3.2 Jabalón HSL Bridge

3.2.1 Description of the structure and properties identification

Jabalón HSL Bridge (Figure 12), is a railway bridge composed by three identical S-S bays of 24.9 m equal spans. The structure crosses Jabalón River with a 134° skew angle. Each deck consists of a cast-in-situ concrete slab with dimensions 11.6 m × 0.3 m (wide × thickness). The slab rests over five prestressed concrete I girders with a height of 2.05 m separated 2.625 m (see Figure 13). The girders lean on the supports through laminated rubber bearings. The slab carries two ballasted tracks with UIC gauge (1435 mm), UIC60 rails and mono-block concrete sleepers every 0.60 m. The substructure consists of two outer reinforced concrete abutments and two inner wall piers. Figure 14 shows the measurement points, all of them located at span 1. Unfortunately, it was only possible to record the response of the first span due to the piers height and the river flow.

Table 4 presents the identified modal parameters of the structure.

Table 5 presents the identified dynamic soil properties. The experimental procedure described in section 3.1.3 is reproduced at this bridge site. The soil in the surroundings of Jabalón HSL bridge is composed of an upper layer of limestone of approximately 2 m with a shear wave

velocity of $C_s = 321$ m/s, a layer of clay gravel of approximately 2 m and $C_s = 176$ m/s on a sand-clay halfspace with $C_s = 225$ m/s. The profile from the SASW test is consistent with that provided by a geotechnical analysis performed at the site prior to the bridge construction [13].

3.2.2 Response due to train passages

Table 6 summarizes the train passages recorded at Jabalón HSL Bridge. The dynamic response of the bridge under the circulation of 20 passenger trains was recorded on May 8^{th} 2019

Layer	h [m]	C_p [m/s]	C_s [m/s]	ρ [kg/m^3]	β [-]
1	2	800	321	2000	0.1

3	∞	500	225	2000	0.1

Table 5: Identified soil properties at Jabalón Bridge.

between 11.52 and 15.24 hours. All the trains that travelled over the bridge in both directions were RENFE High-Speed services. In particular articulated S100 trains, regular S102, S112 and S130 trains, and conventional S104 trains crossed the bridge in single and duplex configurations. The identified travelling velocities are comprised between 236 and 290 km/h and are included in Table 6 along with the trains schemes and average axle loads of the passenger coaches.

The trains inducing the lowest dynamic response on Jabalón HSL bridge are S104 trains. These trains are composed by only two passenger coaches and their maximum speed is 250 km/h. The overall maximum acceleration reaches 1.8 m/s^2 (calculated after the signal is filtered under 30 Hz), and happens for the ninth circulation (S102 duplex at 265 km/h). A similar maximum level of the acceleration is obtained for circulations #4 and #12 for a similar and for the same train. S102 trains are regular Talgo trains with a short characteristic distance (13.14 m) and a high number of axles. Therefore this trains are prone to excite the participation of low frequency modes of the bridge. Again, one should be cautious with this value as some of the sensors overloaded and are not considered in the analysis. Sensors that particularly experienced overload are those close to the supports of the deck under the loaded track (13 and 15 when the trains travel along track 1, and 13 and 14 when they travel along track 2). A non symmetric dynamic behaviour is detected when comparing the responses between accelerometers 10 and 2, which may be related to the deck obliquity. In all the cases the response measured close to the abutments and to the intermediate pile are considerably lower in terms of accelerations than at the intermediate sections.

Figures 15, 16 and 17 compare the bridge response at four sensors under the circulation of three trains Renfe S104, Renfe S102 and Renfe S100 crossing the bridge a two similar (yet non-resonant) speeds. The first figure corresponds to train S104 travelling along track 1 southbound. The response at the sensors close to the loaded track (accelerometers 1 and 2) exhibits contributions in the frequencies v/d_i and corresponding harmonics, being d_i the characteristic length or distance between axles and between bogies of the trains. This train, in particular, does not excite the bridge natural frequencies to a big extent compared to S102 or S100, which are composed by a much higher number of passenger coaches. The responses for two travelling speeds are superimposed: 249 and 255 km/h. The responses are almost identical despite the small difference in the speeds. It should be said that the second and third theoretical resonant speeds for the fundamental mode associated to the coaches lengths are 196 and 294 km/h, far from the actual velocities. For this reason the response is not very sensitive to this parameter.

3.3 Algodor Bridge

The third bridge under study, Algodor Bridge, belongs to the Madrid-Sevilla High-Speed railway line as well. It is a railway bridge composed by three S-S bays with 10.25 m, 10.00 m and 10.25 m spans (distance between centres of neoprene bearings). The bridge crosses Algodor river with a skew angle of $114.3°$ (Figure 18). Algodor Bridge presents a filler beam deck,

composed by a 0.65 m thick and 11.6 m wide concrete slab longitudinally reinforced with 20 inverted T pre-stressed concrete girders enclosed within the depth of the slab and with the required steel rebars for transverse reinforcement (see Figure 19). The girders lean on the supports through laminated rubber bearings. The slab carries two ballasted tracks with UIC gauge (1435 mm), UIC60 rails and mono-block concrete sleepers every 0.60 m, and with an equal eccentricity of 2.15 m measured from its longitudinal axis. The bridge deck is supported on reinforced concrete abutments in its outermost sections and the inner sections of both bays lean on a 0.6 m thick and 12.3 m wide concrete pier. Figure 20 shows the measurement points. In this case, two of the three spans were monitored.

Five modes were identified from the ambient vibration response with frequencies up to 30 Hz. Table 7 and Figures 21 and 22 show the identified modal parameters. The first two modes correspond to the first longitudinal bending mode of each span vibrating out of phase and in phase, respectively. In modes 3 and 4 the deck deforms under torsion: in the former each span deforms independently and, in the latter, the torsional deformations of both spans are coupled. The last mode corresponds to the transverse bending deformation of one the spans. Modal damping is again identified both from ambient vibration and from the free vibration after the train passages. It should be mentioned in this case that modes 1 and 2, and modes 3 and 4 present very similar natural frequencies, which could bias the estimation of this parameter [8]. The identified damping for the fundamental mode from the train passages is 2.1%, higher than the ambient vibration estimation (1.5%) and than the value recommended by Eurocode (1.7%).

Table 8 shows the dynamic soil properties. The soil in the surroundings of Algodor Bridge is composed of an upper layer of gravel of approximately 2 m with $C_s = 314$ m/s on a clay on

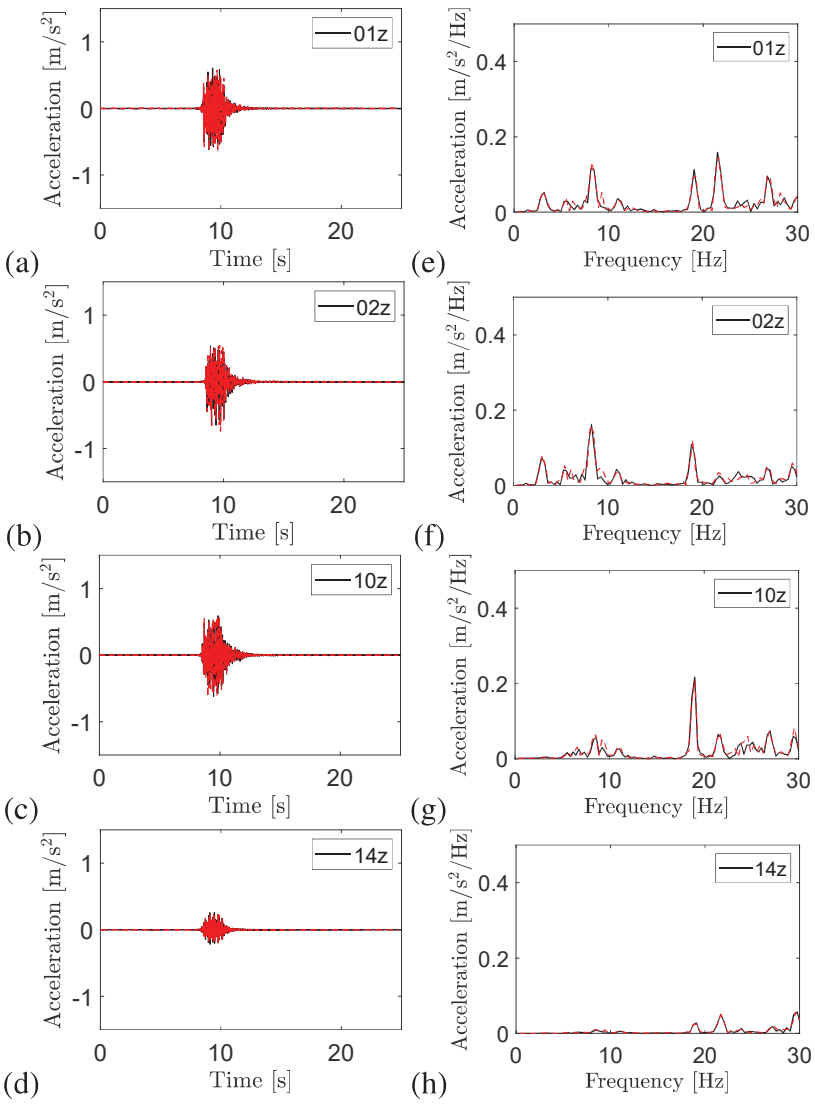

Figure 15: Jabalón HSL Bridge: (a-d) time history and (e-h) frequency content of the acceleration at points 1, 2, 10 and 14 induced by Renfe S104 train circulating on track 1 at (black line) $v = 249$ km/h and (red line) $v = 255$ km/h.

a slate halfspace with $C_s = 800$ m/s. The high identified value of the P-wave velocity indicates that the soil is saturated. The profile is consistent with that provided by a geotechnical analysis performed at the site prior to the bridge construction [14].

3.3.1 Response due to train passages

On May 5^{th} 2019 the response of Algodor Bridge under the circulation of 13 passenger trains was recorded. The particular trains were Renfe S102, S130 and S120, in single and duplex configurations, and Renfe S100. S102 and S130 are regular trains, S120 is a conventional train and S100 is articulated. Table 9 presents information in relation with these train passages. The travelling speeds were comprised between 228 and 307 km/h. The overall maximum acceleration measured was 2.96 m/s^2 under passages #2 and #3 of the S102 train at 304 km/h. This value was measured at accelerometer 1 (central span, central section border girder closest to the

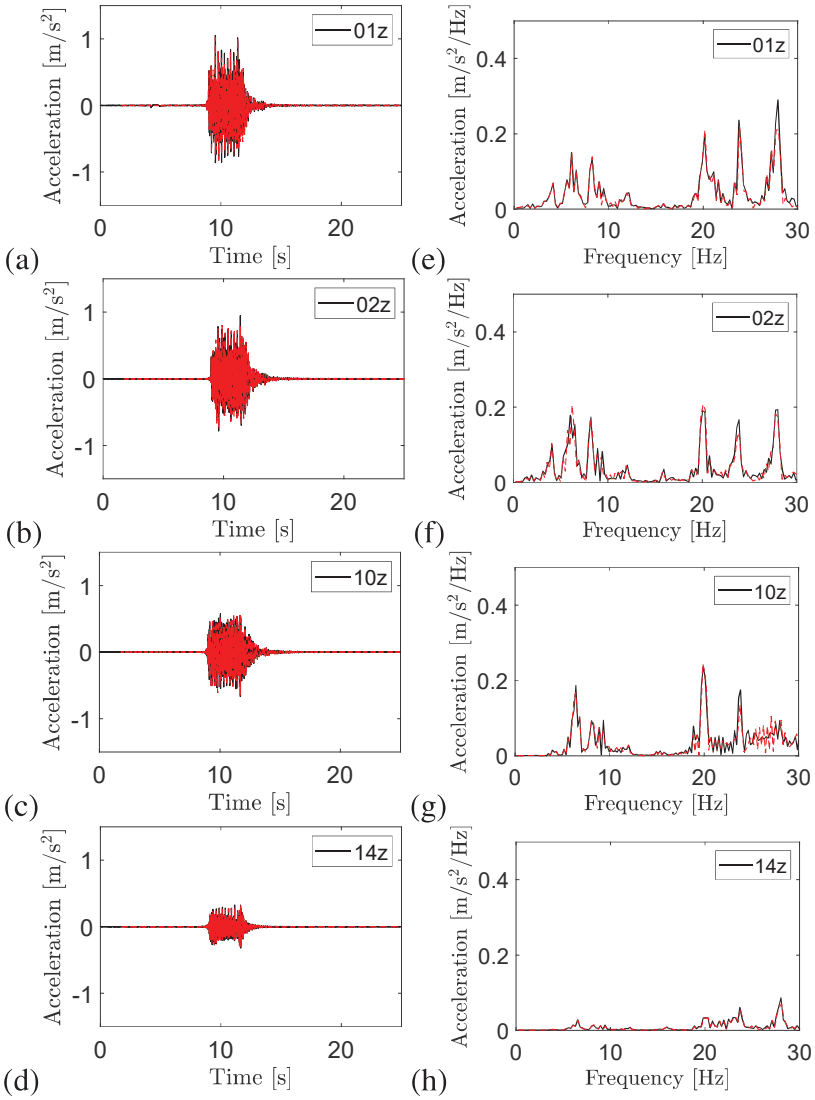

Figure 17: Jabalón HSL Bridge: (a-d) time history and (e-h) frequency content of the acceleration at points 1, 2, 10 and 14 induced by Renfe S100 train circulating on track 1 at (black line) $v = 290$ km/h and (red line) $v = 290$ km/h.

the very centre of the second span, was overloaded under most of the circulations. Therefore, the maximum acceleration of the deck could be somewhat higher than the referred value.

Figure 23 shows the structural response induced by the fourth and ninth trains passages.

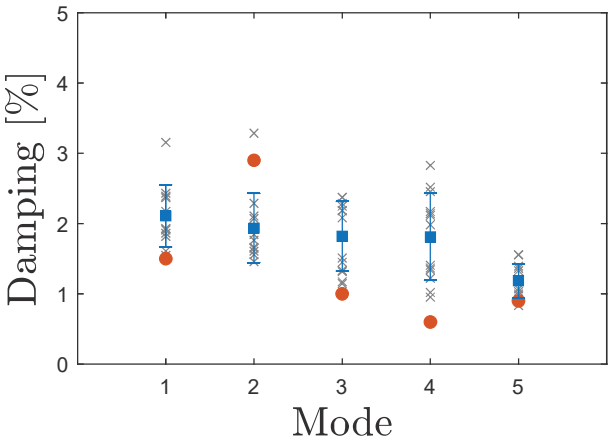

Figure 22: Algodor bridge: estimated damping ratios from (red circle) ambient vibration and (grey crosses) train passages. The (blue square) mean value and (blue line) the mean value $\pm$ the standard deviation (σ) are also presented.

These correspond to the circulation of two Renfe S102 trains travelling at $v = 304$ km/h along track 1 (black trace) and at $v = 306$ km/h along track 2 (red trace). The responses are compared at sensors 1 and 7 (mid section of the central span) and 8 and 11 (mid section of first span). The contribution of torsion modes (with frequencies close to 14 Hz) and transverse bending mode (with frequency close to 20 Hz) are the most relevant regardless of the train direction. In each span the decks of Algodor Bridge present very similar length and width dimensions. Also, the flexural and torsional stiffnesses are uniformly distributed due to the filler-beam typology of the deck. This justifies the plate-type dynamic response that this bridge in particular exhibits. The S102 trains velocities are far from any resonant condition of the longitudinal bending and torsion modes ($v_{1,2} = 274.4$ and $v_{3,2} = 324$ km/h for $f_1 = 11.6$ and $f_3 = 13.7$ Hz, respectively) but the third resonant frequency of the fifth mode (transverse bending mode) is induced by this train travelling at $v_{3,3} = 13.14 \times 19.6 \times 3.6/3 = 309$ km/h. This may be the reason why an important amplification happens close to 20 Hz.

3.4 Jabalón Bridge

Jabalón Bridge (Figure 24), is a steel truss railway bridge composed by three S-S bays of 25 m of span. This bridge also crosses Jabalón river but it belongs to the conventional railway line Alcázar de San Juan-Ciudad Real-Badajoz. In this section nowadays the traffic is very limited and most of the circulations are freight trains and maintenance vehicles. Jabalón and Jabalón HSL are only 200 m apart and one set of tests were performed in the area in order to identify the soil properties (see section 12). Jabalón Bridge carries only one ballastless track (Figure 25 left) with Iberian gauge, UIC60 rails and wooden sleepers. Due to the absence of ballast and direct contact between the rail and the steel structure, unfortunately, several accelerometers were unstuck due to the high level of vibrations induced by the train passages. In what follows a few remarks are included in relation to the behaviour of this particular structure but the information available is much less than in the previous cases.

Figure 26 shows the measurement points. The accelerometers were glued directly at the truss

connections in different orientations (see Figure 25 right). Three modes were clearly identified from ambient vibration (see Table **??**). In increasing frequency order these modes correspond to first lateral bending, first longitudinal bending and first torsion modes. In this case, only damping values identified from ambient vibration are available. The fundamental mode exhibits very low damping, typical in steel structures but the values obtained for the second and third modes are comparable to the values identified in previous bridges. The modal damping value proposed by Eurocode [7] for this steel bridge is 0.5%.

Figure 25: (left) Track in the Bridge over Jabalón River and (right) accelerometer at the truss connection.

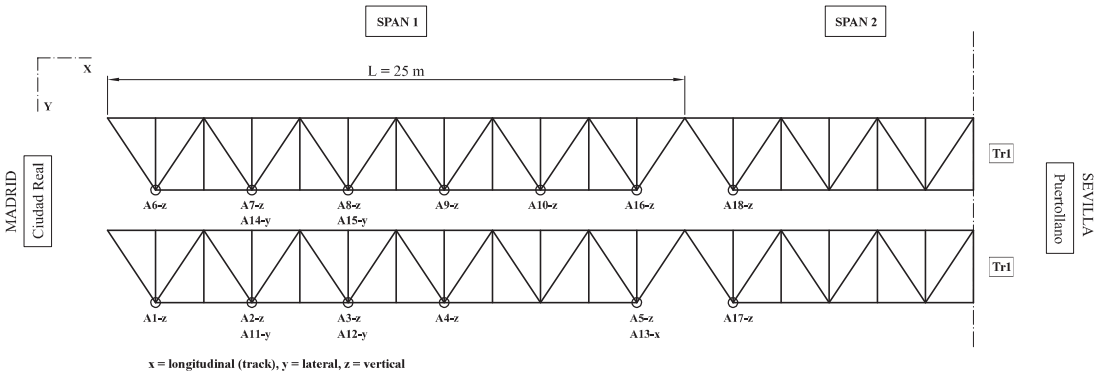

Figure 26: Location of the sensors on Jabalón Bridge.

3.5 Tinajas Bridge

The bridge over the Tinajas Stream (Figure 27) is a three-span continuous bridge with span lengths of 25 m, 35 m and 25 m. At the moment of the experimental campaign this bridge was under construction. It belongs to the conventional railway line between Bobadilla and Algeciras. The bridge presents a steel-concrete composite section formed by two main steel I beams and an upper concrete slab. The slab is 8.6 m wide allowing the installation of a single-track with Iberian gauge, UIC60 rails and mono-block concrete sleepers every 0.60 m (Figure 28). The height of the I beams is 1.8 m. The concrete slab presents variable thickness from 0.20 m to 0.38 m. Close to the intermediate supports the section is completed with a lower concrete slab with a thickness of 0.20 m. The two main steel beams are reinforced with sheets of variable thickness in the lower flange ($30 - 60$ mm) and web ($15 - 20 - 25$ mm), and with steel plates of constant thickness (25 mm) in the upper flange. The beams are braced every 5 m with H-shaped transverse frames. The deck is supported on two abutments at the outermost sections and on two concrete piles at the inner supports, all of them with micropiles. The deck rests on eight POT bearings positioned under each beam longitudinal axis at the piles and abutments. Transversely the deck movement is restricted by seismic supports installed at each pile and abutment. The longitudinal moving support is materialized at one of the abutments. The rectangular concrete piles have a cross section of 4.50 m $\times$ 1.50 m and heights of 16.60 m and 16.01 m, respectively.

Figure 27: Bridge over Tinajas River (37°01'41.0"N 4°45'26.6"W).

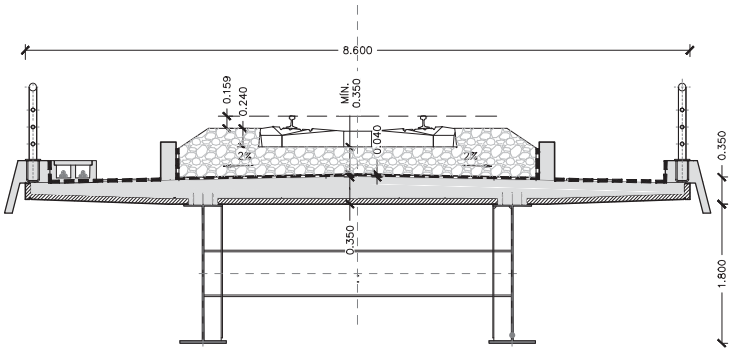

Figure 28: Tinajas Bridge deck cross section (Dimensions in [m]).

The ambient response of the bridge deck was measured at 18 points using triaxial accelerometers (Figure 29). Table 10 and Figure 30 present the identified modal parameters. In the first

five mode shapes the deck deforms under lateral bending (mode 1), longitudinal bending (modes 2 and 5) and torsion (modes 3 and 4). Very low damping values, in the range $[0.4 - 0.7]\%$, were identified for the five modes in ambient vibration, close to the Eurocode recommendation of 0.5% for spans longer than $20\,\mathrm{m}$ in the case of steel-concrete composite bridges. Modal parameters were not identified in free vibration as the bridge was not operational during the measurements. In this case, soil tests were not performed.

3.5.1 Response due to ballast distributing and profiling and stabilisation machines passages

The objective of this test, unlike the previous, was to measure the bridge behaviour under track construction operations: ballast distribution, profiling and stabilisation . Plasser & Theurer Unimat 08-475/4S ballast distributing machine has two bogies with two axles separated $14\,\mathrm{m}$. The distance between axles is $1.8\,\mathrm{m}$ and the axle load is $198\,\mathrm{kN}$. Plasser & Theurer DGS

62N profiling and stabilisation machine consists of two bogies with two axles each one. The distance between bogies is 12 m and the distance between axles of the same bogie is 1.5 m. The front axle load is 140 kN and the rear axle load is 145 kN in this case. The total load is approximately 570 kN. Moreover, Plasser & Theurer DGS 62N applies a maximum vertical load of 356 kN. Both machines are used to maintain the geometry and good condition of the track. The stabilization is done immediately after the tamping operations [15].

Figure 31 shows the longitudinal (x), lateral (y) and vertical (z) acceleration at points 4 and 11 due to the Plasser & Theurer DGS 62N operating at 40 Hz and the Plasser & Theurer Unimat 08-475/4S operating at 35 Hz with a nominal pressure of 20 bar. The frequency content is represented in logarithmic scale. In the case of the profiling and stabilisation machine, the contribution of the load frequency can be clearly observed in the response.

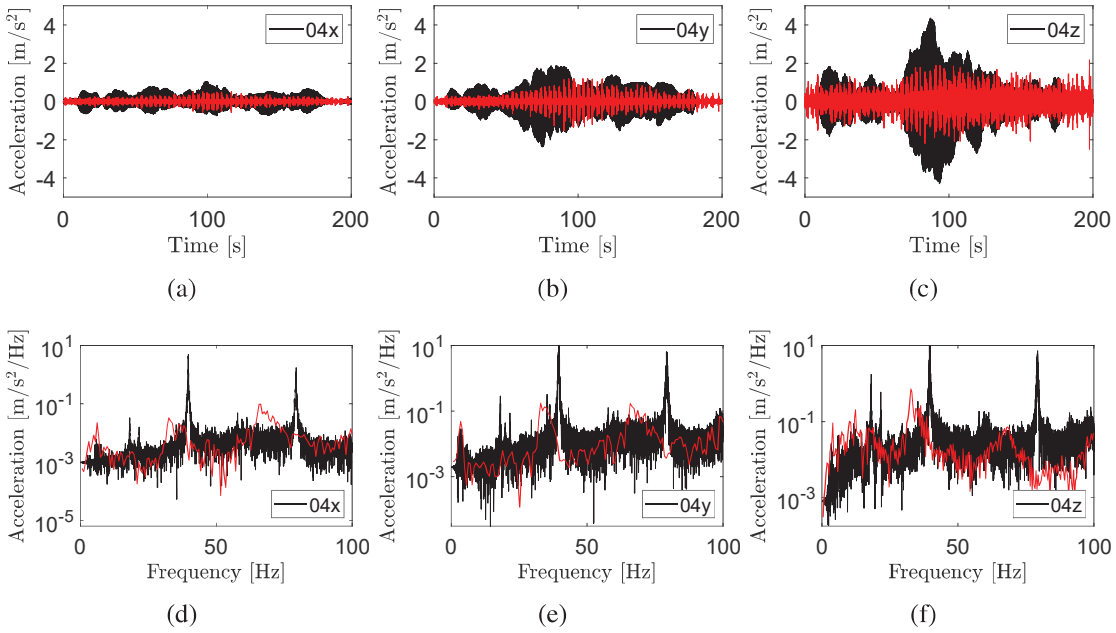

Figure 31: Tinajas bridge: (a-c) time history and (d-f) frequency content of the acceleration at point 4 induced by (black line) Plasser & Theurer DGS 62N profiling and stabilisation machine operating at 40 Hz and (red line) Plasser & Theurer Unimat 08-475/4S ballast distributing machine operating at 35 Hz.

4 Conclusions

The experimental campaign presented in this paper is aimed at analysing the dynamic behaviour of railway bridges. The tests were performed on five bridges with different structural typologies: i) a bridge with spans composed by two adjacent single-track decks sharing a continuous ballast track; ii) a three-span bridge composed by a double-track pre-stressed concrete girders deck; iii) a three-span S-S bridge with a filler-beam concrete deck; iv) a three-span S-S steel truss bridge with a single ballastless track, and v) a steel-concrete composite continuous three-span bridge. The bridge dynamic behaviour, the soil properties and the response under operational and maintenance conditions have been studied in the previous sections.

This work also shows that damping identification is difficult and depends on the chosen methodology. According to previous studies [8] it depends on the time span and bandpass filter applied but, despite that, it can be concluded that the estimated damping ratios in free vibration under operational conditions were always greater than the values obtained in ambient vibration.

The analysis of the acceleration response of the bridges due to train traffic shows, in the frequency domain, clear peaks associated to the excitation (bogie and axle passages, and even its corresponding harmonics) and also to the bridge lowest natural frequencies. The maximum overall acceleration measured is lower (yet significant), than the Serviceability Limit State prescribed by European Standards [12], limited to $3.5\,\mathrm{m/s^2}$ for bridges with ballasted tracks.

The coupling effect between adjacent decks of the same span caused by the continuity of the ballast layer is clearly perceptible in the train-induced vibrations of Old Guadiana bridge, which can be also identified under ambient vibrations. A similar observation was previously reported by Rauert at al. [16] in a S-S bridge formed by one span with two separated decks. Therefore, for an accurate prediction of the dynamic response of bridges composed by several S-S spans and/or structurally independent decks at each span, the consideration of the coupling effect induced by the ballast continuity in the numerical models may become important.

Keywords: Railway bridge, high-speed train, soil-structure interaction, frequency response function.

Abstract. *Corrugated steel culverts are sometimes used as an alternative to portal frame bridges for small and medium crossings under railway lines. From a static point of view, the corrugated steel culverts are rather flexible structures and the load capacity relies on the confinement from the surrounding soil. From a dynamic point of view, especially for potential use on high-speed lines, the structural manner of action is not yet fully explored.*

This paper presents the result from full-scale experimental testing of a corrugated steel culvert, including both forced vibration tests and response from passing trains. The aim is to estimate the dynamic characteristics of the bridge, especially the interaction with the surrounding soil and how that will influence the response at the track level. From the forced vibration tests, the results show that the structure has a high inherent damping owing to the surrounding soil and that both the natural frequency and damping change with load amplitude. The experimental frequency response functions are used for updating numerical models to further understand the dynamic behaviour of these structures.

1 INTRODUCTION

Corrugated steel culverts consist of corrugated pipes or aches, often assembled by bolted curved sheets. The corrugation itself is rather weak but can withstand significant loads when properly confined by backfilling, therefore often denoted soil-steel composite bridges, SSCB. They are built for both road and railway applications and can reach spans up to 20 m. A typical cross-section of a SSCB is illustrated in Figure 1 and a typical corrugation is shown in Figure 2.

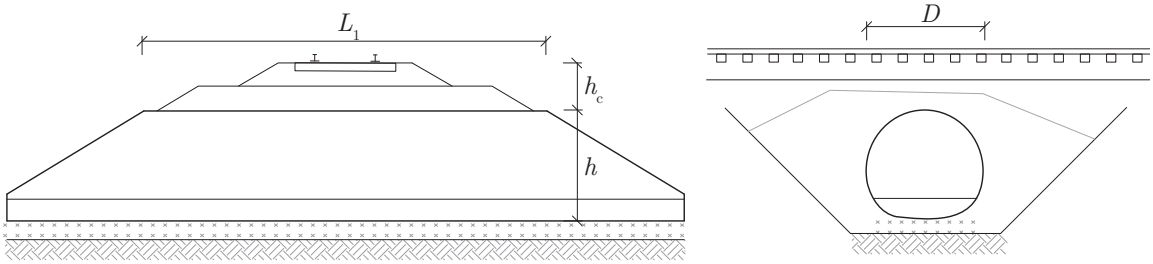

Figure 1: Typical cross-section of a SSCB.

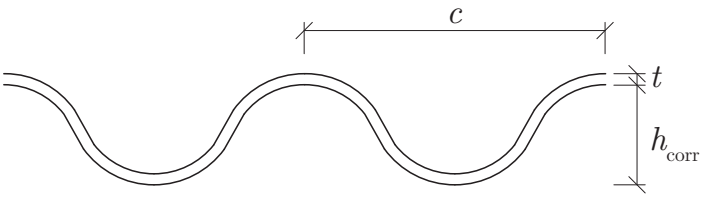

Figure 2: Basic profile of the corrugated plate.

As an example, the Swedish railway network contains about 4200 railway bridges whereof 75 are SSCB. The rate of construction has been relatively constant since the 1960ies. Most bridges have a closed elliptic culvert profile and the average diameter D = 3.3 m. The height of cover h_c is usually not less than 1.1 m. The data from the Swedish bridges is presented in Figure 3. More detailed description of different culvert profiles and corrugation sections can be found in [1] and [2].

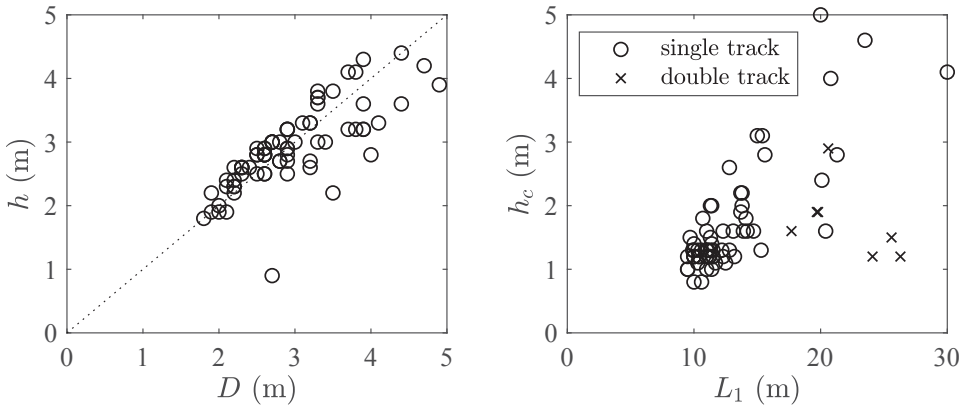

Figure 3: Geometrical data for soil-steel composite bridges in Sweden.

1.1 Previous studies

There is a relatively vast amount of literature on the topic of soil-steel composite bridges, mostly devoted to different aspects of static design and construction methods. Several experimental campaigns are also published, comprising static load tests to failure, fatigue tests and dynamic tests. In this paper however, only work related to dynamic analysis and tests on soil-steel composite bridges for railway traffic is included.

Skivarpsån, Sweden

One of the earlier work the dynamic performance of SSCB for railways is the bridge over Skivarpsån in South of Sweden. It consists of a semi-circular corrugated arch with D = 11 m, h = 4.3 m and h_c = 1.8 m that was installed outside of an existing concrete arch bridge in 2003. The new bridge is founded on separate supports and does not transfer any load to the old bridge that is still in place. A SuperCor S37 corrugation with c = 380 mm, h_{corr} = 140 mm and t = 7.0 mm was used.

The first experimental campaign is reported in [3], comprising the construction stage followed by static and dynamic load tests with trains. Strain gauges were installed on the intrados of the corrugation, at quarter point and the crown. An LVDT was installed at the crown, measuring the relative displacement between the new and the old bridge. The result from a passing freight train showed about 1 mm vertical crown displacement and about 13 MPa stress in the corrugation. The same tests were later published in [4].

More comprehensive dynamic tests were performed in two following campaigns, reported in [5] and [6]. A 78 tonne RC4 locomotive was used, running at different speeds from 10 to 125 km/h. The measured response showed a crown displacement from 0.7 to 0.9 mm and about 11-15 MPa stress in the culvert. Both tests were performed with similar test schedule, in May and October 2004.

The results was later published in [7] and [8]. It was concluded that there was no significant difference between the two tests and that the ballast acceleration was less than 0.5 m/s^2. The work on the bridge over Skivarpsån is also compiled in [9].

Märsta, Sweden

In 2009 and 2010, experimental testing was performed on a double track closed arch culvert in Märsta outside of Stockholm, Sweden, first reported in [10]. The geometry is D = 3.7 m, h = 4.1 m and h_c = 1.9 m and a VE-profile with c = 150 mm, h_{corr} = 50 mm and t = 5.5 mm.

The culvert was instrumented with strain gauges, accelerometers and LVDTs and the response from passing trains was recorded with a top speed of 175 km/h. The results showed a peak displacement of about 0.5 mm, acceleration of 0.8-1.4 m/s^2 and 6 MPa stress in the culvert. Accelerometers were also installed in the track area before, on and after the bridge. The peak ballast acceleration was in the range of 0.5-3.5 m/s^2.

2D and 3D models were developed with relatively good agreement compared to experimental results, reported in [11]. The load distribution from the track to the culvert was found to have a significant importance and the 2D-models were partly based on a best-fit 3D-model in that aspect. Simulations of high-speed trains indicated potential exceedance of the accelerations for train speeds above 250 km/h. It was pointed out however that the models were afflicted with great uncertainties. In [12] a best fit 3D model was found for a soil E-modulus of 120 MPa and simulations indicated that the acceleration limit was reached at about 300 km/h.

A hydraulic system for forced vibration tests on railway bridges was later developed and first

tested in [13]. This equipment was used when performing new tests on the culvert in 2017 and on two additional bridges in 2018.

Culverts in Poland

Experimental testing of a double track twin culvert is reported in [14]. The closed arch culvert has the geometry D = 4.4 m, h = 2.8 m and h_c = 2.4 m and the centre distance between the two culverts is 5.9 m. The corrugation has a geometry with c = 150 mm, h_{corr} = 50 mm and t = 3.0 mm.

The vertical crown displacement was measured using an interferometric radar sensor and a total of 40 trains with speed from 20 to 120 km/h was recorded. The results showed a vertical peak displacement of about 0.6 mm. Based on the same data, further analysis reported in [15] showed a dynamic amplification factor ranging from 1.1 to 1.4. It should be noted however that the resolution and accuracy of the measurement system was rather limited. The same bridge was later instrumented with strain gauges, accelerometers and LVDTs, reported in [16]. The results confirmed previous displacements of about 0.6 mm. In addition, a peak stress of 11 MPa was recorded. From a passing train at 120 km/h the peak acceleration was 0.7 m/s^2 in the culvert and 1.2 m/s^2 in the ballast.

Experimental testing of a similar bridge but with a single span is reported in [17]. The geometry was D = 4.7 m, h = 2.9 m and h_c = 2.4 m and with the same corrugation as the previous bridge. Trains passing at 40 to 130 km/h was recoded during 24h and relatively similar results were obtained as the previous tests; 0.65 mm vertical crown displacement, a peak stress of 13 MPa and 0.7 and 1.3 m/s^2 in the culvert and the track respectively.

1.2 Aim and scope

The aim of this paper is to estimate the dynamic characteristics of an existing SSCB, by means of experimental testing and numerical simulation. Of special interest is the interaction with the surrounding soil and how that influence the response at the track level. By using forced vibration testing, amplitude dependent properties are explored.

2 EXPERIMENTAL TESTING

2.1 The bridge

The experimental testing was performed on a single track close arch bridge at Hårestorp, about 400 km South of Stockholm, Sweden. The geometry is D = 4.9 m, h = 3.9 m and h_c = 1.2 m and an MP 150 profile with c = 150 mm, h_{corr} = 50 mm and t = 5.0 mm. A photo of the bridge is shown in Figure 4. Experimental tests were performed in September 2018.

Figure 4: View of the Hårestorp bridge, during field tests in 2018. Passage of an X14 passenger train.

2.2 Instrumentation

The bridge was instrumented with 16 uniaxial accelerometers (SiFlex SF1500S), two strain gauges (120Ω from HBM) and two displacement transducers (HBM WA10 LVDT). The instrumentation is illustrated in Figure 5 and Figure 6, accelerometers are denoted a1-a16, strain gauges e1-e2 and displacement transducers d2-d3.

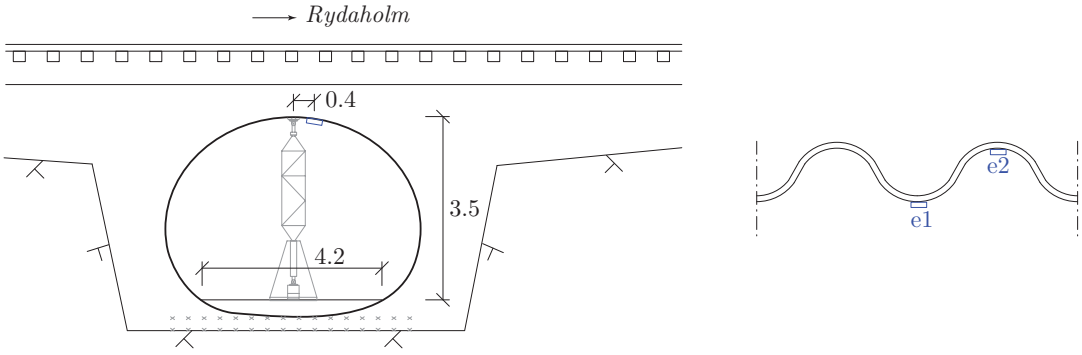

Figure 5: Instrumentation of the bridge at Hårestorp in 2018, section and detail of corrugation.

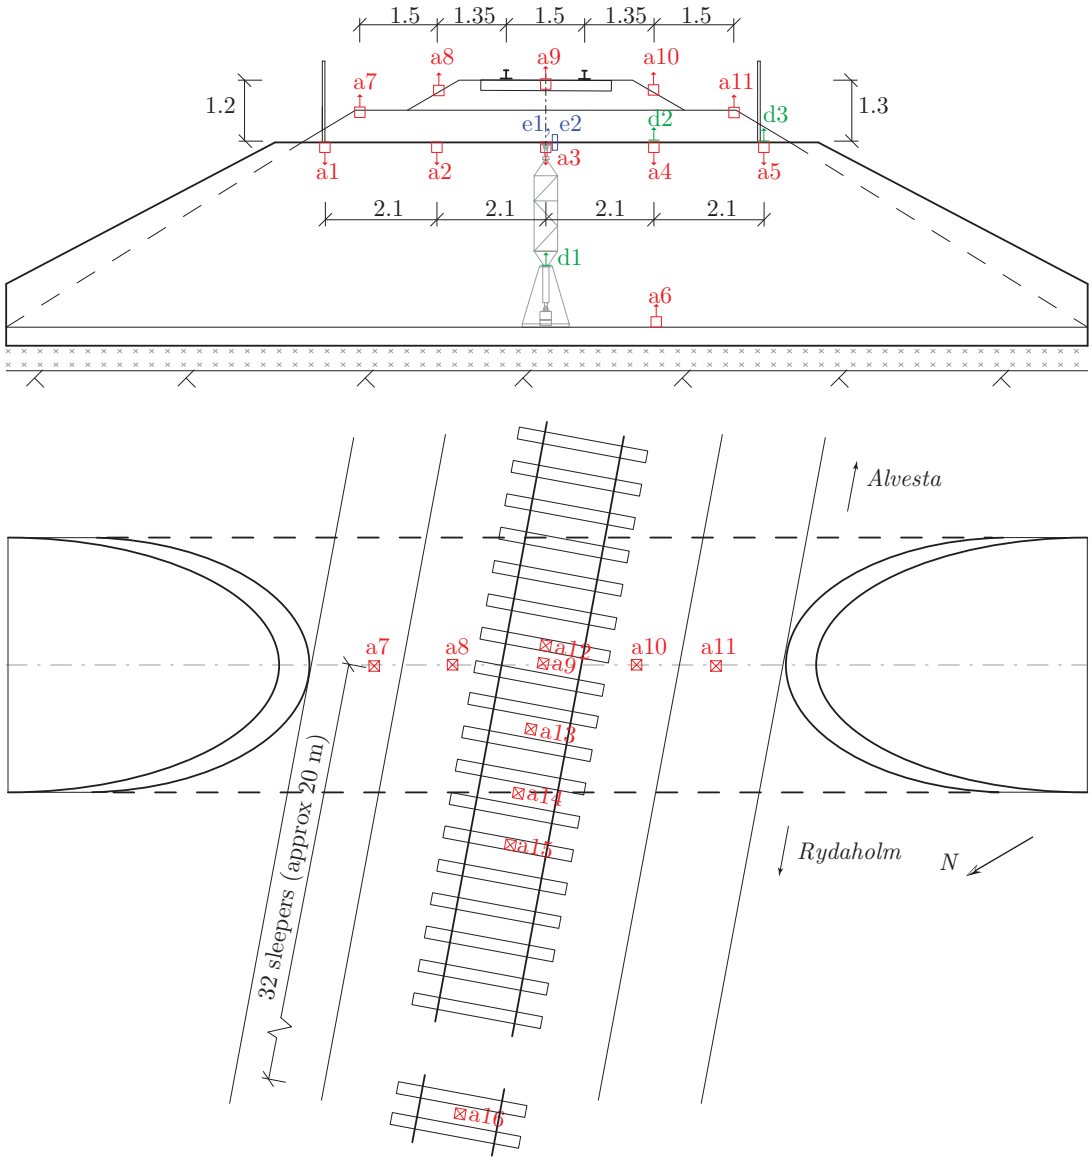

Figure 6: Instrumentation of the bridge at Hårestorp in 2018, plan and elevation.

2.3 The actuator system

The main part of the experimental equipment consists of the actuator system for forced vibration tests. The schematics is illustrated in Figure 7. It consists of a 50 kN MTS load actuator that is powered by an oil pump with a peak pressure of 210 bar and flow rate of 120 litre/min, powered by an integrated 40 hp diesel engine. The total mass of the oil pump is about 1000 kg. The actuator is placed inside the bridge and the load is transmitted to the crown by an aluminium truss system that can be rebuilt to adjustable heights. A load cell is placed on top of the truss and both the lower and upper points of the system is hinged. Load controlled harmonic sweeps are performed by using an MTS FlexTest SE controller. The data is collected by an MGCPlus data acquisition system, consisting of the input force, actuator displacement and the sensors on the bridge.

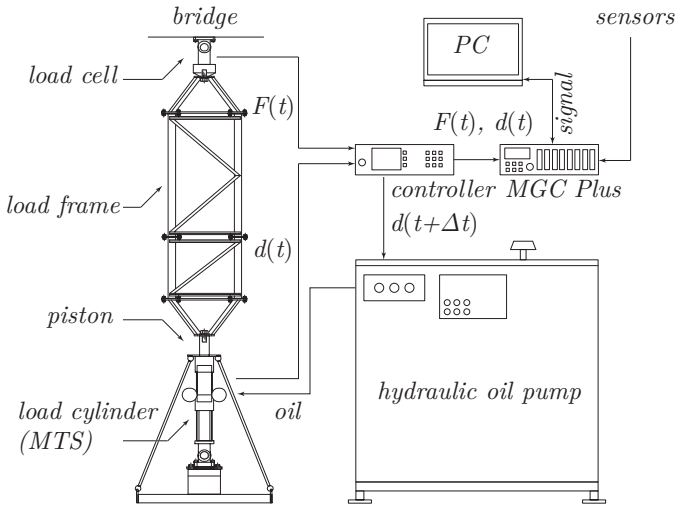

Figure 7: Illustration of the actuator system used during the experimental testing.

2.4 Train passages

A total of 8 train passages were recorded, running at a speed ranging from 120 to 150 km/h. The allowable speed at the location is 160 km/h. The peak vertical displacement during train passage is about 0.8 mm. By integrating the accelerometer a1 to a5, the displacement along the culvert is presented in Figure 8.

The peak acceleration from the culvert and the track during train passages is presented in Figure 9. The results highly depends on the frequency content and a comparison is made between a 30 Hz and 100 Hz LP-filter. The relatively large scatter in results become less when comparing individual sensors for the same type of trains at similar speed.

An example of the stress in the crown during train passage is shown in Figure 10. The largest bending stress is about 7 MPa. The combination of axial and bending stress results in a peak stress of about 4 MPa in tension at e1 and 12 MPa in compression at e2.

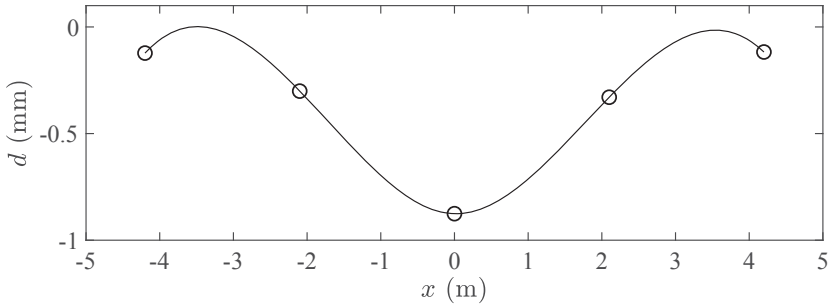

Figure 8: Vertical peak displacement of the culvert estimated from accelerometer a1-a5, X14 train passage.

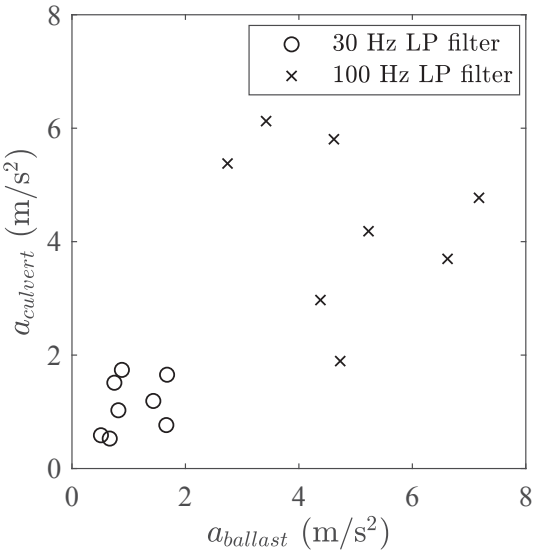

Figure 9: Peak acceleration with 30 Hz and 100 Hz filter, all trains.

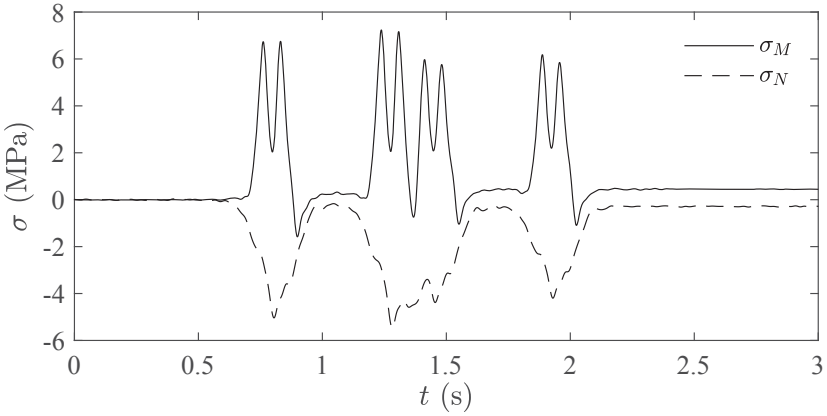

Figure 10: Stress in the crown of the culvert, X14 train passage.

2.5 Forced vibration tests

Forced vibration tests were performed with the actuator in the centre of the bridge near sensor a3. Harmonic frequency sweeps were performed from 1-40 Hz with a rate of Δf = 0.05 Hz/s. Test were performed with load amplitudes from 1-20 kN. The complex-values transfer function $\mathbf{H}(\omega)$ is calculated based on the Fourier transform of the output acceleration $a(t)$ and input force $F(t)$ according to Equation 1. Further in this paper the FRF will have the unit kN/m/s^2.

$$\mathbf{H}(\omega) = \mathbf{A}(\omega)/\mathbf{F}(\omega) \tag{1}$$

The results show that the vibration of the culvert and the track seems to be in phase up to about 30 Hz, as illustrated in Figure 11 for accelerometer a3 and a9. When comparing the FRFs for different load amplitudes, Figure 12, increasing the load amplitude results in a clear decrease in natural frequency, ranging from 16.4 Hz to 14.4 Hz. At the same time the estimated damping increase from 3.8% to 6.5%, using the half-Power Bandwitdh method.

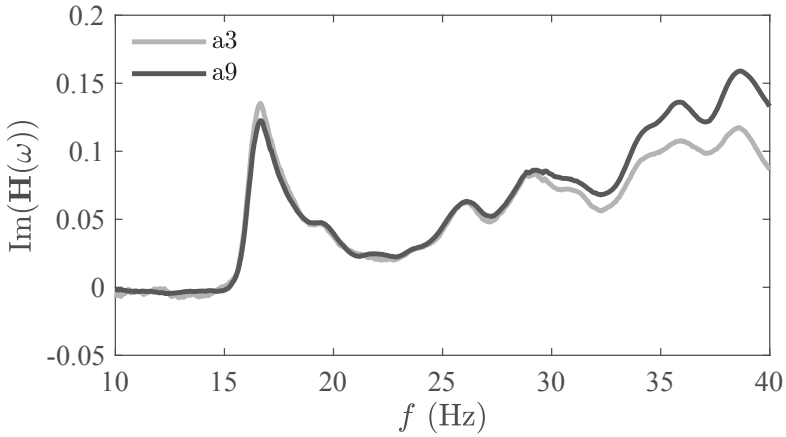

Figure 11: FRF, compare response in culvert and track, F_{amp} = 1 kN.

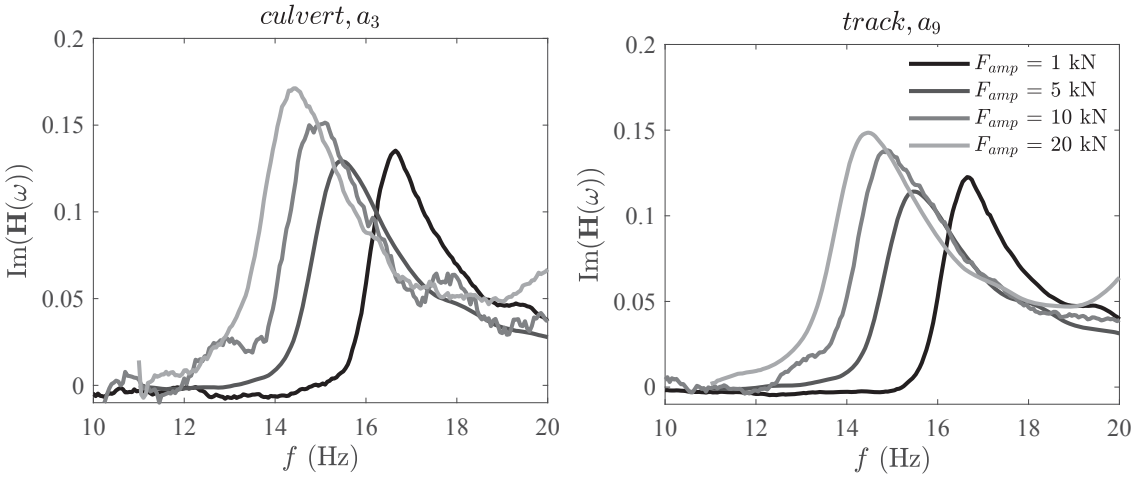

Figure 12: FRF, compare response in culvert and track for different load amplitudes.

3 NUMERICAL SIMULATIONS

A 3D finite element model of the SSCB has been developed, illustrated in Figure 13. The rails are modelled with beam elements but the rail pads, sleepers, ballast and subgrade are modelled with 20-noded quadratic brick elements (C3D20R). The total length of the model is 20 m and each end is modelled with infinite elements (CIN3D12R), h = 4 m. The corrugated steel culvert is modelled with orthotropic shell elements to represent the stiffness of the corrugation in the tangential and radial direction.

An example of calculated FRF is presented in Figure 14. The input is E_b = 160 MPa, E_s = 300 MPa, ν_b = 0.20, ν_s = 0.25, ρ_b = 1800 kg/m^3, ρ_s = 1800 kg/m^3 and ζ = 5%.

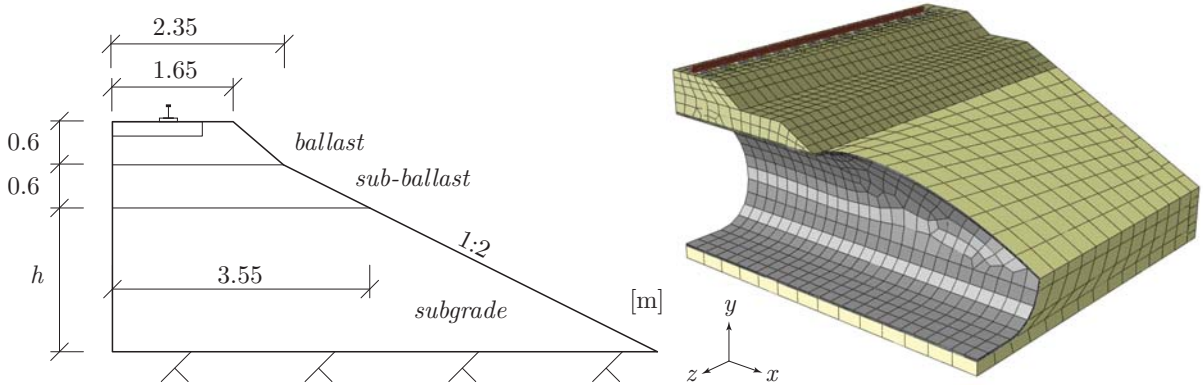

Figure 13: 3D model of the SSCB.

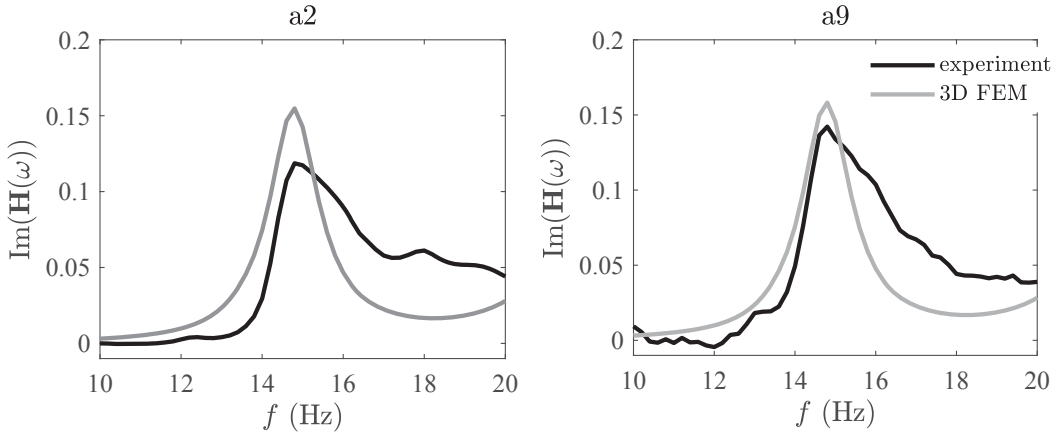

Figure 14: FRF, comparison between experiments and the 3D-model.

4 CONCLUSIONS

From the results presented in this paper the following is concluded.

- The experimental results with forced vibration response shows a significant influence of the load amplitude; higher loads results in lower natural frequency and higher damping.
- The recorded train passages show a vertical crown displacement of about 1 mm and a peak stress of about 6 MPa. The peak acceleration depends on the cut-off frequency, at 30 Hz the peak acceleration is in the order of 2 m/s^2.
- A preliminary FE-model shows a frequency response in the same order of magnitude as the experiments, but may need to be refined for increased performance.

ACKNOWLEDGEMENTS

The research presented in this paper was funded by ViaCon Sp z o.o. The experimental testing was performed by KTH division of Structural Engineering and Bridges.

Abstract.

In this work, the effect of the surrounding soil condition on the fundamental modal characteristics and dynamic response of railway bridges with integral abutments is studied. Due to the computational cost of the full FE models and the lack of reliable simplified models, the effect of the soil-structure interaction is usually neglected in the vibration analysis of the high-speed railway bridges. In the present study, an efficient simplified numerical model is employed to evaluate the modal characteristics of the railway bridge–soil systems. After verifying the accuracy of the simplified numerical model against rigorous models, the effect of the span length and abutment/soil stiffness on the dynamic response of the studied bridges is investigated through a comprehensive parametric study. Several case studies which covers different span lengths and abutment conditions are chosen. It is shown that the SSI has substantial effect on the dynamic response of the short and stiff bridges while its effect decreases as the ratio between the deck stiffness and the abutment/soil stiffness decreases. The results may lead to review the recommended modal damping ratios for this type of bridges in the code provisions and design manuals.

1 INTRODUCTION

The frequency content and amplitude of the vibrations in the resonant response of railway bridges is governed by the fundamental modal characteristics (natural frequency and damping ratio) of the structural system [1, 2]. Hence, to predict the resonant response with reasonable accuracy, it is important to properly estimate the modal characteristics of the structural system, considering the effect of the flexibility and dissipation capacity of the surrounding soil [1]. Bridges with integral abutments and culverts are one of the most common type of underpasses along modern railway lines. This type of bridge is designed as a reinforced concrete rigid frame and is surrounded by backfill soil. Presence of backfill soil may provide an additional stiffness to the system which leads to an increase in the fundamental natural frequency and thus shifts the critical resonant speed to a higher value [3, 4]. The dissipation capacity of the backfill soil could also lead to an increase in the global damping of the system and consequently reduce the amplitude of the resonant response of the bridge [3, 4]. In the field of train-induced vibration analysis of railway bridges, limited results have been published on the bridge with integral abutments considering the effect of soil-structure interaction [4-7]. To study the influence of soil-structure interaction on the modal properties of railway bridges with integral abutment in a systematic manner, implementing simple and accurate models to calculate the natural frequency and modal damping ratio of the bridge-soil system is helpful. In this paper, an efficient and simple approach to model the effect of the surrounding soil on the modal characteristics and resonant response of the railway bridges with integral abutment is proposed. The dynamic soil-structure interaction problem is modelled through a 2D finite element (FE) of the portal frame bridge in which the side walls are surrounded by series of spring/dashpot sets. The merit of using efficient simplified models is that the key factors governing the dynamic response of the studied system can be identified. The accuracy of the proposed analytical expressions will be verified through comparison with the finite element solutions. Then, the variation of the fundamental frequency and modal damping ratio of bridge-soil systems are analyzed through a comprehensive parametric study. This gives valuable information on how SSI can affect dynamic characteristics of railway bridges with integral abutment and when the effect of SSI is negligible.

2 NUMERICAL MODEL

The general configuration of the proposed 2D model for a bridge with integral abutments which is surrounded by backfill soil is shown in Figure 1a. In order to investigate the importance of the backfill soil and to understand the effect of abutment-backfill interaction, the effect of the supporting subsoil is neglected. Thus, it is assumed that the supporting subsoil is rigid and consequently the bottom nodes of the model are fixed.

The structural domain Ω_b is modelled with Euler-Bernoulli beam elements while the surrounding soil domain Ω_s is replaced by its dynamic impedance at the interface nodes. Taking dynamic soil-structure interaction into account, the equation of motion for the coupled soil-structure system in the frequency domain can be expressed as follows:

$$\left[\mathbf{K_b} + \lambda\mathbf{C_b} + \lambda^2\mathbf{M_b} + \mathbf{K_s}(\lambda) + \lambda\mathbf{C_s}(\lambda)\right]\mathbf{u}(\lambda) = \mathbf{p}(\lambda) \tag{1}$$

where $\lambda = i\omega$ is the complex frequency, $\mathbf{u}(\lambda)$ is the nodal displacement vector, $\mathbf{p}(\lambda)$ is the nodal force vector and $\mathbf{K}_b$, $\mathbf{C}_b$ and $\mathbf{M}_b$ are respectively the stiffness, damping and mass matrices of the viscoelastic bridge structure. Finally, $\mathbf{K}_s(\lambda)$ and $\mathbf{C}_s(\lambda)$ represents the frequency dependent dynamic stiffness and damping contribution of the surrounding soil at interface nodes.

2.1 Proposed model for backfill-wall interaction

The wall–backfill interaction behaviour in the normal direction is modelled by using distributed spring/dashpots, k_s and c_s over the whole area of the walls evaluated using Eq. (2) and 3 [8] (see Figure 1a). The spring and dashpot coefficients are chosen based on the recommended values by Veletsos and Yonan [8]. It is well-known that at frequencies below the cut-off frequency of the soil layer, $f_s = V_s/4H$ [9], the radiation damping is negligible and consequently the damping originates only from the hysteretic damping of the soil medium. However, at frequencies higher than the f_s, the radiation damping capacity of the stratum is gradually approaches the maximum value, as shown in Figure 1c [9]. It should be noted that, the frequency dependency of the spring stiffness is disregarded and the average value of the recommended static stiffness by Veletsos and Yonan [8] for the 1st two vibration modes of wall-soil system is considered. As it will be shown in section 3.2, this assumption results in a good agreement between the proposed model and the reference solution.

$$k_s = \frac{2\pi}{\sqrt{2(1-\nu_s)}} \frac{\rho_s V_s^2}{H} \tag{2}$$

$$\begin{cases} c_s(\omega) = c_{s,m}(\omega) = 2\xi_s k_s / \omega_1 & \phi \le 1 \\ c_s(\omega) = c_{s,m}(\omega) + c_{s,rad}(\omega) = 2\xi_s k_s / \omega_1 + \rho_s . V_p \sqrt{1-(1/\phi)^2} & \phi > 1 \end{cases} \tag{3}$$

where ϕ is the relative frequency parameter as defined by Eq. 4 and V_s, V_p , ρ_s, ξ_s , ν_s and H respectively represents shear and compression wave velocities, density, hysteretic damping, Poisson ratio and height of the soil layer.

$$\phi = f_1 / f_s = \omega_1 / (\pi V_s / 2H) \tag{4}$$

2.2 Complex eigenvalue analysis

The complex modal characteristics of the coupled soil-structure system can be found as the solution of the following quadratic eigenproblem:

$$\left[(\mathbf{K_b} + \mathbf{K_s}(\lambda_m) + \lambda_m [\mathbf{C_b} + \mathbf{C_s}(\lambda_m)] + \lambda_m^2 \mathbf{M_b} \right] \varphi_m = 0 \tag{5}$$

where λ_m and φ_m are the complex-valued eigenvalue and corresponding eigenvector of mode m (m = 1, …,n) and n denotes the number of degrees of freedom. Provided that the system is underdamped, the undamped eigenfrequency ω_m and modal damping ratio ξ_m of the system for the m-th mode is calculated by Eq. (5).

$$\omega_m = |\lambda_m|, \quad \xi_m = -\Re(\lambda_m) / \omega_m \tag{6}$$

Following the procedure by Tisseur et al. (2001) [10], the quadratic eigenproblem in Eq. (1) is converted into a bigger equivalent linear matrix pencil that has the same eigenvalues as the original problem. Rearranging Eq. (1) and using the auxiliary vectors, the following linear matrix pencil can be used where $\tilde{\varphi}_m^T = \left\{ \varphi_m^T, \lambda_m \varphi_m^T \right\}$.

$$\left(\begin{bmatrix} \mathbf{K}_b + \mathbf{K}_s(\lambda_m) & \mathbf{0} \\ \mathbf{0} & \mathbf{I} \end{bmatrix} - \lambda_m \begin{bmatrix} -[\mathbf{C}_b + \mathbf{C}_s(\lambda_m)] & -\mathbf{M}_b \\ \mathbf{I} & \mathbf{0} \end{bmatrix} \right) \tilde{\varphi}_m = \mathbf{0} \tag{7}$$

Then, the eigenpairs of the linear matrix pencil in Eq. (6) can be computed by applying a standard linear eigensolver. Since the damping matrix of the surrounding soil $\mathbf{C}_s(\lambda)$ is fre-

quency-dependent, an iterative procedure is used to compute the modal properties of the system, considering the natural frequency of the bridge without SSI, ω_m, as the initial guess.

In non-proportionally damped systems as is the case here, the computed eigenvectors φ_m are complex-valued, implying that the mode shape components will move with different phase angles [11]. The overall phase coherence between the n elements of a complex eigenvector φ_m can be measured by using the modal collinearity factor (MCF) [11] defined as:

$$\mathrm{MCF} = 1 - A_p / A_c \tag{8}$$

where A_p is the convex polygon in the complex plane defined by the extremities of each element in the eigenvector and A_c is the area of a circle whose radius corresponds to the largest magnitude of the eigenvector as shown in Figure 2a. The MCF takes values from 0 to 1 with a value equal to 1 indicating a real-valued mode corresponding to a standing wave.

3 PARAMETRIC STUDY

3.1 Definition of case studies

The parametric study focuses on short to medium size portal frame bridges. Referring to Figure 1a, the parametric variables of four case study bridges are summarized in Table 1. The thickness of the frame bridge ($t = t_f = t_w$) is assumed to vary with the span length L and estimated based on collected data from existing single-track ballasted concrete bridges in Sweden [15]. The height, width, mass density and modulus of elasticity of all four case study bridges are assumed constant at H = 7 m, B = 6 m, ρ_b = 2300 kg/m^3 and E_b = 30 GPa, respectively. No structural damping is assigned to the bridge itself. Eliminating the internal damping of the structure allows a better understanding of the effect of SSI on the global damping of the coupled system. In this simulations, mass of the ballast layer is assumed to be 750 kg/m^2 and added to the deck nodes. Table 2 summarize the parameters of the surrounding soil. The sensitivity of the fundamental modal characteristics of the bridges with respect to the shear wave velocity of the backfill soil is investigated.

Table 1. Geometrical properties of bridges

L	[m]	7	9	11	15
$t_f = t_w$	[m]	0.65	0.75	0.85	1.0
$f_{1,n}$*	[Hz]	24.6	18.9	15.0	10.6

* Natural frequency of the bridge without SSI

Table 2. Backfill soil properties

H (m)	V_s (m/s)	ξ_s (%)	ν_s (-)	ρ_s (t/m^3)
7	{0,...,1000}	2.5	0.2	1.8

As the response of the bridge-soil system is governed by the viscoelastic properties of the bridge and surrounding soil, the following dimensionless parameters are defined to study the sensitivity of the modal properties of the coupled systems:

(a) The relative frequency parameter, ϕ, defined by Eq. (4) which represents the ratio of the coupled-soil-structure eigenfrequency to the resonant frequency of the backfill stratum. This parameter is used to study the sensitivity of the modal properties of the system to the cut-off frequency of the stratum.

(b) The relative stiffness parameter, κ, defined as the ratio of the flexural rigidity of the frame structure to the static stiffness of the backfill soil.

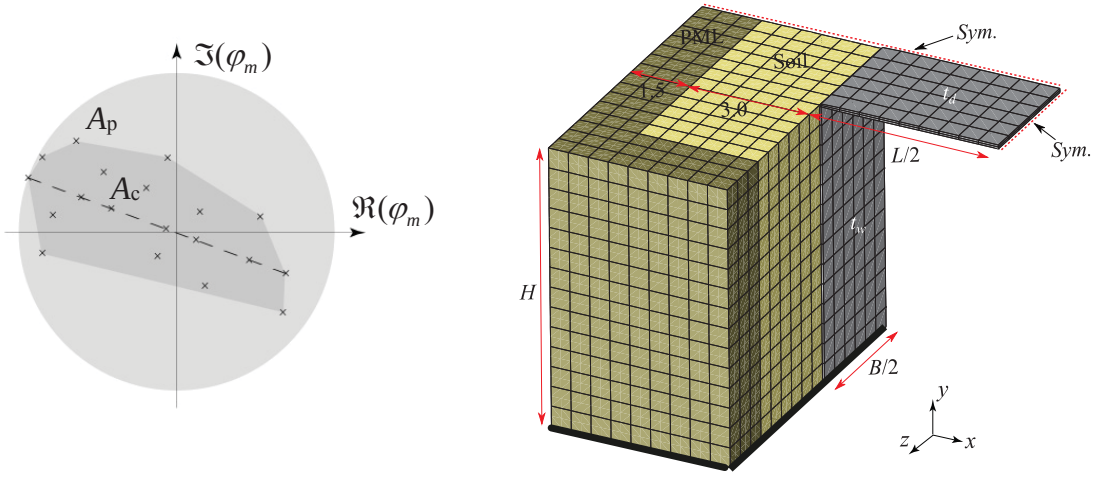
$$\kappa \approx \frac{32EI(H/L+2)/(L^2H)}{2\rho_s V_s^2 B} \tag{9}$$

(c) The abutment impedance ratio, χ, defined as the ratio between the real and imaginary parts of the rotational dynamic stiffness at the top node of the abutment (see Figure 1b).

$$\chi = k_\theta(f_1)/f_1 c_\theta(f_1) \tag{10}$$

3.2 Verification

In this section, the accuracy of the proposed simplified model is verified through comparison with the results of a full 3D FE-PML model. The computed modal properties of some case studies using proposed simplified model are compared to results of full 3D FE-PML model. The configuration of the 3D FE model is shown in Figure 2b. For this comparison, the shear wave velocity of the backfill soil is assumed constant at V_s =300 m/s and the modal properties of the frame-soil system for the 1st vertical bending are calculated for two different span lengths. In each case, the thickness of the wall and deck is assumed to be similar and varied between 0.2 to 1.2 m in increments of 50 mm. The 3D FE model of the wall and backfill soil is discretized using 8-noded shell and 20-noded hexahedral solid elements, respectively. According to the shear wave velocity of the backfill soil layer, the element size in the soil medium is chosen in such a way that there are at least 8 quadratic elements per wavelength at 50 Hz [11]. For the finite element mesh configuration of Figure 2b, the PML parameters are tuned to properly absorb evanescent and propagating waves [13].



(a) (b)

Figure 2: (a) Definition of modal collinearity factor (MCF), (b) Configuration of 3D FE-PML model (units in m).

The comparison between the calculated complex modal parameters of the 1st vertical bending mode of the studied cases are presented in Figure 3. As can be seen, the calculated natural frequencies and modal damping ratios using the proposed simplified model are in a very good agreement with the results of the 3D FE-PML analyses. It should be noted that modal characteristics of the reference 3D FE-PML model have been computed using the procedure in [14].

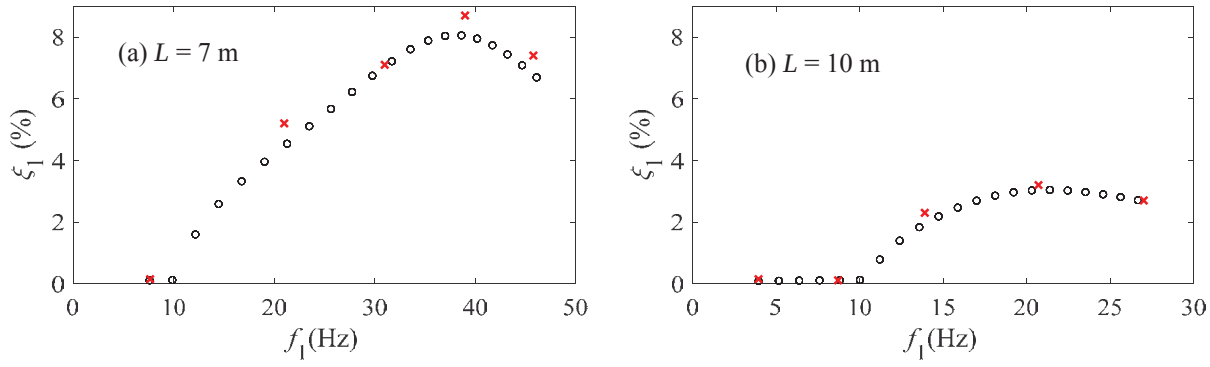


Figure 3: Comparison between computed modal characteristics using 2D simplified model (black o) and 3D FE-PML model (red ×), (a) L = 7 m, (b) L = 10 m.

3.3 Results of parametric studies

The variation of the frequency lengthening $f_1/f_{1,n}$, modal damping ratio ξ_1, MAC_1 and MCF_1 values for the 1st vertical bending mode of the studied cases a function of the shear wave velocity are presented in Figure 4a-d, respectively. As the structure is modeled without any material damping, the increase in modal damping ratios is solely attributed to radiation and material damping of the surrounding soil.

The dynamic stiffness of the backfill leads to an increase in the fundamental frequency of the coupled system and the frequency lengthening due to SSI becomes higher as the backfill soil becomes stiffer (see Figure 4a). The dissipation capacity of the backfill soil generally results in higher modal damping ratios for the coupled soil-structure system. The results in Figure 4b indicates that there exists a critical value V_s in which the fundamental damping ratio reaches its maximum value. The value of $V_{s,crit}$ is found to occur, when MCF_1 (Figure 4d) and the abutment impedance ratio χ_1 (Figure 4e) reach their minimum values. In this case, the maximum modal complexity occurs and the mode shape is most different from a standing wave. Clearly, by increasing the shear wave velocity toward infinity, the natural frequency of the studied system gradually converges to the fundamental frequency of a clamped-clamped beam and consequently, the modal damping ratio approaches zero.

The variation of the modal damping ratio ξ_1 for the studied system as a function of the relative frequency parameter ϕ and the relative stiffness parameter κ are presented in Figure 5a and 5b, respectively. In this Figure, the variation of the shear wave velocity is limited to the range of reasonable values in practice (e.g. V_s =100 to 500 m/s). The results show that the amount of additional damping due to SSI is principally governed by the following two factors:

- The relative frequency parameter which is the ratio between the fundamental frequency of the bridge-soil system and the cut-off frequency of the backfill layer. Theoretically, at frequencies lower than the cut-off frequency of the backfill layer ($\phi < 1$), the radiation damping capacity of the backfill soil is zero. However, at frequencies higher than the cut-off frequency of the backfill layer ($\phi > 1$), the radiation damping capacity of the backfill layer is restored and approaches its maximum capacity with a logarithmic growth (see also Figure 1c).

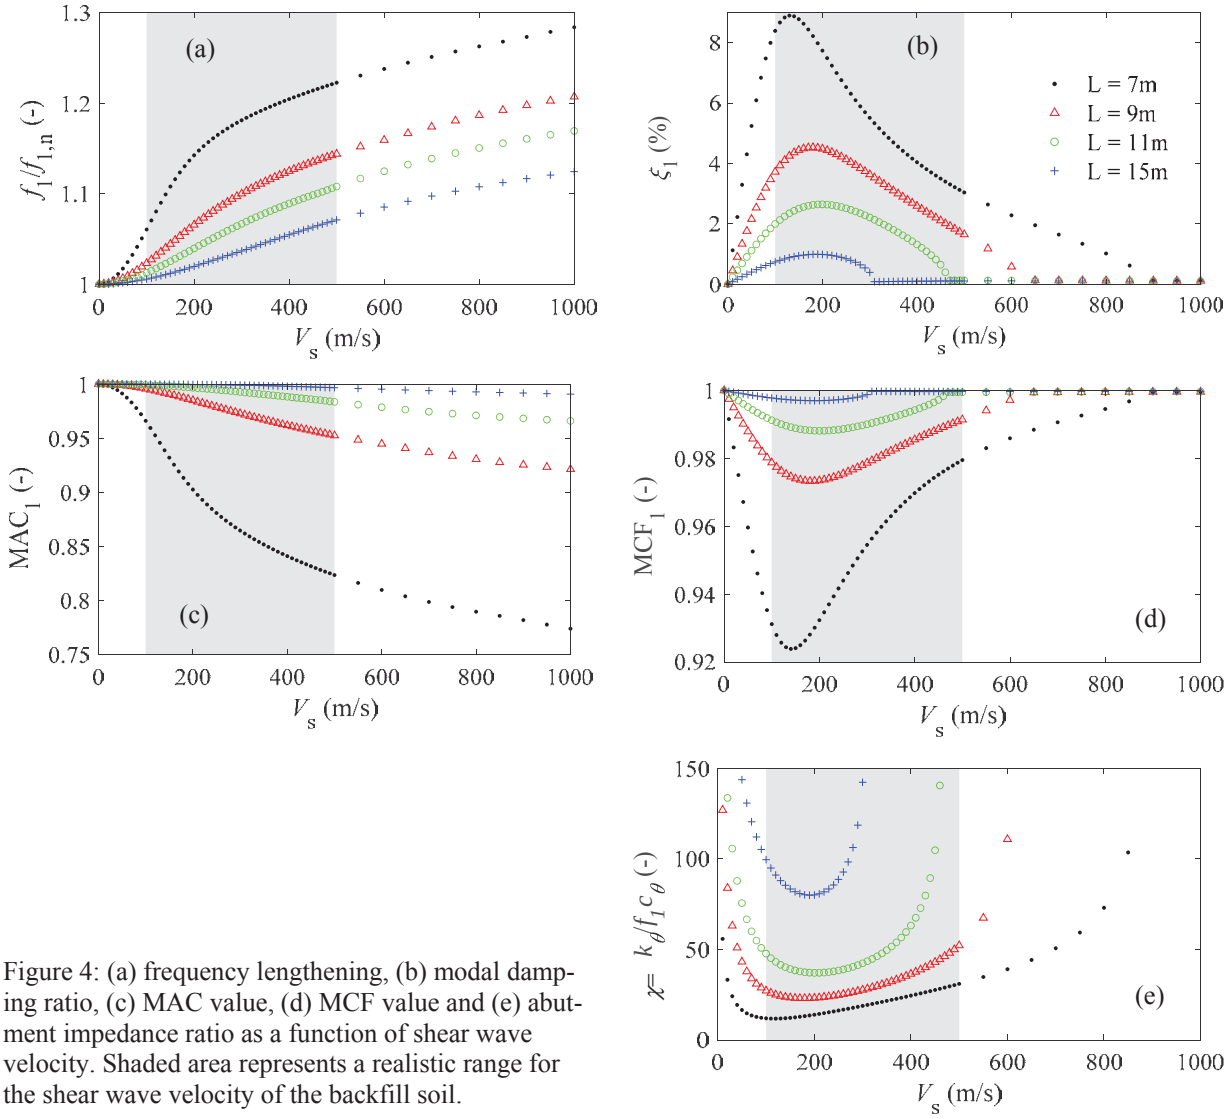

Figure 4: (a) frequency lengthening, (b) modal damping ratio, (c) MAC value, (d) MCF value and (e) abutment impedance ratio as a function of shear wave velocity. Shaded area represents a realistic range for the shear wave velocity of the backfill soil.

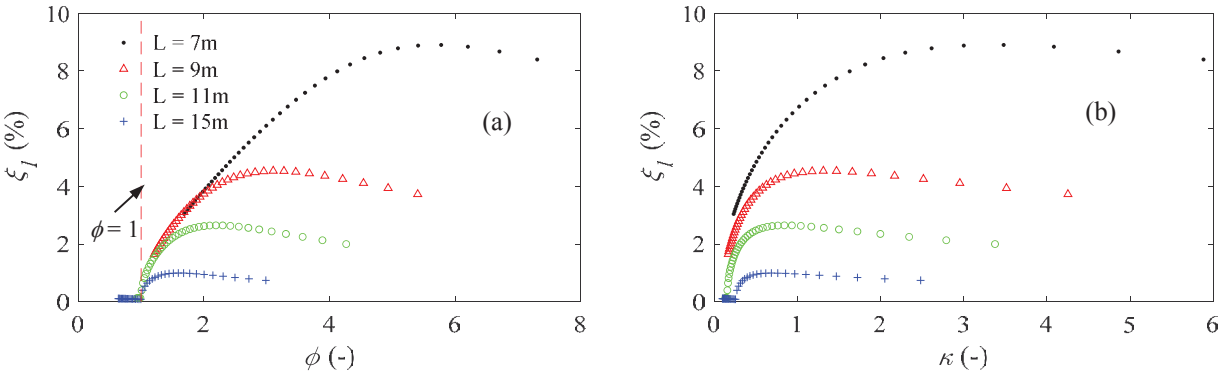

Figure 5: (a) Variation of modal damping ratio as a function of relative frequency parameter, (b) Variation of modal damping ratio as a function of relative stiffness parameter. Results were presented for V_s = 100-500 m/s.

- The relative stiffness parameter which is defined as the ratio between the stiffness of the structure and the backfill soil. The dissipation capacity of the backfill soil is negligible for a flexible structure surrounded by very stiff soil. Generally, there is a critical value for the relative stiffness parameter in which the additional damping of the system due to SSI becomes maximum. This is the case when the ratio between the real and imaginary parts of the abutment impedance reaches its minimum value, as shown in Figure 4e. After this turning point, the additional damping due to SSI is gradually decreased as the relative stiffness parameter increases.

4 CONCLUSIONS

In this paper, a simplified Winkler-based model is proposed for modeling the abutment-backfill soil interaction. Using this model, the effect of dynamic soil-structure interaction on the resonant response of portal frame bridges founded on a rigid base is studied. The fundamental modal characteristics of the short to medium span case study bridges are computed for a wide range of shear wave velocities of the backfill soil. The following remarks can be concluded from the presented results:

- Generally, dynamic soil-structure interaction results in higher eigenfrequencies, modal damping ratios and modal complexities for the studied coupled soil-structure system with the inf uence getting more intense for shorter (stiffer) bridges. The presence of backfill soil provide an additional stiffness and damping to the structural system.
- The dynamic stiffness of the backfill leads to an increase in the fundamental frequency of the system and thus shifts the critical resonant speed to a higher value. The frequency lengthening due to SSI is essentially controlled by the ratio between the stiffness of the frame bridge and the backfill soil.
- The amount of additional damping due to SSI (foundation damping) is principally governed by the following factors: (a) ratio between the fundamental frequency of the coupled system and the cut-off frequency of the backfill layer and (b) ratio between the stiffness of the frame bridge and the backfill soil. The additional damping may lead to a considerable increase in the global damping of the system and consequently reduce the amplitude of the resonant response of the bridge.

Keywords: Post-tensioned segmental columns, Rocking motion, Accelerated bridge construction, Numerical modelling

Abstract. *Application of post-tensioned segmental columns are increasing in accelerated bridge construction, where rocking motion of the segments results in lateral displacement of the column and the post-tensioning tendon provides self-centering capacity of the system. Analytical solution of such system is very complex as the equations of rocking motion are highly nonlinear, and it is almost impossible to solve such systems for seismic excitations. Furthermore, using finite element-based software such as ABAQUS and ANSYS make the dynamic analysis very time consuming and, so computationally inefficient. Therefore, this paper introduces a new technique for modelling of post-tensioned segmental columns in OpenSees program, which is computationally efficient, and exhibits a good agreement with analytical approaches and experimental results. Using the developed model, the frequency response function and seismic response of an exemplary column are extracted which exhibits a lower and an upper branch around the resonance.*

1 INTRODUCTION

Bridges are crucial parts of any transportation system, and any disruption in their functionality can result in tremendous economic and life losses. In particular, lateral seismic effects can cause permanent structural damage. Traditional reinforced concrete (RC) columns are integrally connected to the underlying foundation. Thus, plastic hinges, and consequently permanent plastic deformations are generated in RC columns under lateral seismic loadings. As an excellent alternative to RC columns, precast post-tensioned segmental (PPS) columns are recently used in accelerated bridge construction. The PPS columns are manufactured offsite, which improves concrete quality and shortens construction time. Furthermore, the rocking mechanism of the segments and self-centering property of the post-tensioned tendon substantially decrease the residual drift of the column after the lateral loading events. However, the segments might still be prone to local damages at their contact interfaces.

Many experimental works have been conducted to investigate performance of the PPS columns subject to static cyclic and dynamic loading testing protocols [1].To increase energy-dissipating capacity of the PPS columns, different strategies were recommended ([2-6]). In a series of different studies, high-damping material layers were placed between the segments in small-scale columns inspired by mechanics of the human spine, and damping level of the system was highly increases ([7-10]).

Many numerical studies have been also done to model static and dynamic behavior of the PPS columns. 3D continuum finite element (FE) models ([2, 11]) and fibre-based FE models ([12, 13]) have been employed to capture seismic response of the PPS columns. Complex continuum FE models can capture local damages generated in contact surfaces at the compression zones. However, such models have low calculation efficiency particularly in case of parametric studies when a large number of simulations are required. Fibre-based FE models have been extensively used in seismic response evaluation of RC columns ([14-16]). Unlike continuum FE models, fibre-based FE models are computationally efficient. However, they cannot model the contact surface between segments of PPS columns, i.e. rocking joints and compression zones, as good as continuum FE models. Simplified analytical models ([1, 2]) were also proposed to predict lateral force-displacement behavior of the PPS columns. Therefore, this paper summarizes a computationally efficient approach for modelling the rocking motion of the PPS columns already published in [17]. A new modelling in OpenSees program [18] is developed, and both experimental and analytical results are used to validate the proposed model. Finally, frequency response function of an exemplary column is generated and discussed using the proposed modelling method.

2 THE MODELLING DESCRIPTION

The finite element program OpenSees [18] is adopted to create a model for simulation of rocking motion of the PPS columns shown in Figure 1. A generic two-dimensional (2D) column model is developed with three degrees-of-freedom per node consisting of horizontal and vertical translations as well as a rotational displacement (see Figure 1b).

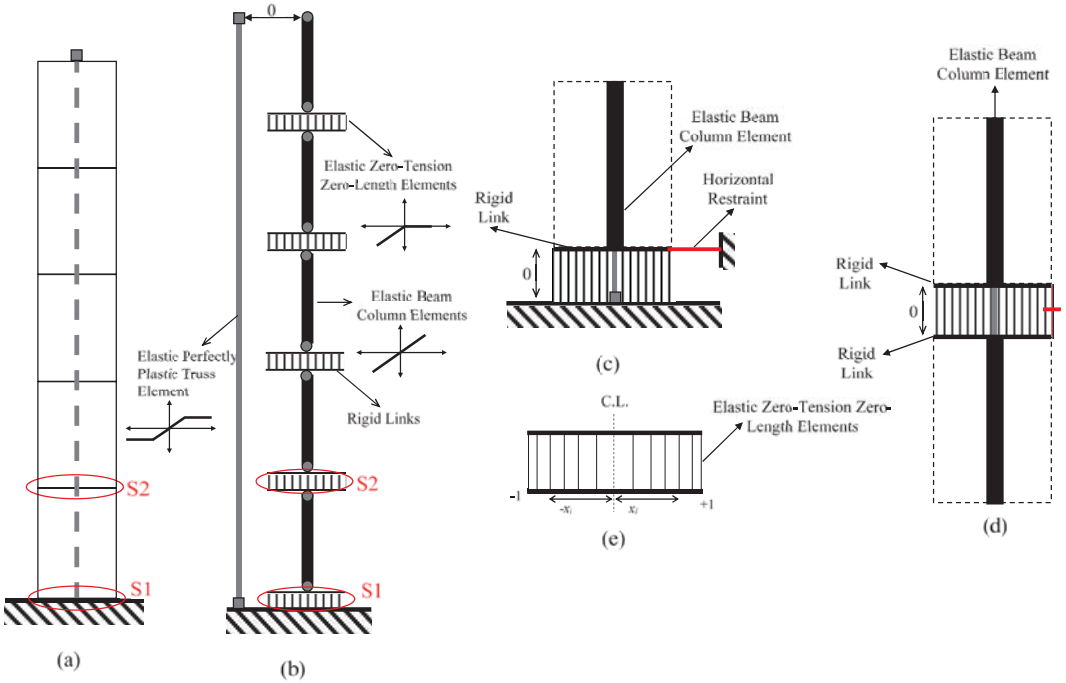

Figure 1: (a) the PPS column, (b) the segments and tendon modelling, (c) detailed modeling of base surface, (d) detailed modelling of the intermediate surfaces, and (c) weighting and positioning of the gap elements.

Uniaxial Elastic Beam-Column elements are used to simulate the segments. The post-tensioning tendon is simulated with a Truss Element with an Elastic Perfectly Plastic uniaxial material. The axial shortening of the post-tensioning tendon is taken into account using an initial strain in the material model. Geometric nonlinearities of the segments and the tendon are accounted for using the Corotational geometric transformation. The axial load at the top of the column is modelled as a vertical force on the topmost node of the column. Further, inertial effects of the bridge deck is incorporated in to the model assigning lumped horizontal and vertical masses to the top node of the column. The modelling details of the compression zones between the segments of the PPS column are shown in Figures 1c and 1d. Given the experimental testing results reported [19], the contact surface between the segments segments are not completely rigid, and thus, it is best modelled with a flexible contact surface with an appropriate stiffness distribution. The Lobatto Quadrature integration scheme [20] is used to spread the normal stiffness of the contact surfaces over the width of each surface. Each surface is modelled as a number of vertical zero-length gap elements. An elastic zero-tension uniaxial material model is used to model flexibility at the contact surfaces. The weight of the stiffness (w_i) and position of each gap element (x_i) determined from Lobatto Quadrature integration scheme.

12 number of gap elements was found to be sufficient to model the contact surfaces. Rigid links are used between adjacent top and bottom nodes of each rocking surface. Linear geometric transformation is used for rigid links. All degrees-of-freedom of the bottom node of the gap elements at the base surface are restrained to simulate a fixed base under the base segment. The horizontal degree-of-freedom of top node of the end gap element is also restrained to avoid sliding at the base (Figure 1c). A horizontal zero-length gap element between top and bottom nodes of the end vertical gap element with an elastic uniaxial material of very large stiffness is used to allow for shear transfer at the intermediate rocking surfaces (shown by red in Figure 1d). Furthermore, to allow for shear transfer between rigid links and adjacent segments, equal degree-of-freedom constraints were adopted.

3 MODELLING VALIDATION

3.1 Analytical approach

Analytical moment-rotation relationship of a single post-tensioned rigid rocking block is used to validate the OpenSees model of the PPS columns. Consider a single post-tensioned rigid block of width b and height h rocking on a rigid surface around its edges. Taking a moment around the pivot point, using kinematic of rigid bodies, and applying the equilibrium rule, the static moment-rotation relationship for a single post-tensioned rigid block is obtained [21]:

$$M(\theta) = \lambda kB\cos(\theta/2)\left[2\lambda B\sin(\theta/2) + F_0/k\right] - WR\sin(\beta+\theta) \tag{1}$$

where λ is 0.5 and -0.5 respectively for positive and rocking motions; k is the elastic stiffness of the post-tensioning tendon; F_0 is the initial post-tensioning force of the tendon, and W is the weight of the block. The clockwise rocking is taken positive, and the block angle, β, and rocking radius, R, are defined as follows:

$$\beta = -\tan^{-1}(2\lambda b/h); \quad R = \sqrt{\lambda^2 b^2 + h^2/4} \tag{2}$$

To reach a rigid segment and a rigid surface at the base, large values are assigned to the bending stiffness of the segment and axial stiffness of the gap elements. Figure 2 shows the static

moment-rotation graphs of a single post-tensioned rigid block obtained from the OpenSees model and the analytical approach. The moment is normalised to the moment due to the gravitational force, i.e. weight of the segment times the width of the segment, bW. As illustrated in Figure 2, the graphs are very similar, which numerically validates the static behavior of the OpenSees model. Note that in Figure 2b, the result of OpenSees model is different from the analytical solution at high base rotation values, which is because of the yielding of the post-tensioning tendon.

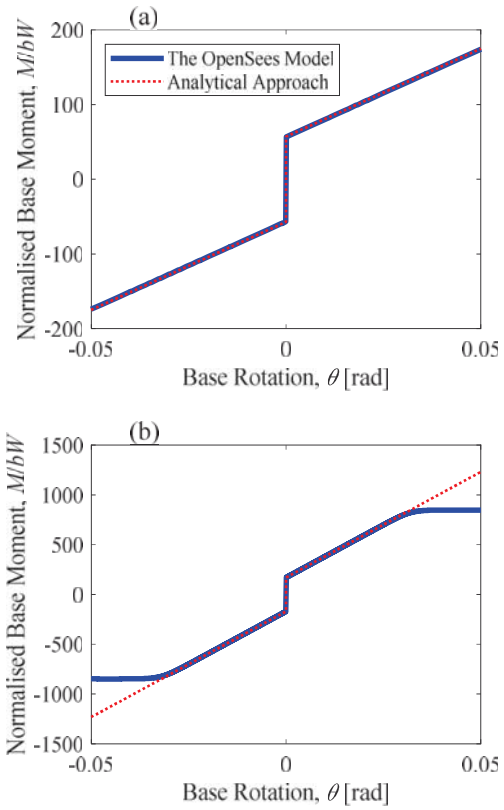

Figure 2: Analytical validation of the PPS model, normalised static moment-rotation relationship for a post-tensioned rigid block on a rigid surface: (a) $h/b = 6$, and (b) $h/b = 2$.

3.2 Experimental approach

In this section, the results of an experimental testing and a reduced-order analytical model already reported in [8] are used to verify the PPS model. The experimental column is a post-tensioned segmental column consisting of 50 mm square wooden segments. The segments are tied together by a 1 mm high-strength stainless steel cable. The elastic modulus of the wooden blocks and stainless steel cable are 12.5 GPa and 118 GPa respectively. To simulate the inertia force of the top deck, a 2.5 kg lump mass is installed at the top of the column. The self-centring mechanism is provided by the cable with a 300N post-tensioning force. Moreover, a reduced-order mode with detailed description in [8], simulates the column as a single-degree-of-freedom (SDOF) systems based only on the base rotation. Figure 3 shows base moment-rotation of the PPS model, the experimental column as well the analytical SDOF model for both static and dynamic tests. For the dynamic analysis of the OpenSees model, a constant stiffness-proportional Rayleigh damping is used for all elements of the model. As seen in Figure 3, the proposed PPS model can reliably simulate both nonlinear static and dynamic behaviors of the PPS columns. For the dynamic modelling, a constant stiffness-

proportional Rayleigh damping well duplicates the damping of the PPS columns (Figure 3b). Note that the damping of the PPS columns mostly come from the behavior of the contact surfaces between the segments, and is dependent on the ground motion amplitude [8],]. Thus, a combination of viscous and Coulomb damping is more appropriate, and this may cause the difference between the PPS model and the experiment results.

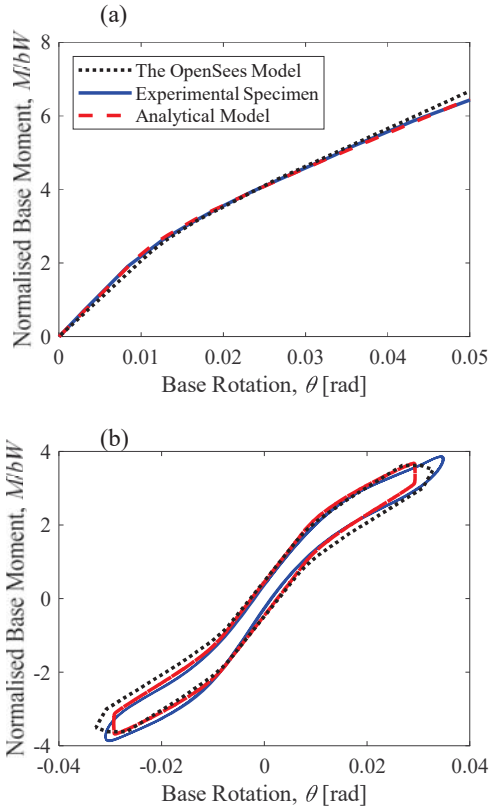

Figure 3: Normalised base moment-rotation from the OpenSees model, experimental specimen, and analytical model: (a) 9 blocks and static behavior, and (b) 6 blocks and dynamic behavior.

4 FREQUENCY RESPONSE FUNCTION AND SEISMIC RESPONSE OF AN EXEMPLARY COLUMN

In this section, an exemplary column of height 3 m and width 0.5 m is presented. To extract frequency response function (FRF) of this column, increasing and decreasing frequency sine-sweep base excitations with varying amplitudes are used to capture possible lower and upper branches due to instability of the dynamic behavior of the column around the resonance. Figure 4 shows frequency response functions of the column. The horizontal axis is the excitation frequency normalised by the first natural frequency of the column at very small vibration amplitudes. For very small excitation amplitudes, the column has not started its rocking motion yet and hence, the resonance occurs at the same frequency as the natural frequency, i.e. normalized excitation frequency of 1. For higher vibration amplitudes, the rocking motion of the column is started, and thus, the FRF curve exhibits a lower and an upper branch. In addition, after the rocking initiation, the natural frequency of the column drops, and is dependent on the excitation amplitude.

The backbone curve clearly shows dynamic softening of the column. The column's frequency drop with the increase in the excitation amplitude demonstrates the reduction in the column's stiffness after initiation of the columns rocking. Further, some subharmonic compo-

nents are seen at low excitation frequencies for high excitation amplitudes. The FRFs also show that the model faces dynamic instability around the resonance frequency of the column.

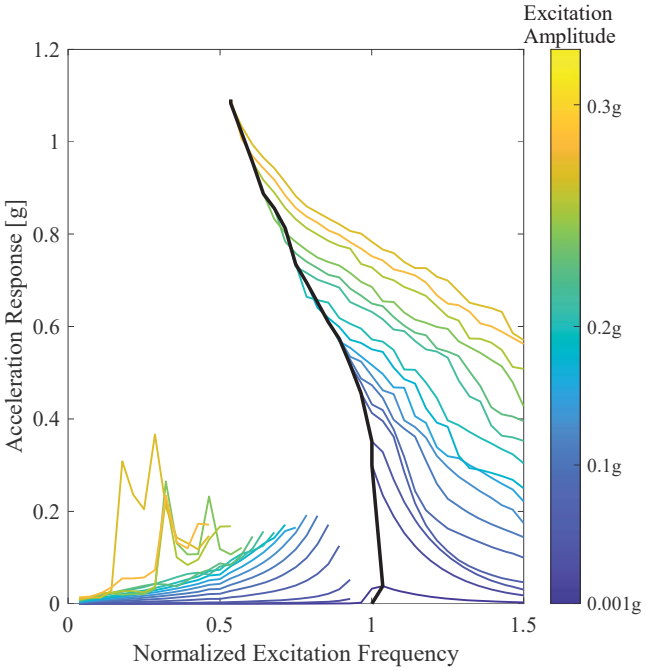

Figure 4: Frequency response function and backbone curve of an exemplary column.

Figure 5 shows hysteretic base shear, V, versus displacement, Δ, of the top of the exemplary column subject to an earthquake ground motion. The base shear is normalised by the total weight of the pier, W, (i.e. weight of the segments and the deck), and the top displacement is normalised by the height, H, of the column, i.e. top drift. The figure highlights the self-centering property and low-damping capacity of the post-tensioned segmental columns.

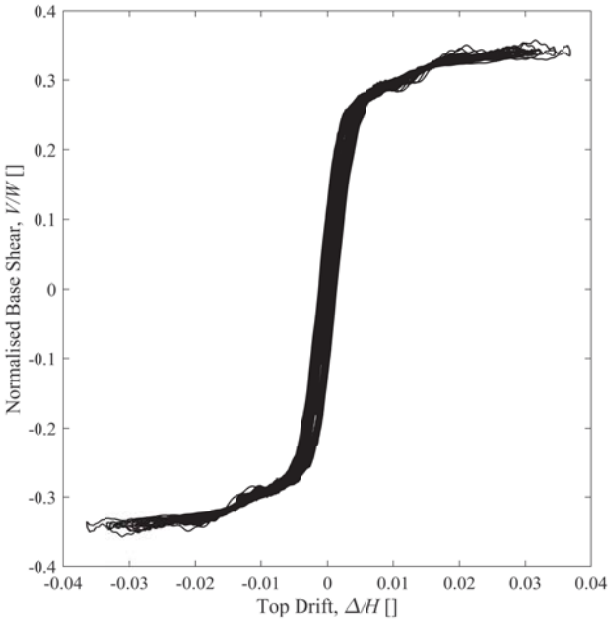

Figure 5: Normalised base shear versus top drift of the column subject to an earthquake ground motion.

5 CONCLUSIONS

In this paper, a new approach is developed in OpenSees program to simulate nonlinear static and dynamic behaviors of post-tensioned segmental columns. In this approach, the segments are modeled as elastic Beam-Column elements, and the post-tensioning tendon is modeled using an elastic-plastic Truss element. More importantly, the contact surfaces at the rocking joints are simulated using elastic zero-tension segments.

The proposed modelled is validated using two approached. First, the analytical static moment-rotation relationship of a post-tensioned rigid block on a rigid base is used and compared with the results of the model. Afterwards, the static and dynamic results of an experimental specimen as well as a reduced-order SDOF model of post-tensioned multi blocks are employed to validate the proposed model. The comparison between the results of the proposed model with those from the analytical and experimental approaches demonstrates the reliability of the proposed model to predict nonlinear static and dynamic behavior of the PPS columns. Frequency response function curve of an exemplary column is also presented using the developed modelling strategy where it shows a two-branch behavior around the resonance. The seismic response of the column also demonstrates low damping capacity of such columns.

Keywords: Maglev, Stochastic Vibration, Probability Density Evolution, Monte Carlo Method

Abstract. *The maglev guideway coupling system is a complex random system, it is worth clarifying the stochastic dynamic vibration of maglev system caused by random vehicle parameters. In this paper, a stochastic vibration analytical approach based on probability density evolution method (PDEM), which can consider multiple stochastic structure parameters, is employed to calculate stochastic vibration. The maglev-guideway coupling stochastic time-dependent equation is established, considering the stochastic vehicle load, the stiffness and damping of second suspension. Then, the Wilson-θ method and the finite deference method with Total Variation Diminishing (TVD) schemes are used to calculate the stochastic dynamic responses. Meanwhile, the validity of proposed method is compared with Monte Carlo Method (MCM). The results show, the proposed random dynamic model is available for dynamic vibration analysis of maglev system with good calculation efficiency. When the same integral step is adopted, the PDEM reduce computing time by 1-2 order of magnitudes compared with MCM. The stochastic vehicle loads have a significant effect on the dynamic deflection of guideway, while both the random damping and stiffness of second suspension have a little effect on deflection of guideway. The stochastic vehicle loads act a more sensitive effect on the car body acceleration than the other two parameters.*

1 INTRODUCTION

Maglev train is a modern advanced technological ground transport tool, which realizes the suspension and guidance between the train and the guideway through non-contact electromagnetic force. There are two types maglev system according to the running speed: high-speed maglev traffic [1, 2] and medium-low-speed maglev traffic [3]. The high-speed maglev train is suitable for long-distance intercity transportation, and has broad application prospects.

The vibration of maglev guideway system has drawn a great attention of researchers over the past few decades [4-9]. In the early research of maglev-guideway system dynamics, Hullender[4] began to pay attention to the influence of track irregularity on guideway. Wang[10] simplified the maglev vehicle as moving uniform force, and simplified the guideway structure as Euler-Bernoulli beam-uniform spring-Euler-Bernoulli beam. He analyzed the influence of structure parameter to the natural frequency of guideway. With the development of maglev vehicle manufacturing technology, the vehicle model is become more complex [11]. To study the high-speed maglev vehicle guideway coupled vibration, Zhao and Zhai [6] established a 10 degree of freedom vehicle model by rigid body dynamics and three types guideway model by modal superposition method. They analyzed the responses of vehicle and guideway and the vehicle ride quality index under different deterministic irregularity. Shi [9] present a EMS maglev vehicle-controller-guideway model, and developed a simulation program. He verified the model by measurement data and investigated the responses of maglev system under irregularity. Yang and Yau [8] presented a iterative method and established a two dimension vehicle-guideway-pier-soil coupled model, in which the PID controller is used to control the maglev force. They analyzed the effect of ground wave propagation on system dynamic. To study the medium-low-speed maglev vehicle guideway vibration, Han [12] present a UTM-02 maglev vehicle model with controller. He analyzed the some factor that affect the natural frequency of guideway. Lee [13] developed a medium-low speed numerical maglev vehicle model with a LQG controller and investigated the effect of some parameters on the vibration of maglev system.

From the above research results, there are little research about the stochastic vibration of maglev system, the stochastic vibration research framework of maglev vehicle guideway system has not been established. Vehicle parameters is an important random source of maglev system due to the boarding and alighting of passengers and manufacturing error [14, 15], which may have a great impact on running safety and smoothness, it is worth clarifying the stochastic dynamic vibration of maglev system caused by random vehicle parameters, however, relevant research has not been done yet.

In this paper, a stochastic vibration analytical approach based on probability density evolution method is employed to calculate stochastic vibration. The maglev-guideway coupling stochastic time-dependent equation is established, considering the stochastic vehicle load, stiffness and damping of second suspension, stiffness and damping of primary suspension. Then, the Wilson-θ method and finite difference method with TVD schemes are used to calculate the stochastic dynamic responses. Meanwhile, the validity of proposed method is compared with MCM.

2 N-DIMENSIONAL REPRESENTATIVE POINT SELECTION OF STOCHASTIC VEHICLE PARAMETER

Due to the boarding and alighting of passengers, the change weight of luggage and backpack, etc., the mass of car body is a stochastic parameter, which may has a great influence of dynamic responses. Due to the microstructure of the material and the manufacturing error, etc.,

the stiffness and damping of secondary suspension also stochastic parameter. Selection of representative parameters is an important part of probability density evolution analysis. The number theory method (NTM) is employed to select the multidimensional representative point of system parameters. Considering the randomness of the mass of car body m_c, the stiffness of second suspension k_s, the damping of second suspension c_s. The stochastic variable space $\boldsymbol{\phi}$ can be expressed as the function of random vehicle parameter:

$$\boldsymbol{\phi} = f(\mathrm{m}_{c1}, \mathrm{m}_{c2}, \ldots, \mathrm{m}_{cN}, \mathrm{k}_{s1}, \mathrm{k}_{s2}, \ldots \mathrm{k}_{sN}, \mathrm{c}_{s1}, \mathrm{c}_{s2}, \ldots, \mathrm{c}_{sN}) \ (i = 1,2, \ldots, \mathrm{N}) \tag{1}$$

$f(\cdot)$ is the transform function of maglev vehicle random parameters, N is the total number of random multidimensional points.

According to research result of NTM [16], a point set can be generate by applying the N-dimensional hypercube distribute C^N. The random variables of the normal distribution are usually symmetric, to generate the representative point set, the ball screening hypercube method is used to filter the point, then an affine transformation is employed to map the representative point set in probability distribution space, it can be expressed as:

$$\boldsymbol{\Theta}_k = \{\theta_{k,1}, \theta_{k,2}, \ldots, \theta_{k,q}\}, k = 1,2, \ldots, n_{sel} \tag{2}$$

The probability subdivision of representative point set are divided with Voronoi Cells. $\mathrm{V}(\boldsymbol{\Theta}_q) = V_q$, $\cup_{p=1}^{n_{sel}} \mathrm{V}(\boldsymbol{\Theta}_q) = \cup_{p=1}^{n_{sel}} V_q$ and $V_i \cap V_j = 0, i \neq j$. The joint probability density of the total subdivision space meets the requirements:

$$\sum_{q=1}^{n_{sel}} P_q = \sum_{q=1}^{n_{sel}} \int_{V_q} P_{\boldsymbol{\Theta}}(\theta)\, d\theta = \int_{\cup_{p=1}^{n_{sel}} V_q} P_{\Theta}(\theta)\, d\theta = 1 \tag{3}$$

P_q is the probability value of representative point.

3 MAGLEV VEHICLE GUIDEWAY COUPLED MODEL

A maglev vehicle guideway coupled model is proposed. The vehicle model is established by multi rigid-body dynamics, which contains one car body, four magnet bogie, and second suspension, the vehicle model is shown in Fig. 1. The model contains 10 independent degree of freedom (DOF), the vertical displacement (z_c) and vertical pitching (β_c) of car body, the vertical displacement ($z_{bi}(i = 1,2,3,4)$) and vertical pitching of magnet bogie ($\beta_{ci}(i = 1,2,3,4)$). The dynamic vibration equation of the maglev system can be established by applying the principle that the total potential energy of the elastic system is constant and "set-in-right-seat" rule. The dynamic motion of vehicle can be written as:

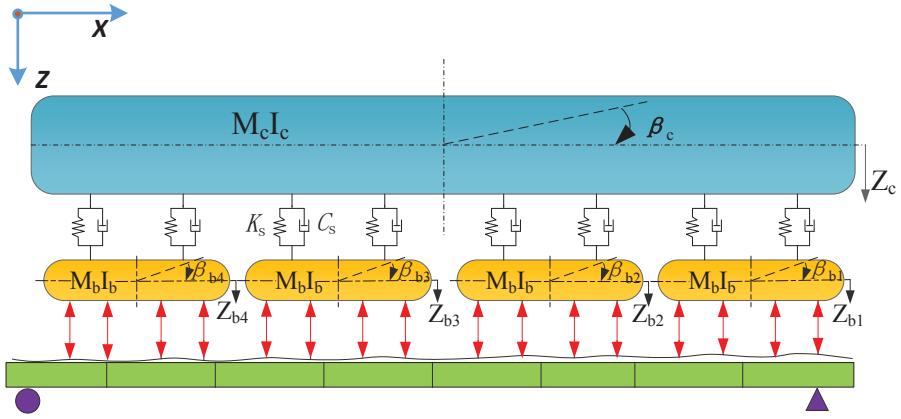

Fig. 1 Maglev vehicle model

$$\begin{bmatrix}\mathbf{M}_{cc} & \\ & \mathbf{M}_{bb}\end{bmatrix}\begin{Bmatrix}\ddot{\mathbf{U}}_{cc}\\ \ddot{\mathbf{U}}_{bb}\end{Bmatrix}+\begin{bmatrix}\mathbf{C}_{cc} & \mathbf{C}_{cb}\\ \mathbf{C}_{bc} & \mathbf{C}_{bb}\end{bmatrix}\begin{Bmatrix}\dot{\mathbf{U}}_{cc}\\ \dot{\mathbf{U}}_{bb}\end{Bmatrix}+\begin{bmatrix}\mathbf{K}_{cc} & \mathbf{K}_{cb}\\ \mathbf{K}_{bc} & \mathbf{K}_{bb}\end{bmatrix}\begin{Bmatrix}\mathbf{U}_{cc}\\ \mathbf{U}_{bb}\end{Bmatrix}=\begin{Bmatrix}0\\ \mathbf{F}_{bb}(\mathrm{t})\end{Bmatrix} \tag{4}$$

Where the subscript cc, bb represent the car body, magnet bogie respectively. **M**, **C**, **K**, **U** are the mass matrix, damping matrix, stiffness matrix and displacement vector vehicle system respectively [17]. The force vector $\mathbf{F}_{bb}(\mathrm{t})$ can be written as:

$$\mathbf{F}_{bb}(\mathrm{t})=\sum_{m=1}^{4}\sum_{k=1}^{4}\frac{\mu_0 N^2 A}{4}\left(\frac{i_0+\Delta i(t)}{c_0+\Delta c_k(t)}\right)^2\boldsymbol{R}_{\boldsymbol{lm}} \tag{5}$$

In which, $\frac{\mu_0 N^2 A}{4}$ is the electromagnetics parameter of levitation magnet. μ_0 is the permeability, N is number of turns in the magnet winding, A is pole area of iron-core. i_0 is the rated current, c_0 is the initial air gap. $\Delta i(t)$ is increment of current, $\Delta c_k(t)$ is the increment of air gap in the kth magnet wheel of mth magnet bogie. Both of Δi and Δc are time-dependent and they will change with the change of vehicle running position. $\boldsymbol{R}_{\boldsymbol{lm}}$ is a transform vector, which can distribute the force to the vertical and pitching of the magnetic bogie.

The guideway is recognized as an Euler-Bernoulli beam, the finite element method is applied to establish the vibration equation of guideway so that local vibration of the guideway could be considered accurately. The dynamic motion of guideway can be expressed as:

$$\begin{bmatrix}\mathbf{M}_{gg} & \\ & \mathbf{M}_{pp}\end{bmatrix}\begin{Bmatrix}\ddot{\mathbf{U}}_{gg}\\ \ddot{\mathbf{U}}_{pp}\end{Bmatrix}+\begin{bmatrix}\mathbf{C}_{gg} & \mathbf{C}_{gp}\\ \mathbf{C}_{pg} & \mathbf{C}_{pp}\end{bmatrix}\begin{Bmatrix}\dot{\mathbf{U}}_{gg}\\ \dot{\mathbf{U}}_{pp}\end{Bmatrix}+\begin{bmatrix}\mathbf{K}_{gg} & \mathbf{K}_{gp}\\ \mathbf{K}_{pg} & \mathbf{K}_{pp}\end{bmatrix}\begin{Bmatrix}\mathbf{U}_{gg}\\ \mathbf{U}_{pp}\end{Bmatrix}=\begin{Bmatrix}\mathbf{F}_{gg(\mathrm{t})}\\ 0\end{Bmatrix} \tag{6}$$

Where the subscript gg, pp represent guideway and pier respectively. **M**, **C**, **K**, **U** are the mass matrix, damping matrix, stiffness matrix and displacement vector of guideway system respectively. $\mathbf{F}_{gg(\mathrm{t})}$ is the force vector of guideway.

4 PROBABILITY DENSITY EVOLUTION METHOD

Based on Eq. (4)and Eq. (6) , we can established the coupled dynamic equation of vehicle and guideway system. Considering the randomness of vehicle parameters, the coupled equation can be simplified as:

$$\mathbf{M}(\boldsymbol{\Theta})\{\ddot{\mathbf{U}}\}+\mathbf{C}(\boldsymbol{\Theta})\{\dot{\mathbf{U}}\}+\mathbf{K}(\boldsymbol{\Theta})\{\mathbf{U}\}=\mathbf{F}(\boldsymbol{\Theta},t) \tag{7}$$

When considering the randomness of vehicle parameters, the mass matrix, damping matrix, stiffness matrix and force vector are all random, which can be uniformly described by random variables $\boldsymbol{\Theta}$.

The step by step integral method Wilson-θ method is used to calculate the stochastic dynamic responses. For the maglev system, the dynamic responses can be determined by displacement and velocity responses. Taking $\Psi = \{\Psi_v, \Psi_g\}^T$ to unified characterize the stochastic responses of structure, they can be expressed as:

$$\Psi = H_\Psi(\boldsymbol{\Theta}, \mathrm{t}) \tag{8}$$

$$\dot{\Psi} = \frac{d(\{\Psi_v, \Psi_g\}^T)}{dt} = \{\dot{\Psi}_v, \dot{\Psi}_g\}^T = h_\Psi(\boldsymbol{\Theta}, \mathrm{t}) \tag{9}$$

In which, the subscript v and g represent the vehicle and guideway respectively. $H_\Psi(\boldsymbol{\Theta}, \mathrm{t})$ and $h_\Psi(\boldsymbol{\Theta}, \mathrm{t})$ replace the system displacement responses and velocity responses. Assuming $\mathbf{U}$ as the response to be calculated, and its first-order differential can be written as:

$$\dot{U} = \mathrm{G}(\Psi, \dot{\Psi}) = \mathrm{G}(H_\Psi(\boldsymbol{\Theta}, \mathrm{t})\ h_\Psi(\boldsymbol{\Theta}, \mathrm{t}))^T \tag{10}$$

$G(\cdot)$ is the transform equation.

Taking $p_{U\boldsymbol{\Theta}}(u, \theta, t)$ as the joint probability density function of $(\boldsymbol{U}, \boldsymbol{\theta})$. Eq. (10) satisfied the general probability density evolution equation[18]:

$$\frac{\partial p_{U\boldsymbol{\Theta}}(u, \boldsymbol{\theta}, t)}{\partial t} + \dot{U}(\boldsymbol{\theta}, t)\frac{\partial p_{U\boldsymbol{\Theta}}(u, \boldsymbol{\theta}, t)}{\partial u} = 0 \tag{11}$$

The initial responses is $U(\mathrm{t}_0) = u_0$, $\boldsymbol{\Theta} = \theta_q$, $(q = 1,2,3, \ldots, n)$, considering the initial probability condition of Eq. (11), two side difference method with Total Variation Diminishing (TVD) scheme are used to solve the partial differential equation (11), then, we can get the probability solution $p_{U\boldsymbol{\Theta}}(u, \boldsymbol{\theta}, t)$, the probability density function can be expressed as:

$$p_U(u, t) = \int_{V_\Theta} p_{U\Theta}(u, \theta, t) d\theta \tag{12}$$

5 CASE STUDY

5.1 Verification of Accuracy and efficiency

To consider the stochastic vehicle parameters, each vehicle has 3 independent random variables $\bar{m}_{ci}$, $\bar{k}_{si}$ and $\bar{c}_{si}$ $(i = 1,2, \ldots,10)$. The point selection method introduced in section 1 is used to select representative points. In this article, there are 300 discrete representative point set have been taken into considered. The three-dimension of PDF and matching contour of acceleration of first car body at center of mass under stochastic vehicle loads are shown in Fig. 2, where it is seen that the real-time probability density function seems like the shape of mountains.

To assess the accuracy and efficiency of the proposed method, the result of PDEM running 500 samples are compared to those of MCM running 8000 samples, the comparison of PDEM and MCM are shown in Fig. 3, where it is seen that the both the mean value and standard deviation of acceleration obtained by PDEM are accord well with MCM. Further, to complete those calculation, the PDEM took only 242min, while the MCM needs 8910 min. Therefore, it could be concluded the proposed method improves 1~2 orders of magnitudes and is of high accuracy and efficiency.

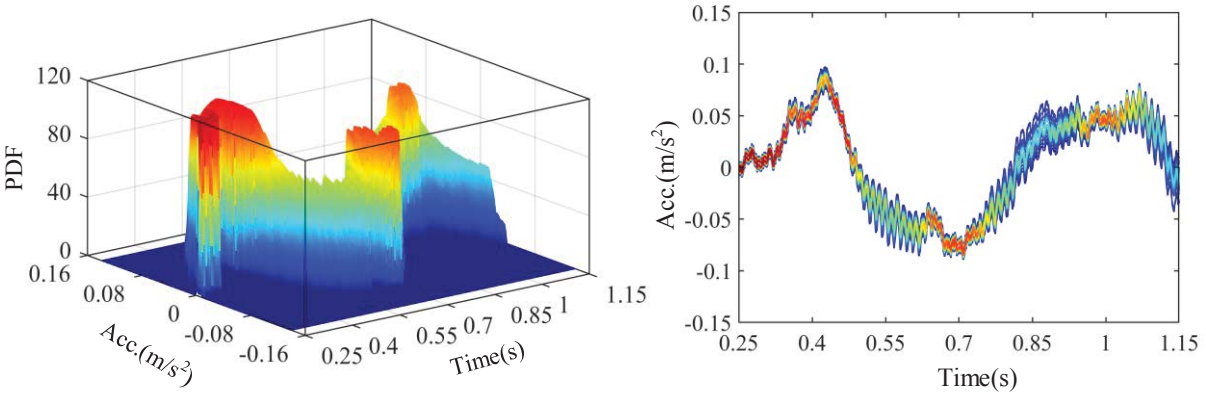

Fig. 2 Acceleration of first car body at center of mass under stochastic vehicle load (CV=0.25)

(a) PDF (b) contour of PDF

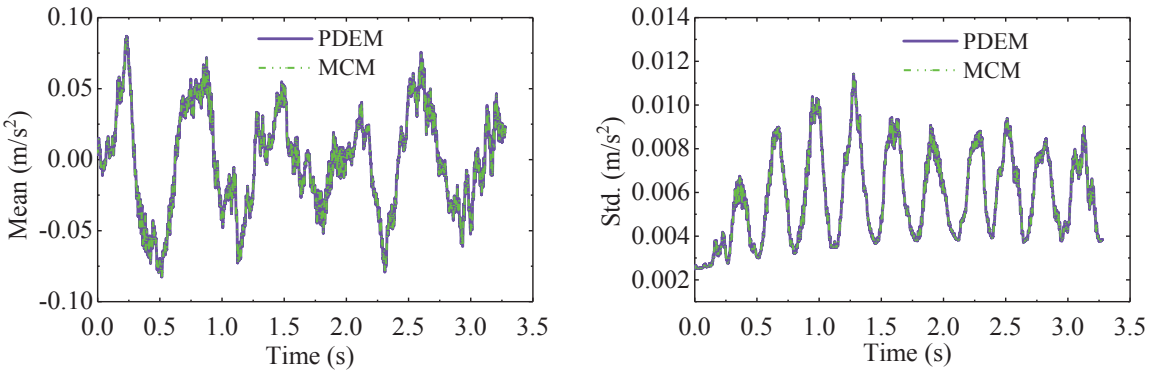

Fig. 3 Mean value and standard deviation of acceleration of the first car body at center of mass under stochastic vehicle load (CV=0.25) (a) mean value (b) standard deviation

5.2 Effect of the level of different vehicle parameters

5.2.1. Dynamic responses analysis of vehicle

Acceleration of car body is important for running safety and riding quality. To study the influence of different vehicle parameters on dynamic responses of the coupled system, the coefficient of variation (COV) are divided into 9 sets, which ranging from 0.05 to 0.25, with an interval of 0.025. Assuming the mean of vehicle mass $\bar{m}_c = 5000kg$, the stiffness of second suspension $\bar{k}_{smean} = 5\%\bar{k}_s$; the damping of second suspension $\bar{c}_{smean} = 5\%\bar{c}_s$. A larger vertical coordinate COV value indicate a greater influence on the dynamics of the corresponding dynamic index, such as acceleration of car body, deflection of guideway, etc.. Fig. 4 shows the vertical acceleration of the first vehicle under the stochastic second suspension stiffness with the COV of 0.25. Clearly, it can be seen that the maximum mean value is $7.88 \times 10^{-2}\mathrm{m/s^2}$, and the maximum value of standard deviation is $4.81 \times 10^{-3}\mathrm{m/s^2}$. Fig. 5 shows the COV of acceleration of the first car body under different vehicle parameters. It can be seen that the COV of acceleration of the car body increase in varying degree with the increases of COV. The maximum value of COV car body acceleration reaches about 0.122, 0.061, 0.059 affected by stochastic vehicle loads, stiffness of second suspension, damping of second suspension respectively. Among the stochastic vehicle loads, stiffness of second suspension, damping of second suspension, the COV curves affected by stochastic vehicle loads the increases steeper

but is not linear increase, while those increase slowly affected by stochastic stiffness and damping of second suspension. It means that the stochastic vehicle loads act a more sensitive effect on the car body acceleration than the other two parameters.

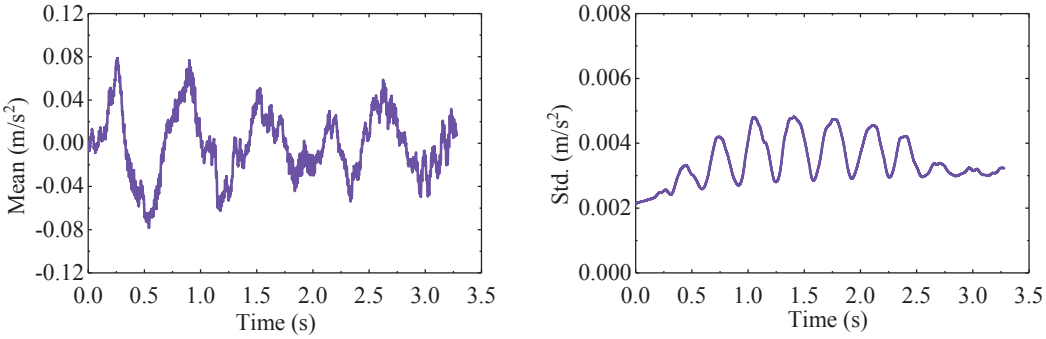

Fig. 4 Acceleration of the first vehicle under stochastic stiffness of second suspension: (a) mean value (b) standard deviation

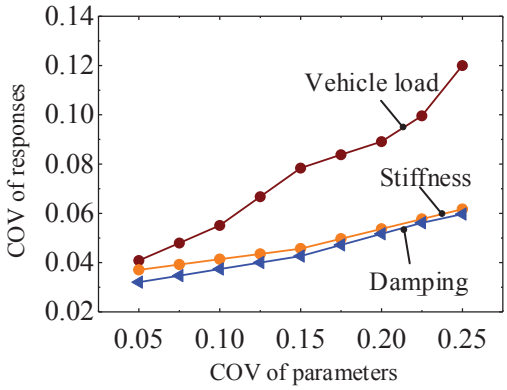

Fig. 5 Variables of coefficient for acceleration of the first car body under different vehicle parameters

5.2.2. Dynamic responses analysis of guideway

The dynamic deflection is an important index of guideway. For the same way, Fig. 6 shows the vertical deflection of guideway in the mid-point of the first span, under the stochastic second suspension stiffness with the COV=0.25. Clearly, it can be seen that the maximum mean value is approximate 1.65mm, and the maximum value of standard deviation is approximate 4.89×10^{-2}mm. The COV of dynamic responses of the deflection is 2.96%, which is less than the COV of second suspension stiffness.

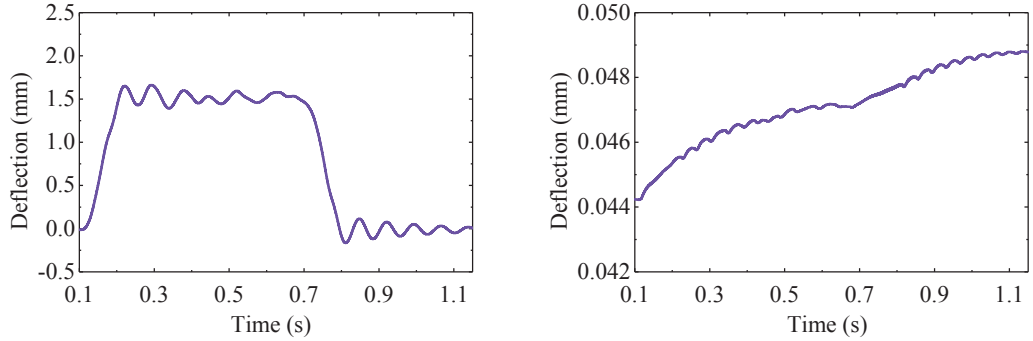

Fig. 6 Deflection of guideway in the mid-point of the first span: (a) mean value (b) standard deflection

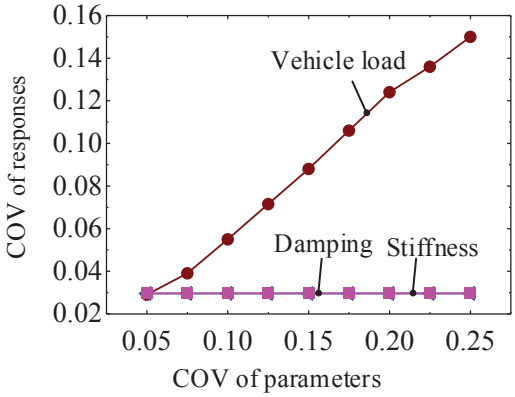

Fig. 7 Variables of coefficient of deflection of first span mid-point under different vehicle parameters

Fig. 7 shows the COV of dynamic deflection of first span mid-point under different vehicle parameters. It can be seen that the COV curves of guideway deflection rise rapidly with the increases of COV of stochastic vehicle loads, while the COV curves affected by stochastic stiffness and damping of second suspension almost do not changes. When the stochastic vehicle loads considered, the maximum value of COV of guideway deflection reaches about 0.151, while the maximum value of COV is 0.028 and 0.029 when the stochastic damping and stiffness of second suspension are considered respectively. This means that the stochastic vehicle loads has a great influence of the deflection of guideway, and the stochastic stiffness of second suspension and the stochastic damping of second suspension have a little influence on the deflection of guideway.

6 CONCLUSIONS

This paper proposed a stochastic vibration analytical approach to calculate maglev vehicle guideway system vertical stochastic vibration. The maglev-guideway coupled stochastic time-dependent equation is established, Wilson-θ method and finite deference method with TVD schemes are used to calculate the stochastic dynamic responses. The results calculated by MCM are compared with the proposed method. Meanwhile, the effects of the stochastic vehicle load, the stiffness and damping of second suspension on maglev vehicle and guideway are investigated and discussed. The conclusion of following can be summarized

(1) The proposed random dynamic model is available for dynamic vibration analysis of maglev system with good accurate and efficient. It can reduce computing time by 1-2 order of magnitudes compared with MCM.
(2) For the vehicle parameters, stochastic vehicle load has a significant effect on the dynamic deflection of guideway, while both the random damping and stiffness of second suspension have a little effect on deflection of guideway.
(3) The acceleration of car body seems to be affected by many factor, the maximum value of COV car body acceleration reaches about 0.122, 0.061, 0.059 affected by stochastic vehicle loads, stiffness of second suspension, damping of second suspension respectively. The stochastic vehicle loads act a more sensitive effect on the car body acceleration than the other two parameters.

Keywords: Railway bridges, rail-bridge interaction, experimental measurements

Abstract. *This paper is devoted to the analysis of rail-bridge interaction effects in railway bridges under the circulation of moving trains. In a first approach, a bidimensional Finite Element model is implemented. The rail and the bridge are represented as Bernouilli-Euler beams, and a three-layer discrete track model accounting for the damping and flexibility of rail pads, ballast and subgrade is considered. In the model, several elastically supported spans are included, coupled by the presence of the track. First a sensitivity analysis is performed on the track parameters. A numerical receptance test is simulated on the rails showing that the track damping parameters influence the response only in the vicinity of the track natural frequencies, which are much higher than the bridge's. Then, the maximum acceleration of the bridge is evaluated under equidistant trains and consistent conclusions are extracted regarding the track parameters. Last, the number of spans included in the model is evaluated showing that limiting the model to one span does not necessarily lead to the highest response in terms of the bridge acceleration. Finally, the response of an existing two-span single-track bridge belonging to a conventional Spanish line is evaluated under the circulation of the Altaria Talgo train. Numerical predictions are compared to experimental results obtained in a recent campaign. The prediction of the vertical acceleration at the sensors located along the longitudinal symmetry axis is adequate. From the experimental results the coupling effect between the adjacent decks in each span is evident suggesting the need of analyzing this phenomenon with more sophisticated models.*

1 INTRODUCTION

Railway induced vibrations are a matter of concern for engineers and authorities in recent societies. In many countries, nowadays High-Speed services allow intense mobility between distant highly populated urban areas. The crescent density of traffic and the train operational speeds require, nonetheless, an outstanding response of railway infrastructures in order to ensure traffic safety, passenger comfort and adequate environmental conditions in the surrounding areas.

Comprising an important proportion of the railway infrastructure, railway bridges have received considerable attention in the last years and, to ensure traffic safety and passenger comfort, their design must accomplish strict requirements [1]. In particular, short-to-medium span simply-supported (SS) bridges with ballasted tracks are prone to experience high deck vertical accelerations which may lead to ballast deconsolidation, rail misalignment and other related problems [2]-[11]. In this context, a deep understanding of train-track-bridge interaction mechanisms is essential in order to be able to predict and assess the dynamic response of such structures. A state-of-the-art review on the evolution of numerical models and experimental tests focusing on validation, safety assessment and long-term performance investigation of train-track-bridge systems was recently presented by Zhai et al. [5].

Railway axle loads and bridges interact through the track infrastructure. The track distributes the axle loads and may exert a restraining effect on the bridges' boundary conditions [6] and a coupling effect among consecutive spans of the same viaduct [7], or between adjacent single-track decks [8]. Nevertheless, in many publications these effects are disregarded and the influence of the super-structure composed by the rails, sleepers and ballast, in ballasted tracks, is still not well known.

In this contribution, the dynamic behavior of multi-span single-track bridges is investigated with the aim of evaluating the effect of the continuity of the track on the bridge vertical response. In section 2 an existing bridge object of study is described, along with the numerical model. In section 3, the results of a preliminary sensitivity analysis on a few track parameters is presented. In section 4, the results of an experimental campaign recently performed on the bridge are compared with numerical predictions. Finally, some conclusions are extracted regarding the effect of the track super-structure on the bridge acceleration response.

2 BRIDGE DESCRIPTION AND NUMERICAL MODEL

2.1 Bridge description

The bridge under study is a bridge crossing the Old Guadiana River in the conventional railway line Madrid-Alcázar de San Juan-Jaén in the Alcázar de San Juan-Manzanares section (see Fig. 1). It is a double track concrete bridge composed by two identical SS bays. In each span, the horizontal structure is formed by two structurally independent decks, one for each track. Each deck is composed by a concrete slab resting on five pre-stressed concrete rectangular girders with no transverse stiffening elements (see Fig. 2). The longitudinal girders rest on the two abutments and on a central support through neoprene bearings. Each deck accommodates a ballasted track with Iberian gauge UIC60 rails and mono-block concrete sleepers with a spacing of 0.60 m.

2.2 Numerical model

In a first approach, the numerical model described in what follows is used. Only one single-track deck is represented in both bays as two successive Bernoulli-Euler (B-E) beams resting on elastic supports, accounting for the neoprene bearings elastic vertical stiffness. The two rails

are treated as an equivalent single B-E beam as well. A three layer discrete track model (see Fig. 3) as the one proposed by Zhai [9] is implemented, where the damping and stiffness of rail pads, ballast and subgrade are included at the sleepers positions.

Figure 1: Old Guadiana Bridge photographs.

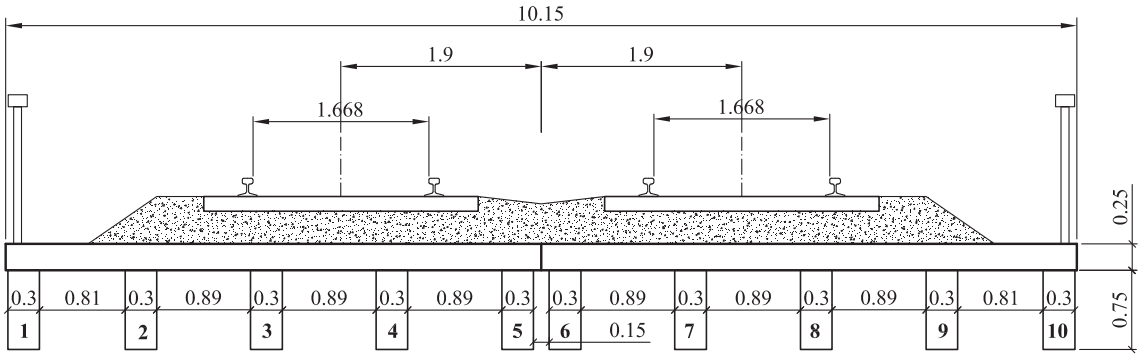

Figure 2: Old Guadiana Bridge cross-section.

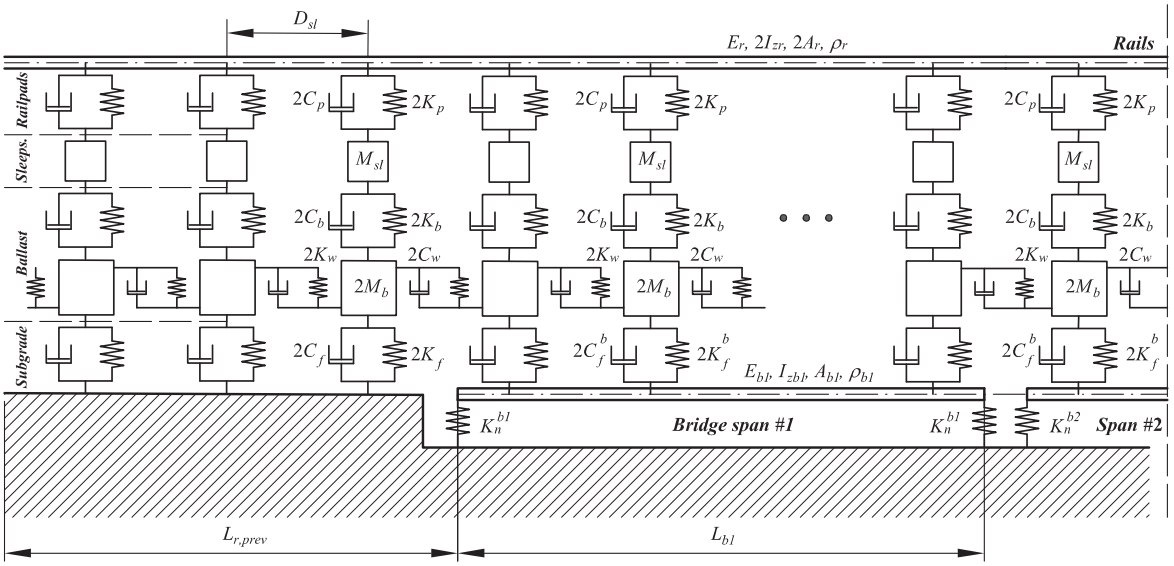

Figure 3: Numerical track-bridge interaction model.

In order to simulate the axle vertical forces, a constant moving load model is selected, therefore neglecting vehicle-structure interaction effects. The model, as described above, is generated using Finite Elements in Ansys software. Then, the equations of motion of the complete system are integrated in the time domain applying Newmark-Betta constant acceleration algorithm programmed in Matlab.

2.3 Parameter selection and model updating

In the last years, different authors have proposed discrete track models for the analysis of railway induced vibrations. Fig. 4 shows the evident dispersity in the values of four parameters admitted in previous publications: the rail pads and ballast vertical stiffness and damping K_p, C_p, K_b and C_b. First, a set of nominal or reference values for all the track parameters is selected on the basis of the literature review. Then, the bridge parameters, assumed identical in both bays, (Modulus of Elasticity E_{bi}, moment of inertia I_{zbi} and linear mass m_{bi}) are adjusted in order to reproduce static and dynamic tests performed on the structure right before its opening [23]. In Table 1 the bridge and track reference parameters are included. These will be the ones used in the experimental validation (section 4). The fundamental frequency of the track-bridge system for these parameters equals 10.07 Hz. A damping ratio of 1.565% is assigned to any mode as per [24] for pre-stressed concrete bridges of the particular span length.

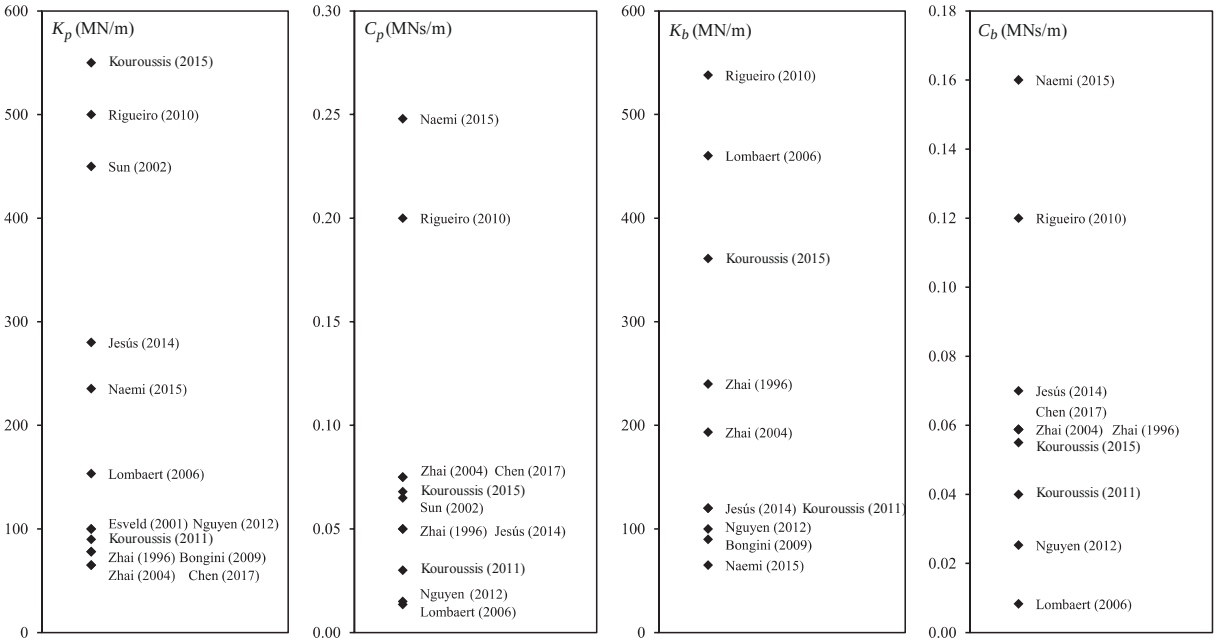

Figure 4: Rail pad and ballast layer stiffness and damping values admitted by different authors in the past for comparable ballast layers thicknesses and sleepers distances [6],[9]-[20].

Rail and bridge parameters		Track parameters per rail seat	
A_r (m^2)	76.86E-4	K_p (N/m)	1E8

Table 1: Bridge-track reference parameters

As per the subgrade stiffness and damping coefficients inside the bridge, 100 K_f and 0 Ns/m have been assigned as it is assumed that the ballast layer rests directly on the concrete slab.

A track length of 20 m is included before and after the two-span bridge, equivalent to more than 30 times the sleeper distance, which is considered adequate attending to previous publications [21], [22]. A convergence analysis is performed on this length ensuring the adequacy of this value.

3 SENSITIVITY ANALYSIS

3.1 Track receptance

Fist, the track dynamic response is evaluated numerically. To this end a harmonic test is performed on approximately 50 m of track (in the absence of bridge). A vertical harmonic load of 210 kN is applied at the central section of the double rail and the vertical displacement amplitude is determined in the same location. The forcing frequency varies between 1 and 2000 Hz in increments of 0.5 Hz. Fig. 5 shows the results for individual variations of C_p, C_b, C_f and C_w with respect to the reference values included in Table 1.

Two resonance frequencies are clearly detected in the proximities of 170 and 1350 Hz. The variations in the damping parameters affect the response only close to resonance. As the maximum frequency of interest in the bridge acceleration response is 60 Hz, the effect of these parameters on the bridge response should be very small. In the following section this particular issue is checked.

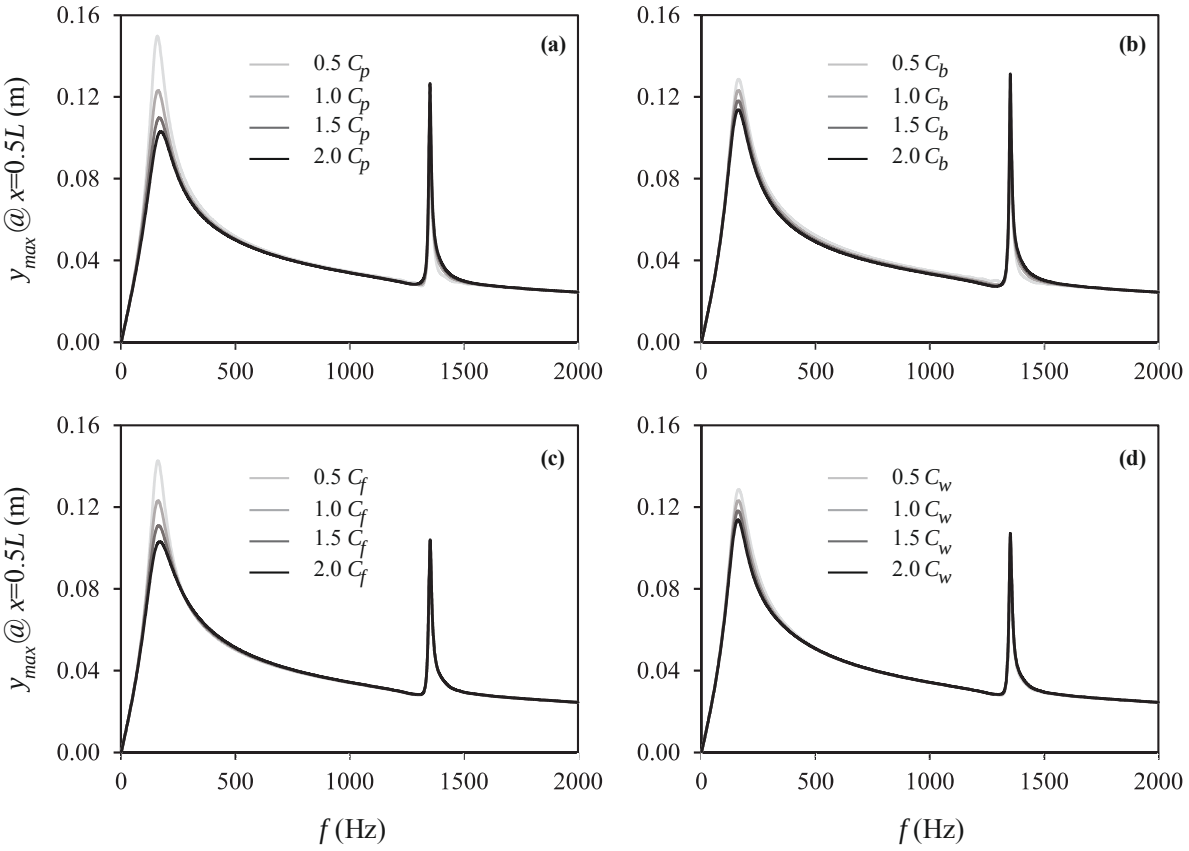

Figure 5: Receptance numerical test performed on the track model for independent variations of C_p, C_b, C_f and C_w.

3.2 Bridge maximum acceleration under train of equidistant loads

Second, the effect of the variations on four track parameters: the stiffness and damping coefficients of the rail pads, K_p and C_p, and of the ballast, K_b and C_b on the bridge maximum acceleration response is investigated. To this end, the response of the bridge is obtained under the circulation of an artificial train of 20 equidistant loads of 210 kN separated 18 m, with the aim of inducing two clear resonances on the structure. The bridge time-history response in terms of displacements and accelerations is obtained for 60 velocities of circulation in the range [40,100] m/s. A Chebyshev order 3 filter is applied to the acceleration response filtering contributions below 1 Hz and above 60 Hz. After filtering, maximum response envelopes are obtained for values of the track parameters:

$$[0.5,1,2,4]\cdot K_p \quad [0,0.5,1,2]\cdot C_p \quad [0.5,1,2,4]\cdot K_b \quad [0,0.5,1,2]\cdot C_b \tag{1}$$

where the values of K_p, C_p, K_b and C_b are those in Table 1. Fig. 6 shows the evolution of the maximum acceleration, which always takes place in the center of the second span, in absolute value in terms of the velocity for individual variations of each track parameter.

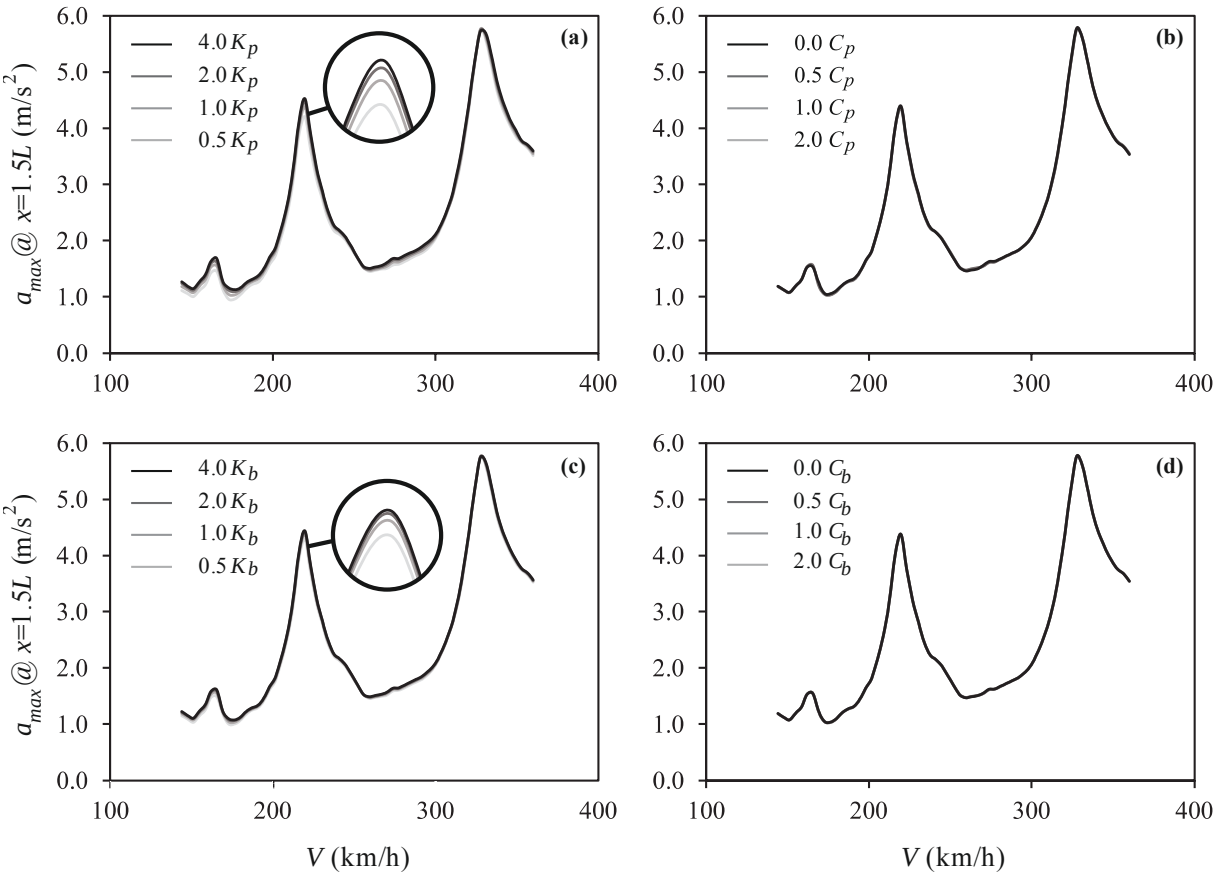

Figure 6: Maximum acceleration vs. velocity for individual variations of K_p, K_b, C_p, and C_b.

In all the plots shown in Fig. 6 three resonant peaks can be detected, corresponding to second, third and fourth resonances of the fundamental mode of the bridge, which in the reference case presents a frequency f_1 = 10.07 Hz. These theoretical resonant speeds can be calculated as:

$$V_1^{r,j=2} = \frac{df_1}{2}3.6 = 326.27\,\frac{km}{h}\; V_1^{r,j=3} = 217.5\,\frac{km}{h}\; V_1^{r,j=4} = 163.1\,\frac{km}{h} \tag{2}$$

The individual variations considered in the track do not affect significantly the reference fundamental frequency. From the observation of Fig. 6 (c)-(d) it may be concluded that the

influence of the variations in the rail pads and ballast damping constants is negligible on the maximum acceleration response of the bridge for the reference values of the remaining parameters, as expected from the results of the receptance study. The parameter that seems to affect the most the acceleration envelope at the most critical section is the rail pad stiffness K_p, leading to a decrease in the maximum acceleration at resonance as K_p reduces (for more flexible rail pads). This effect is more visible for higher resonance orders. The same tendencies, although in a less pronounced manner, are observed in terms of the variations considered in the ballast stiffness K_b.

3.3 Influence of the number of spans

Last in the sensitivity analysis, the effect of including a different number of spans in the numerical model on the maximum bridge response is investigated. Due to the longitudinal coupling exerted by the track on the structurally independent decks, the maximum response could differ depending on the number of spans. The analysis is performed in two cases: including and neglecting the decks neoprene bearings. In Fig. 7 the maximum acceleration at mid-span is represented for the same train of equidistant loads used in the previous subsection. All the bridge and track parameters adopt the reference values. Fig. 7(a) corresponds to the simply-supported (SS) case, i.e. no neoprene bearings , while Fig. 7(b) represents the elastically supported case, i.e. considering the neoprene bearings vertical flexibility. Colors red, black and grey are selected to represent results computed with one, two and three spans, respectively. Then, solid, dashed and dotted lines correspond to the response at mid-span of the first, second and third spans, respectively.

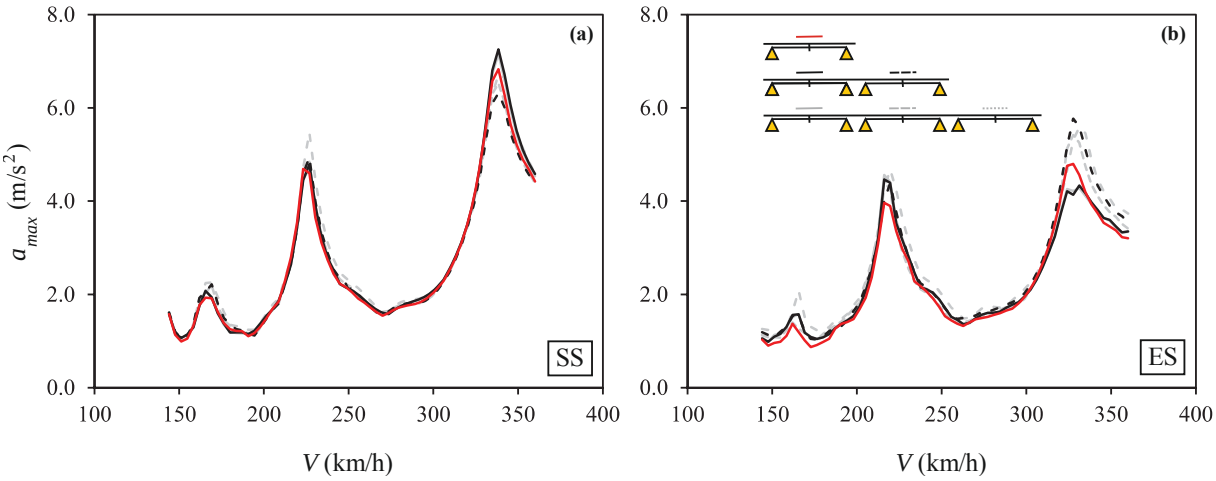

Figure 7: Maximum acceleration vs. velocity for models with one, two and three spans. (a) Simply-supported and (b) elastically-supported decks.

From the analysis of Fig. 7 one may conclude that: (i) the model leading to the maximum predicted acceleration and the most critical section depend on the maximum velocity considered; (ii) the difference between the three models is more relevant at resonance; (iii) in the particular case under study considering just one span does not predict the maximum response at any resonant peak. From the previously said, if the rail is included in the model and computational time is not an issue, including all the spans in the model may be on the safety side when it comes to predicting the maximum vertical acceleration response.

4 EXPERIMENTAL VALIDATION

4.1 Description of experimental campaign

In May 2019 the authors performed an experimental campaign on Old Guadiana Bridge with the purpose of characterizing the structure and soil dynamic properties along with the bridge dynamic response under railway traffic (see Fig. 8). As per the acquisition equipment, a portable acquisition system LAN-XI of Brüel & Kjaer was used. The acquisition system fed the sensors (accelerometers) and an instrumented impact hammer in the case of the soil tests. It also performed the Analog/Digital conversion (A/D). The A/D was carried out at a high sampling frequency that avoided aliasing effects using a low-pass filter with a constant cut-off frequency. The sampling frequency was $f_s = 4096$ Hz. The acquisition equipment was connected to a laptop for data storage. Endevco model 86 piezoelectric accelerometers were used with a nominal sensitivity of 10 V/g and a lower frequency limit of approximately 0.1 Hz. The acquisition system was configured to avoid the sensors' overload.

Figure 8: Experimental campaign photographs.

From the dynamic characterization of the soil, which was carried out by the by Spectral Analysis of Surface Waves test a rather stiff soil was identified with a shear wave velocity higher than 250 m/s in the upper soil layer. The bridge response depends on soil-structure interaction (SSI) and soil stratigraphy. However, due to the high soil stiffness identified, in a first approach these effects are disregarded.

As per the bridge structure, eighteen accelerometers were connected to the lower horizontal surface of the decks longitudinal girders in the locations indicated in Fig. 9.

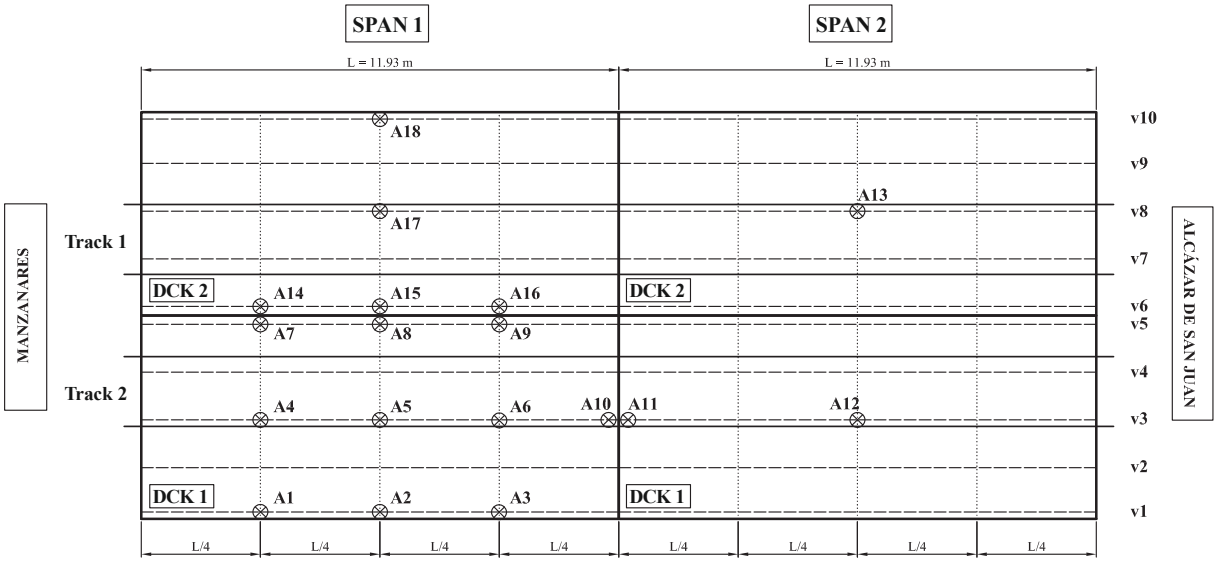

Figure 9: Sensors placement in experimental campaign.

4.2 Numerical predictions vs. experimental measurements

During the campaign the response of the structure was recorded under the circulation of different trains. Two of these circulations are included in this section. Both correspond to the medium distance Renfe Altaria Talgo VI train travelling along tracks 2 and 1 (see Fig. 9) in the directions South-North (Manzanares-Alcázar de San Juan) and North-South, respectively. Fig. 10 and Fig. 11 show photographs of the trains and a scheme of the axles distances. Also, Table 2 includes the train axles arrangement and loads.

First, the speeds were identified from the frequency associated to the bogie distance leading to approximately 155 km/h in both cases. Then, the response of the bridge was calculated using the numerical model described in section 2.2 with the properties included in Table 1, with the exception of structural damping which was assumed as 3.1% for the fundamental frequency, 10.065 Hz, and 1.56% for 90 Hz (Eurocode value). The first value was identified during the proof load test. The numerical response, integrated in the time domain using the full FE model, is also filtered between 1 and 30 Hz, applying the same procedure as with the experimental records. Given the bidimensional nature of the numerical model, only the response at sensors installed underneath beams 3 and 8 is compared with the numerical predictions.

Figure 10: Renfe Altaria Talgo VI trains crossing Old Guadiana Bridge.

It has been verified that the bridge maximum acceleration did not exceed the limit established by the Serviceability Limit State for traffic safety in the case of ballasted tracks [1] according to the measurements in all the sensors.

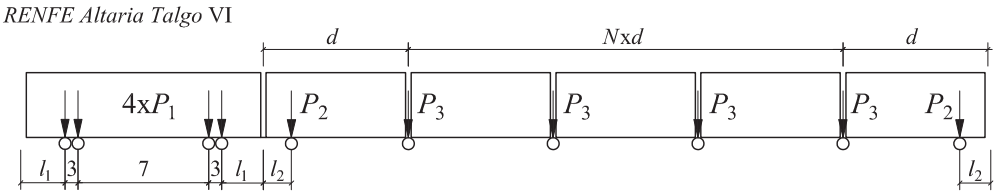

Figure 11: Renfe medium distance Altaria Talgo VI train axle scheme.

Train	N	d(m)	d_1 (m)	l_1 (m)	l_2 (m)	P_1 (kN)	P_2 (kN)	P_3 (kN)
Altaria	7	13.14	--	3.44	3.3	225	70	140

Table 2: RENFE Altaria Talgo VI features

Fig. 12 shows an experimental vs. numerical comparison of the vertical acceleration at sensors 5 and 6 under the circulation of the northbound train, in the time (a)-(b) and frequency (c)-(d) domains. The Talgo passenger coaches present a distance between shared axles of 13.14 m. The theoretical resonant speed associated to this length for the third resonance of the

fundamental mode is approximately 159 km/h, which is close to the real speed. This can be detected in the time-history plots where two oscillations of decreasing amplitude take place between the passage of consecutive axles.

$$V_1^{r,j=3} = \frac{df_1}{3} 3.6 = 158.7 \frac{km}{h} \approx 154.8 \frac{km}{h} = V \tag{3}$$

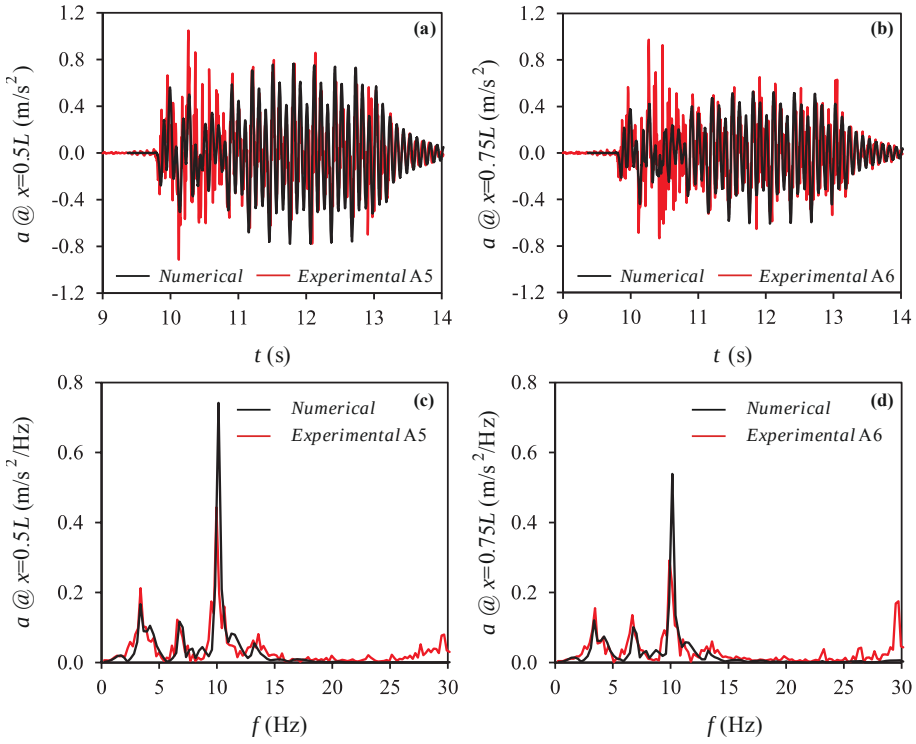

Figure 12: (a)-(b) Time history and (c)-(d) frequency content of the acceleration response at sensors 5 and 6 induced by Altaria Talgo VI train. Numerical prediction (black trace) vs. experimental measurements (red trace). Northbound train (track #2).

The accuracy of the numerical model is found reasonable up to 30 Hz, both at $L/2$ and $3L/4$ of the first span, although the numerical model overpredicts the acceleration for contributions close to the bridge fundamental frequency. This can be associated to vehicle-structure interaction which is not taken into account and can be of importance, specially at resonance; or to other energy dissipation mechanisms amplitude dependent such as the interaction between the adjacent decks, etc.

Fig. 13 shows the same type of comparative for the southbound train. In this case the acceleration is compared at sensors 13 and 17, located at mid-span of the second and first spans, respectively. Again, the time-history response is well reproduced, especially after the passage of the locomotive. In the frequency domain again, a predominant peak is detected showing the important contribution of the fundamental mode with a certain overprediction of the acceleration in the numerical case.

4.3 Coupling effect between adjoining decks

Finally, the coupling effect between the adjacent decks in each span is evaluated in forced vibration. Figs. 14(a)-(c) represent for the northbound train travelling along track #2 the experimental response measured at sensor 5 (at mid-span under the loaded track) and, simultaneously, at sensor 17 (at mid-span under the adjacent unloaded track).

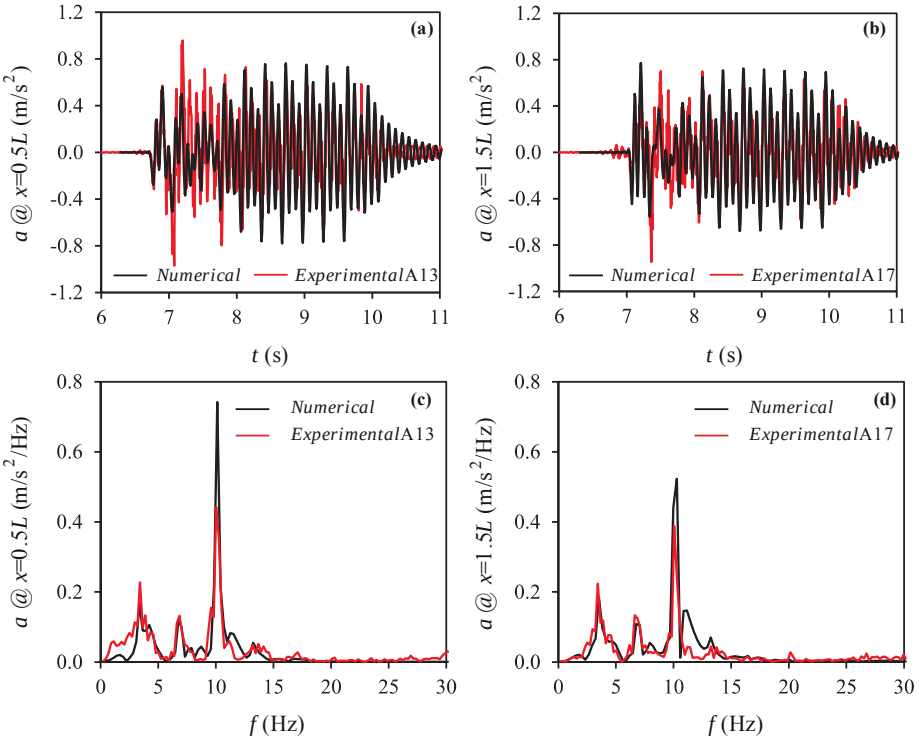

Figure 13: (a)-(b) Time history and (c)-(d) frequency content of the acceleration response at sensors 13 and 17 induced by Altaria Talgo VI train. Numerical prediction (black trace) vs. experimental measurements (red trace). Southbound train (track #1).

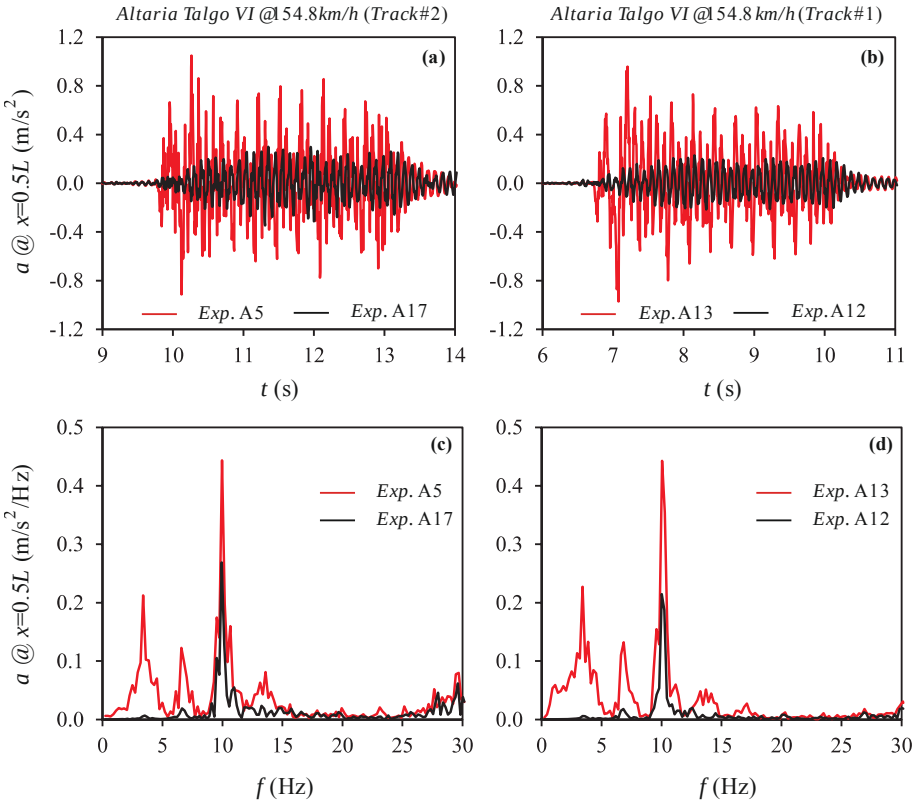

Figure 14: (a)-(b) Time history and (c)-(d) frequency content of the acceleration response at sensors 5 and 17 induced by the northbound train, and at sensors 13 and 12 induced by the southbound train.

The transmission of vibrations between the two decks is evident, even though these are only connected by the continuous ballast layer. At the unloaded sensor the frequency peaks associated to the excitation (e.g. bogie distance) which are visible in the low frequency range in the loaded sensor, are almost not perceptible; but the acceleration at the fundamental frequency reaches 60.6% de value in the loaded sensor. The same effect may be observed under the circulation of the southbound train when one compares the response between sensors 13 (under loaded track) and 12 (adjacent deck at symmetrical position). In this case the maximum acceleration in the unloaded sensor at the fundamental frequency in the frequency domain attains 48.5% the same maximum measured at sensor 13. This vibration transmission can be caused both by the continuous ballast layer and by the common foundations shared by the decks. In the opinion of the authors this phenomenon deserves further investigation. Implementing a 3D model of the bridge-track system would permit to evaluate the vibration transmitted between the decks close to the shared border in the frequency range of interest.

