving, (d) basketball against the wall, (e) truck passage, (f) sonic boom, (g) truck starting engine, and (h) hitting the sensor (by hand).

Figure 10(f), (g) and (h) show examples of a single short-duration transient due to a sonic boom, a starting truck engine near a sensor (~2 m) and a signal with several pulses due to hitting the sensor by hand. Signals with peak factors $g_a > 15$ are probably caused by sources which produce pulse-like or short-duration transient vibrations. These signals are unlikely to be the result of a source producing a monotonic continuous vibration. The only exception is the start-up or stopping of a source producing a monotonic continuous vibration, such as the starting truck engine in Figure 10(g).

Signals with $6 < g_a < 15$ are likely to be the result of sources generating repeated transient vibrations or a sustained transient vibration. Figure 10(c), (d) and (e) show examples of repeated transient vibrations (pile driving and throwing a basketball against the wall) and a sustained transient vibration (truck passage).

Several sources (e.g. mass pile driving, jumping, earthquake, and sonic boom) have relatively large ranges for the peak factor. These large ranges are the result of (1) the number of repeated transients over the 30 s period and (2) the distance between the sensor and the source.

Examples of the influence of the number of repeated transients are shown in Figure 11(a) and (b) for pile driving, and in Figure 11(c) and (d) for jumping. For a pile driving signal and a jumping signal with continuous regular transients over the full 30 s period the peak factor is low, whereas the signals with repeated transients over about 10 s has a relatively large peak factor.

Figure 11(e) and (f) show the velocity and acceleration signal of an earthquake measured at ~1 km and ~20 km. The signal at large distance has small peak factors and looks like a sustained transient vibration. At short distance, however, the signal mainly consists of a large pulse and has a large peak factor g_a. A similar effect is seen in Figure 11(g) and (h) for sonic boom signals.

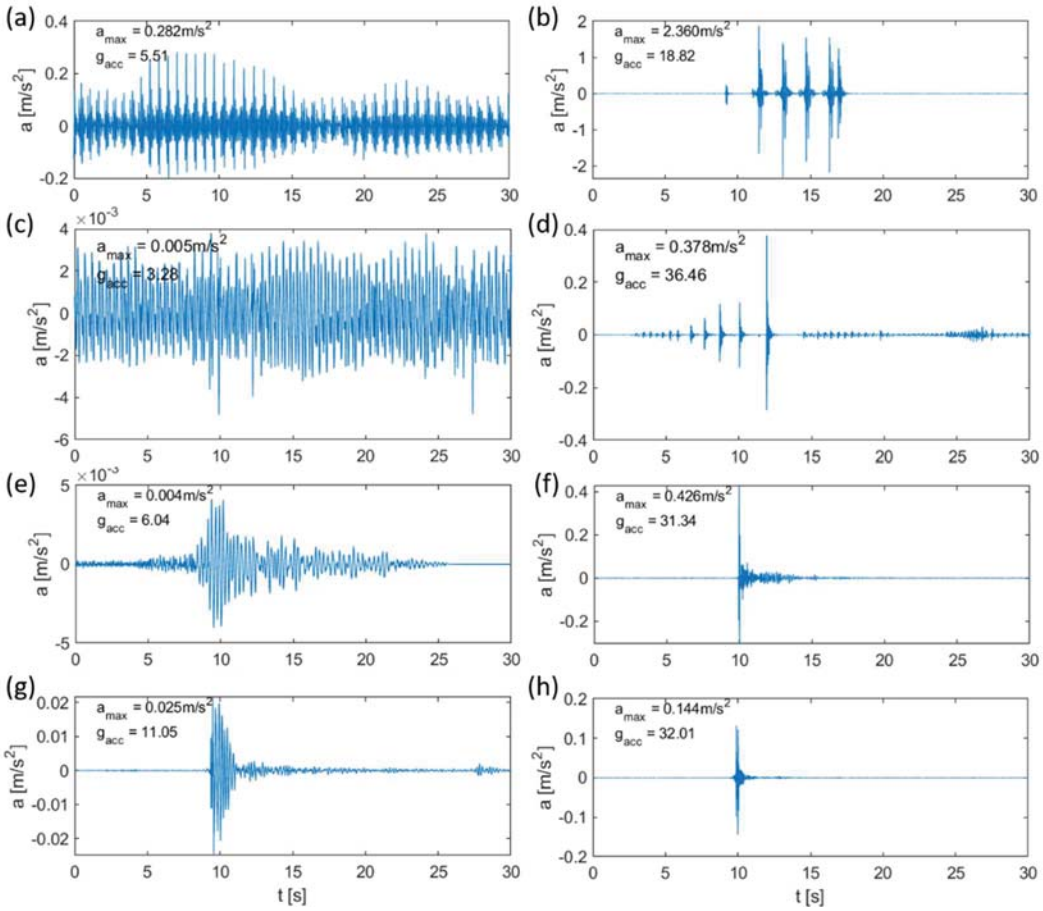

Figure 11: Acceleration signals of various sources which have both small and large peak factors: (a) continuous pile driving, (b) short-period pile driving, (c) continuous jumping, (d) short-period jumping, (e) sustained transient earthquake signal at ~20 km, (f) pulse signal earth-quake signal at ~1 km, (g) transient sonic boom, and (h) pulse signal sonic boom.

5.5 Significant duration, D_s

Figure 12 shows time traces of the acceleration signals and the normalized Arias intensity function. The normalized Arias intensity function shows how the vibration energy is released over the 30 second period. This energy release profile gives useful information about the characteristics of the signal.

Figure 13 shows box plots of the significant duration D_s per studied vibration source. The vibration sources are ranked in order of increasing significant duration, the background vibration results are placed at the top as reference.

Figure 12(a) shows the acceleration signal and normalized Arias intensity function of a hit on the sensor. A single pulse results in a very steep increase in the Arias intensity. The significant duration is therefore very short, i.e. less than 0.1 s. Figure 13 shows that similar short significant durations can occur for blasting, a sonic boom, an earthquake and a falling mass.

Although an earthquake can also have a large peak in the acceleration signal, see Figure 12(b), it is always preceded and followed by low-level vibrations. The resulting Arias intensity function is less steep, which generally gives a significant duration larger than 0.1 s, see Figure 13.

The more sustained the transient vibration becomes, the more gradual is the increase in Arias intensity and the larger the significant duration. Figure 12(c) shows the acceleration signal and Arias intensity function of a truck passage, the significant duration for this signal is close to 4 s. This type of transient vibration signal is for example observed for large road vehicles, trains and earthquakes, and typically has a significant duration larger than 1 s. For larger distance between the source and the sensor, the transient vibration becomes more prolonged and contains less significant peaks. This results in larger significant durations; Figure 13 shows significant durations up to 19 s for train passages. The main reason for these large values are the low vibration levels induced by the train passage, because of the large distance between railway and sensor (125 and 150 m).

A large significant duration can also be the result of a vibration signal consisting of repeated pulses or transients. Figure 12(d) shows a signal of a tennis ball hits against a wall. The repeated pulses result in a stepwise Arias intensity function. Because there are several seconds between each pulse the resulting significant duration is about 4 s, similar to what was observed for the sustained transient signal for the truck passage. This is the main reason for the large variation in significant duration seen in Figure 13 for several sources (e.g. sonic boom, vibratory plate, falling mass, etc.). When a source produces a vibration signal several times in the 30 s period, the significant duration will increase.

A regular repeating transient vibration signal, which can for example be observed for the mass pile driving signal shown in Figure 12(e), results in a regular stepwise Arias intensity function. The significant duration of this signal is ~19 s. A continuous vibration signal gives a similar significant duration. Figure 12(f) shows an example of a continuous vibration signal of a washing machine. The Arias intensity function of this signal increases linearly with time. The sources that are likely to produce these continuous or regularly repeating vibrations typically have significant durations larger than 10 s (see Figure 13). The significant duration for these type of signals is generally smaller than 21 s, i.e. the significant duration of a linearly increasing Arias intensity is 21 s (70% of 30 s).

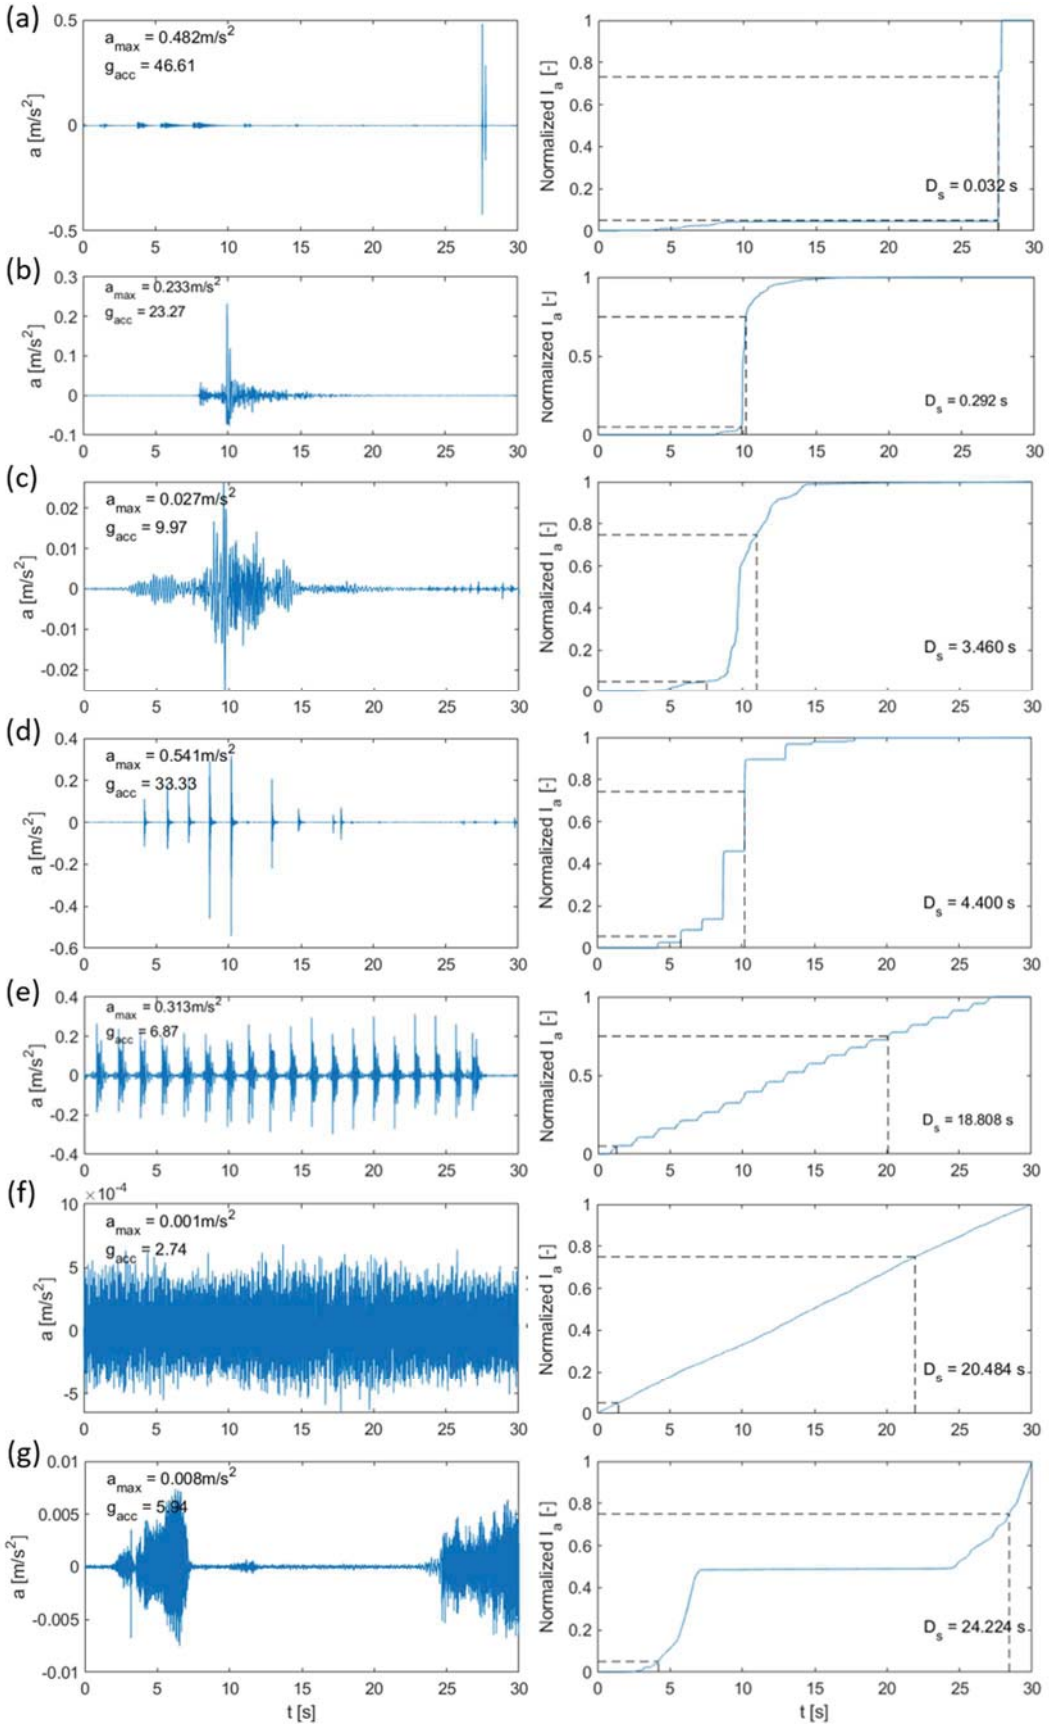

Figure 12: Acceleration signals and the Arias intensity function of various signals: (a) tapping on sensor, (b) earthquake, (c) truck passage, (d) tennis ball, (e) mass pile driving, (f) washing machine, and (g) drilling.

The largest significant durations are found for vibration signals that consist of vibration signals with most energy content at the beginning and end of the 30 s period. Figure 12(g) shows an example of drilling, with two periods of drilling with in-between a 17-18 s period without any significant vibrations. A significant duration larger than 70% of the reference period (in this case 30 s) is an indication that the vibration signal has this particular feature of two separated vibrations at the beginning and end.

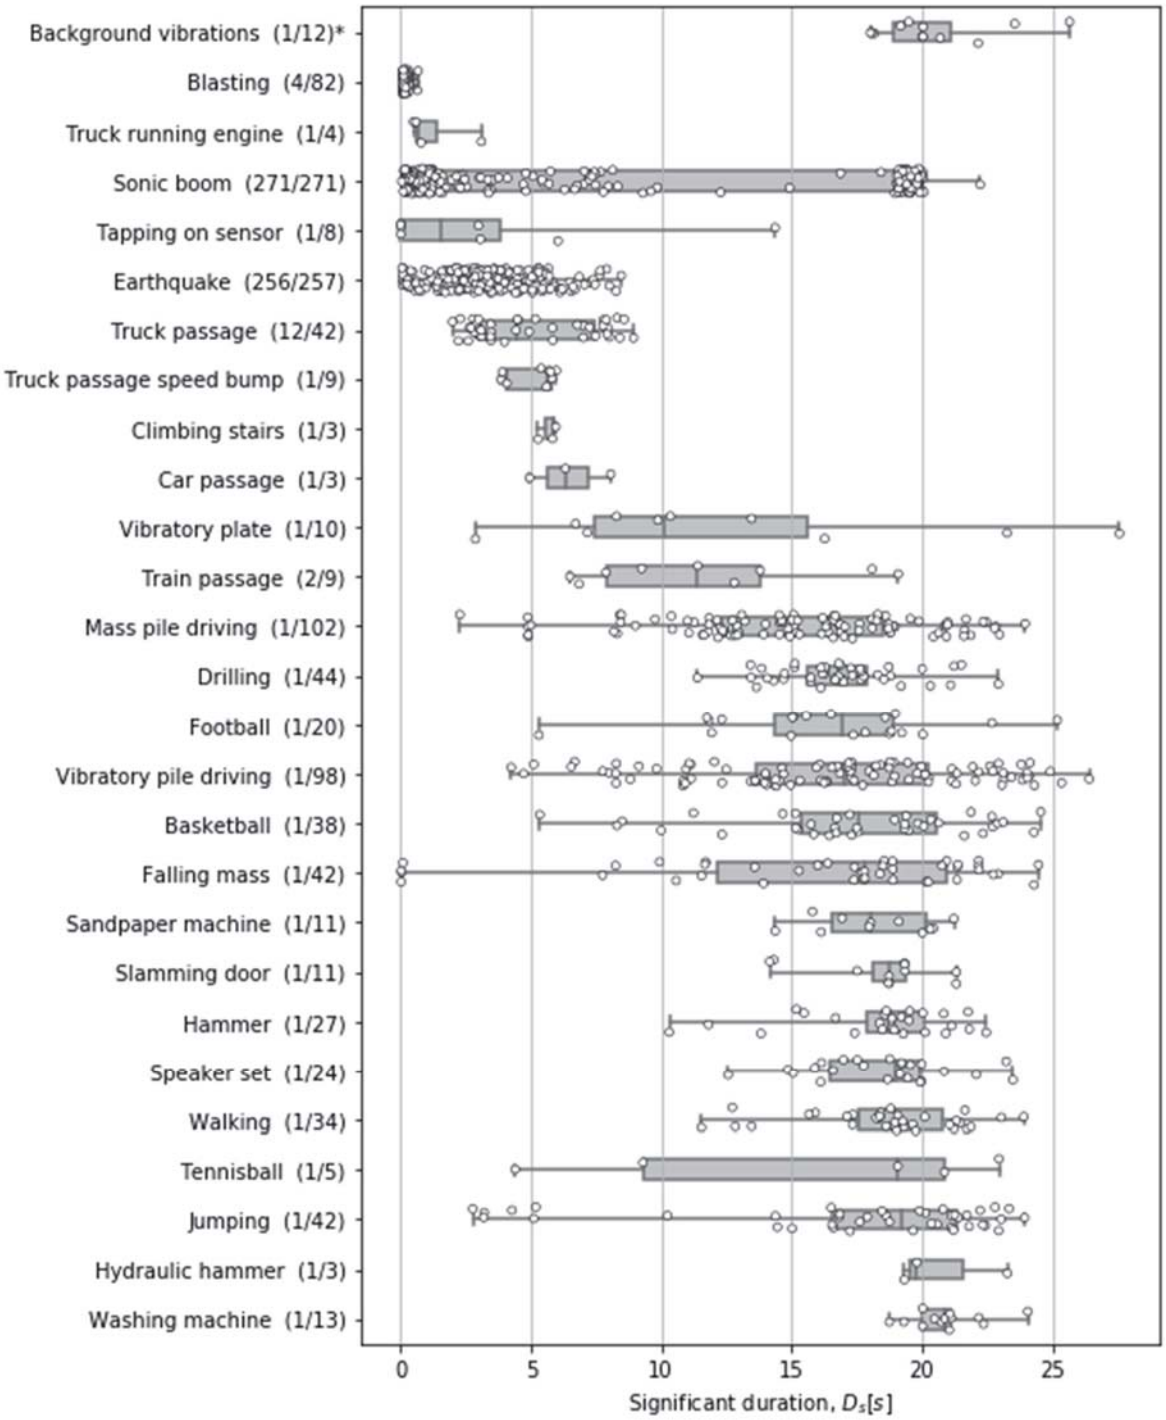

Figure 13: Boxplots and samples for the significant duration D_s obtained in all tests.
*(number of buildings/number of measured signals)

5.6 Number of peaks, N_{peak}

Figure 14 shows the normalized Arias intensity function and the time derivative of the Arias intensity function for some of the signals in Figure 12. Although the time derivative is quite correlated with the Arias intensity function, i.e. $|\rho_{x,y}| \sim 0.5$, it does give some useful additional information on the characteristics of some signals.

Figure 14(a) and (b) show examples of a truck passage and a bouncing tennis ball. Both signals have a significant duration of around 4 s, but the number of peaks of the transient vibration signal of the truck passage is much larger than that of the bouncing tennis ball. This shows that the combination of the significant duration D_s and the number of peaks N_{peak} can in some cases be used to distinguish between a signal with a single transient vibration and a signal with repeated pulses.

A similar difference can be seen for the regular repeated transient and continuous vibration signals in Figure 14(c) and (d). The significant duration of both signals is close to 20 s, while the washing machine vibration signal in Figure 14(d) has a much larger number of peaks than the mass pile driving vibration signal in Figure 14(c).

The drilling vibration signal in Figure 14(e) has a number of peaks much smaller than the washing machine in Figure 14(d). Combined with the large significant duration, the number of peaks is an additional indicator that the vibration signal consists of two separated periods of vibrations at the beginning and end.

The significant duration and the number of peaks are two signal characteristics that mainly provide some quantification of the part of the signal record containing vibrations. Based on the graphs in Figure 14, the periods without (significant) vibration content could also provide useful information on the signal, e.g. the percentage of time the derivative of the Arias intensity function is (close to) zero.

Figure 15 shows box plots of the number of peaks N_{peak} per studied vibration source. The vibration sources are ranked in order of increasing median value, the background vibration results are placed at the top as reference.

Figure 15 shows continuous vibration sources (e.g. a washing machine, drilling or vibratory pile driving) have numbers of peaks which are typically larger than 100.

Repeated or sustained transient vibrations have numbers of peaks which are mostly between 10 and 100. Typical examples are a bouncing ball, hammering, mass pile driving and road or railway traffic.

Vibration signals with a single or small number of pulses have a number of peaks smaller than 10. Sources which are likely to produce these type of vibration signals are tapping on the sensor, blasting or a starting or stopping truck engine.

6 CONCLUSION

This article presented a study on a large dataset of vibration signals from various internal and external vibration sources. The goal of this study was to determine a set of signal characteristics that allow for differentiation between vibration sources in a built environment. The study focused on vibration sources with the main energy content 1 and 100 Hz. The signals in the dataset were trimmed to a period of 30 s. A set of 11 signal characteristics were obtained for all signals in the dataset.

Based on the correlation between these characteristics, 6 signal characteristics were selected for a detailed analysis. Three of these signal characteristics, i.e. a_{max}, v_{max} and $f_{d,f,a}$, are well-established in literature for various vibration sources. The other three characteristics, i.e. g_a, D_s and N_{peak}, have been studied very little for most vibration sources.

The maximum vibration levels a_{max} and v_{max} determined for the various vibration sources fit well with the ranges mentioned in literature. However, for most vibration sources the dataset represents the low end of these ranges; they do not give a good representation of the complete range of levels that can occur in the built environment. Therefore the determined ranges for a_{max} and v_{max} in this study might not be very useful for differentiation between vibration sources.

The results for the dominant frequency $f_{d,f,a}$ also correspond well with literature, and for several sources (e.g. earthquakes, mass pile driving, road traffic) provide a reasonable representation of the mentioned ranges. The results show that vibration signals with dominant frequencies $f_{d,f,a} < 35$ Hz are often due to sources producing (repeated) transient vibrations, such as a truck or train passage, mass pile driving or an earthquake. Sources which generate continuous vibrations, such as drilling or vibratory pile driving typically have dominant frequencies $f_{d,f,a} > 25$ Hz. Other spectral features that could prove useful to allow for more differentiation between vibration sources are the bandwidth of the spectrum (e.g. the 3 dB bandwidth) or harmonic frequencies (cepstrum analysis).

The peak factor g_a provides information on the peakiness of a signal. The smallest peak factors were found for sources with a (monotonic) continuous vibration signal (e.g. vibratory pile driving); these type of signals typically have a peak factor $g_a < 6$. Large peak factors were observed for signals with a single or small number of pulses (e.g. hitting the sensor) or a single short-duration transient (e.g. sonic boom). Signals with peak factors $g_a > 15$ are likely to have been caused by these type of sources. Several sources (e.g. mass pile driving, jumping, earthquake, and sonic boom) have relatively large ranges for the peak factor. These large ranges were found to be the result of the number of repeated transients over the 30 s period or the distance between the sensor and the source, resulting in a prolonged transient vibration.

The significant duration gives information about the length of the period over which a large portion of the vibration energy is released. For a single pulse this gives a very short duration, typically smaller than 0.1 s. This type of duration is typically observed for a (single) hit on the sensor, but can also be observed for blasting, a sonic boom, an earthquake or a falling mass. Large significant durations (> 10 s) are observed for a regular repeated pulse or transient or a continuous vibration signal. The significant duration of these type of signals is generally not larger than 21 s. Signals with $D_s > 21$ s typically have large vibration content at the beginning and end of the 30 s period, with relatively little content in-between.

Although the significant duration D_s and the number of peaks N_{peak} are quite correlated, N_{peak} does give useful additional information on some vibration sources. For example, a signal transient (e.g. truck passage) and a repeated pulse (e.g. tennis ball) a bouncing ball can have the same significant duration, while the number of peaks are generally quite different. A similar behavior was observed for a continuous signal and a repeated transient signal.

The significant duration and the number of peaks are two signal characteristics that mainly provide information on the part of the signal record with vibrations. The periods without (significant) vibration content could also provide useful information on the signal, e.g. the percentage of time the derivative of the Arias intensity function is (close to) zero.

This research presented in this paper indicates that differentiation between vibration sources based on signal characteristics is feasible to a certain extent. Further research should investigate the possibilities and limitations of the dataset and the obtained signal characteristics for identification of vibration sources in the monitoring network. The database with reasons provided by building owners for trigger events is a valuable source to test a first version of an algorithm for vibration source identification.

ACKNOWLEDGMENT

The work presented in this paper was made possible by NAM (*Nederlandse Aardolie Maatschappij*). NAM financed the measurement network and provided for the building in which the tests were carried out.

Keywords: Multiaxial Loading, Fatigue Damage Accumulation, Wind Turbines, Bayesian Methods, Input-State Estimation

Abstract. *Fatigue monitoring and remaining fatigue life estimation of structures using output-only vibration measurements has recently garnered increasing attention, producing advances in theoretical, numerical and experimental studies of this phenomenon. The methodology presented in this paper combines methods for estimating stress time histories at the entire body of the structure with fatigue damage accumulation techniques for multiaxial stress state. A novel sequential Bayesian method is employed to estimate both input and state in the modal space and to reconstruct the full-field time-history response in the physical space using output-only vibration measurements. Stress and strain time histories at the finite element level are obtained by using a linear relationship with nodal displacements. Estimated stresses are then used to find the critical plane where the maximum fatigue damage is expected and the shear stress time histories are resolved on this plane. Shear stress cycles are counted by means of the Rainflow Counting Method, and a Modified Wöhler Curve Method is applied to estimate the fatigue damage, whereby normal and shear stress effects are accounted for. This procedure is capable of tackling inherent complexities found in real world applications, such as the multiaxiality of the applied loads and of the resulting stress state. A finite element model of a wind turbine tower was constructed based on reference specifications available from the National Renewable Energy Laboratory and used to illustrate the method presented herein. The results obtained demonstrate the applicability of the methodology as an efficient way to monitor fatigue damage accumulation in the entire body of a steel structure.*

1 INTRODUCTION

Fatigue damage accumulation in ductile materials does not always produce identifiable indicators of damage. Thus, it is important to develop monitoring methods that would enable to diagnose the fatigue state of a metallic structure and to predict the location(s) where high fatigue damage is most likely to accumulate, as well as the remaining fatigue lifetime of the structure, based on output only vibration measurements.

The work by Papadimitriou et al. [1] was the first to promote the use of output-only vibration measurements to estimate fatigue damage accumulation. It introduced the idea of using a Kalman filter to estimate the stress responses of a metallic structure subjected to stationary stochastic loads, thereby estimating the remaining fatigue lifetime. Nevertheless, this approach and subsequent ones [2]–[4] developed to handle non-stationary unknown excitations, considered uniaxial fatigue damage. The present work expands on this idea and applies techniques capable of handling multiaxial stress states.

Thereupon model reduction techniques have been introduced and used in conjunction with SHM methods, e.g., modal decomposition-expansion was employed by Maes et al. [5] to reconstruct the dynamic strain response of an offshore wind turbine tower; Tchemodanova et al. demonstrated in [6] the use of a substructure approach to estimate remaining fatigue lifetime of a section of a rollercoaster; Eftekhar Azam et al. proposed the use of a Dual Kalman in modal space, allowing the use of a modally truncated model [7].

The purpose of this work is to propose a methodology to monitor fatigue damage accumulation on a structural system or its components when subjected to input or interface loads that are unknown. The present work expands on ideas presented in [3], [8] for response reconstruction and fatigue estimation in linear components of structural systems and applies techniques capable of handling multiaxial stress fields. Moreover, it benefits from the latest advances accomplished in the area of joint input-state estimation [7], [9]–[12], adopting a novel sequential Bayesian approach to reconstruct the full-field dynamic responses using sparse output-only measurements.

The organization of this work is as follows. In Section 2, we present pertinent mathematical formulations for the strain/stress response reconstruction of the entire structure by means of the novel sequential Bayesian filtering technique presented in Section 3. In Section 4, we outline the formulations for the full-field multiaxial fatigue damage accumulation. Section 5 shows an illustrative example of the application of the proposed methodology on a FE model of a land-based wind turbine tower structure subjected to wind loads. Lastly, conclusions are put forth in Section 6.

2 MATHEMATICAL FORMULATION FOR STRAIN/STRESS ESTIMATION

2.1 System and observation models

The dynamical response of a linear time-invariant system can be described through Newton's second law of motion:

$$\boldsymbol{M}\ddot{\boldsymbol{x}}(t) + \boldsymbol{C}\dot{\boldsymbol{x}}(t) + \boldsymbol{K}\boldsymbol{x}(t) = \boldsymbol{S}_p\boldsymbol{f}(t) \tag{1}$$

where $\boldsymbol{M} \in \mathbb{R}^{N\times N}, \boldsymbol{C} \in \mathbb{R}^{N\times N}, \boldsymbol{K} \in \mathbb{R}^{N\times N}$, are the mass, damping and stiffness matrices, respectively; N is the number of degrees-of-freedom; $\boldsymbol{f}(t) \in \mathbb{R}^{N_I\times 1}$, is the dynamic force vector comprised of N_I independent components; $\boldsymbol{S}_p(t) \in \mathbb{R}^{N_I\times 1}$ is a matrix characterizing the spatial distribution of external forces; $\ddot{\boldsymbol{x}}(t) \in \mathbb{R}^{N\times 1}$, $\dot{\boldsymbol{x}}(t) \in \mathbb{R}^{N\times 1}$ and $\boldsymbol{x}(t) \in \mathbb{R}^{N\times 1}$ are the

acceleration, velocity, and displacement responses, respectively. When the vibration response is transformed into a truncated modal space, the following equation of motion is obtained [9]:

$$\ddot{\boldsymbol{\zeta}}(t) + \boldsymbol{\Gamma}\dot{\boldsymbol{\zeta}}(t) + \boldsymbol{\Omega}^2\boldsymbol{\zeta}(t) = \boldsymbol{\Phi}^T\boldsymbol{S}_p\boldsymbol{f}(t) \tag{2}$$

where $\boldsymbol{\Phi} \in \mathbb{R}^{N\times N_m}$ is the truncated modal matrix whose columns are filled with N_m mass-normalized mode shape vectors; $\boldsymbol{\zeta}(t) \in \mathbb{R}^{N_m\times 1}$ is the response in the reduced modal space; $\boldsymbol{\Gamma} \in \mathbb{R}^{N_m\times N_m}$ and $\boldsymbol{\Omega}^2 \in \mathbb{R}^{N_m\times N_m}$ are two diagonal matrices with $2\xi_i\omega_i$ and ω_i^2 entries, respectively; ξ_i and ω_i are, correspondingly, the modal damping ratio and modal frequency of the ith dynamical mode. This equation can be written in the state-space form as follows:

$$\dot{\boldsymbol{z}}(t) = \boldsymbol{A}_C\boldsymbol{z}(t) + \boldsymbol{B}_C\boldsymbol{f}(t) \tag{3}$$

where $\boldsymbol{z}(t) = \left[\boldsymbol{\zeta}(t)^T \quad \dot{\boldsymbol{\zeta}}(t)^T\right]^T$ is the state vector; $\boldsymbol{A}_C$ and $\boldsymbol{B}_C$ are the system and feedthrough matrices, computed as:

$$\boldsymbol{A}_C = \begin{bmatrix} \boldsymbol{0} & \boldsymbol{I} \\ -\boldsymbol{\Omega}^2 & -\boldsymbol{\Gamma} \end{bmatrix}, \quad \boldsymbol{B}_C = \begin{bmatrix} \boldsymbol{0} \\ \boldsymbol{\Phi}^T\boldsymbol{S}_p \end{bmatrix} \tag{4}$$

When the responses are discretized in Δt intervals and the variation of input forces is considered to be constant over each interval, the following stochastic state-space model is obtained in the discrete-time:

$$\boldsymbol{z}_k = \boldsymbol{A}\boldsymbol{z}_{k-1} + \boldsymbol{B}\boldsymbol{f}_{k-1} + \boldsymbol{v}_k \tag{5}$$

where $\boldsymbol{A} = e^{\boldsymbol{A}_C\Delta t}$ and $\boldsymbol{B} = (\boldsymbol{A} - \boldsymbol{I})\boldsymbol{A}_C^{-1}\boldsymbol{B}_C$ are the discrete-time system and feedthrough matrices; $\boldsymbol{z}_k$ is the state vector at $t_k = k\Delta t$, $k = \{0,1,2,\dots,n\}$; $\boldsymbol{v}_k$ is the process noise modeled as a Gaussian White Noise (GWN) process.

In a similar manner, the observed output quantities of interest can be written as a function of the state vector and the input forces leading to [7]:

$$\boldsymbol{d}_k \triangleq \begin{bmatrix} \boldsymbol{\varepsilon}_k \\ \boldsymbol{y}_k \\ \dot{\boldsymbol{y}}_k \\ \ddot{\boldsymbol{y}}_k \end{bmatrix} = \boldsymbol{G}\boldsymbol{z}_k + \boldsymbol{J}\boldsymbol{f}_k + \boldsymbol{w}_k \tag{6}$$

$$\boldsymbol{G} = \begin{bmatrix} \boldsymbol{S}_e\boldsymbol{T}\boldsymbol{\Phi} & \boldsymbol{0} \\ \boldsymbol{S}_d\boldsymbol{\Phi} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{S}_v\boldsymbol{\Phi} \\ -\boldsymbol{S}_a\boldsymbol{\Phi}\boldsymbol{\Omega}^2 & -\boldsymbol{S}_a\boldsymbol{\Phi}\boldsymbol{\Gamma} \end{bmatrix}, \quad \boldsymbol{J} = \begin{bmatrix} \boldsymbol{0} \\ \boldsymbol{0} \\ \boldsymbol{0} \\ \boldsymbol{S}_a\boldsymbol{\Phi}\boldsymbol{\Phi}^T\boldsymbol{S}_p \end{bmatrix} \tag{7}$$

where $\boldsymbol{d}_k \in \mathbb{R}^{N_0\times 1}$ is a vector containing the observed quantities at discrete time t_k, comprised by strains $\boldsymbol{\varepsilon}_k \in \mathbb{R}^{N_e\times 1}$, displacements $\boldsymbol{y}_k \in \mathbb{R}^{N_y\times 1}$, velocities $\dot{\boldsymbol{y}}_k \in \mathbb{R}^{N_{\dot{y}}\times 1}$, and accelerations $\ddot{\boldsymbol{y}}_k \in \mathbb{R}^{N_{\ddot{y}}\times 1}$; the matrices $\boldsymbol{S}_d, \boldsymbol{S}_v, \boldsymbol{S}_a$ and $\boldsymbol{S}_e$ are selection matrices consisting of 0's and 1's used to extract the observed DOF; $\boldsymbol{T}$ is a matrix returning local strains from nodal displacements; $\boldsymbol{w}_k$ is observation noise considered to be GWN.

3 BAYESIAN ESTIMATION OF INPUT AND STATE

We build our method upon the foregoing state-space formulations and the sequential Bayesian method developed in [11], [13]. The reader is referred to [13] for detailed nomenclature and mathematical formulations. This implementation allows estimating the system state and input in real-time based on a limited number of output-only measurements. Another advantage of this novel algorithm is its robust capability to update the process and observation noise covariance matrices in an online manner. On the other hand, a caveat to this method is that, similar to other Kalman-type filters, some initial parameters need to be fine-tuned to

achieve best results; for the sequential Bayesian filter, these parameters are the initial covariance matrices. A good starting point to calibrate the filter is to set the initial state and input covariance matrices equal to identity matrices scaled by a very small number. A more accurate, albeit laborious approach to selecting appropriate initial noise parameters, is to consider different orders of magnitude for the elements the initial estimates for the covariance matrices, in accordance to the modal response quantities (displacement, velocity, acceleration) to which the element corresponds [14].

4 FATIGUE ASSESSMENT

4.1 Maximum Variance Method for locating the critical plane

The so-called critical plane approaches are based on the assumption that fatigue life is mainly dependent on cracks developing along shear planes or tensile planes [15]. Thus, the maximum fatigue damage experienced in an element can be expected to occur at such orientation. To find such orientation, we adopt the use of the Maximum Variance Method (MVM) proposed by Susmel et al. [16]. This method assumes that the critical plane lies along the direction which is anticipated to have the maximum shear stress variation; the rationale stems from the definition of the statistical variance, which measures how much the signal deviates from the mean. Since fatigue damage is caused by cyclic loading, the variance can be an appropriate measure to identify the plane where the signal presents the largest variation range. Therefore, the damage is expected to be the greatest at the aforementioned plane. The advantage of this method lies in that, once the critical plane is found, the shear stress signals can be readily resolved along this orientation by a simple stress transformation.

Lastly, it should be noted that by applying the MVM, the critical plane and its corresponding shear stress are obtained. The latter is a unidimensional parameter, so a cycle counting method, such as the Rainflow Counting Method (RCM), can be used directly with the resolved shear stress signal.

4.2 Modified Wöhler Curve Method for fatigue assessment

In addition to the MVM described above, Susmel et al. [17] formulated the so-called Modified Wöhler Curve Method (MWCM) to be used as a companion method. The motivation behind this method is that the MVM and subsequent cycle counting is based on shear stresses resolved along the critical plane; however, this stress signal alone may fail to account for the multiaxiality of the actual stress state. As such, a modification in the SN-Curve is introduced to account for the level of multiaxiality by considering the stress normal to the critical plane. Ultimately, a modified fatigue lifetime curve is obtained.

For brevity, the detailed formulations of the MWCM are omitted in this paper. The reader is thus referred to [17], [18] for a comprehensive explanation of this method and an illustrative example.

4.3 Fatigue damage accumulation

The last step in the fatigue assessment framework is to use the data generated throughout and to calculate the accumulated damage in the whole structure. The damage accumulation model used herein is the linear Palmgren-Miner's rule, which states that the linear fatigue accumulation damage D is found by [19], [20]:

$$D = \sum_{i=1}^{j} \frac{n_i}{N_{f,i}} \tag{8}$$

where j is the number of different amplitude levels found through RCM; n_i is the number of counted cycles at a given amplitude level, and $N_{f,i}$ is the number of cycles to failure at amplitude level i, found directly in the constructed MWC.

Once the appropriate SN-Curve has been obtained from the MWCM, and the RCM has been applied to the time history of the shear stress relative to the critical plane, this information can then be used to compute the accumulated fatigue damage for each element in the finite element model of the structure. The procedure is repeated for every finite element in the discretized model. The final product is a full-field damage accumulation map.

5 NUMERICAL EXAMPLE

A reference land-based wind turbine tower model was used in this study. Physical and material specifications were obtained from the National Renewable Energy Laboratory (NREL) [21], from which a finite element model (FEM) was constructed. For simplicity, the dynamic response of the rotor nacelle assembly (RNA) was modelled by an equivalent system of forces at the RNA-tower interface, as shown schematically in Figure 1. The model was constructed using four-node shell elements, where at each node, 6 DOF are considered; the varying shell thickness was modeled using the NREL specifications. This type of element was selected due to the type of problem at hand: the structure is, geometrically, a hollow tube constructed by a comparatively thin sheet of steel. The tower model was discretized into 2444 elements, with 2455 nodes, for a total 14,730 degrees of freedom. The elements can be assumed to be in plane strain, which allows performing a reduced order analysis. This assumption also impacts the cost of multiaxial fatigue computations, since the problem reduces to a biaxial problem. Nevertheless, the principles applied still hold for triaxial fatigue computations.

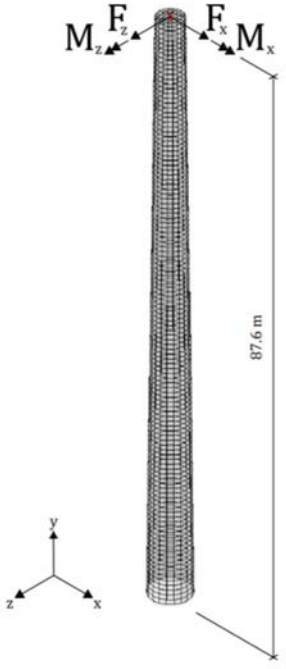

Figure 1. Equivalent system of forces at the RNA-tower interface.

The wind turbine simulation software FAST [22] was employed using the aforementioned tower model specifications. A simulation of 8 s was conducted, recreating operational wind conditions and loads on a tower model with the aforementioned specifications. The time history of the force transmitted through the RNA-tower interface was extracted. The obtained signal time history was subsequently used in the numerical analysis as the system input.

Structural matrices were obtained from the FE model shown in Figure 2, and a modal analysis was performed to obtain the corresponding natural frequencies and mode shape vectors. The dominating dynamic forces at the RNA interface pertaining to the wind loads and rotation dynamics were recorded as 2 concentrated loads and 2 concentrated moments, and frequency analysis was carried out on the input channels. Based on the frequency content of the input, we realized that the first 3 modes predominantly contribute to the system dynamical responses. The natural frequencies are reported in Table 1.

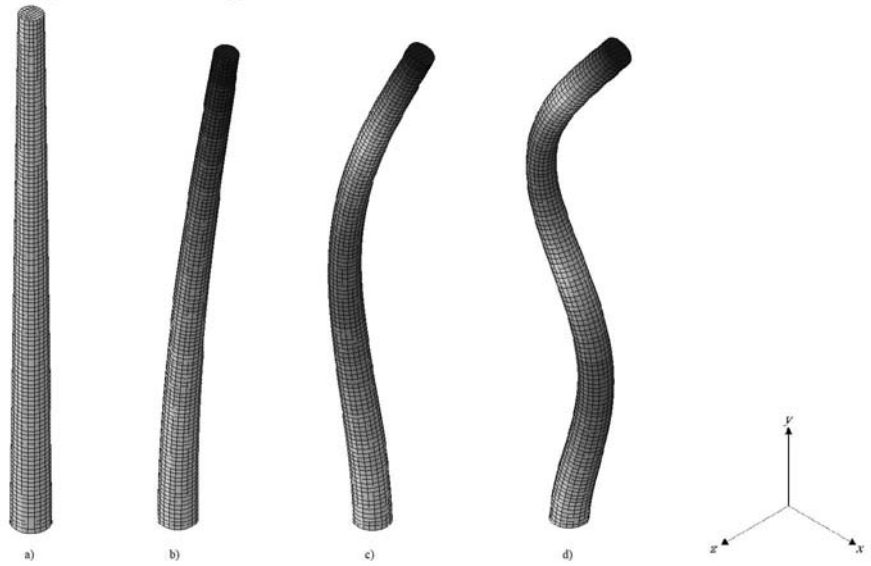

Figure 2: Finite element model of NREL's 5MW land-based wind turbine tower: a) base state, b) first mode, c) second mode, d) third mode.

Mode	Frequency (Hz)
1	0.8761
2	4.1737
3	10.395

Table 1: Finite element model natural frequencies.

The observation model was constructed from a limited number of output measurements; the discussion of stability of an Augmented Kalman Filter (AKF) presented by Lourens et al. [10] pointed out that ill-conditioning in the joint input-state estimator might increase depending on the sensor placement. Additionally, Maes et al. [23] suggested that the number of sensors should at least be equal to the number of forces to be identified. Thus, 2 biaxial acceleration and 4 strain responses were treated as the observed quantities. One set of collocated sensors, comprising 1 acceleration and 2 strain observations, was placed at a height of 86.9 m. from the ground, i.e. in the near-vicinity of the load application point; a similar second set of sensors was placed at a height of 63.5 m. from the ground. Figure 3 shows the locations of the response observations. Noise was introduced to the measurements as 1% of the root-mean-square deviation found in the observed channels, i.e. strains and accelerations.

A dynamic simulation of the first 8 s of operation was conducted. The structure is initially at rest, and the equivalent force system is applied at the beginning of the simulation. The modally-reduced state was estimated using the sequential Bayesian filter, and the full-field system response was reconstructed from the state and input estimation. The stress state time history at the finite element level is computed from a linear relationship between displacements and stresses under static loading cases. Consequently, accuracy in the estimation of nodal displacements is prescribed. Figures 4-5 show the acceleration and displacement, and stress responses, respectively, of an unmeasured near the base of the tower, i.e. a location far from the observations. The response estimates show agreement between the real and estimated responses. Notably, the estimated displacement responses were highly accurate. The stress and strain fields, however, do not display the same level of accuracy; thus, deviations from the real response in the displacement field are amplified in the corresponding stress field.

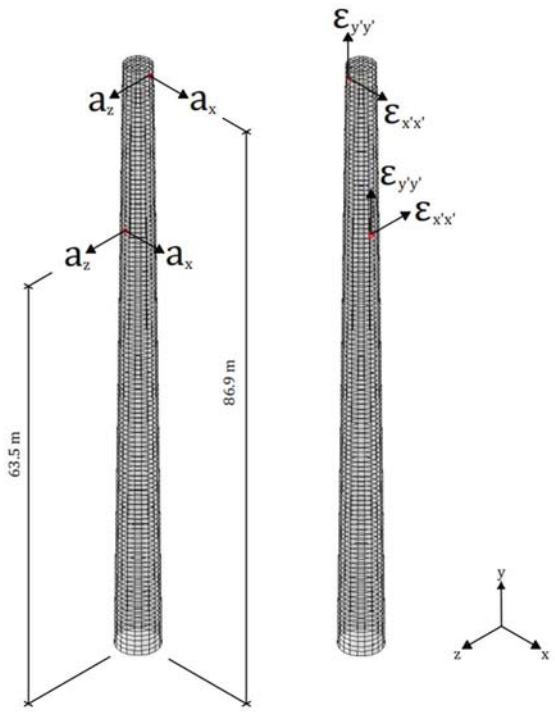

Figure 3: Measurement locations: a) accelerations, b) strains.

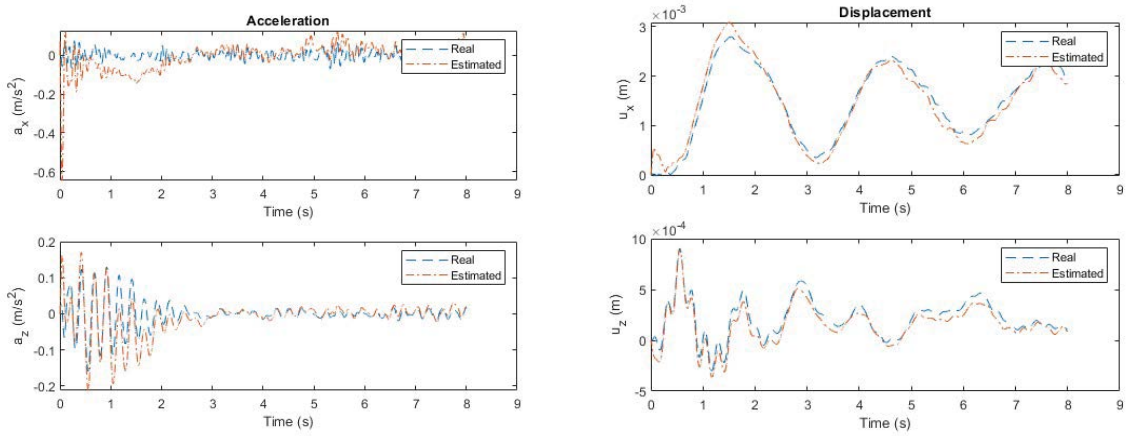

Figure 4: Real vs. estimated acceleration and displacement at unmeasured location near the tower base.

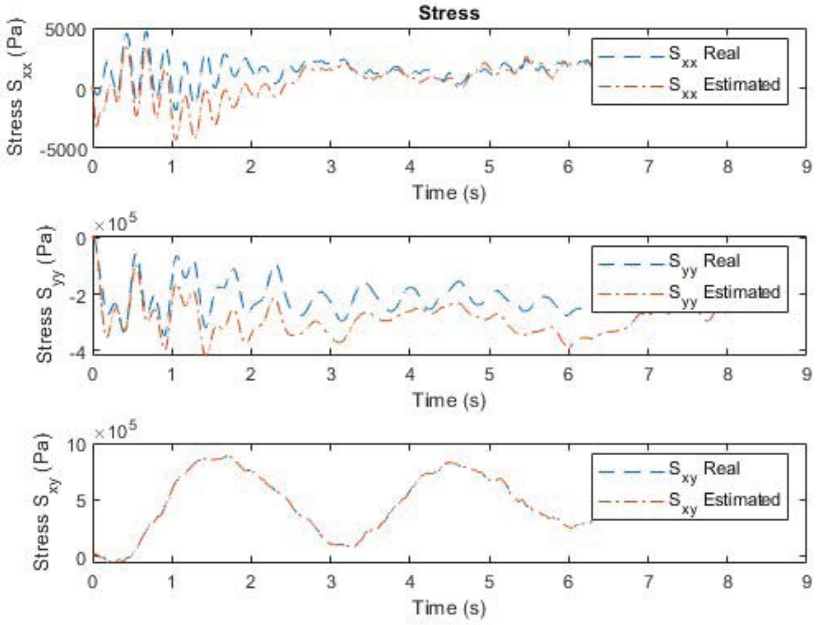

Figure 5: Real vs. estimated responses at unmeasured location near the tower base.

The next step is to identify the critical plane for each finite element by applying the MVM. Figure 6 shows the real and estimated shear stresses resolved along the critical plane. Considering that the shear stress transformation is a function of the stress state, it is evident that the error in the critical plane shear stress depends greatly on the accuracy of the stress tensor estimate. The normal stresses σ_{xx} and σ_{yy} are markedly influenced by the drift in the response estimations. The critical plane shear stress time histories are used to compute the stress amplitude range and the number of cycles at each amplitude range by means of the RCM.

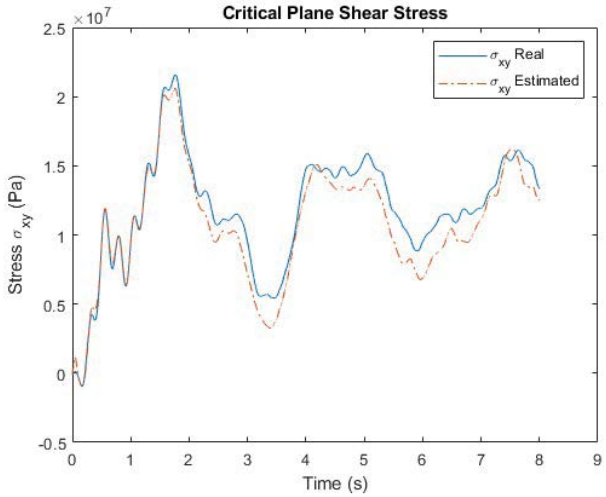

Figure 6: Shear stress resolved along the critical plane.

Lastly, a Modified Wöhler Curve and the linear Palmgren-Miner's rule are applied to compute the accumulated fatigue damage at each finite element. A full-field damage accumulation map and the resulting error are shown in Figures 7-8. The error in the fatigue damage estima-

tion is caused by the deviations in the critical plane shear stress: the error is carried over to the cycle counting, and thence to the damage accumulation computation.

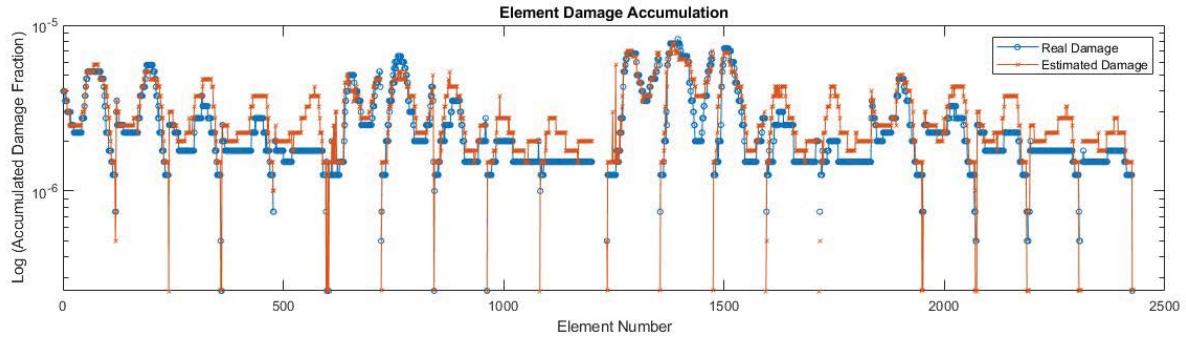

Figure 7: Full-field fatigue damage accumulation.

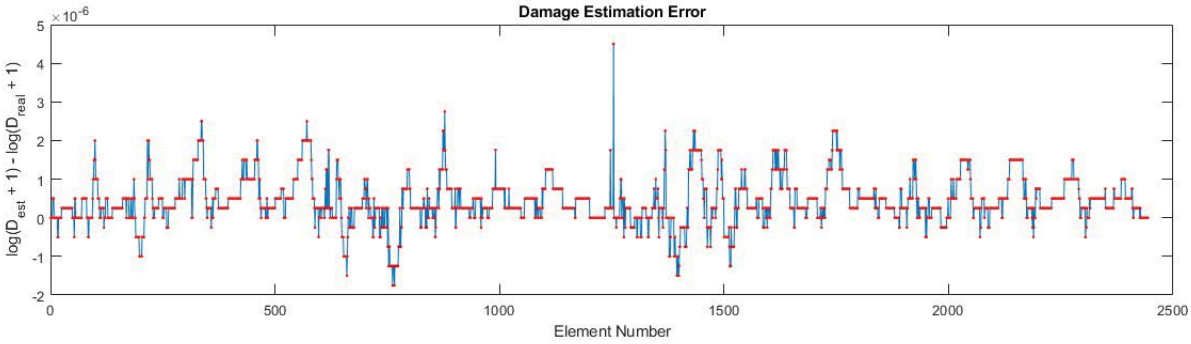

Figure 8: Damage estimation error.

6 CONCLUSION

A framework for computing full-field fatigue damage accumulation from a limited number of output-only measurements was presented. The proposed methodology promises real-world applicability on a variety of structures under unknown excitations, provided the proper calibration of the estimation algorithm is exercised, and an optimal observation location configuration is implemented. Its capability to efficiently produce a full-field fatigue map from limited measurements makes it a powerful tool for monitoring fatigue accumulation in wind turbine tower structures.

Keywords: Steel building, Strong motion, Ambient vibration, System identification

Abstract. *The Building Research Institute (BRI) of Japan is a national institute engaged in research and development in the fields of architecture, building engineering and urban planning. As one of its research activities, the BRI operates a strong motion network that covers buildings in major cities across Japan. As one of the stations in the BRI strong motion network, Miyako City Hall was instrumented in September 2018. More than 80 strong motion records were obtained within 16 months after the installation of the monitoring system.*

The daily natural frequencies and damping ratios in both the horizontal directions of the building were identified from the ambient vibration data recorded on the sixth floor. The natural frequencies decrease slightly for three months after completion but then show stable values. The damping ratios are distributed between 3% and 7%, which are larger than those obtained from the strong motion records.

The fundamental dynamic characteristics of the building are discussed through the analysis of the strong motion data. The natural frequencies in the X-direction vary between 1.6 Hz and 1.9 Hz. It was confirmed that the variation was caused by the amplitude dependence of the natural frequency. The natural frequencies in the Y-direction are close to those in the X-direction and show amplitude dependence as well. The damping ratios in both directions are 3% or less and widely vary.

The seismic monitoring system of the new main building of Miyako City Hall revealed the fundamental dynamic characteristics of the building within 16 months after completion. These results will be useful for structural health assessments of the building in the future.

1 INTRODUCTION

The Building Research Institute (BRI) of Japan is a national institute engaged in research and development in the fields of architecture, building engineering and urban planning. As one of its research activities, BRI operates a strong motion network that covers buildings in major cities across Japan [1]. A great number of strong motion data has been accumulated in the long history of the BRI strong motion network.

As one of the stations in the BRI strong motion network, Miyako City Hall was instrumented in September 2018. The city of Miyako is on the Pacific side of northern Japan and was hit by a tsunami during the 2011 Great East Japan Earthquake (Tohoku Earthquake). The main building of the city hall at that time was inundated to the second floor. The building was restored and used for seven years after the disaster, and then a new office building was built at another location in 2018. BRI had a strong motion instrument in the old city hall building and installed a new system in the new building.

This paper discusses the fundamental dynamic characteristics of the new city hall building using strong motion data and ambient vibration data.

2 TARGET BUILDING

Miyako City Hall was built as a core facility for the central city area development project in 2018. The city hall building is a six-storey steel building and is a complex that combines the functions of a communication and health centre. Table 1 and Figure 1 show the overview and external appearance of the building.

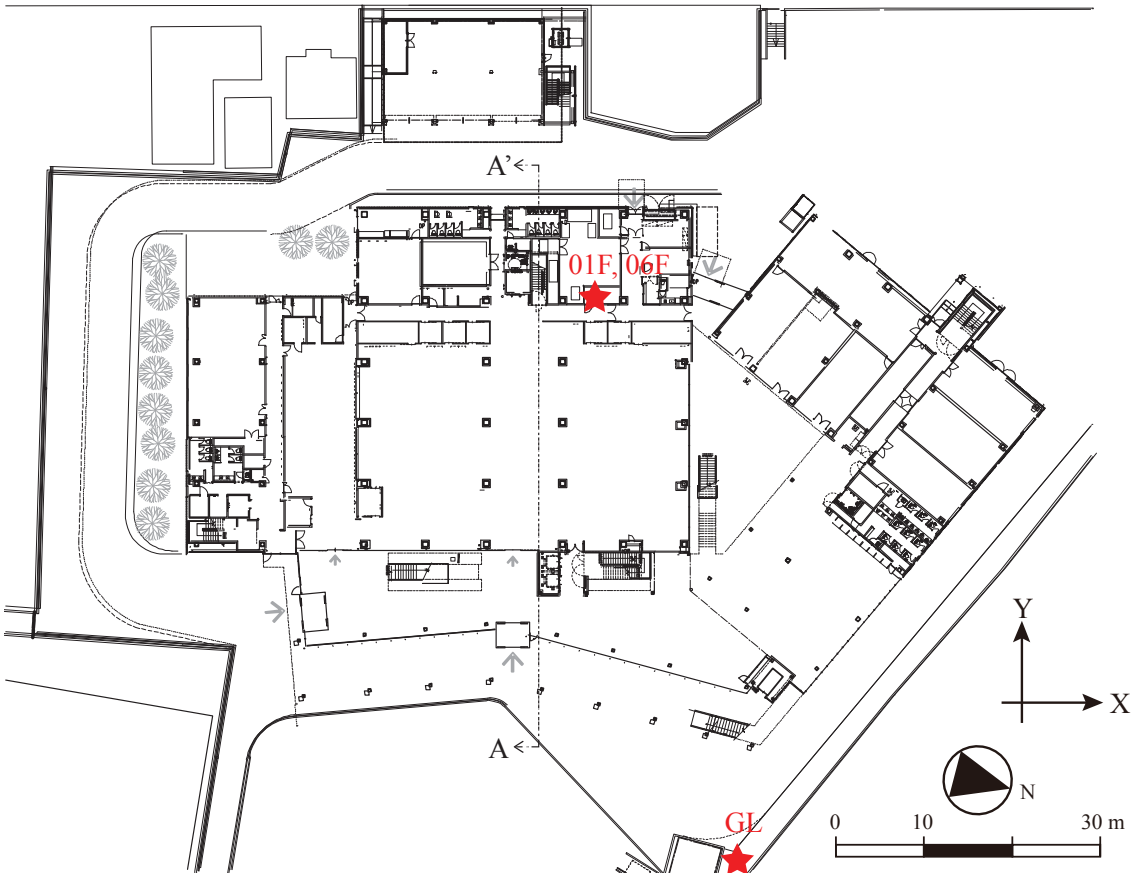
Use	City office, communication centre and health centre
Structure	Steel frame
Number of storeys	6
Building area	4,842.31 m^2
Total floor area	14,068.48 m^2
Height	26.45 m
Foundation	Cast-in-place concrete pile (l=37m)

Table 1: Overview of the target building.

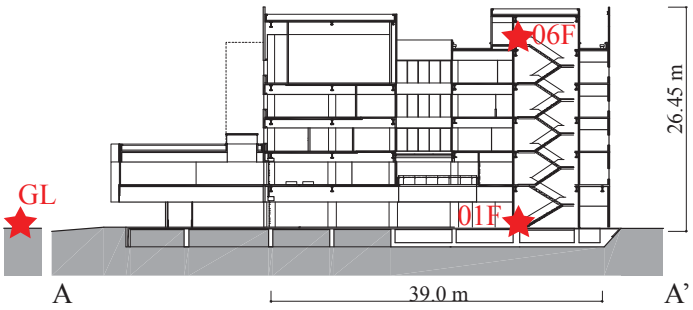
Figure 1: External appearance of the target building.

3 SEISMIC MONITORING SYSTEM

The seismic monitoring system installed in the new building has three triaxial acceleration sensors on the ground, first floor and sixth floor. The sensor configuration is illustrated in Figure 2. The acceleration sensors are installed along the axis of the building, and this paper treats the direction heading north as X and the direction heading west as Y. All acceleration signals are continuously recorded with the logging system placed on the first floor. The system can be accessed via the Internet using the mobile communication network from BRI.



(a) Ground plan



(b) Cross section

Figure 2: Sensor configuration.

4 AMBIENT VIBRATION DATA

The seismic monitoring system stores continuous data as one-hour files. The data files from midnight every day are transferred to BRI manually. The natural frequencies and damping ratios in the X- and Y-directions of the building are identified by the random decrement (RD) technique [2] using the ambient vibration data on the sixth floor ("06F" in Figure 2).

Identified natural frequencies and damping ratios are plotted in Figure 3 as a relation to time. Red circles and blue triangles indicate values in the X- and Y-directions, respectively.

The natural frequencies appear to be stable throughout the monitoring period, and those mean values are 1.88 Hz and 1.79 Hz in the X- and Y-directions as indicated by red and blue dashed lines, respectively. After carefully comparing the daily natural frequencies and mean lines, it was observed that the natural frequencies have been gradually decreasing for a few months after completion.

The damping ratios in both directions widely vary. The mean values are 5.12 % and 4.04 % in the X- and Y-directions, respectively.

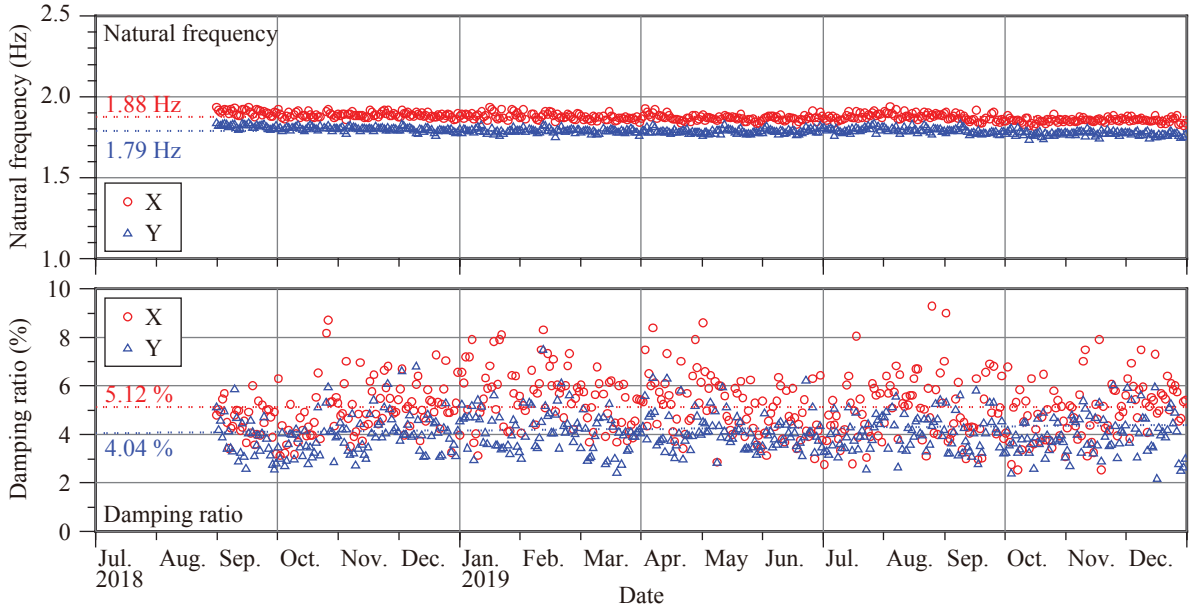


Figure 3: Natural frequencies and damping ratios obtained from ambient vibration data.

5 STRONG MOTION RECORDS

By the end of 2019, more than 80 strong motion records were obtained after the installation of the monitoring system. The amplitudes of the ground motions were small to medium, and the maximum JMA (Japan Meteorological Agency) seismic intensity was 3.

From each strong motion data, the fundamental natural frequencies and damping ratios in two horizontal directions of the building were identified using a parameter optimization technique [3]. With a single-degree-of-freedom system, the natural frequency and damping ratio that had the most fitted response displacement were determined using the grid search. Strong motion data on the first and sixth floors were adopted as the input and output motions, respectively.

Figure 4 indicates changes in the natural frequency and damping ratio of the building with time. Red circles and blue triangles correspond to the X- and Y-directions, respectively. The natural frequencies in both directions are distributed between 1.6 Hz and 1.9 Hz. The damping ratios vary somewhat but are less than 4%, which are smaller than the values obtained from the

ambient vibration data. In the identification using strong motion data, the influence of the soil-structure interaction (SSI) is eliminated by assuming that the first and sixth floors are input and output positions. In contrast, the identification using ambient vibration records is affected by SSI, since it uses only records on the sixth floor. This difference is considered to be one of the causes of difference in damping ratios.

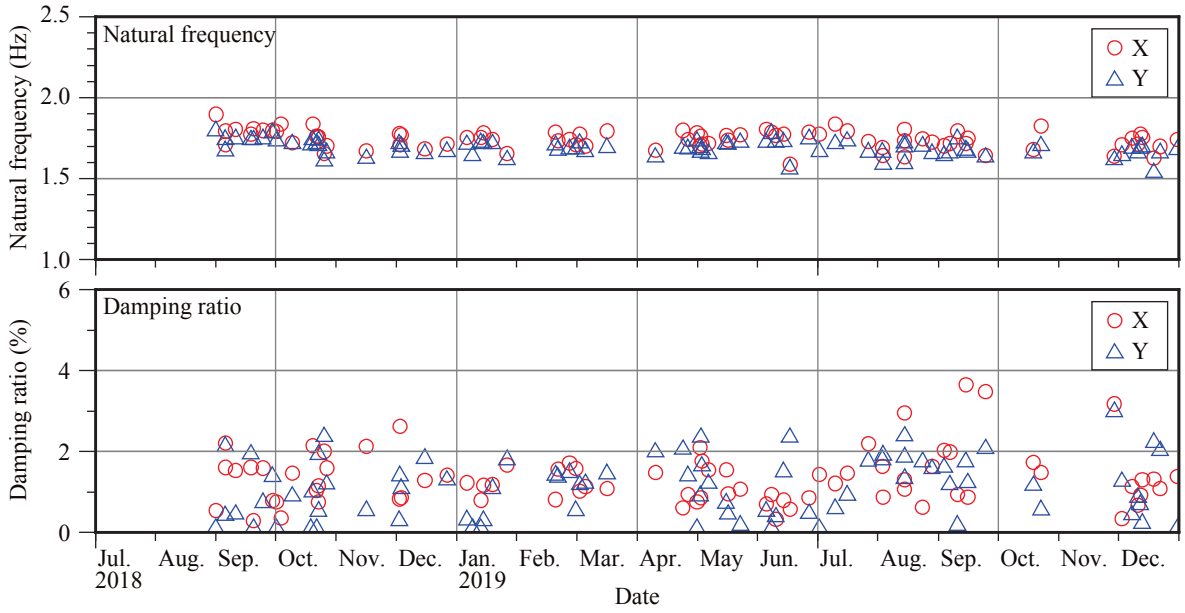

Figure 4: Natural frequencies and damping ratios obtained from strong motion data.

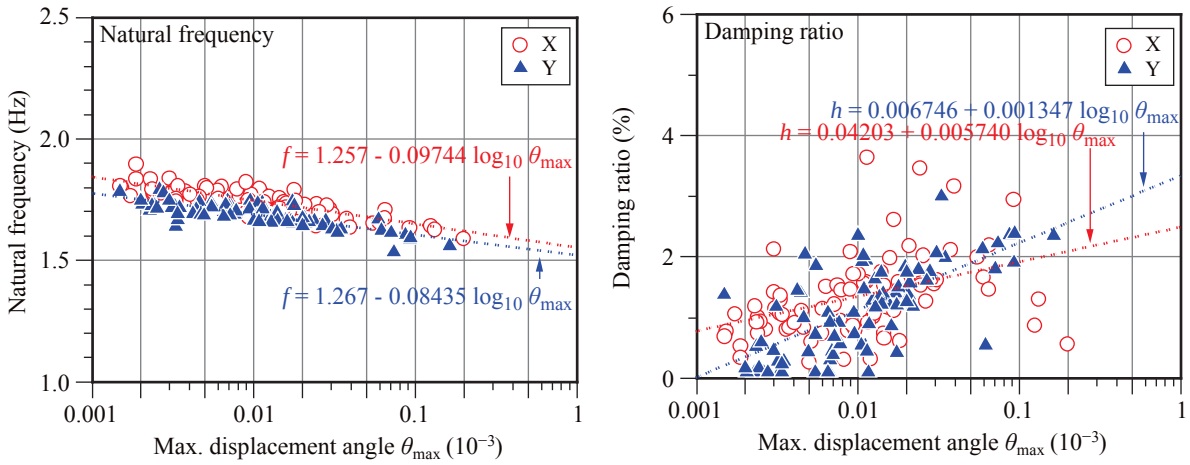
Dependence of dynamic characteristics on response amplitude is examined using the maximum displacement angle $\theta_{\max}$ defined by Eq. (1).

$$\theta_{\max} = |x_{06F}(t) - x_{01F}(t)|_{\max}/H \tag{1}$$

where, $x_{06F}(t)$ and $x_{01F}(t)$ are the time histories of the displacements on the sixth and first floors, respectively, and H is the height of the sixth-floor level from the first-floor level.



(a) Natural frequency

(b) Damping ratio

Figure 5: Relation of natural frequency and damping ratio to maximum displacement angle.

The relation of the natural frequency and damping ratio to the maximum displacement angle $\theta_{\max}$ is plotted in Figure 5. Hollow red circles and solid blue triangles indicate the values in the X- and Y-directions, respectively.

There is evident amplitude dependence in the natural frequency. Dashed lines represent the results of the regression analysis. When the response amplitude increases ten times, the natural frequencies decrease by 0.1 Hz and 0.08 Hz in the X- and Y-directions, respectively. The damping ratios tend to increase as the response amplitude increases. For reference, the results of the regression analysis are indicated by broken lines in the figure.

6 CONCLUSIONS

As one of the stations in the BRI strong motion network, Miyako City Hall, which is a six-storey steel building, was instrumented in September 2018. This paper discussed the dynamic characteristics of the building using strong motion and ambient vibration data.

The daily natural frequencies in the horizontal directions of the building identified from the ambient vibration data were stable and decreased gradually for a few months from completion. The daily damping ratios widely varied and were 5.12 % and 4.04 % in the X- and Y-directions on average, respectively.

The natural frequencies and damping ratios of the building were estimated from the strong motion data as well. The natural frequencies in both horizontal directions showed apparent amplitude dependence and decreased with the increase of the response amplitude. In the case of this building, the natural frequency decreased by nearly 0.1 Hz when the response amplitude increased tenfold. The damping ratios estimated using the strong motion data varied somewhat and showed smaller values compared with the values obtained from the ambient vibration data.

The damping ratios from strong motion records are obtained by treating records of the first floor as inputs and records of the sixth floor as outputs and do not include the effect of the soil-structure interaction (SSI). On the other hand, the damping ratios from ambient vibration records are obtained only from the records of the 6th floor of the building and are affected by SSI. This can be considered to be one of the causes of the difference in damping ratios. The influence of other factors, such as differences in external force conditions, are also considered, and further investigation is necessary.

Keywords: temperature compensation, damage detection, eigenfrequency, bridge, Principal Component Analysis

Abstract. *Structural health monitoring of concrete bridges can be achieved by tracking static load-testing results or dynamic properties as for example eigenfrequencies. Deviations from a healthy reference state can be used as damage indicators and even more, help to localize zones of stiffness reduction, i.e. cracking. However, outdoor temperature effects also lead to changes of monitored physical characteristics in the same order of magnitude as damage. Hence, temperature effects need to be removed prior to any condition analysis. The present paper presents a new two-step approach by applying physical compensation first, before using a statistical method based of Principal Component Analysis (PCA) or more exactly on principal vectors and singular values. This technique is here applied to eigenfrequencies, first of a new bridge without damage, but with extreme temperature variation due to thick asphalt layer and special bearing constraints, thus showing strong sensitivity along seasonal temperatures in the intact state. The second object is the Z24 Bridge in Switzerland, which is well documented in literature and where artificial damage was applied prior to demolition. The proposed techniques allow removing noise and temperature effects in a coherent and efficient way. The corrected measurement data can then be used in subsequent steps for its definite purpose, i.e. detection and localization of damage for instance by updating a numerical finite element model which allows assessing a stiffness loss.*

1 INTRODUCTION

Damage diagnosis in civil engineering systems is often based on static or/and dynamic measurements, which allow to detect, localize and quantify stiffness reduction going along with concrete cracking. For instance, for bridge structures, static displacement or strain measurements are typically done along the length at defined positions for a known test-loading in regular time intervals. Alternatively, modal properties like eigenfrequencies, modeshapes, modal masses or damping values can be measured and tracked. However, both static and dynamic characteristics can show high sensitivity to temperature variations, which show important influence on asphalt-, soil- and bearing-stiffness. Variations of the measured characteristics due to temperature can be typically in the same order of magnitude than those caused by real damage. Therefore, prior to further analysis, compensation of measured data regarding temperature effects is mandatory. Furthermore, tests should be performed in similar conditions due to other non-linearities of concrete bridges, e.g. the level of excitation (force, load) either without temperature gradients or local differences in the structure. In real application, bridge temperature cannot be fully controlled due to day-night and seasonal changes, why compensation algorithms are so fundamental prior to further comparison and damage analysis. Lloyd et al. [1] used the bootstrap for temperature compensation of measured frequencies and displacements to assess bending and shear stiffness of a concrete bridge. Temperature and operational effects were removed by Magalhães et al. [2] through multiple linear regression analysis for damage detection in an arch bridge. Cury et al. [3] normalized data of a PSC box girder bridge by a prediction law using non-linear regression based on neural networks.

After temperature compensation, the measured data can be analyzed to evaluate a bridge's current condition. For example, repeating measured static displacements at many points along the length of bridge can be directly taken to draw the deflection line in [4]. Several researchers fit responses of a finite element model to real measured data [5, 6, 7]. The fitting between numerical and experimental characteristics gives good insight to a structure's behavior. But temperature effects must be removed from the raw measurements prior to their use as input for model updating. Schommer et al. [8] compensated static displacement measurements with a 3D finite element model of a prestressed concrete bridge. In the present paper, the same compensation with subsequent noise removal by PCA is applied for eigenfrequencies for two real bridges. Considerable reductions of the scatter are achieved and corrected data may later either be used for direct analysis or for further processing like the mentioned model updating. Finally, a yes-no indicator based on novelty-index is presented and applied to the two bridges with very good results.

2 TEMPERATURE COMPENSATION AND NOISE ELIMINATION

Two subsequent steps are used here for removal of temperature and noise effects: the first consists in shifting the measured characteristics to a reference temperature along a previously identified physical line, while the second step is based on a statistical mathematics with Singular Value Decomposition (SVD) for general noise removal.

2.1 Physical temperature compensation

Nguyen et al. [4] proposed a technique for temperature compensation and applied it to static displacement data. It is based on the projection of measured data along a measured regression line, identified within data from the intact state. Figure 1 illustrates how a set of data A (e.g. eigenfrequency f) from the healthy state of the structure changes versus temperature $t°$. Measurements for other states, possibly in different ranges of temperature, can be traced back

to a reference temperature and compared to the intact state. The comparison is based on linear dependency of the measured quantity *f* versus temperature, which is more or less true, as can be seen in two examples below. Hence, first data are measured at different temperatures in the reference state. Then a linear regression line is determined by its equation's terms; a corresponding standard-deviation σ with respect to this line is also assessed. Once they are known, different sets of data A, B, C can be projected with the slope of the regression line to the reference temperature t_1, referred here as A_1, B_1, C_1. Thus, temperature effects can be reduced based on a physical measured line.

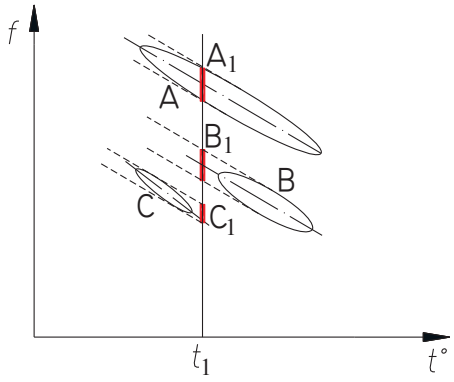

Figure 1: Temperature compensation by data projection

2.2 Principal Component Analysis and Novelty Index

It is known from statistics that Principal Component Analysis (PCA) can be used to remove environmental effects and noise [9]. The Singular Value Decomposition (SVD) of an observation matrix **X** containing *m* records of *N* time samples (e.g. displacements or eigenfrequencies versus time) determines principal vectors and singular values of $\mathbf{X}_{m\times N}$:

$$\mathbf{X} = \mathbf{U}\mathbf{S}\mathbf{V}^T \tag{1}$$

where matrices $\mathbf{U}_{m\times m}$ and $\mathbf{V}_{N\times N}$ are orthogonal; the diagonal matrix $\mathbf{S}_{m\times N}$ contains in decreasing order non-negative singular values while **U** contains column-wise corresponding principal vectors.

When the observation matrix **X** contains for instance *m* eigenfrequencies after temperature compensation, the first singular value in **S** is typically by far larger than subsequent singular values. Hence, there is only a unique dominant singular value and only one principal vector $\mathbf{U}_1$ in **U** has to be considered for reconstruction of the data in order to remove noise:

$$\mathbf{X}_{reconstructed} = \mathbf{U}_1\mathbf{U}_1^T\mathbf{X} \tag{2}$$

By doing so, PCA can be used as additional filter for data processing to clean it from environmental noise.

Furthermore, Novelty Index (*NI*) proposed by YAN et al. in [9] can be used as a damage index, in form of a red-green light index. *NI* sizes up the error of the reconstructed data from the initial observation data through Euclidean norm (Eq. 3) or Mahalanobis norm (Eq. 4):

$$\mathbf{E} = \mathbf{X} - \mathbf{X}_{reconstructed}; \quad NI_k^{Eucl} = \sqrt{\mathbf{E}_k^{\mathrm{T}}\,\mathbf{E}_k} \tag{3}$$

$$NI_k^{Maha} = \sqrt{\mathbf{E}_k^{\mathrm{T}}\mathrm{cov}(\mathbf{X})^{-1}\mathbf{E}_k} \tag{4}$$

where $\mathrm{cov}(\mathbf{X}) = \mathbf{X}\,\mathbf{X}^{\mathrm{T}}$ is the covariance matrix of the features.

Then an actual state can be assessed by two indicators: 1) ratio between the mean values of this actual state and the reference state $\overline{NI}_{actual}/\ \overline{NI}_{reference}$; 2) a statistical threshold as outlier limit e.g. $\overline{NI}_{reference} + 3\sigma$ that σ is the standard deviation of *NI* in the reference (intact) state. A ratio close to unit together a low outlier limit can be assumed no change or damage (i.e. green light); otherwise, statistical relevant changes are very probable (i.e. red light).

3 ANALYSIS

An application of the physical temperature compensation algorithm was presented in [4] with static displacements, which require as reference long-term monitoring without environmental effects and noise. The present work examines eigenfrequencies as characteristic dynamic properties of structure. For bridge systems, the combination of physical and statistical PCA-based temperature compensation can be beneficial as shown below.

First a new composite bridge without damage but with extreme temperature sensitivity is analyzed. Second, an older bridge subjected to multiple artificial damage steps will be dealt with. The data matrix **X** is here frequencies vs. temperature is processed here with the mentioned 2-step procedure. From the reference i.e. initial/ undamaged state, full range of temperature variation is known and a regression line is calculated, i.e. eigenfrequencies f_i versus concrete temperature $t°$. Data from actual measurements are projected with the identified slope of the regression-line to a chosen reference temperature, which is close to the average temperature. The subsequent PCA procedure according to Eq. (2) is also based on the same reference period. For both bridges, the first singular value of matrix **S** is by far larger than the others and occupies more than 95% of the total energy. So only the first principal vector of the reference period $\mathbf{U}_1^{reference}$ is taken into account for data reconstruction.

3.1 Bridge in Useldange, Luxembourg

In 2006 a new bridge was built in Useldange, Luxembourg and then monitored during 4 years. The steel-concrete composite bridge has a very thick asphalt layer, that's why its eigenfrequencies strongly depend on the temperature, e.g. up to 7‰ per °*C* for f_1 [10].

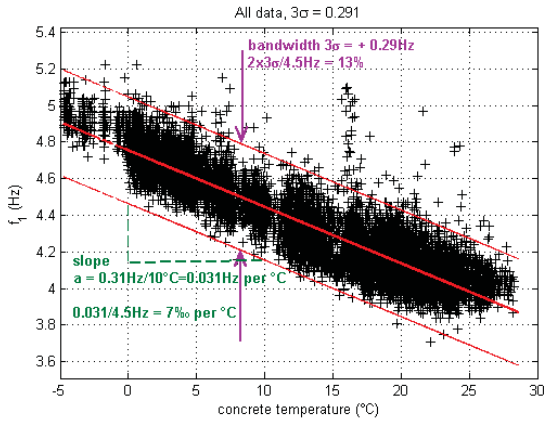

Figure 2: First eigenfrequency f_1 vs. concrete $t°$ for Useldange bridge (Luxembourg - ambient excitation)

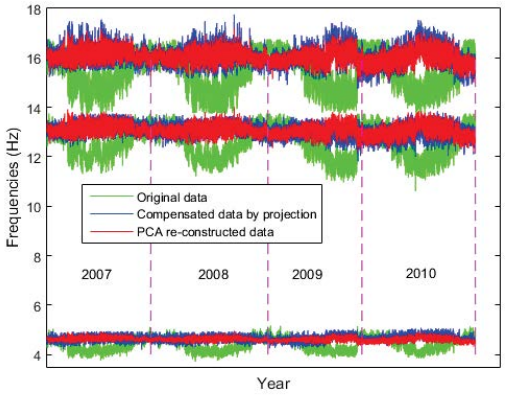

Figure 3: Eigenfrequencies monitored during 4 years- Useldange bridge

Figure 2 show the first eigenfrequency measured from ambient excitation with its regression line. It has an important slope and a quite large scatter of 13%, determined here as 3 times of standard deviation σ. In Figure 3, the data-sets are simply superposed versus time: three classes of data are: original (raw) data in green, data after the physical compensation in

blue and statistical reconstructed data by PCA in red. The original data in green show clearly the seasonal behavior: low stiffness with low frequencies in summer and vice-versa in winter. This behavior is significantly attenuated after the physical temperature compensation and even more after PCA-filtering.

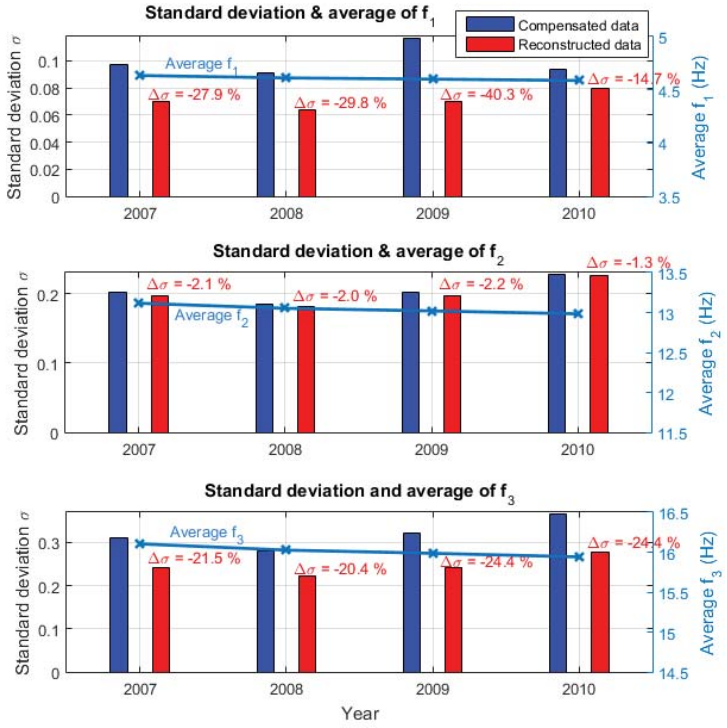

Figure 4: Comparison before and after PCA-filtering for Useldange Bridge

As reported in Figure 4 especially for modes 1 and 3, PCA-filtering reduces the standard deviation σ by approximatively 25% in average even after physical temperature compensation. Also in Figure 4, the mean frequencies are indicated in light blue solid lines with mark "×" referring to the right ordinate axis. It should be noted that for this new bridge without damage, all eigenfrequencies show slight reductions over the first years, which fit well to other studies and other bridges [10], thus confirming the quality of the 2-step compensation.

3.2 Bridge Z24, Switzerland

The Z24-bridge has been studied in several works by Peeters, Teughels, Reynders et al. [11-13]. The bridge was monitored during 1 year and then demolished after about 40 days of testing with progressive damage. Vibration analysis was performed by Peeters et al. [11] together with the measurement of temperature. In Figures 5 and 6, only positive temperatures were selected to avoid freezing periods, where this Z24-Bridge showed quite different behavior.

In Figure 5, the measured eigenfrequencies of 4 modes are plotted against concrete deck temperature. Teughels et al. [12] stated that the first mode is pure bending; while the third and the fourth are coupled bending-torsion modes. They all show decreasing frequencies with increasing temperatures. In contrast, the second is a transversal mode and increases slightly with temperature. Significant differences are noticeable especially for the damaged state, which is shown by red dots.

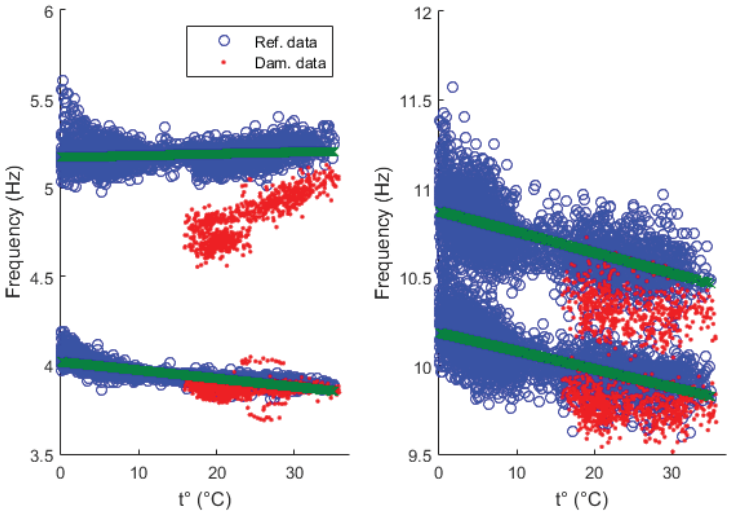

Figure 5: Identified frequencies vs. structural temperature
o - *reference state;* • - *damaged state;*
xxx - *regression line of the reference data*

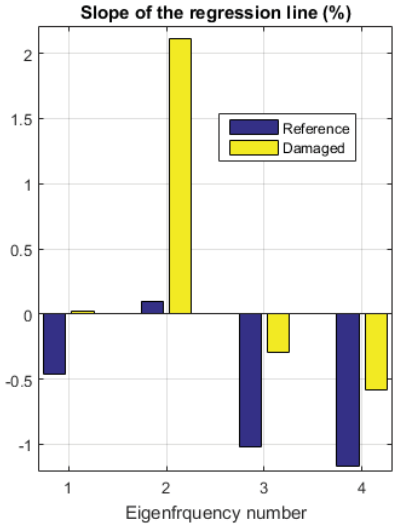

Figure 6: Slopes of the regression lines for the reference and damaged states

Figure 6 highlights the slopes of the regression lines for the reference and the damaged states for each mode. The frequencies f_1, f_3, f_4 show negative gradients whose magnitude decreases with damage. Only f_2 has opposite sign and increases considerably in the damaged state. These are individual characteristics and must be measured at site, i.e. today cannot be ad-hoc simulated.

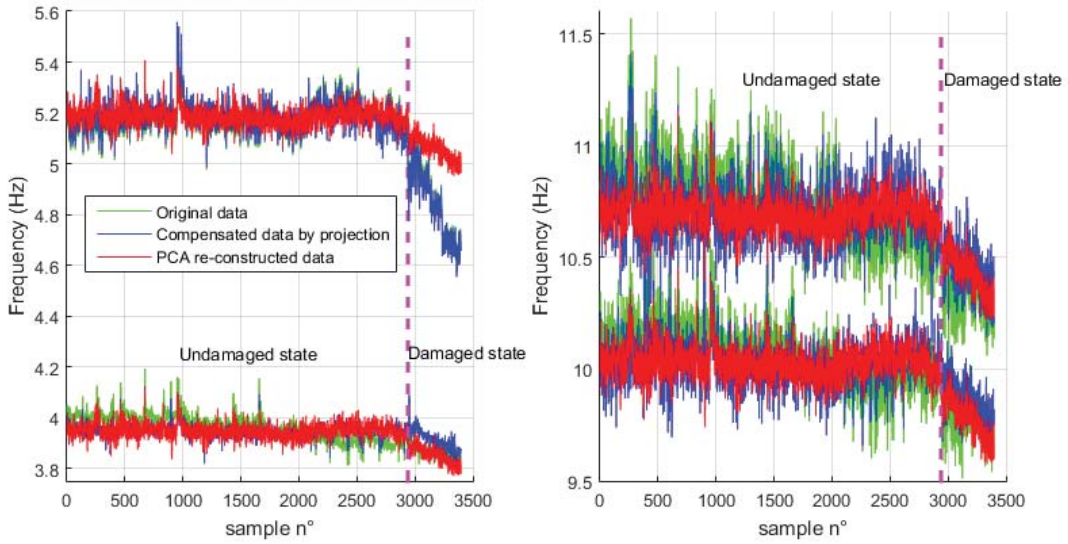

Figure 7: Evolvement of eigenfrequencies during the monitored period

To carry out the physical temperature compensation, all data are projected according to the scheme in Figure 1 to a reference temperature, which is chosen here at medium value $t_{ref} = 20°C$. A PCA-reconstruction step is also performed then the three families of data are presented in Figure 7. Only samples that all the modes could be identified are collected in the observation matrix, in total about 3400 samples. The dashed vertical line separates the intact from the damaged state of the bridge.

For better comparison, eigenfrequencies are analyzed in several small blocks of 150 samples. The scatter of data does not notably differ during the processing and is not presented here. The averaged values of eigenfrequencies are shown on the left of Figure 8, while on the right the relative difference by mean values of each block from the reference state within any family of data is deployed. These results reveal clearly that in the undamaged/reference state, Δf_i can vary up to 2%, but less than 0.5% after the physical temperature compensation. PCA helps additionally a little bit to decrease variation. After introduction of artificial damage, the reduction of eigenfrequencies is much better observed by the proposed compensation procedures. Such processing ensures visibly reliability and thus facilitates comparison between different measurements. Schommer et al. [8] used static deformation data after physical temperature compensation for model-updating and so achieved very good results.

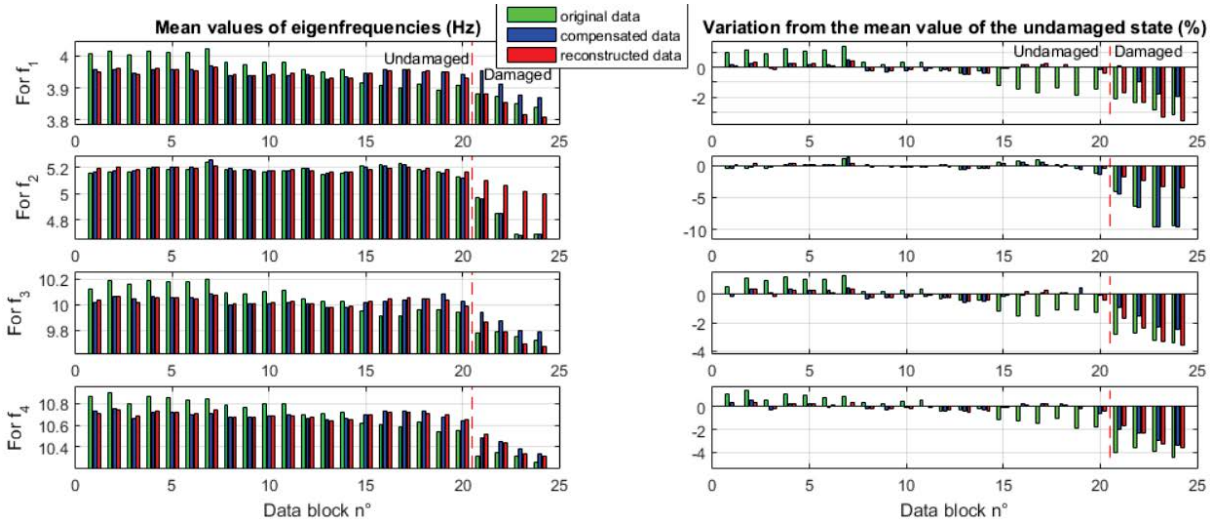

Figure 8: Averaged f_i and Δf_i assessed for each of the 3 families of data

The proficiency of the temperature compensation for damage detection can also be assessed by Novelty Index *NI*, as proposed by Yan et al. [9]. Both initial raw data $\mathbf{X}$ and compensated data - $\mathbf{X}_{reconstructed}$ are used to compute *NI*. Figures 9-10 shows *NI* versus time (or sample number) accordingly to Euclidean and Mahalanobis norms. In each figure, the top image presents the indexes from the original or raw data while the bottom image following to the physical and PCA compensation. Every chart is split into 2 parts, reference and damage states separated around sample n° 2900. An outlier limit is set for instance at $\overline{NI}_{reference} + 3\sigma$. Each state is characterized by its mean value and overshoot counting the percentage of indexes overpassing the outlier limit. By means of Euclidean norm, the ratio between the mean values of the damaged vs. the reference state $\overline{NI}/\ \overline{NI}_r$ weighs 1.9 by the raw data and 2.8 by the compensated data, with overshoot of 16.2% and 41.6% respectively. As for Mahalanobis norm, the ratio is 1.5 with the raw data and doubled to 3.2 after the 2-step compensation, while overshoot grows from 0.6% to 46.6% respectively. So in term of overshoot by the raw data, there is a clear distinction between the two norms but they give quite equivalent outcome based on the compensated data. This confirms the performance and its stability of the proposed compensation technique.

4 CONCLUSIONS

Damage leads to micro-cracking or cracking of concrete and therefore to stiffness loss, which can be detected for instance by reduction of eigenfrequencies. But the stiffness of as-

phalt, bearing pads and subsoil can also be affected by environmental factors, which cause also important perturbation for eigenfrequencies. Hence if eigenfrequencies are used as input for detection, it is necessary to separate temperature from damage effects.

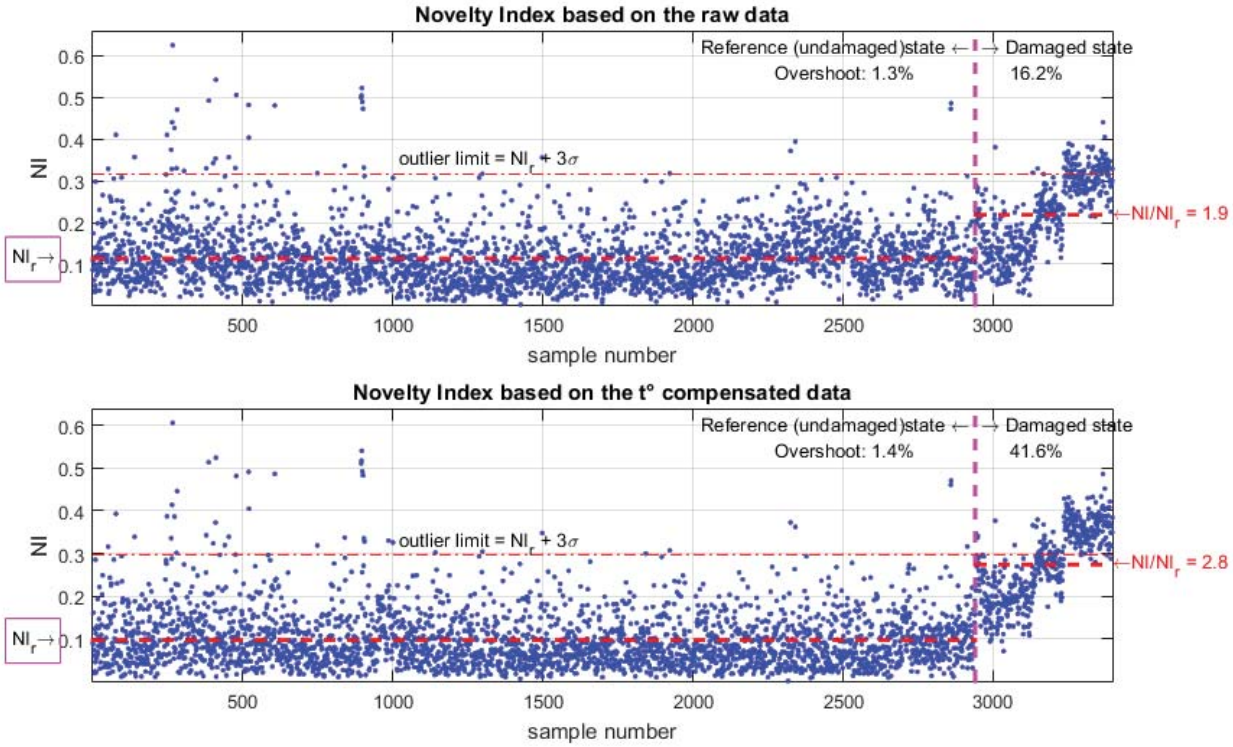

Figure 9: Damage detection by Novelty Index – Euclidean norm, Z24 bridge

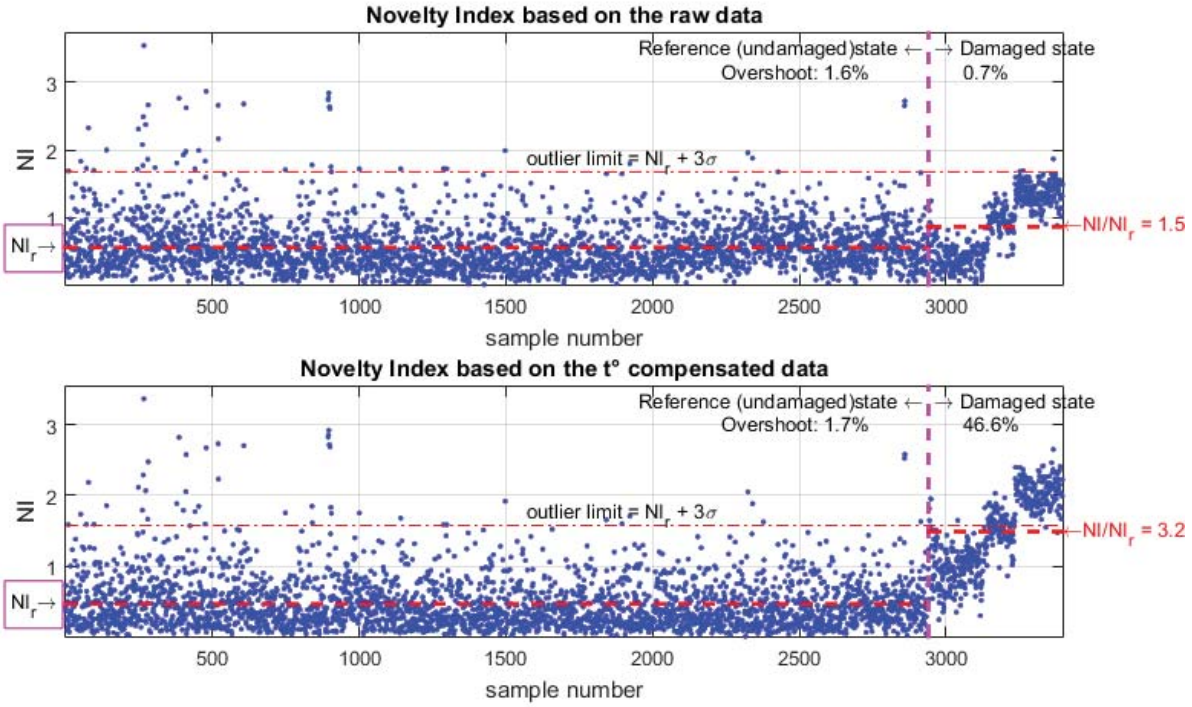

Figure 10: Damage detection by Novelty Index – Mahalonobis norm, Z24 bridge

The present paper does not propose a new damage index, but focuses directly on eigenfrequencies identified from vibrational tests. A two-step procedure is proposed based on measured physical sensitivity and on de-noising by PCA. The technique's efficiency could be proved by its application to two real bridges.

Keywords: Identification, Pavement roughness, Inverse problem, Accelerometer

Abstract. *Pavement roughness profile is one of the important factors for bridge and road health monitoring and there is a variety of methods to measure pavement roughness profile. Laser displacement sensors have been commonly used for measuring pavement roughness profile and they are attached on a measurement vehicle. However, a laser displacement sensor is relatively expensive than an accelerometer. Therefore, methods to identify pavement roughness profile by using accelerometers attached on the measurement car have been developed and relevant studies become more and more popular in recent years. The identification of pavement roughness profile is a challenging task as an inverse problem, especially which is so-called ill-posed problem. In an ill-posed problem, a slight change in the measurement data has a great effect on identification accuracy. In this paper, the accuracy of several methods for identification of pavement roughness profile using only accelerometers attached on the measurement car is investigated utilizing both data from simulation and experiment.*

1 INTRODUCTION

Pavement roughness profile is one of the important indicators which represents conditions of roads or bridges. If a pavement roughness on a road is very rough, vehicles which run on the pavement are more easily vibrated than on a smooth pavement and would worsen the pavement condition. It is a vicious cycle, and appropriate monitoring and repairment are needed to avoid the vicious cycle. By keeping pavement roughness profile as smooth as possible, not only riding comfortability of cars but also a lifespan of roads and bridges can be increased [1].

There are several methods to measure pavement roughness profile. The basic one is direct and manual measurement, such as a profilometer which measures pavement roughness profile by laser displacement sensors and it needs to be run manually. It is an accurate method but takes much work. Therefore a measurement car, which can measure pavement roughness profile utilizing laser displacement sensors has been developed. There is another method to measure the vehicle axle forces directly and convert them to pavement roughness profile. Those direct measurement methods are reviewed in [2]. The direct method utilizing a measurement car has high accuracy and less labor, though the measurement car is a costly pavement measuring method. In recent years, methods to estimate pavement roughness profile utilizing accelerations on a running vehicle have been studied to reduce labor and cost while satisfying accuracy. The method using acceleration of a running vehicle, which is so-called a drive-by method [3], has been studied not only to estimate pavement roughness profile but also to detect change in dynamic parameters [4 - 6] of bridges. However, it is hard to secure higher accuracy in identification by means of the drive-by method, since the input data is only acceleration data which leads to an ill-posed condition in the inverse problem.

One of the ways to identify pavement roughness profile is to estimate the vehicle dynamic forces first, and next obtain the pavement roughness profile by solving a differential equation which represents a relationship between the vehicle dynamic forces and the pavement roughness profile. The estimated dynamic vehicle forces by the first step are useful information not only for estimating pavement roughness profile but also for bridge damage detection in terms of the drive-by bridge inspection. There are several researches relevant to identification of vehicle dynamic forces. Moving Force Identification algorithm (MFI) [7], especially adapting Tikhonov regularization [8], is one of the effective methods. Some numerical studies have been reported for the MFI using measured acceleration data on a moving vehicle [3], [9]. However, only limit number of studies consider experimental data [10 - 11]. Kalman filter method [12] for vehicle dynamic force identification also has been developed [12 - 14], which is an effective way especially if acceleration and angular velocity of vehicle are measured [13].

Suspension spring constant (N/m)	Front axle	75749
	Rear axle	99646
Suspension damping coefficient ($N \cdot s/m$)	Front axle	12535
	Rear axle	3602

Table 1: Vehicle properties.

This study utilizes the method to estimate dynamic vehicle forces in identification of pavement roughness profile. Several methods are investigated and compared focusing on economics of the methods which utilize only accelerometers on the test vehicle. Both numerical and experimental accelerations are considered in the pavement roughness profile identification, and the accuracy of identification results is assessed by an error function and power spectral density (PSD). This paper consists of five sections including Introduction. Identification methods are explained in Section 2 in detail. Section 3 describes pavement roughness profile identification from simulated accelerations and relevant discussions. Pavement roughness profile identification utilizing measured accelerations from a field experiment is discussed in Section 4. Finally, the section of "CONCLUSIONS" summarizes observations.

2 IDENTIFICATION METHOD

2.1 Vehicle model

A vehicle model used in this paper is a two degree-of-freedom half-car model and a scheme of the vehicle model is shown in Figure 1. Properties of the vehicle utilized in pavement roughness profile identification is shown in Table 1. "X-trail" by Nissan Motor Co., Ltd is used during the field experiment as well as in the simulation. A free vibration test was also conducted to determine vehicle properties.

2.2 Method

A pavement roughness profile is identified utilizing accelerations of bounce and pitch motions of the moving vehicle. Here accelerations of bounce and pitch motions at the center of gravity of the vehicle body are estimated utilizing bounce accelerations measured at vehicle floor on the front and rear axles. This study adopts five minimization schemes for the pavement roughness profile identification, and the identification accuracy of each scheme is discussed. Features of those five schemes are summarized in Table 2. Those five schemes are named as DP+LC, PIM+LC, PIM +EM, PIM +LC(L1) and KF, respectively. A least square minimization with L_2 norm regularization, which is so-called Tikhonov regularization, is applied in DP+LC, PIM+LC, and PIM +EM. A least square minimization with L_1 norm as regularization term, which is called as lasso regression, is applied in PIM+LC(L1). A difference between DP and PIM is how to solve the least square minimization. In the DP the least square minimization is solved by dynamic programming [15], and in PIM it is solved by using a pseudo-inverse matrix [16 - 17]. In KF, Kalman filter is applied.

	Basic method	Solution	Regularization parameter determination	Regularization term
DP+LC	Least square minimization	Dynamic programming	L-curve	L_2 norm
PIM+LC	Least square minimization	Pseudo inverse matrix	L-curve	L_2 norm
PIM+EM	Least square minimization	Pseudo inverse matrix	EM algorithm	L_2 norm
PIM+LC (L1)	Least square minimization	Iterative thresholding algorithm	L-curve	L_1 norm
KF	Kalman filter	-	-	-

Table 2: Features of five minimization schemes

In all schemes, vehicle dynamic forces are identified first and in the next step the pavement roughness profile is obtained by solving a differential equation for the relationship between vehicle dynamic forces and pavement roughness profile. Displacements under the front and rear tires of the moving vehicle are estimated by those five schemes. If the vehicle is running on a road, estimated displacements under the tires are equal to estimated pavement roughness profile. Details of each method in Table 2 are explained in the following sub sections.

2.3 DP+LC

Dynamic equation of motion of a vehicle is written as Equation (1).

$$\boldsymbol{M}_v\ddot{\boldsymbol{y}}_v + \boldsymbol{C}_v\dot{\boldsymbol{y}}_v + \boldsymbol{K}_v\boldsymbol{y}_v = \boldsymbol{f}_v \tag{1}$$

where $\boldsymbol{M}_v$, $\boldsymbol{C}_v$ and $\boldsymbol{K}_v$ are matrices of mass, damping and stiffness of 2DOF vehicle respectively. $\boldsymbol{y}_v$ contains vehicle displacements relevant to bounce and pitch motions. Dots above variables stand for derivative. $\boldsymbol{f}_v$ is the force vector applied to vehicle, which is generated by pavement roughness profile and its first derivative, and can be written as Equation (2).

$$\boldsymbol{f}_v = \begin{Bmatrix} \sum_{i=1}^{2}(K_i w_i + C_i \dot{w}_i) \\ -\sum_{i=1}^{2}(-1)^i D_i(K_i w_i + C_i \dot{w}_i) \end{Bmatrix} \tag{2}$$

where w_i, K_i and C_i represent pavement roughness profile, spring constant and damping coefficient respectively. The subscription i is the operator to denote front and rear axles, i.e. i=1 is the front axle and i=2 is the rear axle. D_i is the distance from the centroid of the vehicle body to each suspension. The equation of motion of the vehicle can be rewritten in terms of the state-space representation as Equation (3).

$$\dot{\boldsymbol{X}} = \boldsymbol{A}\boldsymbol{X} + \overline{\boldsymbol{f}_v} \tag{3}$$

$\boldsymbol{X}$, $\boldsymbol{A}$ and $\overline{\boldsymbol{f}_v}$ are defined as shown in Equation (4).

$$\boldsymbol{X} = \begin{Bmatrix} \boldsymbol{y}_v \\ \dot{\boldsymbol{y}}_v \end{Bmatrix}, \quad \boldsymbol{A} = \begin{bmatrix} \boldsymbol{0} & \boldsymbol{I} \\ -\boldsymbol{M}_v^{-1}\boldsymbol{K}_v & -\boldsymbol{M}_v^{-1}\boldsymbol{C}_v \end{bmatrix}, \quad \overline{\boldsymbol{f}_v} = \begin{bmatrix} \boldsymbol{0} \\ \boldsymbol{M}_v^{-1}\boldsymbol{f}_v \end{bmatrix} \tag{4}$$

Equation (4) is converted to time series representation as Equations (5), (6) and (7) by solving the differential equation in Equation (3). *h* is a time step. The subscription *j* stands for a discretized time index.

$$\boldsymbol{X}_{j+1} = \boldsymbol{M}\boldsymbol{X}_j + \boldsymbol{G}\boldsymbol{g}_j \quad ; \; j = 1, \; \ldots, \; N \tag{5}$$

$$\boldsymbol{M} = e^{\boldsymbol{A}h} \tag{6}$$

$$\boldsymbol{G} = \left(\boldsymbol{A}^{-1}(\boldsymbol{M} - \boldsymbol{I})\right)\begin{bmatrix}\boldsymbol{0} \\ \boldsymbol{M}_v^{-1}\boldsymbol{I}\end{bmatrix} \tag{7}$$

where $\boldsymbol{g}_j$ is the vehicle dynamic force vector, which is identification target of dynamic programming. Furthermore, a new state vector and state-space model are defined as Equations (8) and (9) respectively.

$$\widehat{\boldsymbol{X}}_{j+1} = \begin{bmatrix}\boldsymbol{M} & \boldsymbol{G} \\ \boldsymbol{0} & \boldsymbol{I}\end{bmatrix}\widehat{\boldsymbol{X}}_j + \begin{bmatrix}\boldsymbol{0} \\ \boldsymbol{I}\end{bmatrix}\dot{\boldsymbol{g}}_j \quad ; \quad j = 1, \; \ldots, \; N \tag{8}$$

$$\widehat{\boldsymbol{X}}_j = [\boldsymbol{X}_j \quad \boldsymbol{g}_j]^T \tag{9}$$

A least square minimization problem is formulated as Equation (10) using $\widehat{\boldsymbol{X}}_j$ and $\dot{\boldsymbol{g}}_j$.

$$Err\left(\widehat{\boldsymbol{X}}_k, \dot{\boldsymbol{g}}_k\right) = \sum_{k=1}^{m}\left\{\left((\boldsymbol{d}_k - \boldsymbol{Q}\widehat{\boldsymbol{X}}_k), (\boldsymbol{d}_k - \boldsymbol{Q}\widehat{\boldsymbol{X}}_k)\right) + (\dot{\boldsymbol{g}}_k, \boldsymbol{B}\dot{\boldsymbol{g}}_k)\right\} \tag{10}$$

Here $\boldsymbol{d}_j$ is measured acceleration data, $\boldsymbol{Q}$ is a selection matrix to relate $\boldsymbol{d}_j$ and $\widehat{\boldsymbol{X}}_j$. The subscription m stands for bounce and pitch motions. (*x*, *y*) means outer product of *x* and *y*. $\boldsymbol{B}$ contains the regularization parameter as $\mathbf{B} = \lambda\mathbf{I}$ and λ is the regularization parameter which keeps a balance between first and second term's volume. The optimal value of λ can be obtained by the L-curve method [18]. In the L-curve method, candidates of λ are prepared at first. In the next step, E_{norm} and F_{norm} are calculated for each of prepared λ. E_{norm} and F_{norm} can be written as shown in Equations (11) and (12), and they are plotted on a log-log graph, then curvature of L-curve is calculated. At the point which has the maximum curvature, optimal regularization parameter value is obtained. Here E_{norm} and F_{norm} for each λ are obtained by solving Equation (10) by means of dynamic programming. Details on the dynamic programming are shown in [10, 11].

$$E_{norm} = \sqrt{\sum_{k=1}^{m}\left((\boldsymbol{d}_k - \boldsymbol{Q}\widehat{\boldsymbol{X}}_k), (\boldsymbol{d}_k - \boldsymbol{Q}\widehat{\boldsymbol{X}}_k)\right)} \tag{11}$$

$$F_{norm} = \sqrt{\sum_{k=1}^{m}(\dot{\boldsymbol{g}}_k, \dot{\boldsymbol{g}}_k)} \tag{12}$$

By the L-curve method, the optimal λ value, estimated $\widehat{\boldsymbol{X}}_j$ and $\dot{\boldsymbol{g}}_j$ are obtained. $\boldsymbol{g}_j$ is also estimated utilizing $\dot{\boldsymbol{g}}_j$**.** Finally, pavement roughness profile is obtained by solving the differential Equation (2) by means of the 4th Runge-Kutta method, substituting estimated $\boldsymbol{g}_j$ as $\boldsymbol{f}_v$.

2.4 PIM+LC

In PIM+LC, unknown parameters are defined as Equation (13) and measured data are defined as Equation (14). Here $\mathbf{y}_{v,1}$ is a 2×1 matrix and includes displacements for the bounce and pitch motions of the vehicle.

$$\boldsymbol{x} = \begin{bmatrix} \dot{\boldsymbol{g}}_1{}^T & \dot{\boldsymbol{g}}_2{}^T & \cdots & \dot{\boldsymbol{g}}_N{}^T \end{bmatrix}^T \tag{13}$$

$$\boldsymbol{y} = \begin{bmatrix} \boldsymbol{y}_{v,1}{}^T & \boldsymbol{y}_{v,2}{}^T & \cdots & \boldsymbol{y}_{v,N}{}^T \end{bmatrix}^T \tag{14}$$

A least square minimization problem is formulated as Equation (15).

$$L_2 = \min_{\boldsymbol{x}} \{ \|\boldsymbol{y} - \boldsymbol{H}\boldsymbol{x}\|_2^2 + \lambda \|\boldsymbol{x}\|_2^2 \} \tag{15}$$

Here $\boldsymbol{H}$ is a model matrix, which is represented by Equation (16) where K and T are defined as Equation (17).

$$\boldsymbol{H} = \begin{bmatrix} \boldsymbol{QT} & \boldsymbol{0} & \cdots & \boldsymbol{0} & \boldsymbol{0} \\ \boldsymbol{QKT} & \boldsymbol{QT} & \cdots & \boldsymbol{0} & \boldsymbol{0} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ \boldsymbol{QK}^{N-2}\boldsymbol{T} & \boldsymbol{QK}^{N-3}\boldsymbol{T} & \cdots & \boldsymbol{QT} & \boldsymbol{0} \\ \boldsymbol{QK}^{N-1}\boldsymbol{T} & \boldsymbol{QK}^{N-2}\boldsymbol{T} & \cdots & \boldsymbol{QKT} & \boldsymbol{QT} \end{bmatrix} \tag{16}$$

$$\boldsymbol{K} = \begin{bmatrix} \boldsymbol{M} & \boldsymbol{G} \\ \boldsymbol{0} & \boldsymbol{I} \end{bmatrix}, \quad \boldsymbol{T} = \begin{bmatrix} \boldsymbol{0} \\ \boldsymbol{I} \end{bmatrix} \tag{17}$$

Under the assumption that initial conditions are defined as Equation (18), the solution of the least square minimization is obtained as Equation (19).

$$\boldsymbol{X}_0 = [\boldsymbol{0} \quad \boldsymbol{0} \quad \boldsymbol{0} \quad \boldsymbol{0}]^T, \quad \boldsymbol{g}_0 = [\boldsymbol{0} \quad \boldsymbol{0}]^T \tag{18}$$

$$\boldsymbol{x}_{est,LC} = (\boldsymbol{H}^T\boldsymbol{H} + \lambda \boldsymbol{I})^{-1}\boldsymbol{H}^T\boldsymbol{y} \tag{19}$$

where $\boldsymbol{y}$ indicates measured data. Optimal value of λ is obtained by the L-curve method, and finally pavement roughness profile is obtained by solving Equation (2) by means of the 4th Runge-Kutta method.

2.5 PIM+EM

The PIM+EM is basically same with PIM+LC, but the only difference is how to determine the optimal value of regularization parameter λ. In PIM+EM the optimal λ is determined by the EM algorithm [19] while L-curve method is used in PIM+LC. In the EM algorithm, unknown and measured parameters are treated as random variables which follow a normal distribution. A relationship between $\boldsymbol{x}$ and $\boldsymbol{y}$ are modeled as Equation (20).

$$\boldsymbol{y} = \boldsymbol{H}\boldsymbol{x} + \boldsymbol{\varepsilon} \tag{20}$$

The matrix $\boldsymbol{H}$ is same with Equation (16). $\boldsymbol{\varepsilon}$ indicates a noise which follows a normal distribution as Equations (21) and (22).

$$\boldsymbol{\varepsilon} \sim N(\boldsymbol{\varepsilon}|\boldsymbol{0}, \boldsymbol{\Lambda}^{-1}) \tag{21}$$

$$\boldsymbol{\Lambda} = \beta \boldsymbol{I} \tag{22}$$

$\boldsymbol{\Lambda}$ is inverse covariance matrix of the noise. A prior distribution of $\boldsymbol{x}$ is defined as Equations (23) and (24), which follows normal distribution.

$$f(\boldsymbol{x}) \sim N(\boldsymbol{x}|\boldsymbol{\mu}, \boldsymbol{v}^{-1}) \tag{23}$$

$$\boldsymbol{v} = \alpha \boldsymbol{I} \tag{24}$$

There are two steps in the EM algorithm, which are called E step and M step and these two steps are conducted alternatively until estimated parameters converge. In the E step, estimated unknown parameters are calculated utilizing α and β in Equation (25).

$$\boldsymbol{x}_{est,EM} = \left(\boldsymbol{H}^T\boldsymbol{H} + \frac{\alpha}{\beta}\boldsymbol{I}\right)^{-1}\boldsymbol{H}^T\boldsymbol{y} \tag{25}$$

An inverse covariance matrix of $\boldsymbol{x}_{est,EM}$ is estimated by Equation (26).

$$\boldsymbol{\Gamma} = \alpha\boldsymbol{I} + \beta\boldsymbol{H}^T\boldsymbol{H} \tag{26}$$

In the algorithm, an initial value of $\boldsymbol{\Gamma}$ should be defined before iterative calculation starts. In the M step, α and β values are updated by using $\boldsymbol{x}_{est,EM}$ and $\boldsymbol{\Gamma}$ as Equations (27) and (28).

$$\alpha^{-1} = \frac{1}{N}\left[\left\|\boldsymbol{x}_{est,EM}\right\|_2^2 + tr(\boldsymbol{\Gamma}^{-1})\right] \tag{27}$$

$$\beta^{-1} = \frac{1}{M}[\|\boldsymbol{y} - \boldsymbol{H}\boldsymbol{x}\|_2^2 + tr(\boldsymbol{H}^T\boldsymbol{H}\boldsymbol{\Gamma}^{-1})] \tag{28}$$

Repeating the E step and M step alternatively, we can identify unknown parameters by Equation (25) with converged α and β. Pavement roughness profile is obtained by solving Equation (2) by means of the 4th Runge-Kutta method with identified vehicle forces.

2.6 PIM+LC(L1)

In PIM+LC(L1) unknown parameter $\boldsymbol{x}$, measured data $\boldsymbol{y}$ and initial parameters $\mathbf{X}_0$, $\mathbf{g}_0$ are defined as well as PIM+LC. However, a regularization term of the least square minimization becomes different. In PIM+LC(L1), a least square minimization problem is formulated as Equation (29).

$$L_1 = \min_{\boldsymbol{x}}\{\|\boldsymbol{y} - \boldsymbol{H}\boldsymbol{x}\|_2^2 + \lambda\|\boldsymbol{x}\|_1\} \tag{29}$$

It is difficult to obtain an analytical solution of Equation (29) because a regularization term takes absolute value of unknown parameters. Therefore an iterative thresholding algorithm is adopted in order to obtain an approximated solution. In the iterative thresholding algorithm, the least square minimization which has a form as shown in Equation (30) is newly defined in order to make the solution obtainable.

$$L_{new} = \min_{\boldsymbol{x}}\{\|\boldsymbol{y}_{new} - \boldsymbol{x}\|_2^2 + \lambda\|\boldsymbol{x}\|_1\} \tag{30}$$

Equation (31) is a surrogate function which removes $\boldsymbol{H}$ from Equation (29) and help converting Equation (29) to Equation (30). Equation (31) considers any $\boldsymbol{x}_t$ as an input.

$$G(\boldsymbol{x}, \boldsymbol{x}_t) = L_1(\boldsymbol{x}_t) + \sum_{j=1}^{N}\frac{dL_1(x_{t,j})}{dx_j}(x_j - x_{t,j}) + \frac{\rho}{2}\|\boldsymbol{x} - \boldsymbol{x}_t\|_2^2 \tag{31}$$

where ρ is a learning rate of the iterative calculation. Equation (31) can be rewritten as Equation (32).

$$G(\boldsymbol{x}, \boldsymbol{x}_t) = \frac{\rho}{2}\sum_{j=1}^{N}\left\{\left(x_{t,j} - \frac{1}{\rho}\frac{dL_1(x_{t,j})}{dx_j}\right) - x_j\right\}^2 + const. \tag{32}$$

The support function $G(\boldsymbol{x}, \boldsymbol{x}_t)$ has following two characteristics: $G(\boldsymbol{x}, \boldsymbol{x}_t)$ crosses with $L_1(\boldsymbol{x})$ at $\boldsymbol{x} = \boldsymbol{x}_t$; $L_1(\boldsymbol{x}) \leq G(\boldsymbol{x}, \boldsymbol{x}_t)$ for any $\boldsymbol{x}$.
By using $G(\boldsymbol{x}, \boldsymbol{x}_t)$, a new least square minimization problem is formulated as Equation (33).

$$\boldsymbol{x}_{tu} = \underset{\boldsymbol{x}}{\operatorname{argmin}}(G(\boldsymbol{x}, \boldsymbol{x}_t) + \lambda \|\boldsymbol{x}\|_1) \tag{33}$$

$\boldsymbol{x}_{tu}$ is a solution of the least square minimization. The solution of Equation (33) is shown in Equation (34), which is given by a soft thresholding function S_λ.

$$x_{tu,i} = S_\lambda \left(x_{t,j} - \frac{1}{\rho} \frac{dL_1(x_{t,j})}{dx_j} \right) \tag{34}$$

Equation (34) can be expressed as Equation (35).

$$\boldsymbol{x}_{tu} = S_\lambda \left(\boldsymbol{x}_t + \frac{1}{\rho} \boldsymbol{A}^T (\boldsymbol{y} - \boldsymbol{H}\boldsymbol{x}) \right) \tag{35}$$

The soft thresholding function S_λ is defined as Equation (36) for any p.

$$S_\lambda(p) = \begin{cases} p + \lambda & (p < -\lambda) \\ 0 & (-\lambda \leq p \leq \lambda) \\ p - \lambda & (p > \lambda) \end{cases} \tag{36}$$

Again $1/\rho$ denotes a learning rate of repetitive calculation and the value of $1/\rho$ is defined as Equation (37).

$$\frac{1}{\rho} = \frac{1}{\max_j \sum_i \left| \boldsymbol{H}^T \boldsymbol{H}_{ij} \right|} \tag{37}$$

Until convergence Equation (35) is repetitively calculated and $\boldsymbol{x}$ is updated. Once it converged, estimated $\boldsymbol{x}$ is obtained. Details about all process of iterative thresholding algorithm can be confirmed in [20]. The optimal value of the regularization parameter λ is obtained by the L-curve method as well as DP+LC. Finally pavement roughness profile is obtained by solving Equation (2) by means of the 4th Runge-Kutta method.

2.7 KF

In KF, unknown vehicle dynamic forces are estimated by the Kalman filter. Unknown parameters and state-space model are defined as Equations (38) and (39).

$$\boldsymbol{z}_j = \left[\boldsymbol{y}_{v,j}{}^T \quad \dot{\boldsymbol{y}}_{v,j}{}^T \quad \ddot{\boldsymbol{y}}_{v,j}{}^T \quad \boldsymbol{g}_j{}^T \right]^T \tag{38}$$

$$\boldsymbol{z}_{j+1} = \boldsymbol{S}\boldsymbol{z}_j + \boldsymbol{U}\boldsymbol{\varepsilon}_{s,j} \;\; ; \;\; j = 1, \;\; \ldots, \;\; N \tag{39}$$

$\boldsymbol{S}$ is obtained by applying Wilson-θ method to Equation (1), and how to derive $\boldsymbol{S}$ and $\boldsymbol{U}$ can be confirmed in [21]. The state-space model includes system noise term since unknown parameters and measurement data are treated as random parameters in the Kalman filter. System noise is assumed to follow a normal distribution as Equation (40).

$$\boldsymbol{\varepsilon}_s \sim N(\boldsymbol{\varepsilon}_s | \boldsymbol{0}, \boldsymbol{P}) \tag{40}$$

Here system noise is only applied to 1st derivative of vehicle forces and it is treated as a driving noise of the whole system. Measurement noise is also introduced and a relationship between

unknown parameters and measurement data is defined as Equation (41). Measurement noise follows normal distribution as Equation (42).

$$\boldsymbol{d}_j = \boldsymbol{H}\boldsymbol{z}_j + \boldsymbol{\varepsilon}_{m,j} \tag{41}$$

$$\boldsymbol{\varepsilon}_m \sim N(\boldsymbol{\varepsilon}_m | \boldsymbol{0}, \boldsymbol{R}) \tag{42}$$

At first it is needed to set up initial values of inverse covariance matrices $\boldsymbol{P}$, $\boldsymbol{R}$, and $\boldsymbol{W}$. Here $\boldsymbol{W}$ is an covariance matrix of state vector $\boldsymbol{z}_j$. The main process of the Kalman filter includes two steps as follows.

(a) Prediction step

- Utilizing $\boldsymbol{z}_j$, estimate a state vector of the next step, $\bar{\boldsymbol{z}}_{j+1}$ by Equation (43). (Prior prediction)
- Calculate the inverse covariance matrix of $\bar{\boldsymbol{z}}_{j+1}$ by Equation (44). (Prior distribution)

(b) Modification step

- Calculate Kalman gain $\boldsymbol{K}_g$ by Equation (45).
- Modify the estimated state vector by Equation (46). (Posterior prediction)
- Modify the inverse covariance matrix of the state vector, $\widehat{\boldsymbol{W}}_{j+1}$ as Equation (47). (Posterior distribution)

$$\bar{\boldsymbol{z}}_{j+1} = \boldsymbol{K}\boldsymbol{z}_j \tag{43}$$

$$\boldsymbol{W}_{j+1} = \boldsymbol{S}\boldsymbol{W}_j\boldsymbol{S}^T + \boldsymbol{U}\boldsymbol{P}_j\boldsymbol{U}^T \tag{44}$$

$$\boldsymbol{K}_g = \boldsymbol{W}_{j+1}\boldsymbol{H}^T(\boldsymbol{H}^T\boldsymbol{W}_{j+1}\boldsymbol{H} + \boldsymbol{R})^{-1} \tag{45}$$

$$\hat{\boldsymbol{z}}_{j+1} = \bar{\boldsymbol{z}}_{j+1} + \boldsymbol{K}_g\left(\mathbf{d}_{j+1} - \boldsymbol{H}\bar{\boldsymbol{z}}_{j+1}\right) \tag{46}$$

$$\widehat{\boldsymbol{W}}_{j+1} = \left(\boldsymbol{I} - \boldsymbol{K}_g\boldsymbol{H}\right)\boldsymbol{W}_{j+1} \tag{47}$$

For each step from j=1 to j=N, (a)Prediction step and (b)Modification step are processed and $\hat{\boldsymbol{z}}_{j+1}$ can be obtained step by step. Then estimated $\boldsymbol{g}_j$ is extracted from $\hat{\boldsymbol{z}}_j$. Finally, pavement roughness profile is obtained by solving Equation (2) by means of the 4th Runge-Kutta method with using obtained $\boldsymbol{g}_j$.

3 DISCUSSION FROM SIMULATION

3.1 Setting

Accuracy of each method is compared utilizing simulated accelerations. 100 kinds of pavement roughness profiles are generated randomly, and all of them are categorized as rank A following ISO 8608. First, acceleration data are simulated utilizing generated 100 kinds of pavement roughness profiles and the vehicle whose properties are summarized in Table 1. Those simulated accelerations are assumed as measured data. Vehicle running speed is 10.8 m/s and sampling frequency is 100Hz. The Wilson-θ method was adopted to solve Equation (1) with $\theta = 1.420815$. Acceleration data is contaminated by measurement noise and the noise follows a normal distribution whose mean value is 0 and standard deviation is 1/5 of original measured data's standard deviation. For each of simulated acceleration data, pavement roughness profile is identified utilizing methods introduced in section 2. The range and interval of regularization parameters in the L-curve method are summarized in Table 3. Candidates of regularization parameters are expressed as a form of 10^n and by changing the value of n, an array

of candidates of regularization parameters is set up. An example of L-curve is shown in Figure 2.

For the EM algorithm of PIM+EM, initial values of α and β are defined as 0 and 1 respectively. A number of iterations of the EM algorithm is 300. For the KF, a setting of the parameters is shown in Table 4. Those parameters are determined by trial and error. In order to assess identification accuracy of each method, Effective Error Function (EEF) defined as equation (49) is used.

$$\mathrm{EEF} = \min_{a} \frac{1}{N} \sqrt{\sum_{l=1}^{N} \left(r_{true,l} - r_{est,l} - a \right)^2} \tag{48}$$

where r_{true} and r_{est} are true and estimated pavement roughness profile respectively. The identified pavement roughness profile means the identified displacement under the rear tire of the moving vehicle. Subscript l indicates a discrete distance index in vehicle running direction. Shift parameter a is introduced in order to measure the identification error more precisely than the normal RMSE (Root Mean Square Error). The range of shift parameter is from -10^2 to 10^2 and the interval is 10^{-5}.

3.2 Results and discussion

Table 5 shows average and standard deviation of the EEF for 100 identification results by each identification method. EEF of 100 pavement roughness profiles are shown in Figure 3. KF shows the maximum average EEF and PIM+LC(L1) shows the minimum average EEF among all schemes. An example of the identified pavement roughness profiles is shown in Figure 4.

When comparing EEF between DP+LC and PIM+LC, DP+LC showed smaller EEF value, while theoretically same solutions should be obtained by these two methods. A possible reason is that there are errors related to numerical calculation of inverse matrices and it leads to difference in optimal regularization parameter values. Especially PIM+LC includes a calculation of a large inverse matrix, which may lead to a greater error than DP+LC. In DP+LC, a total cost function is broken down into simpler sub-problems in a recursive manner and the process does not include the large size inverse matrix calculation. In terms of accuracy, DP+LC is better than PIM+LC, while PIM+LC has an advantage on simplicity. As already shown in Equation (19), the solution of PIM+LC is much simpler and easier to understand than that of DP+LC. Therefore, it can be said that PIM has much higher potential to be developed and improved than DP.

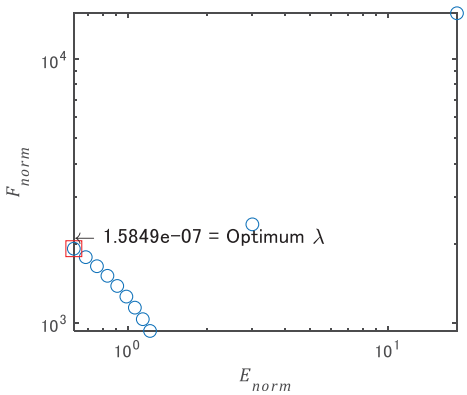

Figure 2: An example of L-curve

Method	Lower edge of n	Upper edge of n	Division interval of n
DP+LC	-7	-6	0.1
PIM+LC	-25	-15	0.1
PIM+LC(L1)	-19	-14	0.1

Table 3: Range of regularization parameter candidates in L-curve method in simulation discussion.

Initial value of state vector	$[0 \quad 0 \quad 0 \quad 0 \quad 0 \quad 0 \quad 0 \quad 0]^T$
Covariance matrix of system noise	$10^{-4} \times \boldsymbol{I_{2\times2}}$
Covariance matrix of measurement noise	$10^{-20} \times \boldsymbol{I_{2\times2}}$
Initial value of covariance matrix of state vector	$10^{-14} \times \boldsymbol{I_{8\times8}}$

Table 4: Initial parameters in KF.

	DP+LC	PIM+LC	PIM+EM	DP+LC(L1)	KF
Average	0.00115	0.00184	0.00183	0.00111	0.00203
Standard Deviation	0.00033	0.00106	0.00106	0.00041	0.00141

Table 5: Average and deviation of EFF of each method.

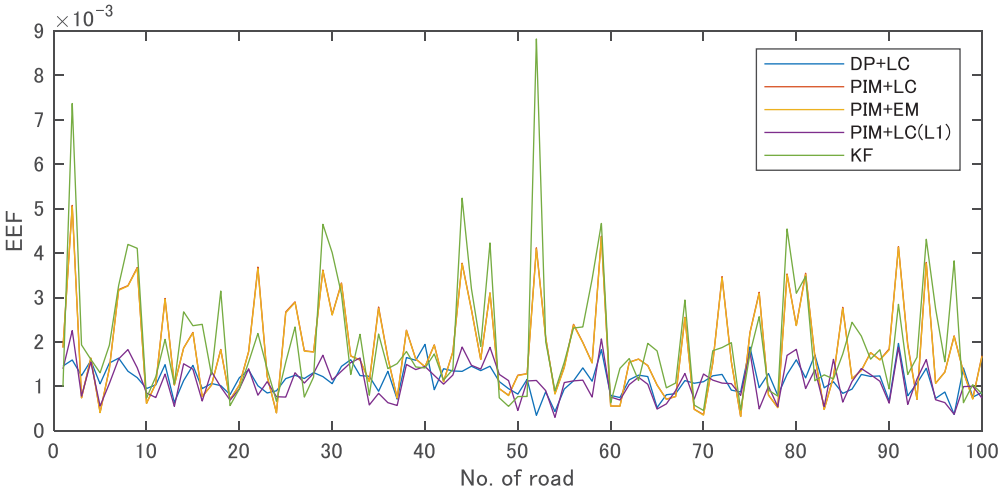

Figure 3 EEF of all methods for 100 pavement roughness profiles in simulation.

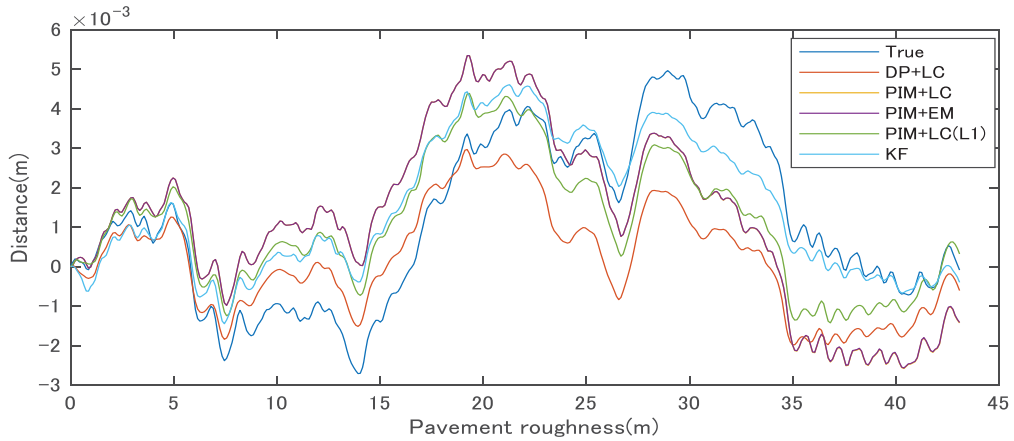

Figure 4: Example of identified pavement roughness profiles by each method.

When comparing EEF between PIM+LC and PIM+EM, little difference on EEF value was observed. The L-curve method needs much less time than the EM algorithm, therefore basically PIM+LC is better than PIM+EM considering calculation time. In comparison of EEFs between

DP+LC and PIM+LC(L1), no clear difference was observed, even though PIM+LC(L1) showed a little smaller EEF. However, PIM+LC(L1) needs more calculation time than DP+LC as PIM+LC(L1) takes an iterative calculation. When comparing EEF between DP+LC and KF, DP+LC resulted in much less EEF than KF. Standard deviation of EEF of DP+LC was smaller than KF. Therefore DP+LC was more accurate and stable method.

4 DISCUSSION FROM EXPERIMENT

4.1 Experimental setting

For further discussion about accuracy of each method, data from a field experiment were examined. In the field experiment, accelerations of the moving vehicle are measured, and then pavement roughness profile under the vehicle passage is identified. Accelerometers were installed at two points in the left side of the test vehicle. The measured acceleration data in the vertical direction are converted to acceleration for the bounce and pitch motions. Quartz sensors (M-A550AC2x by Seiko Epson Corporation) are used in the experiment. The sampling frequency of measurement was 200Hz. The target road was located on a steel plate girder bridge whose span length is 40.5m. An accurate pavement roughness profile is measured by a laser profilometer. This pavement roughness profile measured by the profilometer is called as "True" pavement roughness profile in this paper and compared with identified results. The pavement roughness profile was measured three times during the experiment and called as T1, T2 and T3 respectively.

Identified pavement roughness profiles by DP+LC and KF are compared with the true profile. Two methods were chosen since DP+LC showed higher accuracy and shorter calculation time in simulation based investigations, while KF adopts different concepts comparing to other methods. The range and interval of regularization parameters in the L curve method are shown in Table 6. Those parameters in KF to determine the experimental data are shown in Table 7. Vehicle running speeds for T1, T2 and T3 were about 2.9m/s, 3.2m/s and 3.0m/s respectively.

Method	Lower edge of n	Upper edge of n	Division interval of n
DP+LC	-6.19	-4	0.02

Table 6: Range of regularization parameter candidates in L-curve method in experimental discussion.

Initial value of state vector	$[0 \quad 0 \quad 0 \quad 0 \quad 0 \quad 0 \quad 0 \quad 0]^T$
Covariance matrix of system noise	$10^{-2} \times \boldsymbol{I}_{2\times2}$
Covariance matrix of measurement noise	$10^{-13} \times \boldsymbol{I}_{2\times2}$
Initial value of covariance matrix of state vector	$10^{-14} \times \boldsymbol{I}_{8\times8}$

4.2 Results and discussion

Identified pavement roughness profiles by DP+LC and KF are shown in Figures 5, 6 and 7 for T1, T2 and T3 respectively. The pavement roughness profiles are identified in good accuracy by DP+LC. However, KF resulted in poor identification of the pavement roughness profile. It is noted that running speeds were not constant during the experiment and as a result the location of true and identified pavement roughness profiles did not coincide with each other. Therefore, power spectral density (PSD) of the identified pavement roughness profiles are examined. PSD curves of identified pavement roughness profiles by DP+LC and KF are shown in Figures 8, 9 and 10 for T1, T2, and T3 respectively. PSD curves show that DP+LC has comparable results with the true one. On the other hand, the PSD of KF is completely different level from the true one. In the simulation, by KF, a rough shape of pavement roughness profile is identified even if the accuracy is worse.

5 CONCLUSIONS

From the discussion utilizing simulation data, observed results are summarized as follows.

- Dynamic Programming (DP) has a less identification error than Pseudo Inverse Matrix (PIM) method as the latter method includes a calculation of large size inverse matrix in the identification process.
- Little difference between L-curve method and EM algorithm was observed for determining the optimal regularization parameter value. It was also observed that the L-curve has less calculation time than EM algorithm.
- The least square minimization with L_1 norm (DP+LC(L1)) showed the most accurate identification result. However, it takes more calculation time than L_2 norm regularization as it needs repetitive calculation until the convergence of parameters.

From the discussion utilizing measured data from the field experiment, observed results are summarized as follows.

- DP+LC shows the reasonable accuracy of pavement roughness profile identification. Identified PSD is also comparable with the true.
- KF resulted in poor identification of the pavement roughness profile, which was far from expectation. The remaining task is to investigate reasons for the poor identification results by means of the Kalman filter.

Keywords: Bell tower, OMA, FEM update, damaged detection

Abstract. *This document presents the Operational Modal Analysis and finite element update of the bell tower of the church of Castro (BG), in Italy. This procedure was adopted to identify the actual state of structural damage following the widespread carbonation and oxidation of the surface concrete layer and the significant localized damage of the rebars detected by visual inspections. The 39m high structure is a reinforced concrete tower with a hollow section with a double concavity and a tapered section in elevation. Four uniaxial piezoelectric accelerometers were adopted to record environmental vibrations for dynamic identification using the roving technique. After performing dynamic identification, two types of 3D structural models were compared, namely with shell elements and beam elements. Finally, a calibration of the shell finite element model was carried out to identify the boundary conditions and the extension of the damage. The knowledge of the actual state of the structural damage enables the definition and the design of the retrofit strategy aimed at guaranteeing both static and seismic safety, as well as the future preservation of the structure.*

1 INTRODUCTION

The church of San Giacomo (Figure 1), with its adjoining bell tower, is located in the municipality of Castro in the province of Bergamo in the upper area of Lake Iseo at an altitude of about 200m. Located in the old part of the village, near to the lake, it was designed in 1966 by the architect Vittorio Sonzogni and built in 1969 to replace the pre-existing church. The reinforced concrete (RC) bell tower is 37m high and has a square cross-section, with a concavity on the four sides, tapered in elevation. There are also elongated openings alternating on the sides and horizontal joints with a regular pattern.

The bell tower is in a pronounced state of deterioration, with the presence of a significant crack at the third level, probably due to a number of factors: the concavity of the sections and elevations generates a clear washout of the concrete in the central area of each side, revealed by the chromatic alteration of the surfaces; the areas of discontinuity of the surface, such as the openings and the horizontal joints, collect a greater quantity of rainwater percolating from the top. In these areas, there is a greater presence of deterioration due to the corrosion of the reinforcing bars and the spalling of the concrete cover; and poor casting of the conglomerate is revealed by the gravel nests on the worn out surfaces.

Figure 1. View of the church with the adjacent bell tower.

For such reasons dynamic identification was carried out to evaluate the damage extension and provide a reference finite element model to be used in the conceptual design of the retrofit intervention. To record the environmental vibrations, 4 high sensitivity piezoelectric accelerometers (Wilcoxon 731A) were used. The sensors were placed at each floor level according to the scheme depicted in Figure 2: 2 sensors remained in the same position for all the acquisitions (reference) while the others were moved at each registration (roving) and changed in directions according to the Type A and Type B positions. The configuration A allows the identification of flexural and torsional modes at each level, while the configuration B enables the identification of the flexural modes in the orthogonal direction.

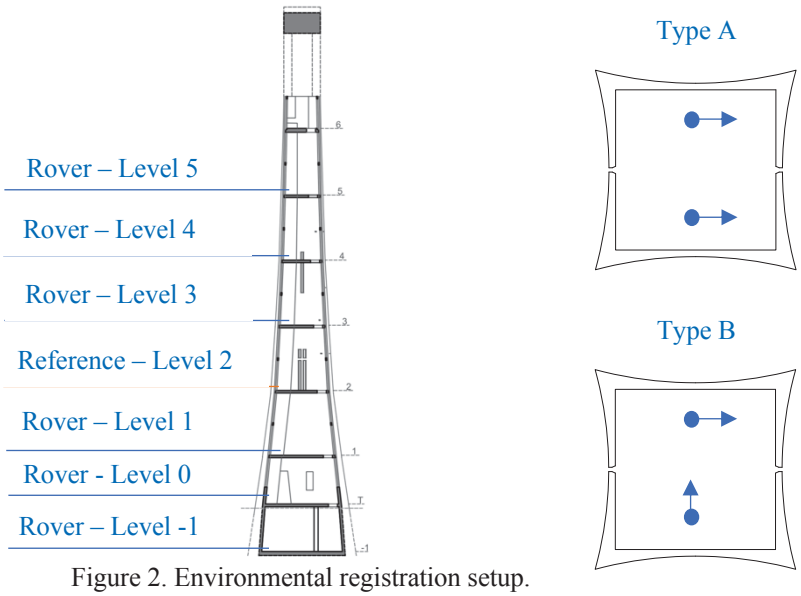

Figure 2. Environmental registration setup.

2 OPERATIONAL MODAL ANALISYS

For the dynamic modal identification, the FDD algorithm was selected [1, 2]. Frequency Domain approaches are based on the processing of a time-correlated signal through a Discrete Fourier Transform (DFT). Frequency Domain Decomposition methods operate a Singular Value Decomposition (SVD) at each line of the frequency spectrum. This procedure separates noisy data from disturbances of various sources and appears to be able to capture close modes of vibration with good accuracy. Typical underlying hypotheses of Frequency Domain Decomposition (FDD) methods are: white noise input, low structural modal damping ratios and geometrically-orthogonal mode shapes of close modes.

The FDD algorithm was used for each recording in order to obtain the modal frequencies and the respective modal forms. A statistical analysis was carried out to obtain mean and variance modal frequencies and the modal forms have been reconstructed starting from the initial knowledge of the eigenvector for each acquisition and the subsequent normalization to the values of the reference sensors [4]. Figure 3 shows the estimated frequencies in a box and whiskers: the central mark indicates the median, and the bottom and top edges of the box indicate the 25^{th} and 75^{th} percentiles, respectively. The whiskers extend to the minimum and to the maximum values excluding the outliers, and the outliers, values that are more than 1.5 times the interquartile range away from the top or bottom of the box, are plotted individually using the '+' symbol. In Figure 3 it is possible to notice the small variance of the estimated frequencies.

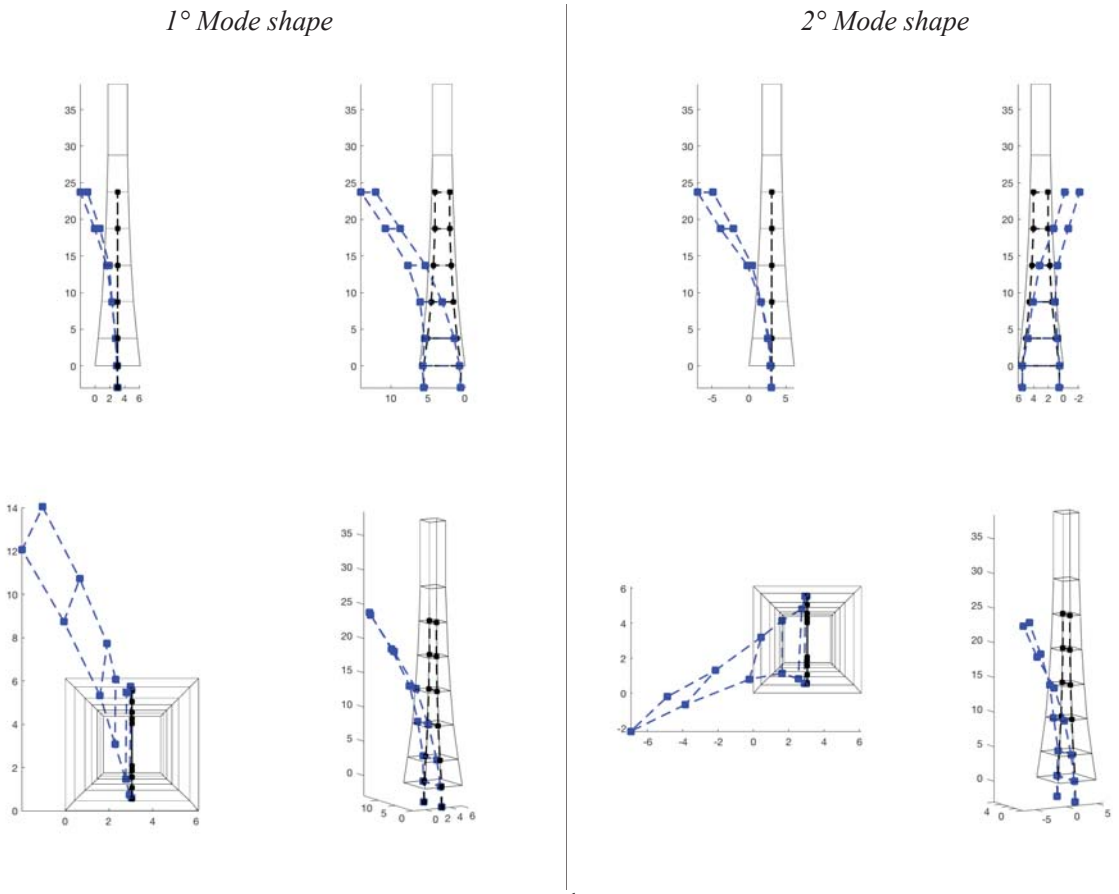

Figure 4. 1st and 2nd modal shapes.

3 FEM CALIBRATION

3.1 FEM Model

A finite element model was built with Midas Gen [3] software using four-node shell elements (Figure 5) connected at the base to a ground point by means of rigid links. To capture the soil-structure interaction, the rotational degrees of freedom of the ground level were released, and two elastic springs were added to simulate rotational stiffness long the principal directions. The model (11412 nodes and 20516 elements) was validated against a brick elements model to check the presence of any geometric locking problem. The mechanical properties of the concrete were calibrated from compressive tests on the bell tower concrete.

Figure 5. FEM model with shell elements.

3.2 Sensitivity analysis

A sensitivity analysis was performed on the parameters that regulate the dynamic behavior: the stiffness of the springs at the base, the percentage and extension of the main crack located at the 3rd level and the Young's modulus of the concrete. The parameters were studied and varied independently from each other to eliminate those that made the matching between OMA and FEM badly conditioned. For example, the stiffness of the spring at the base was found to dominate the curvature of the modal form at the base; so, such stiffness was selected directly looking the modal curvature at the base and it was not further considered in the calibration problem (Figure 6). The elastic modulus of concrete affects mainly the modal frequencies rather than other dynamic properties (Figure 7). Finally, the extent of the main crack at the 3rd level affects the modal form rather than the frequency (Figure 8).

As for the percentage of damage in the crack (evaluated as a reduction of the elastic modulus of the concrete), from a first calibration it resulted in a 98% reduction of the Young modulus, a very high percentage which was confirmed by visual inspections. For such reason, this parameter was kept constant in the calibration problem.

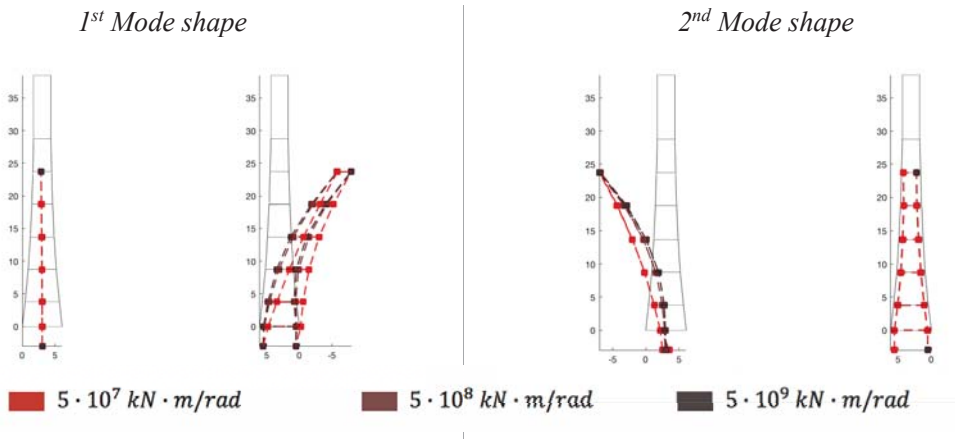

Figure 6. Sensitivity of the 1st and 2nd modal shapes as the stiffness of the rotational base spring.

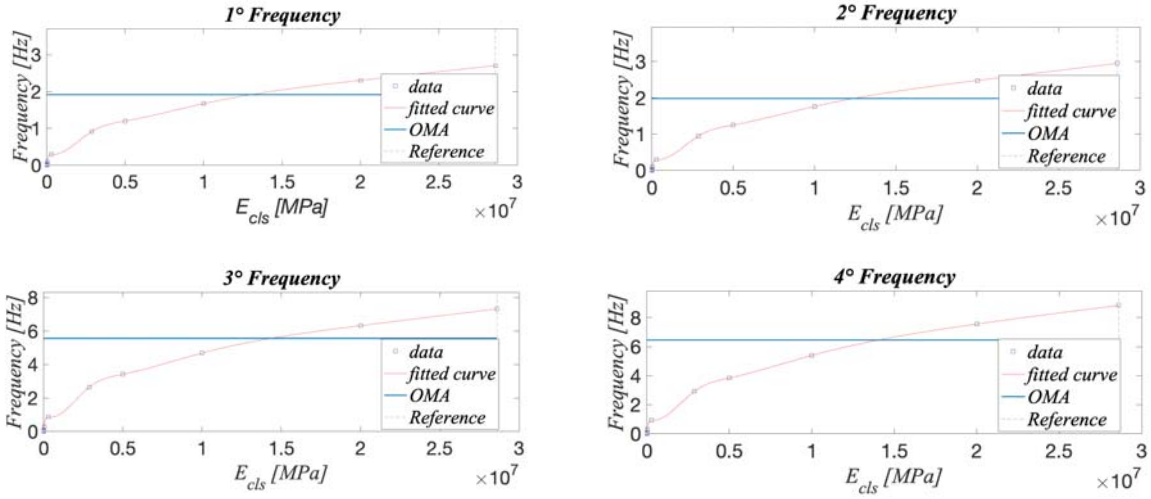

Figure 7. Sensitivity of the modal frequencies as the Young modulus of concrete.

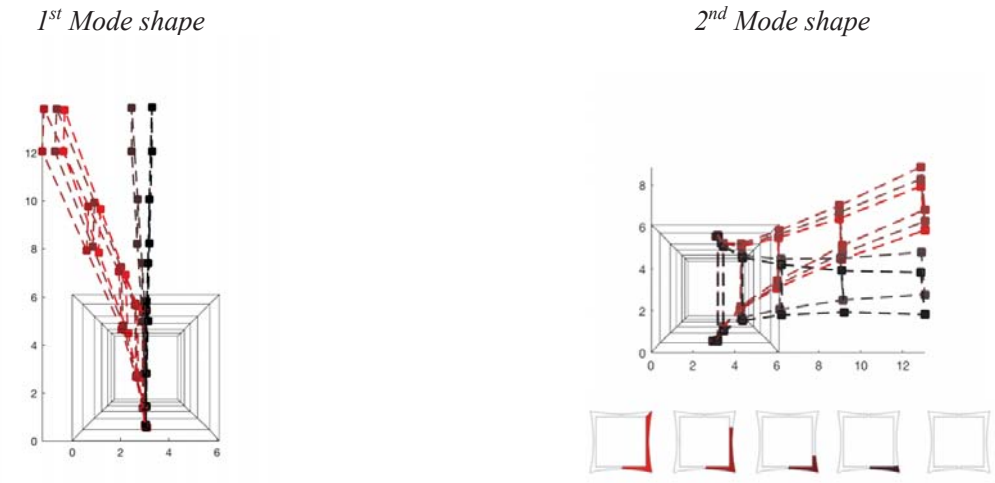

Figure 8. Sensitivity of the 1st and 2nd modal shapes as the extension of damage in the crack at the 3rd level.

3.3 FEM calibration

Starting from the sensitivity analysis, a preliminary manual match on each individual parameter was performed.

Parameter	before calibration	after calibration
Spring Stiffness	500000000 kNm/rad	500000000 kNm/rad
Percentage of damage	0 %	98 %
Young's modulus of concrete	$2.86*10^7$ kN/m^2	$1.7*10^7$ kN/m^2

Table 1: Comparison of parameters before and after calibration.

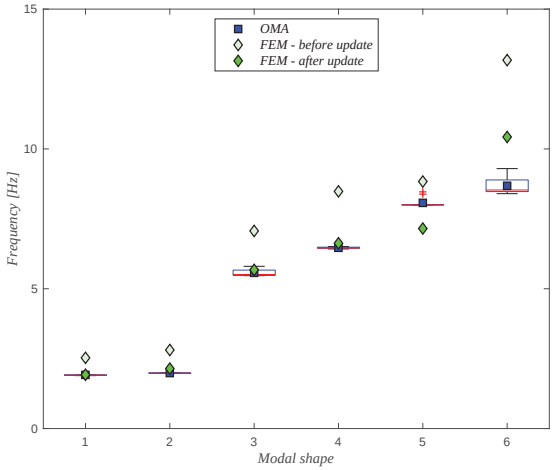

Figure 9. Comparison of modal frequencies before and after calibration.

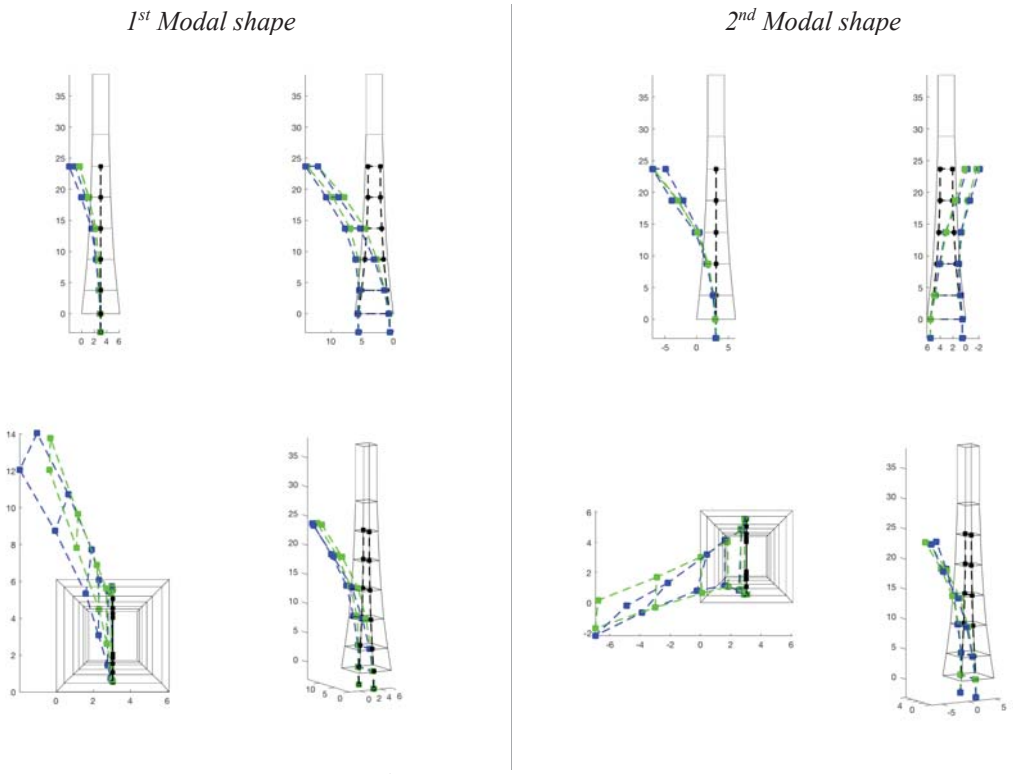

Figure 10. Comparison of 1st and 2nd mode shapes after calibration: OMA (blue) and FEM (green).

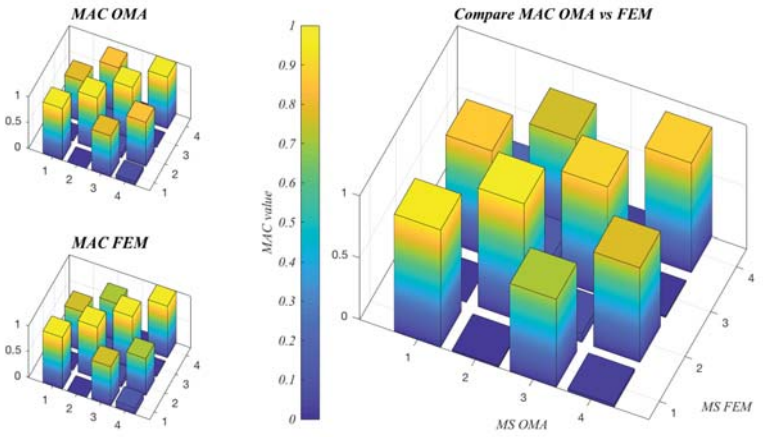

Mode	MAC
1	0.95
2	0.96
3	0.89
4	0.89

Figure 11. Comparison of MAC OMA and FEM post calibration and MAC values.

Figures 9-10-11 show the very accurate matching for the first four modal parameters. This allowed to evaluate, with a good approximation, a first estimate of the state of health of the structure that may be useful for the future retrofit project. It is also interesting to note how the modal forms 1-3 and 2-4 (Figure 11) seem correlated; this is due to the fact that the modal shapes have been calculated only up to the 5th floor (Figures 2-4) and the MAC value of Figure 11 neglects the modal shape above such level.

4. CONCLUSION

The paper presented the dynamic identification of the bell tower of San Giacomo church in the municipality of Castro (Italy). The reinforced concrete tower showed very poor state of preservation with an evident crack extending on the third level. A dynamic identification was performed using the roving technique. The FDD algorithm was applied on each record set and then combined to obtain the full model mode shapes.

A sensitivity analysis was conducted to highlight the influence of a series of parameters on the dynamic properties. In particular, it was found that: damage in the cracked region results in a plan rotation of the modal shapes compatible with the OMA results; the stiffness of the rotational springs at the base can be selected to match the modal curvature at the base of the tower; the concrete modulus of elasticity significantly influences the modal frequencies. Finally, after tuning each parameter, it was possible to obtain a good match of the FE model with the identified OMA properties and quantify the extension of damage in the cracked region.

Abstract. *Almost all offshore wind farms across the world are equipped with a Structural Health Monitoring (SHM) system. Nevertheless, the benefit of using data analysis results for Operation and Maintenance (O&M) optimization is not yet effectively exploited. Reasons for this are manifold but dominated by the fact that usually the development of the SHM system is not integrated from the beginning as part of the project management process. Rather, in most cases, it is mainly implemented to fulfill the minimum requirements by relevant authorities. In addition to this, as the use of monitoring data for possible life time extension is well established, stakeholders miss the benefits for young age wind turbines. However, current research has shown that SHM results are also useful in the early life cycle range to determine healthy state reference parameters and also to optimize the variation of the as-built structure from the designed structure. The information obtained from an SHM system therefore is an added value, which can be estimated before implementing it using value of information concept.*

The main purpose of implementing an SHM system is to reduce uncertainty. This paper makes use of SHM data analysis to reduce the uncertainty of stress ranges when performing reliability analysis for Risk Based Inspection (RBI) planning. For this study, one year strain time history data from four monitored wind turbines in an offshore wind farm in the North Sea is used. The measured stress cycles are counted by Rain Flow Counting (RFC) and grouped into stress range bins. Finally, the distribution of the counted stress cycles are used to fit a Weibull probability distribution function to estimate the parameters and compare them with recommendations from literature and standards. This way, an individual RBI planning for the monitored offshore wind turbines is enabled.

1 INTRODUCTION

In offshore wind energy industry, design optimization and development of innovative construction methods have significantly contributed to cost reduction and increased reliability of wind turbines. However, recently, the focus has shifted towards optimization of Operation and Maintenance (O&M) for further cost reduction. Especially for aging operating offshore wind turbines, with high O&M costs reaching from 25-30% of the energy generation costs [1], [2], [3], making use of this is economically attractive. Corrective maintenance activities are expensive in most cases, as the turbine is usually shutdown for maintenance resulting in loss of revenue from power production. To minimize or avoid corrective maintenance, it becomes necessary to detect faults or damages in their early stage. This can be achieved by having a continuous and reliable information about the performance and condition of the structures through Structural Health Monitoring (SHM). In this paper, one year strain time history data from strain gauges installed in four wind turbines in the North Sea are used. The distribution of the counted stress cycles from the measured stress time history data is fit into a Weibull distribution function to estimate individual Weibull shape parameters and compare them with the values obtained from literature and relevant standards. It is shown that the estimated individual parameters are significantly different from the standard recommendations and using them as an input for RBI planning will result in different inspection plans.

2 STRUCTURAL HEALTH MONITORING AND VALUE OF INFORMATION

The main purpose of implementing a Structural Health Monitoring (SHM) system is to decrease uncertainties and therefore being able to reduce risk. According to ISO 31000 [4], the definition of risk is 'effect of uncertainty on objectives'. In many cases, the objective is the continuous safety and functionality of structures or systems according to design. For the case of offshore wind turbines, the objective is safe and continuous power production with minimum possible unexpected costs.

Vibration-based SHM has been in practice for many decades to monitor bridge structures [5]. The physical properties of a structure are affected by damage or deterioration. Changes in these physical properties (mass, stiffness and damping) of a structure will change its vibration behavior, which can be quantified in terms of the dynamic characteristics such as the Eigenmodes and modal damping or counted stress cycles. These damage and deterioration sensitive performance indicators can be directly measured and/or calculated from the measured quantities of an SHM system.

Earlier monitoring systems were implemented purely from structural engineering point of view for damage detection without Value of Information (VoI) analysis. The term VoI was first used in 1961 by Raiffa and Schlaifer [6] as decision support for selecting the experiment with maximum utility through Bayesian pre-posterior analysis of the experiments. Then, in 2004 VoI analysis was applied by Straub and Faber [7], [8] for inspection optimization of structural systems. Recently, the VoI analysis was applied to SHM [9] and made significant progress as part of the cost action TU1402 project [10], in which pre-posterior decision analysis was used to estimate the expected added value from implementing a monitoring system. Pre-posterior decision analysis is estimation of the VoI before doing the experiment or having any of the expected data [11]. VoI estimates the expected gain from decisions made using the information obtained from the SHM as compared to the decisions made without the SHM and after deducting the cost of the SHM system (or experiment).

The pre-posterior analysis for VoI analysis and comparison is made by Bayesian decision

tree to decide, whether it is beneficial or not to implement a monitoring system. Furthermore, different configurations can also be investigated to optimize for the maximum VOI [12].

$$VoI_{max} = max_{i,j}\{E[C_{T,O}] - E[C_{T,M,i}(d_j)]\} \tag{1}$$

where $E[C_{T,O}]$ is the expected total costs without monitoring and $E[C_{T,M,i}(d_j)]$ is the expected total cost for i^{th} configuration with corresponding j^{th} decision. The benefit from VoI is incorporated to the total cost as a negative component.

VoI also helps to decide when it is most beneficial to start monitoring of a structure. Long et al. [13] investigated the VoI analysis for a truss bridge girder structure by comparing several sensor configuration scenarios. The VoI concept is highly attractive for many industries, which need incorporation of monitoring systems.

In the case of offshore wind industry, during its start the VoI concept was not a well established practice. Also, the pressure to reduce costs has forced the industry to deal with uncharted waters of building bigger wind turbines at deeper waters and far away from the coasts for higher power production. This results in higher uncertainty and made installation of monitoring systems a necessity. As an example, the implementation of a monitoring system on 10% of the wind turbines in an offshore wind farm used to be a BSH (Federal Maritime and Hydrographic Agency) requirement in Germany until 2015 [14]. In 2015, the BSH regulation was revised [15], which gave the wind farm operators more flexibility, concerning the number of monitored turbines, as long as they can prove to the authorities that appropriate safety measures are being taken. After 2015, the operators had a chance to make VoI analysis before implementing a monitoring system and to incorporate the development of a monitoring system as part of their regular project life cycle management. However, still the majority of SHM systems are being implemented based on the outdated BSH recommendation of installing a monitoring system on 10% of the wind turbines in an offshore wind farm. The lack of integrating SHM as part of design and construction process resulted in less interest by the operators to integrate the SHM data analysis results into the O&M decision-making procedures. As a result, the full potential of SHM data analysis results for O&M cost reduction is not yet being effectively exploited.

3 RELIABILITY ANALYSIS AND RISK BASED INSPECTION PLANNING

The expected results of a reliability analysis is estimation of a system's or component's probability of failure (or reliability index). For determination of a failure event it becomes important to formulate a limit state, which can be ultimate, serviceability or fatigue. Violation of the limit state is then considered as a failure event (Melchers and Beck) [16]. In a very simplified form, for a component with a resistance R when exposed to a load S, the probability of failure could be represented by:

$$P_f = P(R \leq S) = P(R - S \leq 0) = P[G(R, S) \leq 0] \tag{2}$$

where G() is a limit state function, for which $G() < 0$ represents a violation. The reliability index (β) can be calculated from the Probability of failure (P_f) as:

$$\beta = -\Phi^{-1}(P_f) \tag{3}$$

with $\Phi()$ assumed as a standard normal distribution function.

Offshore structures are exposed to cyclic loads. As a result, fatigue is the most significant deterioration mechanism. In fatigue reliability analysis, structural failure occurs as a crack growth and the limit state function is violated (failure occurs) when the crack size exceeds the critical crack size. In most cases, failure is considered to occur when crack grows through the steel thickness.

Fatigue analysis is usually done by using Palmgren-Miner rule and S-N curve to estimate fatigue damage. Also, the experiment based Paris law proposed by Paris and Erdogan [17] gives the rate of fatigue crack growth. Fatigue reliability analysis is commonly done by calibrating these both models, the S-N model and the Fracture Mechanics (FM) model [18], [19], [20] to establish the limit state function for crack growth. Furthermore, the calibrated models are also used for inspection planning, see e.g. [8] and [21]. The limit state function involves multiple random variable and is usually solved by making use of First Order Reliability Method (FORM), Second Order Reliability Order (SORM) and recently with the growth of computational capability Monte Carlo Simulation (MCS). The computational time of MCS can further be enhanced using advanced sampling techniques, specially when estimating very low probabilities.

The next step, after reliability analysis (estimating the probability of failure or the reliability index) is Risk Based Inspection Planning (RBIP), which starts by comparison of the estimated reliability index with the acceptance criteria (target reliability index). The central idea of RBIP is to assign the available inspection resources to the structure or component of a structure, where it is mostly needed (with highest risk). For the reliability analysis, input load and structural resistance defining the limit state function need to be analyzed.

Reliability analysis is commonly done using random variables to represent the uncertainty of the input variables to the limit state function. These variables are usually taken from design assumptions. One of the most important inputs is the number and magnitude of stress cycles the structure (hot spot) is exposed to. The probability density function of the stress ranges for offshore structures are commonly represented with a two-parameter (scale and shape) Weibull distribution [22], [23], [24]. The shape and scale parameters represent the distribution and magnitude of the hot spot stress range respectively. ABS (2003) [23] recommends a value which varies from 0.7 to 1.4 for the Weibull shape parameter, while Wirsching and Chen (1988) [25] recommended a value from 0.5 to 1.5. Furthermore, ABS (2003) [23] states that similar offshore fixed platforms structures built in the Gulf of Mexico and the North Sea experience stresses with shape parameter values of 0.7 and more than 1.4 respectively. Figure 1, an example adopted from Straub (2005) [8], shows visualization of stress range ($\Delta\sigma$) Probability Density Function (PDF) for varying shape parameters (γ) of 0.50, 0.75, 1.00, 1.25 and 1.50. A constant scale parameter of 5 MPa is used for all cases.

The Weibull shape parameter is a function of geometry and loading. Generally, an increase in slenderness and dynamic exposure will increase the shape parameter [8], [23]. DNVGL RP-C-210 document [24] illustrates with a graph, that for all S-N curves of varying structure detail, the allowable maximum stress range decreases with increasing Weibull shape parameter. This is obvious from Figure 1, since with increasing of the scale parameter, the contribution of the higher stress ranges become more significant.

The above mentioned Weibull shape parameters recommended in standards are mainly estimated based on wave data [23]. These values are being used for design and reliability analysis of offshore structures. DNVGL RP-C-210 [24] notes that the shape parameter significantly affects the estimated fatigue damage, therefore calibrating these parameter from long term measured stress time history data becomes very important.

For offshore wind turbine structures, there is the benefit of having permanent SHM systems,

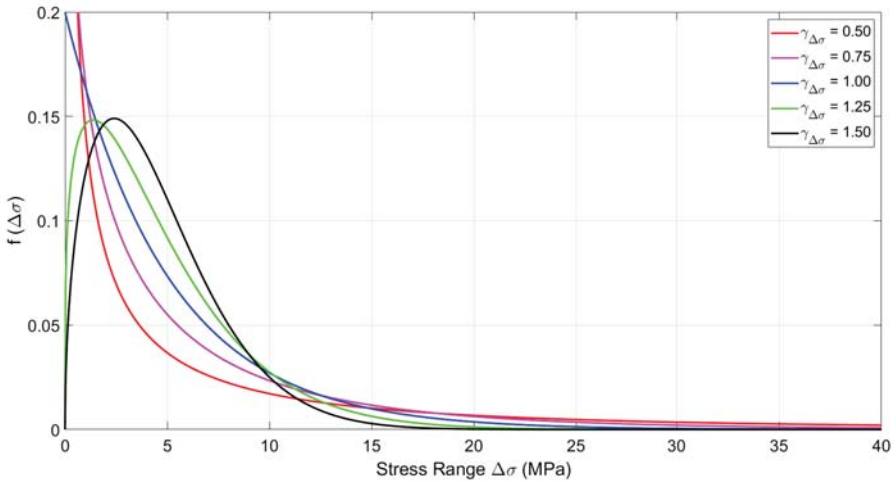

Figure 1: Weibull PDF for varying shape parameter with fixed scale parameter equal to 5MPa

which provide continuous information about the number and magnitude of stresses the structures are exposed to. Moreover, the SHM system measure responses, which represent the collective impact of loads and load combinations on the structure. Comparison of these measured responses against the capacity (resistance) of the structure helps in defining a more realistic limit state function. Experience from many monitored offshore wind turbines showed that most of the offshore wind turbines are built stronger (stiffer) than the design [27].

4 METHODOLOGY

In this section, the analysis procedure of one year strain time history data from four wind turbines in an offshore wind farm in the North Sea is discussed.

The monitoring system installed in all four wind turbines is identical, with eight strain gauges installed at two measurement levels, four sensors at each level at identical positions, in cardinal coordinates. The data is collected with a sampling rate of 100Hz. Before performing Rain Flow Counting (RFC) according to ASTM E1049-85 [28], the raw strain time history data is first pre-processed by removing erroneous data using median filter. Furthermore, the strain data is temperature compensated by removing the apparent strain calculated from the temperature sensors' data installed together with every strain gauge. For calculation of apparent strains relevant manufacturer's temperature compensation curves are used. Finally, the stress time histories are calculated from the corrected strain data by using the relevant young's modulus of steel.

After that, RFC of the stress time history data is done and the counted stress cycles are assigned to predetermined stress range bin sizes. DNVGL recommends a minimum of 20 stress range bins. However, in this study two cases are considered. In case one, uniformly distributed 100 stress bins are used to classify the counted stress cycles. And in the second case, in order to get higher resolution of the bins with very high number of cycles, non-uniform 143 stress bins are used. Finally, for both cases, the counted stress cycles are fitted to Weibull distribution functions for estimation of the scale and shape Weibull parameters. The fitting process is done by using the least square method according to [23].

The estimated Weibull shape parameters are then compared with the values obtained from standards. Furthermore, for the first case, sensitivity analysis of removing the insignificant

stress cycles (the first and second stress range bins) is made. In addition, for both cases, the effect of applying low-pass filters to remove the very small stress cycles before doing RFC is investigated.

5 RESULT

5.1 For uniform sized 100 stress bins

In this subsection, the results obtained from the first case are presented. The stress bins used are 100 uniformly sized stress bins, each with a size of 0.51 MPa. Figure 2 shows the estimated Weibull shape parameters for all four turbines. The x-axis of each subplot indicate the turbine location, for example L-90° means lower level strain gauge at 90°N and U-180° means upper level sensor at 180°N.

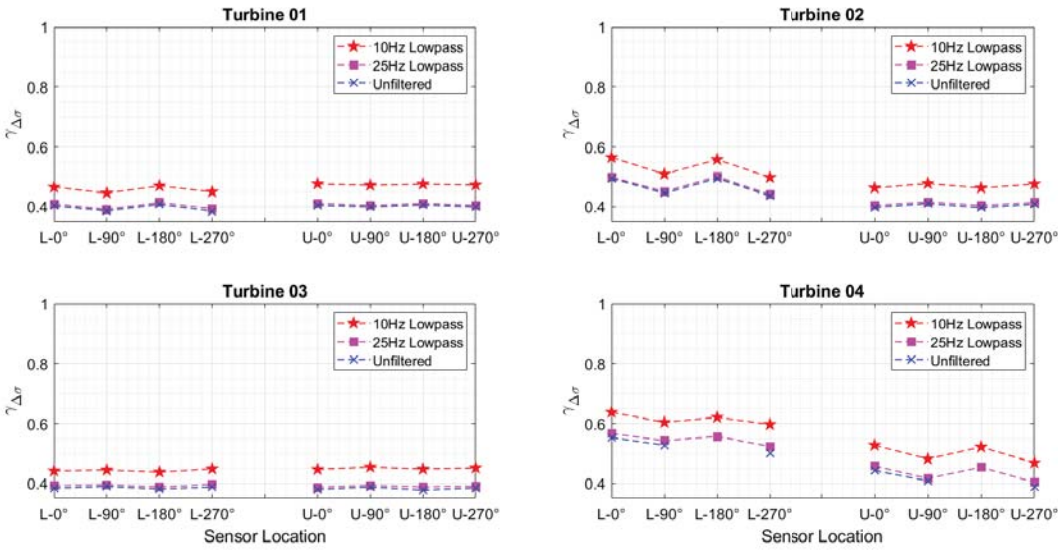

Figure 2: Estimated weibull scale parameter for the 8 sensors in each of the four turbines

The results are generally lower than the recommended value of 1.0 for the North Sea environment [23], [25], [26]. Although all turbines are from the same wind farm, differences between the different wind turbines can be clearly identified, ultimately leading to different risks. The turbines located in the interior of the wind farm (Turbines 02 and 04) have higher shape parameters than those located in the boundary of the wind farm (Turbines 01 and 03). The turbines located in the interior of the wind farm are exposed to higher cyclic loads due to wake effects. In addition, the results for sensors located opposite to each other are of equivalent magnitude and consistent. For example, in every turbine at each measurement level the results for the sensors located at 0°N and 180°N as well as for the sensors at 90°N and 270°N are comparable and consistent.

Furthermore, as expected and shown in all four subplots, the low pass filtering of the small stress cycles before RFC resulted in an increased Weibull scale parameters in all cases. The unfiltered data results in the lowest scale parameter estimation. With decreasing cut-off frequency of the low-pass filter, the magnitude of the scale parameter increases.

To study the effect of removing small stress cycles on the accumulated fatigue damage, the accumulated fatigue damage for every stress bin is calculated using Palmgren-Miner rule and

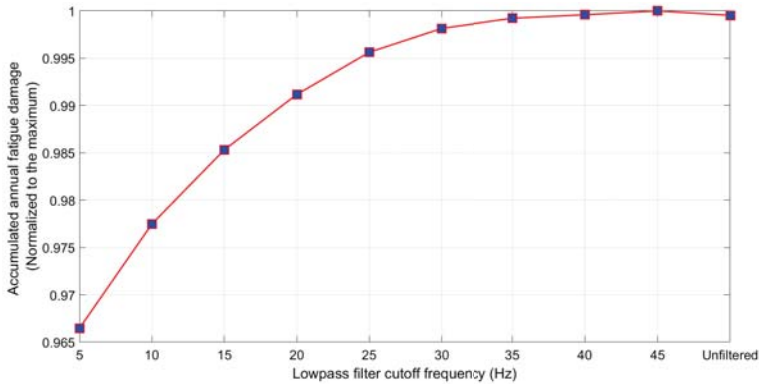

Figure 3: Effect of data low-pass filtering on the accumulated annual fatigue damage

relevant S-N curve. Figure 3 shows the effect of increasing cutoff frequency for the applied low-pass filters. The accumulated annual fatigue damages are normalized to the maximum. This shows that as the sampling frequency decreases the estimated fatigue damage will not be drastically affected as the bigger stress cycles are mainly contributing to the accumulated fatigue damages. For example, using a low-pass filter of 5 Hz will result in an error of 3.35% as compared to the maximum estimate. Although with a very small amount of 0.05%, the fatigue damage estimated from 45 Hz low-pass filter is higher than the estimation from the unfiltered data. This might have something to do with measurement artifact as it was observed in all channels.

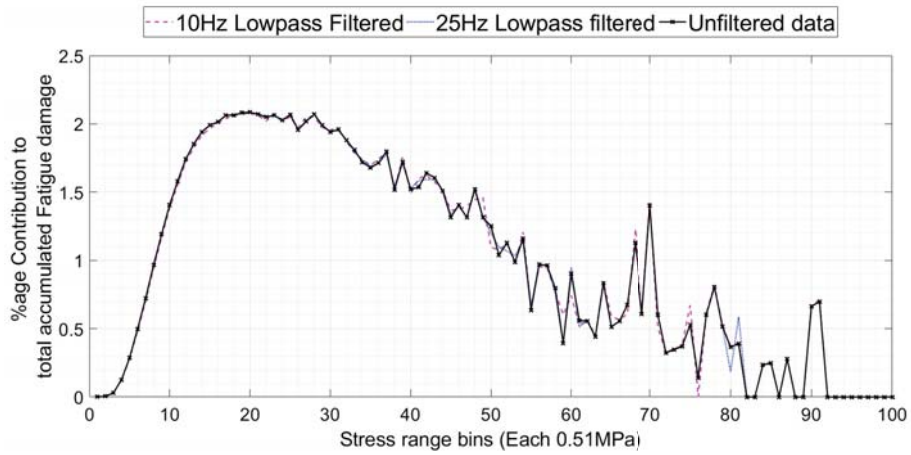

Figure 4: Percentage contribution of each stress bin to the total accumulated Fatigue damage

Furthermore, the fatigue results are used to observe the distribution of the total fatigue damage among the stress bins. Figure 4 show the percentage contribution of all 100 stress bins to the total accumulated fatigue damage. Although the small magnitude stress bins contain a very high number of cycles, they do not contribute to the accumulated fatigue damage. The 100 stress bins have each a size of 0.51 MPa. When the contribution of each stress bin is compared as percentage to the total fatigue damage, the percentage contribution of the first two bins for all three cases are less than 0.004%. The maximum percentage contribution is from stress bin number 20 with appr. 2.08% for all three cases. The third bin has a contribution of appr. 0.03%

in all three cases. From this finding, it might be possible to neglect the first two stress bins to estimate the modified Weibull shape parameter. Also in Figure 4, although not included in order to avoid congestion, the contribution for 45 Hz low-pass filter is higher than for the unfiltered data.

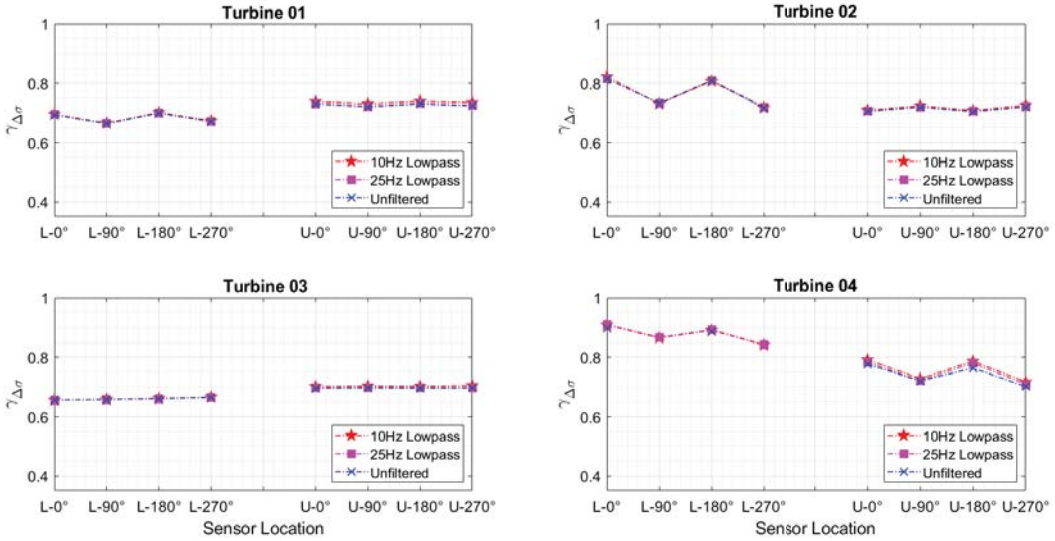

Figure 5: Estimated weibull scale parameter after removing the first stress bin

The estimations in Figure 5 are made by removing only the first stress bin of every sensor in all four turbines. The results plotted in Figure 5 show that all the newly estimated Weibull scale parameters increased, meaning the skewness of the distribution is shifting to the right as the higher stresses are becoming more involved. Another observation is that, that the influence of low pass filtering on the estimated scale parameters is decreased, if the first bin with smallest magnitudes is already removed.

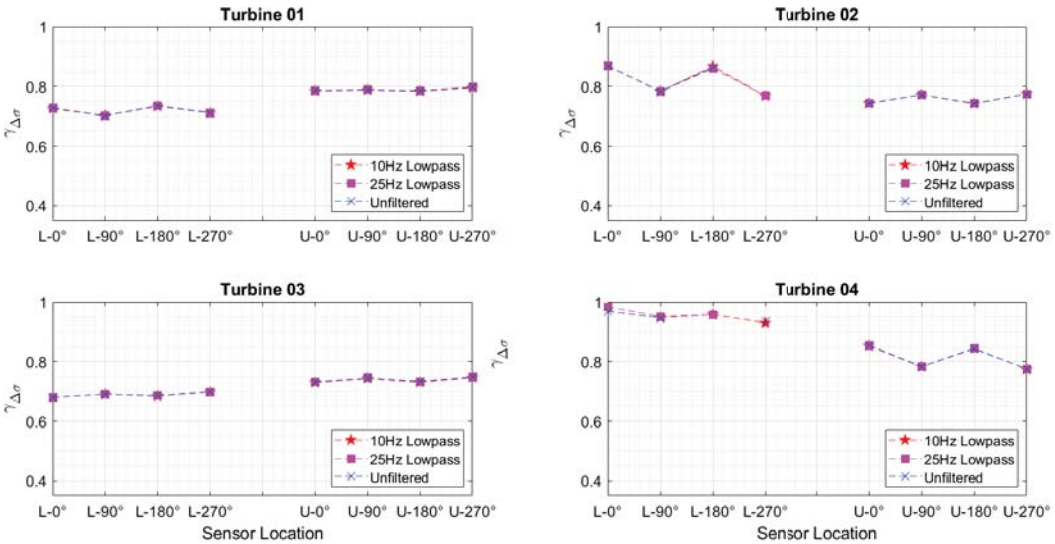

Figure 6: Estimated Weibull scale parameter after removing the first two stress bins

Furthermore, Figure 6 shows the estimated scale parameters after removing the first two stress bins. Again, the estimated scale parameters increased but not very significantly. This indicated that the first stress bin has most effect on the estimated values. Although insignificant on the fatigue damage the number of counted cycles with magnitude less than 0.51 MPa (in the first stress bin) are more than 95% of the total counted number of cycles for all 100 bins. The second bin contains less than 1% number of cycles.

5.2 For non-uniformly sized 143 stress bins

After observing that more than 95% of the total counted cycles belong to the first stress bin, the analysis was repeated by breaking down the first stress bin in to 10 classes. The bin sizes used for the stress ranges between 0 and 0.50 MPa is 0.05, between 0.50 and 2.50 MPa is 0.10, between 2.50 and 10.0 Mpa is 0.25, and for the rest is 0.50 MPa. In this case two, totally 143 non-uniformly sized stress bins are used.

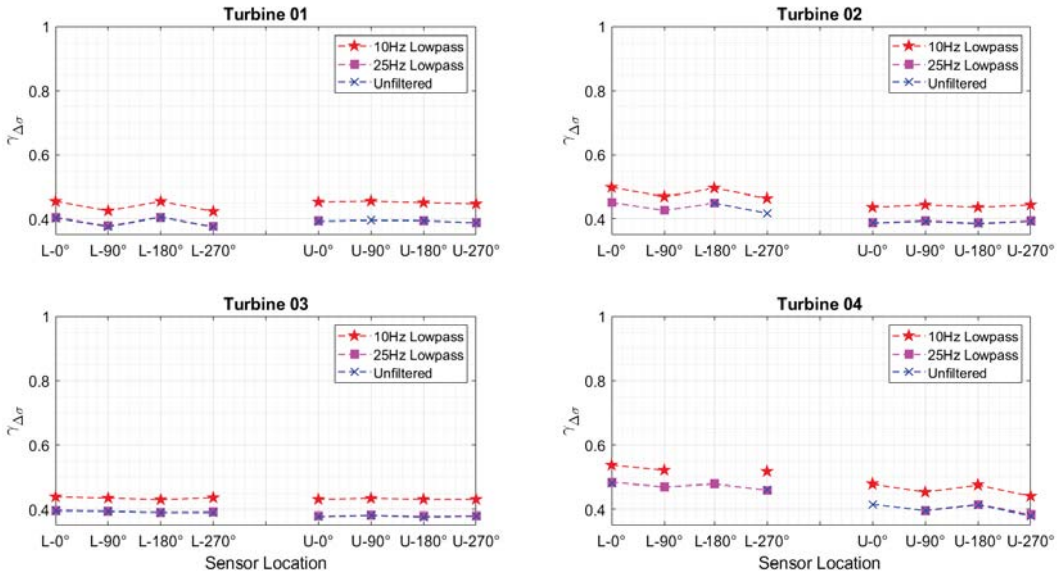

Figure 7: Estimated Weibull scale parameter for 143 stress bins

Figure 7 shows the results for case two. Generally, the results are similar with Figure 2 indicating that increasing the resolution of the stress bins does not significantly affect the estimated Weibull shape parameters.

5.3 Summary of results

Generally, the results show that the Weibull scale parameters estimated from the measured one year strain time history data are less than those recommended by design standards and used for reliability analysis in the North Sea, even when the small value bin is neglected or small cycles are removed by low-pass filters during scale parameter estimation.

The paper shows that, the presence of the lower stress bins does not significantly contribute to the accumulated fatigue damage but significantly affect the estimation of the shape parameter. In addition, removal of high frequency stress cycles with a low-pass filter does not very significantly affect the accumulated fatigue damage and the shape parameter estimation. Furthermore, the wind turbines in the same wind farm have varying shape parameters indicating that they are

exposed to varying risks and can be used as an important input to RBI planning. An important result is also that the wind turbines located in the interior of the wind farm (Turbines 02 and 04) have higher Weibull shape parameters in all estimations than the turbines located at the exterior (boundary) of the wind farm (Turbines 01 and 03). The reason can be that the interior wind turbines are more exposed to cyclic loads from wake effects. This can be important information for extrapolation of the estimated parameters to the unmonitored turbines.

The obtained results, even after removing the lower stress bins are still lower than the recommended values, therefore when used as an input for reliability analysis, more realistic inspection plans can be made. The higher recommended values of scale parameter overestimates the stress cycles the structure is actually exposed to. These results can be considered as one of the added values obtained from incorporating SHM data analysis in the reliability analysis and Risk based inspection planning.

6 CONCLUSION

The paper uses one year strain time history data from four wind turbines in an offshore wind farm located in the North Sea. After pre-processing of the strain data, the corrected strain data is used for calculating the stress time history. Then, Rain Flow Counting (RFC) analysis of the stress time history was made to count the number and magnitude of the stress cycles, the structure is exposed to during the one year monitoring period. The counted stress cycles are first binned in to uniformly sized 100 stress range classes and then for comparison purpose in to a non-uniformly sized 143 classes. For each case, Weibull distribution function is fitted to the counted stress cycles using the least square method. Finally, the stress range Weibull scale parameters are estimated from the fitted Weibull distribution functions. The results obtained from the sensors located opposite to each other (at 0°N - 180°N and at 90°N - 270°N) and at the same measurement level showed good consistency. Furthermore, a sensitivity analysis is made by removing the very small stress cycles which contributed very insignificantly to the total accumulated fatigue damage. The modified scale parameters increased. However, when compared to the stress range scale parameters recommended for North Sea, they are still lower. It is shown that the reliability analysis made using the recommended Weibull shape parameter value of 1.0 for the North Sea would overestimate the stresses the structures are exposed to. In addition, the Weibull shape parameters calculated for the turbines located in the interior of the wind farm are higher than those located in the boundary of the wind farm possibly due to wake effect. This information can also be used for extrapolation of the parameters to the unmonitored wind turbines.

The results contribute as one part of the added values from implementing and analyzing of SHM data. When these results are used to update the scale parameters used for Risk Based Inspection Planning, more realistic inspection plans can be achieved.

Keywords: Modal identification, Bayesian inference, Vector autoregressive model, Uncertainty quantification, Feature extraction.

Abstract. *This study proposes an efficient modal identification method for bridges under operation. The noisy condition caused by the traffic loadings is one of the difficulties involved in the operational modal identification. To cope with the problem, this study quantifies uncertainty involved in the modal properties utilizing Bayesian statistics. The quantified uncertainty enables to determine the reasonable model order and to extract the stably estimated modal properties from the determined model. The proposed method is applied to traffic induced vibration measured from an actual truss bridge. The extracted modal frequencies well correspond to peaks in power spectral density curves. Twelve bending and torsional modes are efficiently extracted by the proposed method. Six modes in the twelve is possibly newly observed modes.*

1 INTRODUCTION

Vibration based structural health monitoring provides a research field for nondestructive evaluation based on physical measurements and computer analyses to complement existing visual inspection methods. Especially for short to medium span bridges, the traffic excites the bridges continuously, and thus vibration monitoring is available without interrupting the traffic. Most of the existing studies examined modal properties such as natural frequencies and mode shapes to assess the bridge condition [1-5].

In actual bridges, however, the noisy condition caused by the traffic loadings is one of the difficulties involved in the operational modal identification. That is because the noisy condition induces spurious estimators of modal properties. In existing methods, it is troublesome to distinguish the physically meaningful estimators from the spurious estimators [6-10]. Aiming at application in noisy condition, several studies provided methodology for uncertainty quantification using Bayesian statistics. For instance, Au [11] proposed a Bayesian modal analysis method using Bayesian inference of modal properties. Several studies investigated the posterior distribution of parameters to assess their variability [12 – 13]. For direct decision-making, Dzunic et al. [14] proposed damage detection and classification methods applying Gibbs sampling. Although the uncertainty is successfully quantified through the previous studies, most of the existing Bayesian methods require computational effort to provide numerical optimization or Monte-Carlo sampling. Aiming at application to on-site damage detection, the difficulty in computation may bother efficient decision making.

To cope with the problem, this study simplifies the uncertainty quantification process using a vector autoregressive (VAR) model. As proposed in an authors' previous study [15], Bayesian inference produce the posterior distribution of regressive parameters of a VAR model without numerical iteration. The posterior distribution is converted to the distribution of poles of the linear system, which related to the modal properties. Uncertainty of the modal properties is quantified through the distribution of the poles. The quantified uncertainty indicates the physically meaningful modal properties among the estimators. The proposed method is applied to traffic induced vibration measured from an actual truss bridge.

2 METHODOLOGY

2.1 Bayesian inference

To formulate a VAR model, first we assume that a synchronized discrete time series of the acceleration measured at *m* measurement locations on a bridge, and assume that the time series includes n time steps. A zero-mean time series is produced by subtracting the mean values from the measured accelerations. Letting $\boldsymbol{y}_k \in \mathbb{R}^{m\times 1}$ $(k = 1 \ldots n)$ denote a column vector of the measured accelerations at the *k*-th time step of the time series whose components corresponding to the measurement locations, then the following VAR model with sufficient model order *p* is known to approximate the time series obtained from a linear structural system excited by white noise [16].

$$\boldsymbol{y}_k = \sum_{i=1}^{p} \boldsymbol{\alpha}_i \boldsymbol{y}_{k-i} + \boldsymbol{e}_k \tag{1}$$

Here, $\boldsymbol{\alpha}_i \in \mathbb{R}^{m\times m}$ denotes the *i*-th AR coefficient matrix and $\boldsymbol{e}_k \in \mathbb{R}^{m\times 1}$ denotes a zero-mean Gaussian white noise vector. Letting $\boldsymbol{\Sigma}$ denote the covariance matrix of $\boldsymbol{e}_k$, the PDF of $\boldsymbol{e}_k$ is given as

$$\mathrm{p}(\boldsymbol{e}_k|\boldsymbol{\Sigma}) = \mathcal{N}(\boldsymbol{e}_k|\boldsymbol{0},\boldsymbol{\Sigma}) = (2\pi)^{-m/2}|\boldsymbol{\Sigma}|^{-1/2}\exp\left\{-\frac{1}{2}\boldsymbol{e}_k{}^{\mathrm{T}}\boldsymbol{\Sigma}^{-1}\boldsymbol{e}_k\right\} \tag{2}$$

where $\mathcal{N}(\boldsymbol{x}|\boldsymbol{\mu},\boldsymbol{\Sigma})$ denotes the PDF of $\boldsymbol{x}$ following the multivariate Gaussian distribution with expectation $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}$, and where $|\cdot|$ denotes the determinant of a matrix.

The VAR model given in Eq. 1 is a linear regressive model composed of the regressive coefficients $\boldsymbol{\alpha}_1, \ldots, \boldsymbol{\alpha}_p$, input variables $\boldsymbol{y}_{k-1} \ldots \boldsymbol{y}_{k-p}$, and output variables $\boldsymbol{y}_k$. Letting $\mathbf{W} = [\boldsymbol{\alpha}_1, \ldots, \boldsymbol{\alpha}_p] \in \mathbb{R}^{m\times mp}$ and $\boldsymbol{\phi}_k = [\boldsymbol{y}_{k-1}; \ldots; \boldsymbol{y}_{k-p}] \in \mathbb{R}^{mp\times 1}$ for simplicity, Eq. 1 can be rewritten as

$$\boldsymbol{y}_k = \mathbf{W}\boldsymbol{\phi}_k + \boldsymbol{e}_k \tag{3}$$

According to Eqs. 2 and 3, $\boldsymbol{y}_k$ follows the following Gaussian distribution.

$$\mathrm{p}(\boldsymbol{y}_k|\boldsymbol{\phi}_k, \mathbf{W}, \boldsymbol{\Sigma}) = \mathcal{N}(\boldsymbol{y}_k|\mathbf{W}\boldsymbol{\phi}_k, \boldsymbol{\Sigma}) \tag{4}$$

This study presumes that the time series are independently measured l times. Let $\boldsymbol{y}_k^{(i)}$ $(i = 1 \ldots l)$ denote the measured acceleration at k-th time step in i-th time series and n_i denote its data length. Let $\mathbf{Y_i} = \left[\boldsymbol{y}_{p+1}^{(i)}, \ldots, \boldsymbol{y}_{n_i}^{(i)}\right] \in \mathbb{R}^{m\times(n_i-p)}$ and $\boldsymbol{\Phi_i} = \left[\boldsymbol{\phi}_{p+1}^{(i)}, \ldots, \boldsymbol{\phi}_{n_i}^{(i)}\right] \in \mathbb{R}^{mp\times(n_i-p)}$. Because the noise term $\boldsymbol{e}_k$ is white noise, the following PDF is obtained.

$$\mathrm{p}(\mathbf{Y_i}|\boldsymbol{\Phi_i}, \mathbf{W}, \boldsymbol{\Sigma}) = \prod_{k=p+1}^{n} \mathcal{N}(\boldsymbol{y}_k|\mathbf{W}\boldsymbol{\phi}_k, \boldsymbol{\Sigma}) \tag{5}$$

In the proposed method, the PDF in Eq. 5 is regarded as the likelihood function for parameters $\mathbf{W}$ and $\boldsymbol{\Sigma}$. Accordingly, the Bayesian theorem provides the following relationship.

$$\mathrm{p}(\mathbf{W}, \boldsymbol{\Sigma}|\mathbf{Y_i}, \boldsymbol{\Phi_i}) = \mathrm{p}(\mathbf{Y_i}|\boldsymbol{\Phi_i}, \mathbf{W}, \boldsymbol{\Sigma})\mathrm{p}(\mathbf{W}, \boldsymbol{\Sigma})\mathrm{p}(\mathbf{Y_i}|\boldsymbol{\Phi_i})^{-1} \tag{6}$$

For Bayesian inference, this study adopts conjugate priors [17], which produce posterior distributions with invariant functional forms. Aiming at fast computation for in-service damage detection, the conjugate priors are beneficial because they produce the posterior distributions without Monte Carlo sampling. For the VAR model, the conjugate prior for $\mathbf{W}$ and $\boldsymbol{\Sigma}$ is known to be given as the following matrix-normal inverse-Wishart distribution [14].

$$\mathrm{p}(\mathbf{W}, \boldsymbol{\Sigma}) = \mathcal{MN}(\mathbf{W}|\mathbf{M}, \boldsymbol{\Sigma}, \mathbf{L}^{-1})\mathcal{IW}(\boldsymbol{\Sigma}|\boldsymbol{\Psi}, \nu) \tag{7}$$

In that equation, $\mathbf{M} \in \mathbb{R}^{m\times mp}$, $\mathbf{L} \in \mathbb{R}^{mp\times mp}$, $\boldsymbol{\Psi} \in \mathbb{R}^{m\times m}$ and $\nu \in \mathbb{R}$ are hyperparameters, i.e. the parameters composing the PDF for $\mathbf{W}$ and $\boldsymbol{\Sigma}$. $\mathcal{MN}(\mathbf{W}|\mathbf{M}, \boldsymbol{\Sigma}, \mathbf{L}^{-1})$ and $\mathcal{IW}(\boldsymbol{\Sigma}|\boldsymbol{\Psi}, \nu)$ respectively stand for the following matrix-normal and inverse-Wishart distributions as

$$\begin{aligned}&\mathcal{MN}(\mathbf{W}|\mathbf{M}, \boldsymbol{\Sigma}, \mathbf{L}^{-1})\\ &= (2\pi)^{-\frac{mp\times m}{2}}|\mathbf{L}^{-1}|^{-\frac{m}{2}}|\boldsymbol{\Sigma}|^{-\frac{mp}{2}} \times \exp\left\{-\frac{1}{2}\mathrm{tr}[\mathbf{L}(\mathbf{W}-\mathbf{M})^{\mathrm{T}}\boldsymbol{\Sigma}^{-1}(\mathbf{W}-\mathbf{M})]\right\}\end{aligned} \tag{8}$$

$$\mathcal{IW}(\boldsymbol{\Sigma}|\boldsymbol{\Psi}, \nu) = 2^{-\nu m/2}\Gamma_m\left(\frac{\nu}{2}\right)|\boldsymbol{\Psi}|^{\frac{\nu}{2}}|\boldsymbol{\Sigma}|^{-\frac{(\nu+m+1)}{2}} \times \exp\left\{-\frac{1}{2}\mathrm{tr}[\boldsymbol{\Psi}\boldsymbol{\Sigma}^{-1}]\right\} \tag{9}$$

where $\Gamma_m(\cdot)$ is the multivariate gamma function.

The likelihood function in Eq. 5 and Bayesian theorem given in Eq. 6 are known to engender the following posterior distribution [14].

$$\mathrm{p}(\mathbf{W}, \boldsymbol{\Sigma}|\mathbf{Y_i}, \boldsymbol{\Phi_i}) = \mathcal{MN}\left(\mathbf{W}|\mathbf{M}', \boldsymbol{\Sigma}, \mathbf{L}'^{-1}\right)\mathcal{IW}(\boldsymbol{\Sigma}|\boldsymbol{\Psi}', \nu') \tag{10}$$

In the equation above, the following variables are used.

$$\mathbf{L}' = \mathbf{L} + \boldsymbol{\Phi_i}\boldsymbol{\Phi_i}^{\mathrm{T}} \tag{11}$$

$$\mathbf{M}' = (\mathbf{M}\mathbf{L} + \mathbf{Y_i}\boldsymbol{\Phi_i}^{\mathrm{T}})\mathbf{L}'^{-1} \tag{12}$$

$$\nu' = \nu + n_i - p \tag{13}$$

$$\mathbf{\Psi}' = \mathbf{\Psi} + \mathbf{Y_i Y_i}^{\mathrm{T}} + \mathbf{MLM}^{\mathrm{T}} - \mathbf{M}'\mathbf{L}'\mathbf{M}'^{\mathrm{T}} \tag{14}$$

For simplicity, this study adopts uniform prior distribution, i.e. $\mathrm{p}(\mathbf{W}, \mathbf{\Sigma}) \propto Const.$, to represent non-informative prior. That is, we assume the hyperparameters as $[\mathbf{L}]_{ij} = 0\ (i, j = 1 \ldots mp\ ),\ \nu = -(mp + m + 1)$, and $[\mathbf{\Psi}]_{ij} = 0\ (i, j = 1 \ldots m)$. Adopting all of the measured time series, Eqs. 11-14 produces following distribution.

$$\mathrm{p}(\mathbf{W}, \mathbf{\Sigma} | \mathbf{Y_1}, \mathbf{\Phi_1}, \ldots, \mathbf{Y}_l, \mathbf{\Phi}_l) = \mathcal{MN}\left(\mathbf{W} | \mathbf{M}'', \mathbf{\Sigma}, \mathbf{L}''^{-1}\right) \mathcal{IW}(\mathbf{\Sigma} | \mathbf{\Psi}'', \nu'') \tag{15}$$

where

$$\mathbf{L}'' = \Sigma_{i=1}^{l} \mathbf{\Phi}_i \mathbf{\Phi}_i^{\mathrm{T}} \tag{16}$$

$$\mathbf{M}'' = (\Sigma_{i=1}^{l} \mathbf{Y}_i \mathbf{\Phi}_i^{\mathrm{T}}) \mathbf{L}''^{-1} \tag{17}$$

$$\nu'' = -(mp + m + 1) + \Sigma_{i=1}^{l} (n_i - p) \tag{18}$$

$$\mathbf{\Psi}'' = \Sigma_{i=1}^{l} \mathbf{Y}_i \mathbf{Y}_i^{\mathrm{T}} - \mathbf{M}''\mathbf{L}''\mathbf{M}''^{\mathrm{T}} \tag{19}$$

2.2 Model selection

To find optimal model order p, this study adopts following Bayesian information criterion (BIC) [17, 18].

$$BIC = -2 \ln \mathrm{p}\left(\mathcal{D} \middle| \widehat{\boldsymbol{\theta}}\right) + M \ln N \tag{20}$$

where the PDF $\mathrm{p}(\mathcal{D}|\boldsymbol{\theta})$ represents likelihood function of parameters $\boldsymbol{\theta}$ with observed data $\mathcal{D}$, and $\widehat{\boldsymbol{\theta}}$ represents its most likelihood estimators. M denotes the number of parameter, and N denotes total data length.

In this study, the total data length of the observed data $\mathbf{Y}_1, \ldots, \mathbf{Y}_l$ is given as $N = \Sigma_{i=1}^{l} (n_i - p)$. It is known that the most log-likelihood of Gaussian distribution is given as

$$\ln \mathrm{p}\left(\mathbf{Y}_1, \ldots, \mathbf{Y}_l \middle| \widehat{\boldsymbol{\theta}}\right) = -\frac{N}{2} \left(m \ln 2\pi + \ln \left|\widehat{\mathbf{\Sigma}}\right| + m\right) \tag{21}$$

where $\widehat{\mathbf{\Sigma}}$ represents the most likelihood estimator of $\mathbf{\Sigma}$. According to Eqs. 16, 17, and 19, the most likelihood estimator is given as

$$\widehat{\mathbf{\Sigma}} = \mathbf{\Psi}''/N. \tag{22}$$

Therefore the BIC given in Eq. 20 is calculated with the following equation.

$$BIC = N(m \ln 2\pi + \ln|\mathbf{\Psi}''/N| + m) + \left(m^2 p + \frac{m(m+1)}{2}\right) \ln N \tag{23}$$

It is supposed that the less BIC provides the better statistical model.

2.3 Uncertainty quantification

The uncertainty of the each identified mode is derived from Eq. 15 as follows. First, this study assumes $\mathbf{\Sigma}$ is fixed to the most likelihood estimator for simplicity, instead of the inverse-Wishart distribution. Therefore, the posterior distribution of $\mathbf{W}$ is given as follows instead of Eq. 15.

$$\mathrm{p}(\mathbf{W} | \mathbf{Y_1}, \mathbf{\Phi_1}, \ldots, \mathbf{Y}_l, \mathbf{\Phi}_l) = \mathcal{MN}\left(\mathbf{W} | \mathbf{M}'', \widehat{\mathbf{\Sigma}}, \mathbf{L}''^{-1}\right) \tag{24}$$

It is known that the VAR model in Eq. 1 is reproduced to the following state space model [19].

$$\boldsymbol{\phi}_{k+1} = \mathbf{A}\boldsymbol{\phi}_k + \begin{bmatrix} \mathbf{I}_m \\ \mathbf{O} \end{bmatrix} \boldsymbol{e}_k \tag{25}$$

$$\boldsymbol{y}_k = [\mathbf{I}_m \quad \mathbf{O}]\boldsymbol{\phi}_{k+1} \tag{26}$$

where $\mathbf{I}_m$ denotes the eigenmatrix of size m, $\mathbf{O}$ denotes the zero matrix with the appropriate size, and $\mathbf{A} \in \mathbb{R}^{mp \times mp}$ represents the following matrix.

$$\mathbf{A} = \left[\begin{array}{c|c} \mathbf{W} & \\ \hline \mathbf{I}_{m(p-1)} \quad \mathbf{O} & \end{array}\right] \tag{27}$$

The eigenvalue decomposition of the matrix $\mathbf{A}$ is given as follows.

$$\mathbf{A} = \mathbf{P}\boldsymbol{\Lambda}\mathbf{P}^{-1} \tag{28}$$

where $\boldsymbol{\Lambda}$ denotes the diagonal matrix composed of the eigenvalues of matrix $\mathbf{A}$, and $\mathbf{P}$ denotes the matrix composed of the corresponding eigenvectors. It is well known that the eigenvalues represent the poles of the transfer function of the dynamic model given in Eqs. 25-26. That is, letting ω_i and ζ_i respectively represent the i-th natural angular frequency and damping ratio, and λ_i denote the i-th eigenvalue of the matrix $\mathbf{A}$, the following relation is given.

$$\lambda_i = \exp\left[\left(-\zeta_i\omega_i + \jmath\sqrt{1-\zeta_i^2}\omega_i\right)\Delta t\right] \tag{29}$$

where Δt represents the sampling interval of the time series and $\jmath$ represents the imaginary unit.

Because the matrix $\mathbf{W}$ in Eq. 24 is composed of random variables, the random distribution of $\mathbf{W}$ is transformed into the the random distribution of λ_i according to Eq. 28. Accordingly, uncertainty involved in λ_i is quantified through there variables. Because λ_i will be an imaginary number, this study quantifies the uncertainty with the following equation.

$$\mathrm{var}(\lambda_i) = \mathrm{E}[(|\lambda_i - \mathrm{E}[\lambda_i]|^2)] \tag{30}$$

where $\mathrm{E}[\cdot]$ denotes the expectation of a random variable and $|\cdot|$ represents absolute value of an imaginary number. This study refers $\mathrm{var}(\lambda_i)$ in Eq. 30 as "variance of pole."

For efficacy, this study produces approximated closed form solution of $\mathrm{var}(\lambda_i)$ as follows. First, according to Eqs. 24 and 27, the expectation of matrix $\mathbf{A}$ is given as

$$\overline{\mathbf{A}} = \left[\begin{array}{c|c} \mathbf{M}'' & \\ \hline \mathbf{I}_{m(p-1)} \quad \mathbf{O} & \end{array}\right]. \tag{31}$$

Let the eigenvalue decomposition of $\overline{\mathbf{A}}$ represent with the following equation.

$$\overline{\mathbf{A}} = \overline{\mathbf{P}}\overline{\boldsymbol{\Lambda}}\overline{\mathbf{P}}^{-1} \tag{32}$$

And let the deviation of matrices $\mathbf{A}$, $\mathbf{P}$ and $\boldsymbol{\Lambda}$ respectively be represented as $\widetilde{\mathbf{A}} = \mathbf{A} - \overline{\mathbf{A}}$, $\widetilde{\mathbf{P}} = \mathbf{P} - \overline{\mathbf{P}}$ and $\widetilde{\boldsymbol{\Lambda}} = \boldsymbol{\Lambda} - \overline{\boldsymbol{\Lambda}}$. According to Eq. 28, following equation is produced.

$$(\overline{\mathbf{A}} + \widetilde{\mathbf{A}})(\overline{\mathbf{P}} + \widetilde{\mathbf{P}}) = (\overline{\mathbf{P}} + \widetilde{\mathbf{P}})(\overline{\boldsymbol{\Lambda}} + \widetilde{\boldsymbol{\Lambda}}) \tag{33}$$

Ignoring the squared deviations, Eqs. 32-33 approximately produce

$$\widetilde{\boldsymbol{\Lambda}} = \overline{\mathbf{P}}^{-1}\widetilde{\mathbf{A}}\overline{\mathbf{P}} + \overline{\boldsymbol{\Lambda}}\overline{\mathbf{P}}^{-1}\widetilde{\mathbf{P}} - \overline{\mathbf{P}}^{-1}\widetilde{\mathbf{P}}\overline{\boldsymbol{\Lambda}}. \tag{34}$$

Since $\overline{\boldsymbol{\Lambda}}$ is a diagonal matrix,

$$\mathrm{diag}(\overline{\boldsymbol{\Lambda}}\overline{\mathbf{P}}^{-1}\widetilde{\mathbf{P}}) = \mathrm{diag}(\overline{\mathbf{P}}^{-1}\widetilde{\mathbf{P}}\overline{\boldsymbol{\Lambda}}) \tag{35}$$

where $\mathrm{diag}(\cdot)$ represents a vector composed from the diagonal elements of a matrix. According to Eqs. 34-35, the variance of eigenvalues are approximated as follows.

$$\mathrm{diag}(\widetilde{\boldsymbol{\Lambda}}) = \mathrm{diag}(\overline{\mathbf{P}}^{-1}\widetilde{\mathbf{A}}\overline{\mathbf{P}}) \tag{36}$$

Eqs. 27 and 31 ensures that matrix $\widetilde{\mathbf{A}}$ is given as

$$\widetilde{\mathbf{A}} = \begin{bmatrix} \mathbf{W} - \mathbf{M}'' \\ \mathbf{O} \end{bmatrix}. \tag{37}$$

Letting $\widetilde{\mathbf{W}} = \mathbf{W} - \mathbf{M}''$ and $\mathbf{V} = \left(\{\overline{\mathbf{P}}^{-1}\}_{[:,1:m]}\right)^{\mathrm{T}}$, where $\{\cdot\}_{[:,1:m]}$ denotes a submatrix consisting of the first m columns, Eq. 36 is transformed as

$$\mathrm{diag}(\widetilde{\mathbf{\Lambda}}) = \mathrm{diag}(\mathbf{V}^{\mathrm{T}}\widetilde{\mathbf{W}}\overline{\mathbf{P}}). \tag{38}$$

Let the $\tilde{\lambda}_i$ represent the i-th diagonal member of $\widetilde{\mathbf{\Lambda}}$. Eq. 38 produces $\tilde{\lambda}_i = \boldsymbol{v_i}^{\mathrm{T}}\widetilde{\mathrm{W}}\boldsymbol{p_i}$, where $\boldsymbol{v_i}$ and $\boldsymbol{p_i}$ are respectively represent the i-th column of the matrices $\mathbf{V}$ and $\overline{\mathbf{P}}$. Accordingly, the following equation is given.

$$\tilde{\lambda}_i = \boldsymbol{v_i}^{\mathrm{T}}\widetilde{\mathrm{W}}\boldsymbol{p_i} = (\boldsymbol{p_i} \otimes \boldsymbol{v_i})^{\mathrm{T}} vec(\widetilde{\mathbf{W}}) \tag{39}$$

where $\otimes$ denotes the Kronecker product and $vec(\cdot)$ denotes a vectorization of a matrix.

According to the definition, the matrix $\widetilde{\mathbf{W}}$ follows the following matrix normal distribution.

$$\mathrm{p}\left(\widetilde{\mathbf{W}}|\mathbf{Y_1}, \mathbf{\Phi_1}, \dots, \mathbf{Y}_l, \mathbf{\Phi}_l\right) = \mathcal{MN}\left(\mathbf{W}|\mathbf{O}, \widehat{\mathbf{\Sigma}}, \mathbf{L}''^{-1}\right) \tag{40}$$

It is known that the matrix normal distribution is equivalent to the following multivariable Gaussian distribution.

$$\mathrm{p}\left(vec(\widetilde{\mathbf{W}})\middle|\mathbf{Y_1}, \mathbf{\Phi_1}, \dots, \mathbf{Y}_l, \mathbf{\Phi}_l\right) = \mathcal{N}\left(vec(\widetilde{\mathbf{W}})|\mathbf{O}, \mathbf{L}''^{-1} \otimes \widehat{\mathbf{\Sigma}}\right) \tag{41}$$

According to Eqs. 39 and 41, $\mathrm{var}(\lambda_i)$ defined in Eq. 30 is calculated as

$$\begin{aligned} \mathrm{var}(\lambda_i) &= \mathrm{E}\left[|\tilde{\lambda}_i|^2\right] = \left|(\boldsymbol{p_i} \otimes \boldsymbol{v_i})^{\mathrm{T}}\ \mathrm{E}\left[vec(\widetilde{\mathrm{W}})vec(\widetilde{\mathrm{W}})^{T}\right](\boldsymbol{p_i} \otimes \boldsymbol{v_i})^{*}\right| \\ &= (\boldsymbol{p_i} \otimes \boldsymbol{v_i})^{\mathrm{T}}\left(\mathbf{L}''^{-1} \otimes \widehat{\mathbf{\Sigma}}\right)(\boldsymbol{p_i} \otimes \boldsymbol{v_i})^{*} = \boldsymbol{p_i}^{\mathrm{T}}\mathbf{L}''^{-1}\boldsymbol{p_i^*}\boldsymbol{v_i}^{\mathrm{T}}\widehat{\mathbf{\Sigma}}\boldsymbol{v_i^*} \end{aligned} \tag{42}$$

where $\{\cdot\}^*$ represents the conjugate pair. The uncertainty of the each mode are quantified using Eq. 42. This study presumes that the physically meaningful mode produces $\mathrm{var}(\lambda_i)$ with lower value than the others. Thus, physically meaningful modes will be effectively extracted by sorting the calculated $\mathrm{var}(\lambda_i)$ values.

3 CASE STUDY

3.1 Target bridge and preliminary investigation

This study provides a case study for a simply supported truss bridge to assess the feasibility of the proposed method through comparison to an earlier investigation [9]. Field experiments were conducted to the bridge with a moving vehicle. The bridge is a single-lane through-type

Figure 1. Photo of the target bridge.

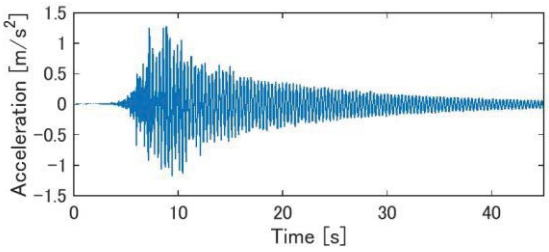

Figure 3. An example of measured acceleration

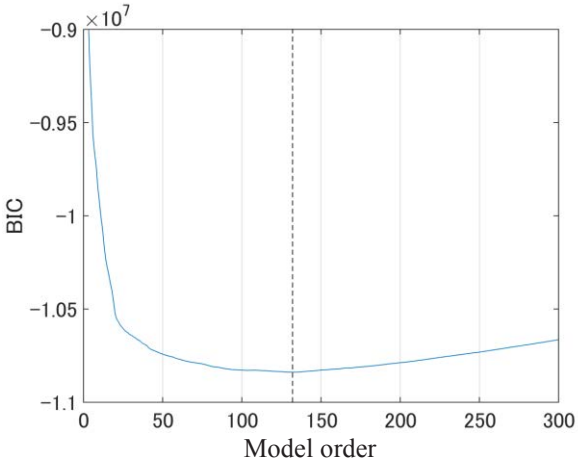

Figure 4. BIC with respect to the model order.

steel Warren truss bridge with 59.2 m span length, 8 m maximum height, and 3.6 m width as presented in Fig. 1. The vehicle used for the experiment is a two-axle recreational vehicle with total weight of about 21 kN. During the experiment, all traffic except the loading vehicle was prohibited. Eight uniaxial accelerometers were installed on the deck of the bridge to measure vertical vibrations as presented in Fig. 2. The sampling rate of each sensor was set as 200 Hz.

Each of the sampled time series is de-trended: the linear trends in the time series are removed in advance. The vehicle was passed over at three speeds: 30 km/h, 40 km/h, and 50 km/h. Table 1 presents the number of vehicle loadings.

Fig. 3 shows a measured time series at A3 accelerometer with vehicle passing by 40 km/h for instance. This case study adopts raw time series data with no pre-processing except the de-trending. BIC in Eq. 23 is calculated using the measured 26 time series as shown in Fig. 4. Fig. 4 indicates that the optimal model order, which produces the minimal BIC, is p=135. This study adopts the optimized model order.

3.2 Identified modes

As mentioned above, the proposed method extract physically meaningful modes by sorting the calculated variance of poles. The proposed Bayesian inference applied to the 26 time series. Fig. 5 shows the sorted variance of poles. In the diagram, the 50 smallest results are displayed. It is observed that 13 poles have smaller variance, i.e. less uncertainty, than the others. This study extracts the 13 poles to identify the physically meaningful modes. In Fig. 5, the vertical dashed line shows the boundary between the extracted and the rest poles. Table 2 shows the 13 smallest variances and corresponding modal frequencies.

Fig. 6 shows comparison between the extracted modal frequencies and power spectral density (PSD) curves obtained from the 8 accelerometers. Fig. 6a provides the PSD curves below

7.40×10 - 8	20.13

Tables 2 Variance of poles and extracted modal frequencies.

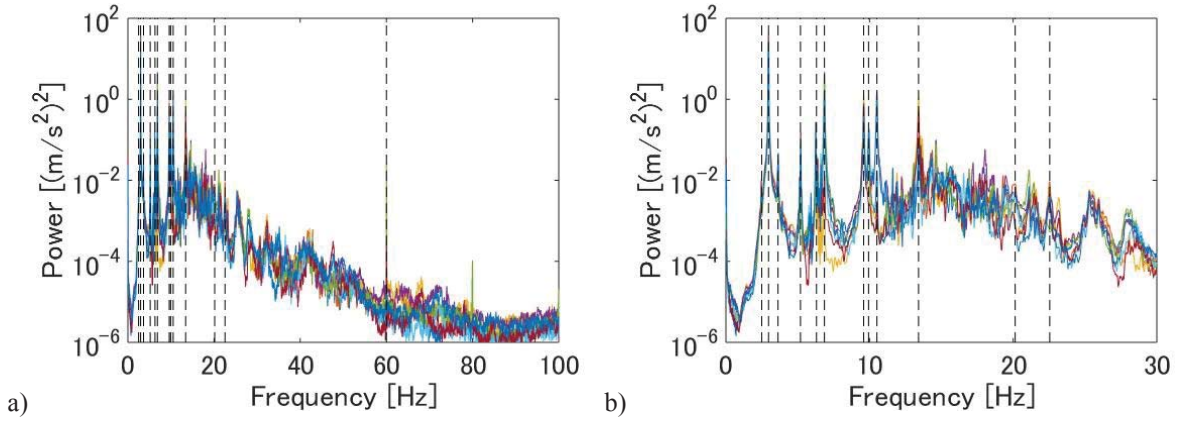

Figure 6. Comparison between the extracted modes and PSD: a) below the Nyquist frequency; b) below 30 Hz.

the Nyquist frequency, i.e. 100 Hz, and Fig. 6b provides the enlarged diagram below 30Hz in Fig. 6a. The PSD curves are estimated from the measured 26 time series as the modified periodograms adopting the Hamming window [20]. The extracted frequencies are depicted as the vertical dashed lines in Figs. 6a and 6b. One of the extracted mode correspond to the peak at 60Hz in Fig. 6a. Apparently, that is signal coming from the power supply in western region of Japan, and thus the mode at 60Hz is not a structural mode. The other 12 modes out of the 13 are below 30 Hz as shown in Fig. 6a. The extracted modes below 30 Hz seem well correspond to the peaks in the PSD curves. This observation describes that the proposed method is comparative to the conventional peak picking for dominant modes. The modes at 3.0 Hz and 3.6 Hz were not identified in the conventional time-domain modal analysis [9]. Fig. 6b also shows that the modes identified at 20.1 Hz and 22.5 Hz are not observed as peaks in PSD diagram. The validity of this result is discussed later considering the mode shapes.

It is well-known that the mode shapes are estimated as a real part of vector $\boldsymbol{v_i}$ [19]. The mode shapes corresponding to the extracted poles are also determined. Fig. 7 shows the extracted mode shapes. In the diagrams, the horizontal axis represents relative location of the sensors along the longitudinal direction on the bridge, and the vertical axis represents relative modal deformation. The markers depicted with blue circles represent the modal deformation from A1 to A5, the markers with orange squares represent the deformation from A6 to A8.

The mode shapes in Fig. 7b), f), g), i), and j) seem to correspond to bending modes because the modal deformations on A1-A5 edge and A6-A8 edge are deforms simultaneously. These results correspond to the previous study by Chang and Kim [9]. Contrarily, it is reasonable to regard the mode shapes in Fig. 7d), h), k), and l) as torsional modes because the both edge deforms alternately. The mode in Fig. 7d) is also observed in the previous study. The other three torsional modes are newly identified in this study. Especially, the modes in Fig. 7k) and l) are not observed in the PSD curves as mentioned above. Also the mode in Fig. 7h) was not observed in the previous study either. That is possibly because the mode is close to the others and Stabilization diagram [19] did not work well in the time-domain analysis. These results suggest that the proposed method has advantage to extract higher modes which is hard to find from the PSD curves.

The mode shapes in Fig. 7a), c), and e) seems like torsional modes also. However, the edges of the bridge do not deform alternately to each other. Further investigation is desired to validate these modes. As mentioned above, the mode shape in Fig. 7m) is derived from the power supply,

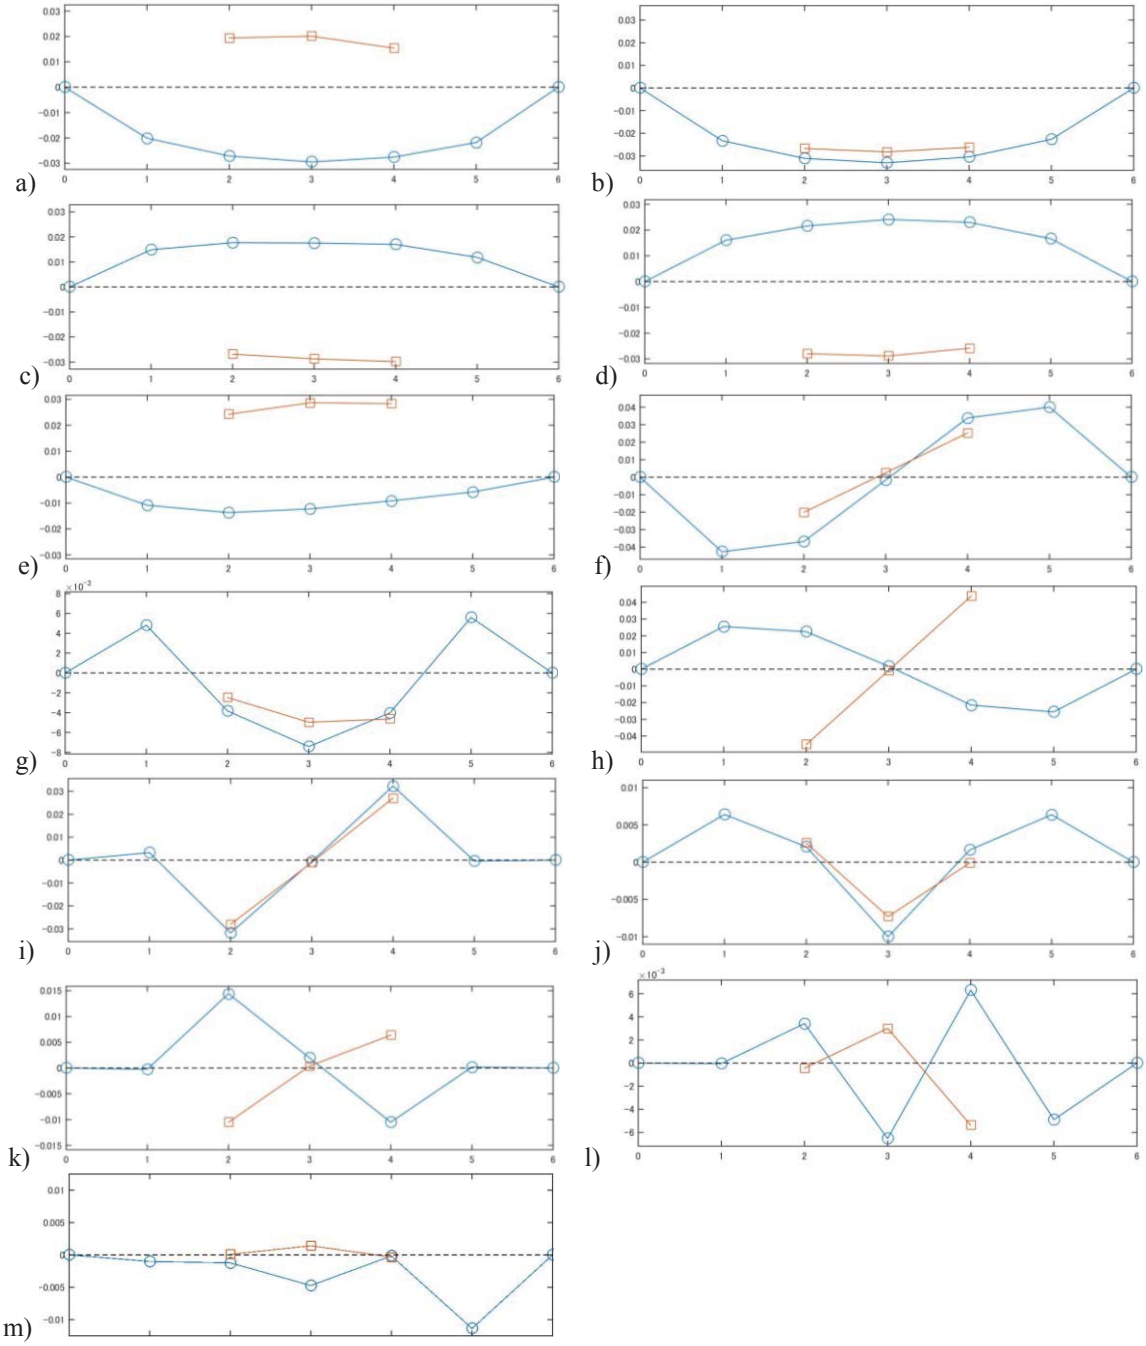

Figure 7. Extracted mode shapes:
a) 2.50Hz； b) 2.97Hz； c) 3.63Hz； d) 5.19Hz； e) 6.31Hz； f) 6.86Hz；
g) 9.59Hz； h) 9.94Hz； i) 10.51Hz； j) 13.41Hz； k) 20.13Hz ; l) 22.54Hz ; m) 60.02Hz.

not from the structural deformation. That is why the mode shapes appear not to correspond to bending or torsional modes.

4 CONCLUSIONS

Aiming to develop effective modal analysis, this study proposed modal identification method applying Bayesian inference. Uncertainty involved modal identification was quantified to extract physically meaningful modes. A vector auto regressive model is applied to produce

posterior distribution of parameters in a dynamical model. Bayesian information criterion is applied to optimize the model order. The uncertainty of the identified modes is quantified evaluating variation of poles of the transfer function of the model.

Time series of acceleration which are actually measured on a simply supported truss bridge are applied for the proposed method. 13 poles produced the variation with lower values than the others. This study investigated the modal properties corresponding to the 13 poles. Power spectrum density curves were compared to the identified modal frequencies. Also, mode shapes were examined to validate the proposed method. One of the identified mode appears to be derived from power supply, and not from structural deformation. Except the one mode, 12 modes seem to correspond to the bending and torsional modes: 5 modes out from the 12 modes correspond to bending modes. 4 modes out from the 12 modes correspond to torsional modes. 5 bending modes and 1 torsional mode were also observed in a previous study [9]. 3 torsional modes were newly observed in this study. This result indicates advantage of the proposed method. The rest 3 modes seem like torsional modes. Further investigation is desired for validation of these 3 modes.

FUNDING

This study was partly sponsored by a Japanese Society for Promotion of Science (JSPS) Grant-in-Aid for Scientific Research (B) under Project No. 16H04398 and for Early-Career Scientists under Project No. 19K15072. That financial support is gratefully acknowledged.

Keywords: structural health monitoring, Bayesian methods, environmental effects

Abstract. *Inspection and maintenance contribute significantly to the lifetime cost of bridges. There is significant potential in using information obtained through structural health monitoring to update predictive models of the condition and performance of such structures, and thus enable an improved decision-making regarding inspection and maintenance activities. Within the AISTEC project funded by the German Federal Ministry of Education and Research, we develop vibration-based structural health monitoring systems aimed at continuously providing information on the structural condition of bridges. Environmental variations such as changing ambient temperatures can significantly influence the dynamic characteristics of bridges and thus mask the effect of structural changes and damages. It remains a challenge to account for such influences in structural health monitoring. To study the effect of ambient temperatures on the dynamic characteristics of beam structures, we monitor the vibration response of a reinforced concrete beam in the uncracked and cracked state at varying temperatures in a climate chamber. We postulate a set of competing parameterized probabilistic structural models, which explicitly account for the effect of varying ambient temperatures on the mechanical properties of the system. We then combine the information provided by the structural models with the information contained in the recorded vibration data to learn the parameters of the temperature-dependent structural models and infer the plausible state of the beam using Bayesian system identification and model class selection.*

1 INTRODUCTION

As transport infrastructure networks are aging, the efforts and thus the costs for inspection and maintenance of the engineering structures within the networks such as bridges are steadily growing. Structural health monitoring (SHM) has the potential of improving predictions of the condition and performance of such structural systems and can thus enhance decisions on inspection and maintenance activities as well as possible lifetime extensions.

The variability in environmental factors such as ambient temperatures can significantly influence the results of structural health monitoring [1] and consequently increase the uncertainty in the prediction of the structural condition and performance. Two strategies have emerged to address this issue [2]: methods that include a model of the structure's mechanics – here termed *model-based* methods – and methods that don't – termed *model-free* methods. The latter eliminate the environmental effects from the data and/or analysis results [1-4]. In the simplest case, a linear regression on the air temperature can be performed. In any case, predictions of a structure's condition and performance can only be made using model-based methods.

In model-based approaches, mechanical models of the structure – typically finite element (FE) models – are updated with knowledge gained from analyzing static or dynamic data [5]. Two approaches are possible to deal with the issue of environmental effects [2]: (a) eliminate these effects from the data prior to updating the model or (b) explicitly include these effects in the model. The former bears the risk of implicitly incorporating the temperature-dependent loadbearing effect of nominally non-loadbearing members such as ballast or asphalt layers. In the latter approach, the thermal actions on the structure and its effects are modelled and as a result, further knowledge on the structure can be gained.

Previous studies show that the environmental effects on structures can be of complex nature. These effects include – with no claims of comprehensiveness – effects of temperature gradients [6], differences between freezing and thawing periods [7], and non-linear behavior around the freezing point [8].

The updating of models can be accomplished either deterministically or probabilistically. The former employs optimization algorithms, which minimize the difference between model predictions and the measured data. The solution comprises of the optimal set of (deterministic) model parameters. Probabilistic model updating can be done within the Bayesian framework and is referred to as Bayesian model updating or Bayesian system identification [9-11]. This approach provides several advantages: No single *true* solution is identified. Instead, a range of plausible solutions and their relative plausibility in the form of the updated joint probability distribution of the parameters defining the problem. In this way, ill-posed problems with non-unique solution can be addressed. The approach explicitly quantifies the uncertainties in the model parameters, in the models themselves and in the data. Different sources and types of data can be included consistently in the analysis. Any prior knowledge on the structural system including expert judgement is quantified – even in the case where none is available. It is possible to perform the analysis with limited or incomplete data.

Bayesian system identification has been applied to several structural systems. Ntotsios et al. [12] used vibration data from a bridge to determine the plausible states of the structure via Bayesian model class selection [13, 14]. Zonta and Pozzi [15] compared two plausible states of a leaning bell tower. Pioneering work on including temperature-dependent material properties has been conducted by Bemanesh and Moaveni [16], who identified the temperature-dependent elastic modulus of a concrete deck of a footbridge. Recent methodological advances include hierarchical Bayesian frameworks [17-19] and sparse Bayesian learning [20].

In this work, we subject a reinforced concrete (RC) beam to different temperatures inside a climate chamber in a cracked and an uncracked state. We apply Bayesian system identification

and model class selection to determine the plausible states of the system based on modal properties extracted from vibration data. The updated model includes a sub-model of the temperature-dependent material properties and a sub-model of the system mechanics. Finally, a structural health monitoring scenario is created to demonstrate the potential of the proposed method.

2 BAYESIAN FRAMEWORK

2.1 System identification

The aim of system identification is to find a parametric model that adequately describes the physics of a system. Different models may be defined, and the parameters of each model are identified based on data obtained from the real system. The plausibility of the different models is subsequently compared. In Bayesian system identification, the parameters $\boldsymbol{\theta}$ of a model are modelled probabilistically and instead of *identifying* deterministic values of the model parameters, their probability distributions are *learned* from the measured data.

Let $\boldsymbol{q}(\boldsymbol{y}, \boldsymbol{\theta})$ be the prediction that a deterministic model yields for observable quantities $\boldsymbol{z}$ for given parameters $\boldsymbol{\theta}$ and input $\boldsymbol{y}$ of a system. The system input $\boldsymbol{y}$ such as the observed temperature of the structural system is here defined deterministically, but the framework can be extended to also capture the uncertainties in the system input.

The model prediction $\boldsymbol{q}$ and the observable quantities $\boldsymbol{z}$ may be related by means of a multiplicative prediction error $\exp(\boldsymbol{e})$, such that

$$\boldsymbol{z} = \boldsymbol{q}(\boldsymbol{y}, \boldsymbol{\theta}) \odot \exp(\boldsymbol{e}). \tag{1}$$

where $\odot$ denotes the Hadamard (element-by-element) product and the random vector $\boldsymbol{e}$ follows a multivariate Gaussian distribution with zero mean and covariance matrix $\boldsymbol{\Sigma_{ee}}$. The prediction error $\exp(\boldsymbol{e})$ jointly models the uncertainty in the data and the parametric model.

The process of linking the output of a parametric system model with the observable response of the system by means of a prediction error is known as stochastic embedding [9].

A natural logarithm transformation of the quantities in Equation (1) gives:

$$\ln \boldsymbol{z} = \ln[\boldsymbol{q}(\boldsymbol{y}, \boldsymbol{\theta})] + \boldsymbol{e}. \tag{2}$$

The ith dataset $\mathcal{D}_i$ consists of the observed input $\hat{\boldsymbol{y}}_i$ and output $\hat{\boldsymbol{z}}_i$, i.e. $\mathcal{D}_i = (\hat{\boldsymbol{y}}_i, \hat{\boldsymbol{z}}_i)$. In a Bayesian setting, the observed data $\mathcal{D}_i$ is linked to the model parameters $\boldsymbol{\theta}$ by the likelihood function $L(\boldsymbol{\theta}|\mathcal{D}_i)$, which is proportional to the conditional probability density of the data $\mathcal{D}_i$ given that the model parameters take a value $\boldsymbol{\theta}$, i.e.:

$$L(\boldsymbol{\theta}|\mathcal{D}_i) \propto p(\mathcal{D}_i|\boldsymbol{\theta}). \tag{3}$$

Based on the error model introduced in Equations (1) and (2), the likelihood function of $\mathcal{D}_i$ can be formulated as:

$$L(\boldsymbol{\theta}|\mathcal{D}_i) = \frac{1}{\sqrt{(2\pi)^n \det(\boldsymbol{\Sigma_{ee}})}} \exp\left[-\frac{1}{2}[\ln \hat{\boldsymbol{z}}_i - \ln[\boldsymbol{q}(\hat{\boldsymbol{y}}_i, \boldsymbol{\theta})]]^T \boldsymbol{\Sigma}_{\boldsymbol{ee}}^{-1} [\ln \hat{\boldsymbol{z}}_\mathrm{i} - \ln[\boldsymbol{q}(\hat{\boldsymbol{y}}_i, \boldsymbol{\theta})]]\right]. \tag{4}$$

where n corresponds to the number of measurements, i.e. n is equal to the length of $\hat{\boldsymbol{z}}_i$.

When multiple datasets are available and the different datasets are conditionally independent for given model parameters $\boldsymbol{\theta}$, the likelihood function $L(\boldsymbol{\theta}|\mathcal{D})$ describing all available datasets is the product of the likelihood functions of the individual datasets $L(\boldsymbol{\theta}|\mathcal{D}_i)$:

$$L(\boldsymbol{\theta}|\mathcal{D}) = \prod_i L(\boldsymbol{\theta}|\mathcal{D}_i). \tag{5}$$

The plausibility of different realizations of the parameters $\boldsymbol{\theta}$ prior to obtaining data is expressed in terms of the prior distribution $p(\boldsymbol{\theta})$. Following Bayes' rule, the posterior distributions of the parameters $\boldsymbol{\theta}$ conditional on the observed data $\mathcal{D}$ is computed as:

$$p(\boldsymbol{\theta}|\mathcal{D}) = c_E^{-1}\, L(\boldsymbol{\theta}|\mathcal{D})\, p(\boldsymbol{\theta}), \tag{6}$$

whereby the constant c_E is referred to as the model evidence, which is calculated by integrating the likelihood function and prior distribution over the outcome space of the parameters:

$$c_E = \int_{\boldsymbol{\theta}} L(\boldsymbol{\theta}|D)\, p(\boldsymbol{\theta})\, \mathrm{d}\boldsymbol{\theta}. \tag{7}$$

Samples from the posterior distribution $p(\boldsymbol{\theta}|\mathcal{D})$ and an estimate of the model evidence c_E are here obtained using BUS (Bayesian updating with structural reliability methods) with subset simulation introduced by Straub and Papaioannou [21] and improved by Betz et al. [22]. The simulations are performed with conditional probabilities of each intermediate event of 0.1 and 3000 Markov chain Monte Carlo samples per subset level.

2.2 Model class selection

Each parametric system model along with the formulation of the likelihood function and the prior distribution of the parameters $\boldsymbol{\theta}$ form a model class $\mathcal{M}_i$. The evidence of each model class in a set of model classes $\{\mathcal{M}_i\}_{i=1}^m$ is proportional to the probability density of the data $\mathcal{D}$ conditional on the model class $\mathcal{M}_i$:

$$c_{E|\mathcal{M}_i} \propto p(\mathcal{D}|\mathcal{M}_i). \tag{8}$$

For each model class $\mathcal{M}_i$, a prior probability $\Pr(\mathcal{M}_i)$ can be assigned. This probability describes the relative plausibility of each model class within the set prior to obtaining any data from the real system. Applying Bayes' rule anew, the probabilities of the model classes can be updated based on the available data $\mathcal{D}$:

$$\Pr(\mathcal{M}_i|\mathcal{D}) = \frac{p(\mathcal{D}|\mathcal{M}_i)\, \Pr(\mathcal{M}_i)}{\sum_{i=1}^m p(\mathcal{D}|\mathcal{M}_i)\, \Pr(\mathcal{M}_i)}. \tag{9}$$

3 EXPERIMENT

To generate data from a real structural system subject to varying environmental conditions, the vibration response of a simply supported reinforced concrete (RC) beam was measured inside a climate chamber at varying ambient temperatures as shown in Figure 1.

Figure 1: RC beam inside the climate chamber with suspended shaker.

3.1 Setup

The dimensions of the beam are 2.96 m × 0.2 m × 0.4 m (length/height/width). Based on experiments with identical beams and samples from the same concrete batch, the elastic modulus was determined as $E = 33$ GPa [23]. The beam is reinforced with two Ø16mm bars, with an effective distance of 48mm from the bottom and 60mm from the sides of the beam. No shear stirrups were used.

The intended analogy of the experiment is structural health monitoring by means of established operational modal analysis (OMA) methods. Due to its low length to height ratio and hence high eigenfrequencies, the beam is not easily excited by the ambient excitations present in the laboratory. To induce ambient excitation, an electromagnetic shaker was suspended from the beam and insulated from the climatic conditions in the chamber. This shaker generated white noise excitations in the frequency range from 30 Hz to 2000 Hz.

Six geophones – with a layout as illustrated in Figure 2 – were placed on top of the beam to measure vibration velocities. The data were acquired with a sampling rate of 5000 Hz and post-processed with a low-pass Butterworth filter with an order of 6 and a cutoff frequency of 1500 Hz.

The experiment was conducted in three stages: First, the vibration response of the *uncracked* beam was measured at five different temperatures $\{-25\ °C, -5\ °C, 5\ °C, 25\ °C, 40\ °C\}$. Second, the beam was subject to a center point load of $F = 28$ kN to introduce cracks. Third, the vibration response of the *cracked* beam was measured at the same temperatures as in the first test series. Two temperature sensors were placed inside the beam. To ensure that a stationary

temperature field has been reached within the beam, the tests were only conducted when the readings of the temperature sensors inside the beam were within a ±1 K range of the target temperature.

The data acquired for the uncracked beam is referred to as dataset $\mathcal{D}_1$, and the corresponding dataset obtained from the cracked beam is referred to as $\mathcal{D}_2$.

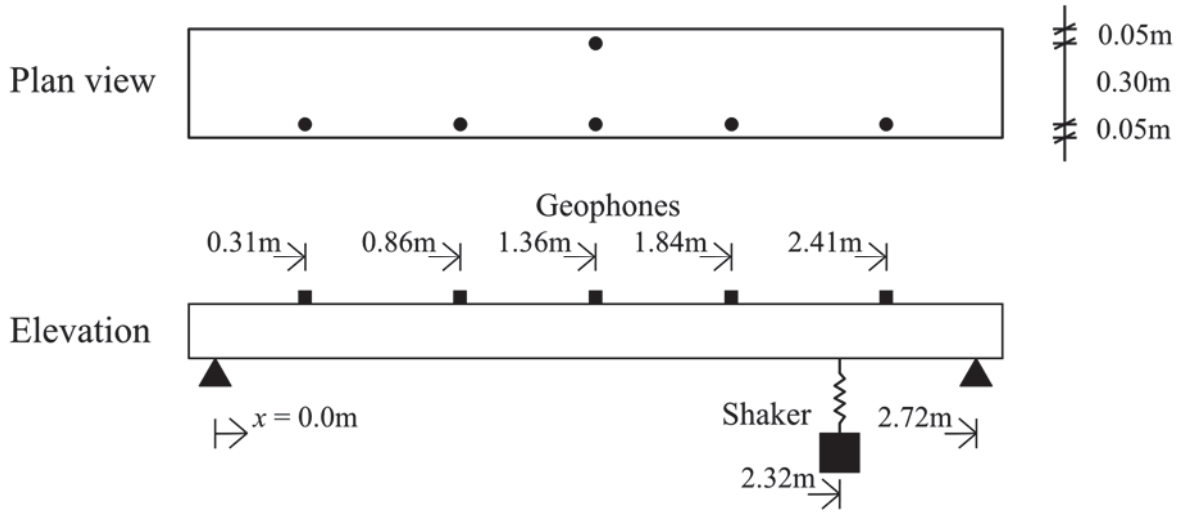

Figure 2: Setup of the experiment with sensor locations and shaker.

3.2 Modal identification

For each run of the experiment, 10 minutes of data were recorded while the beam was excited by the shaker and analyzed with the established frequency domain decomposition (FDD) technique [24]. In Figure 3, the spectrum of the first singular value of the decomposition is shown within a range of 0 Hz to 200 Hz for the test conducted in the uncracked state at -5 °C. The third bending mode, which has been estimated to occur at ~390 Hz, could not be identified from the data. The spectrum of the first singular value is smoothed by applying a gaussian window function with a width of 1001 samples and a standard deviation of 250 samples. At 10 minutes (600 seconds) of data, the frequency resolution is 0.00167 Hz. Thus the window function has a width of 1.668 Hz and a standard deviation of 0.416 Hz in the spectrum.

The distinct double peak at ~40 Hz and ~45 Hz with identical mode shapes corresponds well to a system with a tuned mass damper (TMD). Such a system can be approximated as a two degree of freedom (DOF) system, whereby the two masses correspond to the modal masses of the beam and shaker. In the two closely spaced modes of the double peak, the two masses move in the same and in the opposite direction, respectively. Since only the beam is instrumented, the two identified mode shapes are indistinguishable. The mode shapes of these double-peaked first bending modes and the second bending mode at ~170 Hz of the same test run are displayed in Figure 4.

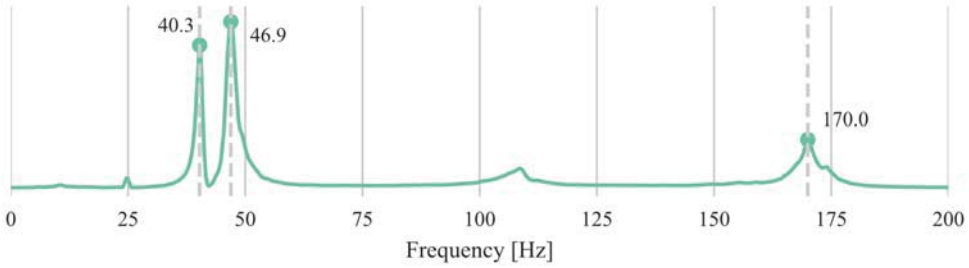

Figure 3: Spectrum (0 ... 200Hz) of the first FDD singular value along with peaks for the uncracked state at -5°C.

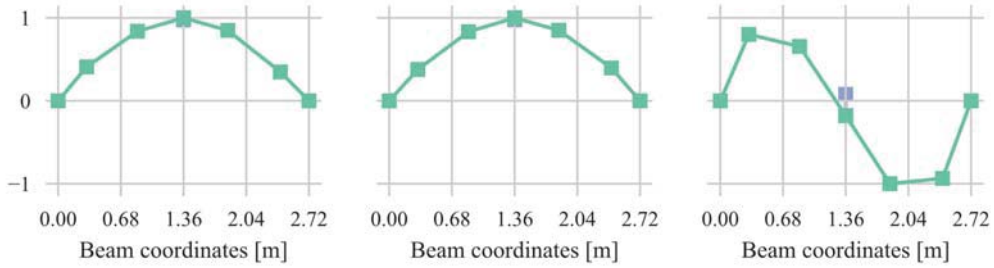

Figure 4: Identified mode shapes (normalized to a maximum amplitude of 1.0) at 40.3 Hz, 46.9 Hz, and 170.0 Hz of the beam in the uncracked state at -5°C.

4 SYSTEM IDENTIFICATION AND MODEL CLASS SELECTION

Structural health monitoring of a structural system can be performed based on Bayesian model class selection in the following steps (see also [15]):

1) A set of m model classes is postulated, where each model class represents a possible state of the structural system. Embedded within the formulation of the likelihood function, these model classes contain deterministic physics-based models of the structural system, and probabilistic models of the model, measurement and statistical uncertainty. In addition, each model class includes the prior knowledge on the model parameters modelled by their prior joint probability distribution.
2) The probability distributions of the model parameters are then updated with observed data from the real system using Bayesian analysis.
3) The relative plausibility of the model classes conditional on the observed data is determined by means of Bayesian model class selection.

4.1 Temperature dependent properties

The proposed model classes consist of a sub-model for the temperature-dependent material properties, a mechanical sub-model, the formulation of the likelihood function based on the prediction error model and prior probability distribution the parameters of the model classes.

In the literature [25-27], the elastic modulus of concrete is modelled as linearly decreasing function of the temperature. Based on these models, a linear model for the temperature-dependent flexural stiffness is applied:

$$EI(T) = EI_0 + \alpha \times T \tag{10}$$

whereby EI_0 is the flexural stiffness at 0°C in [MNm²] and α is the slope in [MNm²/K], while T is the temperature in °C.

4.2 Model class 1: uncracked beam

Model class $\mathcal{M}_1$ represents the temperature-dependent uncracked beam. After the temperature dependent properties of the material – the elastic modulus – have been determined, the observable quantities are calculated with a mechanical sub-model. This mechanical sub-model is implemented via the finite element method (FEM) with the OpenSEES framework [28, 29]. The concrete beam is modelled with linear-elastic Euler-Bernoulli beam elements with a very high spatial resolution of 1cm. The flexural stiffness of these elements is assumed to be constant over the length of the beam with a value determined by Equation (10). To account for the damping effect of the suspended shaker, a single element, which is effectively acting as spring with a linear spring stiffness k, is suspended from the beam at the location of the suspension of the shaker. The mass of the shaker is applied as a point mass m in the lower node of the beam element representing the suspension of the shaker. An illustration of the mechanical model is given in Figure 5.

Geometry and mass of the actual beam can be determined with high certainty and are hence modeled as deterministic values in this model class. The parameters of the temperature-dependency and mechanical sub-model are $\boldsymbol{\theta_{1,sub}} = [EI_0 \quad \alpha \quad k \quad m]^T$.

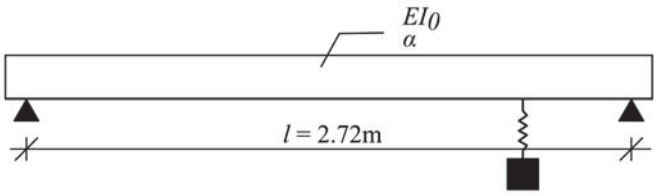

Figure 5: Illustration of the mechanical model embedded in model class $\mathcal{M}_1$

In the current application, only the eigenfrequencies corresponding to the three identified modes are chosen as the observable modal properties of the structural system. Thus, a modal analysis of the finite element model is conducted, and the eigenvalues are expressed in terms of natural frequencies. The model can be parametrized in terms of the known input $y = T$ and written as:

$$\boldsymbol{q}(y, \boldsymbol{\theta_{1,sub}}) = \boldsymbol{q}(T, EI_0, \alpha, k, m) \tag{11}$$

Similar to the model in Equation (1), a multiplicative prediction error is chosen to relate the observable frequencies $\boldsymbol{z} = [f_1 \quad f_2 \quad f_3]^T$ with the frequencies $\boldsymbol{q}$ obtained from the modal analysis of the finite element model:

$$\boldsymbol{z} = \boldsymbol{q}(y, \boldsymbol{\theta_{1,sub}}) \odot \exp(\boldsymbol{e}) \tag{12}$$

The prediction error jointly describes the uncertainty in (a) the vibration data, (b) the method used to extract the modal eigenfrequencies from the vibration data and (c) the eigenvalue analysis based on the FE model. Alternative formulations may adopt an additive error model and/or include information about mode shapes [10, 16-18, 20].

The random vector $\boldsymbol{e}$ is a Gaussian vector with zero mean but covariance matrix $\boldsymbol{\Sigma_{ee}}$. It follows that the prediction errors $\exp(\boldsymbol{e})$ are also correlated. The pairwise correlation coefficient ρ_e for the random variables in $\boldsymbol{e}$ is assumed to be identical. The correlation matrix of $\boldsymbol{e}$ can thus be written as:

$$\boldsymbol{R_{ee}} = \begin{bmatrix} 1 & \rho_e & \rho_e \\ & 1 & \rho_e \\ sym. & & 1 \end{bmatrix} \tag{13}$$

In addition, all random variables in $\boldsymbol{e}$ are assumed to have an identical standard deviation σ_e, so that the vector of standard deviations can be written as $\boldsymbol{\sigma_e} = [\sigma_e \quad \sigma_e \quad \sigma_e]^T$. This assumption simplifies the problem and conceals any possible differences in the prediction errors for the different observable outcomes, but it is justified for multiplicative errors, since higher harmonics of eigenfrequencies are multiples of the base eigenfrequency. If the discrepancy between model predictions and observations is dominated by model errors, the ratio of this discrepancy will be the same for all harmonics, resulting in identical prediction errors.

With these assumptions the covariance matrix $\boldsymbol{\Sigma_{ee}}$ can be determined as:

$$\boldsymbol{\Sigma_{ee}} = \boldsymbol{D_{ee}} \boldsymbol{R_{ee}} \boldsymbol{D_{ee}} \tag{14}$$

where $\boldsymbol{D_{ee}} = \mathrm{diag}(\boldsymbol{\sigma_e})$ is the matrix of standard deviations. This approach effectively parametrizes the covariance matrix. The parameters ρ_e and σ_e of the prediction error model together with the parameters $\boldsymbol{\theta_{1,sub}}$ of the models describing the temperature dependence of the material properties and the mechanical behavior are the parameters of model class $\mathcal{M}_1$ denoted by $\boldsymbol{\theta}_1 = [EI_0 \quad \alpha \quad k \quad m \quad \sigma_e \quad \rho_e]^T$. With the parametrization of the sub-models expressed as $\boldsymbol{q}(y, \boldsymbol{\theta}_1)$ and the parametrization of the covariance matrix as $\boldsymbol{\Sigma_{ee}}(\boldsymbol{\theta}_1)$, the likelihood function $L_1(\boldsymbol{\theta}_1|\mathcal{D}_{i,j})$ describing the relation between the parameters $\boldsymbol{\theta}_1$ and a single sub-dataset $\mathcal{D}_{i,j} = (\hat{y}_{i,j}, \hat{\boldsymbol{z}}_{i,j})$, $i = 1$ (uncracked), 2 (cracked) and $j = 1, \ldots, 5$ can be formulated according to Equation (1):

$$L_1(\boldsymbol{\theta}_1|\mathcal{D}_{i,j}) = \frac{1}{\sqrt{(2\pi)^n \det[\boldsymbol{\Sigma_{ee}}(\boldsymbol{\theta}_1)]}} \times \exp\left[-\frac{1}{2}\left[\ln \hat{\boldsymbol{z}}_{i,j} - \ln\left[\boldsymbol{q}(\hat{y}_{i,j}, \boldsymbol{\theta}_1)\right]\right]^T \boldsymbol{\Sigma_{ee}}(\boldsymbol{\theta}_1)^{-1}\left[\ln \hat{\boldsymbol{z}}_{i,j} - \ln\left[\boldsymbol{q}(\hat{y}_{i,j}, \boldsymbol{\theta}_1)\right]\right]\right]. \tag{15}$$

Given that all five sub-datasets in each dataset $\mathcal{D}_1 = (\mathcal{D}_{1,j})_{j=1}^5$ or $\mathcal{D}_2 = (\mathcal{D}_{2,j})_{j=1}^5$ are conditionally independent for given parameters $\boldsymbol{\theta}_1$, the likelihood function $L_1(\boldsymbol{\theta}_1|\mathcal{D}_i)$ describing the full dataset $\mathcal{D}_i$, $i = 1{,}2$ is given by (see also Equation (5)):

$$L_1(\boldsymbol{\theta}_1|\mathcal{D}_i) = \prod_{j=1}^{5} L(\boldsymbol{\theta}_1|\mathcal{D}_{i,j}) \quad \text{with} \quad i = 1{,}2 \tag{16}$$

Within a Bayesian framework, any prior knowledge on the parameters is quantified by the definition of the prior probability distributions of the parameters. Concerning the flexural stiffness EI_0 at 0 °C, the uncertainty in the geometry is by far outweighed by the uncertainty in the elastic modulus of the concrete. Based on the Probabilistic Model Code [30], the probability density function of the elastic modulus is modelled by a lognormal distribution with a coefficient of variation (c.o.v) 0.15. With a mean cross-sectional area of 0.2 m × 0.4 m and a mean of the elastic modulus of 33 GPa (see Section 3), the mean of the prior distribution of EI_0 is determined as 8.8 MNm².

In the literature [25-27], the slope of the temperature dependent elastic modulus are in the range of -0.3% K^{-1} to -0.8% K^{-1}. For the present system with a flexural stiffness EI_0 of 8.8 MNm², a normal distribution for the slope parameter α with a mean of -0.01 MNm² K^{-1} and a large c.o.v. of 0.5 is chosen.

The mass of the shaker including the construction for suspending the shaker is estimated to be approximately 30 kg. Hence this parameter is modelled with a normal distribution with a mean of 30 kg and a c.o.v. of 0.25.

Since the suspension the shaker does not consist of a single member but a series of members joined by bolted connections, there is a high degree of uncertainty in the value of the equivalent spring constant k, which is expressed through a high c.o.v. Preliminary calculations indicate a range between 2.5 MNm and 4.0 MNm for the value of the spring constant. Negative values are unreasonable, and thus a lognormal distribution with a mean of 3.5 MNm and a c.o.v. of 0.5 is chosen.

The standard deviation σ_e of the prediction errors is assumed to follow a lognormal distribution with a mean of 0.01 and a c.o.v. of 0.25. For the correlation ρ_e of the prediction errors a beta distribution with parameters $\alpha = 5$ and $\beta = 2$ is applied.

All parameters in $\boldsymbol{\theta}_1$ are assumed to be statistically independent. An overview over the prior distributions of the parameters $\boldsymbol{\theta}_1$ is given in Table 1.

Parameter	Distribution	Mean	c.o.v.
EI_0	Lognormal	8.8 MNm²	0.15
α	Normal	-0.01 MNm²/K	0.5
k	Lognormal	3.5 MN/m	0.5
m	Normal	30 kg	0.25
σ_e	Lognormal	0.01	0.25
ρ_e	Beta (5,2)	0.71	0.22

Table 1: Prior probabilistic models of the parameters $\boldsymbol{\theta}_1$ of model class $\mathcal{M}_1$.

4.3 Model class 2: cracked beam

Model class $\mathcal{M}_2$ represents the temperature-dependent cracked beam. It is an extension of model class $\mathcal{M}_1$ where the beam consists of two regions, an uncracked region with material properties $EI_{0,1}$ and α_1, and a cracked region with properties $EI_{0,2}$ and α_2. The transition from the uncracked to the cracked region occurs at symmetric locations of x_D from the supports (see Figure 6). Apart from these assumptions, model class $\mathcal{M}_2$ is analogue to $\mathcal{M}_1$ in the modeling process and formulation of the likelihood function $L_2(\boldsymbol{\theta}_2|\mathcal{D}_i)$, $i = 1,2$. The parameters of model class $\mathcal{M}_2$ is $\boldsymbol{\theta}_2 = [EI_{0,1} \quad \alpha_1 \quad EI_{0,2} \quad \alpha_2 \quad x_D \quad k \quad m \quad \sigma_e \quad \rho_e]^T$. An illustration of the mechanical model of model class $\mathcal{M}_2$ is shown in Figure 6.

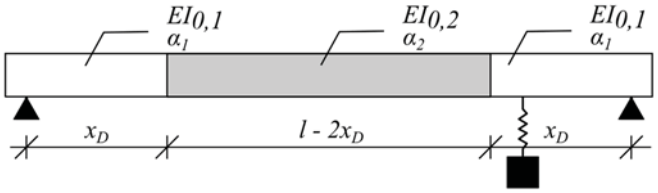

Figure 6: Illustration of the mechanical model embedded in model class $\mathcal{M}_2$

The prior knowledge on the cracked system corresponds to the prior knowledge of the uncracked system. Therefore, the prior distributions of the parameters are identical except for $EI_{0,2}$, α_2, and x_D. It is assumed that the flexural stiffness $EI_{0,2}$ at 0 °C of the cracked region follows a lognormal distribution with a mean of 80% of the mean of $EI_{0,1}$. The prior distribution

of the slope of the linear model of the temperature dependent stiffness is assumed to be alike for the uncracked and cracked region, resulting in identical priors for α_1 and α_2.

A normal distribution is assumed for the location of the transition of the uncracked to the cracked region x_D with a mean located at the quarter points and a standard deviation of 20cm, resulting in a c.o.v. of 0.3. All parameters are assumed to be statistically independent with the exception of the flexural stiffness at 0 °C, $EI_{0,1}$ and $EI_{0,2}$, and the slope of the temperature-dependent stiffness, α_1 and α_2 , which are each correlated with a correlation coefficient of 0.9 . An overview over the prior distributions of the parameters $\boldsymbol{\theta}_2$ is given in Table 2.

Parameter	Distribution	Mean	c.o.v.
$EI_{0,1}$	Lognormal	8.8 MNm²	0.15
α_1	Normal	-0.01 MNm²/K	0.5
$EI_{0,2}$	Lognormal	0.8 × 8.8 MNm²	0.15
α_2	Normal	-0.01 MNm²/K	0.5
x_D	Normal	0.25 * 2.72m	0.3
k	Lognormal	3.5 MN/m	0.5
m	Normal	30 kg	0.25
σ_e	Lognormal	0.01	0.25
ρ_e	Beta (5,2)	0.71	0.22

Table 2: Prior probabilistic models of the parameters $\boldsymbol{\theta}_2$ of model class $\mathcal{M}_2$.

4.4 Results

The data gathered in the experiment are divided into two datasets: A dataset $\mathcal{D}_1$ with data collected from the uncracked beam at all five temperature levels $\{-25\ °C, -5\ °C, 5\ °C, 25\ °C, 40\ °C\}$ and a dataset $\mathcal{D}_2$ with data collected from the cracked beam at the same temperature levels.

The posterior marginal distributions of the parameters $\boldsymbol{\theta}_1$ of model class $\mathcal{M}_1$ conditional on the dataset $\mathcal{D}_1$ are shown in Figure 7 along with their prior distributions. Distinct peaks in the posterior distributions can be seen for the mass m of the shaker and the stiffness k of its suspension, as well as EI_0, the flexural stiffness at 0 °C. These peaks show an information gain through the data while the modest change of the posterior marginal distributions of α, σ_e, and ρ_e compared to their respective prior distributions signify only limited information gain through the data.

The posterior marginal distributions of the parameters $\boldsymbol{\theta}_2$ of model class $\mathcal{M}_2$ conditional on the dataset $\mathcal{D}_2$ are shown in Figure 8 along with their prior distributions. Here, the peaks in the posterior marginal distributions of the parameters are in general less sharp than in the previous case. This is plausible, since the mechanical sub-model with two regions contains more parameters and thus the space of possible solutions is larger. The uncertainty in all the parameters of the mechanical sub-model decreases. The area with the most plausible values of the parameter x_D, which defines the start and extend of the region with reduced stiffness, is between 0.80 m and 1.05 m. Visually observed cracks start at around 1.10 m from the supports from both sides. The observed crack spacing of 0.15 m corresponds to the effective length for the load transfer between reinforcement bars and concrete. The change of flexural stiffness is thus expected to occur at 1.10 m – 0.15 m = 0.95 m, which corresponds to the most plausible values of x_D.

The posterior probabilities of the model classes $\mathcal{M}_1$ and $\mathcal{M}_2$ conditional on the data are shown in Figure 9. A prior probability of $\Pr(\mathcal{M}_1) = \Pr(\mathcal{M}_2) = 0.5$ was assumed for both

model classes. The results show that – as expected – model class $\mathcal{M}_1$ is more plausible for data measured from of the uncracked beam and model class $\mathcal{M}_2$ is more plausible for data obtained from the cracked beam.

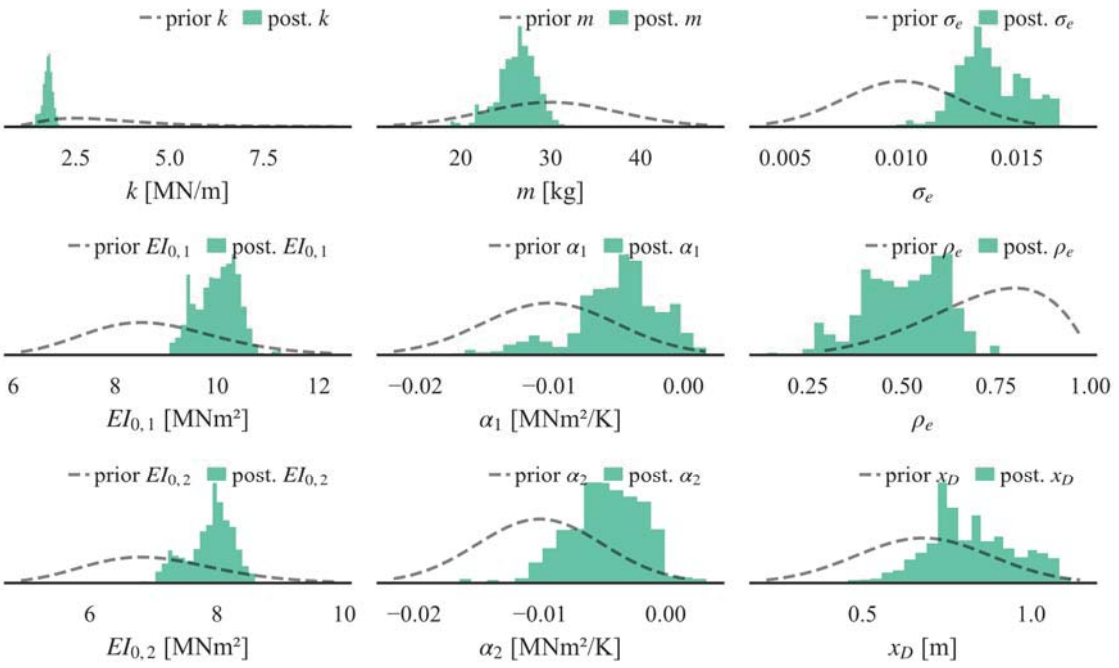

Figure 8: Posterior marginal distributions of the model parameters for model class $\mathcal{M}_2$ conditional on the dataset $\mathcal{D}_2$ (data obtained in the cracked state).

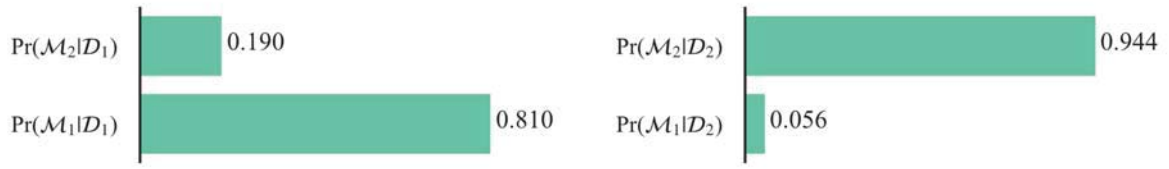

Figure 9: Comparison of the plausibility of the model classes $\mathcal{M}_1$ and $\mathcal{M}_2$ conditional on dataset $\mathcal{D}_1$ measured from the uncracked beam (left) and conditional on dataset $\mathcal{D}_2$ obtained from the cracked beam (right)

5 STRUCTURAL HEALTH MONITORING SCHEME

5.1 Strategy

One of the axioms of structural health monitoring states that damage detection requires the comparison of the current state of a system to an undamaged reference state [31]. To implement this situation, we first split the available data $\mathcal{D}$ into data from the reference state $\mathcal{D}_r$ and data from the current state $\mathcal{D}_c$, which contains all data after the reference state: $\mathcal{D} = (\mathcal{D}_r \quad \mathcal{D}_c)$.

Subsequently, two model classes are introduced: First, a model class is proposed, which assumes that for *both* the data from the current and reference states the beam is in the uncracked state. The likelihood function L_1 is applied to the whole dataset $\mathcal{D}$ and the priors for $\boldsymbol{\theta}_1$ are chosen to be the same as above. This model class is identical with model class $\mathcal{M}_1$.

A second model class denoted as $\mathcal{M}_3$ is proposed, which assumes that the beam is uncracked in the reference state and cracked in the current state. This in effect applies the likelihood function L_1 to the data of the reference state and L_2 to the data of the current state. The parameters of model class $\mathcal{M}_3$ and their prior distributions are identical to those of model class $\mathcal{M}_2$. With $EI_0 \mathrel{\widehat{=}} EI_{0,1}$ and $\alpha_0 \mathrel{\widehat{=}} \alpha_{0,1}$, the parameters $\boldsymbol{\theta}_1$ are a subset of the parameters $\boldsymbol{\theta}_2$ and the likelihood function L_1 can thus also be written as a function of $\boldsymbol{\theta}_2$.

The likelihood functions for the two model classes in this structural health monitoring scheme are formulated as:

$$L_1(\boldsymbol{\theta}_1|\mathcal{D}) = L_1(\boldsymbol{\theta}_1|\mathcal{D}_r) \times L_1(\boldsymbol{\theta}_1|\mathcal{D}_c) \tag{17}$$

$$L_3(\boldsymbol{\theta}_2|\mathcal{D}) = L_1(\boldsymbol{\theta}_2|\mathcal{D}_r) \times L_2(\boldsymbol{\theta}_2|\mathcal{D}_c) \tag{18}$$

5.2 Data

In the current structural health monitoring scenario, the datasets are assembled as follows: The data $\mathcal{D}_r$ obtained in the reference state comprises data measured from of the uncracked beam at five different temperature levels as summarized in Table 3. The data $\mathcal{D}_c$ measured in the current state consists of data measured from the uncracked beam at two temperature levels followed by data obtained from the cracked beam at five different temperature levels as also listed in Table 3.

As the monitoring of a structure progresses, more and more data are accumulated. For this reason, we denote $\mathcal{D}_{1:i}$ as the dataset which includes the individual datasets $\mathcal{D}_1$ to $\mathcal{D}_i$, i.e. $\mathcal{D}_{1:i} = (\mathcal{D}_1 \quad \dots \quad \mathcal{D}_i)$.

	Reference state, $\mathcal{D}_r$					Current state, $\mathcal{D}_c$						
Beam state	uncracked							cracked				
Temperature [°C]	+40	+25	+5	-5	-25	+40	-5	-25	-5	+5	+25	+40
Dataset	$\mathcal{D}_1$	$\mathcal{D}_2$	$\mathcal{D}_3$	$\mathcal{D}_4$	$\mathcal{D}_5$	$\mathcal{D}_6$	$\mathcal{D}_7$	$\mathcal{D}_8$	$\mathcal{D}_9$	$\mathcal{D}_{10}$	$\mathcal{D}_{11}$	$\mathcal{D}_{12}$

Table 3: Datasets for the SHM scenario as a function of the beam state and temperature

5.3 Results

In the same manner as before, a model class selection yields the relative plausibility of the states of the system conditional on the data. Model class $\mathcal{M}_1$ assumes that the beam is uncracked for all available datasets, i.e. it is uncracked in the reference state as well as in the current state. A difference between reference state and current state is made for model class $\mathcal{M}_3$, where the beam is assumed to be uncracked in reference state but cracked in the current state. This means that when – conditional on the data -- $\mathcal{M}_3$ is more plausible than $\mathcal{M}_1$, it is more plausible that the current state of the beam is cracked rather than uncracked.

As before, the prior probabilities of the model classes are assumed to be uniform, representing no prior preference for a specific model class.

With these priors and the evidences obtained from the system identification, for each dataset $\mathcal{D}_{1:i}$ a model class comparison can be conducted, expressing the plausible states of the system for the data acquired at different stages of the monitoring scenario. These model class comparisons are shown in Figure 10. It is apparent that in the reference state, for datasets $\mathcal{D}_{1:1}$ to $\mathcal{D}_{1:5}$, the two model classes are approximately equally plausible.

Datasets $\mathcal{D}_{1:6}$ and $\mathcal{D}_{1:7}$ include additional data from the uncracked beam. In this case, model class $\mathcal{M}_1$, which assumes an uncracked beam for the reference state and current state is far more plausible than model class $\mathcal{M}_3$, which assumes a cracked beam for the current state. For the subsequent datasets $\mathcal{D}_{1:8}$ to $\mathcal{D}_{1:12}$, which also include data from the cracked beam in the current state, model class $\mathcal{M}_3$ gradually becomes more plausible than model class $\mathcal{M}_1$, signifying that a cracked current state is more likely than an uncracked one.

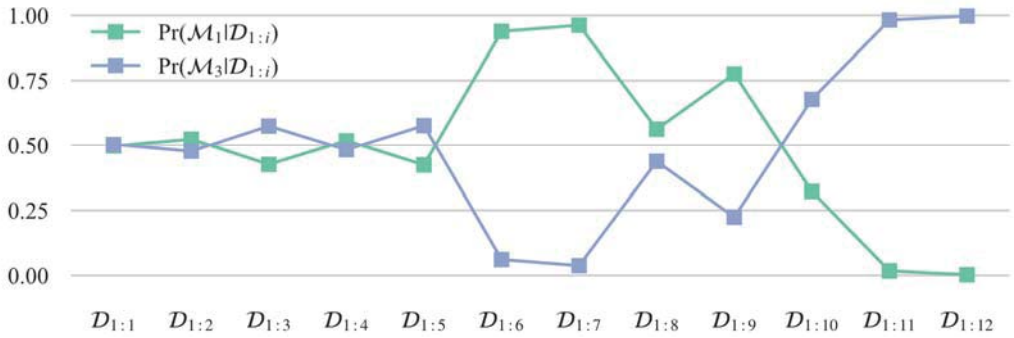

Figure 10: Plausibility of model classes $\mathcal{M}_1$ and $\mathcal{M}_3$ conditional on datasets $\mathcal{D}_{1:i}$.

With the updated parameters of model classes $\mathcal{M}_1$ and $\mathcal{M}_3$ conditional on datasets $\mathcal{D}_{1:12}$, when all observations have been taken into account, the responses of the models can be predicted by using the posterior samples of the parameters as model input. These posterior predictions are shown in Figure 11 for $\mathcal{M}_1$ conditional on datasets $\mathcal{D}_{1:12}$ along with the data. In Figure 12, the posterior predictions for $\mathcal{M}_3$ conditional on datasets $\mathcal{D}_{1:12}$ along with the data.

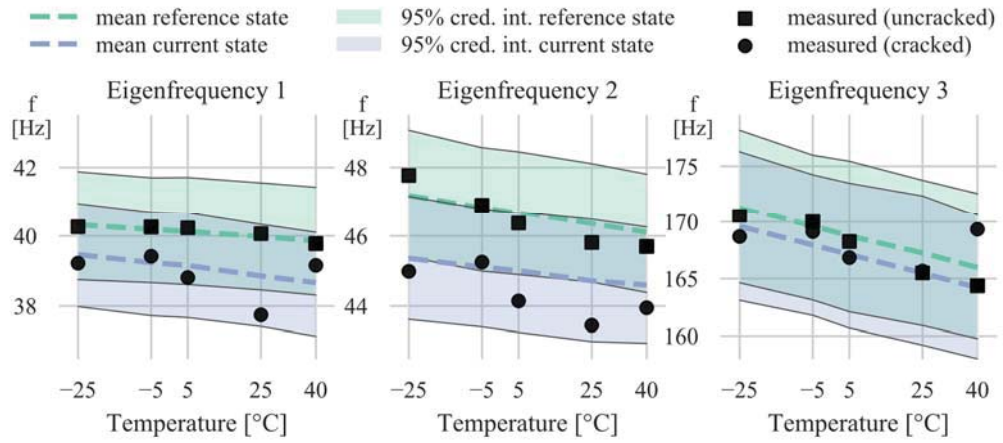

Figure 12: Mean and 95% credible interval for the posterior eigenfrequencies of the beam as well as the identified eigenfrequencies. The statistics of the posterior eigenfrequencies are determined based on model class $\mathcal{M}_3$ conditional on dataset $\mathcal{D}_{1:12}$.

6 CONCLUDING REMARKS

In the current paper, we address the issue of quantifying structural changes in a reinforced concrete beam amid varying environmental conditions based on monitoring data by postulating competing probabilistic models which explicitly describe the temperature-dependency of the structural properties. Each model represents a possible state of the beam. Bayesian model updating is applied based on modal information extracted from vibration data measured from the beam at various temperature levels inside a climate chamber. These updated models include a model of the temperature-dependent material properties and a quantification of the structural changes in the beam. The updated models enable robust predictions of the system responses [32].

By applying Bayesian model class selection, we successfully identify the plausible states of the beam. In a simplistic structural health monitoring scenario, which separates the data into a reference state and a current state and postulates different structural states for the current state, structural changes are detected and quantified.

In the current paper, modal eigenfrequencies were used as data. Additional modal properties such as modes shapes can be included in the analysis and are expected to provide additional information [10, 16-18, 20, 33]. Alternatively, a two-stage approach [34, 35] or time-domain output-only approaches [13, 19, 36] for Bayesian system identification can be applied.

The results presented in this paper are based on limited data and are thus promising for real structural health monitoring applications where more data are typically available. The approach of explicitly modelling the temperature-dependent properties of structural systems is especially beneficial when predicting the performance and condition of structures, which are significantly influenced by the temperature-dependent behavior of nominally non-loadbearing structural components such as ballasted tracks or asphalt layers. Our future work will include structures with nominally non-loadbearing components which (a) exhibit such a strong temperature-dependent behavior and (b) influence the static and dynamic response of the system.

Keywords: Pile penetration monitoring, Non-contact method, Magnetic stray field.

Abstract. *Current methods to infer the penetration of a steel monopile during an offshore installation are rather inaccurate. Since a large number of foundation piles will be installed offshore in the coming years, a reliable technique to infer the penetration depth is vital. This paper proposes a non-contact method to monitor the pile progression into the seabed based on measurements of the magnetic stray field that permeates the air surrounding the structure, eliminating the necessity of a predefined pattern on the pile's surface. A simple magnetisation model for the monopile is proposed from which the relative motion between the moving pile and a stationary magnetic field sensor can be extracted. Comparison between the measured and simulated stray field data show a promising correlation, providing the basis for the new non-contact monitoring technique that is applicable offshore.*

1 INTRODUCTION

In the coming years, a large number of offshore wind farms will be commissioned in the North Sea. The most popular foundation type for wind turbines is the monopile [1], which is a cylindrical shell structure consisting of multiple steel sheets that are welded together. Currently, nearly all of these piles are gradually driven into the seabed by means of hydraulic impact hammers. Real-time knowledge of the pile penetration resulting from each hammer blow is vital to ensure safety during the installation process and to limit the amount of fatigue damage inflicted to the pile, since the energy of the blows can be adjusted accordingly based on the penetration speed. Moreover, after installation, the bearing capacity of the pile is estimated by measuring the pile's response to a single axial impact in a so-called restrike test [2].

Several techniques currently exist to monitor pile penetration. By registering the acceleration with a sensor mounted to the pile, the penetration is computed by integrating the signal twice in time [3]. Disadvantages of this approach include the need to attach the sensor to the surface of the pile, which is a delicate and time-consuming process, and the error in the computed displacement that accumulates due to filtering choices and the integration of the acceleration signal. Alternative techniques rely on optical signals. One such method is to deduce the distance between the top of the pile and a reference level based on the time-of-flight principle [4]. However, in an offshore environment, a steady reference level is not available, since optical signals, instead of reflecting back to the detector, scatter as result of the surface waves at the water level. A different optical approach is to use a camera to track a predefined pattern that is applied to the surface of the pile, e.g. a black and white banded pattern. Several patterns have successfully been administered over the years, especially in the case of restrike tests [5–8]. These approaches share the necessity to prepare the surface of the pile with a distinct predefined visual pattern.

Ideally, a method to register pile penetration is based on a non-contact sensor, simplifying the deployment significantly. Furthermore, such an optimal method does not require any preparation of the pile's surface to operate, i.e. no pattern has to be introduced. A method based on the magnetic stray field generated by a steel structure in the presence of the geomagnetic field could satisfy both of these criteria, since the stray field permeates the space surrounding the monopile. Hence, this paper investigates the feasibility to use the magnetic stray field to monitor the pile's penetration during installation. To this end, first, stray field data measured during a full-scale onshore monopile installation are presented, examining change of the magnetic signature of the structure with increasing penetration depth. Second, the magnetic stray field of the structure is simulated by employing a simple model for the structure's magnetic susceptibility that includes the presence of circumferential welds. Third, the possibility to utilise stray field measurements to determine the relative motion between the pile and a magnetic field sensor is discussed. Finally, the main conclusions of this work are summarised.