5 CONCLUSIONS

The present article constitutes a preliminary analysis on the longitudinal and transverse coupling effects exerted by the track on simply-supported bridges with independent single-track decks. From this study, the following can be concluded:

- There is a very high dispersion in the track parameters admitted by different authors for similar track infrastructures. The rail pad stiffness seems to affect the most the bridge maximum acceleration specially at high-order resonances, leading to lower amplitudes for higher flexibilities of this parameter. The ballast stiffness affects in a similar way, although to a lower extent. The damping parameters of the track do not seem to affect the bridge maximum response below 60 Hz. These parameters do affect the track response but at much higher frequencies.
- Considering one span in multi-span bridges may not lead to the maximum predicted acceleration when the track is included in the numerical model. The effect of the number of spans gains importance at resonance. The model leading to the maximum dynamic response as well as the most critical section depend on the maximum velocity of interest.
- The experimental vs. numerical predictions in the case of Old Guadiana bridge are reasonable in the sensors located along the longitudinal axis of the decks, as there is no contribution of the torsion mode at those locations. The numerical model tends to overestimate the real response close to the bridge natural frequency.
- The transmission of vibrations from the loaded deck to the unloaded deck is relevant. This may be caused by the continuous ballast layer but also by the shared foundations of the two decks. In the authors' opinion this effect is not well known and should be investigated using a 3D model of the complete bridge.

Abstract. *In the present contribution the effect of the continuity of the ballasted track on the dynamic response of simply-supported railway bridges composed by structurally independent adjacent slabs at each span is addressed. Previous research works and experimental campaigns performed on simply-supported structures have shown that the presence of the ballast layer and other track components (rails, sleepers) may induce a dynamic coupling effect between the bridge spans or adjacent decks. In this study the influence of this effect on the train-induced vibrations is assessed. With this purpose a preliminary three-dimensional finite element (FE) model that includes the track components as a set of discrete mass, stiffness and damping elements has been implemented to numerically evaluate the influence of the continuity of the track components on the prediction of the bridge acceleration response under the passage of railway vehicles. The numerical model is calibrated with the load test results performed on a simply-supported railway bridge composed by several adjacent slabs. Finally the measured structural response of the bridge under train induced vibrations is compared with the numerical predictions. Preliminary conclusions regarding the importance of considering the continuity of the track components for the prediction and the assessment of the Serviceability Limit State of vertical acceleration in ballasted simply-supported railway bridges are presented.*

1 INTRODUCTION

The evaluation of the dynamic performance of railway bridges under the passage of the modern railway transportation systems is an issue of main concern to guarantee structural integrity and traveling comfort. In particular, for short-to-medium simply-supported (SS) bridges the Serviceability Limit State of vertical acceleration, limited to 3.5 m/s^2 for ballasted tracks according to Eurocode (EC) [1], is one of the most demanding requirements for their design or upgrading to new traffic requirements, since they are especially susceptible of experiencing considerably high vibration levels at circulating speeds above 200 km/h due to their low associated structural damping and mass [2, 3]. Therefore, the development of reasonably accurate numerical models becomes crucial in practical applications.

However, the dynamic response of these structures can be difficult to predict during the design or upgrading stages, since there is a main source of uncertainty in what concerns the modeling of the super-structure components, formed by ballast, sleepers and rails in ballasted tracks. In many publications and practical applications the effect of the track is disregarded, and the coupling effect exerted by its continuity along SS spans of the same bridge, and also by the shared ballast layer between structurally independent decks that form one span in certain bridges, can be significant. Also the track distributes the axle loads and may exert a restraining effect on the boundary conditions at the end supports of the bridge. Previous studies have already suggested the importance of the coupling and restraining effect induced by the ballasted track [4, 5, 6, 7], but this effect is not yet well known and requires further research.

In this regard a preliminary study of the influence of the track components and its continuity on the bridge acceleration response under the passage of railway convoys, was performed by the authors in a previous work [8]. In this study, the bridge spans were represented by Bernouilli-Euler (B-E) beams resting on elastic supports, and a three layer discrete track model consisting of a set of springs and dampers representing the track components (sleepers, railpads, etc.) as the one proposed by Zhai was used [9]. With this preliminar model a sensitivity analysis over the stifness and damping coefficients of the track parameters was performed, showing that the variation of track damping constants has a negligible effect on the maximum vertical acceleration response induced by train passage. This prelimilar observation is also in accordance with previous works which consider that the dynamic response of the track structure occurs only for frequencies considerably higher that those of the vehicle and the bridge deck, of the order of 100 Hz or above [10]. For this reason, the use of Mode Superposition analysis for solving the dynamic equilibrium equatios of the bridge is a reasonable strategy to reduce computational cost in the prediction of train-induced vibrations. Previous studies apply this technique, therefore neglecting the damping introduced by the track elements at discrete positions but including global damping ratios instead. [5, 11, 12]

In this contribution, the dynamic behavior of multi-span SS bridges formed by structurally independent single-track decks at each span is investigated, in order to evaluate the effect of the continuity of the ballasted track on the vertical acceleration response under train-induced vibrations. As the object of study, a bridge belonging to the spanish railway network is used, which is described in Section 2. The results of an experimental campaign performed by the authors in this bridge are used to calibrate the thtree-dimensional finite element model described in Section 3. In Section 4 the results of the comparison between numerical predictions and experimental measurements are shown, in terms of both natural frequencies and mode shapes and railway-induced vibrations. Finally, some conclusions are extracted regarding the effect of the track superstructure on the dynamic response of the bridge.

2 CASE STUDY: OLD GUADIANA RIVER BRIDGE

2.1 Bridge description

In a view to evaluate the vertical coupling effect of the ballasted track on the bridge dynamic response, an existing double-track bridge composed by two simply-supported (SS) identical bays (span length L=11.9 m) with separated single-track decks is used as the object of study. This bridge belongs to the conventional railway line Madrid-Alcázar de San Juan-Jaén, in Spain (Fig.1).

Figure 1: Old Guadiana river bridge.

As can be seen in Fig.1 the two structurally independent decks that form each span are composed by a reinforced concrete slab resting on five pre-stressed concrete rectangular girders. Each deck accommodates a ballasted track with Iberian gauge UIC60 rails and mono-block concrete sleepers at regular distances of 0.60 m. The longitudinal girders of the decks rest on the two abutments and on a central support through laminated rubber bearings. A cross-section of the bridge is shown in Fig.2.

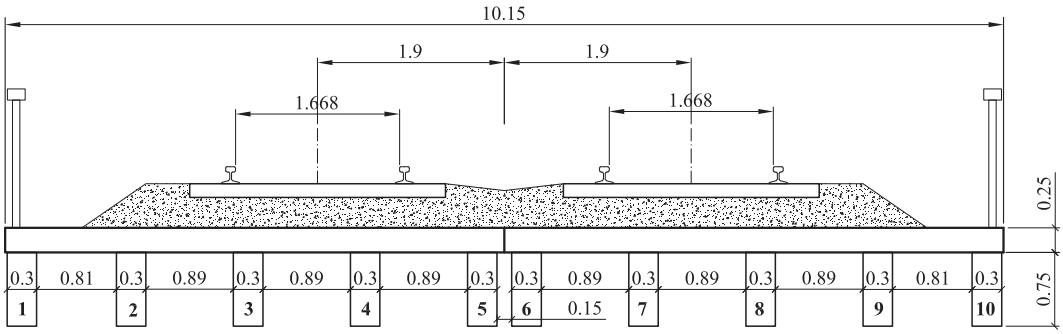

Figure 2: Cross section of the bridge.

2.2 Experimental campaign

In May 2019 the authors performed an experimental campaign on the bridge which included a dynamic characterisation of the soil and of the structure. As per the acquisition equipment, a portable acquisition system LAN-XI of Brüel & Kjaer was used. The Analog/Digital conversion (A/D) was carried out at a high sampling frequency that avoided aliasing effects using a low-pass filter with a constant cut-off frequency. The sampling frequency was fs = 4096 Hz. As

regards the soil characterisation, which was carried out by the by Spectral Analysis of Surface Waves test, a rather stiff soil was identified with a shear wave velocity higher than 250 m/s in the upper soil layer.

For the characterisation of the structure the acceleration response was measured under ambient and train-induced vibrations at 18 points of the lower flange of the pre stressed concrete girders (points 1-18 in Fig.3). Endevco model 86 piezoelectric accelerometers with a nominal sensitivity of 10 V/g and a low frequency limit of 0.1 Hz were installed in the aforementioned locations.

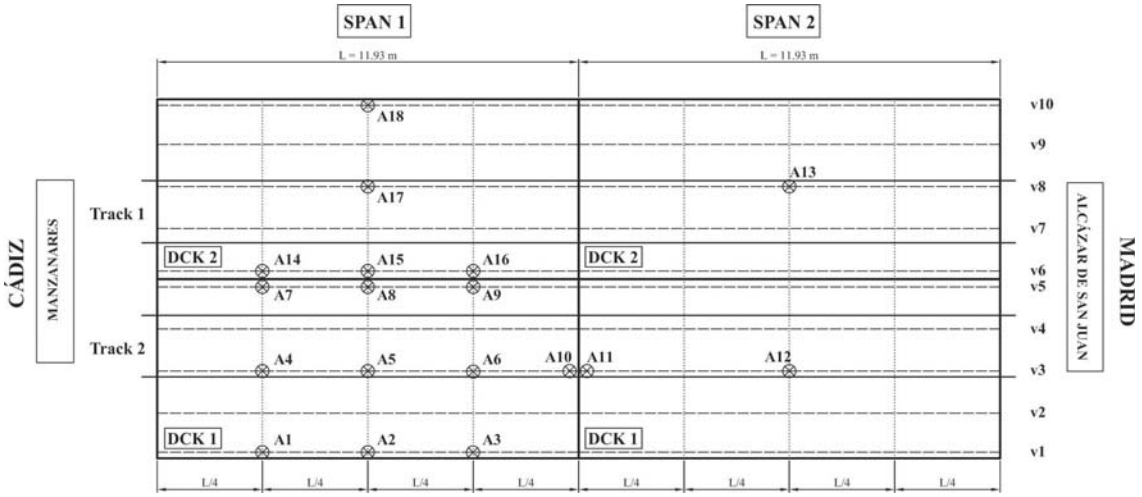

Figure 3: Location of the sensors at Old Guadiana river Bridge.

The ambient vibration data recorded during 3600 s was used for the identification of the modal parameters of the bridge by state-space models, using MACEC software [13]. Table 2 (top) shows the damping ratios and natural frequencies of the first 6 identified modes (fexp) and their mode shapes are shown in Fig.4 in solid black trace. As can be seen the lowest one in frequency order corresponds to the first longitudinal bending of each bay where the two adjacent decks vibrate in phase. The second mode corresponds to the typical first torsion mode of a continuous deck in each span, where the two independent slabs that share the ballast layer deform accordingly. In the third mode, the two adjacent decks in a span deform under independent torsion but out of phase such that they conform a typical first transverse bending mode of a continuous slab. In the aforementioned modes, the deck coupling caused by the ballast layer is very evident. In the higher frequency modes the decks deform under combinations of torsion, longitudinal and transverse bending.

3 NUMERICAL ANALYSIS

3.1 Finite element model

The finite element (FE) model shown in Fig.5 has been implemented in the commercial code ANSYS to obtain preliminary conclusions about the vertical coupling effect of the ballast layer on the dynamic behaviour of Old Guadiana bridge. The main features of the model are:

- The reinforced concrete slabs that form each span are simulated by means of isotropic thin plates discretised with shell elements with 6 degrees of freedom (dof) per node.

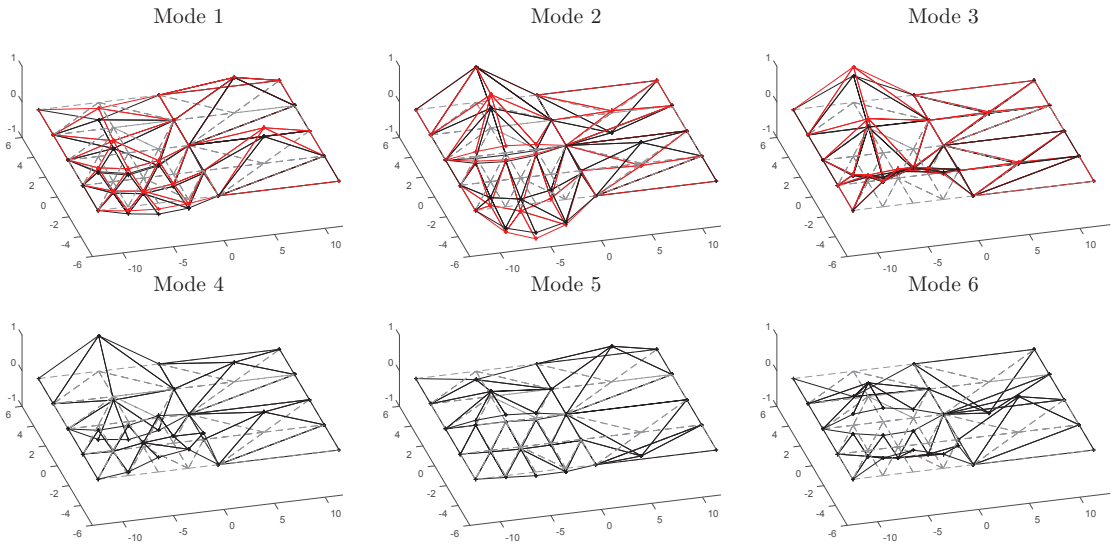

Figure 4: Experimental (black solid line) vs. numerical with coupled spans and decks (red solid line) first six identified mode shapes. Undeformed shape (dashed grey line).

The element size is chosen to adequately reproduce the wavelengths of the modes with frequencies up to 30 Hz as per EC [1].

- For each slab, different mass density elements are defined in order to concentrate the weight of the handrails, sidewalks and concrete slab selfweigth in its corresponding position over the plattform area.

- The vertical interaction effect induced by the ballast layer on the two separated decks at each span is simulated in a first approach by discrete longitudinal springs with vertical constant stiffness K_{wL}, that are distributed along the free longitudinal border of the adjacent slabs.

- A three layer two-dimensional (2D) discrete track model as the one proposed by Zhai [9] is implemented to include the distributive effect of the train axle loads exerted by each rail, as well as the vertical coupling effect among the bridge spans. In this model, the rails are simulated as Bernoulli-Euler beam elements with 6 dof per node, and the damping and stiffness of rail pads, ballast and subgrade are included at the sleepers positions as seen in Fig.5.

- The longitudinal girders are included in the model as beam elements with 6 dof per node. These nodes are connected to those of the upper plate right above them by means of rigid kinematic constraints. The distance between the plate and the beams nodes equals the real separation between the slab neutral plane and the center of mass of the girders.

- The laminated rubber bearings of the bridge are introduced in discrete positions by means of longitudinal springs with vertical constant stiffness $K_{v,dyn}$.

- A point load model is adopted for the railway excitation, therefore neglecting vehicle-structure interaction effects according to Eurocode 1 [14]. In this regard, some previous works also reveal that the incorporation of interaction effects in the design of new high-speed simply supported bridges or in the assessment of existing ones is not well justified,

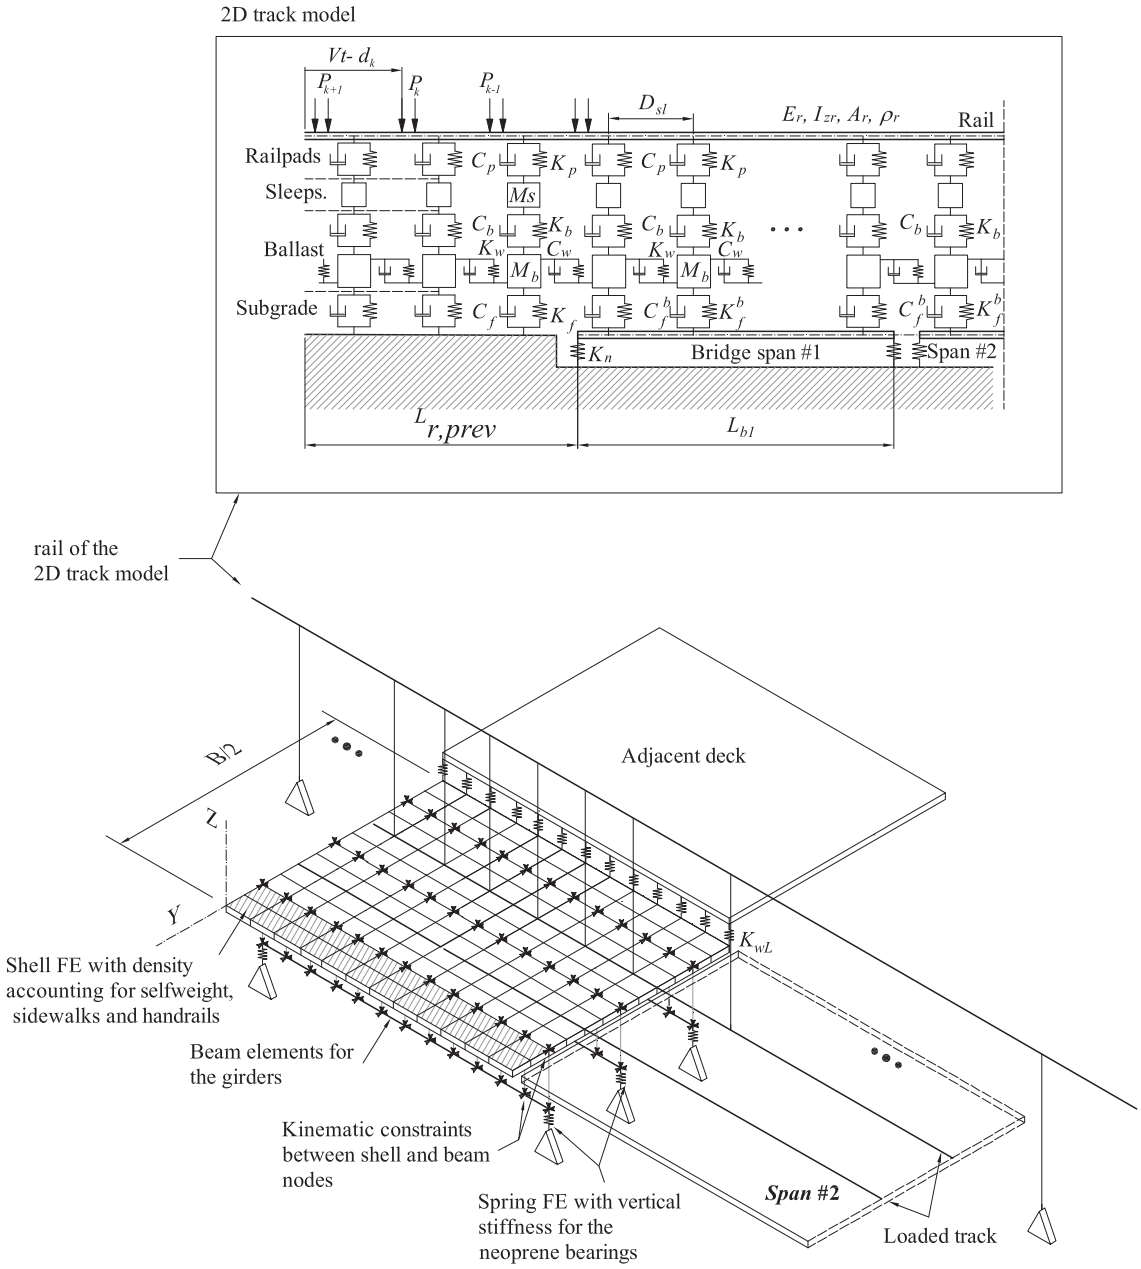

Figure 5: FE model.

since they can be very low due to the marked variability of the vehicle suspension characteristics, the mass and frequency ratios between the bridge and the vehicles suspension systems parameters and coaches masses [15, 16, 17, 18, 19]. Therefore, the use of a point load model in this study seems a reasonable approach to provide essential information concerning the track coupling effect.

- The dynamic equations of motion are transformed into modal space and numerically integrated by the Newmark-Linear Acceleration algorithm. Therefore, in a first approach the additional damping introduced by the track components is neglected for the calculation of the deck acceleration response under train induced vibrations and the modal damping ratios identified in the experimental campaign are used instead. This is in accordance

with the conclusions derived from a sensitivity analysis performed by the authors in a previous work, showing a negligible influence of this parameter on the vertical acceleration response of the deck [8]. The time-step is defined as 1/25 times the smallest period used in the analysis (mode contributions up to 30 Hz as per European Standards [1]).This value avoids period elongation errors and enables to capture properly the oscillations of the modal loading functions and the peak responses obtained by the summation of all modal contributions.

3.2 Description of the analysis procedure

The effect of the continuity of the ballasted track on the dynamic behaviour of railway bridges formed by SS decks is evaluated in this work by comparison with the test results of Old Guadiana bridge.

In a first step, the numerical model described in section 3.1 is calibrated in order to reproduce the static tests performed on the structure right before its opening and also the dynamic results obtained in the experimental campaign performed by the authors in May 2019. The calibration of the model is made considering three different approaches, which are:

(i) Single-deck single-span (SDSS): the 2D discrete track model is not included. Therefore, the four structurally independent decks that form Guadiana Old bridge are not coupled, and the axle railway loads move along the discretised slab following the loaded track position. In order to consider the weight of the track components (rails, ballast, sleepers), the density of the FE located at the position of the track plattform is modified accordingly. Since the track is not included in the model, when a load enters or exits the bridge a transient phenomenon takes place which leads to unrealistic high-frequency modal contributions of the plate. This numerical problem is solved in the model including the distributive effect of rails, sleepers and ballast during the application process of the wheel loads when they are close to the abutments. To this end, the value of each axle load is modulated throughout a load-print distributive function based on the Zimmerman-Timoshenko solution for an infinite beam on Winkler foundation, as described in [20].

(ii) Single-deck double-span (SDDS): in this approach the 2D track model is included but the effect of the transverse continuity of the ballast is neglected by setting the vertical constant stiffness between adjacent decks, K_{wL}, to zero.

(iii) Double-deck double-span (DDDS): the model shown in Fig.5 is fully implemented to simulate the dynamic behaviour of old Guadiana bridge.

For the calibration of the FE model assuming the previously mentioned approaches, a set of nominal or reference values for the track parameters K_p, C_p, K_b, C_b, K_f , C_f , K_{bf}, C_{bf} and M_s, is defined on the basis of the literature review. These parameters remain constant while the main track parameters affecting deck coupling, which are K_w and K_{wL}, and other bridge parameters, such as the deck and girders elastic modulus, vertical stiffness of the rubber bearings $K_{v,dyn}$, thickness of the ballast layer (which affects directly to the ballast mass) are varied in a realistic range until a satisfactory correspondence between numerical and experimental results in terms of natural frequencies and mode shapes is achieved. Table 1 shows the calibrated properties of the three different approaches considered in the numerical model of Guadiana bridge. As regards the ballast shear stiffness between adjacent decks, K_{wL}, it is provided per unit of span length. As per the subgrade stiffness K_f^b and damping coefficients inside the bridge C_f^b, the

values $100K_f$ and 0 Ns/m have been assigned as it is assumed that the ballast layer rests directly on the concrete slab inside the bridge. All these values will be the ones used in Section 4.

		SDSS	SDDS	DDDS
Slabs	ρ [kg/m^3]		2500

Table 1: Calibrated properties of the FE model.

Secondly, a sensitivity analysis is performed to evaluate the influence of the ballast shear stiffness parameters for longitudinal and transverse coupling between the bridge decks (K_w and K_{wL}), on the natural frequencies and mode shapes of the structure. And finally, the vertical acceleration response of the deck predicted with the calibrated numerical model assuming the three different approaches is compared with the experimental measurements at several sensor locations under the passage of real trains at resonant and non resonant speeds.

4 RESULTS

4.1 Ballasted track coupling effect on the natural frequencies and mode shapes

Table 2 (bottom) shows the numerical natural frequencies and the Modal Assurance Criterion (MAC) values [21] of the paired mode shapes obtained with the calibrated FE models. In this table, only the numerical modes that exhibit MAC values higher than 0.7 with a frequency difference with respect to the experimental value below 10% are shown. For a better comparison between the numerical models, the MAC values provided in the table have been calculated with the measurements of the same number of sensors (sensors A1 to A10 of Fig.3).

As can be seen the total number of paired modes that meet this criterion is scarce. However, it should be mentioned that in the remaining identified modes above the third one not all of them could be fully described due to the limited number and spatial distribution of sensors installed. Therefore, a satisfactory correspondence of these mode shapes with the experimental measurements was not expected.

Among the three different modeling approaches used in this work, the better correspondence with the experimental values is achieved with the model that considers the coupling effect be-

Mode		1	2	3	4	5	6
f_{exp} [Hz]		9.82	11.05	12.86	16.53	17.93	21.05
ς_{exp} [Hz]		2.3	0.9	1.0	0.3	0.1	1.0
Numerical approach							
SDSS	f_{num} [Hz]	9.98	–	12.21	–	–	–
	MAC [-]	0.98	–	0.99	–	–	–
SDDS	f_{num} [Hz]	9.97	–	12.75	–	–	–
	MAC [-]	0.98	–	0.99	–	–	–
DDDS	f_{num} [Hz]	9.97	11.05	12.75	–	–	–
	MAC [-]	0.98	0.97	0.99	–	–	–

Table 2: (top) First six experimental frequencies, their corresponding modal damping ratios and (bottom) frequencies and AutoMAC of the paired numerical modes.

tween both the bridge spans and the adjacent decks induced by the continuity of the ballasted track. The prediction of the fundamental mode is less affected by the coupling and the restraining effect on the bridges' boundary conditions exerted by the ballasted track, since the three approaches reach a satisfactory correspondence with the measurements. In the third mode, the consideration of the span coupling with the introduction of the track in the numerical model improves the prediction of the natural frequency, while the MAC value remains unaffected when compared to the other numerical approaches. And finally, the second mode corresponding to a first torsion mode of the double track deck in each span, is only predicted when the coupling caused by the ballast layer that is shared between the two adjacent decks is considered.

Fig. 4 shows, in solid red trace, the paired numerical modes predicted with the DDDS FE model. When the MAC values are calculated considering all the measurement points (A1 to A18) the values change to 0.95, 0.74 and 0.99 for the first three modes, respectively. The MAC of the second mode worsens significantly, and it is caused by the measurements of the sensors A12 and A13 located in the other span.

For a better understanding of the effect of the ballasted track coupling parameters, K_w and K_{wL}, on the natural frequencies and MAC values of the first three experimental modes, a sensitivity analysis has been performed considering variations of each of the cited parameters while the others remain constant according to the values provided in table 1. The proposed variations are: [1/100 1/50 1/10 1/5 1/2 1 10 50 100 10000]$\cdot K_w$ and [1/100 1/50 1/10 1/5 1/2 1 10 50 100 100]$\cdot K_{wL}$.

The results in terms of frequency difference, calculated as $(f_{num} - f_{exp})/f_{exp} \times 100$ and MAC values are shown in Fig.6. The results corresponding to variations of the coupling between spans K_w are shown in black trace, while the coupling between adjacent spans K_{wL} is shown in red trace. As can be seen, there exists an optimum value that ensures the best fitting with the experimental measurements .

4.2 Bridge response under railway traffic

During the experimental campaign performed by the authors in In May 2019 a number of trains crossed the bridge at different speeds. The forced bridge vibrations were recorded showing that the maximum acceleration levels did not exceed the Serviceability Limit State for traffic safety in ballasted tracks, limited to 3.5 m/s^2 as per European Standards [1]. The circulation of one of these trains, the medium distance Renfe Altaria Talgo VI train, is included in this section. It is a regular train with a characteristic distance between axles of the passenger cars of 13.14 m.

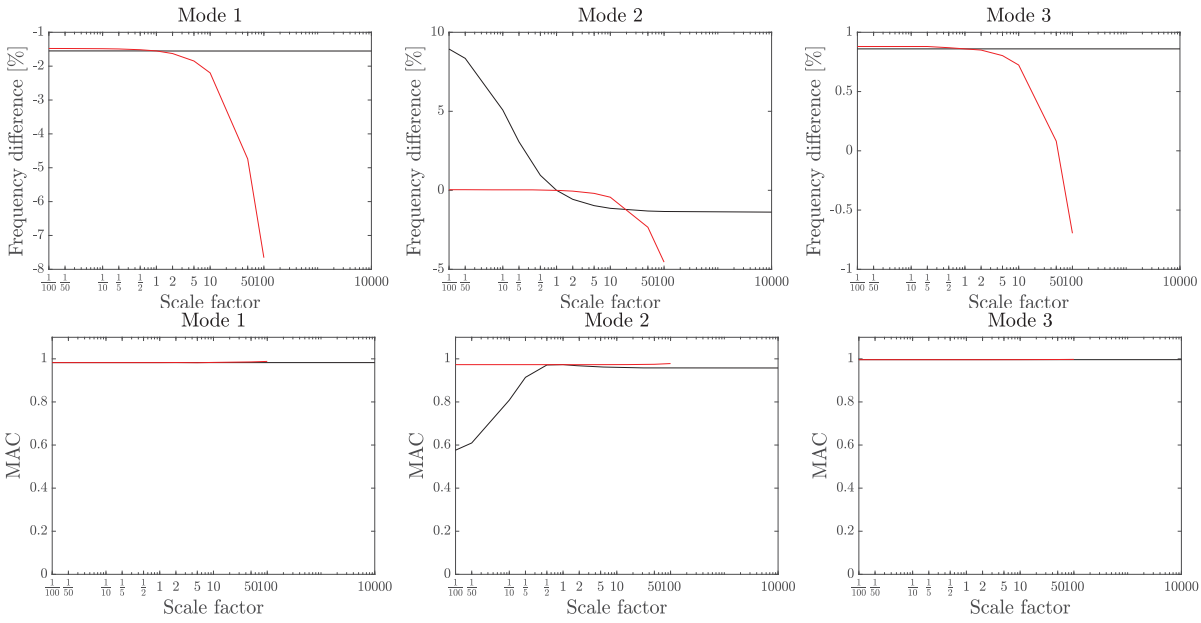

Figure 6: Sensitivity analysis of the influence of K_w (black) and K_{wL} (red trace) on the natural frequencies and MAC values

Figure 7 and Table 3 show the axle scheme and loads. More information about the train can be found in [22]. It travels along track 2 in the direction South-North (Manzanares-Alcázar de San Juan). Its circulation speed was identified from the frequency associated to the bogie distance leading to approximately 155 km/h, which is very close to the theoretical speed associated to a third resonance of the fundamental mode (159 km/h, approximately).

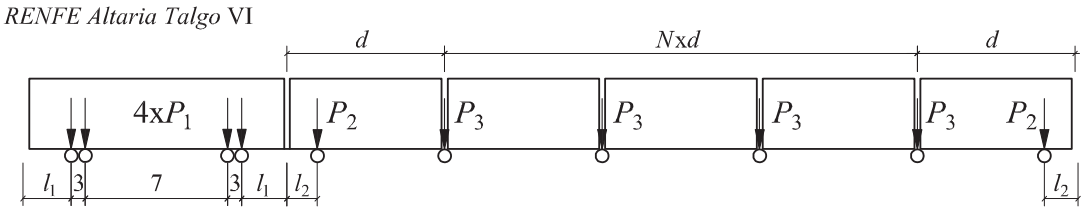

Figure 7: RENFE Altaria Talgo VI axle scheme

Train	N	d [m]	l_1 [m]	l_1 [m]	P_1 [kN]	P_2 [kN]	P_3 [kN]
Altaria	7	13.14	3.44	3.3	225	70	140

Table 3: RENFE Altaria Talgo VI features.

The response of the bridge was calculated using the numerical model described in section 3.1 with the properties included in table 1 by Mode Superposition, including modal contributions up to 30 Hz as per European Standards [1]. A track length of 20 m is included before and after the two-span bridge, a sensitivity analysis of this length was previously performed to guarantee the convergence of the dynamic results.

In a first approach the additional damping introduced by the track elements is therefore neglected, which is also in accordance with previous works [5, 11, 12]. The modal damping

obtained in the experimental campaign was assigned to the paired numerical modes, for the other modes of frequencies up to 30 Hz a value of 1.56% is assumed (Eurocode value [1]).

Fig.8 shows the vertical acceleration response under the passage of the train at different points of the deck, in particular points 2, 5 and 18. The sensors 2 and 5 are located under the loaded decks and the other one under the unloaded deck. The response is plotted in the time domain (first row of the figure) and frequency domain (last row of the figure). In all the plots the experimental signal, plotted in solid black trace, is filtered applying a two third-order Chebyshev filter with high-pass and low-pass frequencies of 1 Hz and 30 Hz. The numerical predictions are plotted with different colours: red line is used for the SDSS model, blue for the SDDS model and green for the DDDS model. Concerning numerical predictions, results at point 18 are only available in the DDDS model, since decks 1 are 2 are uncoupled in the remaining ones and therefore, the acceleration results are zero in the unloaded deck.

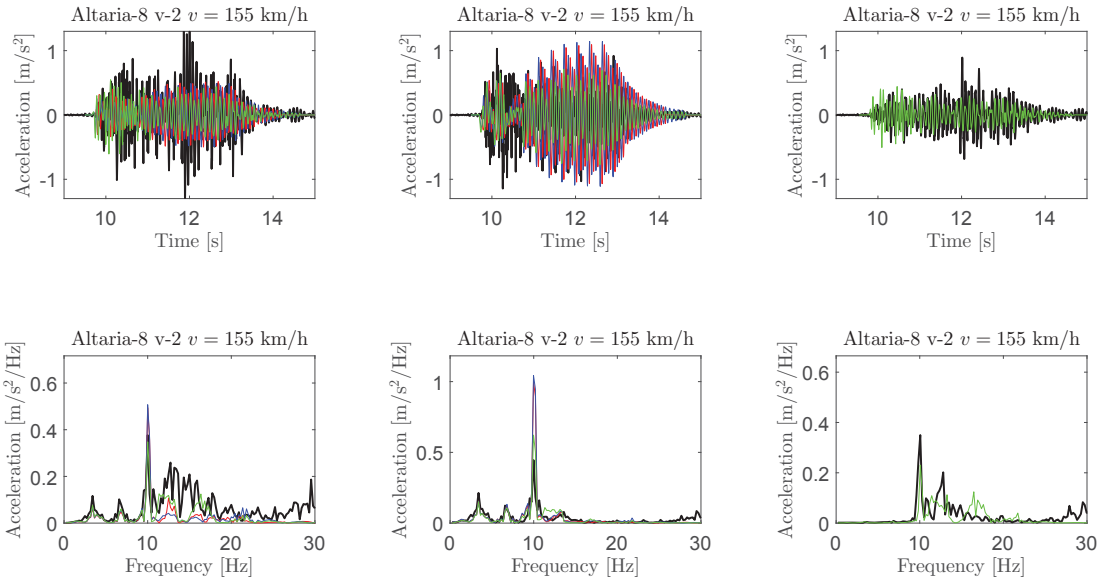

Figure 8: Time history (top) and frequency content (bottom) of the acceleration at point 2 (left), point 5 (center) and point 18 (right) induced by Renfe Altaria: experimental (black line), SDSS model (red line), SDDS model (blue line) and DDDS model (green line)

As can be seen from the frequency domain plots the vertical acceleration response of the bridge is caused by several mode contributions apart from the longitudinal bending one. However, the peak amplitude associated to the fundamental mode predominates when compared to the other frequency contributions, as expected in a resonance situation. This is especially clear at point 5, and is in accordance with the sensor location (at mid-span under the loaded track). The response also presents peaks at low frequencies (in the vicinity of 3 Hz and 6 Hz) associated to the excitation and corresponding to the axle passing frequency (i.e. ratio of train speed v to axle distances v/d_{axle}, respectively, and corresponding multiples). For sensor 18, located in the unloaded deck, the response is still relevant, showing an important coupling between adjacent decks of the same span through the ballast. This effect was also detected under ambient vibration in the mode shapes and seems to be also important under forced vibrations, despite the higher level of vertical vibrations in this case. This coupling effect could be also associated to the shared foundation between both decks.

Regarding the comparison between the response predicted by the three numerical approaches, it is noticeable that the model that considers both the longitudinal and transverse coupling between decks (DDDS model) predicts the frequency contributions in the range [10-15] Hz with higher accuracy, but the three of them overestimate the contribution of the fundamental mode in the response. The authors consider that the additional damping induced by the track elements, that is neglected in this preliminary study and also the effect of the train-bridge interaction, could be responsible of the differences and needs to be investigated in a future work. At frequencies above 15 Hz the predictions worsen, which is in accordance with the model updating, since only the first three experimental modes were successfully identified in the numerical models. In the time domain response, the models tend to underestimate the amplitude of the vibration at points 2 and 18, where the contribution of modes above 15 Hz play a more significant role than at point 5 due to the sensor location. The damping associated to the high frequency modes in the numerical calculations and also the unsuccessful mode pairing with the ones predicted by the numerical models, can be an issue and require further research.

5 CONCLUSIONS

In this work a preliminary evaluation of the effect of the ballasted track continuity on the dynamic response of railway bridges formed by simply-supported spans with structurally independent adjacent decks at each span, is addressed. First, a preliminary FE model that considers the track and therefore, the coupling between adjacent decks and spans has been implemented. The numerical results are compared with the experimental measurements performed on a real bridge formed by several independent decks, and the following conclusions can be extracted:

- The coupling effect exerted by the ballasted track between consecutive spans and adjacent decks that form the same span in railway bridges is clear. In the particular bridge of study, the coupling effect between adjacent decks of the same span predominates over the coupling between different spans. This issue can be detected under both ambient and train-induced vibrations despite the different level of vibration amplitude induced by these excitations. In this regard, the shared foundations of the two decks may also have an important role on this coupling.

- The transmission of vibrations from the loaded deck to the unloaded deck is relevant. The numerical predictions reveal that a more accurate model updating can be achieved if both coupling effects are considered. In terms of natural frequencies and mode shapes, the sole introduction of the coupling between SS spans in the numerical model does not improve the predictions when compared to the ones obtained when the track is neglected for this particular bridge.

- The three implemented numerical approaches overestimate the contribution of the fundamental mode in the response, thus the prediction is more accurate when both couplings effects are considered. The additional damping induced by the track elements, that is neglected in this preliminary study and also the effect of the train-bridge interaction require further research. Also the shared foundation between decks belonging to the same span can have an influence on the deck coupling that is not well known up to date.

- The three implemented numerical approaches overestimate the contribution of the fundamental mode in the response, thus the prediction is more accurate when both couplings

effects are considered. The additional damping induced by the track elements, that is neglected in this preliminary study and also the effect of the train-bridge interaction, could be responsible of the differences and require further research. Also the shared foundation between decks belonging to the same span can have an influence on the deck coupling that is not well known up to date.

Keywords: rocking, uplifting structures, dimensional analysis, dimensionality reduction, displacement based design

Abstract. *The response of a rigid rocking block is traditionally described by its tilt angle. This is a correct description, but this paper suggests that describing rocking via displacements is more meaningful, because it uncovers that two geometrically similar blocks of different size will experience the same top displacement, provided that they are not close to overturn. The above is illustrated for both analytical pulse excitations and for recorded ground motions. Thus the displacement demand of a ground motion on a rocking block is only a function of its slenderness; not of its size. This reduces the dimensionality of the problem and allows for the construction of size-independent rocking demand spectra.*

1 INTRODUCTION

The systematic study of the rocking oscillator started with Housner's seminal paper in 1963 [1]. Motivated by the surprising stability that tall slender "golf-ball-on-a-tee" structures presented in the 1960 Chilean earthquake, he showed that (a) out of 2 geometrically similar planar rigid objects, the larger one is harder to overturn dynamically, and (b) the overturning potential of a ground motion increases with its dominant period.

The interest on the rocking oscillator [2-6] sources from its ability to describe systems that cannot be described adequately by the classical elastic oscillator [7]. Indeed, the rocking oscillator can be used to understand the behavior of masonry structures [8-14], the seismic behavior of non-anchored equipment [15-22], as well as to explain the stability of ancient Greco-Roman and Chinese temples that have been standing for more than 2,500 years in earthquake prone regions [23-27]. Rocking motion has also inspired researchers to use inerters as seismic protection devices [28-29]. What is not widely known in the western world, is that rocking has been used since more than 40 years as a seismic isolation method in the USSR (and now in former USSR countries) [30, 31]. The Soviet system comprises an intentionally designed soft rocking story. The uplift of the rocking columns works as a mechanical fuse and limits the forces transmitted to the superstructure.

Rocking walls have been suggested as a resilient design approach for buildings [32, 33 and references therein].

Moreover, a 33-m-tall chimney at the Christchurch airport has been designed to uplift [34], and three 30 to 38-m-tall chimneys in Piraeus, Greece, have been retrofitted by allowing them to uplift in case of an earthquake.

Rocking systems are perfectly compatible with Accelerated Bridge Construction as they comprise prefabricated elements with dry connections. In fact, restrained rocking systems [35-42] have already found their way to practice, with the Wigram-Magdala restrained rocking bridge in New Zealand [43] being the first restrained rocking bridge constructed.

However, several researchers have suggested that the restraining tendon in rocking bridges is not only obsolete, but might unnecessarily decrease the design forces of both the superstructure and the foundation, maybe requiring a pile foundation when it could have been avoided [44-60]. Makris and Vassiliou [61] and Vassiliou and Makris [62] have suggested that as the size of a rocking bridge increases, the restraining system can become obsolete and merely increases the design forces of both the superstructure and the foundation.

A main drawback of unrestrained rocking bridges stems from their response being absolutely uncorrelated to any elastic system. Therefore, the elastic-based research results are not applicable: e.g. intensity measures, response spectra, motion-to-motion variability, design ground motions need to be re-determined. To this end, the rocking oscillator should be described with the minimum parameters needed.

This paper suggests that the current state of the art of using the tilt angle θ as the DOF of a rocking system is, of course, correct, but it is not the optimal. Using the top displacement of the oscillator, u, reduces the dimensionality of the problem. Then, the displacement *demand* on a rocking block becomes only slightly dependent on its size and is a function only of its slenderness [63].

2 ROTATION BASED DIMENSIONAL ANALYSIS OF THE ROCKING OSCILLATOR

The equation of in-plane motion for a rigid rectangular rocking column (Figure 1) with slenderness α and a semi-diagonal of length R (Figure 1) is:

$$\ddot{\theta} = -p^2 \cdot \left(\sin\left(\pm\alpha - \theta\right) + \frac{\ddot{u}_g}{g} \cos\left(\pm\alpha - \theta\right) \right) \tag{1}$$

where

$$p = \sqrt{(3g)/(4R)} \tag{2}$$

is the frequency parameter of the rocking column. The upper sign in front of α corresponds to a positive, and the lower to a negative rocking angle θ with respect to the defined coordinate system (Figure 1).

It is assumed that energy is only dissipated during impact. Housner [1] assumed that (a) the impact is instantaneous and (b) that the impact forces are concentrated on the impacting corner. Under these assumptions the ratio of post to pre impact rotational velocities is

$$r = \frac{\dot{\theta}_{after}}{\dot{\theta}_{before}} = 1 - \frac{3}{2}\sin^2\alpha \tag{3}$$

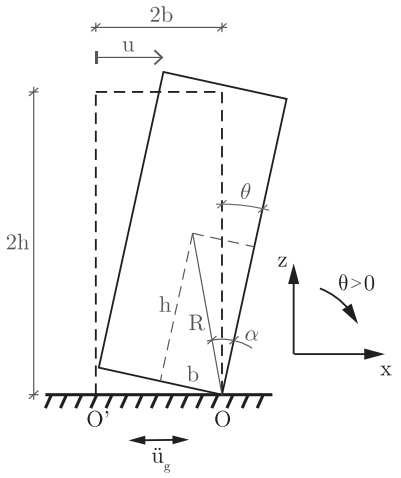

Figure 1: Geometric characteristics of the rigid rocking block.

Researchers (including the senior author of this paper) have critically evaluated the Housner model - especially its damping assumptions [64-68]. Indeed, while assuming the impact to be instantaneous seems a reasonable assumption, there is no evident reason to assume that the impact forces act on the impacting corner. Given the large sensitivity of the time history response of the rocking oscillator to all the parameters that define it, Housner's model might seem simplistic. However, experimental testing shows that even though it cannot predict the response to an individual ground motion, it can predict the statistics of the response to a set of ground motions [69]. Therefore, we consider it adequate within the scope of earthquake engineering [70].

By inspecting Equation (1) and (2) one can conclude that the rotational response of a rocking block to a ground motion is a function of

$$\theta_{\max} = f_1\left(R, \alpha, g, \ddot{u}_g(t)\right) \tag{4}$$

As the gravity acceleration, g, is constant, the rotational response to a given ground motion is a function of 2 parameters α and R, similarly to the elastic oscillator, in which the response is a function of the eigenperiod, T, and damping ratio ζ. Therefore, by keeping one parameter constant (R or α) one can construct rotational spectra for rocking structures. However, unlike

the elastic oscillator, where, for usual structures, one parameter (T) is more influential than the other (ζ), in the case of rocking structures, both R and α strongly influence the rotational response.

Since ground motions containing distinguishable acceleration and/or velocity pulses are particularly destructive [71 and references therein], Zhang and Makris [72] have studied the response of a planar rocking block to acceleration pulses given by analytical expressions. A pulse of a given waveform can be described by two parameters. Zhang and Makris [69] chose the acceleration amplitude a_p and the dominant cyclic frequency ω_p. Then, the response will be a function of

$$\theta_{\max} = f_2\left(R, \alpha, g, a_p, \omega_p\right) \tag{5}$$

Equation (5) involves 6 quantities with 2 reference dimensions (Time and Length). Therefore, according to Vaschy - Buckingham's Π-Theorem of Dimensional Analysis ([73, 74]), the number of dimensionless parameters describing the problem is 6 – 2 = 4. There is not a unique solution for choosing these four parameters. Zhang and Makris [72] suggested describing the problem as

$$\theta_{\max} = \varphi_1\left(\alpha, \frac{\omega_p}{p}, \frac{a_p}{g\tan\alpha}\right) \tag{6}$$

ω_p / p is often called size-frequency parameter and depends on the frequency of the excitation and on the size of the block. $a_p/(g\tan\alpha)$ is usually called non-dimensional acceleration but it can also be perceived as a non-dimensional strength parameter, since $mgR\sin\alpha$ is the moment that withstands uplift ("strength") and is $ma_pR\cos\alpha$ the overturning moment.

Therefore, dimensional analysis reduces the dimensionality of the problem from 6 to 4. Hence, by keeping the slenderness parameter α constant, one can produce contour plots of the maximum tilt angle θ as a function of ω_p / p and $a_p/(g\tan\alpha)$, the so called "rocking spectra". It is worth mentioning that Dimitrakopoulos and DeJong [75] have shown that for small values of α one can drop it as an independent parameter from Equation (6) as long as the coefficient of restitution, r, is treated as an extra independent parameter – however in this section r is not treated independently.

Figure 2 shows the rocking spectra of symmetric and antisymmetric Ricker wavelets. Ricker wavelets are defined as the 2nd and 3rd derivative of the Gaussian:

$$\ddot{u}_g = a_p\left(1 - \frac{2\pi^2t^2}{T_p^2}\right)e^{-\frac{1}{2}\frac{2\pi^2t^2}{T_p^2}} \tag{7}$$

$$\ddot{u}_g = \frac{a_p}{\beta_r}\left(\frac{4\pi^2t^2}{3T_p^2} - 3\right)\frac{2\pi t}{\sqrt{3}T_p}e^{-\frac{1}{2}\frac{4\pi^2t^2}{3T_p^2}} \tag{8}$$

where

$$T_p = \frac{2\pi}{\omega_p} \tag{9}$$

and β_r= 1.3801 to enforce that the function maximum is equal to a_p.

The spectra confirm the remarkable observation that larger structures are harder to overturn dynamically and that higher frequency pulses have a lower overturning potential. Interestingly, they show a heavy dependence of the response on both ω_p/p and $a_p/g\tan\alpha$.

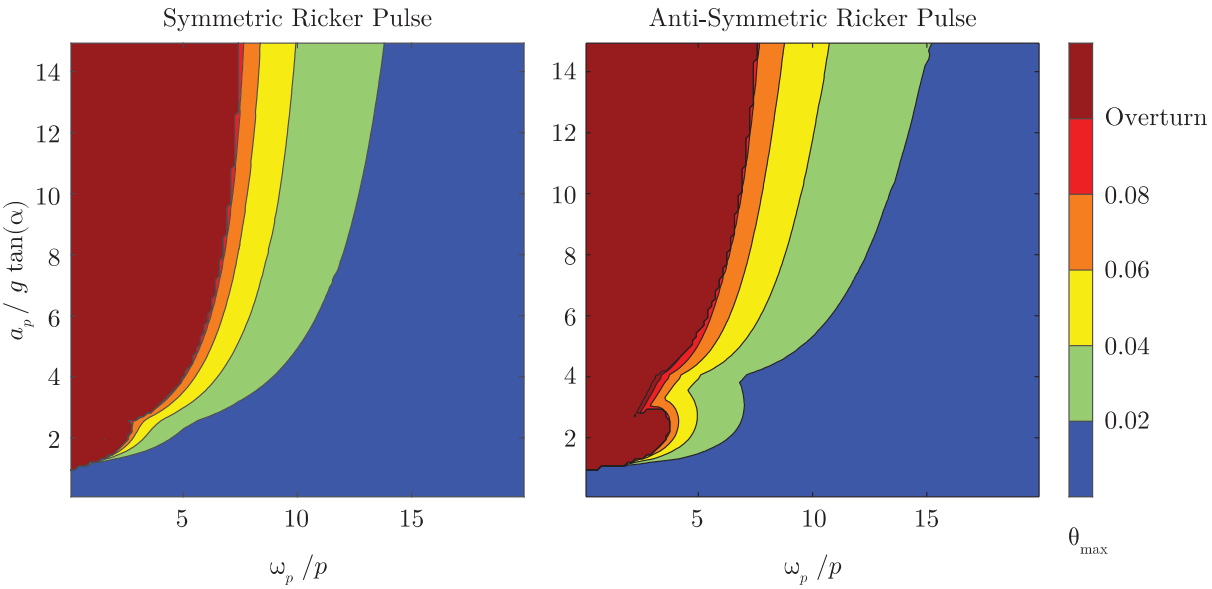

Figure 2: Non-dimensional rocking spectra based on rotations. α = 0.1

3 DISPLACEMENT BASED DIMENSIONAL ANALYSIS OF A ROCKING OSCILLATOR EXCITED BY ANALYTICAL PULSES

3.1 Analysis based on the frequency parameter of the block *p*

The dimensional analysis of the previous section is one of the many correct solutions to describe the problem. It is based on rotations. This section, however, suggests that there is another, displacement based basis of describing the problem, which is also mathematically correct and more convenient. The convenience does not lie only on the fact that earthquake engineers are more used to displacements than rotations: A displacement based analysis further reduces the dimensionality of the problem allowing the construction of 2D rocking spectra.

Indeed, the rotation based analysis of the problem is based on the "recipe for similarity analysis" described in Chapter 5 of the well-known Dimensional Analysis textbook of Barenblatt [76]: "*If the problem has an explicit mathematical formulation, the independent variables in the problem and the constant parameters that appear in the equations, boundary conditions and initial conditions, etc., are adopted as the governing parameters.*" As this section shows, choosing the parameters that appear in the analytical equation might not be the most convenient way of describing this particular problem.

The top displacement of the rocking block can be obtained by a one-to-one mapping on the rotations:

$$u = 2R\sin\left(\pm\alpha\right) - 2R\sin\left(\pm\alpha - \theta\right) \tag{10}$$

The upper sign in front of α corresponds to a positive, and the lower sign to a negative tilt angle θ with respect to the defined coordinate system. If we use the top displacement as the single DOF of the problem, then the maximum response can be described as:

$$u_{\max} = f_3\left(R, \alpha, g, a_p, \omega_p\right) \tag{11}$$

To numerically compute the response of the block, we will resort to Equation (1), which is given in terms of rotation θ. Then, using Equation (10) we compute the displacement response.

Applying Buckingham's Π-theorem on Equation (11), one possible non-dimensionalization is

$$\frac{u_{\max}\omega_p^{\,2}}{a_p} = \varphi_2\left(\alpha, \frac{\omega_p}{p}, \frac{a_p}{g\tan\alpha}\right) \tag{12}$$

Figure 3 shows the contour plots of $\frac{u_{\max}\omega_p^{\,2}}{a_p}$ as a function of ω_p/p and $a_p/(g\tan\alpha)$ for a given α = 0.1. The remarkable observation is that within the non-overturning region the non-dimensional displacement depends heavily (and strongly non-linear) on the non-dimensional strength parameter $a_p/(g\tan\alpha)$ but only loosely on the size-frequency parameter ω_p/p. When the block is not close to overturning, the influence of ω_p/p is practically negligible.

Figure 4 plots $\frac{u_{\max}\omega_p^{\,2}}{a_p}$ as a function of $a_p/(g\tan\alpha)$ for different values of ω_p/p (and a constant slenderness α = 0.1). For reasons of figure clarity, only non-overturning values of $\frac{u_{\max}\omega_p^{\,2}}{a_p}$ are plot, i.e. not plotting $\frac{u_{\max}\omega_p^{\,2}}{a_p}$ means that the block has overturned. Figure 5 plots $\frac{u_{\max}\omega_p^{\,2}}{a_p}$ as a function of ω_p/p for different values of $a_p/(g\tan\alpha)$ (and α = 0.1). Again, it is observed that, as long as the system is away from overturning, the dominant factor that influences $\frac{u_{\max}\omega_p^{\,2}}{a_p}$ is $a_p/(g\tan\alpha)$; not ω_p/p. In fact for small values of non-dimensional acceleration $a_p/(g\tan\alpha)$, the response for all values of size-frequency parameter ω_p/p is practically the same. The response starts to deviate only when the system is close to overturning – or has overturned.

In other words, a small and a large block, geometrically similar to each other and excited by analytical pulses, will have roughly equal top displacement, provided that the displacement is not enough to bring them close to overturn. A given pulse will induce the same *displacement demand*. The larger block is more stable simply because its displacement capacity (i.e. the displacement needed to cause overturn, i.e. its width) is larger.

Therefore, using a displacement basis to describe the problem further decreases the number of parameters needed to define it. Practically, the displacement demand on a rocking oscillator excited by a pulse is only a function of its non-dimensional strength parameter $a_p/(g\tan\alpha)$; not of its size.

The strongly nonlinear nature of rocking motion is also evident in Figures 4 and 5. $\frac{u_{\max}\omega_p^{\,2}}{a_p}$, which expresses the relation of the rocking displacement to the ground motion

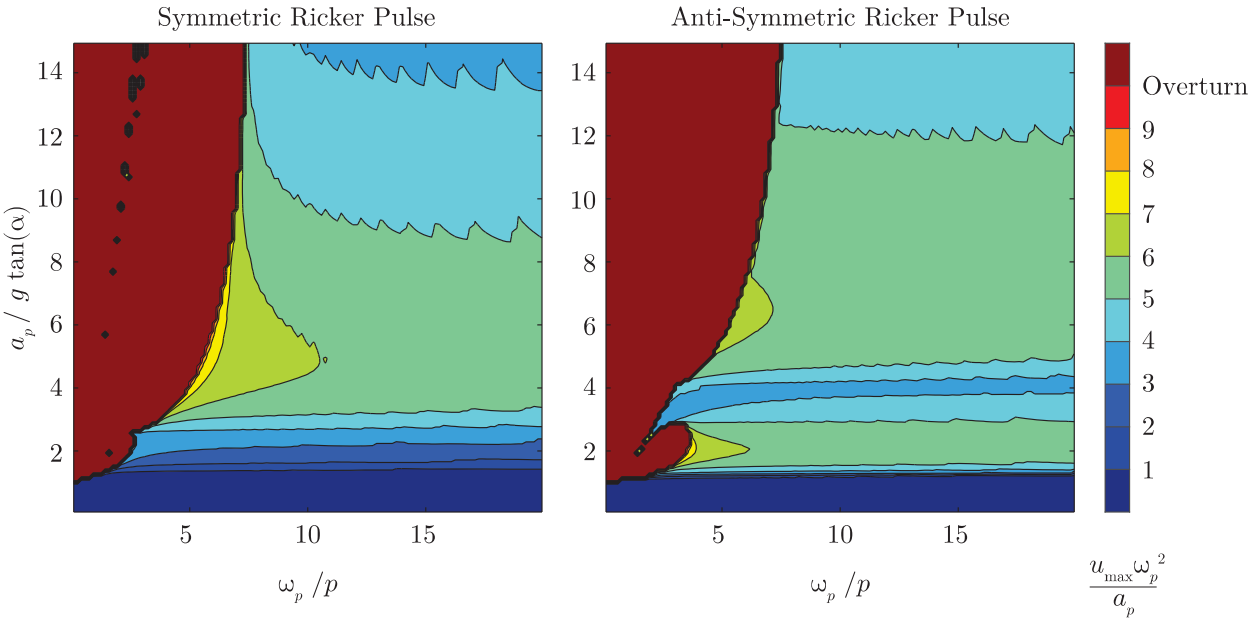

Figure 3: Non-dimensional rocking spectra based on displacements.

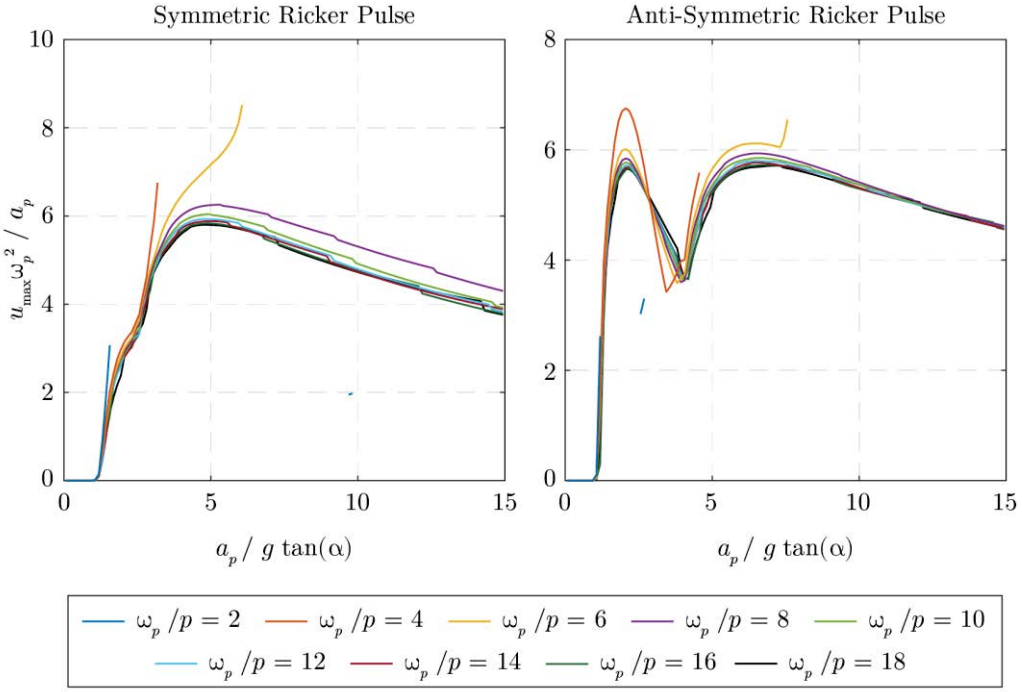

Figure 4: $\frac{u_{max}\omega_p^2}{a_p}$ vs $a_p/(g\tan\alpha)$ plots for constant ω_p/p . $\alpha = 0.1$

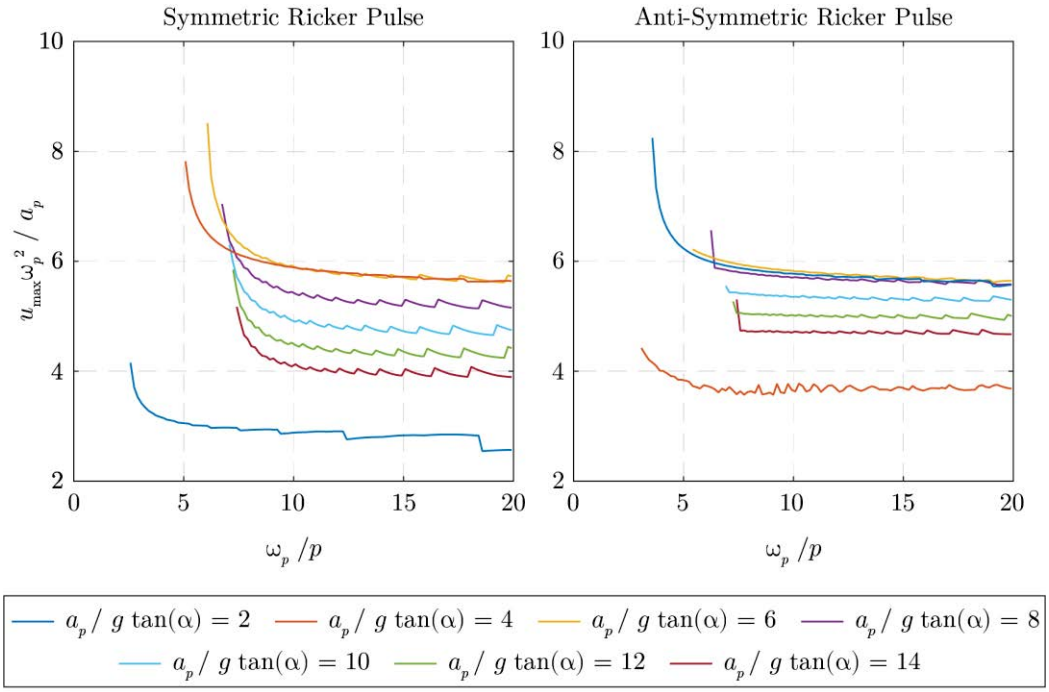

Figure 5: $\frac{u_{max}\omega_p^2}{a_p}$ vs ω_p / p plots for constant $a_p/(g\tan\alpha)$ and $\alpha = 0.1$

displacement, does not depend monotonically on the strength parameter $a_p/(g\tan\alpha)$. In fact, the discontinuities of the $\omega_p/p = 2$ line of Figure 4 convey that a block can survive a stronger pulse and overturn in a weaker one.

Going back to dimensional quantities, Figure 6 plots the displacement response to a symmetric Ricker pulse with a_p = 1g and T_p = 0.5s and to an antisymmetric Ricker pulse with a_p = 1g and T_p = 1s. The plots confirm that the displacement demand only loosely depends on the size, if the block is not close to overturning. The dominant factor is the slenderness. Therefore we can define the displacement demand rocking spectrum of a ground motion as a unary function

$$u_{demand} = f(\alpha) \text{ if } u_{demand} \square\ 2b \tag{13}$$

that is computed via Equations (1) and (10) for a large enough block size. To check the stability of a block, one has to compute the maximum displacement demand via Equation (13) and compare it with the displacement capacity (i.e. the block width).

Therefore the reduction of the dimension of the problem follows two steps: a) Applying Buckingham's theorem and b) Observing that the displacement demand is roughly independent of the size. The first step is exact and follows from dimensional analysis. The second step is approximate and in this section illustrated for analytical pulses. Blöchlinger [77] gave a first indication that the approximation also works for recorded ground motions. Further evidence supporting this approximation and highlighting its limitations are given in a next section of this paper.

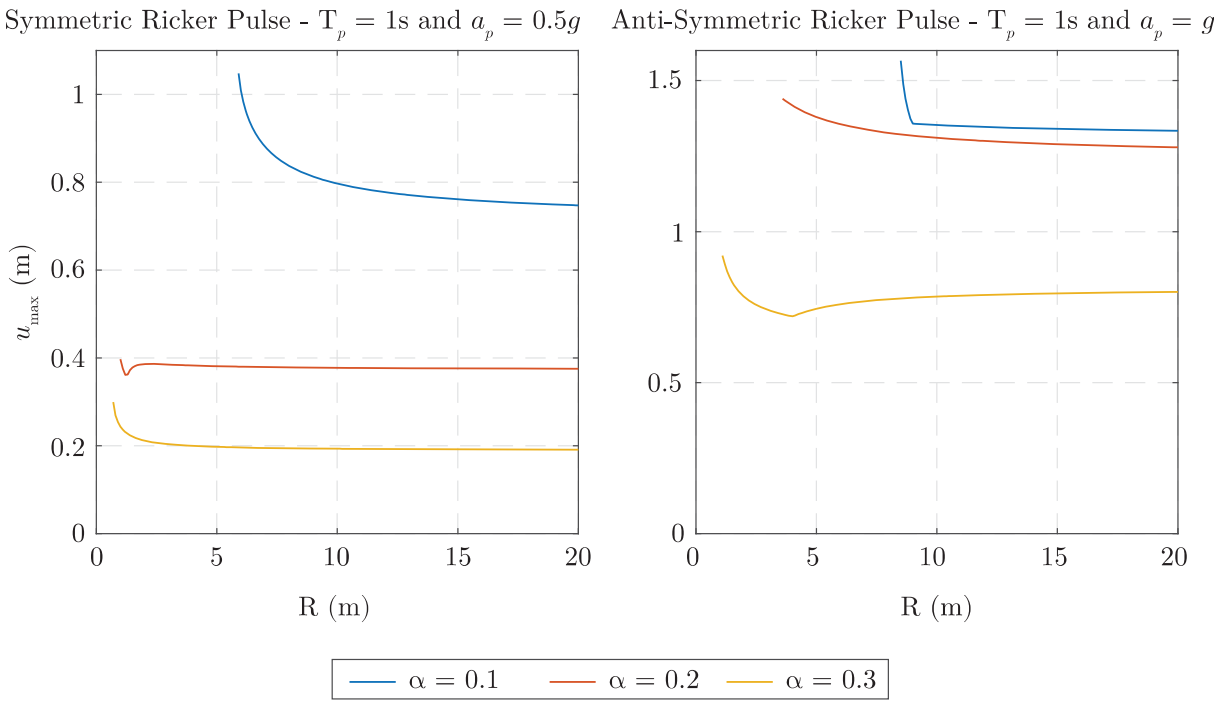

Figure 6: Maximum block displacement as a function of block size for Symmetric and Anti-Symmetric Ricker excitation.

3.2 Analysis based on the base width of the block *b*

The previous section chooses the frequency parameter p and the slenderness of the block, α, as the two parameters to define it. However, p has a physical meaning that is totally unrelated to rocking. It is the natural frequency that the block would have had *if* it was hanging from its corner [75]. But this is merely a coincidence, rocking blocks have no natural frequency [1], and the use of p often creates misunderstandings. In this section we propose to describe the block with two physical parameters that have a clear physical meaning, directly related to the rocking problem. The slenderness α is retained, as it controls the uplift of the structure (and could be parallelized with the strength of a system), but p is replaced by b, which is the half-width of the base and exactly equal to one half of its displacement capacity. Then the displacement response will be:

$$u_{\max} = f_4\left(b, \alpha, g, a_p, \omega_p\right) \tag{14}$$

Using Buckingham's Π theorem we get:

$$\frac{u_{\max}\omega_p^{\,2}}{\alpha_p} = \varphi_3\left(\frac{a_p}{g\tan\alpha}, \frac{b\omega_p^{\,2}}{a_p}, \alpha\right) \tag{15}$$

The term $a_p/(g\tan\alpha)$ would be the reciprocal of the non-dimensional strength, $\left(b\omega_p^{\,2}\right)/a_p$ would be the non-dimensional displacement capacity, and α (taken as an independent parameter) controls damping, because it controls the coefficient of restitution.

Figure 7 plots displacement spectra according to the suggested non-dimensionalization. One can observe that for both pulses a base (i.e a displacement capacity = 2b) of roughly 9

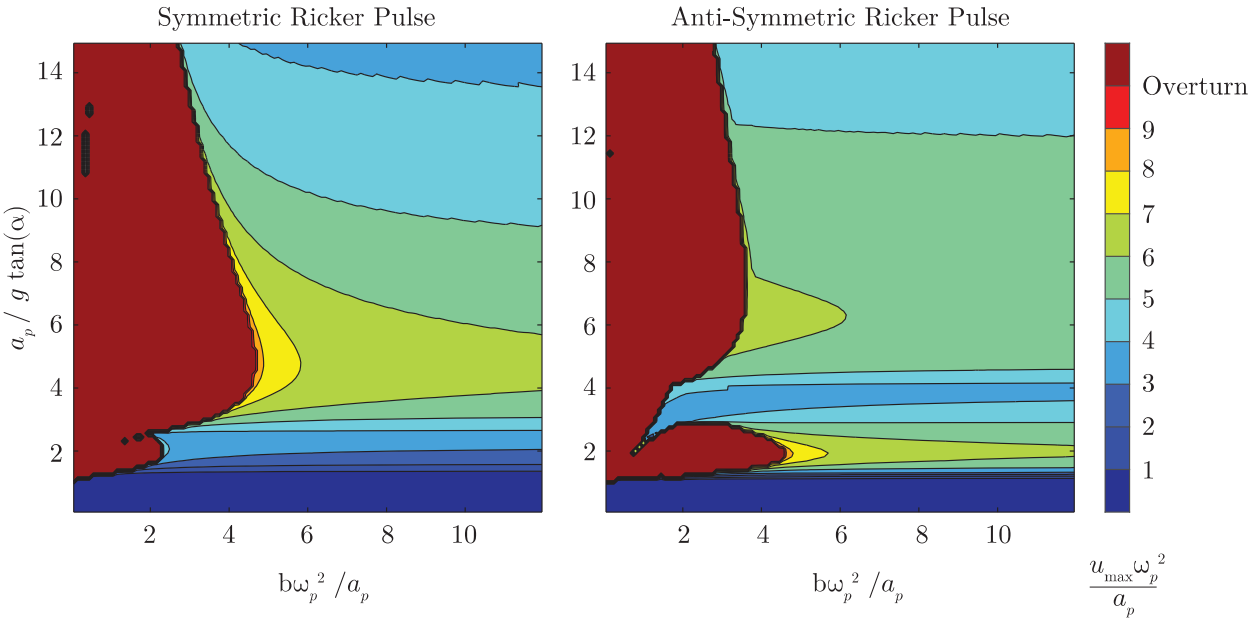

Figure 7: Displacement based non-dimensional rocking spectra using the width of the block to characterize its size.

times the length scale of the pulse $L_e = a_p / \omega_p^2$ is enough to keep the block stable, no matter what the non-dimensional strength parameter is.

4 DISPLACEMENT BASED ANALYSIS OF A ROCKING OSCILLATOR EXCITED BY RECORDED GROUND MOTIONS

Analytical pulses can be used to qualitatively study the rocking oscillator. However, as the rocking problem is very sensitive to all of its parameters, pulses would not suffice to prove that the displacement demand on a rocking structure depends only on its slenderness and not on its size. Therefore, this section examines the displacement response of a rocking block excited by recorded ground motions.

4.1 FEMA P695 Ground motions

There is no consensus in the engineering community on what ground motions should be used in time history analysis. Several approaches exist including using recorded (scaled or unscaled), artificial, or synthetic ground motions. In this paper we choose to use the 3 sets of ground motions proposed by FEMA P695 [79] (far field, near field pulse-like, and near field non-pulse-like) only as a means to illustrate our rocking-related argument, without taking stance on the debate around ground motions. It is evident that any ground motion selection method based on the response of an elastic system is in principle not applicable in the case of the rocking oscillator, as the elastic and rocking oscillator are uncorrelated. More information on the FEMA P695 ground motions can be found in FEMA [79].

4.2 Equal displacement rule for rocking structures and displacements demand spectra

Vassiliou et al. [80] have proven that rigid rocking oscillators of equal height attached to massless foundations of the same size behave identically, no matter what their actual column width is (Figure 8). Therefore, the design question of a rocking structure would be: Find the size, *2B'*, of the foundation for a given oscillator height 2*H*. Hence, it is more meaningful to

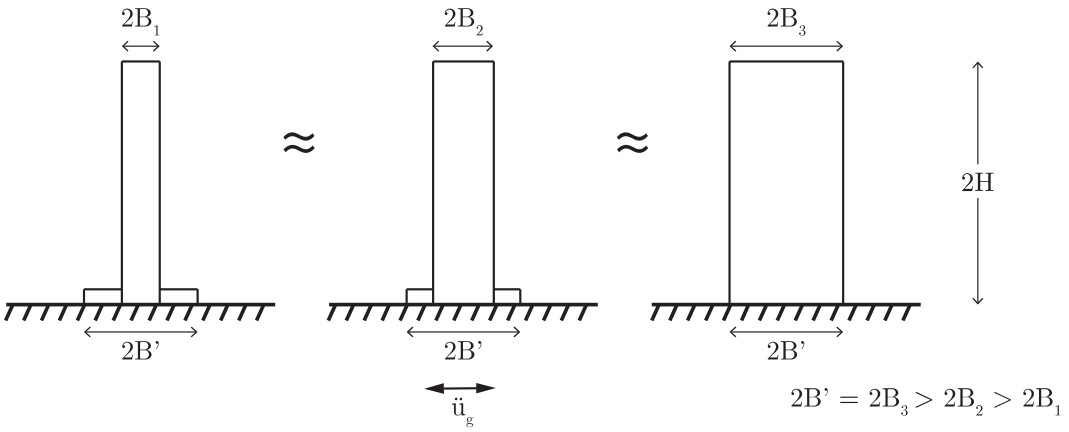

Figure 8: Rocking oscillators of equal height.

use H as a size parameter instead of R, even if the former does not explicitly appear in the equation of motion.

Figure 9 offers the displacement of a rocking oscillator as function of its slenderness α, and for $2H$=*2, 4, 10, 20, 80,* and *1000m*, for a selection of the FEMA P695 ground motions. The $2H$=1000m is offered only for reasons of mathematical completeness, to study the limit case of $H \to \infty$. For reasons of plot clarity, each line is plotted only for $\alpha > \alpha_{\text{crit}}$, where α_{crit} is the minimum slenderness angle for which the block overturns. We observe that all blocks of same slenderness angle present roughly the same displacement, as long as they are not close to overturning. The same observation holds for all the ground motions tested.

As analysis and design of a rocking structure would not involve a single ground motion, but a set of design motions, it makes sense to study the problem by applying sets of multiple excitations and comparing the statistics of the results (e.g. the median displacement among all the ground motions of the excitation set). Figure 10 plots displacement spectra of the median of the displacement for 7 variations of the near-field pulse-like FEMA P695 set: a) Unscaled ground motions, b) scaled so that their PGA is equal to $0.5\overline{PGA}$, or $\overline{PGA}$, or $2\overline{PGA}$, c) scaled so that their PGV is equal to $0.5\overline{PGV}$, or $\overline{PGV}$, or $2\overline{PGV}$, where $\overline{PGA}$, $\overline{PGV}$ are defined as

$$\overline{PGA} = \underset{i=1\ldots N}{median}\left(\sqrt{PGA_{i_x} \times PGA_{i_y}}\right) \tag{16}$$

$$\overline{PGV} = \underset{i=1\ldots N}{median}\left(\sqrt{PGV_{i_x} \times PGV_{i_y}}\right) \tag{17}$$

where N is the number of the ground motions and x and y are the two components of each ground motion. Note that each horizontal component of each ground motion is treated as an independent motion. Figures 11 and 12 plot the same spectra for the far field and near field non-pulse-like ground motions.

The following observations can be made:

a) The median spectra are smoother, likewise design elastic spectra that were derived by statistical processing of elastic spectra of single ground motions are smoother than single ground motion spectra.

b) As long as the system is not close to overturning, the displacement does not depend on the size of the block. For this part of the spectrum, instead of computing a different spectrum for each block size, one can compute the design spectrum for $2H \to \infty$ ($2H$ =

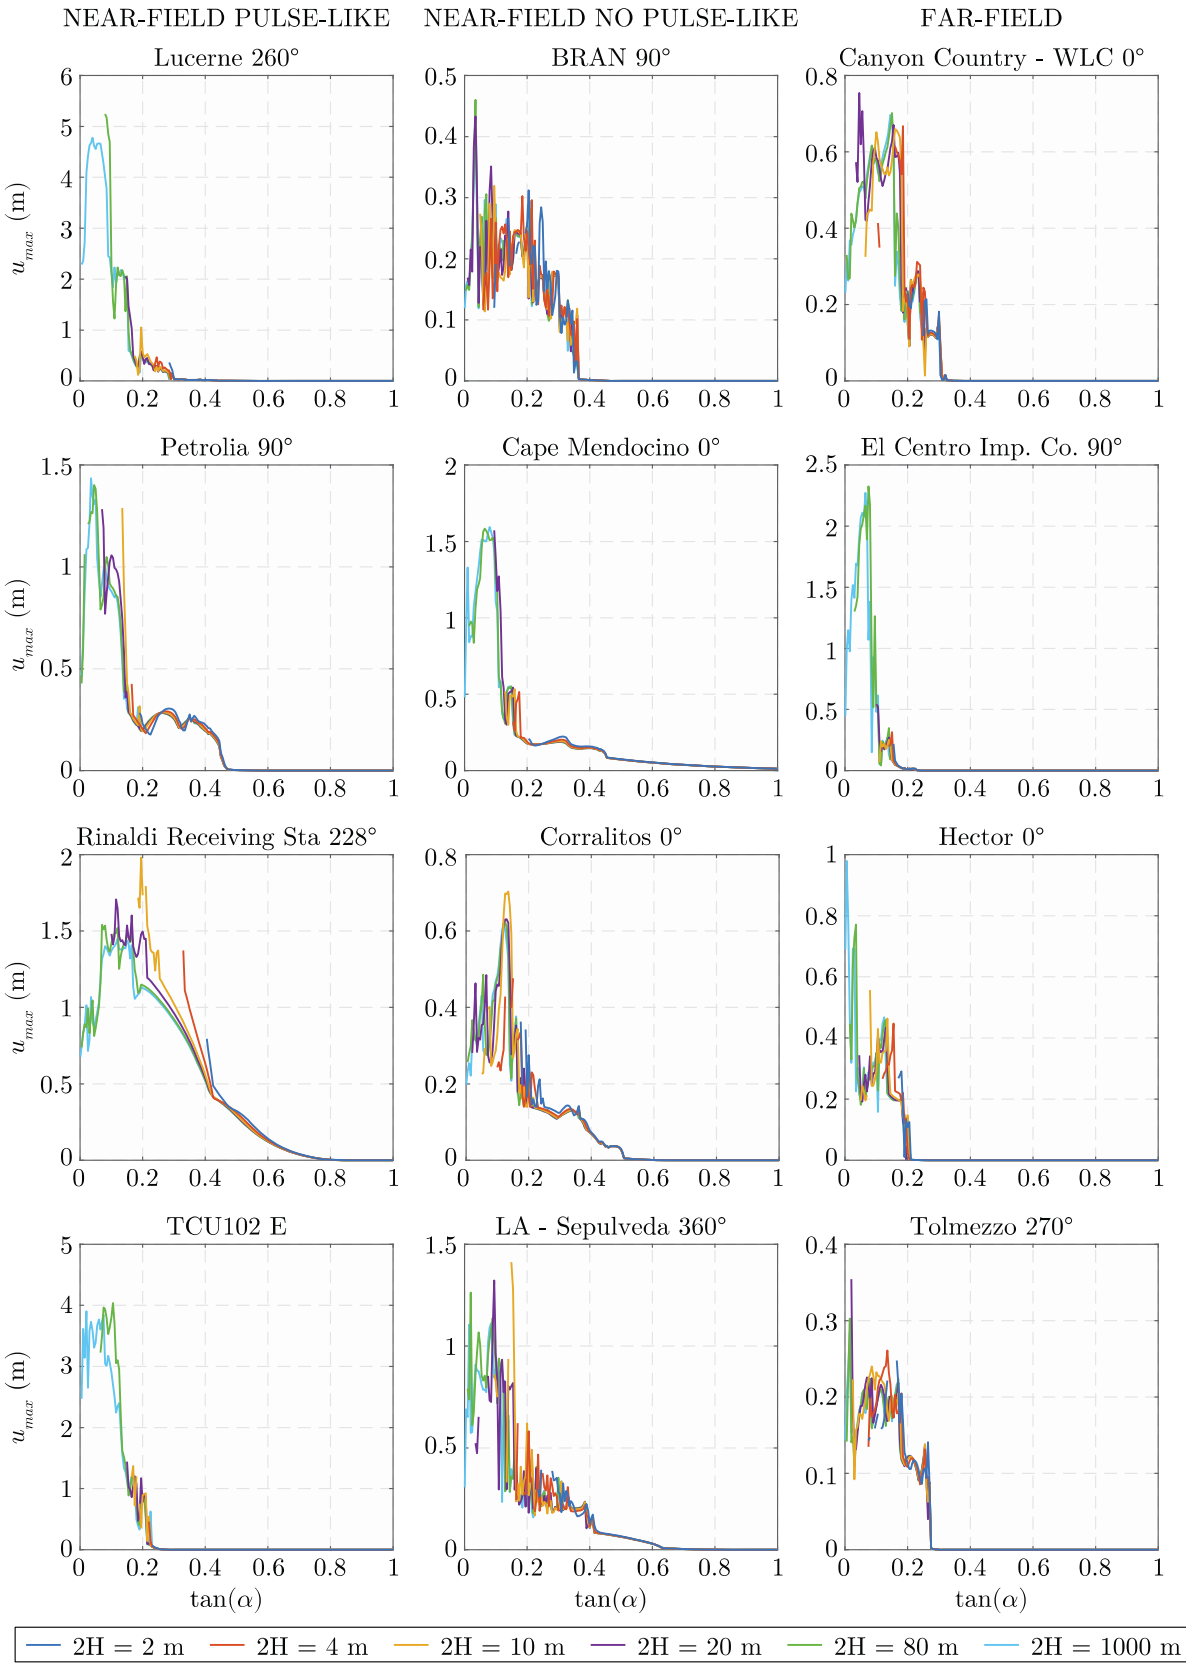

Figure 9: Displacement of a rocking oscillator as function of its slenderness α.

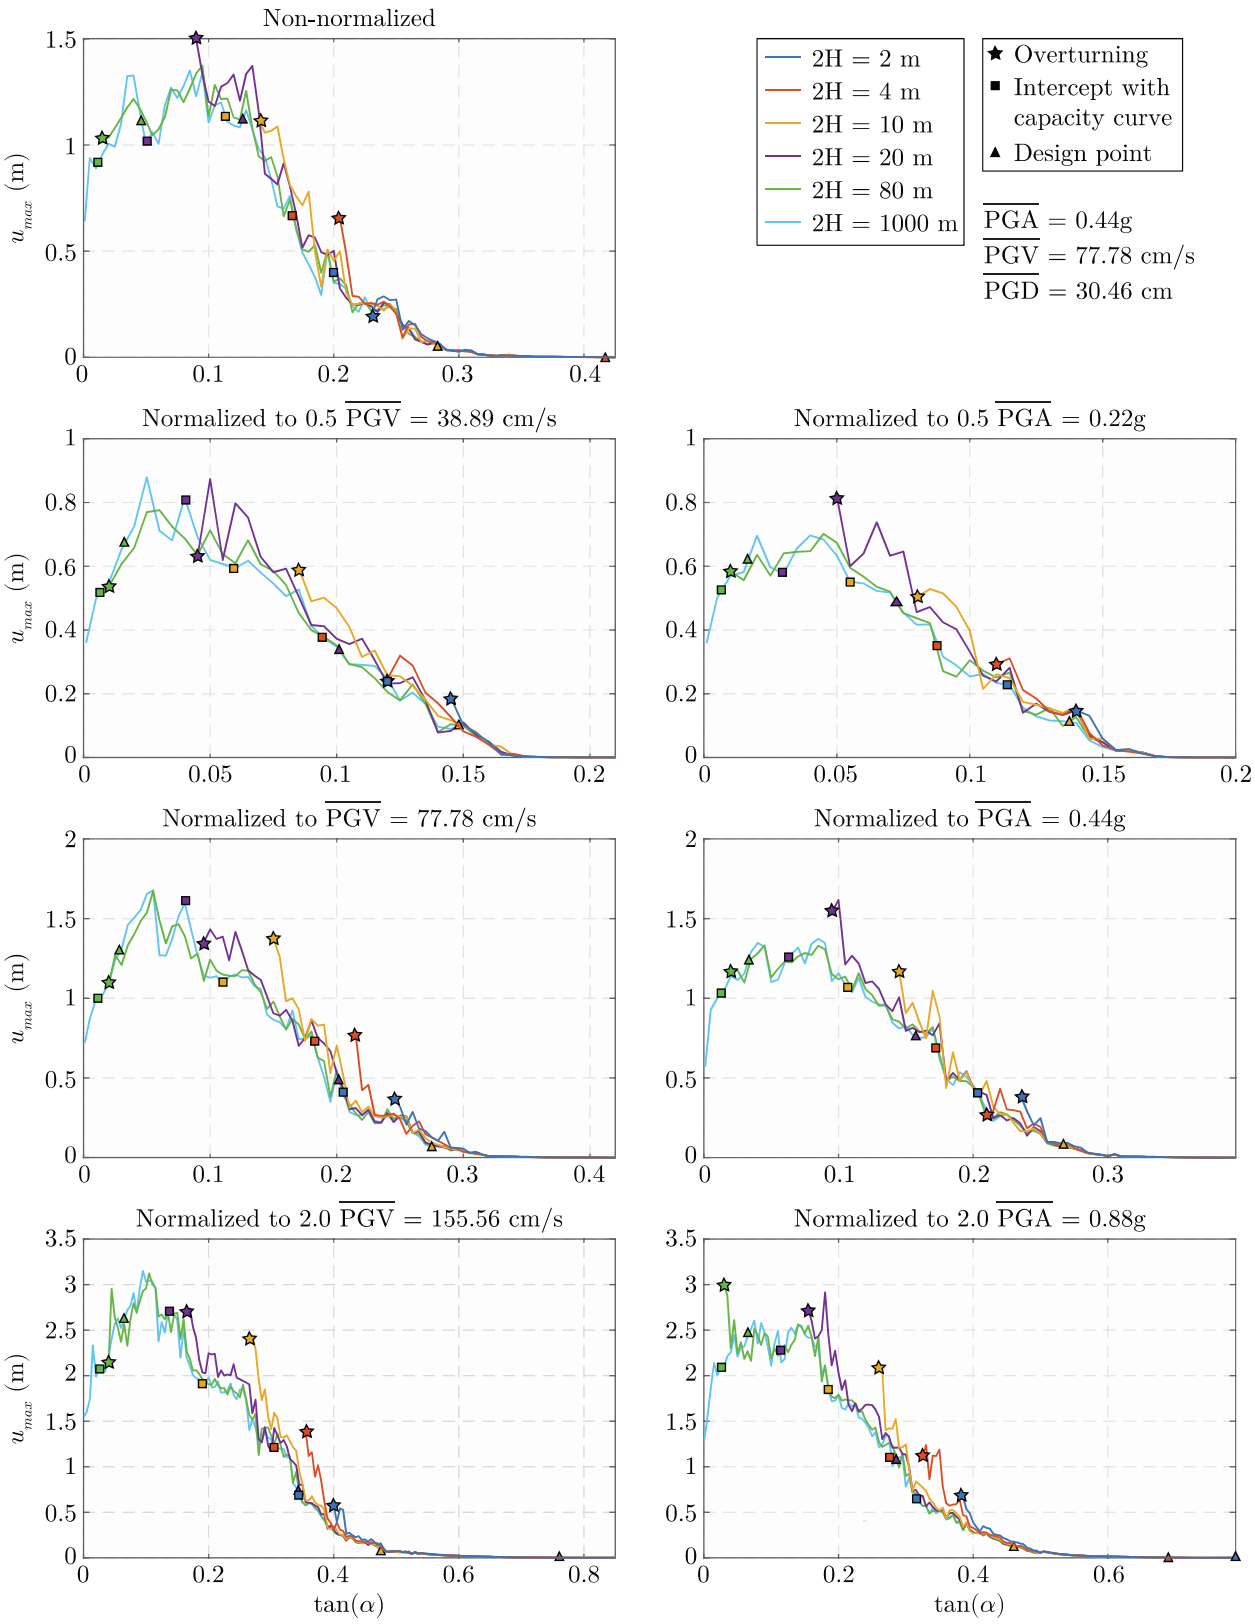

Figure 10: Median Displacement Spectra for Near-Field Pulse-Like Record Set.

1000m seems an adequate value) and use it to calculate the displacement *demand* on any rocking structure (i.e. $u_{max}=f(\alpha)$). We name the above finding "equal displacement rule" for rocking structures.

c) As the system gets closer to overturning the equal displacement rule does not apply: smaller systems present larger displacements than larger ones. Moreover, as the system approaches overturning, the slope of the spectrum increases dramatically i.e. a small decrease in tanα leads to very large increase in displacement. This trend dictates that a rational design of a rocking structure would require that this steep part of the spectrum be avoided. because an earthquake slightly stronger than the design one would cause a tremendous increase in displacement. Therefore, the equal displacement rule applies to the rational design region.

d) The form of the spectrum for all 3 sets of ground motions presents some repetitive pattern:
   i. As α tends to zero, u_{max} tends to a finite value. For spectra of individual ground motions, this value is $\frac{3}{2}PGD$. An explanation for this is offered in the next section.
   ii. As α increases from zero, the displacement demand amplifies 2-2.5 times and reaches a plateau.
   iii. Further increase of α leads to a monotonic decrease of the displacement demand.
   iv. Naturally, when tanα reaches PGA/g, the displacement demand becomes zero, as there is no uplift.

4.3 Preliminary design based on the equal displacement rule

If not for a final design, the equal displacement rule can be used for preliminary calculations. Indeed it is not an exact method, but a preliminary design method that does not aim at being exact, but at providing a tool for initial calculations, that for certain cases and required degree of accuracy can be enough. The same holds for yielding structures, where the "equal displacement rule" is used for many structural systems, while for more complicated systems it is used only for preliminary design and then more refined methods are applied. It could be stated that the findings of this paper constitute the generalization of equal displacement rule from yielding to rocking systems. This section proposes a methodology to design a rocking structure based on the equal displacement rule:

a) On the u_{max} – tanα curve, we plot the capacity line $u_C = 2H\tan\alpha$.
b) We determine the intersection of the capacity line and the $2H = \infty$ line. We define the abscissa of this point as $\tan\alpha_k$.
c) We use a multiplier of 2.5 to determine the design slenderness: $\tan\alpha_D = 2.5\tan\alpha_k$. The multiplier serves as a safety factor to move the design point away from the steep part of the spectrum.

Figure 13 outlines the design procedure applied for a rocking bridge with columns of 6.7m height ($2H$ = 6.7m). Based on Makris and Vassiliou [46] the response of the frame is equal to the response of a solitary block of $2H$ = 10m. For this bridge, twenty one design scenarios are explored, corresponding to the 21 spectra of Figures 10-12. Tables 1-3 and Figure 14 summarize the findings for the 21 design scenarios and compare the displacement predicted

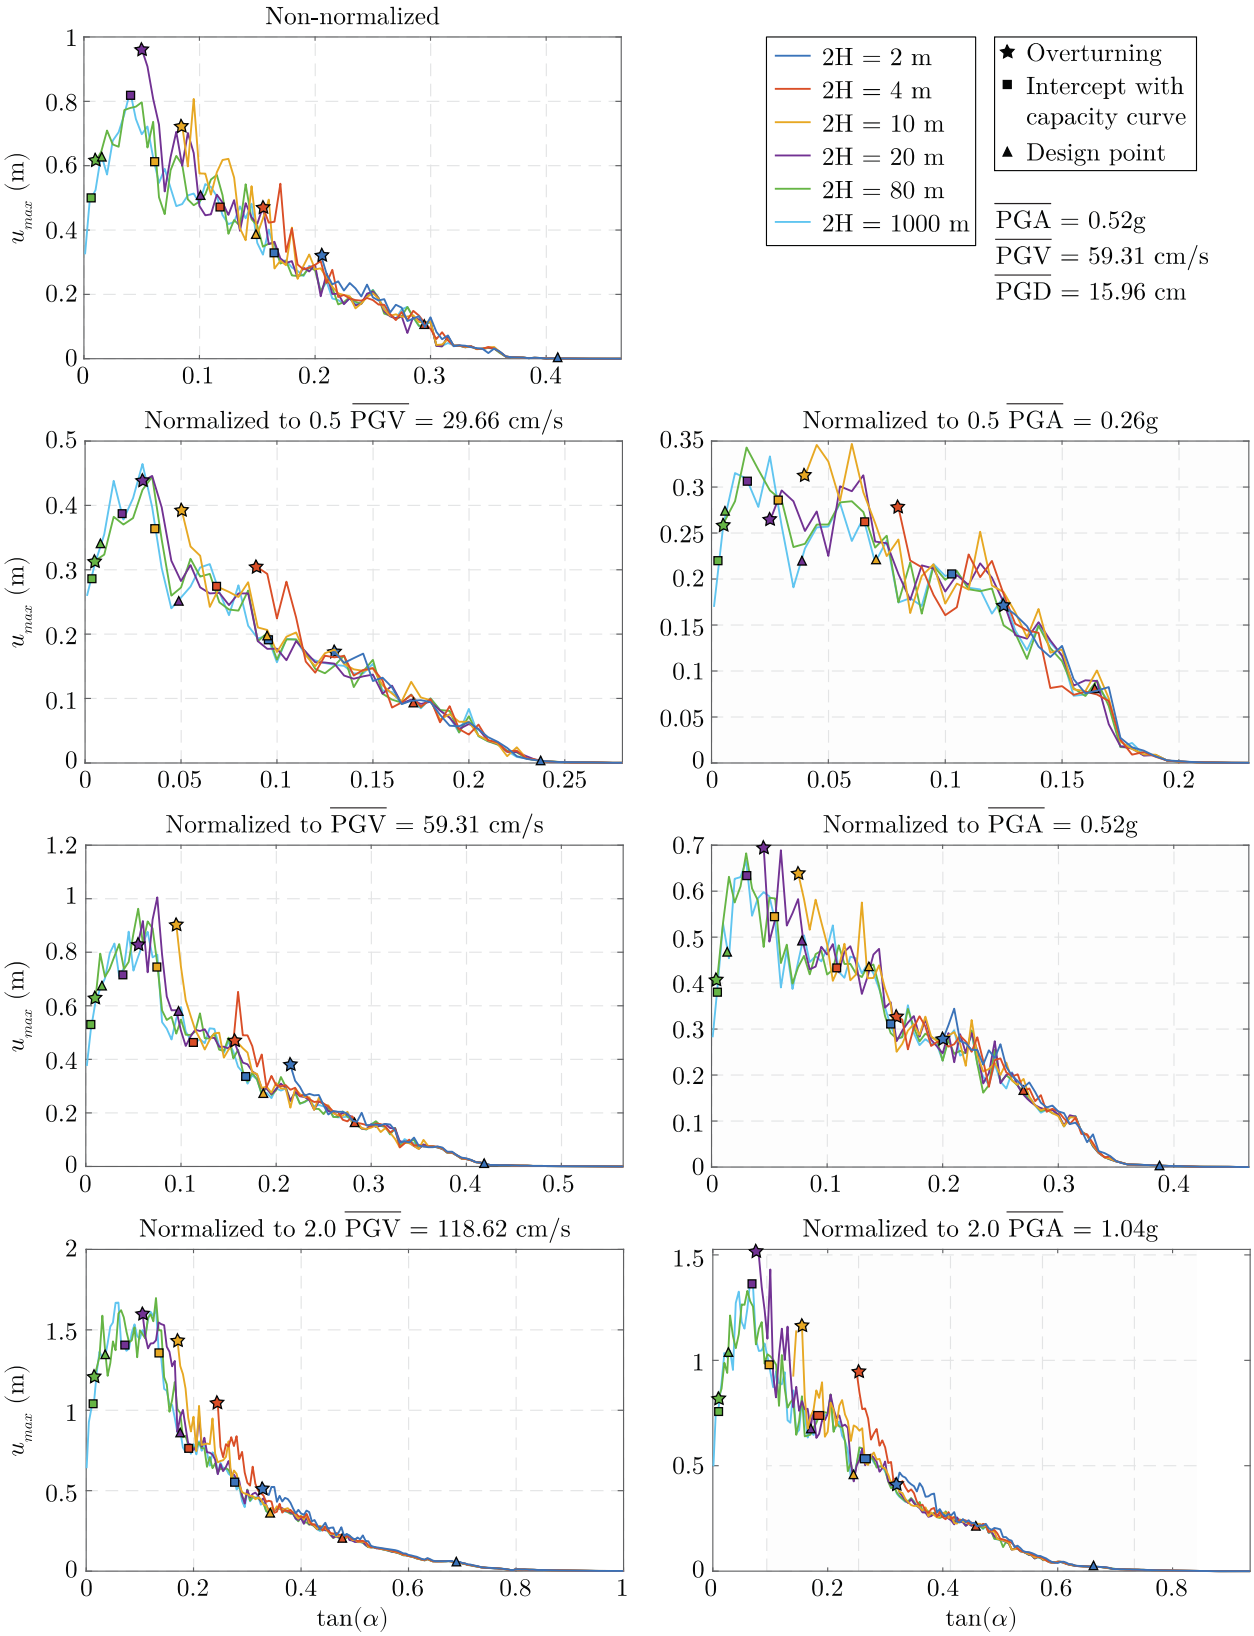

Figure 11: Median Displacement Spectra for Near-Field No Pulse-Like Record Set.

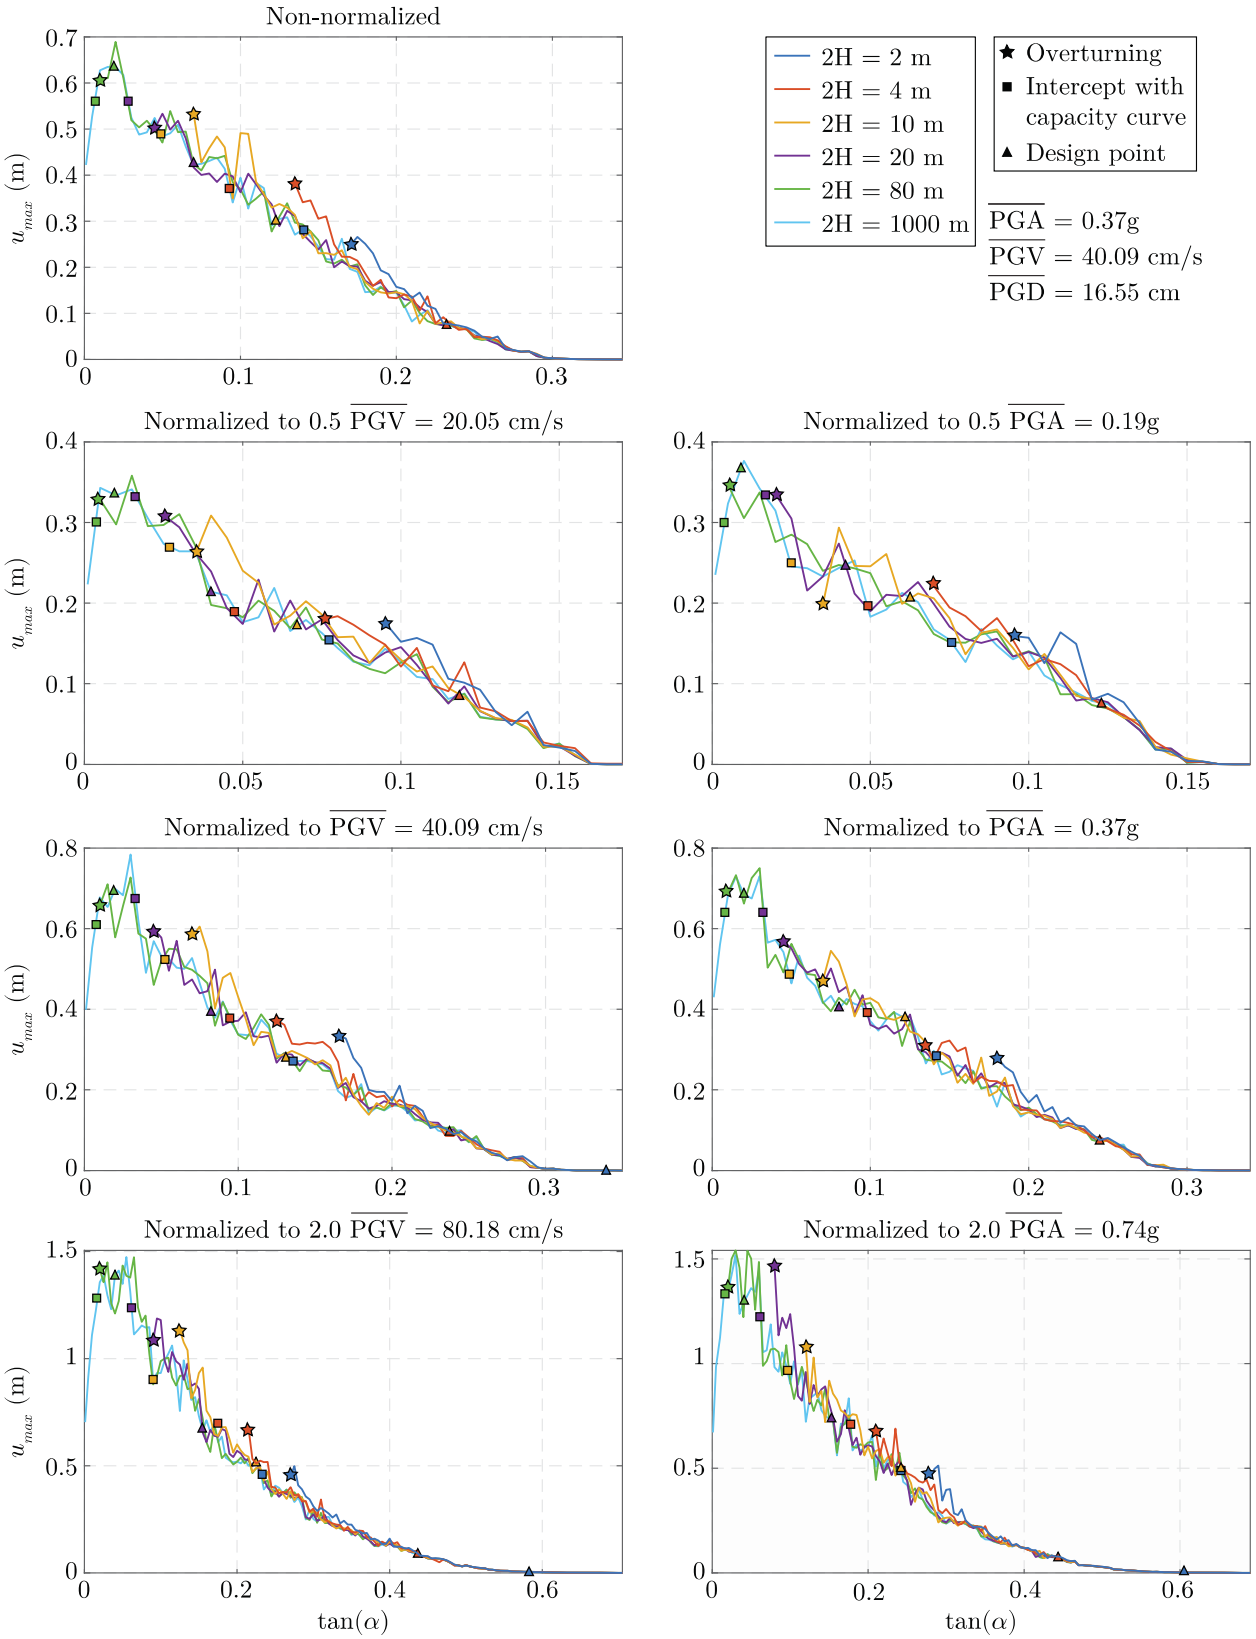

Figure 12: Median Displacement Spectra for Far-Field Record Set.

by the demand spectrum ($2H$ = 1000m) to the displacement predicted by the $2H$=10m spectrum. We observe that in all but two cases (near fault pulse-like scaled to $0.5\overline{PGA}$ and near fault non-pulse-like scaled to $2\overline{PGA}$) the error in predicting the median displacement is less than 20%. In all cases, the error is smaller than 40%, and no system overturned.

5 INTERPRETATION OF THE EQUAL DISPLACEMENT RULE BASED ON THE EQUATION OF MOTION

The equal displacement rule can be interpreted by properly manipulating the equation of motion. Assuming small rotation angles (sin*x*=*x* and cos*x*=1), Equation (1) gives

$$\ddot{\theta} = -\frac{3g}{4H}\cdot\left(\pm\alpha - \theta + \frac{\ddot{u}_g}{g}\right) \tag{18}$$

For small angles, $u = 2H\theta$. Then

$$\ddot{u} = -\frac{3g\alpha}{2}\cdot\left(\pm 1 - \frac{u}{2b} + \frac{\ddot{u}_g}{g\alpha}\right) \tag{19}$$

When $u/2b$ is small (i.e. the block is not close to overturning, the other terms dominate the response and u becomes a function only of α. Furthermore, when $\ddot{u}_g/(g\alpha) \gg 1$, then $\ddot{u} = -3\ddot{u}_g/2$. Therefore, as $\alpha \to 0$ (which can only happen for blocks with $H \to \infty$), $u_{max} \to$ 3/2 PGD.

6 CONCLUSIONS

The widely used description of the rocking block via its rotation is correct, but not optimal. It reveals that larger blocks are more stable and that higher frequency pulses present less overturning potential. However, it does not reveal the "equal displacement rule of rocking structures", namely that a large and a small block of the same aspect ratio will present the same top displacement, if they both are not close to overturning. Not being close to overturning is a design necessity anyway, therefore, for the scope of design, we can claim that the displacement demand is the same and it only depends on the slenderness, not on the size of the block. The above is illustrated for both analytical pulse excitations and for sets of recorded ground motions. As the response of a rocking block away from overturning essentially becomes a unary function, rocking spectra that plot the displacement demand as a function of the slenderness of the block can be developed. The shape of these spectra seem to follow a repetitive pattern, starting for tanα=0 from u=3/2×PGD, reaching a plateau of 2-2.5×3/2×PGD, and then gradually decreasing to zero. More research with more ground motions in needed to better understand the shape of the spectra. Based on the above, a design method that uses a size-

independent rocking spectrum is suggested. This should be taken into account when intensity measures for rocking structures [81-84] designed not to get close to overturning are explored.

Keywords: seismic isolation, double concave friction pendulum (DCFP) isolator, bridge, pier-abutment-deck interaction, non-dimensional form, optimal friction coefficient.

Abstract. *The paper analyzes the influence of double concave friction pendulum (DCFP) isolator properties on the seismic performance of isolated bridges. The behavior of these systems is analyzed by employing an eight-degree-of-freedom model accounting for the first five vibrational modes of the pier and the presence of a rigid abutment, whereas the DCFP isolator behaviour is described combining two single FPSs in series. The uncertainty in the seismic input is taken into account by considering a set of natural records with different characteristics. The variation of the statistics of the response parameters relevant to the seismic performance is investigated through an extensive parametric study carried out for different system properties.*

1 INTRODUCTION

Seismic isolation has emerged as one of the most powerful techniques in the ensemble of retrofitting methodologies [1]-[5] to improve the safety and resilience of infrastructure systems [6]-[7]. In the more general seismic approach, seismic isolation of bridges permits to obtain the uncoupling of the deck from the horizontal earthquake's components, leading to a significant reduction of the deck acceleration and, as consequence, of the forces transmitted to the pier.

Several studies [1]-[4] have been carried out in the last decades investigating the effectiveness of the isolation devices and carrying out experimental and analytical studies on the seismic response of bridges isolated by sliding isolation systems finding out as these kind of devices are quite effective and efficiency in the aseismic bridges' design. Ghobarah and Ali [5] and Turkington et al. [8] showed that the presence of lead-rubber bearings shift the natural period of the structure and increases the amount of damping, moreover they permit to distribute the seismic forces approximately evenly between pier and abutment. Jangid [9] studied the seismic response of bridges seismically isolated by lead-rubber bearings (L-RB) to bidirectional earthquakes outlining that the bidirectional interaction of the restoring forces of the L-RB has not negligible effects on the seismic response of the isolated bridges. In [10]-[11], the seismic behaviour of bridges seismically isolated by adopting friction pendulum system (FPS) was studied. When FPS bearings are used, the natural period of the isolated structure becomes independent of the mass of the superstructure and it just has a dependence on the radius of curvature of the sliding surface [12].

Another important feature of this isolation system is mainly related to the energy dissipation mechanism that becomes possible thanks to the velocity dependent friction between the sliding surfaces and the composite material on the slider [13]-[17]. In addition, it has been demonstrated in [18]-[19] that the characteristics of an FPS become more effective by introducing a second sliding surface obtaining the so called double concave friction pendulum (DCFP). In particular, Kim and Yun [20] studied the positive effects of a double concave friction pendulum system on a bridge response considering different combinations of radii of curvature and of friction coefficients.

Other studies [21]-[22] have been more oriented to define design approaches by means of the seismic reliability-based design (SRBD), in which the main uncertainties such as the seismic input and the system properties have been taken into account. In [23] the optimal properties of FPS able to minimize the seismic response of bridge under earthquake having different frequency contents representative of different soil conditions has been evaluated.

This study analyzes the influence of the double concave friction pendulum (DCFP) isolator properties on the seismic performance of isolated bridges taking into account the pier-abutment-deck interaction. The behavior of these systems, as also described in [10]-[24] is analyzed by employing an eight-degree-of-freedom (8dof) model representative of the reinforced-concrete pier flexibility in addition to the presence of a rigid abutment and deck, whereas the DCFP isolator behaviour is described combining two single FPSs in series [18]-[19]. For each sliding surface, a widespread model which considers the variation of the friction coefficient with the sliding velocity is adopted [15]-[16]. The uncertainty in the seismic input is taken into account by means of a set of natural records with different characteristics. The variation of the statistics of the response parameters relevant to the seismic performance of the isolated bridges is investigated through a nondimensionalization of the motion equations, as also implemented in [25]-[28] developing an extensive parametric study.

2 EQUATIONS OF MOTION

An 8-degree-of-freedom (dof) system is employed to model the isolated bridge configuration of Figure 1. Specifically, 5 dof are given by the lumped masses of the pier, 2 dof correspond to the two slider masses of the DCFP isolators, located respectively on the pier and on the abutment, and 1 dof is related to the rigid deck mass [10].

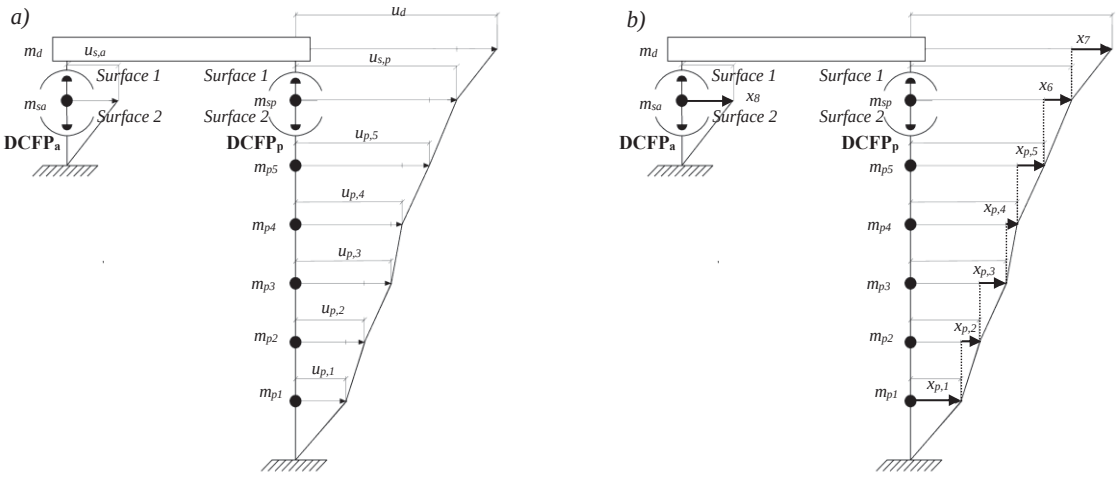

Figure 1: 8dof model of bridge isolated with DCFP bearings: relative displacements with respect to the ground a) and drifts between masses b) .

The equations of motion governing the response of the model representing a bridge on DCFP isolators, in terms of relative displacement with respect to the ground (Figure 1a) subjected to the seismic input $\ddot{u}_g(t)$ is:

$$m_d\left[\ddot{u}_d(t)+\ddot{u}_g(t)\right]+F_{1a}(t)+F_{1p}(t)=0$$

$$m_{sa}\left[\ddot{u}_{sa}(t)+\ddot{u}_g(t)\right]-F_{1a}(t)+F_{2a}(t)=0$$

$$m_{sp}\left[\ddot{u}_{sp}(t)+\ddot{u}_g(t)\right]-F_{1p}(t)+F_{2p}(t)=0 \qquad \text{(1a,b,c,d,e)}$$

$$m_{p5}\left[\ddot{u}_{p5}(t)+\ddot{u}_g(t)\right]+c_{p5}\left[\dot{u}_{p5}(t)-\dot{u}_{p4}(t)\right]+k_{p5}\left[u_{p5}(t)-u_{p4}(t)\right]-F_{2p}(t)=0$$

$$m_{pi}\left[\ddot{u}_{pi}(t)+\ddot{u}_g(t)\right]+c_{pi}\left[\dot{u}_{pi}(t)-\dot{u}_{pi-1}(t)\right]+k_{pi}\left[u_{pi}(t)-u_{pi-1}(t)\right]+$$
$$-c_{pi+1}\left[\dot{u}_{pi+1}(t)-\dot{u}_{pi}(t)\right]-k_{pi+1}\left[u_{pi+1}(t)-u_{pi}(t)\right]=0 \quad for \quad i=1,...,4$$

where u_d denotes the displacement of the superstructure relative to the ground, u_{sp} the displacement of the slider of the DCFP device on the pier with respect to the ground, u_{sa} the displacement of the slider of the DCFP device on the abutment with respect to the ground, u_{pi} (i=1,..,4,5) the displacement of pier i-th mass relative to the ground, m_d , m_{sp} and m_{sa} respectively the mass of the deck and of the two DCFP devices respectively on the pier and on the

abutment, m_{pi} (i=1,..,4,5) the mass the i-th lumped mass of the pier, k_{pi} and c_{pi} (i=1,..,4,5) respectively the stiffness and inherent viscous damping constant for each dof of the pier, t the time instant, the dot differentiation over time, $F_{ja}(t)$ and $F_{jp}(t)$ denote the reaction of the DCFP bearings on the abutment and on the pier, respectively, for the upper (j = *1*) and lower surface (j = *2*). The deck isolated by DCFP isolators is herein considered without any viscous capacities [28].
A DCFP can be modeled as a serial combination of two single FPS. Thus, according with [18]-[19], when the inertial force associated with the movement of the small slider mass is neglected, the reaction forces (F_2 and F_1) at the lower and upper surface become the same and can be readily obtained as follows:

$$F = F_1 = F_2 = \frac{m_d g}{R_1 + R_2}(u) + \frac{m_d g\left(R_1 \mu_1\left(\dot{u}_1\right)\mathrm{sgn}\left(\dot{u}_1\right) + R_2 \mu_2\left(\dot{u}_2\right)\mathrm{sgn}\left(\dot{u}_2\right)\right)}{R_1 + R_2} \tag{2}$$

where u is related to the total deformation of the double concave friction pendulum, u_1 to the deformation of the upper surface and u_2 to the lower one. The first part of the right hand side of Eq.s (2) represents the restoring stiffness (k_{comb}) of the combined DCFP from which the restoring natural period can be obtained as follows:

$$k_{comb} = \frac{m_d g}{R_1 + R_2} \tag{3}$$

$$T_d = 2\pi\sqrt{\left(R_1 + R_2\right)/g} \tag{4}$$

where g is the gravity constant, R_1 and R_2 are the radii of curvature of the DCFP.

In Eq.(2), $f_j\left(\dot{u}_j(t)\right)$ (j=*1,2*) is the coefficient of sliding friction, which depends on the slider slip velocity along one of the two bearing internal surfaces, indicated with $\dot{u}_j(t)$, and $\mathrm{sgn}\left(\dot{u}_j\right)$ (j=*1,2*) with *sgn*(·) denoting the sign function. Note that the subscript 1 refers to the upper surface whereas the subscript 2 refers to the lower surface. On the other hand, the second part of the Eq.s (2a,b), under the hypothesis that sliding occurs on both surfaces and in the same direction, represents the equivalent friction coefficient of the DCFP [18]:

$$\mu_{eqv} = \frac{\mu_1 R_1 + \mu_2 R_2}{R_1 + R_2} \tag{5}$$

In the above discussion, it is also assumed that the DCFP bearings used to isolate the deck and placed, respectively, on the pier and on the abutment have the same characteristics, so that it's obvious they move simultaneously.
Moreover, experimental results [14]-[16] suggest that, for each sliding surface, the coefficient of sliding friction of Teflon-steel interfaces obeys to the following equation:

$$\mu_j\left(\dot{u}_j\right) = \mu_{j,\max} - \left(\mu_{j,\max} - \mu_{j,\min}\right)\cdot\exp\left(-\alpha\left|\dot{u}_j\right|\right) \quad for \quad j = 1,2 \tag{6}$$

in which $\mu_{j,\max}$ represents the maximum value of friction coefficient attained at large velocities of sliding, and $\mu_{j,\min}$ represents the value at zero velocity. To further simplify the problem,

in the following analyses it is assumed that $\mu_{j,\max} = 3\mu_{j,\min}$ based on a regression of the experimental results, whereas the exponent α is assumed equal to 30 [14]-[16].

3 NON-DIMENSIONALIZATION OF THE EQUATIONS OF MOTION

In order to analyze the role of each characteristic parameter controlling the seismic behaviour of the system under investigation, the results obtained solving the equations of motion are reduced to a non-dimensional form as discussed in [26]-[28].
To easily obtain the deformation of the isolators along each sliding surface, Eq.(1) can be rewritten in terms of drifts between the masses of the system instead of displacement respect to the ground:

$$m_d\ddot{x}_7(t)+m_d\ddot{x}_6(t)+m_d\ddot{x}_{p5}(t)+m_d\ddot{x}_{p4}(t)+m_d\ddot{x}_{p3}(t)+m_d\ddot{x}_{p2}(t)+$$
$$+m_d\ddot{x}_{p1}(t)+c_d\dot{x}_d(t)+F_{1a}(t)+F_{1p}(t)=-m_d\ddot{u}_g(t)$$

$$m_{sp}\ddot{x}_6(t)+m_{sp}\ddot{x}_{p5}(t)+m_{sp}\ddot{x}_{p4}(t)+m_{sp}\ddot{x}_{p3}(t)+m_{sp}\ddot{x}_{p2}(t)+$$
$$+m_{sp}\ddot{x}_{p1}(t)-F_{1p}(t)+F_{2p}(t)=-m_{sp}\ddot{u}_g(t)$$

$$m_{sa}\ddot{x}_8(t)-F_{1a}(t)+F_{2a}(t)=-m_{sa}\ddot{u}_g(t)$$

$$m_{p5}\ddot{x}_{p5}(t)+m_{p5}\ddot{x}_{p4}(t)+m_{p5}\ddot{x}_{p3}(t)+m_{p5}\ddot{x}_{p2}(t)+m_{p5}\ddot{x}_{p1}(t)-c_d\dot{x}_d(t)+$$
$$+c_{p5}\dot{x}_{p5}(t)+k_{p5}x_{p5}(t)-F_{2p}(t)=-m_{p5}\ddot{u}_g(t)$$

$$m_{p4}\ddot{x}_{p4}(t)+m_{p4}\ddot{x}_{p3}(t)+m_{p4}\ddot{x}_{p2}(t)+m_{p4}\ddot{x}_{p1}(t)-c_{p5}\dot{x}_{p5}(t)-k_{p5}x_{p5}(t)+$$
$$+c_{p4}\dot{x}_{p4}(t)+k_{p4}x_{p4}(t)=-m_{p4}\ddot{u}_g(t)$$

$$m_{p3}\ddot{x}_{p3}(t)+m_{p3}\ddot{x}_{p2}(t)+m_{p3}\ddot{x}_{p1}(t)-c_{p4}\dot{x}_{p4}(t)-k_{p4}x_{p4}(t)+$$
$$+c_{p3}\dot{x}_{p3}(t)+k_{p3}x_{p3}(t)=-m_{p3}\ddot{u}_g(t) \qquad \text{(7a,b,c,d,e,f,g,h)}$$

$$m_{p2}\ddot{x}_{p2}(t)+m_{p2}\ddot{x}_{p1}(t)-c_{p3}\dot{x}_{p3}(t)-k_{p3}x_{p3}(t)+c_{p2}\dot{x}_{p2}(t)+k_{p2}x_{p2}(t)=-m_{p2}\ddot{u}_g(t)$$

$$m_{p1}\ddot{x}_{p1}(t)-c_{p2}\dot{x}_{p2}(t)-k_{p2}x_{p2}(t)+c_{p1}\dot{x}_{p1}(t)+k_{p1}x_{p1}(t)=-m_{p1}\ddot{u}_g(t)$$

where:

$$F_{1a}=\frac{m_d g}{2}\left[\frac{1}{R_{1a}}\left(\sum_{i=1}^{5}x_{pi}+x_6+x_7-x_8\right)+\mu_{1a}\left(\operatorname{sgn}\left(\sum_{i=1}^{5}\dot{x}_{pi}+\dot{x}_6+\dot{x}_7-\dot{x}_8\right)\right)\right]$$
$$F_{2a}=\left(\frac{m_d}{2}+m_{sa}\right)g\left[\frac{1}{R_{2a}}(x_8)+\left(\mu_{2a}(\dot{x}_8)\right)\left(\operatorname{sgn}(\dot{x}_8)\right)\right] \qquad \text{(8a,b,c,d)}$$
$$F_{1p}=\left(\frac{m_d g}{2}\right)\left[\frac{1}{R_{1p}}(x_7)+\left(\mu_{1p}(\dot{x}_7)\right)\left(\operatorname{sgn}(\dot{x}_7)\right)\right]$$
$$F_{2p}=\left(\frac{m_d}{2}+m_{sp}\right)g\left[\frac{1}{R_{2p}}(x_6)+\left(\mu_{2p}(\dot{x}_6)\right)\left(\operatorname{sgn}(\dot{x}_6)\right)\right]$$

After that, dividing all the equations by m_d , Eq.(7) applies:

$$\ddot{x}_7(t)+\ddot{x}_6(t)+\ddot{x}_{p5}(t)+\ddot{x}_{p4}(t)+\ddot{x}_{p3}(t)+\ddot{x}_{p2}(t)+\ddot{x}_{p1}(t)+2\xi_d\omega_d\dot{x}_d(t)+$$
$$+\frac{g}{2}\left[\frac{1}{R_{1a}}\left(\sum_{i=1}^{5}x_{pi}+x_6+x_7-x_8\right)+\mu_{1a}(v)\left(\operatorname{sgn}\left(\sum_{i=1}^{5}\dot{x}_{pi}+\dot{x}_6+\dot{x}_7-\dot{x}_8=v\right)\right)\right]+$$
$$+\frac{g}{2}\left[\frac{1}{R_{1p}}(x_7)+\left(\mu_{1p}(\dot{x}_7)\right)\left(\operatorname{sgn}(\dot{x}_7)\right)\right]=\ddot{u}_g(t)$$

$$\lambda_{sp}\left(\ddot{x}_6(t)+\ddot{x}_{p5}(t)+\ddot{x}_{p4}(t)+\ddot{x}_{p3}(t)+\ddot{x}_{p2}(t)+\ddot{x}_{p1}(t)\right)+$$
$$-\frac{g}{2}\left[\frac{1}{R_{1p}}(x_7)+\left(\mu_{1p}(\dot{x}_7)\right)\left(\operatorname{sgn}(\dot{x}_7)\right)\right]+\left(\frac{1}{2}+\lambda_{sp}\right)g\left[\frac{1}{R_{2p}}(x_6)+\left(\mu_{2p}(\dot{x}_6)\right)\left(\operatorname{sgn}(\dot{x}_6)\right)\right]=-\lambda_{sp}\ddot{u}_g(t)$$

and the following ratios are introduced:

$$\lambda_{pi}=\frac{m_{pi}}{m_d},\ \lambda_{sa}=\frac{m_{sa}}{m_d},\ \lambda_{sp}=\frac{m_{sp}}{m_d},$$
$$\omega_d=\sqrt{\frac{k_{comb}}{m_d}},\ \omega_{pi}=\sqrt{\frac{k_{pi}}{m_{pi}}},\ \xi_{pi}=\frac{c_{pi}}{2m_{pi}\omega_{pi}} \tag{10a,b,c,d,e,f}$$

where the first three terms are the mass ratios, the third and the fourth terms are the circular frequency of vibration of the isolated deck and of the *i*-th dof of the pier and the one denotes the damping factor of the *i*-th dof of the pier.

Inspired from [26]-[28], let us introduce the time scale $\tau=t\omega_d$ in which ω_d is the fundamental circular frequency of the isolated system with infinitely rigid superstructure, considering

the equivalent stiffness of the DCFP isolator k_{comb}, and the seismic intensity scale a_0, expressed as $\ddot{u}_g(t) = a_0 \ell(\tau)$ where $\ell(\tau)$ is a non-dimensional function of time describing the seismic input time-history, the following non-dimensional equations can be obtained:

$$\ddot{\psi}_7(\tau)+\ddot{\psi}_6(\tau)+\ddot{\psi}_{p5}(\tau)+\ddot{\psi}_{p4}(\tau)+\ddot{\psi}_{p3}(\tau)+\ddot{\psi}_{p2}(\tau)+\ddot{\psi}_{p1}(\tau)+2\xi_d\dot{\psi}_7(\tau)+\frac{g}{2}\left[\frac{1}{R_{1p}}\frac{1}{\omega_d^{\,2}}\psi_7(\tau)+\frac{\mu_{1p}(\dot{\psi}_7)}{a_0}\operatorname{sgn}(\dot{\psi}_7)\right]+$$
$$+\frac{g}{2}\left[\frac{1}{R_{1a}}\frac{1}{\omega_d^{\,2}}\left(\sum_{i=1}^{5}\psi_{pi}(\tau)+\psi_6(\tau)+\psi_7(\tau)-\psi_8(\tau)\right)+\right.$$
$$\left.+\left(\frac{\mu_{1a}}{a_0}\left(\sum_{i=1}^{5}\dot{\psi}_{pi}(t)+\dot{\psi}_6(\tau)+\dot{\psi}_7(\tau)-\dot{\psi}_8(\tau)\right)\right)\left(\operatorname{sgn}\left(\sum_{i=1}^{5}\dot{\psi}_{pi}(\tau)+\dot{\psi}_6(\tau)+\dot{\psi}_7(\tau)-\dot{\psi}_8(\tau)\right)\right)\right]=-\ell(\tau)$$

$$\lambda_{sp}\left[\ddot{\psi}_6(\tau)+\ddot{\psi}_{p5}(\tau)+\ddot{\psi}_{p4}(\tau)+\ddot{\psi}_{p3}(\tau)+\ddot{\psi}_{p2}(\tau)+\ddot{\psi}_{p1}(\tau)\right]-\frac{g}{2}\left[\frac{1}{R_{1p}}\frac{1}{\omega_d^{\,2}}\psi_7(\tau)+\frac{\mu_{1p}(\dot{\psi}_7)}{a_0}\operatorname{sgn}(\dot{\psi}_7)\right]+$$
$$+\left(\frac{1}{2}+\lambda_{sp}\right)g\left[\frac{1}{R_{2p}}\frac{1}{\omega_d^{\,2}}\psi_6(\tau)+\frac{\mu_{2p}(\dot{\psi}_6)}{a_0}\operatorname{sgn}(\dot{\psi}_6)\right]=-\lambda_{sp}\ell(\tau)$$

$$\left.+\left(\frac{\mu_{1a}}{a_0}\left(\sum_{i=1}^{5}\dot{\psi}_{pi}(t)+\dot{\psi}_6(\tau)+\dot{\psi}_7(\tau)-\dot{\psi}_8(\tau)\right)\right)\left(\operatorname{sgn}\left(\sum_{i=1}^{5}\dot{\psi}_{pi}(\tau)+\dot{\psi}_6(\tau)+\dot{\psi}_7(\tau)-\dot{\psi}_8(\tau)\right)\right)\right]+$$
$$\left(\frac{1}{2}+\lambda_{sa}\right)g\left[\frac{1}{R_{2a}}\frac{1}{\omega_d^{\,2}}\psi_8(\tau)+\frac{\mu_{2a}(\dot{\psi}_8)}{a_0}\operatorname{sgn}(\dot{\psi}_8)\right]=-\lambda_{sa}\ell(\tau)$$

$$\lambda_{p5}\left[\ddot{\psi}_{p5}(\tau)+\ddot{\psi}_{p4}(\tau)+\ddot{\psi}_{p3}(\tau)+\ddot{\psi}_{p2}(\tau)+\ddot{\psi}_{p1}(\tau)\right]-2\xi_d\dot{\psi}_d(\tau)+2\xi_{p5}\lambda_{p5}\frac{\omega_{p5}}{\omega_d}\dot{\psi}_{p5}(\tau)+\frac{\lambda_{p5}\omega_{p5}^2}{\omega_d^2}\psi_{p5}(\tau)+$$
$$-\left(\frac{1}{2}+\lambda_{sp}\right)g\left[\frac{1}{R_{2p}}\frac{1}{\omega_d^{\,2}}\psi_6(\tau)+\frac{\mu_{2p}(\dot{\psi}_6)}{a_0}\operatorname{sgn}(\dot{\psi}_6)\right]=-\lambda_{p5}\ell(\tau)$$

$$\lambda_{p4}\left[\ddot{\psi}_{p4}(\tau)+\ddot{\psi}_{p3}(\tau)+\ddot{\psi}_{p2}(\tau)+\ddot{\psi}_{p1}(\tau)\right]-2\xi_{p5}\lambda_{p5}\frac{\omega_{p5}}{\omega_d}\dot{\psi}_{p5}(\tau)+2\xi_{p4}\lambda_{p4}\frac{\omega_{p4}}{\omega_d}\dot{\psi}_{p4}(\tau)-\lambda_{p5}\frac{\omega_{p5}^2}{\omega_d^2}\psi_{p5}(\tau)+$$
$$+\lambda_{p4}\frac{\omega_{p4}^2}{\omega_d^2}\psi_{p4}(\tau)=-\lambda_{p4}\ell(\tau)$$

$$\lambda_{p3}\left[\ddot{\psi}_{p3}(\tau)+\ddot{\psi}_{p2}(\tau)+\ddot{\psi}_{p1}(\tau)\right]-2\xi_{p4}\lambda_{p4}\frac{\omega_{p4}}{\omega_d}\dot{\psi}_{p4}(\tau)+2\xi_{p3}\lambda_{p3}\frac{\omega_{p3}}{\omega_d}\dot{\psi}_{p3}(\tau)-\lambda_{p4}\frac{\omega_{p4}^2}{\omega_d^2}\psi_{p4}(\tau)+$$
$$+\lambda_{p3}\frac{\omega_{p3}^2}{\omega_d^2}\psi_{p3}(\tau)=-\lambda_{p3}\ell(\tau)$$

$$\lambda_{p2}\left[\ddot{\psi}_{p2}(\tau)+\ddot{\psi}_{p1}(\tau)\right]-2\xi_{p3}\lambda_{p3}\frac{\omega_{p3}}{\omega_d}\dot{\psi}_{p3}(\tau)+2\xi_{p2}\lambda_{p2}\frac{\omega_{p2}}{\omega_d}\dot{\psi}_{p2}(\tau)-\lambda_{p3}\frac{\omega_{p3}^2}{\omega_d^2}\psi_{p3}(\tau)+ \qquad \text{(11 a,b,c,d,e,f,g,h)}$$
$$+\lambda_{p2}\frac{\omega_{p2}^2}{\omega_d^2}\psi_{p2}(\tau)=-\lambda_{p2}\ell(\tau)$$

$$\lambda_{p1}\ddot{\psi}_{p1}(\tau)-2\xi_{p2}\lambda_{p2}\frac{\omega_{p2}}{\omega_d}\dot{\psi}_{p2}(\tau)+2\xi_{p1}\lambda_{p1}\frac{\omega_{p1}}{\omega_d}\dot{\psi}_{p1}(\tau)-\lambda_{p2}\frac{\omega_{p2}^2}{\omega_d^2}\psi_{p2}(\tau)+\lambda_{p1}\frac{\omega_{p1}^2}{\omega_d^2}\psi_{p1}(\tau)=-\lambda_{p1}\ell(\tau)$$

Furthermore, the following non-dimensional parameters that control the bridge system of Figure 1 have been adopted:

$$\Pi_{\omega i}=\frac{\omega_{pi}}{\omega_d},\ \Pi_{\lambda i}=\lambda_{pi}=\frac{m_{pi}}{m_d},\ \Pi_{\lambda sa}=\lambda_{sa},\ \Pi_{\lambda sp}=\lambda_{sp},$$
$$\Pi_{\mu a}\left(\dot{\psi}_d\right)=\frac{\mu_a\left(\dot{\psi}_d\right)g}{a_0},\quad \Pi_{\mu p}\left(\dot{\psi}_d\right)=\frac{\mu_p\left(\dot{\psi}_d\right)g}{a_0},\ \Pi_{\xi_{pi}}=\xi_{pi} \tag{12a,b,c,d,e,f,g}$$

$\Pi_{\lambda,}\,\Pi_{\lambda sa,}\,\Pi_{\lambda sp,}$ are the previously defined mass ratios, Π_{ξ_p} describes the viscous damping inherent respectively to the pier dof. Regarding the control parameters of the pier, indeed, the parameters ω_{pi} are related to the fundamental vibration pulsation ω_p (the first vibration mode) as well as the sum of the mass ratios is related to the overall mass ratio $\Pi_\lambda=\lambda_p=\frac{\sum_{i=1,5} m_{pi}}{m_d}$ and, finally, all the damping factors are assumed equal to $\Pi_{\xi_p}=\xi_p$.

The non-dimensional parameters $\Pi_{\mu a,}\,\Pi_{\mu p}$ measure the isolator strengths, provided by the friction coefficients of the two isolators, respectively. Since these parameters depend on the response through the velocities, the following parameters are used in their steads:

$$\Pi^*_{\mu a}=\frac{\mu_{\max,a}g}{a_0},\quad \Pi^*_{\mu p}=\frac{\mu_{\max,p}g}{a_0} \tag{13a,b}$$

It is important to observe that the normalized response of the dynamic system does not depend on the seismic intensity level a_0. Conversely, the seismic response depends also on the function $\lambda(\tau)$ and also on the isolation circular frequency ω_d (or period $T_d=2\pi/\omega_d$).

The non-dimensional response parameters that describe the dynamic response of the deck and of the *i*-th dof for the pier and the two sliders are, respectively:

$$\psi_{u_d}=\frac{u_{d,\text{peak}}\omega_d^2}{S_A(T_d)}\quad,\ \psi_{x_d}=\frac{x_{d,\text{peak}}\omega_d^2}{S_A(T_d)}=\frac{(x_6+x_7)_{\text{peak}}\omega_d^2}{S_A(T_d)},$$
$$\psi_{u_p}=\frac{u_{p,\text{peak}}\omega_d^2}{S_A(T_d)}=\frac{u_{p5,\text{peak}}\omega_d^2}{S_A(T_d)},\ \psi_{x_i}=\frac{x_{i,\text{peak}}\omega_d^2}{S_A(T_d)}\quad \text{with}\ i=1,\ldots,8 \tag{14a,b,c,d}$$

4 PARAMETRIC STUDY

This section presents the results of an extensive parametric study carried out on the bridge system of Fig. 1 to evaluate the performance of bridges isolated with DCFP bearings.

Seismic input description

The evaluation of the seismic performance of any engineered systems should account for the variability of the intensity, frequency content, and duration of the records at the site. Coherently with the performance-based earthquake engineering (PBEE) approach [29]-[30], this study separates the uncertainties related to the seismic input intensity from those related to the characteristics of the record (record-to-record variability) by introducing a scale factor, a_0, i.e. an intensity measure (*IM)*. By this way, the randomness in the seismic intensity can be described by a hazard curve, whereas the ground motion randomness for a fixed intensity level

can be described by selecting a set of ground motion realizations characterized by a different duration and frequency content, and by scaling these records to the common a_0 value. In line with the criteria of efficiency, sufficiency, and hazard computability [34]-[35], in this study, the spectral pseudo-acceleration, $S_A(T_d)$, at the isolated period of the system, $T_d = 2\pi / \omega_d$, is assumed as intensity measure. This *IM* is related to the spectral displacement S_d by the relation $S_A(T_d) = \omega_d^2 S_d(T_d)$. Many studies (e.g., [34]-[35]) demonstrated that S_A is more efficient than the peak ground acceleration, and its use permits to reduce the response dispersion for the same number of ground motion considered and to obtain more confident response estimates for a given number of records employed.

Table 1. Selected ground motions for time history analysis.

In this specific study, the choice of $S_A(T_d)$ as *IM* is motivated by the fact that if all the records are normalized to $S_A(T_d)$, then the normalized displacement response of a system with

period T_d, rigid superstructure and mounted on a frictionless isolator is equal to 1 for each record and it is not affected by the record-to-record variability. Thus, this system can be assumed as reference case for evaluating the influence of the isolator friction and of the isolation period on the response statistics. The record-to-record variability is described through a set of 30 real ground motion records reported in Table 1.

Seismic performance description

This study considers the following set of response parameters relevant to the performance of the isolated system (Eq. (10)): the peak isolator deformation between the two devices $u_{d,\max}$ and $x_{d,\max}$, the peak displacement of pier's top relative to the ground $u_{p,\max}$ and the peak relative displacement along the pier $x_{pi,\max}$. These parameters have be expressed in non-dimensional form according to Eq.s (11) and (13).
By repeatedly solving Eqn. (9) for the ground motions records reported in Table 1, a set of samples is obtained for each output variable used to monitor the seismic performance.
In this paper, the response parameters are assumed to follow a lognormal distribution as widely employed in PBEE [29]-[30] and in many parametric studies concerning the performance of structural systems also since the log-normality assumption permits to estimate, with a limited number of samples, the response at different percentile levels, which is very useful for system reliability assessment [25],[31]-[41].
A lognormal distribution can be fitted to the generic response parameter *D* (i.e., the extreme values $\psi_{u_d}, \psi_{x_d}, \psi_{u_p}$, ψ_{x_i} of Eq.s (11) and (12) by estimating the sample geometric mean, $GM\left(D\right)$, and the sample dispersion, $\beta\left(D\right)$, defined as follows:

$$GM\left(D\right) = \sqrt[N]{d_1 \cdot \ldots \cdot d_N} \tag{15}$$

$$\beta\left(D\right) = \sigma_{\ln}\left(D\right) = \sqrt{\frac{\left(\ln d_1 - \ln\left[GM\left(D\right)\right]\right)^2 + \ldots\ldots + \left(\ln d_N - \ln\left[GM\left(D\right)\right]\right)^2}{N-1}} \tag{16}$$

where d_i denotes the *i*-th sample value of *D*, and *N* is the total number of samples. The sample geometric mean is an estimator of the median of the response and its logarithm coincides with the lognormal sample mean $\mu_{\ln}\left(D\right)$ [26].

Parametric study results

This section shows the results of the parametric study carried out to evaluate the relation between the isolation and bridge properties and the system performance, for the reference seismic input described through the ground motion records of Table 1.
Note that any model uncertainty is considered in the numerical analyses [43]-[45]. The configuration of Table 2 has been used for the DCFP bearings properties.
The two DCFP devices on the abutment and on the pier are identical. So, it follows that $\Pi^*_{\mu a} = \Pi^*_{\mu p} = \Pi^*_{\mu}$ as well as $\Pi_{\lambda sa} = \Pi_{\lambda sp} = \Pi_{\lambda s}$. The parameter $\Pi_{\xi_p} = \xi_p$ is assumed equal to 5%, the isolated bridge period T_d is varied in the range between 2s, 2.5s, 3s, 3.5s and 4s, the pier period T_p in the range between 0.05s, 0.1s, 0.15s and 0.2s. Assuming that each of the pier masses are equal, $\Pi_{\lambda} = \lambda_p$ has been considered varying in the range between 0.1, 0.15 and 0.2, Π^*_{μ} in the range between 0 (no friction) and 2 (very high friction). For numerical reasons, the

ratio $\Pi_{\lambda s}$ is assumed equal to 0.005. Therefore, numerical investigations have been carried out on several different systems by varying the main dynamic parameters and for two different DCFP bearing configurations for 30 different time history seismic input.
For each value of the parameters of interest in the parametric study, the differential equation of motion, i.e., Eqn. (9), has been repeatedly solved for the different ground motion considered. The Bogacki-Shampine integration algorithm available in Matlab-Simulink [42] has been employed choosing a variable step to improve the solution accuracy. The probabilistic properties of the normalized response have been evaluated by estimating the geometric mean, *GM*, and the dispersion, β, of the parameters of interest through Eqns. (15) and (16).

Table 2. DCFP bearings properties within the parametric analysis.

Figs. 2-5 show the statistics (*GM* and β values) of the response parameters considered, obtained for different values of the system parameters varying in the range of interest. Each figure contains three surface plots, corresponding to different values of Π_λ. Only the results corresponding to T_p= 0.1s and T_p= 0.2s are illustrated.

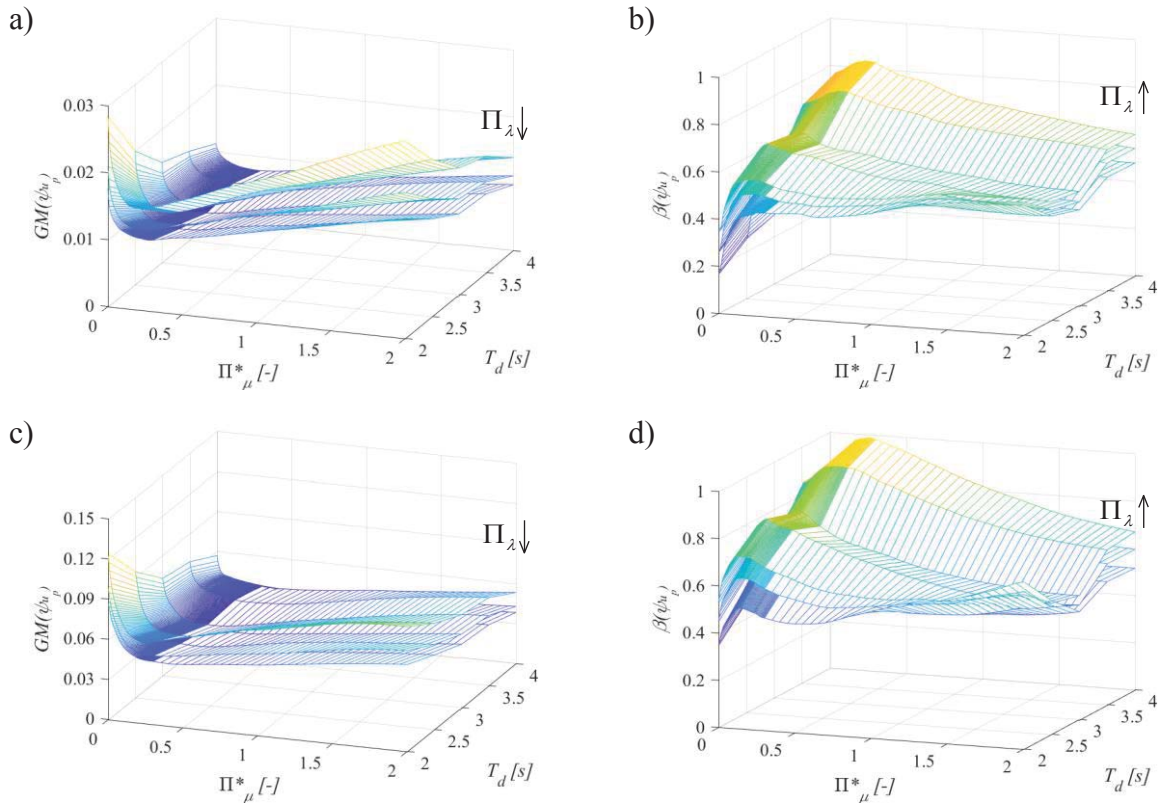

Figure 2. Normalized displacement of pier top vs. Π^*_μ and T_d: median value and dispersion for T_p = 0.1s (a and b) and T_p = 0.2s (c and d) for different values of Π_λ. The arrow denotes the increasing direction of Π_λ.

Fig. 2 plots the results concerning the normalized displacement of pier top ψ_{u_p} with respect to the ground. It is noteworthy that for very low Π_μ^* values, $GM\left(\psi_{u_p}\right)$ decreases by increasing Π_μ^*, whereas for high Π_μ^* values it increases by increasing Π_μ^*. Thus, there exists an optimal value of Π_μ^* such that the displacement of pier top is minimized. This critical value is in the range between 0 and 0.5 depending on the values of T_d, T_p and Π_λ. In addition to that, $GM\left(\psi_{u_p}\right)$ decreases significantly with increasing Π_λ and decreasing T_p, which control directly the main modal period of the pier (for higher ω_d^2, smaller will be the displacement of the pier top). T_d has an influence on $GM\left(\psi_{u_p}\right)$ leading to a general decrease for its increase. The dispersion $\beta\left(\psi_{u_p}\right)$ shows a maximum value approximatively at the same value of Π_μ^* that gives the minimum value of $GM\left(\psi_{u_p}\right)$. The response dispersion increases with increasing vibration period T_p and mass ratio Π_λ. From low to high values of T_d, the dispersion $\beta\left(\psi_{u_p}\right)$ tends to increase.

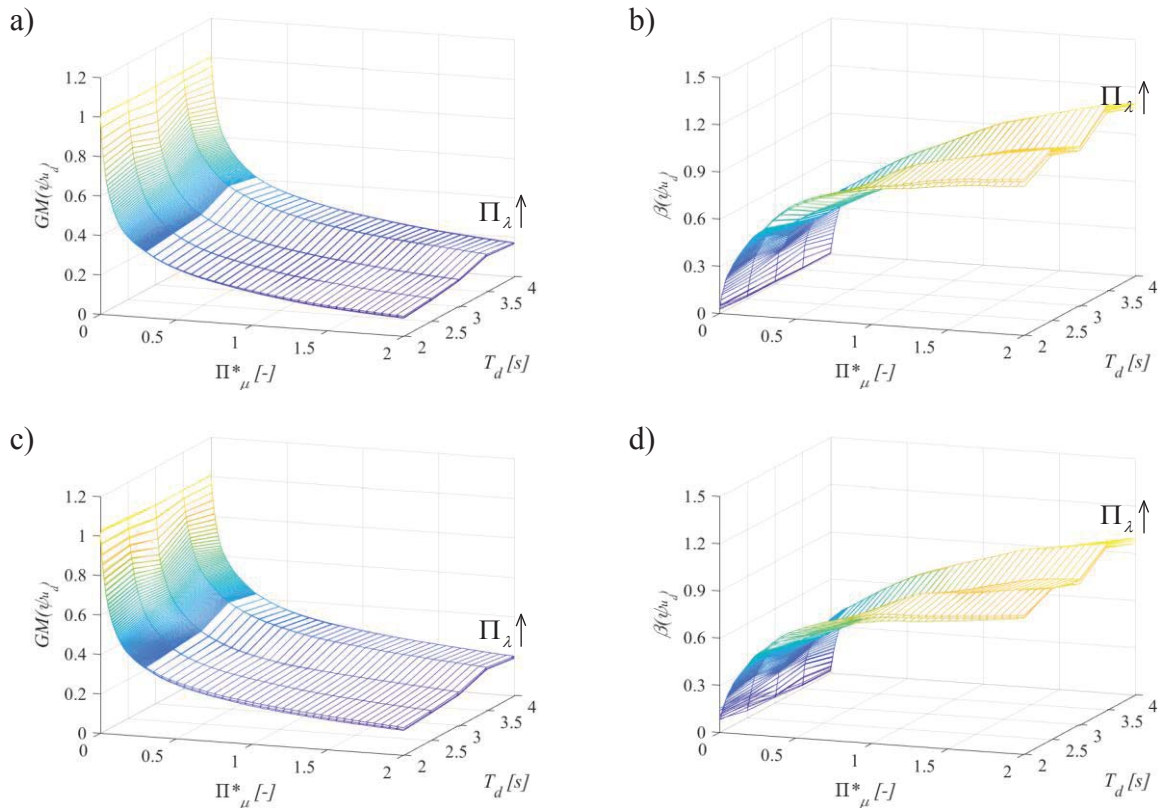

Figure 3. Normalized deck displacement vs. Π^*_μ and T_d: median value and dispersion T_p = 0.1s (a and b) and T_p = 0.2s (c and d) for different values of Π_γ. The arrow denotes the increasing direction of Π_γ.

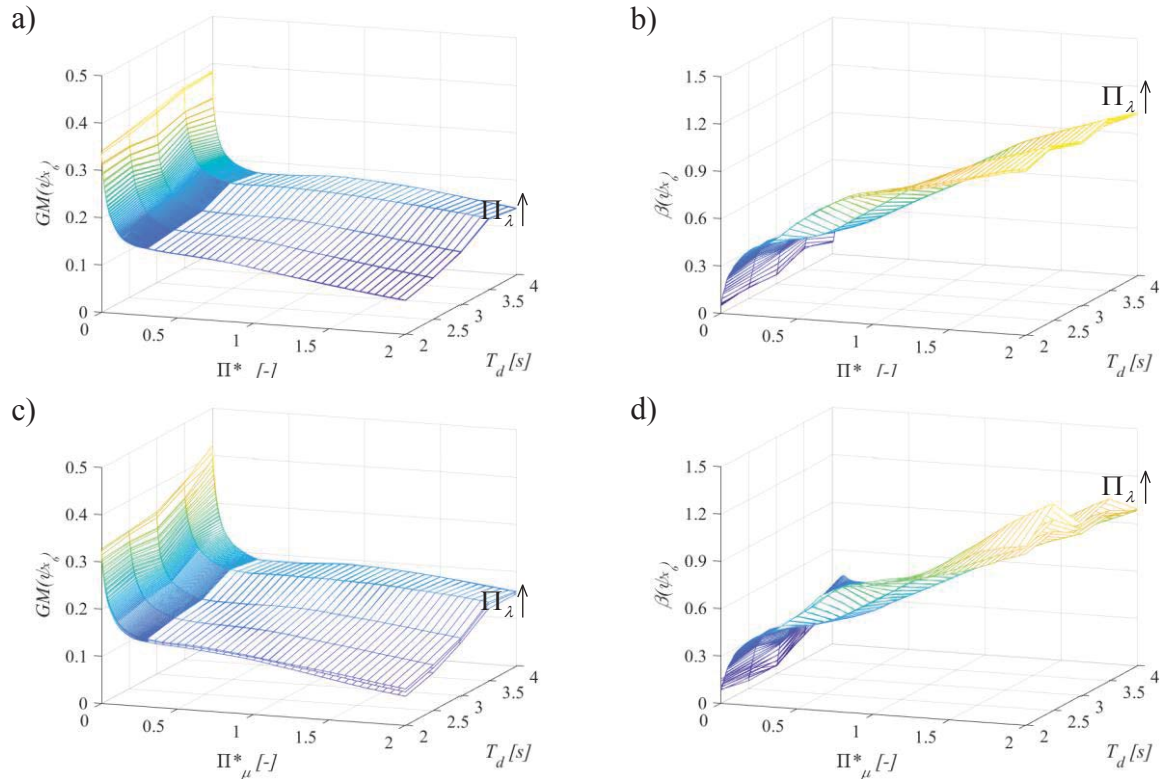

Figure 4. Normalized pier bearing deformation along the lower surface vs. Π^*_μ and T_d: median value and dispersion for T_p = 0.1s (a and b) and T_p = 0.2s (c and d) for different values of Π_λ. The arrow denotes the increasing direction of Π_λ.

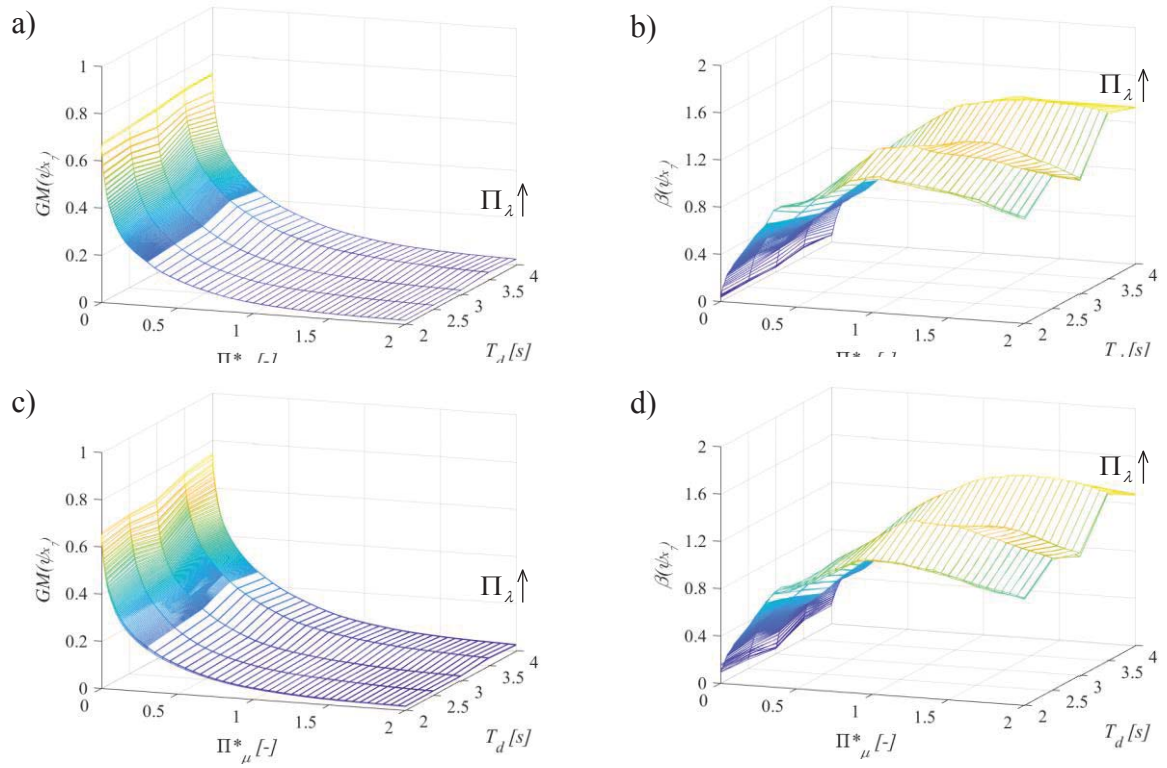

Figure 5. Normalized pier bearing deformation along the upper surface vs. Π^*_μ and T_d: median value and dispersion for T_p = 0.1s (a and b) and T_p = 0.2s (c and d) for different values of Π_λ. The arrow denotes the increasing direction of Π_λ.

Fig. 3 (a,c) shows the response statistics of the normalized deck displacement ψ_{u_d}, which corresponds to the overall deformation of the bearing placed on the abutment, since this latter is the peak value with respect to the displacement relative to the pier top of the other device due to the flexibility of the pier. Obviously, $GM\left(\psi_{u_d}\right)$ decreases significantly as Π^*_μ increases. In general, the values of $GM\left(\psi_{u_d}\right)$ increase slightly for increasing values of T_d and of Π_λ, and they are not affected significantly by T_p. The values of the dispersion $\beta\left(\psi_{u_d}\right)$, plotted in Figs. 3(b,d), are very low for low Π^*_μ values due to the high efficiency of the *IM* employed in the study, and attain their peak for high values of Π^*_μ. The other system parameters have a reduced influence on $\beta\left(\psi_{u_d}\right)$ compared to the influence of Π^*_μ.

Fig. 4(a) and (c) show the variation with the system parameters of the geometric mean of the normalized pier bearing deformation along the lower surface $GM(\psi_{x_6})$, for T_p=0.1s and T_p=0.2s. This parameter decreases at first quickly, and then slightly increases after values of Π^*_μ close to 0.5, reaching a maximum for Π^*_μ close to 1. The values of the dispersion $\beta\left(\psi_{x_6}\right)$, plotted in Figs. 4 (b,d), are very low for low Π^*_μ values, and increase monotonically with Π^*_μ. The other system parameters have a negligible influence on $\beta\left(\psi_{x_6}\right)$ compared to the influence of Π^*_μ.

Fig. 5(a) and (c) show the variation with the system parameters of the geometric mean of the normalized pier bearing deformation along the upper surface $GM(\psi_{x_7})$, for T_p = 0.1s and T_p = 0.2s. This parameter decreases hyperbolically with increasing Π^*_μ. The values of the dispersion $\beta\left(\psi_{x_7}\right)$, plotted in Figs. 5(b,d), are very low for low Π^*_μ values, and show a maximum for $\Pi^*_\mu \approx 1$, reaching very high values close to 1.5. Once again, the other system parameters have a no significant influence on $\beta\left(\psi_{x_7}\right)$ compared to the influence of Π^*_μ.

These last figures demonstrate the highest influence of the upper surface, characterized by higher values of the sliding friction coefficient and of the radius of curvature to define the global response of the seismic DCFP device as shown by the both statistic in Fig. 3. In fact, it is the upper surface that plays a crucial role for high intensity to elongate the isolated period and to dissipate more energy.

5 OPTIMAL VALUES

The existence of an optimal value of the friction coefficient able to minimize the displacement of pier top is the result of counteracting effects that occur for increasing values of the friction coefficient as already highlighted in [23]: increase of the isolator strength with increase of the equivalent stiffness and with a reduction of the corresponding equivalent fundamental vibration period; increase of participation of higher vibration modes as well as transfer of forces towards the superstructure; increase of energy dissipation (equivalent damping).

Fig. 6 reports the variation of $\Pi^*_{\mu,optimum}$ with Π_λ and T_p for T_d = 2s (Fig. 6 a) and T_d = 3s (Fig. 6 b) obtained by considering the minimization of the median (i.e., 50th percentile) of the normalized displacement of pier top ψ_{u_p} in the range of Π^*_μ between 0 and 0.5. It is ob-

served that $\Pi^*_{\mu,optimum}$ generally increases along with Π_λ, T_p and T_d. According to Eqn. (13), the optimal friction coefficient of the upper surface can be easily calculated as $f_{1,\max,opt} = \frac{\Pi^*_{\mu,opt} \cdot S_A(T_d)}{g}$ and of lower surface since the ratio is assumed equal to 4 (Table 2). Thus, it increases linearly with the *IM* level.

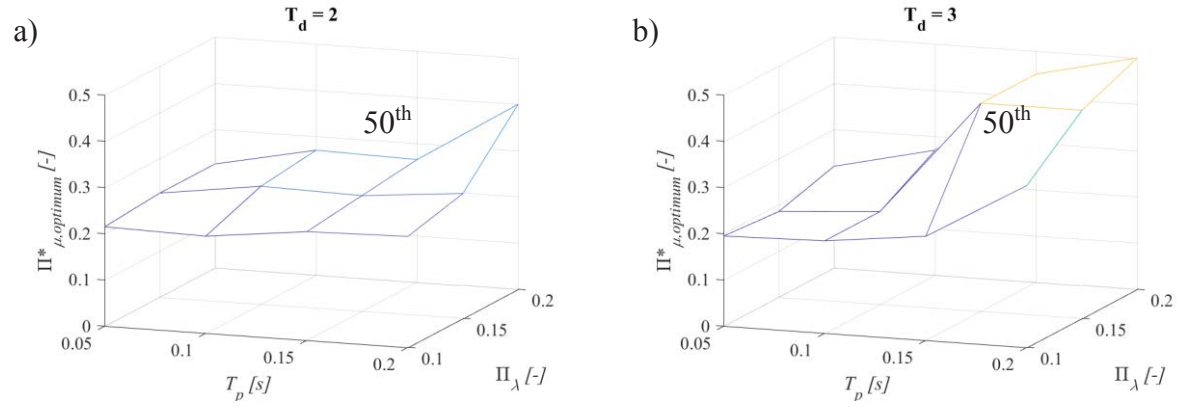

Figure 6. Critical values of normalized friction vs. Π_λ and T_p for T_d =2s (a) and T_d =3s (b).

6 CONCLUSIONS

This paper investigates the seismic performance of bridges isolated with double concave friction pendulum (DCFP) isolators considering the pier-abutment-deck interaction. They are illustrated the results of a parametric study for different isolator and bridge properties and various response parameters that are of interest for monitoring the seismic behavior. The behavior of these systems is analyzed by employing an eight-degree-of-freedom model accounting for the pier flexibility.

An ensemble of ground motions is considered to simulate the record-to-record variability effects, and a nondimensionalization of the results of the equation of motion is proposed to unveil the parameters controlling the problem.

The influence of dynamic and DCFP system properties are evaluated by considering the geometric mean (GM) and dispersion of each normalised response parameter, assumed to follow a lognormal distribution.

The results demonstrate that the increase of the normalized friction coefficient leads to a decrease of the deck response whereas the normalized response of the pier presents a particular trend showing the existence of an optimal value able to minimize this curve. The value of the optimal non-normalised friction coefficient depends on the structural properties. Specifically higher values are required for high pier period combined to high isolated deck period.

Abstract. *This paper deals with the dynamic characterization of a cable-stayed steel-concrete composite bridge located on the Saline river, close to Pescara in central Italy, carried out during the static proof load test. The bridge is 189 m long and is composed by 4 inclined steel pipe pylons that sustain a steel-concrete composite deck by means of 40 stay cables. During the proof test, an extensive experimental campaign is carried out to check the overall structural performance before the bridge openings to traffic. In detail, the main girder deflections, the axial loads on strands, the pylons displacements, and the bearings displacements were monitored through conventional and non-conventional techniques, such as the laser scanner technique. In addition, an accelerometer array is installed during the proof test to evaluate the dynamic characteristics of the structure in its loaded and unloaded conditions through ambient vibration measurements. Sensors are positioned on the deck, on two pylons and on the foundation system, in order to characterize the whole structural dynamic behavior, including the contribution of the soil-foundation compliance. With reference to the unloaded bridge, the latter issue is analyzed in this paper, focusing on the different restraint condition exerted by the soil-foundation system of the pylons, because of the different embedment of the reinforced concrete basements. It is shown that the soil-foundation compliance has greater effects on higher modes for the bridge at hand and that possible non-symmetries due to the different foundation degree of restraint can be suitably captured through ambient vibration tests. Data from experimental tests are crucial not only to check consistency between the design and the real structure before the opening to traffic, but also to calibrate refined finite element models to be used for the structural health monitoring of the bridge. In this sense, a reliable evaluation of the contribution of the soil-foundation system is mandatory, considering that the bridge, having foundations located in the riverbed, is prone to the scour hazard.*

1 INTRODUCTION

System modal identification and structural health monitoring of structures have recently drawn attention within the civil engineering community for developing real time assessment tools and for reducing uncertainties in the design and modelling of structures. In these fields, the estimation of structural dynamic properties through ambient vibration measurements play an important role since such tests are fast and easy to perform [1]. In the case of bridges, ambient vibration tests are usually performed focusing the attention of the deck accelerations, by positioning sensors over the superstructure in correspondence of piers and at midspans [2-3]. This approach generally allows a satisfactory identification of resonance frequencies but provides inaccurate information about mode shapes since displacements at the deck level may be due to both the pier deflection, the bearing compliance (which may be important in the case of isolated bridges) and the deformability of the soil-foundation system [4-6]. The latter, depending on the geotechnical context, may be relevant especially in case of scour phenomena.

This paper deals with the dynamic monitoring of a cable-stayed steel bridge performed during the proof load tests required for the bridge opening to traffic. Firstly, the overall experimental campaign scheduled during the proof load test is described, then results of the performed dynamic tests are presented. The bridge dynamic identification, achieved through ambient vibration tests performed on the unloaded bridge, is presented and results are shown in terms of modal parameters. The latter are compared with those obtained with numerical model developed for design purposes.

Finally, the contribution of the soil-foundation compliance on the bridge dynamics is investigated extending ambient measurements to the foundation system.

2 THE "FILOMENA DELLI CASTELLI" BRIDGE

The "Filomena Delli Castelli" bridge is a 189 m long cable-stayed steel-concrete composite bridge newly built over the Saline river in Pescara, central Italy (Fig. 1), which allows road and cycle-pedestrian connections between the Municipalities of Montesilvano and Città Sant'Angelo.

The bridge has 3 spans of length 42.6, 103.4 e 42.6 m and is composed by a twin girder directly supporting cross-beam composite deck, supported by 40 stay cables anchored in semi-fan system to two pylons made with concrete filled steel tubes. All the stay cables, composed by up to 37 seven-wire parallel-strands with an extruded HDPE sheath, are anchored to the upper flange of the main girders, excepting the four external ones, which are fixed to the concrete abutments to limit displacements of pylons. One strand of each stay is equipped with a load cell. The deck has variable width from 19.2 to 22.8 m, which includes a cycle-pedestrian path on the downstream side, and is composed by two 14.1 m spaced and 1.2 m high I shaped girders, and 4.5 m spaced cross-beams with cantilevers, both supporting a 25 cm thick concrete slab.

Each pylon has two inclined steel tubes of different height and diameter 1.9 m, filled with concrete in the lower part (16 m) and connected by a box steel cross-beam under the deck level; pylons on the upstream side are 34 m high, while those on the downstream side are 37 m high. Each pylon is fixed over a conical trunk shape r.c. basement by means of Dywidag steel anchor bolts and supported by a piled raft foundation. The upstream and downstream pylon foundations are connected to each other through a r.c. tie beam. The seismic protection of the bridge is achieved through Lead Rubber Bearings (LRB) located at the 2 pylon cross-beams in the middle position. The remaining support devices are multidirectional negative load pot bearings.

3 EXPERIMENTAL PROGRAMME

The final proof test of the bridge was executed in October 2019; 12 fully loaded trucks were used, and two load configurations were considered to get the design bending moments at Serviceability Limit State in the most stressed cross-sections of the deck. The load test allows comparison between theoretical displacements (obtained from the design numerical model) and the experimental ones and the evaluation of the residual deflection of the deck after load removal. Moreover, dynamic tests were executed to compare numerical and experimental modal parameters of the bridge at both unloaded and loaded conditions.

The following response parameters were monitored during the different phases of the load tests to evaluate the overall static and dynamic behavior of the bridge:
i) deflections of the main girders, through a topographic measurement station;
ii) axial load of strands, through load cells;
iii) deck and pylons displacements through a Laser Scanner (LS) technology;
iv) horizontal displacements of some support devices, through centesimal comparators;
v) tracking of the modal parameters (frequencies, damping ratios and mode shapes) of the bridge during test, through Ambient Vibration Tests (AVTs);
vi) resonant frequencies from impact tests (obtained by a truck passing over an artificial bump);
vii) resonant frequencies of a typical truck to exclude possible bridge-truck interactions;
viii) continuous measurement of the air temperature and the temperature of the road pavement.

This paper addresses results of the dynamic identification of the overall structure at unloaded conditions, focusing on the contribution of the soil-foundation compliance on the interpretation of the bridge dynamics.

4 DYNAMIC IDENTIFICATION OF THE OVERALL BRIDGE

The bridge dynamic identification is obtained through AVTs performed before the proof load test. The vibrations are due to environment effects, i.e. microtremors, wind, river waves, and anthropic activities, i.e. car and train traffic close to the structure. The latter are measured through low noise uniaxial piezoelectric accelerometers, connected to a data acquisition system by means of coaxial cables. A laptop equipped with a LabVIEW [7] software is used to control and store the data. Sensors are located on the structure according to the arrangement

shown in Fig. 2. As for the superstructure (Fig. 2a), 15 accelerometers are placed on the deck in 5 representative cross sections to identify the bending, transverse and torsional deck modes while 4 accelerometers are positioned on the downstream pylons (2 at each pylon) to measure the longitudinal and transverse accelerations and to capture their contribution on the overall vibration modes of the bridge.

Additionally, 10 sensors are located on the conical r.c. basements of the two downstream side pylons (Fig. 2b): for each basement, 3 sensors are oriented to measure the vertical accelerations in order to identify the foundation rocking, while the remaining 2 sensors are oriented to measure the transverse and longitudinal accelerations, respectively, to capture the translational components of the motion. During the test, 30 minutes long records with 2048 Hz frequency sampling rate are acquired. This time length provides enough data to obtain modal parameters with a good accuracy, as reported in [8], where a length of the acquired time window of about 1000-2000 times the period of the fundamental mode is recommended. In AVTs the input is neither controlled nor known, and it is assumed to have a flat spectrum such as a white noise; therefore, to identify the bridge modal parameters the output-only technique working in the time domain called Covariance-driven Stochastic Subspace Identification (SSI-COV) [9] is used.

The data post-processing provides the natural frequencies, damping ratios and mode shapes of the investigated structure; in detail, Fig. 3 shows the first 6 bridge vibration modes together with the relevant resonant frequency and damping ratio of the bridge at unloaded conditions. The first three modes represent the first bending, the first torsional and the second bending mode of the deck, respectively; the fourth and fifth modes are both typical of the second deck torsional mode, however, mode shapes are also characterized by a significant bending of the edge spans that, in turn, governs the response of the lateral spans more than the torsion. Finally, the sixth mode is the typical third bending deck mode.

Fig. 4 shows the stabilization diagram through which modes have been identified; in detail, a mode is assumed to be stable if the frequency variation Δf, the damping ratio variation $\Delta\xi$ and the Modal Assurance Criterion (MAC) between two subsequent model order are less than 1 and 2% for Δf and $\Delta\xi$, respectively, and higher than 99% for the MAC. The first Singular Value (SV) line is also reported for completeness.

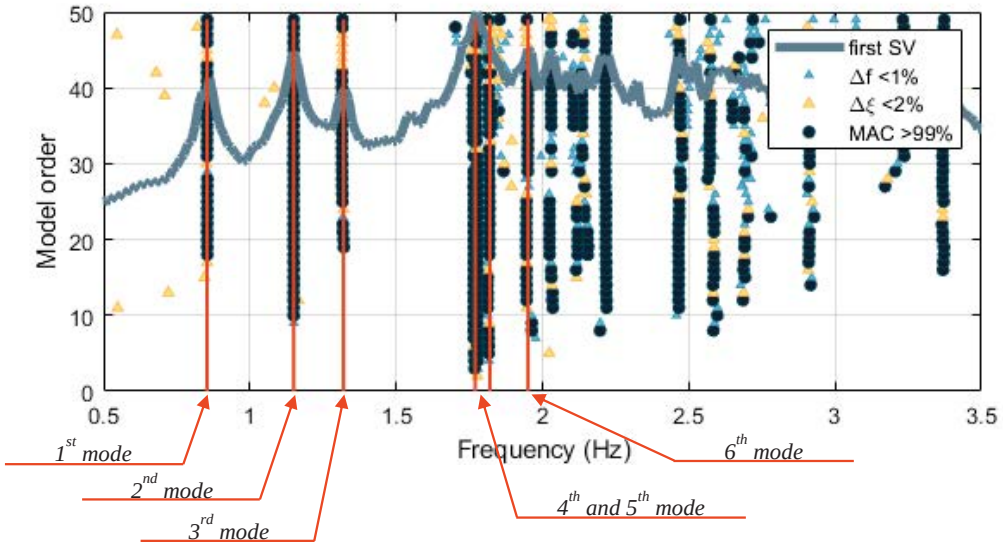

Figure 4: Stabilization diagram.