2 FULL-SCALE MEASUREMENT CAMPAIGN

During the installation of a steel monopile, the magnetic stray field has continuously been measured by means of a stationary magnetometer, which is mounted on top of a ground-based tripod. Since this concerns an onshore installation, a suitable reference level is available (ground level), allowing for a time-of-flight laser sensor to be employed to measure the pile's penetration in conjunction with the magnetic stray field measurements.

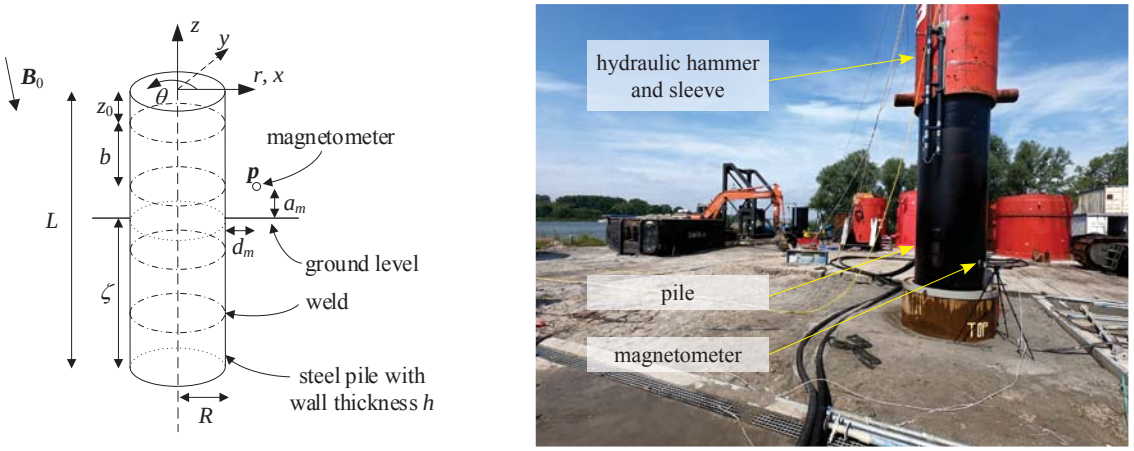

Figure 1: Set-up of the full-scale onshore monopile installation. (a) Schematic indicating the parameters of interest. (b) Photograph of the installation site.

2.1 Description of the set-up

A schematic of the set-up of the pile installation is presented in Figure 1a, which defines two coordinates systems: a cylindrical $r\theta z$-coordinate system—in which r, θ, and z denote the radial, the circumferential, and the axial directions, respectively—and a Cartesian xyz-coordinate system. The coordinate systems share their origin, which is located at the top of the pile. Table 1 lists the numerical values of the relevant parameters of the pile: the radius R, length L, and wall thickness h. The installed pile is composed of cylindrical steel sections with a height b each, which are stacked on top of each other using circumferential welds. Before installation, the pile has been coated for corrosion protection, obscuring the exact locations of the welds. Despite the lack of visible confirmation, their positions relative to the pile top are known *a priori*. The distance z_0 reflects the shorter top segment of pile.

To determine the penetration, a time-of-flight distance sensor is attached to the sleeve of the hydraulic hammer, which is depicted in Figure 1b. The current penetration depth ζ is defined as the distance from lower end of the pile to the ground level, implying that the pile is fully embedded into the soil when $\zeta = L$. The initial penetration depth ζ_0 is also listed in Table 1.

A biaxial magnetometer (type: HMC1022) registers the magnetic stray field while the pile gradually progresses into the soil with each hammer blow. It measures the two dominant components of the stray field: the radial B_r and the axial B_z. Figure 1b shows the magnetometer mounted on top of a tripod. Its position $\boldsymbol{p}$ relative to the ground is given by the offset from the pile's surface d_m, the circumferential position θ_m and the height a_m as specified in Table 1. A final parameter of importance is the direction and intensity of the geomagnetic field, of which the components expressed in the Cartesian xyz-coordinate system are $\boldsymbol{B}_0 = [B_0^x \;\; B_0^y \;\; B_0^z]^T = [15 \;\; 10 \;\; -40]^T\,\mu$T, signalling that it has a predominantly downward component. For the current purpose, the external field is considered to be time and space invariant.

2.2 Magnetic stray field versus penetration depth

Figure 2 shows the magnetic stray field components plotted against the measured penetration depth ζ. Both components of $\boldsymbol{B}$ show a pattern that repeats every 3 m, which is caused by the circumferential welds in the pile. Compared to the fairly homogeneous material in between

Parameter	Value
R	0.6096 m
L	62.0 m
h	0.050 m
b	3.0 m
z_0	0.5 m
ζ_0	48.62 m
a_m	1.5 m
θ_m	300°
d_m	0.2 m

Table 1: Parameters of interest for the pile installed during the measurement campaign.

them, the welds have significantly different magnetic properties, resulting in a local reduction of the magnetic susceptibility, which in turn create distinct markings in the field. Furthermore, it is clear that the magnitude of the radial component B_r increases when the pile penetrates further into the soil, which can be attributed to the sensor approaching the top of the pile. Due to the repeated impacts of the hammer, the pile has become magnetised in the direction of the geomagnetic field. Since that field has a strong downwards component, the top of the pile resembles a magnetic south pole, i.e. a region in space where magnetic field lines appear to converge to. These two observations indicate that the geometry of the pile and the presence of the geomagnetic field create a distinct pattern in the magnetic stray field which might enable one to track the penetration from stray field measurements alone.

3 MODELLING OF THE STRAY FIELD

In this section, the magnetic signature of the pile is simulated to investigate whether the measured data can be captured by a simple model, which would serve as a basis to infer the current penetration depth of the pile from measured magnetic stray field data. To this end, an expression of the magnetic field at an evaluation point $\boldsymbol{B}(\boldsymbol{p})$ generated by the structure's magnetisation $\boldsymbol{M}(\boldsymbol{r})$ is derived, in which $\boldsymbol{r}$ represents all points within the volume of the pile. By applying the same expression to the internal points of the structure in conjunction with a suitable magnetic constitutive equation, the magnetisation induced by the external field is determined. Subsequently, the measured magnetic stray field is reproduced with a proposed simple expression for the magnetic susceptibility.

3.1 The stray field in the presence of an external field

Even though the external field is time and space invariant, the magnetisation of the pile will not be uniform due to the geometry of the structure, which leads to a significant demagnetising field [9]. To compute the magnetic field generated by the structure's magnetisation, a numerical approach applicable to steel sheets is adopted [10], which assumes that the magnetisation component in the normal direction of the sheet (the radial component M_r in the current situation) is negligible.

By evenly subdividing the pile's volume into N_θ elements in the circumferential and N_z elements in the axial direction, the structure is discretised, and the total number of elements equals $N = N_\theta N_z$. Under the assumption that the magnetisation is constant over each element and is concentrated at the element's barycentre $\boldsymbol{r}_i$, i.e. $\boldsymbol{M}(\boldsymbol{r}_i)$, the magnetic field at $\boldsymbol{p}$ is given

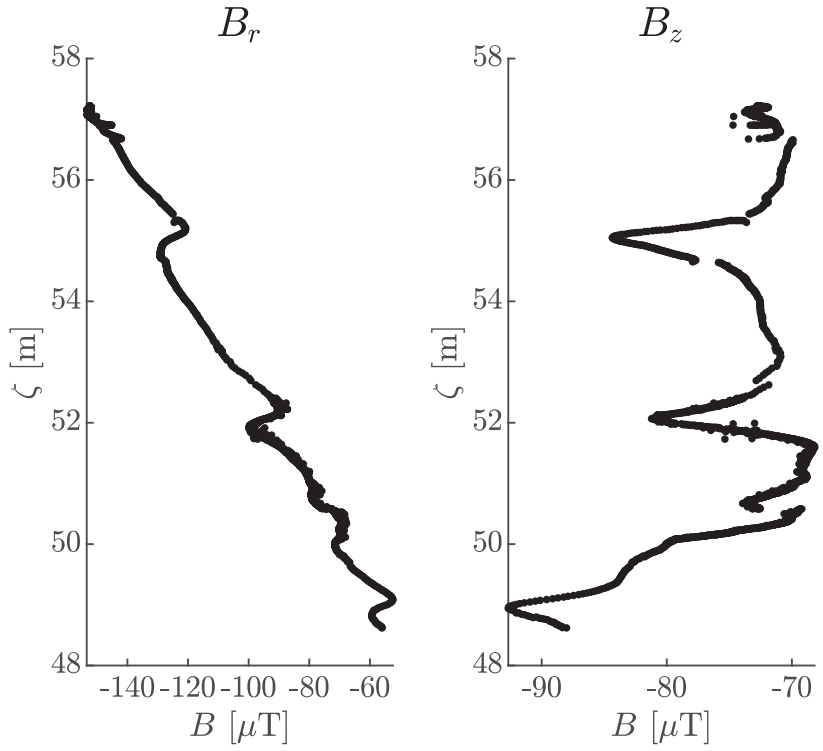

Figure 2: Remanent magnetic stray field versus the penetration depth.

by a summation of the contributions from all elements:

$$\boldsymbol{B}(\boldsymbol{p}) = \frac{\mu_0}{4\pi} \sum_{i=1}^{N} \oint_{\Gamma_i} \boldsymbol{M}(\boldsymbol{r}_i) \cdot \boldsymbol{n}_i \frac{\boldsymbol{p} - \boldsymbol{r}_i}{\|\boldsymbol{p} - \boldsymbol{r}_i\|^3} \, \mathrm{d}\Gamma_i, \tag{1}$$

in which μ_0 denotes the magnetic constant, and $\boldsymbol{n}_i$ is the outward normal to the element's boundary Γ_i. By evaluating the integrals, the expression above is rewritten:

$$\boldsymbol{B}(\boldsymbol{p}) = \mu_0 \sum_{i=1}^{N} \mathbf{G}_i \boldsymbol{M}(\boldsymbol{r}_i) = \mu_0 \mathbf{G}_{\boldsymbol{p}} \boldsymbol{M}, \tag{2}$$

in which $\mathbf{G}_i$ contains the values of the evaluated integrals for each element. In the latter part of the expression, these contributions are condensed into a single matrix $\mathbf{G}_{\boldsymbol{p}}$, and $\boldsymbol{M}$ is a vector incorporating the magnetisation components from all elements. Since the radial magnetisation component is deemed insignificant, $\boldsymbol{M}$ contains $2N$ entries.

To express the magnetisation in terms of the prevailing magnetic field, an appropriate constitutive equation is required. For a (locally) isotropic material, a scalar magnetic susceptibility χ suffices. Hence, the following implicit constitutive equation is employed:

$$\boldsymbol{M} = \chi \left(\frac{\boldsymbol{B}_0}{\mu_0} + \mathbf{G}_{\boldsymbol{r}} \boldsymbol{M} \right), \tag{3}$$

in which $\mathbf{G}_{\boldsymbol{r}}$ is a $2N \times 2N$ matrix representing the non-local interaction of the structure's magnetisation, which is obtained by substituting $\boldsymbol{r}_i$ for each element in Equation (2). Assuming that χ is not a function of the magnetisation itself, rearrangement of the former relation yields

$$\boldsymbol{M} = \chi \left(\mathbf{I} - \chi \mathbf{G}_{\boldsymbol{r}} \right)^{-1} \frac{\boldsymbol{B}_0}{\mu_0}, \tag{4}$$

in which $\mathbf{I}$ is the $2N \times 2N$ identity matrix and $(\cdot)^{-1}$ denotes a matrix inversion. When the susceptibility in known, the structure's magnetisation is computed by means of Equation (4); subsequently, the stray field at $\boldsymbol{p}$ is determined by employing Equation (2).

3.2 Model for the magnetic susceptibility

The experimental stray field data implies that the magnetic properties differ in the vicinity of the circumferential welds. Therefore, the following axial distribution of the magnetic susceptibility is proposed:

$$\chi = \chi_0 - \chi_w \left(\sin\left(\frac{\pi \left(z - z_0 \right))}{b} \right) \right)^n , \tag{5}$$

where χ_0 is the undisturbed susceptibility of the material, χ_w is the reduction of the susceptibility due to the presence of the weld, b is the distance between each weld, z_0 is an offset to correctly position the welds along the pile axis, and n is an even power to localise the reduced susceptibility to a narrow range around the weld's position. In this expression, b and z_0 are determined by the geometry of the pile alone, see Table 1. The numerical values of the remaining parameters have to be calibrated.

3.3 Simulated magnetic signature

To simulate the relative motion between the sensor and the pile, the stray field is evaluated along a line parallel to the axis of the pile, on which the evaluation points $\boldsymbol{p}$ are given in cylindrical $r\theta z$-coordinates by:

$$\boldsymbol{p} = \begin{bmatrix} R + d_m \\ \theta_m \\ \zeta + a_m - L \end{bmatrix} , \tag{6}$$

where $\zeta = [\zeta_0, \zeta_0 + 8.6]\,\mathrm{m}$, which coincides with the recorded penetration range. For these parameters, the corresponding numerical values are presented in Table 1. The volume of pile is discretised in $N_\theta = 25$ and $N_z = 300$ elements. In this case, the penetration is measured independently, and the unknown parameters in the susceptibility can easily be calibrated to match the measured results: $\chi_0 = 2100$, $\chi_w = 1600$, and $n = 20$. Figure 3a shows the susceptibility distribution resulting from these values.

The two components of the simulated magnetic field are presented in Figure 3b along side the measured data. Please note that the modelled values are shifted with a constant to match the measured signal; this shift represents the exact background field at the sensor location. From the figure, it is clear that the trend in the measured data is captured correctly by the simulated data. Only B_z differs for lower values of ζ, which might be attributed to other material inhomogeneities affecting the susceptibility which are not accounted for in the present model. Nonetheless, the simple relation for the magnetic susceptibility that accounts for the presence of circumferential welds is able to reproduce the measured magnetic signature of the pile.

4 DISCUSSION

The correspondence between the simulated magnetic signature and the measurements indicates that the simple susceptibility formulation given in Equation (5) is sufficient to model the magnetic state of the pile after a proper calibration is applied. In this case, the penetration depth is measured, significantly simplifying the calibration, since a fixed reference is present. Normally, however, this reference measurement of the penetration is obviously not available;

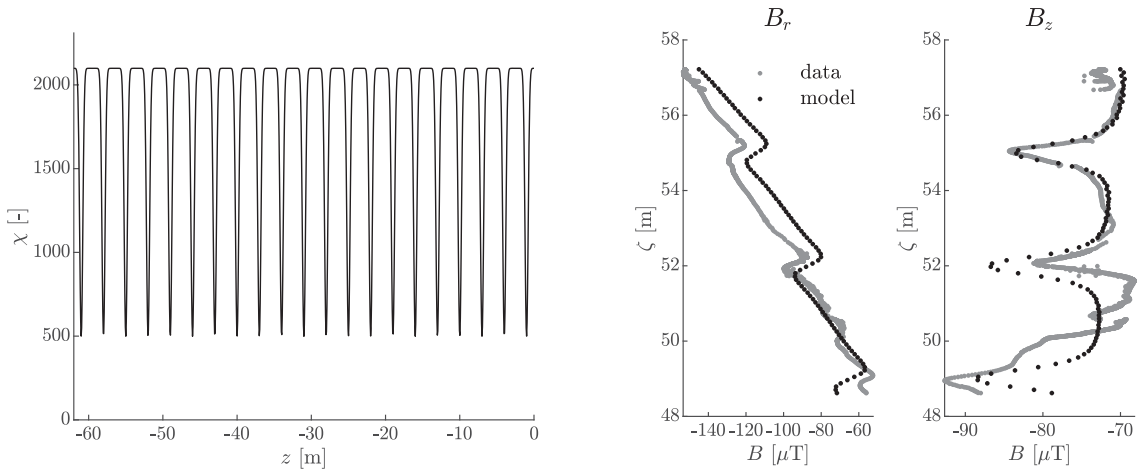

Figure 3: Model results for the magnetic stray field. (a) Modelled magnetic susceptibility along the pile's axis. (b) Modelled magnetic stray field versus the pile penetration compared to the measured data.

only the initial penetration depth is known to some extend. Therefore, the calibration should be founded solely on the measured magnetic field data. Fortunately, the welds create a distinct marking when they pass the sensor, e.g. a peak in the B_z value. Accordingly, as the weld positions are known at the start of the installation, the model can be calibrated based on the passage of one of those fixed markings, perhaps even constantly updating the model while new data is collected.

Once the model is calibrated, the penetration depth can be inferred by comparing the measured stray field to the modelled one. However, the mapping between some values of $\boldsymbol{B}$ and ζ is not unique (Figure 3b). Fortunately, the pile penetrates gradually into the soil; therefore, the penetration depth closest to the previous value should be selected. This additional step to extract the penetration depth from the magnetic data has not been elaborated yet, and it is left for future research.

The proposed method to monitor the pile's penetration has two benefits compared to currently used monitoring techniques; it relies on non-contact measurements, and it does not require an artificial tracking pattern applied to the pile's surface. In its current state, it only considers the magnetic stray field while the pile is unstressed. During the propagation of stress waves in the pile, reversible strain-induced magnetisation changes occur in conjunction to the changes related to the relative motion between the sensor and the pile, complicating the analysis considerably. Thus, the main application of the offered method is to monitor pile penetration during a full installation and not during a single hammer blow, e.g. a restrike test.

5 CONCLUSIONS

Based on magnetic stray field data collected during an onshore pile installation campaign, this paper proposes a new method to monitor the penetration of a steel monopile into the soil during pile driving. Contrary to state-of-the-art techniques, the proposed method is non-contact and does not require the introduction of an artificial pattern onto the surface of the structure. The latter is achieved by taking advantage of the naturally occurring pattern in the magnetic stray field as a result of circumferential welds in the pile. Furthermore, it is shown that this magnetic signature can be simulated by applying simple model for the magnetic susceptibility

proposed in this work. This modelled magnetic signature provides the basis for the method to monitor the penetration of a monopile during installation in real-time.

ACKNOWLEDGEMENTS

This research is part of the EUROS programme, which is supported by NWO domain Applied and Engineering Sciences and partly funded by the Dutch Ministry of Economic Affairs. The authors thank IHC-IQIP for the unique opportunity to perform these measurements at their yard in Sliedrecht, the Netherlands. Furthermore, the technical support provided by Arjan Roest (IHC-IQIP) and Kees van Beek (DEMO, TUDelft) is gratefully acknowledged.

Keywords: Artificial neural networks, cointegration, damage detection, Mahalanobis distance, environmental variabilities

Abstract. *Vibration-based structural health monitoring (VSHM) employs vibration signals as observables from which inferences are made concerning the integrity of structural systems. More specifically, the premise of this work is to detect damage through changes in a set of features extracted from the vibration signals. A major challenge in this regard is that false positives may arise due to the influence of environmental and operational variabilities (EOVs). Environmental variabilities, e.g. shifts in temperature and humidity, introduce changes in mechanical properties. These changes are reflected in the vibration response and can reduce the probability of detecting damage in a structure. This paper conducts a comparative study between a novel semi-supervised damage detection approach and a well known cointegration-based scheme to deal with EOVs. The novel approach uses the pattern recognition capability of an artificial neural network (ANN) to learn how EOVs affect a Mahalanobis distance-based damage index in a reference state. The cointegration-based scheme seeks to mitigate the EOVs by computing stationary linear combinations of non-stationary output response signals. The merits of the damage detection methods are examined in the context of a mass-spring system, which is exposed to a simulated temperature field that renders the output response non-stationary. The system is analysed in a reference state and a perturbed state in which damage is emulated by reducing a single spring stiffness by 2%. Both methods are evaluated with the area under the curve (AUC) for receiver operating characteristic (ROC) and the false alarm rate. The results show that the ANN-based damage detection approach outperforms the cointegration-based one in this particular example.*

1 Introduction

In most applications, structural health monitoring (SHM) systems consist of a sensor network that continuously collects information from a structure in order to extract damage sensitive features (DSFs) which can be used to assess the structural integrity. The DSFs can be evaluated by statistical or machine learning techniques to detect damage in the structure. Damage detection is a widely researched topic in the field of SHM. Researchers have used both numerical simulations and experimental setups to detect damage in different structures, see for instance [1–4]. One of the prevailing challenges in damage detection is to discriminate between structural damage and environmental and operational variabilities (EOVs) [5]. Environmental parameters that vary over time is for instance the temperature, which causes changes in stiffness, thereby globally affecting the structural response as shown by Alampalli et al. [6]. Sohn et al. [7] demonstrated that EOVs may camouflage the effects of structural damage and tend to increase the false alarm rate in damage detection.

Several methods have been proposed to mitigate the influence of EOVs under the framework of semi-supervised learning. Cross et al. [8] adopted the concept of cointegration, which is widely used in the field of econometrics to identify statistical relationship between non-stationary variables [9]. Within the field of SHM it operates on the premise that the EOVs induce non-stationarities in the DSFs. The concept was tested on a ten degree of freedom (DOF) mass-spring system where EOVs were introduced to render the output response non-stationary. Implementation of a cointegration scheme resulted in DSFs free from the effect of EOVs, and these DSFs were used to detect damage. Qadri et al. [10] applied cointegration to data from an operating Vestas V27 wind turbine blade. Artificial damages were introduced to one of the blades. It was demonstrated that cointegration successfully removed the effects of EOVs on DSFs. This led to detecting the smallest of the introduced artificial damages while the wind turbine was operating. Shi et al. [11] used a four DOF mass-spring system where EOVs were introduced on the stiffness. Additional stiffness variabilities were introduced by letting one spring behave distinctly from the other springs. A regime switching cointegration concept was proposed using the augmented Dickey-Fuller (ADF) test as a tool to detect damage.

Another method to mitigate the influence of EOVs consists of the use of machine learning techniques for vibration-based structural health monitoring (VSHM). Especially the use of artificial neural networks (ANNs) has gained attention among researchers in the field of SHM in the past decade. Nevel et al. [12] highlighted the advantage of using ANNs in a semi-supervised approach for damage detection in a railway bridge. A numerical experiment using a three-dimensional finite element model was set up and two different damage scenarios were simulated. ANNs were trained with acceleration response on the healthy bridge and used in a prediction model. The prediction error was served as a damage index. The resulting indices were compared to a damage detection threshold to discriminate between different levels of structural states.

This paper presents a comparative study between a novel ANN-based damage detection method recently proposed by Movsessian et al. [13] and the cointegration-based damage detection concept proposed by Cross et al. [8]. The two methods are evaluated in the context of a six DOF mass-spring system which is exposed to a stochastic temperature field. Damage is emulated by reducing the stiffness in one of the springs. Additional, random local variabilities (i.e. to simulate discrepancies at different stiffness locations) in two of the six springs are introduced to the system. The paper is organized such that section 2 introduces the two damage detection methods, followed by the case study in section 3. Concluding remarks are provided

in section 4.

2 Methods

2.1 Artificial neural networks

ANN is a mathematical model widely used in the field of artificial intelligence due to its strong pattern recognition capability [14]. The structure is expressed in a mathematical model as shown in Fig. 1. A neuron receives a set of inputs ϑ_j, $j = 1, ..., n$ and this results in a single output. The input values are scaled by weights w_i and summed to be passed through the activation function.

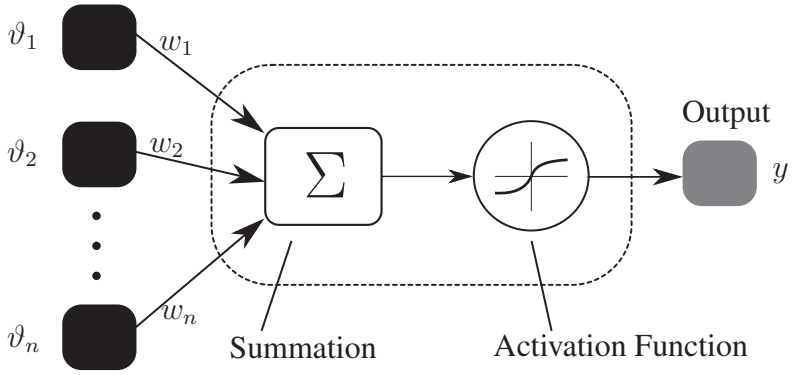

Figure 1: Schematic of an artificial neuron.

The structure shown in Fig. 1 can be expanded to a multilayer ANN by applying Eq. (1) to the next layer of an ANN. In such a system, each node i is connected to each node j in the consecutive layers by a connection with weight w_{ij}. The signals travel through the nodes of each layer in the following manner: in layer k, a weighted summation of all the signals $\vartheta_j^{(k-1)}$ from the preceding layer $k-1$ is calculated, the process is repeated for each node i and results in excitation $z_i^{(k)}$. A non-linear activation function f is applied to $z_i^{(k)}$ and the output of the node $\vartheta_i^{(k)}$ is obtained. Finally, this output is transmitted to the next layer [15].

$$\vartheta_i^{(k)} = f(z_i^{(k)}) = f(\sum_j w_{ij}^{(k)} \vartheta_j^{(k-1)}) \tag{1}$$

The training of an ANN is an adjustment of the connecting weights w_{ij} with the aim to minimize the mean squared error (MSE) between the target and the prediction. The MSE is computed from the output layer backwards. The learning algorithm to reduce the training error is the Bayesian regularization backpropagation as presented by MacKay [16].

2.1.1 Artificial neural networks for mitigating EOVs in damage detection

In the context of continuous monitoring systems, the data from the past and the present is available. To build a regression model by semi-supervised learning for continuous monitoring, DSFs $\boldsymbol{f}_t$ are gathered in a matrix $\boldsymbol{F} = [\boldsymbol{f}_1, \boldsymbol{f}_2, ..., \boldsymbol{f}_t, ..., \boldsymbol{f}_M], \boldsymbol{F} \in \mathbb{R}^{L \times M}$, where L is the length of the DSF vector and M is the number of observations. To provide the ANN regression model

a learning target, the features are labeled by the Mahalanobis distance (MD) Eq. (2):

$$d_t(\boldsymbol{f}_t, \boldsymbol{S}) = \sqrt{(\boldsymbol{f}_t - \boldsymbol{\mu}_{\boldsymbol{S}})^T \boldsymbol{\Sigma}_{\boldsymbol{S}}^{-1} (\boldsymbol{f}_t - \boldsymbol{\mu}_{\boldsymbol{S}})} \tag{2}$$

where $d_t(\boldsymbol{f}_t, \boldsymbol{S})$ is the MD between the observation $\boldsymbol{f}_t$ and the DSF matrix $\boldsymbol{S} \in \mathbb{R}^{L \times E}$ with $E \leq M$, $\boldsymbol{\mu}_{\boldsymbol{S}} \in \mathbb{R}^L$ is the mean of the observations in $\boldsymbol{S}$ and $\boldsymbol{\Sigma}_{\boldsymbol{S}} \in \mathbb{R}^{L \times L}$ is the covariance between observations in $\boldsymbol{S}$. Using the labeled feature matrix, a regression model can be build by training the ANN with the DSF vector $\boldsymbol{f}_t$ and the target $d_t(\boldsymbol{f}_t, \boldsymbol{S})$. For the semi-supervised framework, the ANN function $f_{nn}(\cdot)$ is trained exclusively with observations from a healthy system and their target (label). Let us define the prediction error $\hat{d}_t$ as the new damage index shown in Eq. 3:

$$\hat{d}_t = \frac{f_{nn}(\boldsymbol{f}_t)}{d_t(\boldsymbol{f}_t, \boldsymbol{S})} \tag{3}$$

where the ANN mapping function $f_{nn}(\cdot)$ is learning a unique relationship between the features from the healthy system and its target calculated by the MD metric. If an unlearned relationship between the features and the target occurs, due to e.g. damage in the system, an increased prediction error is expected.

2.2 Cointegration for mitigating EOVs in damage detection

In this study, cointegration is used to compute a linear combination of non-stationary variables in which the EOVs are mitigated. As such, the operating premise is that the EOVs govern the non-stationary behaviour. A brief introduction of cointegration is provided, for a detailed explanation on the method the reader is referred to Cross et al. [8]

The premise of cointegration is to fit a set of non-stationary variables to a p-order vector auto-regressive (VAR) model described as:

$$\boldsymbol{f}_t = \sum_{i=1}^{p} \boldsymbol{A}_i \boldsymbol{f}_{t-i} + \boldsymbol{\epsilon}_t \qquad \boldsymbol{\epsilon}_t \sim \mathrm{NID}(0, \boldsymbol{\Sigma}_\epsilon) \tag{4}$$

where $\boldsymbol{A}_i$, $i = 1, ..., p$ represents the coefficient matrices and p is the number of lags. $\boldsymbol{f}_{t-i}$ is the DSFs that is sought to cointegrate and $\boldsymbol{\epsilon}_t$ is normally and identically distributed (NID) white gaussian noise. The VAR model in Eq. (4) is re-written and formulated as a vector error correction model (VECM) defined by:

$$\Delta \boldsymbol{f}_t = \boldsymbol{\Upsilon} \boldsymbol{f}_{t-1} + \sum_{i=1}^{p-1} \boldsymbol{\Gamma}_i \Delta \boldsymbol{f}_{t-i} + \boldsymbol{\epsilon}_t \tag{5}$$

where $\boldsymbol{\Upsilon} \in \mathbb{R}^{L \times L}$ and $\boldsymbol{\Gamma}_i \in \mathbb{R}^{L \times L}$ are the matrices defined as:

$$\begin{aligned} \boldsymbol{\Upsilon} &= -\boldsymbol{I}_L - \boldsymbol{A}_1 - \boldsymbol{A}_2 - \cdots - \boldsymbol{A}_p \\ \boldsymbol{\Gamma}_i &= \boldsymbol{A}_{i+1} + \boldsymbol{A}_{i+2} + \cdots + \boldsymbol{A}_p \qquad i = 1 \ldots, p-1 \end{aligned}$$

If the DSFs in $\boldsymbol{f}_t$ are cointegrated, then matrix $\boldsymbol{\Upsilon}$ is rank deficient. In that case, the matrix can be decomposed as the product of two matrices:

$$\boldsymbol{\Upsilon} = \boldsymbol{U}\boldsymbol{V}^T \tag{6}$$

where $\boldsymbol{U}$,$\boldsymbol{V} \in \mathbb{R}^{L\times R}$ are matrices spanning the column and row spaces of $\boldsymbol{\Upsilon}$, respectively. The cointegration vectors are found in $\boldsymbol{V}$ and can be used to project the non-stationary variables into stationary residuals by a linear transformation:

$$\boldsymbol{z}_t = \boldsymbol{V}^T \boldsymbol{f}_t \tag{7}$$

where the ADF test is carried out by testing a null hypothesis of the residuals in $\boldsymbol{z}_t$ having a unit-root [17]; if a unit-root is present, then the residual is a non-stationary process and will not be suitable for damage detection. The process is carried out for each residual where the one that constitutes stationarity are used for further examination.

3 Case study

The present section is intended to demonstrate the two aforementioned methods on the six DOF mass-spring system presented Fig. 2. The system consists of six springs that are connected to six masses and fixed at one of the ends.

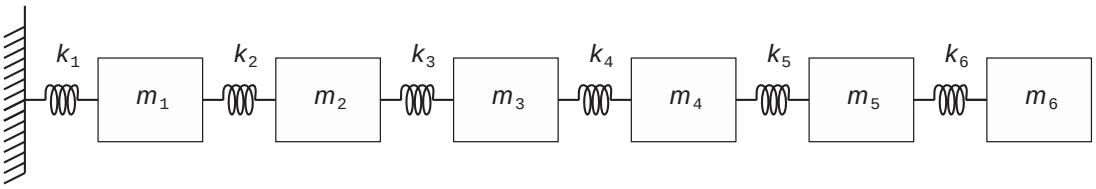

Figure 2: A six DOF mass-spring system.

In this case study, we consider the six natural frequencies of the system as the DSF vector $\boldsymbol{f}_t = [\boldsymbol{s}_1(t), \boldsymbol{s}_2(t), ..., \boldsymbol{s}_6(t)]^T$ where $\boldsymbol{s}_i = \frac{\sqrt{\boldsymbol{\lambda}_i}}{2\pi}$, with the $\boldsymbol{\lambda}$ being the eigenvalues in Eq. 8:

$$(\boldsymbol{K}_\alpha - \boldsymbol{\lambda}\boldsymbol{M})\boldsymbol{\theta} = \boldsymbol{0} \tag{8}$$

with a constant mass matrix where $m_i = 2$. To simulate the effect of EOVs on DSFs, the stiffness of the system is exposed to the temperature field $\boldsymbol{u}(t)$ shown in Fig. 3a. Additionally, stiffness k_2 and k_5 are exposed to random changes. The $\boldsymbol{K}_\alpha$ is the affected stiffness matrix expressed as:

$$\boldsymbol{K}_\alpha = (-\boldsymbol{u}(t) + C)\boldsymbol{K} \tag{9}$$

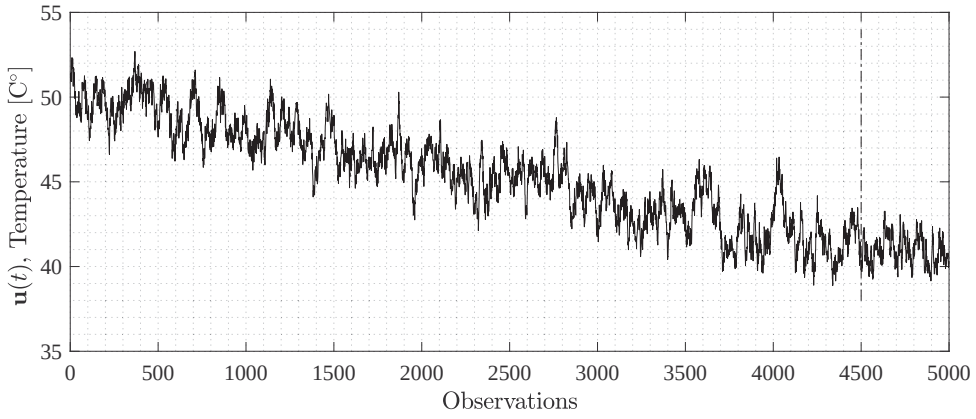
where C is a random constant value that maps the expression $(-\boldsymbol{u}(t) + C)$ to a positive value. For this study $C = 80$. $\boldsymbol{K}$ is the stiffness matrix that holds the k_i coefficients defined as:

$$k_1 = k_3 = k_4 = k_6 = 2 \tag{10}$$

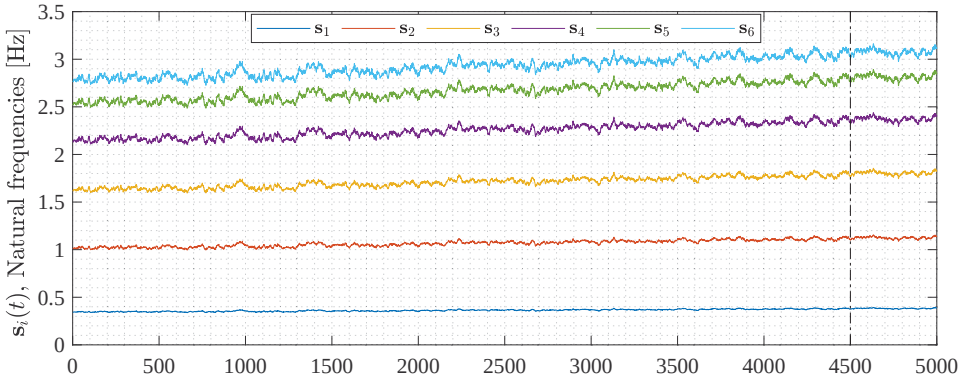
$$k_2 = 2r_2(t) \tag{11}$$

$$k_5 = 2r_5(t) \tag{12}$$

where $r_2(t) \neq r_5(t)$ are independent and uniformly distributed random values with $r_{2,5}(t)$: $[1 - \alpha > r_{2,5}(t) < 1 + \alpha]$ and $0 \leq \alpha \leq 1$. The eigenvalue problem is then solved M times, where M is the total amount of observations.



(a)



(b)

Figure 3: (a) Simulated temperature field $\boldsymbol{u}(t)$ and (b) the six extracted natural frequencies $\boldsymbol{s}_i$. The dashed vertical line indicates when damage is introduced.

In this case study, the eigenvalue problem is solved for a total of 5000 observations: The first 4500 observations are from a system in a healthy state and the remaining 500 refer to a system in a damaged state. The damage is emulated by decreasing k_3 by 2%. The summary of the number of observations used for semi-supervised learning is presented in table 1. To simulate

Table 1: Summary of observations used for training, testing and damage detection

Scenario	Stiffness reduction	Stiffness parameter	Number of observations
Healthy			
Training		-	1 to 4000
Testing		-	4000 to 4500
Damage	2%	k_3	4501 to 5000
Total			5000

the measurement noise, white Gaussian noise with 90dB signal to noise ratio is added to the natural frequencies. Observations 1 to 4000 were used for training. Both methods, ANN- and cointegration-based damage detection are tested using observations 4001 to 5000; of which the

first 500 are from the healthy state and the remaining from the damaged state. The performance, by means of area under the curve (AUC) of the receiver operating characteristic (ROC) and false alarm rate, of the damage detection methods is evaluated based on observations 4501 to 5000 where the damage is present.

3.1 The effect of EOVs

To illustrate the effects of EOVs, the MD-based damage index $d_t(\boldsymbol{f}_t, \boldsymbol{S})$ is calculated, where $\boldsymbol{S} \in \mathbb{R}^{6\times4000}$ and $\boldsymbol{S}$ is based on the first 4000 observations from a healthy system, see Fig. 4. The damage detection threshold is assigned based on 2% allowed outliers for the first 4000 observations. Evidently, the MD-based damage index follows a trend which hinders the discrimination between damage and EOVs.

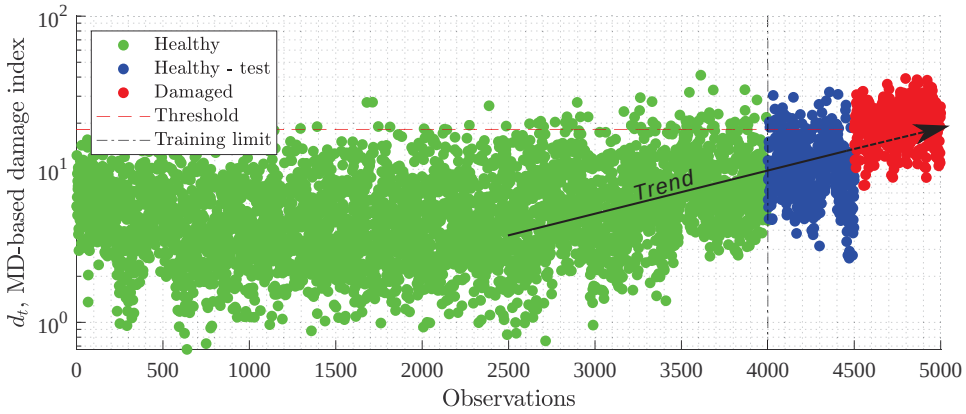


Figure 4: MD-based damage index for $\alpha = 0.15$

3.2 Mitigating the effect of EOVs

To train the ANN the prediction target is calculated by the MD-based damage index with $\boldsymbol{S} \in \mathbb{R}^{6\times500}$ representing the first 500 observations. The ANN is trained with observations from 501 to 4000 which are randomly shuffled. The hyperparameters for the ANN can be found in Appendix A. As shown in Fig. 5 the prediction deviates from the calculated MD once the stiffness reduction is introduced. The prediction error is calculated as per Eq. (3) and used as a new damage index shown in Fig. 6a.

In the cointegration-based approach, the first cointegrating vector that is associated with the highest singular value (i.e. the value that is associated with 'most stationarity') is used to project the natural frequencies into one stationary residual. Evidently the trend is removed as can be observed by comparing Fig. 4 to the cointegration results in Fig. 6b. Due to the additional local variabilities in the stiffness matrix, damage is not clearly separated from observations of the system in a healthy state.

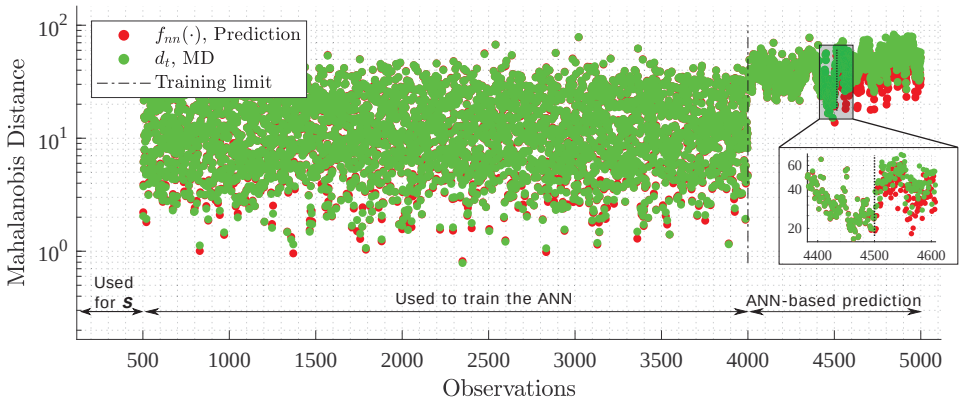

Figure 5: MD and predicted MD by ANN.

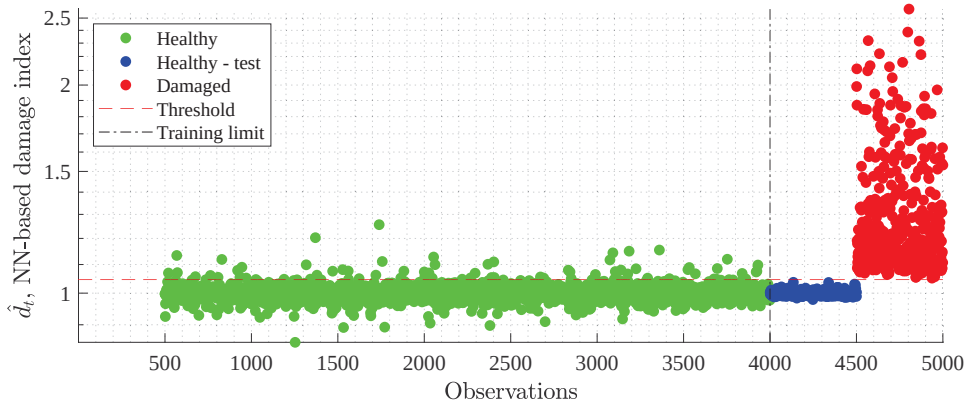
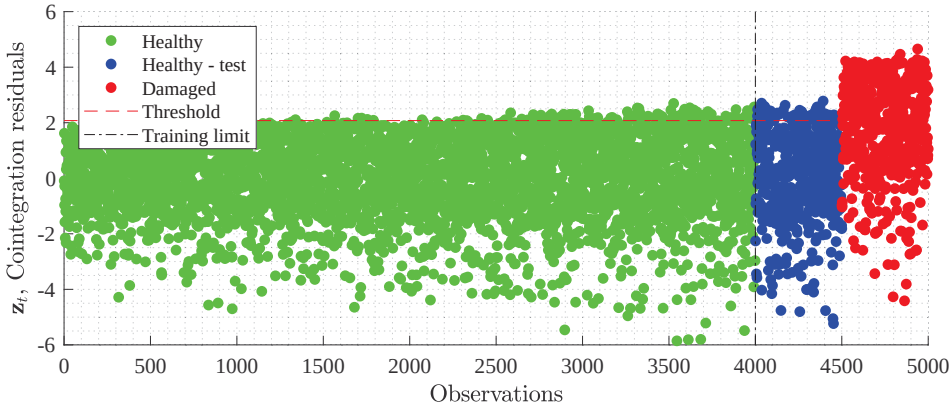


(a)



(b)

Figure 6: (a) The prediction error $\hat{d}_t$ using ANN calculated as per Eq. (3). (b) Cointegration residuals $\boldsymbol{z}_t$. Both methods are evaluated for $\alpha = 0.15$.

3.3 Evaluating scenarios with different local variabilities

Eight different scenarios are analysed with α ranging from 0 to 0.35 where $\alpha = 0$ indicates that no local random variabilities are added. By increasing the α value by 0.05 step-wise to 0.35

different scenarios of random variabilities in spring k_2 and k_5 are introduced. The performances of the methods are evaluated for their ability to first detect healthy-test observations, and second to detect damage. False alarm rates are calculated to evaluate the methods' ability to identify new healthy observations as healthy whilst the AUC of ROC is calculated to assess the performance rate of damage detection with respect to the healthy-test observations. The results are presented in Fig. 7.

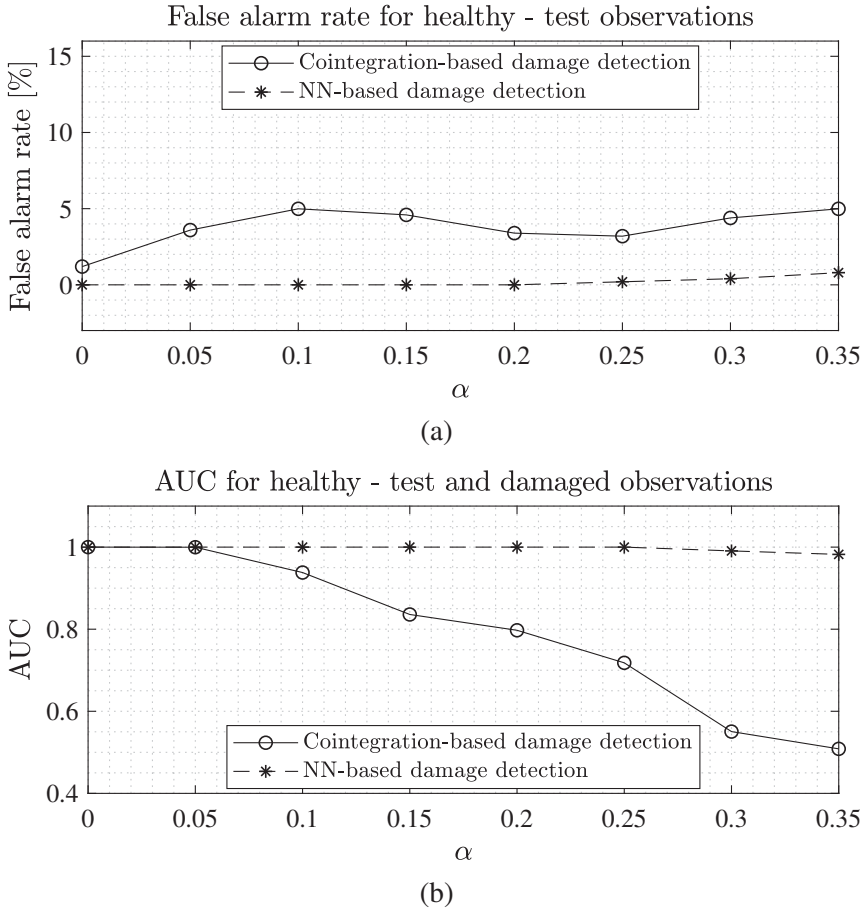


Figure 7: (a) Evaluating performance of the two methods by AUC and (b) false alarm rate for increased α values.

For $\alpha = 0$ the methods perform similar when evaluated by the AUC and false alarm rate. As the α increases, the results indicate a higher or equal performance rate in all cases for the ANN-based damage detection.

4 Discussion

The study demonstrates that both methods are capable of removing environmental trends. Although local variabilities are added to the mass-spring system, the false alarm rate for test observations does not exceed 5% for cointegration-based damage detection and 1% when applying ANN-based damage detection. These results are acceptable considering that 2% false alarm rate is allowed. Nevertheless, the AUC is approaching 0.5 in the case of cointegration when increasing the amount of local variabilities. Increasing the local variabilities does not affect the damage detection performance rate when applying ANN and the AUC is close to 1 in

all cases. The methods show similar results if no additional local variabilities are introduced. For this case, the cointegration approach is preferred due to its interpretability. However, if the mass-spring system is exposed to local variabilities in the stiffness, the ANN-based damage detection yield a higher performance rate by learning the pattern of EOVs for this particular case study. Nevertheless, there is a trade-off with the loss of interpretability inherent in this type of method.

Furthermore, this comparative study is limited to the six DOF mass-spring system defined in section 3 and requires further research. This field could benefit from two streams of research: one where the amount and location of variabilities are further investigated on a simulated system, and another where the methods are tested in real applications.

5 Conclusion

The work presented in this paper compared a novel ANN-based damage detection method in a semi-supervised framework to a well known cointegration approach for mitigating EOVs in damage detection. The methods were tested on a six DOF mass-spring system. The global stiffness of the system was exposed to a stochastic temperature field and additional random variabilities in two of the six springs. Both methods used the natural frequencies as DSFs and were evaluated for their capability to identify healthy-test observations and the emulated damage in the system. Comparing the performance of the two methods on a system exposed to EOVs, the ANN-based damage detection yielded a higher performance rate in terms of AUC and false alarm rate.

Abstract. *At the Bundesanstalt für Materialforschung und -prüfung (BAM) full scale specimens for nuclear transport and storage containers (casks) are tested for their structural integrity in a series of drop tests on the Test Site Technical Safety in Horstwalde, 50 km south of Berlin. These drop tests cause a major stress not only on the casks, but also on the steel tower structure of the test facility, itself. The load pattern makes the structure very interesting for detailed investigation. The focus of the monitoring lies on the bolted joints of the flange connections that are a typical connection for cylindrical elements if welding is technical or economical unfavorable. The definition of the monitoring takes was done by investigating the existing documents and inspection results accompanied by building an initial digital representation of the structure, consisting of two finite element (FE) models and a geometrical 3D point cloud representation. As a first step the structures behavior during static and dynamic loading was analyzed using measurement data and an updated numerical FE Model. The idea behind is to use models for a digital planning and operation/evaluation of the structural health monitoring. A static FE simulation and a dynamic FE simulation are generated, to investigate how the structure behaves under the load conditions.*

1 INTRODUCTION

At the Bundesanstalt für Materialforschung und -prüfung (BAM) full scale specimens for nuclear transport and storage containers are tested for their structural integrity in a series of drop tests on the Test Site Technical Safety in Horstwalde, 50 km south of Berlin. These tests are realized by means of the 200 t drop test facility that was put in operation in 2004 [1]. Since 2004 drop tests were done with varying drop weights up to 180 t. These drop tests cause a major stress not only on the containers to be tested, but also on the steel tower structure of the test facility, itself. During a drop test the tower structure is affected by three load conditions: quasi-static increasing load of the structure until the container left the ground, transient dynamic release of the load and the impact of the container on the target causing ground vibrations with reactions in the tower foundations as well.

The operational loads are below any critical limits for the structure according to the standards that were considered during the design of the structure. However, it is a matter of concern if the unique loading of the drop tests is covered adequately by the considered design procedure, especially for tests with low drop heights. The load regime of the tower is very well known for each drop test. After almost 16 years of operation a details inspection of the structure revealed a loss of the tension in some of the prestressed bolted joints that are fastened with more than 1000 high-strength prestressed bolts of the strength class 10.9. The required scheduled maintenance made it possible to investigate the structures behavior and to start a continuous monitoring by installing a structural health monitoring system (SHM) for the identified deficiencies. The goal of this research is to define a proper workflow for the implementation of a digital twin monitoring task for a well-defined aspect of an existing structure. The focus of the monitoring lies on the bolted joints of the flange connections that are a typical connection for cylindrical elements if welding is technical or economical unfavorable. The definition of the monitoring takes was done by investigating the existing documents and inspection results accompanied by building an initial digital representation of the structure, consisting of two finite element (FE) models and a geometrical 3D point cloud representation. The idea behind is to use models for a digital planning and operation/evaluation of the structural health monitoring. A static FE simulation and a dynamic FE simulation are generated, to investigate how the structure behaves under the load conditions.

The contribution deals with the introduction of this highly interesting dynamically loaded structure, a presentation of test results and related numerical simulation as well as with the conception and implementation of a SHM system.

2 DROP TEST TOWER STRUCTURE AND OCCURRENCES

The large drop test facility consists of a 36 m high drop tower of steel pipe construction; at the top of this tower is a small cabin with a 200 t hoist, with a maximum hook height of 30 m. Below this drop tower is a 24 m x 20 m integrated test hall (steel frame construction independent from the drop tower) with an 80 t portal crane, rolling gates and a roof that can be removed if a cask is connected to the hoist. The impact pad is constructed as an unyielding target realized by reinforced concrete block with dimensions 14 m x 14 m x 5 m depth, with a mass of 2,600 t, and with an impact pad made of steel plates 10 m x 4.5 m x 0.22 m connected to the target with anchor bolts. This construction fulfills the requirements of the International Atomic and Energy Agency (IAEA) [2]. Figure 1 shows the complete drop test facility and the special container detachment device that was designed by BAM to ensure a momentum free release of the specimen. Its construction is based on a hydraulic mechanism rupturing a steel bolt.
The construction of the facility was finished in August 2004 with the static overload test of the whole lifting equipment by lifting weight of 250 t.

Figure 1; BAM Drop Tower at Test Site Technical Safety (left), container detachment device (middle) and overload test (right).

In 2018, after 16 years of operation a regular inspection of the facility found loose bolts at the crane way. For this reason, a detailed inspection of the global structure with specific investigations of the high-strength prestressed bolts at the tower structure was initiated. A selection of seven high-strength prestressed bolts at relevant steel connections of the structure have been examined. The bolts have been unscrewed and the release torque has been measured. Four of the seven bolts showed a reduced released torque. The reasons for the occurrences were not very clear, but dynamic loads induced by more than 150 drop tests performed seem to have an important effect on the prestressed joints of the tower construction. The typical connections at the structure are flange joints and gusset plate joints, see Figure 2.

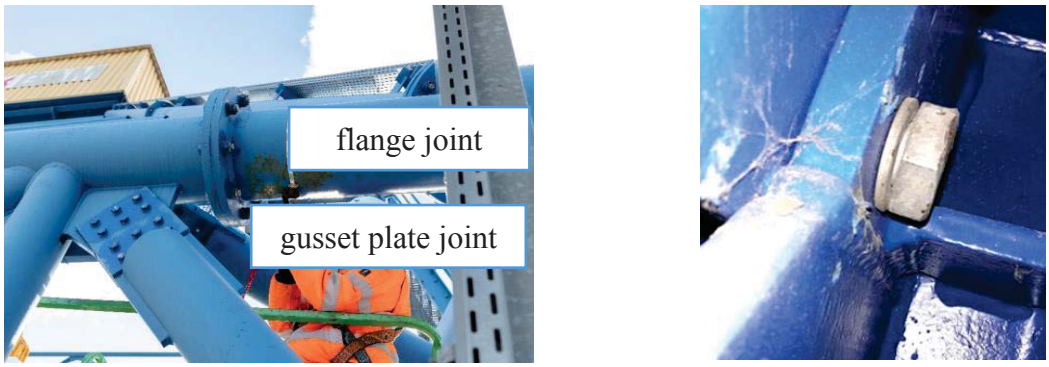

Figure 2: Joints at the tower construction(left) and loosen bolt at one joint (right)

The actions derived from the inspection was to replace the loosened bolts and to develop a monitoring strategy that continuously observes the structure during all operating conditions.

3 DEVELOPMENT OF A MONITORING STRATEGY

The goal for a structural health monitoring is to deliver precise and updated measurements and information of the structure that can be used to asses and predict the current structural condition of the monitored aspect and supports the upcoming inspections with additional insights. The typical process of the design of a monitoring system, like in [3], has been applied but expanded by the implementation of digital models from the start of the design process, see Figure 3.

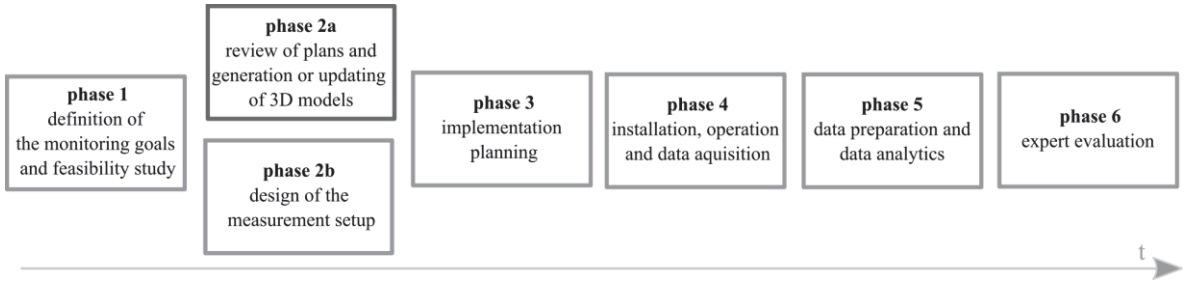

Figure 3: Systematic process of the implementation of a structural health monitoring, according to [3] with an additional process of generating or updating 3D models

In parallel to the design of the measurement concept several digital models of the structure have been developed. The models were several implicit and explicit FE models and BIM model extracted from a 3D point cloud. These models were used to organize the existing data from the visual inspection and from the drawings and to develop a better general understand of the static and the dynamic behavior of the structure and substantial helped to plan the monitoring setup and place sensors. The models were used during the installation phase as planning documents for the monitoring as well as the installation documentation.

The concept of the monitoring covers the following objectives to assess the structure under the testing loads with a long-term monitoring system, see 1. To cover all this monitoring objectives six monitoring tasks with a specific sensor layout has been planned and later realized at the drop tower of BAM, see Table 2.

1	global static behavior	
	1-a	static deflection behavior of the structure under load
	1-b	influence of the temperature distribution on thermal stress
2	pretension losses of the bolts	
	2-a	long term pretension losses
	2-b	pretension losses due to drop tests
	2-c	transient bolt prestress force variation during a drop test
3	dynamic vibration characteristics	
	3-a	structural damage detection based on ambient vibration behavior
	3-b	transient vibration pattern of tower and tower foundation during a drop test
4	comparison to FE models	

Table 1 Identified objectives for the SHM of the BAM drop tower

The monitoring task M covers the metrological conditions of the drop tower. The wind speed, wind direction and the air temperatures at the top and the middle of the tower are continuously measured. On the north facing side of the tower along the southern tower leg, which is full exposed to the sun light, the surface temperature of the steel is measured. In addition, halfway up on all four tower legs, the temperature is measured, too. By the combination of both setups a horizontal and a vertical temperature gradient can be calculated. The detailed temperature measurement is also necessary for an additional temperature compensation of the strain measurements of monitoring task RF and all temperature related effect on the structure, the sensors and the algorithms. The monitoring task RF wants to evaluate the thermal strain at the four corner brackets where the vertical tower legs snap off into the pyramid ridge. This position is

expected to be most influenced by the thermal stress. At each tower leg four strain gauges are installed along the circumference of the steel tube below the corner bracket in longitudinal direction. This setup allows to recognize longitudinal strain due to the test loads but also temperature induced bending strain. The monitoring task RF also deals with the dynamic response of the tower. Together with additional strains gauges at the tower legs near the tower foundations the compression waves that travel through the structure caused by the cask release and the impact on the test foundation during the drop tests will be recorded with a high sampling rate. Especially for low drop heights, the release impulse and the impact impulse can superposition, as the release impulse in independent from the drop height.

monitoring task M (meteorology)	monitoring task G (global deformation)	monitoring task SVD (dynamic bolt pretension)
		temperature sensor wind speed / direction	position captured by 3D point cloud displacement sensor	force washer

monitoring task RF (thermal stress)	mon. task SSDD & BD (dynamics & damage detection)	monitoring task SVS (static bolt pretension)
		strain gauges setup of 4 single strain gauge	biaxial accelerometer uniaxial accelerometer uniaxial geophone	ultra-sonic force transducer
1-b, 2-a, 3-b, 4	3-a, 3-b, 4	2-a, 2-b, 4

Table 2: Overview of the sensor setup for each monitoring task and the related monitoring objective

The structural dynamics under ambient excitation (e. g. wind) are periodically recorded to identify possible changes in the vibration characteristics that indicate a possible damage by stochastic subspace damage detection, see [4] and with special regard to an uncertain reference, see [5]. The damage detection of monitoring task SSDD relies on four biaxial accelerometers, one at each pyramid ridge. During the drop test additional accelerations are measured in the crane house (triaxial), the test foundation (uniaxial) and vibration velocities at the tower foundations with geophones (monitoring task BD). This data can be evaluated by probabilistic methods, like [6] or robust modal analysis algorithms, like [7].

The main interest based on the observation from the tower inspection is the loss of pretension in the high tensile prestressed bolts. The long-term monitoring is carried out by an ultra-sonic monitoring system that records the tension of eight bolts at the flange joint at the corner bracket every 10 minutes (monitoring task SVS). So, it is possible to compare the bolts condition before and after a drop test and the long-term behavior. The force washers of monitoring task SVD are an independent system for the pretension measurements with a much higher dynamic and time resolution so that the transient forces of the drop test can be recorded. This conventional force measurement has the drawback of a quite large influence of the bolt connection, because much longer bolts are needed and it acks like additional washers in the connection. The ultra-sonic pretension measurement of SVS preserve the native connection that's used in all the flange joints at the corner brackets. Regarding the temperature effects and the prestress development both systems can be compared by symmetrical installed measurement bolds at different tower legs.

The monitoring task G observes the global deformation behavior of the structure in a single measurement campaign, where a laser scanner was used two-fold: First, to obtain point clouds of the whole structure under investigation to yield information to create a digital twin. Therefore, several static positions were used to obtain 3D point clouds, which were in the analysis referenced in a unique coordinate system by means of artificial targets. Second, a 3D point cloud by a single position was acquired during a specific load scenario of the structure. In detail, 3D point clouds for two epochs were acquired: the zero epoch without any load and the epoch under a specific load. This acquisition setup supports the estimation of deflections with a focus on the vertical component to learn about the impact of the load on the behavior of the structure. In literature can be found similar experiments for, e.g., infrastructure objects like bridges, see [8] and [9]. A long-term measurement of the deflection of the tower under test loads and temperature influences by means of an optical distance sensor will follow.

4 DIGITAL TWIN CALIBRATION AND MEASUREMENTS

The concept of a digital twin is multidisciplinary method for a comprehensive physical and functional description of an engineering component, system or network in all phases of the lifecycle beginning from the draft to the dismantling including all information that can be useful in each lifecycle phase. Special interest lies in the operation phase where inspection tasks can be optimized by fusing simulated system behavior and failure predictions with real world input parameters and system responses. For civil engineering the verification of the real operation condition, especially in a probabilistic way, like in [10] is an essential task during the long service lifetime of decades.

An efficient 3D object capturing to yield a digital representation or digital twin of nearly arbitrary objects can be realized by using a laser scanner. Millions of single, spatial closely distributed 3D points represent the object of interest. These so-called 3D point clouds carry next to the spatial information, information about the reflectivity by backscattered intensity values and optional color values obtained by a -nowadays- integrated digital camera.

The working principle of the laser scanner is according to the polar measurement principle. This is characterized by an immediately 3D dimensional, direct centric data acquisition with a high spatial resolution of a few millimeters. The most important characteristics of laser scanner is the area-based object acquisition by a remote position, thus no need to directly access the object under investigation since the range measurement is performed reflectorless. There is not special need for a specific structure on the object as if it is mostly necessary for a photogrammetric data acquisition. Supported by the area-based acquisition a proper data analysis is able to deliver information about deformations ranging up to one digit millimeter level.
The 3D point cloud of an existing structure can be converted into a reduced digital model, which can be a BIM model for a specific BIM platform. Although mainly used for the design, planning and construction in the BIM context the common data environment (CDE) fulfils this requirement of a single source of truth (SSoT) and allows the interchangeability of the model information, and enables continuous updating of information based on a central data hub between all involved specialist, see [11]. The CDE seems to be the data resource for the Digital Twin in civil engineering and can be extended to be used by artificial intelligence for machine learning to generate, train, validate and evaluate machine learning models on the provided data.

Figure 4: Geometrical representation as a 3D point cloud of the drop tower (left) used for planning of the SHM and the modelling of FEM and top view situation of the laser scanner setup (right).

For this monitoring project, the 3D point cloud was prototypical used as a CDE for the drop tower, see Figure 4, to evaluate benefits at the following project phases. At the design phase (2b) of the monitoring setup it reflected the as-built situation of the tower and was used to clarify the geometry for the development of FE models and BIM models. The inspection documentation of the bolts was added to the point cloud to get a better insight. During the implementation planning (3) all installation positions, cable lengths and geometrical constrains were cross-checked. In the installation phase (4) the models helped to locate correct positions and keep installation specific data, which is very beneficial to contribute to high data quality, see [12]. This easily accessible data is relevant for the currently ongoing data preparation and analytics phase (5), where the dynamic response of the structure is simulated by time integration numerical analysis in an optimized complexity. Further motivation for establishing numerical analysis lies in the requirement to identify the locations as well as the magnitude of the peak stress values during drop tests to reliable assess the structural safety of the drop tower (6).

4.1 Model

The numerical analysis of the drop tower was performed using a three-dimensional model, developed in ANSYS® software in its version 2019R2. Figure 5, left shows a global view of the drop towers model. The space frame elements of the tower were modelled with beam elements,

taking the pipe cross-sectional parameters into account. For the gusset plates at the structural connections shell elements were chosen to sustain realistic stiffness relations. All structural dimensions as well as material parameter were taken from construction plans. All six support conditions at each of the four foundations were modelled as springs. Concentrated masses, especially the winch on the top of the tower, were modeled as point masses. The described approach with applying beams for the framework ensures a corresponding limited number of degrees of freedom for a sufficiently accurate image of the global dynamic behavior of the structure as well as a limited computational effort executing time integration analysis.

4.2 Model verification by static load test

Preparing numerical simulations, the quality of the model should be verified, i.e. by assessing the accuracy of simulation results comparing them with measured counterparts. In the case of the analyzed drop tower especially the stiffness parameter should have been under investigation. A simple but effective method for verifying the global structural stiffness is a static load test where measured deflections with the computed ones. Here, as part of a periodic routine examination of the winch braking system a 200 t nominal lift test was executed and used as a load test, see Figure 1. The deflection of the top of the tower just beneath the winch housing was measured using tachymeter. In Figure 5, right the computed deflection of the structure is displayed. For the position of the tachymeter reflector the computed deflection is d = 11.05 mm[1], which is very similar to the measurement, see Table 3. This shows a very good conformity of the model's global stiffness with those of the real structure.

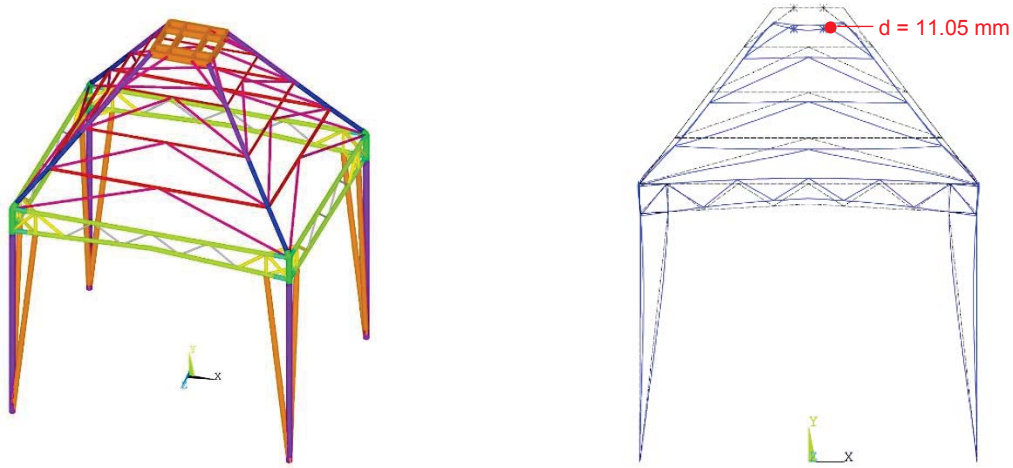

Figure 5: Numerical simulation of the drop tower, left side: ANSYS® model, right side: simulation result of the 200 t load test

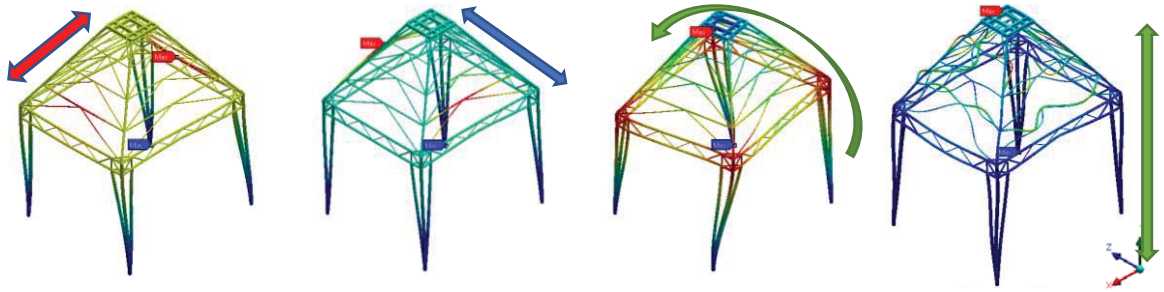
test no.	lifted mass [t]	deflection [mm]
1	0	0.0
2	200	11.2
3	195	10.5
4	0	0.0

Table 3 Deflection of the tower in y direction measured with a tachymeter during the load test

[1] For the tachymeter reflector is not applied on a structural member, the simulated deflection is determined by interpolation.

4.3 Model verification by modal values

Besides the stiffness distribution, for numerical simulations of the dynamic structural behavior it is essential to verify the correctness of the dynamic model parameter. The classic approach for analyzing the accuracy of the numerical model consists in the comparison of the modal parameters, representing the dynamic characteristic of the structure and the model alike. Besides comparing measured with computed eigenfrequencies it is especially the mode shapes which emphasizes differences between the model and the real structure. In the scope of this contribution by now the extensive dynamic measurement campaign has not been executed yet, so a distinguished set of mode shapes cannot be presented here. For that reason, the focus of modal analysis lies on the comparison of the eigenfrequencies. Nevertheless, Figure 6 shows a compilation of global mode shapes and the corresponding eigenfrequencies for modes up to 10 Hz.



$f_{x,sim}$ = 1.21 Hz	$f_{z,sim}$ = 1.24 Hz	$f_{rot,sim}$ = 2.02 Hz	$f_{y,sim}$ = 10.2 Hz
$f_{x,meas}$ = 1.16 Hz	$f_{z,meas}$ = 1.27 Hz	$f_{rot,meas}$ = 1.98 Hz	$f_{y,meas}$ = 9.96 Hz

Figure 6: Selection of global modes

4.4 Model validation by simulation of drop test

For numerical simulations of the impulse induced dynamic answer of the drop tower, especially in the context of the here described investigations on its damage behavior it is essential to validate the damping and inertial parameter of the model.
Therefore, drop test were simulated using transient (time integration) analysis. For comparison, the measured time histories of accelerations, velocities and deflection during a drop test were used.
Within the validation analysis of the numerical model several parameters where analyzed for their influence on the dynamic answer of the tower impulse loaded by releasing the test body. For comparison, a past drop test with a 182 t test body was chosen. The study confirmed that, beside damping components, especially the duration of the impulse has a major influence on the analysis result. The test body releasing device is designed in a way, that the impulse duration is extremely small. But, the impulse time is also significantly affected by the rope elongation and so by the height of the drop event. Since detailed information about the rope were not at hand, a simple proportional relation between drop test height and impulse time was deployed and used for the model validation.
With the described structural and loading parameters a 182 t drop test was simulated. The sampling (response computing) frequency was set to 200 Hz. Figure 7 shows the simulated acceleration and velocity time history plots. The graphs show an adequate similarity of the magnitudes. For acceleration the values are similar, for velocity the simulated values are slightly higher than the measured and for the deflection magnitudes of both graphs are similar again. Compared to the measured accelerations and the deduced velocities the simulation result

is satisfying. Observing the decay behavior of the vibrational answer, it is obvious, that the damping is significantly higher in nature than in the simulation. Here a more sophisticated consideration of damping parameter in the model will improve the case. Noticeable is a second excitation in the real measurement after approximately 1.5 seconds. This is due to the impact of the test body on the ground plate and the transmission of that impact to the tower foundations.

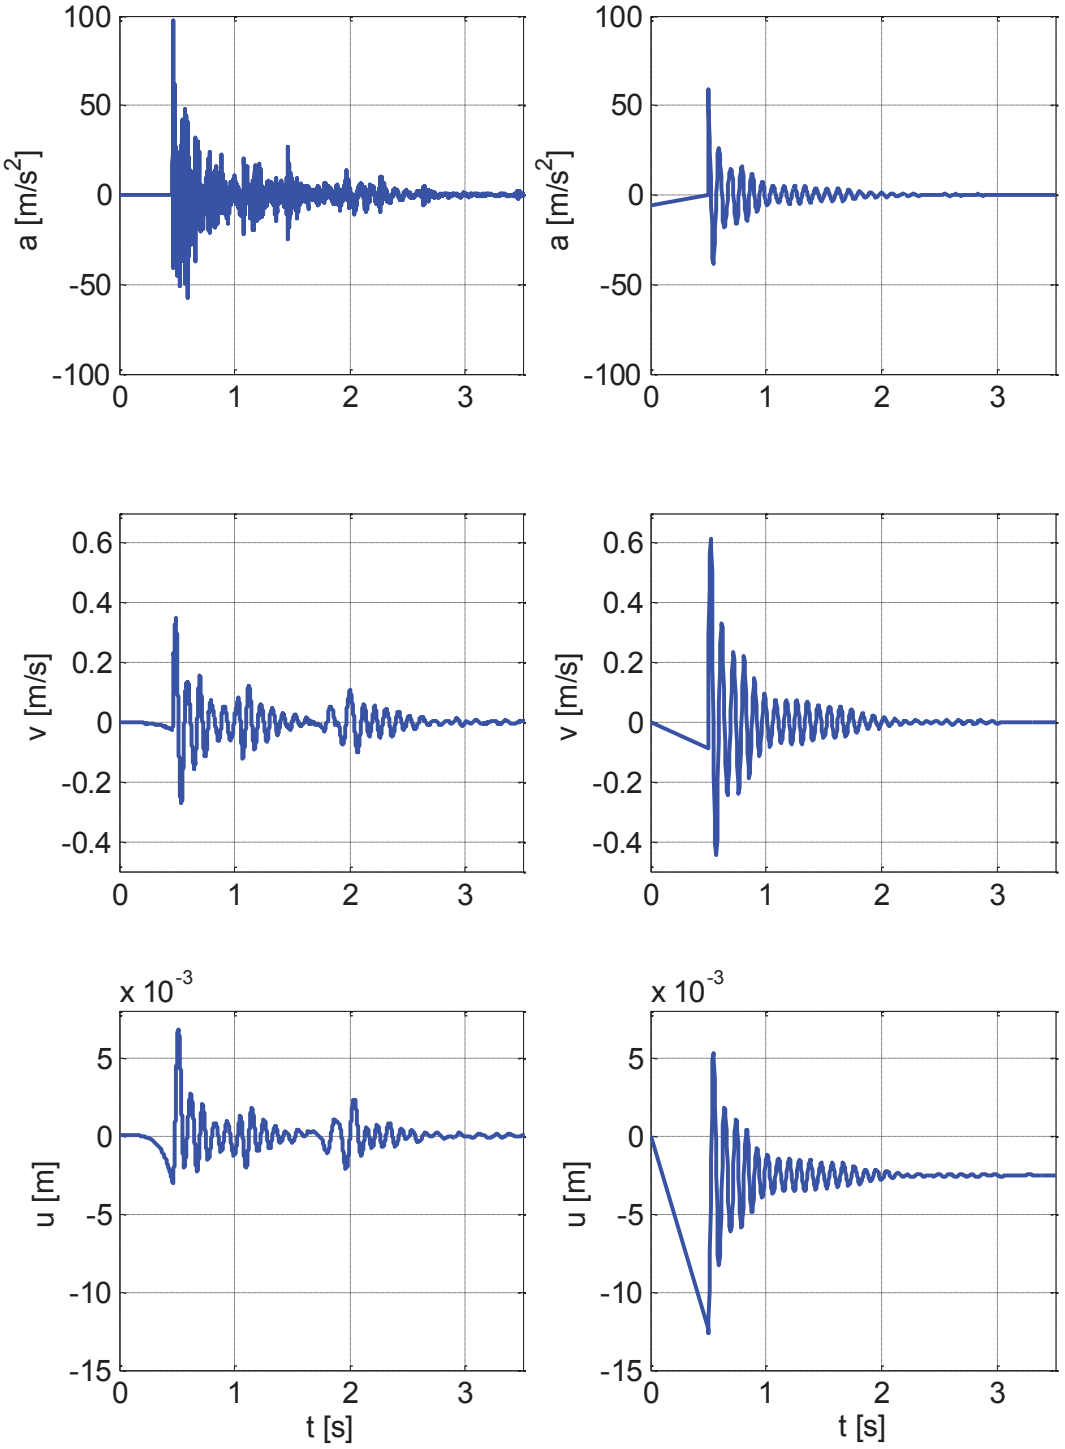


Figure 7: Time history of acceleration, velocity and deflection after a 182 t drop test event, left: measured data and right: simulated data.

5 CONCLUSIONS AND OUTLOOK

In this contribution the planning and the implementation of a structural health monitoring for the large drop tower of BAM by enhancing the standard process with digital models is presented. The models were used in all phases of the structural health monitoring process. The workflows aren't natively implemented in software (BIM, FE, data acquisition software), yet. The quality and the workload can be improved using digital models, especially the traceability, accountability and reproducibility of the results that are valuable for scientific and non-scientific applications. Currently the long-term monitoring of the drop tower just started and results from an upcoming first drop test at the large drop tower will be evaluated, soon.

ACKNOWLEDMENT

The authors would like to thank BAM for its financial support and the BAM personnel for the extraordinary dedication.

Keywords: Negative Selection Algorithm, Masonry Arch, Damage Detection.

Abstract. *The early-stage identification of structural damage still represents a relevant challenge in civil engineering. Localized damages if not readily detected can lead to disruption or even collapse, involving hazard to people and economical losses. Although the final goal of the identification is to localize and quantify the damage, a reliable discrimination between normal and abnormal states of the structure in the very early stage of the damage onset is not an easy task. In the field of Structural Health Monitoring (SHM) great attention has been paid to the development of damage detection methods based on continuous and automatic registration of the system response to unknown ambient inputs. The numerical algorithms exploited must be: (1) easy to implement and computationally inexpensive, eventually being embedded in the sensors; (2) as much independent on human decision as possible; (3) robust to the many sources of uncertainties affecting the monitoring; (4) able to detect small damage extents in order to provide an early warning; (5) suitable for the application in the case of few and sparse measurements collected only in the normal condition. The performance of a novel version of Negative Selection Algorithm, recently developed by the authors, is here analyzed with attention to these issues. The algorithm is tested against data collected on a segmental masonry arch built in the laboratory of the University of Minho and subject to progressive lateral displacement of one support.*

1 INTRODUCTION

In the context of Structural Health Monitoring (SHM), the Damage Identification (DI) and the early warning in case of damage onset are essential to support any engineered system management. Following the Rytter's hierarchy[1,2], the DI process can be summarized according to five main goals of increasing complexity: (1) Detection of existence; (2) Localization; (3) Classification of the type; (4) Quantification of the extent; (5) Prognosis. Such a hierarchical structure requires that all the lower levels are available before attempting a higher level of information. Thus, the detection of existence is the first basic step that a monitoring strategy must fulfil but, in many cases, it is a complex problem to address.

The SHM theory is based on the existence of a function *f* such that:

$$\boldsymbol{x} = f(\boldsymbol{y}, \boldsymbol{v}) \tag{1}$$

where $\boldsymbol{x} \in \boldsymbol{X}$ is a vector whose elements are all the features of the engineered system (e.g. a structure or infrastructure), $\boldsymbol{y}$ is a vector that describes the condition of this system and $\boldsymbol{v}$ is a vector which accounts for the environmental and operational variables that affect the system features. In damage detection, the state vector $\boldsymbol{y}$ is a binary variable, namely $\boldsymbol{y} \in \{Nonself, Self\}$ or $\boldsymbol{y} \in \{1,0\}$. The goal is the discrimination between a normal '0' and an abnormal '1', potentially damaged, state of the system. Each feature vector $\boldsymbol{x}$ is a point of a multidimensional domain called input space, namely the space of the domain of each single feature of the vector. The DI task aims at assessing the system state by analyzing the values assumed by the features. One of the main issues to tackle consists of the feature selection. Indeed, out of the potentially infinite features of the engineered system, whose domains might also be infinite, the detection is carried out on a scalar valued space called feature space $\boldsymbol{F} \subseteq \boldsymbol{X}$ [3]. Thus, the points $\tilde{\boldsymbol{x}} \in \boldsymbol{F}$ are the projection of the points $\boldsymbol{x} \in \boldsymbol{X}$, from the original input space to a space with reduced dimensionality. This process reduces the time requirement and the complexity of the problem, but also reduces the information content of the feature vector, including its sensitivity to damage. A proper selection should aim at identifying features such that:

$$\tilde{\boldsymbol{x}} = f(\boldsymbol{y}) \tag{2}$$

In other words, the selected features must have a high sensitivity to the system condition $\boldsymbol{y}$ and a negligible sensitivity to operational and environmental variables $\boldsymbol{v}$.

Mathematically, the damage detection can be treated as a classification problem: given a point in the feature space related to a new acquisition of the monitoring system, assess whether the system continues in its normal state or shows an abnormal behavior. Thus, the goal is to define a classifier, namely an approximation of the inverse function:

$$\boldsymbol{y} = f^{-1}(\tilde{\boldsymbol{x}}) \tag{3}$$

This approximation is based on a set of known pairs $\langle \boldsymbol{x}, \boldsymbol{y} \rangle$, i.e. a set of pre-measured samples. The nature of such pairs further complicates the damage detection problem as, normally, the only information available is for the system in normal condition, namely all the pairs are like $\langle \boldsymbol{x}, 0 \rangle$. This is a one-class classification problem which can be addressed only through few machine learning algorithms. The present study aims at discussing how a learning algorithm can be applied to real field testing data. A deterministic version of the Negative Selection Algorithm (NSA), developed by the authors of this work and preliminarily tested on other case studies with simulated data [4–6], is here employed making use of the vibration signals collected during a laboratory experimental campaign. The methodology is applied for the first time to a real case study under progressive damage scenarios. After describing the fundamentals of the algorithm in section 2, the structure object of investigation is presented in section 3.1. Then, the methodology to tailor the algorithm to the specific case study is discussed in section 3.2 followed by the description of the numerical tests used for the algorithm validation.

Based on the results, possible improvements to the methodology are provided in section 3.3. Finally, the main conclusions drawn from the work are summarized in section 4.

2 DETERMINISTICALLY GENERATED NEGATIVE SELECTION ALGORITHM

NSAs are a family of algorithms based on a minimal common framework, initially developed by Forrest et al. [7] and later improved with additional contributions [18,19]. The complete framework of the process underlying the NSAs is composed of several steps that are collected in three main consecutive stages: (1) Representation; (2) Censoring; (3) Monitoring.

The first stage is an overhead operation consisting in the definition of the feature space and the coding of the data set. In this stage, the *n* features are projected onto a unitary space $U=[0,1]^n$. To take into account the emergence of measurements that fall outside the range that is known during the training, such a range is increased by 20%. Future samples that fall outside this enlarged range are automatically labelled as damaged. It is also assumed that the unitary space is divided into two complementary subsets, Self and Nonself, such that:

$$Self \cup Nonself = U \qquad Self \cap Nonself = \emptyset \tag{4}$$

During the so-called censoring stage, the NSA analyses the training data set in the feature space to generate the detectors. The detector set is the tool used for anomaly detection, being a set of elements which covers and identifies the nonself portion of the space. Finally, in the monitoring stage, the new feature values, extracted from the system under analysis, are matched against the trained detectors, which bind to the ones that are likely to belong to an anomalous behavior of the system. The version of NSA used in the present study is called deterministically generated (DNSA), since the detectors are not randomly initialized before being matched against the training samples, but they are placed onto the unitary space according to a regular grid of given size. In order to reduce the time requirement and the complexity, the detection is carried out in a 2-dimensional feature space. Indeed, in Structural Health Monitoring for civil engineering systems, it is common to analyze the structural behavior in terms of correlation between pairs of variables (for instance temperature/first frequency, temperature/second frequency, etc.) [10,11].

3 APPLICATION AND VALIDATION THROUGH REAL VIBRATION DATA

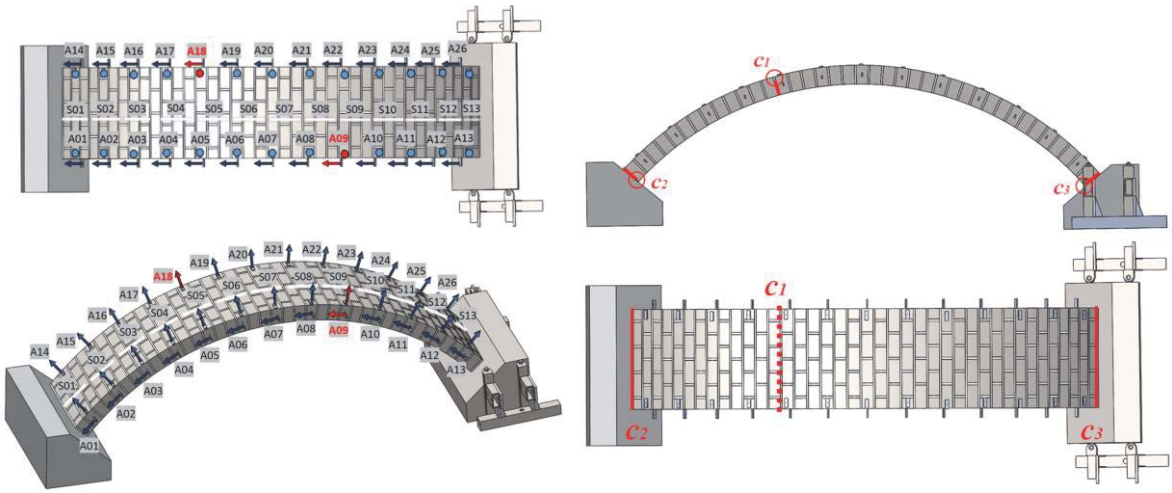
3.1 A masonry arch as case study

The case study used to apply and validate the DNSA algorithm is a small-scale segmental masonry arch (Figure 1) built and tested in the structural laboratory of the Institute of Bio-Sustainability of the University of Minho (Guimarães, Portugal) in order to investigate the effects that support settlements may have on the dynamic behavior of masonry arch bridges. The specimen consists of four rows of 39 brick units (100x75x50 mm3) assembled with staggered lime mortar joints. It has a nominal span of 1900 mm, a springing angle of 40°, a nominal net rise of 430 mm and radial thickness of a 75 mm. Two lime bags of 25 kg each are symmetrically placed on the extrados to simulate the effect of backfill material [12,13].

The structure is supported by two concrete abutments. The left support is fixed to the floor, whereas the other one is allowed to move in horizontal direction through a simple sliding system. Progressive damage is induced by applying, in 5 steps, controlled and uniform increasing displacements to the movable support through a hydraulic jack. After each step, a dynamic identification test is carried out using the ambient noise as source of excitation. The vibration response of the arch is acquired through 8 accelerometers (model PCB 393B12, 0.15 to 1000 Hz frequency range, 10000 mV/g sensitivity, 8μg resolution) of which four are kept fixed and four are moved according to 12 consecutive set-ups, allowing to record the response of 26

measurement points in normal direction and 26 in tangential direction (Figure 2a). This provides a set of 96 acquisitions for each scenario: 48 from the moving accelerometers and 48 from the reference ones. The signals are sampled at 400 Hz for a minimum duration of 180 s, resulting in 72.000 data points per channel.

Figure 1: Configuration of the specimen.



(a) (b)

Figure 2: Test setup and crack pattern: (a) distribution of measurement points and accelerometers (A01 to A26); (b) location of settlement-induced cracks.

Aiming at detecting the damage in the very early stage, only the first two damage scenarios (corresponding to 0.4 and 0.5 mm of incremental displacement, respectively) are considered. After the first step, three cracks start to appear (Figure 2b): *c1* at the intrados, in the left region of the keystone; *c2* at the extrados of the left springing (fixed support) and *c3* at the extrados of the right springing (moving support). The outset of cracks induces a considerable drop of the structural stiffness which is clearly reflected by the downshift of the main natural frequencies of the arch (particularly for modes 1, 4 and 5).

Table 1 reports the dynamic identification results provided by the SSI-UPCX estimator [14] in terms of averaged frequency values for all meaningful vibration modes. In order to test the algorithm in unfavorable conditions, the classification is performed by analyzing the values of the second and third natural frequencies, whose variation between scenarios is the smallest. The test is carried out under constant environmental conditions. For each frequency,

the dataset is composed of 96 values extracted through peak-picking directly from the power spectral density of each acquisition. It is worth noting that the ambient vibrations are weak, and the response signals have a low signal to noise ratio, making the second frequency peak not clearly distinguishable. Nevertheless, it is interesting and reasonable to test the damage detection strategy against a dataset affected by such ordinary sources of uncertainties.

Scenario	Frequencies [Hz]				
	Mode 1	Mode 2	Mode 3	Mode 4	Mode 5
Reference (D0)	30.06	50.95	59.44	95.23	120.62
Damage 1 (D1)	26.31	50.28	59.04	80.47	113.16
Damage 2 (D2)	23.4	48.86	58.14	75.75	111.44

Table 1: Arch eigenfrequencies variation over progressive damage scenarios.

3.2 Training, validation and monitoring

The classifier design and application are divided into three stages: (1) training; (2) validation; (3) monitoring. The latter step is the actual assessment of the system through the analysis of new measurements. The first two steps, instead, are offline preliminary tasks necessary to generate the classifier and tailor it to the specific case study. The training requires a set of samples that are fed to the DNSA to generate the detectors. As mentioned before, in one-class classification problems, the samples belong only to one class (e.g. the self space or normal state). In order to keep some of the collected self data for the validation and the monitoring, out of the 96 records, 50 points are randomly selected to form the training set.

Each algorithm version requires the definition of a set of inner parameters, the so-called parameter setting. Once these parameters' value is fixed, a specific algorithm instance is determined. Different settings lead to different detectors sets and different performances. Thus, the parameter setting consists in comparing different algorithm instances. The parameters are analyzed as controllable variables which assume in their domains different values called levels [15]. The comparison must be cast into a statistical design of the experiment (DOE) and analyzed in terms of a reliable performance metric. Considering the possible outputs of the detection, only two families of errors are possible: false positive (FP), namely normal samples classified as abnormal; and false negative (FN), namely abnormal samples classified as normal. Experience demonstrated that the trend of FPs and FNs for different parameter settings is inverse. Thus, it is not possible to reduce one family of errors without increasing the other and the performance metric should take both into account. When dealing with one-class classification problems, this issue is quite complex because only one type of samples is known, thus the only possible inference is on the number of FPs. In [6] the authors developed a methodology based on the artificial generation of outliers of the normal samples' distribution. The same methodology is here applied, so the classifier can be validated against known self samples and artificial nonself samples, referred as outliers. Three are the main parameters that affect the DNSA performance: (1) number of divisions of the side of the unitary space, which is directly related to the detector radius, r_{det}; (2) self radius, r_{self}; (3) censoring distance, *Cens.dist*. The latter is a qualitative parameter that depends on the values of the other two. Thus, a three-level two-factor full factorial design (3^2 FFD) is used for the experiment, considering the two quantitative parameters (detector and self radii), repeated for three possible formulations of the censoring distance. The validating self set is composed of 23 samples out of the remaining 46 (e.g. 96 minus the 50 used for the training). The validating nonself set is composed of 133 artificial outliers. Figure 3 displays the samples used for both training (D0-T) and validation (D0-V, Outliers) in the unitary feature space.

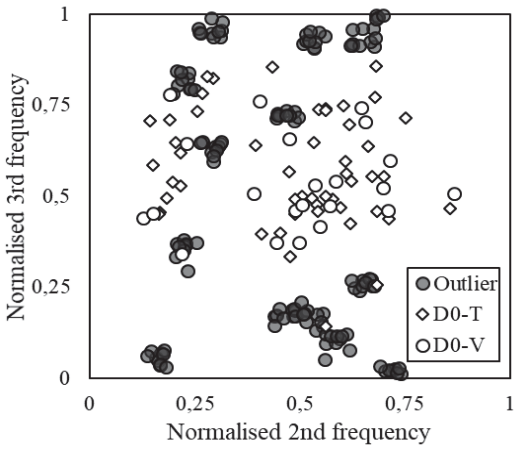


Figure 3: Normalized samples belonging to the training and validating sets.

Table 2 reports the results of the parameter setting together with the performance metric. In the present work, the area under the Reception Operating Characteristic (ROC) curve, called AUC, is used for this purpose. The ROC curve plots, for each classifier, the False Positive Rate (FPR) and the True Positive Rate (TPR). The best combination of parameter levels corresponds to the highest value of the AUC which, for this case study, is: small r_{det}, medium r_{self} and censoring distance equal to $r_{det} + r_{self}$.

Cens.dist=r_{det}			*Cens.dist*=0.5(r_{det}+r_{self})			*Cens.dist*=(r_{det}+r_{self})

Table 2: Results of the parameter setting. In bold the best combination of parameter levels.

The optimized classifier is used to simulate the monitoring of the arch. This means testing the classifier against the samples that it has not met before. The testing self set is composed of the remaining 23 samples, whereas the testing nonself set is composed of just 39 D1 samples and 16 D2 samples, since the others fall outside the unitary space and are automatically classified as damaged. The classifier shows a good performance against the damaged samples with a success rate of 82% for D1 samples and of 94% for D2 samples in terms of correct labelling. However, 48% of the new health samples are wrongly classified.

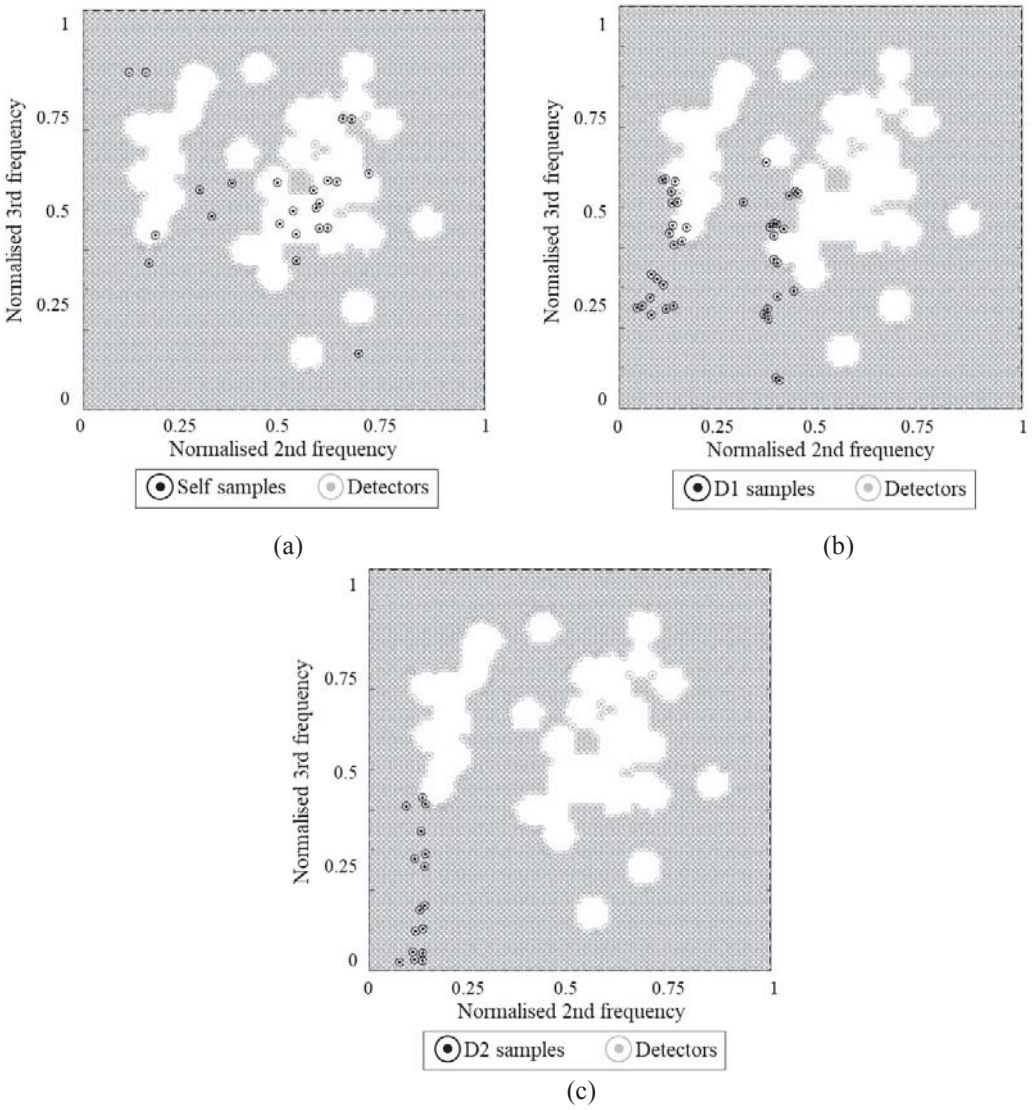

Figure 4: Comparison of the optimized detector set against the testing sets: (a) self samples; (b) D1 samples and (c) D2 samples.

3.3 Improved training

Based on the detector set distribution, the quite "aggressive" behavior highlighted in Figure 4a is likely due to the sparsity of the self samples used for the training. These were mainly distributed in two regions. However, experience supports the idea that frequency values, in conditions similar to the one of the case-study, are continuously distributed over a single region. Thus, new emerging samples are expected to fall in between the two identified areas. Based on this assumption the classifier is improved by artificially generating self points according to a bivariate normal distribution. The mean and the covariance matrices of the 50 training samples are used to define the distribution. Before repeating the training, the new points which fall outside the area within the boundary that envelopes the prior training samples are rejected, assuming that this boundary delimits the known self region. Figure 5 shows the prior and the new training sets. The improved classifier is thus generated keeping the same parameter setting and tested against the same sets. Figure 6 shows the new detector set, compared to the testing sets and Table 3 reports the confusion matrix for the two classifiers. The improved version outperforms the prior one.

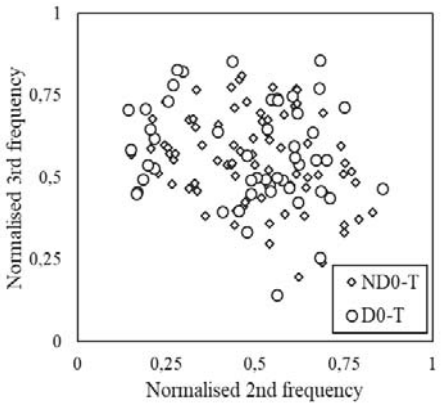

Figure 5: New normalized training samples (ND0-T) compare to the original training set (D0-T).

	TN	FP	Tot. D0 samples	TP1	FN1	Tot. D1 samples	TP2	FN2	Tot. D2 samples

4 CONCLUSIONS AND FUTURE SCOPE

The simple discrimination between the normal and the abnormal behavior of an engineered system is a complex task in many real-world applications. The lack of knowledge regarding possible abnormal conditions and the limited knowledge about the normal behavior itself reduce the number of non-model-based numerical methods suitable for damage detection purposes (e.g. one-class classification). In the present work a combination of real and artificial data is proposed to improve the design of a tailored damage detection strategy for real-world applications. The analyzed case study consists of a segmental masonry arch built and tested in the laboratory of the University of Minho and the applied damage detection algorithm is a customized version of the NSA, developed by the authors in a previous work. Hitherto, the following preliminary conclusions can be drawn:

- the performance is robust against the sources of uncertainties, as the noise in the signals or the modal feature extraction through a simplified peak-picking strategy;
- the classification is successful for small damage extent – indeed the frequency downshift estimated for modes 2 and 3 was on the average 1.6% and 0.9% for the first damage scenario (D1), and 1.9% and 2.3% for the second damage scenario (D2);
- the artificial generation of new self and nonself samples, according to the training data distribution, improved the performance facing the reduced and sparse information available;
- the methodology might be suitable for sensor embedment, since the features are extracted from a single sensor acquisition.

To realize the full potential of the algorithm, more research is needed. Indeed, although the cracks after the first displacement stage are barely visible in the arch, the drop in the first frequency value might suggest that the damage is not as small as required for a proper assessment of the algorithm sensitivity. Moreover, the strategy for artificial data generation should be tested on a larger dataset and the analysis should be cast in a statistical framework to infer the behavior of the final classifier in different conditions.

ACKNOWLDGMENTS

Abstract. *Vibration-based health monitoring systems have been successfully implemented in many different large civil engineering structures such as bridges, wind turbines and belltowers, providing important data about their dynamic behaviour and allowing the establishment of damage detection methodologies based on the evolution of modal properties. Allying this knowledge with the emergence of very sensitive low noise sensors and high-resolution digitizers during the past few decades, an opportunity arose to implement continuously operating dynamic monitoring systems in dams and validate the suitability of these systems to monitor such massive structures with the goal of detecting damage.*

The detection of abnormal structural behaviour, that may indicate the occurrence of damage, can be based on control charts and is associated with shifts in the modal parameters values that are not explained by other physical phenomena but a change in the structure's stiffness. To test these statistical tools, modal parameters obtained from field measured time series may be contaminated with simulated damages.

In this context, the ability of the control charts to identify the emergence of abnormal structural behaviour in dams is studied in this paper using data obtained from the continuous dynamic monitoring of Baixo Sabor arch dam, a concrete dam in Portugal that started operating in late 2015. Since it was not expected to find damage in such a recent structure, a set of plausible damage scenarios were simulated using a numerical model and their influence in the dam dynamic properties was used to contaminate the values of natural frequencies obtained from continuous monitoring.

1 INTRODUCTION

Baixo Sabor hydroelectric development, located in the north of Portugal, is one of the most recent plants in the country. With the aim of studying Baixo Sabor arch dam dynamic properties and their evolution over time, continuous dynamic monitoring of the dam is being carried out, taking into account the variation of ambient and operational conditions [1].

Integrated monitoring systems considering real-time data directly obtained from structures, such as the one implemented in Baixo Sabor dam, are very important for the long-term management of large civil infrastructures [2]. Though health monitoring systems are historically associated with static data, vibration-based systems have already been successfully implemented in different structures such as bridges [3], wind turbines [4], stadia roofs [5] or belltowers [6]. Such vibration-based health monitoring systems rely on operational modal analysis to continuously identify the structures modal properties, which can be used as monitoring features to evaluate the structures health condition evolution over time. Statistical tools such as control charts can be used to detect the occurrence of damage associated with shifts in the modal parameters values that are not explained by other physical phenomena but a change in the structure's stiffness. To test these statistical tools, modal parameters obtained from field measured time series may be contaminated with simulated damages.

In this sense, this paper presents a brief description of the dynamic monitoring system installed in Baixo Sabor arch dam in 2015, and the results obtained during more than three years of continuous dynamic monitoring. The operational and environmental effects that mostly affect the dam's dynamic behaviour are studied and their effects on the natural frequencies are minimized using multiple linear regression models and Principal Components Analysis. Additionally, a numerical model of the dam (developed by the Portuguese National Laboratory for Civil Engineering [LNEC]) is presented and used to simulate damages scenarios. Finally, control charts are used to detect the shifts in natural frequencies evolution due to the simulated damages, and thus evaluate the suitability of these statistical tools for the detection of damages in concrete dams.

1.1 Baixo Sabor arch dam and installed monitoring system

The Baixo Sabor hydroelectric development is located in Sabor river, a tributary of Douro river in the northeast of Portugal. This 123 m high double-curvature concrete arch dam, is 505 meters long and its arch is composed by 32 concrete blocks, separated by vertical contraction joints, and it includes six horizontal visit galleries. The reservoir created by the dam, shown in the aerial picture of the dam presented in the left part of Figure 1, has a capacity of 1095 hm^3 at exploration level (234 m of elevation).

A vibration-based health monitoring system has been working in the dam since December 2015, in order to identify the dam's dynamic characteristics and their evolution over time, while considering the variation of ambient and operational conditions. The continuous dynamic monitoring system consists of 20 uniaxial accelerometers that have been radially disposed in the dam's three upper visit galleries, whose synchronization is achieved using GPS antennas. The right part of Figure 1 shows the position of the accelerometers installed in the dam, marked with red dots in a scheme of the structure. The dynamic monitoring system is configured to continuously record acceleration time series with a sampling rate of 50 Hz and a duration of 30 minutes at all instrumented points, daily producing 48 groups of time series.

To continuously process the data collected by the monitoring system a monitoring software developed at ViBest/FEUP called DynaMo [7] is being used. Besides backing up the original data samples, this monitoring software performs the pre-processing of the acceleration time series, through trend elimination, filtering and re-sampling, it characterizes vibration levels

and it performs the identification of the dam modal properties through automatic operational modal analysis.

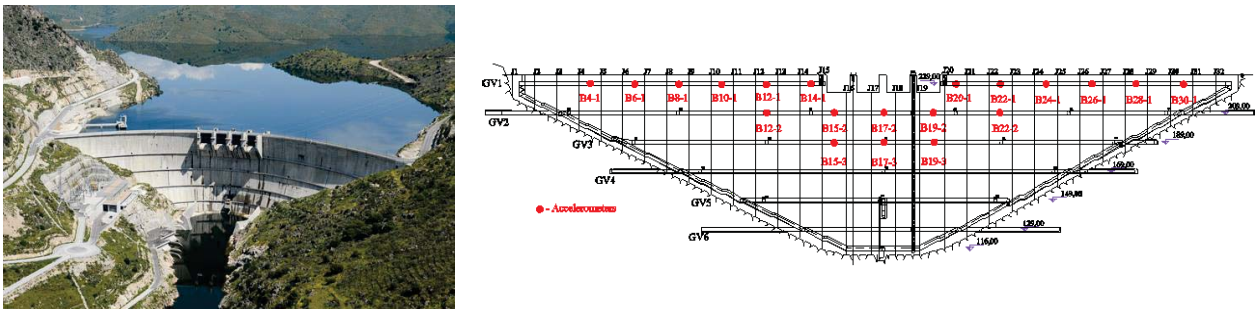

Figure 1: Baixo Sabor arch dam: Aerial view (on the left); position of accelerometers marked with red dots (on the right).

1.2 Modal Tracking

More than three years of data were processed following the steps described in the previous section. The first ten modes of vibration are being identified and natural frequencies, modal damping values and modal configurations tracked over time. The representations of the identified modal configurations can be found in [8]. This work is focused on the evolution of natural frequencies, which are used in the next section to detect novel structural behaviour. In this sense, average natural frequencies (f_{mean}) and their standard deviation (f_{std}) during the studied period are resumed in Table 1 for the first ten vibration modes. It is important to notice the significant standard deviation values verified for all vibration modes, indicating important oscillations during this period.

However, since the evolution of modal properties is easier to understand when graphically depicted, the evolution over three years of the natural frequencies estimates of the first ten modes of vibration of the structure is characterized in Figure 2, where each point corresponds to a 6-hour average. Therefore, two values are presented per day, leading to a figure visually clean, without losing accuracy in the characterization of the modal parameters fluctuations, since their variations are quite slow in very massive structures such as this one. After an initial fast decrease in natural frequency values during the first filling of the reservoir, significant frequency variations due to operational and environmental factors are verified with season succession, indicating the possibility of finding correlation between natural frequencies and these factors.

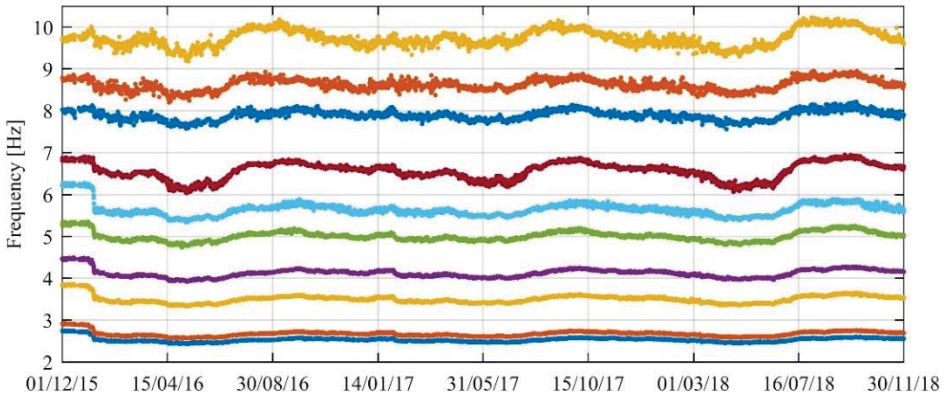

Figure 2: Time evolution of 6-hour average natural frequencies

Mode	1	2	3	4	5	6	7	8	9	10
f_{mean} [Hz]	2.53	2.70	3.50	4.12	5.00	5.62	6.57	7.90	8.63	9.76
f_{std} [Hz]	0.10	0.10	0.14	0.16	0.20	0.25	0.29	0.34	0.38	0.49

Table 1: Statistical characterization of the natural frequencies estimates from 01/12/2015 to 30/11/2018

1.3 Numerical Model

In order to study the static and dynamic behaviour of Baixo Sabor arch dam, the Concrete Dams Department of the National Laboratory for Civil Engineering developed a numerical model of the dam. This model, based on discrete and finite elements, takes into account the dam's contraction joints, the deformability of the foundation and the reservoir [9]. The body of the dam was modelled with 32 vertical blocks, which were discretized into isoparametric 20-node brick finite elements and a simplified representation of the reservoir and foundation was used.

The dynamic dam-reservoir interaction was simulated with Westergaard's added mass technique. The masses had to be scaled since it is known that in arch dams, Westergaard's method overestimates the hydro-dynamic effects [10]. The model was calibrated for several water levels varying from 210 to 234 m, therefore a set of different scaling factors were used to match the first natural frequency estimated with both the results from a forced vibration test performed on the dam [9] and from the continuous dynamic monitoring [11].

The deformability of the foundation was achieved through an elastic joint on the dam's surface of insertion, with stiffness parameters calibrated to provide an approximate deformability of a rock mass with a Young's modulus of 35 GPa, obtained from field tests. A view of the numerical model is presented in Figure 3.

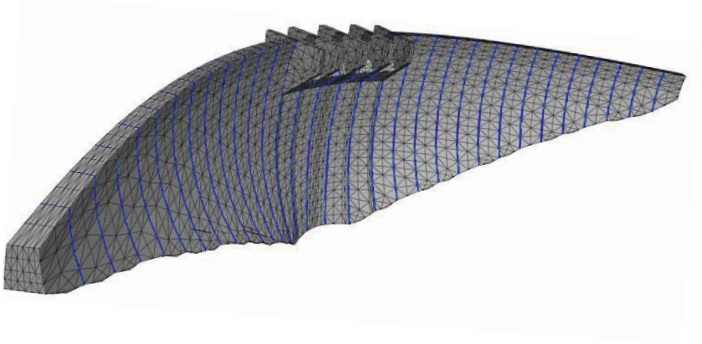

Figure 3: Numerical model of Baixo Sabor arch dam

2 REMOVING THE EFFECTS OF ENVIRONMENTAL AND OPERATIONAL CONDITIONS

In order to detect small variations of the natural frequencies of the structure motivated by structural changes, which may be associated with the occurrence of damages, it is important to minimize the effects of environmental and operational factors, such as reservoir water level and temperature.

Since the factor that more strongly affects natural frequencies is the water level in the reservoir [12], statistical relationships between all the vibration frequencies of the structure and the water level in the reservoir were developed. The representation of the relation between these two variables is presented in Figure 4 (left part of the figure), using the first vibration mode. The adopted quadratic regressions generally provide a good fitting, presenting values for the determination coefficient of the order of 0.95.

The obtained statistical relations were then used to mitigate the effect of water level in the values of natural frequencies and then the process previously described was repeated, now using the values of natural frequencies corrected from the effect of water level and the evolution of ambient temperature. In this case, linear regressions were obtained between ambient temperature and natural frequencies, indicating frequency values increase with the rising of temperature. Lower determination coefficients were obtained, with values between 0.3 and 0.5, depending on the studied vibration mode. The relation between ambient temperature and the frequency of the first vibration mode corrected by the effect of water level is presented in the right part of Figure 4.

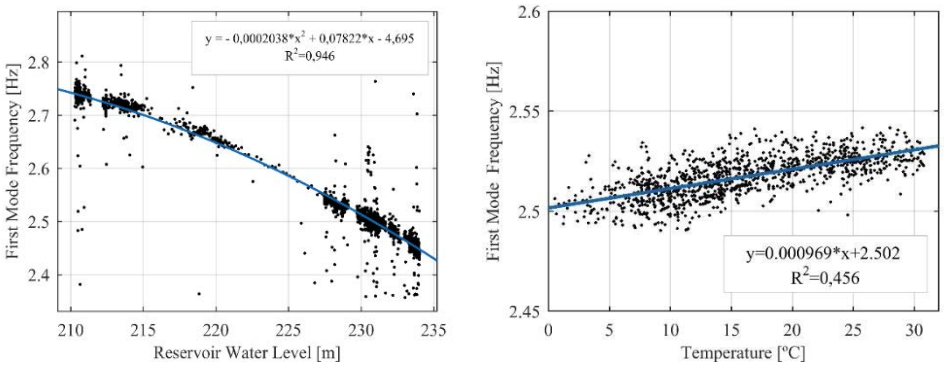

Figure 4: Correlation between the first natural frequency and reservoir water level (on the left); correlation between the corrected first natural frequency and ambient temperature.

Afterwards, multiple linear regression models (MLR) were built using as predictors the evolution of reservoir water level, ambient temperature, concrete temperature and a variable simulating the hardening of concrete over time. Only the first seven vibration modes were considered in this analysis, since modes 8 to 10 presented lower successful identification rates (between 49 and 64 %) that preclude their use in the damage detection process with adequate results.

The experimental natural frequencies were compared to the ones resulting from the regression models and high correlations were verified between them. The values of predicted natural frequencies were subtracted to the values of experimental natural frequencies and the obtained residuals were added to the mean frequency of each mode to obtain a new set of natural frequencies corrected from the effects of operational and environmental factors.

The evolution of the natural frequency of the first two vibration modes after the minimization of operational and environmental effects with the built regression model is presented in Figure 5. A much more stable evolution of natural frequencies around their means was achieved and the sporadic gaps presented are due to missing readings in the predictor variables (mainly ambient temperature).

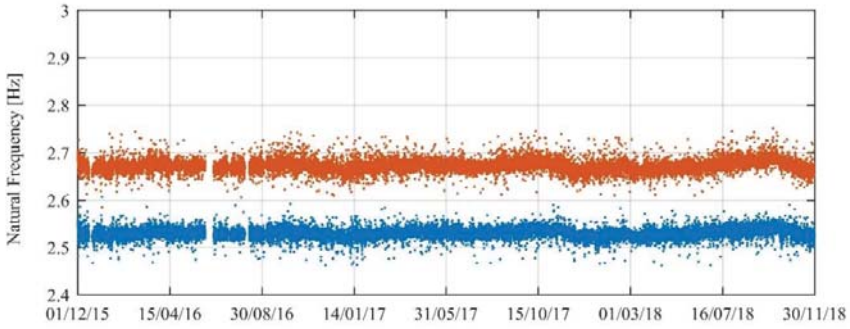

Figure 5: Natural frequency evolution of the first two modes after application of the regression model

To complement the minimization of operational and environmental effects on natural frequencies achieved with the multiple linear regression model, principal components analysis was applied to the residuals previously obtained.

Afterwards, t-statistic control charts based on the obtained residuals were tested to ascertain the quality of the minimization of the effects of external conditions and to define a baseline for damage detection. Data from one entire year was used as reference period (represented in blue) whereas observations between the two following years (represented in orange) were used to build the control part of the chart and verify the quality of the chart associated with the non-damaged situation.

To obtain the upper control limit (UCL) the distribution of the T^2 values during the reference period was considered, thus it was defined as the sum of the average T^2 with two times the T^2 standard deviation (during the reference period), so that approximately 95% of T^2 values would be below the UCL. This approach is only possible as long as the reference period is large enough to confidently define the UCL. Different control charts were tested considering groups from 1 to 96 elements and finally the ones resulting from the consideration of groups with 6 and 96 points, corresponding respectively to 3-hour and 2–day data, are represented in Figure 6.

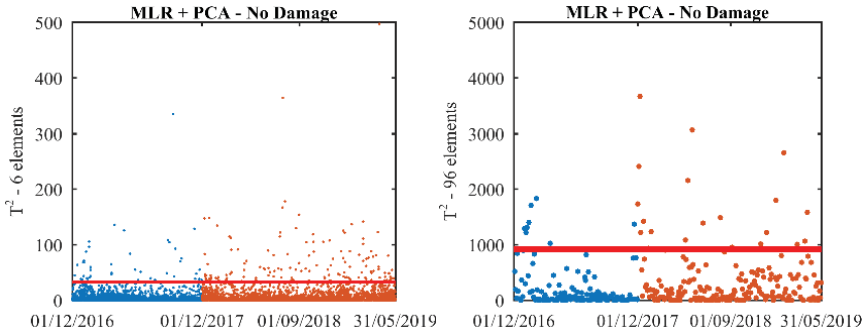

Figure 6: Baseline control charts (no damage) using 6-points (on the left) and 96-points groups (on the right)

3 DAMAGE DETECTION

3.1 Damage Simulation

In the previous section it was shown that it is possible to largely reduce the effects of operational and environmental factors on the identified natural frequencies of an arch dam, to a degree that allows to build stable control charts With the aim of testing the ability of these control charts to identify realistic frequency variations, small damages were simulated with the previously presented finite model of the dam.

Damage in dams may stem from a diversity of occurrences and the accurate numerical modelling of damage scenarios would require the development of very complex non-linear models and a large number of assumptions, resulting only in approximate results. Therefore a simpler approach is followed in this work, namely through reductions of inertia in a few dam components, such as part of concrete blocks, or reduction in stiffness of contraction joints.

In this manner, four different damage scenarios were considered, D1, D2, D3 and D4. The location and extent of each damage considered is presented in Figure 7. The first damage scenario (D1) corresponds to the decrease of the Young's modulus value in a group of 11 elements in the central part of the dam. Only elements in the most upstream layer were considered, which corresponds to a part of the structure that is highly stressed and may be

subjected to cracking. The second damage scenario (D2) is equivalent to the first one, with similar extent, though only 5 elements were damaged in this case, and it is located between the abutment and the central part of the dam. The third scenario (D3) correspond to a more confined damage in the central part of the structure, but it goes from upstream to downstream, through the three layers of elements of the dam model. Finally, in the fourth damage scenario (D4) both the normal and shear stiffness of the six central contraction joints (represented in red in right bottom of Figure 7,) were reduced.

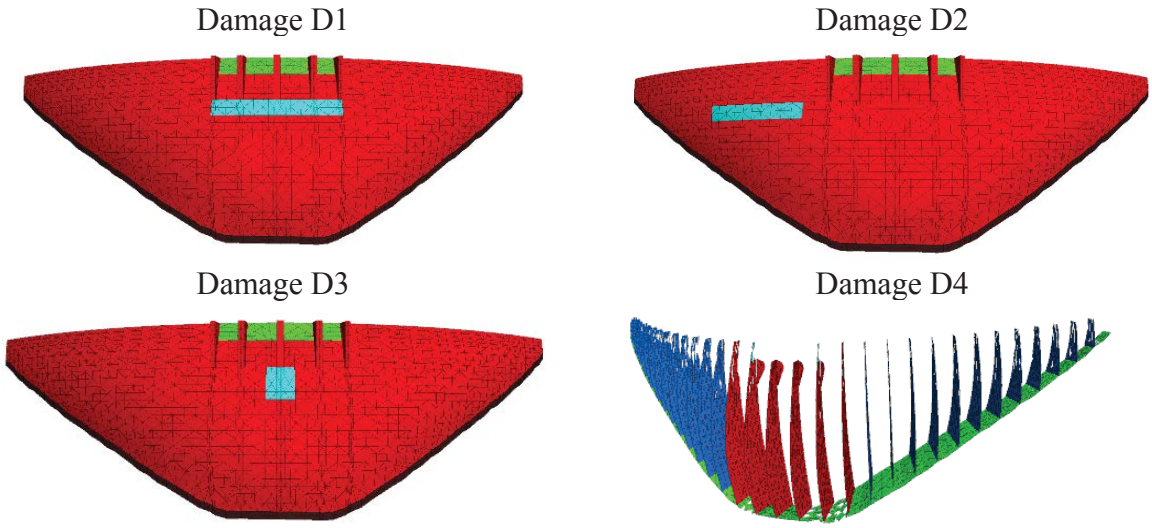

Figure 7: Location, extent and type of simulated damage scenarios.

Natural frequencies obtained after the introduction of each damage were compared with the healthy model and results were obtained for several reservoir water levels between 210 and 234 m. Moreover, five levels of damage intensity were considered, which consisted in the reduction of Young's modulus of selected elements (or normal and shear stiffness in the case of joints) in 10, 30, 50, 70 and 90 %.

The results obtained with full reservoir and damage intensities of just 10 %, which is the most challenging scenario to test the damage detection tools, are presented in Table 2. Frequency reductions between 0.015 and 0.181 % were verified. However, frequency reductions increase to values between 0.1 and 1% when damage intensities rise to 50 %, and to values between 1 and 4 % when 90 % damage intensities are considered. Furthermore, in each damage scenario different frequency reductions were verified for each vibration mode, indicating the possibility of locating damage through the study of the relation of the effect of damages between modes.

Mode	Frequency [Hz]	Δ freq. [%]	Δ freq. [%]	Δ freq. [%]	Δ freq. [%]
1	2.45372	-0.181	-0.014	-0.125	-0.076
2	2.68436	-0.059	-0.052	-0.075	-0.066
3	3.58254	-0.015	-0.122	-0.018	-0.047
4	4.05438	-0.060	-0.076	-0.031	-0.042
5	4.84020	-0.082	-0.073	-0.074	-0.041

Table 2: Natural frequency reductions associated with damage scenarios D1, D2, D3 and D4 (10% of damage intensity) with full reservoir

3.2 Application of damage detection tools

In order to obtain very sensitive control charts, capable of detecting small damages, alternative procedures were tested to minimize the effects of external conditions on natural frequencies, besides the procedure presented in subsection 3, based on the combination of the MLR with PCA. Although good results were achieved with this procedure, it was verified that even better results could be achieved considering just the application of PCA with two principal components. Therefore, this is the procedure considered in this section, and the results that it produces are used as baseline for damage detection.

The damages presented in the previous section were introduced in the estimated natural frequencies obtained from the implemented continuous monitoring processing through the assessed frequency reductions, after which the ability of control charts to detect the presence of such damages is tested.

Since averages of 96 elements were adopted, new points resulting from the collection of new data are only marked in the control charts every two days. As an example, Figure 8 presents two control charts related with the detection of damage, more specifically, the charts obtained considering damage scenario D3 with 30 and 50 % of stiffness reduction. In this case, the healthy state is represented in blue and orange color is used to represent data after he introduction of damages. Damages clearly lead to higher values of T^2, which subsequently increase with the intensity of the damage introduced. In the case of 50 % of stiffness reduction, almost the entire set of T^2 values obtained after the introduction of damage are found above the UCL, thus damage would be unequivocally detected only a few days after its occurrence. A similar situation occurs with the scenario of 30 % of stiffness reduction, which presents the majority of T^2 values clearly above the UCL, thus once again, damage would be detected soon after its occurrence if damage existence is assumed only after a few consecutive points (5 or more) are found above the UCL.

Though not represented, the same conclusions would be achieved for higher damage intensities (70 and 90 % of stiffness reduction), as would be expected. On the other hand, with 10 % of stiffness reduction, the most challenging scenario for the detection algorithms, just a few points are found above the UCL, the average T^2 value increased only marginally and never during the entire tested period is it possible to find five consecutive points above the UCL. In this sense, it would not be possible to detect damage D3 with such low intensity, even if evaluated for several weeks.

This damage detection analysis was repeated with the other three scenarios and similar results were obtained, with the 30 % stiffness reduction scenarios corresponding to the detection threshold. Finally, it is worth noting that damages resulting from 70 % of stiffness reduction, or higher, could be detected just one day after its occurrence, using averages with just 6 points instead of 96.

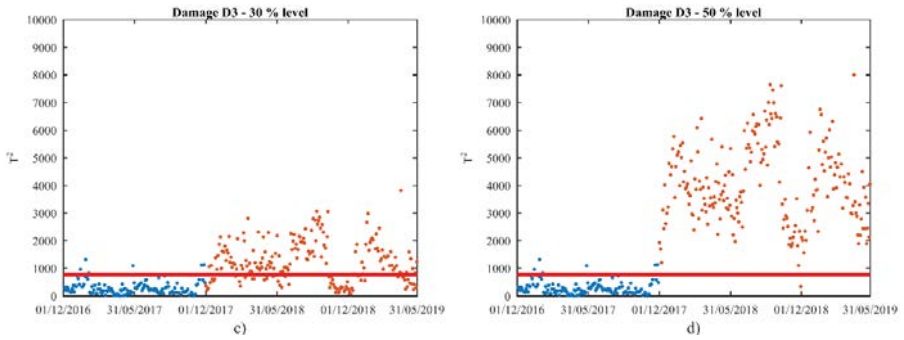

Figure 8: Damage scenario D3 – 30 % to 50 % of stiffness reduction

4 CONCLUSIONS

The dynamic monitoring system installed in Baixo Sabor arch dam has been working almost without failures since it was installed, proving to be an important asset to the long term monitoring and maintenance of the structure.

The time series of accelerations recorded by the monitoring system during the past few years have been used to characterize the structures dynamic behaviour and to study the evolution of natural frequencies over time. It was verified that natural frequency values presented high variability during the monitored period, mostly due to the effects of operational and environmental conditions. The analysis of these effects unveiled an inverse relation between natural frequencies and the level of water in the reservoir, as well as a direct proportionality between air temperature and natural frequencies.

Afterwards, a multiple linear regression model aiming to explain the observed data variability was built and used to minimize the effects of external conditions on natural frequencies. In this particular case study, the application of principal components analysis proved to be more efficient in the delivery of features suitable for damage detection.

The numerical model of the dam developed by LNEC was used to simulate realistic damages that may occur in the dam after strong earthquakes or as the result of long-term material deterioration through ageing and chemical processes. These simulations allowed to ascertain the intensity of the frequency shifts that would be verified in the dam if such damages occurred, after which they were used to manipulate the data obtained from the continuous monitoring.

Finally, it was demonstrated that the construction of control charts with residuals from the application of principal components analysis allows the detection of small frequency shifts due to the numerically simulated damage scenarios.

To conclude, it was verified that a vibration-based monitoring system like the one installed at Baixo Sabor arch dam allows to better understand the dynamic behaviour of concrete arch dams, as well as to prevent the proliferation of small damages through the detection of abnormal structural behaviour.

Keywords: Continuous Structural Health Monitoring (C-SHM), Automated Operational Modal Analysis (AOMA), Cultural Heritage, Masonry towers

Abstract. *During the last decades, the Operational Modal Analysis (OMA) techniques for the dynamic identification have reached a wide application in the large civil structures. Then the focus has been moved on the introduction of the Automated OMA (AOMA) techniques as a component of a wider Structural Health Monitoring (SHM) framework. On the one hand, the automatization of the process is needed to extract the modal properties from huge database of measurements. On the other hand, the methods should be able to minimize the model bias, avoiding the spurious and mathematical modes. Moreover, all the fix thresholds defined a-priori should be carefully set to avoid some tracking errors. This paper presents a new AOMA for the extraction of the modal parameters from long-term monitoring data. The methodology herein discussed aims to minimize the errors that can arise during the modal identification. Moreover, the information obtained during an observation period have been used to define suitable adaptive thresholds. For illustrative purposes, the methodology has been applied to the data acquired from long-term monitoring systems installed on two masonry towers subjected to different operational conditions. The effectiveness of the proposed method has been checked on the extracted modal parameters*

1 INTRODUCTION

Since the beginning of the nineties the long-term monitoring system (LTMS) for the detection of the early stages of damage is an established technique developed for the civil structures. The basic idea was the improvement of the adopted techniques for the inspection of the existing bridges. With the introduction of Vibration Based Inspection (VBI) correlating different extent of damages on a structure with the change in the dynamic properties, a lot of efforts were spent by the researchers. From that pioneering studies, the Structural Health Monitoring framework was fully defined and several examples of full-scale tests on large civil structure have been performed [1–3]. Thanks to the development of the Operative Modal Analysis (OMA) techniques, allowing the extraction of the dynamic properties under operative conditions the attention on the topic was renewed. Moreover, the technology advances in terms of computing and storing information boosts the efforts for the development of effective long-term monitoring techniques. Thus, the challenge has been moved on the definition of automated procedures capable of processing large dataset of measurements. Consequently, in the last years, several Authors have proposed fully or semi-automated OMA procedures [4–9] to extract the modal parameters.

While different strategies have been proposed for the automated extraction of the dynamic properties, not so many studies have investigated the modal tracking phase. Commonly, some fixed thresholds are selected for all the modes and each mode is tracked selecting a reference set of modal parameters usually defined in a preliminary dynamic test. Even if the mode shapes are not sensitive to the changes in the environment [10] like temperature, humidity etc. some changes can occur due to some other effects. Along with that variability in some cases not all the sensors can be online, especially for dense measurements along the time, or if dense spatial grids are used. Moreover, the use of cheap monitoring system with a low-resolution needs a proper selection of the tracking thresholds for each mode. On the top of all that, recently, some Authors have shown how the damage can be detected by the analysis of the outliers of the tracked frequency [11–13] along the time. Hence the definition of suitable automated procedures become crucial point, especially for the application to the cultural heritage buildings [14,15]

In the present paper is introduced an algorithm for the modal tracking of the modal properties of two historic masonry towers with different operational conditions. The accelerations have been collected by a continuous (fifteen minutes of record every hour) wireless monitoring system based on the MEMS technology.

2 THE AOMA PROCEDURE

The AOMA algorithm has been developed considering a Continuous Vibration-Based Structural Health Monitoring (CVB-SHM) approach. As it was stated by Pecorelli [16] with the analysis of the data of a continuous monitoring system in a complex elliptical dome; the input should be selected as those with higher Root Mean Square (RMS) to successfully identify all the modes. Furthermore, Marwitz and Zabel [17] defined a relationship among the quality of the identified modes and the intensity of the input, analyzing the long-term monitoring data of a high-rise telecommunication tower. Hence the presented procedure was developed by introducing some thresholds in the input parameters and in the complexity of the identified modes. That values are defined statistically, considering a suitable observation period where the common operational conditions are present. The full procedure for the extraction of the modal parameters has been fully described in [18].

Here the algorithm to define the adaptive thresholds for each mode is presented and the most relevant operation are described:

1. Selection of one or more calibration periods
2. Definition of a starting thresholds respectively in terms of frequency df_{lim} and mode $d\phi_{lim}$ shapes equal for each mode
3. Random selection of the *b-th* element as a seed of the first cluster
4. Calculate the relative distance d_{bi} in terms of frequency and mode shapes from the *b-th* seed to all the other *i-th* elements of the calibration period
5. The elements within the initial distance d_{lim} are clustered together and the relative distances are saved in the vector
6. For each mode the distance is calculated as the median of the components of d

Thus, the distances in terms of frequency and mode shapes are calculated analyzing the results on the calibration period during the common operational conditions of the structure. Obviously, the initial thresholds d_{lim} should be chosen adequately. For instance, reference values for the MAC can be from 0,05-0,8; while the relative distance in terms of frequency depends on the length of the calibration periods. Anyway, a suitable interval could be between the 1-10 %.

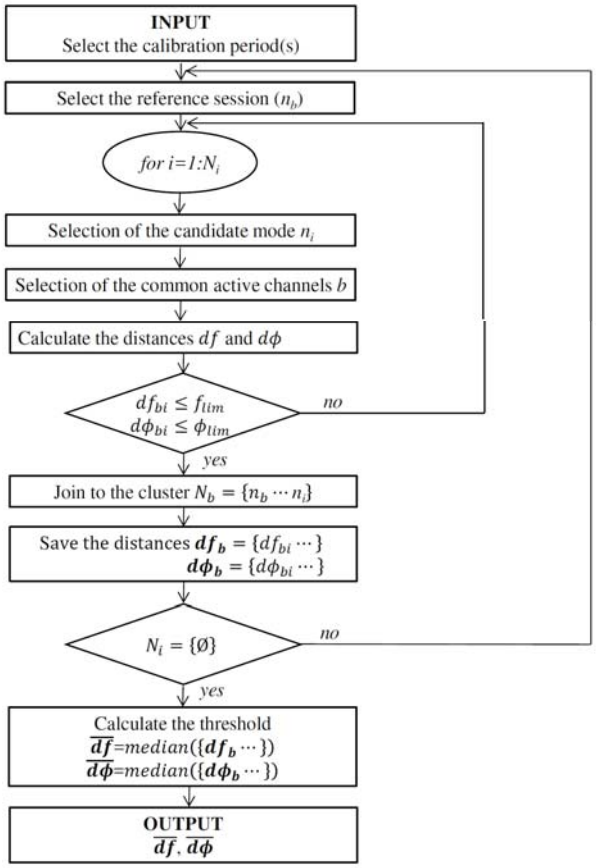

Figure 1: The flowchart of the proposed method.

3 APPLICATION TO TWO HISTORIC MASONRY TOWERS

The two cases of study are the "Torre Grossa" (Tower A) and the "Mastio Matilde" (Tower B). The two towers exhibit different slenderness and different buildings materials: the Tower A made by travertine stones and the Tower B by masonry bricks. Both of them are sorrounded by walls or palaces until a certain level and in an asymettric way. It is worth to

point out that the two towers are subjected to different level of excitations. In one hand, the Tower B arises in the city center of San Gimignano (SI) where the veicular traffic is restricted so the main external dynamic forces are due to the wind. On the other hand, the Tower B is located in the Livorno harbour where the external dynamic excitation level is high and in some cases it is arisen from some colored noise . Hence, these two limits cases for the historic masonry towers seems to be a good test for the proposed automated procedure.

(a) (b)

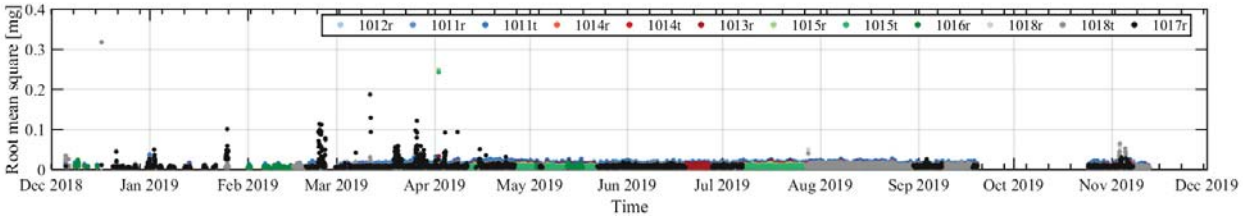
Figure 2: (a) The "Torre Grossa" in San Gimignano (SI) (b) The "Mastio Matilde" in Livorno (LI).

The two towers have been selected as cases of study for the "Moscardo" project, a project funded by the Tuscany region, aiming to investigate the capability of monitoring the cultural heritage using low invasive techniques. Thus, a wireless network of Micro Electic Mechanic Sensors (MEMS) accelerometers has been adopted and tested for two towers for long-term monitoring purposes. In the next sections, the two networks will be briefly described and the results of the proposed adaptive technique for the modal tracking will be discussed.

3.1 Tower A

The "Torre Grossa" is the tallest medieval tower in the city center of San Gimignano with a height of 55 m and a base square of about 9,5x9,5 m. only two levels at the top have a concrete slabs, while an iron staircase has been fixed to the walls to reach the top level. At the top there is a belfry with three bells, that have no longer been used. A full description of the geometry and of the architectural features can be found in [19].

The installed monitoring system is composed by 12 accelerometers, 2 strain gauges, 2 dispacement transducers and 2 metereological stations: one indoor collecting temperature, humidity and the other outdoor collecting temperature, humidity and the average wind speed and direction.



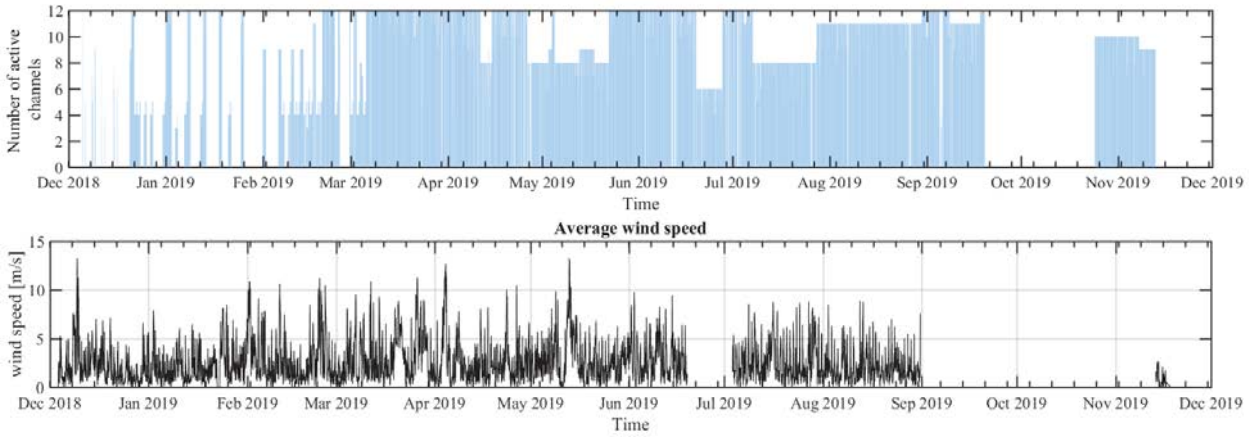


Figure 3: (a) Tower A the rms of the signals collected over the monitoring period, the active channels and the average wind speed recorded in the meteorological station in the last level.

In figure 3 the results of the first year of monitoring are reported in terms of power in the signals and of the measured average wind speed. In the time window from the middle of September to the middle of October the system was off-line. While not all the sensors were working together along the time because of some problems in the network.

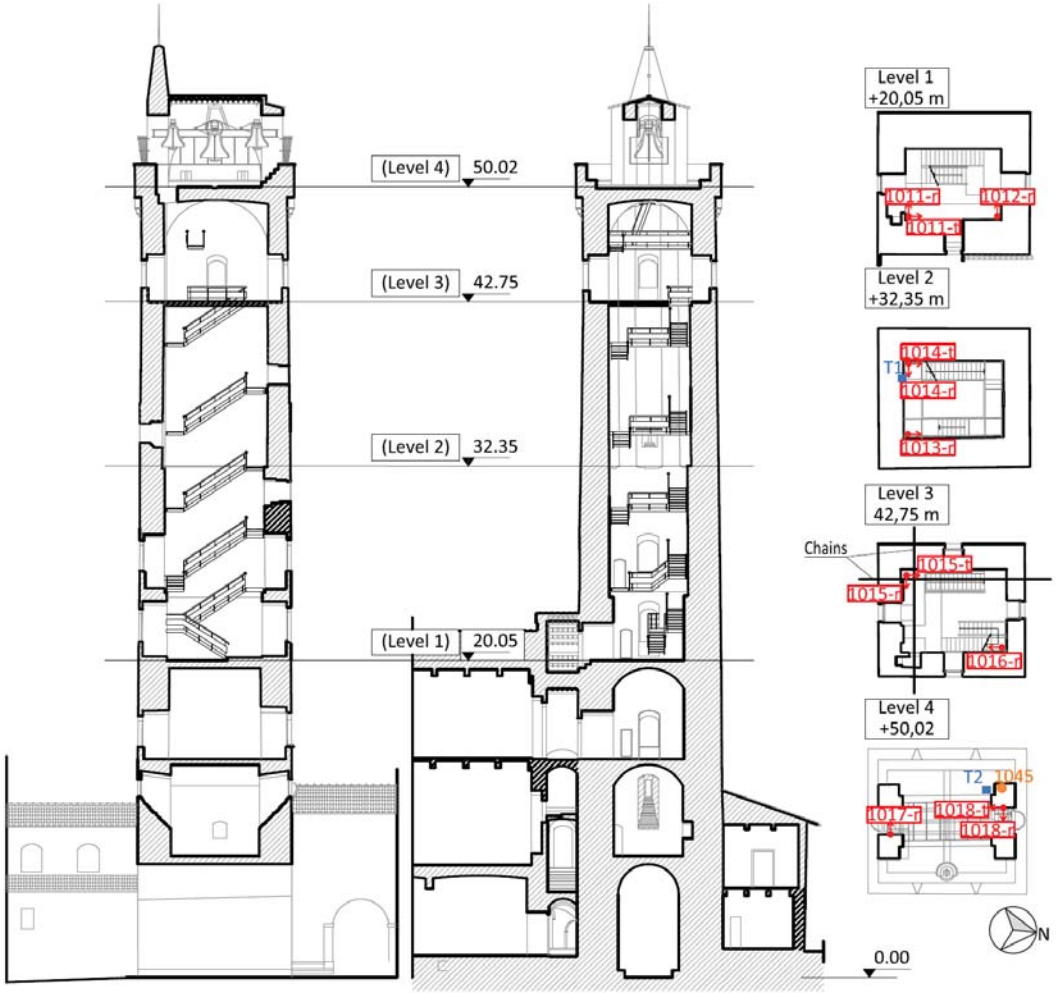

Figure 4: Tower A the long-term monitoring system installed.

3.2 Tower B

The "Mastio Matilde" is an iconic tower of the old fortress in the Livorno harbor. The tower has a round plan with a diameter of 12 m and a total height of about 29 m with four vaulted levels that were retrofitted in the past with steel bars fixed in the vaults. Some more information about the tower can be found in [18].

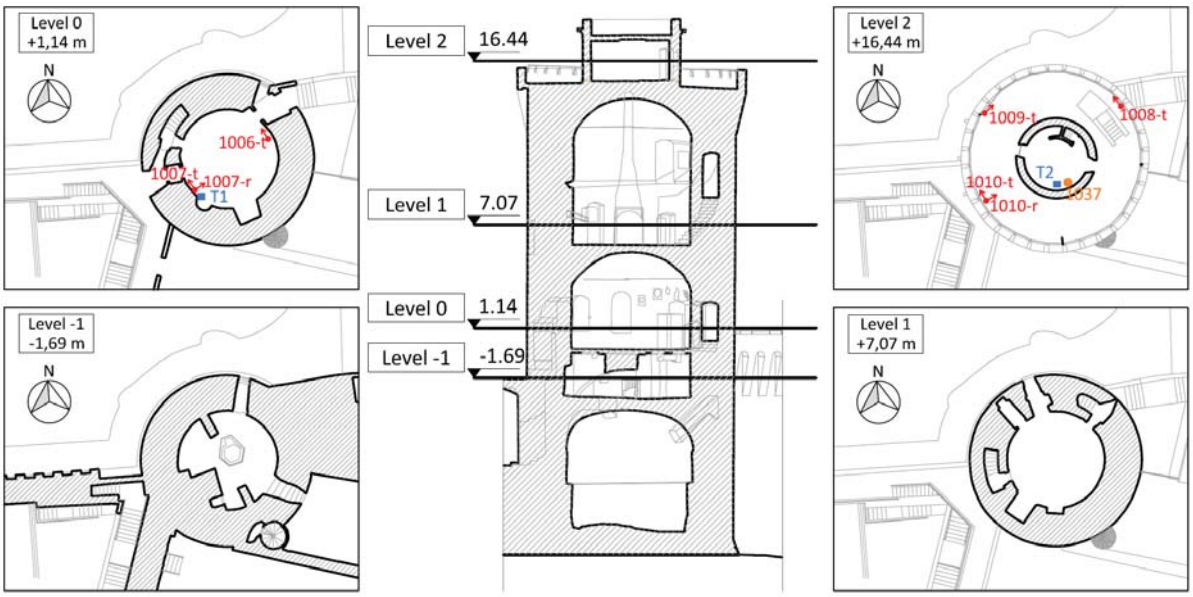

Figure 5: Tower B the long-term monitoring system installed.

Two sections of the tower have been monitored: the top with two mono-axial accelerometers and one biaxial accelerometer; the level 0 with one mono-axial and a biaxial accelerometer. The environmental conditions were monitored with two meteorological stations: one inside and one outside the tower. Both measure the temperature and the humidity, while outside an anemometer measuring the average wind speed and the direction.

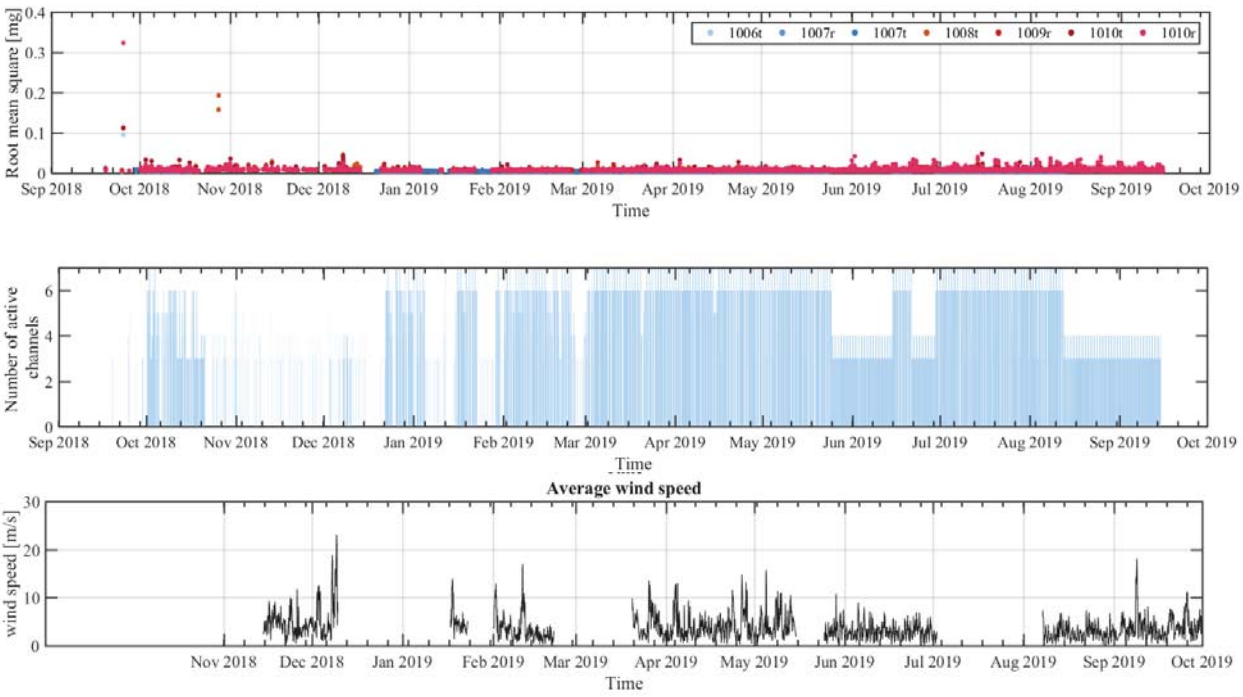

Figure 6: (a) Tower B the rms of the signals collected over the monitoring period, the active channels and the average wind speed recorded in the meteorological station in the last level.

Although also in that case several disconnections of some sensors a large database has been collected (Table 2).

3.3 Observations about the monitoring data

Despite the lacks in the time histories of the recorded signals due to some malfunctioning in the network, is possible to describe the level of vibration of the two cases of study.

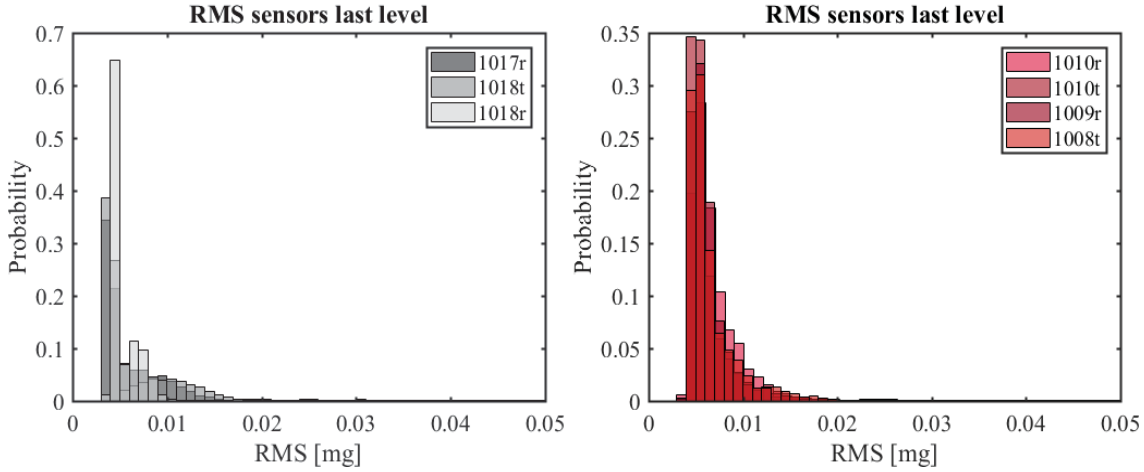

Figure 7: (a) The "Torre Grossa" in San Gimignano (SI) (b) The "Mastio Matilde" in Livorno (LI).

In figure 7 the rms distribution of the last floors of the two towers over the monitoring periods are shown. The level of vibrations of the Tower B is higher of about the 30% than the Tower A, confirming the different operational conditions. For both cases the main dynamic load is the wind and the maximum value has been reached in the Tower B (Figure 6).

	Sensor	Median [mg]	Variance [mg]	Elements
TG	#1017r	0,0045	0,0001	3142
	#1018t	0,0042	0,00003	4382
	#1018r	0,0043	0,00001	4377
MM	#1010r	0,0056	0,0023	2089
	#1010t	0,0057	0,000007	5475
	#1009r	0,0053	0,000009	5471
	#1008t	0,0061	0,00003	5507

Table 1: The rms distribution for the accelerometers in the last floor of the two towers.

4 RESULTS

The two monitoring systems are active from the end of the 2018, but some shutdown of some devices or some errors in the transmission of the data leads to a reduced grid of measuring points (Figures 3b-5b). Hence the adaptive modal tracking procedure proposed herein, considers that issues and the MAC index has been calculated considering the common channels that were recording. Then two suitable calibration periods have been chosen as limit cases of the operational dynamic behavior.

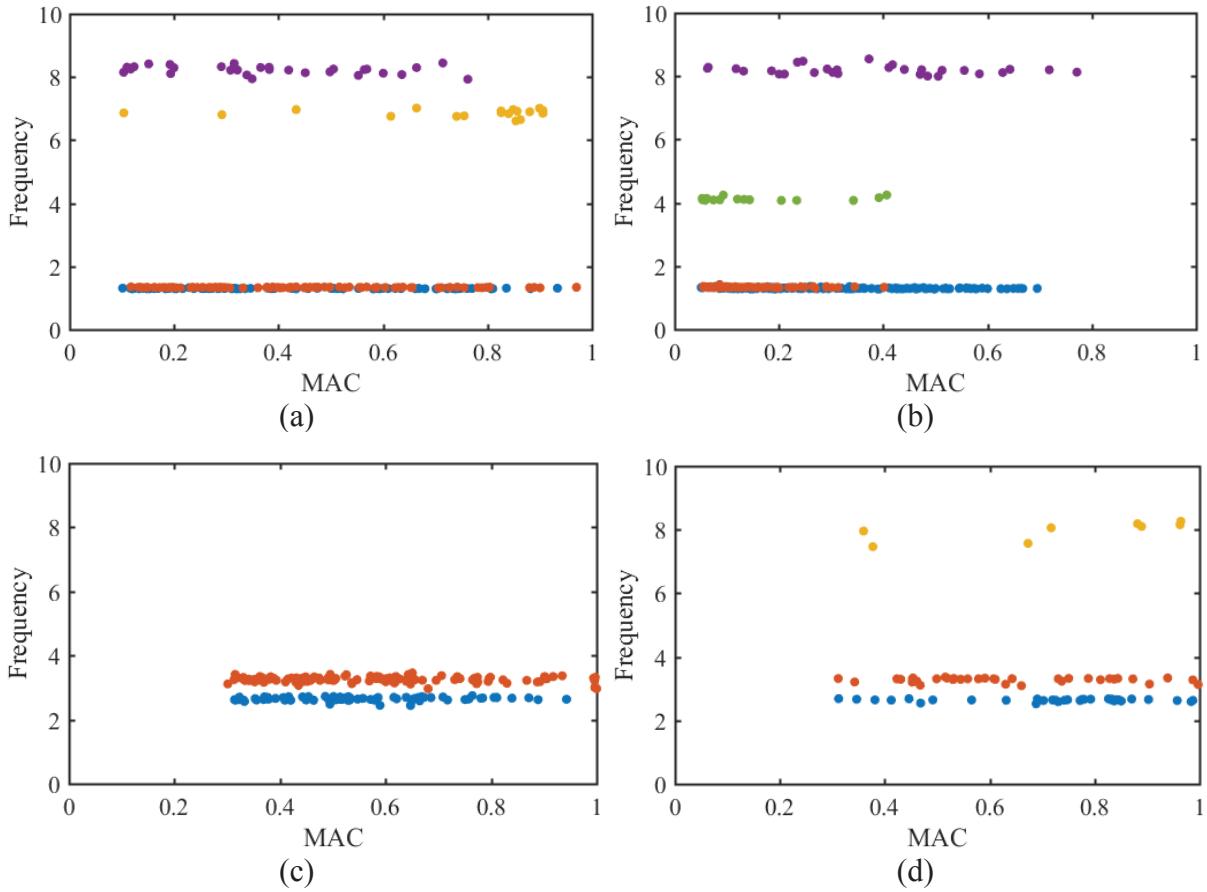

Figure 8: (a) The "Torre Grossa" in San Gimignano (SI) (b) The "Mastio Matilde" in Livorno (LI) (c) (d).

The periods from 10/05/2019-16/05/2019 (#MM1) and from 3/12/2018-9/12/2018 (#MM2) are those where the highest average wind speed has been recorded respectively for the Tower A and Tower B. Meantime, the periods from 1/05/2019-7/05/2019 (#TG1) and from 15/05/2019-21/05/2019 (#TG2) are those where the lowest average wind speed has been recorded respectively for the Tower A and Tower B. Thus, the distances in terms of frequency and mode shapes are calculated with the clustering procedure described in the previous sections.

Lastly, some statistical values of the measured distances for each period can be calculated and the minimum values can be chosen to track the modes. For that cases of study, the median value of the frequency and the third quartile value for the mode shapes.

Period	1st Mode		2nd Mode		3rd Mode	
	f_{lim}	ϕ_{lim}	f_{lim}	ϕ_{lim}	f_{lim}	ϕ_{lim}
#MM1	1,10	0,61	3,65	0,48	-	-
#MM2	3,42	0,83	3,38	0,80	2,48	0,92
#TG1	0,53	0,73	0,56	0,70	1,18	0,78
#TG2	1,04	0,43	1,73	0,65	2,16	0,52

Table 2: Example of the construction of one table.

As a result, the thresholds are not fixed but for each mode are calculated from the observed results in a representative calibration period. The selection of the representative values has been performed statistically analyzing two extreme operative conditions related to the most

relevant dynamic excitation. But the calibration period can be also selected with different approaches that lead to the observation of the operational conditions of the monitored structure.

5 CONCLUSIONS

The paper introduces a novel procedure for the adaptive modal tracking of the modal parameters extracted from long-term monitoring data. That issue is usually underestimated, and it has not been widely deepened by the Authors. This become crucial if the accelerations are measured with low-cost sensors that exhibit a lower resolution. In particular the mode shapes seem to be more sensitive to the background noise than the frequency. Thus, the classical modal tracking approach based on fixed threshold can bring to misleading results.

In addition, the identified modes might be not well excited during the measuring time-window and some channels might be not active.

Consequently, the results show how the tracked modes can exhibit different values based on the level of the ambient vibrations. Therefore, some adaptive threshold for the modal tracking based on the operational conditions should be considered to achieve adequate results.

Here the proposed procedure has been applied to two historic masonry towers monitored with a wireless network system of MEMS devices. That measuring network allows the use of cheaper sensors with a low-visual impact that are highly recommended for the monitoring of cultural heritage structures. Ensuring the use of the structure without compromising the architectonical features.

The proposed method is based on the hierarchical clustering of the modes in a representative observation period. Then the thresholds are selected by a statistical analysis of the results observed in the calibration periods. Nevertheless, the method can be implemented in a fully automated procedure for the modal extraction of the modal properties even if low-cost devices are used. Abstract. *Several approaches can be found in the scientific literature when the subject is damage detection based on vibration signals. In the last few years, increasing attention has been given to the application of Computational Intelligence algorithms in structural novelty identification. In more details, the powerful data mapping capability of computational deep learning methods has been recently exploited to develop strategies of structural health monitoring through appropriate characterization of dynamic responses. Therefore, the present work is aimed at investigating the capability of a deep learning algorithm called Sparse Auto-Encoder (SAE) to identify structural alterations of the Z24 bridge, a classical benchmark for integrity assessment studies. The main idea is to characterize the Z24 dynamic responses via SAE models and, subsequently, to detect the onset of abnormal behavior through the well-known Shewhart T control chart (T^2-statistic), calculated with SAE extracted features. An advantage of the proposed methodology is that data are processed directly in the time domain, avoiding modal parameters estimation and tracking analysis. Moreover, control charts are considered suitable tools for continuous monitoring due to their relatively simple implementation. The obtained results demonstrate that the proposed strategy based on SAE and Shewhart T control chart has potential to be explored in structural damage detection problems, since it is able to distinguish between the two investigated scenarios (i.e., undamaged and damaged) of Z24 bridge.*

1 INTRODUCTION

The proper functioning of structural systems and the safety of users are among the main concerns of engineers throughout the life cycle of any civil engineering construction. In order to avoid catastrophic failures, it is important to continuously monitor the structural condition and detect any abnormal behavior at an early stage, especially when dealing with large structures, such as bridges, viaducts, tall buildings, and towers.

Among the different methodologies available to identify the occurrence of structural anomalies, vibration-based damage detection has been extensively investigated in the scientific literature (see e.g. [1]). Starting from dynamic time histories obtained through Structural Health Monitoring (SHM) systems, these approaches are applied to investigate novelties in terms of structural behavior. In summary, essential features are extracted from measured data and are successively compared to deduce if a structural change has occurred.

Typically, the structural integrity investigation is performed by employing modal analysis [2, 3]. The degrading process alters the physical properties of the structure, such as mass and stiffness, which influence its natural frequencies, mode shapes, and damping ratios. In the last few years, due to the evolution of computer and information technologies, increasing attention has been given to the application of Computational Intelligence (CI) in structural novelty identification [4, 5, 6]. Among all possible CI algorithms, those based on deep learning appear as promising alternatives to traditional techniques. In this paper, a special highlight is given to the Sparse Auto-Encoder (SAE), a deep neural network algorithm that automatically extracts features from data. The SAE reconstructs its inputs through an internal coding - modeled by linear and nonlinear functions - that transforms them into a "new" group of variables (features) [7]. Auto-encoders are known not only for the ability to deal with large volumes of data but also for their capability to provide optimal solutions, particularly for nonlinear problems, such as structural anomaly detection [8, 9]. Therefore, SAE may be an appropriate method for handling vibration signals. It is important to notice that deep learning algorithms are recent tools in the SHM area, and studies focused on evaluating them to solve novelty detection problems are ongoing.

In this context, the present work is aimed at investigating the performance of the SAE algorithm when applied to the identification of structural alterations. The fundamental idea here is to characterize the structural dynamic responses via SAE models and, subsequently, to detect the onset of abnormal behavior through the well-known Shewhart T control chart (T^2-statistic) [10], calculated with SAE extracted features. The Shewhart chart is a sort of statistical process control technique frequently used in SHM strategies and applied to the residuals between measured and predicted (via regression analysis) quantities. Due to the relatively simple implementation, control charts are considered suitable tools for continuous monitoring. The anomaly detection approach is exemplified using data collected on the Z24 bridge [11], before and after damaging the structure.

An advantage of the proposed methodology is that data are processed directly in the time domain, avoiding modal parameters estimation and tracking. Another interesting aspect of such an approach is the unsupervised analysis, which means that it does not use previously labeled observations or desired output variables. Although many methods in the literature are based on the pre-establishment of different degradation levels (supervised analysis), it is difficult to have prior knowledge of the structure's health condition in actual SHM systems.

2 THEORETICAL BACKGROUND

2.1 Deep Learning and Sparse Auto-Encoder

Deep Learning encompasses a variety of machine learning techniques based on Artificial Neural Network (ANN) theory (see e.g. [12]), mainly characterized by their multiple processing layers. As already stated, the present work is focused on the deep learning algorithm called Sparse Auto-Encoder (SAE). In general terms, an Auto-Encoder (AE) is an Artificial Neural Network (ANN) built to return an approximation of its input. According to Goodfellow *et al.* (2016) [7], this network consists of an internal coding layer described by the function $\mathbf{h} = f(\mathbf{x})$, which learns the characteristics $\mathbf{h}$ of input data $\mathbf{x}$, and a decoding layer defined by $\mathbf{y} = g(\mathbf{h})$, which rebuilds the vector $\mathbf{x}$ from the self-learned vector features $\mathbf{h}$, as suggested by the network architecture shown in Figure 1. Since the cost function evaluates the difference between $\mathbf{x}$ and its own output $\mathbf{y} \approx \mathbf{x}$ ($\mathbf{x}$ reconstructed), the learning of an AE is unsupervised. It is worth mentioning that an AE may have several layers between $\mathbf{x}$ and $\mathbf{h}$, as well as between $\mathbf{h}$ and $\mathbf{y}$ (the AE structure has to be symmetric). However, for didactic purposes, Figure 1 represents an AE with only one encoder and decoder layer.

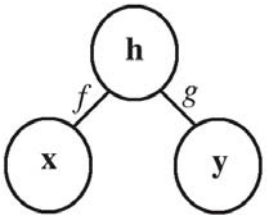

Figure 1: The basic structure of an Auto-Encoder [7].

Nevertheless, the main interest is not in the replicated output of the AE, but in exploring its ability to extract characteristics from "raw data". If the AE is used for data mapping only, without feature reconstruction, it is designed to produce $\mathbf{h}$ with a smaller dimension than $\mathbf{x}$ and is known as Undercomplete Auto-Encoder. The great advantage of reducing the data from $\mathbf{x}$ vector dimension to $\mathbf{h}$ vector dimension is the identification of relevant parameters at a high-level of abstraction, helpful for recognizing patterns in datasets. In this context, the learning of the AE network is accomplished by minimizing a function $Z(\mathbf{x}, g(f(\mathbf{x})))$ that penalizes the differences between $\mathbf{x}$ and $g(f(\mathbf{x}))$. In cases where the coding function is linear, and Z is the mean quadratic error, the Undercomplete Auto-Encoder behaves like the Principal Component Analysis (PCA) [13]. Conversely, when employing nonlinear functions for f and g, the Undercomplete Auto-Encoder may be more powerful than PCA to reduce the dimensionality of a problem [14].

Despite their efficiency in characterizing data, the encoders and decoders may acquire an excessive ability to approximate $\mathbf{y} \approx \mathbf{x}$, resulting in a vector $\mathbf{h}$ with high dimensionality, which many times is not able to provide interesting parameters for modeling the problem. In order to improve the performance of this deep machine learning technique, the Sparse Auto-Encoder (SAE) was proposed. The SAE is an undercomplete auto-encoder where a sparse penalty $\Gamma(f(\mathbf{x}))$ is incorporated into the function Z in the training process. In summary, this penalty allows the AE model to represent large datasets with a small number of $\mathbf{h}$ components, controlling the amount of active neurons in the layers (most weights equal to zero). Consequently, the addition of sparsity-inducing term to auto-encoders usually leads to an increase in the model performance and to a reduction of processing time.

2.2 Shewhart T Control Chart

The Control Chart is a graphical statistical tool used to monitor the variability of a problem's parameters over time. The charts usually depict several data points, which are formed by a specific statistical characteristic and horizontal lines (control limits) responsible for indicating the extreme values of such characteristic when the problem is in-control state. Any point that is beyond these predetermined limits, on the other hand, reveals unusual sources of variability, suggesting an out-of-control situation. [10].

Due to their relatively simple implementation, intuitive interpretation, and effective results, control charts are considered suitable tools for structural on-line monitoring and anomaly detection. The multivariate control technique used herein is the Shewhart T Control Chart. The characteristic plotted in this chart is the Hotelling's T^2-statistic. The T^2-statistic represents the distance between a new data observation and the corresponding sample mean vector - the higher T^2 value, the greater the distance of the new data from the mean. This metric is based on the relationship among the variables and on the scatter of data (covariance matrix). By assuming that matrix $\mathbf{H}_{n\times m}$ represents a dataset during a certain time period (which in this paper are the SAE extracted features), the T^2-statistic may be calculated as follows:

$$T^2 = r(\overline{\mathbf{h}} - \overline{\overline{\mathbf{h}}})^T \mathbf{S}^{-1} (\overline{\mathbf{h}} - \overline{\overline{\mathbf{h}}}) \tag{1}$$

where $\overline{\mathbf{h}}$ is the sample mean vector of the m available features, obtained from a submatrix of $\mathbf{H}$ with r observations ($\mathbf{H}_{r\times m}, r < n$); $\overline{\overline{\mathbf{h}}}$ and $\mathbf{S}$ are the vector of reference averages and the mean of the reference covariance matrices, respectively, both estimated using s preliminary submatrices collected during the in-control state of the problem. In this work, the Upper Control Limit (UCL) is defined as the 95^{th} percentile of the T^2 values of the training data (values greater than UCL may be observed only 5% of the time by chance). The Lower Control Limit (LCL) is zero.

3 THE VIBRATION-BASED ANOMALY DETECTION APPROACH

The present work proposes a structural assessment framework based on SAE models for automatic vibration-data feature learning. Such a framework includes the use of the Hotelling's T^2 control chart applied to SAE extracted characteristics to investigate novelties in terms of structural behavior. Figure 2 shows a general scheme of the suggested anomaly detection methodology.

SHM systems usually comprise a number of accelerometers that record dynamic responses over time. Therefore, it is initially necessary to rearrange the acceleration time histories collected in each measurement point by setting an appropriate window length (duration time) to analyze each measured signal. The vibration measurements are organized in a matrix considering the structural responses of each accelerometer k $(1 \leq k \leq K)$ separately, as illustrated in Figure 3. The rows I indicate each rearranged signal, and the columns J represent the respective dynamic response sampled in time. The definition of the signal duration time should consider the measurements' capacity to represent the current structural condition and the amount of available data. Moreover, since the present approach is focused on continuous monitoring, it is also important to keep the chronological order of the collected signals. In order to make the detection model less sensitive to data scale, after the input matrix is assembled, all data values are divided by the maximum absolute amplitude, leading to acceleration signals between [-1;1].

The developed strategy relies on creating a model with data from the system working in normal conditions, which is named as SAE/T^2-statistic reference model. At this point, the reference matrix previously organized is divided into training and testing data, respecting their

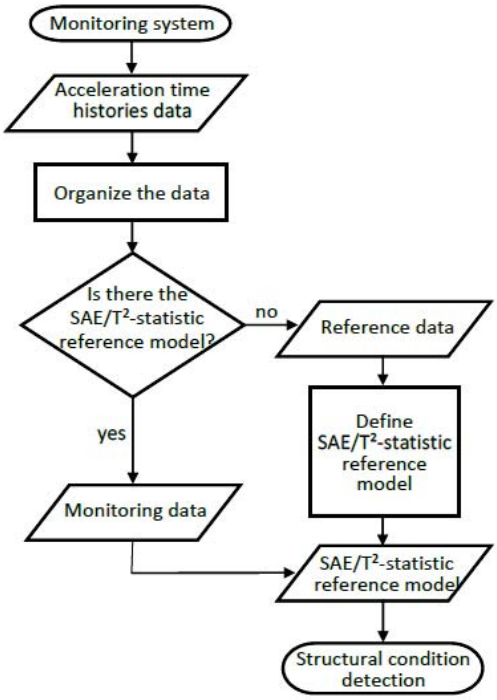

Figure 2: General scheme of the proposed methodology.

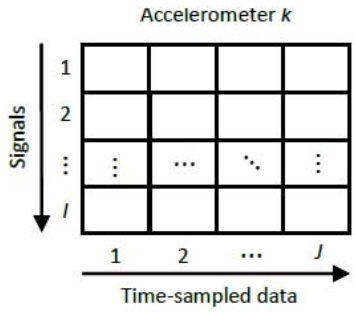

Figure 3: Input data organization for structural anomaly detection approach.

position in time. These two submatrices are used to construct and adjust the SAE/T^2 model through an iterative procedure, described in the following steps:

1. Firstly, the training data are randomized, as usual in algorithms based on ANN theory. This shuffling has the objective of reducing data variance, guaranteeing a greater generalization power for the artificial intelligence model. It is important to emphasize that the randomization is herein performed only on data used to create the artificial intelligence model. After the training task, the data, or rather the SAE extracted features, must be placed in chronological order again;

2. Initial training parameters for the SAE model are defined. These parameters are number of processing layers, number of features to be extracted from time domain responses (number of neurons), optimization method, activation and error functions, maximum number of training iterations (epochs), sparsity proportion ρ and the coefficients β and

λ, related to the sparsity and weights regularization terms of the cost function, respectively. The parameters ρ, β, and λ are related to the sparse penalty function Γ (defined in section 2.1) and assist in the determination of the best solution by the SAE (see e.g. [15]);

3. By using the training data, the SAE model is generated. In the proposed approach, the SAE model is applied to transform the structural signals into a few representative characteristics;

4. The m extracted SAE features are reorganized in chronological sequence (as mentioned in step 1) and used to calculate the T^2-statistic points and the UCL, as shown in Figure 4;

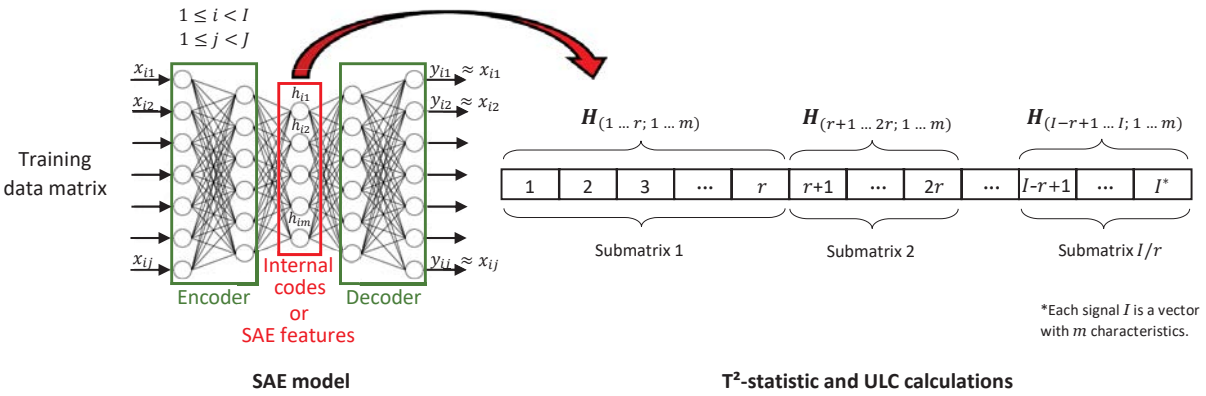

Figure 4: Graphical representation of the T^2-statistic calculation procedure.

5. In order to evaluate the training performance, the SAE/T^2 model is fed with testing data. Since the SAE features are also derived from time measurements collected when the structural system is assumed to be under normal conditions, it is expected that the corresponding T^2-statistic points are below the UCL value. If this statement is not verified, the SAE training parameters are readjusted (empirically), and a new model is created by returning to step 1.

The reference model definition is complete when the SAE/T^2 model developed with the training data is able to correctly represent the current structural behavior by using the testing data. It means that the steps above shall be repeated until all or practically all reference data produce T^2-statistic values bellow the UCL.

Finally, once the SAE/T^2 reference model is properly established, newly acquired data may be classified as being from the normal or abnormal structural condition. SAE features and their T^2-statistics are calculated from monitoring data and plotted in the control chart for comparing the reference structural responses with the newly collected ones. The entire anomaly-detection approach was developed using toolboxes and built-in functions available in Matlab® R2017a.

4 APPLICATION I: Z24 BRIDGE

The Z24 bridge was a highway overpass located at Canton Bern near Solothurn, in Switzerland, built in the early 1960s to connect Koppigen and Utzenstorf. This post-tensioned structure was 58m long composed of three continuous spans with 14m, 30m and 14m, supported on four

piers, as it can be seen in Figure 5. Due to the construction project of a new railway line underneath the highway, the bridge had to be demolished. Therefore, before the structure was completely knocked down, it was instrumented and gradually damaged [11].

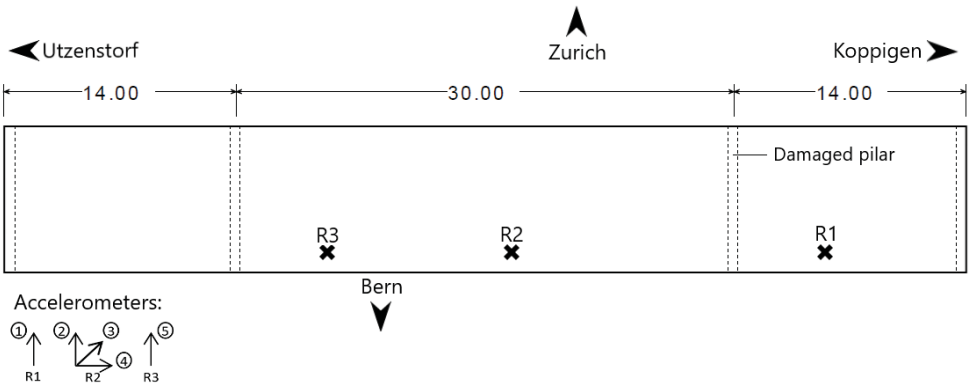

Figure 5: The Z24 bridge - Top view and experimental setup.

The present study evaluates the proposed SHM approach through dynamic signals of forced vibration tests conducted within two structural conditions: undamaged and damaged (settlement of pier - 40mm). Two vertical shakers were used to generate a flat force spectrum excitation with 3-30Hz bandwidth. In each damage scenario, nine dynamic tests were performed considering five accelerometers installed at three measurement points, R1, R2 and R3, as described in Figure 5. Vibration responses have 65535 data points, acquired at a frequency sampling of 100Hz for approximately 11 minutes. The structure's natural frequencies and the temperature variation - before and after the damage - are given in Table 1 for information purposes. The evolution of the eigenfrequencies, as well as the structural modes (see Figure 6), are derived from data of ambient vibration tests by the stochastic subspace identification method [11].

Structural condition	**Temperature**	**1st natural frequency**	**2nd natural frequency**	**3rd natural frequency**	**4th natural frequency**	**5th natural frequency**
Undamaged	17^oC	3.92Hz	5.12Hz	9.93Hz	10.52Hz	12.69Hz
Damaged	29^oC	3.86Hz	4.93Hz	9.74Hz	10.25Hz	12.48Hz

Table 1: Variation of the Z24 eigenfrequencies (values extracted from the work of De Roeck *et al.* (2000) [11]).

For this application, each accelerometer measurement is rearranged into 10-second signals, providing an input matrix [1070×1000]: 1070 dynamic time histories (65 signals per accelerometer × 9 dynamic tests × 2 structural conditions = 1070) composed of 1000 data points (100Hz × 10s = 1000). Henceforth, maintaining its chronological order, the input matrix is subdivided as follows:

- Reference data (undamaged state):

  Training data → matrix [450×1000]

  Testing data → matrix [135×1000]

- Monitoring data (damaged state) → matrix [585×1000]

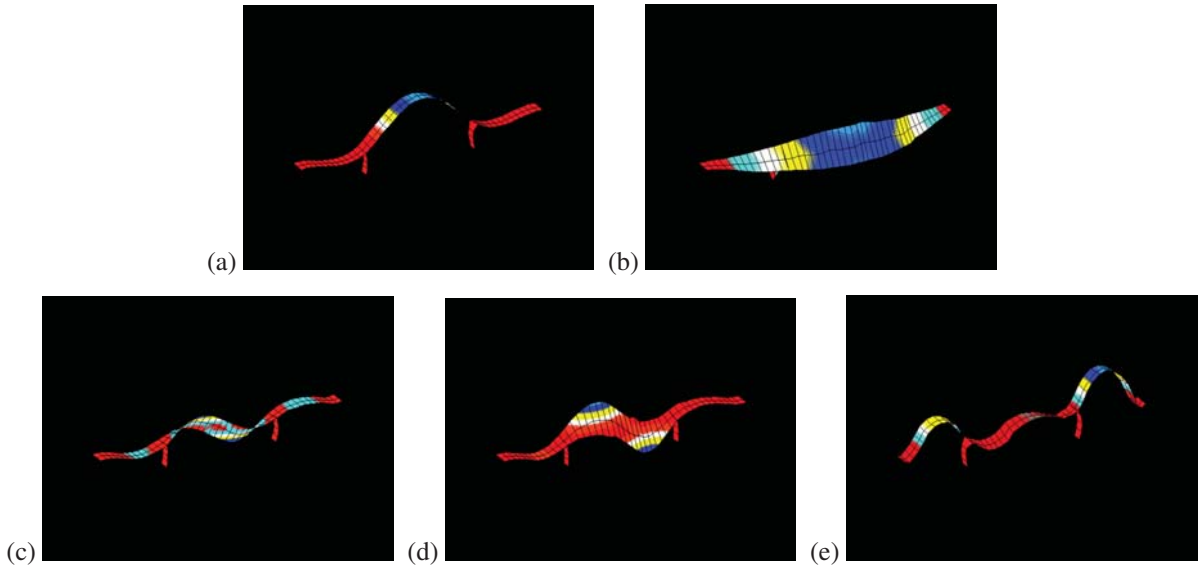

Figure 6: Reference mode shapes of the Z24 bridge - undamaged condition (draws extracted from the work of De Roeck *et al.* (2000) [11]). (a) 1st mode - symmetrical bending mode. (b) 2nd mode - transversal mode. (c) 3rd mode - combined torsional/antisymmetrical bending mode. (d) 4th mode - combined torsional/antisymmetrical bending mode. (e) 5th mode - symmetrical bending mode.

The anomaly detection approach is investigated for each accelerometer channel separately. For all analyses, the achieved SAE model was implemented employing one encoder and decoder layer constituted by 100 neurons (vector $\mathbf{h}$ with 100 components), which reduces the dimensionality of the problem from 1000 data points to 100 features. The other parameters were set to: the sparsity proportion (ρ) $= 0.050$; the sparsity regularization (β) $= 4.000$; the weight regularization (λ) $= 0.001$; the training function = Scaled Conjugate Gradient (SCG) optimization method [16] with gradient maximum value of 1.00×10^{-6}; the encoder and decoder activation functions = logarithmic sigmoid and linear function, respectively; the error metric = mean square; and the maximum number of training epochs $= 1000$. The Hotelling's T^2-statistic was calculated using data subgroups composed of 15 observations ($r = 15$) with the 100 SAE characteristics ($m = 100$). The UCL was estimated considering 30 subgroups of data ($s = 30 = 450$ training examples / 15 observations).

4.1 Results

The results of the proposed approach for the Z24 bridge are shown from Figure 7 to Figure 11. In total, 78 data subgroups were evaluated for each accelerometer channel, considering training (30 subgroups - blue points), testing (9 subgroups - green points), and monitoring data (39 subgroups - red points). In addition to the control chart plotted for one SAE/T^2 model, another control chart was also constructed representing the T^2-statistic for 30 different SAE models. In this case, the UCL is calculated considering the UCL's mean from the 30 models. This practice of examining the performance of various models is usual in ANN-based algorithms. It aims to identify that a specific data ordering (possible correlated samples) is not influencing the model performance.

By analyzing the results, a good performance was achieved for dynamic responses from accelerometers 1 (Figure 7) and 5 (Figure 11). In both cases, during the training and testing periods (undamaged condition), most T^2-statistic values are below the limit line (a small number of false alarms). In the monitoring period (damaged condition), the T^2-statistic abruptly

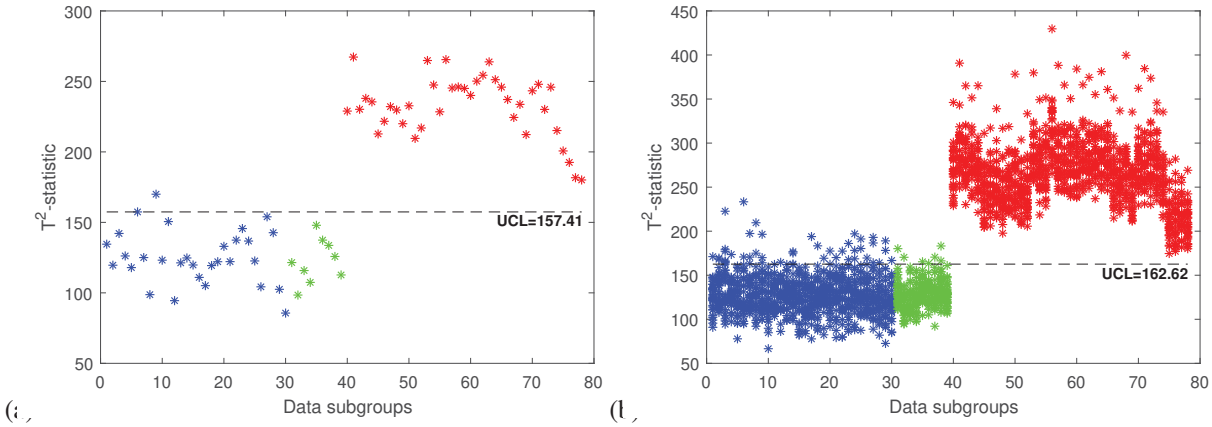

Figure 7: Anomaly detection approach - Output for the accelerometer 1. (a) Control chart for one SAE/T^2 model. (b) Control for 30 SAE/T^2 models.

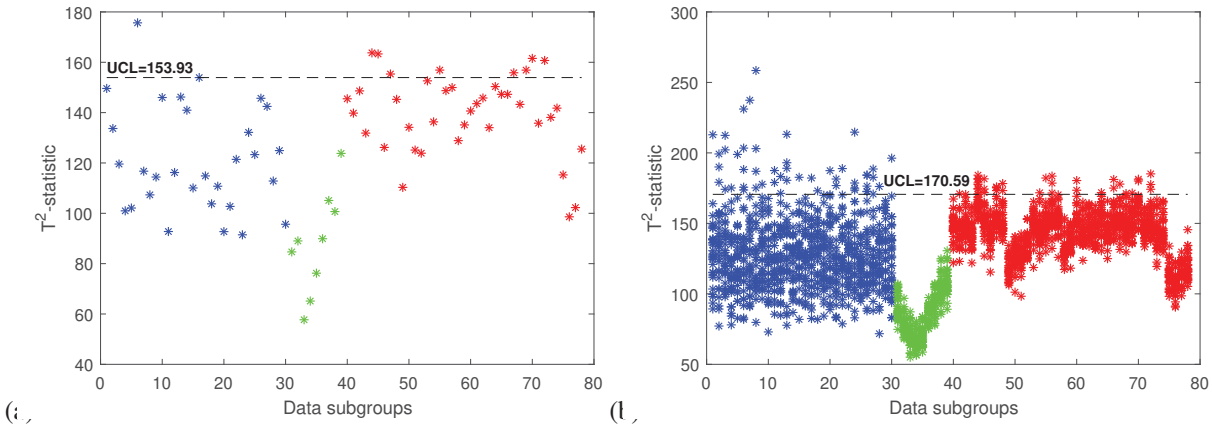

Figure 8: Anomaly detection approach - Output for the accelerometer 2. (a) Control chart for one SAE/T^2 model. (b) Control for 30 SAE/T^2 models.

exceeds the UCL value, laying outside of the in-control region and correctly indicating the presence of the structural anomaly. These outcomes may be attributed to the relation between the position of sensors and the structure's mode shapes. In general, higher natural frequencies are more affected in absolute terms by damage, as seen in Table 1. For this reason, since ac-

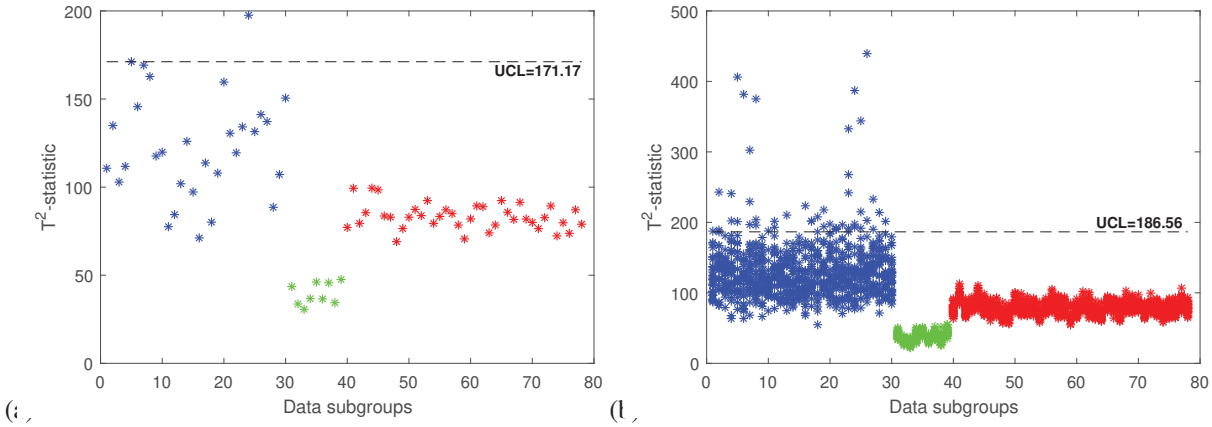

Figure 10: Anomaly detection approach - Output for the accelerometer 4. (a) Control chart for one SAE/T^2 model. (b) Control for 30 SAE/T^2 models.

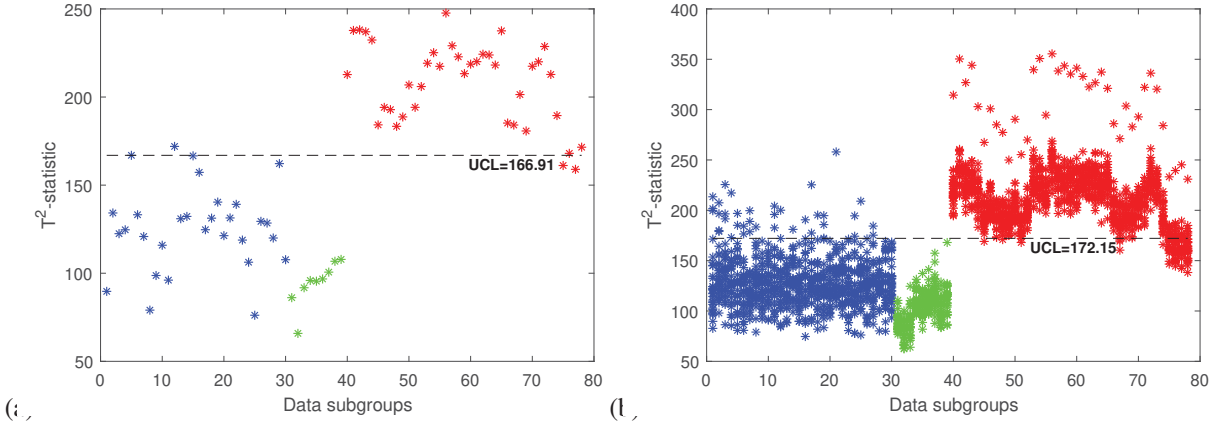

Figure 11: Anomaly detection approach - Output for the accelerometer 5. (a) Control chart for one SAE/T^2 model. (b) Control for 30 SAE/T^2 models.

celerometers 1 and 5 are in positions where the amplitudes related to higher magnitude modes are more significant (absolute difference of 0.27Hz for the 4th frequency and of 0.21Hz for the 5th frequency), they may have had better performance.

The same idea can be used to justify the T^2-statistic of data collected by the accelerometer 2. Even though this channel is more affected by the first vibration mode, due to its location at the midspan, the absolute difference between the natural frequencies is small (0.06Hz), maybe not sufficient for the SAE/T^2 model detects the damage occurrence. Regarding the sensors 3 and 4, they were positioned to capture transversal and longitudinal movements, respectively. Therefore, since the shakers generated components predominantly in the vertical direction and, the structure was considerably rigid on the longitudinal direction, it was expected that the control charts related to these measurement positions would have inconclusive results.

The Mean Square Error (MSE) between original and reconstructed dynamic signals for the 30 SAE models are exhibited in Table 2. It should be noted that the MSE values of training data are smaller than the MSE values of testing and monitoring data, as expected, since the first group of data was used to train the SAE, and the second and third ones were unknown by the created models. Figure 12 displays an example of the SAE reconstructed response in comparison with its respective original signal. Instead of perfectly reconstructs signals, the idea behind the SAE consists of modeling key features of data that are sensitive to structural novelties. Based on

the assumption that lower MSEs are evidence of better signal reconstruction, the slight upward trend in the T^2-statistic verified for testing data of accelerometer 1 may be associated with these values. Table 2 reveals that the responses related to accelerometer 1 have a reconstruction error almost twice as large as the error found for the responses of accelerometer 5, the other channel with good results, where this trend does not appear.

Accelerometer	**1**	**2**	**3**	**4**	**5**
Training data	0.0129	0.0074	0.0057	0.0021	0.0076
Testing and monitoring data	0.0222	0.0120	0.0092	0.0026	0.0138

5 CONCLUSIONS

The paper presented a structural anomaly detection approach based on Sparse Auto-Encoder and Shewhart T control chart. Features extracted by SAE models, directly from time-domain accelerations, were passed along as input variables of the control chart to detect the onset of abnormal behavior in structures. The developed method was exemplified using experimental data from dynamic tests performed on the Z24 bridge.

According to the obtained control charts, the T^2-statistic calculated with the SAE extracted characteristics were efficient in detecting the two different structural states of the Z24 bridge. The results are in agreement with the respective structural scenarios since the damage imposed on the bridge was clearly identified. Nevertheless, more investigation is required to validate the proposed anomaly detection strategy. In particular, the next steps in this work include analyzing the temperature influence on SAE characteristics and applying the methodology in other structures.

Keywords: Optimal sensor placement, structural monitoring, suspension bridge.

Abstract. *The design of systems for structural health monitoring is an exercise that requires careful planning of optimal sensor locations. The number of possible locations usually outnumbers the number of available sensors, which means that solving the problem of optimal sensor placement (OSP) is necessary for a cost-effective network. This paper addresses the design of OSP for a new monitoring system on a long-span suspension bridge. The foremost interest is the response effect of wind loading on the bridge. A finite element model of the bridge is created based on blueprint drawings, and the system model consists of 18 target modes (with frequencies in the range* $[0.05, 0.6]$ *Hz). 22 triaxial force-balance MEMS accelerometers are planned to be deployed. In the design, the sensors are designated into local groups consisting of two or four accelerometers, which are wired to the same data acquisition unit. Two optimization approaches are tried: backward sequential sensor placement and genetic algorithms. The objective metric is the maximization of the determinant of the Fisher information matrix. Six different types of models for the prediction error covariance are tested; one with no correlation and five with varying degrees of error correlation, which is dictated by the sensor distance and a characteristic correlation length. The resulting configurations are compared and discussed.*

1 INTRODUCTION

Structural health monitoring (SHM) of bridges and other civil structures has become a popular method to study the response behavior of structures during the service life. The design of such systems is often subject to cost constraints; thus, it is desired to maximize the information value of the data acquired from the limited available sensors. The problem of optimal sensor placement (OSP) in SHM have been studied widely in the literature, for instance in the in the light of damage detection [1, 2], parameter identification [3, 4], and load reconstruction [5, 6].

The distribution of a small number of sensors in a high number of candidate locations is an OSP problem that cannot be solved by exhaustive searches. Instead, various of optimization methods have been proposed, for instance, backward and forward sequential sensor placement algorithms (FSSP/BSSP) [4], relaxation sequential algorithms [7], genetic algorithms [8], and particle swarm optimization [9]. A review of different methods can be found in [10].

This contribution presents the OSP for a recently opened suspension bridge in the north part of Norway, the Hålogaland bridge. This is a long-span bridge were the wind-induced response is of great importance in both structural reliability and serviceability assessments; thus a SHM system focusing on wind engineering is planned to be deployed to the bridge. The presented OSP design considers the placement of 22 accelerometers. Besides these sensors, it is also planned to install strain gauges, temperature sensors, and several anemometers for wind measurements.

2 OPTIMAL SENSOR PLACEMENT THEORY

This section gives a brief overview of the theory applied in the OSP design. We consider a linear model of the structural vibrations:

$$\mathbf{M}_0\ddot{\mathbf{r}}(t) + \mathbf{C}_0\dot{\mathbf{r}}(t) + \mathbf{K}_0\mathbf{r}(t) = \mathbf{f}(t) \tag{1}$$

Here, the subscript 0 denotes still-air structural properties. This system is modally truncated ($\mathbf{r}(t) = \boldsymbol{\Phi}\mathbf{z}(t)$) using a set of N_m modes:

$$\tilde{\mathbf{M}}\ddot{\mathbf{z}}(t) + \tilde{\mathbf{C}}\dot{\mathbf{z}}(t) + \tilde{\mathbf{K}}\mathbf{z}(t) = \boldsymbol{\Phi}^{\mathrm{T}}\mathbf{f}(t) \tag{2}$$

In this case, the alterations from aeroelastic effects on the mode shapes are not considered, i.e. the modal analysis is performed using still-air vibration modes. We expect that this is reasonable for non-extreme wind conditions. The following linear output model is assumed:

$$\mathbf{y}(t) = \mathbf{S}\boldsymbol{\Phi}\mathbf{z}(t) + \mathbf{S}\boldsymbol{\epsilon}(t) \tag{3}$$

where the binary matrix $\mathbf{S}$ selects the output DOFs of the sensors out of all possible DOFs. It is common to assume that the prediction error $\boldsymbol{\epsilon}(t)$ is a Gaussian stochastic process. This error can be thought to have two independent sources (model errors and measurement noise):

$$\boldsymbol{\epsilon}(t) = \boldsymbol{\epsilon}_{mod}(t) + \boldsymbol{\epsilon}_{meas}(t) \tag{4}$$

These components are associated with their respective covariance matrices:

$$\boldsymbol{\Sigma} = E[\boldsymbol{\epsilon}(t)\boldsymbol{\epsilon}(t)^{\mathrm{T}}] = \boldsymbol{\Sigma}_{mod} + \boldsymbol{\Sigma}_{meas} \tag{5}$$

For the case study presented in Section 3, we expect that errors from the model generally are greater than the measurement noise in Eq. 3-4. This is partly motivated by the fact that currently

available high-quality force-balance MEMS accelerometers have very good noise performance. Previous studies of suspension bridges also indicate that errors from finite element (FE) models are prevailing [11].

When all sensors are of equal type, it is sensible to assume that the latent measurement noise has equal magnitude and is uncorrelated among all outputs, i.e. $\mathbf{\Sigma}_{meas} \propto \mathbf{I}$. Characterizing the model errors, however, is generally more complicated since these usually are propagated from errors on the different physical parameters of the model (stiffness, mass, geometry, etc.). The authors of [12] proposed a correlation structure on the following form:

$$\Sigma_{ij} = \exp(-\delta_{ij}/\bar{\delta}) \tag{6}$$

which penalizes the proximity of two sensors: δ_{ij} is the distance between model DOF i and j, and $\bar{\delta}$ is a characteristic correlation length. Although this model is not physically motivated, it can help avoid problems with sensors clustering close to each other, which can lead to redundant information. An expansion of this model was proposed in [13]:

$$\Sigma_{ij} = \frac{\mathbf{\Psi}_i \mathbf{\Psi}_j^{\mathrm{T}}}{N_m} \exp(-\delta_{ij}/\bar{\delta}) \tag{7}$$

where $\mathbf{\Psi}_i$ and $\mathbf{\Psi}_j$ are scaled rows of the mode shape matrix:

$$\begin{bmatrix} \mathbf{\Psi}_i \\ \mathbf{\Psi}_j \end{bmatrix} = \begin{bmatrix} |\phi_{i\,1}|/\max(|\phi_{i\,1}|,\ |\phi_{j\,1}|) & \dots & |\phi_{i\,N_m}|/\max(|\phi_{i\,N_m}|,\ |\phi_{j\,N_m}|) \\ |\phi_{j\,1}|/\max(|\phi_{i\,1}|,\ |\phi_{j\,1}|) & \dots & |\phi_{j\,N_m}|/\max(|\phi_{i\,N_m}|,\ |\phi_{j\,N_m}|) \end{bmatrix} \tag{8}$$

In essence, the fraction in front of the exponential weighs the similarity in the modal values at model DOF i and j, and assumes a value between zero and one. For instance, if the majority of modes are in orthogonal directions, as often is the case with regular structures that has lateral and vertical bending modes, this weight assigns a low correlation for two DOFs that are orthogonal.

A more advanced idea was proposed in [14], considering the uncertainties in the stiffness matrix $\mathbf{K}$ as the source of the prediction errors. In that case, a first-order perturbation of the mode shapes with respect to uncertain stiffness parameters enters the calculations. A similar approach was proposed in [15], where the robustness of optimal sensor placement under parametric uncertainty was studied. Intervals for parameters were studied in [16].

The present study uses a quite comprehensive FE model of a bridge where the stiffness (or mass) matrix and its derivative are not readily available in a suitable numerical form unless multiple perturbation analysis are performed. For this reason, this contribution mainly uses Eq. 7 as the basis for the error covariance matrix.

Formally, the OSP problem can be cast in a Bayesian framework, see e.g. [3, 4, 8, 17] for details on the theoretical background. In this contribution, we limit the discussion on this topic to defining the Fisher information matrix (FIM) as follows:

$$\mathbf{Q}(\mathbf{S}, \mathbf{\Sigma}) = (\mathbf{S\Phi})(\mathbf{S\Sigma S}^{\mathrm{T}})^{-1}(\mathbf{S\Phi})^{\mathrm{T}} \tag{9}$$

It can be shown that maximizing the determinant of the FIM (or equivalently, minimizing the information entropy) leads to the least uncertainty in the estimate of the modal coordinate vector [12]. Thus, among all possible sensor configurations, the optimal solution is selected as the one that minimizes the following normalized objective function [4]:

$$\mathrm{Obj}(\mathbf{S}, \mathbf{\Sigma}) = \sqrt{\frac{\det(\mathbf{Q}(\mathbf{S}_{ref}, \mathbf{\Sigma}))}{\det(\mathbf{Q}(\mathbf{S}, \mathbf{\Sigma}))}} \tag{10}$$

Figure 1: The Hålogaland bridge (Rendering by Statens Vegvesen).

which is also referred to information entropy index (IEI). Here, $\mathbf{S}_{ref}$ represents a reference configuration where all sensor candidates are included.

3 APPLICATION CASE

3.1 The Hålogaland Bridge

The structure under consideration is the Hålogaland Bridge (Fig. 1), which opened for traffic in March 2019. This suspension bridge has a main span of 1145 m in addition to two side-spans of 240 m and 149 m. The towers are 180 m tall, and the main cable is anchored in bedrock on both sides of the fjord. A cable-supported bridge was chosen for this location due to the high water depths (ca. 340 m) that prohibits short-span bridges with intermediate supports. The main span has a single-box steel girder, which is slenderly designed with two driving lanes and one pedestrian lane. The long span inevitably leads to low natural frequencies, meaning that the structure will be susceptible to excitation from natural wind.

A FE model of the bridge (Fig. 2) is created in the modeling software ABAQUS based on the geometry from technical design drawings. Beam elements are for all structural components. The side-span access roads are discarded from this model as their influence on the dynamic behavior of the main span is deemed negligible.

Typical nominal values are assigned for the structural properties (mass, stiffness, bearing behavior, boundary conditions, etc.). Although there inevitably are uncertainties related to these quantities, the assigned parameter values could later be calibrated in through model updating procedures.

The linearized vibration modes are calculated for the finished state where the structure is in equilibrium under dead loads. The set of selected target modes is chosen as the N_m=18 lowermost vibration modes from the FE model, with natural frequencies ranging from 0.05 Hz and 0.6 Hz. Capturing a higher number of modes would ultimately require a higher number of accelerometers.

As seen from Fig. 3, the different modes can roughly be classified into five types: $i)$ lateral and vertical bending modes, which typically have a $\sin(n\pi x/L)$-type deflection of the bridge deck; $ii)$ torsion modes; $iii)$ cable modes, which mostly have deflects the main cable and hangers; $iv)$ tower modes; $v)$ other combination modes which to some extent excite both the bridge deck and cables. All the mode shapes are normalized so that the maximum amplitude is equal to unity.

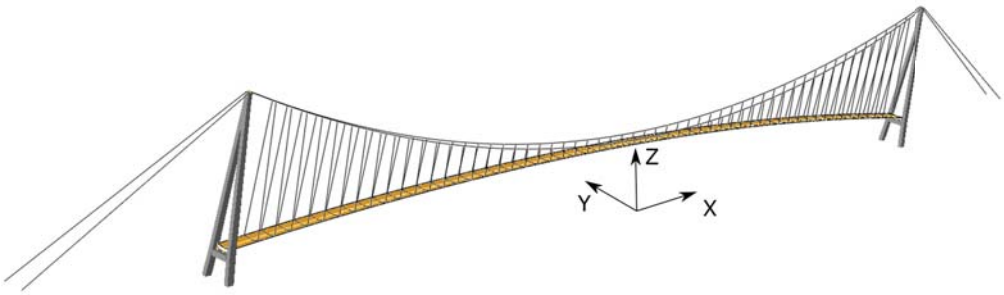

Figure 2: Finite element model of the bridge.

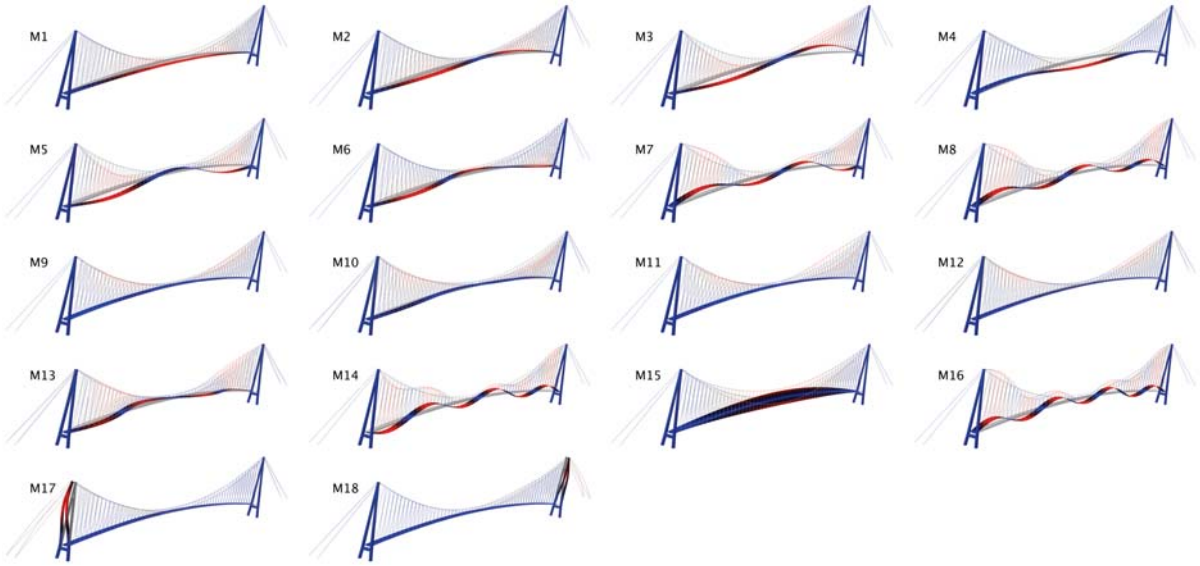

Figure 3: Vibration modes 1-18 from the FE model.

3.2 Strategy of optimal sensor placement

In the OSP, the following strategical points are adopted:

- The sensors are designated into groups of two or four accelerometers in a slice of the box girder, see Fig. 4. The optimization considers the addition or removal of a group of sensors, not individual sensors. This design constraint is adopted for proximity reasons; the sensors in a group must be wired to the same local data acquisition unit (DAU).

- Some output channels are discarded, mainly because the modal deflection is insignificant. Although triaxial accelerometers are used in reality, only the lateral (y) and vertical (z) directions are considered in the for sensors in the main span. For the sensors in the towers, the longitudinal (x) and the lateral (y) directions are included.

- For engineering reasons, some sensors are *a priori* distributed on the bridge. Two accelerometers are chosen to be placed in the mid-span of the bridge since it is desired to have statistics from this location. In addition, one accelerometer is placed in each of the towers.

Two OSP search methods are used in the design: a backward sequential sensor placement (BSSP) algorithm and a genetic algorithm (GA). The BSSP is initiated with sensors in all candi-

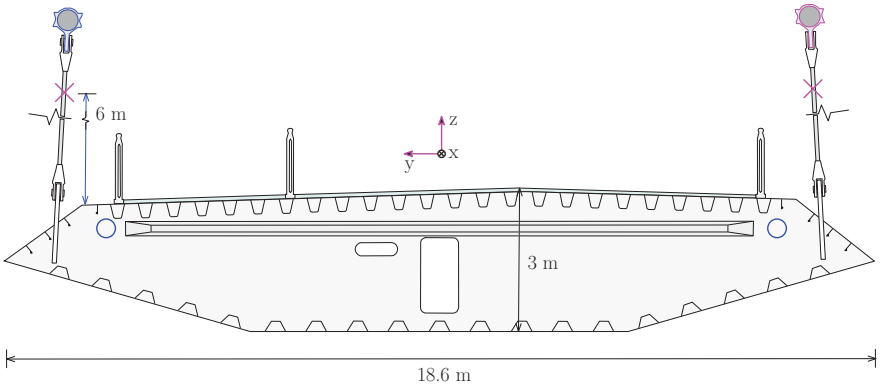

Figure 4: Mounting locations of accelerometers in the box girder (blue circle) and on the hangers (pink cross).

date locations. Then one sensor group is iteratively removed by simply by discarding the group that contributes the least to the objective function in a perturbation analysis. The iterations are stopped when the number of remaining sensors equals the set target of 22 accelerometers. BSSP algorithms are heuristic, and convergence to the optimal configuration (among all possible) is not guaranteed. Therefore, the GA is used to improve the BSSP search, and is given the following rules:

- The population is set to 30 individuals, each corresponding to a sensor configuration. The initial population is chosen to consist of both the obtained BSSP solution and other randomly picked configurations.
- Every iteration, 5 children are generated from 2 parents selected randomly from the population. The sensor locations of a child are a random mix of its parents' locations, with a probability weight of 0.8 and 0.2 assigned to the fittest and least fit parent.
- A child can have random mutations as follows: $i)$ a sensor group can move one or two increments (20 or 40 m) to the left or right with a probability of 0.1; $ii)$ all sensor groups can simultaneously be mirrored about the mid-point of the bridge with a probability of 0.1.
- The next generation is selected as the 30 best configurations among the 35 candidates (30 individuals + 5 children) with respect to the fitness (i.e. the objective function in Eq. 10).
- The iterations are continued for a maximum of 500 generations or until the population is fully homogeneous.

3.3 Optimization resulting

In total, six different optimization cases is performed. The first targets purely measurement errors, where the case of no correlation ($\boldsymbol{\Sigma} = \mathbf{I}$) is tested. The next five cases focuses on model errors using several versions of the covariance model $\boldsymbol{\Sigma}(\bar{\delta})$ from Eq. 7 with $\bar{\delta} = \{10, 100, 250, 500, 1000\}$ m.

For each of these six cases, the BSSP is run first and is next followed by the GA. Compared to the BSSP, the GA is generally found to improve the objective function by 10-20% and only minorly alter the sensor configuration. The resulting sensor locations are shown in Fig. 5. All configurations have 22 accelerometers, and also require 10 local DAUs (8 in the box girder and

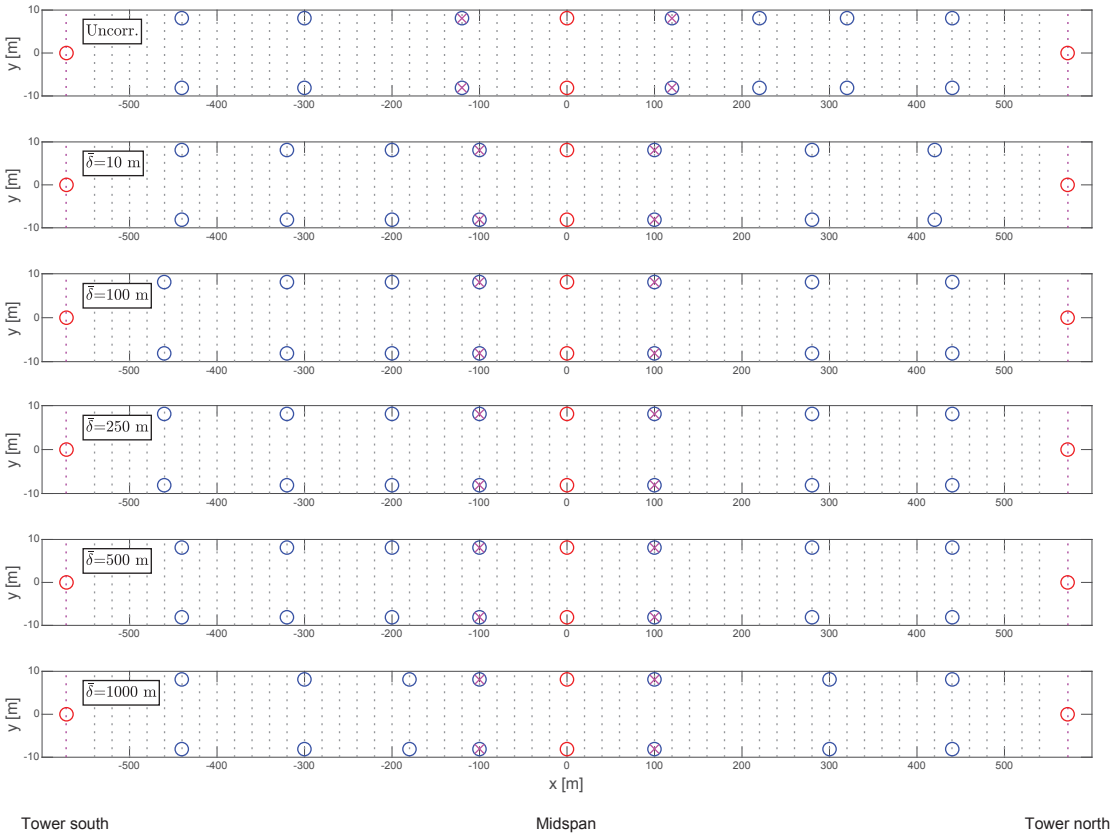

Figure 5: Optimal sensor locations for different covariance models. The black dotted lines indicate the coordinates of the 55 hangers. Blue circles: accelerometer in box girder; pink cross: accelerometer on hanger cable; red circles: apriori chosen locations in the midspan and the towers.

2 in the towers). Notably, all cases (arguably except for the uncorrelated case) display a similar pattern of sensor distribution along the bridge span. Although not shown here, this is only occurring to a lesser extent when instead a lower number of target modes is set ($N_m = 3$ or $N_m = 6$). A plausible explanation for this is that the full target mode selection ($N_m = 18$) contains modes with wavelengths both in the order of 100 and 1000 m, and so a single correlation length variable $\bar{\delta}$ does not highly influence both the higher and lower modes simultaneously.

Since no specific value for $\bar{\delta}$ could be said to be "correct", one can perform a simple robustness check by considering how well the optimal solution from case i performs when evaluated with respect to the objective function from case j. Fig. 6 shows values of the comparative expression:

$$\text{Ratio} = \frac{\text{Obj}(\mathbf{S_i}, \mathbf{\Sigma_j})}{\text{Obj}(\mathbf{S_j}, \mathbf{\Sigma_j})} \tag{11}$$

In Fig. 6, the values on the diagonal ($i = j$) are by definition equal to one, and the others ($i \neq j$) indicate a "cross-performance ratio" larger than one. Not surprisingly, most values in Fig. 6 are close to one. For instance, it could be argued that the optimal solution $\mathbf{S}(\bar{\delta} = 500)$ is attractive since it performs well for all covariance models (1.53 for the uncorrelated case and ≤ 1.05 for the other cases). On the other hand, the sensor configuration for the uncorrelated case does not perform well when it is evaluated using the correlated covariance matrices (ratios ≥ 5).

Besides the FIM and the IEI, the condition number of the matrix $\mathbf{S\Phi}$ has an interest in

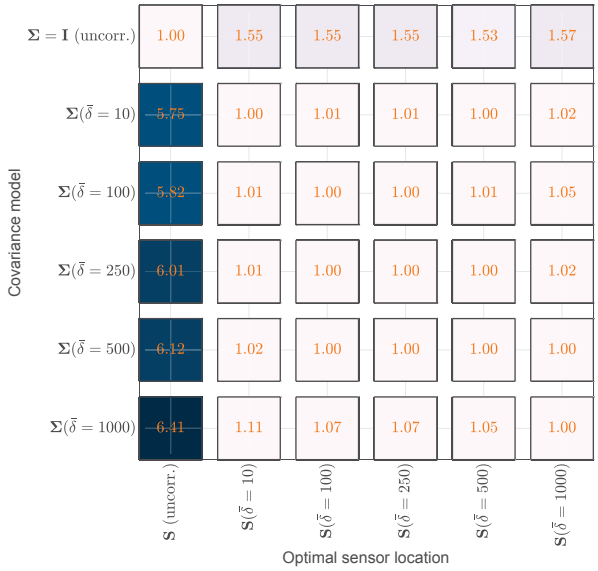

Figure 6: Normalized evaluation of objective functions for different optimal sensor locations (Eq. 11).

applications such as force identification from acceleration data, which is one of the aspirations of this SHM project. Specifically, the matrix rank of $\mathbf{S\Phi}$ plays an important role [5], since this matrix designates the direct influence from the modal loads on acceleration measurements. Generally, it is desired that this matrix has a low condition number, as high condition numbers could lead to numerical rank loss or ill-conditioned pseudo-inversion. Here, it is found that $\text{cond}(\mathbf{S\Phi}) \approx 5.5 \pm 0.5$ for all six cases, which is low and thus very acceptable.

Also the modal assurance criterion (MAC) is a common metric in optimal sensor placement studies [13, 16, 18, 19]. The MAC between mode $\boldsymbol{\phi}_i$ and $\boldsymbol{\phi}_j$ is defined as follows:

$$\text{MAC}_{ij} = \frac{|(\mathbf{S}\boldsymbol{\phi}_i)^{\mathrm{T}}(\mathbf{S}\boldsymbol{\phi}_j)|^2}{(\mathbf{S}\boldsymbol{\phi}_i)^{\mathrm{T}}(\mathbf{S}\boldsymbol{\phi}_i)(\mathbf{S}\boldsymbol{\phi}_j)^{\mathrm{T}}(\mathbf{S}\boldsymbol{\phi}_j)}, \quad 0 \leq \text{MAC}_{ij} \leq 1 \tag{12}$$

As this metric typically is used to distinguish a set of modes, it is desired to have MAC_{ij} close to zero when $i \neq j$. This is particularly important in system identification for structures with close natural frequencies so that that also mode shape information can be effectively utilized for mode matching with FE models. Fig. 7 shows the auto-MAC values for the optimal configuration $\mathbf{S}(\bar{\delta} = 500)$. Although the MAC is not included in the OSP objective, it is reassuring that very low off-diagonal values generally are obtained, except for the single instance $\text{MAC}_{10,13} = 0.59$.

4 SUMMARY

This paper has presented a case study of the OSP with application to the Hålogaland bridge, a long-span suspension bridge. The optimal locations for 22 triaxial accelerometers were designed by maximizing the determinant of the FIM when considering 18 target vibration modes from a FE model. The design was performed by testing several covariance models for the prediction error with different correlation lengths. In this study, it is found the optimal sensor configuration is not very sensitive to the correlation length parameter. This result could be explained by the diversity of characteristic wavelengths in the target modes. In addition, the optimal sensor configurations are found to have low condition numbers (of the mode shape

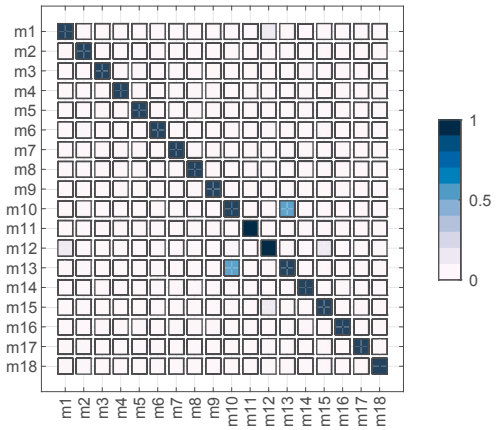

Figure 7: Auto-MAC values for the optimal configuration $\mathbf{S}(\bar{\delta} = 500)$.

matrix), and generally low values for off-diagonal elements in the MAC matrix.

Keywords: Wind turbines; Negative stiffness; Vibration absorption; KDamper; damping;

Abstract. *The application of vibration absorbers to Wind Turbine (WT) towers has the potential to significantly improve the damping of the tower and the nacelle dynamic response, increasing thus the reliability of WTs. The Tuned Mass Damper (TMD) is considered as a benchmark design option for vibration absorption in Wind Turbine towers. However, its effectiveness is limited by the requirement of large masses, in association with its installation location (top of the WT tower). For this reason, two alternative concepts are considered. First, the nacelle is released from the Wind Turbine tower (nacelle isolation concept), using a low stiffness connection. This option is based on the seismic isolation concept of structures with the use of seismic isolation bearings. Alternatively, a novel passive vibration absorption concept is implemented, based on the KDamper concept. The KDamper is essentially based on the TMD, including however an additional negative stiffness element. Instead of increasing the additional mass, the vibration absorption capability of the KDamper can be increased by increasing the value of the negative stiffness element. Thus, the KDamper always indicates better isolation properties than a TMD damper with the same additional mass. In this paper, the performance of these three vibration absorption concepts is examined for increasing the damping of Wind Turbine towers and for the improvement of their dynamic response. Although all methods present a good behavior, the proposed vibration absorption systems present a significant increase of the damping ratio with a minimal value of added mass at the top of the tower.*

1 INTRODUCTION

As wind power continues its rapid growth worldwide, wind farms have a high probability to comprise a significant portion of the total production of wind energy, and can even become a hefty contributor to the total electricity production in some countries. The high-quality wind resource and the closeness to load centers make wind energy a fascinating proposition. The Wind Turbine (WT) is supported by a tower that can experience extreme vibrations caused by both the wind turbine and the wind forces due to its geometry and great height. An accurate analysis of the structural behavior of the tower is of high importance due to its cost, which can represent roughly 20% of the total cost of the system [1]. A lot of researchers have been studying the use of structural control to help overcome the wind-induced vibrations experienced by Wind Turbine towers[2]–[5]. The passive control methods are plain and trustworthy. They do not require an external force, are easy to implement to reduce the structural vibration and are widely used in Wind Turbine technology for the improvement of their damping. They incorporate one or more devices to the main structure to absorb or transfer part of its energy.

The intention with the installation of such devices, for the control of Wind Turbine towers, is the mitigation of their dynamic response because of the fact that the vibrations caused by aerodynamic loads are longstanding and cause fatigue problems to the body of the tower and their foundation.

The installation of a resonant damper like a Tuned Mass Damper (TMD) is the damping concept that has obtained the most consideration in the literature. A Tuned Mass Damper (TMD) is a control device that consists of a mass-spring-dashpot attached to the structure, intending to reduce structural vibration response [6], [7]. The TMD concept was first applied by (Frahm, 1909 [8]). A theory for the TMD was introduced in the paper by (Ormondroyd and Den Hartog, 1928 [9]). A detailed discussion of optimal tuning and damping parameters appears in (Den Hartog, 1956 [10]). Since then, a great number of applications of various forms of TMDs have been reported. Some new examples include vibration absorption in seismic or other forms of excitation of structures (Debnath et al., 2015 [11]). TMDs are available in various physical forms, including solids, liquids, or active implementations (Younespour and Ghaffarzadeh, 2015 [12]). The Active Tuned Mass Damper (ATMD) is a hybrid device comprising of a passive TMD supplemented by an actuator parallel to the spring and damper. It is a well-known concept in structural control and has demonstrated enhanced damping performance compared to the passive TMD [13], [14]. The drawback of such designs is that their performance is directly dependent on the accuracy of the actuator's output, which over time can have alterations in its performance by false estimation of the desired function of the vibration absorption concept. Various forms of Dynamic Vibration Absorbers (DVA) have been used, such as Tuned Liquid Column Damper (TCLD) or a Tuned Mass Damper (TMD). Some of the pioneering work regarding applications in wind turbines include the work by Colwell and Basu [15] in which the damping effect of a TLCD installed in an offshore wind turbine has been examined by assuming correlated wind and wave load conditions. A different geometry of the TMD is the pendulum device [16]. The main structure excites the device, and part of its energy is transferred by its movement and then it is dissipated by the pendulum damper.

In order to be potent, a resonant damper like a TMD should be installed where the absolute motion of the targeted vibration mode is largest, which is at the top of the tower or inside the nacelle. Effective damping by a TMD is correlated with a large damper mass, which forms a major limitation since additional mass is undesirable at the top of the wind turbine.

For this reason, two alternative vibration mitigation concepts are examined in this paper. First, the nacelle is released from the Wind Turbine tower (nacelle isolation concept), using a low stiffness connection. This is the most well-known path to earthquake-resistance designs as

it is based on the concept of reducing the seismic demand instead of increasing the structure's resistant capacity. Modern seismic isolation systems for structures grant horizontal isolation from the seismic effects, by decoupling the structure from its foundation [17]–[21]. Among others, this concept has been shown to behave effectively in bridge decks, supported on flexible piers [22], [23].

Alternatively, the KDamper concept, proposed in Antoniadis et al. 2016 [24], is studied. The KDamper extends the classical Tuned Mass Damper by integrating appropriate negative stiffness elements, rather than increasing the additional mass, which enhances the capability of the KDamper, overcoming the sensitivity problems of TMDs as the tuning is primarily controlled by the negative stiffness element's parameters. Although the KDamper incorporates a negative stiffness element, it is drafted to be both statically and dynamically stable. The KDamper is examined for the protection of bridge structures [25]–[29], Wind Turbines [30], [31] and structural systems [32], [33]. In addition, the KDamper is implemented as an Absorption Base (KDAB) in the bases of structures [34]–[40].

Section 2 of the paper demonstrates the methodology and the modeling procedure for the three approaches. Section 3 presents the method of the optimal selection of the parameters of the three approaches. Section 4 presents a comparison of the approaches with respect to the improvement of the dynamic performance of the Wind Turbine Tower and of the nacelle.

2 METHODOLOGY AND MODELING

The contemporary design of wind turbines requires power rates of more than 5MW which can be accomplished by wider rotors (diameters of more than 120 m); for that reason, a proportionate increase of the tower height is required. However, this height increase has immediate effects on the structural behavior of the wind turbine because of the augmented wind pressure area and the slenderness of the tower. Moreover, considering that both the tower and the foundation are vital components of the wind turbine, reaching a rather large percentage of the overall turbine budget (over 60% including the installation cost) [41], [42] the improvement of the dynamic response of the wind turbine tower is of high importance. In this work, a steel tower of 120 m height that supports the NREL baseline 5-MW nacelle and rotor, is used. The key properties of the wind turbine and the steel tower are listed in Table 1 and Table 2 respectively.

Property	**Value**
Rating	5 MW
Rotor diameter	126 m
Hub diameter	3 m
Cut-in wind speed	3 m/sec
Rated wind speed	11.4 m/sec
Cut-out wind speed	25 m/sec
Cut-in rotor speed	6.9 rpm
Rated rotor speed	12.1 rpm
Nacelle mass	240,000 kg
Rotor mass	110,000 kg
Blade material	Glass-fibre
Blade length	61.5 m
Blade mass	17,740 kg
Blade CM (from blade root)	20.475 m
Blade damping ratio (all modes)	0.48%

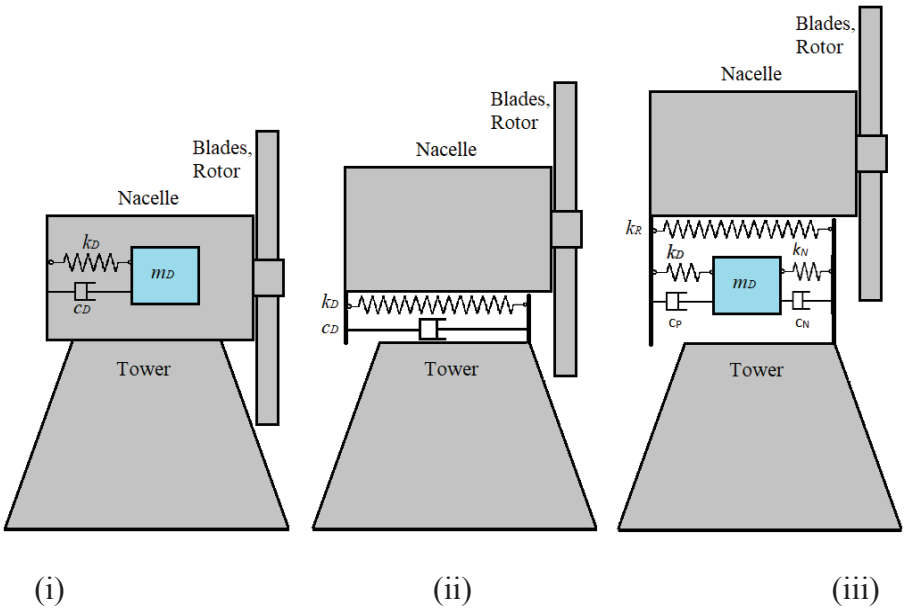
Table 1: Key properties of NREL baseline 5 MW wind turbine.

Property	Value
Height	120 m
Base diameter	8.43 m
Base steel thickness	0.048 m
Top diameter	3.87 m
Top steel thickness	0.025 m
Young's modulus	210 GPa
Steel density	8,500 kg/m^3
Total mass	798,640 kg
Location of CM (above base)	43.042 m
Tower damping ratio (all modes)	2%

Table 2: Key properties of the considered steel tower.

2.1 Vibration mitigation concepts considered

Fig. 1 displays the dynamic vibration absorber design options that will be analyzed in this paper. The first vibration absorption concept is based on the classical tuned mass damper (TMD). Figure 1i presents the schematic image of the TMD concept. An additional mass is attached to the top of the wind turbine tower or inside the nacelle, using a positive stiffness element and a linear damper. The main disadvantage is the need for a large additional mass in order for TMD to attain effective damping. Figure 1ii presents the nacelle-isolation vibration absorption concept, where the mass that correlates to the mechanical parts (nacelle, rotor, and blades) is used as an additional mass of a TMD. The additional mass is no more connected rigidly to the steel tower but is accomplished with a stiffness connection and a linear damper, as in the case of the classical TMD concepts. Figure 1iii presents the realization of the KDamper concept [24] in a wind turbine tower. Again, as in the nacelle-isolation concept, the additional mass of the nacelle, rotor, and blades is no longer rigidly attached to the wind turbine tower but through the interference of a KDamper device. This time the additional mass of the vibration absorption concept is connected with the mass that corresponds to the nacelle, rotor, and blades with a positive stiffness element and a linear damper, and with the top of the wind turbine tower with a negative stiffness element.



(i) (ii) (iii)

Fig. 1: Schematic representation of the considered vibration absorption concepts, (i) TMD concept, (ii) Nacelle-isolation concept and (iii) KDamper concept.

2.2 Dynamic model of the wind turbine

A wind turbine tower (Table 2) of variable tubular cross-section supporting the NREL baseline 5-MW nacelle and rotor [42] is examined. In order to consider the inertial forces applied by the mechanical parts (nacelle, rotor, and blades), an additional mass concentrated at the top, *mtop*=403.22 tn [42] is added at the top of the tower.

The equations of motion of the wind turbine including the respective vibration mitigation concept to be considered are obtained by analyzing the equilibrium of forces at the location of each degree of freedom as follows:

$$[M_S]\{\ddot{x}_S\}+[C_S]\{\dot{x}_S\}+[K_S]\{x_S\}=[P] \tag{1}$$

Where $[M_S]$, $[C_S]$ and $[K_S]$ are the mass, damping and stiffness matrices of the controlled wind turbine tower, respectively of order $(N+n)$ *x* $(N+n)$. Here, N suggests the degrees of freedom (DoF) for the wind turbine tower and n indicates the DoF of each of the vibration isolation options to be considered. In this paper, the degrees of freedom for the wind turbine tower is N=24. The mass matrix is of order $(N+n)$ *x* $(N+n)$ as follows:

$$[M_S]=\left[\begin{bmatrix}[M_N]_{N\times N} & [0]_{N\times n}\\ [0]_{n\times N} & [0]_{n\times n}\end{bmatrix}+\begin{bmatrix}[M_{n,a}]_{N\times N} & [0]_{N\times n}\\ [0]_{n\times N} & [M_{n,d}]_{n\times n}\end{bmatrix}\right]_{(N+n)\times(N+n)} \tag{2}$$

Where $[M_N]_{NxN}$ is the mass matrix of the uncontrolled wind turbine tower and $[M_n]_{nxn}$ indicates the mass matrix of the vibration isolation concept. The condensed stiffness matrix $[K_N]_{NxN}$ of the uncontrolled wind turbine tower is correlating to the sway degrees of freedom taken as the dynamic DoF. The damping matrix $[C_N]_{NxN}$ is not precisely known but is obtained with the help of the Rayleigh's approach using the same damping ratio in all modes, 2%. The stiffness matrix $[K_N]_{NxN}$ and the damping matrix $[C_N]_{NxN}$ are expressed in agreement to the degrees of freedom associated with the respective vibration isolation system to be considered.

The stiffness and damping matrix of the controlled system are formed as follows:

$$[K_S]=\left|\begin{bmatrix}[K_N]_{N\times N} & [0]_{N\times n}\\ [0]_{n\times N} & [0]_{n\times n}\end{bmatrix}+\begin{bmatrix}\lfloor K_{n,a}\rfloor_{N\times N} & -\lfloor K_{n,b}\rfloor_{N\times n}\\ -[K_{n,c}]_{n\times N} & [K_{n,d}]_{n\times n}\end{bmatrix}\right|_{(N+n)\times(N+n)} \tag{3}$$

$$[C_S]=\left|\begin{bmatrix}[C_N]_{N\times N} & [0]_{N\times n}\\ [0]_{n\times N} & [0]_{n\times n}\end{bmatrix}+\begin{bmatrix}\lfloor C_{n,a}\rfloor_{N\times N} & -\lfloor C_{n,b}\rfloor_{N\times n}\\ -[C_{n,c}]_{n\times N} & [C_{n,d}]_{n\times n}\end{bmatrix}\right|_{(N+n)\times(N+n)} \tag{4}$$

The coupled differential equations of motion (Eq.11111) for t1111he isolated wind turbine tower are thus derived and solved using Newmark's integration method.

The wind turbine tower is modeled as a Generalized Single Degree of Freedom System with a shape function based on the first modal eigenform of the non-isolated wind turbine tower. The additional concentrated mass of 403.22 tn, is placed together with the tower's mass m_B. Therefore, the system's parameters are: m_B = 80.57 tn, k_B = 1977.47 kN/m, c_B = 8kN*s/m. Additional assumptions made for the detailed formulation are: (i) the wind turbine tower is considered to remain within the elastic limit under the aerodynamic loads; and (ii) the effects of soil-structure-interaction (SSI) are not taken into account.

2.3 Aerodynamic load

The loading due to the wind is taken into consideration as follows. The tower is deemed to be subjected to the horizontal force $\overline{F}_N(t)$ due to the wind at its top. Moreover, the horizontal force $F_{Nr}(r, t)$ acting as a position r along the wind turbine blade can be acquired by the following relation [43]:

$$F_{N_r}(\mathrm{r},\mathrm{t}) = \frac{1}{2}\rho_{air} C_N(r) c_{bl}(r)(\overline{V}(t))^2 \tag{5}$$

Where ρ_{air} = 1.225 x 10^{-3} tn/m^3 is the air density and $C_N(r)$ is the coefficient calculated by the corresponding lift $C_L(r)$ and drag $C_D(r)$ coefficients. The values of the latter coefficients depend on the airfoil characteristics of the blades and their distribution with consideration to the "angle of attack" of the wind velocity $\overline{V}(t)$ vector passing through the blade profile can be retrieved from. It is noted that $\overline{V}(t)$ is presumed to have a uniform spatial distribution over the actuator disc. $c_{bl}(r)$, $\beta(r)$ is the chord and the pitch angle of the blade profile fluctuating along the blade length r, the distributions of which are acquired according to the blade type employed to equip the turbine. $C_N(r)$ is given as:

$$C_N(\mathrm{r}) = C_L(r)\cos\varphi(\mathrm{r}) + C_D(r)\sin\varphi(r) \tag{6}$$

Where $\varphi(r)$ is the wind flow angle [43]. In order to calculate $\varphi(r)$ and consequently $C_N(r)$, the blade element momentum theory incorporating Prandtl's tip loss factor and Glauert's correction [43] is utilized with a hypothesis of constant angular velocity of the blades $\boldsymbol{\Omega_{bl}}$. Subsequently, breaking $\overline{V}(t)$ down into a mean component V_m and a fluctuating component $V(t)$, the corresponding mean and fluctuating components of $F_{Nr}(r, t)$ can be obtained as:

$$F_{Nm} = \frac{1}{2}\rho_{air} C_N(r) c_{bl}(r) V_m^2 \tag{7}$$

$$F_N(r,t) = \frac{1}{2}\rho_{air} C_N(r) c_{bl}(r)(2V_m V(t) + V(t)^2) \tag{8}$$

In this work, the mean velocity is gained by using a basic velocity at an altitude of 10 m, V_b and applying the corresponding regulations of EC1, Part1,4 [44]. Moreover, in order to take into consideration the wind velocity fluctuation at the altitude of l_t, an artificial velocity time history is produced applying the procedures presented in References [45]–[47]assuming a value of standard deviation σ. After having established $F_{Nr}(r,t)$, the total concentrated force exerted on the top of the tower can be computed as:

$$\overline{F}_N(t) = 3\int_0^{r_{bl}} \overline{F}_N(r,t)dr \tag{9}$$

Besides the concentrated force applied on the top of the tower because of the operation of the turbine, the distributed loading along the tower height is not taken into account due to the fact that it has a minimal influence on the dynamic response of the tower. The basic wind velocity that is employed has equivalent standard deviations V_b = 27.0 m/s with σ = 3.30 m/s ($V_\mathrm{m}(120)$ = 39.93 m/s). The rotor is presumed to develop a constant angular velocity $\boldsymbol{\Omega_{bl}}$ = 12.1 rpm, while all the necessary blade profile characteristics are retrieved from References [42] and [48] (Fig. 2(i)).

Also, a different type of load (Fig. 2(ii)) is employed for the simulation as described in Shkara et al. [49] so that a proper time history of the aerodynamic loads induced to the tower is

obtained, that accurately depicts the alterations of the aerodynamic load in relation with the motion of the wind turbine blades. The basic wind velocity that is aforementioned is still employed in accordance with the response described in [49]. The figure represents the time history of the load for ten seconds but the simulation is performed for a hundred seconds.

The total force $\overline{F}_N\,(t)$ applied at the top of the wind turbine tower is an instantaneously imposed load that is slowly changing over time. Therefore, for each case separately, in order to properly calculate the maximum permanent displacement of the oscillation of the tower, the first value of the total force $\overline{F}_N\,(t)$ is deducted from all the values of the total force so that the fatigue simulation is conducted without the instantaneous imposing of the load interfering with the response of the tower.

3 OPTIMIZATION OF THE VIBRATION MITIGATION CONCEPTS

3.1 Harmony search algorithm and optimization process

In this section, the HS metaheuristic algorithm is shortly described and is also presented with a comprehensive example of the recommended optimization procedure. The four key steps of the algorithm are presented below:

Step 1: Initialization of the HS Memory matrix (HM). HM matrix consists of vectors representing potential solutions to the examined optimization problem. The original HM matrix is formed using randomly generated results. For an n-dimension problem, HM has the form:

$$HM = \begin{bmatrix} x_1^1, x_2^1, \ldots, x_n^1 \\ x_1^2, x_2^2, \ldots, x_n^2 \\ \cdot \\ \cdot \\ \cdot \\ x_1^{HMS}, x_2^{HMS}, \ldots, x_n^{HMS} \end{bmatrix} \tag{10}$$

where $[x^1_1, x^1_2, \ldots, x^1_n]$ $(i=1, 2, \ldots, HMS)$ is a result candidate. HMS is generally set to values between 50 and 100. The value of the objective function is determined for every solution vector of the HM matrix.

Step 2: Improvisation of a $[x'_1, x'_1, \ldots, x'_1]$ new result from the HM. Each one of the components of this new result, x'_j, is gained based on the Harmony Memory Considering Rate (HMCR), which is described as the probability of selecting a component from the HM members. 1 – HMCR is, thus, the probability of creating a new component at random. If x'_j is elected from

the HM matrix, it is further altered according to the Pitching Adjusting Rate (PAR), which regulates the probability of a candidate from the HM to be altered.

Step 3: Update of the HM matrix. The value of the objective function of the new result, gained in Step 2, is determined and measured to the ones that correlate to the original HM matrix vectors. If the outcome is a better fitness than that of the worst member in the HM, it will take over that one. If there is more than one member in the HM with bigger values of the objective function that the new solution, the result with the higher value is replaced. Otherwise, the new solution is erased and the HM matrix remains untouched.

Step 4: Repetition of Steps 2 and 3 until a preset termination benchmark is satisfied. A frequently used termination benchmark is the maximum number of total iterations.

The flowchart of the suggested HS algorithm is shown in Fig. 3.

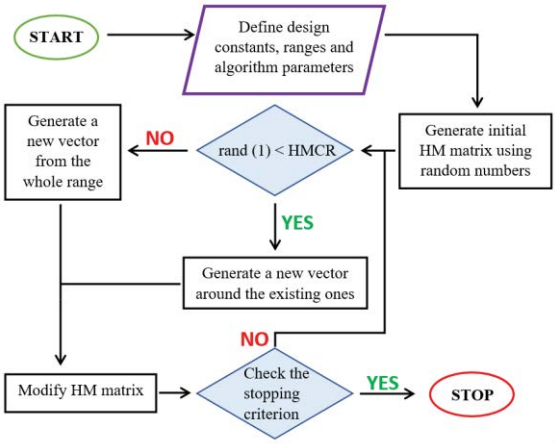

Fig. 3: Flowchart of the proposed HS algorithm.

3.2 Vibration mitigation concepts optimization process

Succeeding the method and flowchart presented above, the features of the inspected optimization problems can be calculated.

First of all, the parameters are selected, whose values shall be optimized for each concept. The KDamper concept has five parameters that control the device's performance and those are k_R, k_D, k_N, c_N, c_p. The additional mass ratio of the KDamper device is selected equal to 1%. The TMD concept has a single parameter ζ_D since the mass ratio is selected equal to 5% and k_D is selected so that the natural period T of the TMD is equal to that of the tower modeled as a Generalized SDOF. The TMD-Nacelle concept has two parameters that control the device's performance, k_D and ζ_D. Furthermore, the restrains of the design variables are decided. Their choice relies on safety, stability and manufacturing parameters that need to be considered. Although these parameters may alter from structure to structure, the restraints presented below produce satisfying results in most cases.

	k_R	k_D(KDamper)	k_N	c_N	c_p	ζ_D(TMD)	k_D(TMD-Nacelle)	ζ_D(TMD-Nacelle)
min	0	0	-40000	0	0	0	0	0
max	120000	120000	0	500	500	1	20000	0.5

Table 3: Variable design limits.

As far as the parameters inherently involved in the HS algorithm are concerned, a common practice is to adopt commonly found values found in relative literature (Table 4). The same is true for the termination criterion, as the maximum number of repetitions is pre-determined.

HMS	HMCR	PAR
75	0.5	0.1

Table 4: Values of the HS algorithm parameters

With the intention of finding the optimum solution for the EC1 [44] aerodynamic load, the top of the tower's displacement is determined as the objective function that needs to be minimized, in each case.

Finally, the constraints and limitations of the inspected optimization problem are specified. Specifically, for the KDamper concept, there are three constraints, the first one demanding that the relative displacement of the additional mass of the KDamper be lower than 1.5 *m*, the second one demanding that the absolute velocity of the nacelle must be lower than 1 *m/sec* and the third one demanding that the relative displacement of the nacelle to the top of the tower be lower than 0.5 *m*. The last two constraints also apply to the other two concepts.

4 COMPARISON OF THE PROPOSED CONCEPTS

The design criterion of the Tuned Mass Damper and KDamper vibration absorption concepts is their mass ratio, which corresponds to the additional mass added to the system, and for the nacelle-isolation concept is that the maximum relative displacement, between the nacelle and the tower, must be under 0.5 m. The mass ratio of the TMD is selected 5% (as a maximum value for constructional reasons), the mass ratio of the KDamper 1% and the relative displacement between the nacelle and the tower, for the nacelle-isolation concept is 0.5 *m*. The exact values derived from the optimization process for each of the employed vibration absorption concepts are the following: (i) KDamper: k_R = 7296 *kN/m*, k_D = 114272 *kN/m*, k_N = -6234 *kN/m*, c_N = 345 *kNs/m*, c_p = 300 *kNs/m*, (ii) TMD: ζ_D = 0.04, (iii) TMD-Nacelle: k_D = 606 *kN/m*, ζ_D = 0.32.

In Table 5 and Table 6, are the results (maximum values) of the controlled wind turbine concerning the dynamic performance of the wind turbine tower for both load cases. In Table 7 are the results (mean values) of the energy dissipated by the dampers of each of the proposed concepts.

	$U_{abs,\,top}$ (m)	$V_{abs,nacelle}$ (m/s)

5 CONCLUSIONS

In this paper, three dynamic vibration absorber options are examined for improving the wind turbine's dynamic behavior, while also satisfying some certain constraints, the TMD, KDamper and Nacelle-isolation concepts. A wind turbine of 5MW supported by a steel tower of 120 m was analyzed under two different horizontal aerodynamic loads due to the wind. Based on the dynamic analysis and the results collected, the following conclusive observations can be made:

- Concerning the dynamic behavior of the wind turbine tower, the nacelle isolation concept yielded the best results along with the KDamper concept, with which the differences are minimal, followed by the TMD concept.
- Concerning the nacelle's velocity, all three concepts yielded the desirable results, reducing the maximum velocity for the aerodynamic load 1 by roughly 50%. For the aerodynamic load 2, the results can still be considered satisfactory as neither of the proposed concepts produced results close to the 1 *m/s* constraint that was set beforehand.
- The KDamper concept achieves better results than the TMD concepts and roughly the same as the nacelle-isolation concept with only 1/5 of the TMD's additional mass.
- The KDamper shows promising behavior in dissipating the energy of the aerodynamic loads and this energy can be gathered, further increasing the efficiency of the system.

According to the observations made above, the KDamper device can bring a realistic alternative to the existing vibration absorption design options in wind turbine towers, enhancing the dynamic performance both of the nacelle and the tower. The reliability and simplicity of the system are also benefits that render the device appropriate for various technological implementations and competitive against other vibration absorption designs.

Abstract. *Nowadays, the need for effective Structural Health Monitoring (SHM) strategies, aiming at preserving the integrity and safety of strategic and historic infrastructures, is increasingly urgent. Within SHM, several vibration-based methodologies have been developed, including those exploiting Heterogeneous Data Fusion (HDF) procedures, as well as Denoising techniques for the treatment of response signals detected through appropriate sensor technologies. In this paper, these two approaches are reconsidered and rejoined, toward developing an innovative signal processing methodology for current condition assessment, specifically referring to historic bridges. In particular, a HDF approach, i.e. the process of combining information from multiple sources, in an effort to enhance the reliability of the monitoring process, and a denoising approach, devoted to the cleaning of spurious noise from the acquired signals, are combined all together, in an integrated strategy. The effectiveness of the proposed platform is tested on data from a real structure (historic bridges). Both dynamic acceleration and displacement response signals, directly detected under operational conditions, can be processed within the proposed methodology, and subsequently employed toward modal dynamic identification purposes and possible model updating of the structure at hand.*

1 INTRODUCTION

This study is motivated by the awareness quest on the critical health conditions that may characterize existing and historical infrastructures, especially those nearing the end of their life cycle. Despite their age, these structures often continue to play a critical role in everyday life, constituting essential connections within the transportation network of several territories and communities. Consequently, a prompt and effective adoption of appropriate and modern strategies and action models toward their conservation and protection shall be set in place. In this scenario, the development of monitoring-based strategies toward structural condition assessment of such important infrastructures, shall constitute a fundamental tool toward the competent analysis.

Accordingly, within the civil engineering context, the Structural Health Monitoring (SHM) research field is becoming increasingly important, since the goal of achieving structural safety is only possible through the possibility to extract more abundant and precise information about the health conditions of a structure to be monitored, for instance by analyzing its current structural dynamic response. As a consequence, within SHM applications, after the signal acquisition stage, to be acquired directly on the structure by predisposing appropriate sensor networks, the subsequent phase of signal processing displays a determinant role, toward the success of the whole monitoring procedure.

In this paper, two complementary and possibly interacting approaches for the post-processing of structural response signals are considered, i.e. a denoising approach, as well as a Heterogeneous Data Fusion (HDF) procedure, aiming at achieving a better screening of real structural response signals, which may be corrupted by some amount of noise, especially in case of a low-cost instrumentation.

In particular, denoising techniques aim at clarifying the signal content, by directly acting on the contaminating noise, reducing its amount, while preserving the useful information embedded in the signal itself. Several denosing-based techniques may be employed for this purpose, including those exploiting Singular Value Decomposition (SVD) or Discrete Wavelet Transform (DWT), as recently investigated in Ravizza et al. [18, 19], where the effectiveness of these approaches has been inspected for both stationary (ambient vibration) and non stationary (seismic excitation) synthetic response signals, and for instances of real vibration signals.

Instead, Heterogeneous Data Fusion (HDF)-based approaches are procedures through which heterogeneous measurements may be combined all together, with the analogous purpose to enhance their quality, by alleviating the amount of noise on the signals and, consequently, reducing the induced uncertainties affecting the monitoring results. Several virtuous examples of HDF applications within the civil engineering field may be found in the literature, as for instance in Chatzi and Fuggini [2, 3], Ferrari et al. [4–6] and in Ravizza et al. [17], where a Kalman Filter (KF) has been involved in a HDF scheme between artificially generated acceleration and displacement response signals, aiming at obtaining enhanced displacement response measurements, for a 3-DOFs numerical dynamic system.

In the present investigation, a denoising-based approach, and a HDF procedure are considered all together and possibly coupled within an integrated monitoring methodology for the purification of real response signals, specifically displacement signals, which usually appear to be affected by higher levels of noise, if compared to accelerations. The obtained post-processed enhanced displacement measurements may then be employed toward modal dynamic identification purposes (see e.g. Pioldi et al. [10–12] and Pioldi and Rizzi [13–16]), and this might result of a crucial interest for real applications related to the SHM context.

Although the proposed methodology aims at a general formulation, as to be suitable for the monitoring of different structural systems, here, a specific real test structure is assumed as a case study for the analysis, in order to highlight the feasibility of the proposed monitoring strategy and show its effectiveness. For this purpose, the historic reinforced concrete (RC) bridge at Brivio (1917), i.e. a strategic infrastructure for some local connections within the northern Italy automotive road notwork, has been considered (Santarella and Miozzi [20], Ferrari et al. [7]).

The multiple goals that this study aims at achieving are:

- to pursue an effective denoising of real acceleration response data, detected on the monitored structure, through appropriate (wireless) acceleration sensors. In fact, although accelerations usually display a good resolution, when the sensor instrumentation employed during the signal acquisition stage is somehow poor, this may become necessary;
- to successfully perform a denoising-based approach on the original (raw) displacement signals, aiming at clarifying their content in the time domain, then resulting in a better representation and reading of the time domain signal features;
- to perform a successful HDF, by involving a KF within the fusion procedure between denoised acceleration and denoised displacement response signals, in order to obtain a further enhancement of the displacement data in the time domain;
- to employ the enhanced displacements, downstream from the HDF processing, toward possible modal dynamic identification purposes within the frequency domain, aiming at estimating the modal characteristics of the considered infrastructure.

To prove that the proposed monitoring methodology is competitive, leading to visible benefits to the structural identification process, the modal natural frequencies identified from post-processed displacements are then compared with the frequencies identified from raw data. The effectiveness of the method is proven, as well as its possible generalization to different typologies of structures.

The paper is organized as follows. In Section 2, a brief description of the structure of interest is outlined, with the reasons behind the choice of taking the Brivio bridge as a benchmark structure for the present analysis. In Section 3, the proposed monitoring strategy is formulated and presented. Then, the obtained results are reported and discussed in Section 4. Finally, last remarks and summary comments are provided within the conclusions reported in Section 5.

2 PRESENTATION OF THE MONITORED STRUCTURE

The peculiar class of structural systems to which this study is addressed to, aims at covering civil engineering structures characterized by a significant and strategic importance, possibly combined with a historical-architectural value. In particular, the monitored structure considered as a case study within the current analysis, is the RC Brivio bridge (1917) (Santarella and Miozzi [20], Ferrari et al. [6]), represented in following Fig. 1.

The bridge, located in northern Italy (Lombardia region), constitutes an important automotive connection between the provinces of Lecco and Bergamo, linking the banks of the Adda river (Brivio (LC) and Cisano Bergamasco (BG)), at an approximate height of 8 m from water.

About its description, the Brivio bridge consists of three spans, each characterized by a couple of parabolic arches, symmetrically located to the mid-longitudinal plane. The two spans

Figure 1: *RC three-span arched Brivio bridge (1917) over the Adda river.*

aside the river banks are 43.4 m long; the central span is 44 m long, for a total length of 130.8 m. The deck is 9.2 m wide and hosts two roadway lanes and two cantilever sidewalks, of a 0.8 m width each. The deck structural frame of each span is constituted by a grid supporting a RC slab of a thickness of 0.15 m. The peculiar parabolic arches of the bridge display a span of 42.80 m and a rise of 8.00 m. The symmetric arches show a cross section that is 0.60 m wide, with a height varying from 1.25 m (at the middle) to 1.37 m (at the ends). Sixteen vertical RC hangers, characterized by a rectangular cross section of sides of 0.32 m and 0.60 m, connect the deck to each arch. The bridge is supported on the river bed through two tapered concrete piers, each one presenting maximum dimensions at the basis equal to 12.8 m (transverse direction) and 3.8 m (longitudinal direction). The piers rest on foundation RC piles driven into the riverbed for a depth of 13 m to 16 m (Froio and Zanchi [9]).

The choice of Brivio bridge being taken as a benchmark structure for this study is motivated by the fact that, despite its age of more than one hundred years, the bridge is still subjected to continuous traffic loading, likely much heavier than that for which it was originally designed way back in 1917. Present use includes daily transit of heavy-duty and various vehicles in both rush hours and all day long. Indeed, similarly to other bridges located in the nearby territories (see e.g. the Paderno d'Adda bridge, Ferrari et al. [8], placed south downstream for just a few kilometers), the Brivio bridge still plays a crucial role in the local transportation network and, for this reason, it may largely benefit from a condition monitoring under operational conditions.

It is worth noting that all signals processed in the present analysis have been acquired during a three-day measurement campaign, performed directly on the Brivio bridge, in June 2014. Further details about such a measurement campaign, as for instance information about the employed measurement instrumentation, as well as on the sensor location, may be found in Ferrari et al. [4–7].

3 MONITORING METHODOLOGY DESCRIPTION

In this section, a comprehensive monitoring strategy for the health condition assessment of historic bridges is presented, by specifically assuming for illustration the case study of the

RC Brivio bridge under operational loading conditions. Both acceleration and displacement response signals, directly detected on the structure as an integrated sensor network are involved within the proposed scheme. In fact, acceleration-based and displacement-based recordings are commonly exploited towards vibration-based monitoring purposes, and the choice of which approach should be preferred, usually depends on the specific monitoring goals to be pursued, as well as on the physical configuration of the analyzed structure.

In particular, acceleration-based monitoring allows to detect changes in the structural health conditions, which may be revealed by identifying variations in the structural modal properties, such as natural frequencies, mode shapes or modal damping ratios, since these quantities may then be employed within damage detection strategies for the current condition assessment of the monitored structure. Displacement-based monitoring, on the other hand, is often exploited both for evaluating the presence of excessive loads under standard service conditions, and for quantifying regular operational loads (e.g. traffic), to serve as reference in bridge design practice.

In this sense, acceleration- and displacement-based monitoring approaches may be considered as complementary, in providing useful tools toward an effective global assessment of historic and strategic infrastructural systems. However, especially due to the increasing demand for the adoption of low-cost monitoring instrumentation during the signal acquisition stage, these measurements may typically be accompanied by a significant amount of noise, which contaminates the structural response itself, by increasing the induced uncertainties and rendering more difficult their employment for SHM purposes. Such a deleterious noise effect is generally more evident on displacement data rather than on acceleration data, due to the intrinsic limits characterizing the present displacement sensor technology.

To address this issue, in the proposed monitoring methodology, a denoising-based approach is possibly integrated with a HDF-based procedure, aiming at exploiting the (more reliable) acceleration measurements for clarifying the dynamic displacement response signal of the bridge, acquired by means of a non-contact QDaedalus system (Bürki et al. [1]). The so obtained purified displacement data may then be employed toward modal identification purposes, e.g. for extracting the natural frequencies and the mode shapes of the monitored structure, and assessing its current structural conditions.

The present methodology combines a time domain analysis and a frequency domain analysis, as illustrated in the flowchart of Fig. 2, representing a global conceptual view of the considered monitoring scheme.

The time domain analysis aims at a better appreciation of the raw displacement recordings, to be later exploited for modal identification purposes. In doing so, the additional availability of acceleration response data, collected by means of wireless MEMS accelerometers, can be taken at a disposal.

Differently from data acquired through wired piezoelectric accelerometers, which may be considered as a rather reliable recording devices, even such raw acceleration data may first need to be purified, by applying appropriate denosing techniques, for reducing the noise level affecting the signal, while preserving the useful information within the recorded signal. To this purpose, a Discrete Wavelet Transform (DWT)-based denoising technique is implemented within the monitoring platform, resulting in the clarification of the detected acceleration response signal. Details about the calibration of the DWT-based denoising settings, adopted within this study, are provided in the next section. It is worth mentioning that also a Singular Value Decomposition (SVD)-based approach might be employed for the denoising of dynamic response signals; however, dealing with non stationary signals, such as those involved in this analysis,

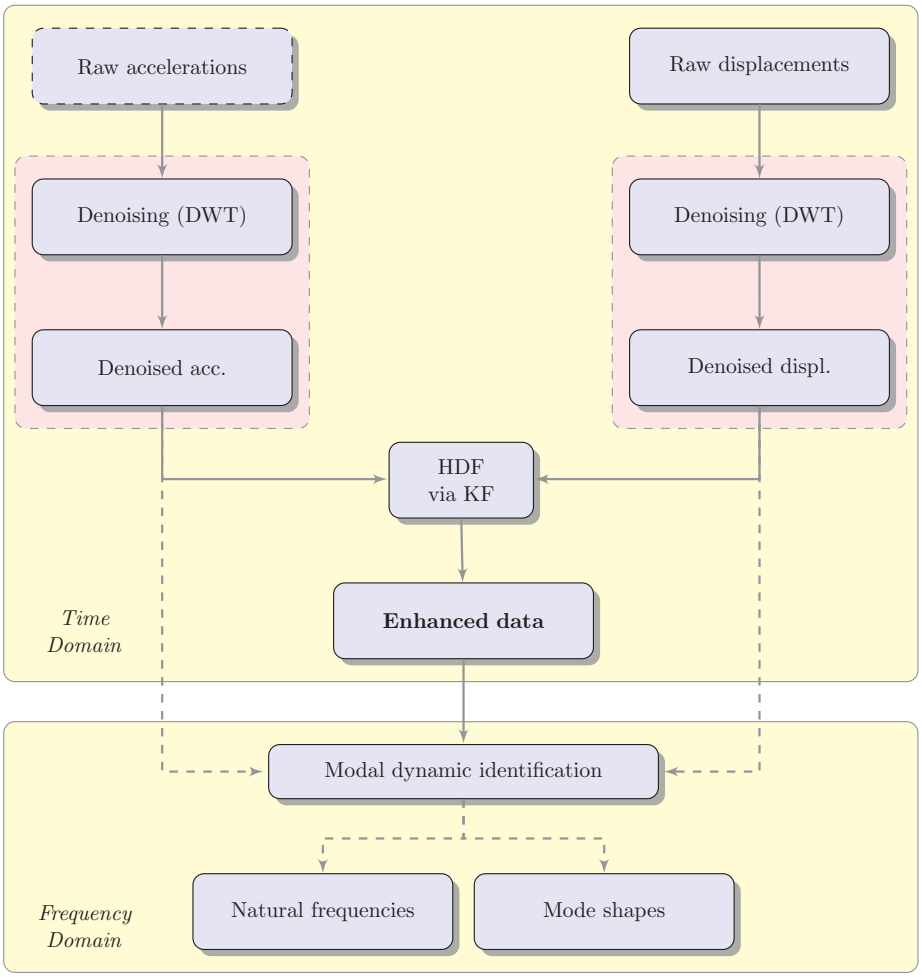

Figure 2: *Flowchart of the proposed monitoring methodology, integrating a denoising-based and a HDF-based approach for the enhancement of response data collected on the structure, and a subsequent structural dynamic identification.*

the DWT-based denoising approach should be preferred, as deeply shown and discussed in Ravizza et al. [18, 19].

In parallel to the (optional) acceleration denoising, a more frequently needed denoising of QDaedalus displacements is also foreseen. The same DWT-based technique is adopted, for the aforementioned reasons, and a preliminary cleaning effect on the signal is made achievable.

The core of the current implementation is now represented by the involvement of a Kalman filter (Chatzi and Fuggini [2]) within the HDF process, resulting in the merge of denoised QDaedalus displacements with acquired denoised accelerations, and an enhanced displacement response signal may be obtained.

A subsequent analysis within the frequency domain is also performed, in which the ambitious goal of successfully performing the modal dynamic identification on displacement data is inspected. In particular, the enhanced displacement response signal is employed for pursuing this purpose and, through an automatic peak-picking procedure performed on the Welch periodogram, the modal natural frequencies of the Brivio bridge may be identified.

It is worth noting that, as it can be appreciated from the flowchart in Fig. 2, the monitoring platform also contemplates the possibility to perform the modal dynamic identification of the structure by solely using either the denoised accelerations or the denoised displacements (dashed arrows in Fig. 2), but the results may be less reliable, especially considering just the displacements. However, they can be exploited for comparative purposes, aiming at highlighting the benefits deriving from a HDF-based methodology in assessing the current health conditions of the specific analyzed bridge, although such a monitoring platform also aims at assuming a more general connotation, being useful for the structural monitoring of any characteristic infrastructure.

4 RESULTS

In this section, some first outcomes obtained by applying the proposed monitoring methodology to the real case of the RC Brivio bridge, are shown. Time domain analysis results are firstly presented, followed by outcomes derived from a subsequent analysis within the frequency domain. Signals are taken from a measurement campaign as acquired and reported in Ferrari et al. [6].

4.1 Time domain analysis

The present analysis (upper box in Fig. 2) aims at purifying a raw displacement signal, making its features to emerge more clearly in the time domain, through an effective HDF with recorded accelerations, supposed to be more reliable. However, in some cases, a preliminary denoising of such acceleration data may also become necessary, e.g. when the sensor instrumentation employed in the signal acquisition phase is not so performing. Therefore, a DWT-based denoising technique is implemented on the detected (original) accelerations (from wireless sensors), and the obtained denoised signal is reported in Fig. 3, as compared with the original one.

Given the non-stationary nature of the response data, a 60 seconds length acceleration response signal from a wireless sensor is denoised, by applying a DWT-based denoising technique, which shall best fit with this signal typology, as shown in Ravizza et al. [18, 19]. In the same study, the optimal calibration of the parameters involved within this technique to deal with non-stationary signals is also inspected, resulting in the adoption of a *Smylet2* mother wavelet, combined with a *Heursure* hard thresholding rule, at decomposition level 2. Thus, the same setting is here assumed.

The effect of the denoising application is visible especially in the time window between 25 s and 40 s, as it may be appreciated in Fig. 3, leading to a signal reduction of 6.58%, in terms of Root Mean Square (RMS). The acceleration peak value is also considered, as it represents one most peculiar time domain signal feature, and a reduction of 9.11% is recorded. Such values are reported in following Table 1, for both the original and the denoised acceleration response signals.

An analogous DWT-based denoising approach is now implemented, for the preliminary clarification of the 60 seconds length QDaedalus displacement response signal, acquired on the Brivio bridge. Despite the very small amplitude of such recordings, which might affect the success of the denoising technique, the denoised estimates appear to be considerably clearer, if compared to the original (raw) data, as represented in Fig. 4.

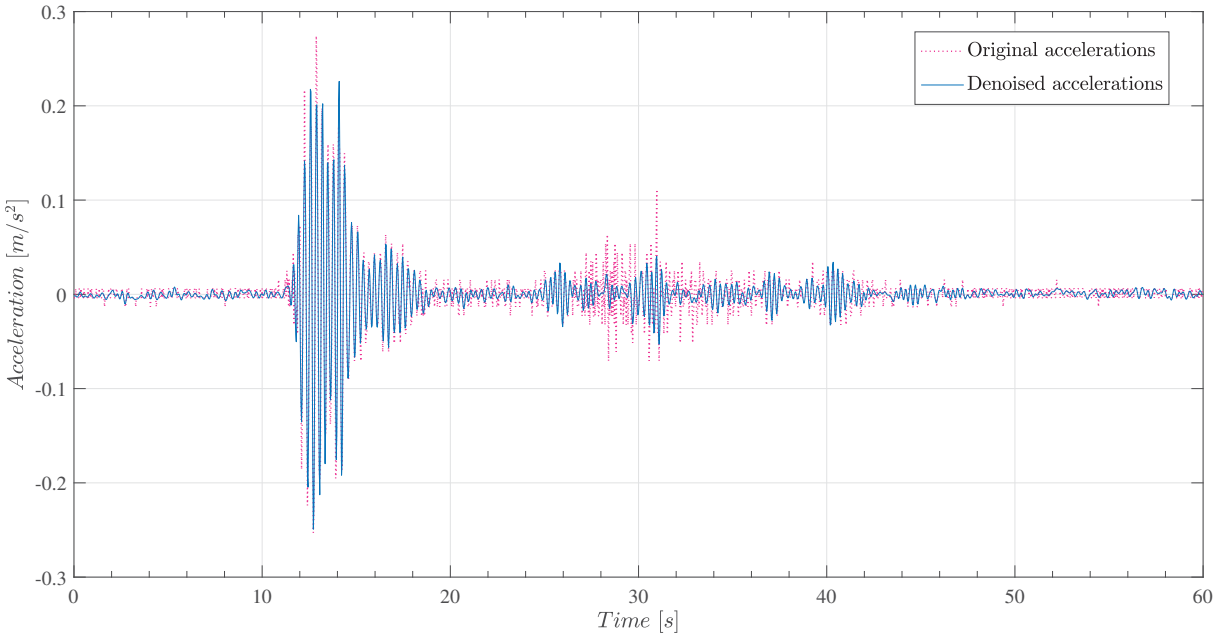

Figure 3: *Brivio bridge (wireless) acceleration response signal, pre and post DWT-based denoising.*

Acceleration signal	**RMS** $[m/s^2]$	Δ [%]	**Peak** $[m/s^2]$	Δ [%]
Original (raw) signal	0.0319		0.2742	
DWT denoised signal	0.0298	-6.58	0.2492	-9.11

Table 1: *Characteristic values of the analyzed acceleration response signals in the time domain and their variation with respect to the original (noise-affected) signal: RMS and peak acceleration values.*

After this preliminary phase, devoted to the pre-treatment of the acquired data, the obtained denoised acceleration and displacement response signals are then processed within a HDF-based implementation, aiming at further enhancing the measured displacements, by enriching them through the information embedded within the denoised accelerations. To this end, a Kalman Filter algorithm is exploited, allowing for the effective merge of the two heterogeneous source signals (Chatzi and Fuggini [2], Ferrari et al. [6], Ravizza et al. [17]). The result is represented by a new enhanced displacement signal, as shown in Fig. 5, which more reliably reflects the response of the monitored bridge.

To complete the time domain analysis, RMS and peak deflection values of the displacement signals are also computed, and summarized in Table 2. A reduction of both values, although lighter than that recorded in the previous acceleration case, is still observable, configuring itself as a peculiar feature of such techniques, as shown for synthetic signals in Ravizza et al. [19].

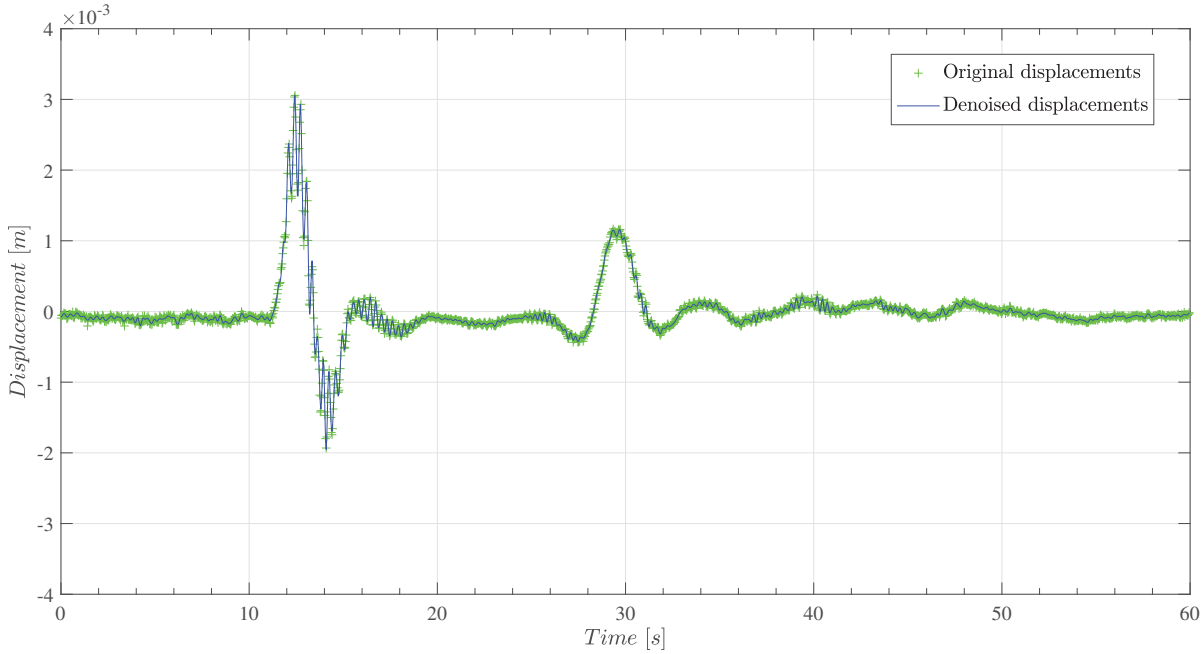

Figure 4: *Brivio bridge (total station) displacement response signal, pre and post DWT-based denoising.*

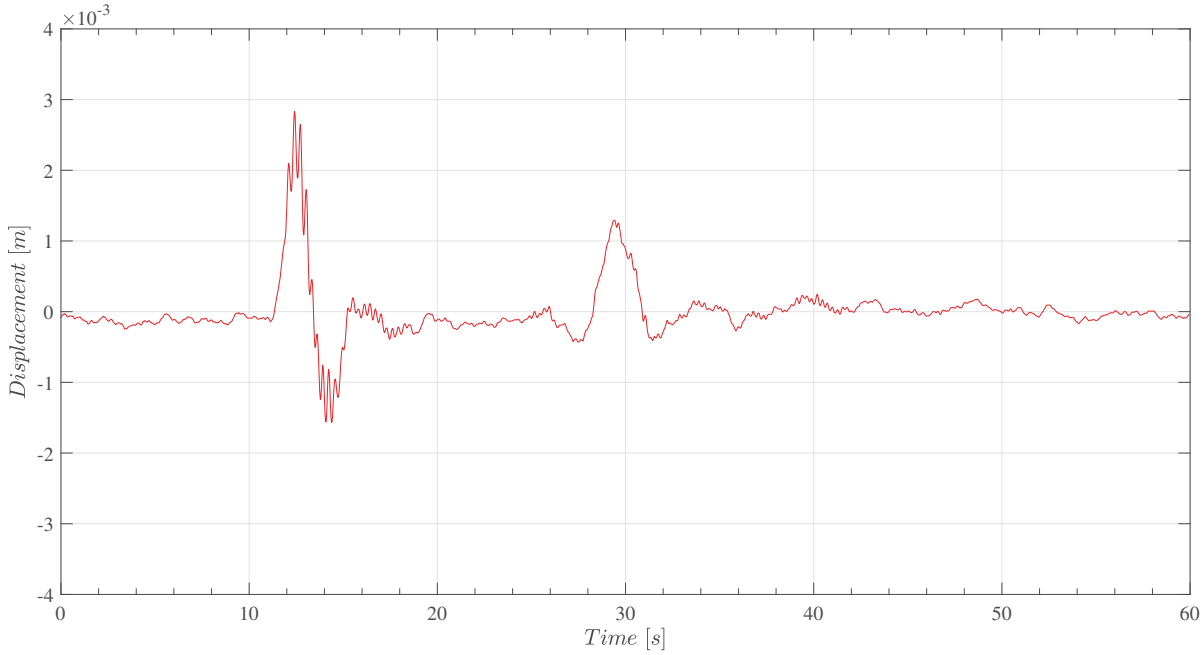

Figure 5: *Enhanced Brivio bridge displacement response signal, obtained by HDF via KF with the denoised acceleration response signal.*

Displacement signal	**RMS** $[mm]$	Δ [%]	**Peak** $[mm]$	Δ [%]
Original (raw) signal	0.4039		3.056	
DWT denoised signal	0.4001	-0.94	3.015	-1.34
HDF enhanced signal	0.3972	-1.66	2.833	-7.30

Table 2: *Characteristic values of the analyzed displacement response signals in the time domain and their variation with respect to the original (noise-affected) signal: RMS and peak deflection values.*

4.2 Frequency domain analysis

The enhanced displacement data, downstream obtained from the HDF procedure with the denoised accelerations, are now employed for performing a modal dynamic identification analysis in the frequency domain. In particular, by applying a Welch method on such displacements, the Power Spectral Density (PSD) function of the signal may be obtained. In following Fig. 6, the response spectrum derived from the HDF displacement signal and from the original (raw) displacement signal are represented and compared.

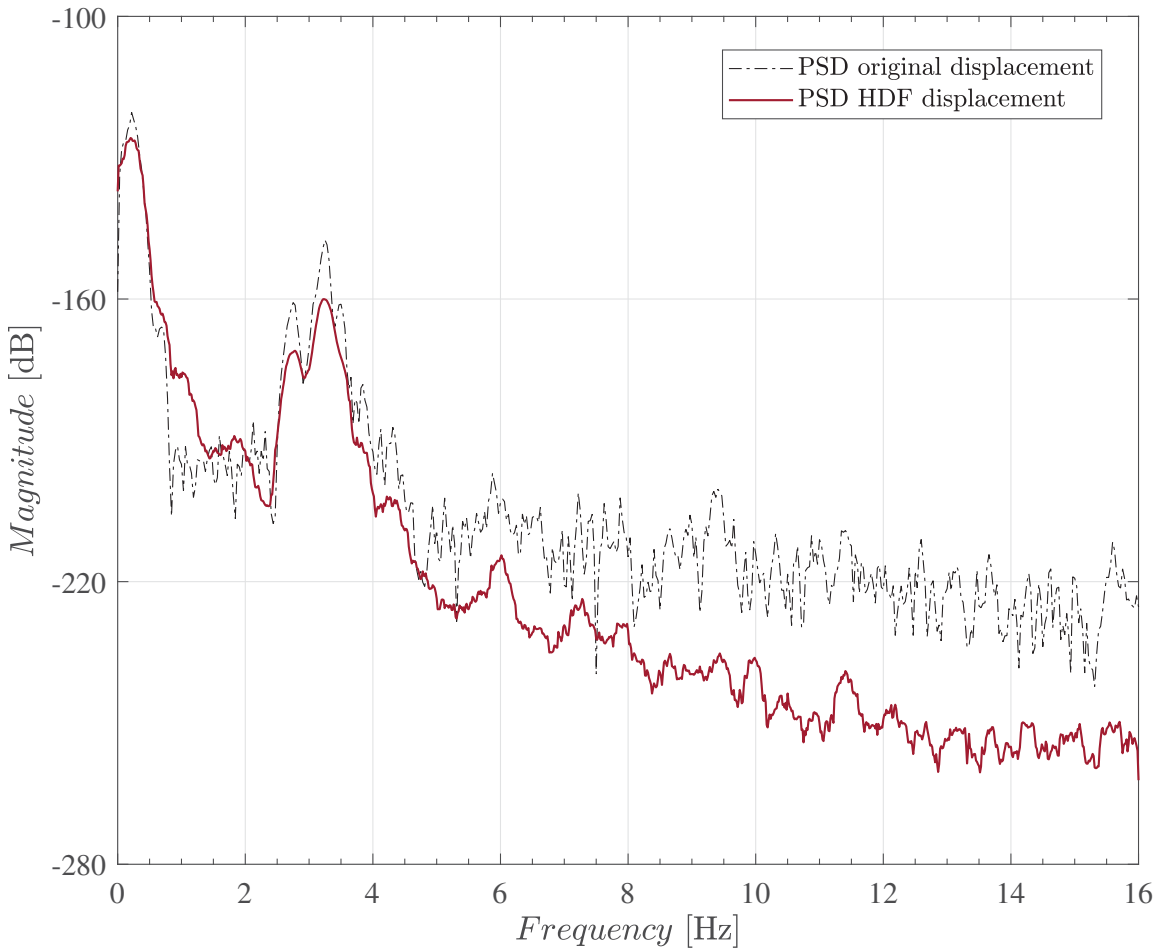

Figure 6: *Brivio Bridge displacement (PSD) response spectrum: original (raw) displacement signal vs. HDF (enhanced) displacement signal.*

The effect of the previously applied time domain filtering techniques (i.e. DWT-based denoising and KF application) is evident, resulting in smoother curves, as well as in the reduction of the signal magnitude, especially within the medium-high frequency region (approximately greater than 6 Hz), where the embedded noise mainly affects the data.

The benefits that the proposed methodology has brought to the identification process emerge by the comparison between the frequency content of the two signals. In fact, whether the original signal allows for the detection of just one frequency peak, corresponding to the first natural frequency of the bridge, the post-processed displacement signal reveals a greater number of frequency response peaks, which were previously indistinguishable, due to the deleterious effect of spurious noise. Consequently, a greater number of natural frequencies may be extracted.

However, due to the limited length of the time window, even the peaks associated to the external loading acting on the bridge (i.e. traffic load) might appear in the response spectrum, making the identification process harder. Thus, to distinguish such peaks from structural modes, an automatic peak-picking procedure is performed on the Welch periodogram, and the first eight natural frequencies of the monitored structure may be identified. To emphasize the benefits that the proposed methodology may bring to the identification process, the same peak-picking technique is performed on the PSD of the original (raw) displacement signal, leading to the identification of the first natural frequency only. Such a comparison is represented in Fig. 7, where the modal natural frequencies are marked by vertical red lines and, then, further reported in Table 3, which coherently compare to analogous results provided in Ferrari et al. [6], namely frequencies identified through a classical FDD method on acceleration signals acquired out of standard wired accelerometer sensors.

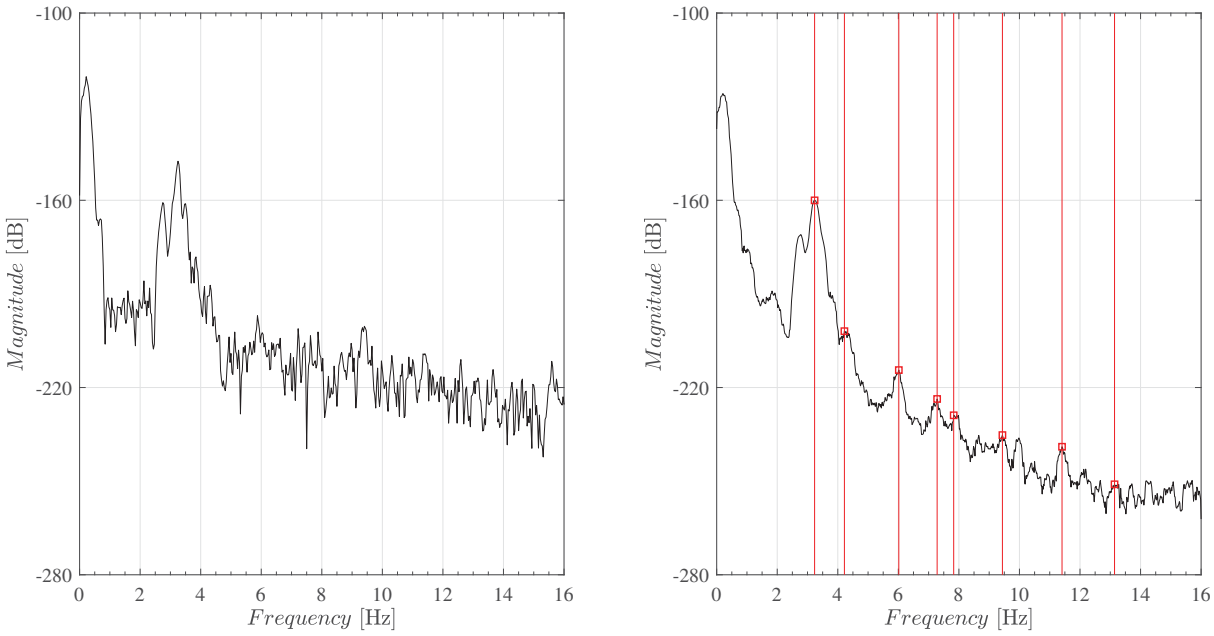

Figure 7: *Brivio bridge identified natural frequencies from displacement signals. Peak-picking procedure on Welch periodogram: original (raw) displacement signal vs. HDF (enhanced) displacement signal.*

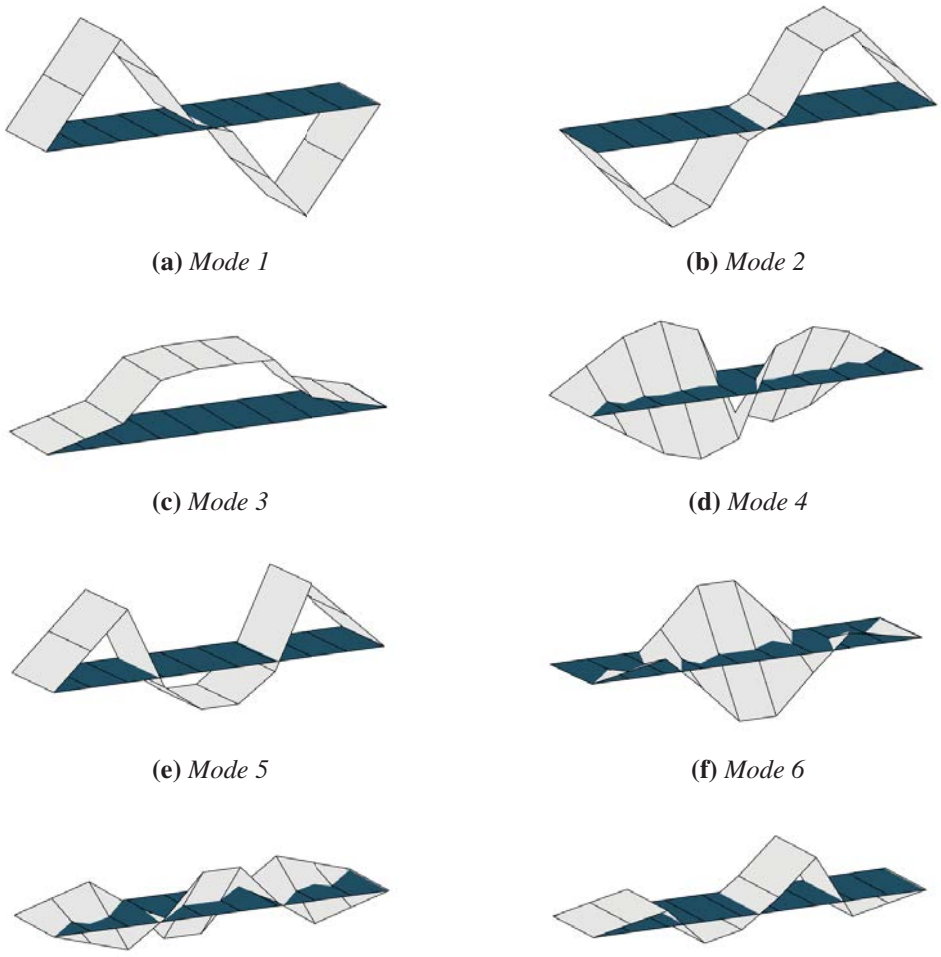
Except for the first two and the sixth natural frequencies, which display a not negligible discrepancy with the respective outcomes deriving from a FDD-based inverse analysis on wired

Modes	**I**	**II**	**III**	**IV**	**V**	**VI**	**VII**	**VIII**
$f_{id,WD}$ [Hz]	3.247	4.211	6.016	7.280	7.815	9.378	11.406	13.140
$f_{id,AC}$ [Hz]	3.564	3.857	6.018	7.178	7.690	9.009	11.377	13.086
Δ [%]	−8.89	9.18	−0.03	1.42	1.63	4.10	0.25	0.41

Table 3: *Brivio bridge natural frequencies $f_{id,WD}$ identified from a HDF displacement response signal (wireless sensor), compared to frequencies $f_{id,AC}$ (Ferrari et al. [6]) identified from an acceleration response signal (wired sensor), and their variation.*

accelerations, assumed here as reference, the results show a good agreement, as the percentage variation is in any case below 2%.

Finally, from a FDD analysis (Pioldi et al. [10–12]) on displacement signals (corroborated as above by acceleration data), the bridge first span mode shapes, corresponding to the previously identified frequencies, are obtained and represented in following Fig. 8. In particular, the QDaedalus displacement data, enriched by reliable accelerations, as those acquired through a wireless detection system, represent the selected 8-channel input considered within the current analysis, for the representation of the mode shapes of the monitored structure.



(a) *Mode 1* **(b)** *Mode 2*

(c) *Mode 3* **(d)** *Mode 4*

(e) *Mode 5* **(f)** *Mode 6*

(g) *Mode 7* **(h)** *Mode 8*

Figure 8: *FDD vibration mode shapes of Brivio bridge first span.*

Even concerning the vibration mode shapes, many analogies with the respective results reported in Ferrari et al. [6] may be observed. In particular, mode 1 and mode 2 show a very similar behaviour, although they are related to different natural frequencies. Moreover, most of the modes seem to be regular, characterized by bending or torsion, except for mode 7, in which bending and torsion appear to be coupled.

These similarities between the results may be considered as a further proof of the reliability of the proposed monitoring strategy, which provides an alternative approach aiming at evaluating the structural health condition of a generic civil structural system.

5 CONCLUSIONS

In this paper, an innovative monitoring methodology that integrates a denoising-based approach with a HDF-based strategy is proposed, for the structural health condition assessment of historic and strategic bridges. In particular, the main achievements that the present study has highlighted may be summarized as follows:

- the beneficial effect of the analyzed denoising technique is more pronounced within the time domain, where, after the DWT-based denoising application, the main signal features (i.e. peak value and RMS) may more clearly emerge;
- the acquired Brivio bridge acceleration and displacement response signals have been successfully denoised and, subsequently, involved within a HDF-based implementation, and an enhanced displacement response signal has been obtained;
- the output-only modal identification analysis performed on the enhanced displacement signal reveals the natural frequencies of the investigated structure, proving the effectiveness of the proposed methodology;
- by comparing the obtained results, by effective post-processing of response signals detected through wireless sensors, with those derived from signals acquired through standard wired sensors, no substantial differences emerge: this reinforces the belief that modern wireless sensor technology may become competitive at the signal acquisition stage, if adequately treated as here described, leading to reliable estimates.

In conclusion, the possibility of setting a monitoring platform that integrates a denoising-based approach with a HDF-based strategy may allow the user to achieve a more complete and reliable description of specific response signals, bringing to light their more peculiar characteristics, in both time and frequency domains. In this sense, the post-processing methodology presented in this study, may constitute a useful tool within structural monitoring applications.

Keywords: Health monitoring, WSST, Vehicle-Bridge interaction

Abstract. *Typically, the identification of resonant frequencies in railway bridges is carried out from free-decay stationary signals as a train leaves the bridge. The same identification proves very challenging when nonstationary vibrations are measured as a train traverses the bridge. Despite the numerous attempts, nonstationary signals with low modulating frequencies are still difficult to be processed. This paper attempts to evaluate the bridge-vehicle first bending resonance by a method known as Wavelet Synchro-Squeezed Transform (WSST). The significant advantage of this signal processing method is to deal with low-frequency modulations, which are typical of long bridges. This research focusses on a Finite Element Model (FEM) of a bridge simulating the nonstationary vibration responses exerted by a spring-mass model traversing the bridge. The paper sets two objectives, and the first one is to investigate how the WSST analyses nonstationary signals generated by the FE model. The instantaneous frequency trace of the bridge-vehicle system will be compared to a similar frequency trace, that is created by performing several modal analyses at different locations of the bridge. The second objective of the paper is to investigate if the instantaneous frequency obtained from WSST is suitable for damage detection, as the FE model is fitted with damages. Both objectives are met, and the results will be presented. The trace of the first natural frequency matches well the one calculated by the WSST, and the instantaneous frequency shows to be capable of detecting damages included in the model.*

1 INTRODUCTION

Understanding the vibration response in Vehicle-Bridge interaction is challenging because the actual instantaneous frequency will depend on the instantaneous location of a moving load. It is therefore understandable that Structural Health Monitoring (SHM) methods, aimed at identifying damage to assess the structural integrity and safety of a structure, have complicated problems to solve. Nevertheless, damage detection techniques have been developed.