5 COMPARISON BETWEEN EXPERIMENTAL AND NUMERICAL RESULTS

The experimental modal parameters obtained from AVTs are compared with the numerical ones achieved from the finite element (f.e.) model of the whole bridge developed for design purposes (Fig. 5). All the structural components are modelled as frame elements and the concrete deck slab is included considering the relevant effective widths above the steel members (both girders and cross-beams). The model, which was adopted for the design of the superstructure, neglects the foundation system, and the pylons are clamped at the base. The two girders are supported by multidirectional supports and links simulating the dissipative devices, consistently with the real restraint scheme of the bridge. An eigenvalue analysis is performed, and the first four numerical natural frequencies obtained are listed in Tab. 1 together with the experimental ones previously described. As can be seen, the numerical model provides natural frequency values lower than the experimental ones (from 9% for the 1st mode to around 30% for the 4th mode) meaning that the global stiffness of the real structure is higher than the expected one, as usually expected from the outcomes of proof static and dynamic load tests. In particular, the torsional stiffness of the real deck is higher than the one captured by the model, which foresees the use of beam element. Indeed, for a more reliable prediction of the contribution of the warping torsion, a more accurate model should be developed adopting shell elements for the steel members.

To compare the mode shapes, the Modal Assurance Criterion (MAC) index is calculated and reported in Fig. 6. It can be observed that the first four numerical mode shapes are very similar to the first four experimental ones, as can be deduced from the matrix diagonal entry values which are close to 100% (MAC = 100% perfect matching, MAC = 0% no matching). However, although numerical and experimental mode shapes are very similar, the experimental and numerical frequency values are not very close. Accordingly, a bridge f.e. model refinement and calibration is suggested to obtain a numerical model able to accurately capture the dynamic behavior of the real bridge not only in terms of mode shapes but also of natural frequency values; this could be useful, for example, as starting point for a Structural Health Monitoring (SHM) system. Research is moving in this direction.

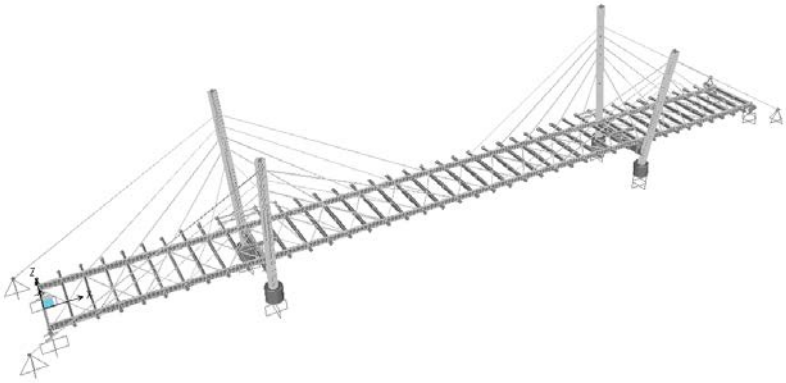

Figure 5: Design f.e. model of the bridge (concrete slab excluded from the view).

Mode	Frequency [Hz]	
	Numerical	Experimental
1st	0.77	0.85
2nd	0.96	1.15
3rd	0.88	1.31
4th	1.47	1.77

6 INVESTIGATION OF THE FOUNDATION DEFORMABILITY

In order to provide useful information for the model refinement and calibration, the contribution of the soil-foundation deformability on the overall bridge dynamics is investigated, extending measurements of vibrations to the foundation basements. As previously stated, pylons are fixed on conical r.c. basements founded on piled raft foundations, which have the same geometry (Fig. 7a).

However, during the execution of the AVTs, the basements were differently embedded in the soil, as can be observed in Fig. 7b from which it is evident that one of the pylon foundations is located within the riverbed. The different foundation embedment can provide different restraint conditions to the basements, as will be analyzed and discussed in this section. In order to verify this assumption, the modal displacements obtained from accelerometers placed on the pylons are analyzed.

A first clue to the fact that the restraint conditions of south pylons may be different is provided by the absolute values of the pylons modal displacements shown in Tab. 2. Indeed, it can be observed that displacements relevant to pylon P1 (with a lower basement embedment) are greater than those relevant to pylon P2, indicating an overall higher deformability of the element. For modes 1, 2 and 6, which are supposed to be symmetric according to the structural geometry, the average modal displacements evaluated experimentally at P1 are about 37% higher than those at P2 in the longitudinal direction (data of P#-L) and about 92% in the transverse direction (data of P#-T). Previous percentages are largely dominated by the contribution of the 6th mode for which an evident larger deformability of the south edge span is evident in Fig. 3.

The soil-foundation compliance is further investigated through the analysis of signals recorded by sensors located at the foundation basements. Fig. 8 shows the Power Spectral Density (PSD) of the sensors together with the first SV line obtained from sensors located on the deck; the superposition of data is useful to address the significance of the soil-foundation compliance on the identified resonance frequencies and mode shapes. Unfortunately, some signals are very noisy (DL, D2Z, D3Z) so that a complete and reliable evaluation of modal displacements at the foundation level is difficult to be obtained.

However, some interesting considerations can be done. Firstly, as expected, the soil foundation compliance produces greater effects on higher modes as demonstrated by high peaks in the PSD of signals registered at the foundation basements that locate mainly in correspondence of the 4th, 5th and 6th modes of the bridge. Furthermore, data confirm the hypothesis of the larger deformability of the soil-foundation system P1 with respect to P2; indeed, accelerations registered at the foundation of P1 are sensibly higher than those registered at the foundation of P2.

Accelerometer (Fig. 2)	Modal displacement					
	Mode 1	Mode 2	Mode 3	Mode 4	Mode 5	Mode 6
P1-L	0.229	0.090	0.379	0.111	0.105	0.264

7 CONCLUSIONS

The dynamic characterization of a cable-stayed steel-concrete composite bridge in central Italy carried out during the static proof load test has been presented in this paper. The bridge is 189 m long and is composed by 4 inclined steel pipe pylons that sustain a steel-concrete composite deck by means of 40 stay cables. Sensors have been installed on the deck, on two pylons and on the foundation system, in order to characterize the whole structural dynamic behavior, including the contribution of the soil-foundation compliance. With reference to the unloaded bridge, the latter issue has been analyzed focusing on the different restraint condition exerted by the soil-foundation system of the pylons, because of the different embedment of the reinforced concrete basement.

Although some signals acquired at the foundations resulted to be very noisy, making it difficult to obtain a reliable and complete evaluation of the effects of the soil-foundation compliance on mode shapes, important considerations arise from the signal analyses, which may be crucial to calibrate refined f.e. models for the SHM of the bridge at hand. Finally, ambient vibration tests extended to foundations revealed capable to capture and to monitor the soil-foundation system compliance, which may be important for bridges subjected to pier scour hazard.

Keywords: Structural control, inertial vibration controllers, lightweight structures, human-structure interaction.

Abstract. *The increasing use of lightweight materials in construction, such as fiber reinforced polymer (FRP) composites or aluminum, together with rising architectural tendencies towards slender and stunning layouts are enabling to dramatically decrease the weight of contemporary structures. This fact involves a positive reduction of the structural carbon footprint, but it poses a challenge to complying with vibration serviceability limit state (VSLS) under human-induced loading. Indeed, ultra-lightweight structures (with relatively low inherent mass and damping) may undergo vertical vibration in a broader frequency band than those built in the past and be prone to human-structure interaction (HSI), which should be considered when assessing VSLS of these structures.*

Instead of adding structural mass or performing expensive structural stiffening to rectify the vibration problem, the integration of smart damping strategies could be an optimum solution that has additional benefits of preserving lightweight nature of these structures. This paper presents a case study of vibration control of an ultra-lightweight FRP truss footbridge. This work investigates the influence of three types of inertial mass controllers (passive, semi-active and active) on the vibration control of the bridge in the presence, as well as in the absence, of HSI. It was found that active vibration control was the less deteriorated when considering HSI in comparison with passive and semi-active control strategies.

1 INTRODUCTION

The contemporary structural design framework is evolving towards a state of greater creative freedom. Nowadays, designers can make use of a wide variety of tools in order to satisfy the increasingly demanding requirements for new structures. The use of lightweight materials such as fiber reinforced polymers (FRP) or aluminium, have enabled development of "minimum weight" structures. Sizing of structures types with moderate strength demands and strict vibration serviceability requirements (e.g. footbridges and composite floor systems) is now governed by vibration criteria rather than ultimate limit state [1]. However, substantial reduction of structural self-weigh, is to be achieved, requires integration of vibration control measures in the design stage in order to satisfy VSLS under Human-induced loading.

Up to now, human-induced vibrations of lightweight structures were mainly caused by resonant behaviours of certain vibration modes located within the high-energy frequency content of dynamic loading generated by humans. For example, traditionally, lightweight steel footbridges with vertical natural frequencies up to 5 Hz were considered prone to excessive vibration in resonance excitation by one of the first two harmonics of dynamic force generated by humans. In the case of lightweight steel floor systems, this resonant vibration has been usually related to the third harmonic of the human loading [2].

Ultra-lightweight structures may additionally undergo undesired vibrations due to either non-resonant responses excited by lower harmonics of the human loading, or resonant loading related to higher and less energetic harmonics of the human loading. Hence, for FRP or aluminium structures even higher modes up to or above 10 Hz could respond considerably [3]. Furthermore, whilst the mass of a human in classic steel lightweight structures is much lower than the structural modal mass, this is no longer the case in ultra-lightweight structures. Indeed, human body mass cannot be simply modelled as equivalent dead load. Instead, their interaction with the structural vibration have to be accounted for. Thus, to properly asses the VSLS in ultra-lightweight structures, it is necessary to model humans as interactive dynamic systems. A simple way to achieve this is to model the human as a Mass-Spring-Damper-Actuator system connected to the structure [4].

Future structures will need to be sustainable in terms of material usage and maintenance, and serviceable in terms of static deflection and dynamic comfort. Fortunately, there are many strategies to minimize the dynamic response of a structural system. Among these strategies, inertial controllers are the most widespread damping technology applied to "lively" civil engineering structures [5]. They consist of an inertial mass that applies counteract forces on the structure. They have an advantage of not needing a reference support to react so they can be simply placed on the structural point to be controlled. In practice, inertial controllers can be implemented in three different ways according to the nature of the control: passive, semiactive or active. The passive devices, most commonly known as Tuned Vibration Absorbers (TVAs), are able to damp resonant vibrations when tuned to a single problematic natural frequency of the structure [6]. The Semi-active Tuned Vibration Absorbers (STVAs) are able to adjust the stiffness or damping properties of the controller in real time, by means of smart dampers (usually magneto-rheological dampers). They can control several closed vibration modes as well as vibration modes with time-varying modal parameters [7]. Active Vibration Absorvers (AVAs) make use of actuators for introducing counteract control forces to the lively structure in real time, allowing to mitigate both resonant and non-resonant responses, even over a relatively broad frequency range [8].

These three control systems can be studied and designed as a feedback system, so the design problem is set to be a closed-loop system. Up to now, many design strategies based on feedback control have been proposed, however, from the authors knowledge, none of them have yet considered the influence of the HSI as another element which also feeds back the structure to be controlled. When considering HSI, the dynamic properties of the structure, change, an so, the inertial controllers which were designed without taking into account this effect could be degraded. This paper intends to asses the influence of the HSI on the performance of three inertial controllers applied to an existing FRP laboratory footbridge, designed to be as lively as possible under human-induced dynamic loading [3].

The remainder of the paper is organized as follows. First the structure will be described in Section 2. Section 3 outlines the closed-loop system model that incorporates HSI. Section 4 provides selected results on the performance of the three inertial mass controllers in presence and absence of HSI. Finally, Section 5 provides conclusions.

2 STRUCTURE

The main aims of designing the studied FRP bridge was to produce a laboratory facility exceptionally responsive to dynamic excitation by human walking and enable research in pedestrian-structure dynamic interaction (Figure 1). To achieve this aim, it was set that the bridge should withstand vibration amplitude of up to 100 mm, on top of the static deflection (of 47.5 mm for the adopted design solution) due to self-weight.

Figure 1: FRP Laboratory Footbridge.

The truss structure with 16.8 m span and 1.4 m overhangs at both ends, is made of three types of FRP structural elements as depicted in Figure 2. The bottom chords are simply supported using four steel bearings, including a roller at one end. All connections are executed using stainless steel bolts. Total mass of the bridge is 1400 kg only. More detailed description of the bridge is available in the paper by Russell et al. 2019 [3].

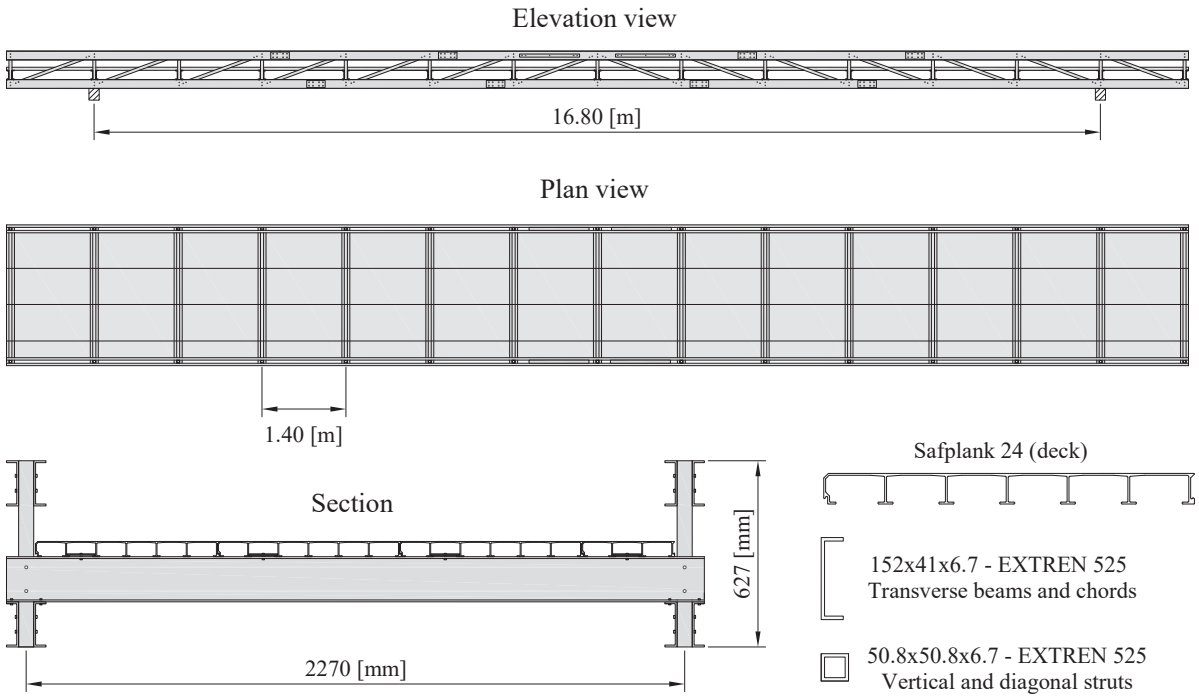

Figure 2: GFRP Laboratory Footbridge: geometrical layout.

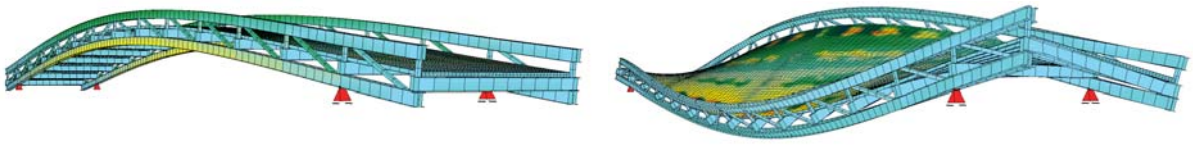

(a) Flexural Mode at 2.5 Hz. (b) Torsion Mode at 3.4 Hz

Figure 3: First two vibration modes of the structure.

The first two vibration modes have natural frequencies at 2.5 Hz (first vertical flexural mode) and at 3.4 Hz (first torsion mode), as shown in Figure 3. It is expected this bridge can achieve vertical acceleration up to around 10 $\mathrm{m/s^2}$ under a single pedestrian walking to excite resonance in the first vibration mode at 2.5 Hz. Indeed, the maximum permitted dynamic deflection of 100 mm (span/170) at 2.5 Hz would correspond to a peak acceleration of almost 25 $\mathrm{m/s^2}$. In practice, these vibrations are likely to be much lower due to vibration attenuation effects caused by walker-footbridge interaction. Therefore, the primary aim of designing a bridge that can resist the stress under single walker exciting the resonance and, at the same time, be lively was executed successfully [10].

Note that the bridge has not been designed to fulfil the usual design requirement of satisfying the Ultimate Limit State under a live load of 5 $\mathrm{kN/m^2}$, as loading of about 500 $\mathrm{kg/m^2}$ by people is not representative for this (and many other) footbridges. The bridge can accommodate several people working on the deck to set up the tests. The deflection due to a single 75 kg person standing at mid-span is 6.5 mm, and therefore deflection due to a few people walking on the bridge at the same time is much less than the 100 mm limit.

This laboratory facility employs much less material than a structure that would comply with VSLS. For this study, an acceleration of 1 $\mathrm{m/s^2}$ has been considered the target value for the control systems. To computationally test the implemented control measures, a single person bouncing loading scenario is utilised.

3 INERTIAL MASS CONTROLLERS AND HUMAN-STRUCTURE INTERACTION

This paper focus on the control of the most responsive first flexural vibration mode at 2.5 Hz. This simplification means that this is only a first step in our study known that ultra-lightweight structures tend to display multi-mode dynamic responses excited by several resonant and non-resonant harmonics. The model for general control scheme considered can be divided in three parts: the structure, the human and the inertial controller.

The human and the inertial controller can be modelled as two different elements feeding back to the main structure and changing the system's dynamic properties (and consequently the dynamic response). In this section, the three parts of the dynamic model are described in detail.

3.1 The structural model

The case study footbridge has been modelled as an equivalent mass-spring-damper system, which represents the vertical dynamic response of the first flexural mode at mid span, with a mass of 650 kg, a natural frequency of 2.5 Hz, and a damping ratio of 0.94 % [10]. The transfer function between the acceleration response and the excitation force is as follows:

$$G_s(s) = \frac{s^2\, X(s)}{F_h(s)} = \frac{1/m_s\; s^2}{s^2 + 2\,\omega_s\,\zeta_s\,s + \omega_s^2}, \tag{1}$$

where $s = j\omega$ is the Laplace variable, $\omega_s = 2f\pi f_s$ is the circular natural frequency of the structure (rad/s), f_s is the responding natural frequency in Hz and m_s and ζ_s are the mass (kg) and damping ratio of the first vibration mode at mid-span. Moreover, $F_h(s)$ is the Laplace transform of the external human force acting on the structure and $s^2 X_s(s)$ is the Laplace transform of the structural acceleration, Where $X_s(s)$ denotes the Laplace transform of the structural displacement. Figure 4 shows the structure block diagram.

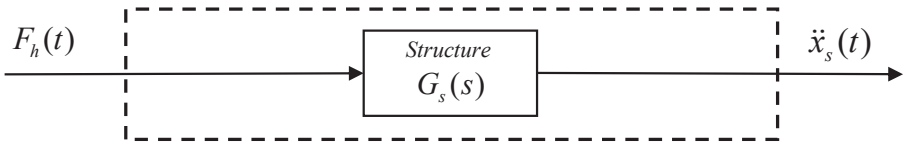

Figure 4: Block diagram of the structure without HSI.

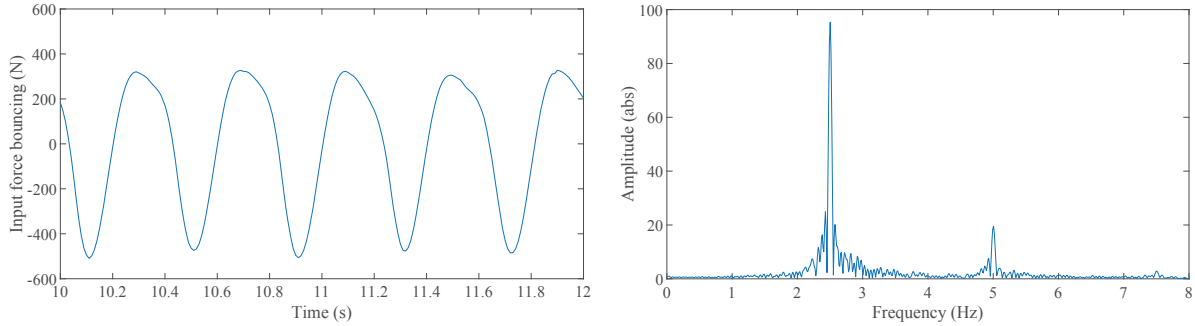
3.2 The human model

First, a non-interactive human model is considered. Given the high accelerations expected (as shown in Section 4), it is reasonable to think that the interaction between the human and the

structure will have significant influence on structural vibration. To account for this, the second model is an interactive model that includes the dynamics of the human.

For the non-interactive model, a dynamic bouncing force measured using a laboratory force plate is used to represent the human on the structure as depicted in Figure 4.



(a) Non-interactive bouncing force at 2.5 Hz. (b) Non-interactive bouncing force spectrum.

Figure 5: Dynamic component of non-interactive bouncing force F_h at 2.5 Hz measured in a laboratory force plate.

Two force waveforms have been applied in the non-interactive simulations: one at resonance conditions of 2.5 Hz (Figure 5) and the other, out of resonance at 2 Hz. Each force record is 20 s long.

The interactive model considers the dynamics of the human body using a Mass-Spring-Damper-Actuator system attached to the structure [11]. Thus, the human is defined by means of its body's natural frequency f_h, damping ratio ζ_h and mass m_h. In addition, a harmonic force generated by the human muscles is also accounted for via a pair of action-reaction forces acting simultaneously on both the footbridge and the human, here named as human interactive force or F_{hi}.

When considering HSI, the dynamic analysis of the new system (structure + human) is performed assuming that this interaction can be modelled as a closed-loop in which the human feeds back to the main structure. This feedback loop is easily deducted from the force balance illustrated in Figure 6, which is governed by the following equations:

$$F_t = k_h(x_h - x_s) + c_h(\dot{x_h} - \dot{x_s}) \tag{2}$$

$$-m_h\ddot{x_h} = (F_t - F_{hi}) \tag{3}$$

$$m_s\ddot{x_s} + c_s\dot{x_s} + k_s x_s = (F_t - F_{hi}) \tag{4}$$

where x_h is the human displacement, $k_h = \omega_h^2 m_h$ is the stifness of the human model, $w_h = 2\pi f_h$ is the natural circular frequency of the human and $c_h = 2\omega_h m_h \zeta_h$ is the viscous damping of the human. Additionally, x_s is the structural displacement, $k_s = \omega_s^2 m_s$ is the structure's stiffness and $c_s = 2\omega_s m_s \zeta_s$ is the viscous damping of the structure. F_t is the transmitted passive force between the structure and the human.

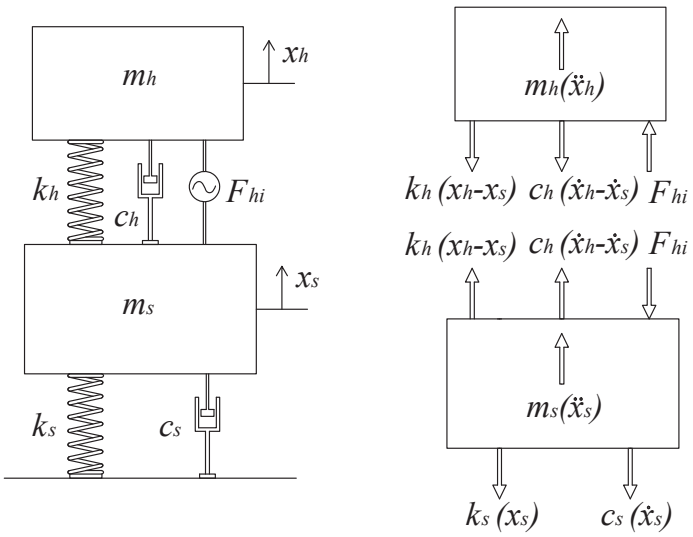


Figure 6: Interactive human model and force equilibrium for each degree of freedom.

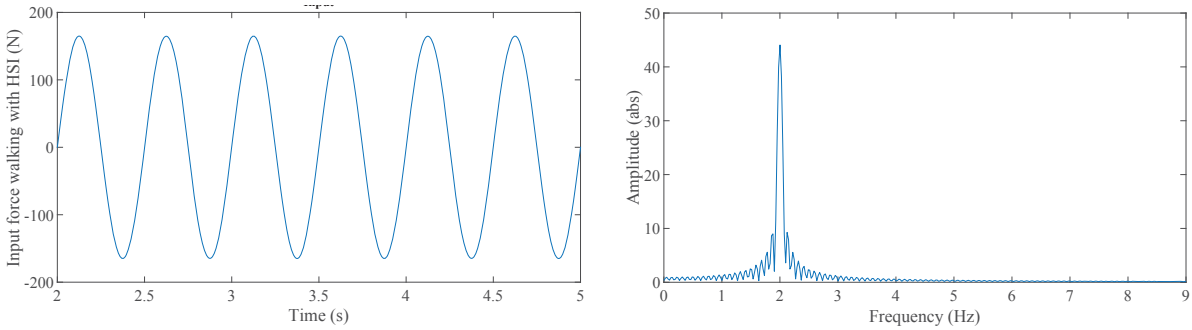
The human parameters considered are: mass m_h of 66 kg, natural frequency f_h of 2.3 Hz and a damping ratio ζ_h of 25 %. Additionally, the muscle force generated by the human modeled as an actuator force F_{hi} has a forcing frequency of either 2.5 Hz or 2.0 Hz while its amplitude is 25 % of the human weight:

$$F_{hi}(t) = Q\alpha \sin(2\pi f t), \tag{5}$$

where Q is the human weight taken of 660 N and $\alpha = 0.25$.



(a) Dynamic interactive bouncing force at 2.5 Hz.

(b) Dynamic interactive bouncing force spectrum.

Figure 7: Human-actuator bouncing force model F_{hi} at 2.5 Hz.

Figure 7 shows the force exerted by the human actuator for bouncing at resonance when accounting for HSI. Note that the amplitude of F_{hi} is lower than the amplitude of F_h used for the non-interactive loading model (Figure 5). Finally, the block diagram for the described system is shown in Figure 8. This diagram makes use of the structure's transfer function described in Equation 1 apart from two additional transfer functions used for modelling the interaction:

$$G_h(s) = \frac{s^2 X_{hi}(s)}{F_{hi}(s)} = \frac{s^2}{m_h s^2 + c_h s + k_h} = \frac{1/m_h\ s^2}{s^2 + 2\,\omega_h\,\zeta_h\,s + \omega_h^2} \tag{6}$$

$$G_{HSI}(s) = \frac{s^2 X_{h-HSI}(s)}{s^2 X_s(s)} = \frac{c_h s + k_h}{m_h s^2 + c_h s + k_h} = \frac{2\,\omega_h\,\zeta_h\,s + \omega_h^2}{s^2 + 2\,\omega_h\,\zeta_h\,s + \omega_h^2} \tag{7}$$

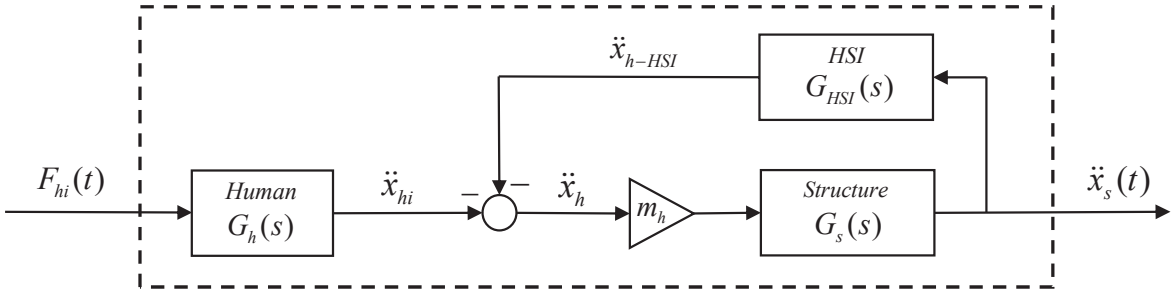


Figure 8: Closed-loop scheme for modelling HSI.

The main idea under this formulation is that the external force entering the structural system is equal to the inverse of the inertial force experienced by the human in real time. Thus, the human acceleration can be decomposed into two different components, one due to its motion $\ddot{x}_{hi}$, and a second human acceleration caused by the structural motion $\ddot{x}_{h-HSI}$. The first one can be directly obtained from the human actuator force by using the transfer function $G_h(s)$. The second is obtained using the transfer function $G_{HSI}(s)$ from the structural acceleration. By summing up the two components and multiplying them by the negative human mass, the external force on the structural system is derived, and so, the interaction loop is closed.

3.3 Tuned Vibration Absorber

The TVA can also be modelled as a closed feedback loop. The same idea used to model the HSI is now applied to the TVA. Hence, the external force entering the structural system due to the TVA is equal to the inverse of the inertial force of the TVA. The following transfer function similar to the one used for the HSI is defined as:

$$G_{TVA}(s) = \frac{s^2 X_T(s)}{s^2 X_s(s)} = \frac{c_T\,s + k_T}{m_T s^2 + c_T\,s + k_T} = \frac{2\,\omega_T\,\zeta_T\,s + \omega_T^2}{s^2 + 2\,\omega_T\,\zeta_T\,s + \omega_T^2} \tag{8}$$

where $\omega_T = 2f\pi f_T$ is the circular natural frequency of the TVA (rad/s), f_T is the respective natural frequency in Hz and m_T, k_T and ζ_T are the mass (kg), stiffness (N/m) and damping ratio of the TVA and $c_T = 2\omega_T\zeta_T m_T$.

The dynamic system is now composed of a two-closed loops scheme, as shown in Figure 9.

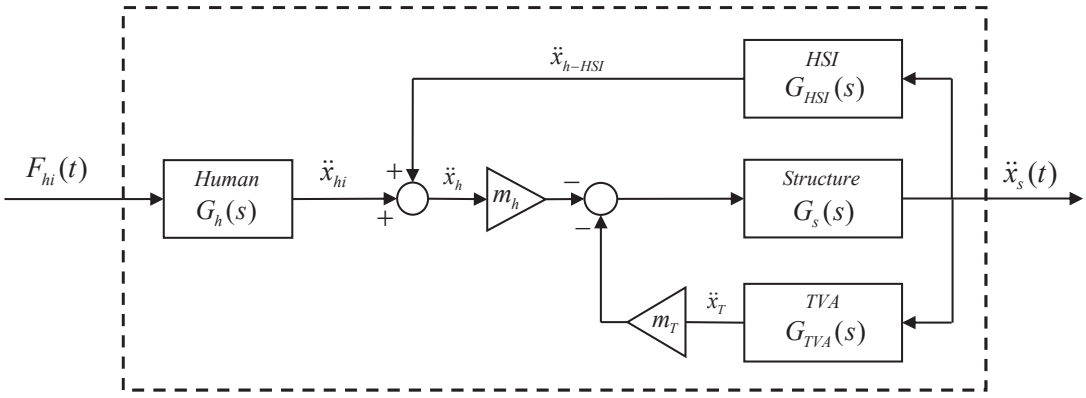

Figure 9: Double closed-loop scheme to model the structure with a TVA and HSI.

The TVA parameters have been designed using the approximation provided by Asami and Nishihara [12], based on the H_∞ for primary structural systems with negligible damping. The following expressions provide the optimal ω_T and ζ_T which minimizes the structure acceleration for a given m_T:

$$\eta = \sqrt{\frac{1}{1+\mu}} \tag{9}$$

$$\zeta_{\mathrm{T}} = \sqrt{\frac{3\mu}{8(1+\mu)^3}} \cdot \sqrt{1+\frac{27}{32}\mu}, \tag{10}$$

where $\mu = m_{_T}/m_{_S}$ is the absorber-to-the-primary-system mass ratio. A mass ratio of 2 % which corresponds to $m_T = 13kg$ has been selected. Parameter $\eta = \omega_{_T}/\omega_{_S}$ is the absorber-to-the-primary-system frequency ratio, in this case 0.99. Finally, ζ_T is 8.7%. The TVA has been designed following an optimum law which does not consider the influence of the HSI.

3.4 Semi-Active Tuned Vibration Absorber

The STVA has been designed using an on-off phase control-strategy [13]. This control strategy has been adopted due to its simplicity for implementing it in practical applications. Indeed, the real-time parameters required for this phase control are easy to measure: the structure acceleration, instead of the displacement, and the inertial mass velocity. The structural response is minimised when the velocity of the inertial mass $\dot{x}_{_T}$ and the structural acceleration $\ddot{x}_{_s}$ have opposite phases. Thus, the inertial controller objective is to facilitate a mass motion as close as possible to this phase. The aforementioned behaviour is equivalent to a 90º phase lag between the structural acceleration and the control force. Thus, when the whole system behaves as desired, the viscous damping of the STVA should be small (ideally zero), however when the phase behaviour is not the correct one, the damper is blocked introducing a control force into the system [14]. The following phase control is summed up as follows:

$$\begin{cases} \ddot{x}_{_S} \cdot \dot{x}_{_T} \leq 0 & \Rightarrow \quad c_{_T} = c_{\min} \quad \text{(normal functioning)} \\ \ddot{x}_{_S} \cdot \dot{x}_{_T} > 0 & \Rightarrow \quad c_{_T} = c_{\max} \quad \text{(blocking functioning)}, \end{cases} \tag{11}$$

where c_{min} is the minimum viscous damping given the minimum damper force when the STVA is working properly. The lower c_{min} results in better performance of STVA. Parameter c_{max} is the maximum viscous damping providing the maximum damper force which corresponds to the state of damper blocked. The magnitude $\ddot{x}_S$ needs to be measured using an accelerometer and $\dot{x}_T$ might be estimated from the integration of an accelerometer signal installed on the inertial mass. Both signals are low-pass filtered in order to avoid control instabilities related to the on-off control law. Note that the design parameters of the STVA correspond to those calculated for the TVA except for c_{min} and c_{max} that are equal to 0.1 and 50 times the value of the c_T for the TVA, respectively. Figure 10 illustrates the non-linear closed loop used to model the STVA, in presence of HSI. Note that if c_T is constant, then block diagrams of Figures 9 and 10 become the same.

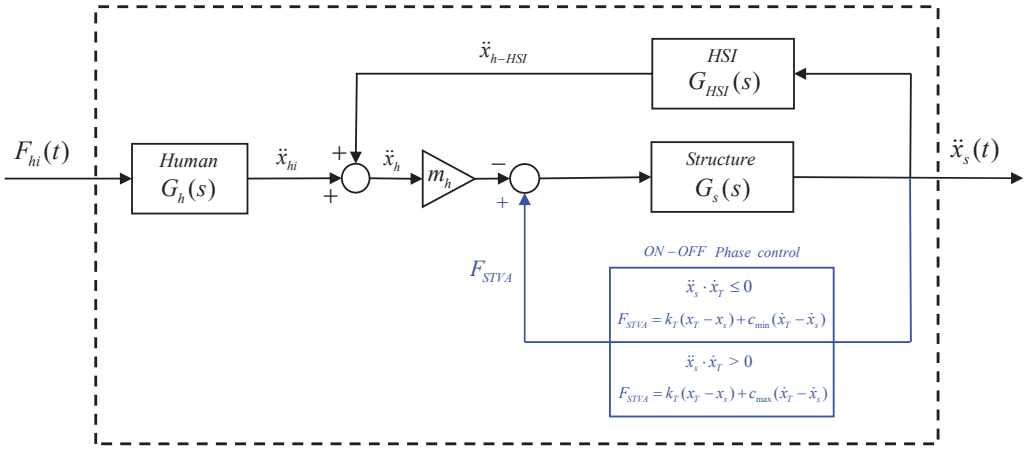

Figure 10: Double closed-loop scheme to model the structure with a STVA considering the HSI.

3.5 Active Vibration Absorber

Direct Velocity Feedback (DVF) control strategy has been used for the AVA. This means that the control force introduced into the system using an actuator is in phase with structure's velocity. Although DVF is, by its nature, unconditionally stable, when accounting for the actuator dynamics, the closed-loop system becomes conditionally stable and the stability margin has to be studied prior to the implementation [15]. The velocity estimated is multiplied by a control gain K_C producing a command signal in terms of voltage to the actuator. Firstly, the limit control gain for stability is derived by classical root locus techniques, $K_{C_{\text{lim}}} \simeq 70$. Finally, a control gain K_C equal to $K_{C_{\text{lim}}}/2$ has been chosen providing enough stability gain margin and leading to a safe implementation [16]. The actuator transfer function between the transmitted control force and the control voltage is considered as a second-order proof-mass actuator model:

$$G_{AVA}(s) = \frac{150\ s^2}{s^2 + 5.7\ s + 8.2^2} \tag{12}$$

where the circular natural frequency of the actuator is $\omega_A = 8.2$ rad/s (1.3 Hz) and $2\zeta_a\omega_a = 5.7$, ζ_a being the actuator damping ratio. The chosen AVA has an inertial mass equal of 13 kg, the same as the one used for the TVA and STVA. The natural frequency of the actuator is a critical parameter when controlling low-frequency vibrations. The lower the natural frequency of the

actuator is, the closer to linear the behaviour of the actuator is. A sufficiently small, but realistic, value for the actuator passive behaviour in terms of natural frequency has been chosen. Note that the shaker's natural frequency can be changed by means of changing the passive stiffness or by the use of more sophisticated control laws [17]. Figure 11 depicts the feedback scheme for the AVA.

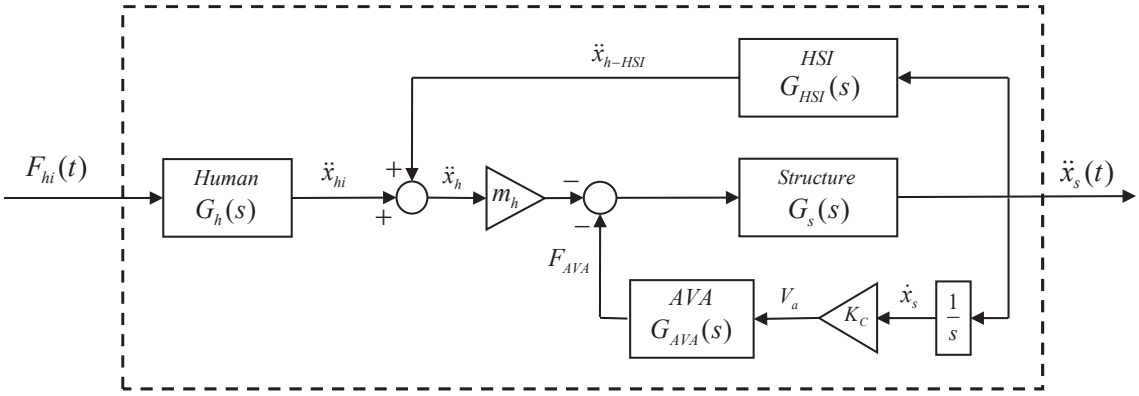

Figure 11: Double closed-loop scheme to model the structure with a AVA considering the HSI

4 RESULTS

Figures 12 and 13 provide the resonant response of the structural system under bouncing action without and with HSI, respectively. Three serviceability indicators are calculated: the Peak acceleration value, the maximum value of the running 1 s root mean square acceleration (often refered to as Maximum Transient Vibration Value or MTVV) and the cumulative Vibration Dose Value (VDV).

When assessing the structural response at resonance, the accelerations reached without considering HSI are not only excessive but also unlikely to be achieved. Once the HSI is taken into account, the dynamic response decreases significantly. In both cases, the structure exceeds the vibration serviceability limit of 1 $\mathrm{m/s^2}$ for peak acceleration. Therefore there is a need to apply inertial vibration controllers to reduce the structural vibration.

When including HSI into the dynamic analysis, the system to be controlled is no longer the structure.The human is a new element to be considered as is influences the dynamic properties of the system to be controlled. The inertial vibration controllers reduce their damping capacity at resonance (especially the TVA and STVA), due to part of the energy introduced into the structure is damped by the very human system which generates it. This fact can be observed in Figure 14 where the VDV of all the dynamic loading cases are compared. The VDV is a suitable vibration serviceability parameter to use for this comparison because of its cumulative nature. To explain the controllers performance out of resonance is a bit more complicated and would require an overall and deep comprehension of the interaction phenomena between all the elements that compound the dynamic system.

The AVA is by far the most effective of the three inertial controllers considered, and it is the only solution capable of reducing the peak acceleration at resonant bouncing below the established threshold of 1 $\mathrm{m/s^2}$ (Figure 13d). Therefore, active control is the most promising damping technique for controlling ultra-weight structures, as it is able to effectively cancel complex dynamic responses compound of resonant and non-resonant harmonics.

5 CONCLUSIONS

In this paper, three types of inertial controllers (Passive, Semi-active and Active) have been applied to an ultra-lightweight FRP footbridge conceived as a unique laboratory facility to investigate the HSI. The dynamic response of the first flexural vibration mode of the structure and the controllers' performance have been numerically studied in the presence and absence of HSI.

The uncontrolled case without HSI leads to an unrealistic acceleration of 23.5 $\mathrm{m/s^2}$. However, when the HSI is included the acceleration is reduced to a realistic value of 2.4 $\mathrm{m/s^2}$. Moreover, when HSI is included, the controllers reduce drastically their performance, mainly due to the fact that they were designed without taking into account the HSI. The improvements for the resonant case (with interaction) were 34%, 60% and 74% for passive, semi-active and active, respectively in terms of VDV. However for non-resonant excitation, the only controller able to mitigate vibration was the AVA with a 50 % of improvement.

This paper is a first study on the performance of inertial controllers for human-induced excitation of structures prone to show HSI. Future works on the design of inertial controllers should include the HSI and the resulting human-structure model should be carefully analyzed in order to propose new controller design strategies for these unexplored systems.

Keywords: Footbridges; Human-induced vibration; Interval Analysis; Serviceability

Abstract. *This paper studies serviceability assessment of footbridges through a non-deterministic approach. The parameters defining pedestrian-induced loading and the structural dynamic properties are characterized through possible ranges of variation. Starting from analytical expressions for the spectral moments of the structural response, the improved interval analysis is applied together with an optimization strategy that allows us to obtain the bounds of the standard deviation of the footbridge acceleration and of the mean value and cumulative distribution function of its maximum value. Based on this approach, a possible interval of variation of the structural response is evaluated, rather than a single deterministic value. Thus, an interval level of comfort can be defined.*

1 INTRODUCTION

Serviceability assessment of footbridges is commonly carried out, based on current guidelines (e.g., [1]), by comparing a deterministic value of the expected maximum acceleration and suitable thresholds defining different comfort classes. Actually, the problem should be tackled through a non-deterministic approach due to the uncertainties characterizing both pedestrian-induced loading (i.e. dynamic loading factor, pedestrian weight and step frequency) and the structural dynamic properties (i.e. modal damping ratios, natural frequencies and modal masses). An approach accounting only for the errors connected with the estimate of structural parameters has been introduced through a fuzzy analysis [2]. Based on the characterization of the coefficient of variation of both the loading and the structural uncertain parameters, the propagation of uncertainties on the serviceability assessment of footbridges has been studied adopting the Taylor series expansion technique [3]. Furthermore, Monte Carlo simulations have been performed assuming plausible probability distributions of the uncertain parameters, and the probability distribution of the mean value of the maximum acceleration has been estimated numerically [3].

Actually, probability distributions of the loading and structural parameters are not available, but the literature analysis in [3] provides possible ranges of variation of these parameters. Thus, a suitable tool for taking into account uncertainties in serviceability assessment of footbridges is interval analysis (e.g., [4], [5]). In this paper, starting from the analytical expression for the spectral moments of the structural response [6], the *improved interval analysis* [4] is applied together with an optimization strategy (see e.g., [7]) that allows us to obtain the bounds of the maximum footbridge acceleration. Based on this approach, serviceability assessment is carried out within a non-probabilistic framework, and an interval level of comfort is estimated.

2 ANALYTICAL FORMULATION

The force exerted on footbridges in multi-pedestrian traffic condition is commonly schematized in the time domain as the sum of moving harmonic loads with random amplitude, frequency and velocity. Based on this force model, serviceability assessment has to be carried out through Monte Carlo simulations.

According to the Equivalent Spectral Model (ESM) [6], multi-pedestrian loading can be modelled as an equivalent Gaussian stationary random process. Considering the first mode shape of a simply-supported beam of length L, $\varphi_j(x)=\sin(\pi x/L)$, the power spectral density function (PSDF) of the modal force $F_j(t)$ is given by:

$$S_{F_j}(\omega) = \frac{N_p}{4}(\alpha G)^2 \, p_\Omega(\omega) \tag{1}$$

where N_p is the number of pedestrians, α is the mean value of the dynamic loading factor, G is the mean value of the weight of pedestrians, $p_\Omega(\omega)$ is the probability density function (PDF) of the circular step frequency of pedestrians, assumed as normally-distributed with mean value $\mu_{\omega p}$ and standard deviation $\sigma_{\omega p}$. The spectral moments of zero- and second-order of the acceleration of the j-th principal coordinate $p_j(t)$ can be approximated as follows:

$$\lambda_{0,\ddot{p}_j} \approx \frac{\pi \omega_j S_{F_j}(\omega_j)}{4\xi_j M_j^2} = \sigma_{\ddot{p}_j}^2; \qquad \lambda_{2,\ddot{p}_j} \approx \frac{\pi \omega_j^3 S_{F_j}(\omega_j)}{4\xi_j M_j^2} \tag{2}$$

where M_j, ω_j and ξ_j are, respectively, the j-th modal mass, natural circular frequency and damping ratio of the structure. The maximum acceleration of the j-th principal coordinate in the time interval T is then defined as the following random process:

$$\ddot{p}_{j,\max}(T) = \max_{0\le t\le T} \left| \ddot{p}_j(t) \right| \tag{3}$$

where the time interval T can be conventionally defined as a multiple of the average crossing time of pedestrians ($T=NL/c_m$, N=10, c_m=0.9 $\mu_{\omega p}/2\pi$).

Under the Poisson's assumption of independent up-crossings of a prescribed threshold, the cumulative distribution function (CDF) of the maximum acceleration is defined as follows:

$$L_{\ddot{p}_{j,\max}}(b,T) = \Pr\left[\ddot{p}_{j,\max}(T) \le b \right] \approx \exp\left[-2\ \nu_{\ddot{p}_j} T \exp\left(-\frac{b^2}{2\sigma_{\ddot{p}_j}^2} \right) \right] \tag{4}$$

where $\nu_{\ddot{p}_j}$ is the expected frequency of the acceleration of the j-th principal coordinate, given by:

$$\nu_{\ddot{p}_j} = \frac{1}{2\pi} \sqrt{\frac{\lambda_{2,\ddot{p}_j}}{\lambda_{0,\ddot{p}_j}}} = \frac{\omega_j}{2\pi}. \tag{5}$$

The mean value of the maximum mid-span acceleration can be approximated according to Davenport's formulation ([8], [9]) as follows:

$$\ddot{q}_{\max} = \mathrm{E}\left[\ddot{p}_{j,\max} \right] = g_{\ddot{p}_j} \sigma_{\ddot{p}_j};\quad g_{\ddot{p}_j} = \sqrt{2\ln(2\nu_{\ddot{p}_j} T)} + \frac{0.5772}{\sqrt{2\ln(2\nu_{\ddot{p}_j} T)}} \tag{6}$$

3 INTERVAL SERVICEABILITY ASSESSMENT

Interval serviceability assessment is based on the assumption of uncertain loading and structural parameters, represented as interval variables [10] according to the interval model of uncertainty:

$$\mathbf{x}^I = \left\{ \mu_{\omega p}^I \quad \sigma_{\omega p}^I \quad \alpha^I \quad G^I \quad \omega_j^I \quad \xi_j^I \quad M_j^I \right\}^{\mathrm{T}} \tag{7}$$

where the apex denotes interval variables. Each component of the vector $\mathbf{x}^I$, i.e. the k-th interval variable x_k^I, is defined as:

$$x_k^I = x_{0,k} \left(1 + \Delta x_k \hat{e}_k^I \right) \tag{8}$$

where $\hat{e}_k^I = [-1,1]$ is the so-called *extra unitary interval* [4], $x_{0,k}$ and Δx_k are the midpoint and normalized deviation amplitude, defined as follows:

$$x_{0,k} = \frac{\overline{x}_k + \underline{x}_k}{2}; \qquad \Delta x_k = \frac{\overline{x}_k - \underline{x}_k}{2x_{0,k}} \tag{9}$$

being $\underline{x}_k$ and $\overline{x}_k$ the lower bound (LB) and upper bound (UB) of the interval variable x_k^I.

Based on the interval representation of the involved quantities, the PSDF of the modal force is an interval function:

$$S_{F_j}^I(\omega) = \frac{N_p}{4}(\alpha^I G^I)^2 \, p_\Omega^I(\omega). \tag{10}$$

As a consequence, also the spectral moments of zero- and second-order of the acceleration of the *j*-th principal coordinate are interval variables:

$$\lambda_{0,\ddot{p}_j}^I = \frac{\pi\omega_j^I S_{F_j}^I(\omega_j^I)}{4\xi_j^I \left(M_j^I\right)^2} = \left(\sigma_{\ddot{p}_j}^2\right)^I; \qquad \lambda_{2,\ddot{p}_j}^I = \frac{\pi\left(\omega_j^I\right)^3 S_{F_j}^I(\omega_j^I)}{4\xi_j^I \left(M_j^I\right)^2}. \tag{11}$$

The interval CDF is defined as:

$$L_{\ddot{p}_{j,\max}}^I(b,T) = \exp\left[-2\ \nu_{\ddot{p}_j}^I T^I \exp\left(-\frac{b^2}{2\left(\sigma_{\ddot{p}_j}^2\right)^I}\right)\right] \tag{12}$$

where the interval expected frequency is:

$$\nu_{\ddot{p}_j}^I = \frac{1}{2\pi}\sqrt{\frac{\lambda_{2,\ddot{p}_j}^I}{\lambda_{0,\ddot{p}_j}^I}} = \frac{\omega_j^I}{2\pi}. \tag{13}$$

Finally, the interval mean value of the maximum acceleration process is defined as follows:

$$\ddot{q}_{\max}^I = g_{\ddot{p}_j}^I \sigma_{\ddot{p}_j}^I; \qquad g_{\ddot{p}_j}^I = \sqrt{2\ln(2\nu_{\ddot{p}_j}^I T^I)} + \frac{0.5772}{\sqrt{2\ln(2\nu_{\ddot{p}_j}^I T^I)}}. \tag{14}$$

The LB and UB of the standard deviation of the acceleration are given by:

$$\underline{\sigma}_{\ddot{p}_j} = \min_{\mathbf{x}\in\mathbf{x}^I}\left\{\sqrt{\frac{\pi\omega_j S_{F_j}(\omega_j)}{4\xi_j M_j^2}}\right\}; \qquad \overline{\sigma}_{\ddot{p}_j} = \max_{\mathbf{x}\in\mathbf{x}^I}\left\{\sqrt{\frac{\pi\omega_j S_{F_j}(\omega_j)}{4\xi_j M_j^2}}\right\}. \tag{15}$$

Analogously, the LB and UB of the CDF of the maximum acceleration are:

$$\begin{aligned}
\underline{L}_{\ddot{p}_{j,\max}}(b,T) &= \min_{\mathbf{x}\in\mathbf{x}^I}\left\{\exp\left[-2\ \nu_{\ddot{p}_j} T \exp\left(-\frac{b^2}{2\sigma_{\ddot{p}_j}^2}\right)\right]\right\}; \\
\overline{L}_{\ddot{p}_{j,\max}}(b,T) &= \max_{\mathbf{x}\in\mathbf{x}^I}\left\{\exp\left[-2\ \nu_{\ddot{p}_j} T \exp\left(-\frac{b^2}{2\sigma_{\ddot{p}_j}^2}\right)\right]\right\}.
\end{aligned} \tag{16}$$

The LB and UB of the maximum mid-span acceleration are given by:

$$\begin{aligned}
\underline{\ddot{q}}_{\max} &= \min_{\mathbf{x}\in\mathbf{x}^I}\left\{\left[\sqrt{2\ln(2\nu_{\ddot{p}_j} T\ )} + \frac{0.5772}{\sqrt{2\ln(2\nu_{\ddot{p}_j} T\ )}}\right]\sigma_{\ddot{p}_j}\right\}; \\
\overline{\ddot{q}}_{\max} &= \max_{\mathbf{x}\in\mathbf{x}^I}\left\{\left[\sqrt{2\ln(2\nu_{\ddot{p}_j} T\ )} + \frac{0.5772}{\sqrt{2\ln(2\nu_{\ddot{p}_j} T\ )}}\right]\sigma_{\ddot{p}_j}\right\}.
\end{aligned} \tag{17}$$

Finally, the *coefficients of interval uncertainty* (*c.i.u.*) for the two response quantities of interest can be defined as the ratio between their deviation amplitude and their midpoint as follows:

$$c.i.u.[\sigma^I_{\ddot{p}_j}] = \frac{\overline{\sigma}_{\ddot{p}_j} - \underline{\sigma}_{\ddot{p}_j}}{\overline{\sigma}_{\ddot{p}_j} + \underline{\sigma}_{\ddot{p}_j}}; \qquad c.i.u.[\ddot{q}^I_{\max}] = \frac{\overline{\ddot{q}}_{\max} - \underline{\ddot{q}}_{\max}}{\overline{\ddot{q}}_{\max} + \underline{\ddot{q}}_{\max}}. \tag{18}$$

4 NUMERICAL APPLICATION

Current guidelines require to perform serviceability assessment of footbridges by comparing a deterministic value of the expected maximum acceleration and suitable thresholds defining different comfort classes. Table 1 reports the threshold values as defined by SETRA [1].

Comfort class	Min [m/s^2]	Max [m/s^2]
Maximum	0	0.5
Medium	0.5	1
Minimum	1	2.5
Unacceptable	2.5	

Table 1: Comfort classes (SETRA).

In this Section, serviceability assessment of an ideal footbridge is carried out. Results of a conventional evaluation are compared with those deriving from interval analysis. In particular, at first interval analysis is carried out assuming fixed normalized deviation amplitudes of the parameters based on [3]. Then, an increasing degree of uncertainty is considered according to the following definition of the interval variables:

$$x^I_k(\beta) = x_{0,k}\left(1 + \beta \Delta x_k \hat{e}^I_k\right), \qquad 0 \le \beta \le 1. \tag{19}$$

Furthermore, three different interval analyses are carried out: considering all the parameters as uncertain, i.e. full uncertainty analysis (FU), taking into account only the uncertainties in the structural parameters (SU), and taking into account only uncertainties in the loading parameters (LU).

An ideal, steel, simply-supported beam with span length L=50 m, a deck width b=2 m is analyzed [3]. Considering load category III, sparse crowd [1], a pedestrian density ρ=0.5 pedestrians/m^2 is assumed, i.e. N_p=50, and the predicted maximum acceleration applying SETRA procedure is $\ddot{q}_{\max}$ =2.15 m/s^2, falling into a minimum comfort class according to Table 1. Interval analysis is carried out assuming the midpoint and the normalized deviation amplitude of the uncertain parameters in Table 2.

Parameter	$x_{0,k}$	Δx_k
$\mu_{\omega p}$ [rad/s]	2 π 1.88	0.03
$\sigma_{\omega p}$ [rad/s]	2 π 0.17	0.17
α	0.35	0.20
G [N]	700	0.10
ω_j [rad/s]	2 π 1.88	0.10
ξ_j [%]	0.42	0.60
M_j [kg]	50000	0.10

Table 2: Midpoint and normalized deviation amplitude of interval variables (Example 1).

The nominal solutions for the standard deviation and the mean value of the maximum acceleration are $\sigma_{\ddot{p}_j} = 0.50$ m/s^2 (Eq.(2)), $\ddot{q}_{\max} = 1.94$ m/s^2 (Eq. (6)). Table 3 reports the LB and UB of $\sigma^I_{\ddot{p}_j}$ (see Eq.(15)) and $\ddot{q}^I_{\max}$ (see Eq. (17)) together with their *c.i.u.* (see Eq. (18)), obtained in the three analyses. The significant deviation amplitudes of the uncertain parameters (Table 2) lead to very large *c.i.u.*, especially if all the parameters (structural and loading) are considered as uncertain (FU). However, the uncertainty in the dynamic response is mainly governed by the uncertainties in the structural parameters. When only loading parameters are assumed as uncertain (LU), the deviation amplitude of the response is significantly reduced. It should be remarked that the maximum acceleration obtained applying SETRA procedure is higher than the nominal value and it is close to the UB provided by interval analysis if only loading uncertainties are accounted for (LU). In all the other cases (FU and SU), SETRA prediction is well below the UB provided by interval analysis, and it can be non-conservative.

Analysis	$\underline{\sigma}_{\ddot{p}_j}$	$\overline{\sigma}_{\ddot{p}_j}$	$c.i.u.[\sigma^I_{\ddot{p}_j}]$	$\underline{\ddot{q}}_{\max}$	$\overline{\ddot{q}}_{\max}$	$c.i.u.[\ddot{q}^I_{\max}]$
FU	0.13	1.29	0.82	0.49	5.02	0.82
SU	0.25	0.88	0.56	0.97	3.42	0.56
LU	0.32	0.72	0.38	1.26	2.81	0.38

Table 3: LB, UB and *c.i.u* of the standard deviation of the response and of the maximum acceleration (Example 1).

Figure 1 provides the UB and LB of $\sigma^I_{\ddot{p}_j}$ (a) and its *c.i.u.* (b) versus the coefficient β which measures the degree of uncertainty according to Eq. (19): results obtained for the three different analyses (FU, SU, LU) are reported. Fig. 1(a) shows that the interval of variation of the standard deviation of the response is very wide, especially if both loading and structural uncertainties are taken into account (FU). From Fig. 1(b) it can be deduced that the *c.i.u.* is almost proportional to the degree of uncertainty β. Furthermore, the *c.i.u.* takes values lower than 10% only if a small degree of uncertainty of the parameters is assumed, or at least structural parameters are assumed as deterministic. When all the parameters are assumed as uncertain, the *c.i.u.* is very large.

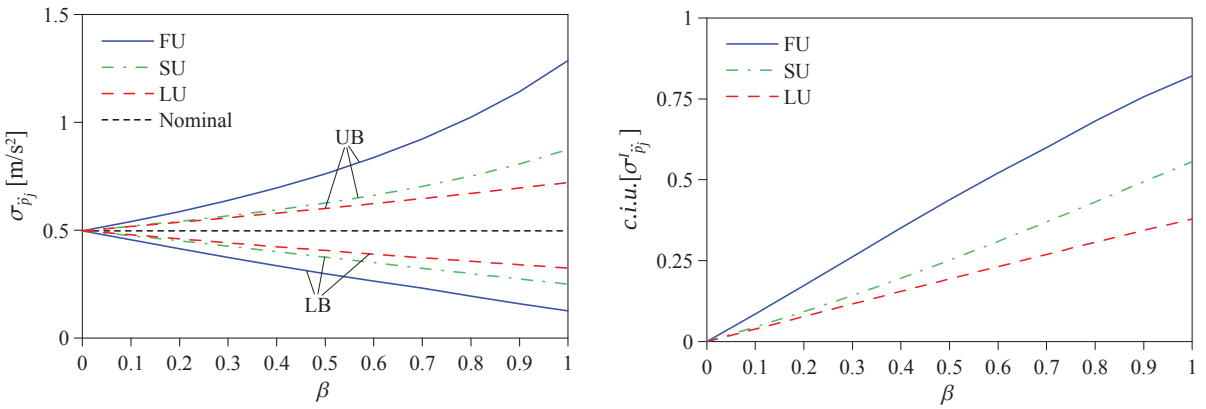

Figure 1: UB and LB of standard deviation of the acceleration (a) and its *coefficient of the interval uncertainty* (b) for increasing degree of uncertainty (Example 1).

Figure 2 provides the LB and UB of the CDF of the maximum acceleration for β=1, for the full uncertainty analysis (FU), taking into account only the uncertainties in the structural parameters (SU), and taking into account only uncertainties in the loading parameters (LU). From Fig. 2, the LB and UB of the probability of falling within each comfort class can be estimated. It can be deduced that, if the nominal values of the parameters are assumed, the footbridge will surely fall within a minimum comfort class. When all the parameters are considered as uncertain, the UB and LB of the CDF are extremely far from each other: considering the LB of the CDF, the maximum footbridge acceleration is surely higher than 4 m/s^2, and thus the comfort level is unacceptable, while considering the UB of the CDF, the maximum acceleration is almost surely lower than 0.5 m/s^2 and the maximum comfort level is assured. When only the structural or the loading parameters are considered as uncertain, the interval of variation of the CDF becomes narrower. For example, if only loading parameters are considered as uncertain, the LB of the CDF falls within unacceptable comfort class and the UB of the CDF falls within a minimum comfort class.

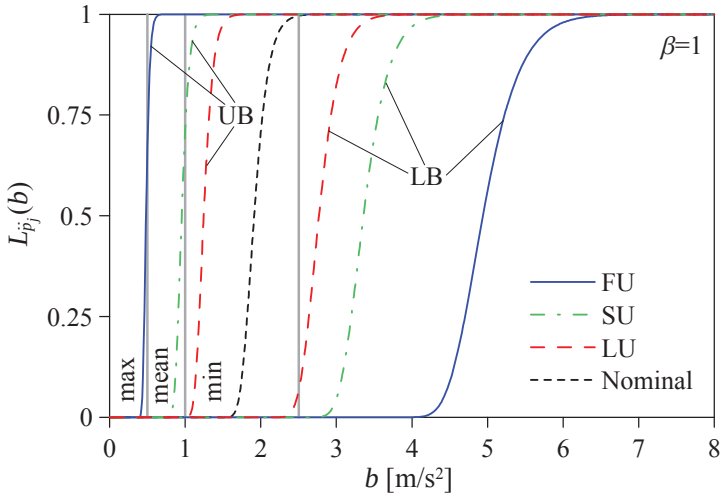

Figure 2 UB and LB of the CDF of the maximum acceleration (β=1) (Example 1).

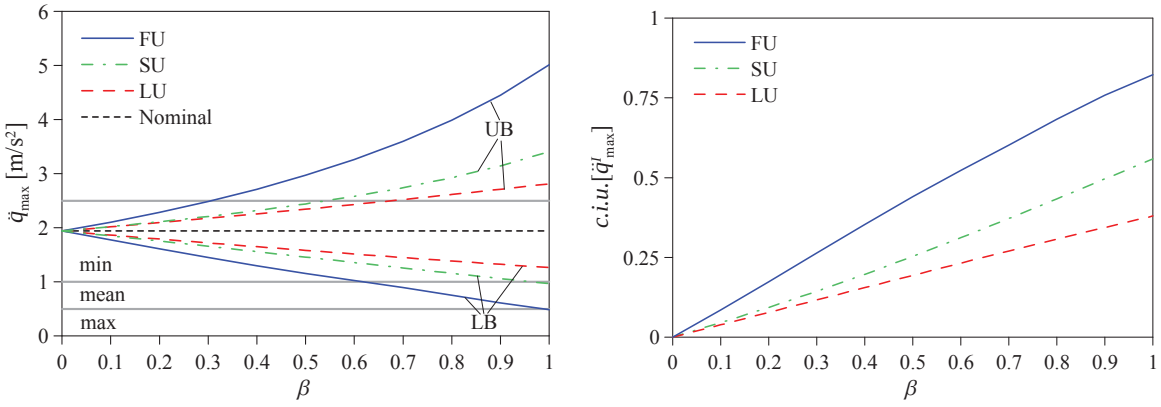
Figure 3 provides the UB and LB of $\ddot{q}^I_{\max}$ compared with the comfort limits provided by SETRA (a) and its *c.i.u.* (b) for increasing degree of uncertainty. Figure 3(a) shows that, if all the parameters are considered as uncertain and the maximum degree of uncertainty is assumed, then the interval of variation of the response is so wide that the footbridge could fall in any comfort class (from unacceptable to maximum comfort). If only the uncertainties of the loading are considered, the footbridge is almost surely in a minimum comfort class, as predicted by SETRA guideline. As regards structural uncertainties, if the degree of uncertainty is small then interval serviceability assessment provides a minimum comfort class, while for large degree of uncertainty a comfort level ranging from minimum to unacceptable can be obtained. From Fig. 3(b), it can be deduced that the *c.i.u.* of the maximum acceleration has the same trend as the one of the standard deviation of the response (Fig. 1(b)). Also from a quantitative point of view, the two *c.i.u.* are almost coincident: the uncertainty in the maximum acceleration is then governed by the uncertainty in the standard deviation.

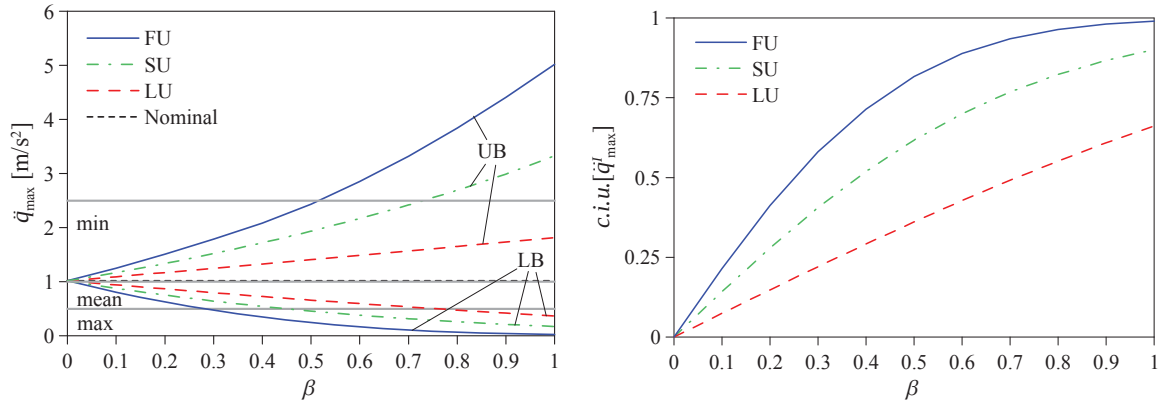
In order to assess the influence of uncertainties on serviceability assessment of footbridges less sensitive to human-induced vibrations, a second footbridge is analyzed. The same parameters listed in Table 2 are considered, except for the natural circular frequency ω_j: its nominal value is not coincident with the nominal value of the mean step circular frequency,

but it is assumed 2 π 2.17 rad/s. Figure 4 is analogous to Figure 3, but it is referred to this second example. Results are similar to the ones obtained for Example 1 from a qualitative point of view. From a quantitative point of view, Figure 4(a) shows that the comfort level of this footbridge is surely higher than the one of Example 1. In particular, if the degree of uncertainty is small (β<0.25) the footbridge comfort class can range between mean and minimum. However, if all the parameters are considered as uncertain and the maximum degree of uncertainty is assumed, then the interval of variation of the response is so wide that also this footbridge could fall in any comfort class (from unacceptable to maximum comfort). Figure 4(b) shows that the coefficient of interval uncertainty is even larger than in Example 1. In particular, if all the uncertainties are taken into account, for high degree of uncertainty the *c.i.u.* tends to an asymptotic value.



(a) (b)

Figure 3: UB and LB of mean value of the maximum acceleration (a) and its *coefficient of the interval uncertainty* (b) for increasing degree of uncertainty (Example 1).



(a) (b)

Figure 4: Non resonant case: UB and LB of mean value of the maximum acceleration (a) and its *coefficient of the interval uncertainty* (b) for increasing degree of uncertainty (Example 2).

5 CONCLUSIONS

Serviceability assessment of footbridges is studied through a non-deterministic approach, modelling structural and loading parameters as interval variables. Based on this approach, the standard deviation of the footbridge acceleration and the mean value of the maximum accel-

eration are also interval variables, while the cumulative distribution function of the maximum acceleration is an interval function.

The application to an ideal case study has shown that the high degree of uncertainty in the loading and structural parameters leads to very large intervals of variation of the response. If all the parameters are considered as uncertain and the maximum degree of uncertainty is assumed, then the interval of variation of the response is so wide that the footbridge could fall in any comfort class (from unacceptable to maximum comfort). The separate analysis of the role of the structural and loading parameters has shown that uncertainty in the structural parameters provides a determinant contribution to the variation of the response. In order to obtain narrow intervals of variation of the response, a reliable characterization of the loading and of the structural properties is mandatory.

Abstract. *This paper presents an analytical approximation to describe the vertical and horizontal vibrations of clamped-clamped beams subjected to a single pedestrian induced load. No intra—person variability is considered and only a single crossing is taken into account. This approximation is performed by choosing a suitable trigonometric function that well estimates the dynamic properties and mode shape of the system. Moreover, the approximation enables to find the relationship between the loading parameters such as the step frequency and velocity and, the dynamic properties of the system as the natural frequency and damping. Furthermore, approximation formulas are presented for peak displacements, velocities and accelerations in the damped, low damped and undamped cases. Finally, amplifications factors and minimum design mass curves are defined using non dimensional parameters, aiming to contribute to a fast pedestrian bridge dynamic assessment for systems whose mode shapes reassemble the mode shape of a clamped—clamped beam, for both walking and running pedestrian load cases.*

1 INTRODUCTION

As high strength materials become more readily available, lightweight structures and slender structures are more commonly produced, having well aesthetic design whilst less material is being used. Consequently, new lightweight and lively structural systems may exhibit larger deformations than old heavy structures, making them susceptible to a dynamic excitation. This is the case for many newly constructed footbridges.

The behaviour of footbridges are heavily dependent on the natural frequency of the structure itself. In this way, the dynamic effects need to be considered due to the high levels of accelerations obtained when the frequencies associated with pedestrian loading are within the range of the fundamental natural frequencies of the structural system. Additionally, the pedestrians introduce both vertical and horizontal forces meaning that, structural systems may become vulnerable in different directions and serviceability criteria of lightweight structures of pedestrian bridges can be easily exceeded.

Different load case scenarios are considered in the design stage and assessment of footbridges. Consider the Sétra design code for footbridges [1], in which by finding the equivalent number of pedestrians synchronized in a footbridge, gives a procedure to address the walking crowd scenario in order to assess serviceability levels of the system. However, no specific procedure is given for the running load event like marathons nor the cases in which a single or few runners excite the structural system while walking or standing pedestrians are present, exceeding the serviceability levels required. This is the case of [2], in which a single runner was able to surpass the acceleration limit. To this aim, fast and reliable tools for design and assessment aiming to address the running load case in footbridges are necessary as well as more research on the subject is required.

In the present work, the moving harmonic load problem is studied in the context of pedestrian bridge dynamics for a clamped—clamped beam system. The interest in this subject relies on the fact that, the symmetric mode shape of vibration of tied arch bridges and frame type bridges, which are typical structural topologies found in footbridges, can be approximated and reassembled to the first mode of vibration of a clamped—clamped beam. In this way, the aforementioned approximation is here presented focusing on the comparison between the influence of walking and running in the response of footbridges.

2 PROBLEM FORMULATION

Consider a theoretical model of a clamped—clamped beam subjected to a single time varying force $F(t)$, moving with a constant velocity v from the left side to the right-hand side of the continuous system shown in Figure 1.

In this work, it is considered $y(x,t)$ as the deflection of the beam along the vertical axis y, evaluated at the horizontal position x in the time t, m is the linear density of the beam, E is the elastic modulus of the beam, I the inertia of the system, c_e the external damping coefficient and c_i the internal damping coefficient as considered in [3]. The span length L of the clamped–clamped beam model is considered as the effective length of the typical symmetric mode shape of a tied arch bridge. The equation of motion of the system is set as:

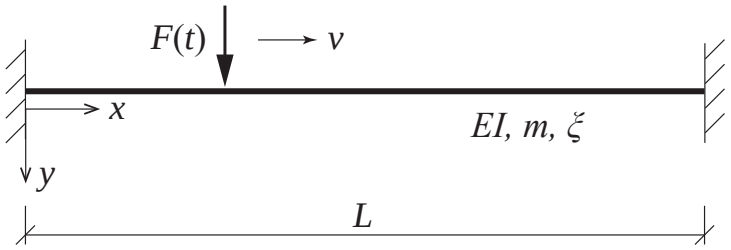

Figure 1: Clamped–clamped beam

$$m\ddot{y} + c_e\dot{y} + c_iI\dot{y}'''' + EIy'''' = F(t)\delta(x - vt), \;\; 0 \leq vt \leq L \tag{1}$$

In which dots $(\dot{})$ represent a time derivative, primes $(')$ indicate a spatial derivative respect to the horizontal coordinate x of the system, δ is the Dirac function. For a clamped—clamped beam, the boundary conditions are:

$$\begin{aligned} y(0,t) &= 0 \\ y(L,t) &= 0 \\ y'(0,t) &= 0 \\ y'(L,t) &= 0 \end{aligned} \tag{2}$$

Initial conditions considered as:

$$\begin{aligned} y(x,0) &= 0 \\ \dot{y}(x,0) &= 0 \end{aligned} \tag{3}$$

And the time varying force $F(t)$ defined as [1]:

$$F(t) = G_0 + \sum_{i=1}^{3} G_i \sin(2\pi f_{step}\, i\, t) \tag{4}$$

Where G_0 denotes the weight of the pedestrian and $G_i = DLF_i \cdot G_0$, in which DLF_i refers to the dynamic load factor i of the pedestrian load in accordance to the activity performed by the pedestrian.

Let us consider, as an approximation, the first vibration mode ϕ_1 of the beam as a linear combination of assumed functions that satisfy boundary conditions as a ”shape function” that well suits the problem as:

$$\phi_1(x) = 1 - \cos^2\left(\frac{\pi x}{L}\right) = 1/2\left(1 - \cos\left(\frac{2\pi x}{L}\right)\right) \tag{5}$$

Considering the modal superposition method, the response of the beam can be approximated by its first mode of vibration as:

$$\begin{aligned} y(x,t) = \sum_{n=1}^{m} \phi_n(x)\, q_n(t) \cong \phi_1(x)\, q_1(t) \\ \dot{y}(x,t) \cong \phi_1(x)\, \dot{q}_1(t) \\ \ddot{y}(x,t) \cong \phi_1(x)\, \ddot{q}_1(t) \end{aligned} \tag{6}$$

Where q_n represents the generalized coordinate of the nth mode. Equation (6) applies under the hypothesis that the first mode of vibration very well suits and represents the system's behaviour under a moving harmonic load with an exciting frequency f_{step} closed to the natural frequency of the system f_1. Substituting (6) in (1), multiplying the resulting equation by the assumed mode shape function ϕ_1 and integrating along the beam axis, one obtains:

$$\begin{aligned} m\ddot{q}_1(t) \int_0^L (\phi_1(x))^2 dx + \dot{q}_1(t) \left[c_e \int_0^L (\phi_1(x))^2 dx + c_i I \int_0^L (\phi_1(x))^{<4>} \phi_1(x) dx \right] + \\ EI q_1(t) \int_0^L (\phi_1(x))^{<4>} \phi_1(x) dx = \int_0^L F(t)\delta(x - vt)\phi_1(x) dx \end{aligned} \tag{7}$$

In which the natural frequency of vibration of the system becomes:

$$\omega_1^2 = \frac{EI}{m} \frac{\int_0^L (\phi_1(x))^{<4>} \phi_1(x) dx}{\int_0^L (\phi_1(x))^2 dx} \tag{8}$$

In this way, the numerator and the denominator of equation (8) denote the modal stiffness and the modal mass of the first mode of vibration, respectively. Solving the integrals one gets:

$$K_1 = EI \int_0^L (\phi_1(x))^{<4>} \phi_1(x) dx = \frac{2\pi^4 EI}{L^3} \tag{9}$$

$$M_1 = m \int_0^L (\phi_1(x))^2 dx = \frac{3}{8} mL \tag{10}$$

And the natural frequency is then defined as:

$$\omega_1^2 = \frac{K_1}{M_1} = \frac{16\pi^4 EI}{3L^4 m} \tag{11}$$

Under the hypothesis of Rayleigh's damping in which $c_e = \alpha_e m$ and $c_i = \alpha_i E$, the damping coefficient ξ_1 is defined as:

$$\xi_1 = \frac{1}{2}\left(\frac{\alpha_e}{\omega_1} + \alpha_i \omega_1\right) \tag{12}$$

And, equation (7) is reduced to the equivalent dynamic equation in the modal coordinates $q_1(t)$ as:

$$\ddot{q}_1(t) + 2\xi_1\omega_1\dot{q}_1(t) + \omega_1^2 q_1(t) = \frac{F(t)\phi_1(vt)}{m\int_0^L (\phi_1(x))^2 dx} \tag{13}$$

$$\ddot{q}_1(t) + 2\xi_1\omega_1\dot{q}_1(t) + \omega_1^2 q_1(t) = \frac{8F(t)\phi_1(vt)}{3mL}$$

Substituting the assumed mode shape function ones gets:

$$\ddot{q}_1(t) + 2\xi_1\omega_1\dot{q}_1(t) + \omega_1^2 q_1(t) = \frac{8}{3mL}F(t)\frac{1}{2}\left(1 - \cos\left(\frac{2\pi vt}{L}\right)\right) \tag{14}$$

By neglecting G_0 and considering a general harmonic component i in the load model presented in equation (4), it follows that:

$$\ddot{q}_{1,i}(t) + 2\xi_1\omega_1\dot{q}_{1,i}(t) + \omega_1^2 q_{1,i}(t) = \frac{8}{3mL}G_i \sin(2\pi f_{step}\, i\, t)\,\frac{1}{2}\left(1 - \cos\left(\frac{2\pi vt}{L}\right)\right) \tag{15}$$

And, using the principle of superposition and trigonometric identities the general problem can be reduced to the summation of the threefold components:

$$q_{1,i}(t) = z_{1,i}(t) + z_{2,i}(t) + z_{3,i}(t) \tag{16}$$

In which $z_{1,i}(t)$, $z_{2,i}(t)$ and $z_{3,i}(t)$ correspond to the following threefold problems:

$$\ddot{z}_{1,i}(t) + 2\xi_1\omega_1\dot{z}_{1,i}(t) + \omega_1^2 z_{1,i}(t) = \frac{8}{3mL}\frac{G_i}{2}\sin(2\pi f_{step}\, i\, t) \tag{17}$$

$$\ddot{z}_{1,i}(t) + 2\xi_1\omega_1\dot{z}_{1,i}(t) + \omega_1^2 z_{1,i}(t) = -\frac{8}{3mL}\frac{G_i}{4}\sin\left(2\pi f_{step}\, i - \frac{2\pi v}{L}\right)t$$

$$\ddot{z}_{3,i}(t) + 2\xi_1\omega_1\dot{z}_{1,i}(t) + \omega_1^2 z_{1,i}(t) = -\frac{8}{3mL}\frac{G_i}{4}\sin\left(2\pi f_{step}\, i + \frac{2\pi v}{L}\right)t$$

From equations (17), a beating phenomena can be identified as a consequence of the definition of the load in terms of harmonic components and the spatial wave that defines the mode shape of vibration. Finally, the solution of the aforementioned equations can be found in [3] and it is here adapted:

$$z_{1,i}(t) = \frac{G_i L^3}{4\pi^4 EI} \frac{1}{(1-S_{1,i}^2)^2 + (2\xi_1 S_{1,i})^2} \Big\{ (1-S_{1,i}^2)\, \sin(\Omega_{1,i} t) - 2\xi_1 S_{1,i}\, \cos(\Omega_{1,i} t) + \\ \mathrm{e}^{-\xi_1 \omega_1 t} \left[2\xi_1 S_{1,i} \cos(\omega_{d1} t) + \frac{S_{1,i}}{\sqrt{1-\xi_1^2}} (2\xi_1^2 + S_{1,i}^2 - 1) \sin(\omega_{d1} t) \right] \Big\} \tag{18}$$

$$z_{2,i}(t) = -\frac{G_i L^3}{8\pi^4 EI} \frac{1}{(1-S_{2,i}^2)^2 + (2\xi_1 S_{2,i})^2} \Big\{ (1-S_{2,i}^2)\, \sin(\Omega_{2,i} t) - 2\xi_1 S_{2,i}\, \cos(\Omega_{2,i} t) + \\ \mathrm{e}^{-\xi_1 \omega_1 t} \left[2\xi_1 S_{2,i} \cos(\omega_{d1} t) + \frac{S_{2,i}}{\sqrt{1-\xi_1^2}} (2\xi_1^2 + S_{2,i}^2 - 1) \sin(\omega_{d1} t) \right] \Big\}$$

$$z_{3,i}(t) = -\frac{G_i L^3}{8\pi^4 EI} \frac{1}{(1-S_{3,i}^2)^2 + (2\xi_1 S_{3,i})^2} \Big\{ (1-S_{3,i}^2)\, \sin(\Omega_{3,i} t) - 2\xi_1 S_{3,i}\, \cos(\Omega_{3,i} t) + \\ \mathrm{e}^{-\xi_1 \omega_1 t} \left[2\xi_1 S_{3,i} \cos(\omega_{d1} t) + \frac{S_{3,i}}{\sqrt{1-\xi_1^2}} (2\xi_1^2 + S_{3,i}^2 - 1) \sin(\omega_{d1} t) \right] \Big\}$$

Where $\Omega_{1,i}$, $\Omega_{2,i}$ and $\Omega_{3,i}$ are the loading frequencies defined as:

$$\begin{aligned} \Omega_{1,i} &= 2\pi f_{step}\, i \\ \Omega_{2,i} &= 2\pi f_{step}\, i - \frac{2\pi v}{L} \\ \Omega_{3,i} &= 2\pi f_{step}\, i + \frac{2\pi v}{L} \end{aligned} \tag{19}$$

The factors $S_{1,i}$, $S_{2,i}$ and $S_{3,i}$ are:

$$\begin{aligned} S_{1,i} &= \frac{\Omega_{1,i}}{\omega_1} \\ S_{2,i} &= \frac{\Omega_{2,i}}{\omega_1} \\ S_{3,i} &= \frac{\Omega_{3,i}}{\omega_1} \end{aligned} \tag{20}$$

And ω_{d1} represents the damped frequency of the system:

$$\omega_{d1} = \omega_1 \sqrt{1-\xi_1^2} \tag{21}$$

Furthermore, magnification factors of the components of each solution in (18) can be defined as:

$$\Phi_{1,i} = \frac{1}{(1-S_{1,i}^2)^2 + (2\xi_1 S_{1,i})^2} \Big\{ (1-S_{1,i}^2)\ \sin(\Omega_{1,i}t) - 2\xi_1 S_{1,i}\ \cos(\Omega_{1,i}t) + \\ \mathrm{e}^{-\xi_1\omega_1 t}\left[2\xi_1 S_{1,i}\cos(\omega_{d1}t) + \frac{S_{1,i}}{\sqrt{1-\xi_1^2}}(2\xi_1^2 + S_{1,i}^2 - 1)\sin(\omega_{d1}t) \right] \Big\} \tag{22}$$

$$\Phi_{2,i} = \frac{1}{(1-S_{2,i}^2)^2 + (2\xi_1 S_{2,i})^2} \Big\{ (1-S_{2,i}^2)\ \sin(\Omega_{2,i}t) - 2\xi_1 S_{2,i}\ \cos(\Omega_{2,i}t) + \\ \mathrm{e}^{-\xi_1\omega_1 t}\left[2\xi_1 S_{2,i}\cos(\omega_{d1}t) + \frac{S_{2,i}}{\sqrt{1-\xi_1^2}}(2\xi_1^2 + S_{2,i}^2 - 1)\sin(\omega_{d1}t) \right] \Big\}$$

$$\Phi_{3,i} = \frac{1}{(1-S_{3,i}^2)^2 + (2\xi_1 S_{3,i})^2} \Big\{ (1-S_{3,i}^2)\ \sin(\Omega_{3,i}t) - 2\xi_1 S_{3,i}\ \cos(\Omega_{3,i}t) + \\ \mathrm{e}^{-\xi_1\omega_1 t}\left[2\xi_1 S_{3,i}\cos(\omega_{d1}t) + \frac{S_{3,i}}{\sqrt{1-\xi_1^2}}(2\xi_1^2 + S_{3,i}^2 - 1)\sin(\omega_{d1}t) \right] \Big\}$$

Then, the solution of the modal coordinates for a given harmonic component i can be written as follows:

$$q_{1,i}(t) = \frac{G_i L^3}{4\pi^4 EI}\left(\Phi_{1,i} - \frac{\Phi_{2,i}}{2} - \frac{\Phi_{3,i}}{2}\right) \tag{23}$$
$$\dot{q}_{1,i}(t) = \frac{G_i L^3}{4\pi^4 EI}\left(\dot{\Phi}_{1,i} - \frac{\dot{\Phi}_{2,i}}{2} - \frac{\dot{\Phi}_{3,i}}{2}\right)$$
$$\ddot{q}_{1,i}(t) = \frac{G_i L^3}{4\pi^4 EI}\left(\ddot{\Phi}_{1,i} - \frac{\ddot{\Phi}_{2,i}}{2} - \frac{\ddot{\Phi}_{3,i}}{2}\right)$$

And, the final solution becomes:

$$y(x,t) = \frac{L^3}{4\pi^4 EI}\left(1 - \cos\left(\frac{2\pi x}{L}\right)\right)\sum_{i=1}^{3} G_i\left(\Phi_{1,i} - \frac{\Phi_{2,i}}{2} - \frac{\Phi_{3,i}}{2}\right) \tag{24}$$
$$\dot{y}(x,t) = \frac{L^3}{4\pi^4 EI}\left(1 - \cos\left(\frac{2\pi x}{L}\right)\right)\sum_{i=1}^{3} G_i\left(\dot{\Phi}_{1,i} - \frac{\dot{\Phi}_{2,i}}{2} - \frac{\dot{\Phi}_{3,i}}{2}\right)$$
$$\ddot{y}(x,t) = \frac{L^3}{4\pi^4 EI}\left(1 - \cos\left(\frac{2\pi x}{L}\right)\right)\sum_{i=1}^{3} G_i\left(\ddot{\Phi}_{1,i} - \frac{\ddot{\Phi}_{2,i}}{2} - \frac{\ddot{\Phi}_{3,i}}{2}\right)$$

3 ACCELERATION RESPONSE

This section considers the response at the mid point $x = L/2$ of the beam. In order to evaluate the acceleration response of the system, the second derivative of equations (22) are computed as the following:

$$\ddot{\Phi}_{j,i} = \frac{\omega_1^2}{(1-S_{j,i}^2)^2 + (2\xi_1 S_{j,i})^2} \Big\{ (1-S_{j,i}^2) S_{j,i}^2 \, \sin(\Omega_{j,i} t) - 2\xi_1 S_{j,i}^3 \, \cos(\Omega_{j,i} t) + \\ \mathrm{e}^{-\xi_1 \omega_1 t} \cos(\omega_{d1} t) \Big[2\xi_1 S_{j,i} (2\xi_1^2 - 1) - 2\xi_1 S_{j,i} (2\xi_1^2 + S_{j,i}^2 - 1) \Big] + \\ \mathrm{e}^{-\xi_1 \omega_1 t} \sin(\omega_{d1} t) \Big[4 S_{j,i} \xi_1^2 \sqrt{1-\xi_1^2} + (2\xi_1^2 - 1) \Big(S_{j,i} / \sqrt{1-\xi_1^2} \Big) (2\xi_1^2 + S_{j,i}^2 - 1) \Big] \Big\} \tag{25}$$

Where $j = 1, 2, 3$. If low damping is assumed, equation (25) can written as:

$$\ddot{\Phi}_{j,i} = \frac{\omega_1^2}{(1-S_{j,i}^2)^2 + (2\xi_1 S_{j,i})^2} \Big\{ (1-S_{j,i}^2) S_{j,i}^2 \, \sin(\Omega_{j,i} t) - 2\xi_1 S_{j,i}^3 \, \cos(\Omega_{j,i} t) + \\ -\mathrm{e}^{-\xi_1 \omega_1 t} \cos(\omega_1 t) \Big[2\xi_1 S_{j,i}^3 \Big] - \mathrm{e}^{-\xi_1 \omega_1 t} \sin(\omega_1 t) \Big[S_{j,i} (S_{j,i}^2 - 1) \Big] \Big\} \tag{26}$$

And, if no damping is considered one gets:

$$\ddot{\Phi}_{j,i} = \frac{\omega_1^2}{(1-S_{j,i}^2)^2} \Big\{ (1-S_{j,i}^2) S_{j,i}^2 \, \sin(\Omega_{j,i} t) - \sin(\omega_1 t) \, S_{j,i} (S_{j,i}^2 - 1) \Big\} \tag{27}$$

Considering a single harmonic i the response is approximated as:

$$\ddot{y}_i(t) = \frac{L^3}{4\pi^4 EI} G_i \left(\ddot{\Phi}_{1,i} - \frac{\ddot{\Phi}_{2,i}}{2} - \frac{\ddot{\Phi}_{3,i}}{2} \right)$$

Finally, by taking in ${\omega_1}^2$ as a common factor from equation (25) and considering equation (11), the response due to a single harmonic i component can be written as:

$$\ddot{y}_i(t) = \frac{G_i/2}{3/8mL} \Theta_i(S_{j,i}\,, \Omega_{j,i}\,, \omega_1\,, \xi_1, t) \\ \ddot{y}_i(t) = \frac{G_i/2}{M_1} \Theta_i(S_{j,i}\,, \Omega_{j,i}\,, \omega_1\,, \xi_1, t) \tag{28}$$

Where Θ_i can be defined as the magnification factor of the dynamic response, that is a function dependent on the frequency ratio ($S_{j,i}$ between the input frequency $\Omega_{j,i}$ and the natural frequency ω_1 of the system, damping ratio ξ_1 and the loading time t.

3.1 ESTIMATION OF MAXIMUM RESPONSE

In order to evaluate the importance of the position of the load, parameters $\Omega_{2,i}$ and $\Omega_{3,i}$ from equation (19) can be written as the following:

$$\Omega_{2,i} = \frac{2\pi v}{L}(i\,k - 1) \qquad (29)$$
$$\Omega_{3,i} = \frac{2\pi v}{L}(i\,k + 1)$$

Where k denotes the number of cycles or steps applied to the system by the pedestrian. The aforementioned equation, when multiply by time t, it allows to evaluate the magnification factor as function of the non-dimensional position vt/L in accordance with $S_{j,i}$, where $j = 1, 2, 3$. Also, equations (29) can be written as follows:

$$\Omega_{2,i} = 2\pi f_{step}\left(i - \frac{1}{k}\right) \qquad (30)$$
$$\Omega_{3,i} = 2\pi f_{step}\left(i + \frac{1}{k}\right)$$

In this way, equations (30) indicate that, as the number of cycles increases the velocity term can be neglected, approaching the steady state response. In this regard, it is important to mention that the equations here exposed, will correctly approximate the response when the step frequency f_{step} is close to the natural frequency f_1 rather than exactly the natural frequency of the bridge. This is understood from the fact that, the differential equation (13) changes when perfect resonance is addressed. Furthermore, the system will achieve its maximum response when the $S_{j,i}$ parameter is close to the unity, meaning that the step frequency f_{step} is at resonance with the natural frequency f_1. This is a consequence of the presence of the velocity term that originates the beating of the system response components as shown in equations (17) and (18). From equation (30), it can be seen that for very short span bridges the velocity term has a greater influence on the $S_{j,i}$ parameter. However, if the pedestrian bridge is short there will not be enough cycles to achieve high amplification in the system's response. Finally, considering the first harmonic component, the envelope of the magnification factor Θ_1 can be evaluated, as shown in Figure 2. The envelop is made by evaluating the magnification factor as a function of different frequency ratios $S_{j,i}$, respect to the non-dimensional position vt/L, given a number of cycles k and damping ratio ξ_1. The maximum values of the magnification factor were taken and plotted in Figure 2, which correspond to the case of a resonant loading case, i.e. $S_{j,i} \cong 1$. This is a consequence of the presence of the velocity term. The obtained magnification factor curves, are consistent with results published by [4, 5, 6, 7, 8], taking into account the modal mass and modal stiffness of the clamped–clamped beam system. It can be seen from from Figure 2 that, the response is highly dependent of the damping ratio of the system; a small change in the damping characteristics of the system has the effect of drastically reducing its dynamic response, even reducing the order of magnitude of the expected accelerations. This exposes the disproportional trade-off between the dissipation capacities of the system and its corresponding response given a resonant input, in regards to a transient event.

Equation (26) has been validated since it produces the same magnification factor curves as the complete solution in equation (25), for the presented damping levels. Then, the maximum response due to the ith harmonic component of the pedestrian load can be estimated as:

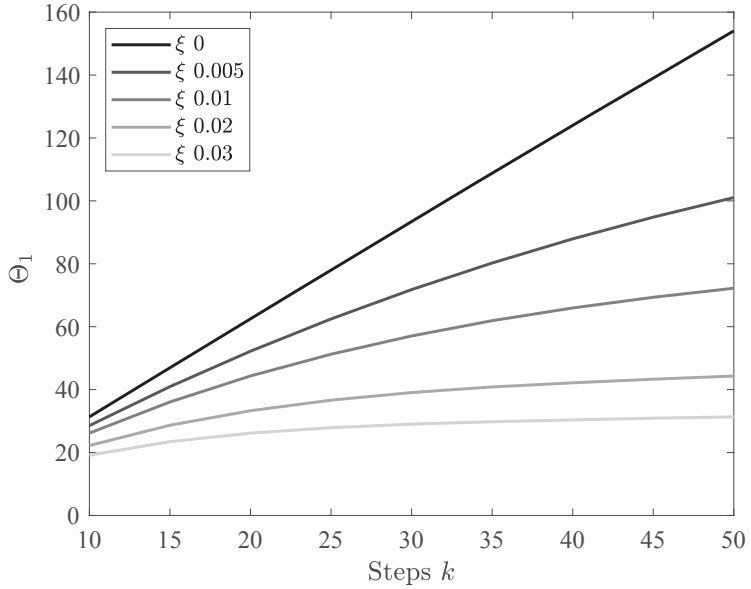

Figure 2: Magnification factor

$$\ddot{y}_i = \frac{G_i/2}{3/8mL}\Theta_i(k,\xi) \tag{31}$$

Finally, equation (31) can be normalized by taking into account the equivalent steady state response of the prescribed single crossing pedestrian $\overline{\ddot{y}}$, i.e. the steady state response produced by a harmonic load placed in the centre of the beam as:

$$\frac{\ddot{y}_i}{\overline{\ddot{y}}} = \Theta_i(k,\xi)\,\xi, \qquad \ddot{y}_i = \Lambda\,\overline{\ddot{y}} \tag{32}$$

In which Λ is defined as $\Lambda = \Theta_i(k,\xi)\,\xi$. The parameter Λ represents the fraction of the transient structural response respect to the equivalent steady state response, quantifying how representative the transient event is in respect to the steady state. Results are shown in Figure 3, in which normal walking and normal running defined with a stride length of 0.75 m and 1.25 m as in [9] have been taken into account. In Figure 3, normal running has plotted with a dash line while normal walking with a continuous line. From the results it can be seen that, due to the difference of the stride length and its immediately consequence in the number of cycles applied to the system between the aforementioned activities, for a given bridge length L and a damping ratio ξ, it is easier to achieve an steady state response for normal walking than normal running. This effect is emphasized as damping increases.

3.2 MINIMUM MASS DESIGN CURVES

By the use of equation (31) , it is possible to generate design curves for minimum mass needed for a single running and a single walking load cases in pedestrian bridges. Given a

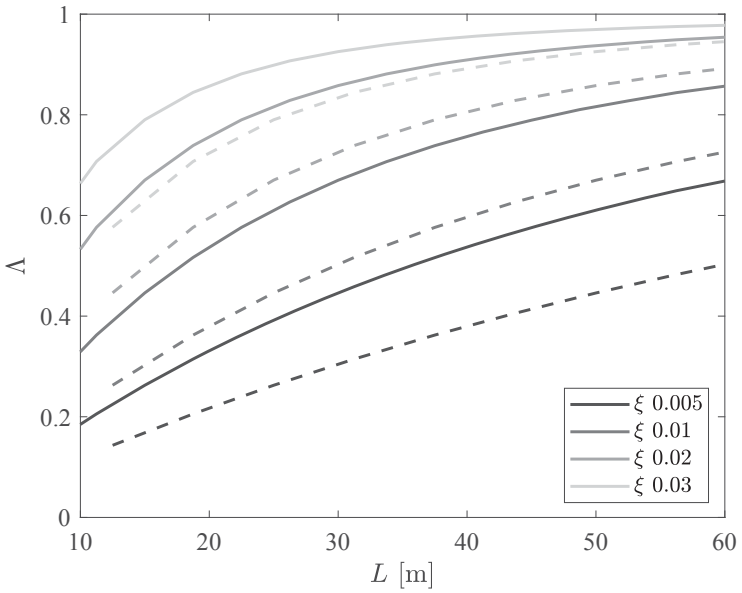

Figure 3: Λ (- - normal running — normal walking)

specific acceleration limit a_{limit} one gets:

$$m = \frac{G_i/2}{3/8\, a_{limit}\, L}\Theta_i(k,\xi) \tag{33}$$

By selecting a specific stride length l_s as reference value and considering $L = k\, l_s$, the minimum linear mass needed can be defined as:

$$m = \frac{G_i/2}{3/8\, a_{limit}\, k\, l_s}\Theta_i(k,\xi) = \frac{G_i/2}{3/8\, a_{limit}\, L}\Theta_i(L/l_s,\xi) \tag{34}$$

It is considered that normal walking and normal running are defined with a stride length of 0.75 m and 1.25 m, respectively [9]. For a given a_{limit}, a general minimum mass design curve can be developed for any given value of a_{limit}, as shown in Figure 4, in which normal running has been plotted with a dash line and normal walking with continuous line. It can be seen in equation (34) that the minimum linear mass is inversely proportionally to the length L of the bridge system and proportional to the magnification factor $\Theta_i(k,\xi)$. In this way, by studying the minimum linear mass m it is possible to appreciate which effect dominates in the verification of the serviceability limit state.

It can be seen from Figure 4 that, under the same levels of damping, running is always more critical than walking, which exposes the need of addressing the running load case scenario for pedestrian bridges. The high differences between normal running and normal walking are explained by the combined effect of the differences in their corresponding dynamic load factors DLF_i and the different magnification factors Θ_i for a given bridge length L, i.e. the number load cycles applied. The importance of the aforementioned results lies on its generality, solved for

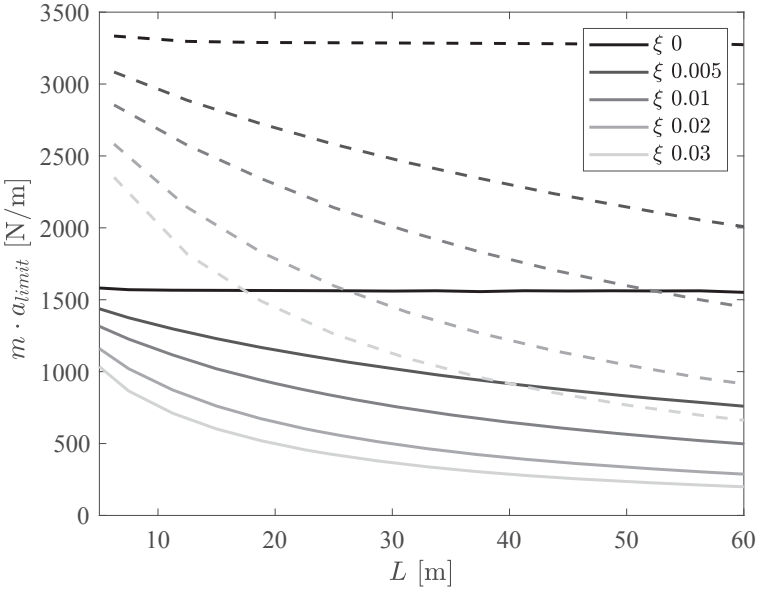

Figure 4: Minimum linear mass (- - normal running — normal walking)

any prescribed acceleration limit a_{limit} in regards to vertical vibrations. Finally, it is important to remark that the equations developed can be used for any type of bridge that reassembles the first mode of a vibration of a clamped—clamped beam, as found in tied arch bridges, portal frame bridges and frame type bridges.

4 CONCLUSIONS

This paper presents an analytical approximation to describe the vertical vibrations of clamped-clamped beams subjected to a single pedestrian induced load, and the following can be concluded.

- A magnification factor is presented and quantified in a closed—form equation. And, the low damping assumption has been introduced and validated for the single passing pedestrian load case scenario. The magnification factor exposes the disproportional trade-off between the dissipation capacities of the system and its corresponding dynamic response given a resonant input, which indicates how pedestrian bridges can be susceptible to experience a large acceleration response.

- It has been quantified how the number load cycles influence the transient response to reach its equivalent steady state response for both normal running and normal walking, in which due to the differences in the stride length, it is easier to achieve steady state under a normal walking regime load than normal running.

- By studying the minimum linear mass parameter, it has been demonstrated that running is more critical than walking for a given damping ratio, exposing the need to address its corresponding load case scenario in the design codes. To this aim, a design chart is given in the present paper in order to perform fast design and assessment of pedestrian bridges for a single crossing pedestrian load case scenario.

- The high differences between normal running and normal walking regarding the minimum mass parameter are explained by the combined effect of the differences in their corresponding dynamic load factors DLF_i and the different magnification factors Θ_i for a given bridge length L, i.e. the number load cycles applied. The importance of this result lies on its generality, since it has been solved for any prescribed acceleration limit a_{limit} in regards to vertical vibrations.

Finally, the moving harmonic load problem applied to clamped—clamped beams has been addressed and it is explained how it can be used for structures that reassemble the mode shape of the studied system such as frame-type bridges and tied arch bridges, exposing the utility and generality of the present work.

Keywords: Crowd Modelling, Footbridges, Pedestrian Loading, Spectral Model

Abstract. *This paper aims to provide a validation of the Generalized Equivalent Spectral Model of pedestrian-induced loading through numerical simulations of crowd dynamics. Pedestrian flows with varying density are numerically simulated based on the social force model. The instantaneous step frequency of each pedestrian is obtained from his instantaneous velocity. Results obtained from numerical simulations are statistically analyzed to obtain probability density functions of the step frequency. Then, each pedestrian is modelled as a moving harmonic load, whose trajectory and velocity are obtained from crowd simulations. The power spectral density function of the modal force obtained from numerical simulations is then compared with the analytical expression provided by the Generalized Equivalent Spectral Model. Possible modifications of the original formulation are analyzed, in order to fit numerical results.*

1 INTRODUCTION

Vibration serviceability assessment of footbridges under human-induced excitation requires the availability of suitable and reliable load models. Several walking load models have been proposed in the last decades, but so far none of them has been fully validated and recognized as the most reliable. Recently, increasing attention has been devoted to stochastic load models, which allow considering the inherent randomness of walking parameters, also known as inter-subject variability. A possible approach is the modelling of pedestrian loading as a stationary random process through the definition of a suitable spectral model (e.g. [1], [2]). Most spectral models proposed so far refer to unrestricted pedestrian traffic, i.e. to very low pedestrian density, so that pedestrians are free to walk at their desired speed. To the authors' knowledge, the only extension to crowded conditions has been proposed by Ferrarotti and Tubino [3]. In the Generalized Equivalent Spectral Model (GESM), the effects of human-human interaction are taken into account in two ways: (1) the mean step frequency of pedestrians is expressed as a function of the crowd density; (2) a coherence function is introduced to model the increasing correlation of the loading at different locations for increasing crowd density. Due to the lack of experimental data, the coherence function has been defined in a qualitative physically-based way. Thus, a numerical and/or experimental validation of the model is needed.

The aim of the proposed work is to numerically validate the GESM through crowd dynamics simulations. These are carried out with the commercial software MassMotion [4], which is based on a microscopic description of pedestrian dynamics, i.e. each pedestrian is modelled as a single agent, whose velocity is determined by the interactions with the environment and the surrounding pedestrians. The simulations are performed on an ideal footbridge, crossed by unidirectional flow of pedestrians with crowd densities varying in the range 0.3-1.5 ped/m^2. The pedestrian trajectories and velocities obtained from crowd simulations are used to derive the pedestrian-induced forces. The power spectral density function of the modal force obtained from numerical simulations is then compared with the analytical expression provided by the GESM to evaluate whether the proposed coherence function is suitable to correctly model human-human interaction effects. A critical analysis is provided, and possible modifications of the original formulation are proposed in order to fit numerical results.

2 PEDESTRIAN-INDUCED FORCES: ANALYTICAL FORMULATION

In this Section, the Generalized Equivalent Spectral Model (Section 2.1) and the time-domain force model (Section 2.2) are introduced.

2.1 Generalized Equivalent Spectral Model

The Generalized Equivalent Spectral Model (GESM) [3] of pedestrian-induced forces is based on the definition of the cross-power spectral density function (cpsdf) of the force per-unit-length $S_{ff}(x,x',n)$, which, under the assumption of uniform equivalent loading, is given by:

$$S_{ff}\left(x,x';n\right)=S_f\left(n\right)Coh_{ff}\left(x,x';n\right) \tag{1}$$

where $S_f(n)$ is the power spectral density function (psdf) of the force per-unit-length, and $Coh_{ff}(x,x',n)$ is its coherence function, given by:

$$S_f\left(n\right)=\frac{\left(\alpha_m G_m\right)^2}{\varepsilon L}\frac{N_p}{4}p_N\left(n\right) \tag{2}$$

$$Coh_{ff}\left(x,x';n\right)=\begin{cases}1 & \text{if} \quad \left|x-x'\right|<\varepsilon \\ \exp\left[-C\left(\left|x-x'\right|-\varepsilon\right)\right] & \text{otherwise}\end{cases} \tag{3}$$

In Eq. (2), α_m and G_m are, respectively, the mean value of the DLF and of pedestrian weight, N_p is the mean number of pedestrians on the footbridge, $p_N(n)$ is the probability density function (pdf) of the step frequency n, ε is interpreted as the separation distance that each pedestrian interposes with others to avoid contact, assumed as ε= 4 m. The exponential decay coefficient in Eq. (3), is expressed as a function of the mean step frequency n_m, $C = \exp(C_1 n_m + C_2)$, (C_1 = 22.7, C_2=-41). The mean step frequency n_m can be obtained as a function of the mean walking velocity v_m [5]:

$$n_m = 0.35v_m^3 - 1.59v_m^2 + 2.93v_m \tag{4}$$

The mean step velocity v_m is related to pedestrian density ρ through the fundamental law:

$$v_m\left(\rho\right)=v_{\max}\left\{1-\exp\left[-\gamma\rho_{\max}\left(\frac{1}{\rho}-\frac{1}{\rho_{\max}}\right)\right]\right\} \tag{5}$$

with $\rho_{\max}$=5.4 ped/m^2, γ=0.354, v_{max}=1.34 m/s according to Buchmueller and Weidmann [6].

Based on the GESM, the psdf of the modal force for a generic mode shape $\varphi_j(x)$ is given by:

$$S_{F_j}\left(n\right)=S_f\left(n\right)\chi_j\left(n\right) \tag{6}$$

where $\chi_j(n)$ is the admittance function, defined as follows:

$$\chi_j\left(n\right)=\int_0^L\int_0^L Coh_{ff}\left(x,x';n\right)\varphi_j\left(x\right)\varphi_j\left(x'\right)dxdx' \tag{7}$$

being L the length of the structure. Under the assumption of unrestricted traffic, and considering the first mode shape of a simply-supported beam $\varphi_j(x)$=sin($\pi x/L$), the psdf of the modal force is given by [3]:

$$S_{F_j\mathrm{unr}}\left(n\right)=\left(\alpha_m G_m\right)^2\frac{N_p}{4}p_N\left(n\right) \tag{8}$$

2.2 Time-domain force model

Pedestrian-induced force is commonly schematized as a moving load. The force per unit length exerted by N_p pedestrians can be expressed as the sum of the forces exerted by each single pedestrian as follows:

$$f\left(x,t\right)=\sum_{i=1}^{N_p}f_i\left(t\right)\delta\left[x-x_i\left(t\right)\right] \tag{9}$$

where t and x are the time and the abscissa along the structure, $x_i(t)$ and $f_i(t)$ are, respectively, the instantaneous position and the force exerted by the i-th pedestrian, and $\delta(\bullet)$ is the Dirac delta function.

If pedestrian traffic is simulated numerically in order to take into account interaction among pedestrians, then the instantaneous position x_i and velocity v_i of the i-th pedestrian are the output of the simulation, and the step frequency n_i can be derived from the step velocity v_i through a suitable law (e.g. Eq. (4)). Since the pedestrian step frequency $n_i(t)$ is time variant during

footbridge crossing, the pedestrian force exerted by the *i*-th pedestrian can be modelled as a sinusoidal carrier signal, whose base frequency $n_{m,i}$ is modulated, as follows:

$$f_i(t) = \alpha_i G_i \sin\left[2\pi n_{m,i} t + 2\pi \int_0^{T_i} \left(n_i(t) - n_{m,i}\right) \mathrm{d}t\right] \tag{10}$$

where $n_{m,i}$ is the mean value of the instantaneous step frequency during footbridge crossing time T_i. Furthermore, α_i and G_i are the dynamic load factor (DLF) and the weight of the *i*-th pedestrian, respectively.

Starting from Eq. (9), the modal force for a generic mode shape $\varphi_j(x)$ can be expressed as:

$$F_j(t) = \int_0^L f(x,t)\varphi_j(x)\,\mathrm{d}x = \sum_{i=1}^{N_p} f_i(t)\varphi_j\left[x_i(t)\right] \tag{11}$$

3 CROWD DYNAMICS NUMERICAL SIMULATION

Numerical simulations of crowd dynamics are carried out on an ideal footbridge, whose dimensions in plan recall the ones of the De Gasperi footbridge in Milan: length L=60 m, width B=2.7 m [7]. Pedestrian initial positions are randomly distributed in a "starting area" before the footbridge entrance, ten times longer than the footbridge length: this assures that pedestrians are initially uniformly distributed with a crowd density ρ. Hence, the total number of generated pedestrians N is set equal to $10\rho BL$. Four values of crowd density, [0.3 0.7 1.1 1.5] ped/m^2, from unrestricted to extremely dense pedestrian traffic, are considered. For each crowd density, 100 simulations are performed to obtain statistical reliability.

For each simulation, mean values of the pedestrian density and velocity are calculated during the period of full occupancy T_{full}. The lower and upper boundaries of T_{full} are determined as the first and last time instant when the 95% of the mean number of pedestrians N_p are on the footbridge [8]. The obtained mean values are then averaged over 100 simulations.

Figure 1 plots the v_m-ρ relation resulting from crowd simulations (MM), together with a fitting law and the fundamental law in Eq. (5). It can be observed that for pedestrian densities below around 1.7 ped/m^2 the mean walking velocities obtained from numerical simulations are lower than those estimated with the Weidmann law in Eq. (5).

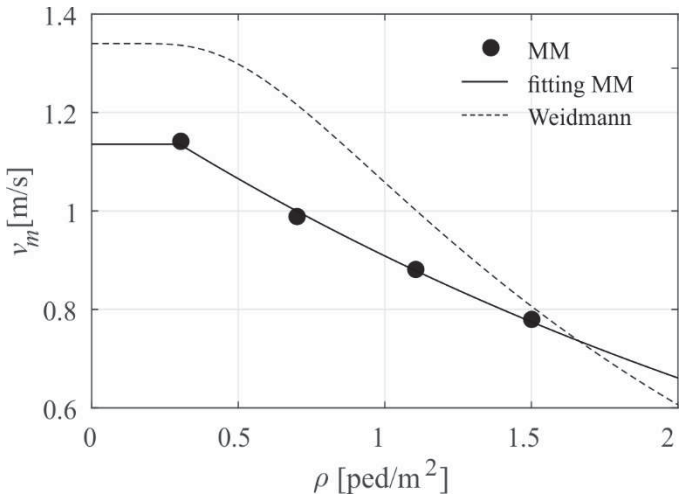

Figure 1: Comparison between v_m-ρ relation obtained with MM and proposed by Weidmann.

Time histories of step frequencies are derived from walking velocities through Eq. (4). Moreover, in order to account for the reaction time needed by pedestrians to adapt their step frequency to variations of the walking velocity, the step frequency is estimated as the 5s-moving average of the instantaneous values.

Table 1 reports the obtained mean value and standard deviation of step frequencies for the four crowd densities.

ρ [ped/m^2]	0.3	0.7	1.1	1.5
n_m [Hz]	1.786	1.676	1.588	1.492
n_{std} [Hz]	0.1083	0.0962	0.0752	0.0598

Table 1: Mean and standard deviation of step frequencies obtained from numerical simulations.

Pdfs of the mean step frequencies during footbridge crossing are estimated from each simulation. Figure 2 plots the obtained numerical mean pdfs and their Gaussian fitting, together with the model adopted in [3]. The numerical pdf is well approximated by a Gaussian fitting, especially for densities below 1.5 ped/m^2, while the pdf in [3], assuming n_{std}=0.18 Hz, does not fit the simulation results.

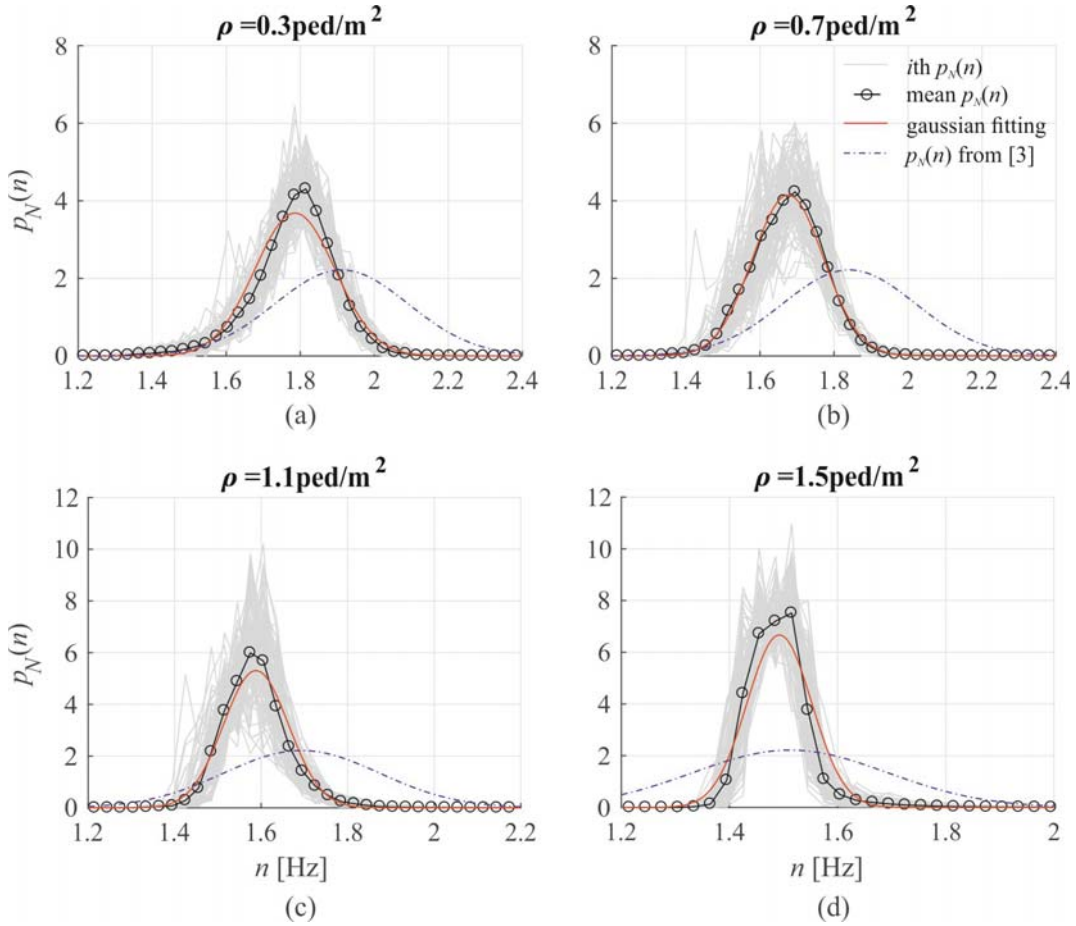

Figure 2: Numerical PDFs of the mean step frequencies and Gaussian fitting.

Figure 3 shows the mean and standard deviation (std) of step frequencies obtained from the fitting of numerical pdfs for each crowd density, compared with the mean step frequencies estimated through Eqs (4), (5). In line with the v_m-ρ trend in Figure 1, numerical mean step

frequencies decrease on increasing crowd density and numerical values are lower than those estimated from Eqs. (4), (5). Standard deviation values also show a decreasing trend for increasing crowd density, meaning that in crowded conditions pedestrians tend to walk at step frequencies closer to the mean value.

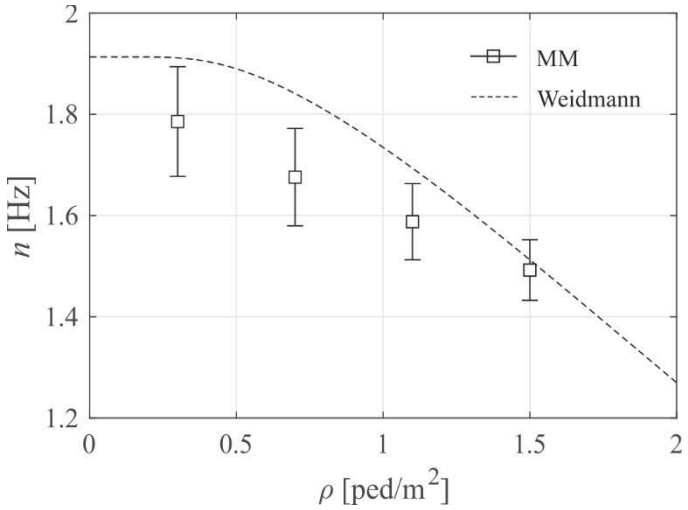

Figure 3: Numerical mean and std of step frequencies in comparison with those estimated from Eqs (4), (5).

The forces induced by each pedestrian are then calculated according to Eq. (9), with each contribution given by Eq. (10), and the modal force is calculated as in Eq. (11), assuming $\alpha_i G_i = \alpha_m G_m = 280$ N. Figure 4 plots an example of the time history of the modal force obtained from a simulation.

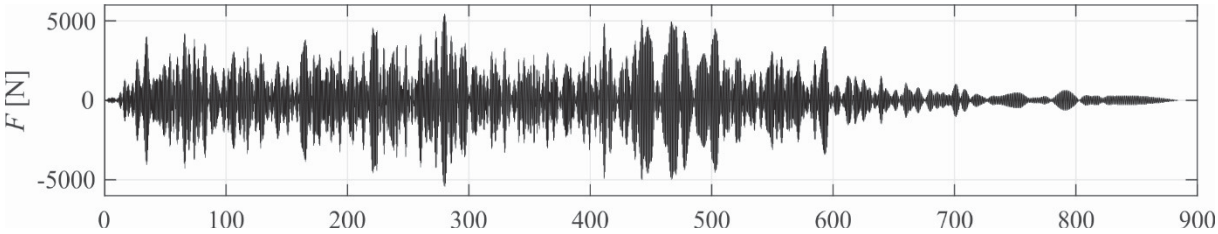

Figure 4: Time history modal force for a simulation with 0.7 ped/m^2.

4 PSDF OF THE MODAL LOAD AND GESM VALIDATION

This section is devoted to the comparison between the numerical psdfs and the analytical expressions provided by the GESM. For each value of the crowd density, the numerical psdfs of the modal force are calculated for each simulation and then averaged over 100 simulations. Concerning GESM, three different psdfs are considered:

- the psdf obtained from Eq. (6), assuming $p_N(n)$ in Eq. (2) as a normal distribution, with mean value from Eq. (4) and std corresponding to 0.18 Hz [3] (GESM);
- the psdf obtained from Eq. (6), assuming $p_N(n)$ as a normal distribution, with mean value and std obtained from numerical simulations in Table 1 ($GESM_{sim}$);
- the psdf obtained from Eq. (8), valid for unrestricted pedestrian traffic, assuming $p_N(n)$ as a normal distribution, with mean value and std obtained from numerical simulations in Table 1 ($GESM_{unr}$).

Figure 5 plots the comparison between the modal psdfs obtained from numerical simulations and the analytical estimates obtained from the GESM. From Figure 5, it can be deduced that

the original formulation (GESM) provides a psdf of the modal force which is far from the one obtained numerically from crowd simulations: the difference comes mainly from the significant difference between the mean step frequency obtained from crowd numerical simulations and the ones provided by Eq. (4), already remarked in Figure 4; furthermore, Table 1 shows that the numerically obtained standard deviation of the step frequency is much smaller than the value assumed in the GESM. The analytical prediction provided by the GESM with mean and std of the step frequency obtained from numerical simulations ($GESM_{sim}$) is in accordance with the numerical result for low crowd density (unrestricted pedestrian traffic), while it greatly overestimates the numerical results for higher crowd densities. The analytical solution that provides results in better accordance with numerical simulations is the one obtained from GESM with numerically estimated mean and std of the step frequency under the hypothesis of unrestricted pedestrian traffic ($GESM_{unr}$). Thus, it seems that interaction among pedestrians can be globally modelled assuming a psdf of the modal load provided by the GESM for unrestricted traffic, adopting a pdf of the step frequency coherent with simulations, i.e. taking into account the reduction of its mean value and std on increasing crowd density.

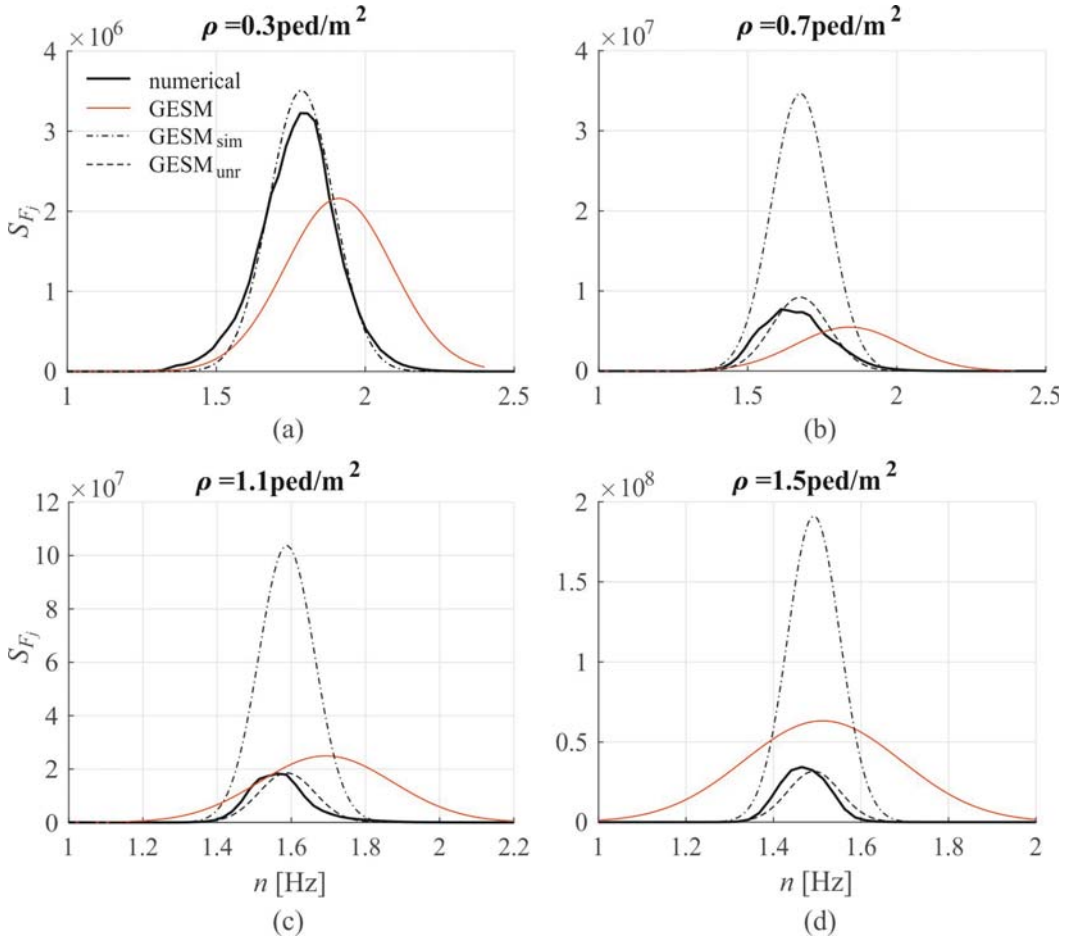

Figure 5: Comparison between psdfs of the modal force obtained from numerical simulations and GESM predictions.

5 CONCLUSIONS AND PROSPECTS

This paper has studied pedestrian-induced forces on footbridges in different traffic conditions. Pedestrian flows have been simulated numerically with the commercial software MassMotion, based on the social force model, and the instantaneous step frequency of pedestrians has been

derived from their velocity. The probabilistic analysis of the step frequency has revealed that, in accordance with the Weidmann law, the mean step frequency tends to decrease on increasing crowd density but numerically obtained walking velocities are lower. Furthermore, also the standard deviation of the step frequency tends to decrease in crowded conditions.

The comparison between the power spectral density function of the modal force obtained from numerical simulations and the analytical expression provided by the GESM has shown that the correlation among pedestrians can be modelled through the GESM including density-dependent values of the mean and standard deviation of the step frequency. The coherence model originally proposed highly overestimates the correlation among pedestrians and provides very large values of the modal force, if compared with numerical simulations. Assuming the coherence model proposed by the GESM for unrestricted pedestrian traffic provides results in accordance with numerical simulations.

The results here obtained are referred to a single deck geometry. Further analyses investigating the influence of the deck width on the equivalent loading spectral properties are necessary. Furthermore, the attention is here focused on the spectral properties of the modal load: a strategy to directly characterize the coherence function of the equivalent distributed loading is under investigation.

ACKNOWLEDGEMENTS

F. Venuti wishes to thank Oasys ltd for having provided free license of the software MassMotion.

Abstract. *Pedestrian-pedestrian interaction (PPI) is one of the fundamental mechanisms purported to influence the amplitudes of structural response under the action of a walking crowd. This is because a pedestrian is likely to alter their gait due to the presence of other pedestrians, which in turns alters the magnitude of structural loading. However, little empirical data are currently available to assess the effect of PPI in the context of vibration serviceability. This is mainly due to logistical challenges in assembling and instrumenting a crowd of walking pedestrians, and the associated cost. To this end, a novel virtual reality platform is developed for experimental investigation of pedestrian-pedestrian interaction. In comparison to real-world crowd testing, the platform enables experimental protocols to be implemented repeatedly in a highly controlled environment while collecting a rich set of data on pedestrian behaviour. The platform incorporates state-of-the-art technology for motion capture, artificial intelligence and three-dimensional computer modelling, and comprises of three core modules: (i) the environment, (ii) the crowd and (iii) the user interface enabling real walking behaviour. To assess the validity of the platform for investigating PPI, tests were conducted to quantify gait synchronisation between a pair of walking pedestrians. The pair of pedestrians consisted of either two real humans or a real human and an avatar generated within a fully immersive VR environment. The test subject was either not explicitly asked to or specifically asked to synchronise their gait while walking side-by-side or front-to-back. It was found that walking with an avatar yields qualitatively the same results as walking with a real person, whether that is with or without the instruction to synchronise gait. However, the results differ quantitatively in terms of the synchronisation strength and the directionality.*

1 INTRODUCTION

In recent years, the industry-wide trend of pushing boundaries in terms of sleek and slender design using light materials often leads to reduced mass, stiffness and damping [1] of the newly built structures. As a consequence, several footbridges failed to satisfy the vibration serviceability criteria when occupied by a crowd of people [2–11]. A number of dynamic force models were put forward to account for the adaptation of pedestrian's stepping behaviour due to the presence other walkers [12–15], known as pedestrian-pedestrian interaction (PPI). However, very few studies attempted to uncover the underlying network of complex dynamic interactions present in a crowd of walking pedestrians and quantify the strength of PPI in the context of structural dynamics [16–18]. This is predominantly due to many uncertainties associated with a full-scale crowd testing, but also low repeatability of experimental conditions and a significant logistical challenge of gathering and instrumenting a group of walkers together with the accompanying costs.

To alleviate these issues, a novel experimental platform is proposed to limit the logistical efforts in investigating PPI whilst providing an accurate representation of real-life environment. This is achieved by employing the latest developments in motion capture, three-dimensional modelling and virtual reality (VR) technology, and by using artificial intelligence (AI) - driven virtual pedestrians capable of simulating complex social interactions present in real crowds.

This paper is structured as follows: Section 2 describes the development of the VR experimental platform for PPI investigation, Section 3 details the validation procedure of the platform, followed by the data analysis process, Section 4 presents the validation results together with the discussion, and Section 5 provides the conclusions.

2 DEVELOPMENT OF THE VIRTUAL-REALITY PLATFORM

A construction of biomechanically representative, virtual reality-based experimental platform for investigating PPI consisted of the following stages. Firstly, an optical motion capturing system was employed to record multiple gait cycles of a real person walking with various speeds along a straight line as well as along an arc of circles with various radiuses, with the procedure repeated at multiple walking speeds. Secondly, the recorded motions were used to create an animation controller which would drive the motion of a realistic humanoid character in VR, referred to as an agent. Lastly, a novel AI system was employed to steer the agent in the virtual setting.

2.1 Motion capture

A twenty-five years old male performer (height 182.5 cm, weight: 80 kg) was recruited from the university cohort. He was outfitted with a motion capture equipped with thirty-seven reflective markers placed on body landmarks. The performer was asked to complete four different types of walks at pacing frequencies ranging from 1.3 Hz to 2.0 Hz at 0.1 Hz increments. The walks consisted of walking along a straight line, and around small, medium and large circles with the radiuses of 63.5 cm, 27 cm and 254 cm (25 in, 50 in and 100 in) respectively. A metronome was used to ensure the consistent pacing frequency of the performer throughout the motion recording process.

The gait cycles were recorded using a set of eight OptiTrack Prime 13 cameras, which provided near real-time tracking data at the sampling rate of 120 Hz. The raw tracking data were transferred over to the processing unit over the IEEE 802.3 compliant, gigabit network. The

data were recorded and post-processed using OptiTrack's proprietary software, Motive:Body 2.0.

The initial post-processing consisted of interpolation of missing markers' trajectories due to occlusions and light reflections. Based on the characteristics of the specific marker's trajectory, this was done by employing a first or third-degree polynomial interpolation algorithm. Furthermore, any noise in the raw tracking data was removed by using a fourth-order two-way Butterworth low-pass filter with the cut off frequency at 6 Hz. The primary noise source was markers' vibration, as they were not directly attached to the bones. Also, changes in air temperature and lighting conditions contributed to the decrease in the tracking quality.

The actual processing of the motion capture data was conducted in Autodesk MotionBuilder 2018. During this stage, the original data were down sampled to 30 frames per second. Furthermore, details such as feet's floor contact and fingers positions were adjusted. Finally, from multiple recordings of the same kind, gait cycles were extracted and stitched together to minimise the repeatability of the avatar's motions.

2.2 Avatars creation

Adobe Fuse CC 1.2 was used to create three-dimensional models of humanoid characters employed in VR. The software allowed physical and visual features of virtual avatars to be adjusted, i.e. dimensions of body parts, facial expression and clothing. In order to create the bone structure of the virtual characters, the models were exported to Adobe Mixamo where they were rigged. This created a puppet-like animation mechanism by tying the skeleton to the skin mesh.

Rigged avatars were then exported to Unity 2018.4.0f1 – a game engine used throughout this project. Unity was chosen predominantly due to its C# scripting API and a vast Asset Store collection compared to other game engines.

The next step consisted of retargeting motion-captured gait cycle animations onto the avatars and creating an animation controller. The animation controller employed two-dimensional linear animation blending to create smooth transitions between recorded animations based on two input parameters: (i) selected pacing frequency and (ii) the desired direction of progression.

Footsteps sound effects were added to avatars to provide realistic auditory ques based on the walking surface. The sound effects were programmed to be triggered by every heel strike.

2.3 Steering system

Polarith AI system was implemented to navigate the avatar around the virtual environment by feeding input parameters into the animation controller. It is an artificial-intelligence navigation system which is fully programmable and operates based on a multi-objective optimisation algorithm. The system works in two stages. Firstly, it samples the surrounding to detect the position of the objective and any obstacles. Secondly, it uses an optimisation algorithm to find the local solution to the optimisation problem [19]. The solution takes the form of the desired direction of movement, which is then fed to the animation controller to move the avatar.

For the purpose of experimental platform validation, a path-follow behaviour was programmed without any obstacles present.

3 PLATFORM VALIDATION

To validate the virtual reality platform, one healthy male test subject (age: 30, height: 191.6 cm, weight: 80.1 kg) was recruited from the cohort of students at the University of Leicester.

Prior to taking part in the experiment, he was asked to: (i) familiarise himself with the participant's information letter, (ii) complete the physical activity readiness questionnaire, and (iii) sign the informed consent form. He was asked to wear flat sole shoes and casual clothing.

The study was approved by the University of Leicester Ethics of Research Committee.

3.1 Location

Due to the space requirement, the Charles Wilson Sports Hall was selected as a suitable location for the validation study. The sports hall is located within the main campus of the University of Leicester, UK. It is 16.7 m wide and 33.5 m long with the clear ceiling height of 5.6 metres at the highest point. To minimise the effect of light reflections on tracking quality, the parquet floor was covered with a dark monotone carpet. This also eliminated visual reference cues offered by the floor markings, which otherwise might have influenced the test subject's movements.

3.2 Experimental protocol

The test subject was provided with a habituation time to familiarise himself with the virtual environment. He was asked to perform a total of sixteen walks around a path consisting of two 10 m long straights and two turns 5 m in diameter. Each walk consisted of 8 laps, resulting in a total distance of 285 m travelled per walk. During each walk, the test subject walked next to (side-by-side; SbS) or behind (front-to-back; FtB) a pacer. The walks were performed in two settings: (i) in the virtual environment (VR), where the pacer was previously created, virtual agent or (ii) in the real environment (RL), where the male performer employed to record virtual agent's motion served as a pacer.

To avoid any directional bias in test subject's behaviour, each walk was performed twice, in a clockwise and an anticlockwise direction around the path. During the first eight walks, the test subject was only directed to maintain his assigned position relative to the pacer, hereafter referred to as uninstructed synchronisation experimental conditions (US). During the last eight walks, the test subject was explicitly asked to walk in step with the pacer, in such manner that the timing of their ipsilateral footsteps was perfectly matched, hereafter referred to as instructed synchronisation experimental conditions (IS).

In order to control real pacer's stepping behaviour, he was equipped with Pioneer SE-M521 over-ear headphones connected to KORG MA-1 metronome. The pacing frequency of the virtual pacer was controlled in the game engine through the animation controller.

The pacing frequency of pacers was based on test subject's height and calculated using the following formula:

$$FR = \frac{v}{gl} \tag{1}$$

where v is the walking velocity, g is the gravitational acceleration, l is a leg length, and FR is the Froude number which was set to 0.15. The leg length l was estimated by using test subject's height, and gender relationship derived by Pheasant [20], and explicitly given by Bocian et al. [21]:

$$l = 0.7028h - 0.3091 \tag{2}$$

where h is the test subject's height. The walking velocity v was converted to the pacing frequency f_p using the Eq. 3, which was derived from experimental data in Soczawa-Stronczyk et al. [22].

$$f_p = 0.66v + 0.99 \tag{3}$$

As a consequence, virtual pacer's pacing frequency was set to 1.81 Hz and the metronome beat for the real pacer was set to 108 BPM.

3.3 Instrumentation

A motion capture system (mocap system) made up of twenty-four OptiTrack Prime 17W and ten OptiTrack Prime 13 cameras was set up in the sports hall. During walks performed in the virtual environment, the test subject was equipped with Oculus Rift CV1 head-mounted display (HMD) together with the MSI VR One 7RE backpack PC used to generate the environment. The HMD had reflective markers affixed to it in order to track its position and rotation using the mocap system. The positional data were wirelessly streamed to the backpack PC from the dedicated mocap processing PC using the NatNet server broadcast protocol version 3.0, through IEEE 802.11n-2009 wireless network.

The virtual environment used during the validation experiment was created using building information modelling (BIM) software - ARCHICAD 23. A high-detail, realistic representation of the Charles Wilson Sports Hall was created.

During all walks, the test subject was instrumented with two APDM Opal™ wireless attitude and heading reference systems (AHRS). One AHRS was attached to the lower back, at the level of fifth lumbar vertebra (L5), whereas the other was strapped to the right ankle, using elastic straps. The data recorded by AHRSs were sampled at 128 Hz and time locked. For the purpose of the subsequent analysis, three-dimensional acceleration signal recorded in the local coordinate system (i.e. sensor) was extracted and resolved to the global coordinate system by means of the quaternion algebra. This allowed the vertical component of the acceleration vector (i.e. that aligned with the gravity vector) to be extracted for further analysis.

The real pacer was outfitted with a set of AHRS of the same type and positioned at the same body locations as in the case of the test subject. This enabled synchronisation to be easily quantified based on a set of compatible signals.

Only the data from the sensor strapped to the ankle were used, as the data were sufficient to describe a gait cycle fully.

Figure 1: A person wearing HMD (right) walking next to the pacer in the virtual environment (left).

As it was impossible to instrument the virtual pacer, the displacement of the right ankle was recorded in the game engine, at a sampling frequency of circa 50 Hz. Considering that the

displacement signal was not time-locked with the AHRS's data, the following time alignment procedure was implemented. An AHRS was fastened to a rigid body with three reflective markers, which were tracked by the motion capture system. The position of the rigid body was isometrically mapped (i.e. preserving distances and rotation angles) onto an unrendered virtual cube, of which displacement was recorded together with the displacement of the virtual pacer's ankle. Before and after each test, the AHRS-rigid body couple was slowly waved using a sinusoidal motion to create a reference signal subsequently used to time-align the data from the game engine and the AHRS.

3.4 Data analysis

The subsequent quantification of the synchronisation strength was performed in MATLAB R2019b and was based on vertical velocity signals from the ankle. This is due to the need to reconcile the displacement signals from the game engine (expressed in m) with the acceleration signals from AHRS (expressed in m/s^2) to a common physical quantity before further processing. In order to minimise the impact of the data loss inherent to the numerical differentiation (high frequency noise), as well as to lessen the signal drift rising from the numerical integration (low frequency noise), it was decided to differentiate game engine's displacement signals and integrate the AHRS' acceleration signals to achieve compatible velocity signals (expressed in m/s), as shown in Figure 2.

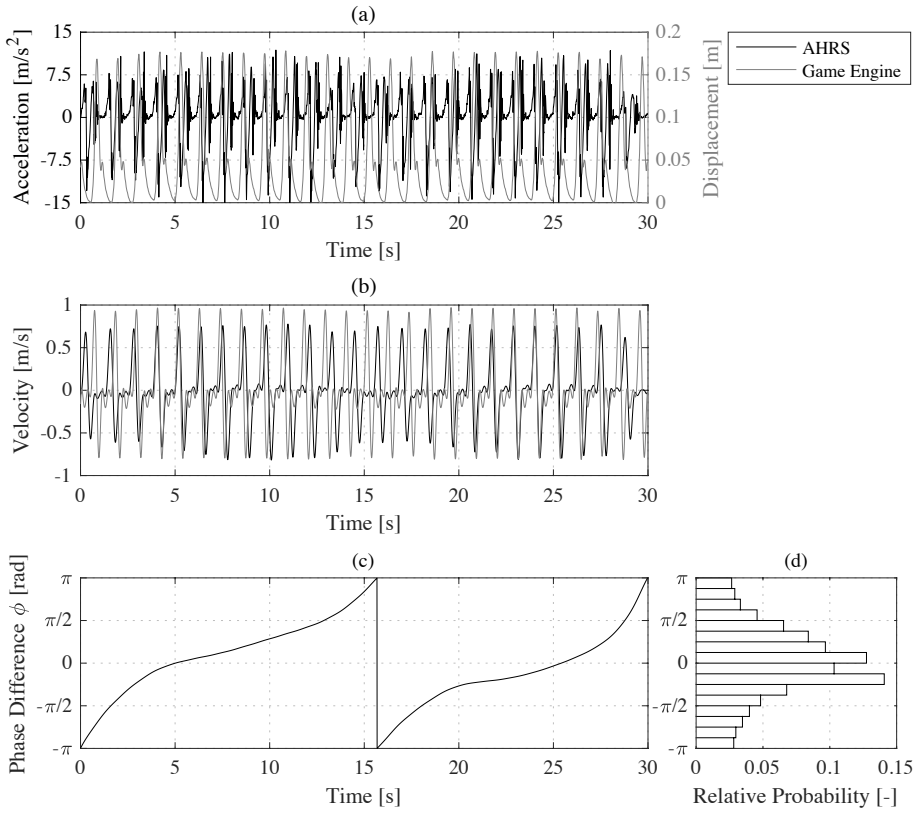

Figure 2: Examples of (a) the raw AHRS acceleration signal and the resampled game engine displacement signal from the ankle, (b) the corresponding velocity signals, (c) the corresponding phase difference signal and (d) the relative probability distribution.

At the start, the displacement signals were upsampled from the variable sampling rate of circa 50 Hz to the uniform sampling rate of 128 Hz to match the sampling rate of AHRS acceleration signals. The upsampling was performed using shape-preserving piecewise cubic interpolation algorithm implemented in MATLAB's *resample* function [23].

In order to differentiate the game engine's displacement signals, a one-dimensional gradient of the vertical displacement vector was calculated and then divided by the numerical gradient of the corresponding time vector. The ensuing velocity vector was post-filtered using the fourth-order two-way Butterworth band-pass filter with the frequency band set to preserve the first three harmonics of the original signal.

The numerical integration of AHRS acceleration signal was proceeded by the pre-filtering of original signals with the fourth-order two-way Butterworth band-pass filter with the same frequency band as in the case of numerical differentiation. The integration was performed by employing the cumulative trapezoidal numerical integration method [24] and post-filtering the resulting velocity signals with the fourth-order two-way Butterworth high-pass filter with the cut-off frequency equal to half of the frequency of the first harmonic.

Finally, with all signals representing the same physical quantity, the two velocity signals derived from the AHRS-rigid body were used to find the delay between AHRS and the game engine's signals for each walk. Using MATLAB's *finddelay* function [25], the cross-correlation between the two velocity signals was calculated at all viable lags. Subsequently, the cross-correlation was normalised, and the estimated delay was given as the negative lag characterised by the largest absolute value of the normalised cross-correlation, which allowed game engine's and AHRS signals to be time-aligned.

3.5 Synchronisation quantification

Before the quantification of pairwise gait synchronisation strength between the test subject and the pacer, analytic representations of velocity signals had to be calculated first. For this purpose, each pair of velocity signals (velocities of test subject's and pacer's right ankles from each walk) was band-pass filtered by utilising the fourth-order two-way Butterworth band-pass filter with a frequency band ranging from 0.70 times the minimum signal (stride) frequency to 1.25 times the maximum stride frequency, as suggested in van Ulzen et al. [26].

For each of the velocity signals $v_i(t)$, the Hilbert transform was then used to obtain the instantaneous phase information contained within the analytic signal $v_i^a(t)$, defined as [27]:

$$v_i^a(t) = v_i(t) + \frac{i}{\pi} P.V. \int_{-\infty}^{+\infty} \frac{v_i(\tau)}{t-\tau} d\tau \tag{4}$$

where $P.V.$ is the Cauchy principal value of the integral. The instantaneous phase angle of the velocity signals $\phi_i(t)$ was calculated by taking the four-quadrant inverse tangent of the imaginary, $\Im$, and real, $\Re$, parts of the analytical signal:

$$\phi_i(t) = \tan^{-1} \frac{\Im[v_i^a(t)]}{\Re[v_i^a(t)]} \tag{5}$$

The phase angle difference of the considered pair of signals $\phi_{p,s}(t)$ was calculated by subtracting test subject's phase angle time series (denoted by subscript s) from the one of the pacer (denoted by subscript p).

$$\phi_{p,s}(t) = \phi_p(t) - \phi_s(t) \tag{6}$$

The synchronisation strength between test subject's and pacer's gait cycles was determined based on the Shannon entropy $E_{p,s}$ of the phase difference distribution, defined as [28]:

$$E_{p,s} = -\sum_{k=1}^{N} P_{p,s}^{k} \ln P_{p,s}^{k} \tag{7}$$

where $P_{p,s}^{k}$ is the probability of the phase difference $\phi_{p,s}(t)$ falling into a k^{th} bin of $\pi/8$ in size, and N is the total number of bins. In order to be able to compare the values of the synchronisation strength across different walks, the synchronisation strength index $\rho_{p,s}$ was then calculated by normalising by the maximum achievable Shannon entropy in the case of the perfect frequency synchrony:

$$\rho_{p,s} = \frac{\ln N - E_{p,s}}{\ln N} \tag{8}$$

The index takes values ranging from 0 to 1, with 0 corresponding to a complete lack of gait synchronisation (i.e. a uniform distribution of phase difference) and 1 representing a perfect gait synchronisation (i.e. a Dirac-like distribution of phase difference).

4 RESULTS AND DISCUSSION

4.1 Stride frequency

In order to assess the influence of the experimental environment on the pacing rate, stride frequency of both pacers and the test subject was calculated using fast Fourier transform for each of the walks. Subsequently, the difference between pacers' and test subject's stride frequencies was quantified. Under US experimental conditions, the mean (± standard deviation) difference was equal to $\bar{\mathrm{f}}_{p-s}^{RL.US} = 0.060 \pm 0.011$ Hz and to $\bar{\mathrm{f}}_{p-s}^{VR.US} = 0.037 \pm 0.008$ Hz during walks in the RL and VR environments, respectively. Similarly, the same comparison made for walks under IS experimental conditions showed an average difference of $\bar{\mathrm{f}}_{p-s}^{RL.IS} = 0.004 \pm 0.005$ Hz and $\bar{\mathrm{f}}_{p-s}^{VR.IS} = 0.003 \pm 0.002$ Hz, respectively. Moreover, the overall increase of test subject's stride frequency in the virtual environment was equal to 2.81% and 0.13%, under US and IS experimental conditions, respectively. Those results show a high level of affinity between the two tested environments and indicate that test subject's stride frequency remained unaltered in the virtual environment, compared to the real equivalent.

4.2 Gait variability

To evaluate the compatibility of the walking stimulus between the real and virtual environments, the gait cycle variability of both pacers was quantified and assessed through the coefficient of variation (CoV) of the stride frequency.

The mean gait variability attained by the real pacer was $\overline{\mathrm{CoV}}_{p}^{RL} = 1.09 \pm 0.09\%$, with the maximum recorded value of $\mathrm{CoV}_{p}^{RL} = 1.26\%$. The virtual pacer achieved the maximum gait variability of $\mathrm{CoV}_{p}^{VR} = 0.56\%$ with the mean of $\overline{\mathrm{CoV}}_{p}^{VR} = 0.52 \pm 0.03\%$. Even though the average gait variability of the real pacer was double the value achieved by the virtual counterpart, the real pacer's variability was deemed acceptable to provide consistent visual and auditory cues to the test subject. A certain level of discrepancy between the two pacers' gait variabilities was expected due to the inherent inability of the real human to replicate their stepping behaviour perfectly, and the finite number of gait cycles available to drive the virtual pacer.

Under the US experimental conditions, the mean gait variability of the test subject was $\overline{\mathrm{CoV}}_s^{RL.US} = 3.63 \pm 1.44\%$ and $\overline{\mathrm{CoV}}_s^{VR.US} = 3.32 \pm 2.00\%$ during walks in the real and virtual environments, respectively, with the corresponding maximum values $\mathrm{CoV}_s^{RL.US} = 5.43\%$ and $\mathrm{CoV}_s^{RL.US} = 5.75\%$.

The walks performed under IS experimental conditions were characterised by test subject's lower gait variability. The maximum gait variability attained during walks performed in the real and virtual environment, respectively, was $\mathrm{CoV}_s^{RL.IS} = 4.24\%$ and $\mathrm{CoV}_s^{VR.IS} = 3.10\%$, with the mean values of $\overline{\mathrm{CoV}}_s^{RL.IS} = 3.01 \pm 0.95\%$ and $\overline{\mathrm{CoV}}_s^{VR.IS} = 2.31 \pm 0.58\%$ respectively.

The instruction to synchronise steps with the pacer resulted in a decrease in the gait cycle variability in both environments. A more considerable increase in the consistency of the gait cycle was observed during the VR walks, which was pronounced under the IS experimental conditions. This can be attributed to the more isolated conditions offered by the virtual environment. Although the virtual environment was constructed to mimic the sports hall's interior where the tests took place, it secluded the test subject from some of the peripheral stimuli present in the real environment. As a consequence, the test subject's cognitive load was relieved, which might have resulted in more cognitive resources being spent on the execution of gait control. In addition, several studies have reported that the virtual environment alters the distance perception while walking [29–33], resulting in shorter strides [34] and more careful feet placement.

4.3 Synchronisation strength

Synchronisation strength index values achieved during walks under US experimental conditions were comparably low, with the mean synchronisation strength index of $\bar{\rho}^{RL.US} = 0.005 \pm 0.004$ and $\bar{\rho}^{VR.US} = 0.015 \pm 0.014$ during walks performed in the real and virtual environments, respectively, with the corresponding highest index values of $\rho^{RL.US} = 0.012$ and $\rho^{VR.US} = 0.037$.

The synchronisation strength index values recorded under US experimental conditions were below the proposed synchronisation threshold of $\rho = 0.2$ [35]. These results are consistent with previous findings for a pair of walkers [26,36] and a group of pedestrians walking on a rigid ground [22] and a bridge [16], and reflect the transient nature of the unprompted gait adaptation mechanism.

The synchronisation strength index values achieved in IS experimental conditions are presented in Figure 3 (represented by the vector magnitude) and are accompanied by the mean circular direction (represented by the corresponding vector angle) to indicate the directionality of the synchronisation phenomenon. The mean circular direction $\bar{r}$ was calculated by transforming all phase difference values into a two-dimensional vector $\bar{r} = (\cos\alpha, \sin\beta)$ and averaging over the number of data points [37]. According to the adopted sign convention, positive values represent test subject’s leading the pacer, and the negative values indicate the test subject lagging the pacer.

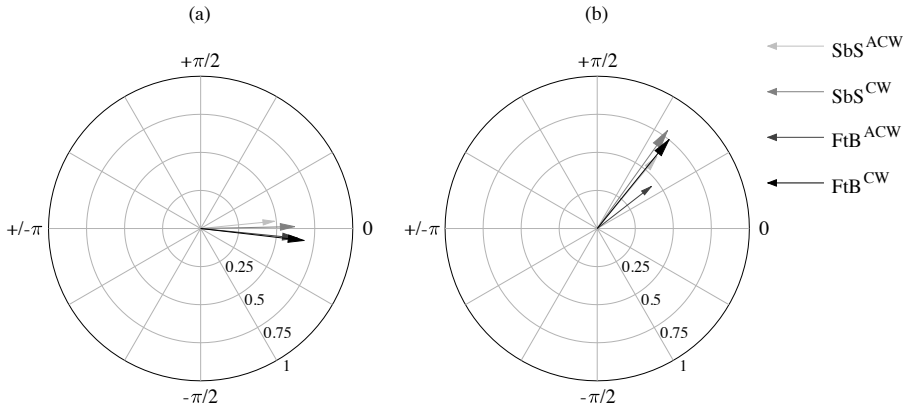

Figure 3: The synchronisation strength index values (magnitude) together with the corresponding mean circular direction (angle) recorded during walks in (a) the real and (b) virtual environments under IS experimental conditions.

The instruction given to the test subject to synchronise his gait cycle with the pacer led to a similar increase in the synchronisation strength values in both environments. The mean synchronisation strength index of $\bar{\rho}^{RL.IS} = 0.605 \pm 0.074$ and $\bar{\rho}^{VR.IS} = 0.650 \pm 0.134$ was attained during walks in the real and virtual environment, respectively. This was the result of the test subject exhibiting increased control over the stepping behaviour in comparison to US walks.

The mean circular direction of the walks performed in the real environment took near-zero values with the front-to-back walks recording slightly negative values, and the side-by-side walks slightly positive values. Negative values of the directionality during front-to-back walks were the result of the test subject reaction to the pacer's action. On the other hand, during side-by-side walks, the pacer was positioned within test subject's horizontal far peripheral vision [38], which might have prompted the emergence of test subject's anticipatory stepping behaviour.

The aforementioned mechanism responsible for the anticipatory behaviour was amplified during the side-by-side walks performed in the virtual environment. This is because of the head-mounted display limiting test subject's horizontal field of view by circa. 110^{o} [39,40], and thus effectively eradicating far peripheral vision. The test subject attempted to compensate for this by falling slightly behind the pacer so that the pacer was within his field of view.

The virtual reality gave rise to an additional mechanism prompting the anticipatory behaviour, as the gait anticipation was also present during the front-to-back walks, where the pacer was no longer positioned in the test subject's far horizontal peripheral but rather in the centre of his gaze. In the front-to-back collocation, the rear walker would attempt to arrive at the double stance phase of gait faster than the person positioned in front in order to allow for a more natural collision avoidance corrections [41].

In the case of side-by-side and front-to-back collocations, the repetitiveness of virtual pacer's gait cycle might have laid grounds for greater predictability of its gait cycle, especially given the more isolated conditions offered by the virtual environment.

5 CONCLUSIONS

This paper presents the development and validation of a novel virtual reality platform for investigating pedestrian-pedestrian interaction and crowd dynamics. The platform utilises the most recent advancements in three-dimensional modelling, motion capturing and virtual reality technology. It comprises of a highly detailed representation of the real environment and an AI-driven virtual pedestrian capable of exhibiting complex social interactions found in real

crowds. The validation process involved a 30 years old male test subject covering the distance in excess of 4 km in the real and virtual environments, walking next to or behind a pacer, that being either a real person or an animated virtual agent. Sixteen walks were recorded in total, including eight without and eight with the instruction to synchronise steps.

No disimilarities were found between test subject's stride frequencies attained in the RL and VR environments, as the stride frequency values increased by a total of 1.42% in the VR. This subsequently resulted in the relationship between test subject's and pacers' stride frequencies being compatible across the two tested environments.

The assessment of the difference between test subject's and pacers' stride frequencies yielded compatible results in both, the real and virtual environments. Furthermore, no significant differences in gait parameters of the tested subject were found between the two tested environments.

The analysis of pacers' gait variability showed that the average difference between real and virtual pacers' gait variability is equal to 0.57%, which ensures the compatibility of the visual and auditory cues provided by the walking stimulus across the two environments. The test subject's gait variability was lower in the virtual environment by 8.5% under US experimental conditions, and by 23.3% under IS experimental conditions. The more consistent stepping behaviour was likely the result of a smaller number of peripheral stimuli offered by the virtual environment, which subsequently allowed for a greater focus on pacer's motion.

Under US experimental conditions, the synchronisation strength index achieved in the virtual reality platform was compatible with the real environment, yielding values not exceeding 0.04. This is consistent with previous results obtained for a pair of walkers [26,36] and during walking in a group [16,22].

The instruction given to the test subject to synchronise his gait with that of the pacer resulted in an increase of the synchronisation strength index in both environments beyond 0.2. The effect of the instruction was stronger in the virtual environment, where the synchronisation strength index was higher by 7.4%. The directionality of gait synchronisation revealed that in the real environment, the test subject was reacting to pacer's stepping behaviour during walks in the front-to-back arrangement and anticipating pacer's footsteps during side-by-side walks. The anticipatory behaviour was further amplified in the virtual environment and also emerged during front-to-back walks.

Overall, the preliminary results presented herein indicate that the developed experimental platform has the potential to become a viable solution for investigating crowd dynamics, within and beyond the context of vibration serviceability.

ACKNOWLEDGEMENTS

The authors acknowledge: Mr Allan Rankin, Mr Harry Piercy and Target3D Ltd. for providing the optical system used in the validation study and their generous hands-on assistance during the experiments; Mr Maksat Kalybek for support in the run-up and in the aftermath of the experimental campaign and Dr Niamh Hynes for assistance in the data collection.

Abstract. *The paper presents selected results of a first experimental campaign on a footbridge over-passing the Lambro River near Milano (Italy). The 3-span footbridge, for a bicycle-pedestrian mixed use, has a reinforced concrete deck supported by a steel structure. The footbridge, 107 m long and with a constant width of 4.4m, is roughly symmetric about both mid-span and the longitudinal axis. As a part of proof tests performed in March 2016, ambient vibration tests identified the footbridge modal properties, detecting at 1.75 Hz the fundamental bending mode with the maximum amplitude recorded at mid-span, a finding confirmed by an ANSYS FE model of the footbridge. A series of forced vibration tests, performed in July 2017, investigated the response of the bridge under different loading conditions. Groups of pedestrians, in number of 1, 2, 3, 4, 6, 8 and 12, crossed the bridge, walking with a step frequency as close as possible to the first fundamental frequency. Different spatial configurations were explored for each number of pedestrians, investigating the spread in data related to different walking people/groups and their formation. Pedestrians followed straight trajectories and their spatial configuration was symmetric about the longitudinal axis of the bridge; single pedestrians walked along the footbridge axis. This paper focuses on a few results related to: (a) single pedestrians; (b) groups of multiple pedestrians in the same configuration, a longitudinal row; (c) 12 pedestrians in different spatial configurations. Experimental results highlight the effect of both intra-subject and inter-subject variability and the influence of spatial configuration on the maximum measured acceleration. The bridge performance is discussed by comparison between experimental results and limit values of the vertical acceleration according to HiVoSS guideline.*

INTRODUCTION

In the last two decades, dynamic testing of bridges has been widely adopted for several purposes, as in identification of dynamic properties in proof tests, validation of FE models, and detection of excessive vibrations for lively footbridges [1]-[5]. Very often, aesthetic aspects have motivated the structural conception of recent footbridges, characterized by significant slenderness. For this reason, a significant amount of research work has been devoted to the problem of their serviceability assessment [6], also because slender structures are prone to a modification of modal properties due to the increase of mass when pedestrians are present [7]. In addition, the problem of human-structure interaction requires the derivation of proper pedestrian models and procedures of analysis [8], [9].

This paper presents selected results of a research work that covers many of the above aspects with reference to a footbridge located in Northern Italy. Ambient vibration tests (AVTs) performed during proof tests provided the footbridge modal properties, indicating that the first flexural mode was at a frequency of 1.75 Hz, well within the critical range of excitation due to walking pedestrians. A FE model confirmed this finding. Subsequently, the experimental response of the footbridge to crossing pedestrians was determined for different groups of pedestrians walking at the first mode frequency. The outcome of these tests provides both an experimental assessment of the serviceability conditions and useful insights on the different footbridge response due to the inter- and intra-subject variability.

In the following, Section 1 describes the case study. Section 2 presents the results of operational modal analysis and structural identification, while Section 3 is devoted to the numerical finite element (FE) modelling. Section 4 presents and discusses the forced vibration tests with walking pedestrians. A few conclusions are drawn in Section 5.

1 DESCRIPTION OF THE FOOTBRIDGE

The footbridge, shown in Figure 1, overpasses the Lambro River (Cerro al Lambro, Italy), and runs parallel to a 3-arch masonry Canal Bridge built on 1806. The straight footbridge, 107 m long and 4.4 m wide, is subdivided into a central span, 58 m long, and two side spans, each 24 m long. Two welded double-T longitudinal beams, 2 m high and located at the two sides of the footbridge are its main resisting elements.

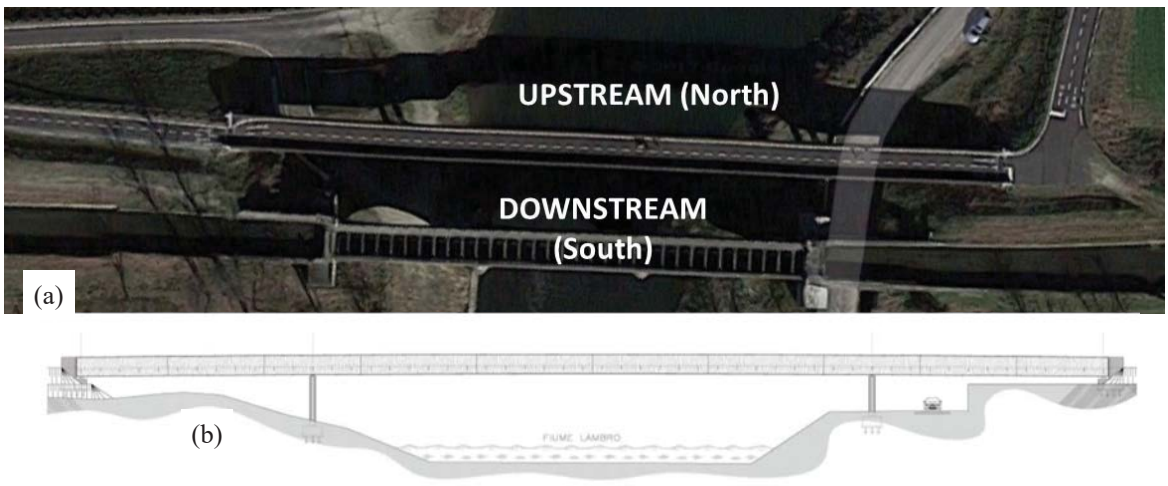

Figure 1: Lambro footbridge: (a) aerial view; (b) side view.

Each longitudinal beam is subdivided in ten on-site welded segments, whose geometry is symmetric about the longitudinal axis and the transverse axis at mid-span. A view from below

of the footbridge and its typical cross-section at an intermediate support are shown in Figure 2a and 2b, respectively. The cross brace system in Figure 2a is made of steel L90×8 profiles bolted at the bottom flange of the longitudinal beams. The same figure also shows the transverse beams and the secondary beam, an IPE100, connecting the mid-span of transverse beams. Figure 2b shows the transverse beam, made of the steel profile IPE240 in the mid-span and of HEA240 on the piles and at the side spans. Transverse beams connect the longitudinal beams and support the deck, where a reinforced concrete (RC) slab with an overlying bituminous conglomerate pavement is cast on a metal corrugated sheet. The deck has an inclination of 2%. As shown in Figure 1b, two couples of circular RC columns provide the intermediate supports subdividing the bridge into three spans. Foundation of columns is on piles. At all supports, the bottom flange of longitudinal beams rest on elastomeric bearings SI-H 300/52. At intermediate supports, a RC 45×45 cm pile cap is interposed between column and beam (Figure 2b).

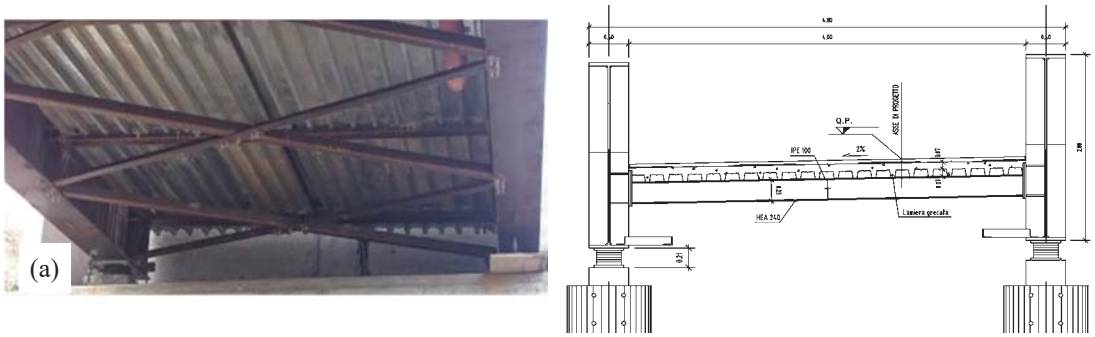

Figure 2: Lambro footbridge: (a) view from below; and (b) cross-section.

With the same corrugated sheet profile A 75/P750 in Figure 3a (units: mm), two cross-sections of the deck are present. In the central span, the sheet thickness is 7/10 mm and the cast in situ slab is 75 mm thick, for a total deck thickness of 150 mm (Figure 3b). At the two ends, for a length of 4.5 m starting from the abutments, the sheet thickness is 15/10 mm and the cast in situ slab is 305 mm thick, for a total thickness of 380 mm. In these zones, where the deck works as a ballast for the central span, the metal sheet is directly connected to the lower flanges of the double-T profiles. Further details on the footbridge geometry can be found in [10].

All steel profiles are made of S335 steel while corrugated sheet is made of S235 steel. Deck is made of concrete of class *C30/37,* having Young's modulus E_c=33 GPa. The class of concrete for columns is *C32/40*, with Young's modulus E_c=33.6 GPa.

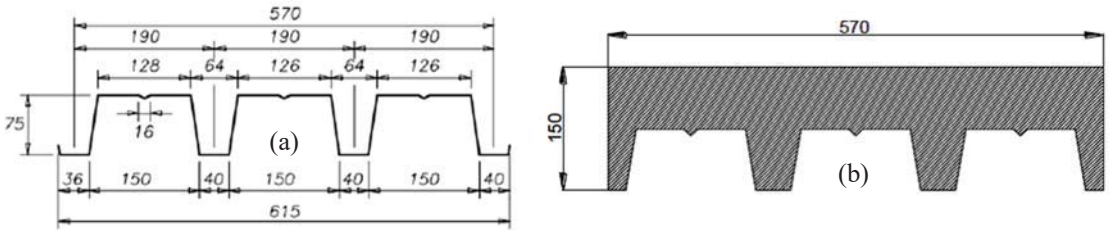

Figure 3: Cross-section of the deck: (a) corrugated sheet A75/P 570; (b) central span, with cast-in-situ concrete.

2 OPERATIONAL MODAL ANALYSIS AND STRUCTURAL IDENTIFICATION

Ambient vibration tests were performed on the footbridge in March 2016 to evaluate its dynamic characteristics. The vertical response was measured in 10 selected points installed on the main side beams (Figure 4), by using high sensitivity piezoelectric accelerometers (WR

model 731A, 10 V/g sensitivity and ±0.50g of peak acceleration). A short cable (1m) connected each sensor to a power unit/amplifier (WR model P31). Two-conductor cables connected the amplifiers to a 24-channel data acquisition system (24-bit resolution, 102 dB dynamic range).

The adopted sampling frequency, in presence of anti-aliasing filters, is equal to 200 Hz, which is fairly larger than that required for the investigated footbridge, as the significant frequency content of collected signals is below 12 Hz (Figure 5). Hence, apart from the already mentioned anti-aliasing filters, the identification tools application was preceded by a second digital step: the time series were low-pass filtered, using a 7th order Butterworth filter with cut-off frequency of 20 Hz, and down-sampled to 40 Hz.

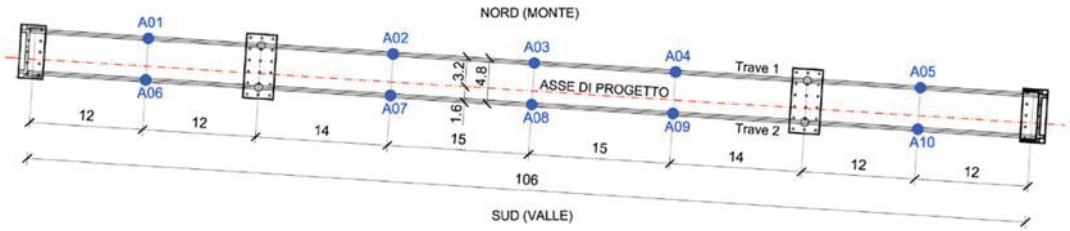

Figure 4: Accelerometer positions on the deck and associated numbers

The modal identification was performed using a time window of 3600 s and applying well-known output-only algorithms, such as the Frequency Domain Decomposition (FDD) [11] and the data-driven Stochastic Subspace Identification (SSI-data) [12] techniques available in the commercial software ARTeMIS [13]. The stabilization diagram, obtained applying the SSI-data algorithm, is shown in Figure 5, along with the first Singular Value (SV) lines of the spectral matrix. The alignments of the stable poles in the stabilization diagram (SSI-data) technique provide a clear indication of the structural modes. Table 1 compares the modal estimates obtained by applying the FDD and the SSI-data techniques through: (a) the identified natural frequencies, f_{FDD} and f_{SSI}; (b) the modal damping ratio and its standard deviation (ζ_{SSI}, σ_ζ) identified by the SSI method and (c) the MAC [14] of the corresponding mode shapes.

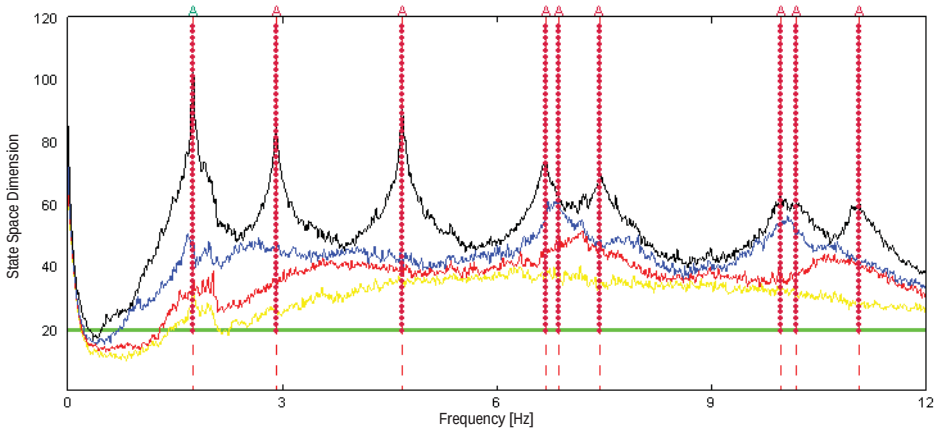

Figure 5: Stabilization diagram (SSI-data) and automatic (A) identification of natural frequencies.

The inspection of Table 1 confirms that the natural frequencies estimated by the two different methods are practically coincident. A similar correspondence was found for most mode shapes (MAC value larger than 0.98), except for the 5th mode (torsion), for which the MAC is about 0.80 and the SSI-data algorithm conceivably provides a better estimation of the mode shape. Figure 6 shows the measurement-based mode shapes identified using the SSI-data technique.

Mode Id.	f_{FDD} (Hz)	f_{SSI} (Hz)	ζ_{SSI} (%)	σ_ζ (%)	MAC
1 (B)	1.748	1.749	0.135	0.83×10^{-3}	1.000
2 (T)	2.910	2.912	0.758	0.81×10^{-2}	1.000
3 (B)	4.668	4.675	0.249	0.13×10^{-2}	1.000
4 (B)	6.660	6.676	1.001	0.35×10^{-2}	0.998
5 (T)	6.797	6.862	3.084	0.34×10^{-2}	0.801
6 (B)	7.441	7.443	1.389	0.79×10^{-2}	0.993
7 (T)	9.954	9.956	1.373	0.16×10^{-1}	0.984
8 (B)	10.190	10.190	1.774	0.71×10^{-2}	0.998
9 (T)	11.030	11.060	1.172	0.21×10^{-1}	0.998

3 FINITE ELEMENT MODEL

The finite element (FE) model of the bridge (Figure 7) is based on the as-built design data extracted from the blueprints. The origin of the reference system for the mesh nodes is on the exterior node of the first segment of the upstream side: *x*- and *y*-axis are the transverse and longitudinal axis, respectively, while the *z*-axis is vertical upwards. Within the ANSYS [15] framework, the steel elements are modeled with two-node Timoshenko elements named BEAM188. Shell elements named SHELL181 describe the deck, with a mesh grid of 1m × 1m. Consistent mass option is adopted for all these elements. A BEAM188 element is adopted also for elastomeric bearings, fixed at its lower end and free to rotate differently from the longitudinal beam node it is connected to. Since the deck in the central span is simply supported by

transverse beams, nodes of the shells and nodes of the transverse beams share the same translational degrees of freedom but can have different rotations. The situation is slightly different at the end spans, where the transverse beam are included within the slab thickness and also rotations are constrained.

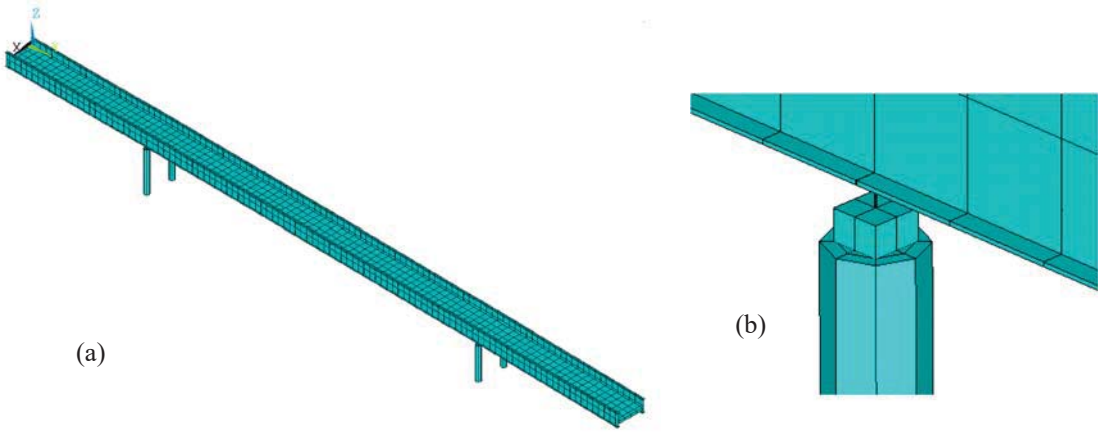

Figure 7: FE model: (a) general view; (b) detail of column with pedestal and elastomeric bearing.

The mesh nodes are located on three different layers, due to the offset among the axes of longitudinal beams, deck, transverse beams and bracing. Thus, in spite of the relatively simple structural scheme, the FE mesh is made complex by the need to account for both offsets and internal releases between adjacent elements. A further problem arises from the orthotropy of the deck, with different values of moments of inertia in longitudinal and transverse direction, due to the shape of the corrugated metal sheet (see Figure 3). SHELL181 elements are characterized by a rectangular cross-section, with a unique value of thickness, density and elastic modulus in both directions. Hence, with a preliminary calibration of these parameters for the two typical cross-sections, an effective shell thickness t_e was determined - equal to 122 mm in the central span and 347 mm for the two side spans - as the one of a rectangular cross-section providing the same moment of inertia of the existing section about the transverse axis. From the t_e value, an effective value of density ρ_e is computed, equal to 3400.7 kg/m^3 in the central span and to 3086.0 kg/m^3 for the two side spans, able to reproduce the total mass of each element, also accounting for dead load. Materials properties have the values defined in Section 1.

3.1 Model updating

A preliminary dynamic analysis on the FE model just presented was performed to check the similarity between experimental and numerical modal parameters. The correlation between the dynamic characteristics of the initial model and the experimental results is shown in column (3) of Table 2 via the frequency discrepancy $\varepsilon_f = (f_{FEM} - f_{SSI})/ f_{SSI}$. Column (4) list the number of order of the numerical mode and a descriptor of the mode shape: bending in the vertical plane (B) or torsional (T). Table 2 shows one-to-one correspondence between the mode shapes and fairly good correlation also in terms of frequency. Only the frequency discrepancy of the second mode is 9.13%, whereas it ranges between –0.76% and 3.35% for the other modes. Hence, the correlation between numerical and experimental behavior seems to provide a sufficient verification of the main assumptions adopted in the initial model.

As previously pointed out, the main uncertainties in the numerical model are related to the footbridge deck and, more specifically, to the Young's modulus of the cast-in-situ concrete (E_{deck}) and to the effective thickness of the shell elements along the span (t_{e1}) and near the

supports (t_{e2}). In order to improve especially the main difference (on the frequency of second mode), the three uncertain parameters of the deck (E_{deck}, t_{e1} and t_{e2}) were updated and their optimal values were identified by minimizing the difference between numerical and experimental natural frequencies. After the updating, a complete correlation analysis was carried out between numerical and experimental modal parameters. The MAC index [14] in column (7) of Table 2 shows an excellent correlation for all the modes. Discrepancy in terms of frequency has a different trend for bending vertical modes, correctly reproduced, and for torsional modes, still affected by an error up to 7.73% for the second mode. Figure 8 shows the numerical counterpart of Figure 6 after updating. The first three numerical modes are "quasi-rigid" modes, transversal, longitudinal and rotational, respectively, involving the bearings deformability. Modes 5 and 9 (f = 1.903 and 6.411 Hz) are lateral/torsional modes and were not identified experimentally.

Exp.	Initial Model			Updated Model		
f_{SSI} (Hz)	f_{FEM} (Hz)	ε_f (%)	Mode #	f_{FEM} (Hz)	ε_f (%)	MAC
1.749	1.749	–	4/B	1.749	–	0.995
2.912	3.178	9.13	6/T	3.137	7.73	0.999
4.675	4.676	0.02	8/B	4.672	–0.06	0.998
6.676	6.702	0.39	10/B	6.683	0.10	0.999
6.862	6.968	1.54	11/T	6.782	–1.17	0.990
7.443	7.508	0.87	12/B	7.483	0.54	0.995
9.956	9.880	–0.76	13/T	9.575	–3.83	0.964
10.190	10.188	–0.02	18/B	10.107	–0.81	0.945

4 FORCED VIBRATION TESTS

After the proof tests of 2016 and the development of the FE model, a series of forced vibration tests under walking pedestrians were performed on July 20, 2017. Tests aimed to assess the extreme values of the bridge response to different pedestrians' configurations, and the effect of pedestrians' inter-subject variability. Table 3 presents the ID, sex, mass *M* and height *H* of the twelve volunteers involved in the tests (including also two Authors). All TSs are young people, with an age between 22 and 30, but TS5 and TS8, whose age is in the range 50-60. Fifty-two tests with different configurations were performed, involving either single pedestrians or groups with different numbers of people, as detailed in Table 4. Configurations differ either in space or in the Test Subjects (TSs) involved, as it is the case for the twelve configurations with a single pedestrian.

ID	TS1	TS2	TS3	TS4	TS5	TS6	TS7	TS8	TS9	TS10	TS11	TS12
Sex	M	M	F	F	M	F	F	M	M	M	M	M
M [kg]	65	86	59	53	70	65	62	84	76	72	73	70
H [cm]	172	182	164	158	181	173	170	177	185	183	175	175

Table 3: General data of test subjects (TS) involved in the walking tests.

Pedestrians #	1	2	3	4	6	8	12
Configurations	12	6	6	9	4	4	11

Table 4: Number of configurations adopted for each of the different numbers of pedestrians crossing the bridge.

To detect the extreme values of the bridge response, the overall layout of the test was designed to excite mainly the fundamental mode. Hence, for all tests, the target walking frequency of pedestrians was 1.75Hz and spatial configurations were either aligned along or symmetric about the longitudinal axis of the bridge. The first tests involved single pedestrians walking on the bridge, to investigate the uncertainty related to the excitation provided by each individual walking on the bridge. Differences concerns coordination, capability to adapt and follow a predefined rhythm on the 100m distance of the bridge length, as well as the capability to adapt to a lock-in condition when the bridge is vibrating in a perceptible way. In the subsequent tests, the maximum acceleration amplitudes given by groups of walking people arranged in different configurations were investigated. Pedestrians, in groups of 2, 3, 4, 6 or 12 people, were aligned either along the bridge axis, or in a transverse row (with a maximum of 4 people) or in staggered formations with one or more transverse rows and at least two people in each row.

The output produced by the walking people in each configuration was detected in terms of vibration measurements at several points. Figure 9 shows the accelerometer layout. In addition to the sensors used for the modal analysis (see Figure 4), there are four vertical sensors located at the intermediate supports and five horizontal sensors in the central span. The measurement set-up adopted the high sensitivity accelerometers and the data acquisition system of the AVTs.

Individuals or groups of pedestrians crossed the whole bridge, entering from the left side in Figure 9 and exiting on the opposite side. Each crossing corresponded to a single record with multiple channels. Recording of the bridge vibrations started a few instants before the entrance of pedestrians on the bridge and stopped when free vibrations following the transit decayed significantly. To detect the time instant at which each pedestrian started to cross the bridge in the records, each volunteer gave a heel strike while entering the bridge.

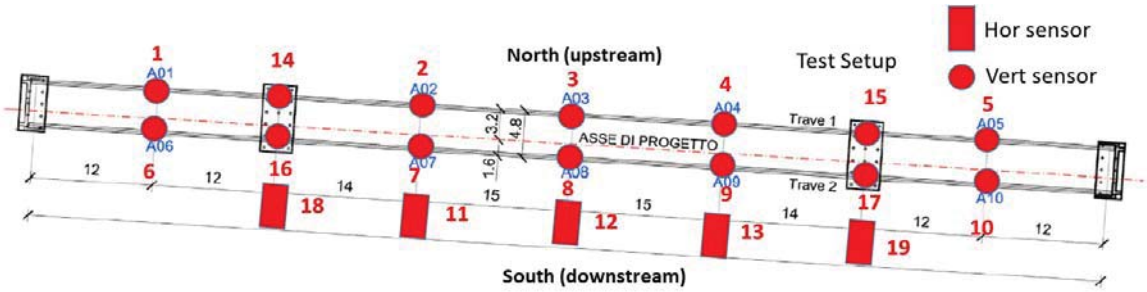

Figure 9: Accelerometer layout during the tests with walking people.

Records of the 19 sensors for the 52 tests show a general trend. The bridge response, in terms of vibration time history, reflects the quasi-symmetry of the bridge. Records on the first half of the bridge almost overlap those on the second half, but the latter show larger acceleration, denoting a resonant phenomenon that builds up during the bridge crossing. Downstream records are similar to but slightly exceed upstream records, possibly due to the effect of the torsional mode. In the following, the presentation of a few results will focus on basic aspects, providing a clear indication of the extreme values of vertical acceleration. A more detailed analysis will concern tests with a single pedestrian, highlighting the effect of intra- and inter-variability.

4.1 Single pedestrian tests

This series of tests aimed at evaluating differences in the excitation produced by each TS. Figure 10 depicts, for each pedestrian, the extreme values recorded by the vertical sensors aligned along the downstream edge during the bridge crossing in the sense from A6 to A10 (see Figure 9). These 12 tests confirm the general trend of the bridge response: the peak values in A6 and A10 are similar but not equal. Values in A10, towards the end of the bridge crossing, exceed those in A6, at the bridge entrance, showing that the resonance phenomenon builds up during the bridge crossing. Sensor A8 at mid-span detects the overall extreme value of the bridge response, reaching 0,30 m/s^2, a value within the comfort range according to Hyvoss Guideline [16]. In addition, the minimum peak value in A8, around 0.06 m/s^2, indicates a wide spread in extreme values produced by different TSs, also visible in the dispersion about the average value (dotted line in Figure 10). The standard deviation (solid lines in Figure 10) has the same pattern of the average value, denoting that dispersion increases as the vibration levels.

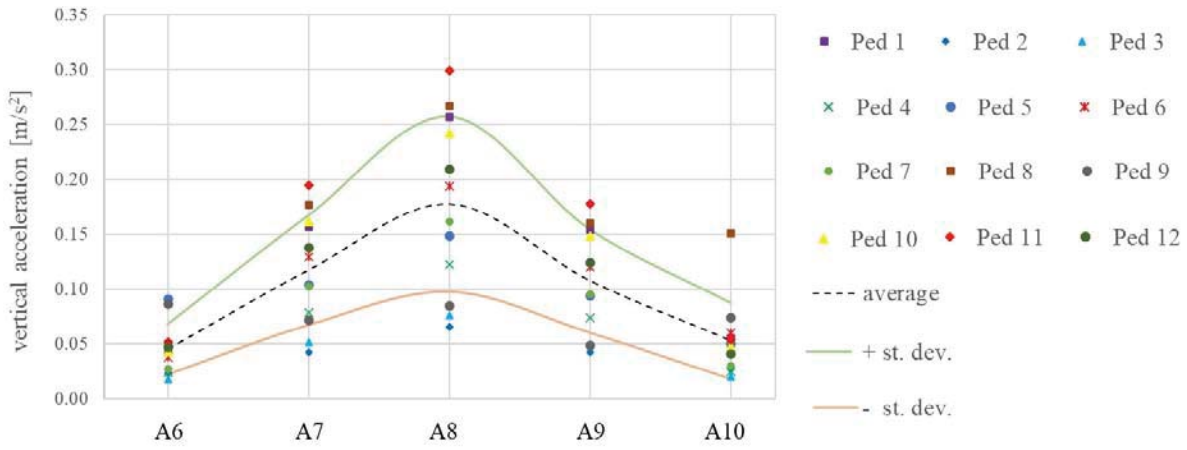

Figure 10: Single pedestrian tests, peak values and standard deviation of vertical downstream acceleration.

Figure 11 shows, for two pedestrians crossing the bridge (TS1 and TS2), the time history of acceleration at the seven downstream vertical sensors, superposed in a single graph. Even though walking at the same frequency, each person has his/her own step speed and, in the three graphs, equal time does not necessarily imply equal position on the bridge. In each graph, the signals of the different sensors differ in amplitude but are eminently in phase. While graph in Figure 11a appears dominated by the first natural mode, more frequency components are visible in Figure 11b where a "beating" phenomenon is appreciated. Largest values are found in the first case. Differences can be justified by the person's capability to keep a constant rhythm (and possibly a centered trajectory) and therefore to excite resonance on the first mode. The excitation under resonant conditions requires some time for the bridge vibrations to reach the maxima, followed by a certain time required for a complete decay, after the person left the bridge.

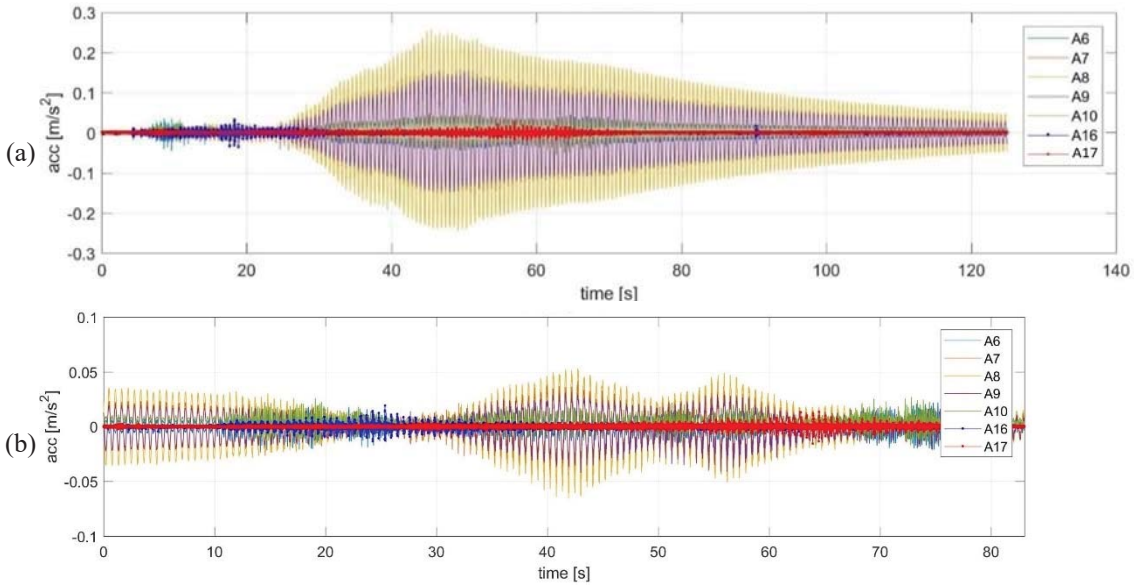

Figure 11: Downstream records for single pedestrians: (a) TS1; (b) TS2.

The trends shown in Figure 10 and Figure 11 can be associated with the different capability of the TSs to lock to the first mode bridge vibration. To investigate this aspect, the time (measured from the beginning of the records) of peak occurrence in downstream sensors is depicted in Figure 12. Two different patterns are apparent: a few pedestrians excite the bridge to high levels while walking on the shorter side spans, while others produce the maximum vibration level in all sensors only when walking close to mid span, where the modal shape allows for the maximum energy input.

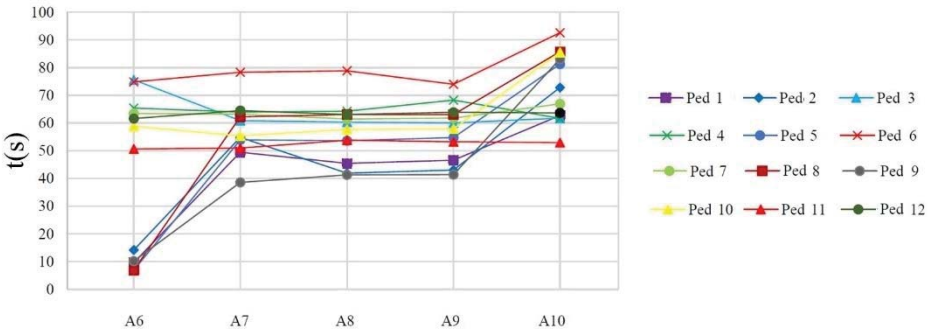

Figure 12: Time at which maxima are reached during each time record (downstream).

Figure 13 and Figure 14 present a time frequency relation for pedestrians TS1 and TS2 at sensors A6 (side span) and A8 (midspan), respectively. Fourier spectra are computed with a moving window, 6 s long, overlapped by 5/6 of the window length. The first natural frequency of the bridge is clearly visible for both people and for both sensors. For both pedestrians the spectral response of the side span includes many higher order harmonics, coherently with the modal shapes at the side span and with the fact that the build up under resonant conditions needs some time to develop fully. The energy dispersion in TS2's response leads to lower values of energy on each frequency and a limited value of vibration (Figure 11b).

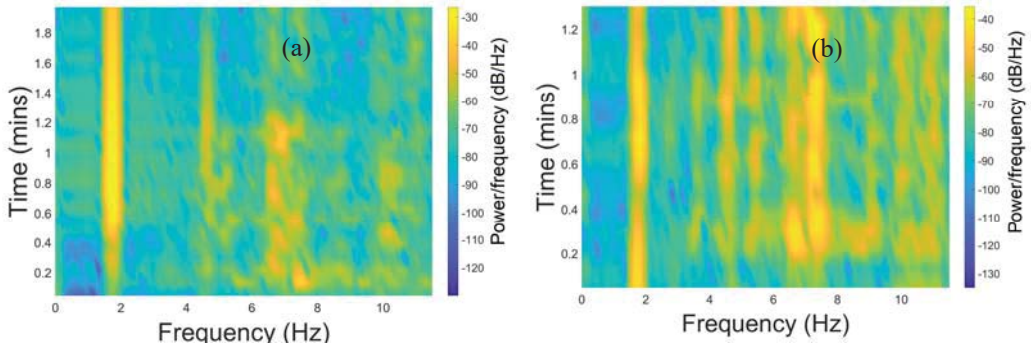

Figure 13: Time frequency representation at sensor A6: (a) TS1; (b) TS2.

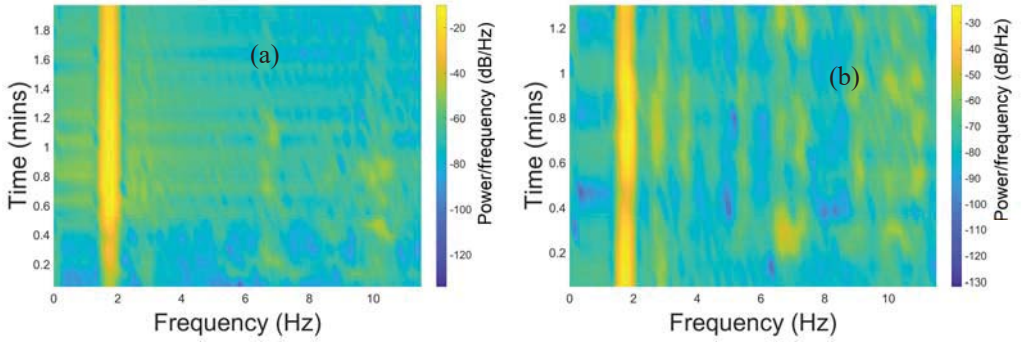

Figure 14: Time frequency representation at sensor A8: (a) TS1; (b) TS2.

A similar pattern is detected at mid-span (Figure 14), where the energy transmitted by TS1 is practically all on the first mode frequency and is associated to significant levels of vibration (see Figure 11a). TS2's response still shows a certain degree of dispersion, even though more limited than that visible in Figure 13b. Again, dispersion is associated to lower values of both energy per frequency and levels of vibration dominated by the first mode.

4.2 Groups

Forty tests concerned groups of two or more pedestrians, as detailed in Table 4. In longitudinal direction, pedestrians were spaced apart of a target distance of 60 cm. In transverse direction, inter distance was not constant, depending on the number of pedestrians involved. For each space configuration of a given group of pedestrians, at least two tests were performed varying the TSs involved. The presentation of these tests is beyond the scope of this paper, and only two aspects are discussed here. First, the average peak value of vertical acceleration at midspan (sensor A8) is investigated in Figure 15, as a function of the number of crossing pedestrians in the same space configuration, a longitudinal row along the bridge axis. The average

is computed for each group of tests concerning the same number of pedestrians. Vertical acceleration increases when the number of pedestrians varies between one and eight, and slightly decreases when pedestrians are 12. The values in Figure 15 can be assumed as a measure of the serviceability conditions of the footbridge.

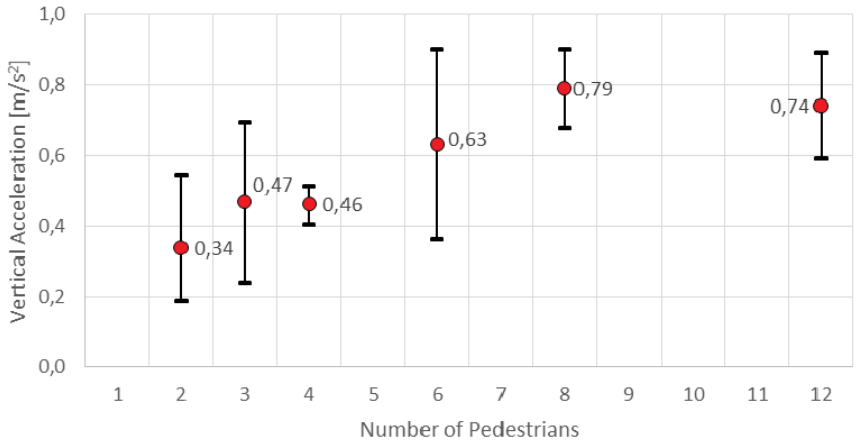

Figure 15 : Average and extreme values of peak acceleration and as a function of the number of pedestrians.

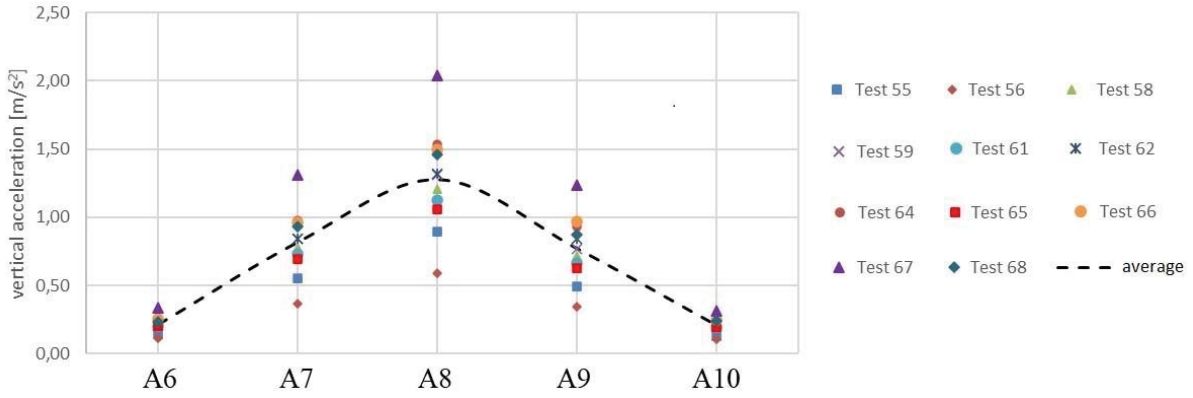

Figure 16: Downstream sensors, peak values for groups of 12 people in different space configurations.

Second, the outcome of the 11 tests with twelve pedestrians in different space configurations is shown in Figure 16 in terms of peak acceleration at downstream sensors. Test 55 and 56 involved a longitudinal row of 12 people. Test 58 and 59 involved two transverse rows of 6 people while Test 61 and 62 had six transverse rows of 2 people. Test 64, 65 and 66 involved four transverse rows of 3 people while Test 67 and 68 had three transverse rows of 4 people.

The most severe load case was generated by Test 67, whose results, however, are quite different from those of Test 68, sharing the same space configuration even though with different positions of pedestrians. While the compact space configuration is able to excite significantly the first mode when all the pedestrians are around midspan where the mode shape has its maximum, the lack (or presence) of synchronization among pedestrians is able to explain both the peak values reached and the difference between Tests 67 and 68.

5 CONCLUSIONS

Aim of this paper was the presentation of selected results on the dynamic testing of a footbridge located in Northern Italy. Experimental tests were performed with different purposes at different times. First, AVT's were carried out in 2016, to identify modal properties, as a part of

proof tests necessary to the footbridge opening. Subsequently, after the derivation of a FE model able to simulate with accuracy the modal properties, forced vibration tests were performed within a sponsored research program. The positive novelty of this work is the link between the two series of tests, where the results of AVTs have driven the subsequent FE modeling and walking tests. The availability of a validated FE model of the footbridge is the base for a future numerical simulation of the walking tests, providing a reliable numerical model of a real structure in the coupled problem of human-structure interaction. Hence, these tests can be adopted to evaluate and validate modelling strategies for pedestrians as mechanical systems moving with a given gait.

The results of numerical modelling showed a problem in reproducing the experimentally detected behavior, relieved but not solved by an optimization procedure. Since vertical bending modes are simulated with an excellent agreement, it appears that the footbridge possesses separated resisting mechanisms in bending and torsion, an aspect that must be tackled in future research works. Foundations on piles, not accounted for in this work, could be the cause of the experimental frequency lower than the numerical one. Their effect is currently under study.

Tests on a limited sample of single pedestrian under similar conditions outlined a meaningful but large spread in their behavior, when trying to walk under resonant conditions. The different response generated by TS1 and TS2, in terms of both peak value and frequency content of vertical acceleration, evidences a dissimilar behavior of the two TSs. Differently from TS2, TS1 locks in to the footbridge vibration, an aspect that should be taken into account when modeling human-structure interaction.

Among the tests performed with groups of pedestrians, in this work only two types of tests are considered. Tests with pedestrians on a single line provides an indirect serviceability assessment, showing an increasing trend with a maximum value as the number of pedestrian increases. Even though in these tests, as in single pedestrian tests, all the peak values are within the range of maximum or medium comfort according to the Hyvoss Guideline [16], it is noticed that a very limited number of pedestrians is able to produce high values of acceleration.

Finally, the results in terms of peak values for the different space configurations of 12 people are analyzed, taking into account that more than one test was performed for each configuration, by varying the position of TSs. At mid-span, the same configuration (the most compact in longitudinal direction) but with different TSs' position produced the overall maximum peak acceleration of the whole test set and the minimum with reference to the configurations of 12 pedestrians. Hence, also in this case two different aspects are brought to the light. First, the importance of the inter-subject variability and of the correlation existing among pedestrians' motion. Second, the need for a numerical serviceability assessment following [16] is confirmed, and is currently under way.

It can be concluded that the experimental research strategy adopted here provided interesting results, opening the way to future numerical and experimental studies.

ACKNOWLEDGEMENTS

The first and last Authors gratefully acknowledge the financial contribution of MIUR (Italian Ministry of Higher Education) under grant PRIN 2015-2018, Project 2015TTJN95, "Identification and monitoring of complex structural systems" for the forced vibration tests of July 2017. The work presented here is based on the MS thesis of G. Lastrico, under the guidance of the other three Authors. AVTs were performed by C. Gentile and forced vibration tests by A. Cigada, with the participation of G. Lastrico and M.G. Mulas. The contribution of V. Racic in devising the pedestrians' configurations is gratefully acknowledged.

Keywords: Pedestrian wooden bridges, Dynamic properties, FE model

Abstract. *The dynamic properties of two pedestrian wooden bridges situated in the Stockholm area have been determined experimentally. The main purpose was to investigate if these properties are season dependent. For that, tests were performed during the winter and the spring. 17 accelerometers were used to measure both vertical and horizontal vibrations. An impact hammer was used to excite the bridges. For the Vega bridge, a large variation for the lowest natural frequencies was observed, both for the first vertical and for the first transversal mode. For the Hägernäs bridge, a large variation was observed for the first transversal mode but not for the first vertical mode. With exception for the first transversal mode for the Hägernäs bridge, no significant differences regarding the damping between winter and spring were observed. Finite element models of the two bridges have also been implemented and a good agreement with experimental results have been obtained. The numerical models have shown that the connections between the different components of the bridges have a significant influence on the dynamic properties. The models have also shown that the variation of the stiffness for the asphalt layer may explain the differencies for the natural frequencies between spring and winter. However, due to the incertainties in the modelling of the asphalt, this conclusion must be taken with caution.*

1 INTRODUCTION

Due to its ecological benefits wood is an attractive alternative for pedestrian bridges. However, the combination of a slender and a light wooden structure may result in uncomfortable vibrations for crossing pedestrians and therefore accurate dynamic analyses are often required in the design process.

Whereas simple finite element models can often be used for static analyses of wooden pedestrian bridges, for dynamic analyses more advanced models are often necessary. The main reason is that the connections between the different structural elements must be modelled carefully in dynamic analyses [1-3]. Another difficulty is related to the stiffness of the asphalt layer, which is due to the stiffness of the asphalt itself but also to the degree of shear action between the asphalt and the timber deck. These effects have been studied by several researchers through dynamic experiments both in laboratory [4,5] and on existing bridges [5-7]. All these works show that the effect of the stiffness of the asphalt pavement on the natural frequencies is low in summer and high in winter. This is due to the viscoelastic properties of the asphalt which change with the temperature but also to the shear action between the asphalt and the deck which is low in summer and high in winter.

The purpose of this paper is to study experimentally and numerically the dynamic properties of two pedestrian wooden bridges. Experimental tests were performed both in winter and in spring in order to investigate the influence of the temperature on the dynamic properties. A finite element model was implemented for each bridges. Two key aspects are the modelisation of the connections and the material parameters for the asphalt layer.

2 VEGA BRIDGE

2.1 Description

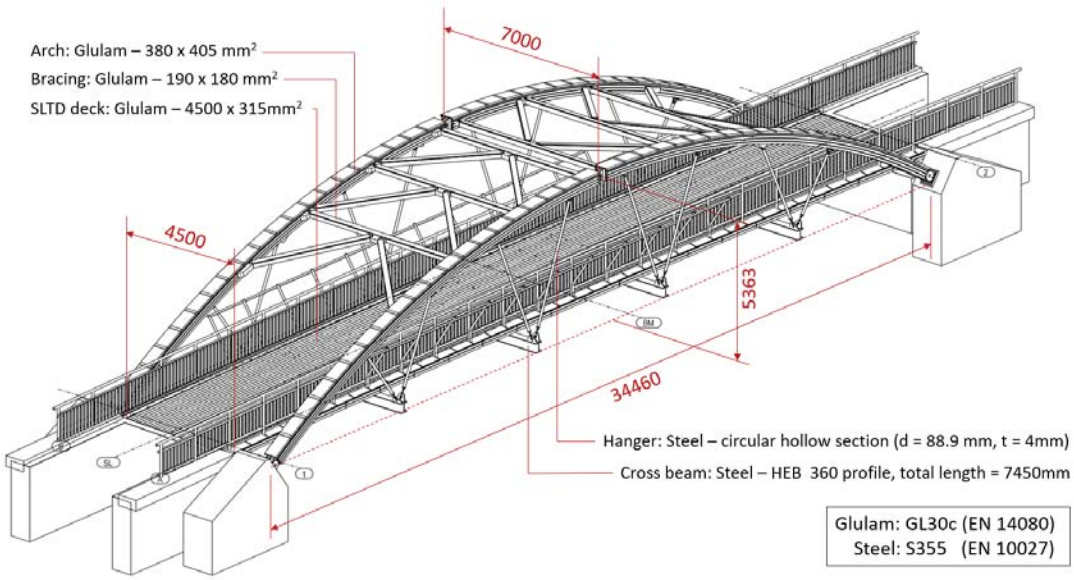

Figure 1 –Vega bridge: dimension, material and cross-sections

The bridge, see Figure 1, is based on a 3-hinged arch. It was prefabricated and hoised in place. The deck consists of Stress Laminated Timber Deck (SLTD), made of a number of glulam beams (each with a 142 × 315 mm^2 cross-section) that are transversally prestressed by steel rods every 60 cm. The deck is covered by an asphalt layer with a thickness of 85 mm. The V-shaped disposition of the steel hangers has been chosen in order to increase the buckling capacity. The deck is supported by four steel cross beams. The two arches are connected through six K-shaped braces. Both the arch and the braces are made of glulam.

2.2 Experimental setup

Experimental testing was performed during cold (March 11th, 2019: -6°C) and warm (May 15th, 2019: 15°C) weather. 17 accelerometers were placed on the deck and measured vertical and transversal accelerations. An accelerometer was also attached to the lowest transverse brace in order to measure the lateral acceleration of the arch. The bridge was excited by using two methods: an impact hammer and a free falling from an 80 kg person from a height of 30 cm. The results were then processed using a low-pass Butterworth filter with a cut-off frequency of 20 Hz and Fast Fourier Transformations in order to identify the natural frequencies and eigenmodes. The damping coefficients were obtained using the half power bandwidth method.

2.3 Finite element model

The finite element model was implemented in Abaqus. It consists of the following parts: arch, braces, hangers, cross beams, deck and asphalt layer.The arch and the bracings were modelled using 3D beam elements. The dimension of the rectangular cross-sections are given in Figure 1. The material parameters of the Glulam were taken as E = 13 GPa, ν = 0.2, ρ = 440 kg/m^3. The hangers and the cross-beams, were also modelled using 3D beam elements. The material parameters for steel were taken as E = 210 GPa, ν = 0.3, ρ = 7850 kg/m^3. The SLTD deck consists of timber beams of height 0.315 m that are prestressed transversally, thus carrying load mainly through friction. It was modelled using 4 node orthotropic shell elements with E_x = 13 GPa, E_y = 0.26 GPa, G_{xy} = G_{xz} = 0.78 GPa, G_{yz} = 0.078 GPa. The asphalt layer, that has a height of 85 mm, was modelled with 4 node isotropic shell elements with ν = 0.3, ρ = 2243 kg/m^3. Two values for the elastic modulus was taken: 3 GPa in warm conditions and 25 GPa in cold conditions.

A hinge at the crown of the arch was introduced by allowing only the rotation around the transversal axis. The interactions arch/bracing, arch/hanger and hanger/cross beams were simulated by using tie constraints that permit rotations and by introducing offsets so that the connections are modelled at the exact positions. The interaction between the cross beams and the deck is performed through steel plates that are welded to the cross beams and inserted in the timber deck. For each steel beams, coupling constraints were defined at three points, with vertical and transversal translational restraints for the middle point and vertical and longitudinal translational restraints for the two other points. A full shear interaction between the asphalt layer and the timber was assumed by using offsets corresponding to half of the thickness for both the deck and the asphalt and by using tie constraints between both surfaces.

The boundary conditions were introduced at the arch springings and at the deck abutments. The arches are connected to a concrete block by a steel device that, ideally, only allows for rotation around the y axis. However, rotational springs around x and z axes were introduced in order to match the experimental results. The deck is supported continuously along the abut-

ment length through steel plates which are embedded in the abutment's concrete in one end and inserted into the deck on the other. The outermost plates are oriented in a way to prevent longitudinal displacement, whereas the one on the center prevents transversal displacement. These boundary conditions were introduced in the deck by defining reference points with an offset of half the deck height. Vertical translations were restrained along the width of the deck and longitudinal or transverse translations, depending on the orientation of the respective plate, were restrained at the location of the steel plates. Longitudinal restraints are present at only one abutment.

2.4 Experimental and numerical results

The experimental and numerical results are presented in Tables 1 and 2 and Figure 2. The experimental results show clearly that the temperature has a significant influence on the natural frequencies and that a decrease of the temperature leads to an increase of the stiffness. Compared to warm conditions, the natural frequencies in cold conditions are 44% higher for the first transversal mode and 22% higher for the first vertical mode. The high impact of the temperature change for the first transversal mode was expected since the change in the stiffness of the asphalt with the temperature affects especially this mode. A change of the damping ratios due to the temperature cannot be identified. However, it can be observed that the values of the damping were almost all higher than the one suggested by the Eurocode (1.5% for structures with mechanical joints).

With exception for the torsional mode, good agreement between experimental and numerical natural frequencies are obtained. The differences for the natural frequencies between Models 2 and 1, which differ only by the *E* value of asphalt, are 39% for the first transverse mode and 17% for the first vertical mode, which is closed to the experimental values given above. Therefore, it seems that the differences in the experimental frequencies between warm and cold conditions can be explained to a large extent by the effect of the asphalt. However, this conclusion must be taken with caution since both the adopted values for the asphalt stiffness and the adopted full shear connection between the deck and asphalt layers can be debated.

Vibration mode	Exp. freq. (15°C)	Exp. freq. (-6°C)	Model 1 (15°C)	Model 2 (-6°C)

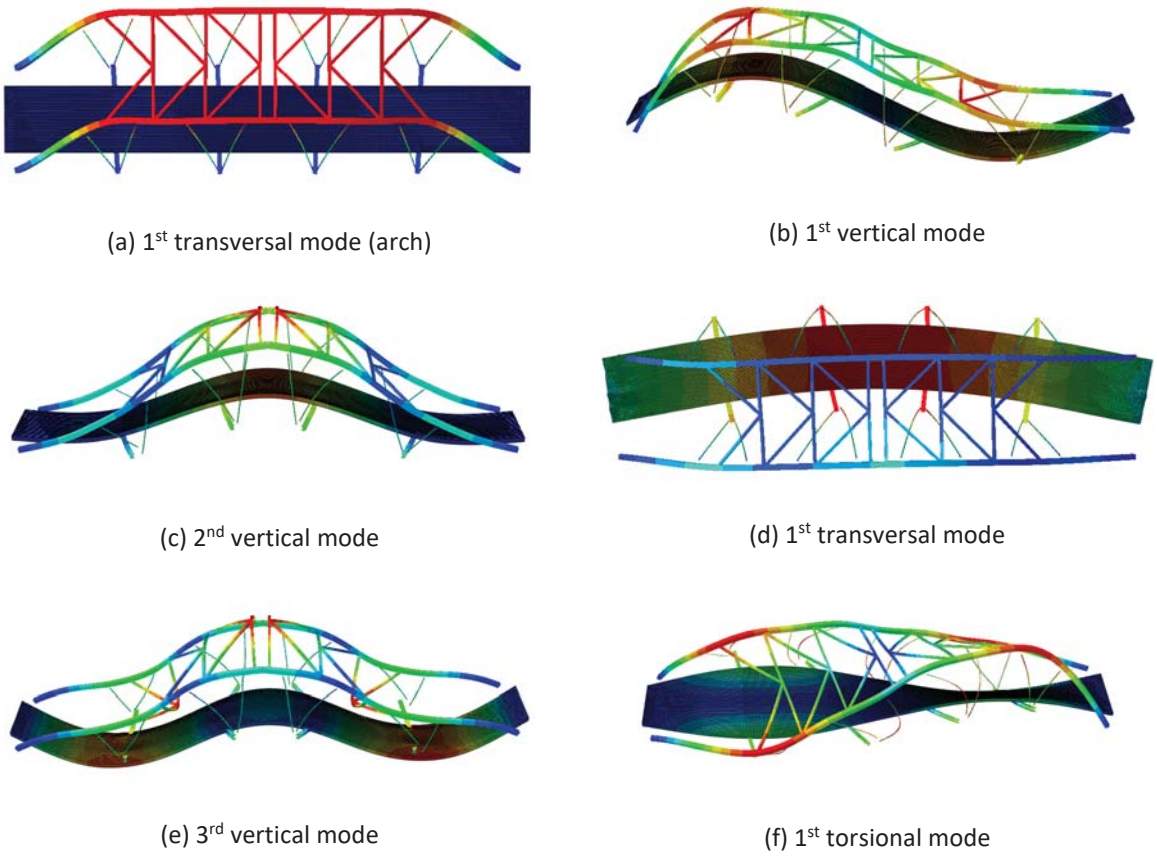

Figure 2 –Vega bridge: numerical mode shapes

3 HÄGERNÄS BRIDGE

3.1 Description

The bridge, see Figure 2, is based on a 3-hinged arch. The deck, 42 m long, consists of two laminated veneer lumber (LVL) plates glued and screwed together. Below the deck lies a grid consisting of 5 longitudinal and 13 transversal glued laminated timber beams. The 5 longitudinal beams support the deck. The longitudinal beams rest on concrete abutments at their ends as well as on four steel beams. Two of the steel beams are attached to the glued laminated timber arches. The other two steel beams are attached to steel hangers which in turn are attached to the arches. The two arches are laterally stabilized through 4 cross braces placed between the concrete abutment of the arches and the steel beams. The deck is covered by an asphalt layer with a thickness of 75 mm.

Figure 3 –Hägernäs bridge

3.2 Experimental setup

Experimental testing was performed during cold (March 5th, 2019: -10°C) and warm (May 17th, 2019: 17°C) weather. 16 accelerometers were placed on the deck and measured vertical and transversal accelerations. 2 accelerometers were also attached to the vertical hangers in order to measure the lateral acceleration of the arch. The same two sources of excitation as for the Vega bridge and also the same processing of the measured signals were used.

3.3 Finite element model

The deck was modelled using 4 node orthotropic shell elements with a thickness of 126 mm. This approach is valid since a full interaction between the two (LVL) plates can be assumed. The material parameters are E_x = 10.5 GPa, E_y = 2.4 GPa, G_{xy} = 0.6 GPa, G_{xz} = 0.12 GPa, G_{yz} = 0.22 GPa, ρ = 550 kg/m^3. The arches as well as the 5 longitudinal and 13 transversal beams were modelled using 3D beam elements. The material parameters were taken as E = 10.4 GPa, ν = 0.2, ρ = 440 kg/m^3. The steel beams and the hangers were also modelled with 3D beam elements whereas the cross braces were modelled using 3D truss elements. The material parameters of steel were taken as E = 210 GPa, ν = 0.3, ρ = 7850 kg/m^3. The asphalt layer with a height of 75 mm was modelled in the same way as for the Vega bridge, with the same material parameters.

The connections between the different parts were modelled as they are expected to work for small amplitudes of vibration. A hinge at the crown of the arch was introduced by allowing only the rotation around a transversal axis. The interactions steel beam/hanger, steel beam/arch, longitudinal beam/transverse beam and longitudinal beam/deck were simulated by using tie constraints for both displacements and rotations. The bolted connection between the hangers and the arches allows a certain rotation in two directions, around the vertical and transversal axes. To model this behaviour a rigid body constraint with two connectors was used.

The longitudinal timber beams are resting on the steel beams and are placed between two steel plates welded to the steel beams. The steel plates have slotted holes to accomodate the difference in thermal expansion between steel and timber. The two beams are connected with steel rods that go through the elongated holes. These connections allow small rotations around the three axes and also some vertical translation. Each connection is modelled using a rigid

body constraint between the midsurface of both beams and the two connectors. A vertical spring was placed at the connector situated at the steel beam.

The bridge rests on concrete foundations. The cross-bracings are fixed in all translations at their ends. At the supports, the arches are connected with hinges that allow only for the rotation around the transversal axis. At the abutments, for each longitudinal beam two steel plates with holes are cast into the concrete. The beam is placed between the plates and screwed to it. At one abutment, the holes in the steel plates allow no movements whereas at the other abutment the holes permit the longitudinal displacement. In the model, reference points with an offset of half the deck height were created at both ends of all the longitudinal beams. At one end, only the rotations around the transversal axis was allowed whereas at the other end, the rotation around the transversal axis and the longitudinal translation were allowed.

3.4 Experimental and numerical results

The experimental and numerical results are presented in Tables 3 and 4 and Figure 4. The experimental results show that the temperature has a significant influence on the natural frequency for the first transversal mode (the difference between cold and warm conditions is 26%) but not for the first vertical mode (the difference between cold and warm condition is 5%). Except for the first transversal mode, no differences regarding the damping coefficients were observed between warm and cold conditions. It can also be noted that almost all the values of the damping were slightly lower than the one suggested by the Eurocode.

The differences for the natural frequencies between Models 2 and 1 are 18% for the first transverse mode and 4% for the first vertical mode, which is closed to the experimental values given above. Therefore, and as for the Vega bridge, it seems that the differences in the experimental frequencies between warm and cold conditions can for a large part be explained by the stiffness of the asphalt. However, as for the Vega bridge, this conclusion must be taken with caution.

Vibration mode	Exp. freq. (17°C)	Exp. freq. (-10°C)	Model 1 (17°C)	Model 2 (-10°C)

4 CONCLUSIONS

In this paper experimental and numerical analyses of two timber pedestrian bridges have been presented. Both bridges are about 40 m long and consist of a timber deck supported by two timber arches. Experimental tests were performed in warm and cold conditions. The experimental results show that the temperature has a significant influence on the natural frequencies of the bridges, especially for the first transversal mode and that a decrease of the temperature leads to an increase of the stiffness. For the Vega bridge, the natural frequencies in cold conditions are 44% higher for the first transversal mode and 22% higher for the first vertical one compared to warm conditions. For the Hägernäs bridge, the corresponding values are 26% and 6%. For both bridges, no significant differences regarding the damping between winter and spring were observed. However, and compared to the values suggested by the Eurocode, higher damping coefficients were measured for the Vega bridge and slightly lower ones for the Hägernäs bridge.

A finite elements model was implemented for each bridge. These models show that the connections between the different components of the bridge must be considered carefully in order to obtain accurate results compared to the experimental natural frequencies. The numerical results tend to show that the differences in the experimental frequencies between warm and cold conditions can for a large part be explained by the stiffness of the asphalt. However, this conclusion must be taken with caution since both the adopted values for the asphalt stiffness and the adopted full shear connection between the deck and asphalt layers can be debated.

Abstract. *The users of the 132-meter-long Kjærra Bridge in Larvik, Norway, noticed severe lateral vibrations due to pedestrian loading on the opening day in 2001. During the period that the bridge was designed, there were no clear guidelines to minimize pedestrian induced vibrations in footbridges. This article aims to explain severe vibrations induced by pedestrians on the Kjærra Bridge, and to highlight the importance of clear guidelines to prevent similar cases in the future. To this end, a series of vibration measurements, both free and forced, are conducted on the Kjærra Bridge. The free- and forced-vibration tests are supplemented by numerical analysis for several different loading scenarios. Field measurements and numerical analysis results are compared with the current guidelines to evaluate the design of the bridge. The analyses results show vibration levels in the unacceptable range put forth by current design guidelines for several loading scenarios indicating that these guidelines can successfully predict human-induced vibrations on footbridges.*

1 INTRODUCTION

The Kjærra Bridge is a 132m long timber footbridge with a free span of 92 metres across the Numedalslågen river in Larvik, Norway. The structure is based on two concrete bridgeheads, each supporting a triangular console. The consoles support a double, undertensioned structural system with laminated timber compression members and steel wires taking the tensional forces. The lateral load carrying system consists of a horizontal steel truss between the laminated timber arches and was designed for wind loads. The width of the bridge is 2.4m and, architecturally, it was designed to fit in its environment which is surrounded by woods and waterfalls leading to a very slender structure; see Figure 1. The bridge was opened to the public on the 5th of July 2001 [1] and the users of the bridge noticed severe lateral vibrations due to pedestrian loading on the opening day of the bridge. The slender structure and the lateral vibrations observed in the bridge were similar to those observed in the London Millenium Bridge, which had been designed in the same period as the Kjærra Bridge.

During the design and construction of the Kjærra Bridge, there were no standards or guidelines available in Norway to minimize human-induced vibrations. Although some dynamic analysis had been conducted during the design stage, these analysis had no effect on the final design mainly due to lack of such guidelines.

The aim of this article is two-folds: (1) to investigate the reasons of the human-induced vibrations observed in the Kjærra Bridge and (2) to investigate whether the current design guidelines such as HIVOSS [2] and Sétra [3] can successfully predict the excessive vibrations observed. To achieve these goals, free- and forced-vibration tests were carried out on the bridge and dynamic analyses were conducted using a detailed numerical model in Autodesk Robot.

Figure 1: The Kjærra Bridge has a total span of 132m and a free span of 92m across the Numedalslågen River in Lardal, Norway. Photo: Lisbeth Michelsen

2 DESIGN LAYOUT

The bridge was designed as part of a municipal effort to improve access to the public riverbanks. The bridge structure consists of two triangular consoles supported by concrete foundations on each riverbank. These consoles are made of three main components: Two 13 metre long side spans with an elaborate truss brackets made of glulam, and a 92 metre long mid-span

with a lower span cable construction system.

The main span is constructed as a truss, consisting of arched glulam girders, compression members made of glulam cigar beams and steel cables to absorb tensile forces. The truss system is jointed at the middle as a variant of the Polonceau system first designed by French railway engineer Jean-Barthélémy Camille Polonceau (1813 - 1859) [4].

The distance between the extremes of the console beams carrying the main span is 66 metres resulting in a maximum free span of 92 meters. The cantilever console-structure is made of beams and compression members in glulam timber, as well as diagonal steel cross-bracing in the transverse direction leading the forces from the main span to triangular concrete foundations. Furthermore, the two console-structures are anchored at reinforced concrete abutments on each riverbank. Figure 2 shows the elevation view of the bridge.

A wind bracing made of steel L-beams are bolted to the primary beams along the bridge main axis. Horizontal forces are obtained by the wind bracing and transferred down to the foundations through cross bracing.

3 CHARACTERISTICS OF DYNAMIC PEDESTRIAN LOADING

The severe vibrations on the Kjærra Bridge normally occurs when relatively dense flows of people cross the bridge simultaneously. Pedestrian loadings are complex loadings that are challenging to carefully define. This dynamic loading is affected and modified by many parameters. However, studies show that the average frequency of the loading, i.e. the number of steps per second, for normal walking is somewhere between 1.6 and 2.4 Hz. For the same walk, the transverse loading frequency is equal to half of the vertical loading, i.e. the transverse loading frequency for normal walking is somewhere between 0.8 and 1.2 Hz [3].

The phenomenon of ***lock-in*** of a pedestrian crowd is defined as "a pedestrian crowd, with frequencies randomly distributed around an average value and with random phase shifts, will gradually coordinate at a common frequency (that of the footbridge) and enters in phase with the footbridge motion". [3]. To compensate for the imbalance from the vibrational behaviour in the structure, crowds tend to instinctively follow the footbridge motion frequency. As soon as the amplitude of the movements are perceptible, crowd behaviour is no longer random and a motion synchronized with the vibrations of the bridge is developed. Thus, the vibrations tend to amplify as crowd-motion synchronizes with the transverse vibrations in the footbridge, ultimately leading to resonance to the accelerations. These vibrations may reach a critical acceleration if a critical number of pedestrians provoke the vibrations [3].

4 GUIDELINES FOR HUMAN INDUCED VIBRATIONS IN FOOTBRIDGES

At the time of construction, there were no clear guidelines in Norway concerning design for human-induced vibrations in footbridges. Currently, EN-1990:2002 [5] is the relevant standard in Norway that sets the criteria for comfort of the pedestrians on footbridges. According to EN-1990:2002, all footbridges that has a frequency lower than 5 Hz in the vertical direction and 2.5 Hz in the horizontal should be verified for comfort criteria. The comfort criteria is further defined in terms of the maximum acceleration created by groups of 8 to 15 walking normally (persistent design situation). The maximum allowed accelerations are 0.7 m/s^2 in the vertical direction and 0.2 m/s^2 in the horizontal direction. For exceptional crowd conditions, i.e. when the number of pedestrians is significantly over 15, the maximum allowed horizontal acceleration is 0.4 m/s^2. Further, EN-1990:2002 also suggests that, due to uncertainty and complexity of the calculations, it may be necessary to make provisions in the design such as use of dampers unless

the comfort criteria is cleared by a substantial margin.

Although EN-1990:2002 [5] provides guidelines and criteria to avoid severe vibrations in footbridges, these guidelines are not very detailed and can be regarded as imprecise. On the other hand, two guidelines, Sétra [3] and HIVOSS (Human-Induced Vibrations of Steel Structures) [2] provide more detailed and precise requirements to minimize human-induced vibrations in footbridges. According to Sétra [3], the critical eigenfrequencies are 0.3-2.5 Hz and 1-5 Hz in horizontal and vertical directions, respectively. HIVOSS [2] sets these critical eigenfrequencies at 0.5-1.2 Hz and 1.25-2.3 Hz, respectively. According to these two documents, the structures whose predominant vibration frequencies fall into these ranges must undergo a more detailed evaluation. This evaluation requires the evaluation of the comfort level based on the maximum expected acceleration in both vertical and horizontal directions computed via dynamic analysis under pedestrial loading [2, 3]. Table 1 presents the range of accelerations in vertical and horizontal directions for different comfort classes. It should be noted that the range of accelerations given in Table 1 are valid for both Sétra and HIVOSS guidelines [2, 3].

Class	Degree of Comfort	a_{limit}-vertical	a_{limit}-lateral
CL1	Maximum	< 0.50 m/s^2	< 0.10 m/s^2
CL2	Medium	0.50 - 1.00 m/s^2	0.10 - 0.30 m/s^2
CL3	Minimum	1.00 - 2.50 m/s^2	0.30 - 0.80 m/s^2
CL4	Unacceptable	> 2.50 m/s^2	> 0.80 m/s^2

Table 1: Defined comfort class with common acceleration ranges for Sétra and HIVOSS

5 FIELD MEASUREMENTS

Free-vibration and forced-vibration measurements were conducted on the bridge in the spring of 2019 in order to understand the vibration characteristics of the bridge. The measurements were done using a one triaxial accelerometer, Diciducer Model 333D01, at a rate of 800 Hz, on various locations on the bridge. Figure 2 presents the elevation view of the bridge and the five points where the measurements were taken. Point 3 in Figure 2 is the mid-point of the bridge and points 1 and 5, and 2 and 4 are symmetric with respect to the mid-point. As expected, the measurements at the symmetrical points gave very similar response. Therefore, results are only presented for points 1 and 2 for brevity.

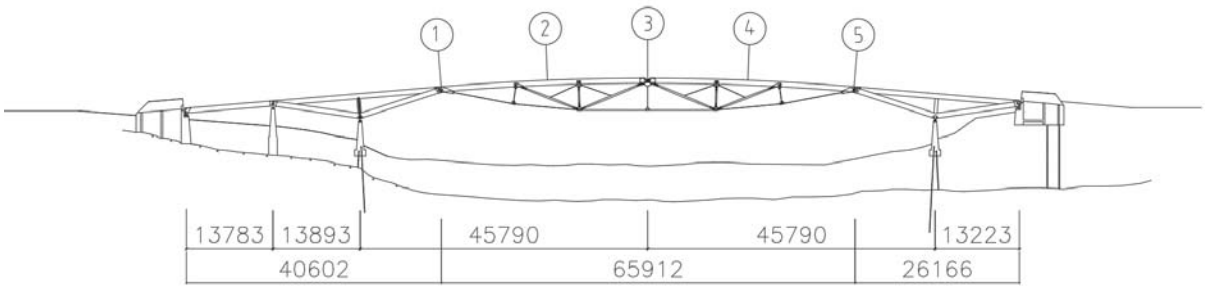

Figure 2: Elevation view: Kjærra Bridge with points of measurements (all dimensions in mm)

The measured acceleration time histories from the free-vibration analyses were converted to

frequency domain using Fast Fourier Transformation (FFT) for the measurements at points 1, 2 and 3. The results plotted in Figure 3 shows that the predominant frequencies in the horizontal and vertical directions are 0.88 Hz and 1.43 Hz, respectively. Measurements at points 1 and 2 also show the frequencies of the higher modes that are suppressed at point number 3. The predominant frequencies fall into the critical range in EN-1990:2002 [5], Sétra and HIVOSS [2, 3] guidelines.

Figure 3: Frequency response function at the mid-span measured from free vibration analyses

In addition to the free vibration measurements, forced-vibration measurements induced by up to three people were conducted to measure the level of accelerations. Around hundred measurements were made on different locations on the bridge to understand the characteristics of the vibrations. However, in this article, we will only focus on the critical results, which are the measurements made at the middle of the main span (point 3 in Figure 2). This area on the bridge shows the highest response to the lowest vibration frequencies on the structure for both horizontal- and vertical vibrations.

The forced-vibration tests conducted on the bridge show that, as expected, the accelerations increase linearly by the number of people inducing the vibrations. By first introducing vibrations induced by one, and then two and three people to amplify the vibrations on the bridge, it is measured that the accelerations (associated to the dominating frequencies) increase by approximately 0.11 m/s^2 for vertical vibrations and 0.28 m/s^2 for horizontal vibrations per person. As a result, maximum horizontal and vertical accelerations were recorded as 0.34 m/s^2 and 0.80 m/s^2 in the vertical and horizontal directions, respectively when the forced-vibrations are introduced by three people; Figure 4 and 5. This shows that, even for a load of three persons, the maximum accelerations recorded on the bridge get fairly close to the *Medium* degree of comfort set forth by Sétra and HIVOSS guidelines; Table 1.

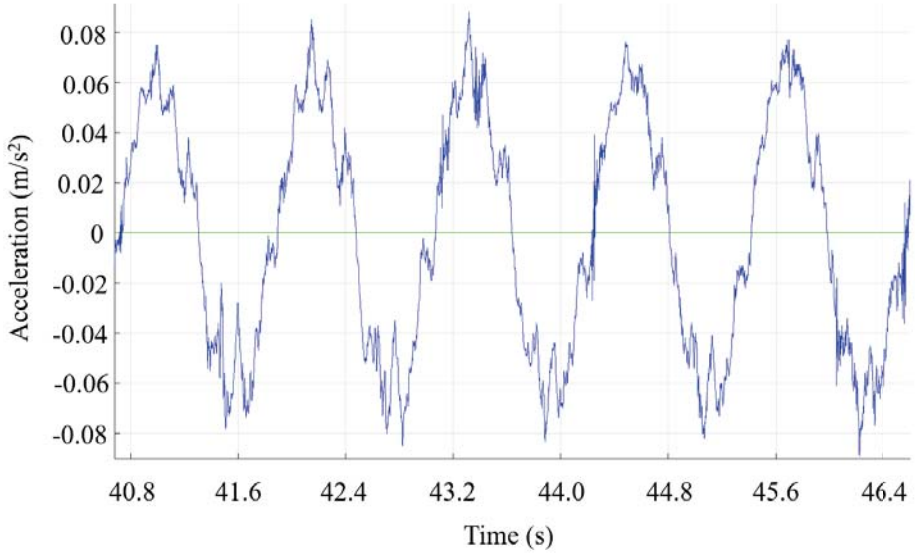

Figure 5: Acceleration measurements for induced vibrations in horizontal direction

6 NUMERICAL ANALYSIS

A detailed finite element model of the bridge was created in the Autodesk® Robot™ Structural Analysis environment to conduct a dynamic analysis of the bridge structure. Both modal analysis and *Footfall Harmonic Analysis (FHA)* of the structure was performed to investigate the free-vibration and forced-vibration behaviour of the bridge. When establishing the dynamic model, the nodal stiffnesses were carefully assessed and modelled, among other things by defining rigid links, master nodes and slave nodes. Furthermore, the hand railing was modelled as imposed load, converted to structural mass prior to the modal analysis, assuming negligable contribution to the overall stiffness of the structure.

A modal analysis of the structure was performed to investigate the dynamic behaviour. The results from the modal analysis show low natural frequencies both in the vertical- and lateral directions. Table 2 presents these frequencies together with the percentage of total mass vibrating in each mode in lateral (UY) and vertical (UZ) directions.

Mode shape [-]	Frequency [Hz]	Period [Sec]	Cur.mas.UY [%]	Cur.mas.UZ [%]
1	1.06	0.94	31.4	0.0
2	1.33	0.75	24.9	0.0
3	1.80	0.56	0.0	42.4

Table 2: Results of the modal analysis for the first five modes

The results of the modal analysis (Table 2) are in quite a good agreement with the free-vibration tests (Figure 3) although the numerical model seems to slightly overestimate the frequencies of the structure. Figure 6 and 7 depict the mode shapes of the predominant lateral and vertical modes obtained from modal analysis. The vibration frequencies in both the horizontal and vertical directions (1.06 Hz and 1.80 Hz, respectively), similar to the frequencies from the free-vibration measurements, fall into the critical range according to all three documents considered. As such, evaluation of maximum expected accelerations is necessary to assess the level of human-induced vibrations in the bridge.

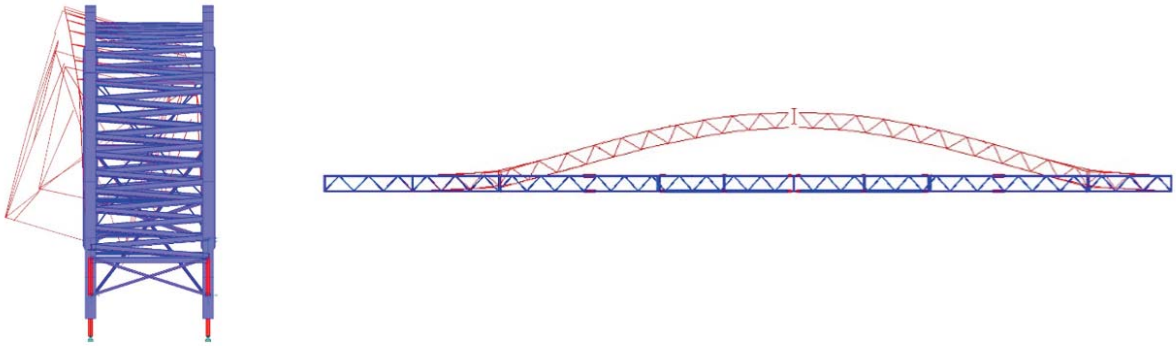

Figure 6: Mode shape of the first lateral mode; f=1.06 Hz

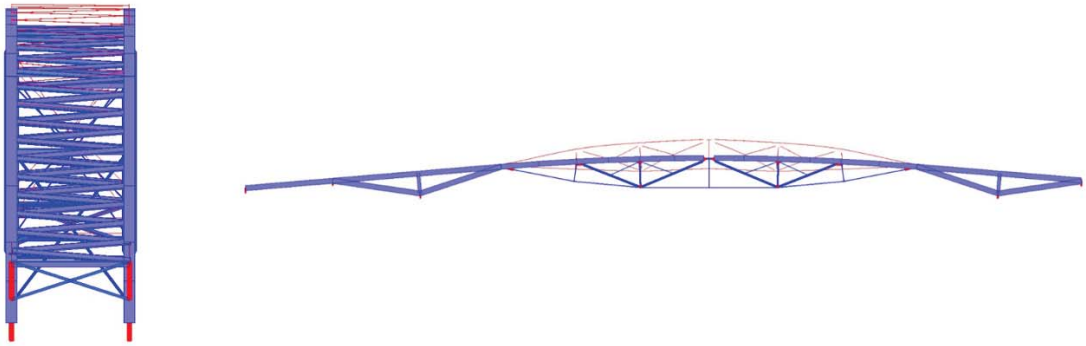

Figure 7: Mode shape of the first vertical mode; f=1.80 Hz

For this, a *footfall harmonic analysis* (FHA) was performed, examining the effect of human footsteps interpreted as a harmonic load at a specific range of frequency on the structure. Due to the limitation of the software used, only vertical direction response was investigated through the FHA. The frequency of movement of the harmonic load was set to be between 0.5 Hz - 5.0 Hz and the number of steps was set to 100. Furthermore, the damping ratio was modelled as 5% of the critical damping and the harmonic load was set to 70 kg based on the average weight of a person.

The FHA has been repeated to simulate different number of people crossing the bridge simultaneously. Figure 8 shows the response of the bridge when the number of people crossing the bridge is set to ten. As expected, the most severe response is observed at 1.80 Hz, which is the predominant frequency in the vertical direction. The footfall analysis show that the maximum acceleration levels in the vertical direction can reach 1.6 m/s^2, which is much higher than the comfort criteria set forth by EN-1990:2002 [5] for groups of 8 to 15 people; 0.7 m/s^2. This level of acceleration also places the comfort level of the bridge at *Minimum* according to Sétra and HIVOSS guidelines.

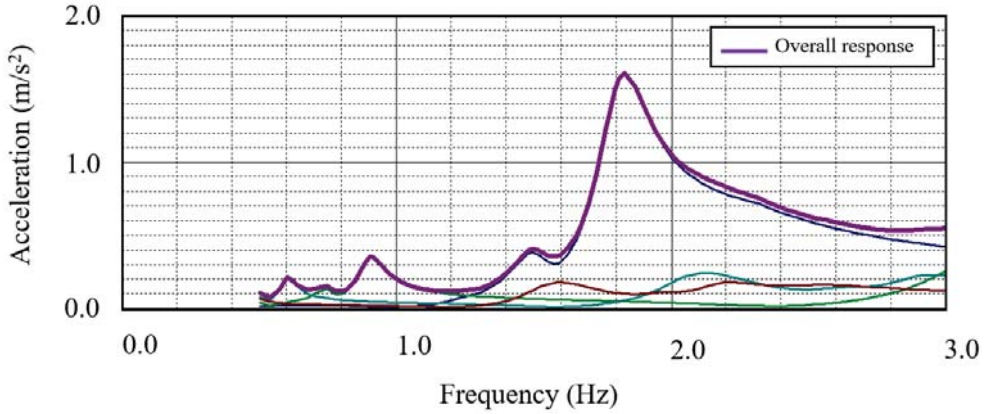

Figure 8: Results of Footfall Harmonic Analysis

Table 3 summarizes the results of the FHA for different number of pedestrians crossing the bridge including the estimated maximum acceleration for all cases. The variation of maximum acceleration with the number of pedestrians computed using FHA is also depicted in Figure 9

together with the maximum accelerations obtained from forced-vibration measurements. Also plotted in Figure 9 is the linear extrapolation of the maximum observed accelerations in the forced-vibration tests. Although the measurements are limited to three people, linear extrapolation of the observed maximum accelerations up to 15 people can be regarded as realistic considering that the behaviour of the bridge most likely remain elastic for a pedestrial load of up to 15 persons.

The maximum acceleration levels presented in Table 3 and Figure 9 show that the human-induced vibrations in the Kjærra Bridge exceeds the comfort criteria of EN-1990:2002 [5] already for five pedestrians. According to the Sétra and HIVOSS guidelines, the comfort level of the bridge reduces from *Maximum* to *Medium* at four pedestrians and further down to *Minimum* at seven pedestrians. Extrapolating the results of the FHA suggests that the threshold of *Unacceptable* vibrations will be exceeded when a group of 16 people cross the Kjærra Bridge at the same time.

$n_{pedestrians}$ [-]	$F_{harmonic}$ [kg]	Accel. [m/s^2]
1	70	0.16
2	140	0.31
3	210	0.47
4	280	0.63
5	350	0.79
10	700	1.60
15	1050	2.40

Table 3: Dynamic response of Kjærra Bridge obtained from FHA

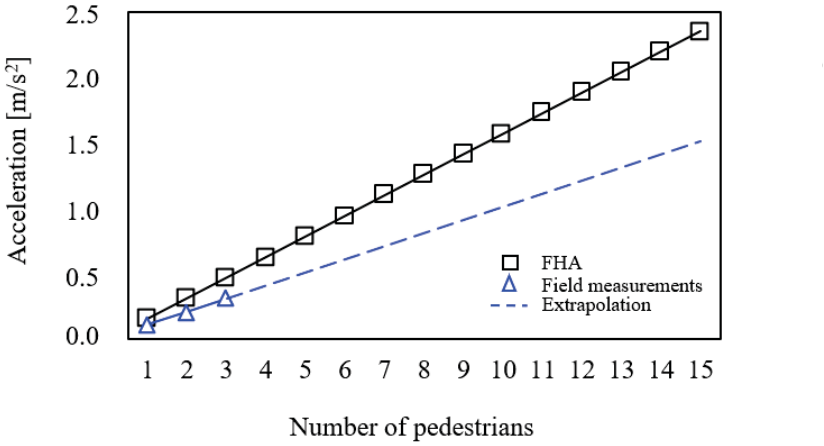

Figure 9: Measured and computed maximum accelerations for Kjærra Bridge

7 CONCLUSION

Kjærra Bridge had been designed and constructed at the beginning of the 21^{st} century, when there were no clear guidelines or standards that has focused on human-induced vibrations on footbridges. As a result of the slender geometry of the bridge, the pedestrians crossing the

bridge in groups have been experiencing severe vibrations. This paper has investigated the dynamic behavior of the bridge through field measurements and numerical analysis. The conclusions drawn from the results of free- and forced-vibration measurements conducted on the Kjærra Bridge and the numerical analysis performed can be summarized as follows:

- The free-vibration measurements indicate that the predominant frequencies in both horizontal and vertical directions are in the critical range according to all three prominent documents that focus on comfort criteria for vibrations in footbridges [2, 3, 5] .
- The forced-vibration measurements show that, even for three persons, the acceleration levels get close to the comfort level *Medium* according to Sétra and HIVOSS guidelines.
- The modal analysis results can be deemed to be in good agreement with free-vibration measurements although the former seems to slightly overestimate the vibration frequencies in both horizontal and vertical directions.
- The footfall harmonic analysis conducted for different number of pedestrians show that the comfort level of the Kjærra Bridge is not acceptable according to EN-1990:2002 [5] for pedestrian groups five or more people. The acceleration level falls into *Minimum* comfort level when the number of pedestrians exceed seven and becomes *Unacceptable* for 16 people according to Sétra and HIVOSS [3, 2] guidelines.
- The results of this study suggest that both EN-1990:2002 [5] and HIVOSS [2] and Sétra [3] guidelines can effectively predict that the human-induced vibrations in Kjærra Bridge can exceed acceptable levels for a relatively small group of pedestrians. As such, it can be argued that any future design that follow the aforementioned guidelines can be expected to have a satisfactory behavior as far as human-induced vibrations are concerned.
- On the other hand, the problems associated with human-induced vibrations for Kjærra Bridge demonstrate the need for a theroetically-sound and precise standard to avoid such problems in future designs.

Keywords: Footbridges, Human-structure interaction, Walking, Vibration, SDOF models

Abstract. *The last two decades saw an increase in the number of studies investigating the problem of excessive structural vibration due to pedestrian dynamic loads. Several models to represent the pedestrian action on the structure have been developed. The simplest model (used in most guidelines) consists of applying a moving force on the structure to predict its dynamic behaviour. However, it is now well known that this model cannot accurately estimate the dynamic response of the structure under human action. This is chiefly because the human body has its own dynamic properties, depending on the activity and posture, and the simplest model does not consider this when modelling a pedestrian. This way, single degree of freedom (SDOF) models considering stiffness, mass and damping of an individual have been initially presented. Such models have been compared with the simplest moving force model in terms of accuracy of the structural response. However, challenges remain in terms of dealing with its mathematical modelling, and validation with experimental measurements. In this context, this paper presents a discussion about the formulations of such SDOF models, in order to clarify conceptual and mathematical similarities and differences between such formulations. A basic formulation was identified to compare values that have been proposed for the body parameters, using as a reference experimental data obtained from tests carried out in resonance condition on a lively footbridge. The SDOF model and, generally, the values of body parameters proposed in the literature, performed well against experimental data. There was evidence that lower natural frequencies of the pedestrian body adopted in one of the formulations led to less accurate results, but further studies are needed to confirm this.*

1 INTRODUCTION

Structures have become increasingly lighter and slender, and consequently more susceptible to excessive vibrations. Thereby, loads that generally did not cause structural problems in the past, for example, human activity (running, walking, bouncing etc.), are now of interest for serviceability limit states. This way, the last two decades has concentrated an increased number of studies that aim to investigate the dynamic behaviour of structures under human loads [1].

To deal with this, for design purposes, several ways of applying these loads on the structure have been presented [2]. Focusing on the vertical direction and walking movement, the simplest model consists in applying a moving periodic force (MF) over the structure, mathematically expressed by a Fourier series [3].

Currently included in most standards and guidelines [e.g., 4-6], it is now well known that the MF model cannot estimate precisely the dynamic properties of the system under human action, and sometimes can result in overestimated responses, as shown by Caprani *et al.* [7].

This is because the dynamics of the pedestrian body is not considered in the MF model. Indeed, Shahabpoor *et al.* [1] and Caprani & Ahmadi [2] emphasized that human-structure interaction (HSI) is the key to understand and estimate the effect of human induced loads in structures, particularly in resonance condition. Thus, biodynamic models have been introduced to model pedestrians, the simplest one being a single degree of freedom spring-mass-damper (SMD model).

However, even among the SMD models, there are significant differences in the formulations, ranging from the absence of an analytical formulation [8-10], to the adoption of additional energy input that generates the pedestrian up and down movement by different means (e.g., actuators [11-13], heel movement [14], additional velocity term [15]), or else none of these additions [7,16,17].

Another aspect regarding the SMD models are the values adopted for the parameters mass, stiffness and damping, and several proposals can be found [10,15,17-20], in which such values were obtained in different ways. However, comparisons of performance of SMD models and associated parameters among each other and against the same experimental data are scarce or even non-existent.

In this context, the aim of this paper is twofold. First, an analysis is presented regarding the formulations of SMD models, as a way of clarifying their similarities and differences in conceptual and mathematical terms. The target is to identify a basic analytical formulation for the SMD model and adopt it to compare different formulations. Then, and adopting this basic formulation, parameters proposed in the literature for stiffness, mass and damping of the SMD models were compared, employing experimental data from a pedestrian crossing of a very lively footbridge that had the first vertical mode easily excited. It should be mentioned that the test was carried out in resonance condition, so as to enhance differences in the response between the MF and several SMD models.

2 ANALYSIS OF SMD MODELS

In this section, SMD models of the literature are critically analysed, and a basic analytical formulation is identified and adopted for further comparison against experimental data. Following this, values for the SMD parameters are presented.

2.1 Formulation of SMD models

The first model known to the authors that proposed the modelling of a moving pedestrian as a dynamic system when calculating footbridge vibrations was proposed in Archbold [8],

see also Fanning *et al.* [9]. Being called later on in the literature as a Moving Oscillator, this model consists of applying a ground reaction force $F(t)$ produced from walking on a rigid surface, simultaneously with a SMD model, the latter representing the dynamics of the pedestrian body.

The ground reaction force is usually assumed to be periodic and represented in terms of a Fourier series. For a rigid surface, this time varying force $F(t)$ is shown in Eq. (1), considering only the first harmonic, as this usually suffices for analyses of typical footbridges in resonance condition. In Eq. (1), W is the weight of the pedestrian ($W = Mg$, in which M is the pedestrian total mass, and g is the acceleration due to gravity), f_p is the pacing rate, and DLF stands for dynamic load factor [3].

$$F(t) = W\,(1 + DLF\ \sin\,(2\,\pi f_p\ t)) \tag{1}$$

It should be noted that there is no specific analytic formulation presented in Archbold [8] and Fanning *et al.* [9] to represent the interaction between pedestrian and footbridge. This proposal is, thus, just a procedure to include the dynamics of pedestrian. This same procedure was adopted by Silva *et al.* [10].

A first analytical formulation to account explicitly for the interaction between pedestrian and footbridge can be found in the work of Caprani *et al.* [7]. It is considered that the ground reaction force produced by the pedestrian is the sum of elastic spring and dissipative forces, that is, the force is transmitted to the mass of the pedestrian through the spring and damper, while walking on a rigid or on a flexible surface.

The outcome of this formulation is that the ground reaction force is equal to the respective inertia force in each case, as will be shown later. Venuti *et al.* [16] adopted the formulation of Caprani *et al.* [7], but with a difference that the former opted to express the interaction force as the sum of the elastic spring and damping forces instead of the inertia force, which led to a different arrangement of terms in the formulation. Shahabpoor *et al.* [17] also adopted this formulation, for investigating the action of a pedestrian flow, which was assumed as continuous and stationary.

This formulation was employed with some modifications by Pfeil *et al.* [14]. First, a function was introduced to represent the up and down movement of the heels. One can think of this function as a conceptual cause of the up and down movement of the pedestrian. However, in the development of the formulation, it can be inferred that this function could be suppressed without affecting the equations of motion.

This way, by omitting this function for the sake of clarity, the model adopted by Pfeil *et al.* [14] can be seen in Figure 1: a walking person represented as a SMD model, with respective modal mass (m_p), damping (c_p) and stiffness (k_p). By considering the equilibrium at the pedestrian's centre of mass (COM) and at contact point, the equation of motion of the pedestrian can be expressed in Eqs. (2) and (3), while walking on rigid and flexible surfaces, respectively.

$$F(t) = \ - c_p\ \dot{u}_{pr} - k_p\ u_{pr} = m_p\ \ddot{u}_{pr} \tag{2}$$

$$F_{int}(t) = -\ c_p\,(\dot{u}_{pr} + \dot{u}_p - \dot{u}_s)\ -\ k_p\,(u_{pr} + u_p - u_s)\ =\ m_p\,(\ddot{u}_{pr} + \ddot{u}_p) \tag{3}$$

In Eqs. (2) and (3), u_{pr} is the vertical displacement of the pedestrian's COM while walking on a rigid surface; u_p is the vertical displacement while walking on flexible surface which takes into account the pedestrian-structure interaction; and u_s is the vertical displacement of the structure at the contact point. It should be noted, as indicated in Figure 1, that the forces $F(t)$ and $F_{int}(t)$ represented in these equations act on the pedestrian. Equal and opposite forces are acting on the structure.

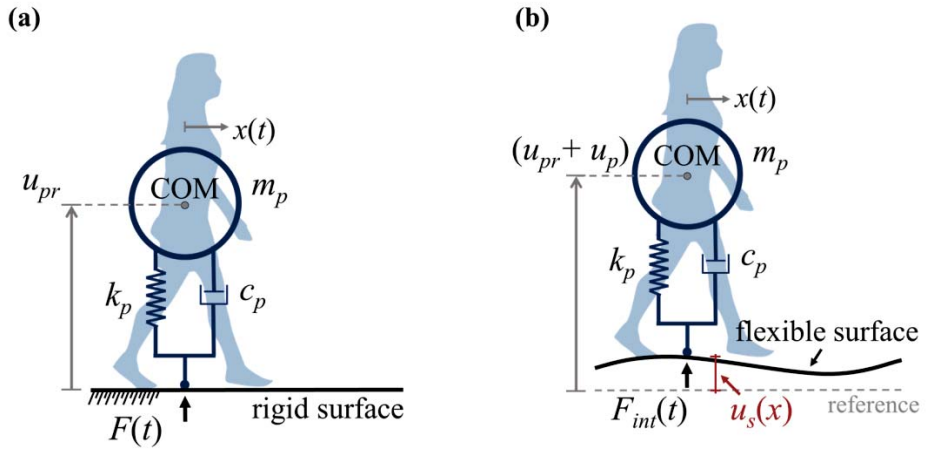

Figure 1: The SMD model (a) on a rigid surface and (b) on a flexible surface, after [14].

Considering all this, Pfeil *et al.* [14] explicitly showed that the ground reaction force from the rigid surface $F(t)$ could be introduced into the expression of the interaction force $F_{int}(t)$ while walking on a flexible surface. This is directly obtained by manipulating Eqs. (2) and (3). Then, by turning around $F(t)$ and $F_{int}(t)$, in order to apply them at the structure, Eq. (4) is obtained:

$$F_{int}(t) = c_p\,(\dot{u}_p - \dot{u}_s) + k_p\,(u_p - u_s) + F(t) \tag{4}$$

The introduction into the formulation of the interaction displacement u_p as a part of the total displacement of the pedestrian's COM while walking on flexible surfaces, led to a difference in this formulation when compared to the ones adopted by the aforementioned authors [7,16,17]. Adoption of u_p is necessary if the ground reaction force from walking on the rigid surface is to be employed into the formulation of walking on the flexible surface. The outcome is that the total displacement of the COM of the pedestrian while walking on a flexible surface ($u_p + u_{pr}$) differs from that adopted by Caprani *et al.* [7].

The equation of motion of the pedestrian body, in terms of the interaction displacement u_p, can be obtained by combining Eqs. (2) and (3):

$$m_p\,\ddot{u}_p \;+\; c_p\,(\dot{u}_p - \dot{u}_s) \;+\; k_p\,(u_p - u_s) = 0 \tag{5}$$

Now, by using the concept of modal superposition, a coupled system (pedestrian-structure) with two degrees of freedom is formulated. For this purpose, the structure displacement (u_s) at the contact point, assuming a single mode structural response, can be expressed as:

$$u_s(x) \;=\; \phi_i(x)\,y_i \tag{6}$$

where y_i is the general coordinate corresponding to the i^{th} mode with the respective mode shape $\phi_i(x)$, and x stands for the pedestrian position at the structure.

Remembering that modal superposition equation is given by:

$$m_i\,\ddot{y}_i \;+\; c_i\,\dot{y}_i \;+\; k_i\,y_i \;=\; P_i \tag{7}$$

where m_i, c_i and k_i are the modal mass, damping and stiffness of the i^{th} mode of the structure, and P_i is the generalized force, given by:

$$P_i = \phi_i(x)\,F_{int}(t) \tag{8}$$

The equation of motion of the joint pedestrian-structure system (unknowns y_i and u_p) can be expressed by Eq. (9), obtained by substituting Eq. (8) into (7), and considering Eqs. (4) and (6).

$$m_i \ddot{y}_i + (c_i + \phi_i^2 c_p)\dot{y}_i + (k_i + \phi_i^2 k_p) y_i - \phi_i c_p \dot{u}_p - \phi_i k_p u_p = \phi_i F(t) \tag{9}$$

The coupled pedestrian-structure system can be also written in a matrix form, as stated by Pfeil *et al.* [14]:

$$\mathbf{M}\,\ddot{\mathrm{U}} + \mathbf{C}\,\dot{\mathrm{U}} + \mathbf{K}\,\mathrm{U} = \mathrm{F} \tag{10}$$

where,

$$\mathbf{M} = \begin{bmatrix} m_i & 0 \\ 0 & m_p \end{bmatrix}, \quad \mathbf{C} = \begin{bmatrix} c_i + \phi_i^2 c_p & -\phi_i c_p \\ -\phi_i c_p & c_p \end{bmatrix}, \quad \mathbf{K} = \begin{bmatrix} k_i + \phi_i^2 k_p & -\phi_i k_p \\ -\phi_i k_p & k_p \end{bmatrix},$$

$$\mathrm{F} = \begin{Bmatrix} \phi_i F(t) \\ 0 \end{Bmatrix} \quad \text{and} \quad \mathrm{U} = \begin{Bmatrix} y_i \\ u_p \end{Bmatrix}$$

Note that the equations are similar to the ones presented by Venuti *et al*. [16]. However, the variable representing the displacement of the pedestrian's COM herein consists only of the interaction displacement u_p of the COM while walking on a flexible surface.

A slight modification of this formulation was introduced by Jiménez-Alonso & Sáez [19] by placing a small part of the pedestrian mass at feet level and in permanent contact with the structure. By doing this, the interaction force $F_{int}(t)$ differs from the expression present in Eq. (3). Nonetheless, bearing in mind that the fraction of the total mass M of the pedestrian that is included in the SMD model (as a modal mass m_p) varies among proposals found in the literature (values will be discussed later), the modification introduced by Jiménez-Alonso & Sáez [19] did not differ much from the previous formulations.

Finally, Gomez *et al.* [15] conceived the source of external energy that caused the pedestrian up and down movement as an initial velocity condition applied to the SMD model, when the heel hits the ground. By comparing their formulation with the one from Pfeil *et al.* [14], this initial velocity condition replaced the use of the ground reaction force $F(t)$ (applied on a rigid surface) when formulating the equations for walking on flexible surfaces.

However, this is more a matter of preference about using or not the ground reaction force from walking on a rigid surface into the formulation. It should be noted that using $F(t)$ has advantages since expressions for it are very deeply studied in the literature [1, 2].

The formulation from Pfeil *et al.* [14], slightly modified by the suppression of the function representing the heel movement, was, thus, selected as a basic one in this paper, and is adopted for the analysis of the values of the SMD parameters.

2.2 SMD parameters

There are studies that proposed values for the SMD parameters based on experimental tests with walking subjects.

One of the first studies was conducted by Silva & Pimentel [18]. Values were determined based on tests with twenty subjects walking on a rigid surface, in which acceleration was measured at waist level only. Regression expressions were then proposed for the modal mass, stiffness and damping, as a function of the total mass and pacing rate of the pedestrian. In a

subsequent work, Silva *et al.* [10] presented additional linear expressions to obtain stiffness and damping.

The study of Toso *et al.* [20] also obtained SMD parameters from walking subjects. In this case, the ground reaction force from a rigid surface was measured simultaneously with the body acceleration for thirty-five subjects and used as an input to determine a set of regression expressions for the SMD parameters.

The main feature for obtaining the SMD parameters in these three studies was a formulation in which the equation of motion of the pedestrian assumed that all forces were applied at the pedestrian's COM, including the ground reaction force.

Gomez *et al.* [15] applied the same test setup as Silva & Pimentel [18], but enrolling only three subjects and employing a different formulation for the equation of motion (see Section 2.1), which led to values for stiffness and damping for each test subject. In addition, they also considered the modal mass as the respective total mass of the test subject.

In all these aforementioned works, the SMD parameters were determined directly from measurements on each individual, walking alone. However, a different approach is reported in other studies, where the values of the SMD parameters were obtained indirectly through measurements of the structural response. This line of reasoning was presented by Jiménez-Alonso & Sáez [19], and they obtained values for the SMD parameters based on experimental results carried out by Geogarkis & Jorgensen [21], in which test subjects walked in group (in varied density scenarios) across a simply supported beam.

By using a genetic algorithm, average values for the SMD parameters for each scenario were obtained, and Jiménez-Alonso & Sáez [19] concluded that there was no significant variability in the sprung mass, equivalent damping ratio and body natural frequency for different scenarios.

Shahabpoor *et al.* [17] also employed tests with group of pedestrians. They assumed that the modal mass was the total mass of the pedestrian and identified a range of values for the body natural frequency and damping.

A synthesis of all of these findings is presented in Tables 1 and 2, where ξ_p and f_{np} are respectively damping ratio and natural frequency of the pedestrian body.

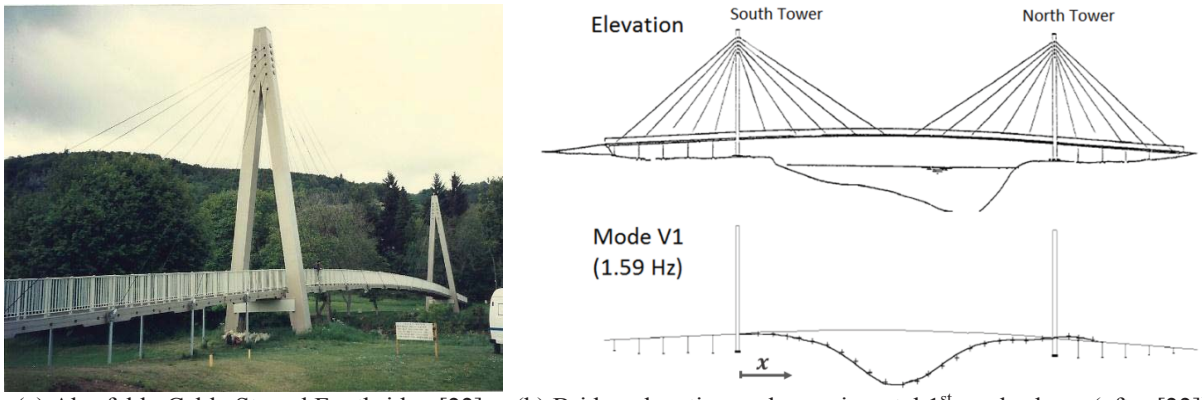
3 TEST STRUCTURE AND EXPERIMENTAL RESULTS

The test structure is the Aberfeldy glass reinforced plastic cable-stayed footbridge, in Scotland (Figure 2a). More details about the test structure can be found elsewhere [14, 22].



(a) Aberfeldy Cable Stayed Footbridge [22] (b) Bridge elevation and experimental 1st mode shape (after [22])

Figure 2: Test structure and mode shape of interest

The test result of interest is the filtered vertical acceleration response at mid span due to the crossing of a pedestrian walking in resonance with the first vertical mode of the structure, in which the maximum acceleration (a_{max}) and root mean square acceleration (a_{rms}) was respectively 2.14 m/s² and 0.89 m/s². The whole measured time response signal was available for comparison with the numerical predictions.

As observed in Pfeil *et al.* [14], even with the control of the pedestrian gait with a help of a metronome, the strong deck vibrations led to a pace losing, causing disturbances in the response signal. This was taken into account in this work.

On the other hand, by analysing the experimental mode shape in Figure 2b, it is clear that the relevant response occurs while walking between the towers and in order to be used in Eq. (10), a mathematical expression for unity scaled $\phi_i(i=1)$ given in Eq. (11) was fit to the experimental mode shape.

$$\phi_1(x) = 0.11867 - \frac{1845.64}{4\pi(x - 31.881)^2 + 513.413\pi} \tag{11}$$

Finally, the absence of some information from the experimental side led to a need of adopting values from the literature. The step length of the pedestrian was assumed as 0.90 m [13]. The DLF of the pedestrian was not experimentally determined; and an initial value of 0.25 was defined based on Young [23] and adjusted in the analysis, as will be shown later on. All information gathered for the analysis is presented in Table 3.

4 RESULTS AND DISCUSSIONS

The performance of the SMD parameters was investigated by comparing numerical results obtained adopting the interaction model of Pfeil *et al.* [14] against the experimental result (see

Table 4). The results were compared in terms of the maximum (a_{max}) and root mean square (a_{rms}) acceleration, as well as the fit to the experimentally measured acceleration response time history (see Figures 3 and 4). For conciseness, only the best results obtained for each of the formulations are shown in these Figures. However, Table 4 contains the whole range of results obtained for all formulations. It can be noted that a range of values was proposed in some formulations for the pedestrian parameters [15,17], and this is the reason why some combinations of these values (in particular, damping and natural frequency of the pedestrian body) were performed (see sets (1) to (4) in Table 4). On the other hand, for the formulations in which regression expressions or average values were proposed [10,18-20], the body parameters were obtained by employing the body parameters of the test subject.

* Best result obtained for the range of the proposed values.
** Values from [10] were close to the ones from [18], and were not shown in Figure 4.
Obs.: The variation in the SMD parameters from [10, 18, 20] was due to the dependence of such parameters with the varied pacing rate throughout the crossing.

Table 4: Results obtained employing different values for the pedestrian parameters

For each case, the unknown *DLF* of the test subject was adjusted to produce a best fit, based on a trial and error process. However, it can be seen from Table 4 that this is not a significant issue since the best value of the *DLF* obtained for each formulation varied very little, around the value 0.27 stated in Pfeil *et al.* [14].

Regarding the values of the SMD parameters, it is noted that despite the wide range of values of the parameters, no great difference was identified among the results (Figure 4).

However, some discrepancies were noted about the proposed values of the natural frequency f_{np} of the pedestrian body. Toso *et al.* [20] values for this parameter are below all the other works and the results with their parameters were the least accurate among the whole set of SMD parameters investigated (Figure 3b). This requires further studies, with a larger sample of experimental data, to confirm or not the relevance of this parameter, since the natural frequency f_{np} may not be the sole cause of the discrepancy.

In general, despite the different ways of obtaining the SMD parameters, the results were in very good agreement with the experimental one and presented a much better performance against MF model (Figure 3a), which overestimated the bridge response. The difference in

peak and RMS values between MF and biodynamic models might be small (see values in Table 4), but this was for a single pedestrian crossing. Actual design cases consider group or streams of pedestrians crossing the structure, which deserves further investigation.

5 CONCLUSIONS

A discussion of SDOF spring-mass-damper models proposed in the literature to model pedestrians in HSI studies was presented. It was shown that the formulations proposed to account for HSI were based on the same concept that the ground reaction force, either on a rigid or on a flexible surface, is equal to the inertia force of the pedestrian body. In general, this led to an analytical formulation to represent the coupled pedestrian-structure system.

The formulation presented by Pfeil *et al.* [14] made it clear that the ground reaction force obtained from rigid surfaces (widely used in the literature) can be inserted into the equations that consider the deformability of the structure. With a slight modification, this so called

'interaction model' [14] was adopted to compare the performance of various SMD parameters proposed in the literature and obtained through experimental measurements with walking subjects, albeit each set of parameters was obtained in different and independent ways.

Despite of the different ways in obtaining the SMD parameters, the different proposals generally resulted in quite good agreement with the experimental result obtained from a pedestrian crossing a lively footbridge. However, a less accurate response was obtained from one of the formulations, when the proposed value for the natural frequency of the pedestrian body was lower, which requires attention and further studies.

In spite of the good performance of the simple SMD models and respective parameters in this case, a more in-depth analysis is required with well instrumented pedestrians. This way, the performance of the SMD models could also be compared against more elaborated biodynamic models currently proposed in the literature. In addition, evaluations employing a larger number of test subjects crossing simultaneously a structure are required, so as to comply with the design cases of current standards.

Abstract. *The most often purported mechanism causing the lateral dynamic instability of the London Millennium Footbridge is the synchronisation of footsteps to the lateral structural motion. However, evidence from full-scale measurements and treadmill tests has challenged this notion. Instead, an active control of foot placement is advocated to be the source of destabilising forces to the structure, occurring even without synchronisation. This is to say that, while walking on a laterally oscillating surface, pedestrians maintain their balance primarily by controlling the position of their feet, rather than adjusting the timing. Similar behaviour was previously observed in experimental tests measuring the response of pedestrians to an impulsive perturbation of gait. The analysis of the collected data suggested a simple linear foot placement control law, whereby the position of the foot at the instant of foot placement immediately following the perturbation depends on the instantaneous lateral velocity of the centre of mass and a constant offset. However, it is has been uncertain whether the same foot placement control law applies while walking on laterally oscillating structures. To test this proposition, an experimental campaign was conducted on a laterally oscillating treadmill with a test subject monitored with an optical motion capture system. The motion of the body centre of mass and the position of the feet were identified and analysed. It was found that a simple linear foot placement control law applies. Further tests were conducted to test the influence of the visual information on pedestrian stepping behaviour using virtual reality delivered via a head mounted display. It was found that the identified foot placement control law is very robust for different walking surface conditions and visual environments.*

1 INTRODUCTION

Lateral dynamic instability under the loading from a walking crowd has been observed on many bridges around the world [1-8]. Despite intensive research in the last two decades to uncover the nature of this phenomenon, a consensus has not yet been reached. The paradigm still dominating in the field is that, in the presence of perceptible bridge motion, pedestrians adjust their stride frequency to match the vibration frequency of the bridge, hence a direct resonance will occur. This is supposedly amplified by a tendency of pedestrians to synchronise their footsteps to one another. However, some measurements from full-scale structures [5, 6] and laboratory environments [9, 10] have challenged the notion of prevalence of the direct resonance, while the natural tendency of pedestrians to synchronise their footsteps with other pedestrians has been found to be quite weak [11, 12]. Meanwhile, it has been shown that destabilising forces to the bridge can arise from simple mechanics of walking, whereby pedestrians adjust the lateral position of their stepping foot in response to perturbations from the oscillating bridge, even in the absence of synchronisation [13]. This analysis was accomplished by employing an inverted pendulum model (IPM) to idealise the dynamics of pedestrian motion in the frontal plane, i.e. the vertical plane perpendicular to the direction of progression. The IPM consists of a mass supported by a rigid massless leg. The transition between steps is instantaneous and the position of foot placement for the stepping leg, u, is assumed to follow the law proposed by Hof *et al.* [14]:

$$u = x_{\mathrm{CoP}} - x_{\mathrm{CoM}} = \frac{\dot{x}_{\mathrm{CoM}}}{\Omega_p} \pm b_{\min} \tag{1}$$

where x_{CoP} and x_{CoM} is the lateral distance, measured from the same arbitrary reference point on the surface, to the centre of pressure (CoP) and the vertical projection of the centre of mass (CoM), respectively, a dot over the symbol represents differentiation with respect to time, $\Omega_p = \sqrt{g/l_{\mathrm{eq}}}$ is the angular pendulum frequency in which g is the gravitational acceleration and l_{eq} is the equivalent pendulum length, the ± sign accounts for the bipedal nature of human gait (i.e. changing point of support from step to step) and $b_{\min}$ is a constant termed the margin of stability. The IPM based on Eq. (1) has been shown to be capable of explaining the forces generated by a pedestrian on a laterally oscillating bridge [13, 15], with good qualitative agreement with experiments involving unimodal [16, 17] and multi-modal [18] bridge motion. However, little direct experimental evidence has been presented to date to specifically support the adopted foot placement control law [19, 20]. Moreover, it is currently unclear whether $\dot{x}_{\mathrm{CoM}}$ in Eq. (1) should be taken relative to the moving bridge, $\dot{x}^{\mathrm{rel}}_{\mathrm{CoM}}$, or some stationary point outside of the bridge relative to which the bridge is moving, $\dot{x}^{\mathrm{abs}}_{\mathrm{CoM}}$ [9].

Considering the gaps in the current state of knowledge, the aim of this study is to verify whether a foot placement control law of the type proposed by Hof *et al.* [14] applies for walking on an oscillating bridge. To this end, tests were conducted on a self-paced treadmill capable of lateral oscillation. Gait kinematics of a test subjects were recorded using an optical motion capture system to obtain an instantaneous position of the body centre of mass (CoM) and feet. Motivated by the form of the Hof *et al.*'s [14] foot placement control law in Eq. (1), a simple linear regression model was fitted to the data relating the step width and lateral velocity of the CoM at the instant of foot placement. To tests the robustness of the pedestrian stepping behaviour, three types of visual environment were provided to the test subject.

2 METHODOLOGY

A 21 year-old healthy female with body mass of 51kg and height 1.64m was recruited for the tests. The test subject wore gym-type clothing and flat-sole shoes. Prior to participating in the tests, the subject familiarised herself with the information letter for participants, completed a physical readiness questionnaire and signed an informed consent form. The tests were approved by the University of Bristol Ethics of Research Committee.

Six tests were conducted in total. The subject walked on the treadmill when stationary (i.e. non-oscillating), denoted NLTM (no lateral treadmill motion), and on the treadmill with it oscillating in the lateral direction with sinusoidal motion of amplitude 10mm and frequency 0.9Hz, denoted LTM (lateral treadmill motion). The test subject was subjected to three visual conditions, including that of the laboratory environment, denoted RL (real life), and two virtual reality environments delivered via a head mounted display, denoted VR1 and VR2. The details of the instrumentation used during the tests and data analysis are given in this section.

2.1 Treadmill

A custom-built treadmill mounted on a shaking table capable of providing lateral motion was used during the tests. A generous walking area of 2m by 1.5m was provided to facilitate the operation of a treadmill speed feedback control mechanism, enabling automatic adjustment of the treadmill speed to that of the user, and to facilitate adaptive pedestrian stepping behaviour.

2.2 Virtual reality

An immersive and interactive virtual reality (VR) environment was delivered via an nVisor SX111 head mounted display, offering a 76 degrees horizontal and 64 degrees vertical field of view and 1280 by 1024 resolution per eye. The VR environment was developed in NetBeans 7.01 IDE using the Jogl platform providing 3D graphics based on the OpenGL® API for applications written in Java™. It consisted of three main elements, (i) the bridge, (ii) the substratum, i.e. stationary objects rendered below the bridge, providing height reference, and (iii) the superstratum, i.e. objects rendered around the bridge, above the substratum. Two VR scenes were built, differing in terms of the number and type of visual reference cues available to the user. In both scenes, the virtual bridge was translating together with the treadmill belt thus providing optical flow as for normal overground walking, i.e. motion of the objects perceived due to self-motion – here realized by walking on a treadmill. In both scenes, the lateral movement of the virtual bridge was enabled by coupling it with the lateral treadmill motion. The first scene, hereafter referred to as VR1, presented in Figure 1 (a), contained visual information enabling motion parallax, i.e. the perception of relative motion of objects against the rest of the visual field caused by self-motion of the observer. This was achieved by inclusion of stationary objects set in the scene, i.e. the substratum (water beneath the bridge) and red posts positioned alongside the bridge, and also bridge railings moving with the bridge and the deck being rendered in a pattern resembling wood. The second scene, hereafter referred to as VR2, presented in Figure 1 (b), was built by stripping VR1 of most of the information facilitating the perception of self-motion to the point that the only object left in the scene was the deck, rendered in a low contrast pattern, surrounded by dense fog.

(a) (b)

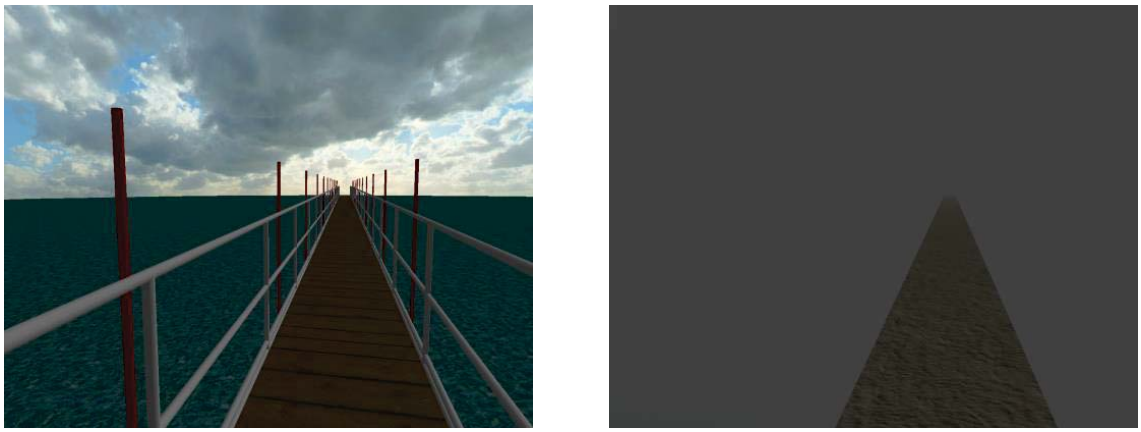

Figure 1: Virtual reality environments projected onto the left-eye screen of head mounted display, (a) VR1, (b) VR2.

2.3 Data capture and analysis

An optical motion capture system consisting of six Qualisys cameras was used to record, at the sampling frequency of 128Hz, the motion of fourteen retroreflective markers attached to the body landmarks of the test subject. This enabled the position of the CoM to be determined using the linked-segments modelling procedure [21]. One marker was attached to the lateral malleolus (i.e. ankle) of each foot to determine the pseudo step width, defined here as the lateral distance between the projections of the position of the CoM and the ankle marker onto the surface at the instant of foot placement. The term *pseudo step width* is used herein, since in the original formulation of the IPM [14] the step width is defined using the centre of pressure (CoP) and the transfer from one leg to the other is instantaneous. However, the CoP was not measured during the tests and the double-support phase of gait is not negligibly short. Therefore, it was assumed herein that (i) the ankle marker, due to anatomical constraints, gives a representative point of reference for the step width in the spatial reference frame, and that (ii) the instant of foot placement gives a representative point of reference for the step width in the temporal reference frame. That instant was determined from the vertical velocity of the ankle markers according to the procedure proposed in [22].

The following function was fitted to the pseudo step width data, compatible with the IPM and lateral foot placement control law in Eq. (1):

$$u^* = x_{\mathrm{ANKLE}} - x_{\mathrm{CoM}} = \rho_1 \dot{x}_{\mathrm{CoM}} \pm \rho_2 \tag{2}$$

where u^* is the pseudo step width, x_{ANKLE} is the lateral position of the ankle marker attached to the stepping foot, $\dot{x}_{\mathrm{CoM}}$ is the lateral velocity of CoM at the instant of heel strike, and ρ_1 and ρ_2 are the coefficients of the fit. Note ρ_1 and ρ_2 in Eq. (2) correspond to the inverse of the IPM angular frequency, Ω_p, and the margin of stability, b_{min}, respectively, from Eq. (1), and have physical units of time and displacement, respectively. The outstanding problem is the definition of the lateral velocity of the CoM, $\dot{x}_{\mathrm{CoM}}$, for LTM tests. Note this ambiguity does not exist for NLTM tests, since $\dot{x}^{\mathrm{rel}}_{\mathrm{CoM}}$ is then equal to $\dot{x}^{\mathrm{abs}}_{\mathrm{CoM}}$. This issue will be taken into consideration in the discussion of the results in Section 3.

The displacement signal of the CoM was differentiated to obtain lateral the CoM velocities $\dot{x}_{\mathrm{CoM}}^{\mathrm{abs}}$ and $\dot{x}_{\mathrm{CoM}}^{\mathrm{rel}}$. A fourth-order two-way Butterworth low-pass filter with cut off frequency of 6Hz was applied to all the data.

3 RESULTS AND DISCUSSION

The empirical data relating pseudo step width, u^*, with the absolute lateral velocity of the CoM, $\dot{x}_{\mathrm{CoM}}^{\mathrm{abs}}$, for all the conducted tests are shown in Figure 2.

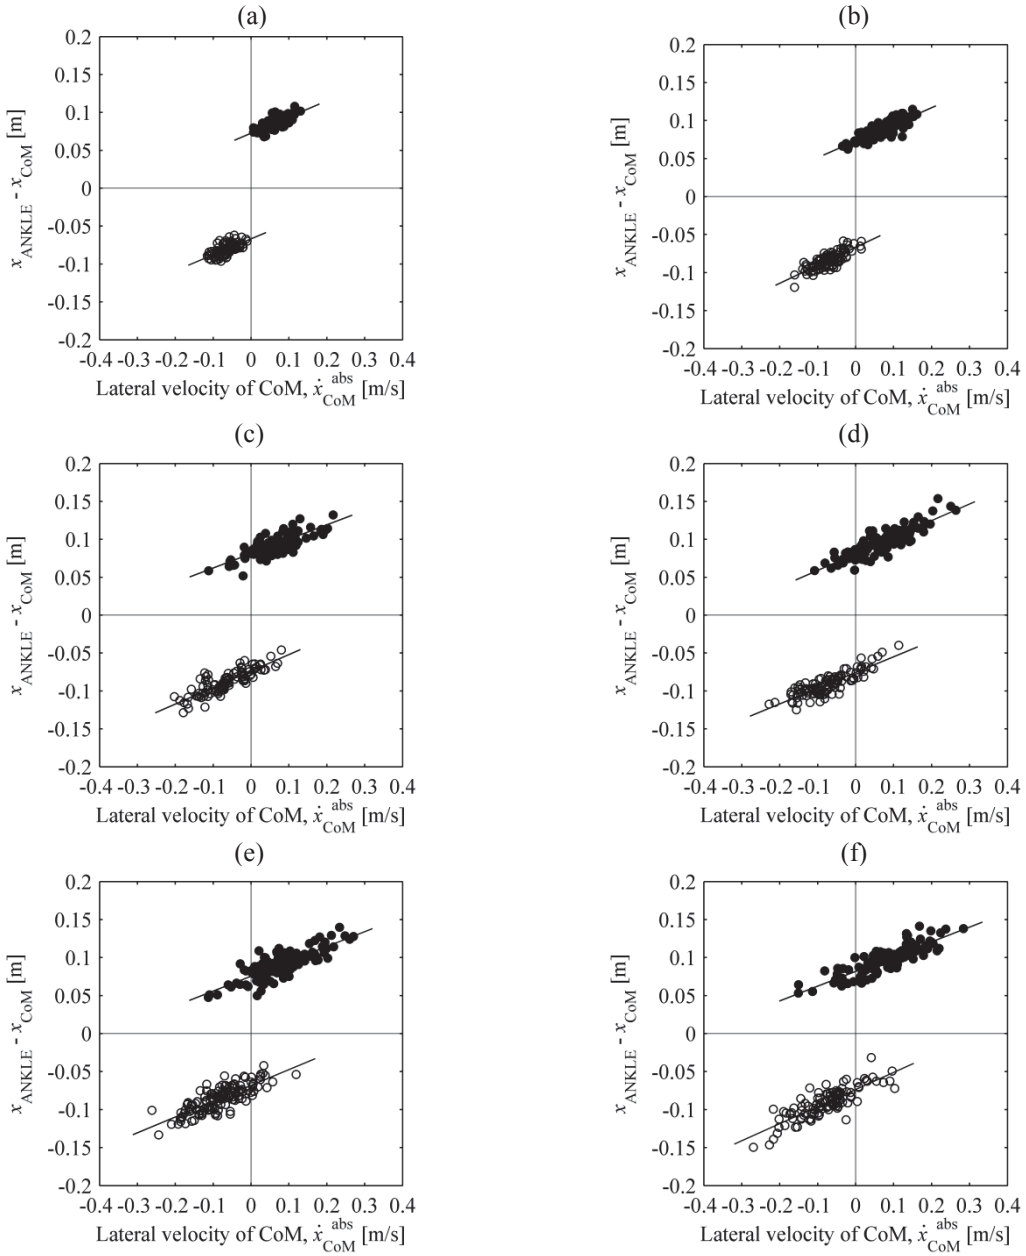

Figure 2: Relationship between the pseudo step width and the absolute lateral velocity of the CoM at the instant of heel strike for (a) RL NLTM, (b) RL LTM, (c) VR1 NLTM, (d) VR1 LTM, (e) VR2 NLTM and (f) VR2 LTM. The data for the right and left leg are denoted by ● and ○ in the top and bottom parts of the plots, respectively.

The least spread of data can be seen in Figure 2 (a) & (b) for walking in the visual environment of the laboratory (RL), without and with lateral treadmill oscillation (NLTM & LTM), respectively. The greatest spread of data can be seen in Figure 2 (e) & (f) for walking in VR2 in NLTM & LTM, respectively. Despite the differences in data variability, the gradients and intercepts (with the vertical axes) of the best linear fits, found separately for the right and left leg data, seem to be compatible.

During all the tests, except for NLTM RL, some steps were taken in which the CoM was travelling towards the stance leg in the frontal plane at the instant of touchdown of the stepping leg. These steps are shown as points in Figure 2 for which $\dot{x}_{\mathrm{CoM}}^{\mathrm{abs}}$ is negative for the right leg or positive for the left leg. No excursion of the foot to the contralateral (i.e. abnormal) side of the CoM can be directly observed from the data in Figure 2. This would be evident if u^* was negative for the right leg or positive for the left leg. However, since the ankle markers were not aligned with the CoP, it is possible that this situation occurred for some steps, when the magnitude of u^* (on the vertical axes) was below 0.05m.

The results of fitting a linear function (i.e. simple linear regression) to the experimental data according to Eq. (2), based on the absolute and relative lateral velocity of the CoM, $\dot{x}_{\mathrm{CoM}}$, are given in Table 1. Note ρ_2 takes positive and negative values depending on the stepping leg. Goodness of fit statistics are quantified in terms of the root mean square (RMS) error, denoted as standard error in Table 1, and degrees-of-freedom adjusted R-square, denoted as adjusted R-square in Table 1.

Table 1: Results of fitting a linear function to experimental data.

A simple linear regression based on the absolute velocity of the CoM, $\dot{x}_{\mathrm{CoM}}^{\mathrm{abs}}$, provides overall better fit to the data than using the relative velocity of the CoM, $\dot{x}_{\mathrm{CoM}}^{\mathrm{rel}}$. The mean adjusted R-square obtained using $\dot{x}_{\mathrm{CoM}}^{\mathrm{abs}}$ is 0.71 for LTM. In comparison, the mean adjusted R-square

obtained using $\dot{x}_{\mathrm{CoM}}^{\mathrm{rel}}$ for LTM is only 0.36. The values of adjusted R-square obtained using $\dot{x}_{\mathrm{CoM}}^{\mathrm{abs}}$ show that a linear foot placement control law can explain 71% of pseudo step width variance for LTM. In the world of biology, and considering the data come from testing a human, this indicates a strong functional relationship between the variables. Therefore, all further discussion is based on the results obtained using $\dot{x}_{\mathrm{CoM}}^{\mathrm{abs}}$ only.

The mean gradients of the fit, ρ_1, for the right and left legs are 0.2s and 0.21s, respectively. The mean intercepts of the fit, ρ_2, for the right and left legs are 0.08m and –0.07m, respectively. The difference in sign reflects the bipedal nature of human gait. The values are consistent throughout all the tests, except RL NLTM, indicating a simple linear foot placement control law is robust against surface oscillation and modifications to the visual field.

The higher variability of data for VR tests visible in Figure 2 is reflected in the higher values of the standard error in Table 1, quantifying the dispersion of the pseudo step width around the fit. This is the case for NLTM and LTM tests. The highest variability in data is observed for VR2. The test subject was then provided the least amount of visual information which, it appears, led to greater variation of the gait.

The values of ρ_1 and ρ_2 differ from the values previously assumed in the use of the IPM [13-15], as defined in Eq. (1). The gradient of the linear foot placement control law is in this case the inverse of the pendulum angular frequency, which for the test subject employed for the test would be 0.34s. This is greater than all of the values from the experiments in Table 1. The intercept is the margin of stability, which for unperturbed walking was assumed to take a value of 0.016m [13-15]. These discrepancies were expected considering the definition of the pseudo step width, stated in Section 2, in particular the difference in the spatial and temporal reference frames used in the formulation of the IPM compared with those used in the experiments.

Overall, it is concluded that the foot placement control law of the type proposed by Hof *et al.* [14], based on lateral velocity of the CoM at heel strike, applies for walking on laterally oscillating bridges. This gives supporting evidence for the assumptions made in the IPM [13,15,19]. Further work will attempt to reconcile the discrepancies between IPM predictions and the experimental data presented in this study.

4 CONCLUSIONS

- A foot placement control law of the form proposed by Hof *et al.* [14] applies for walking on laterally oscillating structures.
- The step width depends on the absolute rather than relative lateral velocity of the centre of mass at the instant of foot placement onto the walking surface.
- The foot placement control law is robust against modifications to the visual environment as well as motion of the walking surface.
- The presented data can help in the calibration of the inverted pendulum pedestrian model for walking on laterally oscillating structures.

Keywords: Motion-based design, Human-induced vibrations, Structural control, Active tuned mass dampers, Footbridges, Uncertainty conditions

Abstract. *Two key aspect must be considered for the design of modern footbridges: (i) their sensitivity to human-induced vibrations; and (ii) the influence of the variation of the operational and environmental conditions on their modal properties. One possible option, to guarantee an adequate behavior of these structures under both conditioning factors, is the installation of a control system. Among the different systems, active damping devices have shown a great effectiveness when they are used to control the dynamic response of civil engineering structures under uncertainty conditions. Different design algorithms have been proposed to guarantee that structures, controlled by these damping devices, meet the design requirements without compromising the budget. Among these proposals, the motion-based design method has shown a high performance when it has been implemented to design passive damping devices for footbridges under uncertainty conditions. Herein, this design method has been adapted and further implemented for the robust optimum design of active tuned mass dampers when they are employed to control the human-induced vibrations in slender footbridges. According to this method, the design problem can be transformed into two coupled sub-problems: (i) a multi-objective optimization sub-problem; and (ii) a reliability analysis sub-problem. Thus, the main objective is to find the parameters of the active damping device which guarantee an adequate comfort level without compromising its cost. The compliance of this vibration serviceability limit state is computed via a reliability index (related to the probability of failure), which takes into account the effect of the variation of the operational and environmental conditions on the modal properties of the structure.*

1 INTRODUCTION

Modern footbridges have experienced an increase in their slenderness due to both the improvement of the strength of the construction materials and the aesthetic requirements of the current societies [1]. Accordingly, this higher slenderness has enhanced the sensitivity of these structures to two phenomena: (i) the human-structure interaction [2]; and (ii) the variability of their modal properties due to the modification of the operational and environmental conditions [3].

In order to overcome these limitations, external damping devices have been widely installed on these structures to guarantee their robust structural behavior during their overall life cycle [4]. Among these damping devices, active control systems have shown a high effectiveness when they have been used to control the dynamic response of civil engineering structures under stochastic conditions [5]. Different algorithms and control laws have been proposed to perform successfully the design process of these damping devices [6]. Among the different approaches, the motion-based design method [7] under a stochastic approach is presented and further implemented herein to design active tuned mass dampers (ATMD) when they are used to control the human-induced vibrations in slender footbridges under uncertainty conditions. Thus, the main contribution of this study is to adapt the abovementioned method, which has been previously implemented for the design of passive tuned mass dampers [8], for the design of ATMDs.

According to this method, the design problem may be transformed into two coupled sub-problems: (i) a multiple-objective optimization sub-problem [9]; and (ii) a reliability analysis sub-problem [10]. The multiple-objective function of the first sub-problem is defined in terms of two different elements: (i) the parameters of the ATMD, which are needed to be determined; and (ii) the design requirements of the structure which are needed to be met [2]. As the main objective of this design process is to control the human-induced vibrations in footbridges, the design requirements may be defined in terms of the comfort level of the structure. Thus, these design requirements are met if the maximum acceleration of the structure is lower than an allowable acceleration established by the designer [2]. Additionally, the aforementioned design requirements have been re-formulated based on a probabilistic approach due to the sensitivity of the modal properties of the structure to the variation of the operational and environmental conditions [11]. According to this approach, the design requirements are met if a reliability index, β, which reflects the probability of compliance of the mentioned vibration serviceability limit state (VSLS), is greater than an allowable reliability index, β_{lim} [10]. Sampling techniques are usually considered to compute this reliability index [10]. Herein a conventional Monte Carlo simulation has been considered [10]. Finally, the performance of the proposed algorithm has been validated via the analysis of a numerical case-study [2]. Concretely, the VSLS of a steel footbridge under uncertainty conditions has been met via the installation of an ATMD designed according to the proposed algorithm.

The paper is organized as follows. In section 2, the mathematical model of the ATMD-footbridge interaction system is formulated and its dynamic response under pedestrian action is computed numerically in time domain. Subsequently, in section 3, the motion-based design method under a stochastic approach is described in detail. Later, in section 4, a numerical case-study is presented to assess the performance of the proposed method when it is implemented for the design of an ATMD used to control the dynamic response of a steel footbridge under pedestrian action. Finally, some concluding remarks are included in section 5 to finish the paper.

2 ACTIVE TUNED MASS DAMPER-FOOTBRIDGE INTERACTION MODEL UNDER PEDESTRIAN LOAD

In order to design an active damping device, according to the mentioned proposal, the dynamic response of an ATMD-footbridge interaction system under pedestrian action must be computed numerically. Thus, four steps must be given: (i) the formulation of the ATMD-footbridge interaction model; (ii) the definition of the pedestrian load; (iii) the selection of the control law which defines the driving force; and (iv) the numerical integration of the equations of motion which governs the ATMD-footbridge interaction model.

For the formulation of the ATMD-footbridge interaction model, the following assumptions have been considered herein: (i) the dynamic response of the structure may be approached (modal coordinates) by a single vibration mode [6], since it is assumed that only a vibration mode is prone to suffer from human-induced vibrations; (ii) the ATMD is modelled via a single degree of freedom system (physical coordinates) [5]; (iii) the pedestrian load is simulated by an equivalent harmonic load [2]; and (iv) the ATMD is located at the point with the maximum modal displacement. Figure 1 shows a scheme of the ATMD-footbridge interaction model.

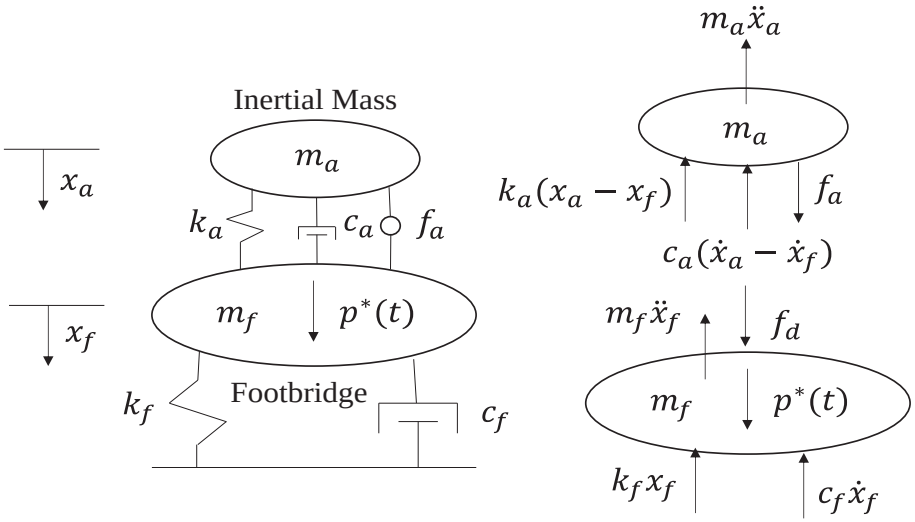

Figure 1: The ATMD-footbridge interaction model.

Thus, the equations of motion of the ATMD-footbridge interaction model can be obtained via the implementation of the second Newton's law to the two masses (ATMD and equivalent modal mass). These equations may be expressed as follows:

$$m_f\ddot{x}_f(t) + c_f\dot{x}_f(t) + k_f x_f(t) = p^*(t) + f_d(t) \quad (1)$$

$$m_a\ddot{x}_a(t) + c_a\left(\dot{x}_a(t) - \dot{x}_f(t)\right) + k_a\left(x_a(t) - x_f(t)\right) = f_a(t) \quad (2)$$

$$f_d(t) = c_a\left(\dot{x}_a(t) - \dot{x}_f(t)\right) + k_a + k_a\left(x_a(t) - x_f(t)\right) - f_a(t) = -m_a\ddot{x}_a(t) \quad (3)$$

where m_f [kg], c_f [sN/m] and k_f [N/m] are respectively the mass, damping and stiffness of the considered vibration mode of the footbridge; $p^*(t) = \phi^T p(t)$ [N] is the projection of the pedestrian load on the considered vibration (being $p(t)$ the pedestrian load [N], ϕ the considered vibration mode and ^{T} the transpose function); $\ddot{x}_f(t)$ [m/s^2], $\dot{x}_f(t)$ [m/s] and $x_f(t)$ [m] are respectively the acceleration, velocity and displacement of the footbridge; m_a [kg], c_a [sN/m] and k_a [N/m] are respectively the mass, damping and stiffness of the ATMD; $\ddot{x}_a(t)$

[m/s^2], $\dot{x}_a(t)$ [m/s] and $x_a(t)$ [m] are respectively the acceleration, velocity and displacement of the ATMD; $f_a(t)$ [N] is the driving force generated by the actuator of the ATMD; and $f_d(t)$ [N] is the control force generated by the ATMD.

These equations can be re-organized in matrix form as follows:

$$\begin{bmatrix} m_f & 0 \\ 0 & m_a \end{bmatrix} \begin{Bmatrix} \ddot{x}_f(t) \\ \ddot{x}_a(t) \end{Bmatrix} + \begin{bmatrix} c_f + c_a & -c_a \\ -c_a & c_a \end{bmatrix} \begin{Bmatrix} \dot{x}_f(t) \\ \dot{x}_a(t) \end{Bmatrix} + \begin{bmatrix} k_f + k_a & -k_a \\ -k_a & k_a \end{bmatrix} \begin{Bmatrix} x_f(t) \\ x_a(t) \end{Bmatrix} = \begin{Bmatrix} 1 \\ 0 \end{Bmatrix} p^*(t) + \begin{Bmatrix} -1 \\ 1 \end{Bmatrix} f_a(t) \quad (4)$$

$$[M]\{\ddot{x}(t)\} + [C]\{\dot{x}(t)\} + [K]\{x(t)\} = \{B_0\}p^*(t) + \{B_c\}f_a(t) \quad (5)$$

where $[M] = \begin{bmatrix} m_f & 0 \\ 0 & m_a \end{bmatrix}$ is the mass matrix; $[C] = \begin{bmatrix} c_f + c_a & -c_a \\ -c_a & c_a \end{bmatrix}$ is the damping matrix; $[K] = \begin{bmatrix} k_f + k_a & -k_a \\ -k_a & k_a \end{bmatrix}$ is the stiffness matrix; $\{B_0\}$ is the input vector associated with the pedestrian load; $\{B_c\}$ is the input vector associated with the driving force; $\{\ddot{x}(t)\}$ is the acceleration vector; $\{\dot{x}(t)\}$ is the velocity vector and $\{x(t)\}$ is the displacement vector.

In order to integrate this equation system and make easier the determination of the driving force, $f_a(t)$, the abovementioned equation system must be transformed into a state space formulation [6]. According to this formulation, the dynamic behavior of a linear invariant system may be expressed by the following differential equation system with initial conditions ($\{z(0)\} = z_0$):

$$\{\dot{z}(t)\} = [A]\{z(t)\} + [B]\{p^*(t)\} + [B]\{f_a(t)\} \quad (6)$$

$$\{y(t)\} = [E]\{z(t)\} + [D]\{f_a(t)\} \quad (7)$$

where $\{z(t)\}$ is the state vector; $\{y(t)\}$ is the output vector; $[A]$ is the system matrix; $[B]$ is the input matrix; $[E]$ is the output matrix; and $[D]$ is the feedthrough matrix [6]. It is possible via matrix transformations to convert the abovementioned equation system into its state space formulation [6]. The state space matrices can be defined as:

$$[A] = \begin{bmatrix} 0 & I \\ -[M]^{-1}[K] & -[M]^{-1}[C] \end{bmatrix} \quad (8)$$

$$[B] = \begin{bmatrix} 0 \\ -[M]^{-1}\{B_i\} \end{bmatrix} \text{ where } \{B_i\} = \begin{cases} \{B_0\} & \text{for } p^*(t) \\ \{B_c\} & \text{for } f_a(t) \end{cases} \quad (9)$$

$$[E] = -[E_a][[M]^{-1}[K] \quad [M]^{-1}[C]] \quad (10)$$

$$[D] = [E_a][M]^{-1}[B] \quad (11)$$

where the state vector $\{z(t)\} = \{x_f(t) \quad x_a(t) \quad \dot{x}_f(t) \quad \dot{x}_a(t)\}$ is defined in terms of the displacements and velocities of both the footbridge and the ATMD; and the output vector, $\{y(t)\}$, is defined in terms of the accelerations experienced by the footbridge (being $[E_a]$ the acceleration matrix which indicates the elements in which the acceleration is computed).

In order to obtain the response of this state space equation system both the pedestrian force, $p(t)$, and the driving force, $f_a(t)$, which simulates the behavior of the actuator of the ATMD, must be defined.

The pedestrian force, $p(t)$, has been simulated based on the recommendations of the French guidelines [2]. Only the vertical contribution of the walking pedestrian action has been considered herein. According to these guidelines, the walking pedestrian action, $p(t)$, can be determined via an equivalent harmonic force defined as follows:

$$p(t) = 280 \cdot \cos(2\pi \cdot f_f \cdot t) \cdot n_{eq} \cdot \psi \tag{12}$$

where f_f [Hz] is the natural frequency of the considered vibration mode of the structure; n_{eq} [-] is the equivalent number of pedestrians; and ψ is a reduction factor which takes into account the probability that the natural frequency is within the range which characterizes the human-structure interaction in vertical direction ($1.25 \leq f_f \leq 2.3$ Hz) [2].

The driving force, $f_a(t)$, is determined via the implementation of a feedback controller to the above mentioned system in the state space [6]. Figure 2 shows the general layout of the feedback controller considered.

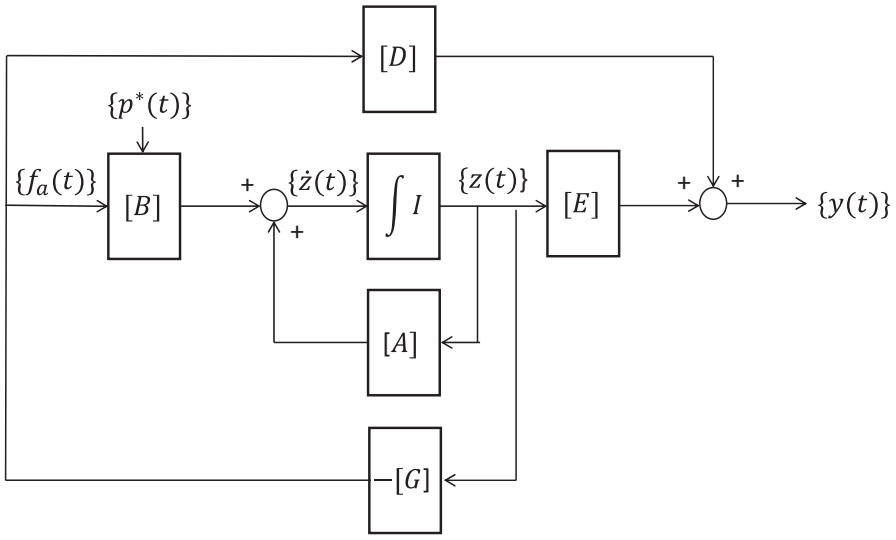

Figure 2: Design of a feedback controller in a state space formulation [6].

The implementation of this feedback controller allows modifying the system equation as follows:

$$\{\dot{z}(t)\} = [A]\{z(t)\} + [B_0]\{p^*(t)\} + [B_c]\{f_a(t)\}] \tag{13}$$

where $[B_0]$ and $[B_c]$ are obtained from equation (9) considering as pattern load vectors $\{B_0\}$ and $\{B_c\}$respectively.

Thus, according to the feedback controller (Figure 2), the driving force, $f_a(t)$, may be determined in terms of a gain matrix, $-[G]$, and the state vector, $\{z(t)\}$. Thus, the system equation may be expressed as:

$$\{\dot{z}(t)\} = [A]\{z(t)\} + [B_0]\{p^*(t)\} - [B_c][G]\{z(t)\} \tag{14}$$

$$\{\dot{z}(t)\} = ([A] - [B_c][G])\{z(t)\} + [B_0]\{p^*(t)\} \tag{15}$$

There are several algorithms [6] to determine the value of the gain matrix, $-[G]$. Among these algorithms, the linear quadratic regular (LQR) method [6] has been considered herein due to its extensive use for practical engineering applications [5]. According to this method, the

value of the gain matrix, $-[G]$, is obtained via the minimization of the following performance-index function, J:

$$J = \int_0^\infty \left[\{z(t)\}^T[Q]\{z(t)\} + \left\{[G]\{z(t)\}\right\}^T[R]\left\{[G]\{z(t)\}\right\}\right]dt \tag{16}$$

where $[Q]$ and $[R]$are two weighting matrices which may be computed in terms of the mass, $[M]$, and stiffness, $[K]$, matrices of the interaction model [6]. According to the recommendations of several authors [6], the weighting matrices may be determined as follows:

$$[Q] = \alpha_d \begin{bmatrix} [K] & 0 \\ 0 & [M] \end{bmatrix} \tag{17}$$

$$[R] = \beta_d [I] \tag{18}$$

where α_d [-] and β_d [-] are the weighting factors; and $[I]$ is the identity matrix. In this manner, once the value of these factors has been fixed, the value of the different element of the gain matrix, $-[G]$, which minimizes the value of the performance-index function, J, is obtained.

Subsequently, the response of the ATMD-footbridge interaction model has been obtained via the integration of the abovementioned state space system using a Runge-Kutta method, as it is implemented in the Matlab software [12].

Therefore, an adequate value of the driving force, $f_a(t)$, is obtained via the adjustment of the value of the weighting factors, α_d and β_d. For this purpose, the following iterative process must be addressed: (i) to develop a linear model of the ATMD-footbridge interaction model in the state space domain (where the value of the mass and stiffness of the ATMD are fixed); (ii) to adjust the value of the weighting matrices, $[Q]$ and $[R]$ in terms of an original value of the weighting factors, α_d and β_d; (iii) to determine an optimum value of the driving force, $f_a(t)$, via the minimization of the performance-index function, J; (iv) to simulate numerically the response of the linear system; and (v) to modify the values of the weighting factors, α_d and β_d, and repeat the steps (ii) to (iv) until the dynamic response of the footbridge meets the design requirements established by the designer [2].

3 MOTION-BASED DESIGN UNDER UNCERTAINTY CONDITIONS

The aforementioned control algorithm has been hybridized with the motion-based design method under uncertain conditions [8] to improve the performance of the design process of active damping devices. The performance-based design method [13] transforms the design problem into two coupled sub-problems: (i) a multi-objective optimization sub-problem; and (ii) a reliability analysis sub-problem. Thus, the main objective of this design problem is to determine the parameters of the ATMD that, minimizing its cost, ensures the compliance of the design requirements [2]. As the design requirements, which need to be accomplished, are defined in terms of the accelerations of the structure, $\ddot{x}_f(t)$, this design process may be understood as a motion-based design optimization method [7].

Therefore, the general formulation of the proposed method may be expressed as follows [13]:

$$\begin{gathered} \text{Find } \theta_i \; i = 1,..,n_d \\ \text{Minimizing } \mathbf{f}(\theta_i) = [f_1(\theta_i) \quad ... \quad f_j(\theta_i) \quad ... \quad f_{n_f}(\theta_i)] \\ \text{Subjected to } \theta_i^l \le \theta_i \le \theta_i^u \end{gathered} \tag{19}$$

where $\mathbf{f}(\theta_i)$ is the multi-objective function; $f_j(\theta_i)$ is the j^{th} terms of the multi-objective function; n_f is the number of terms of multi-objective function; θ_i is the i^{th} design variable; θ_i^l is the lower bound of the ith design variable; θ_i^u is the upper bound of the ith design variables, and n_d is the total number of design variables.

For this case, the design of an ATMD, the above multi-objective function may be formulated in terms of two aspects: (i) the different parameters of the ATMD; and (ii) the compliance of the VSLS of the footbridge. According to the most advances guidelines [2], the VSLS is met if the maximum acceleration of the structure, $\ddot{x}_f(t)$, is lower than an allowable value, $\ddot{x}_{lim}$, established by the designer [2].

Additionally, in order to take into account the random character of the modal properties of the footbridge, which are sensitive to the variation of the operational and environmental conditions [3], the VSLS is re-formulated via a probabilistic approach [10]. According to this approach, the modal properties of the footbridge are assumed to be random variables which follow a normal probability distribution function. Hence, the response of the system is also a random variable, and it is possible to determine the probability of failure associated with the compliance of the different design requirements (in this case, the VSLS). According to this, the VSLS is defined in terms of a reliability index, β, which reflects the probability of failure associated with the compliance of this limit state. Thus, the limit state is met if this reliability index, β, is greater than an allowable value, β_{lim}, established by the design guidelines [14]. In order to compute the reliability index, β, analytical and numerical method can be used [11]. Among these methods, a Monte Carlo simulation has been considered herein [10].

In order to establish the formulation of this design problem, based on the motion-based design, the design parameters must be determined. For this particular case, five are the design variables: (i) the mass ratio of the ATMD, $\mu = m_a/m_f$ [-]; (ii) the frequency ratio of the ATMD, $\delta = f_d/f_f$ [-] (where f_d [Hz] is the natural frequency of the ATMD); (iii) the damping ratio of the ATMD, ζ_a; and (iv) the weighting factors, α_d and β_d (which characterize the driving force, $f_a(t)$). In order to reduce the number of design variables, simplifying the problem, a hybrid strategy has been considered herein [2]. Thus, both the frequency, δ, and damping, ζ_a, ratios of the ATMD have been established according to a conventional criterion for the design of passive tuned mass dampers [2]. According to this, the frequency ratio of the ATMD is set as, $\delta = 1/(1+\mu)$; and the damping ratio of the ATMD is set as, $\zeta_a = \sqrt{3\mu/(8(1+\mu))}$.

In this manner, the formulation of the motion-based design method under uncertainty conditions for this particular problem can be formulated as follows:

$$\begin{aligned} &\text{Find } \mu,\ \alpha_d,\ \beta_d \\ &\text{Minimizing } \{\mathbf{f}(\mu,\alpha_d,\beta_d)\} = \{f_1(\mu) \quad f_2(\mu,\alpha_d,\beta_d)\} = \{\mu \quad \tfrac{\beta_{lim}}{\beta}\} \\ &\text{Subjected to } \mu \in [0.01\ 0.10]\ \alpha_d \in [10\ 1000]\ \beta_d \in [10^{-5}\ 10^{-8}] \end{aligned} \tag{20}$$

Subsequently, in order to solve this optimization problem, global optimization algorithms are normally employed due to their good efficiency to find optimum solutions in nonlinear optimization problems [13]. Among these computational algorithms, a nature-inspired computational algorithm, genetic algorithms, has been considered herein [9]. As result of this optimization process, a set of non-dominated solutions is obtained [9]. This set of solutions may be represented in a functional space, generating the so-called Pareto front [9]. Finally, a subsequent decision-making problem must be addressed, the selection of the best solution among the dif-

ferent elements of the Pareto front. Therefore, an additional condition, β_{lim}/β, has been included herein to select the best element of the Pareto front. Figure 3 illustrates the additional condition considered to solve the decision-making problem.

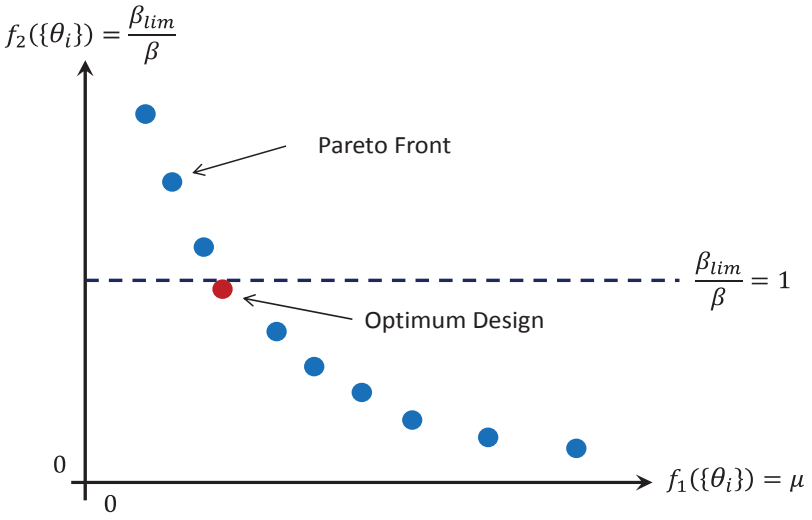

Figure 3: Additional condition considered to solve the decision-making problem.

4 APPLICATION EXAMPLE: MOTION-BASED DESIGN OF AN ATMD FOR A VIBRATING FOOTBRIDGE UNDER UNCERTAINTY CONDITIONS

In order to illustrate the performance of the motion-based design method, when it is implemented to design ATMDs for vibrating footbridges under uncertainty conditions, the following numerical case-study is presented. Thus, the compliance of the VSLS of a numerical footbridge is guaranteed via the installation of an ATMD. A detailed description of this numerical footbridge can be found in the French guidelines [2]. The structural behavior of the structure has been simulated via the finite element (FE) method. The FE package Ansys [15] has been used for this purpose. A numerical model using 646 beam elements and 540 shell elements (BEAM188 and SHELL181 respectively) has been built (Figure 4). A structural damping ratio of $\zeta_f = 0.6$ % has been considered [2]. The numerical modal parameters of the footbridge have been obtained via a numerical modal analysis. As result of this analysis, it was checked that the first vertical vibration mode ($f_f = 2.14$ Hz) is prone to vibrate under pedestrian action (Figure 4). The modal mass, m_f, of this vertical vibration mode is about 34706 kg.

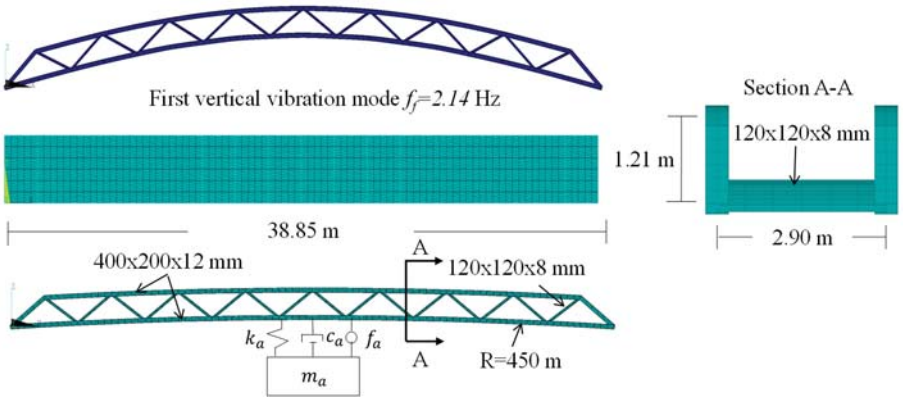

Figure 4: FE model of the benchmark footbridge and first vertical vibration mode.

In order to check the VSLS of this footbridge, the recommendations of the French guidelines [2] have been considered herein. Thus, one design scenario has been taken into account with the following design parameters: (i) a pedestrian traffic of 1 P/m^2 [2]; (ii) an allowable vertical acceleration, $\ddot{x}_{lim}$, of 1.00 m/s^2 [2]; and (iii) an allowable reliability index, β_{lim}, of 1.5 [14]. If this requirement is not met, an ATMD must be installed to reduce the amplitude of the human-induced vibrations according to the mentioned thresholds. According to the results provided by several researchers [3], a range of variation of ± 10 % has been considered for both the first vertical natural frequency of the footbridge and its associated damping ratio. Consequently, it has been checked that the VSLS term of the multi-objective function is a random variable which follows a log-normal probability distribution. In order to obtain the reliability index, β, associated with the VSLS of the footbridge, a Monte Carlo simulation has been performed [10]. For the selection of the sample size (50000 simulations), a convergence analysis has been carried out. The mathematical package Matlab [12] has been employed for this study.

As result of this study, Table 1 shows the reliability index, β, associated with the VSLS without and with the ATMD. As Table 1 shows, the motion-based design method allows control the dynamic response of the footbridge under uncertainty conditions without compromising the cost of the control system. Additionally, the parameters of the ATMD designed according to this method have been included in Table 1.

ATMD	$\ddot{x}_f$ [m/s^2]	β [-]	α_d [-]	β_d x 10^{-8} [-]	m_a [kg]	c_a [sN/m]	k_a x 10^5 [N/m]	f_a [N]
No	---	-0.53	---	---	---	---	---	---
Yes	1.00	1.50	511.30	344.19	625	1343	1.09	286

Table 1: Reliability index, β, of the VSLS of the footbridge (without and with ATMD)..

5 CONCLUSIONS

In this manuscript, the motion-based design method has been presented and further implemented for the design of ATMDs when they are used to mitigate the human-induced vibrations in footbridges under uncertainty conditions. According to this method, the design problem may be formulated via two coupled sub-problems: (i) a multi-objective optimization sub-problem; and (ii) a reliability analysis sub-problem. Thus, the multi-objective function is defined in terms of two aspects: (i) the parameters of the ATMD which are needed to be determined; and (ii) a reliability index, which establishes the probability of compliance of the VSLS of the structure. Sampling techniques, as the Monte Carlos simulation method, can be employed to estimate numerically this reliability index. As application example, a steel footbridge, which is prone to vibrate due to walking pedestrian action, has been selected. In order to mitigate the pedestrian-induced vibrations, an ATMD has been installed at its mid-span. The ATMD parameters have been obtained via the implementation of the aforementioned method. As result of this study, the performance of the proposed method has been shown up. In spite of its good performance, further studies are needed, both to better characterize the probabilistic distribution function of the different modal properties of the structure; and to assess experimentally the performance of structures controlled by active damping devices designed according to this proposal.

Abstract. *Current load models describing the effect of crowd-induced loading require further development and validation. To this end, detailed full-scale operational loading data is required. The Eeklo Footbridge Benchmark Dataset considers loading scenarios up to 0.50 pers./m^2 (148 pers.). The data set comprises a digital twin of the structure and the simultaneous registration of the trajectories of the pedestrians using a camera setup, the body acceleration using low-cost accelerometers attached to the lower back and the structural acceleration using a sensor network. The low-cost accelerometers are subject to higher measurement noise than conventional techniques. The goal is to verify to what extent the low-cost sensors can be used for the contact force reconstruction in vibrating-surface conditions and, more importantly, the quantification of human-structure interaction effects in case of the Eeklo Benchmark Dataset.*

First, a data set is collected comprising the simultaneous registration of contact forces and lower-back accelerations in rigid-surface conditions. The latter are obtained using the low-cost sensors. The measurement noise characteristics of the low-cost sensors are determined. It is found that the signal-to-noise ratio of the human body acceleration at the lower back during walking in rigid-surface conditions is very high. Therefore, the employed sensors are suited for force reconstruction based on the lower-back accelerations in rigid-surface conditions.

Second, the additional accelerations of the human body in case of walking on a vibrating surface are examined by a numerical example. The quantities of the example are set to be representative for the loading scenarios of the Eeklo Benchmark Dataset. The signal-to-noise ratio of the additional human body accelerations is low. As a consequence, it is inaccurate to use the total human body accelerations for the total contact force reconstruction of the participant. Instead, it is found that an inverse approach is more suited. The total human body accelerations are a good approximation of the internally-driven ones. The conclusions of this numerical example are case-specific while the presented methodology is generic and can be readily extended to virtually any other footbridge.

1 Introduction

As a result of ever increasing lighter and stronger materials, footbridge design today is often dominated by its vibrations serviceability [1]. On the other hand, the human-structure interaction (HSI) effects comprising the combined added mass and damping effect, are more prominent for footbridges for increasing ratios of the crowd mass to the structural mass [2]. Normative design codes neglect the effect of HSI [3, 4]. This is in turn a result of the absence of full-scale validation of this phenomenon [2]. Such a validation requires detailed information on the loading data during realistic walking scenarios comprising the simultaneous registration of the induced loads and the structural response [5]. The Eeklo Benchmark Dataset provides, for the first time ever, such a detailed dataset. The trajectories of each pedestrian are registered using a camera setup. The induced loads of the crowd are characterized by the registered body acceleration of each individual. Given the scale of the application, low-cost sensors are employed instead of the conventional measurement systems. Their measurement noise variance is higher compared to their more expensive alternatives.

Multiple strategies exist for the experimental validation, analysis and calibration of HSI phenomena. A first category directly analyzes the induced contact forces [6, 7, 8, 9, 10] or body locomotion [11] during walking on vibrating conditions. A second category consists of inverse techniques. In this case, the governing parameters of the HSI models are determined such that the discrepancy between the reconstructed and measured structural response is minimized [12, 13, 14].

The goal of the present study is to verify that the employed low-cost sensors are suited for the characterization of the human body motion. Furthermore, it is investigated which techniques are suited for the validation and calibration of HSI models given the specific load-structure conditions of the Eeklo Benchmark Dataset and the employed low-cost sensors.

This contribution starts with a discussion of the dynamics of the coupled crowd-structure system (Section 2). Next, the contact force reconstruction using low-cost sensors on rigid surface conditions is verified (Section 3). Furthermore, the contact force reconstruction on vibration surfaces is investigated (Section 4). The most important conclusions are summarized in Section 5.

2 Dynamics of the coupled crowd-structure system

2.1 Human body dynamics

The human body is in reality composed of a large number of body segments [15]. It is common practice to lump all the activated masses in one single activated mass m_{H1} and all the non-activated masses into a single non-activated mass m_{H0} [16, 17, 18]. Obviously, the sum equals the body weight of the pedestrian: $m_{\mathrm{ped}} = m_{\mathrm{H0}} + m_{\mathrm{H1}}$. The activated mass m_{H1} is driven by an internal driving term $G(t)$ while the connection between the non-activated mass m_{H0} and activated mass m_{H1} is modeled by an internal reaction force $\mathcal{G}(t)$ (Fig. 1-a).

Expression of the force equilibrium at the contact plane and applying Newton's second law gives:

$$F(t) = m_{\mathrm{H0}}\ddot{u}_{\mathrm{s}}(t) + m_{\mathrm{H1}}\ddot{u}_{\mathrm{H1}}(t) = (1-\mu_{\mathrm{H1}})m_{\mathrm{ped}}\ddot{u}_{\mathrm{s}}(t) + \mu_{\mathrm{H1}}m_{\mathrm{ped}}\ddot{u}_{\mathrm{H1}}(t) \tag{1}$$

where F is called the contact force and $\mu_{\mathrm{H1}} = m_{\mathrm{H1}}/m_{\mathrm{ped}}$ the ratio of the activated mass to the total mass of the pedestrian.

In case of walking on a rigid surface, the kinetics of the supporting surface are zero ($u_{\mathrm{s}} = 0$)

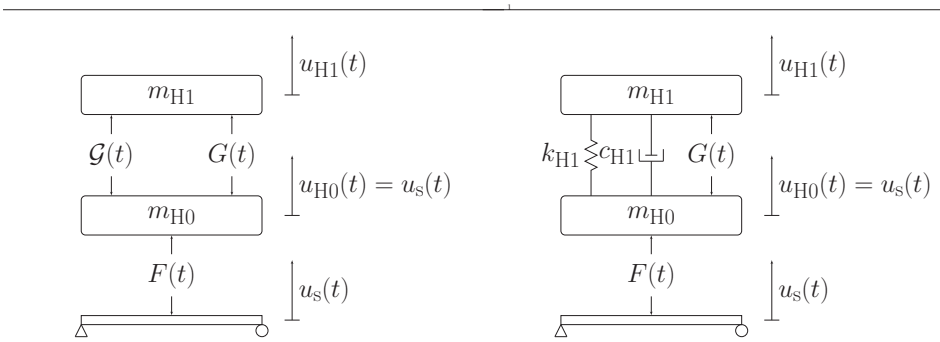

Figure 1: Schematic representation of the human body dynamics modeled by a non-activated (m_{H0}) and activated mass (m_{H1}). Connection with the supporting surface modeled (left) generically and (right) by a spring and viscous damper.

yielding the following simplifications: $G = G^{\mathrm{RS}}$, $F = F^{G} = F^{G^{\mathrm{RS}}}$ and $u_{\mathrm{H1}} = u_{\mathrm{H1}}^{G} = u_{\mathrm{H1}}^{G^{\mathrm{RS}}}$ where the subscript RS denotes that it concerns rigid-surface conditions. The subscript G^{RS} denotes that the contact force and human body kinetics are purely a result of the internally-driven force G^{RS}. The contact force in this case reads:

$$F^{G^{\mathrm{RS}}}(t) = m_{\mathrm{H1}}\ddot{u}_{\mathrm{H1}}^{G^{\mathrm{RS}}}(t) = \mu_{\mathrm{H1}} m_{\mathrm{ped}} \ddot{u}_{\mathrm{H1}}^{G^{\mathrm{RS}}}(t) \tag{2}$$

For walking on vibrating surfaces, it is obvious that $u_{\mathrm{s}} \neq 0$. In this study, it is assumed that the internal driving term G is unaltered with respect to the rigid-surface conditions: $G = G^{\mathrm{RS}}$. This corresponds to the assumption that there is no active human-structure interaction. Moreover, in case of walking on vibrating surfaces the human body kinetics do not only consist of the internally-driven kinetics $u_{\mathrm{H1}}^{G^{\mathrm{RS}}}(t)$ but an additional mechanical interaction term $u_{\mathrm{H1}}^{\mathrm{int}}(t)$, resulting from the mechanical interaction of the human body with the vibrating surface. In this study it is assumed that the superposition principle holds i.e. $u_{\mathrm{H1}}^{\mathrm{tot}}(t) = u_{\mathrm{H1}}^{G^{\mathrm{RS}}}(t) + u_{\mathrm{H1}}^{\mathrm{int}}(t)$. Combining the total human body kinetics with Eq. (1) allows to write the contact force in the following form:

$$F^{\mathrm{tot}}(t) = \underbrace{m_{\mathrm{H1}}\ddot{u}_{\mathrm{H1}}^{G^{\mathrm{RS}}}(t)}_{=F^{G^{\mathrm{RS}}}(t),\ \mathrm{Eq.\ (2)}} + \underbrace{m_{\mathrm{H0}}\ddot{u}_{\mathrm{s}}(t) + m_{\mathrm{H1}}\ddot{u}_{\mathrm{H1}}^{\mathrm{int}}(t)}_{=F^{\mathrm{int}}(t)} \tag{3}$$

and illustrates how the **total contact force** (F^{tot}) is the combination of the **internally-driven contact force** equal to the contact force on a rigid surface ($F^{G^{\mathrm{RS}}}$) and an additional **mechanical interaction contact force** (F^{int}).

2.2 Equations of motion of the coupled crowd-structure system

The structural response to the walking excitation of a crowd composed of n_{p} pedestrian is calculated using the well-known equations of motions in modal coordinates of the reduced-order finite element (FE) model:

$$\ddot{\mathbf{Z}}(t) + \mathbf{\Gamma}\dot{\mathbf{Z}}(t) + \mathbf{\Omega}^2\mathbf{Z}(t) = \mathbf{\Phi}^{\mathrm{T}}\mathbf{S}_{\mathrm{p}}(t)\mathbf{F}^{\mathrm{tot}}(t) = \mathbf{\Phi}^{\mathrm{T}}\mathbf{S}_{\mathrm{p}}(t)\left[\mathbf{F}^{G^{\mathrm{RS}}}(t) + \mathbf{F}^{\mathrm{int}}(t)\right] \tag{4}$$

where $\mathbf{Z}(t) \in \mathbb{R}^{n_{\mathrm{m}}}$ are the modal displacements of the n_{m} retained modes, $\mathbf{\Omega}^2 \in \mathbb{R}^{n_{\mathrm{m}} \times n_{\mathrm{m}}}$ a diagonal matrix containing the squared circular eigenfrequencies in increasing order, $\mathbf{\Gamma} \in \mathbb{R}^{n_{\mathrm{m}} \times n_{\mathrm{m}}}$ a diagonal matrix containing the modal damping ratios in corresponding order, $\mathbf{\Phi} \in$

$\mathbb{R}^{n_{\text{DOF}} \times n_{\text{m}}}$ the matrix containing the corresponding mode shape values at each degree of freedom (DOF) of the structure as columns, $\mathbf{S}_{\text{p}}(t) \in \mathbb{R}^{n_{\text{DOF}} \times n_{\text{p}}}$ the force-selection matrix containing the time-varying position of the n_{p} pedestrians and thus relating each position to a corresponding degree of freedom of the system, $\mathbf{F}^{\text{tot}}(t) \in \mathbb{R}^{n_{\text{p}}}$ the matrix containing the total contact force of each pedestrian which is the combination of the internally-driven contact forces $\mathbf{F}^{G^{\text{RS}}}(t) \in \mathbb{R}^{n_{\text{p}}}$ and the mechanical interaction contact forces $\mathbf{F}^{\text{int}}(t) \in \mathbb{R}^{n_{\text{p}}}$.

As the interaction contact forces depend on the surface vibrations, it is convenient to place $\mathbf{F}^{\text{int}}(t)$ at the left-hand side of Eq. (4), allowing for a closed-form solution of the structural response. To this end, it is necessary to make an assumption on how the internal reaction force $\mathcal{G}(t)$ is modeled. A popular approach is to model the connection of the activated mass m_{H1} with the supporting surface by a linear spring and linear viscous damper (Fig. 1-b) [19, 20, 8, 10, 17]. The internal reaction force reads: $\mathcal{G}(t) = c_{\text{H1}}[\dot{u}_{\text{s}}(t) - \dot{u}_{\text{H1}}(t)] + k_{\text{H1}}[u_{\text{s}}(t) - u_{\text{H1}}(t)]$ where k_{H1} and c_{H1} respectively denote the spring and damping coefficient. The operator is linear this case. The spring-mass-damper is often characterized in terms of its natural frequency f_{H1} and damping ratio ξ_{H1} [2]. Eq. (4) is rewritten to:

$$\mathbf{M}_{\text{HB}}(t) \begin{bmatrix} \ddot{\mathbf{Z}}(t) \\ \ddot{\mathbf{U}}^{\text{int}}_{\text{H1}}(t) \end{bmatrix} + \mathbf{C}_{\text{HB}}(t) \begin{bmatrix} \dot{\mathbf{Z}}(t) \\ \dot{\mathbf{U}}^{\text{int}}_{\text{H1}}(t) \end{bmatrix} + \mathbf{K}_{\text{HB}}(t) \begin{bmatrix} \mathbf{Z}(t) \\ \mathbf{U}^{\text{int}}_{\text{H1}}(t) \end{bmatrix} = \begin{bmatrix} \mathbf{\Phi}^{\text{T}} \mathbf{S}_{\text{p}}(t) \mathbf{F}^{G^{\text{RS}}}(t) \\ \mathbf{0} \end{bmatrix} \tag{5}$$

where $\mathbf{M}_{\text{HB}}(t)$, $\mathbf{C}_{\text{HB}}(t)$ and $\mathbf{K}_{\text{HB}}(t)$ are the system matrices of the coupled crowd-structure system. Their derivation and definition is given in [2]. For a certain loading scenario ($\mathbf{S}_{\text{p}}(t)$ and $\mathbf{F}^{G^{\text{RS}}}(t)$) Eq. (5) is solved for the response of the coupled crowd-structure system ($\left[\mathbf{Z}(t)\ \mathbf{U}^{\text{int}}_{\text{H1}}(t)\right]^{\text{T}}$) using a discrete-time state space approach [2].

3 Experimental study of the contact force reconstruction on rigid surfaces

3.1 Measurement protocol and experimental results

Fifteen healthy Belgian adults (age: 21-51 years, weight: 54-85 kg, height: 1.66-1.90 m, females: 2, males: 13) participated in the experimental program in the Movement and posture Analysis Laboratory Leuven (MALL) at the Department of Kinesiology of KU Leuven [21]. The participants provided informed consent in accordance with the ethical guidelines for research involving human participants at the University of KU Leuven.

An instrumented treadmill with two separate belts (Forcelink) is used to register the tri-axial contact forces with a sampling rate of 1 kHz. Three different speeds per pedestrian are considered (between 4 km/h and 6 km/h). The walking speeds were randomized to avoid a bias due to fatigue or psychological adaptation of the walking gait. Each test duration is approximately 2 minutes. The first 15 seconds are removed in the further analysis as this is considered to be the time to adapt to the walking speed of the treadmill. The test results of pedestrian 7, trial 1 and pedestrian 12, trial 1 are discarded in the further analysis due to the presence of severe measurement errors.

Besides the contact force, the human body acceleration is registered near the 5$^{\text{th}}$ lumbar vertebrae using a low-cost tri-axial USB accelerometer of the type GCDC X-16D (range $\pm 16\ g$, LSB 4.8828 $10^{-4} g$ [22]) with a sampling rate of 200 Hz. This sensor is identical to the one used in the Eeklo Benchmark Dataset.

The force plate data is decimated to 200 Hz. To mitigate the effect of measurement noise, all signals are low-pass filtered using a 4$^{\text{th}}$ order Butterworth filter with a cutoff frequency of

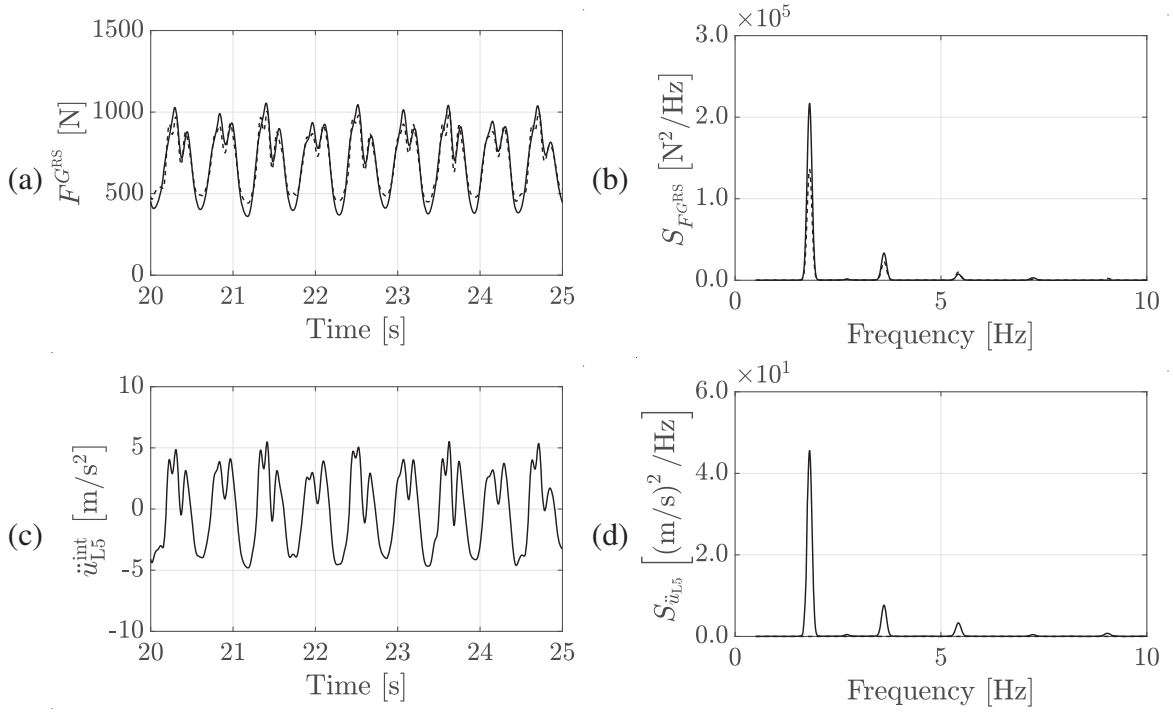

Figure 2: The reference pedestrian during the instrumented treadmill laboratory measurements. Internally-driven contact force: measured (solid) versus reconstructed (dashed): (a) time series and (b) PSD. Measured internally-driven human body acceleration: (c) time series and (d) PSD with indication of the measurement noise of the low-cost sensors (dashed line).

12 Hz. As such, the relevant frequency content (0 Hz-10 Hz) for the vibration serviceability assessment of footbridges (scope of application) is retained [23]. The force plate data and low-cost accelerometer data are synchronized offline using a common trigger event.

To characterize the measurement noise of the low-cost sensors, long-term duration measurements ($>$ 20 hours) are performed on a rigid surface. It is found that the measurement noise can be characterized as bandpass-limited white Gaussian noise comprised between 0 Hz and 70 Hz with a 95% percentile value of the variance of 0.0124 $(\mathrm{m/s^2})^2$.

A typical time series and amplitude spectrum of the reference pedestrian (pedestrian 2 during trial 2) is shown in Fig. 2. The signal-to-noise ratio in the frequency range 0.5 Hz-10 Hz is very high $3286 \approx 35.17$ dB and therefore it is concluded that the low-cost sensors are sufficiently accurate compared to the conventional measurement methods.

3.2 Relating the lower-back acceleration and the contact force

The internally-driven contact force is reconstructed using Eq. (2): $\tilde{F}^{G^{\mathrm{RS}}}(t) = m_{\mathrm{H1}} \ddot{u}_{\mathrm{H1}}^{G^{\mathrm{RS}}}(t)$. The tilde denotes that it concerns a reconstructed quantity. The vertical acceleration measured at the lower back is assumed to be a good approximation of the acceleration of the activated human body mass [24]. Moreover, in [24] it is found that the fraction of the activated body mass compared to the total body mass is $\mu_{\mathrm{H1}} = 0.76$ which is adopted in the present work. An example of the reconstructed internally-driven contact force is shown in Fig. 2. The reconstruction inevitably yields some reconstruction error. This is a combined result of the modeling assumption of the human body dynamics (Section 2.1) and the fact that the measured acceleration at the lower back does not perfectly coincide with the acceleration of the actived human

body mass. The latter stems from the measurement error of the sensors, but also the soft tissue artifacts [25]. Moreover, the factor μ_{H1} is subject to inter-person variability and depends on the walking speed [24].

4 Contact force reconstruction on vibrating surfaces

4.1 Framework of the numerical-experimental example

The contact force reconstruction procedure on vibrating surfaces is illustrated by a numerical example. The quantities of the example are chosen such that a representative scenario of the Eeklo Benchmark Dataset is obtained.

The modal parameters of the Eeklo footbridge of the corresponding benchmark dataset are considered and stored in $\mathbf{\Phi}$, $\mathbf{\Omega}^2$, $\mathbf{\Gamma}$. The structure consists of 14 modes below 12 Hz and are calculated with a detailed FE model which is calibrated using experimental operational modal analysis data [26]. The digital twin describing the dynamic behavior of the footbridge, is part of the open access benchmark dataset (See accompanying paper: 'An open access benchmark dataset on pedestrian-induced vibrations collected on the Eeklo footbridge'). A flow $\mathbf{S}_{\text{p}}(t)$ consisting of 148 persons (≈ 0.50 pers./m^2) is considered where the trajectories of the participants correspond to those as registered in the Eeklo Benchmark Dataset (total duration of 20 minutes). The HSI is modeled by a moving spring-mass-damper at each location of the pedestrian occupying the bridge (see also Fig. 1-b). The values are adopted from [17]: $f_{\text{H1}} = 3.25$ Hz and $\xi_{\text{H1}} = 0.30$.

The crowd-induced loading and related of response of the numerical study is established by the following steps:

1. The internally-driven contact forces $\mathbf{F}^{G^{\text{RS}}}(t)$ are selected from the registered trials during the laboratory measurements on rigid surfaces (Section 3.1). As the total test duration is longer than the typical trial duration, the contact force and lower-back acceleration vector are repeated. As trials are selected multiple times, they are assigned a random uniformly-distributed time shift (outer values $\pm$ the average step duration) to avoid an artificial correlation between the pedestrians in the crowd.

2. The corresponding part of the lower-back acceleration as registered during the laboratory experiments is selected and stored in the matrix $\ddot{\mathbf{U}}_{\text{H1}}^{G^{\text{RS}}}(t)$. This quantity is later used for the contact force reconstruction (Section 4.2) and to determine the total human body accelerations (step 5).

3. The reference response is calculated by plugging in the internally-driven contact forces $\mathbf{F}^{G^{\text{RS}}}(t)$ in Eq. (5). The equation is solved for the modal accelerations $\ddot{\mathbf{Z}}(t)$ and the interaction human body accelerations $\ddot{\mathbf{U}}_{\text{H1}}^{\text{int}}(t)$.

4. The modal accelerations $\ddot{\mathbf{Z}}(t)$ are used to calculate the vertical acceleration at the middle of the central span $\ddot{u}_{\text{midspan}}(t)$ (Fig. 3). This structural acceleration quantity is hereafter referred to as the reference response.

5. The interaction human body accelerations are assumed to correspond to the additional kinetics that a pedestrian registers in case of walking on a vibrating surface as a result of the HSI. The total acceleration registered at the lower back is: $\ddot{\mathbf{U}}_{\text{H1}}^{\text{tot}}(t) = \ddot{\mathbf{U}}_{\text{H1}}^{G^{\text{RS}}}(t) + \ddot{\mathbf{U}}_{\text{H1}}^{\text{int}}(t)$. This quantity is later used for the contact force reconstruction (Section 4.2).

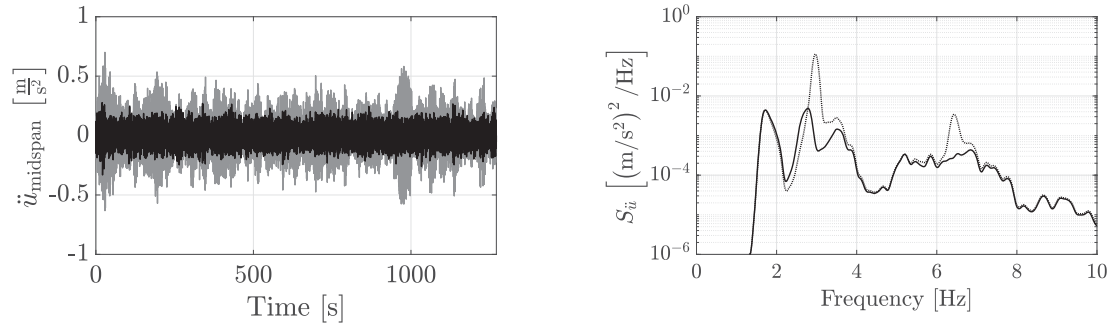

Figure 3: Structural accelerations at midspan of the reference response with (black) and without (gray) consideration of HSI: time series (left) and PSD (right).

An example of the interaction contact force and interaction human-body acceleration (Fig. 4) illustrates that the interaction components are very small compared to their internally-driven counterparts (Fig. 2). The reference structural response is additionally calculated without considering HSI (Fig. 3). The comparison shows that the structural response is highly sensitive to the presence of HSI, despite the low amplitudes of the interaction contact forces and related interaction human body accelerations. This can be explained by the fact that a part of the frequency content of the interaction contact forces is near-resonant with modes 2 ($f_2 = 2.97$ Hz) and mode 5 ($f_5 = 5.68$ Hz) which are characterized by a low modal mass (See also accompanying paper: 'An open access benchmark dataset on pedestrian-induced vibrations collected on the Eeklo footbridge').

Compared to the measurement noise of the low-cost sensors (frequency band 0.5 Hz-10 Hz), a signal-to-noise ratio of the mechanical interaction human body accelerations of $1.58 \approx 1.99$ dB is found, which is very low.

The difference in PSD of the structural response with and without the incorporation of HSI is expressed in terms of the relative difference in power spectra density (PSD). The considered frequency range is 0.5 Hz to 10 Hz. The relative difference in PSD of a time series $\ddot{u}_{\text{B}}(t)$ relative to a the PSD of a time series $\ddot{u}_{\text{A}}(t)$ is defined as:

$$\Delta S_{\ddot{u}} = \frac{\int_{f=0.5\text{ Hz}}^{f=10\text{ Hz}} |S_{\ddot{u}_{\text{A}}}(f) - S_{\ddot{u}_{\text{B}}}(f)| df}{\int_{f=0.5\text{ Hz}}^{f=10\text{ Hz}} S_{\ddot{u}_{\text{A}}}(f) df} \tag{6}$$

The relative difference of the reference response without incorporation of HSI to the reference response with HSI is 4.71. This value is a measure for the sensitivity of the reference response to HSI. This high difference indicates that HSI has a prominent influence on the structural response. This indicates the potential of the Eeklo Benchmark Dataset for the identification and quantification of HSI effects.