In general, the majority of vibration-based damage detection techniques can be grouped into four categories. The first group, the traditional approach, contains the modal-based damage detection techniques [1,2]. These techniques are based on extracting and monitoring the modal properties, which can vary due to the presence of damage. The second group contains structural health monitoring based on Vehicle-Bridge interaction (VBI) response [1-3]. The third one involves model-based techniques which are based on updating the parameters of an analytical or numerical model such that the model matches the real measurements [3,4,5]. The fourth group contains data-driven methods (DDMs). Silva et al. [6,7,8] believe that SHM approaches are in the statistical pattern recognition paradigm.

Most damage detection researches have shown that a singularity appears in the forced vibration signal once damage occurs [9]. Yang et al [10] stated that a discontinuity appears in the acceleration signal when the moving load is in the vicinity of damage. The structure also exhibits non-linear behaviour once the moving load crosses the damage [11]. Therefore, the forced vibration response contains a 'damage event' triggered by the moving load making it more sensitive than the free vibration response. For this reason, a large number of research studies has been devoted to the second group, the vehicle-bridge interaction response.

VBI refers to the dynamic coupling between a bridge and a moving vehicle. VBI has been widely studied in the literature for detecting damage in bridges by analyzing the bridge response (direct methods) or the vehicle response (indirect methods). The focus of the current study is on the damage detection techniques of bridges by analyzing the VBI response measured on the bridge (direct methods). Literature [11,12,13] indicates that the target signal for the majority of the techniques is the bridge mid-span time-deflection response. From a practical point of view, there are motivations to study the bridge acceleration rather than the deflection signal. Firstly, it might not be possible to measure the bridge deflection signal at mid-span directly. Secondly, in comparison with the deflection signal, the bridge acceleration signal is more sensitive to damage [14]. However, the acceleration signal also contains more noise making it challenging to analyze. Continuous Wavelet Transform (CWT) , Discrete Wavelet Transform (DWT) [1], Hilbert Huang Transform (HHT) [4], Empirical Mode Decomposition (EMD) [5] and Ensemble Empirical Model Decomposition (EEMD) [6] have been mostly applied to identify damage [15,16].

Regardless of the applied method, the damage indicators are associated with a singularity. This one does not exist in the healthy bridge and appears in the response of the damaged structures [9]. Furthermore, the singularities are caused by a stiffness change and, therefore, the time-dependent stiffness should be visible in time-dependent resonances (the Instantaneous Frequency: IF). However, IF has only been investigated for the bridge mid-span displacement signal. Roveri et al [11] applied HHT on the mid-span deflection of a modelled bridge. In the first IF of the system, a crest appeared at the instant of damage occurrence. The current paper proposes an approach by applying Synchrosqueezed Wavelet Transform (WSST) on the VBI acceleration response to extract the Instantaneous Frequency (IF) of the system to detect a localized stiffness change. The research work is based on numerical simulations obtained from a Finite Element Model of a real bridge (Boyne Viaduct) located in Ireland. The bridge was refurbished and instrumented with a vibration response monitoring system, which provides many

test data. Considering the healthy conditions of the bridge, the authors decided to investigate the matter numerically and evaluate the WSST technique, as provided in the MATLAB function toolbox.

2 NUMERICAL MODEL AND MODAL SIMULATIONS

Although a large amount of vibration data is available for the Boyne bridge, the measurements are not applicable for the validation of the proposed damage detection approach, because of the recent refurbishments. Hence, to verify the proposed approach, a bridge is modelled numerically.

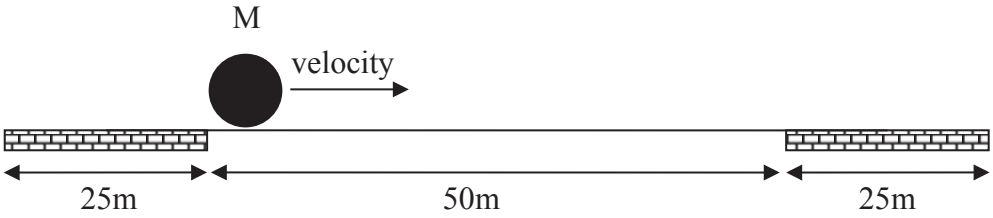

Figure 1: The schematic of the numerical model

All finite element simulations are conducted in a two-dimensional space in ABAQUS where the analysis scheme is chosen to be the implicit time integration. A beam with 50 m of length, 1 m of thickness and 0.5 m of width with Young's modulus of E = 210 GPa and density of ρ = 7860 kg/m3 is implemented as a bridge model. The same geometry has been already used in [17,18] for damage detection. However, the model is modified for the current study due to the moving mass. The forced response of the bridge corresponds to the period during which the mass is moving on the bridge. Achieving free vibrations from the bridge requires the mass should be removed from the bridge. However, the moving mass generates kinetic energy during the forced response analysis, which cannot be removed instantaneously to simulate the free vibration. Hence, approaching and leaving length are added before and after the bridge to properly locate the mass during the forced and free vibrations (see Figure 1).

Three dynamic analysis steps are implemented to calculate the bridge acceleration, corresponding to the mass approaching, crossing and leaving the bridge, as shown in Figure 1. Both approach and leave phases are modelled with beam elements that are clamped in all their nodes. The approaching part is not strictly necessary but is used to provide symmetry to the structure. The bridge model (the centre part of 50 m) has 200 elements, and the benchmark simulation corresponds to a point mass equal to 10% of the bridge mass which slides with a speed of 5 m/s over the bridge. The contact of the mass with the bridge is modelled using a hard node to surface interaction [19]. In the FEM model, the vehicle is considered to be a moving point mass (M) (i) to induce a non-stationarity to the simulated signal [20] and (ii) to investigate the time-varying resonance of the system due to the moving mass.

To implement the damage in the model, the stiffness (or equivalently the elastic modulus E) of a single element at the damage location (mid-span) is reduced [21] to simulate pitting- corrosion or a loose connection. In addition to the benchmark simulation, four groups of simulations are executed to verify the proposed approach for various operational conditions and health states. In the first group, moving masses equal to 5% and 20% of the bridge mass are simulated, and the bridge is considered healthy.

Modal analysis solutions were initially carried out with the mass positioned at specific locations of the bridge. Figure 2 shows the first and second resonances of the bridge as a collection of all the natural frequencies calculated at several locations. Interestingly, the location of the mass on the bridge has a relevant effect on the natural frequencies, which for the first resonance

is very marginal at the extreme locations but more relevant as it is moved towards the mid-span of the bridge. Similarly to the first one, the second shows an equivalent behaviour. The second resonance frequency is unaffected when the mass is positioned mid-span, which as expected as this is a nodal point of the second resonance. This basic modal analysis approach provides a useful insight on what one should expect from the IF recovered by the WSST method, in particular regarding the first bending resonant mode.

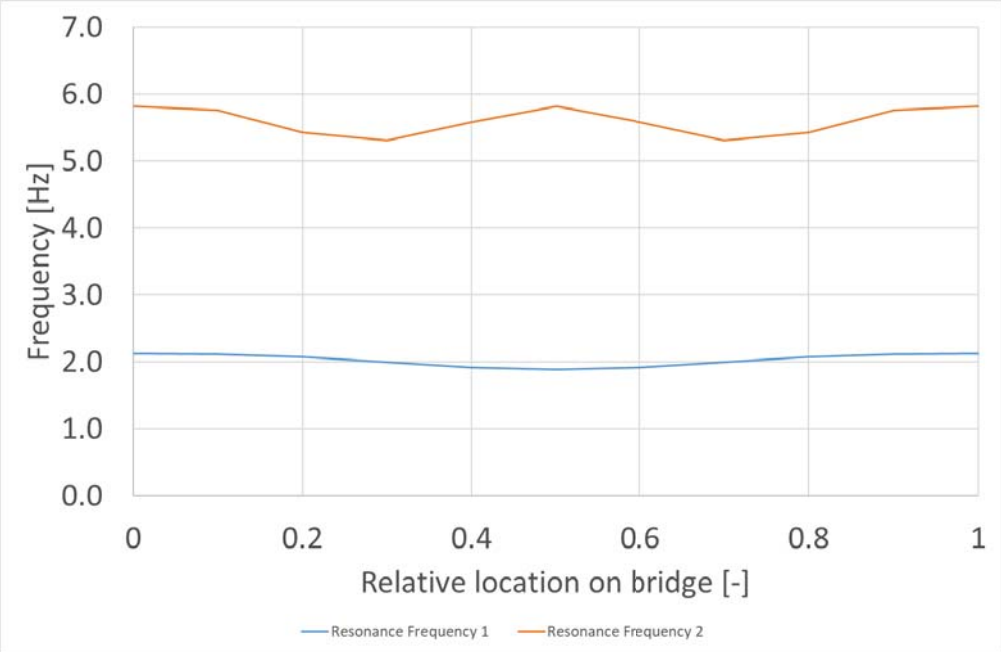

Figure 2: First and Second modal frequencies of the bridge with the mass moved at various locations

3 TIME RESPONSE SIMULATIONS AND RESULTS

A time response simulation of the moving load is carried out in Abaqus with the model earlier introduced. This paper will not focus on any uncertainty deriving from the non-uniform stiffness distribution of the bridge or the non-uniform crossing velocity or the Signal-to-Noise Ratio of typical real acquisitions.

Figure 3 shows the simulated acceleration signal for the undamaged bridge, at the bridge mid-span, where both the forced and the free decay vibration can be appreciated. Despite the simple approach, it was immediately noticed that the very first sample of the vibration vector contained high spikes, as the mass slide from an infinitely rigid surface to a flexible one. Those were removed and not taken into account since most of the vibration energy of those spikes would affect high-frequency modes, not relevant in this paper. Therefore, the signal for the Entrance Phase is a horizontal line at zero acceleration which is not plotted and not used for this study. The Traverse Phase and the Leaving Phase will be analyzed in two steps, such as (i) time series separation and (ii) application of the WSST to each of the time series.

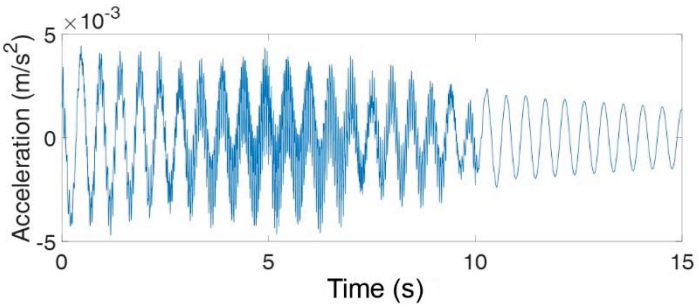

Figure 3: Acceleration simulated during the traversing and leaving phase.

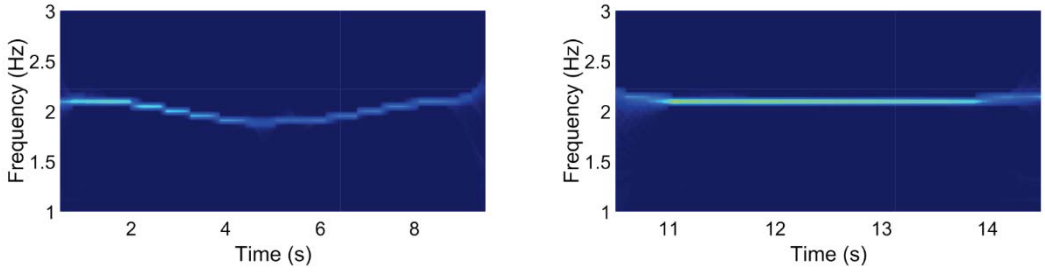
Given the velocity of the moving mass 5 m/s and the length of the bridge, 50 m, the mass leaves the bridge at t = 10 s. The second step is to extract the bridge frequencies by applying WSST to the signal of the Leaving Phase. Figure 4 a&b presents the Instantaneous Frequency of the traversing and leaving (bridge free vibration signal) phases. It can be seen that the Leaving Phase signal only contains the bridge first frequency (2.1 Hz) which is constant in time as expected for a stationary signal. Then, this frequency component should be tracked in the Traverse Phase by again applying WSST. The result is the Synchrosqueezed transform (SST) matrix with the rows and columns corresponding to frequency and time, respectively. The 2D density plot of the SST matrix is shown in Figure 4a in which the IF is displayed as a frequency ridge. This ridge can be extracted as a time-frequency vector by finding the corresponding frequency of the local maxima at each time instant. It is straightforward to observe the similarity between the frequency traces described by the modal solution for the first natural frequency and the one retrieved by processing the time series with the WSST method. Furthermore, Figure 4 shows how the resonance conditions are time-dependent because of the instantaneous location of the moving load.



a: Traverse phase *b: Leaving phase*

Figure 4: Ifs of the first resonance frequency in the traversing and leaving phase.

3.1 Simulation results

A set of time response simulations were carried out to observe how the IF changes when the mass ratio is changed, to simulate different operating conditions as different train weight traversing the bridge. Figure 4 displays the bridge first resonance frequency, which varies in time depending on the magnitude and the location of the moving mass. For the benchmark simulation, the bridge frequency reduces to 1.9 Hz due to the added mass of the vehicle when it is located at mid-span (t = 5 s). As expected, IF depends on the different mass ratio, the highest the lowest the resonant frequency. Several papers investigated the dynamic behaviour of a bridge subjected to damage, some of those are referenced in here [22-27].

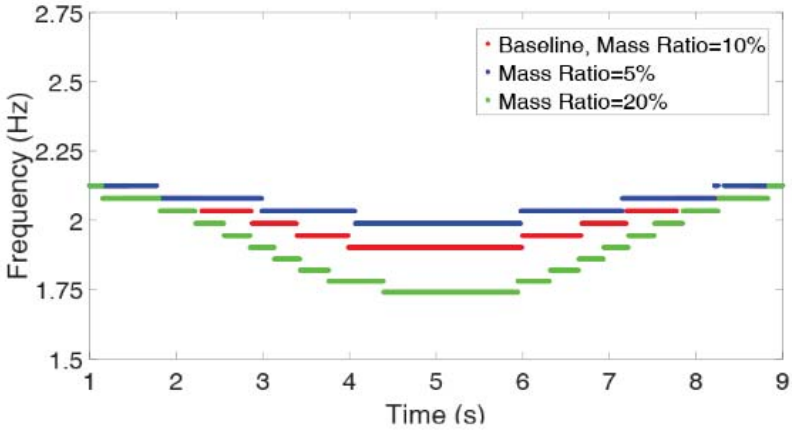


Figure 5: Change of IF caused by various Mass Ratios

The simulations were carried out by changing the mid-span element Young's modulus by 30%, 50% and 70%, respectively, by using the baseline model with mass ratio 10%. Both 50% and 70% are somewhat unrealistic damage conditions for a bridge. However, the purpose is to investigate the sensitivity of the IF to the appearance of damage. Figure 6 shows how the instantaneous resonant frequencies change as the moving load traverses the region where the damaged element was setup. This statement is not difficult to comprehend because the WSST resolves for the highest vibration energy at every point and frequency and, therefore, the instantaneous resonant frequency becomes even lower as the load is near to the weak spot.

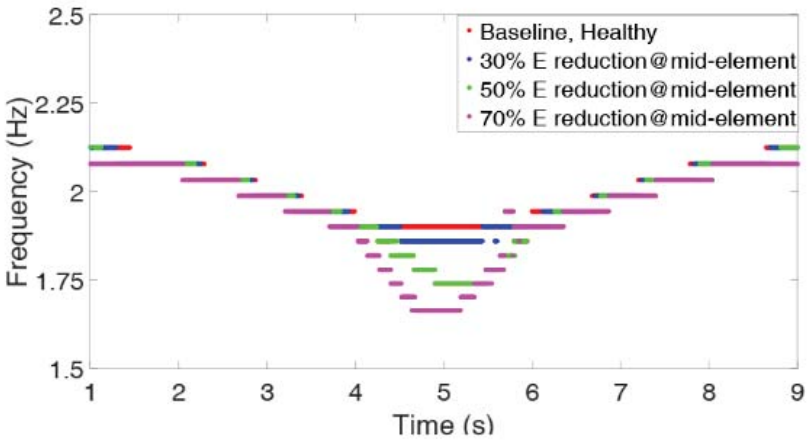

Figure 6: Change of IF caused by element stiffness reduction at the mid-span

As a closing remark of this section, one can appreciate that potential of the WSST as provided by the function toolbox of Matlab. Hence, a much thorough investigation of the system parameters governing the signal processing of the WSST method may increase its capacity beyond this simple simulated case study.

4 CONCLUSIONS

This paper presents for the first time a novel application of the WSST signal processing to the calculation of the instantaneous first resonant frequency of a bridge traversed by a moving mass. The WSST can be potentially exploited in health monitoring where the vibration signals could be processed in a *quasi* real-time as the train has crossed a bridge. It was demonstrated

that the WSST identifies the instantaneous resonant frequency, and which was verified against modal analysis results. Furthermore, it was showed that the IF is sensitive to the presence of damage. This behaviour was demonstrated by fitting the model with damages at the mid-span of the bridge. The IF presented a sudden discontinuity where the damage was set up for all three severity selected for these attempts.

Keywords: Rail support, bolted joint, clamping force, electro-mechanical impedance, SHM.

Abstract. *Rail supports are important components of rail construction as their task is to attach rail tracks and transfer occurring loads to the ground. Failure e.g. caused by fatigue cracking or loss of clamping force can cause catastrophic consequences up to derailment. In this work a possible approach for feature detection in order to detect a loss of clamping forces is investigated by applying the electro-mechanical impedance (EMI) method. The EMI method is a high frequency vibration-based structural health monitoring technique which is carried out by piezoelectric wafer active sensors (PWAS) attached to the mechanical structure to be monitored. In order to detect a loss of clamping force in this work two PWAS where attached to the bolted joint of a rail support and the imaginary part of the complex electro-mechanical admittance spectrum (reciprocal of the impedance) was evaluated. As it is known that PWAS measurements are sensitive to variations of ambient temperature a strategy to reduce temperature effects in a range of 0 °C-50 °C is also considered. First experiments show that the investigated technique is promising to distinguish variations of the measured signals which are caused by variations of clamping force from variations caused by changing ambient temperature.*

1 Introduction

The task of Structural Health Monitoring (SHM) is to observe structural properties to ensure the structure's integrity. Its field of application is wide; typical structures to be monitored are aerospace, civil structures or wind energy plants. The monitoring process entails several advantages e.g. the prolongation of service life due to condition-based maintenance and the reduction of inspection time as a consequence of the automated monitoring process [1]. In this study the structures to be monitored are rail supports. These components are an important part of rail construction as their task is to attach rail tracks and transfer occurring loads to the ground. Failure due to the loss of clamping force can cause catastrophic consequences. As real structures like rail supports exist in an environment they are affected by environmental influences like vibrations, humidity, ambient induced noises, etc.. To take changing ambient temperature into account a strategy to reduce temperature effects is investigated. The purpose is to detect variations of clamping forces in the presence of changing temperature by application of the electromechanical impedance method (EMI). As the temperature effects alter the measured signals and can cause 'false alarm' [2, 3] they have to be compensated. There are different methods to remove temperature influences. In [2] it is presented that temperature variations lead to horizontal and vertical shifts of impedance signatures. The efficient frequency shift (EFS) concept based on minimization of the root mean square deviation (RMSD) was introduced in order to shift the signals horizontally for removing the temperature induced shifts. In [4, 5] the authors also utilize EFS based on the maximization of the correlation coefficient (CC).

Table 1: Studies utilized EMI under varying temperatures

Analysed quantity	**Load**	**Damage**	**Publication**
real(Z)	-	X (added mass, hole, cut,..)	[5, 2, 6]
real(Z)	-	X (bolt loosening)	[9]
real(Z)	X	X (bolt loosening)	[10]
real(Z)	X	-	[8]
real(Z), imag(Z)	-	X	[7]
imag(Y)	-	-	[3]
imag(Y)	-	X (detection of clamping force)	this study

The EFS was applied in further studies [6, 7, 2] in order to compensate the temperature effects on the real part of the impedance (real(Z)). In [8] the EFS was used to monitor prestress-loss in prestressed concrete (PSC)-girders and it was found that in presence of varying temperature as well as varying prestress the resonances of the real part of the impedance spectra shift

horizontally. Whereas temperature changes cause approximately the same frequency shifts of

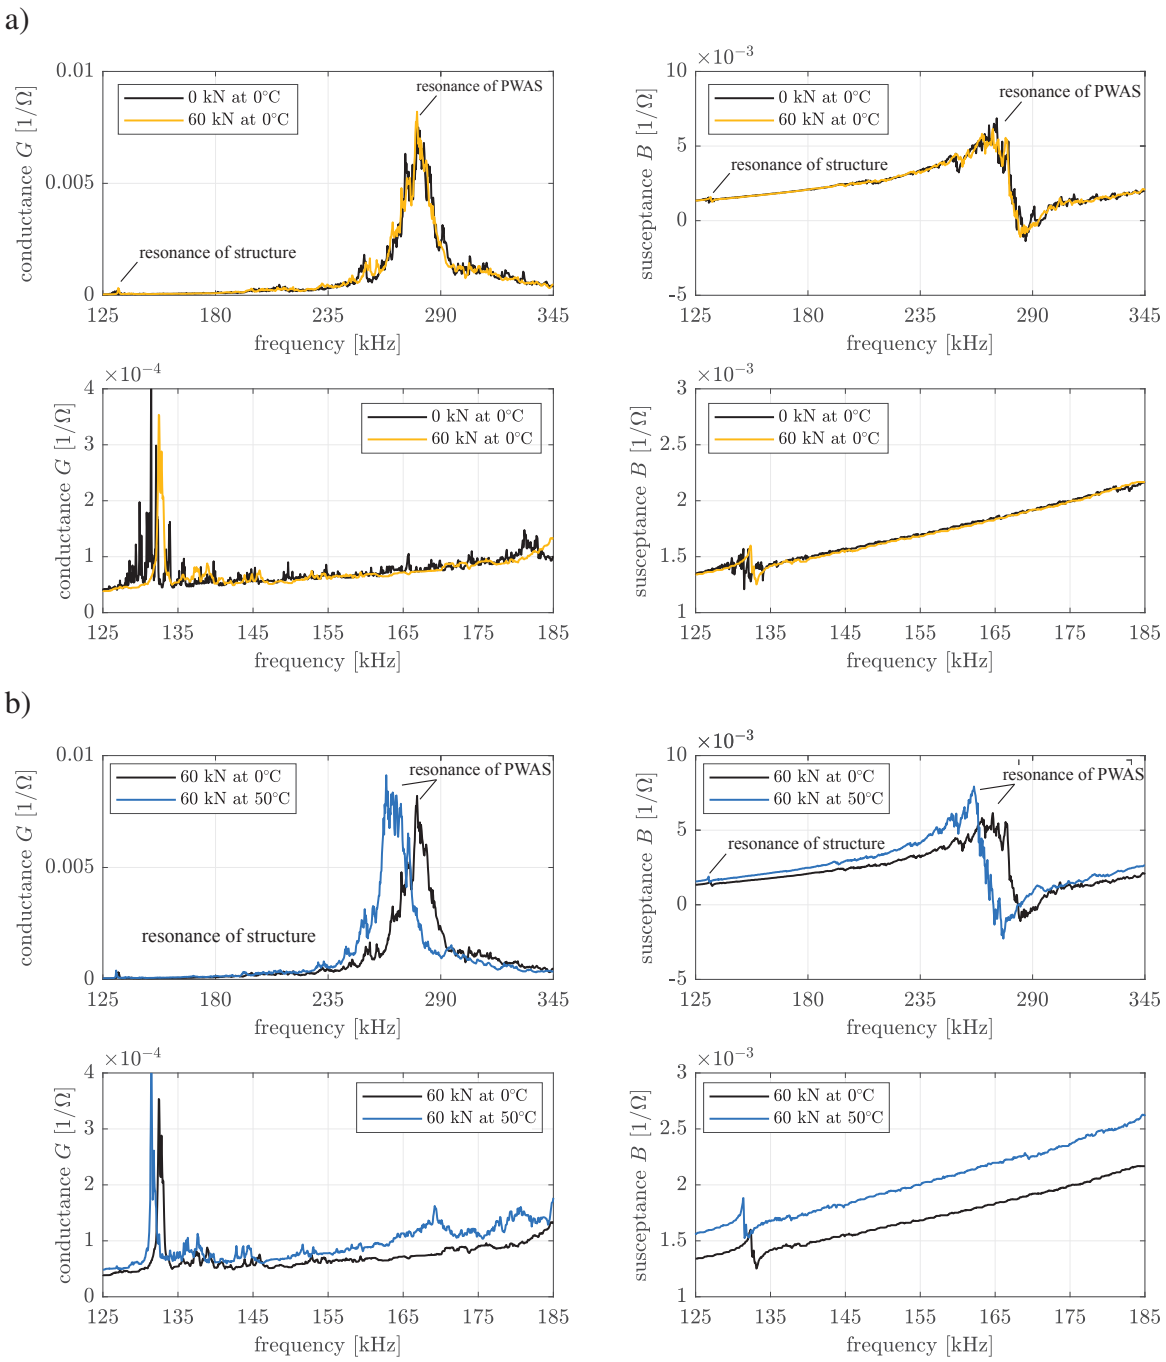

Figure 1: Temperature compensation a) Effects of changing clamping force on conductance and susceptance in a frequency range of 125-185 kHz and 125-345 kHz, respectively b) effects of changing ambient temperature on conductance and susceptance in a frequency range of 125-185 kHz and 125-345 kHz, respectively

the resonant peaks but damage generates different frequency shifts of the resonances. In [9] a bolted steel girder connection was monitored in the presence of varying temperatures. In the damaged cases one or more bolts were loosened from reference torque to a torque of 35 Nm. In [10] also bolt loosening was monitored under varying temperature but also under varying loading. The damage was introduced by loosening one of ten bolts with a half turn. The object to monitor was an aircraft composite wing segment model. An overview of works that applied

the EMI method under varying temperature conditions can be found in table 1. Instead of the real part of the impedance which was used to identify the structural's state in the studys mentioned before, in this work the imaginary part of the admittance Y (reciprocal of impedance), the susceptance (Im(Y)), was used to monitor the loss of clamping force in the presence of temperature variations. As the susceptance also includes resonances of the structure and therefore reflects the structure's state. In [3] it was found that a great effect of temperature influence on the susceptance spectra is the changing signal's slope. At increasing temperature the slope also increases. Furthermore the resonance frequencies move into direction of lower frequencies. These properties and also the EFS concept have been used in this work for reducing the temperature effects on the signals. The purpose of this study is to find an approach for a possible indicator which detects a loss of the clamping force at an incipient state under varying temperature to adjust this defect before failure of the joint occurs.

2 Methodology

In own preliminary studies the effects of temperature and clamping force on conductance and susceptance have been investigated. Exemplary results of these studies are shown in figure 1 which represent the effects of temperature and varying clamping force on the conductance (Re(Y)) and the susceptance (Im(Y)) spectra in the investigated frequency range of 125-185 kHz and additionally 125-345 kHz. The broad frequency range between 125 kHz-345 kHz contains the structural resonances as well as the resonance of the PWAS. In contrast to that the narrow frequency range of 125 kHz-185 kHz only contains the structural resonances but with higher resolution. This is justified by the utilized measurement device which provides a maximum resolution of 1024 points in the defined frequency range. In figure 1 a) the influence of changing clamping force is visible by observing the conductance as well as the susceptance spectra. Whereas in relation to the susceptance this effect is mainly visible in the frequency range very close to the structural resonance. In figure 1 b) the effect of varying temperature is shown. The narrow frequency plot of the conductance shows large changes over the complete displayed frequency range. In contrast to that the susceptance mainly shows a shifting and a changing of the slope. Additionally the height of the peaks at the resonance frequency changes and the signals fluctuate more with rising temperatures (see blue graph at $\approx$ 170 kHz). But apart from that the curve almost remains invariant in the presence of changing ambient temperature. As the temperature effects are easier adjustable it has been As a result of these observations it has been decided to evaluate the susceptance in order to develop a strategy to reduce temperature effects on the signals. The aim of this strategy is to remove the slope as well as the horizontal and vertical shift of the temperature affected signals. The reduction of the temperature effects of the recorded signals was conducted in four steps: First the signal's slopes were determined by means of the linear least squares method. Second the slope and the difference between the offset of the baseline and the x-axis were removed. As a result the signals have horizontal orientation and zero offset. Therefore the peaks at the resonance frequency as well as the surrounding peaks can be easier identified and EFS can be applied. The EFS was carried out by finding the frequency shift $\delta\hat{f}$ were correlation is highest in the third step and shifting the signals horizontally about this distance in the fourth step. In order to detect the differences of clamping forces the RMSD-metric shown in equation 7 was used. For removing the slope of the signals a rotation matrix according to equation 1 was applied in order to rotate the signals about the origin $(0 \mid 0)$:

$$\hat{X_j}^{(k)} = R_{\perp}^{(k)}(\alpha_k) X_j^{(k)} \tag{1}$$

where $\hat{X}_j^{(k)}$ contains the rotated data vectors and $X_j^{(k)}$ the original data of the k'th state.

$R_\perp^{(k)}(\alpha_k)$ is the rotation matrix for computing rotations by the angle α_k about the normal axis. The rotated data matrix $\hat{X}_j^{(k)}$ is given in equation 2:

$$\hat{X_j}^{(k)} = \begin{bmatrix} \text{——} & \hat{f}_j^{(k)T} & \text{——} \\ \text{——} & \hat{B}_j^{(k)T} & \text{——} \end{bmatrix} \tag{2}$$

where $\hat{f}_j^{(k)}$ and $\hat{B}_j^{(k)}$ are the rotated data vectors of the frequency and the susceptance of the k'th state. The original data matrix $X_j^{(k)}$ is given in equation 3:

$$X_j^{(k)} = \begin{bmatrix} \text{——} & f_j^{(k)T} & \text{——} \\ \text{——} & B_j^{(k)T} & \text{——} \end{bmatrix} \tag{3}$$

where $f_j^{(k)}$ and $B_j^{(k)}$ are the original data vectors of the frequency and the susceptance of the k'th state. The rotation matrix is defined as follows:

$$R_\perp^{(k)}(\alpha_k) = \begin{bmatrix} cos(\alpha_k) & -sin(\alpha_k) \\ sin(\alpha_k) & cos(\alpha_k) \end{bmatrix} \tag{4}$$

where α_k is the slope angle of the k'th state signal. Its connection to the slope m_k of a linear function is defined in equation 5:

$$m_k = tan(\alpha_k) \tag{5}$$

Afterwards the converted signals are shifted by the EFS horizontally and vertically by removal of the mean value according to equation 6.

$$\tilde{B}_j^{(k)} = \hat{B}_j^{(k)}(\hat{f} - \delta\hat{f}) - \mu_k \tag{6}$$

where $\delta\hat{f}$ is the EFS and μ_k the mean value of the signal's k'th state. By this operation the signal's offset is 0 and the signals have a comparable range. Which also leads to an approach of the heights of the susceptance peaks of the temperature affected signals. For evaluation the root mean square deviation (RMSD) was applied as follows:

$$RMSD^{(k)} = \frac{\sum_{j=1}^{N}\left[\tilde{B}_j^{(k)} - \tilde{B}_j^{(0)}\right]^2}{\sum_{j=1}^{N}\left[\tilde{B}_j^{(0)}\right]^2} \tag{7}$$

Where $\tilde{B}_j^{(0)}$ is the susceptance signal of the baseline's state and $\tilde{B}_j^{(k)}$ the k'th state. For showing the efficiency of the temperature compensation strategy introduced before the temperature affected original data is compared with the temperature compensated data. The RMSD-algorithm shown in equation 7 is normalized by the baseline. As the baseline is converted by the temperature compensation strategy, too, the RMSD is not suitable for comparing the original and converted data. Therefore only residuals are computed according to equation 8 and 9.

$$R^{(k)}(B_j) = \sum_{j=1}^{N}\left[B_j^{(k)} - B_j^{(0)}\right]^2 \tag{8}$$

$$R^{(k)}(\tilde{B}_j) = \sum_{j=1}^{N}\left[\tilde{B}_j^{(k)} - \tilde{B}_j^{(0)}\right]^2 \tag{9}$$

3 Experimental Setup and Test

In this section the analysed specimen, the experimental setup and data acquisition for performing EMI measurements are briefly described. The experiments were carried out on three specimen.

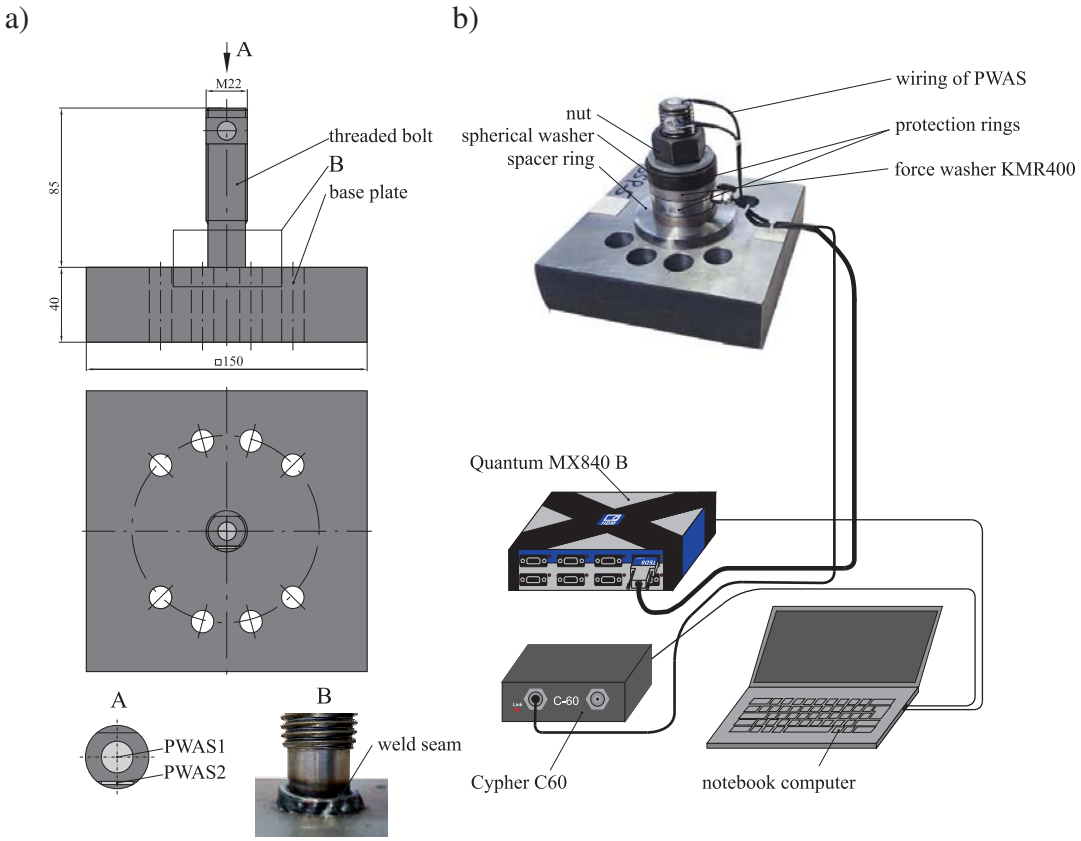

Figure 2: Experiments a) specimen with attached PWAS b) experimental setup

3.1 Specimen and Sensor Technology

The specimen consist of threaded M22-bolts which are welded onto base plates. The welding process is a fusion welding process without filler material. Both parts are composed of structural steel S355. For the experiments the bolts with a length of 85 mm have been welded onto squared 150 $\times$ 150 mm base plates having a thickness of 40 mm. The specimen including the sensors and actors, respectively, is depicted in figure 2a). For EMI measurements two piezoelectric wafer active sensors (PWAS) PI (type *PIC*) with a diameter of 10 mm and a thickness of 0.5 mm were installed according to figure 2. One transducer is positioned at the face side of the bolt (PWAS1). The second one (PWAS2) is arranged laterally at the circumferential surface of the bolt.

3.2 Experiments

For investigating temperature effects under varying clamping force the bolted connection was preloaded in steps of 10 kN starting at 30 kN until the maximum of 60 kN. The clamping force was increased at a temperature of 0°C. At every load step the specimen was heated in steps

of $10°C$ starting at $0°C$ until the maximum of $50°C$. The EMI measurements were carried out at every temperature step with PWAS 1 and PWAS 2 in the frequency range 125-185 kHz. During the experiments the specimen were placed in a *ACS* climatic chamber. The temperature was regulated by the temperature of the specimen with a *PT100* temperature sensor coming along with the *ACS* climatic chamber.

3.3 Measuremental Setup

In figure 2b) the measurement setup is shown. The clamping force was measured by a force washer *KMR400* coming along with two protection rings per flange which was clamped by a nut. Additionally a spherical washer was mounted between the nut and the force washer for compensation of misalignment of the bolt and to transfer the load orthogonal to the force washer. Beneath the bottom of the force washer a spacer ring having a bigger inner diameter than the other parts was mounted because the weld seam at the bottom of the bolt has also a bigger diameter than the bolt itself. The impedance analyser, *Cypher C60*, was used to supply an alternating voltage in the specified frequency range and to measure the corresponding admittance signatures across the two PZT transducers one by one. A notebook computer with Cypher software coming along with the *C60* was used for configuring the measurement settings and recording the admittance spectra. For excitation via *Cypher C60* the set frequency range is divided into 1024 discrete frequencies f_i in order to excite the structure at every single frequency sequentially and to measure the corresponding electro-mechanical impedance and admittance signatures, respectively. The structural response of one state is measured as the impedances Z_i at the single frequencies f_i. The signals of the *KMR400* as well as signals of the *PT100* sensor were measured with the amplifier *Quantum MX840 B* from *HBM*.

4 Results and Discussion

In order to show the efficiency of the temperature compensation strategy described previously in figure 3 the compensation of the temperatures for maximum clamping force are shown.

	frequency with highest amplitudes	evaluated frequency range
first sample	138,3 kHz	142 - 147 kHz
second sample	136,6 kHz	140 - 145 kHz
third sample	136,2 kHz	140 - 145 kHz

Table 2: Overview of frequency with highest amplitudes at $20°C$ and 60 kN clamping force and evaluated frequency ranges for all samples

The original susceptance signals shown in figure 3a) have been measured by PWAS1. The increasing slope and the horizontal shift of the resonance with increasing temperature are apparent. There are two clearly visible resonances. The resonance in the lower frequency range has higher amplitudes than the resonance in the higher frequency range. In figure 3b) the minimization of the temperature effects described previously are visible. This is confirmed by the residuals computed in the diagrams of figure 3c) and d). Note that in both cases the third measurement at $20°C$ was used as baseline and therefore is zero valued. In case of the maximum clamping force the residuals's of the temperature compensated data decreased between 85%

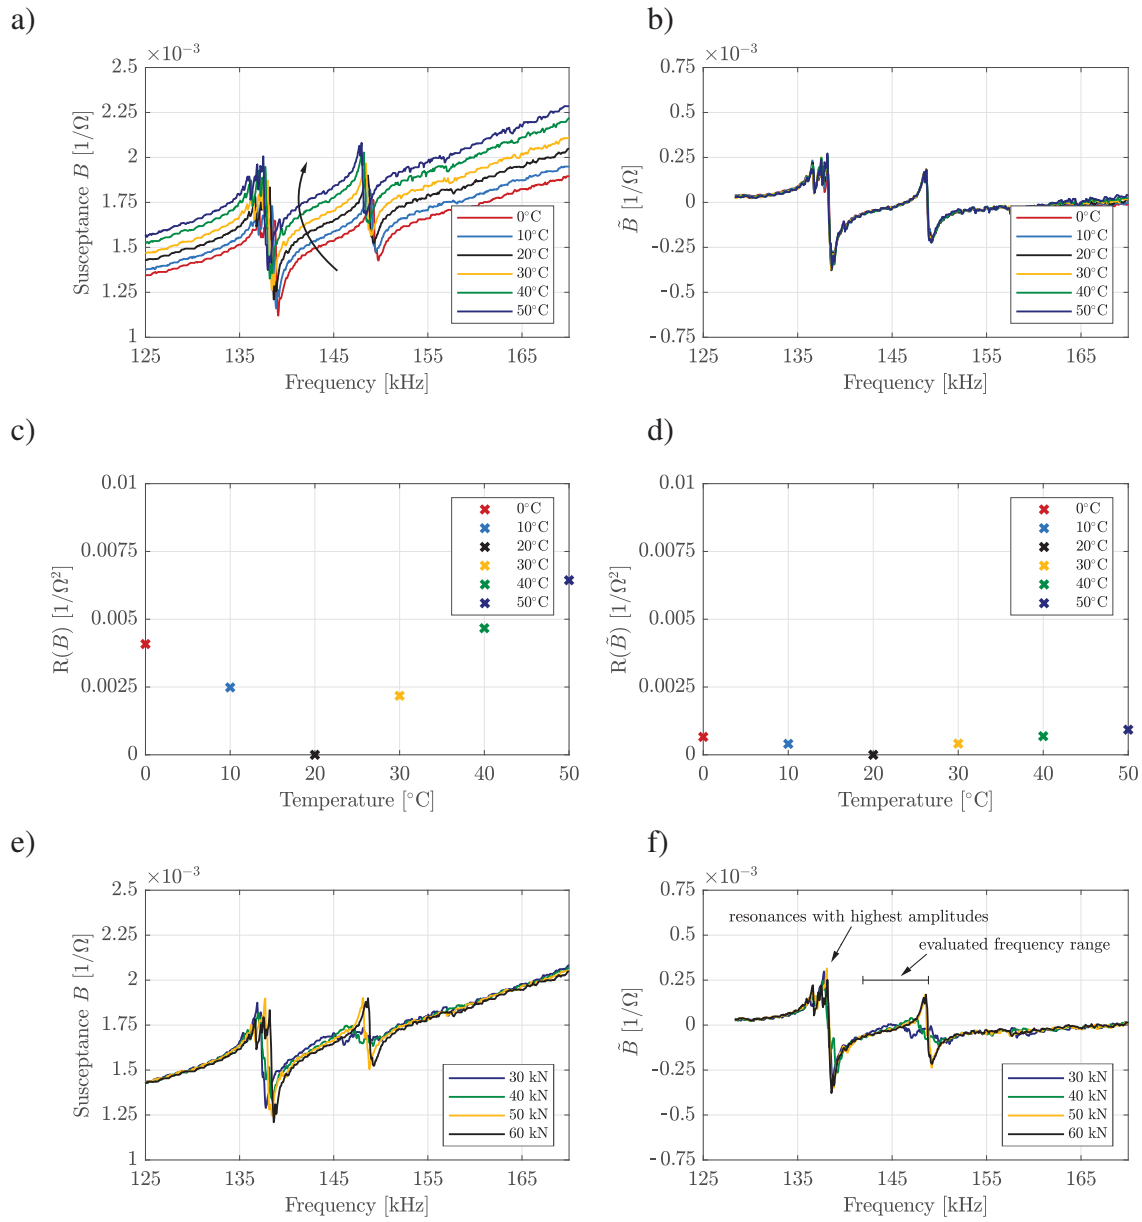

Figure 3: Temperature compensation a) original susceptance signals of 60 kN clamping force and varying temperatures b) temperature compensated signals for 60 kN clamping force c) residuals of original signals for 60 kN clamping force d) residuals for temperature compensated signals for 60 kN clamping force e) original susceptance signals measured at 20°C and variable load states f) temperature compensated signals measured at 20°C and variable load states

and 80% in comparison to the original data. In figure 3e) the original signals measured at 20°C and under variable load states from 30 kN to 60 kN are plotted. The corresponding temperature compensated signals are shown in figure 3f). Because the temperature compensation algorithm is based on maximum correlation, the signals are shifted until the resonances with higher amplitudes coincide. Temperature variation causes approximately the same frequency shift for the two resonances (see figure 3b)) and load variation causes different frequency shifts of the two resonances. Therefore the variation of the load state can be detected by evaluating the frequency range where the second resonances of the four load states are located. This frequency range is labelled in figure 3f). As the several resonance frequencies vary for the three specimen the

evaluated frequency range varies, too. The evaluated ranges are shown in table 2. In figure 4 the RMSD's for three specimen are depicted.

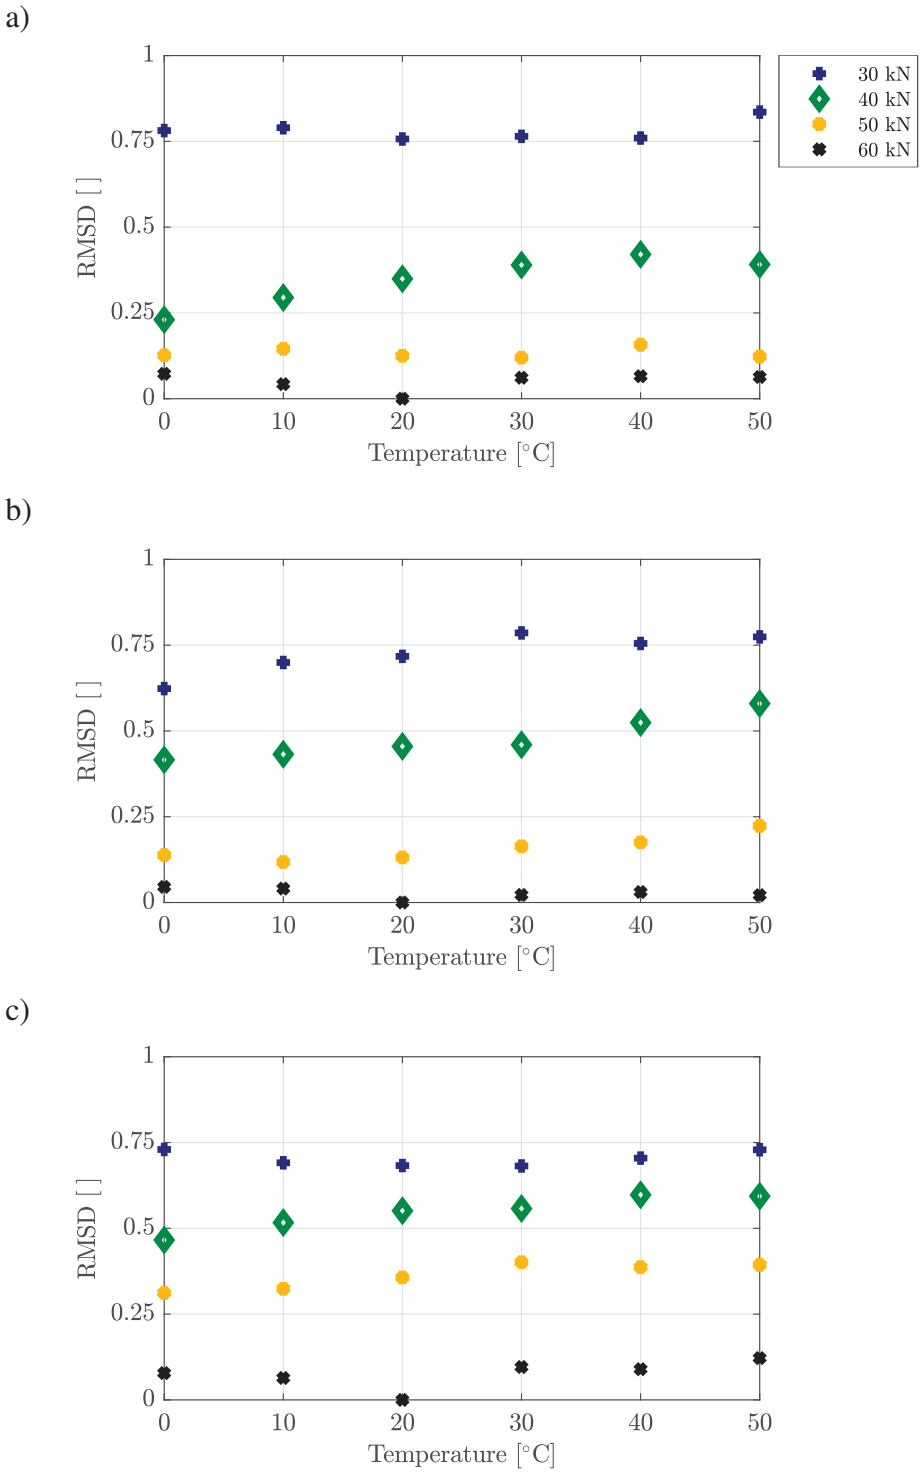

Figure 4: RMSD index for three specimen and seven load states under varying temperatures between 0°C and 50°C in comparison to the baseline at 60 kN load state and 20°C a) evaluated at 142-147 kHz b) evaluated at 142-147 kHz b) evaluated at 140-145 kHz b) evaluated at 140-145 kHz

The diagrams show four load states under varying temperature between $0°C$ and $50°C$. The state of 60 kN at a temperature of $20°C$ was used as baseline state. The load states of 30 kN, 40 kN, 50 kN and 60 kN are separable for each specimen. But the RMSD values for the several load states move in different ranges and fluctuate. A possible explanation regarding the fluctuations for constant load stages and varying temperatures can be made: Due to thermal expansion of the material the contact and tensioning, respectively, between the several components changes. But in total these changes can cancel each other out and as a result they may not be measurable by the force washer. Changing of the clamping force due to thermal expansion or setting behaviour can be precluded because the force washer itself has only shown negligible changes with varying temperatures. For the different behaviour of the indicator in case of the three samples two explanations are possible: As the specimen are manually welded and manual processes are often imprecise the specimen may differ from each other significantly. A further reason can be attributed to the tensioning and contact conditions between the clamped components of the bolted joints which can differ from each other.

5 Summary and Conclusions

In this work a possible feature for detection of the clamping force loss in the presence of varying temperatures in a range of $0°C$ to $50°C$ and a load range of 30 kN to 60 kN has been investigated. The susceptance as the imaginary part of the electromechanical admittance was used to detect changes of the pretension. In order to avoid 'false alarm' caused by temperature effects a temperature compensation strategy had to be applied. Temperature effects on the susceptance have been identified and minimized. First the technique was applied to measurements of one load state at varying temperature. The defined indicator for the assessment of the temperature compensation technique has shown a significant reduction of the discrepancies between the temperature affected signals within 80% and 85%. Afterwards the technique was applied to measurements of varying clamping force and varying temperature. The baseline was defined at the maximum clamping force and a temperature of $20°C$. Fluctuations of the indicator for constant load and under varying temperatures were observed. This behaviour was attributed to changing restraints of the individual clamped components caused by varying temperatures which in total may cancel out each other and therefore can not be registered by the force washer. By application of the proposed technique it may not be possible to detect the exact current load state but it could be used as a possible technique for detection of a significant loss of the clamping force.

Keywords: Seismic isolation, Roller isolation systems, Bi-directional roller bearings.

Abstract. *Base isolation systems (BISs) are devices that mitigate the harmful effects of earthquakes on structures. Nowadays, designers are implementing this technology to bridge and building special projects located in areas of high seismic risk to improve their performance under earthquake excitations. However, high cost, uncertainty and lack of knowledge in the design have limited its massive use, specially in developing countries. According to the mechanical behavior, BISs are clasiffied in elastomeric bearings, sliding bearings and roller bearings. In this work, the performance of a bi-directional roller bearings system was evaluated; thus, the main objective of this publication is to show the efficiency of a bi-directional roller bearing in improving the structural seismic response of multicolumn systems by means of reducing accelerations and displacements. A numerical code in Matlab was written to simulate the response of the structures under base excitations, the finite element method (FEM) in conjunction with frame elements was used to solve the governing equations. The validation of the numerical model was done by direct comparisons between experimental and numerical data.*

1 INTRODUCTION

Various seismic isolation systems have been developed to protect buildings and reduce the potentially harmful effects produced by earthquakes. Isolations systems are commonly grouped into three types: (1) elastomeric bearings, (2) sliding bearings and (3) roller bearings. Jangid and Datta [1], Naeim and Kelly [2], Kunde and Jangid [3] and Harvey and Kelly [4] presented a comprehensive review of the study and use of these systems over the past three decades.

Seismic isolation systems, regardless of their type, partially decouple the horizontal motion between the structure and its base by incorporating a flexible interface with low lateral stiffness at the foundation level. This flexible interface corresponds to the isolation devices or seismic isolators, which allow to avoid that the natural frequencies of the structure coincide with the predominant frequencies contained in the seismic excitation; thus, reducing acceleration and horizontal displacements of the structure [1, 5]. Likewise, it is important to highlight that all types of seismic isolation systems have to return to their initial position, self-centering, after the excitation occurred; in addition, isolation systems should have the capacity of dissipate energy through different mechanisms, typical of each type of system.

Isolation systems have been successfully used since 1969 in 12.720 projects around the world [6]. New construction projects, the retrofitting of structures with insufficient resistance to withstand earthquakes and the updating of structures to current regulations are some examples in which this technology have been implemented [e.g. 2, 7–11]. Spencer Jr. and Nagarajaiah [12] attributed the success of seismic isolation to its reliability, stability, simplicity of design and low cost compared to other seismic protection techniques.

The main objective of this publication is to show the efficiency of a bi-directional roller bearings in improving the structural seismic response of multicolumn systems. This type of isolator was developed by Lee et al. [13] and it is composed of a cylindrical bearing system supported by an inclined V-shaped surface. Initially, this system was studied and implemented in bridges and subsequently studied by Ortiz-Cano et al. [14] to be used in multicolumn structural systems.

Following the work done by Ortiz-Cano et al. [14], in this work a numerical code in Matlab was written to simulate the response of the structures under base excitations, the finite element method (FEM) in conjunction with frame elements was used to solve both the governing equations and boundary conditions. The validation of the numerical model was done by direct comparisons between experimental and numerical data. Finally, a parametric study allowed to verify the efficiency of the isolation system in the control of vibrations under conditions of real earthquake records.

2 MOTION EQUATIONS OF ISOLATED BUILDINGS WITH RB SYSTEM

The equation of motion, in the time domain, that represents the dynamic bahavior of isolated buildings with RB systems under base excitations in a multiple degrees of freedom (MDoF) system is given in Eq.(1),

$$M\ddot{u} + C\dot{u} + Ku + R\left(f_s + f_{dr} + f_{ds}\right) = -M\Gamma\ddot{u}_g \tag{1}$$

Where M, C and K are the mass, damping and stiffness matrices of the MDoF system, respectively. $\ddot{u}$, $\dot{u}$ and u are the acceleration, velocity and displacement vectors.

On the other side, in Eq.(1), $\ddot{u}_g$ is the seismic excitation vector that contains the base accelerations for each direction in which the building can be excited; i.e., 3 translational and 3 rotational DoF's in the Cartesian space. The term Γ is an influence matrix that relates the excited DoF's i with the direction of the seismic excitation j. The elements of the Γ matrix take values of 0 or 1 according to the following expression:

$$\Gamma_{ij} = \begin{cases} 0 & \text{if the DoF } i \text{ isn't excited in the direction } j \\ 1 & \text{if the DoF } i \text{ is excited in the direction } j \end{cases} \tag{2}$$

where, R is a matrix that allocates the forces of restoration f_s, rolling friction f_{dr} and sliding friction f_{ds} developed by the RB system in j direction into a matrix that contains the forces in the DoF's system in i direction. The elements that make up the R vector take values of 0 or 1 as follows.

$$R_{ij} = \begin{cases} 0 & \text{if in the DoF } i \text{ the forces } f_s, f_{dr} \text{ and } f_{ds} \text{ aren't developed in the direction } j \\ 1 & \text{if in the DoF } i \text{ the forces } f_s, f_{dr} \text{ and } f_{ds} \text{ are developed in the direction } j \end{cases} \tag{3}$$

The forces f_s, f_{dr} and f_{ds}, which characterize the RB system, are defined through Equation (4), (5), (6) and (7) as follows,

$${f_s}^{\mathrm{T}} = \{ \ \tfrac{1}{2} m_1 g \sin(\theta_1) f_{H_1}(u) \quad \tfrac{1}{2} m_2 g \sin(\theta_2) f_{H_2}(u) \ \} \tag{4}$$

$${f_{dr}}^{\mathrm{T}} = \{ \ \mu_{r_1} m_1 g f_{H_1}(\dot{u}) \quad \mu_{r_2} m_2 g f_{H_2}(\dot{u}) \ \} \tag{5}$$

$${f_{ds}}^{\mathrm{T}} = \{ \ \mu_{s_1} N_1 f_{H_1}(\dot{u}) \quad \mu_{s_2} N_2 f_{H_2}(\dot{u}) \ \} \tag{6}$$

$$f_H(x) = \begin{cases} 1 & \text{if} \quad x \geq d \\ \frac{1}{d} x & \text{if} \quad -d < x < d \\ -1 & \text{if} \quad x \leq d \end{cases} \tag{7}$$

where m is the mass supported by the isolator, g is the gravitational acceleration, μ_r is the rolling friction coefficient, μ_s is the sliding friction coefficient, N is the normal force applied on the sliding interface, θ is the angle of the inclined V-shape surfaces and f_H is a function governed by a parameter called yield displacement d and a variable auxiliary x associated with the displacement and speed of the base of system (7). Additionally, the subscripts 1 and 2 denote the proper direction of each parameter in the horizontal plane.

In order to solve Eq.(1), the numerical solver of ordinary differential equations (ODE's) `ode23t` implemented by MATLAB was used; it showed greater efficiency and numerical stability compared to others methods offered by MATLAB ODE pack. In general, the algorithm of this solver is an implementation of the trapezoidal rule with an adaptive step-size associated with the use of a "free" interpolant [15]. The use of this solver requires that Eq. (1), which is a second order equation, be rewritten as a two first-order ODE system, as shown in the following expression:

$$\dot{v} = A_1 v(t) + A_2 H(u, \dot{u}) + A_3 \ddot{u}_g \tag{8}$$

with

$$A_1 = \begin{bmatrix} 0 & \mathrm{I} \\ -M^{-1}K & -M^{-1}C \end{bmatrix}; \quad A_2 = \begin{bmatrix} 0 \\ -M^{-1}R \end{bmatrix}; \quad A_3 = \begin{bmatrix} 0 \\ -\Gamma \end{bmatrix} \tag{9}$$

where, A_1 and $v\left(t\right)^{\mathrm{T}} \left(= \left\{u \quad \dot{u}\right\}\right)$ represent the state matrix and state vector of the system. The non-linearity of the system is represented by $H\left(u, \dot{u}\right)$ function, which includes the effects of the RB system previously described.

3 VALIDATION OF THE NUMERICAL SIMULATION ROUTINE

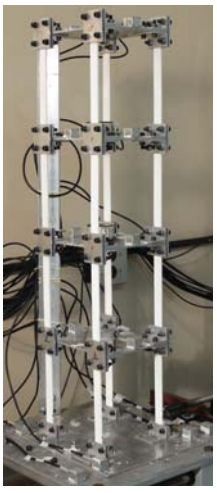
To validate the numerical simulation routine, the results of an experimental evaluation [14] and a numerical simulation of a building with and without RB isolation were compared.

The characteristics of the building model and the numerical simulations that validate the routine are presented in the next subsections.

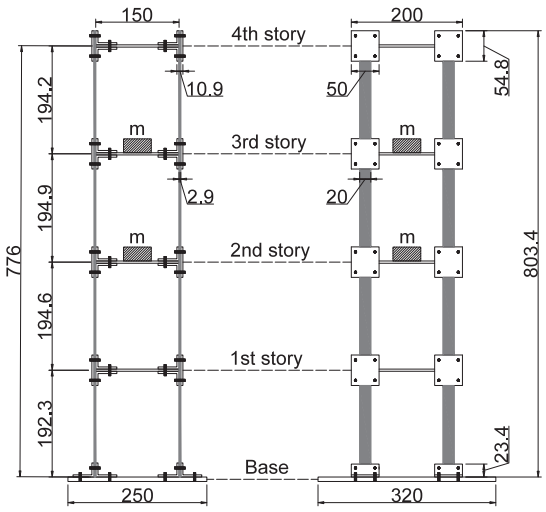
3.1 BUILDING MODEL

3.1.1 Description of the physical model

The physical model consists of 4 storys supported by columns of polymeric material with rectangular section of $20.0 \times 2.9\, mm$. The model has a total height of $803.4\, mm$ and a rectangular plant with dimensions of $150 \times 200\, mm$. The slabs that make up each story and the story-column connections are constructed of aluminum plates. The base of the building has a thickness of $8.0\, mm$, storys and story-column connections a thickness of $4.0\, mm$. On the other hand, the building supports superimposed masses of $0.50\, kg$ on the second and third storys. A detailed outline of the geometry of the physical model is presented in Figure 1.



(a) Picture of physical model.



(b) Scheme of physical model, measures in mm.

Figure 1: Physical model.

3.1.2 Modal parameters identified

According to the experimental tests carried out and the analysis methodologies adopted by the author, the modal parameters identified for the fixed-base building model are summarized in Table 1.

Mode	f_{exp} (Hz)	ξ_{exp} (%)
1st flexural (weak direction)	6.82±0.02	0.59±0.03
2nd flexural (weak direction)	20.44±0.03	0.51±0.01
1st torsional	21.55±0.02	2.88±0.03
3rd flexural (weak direction)	31.70±0.02	0.30±0.01
4th flexural (weak direction)	36.65±0.03	0.34±0.02
2nd torsional	77.44±0.02	3.92±0.01

Table 1: Modal parameters identified in the building.

In addition, considering the *Rayleigh* damping, values of the damping constants $\alpha = 4.03 \times 10^{-1}$ and $\beta = 5.58 \times 10^{-5}$ were determined for the first two modes of vibration, which add up to 95% modal participation of the total mass of the building.

3.2 NUMERICAL MODELING

The structural system that makes up the physical model of the building was modelled using three-dimensional frame elements, 68 elements were defined with 56 nodes as presented in Figure 2.

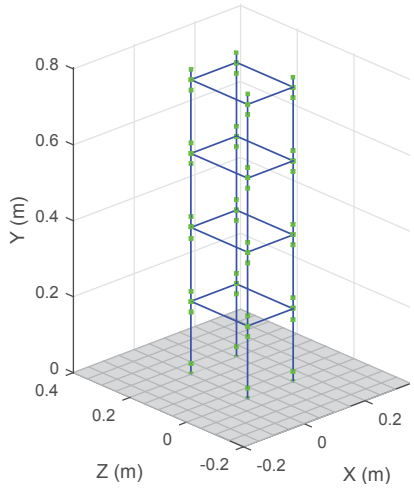


Figure 2: Numerical model raised.

In the numerical model, 3 types of frame elements were used, which are characterized by an elasticity modulus E, a Poisson ratio ν that defines the shear modulus G, a density ρ, a area A, a polar moment of inertia J_x and a moments of inertia I_y and I_z. Table 2 lists the characteristics of the elements used in the numerical representation of the physical model.

Element type	E (GPa)	ν	ρ (Kg/m^3)	A (m^2)	J_x (m^4)	I_y (m^4)	I_z (m^4)
1	28	0.325	1800	5.9×10^{-5}	1.5×10^{-10}	2.0×10^{-9}	4.1×10^{-11}
2	70	0.331	2700	4.0×10^{-4}	7.7×10^{-9}	1.3×10^{-7}	2.5×10^{-9}
3	70	0.331	0	4.0×10^{-4}	7.7×10^{-9}	1.3×10^{-7}	2.5×10^{-9}

Table 2: Mechanical and geometric characteristics of the elements.

The elements type *1* represent the columns constructed in polymeric material, while the elements type *2* and *3* represent the aluminum connections and slabs defined as beams in the numerical model. It is important to highlight that the density of the elements type *3* takes the value of 0 because the slab masses, and other elements that provide mass on each story, were modelled as masses concentrated on the nodes of each story. In this way, concentrated masses of 539.3 g, 196.6 g, 321.2 g, 321.1 g and 196.6 g were incorporated into each of the nodes of the base, 1st, 2nd, 3rd and 4th story.

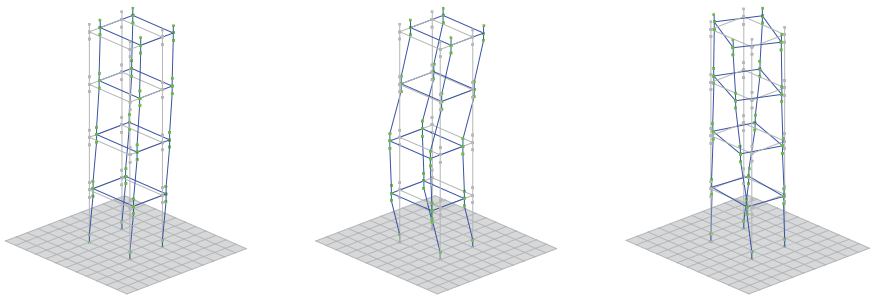
3.2.1 Building with fixed base

The validation of the numerical model corresponding to the fixed-base building was performed taking in to account both the domain of frequencies and the domain of time; in addition, the frequency response functions (FRFs) and the acceleration response of the model storys were used.

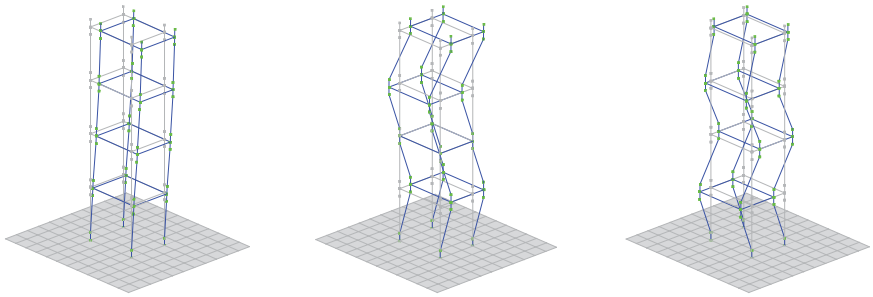
Firstly, the validation in the frequency domain was carried out by direct comparison between the natural frequencies and the FRFs obtained experimentally and numerically.

In Figure 3 the natural frequencies obtained numerically and the vibration modes associated with each frequency are presented, while Figures 4 and 5 show a comparison of the experimental and numerical FRFs of the structure. Accordingly, it is observed that the numerical vibration frequencies are in agreement with the experimental vibration frequencies with a relative difference less than 0.6% in the first four vibration modes (Fig. 3a, b, c, d).

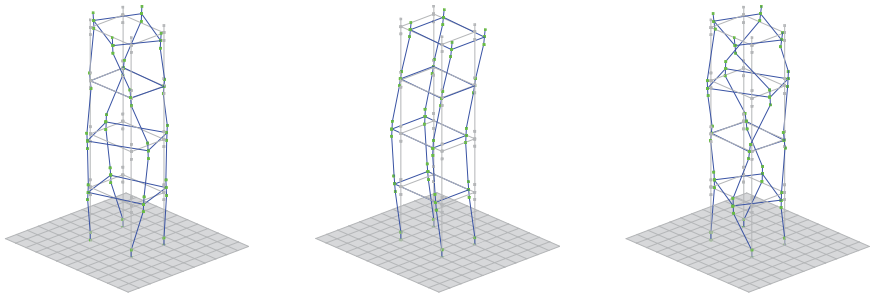
Likewise, using the damping ratios presented in Table 1 the FRF's were computed and then compared with the experimental ones; there is an excellent correlation between experimental and numerical FRFs as shown in Figures 4 and 5. However, it is noteworthy that if the damping ratios given by *Rayleigh* damping model are used (instead of those obtained experimentally) there is a significant difference for high vibration modes.



(a) 1st mode, 6.83 Hz. (b) 2nd mode, 20.44 Hz. (c) 3rd mode, 21.55 Hz.



(d) 4th mode, 29.92 Hz. (e) 5th mode, 31.55 Hz. (f) 6th mode, 36.86 Hz.



(g) 7th mode, 67.97 Hz. (h) 8th mode, 97.49 Hz. (i) 9th mode, 116.10 Hz.

Figure 3: Vibration modes and vibration frequencies.

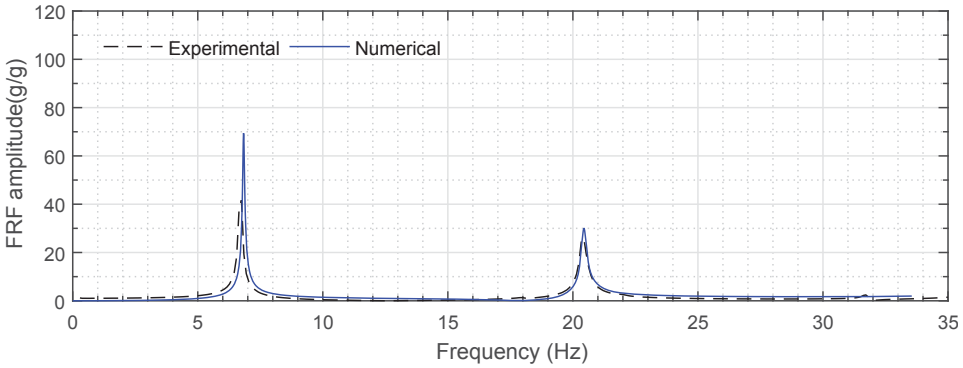


Figure 4: FRFs comparison of the 2nd story with base excitation.

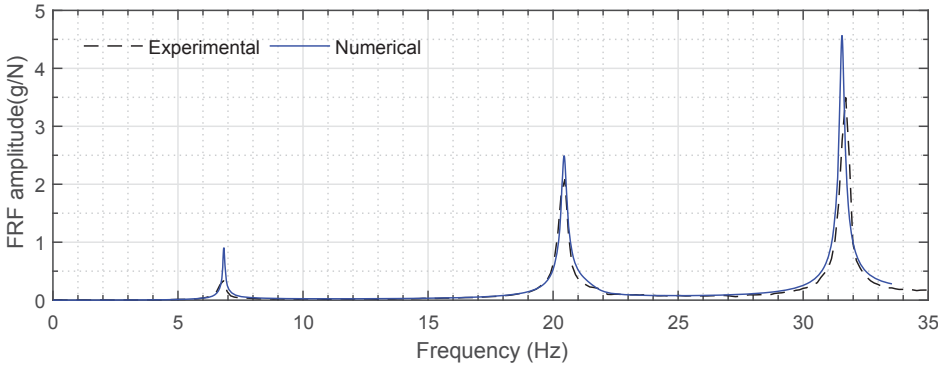

Figure 5: FRFs comparison of the 4th story with impact excitation in the 1st story.

Secondly, in the time domain, the validation of the numerical model was carried out by comparing the numerical and experimental response of the structure when subjected to random base excitation. The comparison of the responses is shown in Figure 6, it is evident that the numerical model represent the response of the fixed-base building.

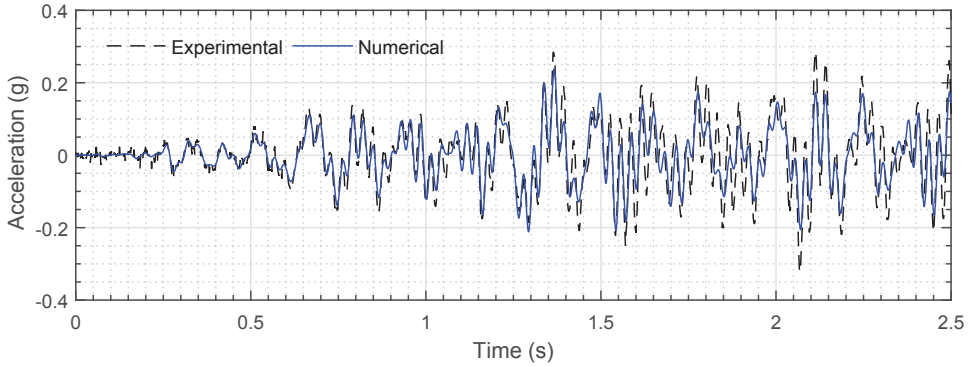

Figure 6: Time series of acceleration response of the 3rd story.

3.2.2 Building with RB system

Turning the attention to the use of roller bearings, the numerical model representing the building with RB was validated by comparing the numerical and experimental response of the structure in both free vibration and base excitation conditions.

To model the building + RB system, the characteristics of the fixed base structure and the RB system parameters $\mu_r = 0.0054$, $d = 1.2 \times 10^{-3}\, m$ and $\theta = 5°$ were used. In the free vibration simulations the initial lateral displacement condition $u_0 = 0.025\, m$ and initial velocity $\dot{u}_0 = 0\, m/s$ were considered, while in the simulations of the building + RB under base excitation initial conditions $u_0 = 0\, m$ and $\dot{u}_0 = 0\, m/s$ were considered in conjunction with a random base excitation record that contained predominant frequencies between 0 and 6 Hz.

In Figures 7 and 8 are shown the comparisons between numerical simulations and experimental responses of the building + RB system in both conditions free vibration and base excitation. In both figures certain degree of dispersion between the responses is noticeable; this dispersion could be related to deficiencies in the isolation system since it is not possible to completely restrict motion in the different directions in which the RB system operates Ortiz-Cano

et al. [14]. However, despite some dispersion, there is a very good agreement between the measured and numerically responses, which prove that the numerical model is able to adequately represent the dynamic behavior of a building + RB system.

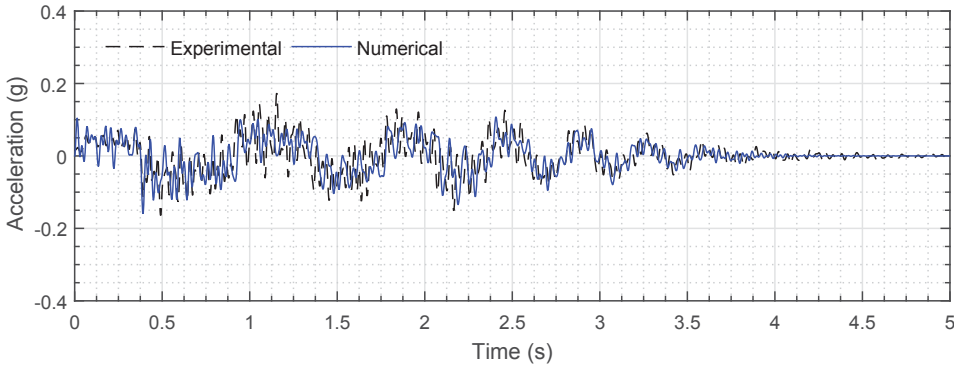

Figure 7: Time series of acceleration response of the 1st story with RB in free vibration.

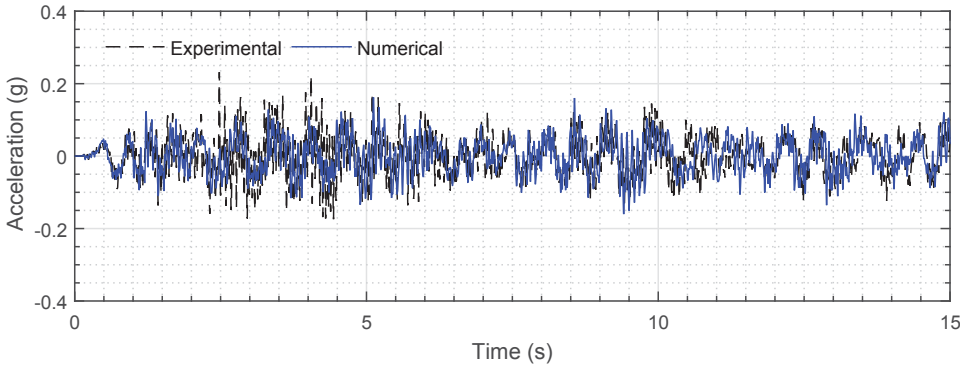

Figure 8: Time series of acceleration response of the 1st story with RB under base excitation.

4 RB SYSTEM PERFORMANCE UNDER BI-DIRECTIONAL SEISMIC EXCITATION

To evaluate the performance of the RB system in structures under base excitations, simulations using the numerical model previously described were carried out employing three earthquake records and four different RB configurations; thus, comparing the response of the fixed-base building with the response of the system when employing the RB system with different configurations. Accordingly, these results let us conclude about the performance of RB systems as seismic isolators in multicolumn structures.

Earthquake records were selected in order to have: I) excitations that produce high velocities at soil surface, II) excitations with both high frequency and high acceleration and III) moderate excitations [2]; in Table 3 are shown the seismic excitations selected for this work.

Earthquake	Station	Component	PGA (g)	PGV (m/s)	PGD (m)
Imperial Valley (1979)	El Centro Array # 6	140	0.339	0.665	0.287
		230	0.437	1.131	0.720
Loma Prieta (1989)	Corralitos	90	0.478	0.475	0.115
		0	0.630	0.552	0.095
Northridge (1994)	Century City	90	0.256	0.214	0.060
		360	0.222	0.251	0.060

Table 3: Seismic excitations.

It is timely to mention that each of the RB system configuration is determined by a different inclination angle θ and a different dissipation force f_{ds}; i.e., first RB configuration corresponds to $\theta = 2.0°$, second one corresponds to $\theta = 3.5°$, third one is given by $\theta = 5.0°$ and the fourth one is defined by $\theta = 5.0°$ + $f_{ds} = 1.14\ N$.

To continue, time series responses of displacement, speed and accelerations were obtained, however, only the responses in displacements will be presented. In Figures 9, 10 and 11 are shown the time series of displacement response at the fourth story obtained in the numerical simulations obtained for each of the earthquake records employing the four different RB configurations. Displacements were normalized by the maximum displacement obtained in the simulation of the fixed-based building u_{max}. Due to the fact that only in the weaker direction of the structure the seismic excitation produced noticeable displacements, the parametric analysis was performed only in that direction. By contrast, the seismic excitation, by means of amplitude and frequencies, did not produced noticeable displacements in the stronger direction of the structure.

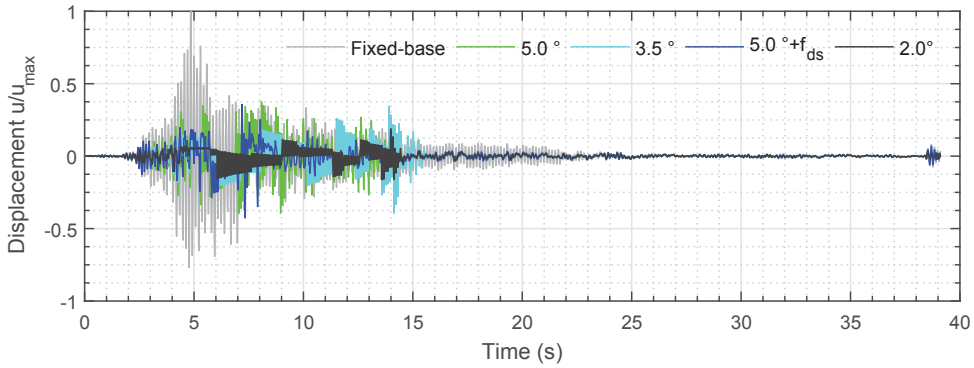

Figure 9: Performance of RB system: Time series of displacement response of the 4st story under base excitation Imperial Valley Earthquake (1979), $u_{\max} = 0.0109\ m$.

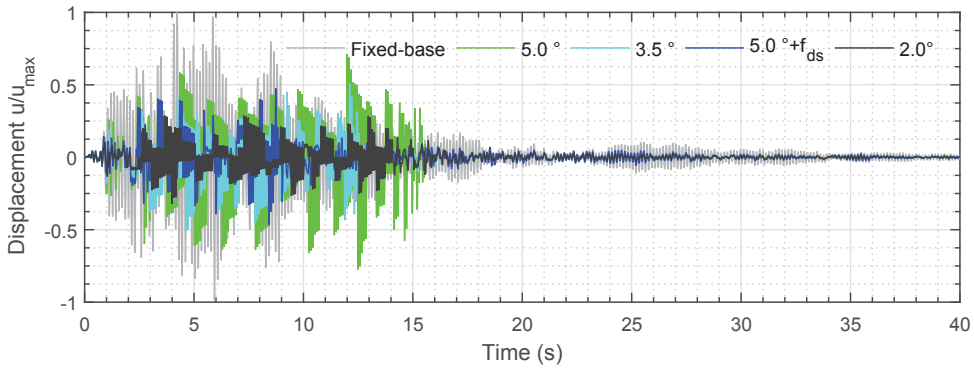

Figure 10: Performance of RB system: Time series of displacement response of the 4st story under base excitation Loma Prieta Earthquake (1989), $u_{\max} = 0.0075\ m$.

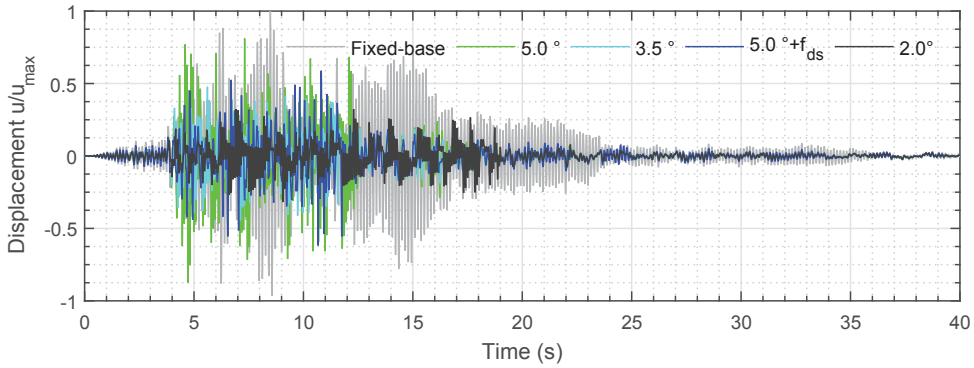

Figure 11: Performance of RB system: Time series of displacement response of the 4st story under base excitation Northridge Earthquake (1994), $u_{\max} = 0.0068\ m$.

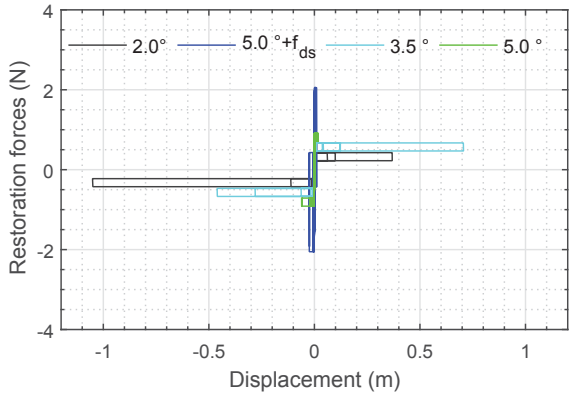

Figure 12: Hysteresis diagrams of isolation devices under base excitation Imperial Valley Earthquake (1979).

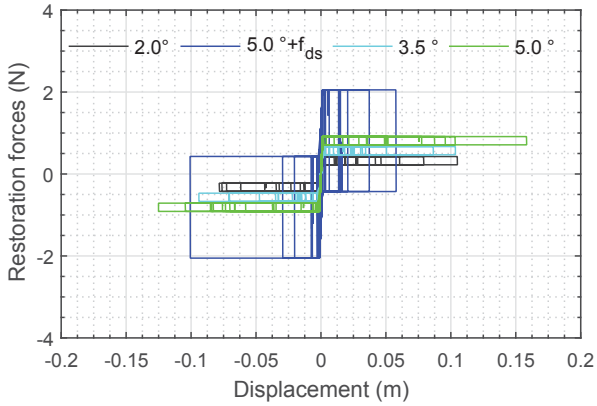

Figure 13: Hysteresis diagrams of isolation devices under base excitation Loma Prieta Earthquake (1989).

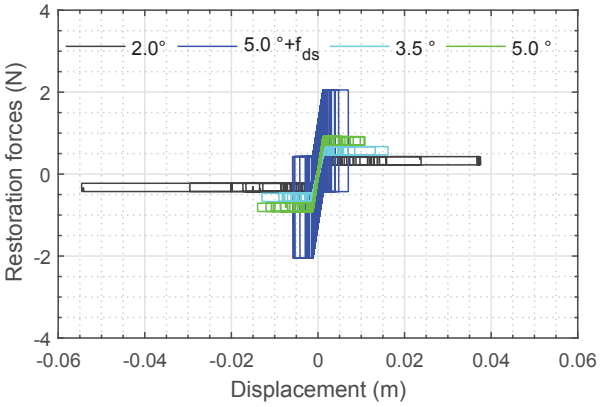

Figure 14: Hysteresis diagrams of isolation devices under base excitation Northridge Earthquake (1994).

Based on the obtained results, it is noticeable that the use of RB system reduce building displacements between 60% to 80% for all three seismic excitations compared with the same results obtained in the simulations without RB systems. The seismic building response improve as θ decreases; however, as θ decreases, large horizontal displacements result at the base of the structure thus limiting the use of RB systems. To avoid this problem, energy dissipation systems must be implemented to control those large displacements at the base of the structure; thus, improving the performance of the whole seismic isolation system (Fig. 12, 13, 14). It is important to mention that the energy dissipation system have to maintain both the decoupling between the structure and the base and the self-centering capability of the isolator device.

5 CONCLUSIONS

The response of a multicolumn structural model employing a Roller Bearing seismic isolation system and the performance of the RB system have been presented. Its performance has been assessed through the simulation of the structural model subjected to seismic excitations. The structural model's response was evaluated by direct comparison between the results of the simulation under fixed-base structure conditions and employing the RB system. It was found that the RB isolation system considerable reduces horizontal displacements relative to the

base for all earthquake records reviewed in this work. Maximum accelerations also decrease by means of the RB systems compared with those ones computed in the fixed-base structure simulations. In addition, it is important to mention that an energy dissipation system reduced the maximum horizontal displacement at the base of the structure improving the overall performance of the seismic isolation system. Finally, a proper relation between parameters θ y f_{ds} will give the best performance to the RB system in different seismic excitations.

Abstract. *This paper considers different vibration control options for a real high-rise tower subjected to real wind loading. To mitigate excessive responses, the tower utilizes a hybrid passive - active control system with a relatively small actuator capacity. Firstly, the methodology for establishing a reduced order numerical model of the tower from a finite element realization is presented. Subsequently, to deal with physical constraints, a Model Predictive Control (MPC) algorithm is employed and compared to a more conventional Linear Quadratic Regulator (LQR). In both cases, the algorithms managed to keep the dynamic displacements within the set desired limit. It was concluded that, the MPC had a better performance when compared to the LQR in terms of peak amplitudes at the expense though of energy.*

1 INTRODUCTION

The technological advancement and increase of cost-efficient computational power , create the ideal conditions for the broader implementation of active control systems. Traditionally, disciplines such as aerospace and automotive, have been utilizing active control schemes in order to enhance performance for a range of applications[1, 2]. Yet, active control is now also growing in disciplines that, it was not popular, or even viable, in the near past. More specifically, the recent trend of building tall and slender structures led to the development of structural control systems that utilize active components for vibration mitigation under extreme loads.

Generally speaking, active and semi-active structural control systems can achieve enhanced control performance when compared to passive equivalents. However, the performance of active control systems may be limited due to various practical and operating constraints. For the case of a mass damper such can be the actuator dynamics, mass stroke, and energy consumption. To this goal, extensive efforts have been made by the structural control research community and smart methods have been developed to minimize, if not eliminate, any performance compromising effects of constraints.

This paper will investigate the application of an active hybrid mass damper system on a real 245m tower subjected to wind loading, without accounting for any aeroelastic effects. For the control of the hybrid system, Model Predictive Control (MPC) algorithm will be used and compared to a more conventional Linear Quadratic Regulator (LQR). Previously, the MPC algorithm was investigated by Mei et al. [3, 4] for the control of the famous 76-storey benchmark building. Moreover, applications of the MPC on different control systems were practiced by Mei et al. [5, 6] for the case of a single and a three-storey structure, by Chen et al. [7] for a ten-storey structure, explaining additionally a more practical implementation of the algorithm, by Peng et al. [8] for two adjacent 20-storey buildings and by Lopez et al. [9] for a six-storey experimental structure.

Herein, the constraint effect of the actuator maximum capacity on the overall performance of the hybrid control system will be examined, and methodologies for minimizing it will be reviewed. More specifically, the actuator that was utilized on the hybrid control system of the 245m tower has a maximum force rating of 35kN, which is relatively low compared to the 180,000t tower mass. For reference and comparison, the actuators deployed for the control of the Nanjing TV tower had a capacity of 100kN [10], for the Shanghai World Financial Center Tower 142.5kN [11], for a 36-storey building reported in [12] 25.4kN, and for a benchmark cable-stayed bridge (Cape Girardeau Bridge, Missouri, USA) up to 7000kN [13] with typical values around reaching 1000kN [14]. For the 76-storey benchmark building, which is of significance to this study, the actuator capacity was limited to lower than 300kN [15], while Mei et al. [3] using the MPC algorithm, found that the maximum actuator force needed was 118kN.

2 APPLICATION DEFINITION

The 245m tower is the Rottweil Tower in Germany and was commissioned with specific requirements for experiencing limited wind-induced vibrations within certain bounds. According to wind tunnel tests, it was expected that wind speeds of the order of 15.3 – 16.7 m/s, referring to ground values at a height of 10m, could excite top floor dynamic response with amplitude of up to 750mm when no added control measure is provisioned. Such vibrations are primarily of vortex shedding type. Associated sway disturbance is anticipated to cause discomfort to the occupants and also impact the structural integrity of the tower particularly in terms of long term fatigue [16].

For ensuring comfort and safety, a limit displacement of up to 200mm was implemented and a hybrid structural control system was designed. The proposed hybrid system combines a

passive Tuned Mass Damper (TMD) with one actuator for each of the two principal directions. In reality, the passive TMD has adjustable stiffness that renders it semi-active; for simplification purposes this adaptiveness will not be considered any further in this study. Based on closed form formulas [17], a mass of 240t was opted for the TMD element of the system; this corresponds to a mass ratio of μ =1.3%. On the sensing side, the system consists of four uniaxial MEMS accelerometers which are able to capture horizontal accelerations at the top of the structure and the TMD mass. The displacements of the actuators are monitored by string pot transducers and an inductive length measuring system integrated within the linear motors [18].

3 PAPER CONTRIBUTIONS

1) Application of the MPC algorithm for the active hybrid control of a real structure and assessment of its performance by comparing it to an LQR controller
2) Optimization of the hybrid control system performance when acting in a passive-active mode of operation, taking into account its limited actuation capacity
3) Presentation of a real case-study that can become a benchmark for subsequent vibration control studies

4 SIMPLIFIED NUMERICAL MODEL DERIVATION

A detailed 3D Finite Element (FE) model of the tower, seen in Figure 1 (b), which falls very close in terms of observed and modelled frequencies, was used as the base for acquiring the reduced 2D lumped mass model shown in Figure 1 (c). In the reduction process, the entire mass of the tower, including the structural and non-structural components, was distributed evenly at the floors of the structure. This method results a diagonal mass matrix **M** of size *n x n* where, *n=34* is the considered number of lumped masses in the reduced model.

To derive the *n x n* stiffness matrix **K**, the methodology described by Qu et al., (2001) [19] was followed. Based on their methodology, the flexibility coefficients δ_{ij} of each floor were determined by evaluating the static responses of the i^{th} floor of the original FE model to unit horizontal forces at each node of the j^{th} floor, with $i,j= 1, 2, 3, \ldots ,n$. Thus, the flexibility matrix was constructed, and the stiffness matrix **K** was obtained by inverting it.

The damping matrix $\hat{\mathbf{C}}$ of size *n x n* for the lumped mass model was determined using the Rayleigh approximation whereby $\hat{\mathbf{C}}$ is described by Eq. 1. Parameters α and β are the mass and stiffness proportional damping coefficients, respectively and were obtained based on critical damping ratio of 1% for modes 1 and 5. For this assumption, α and β are becoming 2.11×10^{-2} and 5.26×10^{-4}, respectively.

$$\hat{\mathbf{C}} = \alpha \mathbf{M} + \beta \mathbf{K} \qquad (1)$$

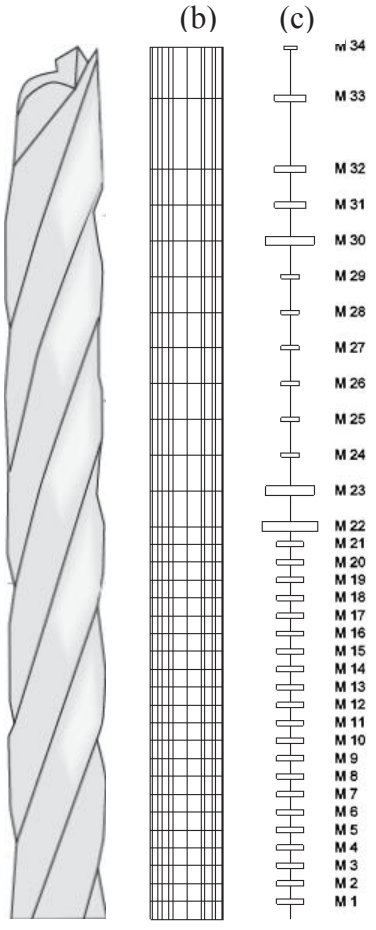

Figure 1: Three models of the tower: (a) architectural model, (b) original 3D FE model, (c) lumped mass model with equivalent masses

5 EQUATIONS OF MOTION FOR THE SYSTEM

The matrix equation of motion for the system in-hand can be expressed by Eq. 2. The nominal properties of the TMD were added to the mass **M**, stiffness **K,** and damping $\hat{\mathbf{C}}$**,** matrices derived in section 4, resulting to matrix sizes n_{tmd} *x* n_{tmd} where, n_{tmd} = 35. **f**(*k*) is an *r*-size vector which contains the external excitations applied on the structure, **u**(*k*) is the active *m*-size control force vector and **s**(*k*) is the n_{tmd} -size displacement vector, all at discrete time *k*. $\hat{\mathbf{D}}$ is the n_{tmd} *x m* matrix that describes how the control force is acting on the system, and **H** is the n_{tmd} *x r* matrix that describes how the excitation inputs are exciting the system.

$$\mathbf{M}\ddot{\mathbf{s}}(k)+\hat{\mathbf{C}}\dot{\mathbf{s}}(k)+\mathbf{K}\mathbf{s}(k)=\hat{\mathbf{D}}\mathbf{u}(k)+\mathbf{H}\mathbf{f}(k) \tag{2}$$

The equivalent spate-space equations are formulated as follows,

$$\dot{\mathbf{x}}(k)=\mathbf{A}\mathbf{x}(k)+\mathbf{B}\mathbf{u}(k)+\mathbf{G}\mathbf{f}(k),\qquad \mathbf{x}(0)=\mathbf{x}_0, \tag{3}$$

$$\mathbf{y}(k)=\mathbf{C}\mathbf{x}(k)+\mathbf{D}\mathbf{u}(k) \tag{4}$$

where **y**(*k*) represents the measured outputs, **C** is the output matrix, **D** is the feedthrough matrix, $\mathbf{x}_0$ is the initial point and,

$$\mathbf{x}(k)=\begin{bmatrix}\mathbf{s}(k)\\ \dot{\mathbf{s}}(k)\end{bmatrix},\ \mathbf{A}=\begin{bmatrix}\mathbf{0} & \mathbf{I}\\ -\mathbf{M}^{-1}\mathbf{K} & -\mathbf{M}^{-1}\hat{\mathbf{C}}\end{bmatrix},\ \mathbf{B}=\begin{bmatrix}\mathbf{0}\\ \mathbf{M}^{-1}\hat{\mathbf{D}}\end{bmatrix},\ \mathbf{G}=\begin{bmatrix}\mathbf{0}\\ \mathbf{M}^{-1}\mathbf{H}\end{bmatrix} \tag{5}$$

6 MPC STATE SPACE FORMULATION

This section includes the general formulation of MPC in state-space form. It is noted that derivation of the LQR controller, used only for comparisons, can be found in [20] and is not shown here for brevity. The MPC is based on an iterative, finite-horizon optimization of a plant. It receives a reference trajectory as the target output of the process. The overview of the algorithm is seen in Figure 2 [21]. The MPC computes a sequence of control actions **u** over a control horizon *q*, that will achieve the optimal behavior of the dependent variables **x** of the system, over a prediction horizon *p* (*p*≥*q*). It then implements only the first computed action **u**(*k*), measures the response of the system **y**(*k*), and repeats the previous process.

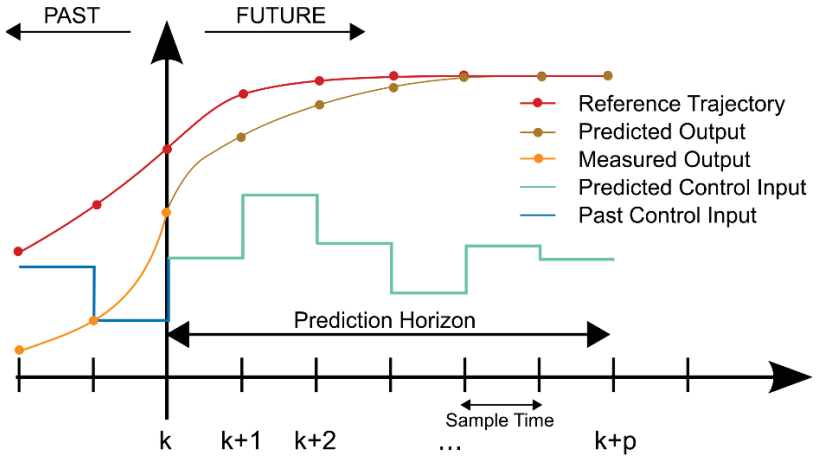

Figure 2: Basic concept for Model Predictive Control with q=p [22]

Since there might be inaccuracies and statistical noise in the measurements received and model used, a Kalman estimator is employed both for estimating the current state $\mathbf{x}(k)$ but also for the predictions needed for the MPC [21]. Eq. 6 describes how the estimates of the current state, $\hat{\mathbf{x}}(k|k-1)$, is generated by the Kalman estimator.

$$\hat{\mathbf{x}}(k \mid k-1) = \mathbf{\Phi}\hat{\mathbf{x}}(k-1 \mid k-2) + \mathbf{\Gamma}\mathbf{u}(k-1) + \mathbf{L}\mathbf{e}(k-1) \tag{6}$$

where, $\mathbf{L}$ the estimator gain matrix, and $\mathbf{C}$ the output matrix. $\mathbf{\Phi}$, $\mathbf{\Gamma}$, and $\mathbf{e}(k)$ are defined in Eq.7 for the control interval T.

$$\mathbf{\Phi} = e^{\mathbf{A}T}, \qquad \mathbf{\Gamma} = e^{\mathbf{A}T}\int_0^T e^{-\mathbf{A}x}dx, \qquad \mathbf{e}(k) = \mathbf{y}(k) - \mathbf{C}\hat{\mathbf{x}}(k \mid k-1) - \mathbf{D}\mathbf{u}(k \mid k) \tag{7}$$

The future state predictions $\hat{\mathbf{z}}(k|k+j)$ for $j=1,2,\ldots p$, are similarly determined by:

$$\hat{\mathbf{z}}(k \mid k+j) = \mathbf{\Phi}\hat{\mathbf{z}}(k+j-1) + \mathbf{\Gamma}\mathbf{u}(k+j-1 \mid k) + \mathbf{L}\mathbf{e}_f(k) \tag{8}$$

where,

$$\hat{\mathbf{z}}(k) = \hat{\mathbf{x}}(k \mid k-1) \tag{9}$$

Unlike the LQR, the constrained MPC is able to take into account bounds on the control actions $\mathbf{u}$ and future states $\hat{\mathbf{z}}$. With the target states and inputs defined by $\mathbf{z}_s$ and $\mathbf{u}_s$, respectively, the MPC objective for time instance k becomes:

$$\underset{\mathbf{u}}{Min}\, J(k) \tag{10}$$

where,

$$J(k) = [\hat{\mathbf{z}}(k+p) - \mathbf{z}_s(k)]^{\mathrm{T}}\mathbf{w}_\infty[\hat{\mathbf{z}}(k+p) - \mathbf{z}_s(k)] + \sum_{j=1}^{p}[\hat{\mathbf{z}}(k+j) - \mathbf{z}_s(k)]^{\mathrm{T}}\mathbf{w}_x[\hat{\mathbf{z}}(k+j) - \mathbf{z}_s(k)] +$$
$$\sum_{j=0}^{q-1}[\mathbf{u}(k+j \mid k) - \mathbf{u}_s(k)]^{\mathrm{T}}\mathbf{w}_u[\mathbf{u}(k+j \mid k) - \mathbf{u}_s(k)] \tag{11}$$

In Eq. 11, $\mathbf{w}_x$ and $\mathbf{w}_u$ are positive definite matrices representing the state error and the input weighting, respectively. $\mathbf{w}_\infty$ represents the terminal state matrix and can be found by solving the discrete Lyapunov equation [21]. The minimization problem is subject to constraints from Eqs. 6-9 (state estimation and predictions), alongside with the control input constraints shown in Eqs. 12-14.

$$\mathbf{u}(k+q \mid k) = \mathbf{u}(k+q+1 \mid k) = \ldots = \mathbf{u}(k+p-1 \mid k) = \mathbf{u}(k+q-1 \mid k) \tag{12}$$

$$\mathbf{u}_{\min} \le \mathbf{u}(k+j \mid k) \le \mathbf{u}_{\max} \qquad j=0, 1, 2 \ldots, q-1. \tag{13}$$

$$\Delta\mathbf{u}_{\min} \le \Delta\mathbf{u}(k+j \mid k) \le \Delta\mathbf{u}_{\max} \qquad j=0, 1, 2 \ldots, q-1. \tag{14}$$

7 PRELIMINARY RESULTS

An MPC and an LQR controller have been designed for the dynamic (response) control of the Rottweil tower, when subjected to real wind loading, using a hybrid mass damper. The passive-active mode of operation implies that, the hybrid mass damper is acting passively, and the actuators are constantly adding forces on top. A Kalman filter was used in both control cases for the state estimation using the four actual sensors located on the structure. Both controllers were designed in Matlab®. The MPC controller was realised based on the YALMIP toolbox, which is mainly used for treating prototype optimization problems [23]. The toolbox can utilize several solvers to carry out the optimization. In this study, the Gurobi optimizer was used [24]. Moreover, a hard constraint was introduced in the optimization procedure for the control input ($\mathbf{u}_k$) where, $\mathbf{u}_{min}$ and $\mathbf{u}_{max}$ were set to -35kN and 35kN respectively, T was set to 100ms and $\mathbf{z}_s$, $\mathbf{u}_s$ and $\mathbf{w}_\infty$ were set to 0. It is noted that the limit for the actuator capacity in the case of the LQR was introduced artificially in the simulation.

To simulate the dynamics of wind loading, a stochastic gust loading based on the Davenport spectrum with a linearly superimposed resonant, vortex shedding-type contribution were used [16]. The wind excitation caused a peak displacement of 248.2mm at the top floor in the case of no TMD installation.

Table 1 summarizes the maximum displacements of the floors of the structure in the uncontrolled and controlled cases. As it can be seen, both algorithms managed to reduce the structural responses at the top of the tower within the desired limit (200mm). However, the MPC had better performance than the LQR in controlling floor displacements throughout.

Floor No.	No control s(mm)	TMD s(mm)	LQR s(mm)	MPC s(mm)
1	1.8	1.6	1.4	1.35
10	53.2	48.3	42.4	40.6
20	160.7	146.1	128.1	122.6
34	248.2	225.7	197.9	189.4

Table 1: Maximum responses for the uncontrolled, TMD, LQR and MPC schemes

Based on the analysis, the maximum force exerted by the TMD without and with the active control component was 135.5kN and 170.5kN, respectively. Figures 3, 4 and 5 show displacement time series of the top floor of the structure with and without control, for the different control variants.

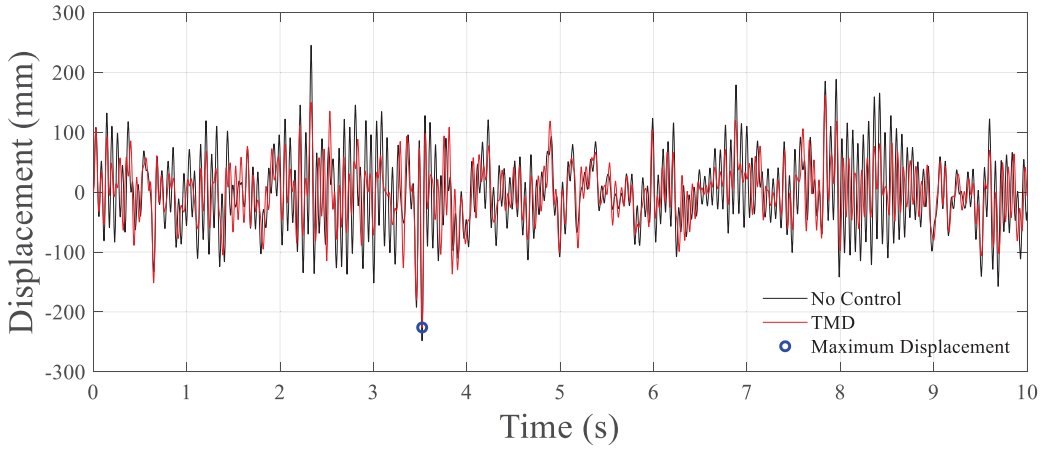

Figure 3: Displacement – Time graph for the uncontrolled case and the structure with a TMD

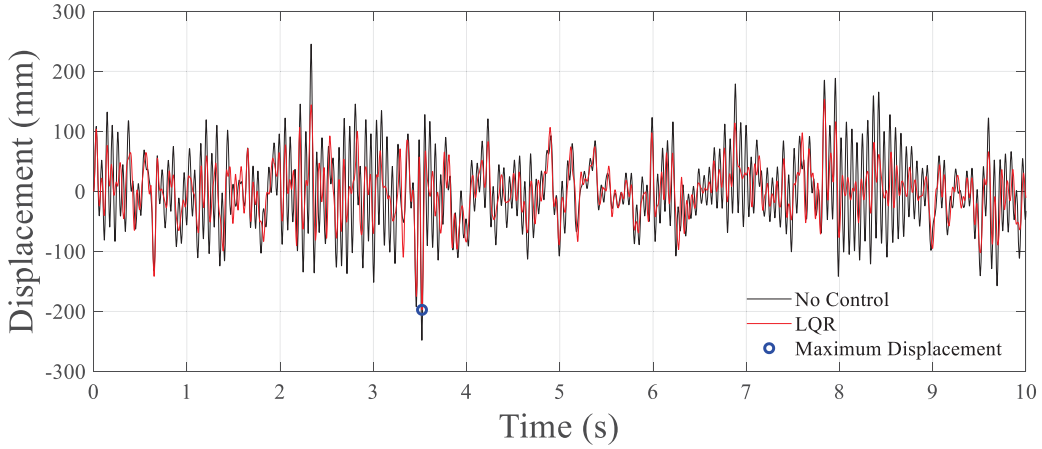

Figure 4: Displacement – Time graph for the uncontrolled case and the structure with active (LQR) control

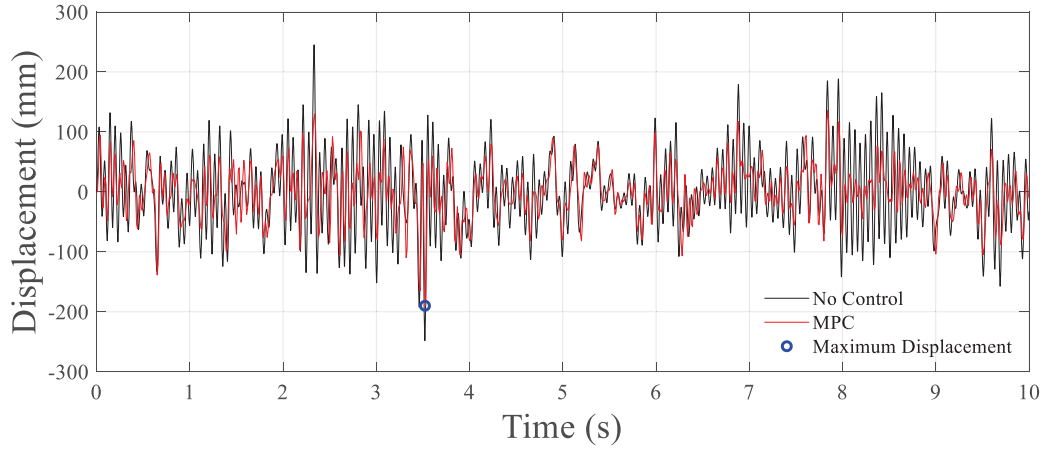

Figure 5: Displacement – Time graph for the uncontrolled case and the structure with active (MPC) control

It is observed that the active control algorithms can limit displacements even when, the actuator capacity is constrained to a fraction of the TMD passive force, as seen in Figures 6. To further asses the relative performance of the two controllers, while on a mixed passive-active

mode of operation, the actuator power, or else the product of actuator force and velocity was considered. It was found that the maximum power needed when using the LQR controller was lower than the equivalent needed for the MPC controller, as seen in Figure 7. When considering the average power the same relation pertains is with differences also in terms of extreme values and positive to negative value balance.

As such, when the hybrid system is acting in the considered passive-active mode, the MPC algorithm had the best performance on limiting dynamic displacements but in the expense of having higher energy demands than the LQR. This makes the consideration of also other modes of operation, (e.g. revised passive-active mode, having the active forces acting only when the passive forces are not sufficient and semi-active – active mode where performance can be gained at lower energy consumption) vital prior to holistically optimising the hybrid mass damper's performance, through control law considerations alone.

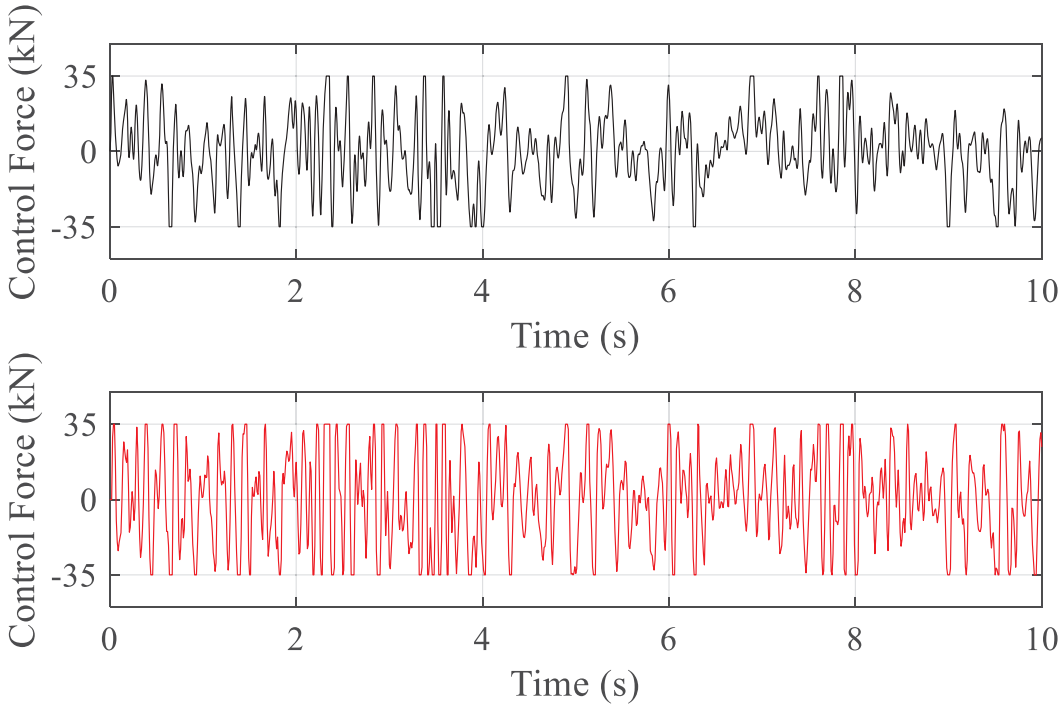

Figure 6: Active control forces when using the LQR (top) and the MPC (bottom) algorithms

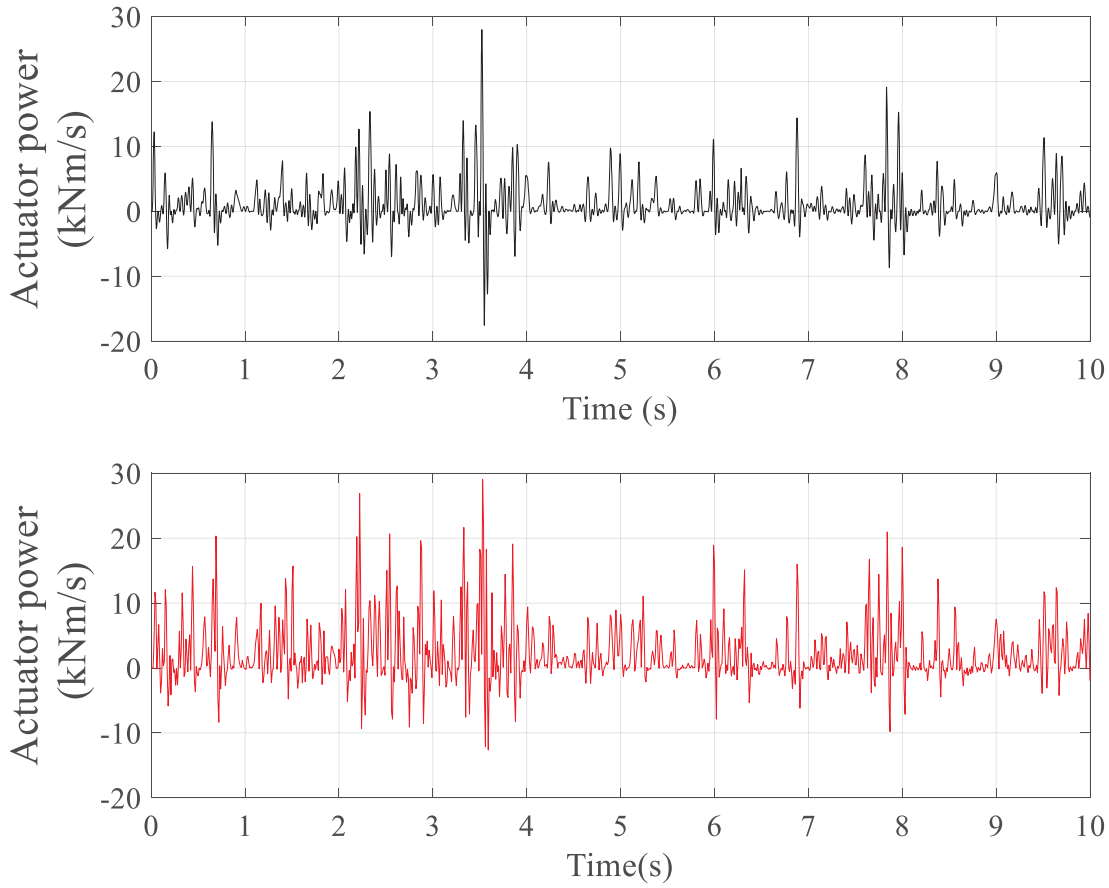

Figure 7: Actuator power when using the LQR (top) and the MPC (bottom) algorithms

8 CONCLUSIONS AND FUTURE RECOMMENDATIONS

This paper presented a real case-study which can introduce a new benchmark problem for structural control purposes. After deriving a reduced order model based on a detailed finite element model of the Rottweil tower, two control laws, namely the LQR and MPC, were applied and their performance was compared, for a passive-active mode of operation of a hybrid mass damper installation.

Based on the analysis it was found that the uncontrolled case-study building, under strong wind excitation developed dynamic displacements with maximum amplitude of 248.2mm at the top floor. When adding a perfectly tuned passive TMD the same displacement reduced to 225.7mm. In both cases, the displacements exceeded a notional serviceability limit that was set at 200mm. When considering active contribution in the control, the LQR algorithm reduced response to 197.9mm whereas, the MPC achieved 189.4mm. It was concluded that, in both cases, the algorithms managed to keep the dynamic displacements within the desired limit however, the MPC had a better dynamic reduction performance than the LQR. Still, the average energy needed for the two controllers was lower for the LQR, leading to the need for holistically optimising performance on mixed objectives.

Future work would involve semi-active – active mass damper devices, consideration of actuator dynamics and different modes-of-operation for the hybrid setup towards achieving a low energy-consumption scheme. Lastly, state-of-the-art data driven controllers, based on Artificial

Intelligence, should also enter the comparison against the presented conventional controllers in order to evaluate any performance gains.

9 ACKNOWLEDGEMENT

The authors would like to thank GERB for providing the hybrid system specifications, the FE models of the tower and the wind loading profiles. Additionally, the authors would like to thank the University of Leeds for providing the scholarship to the 1st author for conducting his PhD studies.

Keywords: Inerter, Tuned mass damper, Seismic response, Optimization algorithm

Abstract. *The introduction of improved structural control systems is an efficacious solution for reducing the seismic damage induced to structures. Due to the high development in control systems and the growing interest for this research area, multiple control devices were developed, tested and used with a remarkable efficiency. During the last few years, a novel passive damper, called inerter has been introduced, mainly known for its ability to develop a large fictive mass and largely used in combination with tuned mass damper TMD resulting in a TMD-Inerter device. This research work presents a double tuned mass damper inerter DTMDI, which consists of two masses connected with an inerter, this configuration will result in large fictive mass ratio without any retroaction force on the structure. The effectiveness of the double tuned mass damper inerter DTMDI has been demonstrated using a multi-degree of freedom structure submitted to seismic excitations. The results obtained show a significant response reduction compared to simple tuned mass damper inerter TMDI and classical tuned mass damper TMD. The dynamical parameters investigated in this study are the top floor displacement, top floor acceleration, inter-story drift and base shear. The study also underlines optimal parameters for the double tuned mass damper inerter DTMDI.*

1 INTRODUCTION

During the last century earthquakes have been one of the most observed natural phenomena, due to their destructive nature they constituted a main cause of live and economical losses. Hence, earthquakes represent a constant challenge for structural and civil engineers. Aseismic design of structure caught the attention many researchers around the word.

Research, test and experiment of new seismic vibration control strategies lead to the development of many control devices that can be regrouped into three sets, passive, active and semi-active, any combination of two or more control strategies in known as hybrid control [1-3]. Due to their simplicity and efficiency passive devices are the most used around the word, such as base-isolation, viscous dampers and tuned mass damper TMD.

Tuned mass damper (TMD) is a passive device. It is constituted of a moving mass attached to the structure through a spring and a dashpot, the frequency of the TMD as a single degree of freedom system is tuned to the frequency of the main structure, with the participation of it mass inertia the TMD acts as a restoring force to prevent large displacement of the main structure during dynamical loading (wind, earthquake) [4, 5]. Hence, it is obvious that TMD requires relatively a large mass to achieve a response reduction, which may constitute a structural problem in terms of space, vertical load and even cost [6].

During the last year, a new control device was introduced to the civil engineering domain, known as the "inerter" this device uses rotational inertia to produce a force relative to the acceleration between its extremities [7]. The force produced is depending on a factor known as the "inertance" or fictive mass. Therefore, the inerter may produce a large fictive mass if his high inertance is combined with a large relative acceleration [8]. The main use of the inerter in civil engineering is it combination with conventional tuned mass dampers (TMD) to form a new device known as TMDI, this new device attracted the attention of many researchers during the last years. Hence, The performances of these systems were studied by Lazar, Neild [9] for multi-degrees of freedom system subjected to both, sinusoidal and seismic excitations. It was concluded that the optimal location for an inerter based tuned mass damper (TMDI) or a tuned inerter damper (TID) is at the bottom of the structure, where the inerter second terminal can be grounded also known as single terminal inerter. Marian and Giaralis [10] presented an optimal design for inerter based tuned mass damper (TMDI), this design aims to suppress the oscillatory motion of stochastically excited support, hence it was derived from classical tuning methods presented by Den Hartog [11] and Warburton [12]. The damping system was designed for a single degree of freedom undamped system equipped with a TMDI. De Domenico and Ricciardi [13] proposed an optimization procedure for a TMDI tuning, this optimization aims to protect a multi-degree base-isolated system equipped with a grounded TMDI under different seismic records, the optimization was applied on a simple three degree of freedom system composed of a TMDI, a base-isolation level and a superstructure. Further, the procedure was generalized to a five-story model proposed by Xiang and Nishitani [14]. It can be seen that most of the research on the TMDI concluded to the necessity of grounded inerter used (i.e. the second end of the inerter to be fixed to the ground). This is mainly motivated by the retro-action nature of the inerter as a passive device. Hence, if the force of the inerter is to be returned to the structure this will reduce the effect of the TMDI or even increase the response of the structure. This resulted in the limitation of the TMDI for base-isolated and low to mid rise buildings.

In this work, a novel tuned mass damper is proposed and simulated with the aim of using such device into high-rise building, the main idea of this device is to return the force of the inerter two a second mass, this can be achieved by connecting the TMDI mass and the second

mass with the inerter. This structural configuration is herein defined as double tuned mass damper inerter (DTMDI).

2 MATHEMATHICAL FORMULATION

In this study a 10-story fixed base building is equipped with a double tuned mass damper inerter. The system consists of a classical tuned mass damper located at the top floor. The TMD is attached to an adjacent movable mass through an inerter as it can be shown in figure 1. This configuration is denoted double tuned mass damper inerter (DTMDI).

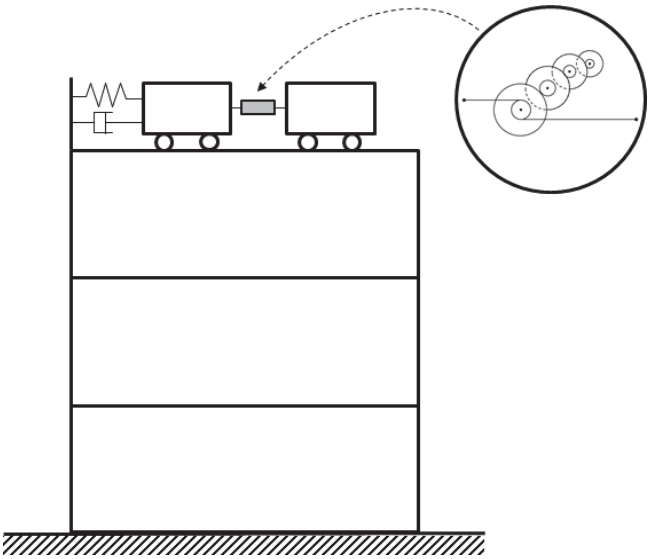

Figure 1. Structural configuration of a double tuned mass damper inerter.

The main motivation behind this configuration is to avoid returning a large amount of force from the second end of the inerter to the main structure. Usually, increasing the inerter fictive mass results in a large force, when returned to the main structure this force may increase the system response, despite the fact that it enhances the total mass of the TMD, thus enhancing it performance. Due to this inconvenience the efficiency of the TMDI remains limited and the amount of fictive mass reached remains low, except for the cases where the second end of the inerter is grounded (fixed to the ground) or connected to lower floors which represents a structural challenge especially for tall buildings .

The general equation of motion of the system shown in figure 1 can be written as follow according to d'Alembert's principle:

$$[M]\{\ddot{x}\}+[C]\{\dot{x}\}+[K]\{x\}=-[\bar{M}]\{r\}\{\ddot{x}_g\} \tag{1}$$

The detailed form of the $[M],[C]$ and $[K]$ matrices can be given as follow

$$\begin{bmatrix} m_1 & 0 & \cdots & \cdots & \cdots & 0 \\ 0 & m_2 & & & & \\ \vdots & & \ddots & & & \\ \vdots & & & m_n & & \\ \vdots & & & & m_{tmdi\ 1}+b & -b \\ 0 & & & & -b & m_{tmdi\ 2}+b \end{bmatrix}_{(n+2)\times(n+2)} \tag{2}$$

$$\begin{bmatrix} c_1+c_2 & -c_2 & \cdots & \cdots & \cdots & 0 \\ -c_2 & c_2+c_3 & & & & \\ \vdots & & \ddots & & & \\ \vdots & & -c_n & c_n+c_{tmdi\ 1} & -c_{tmdi\ 1} & \\ \vdots & & & -c_{tmdi\ 1} & c_{tmdi\ 1} & \\ 0 & & & & & 0 \end{bmatrix}_{(n+2)\times(n+2)} \tag{3}$$

$$\begin{bmatrix} k_1+k_2 & -k_2 & \cdots & \cdots & \cdots & 0 \\ -k_2 & k_2+k_3 & & & & \\ \vdots & & \ddots & & & \\ \vdots & & -k_n & k_n+k_{tmdi\ 1} & -k_{tmdi\ 1} & \\ \vdots & & & -k_{tmdi\ 1} & k_{tmdi\ 1} & \\ 0 & & & & & 0 \end{bmatrix}_{(n+2)\times(n+2)} \tag{4}$$

Where b denotes the additional inerter fictive mass, $m_{tmdi\ 1}$, $c_{tmdi\ 1}$ and $k_{tmdi\ 1}$ denotes the mass, damping and stiffness of the DTMDI, $m_{tmdi\ 2}$ denotes the second mass connected to the first mass through the inerter. $\left[\overline{M}\right]$ denotes the real mass matrix $(b=0)$ and n denoted the degrees of freedom of the structure.

2.1 Governing equations of the inerter

A basic model of the inerter is represented with the scheme shown in the Fig. 2. The inerter comprises of a rack and pinion arrangement rotating about a shaft, represented by the point O. The two extremities of the inerter, represented by *a* and *b* in Fig. 2, are connected to the pinion (of radius ρ) through racks and are responsible for reversing the direction of retro-action (represented by *F(t)*) at both ends. A flywheel having a radius *R* and mass m_i is mounted on the other end of the shaft, to reduce the impact through its higher inertia.

The rotation of the flywheel can be written as:

$$\theta(t)=\frac{x_a(t)-x_b(t)}{\rho} \tag{5}$$

The displacements at the extremities of the inerter element are expressed by x_a and x_b. The dynamic moment equilibrium about the point *O* can be represented by:

$$I_O\theta(t)=F(t)\rho \tag{6}$$

Thus, the moment of inertia of the flywheel rotating about point *O* will be $I_O=(1/2).m.R^2$
Substitution of Eq. (5) and Eq. (6) results in the mechanical linear equation of the inerter

$$F(t)=\frac{1}{2}m\frac{R^2}{\rho^2}\left[\ddot{x}_a(t)-\ddot{x}_b(t)\right] \tag{7}$$

It can be seen from Eq. (7) that the force generated by the inerter is related to the relative acceleration between it extremities. The term multiplied by the relative acceleration is denoted as the inertance b of the device, and is expressed in unit of mass (kg). The inertance of the

device can be enhanced by serially increasing the number of pinions. Hence, the general equation of inerter become

$$F(t) = b\left[\ddot{x}_a(t) - \ddot{x}_b(t)\right] \tag{8}$$

For instance, if a single pinion inerter can produce an inertance of 1440 kg for a device that weights 10 kg [15].

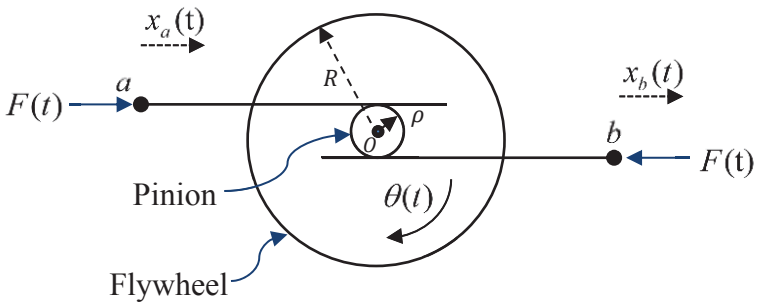

Figure 2. Rheological model of a single flywheel inerter [8].

2.2 Device tuning approach

In order to ensure a maximum efficiency, the DTMDI control strategy formulated in this paper needs a proper tuning, this involves the choice of a proper frequency, stiffness, damping and mass ratio. Hence, a tuning approach proposed by Marian and Giaralis [15] is adopted in this study.

Following the formulation originally proposed by Den Hartog [11] for a classical TMD, Marian and Giaralis [15] proposed an equivalent tuning for TMDI systems. Consider the class of dynamically excited structures amenable to be modelled as single-degree-of-freedom (SDOF) systems equipped with a tuned mass damper inerter as shown in figure 3.

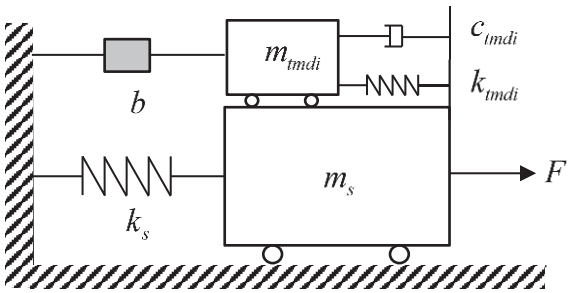

Figure 3. Primary SDOF structure equipped with a TMDI subjected to force excitations

The motion equation of the represented system is figure 3 is given as follow:

$$\begin{bmatrix} m_s & 0 \\ 0 & m_{tmdi}+b \end{bmatrix}\begin{Bmatrix} \ddot{x}_s \\ \ddot{x}_{tmdi} \end{Bmatrix} + \begin{bmatrix} c_{tmdi} & -c_{tmdi} \\ -c_{tmdi} & c_{tmdi} \end{bmatrix}\begin{Bmatrix} \dot{x}_s \\ \dot{x}_{tmdi} \end{Bmatrix} + \begin{bmatrix} k_s + k_{tmdi} & -k_{tmdi} \\ -k_{tmdi} & k_{tmdi} \end{bmatrix}\begin{Bmatrix} x_s \\ x_{tmdi} \end{Bmatrix} = -\begin{Bmatrix} m_s \\ m_{tmdi} \end{Bmatrix} F(t) \tag{9}$$

Equation (9) is elaborated and derived in close form, out of this procedure a TMDI tuning is obtained representing optimal frequency ratio υ_{tmdi} and damping ratio ζ_{tmdi} given in Eq. 10 and 11 respectively.

$$\upsilon_{tmdi} = \frac{1}{1+\beta+\mu} \tag{10}$$

$$\zeta_{tmdi} = \sqrt{\frac{3(\mu+\beta)}{8(1+\mu+\beta)}} \tag{11}$$

Where: β is the inertance ratio defined by $\beta = \frac{b}{m_s}$.

μ: is the TMDI mass ratio, it can be written as $\mu = \frac{m_{tmdi}}{m_s}$, m_{tmdi} and m_s are the masses of the TMDI and the primary structure, respectively.

Regarding the DTMDI tuning, the 2nd mass connected to the inerter can be considered as a floor mass or any other structural part of the structure, hence there will be no difference in the tuning of a classical TMDI or a DTMDI using the approach proposed above. Which will be used during this study.

3 NUMERICAL STUDY AND RESULTS

In order to study the performance of the proposed system four structural configurations are submitted to a set of earthquakes as shown in table 1, the structural configurations can be listed as follow:

- Uncontrolled structure, the structure without any device,
- Structure with a tuned mass damper (TMD) at the top floor,
- Structure with a tuned mass damper Inerter (TMDI) at the top floor, the 2nd extremity of the inerter is fixed to the last floor,
- Structure with a double tuned mass damper inerter (DTMDI) at the top floor (as shown in figure 1).

The mass ratios of the three control devices (*i.e.* TMD, TMDI and DTMDI) are kept equal in order to keep the control devices performance comparable.

The performances of the DTMDI are compared to a classical TMD and a conventional TMDI. In order to achieve the comparison, the structure is submitted to a set of earthquakes.

The structure used in study was presented by Özsarıyıldız and Bozer [16]

N°	Name	Record serial number (RSN)	Component	Fault type	PGA (m/s^2)
1	Northridge	1048	180	Near	4.50
2	Duzce	1605	270	Near	5.05
3	Landers	848	CLW-LN	Far	3.09
4	Kobe	1111	000	Far	4.74

Table 1. Earthquake records used in this study

3.1 Inertance effect on response reduction

In this part the effect of the inertance (ratio of fictive mass to total mass of the structure) is studied for both TMDI and DTMDI. Hence, the inertance will be varied from 0 to 0.1. It is worth noticing that a null inertance is equivalent to a classical TMD. The mass ratio (ratio of the real mass to total mass of the structure) μ is equal to 5% for both TMDI and DTMDI. However, for the DTMDI it will be equally partitioned between the two masses.

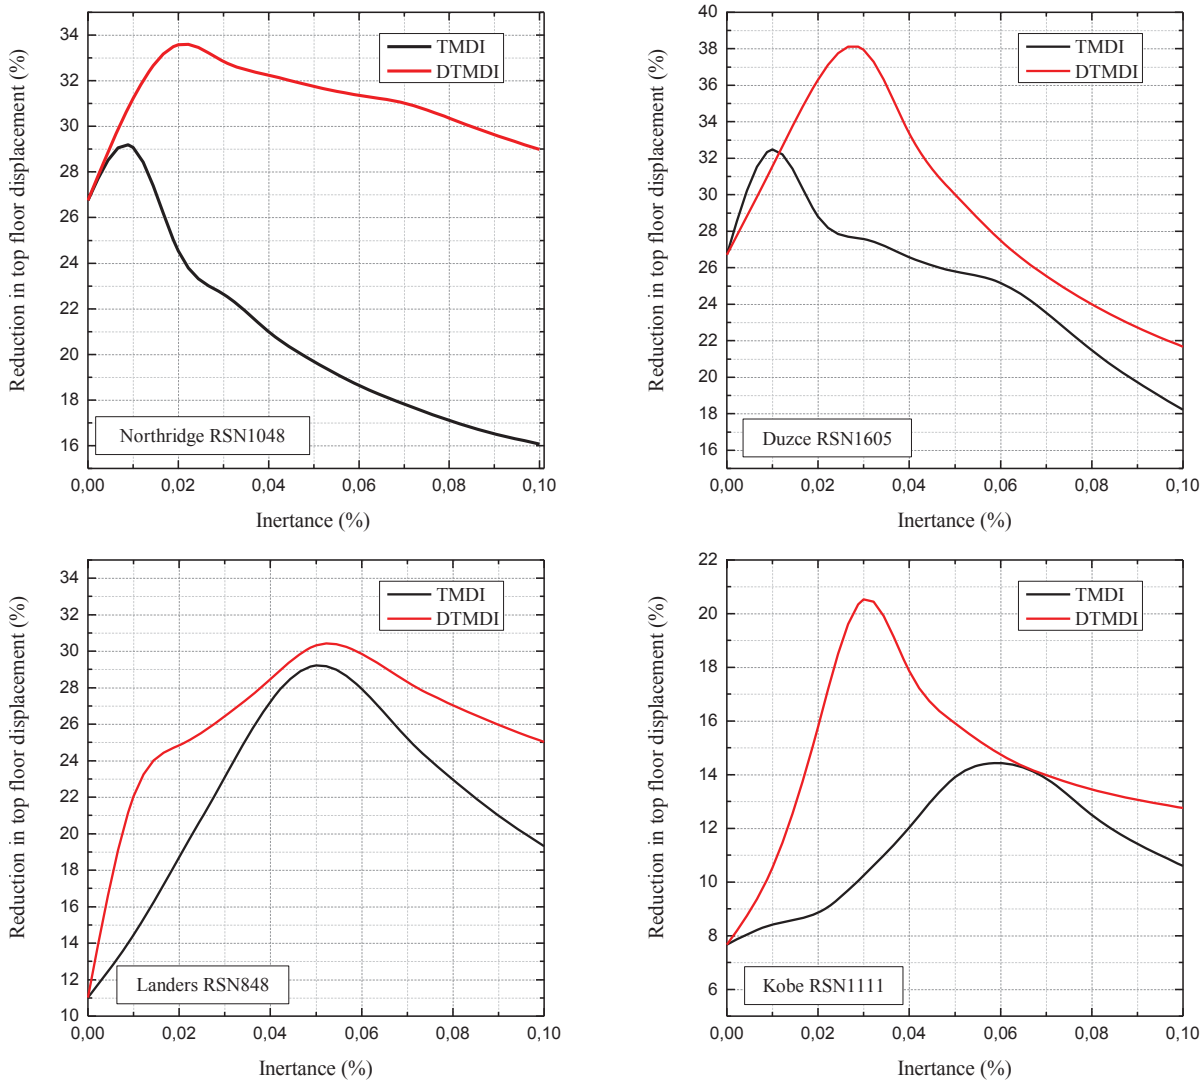

Figure 4. The inertance (β) effect on top floor displacement for both TMDI and DTMDI

From figure 4 it can be clearly seen that the inertance has an important and considerable effect on the response reduction for both TMDI and DTMDI. However, higher inertance involves less response reduction for TMDI; this is mainly due to retro-action force of the inerter being returned to the structure (i.e. the second extremity of the inerter is fixed to the last floor in this case). On the other hand, higher inertance results in more response reduction for the DTMDI, this is mainly motivated by the fact that the retro-action of the inerter is returned to the second mass of the DTMDI. It is also observed that for each earthquake there exists an optimal inertance value for both TMDI and DTMDI. In overall, the performance of DTMDI surpasses the performance of TMDI for the studied earthquakes.

With this in background, an average optimal inertance is defined for both TMDI and DTMDI. The inertance will be set to 1% and 3% of the total mass of the building for both the TMDI and the DTMDI, respectively

3.2 Time history analysis

In order to assess the performances of the proposed DTMDI a time history analysis is performed, for top floor displacement using three control strategies namely, TMD, TMDI and DTMDI, results obtained are shown in figure 5.

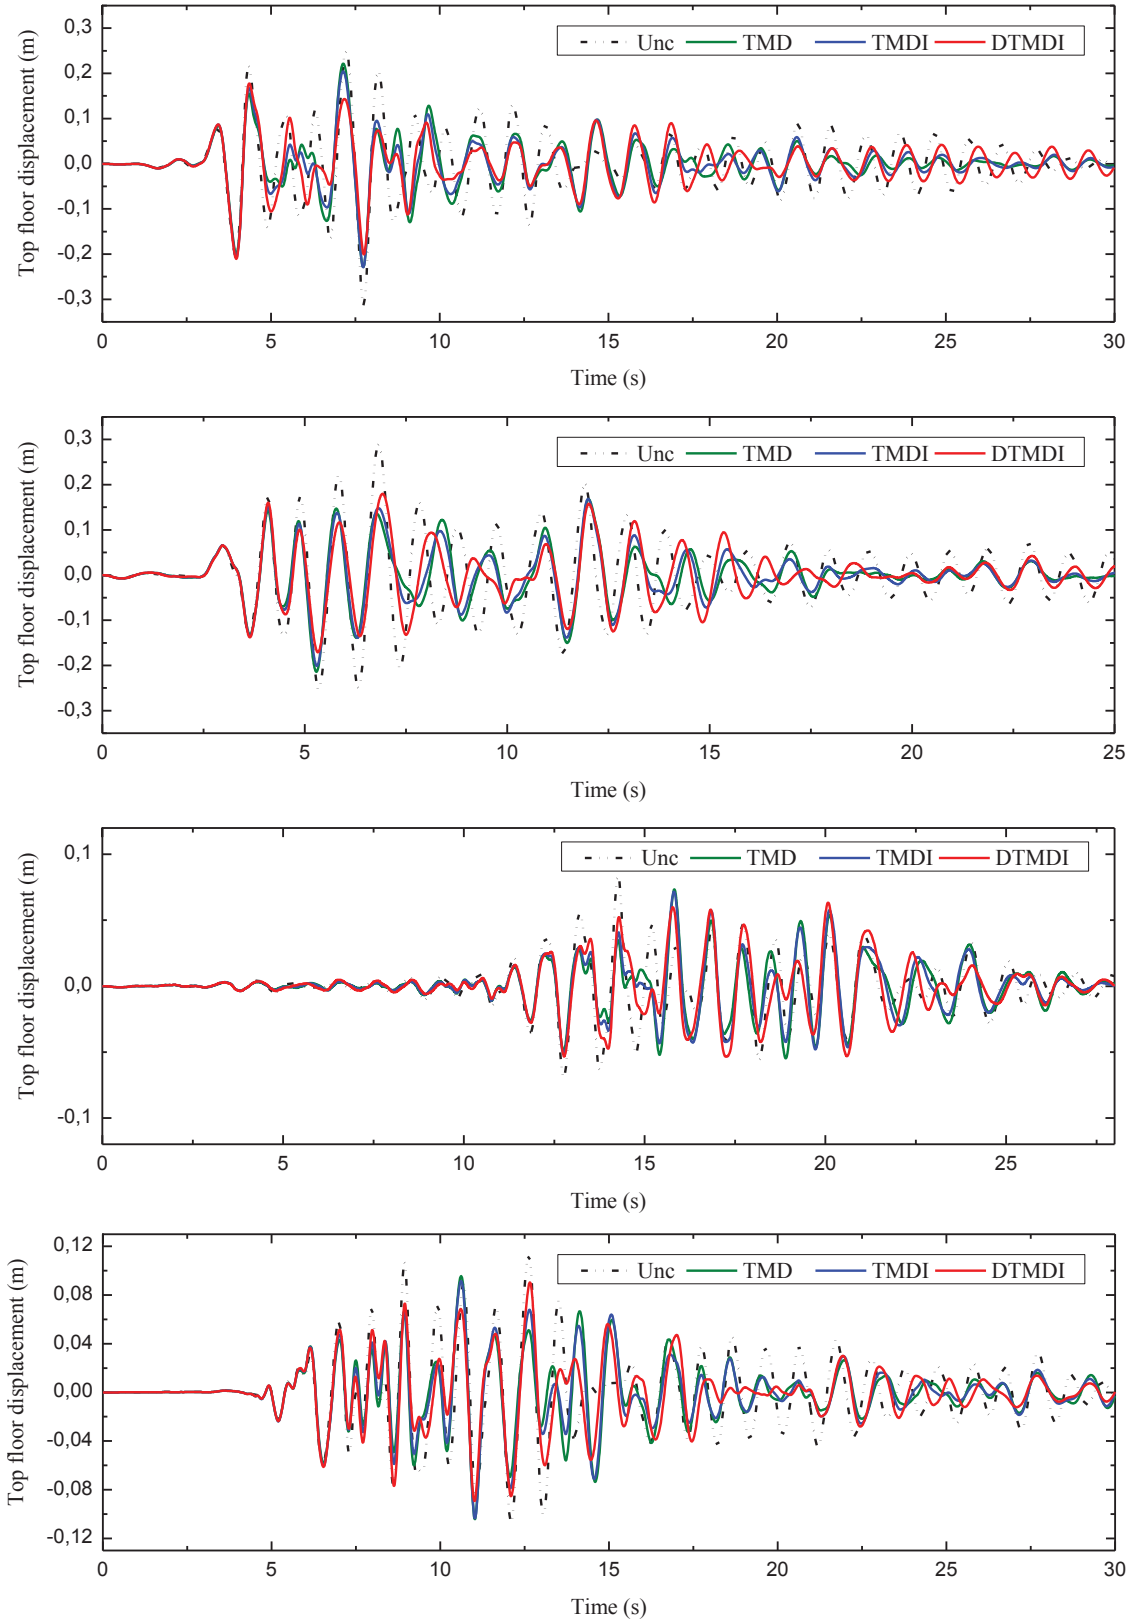

Figure 5. Time history analysis of top floor displacement under three control strategies

As it can be seen from figure 5 the performance of DTMDI is better than both TMDI and TMD, the reduction is clearly visible in peak displacement. The response reduction is achieved for all studied earthquakes. Table 2 shows the top floor maximum displacement for all control devices and also the percentage reduction in brackets.