4.2 Contact force reconstruction from the human body accelerations

The reconstruction of the contact forces based on the lower-back accelerations yields some reconstruction error, even in rigid-surface conditions (Section 3.2). It is first investigated how this reconstruction error propagates to the related reconstructed response. The internally-driven contact forces of each pedestrian is reconstructed as $\tilde{F}^{G^{\text{RS}}}(t) = m_{\text{H1}} \ddot{u}_{\text{H1}}^{G^{\text{RS}}}(t)$ (Section 3.2) and

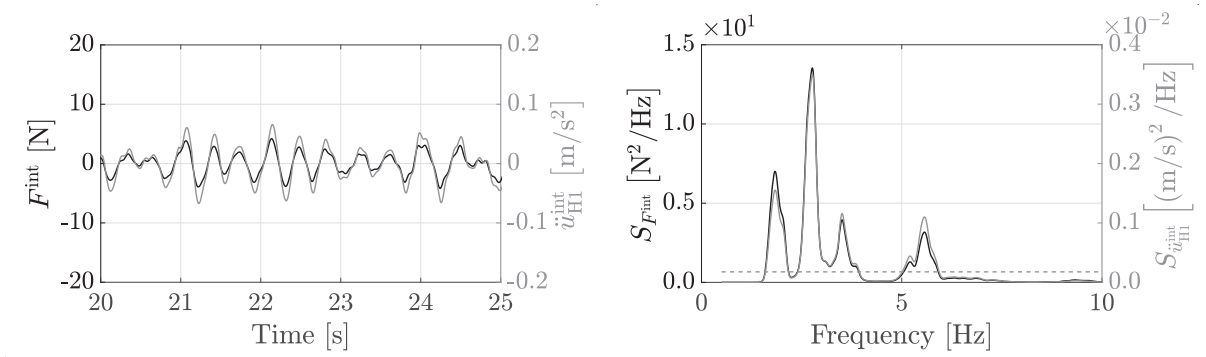

Figure 4: The interaction contact force (black) and interaction human body acceleration (gray) of reference pedestrian during the numerical example: relevant zoom of the time series (left) and PSD (right) with indication of the measurement noise of the low-cost sensors (dashed line).

stored in $\tilde{\mathbf{F}}^{G^{\mathrm{RS}}}(t)$. This matrix is applied on the equations of motion of the coupled crowd-structure system (Eq. (5)). The results (Fig. 5) show that the reconstructed response has a relative difference in PSD with respect to the reference response of 0.51 (calculated with Eq. (6)). This corresponds to 0.51/4.71 = 11% of the sensitivity of the reference response to HSI. It is noteworthy that this is a purely theoretical situation as in reality one always registers the total human body accelerations in measurement campaigns which cannot be separated into the internally-driven and interaction component.

Since the total human body accelerations are the ones that are registered during an experimental campaign, the most logical choice is to reconstruct the total contact forces as $\tilde{F}^{\mathrm{tot}}(t) = m_{\mathrm{H0}}\ddot{u}_{\mathrm{s}}(t) + m_{\mathrm{H1}}\ddot{u}^{\mathrm{tot}}_{\mathrm{H1}}(t)$ where $\ddot{u}_{\mathrm{s}}(t)$ are the structural vibrations at the position of the pedestrian. The reconstructed total contact forces are substituted into Eq. (4) to reconstruct the structural response. The results (Fig. 5) show that the relative difference in PSD increases from 0.51 to 2.13 (= 45% of the sensitivity). This can be explained by the low signal-to-noise ratio of the interaction human body accelerations (Fig. 4) while their importance is high (Fig. 3). In this theoretical example, the structural accelerations at the position of the pedestrian are easily obtained as $\ddot{u}_{\mathrm{s}}(t) = S_{\mathrm{p}}^{\mathrm{T}}(t)\boldsymbol{\Phi}\ddot{\mathbf{Z}}(t)$. In reality, however, the structural accelerations are measured at a limited number of points. Estimates of the structural accelerations at the contact points of pedestrians could be made using for instance techniques such as joint input-state estimation [27] but will slightly deviate from the true accelerations. As such, an additional reconstruction error is introduced leading to an even higher relative difference in PSD of the structural response. Therefore, it is concluded that a direct total force reconstruction is not suited in case of the Eeklo Benchmark Dataset.

Given the small power of the interaction human body acceleration compared to the internally-driven ones (Figs. 2 and 4), it could be opted to neglect the interaction accelerations. As such, it is assumed that the total human body accelerations is as a good approximation of the internally-driven ones: $\ddot{u}^{G^{\mathrm{RS}}}_{\mathrm{H1}}(t) \approx \ddot{u}^{\mathrm{tot}}_{\mathrm{H1}}(t)$. As such, the internally-driven contact forces can be estimated as: $\tilde{F}^{G^{\mathrm{RS}}}(t) = m_{\mathrm{H1}}\ddot{u}^{\mathrm{tot}}_{\mathrm{H1}}(t)$. The reconstructed structural response is obtained by plugging in the reconstructed internally-driven contact force into the equations of motion of the coupled crowd-structure system (Eq. (5)). The results (Fig. 5) show that the response is more accurately reconstructed compared to the previous case. The relative difference in PSD increases from 0.51 to 0.87. This is only a fraction of the sensitivity of the response to human-structure interaction (0.87/4.71 = 18%). This difference can be exploited for the estimation of the parameters of the

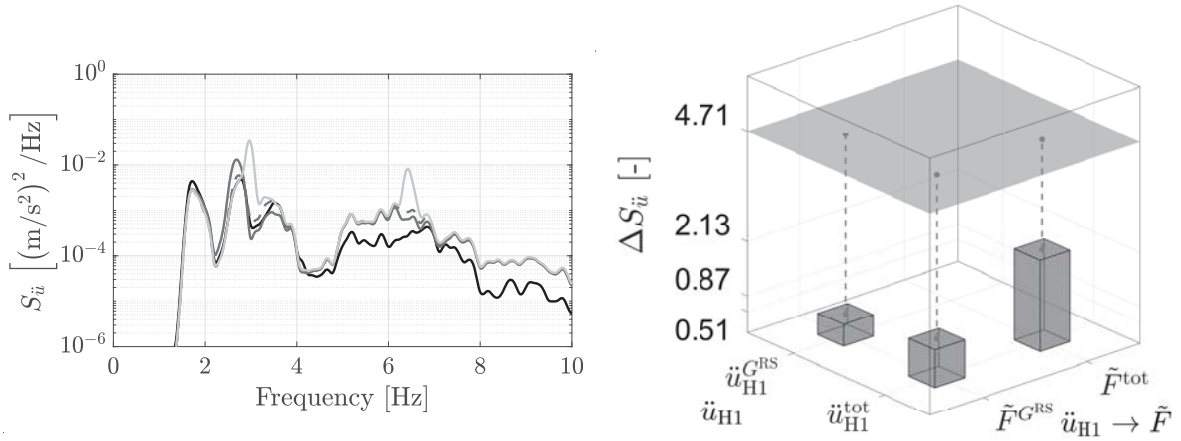

Figure 5: Assessment of the different reconstruction techniques based on the structural accelerations at midspan. Left: PSD of the reference response (black solid), the reconstructed response using either the total human body accelerations (solid) to reconstruct the total (light gray) or internally-driven (dark gray) contact forces or using the internally-driven human body accelerations to reconstruct the internally-driven contact forces (dashed). governing HSI in an inverse way where the internally-driven contact forces are reconstructed using the total human body accelerations.

5 Conclusions

The present contribution focuses on the human body dynamics and the HSI that occurs in case a walking crowd occupies a vibration structure. It is shown how the registration of the human body accelerations can be exploited to reconstruct the contact forces.

An experimental dataset using an instrumented treadmill and comprising 43 trials is collected. The internally-driven contact forces and internally-driven human body accelerations are simultaneously registered. The human body accelerations are collected using sensors which are identical to the ones used in the Eeklo Benchmark Dataset. It is found that the signal-to-noise ratio of the internally-driven human body accelerations during walking is very high compared to the noise characteristics of the low-cost sensors. Hence the employed sensors are competitive with the sensor equipment conventionally used for the registration of the human body acceleration.

Next, a numerical study of the Eeklo footbridge is considered where the applied internally-driven contact forces are the ones as registered in the laboratory setup and the HSI is modeled using a popular approach with parameter values established in the literature. The structural response is sensitive to the presence of HSI. This confirms the potential of the Eeklo Benchmark Dataset for the quantification of HSI effects. The signal-tot-noise ratio of the interaction human body accelerations to the low-cost sensor's noise characteristics is found to be low, suggesting the inadequacy to directly reconstruct the total contact forces using the registered total human body accelerations.

The first approach reconstructs the total contact force using the total human body accelerations. Due to the low signal-to-noise ratio of the interaction human body accelerations, a large

reconstruction error is found indeed confirming the inadequacy for a direct total contact force reconstruction. Instead, it is found that a more accurate reconstruction of the structural response is found if the internally-driven contact forces are reconstructed by considering the total human body accelerations as a good approximation of the internally-driven ones. This means that for the specific case of the Eeklo footbridge, an inverse approach to estimate the governing HSI parameters is advised.

While the obtained conclusions are case-specific and depend on the modeling strategy and related parameters of the HSI model, the methodology to determine the optimal reconstruction method is generic as it can be applied on virtually any structure in combination with any HSI model.

Keywords: footbridge, pedestrian-induced vibrations, dataset, open access.

Abstract. *This paper presents a new and publicly available full-scale dataset collected specifically for the further development and validation of models for crowd-induced loading. The dataset is collected on a real footbridge, with multiple modes sensitive to pedestrian-induced vibrations and with a digital twin available. Video cameras are used to capture the walking trajectories of the pedestrians. The bridge and pedestrian motion are registered simultaneously using wireless tri-axial accelerometers on the deck and the lower back of the pedestrians. Two data blocks are collected involving pure ambient excitation. Four data blocks are collected involving two pedestrian densities, 0.25 persons/m^2 and 0.50 persons/m^2, representing a total of more than one hour data for each pedestrian density. Analysis of the structural response shows that the different data blocks can be considered representative for the involved load case. The identified distribution of step frequencies in the crowd indicate a significant contribution of (near-)resonant loading with multiple modes of the footbridge. Furthermore, the dataset displays clear signs of human-structure interaction, suggesting a significant increase in effective modal damping ratios due to the presence of the crowd.*

1 INTRODUCTION

The vibration serviceability under crowd-induced loading has become a key design criterion for footbridges. Although increased research efforts are put into the characterization of crowd-induced loading including related interaction phenomena, a major challenge lies in the further development and validation of these load models. Full-scale benchmark datasets that simultaneously register the structural and crowd motion make an invaluable contribution to meeting this need by providing detailed information on representative operational loading and response data. Currently available datasets either (1) involve a (too) low number of pedestrians [1, 2, 3, 4, 5], (2) do not involve the simultaneous registration of pedestrian and bridge motion [1, 2, 6, 7, 8, 9], (3) do not involve a footbridge with multiple modes sensitive to walking excitation [3, 10, 11] and/or (4) for which a suitable digital twin is available, or (5) are not open access. To the knowledge of the authors, only the dataset collected by Živanović [10] and Gómez et al. [11] are publicly available.

In this paper, a novel publicly-available full-scale dataset is introduced, documenting a comprehensive experimental study involving pedestrian-induced vibrations on the Eeklo footbridge. The experimental study is unique and suitable for comprehensive validation purposes as it involves multiple pedestrian densities, the synchronous and detailed registration of the pedestrians' body motion and footbridge vibrations, a duration of the tests sufficient to be representative for the involved load cases, and a structure for which a reliable digital twin is available.

2 EEKLO FOOTBRIDGE

The Eeklo footbridge has three spans, a main central span of 42 m and two side spans of 27 m. In total, 14 modes were identified with a frequency up to 12 Hz (Figure 1). An excellent agreement is found between the experimentally identified modal characteristics and the ones calculated by the calibrated FE model. For more information related to the footbridge and the model calibration, the reader is referred to [12]. The corresponding digital twin describing the dynamic behavior of the footbridge, is part of the open access benchmark dataset.

3 EXPERIMENTAL STUDY

The bridge deck accelerations were measured using 10 wireless tri-axial acceleration sensors (GeoSIG GMS sensors [13]) with a sample rate of 200 Hz. The accelerations at the lower back of each participant was registered by a wireless inertial sensor [14] with a sample rate of 100 Hz. 21 cameras were used to capture the entire bridge deck at 30 frames per second. The acceleration signals registered on the bridge deck and at the lower back of the pedestrians are synchronized off-line using regular synchronization events. The cameras are synchronized off-line based on common events captured in adjacent cameras.

The experimental study considered ambient excitation of the empty footbridge and multiple tests with a duration of about 10 up to 20 minutes involving the pedestrian densities 0.25 persons/m^2 and 0.50 persons/m^2, and amounting to a total of more than one hour test data for each pedestrian density.

4 OBSERVATIONS

4.1 Distribution of step frequencies

Based on the measurements of all USB sensors, the time-variant pacing rate for each pedestrian is determined, using the procedure detailed in [15]. Figure 2-a shows the histogram of the

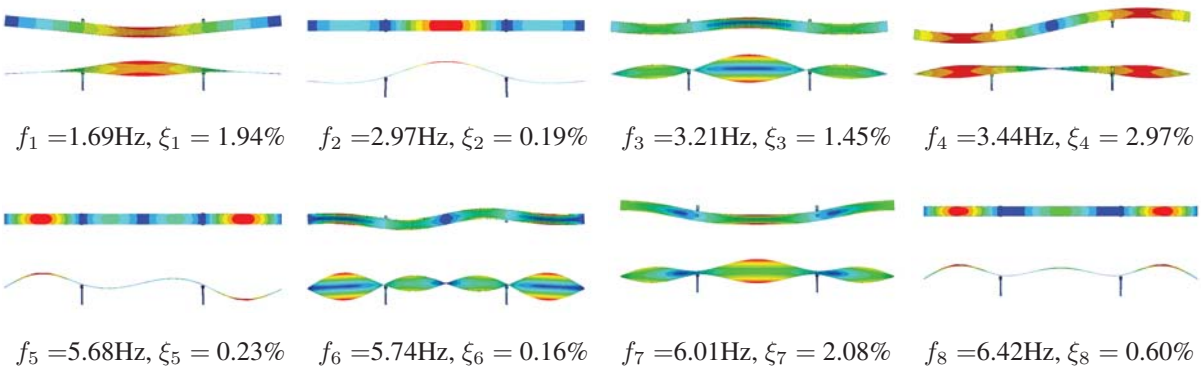

Figure 1: Top and side view of the first eight modes of the Eeklo footbridge (cfr. digital twin).

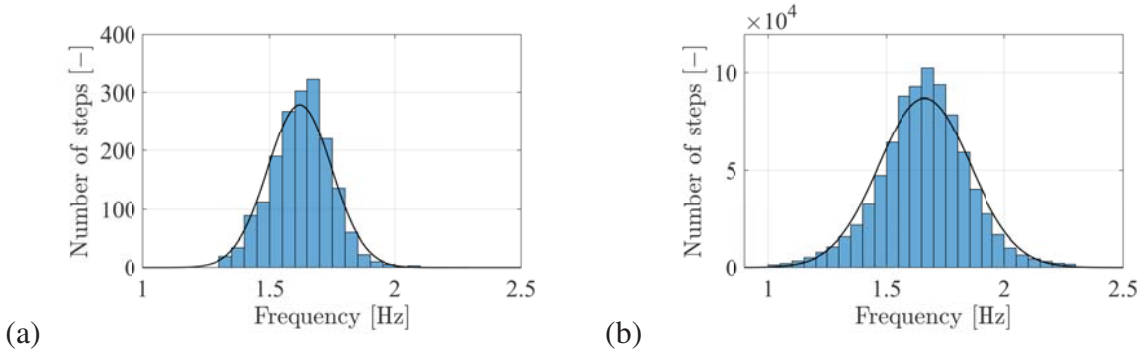

Figure 2: Histogram with fitted Gaussian distribution of the identified pacing rates (a) for a single pedestrian and (b) the corresponding aggregated distribution for all 148 pedestrians for a pedestrian density of 0.50 persons/m^2.

identified pacing rates for pedestrian 1 during free walking. This figure shows that the distribution of steps can be well fitted by a Gaussian distribution. A goodness of fit (chi-squared or χ^2 test) of 84% is found. Similar observations are made for the other pedestrians in the crowd.

Figure 2-b presents the histogram and fitted Gaussian distribution of the experimentally identified pacing rates of all pedestrians for pedestrian density of 0.50 persons/m^2. These results show that the distribution of step frequencies can again be well fitted by a Gaussian distribution. The distribution of step frequencies is characterized by $\mathcal{N}(1.66, 0.19)$ Hz (χ^2 test of 87%). Similarly, for a pedestrian density of 0.25 persons/m^2, a good fit is found with the distribution $\mathcal{N}(1.77, 0.13)$ Hz (χ^2 test of 94%). These results show that as the pedestrian density increases from 0.25 persons/m^2 to 0.50 persons/m^2, the mean walking speed slightly decreases [16, 17]. This, in turn, results in a decrease of the mean step frequency from 1.77 Hz to 1.66 Hz. It is also observed that the standard deviation in step frequency increases with the pedestrian density, from 0.13 Hz to 0.19 Hz. This phenomenon could be attributed to the impact of human-human interaction that increases with the pedestrian density: as the number of interactions between pedestrians increases, the pedestrians display more variations in their walking behavior, as also observed in [18].

4.2 Pedestrian trajectories

The video footage is used to obtain the pedestrian trajectories by a sequence of pedestrian detection and tracking, as comprehensively described in [19]. The time-averaged spatial dis-

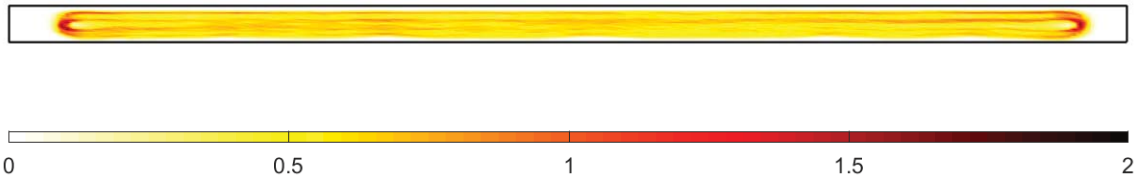

Figure 3: (Top) Heat map of the pedestrians during a test involving a pedestrian density of 0.50 persons/m^2 and (bottom) the corresponding color bar expressed in persons/m^2.

tribution of the pedestrians of a test involving a pedestrian destiny of 0.5 persons/m^2 is shown by means of a heat map in Figure 3. This figure shows that the spatial distribution is (slightly) non-uniform. This is the case for both pedestrian densities. Further analysis also shows that the spatial distribution (slightly) varies over consecutive time blocks, indicating that the spatial distribution is non-stationary. Also, during all tests the formation of 4 lanes over the width of the bridge deck is observed. This so-called lane-formation is a natural phenomenon in pedestrian flows [20].

The average speed of the pedestrians is calculated, resulting in the following distributions for the densities 0.25 and 0.50 persons/m^2: $\mathcal{N}(1.28, 0.02)$ m/s and $\mathcal{N}(1.10, 0.03)$ m/s.

4.3 Structural response

The structural response is low-pass filtered with a cut-off frequency of 10 Hz. Figure 4 presents the full time series and a 10-second zoom of the structural accelerations induced by ambient excitation and a pedestrian density of $0.50\ \mathrm{pedestrians/m^2}$. The Power Spectral Density (PSD) of the structural response is calculated considering consecutive time windows of length $T = 25$ s, with 50% overlap. Figure 5 presents the PSD of the structural accelerations induced by ambient excitation and a pedestrian density of $0.50\ \mathrm{pedestrians/m^2}$. It is noted that ambient excitation is also present when pedestrian excitation is considered. The following observations are made:

- When comparing the time series for ambient excitation to those involving pedestrian excitation, the vibration levels appear to be in the same order of magnitude.
- For ambient excitation, the PSD shows that the vertical structural accelerations are dominated by the contributions of the first (1.69 Hz) and the second (2.97 Hz) mode of the footbridge.
- For the entire frequency range up to 10 Hz, with the exception of a small interval around 2.97 Hz (structural mode 2), the PSD corresponding to pedestrian excitation is significantly larger than the one corresponding to ambient excitation. This observation indicates that pedestrian excitation is the dominant source of vibrations for the tests involving walking persons.
- The peak value of the PSD close to the fundamental mode of the footbridge (f_1 =1.69 Hz) is about 20 times larger when excited by a pedestrian density of $0.50\ \mathrm{pedestrians/m^2}$, compared to the peak value for ambient excitation. This observation indicates that the pedestrian excitation clearly prevails over the impact of ambient excitation. This observation is furthermore confirmed by the identified distributions of step frequencies (Figure 2)

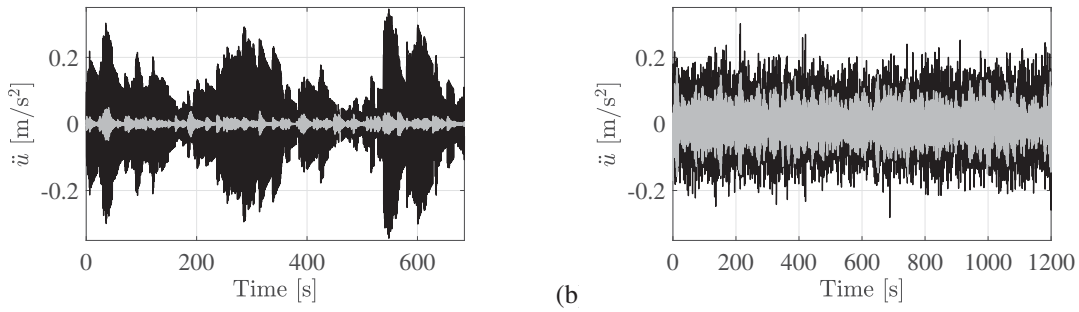

Figure 4: Time series of the structural accelerations induced by (a) ambient excitation and (b) a pedestrian density of $0.50\ \mathrm{pedestrians/m^2}$, low-pass filtered with a cut-off frequency of 10 Hz: the vertical (black) and lateral (gray) component in the middle of the center span.

which shows that a considerable fraction of the pedestrians is walking at (near-)resonance with the fundamental mode.

- The peak value of the PSD close to the second mode of the footbridge (2.97 Hz), is about 20 times *smaller* when excited by a pedestrian density of $0.50\ \mathrm{pedestrians/m^2}$, with respect to the peak value due to ambient excitation. Considering the second harmonic of the walking load, it is clear that also in this case a considerable fraction of the pedestrians is walking at (near-)resonance with the second mode of the footbridge (see Figure 2). In addition, the second mode is highly sensitive to (near-)resonant excitation, much more even than the fundamental mode, because of its very low modal damping ratio (0.2%) and modal mass. Therefore, it can be assumed that also in this frequency range, pedestrian excitation dominates the structural response. The fact that the peak value of the PSD close to the second mode is considerably smaller than when only ambient excitation is considered, can be assumed to be attributed to HSI. This is in line with recent studies [21, 22, 23, 24, 25] indicating that the effective damping ratio of the coupled crowd-structure system increases considerably for increasing crowd to structure mass ratios and for natural frequencies of the empty structure close to that of the human body of a pedestrian. This presumed increase in effective damping ratio is also in line with the observation that the peak in the PSD in figure 5 around the second mode (2.97 Hz) is considerably wider for the tests involving pedestrian excitation in comparison to the peak due to ambient excitation. Evidence of the increase in effective damping due to the presence of persons on the Eeklo footbridge, in particular for the second mode, has also been reported in [12].

5 CONCLUSIONS

This paper presents the benchmark full-scale dataset on pedestrian-induced vibrations collected on the Eeklo footbridge, involving the simultaneous registration of pedestrian and bridge motion. The Eeklo footbridge is a lightweight steel structure characterized by multiple low-frequent modes that lie within the dominant spectrum of pedestrian excitation. The structural vibrations are registered by wireless tri-axial accelerometers. The 3D body motion of each pedestrian is registered using a wireless tri-axial accelerometer, securely fixed close to the body center of mass, and the position along the bridge deck is captured by video cameras. The experimental study considered multiple tests involving the pedestrian densities 0.25 persons/m^2 and 0.50 persons/m^2, as well as two tests involving pure ambient excitation.

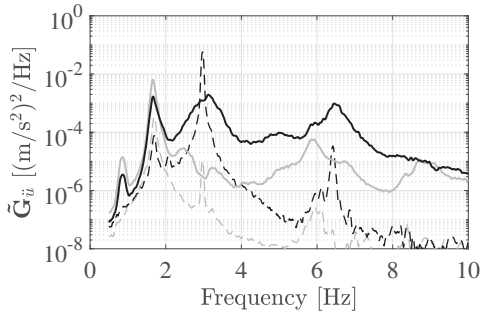

Figure 5: The average PSD of the structural accelerations due to ambient (dashed) and pedestrian (solid) excitation for a pedestrian density of 0.50 pedestrians$/\mathrm{m}^2$, low-pass filtered with a cut-off frequency of 10 Hz: the vertical (black) and lateral (gray) component in the middle of the center span.

Analysis shows that the different tests involving the same load case, can be considered representative for that involved load case. It is shown that pedestrian excitation dominates over ambient excitation when walking persons are involved. The dataset displays clear signs of HSI, suggesting a significant increase in effective modal damping ratio(s) due to the presence of the crowd, in particular for modes with a natural frequency close to that of the human body.

6 Data availability

The Eeklo footbridge benchmark dataset is freely available upon request to the corresponding author(s) and at (`www.kuleuven.be/structural-mechanics-ghent`, Tools and Downloads).

Abstract. *The further development and improvement of prediction models for crowd-induced vibrations of footbridges requires detailed information on representative operational loading data. This paper uses an inverse method to estimate the parameters that govern human-structure interaction from the resulting structural response. The parameters of interest concern the dynamic characteristics of a single-degree-of-freedom (SDOF) system, applied to describe the mechanical interaction between the pedestrian and the structure. The parameter estimation procedure assumes that the dynamic behavior of the empty structure, the average pedestrian weight and the distribution of step frequencies in the crowd are known. The dynamic characteristics of the mechanical interaction model are estimated by minimizing the discrepancy between the observed and the simulated power spectral density of the structural response.*

The approach is applied to the Eeklo Footbridge Benchmark Dataset where the pedestrian and bridge motion are registered simultaneously using wireless tri-axial accelerometers, involving pedestrian densities up to 0.5 persons/m^2. A digital twin of the Eeklo footbridge, the average weight of the pedestrians and the distribution of step frequencies, identified from the accelerations registered on the lower back of each pedestrian, are used as input for the proposed parameter estimation procedure. The results show that an estimate of the natural frequency and damping ratio of the mechanical interaction model is obtained that is in line with recent findings in the literature. These estimates are, however, for the first time ever based on a comprehensive set of full-scale observations.

1 INTRODUCTION

Footbridges are often sensitive to human excitation. Although the dynamic performance under high crowd densities is often imperative for the design, these loading conditions have virtually never been verified [1]. The need for the validation of load models for crowd-induced loading is high, in particular due to the impact of human-structure interaction (HSI) that is predicted to play a vital role in the vibration serviceability assessment [2, 3, 4, 5].

In-field observations are the only way to obtain detailed and accurate information on representative operational loading data. As direct force measurements are in this case practically infeasible, inverse methods, where the unknown input parameters are identified from the resulting vibration response and a dynamic model of the structure, constitutes a promising alternative.

This paper uses a parameter estimation procedure to estimate the parameters that govern HSI from the resulting structural response. This procedure is applied to a dataset of in-field observations on a slender footbridge involving a pedestrian density of 0.5 persons/m^2.

2 METHODOLOGY

2.1 Coupled crowd-structure model

The mathematical framework introduced in [4] is used. In this framework, each pedestrian in the crowd is modeled as the superposition of an autonomous force term, corresponding to the forces induced on a rigid surface, and a linear SDOF system used to simulate the mechanical interaction with the supporting structure. This SDOF system is composed of a rigid and an activated mass, representing respectively 5% and 95% of the total mass of the pedestrian. The dynamic behavior of the supporting structure, which in this study is referring to a footbridge, is represented by its modal parameters. The equations of motion of the coupled crowd-structure model read:

$$\dot{\mathbf{x}}(t) = \mathbf{A_c}\mathbf{x}(t) + \mathbf{B_c}\mathbf{S_p}(t)\mathbf{p}_{\text{F}}(t) \tag{1}$$

$$\text{with} \quad \mathbf{x}(t) = \begin{bmatrix}\mathbf{z}(t) & \mathbf{u}_{\text{H}}(t) & \dot{\mathbf{z}}(t) & \dot{\mathbf{u}}_{\text{H}}(t)\end{bmatrix}^\top \tag{2}$$

$$\mathbf{A_c} = \begin{bmatrix}\mathbf{0} & \mathbf{I} \\ -\bar{\mathbf{M}}_{\text{HS}}^{-1}\bar{\mathbf{K}}_{\text{HS}} & -\bar{\mathbf{M}}_{\text{HS}}^{-1}\bar{\mathbf{C}}_{\text{HS}}\end{bmatrix} \tag{3}$$

$$\mathbf{B_c} = \begin{bmatrix}\mathbf{0} \\ \mathbf{T_p}\end{bmatrix} \tag{4}$$

with $\mathbf{x}(t) \in \mathbb{R}^{n_s}$ the state vector and $n_s = 2(n_m + n_{\text{H}})$, $\mathbf{z}(t) \in \mathbb{R}^{n_m}$ the modal coordinate vector, n_m the number of modes, $\mathbf{u}_{\text{H}} \in \mathbb{R}^{n_{\text{H}}}$ the vector of displacements of SDOF interaction models, n_{H} the number of pedestrians, $\mathbf{p}_{\text{F}}(t) \in \mathbb{R}^{n_{\text{H}}}$ is the force vector collecting the time history of the autonomous force term $p_{\text{F},k}(t)$ of each pedestrian k of the n_{H} pedestrians as rows and $\mathbf{S_p}(t) \in \mathbb{R}^{n_{\text{DOF}} \times n_{\text{H}}}$ a selection matrix which transfers the forces to the corresponding n_{DOF} DOFs of the model of the structure. $\bar{\mathbf{M}}_{\text{HS}}$, $\bar{\mathbf{K}}_{\text{HS}}$ and $\bar{\mathbf{C}}_{\text{HS}}$ are the generalized mass-, stiffness and damping matrices of the coupled crowd-structure system and $\mathbf{T_p}$ is the generalized input transformation matrix, as defined in [4]. The autonomous force term $p_{\text{F},k}(t)$ depends on the weight and the step frequency ($f_{s,k}$) of the pedestrian and is modeled using the probabilistic single-person force model developed by Živanović et al. [6].

2.2 Parameter estimation problem

The parameter estimation problem is highly similar to the one introduced in [7]. The objective is to identify the parameters that determine the effect of HSI on the resulting structural

response: the dynamic characteristics of the linear mechanical systems representing the pedestrians in the crowd. The following inputs are assumed to be known:

1. The dynamic behavior of the empty footbridge.
2. The structural response induced by the pedestrians at one or more locations on the footbridge.
3. The average (total) mass of the pedestrians.
4. The distribution of step frequencies in the crowd: $f_s = \mathcal{N}(\mu_{f_s}, \sigma_{f_s})$ [Hz].

The first three items can be obtained using conventional techniques or tests. The fourth item can, for example, be identified from acceleration measurements performed at the lower back of each pedestrian (See accompanying paper: 'An open access benchmark dataset on pedestrian-induced vibrations collected on the Eeklo footbridge').

In [7] it is shown that when a sufficiently long duration of the structural response induced by a pedestrian density d is considered, the statistical effect of the autonomous force term (resulting from the random arrival times and the intra-person variabilities) on the power spectral density (PSD) of the resulting structural response can be averaged out.

The optimization problem is now formulated where the objective function measures the difference between the PSD of the experimentally observed ($\tilde{\mathbf{G}}_{\ddot{u}}$) and the numerically simulated ($\mathbf{G}_{\ddot{u}}$) structural response within a frequency range defined by a lower (ω_{l} [rad/s]) and upper bound (ω_{u} [rad/s]). The residuals are computed at discrete frequencies ω_k [rad/s]: $\omega_k = \omega_{\mathrm{l}} + k\Delta\omega \quad \text{for} \quad k = 0, ..., N$, with $N + 1 = (\omega_{\mathrm{u}} - \omega_{\mathrm{l}})/\Delta\omega + 1$ the number of samples and $\Delta\omega$ the selected frequency resolution. The parameters of the SDOF model are assumed identical for the different persons on the structure. The average total mass of the pedestrians is a known input, determining the rigid (5%) and activated mass (95%) of the SDOF model. The decision variables in this optimization problem are the natural frequency f_{H1} and the modal damping ratio ξ_{H1}, and are subject to the following physical constraints: $f_{\mathrm{H1}} > 0$ and $\xi_{\mathrm{H1}} > 0$. The problem, subject to two inequality constraints, is formulated in standard form:

$$\underset{f_{\mathrm{H1}},\, \xi_{\mathrm{H1}}}{\text{minimise}} \quad \frac{\| \tilde{\mathbf{G}}_{\ddot{u}} - \mathbf{G}_{\ddot{u}}(f_{\mathrm{H1}}, \xi_{\mathrm{H1}}) \|_2^2}{\| \tilde{\mathbf{G}}_{\ddot{u}} \|_2^2} \tag{5}$$

$$\text{subject to} \quad f_{\mathrm{H1}} > 0 \tag{6}$$

$$\xi_{\mathrm{H1}} > 0 \tag{7}$$

and can be categorized as a nonlinear programming problem due to the nature of the objective function. The inequality constrained optimization problem is solved using the lsqnonlin-solver (MATLAB®) by means of the trust-region-reflective algorithm.

3 EEKLO FOOTBRIDGE

The Eeklo footbridge has three spans, a main central span of 42 m and two side spans of 27 m. The dynamic behavior of the footbridge is characterized by 14 modes with a frequency up to 12 Hz. The corresponding digital twin describing the dynamic behavior of the footbridge, is part of the open access benchmark dataset (See accompanying paper: 'An open access benchmark dataset on pedestrian-induced vibrations collected on the Eeklo footbridge').

3.1 Numerical verification

In this numerical verification section, the objective is to verify the parameter optimization procedure for the Eeklo footbridge. In addition, the impact of modeling errors on the solution of the parameter estimation problem is investigated.

In this numerical verification example, the pedestrian density is set to match the one considered in the in-field tests (see next section): 148 persons (≈ 0.5 persons/m^2). The distribution of step frequencies is set to follow a Gaussian distribution: $f_s = \mathcal{N}(1.89, 0.18)$ [Hz]. The weight of the pedestrians is set to 70 kg. The corresponding PSD of the pedestrian load is defined based on the procedure detailed in [8], using the dynamic load factors for the main and sub-harmonics of the walking load defined in [6]. The PSD of the pedestrian load is presented in Figure 1.

The natural frequency (f_{H1}) and the modal damping ratio (ξ_{H1}) of the interaction model are set to respectively 3 Hz and 30%. Figure 2 visualizes the FRF of the Eeklo footbridge, empty and with HSI. This figure shows that the impact of HSI is high for mode 2 ($f_2 = 2.97$ Hz), mode 5 ($f_5 = 5.68$ Hz) and mode 8 ($f_8 = 6.42$ Hz). These modes are bending modes characterized by a low modal mass (22×10^3 kg – 26×10^3 kg) and a low damping ratio ($0.2\% - 0.6\%$). The highest impact is found for mode 2, as the natural frequency of the interaction model is in this case close to the optimal tuning frequency for accelerations [9].

When no modeling errors are assumed, the parameter estimation procedure converges to the true minimum. This was also illustrated for a hypothetical example in [7]. This contribution in addition analyses the influence of modeling errors. These modeling errors ($\epsilon_{\square}$) are related to the inputs that the parameter estimation procedure assumes to be known. Given the high accuracy with which the structural response can be measured, and the ease with which the total mass of the pedestrians can be determined, the impact of related errors is not investigated. Also, it is assumed that the impact of (correlated) measurement noise, e.g. related to the sensor placement, is negligible. The modeling errors considered in this study are related to:

- The dynamic behavior of the empty structure, or thus the structural modal parameters: Given the uncertainty bounds on the modal parameters identified using state-of-the-art system identification techniques [10, 11], it is reasonable to assume errors of ϵ_f =1% and ϵ_ξ =10% on respectively the experimentally identified natural frequencies and modal damping ratios. The corresponding modal masses can be calculated using a (preferably calibrated) FE model of the structure. For the calculated modal mass, an error of ϵ_m =2% is considered reasonable. Less satisfactory results may be characterized by errors of 5%, 30% and 5% (upper bound error) on respectively the natural frequencies, modal damping ratios and modal masses.

- The distribution of step frequencies in the crowd: Assuming that the distribution of step frequencies follows a Gaussian distribution, the impact of an error of 2% and 5% on the mean value (ϵ_μ) and standard deviation (ϵ_σ) of the step frequencies is investigated.

The parameter estimation procedure now uses the PSD of the vertical and lateral acceleration levels calculated at the center of the main and the side span of the footbridge (close to the parapet). Analysis shows that as little information on HSI is contained in the PSD of the lateral acceleration levels, including these PSDs in the objective function (Eq. 5) has a negligible impact on the obtained optimal solution. These PSDs can therefore be excluded from the selected input data.

For the sake of conciseness, this paper only reports the joint impact of the modeling errors on the solution of the parameter estimation problem (estimation error). The estimation error

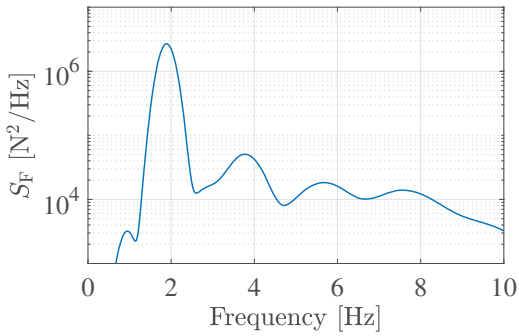

Figure 1: PSD of the pedestrian load (S_F) for 148 persons.

($\Delta_\square$) is expressed in terms of the percentage of difference with the true optimal solution of the parameter estimation problem ($f^\star_{H1} = 3$ Hz, $\xi^\star_{H1} = 30$ %). The following results are found:

- $\Delta_{f^\star_{H1}} = 3\%$ and $\Delta_{\xi^\star_{H1}} = 9\%$ for ϵ_f =1%, ϵ_ξ =10%, ϵ_m =2%, $\epsilon_\mu = \epsilon_\sigma = 2\%$.
- $\Delta_{f^\star_{H1}} = 5\%$ and $\Delta_{\xi^\star_{H1}} = 20\%$ for ϵ_f =2%, ϵ_ξ =30%, ϵ_m =5%, $\epsilon_\mu = \epsilon_\sigma = 5\%$.

These results show that the impact of the reasonable range of modeling errors that can be expected for the present case, have a small impact on the estimated natural frequency of the interaction model (5%). The impact on the estimated damping ratio is higher (20%), but is still reasonable given that the structural response is less sensitive to changes in this parameter. Further analysis shows that in this case, the errors on the distribution of step frequencies (ϵ_μ and ϵ_σ) have the largest impact on the estimation error. The low impact of the relatively large modeling errors assumed on the modal damping ratios, stems from the fact that the modal damping ratios of the dominant modes are very low in relation to the damping added by HSI. By consequence, the impact of these inherent structural modal damping ratios on the corresponding effective damping of the coupled crowd-structure system is very low.

However, it is noted that the low impact of the modeling errors, in particular those related to the modal parameters of the footbridge, on the estimated parameters is in this case due to the high impact of HSI on multiple modes of the footbridge (mode 2, mode 5 and mode 8). This is, in turn, due to the involved low modal masses, low damping ratios and natural frequencies of these modes. These results are highly case-specific and should be investigated for each case prior to the application of the parameter estimation procedure. Furthermore, this investigation does not consider the impact of other modeling errors, such as for example lateral mechanical HSI that is neglected here or errors in the load model that is used to describe the autonomous force term.

3.2 Application to full-scale data

The inputs for the parameter estimation procedure are set to match the conditions of the in-field observations involving 148 pedestrians (See accompanying paper: 'An open access benchmark dataset on pedestrian-induced vibrations collected on the Eeklo footbridge'):

1. The digital twin of the Eeklo footbridge is used to describe the dynamic behavior of the empty footbridge.

2. The structural response measured at the center of the main and the side span is used (close to the parapet). As the numerical verification section has shown that HSI is most relevant

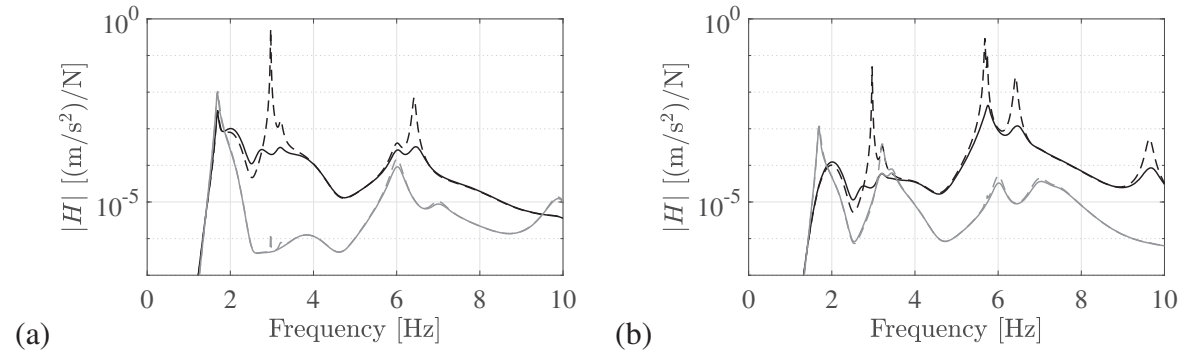

Figure 2: The FRF for a (black) vertical and (gray) lateral input and output acceleration at the center of the (a) central and (b) side span of the Eeklo footbridge, (dashed) empty and (solid) with HSI, for a pedestrian density of 0.50 persons/m^2.

for the vertical output, only the acceleration levels registered in the vertical direction are used. The Power Spectral Density (PSD) of the structural response is calculated considering consecutive time windows of length $T = 25$ s, with 50% overlap.

3. The average body mass of the pedestrians is 73.2 kg.

4. The distribution of step frequencies in the crowd: $f_s = \mathcal{N}(1.66,\ 0.19)$ [Hz].

Given that the highest impact of HSI is expected for mode 2, mode 5 and mode 8, the frequency range [2.5, 8.0] Hz is taken into account for the parameter estimation procedure.

In Figure 3, the objective function defined in Eq. 5 is evaluated for a realistic range of the two decision variables: the natural frequency $1 \leq f_{\text{H}} \leq 5$ [Hz] and the modal damping ratio $0.2 \leq \xi_{\text{H}} \leq 0.6$ [-]. This figure shows that the objective function, and thus the impact of HSI, is mainly sensitive to changes in the natural frequency f_{H} of the interaction model. Figure 3 illustrates a generally low sensitivity of the objective function to the modal damping ratio ξ_{H} of the interaction model.

The following optimal solution is found for the interaction model:

- $f^{\star}_{\text{H1}} = 3.02$ Hz
- $\xi^{\star}_{\text{H1}} = 46$ %

Figure 4 compares the PSD of the measured output with the one calculated for the footbridge with and without HSI, whereby HSI is modeled with the fitted interaction model. In turn, Figures 5 and 5 present the measured and calculated (with and without HSI) vertical acceleration levels at respectively the midspan and the sidespan. These figures show that when HSI is disregarded, the structural response is significantly overestimated. More importantly, this figure shows that the fitted interaction model allows to arrive at a good fit with the measurements. Based on the insights gained in the numerical verification section, an indicative uncertainty bound of 5% and 20% on respectively the estimated natural frequency and modal damping ratio is assumed, where this uncertainty in this case mainly stems from the modeling errors related to the distribution of the step frequencies in the crowd. These uncertainty bounds are also indicated on Figure 3.

Finally, it is noted that the identified natural frequency ($f_{\text{H1}} = 3.02 \pm 0.15$ Hz) and damping ratio ($\xi_{\text{H1}} = 0.46 \pm 0.10$) of the interaction model are in line with recent findings in the literature [3, 4].

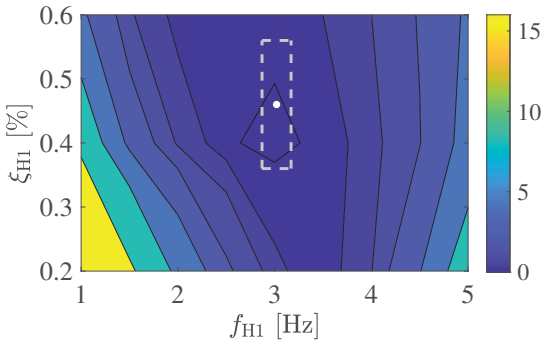

Figure 3: Evaluation of the objective function in terms of the natural frequency f_{H1} and the damping ratio ξ_{H1} of the interaction model, and the indicative uncertainty bounds (dashed lines) on the optimal solution (•).

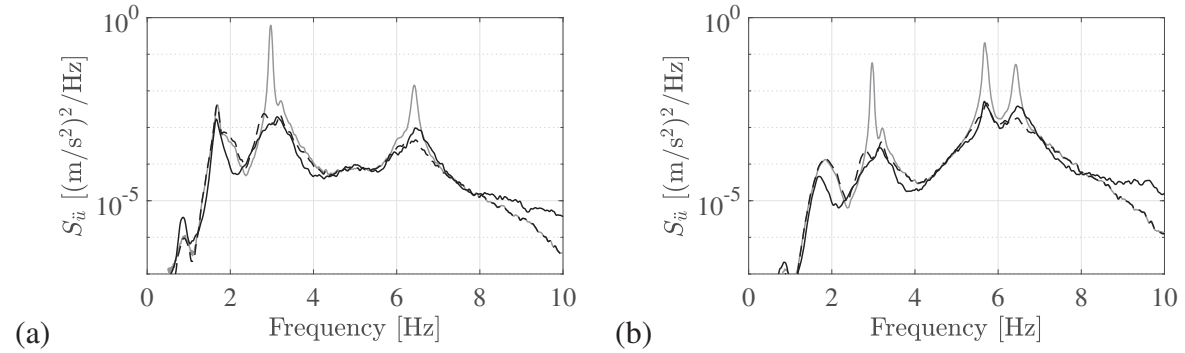

Figure 4: The PSD of the vertical acceleration levels at the center of the (a) central and (b) side span of the Eeklo footbridge for a pedestrian density of 0.50 persons/m^2: (black, solid) measurements, and numerically simulated (gray, solid) without HSI and (black, dashed) with HSI based on the fitted interaction model.

4 CONCLUSIONS

This paper estimates the natural frequency and damping ratio of an SDOF interaction model, applied to describe the mechanical interaction between the pedestrian and the structure, by minimizing the discrepancy between the observed and the simulated power spectral density of the structural response. The approach is applied to the Eeklo Footbridge Benchmark Dataset where the pedestrian and bridge motion are registered simultaneously using wireless tri-axial accelerometers and video cameras, involving a pedestrian density of 0.5 persons/m². A digital twin of the Eeklo footbridge, the average weight of the pedestrians and the distribution of step frequencies, identified from the accelerations registered on the lower back of each pedestrian, are used as input for the proposed parameter estimation procedure. A natural frequency of 3 Hz and a damping ratio of 46% are identified for the mechanical interaction model. These results are in line with recent findings in the literature and are, for the first time ever, based on full-scale observations.

Abstract. *This paper presents a novel method for the indirect determination of the ground reaction forces (GRF) induced by a pedestrian during forward locomotion on a vibrating structure. It is based on the formulation of an inverse problem for the identification of the unknown time dependent moving load, which is solved by means of a gradient-based optimization algorithm. The force identification is performed in the time domain using accelerations and/or displacement time histories recorded at different locations on the structure as input data. The practicability and accuracy of the method is evaluated using both simulated measurements and real experimental data recorded on the HUMVIB experimental footbridge on the campus of the Technical University of Darmstadt, Germany. For the validation of the reconstructed forces, an array of biomechanical force plates as well as classical load cells at the supports of the test structure were used. The results show that the proposed method allows a very accurate estimation of the GRF induced by a subject during walking on the experimental structure.*

1 INTRODUCTION

Classical direct measurement methods of ground reaction forces (GRF) induced by pedestrians on rigid surfaces usually imply either force plates [1] or treadmills instrumented with force sensors [2], which are commonly used in biomechanical studies of the human gait. The GRFs can also be directly acquired by means of foot pressure insoles, i.e. instrumented shoes [3, 4]. Their main advantage is that the subject does not have any locomotion constraints, such as targeting the force plates [5], allowing thus the execution of a natural gait. Besides the direct measurement methods, there are also indirect approaches, which try to reconstruct the GRF by means of three dimensional recordings of the body motion and an assumed distribution of the body mass under consideration of the second Newton's law of motion [6, 7, 8, 9, 10]. Extensive literature overviews on the measurement methods of GRFs are given in [5] and [11].

When it comes down to the direct GRF measurement during walking on vibrating structures, only few methods are feasible with justifiable effort. The installation of classical force plates on vibrating structures is possible, it implies however high costs and is rather only feasible for laboratory experiments [12, 13]. In case of laboratory structures, it is also possible to install conventional load cells at the supports [12, 13]. However, both in case of the force plates and the the load cells, the measured forces are "polluted" by a significant component generated by the inertia of the force plate or of the vibrating structure itself, which leads to additional analysis effort and to certain inaccuracies [13, 14]. A good alternative for GRF measurement on vibrating structures are the in-shoe pressure sensors, which have already been used in civil engineering applications [13, 15]. However, they present a limited accuracy of the force amplitudes, which are obtained by integrating the distributed pressure over the foot insole area [5].

In comparison to the drawbacks of the aforementioned direct measurement methods, the time histories of the structural displacements and accelerations can be recorded with high accuracy and reasonable effort. In this sense, this paper addresses a novel method for the indirect determination of the GRF induced by a pedestrian on a vibrating structure, which is based on conventional measurements of structural responses, avoiding thus the use of costly and sensitive biomechanical equipment. The method implies the formulation of an inverse problem for the identification of the unknown time dependent moving load, whose solution is addressed by means of a gradient-based optimization algorithm. The force reconstruction is executed in the time domain using accelerations and/or displacement time histories recorded at different locations on the structure as input data. The practicability and accuracy of the method is evaluated using real experimental data recorded on the HUMVIB experimental footbridge at the Technical University of Darmstadt, Germany. For the validation purposes, an array of biomechanical force plates as well as classical load cells at the supports were used. The method aims to facilitate the analysis of the human-structure interaction effects on bridges in operation.

2 FORMULATION OF THE PROBLEM

2.1 The forward problem

The computation of the motion quantities for a damped linear system containing n_{dof} degrees of freedom can be performed by solving the differential equation of motion:

$$\boldsymbol{K} \cdot \boldsymbol{u}(t) + \boldsymbol{D} \cdot \dot{\boldsymbol{u}}(t) + \boldsymbol{M} \cdot \ddot{\boldsymbol{u}}(t) = \boldsymbol{P}(t) \tag{1}$$

where $\boldsymbol{K}^{n_{\mathrm{dof}} \times n_{\mathrm{dof}}}$, $\boldsymbol{D}^{n_{\mathrm{dof}} \times n_{\mathrm{dof}}}$ and $\boldsymbol{M}^{n_{\mathrm{dof}} \times n_{\mathrm{dof}}}$ are the stiffness, damping and mass matrix, respectively, while $\boldsymbol{P}^{n_{\mathrm{dof}} \times 1}$ represents the vector of external forces at each time instant. $\boldsymbol{u}$, $\dot{\boldsymbol{u}}$ and

$\ddot{\boldsymbol{u}}$ denote the vectors of motion quantities (displacement, velocity and acceleration, respectively). In order to achieve the solution of Eq. 1, it can either be directly integrated or it can be solved by means of the modal superposition principle [16]. The force reconstruction method of the present study is based on the latter one, whereas the modal equations are solved using the time step integration method of Newmark [16].

2.2 The inverse problem

The inverse problem of GRF reconstruction on a vibrating structure formulated within this work implies that the entries of the load vector $\boldsymbol{P}(t)$ are considered to be unknown, while the system matrices $\boldsymbol{K}$, $\boldsymbol{D}$ and $\boldsymbol{M}$ in Eq. 1 are given and assumed to be constant. In addition, it is considered that a set of n_{md} displacement and n_{ma} acceleration time histories are acquired over a finite number n_{t} of discrete time points through experimental investigations. Basically, the inverse problem seeks to find an optimal time-dependent force vector $\boldsymbol{P}(t)$, which caused the measured motion quantities. This can be expressed by means of an unconstrained and unbounded optimization problem:

$$\begin{aligned}\min_{\boldsymbol{s}} \mathcal{F}(\boldsymbol{s}) = & w_{\mathrm{d}} \cdot \sum_{h=1}^{n_{\mathrm{md}}} \sum_{i=1}^{n_{\mathrm{t}}} (u_{h,i} - \bar{u}_{h,i})^2 + w_{\mathrm{a}} \cdot \sum_{h=1}^{n_{\mathrm{ma}}} \sum_{i=1}^{n_{\mathrm{t}}} (\ddot{u}_{h,i} - \bar{\ddot{u}}_{h,i})^2 + \\ & \underbrace{w_{\mathrm{p1}} \cdot \left\| \left(\overbrace{\boldsymbol{Q}_{\mathrm{loc}}^{n_{\mathrm{var}} \times n_{\mathrm{var}}} - \boldsymbol{Q}_{\mathrm{glo}}^{n_{\mathrm{var}} \times n_{\mathrm{var}}}}^{\boldsymbol{Q}_{\mathrm{p1}}} \right) \cdot \boldsymbol{s}^{n_{\mathrm{var}} \times 1} \right\|_2^2}_{\text{Penalty function 1}} + \\ & \underbrace{w_{\mathrm{p2}} \cdot \left\| \left(\overbrace{\boldsymbol{I}^{n_{\mathrm{var}} \times n_{\mathrm{var}}} - \boldsymbol{Q}_{\mathrm{loc}}^{n_{\mathrm{var}} \times n_{\mathrm{var}}}}^{\boldsymbol{Q}_{\mathrm{p2}}} \right) \cdot \boldsymbol{s}^{n_{\mathrm{var}} \times 1} \right\|_2^2}_{\text{Penalty function 2}}\end{aligned} \tag{2}$$

here, $\boldsymbol{s} \in \mathbb{R}^{n_{\mathrm{var}}}$ comprises the n_{var} load values s_k, each of them denoting the value of the moving force at a certain time step t_k, while k represents the index of the n_{var} time steps, in which the force is present on the bridge. $\bar{u}_{h,i}$ and $\bar{\ddot{u}}_{h,i}$ denote the measured displacement and acceleration in the i-th time step for the h-th measurement point. $u_{h,i}$ and $\ddot{u}_{h,i}$ represent the corresponding motion quantities resulting from the numerical analysis (forward problem). The formulation of Eq. 2 implies that the force location is known for each time step. The weighing factors w_{d} and w_{a} are introduced to control the importance of each term in the multiobjective optimization problem described by Eq. 2. The objective function includes also two penalty functions, whose weights are defined by the factors w_{p1} and w_{p2}. They will be discussed in the following.

The first penalty function accounts for a special feature of traffic loads on bridges, which states that their dynamic components vary around the static weight of the pedestrian or vehicle passing the structure, denoted as discrete finite signal with a stable average value (DFS-SAV) [17]. Practically, this means that the local (moving) average values of the force time history to be identified lie not too far from their global average values. This can be expressed mathematically by minimizing the squared differences between the vectors of local and global average values of the force vector $\boldsymbol{s}$. The local and global average values are obtained using a local and a global average matrix $\boldsymbol{Q}_{\mathrm{loc}}$ and $\boldsymbol{Q}_{\mathrm{glo}}$. They are constructed in such a way, that their multiplication by the load vector $\boldsymbol{s}$ delivers the local or the global average value. It is to be mentioned that the

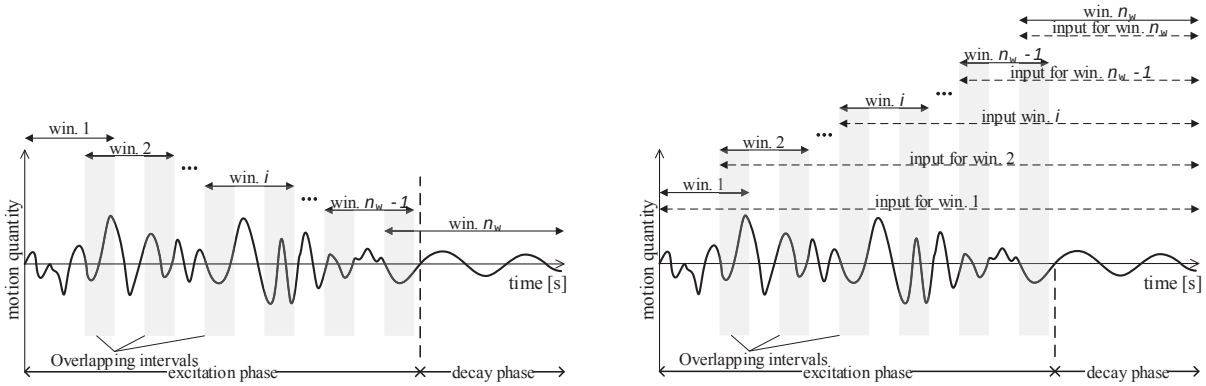

Figure 1: Moving window: forward optimization (left) and backward optimization (right)

local averaging in this study is formulated using a moving window of five samples. The second penalty function controls the smoothness of the solution by minimizing the distance between each value in the solution vector $\boldsymbol{s}$ and the local average of the force. $\boldsymbol{I}$ is the identity matrix, its multiplication with $\boldsymbol{s}$ delivers the unchanged vector $\boldsymbol{s}$.

In order to allow the solution of large problems, the inverse problem in Eq. 2 is addressed using a forward sliding window approach with a certain overlapping interval (Fig. 1 left). It implies that an optimization problem acc. to Eq. 2 has to be formulated and solved for each of the n_w windows. By selecting a reasonable window length, the computational efficiency can be significantly increased in comparison to the direct solution for the whole time frame. After terminating the forward optimization, a subsequent backward optimization problem is enabled (Fig. 1 right). It allows the optimization of the load values in each window under consideration of a more extensive set of input data, which stretches from the starting point of the time window to the end of the decay phase (Fig. 1 right).

The solution the optimization problem elaborated above is obtained using a trust region optimization algorithm, which achieves super-linear convergence when it is supplied with exact sensitivity information (gradient and Hessian) [18].

2.3 Sensitivity analysis

The total derivative of the objective function with respect to a load value s_k can be determined using the the chain rule:

$$\frac{\mathrm{d}\mathcal{F}}{\mathrm{d}s_k} = \underbrace{\sum_{h=1}^{n_\mathrm{md}} \frac{\partial \mathcal{F}}{\partial \boldsymbol{u}_h} \cdot \frac{\partial \boldsymbol{u}_h}{\partial s_k} + \sum_{h=1}^{n_\mathrm{ma}} \frac{\partial \mathcal{F}}{\partial \ddot{\boldsymbol{u}}_h} \cdot \frac{\partial \ddot{\boldsymbol{u}}_h}{\partial s_k}}_{\text{implicit}} + \underbrace{\frac{\partial \mathcal{F}}{\partial s_k}}_{\text{explicit}} \tag{3}$$

The implicit component of the sensitivity expression in Eq. 3 is determined by analytical differentiation the first two terms on the right side of Eq. 2, while the explicit dependencies of the objective function on the load values are given solely by the analytical differentiation of the penalty functions with respect to s_k. The determination of the sensitivity of displacement and accelerations of the h-th measured point with respect to the load value s_k ($\partial \boldsymbol{u}_h / \partial s_k$ and $\partial \ddot{\boldsymbol{u}}_h / \partial s_k$) was also performed analytically. It implies the differentiation of Eq. 1 on both sides with respect to s_k. Considering constant (and thus load independent) system matrices $\boldsymbol{K}$, $\boldsymbol{D}$ and $\boldsymbol{M}$, the differentiation yields:

$$\boldsymbol{K} \cdot \frac{\partial \boldsymbol{u}(t)}{\partial s_k} + \boldsymbol{D} \cdot \frac{\partial \dot{\boldsymbol{u}}(t)}{\partial s_k} + \boldsymbol{M} \cdot \frac{\partial \ddot{\boldsymbol{u}}(t)}{\partial s_k} = \frac{\partial \boldsymbol{P}(t)}{\partial s_k} \tag{4}$$

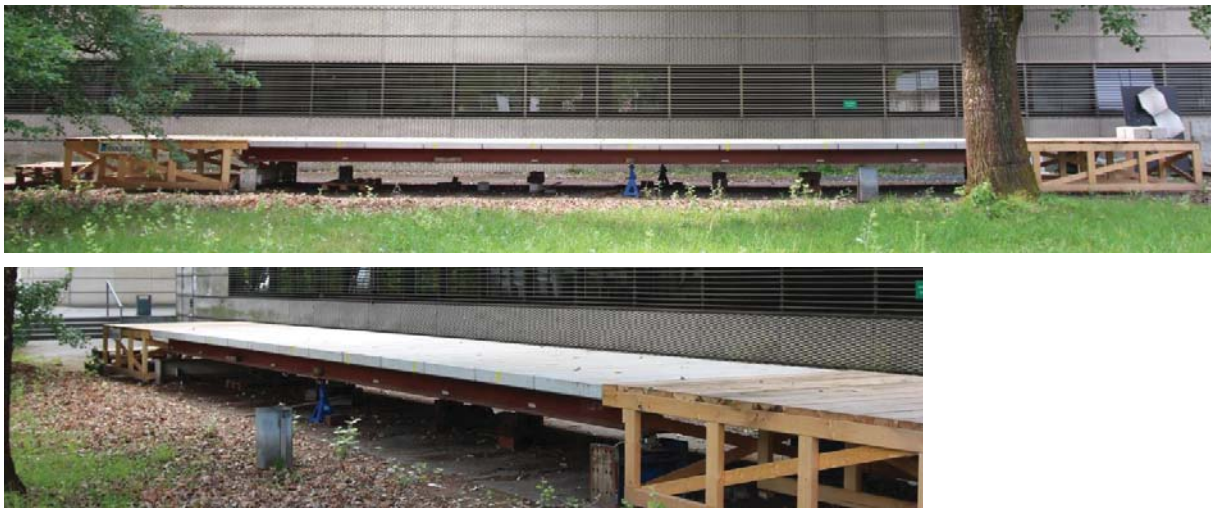

Figure 2: HUMVIB experimental pedestrian bridge (the middle support was removed during the experimental investigations)

where $\partial \boldsymbol{u}/\partial s_k$, $\partial \dot{\boldsymbol{u}}/\partial s_k$, $\partial \ddot{\boldsymbol{u}}/\partial s_k$ denote sensitivity vectors. Evidently, Eq. 4 has a similar form as Eq. 1, if the term $\partial \boldsymbol{P}/\partial s_k$ on the right hand side is considered as an equivalent force vector. Therefore, the unknown sensitivity vectors can be obtained through forward analysis using the mode superposition principle and the time-stepping integration method of Newmark. $\partial \boldsymbol{P}/\partial s_k$ represents the derivative of the vector of external forces with respect to one force in a certain time step. It contains only one value of 1, corresponding to the entry s_k, while all the other values are zero. The entries of the analytical Hessian can be determined by differentiating Eq. 4 with respect to another load value s_i.

3 INVESTIGATIONS ON AN EXPERIMENTAL PEDESTRIAN BRIDGE

3.1 Investigation object

The experimental HUMVIB-Bridge (Fig. 2) is a simply supported pedestrian bridge with a span of $l = 13.24$ m, consisting of two longitudinal steel beams (steel type S235JR) with HEB240 cross section (Fig. 3). The deck plate is made of 13 precast reinforce concrete stripes having the dimensions $250 \times 100 \times 12$ cm. The concrete elements and the steel beams are separated by an elastomeric interlayer with a thickness of 5 mm. The total mass of the experimental pedestrian bridge is about 12 tons, leading to a fundamental frequency of the structure

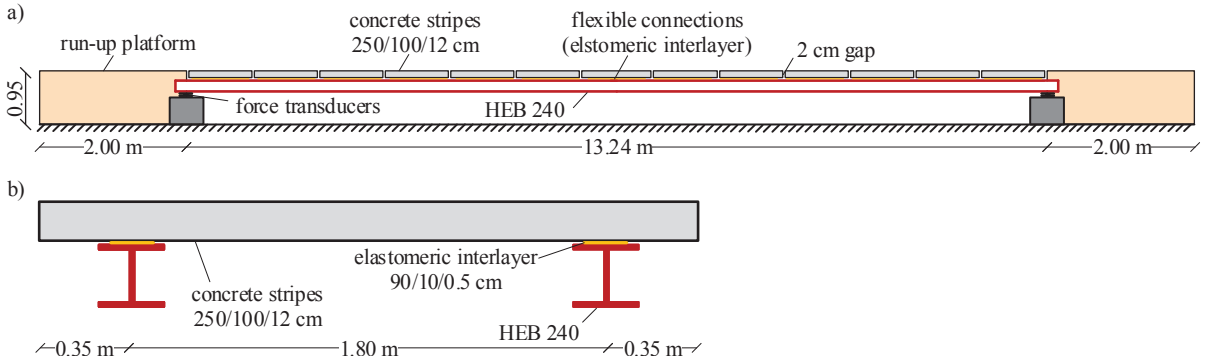

Figure 3: Experimental pedestrian bridge HUMVIB: a) side view; b) cross section

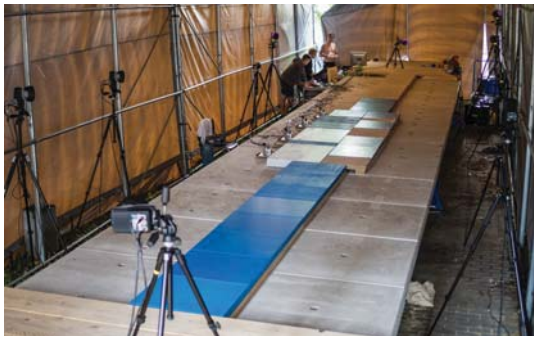

Figure 4: Measurement set-up used in the experimental investigation

of 2.04 Hz. The first five mode shapes and their frequencies were determined experimentally using the reference based combined deterministic-stochastic subspace identification algorithm [19, 20] (s. Fig. 7).

3.2 Measurement set-up

The measurement set-up used in the present investigation is shown in Fig. 4 and schematically illustrated in Fig. 5. The structural responses in vertical direction were recorded at 12 different measurement points (MP) disposed along the steel beams. MP1 to MP4 were instrumented with both acceleration and displacement sensors, while only accelerations were recorded at the locations of MP5 to MP12. Besides the measurement of the motion quantities, the reaction forces at the four supports (MP13 to MP16) were acquired using a set of load cells. In addition, a set of five force plates (FP1 to FP 5) of type KISTLER 9260AA6 ($600\times500\times50$ mm) and two force plates (FP6 and FP7) of type KISTLER 9287CA ($900 \times 600 \times 100$ mm) were installed on the bridge for recording the pedestrian induced GRFs. In order to ensure proper conditions for a natural gait and to reduce the tripping hazard of the subjects, the walking path was leveled using dummy plates with a thickness of 100 mm.

3.3 Structural model

The finite element software ANSYS 2020 R1 was used to generate a numerical model of the experimental pedestrian bridge (Fig. 6a). The steel beams were modeled using beam elements (BEAM188), while the concrete elements were represented through shell elements (SHELL181). Typical (deterministic) material parameters were assigned to the steel beams

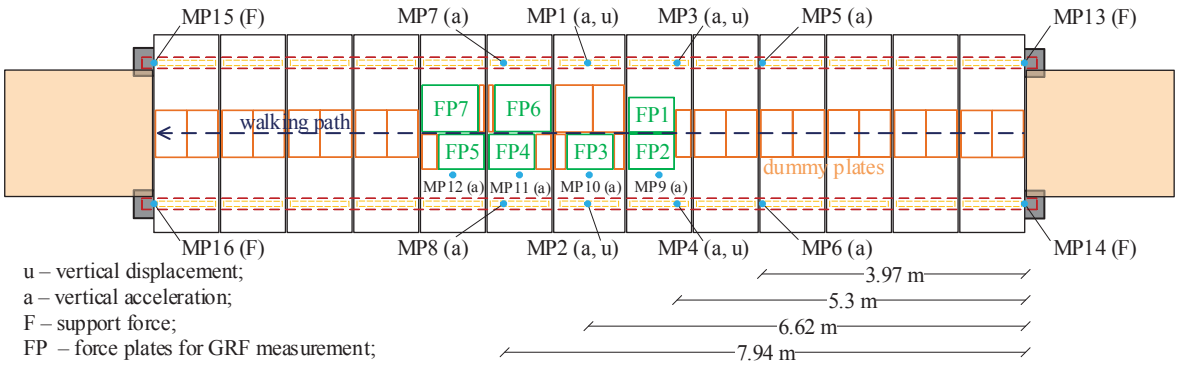

Figure 5: Measurement set-up of the HUMVIB-Bridge

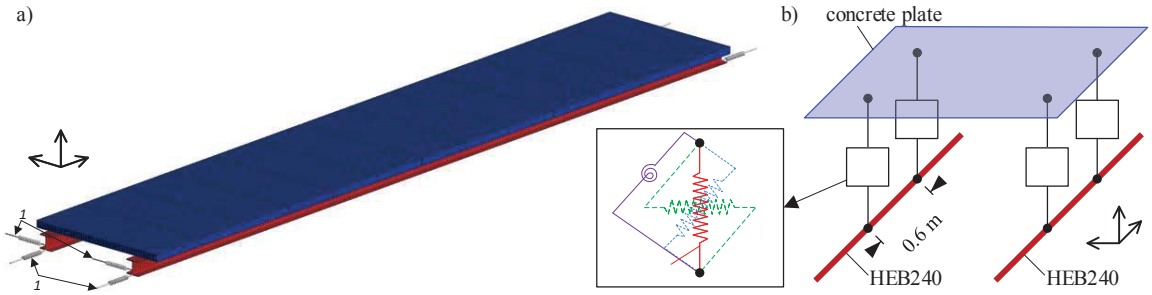

Figure 6: a) Finite element model of the HUMVIB-Bridge; b) Idealized connection between the steel beams and concrete plates

(density $\rho = 7850\ \mathrm{kg/m^3}$, Young's modulus $E = 2.1 \cdot 10^8\ \mathrm{kN/m^2}$ and Poisson ratio $\nu = 0.3$) and the concrete plates ($\rho = 2500\ \mathrm{kg/m^3}$, $E = 3 \cdot 10^7\ \mathrm{kN/m^2}$ and $\nu = 0.2$). The elastomeric interlayer connecting the concrete elements and the steel structure was idealized using a group of three translational springs ($k_{\mathrm{t},2,x}$, $k_{\mathrm{t},2,y}$ and $k_{\mathrm{t},2,z}$ along the x, y and z axis, respectively) and one rotational spring ($k_{\mathrm{r},2,x}$ around the longitudinal x-axis) (Fig. 6b). The beam supports were disposed at the lower flanges and are assumed to be rigid in vertical direction, while horizontal displacements at the supports (in x and y directions) are permitted. In this sense, a set of two translational springs, $k_{\mathrm{t},1,x}$ and $k_{\mathrm{t},1,y}$, were defined at each support (Fig. 6a).

The values of the rotational and translational springs were determined by solving an optimization problem, which seeks to minimize the sum of squared differences between the measured and computed natural frequencies for the first three bending modes and first two torsional modes. The optimization process delivered the following set of optimized stiffness coefficients: $k_{\mathrm{t},1,x} = 12.64 \cdot 10^3\ \mathrm{kN/m}$, $k_{\mathrm{t},1,y} = 10.72 \cdot 10^3\ \mathrm{kN/m}$, $k_{\mathrm{t},2,x} = 11.14 \cdot 10^3\ \mathrm{kN/m}$, $k_{\mathrm{t},2,y} = 2.52 \cdot 10^3\ \mathrm{kN/m}$, $k_{\mathrm{t},2,z} = 18.22 \cdot 10^3\ \mathrm{kN/m}$ and $k_{\mathrm{r},2,x} = 11.95 \cdot 10^3\ \mathrm{kNm}$. The resulting mode shapes and their frequencies are shown in Fig. 7 together with the results obtained from the experimental investigations. The MAC (Modal Assurance Criterion) values determined using the measured and computed values of the five considered mode shapes are 0.9998 (1st mode), 0.9981 (2nd mode), 0.9933 (3rd mode), 0.9959 (4th mode) and 0.9618 (5th mode). Thus, a very good agreement of the results is achieved both on frequency and mode shape level.

3.4 Testing with simulated measurements

In order to generate simulated measurement data, the reference force time history shown in Fig. 10 was applied to the finite element model presented in Section 3.3. The response was evaluated by a forward analysis under consideration of the five modes of vibration shown in Fig. 7. The results of the forward analysis were subsequently polluted with an inconvenient (rather unrealistic) amount of artificial noise, in order to obtain the simulated measurements used for the inverse analysis. Fig. 8 shows exemplarily simulated measurements of displacement and acceleration at the measurement location MP2.

A time step $\Delta t = 0.00333\ \mathrm{s}$, a window size of 400 samples and an overlapping interval of $1/3$ of the window length (s. Fig. 10) were selected. The weighting factors w_{p1} and w_{p2} were determined by means of a parametric study to $w_{\mathrm{p1}} = 5.5 \cdot 10^{-8}$ and $w_{\mathrm{p2}} = 1.0 \cdot 10^{-4}$ (s. Fig. 9). Its aim was to determine the optimal combination of weighting factors, which leads to the lowest error between the reference and the identified forces with simulated measurement data:

$$P_{\mathrm{err}} = \frac{\|\boldsymbol{P}_{\mathrm{identified}} - \boldsymbol{P}_{\mathrm{reference}}\|_1}{\|\boldsymbol{P}_{\mathrm{reference}}\|_1} \cdot 100\ \% \tag{5}$$

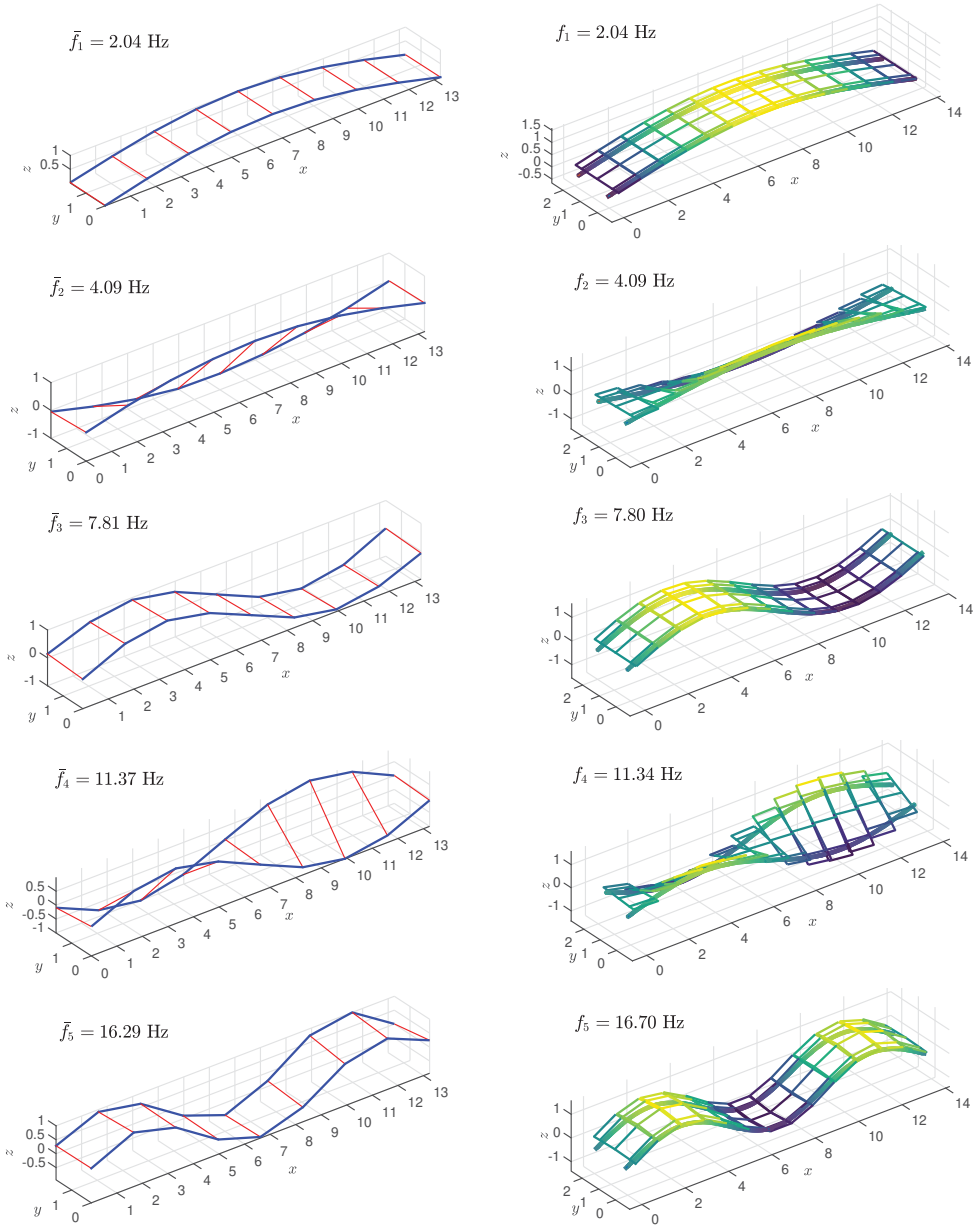

Figure 7: Measured (left) and computed (right) mode shapes and the corresponding natural frequencies

Input data from eight accelerations (MP1 to MP8) and four displacements (MP1 to MP4) was considered. The corresponding weighing factors are $w_\mathrm{a} = 1$ and $w_\mathrm{d} = 5 \cdot 10^5$. The latter seeks to balance the order of magnitude of the displacement and acceleration measurements and ensures a dominant contribution of the displacement term within the objective function.

The result of the optimization problem is shown in Fig. 10. The iteration in each window is terminated when the relative drop of the value of the objective function between two subsequent iterations is less than 10^{-8}. The relative error evaluated according to Eq. 5 at the end of the backward optimization is $4.72\ \%$. This result indicates a very good global agreement between the reference and the identified force time history. A slightly lower accuracy can be only observed for the rather short intervals, in which the force is located in the proximity of the supports (at the beginning and the end of the bridge). This effect occurs most likely due to the low sensitivities of acceleration and displacement at the measurement points with respect to forces acting at the

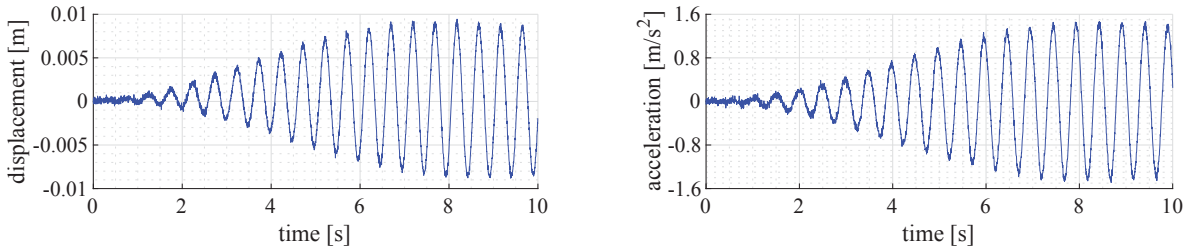

Figure 8: Simulated measurements at MP2: displacement (left) and acceleration (right)

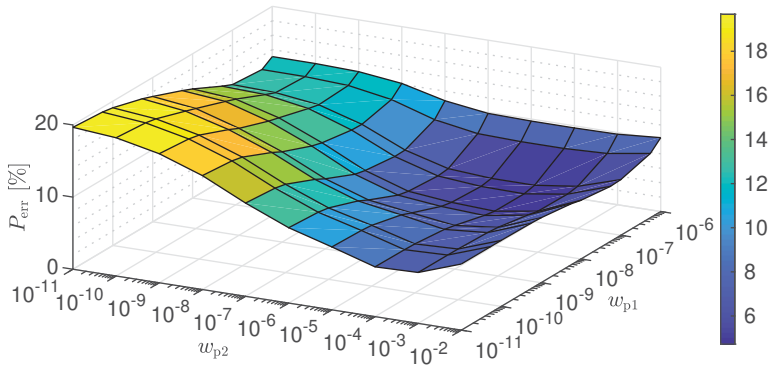

Figure 9: Parametric study for determination of the weighing factors w_{p1} and w_{p2}

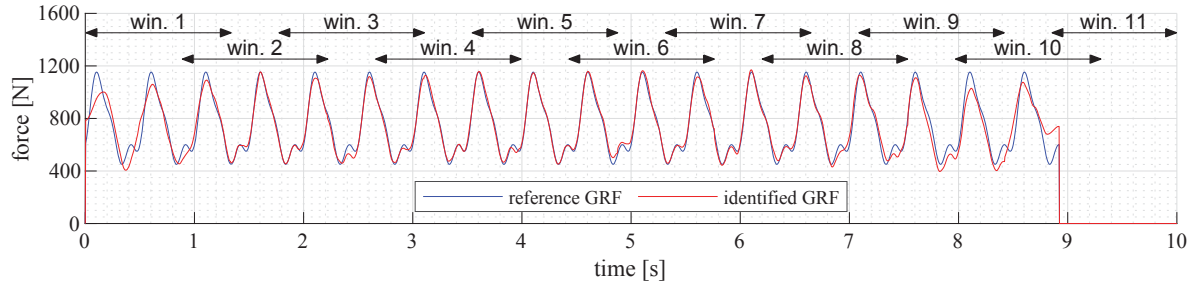

Figure 10: Comparison of the reference force used to simulate the measurement data with the result of the inverse computation

beginning and the end of the bridge. However, the penalty functions ensure stable results even at these locations. A further computation with consideration of only four sensors as input data (accelerations and displacements at MP3 and MP4) delivers an error of $7.16\ \%$, confirming thus the robustness of the method also with a more practicable number of sensors.

3.5 Testing with real measured data

The validation procedure with real measurements implies the acquisition of the measurement data during the passage of a subject weighting $747\ \mathrm{N}$ with a predefined step frequency of $2\ \mathrm{Hz}$. Fig. 11 shows exemplarily the measured displacement and acceleration time histories at MP2. The measured data was filtered using a lowpass filter with a cut-off frequency of $18\ \mathrm{Hz}$, in order to adapt the frequency content of the measurement to the frequency content of the computation. It is to be mentioned that all computational parameters (time step, weighting factors, window size, convergence criteria etc.) were adopted from Section 3.4. In this sense a resampling of

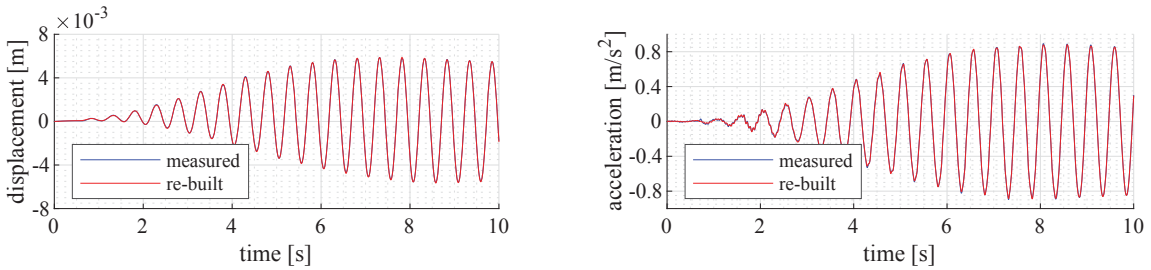

Figure 11: Measured and re-built responses at MP2: displacement (left) and acceleration (right)

the measured signals was carried out, because the measurements were recorded at a sample frequency of 1200 Hz. Also in this case signals of eight acceleration (MP1 to MP8) and four displacement (MP1 to MP4) sensors were used as input data.

In order to use the load cell and force plate signals as reference values for the validation of the GRF reconstruction, the inertial effects of the bridge (in case of load cells) and of the force plate masses had to be removed from the measured force signals [13]. The results after the correction are shown in Fig. 12. Furthermore, in order to account for a possible imperfect walking behavior (e.g. unequal step lengths), the time dependent location of the subject was determined by means of static equilibrium, using the signals of the load cells signals (free of dynamic components) at the two ends of the bridge.

Due to the system changes arising because of the additional mass of the biomechanics equipment, a new model adaptation was necessary for the validation process with real measurement data. In this sense, an additional mass of about 60 $\mathrm{kg/m}$ was applied to the numerical model described in Section 3.3. This leads to a first natural frequency of 1.98 Hz (first bending mode), confirmed also by Fourier analyses of the free decay phases measured during different trials. The further computational natural frequencies are: 3.97 Hz (1st torsional mode), 7.56 Hz (2nd bending mode), 11.02 Hz (2nd torsional mode) and 16.02 Hz (3rd bending mode).

The results of the optimization problem based on real measured data are shown in Fig. 12 together with the reference force time histories from the load cells and the force plates. The relative error $P_{\mathrm{err,LC}}$ of the identified force with respect to the load cell signals (support forces) is 10.18 %. Considering that there are still various uncertainties in the problem definition (e.g. with respect to the modeling, subject velocity, measurement inaccuracies etc.), the result can be interpreted as very satisfactory. However, the quantitative evaluation of the force reconstruction method based on comparisons with the signals of the support forces has to be done with caution,

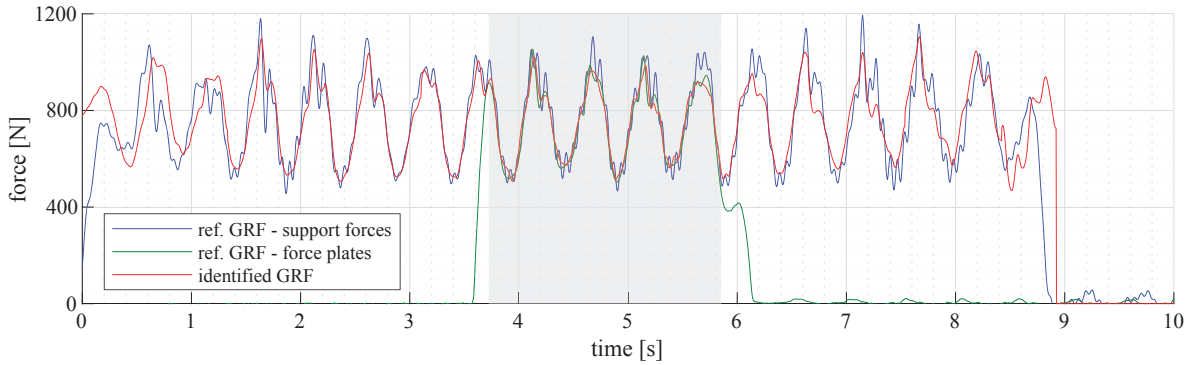

Figure 12: Measured and identified GRF time historie of a subject walking over the HUMVIB-Bridge

since $P_{\mathrm{err,LC}}$ is highly uncertain due to the inexact elimination of the inertial forces from the measured load cell signals (s. interval between 9 and 10 s in Fig. 12). Nevertheless, the load cell signals provide a valuable tool for the general comparison of the GRFs along the bridge. A more reliable validation of the identified GRF is expected when analyzing the relative error $P_{\mathrm{err,FP}}$ of the identified force with respect to the force plate signals for the time interval of passing the force plate array (grey area in Fig. 12). The result is $P_{\mathrm{err,FP}} = 3.20\ \%$, indicating an excellent agreement of the two force signals.

In order to emphasize the efficiency of the method, a forward analysis was performed with the identified force time history. The displacement and accelerations at MP2 (Fig. 11) revealed a nearly perfect match between the real measured data and the re-built structural responses. A further great achievement of the method is the successful qualitative and quantitative reconstruction of the imperfect GRF time history, which shows lower force amplitudes when the pedestrian is located around the middle of the bridge than in case of a location towards the supports. This effect is thought to occur because of the passive and active HSI effects, which are expectedly higher at locations with higher amplitudes, i.e. towards the middle of the bridge. The computation under consideration of accelerations and displacements measured and MP3 and MP4 (total of four sensors) resulted in $P_{\mathrm{err,LC}} = 10.13\ \%$ and $P_{\mathrm{err,FP}} = 3.48\ \%$, indicating a similar results quality as for the configuration with 12 sensors.

4 CONCLUSIONS

- A novel method for an indirect determination of ground reaction forces on vibrating structures was presented. It implies the formulation of an inverse problem in time domain, which is based on the minimization of the difference between a set of computed and a set of measured displacement and acceleration time histories. An important boundary condition of the method is that the location of the force in each time step has to be provided.

- In order to enable the solution of large problems at reasonable computational cost, an approach based on a forward and backward sliding window was developed. It implies the splitting of the total time of analysis into different windows of given length with a certain overlap. An optimization problem of pre-defined dimensions has to be solved in each window both during the forward and backward sliding.

- The tests with simulated measurements under consideration of a worst case noise level indicated that the developed method achieved an accuracy of the identified GRFs of about $5-7\ \%$ with respect to the reference forces, indicating thus a very satisfactory agreement of the results. A slightly lower accuracy was revealed solely for the time intervals, where the force enters and leaves the bridge. This is an effect of the low sensitivities of the measured quantities with respect to the forces acting at those locations.

- The method was subsequently tested using real measurement data recorded during walking trials on the experimental HUMVIB-Bridge on the campus of Technical University of Darmstadt. The measurement set-up included load cells at the supports and an array of biomechanical force plates, which were used as reference values for the validation of the method. The reconstructed forces revealed a very good accuracy of about $10\ \%$ with respect to the highly uncertain load cell measurements and $3\ \%$ related to the more accurate force plates signals. These results were obtained for both a configuration with 12 sensors and a configuration with four sensors as input data, confirming thus the robustness of the method for practical applications. Moreover, the experimentally recorded

trend of decreasing force amplitudes towards the middle of the bridge (correlated with higher response amplitudes) could be successfully reproduced by the developed method. The re-built responses using the identified forces revealed a nearly perfect match with the measured time-histories.

- The developed method can be used for the study of HSI effects by means of ground reaction forces induced by a pedestrian during walking on a vibrating structure. So far, the method was tested on a full-scale experimental structure. The promising results indicate that the method is suitable also for the use within field experiments on real footbridges, as long as a relatively accurate structural model is available.

- The force identification method presented in this paper can be adapted and used for different applications, e.g. the reconstruction of the dynamic axle loads of a complete railway vehicle passing a bridge structure [21].

Keywords: Structural dynamics, timber floor, human induced vibration

Abstract. *Timber floors are sensitive to vibrations because of their lightweight. Walking on this type of floor could cause motion sickness for the walkers or the other people in the room. Timber floors have to be designed correctly to ensure a good comfort, especially in countries like France where people are used to the vibration comfort level of concrete floors. This paper proposes new methods to assess the dynamical properties of timber floors, and the accelerations due to the walk of an individual. Experimental and numerical tests are made to evaluate the relevance of the method.*

1 Introduction

1.1 Problematic

Due to timber buildings lightweight, their dynamical properties must be studied carefully. Vibration comfort level is an important aspect of the quality of a building. Discomfort is dependent of the sensitivity of each person, their activities and mainly of vibration physical values (frequencies, accelerations, velocities and displacements). These physical quantities have to be assessed to design correctly timber floors. This paper presents a methodology to predict the frequency of the first floor mode and assess the vibration level from walking of individual.

1.2 State of the art

The ISO-10137 norm [1] gives some clues to size floors and footbridges against vibrations. The main point of this norm is to assess the vibration effects due to different sources on the comfort of users. A criterion based on the root mean square (RMS) acceleration is proposed which depends on the building use (figure 1).

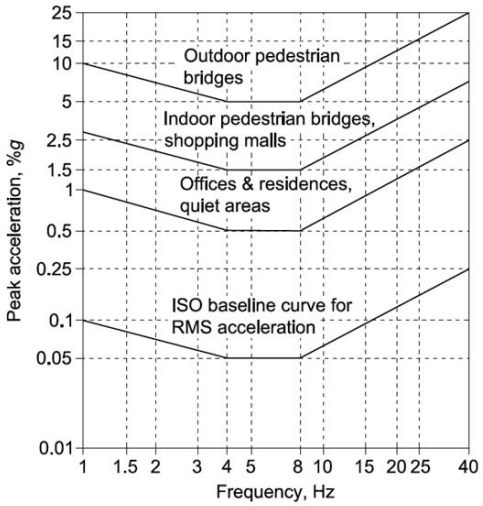

Figure 1: Comfort criterion depending of the frequency and the acceleration of the floor

The Eurocode 5 [2] gives also criteria to assess the comfort of wooden floors. Those criteria are different from ISO ones. This norm focuses on only wooden floors with resonance frequency higher than 8Hz. The other ones have to be evaluated differently. The criteria given are based on the Ohlsson works [4] and depends on the floor velocity due to a theoretical impulsive shock and the floor stiffness. The next edition of the Eurocode will provide criteria for each kind of floors and estimations of the floor acceleration due to the walking of a person. Beyond these norms, a large number of guides exist to design floors regarding vibrations and comfort, including the guide from the American Institute of Steel [3]. This guide gives a method to compute floor acceleration by considering a simplified theoretical model and the average frequency content of load due to walking. This acceleration is confronted to the criteria given by the ISO-10137 [1].

In Europe, HIVOSS guidelines [5] aims to assess the floor comfort with a method called OS-RMS90 (one step, root mean square) [6] . The maximal RMS response of a floor is given

for 90% of kind of walking. Some similar guidelines exist for footbridges, which are also very sensitive to vibrations [7, 8].

Recently, specific studies on wooden floor show that every physical values (displacement, velocity, acceleration and frequency) can be used to judge the comfort of floors. Hu and Chui [9] suggest a empiric criterion based on the ratio between the floor displacement and its frequency. Several kinds of criteria have been reviewed and used on CLT (Cross Laminated Timber) by Weckendorf [10]. Patricia Hamm [11] puts forward that the floor frequency is not a discriminatory factor to provide comfort because some high frequencies floor are evaluated uncomfortable. Then, in 2018, a research group has summarized experimental tests on floors in order to determine an ISO criterion [12]. No consensus has actually been built up on a comfort threshold but in order to be able to use a comfort criterion, the dynamic behavior of timber floors must be well known. Few studies estimate accurately the resonance frequency of timber floors considering their boundaries conditions and orthotropy. Then, Eurocode 5 gives a formula to compute acceleration of a low frequency floor. However, a formula for high frequency floor is missing.

1.3 Objectives and methodology

The purpose of this paper is to define a simplified methodology which can be used by professionals or design department to assess the vibration levels on floors due to human activities. The physical values obtained will have to be compared to a comfort criterion. The assessment of vibration levels requires to identify the floor dynamic properties. First, the frequency of the first floor mode is computed, taking into account wood specificities. Then, according to the properties of the walker (weight, walking frequency), the floor acceleration is determine under theoretical assumptions for low and high frequency floors.

2 Modal frequencies assessment

The knowledge of the floor dynamical properties is necessary to assess its dynamical response due to human activities, like resonance frequency and modal mass. The first frequency mode of wooden floors can be difficult to estimate because of the wood orthotropy and boundary conditions. A method is suggested introducing some scalars deduced from analytical and numerical studies in order to take into account specificities of wooden floors.

2.1 Basic formulas

Leissa has analyzed the vibrational response of rectangular plates with different boundary conditions [13]. In civil engineering, two combinations of boundary conditions occur frequently : two opposite simply supported sides and two free side (SS-F-SS-F) or four simply supported sides (SS-SS-SS-SS). In situ experiments show that boundary conditions on the sides of floors are more likely simply supported than clamped conditions, but it exists a rotational stiffness which will be discussed further.

The formula for the (SS-SS-SS-SS) boundary conditions can be determined analytically [13] :

$$f_{1_{4SS}} = \frac{\pi}{2a^2}\sqrt{\frac{D}{\rho h}}(1+(\frac{a}{b})^2) \tag{1}$$

$f_{1_{4SS}}$ is the resonance frequency of the first mode in the (SS-SS-SS-SS) condition. $D = Eh^3/12(1-\nu^2)$ is the flexural rigidity, E is Young modulus, h is plate thickness, ν is Poisson's

ratio, ρ is mass density per volume, a and b are respectively the largest and smallest dimensions of the studied rectangular floor.

For the (SS-F-SS-F) conditions, the solution has to be estimated from an analytical equation [13]:

$$\begin{aligned} f_{1_{2SS-2F}} &= \frac{C}{2\pi a^2}\sqrt{\frac{D}{\rho h}} \\ C &= 0.051(\frac{a}{b})^2 - 0.28\frac{a}{b} + 9.86 \end{aligned} \tag{2}$$

The equations 1 and 2 are standard results for an isotropic plates with ideal boundary conditions. It is the reference frequency f_{ref} for the rest of the computation. The first step is to homogenize the wooden floor and find the equivalent plate. In most cases, wooden floors are strongly orthotropic. The mechanical parameters in the stiffest direction are the only ones considered in the previous formulas. The effect of orthotropy will be considered further.Then, three coefficients will be added to take into account the wood specificities :

$$f_1 = R_c R_\lambda R_F f_{ref} \tag{3}$$

f_1 is the 'real' frequency of the floor. R_c represents the effect of a continuous floor on several supports on the resonance frequency. R_λ represents the effect of orthotropy. This coefficient is always inferior or equal to 1. R_F describes the effect of the added torsional stiffness due to the load at the extremities of the floor. This coefficient is always superior or equal to 1.

2.2 Orthotropy

Several authors have worked on the vibration properties of orthotropic plates [14, 15]. The Jayaraman results [16] have been used in this paper. For several set of boundary conditions with at least two parallel sides simply supported, it is possible to find complex relationship between the resonance frequencies and the flexural rigidity D_x and D_y (describing respectively the flexural rigidity on the strongest and the weakest direction).

A numerical resolution has been realized for several ratio of orthotropy D_x/D_y, and ratios of floor dimensions a/b. The first observation is that for a (SS-F-SS-F) configuration, the orthotropy has a minor influence on the resonance frequency value : the frequency decreases just by 2% for $a/b = 2$ and $D_x/D_y = 20$. Difference are larger for the following modes. For a (SS-SS-SS-SS) configuration, the impact of orthotropy is major. For the same conditions ($a/b = 2$ and $D_x/D_y = 20$), the frequency falls by 39%.

A statistical resolution has been made to establish the factor R_λ. For a (SS-F-SS-F) configuration, it is possible to consider $R_\lambda = 1$ whereas for a (SS-SS-SS-SS) configuration, R_λ is expressed as followed

$$R_\lambda = 1 - (1 - e^{-0.4\frac{D_x}{D_y}} + 0.4)(0.25\frac{a}{b} - 0.021(\frac{a}{b})^2) \tag{4}$$

2.3 Continuous floors

Floors are usually supported on more than two supports. The continuity of the floor can influence its dynamic behavior. In short, the frequency of a span of continuous floor is higher

than its isostatic equivalent if the neighboring span are shorter and inversely. Then, if one of the support can not be considered as rigid (like a wood joist assembly), it has to be considered in the computation by considering a spring instead of a rigid support. Two situations are presented in this paper.

- **One span floor supported by a rigid support and by a spring**.

Figure 2: One span floor

The spring stiffness can be estimated with the average stiffness of a beam resting on two flat supports separated by a length of L.

$$k = \frac{120EI}{L^3} \tag{5}$$

Thanks to numerical computations, it is possible to compute the ratio R_c which linked the frequency of the beam on rigid support and spring with the frequency of a beam on two rigid supports (figure 3).

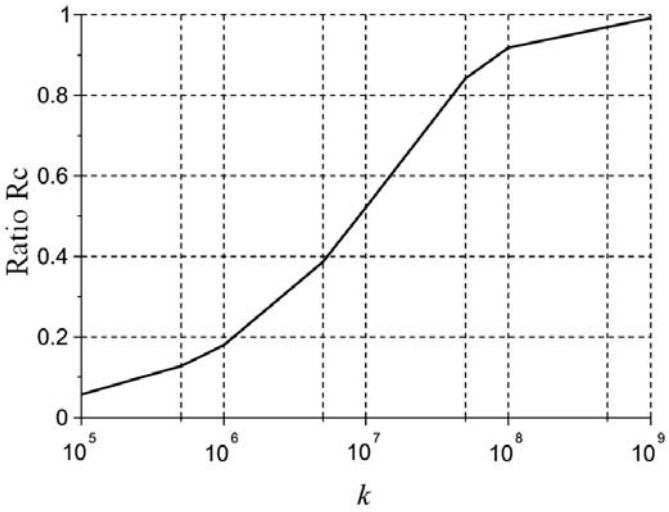

Figure 3: Impact of the spring stiffness on the reatio R_c for a one span floor supported by a rigid support and a spring

The ratio R_c drops when the spring stiffness decreases and moves toward 1 when stiffness increases.

- **Two-spans floor supported on two rigid support and one spring**

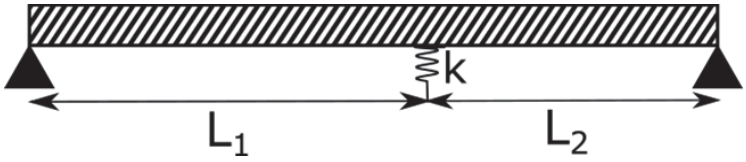

Figure 4: Two spans floor

This configuration is very usual when a floor is supported by two walls at its extremities and a wood joist (figure 4). Considering the first span of length L_1, the ratio R_c corresponds to the resonance frequency of this span divided by the resonance frequency of a equivalent isostatic span with the same length supported on two rigid support. Results are given in figure 5.

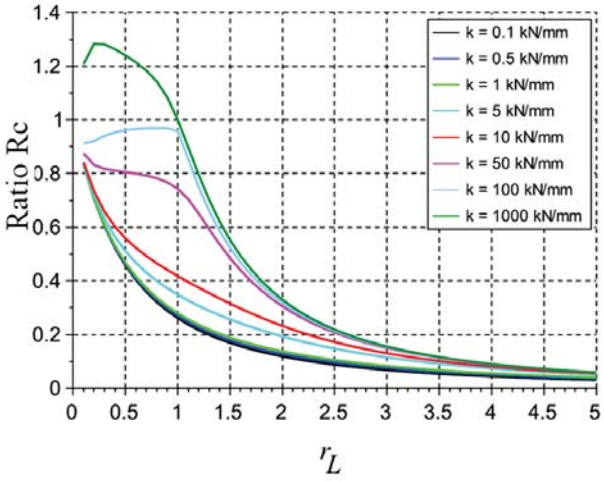

Figure 5: Impact of k and r_L on the ratio R_c for a two spans floor with a spring support in the middle

The ratio R_c will be dependent of the stiffness of the joist, symbolized by a spring and the ratio between the length of the span $r_L = L_2/L_1$. When the stiffness of the spring is very high, $R_c > 1$ for $r_L < 1$ and $R_c < 1$ for $r_L > 1$. It illustrates the fact that a short span next to a large span increases the rigidity of the large span. Then, when spans have the same length, the ratio R_c is equal to one. When the stiffness of the spring decreases, the ratio R_c drops regardless of the r_L value. When the spring stiffness is very low, the continuous floor can be considered as an isostatic floor with a length $L = L_1 + L_2$.

2.4 Wall effect

Loads are often applied on the sides of the floor which can increase its rotational stiffness, and so increase its natural frequency. Experiments have been realized at the FCBA technological institute: natural floor frequency have been measured on CLT or joist-OSB floor while applying an increasing force at their extremities. When the clamping force increases, the floor resonance frequency increases until a threshold. This phenomenon is complex. When a clamped force is imposed on the floor, a rotational stiffness is added but locally, the floor 'crushes' a little in the wall axis. (see figure 6).

This phenomenon depends on several parameters : the ratio a/b, the wall thickness of the

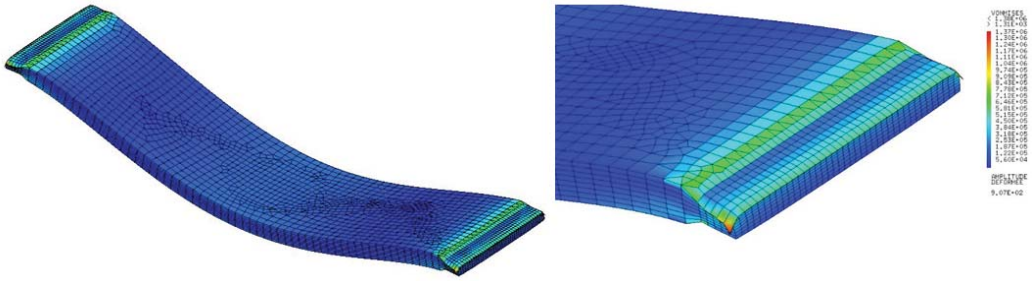

Figure 6: Deflection of a CLT beam with a clamped force at its extremities. The deflection is amplified by 100

wall hw, the floor thickness h, the floor length L, the Young modulus in the direction of the wall load E_z and the force F applied by the wall. A numerical statistical study with finite elements has been made to determine the frequency of a (SS-SS-SS-SS) floor with wall load at its extremity and leads to the following R_F expression.

$$\begin{aligned} R_F &= \sqrt{\frac{1}{\alpha F.10^{-4}}} \text{ if } R_F < \sqrt{\frac{1}{\beta}} \\ R_F &= \sqrt{\frac{1}{\beta}} \end{aligned} \tag{6}$$

with

$$\begin{aligned} \alpha &= (0.87(\frac{a}{b})^{-0.7}(-0.44L+3)\frac{9.2x10^{-2}}{h}\frac{5hw-8.7x10^{-2}}{0.6} \\ \beta &= 0.74((\frac{a}{b})^{-0.2}L^{-0.5}(2h+0.2)hw^{-0.4}E_z^{-0.09} \end{aligned} \tag{7}$$

Several parameters are involved in this phenomenon. In pratical terms, it will be difficult to assess precisely these values. Furthermore, even if the wall load can affect the floor frequency, this effect seems limited as illustrated by in situ measures in a building [17]. Our recommendation is to consider $R_F = 1$. The real frequency should be a little be higher than the calculated one.

2.5 Modal mass

The modal mass can be computed with the following formula [18] :

$$M_{mod} = \frac{M}{ab}\int_S \delta^2(x,y)dS \tag{8}$$

with M the floor total mass and δ the floor modal displacement. In case of isostatic floors with rectangular shapes, it is possible to compute easily the modal mass of the first mode :

$$\begin{aligned} M_{mod} &= \frac{M}{2} \text{ in the SS-F-SS-F configuration} \\ M_{mod} &= \frac{M}{4}(2-\frac{a}{b}) \text{ in the SS-SS-SS-SS configuration} \end{aligned} \tag{9}$$

In case of complex floor shapes, continuous floors or stiff partition, the modal mass can be strongly altered and more often its value will be lower that the one predicted by equation 9.

3 Acceleration on floor due to walking

3.1 Footstep model

A simplified model is considered to represent the floor first mode (figure 7). The mass M is equal to the modal mass M_{mod} of the first mode and the stiffness $K = \omega_1^2 M$ with the first resonance pulse $\omega_1 = 2\pi f_1$.

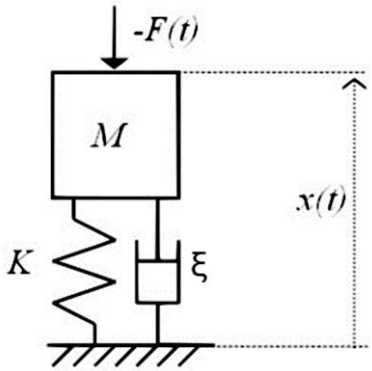

Figure 7: Spring-dashpot system

The HIVOSS guide [5] proposes to model the force load due to a footstep as below:

$$\frac{F(t)}{Q} = \sum_{i=1}^{8} K_i t^i \tag{10}$$

With $F(t)$ the footstep load, Q the weight of the walker in Newton and K_i a parameter defined in [5]. With this formulation, the ratio $F(t)/Q$ is given on the figure 8.

The AISC guide [3] formulates a series of footstep load with the following formula :

$$F(t) = \sum_{i=1}^{4} Q\alpha_i sin(i\omega_1 t) \tag{11}$$

With α_i a parameters different for the walking frequency and its harmonics. For the walk, Murray gives the values of α_i : $\alpha_1 = 0.4, \alpha_2 = 0.07, \alpha_3 = 0.06, \alpha_4 = 0.05$. The decrease of the parameters α_i broadly follows the function $\alpha(f) = e^{-0.4f}$.

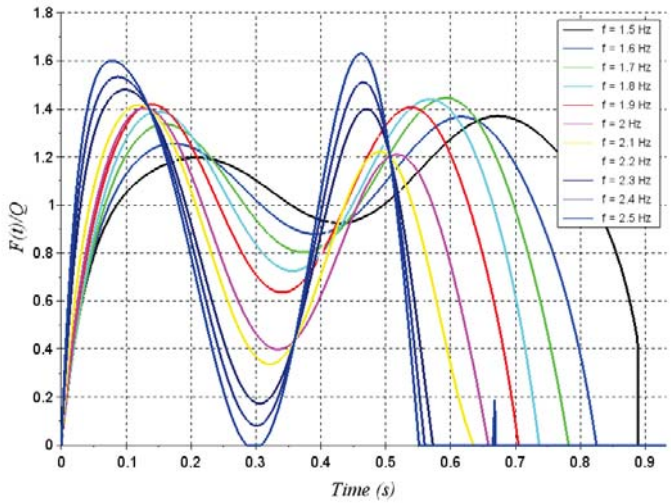

Figure 8: Ratio $F(t)/Q$ for different walking frequencies. The first peak correspond to the load produced by the heels and the second to the load induced by the toes

3.2 Low frequency floor

The next version of Eurocode 5 proposes a formula to compute the acceleration of a low frequency floor subjected to walking loads. Several assumptions are made :

- Only the first mode is considered, the floor is reduced to a simple spring-dashpot system as presented on figure 7.
- The main acceleration is due to the floor solicitation at its resonance frequency. The effect of the other frequencies are neglected.

Under these assumptions, the system acceleration for a walking load can be written :

$$a_{Lf} = \frac{\alpha(f_1)Q}{2\xi\sqrt{2}M_{mod}} \tag{12}$$

ξ is the first modal damping of the floor. $Q/(2\xi M_{mod})$ is the response of a spring damping system to a harmonic oscillation with an amplitude Q at its resonance frequency. α is the amplitude of the footsteps signal at the floor resonance frequency and is equal to $\alpha(f_1) = e^{-0.4f_1}$. The factor $1/\sqrt{2}$ takes into account the responsiveness of the walker to the effective acceleration. The expression is multiplied by a factor 0.4 in Eurocode to take into account that the walker is rarely in the center of the floor span. The factor has not be used here.

3.3 High frequency floor

For an high-frequency floor, the second EUROCODE 5 assumption which was previously presented is invalid. The load at the resonance frequency of the floor is marginal, but the effect of the other frequency of the load can not be neglected. In fact, the load can be considered as quasi-static regarding to the floor resonance frequencies and the floor accelerations are then induced by the floor free vibrations.

By using the formulation of the footstep load proposed by HIVOSS (equation 10), it is possible to determine the maximal load during a walk F_{max}.

$$F_{max} = Q(0.5 f_{step} + 1.5) \tag{13}$$

With f_{step} the frequency of the footstep load.

By considering the simplified spring-dashpot system and a quasi-static response of the system during the load increase, the displacement of the mass can be written :

$$\Delta u = \frac{F_{max}}{K} \tag{14}$$

Then, at the end of the load increase, the system freely oscillates and the mass acceleration is equal to :

$$a = -\frac{F_{max}}{K}\omega_1^2 cos(\omega_1 t) e^{-\xi\omega_1 t} = -\frac{F_{max}}{M_{mod}} cos(\omega_1 t) e^{-\xi\omega_1 t} \tag{15}$$

Generally, persons have a walking frequency inferior to $2.3Hz$. A conservative simplification can be made by considering $F_{max}/Q = 2.4$.

The ISO 2631-1 norm [20] proposes to compute the effective acceleration as the maximal RMS value of 1s of the signal, to take into account the load variability. To obtain the effective acceleration on 1s of a sinus which decreases exponentially, the maximal acceleration have to be multiplied by a factor :

$$V_{eff} = \frac{1}{2}\sqrt{\frac{((2\xi^2+1)e^{2\xi\omega_1} - 1)e^{-2\xi\omega_1}}{\omega_1\xi^3 + \omega_1\xi}} \tag{16}$$

By the way, the maximal effective acceleration for a high frequency floor can be written :

$$a_{Hf} = F_{max} V_{eff} \frac{Q}{M_{mod}} \tag{17}$$

3.4 Validation

The equations 12 and 17 can be used to determine the acceleration due to a walker whatever the floor resonance frequencies. The expression 12 should be used when the frequency of the floor is under 8Hz, otherwise the expression 17 is more appropriate.

The formula 10 has been used to create a representative load of ten footsteps with a footstep frequency of 2Hz. The dynamic response of a spring-dashpot system to this load has been computed for different values of system frequency and for a damping of 2%. The maximum of acceleration computed during the test is confronted with formulas 12 and 17 (figure 9).

In this theoretical example, these formulas allow to conservatively predict system maximal effective acceleration. They have also been confronted to experimental tests.

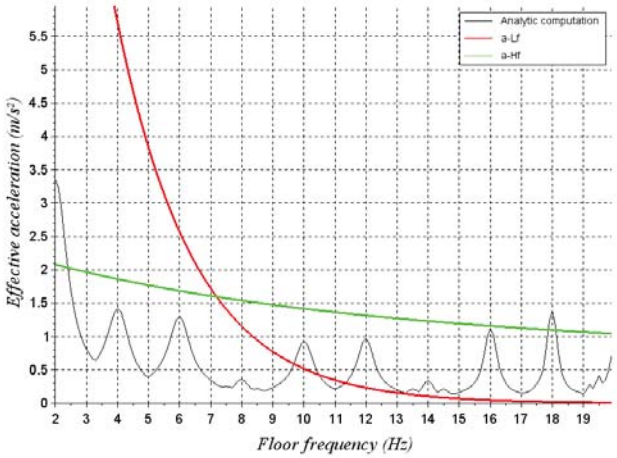

Figure 9: Comparison between accelerations predicted by equations 12 and 17 and the maximal effective acceleration of a spring-dashpot systems with different resonance frequencies subjected to a sequel of ten footsteps with $f_{step} = 2Hz$

Figure 10: Test floors : Joist-OSB floor (left) and CLT floor (right)

4 Experimental and numerical analysis

4.1 Presentation of the experiments

Two floors have been designed and tested, a squared joist-OSB floor and a squared CLT floor of 4.5 metres in length (figure 10). They have been nailed to a piece of wood to ensure a simply supported condition at two of their extremities in order to be in a (SS-F-SS-F) configuration.

Experimental modal analysis have been done on test floors. With a grid of accelerometers and a CMIF (complex mode indicator function), the mode shapes and the mode frequencies have been identified. The most important modes have been discriminated by using an AutoMAC [19]. The two floors are high frequency floors with a resonance frequency of 17.5Hz for the joist-OSB floor and 13.8Hz for the CLT floor.

Walking experiments have been done on each of the test floors. Around 30 persons have walked along the center span of the floors with several accelerometers located on the displacements peaks of the first five modes (figure 11).

The weights, the average step frequencies and the kind of shoes of each person participating to the experiments have been recorded. The floor maximal effective acceleration during the test

Figure 11: People walking on instrumented test floor

has been computed with the method recommended by ISO 2631-1 norm [20] for a transient solicitation:

$$a_{RMS}(t_0) = \sqrt{\frac{1}{T}\int_{t_0-T}^{t_0} a(t)^2 dt} \tag{18}$$

The effective acceleration is computed for short windows of width $T = 1s$.

4.2 Numerical model

A numerical model using shell or cubic finite elements has been created for each test floors in order to understand phenomena occuring during the walk and to make a sensitivity analysis. The measured parameters (Young's modulus and density) of each joist have been considered. Its accuracy has been estimated by confronting numerical modal analysis and experimental modal analysis. An example is given on figure 12.

The numerical model and the experimental results have a very good correlation on a MAC analysis for the first six modes. Dynamical computations are realized using a footsteps load along the center of the floors span. The system is reduced on the first 30 modes to reduce computation times and then solved with an explicit integration scheme. The HIVOSS footstep load (equation 10) is used with randomly generated mass and frequency chosen through a representative distribution law. The maximal effective acceleration is computed just as the experimental tests, with the equation 18.

4.3 Campaign results and interpretation

The effective acceleration identified experimentally and computed numericaly can be plotted according to different factors. The most relevant ones seem to be the weight of the walkers and their walking frequencies (figure 13 and 14).

Results are similar for CLT floor. The numerical and the experimental results have the same order of magnitude (figures 13 and 14). Numerical results are broadly superior to experimental

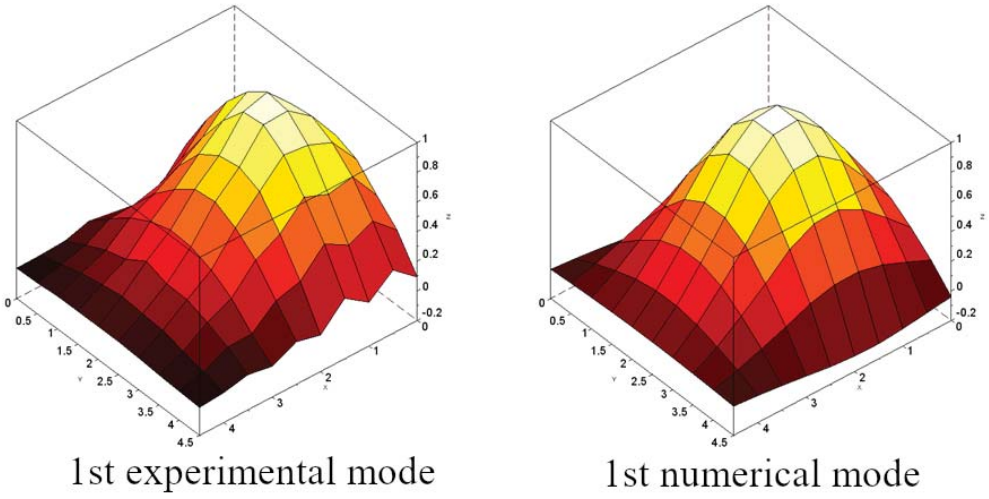

Figure 12: First mode computed numerically and identified experimentally for the joist-OSB floor

ones. It can be explained by the fact that, in the numerical model, the footsteps are very regular with a constant walking frequency whereas during experimental test, the walking frequency varied slightly which induced a lower impact of the harmonics of walking frequency. With the numerical model, the effective acceleration increases with the weight of the walker (figure 13). The uncertainties are greater experimentally and it is difficult to extract a tendency. The same observation can be made by confronting the effective acceleration with the walking frequency (figure 14).

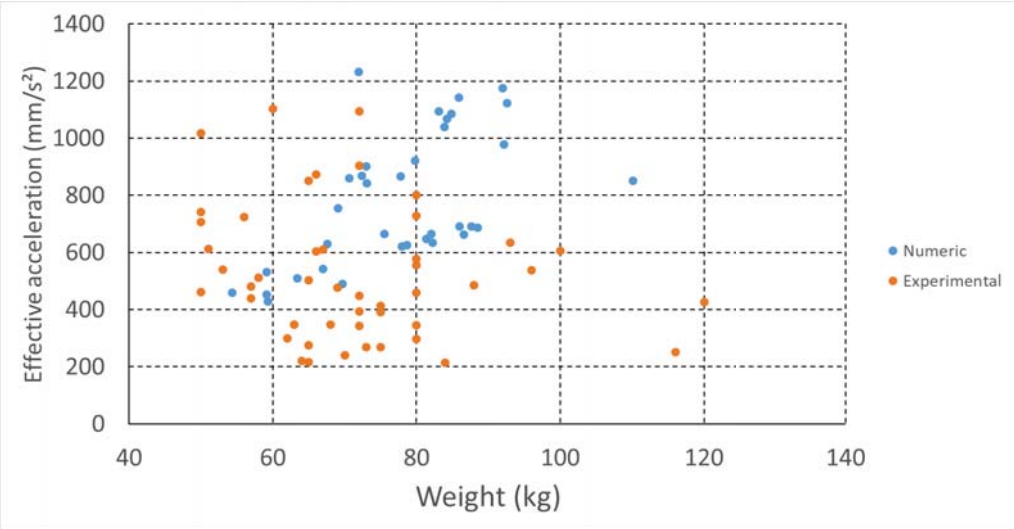

Figure 13: Maximal effective acceleration depending on the weights of the walkers on the joist-OSB floor

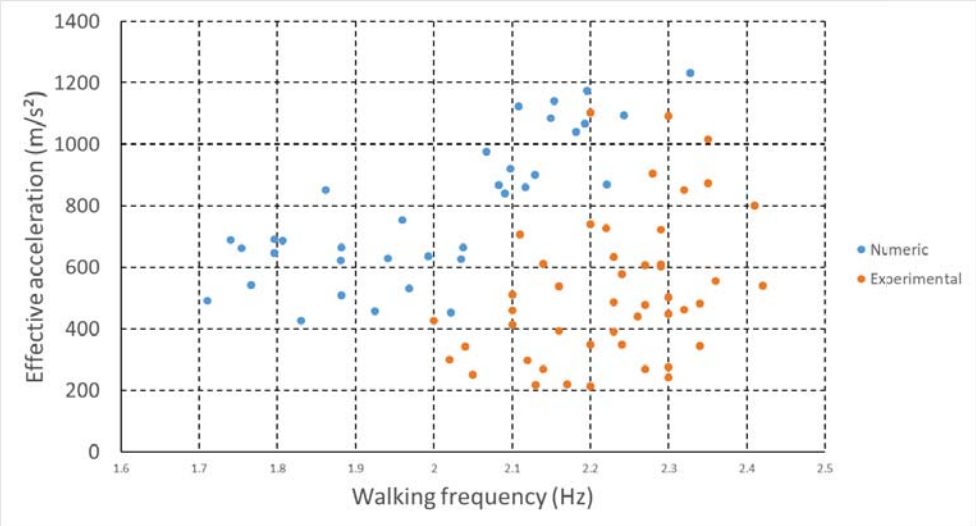

Figure 14: Maximal effective acceleration depending on the walking frequency of the walkers on the joist-OSB floor

4.4 Confrontation to simplified computation

The equation 17 enables a conservative estimation of the acceleration due to the walk of an individual. This formula has been confronted to experimental results. Figure 15 gives an example of results for a 80kg person walking on the joist-OSB floor.

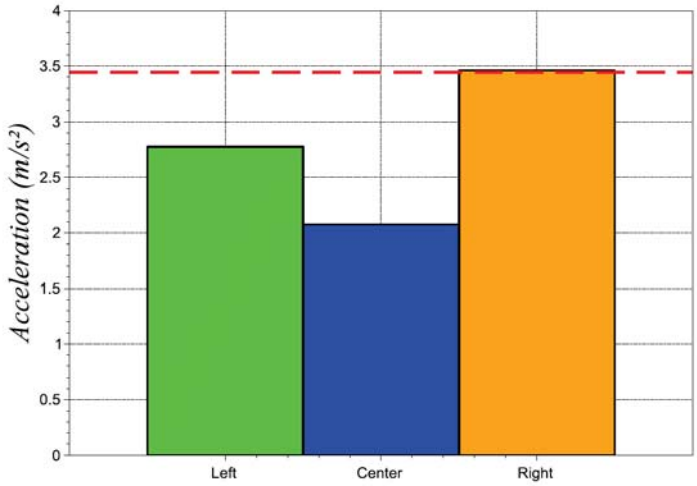

Figure 15: Maximal acceleration measured during the walk by 3 accelerometer on each side of the floor. The dashed line in red correspond to the maximal acceleration predicted by the formula 17

Note that in this figure, the peak of acceleration is considered, so the coefficient V_{eff} of the equation 17 has not been used. This equation gives an accurate value of the acceleration peak, without overestimating it. Based on all the experiments, a margin coefficient has been created, which links the effective acceleration predicted by the formula 17 with the effective acceleration measured experimentally. Results are given in the form of a boxplot on figure 16.

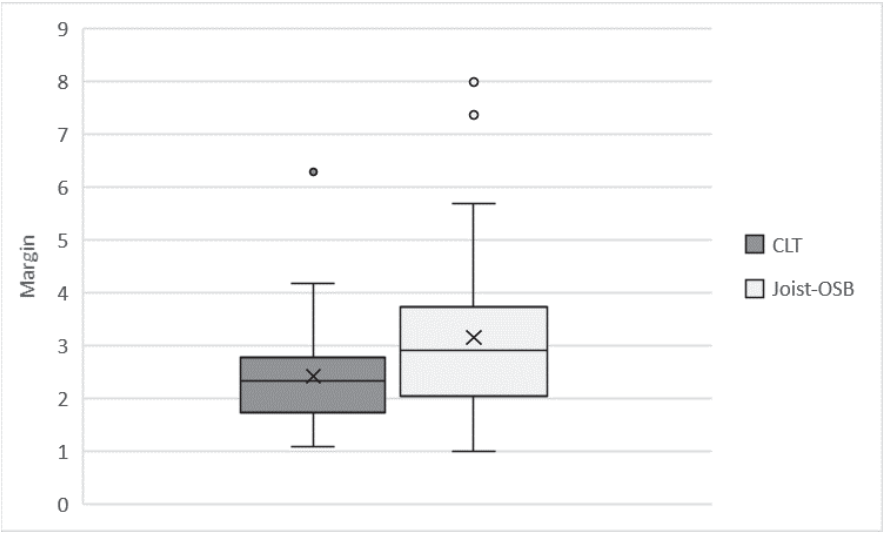

Figure 16: Boxplot of the margin coefficients between simplified formulation and experimental results

The results remain always conservative : the margin coefficient is always superior or very close to 1. On average, the simplified formulation overestimates the floor response, probably because the theory used to build this formula considers an homogeneous floor and a constant walking frequency. By the way, the average coefficient is higher for a joist-OSB floor than for a CLT floor. The joist-OSB floor is very heterogeneous, the joists have different densities and stiffnesses. Moreover, the connections can dissipate some energy. It explains why the joist-OSB floor has a better behavior regarding vibration than the one predicted with the theory.

5 Conclusion

This article presents a new simplified method to compute resonance frequency for a timber floor and its acceleration during walking of an individual. This method is based under theoretical assumptions and numerical computations. The simplified method has been confronted to experimental results on two kind of floors and gives conservative results with a moderate overestimation. This method has to be applied for in situ floors in order to validate its relevance.

Thereafter, the influence of a group of persons on the floor vibrations will be studied, depending on their activities. Then several ways to mitigate floor vibrations, with construction method adjustment or passive system should be conceived. However, one of the most important step is to define criteria to assess the comfort level of timber floors depending on the physical values of the vibration.

Abstract. In recent years, various man-made structures, such as grandstands and footbridges, have shown significant vibration problems during human jumping causing concern for maintenance and serviceability. To understand the interactions observed between a human and a structure, a 5.5m timber beam was constructed and instrumented. This was designed to simulate a cantilever tier of a grandstand, with similar natural frequency and damping ratio to the full-scale structure and with a similar mass ratio of a single human to the beam as for a crowd to the full-scale structure. Measurements of accelerations and displacements of both the jumper and beam, and of the contact force between them, were acquired. Tests for a range of target jumping frequencies, from below to above the structure's natural frequency, were performed to identify the jumper's dynamics and the induced vibrations of the structure and to observe interactions. System identification techniques were performed to evaluate and model the human leg mechanics of a jumper on a vertically oscillating surface. Force-displacement curves, for both relative (jumper to beam) and absolute displacements, have been obtained. The corresponding leg spring stiffness has been evaluated using a linear fit. Variations in the stiffness for different jumping frequencies is discussed.

1 INTRODUCTION

Previous experimentation into human-structure interaction (HSI) during rhythmic jumping and bobbing on a perceptibly moving surface has shown that periodic jumping close to the natural frequency of the structure was not possible [1,2,3]. A simple reduced-order model [4] was presented to provide an explanation for this problematic jumping. The model assumes an approximate linear spring-mass-damper-actuator system, as an approximation, that is included in IStructE guidelines [4] and other literature [5,6]. Unfortunately, the values of the parameters of the system, are uncertain. Furthermore, a frequency-invariant linear model may not be sufficient. In this paper, force-displacement curves, for absolute and relative displacement, are presented to characterise the leg stiffness from direct measurements of force and displacement. This is performed for low-and high jumping frequencies, above and below a structure's natural frequency. A linear polynomial is applied, using regression analysis, to capture and model the leg stiffness. The evaluated coefficients are observed to be frequency-dependent.

2 EXPERIMENTAL MODELLING

To investigate the interactions of a human jumping rhythmically on a perceptibly moving surface a small beam section was constructed. This was assembled to simulate an oscillating cantilever tier of a grandstand structure due to human jumping loads. These have been known to contain low frequency resonant modes in the region of 1-6Hz with low damping ratios as a result of the long, thin slender structures [7]. This makes them susceptible to significant vertical excitation from humans jumping at various jumping frequencies.

2.1 Beam construction & instrumentation

The beam was designed to be cost effective and simple to construct. The main beam span was constructed from five 150mm x 47mm x 5500mm C24 structural timber beams fixed together side-by-side using thirteen 750mm x 20mm x 100mm plywood slats evenly and symmetrically distributed. This is displayed in Figure 1(a) and 1(b). The beam was clamped at both supports, 75mm from the ends. The clamps were formed from scaffolding pipe tubes, 50mm cross-sectional diameter, cut a length of 900mm. This is shown in Figure 1(c). 10mm holes were drilled into the top and bottom to allow secure fastening of the clamps to the beam using M8 threaded rods. The beam was built into a simple scaffolded system to raise it to provide a clearance of 300mm from the underside of the beam to the finished floor level. This was to ensure that the beam would not make contact with the floor during experimentation. An AMTI OR6-7 force-plate was mounted in the centre of the beam. The total mass of the beam was approximately 170kg. Handrails were constructed for safety of the test subjects. The linear natural frequency and damping ratio of the first bending mode were measured as $f_1=1.89Hz$ and ς_1=0.11%.

Direct measurements of displacement and acceleration of the beam were acquired using two Sétra uniaxial accelerometers and reflective motion capture markers. These were positioned either side of the force plate, across the width of the beam section, at mid-span. The generalised beam dynamics were evaluated by averaging the measurements from each pair of sensors, to evaluate a single measurement for acceleration and displacement respectively.

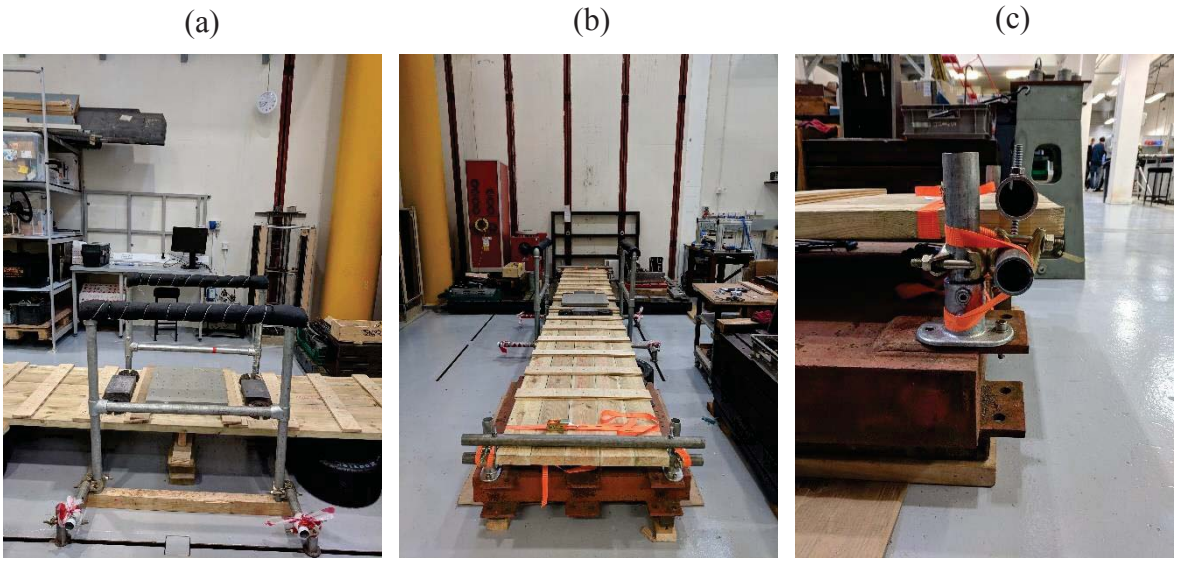

Figure 1 Breakdown of constructed bridge (a) Central jumping zone; (b) Length of bridge; (c) Bridge beam end-fixtures

2.2 Procedure and human instrumentation

Biomechanical jumping experiments on the beam were performed for a single male test subject, age 26, mass 74.5kg, height 189cm, leg length 114cm. The test subject's bodyweight corresponded to a human-structure mass ratio of 0.44. Experimental tests were performed above and below the beam's natural frequency. The test subject was given a two-minute rest between each jumping test to ensure that fatigue or physical exhaustion did not occur. Each test were performed over a 50s window with a rhythmic jumping period of 30s. 20s was allowed for the person to step on and off the beam comfortably. Jumping tests were performed at multiple frequencies above and below the beam's natural frequency, (f_1=1.89Hz):1.25Hz, 1.50Hz, 2.70Hz and 3.00Hz.

A 14-marker body system was adopted for the tracking of the human jumping kinematics using Qualisys motion capture software. Markers were fastened using double-sided medical (hypo-allergenic) tape. The test subject wore fitted gym attire to minimise any soft tissue artefacts. From the marker setup, a nine – segment body model was defined following the procedure illustrated by Winter [8] to locate the human body centre of mass (COM) during the tests. This is common practice within the biomechanics research field.

3 DATA PROCESSING

During acquisition of force plate and accelerometer measurements an anti-aliasing low-pass Butterworth filter with a cut-off frequency of 1400Hz was used. The force plate and accelerometer sensor measurements were down-sampled and decimated to the motion capture system's sampling frequency of 100Hz for data processing and analysis. A fourth order low-pass Butterworth filter with a cut-off frequency of 20Hz was applied to all measurements to mitigate any high-frequency noise effects, whilst still capturing higher harmonic responses. Using the 30s jumping record, for each test, a 20s record was extracted for analysis of displacement, acceleration and force data measurements.

The force plate instrumented on the beam measured the loading induced by a human jumper for each target jumping frequency test performed. To quantify the contact force, the inertial force of the force plate itself was first evaluated from a free vibration test. This provided the

'dynamic mass' of the force plate which was found to be 15.3kg. The contact force of the test subject was evaluated as follows:

$$F_{\mathrm{GRF}} = F_{\mathrm{meas}} - m_{fp}\ddot{x}_b \tag{1}$$

where F_{GRF} is the contact force exerted between the test subject and beam, F_{meas} is the directly measured force from the force plate, m_{fp} is the dynamic mass of the force plate, $\ddot{x}_b$ is the measured acceleration at midspan of the beam.

The three-dimensional coordinates of the subject body COM were calculated as follows:

$$\begin{Bmatrix} x_{\mathrm{COM}} \\ y_{\mathrm{COM}} \\ z_{\mathrm{COM}} \end{Bmatrix} = \frac{1}{m_p} \sum_{i=1}^{N_s} m_{\mathrm{seg},i} \begin{Bmatrix} x_{\mathrm{seg},i} \\ y_{\mathrm{seg},i} \\ z_{\mathrm{seg},i} \end{Bmatrix} \tag{2}$$

where x_{COM}, y_{COM}, and z_{COM} are three-dimensional coordinates of the position of the COM of the subject's body, m_p is the subject's total body mass, N_s is the total number of body segments (nine in this case), i is the segment index, $m_{\mathrm{seg},i}$ is the mass of the i-th segment and $x_{\mathrm{seg},i}$, $y_{\mathrm{seg},i}$, and $z_{\mathrm{seg},i}$ are three-dimensional coordinates of the position of the COM of the i-th segment.

Considerable variability in loading/displacement from cycle to cycle was observed in these jumping tests. This is a direct result of the oscillating surface affecting the jumper to be slightly in or out-of-phase with the beam. One consequence was a difficulty in defining, based on period, the flight and contact phases. In order to distinguish the flight and contact phases of the jump cycle, and to allow for noise on the force measurements, the times of take-off and landing were defined as when the contact force equalled 5% of the bodyweight. Smaller values were zeroed as they were assumed to be during the flight phase.

Figure 2 depicts a time-history breakdown for the test subject's dynamics of a test at their preferred jumping frequency. Figure 2(a) indicates the jumper's body segments and centre-of-mass trajectories, as described in Eq.2. This is detailed as grey and black respectively. Figure 2(b) shows the processed contact force to distinguish clear contact and flight phases, normalised to the person's bodyweight. Figure 2(c) displays the beam mid-span displacement. The positive sign convention for the jumper COM and beam displacements are defined as the downward displacement corresponding to a positive contact force indicating compression. The reference (zero) displacement for the jumper is defined as the static COM displacement. These measurements are processed further into overlaid cycle-by-cycle time-histories to signify the jumper's variability performing rhythmic jumping on the oscillating beam, as shown in Figure 3.

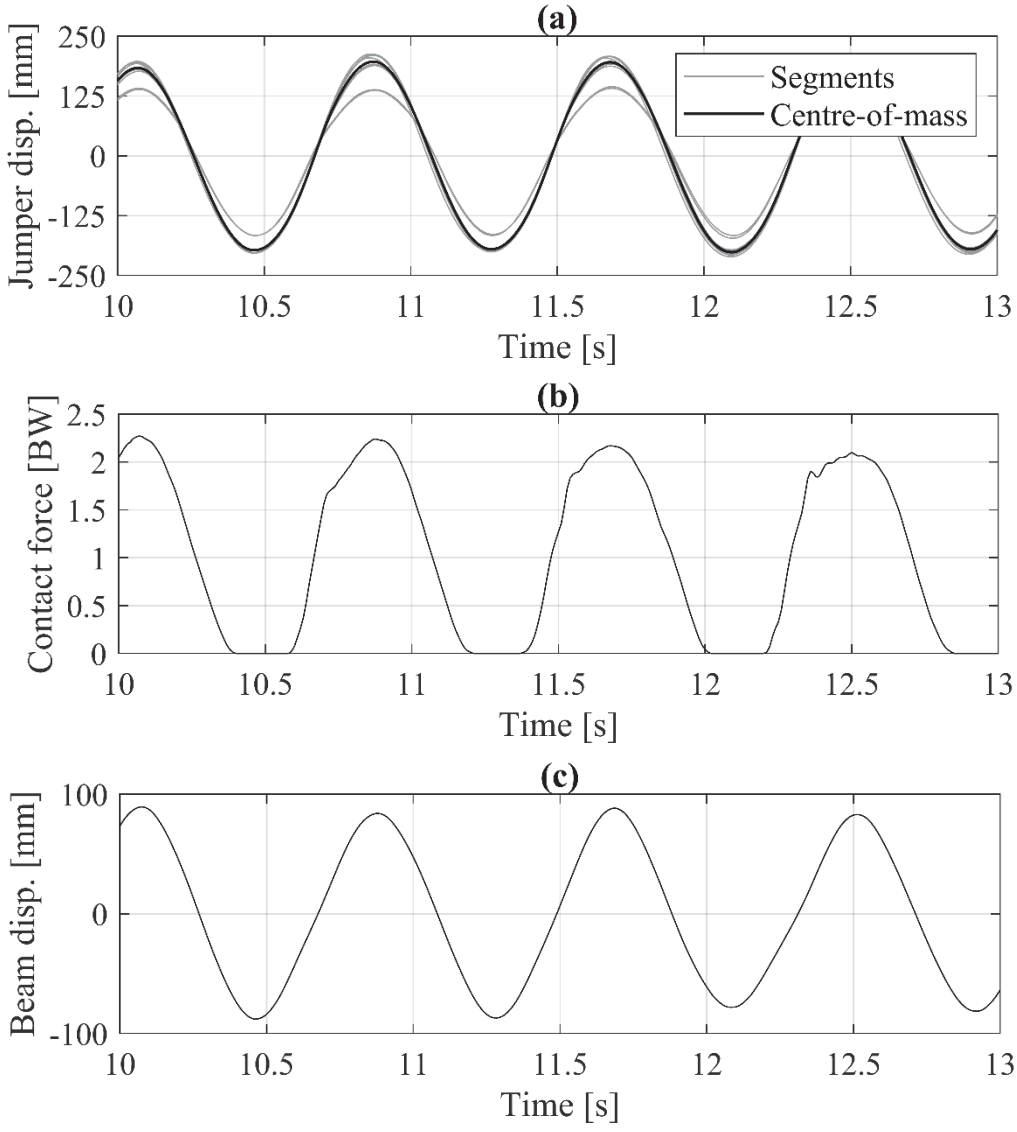

Figure 2 Example time-histories of test subject's dynamics jumping at their preferred frequency (a) jumper COM (grey indicates the defined body segment trajectories and black indicates the evaluated centre-of-mass); (b) Contact force; (c) Beam mid-span displacement

Figure 3 displays the time-histories of the contact force (a), relative displacement (b), jumper to bridge, jumper COM displacement (c) and beam displacement (d) for a test at the test subject's preferred jumping frequency. The relative displacement is defined as the jumper COM to bridge displacement. The mean achieved jumping frequency for this test was found to be 1.26 ± 0.05Hz. A jumping cycle is characterised by the contact and flight phases. These are indicated in Figure 3 as a comparative measure of the time spent and response shape for each phase. The dashed grey lines indicate approximate contact and flight phases. For this specific test, the contact phase is observed to be the majority of the period of oscillation and displays significant deflection of both the jumper and beam resulting in a large relative displacement (leg compression).

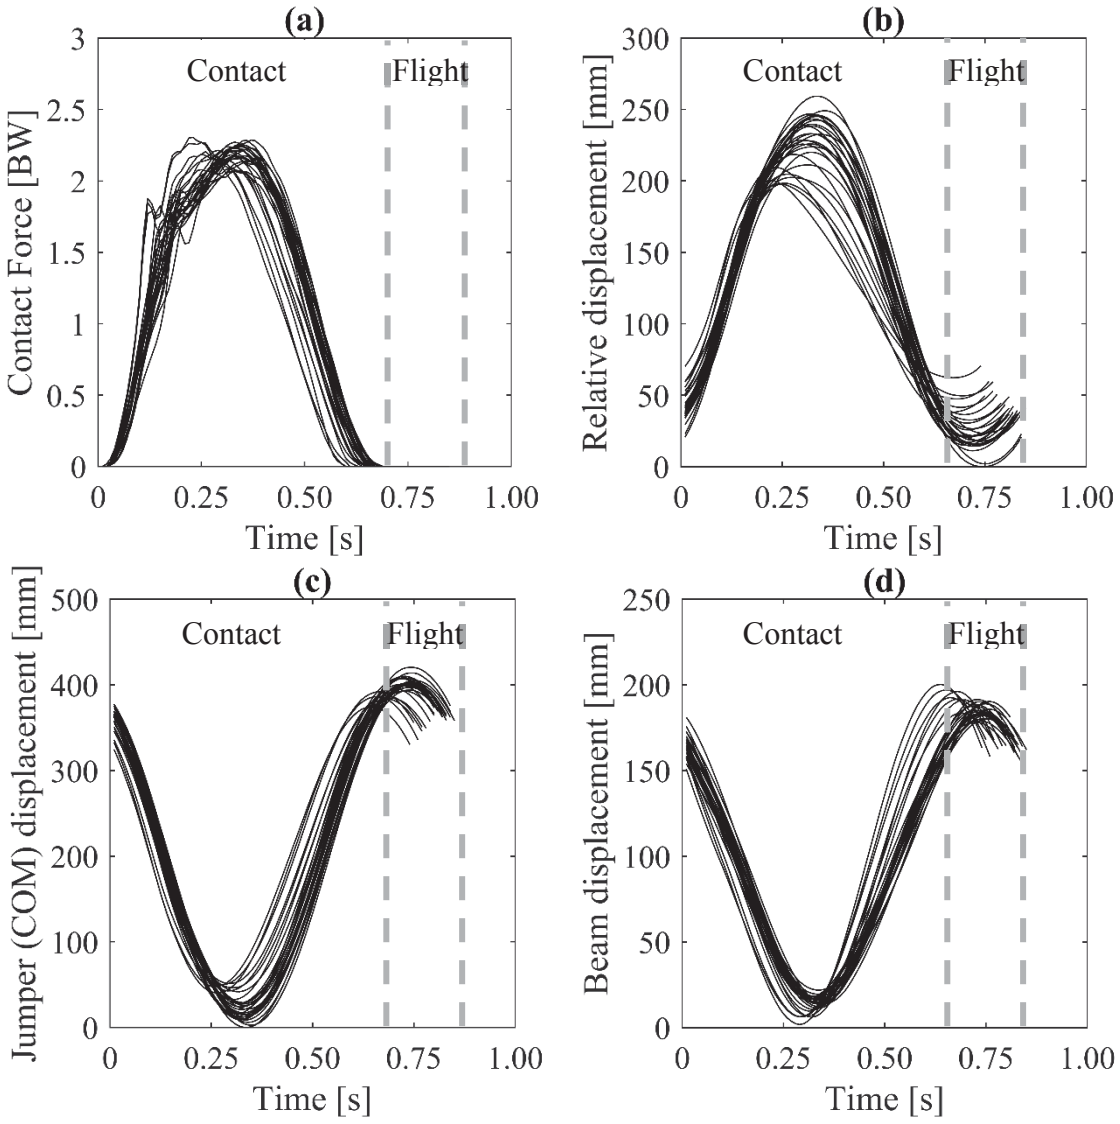

Figure 3 Example time-histories of test subject jumping at their preferred frequency, mean 1.26Hz (a) Contact force; (b) Relative displacement; (c) Jumper centre-of-mass displacement; (d) Beam centre-of-mass displacement

Table 1 summarises the dynamics observed during jumping tests above and below the structure's natural frequency. These are evaluated as the mean peak values observed for each test case. The peak contact force is normalised to the test subject's bodyweight, BW.

Jumping frequency [Hz]	Displacement (mm)			Beam acceleration (m/s^2)	Peak contact force (BW)
	Jumper centre-of-mass	Beam	Relative		
1.26	216	106	125.42	9.56	2.36
1.50	172	151	321.25	14.21	2.91
2.70	105	55.8	137	12.7	3.00
3.00	52.9	37.8	91.9	13.97	3.05

Table 1 Summary of mean peak values of dynamics measured for jumping frequency test cases above and below the structure's natural frequency (f_1=1.89Hz)

4 FORCE-DISPLACEMENT CURVES

Force-displacement curves for the coupled oscillating jumper and beam system have been plotted for the absolute (jumper's COM) and relative displacement (jumper to bridge). This is performed as a comparison to explore the leg stiffness effects for each case to understand the underlying interactions.

The compressing and extending stages of the contact phase were identified for each jumping test case to examine the loading and unloading relationships. These are overlaid in Figures 4 and 5. The red dots denote compressing, whilst blue indicates extending. This was important to understand any subtle changes in the leg stiffness during each stage of the contact phase. In order to distinguish the compressing and extending stages during the contact phase, the velocity was evaluated, for each displacement measurement, to identify the loading conditions. To be consistent with the positive sign convention of downward displacement, corresponding to a positive contact force, compressing was defined as positive velocity, whilst extending was defined as negative velocity.

A simple linear relationship, Eq.(5), was applied to each jumping test case, for both displacements, to characterise the leg stiffness profile during the compression and extension stages of the contact phase.

$$F_{GRF} = kZ \tag{3}$$

Where k is the linear stiffness coefficient of Eq.(5) and Z is the displacement of interest (absolute or relative). These were found using regression analysis.

4.1 Relative displacement

Figure 4 displays the force-displacement curves for jumping at 1.25Hz, 1.50Hz, 2.70Hz and 3.00Hz, using the measured relative displacement. Below the structure's natural frequency (f_1=1.89Hz), the 1.25Hz and 1.50Hz test cases indicate large relative displacements with similar contact forces. The shapes are observed as being approximately linear with the compressing and extending stages following very similar paths indicating similar stiffness. For the 1.50Hz test case, the compressing stage of the cycle is seen to be considerably variable. Table 1 indicates that the beam displacement amplitude is largest at the 1.50Hz which could be due to a jumping frequency near resonance.

Above the structure's natural frequency, the 2.70Hz and 3.00Hz cases indicate less deflection (approximately 200mm max displacement corresponding to 2kN of force, 2.36BW). Interestingly, both curves of these test cases display hysteresis loops indicating that the energy exchanged during the leg compression and extension is significantly different. The stiffness

profiles during each stage of contact are observed to be considerably different suggesting a larger stiffness spring during compression in comparison to extension.

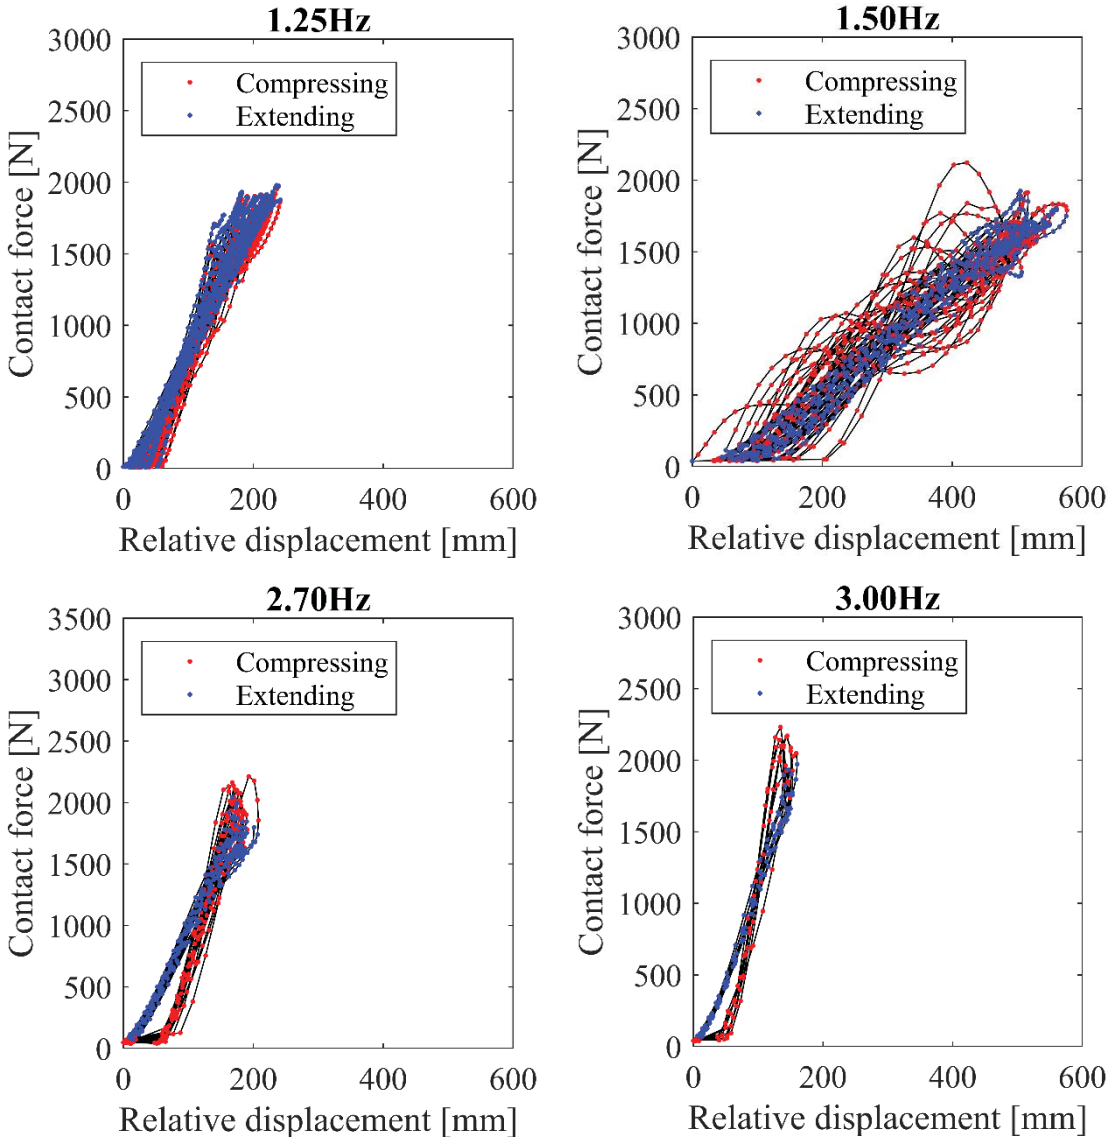

Figure 4 Contact force - relative displacement relationships for jumping frequencies above and below the structure's natural frequency (f_1=1.89Hz). Red dots denote compression, whilst blue indicates extension.

4.2 Absolute displacement

Figure 5 displays the force-displacement curves for jumping at 1.25Hz, 1.50Hz, 2.70Hz and 3.00Hz, using the measured jumper's COM displacement. Below the structure's natural frequency (f_1=1.89Hz), the jumper's COM observes large displacements, approximately 300mm max deflections corresponding to 2kN of force (a bodyweight factor of 2.36). The 1.25Hz test case shows a clear linear trend with the compressing and extending stages following very similar paths. The 1.50Hz jumping is rather variable, particularly during compression, suggesting the test subject found this frequency difficult to periodically jump at. The extension is observed to be clearly linear.

The force-displacement relationship, for the absolute displacement at 2.70Hz jumping, is observed to be linear. The evaluation of the compressing and extending stages, of the contact phase, indicates slightly different leg stiffnesses. This suggests tentative evidence of a hysteresis loop like the relative displacement case. At 3.00Hz, the force-displacement curve observes a subtle hysteresis loop, mirroring the effects of the relative displacement case. The compressing and extending stages follow distinctly different paths corresponding to distinctive stiffness profiles. The relationship during extension is observed to be linear in comparison to compression which is clearly complex in nature.

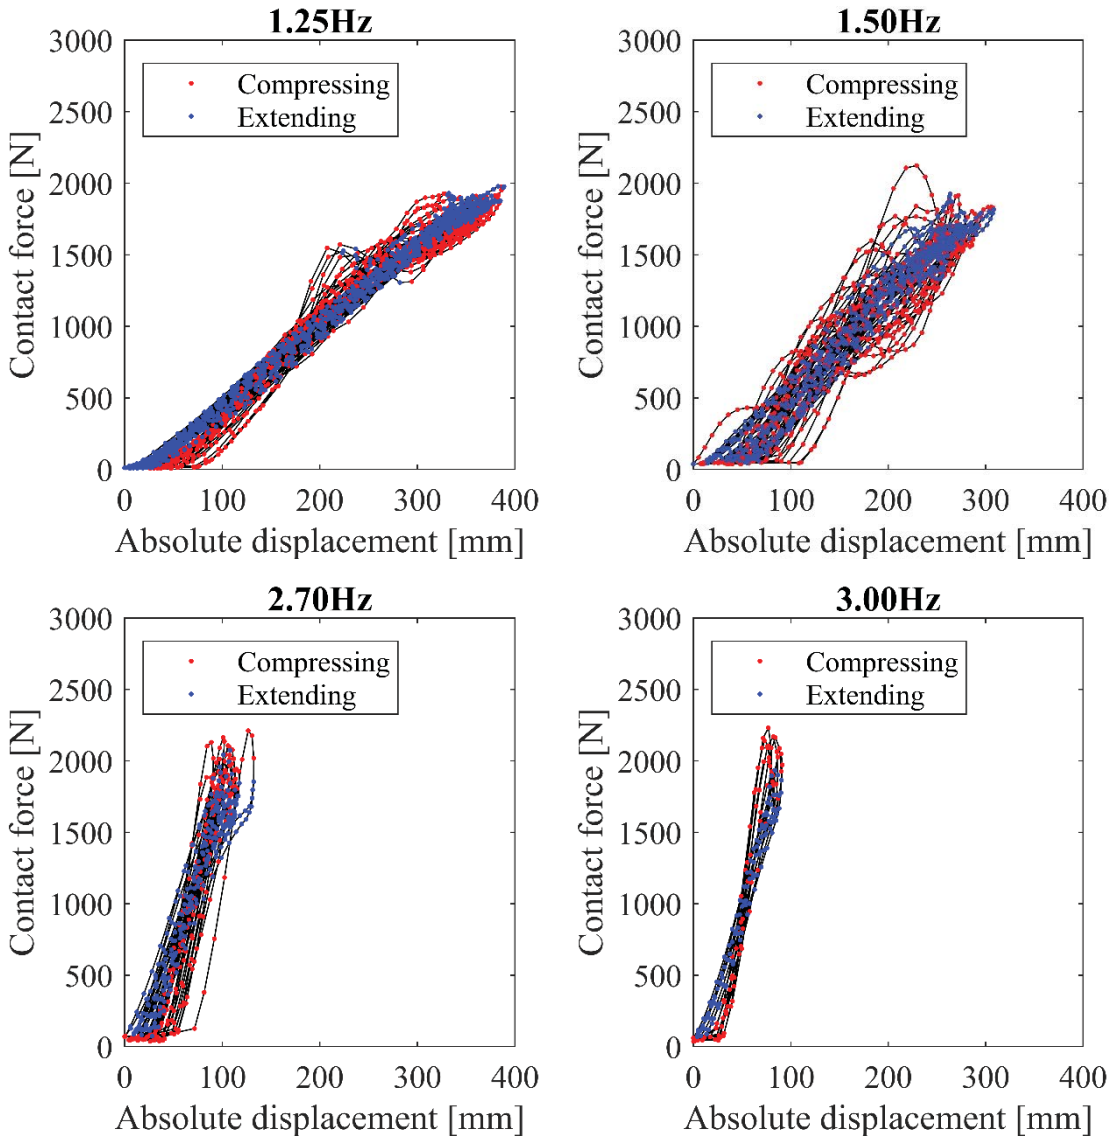

Figure 5 Contact force - absolute displacement relationships for jumping frequencies above and below the structure's natural frequency (f_1=1.89Hz). Red dots denote compression, blue dots indicate extension.

5 LEG STIFFNESS

Figure 6 displays the frequency-dependency of the linear fits. The compression stiffness coefficients are indicated as red crosses whilst the extension stiffness coefficients are presented as blue circles. The leg stiffness coefficients, displayed in Figure 6, are computed using the calculated stiffness coefficients, in Figures 4 and 5, divided by the test subject's body mass. The stiffness coefficients evaluated from the relative and absolute displacements are represented in Figure 6(a) and 6(b) respectively. In Figure 6(a), the compressing and extending stiffness are seen to increase at high frequency jumping whilst the stiffness indicates a decrease from 1.25Hz to 1.50Hz. The rates of increase for the stiffness coefficients are suggestive of being non-linear. Figure 6(b) displays an increase in stiffness from 1.25Hz to 1.50Hz followed by an increase in 2.70Hz to 3.00Hz. The compressing stiffness at these frequencies increase significantly in comparison to the extending stiffness. At low jumping frequencies, the stiffness coefficients for the two stages, obtained for both absolute and relative displacement, are approximately the same in value. Above the structure's natural frequency (f_1=1.89Hz), the compressing and extending stiffness coefficients are observed to differ considerably indicating a complex stiffness mechanism of the leg. This is more evident in the case of the absolute displacement, Figure 6(b).

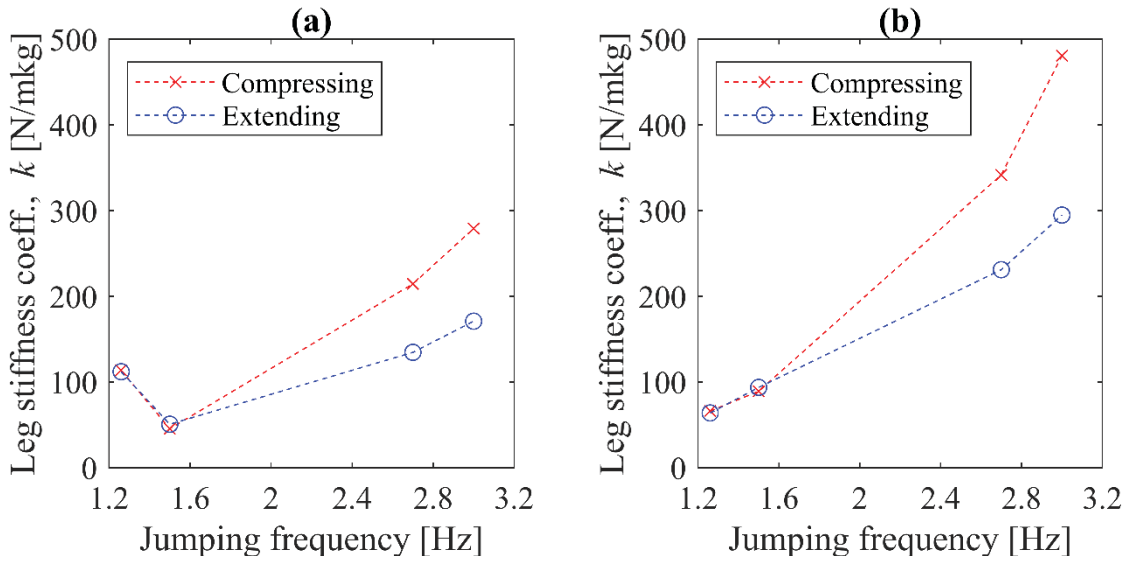

Figure 6 Frequency dependency of linear stiffness coefficients (a) relative displacement; (b) absolute displacement

6 CONCLUSIONS

Force-deflection curves for absolute and relative displacement measurements have been presented with the corresponding stiffness profile being explored. At low jumping frequencies, the force-displacement relationships are observed to be close to pseudo-linear. However, at high jumping frequencies, the relationships are observed to be more complex. The relative displacement exhibits hysteresis loops, indicating a complex energy exchange at high frequency jumping. Hysteresis is subtly mirrored in the absolute displacement case for the 3.00Hz jumping case. The frequency-dependencies of the stiffness coefficients suggest that at low jumping frequencies the stiffness profile during compression and extension are extremely similar. At high jumping frequencies, the stiffness is observed to be larger and complex during

compression in comparison to extension. This suggests that the leg stiffness mechanism is considerably more complex at high jumping frequencies.

ENVIRONMENTAL IMPACT OF STRUCTURAL MODIFICATIONS IN OFFICE FLOORS TO SATISFY VIBRATION SERVICE ABILITY

Abstract. *Modern office floors (featuring slender slabs, longer spans, open-plan spaces, less furniture) are increasingly susceptible to walking-induced excessive vertical vibrations. Therefore, vibration serviceability has become the governing design criterion for office floor structures. Structural modifications are normally performed to tackle this problem, but they considerably increase the amount of construction materials needed, which is directly linked to the embodied energy (EE) and embodied carbon (EC) in floor design. In fact, reduction of EE and EC is becoming a necessary feature in building construction due to urgent global sustainability issues.*

However, structural modifications are frequently carried out with no optimisation analysis, resulting in reduced sustainability of office floor design. This paper investigates the environmental impact of structural modifications to satisfy vibration serviceability, in terms of embodied energy and carbon, for a finite element model of a steel-concrete composite office floor, featuring a trapezoidal steel deck supported by downstanding steel beams. The original floor design has minimal structural dimensions to comply with all design criteria (i.e. strength, thermal comfort, acoustic insulation, fire protection, maximum deflection), except for vibration serviceability under walking-induced loads.

The desktop study was performed by employing structural modifications in the slab depth and beam profiles until the response factor of 4 was achieved over the whole floor area, for pacing frequencies from 1.4 Hz to 2 Hz. Results showed that the compliant floor design nearly features 14 %, 27 % and 37 % extra EE, EC and structural weight (SW), respectively, compared with their counterparts in the original design. This is one of very few studies in the public domain demonstrating the huge financial and environmental costs of meeting current vibration serviceability criteria for office floors.

1 INTRODUCTION

The built environment is responsible for nearly 40% of CO_2-related energy globally consumed and construction of the built environment accounts for 13% of the international gross domestic product (GDP) [1]. Also, as rigorous goals for minimisation of the overall energy (i.e. embodied and operational) consumption have been established for the near future [2] and the operational energy of buildings has been successfully reduced, embodied energy (including carbon footprint) is becoming crucial to minimise in the life cycle of modern buildings [1].

Related to this, vibration serviceability is well known as the floor design criterion that frequently leads to structural modifications that is increasing embodied energy in modern office floors.

Modern office floors are frequently long-span supporting open-plan paperless working environments. This feature has led to lowering of the vertical fundamental natural frequency of the floor to below 10 Hz [3], reduced modal damping ratios (lower than 2%) and lightweight structure (lower than 150 kg/m^2). These characteristics, in turn, have made modern office floors more susceptible to excessive near-resonant walking-induced vibrations.

Structural modifications are commonly carried out to make office floors vibration serviceable, especially steel-concrete composite slabs. Such modifications are normally carried out by increasing the slab depth and placing heavier downstanding beam profiles. These modifications can substantially increase the amount of embodied energy (EE), embodied carbon (EC), and structural weight (SW) per unit area of the floor.

This paper, therefore, presents a parametric study of structural modifications in a modern steel-concrete composite office floor design to meet vibration serviceability requirements. The vibration performance of the floor design was assessed and compared with different potential structural solutions. The EE, EC, and SW of each redesign were evaluated for their energy consumption, carbon footprint, and material usage.

2 PROTOTYPE OFFICE FLOOR STRUCTURE

A steel-concrete composite office floor was sized to just about satisfy all floor design criteria apart from vibrations (i.e. strength, thermal comfort, acoustic insulation, fire protection, maximum deflection). The floor was then assessed against the criterion for vibration serviceability under walking-induced loads.

The structure was a 30 m x 44.1 m floor composed of seven spans of 6.1 m length and three bays of 10 m width (21 panels in total) supported by a composite slab (8 cm deep concrete deck and an 1 mm thick 6 cm deep steel deck profile), as shown in Figure 1.

The floor was modelled using finite element (FE) software ANSYS [4]. Each panel was supported by I-profiled universal steel beams: two secondary beams (UB 356 x 171 x 51) in the x-direction, spaced by 2.1 m; two secondary beams, between columns, in the x-direction (UB 356 x 171 x 57); and two primary beams in the y-direction (UB 406 x 140 x 53). The primary beams were connected to 3 m high I-profiled universal steel columns (UC 203 x 203 x 60).

The floor area was modelled using SHELL181 (isotropic, four-noded) elements. Beams and columns were modelled using BEAM189 (three-noded) elements. Both shell and beam elements featured six degrees of freedom (translations and rotations relative to X, Y, and Z axes) in all nodes. The FE model featured 4,186 nodes, forming a 70 x 70 cm grid. For vibration serviceability assessment purposes, the columns were modelled assuming fixed end supports (Figure 1).

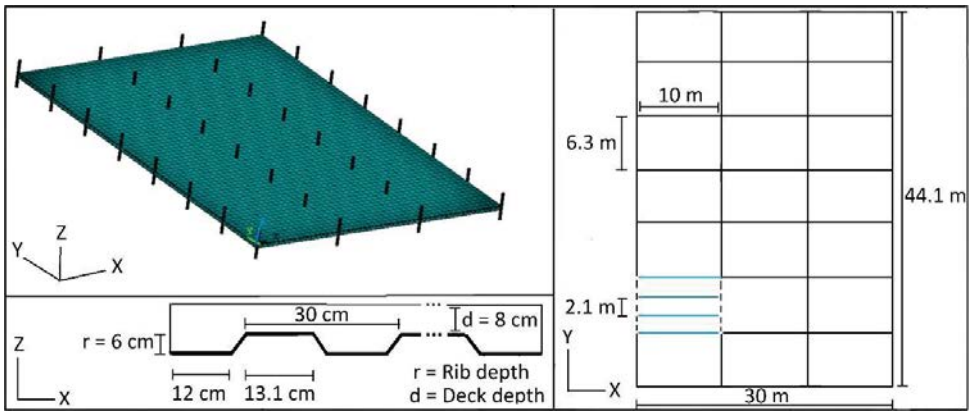

Figure 1: Office floor FE model (top left) and floor slab cross section (bottom left). Floorplan dimensions (right) with example secondary beams (solid blue) and primary beams (dashed red). Columns present at line intersections.

Modal analysis was performed and 36 modes of vibration, up to 15 Hz, were calculated. The first four unit-scaled modes of vibration are shown in Figure 2.

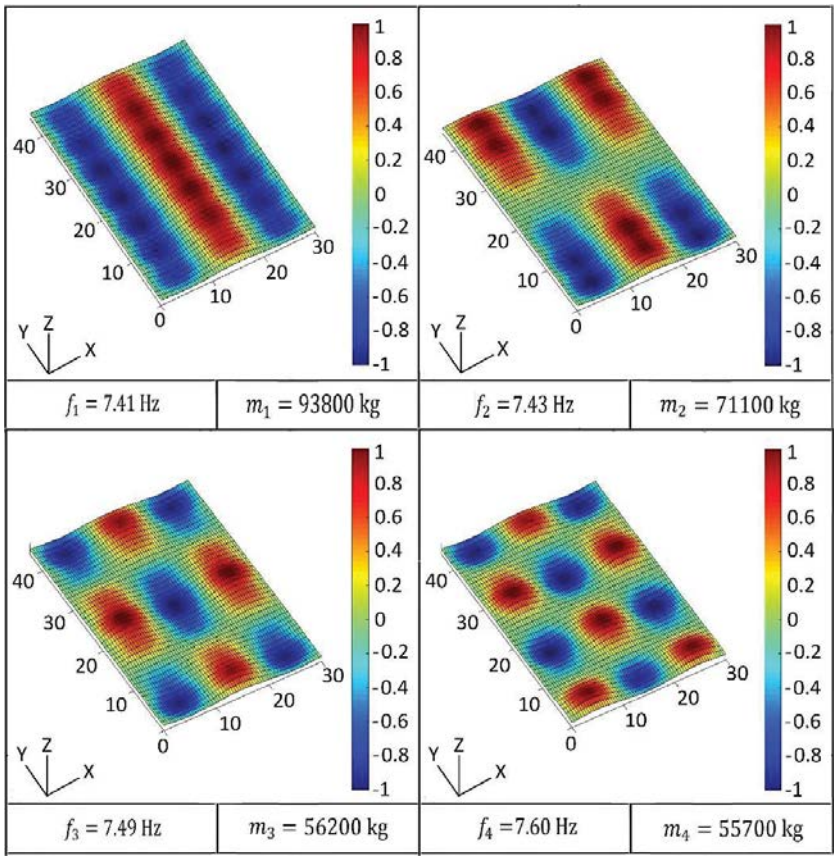

Figure 2: First four modes of vibration of the office floor Model 1 (floor dimensions in meters).

3 ANALYSIS APPROACH

The goal was to design a modern steel-concrete composite office floor compliant with all design criteria, including vibration serviceability, using as little steel and concrete as possible. The vibration serviceability assessment procedure of the CCIP-016 design guide [5] was used in this study.

The excitation was placed at each node of the floor area, and the response was calculated at the same location. The R factor was then calculated and assessed over the whole floor area, for walking frequencies from 1.4 Hz to 2 Hz, in steps of 0.005 Hz. A damping ratio of 2% was assumed for all modes. The starting office floor configuration (Model 1), in turn, did not comply with the assessment criterion (Figure 3).

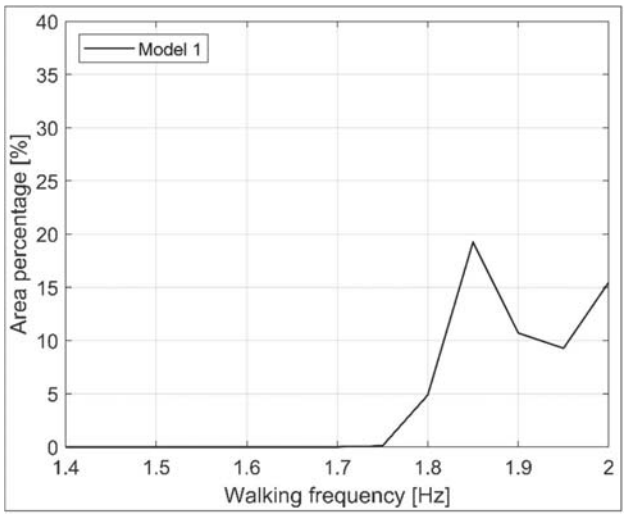

Figure 3: Percentage of the floor area that exceeded R factor of 4 at different walking frequencies.

A contour plot of the response factors calculated over the floor area, for a walking frequency of 1.85 Hz (that corresponds to the highest percentage in Figure 3), is shown in Figure 4.

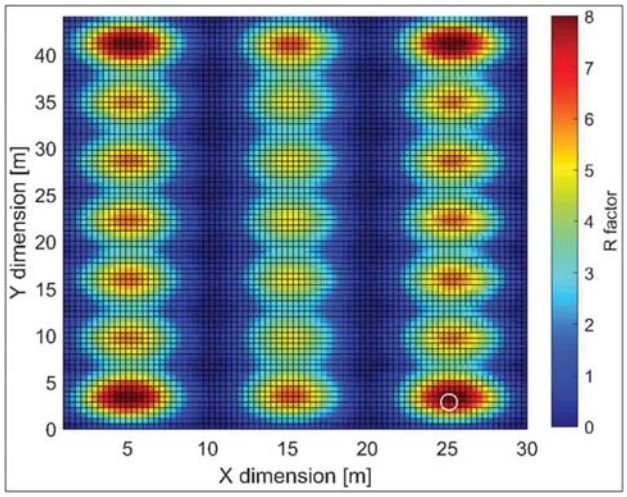

Figure 4: Contour plot of R factors over the floor area at the walking frequency of 1.85 Hz. White circle indicates the most responsive location.

In Figure 4, an adequate floor vibration performance across the whole floor would be represented by a flat line at 0% from 1.4 Hz to 2 Hz, which means that no floor area exceeds R factor of 4. Nearly 20% of the floor area of Model 1 exceeded the R factor of 4, which meant the need for redesign.

Different redesigns were carried out (generating FE models 2 to 10), by modifying the slab depth and both primary and secondary steel beam profiles, until a response factor of less than 4 was achieved for the whole floor area. Table 1 shows all redesigns and their corresponding structural modifications of primary beams (PUB), secondary universal beams (SUB), secondary universal beams between columns (SUBC), relative to Model 1. All models feature the same column profiles (UC 203x203x60).

Model	Slab depth [cm]	PUB	SUB	SUBC
1	8	406x140x53	356x171x51	356x171x57
2	9	406x140x53	356x171x51	356x171x57
3	10	406x140x53	356x171x51	356x171x57
4	8	406x140x53	356x171x57	356x171x57
5	9	406x140x53	356x171x57	356x171x57
6	11	406x140x53	356x171x57	356x171x57
7	12	406x140x53	356x171x57	356x171x57
8	13	406x140x53	356x171x57	356x171x57
9	11	406x140x53	406x140x53	406x140x53
10	13	406x140x53	406x140x53	406x140x53

Table 1: Structural dimensions of all office floor designs (Models 1 to 10).

Table 2 shows the first four natural frequencies of all floor designs.

Model	f_1 (Hz)	f_2 (Hz)	f_3 (Hz)	f_4 (Hz)
1	7.41	7.43	7.49	7.60
2	7.26	7.30	7.38	7.53
3	7.13	7.18	7.29	7.49
4	7.59	7.61	7.67	7.79
5	7.58	7.60	7.66	7.77
6	7.16	7.23	7.36	7.59
7	7.06	7.14	7.30	7.58
8	6.97	7.06	7.26	7.57
9	7.62	7.67	7.80	8.01
10	7.38	7.47	7.65	7.67

Table 2: First four natural frequencies of office floor redesigns (Models 2 to 10).

A comparison of the floor vibration performance of all designs is shown in Figure 5.

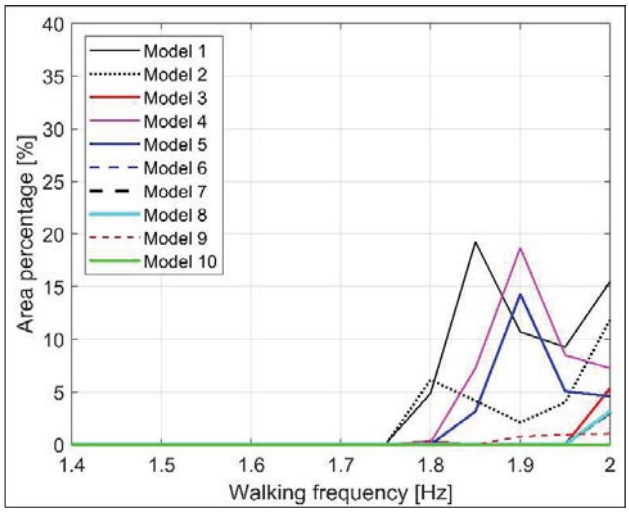

Figure 5: Vibration serviceability assessment of all office floor designs.

It is important to mention here that structural modifications can make the office floor susceptible to near-resonant vibrations at other walking frequencies without solving the problem: Models 4 and 5 became more susceptible to frequencies close to 1.9 Hz (instead of 1.85 Hz, in Model 1) and still have nearly 20% and 15% of the floor area, respectively, exceeding R factor of 4. Therefore, modifications of this kind should be carefully interpreted, as increasing weight and stiffness will not always improve the vibration serviceability performance of the floor.

Once the vibration serviceability was achieved in floor Model 10, the next stage was the quantification of the structural weight of each floor design relative to Model 1 (Table 3).

Model	Concrete %, floor SW	Steel %, floor SW	Total SW [t]	SW relative to Model 1
1	81 %	19 %	341.1	-
2	82 %	18 %	366.2	+7 %
3	83 %	17 %	391.4	+15 %
4	80 %	20 %	343.6	+1 %
5	82 %	18 %	368.6	+8 %
6	84 %	16 %	419.0	+23 %
7	85 %	15 %	444.2	+30 %
8	85 %	14 %	469.3	+38 %
9	84 %	16 %	416.6	+23 %
10	86 %	14 %	466.9	+37 %

Table 3: Comparison of structural weight for office floor designs.

The embodied energy (EE) and embodied carbon (EC) were calculated based on the amount of concrete (2 GJ per ton, 1 tCO_2 per ton) and steel (20 GJ per ton, 3 tCO_2 per ton) used [6]. Values, relative to Model 1, are also shown in Table 4.

Model	EE [GJ]	Relative EE	EC [tCO_2]	Relative EC
1	1858	-	471.8	-
2	1908	+3 %	496.9	+5 %
3	1959	+5 %	522.0	+11 %
4	1909	+3 %	479.3	+2 %
5	1955	+5 %	503.9	+7 %
6	2059	+11 %	554.7	+18 %
7	2110	+14 %	579.9	+23 %
8	2160	+16 %	605.0	+28 %
9	2059	+11 %	554.7	+18 %
10	2111	+14 %	597.7	+27 %

Table 4: Comparison of embodied energy and embodied carbon among office floor designs.

The structural modifications converted the original office floor design (Model 1) into a vibration serviceable floor (Model 10). However, the whole redesigning process was very time-consuming: nine attempts were made to get the structural design needed. Relative to Model 1, Model 10 had 14%, 27%, and 37% extra EE, EC, and SW, respectively, just to satisfy the vibration serviceability criterion.

The structural weight also increased substantially and resizing of structural elements of lower storeys, as well as building foundations, may be required, resulting in further structural modifications. All these implications can indicate the need for a more efficient design process for a sustainable vibration serviceable office floor.

4 CONCLUSIONS

Structural modifications were carried out in the design of a modern steel-concrete composite office floor to make the structure vibration serviceable. The structure was initially sized to just about satisfy all typical floor design criteria (i.e. strength, thermal comfort, acoustic insulation, fire protection, maximum deflection), except for the vibration serviceability requirement. Subsequently, structural redesigns were carried out through gradual structural modifications: increase of slab depth and changes of primary and secondary steel beam profiles.

The fully compliant office floor design met vibration serviceability criteria but required 14%, 27%, and 37% extra embodied energy, embodied carbon and structural weight, respectively, which is quite a lot just to satisfy vibration serviceability.

Keywords: Human comfort, Vibration serviceability, Temporary grandstand, Lateral vibration experiment.

Abstract. *Excessive vibrations of temporary grandstand due to crowds who had rhythmic motions can cause human in panic, which have been attracted increasing attention in recent years. This paper based on an experiment that a temporary steel grandstand occupied 20 participants is oscillated by crowd with rhythmic swaying motions at lateral direction. And then a series of vibration perception questionnaires about crowd reactions are obtained. Evaluation of annoying level derives from concept of degree of membership and annoying rate method is proposed, then the human comfort of vibration serviceability of temporary grandstand is assessed with acceleration vibration dose value (VDV). The result shows that standing crowds have more tolerant to vibration than seated crowds. The measured vibrations generated by crowd activities on temporary grandstand can cause panic in crowd. New relationship between the annoyance rate and structural acceleration VDV at logarithmic coordinate is proposed. The findings of this study may be utilized to manage the vibration of temporary grandstand and assess the human comfort when structure was oscillated at lateral excitations.*

1 INTRODUCTION

The problems of vibration serviceability of structure such as in long-span floor structures[1], footbridges[2] and grandstands[3,4], have become more prevalent in recent years, because the structures can gather large crowd. It is different in the safety of structure due to the failure of structural component; excessive vibration of structure can cause crowd discomfort or panic. Vibration serviceability of grandstand relates to the comfort of spectators, and human perception is of primary importance with any tendency to panic or feeling of discomfort being related to the dynamic response of the structure[5]. This seems to be a common problem in temporary demountable grandstands (TDGs), the lightweight structural components of TDG can be rapidly assembled, easily dismantled and reused that result in low stiffness of structure at lateral direction, so it can be susceptible to vibrations that caused by active crowds.

It is a fact that human can feel the vibration from structure, the degrees of perception for structural vibration but cannot be measured with any direction assessment methods or instruments. Studying the relationship between human perception and spur belongs to the branch of psychophysics subject. Vibration environments, in terms of human sensation of vibration levels, need to be quantified by psychological research. Introspection is used to describe an experimental technique that was first developed by psychologist Wilhelm Wundt, in Wundt's lab, there were two key components that make up the contents of the human mind: sensations and feelings, and Wundt believed that researchers needed to do more than simply identify the structure or elements of the mind, instead, it was essential to look at the processes and activities that occur as people experience the world around them[6]. Therefore, it is necessary to conduct a psychophysical experiment survey by means of a category judgment method[7]. Although evaluation and assessment of vibration serviceability is a complicate task, it is a reasonable and available method that using experimental introspection with questionnaire to evaluate the reaction of human perception. So from the early years such as in 1931 Reiher and Mesiter used a shaking platform[8], 1971 Khan and Parmelee used a rotating display table[9], 1972 Chen and Roberts experimented human at a wheeled windowless test room[10] and 1974 Wiss and Parmelee measured human at a rise floor[11], all of them used this method to investigate the vibration serviceability of structure.

A number of research projects have, to date, largely focused on producing load models to accurately represent the dynamic crowd load and the human-structure interaction, however, the vibration response of grandstand structure is becoming better understood, the question arises as to what level of dynamic response is acceptable to the users[12]. There have been few findings on the subject of serviceability of grandstands, for example Kasperski has carried out full scale test on one bay of a permanent cantilevered stand[3]; Browning determined the key factors of influencing human perception and acceptability of vibrations in permanent grandstands through by synchronized crowd loading with 17 persons[12]. Meanwhile, a resemblance grandstand occupied 15 spectators that attached to a motion simulator located on each corner has been experimented, in order to investigate human vibration perception and comfort states[13]. In particular, Setareh proposed new relationships between the current vibration evaluation parameters along with guidance for the assessment of human exposure to vibration owing to rhythmic activities[4]. What these reviews have highlighted is that vibrations were induced by human have vertical motions and few research analyzed the human vibration perception in the TDG. And what's more, lateral vibration is more likely to be induced than vertical vibration happen in reality for TDG[14]. This remains an open problem in the area, the aim here is to investigate the vibration serviceability of TDG.

So with this aim in mind, this paper presents a new experiment that a TDG occupied 20 persons which vibrations derived from crowd motions, to investigate the human horizontal vibrations perception with vibration questionnaires. Based on these experimental results, the vibration acceptability of the TDG is analyzed by a annoyance rate method that the fuzzy logic method and the probability theory was combined with the signal detecting theory of psychophysics[15-17]. As alluded to earlier, this method has been available for appraising the vibration comfort of vehicle suspension system[18,19], high-speed train[20], pedestrian bridge[21], floor structure[22,23], and noise annoyance[24,25].

The next section presents the lateral oscillation experiment in this study. In Section 3, the evaluation method is introduced and the relationships of evaluation parameters of structural vibration are analyzed. New relationship between annoyance rate and structural acceleration VDV is proposed, and the main findings and discussions are outlined in Section 4. The conclusions will be presented in the final chapter.

2 LATERAL VIBRATION EXPERIMENTS OF TEMPORARY GRANDSTAND

Experimenting was executed on the basis of a rigorous risk assessment and approval of the experiment program by the University's research ethics committee, using its standard procedures for protect the safety of participants and acquired sensible data. For simulating the lateral vibration of temporary grandstand, structural vibration derived in the active crowd when they have rhythmic movements on the test temporary grandstand, and it is considered as internal excitation to investigate the passive and/or active crowd annoying levels of vibration.

2.1 Ethics statement

This study was approved by the School of Civil Engineering and the Key Lab of Structures, Dynamic Behavior and Control of the Ministry of Education at the Harbin Institute of Technology. All participants provided written informed consent, and agreed to put their photos with no argument.

2.2 Test condition

The details of test structure and instruments can be found in the document[35]. For crowds excitation, there are 11 experiment conditions that crowd has swaying activities at temporary grandstand, the detail of swaying person's number, test conditions and crowd swaying frequencies are shown in the Table 1. For the first and second condition twenty persons finished nine frequencies swaying movements, some of them finished six frequencies swaying movements in the rest conditions. In order to follow the tempo of swaying more better for participants, they were asked to sway the hips to the left on one beat and then to the right on the next which guided by a constant metronome beat, just as the Fig.1 depicts crowd followed the one beat at the time of t_1 and next beat at the time of t_3, so participants completed a sway cycle that will need two beats, and the frequency $f_{\text{metronome}}$ was inspired by metronome which is twice the frequency of participant swaying f_{crowd}. All participants moved in a way that was natural to him or her according to the frequency of metronome.

Test condition number	Test conditions	$f_{metronome}$ (Hz)
1	All standing persons swaying	0.5,0.75,1.0,1.1,1.25,1.4,1.5,1.7,1.8
2	All seated persons swaying	0.5,0.75,1.0,1.1,1.25,1.4,1.5,1.7,1.8
3	Number 6-20 person standing swaying, 1-5 person seated	0.5,0.75,1.0,1.1,1.25,1.4
4	Number 11-20 person standing swaying, 1-10 person seated	0.5,0.75,1.0,1.1,1.25,1.4
5	Number 16-20 person standing swaying, 1-15 person seated	0.5,0.75,1.0,1.1,1.25,1.4
6	Number 6-20 person standing swaying, 1-5 person standing	0.5,0.75,1.0,1.1,1.25,1.4
7	Number 11-20 person standing swaying, 1-10 person standing	0.5,0.75,1.0,1.1,1.25,1.4
8	Number 16-20 person standing swaying, 1-15 person standing	0.5,0.75,1.0,1.1,1.25,1.4
9	Number 6-20 person seated swaying, 1-5 person seated	0.5,0.75,1.0,1.1,1.25,1.4
10	Number 11-20 person seated swaying, 1-10 person seated	0.5,0.75,1.0,1.1,1.25,1.4
11	Number 16-20 person seated swaying, 1-15 person seated	0.5,0.75,1.0,1.1,1.25,1.4

2.3 Vibration perception questionnaire

As mentioned previously, no standard or code can provide specific clause on the assessment of human vibration acceptability for TDG, even not to mention the vibration comfort when the excitation main from lateral direction. But, a series of classic experiments about human perception that participants rate their feeling of the vibration were carried out[3,8,9,12,13]. All these researchers classed the human perception and vibration level three to six categories, which based on the concept of equidistance followed human psychological changes. Some achievements have been adopted by BS6472-1[27] and ISO2631-1[28] standards. So, according to these findings, the level of vibration perception (Six categories) and comfort are provided with vibration perception questionnaires, which require participants to select their subjective perception and/or levels of comfort during exposure to vibration are used in this paper. The questionnaires contain the level of vibration perception with the level comfort and shows in the Table 2.

Ordinal	Perception Category	Subjective Response
1	Imperceptible	No response(Not uncomfortable)
2	Litter Perception	Normal(A little uncomfortable)
3	Clear Perception	Accept(Fairly uncomfortable)
4	Little Strong Perception	Litter nervous(Uncomfortable)
5	Strong Perception	Nervous(Very Uncomfortable)
6	Very Strong Vibration	Panic(Extreme Uncomfortable)

Table 2: Human perception and comfort category

3 EVALUATION METHOD

According to record the human sensation of vibration levels from participant's perception and comfort, the basic evaluation methods for measuring vibration is calculated using three forms of acceleration: peak acceleration limits(was cited in NBCC[29]); acceleration root mean square (RMS) of weighted frequency; vibration dose value (VDV). The latter two are acceptable by most standards (BS7085[30], BS6472[31] and ISO10137[32]) to quantify vibration levels. They are calculated by the Eq.(1).

$$a_w(t) = W(f) \cdot a(t)$$

$$a_{wp} = \max\left|a_w(t)\right|$$

$$a_{wrms} = [\int_0^T a_w^2(t)dt]^{0.5} (\lim_{\lambda \to 0} \sum_{i=1}^{n} a_w^2(\zeta_i) \cdot \Delta t_i)^{0.5} = (\sum_{i=1}^{n} [W(f)a(t_i)]^2 \cdot f')^{0.5}, \lambda = \max\{\Delta x_1, \Delta x_2, \cdots, \Delta x_n\} \quad (1)$$

$$a_{wvdv} = \left[\int_0^T a_w^4(t)\mathrm{d}t\right]^{0.25} = (\lim_{\lambda \to 0} \sum_{i=1}^{n} a_w^4(\zeta_i) \cdot \Delta t_i)^{0.25} = (\sum_{i=1}^{n} [W(f)a(t_i)]^4 \cdot f')^{0.25}, \lambda = \max\{\Delta x_1, \Delta x_2, \cdots, \Delta x_n\}$$

With $a_w(t)$=frequency weighted acceleration in $m \cdot s^{-2}$;
$W(f)$=the overall frequency weighting function from ISO2631-1[28];
$a_{wp}(t)$=frequency weighted peak acceleration in $m \cdot s^{-2}$;
$a_{wrms}(t)$=frequency weighted RMS of acceleration in $m \cdot s^{-2}$;
$a_{wvdv}(t)$=frequency weighted VDV of acceleration in $m \cdot s^{-1.75}$;
f'=sample frequency in s;
T=vibration duration in s.

3.1 Annoyance rate method

Although the limit acceleration value was given in some standards like ISO2631-1[28], the membership between the limit value and comfortable level was not reasonable extrapolated. The result of questionnaires includes the ambiguity of seismesthesia and the sensitivity randomness existing in participants' response to vibration environment. All these uncertainties need to be analyzed from a view psychophysics. So firstly the seismesthesia of membership function and corresponding conditional probability distribution[14] is calculated by Eq.(2) based on the Table 1 and questionnaires.

$$v_j = \frac{j-1}{K-1}, j = 1,2,...,K \quad (2)$$

With v_j=the seismesthesia of membership value of the jth type of the unacceptable range;
K=the class number of the subjective response, according to Table 2, K=6.

So the subjective response corresponding to the value of the membership value can be shown in the Table 3.

Subjective response	Membership value
j=1 No response	0.0
j=2 Normal	0.2
j=3 Acceptable	0.4
j=4 Litter nervous	0.6
j=5 Nervous	0.8
j=6 Panic	1.0

Table 3: Seismesthesia membership values

Secondly, a new evaluation index annoyance rate method is presented, which is a fuzzy stochastic model for participant response to vibrations. The method considers these uncertainties with the fuzzy logic method and the probability theory, combined the objective experimental data statistics. So, annoyance rate is the proportion of some kind of subjective response under certain external stimulus intensity, which considers synthetically response ambiguity and randomness with fuzzy membership value. It is useful as a benchmark to determine the annoyance threshold for vibration serviceability criteria, that threshold indicates the ration of people who cannot accept the vibration to the statistical that total number. Under discrete distribution, the annoyance rate can be calculated by Eq.(3):

$$R(x=i)=\frac{\sum_{j=1}^{K} v_{ij} n_{ij}}{\sum_{j=1}^{K} n_{ij}} \tag{3}$$

With $R(x=i)$=Annoyance rate of the ith vibration intensity;

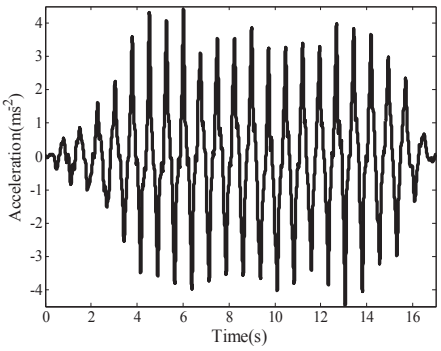
v_{ij}=the membership of value is calculated by Eq. (2) at the ith vibration intensity;

n_{ij}=the number of subjective response of the jth type of the ith vibration intensity;

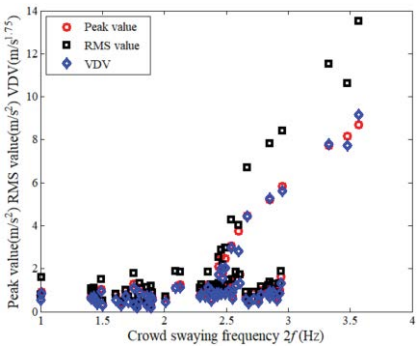
K=The class number of the subjective response, K=6 (see Table 3).

3.2 Relationship of structural vibration evaluation parameters

For human induced vibration experiment, the results are investigated. For example, Fig.2(a) shows one of the time history of structural acceleration which was oscillated by twenty persons when they have rhythmic movements. Then the peak acceleration, RMS and VDV of each test condition (Table 1) results are calculated, and the scatter plots the three measures plotted against crowd swaying frequencies is shown in Fig.2(b). In this Figure, also the hollow dots stand for peak accelerations, square dots stand for RMS values and diamond dots stand for VDV. It is found that RMS values are higher than peak value and VDV, the max value is about 13.49m/s^2, which is out of the limits were given by Kasperski[3], Setaerh[4], Nhleko[13], BS6841[26], BS6472[27], and BRE[34]. According to these above results, when enquired the vibration serviceability of these participant, they are in panic.



(a) Structural acceleration curve of seated crowd with 1.6Hz swaying



(b) Three measures acceleration against crowd swaying frequencies

Fig.2 The structural acceleration peak acceleration、RMS and VDV relationship with crowd swaying frequencies

When the scatter a_{wp}, a_{wrms} plotted against a_{wvdv} respectively, as shown in Fig.3, both of them have a linear relationship with a_{wvdv} and the fitting curve is Eq.(4):

$$a_{wvdv} = 0.9995a_{wp} - 0.1486$$
$$a_{wvdv} = 0.6873a_{wrms} - 0.0316 \tag{4}$$

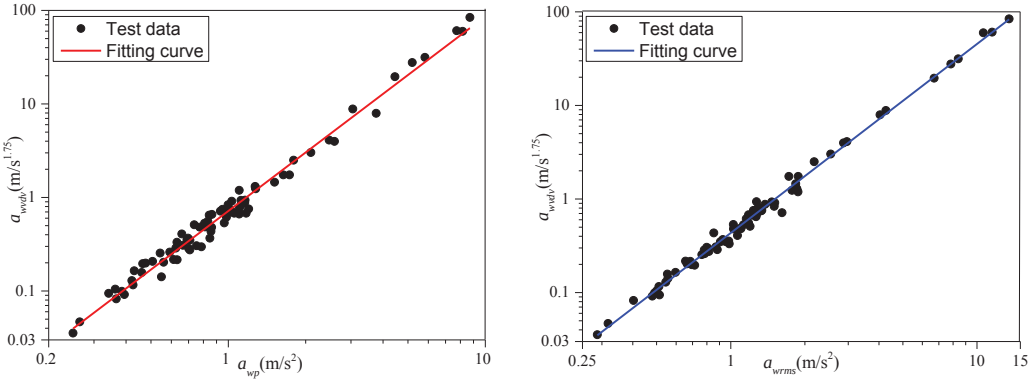


Fig.3 a_{wvdv} plotted against a_{wp} and a_{wrms} from human induced measured data

Bearing all this in mind, the structure was oscillated by crowd have rhythmic activities with linear increasing swaying frequencies, the structural acceleration VDV have a linear relationship with RMS and peak acceleration at Logarithmic coordinate system. And what's more, crowd swaying movements can induce structure has more than 1g acceleration, which can cause crowd have panic.

4 ASSESSMENT OF THE EXPERIMENT RESULTS

4.1 Acceptable VDV limits

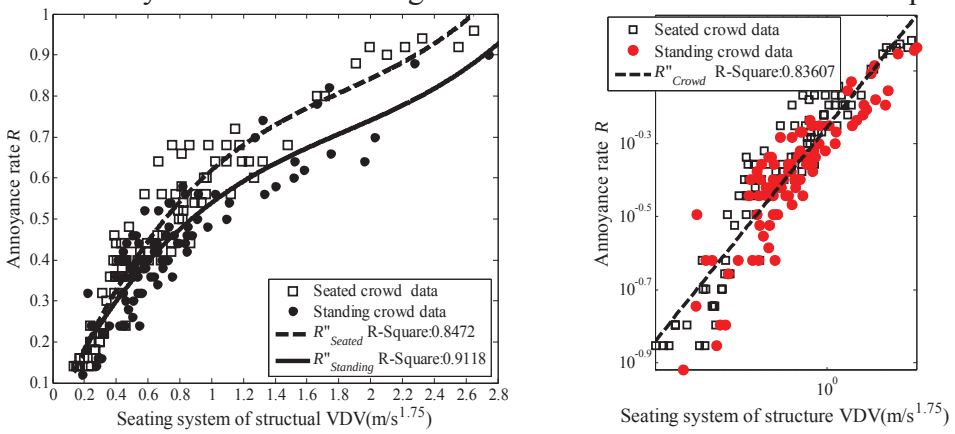
Due to VDV is versatility than RMS that has been calculated to quantify human reaction to numerous types of vibration, and VDV will be used for finding the relationship with annoyance ratio in this paper.

Active crowd induced structure vibration experiment results are also investigated to find the relationship between annoyance rate and structural VDV. Due to when the VDV is high than 2.8m/s$^{1.75}$, the crowd have in panic, and the annoyance rate is 1.0, So only the corresponding value which the annoyance rate is lower than 1.0 are shown in Fig.4(a). It may indi-

cates standing crowd can tolerate more strong structural vibration than seated crowd when the structural vibration was induced by swaying crowd, this finding consistent with Nhleko's research[13].In order to demonstrate the nonlinear relationship between VDV and annoyance rate, the two kinds of data were fitted by a 3-rd degree polynomial formula respectively, and shown in Eq.(5):

$$\begin{aligned} R''_{seated} &= 0.0777a^3_{wvdv} - 0.4280a^2_{wvdv} + 0.9642a_{wvdv} + 0.0041 \\ R''_{standing} &= 0.0585a^3_{wvdv} - 0.3224a^2_{wvdv} + 0.7594a_{wvdv} + 0.0430 \end{aligned} \tag{5}$$

With R''_{seated} is the annoyance rate of seated crowd at human induced vibration experiments; $R''_{standing}$ is the annoyance rate of standing crowd at human induced vibration experiments.



(a) Cartesian coordinate system (b) Logarithmic coordinate system

Fig.4 The distribution of crowd annoyance rate at human induced structural vibration

Also, a linear relationship between structural VDV and annoyance rate at Logarithmic coordinate system is fitted by Eq.(6)when considered the seated crowd data and standing crowd data as a whole sample, and the fitting curve is shown in Fig.4(b):

$$\log_{10}(R''_{crowd}) = 0.67556\log_{10}(a_{wvdv}) - 0.25358 \tag{6}$$

With R''_{crowd} is the annoyance rate of crowd at human induced vibration experiment.

In this paper, when R is lower than 0.4, which indicates crowd in comfort at structure; R varies at 0.4 to 0.6 means some persons in crowd have uncomfortable feelings; R varies at 0.6 to 0.8 means most of them in crowd have uncomfortable feelings; and when R is larger than 0.8 that shows crowd in panic. Based on this annoyance levels of vibration and according to the Eq.(6), the structural acceleration VDV 1.11m·s$^{-1.75}$ that corresponding to R=0.6 as the serviceability limit, and 1.71m·s$^{-1.75}$ that corresponding to R=0.8 as the serviceability limit of the upper boundary.

4.2 Discussion with other standards or guides and research

The obtained comfort levels data in this paper are compared with the limits recommended in the provisions of BS6841[26], which are mainly for vibrations encountered in transportation and industrial activities. This standard used RMS as the limit and given five vibration levels. According to the annoyance rate with structural vibrations of the experiment data in this paper, the VDV can be calculated by Eq.(6) at each value of annoyance rate R firstly, and then the corresponding RMS can be calculated by Eq.(4). So on the basis of the conversion procedure, the level of comfortable corresponding to R=0.2 and RMS is 0.365m·s^{-2}; the level of little uncomfortable corresponding to R=0.4 and RMS is 0.936m·s^{-2}; the level of fairly

uncomfortable corresponding to R=0.6 and RMS is 1.661 m·s^{-2}; the level of very uncomfortable corresponding to R=0.8 and RMS is 2.186m·s^{-2}; and the level of extremely uncomfortable corresponding to R>0.8 and assumed RMS is greater than 2.186m·s^{-2}. It is found that the experiment data is slightly higher than the design criteria when the specified level under fairly uncomfortable and the data 2.29-3.69m·s^{-2} appear in the specified limits when the level is very uncomfortable. This means that the limits for temporary grandstand appear upper the design criteria for public facilities such as permanent concrete structure, that is reasonable for believe temporary structures can allow to with big displacement or vibration.

The standard BS6472[31] has given some acceleration limit curves for labs, residential, office building and workshops. Nhleko[13] used 25 times the base curve and 50 times the base curve specified in this standard as a basis and the upper boundary of acceleration limit for grandstand design (shown as two purple broken lines), respectively. In addition, NBCC2005[29] specifies serviceability acceleration limits at 0.4-0.7m·s^{-2} for grandstand, and IStructE2008[33] also recommends values of 0.3m·s^{-2}, 0.75m·s^{-2} and 2.0m·s^{-2} for grandstand hosting predominantly seated crowd, pop music concerts and extreme events(crowd has strong rhythmic activities)，respectively. If the mean of the 'fairly uncomfortable' of comfortable obtained in this study is used to defined the serviceability limit state for temporary grandstand, the value of limit is 2.18m·s^{-2}, which is higher than Nhleko's[13] research and NBCC2005[29] limits, but it remains in the range of IStructE2008[33]specifies limits.

When the VDV as serviceability limit, the guide BRE[34] based on the standard BS6841[26]and BS6472[31]given the limit with human perception of vibration, and Setaerh[4]based on Kasperski's[3] experiment results also gives the limits. It is noticeable that the published standards and literatures have given the limits for permanent grandstand, and the structure was induced by vertical human motions. So the serviceability limits are different from the results in this paper. It may be possible that the vibration direction and more flexible temporary grandstand have larger effects on crowd reactions than they occupied at stiffness permanent grandstand when subjected to excitations which mainly derived from vertical vibration and using different frequency weighting value may also influence the results. Due to the participants are just only young individuals, not including children and/or old persons, the distribution of annoyance rate may be different when participants are a typical population sample, and although the experiment environment is quiet, the vibration annoyance may be influenced by the noise, it is need to focus on combined or interactive effect of noise and vibration exposures on annoyance for TDGs, so it will be researched in the future work. Also, more research is needed to investigate different and bigger temporary grandstands with different crowds, along with better identification of human reactions.

5 CONCLUSION

This paper addresses the annoyance levels of lateral vibration on temporary grandstand. A temporary grandstand occupied 20 participants was induced by crowd with rhythmic swaying activities, meanwhile the vibration questionnaires of participants are obtained. Occupant comfort was evaluated by annoyance rate method and assessed by the RMS and VDV of structure. There are some conclusions are obtained.

- Crowd annoyance rate has not a linear relationship with vibration, and indicated crowd may adjust their reaction for comfort when they under a certain range of vibration intensity.
- Standing crowd may have more tolerant to vibration than seated crowd.

- The serviceability limit of 1.11m·s$^{-1.75}$ and the upper boundary of 1.71m·s$^{-1.75}$suggested by VDV are obtained.
- It may be useful for analyzing the vibration serviceability of temporary grandstand.

Abstract. *An aeroelastic experimental study is ongoing at the NSF designated Experimental Facility Wall of Wind (WOW) aiming at advancing the knowledge pertaining to the dynamic behavior of power transmission infrastructure during strong windstorms including hurricanes. The WOW is a large open jet wind testing facility capable of simulating hurricane winds at different wind speeds and up to 70 m/s (Category 5 hurricane). The study is motivated by the increasing storms including hurricanes which recently are reported to cause substantial losses to the U.S. energy infrastructure. A multi-spanned aeroelastic transmission line system is designed and constructed at the WOW using a length scale of 1:50 for the tower and a distorted length scale of 1:150 for the conductors. The selected length scales enable considering several test configurations including various wind directions ranging between 0° to 90°. While adopting the Froude number scaling, the tests are conducted at speeds ranging between 5 m/s to 10 m/s, representing full-scale wind speeds ranging between 35 m/s to 70 m/s. The aeroelastic test results are analyzed in order to assess the dynamic response of the transmission towers during the simulated hurricane conditions. This includes an investigation of the modal properties, the development of a new technique to estimate structural and aerodynamic damping, and comparison of the resulting drag coefficients with values specified in ASCE 7-16.*

1 INTRODUCTION

Electric power grids in the United States are constantly threatened by wind-induced loads caused by hurricanes, tornadoes and downbursts. Generation, supply and delivery of power to several areas of the country have been severely impacted by these wind hazards. Between 2003 and 2012, 87% of all power outages were triggered by severe weather, making it the leading cause of blackouts in the United States [1]. Weather-related power outages exacted huge losses on the U.S economy, with figures ranging between $20 to $55 billion [1]. Therefore, it is of the utmost importance to improve the resiliency of the transmission grid against threats from strong winds including hurricanes.

Support towers, conductors, ground wires and insulators are the main components of overhead transmission lines systems. Electricity is transported from the generation station to different cities through conductors that span for kilometers. Conductors are attached to the towers using porcelain insulators. The function of ground wires is to protect the line from possible lightning strikes [2]. In general, many structures are not designed to withstand hurricane or tornado loads because of the very low probabilities of occurrence and exposure to them. However, that is not the case for transmission systems due to the fact that they are long span structures and extend for kilometers. Therefore, in the event of occurrence of high intensity winds coming from a hurricane or tornado, their probability to hit one of the towers become significantly larger. Subsequently, the failure of one tower can lead to cascading failures of other towers due to the unbalanced forces triggered by the snapping of one or more conductors [3, 4, 5, 6]. The responses of transmission lines to wind-induced dynamic loading can be divided into three phenomena: galloping, vortex shedding and buffeting from incoming turbulence [2, 7, 8]. On the one hand, the tower's natural frequency is typically higher than 1 Hz, leading to insignificant resonant tower responses. On the other hand, the tower's conductors have a frequency ranging between 0.2 and 0.3 Hz. This range could be very close to the natural frequency of the turbulent winds. Various studies have reported that, at high wind speeds, the conductor's behavior increases the aerodynamic damping, thus, rendering the resonant effect almost negligible [3, 7, 9, 10, 11, 12]. In general, wind tunnel experiments on transmission structures can be grouped into aerodynamic testing and high-frequency force balance testing. For the latter, by carefully estimating aerodynamic coefficients from the previous methods and combining them with analytical approaches, one can estimate the dynamic responses of a certain system [10, 11]. However, such tests do not consider the aeroelastic forces induced by motions of the structure and its various components. In addition, the response of transmission towers and conductors as one system was barely examined by previous wind tunnel studies due to the complexity of satisfying basic scaling laws concerning geometric, dynamic and kinematic similitudes [12, 13]. Other experimental studies on tower-conductor systems only considered a single span system and did not properly model the boundary effects caused by the presence of adjacent spans when a multi-span system is subjected to turbulent winds [14, 15].

The aim of this research is to advance the current knowledge by conducting an extensive experimental program to study the aeroelastic response of a multi-spanned transmission line system subjected to hurricane winds. These tests will provide deeper insights into the highly complex coupled dynamic behavior at system levels.

2 METHODOLOGY

2.1 Wall of Wind Experimental Facility

The aeroelastic model was designed, constructed and tested at the NSF Natural Hazards Engineering Research Infrastructure (NHERI) Wall of Wind Experimental Facility (WOW EF). The WOW EF is designated as an open-jet testing facility capable of testing full- and large-scale structures using a powerful 12-fan system. The 12 fans are arranged in two arced rows, which can generate wind speeds up to 70 m/s along with specified turbulence characteristics of terrain exposures [16]. Figure 1 depicts the WOW intake side along with the 12-fan system.

Figure 1: WOW intake side and 12-fan system

2.2 Full-Scale Model

For this project, the transmission tower illustrated in Figure 2 is selected. This tower is classified as double circuit vertical self-supported steel lattice tower with a height of 27.5 m, and a rectangular base having a length of 7.6 m and a width of 2.7 m. The tower has three different levels of identical cross-arms. Such a configuration allows the attachment of six bundles of conductors, two at each vertical level. The conductors span a horizontal length of 180 m between supporting transmission towers and have a diameter of 0.028 m. Moreover, the conductors are sagged at midspan by around 3.6 m and they are attached to the towers by porcelain insulators having a length of 1.5 m and diameter of 0.08 m.

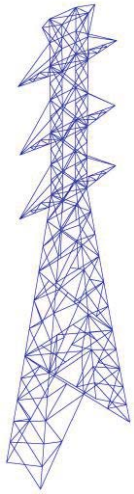

Figure 2: Three-dimensional view of the transmission tower

2.3 Aeroelastic Model Design and Construction

Whenever the geometry and physical properties of a prototype have to be reproduced as a model at a smaller scale, great care needs to be taken in order to reproduce the same dynamic behavior. For aeroelastic modelling, this scaling exercise becomes more tedious. This means that the scaling relationship between elastic, inertia, viscous, gravity and damping forces needs to be maintained. While preserving the geometry is essential for the reproduction of the aerodynamic loads, maintaining the mass and stiffness is vital for the dynamic loads associated with the response of the model [18]. Some of the advantages of using aeroelastic models include: (i) the proper simulation of turbulence effects and wind-structure interaction, (ii) the subtle interactions between the coupled modes of vibration of the system and (iii) local, topographical as well as three-dimensional effects can be investigated [19]. Generally, for any quantity Q_p measured on the prototype, Equation 1 can be used to calculate its model counterpart Q_m, where λ_Q is the scaling factor:

$$Q_m = Q_p \times \lambda_Q \tag{1}$$

Normally, it is preferred to use prototype material in the construction of the aeroelastic model to maintain the structural damping which is crucial in the dynamic responses of the system [20]. However, since lattice towers are lightweight structures, it is challenging to satisfy the mass scaling using prototype steel material. Therefore, a different metal such as aluminum is usually selected to satisfy the mass scaling requirement. In addition, it is worthwhile mentioning that the damping ratio of aluminum is close to that of its steel counterpart.

For this project, a length scale λ_L of 1:50 is selected. Moreover, Froude number scaling is maintained in the model as that in the prototype. This means that the ratio between the inertial and gravitational forces is preserved. This is simply achieved by linking the velocity scale λ_U to the square root of the length scale λ_L, i.e., the velocity scale is equal to 1:7.07. Some of the essential parameters required to correctly design the aeroelastic model along with their scaling ratios are presented in Table 1.

Quantity Q	Scaling factor λ_Q
Length L	1:50
Velocity U	1:7.07
Mass m	$1:50^3$
Mass moment of inertia I	$1:50^5$
Time t	1:7.07
Acceleration a	1
Damping ζ	1
Elastic stiffness EI	$1:50^5$
Elastic stiffness EA	$1:50^3$
Force F	$1:50^3$
Bending and torsional moments M, T	$1:50^4$

Table 1: Essential scaling parameters required for aeroelastic design

The system of this experimental program consists of three transmission towers, two rigid end frames and six conductors spanning in between (Figure 3). This means that four full spans are considered. This is an improvement over previous synoptic wind tunnel testing on transmission lines that considered single spans and did not consider the boundary effects caused by the presence of adjacent spans [11, 17]. However, in order to accommodate the entire system

on the WOW turntable, a distorted length scale of 1:150 will be used for the span length only. This new approach of horizontally distorting the cable length by a factor of three while maintaining the properties of the non-distorted model, i.e. frequency, drag and mass along with the conductor sag does not significantly alter the behavior of the conductors [21]. This approach is reinforced by the idea that conductors' natural frequencies are controlled by their sags when the tension they carry is not high, such as the case of transmission lines. All other parameters are kept the same, i.e. scaled down to a length scale λ_L of 1:50, including wind tunnel simulation [21]. Figure 3 shows a CAD drawing of the entire system to be constructed at the WOW.

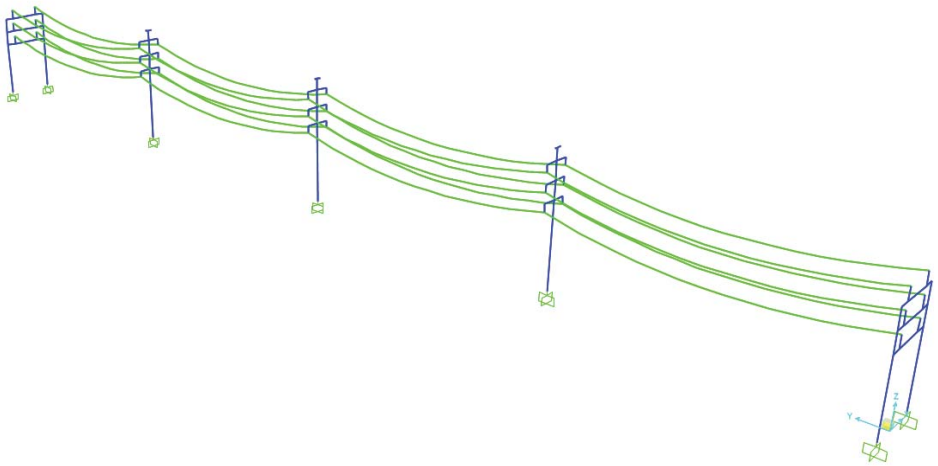

Figure 3: CAD drawing showing the entire system

In order to replicate the behavior of its full-scale counterpart, the aeroelastic transmission tower is designed and constructed in two parts: (i) an aluminum rectangular spine that encompasses the structural properties of the lattice structure and (ii) non-structural cladding elements that replicate the exact shape of the tower angle members to maintain its geometry and aerodynamics. The spine has a height of 55 cm and is embedded inside an aluminum bearing plate at the bottom to create a fixity. Furthermore, the spine has cross-sectional dimensions of 5.6 mm depth and 14.7 mm width. The previous dimensions were calculated using the factors stated in Table 1. This ensured the replication of the along-wind, across-wind and torsional behavior of the prototype. The non-structural cladding elements are 3D printed using a plastic like material and are glued to the spine. For the conductors, a steel wire having a diameter of 0.56 mm was utilized. Likewise, non-structural foam rods were attached over the entirety of the spans to maintain the same drag, distributed weight and average diameter over the entire length as the prototype. The insulators are represented by aluminum cylindrical rods with lengths of 3 cm and diameter of 0.25 mm. The insulators are connected to the cross-arms at their top and conductors at their bottom using 3D printed sections. Finally, aluminum rigid frames constructed from hollow rectangular tubes are used as end supports to the system to carry unbalanced tensile forces in the conductors. Figures 4a, 4b and 4c portray the single tower, the entire system and the insulator along with its connections, respectively.

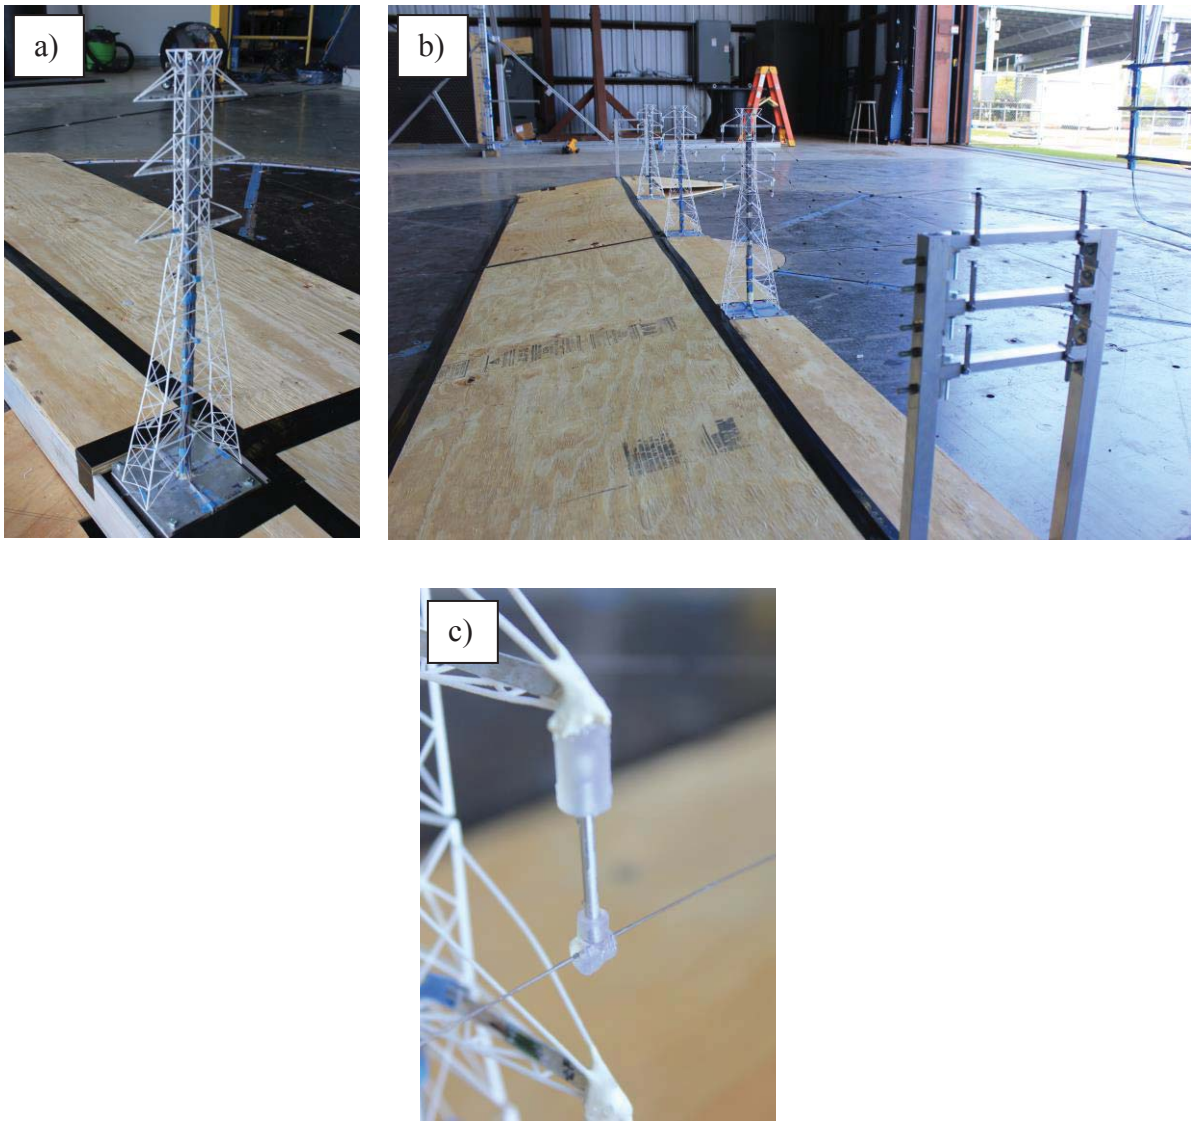

Figure 4: Models constructed at the WOW; a) Transmission tower with no insulators, b) Entire system, and c) Insulator with top and bottom connections

2.4 Instrumentation and Testing Protocol

To measure the complex and coupled response of the system to synoptic winds, the model was carefully instrumented. At the base of each tower (total of three), one six-degrees-of-freedom (6-DOF) load cell was mounted to capture the base shears and moments. In addition, three 3-DOF accelerometers were attached on the middle transmission tower to collect accelerations and subsequently, system frequencies. Lastly, a total of twenty strain gauges were applied at different parts of the spines and cross-arms to record forces and stresses. Strain gauges mounted on cross-arms allow the collection of drag forces experienced by the conductors.

The testing protocol consisted of varying wind speeds ranging between 5 m/s and 10 m/s at model height (0.55 m), representing full-scale speeds of approximately 35 m/s and 71 m/s at prototype height (27.5 m). The model was exposed to various wind directions ranging between 0^o (wind normal to conductors) and 90^o (wind parallel to conductors) at 15^o increments. The duration of each test case was about 2 min (equal to 14 min, full-scale) and the exposure

simulated was open terrain. Figures 5a and 5b depict some of the instrumentation used in the testing.

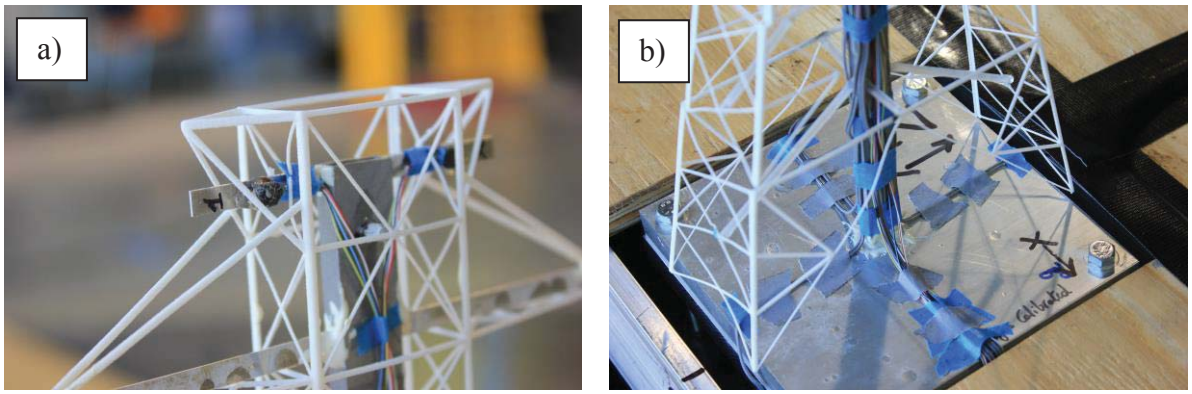

Figure 5: Some of the instrumentation used; a) Accelerometers mounted on the top cross-arm, and b) 6-DOF load cell installed at the base of the spine

3 VALIDATION OF THE AEROELASTIC MODEL

Two layers of validation are conducted. First, the generation of the aeroelastic model on a Finite Element Method (FEM) software allows the checking of selected materials and sections for design purposes. Second, a free vibration test is conducted inside the WOW facility for the test model. Such testing will ensure the accuracy of the construction and material selection since human errors are inherent in any experiment, especially at such a small-scale. For both validation procedures, the model natural frequencies of the system are compared with the target ones, which are obtained from their scaled prototype counterparts.

System	Mode of vibration	Prototype frequency f_p (Hz)	Target frequency f (Hz)	Model frequency f_m (Hz) (design)	Model frequency f_m (Hz) (construction)	Percent difference (%) (design, construction)
Single tower	Longitudinal	2.25	15.88	15.56	16.01	2.02, 0.82
	Transverse	5.10	36.08	35.82	35.10	0.72, 2.72
Full model	Conductor only	0.25	1.80	1.77	1.61	1.67, 10.56
	Longitudinal	2.28	16.10	16.45	17.52	2.17, 8.82
	Torsional	5.11	36.11	36.1	32.22	0.03, 10.74
	Transverse	5.12	36.24	37.1	39.95	2.37, 10.24

Table 2: Target and aeroelastic model frequencies

For the validation of the aeroelastic model design, a FEM replica is generated using the scaled down sections and materials selected in section 2.3, above. The software used for design validation in terms of frequency comparison is SAP2000 [22]. Concerning the validation of the construction, the aeroelastic model is carefully and meticulously assembled together. The tower-insulator and insulator-conductor connections are reproduced to depict the realistic boundary conditions and behavior in prototype transmission lines systems. Subsequently, a free vibration test is conducted to evaluate the natural frequencies of the model. The latter are obtained from the peaks in the power spectral density (PSD) of the acceleration responses when the system is excited in its natural modes of vibration. Table 2 shows the modes of vi-

bration of interest for two models: a single lattice tower with no insulators and the complete aeroelastic model previously described. As indicated in Table 2, the model frequencies for both design and construction phases are in good agreement with the target ones for the single tower system. Obtained frequencies for the design of the full model system are also well in agreement with a maximum difference of around 2.37%. However, the frequencies obtained from the free vibration tests yielded a maximum difference of about 10.74% with the target ones. This could be due to some discrepancies in the distribution of the masses along the model during construction. Another reason for the minor discrepancies could be attributed to unequal sags in the conductors of the transmission lines system, which could alter the behavior of the model during dynamic loading since the sags greatly contribute to the frequency of the conductors. Nevertheless, the obtained results and percent differences gave enough confidence for the team to carry on with the wind tunnel testing and subsequent data analysis.

4 DAMPING ESTIMATION

The self-supported transmission tower can be compared to a single-degree-of-freedom (SDOF) system. For approximation purpose, the system consists of a particle of mass M concentrated at the top of the tower. The tower has a linear elastic behavior and negligible mass with the particle being subjected to an aeroelastic force $F_{ae}(t)$. The displacement at the top of the tower $x(t)$ is opposed by: (i) a restoring force $-kx$ where k is the stiffness of the tower, and (ii) a damping force $-c\dot{x}$ where is c is the damping coefficient [22]. Equation 2 shows Newton's second law of motion of the system, which states that the product of the particle's mass M by its acceleration $\ddot{x}$ is equal to the total aeroelastic force applied to the particle above:

$$M\ddot{x} = - c\dot{x} - kx + F_{ae}(t) \tag{2}$$

Assigning n (= $\sqrt{(k/M)}/(2\pi)$) and ζ_{eff} (= $c/(2\sqrt{(kM)})$) as the frequency of vibration and the effective damping ratio in the direction of the motion respectively, Equation 2 can then be re-written as Equation 3:

$$\ddot{x} + 2\zeta_{eff}(2\pi n)\dot{x} + (2\pi n)^2 x = F_{ae}(t)/M \tag{3}$$

In case of free vibrations of a SDOF system in one direction, the damping ratio ζ_{eff} becomes the structural damping of the system ζ_{st} and the term on the right side of Equation 3 becomes zero. Chowdhury et al. [24] developed a new system identification technique, called the Iterative Least Squares (ILS) approach in order to obtain all eighteen flutter derivatives for a streamlined bridge deck from free vibrations displacement time histories. In order to obtain the flutter derivatives using the ILS approach, it is imperative to first find the aeroelastically modified effective damping C^{eff} and stiffness K^{eff} matrices, respectively, which include the aeroelastic vector component [25, 26]. In this case, the latter component in the aeroelastic drag force D_{ae}. Subsequently, if the free vibrations tests are done twice, with and without the WOW fans turned on, then one can obtain the structural and effective damping ratios ζ_{st} and ζ_{eff}, correspondingly. Hence, the aeroelastic damping ratio ζ_{aero} can be calculated by subtracting ζ_{st} from ζ_{eff}. However, Equation 3 needs to be represented as the state-space model shown in Equation 4:

$$\dot{\underline{X}} = \underline{A}\underline{X} \text{ with, } \quad \underline{X} = \begin{Bmatrix} \underline{y} \\ \dot{\underline{y}} \end{Bmatrix}, \underline{A} = \begin{bmatrix} \underline{0} & \underline{I} \\ -\underline{K}^{eff} & -\underline{C}^{eff} \end{bmatrix} \tag{4}$$

The $\underline{A}$ matrix is a $2n$ x $2n$ square matrix, where n is the number of degrees of freedom for the dynamic system and $\underline{I}$ is the identity matrix of size n x n. Consequently, the $\underline{A}$ matrix in Equation 4 can be determined if the acceleration $\underline{\ddot{y}}$, the velocity $\underline{\dot{y}}$ and the displacement $\underline{y}$ can be recorded for all n degrees of freedom (n = 1 in the case of the transmission tower) for at least $2n$ different instants of time [24, 27].

A mechanism was constructed at the WOW using steel supports and electromagnets in order to free vibrate the transmission tower by giving it an initial displacement in both strong and weak axes (0° and 90°). The three accelerometers previously used in the wind testing were also utilized in this set of experiments in order to record the acceleration time histories of the transmission tower at its topmost point. Subsequently, a MATLAB [28] code was developed in order to integrate the acceleration data and obtain the subsequent velocity and displacement time histories using the Newmark integration method [29]. Last but not least, the ILS method was adopted along with the obtained time histories until the convergence of $\underline{A}$ matrix was determined to be sufficient. Hence, C^{eff} and K^{eff} are determined and the damping ratios, both structural and effective, could be estimated.

For the purpose of this paper, the ILS algorithm will be applied to a no wind loading case in order to extract the structural damping ζ_{st}. Consequently, the transmission tower was given an initial displacement of 2 cm, then the structure was allowed to freely oscillate until reaching its rest position, with the WOW fans turned off. The time histories of acceleration data at the top of the tower were recorded. This exercise was repeated five times for each direction (0° and 90°) and the values were averaged. This paper will only tackle the 0° direction (displacement along the weak axis). Then, the obtained results of the variable were the following: K^{eff} = 9,350 N/m and C^{eff} = 0.56. The mass of the aeroelastic transmission tower is around 1.1 kgs. By using the equations of the natural frequency n and damping ratio ζ previously stated, the obtained values are: n = 14.7 Hz and ζ = 0.25% for mode shape 1. Figure 6 shows the acceleration time history of the free vibration test conducted along the weak axis.

$$\zeta = (1/(2\pi j)) \times ln\,(\ddot{x}_1/\ddot{x}_{j+1}) \tag{5}$$

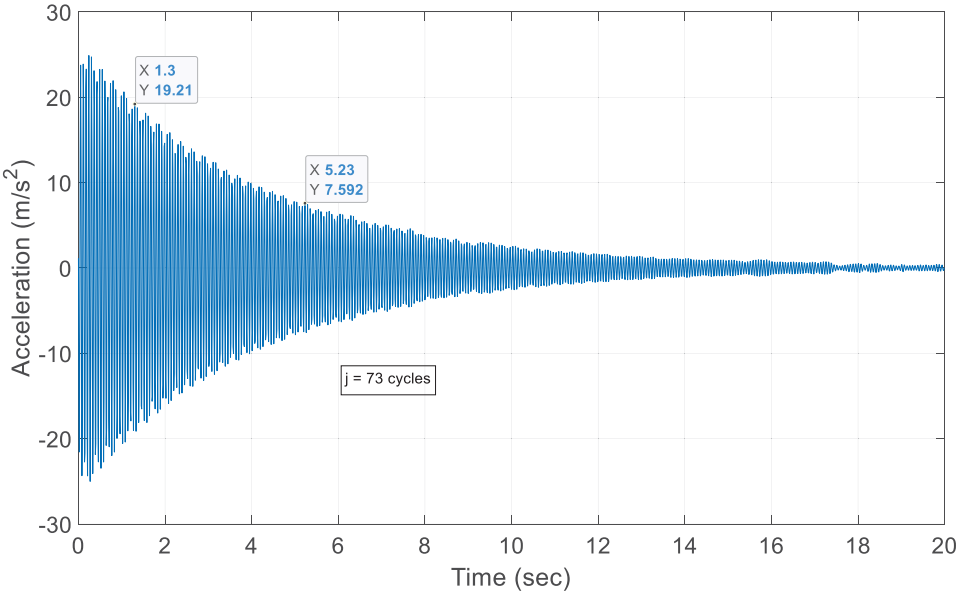

Figure 6: Acceleration time history of free vibration test

By comparison with Table 2, the obtained frequency for mode 1 is well in agreement with its design counterpart (14.7 Hz compared to 15.9 Hz). Furthermore, and by comparison with

the estimation of the damping coefficient using the decay of motion (Figure 6), the obtained structural damping ζ_{st} using the ILS approach is also well in agreement. From Figure 6, the estimated structural damping using the decay of motion (Equation 5) is around 0.21%. The previous results show the accuracy of the ILS approach in obtaining the stiffness and the damping ratio of the system in any direction. This approach will be used later to estimate the damping ratio in the strong axis. Moreover, the ILS approach will be adopted to obtain the effective damping ratio (experiment repeated with the WOW fans turned on) and therefore, propose values for the subsequent aerodynamic damping for along- and across-wind directions at different wind speeds.

5 DRAG COEFFICIENT COMPARISON

This section tackles the determination of the drag coefficients from the aeroelastic transmission tower model and compares the values to the ones suggested in the ASCE 7-16 [30] standard. Note that during the design stage of the model and more specifically the cladding elements, the tower geometry was divided into seven zones. Each zone had its own drag coefficient, based on its solidity ratio. For the sake of this paper, the drag coefficients of the entire tower are assessed with respect to both wind speeds and directions. The drag coefficients are calculated based on the data collected from the strain gauges installed on different parts of the spine and cross-arms, as shown in Equation 6:

$$C_D = 2\varepsilon EI/bM \tag{6}$$

In Equation 6, ε is the strain in the direction of loading, E is the modulus of elasticity of the material in N/m^2, I is the moment of inertia of the section in m^4, b is the distance to the centroid and M is the measured bending moment at the point of location of the strain gauge. Likewise, M is given in Equation 7:

$$M = \sum F_{Di} d_i = \sum 0.5\rho A_i C_D U^2 d_i \tag{7}$$

In Equation 7, i represents the zone number (total of seven zones), U is the wind speed at the height of the zones in m/s, A_i is the area of the elements in the plane perpendicular to the wind direction in zone i in m^2 and d_i is the distance from the strain gauge to the point of application of the force on zone i in m. Figure 7 shows a schematic of the forces on the spine.

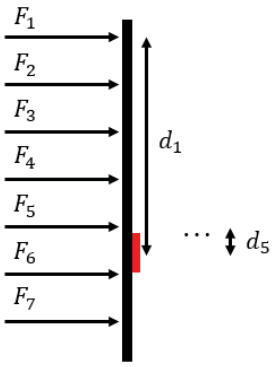

Figure 7: Schematic of forces applied on the seven zones of the spine

Similarly, and for squared trussed towers as in the case of the aeroelastic transmission tower, ASCE 7-16 [30] suggests Equation 8 for the calculation of the force coefficients (or drag coefficients per zone). Equation 8 presents C_D as a function of the solidity ratio ϕ, which is defined as the ratio of the solid area to the gross area of the tower zone, in the direction of

loading. Figure 8 showcases the comparison between values of C_D calculated using Equation 6 using experimental data and ASCE 7-16 [30] recommended ones (Equation 8).

$$C_D = 4\phi^2 - 5.9\phi + 4 \tag{8}$$

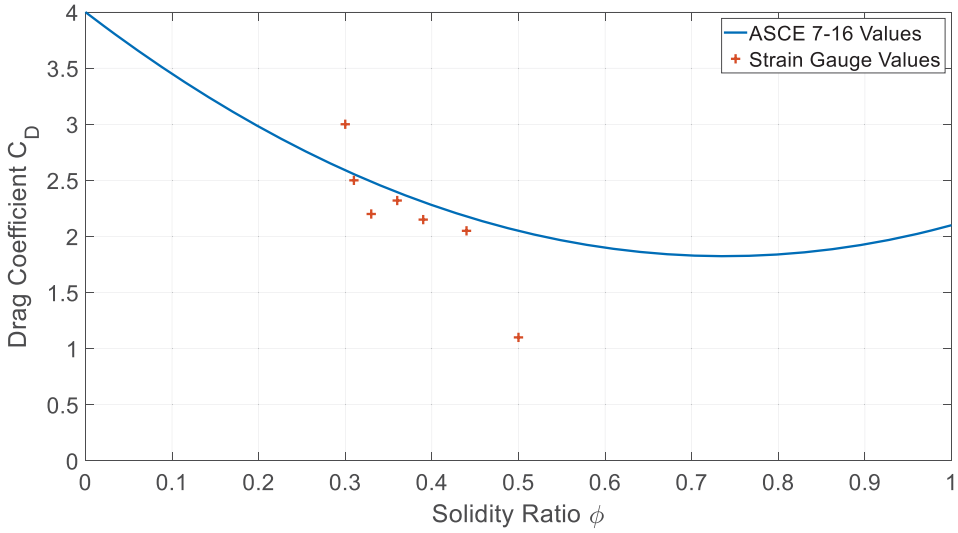

Figure 8: Comparison between experimental and ASCE 7-16 C_D values for 0° wind direction

By inspecting Figure 8, it can be noted that the experimental values of C_D obtained using strain gauge data are well in agreement with values suggested in ASCE 7-16 [29] using Equation 8. This trend is seen for all experimental values besides one. For a solidity ratio ϕ of 0.5, and at a wind direction of 0° (across conductors), the drag coefficient C_D obtained from the experiment was almost half the value suggested in the standard. This could possibly be explained by a large vibration in the across-wind direction, leading to bending moments M higher than the expected ones (Equation 7). This would lead to a decrease in the value of C_D. Nevertheless, for the rest of the wind directions, the C_D values were well in range of the theoretically suggested ones. Further data analysis is required in order to obtain force and moment coefficients C_F and C_M, respectively, and compare them with values suggested in ASCE 7-16 [30] for truss structures.

6 CONCLUSION

An aeroelastic model for a multi-spanned transmission line system was designed and constructed at the NSF NHERI WOW EF. This paper only discussed the behavior of a single self-supported lattice tower to synoptic winds. The geometric scale of the tower model was selected to be 1:50. A detailed description of the design, instrumentation and construction of the aeroelastic model is presented in this paper. The specimen was validated for both design and construction by comparing the subsequent natural frequencies to their prototype counterparts. The results were well in agreement. An ILS method was introduced in order to suggest values for the aerodynamic damping of lattice towers for both along- and across-wind directions. Last but not least, drag coefficient values obtained from experimental data were in good agreement with the ones suggested in the ASCE 7-16 [30] standard. In the future, more detailed data analysis will be conducted to obtain force and moment coefficients for the transmission tower and the entire system.

Keywords: Long span bridges, Wind Induced Vibrations, Machine Learning.

Abstract. *The Hardanger bridge is a long span suspension bridge located in western Norway and it is subjected to wind-induced-vibrations (WIV). Since the existing methods for WIV simulation demand high computational effort, it is appealing to use Machine Learning models to perform faster analyses. Therefore, this study applies Artificial Neural Network (ANN) and Support Vector Regression (SVR) algorithms to the analytical buffeting response predictions of the Hardanger bridge. The aim is to develop a strategy for training Machine Learning models that can be extended to real datasets. The samples of WIV features were analyzed with three different models: the single hidden layer perceptron, the multilayer perceptron and the support vector regression. Using the Normalized Root Mean Square Error as the performance metric, it was possible to obtain similar results with the different models.*

1 INTRODUCTION

The Hardanger bridge is by now the longest suspension in Norway and among the slenderest bridges in the world. It has been the subject to several research campaigns focusing on wind-induced-vibrations (WIV), on which high computational effort in analytical predictions was a constant [1] [2] [3] [4]. Thus, the deployment of a surrogate model for faster WIV assessment in real datasets is required to extend the experience gained with the Hardanger bridge not only for structural health monitoring applications, but also, for design of structures with similar characteristics. Nevertheless, the application of Machine Learning to datasets of WIV on long span bridges has not been well documented yet, and the comparable studies do not cover the specific category of structure and/or dynamic effect [5] [6].Therefore, this document presents the application of Machine Learning algorithms, specifically Artificial Neural Network (ANN) and Support Vector Regression (SVR), to the Hardanger Bridge WIV simulations with the purpose of developing a training strategy that could be extended to real datasets. This development involved the construction of a training dataset with simulated WIV of the Hardanger bridge which was fed into a group of Machine Learning models. Successively, the models' predictions were tested using a new dataset. The quality of the predictions was verified and compared using the Normalized Root Mean Squared Error (NRMSE). Finally, the training and testing procedure were repeated for different noise conditions added to the structural response fields.

2 MATERIALS & METHODS

2.1 Artificial neural network

An ANN is an assembly of connected and layered sets of units, where: the unit (also known as neuron or node) is an operational entity that stores and distributes information, the layers are the set of neurons, and the connections are the arrays governing the transformation rule between nodes in the contiguous layers. The neurons in a generic layer are stimulated by numeric values or signals coming from those of the previous layer. Then, a neuron is said to be activated or "fired" whenever the algebraic sum of the incoming signals overcomes a certain threshold [8]. To generalize the concept of the linear discriminant involved in the algebraic sum [9], a non-linear activation function, $f(\blacksquare)$, is applied to the result as shown in Equation (1).

The type of neural network used in this study was the so-called Multilayer Perceptron, schematically shown in Figure 1. This type of model overcomes the limitations of the single layered network by allowing the representation of higher complexity functions with their consecutive transformations of the input signals [9]. Nevertheless, to avoid feedback loops, they must be restricted to a feed-forward information flow only.

Equation (1) shows the output of a *j-th* node in the arbitrary *k-th* layer of a Multilayer Perceptron (MLP), where y_j^k is related to an activation threshold, ϑ_j^k and with, $w_{i,j}^{k-1}$ are the connection weight and x_i^{k-1} is the incoming stimulus from the *i-th* node of the previous layer. Subsequently, Equation (2) presents the operations in matrix notation. Combining these operations until the *M-th* layer corresponding to the model physical output, it is possible to obtain an estimation of the of the same $\hat{\boldsymbol{y}}$ as shown in Equation (3).This process is known as feed-forward mapping.

$$y_j^k = f\left(\sum_{i=1,j=j}^{N} w_{i,j}^{k-1}\, x_i^{k-1} + \vartheta_j^k\right) \tag{1}$$

$$y^k = f\{(w^{k-1})^T * x^{k-1} + \vartheta^k\} \tag{2}$$

$$\hat{\boldsymbol{y}}^{k=M} = f\{(w^{M-1})^T \ldots f\{(w^1)^T x^1\} + \vartheta^M\} \tag{3}$$

In the training step of the analysis, the actual output of the network is known. Therefore, a measure in the accuracy of the network can be obtained as shown in Equation (4).

$$\varepsilon = L(\hat{y}_j, y_j) \tag{4}$$

Where ε denotes the actual error and $L(\blacksquare)$ denotes the "loss" or "cost" function.

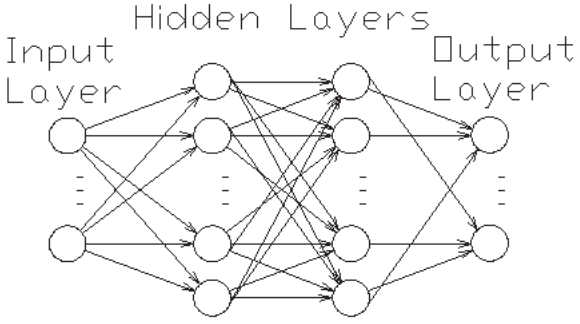

Figure 1: Architecture of ANN

The learning process consists of minimizing the loss function. For multilayered models, this is achieved by transmitting the error through all the layers within the network resulting in an

iterative optimization procedure which is known as backpropagation [10]. It is worth noting that the backpropagation procedure refers only to the error feeding and it is independent of the optimization algorithm used. Since the initial input signal, or origin, is fixed to the dataset, the only parameters to be updated in each iteration are the network weights and the neuron thresholds. Thus, the optimization problem can be written as Equation (5).

$$find\ (W_k\ \&\ \theta_k) \therefore L(\hat{y}_j, y_j) = \min(\varepsilon) \tag{5}$$

2.2 Supporting vector regression

Supporting vector regression is a machine learning tool developed by Vapnik et al. and its historical background can be found in [11]. It is the application of the supporting vector approximation to a regression problem using a ε-insensitive loss function [12]. Given a dataset with corresponding input and output features $\{x_i, y_i| \ldots |x_n, y_n\}$, the idea is to find a function $f(x)$ that approximates y_i with a certain tolerance ε. The regression estimation can be obtained with the linear function shown in Equation (6).

$$f(x) = x'w + \vartheta \tag{6}$$

Introducing the ε-insensitive loss function $L(\blacksquare)$ equal to zero when the difference of the estimation $f(x)$ and the target is less than ε, the constraint shown Equation (7) is added.

$$L(y_i - f(x,w) = \begin{cases} 0 & if|y_i - f(x,w)| \le \varepsilon \\ |y_i - f(x,w)| & otherwise \end{cases} \tag{7}$$

The best estimation minimizes the loss function and thus, the problem can be written as a convex optimization problem shown in Equation (8).

$$\begin{aligned} &minimize && \frac{1}{2}\|w\|^2 \\ &with\ constraints: && y_i - f(x,w) \le \varepsilon \quad f(x,w) - y_i \le \varepsilon \end{aligned} \tag{8}$$

To make the solution more feasible, the tolerance margin is softened by adding a set of slack variables ξ_i, ξ_i^*. The optimization then becomes as shown in Equation (9), where C is the so-called box constraint, a positive valued parameter that balances the accuracy of the model by imposing the penalty of the estimations outside the ε-margin.

$$\begin{aligned} &minimize && \frac{1}{2}\|w\|^2 + C\sum_{i=1}^{N} \xi_i + \xi_i^* \\ &with\ constraints: && \begin{cases} y_i - f(x,w) \le \varepsilon + \xi_i \\ f(x,w) - y_i \le \varepsilon + \xi_i^* \\ \xi_i, \xi_i^* \ge 0 \end{cases} \end{aligned} \tag{9}$$

Solving the posted optmization problem with inequality constraints is equivalient to finding the saddle point in the Lagrange functional of Equation (10).

$$L(\alpha) = \frac{1}{2}\sum_{i=1}^{N}\sum_{j=1}^{N}(\alpha_i - \alpha_i^*)(\alpha_j - \alpha_j^*)\, x_i' x_j + \varepsilon\sum_{i=1}^{N}(\alpha_i + \alpha_i^*) + \sum_{i=1}^{N} y_i(\alpha_i^* - \alpha_i) \tag{10}$$

Where α_n and α_n^* are the Lagrange multipliers with following constraints:

$$\sum_{n=1}^{N}(\alpha_n^* - \alpha_n) = 0;\ 0 \le \alpha_n \le \mathrm{C}\ \&\ 0 \le \alpha_n^* \le \mathrm{C} \tag{11}$$

The w-parameters may be found by:

$$w = \sum_{i=1}^{N} (\alpha_i - \alpha_i^*) x_i \tag{12}$$

Finally, the estimate is found by the expansion of the supporting vectors:

$$f(x) = \sum_{i=1}^{N} (\alpha_i - \alpha_i^*)(x_i{}' x) + \vartheta \tag{13}$$

The parameters ϑ can be obtanied by exploiting the Karush Kun Tuker (KKT) conditions [13] [14], which state that the product between dual variables and constraints vanishes at the optimal solution. Thus, the constraints shown in Equation (14) are added to the problem.

$$\begin{gathered} \alpha_i(\varepsilon + \xi_i - y_i + x_i' w + \vartheta) = 0 \\ \alpha_i{}^*(\varepsilon + \xi_i^* + y_i - x_i' w - \vartheta) = 0 \\ \xi_i(C - \alpha_i) = 0 \\ \xi_i^*(C - \alpha_i{}^*) = 0 \end{gathered} \tag{14}$$

To extend the formulation to nonlinear regression problems, it is required to replace the dot product $(x_i' x)$ with a nonlinear mapping function, known as the kernel function $K(x_i' x)$

$$f(x) = \sum_{i=1}^{N} (\alpha_i - \alpha_i^*) K(x_i{}' x) + \vartheta \tag{15}$$

In this study, a polynomial kernel function of degree d is chosen as shown in Equation (16).

$$K(x_i{}' x) = (1 + x_i{}' x_j)^d \tag{16}$$

2.3 Dataset simulations

The simulations of the structural response were carried out using the multimode theory in the frequency domain, more details in [15].The along-wind turbulent spectrum (S_u) on the bridge girder was obtained from a Kaimal-type spectrum [16] given in Equation (17), where the frequency axis is represented by f, the wind field is characterized by its mean and standard deviation $V\ and\ \sigma$, respectively. The subscript u indicates the along-wind turbulent components and the term A represents the spectral quantity related to the turbulence length scale at a reference height z.

$$\frac{S_u f}{\sigma_u^2} = \frac{\mathrm{A_u} f_z}{(1 + 1.5\mathrm{A_u} f_z)^{5/3}}, f_z = \frac{zf}{V} \tag{17}$$

The inputs for the dataset were the first two statistical moments of the random wind field. Therefore, several realizations of the couples (V, σ_u) were generated and introduced in Equation (17) to obtain the wind turbulence spectra. Further, the CPSD of the structure's response for each generation was computed. Finally, by numerical integration, the output features, namely the standard deviation of the lateral, vertical and torsional responses at the midspan $(\sigma_y, \sigma_z, \sigma_\vartheta)$ were obtained.

According to the observations of the Hardanger bridge measurement campaign reported in [1] (Figure 2), most of the data points lay in a central region. This uneven spread of the samples over the variable-space leads to a strong challenge for training the machine learning models. Therefore, the couples of input features in the training dataset were generated from a uniform linearly spaced function (Figure 3) which evenly distribute the samples. On the other hand,

those of the testing set were random numbers generated from two independent normalized functions (Figure 4) which represent a behavior closer to the real observations. The parameters for the numeric generation are reported in Table 1.

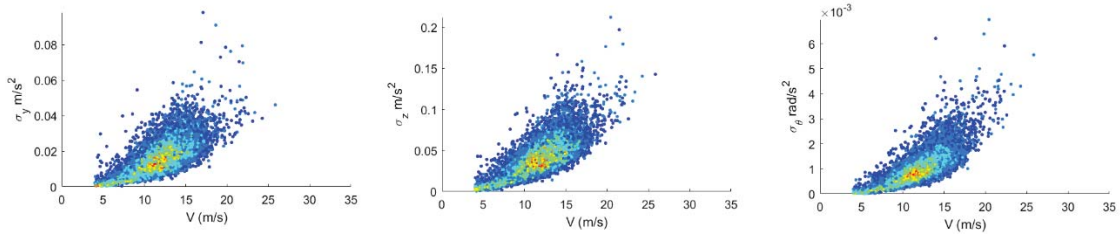

Figure 2: Structural response at midspan

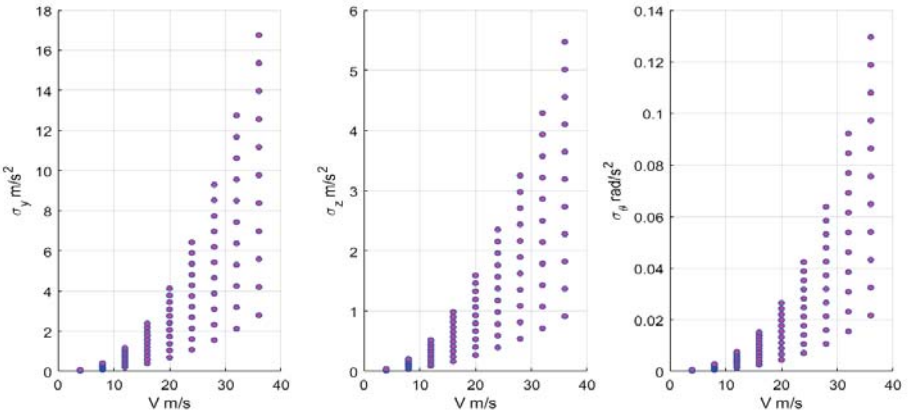

Figure 3: Training dataset

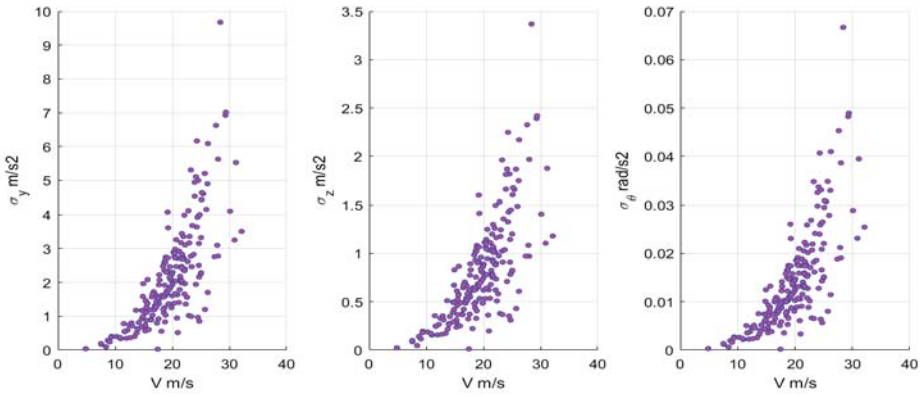

Figure 4: Validation dataset

Set	Function	Mean velocity	Turbulence Intensity	Size
Training set	Uniform Linear Spaced	[4: Δ=3.44:35].	[0.05: Δ=0.27:0.3].	100
Testing set	Rnd. Normal	$\mu = 20\ \sigma = 5$	$\mu = 0.15\ \sigma = 0.05$	200

Table 1: Dataset input generation.

2.4 Noise addition

With the aim of reproducing the challenges found on the measurement campaign, the training procedure was modified by adding a white noise to the output. The mean noise levels were of 2, 15 and 20% added to the structural responses. Nevertheless, since a decrease in the prediction's accuracy is expected with the addition of noise, a strategy for increasing the dataset size was adopted. First, several sets of random numbers were generated from a uniform

distribution according to Equation(18). Then, the different *N-terms* were added independently to the original output and stacked together to create a new larger dataset, Equation(19). The original dataset input was stacked *N-times* to match the size of the noise-output.

$$\begin{gathered} seed_i = Rand\{magnitude: [-0.5 \div 0.5] | size: OutputSet_{original}\} \\ output_{noise}(seed_i) = OutputSet_{original} \otimes \left[1 + \frac{Noise\ level}{25} seed_i\right] \\ Noise\ level \cong mean(output_{noise} - output_{original}) \\ where\ \otimes\ stands\ for\ point\ wise\ multiplication \end{gathered} \tag{18}$$

$$DataSet_{new} = \begin{bmatrix} InputSet_{original} & OutputSet_{original} + output_{noise}(seed_1) \\ InputSet_{original} & OutputSet_{original} + output_{noise}(seed_2) \\ \vdots & \vdots \\ InputSet_{original} & OutputSet_{original} + output_{noise}(seed_n) \end{bmatrix} \tag{19}$$

2.5 Models

Two ANN models were trained and validated: A Single Hidden Layer (SHL) and a Multi-layer Perceptron (MLP). The MLP model is as introduced before and the SHL perceptron model is obtained when the maximum layer index, k, in Equation (1) is equal to 2. The main challenge facing ANN training is the so-called hyperparameter setting. Equation (5) can only find the optimal weights and thresholds (parameters of the problem) as functions of the given network settings. Therefore, the size of the networks, the number of nodes, the learning rate and the selection of the networks functions (activation and loss) were tuned in advance and reported in Table 2.

Setting	SHL	MLP
Activation function	Sigmoid	Relu
Cost function	Mean Squared error	Mean Squared error
Optimization	Bayesian	Bayesian-Adaptative moment
Layers	1	2
Size	64	32-32
Learning rate	-	Min=1e-7
Number of cycles	-	1000

Table 2: Networks settings.

The main challenge for training SVR models is that Equation (15) must be solved separately for each output feature. Therefore, three different models, one for each component of the structural response, were trained with the settings presented in Table 3. The numerical values reported correspond to the hyperparameter optimization result.

Setting	SVR-σ_y	SVR-σ_z	SVR-σ_ϑ
Box constrained	0.1689	0.5511	1.1781
Epsilon	0.0010	0.0016	0.0013
Kernel Function	Polynomial degree:4 scale:2.1438		
Solver	Sequential Minimal Optimization SMO		

Table 3: SVR settings.

3 RESULTS

For each sample point in the testing set, a prediction was obtained. A comparison plot of the standard deviation of the lateral response component σ_y is shown in Figure 5 where the stars represent the model predictions while the dots show the simulated data. The global performance of the models in terms of their NRMSE are as reported in Table 4. The results indicate that the SVR and MLP models showed better performance than the SHL model.

Error	σ_y	σ_z	σ_ϑ
SVR	4,528e-05	4,101e-05	8,682e-04
SHL	5,686e-05	4,487e-05	2,738e-04
MLP	6,481e-06	1,235e-05	2,035e-04

Table 4: NRMSE.

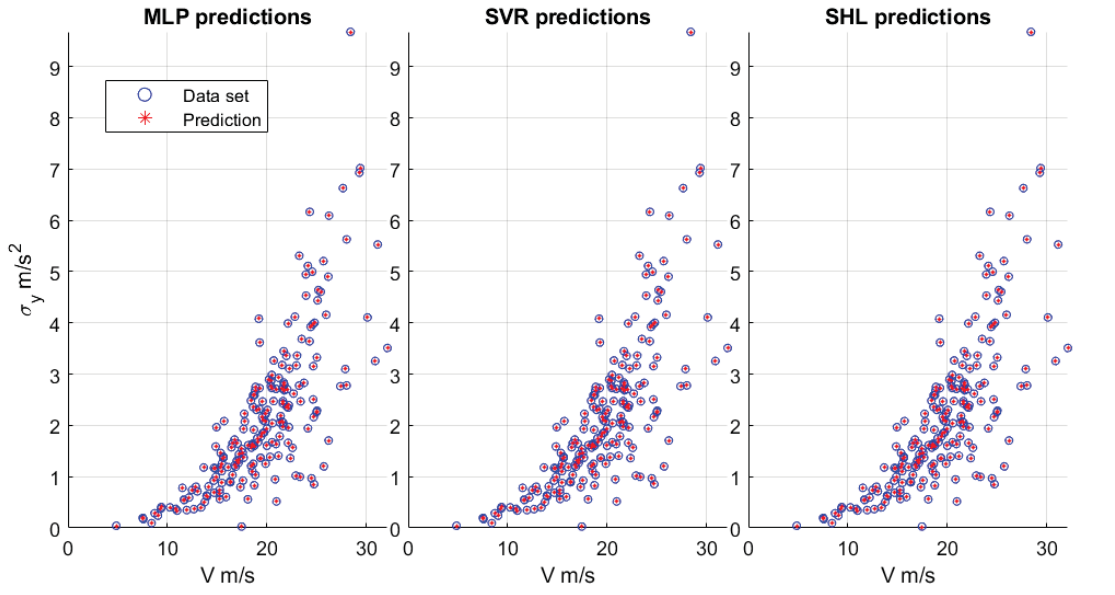

Figure 5: Prediction Scatter plot for σ_y

The performance comparison was extended to the experiment with the noise addition. The dataset creation followed Equation (19). Table 5 reports the Mean Average Percentual Error (MAPE) for the σ_y response component estimated with SVR and MLP models and with noise levels ranging from 2 to 20%. Further, Figure 6 shows a graphical comparison of the target and the estimation of the quantities for noise levels of (a) 2% and (b) 20 %. The MAPE was used for the accuracy metrics because it has comparable units with the added noise level.

Noise	*SVR*	*MLP*
2	1,02	1,12
15	10,95	6,86
20	26,97	6,91

Table 5: σ_y MAPE for different noise levels.

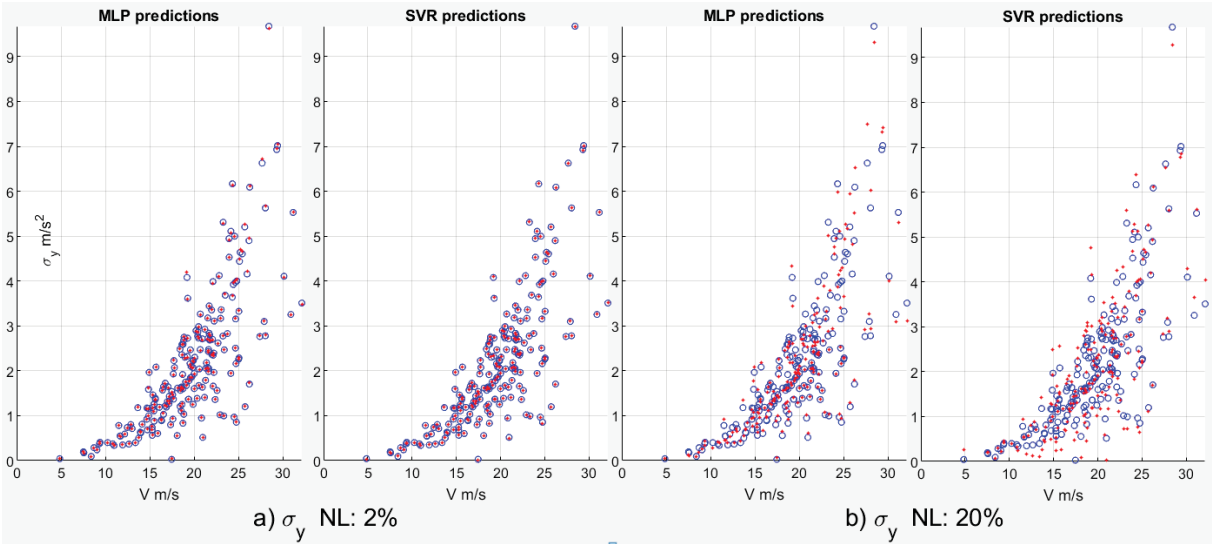

Figure 6: σ_y for: a) NL Noise level 2% b) Noise level 20%

The 27% error reported for a noise level of 20% in the case of the SVR model is particularly high. Nevertheless, after applying the dataset size-increasing strategy (Figure 7) the accuracy improves significantly. Table 6 reports the evolution of the MAPE-σ_y for the different noise levels as the dataset size is increased.

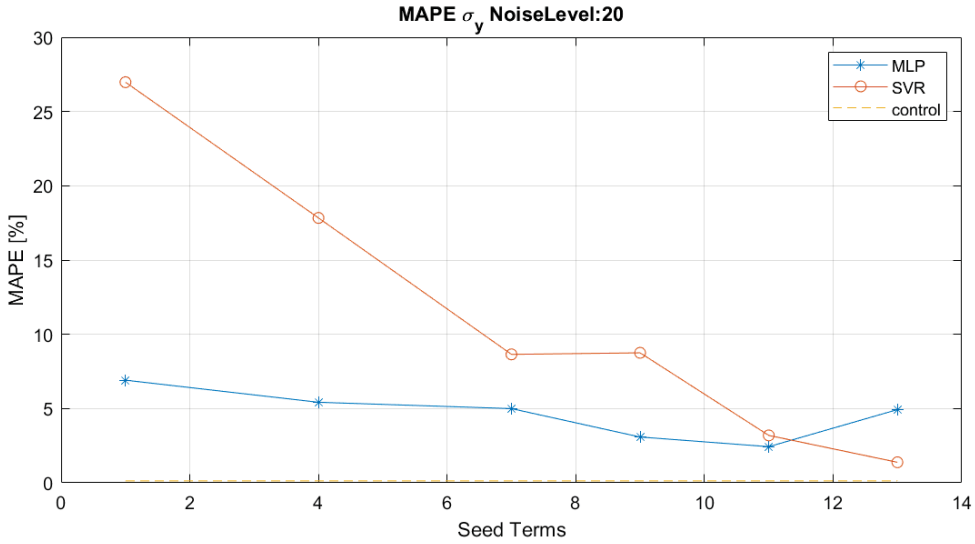

Figure 7: σ_y MAPE evolution with data size increase for 20% noise level

Random Terms	Dataset Size	Noise Level 2%		Noise Level 15%		Noise Level 20%	
		SVR	*MLP*	*SVR*	*MLP*	*SVR*	*MLP*
1	100	1.0246	1.1211	10.9553	6.8677	26.9745	6.9103
4	400	0.7315	1.6877	8.4082	3.5602	17.8352	5.4231
7	700	2.4348	1.7832	3.6389	3.8424	8.6487	4.9967
11	1100	3.2335	0.8224	3.4141	6.2085	3.1915	2.4334
13	1300	0.7284	1.5060	3.4606	9.8955	1.3829	4.9280

Table 6: σ_y MAPE evolution for different Random terms.

4 DISCUSION

The scatter plots from Figure 5 show that the methods can describe the behavior of the structural response in the testing set with reasonable accuracy. This is supported by the NRMSE reports in Table 4. The predictions of the Multilayer perceptron model gave the lowest error for all three response components; however, the other two methods also described the behavior reasonably well.

With the addition of noise to the response, an increase in the MAPE of the predictions were observed. In particular Table 5 reported that for a 20% noise level the error in the SVR model was 27% while that of the MLP model was around 7%. Therefore, the MLP model seems to be more resilient to noise addition than SVR. However, by increasing the size of the dataset the SVR model performance becomes better than the MLP model. According to Table 6, after adding 13 random terms to the dataset with 20% noise level the SVR model showed 25% reduction in the MAPE compared to almost 1% for the MLP. It is also remarkable that for the low noise level i.e. 2%, no appreciable improvement was obtained by increasing the data size. Additionally, the MAPE was almost half of magnitude of the added noise. It is worth noting that the MAPE does not necessarily descreases with increasing data size. For the MLP model an increase in the error was observed for all the noise levels. This behavior implies overtraining phenomena in this type of model.

5 CONCLUSION

The paper showed that it is possible to train machine learning models with the simulated wind induced vibrations of the Hardanger bridge dataset and obtain accurate results. The testing procedure showed a good match between the predictions and the simulations, confirmed by the low NRMSE values. The Multilayer perceptron algorithm implemented in the study gave better results mainly because of the tuning of the hyper parameters. However, to apply the methods to real datasets further analysis must be performed by adding noise to the training samples and checking the accuracy of the predictions.

The MLP model is more resistant to noise for reduced data sizes. Nevertheless, the SVR model improves with increasing data size. Additionally, the MLP model shows a tendency to overtraining as the data size increases. Therefore, extending this experience to the measurement campaigns, it is recommended to use ANN models, specifically MLP, for small datasets with high noise level and SVR models for larger datasets.

Keywords: wind engineering, aeroelastic model, vibrational comfort, high-rise buildings

Abstract. *Wind-induced vibrations are an issue not only for the structure safety, but also for the comfort of its occupants, especially in residential buildings. This paper provides the setup, methodology and results of wind tunnel aeroelastic model tests of twin high-rise (95 m high) residential buildings located in Warsaw, Poland. The aim of the tests was to assess the degree in which vibrations may be uncomfortable or harmful to the occupants of these buildings. The evaluation of vibrational comfort was conducted according to the general rules provided in ISO 6897. Measurements during both the tuning and the wind tunnel tests were performed with a system of accelerometers which allowed for direct measurement of structure accelerations, comparable with threshold values provided in the standard. The tests for each building were performed for 12 different angles of wind attack. Main non-dimensional dynamic numbers considered in the analysis were the ratios of corresponding natural frequencies in model and real-life scales, Strouhal numbers, mass scales and logarithmic decrements of damping. A mathematical model was developed which allowed for addressing the problem of coupling between the vibrations in the two main directions for angles of wind attack that are not perpendicular to the main axes of the building. As the buildings are located in dense urban development with many even taller neighbors, the influence of aerodynamic interference was crucial for the tests. Moreover, performing the tests on two buildings with a similar shape allows for comparison and assessment of the scale of influence of this interference. Besides the direct results which could be applied by the designers, these tests show the practical aspects of scaling and dimensional analysis for model tests of complicated physical phenomena, which can be used for solving actual technical and engineering problems.*

1 INTRODUCTION

The aim of this paper is to present aeroelastic wind tunnel model tests of a complex of two high-rise buildings connected with a lower link. The purpose of the tests was to assess the level of wind-induced vibrations in the buildings and compare the results with thresholds for human discomfort. This allowed to identify potential uncomfortable or unhealthy conditions at the stage of construction design, when such problems can still be mitigated to great effect through the inclusion of mechanical or mass dampers, or structural stiffening elements.

1.1 Subject of model tests

Subject of the model tests is a complex of two high-rise (95 m high) buildings connected with a lower link. The buildings are located in the inner center of Warsaw, where they will be surrounded by other buildings of similar height (or even higher), of which *The Hub* (complex of three buildings of 86-130 m high) and *Skyliner* (195 m high) are the most notable. The visualization of the buildings can be seen in Figure 1, while their location in plan is shown in Figure 2.

Figure 1. Visualization of the twin high-rise buildings

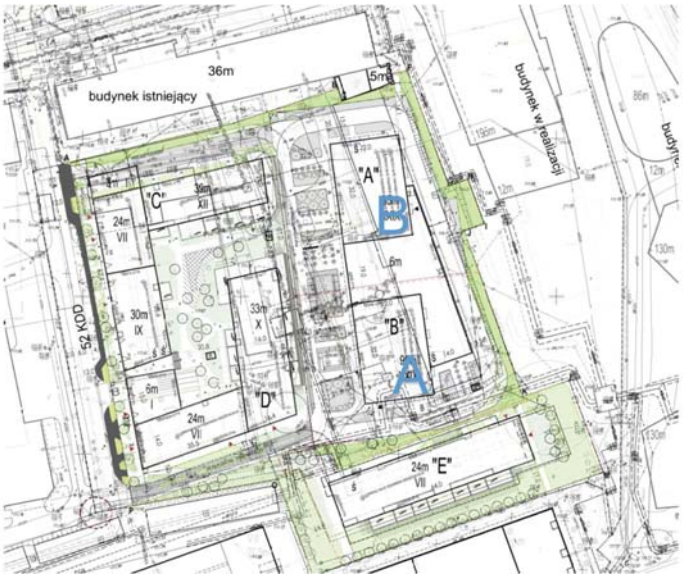

Figure 2. Location in plan of the subject buildings

1.2 Criteria of evaluation

Evaluation of perceptibility degree of horizontal vibrations by residents of high buildings was conducted in accordance with ISO/6897 91983 [1]. This document only takes into account the influence of horizontal vibrations of the building in the limited frequency range: $f \in (0{,}063;\ 1)$ Hz. The limit values of vibrations (criteria of vibrations perceptibility, levels of vibrations perception) for residents are presented on the charts in logarithmic rectangular co-ordinate system: standard deviation of acceleration σ_a – frequency of vibrations *f*.

Criteria of vibrations perceptibility depends on buildings type (general buildings, special buildings, maritime constructions) and on the nature of dynamic action (non-frequently repetitive, frequently repetitive). Charts of levels (thresholds) of vibrations perceptibility by residents are presented in Figure 3.

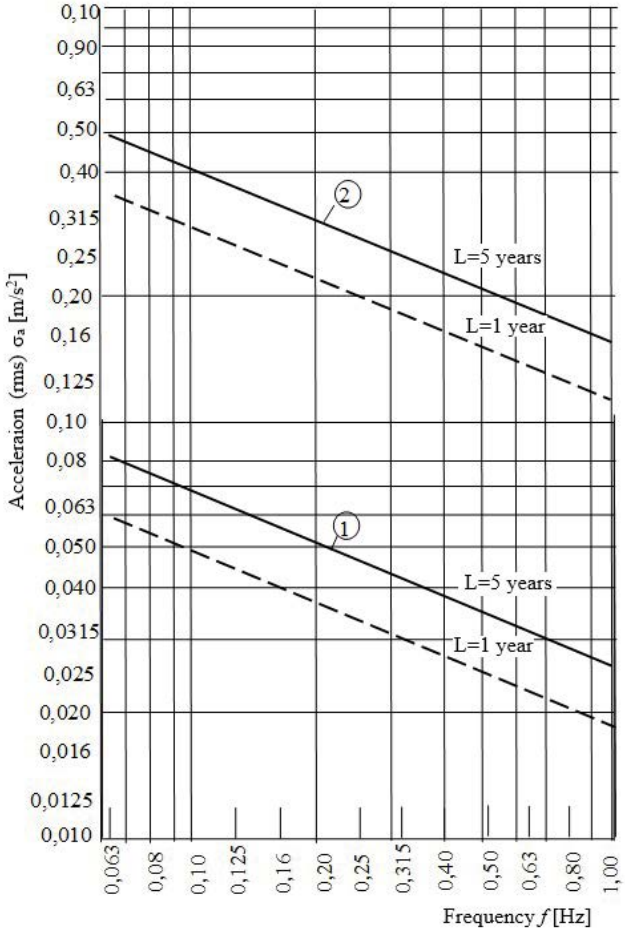

Figure 3. Limit values of horizontal vibrations of general buildings 1 and maritime constructions 2 in the case of non-frequently repetitive dynamic actions [1]

The criteria of vibrations perceptibility cannot be applied in the case of specific dynamic actions, such as earthquakes, explosions, etc. or in the case of coastal floating buildings.

Level of vibrations perception by occupants concerns people of so-called normal, mature population. No other correction factors considering age, sex, etc. were introduced.

Moreover, the influence of the following factors on the level of vibrations perception was not taken into account: body position (vertical, sitting, horizontal, aslant), visual sensations during building movements (horizontal or torsional vibrations of the building, minimal displacements of the objects inside the building). However, it should be mentioned that even minimal torsional vibrations of the building can reduce permissible level of vibrations perception significantly [2].

Level of vibrations perceptibility in the case of non-frequently repetitive vibrations depends on return period L of special intensity events and duration time of each of special intensity event; the shorter return period L, the lower limit level of vibrations perceptibility.

Criterion of vibrations perception by occupants in general buildings can be characterised as follows: vibrations causing complaints or unfavourable comments (concerning the influence of vibrations on residents comfort) in no more than 2% of residents who are in these parts of buildings where the highest vibrations appear, are considered as permissible. The considered time of vibrations are the worst 10 minutes of strong wind (storm) with return period $L = 5$ years (or more).

Available data which is necessary to determine criterion of vibrations permissibility usually concerns return periods shorter than 5 years. Regarding to this, the additional criterion of vibrations permissibility for return period of $L = 1$ year was introduced in ISO document [1]. It should be mentioned that values of permissible acceleration in the case of frequently repetitive loads (of everyday nature) are four times lower for special buildings (where precision and routine work is performed) than for general buildings.

The highest values of acceleration for high buildings appear mostly in their higher parts and usually refer to basic natural frequency of buildings vibrations f1. However, considering the level of vibrations permissibility by the buildings occupants, it may happen that accelerations related to second (or higher) natural frequency of building vibrations are more dangerous/uncomfortable for people.

Investigations of the level of vibrations perceptibility by residents were conducted in wind tunnel, where acoustic effects were not taken into account. It should be emphasised that air flows in the nature can cause infrasounds effects or noise, which influence on the level of vibrations perception by residents of buildings.

2 EXPERIMENTAL SETUP

2.1 Similarity criteria and their fulfilment

The most important similarity criteria for aeroelastic models of buildings and resulting similarity scales which were taken into account in wind tunnel model tests are presented below [3]:

Geometrical similarity scale

Wind tunnel tests were conducted using the models in scale of 1:300, hence geometrical similarity scale:

$$k_D = \frac{D_{ref,M}}{D_{ref,P}} = \frac{1}{300} \tag{1}$$

where indexes: „*M*" and „*P*" concern model and prototype, respectively. Moreover, external surfaces of aeroelastic models were accurately simulated comparing with the prototype (real life scale). Considering above, it can be concluded that geometrical similarity criteria were fulfilled in wind tunnel model tests.

Similarity criteria for inflowing air

Basic similarity criteria for inflowing air are the most commonly the following quantities:

- exponent α of power-law profile of mean wind velocity;
- the level of turbulence intensity I_v and profile of turbulence intensity;
- direction of inflowing air defined by mean angle of wind attack $\bar{\theta}$;
- Reynolds number $Re = \frac{v_{ref} D_{ref}}{\nu}$, where: ν – kinematic viscosity of air.

Profiles of mean wind velocity and turbulence intensity, obtained from wind tunnel tests, are shown in Fig. 4. and Fig. 5., respectively. They correspond to the profiles in nature with sufficient accuracy. Discrete values of angle $\bar{\theta}$, with increment of 30°, were adopted during wind tunnel tests to take into account the influence of mean wind direction. The analysed buildings are low flow bodies, so the influence of Reynolds number is negligible in this case.

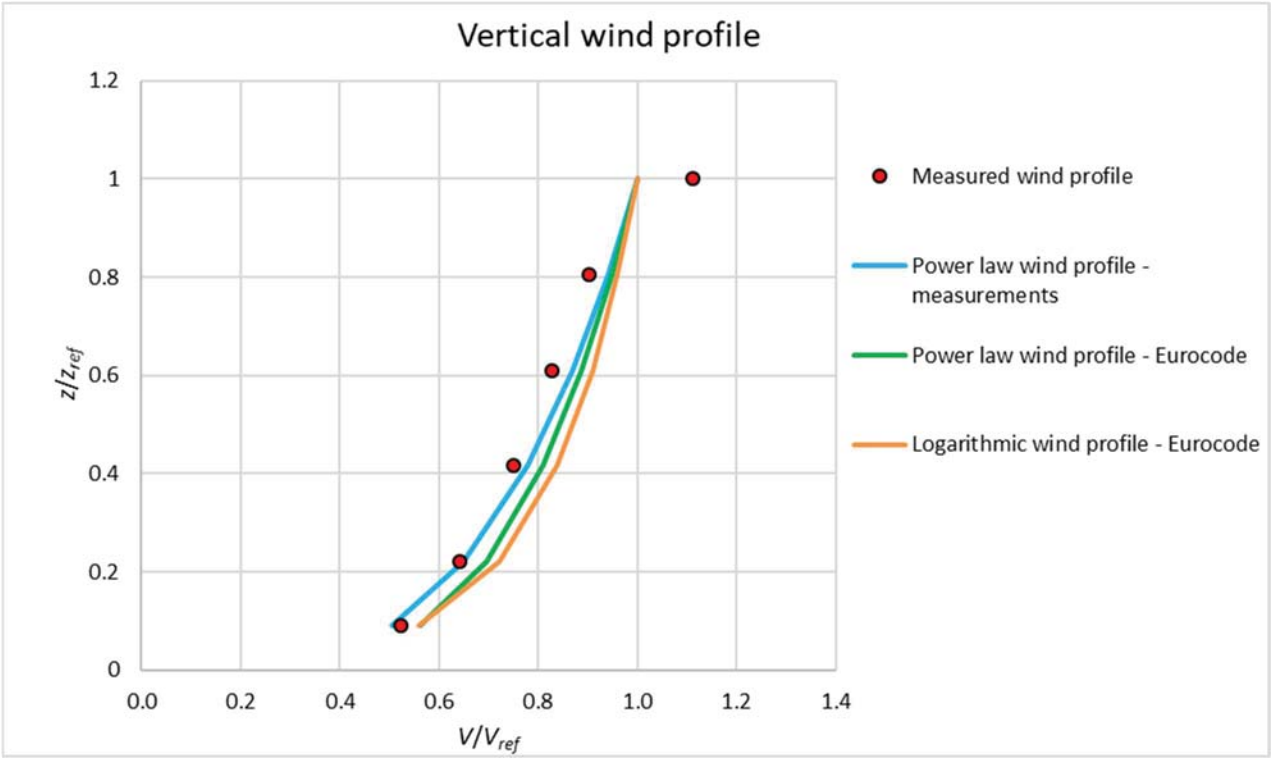

Figure 4. Vertical wind profile obtained in wind tunnel for the measurements

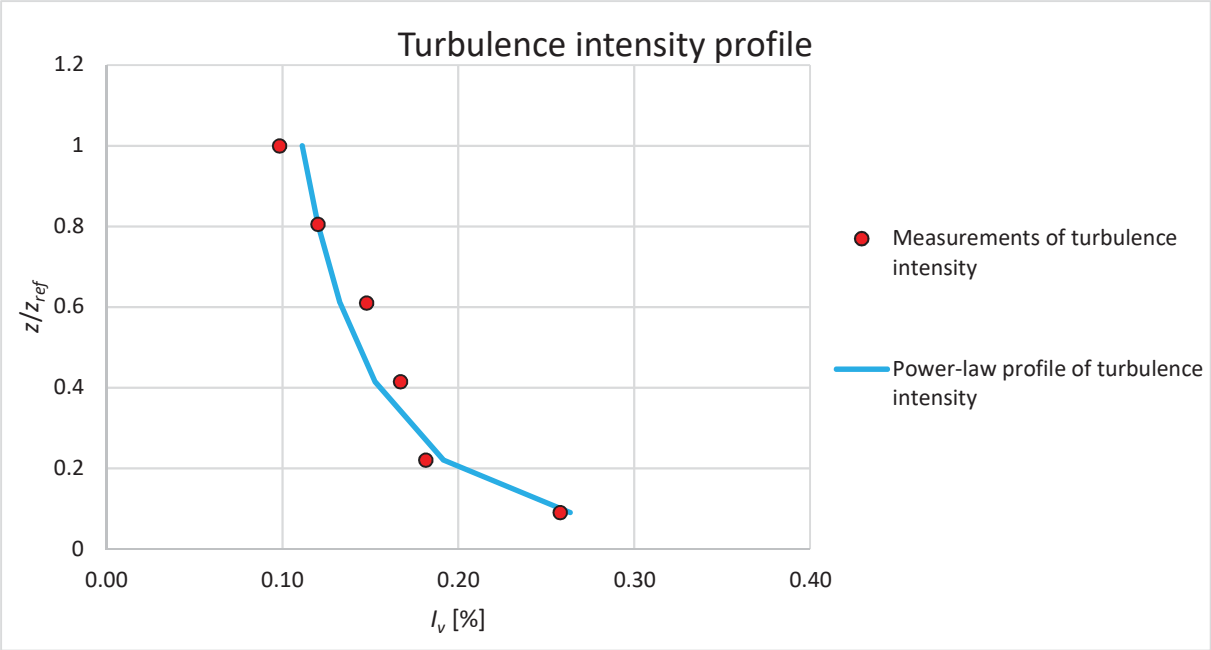

Figure 5. Vertical turbulence intensity profile obtained in wind tunnel for the measurements

Summing up, it can be concluded that basic similarity criteria of inflowing air were almost fully fulfilled in wind tunnel tests.

Mechanical similarity criteria

Similarity criterion of mass (inertia forces)

Similarity criterion of mass can be expressed by the formula:

$$M_{\rho M} = M_{\rho P} \tag{2}$$

or:

$$\frac{M_{\rho M}}{M_{\rho P}} = k_{M\rho} = \frac{\left(\rho D_{ref}^2 \frac{H}{M_{total}\breve{M}}\right)_M}{\left(\rho D_{ref}^2 \frac{H}{M_{total}\breve{M}}\right)_P} = \left(\frac{H_M}{H_P}\right)^3 \frac{(M_{total}\breve{M})_P}{(M_{total}\breve{M})_M} = 1.0 \tag{3}$$

where:

ρ – density of atmospheric air; M_{total} – total mass of aboveground part of the building; $\breve{M}$ – dimensionless generalized mass, taking into account free vibrations modes of the building.

Assuming that free vibrations modes of the buildings and their models corresponding to frequencies of free vibrations f_{1X} and f_{1Y} are similar and that equivalent masses of above-ground part of the buildings and their models on the unit of height are distributed uniformly – it can be adopted that: $\breve{M}_M \cong \breve{M}_P$. Then:

$$k_{M\rho} \cong \left(\frac{H_M}{H_P}\right)^3 \frac{M_{total,P}}{M_{total,M}} = 1.0 \tag{4}$$

which results in the following relationship:

$$\frac{M_{total,M}}{M_{total,P}} = \left(\frac{H_P}{H_M}\right)^3 = 300^3 = 27 \cdot 10^6 \tag{5}$$

Similarity criterion of vibrations damping (damping forces)

Mean logarithmic decrements of vibrations damping $\Delta_{mean,X}, \Delta_{mean,Y}$ (or decrements of critical damping $\gamma_{mean,X}, \gamma_{mean,Y}$) for equivalent systems of one degree of freedom for directions X and Y, respectively, can be defined as follows:

$$\Delta_{mean,X} = \frac{1}{N} \ln \frac{A_{1,X}}{A_{N+1,X}} \tag{6}$$

$$\Delta_{mean,Y} = \frac{1}{N} \ln \frac{A_{1,Y}}{A_{N+1,Y}} \tag{7}$$

where: N – number of the consecutive amplitudes of damped free vibrations adopted to determine mean values of Δ_{mean}.

Quantities $\Delta_{mean,X}$ and $\Delta_{mean,Y}$ are dimensionless quantities constituting another similarity criteria, hence:

$$\frac{(\Delta_{mean,X})_M}{(\Delta_{mean,X})_P} = k_{\Delta_{mean,X}} = 1; \frac{(\Delta_{mean,Y})_M}{(\Delta_{mean,Y})_P} = k_{\Delta_{mean,Y}} = 1 \tag{8}$$

Similarity criteria of vibrations frequency (elastic forces)

Similarity criteria of vibrations frequency $f_{1,X}$ and $f_{1,Y}$ result from respective kinematic Strouhal numbers St_X and St_Y :

$$St_{X,M} = St_{X,P}; St_{Y,M} = St_{Y,P} \tag{9}$$

$$\left(\frac{f_{1,X} D_{ref}}{v_{ref}}\right)_M = \left(\frac{f_{1,X} D_{ref}}{v_{ref}}\right)_P \tag{10}$$

$$\left(\frac{f_{1,Y} D_{ref}}{v_{ref}}\right)_M = \left(\frac{f_{1,Y} D_{ref}}{v_{ref}}\right)_P \tag{11}$$

or:

$$\left(\frac{f_{1,Y}}{f_{1,X}}\right)_M = \left(\frac{f_{1,Y}}{f_{1,X}}\right)_P \tag{12}$$

It results in the following similarity criteria:

$$k_{f1,X} = \frac{f_{1,X,M}}{f_{1,X,P}} = \frac{D_{ref,P}}{D_{ref,M}} \frac{v_{ref,M}}{v_{ref,P}} \tag{13}$$

$$k_{f1,X,Y} = \frac{f_{1,Y,M}}{f_{1,Y,P}} = \frac{f_{1,X,M}}{f_{1,X,P}} \tag{14}$$

Assessment of fulfilment of similarity criteria for aeroelastic models

Aeroelastic model for each of the buildings was created and calibrated taking into account fulfilment of the most important mechanical similarity criteria with iterative method. The assessment of fulfilment of mechanical similarity criteria, considering the parameters of adopted aeroelastic model, can be characterised as follows:

Total mass of aboveground part of model: $M_{total,M} = 0.149$ kg
Hence:

$$\frac{M^{*}_{\rho,M}}{M_{\rho,P}} = \varkappa = \left(\frac{1}{300}\right)^{3} \frac{29.113^{6}\ kg}{0.149\ kg} = 7.25 \neq 1 = \frac{M_{\rho,M}}{M_{\rho,P}} \tag{15}$$

According to above, it can be concluded that criterion of similarity of masses is not fulfilled. Taking this into account, if other similarity criteria were fulfilled with enough approximation, the results of measurements of the response of such aeroelastic model (eg. vibrations acceleration) should be decreased $\varkappa$ times (in this case, divided by 7.25).

Mean logarithmic decrements of vibrations damping

Time series of free vibrations along *X* and *Y* axes is presented in Fig. 6. and 7.

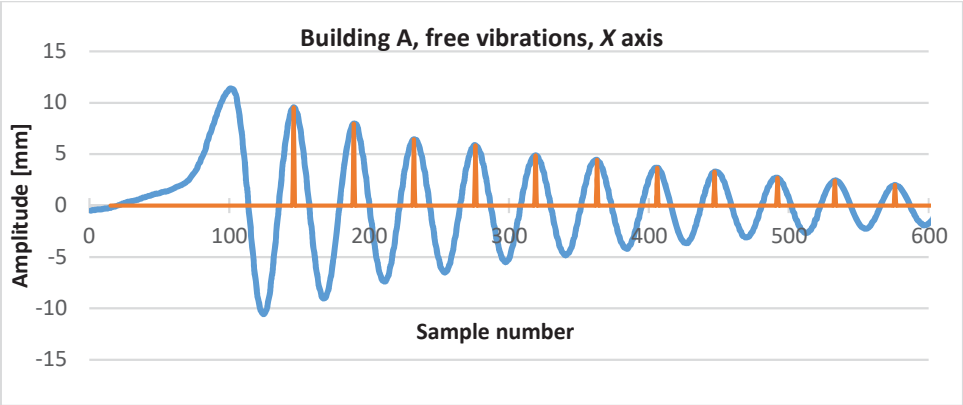

Figure 6. Free vibrations of model of building A along *X* axis

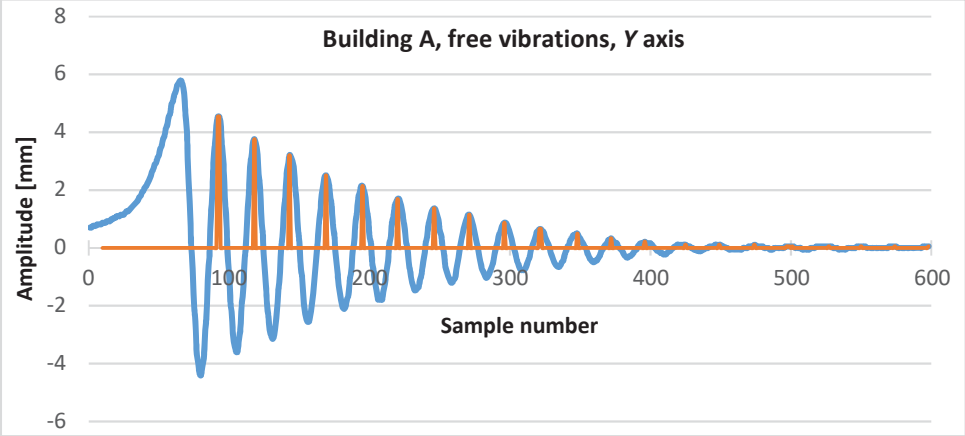

Figure 7. Free vibrations of model of building A along *Y* axis

Basing on above time series, mean decrements of damping vibrations were assessed: $\Delta_{mean,X,M} = 0.15$ and $\Delta_{mean,Y,M} = 0.09$. Taking into account real value of $\Delta = (0.08 \div 0.15)$, it can be concluded that similarity criteria of damping forces are fulfilled with a good approximation.

Frequency of model free vibrations: $f_{1X} = 11.66$ Hz; $f_{1Y} = 18{,}34$ Hz.

From criterion of kinematic Strouhal number (1.11) for first frequency of free vibrations in *X* direction it results that:

$$k_{f1,X} = \frac{11.66}{0.27} = 300\frac{v_{ref,M}}{18.8} \tag{16}$$

hence:

$$v_{ref} = \frac{11.66 \cdot 18.8}{0.27 \cdot 300} = 2.71 \frac{\mathrm{m}}{\mathrm{s}} \tag{17}$$

Wind tunnel tests should be conducted at mean wind velocity v_{ref}. However, this velocity was increased to value of $v_{ref}^{*} = 3.4 \frac{\mathrm{m}}{\mathrm{s}}$ because of small vibrations amplitudes at lower velocity (amplitudes were close to measurement range of measuring instruments). Because of this measurements results should be scaled with the use of respective factor.

When increasing $v_{ref,M}$ from 2.7 m/s to 3.4 m/s fluctuations of wind velocity are increased from v_M' to $v_M'^{*}$ as well. It can be assumed with a good approximation that $\frac{v_{ref,M}^{*}}{v_{ref,M}} \cong \frac{v_M'^{*}}{v_M'}$. Therefore, dimensionless dynamic component of wind action, appearing on the right side of the motion equation of models is almost unchanged. Nevertheless, kinematic Strouhal number changes as follows: $\frac{St_{ref,M}^{*}}{St_{ref,M}} = \frac{v_{ref,M}}{v_{ref,M}^{*}} = \frac{2.7}{3.4} = 0.79$. In turn, this change causes that model responses in resonance zones increase by the factor resulting from the following relation:

$$\mu = \frac{\frac{1}{St_{ref,M}^{*}}}{\frac{1}{St_{ref,M}}} = \frac{v_{ref,M}^{*}}{v_{ref,M}} = \frac{3.4}{2.7} = 1.26 \tag{18}$$

The second similarity criterion for vibrations frequency has the following form:

$$\frac{f_{1,Y,M}}{f_{1,X,M}} = \frac{18.34}{11.66} = 1.57 \tag{19}$$

$$\frac{f_{1,Y,P}}{f_{1,X,P}} = \frac{0.47}{0.27} = 1.74 \tag{20}$$

Taking into account uncertainties given above (concerning real values of frequencies of buildings free vibrations $f_{1,X,P}$ and $f_{1,Y,P}$), it can be concluded that above similarity criterion regarding ratio of frequency of free vibrations is fulfilled with a good approximation.

Relationships for other similarity scales

Assuming that:

- geometrical scale k_D is:

$$k_D = \frac{D_{ref,M}}{D_{ref,P}} = \frac{1}{300} \tag{21}$$

- frequency scale k_f is:

$$k_f = k_{f1,X} = \frac{11.66}{0.27} = 43.18, \qquad k_{f1,X}^{*} = \frac{D_{ref,P}}{D_{ref,M}} \frac{v_{ref,M}^{*}}{v_{ref,P}} = \frac{300}{1} \frac{3.4}{18.8} = 54.25 \tag{22}$$

- time scale k_t is:

$$k_t = \frac{1}{k_f} = \frac{0.27}{11.66} = 0.023, \qquad k_t^{*} = \frac{1}{k_f} = \frac{1}{54.25} = 0.01843 \tag{23}$$

Then velocity scale k_v is:

$$k_v = \frac{k_D}{k_t} = \frac{\frac{1}{300}}{0.023} = 0.145, \qquad k_v^{*} = \frac{k_D}{k_t^{*}} = \frac{\frac{1}{300}}{0.01843} = 0.181 \tag{24}$$

and acceleration scale k_a is:

$$k_a = \frac{k_D}{k_t^2} = \frac{\frac{1}{300}}{0.023^2} = 6.30, \qquad k_a^* = \frac{k_D}{k_t^{*2}} = \frac{\frac{1}{300}}{0.01843^2} = 9.814 \tag{25}$$

Hence, due to unfulfilment of criterion of kinematic Strouhal number, relationships between accelerations of building models a_M^* and prototypes a_P are as follows:

$$a_M^* = k_a^* a_P = \mu \cdot k_a \cdot a_P \tag{26}$$

Moreover, taking into account remarks about unfulfilment of similarity criteria of mass for buildings models and their prototypes, relationships between accelerations measured on the buildings models a_M^{**} and on their prototypes a_P can be defined as:

$$a_M^{**} = \varkappa \cdot \mu \cdot k_a \cdot a_P \tag{27}$$

or in another form:

$$a_P = \frac{a_M^{**}}{\varkappa \cdot \mu \cdot k_a} = \frac{a_M^{**}}{7.25 \cdot 1.26 \cdot 9.814} = 0.0112 \cdot a_M^{**} \tag{28}$$

2.2 Wind tunnel parameters and apparatus

Wind tunnel tests were conducted for 12 angles of wind inflow, with increment of 30°. The accelerometers, placed in upper parts of the model, were used to register building accelerations in X and Y direction. The measurement results were processed using narrow-band filter for first frequencies of free vibrations for directions X and Y. Then, the results of this process were multiplied by scale factors resulting from similarity criteria. Finally, they were compared with limit accelerations.

Model tests were conducted at the boundary layer aerodynamic tunnel of Wind Engineering Laboratory of Cracow University of Technology. The dimensions of the working section are 1.6 m height and 2.2 m width; however, with adjacent compensation chambers bordered by slotted walls on both sides, the width is about 3.5 m. Such design allows for a significant reduction of boundary layer disturbances during partially blocked flow, enabling for investigations on larger model while minimizing the errors resulting from blockage effect. Details of the wind tunnel are shown in Fig. 8 and Fig. 9.

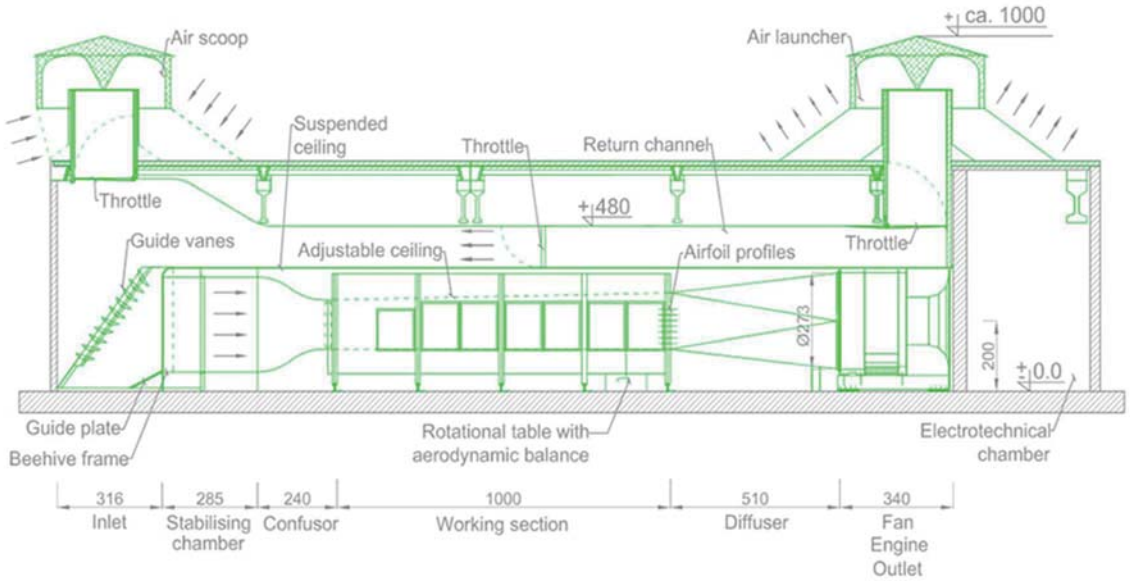

Figure 8: Longitudinal cross section of Wind Engineering Laboratory of Cracow University of Technology wind tunnel (all dimensions in [cm]).

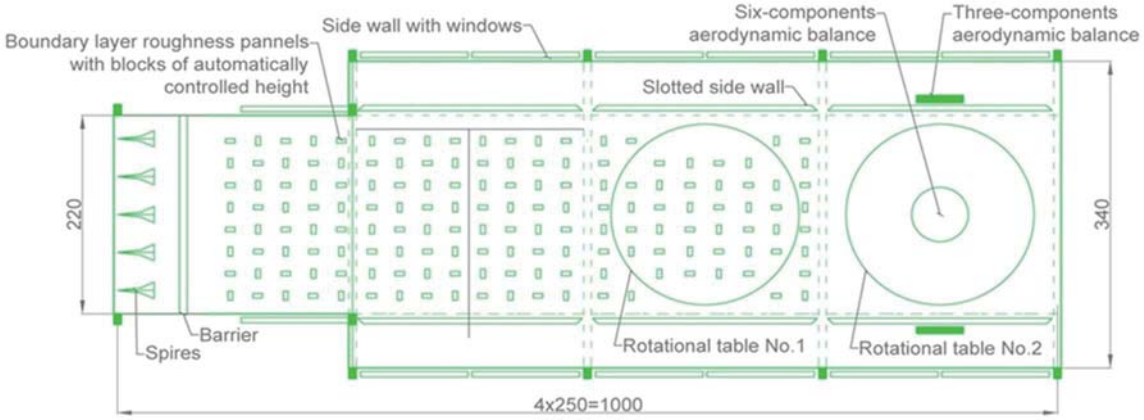

Figure 9: Top view of Wind Engineering Laboratory of Cracow University of Technology wind tunnel working section (all dimensions in [cm]).

The working section is ended with a cascade of horizontal airfoil profiles that reduces the influence of vortices generated by the fan on an air flow in the area of the rotational table. Guide vanes, inlet, beehive frame, stabilization chamber, confusor are the elements designed to take over the stream either returning through the return channel or taken from above the building roof by external air scoop and direct it respectively, making the stream homogeneous and of a very low turbulence before the inflow to the working section. The diffuser which is behind the working section is of a rectangular shape at the beginning part and of a circular shape at the end part (cross-section of the fan) and its length is equal to 5 m.

The axial fan, single-stage of efficiency 0.8 – 0.9, the outer diameter 2.72 m and the velocity of the end of the fan blade up to 100 m/s, is located on the suction side of the wind tunnel. The engine of the alternate current, shorted, driving the fan with a power of 200 kW, of nominal revolutions 750 rpm and supply voltage 220 V, controlled by inverter. Maximum mean flow velocity in the working section is 40 m/s.

The vibrations of aeroelastic model were measured with *Brüel & Kjær* Type 3050-B-060 module with DeltaTron Accelerometers Type 4507 B 002. This allowed for direct measurement of amplitudes of model accelerations under the effect of strong wind.

2.3 Wind and dynamic characteristics adopted in model tests and in analysis of tests results for subject buildings

Wind characteristics of inflowing air according to [4] and dynamic characteristics of the analysed buildings which were adopted in model tests and in analysis of tests results are as follows:

- Category of terrain roughness: IV; exponent of power law wind profile: $\alpha = 0.24$;
- Basic wind velocity: $v_b = 22$ m/s;
- Reference height in the nature: $z_{ref} = 102.5\ m$;
- Mean wind velocity at the reference height:

$$v_{ref} = v_m(102.5) = 22.0 \cdot 0.62 \left(\frac{102.5}{10}\right)^{0.24} = 23.8 \text{ m/s} \tag{29}$$

- Reference velocity for 5-years return period:

The following denotations are used: v_L – mean wind velocity with L years return period, v_k – characteristic wind velocity (i.e. mean wind velocity with $L = L_k = 50$ years return period). Assuming Gumbel distribution and averaged values of the parameters of this distribution in European conditions, the following relationships can be written [3]:

$$v_L = U - \frac{1}{a}\ln\left[-\ln\left(1-\frac{1}{L}\right)\right];\ \frac{1}{a} \approx (0.1 \div 0.3);\ \text{on average: } \frac{1}{a} \approx 0.13U \tag{30}$$

$$\frac{v_L}{v_k} \approx \frac{1-0.13\ln\left[-\ln\left(1-\frac{1}{L}\right)\right]}{1-0.13\ln\left[-\ln\left(1-\frac{1}{L_k}\right)\right]} \tag{31}$$

Assuming $L_k = 50$ years, values of $\frac{v_L}{v_k}$ were calculated using different values of L. This value can be calculated for return period of $L = 5$ years:

$$v_{ref,L(5year\ )} = v_{ref,L(50years)}(0.79) = 23.8 \cdot 0.0.79 = 18.8\ \frac{m}{s} \tag{32}$$

Above relationship concerns mean wind velocity in open agricultural area at the height of 10 m above ground. However, it can be assumed (due to lack of data) that this relationship can also be adopted for mean wind velocity at any height z above terrain of other type and, in consequence, for dynamic component of wind action $w(z,t)$ which linearly depends on mean wind velocity $\bar{v}(z)$ and its fluctuations $v'(z,t)$. Fluctuations $v'(z,t)$ depend on mean wind velocity $\bar{v}(z)$ and decrease with decreasing of mean wind velocity $\bar{v}(z)$. Then, it can be assumed that dynamic component of wind action corresponding to v_5 (ie. $L = 5$ years) is $(0.79)^2$ times smaller than this component in the case if $v_k = v_{50}$.

- Building height: $H_A = H_B = 102.5$ m;
- Total mass of aboveground part of each building: $M_{total,P} = 29.113 \cdot 10^6$ kg;
- Total mass of aboveground part of each model: $M_{total,M} = 0.149$ kg;
- Basic frequencies of free vibrations of the buildings for direction *X* and *Y*, received from the consulting engineers basing on the calculations of free vibrations of these buildings, are as follows: $f_{1X} = 0.27$ Hz; $f_{1Y} = 0.47$ Hz. It is worth to mention that adopted frequencies f_{1X} and f_{1Y} can differ from these for real objects because of the following reasons:

  1. Stiffness of so called non-structural elements of the buildings are not taken into account;

  2. Mass of the buildings resulting from variable payload of the buildings can be different;

  3. Material and mechanical characteristics of structural elements of the buildings adopted in dynamic calculations can differ from these for real objects;
- Basic frequencies of free vibrations of the buildings models in direction *X* and *Y* are: $f_{1X} = 11.66$ Hz; $f_{1Y} = 18.34$ Hz
- Logarithmic decrements of vibrations damping for each building relating to frequencies f_{1X} and f_{1Y} should be in the range of: $\Delta \in (0.08 \div 0.15)$ [5].

2.4 Models for the tests

The models for the aeroelastic tests were created in the scale of 1:300. Such scale allowed for recreation of the surroundings of the subject buildings in a radius of 300 m. Due to its close

proximity to the subject buildings and towering height, possibly impacting the results, also the *Warsaw Spire* building (180 m) was added to the model, despite its location outside of the surroundings radius. Fig. 10 shows the computer model of the buildings and their surroundings, while the physical model in the working space of wind tunnel is presented in Fig. 11.

Figure 10: Computer model of the analyzed buildings (marked in red) and their surroundings.

Figure 11: Physical model of the analyzed buildings and their surroundings in the working space of wind tunnel.

On the contrary of the rest of the model which was made as rigid models from PVC, ABS and HIPS plastics, the aeroelastic models of the two subject buildings were made from light plywood (cover) and steel or aluminum core (depending on the variant of the model). Three different variants were created with different structural design (see Fig. 12). For each of the variants, dynamic characteristics were investigated, which allowed for the comparison and final choice of the model which best corresponds to the real life characteristics of the buildings.

Model shown in Fig. 12c was chosen. Subsequently, this model has been tuned and calibrated to the real life dynamic characteristics of the buildings (mostly concerning the ratio of first two natural frequencies and damping).

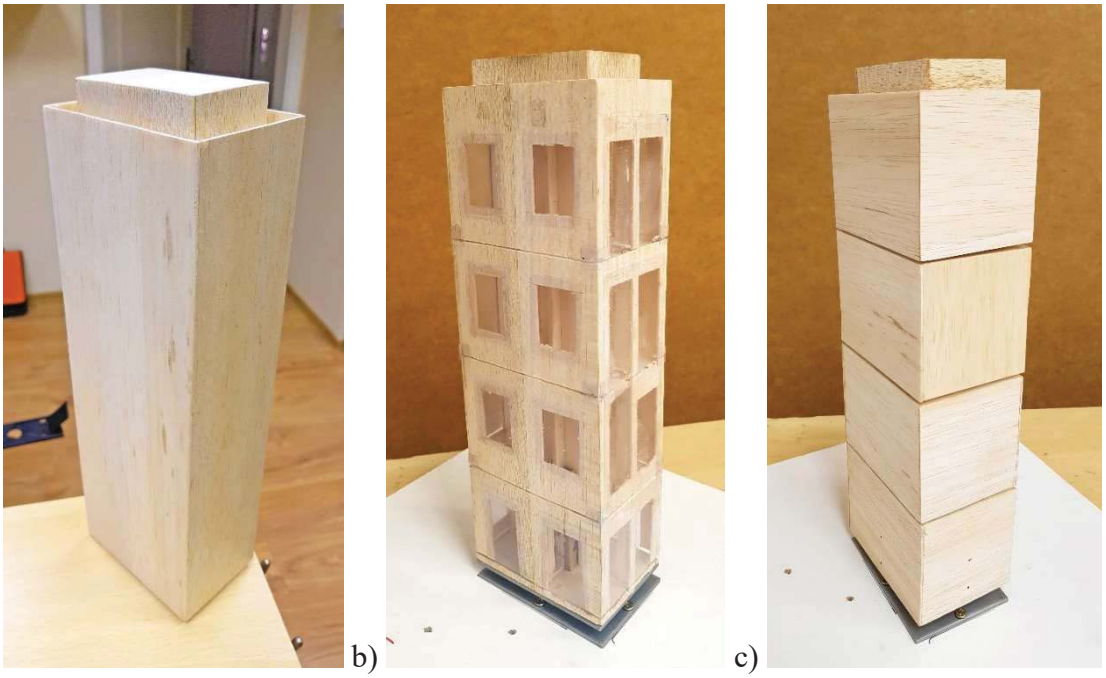

Figure 12: Different variants of aeroelastic model of the subject buildings.

3 RESULTS AND ANALYSIS

3.1 Results of aeroelastic tests

Basing on the results of wind tunnel model tests conducted on aeroelastic models of buildings A and B, RMS values of filtered signals of vibrations acceleration in natural scale were determined. The appropriate similarity scales were taken into account. Then, RMS values were compared with limit values of vibrations acceleration RMS_{dop} in accordance with Fig. 3.

RMS values obtained for directions X and Y (RMS_X and RMS_Y) and values of $RMS_{max} = \sqrt{RMS_X^2 + RMS_Y^2}$ as well as limit values of RMS_{lim} were summarised in Tab. 1, 2 and were presented in Fig. 13 and 14.

3.2 Results analysis and evaluation of vibrational comfort

RMS values of vibrations acceleration meet the requirement of vibration comfort in all considered cases:

$$RMS_{max} \leq RMS_{lim}$$

which proves there is sufficient stiffness of the analysed buildings.

It should be mentioned that one can observe unevenness of vibrations level with respect to the angle of wind inflow in the Figure 5 and 6. It may be the result of significant aerodynamic

interference appearing between the analysed buildings and the neighbouring buildings (mainly from the east). However, the observed phenomena are not dangerous for the analysed buildings.

It can be concluded that the stiffness of the building is sufficient and the building meets requirements of vibrational comfort.

4 CONCLUSIONS

The proposed method allowed for obtaining reliable results, which could be implemented in practical engineering design. Combining the deeply developed mathematical model based on similarity criteria with tests in wind tunnel on physical models proved to be a good solution of the problem. The authors are planning to extend this approach in further works by also including the torsional mode of vibrations along with two basic axial ones. In this case the torsional frequency was much higher, but in taller slender buildings it also plays an important role in the evaluation of the vibrations as it can have values which are even below 1 Hz.

The obtained results are what can be expected for buildings of this height and massing. The problems with vibrational comfort of building's occupants occur mostly in taller buildings with lower natural frequencies. In this case, there clearly should be no problem with harmful wind-induced vibrations (in light of employed evaluation criteria) as the measured and calculated values are much below the limit thresholds. However, the buildings – due to their regular shape and similarity – provided to be a good way of validating the used method. Furthermore, the differences of vibration acceleration RMS values, which can be noticed between Fig. 13 and Fig. 14 for each of the buildings, highlight the significant role of aerodynamic interference of surrounding buildings. The location between two other tall buildings (comp. Fig. 10) of building B seems to be having a significant impact on the values of its vibrations along *X* axis, which are considerably smaller than what can be observed for building A.

Keywords: Motion-induced vortex vibration, Wind tunnel tests, Separated vortex from leading edge, Secondary vortex at trailing edge, Spring-supported tests, Flow visualization tests

Abstract. *In 2009, a crack was discovered in the bracing member around the intermediate pier of Ikitsuki Bridge, a truss bridge in Nagasaki Prefecture, Japan. As a result of a field oscillation measurement by Nagasaki University, the main cause of the crack was identified as the Kármán vortex-induced vibration. However, aerodynamic vibrations were also observed even in the wind speed range lower than the resonance wind speed of the Kármán vortex-induced vibration. Conventionally, according to the result of a wind tunnel test using side ratios of B/D=2.0-8.0 (B: along-wind length, D: cross-wind length), the motion-induced vortex vibration caused by unification of the separated vortex from leading edge and the secondary vortex at trailing edge was recognized. However, considering the fact that the side ratio of the section of the bracing member of Ikitsuki Bridge is B/D=1.18, there has been a little past research on motion-induced vortex vibration on a rectangular cross section of B/D of less than 2. Therefore, the authors moved forward with a research of the motion-induced vortex vibration, focusing on the rectangular cross sections with small side ratios including B/D= 1.18. In order to clarify the generation of motion-induced vortex vibration, a spring-supported test and a smoke flow visualization test were conducted on the said cross sections. A possibility was shown that without the formation of the secondary vortex at trailing edge, a motion-induced vortex vibration might occur. Based on the wind tunnel test results, this research aimed to verify whether or not the secondary vortex at trailing edge is essential for the generation of motion-induced vortex vibration. As a result, it was found that it is considered that the secondary vortex at trailing edge is not always necessary not only for rectangular cross-sections with less than a side ratio of B/D=2, but also for a cross section similar to the rectangular cross section at both small amplitude range at the onset reduced wind speed of motion-induced vortex vibration and a comparatively large amplitude range where the maximum response amplitude of motion-induced vortex vibration occurs.*

1 INTRODUCTION

The vortices separated from rectangular cross sections are broadly classified into Kármán vortices and motion-induced vortices (separated vortices from leading edge) [1, 2]. The former are those that are accompanied by the interferences of two separated shear layers at both the top and bottom surfaces of the structures. The latter are the ones that are shedding separately from the leading edges of the top and bottom surfaces caused by the separated shear layers at the top and bottom surfaces excited alternately due to the vibration of the rectangular cross section. The vibration caused by the latter vortices was found in the past wind tunnel tests [3, 4]. The vibration is known as either motion-induced vortex vibration [1, 2] or impinging-shear-layer instability [5-8]. The onset wind speed of this vibration depends on the side ratio of the rectangular cross section and this relation was schematically clarified [1, 8]. The mechanisms of the motion-induced vortex vibration of the rectangular section and H-shaped section cylinders were also revealed [9-12]. This research is involved in the motion-induced vortex vibration generated in a bracing member of a real truss bridge in Japan.

In 2009, Ikitsuki Bridge, a truss bridge in Nagasaki Prefecture with a center span length of 400 m, was discovered to have a crack in the bracing member of the bridge [13]. As a result of the subsequent vibration measurement at the site, the main cause of the crack was identified as Kármán vortex-induced vibration. However, vibrations were also observed in the wind speed range of 7-8 m/s, which was lower than the resonance wind speed of Kármán vortex-induced vibration. Conventionally, according to the results from a wind tunnel test using a side ratio of B/D=2-8, the motion-induced vortex vibration was confirmed [1]. However, the side ratio of the section of the bracing member is B/D=1.18, and there has been a little past research on motion-induced vortex vibration on a rectangular cross section of B/D of less than 2. Therefore, in the past research, a spring-supported test was carried out targeting a rectangular cross section of B/D=1.18. Furthermore, unsteady aerodynamic lift measurement and flow field visualization were performed and the results of the spring-supported test were discussed. It was found in the past research that it is considered that the secondary vortex at trailing edge is not always essential for the generation of the motion-induced vortex vibration for the cross section of B/D=1.18 at the onset reduced wind speed region.

The purpose of this research is to further assure the conclusions of past research. Specifically, in this research, the necessity of a secondary vortex at trailing edge not only at the onset reduced wind speed region, but also at the reduced wind speed region where the maximum response amplitude of motion-induced vortex vibration occurs were discussed through spring-supported tests and flow visualization tests using the models of three kinds of cross-sectional shapes where a secondary vortex at trailing edge is considered less likely to occur.

2 PAST RESEARCH RESULTS

Figure 1 shows the result of the spring-supported test of the cross section of B/D=1.18 for an angle of attack of 0 degrees [14]. Vibrations were confirmed from the neighborhoods of reduced wind speed Vr=2 and 8. Because the reduced wind speed at motion-induced vortex vibration is calculated as Vr=1.67B/D=1.67×1.18=2.0 [1], vibrations around Vr=2 were considered to be motion-induced vortex vibrations. The effects of the existence or non-existence of flange on the maximum response amplitude of motion-induced vortex vibration are extremely small.

The Strouhal number measured on the cross-section with flanges was St=0.124 [14]. Its inverse number is the critical reduced wind speed of the beginning of the Kármán vortex-induced vibration. In other words, because Vr=1/St=1/0.124=8.1, a vibration beginning in the neighborhood of a reduced wind speed of 8 can be judged as Kármán vortex-induced vibra-

tion. However, from the fact that the Scruton number in this experiment's case was small at *Sc*=1.32, it was found that Kármán vortex-induced vibration was changed to a galloping along with the increase in wind speed.

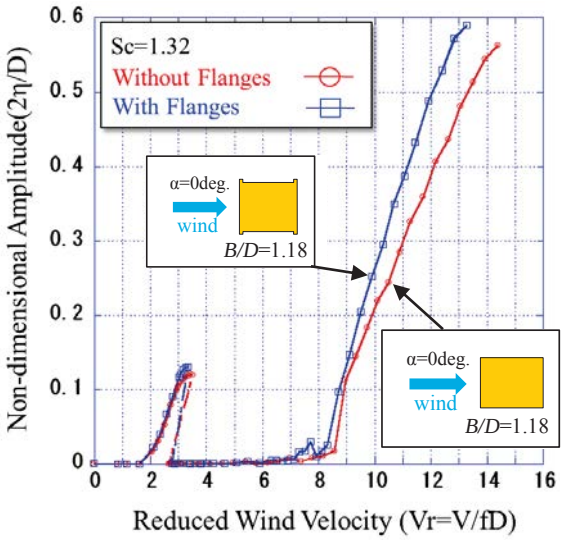

Figure 1: Spring-supported test result (*B/D*=1.18, angle of attack, α=0 deg.) [14]

Figure 2 shows unsteady aerodynamic lift coefficients $C_{L\eta i}$ in the wind speed range of *Vr*=0-5. $C_{L\eta i}$ in the ranges of the wind speed of motion-induced vortex vibration are positive values and they correspond to the responses in Figure 1. This shows the same tendency as the result that was confirmed by Yagi et al [15] that unsteady aerodynamic force coefficient H_1^* of rectangular cross-section with a side ratio of *B/D*=1 becomes a positive value in the neighborhoods of *Vr*=1.67*B/D*=1.67 and *Vr*=1/*St*. Furthermore, Nakamura and Mizota suggested the existence of low speed instability from the results of measuring unsteady aerodynamic lifts using a rectangular cross section of *B/D*=1 [16,17].

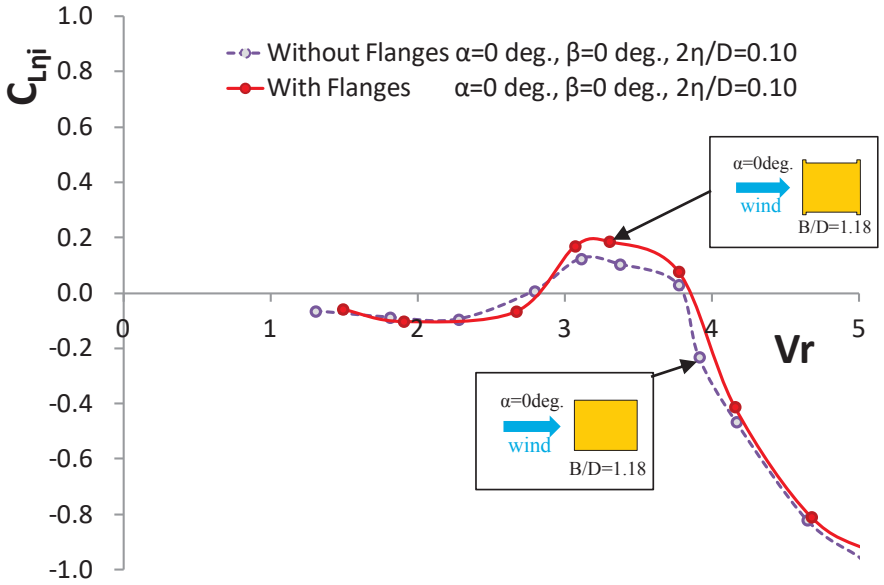

Figure 2: Unsteady aerodynamic lift coefficients [14]

Figures 3(a) shows the relation between the amplitude of forced-oscillation and the generation probability of the secondary vortex at trailing edge, regarding a model of B/D=1.18. The generation probability of the secondary vortex at trailing edge is defined as (the number of secondary vortex at trailing edge/20) ×100(%). Figures 3(b) shows the relation between reduced wind speed, Vr and non-dimensional double amplitude, $2\eta/D$ which is obtained on a time-averaged basis. Figures 3(c) shows the results of the flow visualizations. Additionally, the generation of the secondary vortex at trailing edge for the model with a side ratio of B/D=1.18 is usually recognized when the amplitude of oscillation is more than $2\eta/D$=0.05, shown in Figure 3(a). However, according to the result of the spring-supported test of this model, shown in Figure 3(b), the motion-induced vortex vibration was observed to form in the amplitude below $2\eta/D$ =0.05 at a reduced wind speed of Vr=2.0. There was a hysteretic behavior observed in between Vr=2.6 and Vr=3.3.

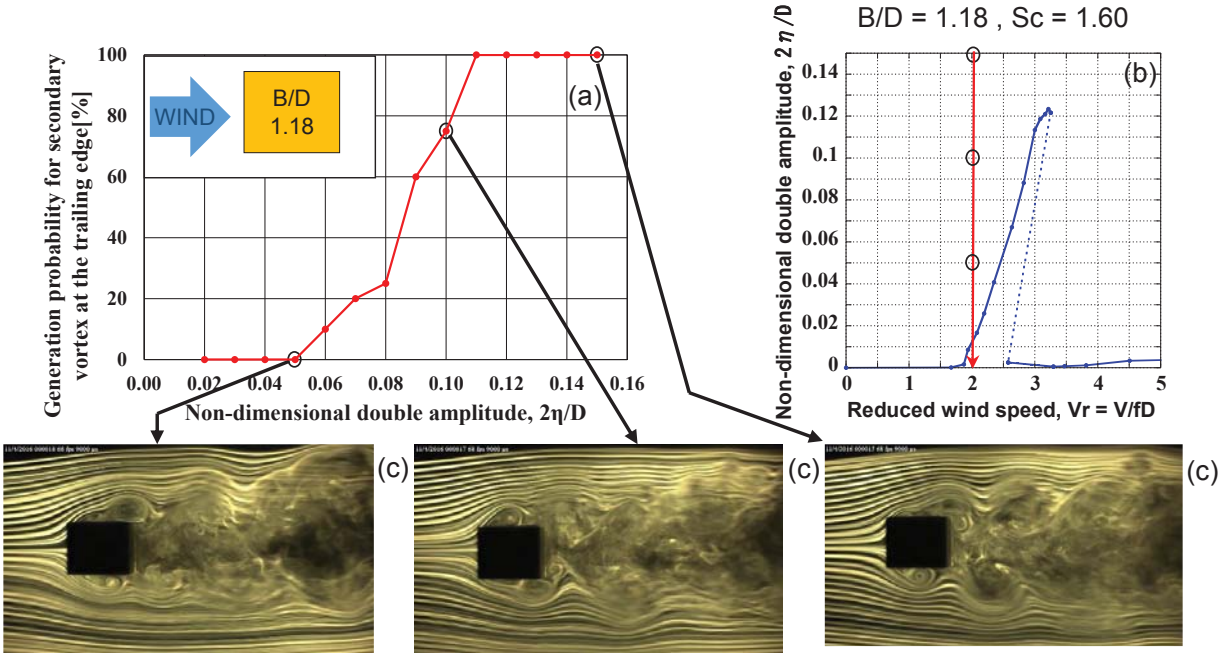

Figure 3: B/D=1.18, (a) Generation probability for secondary vortex at trailing edge at Vr=2.0, (b) Relation between Vr and $2\eta/D$, (c) Flow visualization test results of forced-oscillating model at the top displacement in $2\eta/D$=0.05 and 0.15, at the bottom displacement in $2\eta/D$=0.10 [18].

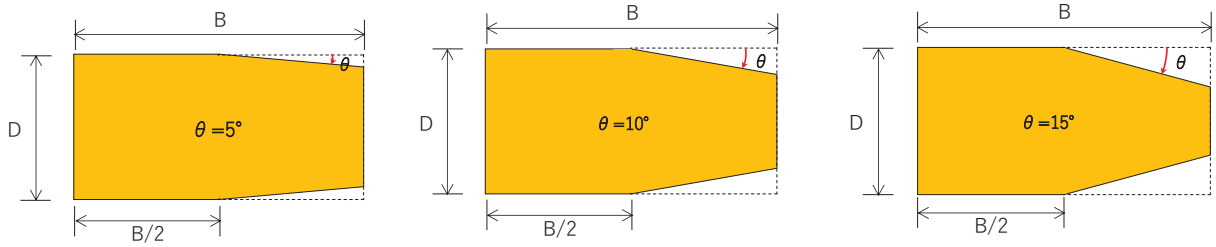
3 EXPERIMENTAL SETUP

3.1 Section models

Cross-sectional shapes where a secondary vortex at trailing edge is considered not to occur or to be less likely to occur during vibration were selected, as shown in Figure 4. The gradient θ was provided in a mainstream direction at the downstream side of a rectangular cross-section of a side ratio of B/D=2, and θ was changed to θ=5 degrees, 10 degrees and 15 degrees. In addition to that, a rectangular cross section with a side ratio of B/D=2 was added for a spring-supported test for comparison, and the wind-tunnel tests were conducted in a smooth flow for four cross-sections in total.



Test	B(mm)	D(mm)
Spring-supported tests	180	90
Flow visualization tests	40	20

Figure 4: Model cross sections.

3.2 Spring-supported tests

The spring-supported test was conducted in the middle-sized wind tunnel (cross-section: 1.8m high×0.9m wide) at Kyushu Institute of Technology. Main experimental conditions for the model were: mass per unit length=2.82-5.43 kg/m, natural frequency of heaving vibration=5.25-7.29 Hz, logarithmic decrement of structural damping=0.004-0.008 and Scruton number=4.7. Table 1 shows the conditions for the spring-supported tests. Figure 5 shows a photo of the section model installed in the wind tunnel.

Table 1: Spring-supported test conditions.

θ (deg.)	D (m)	Air density ρ (kg/m^3)	Natural frequency f (Hz)	Mass per unit length m (kg/m)	Logarithmic decrement δ	Scruton Number $Sc=2m\,\delta/\rho D^2$

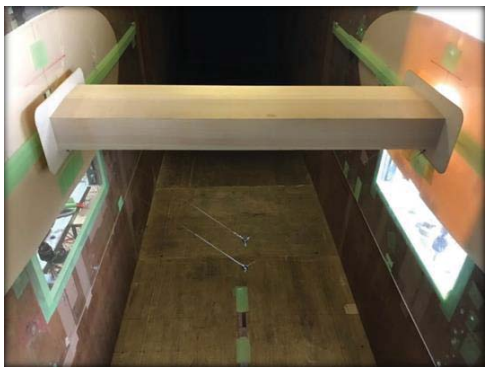

Figure 5: Section model for a spring-supported test mounted in Kyushu Institute Technology wind tunnel.

3.3 Flow visualization tests

Figure 6 shows the experimental system of the flow visualization test. The flow field visualizations around the model during forced-oscillating times were conducted using a small-sized wind tunnel (0.4m high×0.4m wide) at Kyushu Institute of Technology. It was considered that the wind speeds in the wind tunnel of V=0.6-1.0 m/s are good for visualization, so that eventually V=0.6 m/s was selected. As for the forced-oscillating amplitude η, because the

peak of aerodynamic response in the range of low wind speed is $2\eta/D$=0.30 approximately, the non-dimensional double amplitudes were set up as $2\eta/D$=0.02-0.35 in accordance with the spring-supported test results. Figures 7 and 8 show the forced oscillation system and the installation status of a model, respectively. Table 2 shows the conditions for the flow visualization tests.

4 EXPERIMENTAL RESULTS AND DISCUSSION

Figure 9 shows the results of the spring-supported tests of the three kinds of cross-sections and a rectangular cross-section of *B/D*=2. The onsets of vortex-induced vibrations were confirmed at the approximate reduced wind speed *Vr*=4.0, in all cross-sections. These vibrations are considered to be motion-induced vortex vibrations because the onset reduced wind speed of the motion-induced vortex vibration of a rectangular cross-section of a side ratio, *B/D* = 2, is approximately *Vr* =1.67*B/D*=3.34, which is close to the values of the onset wind speeds of these vortex-induced vibrations. In the four kinds of cross-sections, it was confirmed that Kármán vortex vibrations were generated at the approximate reduced wind speed *Vr*=13, and shifted to galloping along with wind speed increase. It was confirmed that the maximum amplitudes of the three kinds of motion-induced vortex vibrations on the cross sections which have the gradient θ are just about the same even if the gradient θ of the downstream side cross section changes. It was confirmed that in the cross section of θ = 15 degrees, compared with other cross-sections, the onset wind speed range of motion-induced vortex vibration shifts to the side of high wind speed.

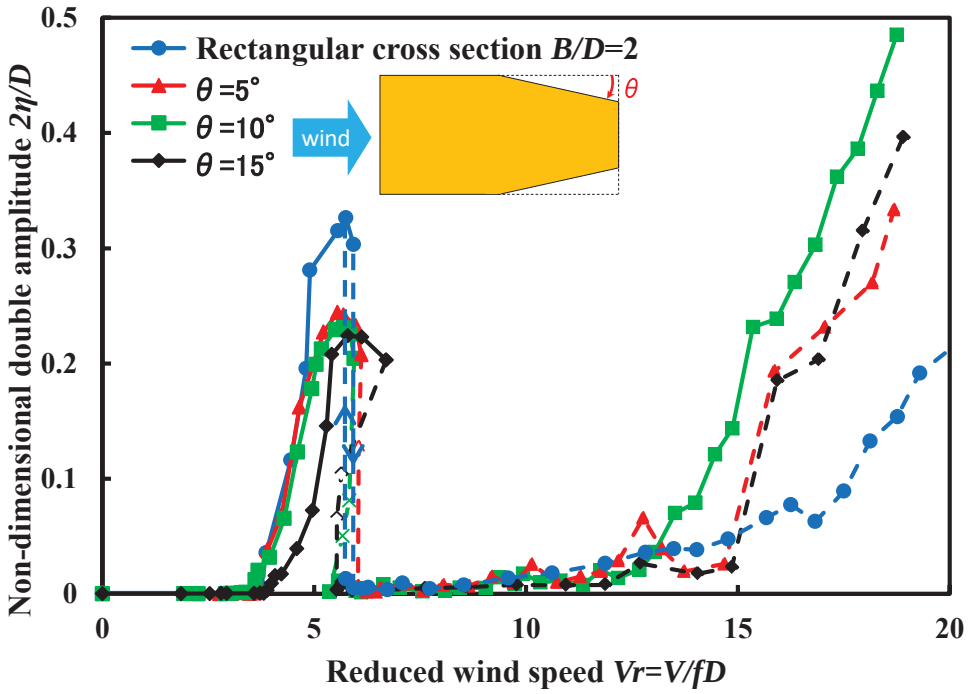

Figure 9: Spring-supported test result (angle of attack: α=0 deg., Scruton number: *Sc*=4.7).

4.1 Onset reduced wind speed region

Figure 10 shows the measuring results of the generation probability of a secondary vortex at trailing edge of the three kinds of cross-sections having the gradient θ and a rectangular cross-section with a side ratio of *B/D*=2 [19] at the onset reduced wind speed of motion-induced vortex vibration. Figure 11 shows the visualized images of the flows at the neighborhood of the onset reduced wind speed of motion-induced vortex vibration. From Figure 10, it was confirmed that a secondary vortex at trailing edge at the onset reduced wind speed in the three cross-sections, compared with a rectangular cross-section of *B/D*=2, is less likely to occur if the gradient θ becomes larger. Furthermore, in the cross section of θ=15 degrees, almost no generation of a secondary vortex at trailing edge was confirmed until non-dimensional double amplitude $2\eta/D$=0.35. Although from Figure 11, the generation of a secondary vortex

at trailing edge was confirmed at non-dimensional double amplitude $2\eta/D$=0.20, in the cross sections of θ =5 degrees and 10 degrees, no generation of a secondary vortex at trailing edge was confirmed in the cross section of gradient θ=15 degrees. Therefore, it was confirmed that the larger the gradient θ is, the less the secondary vortex at trailing edge is likely to occur. By comparing the results of the spring-supported tests of Figure 9 and those of the generation probability of a secondary vortex at trailing edge at the approximate onset reduced wind speed of motion-induced vortex vibration of Figure 10, it was confirmed that no secondary vortex at trailing edge was generated in all three kinds of cross sections having the gradient θ at the small amplitude range of $2\eta/D \leqq 0.04$ at the onset of motion-induced vortex vibration. From this fact, as with the case of the experimental result of a rectangular cross section of a side ratio B/D = 2 of the past research [19], a secondary vortex at trailing edge is not always necessary for the onset of motion-induced vortex vibration relating to the three kinds of cross sections having the gradient θ.

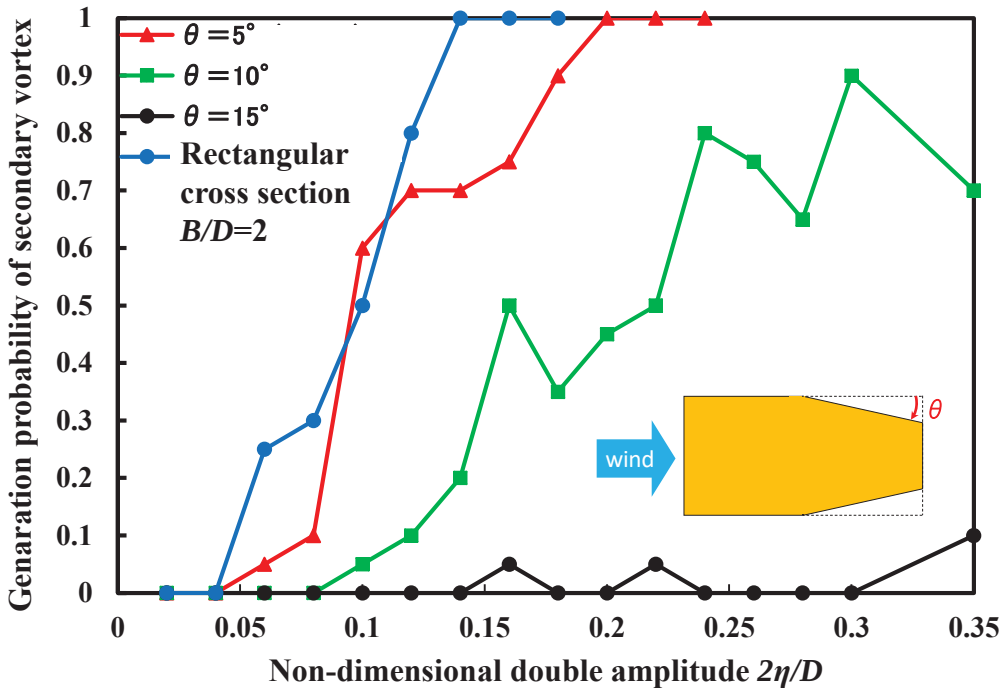

Figure 10: Generation probability for secondary vortex at the trailing edge at onset reduced wind speed region Vr=3.9-4.6

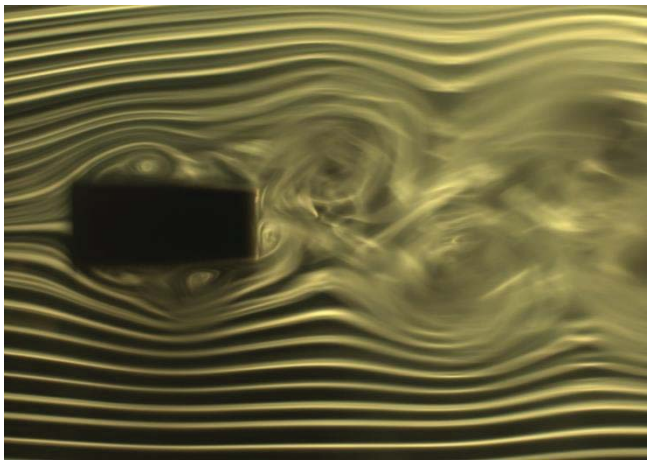
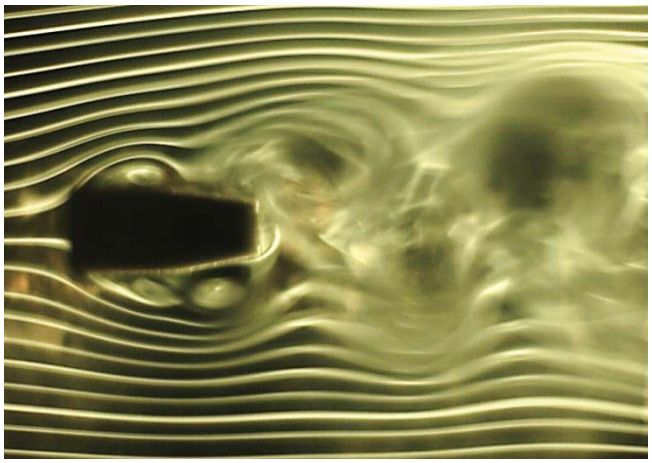
4.2 Reduced wind speed region where the maximum response amplitude of motion-induced vortex vibration occurs

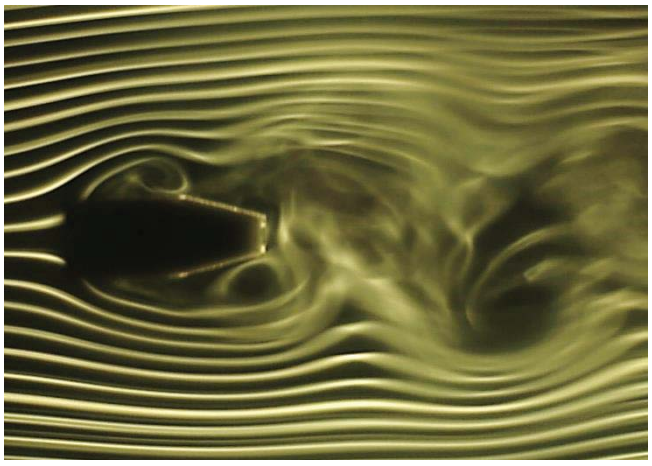
Figure 12 shows the results of the measurements of the generation probability of a secondary vortex at trailing edge of the three kinds of cross-sections having the gradient θ and a rectangular cross section with a side ratio of B/D=2 [19] at the reduced wind speed of Vr=5.2 where the maximum response amplitude of motion-induced vortex vibration occurs. Figure 13 shows the visualized images of the flows at the reduced wind speed with maximum amplitude of motion-induced vortex vibration. As shown in Figure 12, it was confirmed that as with the case of the generation probability of a secondary vortex at trailing edge at the onset wind speed, the greater the gradient θ is, the less the secondary vortex at trailing edge is likely to be



(a) θ = 5 degrees, Vr=3.9, generation probability=100%



(b) θ = 10 degrees, Vr=3.9, generation probability=45%



(c) θ = 15 degrees, Vr=4.6, generation probability=0%

Figure 11: Flow visualization test results at onset reduced wind speed region ($2\eta/D$ = 0.20 at the maximum downward speed).

generated. From the visualized images of the flows shown in Figure 13, the generation of a secondary vortex at trailing edge could be confirmed at trailing edge of a cross section in each cross section of gradient θ= 5 degrees and 10 degrees; however, that could not be confirmed in the case of the cross section of gradient θ=15 degrees. In the cross sections of gradient θ=10 degrees and θ=15 degrees, the generation probability of a secondary vortex at trailing edge was 15% at maximum at the non-dimensional double amplitude range less than $2\eta/D$ = 0.26, where motion-induced vortex vibration occurred, it was confirmed that a secondary vortex at trailing edge is not generated strongly enough.

Furthermore, the maximum amplitude of each motion-induced vortex vibration in the cross section of gradient θ=5 degrees where the generation probability of a secondary vortex at trailing edge at the non-dimensional double amplitude $2\eta/D$=0.26 is 60% and in the cross-section of θ=15 degrees where the generation probability of a secondary vortex at trailing edged at the non-dimensional double amplitude $2\eta/D$=0.26 is 0% is approximately the same. From this fact, it is considered that after the onset of motion-induced vortex vibration, a secondary vortex at trailing edge does not contribute enough to the exciting force of motion-induced vortex vibration at the stage where the maximum response amplitude of motion-induced vortex vibration occurs.