Earthquake	Uncontrolled	TMD	TMDI	DTMDI
Northridge	0.3131	0.2288	0.2294	0.2106
(RSN1048)	--	(26.95)	(26.75)	(32.73)
Duzce	0.2888	0.2142	0.2010	0.1798
(RSN1605)	--	(25.83)	(30.40)	(37.72)
Landers	0.0837	0.0734	0.0716	0.0634
(RSN848)	--	(12.32)	(14.43)	(24.26)
Kobe	0.1132	0.1042	0.1037	0.0904
(RSN1111)	--	(07.93)	(08.40)	(20.09)

Table 2. Top floor displacement in *[m]* and percentage reduction in (%) under different control strategies

From table 2 it can be seen that performance of TMD and TMDI remain close in terms of top maximum floor displacement reduction. On the other hand, the DTMDI surpasses both the devices in terms of maximum top floor reduction using the same mass ratio μ (which is equal to 5% of the total mass of the structure). The percentage reduction varies from 20 to 32% depending on the earthquake. It is worth noticing that for far-fault earthquake less reduction is obtained due to the small displacements of the building.

3.3 Stroke displacement

One of the performance indexes of the tuned mass damper in the stroke displacement of the damper mass. Hence, in this part of the paper the stroke displacement of the three studied systems will be compared.

Earthquake	TMD	TMDI	DTMDI		
			Mass 1	Mass 2	Sum
Northridge (RSN1048)	0.6252	0.4665	0.4223	0.2357	0.6580
Duzce (RSN1605)	0.5284	0.4476	0.4352	0.3259	0.7611
Landers (RSN848)	0.1381	0.1238	0.1394	0.1516	0.2910
Kobe (RSN1111)	0.2087	0.1992	0.2053	0.1211	0.3264

Table 3. Stroke displacement in *[m]* under different control devices

From table 3 it can be seen that the TMDI achieved the lesser stroke displacement compared to the other devices this is mainly due to the inerter configuration connecting the TMDI mass to the last floor of the structure. Hence limiting the mass displacements. The performance of each mass of the DTMDI remains comparable the TMDI. However, if summed up the total displacement remains high and comparable to a classical TMD. This is directly related to the configuration of the DTMDI device. These large displacements may be reduced by adding a low damping and stiffness devices to the right side of the 2nd mass of the DTMDI.

3.4 Inertance effect on control the control force

In this part the inertance effect on the control force generated by the inerter is examined, for this purpose the inertance β is varied from 0 to 10 percent and the control force generated by the inerter is evaluated for both the TMDI and DTMDI. This can be achieved by multiplying the relative acceleration between the two extremities of the inerter by the inerter parameter b .

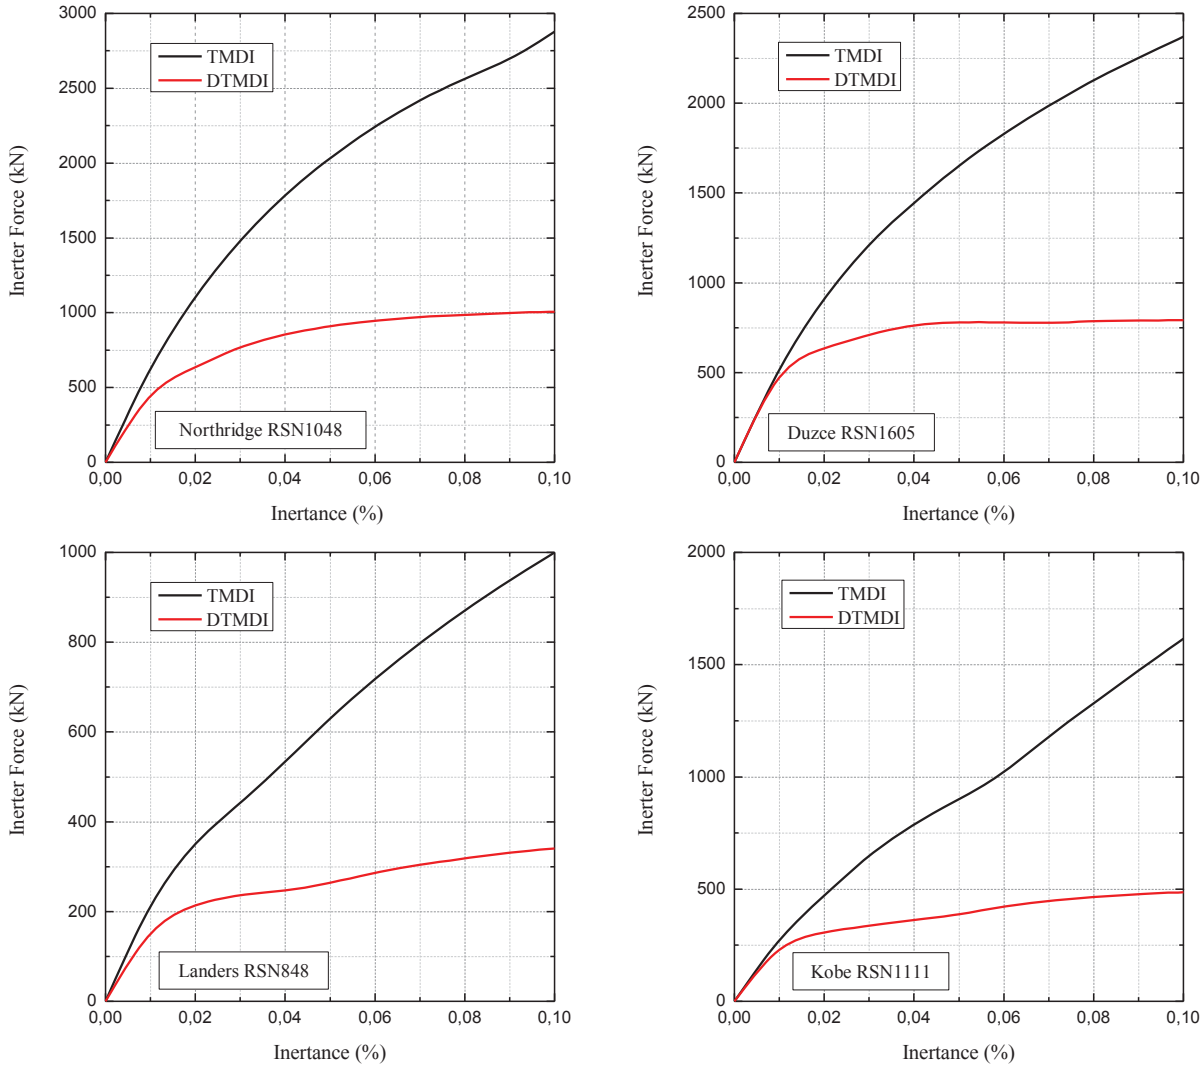

Figure 6. The inertance (β) effect on the inerter force

In figure 6, it can be seen that the inerter force is relative to the inertance. Hence, increasing the inertance results in the augmentation of the inerter force generated. This can be observed for all the studied earthquakes for both TMDI and DTMDI. The force generated by the classical TMDI increases at a higher rate inducing large force to the floor to which the inerter is connected which affects it efficiency at higher inertance values as shown in figure 4. Regarding the DTMDI the curve tends to saturate at high values of inertance, the force generated by the inerter is lower than the classical TMDI case involving less force applied to the secondary mass. It is worth noticing that the DTMDI results in better reduction with less generated force. It can be observed that the force generated by the inerter is relative to the earthquake PGA and fault type.

4 CONCLUSIONS

In this work, a new configuration for tuned mass damper inerter was proposed, the configuration is based on the use of a second mass. This mass will be coupled to the conventional TMDI through an inerter. This disposition will result in a so called double tuned mass damper inerter DTDMI, this later will enhance the performance of the structure by reducing it response to earthquakes compared TMD and TMDI. The main advantage of this configuration is the suppression of the inerter force returned to the structure. Based on the obtained results the following conclusions can be draw:

- Using a second mass connected to a TMDI by an inerter will prevent the application of the inerter retro-action force to the structure. Hence the performance of the DTMDI will reduce the response of the structure to dynamical loading such as earthquakes.
- There exists an optimal inertance parameter for both TMDI and DTMDI for each earthquake. However, the TMDI performs better at low values of inertance while the DTMDI requires higher inertance values to accomplish optimal reduction.
- The response reduction is obtained under four different earthquakes with different fault types.
- The DTMDI performances surpasses both TMD and TMDI despite using the same total mass ratio μ
- The stroke displacement of the TMDI mass is the lesser compared to classical TMD and DTMDI. However, the performance of the DTMDI regarding stroke displacement remains acceptable and comparable to a classical TMD.
- The large stroke displacement of the DTMDI can be limited by adding additional damping and stiffness to the right side of the 2nd mass of the system.
- The DTMDI achieves better reduction with less inerter force generated compared to the TMDI.

Keywords: Viscoelasticity, Memory effects, Optimal control, Feedback control, Fractional derivatives, Integral-differential equations

Abstract. *Viscoelastic materials have excellent properties of absorbing vibrational energy which makes their use very attractive in structural, aerospace and biomechanics engineering applications. The macroscopic dynamical behaviour of such materials depends on the time history, or memory, of the strain. The stress-strain viscoelastic relation can be described by a convolution integral with a memory kernel, according to Boltzmann's formulation of hereditary elasticity, or by using Caputo or Riemann-Liouville fractional derivatives. In order to emphasize the vibrations damping attitude of these materials, by actively controlling their stress-strain behaviour, novel optimal control logics are required which involve memory effects. This paper deals with a feedback control strategy applied to a structural-dynamic problem described by integral-differential equations. It is shown how to obtain a feedback control, called $PD^{(N)}$, i.e. Proportional-Nth-order-Derivatives control, by using a variational approach. Numerical simulations show how the $PD^{(N)}$ controller is an effective tool to improve the viscoelastic materials performance.*

1 INTRODUCTION

The use of viscoelastic materials is crucially important in many engineering disciplines and there are applications in a wide variety of areas such as aerospace, transport components, biomechanics and civil infrastructures [1-5]. These materials have excellent properties of absorbing vibrational energy which makes their use in engineering applications very attractive, such as the dynamic instabilities and the fluid-structures interaction control.

Often, the macroscopic dynamical behaviour of such materials depends on the time history or memory effects, of the strain response. According to Boltzmann's formulation of hereditary elasticity [6], the stress-strain relation in linear viscoelasticity can be described by a convolution integral with a memory kernel. However, the mathematical form of this kernel is not easily predictable by theoretical tools, but it rather relies on experimental identification.

In the past, combinations of elemental rheological components such as the spring and dashpot, were used to generate a whole family of rheological models, such as Maxwell and Kelvin–Voigt, or the four-parameters Burger's model, generalizing the viscoelastic response, but without including memory effects [7]. Moreover, experimental tests have shown some inconsistencies of viscoelastic materials, especially when the effects of relaxation and creep would be kept into the model [8]. For these reasons in the second part of the last century, many researches have been carried out a more realistic description of creep and/or relaxation given by the use of power law functions with real order exponent [9]. Such formulation captures the creep behaviour and generates the fractional hereditary model. In fact, the constitutive law of viscoelastic materials makes use of the Riemann-Liouville and Caputo's fractional derivative [10, 11]. Due to the high mathematical complexity of such models, which imply integral-differential equations (IDEs), difficulties arise in the formulation of optimal control algorithm.

In recent years the interest in model-based control of mechanical systems incorporating active controlled viscoelastic dampers has been increased in order to improve the mechanical system efficiency. Systems with viscoelastic dampers has been investigated by [12] where the viscoelastic term is approximated by damping terms which are converted into stochastic differential equations solved by a dynamic programming method; meanwhile multi-input and multi-output mechanical systems incorporating viscoelastic dampers are controlled with discrete-time sliding mode control algorithm [13]. Fractal-fractional model are used by [14] where the nonlinear algebraic system is solving by the Gauss-Legendre quadrature rule. Moreover, active control for standard Kelvin-Maxwell viscoelastic structures can be designed accurately with poles and zeros assignment defining an ad-hoc receptance transfer function [15]. Numerical scheme for solving fractional differential equations are proposed by [16] using the approximation of Laguerre integral formula.

In general, the optimal control strategies, applied to viscoelastic model, make use of direct methods. This paper introduces an indirect optimal feedback control algorithm, which is still missing in the literature panorama. Starting from the prototype integral-differential beam equation, the authors show how it is possible to obtain a Proportional-Nth-order-Derivatives control, called PD(N), by using the variational approach. PD(N) algorithm depends on the structure of the kernel and is a sort of hyper-derivative proportional control. The PD(N) control belongs to the category of Variational Feedback Controls-VFC, in the context of which the authors are developing different control architectures [17-19].

The paper consists of three main sections. The first presents the viscoelastic mathematical beam model, using the Caputo's fractional derivatives. The PD(N) feedback optimal control algorithm is derived in the second section, and in the third, numerical results show the effective performance of the proposed control for a bridge deflection control when it is subject to earth-

quake excitation and impulsive disturbances, still maintaining low the cost function in comparison with the LQR method and the implicit Pontryagin solution for IDEs already formulated by authors [20-22].

2 VISCOELASTIC BEAM MODEL

A brief description of the viscoelasticity fractional Kelvin–Voigt model is the premise to obtain the partial differential equations (PDE) of an Euler–Bernoulli viscoelastic beam, of length *L* and subjected to a basement seismic motion z_b (see Figure 1).

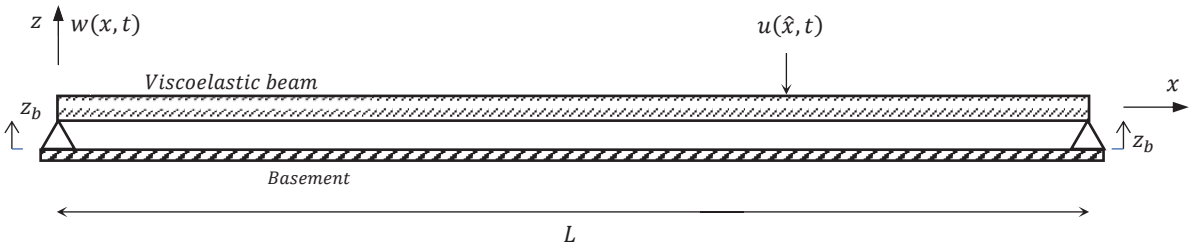

Figure 1: Viscoelastic beam.

The classical Kelvin–Voigt model, using one spring and one viscous pot in parallel, presents a time-varying linear stress-strain relationship $\sigma(\varepsilon)$ which can be expressed by the Caputo's fractional derivative D^{β}:

$$\sigma = E\varepsilon + E_{\beta} D^{\beta}[\varepsilon] \tag{1}$$

with E the Young's modulus, E_{β} the damping modulus and the time varying operator $D^{\beta}[\ \ ]$, with $0 \leqslant \beta \leqslant 1$ depending on material proprieties, defined as:

$$D^{\beta}[\varepsilon] = \frac{1}{\Gamma(1-\beta)} \int_0^t \frac{\dot{\varepsilon}(\tau)}{(t-\tau)^{\beta}} d\tau \tag{2}$$

with $\Gamma(\cdot)$ the Gamma function.

Considering constant ρ density, *A* cross-section area and *I* inertial moment the PDE is derived by defining the conservation of momentum and of moment of momentum:

$$\begin{aligned} \frac{\partial T_z(x,t)}{\partial x} &= \rho A \frac{\partial^2 w_b(x,t)}{\partial t^2} - u(\hat{x},t) - \rho A \ddot{z}_b(t) \\ \frac{\partial M_y(x,t)}{\partial x} &= T_z(x,t) \end{aligned} \tag{3}$$

where $w_b(x,t)$, $T_z(x,t)$, $M_y(x,t)$ and $u(\hat{x},t)$ are the vertical displacement along the z-axis, the shear, the bending moment and the punctual actuation acting on $\hat{x}$, respectively.

The introduction of the kinematic Euler-Bernoulli and the σ stress and bending moment M_y relations

$$\begin{aligned} \varepsilon(x,t) &= -z \frac{\partial^2 w_b(x,t)}{\partial x^2} \\ \sigma(x,t) &= z \frac{M_y(x,t)}{I} \end{aligned} \tag{4}$$

leads to the definition of the viscoelastic beam equation as formulated by [23]:

$$\rho A \frac{\partial^2 w_b(x,t)}{\partial t^2} + EI \frac{\partial^4 w_b(x,t)}{\partial x^4} + E_{\beta} I D^{\beta} \left[\frac{\partial^4 w_b(x,t)}{\partial x^4} \right] = u(\hat{x},t) + \rho A \ddot{z}_b(t) \tag{5}$$

Finally, equation (5) can be expressed in a compact form with the convolution integral term $k * \dot{w}_b^{IV}$ instead of the fractional operator $E_{\beta} D^{\beta}[w_b^{IV}]$ as formulated by Nutting [24]. By using

the derivative convolution properties and considering the supported beam case, the final equation with the associated boundary conditions is:

$$\begin{gathered}\rho A\ddot{w}_b(x,t) + EIw_b^{IV}(x,t) + I\dot{k} * w_b^{IV}(x,t) = \delta(x-\hat{x}\,)u(t) + \rho A\ddot{z}_b(t) \\ w_b''|_0^L = 0 \\ w_b|_0^L = 0\end{gathered} \tag{6}$$

where $\delta(\quad)$ is the Dirac function. In the case of translational base motion, the final transverse displacement w is given by the summation of two contributions:

$$w(x,t) = w_b(x,t) + z_b(t) \tag{7}$$

Decoupling equation (6) by the modal decomposition:

$$w_b(x,t) = \sum_r^{\infty} q_r(t)\phi_r(x) \tag{8}$$

with ϕ_r the eigenfunction of the r-*th* vibration mode, one obtains:

$$\rho A\phi_r\ddot{q}_r + EI{\phi_r}^{IV}q_r + I{\phi_r}^{IV}\,\dot{k} * q_r = \delta(x-\hat{x}\,)u(t) + \rho A\ddot{z}_b(t) \tag{9}$$

With the following normalization:

$$\begin{gathered}\int_0^L \phi_m\rho A\phi_r = \delta_{mr} \quad , \qquad \int_0^L \phi_m EI\phi_r^{IV} = \omega_r^2\delta_{mr} \quad , \quad \widehat{\omega}_r^2 = \frac{\omega_r^2}{E} \\ \gamma_r = \int_0^L \phi_r\,\rho A\end{gathered} \tag{10}$$

equation (9) becomes:

$$\ddot{q}_r + \omega_r^2 q_r + \widehat{\omega}_r^2\,\dot{k} * q_r = \phi_r(\hat{x})u(t) + \gamma_r\ddot{z}_b(t) \tag{11}$$

Finally, equation (11) is a second order integral-differential equation which represents the decoupled dynamic of the controlled viscoelastic Euler-Bernoulli beam when an external basement disturbance is acting on it. In the following section, is investigated a novel optimal control approach to equation (11).

3 THE VISCOELASTIC OPTIMAL CONTROL

For equation (11), it is possible to introduce an optimal feedback control law by using the variational calculus. The control solution is a sort of hyper-derivative proportional control called Proportional-Nth-order-Derivatives, i.e. PD$^{(N)}$ controller, depending on the structure of the kernel [25]. Introducing the new state variable $\boldsymbol{x} = [\boldsymbol{q}, \dot{\boldsymbol{q}}]^T$ and $\boldsymbol{q} = [q_1, \dots, q_r, \dots q_N]^T$ equation (11) takes the space state form:

$$\dot{\boldsymbol{x}} = \boldsymbol{A}\boldsymbol{x} + \boldsymbol{K} * \boldsymbol{x} + \boldsymbol{B}\boldsymbol{u} + \boldsymbol{d} \tag{12}$$

where $\boldsymbol{A} \in \mathbb{R}^{N,N}$ and $\boldsymbol{B} \in \mathbb{R}^{N,1}$ are constant matrixes, $\boldsymbol{u}$ in this example is a scalar control variable, $\boldsymbol{d} \in \mathbb{R}^{N,1}$ the external disturbances vector and $\boldsymbol{K} \in \mathbb{R}^{N,N}$ include the Caputo's fractional derivative.

The optimal control law is based on the minimization of a generic quadratic cost function J which depends on the state and the control variables together with the Lagrange multiplier vector $\boldsymbol{\lambda}$, introduced to account for the system's dynamics expressed by equation (12):

$$J(\boldsymbol{x},\boldsymbol{u},\boldsymbol{\lambda}) = \int_0^T \frac{1}{2}\boldsymbol{x}^T\boldsymbol{Q}\boldsymbol{x} + \frac{1}{2}\boldsymbol{u}^T\boldsymbol{R}\boldsymbol{u} + \boldsymbol{\lambda}^T[\dot{\boldsymbol{x}} - \boldsymbol{A}\boldsymbol{x} - \boldsymbol{K} * \boldsymbol{x} - \boldsymbol{B}\boldsymbol{u} - \boldsymbol{d}]dt \tag{13}$$

The variational calculus finds a solution to the stated problem by using the stationary condition $\delta J(\boldsymbol{x},\boldsymbol{u},\boldsymbol{\lambda}) = 0$. The variations of the term $\boldsymbol{K} * \boldsymbol{x}$ present some nontrivial problems, and a technique to deal with this term is considered in details in [21, 25]. Considering a scalar term

$k * x$, the kernel causality proprieties $k(t-\tau) = 0$ for $t < 0$ and $\tau > t$, produces its variation in the form:

$$\delta \int_0^T x(t) \int_0^t k(t-\tau)x(\tau)d\tau\, dt = \int_0^T \int_t^T k(\tau - t)x(\tau)d\tau\, \delta f dt = \int_0^T k \diamond x\, \delta x\, dt \tag{14}$$

Proceeding with standard variational calculus rules, and using equation (14), the associated extremal conditions are found:

$$\begin{aligned} &\dot{\boldsymbol{\lambda}} = \boldsymbol{Q}\boldsymbol{x} - \boldsymbol{A}^T\boldsymbol{\lambda} - \boldsymbol{K}^T \diamond \boldsymbol{\lambda} \\ &\dot{\boldsymbol{x}} = \boldsymbol{A}\boldsymbol{x} + \boldsymbol{B}\boldsymbol{u} + \boldsymbol{K} * \boldsymbol{x} + \boldsymbol{d} \\ &\boldsymbol{u} = \boldsymbol{R}^{-1}\boldsymbol{B}^T\boldsymbol{\lambda} \\ &\boldsymbol{\lambda}(T) = \boldsymbol{0}\,, \boldsymbol{x}(0) = \boldsymbol{x_0} \end{aligned} \tag{15}$$

Eq. (15) gives the optimal open loop solution to problem (13) and it can be solved with several direct control methods [26]. However, our goal is to obtain an explicit feedback formulation of the control $\boldsymbol{u}(\boldsymbol{x})$, that has tremendous advantages under the engineering application point of view. To this aim, we replace the fractional operator (2) by its approximation by a truncated exponential series. Therefore, the Nutting's kernel $k(t)$ in (11), can be reformulated as:

$$k * x = \frac{E_\beta}{\Gamma(1-\beta)} \int_0^t \frac{x(\tau)}{(t-\tau)^\beta} d\tau \approx \frac{E_\beta}{\Gamma(1-\beta)} \int_0^t \sum_i^N \alpha_i e^{-c_i(t-\tau)} x(\tau) d\tau = \hat{k} * x \tag{16}$$

where α_i and c_i are the N-constants of the exponential series approximation and $\hat{k}$ is introduced to indicate the approximated kernel. In this way, eq. (16) leads to transform the integral-differential equations (15) into the Laplace domain. In fact, both the terms, $\hat{k} * x$ and $\hat{k} \diamond x$ have the corresponding Laplace transform $\mathcal{L}\{\quad\}$ in s as sum of polynomials:

$$\begin{aligned} \mathcal{L}\{\hat{k} * x\} &= X(s) \sum \frac{\alpha_i}{s + c_i} = X(s) \frac{P(N-1)(s)}{D(N)(s)} \\ \mathcal{L}\{\hat{k} \diamond x\} &= X(s) \sum \frac{\alpha_i}{s - c_i} = -X(s) \frac{P(N-1)(-s)}{D(N)(-s)} \end{aligned} \tag{17}$$

where P and D are used to indicate the N-order polynomials.

Then, using the equations (16) and (17) to express the integral terms in the first two of equations (15), setting $\boldsymbol{d} = \boldsymbol{0}$ and eliminating the control $\boldsymbol{u}$ in the equation $\dot{\boldsymbol{x}} = \boldsymbol{A}\boldsymbol{x} + \boldsymbol{B}\boldsymbol{u} + \boldsymbol{K} * \boldsymbol{x}$, using $\dot{\boldsymbol{x}} = \boldsymbol{A}\boldsymbol{x} + \boldsymbol{B}\boldsymbol{R}^{-1}\boldsymbol{B}^T\boldsymbol{\lambda} + \boldsymbol{K} * \boldsymbol{x}$, we can produce the Laplace transform of the obtained equations in terms of $\boldsymbol{X}(s)$ and $\boldsymbol{\Lambda}(s)$ only. Rearranging these equations, and transforming back to time domain, we finally obtain:

$$\begin{aligned} &\sum_{i=0}^{N+1} \boldsymbol{C}_i \boldsymbol{x}^{(i)} + \sum_{i=0}^{N} \boldsymbol{D}_i \boldsymbol{\lambda}^{(i)} = \boldsymbol{0} \\ &\sum_{i=0}^{N+1} \boldsymbol{F}_i \boldsymbol{\lambda}^{(i)} + \sum_{i=0}^{N} \boldsymbol{E}_i \boldsymbol{x}^{(i)} = \boldsymbol{0} \end{aligned} \tag{18}$$

where $\boldsymbol{x}^{(i)} = \frac{d^i \boldsymbol{x}}{dt^i}$, and the problem is reduced to a pure differential equation set, linear and time-invariant. Collecting the variables into $\boldsymbol{\xi} = \left[\boldsymbol{x}^{(N)} \ldots \boldsymbol{x}^{(i)} \ldots \boldsymbol{x}\right]$ and $\boldsymbol{\eta} = \left[\boldsymbol{\lambda}^{(N)} \ldots \boldsymbol{\lambda}^{(i)} \ldots \boldsymbol{\lambda}\right]$, equations (18) can be reduced to a first order normal form differential problem:

$$\begin{cases} \dot{\boldsymbol{\xi}} = \boldsymbol{H}_{\xi\xi}\boldsymbol{\xi} + \boldsymbol{H}_{\xi\eta}\boldsymbol{\eta} \\ \dot{\boldsymbol{\eta}} = \boldsymbol{H}_{\eta\xi}\boldsymbol{\xi} + \boldsymbol{H}_{\eta\eta}\boldsymbol{\eta} \end{cases} \tag{19}$$

Equation (19) is characterized by the matrix $\boldsymbol{H} = [\boldsymbol{H}_{\xi\xi}, \boldsymbol{H}_{\xi\eta}; \boldsymbol{H}_{\eta\xi}, \boldsymbol{H}_{\eta\eta}] \in \mathbb{R}^{2N,2N}$ that is not in general of Hamiltonian type. For this reason, it is not possible to solve the optimal problem by satisfying the Riccati's stationary equation, but a direct solution through the *2N*-eigenvalues and *2N*-eigenvectors is used. By assuring at least *N* negative real part eigenvalues of matrix $\boldsymbol{H}$, one obtains:

$$\begin{aligned} &\boldsymbol{\eta} = \boldsymbol{G}\boldsymbol{\xi} \qquad with \qquad \boldsymbol{G} = \boldsymbol{\Theta}\boldsymbol{\Psi}^{-1} \in \mathbb{R}^{N,N} \\ &\boldsymbol{\Psi} = [\boldsymbol{\psi}_1, \dots, \boldsymbol{\psi}_N] \\ &\boldsymbol{\Theta} = [\boldsymbol{\theta}_1, \dots, \boldsymbol{\theta}_N] \end{aligned} \tag{20}$$

where $\boldsymbol{\psi}_i$ and $\boldsymbol{\theta}_i$ are half of the *2N* eigenvectors of $\boldsymbol{H}$, those associated to negative real part eigenvalues. Finally, since $= \boldsymbol{R}^{-1}\boldsymbol{B}^T\boldsymbol{\lambda}$, extracting from $\boldsymbol{\eta}$ the last sub-vector $\boldsymbol{\eta}_N = \boldsymbol{\lambda}$, the optimal feedback control variable $\boldsymbol{u}$ is:

$$\boldsymbol{u} = \boldsymbol{R}^{-1}\boldsymbol{B}^T \sum_{i=1}^{N+1} \boldsymbol{G}_{ji}\, \boldsymbol{x}^{(i-1)} = \boldsymbol{K}_{\boldsymbol{pdn}}\boldsymbol{\xi} \tag{21}$$

The structure of the solution (21) shows that the optimal control of an integral-differential system is strongly related to the structure of the kernel $\hat{k}(t)$ and contains a combination of state derivatives of order equal to the number of exponential terms of $\hat{k}(t)$. For this reason, (21) is called hyper-derivative proportional control, PD(N). The (21) can also be expressed through a $\boldsymbol{K}_{\boldsymbol{pdn}}$ gain matrix multiplied by the vector $\boldsymbol{\xi}$. The initial state derivatives $\frac{d^i \boldsymbol{x}(0)}{dt^i} = \boldsymbol{x}_0^{(i)}$ for $i > 2$ can be evaluated from the Laplace transformation of (12) in the case of uncontrolled and undisturbed system and replacing the approximated $\hat{k}$ exponential kernel function.

4 NUMERICAL RESULTS

In the following section the numerical results are shown for the deflection control of a bridge when external excitations are acting on it. The bridge has been considered as a three-mode decomposition model. Two different simulations have been performed, considering an impulsive and an earthquake disturbance on the bridge basement. For both cases, we assume the actuator is placed at $\hat{x} = L/2 + 0.2L/4$ in order to control not only the first and third vibrational modes but also the 20% of the second mode. To measure the vibrations of the bridge, three sensors $s1$, $s2$, $s3$, for example accelerometers, have been placed on the structure at $x_{s1} = L/2$, $x_{s2} = L/4$ and $x_{s3} = L/3$, in such a way that it can be easily reconstruct the modal displacements $\boldsymbol{q}$. Table 1 shows the geometrical parameters describing the simulated bridge which has been chosen with a H-beam cross-section.

Description	Parameters	Value
Density [kg/m^3]	ρ	7500
Young modulus [N/m^2]	E	$200 \cdot 10^9$
Length [m]	L	24
Thickness [m]	b	0.18
Height [m]	h	0.4
Momentum of inertia [m^4]	I	$23130 \cdot 10^{-8}$
Cross-sectional area [m^2]	A	$84.46 \cdot 10^{-4}$

Table 1**:** H-beam parameters.

In Table 2 are listed the main dynamic parameters and control settings used to develop numerical simulations in which a kernel function composed by two exponential terms has been considered.

Description	Parameters	Value
Beam eigenfunctions in x_{s1}	$[\phi_1(L/2); \phi_2(L/2); \phi_3(L/2)]$	[0.036; 0; -0.0363]
Beam eigenfunctions in x_{s2}	$[\phi_1(L/4); \phi_2(L/4); \phi_3(L/4)]$	[0.0256; 0.0363; 0.0256]
Beam eigenfunctions in x_{s3}	$[\phi_1(L/3); \phi_2(L/3); \phi_3(L/3)]$	[0.0314; 0.0314; 0]
Beam eigenfunctions in $\hat{x}$	$[\phi_1(\hat{x}); \phi_2(\hat{x}); \phi_3(\hat{x})]$	[0.0358; -0.0112; -0.0323]
Natural frequencies [rad/s]	$[\omega_1; \omega_2; \omega_3]$	[14.6434; 58.6032; 131.8943]
Modal kernel frequencies	$[\widehat{\omega}_1; \widehat{\omega}_2; \widehat{\omega}_3]$	$[0.0327; 0.13; 0.29]\cdot 10^{-3}$
Kernel coefficients	$\left[\frac{\alpha_1 E_\beta}{\Gamma(1-\beta)}; c_1; \frac{\alpha_2 E_\beta}{\Gamma(1-\beta)}; c_2\right]$	$[8\cdot 10^{10}; 100; 2\cdot 10^{10}; 10]$
Control gain	$\mathbf{Q}$; $\mathbf{R}$	$\begin{bmatrix} 10 & 0 & 0 & 0 \\ 0 & 10 & 0 & 0 \\ 0 & 0 & 80 & 0 \\ 0 & 0 & 0 & 80 \end{bmatrix}$; 0.01
Control gain PDN	$\boldsymbol{K_{pdn}}$	$[-102.6;\ 63.7;\ 4.1; -3;\ 1.2; \ldots$ $-0.0117; -0.0833;\ 0.0009]$
Initial displacement [m]	$\boldsymbol{q_0}$	[0; 0; 0]
Initial velocity [m/s]	$\dot{\boldsymbol{q}}_{\boldsymbol{0}}$	[0.1; 0.1; 0.1]

Table 2: Parameters and control settings used for the simulations.

Regarding the first simulation, the impulsive basement disturbance is simulated by considering an initial condition on the modal velocity $\dot{\boldsymbol{q}}_{\boldsymbol{0}}$ different from zero taking into account the first three vibrational modes $r = 1,2,3$ of eq. (11). The performances of the PD(N) controller are compared with the Pontryagin implicit solution, recently proposed by the authors [20, 21], and the benchmarking LQR method by solving eq. (12) neglecting the convolution term.
From Figure 2 to Figure 6 the time evolution of the beam displacement $w(x,t)$, cost function J, power and force actuation, are shown respectively. The bridge deflection has been computed in two different positions x_{s1} and x_{s2} in order to be able to catch the contributions of all the three vibrational modes.

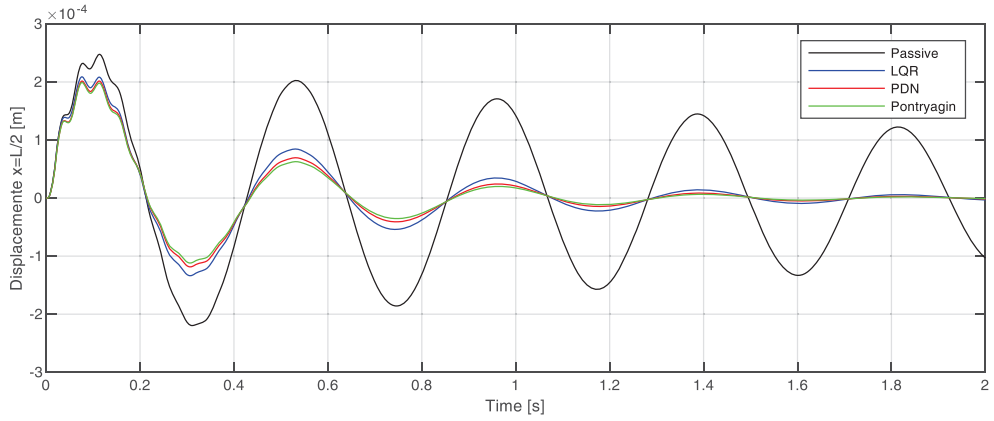

Figure 2: Beam vertical displacement at x_{s1} under impulsive load.

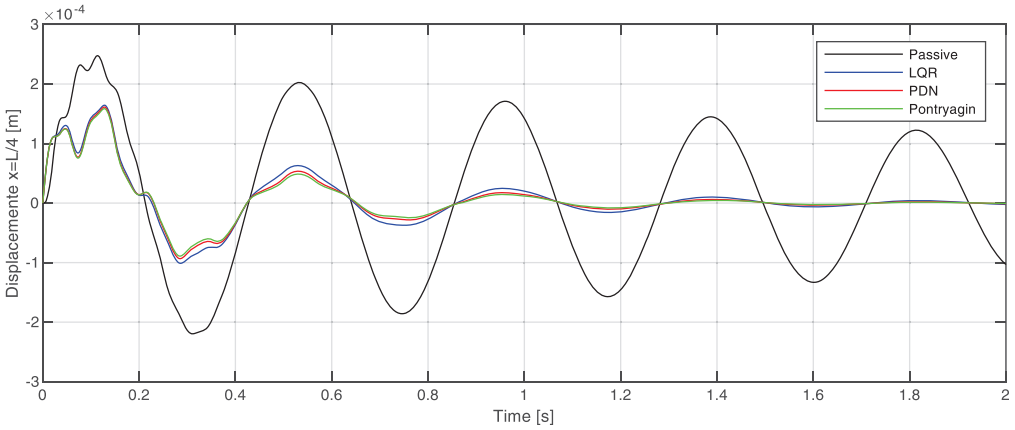

Figure 3: Beam vertical displacement at x_{s2} under impulsive load.

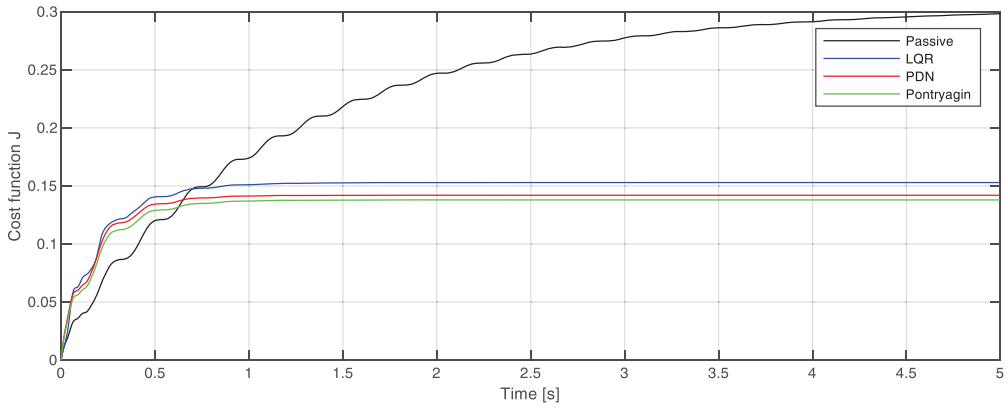

Figure 4: Comparisons of cost functions under impulsive load.

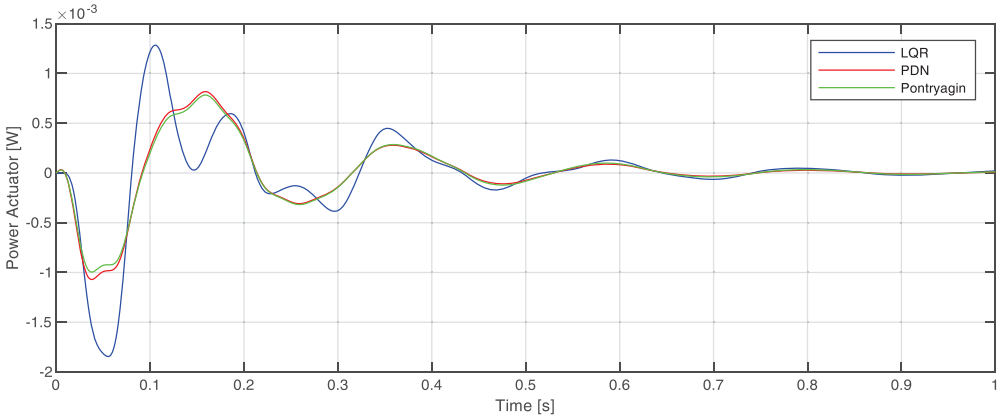

Figure 5: Comparisons of power actuation under impulsive load.

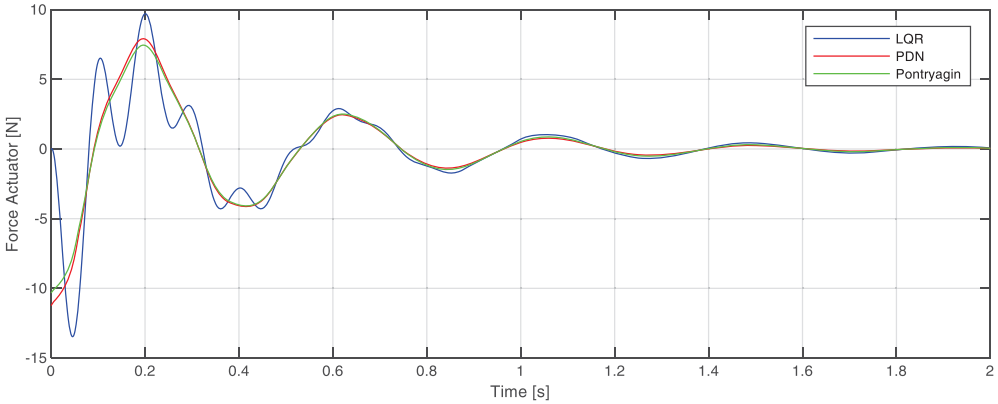

Figure 6: Comparisons of force actuation under impulsive load.

The numerical results show very good performances of the PD(N) algorithm in comparison with the standard LQR method in terms of vibrations minimization. In fact, the LQR, which cannot take into account the viscoelastic memory effects, shows higher values of the actuation force and power in comparison with the PD(N) controller. In fact, the PD(N) algorithm reach half of the actuation power and the 80% of the maximum force reached by LQR, respectively. Moreover, observing Figure 2 and Figure 3 the proposed controller presents lower beam deflection (higher in x_{s2}) and a lower cost function value (Figure 4), stretching its convenience in comparison to the LQR method. The PD(N) performance are at the same level of the Pontryagin implicit solution. Of course, the implicit solution, which is the best optimal solution, presents the lower values of cost function and arrival time.

In the second tested case, the bridge is excited by an earthquake disturb. The Class A earthquake load has been formulated by [27] according to the Eurocode 8 which introduce the possibility to use the stochastic analysis in the design of structures in seismic zone. Figure 7 and Figure 8 describe the earthquake disturbance in term of PSD and acceleration, respectively.

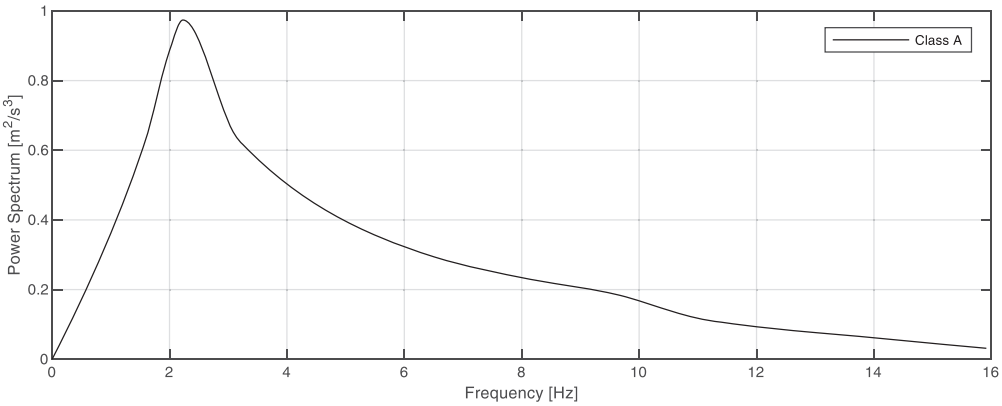

Figure 7: Earthquake PSD

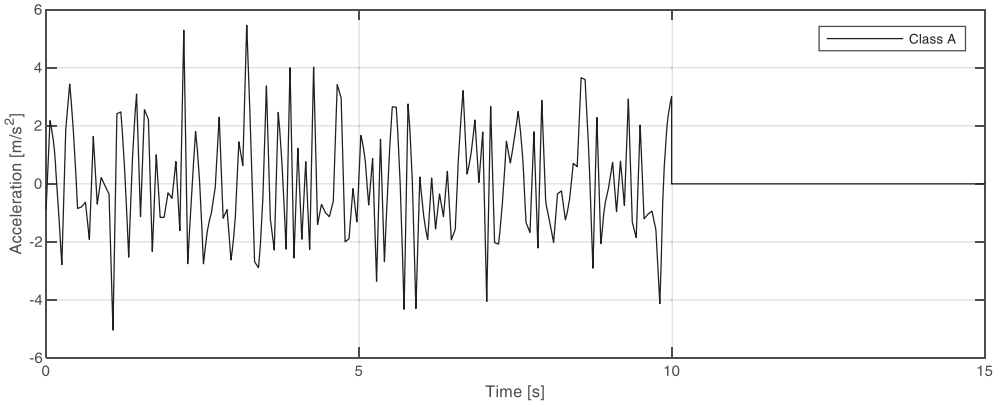

Figure 8: Earthquake acceleration

The class A earthquake PSD amplified the first vibrational mode of the bridge showing a maximum value corresponding to the bridge first natural frequency ($\sim 2Hz$) and on the contrary it does not excite the third mode, because is very far from the spectrum. Moreover, given the symmetry of the noise, even modes are not excited. For all these reasons, the results will be shown only for the position x_{s1}. The earthquake acceleration, $\ddot{z}_b(t)$, in Figure 8 has been generated from the PSD in Figure 7, acting for 10s and in the final 5s the bridge system is free to extinguish its residual vibrations.

In this simulation the performance of the proposed PD(N) controller are only compared with the benchmarking LQR method. In fact, the external disturbance considered in this case is stochastic one, which is impossible to predict and to include in the Pontryagin solution.

From Figure 9 to Figure 12 the time evolution of the bridge deflection in x_{s1}, the cost function J, the power and the force actuation, are illustrated respectively. It is possible to notice that, even when an external random disturbance is acting on the bridge, the proposed PD(N) controller presents better performance respect to the LQR method. The PD(N) algorithm shows a minimization of the bridge deflection requiring a lower force and power of actuation and for these reasons, it is also presenting a lower cost function J.

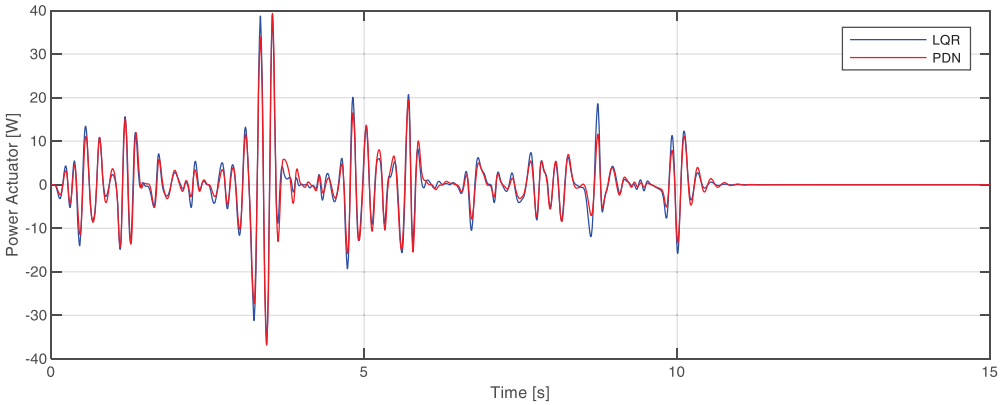

Figure 11: Comparisons of power under earthquake load.

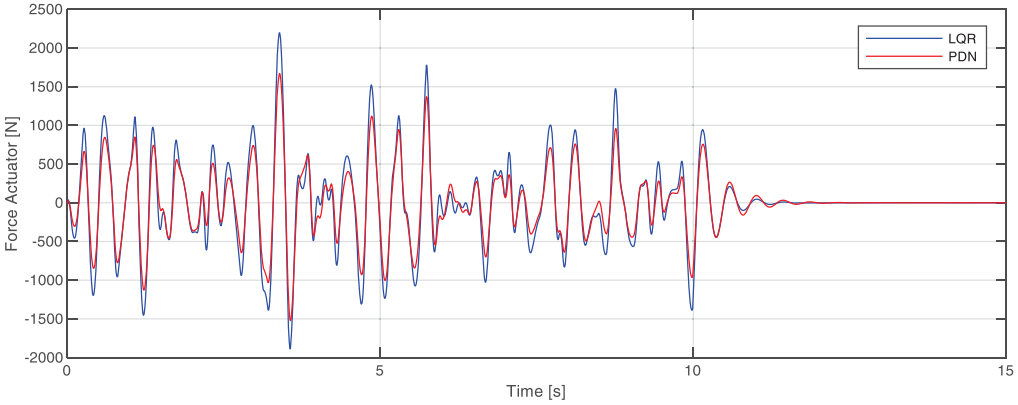

Figure 12: Comparisons of force actuation under earthquake load.

5 CONCLUSIONS

In this paper the authors propose an optimal control algorithm to actively control viscoelastic materials for the structural vibration's minimization.

The proposed algorithm applies to a viscoelastic Euler-Bernoulli beam including Boltzmann hereditary effects by using a Nutting's memory kernel function. The prototype equation is of integro-differential type and requires a non-conventional optimal control strategy, which considers convolution terms (memory effects). In general, the optimal control strategies, applied to

this viscoelastic model, make use of direct methods, while in this paper the authors offer an indirect optimal feedback control algorithm, which is still missing in the literature panorama. The authors show how it is possible to obtain a Proportional-Nth-order-Derivatives control, called PD(N), by using the variational approach. Numerical simulations show very good result of the PD(N) solution compared to the benchmarking LQR and the implicit Pontryagin solution for IDEs, already formulated by the authors in recent works.

Thanks to the hyper derivative properties, the PD(N) controller shows a capability of minimization of beam deflection, in term of force and power of actuation and cost both for different external disturbances acting on the model and also for multiple kernel function compared to the benchmarking optimal control algorithm.

Keywords: Soil-structure interaction, viscous damping, optimal dampers, sandy soil

Abstract. *When there is an optimal damper application issue, superstructure models are installed and strongly connected to the ground. However; there is no consideration of the ground influences. Within this current research, the influence of sandy soil relative density upon damper issues has been analysed. Assessment has been carried out upon the optimal distribution of viscous dampers along with the influence of sandy soil relative density on the structural dynamic response for the n-storey shear building model. The soil-structure model governing equation has also been derived and the Fourier Transformation is used to present the frequency domain equations. An optimized procedure, which is the Steepest Direction Search Algorithm (SDSA), is applied. Minimization of the objective function, which is the base moment behaviour of structure stated within the frequency domain, is done. The fundamental mode response of structural model has been considered and the El Centro (NS) earthquake ground acceleration record is used to conduct the time history analyses. Investigation has been carried out for the sandy soil relative density influence upon the optimal design of structure responses along with the total damper capacity variation influence applied within the optimization level. Since the optimal design alters due to the base moment, the sandy soil influences have been assessed thoroughly. As compared to no damper at all case, the damped system has taken place with low base moment. At a rigid level, the structural response is lower as compared to a different sandy soil relative density. The structural response is enhanced after dampers are added based on proposed objective function. Furthermore, the damaging influence created by the poor ground conditions has also been reduced.*

1 INTRODUCTION

Since the past few years, the conventional devices have been replaced with passive control devices to reduce vibration and dynamic influences. To attain efficient performance of damping, the regulations have been set to manage the structure design for earthquake resistance through various processes. Recently, many research studies have been carried out upon the tuning of mass dampers applied for the wind and seismic reactions soil-structure collaboration [1-4]. A two-phase soil model has been applied to assess the soil stiffness variations along with the monopile wind turbine foundations offshore damping that is affected by lateral dynamic loads [5]. Two kinds of polypod foundations, ground surface that includes two rigid footings and two flexible embedded piles, have been assessed through the dynamic structure–soil–structure interaction (SSSI) [6].

Civil engineering applications, aerospace, military and other fields make use of a recognized passive damper which is the fluid viscous damper. Building applications have also started making use of this device. Recently, due to globalization, there has been an enhancement in the damper construction and application, specifically for the earthquake-resistant construction design. Keeping these technological aspects in mind, the construction is being carried out within the elastic limits within the seismic and wind loads where they are able to captivate vigorous external consequences. Structural behaviours are enhanced through damping elements. Furthermore, various studies have tried to recognize the optimal damping element placements.

There are various research studies present in the literature upon the structure dynamic response and optimal damper design [7-16]. However, these do not take into account the soil influence. Usually, it is believed that a rigid structure is present within the ground. Hence, the soil influences must be observed to understand how earthquakes affect these structures. Recently, Aydin et al. [17] investigated comparison of optimal damper distributions in shear frames in terms of soil conditions.

The optimal passive structural control has been researched upon in a limited manner even though the literature stated soil structure interaction influences. The objective is upon the optimal control using the tuned mass damper [18-25]. Yet, there are some research studies upon structures that have viscoelastic dampers keeping in mind the soil-structure interaction influence [26, 27]. For the soil structure interaction model, there are research studies which include the tuned mass damper and the viscous damper [28].

Within this current research, the optimal placement of the viscous damper and the structural response would be analysed. This aspect has not been focused upon in earlier research studies. This is why the analysis would be carried out with the help of base moment transfer function as part of the soil structure interaction. For the modelling structural response, the soil influence is taken into account and the optimization procedure is used for the viscous damper placement where no soil influence is present [29]. Furthermore, the viscous damper optimal design for the sandy soil conditions (loose, medium dense and dense) would be analysed and comparison of the results would be made.

2 FORMULATION OF PROBLEM

Figure 1 indicates the model for soil structure interaction and *n*-storey shear building. Horizontal ground acceleration occurs within the system. The assumption present is that the generalized displacement vector is $\boldsymbol{u}$, the system mass matrix is $\boldsymbol{M}$, system stiffness matrix is $\boldsymbol{K}$, structural damping matrix is $\boldsymbol{C}$, and the influence vector is $\boldsymbol{r}$ which is defined as

$\boldsymbol{r} = \{0, \ldots, 0, 1, 0\}^{\mathrm{T}}$. Ground acceleration has been presented using $\ddot{u}_g$ parameter. There are known $\boldsymbol{M}$ and $\boldsymbol{K}$ matrix elements. The stiffness and structural damping matrices are proportional as $\boldsymbol{C} = \alpha \boldsymbol{M}$ where $\alpha = 2\zeta_1\omega_1$. There are known first damping ratio ζ_1 and undamped fundamental natural circular frequency ω_1.

The differential equation of motion within the context of time is presented as follows.

$$\boldsymbol{M}\ddot{\boldsymbol{u}} + \boldsymbol{C}\dot{\boldsymbol{u}} + \boldsymbol{K}\boldsymbol{u} = -\boldsymbol{M}\boldsymbol{r}\ddot{u}_g \tag{1}$$

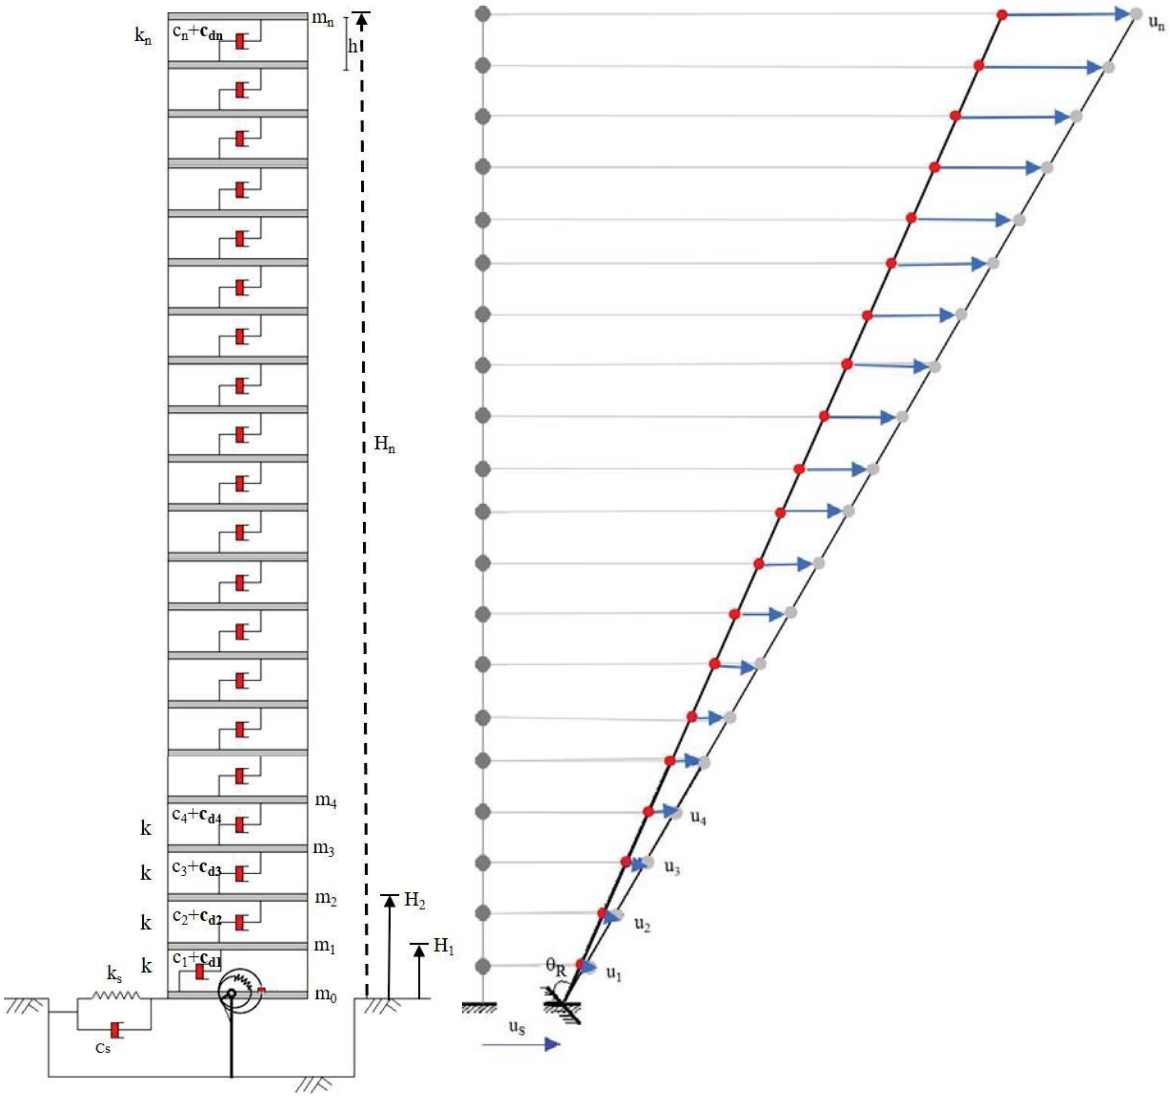

Figure 1: Shear-building soil-structure model and its deformation

The generalized displacements vector is the set $\mathbf{u} = \{u_1, \ldots..u_n\ u_S\ \theta_R\}^{\mathrm{T}}$ in which the u_S and θ_R parameters sway with rocking rotation and displacement. The rocking springs and swaying stiffness are indicated using k_S and k_R. The rocking and swaying dashpots damping coefficients are shown through c_S and c_R.

Hence, the system mass matrix is indicated as following.

$$\boldsymbol{M} = \begin{bmatrix} \boldsymbol{M_B} & \boldsymbol{M_{BS}} & \boldsymbol{M_{BR}} \\ & E_1 & E_2 \\ \text{Sym.} & & E_3 \end{bmatrix} \tag{2}$$

The soil-structure interaction system mass matrix is $\boldsymbol{M}$ and building mass matrix is $\boldsymbol{M_B}$. $\boldsymbol{M_B}$, $\boldsymbol{M_{BS}}$ and $\boldsymbol{M_{BR}}$ matrices are shown below.

$$\boldsymbol{M_B} = \begin{bmatrix} m_1 & 0 & 0 & 0 & 0 \\ 0 & m_2 & 0 & 0 & 0 \\ 0 & 0 & . & 0 & 0 \\ 0 & 0 & 0 & . & 0 \\ 0 & 0 & 0 & 0 & m_n \end{bmatrix} \quad \boldsymbol{M_{BS}} = \begin{bmatrix} m_1 \\ m_2 \\ . \\ . \\ m_n \end{bmatrix} \quad \boldsymbol{M_{BR}} = \begin{bmatrix} m_1 H_1 \\ m_2 H_2 \\ . \\ . \\ m_n H_n \end{bmatrix} \tag{3}$$

From the ground level, the i^{th} floor height is indicated using H_i $(i=1,\ldots,n)$. Considering Equation (2), E_1, E_2 and E_3 are calculated using:

$$E_1 = m_0 + m_1 + \cdots + m_n \tag{4}$$

$$E_2 = m_1 H_1 + m_2 H_2 + \cdots + m_n H_n \tag{5}$$

$$E_3 = m_1 H_1^2 + m_2 H_2^2 + \cdots + m_n H_n^2 + I_{R0} + I_{R1} + I_{R2} + \cdots + I_{Rn} \tag{6}$$

If Equations (3), (4), (5) and (6) are included in Equation (2), it would become Equation (7) as mentioned below.

$$\boldsymbol{M} = \begin{bmatrix} m_1 & 0 & 0 & 0 & 0 & m_1 & m_1 H_1 \\ 0 & m_2 & 0 & 0 & 0 & m_2 & m_2 H_2 \\ 0 & 0 & . & 0 & 0 & . & . \\ 0 & 0 & 0 & . & 0 & . & . \\ 0 & 0 & 0 & 0 & m_n & m_n & m_n H_n \\ m_1 & m_2 & . & . & m_n & \sum_{i=0}^{n} m_i & \sum_{i=1}^{n} m_i H_i \\ m_1 H_1 & m_2 H_2 & . & . & m_n H_n & \sum_{i=1}^{n} m_i H_i & \sum_{i=1}^{n} m_i H_i^2 + \sum_{i=0}^{n} I_{Ri} \end{bmatrix} \tag{7}$$

The following is the system stiffness matrix.

$$\boldsymbol{K} = \boldsymbol{K_B} + \boldsymbol{K_S} + \boldsymbol{K_R} \tag{8}$$

In which,

$$\boldsymbol{K_B} = \begin{bmatrix} k_1+k_2 & -k_2 & 0 & 0 & 0 & 0 & 0 \\ -k_2 & k_2+k_3 & . & 0 & 0 & 0 & 0 \\ 0 & . & . & . & 0 & 0 & 0 \\ 0 & 0 & . & . & -k_n & 0 & 0 \\ 0 & 0 & 0 & -k_n & k_n & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \tag{9}$$

$$\boldsymbol{K_S} = \begin{bmatrix} 0 & 0 & 0 & . & . & 0 & 0 \\ 0 & 0 & 0 & . & . & 0 & 0 \\ 0 & 0 & 0 & . & . & 0 & 0 \\ . & . & . & . & . & 0 & 0 \\ . & . & . & . & . & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & k_s & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \quad \boldsymbol{K_R} = \begin{bmatrix} 0 & 0 & 0 & . & . & 0 & 0 \\ 0 & 0 & 0 & . & . & 0 & 0 \\ 0 & 0 & 0 & . & . & 0 & 0 \\ . & . & . & . & . & 0 & 0 \\ . & . & . & . & . & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & k_R \end{bmatrix} \tag{10}$$

In this case, the total system stiffness matrix is denoted by $\boldsymbol{K}$, superstructure stiffness matrix by $\boldsymbol{K_B}$ and the stiffness matrices including only swaying (k_s) and rocking (k_R) springs are $\boldsymbol{K_S}$ and $\boldsymbol{K_R}$, respectively. The following are the system stiffness matrix and the ground stiffness parameters.

$$\boldsymbol{K} = \begin{bmatrix} k_1+k_2 & -k_2 & 0 & 0 & 0 & 0 & 0 \\ -k_2 & k_2+k_3 & . & 0 & 0 & 0 & 0 \\ 0 & . & . & . & 0 & 0 & 0 \\ 0 & 0 & . & . & -k_n & 0 & 0 \\ 0 & 0 & 0 & -k_n & k_n & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & k_s & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & k_R \end{bmatrix} \tag{11}$$

$$k_s = \frac{6.77}{(1.79-\mu)} Gr \qquad k_R = \frac{2.52}{(1-\mu)} Gr^3 \tag{12}$$

The soil shear modulus is denoted by G, Poisson's ratio through μ and equivalent circular footing plate radius through r. The structural and ground damping parameters are used for the description of the system damping matrix $\boldsymbol{C}$.

$$\boldsymbol{C} = \boldsymbol{C_B} + \boldsymbol{C_S} + \boldsymbol{C_R} \tag{13}$$

$$\boldsymbol{C} = \begin{bmatrix} c_1+c_2 & -c_2 & 0 & 0 & 0 & 0 & 0 \\ -c_2 & c_2+c_3 & . & 0 & 0 & 0 & 0 \\ 0 & . & . & . & 0 & 0 & 0 \\ 0 & 0 & . & . & -c_n & 0 & 0 \\ 0 & 0 & 0 & -c_n & c_n & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & c_s & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & c_R \end{bmatrix} \tag{14}$$

$$c_S = \frac{6.21}{(2.54-\mu)}\rho v_s r^2 \qquad c_R = \frac{0.136}{(1.13-\mu)}\rho v_s r^4 \tag{15}$$

In this case, the system damping matrix is $\boldsymbol{C}$, the structural damping matrix of superstructure is $\boldsymbol{C_B}$ and the ground linear damping matrices including only swaying (c_s) and rocking (c_R) damping coefficients are $\boldsymbol{C_R}$. The shear wave velocity is v_S and mass density of soil is ρ. Takewaki [30] has stated the mass construction, stiffness and damping matrices. The additional damper parameters are not integrated within matrix $\boldsymbol{C}$. If Equation (1) includes the Fourier Transform, then it would be converted to Equation (16).

$$(\boldsymbol{K} + i\omega\boldsymbol{C} - \omega^2\boldsymbol{M})\boldsymbol{U}(\omega) = -\boldsymbol{M}\boldsymbol{r}\ddot{U}_g(\omega) \tag{16}$$

The excitation circular frequency is denoted by ω, i, $\boldsymbol{U}(\omega)$, $\ddot{U}_g(\omega)$ and $\sqrt{-1}$, the Fourier Transform of $u(t)$ and $\ddot{u}_g(t)$. Equation (16) is written as follows, after the structure includes the dampers.

$$(\boldsymbol{K} + i\omega(\boldsymbol{C} + \boldsymbol{C_d}) - \omega^2\boldsymbol{M})\boldsymbol{U_d}(\omega) = -\boldsymbol{M}\boldsymbol{r}\ddot{U}_g(\omega) \tag{17}$$

The displacement vector Fourier Transform is $\boldsymbol{U_d}(\omega)$ and it includes the viscous dampers. The unknown damping matrix is $\boldsymbol{C_d}$ and it is associated with the added damper damping coefficient.

Hence, $\boldsymbol{C_d}$ is stated as:

$$\boldsymbol{C} = \begin{bmatrix} c_{d1}+c_{d2} & -c_{d2} & 0 & 0 & 0 & 0 & 0 \\ -c_{d2} & c_{d2}+c_{d3} & . & 0 & 0 & 0 & 0 \\ 0 & . & . & . & 0 & 0 & 0 \\ 0 & 0 & . & . & -c_{dn} & 0 & 0 \\ 0 & 0 & 0 & -c_{dn} & c_{dn} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \tag{18}$$

In Equation (19), it is stated as the new parameter.

$$\widehat{\boldsymbol{U}}(\omega) = \frac{\boldsymbol{U_d}(\omega)}{\ddot{U}_g(\omega)} \tag{19}$$

Hence, Equation (17) is written as:

$$\mathbf{A}\widehat{\boldsymbol{U}} = -\boldsymbol{M}\boldsymbol{r} \tag{20}$$

In this case, the displacement transfer function vector is $\widehat{\boldsymbol{U}}$ along with the $\boldsymbol{A}$ matrix and is stated as:

$$\mathbf{A} = (\boldsymbol{K} + i\omega(\boldsymbol{C} + \boldsymbol{C_d}) - \omega^2\boldsymbol{M}) \tag{21}$$

There exists prescription of $\boldsymbol{K}$, $\boldsymbol{M}$ and $\boldsymbol{C}$.

If subtraction is made from Equation (20) for the displacement vector associated with the transfer function, then it would be stated as.

$$\widehat{\boldsymbol{U}} = -\mathbf{A}^{-1}\boldsymbol{Mr} \tag{22}$$

Matrix $\boldsymbol{A}$ represents the unknown c_{di} damping parameters. The $\widehat{\boldsymbol{U}}$ vector includes the top displacement transfer function value. Takewaki [29] includes the governing equations and is applied within the planar building frame which does not have soil influences. Aydin et al. [11] has helped to derive the elastic forces transfer function. Equation (22) includes the displacement transfer vector which would be multiplied by stiffness matrix to attain the elastic forces transfer function vector.

$$\boldsymbol{F} = -\boldsymbol{KA}^{-1}\boldsymbol{Mr} \tag{23}$$

3 OPTIMAL DAMPER PROBLEM

The optimal damper issues can be resolved using the various objective functions. Hence, the several objective functions hold importance in terms of the various kinds of structures. Within the current research, the objective function is the base moment transfer function amplitude that includes the rocking displacement, forces and swaying.

The following is the objective function within the context of the transfer function amplitude for the elastic base moment.

$$f = |M_B| \qquad \text{(Min)} \tag{24}$$

The base moment transfer function amplitude is the following.

$$|M_B| = |F_1| * h_1 + |F_2| * h_2 + \cdots + |F_n| * h_n + |M_R| \tag{25}$$

For the i^{th} storey elastic shear force, the transfer function amplitude is denoted as $|F_i|$ which has been assessed as the undamped fundamental natural frequency. The rocking spring moment transfer function amplitude is $|M_R|$ and the height of the i^{th} storey is h_i (i=1,…,n) as per the base.

The following are the active and passive constraints performed at the sum of the damping coefficients of the added dampers.

$$\sum_{j=1}^{n} c_{dj} = W \tag{26}$$

$$0 \le c_{dj} \le \bar{c}_d \qquad (j = 1,...,n) \tag{27}$$

In this case, the damping coefficients sum for the added dampers (total damper capacity) is W. For each damper, the damping coefficient upper bound is $\bar{c}_d$. The Lagrangian L within the context of objective functions and constraints is indicated by:

$$L(c_d, \lambda, \alpha, \beta) = f + \lambda\left(\sum_{j=1}^{n} c_{dj} - W\right) + \sum_{j=1}^{n} \alpha_j\left(0 - c_{dj}\right) + \sum_{j=1}^{n} \beta_j\left(c_{dj} - \bar{c}_d\right) \tag{28}$$

In this case, the Lagrange Multipliers are λ, $\boldsymbol{\alpha} = \{\alpha_j\}$ and $\boldsymbol{\beta} = \{\beta_j\}$; the objective function is f . For objective function minimization, without the damping coefficient upper and lower bound constraints, the Lagrangian L ($\boldsymbol{\alpha} = 0$, $\boldsymbol{\beta} = 0$) derivatives would be considered within the context of c_{dj} and λ. Then, the following would be Equations (29) and (30).

$$f_{,j} + \lambda = 0 \quad (j = 1,...,n) \qquad 0 < c_{dj} < \bar{c}_d \tag{29}$$

$$\sum_{j=1}^{n} c_{dj} - W = 0 \tag{30}$$

The objective function partial differentiation is denoted by $f_{,j}$ keeping in mind the design variable c_{dj}. It is necessary to make sure that there are no negative damping coefficients for the additional dampers. A physical importance does not hold that there are negative damping coefficients. If there are active damping coefficient upper and lower bound constraints, then modification of Equation (29) occurs as follows.

$$f_{,j} + \lambda \geq 0 \qquad c_{dj} = 0 \tag{31}$$

$$f_{,j} + \lambda \leq 0 \qquad c_{dj} = \bar{c}_d \tag{32}$$

With the help of the Steepest Direction Search Algorithm (SDSA), the optimality criteria have been extracted and the nonlinear Equations (29-32) have been solved [29].

4 DERIVATION OF SENSITIVITIES AND SOLUTION ALGORITHM

Derivation of the first order sensitivities of transfer function vector of displacements [29] and elastic forces [11] are mentioned.

$$\widehat{\boldsymbol{U}}_{,j} = -\boldsymbol{A}^{-1}\boldsymbol{A}_j\widehat{\boldsymbol{U}} \tag{33}$$

$$\boldsymbol{F}_{,j} = -\boldsymbol{K}\boldsymbol{A}^{-1}\boldsymbol{A}_j\widehat{\boldsymbol{U}} \tag{34}$$

Equation (23) quantities of F_i are stated as

$$F_i = Re[F_i] + Im[F_i] \tag{35}$$

The transfer function values are F_i with i^{th} storey elastic forces within a complex form. The quantities of first order sensitivities of F_i are stated as:

$$F_{i,j} = Re\left[F_{i,j}\right] + Im\left[F_{i,j}\right] \tag{36}$$

The absolute value of F_i is stated as:

$$|F_i| = \sqrt{(Re[F_i])^2 + (Im[F_i])^2} \tag{37}$$

The transfer function amplitude first order sensitivity of the absolute value for the i^{th} elastic force is extracted, if the $|F_i|$ are differentiated with respect to the j^{th} damping coefficient c_j.

$$|F_i|_{,j} = \frac{1}{|F_i|}\left\{Re[F_i]\left(Re\left[F_{i,j}\right]\right) + Im[F_i]\left(Im\left[F_{i,j}\right]\right)\right\} \tag{38}$$

The transfer function amplitude for the first order derivative of the base moment is stated as the transfer function sensitivities sum for the story shear forces multiplied with the storey height from the base and rocking moment.

$$|M_B|_{,j} = \sum_{i=1}^{n} |F_i|_{,j} * h_i + M_{R,j} \tag{39}$$

The equation for partial differentiations of Equation (38) within the context of other design parameter c_l

$$|F_i|_{,jl} = \frac{1}{|F_i|^2}\left(|F_i|\left\{Re\left[F_{i,l}\right]Re\left[F_{i,j}\right] + Re[F_i]Re\left[F_{i,jl}\right] + Im\left[F_{i,l}\right]Im\left[F_{i,j}\right] + Im[F_i]Im\left[F_{i,jl}\right]\right\} - |F_i|_{,l}\left\{Re[F_i]Re\left[F_{i,j}\right] + Im[F_i]Im\left[F_{i,j}\right]\right\}\right. \tag{40}$$

With the help of Equation (41), it has been possible to calculate $Re\left[F_{i,jl}\right]$ and $Im\left[F_{i,jl}\right]$ in Equation (40), and this is the second derivative of $\boldsymbol{F}$. For elastic forces, the equations have been integrated with the storey forces by Aydin et al. [11] within Equation (34). The following equation is present for the differentiation of Equation (34) with respect to c_l

$$\boldsymbol{F}_{,jl} = \boldsymbol{K}(\boldsymbol{A}^{-1}\boldsymbol{A}_{,l}\boldsymbol{A}^{-1}\boldsymbol{A}_{,j}\hat{\boldsymbol{U}} - \boldsymbol{A}^{-1}\boldsymbol{A}_{,j}\hat{\boldsymbol{U}}_{,l}) \tag{41}$$

The second order sensitivities of base shear and base moment objective functions have been stated in the form of second derivatives of the transfer function of the storey shear forces in the following manner.

$$|M_B|_{,jl} = \sum_{i=1}^{n} |F_i|_{,jl} h_i + |M_R|_{,jl} \tag{42}$$

There is satisfaction of the constraint $\sum_{i=1}^{n} \Delta c_{di} = \Delta W$ for each design step [29]. Reduction in objective function and direction updates based on index k is observed. Takewaki [29] brought forward this algorithm. Keeping in mind the new objective functions presented in [11] and [13], the algorithm was modified. Within this damper optimization algorithm, the location of additional dampers can be attained through first order sensitivities. Within step 4, if index k is available, and it is corresponding to the design variable, then ΔW and the dampers current damping coefficient is added. Within the next step, there should be an update of the first order sensitivity through the use of second order sensitivity coefficients. If various indices are available $k_1 \ldots k_m$ as stated within the flowchart, there should be a distribution of ΔW within the structure. To satisfy the mentioned formula, it is necessary to attain the ratio within the magnitudes of $\overline{\Delta c_{dk}}$ (k=1,…m).

$$f_{,k1} + \sum_{i=k_1}^{k_m} f_{,k_1 i}\,\overline{\Delta c}_{di} = f_{,k_m} + \sum_{i=k_1}^{k_m} f_{,k_m i}\,\overline{\Delta c}_{di} \tag{43}$$

In Equation (43), the ratio presented within the magnitudes of $\overline{\Delta c_{dk}}$ along with the constraint $\sum_{i=1}^{n} \Delta c_{di} = \Delta W$ helps to attain the value of $\overline{\Delta c_{dk}}$. If various indices are present, $k_1 \ldots k_m$, update should be carried out for the objective function along with the first derivative.

$$f \rightarrow f + \sum_{i=k_1}^{k_m} f_{,i}\, \Delta c_{di} \tag{44}$$

$$f_{,i} \rightarrow f_{,i} + \sum_{i=k_1}^{k_m} f_{,il}\, \Delta c_{dl} \tag{45}$$

5 NUMERICAL EXAMPLE

As an example, a building model with 20 stories would be used. A 20 story structure is observed in Figure 1. For each floor, the masses (m) and mass moment of inertia (I_R) are m_i=30x10^3 kg and I_{Ri}=1.6x10^5 kg.m^2 (i=1,..,20) , respectively. For the ground floor, it is m_0=90x10^3 kg (masses) and I_{R0}=4.8x10^5 kg.m^2 (mass moment of inertia) [30]. Height (h) for each storey is 3.0 m. The structure-ground interaction horizontal motion and angular motion stiffness coefficients (k_S, k_R) and damping coefficients (c_S, c_R) would be extracted using Equations (12) and (15) which have been presented [31]. The uniform selection of structural damping is 2% and story stiffness is 2.5x10^7 N/m. The equivalent circular footing plate radius is 4m and is denoted as r. The total damper capacity (W) of 1x10^7 Ns/m has been taken into account to analyse the damping optimization issue within the context of various sandy soil relative densities. These capacities are within the ranges mentioned in literature [14]. There are three kinds of soil conditions taken into account. Table 1 shows the soil properties that are used for analysis.

Table 1: Soil properties used in analyses [32-34]

Soil type	v_s (m/s)	μ	G (MPa)		ρ (kg/m^3)
			Static	Dynamic	
Loose sand	150	0.25	8	33	1450
Medium dense sand	300	0.30	15	151	1650
Dense sand	550	0.35	24	570	1850

The optimal damper algorithm, mentioned earlier, has been applied to extract the optimal placement of the damper within the soil-structure interaction model. For the analysis, one kind of damper capacity is applied. At the time of optimization, the objective function (f) within the context of step number in case of W=1x10^7 Ns/m and ground conditions (three kinds of soil conditions and rigid case) have been analysed and Figure 2 mentions the variations. The transfer function amplitude is negatively influenced when there are poor soil conditions. There is a general trend for the soil conditions to alter the transfer function amplitude from loose towards medium dense and then dense sand to rigid eventually. As compared to other soil conditions, the loose sand condition has a stronger influence. The dense and medium dense sands maintain similar transfer function amplitudes that are also close to the rigid case. Therefore, when dampers are added at an optimum level to a structure with poor ground condition, the structure behaviour would be close to that of the rigid ground condition. In this

case, when there is an increase in step number, there will be a decrease in the transfer function amplitude, and there is lowest level of response for the rigid case as expected.

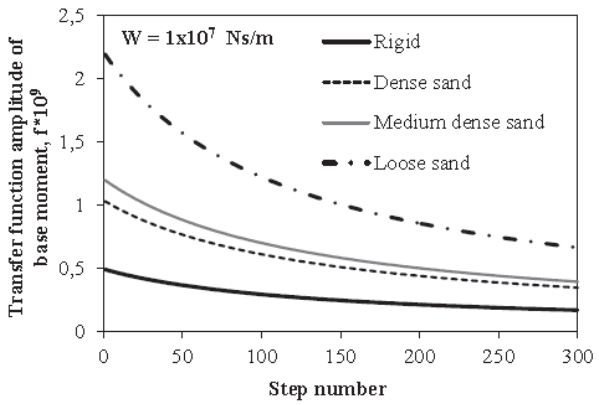

Figure 2: The variations of objective function in terms of ground conditions

Table 2 shows the optimum damper designs that have been extracted using the earlier mentioned optimization method. The objective function found for the optimum design at base moment is also mentioned in Table 2. Force-based designs are extracted through procedures where the base moment is used as the objective function. The table also indicates that the poorness in the ground causes a little change in the floors where the dampers are placed.

Table 2: Optimal damper designs for base shear and base moment

	Optimal Damper Coefficient (Ns/m)*10^6								
Soil Type	c_1	c_2	c_3	c_4	c_5	c_6	c_7	c_8	c_9 - c_{20}
Rigid	2.2	2.1	1.8	1.5	1.1	0.7	0.4	0.1	-
Dense Sand	2.5	2.3	2.0	1.6	1.0	0.5	0.1	-	-
Medium Dense Sand	2.5	2.4	2.0	1.6	1.0	0.4	1.0	-	-
Loose Sand	2.8	2.6	2.2	1.5	0.7	0.2	-	-	-

Additionally, the base moment objective function (f_j) sensitivities within the context of damping coefficients for additional dampers have been assessed for the various sandy soil conditions. Figure 3 indicates the sensitivity of objective function (f_j) variations within the context of step number stated for the objective function and four soil conditions. The objective function first order derivation is denoted by f_j within the context of j^{th} storey damper. In all cases, convergence has taken place. When the negative region is taken into account for their sensitivity values, the objective function first order derivatives indicates the design direction at the initiation of the algorithm. Since the initial stages, derivatives at each step are compared and checking is done for the maximum derivative value. The gradient based procedure is observed and procedure details have already been mentioned. The sensitivity values enhance when soil conditions are subjected to variations from rigid to loose sand case (Figure 3). The total damper capacity is taken as W=1x10^7 Ns/m and comparison is made for rigid and loose sandy ground condition. There is difference in the sensitivity of the numerical values but there is similarity in the design step trends. It is essential to indicate the sensitivity

presentation where the optimal design issue is integrated within the gradient based procedures.

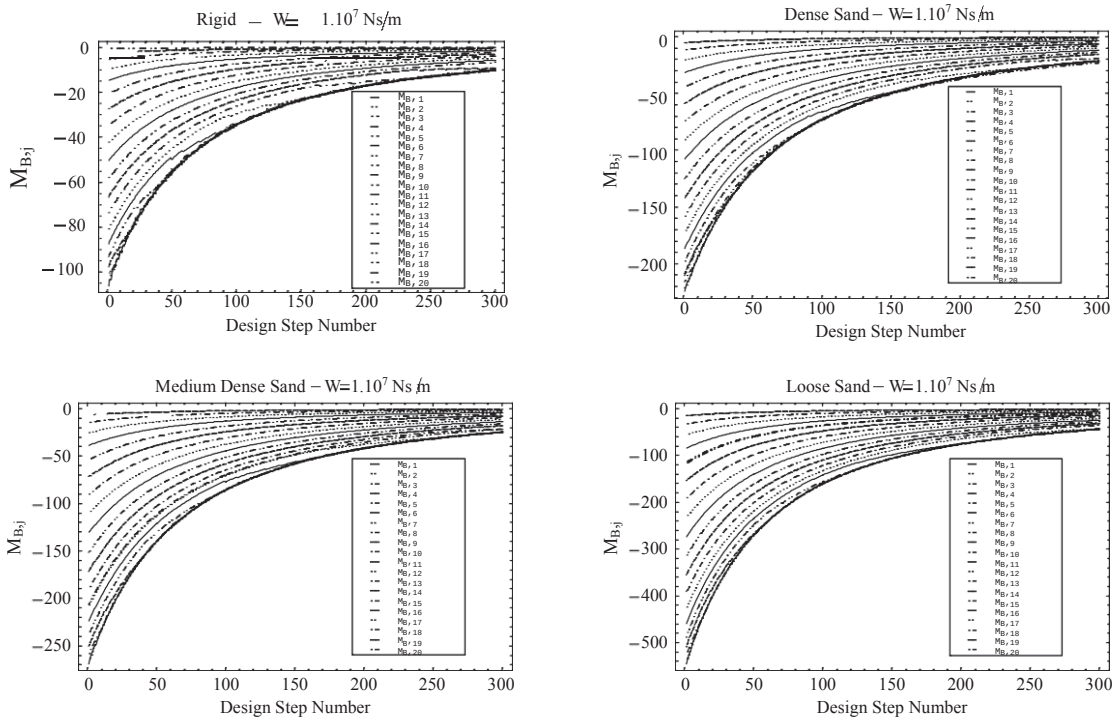

Figure 3: The sensitivities of objective function with respect to ground conditions

For rigid soil and various sandy soil conditions, plotting is carried out through the frequency response of the base moment transfer function amplitude variations in Figure 4. Analysis for frequency behaviours is conducted for $W=1x10^7$ Ns/m. Yet, the structural response is negatively influenced by the soil density conditions. From the rigid to loose sand case, there is an enhancement in the response. Within the context of the transfer function amplitudes, there is a similar behaviour of the medium dense, dense and rigid sand cases. When four kinds of behaviour parameters are applied to assess the frequency behaviour, it is observed that for amplitude, the rigid ground performance is most suitable and worst performance is indicated by loose sand. For ground conditions, the frequency behaviours have been analysed with and without dampers. The amplitudes have also been reduced significantly. When the dampers are added, the rigid and loose sandy soil difference reduces significantly. If optimal dampers are added, the negative influence can be managed. For the current research, this is considered as a significant outcome. The current research also calculates structural behaviours where the structure first mode behaviour indicates that there is minimization of behaviour. Figure 4 indicates that frequency behaviour would be significantly reduced within other higher modes through the first mode optimal dampers. The rigid case can not indicate a structural response, even though there is presence of a comparable optimal damper placement for altered relative sandy soil densities.

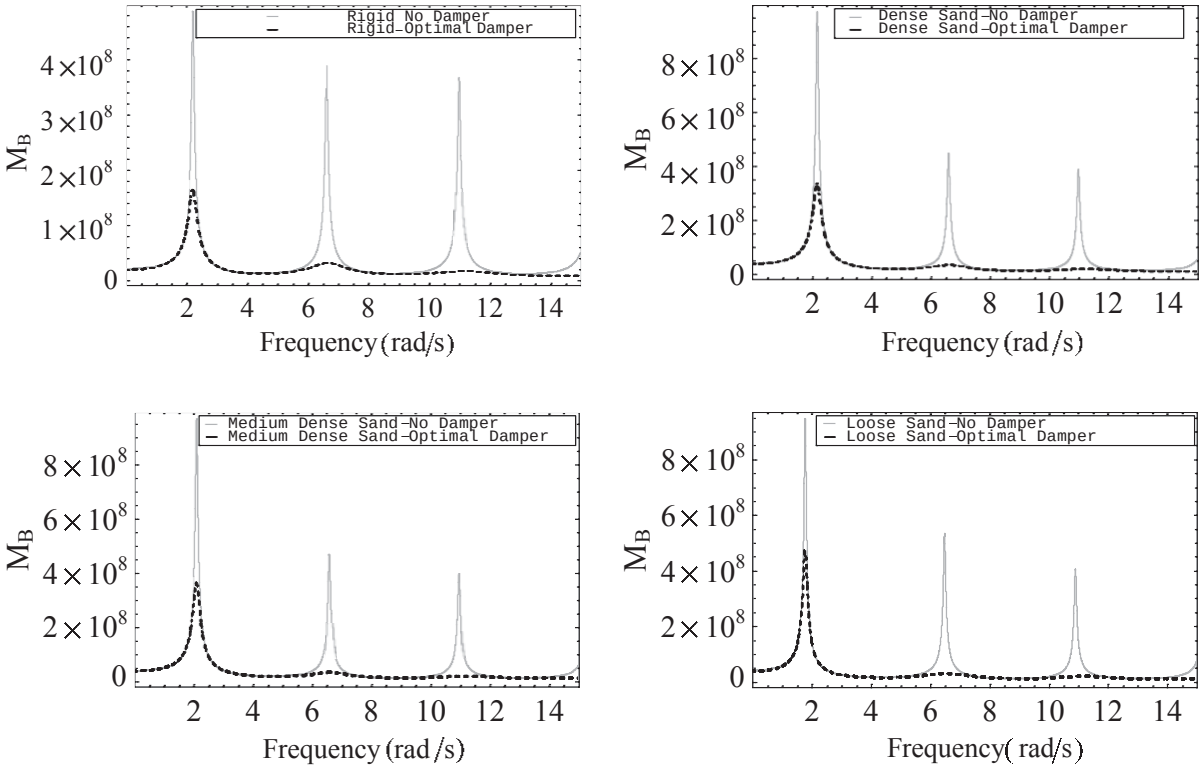

Figure 4: The variations of transfer function amplitude of base moment according to excitation frequency in terms of ground conditions

Within the current research, analysis has been made upon the influence of earthquakes over the structures base moment within the presence of optimal dampers and ground conditions. For the time history analysis, the El Centro earthquake acceleration (NS) record has been implemented. It is observed in Figure 5 that forces are enhanced significantly due to ground weakness within the context of the base moment without damper cases. If dampers are added, the base moment behaviour enhances significantly.

Fig. 5. The variations of transfer function amplitude of base moment according to excitation frequency in terms of ground conditions

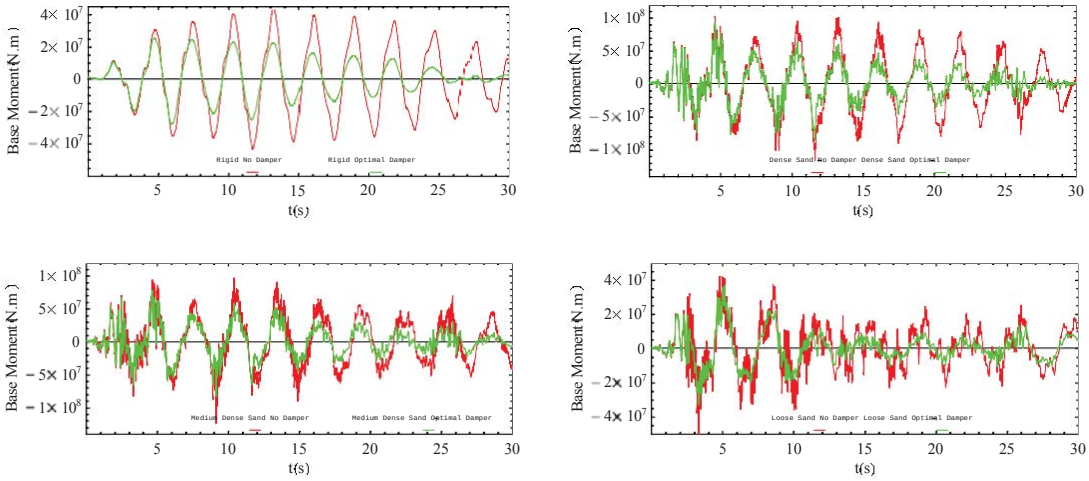

Fig. 9. Time history response of base moment under El Centro earthquake ground motion

Figure 5: Time history response of base moment under El Centro earthquake ground motion

The structure behaviour upon poor ground indicated significant enhancement, when dampers are added. For instance, the loose sand is dependent upon the location and capacity of the damper. The structure can be enhanced using optimal dampers, when there is an issue with the ground conditions keeping in mind the soil-structure interaction issue. For the engineering design, there would be a development, if the adverse situations are prevented through the addition of dampers on the superstructure and the ground conditions are not improved.

6 CONCLUSIONS

Within this current research, the base moment objective function in the case of different sandy soils is studied to investigate the optimal damper distributions and the structural response. Analysis has been carried out upon the objective function sensitivities keeping in mind the design variables of soil structure model frequency and time behaviour. Various sandy soil densities have been investigated within this context. Hence, keeping in mind the above mentioned aspects, the following conclusions are made.

The optimal damper distributions on the floor are influenced by the sandy soil relative densities which are observed through minimization of the structure base moment transfer function amplitude. The analyses of the 20-storey structure showed that dampers are placed on more floors for the rigid state, compared to the sandy ground conditions. As the looseness of the sandy ground increases, the dampers concentrate towards the lower floors. This reveals that if the weakness of the ground increases, the distribution of the dampers concentrates downwards in order to improve the behavior. According to the assessment, the structure behaviour of sandy soils is associated with the rigid ground structure response level at the time when there is optimal addition of the dampers to the poor ground structures.

On the other hand, the sandy soil relative density maintains a large influence upon the structural behaviour parameters that are the transfer function amplitude of four kinds of structural response, its sensitivities, frequencies and time behaviours. For the design steps, within the transfer function amplitude context, there is similar behaviour of the rigid, dense sand and medium dense sand conditions. The highest is of the loose sand which is also different from the rest. When the time domain and frequency were assessed, the relative density influence for sandy soil upon structural response was found. For loose sand, the response structure is not associated with the rigid, dense sand and medium dense sand conditions when the damper is not present. The behaviours for all cases are considered with the addition of the dampers. Within the current research, it is observed that the structural behaviours presented within the poor soil conditions decreased, when the dampers are added without making any soil improvements.

Keywords: Nonlinear active noise control (NANC), Functional link networks (FLNs), Narrowband noise, Maritime environment.

Abstract. *Active noise control (ANC) is an important subject that plays a central role in many practical problems. In essence, the ANC technique is based on the principle that a noise can be cancelled by another noise with the same amplitude but an opposite phase. Compared with the passive noise control technique, the ANC method is efficient to suppress noise with lower frequency. As an adaptive controller, the filtered-x least mean square (FxLMS) algorithm has gained substantial popularity owing to its simplicity. Unfortunately, in the physical world, many ANC systems exhibit certain degrees of nonlinearity in the primary or secondary path. In such situations, nonlinear ANC (NANC) algorithm is necessary for further implementation. A novel nonlinear filter, which incorporates the concept of exponential sinusoidal models into nonlinear filters based on functional link networks (FLNs) has been applied in this paper. The proposed filter is designed to provide improved convergence characteristics over traditional FLN filters. The conventional trigonometric FLN (TFLN) may be considered as a special case of the proposed adaptive exponential FLN (AEFLN). An adaptive exponential least mean square (AELMS) algorithm has been derived and the same has been successfully applied for identification of a couple of nonlinear plants. This paper investigates the application of active noise control to the attenuation of the noise produced by two asynchronous generators in a luxury yacht, with the specific aim of creating a quiet region in a twin cabin around the sleeping area.*

1 INTRODUCTION

Passive noise control treatments are an effective means of reducing the levels of noise and vibration experienced by humans in a variety of applications. However, due to both weight and size restrictions their performance in practice is generally limited to the control of higher frequency noise and vibration. To overcome this limitation and achieve significant levels of low frequency noise attenuation, active control methods have been widely investigated. Ac-

tive control systems reduce the unwanted primary disturbance by the introduction of secondary sources, which produce either additional noise or vibration to control the original source.

Active control has been successfully demonstrated in a variety of engineering applications where the perception of the acoustic environment is particularly important. For example, in the aircraft environment the low frequency tonal noise induced by the propellers has been successfully controlled using a feedforward active noise control system [1]. In the automotive environment a variety of active control systems have been proposed for both engine [2] and road noise control [3]. More broadly, active control technology has been applied to fan noise [4], active earmuffs [5], noise transmission through windows [6], sound radiation from a helicopter transmission [7] and diesel generator noise in the master cabin of a luxury yacht [8].

Active noise control (ANC) system is an electro-acoustic device based on the principle of destructive interference by generating the signal which has the same amplitude and opposite phase with the undesired noise. Because of the potential industrial applications and digital signal processing advantages, many different kinds of ANC algorithms are developed quickly in recent years [9, 10]. More widely used of them is filtered-x least mean square (FXLMS) algorithm based on linear finite impulse response (FIR) filter [11], which works well in most cases. However, these superiorities are only applied in linear control problem. In other words, when the reference signal measured by the acoustic sensor or the transfer functions of the primary path and secondary path are nonlinear, the ANC system based on FXLMS algorithm performs poorly and even fails to work [12].

In order to solve the nonlinear distortions in ANC system, a variety of nonlinear structures and algorithms are proposed over past fifteen years [13, 14].

Nonlinear filters based on functional link networks (FLNs) have received significant attention owing to its single layer structure, which offers lesser computational complexity and due to the simple learning rule [15]. FLN-based nonlinear system identification by using FLN-based filters has been attempted in [16] and FLN filters have found applications in other areas of nonlinear filtering including channel equalization [17] and echo cancellation [18]. In a traditional trigonometric FLN (TFLN), the input signal is functionally expanded using a set of trigonometric functions, before applying to an adaptive weight matrix. FLNs which employ other functional expansions than trigonometric functions have also been proposed recently. A Chebyshev FLN was presented in [19] for identification of dynamic systems. A Legendre neural network (LeNN), which employs a Legendre functional expansion, has been successfully applied for nonlinear channel equalization in wireless communication systems [20]. The lower computational load offered by TFLN-based nonlinear filters has made TFLN a popular candidate for nonlinear controllers in an ANC scenario also.

Thus, in this work, a nonlinear filter, which is based on an exponentially decaying trigonometric functional expansion has been applied in a yacht environment [21]. The performance of the filter has been enhanced by incorporating an adaptive exponential factor [21]. The effectiveness of the proposed filter has been tested using an extensive real world study. In this work, the filter has been shown to provide an improved noise cancellation in an ANC scenario.

2 DIESEL GENERATOR NOISE CONTROL

The acoustic environment in luxury yachts has become an important consideration for yacht manufacturers. High levels of noise and vibration can result in an uncomfortable environment and, therefore, there is a desire to achieve low levels of noise and vibration. At mid to high frequencies passive noise and vibration control treatments can be employed to achieve a quiet living space on-board. At low frequencies, however, the size and weight of passive treatments becomes too large and is often either impractical or significantly increases the

weight of the yacht, which in turn limits its efficiency. Thus, the occupants are sensitive to the noise produced by the electrical generators whilst moored.

Therefore, focus has been made on controlling the noise produced by the generators in a twin cabin, and especially when the generators are asynchronous.

Fig. 1 shows the yacht and the twin cabin considered in this work. The yacht specification are presented in the Table 1. In order to characterise the noise produced by the asynchronous generators, the sound pressure level has been measured at the head of the bed in the twin cabin using a microphone B&K model 4189 when the diesel generators are running on the mooring. The spectrum of the A-weighted sound pressure level measured by the microphone has been calculated. From the results illustrated in Figs. 6 and 7 it can be seen that the noise signal and its spectrum are characterised by an interference pattern between two sounds of slightly different frequencies, which comprise a series of harmonics of the fundamental engines orders at the mains frequencies of f_o=52 and f_1=55 Hz due to the asynchronous disturbance.

3 TFLN AND AEFLN BASED NONLINEAR FILTERS

In an FLN, the functionally expanded input signal is multiplied with a set of adaptive weights and then added together to obtain the output signal. Assuming *x(n)* as the input signal, in a TFLN, the functionally expanded signal vector may be written as:

$$f(n) = \{1, x(n), sin[\pi x(n)], \dots, sin[B\pi x(n)], cos[B\pi x(n)], x(n-1), sin[\pi x(n-1)], cos[\pi x(n-1)], \dots, x(n-N+1), sin[\pi x(n-N+1)], cos[\pi x(n-N+1)], \dots, sin[B\pi x(n-N+1)], cos[B\pi x(n-N+1)]\}^T \quad (1)$$

where B is the order of the functional expansion. The output of the TFLN may be written as:

$$y(n) = wf_o(n) + wf_1(n)x(n) + wf_2(n)sin[\pi x(n)] + wf_3(n)cos[\pi x(n)] + \cdots wf_{(M-2)}(n)sin[B\pi x(n)] + wf_{(M-1)}(n)cos[B\pi x(n)] \quad (2)$$

with $\boldsymbol{w_f}(n)=[\, w_{f0}(n), w_{f1}(n), \ldots, w_{f(M-1)}(n)]^T$ as the adaptive weight vector of the TFLN. The weights of the TFLN are usually updated using a gradient descent approach as

$$\boldsymbol{wf}(n+1) = \boldsymbol{wf}(n) + \mu te(n)\boldsymbol{f}(n) \quad (3)$$

where $e(n)$ is the error signal and μ_t is the learning rate.

It may be noted that TFLN attempts to model the nonlinearities in a system using sinusoids. Many of the natural signal-like speech which has fast amplitude variations cannot be effectively modeled using nonlinear filters based on pure sinusoids [22]. It has also been reported that the modeling of such signals can be achieved with better accuracy using sinusoids with exponentially varying amplitudes [23]. In order to overcome this limitation of pure sinusoids-based nonlinear filter like TFLN, we attempt to design a new nonlinear filter, which incorporates exponentially varying sinusoids in the modeling process. The new filter, which is hereafter referred to as AEFLN, is also designed to handle both growing as well as decaying exponential nonlinearities.

Similar to that in a TFLN, in an AEFLN, the tap delayed input signal

$$\boldsymbol{x}(n) = [x(n), x(n-1), \ldots, x(n-N+1)]T \quad (4)$$

of length N is functionally expanded to $M=N(2B+1)+1$ terms. The expanded input signal vector is given by

$$\begin{aligned}\boldsymbol{g}(n) &= \{1, x(n), e^{-\alpha(n)|x(n)|}\sin[\pi x(n)], e^{-\alpha(n)|x(n)|}\cos[\pi x(n)], \ldots, e^{-\alpha(n)|x(n)|}\sin[B\pi x(n)], \\ &e^{-\alpha(n)|x(n)|}cos[B\pi x(n)], x(n-1), e^{-\alpha(n)|x(n-1)|}\sin[\pi x(n-1)], e^{-\alpha(n)|x(n-1)|}\cos[\pi x(n-1)], \ldots, \\ &e^{-\alpha(n)|x(n-1)|}\sin[B\pi x(n-1)], e^{-\alpha(n)|x(n-1)|}\cos[B\pi x(n-1)], \ldots, x(n-N+1), e^{-\alpha(n)|x(n-N+1)|}\sin[\pi x(n-N+1)], \\ &e^{-\alpha(n)|x(n-N+1)|}\cos[\pi x(n-N+1)], \ldots, e^{-\alpha(n)|x(n-N+1)|}\sin[B\pi x(n-N+1)], \\ &e^{-\alpha(n)|x(n-N+1)|}\cos[B\pi x(n-N+1)]\}\end{aligned} \quad (5)$$

where $a(n)$ is an adaptive exponential parameter. The expanded input signal vector $\boldsymbol{g}(n)$ is multiplied by the adaptive weight vector

$$\boldsymbol{w}(n) = [wo(n), w1(n-1), \ldots, wM-1(n)]T \quad (6)$$

to obtain the filter output, which is given by

$$y(n) = w_o(n) + w_1(n)x(n) + w_2(n)sin|\pi x(n)|/\, e^{\alpha(n)|x(n)|} + w_3(n)cos|\pi x(n)|/\, e^{\alpha(n)|x(n)|} + \cdots w_{(M-2)}(n)sin|B\pi x(n)|/\, e^{\alpha(n)|x(n)|} + w_{(M-1)}(n)cos|B\pi x(n)|/\, e^{\alpha(n)|x(n)|} \tag{7}$$

(7) may be written in a compact form as

$$y(n) = \boldsymbol{g}T(n)\boldsymbol{w}(n) \tag{8}$$

The weight vector is updated as

$$\boldsymbol{w}(n+1) = \boldsymbol{w}(n) + \mu we(n)\boldsymbol{g}(n) \tag{9}$$

where μ_w is the step size. In a similar fashion, the adaptive exponential factor *a(n)* is updated as:

$$a(n+1) = a(n) + \mu\alpha e(n)\boldsymbol{z}T(n)\boldsymbol{w}(n) \tag{10}$$

where μ_a is the learning rate of *a(n)* and *z(n)* is an $M\times 1$ vector

$$\boldsymbol{z}(n) = \{0, 0, -|x(n)|\, e^{-\alpha(n)|x(n)|}\sin[\pi x(n)], -|x(n)|\, e^{-\alpha(n)|x(n)|}\cos[\pi x(n)], \ldots, -|x(n)|e^{-\alpha(n)|x(n)|}sin[B\pi x(n)], -|x(n)|e^{-\alpha(n)|x(n)|}cos[B\pi x(n)], \ldots, 0, -|x(n-N+1)|\, e^{-\alpha(n)|x(n-N+1)|}sin[\pi x(n-N+1)], -|x(n-N+1)|\, e^{-\alpha(n)|x(n-N+1)|}cos[\pi x(n-N+1)], -|x(n-N+1)|\, e^{-\alpha(n)|x(n-N+1)|}sin[B\pi x(n-N+1)], -|x(n-N+1)|\, e^{-\alpha(n)|x(n-N+1)|}cos[B\pi x(n-N+1)]\}^T \tag{11}$$

(9) and (10) together forms the adaptive exponential least mean square (AELMS) algorithm. Fig. 2 shows the block diagram of AEFLN updated using an AELMS algorithm.

4 PERFORMANCE ASSESSMENT

The effectiveness of the proposed nonlinear filter has been evaluated through an experimental study a twin cabin of a yacht (Fig. 1). The performance of AEFLN has been compared with that obtained using TFLN.

The mean square error (MSE) has been used as the metric of comparison

$$MSE = 10loog10\{E[e2(n)]\} \tag{12}$$

$$e(n) = d(n) - y(n) \tag{13}$$

where *d(n)* is the output of the system and *y(n)* is the anti-noise signal (Fig. 2).

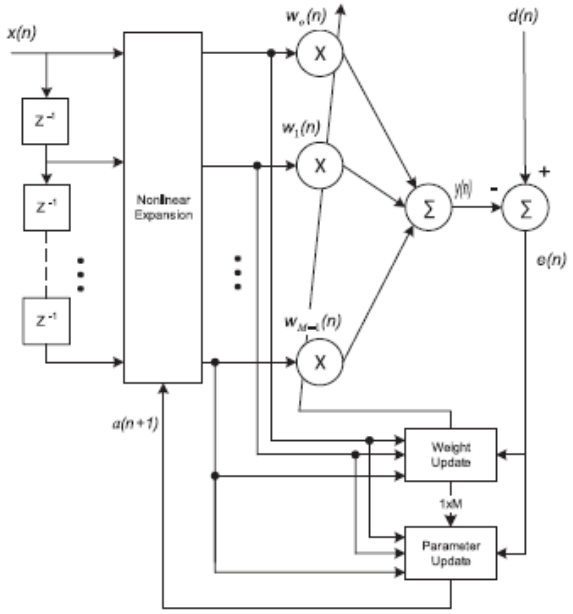

Figure 2: Block diagram of an AEFLN updated using an AELMS algorithm [21].

Initially, an attempt has been made to study the effect of the buffer size *BS* on the performance and the convergence behavior of the AEFLN-based model.

Fig. 3, shows the variations of MSE with respect to the iterations for fixed values of order *ORD*=2, learning rates μ_w=0.01 and μ_a=0.05, and initial value of a=10. As illustrated in Fig. 3, the MSEs computed over the last 3000 iterations are about -36, -28 and -18 dBs for *BS* 30, 20 and 10, respectively. Thus, the AEFLN-based ANC system has been shown to provide a better performance for buffer size greater than 30. The enhanced noise cancellation performance of AEFLN controller with respect to *BS* is confirmed in the Figs. 4 and 5. The error signal *e(n)* measured at the point of interest is presented in Fig. 6, while its spectrum is shown in Fig. 5. From those plots it can been seen that significant levels of narrowband attenuation achieved around the 'beat' components and their harmonics for *BS* greater than 30 samples. In addition to the noise attenuation performance shown in the waveforms of the Fig. 4, it is also interesting to observe the enhanced convergence behavior of the AEFLN controller.

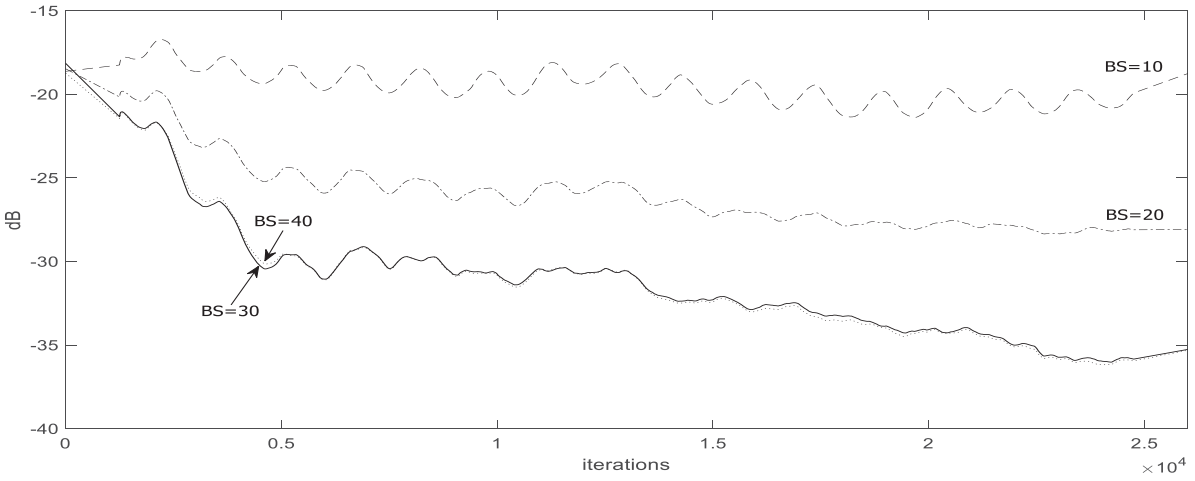

Figure 3: Comparison of convergence characteristics (MSE) obtained for different buffer sizes *BS* and AEFLN order *ORD*=2, a=10, μ_w=0.01 and μ_a=0.05.

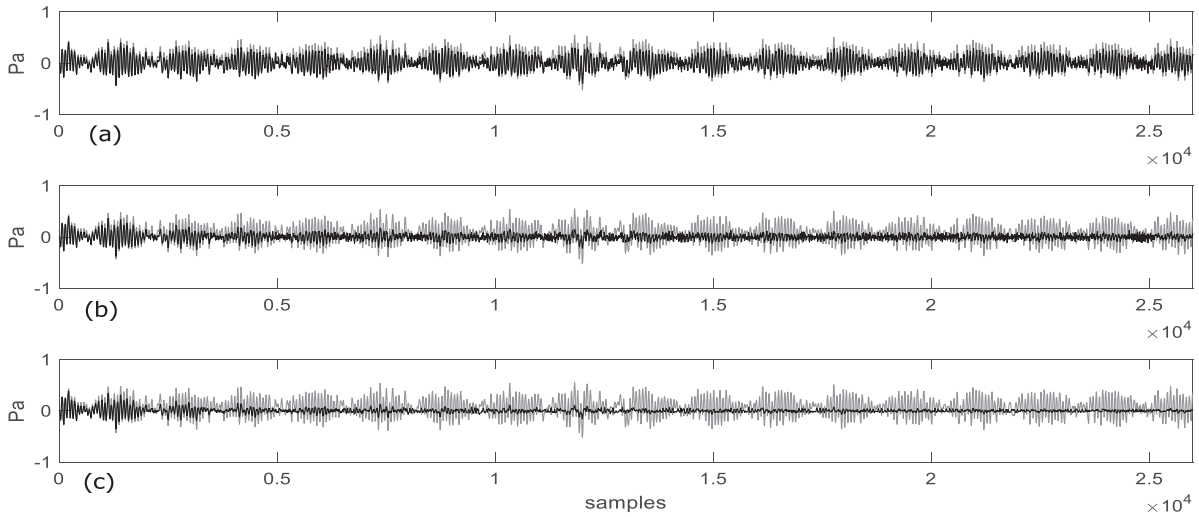

Figure 4: Error (black) and desired (gray) signals for buffer size *BS* (a) 10, (b) 20 and (c) 30 (*ORD*=2, a=10, μ_w=0.01 and μ_a=0.05).

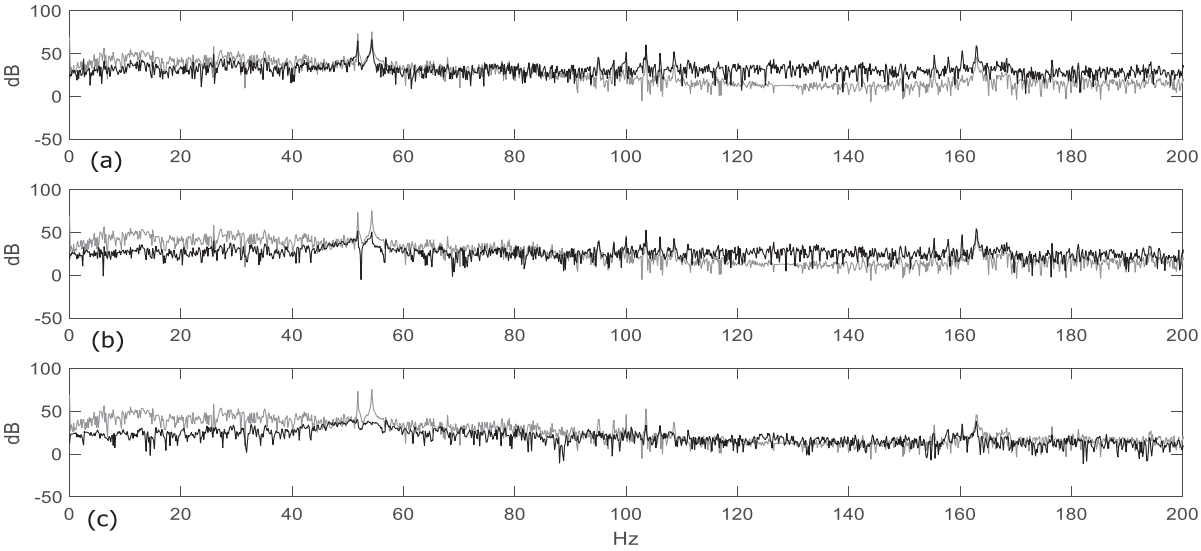

Figure 5: Spectrum of the error (black) and desired (gray) signals for buffer size *BS* (a) 10, (b) 20 and (c) 30 (*ORD*=2, a=10, μ_w=0.01 and μ_a=0.05).

Moreover, it may be noted, as shown in Table 2, that the ANCS using *BS*=30 achieved up to 40 dB noise reduction at the desired 'beat' components f_o and f_1.

Freq. (Hz)	ANC OFF SPL (dB)	ANC ON/SPL (dB)		
		BS=10	*BS*=20	*BS*=30
f_o=52	73.33	64.98	51.77	39.32
f_1=55	75.48	66.32	50.74	34.26

Table 2: AEFLN controller performance in accordance to the buffer size *BS*.

Then, the effect of the step size μ_w on the performance and the convergence behavior of the AEFLN controller is studied with respect to the iterations for fixed values of order *ORD*=2, buffer size *BS*=30 and μ_a=0.05, and initial condition of *a*=10.

Thus, as it is observed in Fig. 6, the MSEs computed over the last 6000 iterations are about -50, -35 and -23 dBs for μ_w 0.01, 0.001 and 0.0001, respectively. This means that the AEFLN approach achieves an improved steady state MSE for μ_w close to 0.01. Thus, the AEFLN-based ANC system has been shown to provide a better performance for step size μ_w greater than 0.01 and smaller than 0.1. Also, the noise cancellation performance of AEFLN controller with respect to step size μ_w is confirmed in the Figs. 7 and 8, and the Table 3.

The measured error signal *e(n)* and its spectrum are shown in Figs. 7 and 8. Again, a high narrowband attenuation and an enhanced convergence behavior of the AEFLN controller is achieved around the 'beat' components and their harmonics for step size μ_w close to 0.01. As shown in Table 3, that the ANCS using μ_w =0.01 achieved up to 37 dB noise reduction at the desired 'beat' components f_o and f_1.

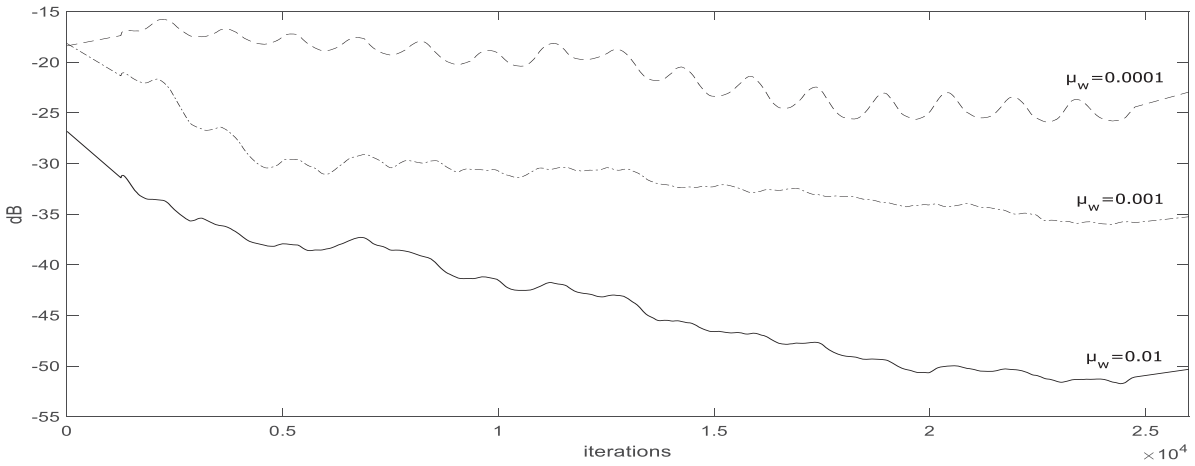

Figure 6: Comparison of convergence characteristics (MSE) obtained for different step sizes μ_w (*ORD*=2, *BS*=30, *a*=10 and μ_a=0.05.

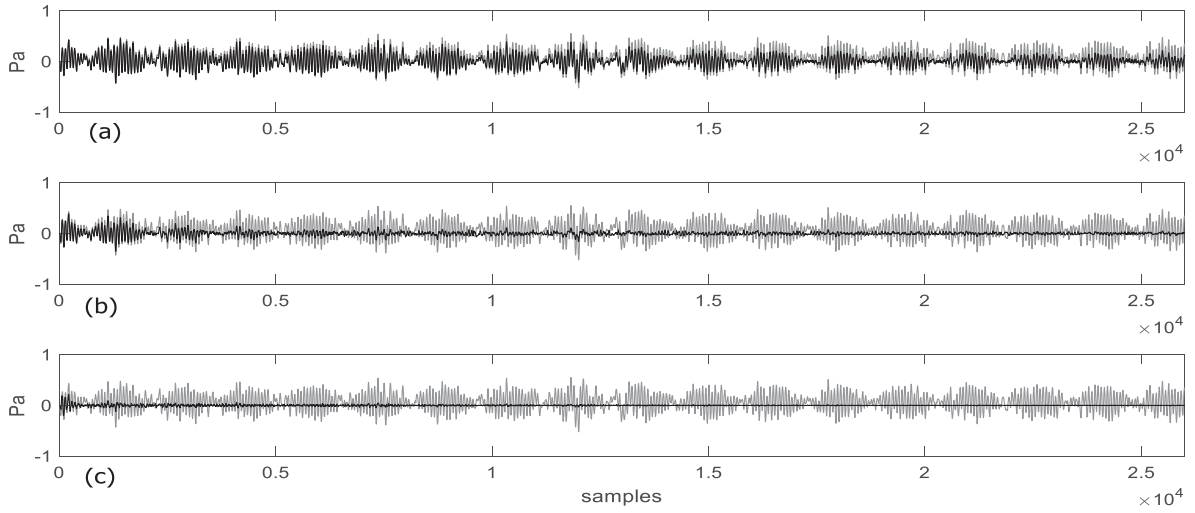

Figure 7: Error (black) and desired (gray) signals for step size μ_w (a) 0.0001, (b) 0.001 and (c) 0.01 (*ORD*=2, *BS*=30, *a*=10, μ_a=0.05).

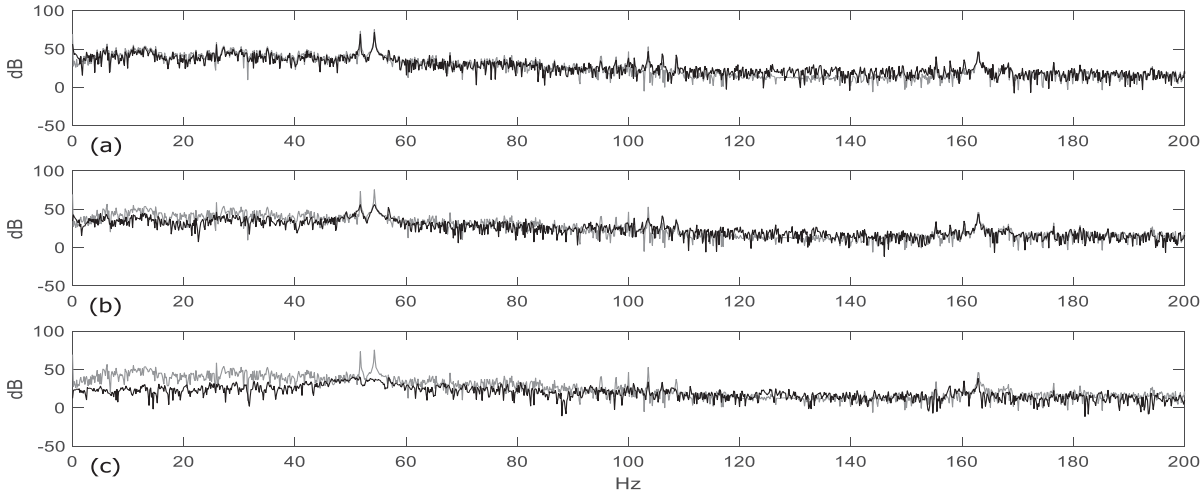

Figure 8: Spectrum of error (black) and desired (gray) signals for step size μ_w (a) 0.0001, (b) 0.001 and (c) 0.01 (*ORD*=2, *BS*=30, a=10, μ_a=0.05).

Freq. (Hz)	ANC OFF SPL (dB)	ANC ON/SPL (dB)		
		μ_w=0.0001	μ_w=0.001	μ_w=0.01
f_o=52	73.33	69.38	55.94	39.32
f_1=55	75.48	71.41	56.02	34.26

Table 3: AEFLN controller performance in accordance to the step size μ_w.

In addition, as presented in Fig. 9, the step size μ_w affects the steady state and the convergence of the exponential factor a. The attempt to study the convergence behavior of a has been achieved considering fixed values of order *ORD*=2, buffer size *BS*=30 and μ_a=0.05, and initial condition of a=10. Thus, a fast and steady convergence speed and behavior of a can be expected increasing the value of μ_w close to 0.01.

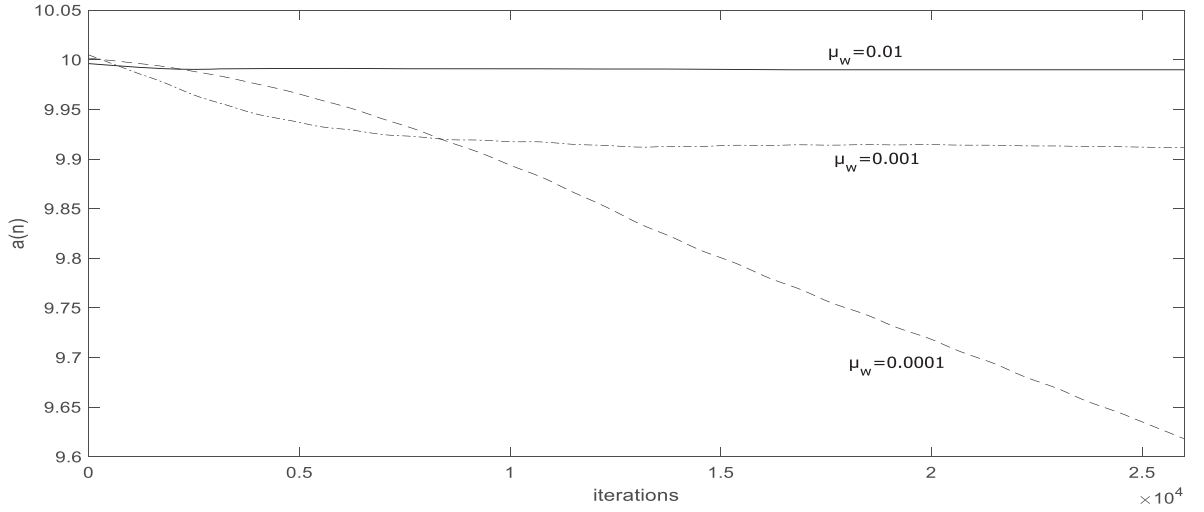

Figure 9: Exponential factor a(n) convergence for different step sizes μ_w (*ORD*=2, *BS*=30, a=10, μ_a=0.05).

Moreover, a study of the AEFLN convergence behavior in respect of the initial condition of a has been achieved considering fixed values of order ORD=2, buffer size BS=30, μ_w=0.01 and μ_a=0.05.

As it is observed in Fig. 10, the MSEs computed over the last 3000 iterations are about -60, -52, -45, -50 and -55 dBs for a equal to -1, 0, 2, 10 and 20, respectively. Thus, the convergence speed and AEFLN performance are slightly affected by the initial condition of a.

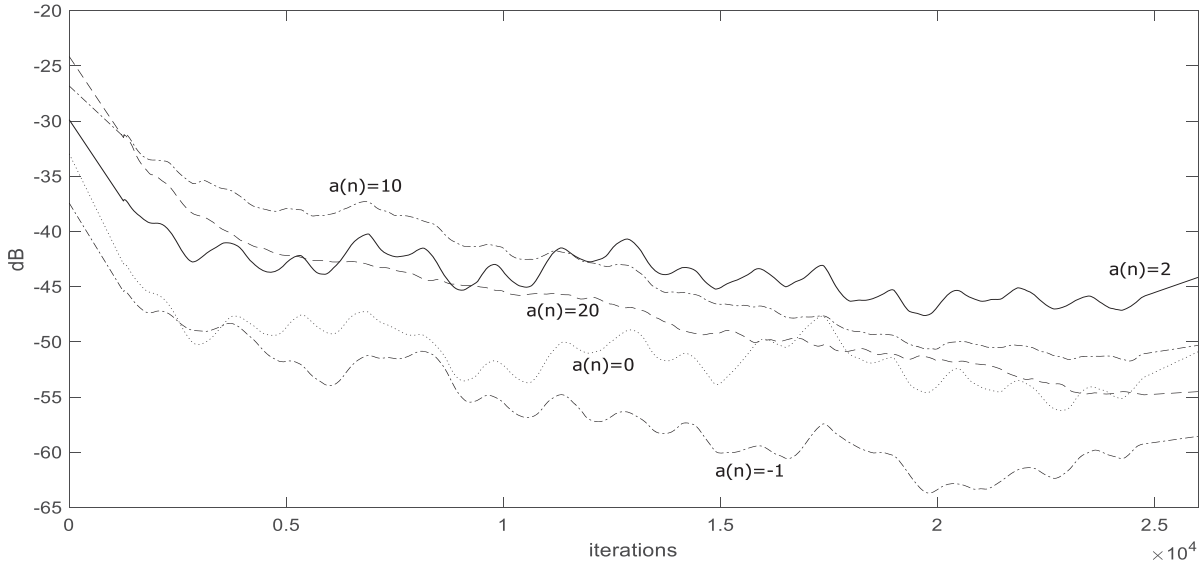

Figure 10: Comparison of convergence characteristics (MSE) obtained for different adaptive exponential parameters $a(n)$ (ORD=2, BS=30, μ_w=0.01 and μ_a=0.05).

In contrast to the buffer size and the step size μ_w, the order of the AEFLN controller in this case does not affect the convergence speed and performance of AEFLN and exponential factor a. The following results illustrated in Figs. 11 and 12 confirm the above conclusion.

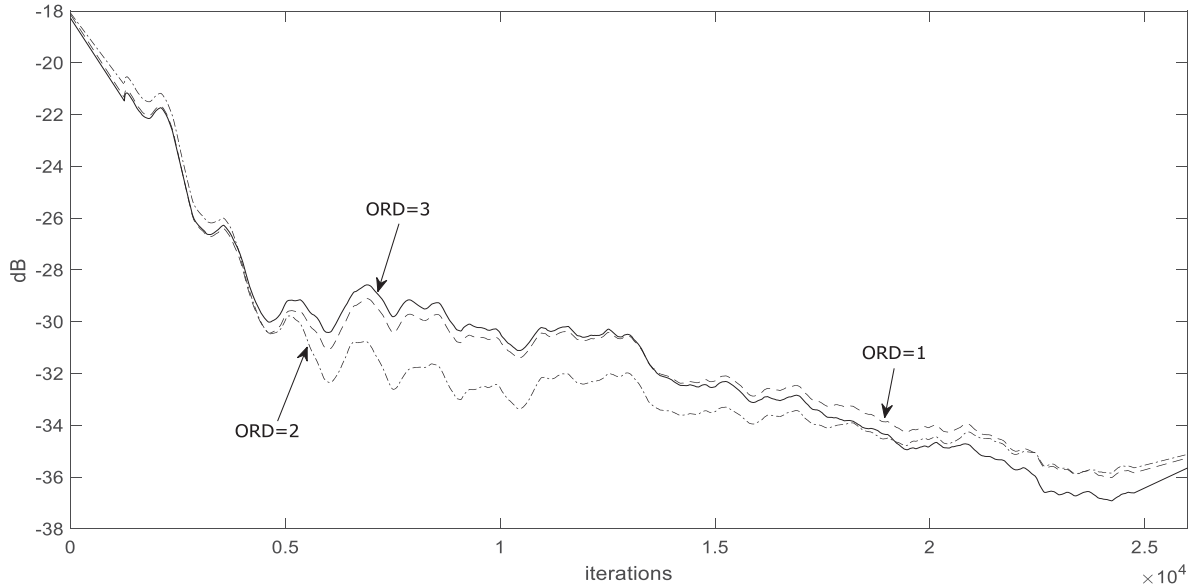

Figure 11: Comparison of convergence characteristics (MSE) obtained for different AEFLN orders (a=10, μ_w=0.01 and μ_a=0.05).

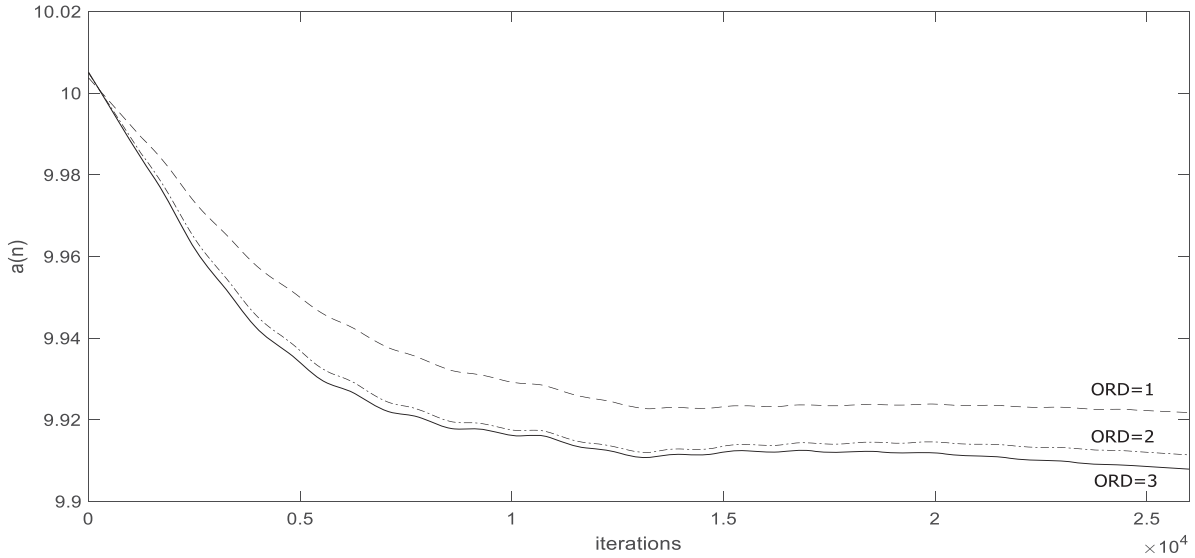

Figure 12: Exponential factor a(n) convergence for different AEFLN orders *ORD* (a=10, μ_w=0.01 and μ_a=0.05).

Next, another attempt has been made to study the effect of the buffer size *BS* on the performance and the convergence behavior of the TFLN-based controller.

Fig. 13, shows the variations of MSE with respect to the iterations for fixed values of order *ORD*=2 and learning rate μ_t=0.001. As illustrated in Fig. 13, the MSEs computed over the last 12000 iterations are about -45, -34, -23 and -20 dBs for *BS* 30, 20, 10 and 5, respectively. It is obvious that the TFLN controller provides a better performance for buffer size close to 30. Also, the Figs. 14 and 15 confirm the enhanced noise cancellation performance of TFLN controller with respect to *BS*. Figs. 14 and 15 present the error signal *e(n)* and its spectrum, respectively. The plots of Figs. 14 and 15 confirm that significant levels of narrowband attenuation achieved around the 'beat' components and their harmonics for *BS* greater than 30 samples. In the Fig. 14, it is also interesting to observe the enhanced convergence behavior of the TFLN controller.

Moreover, as shown in Table 4, the ANC system using *BS*=30 can achieve up to 45 dB noise reduction at the desired 'beat' components f_o and f_1.

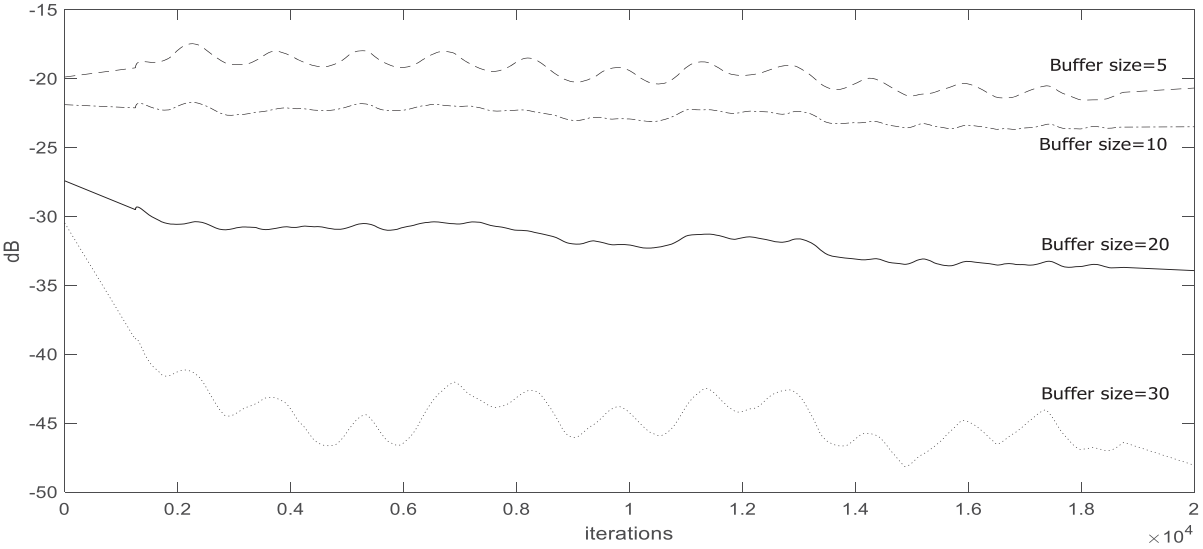

Figure 13: Comparison of convergence characteristics (MSE) obtained for different buffer sizes *BS* and TFLN order *ORD*=2, and μ_t=0.001.

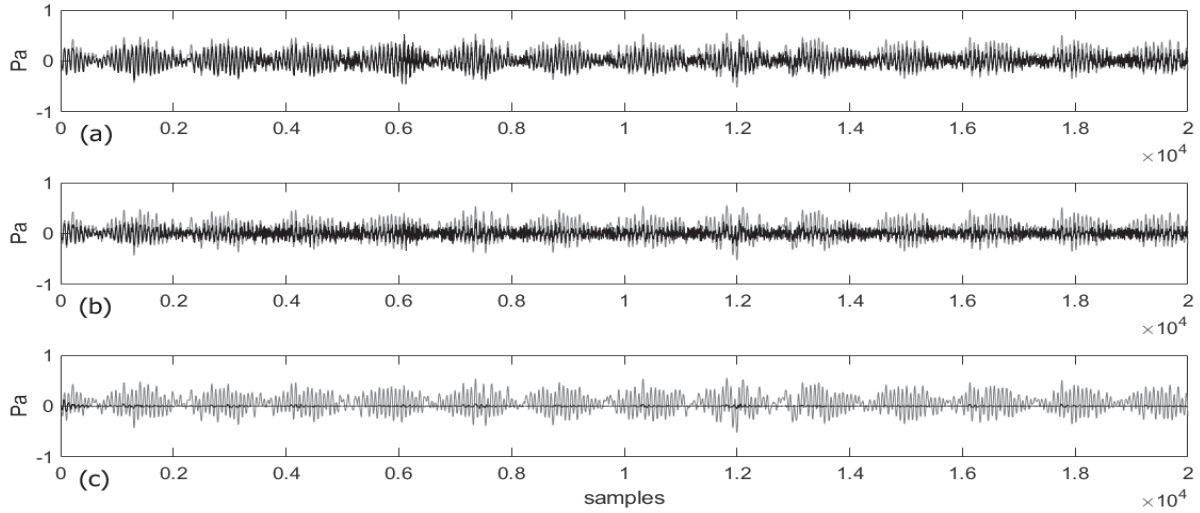

Figure 14: Error (black) and desired (gray) signals for buffer size *BS* (a) 5, (b) 10 and (c) 30 (*ORD*=2 and μ_t=0.001).

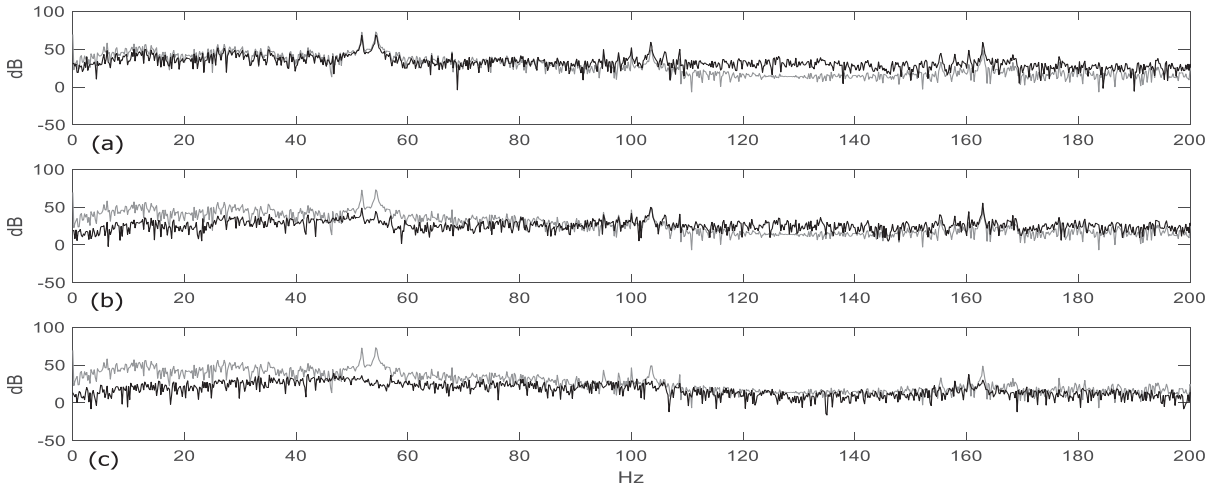

Figure 15: Spectrums of error (black) and desired (gray) signals for TFLN buffer size *BS* (a) 5, (b) 20 and (c) 30 (*ORD*=2 and μ_t=0.001).

Freq. (Hz)	ANC OFF SPL (dB)	ANC ON/SPL (dB)		
		BS=5	*BS*=20	*BS*=30
f_o=52	73.33	68.41	48.81	35.98
f_1=55	75.48	68.92	44.31	25.93

Table 4: TFLN controller performance in accordance to the buffer size *BS*.

Similarly to the AEFLN controller, the order of the TFLN controller does not affect the convergence speed and performance. The following results illustrated in Figs. 11 and 12 confirm the above conclusion.

Fig. 16, shows the variations of MSE with respect to the iterations for fixed values of buffer size *BS*=2 and learning rate μ_t=0.001. As illustrated in Fig. 16, the TFLN controller performance has slight variations in accordance to the order. Also, the Figs. 17 and 18, and the Table 5 confirm the performance and convergence speed of TFLN controller with respect to *ORD*.

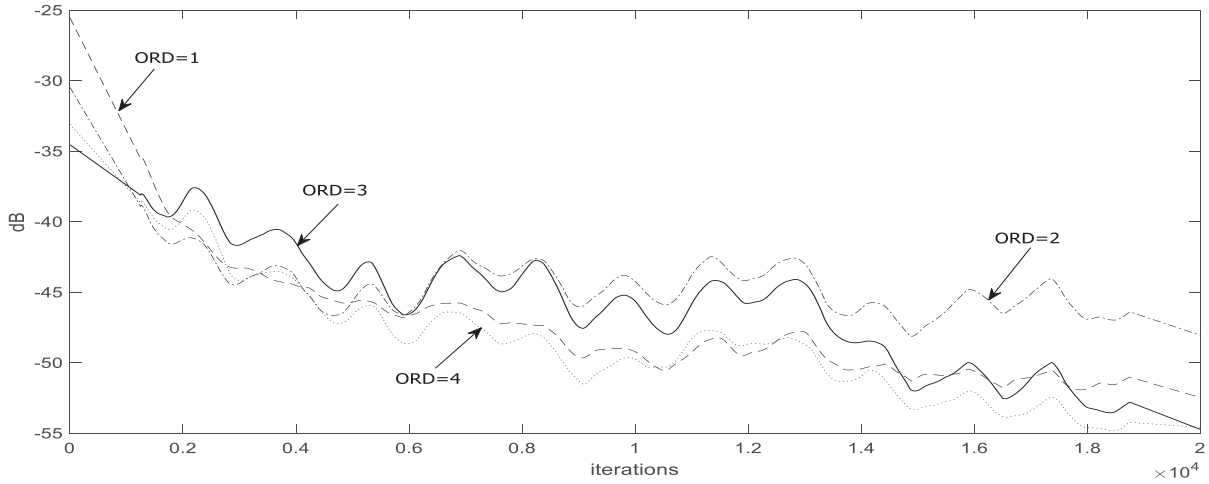

Figure 16: Comparison of convergence characteristics (MSE) obtained for different TFLN orders (μ_t=0.001 and buffer size *BS*=30).