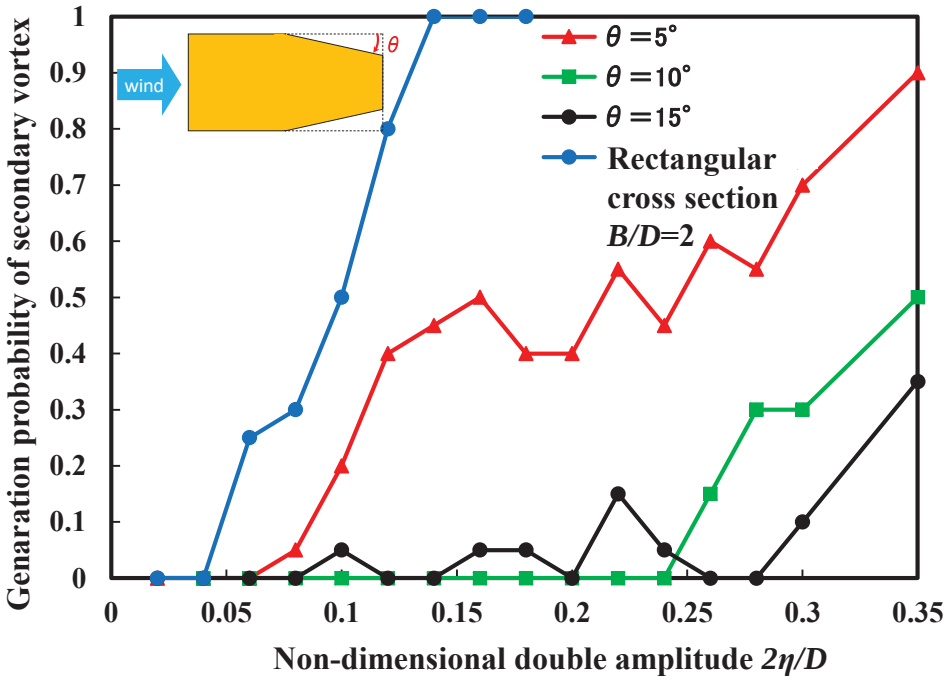


Figure 12: Generation probability for secondary vortex at the trailing edge at reduced wind speed region where maximum response amplitude of motion-induced vortex vibration occurs, Vr=5.2

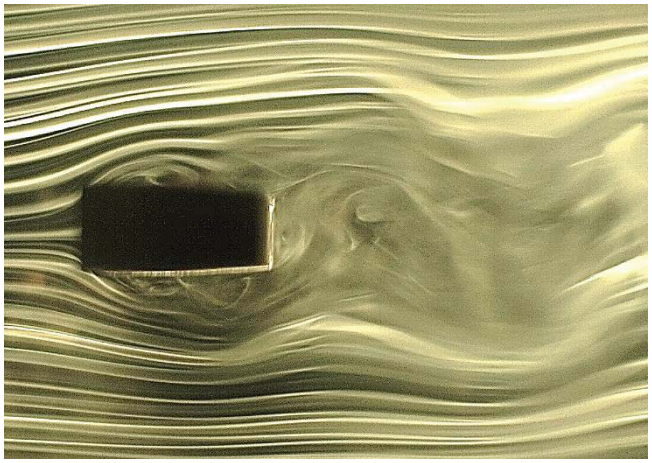
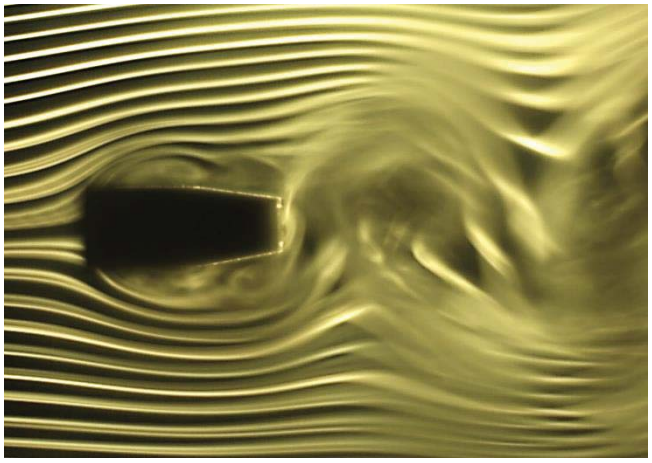
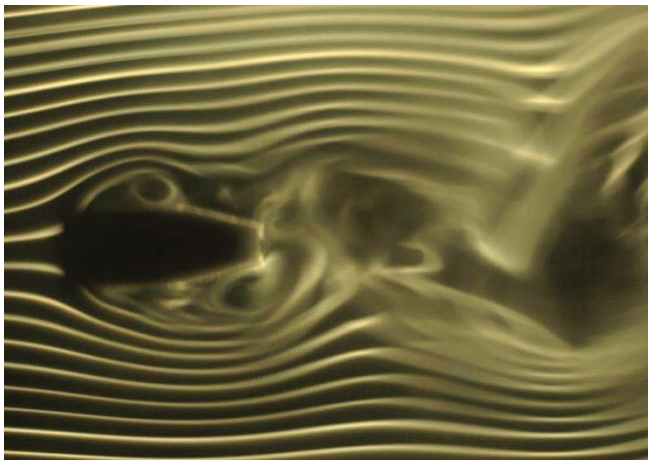


(a) θ = 5 degrees, Vr=5.2, generation probability=60%



(b) θ = 10 degrees, Vr=5.2, generation probability=15%



(c) θ = 15 degrees, Vr=5.2, generation probability=0%

Figure 13: Flow visualization test results at reduced wind speed region where maximum response amplitude of motion-induced vortex vibration occurs ($2\eta/D$ = 0.26 at the maximum downward speed).

5 CONCLUSIONS

It was found that it is considered that the secondary vortex at trailing edge is not always necessary not only for rectangular cross-sections with less than a side ratio of $B/D = 2$, but also for a cross section similar to the rectangular cross section at both small amplitude range at the onset reduced wind speed of motion-induced vortex vibration and a comparatively large amplitude range where the maximum response amplitude of motion-induced vortex vibration occurs.

Keywords: container crane, lifting equipment, wind actions, stochastic wind field design, dynamic behavior, dynamic analyses, finite element analysis.

Abstract. *The focus of this research is to evaluate and compare the mechanical behaviour of three different big cranes (low profile container crane, ship to shore container crane and derrick crane) subjected to wind actions, which are schematized in two different ways: the first considering the constant actions over time and the second considering that changing over time. Regarding this second point, it was assumed a Kaimal, Wingaarard, Izumi and Cotè [1] model, and the actions were determined by developing a specific Mathcad program. After a preliminary analytical cranes design, the successive steps regards the solid model and the numerical analyses performed by finite element method. The numerical results show that, if the wind actions were schematized like variable in time, the maximum displacement is greater respect the one obtained with the constant actions. This gain is important and it is not constant, but changes with the cranes type and the geometrical configurations. For low profile container crane, the increment is approximatively three time while for the derrick crane with the arm at 5° position this value is only about 20%. The research is still in progress primarily in order to extend this methodology to other lifting equipment.*

1 INTRODUCTION

The scope of this research is to analyze the dynamical behaviour of three different crane types subjected to wind actions. In particular, the goal of this study is to analyze the wind effects on three different geometrical crane considering different wind actions schematizations.

The cranes can be subjected to many different actions, dead load and inertia actions due to moving loads or crane parts [2,3,4,5,6], moving trolley [7,8], impulse loading [9], wind [10,11,12], earthquake [13,14]. Earthquake actions can be very dangerous, in fact, for example during Kobe earthquake, (17/1/1995) [15, 16] different cranes collapsed causing considerable damage also on the economic point of view. In this case, the principal failure modes for these structures are local or global buckling phenomena.

The wind actions are one of the main load conditions that act on lifting equipment like crane. These actions can lead the structures to collapse (for example due the overturning moment, buckling phenomena local or global, and so on) [17, 18, 19, 20]. In general, and according to the several standards (as, for example, EN 13000), the wind action and the relative load can be estimated assuming a constant force.

The magnitude of this load is correlated to the wind velocity, the area interested by the wind and some aerodynamical coefficients. However, it is important to underline that, compared to the civil structures, the mechanical ones in general are more flexible and composed by many different elements (like beam, or truss elements). Based on this point of view, assuming a constant load action applied to the structure can be unsafe for the structure. For the components, it is important to study the interaction between wind action and the dynamical behaviour of the whole crane or its parts.

In this research three different crane types (low profile container crane with retractable boom, container crane with lift arm and derrick crane) were analyzed in order to study the mechanical behaviour of the structures subjected to stochastic wind load actions.

The reason of this research is to study, evaluate and compare the results obtained by numerical analyses on crane subjected to two different wind loads schematizations i.e. constant and variable in time.

2 WIND ACTIONS

The wind actions applied to the crane produce a force that acts in two directions: one in the wind direction, and one in orthogonal direction (figure 1). The forces intensity can be evaluated by equations1 and 2.

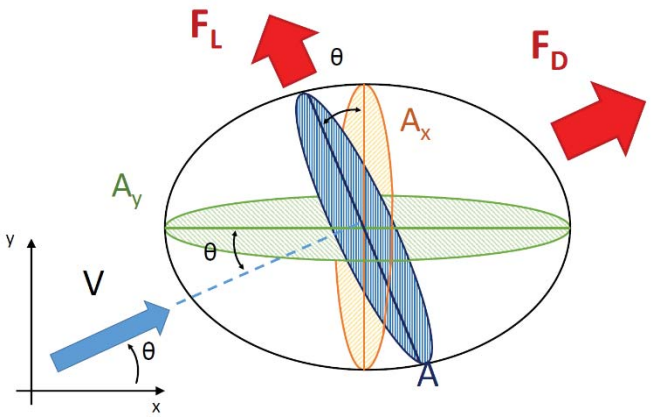

Figure 1: Actions on the structure by wind.

$$F_D = \frac{1}{2}\rho[V(x,y,z,t)]^2 c_D A \quad (1)$$

$$F_L = \frac{1}{2}\rho[V(x,y,z,t)]^2 c_L A \quad (2)$$

Where:
ρ =air density;
$V(x,y,z,t)$=field velocity;
$c_L$and c_D= lift and drag coefficients;
$A = |A_x * \cos\vartheta| + |A_y * \sin\vartheta|$ is area and $\vartheta$is the yaw angle.

The numerical analyses were carried out considers two different wind action schematizations. The first schematization considering the wind action varying in time; the second one considering the action constant over time. In general, the first approach was studied by stochastic method [21, 22, 23].

2.1 Kaimal's model [1.]

The wind field velocity can be expressed by formula (3):

$$V(x,y,z,t) = V_m(z) + v(x,y,t) \quad (3)$$

Where:
$V_m(z)$= is the mean velocity, it is independent of space and time but only varies along the height of the structure (z) by formula (4):

$$V_m(z) = V_g\left(\frac{z}{Zg}\right)^{\alpha} \quad (4).$$

Assuming:
V_g =20 m/s; $Z_g = 7.5\ m$; $\alpha = 1/7$.
$v(x,y,t)$= is the component variable over time i.e. the fluctuating wind speed.

By summarizing as much as possible in [1, 24, 25, 26], the fluctuating part of wind velocity can be evaluated by power spectrum method (point j) (5):

$$S_u(\omega,z) = \frac{1}{2}\frac{1}{2\cdot\pi}\cdot 200\cdot u(z_j)^2\cdot\frac{z_j}{V_m(z_j)}\cdot\frac{1}{\left[1+50\left(\frac{|\omega|z_j}{2\pi V_m(z_j)}\right)\right]^{\frac{5}{3}}} \quad (5)$$

.

With these expression it is possible to evaluate the coherence function between two points and the fluctuating part of the wind speed (v) by formula (6) which consider a random variable in $B(\omega, j, k)$ function.

$$v(j,\frac{t}{\Delta t}) = \mathrm{Re}\left[\sum_{k=0}^{j}\sum_{l=2}^{M} B(\omega,j,k)e^{ilp2\frac{\pi}{2N}}\right] \quad (6)$$

3 NUMERICAL PROCEDURE

For all the cranes analyzed, the main points developed are reported below.

Design a crane considering the "classical" actions: dead load, working load or payload, inertia loads and wind loads. For this point it was assumed a classical structural high strength steel (S460M or S460ML according to European standard EN 10025:2004).

After a preliminary analytical design, a solid model (Solid Works® software) and finite element analyses were carried out (Autodesk Simulation ® software).

Through a specific developed Matchcad ® program, the wind velocity (equation 6), the power spectrum (equations 5) and the wind forces (equations 1 and 2) were evaluated.

Each crane was divided in different sub-structures, characterized by area, position (z), and drag and lift coefficients; on each one the forces calculated at previous point were applied. It is important to underline that the number of sub-structures was chosen considering two parameters i.e. the convergence solution to the maximum crane displacement and the computational cost. In general, each fem model was composed by 5000 quadratic beam elements and by 8000 nodes. The numerical procedure adopted for fem analyses is direct integration method. For this technique, the most important parameter is the delay time between two steps. The value assumed after some iterations in order to evaluate the convergence solution on the maximum displacement is $\Delta t = 0.05s$.

4 LOW PROFILE CONTAINER CRANE

Figure 2 shows the solid crane model; the main crane parameters are: payload=50 t; lifting velocity (without load) =85 m/min; lifting velocity (with load) =35 m/min; maximum height (under spreader) =30 m; overall height =55 m; boom length =80 m.

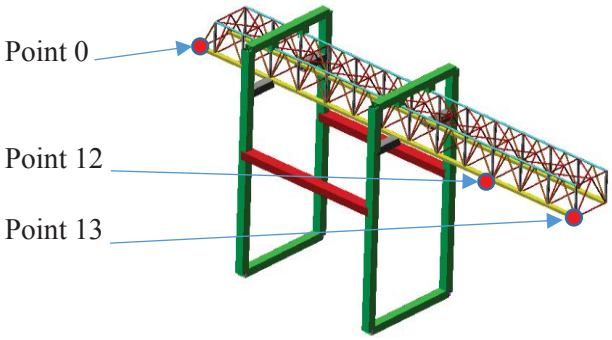

Figure 2: Solid model of low profile container crane with some specific points on main arm.

Figures 3 and 4 show the trend of the wind velocity and the drag and lift forces applied to different points of the crane. Figure 5 shows the crane displacement.

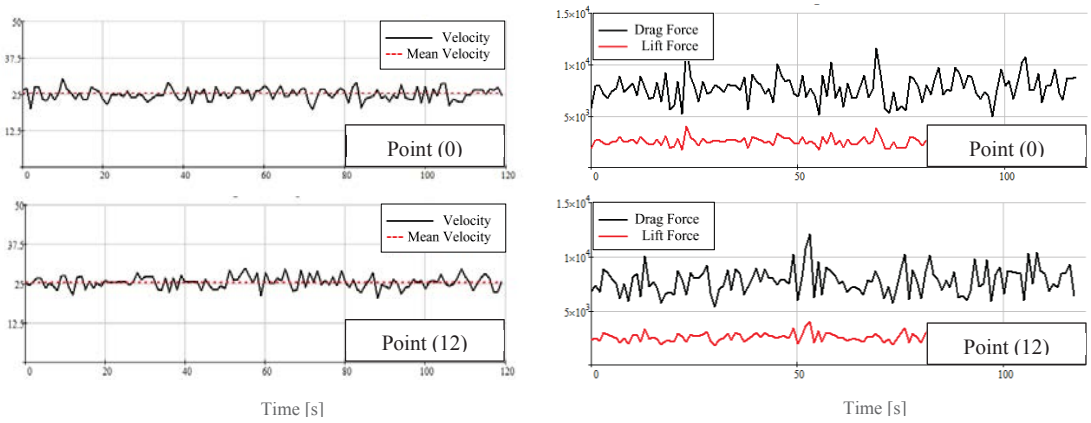

Figure 3 Wind velocity [m/s] and drag and lift forces [N] in different crane points [(0), (12)].

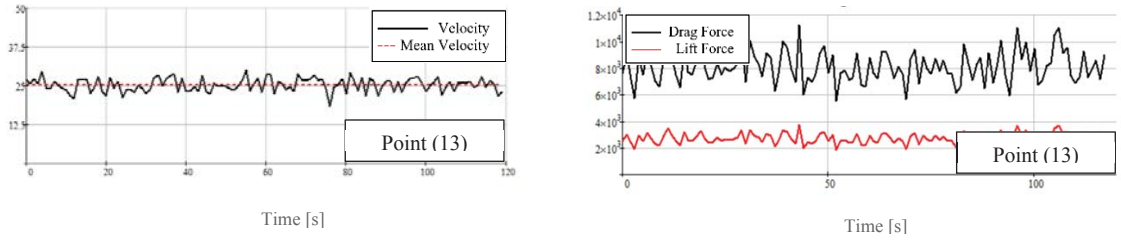

Figure 4 Wind velocity [m/s] and drag and lift forces [N] for the point of crane n°13.

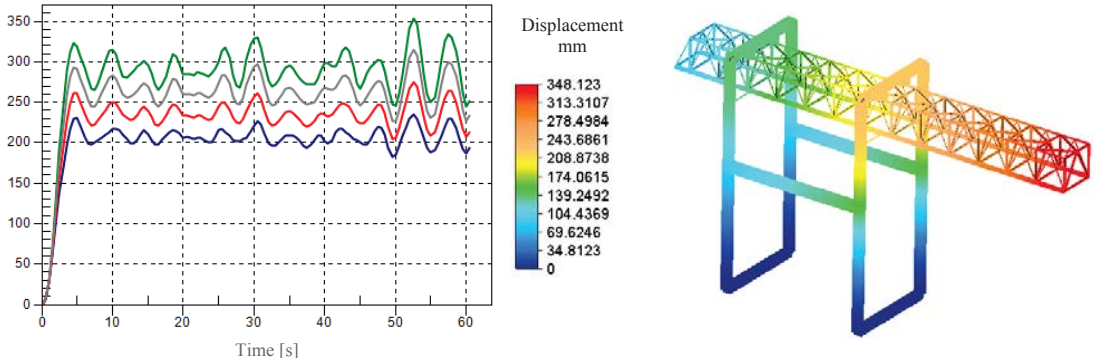

Figure 5 Crane displacement [mm] for low profile container crane (arm at seaside position) subjected to Kaimal wind spectrum actions.

5 CONTAINER CRANE

The main parameters of this crane are payload =45t, total length of the main beam =125 m, and height =74 m. Figure 6 shows the crane solid model and the fem model.

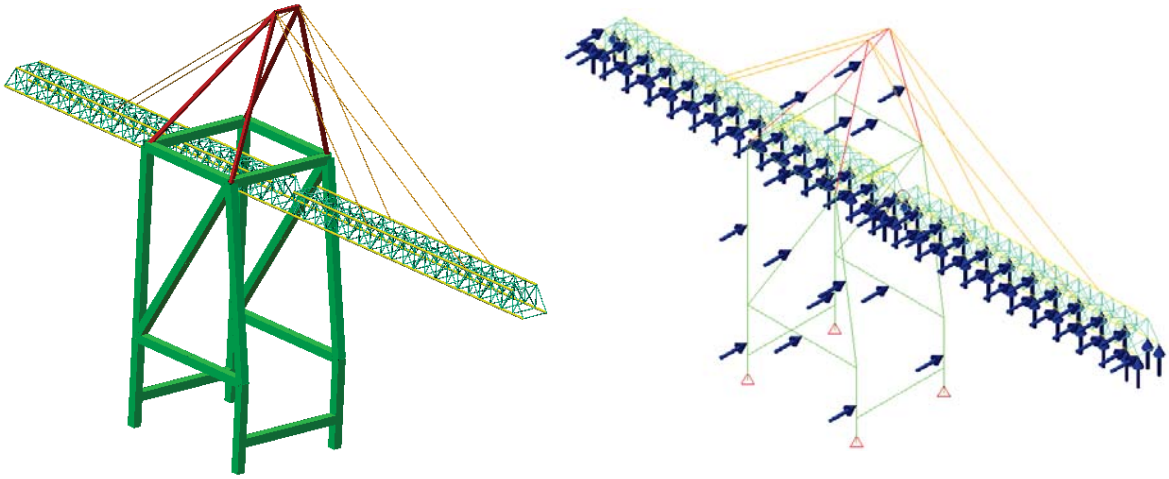

Figure 6 Solid model and fem model for container crane.

Figure 7 shows the crane displacement for different points. It is important to underline that the maximum displacement is located at the arm end and the maximum magnitude is in the wind direction (y direction) i.e. orthogonal to the main beam (the translation in the other direction x and z is very low if comparted with the value in y direction).

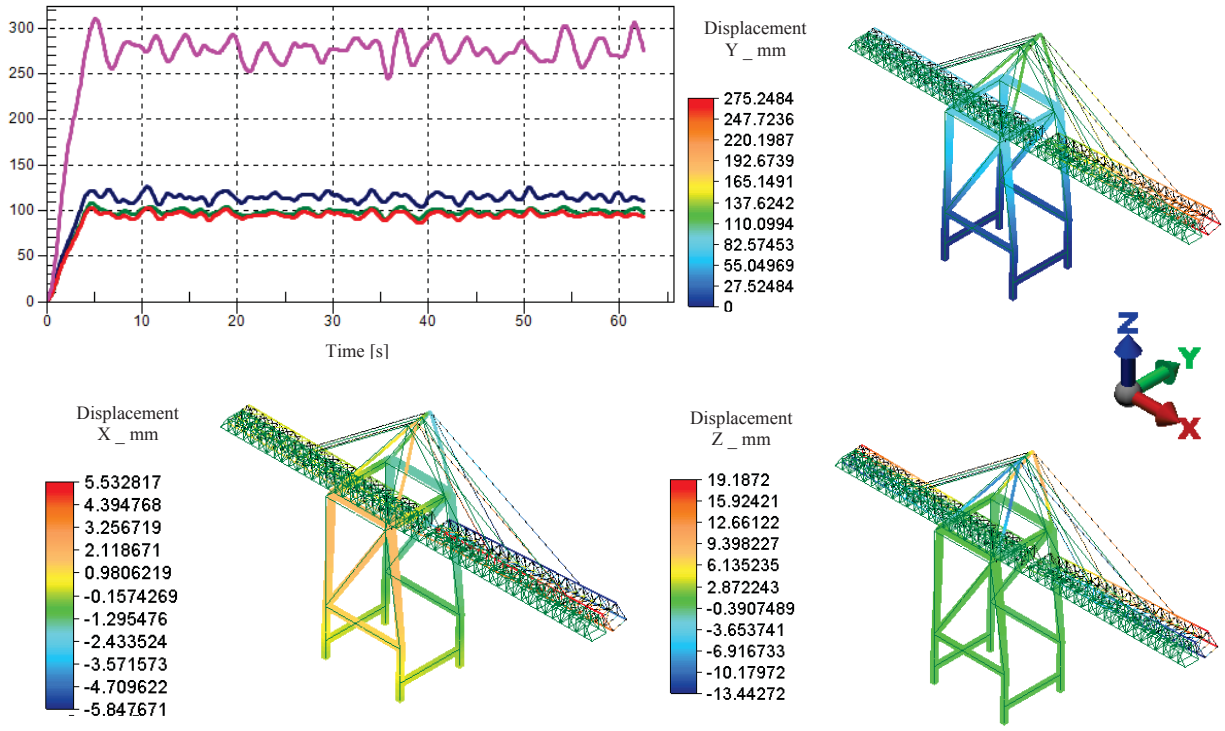

Figure 7 Crane displacements.

6 DERRICK CRANE

The crane parameters considered in this research are an 80-m long arm and a payload equal to 40 t when the inclination of the arm, with respect to the ground, is between 0 ° and 30 °; while the payload equal to 60 t for an inclination of the arm between 30 ° and 85 °. The height of central tower is 45 m. The load lifting speed was assumed equal to vs = 20 m / min; while the arm lifting speed (speed at the height of the arm) was assumed equal to va= 10 m / min. Figure 8 reports the fem model for the two geometrical configurations i.e. 5° ad 85° analyzed. The figures 9 and 10 show the displacement results from numerical analyses.

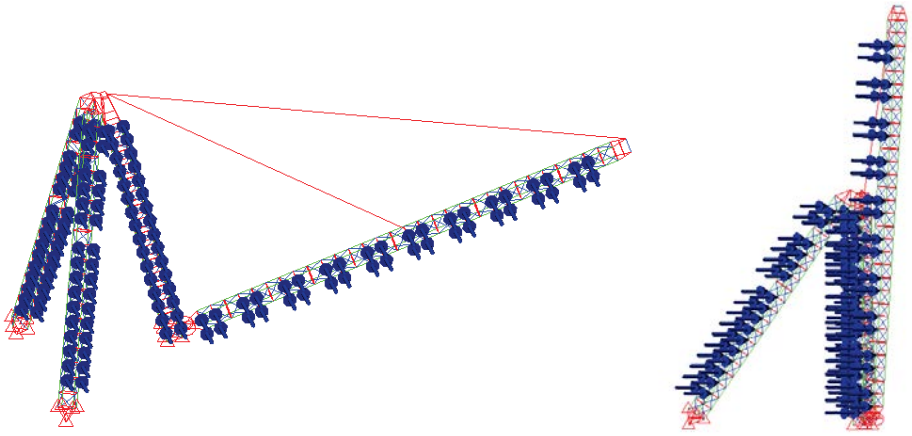

Figure 8 Derrick crane fem model.

7 RESULTS

The main results of this research in order to evaluate the effect of different wind actions schematizations (constant ad variable in time) on crane displacement are summarized in table 1. This table reposts also the perceptual variation with respect to the displacement values obtained considering constant wind action.

Crane /configuration	Wind action=constant (A)	Wind action=variable in time (B).	Variation (B-A)/A*100
Low profile	120.5	348.1	188.9
Container crane	158.7	320.5	101,9
Derrick crane / 5°	310.8	382.9	23,1
Derrick crane / 85°	384.6	606.7	57,7

Table 1: Maximum displacement [mm] for three different cranes and with different wind loads schematizations.

The results show that, for all numerical analyses carried out, the displacements evaluate considering that the forces variable in time are greater than the one evaluated with constant forces.

This result is very important because, correlated to the displacement value, there are three phenomena that must be taken into account in order to avoid the structures damage due to the wind actions, and these are stress state, fatigue phenomenon and the overturning moment.

Another observation is important: the increase displacement value changes with the crane typologies end the geometrical configurations. The aspect that needs further investigations may be correlate to the mechanical behavior of the crane and in particular to the natural frequencies and the mass participations factors involved in the wind load direction.

8 CONCLUSIONS

This research reports the main numerical results for three different port cranes subjected to wind actions. These actions were schematized in two different ways, one considering the velocity constant in time and the second considering the velocity changing in time.

After the design process for all cranes, a specific Mathcad® program was developed in order to evaluate the forces trend (lift and drag). The structures were divided in many different substructures and on each of these, specific actions were applied. The numerical results show that the maximum displacements are quite different and these shifts is not constant but depends on the crane type and geometrical configuration.

These results need more investigation because, correlated to the displacement, there are other phenomena like stress state (and fatigue) and overturning moment that can induce the crane to collapse. The next step of this research regards two points.

The first point concerns the implementation of this methodology to evaluate the structure mechanical behavior on other cranes type. The second point relates to the wind actions schematization and, in particular, this second point want to analyze the effect of different wind schematization or model assumptions, as reported in [27], on the crane response, especially in the displacement values, and compare it to the one obtained in the static load conditions.

Keywords: Overhead power lines, aeolian vibrations, fretting-fatigue.

Abstract. *Several factors are involved in estimating the lifetime of overhead lines. Focusing on the mechanical part, conductor vibrations represent an important contribution to the creation and propagation of cracks, which has led us to investigate the behavior of a suspended cable subject to wind. Among the already available tools, there is either the simple energy balance principle, which is physically less accurate, or a more complete mechanical modelling, which is computationally expensive. In this paper, we present a model that fills this gap: we are able to perform large parametric studies in a moderate amount of time without compromising the physical accuracy of the results. Results from this model compare well with Code_Aster simulation results. We outline a steady state which can be characterized with a few parameters, and demonstrate an example of a parametric study that can be performed.*

1 Introduction

Asset management is a major challenge for RTE (Réseau de Transport d'Electricité), the French TSO (Transmission System Operator), because electrical grid component maintenance and renewal represent important economic issues. Thus, improved lifetime assessment could lead RTE to substantial savings while still assuring a high quality service. Overhead power cables, or conductors, which are stranded wire assemblies, are one of RTE's main assets. It is well known in the overhead lines community that aeolian vibrations cause fretting fatigue in or around the clamp/conductor system and lead to aging of the conductors [1, 2].

Aeolian vibrations are an aero-elastic phenomenon, where the wind induces vortex shedding that causes alternating lift and drag forces. If the structural damping is not sufficient, the conductor can vibrate under low-speed wind conditions (velocities ranging from about one to seven $\mathrm{m\,s^{-1}}$). These vibrations can be quantified by studying the equation of motion of a conductor exposed to wind, where the model for the conductor can be represented as a suspended cable. This system can be solved using the Code_Aster finite-element solver, and the obtained results are found to compare well with experiments [3]. Yet, running this type of simulation for a significant part of RTE's network ($300\,000$ spans) is prohibitively expensive. The Energy Balance Principle (EBP) is a simple model that is widely used in the literature, and this can be used to compute the vibration amplitude. The EBP is reliant on balancing the energy introduced by the wind and the energy dissipated by the conductor [4]. Yet, this method does not adequately cover low wind speeds because it relies on experimental data which is difficult to acquire. This is the motivation for the development of a simpler equivalent model (1D, nonlinear, finite-difference method solution), which is based on the cable dynamics and thus is physically more accurate than the EBP. Compared to Code_Aster, the same vibration amplitudes are found, while the computation is much faster.

Section 2 presents two models, one for the conductor and another for conductor-wind interaction; in section 3 the conductor model is validated before an example parametric study that can be performed with the model is shown in section 4. Finally, in the discussion (section 5) several improvements are outlined that can be made to both models to better capture aeolian vibrations.

2 Models

2.1 Equation of Motion for a Suspended Cable

Let us consider an elastic cable suspended between two poles separated by a distance L_s. We denote m as the cable mass per unit length, H is the equilibrium tension, EA is the axial stiffness of its cross section and g is the standard gravity. At equilibrium, the cable has the shape of a catenary due to its own weight, and its length is given by (1).

$$L \;=\; 2a\,\sinh\left(\frac{L_\mathrm{s}}{2a}\right)\;, \quad \text{with } a \;=\; \frac{H}{mg} \tag{1}$$

The dynamic displacement of the cable from its equilibrium is given by $\mathbf{U} = U_\mathrm{T}\,\mathbf{e}_\mathrm{T} + U_\mathrm{N}\,\mathbf{e}_\mathrm{N} + U_\mathrm{B}\,\mathbf{e}_\mathrm{B}$, where the unit vectors $\mathbf{e}_\mathrm{T}$, $\mathbf{e}_\mathrm{N}$ and $\mathbf{e}_\mathrm{B}$ respectively represent the tangential, normal and binormal directions of the Frenet triad defined by the equilibrium position of the cable (see also figure 1). All U_i components depend on time T and S, which is the curvilinear abscissa along the cable.

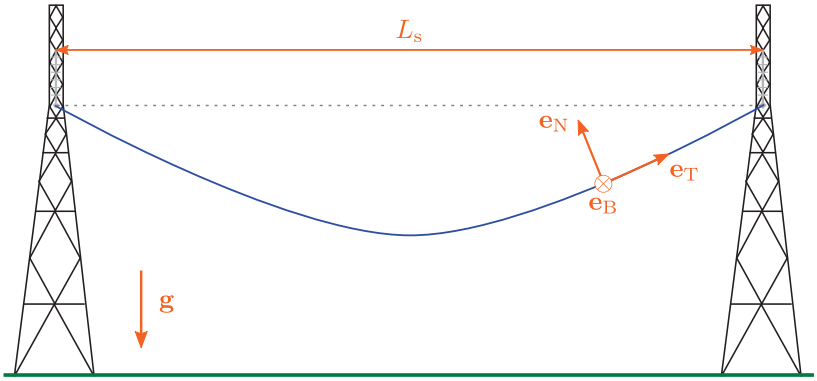

Figure 1: Vibration model notations.

Considering that $H \gg mgL$ (which implies that the equilibrium curvature is small and that the catenary is well approximated by a parabola), and that $EA \gg H$ (such that we have ${}^{EA}/_{H} > {}^{H}/_{mgL}$), the equations of motion when the cable is subject to an external force $\mathbf{F} = F_T\,\mathbf{e}_T + F_N\,\mathbf{e}_N$ regarding the equilibrium are given by [5]

$$\left\{ \begin{array}{rcl} \dfrac{\partial^2 u_N}{\partial t^2} & = & \left(v_t^2 + v_\ell^2 e\right) \dfrac{\partial^2 u_N}{\partial s^2} \; + \; \dfrac{v_\ell^2}{v_t^2} e \; + \; f_N \\ \dfrac{\partial^2 u_B}{\partial t^2} & = & \left(v_t^2 + v_\ell^2 e\right) \dfrac{\partial^2 u_B}{\partial s^2} \; + \; f_B \end{array} \right. , \tag{2}$$

where

$$e(t) = \int_0^1 \left\{ -\frac{u_N}{v_t^2} + \frac{1}{2} \left[\left(\frac{\partial u_N}{\partial s} \right)^2 + \left(\frac{\partial u_B}{\partial s} \right)^2 \right] \right\} \mathrm{d}s \; . \tag{3}$$

All quantities in equations (2) and (3) are dimensionless: we have $s = {}^{S}/_{L}$, $t = {}^{T}/_{\sqrt{L/g}}$, $u_i = {}^{U_i}/_{L}$ and $f_i = {}^{F_i}/_{mg}$; the coefficients v_t and v_ℓ stand for the (non-dimensional) velocity of transverse and longitudinal waves along the cable (4). Since the cable has fixed ends, Dirichlet boundary conditions are used for each component of the displacement.

$$v_t \; = \; \sqrt{\frac{H}{mgL}} \; , \quad v_\ell \; = \; \sqrt{\frac{EA}{mgL}} \tag{4}$$

After solving this system, it is possible to retrieve the u_T component by identifying a function $h(s,t)$ such that $e(t) = \int_0^1 h(s,t)\,\mathrm{d}s$; we then have

$$u_T(s,t) \; = \; e(t)\, s \; - \; \int_0^s h(s,t)\,\mathrm{d}s \; . \tag{5}$$

The system (2) is solved using a finite difference approach with second order approximation in space and a linearized Crank-Nicolson scheme (also second order) in time. The solver has been implemented with Python for its flexibility, but a C/C++ version could also be implemented if performance improvements are necessary.

2.2 Wind Interaction

Aeolian vibrations are attributed to a fluid dynamics phenomenon called vortex shedding. In simple terms, this is when a fluid (*e.g.* air) flowing past a cylindrical body causes vortices to be formed downstream of the cylinder, which then become unstable and detach. The vortices detach periodically from either side of the body, creating a von Karman vortex street, and also inducing an alternating lift force along with an oscillation in the drag force. The detachment frequency is characterized by

$$f_{\mathrm{w}} \;=\; \frac{U}{d}\,\mathrm{S_t}\;, \tag{6}$$

where U is the fluid speed, d the cylinder's diameter and $\mathrm{S_t}$ a dimensionless number (called the Strouhal number) which depends on the shape of the body and the Reynolds number ($\mathrm{S_t} \approx 0.2$ for $\mathrm{Re} \in [10^2, 10^5]$ in the case of a fixed, infinite and smooth cylinder).

No theoretical prediction for vortex shedding exists in the literature, so empirical formulations from experiments in wind tunnels are used. Especially important is the work of Bishop and Hassan [6], who ran experiments with a smooth cylinder subject to a uniform air flowing normal to the cylinder axis, and made detailed force measurements. The force per unit length on the cylinder is given by

$$\begin{cases} F_{\mathrm{L,D}} \;=\; {}^1\!/_2\,\rho_{\mathrm{air}}\,d\,|U|\,U\,\bar{C}_{\mathrm{L,D}}(t) \\ \bar{C}_{\mathrm{L}}(t) \;=\; C_{\mathrm{L}} + C_{\mathrm{L0}}\sin(\;\omega_{\mathrm{w}}t) \\ \bar{C}_{\mathrm{D}}(t) \;=\; C_{\mathrm{D}} + C_{\mathrm{D0}}\sin(2\omega_{\mathrm{w}}t) \end{cases}\;, \tag{7}$$

with $\omega_{\mathrm{w}} = 2\pi f_{\mathrm{w}}$, ρ_{air} being the air volumic mass. Indices L and D correspond to *lift* and *drag* directions: the drag direction is parallel to the air flow, and L is normal to both the air flow and cylinder axis. The dimensionless coefficients C_{D}, C_{D0}, C_{L} and C_{L0} are measured experimentally or can be found with fluid dynamics computations [7]. Bishop and Hassan give the following values for a Reynolds number around 10^4: $C_{\mathrm{D}} = 1.1$, $C_{\mathrm{D0}} = 0.075$, $C_{\mathrm{L}} = 0$ and $C_{\mathrm{L0}} = 0.6$.

When using the force formulation (7) as an input in (2), we consider the wind along the binormal direction, hence $f_{\mathrm{N}} \equiv {}^{F_{\mathrm{L}}}\!/_{mg}$ and $f_{\mathrm{B}} \equiv {}^{F_{\mathrm{D}}}\!/_{mg}$. A geometric correction is not added because the curvature of the cable is assumed to be small. However, as our cylinder will be moving, we do need to modify (7) to take the relative speed of the cable into account. Equation (8) is obtained using projections, but it was chosen to keep the frequency in (6) unchanged.

$$\begin{cases} f_{\mathrm{N}} \;=\; \dfrac{\rho_{\mathrm{air}}dL}{2m}\sqrt{\dot{u_{\mathrm{N}}}^2 + \left(\dfrac{U}{\sqrt{Lg}} - \dot{u_{\mathrm{B}}}\right)^2}\left[-\dot{u_{\mathrm{N}}}\,\bar{C}_{\mathrm{D}}(t) + \left(\dfrac{U}{\sqrt{Lg}} - \dot{u_{\mathrm{B}}}\right)\bar{C}_{\mathrm{L}}(t)\right] \\ f_{\mathrm{B}} \;=\; \dfrac{\rho_{\mathrm{air}}dL}{2m}\sqrt{\dot{u_{\mathrm{N}}}^2 + \left(\dfrac{U}{\sqrt{Lg}} - \dot{u_{\mathrm{B}}}\right)^2}\left[\left(\dfrac{U}{\sqrt{Lg}} - \dot{u_{\mathrm{B}}}\right)\bar{C}_{\mathrm{D}}(t) + \dot{u_{\mathrm{N}}}\,\bar{C}_{\mathrm{L}}(t)\right] \end{cases} \tag{8}$$

3 Validation

3.1 Utilization in Overhead Lines Context

The model in section 2.1 is to be applied to the case of electrical overhead lines, and thus it is necessary to ensure that the conditions are representative. For this a dataset of about $82\,000$ spans from the RTE network is used in which all the required physical properties are well

quantile	$1/vt^4$	v_t^4/v_ℓ^2
0.1	0.0132	0.00253
0.2	0.0192	0.00306
0.3	0.0242	0.00348
0.4	0.0291	0.00387
0.5	0.0338	0.00428
0.6	0.0390	0.00476
0.7	0.0451	0.00533
0.8	0.0531	0.00619
0.9	0.0655	0.00791

Table 1: Quantiles for error terms computed on a sample of spans.

known. Lee's model does not account for height difference, so we remove the spans that have a height difference h larger than 20 m or such that $h/L_\mathrm{s} < 5\%$, which leaves about $65\,000$ spans.

To obtain (2), several Taylor expansions using $k = 1/v_t^2$ as a parameter were performed; the error is $O\left(1/vt^4\right)$ when neglecting terms on the order of k^2 or smaller. The second hypothesis, which compares longitudinal and transverse wave speeds ($v_\ell^2 > v_t^4$), is easier to meet since conductor materials often have high axial stiffness and relatively low tension. Both ratios have been computed on the sample of spans. The results in table 1 show that the curvature error is quite limited (below 7%) for 90% of the spans, and that the error in the wave-speeds is even lower. This would not be the case if we had kept spans with higher height difference.

3.2 Comparison with Code_Aster

Code_Aster open source software is used to solve numerical problems in structural mechanics [8]. It is a continuum mechanics solver based on the finite element method that can be employed for different types of mechanical, thermal or acoustic problems. In our case, we use a three-dimensional large displacement model to compute a cable displacement when it is subject to wind. We performed our comparison using an ASTER570 conductor (m = 1.57 $\mathrm{kg\,m^{-1}}$, EA = 37.6 MN, d = 31.1 mm) on a span of length L_s = 400 m and with tension H = 37 kN; we used ρ = 1.20 $\mathrm{kg\,m^{-3}}$ for the air volumic mass and a wind speed of U = 3.00 $\mathrm{m\,s^{-1}}$; other wind parameters are given in section 2.2. The cable is considered at rest at initial time. In this comparison, we do not take into account the speed correction raised in section 2.2, since it requires deeper modifications in Code_Aster's source code; this is not important here as we only want to compare the cable models. The simulation time is 45 s; discretization parameters are respectively n = 257 and 250 elements for Code_Aster and Lee's model and we use the same time step $\Delta t = 1.0 \times 10^{-3}$ s. Results in figure 2 show near identical vibrations. The comparison between the two approaches remains good if the input parameters are changed, and the best correspondence is observed far from the span ends.

Comparing execution times of a three-dimensional model, such as the one used here in Code_Aster, with a much simpler model is a bit unfair, but this is important when we want to perform numerous simulations for a parametric study. On a standard desktop computer (using an Intel i7-3770 processor and 12 GB of memory), a computation of two and a half hours was necessary to complete a simulation using Code_Aster and about 80 seconds for Lee's model, which gives a time ratio slightly above 100.

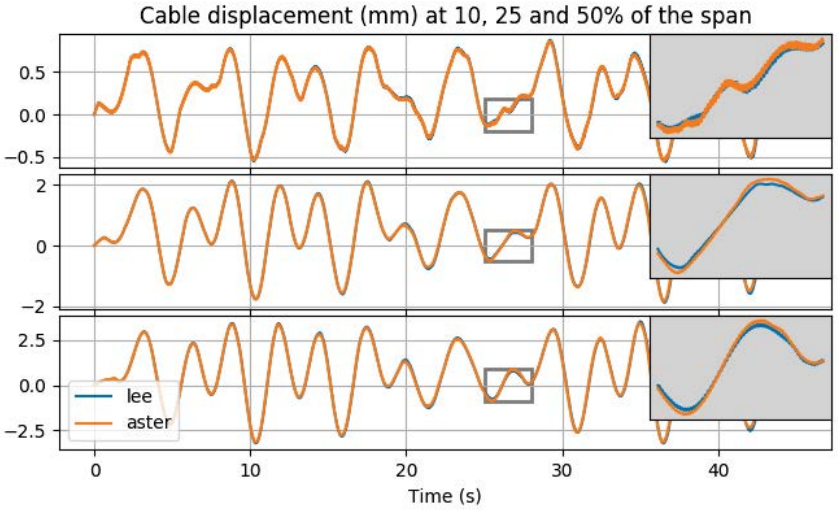

Figure 2: Comparison of displacement with regard to equilibrium position for u_{N} component obtained by solving Lee and Code_Aster models.

3.3 Observations

Let us consider the same cable at the mid-span and with the speed correction taken into account (figures 3 and 4). Focusing on the binormal component (parallel to the wind), we observe damped oscillations that seem to tend to a stationary state. The oscillation frequency matches the natural frequency of the cable $f_1 = \frac{1}{2L_{\mathrm{s}}}\sqrt{\frac{H}{m}}$, and the time constant can be estimated with $\tau = \frac{2m}{\rho_{\mathrm{air}} d U C_{\mathrm{D}}}$. The limiting value for u_{B} can be computed using a static version of (2), but it can be well approximated by a catenary equation using an analogy with the gravity case

$$u_{\mathrm{B}}^{\infty}(s) \;=\; 2\tilde{a}\,\sinh\left(\frac{L_{\mathrm{s}}}{2\tilde{a}}(1-s)\right)\,\sinh\left(\frac{L_{\mathrm{s}}}{2\tilde{a}}s\right)\;, \quad \text{with } \tilde{a} \;\equiv\; \frac{H\tau}{mU}\;, \tag{9}$$

where $s \in [0,1]$ is the curvilinear abscissa along the span. By combining these observations, a good analytical approximation can be written for the binormal component:

$$u_{\mathrm{B}}(s,t) \;\approx\; \left[1 \;-\; \exp\left(-t/\tau\right)\cos\left(2\pi f_1 t\right)\right]\; u_{\mathrm{B}}^{\infty}(s)\;. \tag{10}$$

Focusing on the normal component, damped oscillations are also observed, but these are much less regular than for the binormal component; a steady state is observed after approximately 200 seconds. The frequency of these oscillations is close to, but different to twice the cable natural frequency. In fact, it exactly matches the first out-of plane frequency f_1' defined in [9] using a transcendental equation. The steady-state vibrations have a small amplitude (about $50\ \mu\mathrm{m}$) and their frequency is exaclty f_{w}. Similar to the binormal component, the mean of the steady state vibrations $u_{\mathrm{N}}^{\infty}(s)$ can be computed. However, a good analytical approximation for the oscillation amplitude was not found.

4 Example of a parametric study

Typically, how vertical vibrations vary with span length, tension and wind speed are of interest. Since an expression for the normal component vibration amplitude has not been found, several simulations have been performed to cover the different cases. Considering an ASTER570 cable, most span lengths go from 100 to 800 m, and the tensions between 10 and 60 kN. Two

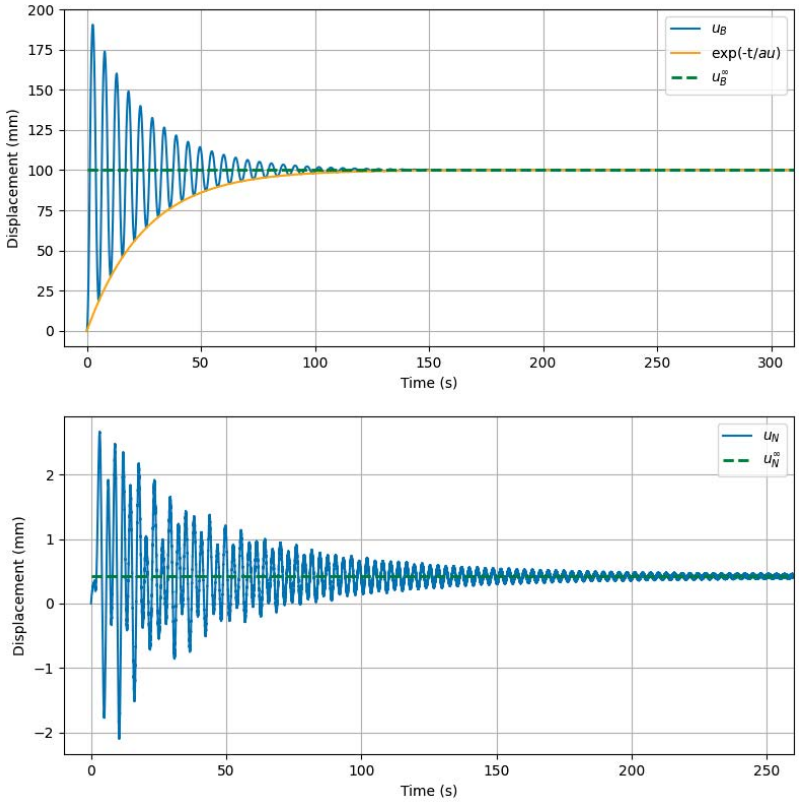

Figure 3: Cable displacement (mm) at mid-span regarding equilibrium position for the binormal (top) and the normal (bottom) component. The green line can be computed by solving a static problem and the orange line outlines the damping in $\exp(-t/\tau)$.

sets of simulations have been performed; one with a small number of points for L_s and H, and several wind speeds (15 lengths, 11 tensions and 11 wind speeds) to cover the wind speed dependency, and another with one wind speed but a greater number of points (56 lengths and 41 tensions) to obtain a more detailed map. The same parameters as in previous section are kept, but only the steady state is considered when performing amplitude measurements.

Figure 5 shows the value of u_N^∞ in the span-length/tension plane for different wind speeds. The same pattern is observed in all cases, with the amplitude increasing with the wind speed. To investigate further, five length/tension points were selected and the variation of the vibration amplitudes with wind speed for these points is shown in figure 6. It appears that all the curves follow the same pattern, which leads us to assume that the expression for the vibration amplitude (for a given type of conductor, *i.e.* a fixed mass, diameter and axial stiffness) can be expressed as the product of two functions; one that depends on span length and tension, and the other that only depends on the wind speed (with other parameters, such as ρ_air, and C_D, being fixed). Thus, we can omit the wind speed factor and only analyze one high-resolution map. This is what has been done in figure 7, where it is observed that larger values of u_N^∞ are obtained for longer span lengths and lower tension cables.

The amplitudes of the steady state vibrations (figure 8) are observed to have very small values for all wind speeds. The amplitude is always below $2.5\ \mathrm{mm}$ at mid-span, whereas cable damage would be expected at higher amplitudes [10].

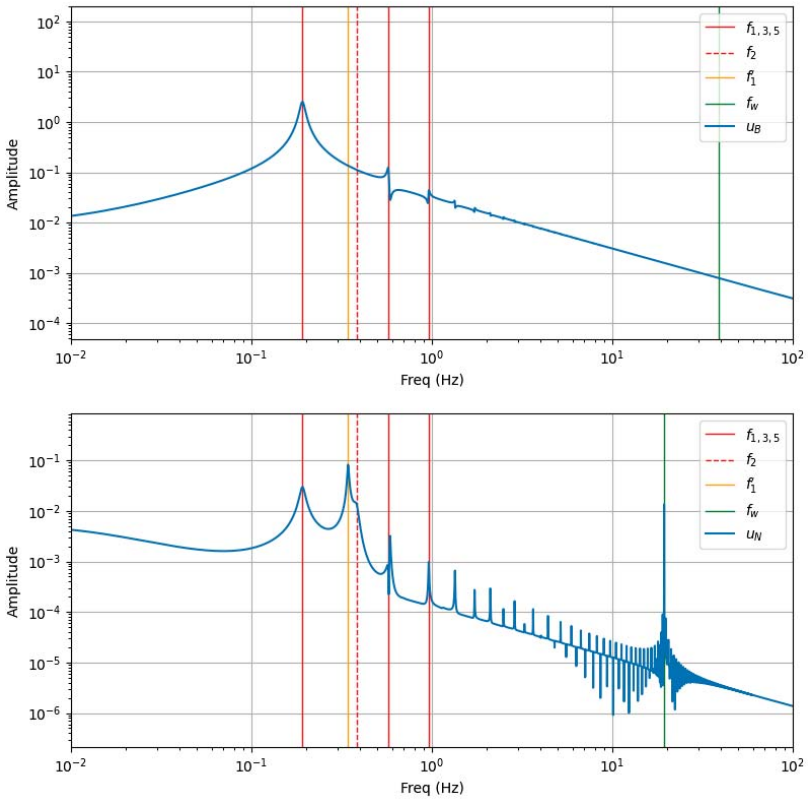

Figure 4: Mid-span vibration spectra for the binormal (top) and the normal (bottom) component. Red lines are natural frequencies of the cable (solid for odd modes, dashed for even), the orange line is the frequency given in [9] and the green one is the wind frequency.

5 Discussion

Several points in Lee's model should be improved: there is currently no consideration of any kind of damping. This explains why vibration amplitudes continue to increase with wind speed, instead of reaching a peak value and then returning lower values, like with the EBP model. A viscous damping term could be added to (2), but it is well known that damping is non-linear in cables due to the friction between wires. Part of our future work consists of evaluating friction in different conductors and its dependence on common parameters, such as span tension or local curvature, before implementing a damping term in Lee's model.

The model does not take height difference between suspension points of the cable into account. Even if the model is already able to perform simulation of a significant fraction of the RTE network, a model that includes this effect would be a improvement. This could be done with [11] for instance.

The wind interaction model used here is also not satisfactory, as the computed amplitudes are too low to explain fretting fatigue close to the suspension points. Several factors can explain these results:

- Use of the Bishop and Hassan model assumes a fixed cylinder, which is an assumption that is not met; therefore, another wind interaction formulation should be used.
- Furthermore, the Bishop and Hassan model includes no influence of the vortex shedding on the cable motion. In reality, the motion of the structure and the vortex shedding interact to increase the possibility of resonance, which is referred to as lock in.

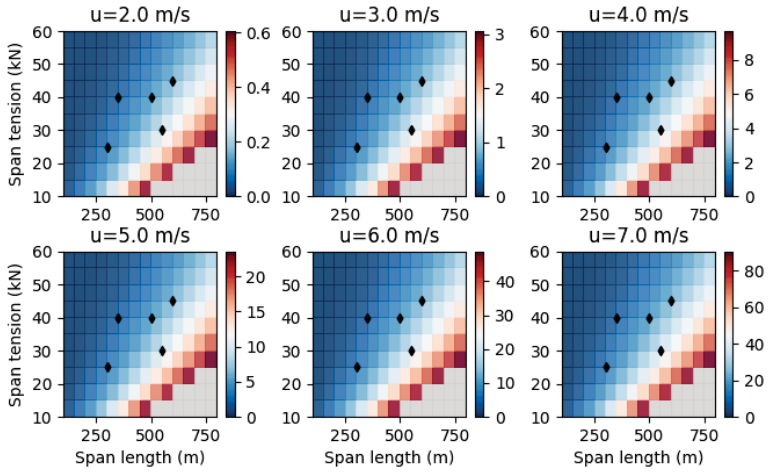

Figure 5: Values of u_N^∞ (mm), ie the mean value of normal steady state vibrations, in the span-length/tension plane for different wind speeds. Black points are a reminder of the points used in figure 6.

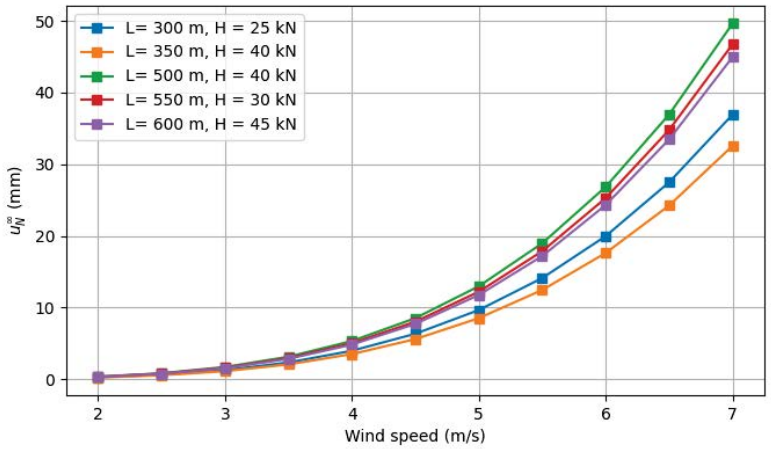

Figure 6: Mean value of normal steady state vibrations (mm) with wind speeds for selected span lengths and tensions.

- A constant wind in space and time is unlikely to occur in the field; the cable motion under dynamic wind loading should be studied.

In order to address these questions, the Bishop and Hassan formulation will be compared with a wake oscillator, like that in [12]. In such a model the vortex shedding is influenced by the cable motion, while the tool is still simple and fast; simulations will also be performed using dynamic wind fields. This appoach will allow confirmation on whether aeolian vibrations are caused by VIV.

6 Conclusion

A simple model is presented to investigate the interaction between a suspended cable and a weak wind. The purpose is to have a model with more physics and parameters than the EBP, but that is also less complicated and computationally demanding than a full three-dimensional structural mechanics simulation. Ideally, computation of a large number of configurations in a short period of time will allow parametric investigation of the RTE network, but without compromising the physical accuracy of the results. The model has been validated using Code_Aster

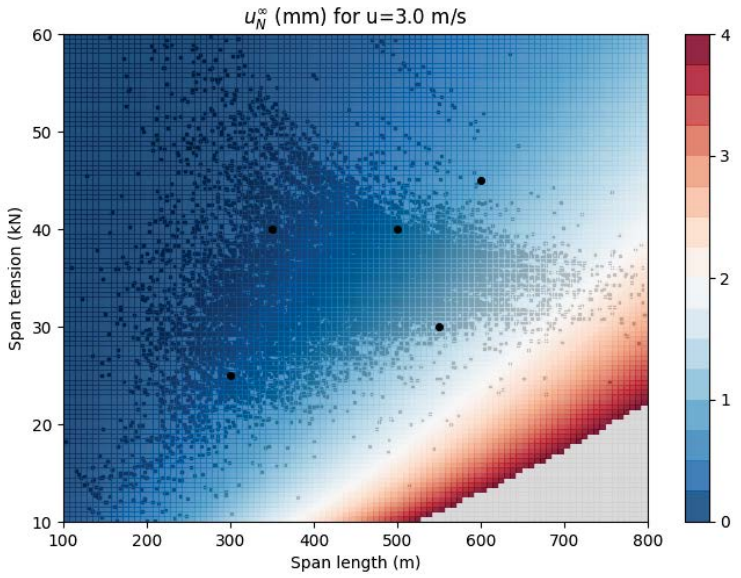

Figure 7: Mean value of normal steady state vibrations (mm) in the span-length/tension plane for a wind speed of $3\ \mathrm{m\,s^{-1}}$ (high resolution). Background points show the ASTER570 spans from the RTE network; black points are the values used in figure 6.

as a reference, which showed little difference in the results from both models while having a factor of 100 improvement in computational performance. A steady state has been outlined that can be characterized by a few parameters (vibration mean, amplitude and frequency). The mean can be recovered with static computations and formulations were obtained for the frequencies, however it was not possible to find a simple expression for the amplitude, which is why a parametric study was performed. Considering vertical vibrations, both mean value and amplitude of the steady state are too small to explain aging of conductors; this will lead us to improve the wind interaction model. Some limitations in the model itself and potential solutions to overcome them have been identified. In future, we intend to evaluate cumulative damage for a span within the simulated vibration histories. This will be done by counting the number of cycles and the related vibration amplitudes, and then combining these with results from simulations at the microscopic scale. The end result will be a crack initiation risk function for the wires at the contact location. This should allow ranking of all spans of the RTE network in order to help and improve maintenance operations.

Keywords: Free-vibration wind tunnel tests, Fatigue, Rainflow Cycle Counting, Quasi-Periodicity

Abstract. *The paper presents free-vibration wind tunnel tests on the aeroelastic model of a free-standing tower that shows vortex-induced vibrations in the lock-in range. Previous research by the authors focused on the investigation of the negative aerodynamic damping through forced-vibration tests. This knowledge allowed a realistic prediction for the maxima of the cross-wind oscillation amplitudes. In view of fatigue analysis, however, not only the maxima, rather a proper characterization of the cross-wind response is needed to determine the actual damage accumulation. Depending on the reduced wind velocity and the Scruton number of the vibrating structure, the experiments on the aeroelastic model in free vibrations show evidence of an intermittent – mathematically speaking quasi-periodic – behavior. It results from a beating effect between the natural oscillation frequency of the structure and the vortex shedding load, which may lock-in and lock-out in consequence of low frequency turbulence fluctuations. In addition, the frequency of the vortex shedding load along the height of the structure varies due to the varying mean velocity according to the wind profile and the varying Strouhal number. This exhibits smaller values close to the tip region. Outcomes of this investigation are the estimation of the negative aerodynamic damping through free-vibration wind tunnel tests and the estimation of the fatigue lifetime considering the quasi-periodic aeroelastic response through a rainflow fatigue load cycle counting.*

1 INTRODUCTION

Slender structures subjected to vortex-induced vibrations (VIV) experience an aeroelastic interaction in the lock-in range. The negative aerodynamic damping, interpreted as energy transferred from the flow into the structure, is the governing parameter for the onset of self-induced vibrations. However, available literature models still lack of a unified behavior of the aerodynamic damping as a function of the oscillation. This is also reflected in codified methods to design slender structures in view of cross-wind actions. This evidence applies firstly for the maxima of the oscillation amplitudes, i.e. the maxima of the structural stresses. Additionally, concerning the modelling of load processes for the analysis of fatigue strength, theoretical deficiencies cause even larger deviations between the prediction of fatigue life and its actual value.

A deeper knowledge about the non-linear behavior of the negative aerodynamic damping for a circular cylinder was gained by the authors from two-dimensional wind tunnel experiments in forced vibrations. The experiments were performed at the WISt Boundary Layer Wind Tunnel at Ruhr-Universität Bochum, Germany [10]. The experimental model of the aerodynamic damping developed in [10] was implemented in the spectral method originally proposed by Vickery&Basu [14] and applied to 27 full-scale steel chimneys collected from literature. This novel spectral method, known also as "Damping Modified Spectral Method" (DMSM), allows the calculation of the largest oscillation of structures in the lock-in range [9]. Compared to other codified methods for structural analysis (e.g. [12], [13], [14]), DMSM provides a safe but more realistic prediction of the maxima of the cross-wind oscillation amplitudes. In view of fatigue analysis, however, not just one amplitude determines the damage, rather a proper characterization of the cross-wind response is needed to determine the actual damage accumulation.

Wind tunnel experiments on an aeroelastic model of a full-scale tower immersed in uniform, low-turbulent flow (I_v = 4,5%) are analyzed in this paper. The wind tunnel tests are performed at WISt Boundary Layer Wind Tunnel at Ruhr-Universität Bochum, Germany. First, the concept of the negative aerodynamic damping developed in [10] with the support of forced-vibration tests is now assessed in case of free-vibration experiments. Furthermore, the experiments on the aeroelastic model in free-vibrations demonstrate an intermittent – mathematically speaking quasi-periodic – behavior [11]. It results from a beating effect between the natural oscillation frequency of the structure and the vortex shedding load, which may lock-in and lock-out in consequence of low frequency turbulence fluctuations. Additionally, the frequency of the vortex shedding load along the height of the structure may vary due to varying mean velocity and varying Strouhal number, which exhibits smaller values close to the tip region.

For the purpose of fatigue calculations, current design models usually assume that the resonant vibration always occurs in the lock-in range with its largest value (see [5], [13]). This may lead, however, to an excessively conservative estimation of the fatigue damage.

In this paper, the contribution of the intermittent oscillations to fatigue life can be assessed from the aeroelastic measurements with the help of a rainflow load cycle counting. The load collectives that are determined from the time histories of the tower responses in the lock-in range for different Scruton numbers are then applied to a full-scale chimney sample, thereby allowing a realistic prediction of fatigue life. The result is then compared to the prediction of fatigue life by applying the standard procedure of the Eurocode [5].

2 WIND TUNNEL EXPERIMENTS

2.1 Setup of free-vibration wind tunnel tests

Free-vibration wind tunnel tests on a free-standing, aeroelastic model with circular cross-section are performed at WISt Boundary Layer Wind Tunnel at Ruhr-Universität Bochum, Germany. It is an open circuit wind tunnel with a test section of 1.8 m in width and 1.6 m in height (Figure 1). The tests are performed in uniform flow, with turbulence intensity Iv = 4.5%.

Figure 1: WISt Wind tunnel at Ruhr-Universitaet Bochum, Germany (left) and wind tunnel model (right)

The aeroelastic model for the free-vibration wind tunnel tests is a cantilever beam with circular cross-section (Figure 1). The model is fabricated with a carbon tube (external diameter 32 mm and internal diameter 29 mm) that arises above the wind tunnel floor up to the height of 775 mm (measured from the wind tunnel floor). Below the wind tunnel, the carbon tube is connected to a steel bar (length = 210 mm, diameter 15 mm). The steel bar provides the necessary stiffness to the model and benefits from small damping dissipation. The steel bar is fixed to a force balance located at the model foot. Being the model surface smooth and the wind velocity below ca. 10 m/s, the Reynolds number of the investigation is subcritical ($Re < 2{,}1 \cdot 10^4$).

The structural characteristics of the model that are relevant for the dynamic investigation such as the mode shape, the modal mass and the equivalent mass, are calculated through a finite element model of the wind tunnel prototype. It results the modal mass $M_1 = 0.0630$ kg and equivalent mass $m_{eq} = 0.2286$ kg/m. The finite element model also serves for a preliminary estimation of the natural frequencies and thus of the critical velocity of vortex resonance. The actual natural frequency of the model is measured through wind tunnel experiments in still air and in existence of wind. In addition, the snap-back tests in still air (free-decay tests) allow the estimation of structural damping. The behavior of the model in still air is described in the next section.

The reactions at the base of the model are measured by a 6-component force balance of the type K6D154 (ME-Meßsysteme). The measuring range is up to 200N for the forces and up to 20Nm for moments. The force balance is composed by six independent sensors, which are equipped with strain gauges. The three forces along the axes x, y and z (named F_x, F_y, F_z) and the three bending moments around same axes (M_x, M_y, M_z, respectively) can be calculated in time-domain through a calibration matrix applied to the volt signals measured by the sensors. The sampling frequency is set to 2000 Hz. Every measurement lasts for 98,304 s.

The stiffness of the wind tunnel model is measured through static calibration tests with increasingly higher horizontal forces of known value applied at the top of the model. At the same time, the static displacement of the tip of the model is measured by a laser sensor. The stiffness of the model is linear. By means of the model flexibility, during dynamic tests the oscillation

at the top of the model can be calculated from the forces or the bending moments measured at the base.

2.2 Behavior of the model in still air

Snap back tests are performed in still air to test the natural frequency of the model and its structural damping. The latter also includes the contribution of the still air damping. Figure 2 (left) shows a free-decay tests. The natural frequency in still air is about 22,3 Hz. The structural damping is evaluated from the oscillation amplitudes as logarithmic decrement:

$$\delta_s \cong \frac{1}{m} ln\left(\frac{A_n}{A_{n+m}}\right) \tag{1}$$

The reversals considered for the evaluation of the structural damping are marked in blue in Figure 2 (left). The overall value of the damping, calculated considering the first and the last reversals in the free-decay time history, is $\delta_s = 0{,}018$. Additionally, a sensitivity study has been performed concerning the proper number m of cycles to be counted between two amplitudes in equation (1), in order to capture the non-linear behavior of the structural damping. Figure 2 (right) shows the behavior of the structural damping in case m = 25. The structural damping varies nonlinearly with the amplitude of oscillation between $\delta_s = 0{,}010$ and $\delta_s = 0{,}030$.

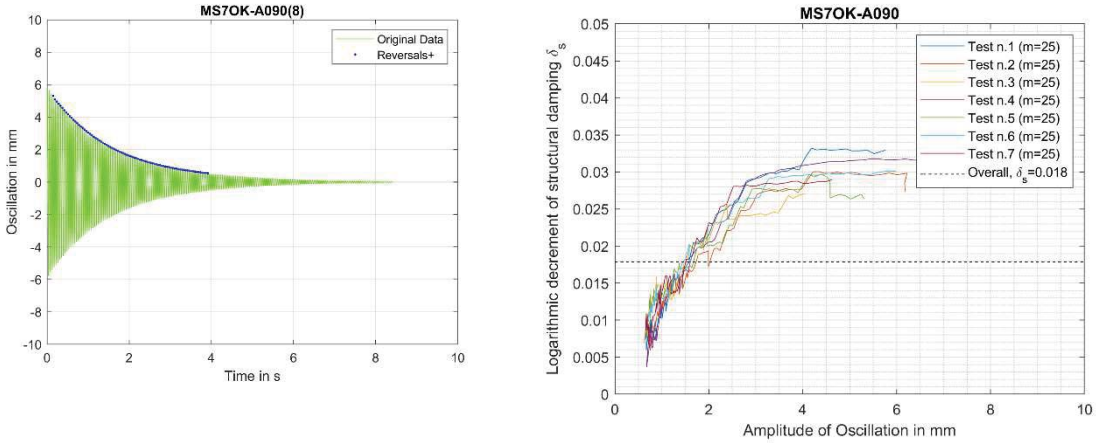

Figure 2: Snap back test and non-linear evaluation of the structural damping

2.3 Resonant vibrations in the lock-in range

The aeroelastic model of the tower is excited in the lock-in range for different wind velocities. Figure 3 shows the spectrum of the base force in the lift direction in case $V_H/V_{cr} = 0{,}85$. V_H is the wind velocity referred to the height of the model. The natural frequency of the model remains substantially unchanged with respect to still air tests: $f_l = 22{,}22$ Hz. The Strouhal number is St = 0,203 and this follows: $V_{cr} = 3{,}50$ m/s.

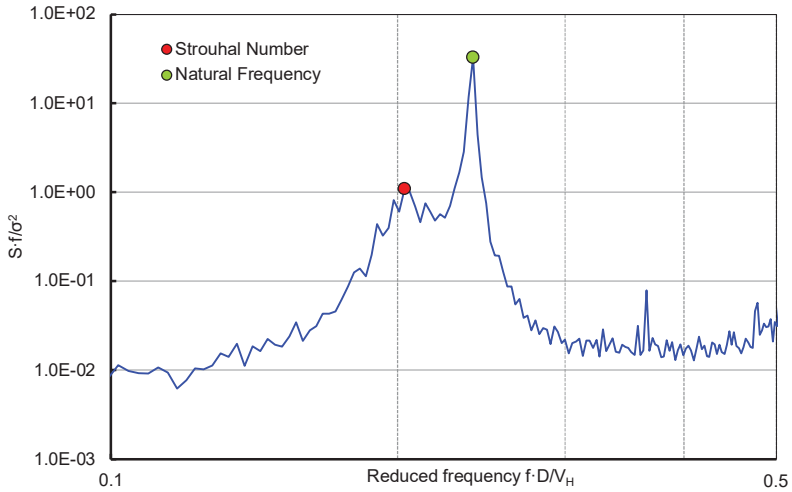

Figure 3: Spectrum of the base force in the lift direction, V_H = 2,99 m/s, V_H/V_{cr} = 0,85

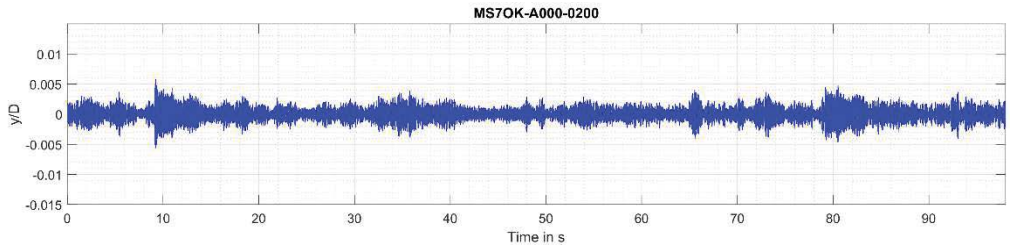

Figure 4: Time history of the response y/D at V_H/V_{cr} = 0,85

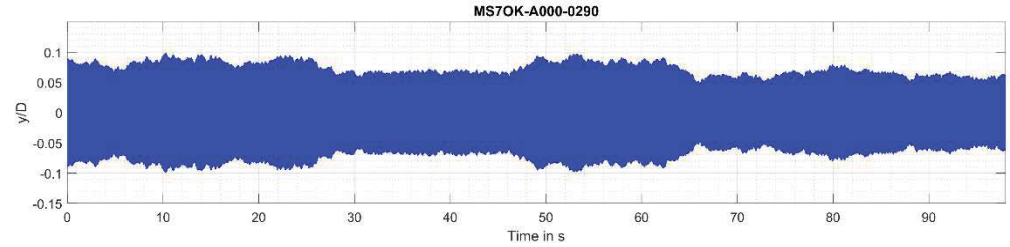

Figure 5: Time history of the response y/D at V_H/V_{cr} = 1,13 (max)

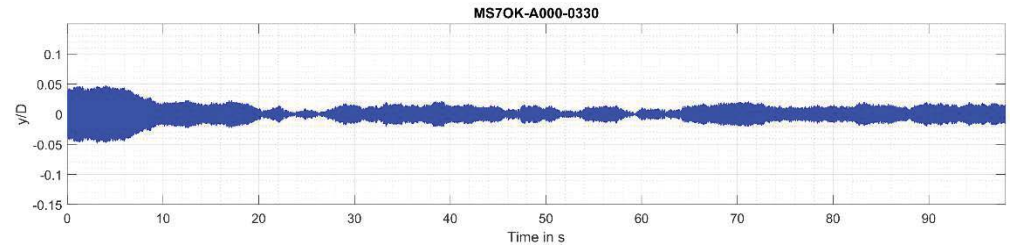

Figure 6: Time history of the response y/D at V_H/V_{cr} = 1,25

Figure 4, Figure 5 and Figure 6 show the time histories of the nondimensional response y/D for different velocities in the lock-in range. Because of the intermittency of the response, a question arises: is the response stationary, i.e. is the standard deviation a suitable parameter to describe the VIV response in the lock-in range? This issue is particularly important especially in view of the spectral analysis presented in the following sections, which considers the standard deviation of the response as governing parameter for the structural design.

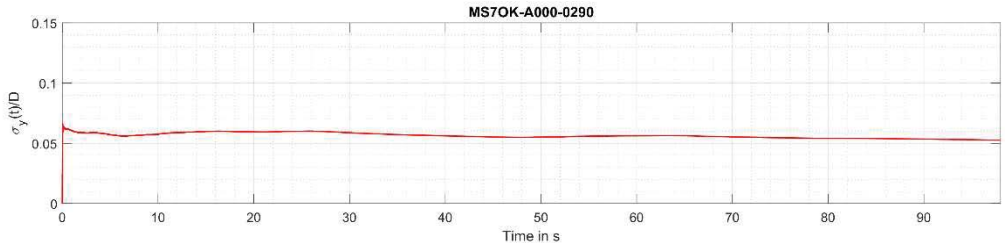

Figure 7: Convergence of the standard deviation of the response at V_H/V_{cr} = 1,13 (max)

First, the convergence of standard deviation of the response for increasingly higher time intervals is investigated. Figure 7 shows that the recorded signal is long enough to ensure a robust estimation of standard deviation of the response.

Second, the stationarity of the response is investigated by dividing the time history in blocks of 10-min events in full-scale. The full-scale similarity considers a full-scale frequency $f_{1,FS}$ = 0,629 Hz, as it will be explained later in Table 2. Being the natural frequency in the wind tunnel experiments $f_{1,WT}$ = 22,22 Hz, it follows that the frequency scale is λ_F = 35,33 and the time scale is its inverse, i.e. $\lambda_T = 1 / \lambda_F$ = 0,028. Therefore, 600 seconds in full-scale correspond to 16,98 seconds in the wind tunnel. Each of the recorded time histories includes five 10-min events in full-scale. For each event, the maximum amplitude and the standard deviation of the oscillation are calculated. Then, a statistical analysis of the maxima is performed to evaluate the mean value of the peak amplitudes among different events and the mean value of the standard deviations among different events. These two last parameters represent the statistical maximum and the statistical standard deviation, respectively, and they will be referred to in the following analysis. Their ratio allows calculating a statistically representative peak factor for the time history. Figure 8 shows the result for the case V_H/V_{cr} = 1,13. In particular:

Mean value of maxima, $y_{max} / D = 0{,}0932$
Mean value of standard deviation, $\sigma_y / D = 0.0536$
$k_p = y_{max} / \sigma_y = 1.74$

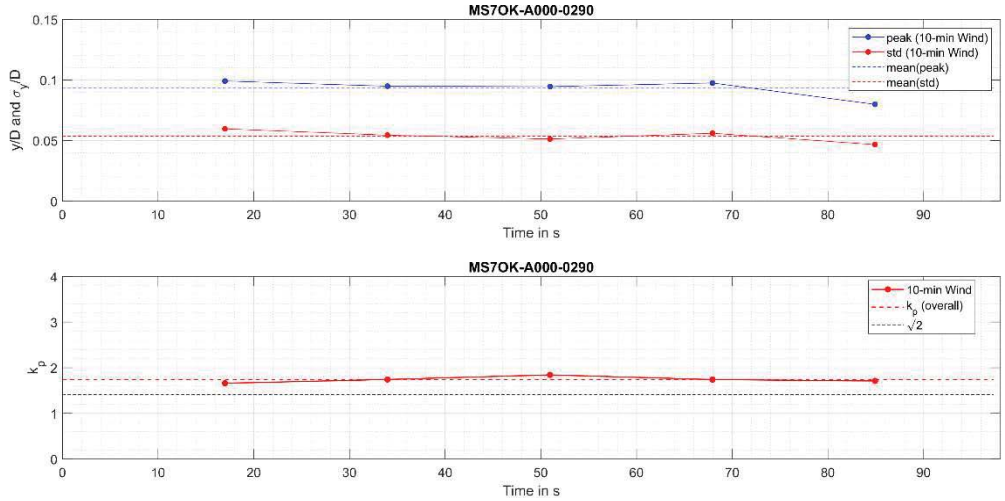

Figure 8: Analysis of peak amplitudes, standard deviations, peak factors k_p for 10-min events and for the overall time history (V_H/V_{cr} = 1,13 (max))

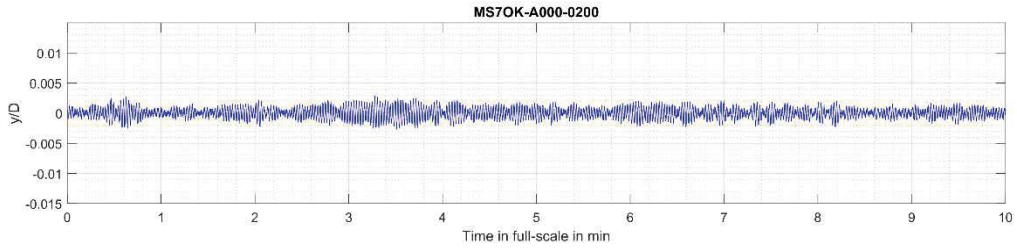

Figure 9: Time history of the response y/D in 10-min full-scale interval at V_H/V_{cr} = 0,85

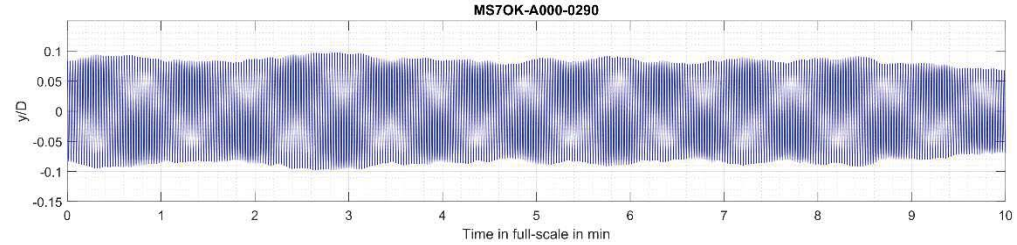

Figure 10: Time history of the response y/D in 10-min full-scale interval at V_H/V_{cr} = 1,13 (max)

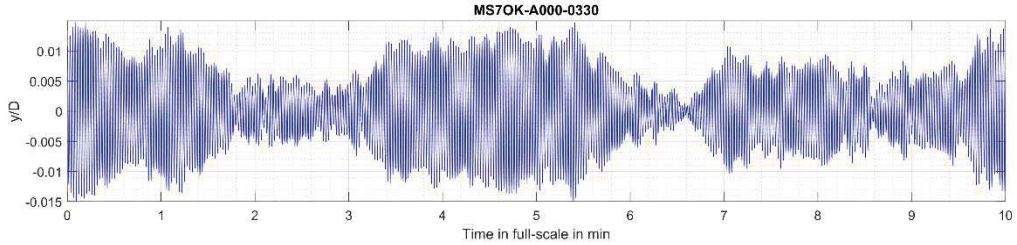

Figure 11: Time history of the response y/D at V_H/V_{cr} = 1,25

Furthermore, Figure 9, Figure 10 and Figure 11 show the time history of the response in a selected 10-min full-scale interval. For the sake of clarity, the y-axis is scaled 10 times in Figure 9 and Figure 11 with respect to Figure 10.

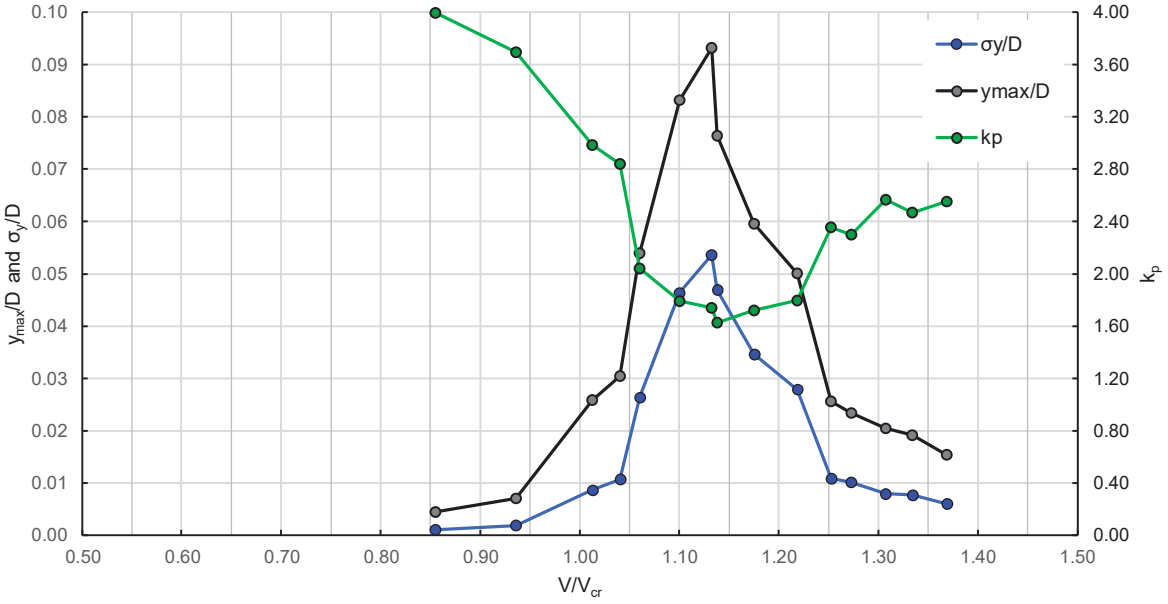

Figure 12: Statistical maxima of the oscillation, standard deviations and peak factors in the lock-in range

Figure 12 shows the lock-in phenomenon. As it often occurs, the largest oscillation occurs for $V > V_{cr}$. The right-hand side of the figure shows, instead, the distribution of the peak factors in the lock-in range. As expected, at the beginning and at the end of the lock-in range the stochastic behavior predominates and the peak factor increases. In full resonance, due to the predominant harmonic character, the peak factor is reduced. The ideal value $\sqrt{2}$ corresponds to the peak factor of a pure harmonic signal.

3 ESTIMATION OF THE NEGATIVE AERODYNAMIC DAMPING FROM FREE-VIBRATION WIND TUNNEL TESTS

Previous work of the authors allowed the measurement of negative aerodynamic damping K_a in vortex-induced vibrations through forced vibration wind tunnel tests [10]. The behavior of the negative aerodynamic damping as a function of rms oscillation is described by the following curve:

$$K_a = a \cdot e^{-b \cdot \frac{\sigma_y}{D}} \cdot \left(\frac{\sigma_y}{D}\right)^c \tag{2}$$

with a = 0,3464, b = 5,808 and c = 0,3582.

With regard to Equation (2), the largest oscillation in the lock-in range can be predicted by the following model, which originates from a modification of the Vickery&Basu model [14]:

$$\sigma_y^2 = \frac{S_{L1}(f_n)}{\left(\omega_1^2 \cdot M_1\right)^2} \cdot \frac{\omega_1}{\frac{4}{\pi}(\delta_s + \delta_a)} = \frac{S_{L1}(f_1)}{\left(\omega_1^2 \cdot M_1\right)^2} \cdot \frac{\omega_1}{8 \cdot \frac{\rho \cdot d^2}{m_{eq}} \cdot \left(\frac{Sc}{4\pi} - K_a\right)} \tag{3}$$

The background of equation (3) is explained in [9] and goes back to the evaluation of the resonant response to stochastic load in the first mode shape. The stochastic load is the vortex shedding load, which has a spectral density centered around the Strouhal frequency:

$$S_{L1}(f_1) \cong 2\lambda \cdot \int_0^H \left(\frac{1}{2}\rho V_m(z)^2\right)^2 \cdot D(z)^3 \cdot \frac{\sigma_{cL}^2}{\sqrt{\pi} \cdot St(z) \cdot \frac{V_m(z)}{d(z)} \cdot B(z)} \cdot \exp\left(-\left(\frac{1 - \frac{f_1}{St(z) \cdot \frac{V_m(z)}{d(z)}}}{B(z)}\right)^2\right) \cdot \Phi_n(z)^2 \cdot dz \tag{4}$$

By definition, the Vickery&Basu model considers the load on the non-vibrating structure and includes all aeroelastic effects in the negative aerodynamic damping. Although this assumption may be questionable, it has little effect on the response prediction, as long as the response is predominantly governed by the motion-induced forces. This condition happens in the case of sufficiently small Scruton numbers, i.e. pronounced lock-in range. In this case, the major role in the response prediction is played by the accurate estimation of both structural and aerodynamic damping terms.

A further remark to equation (4), which follows from the assumption of the Vickery&Basu model to consider load on the non-vibrating structure, is the absence of lock-in effect for $V \neq V_{cr}$, i.e. $f_s = St \cdot V_m/d \neq f_1$. For example, the largest oscillation occurs for $V / V_{cr} = 1{,}13$ in the present experiment (see Figure 12). This is a typical behavior particularly for sufficiently small Scruton numbers. According to the equation (4), $S_{L1}(f_1)$ calculated for $V_m = 1{,}10 \cdot V_{cr}$ is smaller than $S_{L1}(f_1)$ calculated for $V_m = V_{cr}$, due to the negative exponential function. Since the Strouhal law is violated in the lock-in range, it would be more reasonable not to apply any reduction to $S_{L1}(f_1)$ caused by the exponential term in the lock-in range, especially for $y = y_{max}$. However,

no further correction to the Vickery model is applied in this paper. Additional experimental evidence would be needed.

In present case, the nonlinear behavior of the structural damping needs to be considered, in order to ensure the most accurate estimation of the Scruton number which corresponds to the oscillation amplitude reached in lock-in. Referring to Figure 12 and considering the largest oscillation $y_{max}/D = 0{,}0932$ (i.e. $y_{max} = 2{,}98$ mm), the corresponding structural damping is estimated as $\delta_s = 0{,}028$. The air density during the experiments is 1,16 kg/m^3. It follows Sc = 10,74, being Sc defined as follows:

$$\mathrm{Sc} = \frac{2 \cdot m_{eq} \cdot \delta_s}{\varrho \cdot D^2}$$

Table 1 lists all the model parameters that are applied in this work to solve the equation (3). Unfortunately, some load parameters in equation (4), such as the rms value of the lift coefficient σ_{cL}, the correlation length relative to the diameter λ and the spectral bandwidth B, could not be measured during the experiments and therefore could only be estimated from literature and comparison with the Standard Codes.

Parameter	Symbol	Unit	Value	Reference
Model diameter	D	m	0,032	Wind tunnel model
Model height	H	m	1,016	Wind tunnel model
Model natural frequency	f_1	Hz	22,22	Measured
Structural damping	δ_s	-	0,028	Measured
Modal mass	M_1	kg	0.0630	Calculated from FE model
Equivalent mass	m_{eq}	kg/m	0.2286	Calculated from FE model
$\int_0^H \Phi_n(z)^2 \cdot dz = M_1 / m_{eq}$	-	-	0,276	Calculated from FE model
Scruton number	Sc	-	10,74	Calculated

Wind velocity at $y = y_{max}$ (uniform profile)	V_m	m/s	3,97	Measured at $y = y_{max}$
Velocity ratio at $y = y_{max}$	V_m / V_{cr}	-	1,13	Result
Air density	ρ	kg/m^3	1,16	Measured
Max amplitude of oscillation	y	mm	2,98	Measured (Figure 12)
Rms of the oscillation at max	σ_y	mm	1,72	Measured (Figure 12)

Table 1: List of model parameters

Considering all the parameters in Table 1, it is clear that the only unknown in equation (3) is the aerodynamic damping parameter K_a, which could be calculated. The result is $K_a = 0{,}82$. Considering the K_a-curve proposed in [10] (equation (2)), the agreement is satisfying, as shown in Figure 13. On the other hand, the well-known Vickery curve

$$K_a = K_{a0}\left(1 - \left(\frac{\sigma_y}{a_L \cdot D}\right)^2\right) \tag{5}$$

would give $K_a = 1{,}97$ at $\sigma_y/D = 0.054$ by assuming $K_{a0} = 2$ and $a_L = 0{,}4$ in accordance with [5] for the subcritical range of Reynolds number.

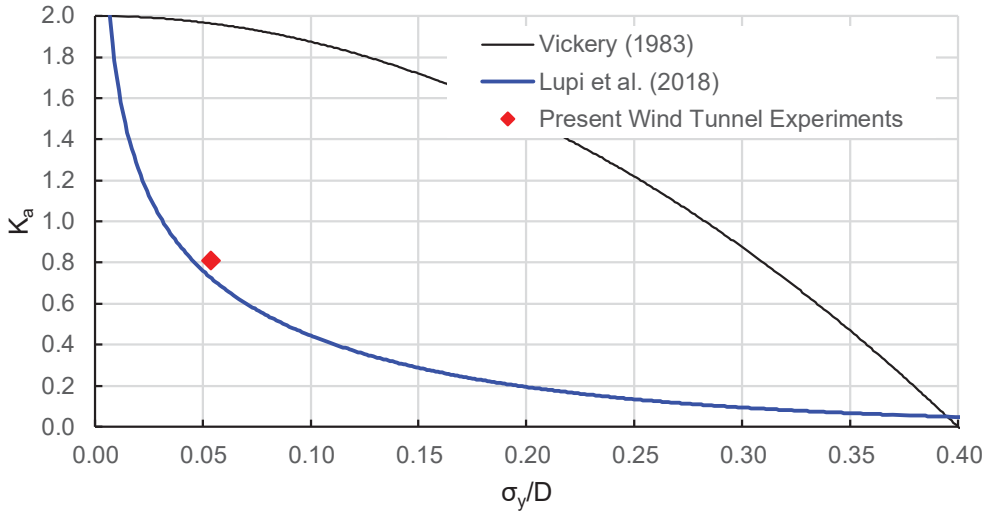

Figure 13: Estimation of negative aerodynamic damping parameter K_a from free-vibration tests and comparison with literature

4 PREDICTION OF FATIGUE LIFE

4.1 Case study

For the purpose of fatigue life prediction, wind stresses caused by vortex excitation need to be calculated on a sample structure. For this purpose, the full-scale chimney in Skjern (Denmark), described in [8] and [3] and investigated by the authors in [9] is chosen as case study. The governing parameter is the similar Scruton number used. In details, the structural parameters of the full-scale chimney applied for this work are reported in Table 2.

Parameter	Symbol	Unit	Value	Reference
Tower diameter (constant)	$D^{(FS)}$	m	1.1	[8]

4.2 Fatigue life estimation according to the Eurocode Method

The Eurocode EN 1991-1-4 [5] proposes a method to calculate the fatigue life of a structure subjected to vortex excitation, which was originally developed in [13]. The method is based on the calculation of the number of load cycles around $V = V_{cr}$ according to the Weibull distribution of the wind velocity. It further assumes that the vibration in the lock-in range is harmonic and its amplitude corresponds to the maximum resonant oscillation. The method is suitable for practical applications and generally provides safe results. The procedure is briefly described here and applied to the sample chimney in Table 2, in order to compare the results with a more sophisticated rainflow analysis for cycle counting, which is later applied to the wind tunnel measurements.

The Weibull probability distribution of the wind velocity is characterized by two parameters, the shape parameter k and the scale parameter A. The probability density function is:

$$f(V) = \frac{k}{A} \cdot \left(\frac{V}{A}\right)^{k-1} \cdot e^{-\left(\frac{V}{A}\right)^{k}} \tag{6}$$

The cumulative distribution function is the probability when the wind velocity V assumes a value less than or equal to V_i:

$$F(V) = P(V \leq V_i) = 1 - e^{-\left(\frac{V_i}{A}\right)^{k}} \tag{7}$$

It follows that the probability when the wind velocity assumes values comprised between V_1 and V_2 is expressed as:

$$P(V_1 \leq V \leq V_2) = F(V_2) - F(V_1) = e^{-\left(\frac{V_1}{A}\right)^{k}} - e^{-\left(\frac{V_2}{A}\right)^{k}} \tag{8}$$

In absence of wind statistics at the location of the structure, the Eurocode recommends:

- k = 2 (Rayleigh-Distribution)
- $A = \sqrt{2} \cdot V_{mod}$, being V_{mod} the modal value of the Weibull probability distribution. The parameter "A" can be taken as 20% of the mean wind velocity at the height of the cross-section where the vortex shedding occurs [5].

Assuming that the wind velocities V_1 and V_2 mark the beginning and the end of the lock-in range, respectively, the equation (8) describes the probability when the wind velocity excites the structure in the lock-in range. Considering the natural vibration frequency f_1, the number of load cycles in the lock-in range in the whole design lifetime of the structure (T = 50 years = $3{,}1536 \cdot 10^7 \cdot 50$ seconds) amounts to:

$$N = 3{,}1536 \cdot 10^7 \cdot \mathrm{T} \cdot \mathrm{f}_1 \cdot \left(e^{-\left(\frac{V_1}{A}\right)^{k}} - e^{-\left(\frac{V_2}{A}\right)^{k}}\right) \tag{9}$$

For the purpose of simplicity, [13] proposes:

$$e^{-\left(\frac{V_1}{A}\right)^{k}} - e^{-\left(\frac{V_2}{A}\right)^{k}} = f(V_{cr}) \cdot \Delta V = f(V_{cr}) \cdot \varepsilon_0 \cdot V_{cr} = \frac{k}{A} \cdot \left(\frac{V_{cr}}{A}\right)^{k-1} \cdot e^{-\left(\frac{V_{cr}}{A}\right)^{k}} \cdot \varepsilon_0 \cdot V_{cr} \tag{10}$$

[13] recommends $\varepsilon_0 = 0{,}3$, meaning that the lock-in range extends for $0{,}3 \cdot V_{cr}$, (e.g. $V_1 = 0{,}9 \cdot V_{cr}$ and $V_2 = 1{,}2 \cdot V_{cr}$), which is often the case.

For the case under investigation, considering the natural frequency $f_1 = 0{,}629$ Hz (see Table 2), the scale parameter A as $0{,}2 \cdot V_m(H)$, assuming the second terrain category and $v_b = 25$ m/s (see [5] and [6]), it results:

$$A = 0{,}2 \cdot V_m(H) = 0{,}2 \cdot v_b \cdot \left(\frac{H^{(FS)}}{10}\right)^{0{,}16} = 0{,}2 \cdot 25 \cdot \left(\frac{45}{10}\right)^{0{,}16} = 6{,}36\ m/s \tag{11}$$

The critical wind velocity V_{cr} is:

$$V_{cr} = \frac{f_1 \cdot D^{(FS)}}{St} = \frac{0{,}629 \cdot 1{,}1}{0.203} = 3{,}41\ m/s \tag{12}$$

Therefore:

$$N = 3{,}1536 \cdot 10^7 \cdot \mathrm{T} \cdot \mathrm{f}_1 \cdot \frac{k}{A} \cdot \left(\frac{V_{cr}}{A}\right)^{k-1} \cdot e^{-\left(\frac{V_{cr}}{A}\right)^k} \cdot \varepsilon_0 \cdot V_{cr} = 1{,}2823 \cdot 10^8 \tag{13}$$

The Eurocode Method assumes that the resonant vibrations of the structure in the lock-in range are harmonic with constant amplitude. Their amplitude corresponds to the maximum oscillation in the lock-in range. Using y_{max}/d value from the wind tunnel tests (Figure 12), it follows:

$$y_{max}^{(FS)} = \frac{y_{max}}{d} \cdot D^{(FS)} = \frac{y_{max}}{d} \cdot 1{,}1 = 0{,}0932 \cdot 1{,}1 = 0{,}103\ m \tag{14}$$

The wind stresses result from the following distribution of inertial forces along the height of the structure [5]:

$$F_w(z) = m(z) \cdot (2 \cdot \pi \cdot f_1)^2 \cdot \Phi_1(z) \cdot y_{max}^{(FS)} \tag{15}$$

For the purpose of this investigation, the bending moment at the base of the chimney is considered. Referring to the cross-section at the based described in [8] (diameter D = 1,1 m and wall thickness t = 0,016 m), the maximum of the wind stress in resonance corresponds to σ_{max} = 13,91 N/mm^2, i.e. stress range $\Delta\sigma_{max}$ = 27,82 N/mm^2. The stress range corresponds to the difference between two extremes. The relationship between the maximum oscillation on top and the stress range at the base is as follows:

$$\Delta\sigma = 2 \cdot \frac{\int_0^H m(z) \cdot (2 \cdot \pi \cdot f_1)^2 \cdot \Phi_1(z) \cdot z \cdot dz}{W} \cdot y_{max}^{(FS)} \tag{16}$$

The cumulative damage and the fatigue lifetime follow from the assumption of a detail category. Let us consider, for instance, the detail category 45 according to [7]. In this case, according to the Wöhler line, the number of load cycles N_R to cause failure amounts to 1,2019*10^7. From the previously calculated total number of load cycles of stress range $\Delta\sigma_{max}$ during the required design life (equation (13)), it results:

$$D_d = \frac{N}{N_R} = \frac{1{,}28.23 \cdot 10^8}{1{,}2019 \cdot 10^7} = 10{,}67 > 1 \tag{17}$$

Being $D_d > 1$, the structure will be damaged by fatigue during its lifetime of 50 years, i.e. after about 5 years. This result follows from the assumption that the vibration of the structure occurs in the lock-in range with constant amplitude equal to its maximum value. This assumption is particularly convenient for Code applications and is on the safe side. However, a more realistic fatigue lifetime may be estimated by considering the actual variability of the oscillation amplitude in the lock-in range, e.g. through rainflow counting.

4.3 Fatigue life estimation considering rainflow cycle counting

The rainflow analysis is a method to count the number of load cycles and produce a stress range spectrum in case of time histories with varying amplitude. In this work, it is referred to the algorithm for rainflow counting that is described in ASTM E1049-85 [1].

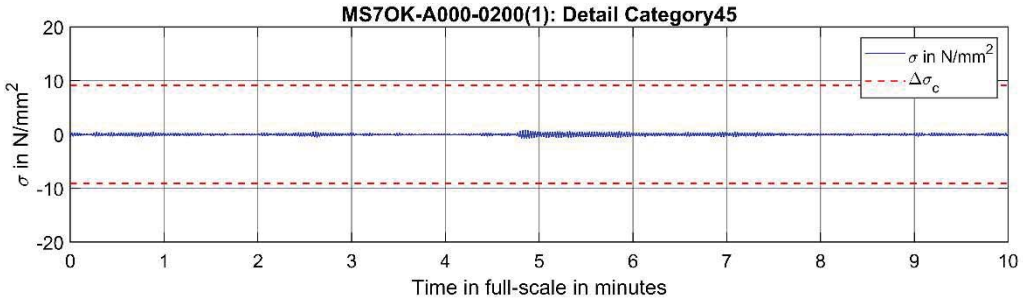

Figure 14: Time history of the stress response in 10-min full-scale interval at V_H/V_{cr} = 0,85

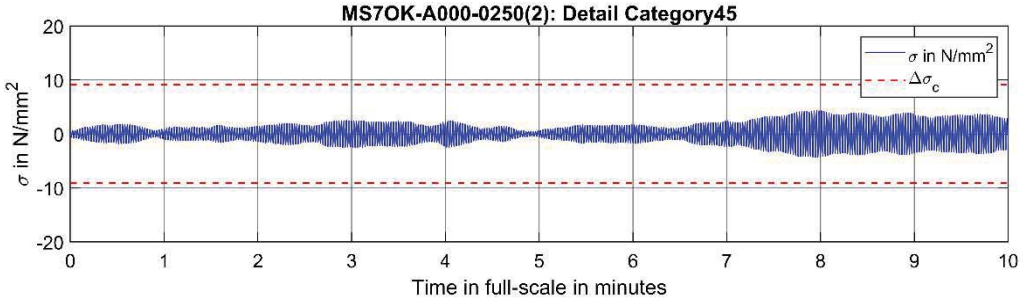

Figure 15: Time history of the stress response in 10-min full-scale interval at V_H/V_{cr} = 1,01

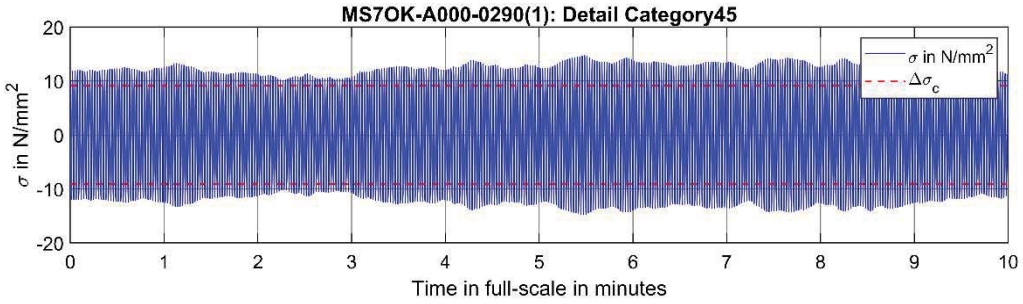

Figure 16: Time history of the stress response in 10-min full-scale interval at V_H/V_{cr} = 1,13 (max). The dashed line indicates the cut-off stress for the Detail Category 45.

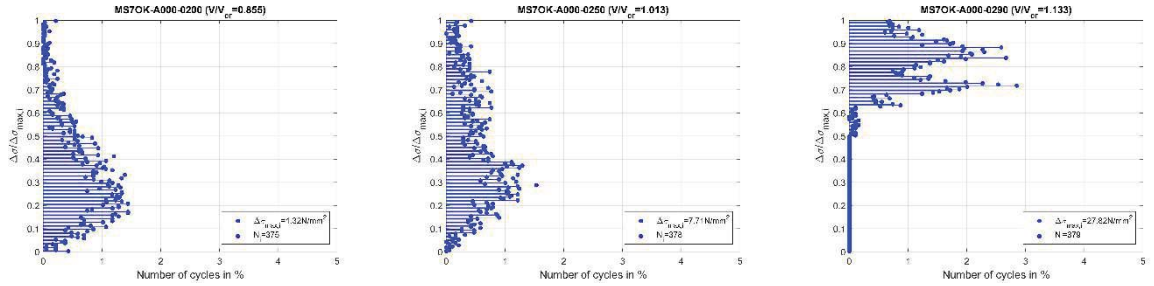
Figure 14, Figure 15, Figure 16 show some typical time histories of the stresses at the foot of the chimney in the lock-in range, which are calculated by integration of the inertial forces along the height according to the equation (15). The figures also plot $\Delta\sigma_L$, i.e. the cut-off limit for the given detail category (in this case: DC = 45), i.e.:

$$\Delta\sigma_L = \left(\frac{2}{5}\right)^{\frac{1}{3}} \cdot \left(\frac{5}{100}\right)^{\frac{1}{5}} \cdot DC = 18{,}21\ N/mm^2 \tag{18}$$

For all stress ranges above the $\Delta\sigma_L$ stress range, damage is accumulated.



(a) (b) (c)

Figure 17: Stress collectives in the lock-in range by rainflow counting

Figure 17 describes the collectives, i.e. the stress range spectra, which correspond to the time histories in Figure 14, Figure 15, Figure 16, respectively. Figure 17 (a) shows a typical collective shortly before beginning of the lock-in range. In accordance with a stochastic signal, the number of cycles that correspond to the maxima of the oscillation is small compared to the number of cycles for smaller oscillation. A similar pattern is observed in Figure 17 (b). Figure 17 (c) - which corresponds to a fully resonant time history (see Figure 16), where the largest oscillation in the lock-in range is reached - indicates another behavior. Due to the predominant harmonic component, most of load cycles occur with the larger oscillations.

The calculation of the stress collectives from the experiments at different V/V_{cr} through rainflow cycle counting allows the calculation of actual cumulative damage in the structure. For each ratio V/V_{cr}, a velocity class can be identified such that $V_1 \leq V/V_{cr} < V_2$. For each velocity class, depending on the Weibull distribution defined in equation (6), the probability when the wind velocity assumes values within the velocity class can be calculated (equation (8)). In this way, the number of load cycles for each velocity class can be calculated (N_i) according to the equation (9).

Table 3 shows the calculation of the cumulative damage by considering largest stress range $\Delta\sigma_{max,i}$ for each velocity class and attributing it to the number of cycles N_i. The calculation assumes that the vibration in each velocity class is harmonic and its amplitude corresponds to $y_{max,i}/D$ in the lock-in curve shown in Figure 12. The rainflow counting is not considered in this calculation. The cumulative damage then results:

$$D_d = 1{,}752 > 1 \text{ (considering the lock-in range but without rainflow counting)}$$

It means a reduction of the fatigue lifetime to about 28,5 years. On the other hand, if the intermittent behavior is considered through rainflow analysis and each stress collective such as those in Figure 17 is considered for each velocity class, the cumulative damage results smaller than 1, i.e. the structure will not be damaged by fatigue during the whole lifetime (50 years):

$$D_d = 0{,}659 < 1 \text{ (considering rainflow counting)}$$

Finally, given the cumulative damage calculated through rainflow analysis, the equivalent stress ranges which correspond to the cumulative damage can be calculated for each velocity class (Table 5). From that, equivalent oscillation amplitudes and equivalent peak factors for fatigue analysis in the lock-in range are developed. Figure 18 shows the peak factors for the ultimate limit state (already shown in Figure 12), which provide the maxima in the lock-in range. The peak factors for fatigue analysis, which provide equivalent stresses that give the same cumulative damage as the rainflow analysis, are also shown in the figure.

Table 5: Equivalent peak factors for fatigue analysis

5 CONCLUSIONS

The paper analyzes the negative aerodynamic damping in vortex-induced vibrations through free-vibration tests on an aeroelastic model. The result is compared with the curve previously gained by the authors through forced-vibration tests and shows a good agreement. Then, fatigue analysis through rainflow cycle counting is applied to the time histories measured in the wind tunnel experiments, which show a quasi-periodic behavior in the lock-in range. In view of fatigue, not the maxima, but rather the stress distribution needs to be considered for the evaluation of the fatigue lifetime. The rainflow analysis allows the calculation of equivalent stresses which produce the same cumulative damage as the actual time histories with varying amplitude. In this way, a peak factor for fatigue analysis can be defined. Similarly, using the ultimate limit state peak factor that is applied to the standard deviation of the response, the largest oscillation in the lock-in range is calculated.

Keywords: Galloping; Vortex induced vibration; steel-concrete composite bridge; Wind tunnel tests; wake-oscillator model

Abstract. *Aeroelastic galloping instability and vortex induced vibration can be both relevant during the launching phase of steel-concrete composite bridges, due to the light weight and bluff shape of the normally first-launched steel box. A bridge deck sectional model with an open cross section, which is typical during the construction phase of steel-concrete composite bridges, was tested by means of wind tunnel techniques in smooth flow. Strong interaction between galloping and vortex induced vibration was observed for this bridge deck at a wind angle of attack of 4°， being the actual galloping onset fixed at the Kármán-vortex-resonance wind speed up to a high value of the mass-damping parameter. Tamura's wake-oscillator model was selected to model the interaction phenomenon observed for this bridge deck, following a recently proposed parameter identification method. For a wide range of the mass-damping parameter examined, satisfying agreements were found between the solutions of the mathematical model and the wind tunnel aeroelastic test results. This mathematical model was then applied to a full-scale case study, which is a 7-span continuous steel-concrete bridge during the critical launching phase.*

1 INTRODUCTION

Slender structures with special cross sections, like square and D shapes, can be susceptive to both galloping instability and vortex induced vibration (VIV) in the across wind direction. Under certain circumstances, these two phenomena are supposed to interact with each other, promoting a combined VIV-galloping instability [1]. The mass-damping parameter, namely the well-known Scruton number (*Sc*), plays a key role in this complex behavior [2]. And a high value of *Sc*, dependent on the cross section geometry, is usually needed to well separate these two phenomena. Otherwise, the complex behavior of the VIV-galloping instability is unable to be predicted by either the classical quasi-steady galloping theory or the VIV theory.

Two important mathematical models aiming at capturing the interaction mechanics of VIV and galloping were proposed by Corless and Parkinson [3] and Tamura and Shimada [4], by coupling an equation modelling the dynamics of the vortex-shedding force to the classical nonlinear equation describing the transverse motion of the cylinder according to the quasi-steady theory. In describing the self-excited and self-limited characteristics of the vortex shedding force, the former adopted the lift-oscillator model which is a Rayleigh-type oscillator, while the latter adopted the wake-oscillator which is a Van der Pol-type oscillator. In particular, the model proposed by Tamura and Shimada [4] was deduced based on physical considerations of the near-wake [5], rather than simply with an empirical approach. Recently, the wake-oscillator model was slightly modified and applied to a 3:2 rectangular cylinder, showing good agreements with the experimental results in a wide range of Scruton number [6].

For engineering practice, this combined VIV-Galloping instability may occur when the Scruton number of the structure is not high enough. In particular, this combined instability seems very relevant for the modern launching of steel-concrete composite bridges, since the steel box girder, which is normally launched first, could feature light weight, low damping and bluff cross section. A typical case should be mentioned is the Aftetal Bridge (in Germany), since its 90-m steel box girder was totally modified during the construction phase with temporary wind fairings to eliminate the risk of transverse galloping [7], as shwon in Figure 1.

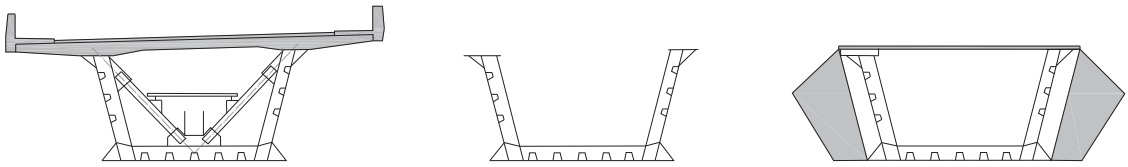

Figure 1. Cross-section modification of the Aftetal bridge, Germany, during the launching phase: (a) complete steel-concrete composite deck in service; (b) original steel box, and (c) modified steel box with temporary wind fairings during the launching phase [7].

In our previous work [8], a bridge deck model with typical open cross section was experimentally tested in smooth flow, showing a strong VIV-galloping tendency at its mean wind angle of attack of 4° (see the velocity-amplitude curve replotted in Figure 4). There, the actual galloping onset is fixed at the Kármán-vortex-resonance reduced critical wind speed V_r for Scruton number up to at least 70.

In this work, additional wind tunnel static tests were supplemented for the bridge deck model particularly at its 4° flow incidence, aiming at clarifying the dependence of the vortex shedding force coefficient C_{L0} on Reynolds number that reported in [8]. Mathematical modeling for the VIV-galloping instability of the bridge deck is firstly carried out on the wind tunnel sectional model. Then, the wake oscillator model with the parameters obtained from wind

tunnel tests was applied to a full-scale case study, which is a 7-span continuous steel-concreted bridge during its critical launching phase.

2 WIND TUNNEL TESTS

The extra wind tunnel static tests were carried out with the same wind tunnel model in the same wind tunnel facility as reported in [8], except that the static setup was re-mounted after one year later. More measures were added for the 4° angle of attack at various Reynolds number ($Re = \rho Ud/\mu$, being μ the dynamic viscosity of air). Details about the geometry of the bridge deck model is given in Figure 2. The length of the bridge deck model between two end-plates is l_e = 1300 mm.

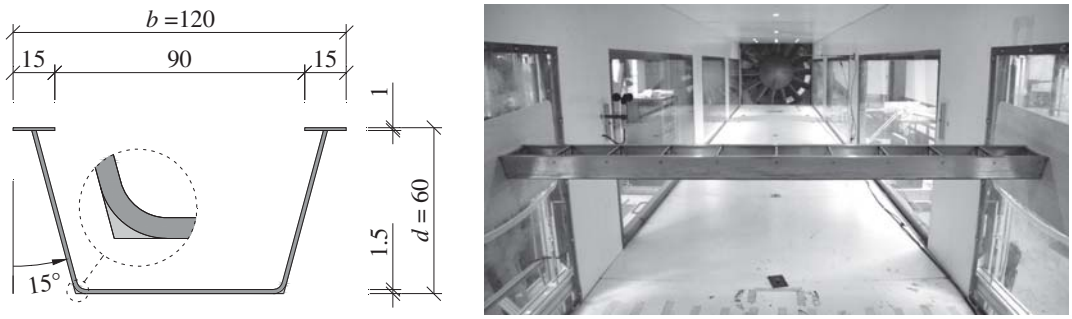

Figure 2. (a) Geometry of the open cross section, and (b) photo of the bridge deck model mounted in the wind tunnel (dimensions in mm).

The method of calculating the sinusoidal equivalent amplitude of the fluctuating lift coefficient C_{L0} was also improved. In [8], the C_{L0} coefficient was obtained by integrating the power spectral density of the fluctuating lift with a narrow band around the Strouhal frequency n_{st}, then square-rooting, normalizing with $0.5\rho U^2 dl_e$ and finally timing $\sqrt{2}$. However, the C_{L0} obtained in this way is affected by the dynamic amplification effect, unless the first bending natural frequency of the model is very high compared to the vortex-shedding frequency. To correct this bias, the classical dynamic amplification factor for a single-degree-of-freedom system was employed. First, a sensitivity analysis showed that for damping ratios up to 5% the amplification factor exhibits negligible variations, if the ratio of the vortex-shedding frequency to the model natural frequency is lower than 0.84 (this is the maximum frequency ratio encountered during the static tests). Consequently, since for an aluminum model rigidly mounted in the static setup, the damping ratio of the first bending mode is unlikely to be higher than 5%, a null damping ratio was therefore considered to calculate the amplification factor and to correct the C_{L0} values.

Finally, the main results in our previous work were given here again, which is supposed to facilitate the mathematical modeling work that is to be presented in the following. Figure 3 shows the mean drag and lift coefficients for the bridge deck model, respectively defined as $C_D = D/(0.5\rho U^2 dl_e)$ and $C_L = L/(0.5\rho U^2 dl_e)$, being D and L respectively the mean drag and lift over records of 100 s. C_D and C_L will be used to calculate the C_{Fy}^{QS} coefficient in the mathematical modeling work. Figure 4 shows the aeroelastic response of the bridge deck at its 4° mean flow incidence, with various Scruton number considered. The natural frequency of the model in still-air is n_0 = 9.63 Hz and n_0 = 9.53 Hz respectively for test case #a1-a6 and #a7-a9. y_{rms} represents the root mean square value of the across wind displacement y in the steady or statistically steady oscillation state. $V_r = 1/(2\pi St)$ denotes the Kármán-vortex-resonance wind

speed in reduced form. And for the bridge deck model at 4° flow incidence, the static test reports a Strouhal number St = 0.102. Finally, Scruton number is defined as $Sc = 4\pi M\zeta_0/\rho d^2 l_e$, with ζ_0 the damping ratio and M the effective oscillation mass (3.6 kg for test case #a1-a6 and 3.67 kg for test case #a7-a9).

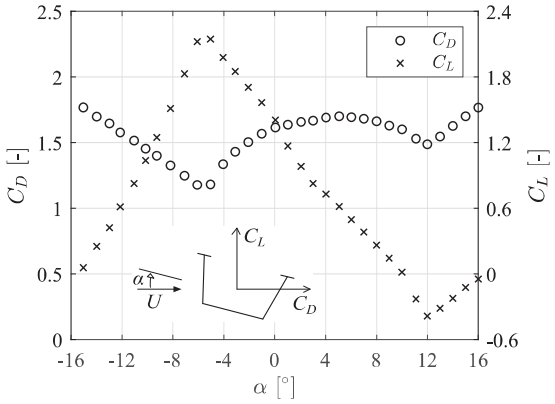

Figure 3. Mean drag and lift coefficient for various wind angle of attack of the bridge deck model at $Re = 6.0 \cdot 10^4$.

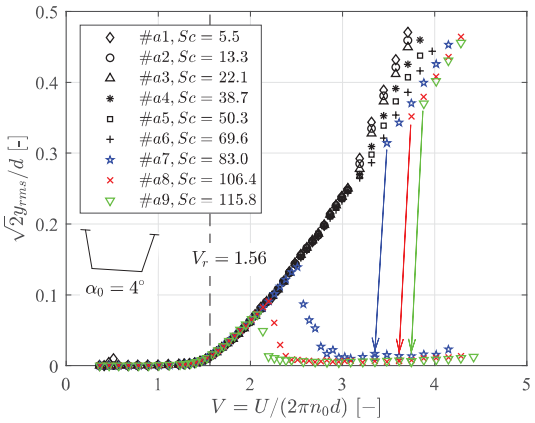

Figure 4. Effect of the Scruton number on the dynamic response of the bridge deck model at $\alpha_0 = 4°$.

3 WAKE OSCILLATOR MODEL FOR SECTIONAL MODEL

3.1 The wake oscillator model

The wake-oscillator nonlinear model proposed by Tamura and Shimada [4] was selected to simulate the VIV-galloping interaction for the bridge deck at 4° mean flow incidence. The near-wake lamina is supposed to pivot about the centroid of the bridge deck (following the modified form of wake oscillator in [6]), as schematized in Figure 5. The transverse motion of the bridge deck y and the rotation of the wake lamina ϑ are respectively governed by the two coupled equations in a dimensionless form:

$$Y'' + 2\zeta_0 Y' + Y = \frac{V^2}{m^*} f \cdot \left(\vartheta - \frac{Y'}{V} \right) + \frac{V^2}{m^*} C_{Fy}^{QS}(\alpha) \tag{1}$$

$$\vartheta'' - 2\beta v \vartheta' \cdot \left(1 - \frac{4f^2}{C_{L0}^2} \vartheta^2 \right) + v^2 \vartheta = \lambda Y'' + v^2 \frac{Y'}{V} \tag{2}$$

where $Y = y/d$ is the normalized displacement, $m^* = M/(0.5\rho d^2 l_e)$ the mass ratio, $C_{Fy}^{QS}(\alpha)$ the quasi-steady transverse force coefficient, $\upsilon = n_{st}/n_0$ the frequency ratio. f is a parameter relating the rotation of the wake ϑ to the resulting unsteady lift coefficient. $(\cdot)'$ represents differentiation with respect to non-dimensional time $\tau = 2\pi n_0 t$. The expression of β and λ are:

$$\beta = \frac{4\sqrt{2}}{\pi} St^2 h^* f \tag{3}$$

$$\lambda = 8\pi St^2 h^* \tag{4}$$

The restoring force F_L on the wake lamina is supposed to act at 1/4 of its chord, as suggested in [6], resulting in following relationship representing an additional restriction between the St, h^* and l^*:

$$St = \frac{n_{st} d}{U} = \sqrt{\frac{1}{8\pi l^* h^*}} \tag{5}$$

being $h^* = h/d$ and $l^* = l/d$ are the normalized wake width and semi-length.

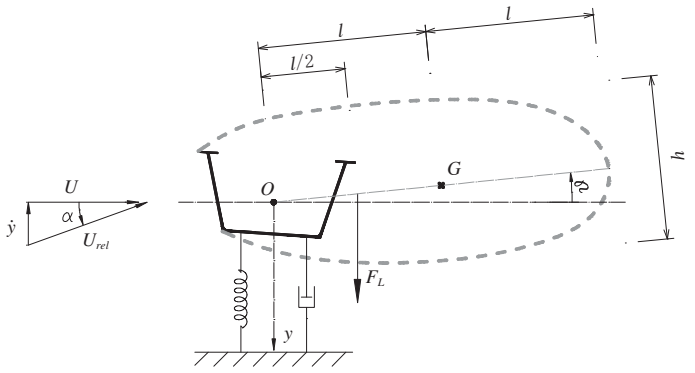

Figure 5. Schematic of the wake oscillator implemented for the bridge deck. G is the centroid of the equivalent near-wake lamina, and O is the pivot position of the wake, which is assumed to coincide with the centroid of the bridge deck.

3.2 Parameter setting

The parameters that need to be set in the equations are h^*, f, C_{Fy}^{QS}, C_{L0} and St. In particular, the last three can be obtained from the static test results. Figure 6(a) shows the cubic spline interpolation of the experimental $C_{Fy}^{QS}(\alpha)$ data measured at $Re = 6.0 \cdot 10^4$, obtained by applying:

$$C_{Fy}^{QS}(\alpha) = -\sec(\alpha)\left[C_L(\alpha) + C_D(\alpha)\tan(\alpha)\right] \tag{6}$$

The coefficient was shifted by resetting $\alpha = 4°$ as a new null wind angle of attack and neglecting the part of C_{Fy}^{QS} inducing only static deformation. A proper linear extrapolation of the experimental data was necessary for large α to ensure stable numerical solutions for large-amplitude oscillation. Given the extra static test results and the improved calculation method of the C_{L0}, the dependence of C_{L0} on Re is clearer for Re up to about $4.9 \cdot 10^4$, as shown in Figure 6(b). The experimental C_{L0} was therefore interpreted by piecewise-linear approximation in the range of Re between $1.6 \cdot 10^4$ and $8.0 \cdot 10^4$, corresponding to the wind speed range in which the aeroelastic tests were conducted. For $Re < 1.6 \cdot 10^4$, C_{L0} was assumed constant due to the accuracy problem of the instruments for very low wind speeds. Finally, a constant $St = 0.102$ was adopted.

A constant $h^* = 1.8$ was assumed for the bridge deck, kept the same as for a square cylinder in [4] and for a 3:2 rectangular cylinder in [6], where it also shows the solution of the wake-oscillator model is not sensitive to the h^*. To obtain the value of f parameter, the method recently proposed in [6] was adopted, calibrating the parameter f in the VIV range with a set of experimental results for a high value of the Scruton number. The calibration process is shown in Figure 7 with the experimental data of test case #a9, especially aiming at a good match of the amplitude-velocity curve slope between the experimental results and the numerical solutions. A good match of the numerical solution and the experiment was obtained when the value of f is set about 15.

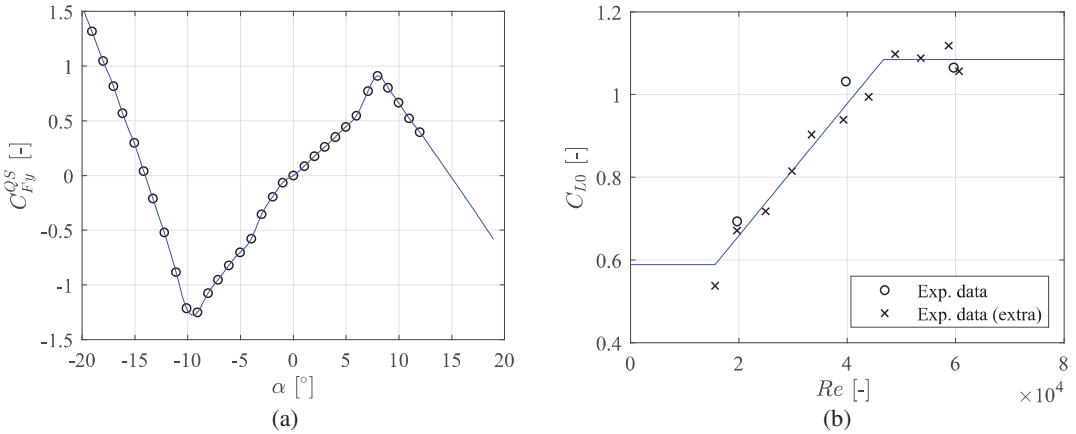

Figure 6. (a) Cubic spline interpolation and linear extrapolation of the experimental $C_{Fy}^{QS}(\alpha)$ data (Re =6.0·10^4) after the shift of the coefficient for α = 4°; (b) piecewise-linear approximation of the experimental $C_{L0}(Re)$ data.

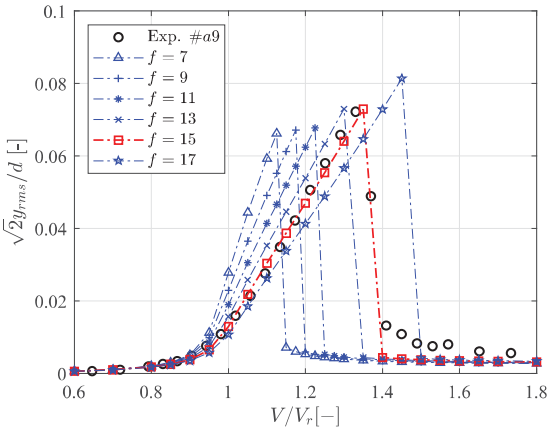

Figure 7. Calibration of the f parameter with experimental results for test case #a9, being the initial condition for numerical integration set as [Y, Y', ϑ, ϑ'] = [0.001, 0, 0, 0].

3.3 Numerical results for the wind tunnel sectional model

The equations were numerically solved by the ODE45 function of Matlab®. The relative and absolute error tolerance of the solver were respectively set to 10^{-6} and 10^{-8}, well balancing computational cost and accuracy (several tests with lower tolerances were also carried out). The performance of the mathematical model was examined by comparing the solution with the experimental results for a wide range of Sc, in terms of the amplitude-velocity curves shown in Figure 8. The QS galloping solutions are also reported as a reference.

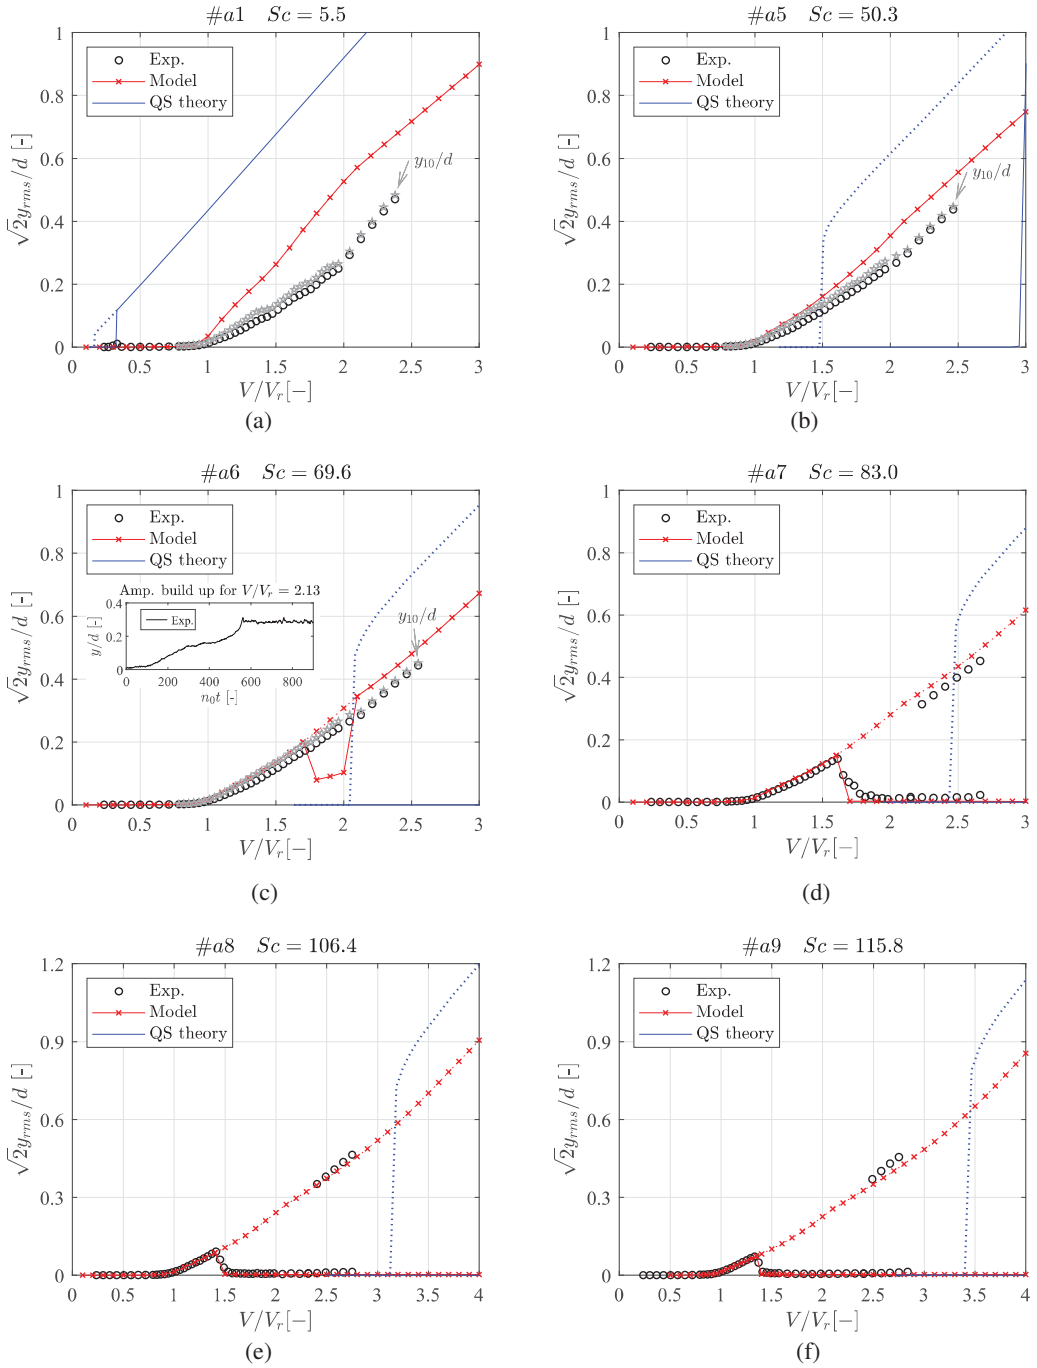

Figure 8. Numerical solution of wake-oscillator model equations for various *Sc*. Solid and dotted lines indicate steady-state solutions respectively for initial conditions [Y, Y', ϑ, ϑ'] = [0.001, 0, 0, 0] and [tan(15°)·V, 0, 0, 0].

For very low *Sc* values, such as in test case #a1, the mathematical model is able to successfully predict the onset of galloping at V_r, as observed in the experiments. The calculated amplitude is higher than the measured one, especially for V close to V_r. Even considering the average of the 10% largest peaks in the time histories (y_{10}), which represents a

statistical maximum amplitude for the experimental results, the agreement with the solutions of the mathematical model is not significantly improved. Increasing Sc up to 50.3 (test case #a5), the numerical solution gradually approaches the experimental data, the galloping onset remaining fixed at V_r. For a slightly higher Sc (test case #a6), the mathematical model starts to show a "drop and recover" of the steady-state amplitude around $V/V_r = 1.9$, when the solution is attained from a small initial condition. In contrast, a branch with higher amplitude can be found when a much larger initial condition is imposed. The existence of the moderate-amplitude branch around $V/V_r = 1.9$, which is not predicted by the quasi-steady theory, must be related to the strong nonlinearity of the Van der Pol wake equation in the model [9]. During the experiments for test case #a6, the wind tunnel model was released from rest for $1.63 \leq V/V_r \leq 2.55$, but no second branch was found. However, a careful inspection of the time records shows that the amplitude build-up at $V/V_r = 2.13$ is different from those at different reduced wind speeds. This amplitude build-up pattern is reported in Figure 8 (c). Two inflection points can be seen in the build-up envelop, revealing the tendency of the system to exhibit a lower-amplitude branch. This branch is unstable in the considered case but may become stable for a slightly larger Scruton number. For $Sc \geq 83.0$, the mathematical model shows a classical VIV response when the solution is attained from a small initial condition. The lock-in wind speed range, the maximum amplitude and the shape of amplitude-velocity curve are all well predicted (Figure 8 (d)-(f)). Nevertheless, a second branch with larger amplitudes can also be found just after the end of the lock-in range. It represents the extension of the VIV response branch and it tends to approach the QS solution, spanning a wind speed range where no vibration is expected according to the QS theory. Interestingly, such a branch was also found during the wind tunnel tests by releasing the wind tunnel model from a large displaced position, though it does not extend down to the lock-in range.

In general, the mathematical model provides satisfying predictions on the VIV-galloping behaviors of the bridge deck model at its 4° mean flow incidence.

3.4 Sensitivity study

Before applying the wake-oscillator model to full-scale structure, it is to check the sensitivity of the wake-oscillator model to the unmatched mass ratio m^* between the wind tunnel tests and the full-scale condition. The mass ratio is about $m^* = M/(0.5\rho d^2 l_e) = 1300$ for the wind tunnel model, while this is about 510 for bridge deck like the Aftetal bridge in full scale (510 is calculated according to the open cross section of Aftetal bridge [7], which has a similar side ratio $b/d = 2$, a height about $d = 5$ m and a mass about 7.7 ton/m). Therefore, the mass ratio in the full scale is about 40% of the wind tunnel model. In the wake oscillator model, this sensitivity study was implemented by manually setting the mass ratio of the bridge deck 40% of its original value, and increasing the damping ratio to maintain an unchanged Scruton number for each test case. The numerical solutions attained from small initial conditions are provided in Figure 9, for test case #a1 and test case #a7. It is clear that the wake oscillator is not sensitive to the mass ratio difference between the wind tunnel model and the full scale case.

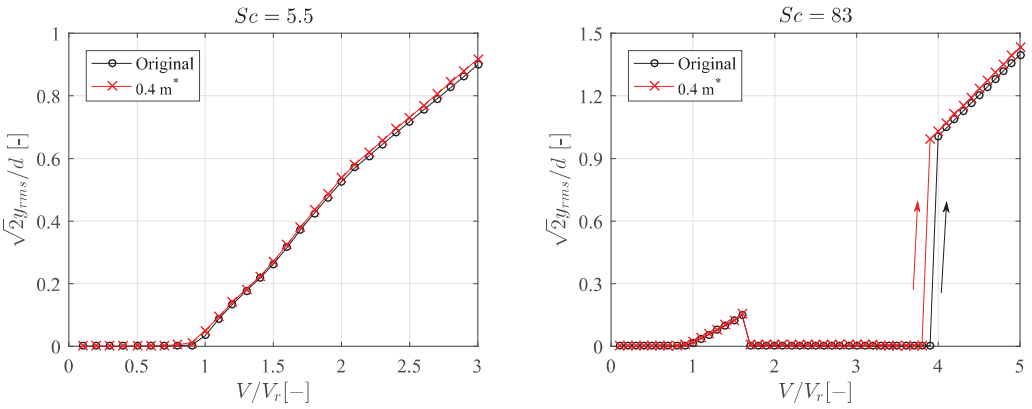

Figure 9. Checking the sensitivity of the wake oscillator model to mass ratio m^* for two maintained Scruton number (solution obtained from mall initial condition).

4 APPLICATION OF THE WAKE-OSCILLATOR MODEL FOR CONTINUOUS BEAM BRIDGE

4.1 Extending the wake-oscillator model for slender continuous structures.

For slender structures in the natural wind field, the turbulence in incoming flow and many three-dimensional conditions play important roles in the flow-structure interaction. To apply the wake oscillator model to predict the VIV-galloping instability for continuous flexible structure, at this stage, assumptions have to be made: (i) Two- dimensional flow is maintained at each point along the axis of the continuous structure; (ii) Only the mean component of the approaching air flow is considered, namely ignoring the turbulent parts.

In [10], Tamura's wake oscillator was used for the vortex induced vibration of the continuous system with circular cross section. There, the wake rotation angle and the across wind displacement are considered as a $\vartheta(x, t)$ and $y(x, t)$, which depends right now on the along-axis position x. By considering a single mode shape for the continuous system, the controlling equation for $\vartheta(x, t)$ and $y(x, t)$ were finally expressed by a single differential equation of order of 4, with the normalized mode shape and the mean wind profile collected in several constants. This method is not used here, because the quasit-steady force coefficient C_{Fy}^{QS} for non-circular cross section is much more complicated (for circular cross section this can be simply expressed as $C_D \cdot (Y'/V)$ as in [10]).

As an alternative way, multiple discrete wake oscillators were considered here for the continuous system, and the dynamics of the continuous system is described by finite element method. Figure 10 illustrates the idea, where wake oscillators were coupled on the continuous system by every two nodes. As an example, the wake oscillator at node N_{2i} will be only excited by the transverse motion y at N_{2i}, and the reference length to calculate the aerodynamic force on node N_{2i} is the distance between node N_{2i-1} and N_{2i+1}. Such a measure is just to facilitate the practical programming. The equations for the dynamics of the continuous system is first written in matrix form, applying the classical 2-d beam element and considering only the bending deformation. The discrete wake oscillators were expressed also in matrix form and combined together with structural matrix to form new matrixes (including both the degree of the freedom of nodes and the wake oscillators), with the coupled items expressed in submatrix of the new matrix. For brevity, these matrixes are not given here.

With this way, multiple mode shapes can be included in the calculation, and it is easy to take into account when the cross section of the continuous system is changed, for example,

the launching nose in the following case study. The disadvantage is that more computational cost is needed, due to the increased number of wake oscillators.

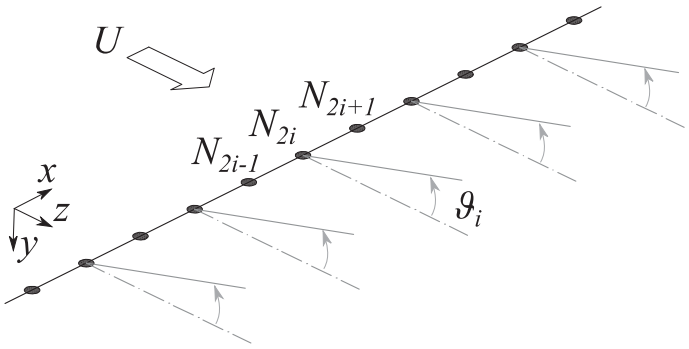

Figure 10. Discrete wake oscillators on continuous system.

4.2 The case study

The Aftetal bridge [7] during its critical launching is considered here as a case study. The span arrangement is shown in Figure 11. For the 5m high steel open box (assumed here the same aerodynamic shape as our wind tunnel model), the mass per unit length is assumed 7.7 ton/m, the moment of inertia of the cross section I_{zz} = 4.89 m^4, Young's-modulus 210·10^9 N/m^2 and Poisson's ratio 0.3.

For the launching nose, due to the lack of the wind tunnel test results, we simply assumed here a lattice structure with a solidity ratio of 0.334 as shown in Figure 12. The mass of this launching nose is assumed half of the open cross section, and the bending stiffness is assumed the same as the open cross section. The length of the launching nose is 30m.

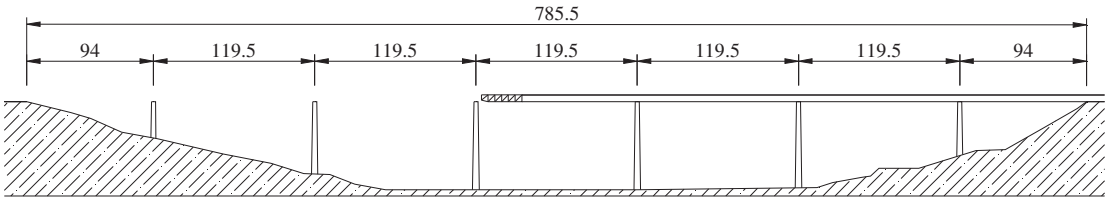

Figure 11. Span arrangement of the Aftetal bridge [7] (during the critical launching phase, dimension in m).

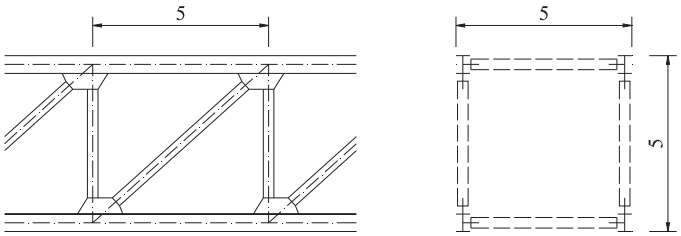

Figure 12. Assumed lattice structures for the launching nose (dimension in m).

The continuous structural system is discrete into 92 elements and 93 nodes, shown in Figure 13. Fini. Depending on whether the launching nose is used or not during the launching phase, the total number of implemented wake oscillators is 43 or 46. In the case of with the launching nose, the quasi-steady aerodynamic force of the lattice structure is still taken into

account, although no wake oscillator is applied. The structural damping matrix is calculated using the classical Rayleigh damping, assuming the same damping ratio for the first mode and second mode shape.

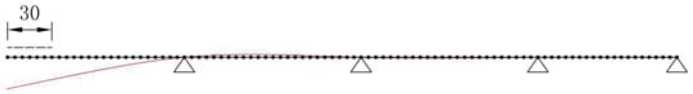

Figure 13. Finite element discrete of the structure and its first mode shape.

The natural wind is assumed to attack at a mean angle of 4° of the bridge deck, leading to the oscillation of the structure not strictly in the across-wind direction. However, considering the attack angle is still very small, this influence is ignored. Therefore, the aerodynamic parameters for the open cross section and the wake-oscillator are kept the same as in Chapter 3. For the launching nose, the drag and lift coefficient is calculated according to [11], shown in Figure 14. It is to note that the lattice launching nose is able to introduce positive aerodynamic damping into the structural system due to the drag force.

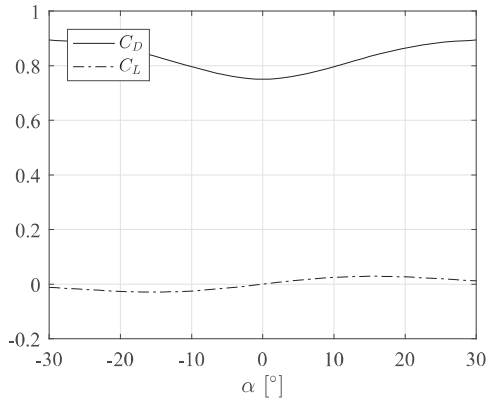

Figure 14. Drag and lift coefficients for the lattice launching nose (referred to the enclosed area $A = 5\text{m} \cdot$ per unit length).

Finally, the first bending frequency is 0.3671Hz or 0.3045 Hz depending on whether the launching nose is used or not (corresponding mode shape shown in Figure 13. Fini). For both cases, the second bending frequency is higher than 4 times the first one. Therefore, the VIV-galloping instability is only considered for the first mode. The critical wind speed for the vortex induced vibration is 18.0m/s or 14.9 m/s, taking $St = 0.102$ and the height of the bridge deck $d = 5$ m.

4.3 Results

4.3.1. Effect of the mode shape

First of all, the effect of the mode shape is examined here without considering the launching nose. The numerical results for the wind tunnel sectional model are re-computed with the same mass ratio as the full-scale one, C_{L0} was also set constant as 1.085 which is the value for high Reynolds number. Therefore, the only difference between the sectional model and the continuous system is the mode shape. The numerical results are shown in Figure 15, with the amplitude at the tip of the cantilever (see Figure 13. Fini) representing the response of the continuous system. According to the numerical results, the effect of the mode shape is mainly reflected by the oscillation amplitude. The onset wind speed for galloping and the lock-in

wind speed range for vortex induced vibration is not significantly influenced by the mode shape. On the other hand, the ratio of the oscillation amplitude between the continuous system and the sectional model seems dependent on the wind speed, rather than a constant value. Taking the results of Sc =83 for example, the oscillation amplitude ratio is 1.59, 1.36 and 1.25 for V/V_r = 1.1, 1.6 and 5.0.

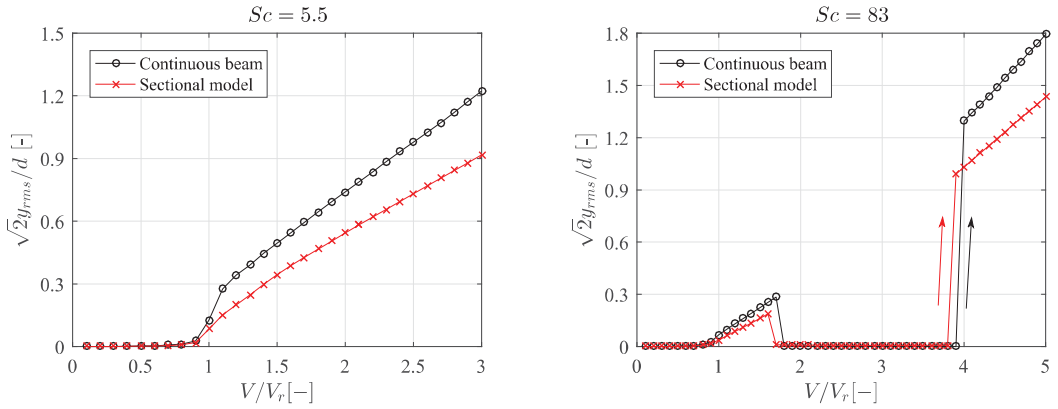

Figure 15. Effect of the mode shape: (a) for a low Scruton number; (b) for a high Scruton number. Solutions are obtained with small initial conditions.

4.3.2. Effect of the launching nose

For bridge construction with launching method, the use of a light-weight launching nose will not only increase the first bending frequency in the critical launching phase, but also could contribute to stabilizing the possible wind induced vibration if the launching nose is well-designed. Figure 17 shows the effect of launching nose considering a very low damping ratio for the first mode. There, "TS" stands results of the wake oscillator model, "QS" the results according to quasi-steady theory and "L. N." the launching nose. With or without launching nose, the equivalent mass m_e is = 5.3 ton/m or 7.7 ton/m in the first mode. Quasi-steady solution is also provided for comparison. From the quasi-steady solution, it is clear that the one with launching nose features a much higher galloping onset though the Scruton number in this case is even lower (due to a lower equivalent mass). This is because the launching nose locates at the tip of the cantilever. The positive aerodynamic damping due to a low value of drag coefficient can still influence the dynamics of the structural system a lot. Nevertheless, the wake-oscillator will still predict a galloping onset at the critical wind speed for vortex induced vibration.

The damping value is further increased, and the results from the wake-oscillator model with or without launching nose are shown in Figure 17. The solutions of the wake-oscillator model right now also show the benefits of the launching nose. At a damping ratio of 1.17% (logarithmic damping δ = 0.074), the response with launching nose turns into a VIV response rather than a galloping starting at V_r. This is still not reached for the one without launching nose up to a damping ratio of 1.54% (logarithmic damping δ = 0.097). Finally, it is worth stating that, in Figure 17 (a), the quasi-steady theory predicted galloping onset for the damping ratio 0.67% is already about 4 times the vortex resonance wind speed. However, the wake-oscillator model still predicts a galloping response starting at V_r.

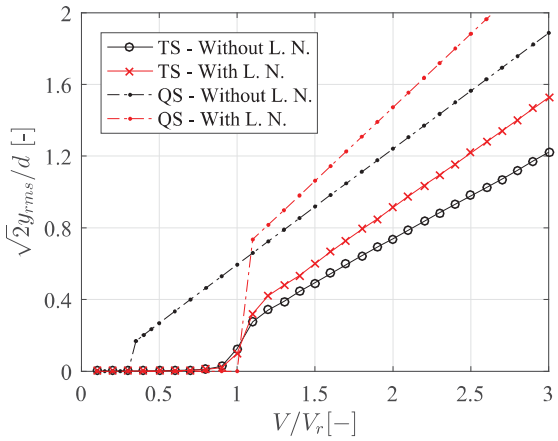

Figure 16. Effect of the launching nose for a very low damping ratio of 0.17% (logarithmic damping $\delta = 0.011$). Solutions are obtained with small initial conditions.

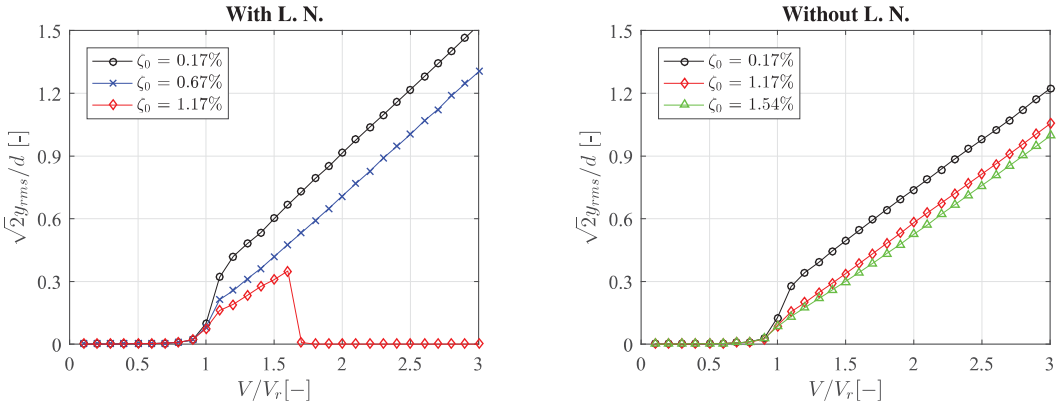

Figure 17. Comparison of the response with or without launching nose by increasing damping ratio. Solutions are obtained with small initial conditions.

5 CONCLUSIONS

- Tamura's wake oscillator model was used to capture the VIV-galloping instability of a bridge deck with open cross section. Compared with the wind tunnel test results, satisfying predictions were obtained with this wake oscillator model. In particular, the galloping onset wind speed was well captured for a wide range of Scruton number.
- The wake oscillator model was then extended to continuous system, and a 7-span continuous bridge during its critical launching phase was considered as a case study. Due to the effect of mode shape, the wake oscillator model predicts a larger amplitude response at the cantilever tip, compared with the predictions for the wind tunnel sectional model. But the critical wind speed seems not affected.
- The launching nose was found able to make an important contribution in stabilizing the VIV-galloping instability if its aeroelastic effect is well taken into account. This also implies that particular aerodynamic optimization made on the launching nose could be a more efficient way in suppression the vibration, due to the special location of the launching nose.

- Finally, the predictions provided by the wake oscillator model for the continuous system need to be verified by future wind tunnel tests.

Abstract. *Structural cables have been commonly used as tension members for both high-rise and long-span structures. Wind-induced vibrations along with the traffic loads are the main factors causing fatigue damages of cables. Moreover, the vibration of these essential supporting elements can influence the response of the superstructure (and vice versa) in the form, e.g., of parametric vibration, damage, or the consequent destructive vibration of the superstructure itself. The most common cable types for guyed masts, roofs, cable stayed and suspension bridges are: parallel wire strand, helical wire strand, locked-coil cable. Each of them has its own advantages, such as: corrosion resistance, fatigue endurance, and low production cost. Cables have a characteristic surface and roughness depending on the production technology and design. The surface modifications have a major effect on aerodynamic properties. This presented work aims at determining the functionality of the open wire helical strand cable construction in various turbulence conditions via experimental investigation in a wind tunnel. According to the results in moderately turbulent conditions, the surface roughness of helical strand cables reduces the lock-in range compared to the reference smooth model. The hysteresis character of resulting amplitude at an increased/decreased flow velocity was observed for all models. The most pronounced effect was for the case of a model with bigger surface roughness and higher lay angle. This trend was observed also for the more turbulent flows. Vibration also starts at the lower critical flow velocities indicating an increase of the Strouhal number.*

1 INTRODUCTION

Wind related aerodynamic forces can be divided into the following groups: forces originating directly from the impact of wind on a cable (drag forces, buffeting), and so-called aeroelastic phenomena resulting from the interaction between a cable and air flow (vortex shedding, galloping, rain-wind induced vibrations, etc.) that pose a particular risk due to a large number of loading cycles.

Oscillations of cylindrical structural elements are in most cases induced by the wind, which forms regions of disturbed flow around such structures. Usually, four regions are distinguished:

- a region of retarded flow upstream of the body,
- boundary layer regions attached to the cylinder,
- regions above and below the cylinder characterized by an accelerated flow,
- a wake with a separated flow, e.g., [1].

The flow conditions in each of the regions affect the vibration: fluctuating in-plane pressures called buffeting, vortices shed at the cable surface imposing the out-of-plane pressures, and the oscillating wake flow, see, e.g. [2]. The vibration can affect the stability of the supported structure; it may also cause high stresses in the cables (or the individual strands of a cable) and high internal forces in structural members. The fatigue damage caused by the cyclic loads, leading to normal stress in the cables or to fretting friction damage is significant [3]. This is one of the disadvantages of using steel cables with high tensile strength, as it is accompanied by a reduction in ductility and an increase in the susceptibility of cable wires to brittle fatigue failure [4], [5]. During inspection of bridge suspension cables, defects of various types were observed, e.g., cracking, pitting, fretting, fatigue, etc., see [6], [7]. vortex-induced vibration (VIV) can occur at moderate wind speeds and produce a large number of loading cycles, potentially causing serious problems.

VIV is a result of the fluid-structure interaction. It is due to alternating vortices shed at the cylinder surface, which produce the periodic forcing. If the damping and structure-air mass relations, expressed by the non-dimensional parameter called Scruton number (*Sc*) is low, the structural motion influences the flow field. analysis of the cylinder response requires knowledge of the vortex shedding frequency, which is commonly expressed as the non-dimensional Strouhal number (*St*). This expression helps to transfer the results among different experiments and studies on vibrating bluff cross-sections with different geometries and fluid properties. Knowledge of *St* is necessary for determination of the critical wind velocity at which the resultant vibration of the cylinder is at, or near to, resonance. The *St* value depends on the shape (geometry) of the cylinder, surface roughness of the cylinder, turbulence intensity, and on the Reynolds number (*Re*) which determines the flow regimes for structures with both circular cross-sections and non-circular ones.

For both theoretical and computational investigations, structural cables are often assumed to have perfectly circular cross-sections. In contrast to aerodynamic bodies (wings) and bodies with sharp edges (rectangular profiles), cylinders, which may be classified as semi-aerodynamic, can have their flow separation point at varying positions along the body surface. The position of this point depends on the free-stream velocity, turbulence intensity, and roughness of the body surface [8]. Not even dry, wrapped or coated bridge cables have ideally smooth surfaces. Roughness on the surface commonly influences turbulence characteristics in the proximity of the body surface.

The location of the flow separation point is important especially for cables manufactured using individual steel wires with no coated protection as in the case of guy ropes. In the case of steel strands covered with polyethylene (HDPE) tubing, local alterations of the inherent

surface roughness, resulting from mechanical damage, manufacturing, creep, and exposure to atmospheric pollution and solar activity, are expected. Such geometrical deviations, corrosion and other types of surface changes can be defined as technological roughness. Such microscopic variations on the body surface can induce macroscopic changes in the flow around it [9], and therefore they require analysis. The Reynolds number is closely related to the flow separation on the cable surface, as it is the governing parameter of the transitions (critical state) occurring in the disturbed regions, i.e. the wake, the free shear layers, and the boundary layers [10]. This critical state in the boundary layer has attracted the most attention, as it is within this range of the Reynolds numbers that one can expect significant variations in the aerodynamic coefficients. They are provoked by changes in the flow and by the occurrence of flow instabilities which are expressed as a drop in the drag coefficient and a simultaneous appearance of a steady lift. A theoretical and experimental work focused on the wind-induced response of a full-scale yawed bridge cable section model for varying Reynolds numbers and wind angles-of-attack was addressed in [11]. The study also demonstrated the influence of cable surface roughness and wind incidence angle on the force coefficients. Roughness produced using sand paper, a wire mesh screen, and ribs were investigated in [12]. The drag coefficient for rough cylinders and the related change in the critical Reynolds number were reported in [13], [14], [15]. In [16], two types of cylinder roughness were classified and tested. In [17], alterations in surface roughness were observed to shift the vortex shedding to post-critical regimes.

A large number of television broadcasting and meteorological masts in the Czech Republic were built in the 70-90s of the 20th century. At the moment, guys of these masts are at the end of their life cycle and the problem of assessing their residual life and replacement is actual. The idea to improve the aerodynamic and fatigue performance of cables by selecting the optimal surface parameters of cable for specific turbulence conditions at a construction site is very attractive. This presented work aims at determining the functionality of the open wire helical strand cable construction in various turbulence conditions via experimental investigation in a wind tunnel.

2 EXPERIMENTAL SETUP

Experiments were carried out in the climatic wind tunnel of the Institute of Theoretical and Applied Mechanics in Czech Republic. The aerodynamic section equipped with the turntable has a 1.9 m wide and 1.8 m high rectangular cross section. The total length of the test section is 11.0 m.

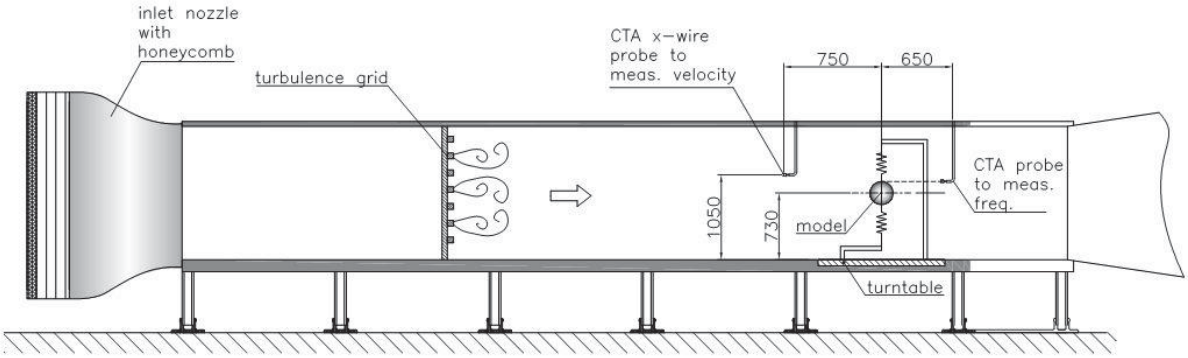

Figure 1: Arrangement of the experiment in the aerodynamic test section of the climatic wind tunnel.

2.1 Structural models for wind tunnel testing

Open wire helical strand cables were selected as the structural models for the experimental study in the wind tunnel. In order to evaluate separately an impact of the lay angle and surface roughness factors, the structural model with next parameters were manufactured:

- Model of helical strake cable (construction 1x61 according ISO 17893:2004) with relative surface roughness $k/D = 5.6\%$ and lay length $l = 12 \cdot D$;
- Model of helical strake cable (construction 1x61), $k/D = 5.6\%$, $l = 24 \cdot D$;
- Model of helical strake cable (construction 1x91), $k/D = 4.5\%$, $l = 12 \cdot D$;
- Circular cylinder as a reference model.

All models were made from polystyrene, polished and varnished. The length of the models was 1.27 m with diameter $D = 0.13$ m. The length-to-diameter ratio was approximately equal to 10. A rigid carbon fiber tube with the outer diameter of 13 mm and the wall thickness of 2 mm was used as an axis that can be fixed to the experimental stand, [18].

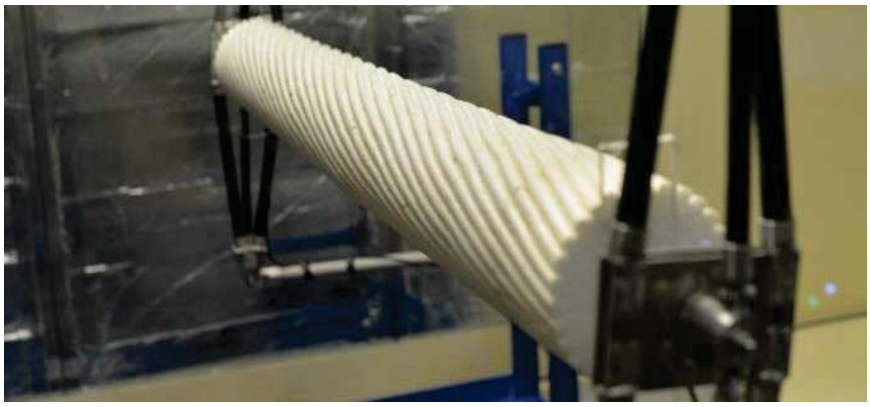

Figure 2: Model of 1x91 cable on the dynamic force balance stand.

The logarithmic decrement of structural damping obtained from the vibration decay is $\delta = 0.035$ and $Sc = 6.4$. The duration of each measurement was 120 seconds. The measurement of the response was carried out in the range of the reduced velocity $U/(f_n \cdot D) = 2 \div 8$ and $Re = 1.12 \cdot 10^4 \div 4.5 \cdot 10^4$. The lock-in range was measured in two directions. The flow velocity increased in steps from the value lower than the theoretically predicted critical flow velocity until the resonant (lock-in) vibrations were obtained. After the end of the lock-in range, the flow velocity was changed in the opposite direction. The Plexiglas screens were installed on both sides of the structural models to create two dimensional (2D) flow conditions.

2.2 Turbulence generation in the wind tunnel

All configurations were tested in the low turbulent flow at the free stream turbulence $I_u = 0.75\%$ and in turbulent flows generated by using the square mesh arrays of rectangular bars placed upstream of the structural models.

Figure 3: Wooden grid used for turbulent flow generation.

To obtain detailed characteristics of turbulence in the wind tunnel test section, the flow profiles were measured at a step of 75 mm along the model axis using x-wire CTA probe. The exponential autocorrelation method was used to obtain the integral length scales of turbulence, see Figure 4.

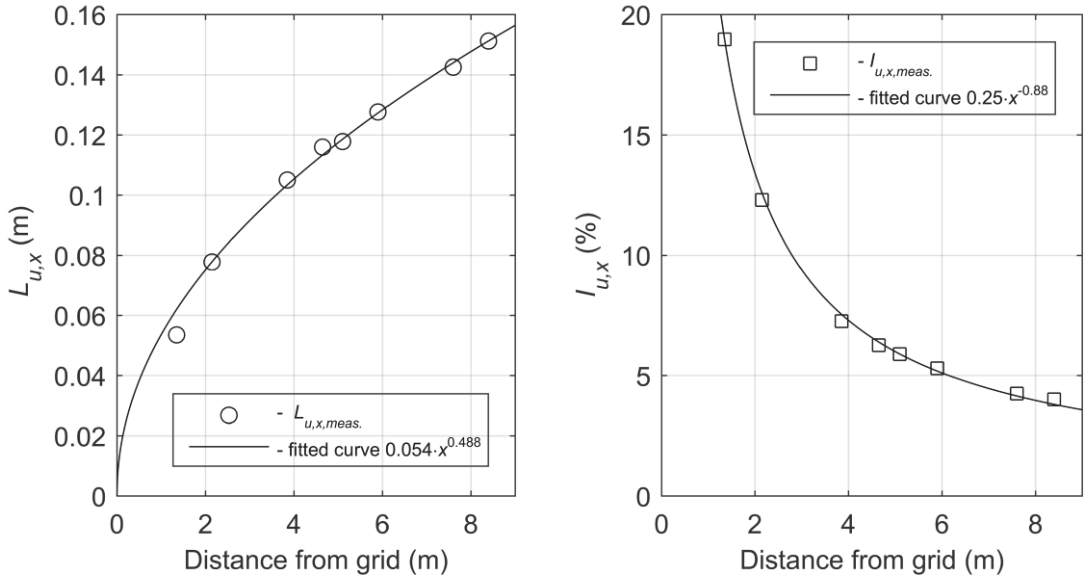

Figure 4: Turbulence integral length scale (left) and turbulence intensity (right) dependency on the distance from grid.

Distance from the grid (m)	Turbulence intensity $I_{u,x}$ (%)	Turbulence length scale $L_{u,x}$ (m)
7.1	4.5	0.141
4.6	6.5	0.114
2.1	12.3	0.078

Table 1: Turbulence intensity and integral length scale of turbulence (obtained by exponential method) at the location used in the mechanical response experiments.

The same x-wire probe was installed to measure flow velocity during mechanical response tests at 0.75 m upstream of the models and the sampling rate was 1000 Hz.

3 RESULTS

The experimental results obtained on the smooth circular cylinder are shown in graphs of dimensionless amplitude vibration Amp_{red} versus reduced wind velocity U_{red} in Figure 5, the model of 1x61 cable with lay length $l = 12 \cdot D$ in Figure 6, 1x61 cable with the lay length $24 \cdot D$ in Figure 7, 1x91 cable with the lay length $12 \cdot D$ in Figure 8. The results taken during a step-wise increase of the flow velocity are indicated by the empty markers, and the results taken during a stepwise decrease of the flow velocity by the filled markers.

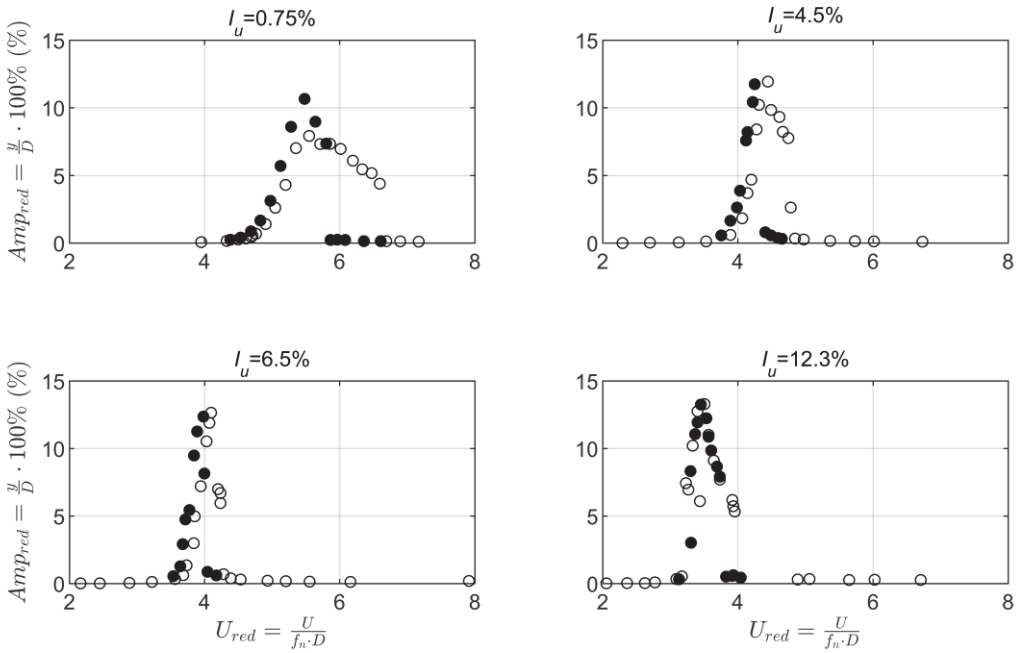

Figure 5: Amplitude response plot of smooth surface cable model.

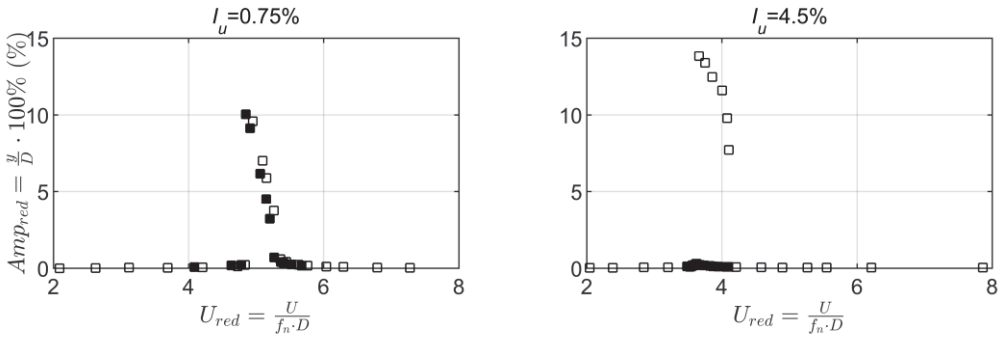

Figure 6: Amplitude response plot of helical cable 1x61-12.

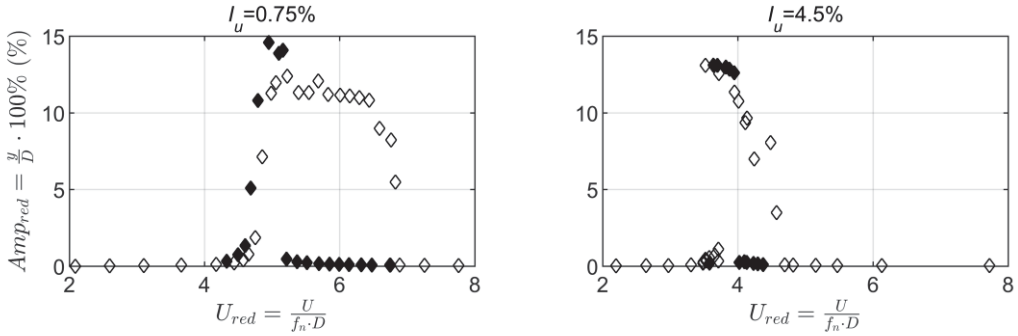

Figure 7: Amplitude response plot of helical cable 1x61-24

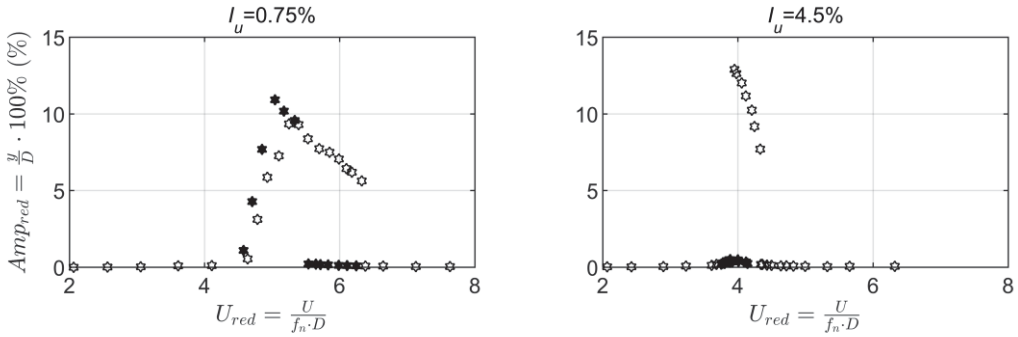

Figure 8: Amplitude response plot of helical cable 1x91-12 model.

Test results showed the hysteresis character of the `increased/decreased velocity trend lines` for the response of all the structural models and all turbulence intensities. The trend obtained by reducing the flow velocity has a peak amplitude approximately equal to or higher than for the case of the increasing velocity. The lock-in range for the cases of stepwise increasing of the flow velocity is wider. In low turbulent flow the helical surface roughness can lead to an increase in the peak amplitude and widening of the lock-in range for the case of stepwise velocity increasing compared to the smooth reference model. Higher values of surface roughness and turbulence intensity lead to a reduction of the lock-in range. The most pronounced effect was observed for the case of the cable model characterized by larger lay angle. This trend remains present in more turbulent flows where the vibrations start at lower critical flow velocities. This yields an increase in *St*. For the helical cable models, no vibrations at the dimensionless amplitude exceeding 2% in the lock-in range were observed in turbulent flows at turbulence intensities 6.5% and 12.3%.

4 CONCLUSIONS

The rationality of using cables with a smooth or rough surface is determined by the turbulent wind conditions at the construction site and the arrangement of structural elements. Smooth circular shape is optimal for single or widely spaced cable in open areas, where wind turbulence is low. Cables with the helical shape are optimal for moderate to strong turbulence wind conditions, while preference should be given to higher values of surface roughness and lower lay lengths. The present work has practical results, which could improve the knowledge of the complex wind loading of bridge cables, cables of the mast towers as well as the loading on the broadcast towers with tubular structural elements.

Keywords: catenary bridge, geometrically non-linear dynamics, iso-tensioning

Abstract. *Catenary pedestrian bridges are apparently spreading all over the world. These structures are highly popular as they can form the landscape and provide the pedestrians with excitement and adventure. Consequently, there is a strong need to increase the span length, which might call for the reconsideration of the conventional approaches. A novel concept was proposed with special focus on feasibility and proper static and dynamic performance of slender catenary bridges. A dedicated physical model was built and measured in order to demonstrate the advantages. A long span catenary bridge designed in the framework of a feasibility study was also considered as an ideal candidate for our proposed method.*

1 INTRODUCTION

1.1 Catenary bridge structures

The main elements of these bridges are the catenary cables that are fixed at both ends. These cables carry the vertical loads, such as the self-weight or ice loading. When necessary, wind cables and connecting cables are also involved in order to provide extra stiffness to the whole structure, which was studied in detail in [1]. The problem with these bridges is that the connecting cables are complicated to tension evenly due to their mutual interaction. There can be loose cables that may vibrate, and the others can be overloaded. On top of all, the overall structural behavior is strongly temperature dependent. The novel approach has been first introduced at the WIBE (World Innovation in Bridge Engineering) prize competition. In this paper a more detailed introduction is addressed.

1.2 The proposed iso-tensioning system

To overcome the above mentioned problems, a novel concept is proposed shown in Figure 1. In contrast to conventional catenary bridges, the evenly distributed and temperature independent connecting cable forces can be conveniently ensured by adopting pulleys that are used for railway overhead electric wires for instance. Post-tensioning cables on both sides of the catenary with ballasts at their end points are used to adjust the desired pre-stressing to the structure.