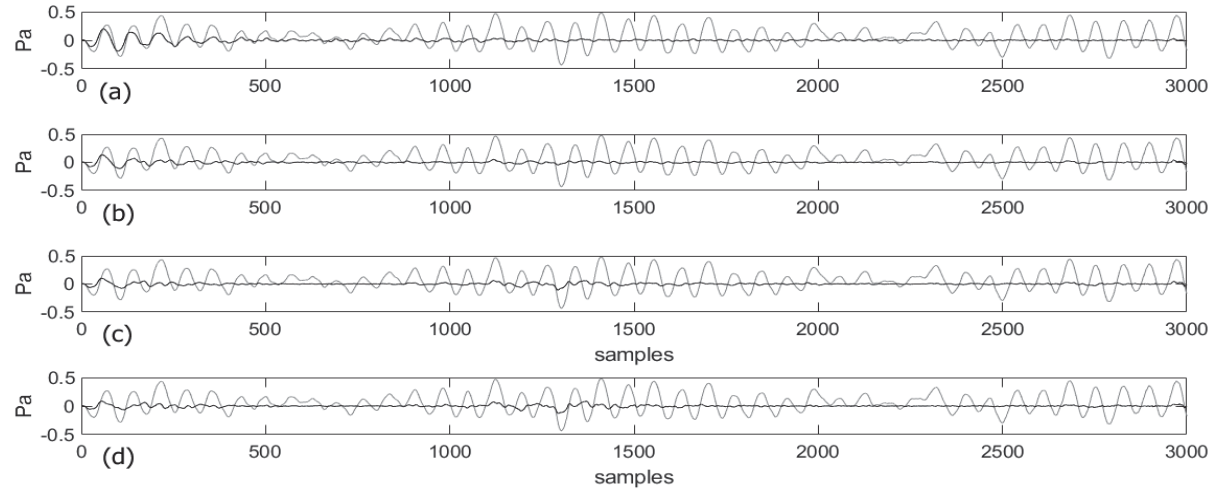

Figure 17: Error (black) and desired (gray) signals for TFLN order size (a) 1, (b) 2, (c) 3 and (d) 4 (μ_t=0.001 and *BS*=30).

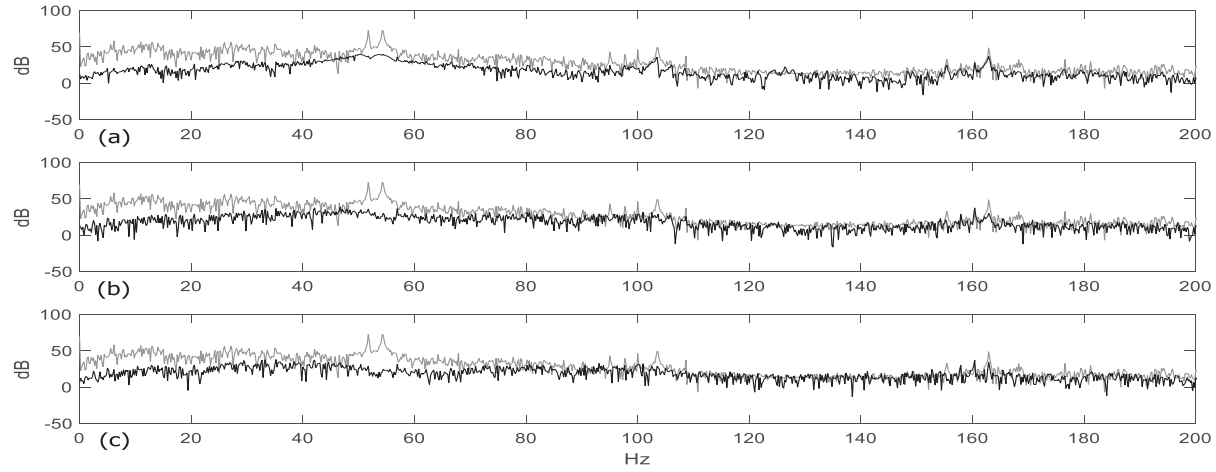

Figure 18: Spectrums of error (black) and desired (gray) signals for TFLN order size (a) 1, (b) 2 and (c) 3 (μ_t=0.001 and *BS*=30).

Freq. (Hz)	ANC OFF SPL (dB)	ANC ON/SPL (dB)		
		ORD=1	*ORD*=2	*ORD*=3
f_o=52	73.33	37.51	35.98	28.96
f_1=55	75.48	38.47	25.93	27.00

Table 5: TFLN controller performance in accordance to the order *ORD*.

Finally, the effect of the step size μ_t on the performance and the convergence behavior of the TFLN approach is studied for fixed values of order *ORD*=2 and buffer size *BS*=30.

Thus, as it is observed in Fig. 19, the MSEs computed over the last 15000 iterations are about -50, -48 and -40 dBs for μ_t 0.01, 0.001 and 0.0001, respectively. This means that the TFLN approach achieves an improved steady state MSE for μ_w close to 0.01. Also, the noise cancellation performance of TFLN controller with respect to step size μ_w is confirmed in the Table 6. As shown in Table 6, that the ANCS using μ_w =0.01 achieved up to 23 dB noise reduction at the desired 'beat' components f_o and f_1.

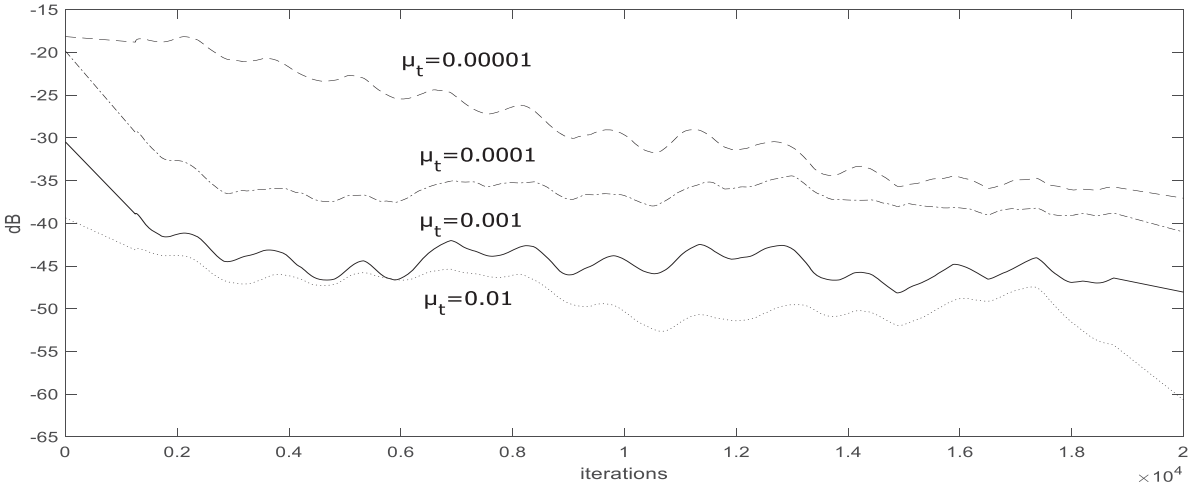

Figure 19: Comparison of convergence characteristics (MSE) obtained for different step sizes μ_t (*ORD*=2, and *BS*=30).

Freq. (Hz)	ANC OFF SPL (dB)	ANC ON/SPL (dB)		
		μ_t=0.0001	μ_t=0.001	μ_t=0.01
f_o=52	73.33	46.66	35.98	24.30
f_1=55	75.48	43.83	30.34	19.25

Table 6: TFLN controller performance in accordance to the step size μ_t.

5 CONCLUSIONS

In this paper the potential of applying a nonlinear active noise control system to reduce the levels of noise produced by two asynchronous diesel generators in the twin cabin of a luxury yacht has been investigated. It is difficult to control this using passive control treatments due to both weight and size limitations. Global active noise control is also not feasible due to the relatively wideband frequency content and the modally dense nature of the master cabin. Therefore, a practical active control system has been implemented which focuses a zone of

control at the head of the bed, where the generator noise is most disturbing when occupants are trying to sleep.

It has been shown that, due to the 'beat' components and their harmonics present in the disturbance noise spectrum, it is necessary to control multiple tones in order to achieve a significant level of narrowband attenuation. Therefore, a feedforward nonlinear control system has been investigated. It has been shown that this controller achieves significant narrowband attenuation in the sound pressure level at the error microphone located at the head of the bed. The performance, the stability as well as convergence of AEFLN and TFLN algorithms are dependent on the proper selection of the buffer size (*BS*) and the learning rates.

Keywords: Vibration, Control, Distributed MTMD, Wind, Differential Evolution.

Abstract. *Tuning frequency and TMD placement have a great impact of the effectiveness of a control device. A comparative study between three tuning and placement strategies for distributed multiple tuned mass dampers for vibration control in high-rise buildings was conducted. A new design approach based on Differential Evolution was introduced and used to optimize damping, stiffness and placement for a controller with known mass. The proposed approach implemented an iterative optimization of the MTMD by updating structural parameters and the tuning frequency after every iteration. The Designs produced by the three methods were evaluated. A frequency response analysis was performed, and the effectiveness of the control systems was measured through their ability to reduce average and maximum RMS and peak displacement and acceleration time responses.*

1 INTRODUCTION

With the recent advancements in construction technologies and materials, buildings are becoming taller and lighter. As such, multiple systems for mitigating the effects of earthquakes and wind induced loads were invented and developed. Since then, Tuned Mass Damper (TMD), a relatively easy to implement vibration absorber, has known a huge success and was adopted in multiple real world situations. In fact, Soong and Dargush [1] concluded that a TMD is very effective in controlling buildings with a dominant first vibration mode, which is typically the case for high-rise buildings. In a research conducted by Tsai and Lin [2], they showed that the TMD was able to reduce the effects of resonance, however, in some cases, they noticed response amplification under low frequency excitations. Furthermore, while a single TMD is able to control structural vibration, it is very sensitive to changes and identification errors in structural parameters, which can reduce its effectiveness. As a solution, Xu and Igusa [3] showed that using Mutiple TMDs (MTMD) improves the robustness of the control system, and its effectiveness in reducing structural response.

MTMD tuning and placement greatly affect their ability to control vibrations. In this regard, multiple researchers studied the effects of tuning and placement strategies of MTMDs on their effectiveness. Xu and Igusa [3] researched equally spaced MTMDs under wide-band random excitation. Bakre and Jangid [4] looked for optimal parameters of MTMD under harmonic base excitation .Elias and Matsagar [5] showed that distributed absorbers are more effective than non-distributed absorbers placed at the top floor. Moreover, they concluded that as the number of controllers increases, the difference in effectiveness increases. Moon [6] stated that the loss of effectiveness is minimal if placement is based on modal shape. As for tuning, Han and Li [7] concluded that uniformly distributed tuning frequencies produce an effective control system.

In this paper, we studied three different tuning and placement strategies for distributed MTMDs. The first strategy consisted of tuning and placing the absorbers according to natural frequencies and modal shapes. The second, used natural frequencies for tuning, and an algorithm based on differential evolution to find the optimal placement. The third and proposed strategy, relied on differential evolution [8] to tune and place the controllers. We also considered the maximum gain of the controlled building, calculated using the transfer matrix of the structure, as the cost function that is subject to minimization. We conducted a comparison between the resulting frequency response curves, and evaluated the performance of every control system using 8 different criteria.

2 FORMULATION

In this study, we considered a 76-story benchmark building with a total mass of 150,000t. The structure is sensitive to wind load since it presents an aspect ratio of height to base width of 7.3. A detailed description of the building's model was given by Yang et al. [9], where they removed rotational degrees of freedom by the means of static condensation. All data about the structure and across-wind load is available at the website [10]. The results of wind tunnel tests can be found in the paper by Samali et al. [11].

The equations of motion for the controlled structure using p controllers is written as

$$\mathbf{M}\ddot{\mathbf{X}} + \mathbf{C}\dot{\mathbf{X}} + \mathbf{k}\mathbf{X} = \mathbf{F} \tag{1}$$

where $\mathbf{M}$, $\mathbf{C}$ and $\mathbf{K}$ are the mass, damping and stiffness matrices for the controlled structure, respectively. $\ddot{\mathbf{X}}$, $\dot{\mathbf{X}}$, $\mathbf{X}$ are the acceleration, velocity and displacement vectors, respectively. $\mathbf{F}$

is the wind load vector.

$$\mathbf{M} = \begin{bmatrix} \mathbf{M_s} & 0 \\ 0 & 0 \end{bmatrix} + \sum_{i=1}^{p} m_{d,i} \mathbf{r_i} \mathbf{r_i}^T, \quad \mathbf{C} = \begin{bmatrix} \mathbf{C_s} & 0 \\ 0 & \mathbf{c_d} \end{bmatrix}, \quad \mathbf{K} = \begin{bmatrix} \mathbf{K_s} & 0 \\ 0 & \mathbf{k_d} \end{bmatrix} \tag{2}$$

where $\mathbf{M_s}$, $\mathbf{C_s}$ and $\mathbf{K_s}$ are the mass, damping and stiffness matrices of the uncontrolled structure, respectively. For $i \in \{1, 2, \ldots, p\}$, $m_{d,i}$ is the mass of the controller and $\mathbf{r_i}$ is the controller location column vector. $\mathbf{c_d}$ and $\mathbf{k_d}$ are diagonal matrices containing the dampings and stiffnesses of the controllers.

The transfer matrices for displacement $\mathbf{G_X}$ and acceleration $\mathbf{G_{\ddot{X}}}$ of the controlled system at input frequency ω can be extracted from Eq. (1) and are expressed as

$$\mathbf{G_X}(\omega) = (-\omega^2 \mathbf{M} + j\omega \mathbf{C} + \mathbf{K})^{-1} \tag{3}$$

$$\mathbf{G_{\ddot{X}}}(\omega) = -\omega^2 \left(-\omega^2 \mathbf{M} + j\omega \mathbf{C} + \mathbf{K}\right)^{-1} \tag{4}$$

where $j^2 = -1$.

The gain of the system at frequency ω is defined as the ratio of output over input, and is represented by the maximum singular value σ of the transfer matrix. The proposed approach aims to reduce the maximum system gain for all input frequencies, thus, reducing dynamical effects and structural response. Hence, the cost function f_c of the considered optimisation problem is subject to minimization and is defined as

$$f_c = \frac{\max\left\{\sigma_X \quad / \, \omega \geq 0\right\}}{\sigma_{Xo}} + \frac{\max\left\{\sigma_{\ddot{X}} \quad / \, \omega \geq 0\right\}}{\sigma_{\ddot{X}o}} \tag{5}$$

where $\sigma_X = \max\left\{\frac{\|G_X(\omega)u\|}{\|u\|} \quad / \, \|u\| \neq 0\right\}$ and $\sigma_{\ddot{X}} = \max\left\{\frac{\|G_{\ddot{X}}(\omega)u\|}{\|u\|} \quad / \, \|u\| \neq 0\right\}$. σ_{Xo} and $\sigma_{\ddot{X}o}$ are the maximum displacement and acceleration frequency responses for the uncontrolled structure.

3 METHODS

3.1 Five modes control strategy

Elias and Matsagar [5] considered the first five modes of vibrations to design the controllers, since the total modal mass contribution of the first five modes is more than 90% of the mass of the building. The first five natural frequencies of the building are 0.16, 0.77, 1.99, 3.79 and 6.40 Hz. The mass ratio of the whole control system is 0.82%, which is the optimal mass ratio for the considered structure as suggested by Patil and Jangid [12]. Elias and Matsagar used five TMDs to mitigate the effects of wind on the benchmark building, such that

$$f_i = \frac{\omega_i}{\Omega_i} = 1, \quad k_i = \frac{m}{\sum_{j=1}^{5} (1/\omega_j)^2} \quad \text{for } i \in \{1, 2, 3, 4, 5\} \tag{6}$$

where f_i, ω_i and k_i are the frequency ratio, natural frequency and stiffness of the i-th controller. Ω_i is the i-th natural frequency of the uncontrolled structure. m is the total mass of the control system.

$$m_i = \frac{k_i}{\omega_i^2}, \quad \xi_i = 0.05, \quad c_i = 2\xi_i m_i \omega_i \quad \text{for } i \in \{1, 2, 3, 4, 5\} \tag{7}$$

where m_i, ξ_i and c_i are the mass, damping ratio and damping of the i-th controller.

The controllers' placement was decided as follows: the i-th controller is placed at the floor which exhibits the highest modal shape amplitude for the i-th vibration mode without taking into account the floors where a controller is already installed. Using this rule, the first TMD was placed at the 76th floor, the second at the 75th floor, the third at the 74th floor, the fourth at the 61st floor and the fifth at the 65th floor.

3.2 Proposed approach

The proposed approach uses an evolutionary meta-heuristic search algorithm, called Differential Evolution, to optimize damping, stiffness and placement for a TMD with known mass. Differential Evolution (DE) is a meta-heuristic evolutionary algorithm for global optimization over continuous spaces proposed by Storn and Price [13]. Unlike other evolutionary algorithms, DE uses mutation as the main search mechanism and a greedy selection process to direct the search. Moreover, it employs a non-uniform crossover operation. Therefore, it can successfully find the true global optimal solution regardless of initial values [8]. DE is fast, easy to implement and uses few control parameters. Additionally, it is self-adaptive and can be used in constrained, multi-objective, continuous or discrete optimization problems [8]. With its superiority to other search algorithms, it has been successfully and widely applied in multiple engineering fields. DE has three control parameters, the population size NP, differential weight F and crossover probability CR. The population size greatly affects the search efficiency. A higher NP is recommended and should be proportional to the number of parameters to optimize. F controls new solutions generation which is based on weighted differences between two randomly selected solutions and the updated best solution. Randomizing F every iteration accelerates the convergence. CR determines, at recombination (crossover), which solution's components are more favoured, (i.e., whether more of the components of old or new solutions are kept). DE consists of three operations: mutation, recombination and selection, that are performed in succession until the stop condition is met.

The population of solutions can be represented by a set of NP vectors of size 2.

$$population = \{\mathbf{x}_1,\ \mathbf{x}_2,\ \cdots,\ \mathbf{x}_{NP}\} \tag{8}$$

where $\mathbf{x_k} = \{\xi_k,\ f_k\}$ is the state of solution k, ξ_k and f_k are the damping and frequency ratios.

For every parent vector $\mathbf{x_k}$, a solution vector $\mathbf{x_i}$ is chosen, and a mutant vector $\mathbf{v_i}$ is created by

$$\mathbf{v_i} = \mathbf{x_{best}} + F\left(\mathbf{x_{r1}} - \mathbf{x_i}\right) \tag{9}$$

where $i, r1 \in \{1, 2, \cdots, NP\}$ are randomly selected and different form each other, and $\mathbf{x_{best}}$ is the best solution found so far.

Next, a trial vector $\mathbf{u_k}$ is produced. The j-th component $u_{k,j}$ of the trial vector is selected randomly based on

$$u_{k,j} = \begin{cases} v_{i,j}, & \text{if } rnd_j \leq CR \text{ or } j = rn_i \\ x_{k,j}, & \text{if } rnd_j > CR \text{ and } j \neq rn_i \end{cases} \quad \text{for } j \in \{1,\ 2\} \tag{10}$$

where $rnd_j \in [0, 1]$ is a random number and $rn_i \in \{1,\ 2\}$ is a randomly selected.

The best possible placement for the trial vector is determined by trying all possible placement whithin the search domain. The trial vector $\mathbf{u_k}$ is then evaluated using the cost function and

compared to the parent $\mathbf{x_k}$, the best of the two is retained as an individual for the next generation, the state of the parent vector is updated.

$$\mathbf{x_k} = \text{best}(\mathbf{x_k}, \mathbf{u_k}) \tag{11}$$

The best solution is compared to the new produced vector and both optimal placement and optimal solution are updated if necessary. This process is repeated NP times. Afterwards, the convergence condition in Eq. (12) is checked, in case it is verified, the algorithm returns $\mathbf{x_{best}}$ and optimal placement, otherwise the process is run again for the new population of solutions.

After every generation, the population of solutions converges to an optimal solution, as a result, the variation and diversity in the population decreases. Therefore, the condition for convergence can be expressed as a function of the standard deviation (std) of the population, and is written

$$\frac{tol}{\text{std}(population)} \geq 1 \tag{12}$$

where tol is the maximum acceptable standard deviation for the population.

The proposed approach consists of using the described algorithm to optimize a single TMD. Structural matrices are then updated to take into account the new TMD. The new tuning frequency which corresponds to the new fundamental frequency is calculated. The floor which contains the new controller is removed form the placement search domain. Afterwards, the algorithm is used again to design the next TMD, but this time to control the system composed of the structure and the previous TMD. This process is repeated p times, until all controllers are optimized. The proposed method is illustrated in Figure 1.

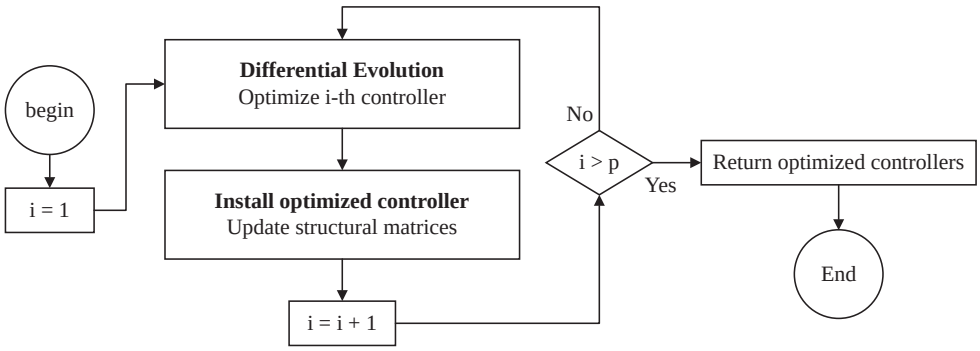

Figure 1: Proposed approach flow chart

4 RESULTS

Three tuning and placement strategies were compared. The first is the one proposed by Elias and Matsagar. The second used the controllers proposed by the first strategy, however, optimal placement was decided using the proposed algorithm. The third strategy employed our approach to optimize five controllers with equal mass considering the updated natural frequency of the building. After optimizing and installing a controller, the tuning frequency for the next controller is chosen to be the new fundamental frequency of the controlled structure using the already designed TMDs. For the second strategy, the algorithm proposed installing the controllers on the 76th, 75th, 74th, 73rd and 72nd floors. The optimized TMDs for the third strategy are shown in Table 1.

TMD	μ (%)	ξ	f	floor	ω_{tuning} (rad/s)
1	0.164	0.066	0.996	76	1.01
2	0.164	0.100	1.039	75	0.96
3	0.164	0.111	1.072	74	0.95
4	0.164	0.324	1.070	73	0.94
5	0.164	0.177	1.055	72	0.93

Table 1: Optimization results for the third strategy

Given the three proposed systems of controllers, we performed a frequency response analysis. Figures 2 and 3 show the displacement and acceleration response curves. Where ω_s is the fundamental frequency of the building.

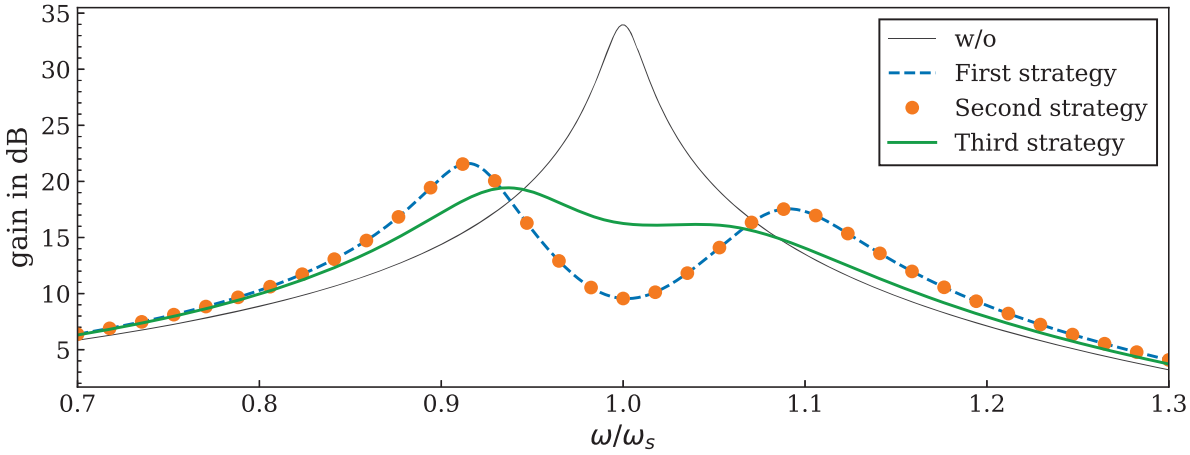

Figure 2: Displacement frequency response

For both displacement and acceleration frequency responses, the third strategy, which used our approach, was successful in reducing peak gain and also in reducing response amplification that usually occurs for low input frequencies. For the first and second strategies, although the controllers placements aren't the same, they produced the same frequency response.

In order to evaluate the performance of the proposed TMDs, Yang et al. [9] introduced 8 performance indices. The first four indices describe the controllers' ability to reduce Root Mean Square (RMS) displacement and acceleration, while the last indices four measure the reduction in peak floor displacement and acceleration.

The first index measures the reduction in maximum floor RMS acceleration and is written as

$$J_1 = \frac{\max\left(\sigma_{\ddot{X}1}, \sigma_{\ddot{X}30}, \sigma_{\ddot{X}50}, \sigma_{\ddot{X}55}, \sigma_{\ddot{X}60}, \sigma_{\ddot{X}65}, \sigma_{\ddot{X}70}, \sigma_{\ddot{X}75}\right)}{\sigma_{\ddot{X}75o}} \tag{13}$$

where $\sigma_{\ddot{X}i}$ is the RMS acceleration of the i-th floor and $\sigma_{\ddot{X}75o}$ is the RMS acceleration of the 75th without control.

The second index measures the average reduction in RMS acceleration and is defined as

$$J_2 = \frac{1}{6}\sum_i \frac{\sigma_{\ddot{X}i}}{\sigma_{\ddot{X}io}} \text{ for } i = 50,\ 55,\ 60,\ 65,\ 70,\ 75 \tag{14}$$

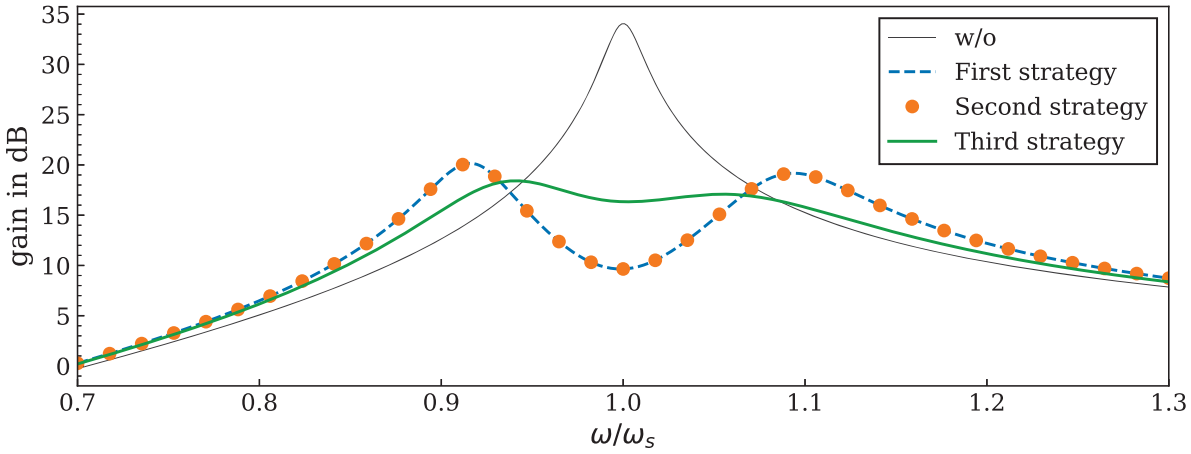

Figure 3: Acceleration frequency response

where $\sigma_{\ddot{X}io}$ is the RMS acceleration of the i-th in absence of control.

The third and fourth indices describe the reduction in maximum and average RMS floor displacement and are expressed as

$$J_3 = \frac{\sigma_{X76}}{\sigma_{X76o}} \tag{15}$$

$$J_4 = \frac{1}{7}\sum_i \frac{\sigma_{Xi}}{\sigma_{Xio}} \text{ for } i = 50,\ 55,\ 60,\ 65,\ 70,\ 75,\ 76 \tag{16}$$

where σ_{Xi} and σ_{Xio} are the RMS displacement of the i-th floor with and without control, respectively.

The last four indices are defined the same as the first ones while replacing RMS values with peak values.

$$J_7 = \frac{\max\left(\ddot{X}_{p1}, \ddot{X}_{p30}, \ddot{X}_{p50}, \ddot{X}_{p55}, \ddot{X}_{p60}, \ddot{X}_{p65}, \ddot{X}_{p70}, \ddot{X}_{p75}\right)}{\ddot{X}_{p75o}} \tag{17}$$

$$J_8 = \frac{1}{6}\sum_i \frac{\ddot{X}_{pi}}{\ddot{X}_{pio}} \text{ for } i = 50,\ 55,\ 60,\ 65,\ 70,\ 75 \tag{18}$$

$$J_9 = \frac{X_{p76}}{X_{p76o}} \tag{19}$$

$$J_{10} = \frac{1}{7}\sum_i \frac{X_{pi}}{X_{pio}} \text{ for } i = 50,\ 55,\ 60,\ 65,\ 70,\ 75,\ 76 \tag{20}$$

where $\ddot{X}_{pi}$ and $\ddot{X}_{pio}$ are the peak acceleration of the i-th floor with and without control, respectively. X_{pi} and X_{pio} are the peak displacement of the i-th floor with and without control, respectively.

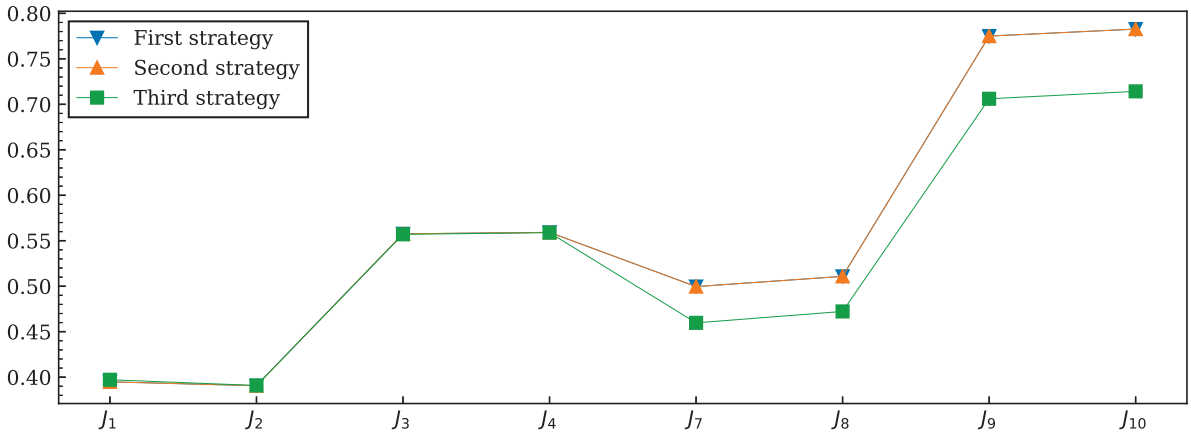

Figure 4: Performance indices

Using the generalized-α method and a time step of $1ms$, a forced time response under across-wind load was performed, and the performance indices were calculated for the three strategies. The results are shown in Figure 4.

Considering displacement and acceleration RMS reduction, indicated by the first four indices, all three strategies were able to reduce RMS response and performed equally. Looking at peak displacement and acceleration reduction, indicated by the last four indices, all three strategies succeeded in mitigating the effects of wind on the benchmark building, however, our approach produced a better reduction, especially for average and peak displacement, we noticed a bigger improvement.

5 CONCLUSION

A comparative study between tuning and placement strategies for MTMDs for the benchmark building was conducted. Tuning based on the first five vibration modes and on the updated fundamental frequency were both considered. In the first method, frequency ratio was similar between the TMDs, while in the second, TMDs shared the same mass ratio. For placements, a distributed TMD scheme was adopted. Optimal placement based on maximal modal shape was considered for the first tuning strategy. The proposed algorithm based on DE, which minimized peak displacement and acceleration frequency responses, was employed, first to find optimal placements for the previously tuned DTMDs, and second to tuned and place controllers for the second tuning strategy. Frequency response and time history analyses were conducted and the effectiveness of the designed MTMDs were compared.

First, all strategies were successful in producing an MTMD design that was effective in controlling the wind-induced vibration in the benchmark building. We observed a noticeable reduction in peak and mean RMS displacement and acceleration, and in mean and peak acceleration.

Second, while the first two strategies were different in terms of placement, the performance of the control systems were similar. This suggests that, for the first tuning strategy, MTMD placement based on modal shape is a good approximation for optimal placement for the considered cost function.

Finally, the proposed strategy improved the effectiveness of the control. Both displacement and acceleration peak frequency responses were reduced. Furthermore, while peak and mean

RMS responses were similar to the other strategies, the proposed design improved peak and mean displacement and acceleration reduction for the benchmark building. This shows that the proposed method enhanced the control effectiveness with no cost in terms of RMS response.

While the present paper compared the three control systems in terms of effectiveness in structural response reduction, it could be interesting to consider analyzing the robustness of the proposed MTMDs in comparison to other approaches.

Abstract. *This paper discusses optimum design approaches for a novel tuned-inerter-hysteretic-damper (TIhD) which is a passive vibration suppression device for building structures subject to earthquake base excitations. The TIhD has a linear hysteretic damping element connected in series with an inerter. This device exploits the advantage of linear hysteretic damping which can reduce the structural response amplification at frequencies above resonance, due to the frequency dependent damping. In the present study, the effectiveness of this device in reducing seismic response of building structures is assessed and the optimum tuning of the device parameters is explored. In particular, eight different earthquakes are selected for a case study. The optimum parameters of the TIhD are obtained numerically by using the Self-Adaptive Differential Evolution (SADE) algorithm. The optimisation criterion is the minimum root-mean-square (RMS) value of the top-storey displacement response of the structure. The performance of this tuning configuration is then compared to that of a classically tuned device. The tuning performance is also compared across a range of simulated earthquakes, giving new insight into the challenges of optimising inerter designs that involve hysteretic damping.*

1 INTRODUCTION

In earthquake engineering practice, the use of inerters for suppressing structural vibration due to earthquakes has received a significant attention recently. An inerter is a two terminal mechanical device that generates forces proportional to the relative acceleration between its two terminals. In most studies, the inerter is combined with a spring and dashpot to form an inerter-based-damper (IBD). Several IBD concepts have been proposed in literature. Three of the most popular ones are the tuned-inerter-damper (TID), tuned-mass-damper-inerter (TMDI) and tuned-viscous-mass-damper (TVMD).

The TID was first introduced by Lazar et al. [1] in 2014. The layout of the TID is very similar to a classical tuned mass damper (TMD), but the mass m_d is replaced by an inerter element with inertance constant b_d. It has been shown to have a similar behavior with TMD. For example, the optimum tuning of the TID shows two equal peaks in the host structure frequency response assuming harmonic case. However, the presence of an inerter makes it possible to achieve a large mass ratio with a small physical mass. Furthermore it has been proven that the optimum location of the TID in a multi-storey building structure is on the base [1]. This is another benefit of the TID compared to the TMD, whose optimum location is on the top storey of a structure.

A study to enhance the TMD performance by employing an inerter led to a concept called tuned-mass-damper-inerter (TMDI) [2]. It is basically a TMD with an inerter connected in series. The TMDI can be considered as an ideal TID with the TMDI mass element m_d representing the physical mass of the inerter. When the inerter mass is zero ($m_d = 0$), the TMDI becomes a TID.

The first IBD introduced in the literature was the TVMD [3]. It consists of a parallel connected inerter and dashpot in series with a spring. A simple design method of the TVMD for MDOF structures can be found in [4]. The TVMD proposed in [4] combines a device called viscous-mass-damper (VMD) with a chevron bracing. The VMD is a combined inerter and dashpot in parallel. The inerter is given by a flywheel driven by a ball-screw mechanism and the dashpot is given by fluid flow. Another reaslisation of the TVMD can be found in [5], where a rack-and-pinion type of inerter was combined with an viscous damper in parallel. The spring element is given by a chevron bracing.

Recently, research on the IBD has been focused on three main areas: (1) The application and optimisation of IBD for different systems and condition, for examples see [6–8]; (2) Experimental validation, for examples see [9–11]; (3) studies of the IBD considering different layout or different type of inerter, stiffness and damping, for examples see [12–15]. From these three areas of research, one common discussion is about the IBD optimisation. Mostly, the optimisations of the IBD are based on the fixed-point theory (FPT) of Den Hartog [16]. However this is limited to the harmonic excitation case. For random and nonstationary signals such as earthquakes, often numerical approaches are used, for example see [8].

In this paper, an optimisation of a novel tuned-inerter-hysteretic-damper (TIhD) is discussed. The TIhD is the case when a material damper is connected in series with an inerter. In this case the material damper is represented by a linear hysteretic damping or complex stiffness. An extensive discussion about this concept has been discussed by the authors in a separate paper [17]. In the present work, a particular emphasis is given to the TIhD optimisation for building structures subject to earthquake base excitations. Specifically, a self-adaptive-differential-evolution (SADE) algorithm [18] is used to obtain the TIhD optimum parameters.

2 STRUCTURAL SYSTEM

To assess the structural performance with an optimized TIhD, a SDOF structure is selected as shown in Figure 1. Here m and k are the structural mass and stiffness respectively, and b_d is the

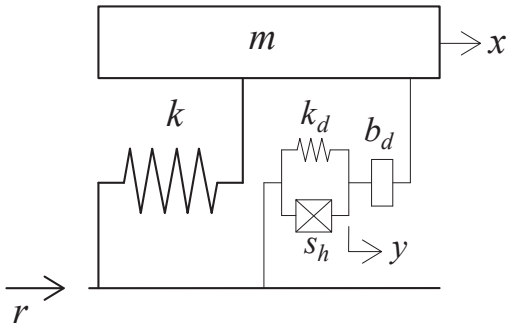

Figure 1: SDOF structure with a TIhD

TIhD inertance. For a numerical example in this paper, m and k are assumed to be 1tonne and 10kN/m. The hysteretic damping of the TIhD is represented by a complex stiffness $k_d(1+j\eta)$, where $j=\sqrt{-1}$. k_d and s_h are the real and imaginary stiffness terms so that the loss factor is $\eta = s_h/k_d$. The structure is subjected to earthquake base displacement $r(t)$. The equation of motion of the structure is given by

$$\begin{cases} m\ddot{x}(t) + k(x(t)-r(t)) + b_d(\ddot{x}(t)-\ddot{y}(t)) = 0 \\ b_d(\ddot{x}(t)-\ddot{y}(t)) = k_d(1+j\eta)(y(t)-r(t)) \end{cases} \tag{1}$$

where $x(t)$ and $y(t)$ are the displacement response of the lumped mass, m, and the TIhD displacement repectively.

It is important to note that the complex stiffness $k_d(1+j\eta)$ is a noncausal model meaning physically it is not realisable. However, this model has been widely accepted in analysis [19] to accurately represent a class of nonlinear damping [20], as well as the phenomena of energy dissipation in a variety of materials such as rubber and viscoelastic polymers [21–24]. Due to its noncausality, it is common in practice to simplify the damping as a viscous damping via an equivalent viscous damping. This is in fact not accurate, especially at frequencies away from the resonance. Therefore a special time domain method is required to analyze such structure in the time domain as has been extensively discussed by the authors in [17].

3 OPTIMISATION PROCEDURE

In this paper, the time domain technique was adopted to optimize the TIhD parameters for a seismic application. Firstly, the TIhD was optimized based on an extended FPT adopted from Hu et al. [25] with an additional fine tuning procedure as discussed in [17]. For a given mass ratio, $\mu = \frac{b_d}{m} = 0.9$, the result is shown in Figure 2. In earthquake engineering practice this approach is not appropriate due to the broad band nature of the earthquakes, but it is often used for a preliminary design due to its simplicity.

Secondly, a SADE algorithm [18] was adopted to find the TIhD optimum parameters for some different earthquakes. The objective function is the minimum root-mean-square (RMS) value of the structural response $x(t)$. For one specific earthquake it is expressed by

$$\begin{gathered} b_{d_{min}} \le b_d \le b_{d_{max}}; k_{d_{min}} \le k_d \le k_{d_{max}}; \eta_{min} \le \eta \le \eta_{max} \\ min|\text{RMS}(x(t))| \end{gathered} \tag{2}$$

It is important to set a feasible limitation for b_d, k_d and η as shown in Eq.2 to reduce the computational cost. In this study, the limitations are $0.1 \leq b_d \leq 0.9; 0.1 \leq k_d \leq 10; 0.1 \leq \eta \leq 2$. Another important note is that the use of the SADE algorithm to obtain the RMS value of the structural response requires a time domain analysis. In this case, it has been made possible because of the time domain analysis proposed by the authors [17] for structures with linear hysteretic damping.

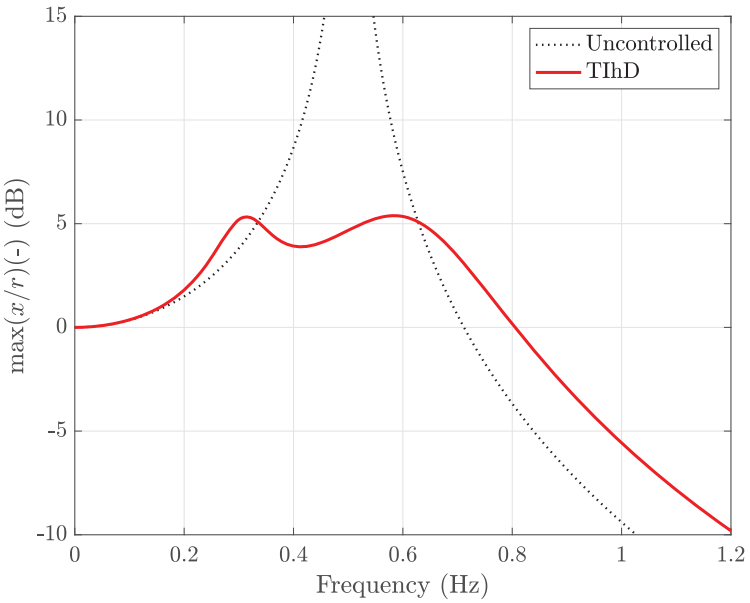

Figure 2: Maximum absolute displacement for $\mu = 0.9$, $k_d = 3.47$kN/m and $\eta = 1.26$

4 RESULTS AND DISCUSSION

In order to asses the effectiveness of the SADE algorithm against the FPT for minimizing a structural response subject to seismic excitations, eight different earthquakes were selected as shown in Figure 3.

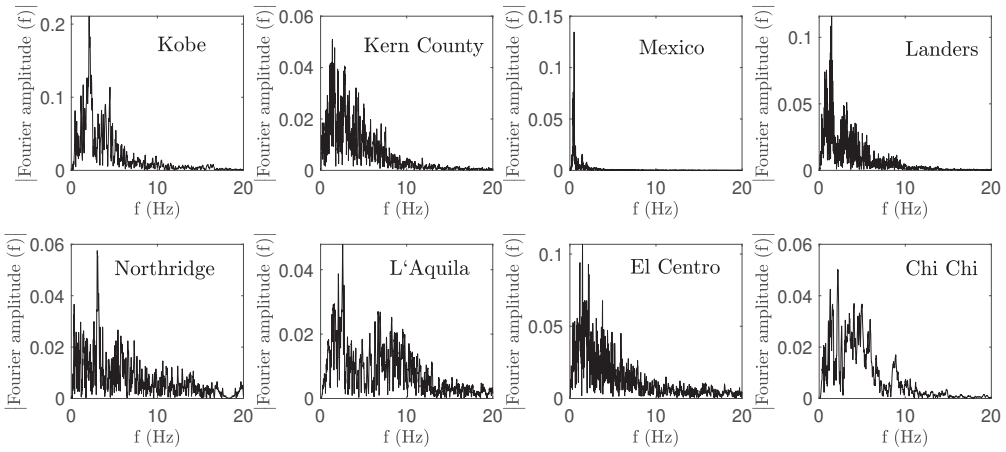

Figure 3: Fourier spectrum of the considered earthquakes ground motion

Figure 4 shows the RMS of the structural displacement response comparison between the

optimised TIhD obtained by the FPT and by the SADE algorithm given by the Eq. 2. In this Figure, the RMS value of each earthquake is normalised against the RMS value from the FPT which is set to 100%. It is obvious that the SADE algorithm gives better reduction of the RMS value for all of the selected earthquakes. This is however not a practical solution because it leads to many inertance-stiffness-loss factor (ISL) configurations as shown in Table 1. For a realistic implementation, one configuration must be chosen, without prior knowledge of the specific earthquake excitation.

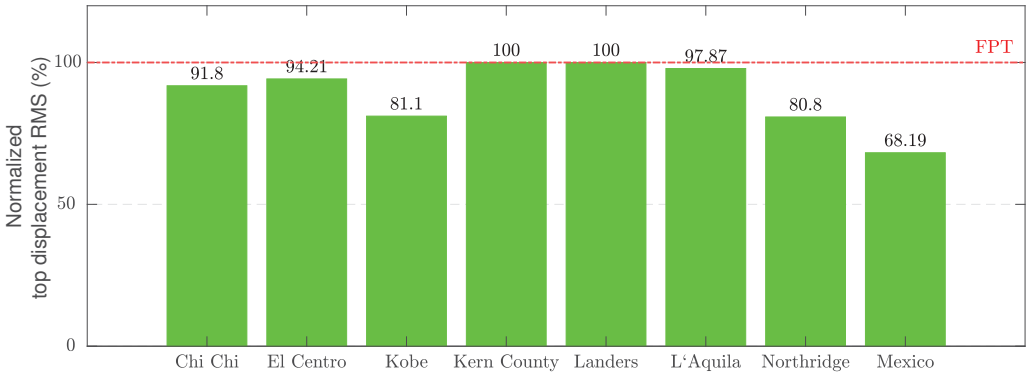

Figure 4: Normalised root mean square of the structural displacement response, SADE - Eq. 2

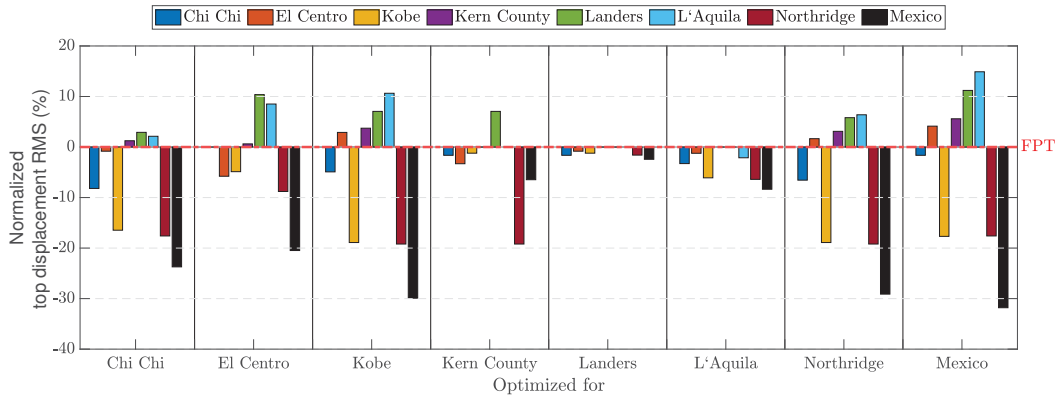

Figure 5: Cross-optimisation, SADE - Eq. 2

Figure 5 shows a cross-optimisation, meaning one configuration was selected from one particular earthquake to be used for simulation of other earthquake cases. For example, the first group of bars shows the structural response subjected to the eight considered earthquakes using one ISL configuration optimized for Chi Chi earthquake. The structural performance is being compared with the FPT which is set to 0%. Hence any negative values means a reduction on the structural response, on the other hand, any positive values means an amplification on the structural response relative to the FPT. For example, the group of bars for Landers implies that using one ISL configuration optimised for Landers earthquake for all other considered earthquakes makes the structural performance better than the one obtained via the FPT.

The group of bars for L'Aquila and Landers in Figure 5 in this case are the best result of this cross-optimisation since all other groups of bars show both positive and negative values. This

simulation also implies that a correct formulation to chose or obtain the best ISL configuration is required. For this reason, a method that is based on the SADE algorithm was developed to find the best ISL configuration that gives minimum average RMS values of the structural performance subjected to a number of ground motions. It is expressed as

$$b_{d_{min}} \leq b_d \leq b_{d_{max}}; k_{d_{min}} \leq k_d \leq k_{d_{max}}; \eta_{min} \leq \eta \leq \eta_{max}$$
$$min \left| \frac{\sum_{i=1}^{n} \text{RMS}(x_i(t))}{n} \right| \tag{3}$$

where n is the number of considered earthquake input signals.

Figure 6 shows the structural performance comparison between the two approaches against the FPT. The second approach is (although not strictly better than the first approach) almost as good and clearly still superior than the FPT. It is in fact is more practical than the first approach because, as shown in Table 1, it has only one ISL configuration as in the case of the FPT. Two

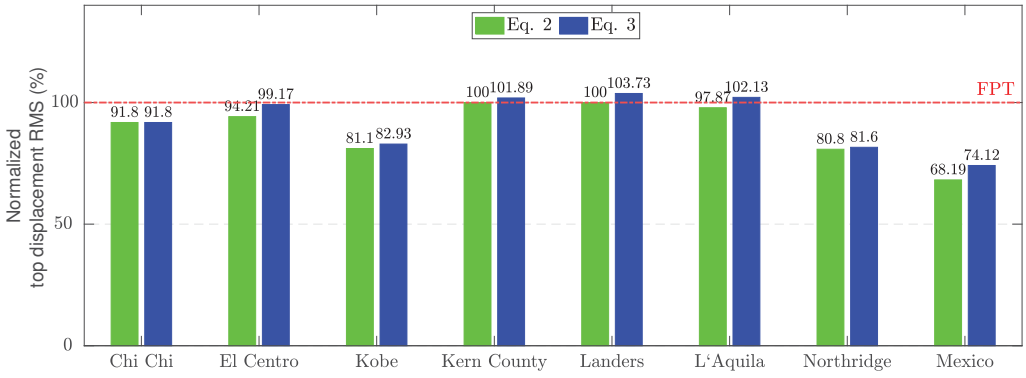

Figure 6: Normalised root mean square of the structural displacement response, SADE - Eq. 2 and 3

.

examples of the displacement response time history of the considered structure are given in Figure 7.

Mexico				0.9	8.16	0.39			

5 CONCLUSION

This paper presents the optimum design of the TIhD for long-period structures subjected to seismic ground motions. The optimisation method is based on the combined SADE algorithm and the time domain method for the TIhD to obtain the best ISL configuration of the TIhD.

There are two approaches presented in this study. The first approach is to find the minimum RMS value of the structural response for each of the considered earthquakes. Although the results show a superior benefit compared to the fixed point theory, it is however not practical because there is one ISL configuration obtained for one specific earthquake. As a result, there are many ISL configurations obtained depending on the number of the considered earthquake. The second approach is to find the best ISL configuration that gives minimum average RMS value of the structural response for all of the considered earthquakes. The second approach is considered to be a more practical solution and can be directly compared to the fixed point theory.

It has been shown that numerically optimised designs of TIhD can outperform those design using the classical fixed point theory. This is because the numerical method accommodates frequency independency, relying on a recently developed time-domain solution algorithm for hysteretic damping [17]. However this obviously requires a priori knowledge of the seismic excitation. Consequently further work should extend this approach to consider more formal earthquake design methodologies as part of the time-domain optimisation.

Keywords: Earthquake, High-rise building, TMDi, Wind forces

Abstract. The objective of this article is to investigate vibration mitigation technique of a reinforced concrete (RC) building subjected to wind or earthquake ground motion. Numerical analysis of a RC building controlled by inerter tuned mass damper (TMDi) is conducted under independent action of wind forces and earthquake ground motion. The performance of the control devices is evaluated in terms of reduction in response parameters such as floor acceleration and displacements. The results show that vibration mitigation achieved from the TMDi system employed in the RC building varies significantly with the type of excitation. Nevertheless, the TMDi system is found to be more reliable than a TMD system.

1 INTRODUCTION

Tall buildings are exposed to natural hazards such as wind and earthquakes during their lifetime. Tuned mass damper (TMD) is commonly recommended for vibration control of tall structures [1-8]. A detailed literature survey is presented by Elias and Matsagar [9]. It is well-established that heavier TMDs are more effective than lighter ones. However, heavier TMDs are not practically efficient as they exert additional loads on the floors they are placed on. Dividing the total mass of the TMD and distributing over different floors is an option to reduce excessive loads on a single floor [10-16]. The other attractive solution is use of inerters combined with a TMD (TMDi) [17-22]. Inerters can generate very large inertial force with very small physical mass. The application of TMD and TMDi on base-isolated (BI) structures have been reported in the literature [23-29]. Such control strategies often consider a single type of hazard, often seismic ground motion or wind action, and studies covering multiple hazards are limited in the literature. Some studies have addressed multi hazard issues in structural vibration control [30-35]. Recently, Elias et al. [36] reported the performance of TMDs in response control of a tall building subjected to wind and earthquakes. They showed that a system designed for earthquakes may not be as effective for wind forces. They also proposed a solution that is optimal considering both the hazards. This study extends the work of Elias et al. [36] to TMDi devices.

2 MATHIMATICAL MODELLING

The building considered in this study is a 76-story benchmark building, which is very sensitive to wind [36-38]. Detailed information of the building can be found elsewhere [38]. Figure 1 shows the schematic models of the benchmark building equipped by a) TMD and b) TMDi. The optimum frequency and damping ratio of the TMD is calculated from the formulation given in Sadek et al. [39], whereas the optimal frequency and damping ratio of TMDi is based on formulations given in Giaralis and Petrini [18]. By assuming a mass (m_1) for TMD, its stiffness (k_1) and damping (c_1) are calculated from the optimal frequency of the TMD which is tuned to the first mode of vibration of the building. The physical mass of the TMDi is the same as that of the TMD. The TMDi contains an additional inertial device, an inerter, whose inertance is denoted by b. The stiffness (k_{TMDi}) and damping (c_{TMDi}) are estimated from the optimal tuning frequency. The position of the inerter is varied in different floors to find its optimal location. Many studies report benefits of attaching the inerters to the lower floors, however, a thorough study about the optimal placement of inerters is lacking in the literature. Three different models are created: uncontrolled (NC), controlled with TMD (TMD), and controlled with TMDi (TMDi). The models are subjected to wind and earthquake forces. I

3 NEWMERICAL STUDY

The building in this study has a height of 306.1 m and width of 40 m, and this ratio is 7.6525>5. This confirms that the building is wind sensitive. It is assumed that the building lies in a seismic area and might experience strong ground shaking. Wind forces are by varied by using mean velocity at the top of the building from 14 m/sec to 66 m/sec by an incremental value of 1 m/sec. A set of 100 ground motions used by Saha et al. [40] are used as seismic action.

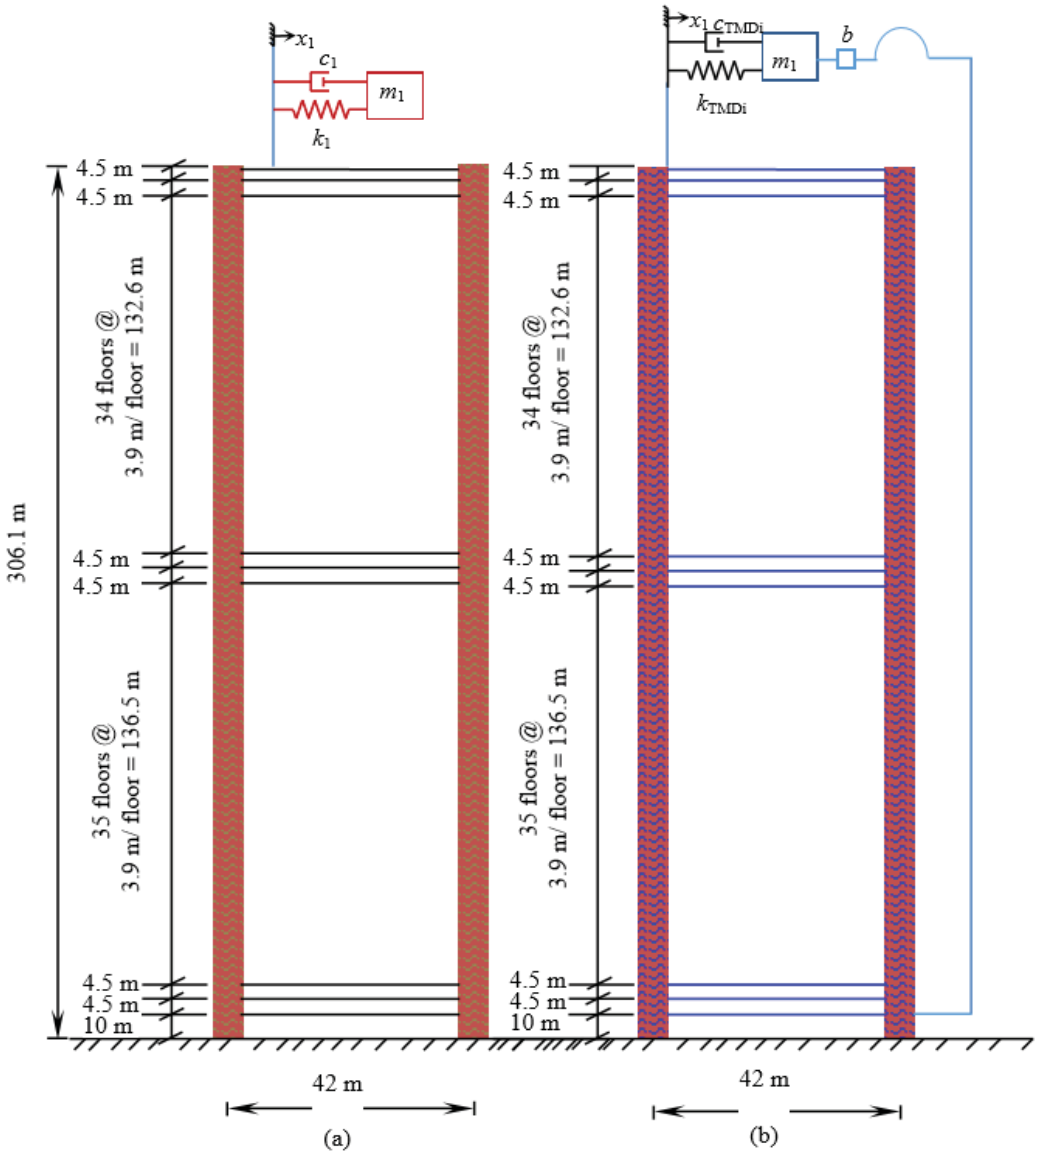

Figure 1: Schematic models of benchmark building equipped by a) TMD, b) TMDi.

In this study mass (m_1) is assumed to be 0.0082 times the total mass of the building. The corresponding value of generalized mass used in the formulation of Sadek et al. [39] is 0.01123. The b value of the inerter is assumed to be 0.3.

3.1 Optimal Placement of Inerter

Figures 2 and 3 show the response of the building equipped by a TMDi while subjected to wind and ground motions. The location of inerter is varied from first floor to the top floor under both hazards. Optimal location is identified based on displacement response. Figure 2 shows lower floors are not necessarily the optimal location for the inerter. While the response to wind forces seems relatively independent of the inerter location for low wind velocity, floor 65 seems to be the best location when the wind velocity is high.

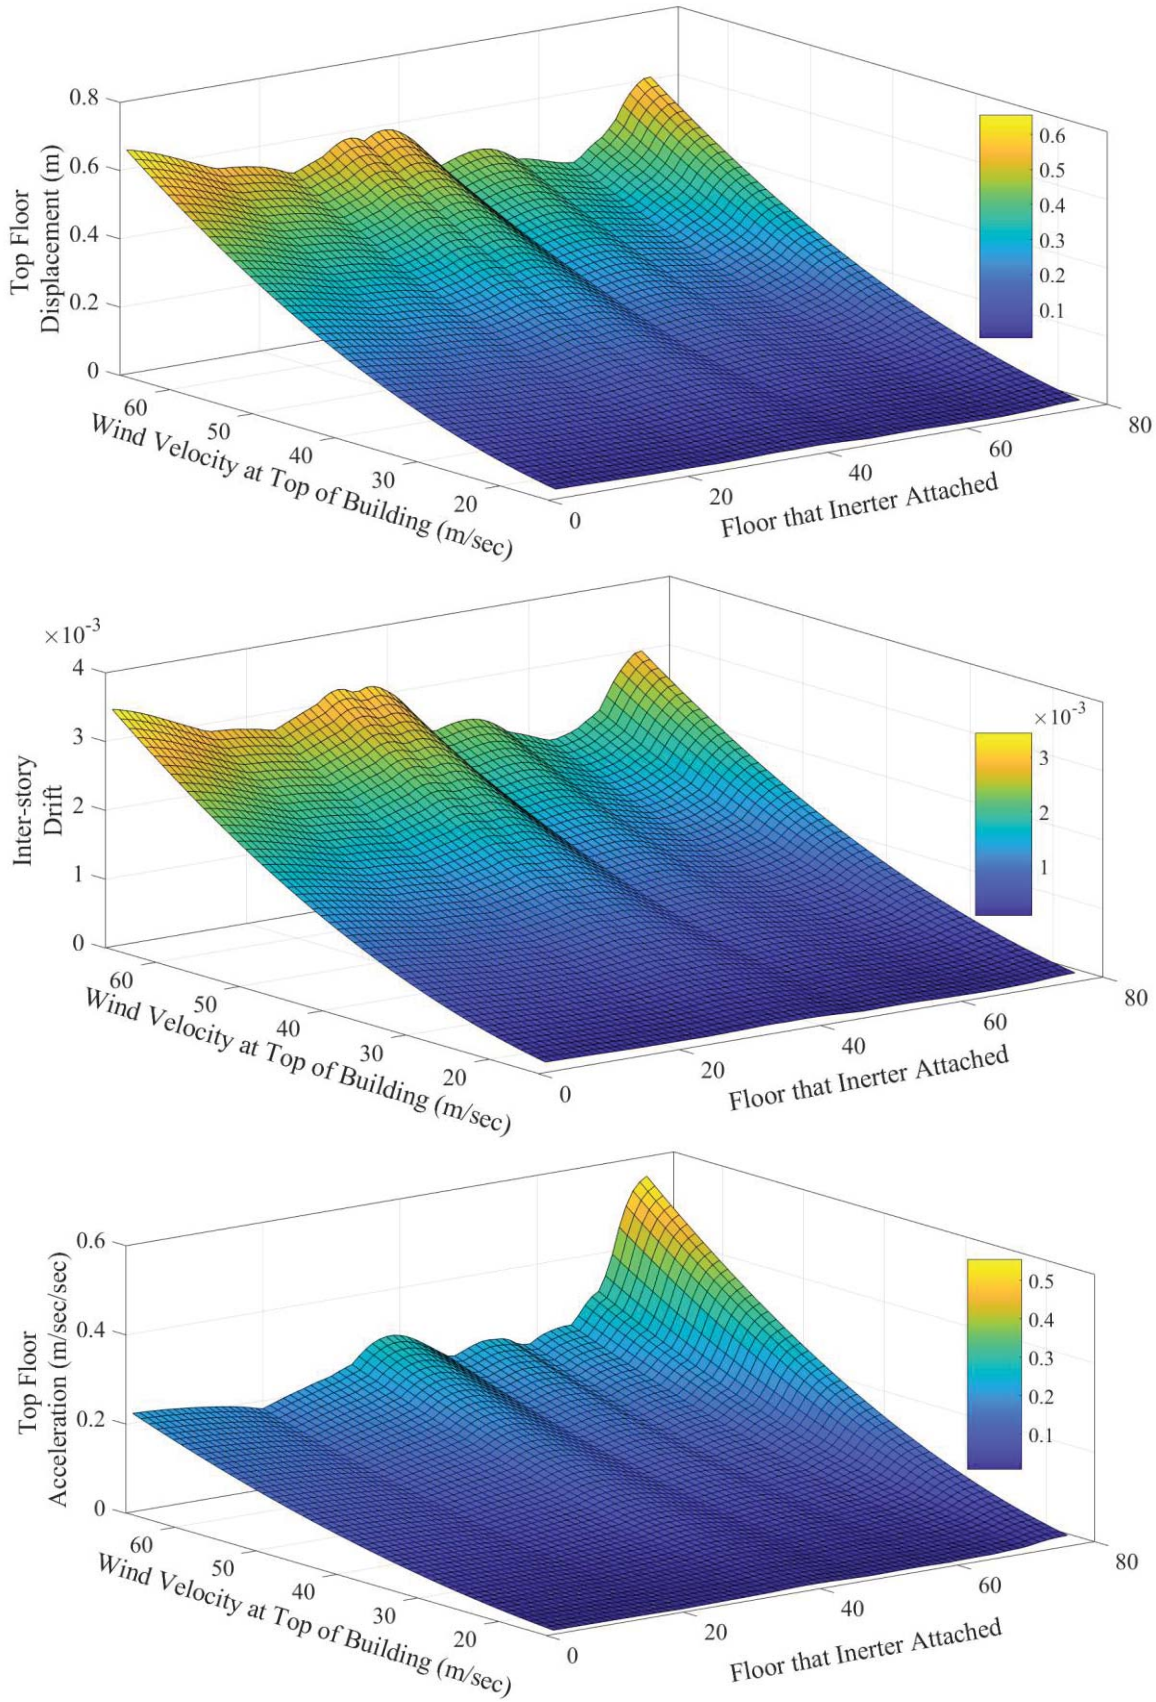

Figure 2: Response of the building equipped by a TMDi with inerter connected at different floors under wind forces.

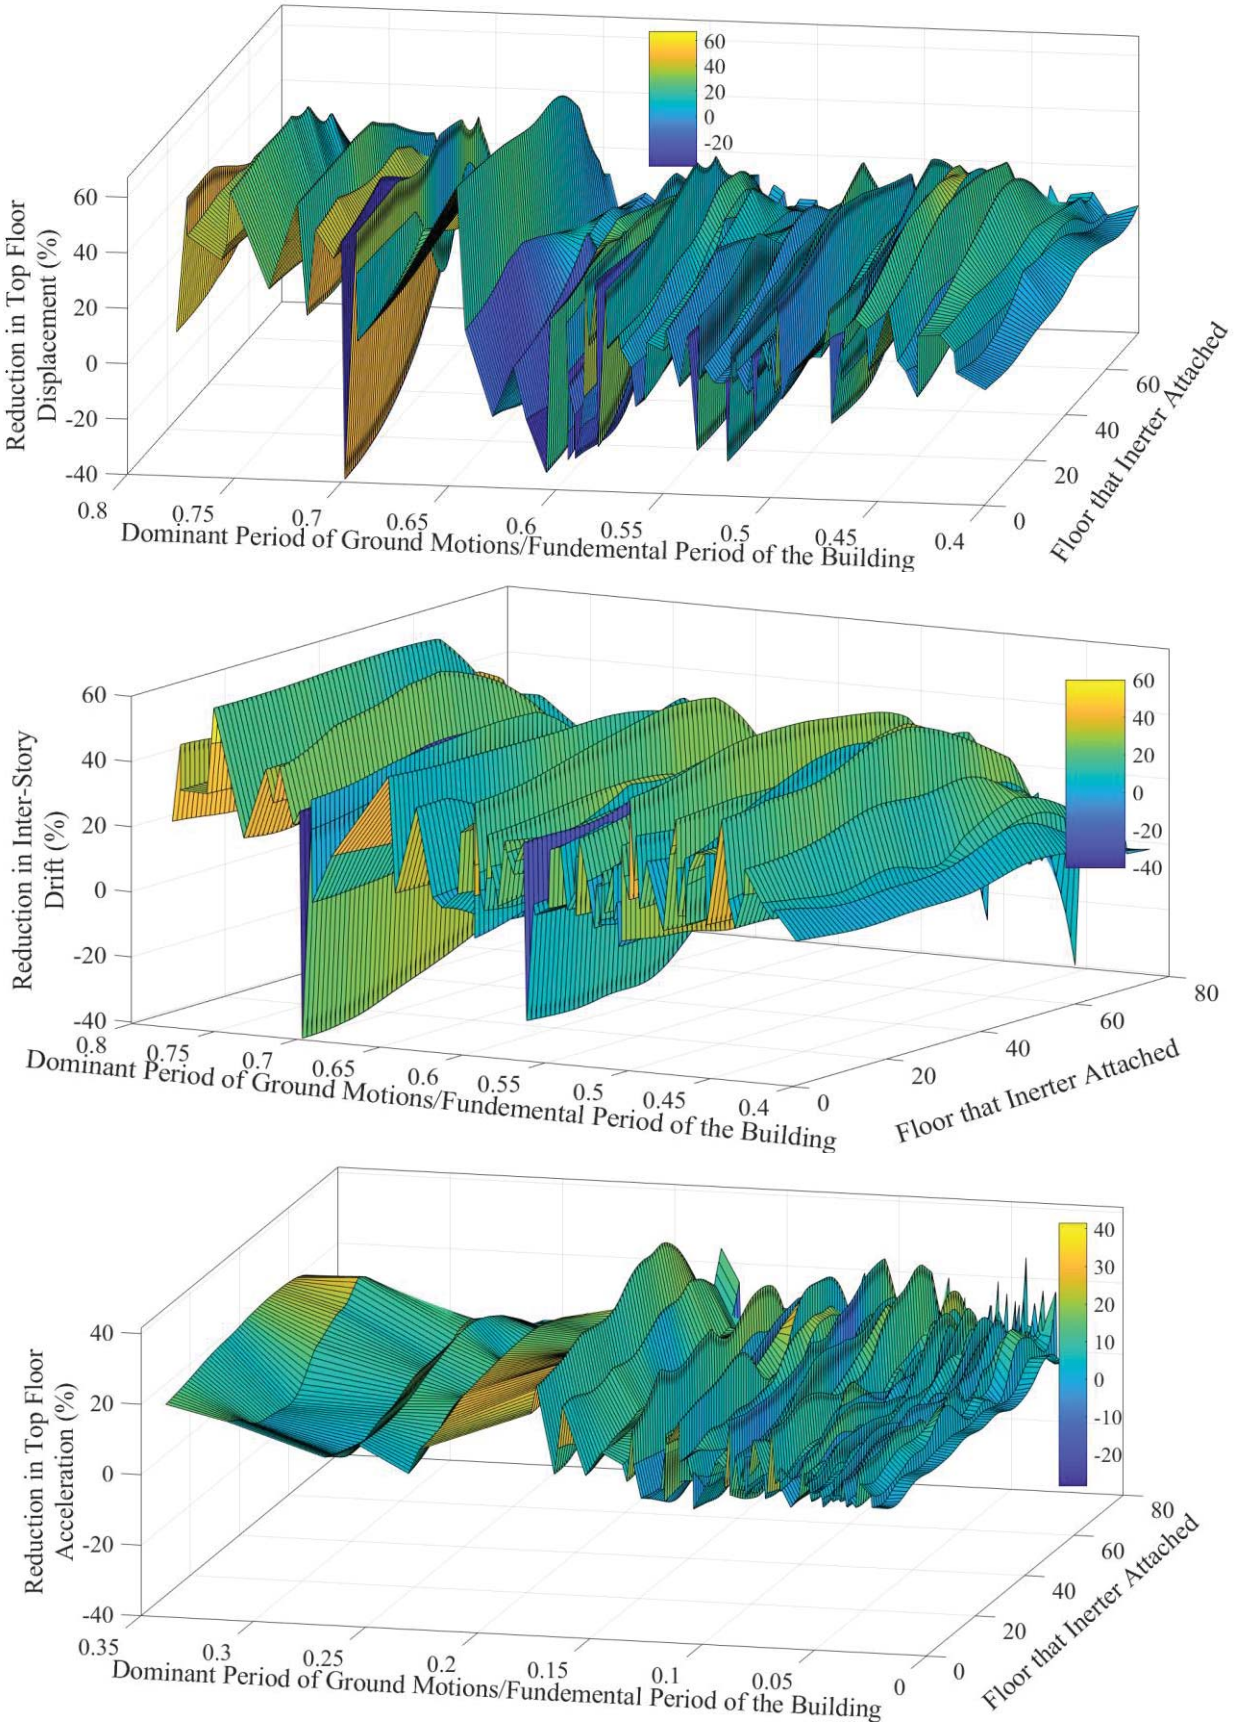

Figure 3: Response of the building equipped by a TMDi, inerter connected at different floors under earthquakes.

Optimal response in terms of interstory is attained by placing the inerter at floor number 63 and. These locations are, however, not optimal for controlling floor acceleration. Selection of the inerter floor for optimal control of floor acceleration results in poor performance in controlling displacement and interstory drift. It therefore seems that the optimal location depends on the response parameter being controlled. In this study, floor number 65 is selected as the best location. Figure 3 shows that the performance of the device is greatly variable depending on the frequency content of ground motion (measured by its dominant period) and the location of the inerter. For a given ground motion, the response is fairly independent of the location of the inerter. However, the optimal location of the inerter is highly dependent on the ground motion. By maximizing the average displacement reduction across all the ground motions, floor 45 is selected as the optimal position in this study. It is, however, important to note that the designer/analyst might choose other criteria for such optimization. Other options such as optimization for the worst-case ground motion, or scenario hazard at a given site might be selected based on the performance requirements of the building. Comparative study between TMD and TMDi

In this section the performance of the TMD and TMDi are compared. Figure 4 shows the response of the NC and building equipped with a TMD and TMDi to winds of different velocities. The peak response corresponding to the largest wind velocity and different locations of the inerters is shown in the inset plots. The response shown in the main plots correspond to the inerter device connected at floor 65. It is observed that the TMDIs provide slightly better response reduction that the TMDs. For the largest wind velocity considered here, which is 66 m/s, displacement response at the top of the building is reduced by 32% and 42%, respectively by the TMD and TMDI.

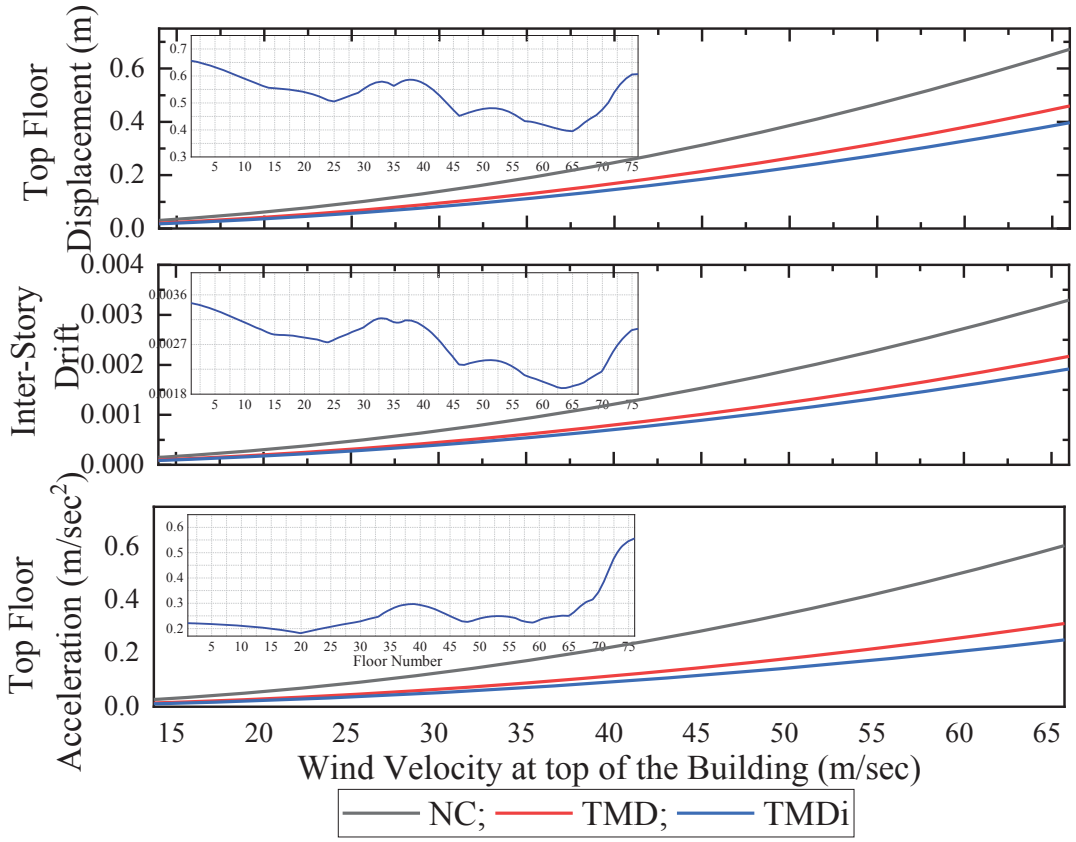

Figure 4: Response of the NC and building equipped by a TMD and TMDi, inerter connected at different floors under wind forces.

In case of earthquakes the response reduction is highly dependent on earthquake ground motion. The plots in the left panel show response reduction as a function of the ratio dominant period of ground motion to the fundamental period of the building. For each ground motion, the maximum reduction achieved by varying the location of the inerter is shown with the grey line while the blue line corresponds to the inerter placed at floor 45. The results show that the maximum reduction is not very different from the reduction obtained by placing the inerter at floor 45. It is also noticed that the TMDi provides very good response reduction while the TMDs are mostly ineffective. It is also interesting to note that the performance of the TMDi is highly dependent on the frequency content of the ground motion. The plots in the right panel of Figure 5 show the variation in response reduction with the location of inerter when subjected to the ground motion against which the TMDi is the most effective. The results show that response reduction is fairly independent of the inerter location up to floor number 55-60, but installing the inerter at higher floors reduces the effectiveness significantly. The overall results show that placement of the inerter is more critical for wind forces than seismic excitation for this building. Some practical issues for connection of inerter is provided by Giaralis and Petrini [18]. However, optimal location of the inerter and the practical difficulties associated in their installation requires further investigation.

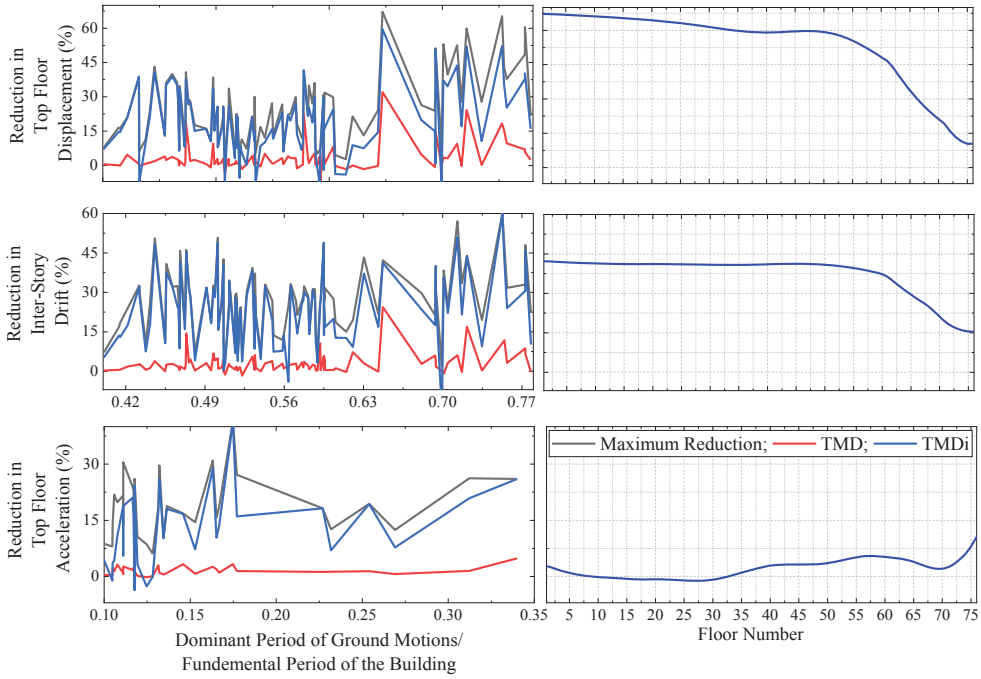

Figure 5: Response of the NC and building equipped by a TMD and TMDi, inerter connected at different floors under earthquakes.

4 CONCLUSIONS

The following conclusions can be made from the results presented in this study.

- Lower floors are not necessarily better for the location of inerter devices used to control wind-induced response of tall buildings like the one studied here. The optimal floor for the inerter depends on the response parameter to be controlled, especially when the wind velocity is high. Therefore, optimal location is expected to be structure and excitation dependent.

- The performance of TMDi when subjected to ground motion is highly dependent on the frequency content of ground motion. An optimal inerter location for one ground motion might be adverse for another ground motion. In this sense, the optimal location for seismic excitation is more critical than that for wind excitation. However, for a given ground motion, the optimal location is not very variable across the height of the building, as long as it is not near the top of the building. In this respect, optimal location of the inerter needs to consider frequency content of expected ground motion based on the site-specific seismic hazard. As the frequency content of ground motion changes with earthquake magnitude, a performance-based framework seems essential for optimizing TMDi devices for seismic response control.
- TMDIs provide much better response control seismic response of this building than TMD.
- Optimal parameters and locations of inerters for controlling response to different types of environmental actions might be different, and a more rigorous procedure for multi-hazard scenarios needs to be developed.

Keywords: Vibration transmission, Inerter, Vibration power flow, Force transmissibility

Abstract. *This paper investigates the dynamic characteristics and vibration transmission behaviour of harmonically forced oscillators coupled via an inerter-based joint. The inerter is a recently proposed passive mechanical element that can be used for vibration suppression purpose. The coupled oscillators represent simplified models for the dominant modes of engineering structures such as beams and plates, while the inerter-based joint serves as the vibration transmission path between the two subsystems. The effects of the inerter on the level of vibration transmission are examined for enhanced design of suppression devices. The steady-state dynamic responses of the oscillators and vibration power flow between them are derived analytically. Vibration transmission between the two subsystems is evaluated by both the force transmissibility and time-averaged vibration power flow transmission. It is shown that the use of the inerter in the joint can reduce force and vibration power flow transmission over a large band of excitation frequencies. It is found that the addition of the inerter can also introduce anti-resonances in the frequency-response curves and in the curves of the force transmissibility, where the vibration transmission can be suppressed at specific excitation frequencies. It is shown that force transmissibility reduces at low frequencies and tends to an asymptotic value as the excitation frequency decreases. These findings provide a better understanding of the effects of inerters in the joint on vibration transmission and benefit future designs of mechanical joints of coupled structures for vibration mitigation purpose.*

1 INTRODUCTION

There has been a growing demand for high performance vibration control devices that change the vibration transmission behaviour of dynamical systems to meet specific requirements [1]. Some work considers the use of metamaterials for vibration suppression purpose [2-6]. Recently, a passive mechanical element, the inerter, which can be used to provide inertial coupling such as to modify the dynamic behaviour was proposed [7]. The forces applied to the two terminals of the inerter are proportional to the relative accelerations of the two ends, i.e., $F_b = b(\dot{V}_1 - \dot{V}_2)$, where F_b is the coupling inertial force, b is an intrinsic parameter of the inerter named inertance, $\dot{V}_1$ and $\dot{V}_2$ are the accelerations of the two terminals. Since the introduction of the inerter concept, it has been applied to aircraft landing gear shimmy suppression [8], vehicle suspension systems [9] and building vibration control system [10]. Some studies have also been reported on the performance of inerter-based single degree-of-freedom (DOF) vibration isolators [11], dual-stage isolator [12] and nonlinear inerter-based isolator [13].

In many mechanical systems and engineering structures, subsystems are connected via mechanical or structural joints, the design of which is important to reduce vibration transmission between different parts of the integrated system. For the evaluation of vibration transmission level, the force transmissibility and time-averaged vibration power flow quantities may be used. Vibration power flow analysis (PFA) method is a widely accepted tool to characterize the dynamic behaviour of coupled systems and complex structures [14]. Various PFA approaches have been developed to investigate linear vibration control systems. The power flow characteristics of single-DOF inerter-based isolators [11] and two-DOF inerter-based isolators [12] were also investigated. In recent years, this dynamic analysis approach has been developed to investigate vibration power flow in nonlinear vibration isolation systems [15], in oscillators coupled with a nonlinear interface[16], in coupled nonlinear oscillators [17], nonlinear systems with bilinear stiffness and bilinear damping [18] and in impact oscillator systems [19]. It is accordingly beneficial to examine the effects of inerters from a vibration power flow viewpoint for enhanced designs of inerter-based vibration suppression systems.

This paper investigates the influence of introducing the inerter to a mechanical joint on vibration transmission between coupled oscillators. The steady-state response amplitude, force transmissibility and vibration power flow quantities are obtained. The remaining content of the paper is organized as follows. In Section 2, the coupled oscillator system will be briefly introduced and modelled. Then the force transmissibility of the system will be derived in Section 3. The vibration power flow variables and maximum kinetic energies of the system will be formulated in Section 4. Conclusions are drawn in at the end of the paper.

2 THE COUPLING OSCILLATORS MODEL

In this section, the effects of including an inerter in the joint of coupled oscillators on the dynamics and vibration transmission behaviour are investigated. Figure 1 provides a schematic presentation of the model comprising two subsystems coupled with a mechanical joint characterized by an inerter with inertance b and a spring with stiffness coefficient k_0. Subsystem one is a single-DOF system consisting of a mass m_1 subject to an external harmonic excitation of amplitude f_0 with frequency ω, a viscous damper of damping coefficient c_1, and a linear spring with stiffness coefficient k_1. Subsystem two is another single-DOF system having mass m_2, a viscous damper with damping coefficient c_2, and a linear spring with stiffness coefficient k_2. It is assumed that the masses both move horizontally without frictions and their static equilibrium positions, where $x_1 = x_2 = 0$ and the springs are unstretched, are taking as the reference. The dynamic governing equations of the system could be written as

$$m_1\ddot{x}_1 + c_1\dot{x}_1 + k_1x_1 + f_b + k_0(x_1 - x_2) = f_0e^{i\omega t}, \tag{1a}$$

$$m_2\ddot{x}_2 + c_2\dot{x}_2 + k_2x_2 - f_b - k_0(x_1 - x_2) = 0, \tag{1b}$$

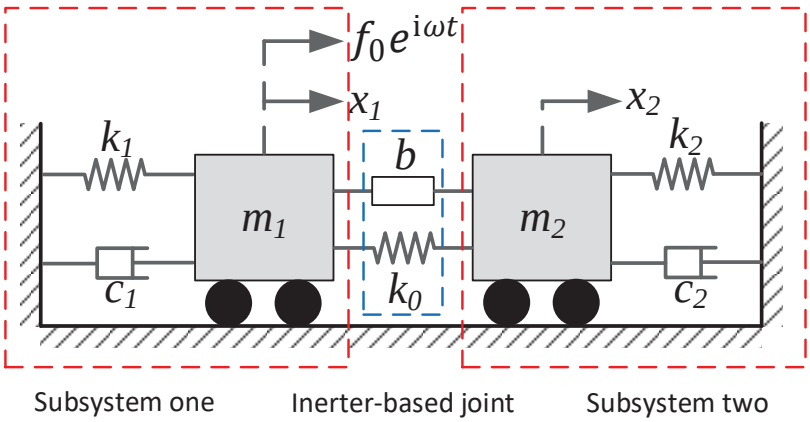

Figure 1: A schematic representation of the coupled oscillator coupled with an inerter-based joint.

where $f_b = b(\ddot{x}_1 - \ddot{x}_2)$, m_i, c_i and k_i $(i = 1, 2)$ are the masses, damping coefficients and spring stiffness coefficients respectively. $x_i, \dot{x}_i$ and $\ddot{x}_i$ $(i = 1, 2)$ represent the displacements, velocities and accelerations respectively. To facilitate later derivations of the response and vibration transmission, the following parameters are introduced

$$\omega_1 = \sqrt{\frac{k_1}{m_1}}, \omega_2 = \sqrt{\frac{k_2}{m_2}}, \mu = \frac{m_2}{m_1}, l_0 = \frac{m_1 g}{k_1}, X_1 = \frac{x_1}{l_0}, X_2 = \frac{x_2}{l_0}, \gamma = \frac{k_2}{k_1}, \delta = \frac{k_0}{k_1},$$

$$\xi_1 = \frac{c_1}{2m_1\omega_1}, \xi_2 = \frac{c_2}{2m_2\omega_2}, \lambda = \frac{b}{m_1}, F_0 = \frac{f_0}{k_1 l_0}, \Omega = \frac{\omega}{\omega_1}, \tau = \omega_1 t,$$

where ω_1 and ω_2 are the undamped natural frequencies of thee subsystems one and two, μ is the mass ratio, l_0 is the characteristic length, X_1 and X_2 are the nondimensional displacements of m_1 and m_2, γ is stiffness ratio of the springs, ξ_1 and ξ_2 are damping ratios, λ is nondimensional inertance ratio, F_0 is nondimensional force amplitude, Ω is the dimensionless excitation frequency and τ is the dimensionless time. Thus, Eq. (1a) and (1b) can be rearranged into the following nondimensional form

$$X_1'' + 2\xi_1 X_1' + X_1 + F_b + \delta(X_1 - X_2) = F_0e^{i\Omega\tau}, \tag{2a}$$

$$X_2'' + 2\xi_2 X_2' + X_2 - \frac{1}{\gamma}F_b - \frac{\delta}{\gamma}(X_1 - X_2) = 0, \tag{2b}$$

where $F_b = \lambda(X_1'' - X_2'')$. By introducing $X_1 = X_0e^{i\Omega\tau}, X_2 = Y_0e^{i\Omega\tau}$, Eq. (2) can be transformed as

$$-\Omega^2 X_0 + 2\xi_1 X_0 i\Omega + X_0 + \lambda(\Omega^2 Y_0 - \Omega^2 X_0) + \delta(X_0 - Y_0) = F_0, \tag{3a}$$

$$-\Omega^2\gamma Y_0 + 2\xi_2\gamma Y_0 i\Omega + \gamma Y_0 - \lambda(\Omega^2 Y_0 - \Omega^2 X_0) - \delta(X_0 - Y_0) = 0. \tag{3b}$$

The response amplitudes may be written in the non-dimensional form

$$Y_0 = \frac{\frac{\delta}{\gamma} - \frac{\lambda}{\gamma}\Omega^2}{1 + 2\xi_2 i\Omega - \Omega^2 - \frac{\lambda}{\gamma}\Omega^2 + \frac{\delta}{\gamma}} X_0, \tag{4a}$$

$$X_0 = \frac{F_0}{1+2\xi_1 \mathrm{i}\Omega-\Omega^2-\frac{1+2\xi_2 \mathrm{i}\Omega-\Omega^2}{1+2\xi_2 \mathrm{i}\Omega-\Omega^2-\frac{\lambda}{\gamma}\Omega^2+\frac{\delta}{\gamma}}(\lambda\Omega^2-\delta)}. \tag{4b}$$

Figure 2 shows the influence of adding the inerter to the mechanical joint on the the response amplitudes of the oscillator masses. Four different values of inertance ratio with $\lambda = 0, 0.5, 1$ and 2 are selected and the corresponding results are shown by solid, dashed, dash-dot and dotted lines. The other parameters are set as $\xi_1 = \xi_2 = 0.02, \gamma = 1, \delta = 1, F_0 = 1$. In the figure, $X = |X_0|$ and $Y = |Y_0|$, denoting the response amplitudes of masses m_1 and m_2, respectively. When the inerter is not included in the joint, two resonant peaks are observed in each curve of X and Y, one of which moves to the lower frequency range with the increase of inertance ratio λ. However, the other peak remains at the same frequency when the inertance ratio λ changes. The anti-peak in Figure 2(a) also moves to low frequency range with the increase of inertance ratio λ. When $\lambda = 1$, two peaks in Figure 2(a) become close with an anti-peak at $\Omega \approx 1$, which indicates the benefit of using inerter for vibration suppression at high frequencies. In Figure 2(b), the addition of inerter introduces an anti-peak in each curve, which can be used to reduce vibration level of mass m_2 at a prescribed excitation frequency.

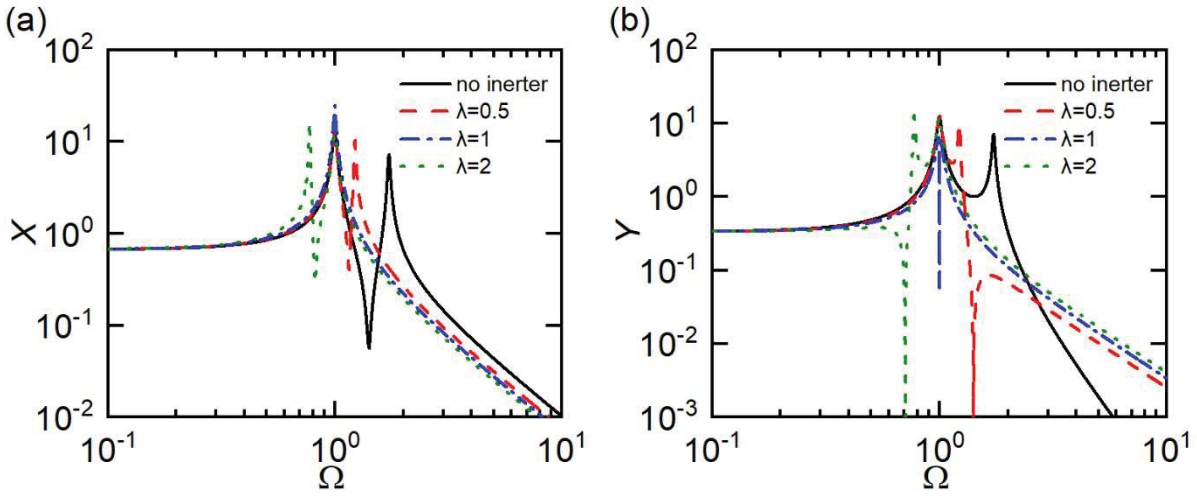

Figure 2: Response amplitude of (a) mass m_1 and (b) mass m_2 ($\xi_1 = \xi_2 = 0.02, \gamma = \delta = F_0 = 1$).

3 FORCE TRANSMISSIBILITY

The force transmissibility has been widely used to evaluate the level of vibration transmission between different subsystems of an integrated structure. It is used here to access the performance of inerter-based mechanical joint in reducing the force transmission. For the current system, the force transmitted to the second mass can be expressed as

$$F_t = F_b + \delta(X_1 - X_2) = \lambda(X_1'' - X_2'') + \delta(X_1 - X_2) = F_{t0}e^{\mathrm{i}\Omega\tau}. \tag{5}$$

As the fore transmissibility is defined as the ratio between the amplitude of the transmitted force and that of the external force, we have

$$TR = \left|\frac{F_{t0}}{F_0}\right| = \left|\frac{\delta-\lambda\Omega^2}{F_0}(X_0 - Y_0)\right|. \tag{6}$$

Figure 3 shows the force transmissibility characteristics of the system with parameters set as $\xi_1 = \xi_2 = 0.02, \gamma = \delta = F_0 = 1$. The figure shows that the use of inerter introduces an anti-peak in each curve, which moves to lower frequency range with the increase of the inertance ratio λ. Figure 3 shows that with the use of inerter in the joint, the force transmissibility TR

remains smaller than 1 in a large range of excitation frequencies. This characteristic can be used to reduce the transmitted force at low excitation frequencies.

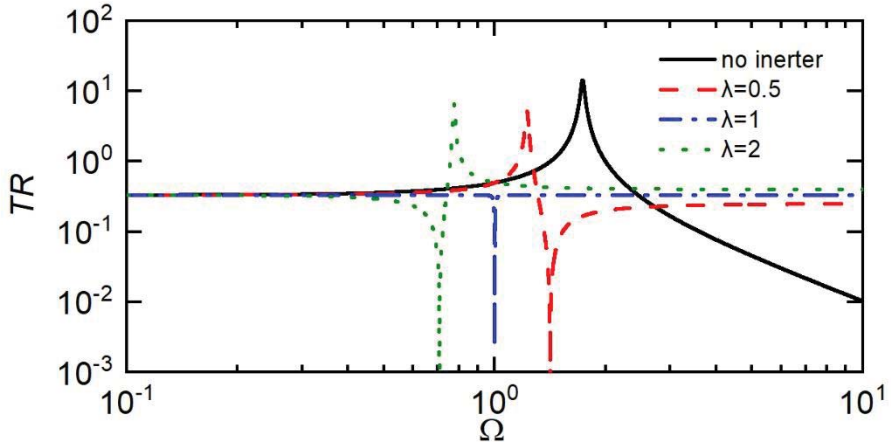

Figure 3: Force transmissibility between oscillators coupled with an inerter-based joint ($\xi_1 = \xi_2 = 0.02, \gamma = \delta = F_0 = 1$).

4 VIBRATION POWER FLOW ANALYSIS

In this section, the vibration transmission behaviour of the inerter-based coupled oscillator system is examined from the perspective of vibration power and energy. The non-dimensional instantaneous input power of the system is the product of the excitation force and the corresponding velocity of the mass

$$P_{in} = F_0 e^{\mathrm{i}\Omega\tau} X_1', \tag{7}$$

where X_1' is the non-dimensional velocity of the mass m_1, which can be expressed as

$$X_1' = \mathrm{i}\Omega X_0 e^{\mathrm{i}\Omega\tau}. \tag{8}$$

Thus, the non-dimensional steady-state time-averaged input power over an excitation cycle is

$$\bar{P}_{in} = \frac{1}{T}\int_{\tau_0}^{\tau_0+T} P_{in}\,\mathrm{d}\tau = \frac{1}{2}\mathrm{Re}\{F_0{}^* X_0 \mathrm{i}\Omega\}, \tag{9}$$

where Re indicates the real part of a complex value and * denotes the complex conjugate. Based on Eq. (4b), the input power for the system can be expressed as

$$\bar{P}_{in} = \frac{1}{2}|F_0^2|\mathrm{Re}\left\{\frac{\mathrm{i}\Omega}{1+2\xi_1\mathrm{i}\Omega-\Omega^2-\frac{1+2\xi_2\mathrm{i}\Omega-\Omega^2}{1+2\xi_2\mathrm{i}\Omega-\Omega^2-\frac{\lambda}{\gamma}\Omega^2+\frac{\delta}{\gamma}}(\lambda\Omega^2-\delta)}\right\}. \tag{10}$$

The corresponding time-averaged transmitted power $\bar{P}_t$ to mass m_2 is

$$\bar{P}_t = \frac{1}{T}\int_{\tau_0}^{\tau_0+T} P_t\,\mathrm{d}\tau = \frac{1}{2}\mathrm{Re}\{F_{t0}{}^* Y_0 \mathrm{i}\Omega\}, \tag{11}$$

The power transmission ratio R_t to mass m_2 may be defined as the ratio between the time-averaged transmitted power $\bar{P}_t$ and the time-averaged input power $\bar{P}_{in}$

$$R_t = \frac{\bar{P}_t}{\bar{P}_{in}}. \tag{12}$$

As the velocity amplitude of mass m_1 in the steady-state motion is $X\Omega$, the non-dimensional maximum kinetic energy of mass m_1 in the steady-state motion is

$$K_{max} = \frac{1}{2}X^2\Omega^2. \tag{13}$$

Based on those formulas, Figure 4 investigates the effects of introducing an inerter-based coupled oscillator on the power flow behaviour. The system parameter values are set as $\xi_1 = \xi_2 = 0.02, \gamma = \delta = F_0 = 1$, the same as those used in Figure 2. Two peaks can be observed in each curve of $\bar{P}_{in}$ and $\bar{P}_t$, Figure 4(a) shows that the use of inerter moves the second peak of $\bar{P}_{in}$ to the low-frequency range with the increase of inertance ratio λ, but corresponding peak value changes little. The first peak frequency and value of $\bar{P}_{in}$ remain almost the same despite of the variations of the inertance ratio λ. The effect of inerter on the time-averaged input power $\bar{P}_{in}$ is relatively small at low and high excitation frequencies. Figure 4(b) shows that the addition of inerter introduces an anti-peak in the curve of time-averaged transmitted power $\bar{P}_t$. The first peak in $\bar{P}_t$ is little affected by the changes of λ. The second peak of $\bar{P}_t$ moves to low frequency range with the increase of inertance ratio λ, but the corresponding peak value remains almost the same. Figure 4(c) plots the variations of the maximum kinetic energy of mass m_1. It shows that for the mechanical joint with inerter, the anti-peak as well as the second peak in the curve without inerter move to the low-frequency range. When $\lambda = 1$, two peaks and one anti-peak merge together as one peak with a higher peak value. This indicates the system in this case is beneficial at high frequencies. The effect of the inerter is little when the frequency is low.

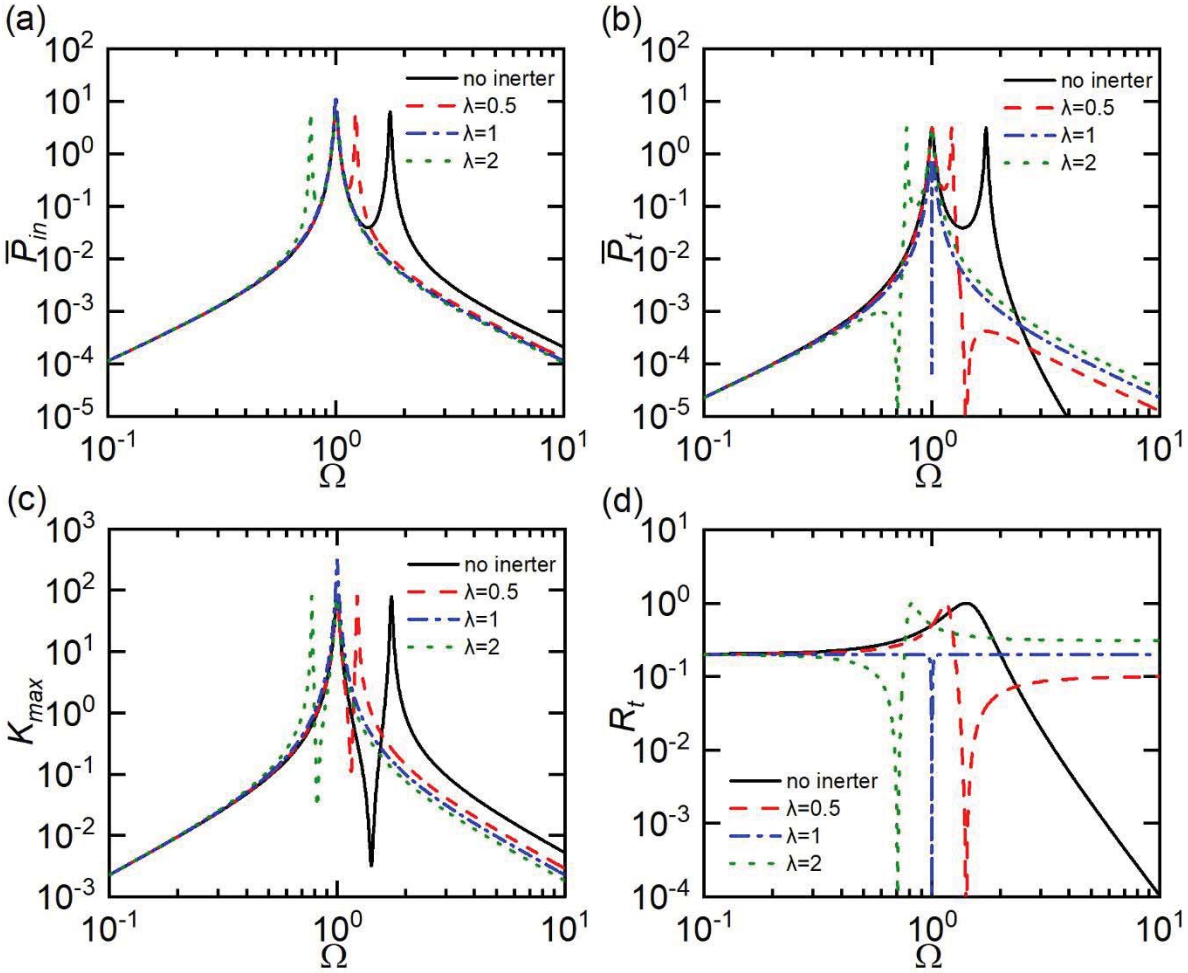

Figure 4: Power flow behaviour of oscillators coupled with an inerter. (a) Time-averaged input power (b) time-averaged transmitted power (c) maximum kinetic energy and (d) power transmission ratio

Figure 4(d) illustrates the influence of inerter in the joint on vibration transmission in terms of the power transmission ratio R_t. An anti-peak is introduced in the curve of R_t, and the peak of the curve moves to the low-frequency range with the increase of inertance ratio λ. When $\lambda = 1$, there is a local minimum point. This characteristic shows the benefits of adding the inerter to the joint at specific excitation frequencies. When Ω is small, the effect of inerter is little, and there is an increase of power transmission ratio R_t with the increase of inertance ratio λ in high frequency range.

5 CONCLUSIONS

The dynamics and performance of an inerter-based mechanical joint between coupled oscillators were investigated in this paper. The force transmissibility and vibration power flow characteristics of the system were examined to evaluate the effects of the inclusion of inerter on the suppression of vibration transmission. It was shown that a larger inertance value leads to a shift of response peaks of the two masses to the low-frequency range. Adding the inerter to the joint results in increases in the force transmission at high excitation frequencies but less time-averaged input power and lower maximum kinetic energy of one of the subsystems. It was found that the inclusion of inerters can provide benefits to vibration mitigation by creating a large frequency band where the force transmissibility and power transmission ratio are relatively low. By properly setting the inertance value, anti-peaks may be created in curves of force transmissibility and power transmission ratio so that their values can be substantially reduced. Based on this property, vibration transmission between the two coupled oscillators can be greatly suppressed at pre-determined excitation frequencies. Asymptotic behaviour of force transmission and power transmission was found when the excitation frequency extends to high frequencies.

Abstract. *Recent studies on seismic control of rocking structures have proposed the use of inerters, mechanical devices that develop resisting forces proportional to the relative acceleration between their terminals. Analytical analyses have shown that these devices effectively reduce the frequency parameter of a rocking block resulting in lower seismic demands and enhanced stability due to the well-known size effect of the rocking behaviour. As with most of such strategies, the efficiency of the inerter has been assessed for perfectly rigid bodies in the first place. However, in real practical applications, rocking structures will exhibit some degree of flexibility. Moreover, some of the underlying assumptions of the analytical models used to study rigid bodies imply that the structures are slender, and therefore more likely to deform during the rocking motion. In this paper, the dynamic response of multi-mass flexible rocking bodies equipped with inerters is examined. Firstly, a numerical model is formulated and implemented in OpenSees. This model is then validated against analytical analyses of single-mass flexible structures. Subsequently, the responses of buildings ranging from 3 to 9 stories are studied and compared in terms of elastic deformations, base rotations and floor accelerations. The effect of increasing levels of flexibility in the efficiency of the inerter is also assessed.*

1 INTRODUCTION

The uplifting and rocking of free-standing structures can significantly reduce the seismic shear and moment demands at their base [1]. During the last decades, this concept has been widely studied and applied to the protection of earthquake resistant structures [2, 3]. While allowing the base to rock can help to control structural damage by reducing deformations, previous studies suggest that it can also induce higher inter-storey drifts that may be associated with unacceptable non-structural damage [4].

Seismic control systems for rocking structures have been mainly oriented to the protection of museum artefacts and non-structural equipment. Early strategies were based on simple measures, such as lowering the centre of mass or anchoring the object to a fixed support, and are usually not practical [5]. On the other hand, traditional strategies used in building structures, such as base isolation, have been shown not to be effective for a wide range of rocking structures [6]. In this context, recent studies have proposed the use of inerters, mechanical devices that develop resisting forces proportional to the relative acceleration between their terminals. This strategy effectively reduces the frequency parameter of a rocking block leading to lower seismic demands and enhanced stability due to the well-known size effect of the rocking behaviour [7]. As with most of such strategies, the efficiency of the inerter has only been assessed for perfectly rigid bodies. However, in real building applications, rocking structures will exhibit some degree of flexibility. Moreover, some of the underlying assumptions of the analytical models used to study rigid bodies imply that the structures are slender, and therefore more likely to deform during the rocking motion.

In this paper, the dynamic response of multi-mass flexible rocking bodies equipped with inerters is studied considering configurations representative of real building structures. Firstly, a numerical model for the rocking structure-inerter system is formulated and implemented in OpenSees [8]. This model is then validated against analytical responses of single-mass flexible structures. Subsequently, the dynamic response of three buildings ranging from 2 to 9 stories subjected to acceleration pulses is studied and compared in terms of elastic deformations, base rotations and floor accelerations. The effect of increasing levels of flexibility on the efficiency of the protective system is also assessed.

2 DEFINITION OF THE NUMERICAL MODELS

2.1 Model parameters

The dynamic response of multi-mass rocking structures equipped with inerters can be studied considering the system illustrated in Figure 1a. In this model, the rocking body is represented by n lumped masses, m_i, connected by elastic beam-column elements of flexural stiffness EI_i, and supported by a rigid base allowed to uplift. Two degrees of freedom per level are considered, namely, lateral displacement and rotation. The geometry of the structure is characterized by the radial distance between the pivot points and the masses, R_i, and the corresponding slenderness, α_i. Accordingly, the frequency parameter of the multi-mass structure can be defined as [9]:

$$p_n = \sqrt{\frac{\underline{1}^t[M]\underline{H}\,g}{J_p}} \tag{1}$$

where [M] corresponds to the mass matrix, $\underline{H}$ to the heights vector and J_p is the rotational

inertia of the system obtained as:

$$J_p = \underline{R}^t \, [M] \, \underline{R} \tag{2}$$

where $\underline{R}$ is the radial distances vector. Finally, a grounded inerter of inertance $m_{r,1}$ is connected to the horizontal displacement of the first level mass. The apparent mass ratio is defined as $\sigma = m_r / \sum_{n=1}^{n_{levels}} m_i$.

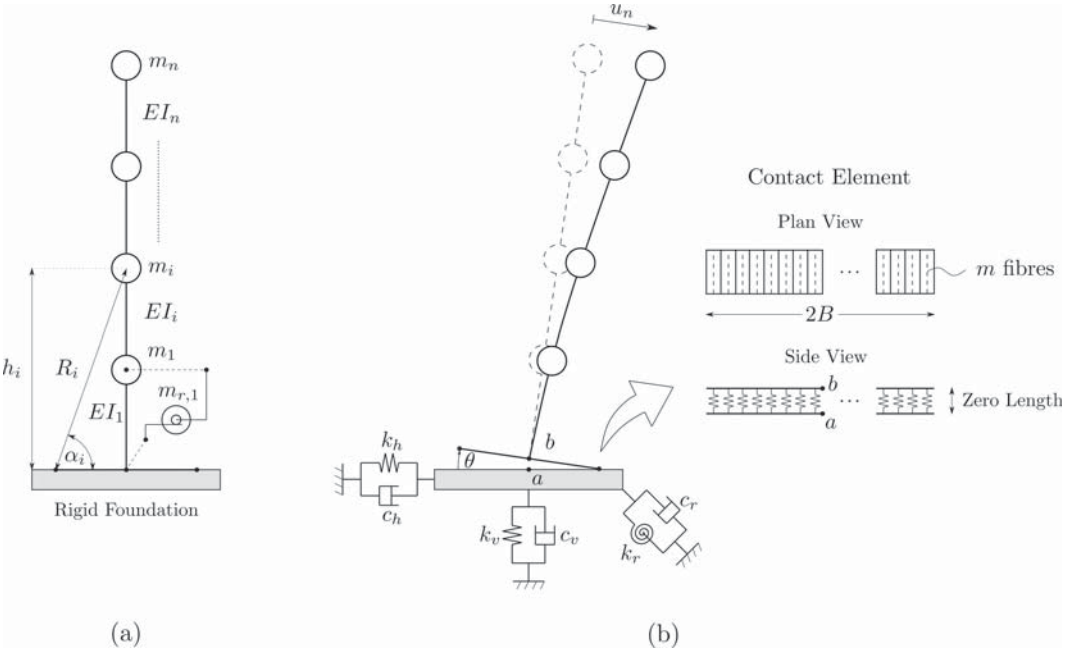

Figure 1: Schematic diagram of the numerical model of the rocking structure-inerter system.

2.2 Numerical model of the rocking structure

The modelling strategy adopted in this study is based on the finite element model for flexible rocking structures proposed by Vassiliou et al. [10]. The model, illustrated in Figure 1b, consists of 3 components: The deformable body, the rocking surface and the underlying soil. Linear-elastic beam-column elements are used to represent the flexible structure, whereas a zero-length element with 2048 sectional fibres is considered for the rocking surface. A non-dissipative compression-only material is assigned to the rocking section, so the system is free to rotate about the pivot points. Unless otherwise stated, the stiffness of the fibres is set at very high values in order to represent a rigid rocking surface. Energy loss during impact is incorporated by taking into account the energy radiated into the underlying ground. Accordingly, the soil underneath the rigid foundation is represented by a set of vertical, horizontal and rotational springs and dashpots whose mechanical properties are determined according to machine vibration theory [11]:

$$\begin{aligned} K &= k \, K_{st} \\ C &= c \, K_{st} \, \frac{R_f}{V_s} \end{aligned} \tag{3}$$

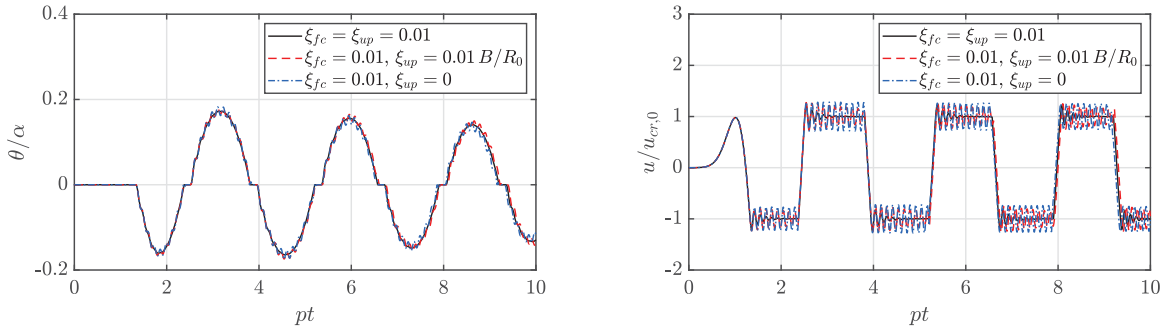
with

$$K_{st,v} = \frac{4 \, \rho \, V_s^2 \, R_f}{1 - \nu} \qquad K_{st,h} = \frac{8 \, \rho \, V_s^2 \, R_f}{2 - \nu} \qquad K_{st,r} = \frac{8 \, \rho \, V_s^2 \, R_f^3}{3(1 - \nu)} \tag{4}$$

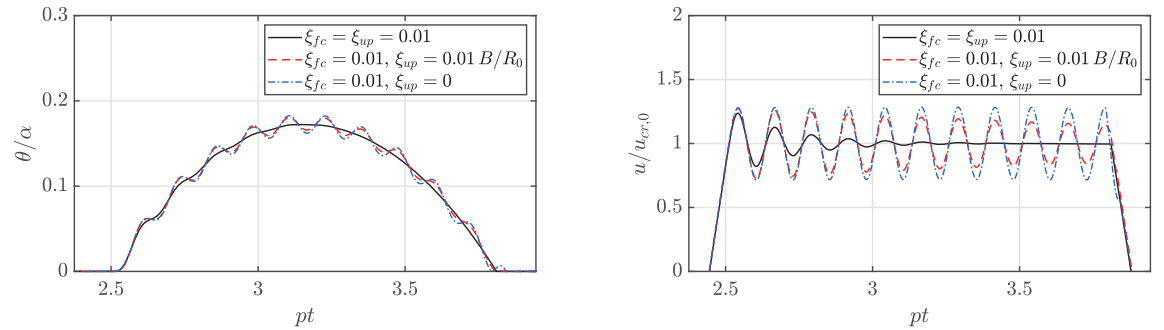
where K_{st} is the static stiffness, ρ, ν and V_s are the density, Poisson's ratio and shear wave velocity of the supporting soil, k and c are dynamic amplification factors given in [11], and R_f is the foundation's radius. The values of the dynamic amplification factors $k_v = k_h = k_r = 1$, $c_v = 0.75$, $c_h = 0.6$ and $c_r = 0$ are obtained considering a stiff soil of $V_s = 1000\,[m/s]$, $\rho = 2\,[ton/m^3]$ and $\nu = 0.3$. The foundation, on the other hand, is assumed to be circular with a radius of $R_f = 2B$.

2.2.1 Energy dissipation in the deformable structure

Several analytical and experimental studies have suggested that the addition of viscous damping to rocking models may lead to a significant overestimation of the energy dissipated in the uplifted state [1, 12, 13]. In order to address this shortcoming, a variable damping ratio is introduced to the model presented in the pevious section. Inherent structural damping during the full contact phase is modelled using Rayleigh's classical damping, assigning a prescribed damping ratio, ξ_{fc}, to the first and third vibration modes of the fixed base structure [14]. Once the base uplifts, the analysis is halted and the damping ratio is adjusted before continuing, so that the resultant uplifted damping agrees with experimental observations [13]. The effect of considering different levels of uplifted damping ratios in single-mass rocking oscillators is illustrated in Figure 2. For the first structure (black line), a constant damping ratio of $\xi_{fc} = \xi_{up} = 0.01$ is considered. In the second case (red line), the uplifted damping ratio is modified as outlined above so that the resultant damping corresponds to that of a 1% damped oscillator. In the final case (blue line), no damping is considered during the rocking phase (numerically very small).



(a) Rotation and deformation responses for different levels of damping ratio.



(b) Detailed view of the rotation and deformation responses during a rocking cycle.

Figure 2: Response of a single-mass rocking structure of $\omega_n/p = 5$, $\alpha = 0.1$, and different values of damping ratio, subjected to a single Ricker pulse of $\omega_g/p = 5$ and $a_g = 1.5\,g\tan\alpha$.

The results presented in Figure 2 confirm that the use of a constant damping ratio (black line) results in significantly higher dissipative forces which quickly attenuate the oscillations in the uplifted state. This, in turn, leads to a smother and slightly lower rotation response, as it can be observed in the detailed view of Figure 2b. On the other hand, the difference between the maximum responses of the small damping ($\xi_{up} = 0.01B/R_0$) and no damping cases ($\xi_{up} = 0$) is not significant. Consequently, a conservative assumption of no damping during the rocking phase is adopted in this study, unless otherwise stated.

2.2.2 Validation of the structural model

The structural model described in the previous section is implemented in the open-source finite element framework OpenSees [8] and validated against experimental data published in [13]. Based on this experimental evidence, a variable damping ratio is consider for the models, so that the resultant uplifted damping matches the one of the full contact phase (red line case in Figure 2). Four single-mass rocking oscillators of natural frequencies ranging from 1[Hz] to 4[Hz] are selected for the validation process. The properties of the structures are summarized in Table 1. For further details about the specimens and the experimental program, the reader is referred to [13].

Specimen	f_{fix} $[Hz]$	ξ $[\%]$	α $[rad]$	p $[Hz]$
1 Hz Long Base	0.94	0.26	0.159	3.22
2 Hz Long Base	2.07	0.28	0.160	3.23
3 Hz Short Base	3.12	0.35	0.081	3.25
4 Hz Long Base	3.84	1.32	0.081	3.24

Table 1: Description of the single-mass rocking specimens selected for the validation process (Truniger et al. [13]).

Figure 3 compares the predicted and measured rotation and elastic deformation responses of the specimens when subjected to single-pulse ground motions. One of the main difficulties in the prediction of rocking time history responses is related to the fact that small errors in the rotation amplitude lead to accumulative errors in the phase. This situation can be clearly observed in the 1[Hz], 2[Hz] and 4[Hz] specimens. Nevertheless, very good agreement is observed in the amplitude of the base rotation for the whole range of flexibilities under consideration. On the other hand, accurate predictions of the maximum elastic deformation response are also obtained for the more flexible oscillators, however, results show that the numerical model tends to overestimate the deformation as the structures become more rigid.

(d) 4 [Hz] Long Base (Test 52)

Figure 3: Comparison of the OpenSees numerical model with experimental results from Truniger et al. [13]

2.3 Numerical model of the inerter

In this section, a numerical model for the inerter is presented and validated against theoretical results. The proposed model, schematized in Figure 4, consists of two nodes connected through a rigid link, and an angular mass, J, assigned to the rotational degree of freedom of the system.

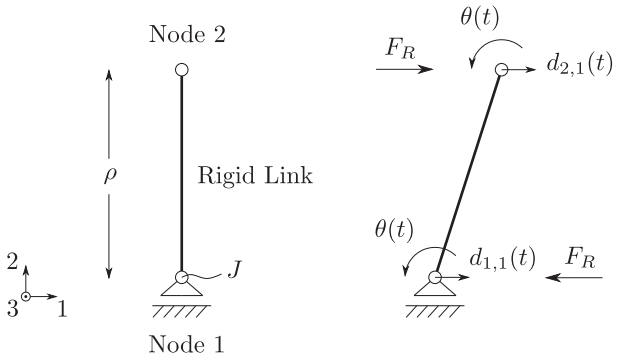

Figure 4: Schematic diagram of the numerical model of the inerter

The relative lateral displacement between the nodes is transformed into a rotation in Node 1 through a rigid link. Since a linear geometric transformation is considered for the link element, the relative displacement and rotation of the system are related according to:

$$d_r = d_{2,1}(t) - d_{1,1}(t) = -\rho\theta \tag{5}$$

The force couple required to impose this relative displacement, $F_R(t)$, can then be obtained evaluating the rotational equilibrium about Node 1:

$$F_R(t) = \frac{J\,\ddot{d}_r(t)}{\rho^2} = m_r\,\ddot{d}_r(t) \tag{6}$$

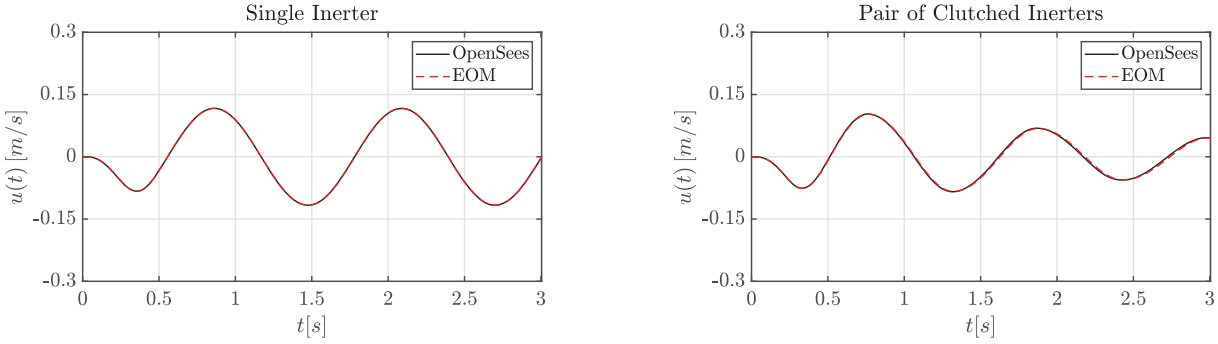
Therefore the reactive force developed by the model is proportional to the horizontal relative acceleration between Node 1 and Node 2. The parameters of the model, J and ρ, are then defined in terms of the inertance, m_r, according to Equation 6.

When the structure-inerter system is subjected to a ground excitation, part of the energy is transferred to the inerter and accumulated as angular momentum. As the translating mass of the structure tends to move slower, the rotating flywheels might drive the mass and induce undesirable deformations. Makris et al. [15] proposed the use of a clutch mechanism in order to ensure the system can only resist the motion of the structure. As a clutch-inerter device can only oppose one sense of motion, a parallel pair of inerters is necessary for this configuration. Additionally, a dissipative mechanism is needed to decelerate the flywheels once disengaged. The sequential engagement of the two parallel inerters that can only resist the motion is modelled redefining the rotational mass, J, after each time step according to:

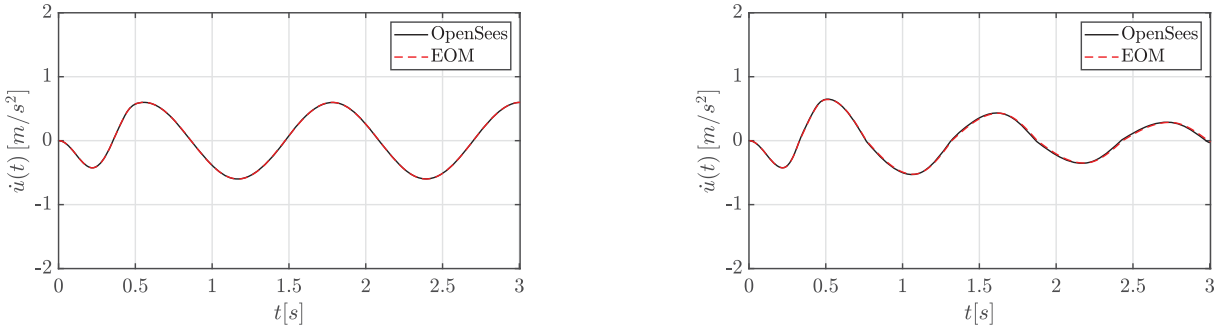
$$F_R(t) = \begin{cases} m_r\,\ddot{d}_r, & \left[\frac{\ddot{d}_r}{\dot{d}_r}\right] > 0 \\ 0, & \left[\frac{\ddot{d}_r}{\dot{d}_r}\right] < 0 \end{cases} \tag{7}$$

2.3.1 Validation of the inerter model

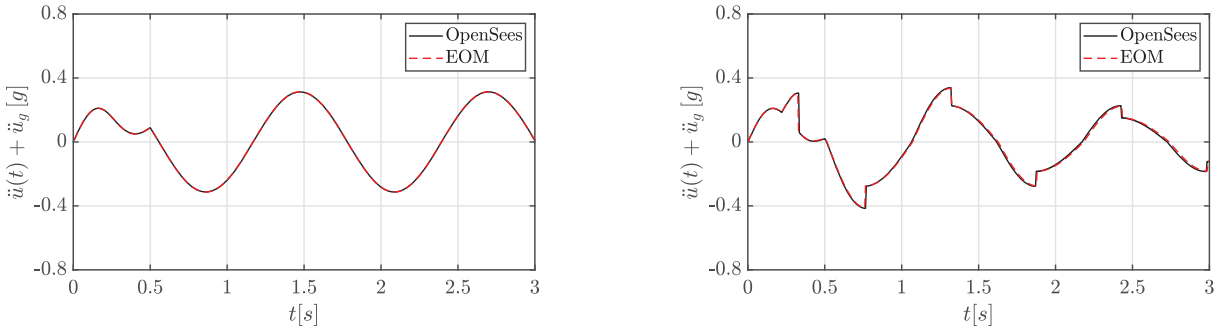
The proposed numerical model was implemented in OpenSees [8] and validated against the analytical model developed by Makris et al [15]. The responses obtained with the numerical model and the corresponding solution of the equation of motion for a SDOF structure of period $T = 1[s]$ and $\sigma = 0.5$, subjected to a single sinusoidal pulse, are presented in Figure 5.



(a) Displacement response.



(b) Velocity response.



(c) Absolute acceleration response.

Figure 5: Comparison of the inerter numerical model and the solution of the equation of motion for a SDOF structure equipped with inerters of $\sigma = 0.5$, subjected to a single sine pulse of $T_0/T_g = 2$ and acceleration amplitue $a_g = 0.5[g]$.

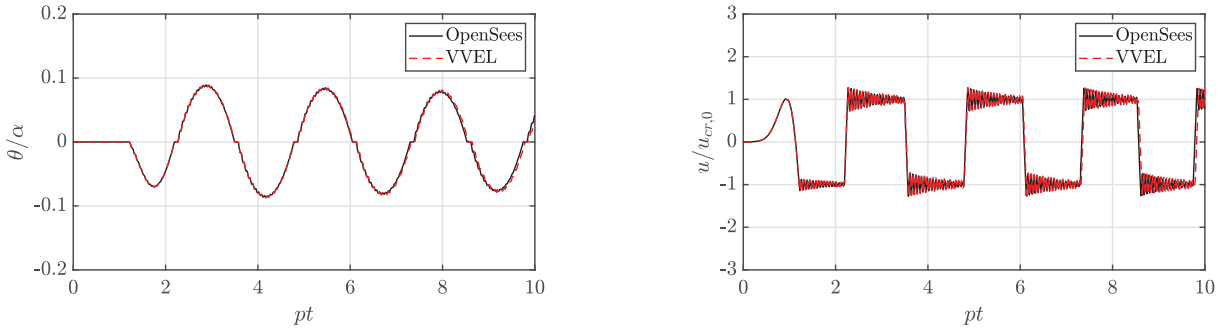
2.4 Validation of the rocking structure-inerter model

As a final validation, the numerical models described in the previous sections are combined and compared with the analytical model for single-mass rocking structures equipped with inerters developed by Thiers-Moggia and Málaga-Chuquitaype [4]. This formulation, referred as VVEL, considers large rotations for the base and small deformations for the oscillator. The

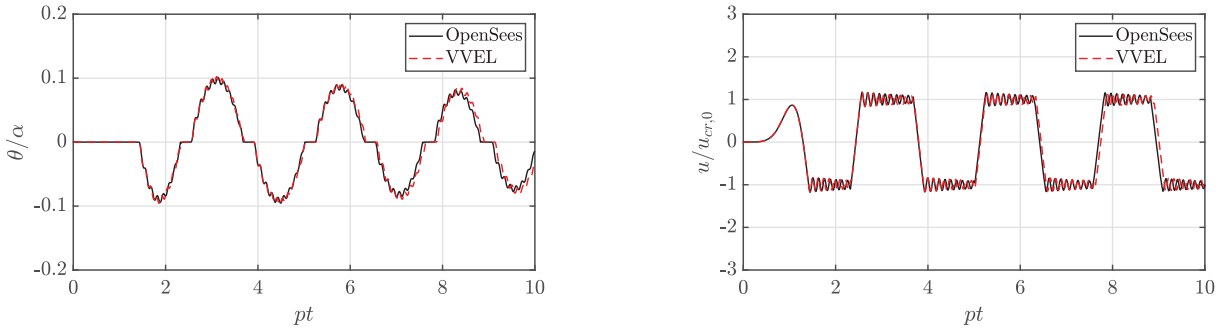
numerical model, on the other hand, considers a corrotational transformation for the rocking body. In order to make both formulations comparable, the natural frequency of the OpenSees model is obtained considering P-Δ effects in the lateral stiffness of the system.

$$\omega_{n,OS} = \sqrt{\frac{3EI/h^3 - N/h}{m}} \tag{8}$$

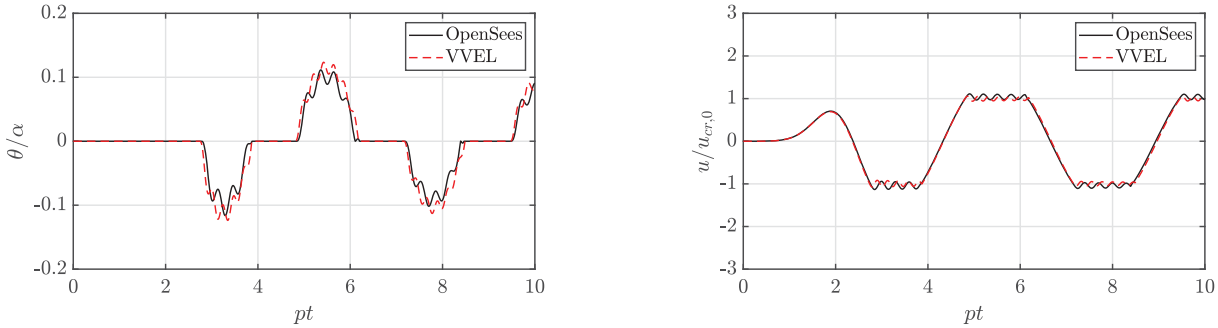
Figure 6 compares the responses obtained for three structures of different levels of flexibilities and apparent mass ratios, subjected to single Ricker pulses of frequency ω_g and acceleration amplitude a_g.



(a) $\omega_n/p = 10$, $\omega_g/p = 5$, $a_g = 1.5\,g\tan\alpha$, $\alpha = 0.1$, $\xi_{fc} = 0.01$, $\xi_{up} = 0.01\,B/R_0$ and $\sigma = 1$.



(b) $\omega_n/p = 5$, $\omega_g/p = 5$, $a_g = 1.5\,g\tan\alpha$, $\alpha = 0.1$, $\xi_{fc} = 0.01$, $\xi_{up} = 0.01\,B/R_0$ and $\sigma = 0.5$.



(c) $\omega_n/p = 2$, $\omega_g/p = 3$, $a_g = 1.5\,g\tan\alpha$, $\alpha = 0.1$, $\xi_{fc} = 0.01$, $\xi_{up} = 0.01\,B/R_0$ and $\sigma = 0.5$.

Figure 6: Comparison of the OpenSees numerical model and VVEL analytical model for rocking structures equipped with single inerters.

Excelent agreement between the two models is observed for the stiffer structures. However, small differences emerge in the amplitude of the rotation and elastic deformation responses as the oscillators become more flexible. This difference is partially explained by the variation of

the axial load, N, during the rocking motion which alters the lateral stiffness of the oscillator in the numerical model, an effect that becomes more significant in more flexible structures.

3 RESPONSE UNDER PULSE GROUND MOTIONS

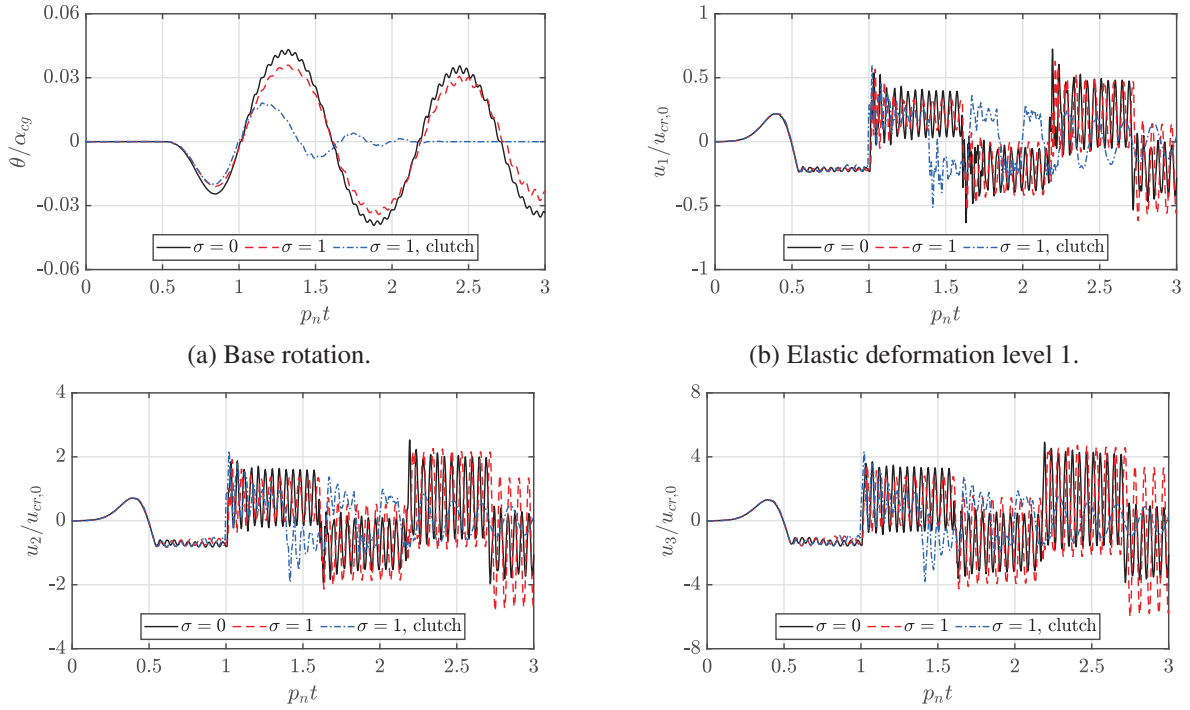
Assuming a uniform distribution of stiffness and masses along the height of the structure, the rotation and deformation responses of the system shown in Figure 1a are a function of 10 parameters involving three fundamental dimensions:

$$[\theta, \underline{u}] = \phi \left(EI\,, m\,, m_r\,, \xi\,, n_{levels}\,, \alpha_{cg}\,, R_{cg}\,, \omega_g\,, a_g\,, g\,, t \right) \tag{9}$$

where α_{cg} and R_{cg} are the slenderness and radial distance of the centre of gravity, and ω_g and a_g are the excitation's frequency and acceleration amplitude, respectively. According to Vaschy-Buckingham's Π-theorem [16, 17], the response of the system can be described by $10 - 3 = 7$ dimensionless parameters:

$$\left[\frac{\theta}{\alpha_{cg}}, \frac{\underline{u}\,\omega_{n1}^2}{g \tan \alpha_{cg}} \right] = \phi \left(\frac{\omega_{n1}}{p_n}\,, \sigma\,, \xi\,, n_{levels}\,, \alpha_{cg}\,, \frac{\omega_g}{p_n}\,, \frac{a_g}{g \tan \alpha_{cg}}\,, p_n t \right) \tag{10}$$

where ω_{n1} is the first frequency of the MDOF oscillator, and $\omega_{n1}^2 / g \tan \alpha_{cg}$ represents the critical displacement of an equivalent SDOF oscillator of frequency ω_{n1} and slenderness α_{cg}. Figure 7 compares the dimensionless response of a 3-storey rocking structure of $\omega_{n1}/p_n = 35$, $\alpha_{cg} = 0.165$, $\xi = 0.01$, with and without inerters, subjected to a single Ricker pulse of frequency $\omega_g/p_n = 10$ and acceleration amplitude $a_g = 2\,g \tan \alpha_{cg}$.



(a) Base rotation.

(b) Elastic deformation level 1.

(c) Elastic deformation level 2.

(d) Elastic deformation level 3.

Figure 7: Response of a 3-storey rocking structure of $\omega_{n1}/p_n = 35$, $\omega_g/p_n = 10$, $\alpha_{cg} = 0.165$, $\xi = 0.01$ and $a_g = 2\,g \tan \alpha_{cg}$ with and without inerters.

While the inclusion of the inerters considerably reduced the maximum base rotation, little effect is observed on the amplitude of the elastic deformations. This observation agrees with conclusions obtained in previous studies involving single-mass rocking oscillators [4]. Importantly, the introduction of the clutch significantly improves the efficiency of the inerter in reducing the rotation response. The effect of the clutch can be better examined by inspecting the total energy of the structure-inerter system, given by:

$$E_T = \frac{1}{2}\sum_{n=1}^{n_{levels}} m(\dot{x_i}^2 + \dot{y_i}^2) + \sum_{n=1}^{n_{levels}} mg(y_i - h_i) + \int_0^H \frac{M(y)^2}{2EI}dy + \frac{1}{2}\, m_r\, \dot{x_i}^2 \qquad (11)$$

where $\dot{x}_i$ and $\dot{y}_i$ are the horizontal and vertical velocities of the mass at the ith-level, and $M(y)$ corresponds to the bending moment at a height equal to y. Figure 8 shows the total energy of the same structure with different configurations of inerter devices normalized by $E_{ref} = mgR_{cg}(1 - cos\alpha_{cg})$, where E_{ref} represents the difference in potential energy of a rigid rocking structure between its unstable ($\theta = \alpha_{cg}$) and stable ($\theta = 0$)) equilibrium positions. Impact in each case is indicated with a solid circle.

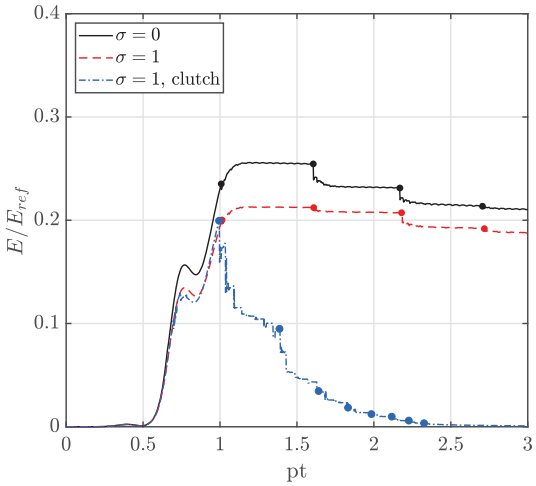


Figure 8: Total Energy of the structure-inerter systems.

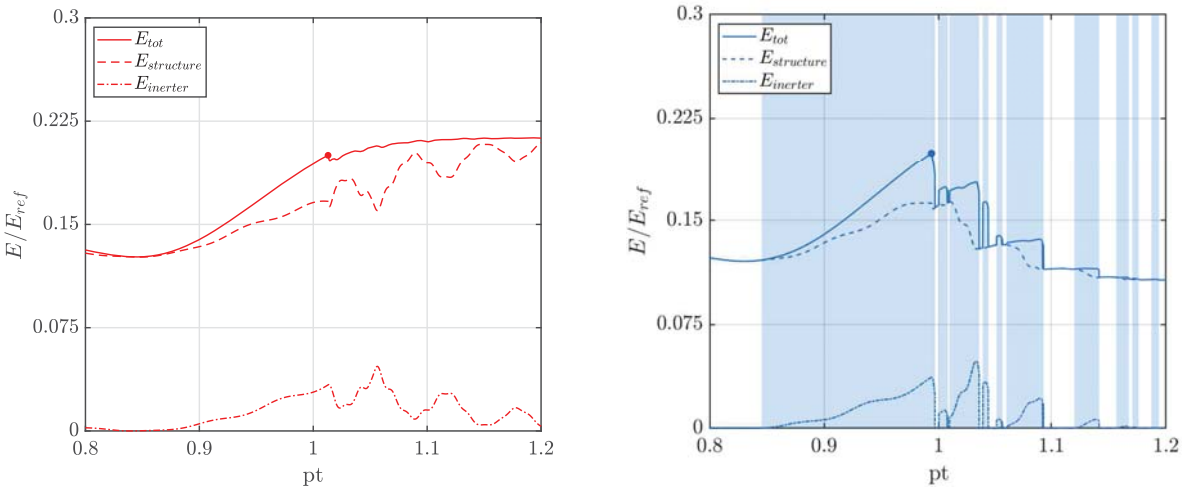
It is clear from Figure 8 that the inclusion of the inerter limits the total energy absorbed by the system, while at the same time it reduces the amount of energy dissipated during each impact. This results in the lower peak rotation observed in Figure 7, with similar amplitudes in the later cycles of the rocking response. Such increase in the restitution coefficient is also predicted by conservation of moment of angular momentum equations [7].

Part of the total energy absorbed by the system is stored in the inerter device, as shown in the close-up view of Figure 9a. As the structure rocks and oscillates this energy is transferred back and forth, with the inerter alternately opposing and driving the motion. When the clutch is introduced, the inerter disengages from the structure and the energy stored in it is not transferred back to the oscillator. Assuming that the disconnected inerter is then able to dissipate this energy, every engagement-disengagement cycle removes energy from the structural system, increasing the speed at which the rotation and deformation responses are attenuated. Experimental analyses conducted by Málaga-Chuquitaype et al. [18] suggest that friction within the inerter can effectively dissipate part of the energy, while other researchers have suggested the addition of viscous fluids [15, 19]. This behaviour is illustrated in Figure 9b., where the engagement and disengagement of the inerter is indicated with blue and white backgrounds respectively.



(a) Single inerter.

(b) Pair of clutched inerters.

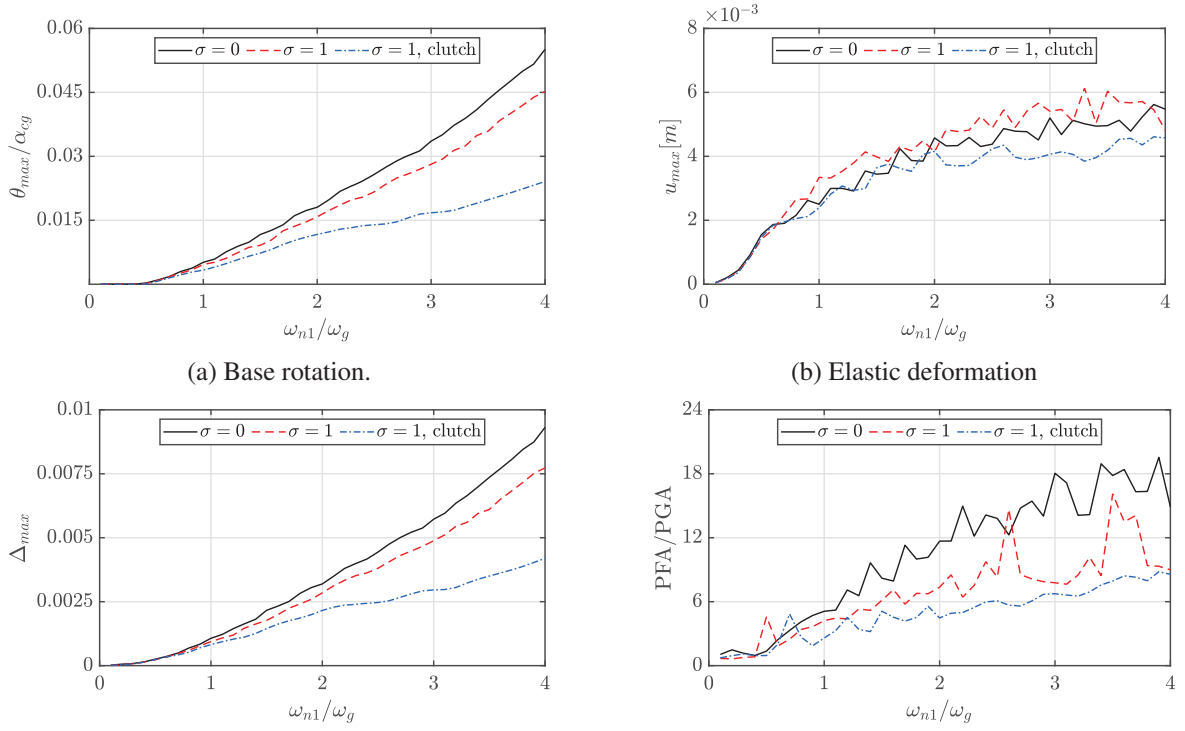
3.1 Response spectra

This section examines the response of multi-mass rocking structures equipped with inerters under a wider range of Ricker pulse ground motions. Figure 10, 11 and 12 summarize the response of a set of 3, 5 and 9-storey structures representative of walled buildings of $2B = 2\,[m]$ by $H = 9\,[m]$, $2B = 3\,[m]$ by $H = 15\,[m]$ and $2B = 3\,[m]$ by $H = 27\,[m]$, respectively.



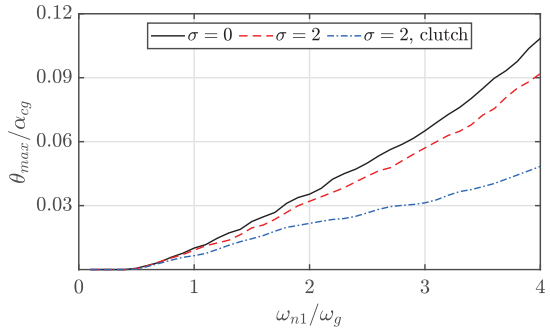
(a) Base rotation.

(b) Elastic deformation

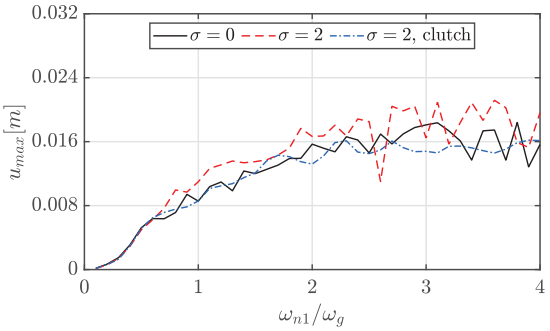
(c) Drift

(d) Floor acceleration

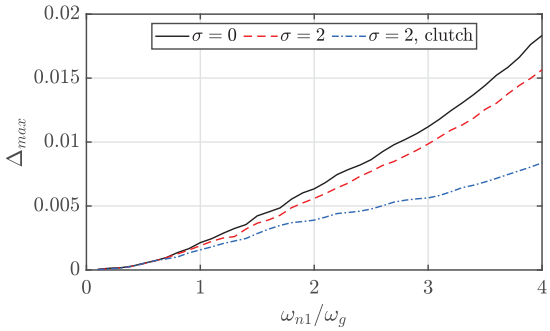
Figure 10: Response of a 3-storey rocking structure of $\omega_{n1}/p_n = 35$, $\alpha_{cg} = 0.165$, $\xi = 0.01$, with and without inerters, under Ricker pulses of $a_g = 2\,g\tan\alpha_{cg}$.



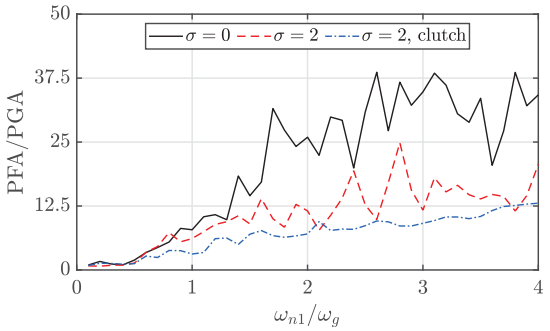
(a) Base rotation.



(b) Elastic deformation.

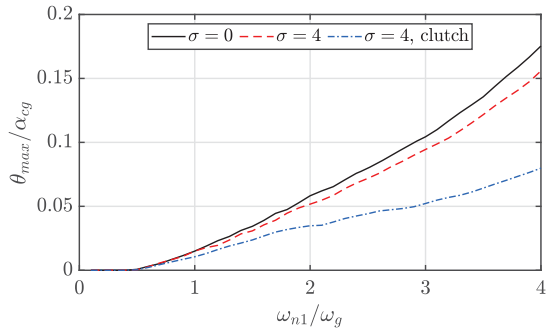


(c) Drift.

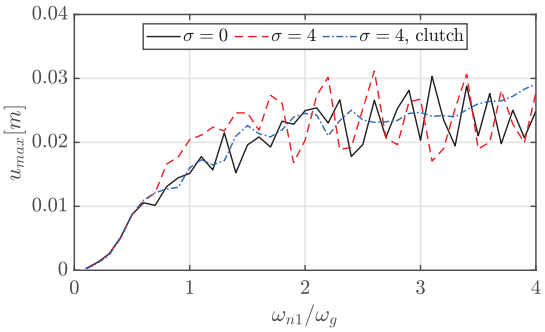


(d) Floor acceleration.

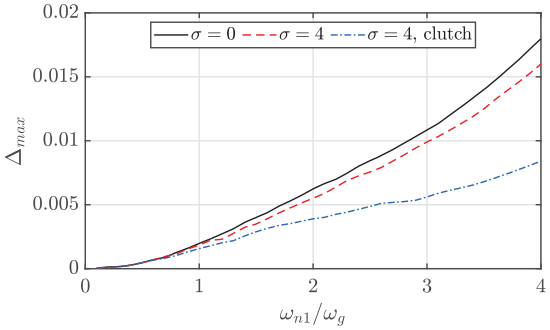
Figure 11: Response of a 5-storey rocking structure of $\omega_{n1}/p_n = 25$, $\alpha_{cg} = 0.12$, $\xi = 0.01$, with and without inerters, under Ricker pulses of $a_g = 2\,g\tan\alpha_{cg}$.



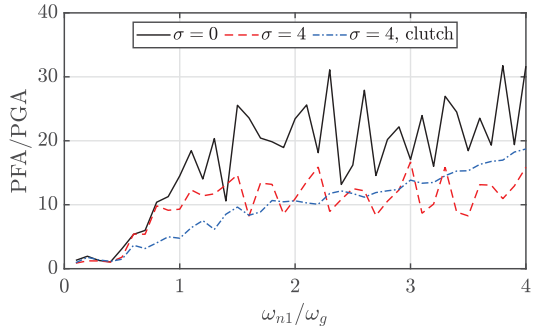
(a) Base rotation.



(b) Elastic deformation.



(c) Drift.



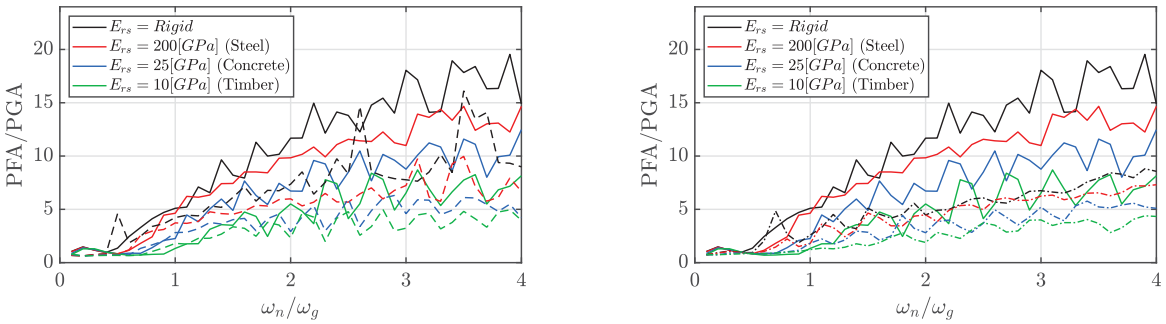
(d) Floor acceleration.

Figure 12: Response of a 9-storey rocking structure of $\omega_{n1}/p_n = 20$, $\alpha_{cg} = 0.1$, $\xi = 0.01$, with and without inerters, under Ricker pulses of $a_g = 2\,g\tan\alpha_{cg}$.

In all three cases, the addition of the inerter has very little effect on the rotation and elastic deformation responses for high frequency excitations ($\omega_{n1}/\omega_g < 1$). As the duration of the pulses increases, the rotation demands grow and the effect of the inerter becomes more significant, reaching reductions between 15% and 20% for $\omega_{n1}/\omega_g = 4$. Although this improvement happens at the expense of inducing slightly higher elastic deformations, this drawback does not translate into higher drifts, since the total lateral deformation is mainly controlled by the base rotation. On the other hand, the introduction of the clutch significantly improves the performance of the inerter, reducing also the elastic deformation response for the cases where uplift and rocking occurs. It is also important to note that, as the structure becomes taller, higher levels of inertances are required to obtain similar levels of response suppression. However, the actual mass of the inerter can be reduced thousands of times using amplification mechanisms such as ball-screws [20] or gear systems [21].

The maximum acceleration response in rocking structures is often controlled by impact forces. When a rigid elastic rocking surface is considered, these forces can cause significant spikes in the acceleration history. This behaviour can be clearly identified in Figure 10d, 11d and 12d, where considerably higher acceleration amplification ratios are registered once the rocking motion is triggered ($\omega_{n1}/\omega_g > 0.65$). The inclusion of the inerter consistently reduces these spikes, with further improvements when the clutch is added. Nevertheless, in very limited cases the protected structures may experience peak accelerations of slightly higher magnitude.

A sensitivity analysis is carried out in order to evaluate the effect of the rocking surface stiffness on the peak floor accelerations and the efficiency of the inerter in reducing them. Four stiffness values are considered: Rigid (10^{10}[GPa]), Steel (200[GPa]), Concrete (25[GPa]) and Timber (10[GPa]), while a depth of 0.3[m] is assumed for the rocking element.



(a) Single inerter.

(b) Pair of clutched inerters.

Figure 13: Effect of the rocking base stiffness on the peak floor accelerations in a 3-storey building of $\omega_{n1}/p_n = 35$, $\alpha_{cg} = 0.12$, $\xi = 0.01$ and $a_g = 2g \tan \alpha_{cg}$ with and without inerters (dashed and continue lines respectively).

The results summarized in Figure 13 show that more rigid rocking surfaces are associated to larger floor accelerations . On the other hand, the efficiency of the inerter in reducing peak floor accelerations is not significantly affected by the flexibility of the rocking surface.

4 CONCLUSIONS

This paper investigated the alternative of using inerters to improve the seismic response of multi-mass rocking structures. Firstly, the numerical model proposed by Vassiliou et al. [10] was modified in order to account for experimental evidence related to the energy dissipated by

the rocking oscillator during the uplifted phase. Additionally, the study presented a numerical strategy to represent the inerter in finite element frameworks, such as OpenSees. The model of the full structure-inerter system was then validated against an analytical model of a single-mass rocking oscillator. Both formulations showed very good agreement for different levels of flexibility and excitation frequencies.

The proposed model was subsequently used to assess the dynamic response of a set of 3, 5 and 9-level structures subjected to analytical pulse excitations. Two inerter configurations were considered; a single inerter connected to the first level diaphragm, and a pair of clutched inerters that can only oppose the motion of the mass. The analyses showed that the inerter increasingly reduces the amplitude of the base rotation as the demands grow, with very little effect for high frequency excitations. Although this improvement happened at the expense of inducing slightly higher elastic deformations, this was not reflected on the total drift, as the lateral deformation of the system is mainly controlled by the base rotation. On the other hand, the introduction of the clutch consistently reduced both the rotation and elastic deformations demands. It was shown that this improvement is caused by the disengagement of the inerter which prevents the transference of the energy stored in it back into the structure. Finally, a sensitivity analysis was conducted in order to examine the influence of the rocking surface stiffness on the acceleration demands. The analyses showed that the efficiency of the inerter in reducing floor accelerations is not affected by the level of flexibility of the rocking interface.

Keywords: Inerter, Parasitic mass, Inerter-based dynamic vibration absorber.

Abstract. *This study investigates the effects of parasitic mass on the performance of inerter-based dynamic vibration absorbers (IDVAs). IDVAs have been increasingly employed to suppress vibrations in applications of civil engineering structures and vehicle suspension systems. While the masses of the components in a traditional dynamic vibration absorber can be easily compensated for due to its simple layout, the masses of the components in an IDVA can act as parasitic mass and might affect the performance of IDVAs. This can lead to the loss of benefits which is provided by the IDVAs. The negative effect of a parasitic mass in an IDVA can be observed in applications which have smaller inertance values. In such cases, it is important to consider masses of the components while selecting optimal parameters to maximize the performance improvement which can be obtained by an IDVA. In this study, a milling operation is modelled and its machining stability is increased by utilizing an IDVA. The negative effect of a parasitic mass on the performance is shown, and the performance improvement is regained by considering the parasitic mass in the tuning strategy.*

1 INTRODUCTION

Tuned mass dampers (TMDs) have been successfully employed to suppress vibration since the concept was introduced by Frahm [1] in the early 20th century. The device which was proposed by Frahm, the so-called dynamic vibration absorber (DVA), consists of an auxiliary mass and a spring. It targets the natural frequency of the system that is required to be controlled. Although it can successfully suppress vibrations at the resonance frequency, it allows high amplitude vibrations near the resonance frequency. This drawback of the DVA was modified by adding a viscous damper in the work of Den Hartog [2]. The resulting tuned mass damper (TMD) has the capability to suppress vibration at a wider range of frequencies. The tuning methodology was also developed by Den Hartog [2] using the fixed-points-theory.

To increase the performance of the TMD, a relative-acceleration-dependent-inertial element in conjunction with a spring and a damper, was studied by Kuroda [3]. This concept was analysed by many authors, for example Saito [4] investigated how it could be used to control seismic response of the structures. Similarly, the inerter, which was first introduced by Smith [5] by using the force-current analogy between mechanical and electrical networks, applies forces proportional to the relative acceleration between the two terminals. There are three types of inerter which have been mostly studied in the literature: the ball-screw inerter [6], the rack and pinion inerter [5, 6], and the fluid inerter [7]. Recently, the frictionless mechanical inerter that consists of a disc as flywheel and the living-hinges was presented to eliminate the friction that is caused by gears or ball-screw interaction [8]. Inerter-based vibration absorbers have been studied to improve the vibration performance of the system in vehicle suspensions [9, 10], civil engineering applications [11, 12, 13], landing-gear systems [14] and machining applications [15, 16].

Tuning parameters of the components of the inerter-based device plays an important role in the their vibration suppression performance. Lazar et al. [11] proposed a tuning strategy based on Den Hartog's fixed-points-theory for a tuned inerter damper (TID). Hu and Chen [17] used a direct search method to obtain design parameters of inerter-based dynamic vibration absorbers (IDVAs) for H_2 and H_∞ optimisations. Shen et al. [18] utilized a genetic algorithm to find the optimal parameters for the vibration suppression of the vehicle body controlled by an IDVA. Barredo et al. [19] presented an analytical methodology to obtain close-form solutions of three inerter-based configurations for an undamped primary system. Generally, the mass of the inerter is neglected in the mathematical model of the system during the process of finding the optimal parameters. This is because the inertance value of the inerter is generally very large compared to the mass of the inerter. However, for instance, the optimal inertance value for a small-primary-mass application can be small so that the mass of the inerter cannot be constructed small enough to neglect. In such cases, the mass of the inerter can act as a parasitic mass and lower the vibration suppression performance of the system being controlled.

This study investigates the effect of the parasitic mass caused by the mass of the components of the inerter. The novelty is that this parasitic mass is considered in the mathematical model and included in the evaluation of the performance of an IDVA. The effect of the parasitic mass is shown with two scenarios: the vibration suppression of a structure and the chatter stability of a milling operation. The effects of the parasitic mass are evaluated in the discussion section and finally the conclusions are presented.

2 PARASITIC MASS DUE TO AN INERTER

The inerter is a mechanical device which generates equal and opposite inertial forces proportional to the relative acceleration applied at the two nodes [5]. An ideal inerter can be represented as shown in Figure 1(a) and the schematic view of a physical realisation of the inerter [8] can be seen in Figure 1(b). The inerter in Figure 1(b) consists of a disc, which is the flywheel, in the middle and two legs that are the nodes of the inerter. The connections between the legs and the flywheel can be established by living-hinges to eliminate the friction and the backlash or by simple pin joints. The inertance of the inerter can be calculated as [8]

$$b = \frac{I_{disc}}{l_a^2} \tag{1}$$

where I_{disc} is the moment of inertia of the disc and l_a^2 is the distance between the points where the two legs are connected to the flywheel disc. Hence the inertial force generated by the inerter is

$$F_{inerter} = b(\ddot{x}_2 - \ddot{x}_1) \tag{2}$$

Equation 1 gives the inertance of an ideal inerter using a disc as a flywheel in Figure 1(b). The inertance values for the different types of inerters are calculated in a similar manner [5, 7, 20]. Once again, these inertance values are for an ideal inerter so the masses of the components of the inerter (e.g. the mass of the housing in a ballscrew inerter, the mass of the rack in a rack and pinion inerter or the mass of the legs in an inerter as shown in Figure 1(b)) are neglected. This is because the inertia of these parts is typically small compared with the inertance of the inerter device. Intrinsically, an inerter works as a kind of an inertia amplifier in most cases. Thus, it has higher inertance and the inertial increment in the device allows one to neglect the inertia of those which do not contribute this increment.

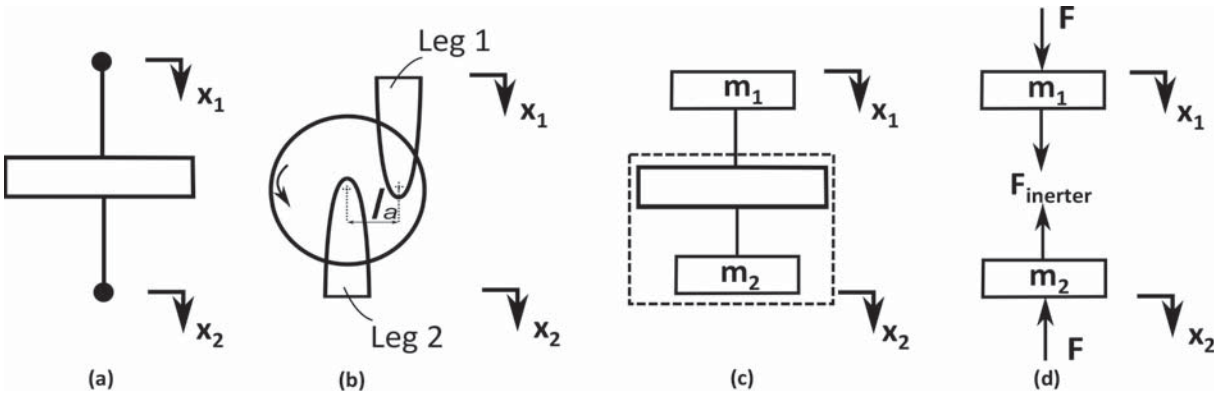

Figure 1: (a) Mathematical model of an ideal inerter, (b) schematic view of a small-scale mechanical inerter, (c) mathematical model of the inerter including the masses of legs and disc (the inertance value of the inerter involves only the rotational inertia of the disc.), (d) free body diagram of the inerter.

If the inertia of all components is considered, the mathematical model of an inerter becomes as shown in Figure 1(c) rather than in Figure 1(a). Leg 2 in Figure 1(b) is connected to the centre of the mass of the disc. The living-hinges or the pin joints, which are considered in the realisation, allow only rotational motion so that the disc and Leg 2 can be considered as rigidly connected in the translation motion. Hence, m_2 is the sum of the mass of the disc and the mass of Leg 2 while m_1 is equal to the mass of the Leg 1. The inertia of the inerter in Figure 1(c)

involves only the rotational inertia of the disc as expressed in Equation 1. Two inertial elements (m_1 and m_2) appear on the two nodes of the inerter in Figure 1(d) and induce the forces $m_1\ddot{x}_1$ and $m_2\ddot{x}_2$.

If the node with the inertial element is mounted on a spring or a damper, the inertial element (mass) acts as a parasitic mass between the inerter and the spring or the damper. The parasitic mass can be neglected in two cases where (1) the node with the inertial element has a ground connection or is mounted to another mass, and (2) the inertance value of the inerter is too large compared with the inertial element. Otherwise, the parasitic mass must be considered in the calculations.

3 MATHEMATICAL MODEL WITH A PARASITIC MASS

A tuned inerter damper consists of a spring which is connected to a damper in parallel, and an inerter which is in a series connection with the spring and the damper. Since one of the terminals of the inerter is connected to the spring and the damper, the parasitic mass can be observed in this configuration. The mathematical model of the TID with an ideal inerter is represented in Figure 2.

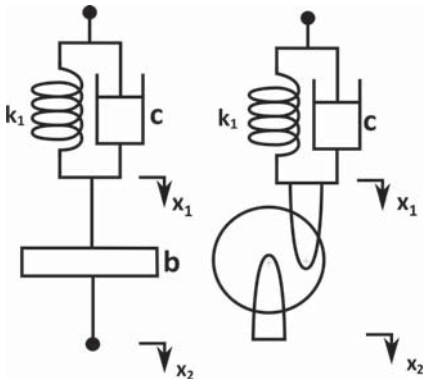

Figure 2: Mathematical model of a tuned mass damper with an ideal inerter, where the masses of the body of the inerter and the legs are neglected.

The TID can be employed to suppress a single-degree-of-freedom system which is under an excitation. The TID in a series connection with a spring, which is an IDVA, can be mounted to the primary system with a spring in series connection as shown in Figure 3(a). In reality, depending on the location of the inerter, either of the mathematical models in Figures 3(b) and 3(c) is a better representation than the model in Figure 2 due to the parasitic mass as discussed in the previous section. The upper nodes in Figures 3(b) and 3(c) are connected to the primary mass in Figure 3(a), and the bottom nodes are fixed to the auxiliary mass. Therefore, the inertial elements on these nodes can be neglected as the inertial element can be simply added to the mass which the nodes are connected to. Both of the mathematical models in Figure 3(b) and Figure 3(c) involve the parasitic mass m_p owing to the mass of the inerter as well as the masses of the spring and damper.

The location of the inerter, whether it is located in the bottom or the upper side, is not important if there is no parasitic mass between the inerter, and the spring and the damper. It matters if there is a parasitic mass since the equations of motion of the whole system will differ. The equations of motion for Figure 3(b), where the inerter is connected to the auxiliary mass (This layout is named in this paper as $icma$), can be written as

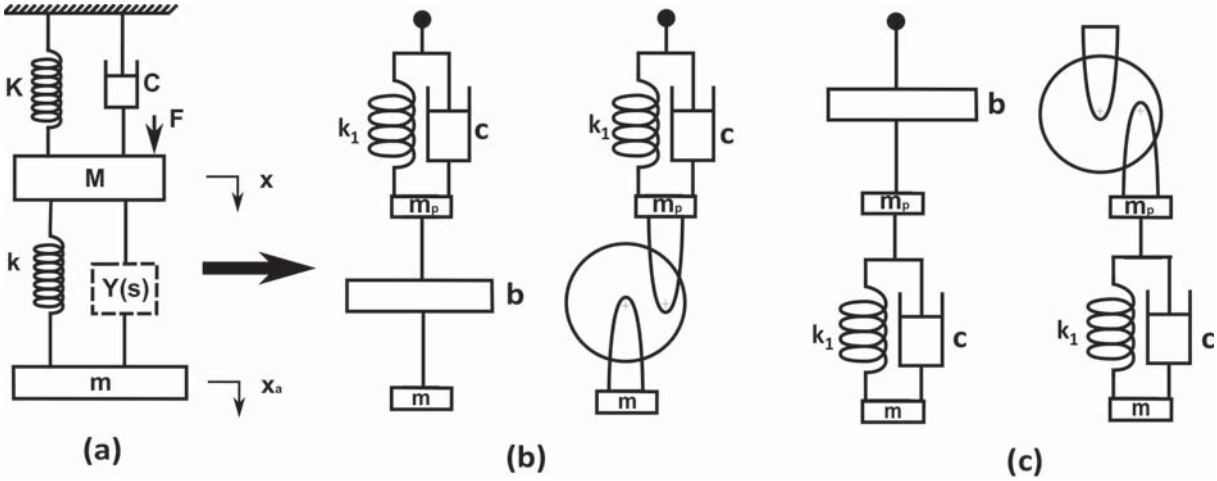

Figure 3: (a) Mathematical model of a structure controlled by an IDVA. Y(s) represents the impedance of the configuration in series connection with a spring. (b) Mathematical model of the case where the inerter is connected to the auxiliary mass,m (the $icma$). (c) Mathematical model of the case where the inerter is connected to the primary mass,M (the $icmp$).

$$\begin{aligned} M\ddot{x} + (C+c)\dot{x} + (K+k_1)x - c\dot{x}_p - k_1 x_p &= F \\ -c\dot{x} - k_1 x + (m_p+b)\ddot{x}_p + c\dot{x}_p + k_1 x_p - b\ddot{x}_a &= 0 \\ -b\ddot{x}_p + (m_a+b)\ddot{x}_a &= 0 \end{aligned} \tag{3}$$

where x, x_p and x_a are the displacements of the primary, parasitic and auxiliary masses, respectively. The equations of motion for Figure 3(c), where the inerter is connected to the primary mass (this layout is named in this paper as $icmp$), can be written as

$$\begin{aligned} (M+b)\ddot{x} + C\dot{x} + Kx - b\ddot{x}_p &= F \\ -b\ddot{x} + (m_p+b)\ddot{x}_p + c\dot{x}_p + k_1 x_p - c\dot{x}_a - k_1 x_a &= 0 \\ -c\dot{x}_p - k_1 x_p + m_a\ddot{x}_a + c\dot{x}_a + kx_a &= 0 \end{aligned} \tag{4}$$

The inertia of the parasitic mass is always added to the inertance of the inerter as seen Equations 3 and 4. Hence, the mass of the inerter is neglected if the inertance is too high.

4 THE EFFECT OF THE PARASITIC MASS

The system considered in this study to investigate the effect of the parasitic mass on the performance of a tuned inerter damper is depicted in Figure 3(a). A TID in series with a spring is mounted to the primary mass in a single-degree-of-freedom system to examine three mathematical models: No parasitic mass, the $icma$, and the $icmp$ cases. The effect of the parasitic mass on the vibration and chatter suppression performances is analysed.

4.1 Vibration Suppression Case

The study of Hu and Chen [17] has already shown that the inerter-based configuration which is presented in this work improved the vibration suppression performance of an undamped system. Therefore, a parasitic mass in this configuration can be considered to observe the effect

of the parasitic mass. The system with a parasitic mass is governed by either Equations 3 or 4, depending on the position of the inerter. The frequency response function (FRF) is given in the form as

$$H_i(j\omega) = \frac{X(jw)}{F(jw)} = \frac{R_{Ni} + jI_{Ni}}{R_{Di} + jI_{Di}}, \quad i = 1, 2, 3 \tag{5}$$

where $i = 1$, $i = 2$ and $i = 3$ represent for three mathematical models: No parasitic mass, the $icma$ and the $icmp$ cases, respectively.

The primary mass and the natural frequency of the primary system were taken as $M = 5\ kg$ and $f_n = 200\ Hz$. The primary system considered an undamped system and thus, $\zeta_{primary} = 0$. In order to obtain optimal design parameters (k, k_1, c and b), Self-adaptive Differential Evolution (SaDE) algorithm [21] can be utilized as a numerical optimisation method. The objective function for a constant mass ratio ($\mu = m/M$) can be written as

$$min_{k,k_1,c,b}\Big(max_{\omega}\big(|H_i(j\omega)|\big)\Big), i = 1, 2, 3 \tag{6}$$

since the minimisation of the maximum absolute value of the FRF is desired.

The optimal design parameters were found for mass ratio $\mu = 0.1$ and the case with no parasitic mass. The optimal inertance value for the case with no parasitic mass was found $b = 0.0965\ kg$. 5% and 10% of the inertance value, which are $4.8\ g$ and $9.6\ g$, were added as the parasitic mass to examine the two cases. For 5% parasitic mass, the optimal design parameters was obtained. The optimal parameters are given in Table 1 and the results are demonstrated in Figures 4 and 5.

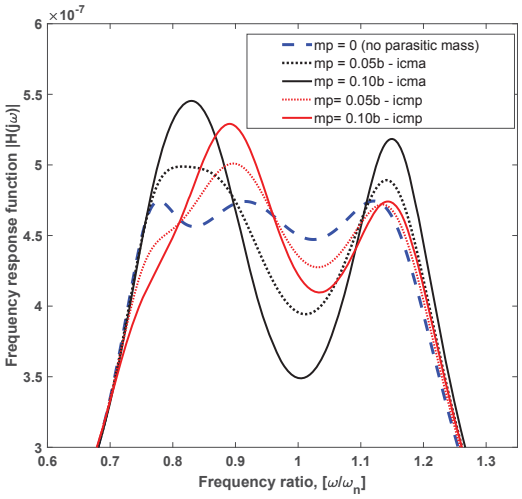

Figure 4: The magnitude of the FRF obtained from three cases: No parasitic mass, the $icma$ and the $icmp$ for parasitic masses of 5% and 10% of the optimal inertance value.

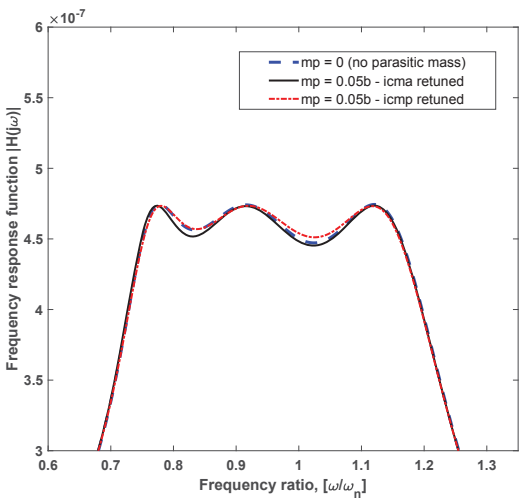

Figure 5: The magnitude of the FRF after retuning the optimal parameters considering a parasitic mass of 5% of the optimal inertance value.

The results show that both of the parasitic masses increased the amplitude of the vibration. The higher parasitic mass added caused the higher amplitude as shown in Figure 4. The $4.8\ g$ parasitic masses increased the amplitude of the displacement by 4.84% for the $icma$ and 5.39% for the $icmp$ After retuning the parameters for $4.82\ g$ parasitic mass, Figure 5 shows that the

Configurations	$m_p\ [g]$	$k\ [kN/m]$	$k_1\ [kN/m]$	$b\ [kg]$	$c\ [Ns/m]$
No parasitic mass	0	712.4	11.7	0.0965	60.3
$icma$	4.8	709.0	121.5	0.0999	64.5
$icmp$	4.8	721.5	115.2	0.0950	63.6

Table 1: Optimal design parameters obtained to suppress the vibrations in Figure 3(a) for $\mu = 0.1$.

same level of vibration suppression was provided again. Furthermore, the amplitude of the displacement was decreased by 0.2% compared to the case with no parasitic mass.

5 CASE STUDY ON MACHINING STABILITY

One potential application of inerters is in the suppression of vibrations during machining [15, 16]. Here, alternative methods for passive vibration control have already been proposed [22], and it has been shown that such approaches can improve the productivity by avoiding the onset of unstable self-excited vibrations known as chatter.

Consequently, this section provides a brief numerical case study to demonstrate how inerter systems can be used to suppress chatter. For simplicity, a turning configuration is chosen in order to demonstrate the concept without recourse to detailed theoretical analysis.

The mechanism which leads to regenerative chatter for a turning operation is briefly given here and explained comprehensively in [23, 24]. The cutting force which is applied to a flexible cutting tool leads to the waviness on the surface of the workpiece as shown in Figure 6. The phase difference (ε) between the waviness of the previous and the current cuts which are induced by the previous and the current displacements of the cutting tool, $y(t)$ and $y(t-T)$, causes a change in the instantaneous chip thickness. This variation in the instantaneous chip thickness induces a variation in the cutting force as the cutting force is proportional to the cross-sectional area of the chip and thus, the chip thickness. The variation in the cutting force leads to the waviness on the surface of the workpiece again. This regenerative mechanism can cause instability in the cutting operation.

The delay term T in the displacement in the previous cut $y(t-T)$ is introduced by the spindle rotation. Hence, for a machinist, two parameters which define the cutting force and accordingly a stable cut in a machining operation are the depth of cut and the spindle speed. The chatter stability of a machining process is generally evaluated over stability lobe diagrams (SLDs), which give the stability boundary in terms of the depth of cut for each spindle speed. The results for this study case will be presented as SLDs.

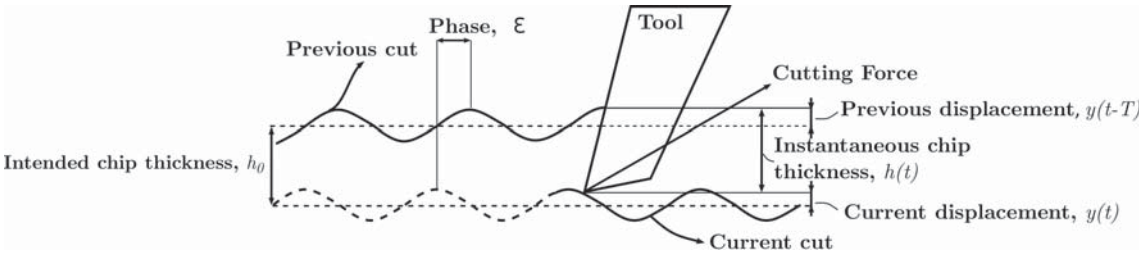

Figure 6: Depiction of a regenerative chatter mechanism

A chatter stability condition can be defined as the limiting depth of cut b_{lim}, which can be

simply expressed as [23]

$$b_{lim} = -\frac{1}{2K_s\Re\{H(j\omega)\}} \tag{7}$$

where K_s is specific cutting coefficient, which can be accepted as a constant term in this case and $Re\{H(j\omega)\}$ is the real part of the FRF of the system. The limiting depth of cut b_{lim} gives the stability boundary so the system becomes unstable beyond this value. The stability boundary can be increased by maximising the negative real part of the FRF when considering the depth of cut as a positive real number. Although Equation 6 is derived basing on a turning operation, it is approximately valid for a milling operation [22].

A milling operation can be reduced in a single-degree-of-freedom system so that Figure 3(a) can be used as the mathematical model of a machining operation controlled by a passive control device. Similar to the previous analysis, a parasitic mass can be added to the structure and the effects of the parasitic mass can be evaluated.

A similar analysis to the previous section was conducted. The primary mass, the natural frequency of the primary system and the damping ratio were taken as $M = 5\ kg$, $f_n = 200\ Hz$ and $\zeta_{primary} = 0.0035$. The milling operation parameters are presented in Table 2. The objective function for this case can be defined to maximise the negative minimum real part of the FRF of the system. Therefore, the objective function can be written as

$$max_{k,k_1,c,b}\left(min_{\omega}\big(\Re\{H_i(j\omega)\}\big)\right), i = 1, 2 \tag{8}$$

subject to $\Re\{H_i(j\omega)\} > 0$ and where $i = 1$, $i = 2$ and $i = 3$ represent for three mathematical models of no parasitic mass, the $icma$, and the $icmp$ cases, respectively.

Tool diameter	16 mm
Number of teeth	4
Radial immersion	4 mm
Tangential cutting stiffness	796.1 N/mm^2
Radial cutting stiffness	168.8 N/mm^2

Table 2: Milling simulation parameters

The optimal design parameters were found for mass ratio $\mu = 0.1$ and the case with no parasitic mass. The optimal inertance value for the case with no parasitic mass was almost the same as the previous case. Only 10% of the inertance value was added as the parasitic mass in the other two cases and the optimal design parameters were retuned. The optimal parameters are presented in Table 3. The stability boundaries are presented in Figures 7 and 8. The region under the stability boundary/curve represents a stable cutting condition. Thus, the higher curve means higher stability and hence improved productivity from the machining operation.

The stability lobe diagrams were compared with the stability diagram of the one controlled with a TMD whose optimal design parameters were obtained by Sims' tuning methodology [22]. It can be seen that the parasitic mass added into the configuration, whether the $icma$ or the $icmp$, removed the benefit of using an inerter as the stability boundary lowered to the level of one obtained with the TMD. The parasitic mass of $9.6\ g$ decreased the limiting depth of cut (the stability boundary) by 34.4% for the $icma$ and 17.6% for the $icmp$ configuration. After retuning the parameters considering the parasitic mass, the improvement obtained by using an inerter was regained as shown in Figure 8.

Configurations	m_p	$k\ [kN/m]$	$k_1\ [kN/m]$	$b\ [kg]$	$c\ [Ns/m]$
No parasitic mass	0	974.1	152.3	0.0956	69.2
$icma$	9.6 g	970.2	181.5	0.1048	82.7
$icmp$	9.6 g	996.6	157.6	0.0893	72.3

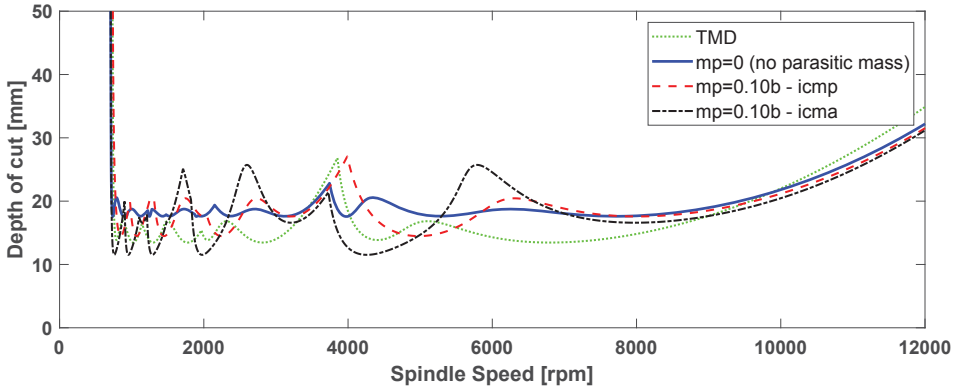

Figure 7: Stability lobe diagram obtained for three cases: No parasitic mass, the $icma$ and the $icmp$ by considering a parasitic mass of 10% of the optimal inertance value.

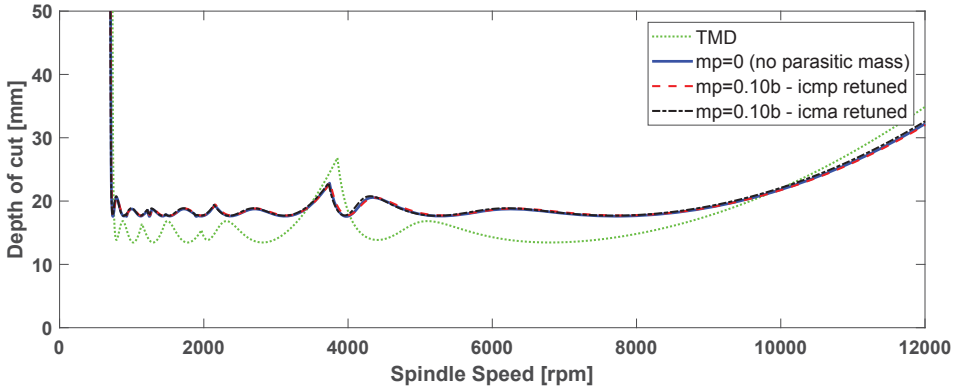

Figure 8: Stability lobe diagram after retuning the optimal parameters considering a parasitic mass of 10% of the inertance value.

6 Discussion

The results have shown that neglecting the mass of the inerter leads to a decrease in the vibration suppression and machining chatter stability performances since the optimal design parameters were obtained for the ideal condition, where the mass of the inerter is assumed as zero. For high ratios of the mass of the inerter to the inertance, the inertial effect of the mass of the inerter becomes insignificant as it is always coupled to the inertance (m_p+b) in the equations of motion. The structural mass of the inerter is generally designed to be small compared to the inertance but this cannot be always the case, especially for the applications where the modal mass of the primary system is small. It can be noted that the two cases for the location of the inerter the $icma$ and the $icmp$, had different behaviours. This should be considered in the design of the control device if the parasitic effect is inevitable.

Finally, it has seen that the improvement which is provided by using an inerter can be gained again by retuning the optimal parameters considering the parasitic mass. After the retuning the parameters, the results were slightly better than the result for an ideal inerter. The reason for this can be commented that the overall mass of the control device is increased by the parasitic mass. This can be seen as equal to the increase in the mass ratio. Therefore, it demonstrates slightly better performance.

7 Conclusion

The effects of the mass of the inerter on the performance of a system controlled by a inerter-based device was investigated for a generic vibration suppression scenario and also for the specific case of a machining dynamics problem. The mass of the inerter was assumed to be a lumped mass in the mathematical model and the FRFs were derived. Using the FRFs, the vibration suppression and machining stability performances of the system were examined. The result showed that if the ratio of the mass of the inertance to the inertance is not small enough, the mass of the inerter reduces the vibration performance of the system. However, the vibration performance was regained by retuning the optimal design parameters considering the parasitic mass.

VIBRATION CONTROL OF STEEL LIQUID STORAGE TANKS EQUIPPED WITH INERTER-BASED ISOLATION SYSTEMS

Daniele Zahedin Labaf[1], Maurizio De Angelis[1], and Daniele Pietrosanti[1]

Keywords: Vibration control; Base isolation; Inerter; cylindrical tanks; multiobjective optimal design; seismic response.

Abstract. *Base isolation represents a very widely used strategy to mitigate the effects of earthquake excitation on structures. However, it can induce high displacements between the isolation layer and the ground, which may cause serious damage, and even heavy and dangerous consequences in case of industrial components. Among them, big steel tanks for storage of petroleum or other chemical products, should be considered very carefully. Moreover, isolation technique doesn't seem to be effective in the control of the sloshing modes, due to the length of their periods of vibration. This fact can imply severe negative effects on the free surface of the storage tank, where the sloshing wave can exceed the upper limit of the tank, overtopping it, or inducing breaking on the floating roof.*

Moving from the results available in the Literature, in which the introduction in civil applications of a two terminal device, named inerter, able to generate an inertial mass much greater than its gravitational mass, is proposed; the force produced by the inerter is proportional to the difference of acceleration between its terminals. This work concerns the evaluation, through numerical models, of the seismic performance of a passive base isolation system involving a ground inerter system, called IBIS in the following, connecting the isolation layer of a steel liquid storage tank to the ground. The model considered in the numerical analysis consists in a reduced 2DOF linear system. The first degree of freedom is represented by the first sloshing mode; the second is relative to the base isolation system, whose mass includes the basement, the tank and the impulsive component of liquid mass.

The aim is to gain a reduction of the response in terms both of isolation layer displacement and of sloshing height.

The effectiveness of the control strategy proposed has been evaluated considering both a random white noise process and earthquakes (near-fault and far-field) as base input, achieving strong reduction of the response, in terms of sloshing height and isolation displacement.

1 INTRODUCTION

The seismic response of liquid storage tanks has been extensively studied by authors in the past decades [5, 6, 11]. The growth of interest in the engineering field is essentially due to the extremely severe consequences of accidents involving tanks, often occurring in petrochemical plants.

The seismic traditional base isolation has been the topic of both theoretical and experimental works, and its employment in the mitigation of the response of storage tanks has been already proposed, both in passive and semi-active control [7, 16]. Base isolation represents, in fact, a consolidated strategy, commonly used in passive structural control, as it is founded on modifying the structural stiffness of a structure, connecting the basement to the ground by deformable layer of isolators, able to create a flexible level in which the deformation is concentrated, uncoupling the structural displacement from the shaking ground. Therefore, the isolation technique typically acts on the structural stiffness, increasing the fundamental period of the structure, with the result of reducing both the base shear and the overturning moment of the tank, cutting the transfer of the earthquake-induced forces to the superstructure [1].

The employment of this technique presents two main drawbacks. One is related to the onset of the deformable layer, which can experience high displacements. The second one is due to the fact that the isolation period may draw a value comparable to the period of the sloshing modes, implying the incapability of controlling the convective response, or even increasing it.

This paper concerns the optimal design and effectiveness investigation of an isolation system arranged in parallel with a two-terminal device named inerter.

This device has been proposed by Smith and developed in the past years in mechanical engineering with the aim to suppress vibrations in vehicles. In fact, it is able to establish a difference in acceleration between its two terminals, so to produce an amplification mass effect, making the inertial mass much greater than the gravitational mass. This feature makes its use particularly interesting in passive vibration control. The constant of proportionality between the force produced by this device and the relative acceleration takes the name of inertance and has the dimensions of a mass.

The introduction of this device in Civil Engineering has been object of a series of theoretical [3, 4, 9, 10, 12] and experimental [13, 14] research studies. In fact, adding to a conventional TMD -small auxiliary mass- an inerter device- small gravitational mass but large inertial mass- it is possible to obtain a new system, named in literature TMDI, with high inertial mass ratio. This new system manages to combine positive features of a conventional TMD- small mass ratios- with those of an unconventional TMD- high mass ratio: lightness, due to a small auxiliary gravitational mass, and high efficacy and robustness, due to a high inertial mass ratio.

The introduction of inerter-based systems for the mitigation of the response of storage tanks has been already proposed in studies available in the Literature [8, 17]. For instance, Luo et al. proposed to introduce, in parallel with the isolation system, modeled as a linear visco-elastic, a system, called VMD, through which reductions of the sloshing response are achieved. Zhang et al. compared the performances of two different auxiliary control systems, which they plan to place in parallel, with respect to the linear visco-elastic isolation system, respectively a series or a parallel of an inerter and a linear viscous damper.

This work aims at proposing an optimization procedure used for the design of a novel non-conventional isolation system, based on a multi-objective approach, in order to achieve, concurrently, an effective control of the behaviour of both the convective and the impulsive part. Each of them represents a SDOF system, according to the model with lumped masses available in

literature. It is worth noticing that the problem the authors dealt with in this paper is similar to a procedure for the optimal tuning of a Tuned Mass Damper system [2, 7, 15], with the difference that the superstructure is here assigned and the aim of the design procedure is the identification of the optimal substructure, whose dissipative capacity, stiffness and inertance have to be found through the multi-objective optimization procedure.

The focus is mainly represented by broad tanks with a large radius, which are widespread throughout the country and typically characterized by a little ratio between the impulsive and the convective masses and by a great first sloshing period.

The paper is organized as follows. The mechanical model is illustrated and the governing equations of motion are derived in the next section. A multi-objective optimization problem is then set in section 3. The main results, in terms of Pareto fronts, frequency response functions and time-history analyses, are discussed in section 4.

2 MECHANICAL MODEL AND EQUATIONS OF MOTION

2.1 Mechanical model

Due to the complexity of the exact mathematical procedure to describe the complete model, an equivalent model, based on lumped masses and stiffnesses, can be introduced, assuming the fluid stored in the tank to be non viscous, incompressible and homogeneous and the flow field to be irrotational. Introducing hypotheses on the distribution of the hydrodynamic pressures, according to the model proposed by Housner for cylindrical tanks and developed by others, the liquid can be considered constituted by three components. The first one, known as impulsive, moves rigidly with the tank walls; the second one represents the interaction between the liquid stored in the tank and the walls; the last one experiences the sloshing motion.

Considering a cylindrical broad tank with circular shape, radius R, filled with a liquid of density ρ_L till a height H, the mass of the $i{-}^{th}$ convective mode can be expressed as:

$$m_U^i = m\frac{2}{s\lambda_i(\lambda_i^2-1)}tanh(s\lambda_i) \tag{1}$$

where m is the total liquid mass, calculated as $m = \pi\rho_L HR^2$, $s = \frac{H}{R}$ is the aspect ratio and λ_i is the $i{-}^{th}$ zero of the first derivative of the Bessel function of the first kind. The $i{-}^{th}$ circular frequency is represented by:

$$\omega_U^i = \sqrt{\frac{\lambda_i g tanh(s\lambda_i)}{R}} \tag{2}$$

The mass and the circular frequency of the first sloshing mode can be obtained substituting λ_1 = 1.8412 in Eqs.1-2. The component related to the liquid-walls interaction has been neglected. Furthermore, only the first sloshing mode is taken into account. The impulsive mass m_L can be derived as:

$$m_L = m - m_U^1 \tag{3}$$

The mechanical model of the proposed isolated reduced order 2DOF system is sketched in Fig.1. A traditional linear base isolation system, called BIS in the following, represented by a SDOF system, whose mass, stiffness and viscous damping coefficients are denoted by m_L, k_L and c_L, is combined with an inerter. Therefore, the connection between the basement and the ground is modeled as a parallel of a Kelvin-Voigt viscoelastic element and a linear inerter.

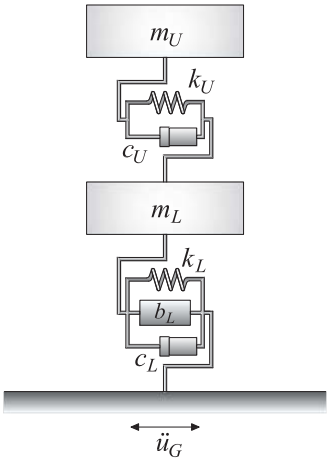

Figure 1: Mechanical model of the 2DOF system.

Table 1: Dimensionless parameters involved in the proposed model.

Description	Symbol	Definition
Isolation damping ratio	ξ_L	$\frac{c_L}{2\sqrt{k_L m_L}}$
Convective damping ratio	ξ_U	$\frac{c_U}{2\sqrt{k_U m_U}}$
Mass ratio	μ	$\frac{m_U}{m_L}$
Frequency ratio	δ	$\frac{\omega_L}{\omega_U}$
Inertial mass ratio	β	$\frac{b_L}{m_L}$

2.2 Equations of motion

The equations of motion of the reduced 2 DOFs for the Inerter Base Isolated System (IBIS), written in terms of the dimensionless parameters listed in Tab.1, result:

$$\begin{gathered}\ddot{u}_L(t) + 2\mu\xi_U\omega_U(\dot{u}_L(t) - \dot{u}_U(t)) + \mu\omega_U^2(u_L(t) - u_U(t)) + \frac{f_c(t)}{m_L} = -\ddot{u}_g(t) \\ \mu\ddot{u}_U(t) + 2\mu\xi_U\omega_U(\dot{u}_U(t) - \dot{u}_L(t)) + \mu\omega_U^2(u_U(t) - u_L(t)) = -\mu\ddot{u}_g(t) \\ \frac{f_c(t)}{m_L} = [\beta\ddot{u}_L(t) + 2\xi_L\delta\omega_U\dot{u}_L(t) + \delta^2\omega_U^2 u_L(t)]\end{gathered} \tag{4}$$

where $u_L(t)$ and $u_U(t)$, collected in $\mathbf{u}(t)$, respectively represent the displacement of the lower (L) and upper (U) oscillators with respect to the ground, the overdot indicates differentiation with respect to time t and where $\omega_U = \sqrt{\frac{k_U}{m_U}}$ and $\omega_L = \sqrt{\frac{k_L}{m_L}}$. Then, the dimensionless sloshing height, with respect to R, can be calculated as:

$$h(t) = \frac{2(\ddot{u_U}(t) + \ddot{u_g}(t))}{g(\lambda_1^2 - 1)} \tag{5}$$

The Equations which govern the problem of a base isolated system without involving the linear inerter can be obtained from the Eq.4 equaling to zero the inertance contribution. In fact, if the inertance is null, the control system falls back in a base isolation system.

Taking into account the probabilistic nature of the earthquake excitation, neglecting instead the dependence on the excitation frequency, the ground acceleration $\ddot{u}_g(t)$ is firstly modeled

as a Gaussian zero mean white noise random process with power spectral density $S_{\ddot{u}_g} = S_0$. Therefore the stochastic properties are assumed to describe the system response. Rewriting the governing equations of motion in the first-order state space form:

$$\dot{z}(t) = \mathbf{A}\mathbf{z}(t) + \mathbf{B}a(t) \tag{6}$$

where

$$\mathbf{z}(t) = \left[\begin{array}{cc} \mathbf{u}(t) & \dot{\mathbf{u}}(t) \end{array} \right]^{\mathrm{T}} \tag{7}$$

is the state vector, $a(t)$ is the applied input process, the matrices **A** and **B** are the state matrix and the input vector, respectively. Since the stationary input process has zero mean and the initial conditions are zero, the response is fully represented by the covariance matrix $\mathbf{G}_{zz}$, that satisfies, by virtue of the stationarity of $\mathbf{z}(t)$, the Lyapunov Equation:

$$\mathbf{A}\mathbf{G}_{zz} + \mathbf{G}_{zz}\mathbf{A}^T + 2\pi S_0 \mathbf{B}\mathbf{B}^T = \mathbf{O} \tag{8}$$

The variances of the displacements of the two oscillators in the controlled configuration, found solving numerically the Eq.8, respectively σ_L^2 and σ_U^2, have been normalized by dividing each of them by σ_{U0}^2, which represents the variance of the displacement of the upper mass with respect to the ground in absence of control, obtaining:

$$I_U = \sqrt{\frac{\sigma_U^2}{\sigma_{U0}^2}} \quad \text{and} \quad I_L = \sqrt{\frac{\sigma_L^2}{\sigma_{U0}^2}} \tag{9}$$

3 MULTI-OBJECTIVE OPTIMIZATION OF THE IBIS

In this section the optimal design of the control system is discussed.

Not all the dimensionless parameters listed in Tab.1 get involved in the optimization procedure as design parameters. In fact, in this work, the sloshing damping factor ξ_U and the mass ratio μ have been supposed known; whereas the three dimensionless parameters referred to the IBIS, i.e. the frequency ratio δ, the damping factor ξ_L and the inertial ratio β, assume the role of design parameters to be optimized. Therefore the proposed procedure aims at designing the optimal connection between the basement of the tank and the ground.

Aiming at achieving the overall protection of both the sub-structures, preserving both the primary and the secondary structures, a multi-objective design criterion has been adopted. Two objective functions have been selected to be minimized: these are the displacement of the upper system relative to the basement- the sloshing displacement- and the lower system displacement relative to the ground- basement displacement. These two functions are in conflict. It is in fact worth noticing that a more effective reduction of the secondary system displacement inevitably corresponds to a worse control of the response of the impulsive displacement. The identification of a solution which corresponds to a minimum- optimal value- for all the objective functions is allowed if they do not conflict with each other.

Therefore, in this case, none of the objective functions can be improved without negative consequences on the other one. Thus, the problem can be stated in the form:

$$\text{find} \qquad min \quad [\mathbf{F}(\mathbf{x})] \qquad \text{subjected to } \mathbf{x}^{min} \leq \mathbf{x} \leq \mathbf{x}^{max} \tag{10}$$

In other terms, the multi-objective optimization procedure consists in finding the design vector **x**, which components vary in a space, capable to minimize the vector of the objective functions **F**(**x**). As a consequence the identification of a unique solution is no longer possible, instead a set of solutions which constitute the Pareto front can be detected.

Table 2: Geometrical and mechanical tank properties [1].

Radius	$R\ [m]$	27.43
Maximum filling level	$H\ [m]$	13.71

4 NUMERICAL INVESTIGATIONS

The procedure explained in the previous section has been adopted assuming a case study, whose geometrical and mechanical properties are collected in Tab.2. The results are discussed in this section.

The sloshing damping factor ξ_U = 0.005 and the mass ratio μ = 2.0 have been fixed (see Tab. 1-2) .The three dimensionless design parameters vary in the ranges shown in Tab.3.

4.1 Multi-objective optimization

The problem stated in the previous section can be fitted to the case under consideration substituting in **x** the vector containing the three design parameters:

$$\mathbf{x} = \left[\begin{array}{ccc} \xi_L & \delta & \beta \end{array} \right]^{\mathrm{T}} \tag{11}$$

and considering the following vector of the objective functions:

$$\mathbf{F}(\mathbf{x}) = \left[\begin{array}{cc} I_U(\mathbf{x}) & I_L(\mathbf{x}) \end{array} \right]^{\mathrm{T}} \tag{12}$$

The results obtained applying to the system a base motion, modeled as a white noise random input, are illustrated in this section. Both the Pareto front and the performance of the proposed

Table 3: Space of the dimensionless design parameters.

Description	Symbol	$\mathbf{x}^{min}$	$\mathbf{x}^{max}$
Isolation damping ratio	ξ_L	0.01	0.50
Frequency ratio	δ	0.10	10.0
Inertial mass ratio	β	0	10.00

Table 4: Optimal dimensionless parameters found through the multi-objective procedure.

Description	Symbol	Optimal value
Isolation damping ratio	ξ_L	0.50
Frequency ratio	δ	2.24
Inertial mass ratio	β	5.10

IBIS are shown in Fig.2, from which the achievement of a meaningful reduction of the structural response in a large portion of the plan can be deduced.

Moreover the existence of a limit curve, the Pareto front, which delimits a region to whom the access is denied, is highlighted. Among all the points belonging to the Pareto front, the point of minimum distance- blue line in Fig.2- from the origin of the axes has been chosen as the point of the optimality.

At least a triplet of specific values of the dimensionless parameters ξ_L, δ, β can be associated to each point on the plan in Fig.2. Depending on both the ranges of variation of parameters and the number of steps assumed in the analysis, a complete filling of the plan (I_U, I_L) can be achieved, except for the forbidden area.

The triplet of dimensionless parameters associated to the point of optimal performance is listed in Tab.4. Some comments on the optimal values obtained should be done. It is, in fact, worth noticing that ξ_L attains the maximum value ξ_L^{max}, β^{opt} falls in the middle of the range of variation, taking a fairly high value, attesting the inertance beneficial contribution, and δ^{opt} is greater than one, which implies that the period of the control isolation system is lower than the convective period. Instead, values of δ lower than one stand for sloshing mode period stiffer than the isolation system. With the aim of avoiding the onset of crises due to static actions, the adoption of a too flexible isolation system, i.e. the assumption of small values of δ, should be also excluded.

4.2 Sensitivity analyses

Dealing with the issue of establishing the robustness of the proposed seismic mitigation strategy, sensitivity analyses have been performed in order to evaluate the influence of each dimensionless parameter pertinent to the control system on the reduction of the response, paying attention to the system behaviour in a neighborhood of the optimal point.

Denoting with I the ratio between the distance of the current point on the plan (I_U, I_L) from the origin of the axes and the distance of the point of optimal performance, the contour plots obtained fixing $\delta = \delta^{opt}$ and varying the other two parameters around the optimal values are illustrated in Fig.3. The values of the dimensionless parameters divided by the corresponding values in Tab.4 take the superscript N.

The red point in the middle of Fig.3 (B) represents the point of optimality (see Tab.4). It can be noticed that a better control of the response can be achieved increasing ξ_L, suggesting that ξ_L increments induce an advancement of the Pareto Front towards the origin of the axes. Refer, e.g., to the green (D) and red (B) points in Fig.3, which are associated to the same value

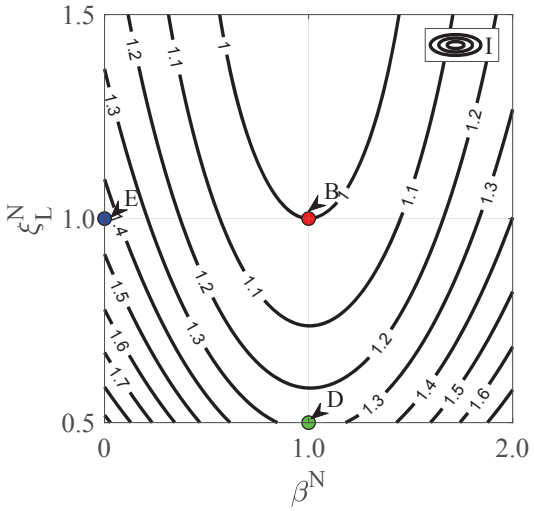

Figure 3: Contour plots of I, assuming δ^{opt}.

Table 5: Optimal dimensionless parameters found through the multi-objective procedure selected for the analyses performed in time and frequency domain.

Description	Symbol	A	B	C
Isolation damping ratio	ξ_L	0.15	0.50	0.50
Frequency ratio	δ	2.56	2.24	1.55
Inertial mass ratio	β	6.8	5.1	0

of β but to different values of ξ_L. Moving on a vertical line, it is also shown in Fig.3 that further increasing ξ_L beyond the optimal value does not lead to a meaningful improvement of the performance. Furthermore, the existence of a minimum for β is well stressed, implying that the selection of a β value should be done carefully.

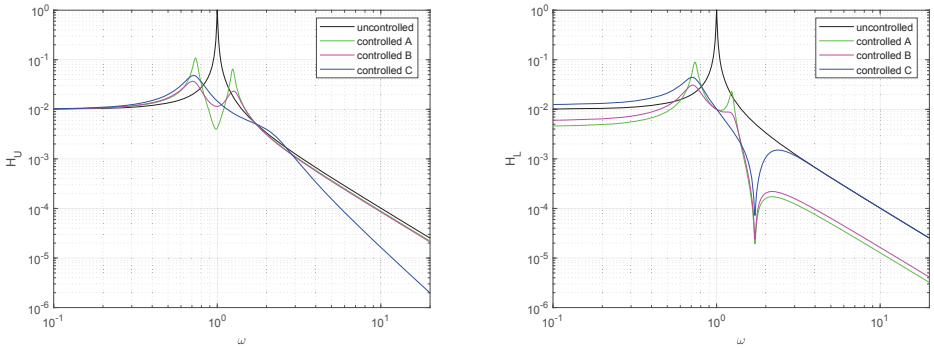
Fig.3 can be used in order to compare the performance of a IBIS - red point- with respect to a BIS- blue point (E), characterized by the same ξ_L, highlighting the achievement of a reduction of I thanks to the employment of the inertance.

4.3 Evaluation of the IBIS seismic performance

The frequency transfer function curves of sloshing displacement and isolation displacement are represented. The values of the parameters are listed in (Tab.5).

In (Fig.4) the effectiveness of the optimally designed IBIS is shown, through the representation of the frequencydomain transfer function curves, from which an effective response mitigation for both sloshing height and isolation displacement can be deduced. For comparative purposes, the responses of an optimized system characterized by a lower xi_L value (A) and of an optimized BIS (C) are shown.

In order to evaluate and assess the seismic effectiveness of the designed control system object of this work, numerical simulations have been carried out, assuming different base motion histories. Time-history analyses have been carried out on the 2DOF system both in the fixed



(a) (b)

Figure 4: Frequency transfer functions of a) sloshing height and b) isolation displacement.

base tank configuration and in the IBIS.

Two quantities have been monitored in order to evaluate the response, i.e. sloshing heights and basement displacements relative to the ground. The responses in time domain in terms of sloshing heights and isolation displacement are illustrated. The values are normalized by dividing the sloshing height and the basement displacement by the peak value of the sloshing height in the uncontrolled configuration. The dimensionless indices obtained make the interpretation of the results easier, in the sense that a value smaller than one means an effective reduction of the response quantities, whereas a value greater than one implies an amplification of the response with respect to the reference configuration. The results shown refer to a system involving the optimal set of parameters.

5 CONCLUSIONS

A novel strategy for controlling the sloshing response of seismically excited liquid storage tanks with rigid walls based on an inerter- based isolation system has been developed in this paper. The studies are carried on a reduced 2DOF system. With the aim of controlling at the same time the displacements of the two coupled oscillators- one pertinent to the sloshing part of liquid mass, the second one comprehensive of the impulsive part of the total liquid mass- the design parameters of the inerter- based isolation system, that is, its damping coefficient, its stiffness and its inertial mass, called inertance, are optimized by stating a Pareto multi-objective optimization problem, minimizing the two objective functions related to the displacements of the two oscillators, assuming as a base input a ground acceleration modeled as a Gaussian stochastic process with white noise power spectral density. On the basis of the defined design method an optimized system, able to effectively control both the sloshing and the isolation response, has been obtained.

Sensitivity analyses, in which the influence of the dimensionless parameters selected as representative of the added vibration control system is investigated, have been conducted. Thus, the role of the design parameters in the deployment of points in the plan depicted has been extensively investigated.

Results obtained by subjecting the system to a series of near fault and far field earthquakes as well as synthetic accelerograms were subsequently reported, showing the gaining of mean-

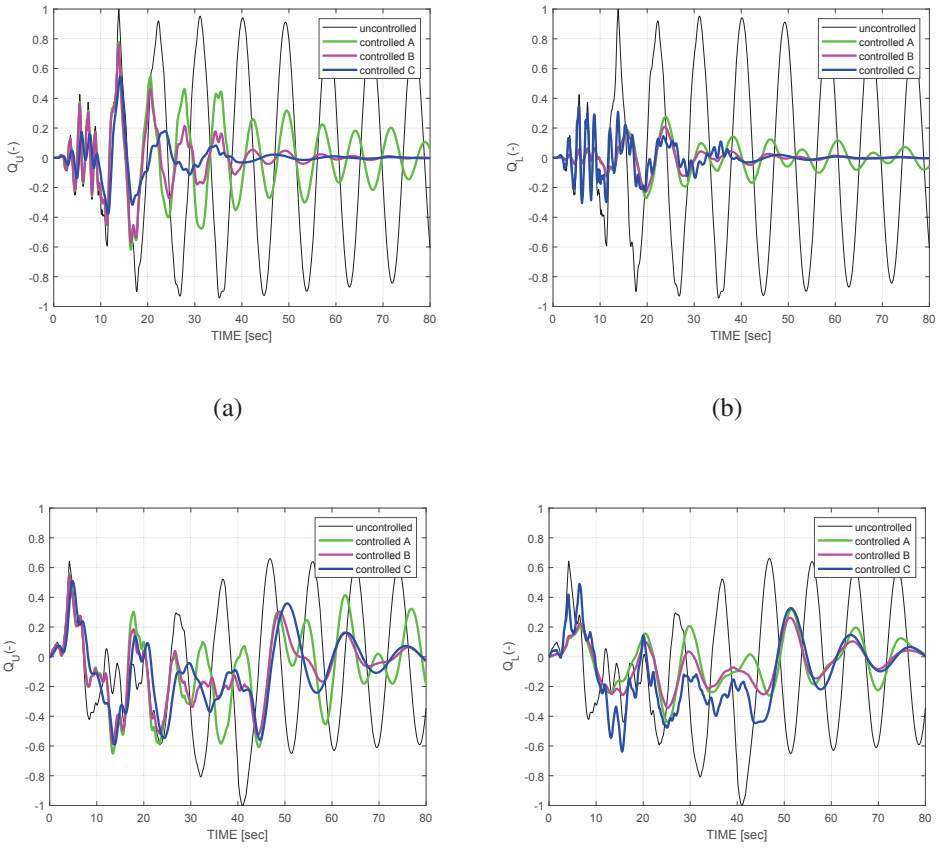


Figure 5: Time histories of: a) normalized sloshing height, b) normalized isolation displacement for Kobe earthquake; c) normalized sloshing height, d) normalized isolation displacement for Hachinohe earthquake.

ingful reductions of the response.

Further developments will involve a TMDI system in order to study any beneficial effects of its employment in such kind of problems.

INERTER-BASED VIBRATION ABSORBERS FOR ROTATING WIND TURBINE BLADES

Zili Zhang[1]

[1]Department of Engineering, Aarhus University
8000 Aarhus, Denmark
e-mail: zili_zhang@eng.au.dk

Keywords: Inerter, Vibration absorber, Wind turbine blades, Closed-form expressions.

Abstract. *Rotating wind turbine blade is lightly damped in the edgewise mode due to low aerodynamic damping. Adding damping into edgewise mode becomes an important design consideration for protecting the wind turbine blades from damage during the design period. This paper proposes the use of two novel inerter-based vibration absorbers, the tuned mass-damper-inerter (TMDI) and the rotational inertia double tuned mass damper (RIDTMD), for mitigation of edgewise blade vibrations. A 2-DOF model is established for the rotating blade-TMID system, and a 3-DOF model is established for the blade-RIDTMD system. Closed-form expressions for the optimal tuning and damping ratios of the blade-mounted TMDI and RIDTMD are derived, as well as for a classic tuned mass damper (TMD). Performance of the TMD, TMDI and RIDTMD are compared in terms of the blade vibration mitigation and the damper stroke, in both frequency domain and time domain. Results indicate that comparing with TMD, TMDI has the advantage of significantly less damper stroke at the cost of slight degradation in blade vibration control performance. On the other hand, RIDTMD achieves better vibration control performance comparing with an optimal TMD, with slightly increased stroke. The results indicate encouraging prospects for the use of TMDI and RIDTMD in the control of vibrations of wind turbine blades.*

1 INTRODUCTION

The increased size of wind turbines results in more flexible blades and tower that are more susceptive to dynamic loads due to turbulent winds and irregular sea waves. Structural vibrations of the wind turbine tower and blades negatively affect both the fatigue life of the structure and the power production.

The modes of vibrations in wind turbine blades are classified as flapwise and edgewise modes, representing vibrations out of the rotor plane and in the rotor plane, respectively. The flapwise vibration is highly damped under normal operational conditions because of the very high aerodynamic damping [1, 2], and thus is mainly quasi-static. On the other hand, edgewise vibration is associated with negligible aerodynamic damping [1, 2], and is dominated by dynamic response instead of quasi-static. There is also risk of aeroelastic instability in the edgewise mode for some combinations of blade properties and operational conditions, where the sum of structural damping and aerodynamic damping becomes negative. Therefore, adding damping into edgewise mode becomes an important design consideration for protecting the wind turbine blades from damage during the design period.

Structural control of wind turbine blades has received much attention in the literature in recent years. Comparing with active control [3, 4], passive and semi-active control technologies are more cost-effective and simple to implement, thus more applicable for applications in wind industry. Various types of pendulum-like passive vibration absorbers have been proposed for damping edgewise vibrations [5, 6, 7, 8], where nonlinear equations of motion have been derived for these devices (coupled to the rotating blade). Due to the inherent nonlinearities of these devices, the dampers can only be optimized through numerical optimization. On the other hand, the classic tuned mass damper (TMD) and the inerter-based vibration absorbers [9, 10, 11] provide the possibility for optimal design using closed-form formulas, since their behavior is rather linear. Furthermore, using the inerter in a smart way can improve the performance of the inerter-based vibration absorbers, thus resulting in devices that are more promising to be employed for wind turbine blades.

This paper proposes the use of two novel inerter-based vibration absorbers, the tuned mass-damper-inerter (TMDI) [10] and the rotational inertia double tuned mass damper (RIDTMD) [11], for mitigation of edgewise blade vibrations. A 2-DOF model is established for the rotating blade-TMID system, and a 3-DOF model is established for the blade-RIDTMD system. Closed-form expressions for the optimal frequency tuning and damping ratios of the blade-mounted TMDI and RIDTMD are derived, as well as for a classic TMD. Results indicate that comparing with TMD, TMDI has the advantage of significantly less damper stroke at the cost of slight degradation in blade vibration control performance. On the other hand, RIDTMD achieves better vibration control performance comparing with an optimal TMD, with slightly increased damper stroke.

2 FORMULATION OF EQUATIONS OF MOTION

2.1 Problem definition

The model of a rotating blade equipped with a vibration absorber (TMD or TMDI or RIDTMD) is shown in Figure 1. The blade is modelled as a rotating Euler-Bernoulli beam in the rotating (x_1, x_2, x_3)-coordinate system, with a rotational speed Ω. So the azimuthal angle $\Psi(t)$ of the blade becomes $\Psi(t) = \Omega t$. The blade edgewise vibration is described by the local degree of freedom (DOF) $q(t)$, representing the tip displacement in the negative x_2- direction. Assuming the blade vibration to be dominated by its fundamental mode, the local edgewise displacement

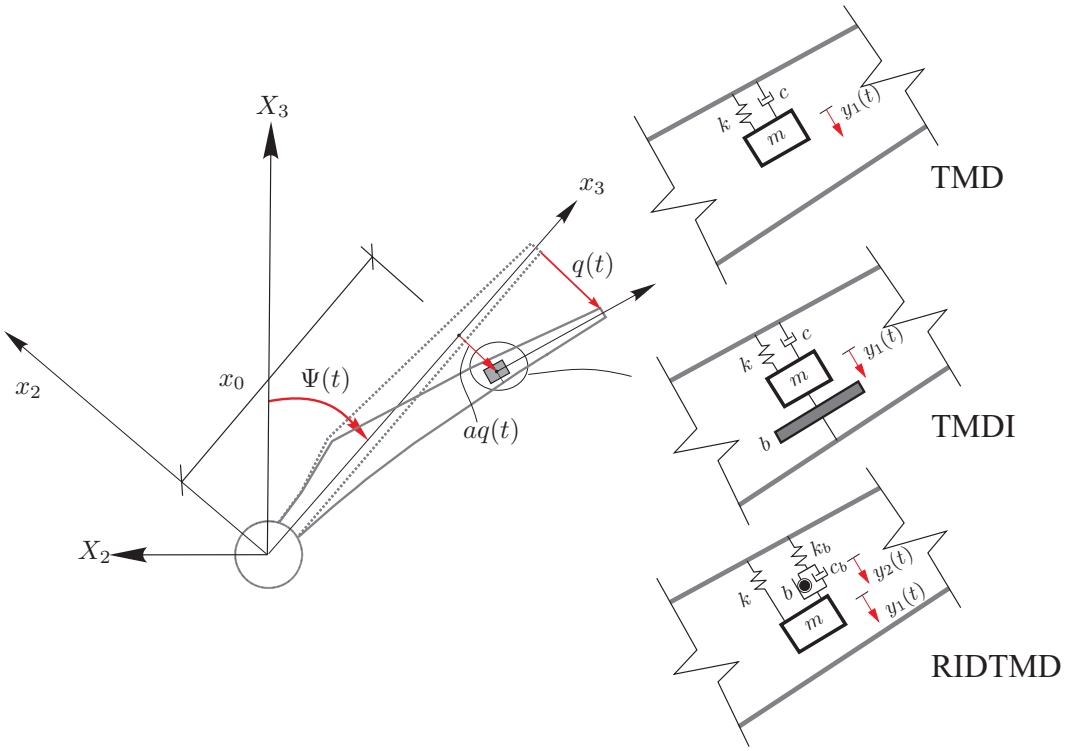

Figure 1: Definition of coordinate systems, layout of the three vibration absorbers, and degrees of freedom.

field $u_2(x_3,t)$ of the blade can be written as $u_2(x_3,t) = -\Phi(x_3)q(t)$, where $\Phi(x_3)$ is the fundamental edgewise eigenmode that is normalized to unit at the blade tip.

The vibration absorbers are assumed to be installed at the coordinate $x_3 = x_0$. So the local displacement of blade at the damper location becomes $u_2(x_0,t) = -aq(t)$, with $a = \Phi(x_0)$ being a design parameter representing the damper location. For TMD or TMDI, only one DOF, $y_1(t)$, is needed to model the device. $y_1(t)$ indicates the displacement of the TMD block mass m relative to the deformed blade. On the other hand, for RIDTMD, two DOFs, $y_1(t)$ and $y_2(t)$, are needed to model the device. $y_1(t)$ again indicates the displacement of the TMD absorber mass m relative to the deformed blade, while $y_2(t)$ indicates the displacement of the inerter b with respect to the deformed blade. Therefore, $q(t)$ and $y_1(t)$ make up the 2 DOFs of the rotating blade-TMDI (or blade-TMD) system, while $q(t)$, $y_1(t)$ and $y_2(t)$ make up the 3 DOFs of the rotating blade-RIDTMD system.

2.2 Equations of motion based on analytical dynamics

Take the blade-TMDI system as an example, the velocity components of the vibrating blade described in the local (x_2, x_3)-coordinate system are:

$$\begin{aligned} v_2(x_3,t) &= -\Omega x_3 - \Phi(x_3)\dot{q}(t) \\ v_3(x_3,t) &= -\Omega\Phi(x_3)q(t) \end{aligned} \tag{1}$$

Described in the fixed global (X_2, X_3)-coordinate system, the components of the velocity vector of the TMDI absorber mass become:

$$\begin{aligned} V_{2,d}(t) &= -\left(x_0\Omega + a\dot{q} + \dot{y}_1\right)\cos\Psi + \left(aq + y_1\right)\Omega\sin\Psi \; v_3(x_3,t) \\ V_{3,d}(t) &= -\left(x_0\Omega + a\dot{q} + \dot{y}_1\right)\sin\Psi - \left(aq + y_1\right)\Omega\cos\Psi \end{aligned} \tag{2}$$

The total kinetic energy of the system (i.e. one blade and one TMDI including the absorber mass and the inerter) becomes:

$$T(t) = \frac{1}{2}\int_0^L \mu(x_3)\Big(v_2^2(x_3,t) + v_3^2(x_3,t)\Big)dx_3 + \frac{1}{2}m\Big(V_{2,d}^2(t) + V_{3,d}^2(t)\Big) + \frac{1}{2}b\dot{y}_1^2 \tag{3}$$

where $\mu(x_3)$ is the mass per unit length of the blade. The total potential energy of the system is:

$$U(t) = mg\left(x_0\cos\Psi - aq\sin\Psi - y_1\sin\Psi\right) + \frac{1}{2}k_0q^2 + \frac{1}{2}ky_1^2 \tag{4}$$

where $k_0(\Omega)$ is the modal stiffness of the blade including the geometric stiffness effect from centrifugal acceleration [12].

Inserting Eqs. (3) and (4) into Lagrange's equation, the equations of motion of the blade-TMDI system becomes:

$$\begin{bmatrix} m_0 + a^2m & am \\ am & m+b \end{bmatrix}\begin{bmatrix}\ddot{q}\\ \ddot{y}_1\end{bmatrix} + \begin{bmatrix}0 & 0\\ 0 & c\end{bmatrix}\begin{bmatrix}\dot{q}\\ \dot{y}_1\end{bmatrix} + \begin{bmatrix} k_0 - (m_0 + a^2m)\,\Omega^2 & -am\Omega^2 \\ -am\Omega^2 & k - m\Omega^2\end{bmatrix}\begin{bmatrix}q\\ y_1\end{bmatrix} = \begin{bmatrix} f(t) + amg\sin\Psi \\ mg\sin\Psi\end{bmatrix} \tag{5}$$

where structural damping has been neglected for the following derivation of closed-form expressions. $m_0 = \int_0^L \mu(x_3)\,\Phi^2(x_3)dx_3$ is the modal mass of the blade. Hence, $\omega_0 = \sqrt{k_0/m_0}$ is the angular eigenfrequency of the blade. Further, $f(t)$ is the modal load on the blade from turbulence and gravity.

By setting $b = 0$ in the above equation, the equations of motion for the blade-TMD system [12] is recovered.

Using a similar analytical dynamics approach, the equations of motion of the 3-DOF blade-RIDTMD become:

$$\begin{bmatrix} m_0 + a^2m & am & 0 \\ am & m+b & -b \\ 0 & -b & b\end{bmatrix}\begin{bmatrix}\ddot{q}\\ \ddot{y}_1\\ \ddot{y}_2\end{bmatrix} + \begin{bmatrix}0 & 0 & 0\\ 0 & c_b & -c_b\\ 0 & -c_b & c_b\end{bmatrix}\begin{bmatrix}\dot{q}\\ \dot{y}_1\\ \dot{y}_2\end{bmatrix} +$$

$$\begin{bmatrix} k_0 - (m_0 + a^2m)\,\Omega^2 & -am\Omega^2 & 0 \\ -am\Omega^2 & k - m\Omega^2 & 0 \\ 0 & 0 & k_b\end{bmatrix}\begin{bmatrix}q\\ y_1\\ y_2\end{bmatrix} = \begin{bmatrix} f(t) + amg\sin\Psi \\ mg\sin\Psi \\ 0\end{bmatrix} \tag{6}$$

3 Closed-form expressions for optimal tuning

Based on Eq. (5) or Eq. (6), closed-form expressions for optimal parameter tuning can be performed. The fixed-point method [13] has been used for blade-mounted TMDI (also TMD), while the pole placement method [14] has been used for the blade-mounted RIDTMD.

3.1 Optimal tuning of the bladed-mounted TMDI

Representing the responses $q(t)$ and $y_1(t)$ and the load $f(t)$ to be harmonic varying with angular frequency ω, the normalized (by the static response f_0/k_0 with f_0 being the amplitude of the load) complex structural response q_0 can be obtained. $\frac{q_0}{f_0/k_0}$ is a function of ω and the following normalized parameters:

$$\mu = \frac{m}{m_0}, \quad \beta = \frac{b}{m_0}, \quad \gamma = \frac{b}{m} = \frac{\beta}{\mu}, \quad \omega_{\text{TMDI}} = \sqrt{\frac{k}{m+b}}, \quad \zeta_{\text{TMDI}} = \frac{c}{2\sqrt{k\,(m+b)}} \tag{7}$$

where μ and β are the mass ratio and inertance ratio, respectively. ω_{TMDI} and ζ_{TMDI} are the angular eigenfrequency and damping ratio of the TMDI, respectively.

It turns out that the two fixed points also exit in the present case, i.e. rotating blade with a TMDI. Following the similar procedure in [13], by equalizing the dynamic amplification (absolute value of the normalized complex amplitude) at these two fixed frequencies, the optimal frequency tuning formula becomes:

$$\left(\omega_{\text{TMDI}}\right)_{opt} = \sqrt{\frac{\left(1+\gamma+a^2\beta\right)\omega_0^2 - \left(1+a^2\mu\right)\left(\gamma+a^2\beta\right)\Omega^2}{\left(1+\gamma\right)\left(1+a^2\mu\right)^2}} \tag{8}$$

which not only depends on the mass ratio and inertance ratio, but also is dependent on the rotational speed Ω.

The optimal TMDI damping ratio is chosen to ensure that the dynamic amplifications are equal at the two fixed-frequencies and ω_∞ (the natural frequency of the blade with a locked TMDI) [13]. The closed-form formula for the optimal TMDI damping ratio tuning becomes:

$$\left(\zeta_{\text{TMDI}}\right)_{opt} = \sqrt{\frac{1}{2}\frac{\left(a^2\mu+a^2\beta+a^4\mu\beta\right)}{\left(1+\gamma\right)\left(1+a^2\mu\right)}\frac{\omega_0^4}{\left(1+\gamma+a^2\beta\right)\omega_0^4 - \left(1+a^2\mu\right)\left(1+2\gamma+2a^2\beta\right)\omega_0^2\Omega^2 + \left(1+a^2\mu\right)^2\left(\gamma+a^2\beta\right)\Omega^4}} \tag{9}$$

By setting $\beta = 0$ (and thus $\gamma = 0$) in Eqs. (8) and (9), the optimal tuning formulas for the blade-mounted TMD [12] are recovered:

$$\left(\omega_{\text{TMD}}\right)_{opt} = \frac{\omega_0}{1+a^2\mu} \tag{10}$$

$$\left(\zeta_{\text{TMD}}\right)_{opt} = \sqrt{\frac{1}{2}\frac{a^2\mu}{1+a^2\mu}\left(\frac{\omega_0^2}{\omega_0^2 - \left(1+a^2\mu\right)\Omega^2}\right)} \tag{11}$$

3.2 Optimal tuning of the bladed-mounted RIDTMD

Again, the normalized complex structural amplitude q_0 can be obtained by assuming all responses and the load to be harmonically varying. The expression becomes much more lengthy because the system has 3 DOFs now. For the RIDTMD, four parameters (instead of two for the TMDI) need to be optimized, i.e. k, k_b, b and c_b.

The idea is to optimally place the poles of the system [14], i.e. the complex roots of the sextic characteristic equation (the denominator of the complex structural amplitude), in order to obtain the optimal damper parameters. The mathematical derivations are rather exhaustive, and will be detailed in a separate publication. The general steps are: 1) Choose the mass ratio μ. 2) The two springs k and k_b are optimally tuned so that two of the three poles are inverse points with respect to a quarter circle (resulting in equal modal damping ratio), while the other pole is placed on this circle. 3) The inertance b and the damping coefficient c_b are optimally calibrated based on the triple-root bifurcation point together with two scaling parameters. The closed-form expressions indicate that the optimal parameters all depend on the rotational speed.

4 Results

Data from the NREL 5 MW reference turbine [15] were employed to calibrate the structural model of the wind turbine blade. Each blade has a length of 61.5 m and an overall mass of 17740 kg, with the edgewise bending stiffness, the mass per unit length and the fundamental edgewise mode shape given by [15]. The rated rotational speed of the rotor is Ω_0=1.27 rad/s.

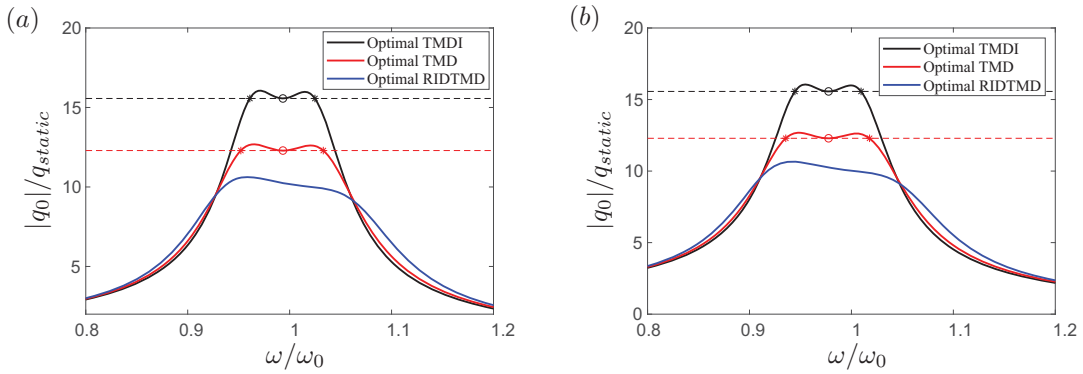

Figure 2: Dynamic amplification of the structural response, $x_0 = 45$ m and $\mu = 0.05$ for all three dampers. $\beta = 0.03$ has been chosen for TMDI. Asterisk: the fixed-point frequencies. Circle: ω_∞. (a) $\Omega = 0$ (non-rotating blade). (b) $\Omega = \Omega_0$ (1.27 rad/s).

Figure 2 shows the dynamic amplification of the structural response, with the three optimally-tuned dampers attached. Both cases of $\Omega = 0$ (non-rotating blade) and $\Omega = \Omega_0$ have been considered. The dampers are located at the location of $x_0 = 45$ m, and the mass ratio of the TMD absorber for all of them is kept at $\mu = 0.05$. For TMDI, the inertance ratio should also be chosen in advance, here β is chosen to be $\beta = 0.03$. It is seen that the optimal RIDTMD has the best performance in reducing the blade response comparing with the optimal TMD and the optimal TMDI. The TMDI has the least reduction effect. Furthermore, for the optimal TMDI or optimal TMD, the dynamic amplifications at the two fixed frequencies and ω_∞ are on the same horizontal line. This is as expected since the optimal tuning formulas for TMDI or TMD have been derived exactly based on this criterion. It is also seen that for the optimal RIDTMD, the dynamic amplification curve is skewed, which is in agreement with the finding in [14] and is due to the fact that equal modal damping ratio does not guarantee the equal height of dynamic amplifications.

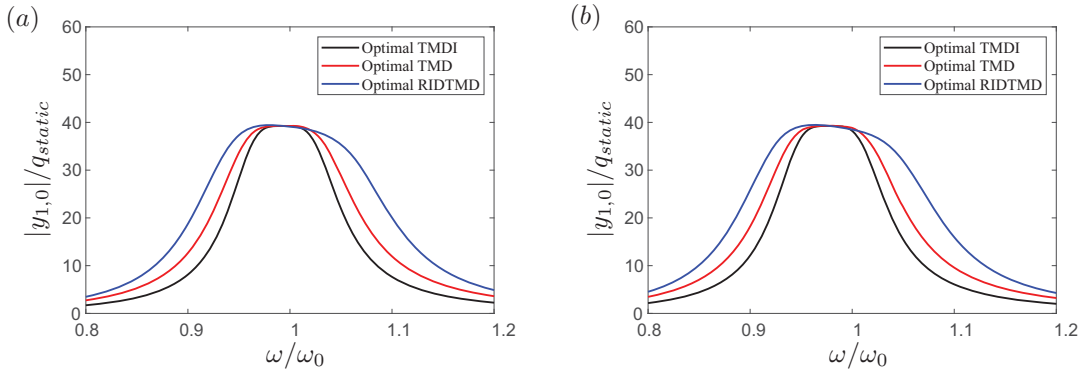

Figure 3: Dynamic amplification of the damper stroke, $x_0 = 45$ m and $\mu = 0.05$ for all three dampers. $\beta = 0.03$ has been chosen for TMDI. (a) $\Omega = 0$ (non-rotating blade). (b) $\Omega = \Omega_0$ (1.27 rad/s).

Correspondingly, Figure 3 shows the dynamic amplification of the relative absorber motion (the damper stroke). Even though the peak heights of the three curves are similar, the curve corresponding to optimal RIDTMD is the most broad-banded, while the optimal TMDI is the most narrow-banded. This implies that the optimal TMDI performs best in terms of the smallest damper stroke, while the optimal RIDTMD has the largest stroke. The finding from Figure 3 is in contrary to that from Figure 2, which makes sense because the improvement of one performance indicator is normally at the cost of worsening another indicator. Comparing with TMD,

both TMDI and RIDTMD improve one certain type of the damper performance. It is up to the designer to decide which performance indicator is more important.

5 CONCLUSIONS

Closed-form expressions have been derived for optimal tuning of the blade-mounted TMDI and the blade-mounted RIDTMD, the former based on fixed-point method and the latter based on pole-placement method. Using the NREL 5-MW wind turbine as the numerical example, it is observed that comparing with the optimal TMD, the optimal TMDI has the advantage of less damper stroke at the cost of slight degradation in blade vibration control performance. On the other hand, the optimal RIDTMD is superior in damping blade vibrations comparing with the optimal TMD, with slightly increased stroke. This work provides rigourous theoretical formulations as well useful design formulas for the blade-mounted inerter-based vibration absorbers.

Keywords: Tuned mass damper inerter, optimal passive vibration control, white-noise excitation, low-order modelling.

Abstract. The tuned mass-damper-inerter (TMDI) is a linear passive dynamic vibration absorber for motion control of dynamically excited building (primary) structures. It couples the classical tuned mass damper (TMD), comprising a secondary mass attached to the top building floor via a spring and dashpot, with an inerter, a mechanical element resisting relative acceleration, which links the secondary mass to a lower floor. Recent studies demonstrate that TMDI motion control effectiveness is influenced by the vibration modes of the uncontrolled primary structure. Herein, this influence is quantified through a parametric investigation considering a wide range of white-noise excited primary structures modelled as cantilevered continuous beams with various shapes and, therefore, different vibration modes. This quantification is facilitated by considering a low-order model of TMDI-equipped flexural cantilever which accounts for the effect of flexural rigidity and mass distribution of the primary structure as well as the influence of the fundamental mode shape to the location that the inerter connects the secondary mass to the primary structure. The investigation is further supported by optimal H_2 tuning of TMDI aiming to minimize the free-end primary structure displacement under white noise excitation. It is shown that the TMDI achieves enhanced structural performance as the inerter links the secondary mass further away from the top of the primary structure where the mass is attached to for all primary structure shapes. Moreover, it is found that improved TMDI performance and reduced stroke (relative secondary mass displacement with respect to the primary structure) are achieved for primary structure shapes with stiffness and mass distribution weighted heavier towards the base of the structure (i.e., when most of material is concentrated towards the bottom end of the structure) either through appropriate shaping or through increase of base to free-end depth ratio for fixed non-uniform shapes.

1 INTRODUCTION

In recent years the use of the inerter, defined in [1] as a mechanical element that resists relative acceleration through the inertance constant, has been widely considered in various linear passive dynamic vibration absorber configurations for enhanced motion control in dynamically excited structures [2]. Among these absorbers, the tuned mass damper inerter (TMDI) introduced in [3] attracted significant attention in the literature and its potential to achieve improved vibration suppression compared to the standard tuned mass damper (TMD) has been verified in various applications including for the seismic protection of building structures [3-5] as well as for safeguarding occupants' comfort in wind excited slender tall buildings [6-8]. In the TMDI configuration for building (primary) structures, an inerter is used to link a secondary mass attached to one building floor (commonly the top floor) through a spring in parallel with a viscous damper (dashpot) to a different (lower) floor.

Giaralis and Taflanidis [9] were the first to demonstrate for a seismically excited TMDI-equipped 10-storey shear frame structure that the more floors the inerter spans (i.e., the further lower the floor that the inerter connects the secondary mass) the more improved vibration suppression is furnished by an optimally tuned TMDI. This observation was more recently confirmed for seismically and wind excited real-life benchmark multi-storey structures [5,7]. Further, recognizing that spanning several floors may not be economically feasible in routine practical applications, Wang and Giaralis [8] proposed a local primary structure modification namely top-floor softening, which leads to an increased local difference in the primary structure mode shapes and was shown to have a similar beneficial effect with spanning more floors in wind-excited buildings equipped with a top-floor TMDI. This result suggests that the mode shapes of the uncontrolled primary structure and, hence, the mass and stiffness distribution of the primary structure influences the motion control potential of the TMDI. To this end, this paper aims to quantify this influence through a parametric investigation considering a wide range of white-noise excited primary structures modelled as cantilevered continuous beams with various shapes and, therefore, different vibration modes. This quantification is facilitated by considering a low-order model of TMDI-equipped flexural cantilever which accounts for the effect of flexural rigidity and mass distribution of the primary structure as well as the influence of the fundamental mode shape to the location that the inerter connects the secondary mass to the primary structure. The investigation is further supported by optimal H_2 tuning of TMDI aiming to minimize the free-end primary structure displacement under white noise excitation. The presentation starts from the definition of the simplified model and the derivation of frequency response functions used in random vibration analyses.

2 SIMPLIFIED 2-DOF DYNAMIC MODELLING AND ANALYSIS OF TMDI-EQUIPPED CONTINUOUS FLEXURAL CANTILEVERED BEAMS

2.1 Model description and equations of motion

Consider the TMDI-equipped continuous flexural cantilever beam (primary structure) depicted in Figure 1(a). The beam height is H and has distributed flexural rigidity $EI(x)$ and distributed mass $m(x)$, with $0 \leq x \leq \mathrm{H}$, while it is taken as undamped. A TMDI is attached to the free-end of the primary structure to control its lateral motion due to horizontal distributed dynamic load $p(x,t)$. Specifically, the TMDI consists of a secondary mass, m_{TMDI}, attached to the free-end of the primary structure through a linear spring with stiffness k_{TMDI} in parallel with dashpot with damping coefficient c_{TMDI} and further connected to the primary structure at height $x=\chi$ through an inerter with inertance b.

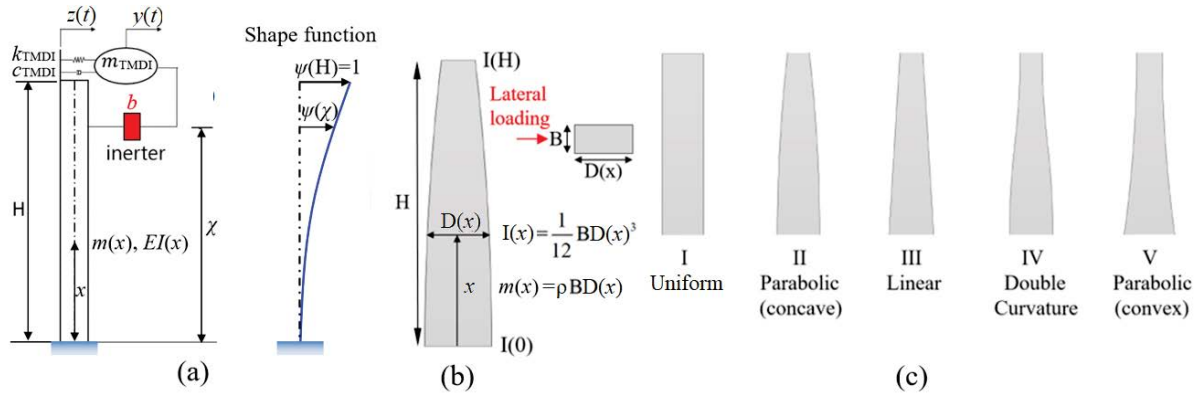

Figure 1 (a) Primary structure (cantilevered beam) equipped with TMDI and assumed mode shape, (b) Parametric variation of the primary structure, and (c) Considered primary structure geometrical shapes.

Let the lateral motion of the uncontrolled primary structure be governed by a single time-invariant shape function $\psi(x)$ which complies to the fixed support conditions at x=0 and, without loss of generality, is normalised such that ψ(H)=1 as shown in Figure 1(a). Under this assumption, the primary structure can be modelled as a generalized single degree of freedom (SDOF) system [10] and its lateral deflection can be written as $u(x,t)=\psi(x)z(t)$ where $z(t)$ is the tip displacement of the primary structure. In this setting, a simplified two degree of freedom (2-DOF) model is herein employed to approximate the lateral deflection of the TMDI-equipped cantilever beam in terms of its tip displacement $z(t)$ and the TMDI mass displacement $y(t)$ written in matrix form as

$$\mathbf{M}\ddot{\mathbf{q}}+\mathbf{C}\dot{\mathbf{q}}+\mathbf{K}\mathbf{q}=\mathbf{p}\,. \tag{1}$$

In the above equation, the displacement and forcing vectors are defined as

$$\mathbf{q}=\begin{Bmatrix} z(t) \\ y(t) \end{Bmatrix} \quad \text{and} \quad \mathbf{p}=\begin{Bmatrix} p^*(t) \\ 0 \end{Bmatrix}, \tag{2}$$

respectively, while the mass, damping, and stiffness matrix are

$$\mathbf{M}=\begin{bmatrix} m^*+b\psi(\chi)^2 & -b\psi(\chi) \\ -b\psi(\chi) & m_{TMDI}+b \end{bmatrix}, \mathbf{C}=\begin{bmatrix} c_{TMDI} & -c_{TMDI} \\ -c_{TMDI} & c_{TMDI} \end{bmatrix}, \text{and } \mathbf{K}=\begin{bmatrix} k^*+k_{TMDI} & -k_{TMDI} \\ -k_{TMDI} & k_{TMDI} \end{bmatrix}, \tag{3}$$

respectively and a dot over a symbol signifies differentiation with respect to time. Further, in the above expressions, $p^*(t)$, m^*, and k^* are the generalized load, mass, and stiffness of the generalized SDOF representation of the primary structure defined as [Clough and Penzien 1993]

$$p^*(t)=\int_0^H p(x,t)\psi(x)dx, \quad m^*=\int_0^H m(x)\psi(x)^2dx, \quad \textit{and} \quad k^*=\int_0^H EI(x)\psi''(x)^2dx\,, \tag{4}$$

where a prime over a symbol denotes differentiation with respect to x.

Notably, in the herein considered 2-DOF model the assumed (single) mode shape of the primary structure, $\psi(x)$, is explicitly accounted for in defining the primary structure generalized properties in Eq.(4) as well as the inerter force through the expression

$$F_b(t)=b\left(\psi(\chi)\ddot{z}(t)-\ddot{y}(t)\right). \tag{5}$$

In the above equation, it is clearly seen that the inerter force depends on the mode shape coordinate at location $x=\chi$ (i.e., where the inerter links the attached mass to the primary structure), including the limiting case of $\psi(\chi=0)=0$ for which the inerter is grounded and the mass

matrix in Eq.(3) becomes diagonal [11]. Moreover, the 2-DOF model can also treat TMD-equipped primary structures as a special case for which b=0. In this regard, the 2-DOF model in Eq.(1) can be effectively used as a vehicle to study the response of TMD(I)-equipped cantilevered beams with different assumed uncontrolled dominant vibration modes as well as different inerter connecting location to the primary structure.

2.2 Frequency domain random vibration analysis for white noise excitation

In the ensuing numerical part of this work, three dynamic response quantities of practical interest are monitored under the assumption of uniformly distributed zero-mean spatially uncorrelated white noise excitation. These are the root mean square (RMS) values of the free-end primary structure displacement, $z(t)$, of the TMDI stroke, $z(t)$-$y(t)$ (i.e., relative displacement of the secondary mass with respect to the free-end of the primary structure), and of the inerter force in Eq.(5). These quantities are readily determined using frequency domain analysis via the expressions

$$\sigma_z = \sqrt{\int_0^{\omega_{\max}} \left| p_o^* H(\omega) \right|^2 W_o d\omega},$$

$$\sigma_{y-z} = \sqrt{\int_0^{\omega_{\max}} \left| p_o^* G(\omega) \right|^2 W_o d\omega}, \quad \text{and} \tag{6}$$

$$\sigma_{F_b} = b\sqrt{\int_0^{\omega_{\max}} \left| p_o^* B(\omega) \right|^2 W_o d\omega}.$$

In the above expressions, ω is angular frequency, $\omega_{\max}$ is a cut-off frequency above which the frequency response functions in the arguments of the integrals attain negligible values, W_o is the amplitude of the white noise power spectral density function and $p_o^* = \int_0^H \psi(x)dx$. Further, $H(\omega)$, $G(\omega)$, and $B(\omega)$ are given as

$$H(\omega) = \frac{Z(\omega)}{P^*(\omega)} = \frac{k_{22} - \omega^2 m_{22} + i\omega c_{22}}{(k_{11} - \omega^2 m_{11} + i\omega c_{11})(k_{22} - \omega^2 m_{22} + i\omega c_{22}) - (k_{12} - \omega^2 m_{12} + i\omega c_{12})(k_{21} - \omega^2 m_{21} + i\omega c_{21})},$$

$$G(\omega) = \frac{Z(\omega) - Y(\omega)}{P^*(\omega)} = \left(1 + \frac{k_{21} - \omega^2 m_{21} + i\omega c_{21}}{k_{22} - \omega^2 m_{22} + i\omega c_{22}}\right) H(\omega), \quad \text{and} \tag{7}$$

$$B(\omega) = \frac{\omega^2 \left[\psi(\chi) Z(\omega) - Y(\omega)\right]}{P^*(\omega)} = \omega^2 \left[\psi(\chi) + \frac{k_{21} - \omega^2 m_{21} + i\omega c_{21}}{k_{22} - \omega^2 m_{22} + i\omega c_{22}}\right] H(\omega),$$

respectively, where $i = \sqrt{-1}$, and m_{mn}, c_{mn} and k_{mn}, with m,n=1,2 are the elements of the matrices in Eq. (3).

3 OPTIMAL TMDI DESIGN USING THE SIMPLIFIED 2-DOF MODEL

To support meaningful discussion on motion control performance of TMDI-equipped structures, it is deemed essential to optimally design/tune the TMDI to minimize primary structure response. To this aim, an optimization problem is formulated to tune TMDI stiffness and damping properties such that the RMS displacement of the primary structure free-end under white noise excitation, taken as the objective function (OF), is minimized. That is,

$$\text{OF}=\sigma_z \,. \tag{8}$$

The design problem has 5 non-dimensional design variables (DVs), namely the inerter connectivity ratio CR, the mass ratio μ, the inertance ratio β, the TMDI frequency ratio υ_{TMDI}, and the TMDI damping ratio ξ_{TMDI} defined as

$$\text{CR}=\frac{\text{H}-\chi}{\text{H}},\quad \mu=\frac{m_{TMDI}}{m^*},\quad \beta=\frac{b}{m^*},\quad \upsilon_{TMDI}=\frac{\sqrt{\dfrac{k_{TMDI}}{(m_{TMDI}+b)}}}{\omega_1},\ \text{and}\ \xi_{TMDI}=\frac{c_{TMDI}}{2\sqrt{(m_{TMDI}+b)k_{TMDI}}}, \tag{9}$$

where ω_1 is the first natural frequency of the uncontrolled primary structure. Then, optimal primary DVs, υ_{TMDI} and ξ_{TMDI}, are sought that minimize the OF given values of the secondary DVs: CR, μ, and β. The optimization problem is numerically solved in the ensuing numerical work using a pattern search algorithm [12] with iteratively updated search range of the primary variables hard-coded in MATLAB®.

4 PERFORMANCE ASSESSMENT OF TMDI-EQUIPPED CANTILEVERED BEAMS WITH DIFFERENT GEOMETRIC SHAPES

4.1 Parametric variation of primary structure geometric shape

As seen in section 2, the dominant vibration mode of the uncontrolled primary structure $\psi(x)$ enters explicitly in the definition the generalized primary structure properties as well as in the mass matrix of the simplified 2-DOF model used to capture the response of TMDI-equipped cantilevered beams. Given that in many practical applications the first mode, $\varphi_1(x)$, of the primary structure dominates its dynamic response, the choice of $\psi(x)= \varphi_1(x)$ is meaningful. However, $\varphi_1(x)$ depends heavily on the stiffness (flexural rigidity) and mass distribution along the height of the primary structure. To this end, the influence of the dominant vibration mode to the motion control potential of the TMDI is herein studied by varying parametrically the geometric shape (profile) of the primary structure as shown in Figure 1(b). Specifically, primary structures with fixed width B along the height of the structure but varying depth $D(x)$ within the direction of the lateral load are considered which further influence the flexural rigidity and mass distribution as specified in Figure 1(b). The five different primary structure shapes plotted in Figure 1(c) are considered. Shape I (uniform) has constant cross-section along the primary structure height and slenderness ratio H/D= 20, whereas two different depth ratios defined as R=D(0)/D(H), i.e., R=2 and R=5, are considered for the remaining four non-uniform shapes. Importantly, all 9 considered primary structures have the same total area/volume and, thus, total mass which is taken as a practical reference criterion in the herein undertaken comparative study.

4.2 Numerical derivation of fundamental mode shapes and optimal TMDI tuning

The fundamental mode shape of each of the 9 in total different uncontrolled primary structures herein considered is obtained numerically using finite element (FE) discretization. Specifically, each primary structure is discretized using 40 tapered equal-length beam elements. A 41-DOF planar dynamic system is then derived involving only one lateral translational DOF per FE node grid along the horizontal load direction in terms of a diagonal mass matrix and a full stiffness matrix. The mass matrix is formed by lumping the own-mass of the elements at the nodes while the stiffness is constructed using standard static condensation to eliminate vertical and rotational DOFs at each FE node. Next, standard modal analysis is conducted to obtain the first mode shape vector with 41 elements. The central difference method is used to obtain the second derivative of the fundamental mode shapes. Next, the standard trapezoid quadrature rule is used to calculate the integrals defining the generalized primary structure properties in Eq.(4) for each of the 9 primary structures. Finally, the optimization problem described in section 3 is solved to find optimal k_{TMDI} and c_{TMDI} from the non-dimensional frequency and damping ratios in Eq.(9) for each primary structure. Given that the focus of this paper is to investigate the influence of mode shapes to TMDI performance, fixed values for the mass ratio and inertance ratio are herein assumed taken equal to μ= 0.1% and β=16% and the average generalised mass from all 13 primary structures is used in the numerator of these ratios in Eq.(9). However, the CR in Eq.(9) is parametrically investigated as its influence is coupled with the influence of the fundamental mode shape through the modal coordinate $\psi(\chi)= \varphi_1(\chi)$ affecting the mass matrix of the mode in Eq. (3). In this regard, CR is let to vary within the range [0 1], where CR=1 corresponds to grounded inerter (χ=0).

4.3 Influence of depth ratio R

The influence of fundamental mode shape variation due to different depth ratio R=D(0)/D(H) values of the primary structure to the TMDI motion control potential is firstly investigated. This is facilitated by plotting the RMS free-end displacement of optimal TMDI-equipped primary structures against CR for fixed R separately for each of the geometric shapes II-V of Figure 1(c). These plots are presented in Figure 2 where the free-end TMDI-equipped primary structure displacement is normalized by the corresponding TMD-equipped primary structure obtained by solving the optimization problem in section 3 for b=0. In all plots the same R=1 curve corresponding to the uniform section shape (I) is included as a base-line.

It is evidenced that improved vibration suppression is achieved, though at a decreasing rate, as CR increases (i.e., as the further away from the free-end the inerter links the secondary mass to the primary structure) irrespective of the geometric shape and, thus, the mode shape of the primary structure. Further, for relatively small CR values the TMD outperforms the TMDI. These results agree with previous numerical studies addressing different structures and dynamic loads [4,5,7] which confirms the validity of the herein considered simplified 2-DOF model for optimal TMDI design. More interestingly, it is seen that for all the considered primary structure shapes TMDI performance improves as the depth ratio increases for any fixed CR and this improvement is more substantial for lower CR values. This observation suggests that the TMDI becomes more effective in mitigating lateral vibrations in cantilevered beam-like primary structures (such as tall buildings, and chimneys) as their upper part becomes more flexible through upwards tapering. In this regard, the critical CR value for given host structure geometric shape and inertial TMDI parameters (i.e., mass m_{TMD} and inertance b), that needs to be exceeded for TMDI to outperform TMD depends heavily on the depth ratio R. For instance, for double curvature shape (IV) shown in Figure 2(c), the critical CR values are 7.4%, 5.1%, and 2.75% for

depth ratios R 1, 2, and 5, respectively. Hence, the requirement to the inerter span reduces as the primary structure tapering rate towards reduced cross-section with height increases.

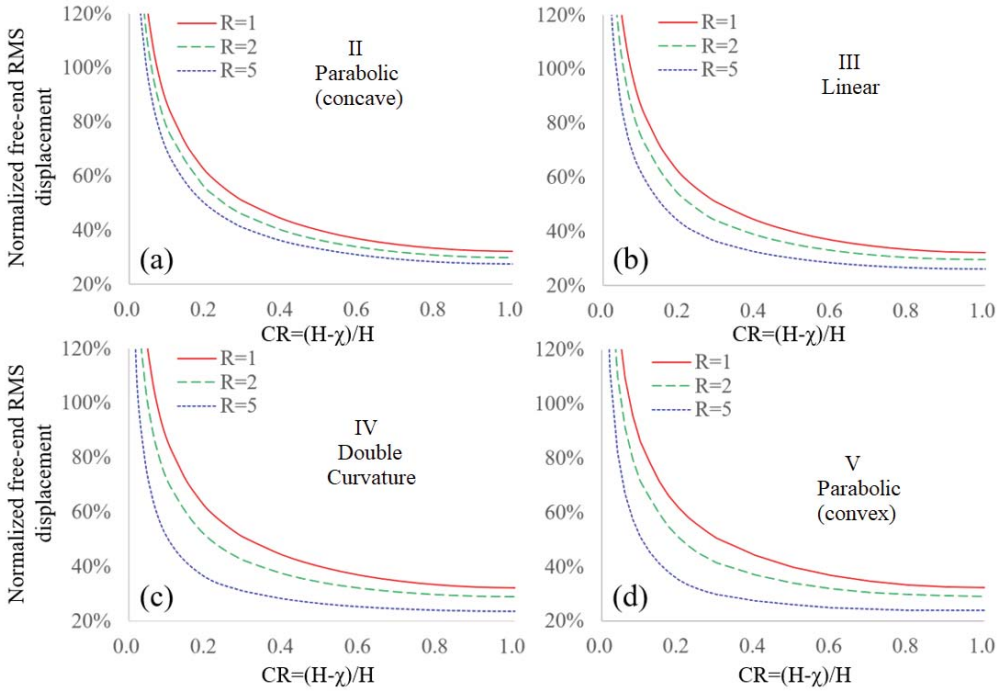

Figure 2. Free-end RMS displacement performance of optimal TMDI-equipped primary structures as function of the inerter connectivity ratio (CR) for various depth ratios R=D(0)/D(H).

4.4 Influence of depth profile D (primary structure shape)

Here, attention is firstly focused on exploring the influence of fundamental mode shape variation due to different primary structure shaping (see Figure 1(c)) to the TMDI motion control potential. This is facilitated by bar-plotting the RMS free-end displacement of TMDI-equipped primary structures with different shapes for CR=2.5%, 5.0%, and 7.5%, and for all different depth ratios in the upper row of panels in Figure 3. The same normalization of the RMS displacement as in Figure 2 applies. A consistent trend in these plots appears: the TMDI motion control potential increases for fixed CR and R as the primary structure shape changes from type "II" towards type "V". With reference to the shapes in Figure 1(c), this trend ultimately confirms again that better TMDI motion control is achieved as mass and stiffness distribution is heavier weighted towards the fixed-end of the primary structure. Interestingly, worst performance is noted for uniformly distributed mass and stiffness. For example, for depth ratio R=2 and CR= 5.0%, the TMDI with β=16% achieves gradually improved performance compared to the TMD by 0.5%, 2.7%, 4.7%, and 5.3% for primary structure shapes II, III, IV, and V respectively. As discussed before, for the relatively low CR=2.5% value in Figure 3(a), the TMD always outperforms the TMDI, but as CR increases (compare e.g. Figure 3(b) with 3(c) and note the difference in the y-axis scale) improvement of TMDI versus TMD become more substantial. The improved TMDI performance as the upper part of primary structure becomes more flexible is readily attributed to smaller values of $\psi(\chi)$ as the mode shape curvature increases (i.e., as the difference of ψ(H)- $\psi(\chi)$ increases). Nevertheless, the improvement achieved through increase of R is less significant for shapes II and III compared to shapes IV and V. This

result demonstrates that careful design/shaping of the primary structure is required to achieve increased TMDI control performance.

Moreover, the second row of panels in Figure 3 furnishes bar-plots of RMS stroke values σ_{y-z} computed from Eq.(6) for the same cases as the first row of panels of Figure 3 and normalized by the RMS stroke for the TMD. As has been reported in several previous studies [6,7], the inclusion of the inerter to the TMD reduces dramatically the secondary mass stroke (relative displacement of secondary mass with the primary structure free-end) with higher reductions achieved as CR increases. For all the herein considered primary structures and CRs, the reduction is more than 80%. Here, a novel observation is that mode shape differences due to either the shape of the primary structure or its depth ratio do not influence as much the stroke as they influence the free-end displacement. Still, it is important to note that stroke demands follow consistently the same reduction trend as free-end displacement demand with mode shape variation: as R increases for the same primary structure shape or as shapes go from type II to type V for fixed R the normalized stroke reduces by about 1% irrespective of the CR. This is a quite welcoming result as stroke is proportional to TMDI cost in several practical applications [5,6].

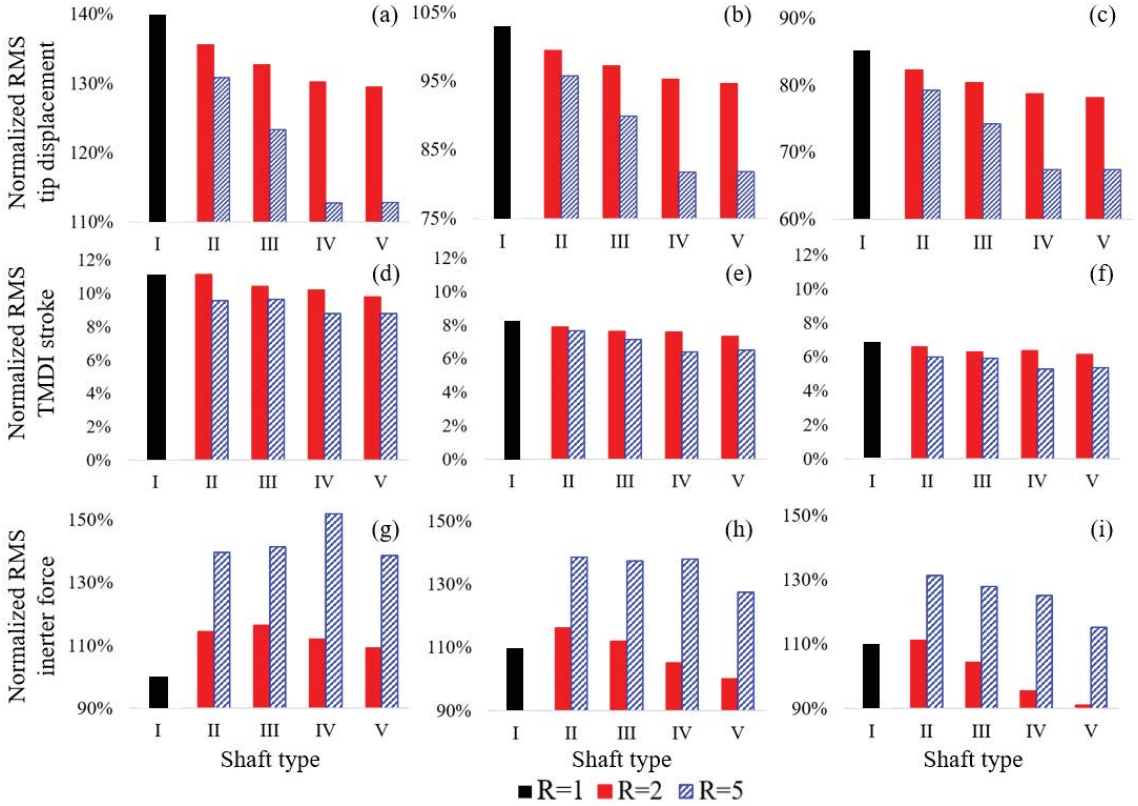

Figure 3. Free-end RMS displacement performance (upper panels), RMS TMDI stroke performance (middle panels) and RMS inerter force (lower panels) for different primary structure shape, depth ratio R and connectivity ratio CR. Values in the first two rows of panels are normalized with respect to TMD case (b=0) and values in the last row of panels are normalized with the respect to R=1, CR=2.5% TMDI case.

Lastly, considering that modal information affects explicitly the magnitude of the inerter force exerted to the primary structure at x=χ location, it is deemed practically important to gauge the influence of mode shapes variation to the inerter force in the last row of panels of Figure 3. In these plots, inerter force values are normalized by the inerter force developing at the uniform cantilever with CR=2.5%. Interestingly, it is seen that lower force develops at the uniform shaped primary structure compared to all the other shapes for the relatively large depth ratio

R=5. On the other hand, inerter force decreases for R=2 and 5 as shapes vary from type II to type V for relatively large CRs, e.g., CR=5.0% and 7.5%. One may be tempted to interpret this decrease of inerter force as the cause of TMDI achieving improved vibration suppression with primary structure shape variation seen in the first row of panels in Figure 3. However, this trend changes for a given primary structure shape with increasing depth ratio R: inerter force increases significantly as R increases from 2 to 5 for all primary structure shapes considered. Thus, the inerter force is not necessarily consistent with TMDI performance in terms of free-end displacement which, ultimately, is mostly related to the control force exerted at the free-end of the cantilever through the spring and dashpot. However, with reference to the upper row of panels in Figure 3, the increase in inerter force is accompanied with enhanced TMDI performance through increasing the depth ratio R. In this respect, it can be concluded that modifying the primary structure fundamental mode shape through more elaborate primary structure shaping rather than through increasing the depth ratio R is more advantageous in enhancing TMDI performance as it does not lead to increased inerter force exerted at the primary structure.

5 CONCLUDING REMARKS

The influence of the geometric shape of cantilevered primary structures to the TMDI performance for suppressing vibrations due to white noise external loading has been parametrically investigated. Five different shapes of primary structure have been considered with different base to free-end depth ratio with a TMDI attached to their free-end. Parametric analysis has been facilitated by a simplified 2-DOF in which the primary structure is represented by a generalized SDOF system whose properties account for the geometric shape of the structure through the mass and stiffness distribution along the structure height as well as through the fundamental mode shape of the structure. Further, the adopted 2-DOF model explicitly accounts for the location of the primary structure to which the inerter links the secondary mass. Since the primary structure modal coordinate at this location multiplies the inertance and depends on the shape on the shape of the primary, the inerter connection location was also varied in the parametric investigation. TMDI performance has been evaluated in terms of RMS free-end displacement for which the TMDI was optimally tuned. It is found that TMDI performance improves monotonically but at a reduced rate as the inerter connecting location to the primary structure moves away from the free end for all nine different primary structure shapes. Moreover, it was shown that improved TMDI performance as well as stroke are achieved for primary structure shapes with stiffness and mass distribution weighted heavier towards the base of the structure (i.e., when most of material is concentrated towards the bottom end of the structure) either through appropriate shaping or through increase of base to free-end depth ratio for fixed shape. Lastly, numerical data suggest that the primary structure shaping (i.e., considering more "pointy" primary structure geometry/shape) is practically most beneficial as it does not create increased inerter force exerted to the primary structure. Overall, the herein investigation point to the importance of primary structure design to enhance the dynamic performance of optimal TMDI-equipped structures.

Abstract. *This work is devoted to the experimental evaluation of the dynamic response of railway bridges with common typologies in short-to-medium spans. An extensive experimental campaign is performed in several railway bridges belonging to the High-Speed (HS) and conventional Spanish railway network. The main objectives are to (i) characterise the structures main features affecting their dynamic behaviour, (ii) determining the soil properties at the structures respective locations; and analysing the bridge dynamic responses under different operating conditions. All the bridges are composed by simply-supported (S-S) bays with different steel, concrete and steel-concrete composite typologies. Five bridges have been experimentally investigated: i) Old Guadiana Bridge: a double-track simply-supported bridge with two $13\,m$ equal spans composed by two adjacent single-track decks with continuous ballast; ii) Jabalón High-Speed Bridge: an isostatic bridge of three S-S bays of $20\,m$ equal spans composed by a double-track pre-stressed concrete girders deck; iii) Algodor Bridge: an isostatic double-track bridge with three S-S bays of $10\,m$ equal spans and a pseudo-slab concrete deck; iv) Jabalón Conventional Line Bridge: a steel truss single-track structure composed by three $25\,m$ equal spans; and v) Tinajas Bridge: a steel-concrete composite single-track bridge with three bays of 25, 35 and $22\,m$ spans, respectively. The first four bridges are nowadays at full operation while the latter is under its construction final stage. The study includes the identification of bridge modal parameters and dynamic soil properties, a discussion on the identified structural damping in all the bridges, the measurement of vibration levels induced by railway traffic under operational conditions in the first four bridges and under construction operation machinery in the fifth case, and an analysis of the differences found in the structural behaviour of different bridge typologies for the same traffic. This paper summarizes a vast experimental campaign.*

1 Introduction

The dynamic effects in railway bridges have become an issue of interest and concern for scientists and engineers in the last decades, especially since the advent of High-Speed [1]. An excessive level of vertical accelerations on the deck platform (greater than 3.5 or $5\,\mathrm{m/s^2}$ in ballast or slab track bridges, respectively), can lead to misalignment of the rails as a result of premature deconsolidation of the ballast layer, to the loose of contact between wheel and rail with the subsequent increase of the risk of derailment, to fatigue problems in the structures in the long term or to an increase of the maintenance costs in the best scenario. Consequently, the Serviceability Limit States for Traffic Safety and, in particular, the vertical acceleration of the deck has become one of the most restrictive requirements in the design of new bridges. The bridges composed by simply-supported spans with short to medium span lengths are especially critical in this regard, due to their natural frequencies and usually low mass and damping associated levels. This problem of high accelerations is particularly relevant at resonance [2, 3].

A comprehensive experimental campaign in five railway bridges in Spain is presented in this work. The tests include the identification of the modal parameters of the structures, the characterization of the soil at the respective sites and the measurement of the bridge dynamic responses under railway traffic. Five bridges were tested: i) Old Guadiana Bridge: a double-track S-S bridge with two $13\,\mathrm{m}$ equal spans composed by two adjacent single-track decks sharing a continuous ballast layer; ii) Jabalón High-Speed Bridge: an isostatic bridge with three S-S bays of $20\,\mathrm{m}$ equal spans composed by a double-track pre-stressed concrete girders deck; iii) Algodor Bridge: a double-track bridge with three S-S bays of $10\,\mathrm{m}$ equal spans and a filler beam concrete deck; iv) Jabalón Conventional Line Bridge: a steel truss single-track structure composed by three $25\,\mathrm{m}$ equal spans; and v) Tinajas Bridge: a steel-concrete composite single-track continuous bridge with three spans of 25, 35 and $22\,\mathrm{m}$, respectively.

The outline of the paper is as follows. In Section 2, a general description of the experimental tests performed during the campaigns is included. The results of the experimental measurements on each particular bridge are given in the different subsections of Section 3. A final analysis on the differences found in the structural behaviour of the different typologies for similar traffic is included in Section 4.

2 Experimental set-up

In April and May 2019, the authors performed an experimental campaign on several railway bridges with the purpose of characterizing the structure and soil dynamic properties along with the bridge dynamic response under railway traffic. As per the acquisition equipment, a portable acquisition system LAN-XI of Brüel & Kjaer was used. The acquisition system fed the sensors (accelerometers) and an instrumented impact hammer in the case of the soil tests. It also performed the Analog/Digital conversion (A/D). The A/D was carried out at a high sampling frequency that avoided aliasing effects using a low-pass filter with a constant cut-off frequency. The sampling frequency was $f_s = 4096\,\mathrm{Hz}$. The acquisition equipment was connected to a laptop for data storage. Endevco model 86 piezoelectric accelerometers were used with a nominal sensitivity of $10\,\mathrm{V/g}$ and a lower frequency limit of approximately $0.1\,\mathrm{Hz}$. The acquisition system was configured to avoid the sensors overload. Nevertheless, in some cases, the signals were overloaded. In the case of Tinajas Bridge, Etna stations of Kinemetrics were used with internal triaxial accelerometers with a nominal sensitivity of $1.25\,\mathrm{V/g}$. Here, the sampling frequency was $f_s = 250\,\mathrm{Hz}$.

The modal parameters of the bridges were identified from ambient vibration data by the

(a)

(b)

Figure 1: (a) Location of the bridges in Spain and (b) experimental set-up.

stochastic subspace identification technique [4]. The ambient vibration response was acquired during the tests while the trains were not crossing the bridges. Data were decimated to carry out data analysis in the frequency range of interest ($0 - 30$ Hz). The signals were filtered applying two third-order Chebyshev filters with high-pass and low-pass frequencies of 1 Hz and 30 Hz, respectively.

The dynamic characterisation of the soil was carried out by the seismic refraction and the Spectral Analysis of Surface Waves (SASW) tests. The seismic refraction test allowed the identification of the P-wave velocity (C_p) of the soil layers. The SASW test was used to determine the S-wave velocity (C_s), and the material damping ratio of the soil layers (β) was estimated by the half-power bandwidth method [5]. 100 hammer impacts were applied to a 50 cm $\times$ 50 cm $\times$ 8 cm aluminium foundation anchored to the soil surface (Figure 2). The instrumented hammer included a PCB 086D50 force sensor. The vertical free field response was recorded by means of accelerometers anchored to the soil surface every 2 m (from 2 m to 72 m). Steel stakes of cruciform section and 30 cm of length were driven into the ground surface and the accelerometers were screwed to these stakes. After each impact, a time signal of 16348 samples (4 s) was stored. The force channel was used as a trigger, a pre-trigger of 1 s, and a post-trigger of 3 s. In this case, the signals were decimated (order 4), filtered with a third-order

Chebyshev filter with a high-pass frequency of 1 Hz and a low-pass frequency of 100 Hz.

3 Railway Bridges

In what follows, the specificities of the experimental set-ups and the experimental measurements recorded in Old Guadiana, Jabalón HSL, Jabalón, Algodor and Tinajas bridges are outlined.

During the recordings, several RENFE trains (S100, S102, S104, S112, S120, S130, S449, S599, Altaria and freight trains) crossed the bridges. Figure 3 includes the axle schemes and coach distributions of series S100, S102, S104, S120 and Altaria trains. Also the axle distances d and axle loads P are provided. More information in this regard can be found in Reference [6].

3.1 Old Guadiana Bridge

3.1.1 Description of the structure

This first bridge under study crosses Old Guadiana River in the conventional railway line Madrid-Alcázar de San Juan-Jaén, in the Alcázar de San Juan-Manzanares section (see Figure 4). It is a double-track concrete bridge composed by two identical simply-supported bays. The horizontal structure is formed by two structurally independent although adjacent decks, one for each track, sharing the ballast layer. Each deck is composed of a concrete slab resting on five pre-stressed concrete $0.75\,\text{m} \times 0.3\,\text{m}$ rectangular girders with no transverse stiffening elements (see Figure 5). The longitudinal girders rest on the two abutments and on a central pile support through neoprene bearings. Each deck accommodates a ballasted eccentric track with Iberian gauge (1668 mm), UIC60 rails and mono-block concrete sleepers separated $0.60\,\text{m}$.

The vertical acceleration response was measured at 18 points of the lower flange lower horizontal face of the pre-stressed concrete girders (points $1 - 18$ in Figure 6). The accelerometers were attached to the girders using circular aluminium plates with $9\,\text{cm}$ of diameter and $6\,\text{mm}$ of thickness fixed with epoxy resin to the concrete surface (see Figure 1.(b)) which was previously treated for proper adherence. The response at points of the two decks in both spans was recorded.

3.1.2 Modal parameters identification

Ten modes with natural frequencies below 30 Hz are identified from the ambient vibration recorded during 3600 s. In Figure 7 the first ten mode-shapes are represented.

In Table 1 the identified natural frequencies and the damping ratios from the ambient response are included for the first ten modes. In the fundamental mode the identified damping ratio reaches 2.3%, higher than the value prescribed by standards for design purposes for this particular length and bridge typology (1.5% as per [7]).

The bridge response under operational conditions strongly depends on structural damping. Obtaining a realistic value of modal damping representative of the bridge dynamic response

Figure 4: Old Guadiana Bridge (39°17'37.8"N 3°12'22.5"W).

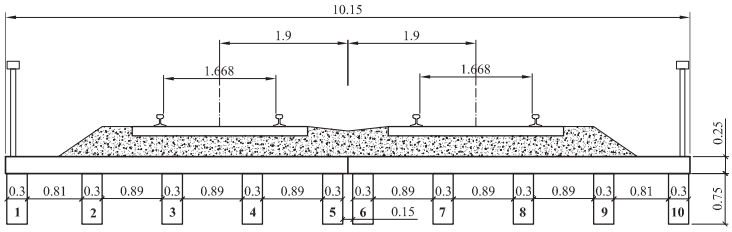

Figure 5: Old Guadiana Bridge deck cross section (Dimensions in [m]).

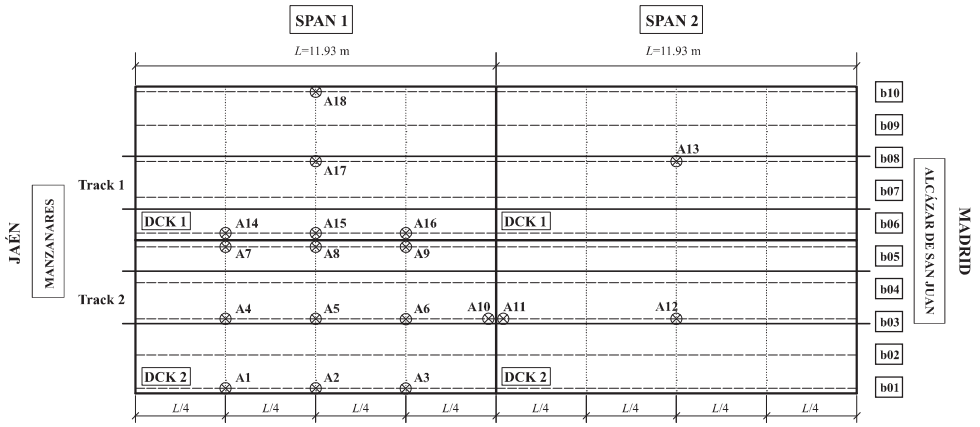

Figure 6: Location of the sensors at Old Guadiana Bridge.

under forced vibration is complicated, partially due to the dependency of this parameter with the amplitude of vibration. For this reason, modal damping has been also identified from the free vibration response recorded after the train passages indicated in section 3.1.4, using 10 s of free vibration. The modal damping ratios are extracted by the methodology presented by Kim et al. [8].

The damping ratio estimations are presented in Figure 8 and Table 1. The values of damping estimated from ambient vibration are represented with solid circles and compared to the values obtained from the train passages. The obtained results for the same vehicle crossing the bridge along the same track are consistent. As a general conclusion, it can be mentioned that the damping ratios from the train passages were considerably higher than those obtained from

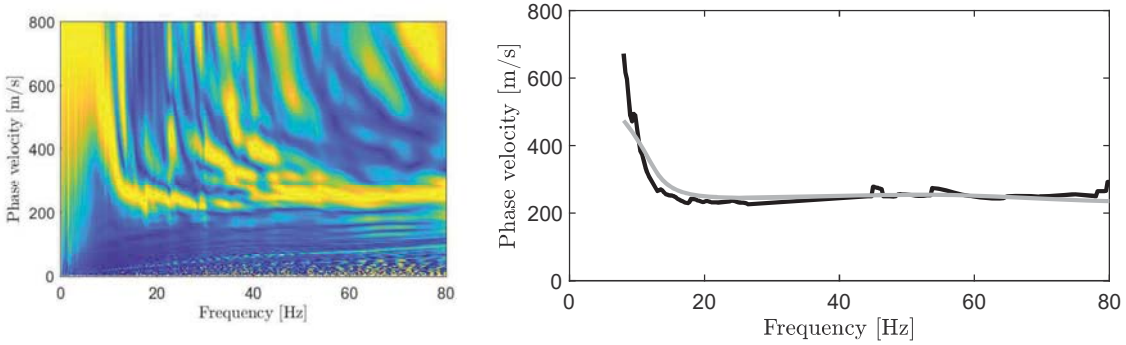
3.1.3 Soil properties identification

Following the procedure described in Section 2, the main dynamic properties of the soil are identified in the proximities of Old Guadiana Bridge. Figure 9 shows the resulting dispersion curve. The maxima in the spectrum are due to the Rayleigh waves. Table 2 shows the soil properties obtained from the resolution of the inverse problem using the elastodynamics toolbox (EDT) from Schevenels et al. [9].



(a) (b)

Figure 9: Old Guadiana Bridge: (a) experimental dispersion curve and (b) solution of the inverse problem: experimental (black line) and numerical (grey line).

Layer	h [m]	C_p [m/s]	C_s [m/s]	ρ [kg/m^3]	β [-]
1	2	499	298	1900	0.08
2	4.5	350	207	1900	0.05
3	3.6	1300	719	1900	0.05
4	∞	500	250	1900	0.09

Table 2: Identified soil properties at Old Guadiana Bridge.

The soil presents two upper layers with a shear wave velocity lower than 300 m/s on a half-space with $C_s = 250$ m/s. The bridge supports at the abutments consist of spread footings. Therefore, in this case, SSI could affect to a certain extent the dynamic properties of the structure and its structural behaviour [10, 11].

3.1.4 Response due to train passages

The bridge response under thirteen circulations was recorded on May 6^{th} between 12:18 and 17:38 hours. In Table 3 the following information is included for each passage: train type, track number according to Figure 6, traffic direction, travelling speed, coaches scheme (L: locomotive, C: carriage) and average axle load P_k for the passenger coaches. Altaria trains, composed by a Talgo 252 locomotive and either 9 or 13 passenger coaches, are regular trains with a characteristic distance between shared axles of 13.14 m. S449 trains are articulated trains with distributed power, five coaches in total and a distance between shared bogies in the central carriages of 17.75 m. Trains S599 are conventional trains composed by two external power cars and a central carriage, and present a car length of approximately 25 m. Only one of the trains was a freight train with a conventional scheme as well. All passenger trains were commercial RENFE medium distance trains. Except for the second circulation, all the trains crossed the bridge at speeds in the interval $[140, 160]$ km/h.

Passage	Train	Track	Ride	Speed [km/h]	Scheme	$P_k/axle$ [kN]
1	Altaria-9	2	M-A	160	L-9C	140
2	S599	2	M-A	80	L-C-L//L-C-L	131
3	Altaria-13	2	M-A	160	L-13C	140
4	S449	1	A-M	160	L-3C-L	161
5	S449	1	A-M	160	L-3C-L	161
6	S449	2	M-A	160	L-3C-L	161
7	S599	1	A-M	143	L-3C-L	131
8	Altaria-13	1	A-M	157	L-13C	140
9	Altaria-9	1	A-M	155	L-9C	140
10	Freight train	1	A-M	-	L-13C	-
11	S449	2	M-A	160	L-3C-L	161
12	S449	1	A-M	160	L-3C-L	161
13	S449	2	M-A	160	L-3C-L	161

Table 3: Train passages recorded at Old Guadiana Bridge. M: Manzanares and A: Alcázar de San Juan.

In Figure 10 the acceleration response at two pair of sensors located at midspan of either span is represented in the frequency domain for train passages #1, #3, #5, #6, #9, #11, #12 and #13. One of the sensors is located under the loaded track and the other one under the unloaded track in all the cases. The maximum static load acting simultaneously on each of the spans, taking into account the span length, the particular axle loads, and the bogie and axle distances for the three types of trains is quite different: 140 kN for Altaria Talgo trains (one axle), 322 kN for S449 (two axles) and 524 kN for S599 trains (four axles). This may be the reason why many of the sensors were overloaded during train passages #2 and #7. In all the cases the response presents peaks associated to the excitation (i.e. ratio of train speed v to bogie and axle distances v/d_{bogie} and v/d_{axle}, respectively, and corresponding multiples) and to the bridge lowest natural

frequencies. In the case of Altaria Talgo trains, the acceleration amplitude in the vicinity of the bridge fundamental frequency stands out considerably in comparison to the peaks associated to the excitation. This is not the case for the S449 or the S599 trains. This is partially related to the fact that the former trains with a characteristic distance of $13.14\,\mathrm{m}$ travel at a velocity close to the theoretical third resonant speed of the fundamental mode of the bridge: $v_{1,3} = 9.8 \times 13.14/3 \times 3.6 = 154\,\mathrm{km/h}$, in combination with the high number of passenger coaches. The maximum overall acceleration measured during the train passages for frequency contents below $30\,\mathrm{Hz}$ reaches $1.61\,\mathrm{m/s^2}$, close to one half of the limit established by the Serviceability Limit State for traffic safety $3.5\,\mathrm{m/s^2}$ for bridges with ballasted tracks [12]. This maximum takes place under Altaria train with 9 passenger coaches crossing the bridge along track 2 northbound (circulation #1). Similar amplitudes of the vertical acceleration are measured for the second circulation. Nevertheless, it should be said that the actual maximum acceleration most probably took place in an overloaded sensor and is higher than the previously mentioned value. In the plots included in Figure 10 the acceleration response in the sensor located in the unloaded deck is, in some cases, of the same order of magnitude than that measured in the loaded deck. For sensors 5 and 17 (centre of the decks) the response at the unloaded sensor is relevant at the fundamental frequency (first longitudinal bending mode); and for sensors 2 and 18 (external borders of the decks) the unloaded sensor response has also important contributions at other identified frequencies, indicating an important coupling between the two decks of the same span through the ballast layer. This issue was already detected under ambient vibration and seems to be also important under the circulation of trains, despite the much higher vibration amplitudes of the structure in this case. The coupling between the adjacent decks is analysed in more detail for the Altaria trains in what follows.

Figure 11 shows the bridge response at sensors 5, 17, 8 and 15 due to a Renfe Altaria train travelling along tracks 1 (red trace) and 2 (black trace) at $v = 160\,\mathrm{km/h}$ and $v = 155\,\mathrm{km/h}$, respectively (circulations #1 and #9). Therefore, this figure shows the response of the two adjacent decks in the first span under the circulation of two identical trains travelling at very similar speeds in the two opposite directions. As mentioned before, the resonant speeds for the fundamental mode and third resonance is $v_{1,3} = 154\,\mathrm{km/h}$, very close to the actual speeds. The damping ratios for the first mode obtained from the free vibration response after the trains left the structure were in these cases 2.2% and 2.8%, respectively. The response measured at points 5 and 17 (Figure 6) presents a very high similarity when the trains cross the bridge along either of the two tracks (i.e. the unloaded and loaded sensor responses are very similar no matter what is the train direction). This shows that both decks dynamic responses are very similar and that the coupling effect is bidirectional. The contribution of mode 1 clearly prevails in all the sensors and that of the third mode (transverse bending mode) is clearly visible at points 8 and 15. Moreover, the characteristic vehicle frequency $v/d = 160/3.6/13.14 = 3.4\,\mathrm{Hz}$ and its second harmonic can also be observed at the sensors installed at the loaded deck (and are almost imperceptible at the unloaded one). When the Altaria train crosses the bridge along track 2 induces a higher acceleration response in deck 2 (sensors 5 and 8), as expected. Nevertheless, the levels of the amplitudes measured at deck 1 (sensors 15 and 17) are considerable. The maximum acceleration amplitude in deck 1 is in that case approximately 45% of the highest acceleration measured in deck 2. Among the four selected sensors the one exhibiting the highest response is sensor 8, at the longitudinal edge of deck 2, in the loaded case, showing an important contribution of the fourth mode. Again, the coupled responses of the decks through the ballasted track are significant.