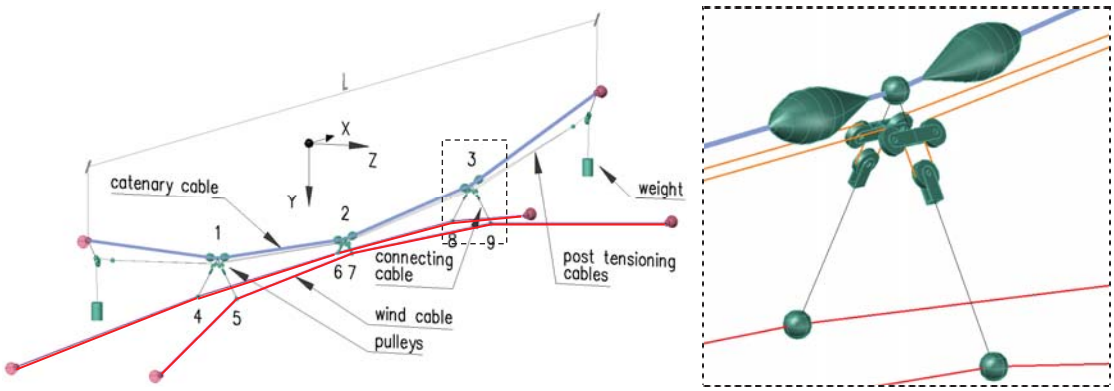

Figure 1: Structural setup of the proposed system.

2 PRELIMINARY PHYSICAL MODEL

The structural behavior was investigated by using physical models that are most common in wind engineering [2]. A preliminary model was created in order to qualitatively demonstrate that the proposed system behaved according to our expectations; the connecting cables were indeed evenly pre-stressed, no loose cables were observed. A horizontal load test was also carried out. All the cables were modeled by using fishing line, with lead as weight. The proposed configuration consists of three pulleys in a group belonging to each connecting cable; two of them are joined together and to the catenary, and the third one is fixed to the upper end of the connecting cable. Two post-tensioning cables were driven through the corresponding pulleys with ballast weights at their end points providing the desired internal forces in the connecting cables, resulting in a spatial pre-stressed structure. Although the results were in line with the expectations as to the structural behavior, the unpredictable material of the applied fishing line hindered a precise comparison with numerical results. Therefore, a detailed physical model was constructed based on the experiences gained on this preliminary model.

3 DETAILED PHYSICAL MODEL

3.1 Model fabrication

In order to carry out quantitative validation, steel wire ropes were used for the main catenary cable as well as the wind cables. Despite the fact that fishing line found to be improper due to its nonlinear material properties, it was still used for the post-tensioning and the connecting cables with respect to the moderate cable forces in these elements; the strain remained in the linear range. Besides, a multi-strand fishing line is advantageous due to its bending flexibility, which reduces the overall friction of the pulley system. The structure is shown in Figure 2 with coloring the different cable types for better visibility, which will be used later where necessary. The span of the main catenary cable is L=14 m. The diameter of the catenary cables is 3.0 mm (EA=560 kN), and that of the wind cables is 1.0 mm (EA=75 kN). The fishing line diameter of the post-tensioning and the connecting cables is 0.40 mm (EA=2 kN). When the bridge was ready and the ballasts were released, the spatial pre-stressed structure was qualitatively studied; the connecting cable forces were indeed close together as desired, loose cables were not found.

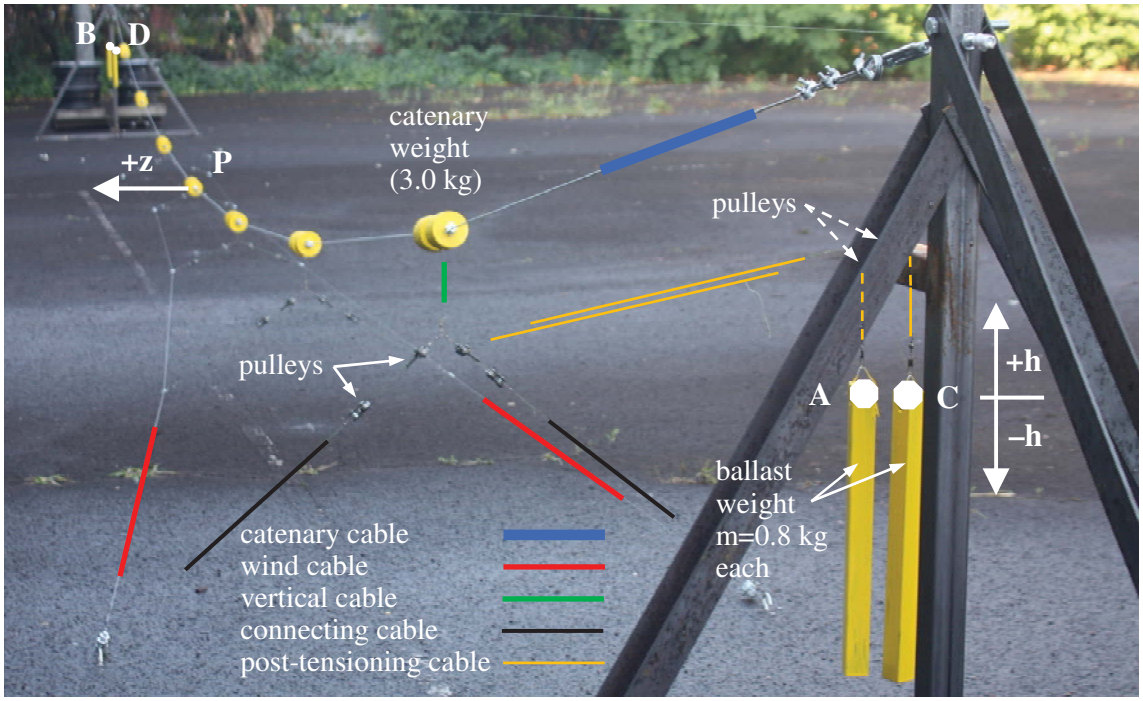

Figure 2. View of the 14 m long physical model with the monitored points and the colored cable types.

The projected schematic top view of the original and the proposed structural configuration is shown in Figure 3. In case of the conventional structure, the connection between the main catenary cable and the wind cables is made by using connecting cables. The desired internal forces can be adjusted by pre-stressing the wind cables and the connecting cables, which is tedious to carry out precisely due to the mutual interaction of the cables. The connecting cable force distribution depends on the stiffness properties of the whole structure and the pre-stress applied to the cables. The original system is referred to as model v1.

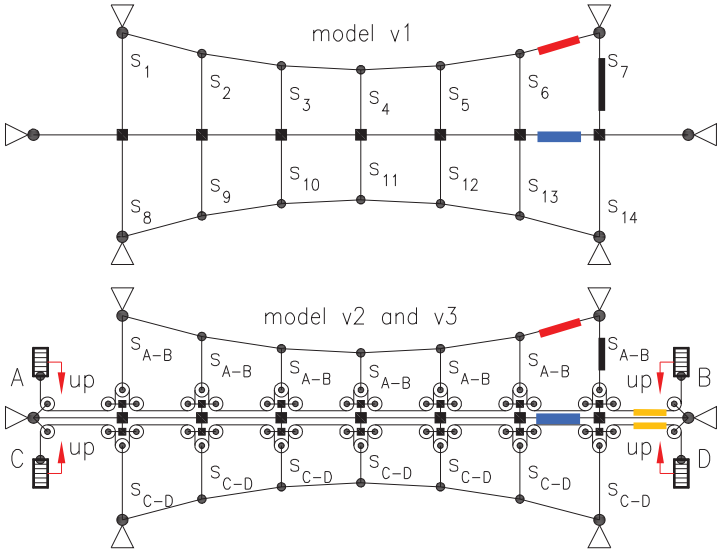

Figure 3: Conventional (top) and the proposed structural system with the connecting cable forces (s).

The proposed system requires ballast weights in order to set the desired cable forces. In contrast to model v1, the connecting cables do not connect the wind cables and the catenary directly, but two post-tensioning cables are included in the whole system belonging to the two wind cables on the two sides of the catenary.

The post-tensioning cables are referred to as A-B and C-D, according to the points on the ballast weights (Figure 3). The whole system of a post-tensioning cable and the belonging connecting cables are referred to as branches A-B and C-D. There are two versions of the proposed system; in case of model v2 all the four ballast weights move independently from each other. Model v3 is different, as the neighboring ballasts are connected together; the motion of ballasts A and C is not independent, instead a common upward or downward motion is allowed only. The same applies to ballasts B and D. Model v2 and v3 both produce equal connecting cable forces within a branch if the friction of the pulleys is neglected. For model v2 the connecting cable forces of the two branches are equal, that is $s_{A\text{-}B}=s_{C\text{-}D}$.

The pulley system gives an additional flexibility to the system, which may reduce the horizontal stiffness of the main catenary. Therefore, it was of utmost importance to compare the static and dynamic behavior of the proposed models v2 and v3 to the original one of v1. The physical model was constructed with special attention to this need; the pulley system was equipped with a constraint that was capable of fixing the post-tensioning cable, which made it feasible to investigate and compare the behavior of model v1, v2 and v3. The structural details of the physical model are shown in Figure 4.

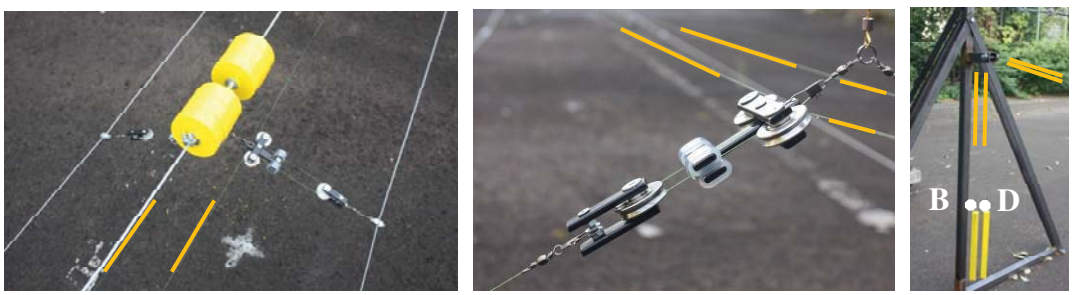

Figure 4: Structural details of the physical model: catenary node, pulleys and ballast weights.

3.2 Measurements

The slender catenary bridges are sensitive to wind loading; therefore the behavior due to horizontal static loading was studied and compared. The catenary nodes were loaded horizontally at each node. The load test can be seen in Figure 5. All the three configurations were tested. Model v1 was set by fixation of the post-tensioning cables around the pulleys. The connecting cable forces are independent from each other in this case. For model v2 the above mentioned fixation was released. Model v3 was set by joining the neighboring ballasts together. The pulley friction can be an important factor in the proposed system; therefore the initial friction value was measured by applying force difference onto the two ends of a test cable hanging on the two sides of a solo V-groove ball bearing. The force difference reached 5 % at the boundary of stall and motion, but drops to 1-2 % when even moderate motion appears. Time-dependent behavior was also observed, which was explained by the presence of grease in the bearings. Due to the high friction and viscous properties of the pulleys, the whole structure was given slight vibration at each static measurement in order to help the pulleys and the post-tensioning cables arrange and approach to the ideal frictionless state. This was particularly important for model v2. In case of model v1 the ballast weights do not move and there is no pulley rotation either. In case of model v2, on the side the horizontal force pushes the structure toward, the ballasts move downwards as the distance between the catenary and the wind cable decreases. The post-tensioning cable releases ballasts A and B down. On the opposite side, the ballasts C and D are lifted upwards. The horizontal displacement of the catenary and the corresponding vertical displacement of ballasts A and C can be seen in Figure 5. In case of model v3 the neighboring ballasts are joined together, therefore no significant ballast motion was observed.

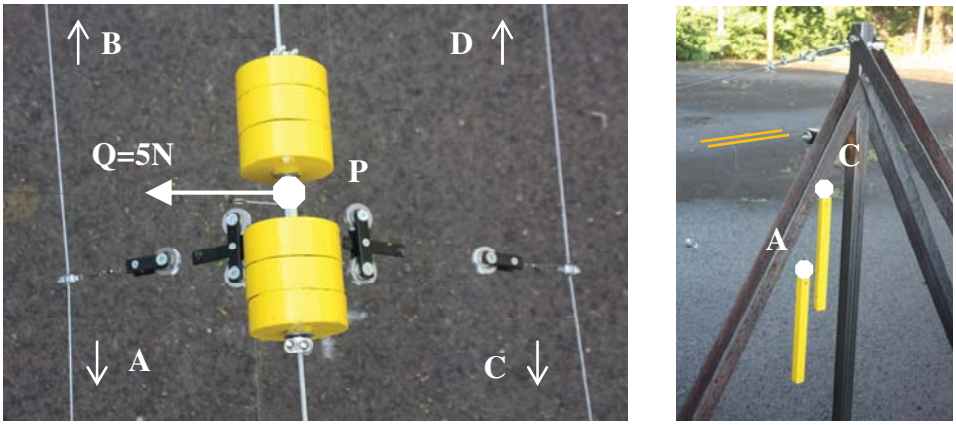

Figure 5: Horizontal static deflection of the catenary and the vertical displacement of the ballasts for model v2.

The dynamic properties were studied by using an accelerometer attached to the middle catenary point P (see Figure 2 and 5). The first vibration mode of the bridge was considered only, which was excited simply by hand. The symmetrical sway mode was the same for every model. In case of model v2, the sway motion of the catenary was accompanied by the vertical motion of the ballasts with small amplitudes of 1-2 cm only, nevertheless. In case of model v1 and v3 there were no ballast motion amplitudes observed.

4 STATIC NUMERICAL MODEL

4.1 Introduction of the numerical approach

The static behavior was studied on a 72 DOFs numerical model, which was written in Octave (Figure 6). The model consists of two-node spatial truss elements with tension capabilities only. The structural elements are the main catenary cable (blue), the wind cables on both sides (red), the connecting cables (black) and the vertical elements (green). The post-tensioning cables and the ballasts are not shown in this model, but their effect is included as described below.

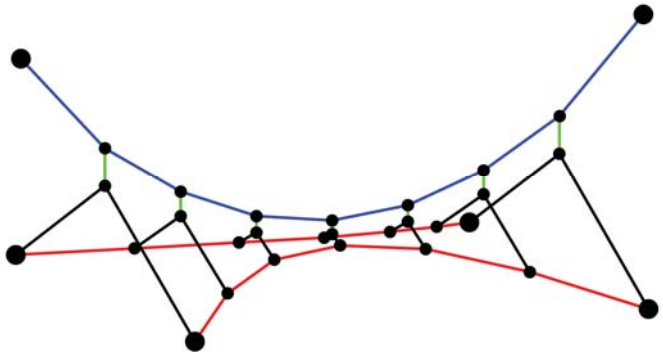

Figure 6: Geometry of the numerical model.

4.2 Static equations with geometrical non-linearity

The considered mechanical system involves geometrical non-linearity; therefore the (load control) New-ton-Raphson iterative approach was applied to find static equilibrium. The key step of the process is solving the $\mathbf{K}_i(\mathbf{x}_i)\Delta\mathbf{x}_i=\Delta\mathbf{q}_{red,i}$ matrix-equation for the $\Delta\mathbf{x}_i$ displacement error vector due to the reduced force error vector of $\Delta\mathbf{q}_{red,i}=-\mathbf{G}_i\mathbf{F}^{-1}d\mathbf{t}_i+\Delta\mathbf{q}_i$. The iterative process is to be continued until the $\Delta\mathbf{t}_i=\mathbf{t}-(\mathbf{l}_i-\mathbf{l}_0-\mathbf{F}\mathbf{s}_i)$ and $\Delta\mathbf{q}_i=\mathbf{q}-(-\mathbf{G}_i\mathbf{s}_i)$ unbalanced kinematic and force vector norms are smaller than a tolerance. In the equations above $\mathbf{x}_i$ = displacement vector of the 24 nodes (see Figure 6); $\mathbf{l}_i$ = stressed cable length vector; $\mathbf{l}_0$ = stress-free cable length vector; $\mathbf{t}$ = kinematic load vector; $\mathbf{q}$ = external force vector; $\mathbf{G}_i$ = geometry matrix containing the direction unit vectors of each cable; $\mathbf{K}_i$ = tangential stiffness matrix; $\mathbf{F}$ = flexibility matrix. All the matrices and vectors are to be updated at each i^{th} iteration step. The above detailed Newton-Raphson iteration was carried out in two steps. At the first construction stage the main catenary cable was activated with its vertical loading, which was complemented by the wind cables and the connecting cables at the second stage. Therefore, the sizes of the matrices and vectors are different in these two construction stages. The results of the first stage (e.g. cable length and forces, geometry and stiffness matrices) are used as initial condition for the second one. The first stage is the same for the three models. In case of model v1 the prestressing is defined onto the wind cables and the connecting cables as kinematic loads, i.e. cable shortening. The connecting cable force distribution strongly depends on how the kinematic loads are defined. In case of model v2 and v3, however, the connecting cable forces are the same in every cable and depend on the ballast weight only. The additional horizontal forces are applied at stage two.

4.3 Formulation of stiffness matrices

The key step during the Newton-Raphson process is the formulation of the tangential stiffness matrix that belongs to the actual state of the structure, which can be assembled from the element stiffness matrices. Spatial truss elements were used with an element stiffness matrix:

$$\mathbf{K}_e = \left[k - \frac{s}{L}\right]\mathbf{e}\cdot\mathbf{e}^T + \frac{s}{L}\mathbf{I} \tag{1}$$

The spring stiffness is k = EA/L, with EA = normal stiffness; L = cable length; **e** = cable orientation unit vector; s = cable force; **I** = identity matrix. The element matrix takes structural and geometrical stiffness into account. For model v1 the formulation of the element matrices is straightforward, the internal force variation of the j^{th} connecting cable is $\Delta s_j = f(\Delta L_j)$, which is the function of the length variation. For model v2 and v3, however, special further considerations have to be made. The force of the j^{th} connecting cable depends not only on the displacement of the nodes of its two end points, but of every connecting cable. Therefore, a compatibility equation of the coupled system of the post-tensioning and connecting cables has to be solved at each iteration step in order to obtain the cable force changes based on the displacement variation vector Δx_i. The arrangement of branch A-B can be seen in Figure 7.

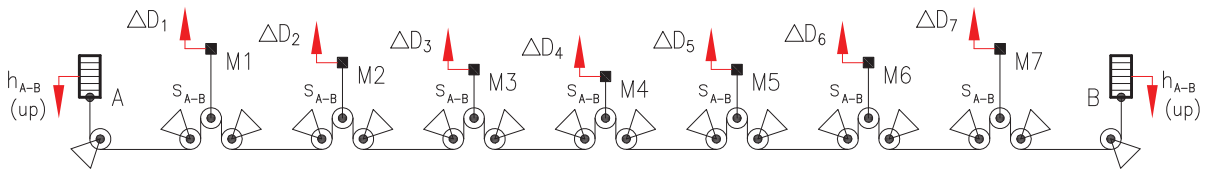

Figure 7: Schematic projected arrangement of branch A-B (D and h are displacement, s is the cable force).

The forces in the connecting cables of a branch are equal, provided that pulley friction is neglected, which leads to the analogy of serial coupling in electricity. By using this principle, the system shown in Figure 7 was reduced into an inhomogeneous spring, which includes all the connecting cables and the tensioning cable of branch A-B (see Figure 8). The points M_j were merged into point M, and points A and B into A-B. The total displacement variation onto point M is calculated as $\Delta x_{A\text{-}B} = \Sigma \Delta D_j$, where ΔD_j = end points distance variation (see Figure 8 and 9) of the j^{th} connecting cable of branch A-B. The linear reduced stiffness can be calculated by using a reciprocal formula for the serially coupled linear springs of a branch as:

$$k_{red,A-B} = \frac{1}{\sum \frac{L_j}{EA_j} + \frac{L_{A-B}}{4EA_{A-B}}} \tag{2}$$

L_j = length of a connecting cable; EA_j = normal stiffness of a connecting cable, $L_{A\text{-}B}$ = length of the post-tensioning cable, $EA_{A\text{-}B}$ = normal stiffness of the post-tensioning cable. Branch C-D can be handled likewise. Symmetrical horizontal loading was considered only.

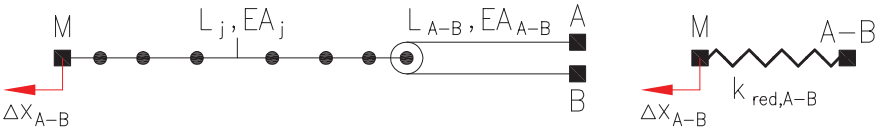

Figure 8: Construction of the idealized spring (left) and its reduced model (right).

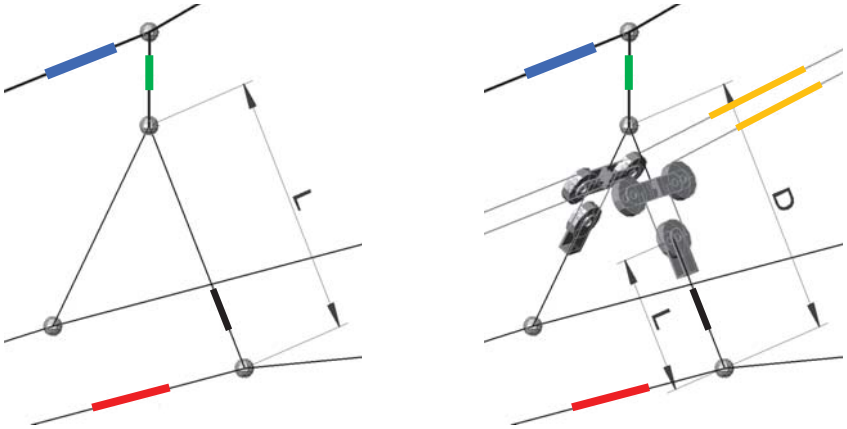

Figure 9: Connecting cables of model v1 (left) and v2-v3 (right) with connecting and post-tensioning cables.

If there is no horizontal load, models v2 and v3 are the same as the force is s=2mg in every connecting cable, where m = weight of one ballast and g=9.81 m/s. The behavior of these two models, however, is different if horizontal load is also applied, which is illustrated in Figure 10. In case of model v2, branches A-B and C-D are independent; therefore the ballast weights can move freely. Consequently the connecting cable forces do not change due to any structural displacement field, that is $\Delta s_{A\text{-}B}=0$ and $\Delta s_{C\text{-}D}=0$. This can be modeled by simply eliminating term k in the element stiffness matrix of the connecting cables (1), which means that the geometrical stiffness belonging to the constant connecting cable forces exists only. It should be noted, however, that instead of using zero value for k, a small nonzero value is better to use for faster convergence. In case of model v3 points A-C and B-D are connected together; the two inhomogeneous springs belonging to the branches A-B and C-D are now coupled in a parallel way.

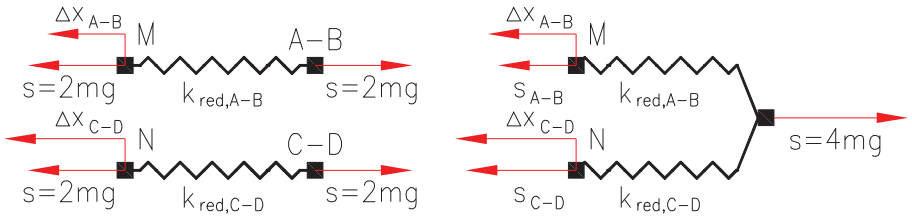

Figure 10: Difference between the behavior of model v2 (left) and v3 (right).

The internal force variation for branch A-B is $\Delta s_{A\text{-}B}=f(\Delta D_j, j=1..2n)$ and that for the branch C-D is $\Delta s_{C\text{-}D}=g(\Delta D_j, j=1..2n)$, where n = number of the connecting cables on one side, namely 7 in our case. Unlike model v2, the connecting cable forces are not invariant of the reduced displacement variation in case of model v3. If the reduced displacement variation of $\Delta x_{A\text{-}B}$ and $\Delta x_{C\text{-}D}$ are not equal, a difference will appear between the connecting cable forces of the two branches.

The reduced displacement variations for branch A-B is $\Delta x_{red,A\text{-}B}=\Delta x_{A\text{-}B}-(\Delta x_{A\text{-}B}+\Delta x_{C\text{-}D})/2$ and for branch C-D is $\Delta x_{red,C\text{-}D}=\Delta x_{C\text{-}D}-(\Delta x_{A\text{-}B}+\Delta x_{C\text{-}D})/2$. If symmetrical horizontal forces are applied, the connecting cable force variations is be calculated as $\Delta s_{A\text{-}B}=\Delta x_{red,A\text{-}B}\cdot k_{red,A\text{-}B}$ and $\Delta s_{C\text{-}D}=\Delta x_{red,C\text{-}D}\cdot k_{red,C\text{-}D}$. Compared to model v2, stiffness k in the element stiffness matrix is not zero. The normal stiffness k for each connecting cable of branch A-B and C-D were selected as $n\cdot k_{red,A\text{-}B}$ and $n\cdot k_{red,C\text{-}D}$, respectively. This intuitive stiffness approximation of the connecting cables gave fast convergence in case of symmetrical total horizontal loading.

5 DYNAMIC NUMERICAL MODEL

The dynamic behavior of the three models was studied by extending the static equations with the inertia and damping forces. A non-iterative incremental time advancement version of leap-frog scheme was used. Also, a nested Newton-Raphson scheme can also be developed.

Model v1 required to solve Equation (3):

$$\mathbf{M}\Delta\mathbf{a}_t + \mathbf{C}\Delta\mathbf{v}_t + \mathbf{K}_t(\mathbf{x}_t)\Delta\mathbf{x}_t = \Delta\mathbf{Q}_t \tag{3}$$

In (3) **M** = mass matrix; **C** = damping matrix; **a** = acceleration vector; **v** = velocity vector; **x** = displacement vector; **Q** = external load vector. As the structure is geometrically non-linear, the stiffness matrix had to be updated at each time step based on the geometrical position of the nodes (see Figure 6) and the cable forces. Although the explicit scheme was easy to implement, the time step for a stable and accurate solution was typically 10 times less than usual in linear dynamics.

Model v2 required the modification of the equation (3) into (4):

$$\mathbf{M}\Delta\mathbf{a}_t + \mathbf{C}\Delta\mathbf{v}_t + \mathbf{K}_t(\mathbf{x}_t)\Delta\mathbf{x}_t + \Delta\mathbf{P}(a_t, v_t) = \Delta\mathbf{Q}_t \tag{4}$$

The elements of vector $\Delta\mathbf{P}_t$ are determined by solving $\Delta\mathbf{P}_t=\mathbf{G}_t\Delta\mathbf{s}_t$, where $\Delta\mathbf{s}_t$ = internal force vector increment belonging to the connecting cables. Unlike static behavior, the connecting cable forces do change due to inertia and damping forces accompanied by the ballast weight motion, therefore $\Delta\mathbf{P}_t$ is the function of $\mathbf{a}_t$ and $\mathbf{v}_t$ of the structural nodes. In Figure 11 the coupled system of the post-tensioning cable and the connecting cables is shown for model v2, which was reduced into an idealized spring system. The two ballasts of a branch move identically due to symmetrical horizontal loading. The spring representing branch A-B is excited at point M with displacement increment of $\Delta x_{A\text{-}B}=\Sigma\Delta D_j$, where D is illustrated in Figure 9. The spring of branch C-D is derived likewise. In order to improve the performance of model v2, each ballast can be equipped with a linear hydraulic damper (c) and a nonlinear spring that is inactive until a prescribed displacement (δ) is reached. The dynamic equation of motion is solved for the vertical ballast displacement variation Δh, from which the cable force change in the reduced spring of a branch is $\Delta s=(\Delta x-\Delta h)\cdot k_{red}$, which is equal to the connecting cable force increments of the same branch. Based on the connecting cable force increments, $\Delta\mathbf{P}_t$ can be compiled, and the displacement, velocity and acceleration increments of the 24 structural nodes and the four ballasts can be calculated at a time step.

Model v3 is simpler than v2 in case of horizontal loading, as the vertical motion of the ballast and the consequent dynamic forces can be neglected. Instead, the principles introduced at the static numerical modeling apply here. The difference is that the internal forces of the connecting cables are taken into consideration in the $\Delta\mathbf{P}_t$ vector rather than in the term $\mathbf{K}_t\Delta\mathbf{x}_t$, which means that the internal forces are handled as external loadings. This is important with respect to the explicit time advancement scheme as there is no internal iteration within a time step. The nonlinear dynamic calculation was tested by applying quasi-static test loading; the results were in good agreement with that of the nonlinear static calculations for all the three models.

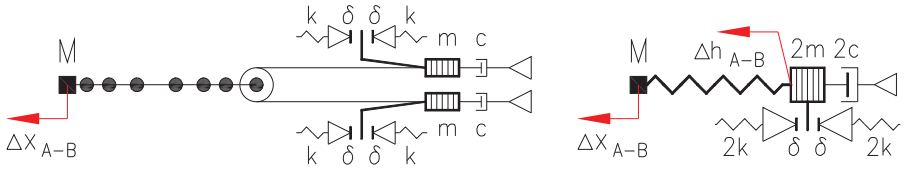

Figure 11: Dynamic model of the idealized spring for branch A-B (left) and its reduced model (right).

6 VALIDATION

In the previous chapters the proposed structural system was investigated by means of physical and numerical approaches. The input for the numerical simulation was set in accordance with the measured physical model; the normal stiffness of the steel wires and the multi-strand fishing line were measured through tensional tests. The weight of each structural part was also determined. Neither hydraulic damping, nor nonlinear springs were applied to the ballasts. A horizontal static load of 5 N was applied to the catenary nodes. The horizontal displacement showed linear tendency for every model for this load. In Table 1 the measured and calculated horizontal displacement in mm of point P (see Figure 12) and vertical displacement of ballast points A and C are compared. The measured and simulated displacement values are in good agreement for model v1 and v3. The results of model v1 and v3 are close together, showing that there is no significant loss in the overall stiffness due to the dominant horizontal loading by applying the proposed post-tensioning system of model v3. Model v2, however, gave 2-3 times larger displacement, which can be explained by the unconstrained vertical displacement of the ballasts and the consequently constant connecting cable forces. The connecting cables with constant forces need to change spatial orientation in order to balance the horizontal load, which is the source of the significantly larger horizontal displacement. The measured horizontal displacement is lower by 35 percent than the calculated one due to the friction of the pulleys. The ballast displacement shows the difference between models v2 and v3; points A and C move in the opposite direction and so do points B and D in case of model v2. On the other hand, in case of model v3, points A-C and B-D are connected together, resulting in a small common displacement, which constrains the horizontal displacement of the catenary.

Models	Physical			Numerical		
	P_hor	A_vert	C_vert	P_hor	A_vert	C_vert
v1	21	-	-	22	-	-
v2	50	-190	178	67	-276	276
v3	28	3	3	29	8	8

Table 1: Horizontal displacement of point P and vertical displacement of points A and C [mm].

The developed dynamic numerical method was also validated. The natural frequencies were determined by FFT analysis of the time series of the geometrically non-linear time stepping method. The simulation was started on the completed bridge structure as a result of the nonlinear static calculation. The time dependent horizontal load was applied to each catenary node; it was ramped up in a quasi-steady manner and then set to zero in one time step, obtaining a free decay oscillation to study.

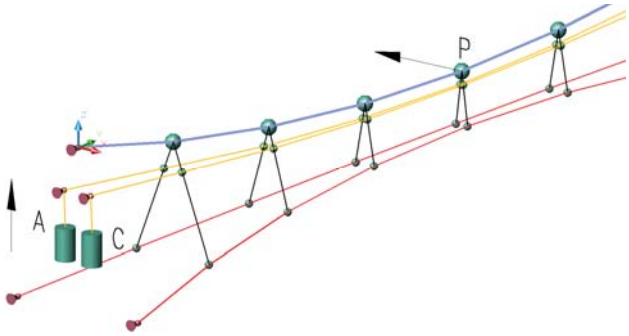

Figure 12: Investigated points and displacement directions.

The results are shown in Table 2 for the three models and with stage1 for the catenary alone state. The measured and simulated natural frequencies of the sway mode are in good agreement. According to expectations, model v1 has the highest frequency as it has the highest stiffness. Model v3 showed higher static deflection and the frequency is consequently lower. Model v2 is interesting as the sway mode has a frequency close to that of models v1 and v3. On the other hand, the extra freedom of the ballasts provided a slow vibration mode that belongs to the vertical motion of the ballasts and the horizontal motion of the catenary. The frequency is around 0.30 Hz, which is shown in Table 2 in parentheses. This mode was spotted numerically but did not show up in the measurements, which is explained by the behavior of the pulleys; the bearings of this size give relatively high friction and viscosity, which might hinder the whole pulley system from accommodating this vibration mode.

Models	Physical	Numerical
stage1	0.68	0.66
v1	1.50	1.44
v2	1.37	1.30(0.30)
v3	1.38	1.28

Table 2: Natural frequencies of the symmetrical sway mode.

7 INDUSTRIAL APPLICATION

7.1 The considered long-span catenary bridge

In this chapter an L=700 m main span catenary is considered that has been designed by Pont-TERV Ltd in the framework of a feasibility study in 2017 (see Figure 13). The bridge geometry is similar to the physical model that was studied earlier. The proposed novel tensioning system and the adequate numerical approach were adopted to this bridge structure. It is highlighted that this span length maximization is under research in case of road bridges [4].

Figure 13: The considered long span catenary structure (Feasibility study, courtesy of Pont-TERV Ltd, 2017).

7.2 Application of the proposed iso-tensioning system

At first, the horizontal displacement of the structure due to horizontal loading on the catenary is illustrated in Figure 14. It can be seen that the catenary together with the wind cables moves sideways.

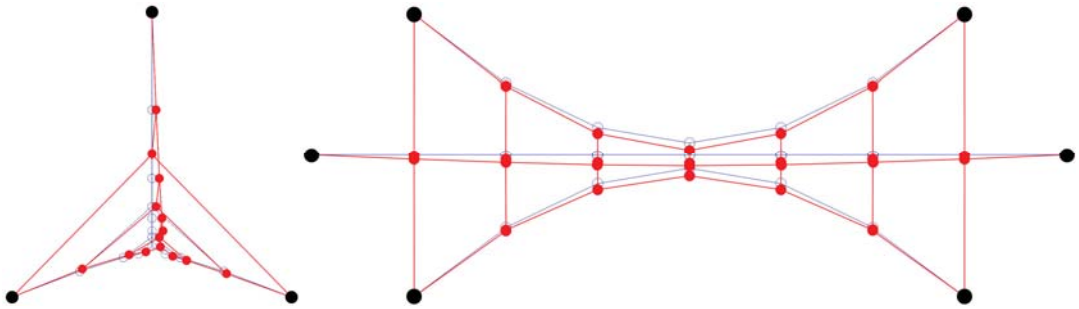

Figure 14: Horizontal deflection of the catenary.

The selected ballast weight is 4 t each. The static test loading was horizontal Q_{top}=14 kN at the nodes of the catenary, and Q_{bottom}=31 kN at the nodes representing the bridge walkway. The horizontal loading was ramped up within 20 seconds and then was kept constant. The horizontal displacement of point P for models v1, v2 and v3 is shown in Figure 15. Both models are common in reach a horizontal displacement around 60-80 cm when the ramped load reaches its maximum value. This displacement belongs to the spatial deformation of the whole bridge structure (see Figure 14).

The displacement values remain constant except for model v2, which shows increasing tendency with time. This creep-like behavior is due to the ballast motion pulled by the post-tensioning cables, which is explained in Figure 15 (right hand side); z_0 is the deflection due to short-term load, z_t is the long-term deflection. The displacement growth speed can be decreased by involving dampers shown in Figure 11. In our calculations a value of c=10 kNs/m was selected. The maximum displacement of model v2 was reached when the orientation of the connecting cables changed in order to reach equilibrium. It is important to note that there is a limit for the static horizontal loads to be balanced by the connecting cables, as the forces in these cables are constant under any external load conditions. To overcome this problem, the ballast motion was constrained by using supports that were activated after a prescribed vertical motion (h), which restricted the horizontal displacement of the catenary as well. At each ballast, a spring with k=10000 kN/m was defined that was activated when the ballast vertical displacement exceeded δ=2.00 m. With this non-linear constraint the creep-like behavior could be well controlled. In Figure 15 (left hand side), the results of model v2 both with and without constraint are shown (red and green curves).

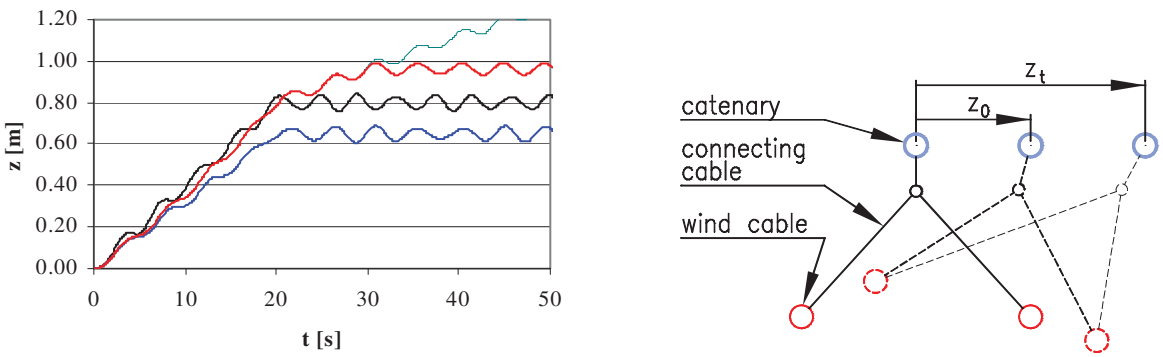

Figure 15: Horizontal displacement due to static load (v1: black, v2-constrained: red, v2: green, v3: blue).

In Figure 16 the dynamic performance of the three models are compared. The model v2 is investigated with the above mentioned constraint, the no-constrain condition is not shown now. The test load is the same as the quasi-static one, but when its maximum was reached, the load was dropped to zero in one time step, leading to a free decay oscillation. The results of model v1 and v3 are close together. Model v2 shows larger damping, which can be explained by the damped motion of the ballasts; the horizontal displacement of the walkway are transferred by the post-tensioning cables to the ballasts that can move freely making the dampers work. The neighboring ballasts are prevented from moving in the opposite direction in case of model v3; therefore the hydraulic dampers do not increase the overall damping at all.

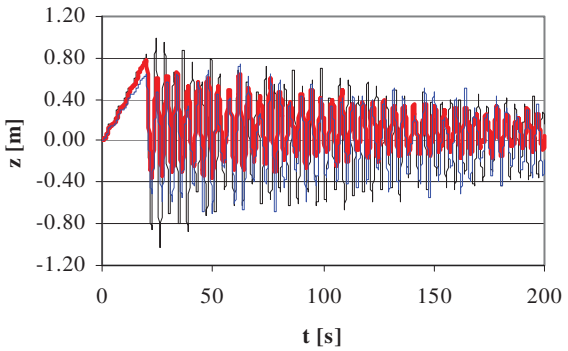

Figure 16: Horizontal displacement due to sudden load (v1: black, v2-constrained: red, v3: blue).

Having studied the structural behavior of the three different models due to ideal loads, a real test was also carried out. An along-wind time series was generated based on the turbulent spectrum proposed by the Eurocode. By using the wind speed values at each time step, the loading to the catenary and walkway nodes was determined. Unlike nonlinear aerodynamic load models, a simplified along-wind loading of $q_x=0.5\rho U^2 c_x A$ was chosen, where ρ = air density; U = wind velocity; c_x= static force coefficient of the certain structural element; A = reference area. The effect of the displacement and velocity of the bridge on the aerodynamic forces is neglected. The structural logarithmic damping value of $\delta=0.22$ was selected as a sum of the inherent structural damping ($\delta=0.02$) and the aero-dynamic damping.
All the parameters were chosen in accordance with Eurocode (terrain category: III, height over ground: 80 m). Due to the high reduced wind speed, the simplified aerodynamic load model is justified; therefore advanced three-dimensional fluid-structure interaction model [2] can be omitted for this problem. The results are shown in Figure 17. For model v2 each ballast was equipped with a hydraulic damper and a non-linear spring that was introduced earlier. The dynamic displacement values of model v1 and v3 show the same tendency, but that is apparently lower in case of model v2 due to the additional effect of the dampers of the ballasts.

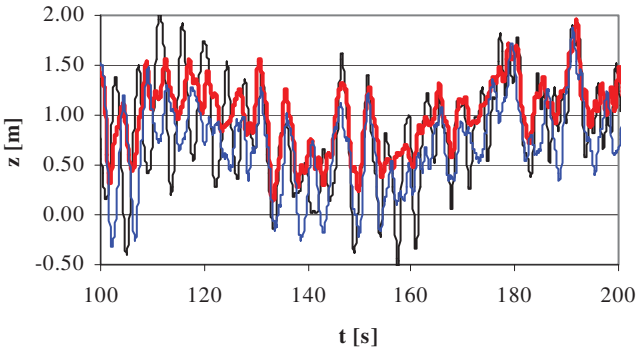

Figure 17: Horizontal displacement of point P due to buffeting (v1: black, v2-constrained: red, v3: blue).

8 CONCLUSIONS

- In this paper a novel post-tensioning method was proposed for long span catenary bridges. The system involves pulleys that has a number of advantages. First of all, the prestressing is temperature-independent. Seconly, the connecting cable forces are evenly distributed, therefore any vibration of a loose cable is unlikely. The proposed structural configuration was tested on a physical model. The evenly distributed connecting cable forces were indeed observed, which was our main goal to achieve. An adequate numerical model was also developed. Three configurations were investigated; a conventional one named model v1, and the novel pulley based system with and without fixing the neighboring ballasts together, which are models v3 and v2, respectively. The measured and calculated results were in good agreement.
- The friction of the pulleys were not considered in the numerical models. Their effect will be studied in our advanced models in the future.
- The validated numerical model was tested on a catenary bridge of real sizes as well. It was found that model v2 and v3 worked properly due to buffeting forces, as the dynamic responses did not exceed that of model v1, which indicated that the loss in the horizontal stiffness of the proposed systems can be avoided. The novel configuration v2 and v3 are basically different in nature; v3 is simpler as the neighboring ballasts are connected together, which results in a stiffness close to model v1 and a consequently similar static and dynamic behavior. The more sophisticated v2, however, requires special treatment in order to preserve stiffness; a constraint is necessary to the ballasts that controls the displacement. On the other hand, applying hydraulic dampers too, the overall damping of the bridge can be increased. The choice between model v2 and v3 therefore requires profound design and economic considerations.
- To conclude, the main goal of a temperature-independent and evenly distributed connecting cable forces has been achieved by the proposed structural configuration(s) with at least equivalent static and dynamic performance compared to the conventional catenary bridges. The additional damping experienced in case of model v2 is beyond our expectations, which will be further investigated as it can be essential in span length maximization.

Keywords: Fatigue damage, Slender structures, Wind-induced fatigue, Fatigue standard methods, Antenna masts.

Abstract. *A major shortcoming in the structural and wind engineering sectors concerns wind-induced fatigue design and verification procedures. Despite wind-induced fatigue is a critical phenomenon which may lead many slender structures to damage and collapses, suitable engineering and standards procedures are still fragmentary and almost lacking. Structural typologies sensitive to this problem are, for example, wind turbines, bridges, cranes, poles and towers. A method was proposed by one of the authors, which allows to evaluate in closed form the mean damage in the unit time induced by alongwind turbulence effect on steel slender structures or steel structural elements. The procedure is suitable for engineering calculations and code provisions. The present paper describes the more recent advance in generalizing the procedure for determining the wind-induced fatigue damage of slender structures, taking into account simultaneous alongwind and crosswind structural responses due to turbulence and discussing the main analytical features and the simplifying hypotheses adopted. The set of input parameters is coherent with standard format. An application of the proposed generalized procedure to a real case study is reported and discussed, showing the capability of the proposed method to catch the main feature of the fatigue damage phenomenon with quite simple calculation procedure.*

1 INTRODUCTION

Fatigue is a critical phenomenon producing localized and progressive damage and subsequent weak structural collapses, due to moderate but repeated loading conditions. Metallic elements often experience this process in the welded or bolted joints. Such phenomenon may determine failures under cyclic actions of amplitude lower than design loads, thus without exceeding ultimate strength and without appreciable plastic deformations. Ultimate verification methods provided by standards and codes are therefore not suitable for fatigue analysis.

The fatigue analysis under variable amplitude stress histories implies the application of a suitable accumulation rule because fatigue damage increases in a cumulative manner. The fatigue failure occurs when the total accumulated damage reaches a critical value. The cumulative damage rate depends both on the amplitude of the cycles and on their sequence, as well as many other aspects. In 1945 the Palmgren-Miner linear accumulation rule was proposed, according to which one block of cycles of n_j constant amplitude Δ_j produces a fraction of damage $d_j(\Delta_j)$ proportional to the ratio n_j/N_j. The total cumulative damage D is expressed linearly adding the fractional damages due to different stress cycles amplitude [1]. The Palmgren-Miner rule, which remains the most commonly adopted accumulation law so far, basically disregards the loading sequence. The critical total damage value, corresponding to failure, is conventionally defined as equal to one; the fatigue life is defined as the time in which D reaches the unit.

Existing literature and codes provide information on structural fatigue resistance of structures through *S-N* experimental curves in the bi-logarithmic diagram, which associate to every constant stress amplitude Δ the number of cycles that leads to collapse N, giving different shapes of curves depending on different materials and cyclic loading applications. Adopting the commonly used nominal stress approach, *S-N* resistance curves are given for classified structural details and the level of stress analysis adopted corresponds to the global stress calculated in the cross-section under consideration, assuming a linear elastic behaviour of the material and disregarding the local stress raising effects of the welded joint [2, 3, 4].

Wind actions may produce large vibrations of exposed slender structures and repeated stress cycles in critical details during the whole structural life. The dynamic response of structure to turbulence actions or to the vortex shedding phenomenon can be critical for moderate and frequent wind velocities, inducing the propagation of fatigue crack. Thus, wind-induced fatigue is a frequent reason of structural damages and collapses [5, 6]. Slender structures or slender structural elements are particularly sensitive to this phenomenon. Poles, masts and antennas supports are typical kinds of structures sensitive to wind induced fatigue, strongly affected by dynamic response due to turbulence action. Vortex shedding actions usually are negligible for these kinds of structures, unless particular shapes are used [6].

Despite a wide research literature addressed to this problem, standards and codes related to wind-induced fatigue are still fragmentary. Eurocode [7] provides a calculation procedure for alongwind fatigue assessment based on very simplified assumptions [8], furnishing results than can be high uncertain. This code also provides methods for evaluating vortex shedding-induced response and fatigue. Other international standards are addressed to particular kinds of structures, such as steel chimneys [9], poles and infrastructural supporting constructions [10] and wind turbines [11], adopting different approaches. A wide research project aimed at formulating and calibrating a procedure for determining wind-induced fatigue has been carried out by the authors. This paper presents an overview of the proposed procedure, focusing on more advanced generalizations to alongwind and crosswind buffeting actions and different resistance curves. The procedure is finally applied to a monopole antenna mast.

2 BASES OF THE PROPOSED METHOD

Time is conventionally subdivided into successive ΔT time intervals of 10 minutes – 1 hour, falling in the spectral gap, which separates the macro-meteorological and the micro-meteorological peaks. Wind velocity at a reference height above the ground is schematized, in each ΔT interval, through its mean value $\bar{u}$, its direction, and the three zero-mean fluctuating orthogonal components, *u'*, *v'*, *w'*, referred to, respectively, as longitudinal, lateral and vertical turbulence; these are modelled as stochastic stationary Gaussian processes. The mean wind velocity at the structural site is linked with the mean wind velocity at a reference site, namely the mean wind velocity at a reference height on a reference terrain, probabilistically characterized by the Weibull distribution parameters.

Let us consider a slender structure or structural element whose length l is much greater than the reference size b of its cross-section. Let x, y, and z be a local Cartesian reference system with origin at o; z coincides with the structural axis, x is aligned with the mean wind direction, o lies on the face of the structure with $z = 0$. The wind loading is schematized as a three-variate two-dimensional random stationary Gaussian process, whose i-th component ($i = x, y, \theta$) is given by:

$$F_i(z,t) = \bar{F}_i(z) + F'_i(z,t) \tag{1}$$

where $0 \le z \le l$; t = time; F_x, F_y, F_θ = alongwind force, crosswind force and torsional moment around z per unit length; $\bar{F}_i$ = mean value of F_i ; and F'_i = nil mean fluctuation of F_i around $\bar{F}_i$. Using a quasi-steady theory and dealing with the structure as a linear system, the wind-induced stress at a coordinate z of the structure in a ΔT time interval is a stochastic stationary Gaussian process given by the sum of the mean static stress caused by the mean wind action and the fluctuating stress components, caused by the buffeting and vortex shedding actions. Therefore, the wind-induced stress at a coordinate z of the structure in a ΔT time interval is given by:

$$s_i(z,t) = \bar{s}_i(z) + s'_i(z,t) \tag{2}$$

where $\bar{s}_i$ is the mean static stress and s'_i is the fluctuating stress. The fluctuating stress, varying on time, may produce fatigue phenomenon. In alongwind direction, the stress process is caused by the buffeting actions due to turbulence and it can be schematized as a bi-modal process [12, 13], with a low frequency quasi-static component and a high frequency resonant component. Crosswind fluctuating part of the response is due to the joint action of the oncoming wind turbulence and of the vortex wake. Resonant response to vortex shedding actions occur at critical wind velocity, corresponding to the condition in which the shedding frequency is equal to the fundamental mode of vibration of the structure.

In order to verify a structural component with regard to wind-induced fatigue, a cycle histogram has to be determined, which provides the number of cycles associated with every stress amplitude on varying of mean wind velocity. The cycle histogram evaluation is not trivial, requiring the application of a suitable cycles counting method to the wind-induced response processes associated to the whole range of wind velocity loading conditions [14, 15, 16]. As the response due to wind is dealt with as a random stationary process in frequency-domain, definition of cycle counting for random loads and definition of the mean fatigue damage or mean fatigue life are required. The analysis is strongly dependent from random process characteristics [17, 18].

In order to obtain the cycle histogram, structural response must be evaluated at a large number of wind velocity values, usually at intervals of 1 m/s up to the reference mean veloci-

ty with 50 years return period, then the number of cycles that stresses the structure is identified by the bi-modal counting method [12, 13]. From the cycle histogram it is possible to evaluate the damage histogram and then the total cumulative damage, expressed by means of the linear accumulation law [1]. Finally, the fatigue life is defined by $T_F = 1/\bar{D}(1)$, where $\bar{D}(1)$ is the cumulated mean damage in the unit time. Then, a refined closed-form solution of the alongwind turbulence-induced fatigue has been obtained [19, 20], expressing $\bar{D}(1)$ in analytical form as the product of a basic "0 level" solution, multiplied by three corrective factors:

$$\bar{D}(1) = \bar{D}_0(1) C_{BM} C_M C_{SN} \tag{3}$$

where the "0 level" solution of damage adopts three classic simplifications: 1) the stress process is narrow band; 2) the stress process is zero mean; 3) the *S-N* fatigue curve is a straight line on a bi-logarithmic diagram, with constant slope equal to 3. The corrective factors have been provided analytically by removing independently the three simplifications one by one: the bi-modal factor C_{BM} considers the process as bi-modal, with a quasi-static and a resonant component; the mean stress factor C_M takes into account the non-null value of the mean stress; the fatigue curve factor C_{SN} regards the tri-linear trend adopted for steel structural details subjected to normal stresses according to the Eurocode [2].

This achievement allows to evaluate the mean total fatigue damage due to alongwind turbulence in closed-form computing the structural response just for two values of wind velocity. In order to reach this aim, three hypotheses have been assumed. The first main simplifying hypothesis is that basic stress parameters of the random process are expressed as functions of the mean wind velocity by the power law approximation. This rule was first introduced by Holmes [5] limited to the standard deviation and later generalized by Repetto and Solari [19, 20] to any stress parameter due to alongwind loadings. It is possible to estimate the exponent of the power law in function of two different values of wind velocity, conventionally the "reference" mean wind velocity, that is the velocity with 50 years return period in the site at a fixed reference height adopted for ULS analysis, and a "fatigue" velocity, which represents the wind velocity that produces the maximum fatigue damage. The second hypothesis is that the density function of the mean wind velocity is represented by the hybrid Weibull model [21]. The third hypothesis assumes that the considered *S-N* resistance curve follows the tri-linear trend adopted in the mechanical and structural practice for steel details subjected to normal stresses, according to the nominal approach [2].

Two classes of formulas at different level of calculation, simplified and detailed calculations, has been defined [22]. The first one provides preventive values of fatigue damage and fatigue life, strongly on the safe side, to detect whether the structure is sensitive to fatigue or not; the second one gives reliable values of fatigue evaluation. The alongwind-induced fatigue assessment method has been completed discussing input parameters and defining their expressions in accordance with Eurocode standards format for wind induced Ultimate Limit State (ULS) analysis [22]. This preliminary work has allowed to introduce the alongwind method in new reviewed CNR [23].

3 THE GENERALIZED MODEL

Starting from the model outlined in Section 2, the method is generalized considering a wide range of *S-N* fatigue resistance curves shapes, in order to evaluate different materials affected by fatigue damage and to evaluate structures susceptible to normal or shear stress conditions. Then the generalization has taken into account both alongwind and crosswind buffeting-induced fatigue; since vortex shedding induced vibrations are generally negligible in cross-

wind response of structures like slender supports and antenna masts, in this paper vortex induced fatigue is not considered. The whole procedure is therefore reformulated, also defining input parameters expressions totally coherent with current Eurocode standards.

3.1 *S-N* fatigue resistance curves

One of the most evident limit of the model described Section 2 is that is valid only for fatigue due to normal stresses in steel structural elements, referring to a particular type of fatigue resistance curve. *S-N* curves in standards and recommendations may assumes different shapes depending on the material, the type of loading application and the stress condition. Linear curves in the bi-logarithmic diagram are provided for some particular materials such as some types of glasses, composites and concretes. Bilinear curves may be distinct in two families, characterized by a cut-off limit and by two different slopes, respectively. Examples of bilinear *S-N* curves are related to shear stresses in steel elements and to aluminium details. Finally, trilinear curves (e.g. *S-N* curves for normal stresses in steel elements) have two different slopes and a cut-off limit, but they are going to be adapted to bilinear shape [4].

In the method proposed in 2012 [20], the total annual mean damage (3) takes account of *S-N* curves trend through the fatigue curve factor C_{SN}, which reduces the "0 level" solution of damage considering only the particular trilinear *S-N* curves for normal stresses in steel details. The generalization of the whole formulation, and in particular of fatigue curve factor C_{SN}, has been carried out, expressing this corrective factor in a more general format, on varying the characteristics of the concerned bilinear *S-N* curve. Indeed, different bilinear shapes in bi-logarithmic diagram may represent fatigue resistance of a wide range of structural details of different materials affected by normal or shear stress processes. Furthermore, two particular cases have been analysed, in accordance with the generalized formulation. These are the case of fatigue due to cyclic normal stresses in steel details, completely coherent with the one proposed in [20], and the case of fatigue due to cyclic shear stresses in steel details. The simplified and detailed calculations have been also defined for the latter particular case.

3.2 Alongwind and crosswind buffeting-induced fatigue

Since the power law approximation for the basic stress input parameters is effective for alongwind and crosswind turbulence induced response, if vortex shedding contribution is neglected the analytical formulation is formally equal for alongwind and crosswind buffeting-induced fatigue analysis. Coherently, the closed-form solution of wind-induced cumulated mean damage in the unit time can be again expressed as the product of the "0 level" solution, multiplied by the corrective factors (3). The stress input parameters have been defined analytically starting from the method recently proposed by Solari [24], which allows to determine the simultaneous alongwind, crosswind, and torsional loading and response of slender structures by means of calculations suitable for standard verifications, within the gust factor technique framework [25, 26]. The generalized formulation of terms in (3) are then given by:

$$\begin{aligned}\bar{D}_0(1) &= 31.536 \cdot 2^{\left(\frac{3m_1-1}{2}\right)} \sqrt{\pi} \cdot \Gamma\left(\frac{m_1}{2}+1\right) \frac{\sigma_{i,ref}^{m_1}}{\Delta_C^{m_1}} \nu_{i,ref} \\ &\times \left(0.2k-0.12\right)^{m_1\alpha_{\sigma,i}} \left(\frac{m_1\alpha_{\sigma,i}}{k}+1\right)^{\left(\frac{m_1\alpha_{\sigma,i}}{k}+0.5\right)} \exp\left[-\left(\frac{m_1\alpha_{\sigma,i}}{k}+1\right)\right]\end{aligned} \tag{4}$$

$$C_{BM} = \frac{\nu_{i,Q,ref}}{\nu_{i,ref}} + \frac{n_{i1}}{\nu_{i,ref}} \lambda_{i,ref}^{\frac{m_1}{2}} \left(0.2k - 0.12\right)^{\frac{m_1}{2}\alpha_{\lambda,i}} \left(\frac{m_1 \alpha_{\sigma,i}}{k} + 1\right)^{\frac{m_1 \alpha_{\lambda,i}}{2k}} \tag{5}$$

$$C_M = \left[\frac{s_u}{\left(s_u - \overline{s}_P\right)}\right]^{m_1} \left[1 + \frac{\overline{s}_{i,ref}}{\left(s_u - \overline{s}_P\right)} m_1 \left(0.2k - 0.12\right)^2 \left(\frac{m_1 \alpha_{\sigma,i}}{k} + 1\right)^{\left(\frac{2}{k}\right)}\right] \tag{6}$$

$$C_{SN} = 1 - \exp\left\{-\left\{\left[\left(a^I \left(m_1 + \frac{N_L - 10^7}{45 \cdot 10^6}\right) + a^{II}\right)^{\frac{1}{k}} \left(0.2k - 0.12\right)\right]^{\alpha_{\sigma,i}} \times \left(\frac{\sigma_{i,ref}}{\Delta_C}\right)\right\}^{\left[\frac{k}{\alpha_{\sigma,i}}\left(0.15\left(m_1 + \frac{N_L - 10^7}{45 \cdot 10^6}\right) + 1.55\right)\right]}\right\} \tag{7}$$

where "*i*" is the directional index, with $i = D, L$ for alongwind and crosswind structural response parameters, respectively; m_1, Δ_C and N_L are parameters of the considered *S-N* fatigue curve; a^I, a^{II} are constant values depending on the shape of the considered *S-N* fatigue curve, in particular $a^I = 7.44$, $a^{II} = -3.81$ for bilinear *S-N* curves with cut-off limit, $a^I = 6.33$, $a^{II} = 2$ for bilinear *S-N* curves without cut-off limit; $\Gamma(\bullet)$ is the gamma function; k is the shape parameter of the Weibull probability distribution of the current values of the wind velocity in situ [27]; $\nu_{i,Q,ref}$ is the expected frequency of the *i*-component of turbulence [26]; n_{i1} is the first mode of vibration frequency in the *i*-direction; s_u is the material failure characteristic stress; $\overline{s}_P$ is the permanent loadings-induced stress in the examined section (calculated at serviceability); parameters of the response process in *i*-direction at reference wind velocity are $\overline{s}_{i,ref}$, $\sigma_{i,ref}$, $\nu_{i,ref}$, $\lambda_{i,ref}$, which are the mean value, standard deviation, expected frequency and normalized variance of the resonant part of the process in the critical section, respectively; $\alpha_{\sigma,i}$ is the exponent of the power law expressing the standard deviation of the fluctuating stress, σ_i, on varying wind velocity; $\alpha_{\lambda,i}$ is the exponent of the power law expressing the normalized variance of the stress resonant part, λ_i, on varying wind velocity [22, 24]. Only the exponents of power laws parameters, $\alpha_{\sigma,i}$ and $\alpha_{\lambda,i}$, require the calculation of the structural response at reference and fatigue wind velocity values.

4 ANTENNA MAST CASE STUDY

Antenna mast structures are built in such a large and growing number. They are characterized by increasing height, lightness, slenderness and complicated shape that make them extremely sensitive to complex aeroelastic phenomena and wind-excited vibrations, such as to require refined analyses in order to capture their physical behaviour. An impressive number of damage and collapses that increasingly involved these structures, often due to wind-excited fatigue, but in many cases not so well understood, emphasizes their susceptibility to wind actions and their potentially dangerous role in the anthropogenic territory.

A case study concerning a real antenna mast, taken from existing literature [28], is analyzed. This structure is a telecommunication antenna mast composed by two steel shafts with tubular circular section, whose total height is $H = 30$ m (Fig. 1). The first shaft is 24 m long; the outer diameter of its section, whose thickness is constant and equal to 5 mm, varies from

950 mm at the bottom to 350 mm at the top; the cables attached along this shaft have a distributed mass per unit length 5 kg/m. The second shaft, put above the first one, is 6 m long and carries 6 antennas. Its section has constant outer diameter 193.7 mm and constant thickness 7.1 mm; the total mass of the shaft is 540 kg. A stair is placed along the whole structure and has a mass per unit length 7 kg/m. The additional components, namely the stair, the cables and the antennas, give rise to a distributed mass eccentricity; however, they are assumed to be ineffective with regard to the structural stiffness. The pole is located in a terrain characterized by a roughness length z_0 = 0.3 m and a basic reference wind velocity u_{ref} = 25 m/s (i.e. the mean wind velocity at 10 m height above ground, in a flat homogeneous terrain with roughness length z_0 = 0.05 m and return period 50 years); the mean wind velocity profile is logarithmic. Assuming that the reference height is z_e = 24 m, i.e. the top of the main shaft, the design mean wind velocity at such a height is $\bar{u}(z)$ = 23.6 m/s. The aerodynamic characteristics of the structure have been determined by static wind tunnel experiments [28]. The first natural (flexural) frequency in both alongwind and crosswind directions is n_{i1} = 0.77 Hz. The test-case clearly points out the importance of mechanical and aerodynamic eccentricities; in fact, the presence of external devices such as cables and stairs substantially changes the drag coefficient, which results deeply dependent on the direction of the oncoming flow; in addition, large lift forces arise that rapidly change on varying the wind direction.

The proposed procedure to evaluate alongwind and crosswind-induced fatigue results easy to apply from an engineering point of view. The considered *S-N* fatigue curve corresponds to steel detail category 36 provided by IIW [4], so that m_1 = 3, Δ_C = 36 and $N_L = 10^7$; a^I = 7.44 and a^{II} = -3.81. The shape parameter of the Weibull probability distribution of wind velocities k is taken equal to 1.15; the expected frequencies of turbulence components are $\nu_{D,Q,ref}$ = 0.058 Hz and $\nu_{L,Q,ref}$ = 0.078 Hz [26]; the steel failure characteristic stress is s_u = 510 MPa; the permanent loadings-induced stress in the examined section is calculated as $\bar{s}_P$ = 1.818 MPa; parameters of the response process in the critical section at reference wind velocity are evaluated as $\bar{s}_{D,ref}$ = 39.066 MPa, $\sigma_{D,ref}$ = 29.263 MPa, $\nu_{D,ref}$ = 0.567 Hz, $\lambda_{D,ref}$ = 0.543 in alongwind direction [22] and $\bar{s}_{L,ref}$ = 10.162 MPa, $\sigma_{L,ref}$ = 32.349 MPa, $\nu_{L,ref}$ = 0.727 Hz, $\lambda_{L,ref}$ = 0.892 in crosswind direction [24]; the exponents of power laws parameters are assessed as $\alpha_{\sigma,D}$ = 2.321 and $\alpha_{\lambda,D}$ = 0.920 in alongwind response analysis [22] and $\alpha_{\sigma,L}$ = 2.558 and $\alpha_{\lambda,L}$ = 0.221 in crosswind response analysis [24].

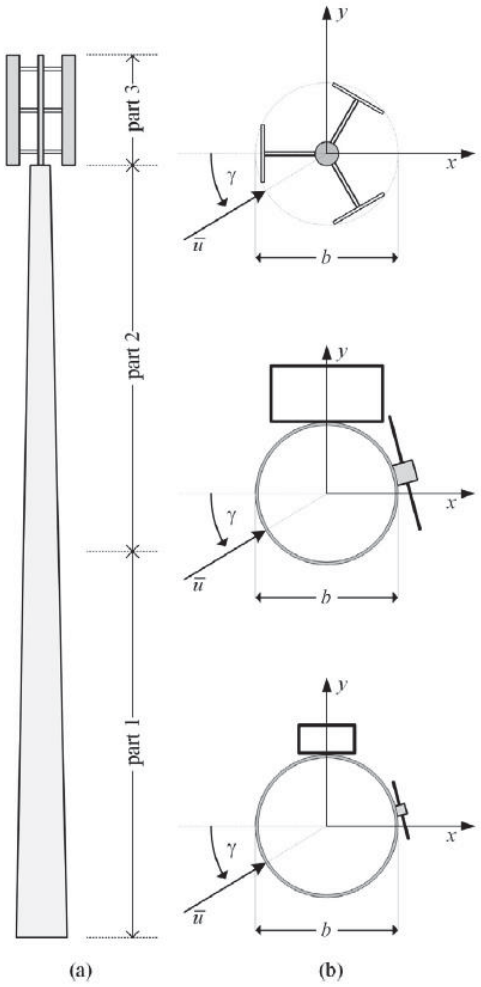

Figure 1: Schematic representations of the antenna mast (a) and of cross-sections at different heights (b).

Dealing with alongwind fatigue analysis, Eqs. (4)-(7) are applied obtaining values in the first column of Tab. I, leading to a mean total damage in the unit time equal to $\bar{D}(1) = 0.0081$ (Eq. (3)), therefore the fatigue life of the structure is predicted as 124 years. On the other hand, dealing with crosswind fatigue analysis, values in the second column of Tab. I are obtained, leading to a mean total damage in the unit time equal to $\bar{D}(1) = 0.0225$, therefore the fatigue life of the structure is predicted as 44 years. In both analyses, the 0 level solutions results comparable, with a slightly larger value in crosswind direction, due to larger standard deviation of crosswind response. The bi-modal factor C_{BM} reduces the 0 level damage taking into account the quasi-static part of the response spectrum; in alongwind assessment the quasi-static part of the response has a high role, strongly reducing the total damage; on the contrary, in crosswind assessment the role of quasi-static part of the response is reduced, prevailing the resonant contribution, thus also the reduction of the total damage is lower. The mean stress corrective factor C_M slightly increases the total damage in both analysis, meaning that the mean response to wind loading is not all that important. Finally, the fatigue curve factor C_{SN} reduces the damage in both cases to the almost same extent, taking into account the cut-off limit of fatigue resistance in steel details. All these considerations highlight that, due to the difference between alongwind and crosswind response spectral characteristics, crosswind turbulence-induced fatigue is widely more critical than alongwind-induced fatigue. In general,

the procedure outlines outcomes in accordance with [28] about the critical issue of exceptional large lift forces on this structure due to mechanical and aerodynamic eccentricities, showing that this also propagates fatigue damage.

	Alongwind buffeting-induced fatigue analysis	Crosswind buffeting-induced fatigue analysis

$\bar{D}(1)$	0.0081	0.0225
Fatigue life	124 years	44 years

Table 1: Outcomes of the application of the procedure to the antenna mast.

5 CONCLUSIONS AND PERSPECTIVES

The resulting model proposed in the paper is a general method of wind-induced fatigue assessment of slender structures, suitable for engineering applications. The proposed procedure can be applied in general situations, concerning different kinds of slender structures of different materials with different possible loading conditions. The model allows to evaluate both alongwind and crosswind turbulence-induced fatigue of structures, leading to reasonable values of fatigue life. A case study is analyzed adopting the proposed procedure, showing its ease of use and effectiveness and highlighting the potential sensitivity of this kind of structures to wind induced fatigue. Crosswind turbulence-induced response and fatigue is actually disregarded in antenna mast structural typology. Engineering calculations idealize antenna masts as polar symmetric structures, even if this is usually not correct due to several peculiar features such as stairs, cable bundles, solar panels, lighting devices, top balcony, antennas and parabolas, and cylinder hulls covering the transmission devices. One or the whole of these elements gives rise to mass and shape eccentricities, which make these structures complex both in mechanical and aerodynamic terms. Such an aspect greatly contributes to make antenna masts sensitive to potential instabilities caused by aeroelastic phenomena and exposed to intense and non-conventional wind-excited vibrations. The proposed method allows to catch the main feature of the fatigue damage phenomenon also in non-conventional situations with quite simple calculation procedure.

Future perspectives are to examine the significance of different contributions to crosswind-induced fatigue damage accumulation, due to the joint action of the oncoming wind turbulence and of the vortex wake. As regards crosswind response of slender structures, engineering procedures estimates separately crosswind maximum response to gust buffeting and to critical vortex shedding conditions. This is reasonable for ULS analysis, but there's no guarantee such assumption would provide reliable outcomes in fatigue analysis (superposition principle does not apply due to the strong non-linearity of the fatigue damage phenomenon). The possibility of separating the effects of the vortex shedding also in fatigue analysis needs to be further investigated, as well as the role of parameters uncertainties in response and in fatigue evaluations.

Keywords: Aeolian vibrations, Cable dynamics, Overhead power lines, Stockbridge dampers.

Abstract. *Suspended conductors and guard wires of overhead electrical transmission lines (OHL) are prone to aeolian vibrations, resulting from the alternate shedding of vortices in the wake of the cable. These vibrations can occur under light to moderate wind and, whenever not properly controlled, can induce wear damage and fatigue failures of the cables. Nonlinear passive control devices such as Stockbridge dampers, hence, are often installed along the line spans to reduce the vibration severity. The technical approach to the assessment of aeolian vibrations is based on the Energy Balance Method (EBM) and relies on the simplifying assumption of mono-modal oscillations. Typical aeolian vibration records, however, clearly show that several modes can be simultaneously excited due to wind variations in time and along the span. Aiming at overcoming the mono-modal vibration assumption of the EBM, in the present paper wind forces are modeled as a narrow band stochastic process, centered around the Strouhal frequency of the conductor and with arbitrary cross-correlation in space. A new approach, based on the well-known smooth endochronic Bouc-Wen model, is developed to describe the hysteretic dynamic response of Stockbridge dampers. An iterative solution strategy based on a stochastically equivalent linear damper model is then developed to investigate aeolian vibrations of a suspended cable with a Stockbridge damper attached along its length.*

1 INTRODUCTION

Suspended conductors and guard wires of overhead electrical transmission lines (OHL) are prone to aeolian vibrations, resulting from the alternate shedding of vortices in the wake of the cable. These vibrations can occur under light to moderate wind and are characterized by small-amplitude (typically less than one diameter) transverse oscillations in the cross-wind direction. Vibration frequencies can be in the broad range of 3-200 Hz, depending on the geometry and axial load of the cable (see e.g. [3, 10, 11, 17]). Whenever not properly controlled, aeolian vibrations can induce wear damage and fatigue failures of the cables (e.g. [11]). Nonlinear passive control devices such as Stockbridge dampers, hence, are often installed along the line spans to reduce the vibration severity (e.g. [9]).

The technical approach currently adopted to assess the aeolian vibration level is based on the Energy Balance Method (EBM) and relies on the simplifying assumption of mono-modal oscillations (see e.g. [13]). Typical aeolian vibration records, however, clearly show that several modes can be simultaneously excited due to wind variations in time and along the span [5]. Aiming at overcoming the mono-modal vibration assumption of the EBM, Hagedorn and coworkers [15, 16] developed a promising analytical model to evaluate aeolian vibrations of overhead electrical transmission lines within a probabilistic framework. Wind forces were modeled as a narrow band stochastic process, centered around the Strouhal frequency of the conductor and with arbitrary cross-correlation in space. Aeolian vibrations of damped conductors, then, were rigorously studied under the simplifying assumption of linear behavior of the attached passive control devices.

Stockbridge dampers, however, are characterized by a markedly hysteretic dynamic behavior [28, 27]. In the present paper, the formulation proposed by Hagedorn and coworkers is extended to fully account for the nonlinearities related to the damper mechanical response. A new approach, based on the well-known smooth endochronic Bouc-Wen model [23, 6], is first developed to describe the hysteretic dynamic response of Stockbridge dampers. An iterative solution strategy based on a stochastically equivalent linear damper model is then developed to investigate aeolian vibrations of a suspended cable with a Stockbridge damper attached along its length. Finally, the main features and the potential drawbacks of the proposed formulation are illustrated with reference to a simple yet meaningful benchmark case.

2 FORMULATION OF THE PROBLEM

2.1 The cable model

Let us consider a cable suspended to horizontal supports and with a Stockbridge damper attached at a distance x_d from its left end-section (see Figure 1). The cable is subject to the combined action of a constant axial force H and a dynamic load $f = f(x,t)$, where x is a coordinate spanning the free length l of the cable and t is the time. Consistently with classic approximate "externally forced models" for VIV of bluff bodies (see e.g. [25]), the force f is herein introduced to describe the fluctuating lift force induced by the alternate shedding of vortices in the wake of the cable. By neglecting both sag-extensibility effects and bending stiffness terms, small planar vibrations are governed by the linear partial differential equation:

$$-H\partial_x^2 w + \beta\partial_t w + \gamma\partial_t^2 w = f - F_d\delta(x - x_d), \quad x, x_d \in (0, l) \tag{1}$$

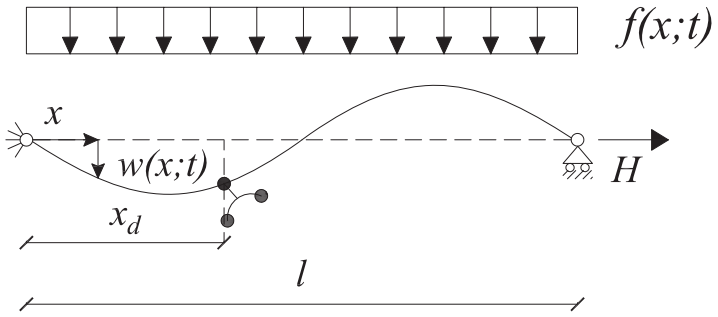

Figure 1: Schematic representation of a suspended cable with length l subject to a constant axial force H and a fluctuating lift force $f(x,t)$. A passive vibration control device is attached at $x = x_d$.

where $w = w(x,t)$ is the transverse displacement of the cable centerline, γ is the mass per unit of length, β is a viscous damping coefficient, F_d is the force exerted by the damper on the cable and the symbol $\delta(\cdot)$ denotes the delta Dirac's function. It is worth noting that the herein adopted viscous damping model is frequently adopted in practical applications and research works, in spite of not being fully compliant with experimental evidence and theoretical arguments (see e.g. [7, 8]). This is felt as a possible drawback of the proposed formulation that will be dealt with in the future.

By neglecting the flexibility of the cable supports, Eq. (1) can be solved for prescribed initial conditions under the homogeneous boundary conditions:

$$w(x=0,t) = w(x=l,t) = 0, \quad \forall t \tag{2}$$

Consistently with the previously stated modeling assumptions, the distributed external force acting on the cable can be defined as:

$$f(x,t) = \frac{1}{2}\rho d U^2 q(x,t) \tag{3}$$

where ρ is the air density, d is the cable diameter, U is the mean wind velocity and $q = q(x,t)$ can be regarded as a space- and time-variable lift coefficient. The lift coefficient can be conveniently modeled (see e.g. [29, 15, 16]) as a stationary stochastic field process with correlation function:

$$R(x_1, x_2, t) = \Psi(x_1, x_2)\, k(t) \tag{4}$$

where $\Psi(x_1, x_2)$ and $k(t)$ are, respectively, a space correlation function and the auto-correlation function of a narrow-band process, centered around the Strouhal frequency

Ω_s, with uni-lateral power spectral density:

$$G_q(\omega) = \frac{1}{2\pi} \int_0^{+\infty} k(t) \exp(-j\omega t)\, dt = \frac{C_{L,rms}^2}{B\Omega_s\sqrt{\pi}} \exp\left[-\left(\frac{1-\frac{\omega}{\Omega_s}}{B}\right)^2\right], \quad \omega \in \mathbb{R}^+ \tag{5}$$

where $C_{L,rms}$ is the root mean square (r.m.s.) value of the lift coefficient (cf. [29]), and B is a parameter controlling the bandwidth of the spectral peak. By denoting as S_t the Strouhal number of the cable, the frequency Ω_s reads:

$$\Omega_s = 2\pi \frac{S_t U}{d} \tag{6}$$

The Strouhal number can be assumed equal to $S_t = 0.185$ for Reynolds numbers and wind conditions typical of overhead electrical line (OHL) conductors [10, 3]. On the other hand, reference values of the r.m.s. lift coefficient $C_{L,rms}$ and the bandwidth parameter B typical of OHL conductors, are site-dependent and have not been explicitly reported in the literature, to the authors' knowledge. They could be, however, obtained through in-situ experimental campaigns (e.g. [5]) or wind tunnel tests on scaled models (e.g. [29]). An aperçu of the expected order of magnitude of the model parameters $C_{L,rms}$ and B can be obtained by looking at the values reported by Vickery and Clark [29] for a slightly tapered cylindrical stack model: $C_{L,rms} = 0.2$ and $B = 0.08 - 0.32$, where the smaller value is associated to smooth flow conditions and the larger one to a turbulence intensity equal to about 10%.

Both Hagedorn and coworkers [15, 16] and Vickery and Clark [29] adopt an exponentially decaying space correlation function $\Psi(x_1, x_2)$ (see Eq. (4)). Hagedorn and coworkers introduce the following definition:

$$\Psi = \Psi_H(x_1, x_2) = \psi(x_1)\,\psi(x_2) \exp\left[-\left(\frac{x_1 - x_2}{\delta_x}\right)^2\right] \tag{7}$$

without providing, however, experimental information on both the function $\psi(x)$ and the space correlation coefficient δ_x . Based on the fitting of experimental measurements on a tapered cylindrical stack model, Vickery and Clark [29] propose the following definition:

$$\Psi = \Psi_{VC}(\bar{r}(x_1, x_2)) = \cos\left(\frac{\eta_2}{\eta_1}\bar{r}\right) \exp\left[-\left(\frac{\bar{r}}{\eta_1}\right)^2\right] \tag{8}$$

where $\eta_1 = 3$, $\eta_2 = 2$ and $\bar{r}$ is the non-dimensional distance between two points of the cable identified by the coordinates x_1 and x_2:

$$\bar{r} = \frac{|x_1 - x_2|}{d} \tag{9}$$

In the absence of experimental information explicitly referred to OHL conductors, the space correlation function proposed by Vickery and Clark [29] will also be adopted in the present work to model the lift forces acting on the suspended cable (Eq. (4)).

Figure 2(a) shows the uni-lateral power spectral density of the lift coefficient, $G_q(\omega)$, obtained through Eq. (5) under the assumption: $C_{L,rms} = 0.2$. The results are shown for two different values of the bandwidth parameter B (i.e. $B = 0.1, 0.3$) and of the Strouhal

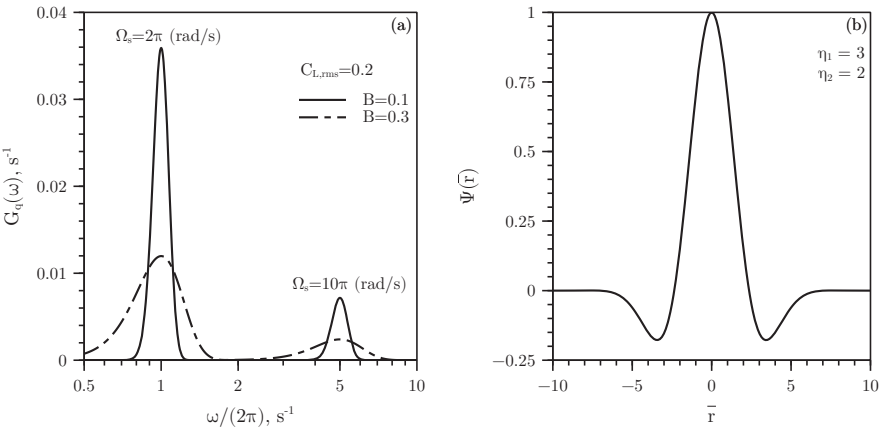

Figure 2: (a) Uni-lateral power spectral density of the lift coefficient, $G_q(\omega)$ (see Eq. (5)). The root mean square value of the lift coefficient is assumed equal to $C_{L,rms} = 0.2$. The function $G_q(\omega)$ is shown for different values of the bandwidth parameter B (i.e. $B = 0.1,\ 0.3$) and of the Strouhal frequency (i.e. $\Omega_s = 2\pi,\ 10\pi$ rad/s). (b) Space coherence function $\Psi(\bar{r})$ (see Eq. 8). Parameters η_1 and η_2 are respectively set equal to $\eta_1 = 3$ and $\eta_2 = 2$.

frequency (i.e. $\Omega_s = 2\pi,\ 10\pi$ rad/s). Increasing values of the bandwidth parameter B, physically related to increasing values of wind turbulence [29], affect the power spectral density of the lift coefficient yielding lower and broader peaks. It is however worth noting that the total energy content of the function $G_q(\omega)$ is not affected by the parameter B, since $\int_{-\infty}^{+\infty} G_q(\omega)\, d\omega = C_{L,rms}^2$.

It is also worth noting that, not only the total energy content is insensitive to the intensity of turbulence, but also so is the space correlation function $\Psi(\bar{r})$ (depicted in Figure 2(b)) due to the definition herein adopted. These aspect do not appear fully consistent with experimental evidences (e.g. [7, 8]). A thorough experimental testing campaign would be necessary to further assess the validity of these assumptions.

2.2 The damper model

The most common type of Stockbridge dampers is made of a metallic clamp, a short metallic strand, also known as "messenger cable," with two inertial bodies attached at its end-sections [10, 9]. The clamp is rigidly attached to the messenger cable and allows connecting the damping device along the span of the OHL conductor. Whenever the clamp undergoes a vertical translation, the two sides of the messenger cables behave as uncoupled flexible cantilevers with lumped translational and rotational masses attached at their ends. Differently than classic linear tuned mass dampers [4], Stockbridge dampers are characterized by a markedly hysteretic dynamic behavior due to the frictional dissipation mechanisms activated by the bending of the messenger cable [28, 9].

In the present work, we will focus on the special, but practically meaningful case, of symmetric Stockbridge dampers (see Figure 3) under the following simplifying assumptions: (i) the clamp can only undergo vertical translations $w_d(t) = w(x = x_d, t)$, and (ii) the rotational inertia of the rigid bodies attached to the end-sections of the messenger cable is neglected. By denoting as $v = v(t)$ the vertical displacement of the tip of the messenger cable with respect to the clamp, the force F_d exerted by the damper on the

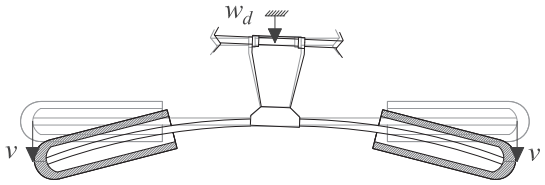

Figure 3: Schematic representation of a symmetric Stockbridge damper. Symbols w_d and v denote, respectively, the vertical translation of the clamp and the relative displacement of the tip of the messenger cable with respect to the clamp.

cable (also see Eq.(1)) can be expressed as [9]:

$$F_d = (2m_d + m_c)\,\ddot{w}_d + 2m_d\ddot{v} \tag{10}$$

where m_d is the mass of each rigid body attached at the tips of the messenger cable, m_c is the mass of the clamp and a dot denotes derivation with respect to time t. The mass of the clamp is often significantly smaller than the total mass of the damper and Eq. (10) can be approximately re-written as:

$$F_d = 2m_d\,(\ddot{w}_d + \ddot{v}) \tag{11}$$

The relative motion of the tip of the messenger cable is governed by the nonlinear ordinary differential equation:

$$m_d\ddot{v} + F_R = -m_d\ddot{w}_d \tag{12}$$

where F_R is the hysteretic restoring force exerted by the messenger cable on the damper mass. Inspired by the work of Pivovarov and Vinogradov [26], a phenomenological modeling approach is adopted to characterize the restoring force F_R based on an application of the well known smooth endochronic Bouc-Wen hysteretic model [23, 6]. To this aim, the five-parameter Bouc-Wen model summarized by Ikhouane and coworkers [20, 21, 22] is herein re-stated in a slightly modified form:

$$\begin{cases} F_R = \alpha k_d v + (1-\alpha)\,k_d v_0 z \\ \dot{z} = \frac{1}{v_0}\left[\dot{v} - \sigma\,|\dot{v}|\,|z|^{n-1}\,z + (\sigma-1)\,\dot{v}\,|z|^n\right] \end{cases} \tag{13}$$

where $z\,(t) \in [-1,1]$ is a non-dimensional hysteretic variable, $k_d > 0$ is the initial stiffness of the first-loading branch of the load-displacement curve $F_R = F_R\,(v(t), z\,(t))$, $\alpha > 0$ is the ratio between the minimum theoretical value of the post-yielding tangent stiffness of the of the first-loading branch and k_d, v_0 is a non-negative parameters with the units of a displacement. Finally, σ and n are non-dimensional parameters controlling the shape of the hysteresis cycles. It is worth noting that, to ensure the stability and the thermodynamic admissibility of the Bouc-Wen model (13), the parameters σ and n should satisfy

the following inequalities: $\sigma \geq 1/2$ and $n \geq 1$ [22]. In order to avoid cumbersome calculations and to keep the model as simple as possible, in the present work the parameters σ and n are both set equal to the unity and the second Eq. in (13) is re-written as:

$$\dot{z} = \frac{1}{v_0} \left(\dot{v} - |\dot{v}| \, z \right) \tag{14}$$

2.3 Non-dimensional formulation

In the following, the governing equations of the problem introduced in Sections 2.1 and 2.2 will be re-stated in a more convenient non-dimensional form. To this aim, let us introduce the non-dimensional space (ξ) and time (τ) variables:

$$\xi = \frac{x}{l} \in [0, 1] \, , \quad \tau = \Omega_c t \in \mathbb{R}^+ \tag{15}$$

where Ω_c is the characteristic frequency of the cable:

$$\Omega_c = \sqrt{\frac{H}{\gamma l^2}} \tag{16}$$

Substitution of Eqs. (15) and (16) in Eq. (1) yields the non-dimensional equation of motion:

$$-\partial_\xi^2 \bar{w} + 2\zeta_c \partial_\tau \bar{w} + \partial_\tau^2 \bar{w} = \bar{f} - \bar{F}_d \delta \left(\xi - \xi_d \right) , \quad \xi, \xi_d \in (0, 1) \tag{17}$$

where $\bar{w} = \frac{w(x(\xi), t(\tau))}{d}$, $\zeta_c = \frac{l^2 \Omega_c}{2H} \beta$, $\bar{f} = \frac{l^2}{Hd} f \left(x \left(\xi \right), t \left(\tau \right) \right) = \frac{\rho l^2 U^2}{2H} q \left(x \left(\xi \right), t \left(\tau \right) \right)$, $\bar{F}_d = \frac{l}{dH} F_d$, and $\xi_d = \frac{x_d}{l}$. The non-dimensional counterpart of the homogeneous boundary conditions (2) reads:

$$\bar{w} \left(\xi = 0, \tau \right) = \bar{w} \left(\xi = 1, \tau \right) = 0, \quad \forall \tau \tag{18}$$

Starting from Eq. (11), the non-dimensional force $\bar{F}_d$ exerted by the damper on the cable can be expressed as:

$$\bar{F}_d = \mu \left(\frac{d^2 \bar{w}_d}{d\tau^2} + \frac{d^2 \bar{v}}{d\tau^2} \right) \tag{19}$$

where $\bar{v} = \frac{v(x(\xi), t(\tau))}{d}$, $\bar{w}_d = \frac{w_d}{d} = \bar{w} \left(\xi = \xi_d, \tau \right)$ and μ is the mass ratio:

$$\mu = \frac{2 m_d}{\gamma \, l} \tag{20}$$

The relative motion of the tip of the messenger cable (see Eqs. (12), (13)-a and (14)), then, is governed by the non-dimensional equations:

$$\begin{cases} \frac{d^2 \bar{v}}{d\tau^2} + \alpha \Theta^2 \bar{v} + (1 - \alpha) \, \Theta^2 \bar{v}_0 \bar{z} = -\frac{d^2 \bar{w}_d}{d\tau^2} \\ \frac{d\bar{z}}{d\tau} = \frac{1}{\bar{v}_0} \left(\frac{d\bar{v}}{d\tau} - \left| \frac{d\bar{v}}{d\tau} \right| \bar{z} \right) \end{cases} \tag{21}$$

where $\Omega_d = \sqrt{\frac{k_d}{m_d}}$, $\Theta = \frac{\Omega_d}{\Omega_c}$, $\bar{v}_0 = \frac{v_0}{d}$ and $\bar{z} = z \left(t \left(\tau \right) \right)$.

3 PROPOSED SOLUTION STRATEGY

In this Section, the response of a bare suspended cable (i.e. a cable without attached damper) to the stochastic wind model defined in Section 2.1 is first considered (Section 3.1). The solution is then extended to the case of a cable equipped with a linear passive damping device (Section 3.2), by following the same approach proposed by Hagedorn and coworkers [15, 16]. Finally, the solution strategy is generalized to deal with the non-linearities that characterize the Stockbridge damper model presented in Section 2.2.

3.1 Response of a bare cable

Let us preliminary consider the response of a bare suspended cable subject to a concentrated force $F_1 = \frac{dH}{l}\exp(j\omega t)$ applied at the generic abscissa $x = x_1$. The non-dimensional equation of motion (see Section 2.3), hence, reads:

$$-\partial_\xi^2\bar{w} + 2\zeta_c\partial_\tau\bar{w} + \partial_\tau^2\bar{w} = \delta(\xi-\xi_1)\exp(j\bar{\omega}\tau), \quad \xi,\xi_1 \in (0,1), \quad \bar{\omega} = \frac{\omega}{\Omega_c} \tag{22}$$

Stationary oscillatory solutions of Eq. (22) satisfying the homogeneous boundary conditions (18) can be expressed as $\bar{w}(\xi,\tau) = \phi(\xi)\exp(j\bar{\omega}\tau)$, where ϕ is the solution of the boundary value problem ("Green's function", see e.g. [18]):

$$\begin{cases} -\phi'' + 2\zeta_c j\bar{\omega}\phi - \bar{\omega}^2\phi = \delta(\xi-\xi_1) \\ \phi(0) = \phi(1) = 0 \end{cases} \tag{23}$$

and an apex denotes derivation with respect to ξ.

Solution of (23) is straightforward and can be expressed, by explicitly highlighting its dependence on both ξ_1 and $\bar{\omega}$,as:

$$\phi(\xi,\xi_1,\bar{\omega}) = \begin{cases} \frac{\sin[\nu(\bar{\omega})\,\xi]\sin[\nu(\bar{\omega})\,(1-\xi_1)]}{\nu(\bar{\omega})\sin[\nu(\bar{\omega})]} & 0 \le \xi \le \xi_1^- \\ \frac{\sin[\nu(\bar{\omega})\,(1-\xi)]\sin[\nu(\bar{\omega})\,\xi_1]}{\nu(\bar{\omega})\sin[\nu(\bar{\omega})]} & \xi_1^+ \le \xi \le 1 \end{cases} \tag{24}$$

with the definition:

$$\nu = \sqrt{\bar{\omega}^2 - 2\zeta_c j\bar{\omega}} \tag{25}$$

Let us consider now a bare cable subject to the the stochastic wind model fully detailed in Section 2.1. Knowledge in closed form of the Green function $\phi = \phi(\xi,\xi_1,\bar{\omega})$ allows one to easily evaluate (see e.g. [24]) the uni-lateral cross power spectral density function $G_w(x_1,x_2,\omega)$ of the transverse displacements ($w = w(x,t)$) as:

$$G_w(x_1,x_2,\omega) = \left(\frac{1}{2}\rho d U^2\right)^2 \frac{l^4}{H^2}\,\bar{C}\left(\xi_1(x_1),\xi_2(x_2),\bar{\omega}(\omega)\right) G_q(\omega) \tag{26}$$

where $G_q(\omega)$ is defined in Eq. (5) and $\bar{C}$ is the two-dimensional integral:

$$\bar{C}(\xi_1,\xi_2,\bar{\omega}) = \int_0^1\int_0^1 \phi^*(\zeta_1,\xi_2,\bar{\omega})\,\phi(\xi_1,\zeta_2,\bar{\omega})\,\bar{\Psi}(\zeta_1,\zeta_2)\,d\zeta_1 d\zeta_2 \tag{27}$$

where an asterisk is adopted to denote complex conjugate values. Finally, the variance of the displacement is a function of the arc-length coordinate x and reads:

$$\sigma_w^2(x) = \int_0^{+\infty} G_w(x, x, \omega)\, d\omega \tag{28}$$

3.2 Response of a cable equipped with a linear damper

By following the same approach adopted in Section 3.2, let us preliminary consider the response of a suspended cable with a damper attached at $x = x_d$ and subject to a concentrated force $F_1 = \frac{dH}{l}\exp(j\omega t)$ applied at the generic abscissa $x = x_1$. The non-dimensional equation of motion (see again Section 2.3), hence, reads:

$$\begin{gathered} -\partial_\xi^2 \bar{w} + 2\zeta_c \partial_\tau \bar{w} + \partial_\tau^2 \bar{w} = -\bar{F}_d \delta(\xi - \xi_d) + \delta(\xi - \xi_1)\exp(j\bar{\omega}\tau), \\ \xi, \xi_d, \xi_1 \in (0,1), \quad \bar{\omega} = \frac{\omega}{\Omega_c} \end{gathered} \tag{29}$$

where $\bar{F}_d$ is the non-dimensional counterpart of the force exerted by the damper on the cable.

Under the assumption of linear behavior of the attached damper, the non-dimensional force of the damper and clamp displacement can be respectively expressed as:

$$\bar{F}_d(\tau) = \hat{F}_d \exp(j\bar{\omega}\tau) \quad \text{and} \quad \bar{w}_d(\tau) = \hat{W}_d \exp(j\bar{\omega}\tau) \tag{30}$$

Moreover, the following linear relation can always be introduced:

$$\hat{F}_d = Z_{d,FW}(\bar{\omega})\, \hat{W}_d \tag{31}$$

where $Z_{d,FW} = Z_{d,FW}(\bar{\omega})$ is the non-dimensional frequency response function of the linear damper. Substitution of Eqs. (30) and (31) in Eq. (29) yields:

$$\begin{gathered} -\partial_\xi^2 \bar{w} + 2\zeta_c \partial_\tau \bar{w} + \partial_\tau^2 \bar{w} = \left[-Z_{d,FW}(\bar{\omega})\, \hat{W}_d\, \delta(\xi - \xi_d) + \delta(\xi - \xi_1)\right] \exp(j\bar{\omega}\tau), \\ \xi, \xi_d, \xi_1 \in (0,1), \quad \bar{\omega} = \frac{\omega}{\Omega_c} \end{gathered} \tag{32}$$

Stationary oscillatory solutions of Eq. (32) satisfying the homogeneous boundary conditions (18) can be expressed as $\bar{w}(\xi, \tau) = \phi_d(\xi)\exp(j\bar{\omega}\tau)$, where ϕ_d is the solution of the boundary value problem ("Green's function"):

$$\begin{cases} -\phi_d'' + 2\zeta_c j\bar{\omega}\phi_d - \bar{\omega}^2\phi_d = -Z_{d,FW}(\bar{\omega})\, \hat{W}_d \delta(\xi - \xi_d) + \delta(\xi - \xi_1) \\ \phi_d(0) = \phi_d(1) = 0 \end{cases} \tag{33}$$

and an apex denotes derivation with respect to ξ. By exploiting the definition of the Green's function $\phi = \phi(\xi, \xi_1, \bar{\omega})$ introduced in the previous Section (Section 3.1, Eq. (23)) and the superposition principle, it can be easily shown that:

$$\hat{W}_d = \frac{\phi(\xi_d, \xi_1, \bar{\omega})}{1 + \phi(\xi_d, \xi_d, \bar{\omega})\, Z_{d,FW}(\bar{\omega})} \tag{34}$$

and

$$\phi_d\left(\xi,\xi_1,\xi_d,\bar{\omega}\right)=\frac{-Z_{d,FW}\left(\bar{\omega}\right)\phi\left(\xi_d,\xi_1,\bar{\omega}\right)\phi\left(\xi,\xi_d,\bar{\omega}\right)}{1+\phi\left(\xi_d,\xi_d,\bar{\omega}\right)Z_{d,FW}\left(\bar{\omega}\right)}+\phi\left(\xi,\xi_1,\bar{\omega}\right) \tag{35}$$

The response of the suspended cable subject to the stochastic wind model, defined in Section 2.1, then, can be calculated through Eqs. (26)-(28) by simply replacing the Green function ϕ with ϕ_d.

3.3 Response of a cable equipped with a Stockbridge damper

Let us now consider the case of a suspended cable with a Stockbridge damper attached at $x=x_d$. The dynamic behavior of the damper is described through the non-linear model detailed in Section 2.2, based on an application of the Bouc-Wen hysteretic model. The response of the coupled cable+damper system subject to the stochastic wind model defined in Section 2.1 can be sought through an iterative solution strategy based on: (i) the definition of a stochastically equivalent damper model and (ii) the solution strategy already developed in Section 3.2 under the simplifying assumption of linearity of the damper behavior.

The motion of the Stockbridge damper subjected to a prescribed clamp displacement $w_d\left(t\right)=w\left(x=x_d,t\right)$ is governed by the non-dimensional system of Eqs. (21). Under a stochastic loading, the motion of the clamp is a stochastic process with uni-lateral power spectral density $G_{wd}=G_{wd}\left(\omega\right)=G_w\left(x_1=x_d,x_2=x_d,\omega\right)$ (see Eq. (26)) and variance $\sigma_{wd}^2=\sigma_w^2\left(x=x_d\right)$ (Eq. (28)). A stochastically equivalent linear system of equations describing the motion of the Stockbridge damper, then, can be defined by replacing the second equation in (21) with a linear evolution law for the hysteretic variable $\bar{z}$, i.e.:

$$\begin{cases}\frac{d^2\bar{v}}{d\tau^2}+\alpha\Theta^2\bar{v}+\left(1-\alpha\right)\Theta^2\bar{v}_0\bar{z}=-\frac{d^2\bar{w}_d}{d\tau^2}\\ \frac{d\bar{z}}{d\tau}=\frac{1}{\bar{v}_0}\left(c_e\frac{d\bar{v}}{d\tau}+k_e\bar{z}\right)\end{cases} \tag{36}$$

The linearization coefficients c_e and k_e can be evaluated in order to minimize the expectation of the squared error $\epsilon^2=\left(\frac{d\bar{v}}{d\tau}-\left|\frac{d\bar{v}}{d\tau}\right|\bar{z}-c_e\frac{d\bar{v}}{d\tau}-k_e\bar{z}\right)^2$. By assuming a joint gaussian probability density function for the variables $\left(\bar{v},\frac{d\bar{v}}{d\tau},\bar{z}\right)$, the coefficients c_e and k_e can be evaluated as a special case of the more general expressions proposed by Hurtado and Barbat [19] and read:

$$c_e=1-\frac{2\sqrt{2}}{\pi}\Gamma\left(\frac{3}{2}\right)\sigma_z\rho_{\dot{v}z} \tag{37}$$

$$k_e=-\frac{2\sqrt{2}}{\pi}\Gamma\left(\frac{3}{2}\right)\sigma_{\dot{v}} \tag{38}$$

where σ_z, $\sigma_{\dot{v}}$ and $\rho_{\dot{v}z}$ denote the standard deviations and the correlation coefficient of the variables $\bar{v}$ and $\bar{z}$. The variables σ_z, $\sigma_{\dot{v}}$ and $\rho_{\dot{v}z}$ can be evaluated, for a prescribed motion of the clamp, by solving the linear system of equations (36). By following the approach proposed by Giaralis ([14], Section 6.2.3, pp. 151-157) the following equations can be easily derived:

$$\sigma_{\dot{v}}^2=\int_0^{+\infty}A\left(\bar{\omega}\right)A^*\left(\bar{\omega}\right)\bar{\omega}^6\frac{\Omega_c G_{wd}\left(\omega\left(\bar{\omega}\right)\right)}{d^2}d\bar{\omega} \tag{39}$$

$$\sigma_z^2 = \int_0^{+\infty} B\left(\bar{\omega}\right) B^*\left(\bar{\omega}\right) \bar{\omega}^4 \frac{\Omega_c G_{wd}\left(\omega\left(\bar{\omega}\right)\right)}{d^2} d\bar{\omega} \tag{40}$$

$$\rho_{\dot{v}z} = -\frac{k_e}{c_e} \cdot \frac{\sigma_z}{\sigma_{\dot{v}}} \tag{41}$$

with the definitions:

$$A\left(\bar{\omega}\right) = \frac{\frac{-k_e}{\bar{v}_0} + j\bar{\omega}}{\left(\alpha\Theta^2 - \bar{\omega}^2\right)\left(\frac{-k_e}{\bar{v}_0} + j\bar{\omega}\right) + j\bar{\omega}\left(1-\alpha\right)\Theta^2 c_e} \tag{42}$$

$$B\left(\bar{\omega}\right) = \frac{j\bar{\omega}c_e}{\left(\alpha\Theta^2 - \bar{\omega}^2\right)\left(\frac{-k_e}{\bar{v}_0} + j\bar{\omega}\right) + j\bar{\omega}\left(1-\alpha\right)\Theta^2 c_e} \tag{43}$$

Finally, after some straightforward calculations, herein omitted for the sake of conciseness, the non-dimensional frequency response function of the stochastically equivalent linear damper (see Eq. (31)) can be expressed as:

$$Z_{d,FW}\left(\bar{\omega}\right) = -\mu\bar{\omega}^2\left(1 + A\left(\bar{\omega}\right)\right) \tag{44}$$

Once $Z_{d,FW}\left(\bar{\omega}\right)$ is known, a chain substitution into Eqs. (35), (27), (26) and(28) allows one to find a new uni-lateral power spectral density $G_{wd}\left(\omega\right)$ and variance σ_{wd}^2. The process is iterated until convergence on $\sigma_w^2\left(x\right)$ is obtained within a prescribed tolerance. This fixed point algorithm is known to be less efficient than a Newton-Raphson approach [2] but has been sufficiently efficient to solve the problem at hand without any big convergence issues.

4 APPLICATION

In the following, the proposed modeling procedure is used to investigate the dynamic response of a benchmark OHL span already studied elsewhere (see e.g. [12, 13]). The length of the span is 450 m and the cable is a ACSR Bersfort 48/7 conductor (diameter $d = 35.6$ mm, mass per unit of length $\gamma = 2.375$ kg/m, Rated Tensile Strength $RTS = 180$ kN) subject to an axial force $H = 0.2\,RTS = 36$ kN. The non-dimensional viscous damping coefficient ζ_c, that approximately account for both the aerodynamic and internal damping of the cable, is assumed equal to $\zeta_c = 0.001$. It is worth noting that, although the order of magnitude of this value seems to be consistent with some experimental data reported in the literature (e.g. [1]), as already noticed in Section 2.1 the adopted viscous damping model is not expected to be fully compliant with all experimental evidences and theoretical arguments of the literature (see e.g. [7, 8]).

A symmetric Stockbridge damper that was experimentally tested by Sauter and Hagedorn [27, 28] is assumed to be applied at the 5% and 10% of the span (i.e. at the non-dimensional arc-length coordinate $\xi_d = 0.05$ and $\xi_d = 0.10$). The mass attached at the both tips of the messenger cable is equal to $m_d = 0.856$ kg, leading to a mass ratio $\mu = 8 \cdot 10^{-4}$ (Eq. (20)).

Sauter and Hagedorn [27, 28] tested the damper on a shaker with sweep tests in frequency at two different constant values of the clamp velocity ($\dot{w}_d$), namely 0.05m/s and 0.2 m/s. From these tests the parameter of the proposed Bouc-Wen model of the damper (see Section 2.2) were identified to match the experimental data obtained for the clamp velocity 0.2 m/s. The identified model parameters are: $k_d = 8$ N/mm, $\alpha = 0.25$ and

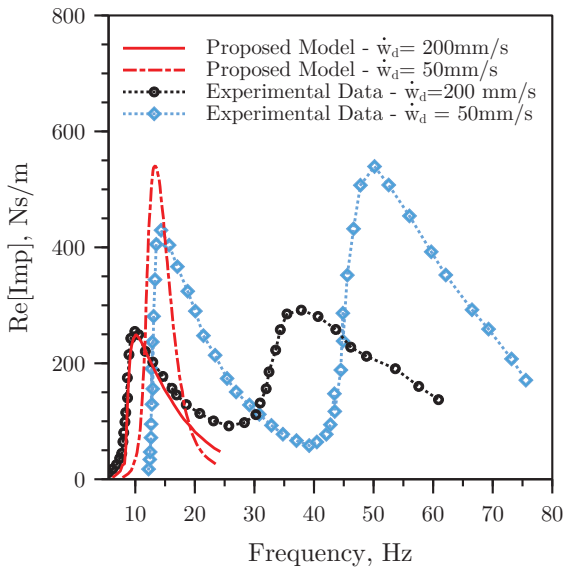

Figure 4: Real part of the impedance curve of the Stockbridge damper tested on a shaker for sweep tests in frequency with an imposed vertical translation of the clamp having a constant value of the clamp velocity equal to $\dot{w}_d = 0.05$ m/s and$\dot{w}_d = 0.2$ m/s. Comparison between the results of the proposed non-linear damper model (see Section 2.2) and experimental data from [27].

$v_0 = 2$ mm. The required numerical simulations were performed by applying a sinusoidal motion of the clamp with a frequency undergoing a linear sweep from 0 to 50 Hz during a total duration of 100 s. The non-linear equations of motion of the damper, then, were numerically integrated at constant time step $\Delta t = 10^{-5}$ s with a Newmark constant acceleration time-stepping strategy. Iterative corrections were performed through a standard Newton-Raphson scheme at each step.

Figure 4 shows the comparison between experimental results and numerical results in terms of the real part of the impedance function of the damper. It is worth noting that the predictions of the proposed damper model match very well the experimental results not only for the clamp velocity used in the BW identification process ($\dot{w}_d = 0.2$ m/s), but also for $\dot{w}_d = 0.05$m/s.

Based on the input data listed above, application of the proposed procedure leads to the results depicted in Figure 5.

Figure 5(a) reports for a line without dampers the standard deviation of the displacement ad the line midspan, expressed as a fraction of the conductor diameter, as a function of the mean wind velocity. Results are reported for two different values of the bandwidth parameter B. Figure 5(b) reports the same quantities for $B = 0.1$ and a line with a damper located at 5% the span (grey broken line), 10% the span (grey solid line). The results referred to the base cable (black solid line) are also reported to facilitate compartison. From this figure some comments can be drawn. As it can be appreciated, (a) in spite the damper was not optimized, it is nevertheless effective over a wide range of wind velocities; (b) at higher wind velocities, the damper is less effective, as it was expected since the proposed model does not account for the second resonance peak shown in Figure 4 (e.g. at 37 Hz and 55 Hz for the 50 mm/s and 200 mm/s clamp velocity values, respectively).

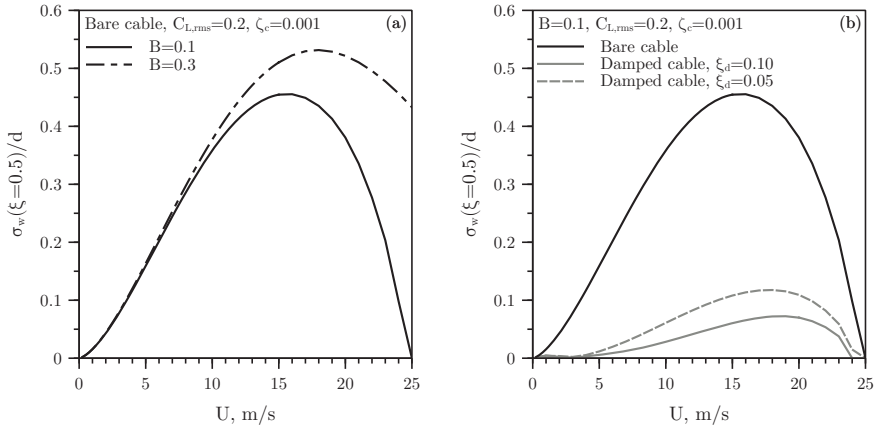

Figure 5: Standard deviation of the cable response at midspan, expressed as a fraction of the cable diameter (a) without attached Stockbridge damper, (b) with attached Stockbridge damper. The curve $B = 0.1$ is similar in both plots to facilitate comparison.

5 CONCLUSIONS

A stochastic and continuous model of aeolian vibrations of overhead electrical line conductors equipped with Stockbridge dampers has been presented in this paper. Focusing on small-amplitude planar transverse vibrations, suspended cables were modeled through the classic taut-string model. Consistently with classic approximate "externally forced models" for vortex induced vibrations (VIV) of bluff bodies, the wind forces acting on the continuous cable model were described as a narrow band stochastic process, centered around the Strouhal frequency of the conductor and with arbitrary cross-correlation in space. A new approach, based on the well-known smooth endochronic Bouc-Wen model, was developed to describe the hysteretic dynamic response of Stockbridge dampers. An iterative solution strategy based on a stochastically equivalent linear damper model, then, was presented to investigate aeolian vibrations of a suspended cable with a Stockbridge damper attached along its length. Finally, the main features and the potential drawbacks of the proposed formulation were illustrated with reference to a simple yet meaningful benchmark case.

Keywords: Tuned mass damper inerter, optimal passive vibration control, wind-excited tall buildings, vortex shedding, occupants' comfort, floor acceleration.

Abstract. A local structural modification, namely top-storey softening, is herein considered in conjunction with optimally tuned top-floor tuned mass damper inerter (TMDI) for improved serviceability performance in mid-to-high rise buildings (host structures). The focus is to reduce floor accelerations on typical core-frame host structures with rectangular footprint due to wind-induced vortex shedding (VS) effects causing occupants' discomfort. This aim is achieved by formulating an optimal TMDI tuning problem in which TMDI inertial and top-storey host structure properties (i.e., attached mass and inertance, and top-storey height) are treated as design variables, to a case-study building aiming to minimize peak floor acceleration in the across-wind direction. The optimal TMDI tuning problem is numerically solved for a wide range of design variables for a 34-storey composite core-frame building subject to stochastic spatially-correlated wind-force field accounting for VS effects. A planar low-order dynamical model capturing faithfully modal properties of the 34-storey building is developed to facilitate computational work and parametric investigation. It is found that top-storey stiffness reduction, herein regulated through storey height, not only relaxes attached TMDI mass/weight requirements, but also reduces TMDI stroke, and inerter force for fixed performance and inertance. It is concluded that by leveraging inertance and top-storey stiffness, the considered solution can efficiently control VS-induced floor acceleration with small additional gravitational (added weight) and horizontal damping forces to the satisfaction of standard code requirements for occupants comfort.

1 INTRODUCTION

Passive dynamic vibration absorbers, including tuned mass-dampers (TMDs), have been widely used for mitigating wind-induced vibrations in tall buildings (e.g., [1,2]). A typical linear TMD comprises a mass attached towards the top of the building (host structure) via linear stiffeners and dampers [3]. The TMD is tuned to the first natural frequency of the building aiming to dampen the fundamental lateral mode shape which tends to be mostly excited due to resonance with the frequency of wind-induced forces. Such forces typically develop in the across-wind direction of tall buildings with rectangular foot-print due to vortex shedding (VS) [4] and may induce large floor accelerations causing occupants' discomfort [5] and, consequently, serviceability structural failure. This consideration becomes critical for slender tall buildings and governs their design [6]. Meanwhile, the applicability of passive TMDs for wind-induced vibration suppression is limited by structural and economical considerations. This is because their motion control potential relies on the attached mass (i.e., the larger it is, the more effective the TMD becomes [7]), but constraints apply to the TMD weight that can be safely accommodated at the top floor of slender/tall buildings while TMD up-front cost increases proportionally with its mass [8].

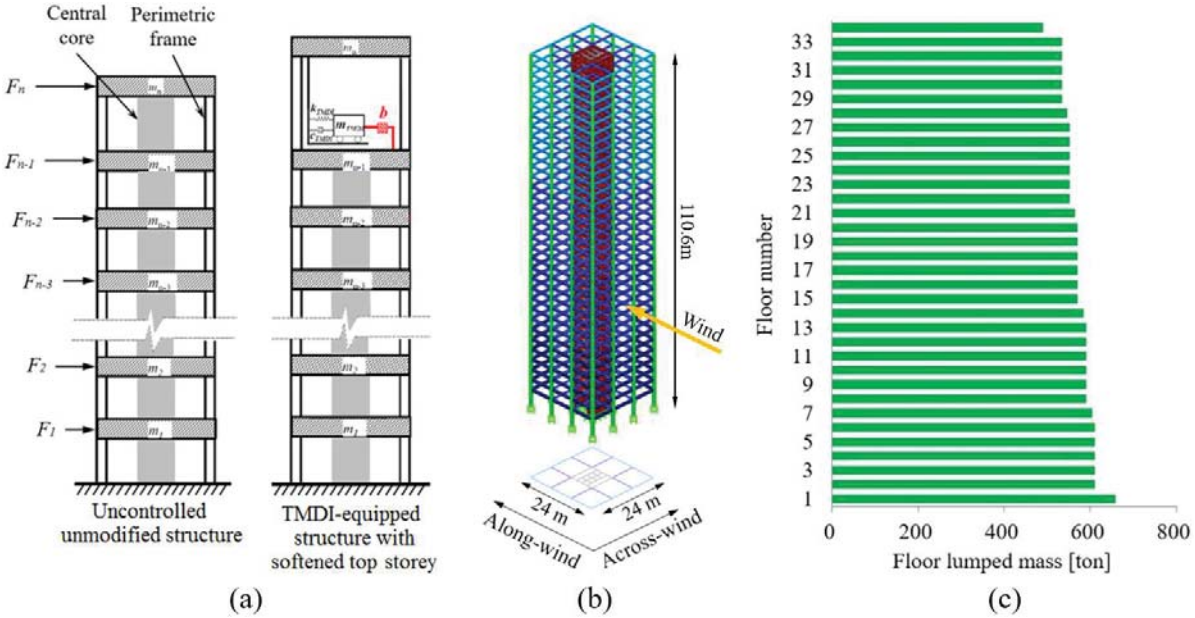

Figure 1 (a) Schematic of a TMDI-equipped planar coupled core-frame building with soft top-storey, (b) case-study 34-storey building, and (c) lumped floor mass distribution.

Recently, it has been shown [9,10] that the incorporation of an inerter to TMD-equipped tall buildings in the so-called tuned mass damper inerter (TMDI) configuration enhances serviceability performance against VS-induced wind forces without increasing the required attached weight, thus overcoming the above TMD limitations. Specifically, the inerter is defined as a linear mechanical element that resists relative acceleration through the inertance constant assuming mass units (kg) [11]. In the TMDI, originally proposed for seismic protection of building structures [12-14], an inerter element is used to link the TMD attached mass to a different floor from the one that the TMD is attached to. It is then found [9,10] that improved floor acceleration mitigation is achieved in tall wind-excited TMDI-equipped buildings by increasing the inertance, which scales-up independently of physical mass in prototyped inerter devices [15,16], and, even more so, by letting the inerter span more than one storey. Nevertheless, for

routine slender mid-to-high-rise buildings with 20-40 storeys, TMDI configuration with inerter spanning more than one floor is not as practical as in the case of tall landmark structures (e.g., [2]) since occupying high-premium space across several upper floors of such structures for accommodating a control device is not cost effective. To this end, this paper explores the potential of a local structural modification, top-storey softening, in conjunction with top-storey TMDI placement as shown in Figure 1(a), to mitigate floor accelerations in the across-wind direction of VS-sensitive buildings with no more than 40 stories. Notably, the above vibration mitigation solution is practically meritorious for such buildings in which standard coupled core-frame systems are used for lateral wind load resistance [17]. This is because: (1) the considered solution does not utilize premium space since the TMDI is fully contained within a single (last) floor which is commonly reserved for accommodating various building services, and (2) top-storey softening can be readily achieved by simple local modifications such as discontinuation of the core at the last floor as well as increasing the top-storey height as depicted in Figure 1(a).

Herein, the effectiveness of top-storey softening to improve TMDI motion control efficiency is numerically illustrated with the aid of a 34-storey composite core-frame building structure shown in Figure 1(b) subject to a parametrically defined stochastic across-wind force model accounting for VS effects. An optimal TMDI design problem is formulated and numerically solved to minimize floor acceleration (i.e., occupants' comfort criterion) of the case-study building in which top-floor height along with TMDI inertial properties (i.e., mass and inertance) are explicitly taken into consideration. Optimal TMDI-equipped structure performance is assessed in terms of floor acceleration, TMDI stroke, and damping and inerter forces and attention is focused to quantify gains in the required attached mass and to check for occupants' comfort criteria. The presentation begins with a brief description of the case-study building and its numerical modelling enabling efficient TMDI incorporation and dynamic analysis.

2 CASE-STUDY BUILDING STRUCTURE AND NUMERICAL MODELLING

The adopted structure is 110.6m high and has square 24m-by-24m footprint as shown in Figure 2(b). The lateral load-resisting structural system is composite consisting of a perimetric three-bay per side steel moment resisting frame (MRF) and a central reinforced concrete (r/c) core. MRF members are rigidly connected and have hollow rectangular sections with varying dimensions along the building height. The r/c core has 8m-by-8m plan-view dimensions and consists of outer wall segments whose thickness reduces progressively with building height and inner (stiffening) wall segments with same thickness along the building height. Hinged primary beams are used to couple the MRF with the core at each floor level which do not participate in resisting lateral loads and floor slabs behave as rigid diaphragms. The total mass of the structure accounting for dead and live loads, M_{tot}, is 92830tons and is distributed at each floor level as shown in Figure 1(c). To expedite computational work required in TMDI optimal design, a planar dynamic model with 34 degrees of freedom (DOFs) corresponding to the uncoupled lateral in-plane translations of rigid slabs along the across-wind direction of the case-study building is defined in terms of a diagonal mass matrix, $\mathbf{M}_s \in \mathbb{R}^{34\times34}$, and full stiffness and damping matrices, $\mathbf{K}_s \in \mathbb{R}^{34\times34}$ and $\mathbf{C}_s \in \mathbb{R}^{34\times34}$, respectively. The main diagonal of the $\mathbf{M}_s$ matrix is populated with the lumped floor masses of Figure 1(c). Further, the stiffness matrix $\mathbf{K}_s$ is obtained from a detailed linear finite element (FE) model of the lateral load-resisting structural system of the building developed in SAP2000® software package. The accuracy of the modal properties (mode shapes and natural frequencies) of the 34-DOF dynamic model is verified against modal analysis results from the detailed FE model. Lastly, the inherent structural damping is incorporated in the modelling through a full damping matrix $\mathbf{C}_s$ obtained by assuming

modal damping ratios $\xi_j = 1\%$ for $j = 2,3,4$; $\xi_j = 2\%$ for $j = 5,6,7$; $\xi_j = 4\%$ for $j = 8,9,10$; $\xi_j = 8\%$ for $j = 11,...,20$; and $\xi_j = 16\%$ for $j = 21,...,34$.

3 WIND EXCITATION MODEL

The input wind action to the 34-DOF dynamic model capturing the across-wind dynamics of the case-study building is herein represented by the stochastic across-wind force model developed in [2] for buildings with rectangular footprint. This wind forcing model is based on wind tunnel testing data and accounts for both the turbulence and the VS components of the wind force in the across-wind direction. It is defined by a zero-mean stationary Gaussian spatially correlated random field represented in frequency domain by a full power spectral density (PSD) matrix. For the 34-DOF dynamic model, a $\mathbf{S}_{\mathbf{FF}}^{34} \in \mathbb{R}^{34\times 34}$ wind force PSD matrix is determined upon spatial discretization of the wind random field at each building floor. The assumed mean wind velocity profile is plotted in Figure 2(a). It follows the Eurocode-compliant logarithmic law [18] and terrain category IV (i.e., area in which at least 15% of the surface is covered with buildings and their average height exceeds 15 m) and is defined for basic wind velocity of 22m/s (i.e., 10mins mean wind velocity at 10m height above open flat terrain). For illustration, wind force PSDs computed by the model in [2] at four different floor slab heights are plotted in Figure 2(b) following the assumed mean wind velocity profile.

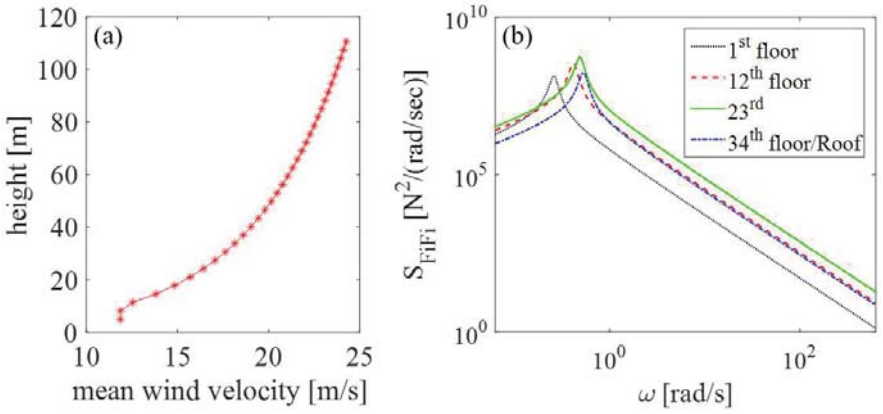

Figure 2. Assumed wind excitation model: (a) mean wind velocity profile, (b) power spectral density functions (PSDs) of across-wind forces acting at different floor levels of the case-study building.

4 TMDI-EQUIPPED STRUCTURE AND FREQUENCY DOMAIN ACROSS-WIND RESPONSE ANALYSIS

Mathematically, a top-floor TMDI is added to the 34-DOF system model following [9,10] to yield a 35-DOF augmented model with mass, $\mathbf{M} \in \mathbb{R}^{35\times 35}$, damping, $\mathbf{C} \in \mathbb{R}^{35\times 35}$, and stiffness, $\mathbf{K} \in \mathbb{R}^{35\times 35}$, matrices written as

$$\mathbf{M} = \begin{bmatrix} m_1 & 0 & \cdots & \cdots & \cdots & 0 \\ & m_2 & \cdots & \cdots & \cdots & \vdots \\ & & \ddots & 0 & 0 & 0 \\ & & & m_{33}+b & 0 & -b \\ & SYM & & & m_{34} & 0 \\ & & & & & m_{TMDI}+b \end{bmatrix}, \quad \mathbf{C} = \begin{bmatrix} c_{1,1} & c_{1,2} & \cdots & \cdots & c_{1,34} & 0 \\ & c_{2,2} & \cdots & \cdots & \vdots & \vdots \\ & & \ddots & c_{32,33} & c_{32,34} & 0 \\ & & & c_{33,33} & c_{33,34} & 0 \\ & SYM & & & c_{34,34}+c_{TMDI} & -c_{TMDI} \\ & & & & & c_{TMDI} \end{bmatrix}, \quad (1)$$

$$\text{and } \mathbf{K} = \begin{bmatrix} k_{1,1} & k_{1,2} & \cdots & \cdots & k_{1,34} & 0 \\ & k_{2,2} & \cdots & \cdots & \vdots & \vdots \\ & & \ddots & k_{32,33} & k_{32,34} & 0 \\ & & & k_{33,33} & k_{33,34} & 0 \\ & SYM & & & k_{34,34}+k_{TMDI} & -k_{TMDI} \\ & & & & & k_{TMDI} \end{bmatrix},$$

in which $m_k = \mathbf{M}_s[k,k]$, $c_{k,l} = \mathbf{C}_s[k,l]$, and $k_{k,l} = \mathbf{K}_s[k,l]$ where k,l=1,2,…,34 are the elements of the mass, damping, and stiffness matrices of the uncontrolled host structure, respectively, while the 35-th DOF corresponds to the lateral TMDI mass displacement. Further, in the previous expressions, m_{TMDI} is the TMDI mass attached to the top (34th) floor via a spring with k_{TMDI} stiffness in parallel with a linear dashpot with damping coefficient c_{TMDI}, and b is the inertance of the inerter element highlighted in red in Fig. 1(a), connecting the TMDI mass to the penultimate (33rd) floor.

Response displacement, velocity, and acceleration PSD matrices of the TMDI-equipped structure subject to the wind force PSD matrix defined in section 3 can be obtained as

$$\mathbf{S}_{\mathbf{xx}}(\omega) = \mathbf{B}(\omega)^{*}\,\mathbf{S}_{\mathbf{FF}}(\omega)\mathbf{B}(\omega), \quad \mathbf{S}_{\dot{\mathbf{x}}\dot{\mathbf{x}}}(\omega) = \omega^2\mathbf{S}_{\mathbf{xx}}(\omega), \quad \text{and} \quad \mathbf{S}_{\ddot{\mathbf{x}}\ddot{\mathbf{x}}}(\omega) = \omega^4\mathbf{S}_{\mathbf{xx}}(\omega) \tag{2}$$

respectively. In Eq. (2), $\mathbf{S}_{\mathbf{FF}}(\omega) \in \mathbb{R}^{35\times 35}$ is the wind force PSD matrix $\mathbf{S}_{\mathbf{FF}}^{34}$ augmented by a bottom zero row and a right-most zero column corresponding to the TMDI displacement DOF as the TMDI is internally housed and not subjected to any wind load. Further, the "*" superscript denotes complex matrix conjugation, and the transfer matrix **B** is given as

$$\mathbf{B}(\omega) = \left[\mathbf{K} - \omega^2\mathbf{M} + i\omega\mathbf{C}\right]^{-1} \tag{3}$$

where, $i = \sqrt{-1}$, and the "-1" superscript denotes matrix inversion. Next, response displacement, velocity, and acceleration variance of the k-th floor are obtained as

$$\sigma_{x_k}^2 = \int_0^{\omega_{\max}} S_{xx}[k,k]\,d\omega, \quad \sigma_{\dot{x}_k}^2 = \int_0^{\omega_{\max}} S_{\dot{x}\dot{x}}[k,k]\,d\omega, \quad \text{and} \quad \sigma_{\ddot{x}_k}^2 = \int_0^{\omega_{\max}} S_{\ddot{x}\ddot{x}}[k,k]\,d\omega, \tag{4}$$

respectively, where $\omega_{\max}$ is a cut-off frequency above which the energy of the underlying processes is negligible. Moreover, the variance of the relative response displacement, velocity, and acceleration between floors/DOFs k and l are obtained by

$$\begin{aligned} \sigma_{x_{k,l}}^2 &= \sigma_{x_k}^2 + \sigma_{x_l}^2 - 2\int_0^{\omega_{\max}} S_{xx}[k,l]\,d\omega, \\ \sigma_{\dot{x}_{k,l}}^2 &= \sigma_{\dot{x}_k}^2 + \sigma_{\dot{x}_l}^2 - 2\int_0^{\omega_{\max}} S_{\dot{x}\dot{x}}[k,l]\,d\omega, \text{ and} \\ \sigma_{\ddot{x}_{k,l}}^2 &= \sigma_{\ddot{x}_k}^2 + \sigma_{\ddot{x}_l}^2 - 2\int_0^{\omega_{\max}} S_{\ddot{x}\ddot{x}}[k,l]\,d\omega. \end{aligned} \tag{5}$$

Ultimately, peak response quantities are estimated by multiplying the square root of the variances in Eqs. (4) and (5) with the peak factor g given by the empirical formula [18]

$$g = \sqrt{2ln(\eta T_{wind})} + \frac{0.577}{\sqrt{2ln(\eta T_{wind})}}, \tag{6}$$

where $\eta=2\pi/\omega_{n(1)}$ and T_{wind} is the time duration of exposure to the wind action. In the ensuing numerical work, T_{wind} is taken equal to 3600s (i.e., one hour of stationary wind excitation is assumed).

5 OPTIMAL TMDI DESIGN WITH TOP-STOREY SOFTENING FOR SERVICEABILITY PERFORMANCE

To investigate the potential of top-storey softening in TMDI-equipped buildings for enhanced serviceability performance under wind excitation, the properties of the TMDI in Fig. 1(a) are optimally designed to mitigate floor accelerations in the case-study building subject to the wind forces defined in section 3. To this aim, an optimal TMDI tuning problem is formulated taking as the objective function (OF) to be minimized the peak floor acceleration of the highest occupied of the case-study building (i.e., the 32nd floor). That is,

$$\text{OF}=g\sigma_{\ddot{x}_{32}}. \tag{7}$$

The problem has 5 design variables (DVs), namely the top-storey height H_{top}, the mass ratio μ, the inertance ratio β, the TMDI frequency ratio υ_{TMDI}, and the TMDI damping ratio ξ_{TMDI}. The last four DVs are defined as

$$\mu=\frac{m_{TMDI}}{M_{tot}},\ \beta=\frac{b}{M_{tot}},\ \upsilon_{TMDI}=\frac{\sqrt{\frac{k_{TMDI}}{(m_{TMDI}+b)}}}{\omega_1}\ \text{and}\ \xi_{TMDI}=\frac{c_{TMDI}}{2\sqrt{(m_{TMDI}+b)k_{TMDI}}}, \tag{8}$$

where ω_1 is the first natural frequency of the uncontrolled structure. Then, optimal primary DVs, υ_{TMDI} and ξ_{TMDI}, are sought that minimize the OF given values of the secondary DVs, H_{top}, μ, and β. (secondary design parameters). The optimization problem is numerically solved for the case-study structure using a pattern search algorithm [19] with iteratively updated search range of the primary variables hard-coded in MATLAB®.

6 PERFORMANCE ASSESSMENT OF OPTIMAL TMDI-EQUIPPED STRUCTURE WITH SOFTENED TOP-STOREY

In this section, numerical results are furnished to demonstrate the effectiveness of optimally designed TMDI in containing VS induced vibrations in the case-study building exposed to the PSD wind force matrix as top-floor lateral stiffness reduces. To this aim, TMDIs with different inertance ratios (β = 0% (TMD), 2%, and 10%) are examined for fixed attached mass μ=0.1% while the top-storey of the case-study building is softened laterally by discontinuing the r/c core at the penultimate (33rd) storey (see Fig. 1(a)) and by varying its height within H_{top}= [4.0, 6.0] (m) interval.

Figure 3(a) reports percentage reduction factor (RF) of peak floor acceleration at the 32nd floor of optimal TMDI-equipped structure with respect to the uncontrolled case-study building with coreless top-storey for three different inertance ratios as a function of top-storey lateral stiffness. The latter is given as a percentage of the top-storey stiffness of the case-study structure without r/c core at the 33rd storey and H_{top}=3.2m. It is observed that optimal TMDI capability to suppress floor accelerations increases appreciably and monotonically as the top-storey stiffness reduces for fixed inertance. On the antipode, for the TMD case (i.e., no inerter and β = 0%) acceleration RFs remain practically constant with top-storey flexibility. These results reveal that the presence of the inerter enables improved TMDI vibration control potential as top-storey stiffness reduces. This fact is attributed to the coupling of the acceleration of the attached mass to the acceleration of the 33rd floor achieved by the inerter mathematically manifested through

the non-diagonal terms in the mass matrix **M** in Eq. (1). And the herein advocated host-structure modification (i.e., top-storey softening) leverages the positive effect of this coupling in reducing floor accelerations below the top-storey. Nevertheless, when no such coupling exists (i.e., conventional TMD case), top-storey flexibility has no effect to the overall motion control level achieved. In this regard, top-storey lateral stiffness becomes a critical TMDI design parameter. Moreover, it is seen that for given β there is a limiting top-storey stiffness reduction defined by the intersection of the TMD RF curves with the TMDI RF curves, above which the TMD outperforms TMDI. This limiting value increases as inertance increases. Thus, top-storey softening reduces demands for large inertance.

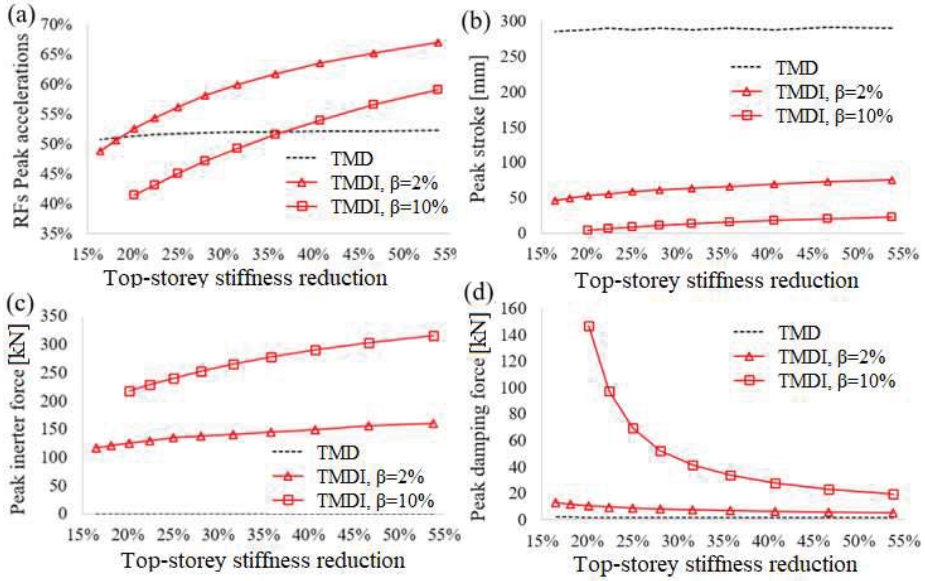

Figure 3. (a) Peak acceleration percentage reduction of 32nd floor, (b) secondary mass stroke, (c) peak inerter force, and (d) peak damping force in TMD(I)-equipped structure for attached mass ratio, μ=0.1%, and inertance ratios, β, against lateral top-storey stiffness reduction.

Turning the attention to the peak stroke of the secondary mass, that is, the peak relative displacement of the TMD(I) mass with respect to the floor that the mass is attached to, $g\sigma_{x_{35,33}}$, Figure 3(b) plots peak TMDI stroke versus top-storey stiffness reduction. It is seen that stroke dramatically reduces with increasing inertance, which is a well-reported effect in the literature [9,10]. Further, stroke demand is positively (though insignificantly) affected by top-storey stiffness reduction. This is quite welcoming result suggesting that the favourable effect of increasing top-storey flexibility to the TMDI effectiveness for suppressing floor accelerations does not come with any increasing cost/demand related to the stroke of the damping device or to the clearance of the secondary mass.

Peak inerter and damping forces developing at the inerter and at the dashpot of optimally designed TMDIs are also deemed essential to check as they need to be economically accommodated locally by the host structure. In this respect, Figures 3(c) and (d) report peak inerter and damping forces, respectively. It is seen that peak inerter force decreases as the top-storey softens at an increasing rate. On the contrary, damping force increases exponentially as the top-storey stiffness reduces for β = 10%. These trends indicate that top-storey stiffness reduction improves TMDI motion control performance through significant increase of the damping force but not of the inerter force.

Numerical results reported in Figure 3(a) suggest that the same structural performance, in terms of peak floor acceleration, can be achieved by using different sets of secondary design

parameters. From practical viewpoint, this is an important consideration as it enables exchanging attached mass to inertance and/or to top-storey stiffness within a performance-oriented design context. To illustrate this point, Figures 4(a) and (b) plot optimal iso-performance curves on the TMDI inertial μ-β plane for fixed top-storey stiffness and for fixed performance, respectively. It is seen that all iso-performance curves have negative slope on the μ-β plane establishing the direct mass reduction/substitution effect endowed by the inertance leading to overall more lightweight inertial dampers. Furthermore, as suggested by Figure 4(b), the same performance can be achieved with reduced average required inertance by approximately 1.6% at μ=0.1%, for every 2% reduction to the top-storey stiffness. As a final remark, top-storey softening further leads to attached mass reduction for fixed inertance to achieve/maintain a preset performance: Figure 4(b) shows that 2% reduction of top-storey stiffness reduces the required mass ratio by about 0.1%, which corresponds to a 20ton TMDI weight reduction for the considered building structure.

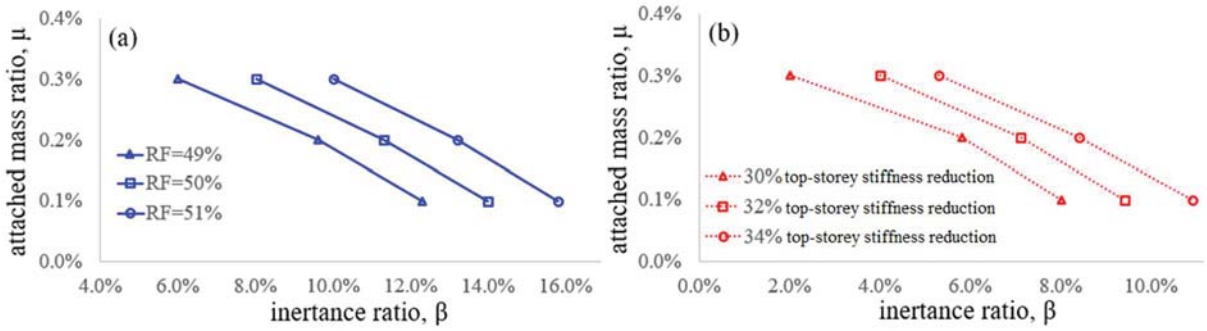

Figure 4. Quantification of mass-inertance-damping coefficient trade-off for (a) fixed normalized stiffness 38%, and (b) fixed performance RF=50%.

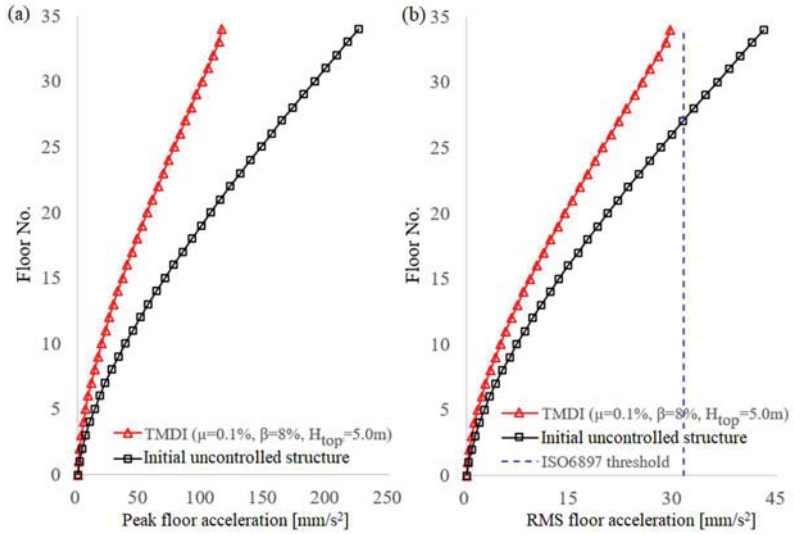

Figure 5. Floor acceleration distribution along the building height and check for occupants' comfort.

As a final check, Figure 5 plots peak and RMS floor accelerations along the building height for the uncontrolled and for a TMDI controlled structure with about 28% top-storey stiffness reduction. The benefit of TMDI is clearly seen and the rationale behind optimal TMDI tuning for minimizing floor acceleration of the 32nd floor is justified as it leads to floor acceleration reductions in all lower floors. More importantly, Figure 5(b) shows that the uncontrolled structure did not meet occupants' comfort threshold according to ISO6897 [5] at floors 26 and above

for the specific wind excitation, while the particular optimally tuned TMDI with top-storey softening meets the ISO6897 criterion for all floors.

7 CONCLUDING REMARKS

The effectiveness of optimally tuned top-storey TMDIs in conjunction with local top-storey softening has been numerically explored for mitigating floor accelerations in the across-wind direction of slender core-frame buildings which become critical for serviceability design associated with occupants' comfort. Numerical results for different TMDI inertance and top-storey stiffness have shown that improved structural performance in terms of peak floor acceleration and attached mass stroke are achieved by increasing inertance and/or by reducing top-storey stiffness for fixed TMDI attached mass. Meanwhile no improved performance is achieved by conventional TMD through top-storey softening. It was further demonstrated that the required TMDI mass/weight can be reduced either by increasing inertance or by softening the top-storey for a preset performance level. Therefore, top-storey softening facilitates practical implementation of TMDI as it relaxes requirements for large inertance.

Keywords: tensegrity structures, dynamic solar façades, energy harvesting, energy efficient buildings.

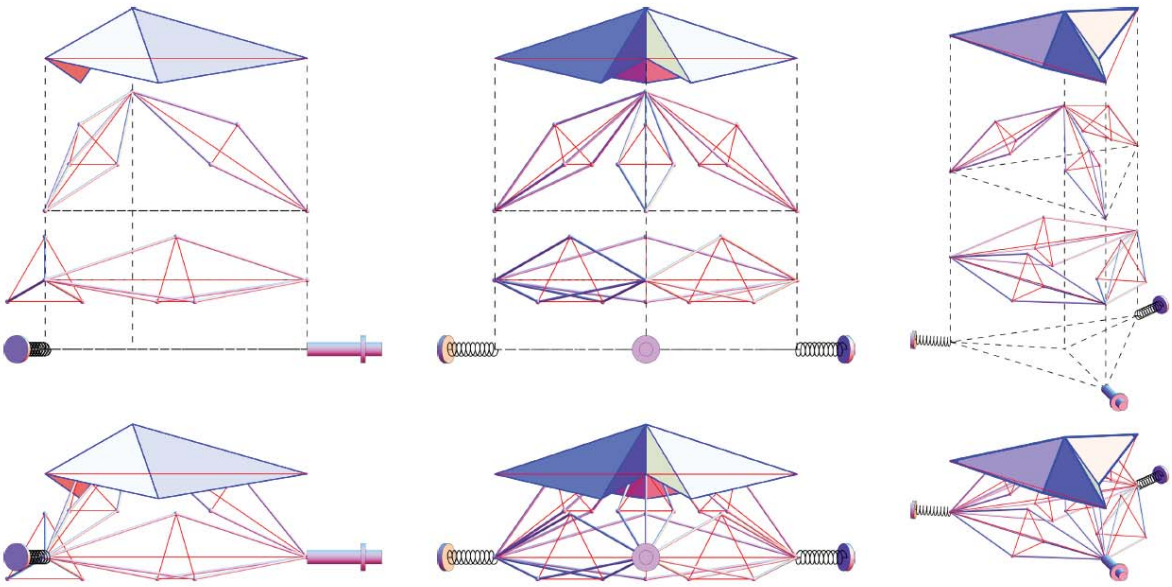
Abstract. *Deployable sunscreens with tensegrity architecture have been recently proposed for dynamic solar façades of buildings working on low energy consumption. Such structures are aimed at ensuring well-being indoor conditions while using reduced electrical-grid energy. The present paper studies the dynamical response of the tensegrity shading screens recently appeared in the literature, by studying structures formed by modular panels suitably assembled to form an origami pattern. The origami tensegrity façade is activated by stretching or releasing selected cables. Its energy-harvesting ability arises from the action of piezoelectric effects under the opening/closure motion of the origami panels, and wind-induced fluctuations. The dynamic response of the origami panels is simulated through a fully tensegrity model, with the aim of estimating their energy harvesting ability. The given results show that the overall tensegrity façade can daily produce a quantity of electric energy equivalent to the electric power produced by more than 200 squared meters of photovoltaic panels, and about 90 squared meters of rooftop wind turbines.*

1 INTRODUCTION

An energy-efficiency building (EEB) ensures well-being indoor conditions with the least consumption of energy from fossil and non-renewable sources [1]. Design of new constructions to reach performances of so-called nearly zero-energy buildings (nZEB) is introduced by the 2010 European Union Directive for the optimization of the energy performance of buildings [2], which enforces the EU states to provide the minimum requirements for the energy performance of buildings and constructive elements. Indeed, buildings are responsible for approximately 40% of EU energy consumption, so that the challenge for the near future is to drastically reduce energy dependency on fossil sources, while maintaining current living standards. In this direction, the building envelope is among the most important components to take into consideration in design of a EEB [3, 4], since it can significantly help in reducing energy losses. For instance, the building envelope may be exploited to increase energy efficiency in the summer by controlling the incident solar radiation through dynamic shading systems. In recent studies, it has been proposed to exploit the deployment ability of tensegrity structures to design dynamic envelopes [5, 6]. Tensegrity systems are composed of bars, generally under compression, assembled inside a net of strings undergoing tensile stresses, only [7]. Furthermore, it is possible to take advantages from vibratory motion of such systems under environmental actions to harvest energy. The present paper is devoted to a tensegrity-like module merging the function of sunscreen to some harvesting ability.

2 THE LAYOUT OF THE TENSEGRITY SUNSCREEN MODEL

The present contribution briefly details about an origami module based on tensegrity architecture equipped with piezoelectric strings. The module is designed to be mounted in front of or to cover building façades and pursue the two-fold objective to serve both as screen and mechanical energy harvester and enriches a unit introduced in [5] and further studied in [6, 8, 9] named as TABS, acronym of *tensegrity Al Bahar screen*, because of its shape resembling that of shading systems designed by Aedas architects to protect the external façades of the Al Bahar towers, in Abu Dhabi [10, 11]. While Al Bahar screen are piston actuated, motion of TABS depends on its tensegrity architecture. The enriched module, referred as WTABS [12], where 'W' stands for *wind*, introduces as a novelty with respect TABS the addition of six D-bar systems. The basic module of the WTABS system is shown in Fig.1, both through exploded and assembled views. With reference to Fig.1, starting from the top (which indeed does mean from external, i.e. away from the building), WTABS is composed by a macro-triangle, *origami* screen module, subdivided into six micro-triangles made of PTFE (glass fiber), able to generate a rigid motion in space, infilling a tensegrity system formed by 12 bars and 3 external strings. Below, there is a complex made of six D-bar, two elastic restraints (linear springs with stiffness $K = 67$ kN m^{-1}) and a linear actuator (model Rolaram®R2501190 [13]). While three D-bars, the springs and the actuator have axes which are and, during the morphing process, stay in a plane parallel to the rear building, the remaining three D-bars are mounted inclined. The actuator Rolaram®R2501190 (294 kN dynamic loading, 3500 mm maximum stroke [13]) stretches and relaxes cables, thus activating the folding/unfolding mechanism of the system. Bars and strings composing the module are respectively made with 6082-T5 Aluminum profiles and wire ropes composed of a nylon core string with 8.9 mm diameter, wrapped by piezoelectric cables [14].



(a) (b) (c)

Figure 1: Three exploded (top panels) and assembled (bottom panels) views of TABS: (a) side view, parallel to the axis of actuator; (b) side view, in front of the actuator; (c) axonometric view. Exploded views allow to recognize the main components of TABS. From top: screen; D-bars inclined with respect to the rear building wall; D-bars parallel to the rear building wall; elastic restraints and actuator.

3 WTABS MOTION EQUATIONS AND LOADS

This section introduce the WTABS equations of motion, in matrix form, and reports about the evaluation of wind pressure to adopt in numerical simulations.

3.1 Matrix form of equation of motion

The WTABS module is a tensegrity network made up of n_n nodes, modeled as frictionless joints, n_b bars, and n_s elastic strings. The generic node i, with $i \in [1, \dots, n_n]$ is located by the vector $\mathbf{n}_i \in \mathbb{R}^3$ and is loaded by the external force $\mathbf{w}_i$. Hence the nodal matrix $\mathbf{N} \in \mathbb{R}^{3\times n_n}$ and load matrix $\mathbf{W} \in \mathbb{R}^{3\times n_n}$ can be written as

$$\mathbf{N} = \begin{bmatrix} \mathbf{n}_1 & \mathbf{n}_2 & \cdots & \mathbf{n}_i & \cdots & \mathbf{n}_{n_n} \end{bmatrix}, \quad \mathbf{W} = \begin{bmatrix} \mathbf{w}_1 & \mathbf{w}_2 & \cdots & \mathbf{w}_i & \cdots & \mathbf{w}_{n_n} \end{bmatrix}. \tag{1}$$

The vectors representing i^{th} bar and string are $\mathbf{b}_i \in \mathbb{R}^3$ and $\mathbf{s}_i \in \mathbb{R}^3$, respectively, and can be stacked in matrices $\mathbf{B} \in \mathbb{R}^{3\times n_b}$ and $\mathbf{S} \in \mathbb{R}^{3\times n_s}$, as

$$\mathbf{B} = \begin{bmatrix} \mathbf{b}_1 & \mathbf{b}_2 & \cdots & \mathbf{b}_i & \cdots & \mathbf{b}_{n_b} \end{bmatrix}, \quad \mathbf{S} = \begin{bmatrix} \mathbf{s}_1 & \mathbf{s}_2 & \cdots & \mathbf{s}_i & \cdots & \mathbf{s}_{n_s} \end{bmatrix}. \tag{2}$$

By introducing the connectivity matrices of bars $\mathbf{C_B} \in \mathbb{R}^{n_b\times n_n}$ and strings $\mathbf{C_S} \in \mathbb{R}^{n_s\times n_n}$, the matrices given by Eqn.(2) are written as

$$\mathbf{B} = \mathbf{N}\mathbf{C}_\mathbf{B}^\mathbf{T}, \quad \mathbf{S} = \mathbf{N}\mathbf{C}_\mathbf{S}^\mathbf{T}. \tag{3}$$

The generic $(i, j)^{\text{th}}$ entry of $\mathbf{C_B}$ (or of $\mathbf{C_S}$) takes value -1 if vector $\mathbf{b}_i$ (or $\mathbf{s}_i$) is directed away from node j^{th}, 1 if vector $\mathbf{b}_i$ (or $\mathbf{s}_i$) is directed toward node j and 0 if vector $\mathbf{b}_i$ (or $\mathbf{s}_i$) does not touch node j. On introducing the class number m of a tensegrity network, we may state that a tensegrity is of class m if the maximum number of the compressive elements concurring in

each node is equal to m [7, 15, 16]. In this case, the tensegrity sunscreen module that we are considering is a tensegrity of class 6.

By introducing the matrices $\mathbf{M} \in \mathbb{R}^{n_n \times n_n}$ and $\mathbf{K} \in \mathbb{R}^{n_n \times n_n}$, respectively defined as

$$\mathbf{M} = \frac{1}{12} \mathbf{C_B}^T \hat{\boldsymbol{m}} \mathbf{C_B} + \mathbf{C_R}^T \hat{\boldsymbol{m}} \mathbf{C_R} \,, \tag{4}$$

$$\mathbf{K} = \mathbf{C_S}^T \hat{\boldsymbol{\gamma}} \mathbf{C_S} - \mathbf{C_B}^T \hat{\boldsymbol{\lambda}} \mathbf{C_B} \,, \tag{5}$$

we can write the equations of motion (of a class 1 tensegrity system) as [17]

$$\ddot{\mathbf{N}}\mathbf{M} + \mathbf{N}\mathbf{K} = \mathbf{W} \,, \tag{6}$$

where $\mathbf{N}$ has been already given by the first of Eqns.(1) and $\ddot{\mathbf{N}}$ stands for its second derivative with respect to time.

Similarly to matrices $\mathbf{C_B}$ and $\mathbf{C_S}$, $\mathbf{C_R} \in \mathbb{R}^{n_b \times n_n}$ in Eqn.(4) is a connectivity matrix. Its i^{th} row corresponds to the bar $\mathbf{b}_i$ and its $(i,j)^{\text{th}}$ entry takes value 1/2 if vector $\mathbf{b}_i$ touches node j, or 0 otherwise [18]. Furthermore, $\hat{\boldsymbol{m}} \in \mathbb{R}^{n_b \times n_b}$, and $\hat{\boldsymbol{\gamma}} \in \mathbb{R}^{n_s \times n_s}$ in Eqns.(4)-(5) are diagonal matrices, whose $(i,i)^{\text{th}}$ entries are, respectively, masses m_i, $i \in [1, \ldots, n_b]$ and force densities along strings γ_i, $i \in [1, \ldots, n_s]$ given by

$$\gamma_i = \begin{cases} \max\left[0, \dfrac{E_{sj} A_{sj}}{L_j}\left(1 - \dfrac{L_i}{s_i}\right) + c_i \dfrac{\mathbf{s}_k^T \dot{\mathbf{s}}}{s_i^2}\right] \,, & \text{if } s_i \geq L_i \,, \\ 0 \,, & \text{otherwise,} \end{cases} \tag{7}$$

being E_{si} the Young's modulus of the material, A_{si} the cross-sectional area and L_j the rest length of the string, c_i the damping coefficient and $s_j = \|\mathbf{s}_j\|$. Finally $\hat{\boldsymbol{\lambda}} \in \mathbb{R}^{n_b \times n_b}$ denotes the diagonal matrix of force densities in bars and is given by

$$-\hat{\boldsymbol{\lambda}} = \frac{1}{12} \left\lfloor \dot{\mathbf{B}}^{\mathbf{T}} \dot{\mathbf{B}} \right\rfloor \hat{\boldsymbol{m}} \hat{\boldsymbol{\ell}}^{-2} + \frac{1}{2} \left\lfloor \mathbf{B}^T \left(\mathbf{W} - \mathbf{S} \hat{\boldsymbol{\gamma}} \mathbf{C_S}\right) \mathbf{C_B^T} \right\rfloor \hat{\boldsymbol{\ell}}^{-2} \,, \tag{8}$$

where $\hat{\boldsymbol{\ell}}^{-2} \in \mathbb{R}^{n_b \times n_b}$ is a diagonal matrix of terms $\ell_k^{-2} = \|\mathbf{b}_k\|^{-2}$ and $\lfloor \mathbf{A} \rfloor$ is a matrix keeping the diagonal terms of the square matrix $\mathbf{A}$, while all the off-diagonal entries are set to zero.

3.2 Modeling of the wind forces

We model the action of wind on WTABS on assuming the wind speed as depending on time and only one space variable, the height (took along the axis y in a three dimensional Cartesian frame), and is given by

$$v(y,t) = v_m(y) + v'(y,t) \,, \tag{9}$$

where v_m is averaged over a time interval of 10 min and v' accounts for high frequency fluctuations. The latter is suitably represented as a single stationary Gaussian random process with zero mean described by the spectral density [19]

$$S_L(y,n) = \frac{6.8\, f_L(y,n)}{\left(1 + 10.2\, f_L(y,n)\right)^{5/3}} \,, \tag{10}$$

where $f_L(y,n)$ is a dimensionless frequency

$$f_L(y,n) = \frac{n\, L(y)}{v_m(y)} \,, \tag{11}$$

$L(y)$ being the turbulence scale, and n the natural frequency. By choosing a frequency step $\Delta n = 0.05$ Hz, and a set of $N = 100$ frequencies $n_k = (k - 1/2)\Delta n$, we obtain [20]

$$v'(y,t) = \sum_{k=1}^{N} \sqrt{2S_L(y,n)\Delta n}\cos\left(2\pi n_k t + \varphi_k\right), \tag{12}$$

φ_k denoting randomly generated phases (in radians) over the angle interval spanning from 0 up to 2π.

Finally, we cast the peak value of the wind kinetic pressure, expressed in Pa, as

$$q(y,t) = \frac{1}{2}\rho\left(v_m(y) + v'(y,t)\right)^2, \tag{13}$$

$\rho = 1.25$ kg m^{-3} being the density of air.

The effect of wind pressure on nodes of WTABS is then computed as follows.

On introducing two vectors $\mathbf{a}_p$ and $\mathbf{b}_p$ lying along the edges of the generic micro-triangle on WTABS, the surface area A_p of such an element and its unit normal are given by

$$A_p = \frac{1}{2}||\mathbf{a}_p \times \mathbf{b}_p||, \quad \mathbf{n}_p = \frac{\mathbf{a}_p \times \mathbf{b}_p}{||\mathbf{a}_p \times \mathbf{b}_p||}. \tag{14}$$

The wind force acting over the panel p, along its normal vector, is computed through

$$\boldsymbol{\omega}_p = q\, A_p(\boldsymbol{n}_p \otimes \boldsymbol{n}_p)\mathbf{k}, \tag{15}$$

$\mathbf{k}$ and $\otimes$ denoting the unit vector along the axis z, towards the building, and the tensor product symbol, respectively. Finally, the wind force acting on the generic node i is

$$\mathbf{w}_i = \frac{1}{3}\sum_{p=1}^{n_i} \boldsymbol{\omega}_p, \tag{16}$$

n_i being the number of panels attached to node i.

4 NUMERICAL APPLICATIONS

The present section is devoted to the dynamic analyses of the WTABS system undergoing the wind forces and actuation motion. The numerical integration of Eqn.(6) is performed applying fourth order Runge-Kutta theory with a time step of 0.025 s.

4.1 Actuation motion

The motion of WTABS is driven by the linear actuator Rolaram®R2501190 [6, 13]. We consider a simulation in which the screen is deployed in 40 s, starting from the folded configuration. Then, the force impressed on the node is held constant for 40 s more. Figure 2 graphically illustrates the simulation. In particular, it is shown how the position of the central point of the module changes over time during the actuation motion. Four top views of deformed configurations, from folded to deployed state, are reported.

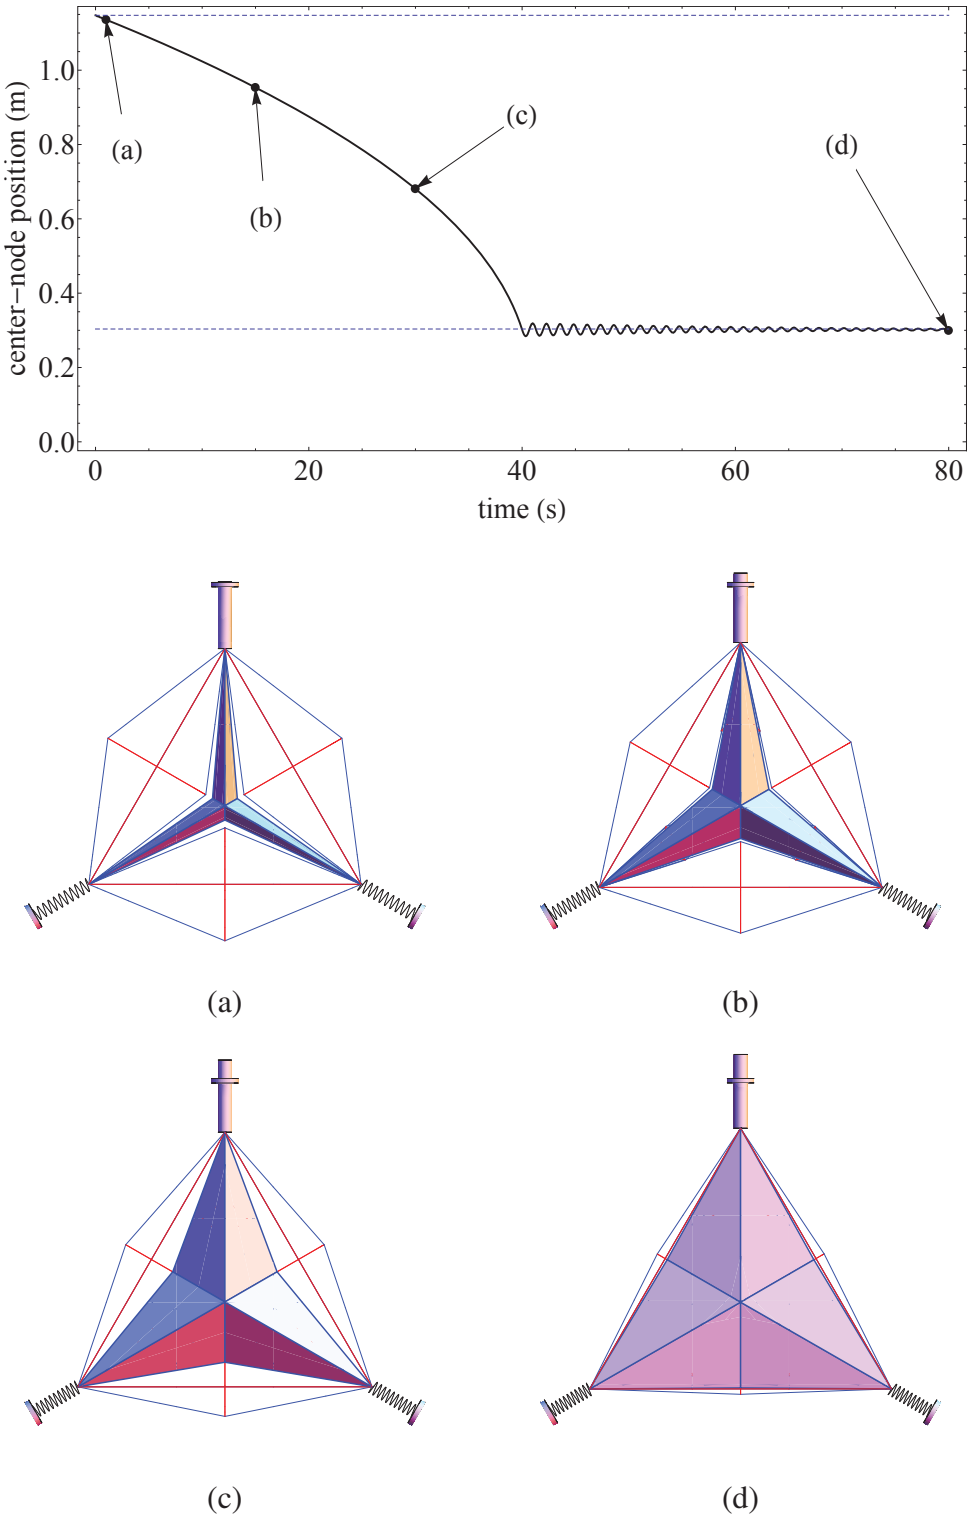


Figure 2: Deployment of WTABS driven by the actuator. Position of center node (top panel) and four top views of selected configurations, namely after 1 (a), 15 (b), 30 (c), and 80 (d) s from actuation start.

4.2 Fluctuations due to wind

The simulate wind pressure we consider environmental characteristics of the Al Bahar Towers and the height of the towers. By considering ??$y^* = 120$ m in a coastal area exposed to wind, we get the turbulence scale value $L(y^*) = 40.1589$ m [19]. As average speed we set $v_m(y^*) = 73.4$ m s^{-1}, which produces a wind pressure of 3.5 kPa, that is the value considered for the real scale prototypes of the towers [11]. Relevant information and results of the simulation are graphically shown in Figure 3.

5 MECHANICAL ENERGY HARVESTING

The WTABS module is equipped with PVDF-coated piezoelectric cables (see [12] for details on the cable structure) that, by virtue of the electromechanical effect, allows energy conversion described by

$$W_E = k_{33}^2 W_M \tag{17}$$

where W_E and W_M stand for electric and mechanical energy and k_{33} is the electromechanical coupling coefficient along the longitudinal axis of the piezoelectric cable. By using the strain history of the cables during the simulations briefly reported in Sect. 4, mechanical energy can be computed as

$$W_M = \frac{1}{2T} \sum_{s=1}^{n_s} \left(E_f A_f L_{is} \int_0^T \varepsilon_s(t)^2 \mathrm{d}t \right) , \tag{18}$$

with reference to the two different implementation hypotheses we obtain [12]

$$W_E^{\text{actuation}} = 321.3 \text{ kJ} , \qquad W_E^{\text{wind}} = 5.749 \times 10^{-4} \text{ kJ} . \tag{19}$$

In [12], it has been observed that, although the amount of energy harvested by a single WTABS is low, the total energy that can be daily generated by a WTABS modules in reference to the size of the towers (composed of over a thousand shading systems) m^2 [10, 11], is considerable and can be employed to power microelectronic devices, WiFi repeaters, cellular phones, and LED lighting systems [21].

6 CONCLUDING REMARKS

This work has dealt with the generalization of the TABS shading system proposed in [6] from the energetic point of view, by integrating such a system with additional D-bar modules equipped with piezoelectric cables for energy harvesting (WTABS design [12]). The dynamics of the WTABS module has been numerically simulated, on accounting for the opening and closure operations of the screens and the dynamic action of wind forces. The obtained results have allowed us to calculate the amount of mechanical energy harvested by the shading system under such loading conditions. Overall, the electric power that can be daily generated by the WTABS modules is equivalent to the power produced by approximatively 200 photovoltaic panels, and nearly 90 microeolic wind turbines with one squared meter surface area. We address the generalization and the experimental identification [22] of the WTABS concept to different façade geometries and a variety of energy harvesting materials to future work.

Keywords: Wind turbine tower, Offshore Wind Turbines, Monopiles, Dynamic analysis, Current-wave-wind interaction

Abstract. *In the present paper the dynamic response of tall offshore monopile steel wind turbine towers under wind, wave and current during the erection stage is studied. In particular, in the present paper the effect of current-wave-wind interaction as dynamic loading on the dynamic response of offshore wind turbine towers is for first time studied experimentally. A statistical analysis of the dynamic displacements of the model is conducted to study the effect of various loading states on the respective dynamic response. As outcome of the present study it was confirmed that the current field strongly affects the dynamic response of offshore monopoles and in particular, more significantly than the wave field. In the final part, an advanced finite element model is proposed for the efficient study of the structural response of the tower model during erection under current, wave and wind interaction.*

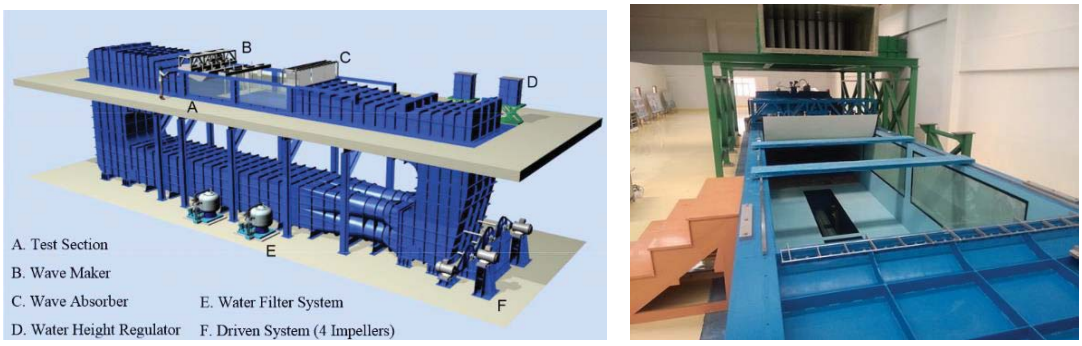
1 INTRODUCTION

In marine environment there are more complicated environmental actions on offshore wind turbine towers (e.g. wind, wave and current loadings) than on the onshore ones. In engineering practice, the wind turbine towers as monopiles need to be constructed during the erection stage in marine environments where current and waves interact. Several researchers have studied the structural characteristics of wind turbine towers during the erection stage by using numerical simulation methods. Tziavos *et al*. [1, 2] studied current practice in terms of engineering methods used for the determination of loads acting on monopile offshore towers and the numerical methods used for the investigation of its structural behaviour. With respect to hydrodynamic loads on monopile wind turbines, the popular linear wave theory along with the Morison equation can be used to model normal sea states, whereas higher-order wave models are necessary to investigate severe events such as wave breaking. Offshore monopile wind turbine towers during the construction stage in marine environment have to resist wind, waves and currents. In this paper the effect of the current action on the dynamic behavior of offshore monopile wind turbine towers is first considered experimentally and then, an appropriate numerical model to study the respective structural dynamic response of the tower is proposed.

2 EXPERIMENTAL SETUP

2.1 Test facility

The experiment of a monopile subjected to wind, waves and current was performed at the Wind Tunnel and Circulating Water Channel Lab, Shanghai Jiao Tong University in China. The Lab consists of two large-scale facilities, the multifunctional wind tunnel and the circulating water channel with the capability to create an environment of currents, waves and sea wind. In particular, the channel is able to simulate various marine environments including current, waves, sea wind and stratified flow. For the specific experimental setup, wind field and current field at a uniform velocity along the tower height and periodic regular wave was provided.



a. A full image b. Actual test section

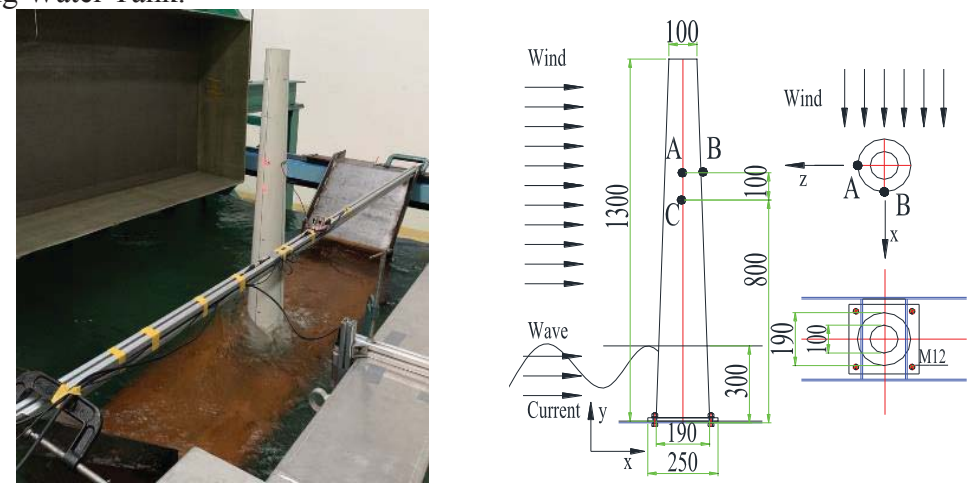
Figure 1. The facilities at the Wind Tunnel and Circulating Water Channel Lab, SJTU.

2.2 Description of the tower model

The prototype monopile structure is a 75m height offshore wind turbine tower during the erection stage. Figure 2 depictes that experimental measurement setup and the dimensions of the tower model. The experimental model is installed in the Wind Tunnel and Circulating Water Tank as shown in Figure 2. The prototype is located at a site with a water depth of 23m, its external radius on the base is 7m and that on the top is 3.75m. The monopile is fixed in the

seabed, whilst the model was manufactured with a geometrical scaling of 1:75. The dimensions of the tower model are displayed in Figure 2b. The height of the scaled down tower is 1.3m, 1.0m height above the water surface level and 0.3m height under water depth respectively. The diameter of the tower model varies linearly along its height from 190mm at the bottom to 100mm at the top as shown in Figure 2b. The thickness of the tower model is 0.5mm and the tower is fixed by four Φ12 bolts. As is well-known in an actual wind tunnel or water tank test to balance Froude and Reynolds numbers is a hard task and to this end, the Froude laws of similitude had been used for the physical modelling of the properties of the tower model.

The monopile response was measured by using one accelerometer at 90cm height of point B on the leeside of the tower model in x-axis direction and one sensor head at the 80cm height of the point C in cross section direction in z-axis direction and the other one at the 90cm height of the point A in cross section direction to measure the velocity values in z-axis direction. All the transducers were connected with their corresponding data acquisition instruments. The wave gauge is employed to measure the wave elevation when applying wave loads in the Circulating Water Tank.



a. Actual experiment setup b. Dimensions of the tower model (in mm)

Figure 2. Experimental setup and dimension of tower model

2.3 Loading states

In the experiment various loading cases were considered to study the effect of wind, waves and current loadings on the dynamic response of offshore wind turbine towers. For the wind loading, the wind speed was gradually increased from 5m/s to 28m/s in the wind tunnel. For the current loading, its velocity with a stepwise increase was performed in the range of 0.3m/s to 2m/s. For wave loading, as wave elevation was ranged from 20mm to 50mm for wave periods from 0.5s to 1.25s in the water tank, the corresponding wave heights at the wave periods of 0.5s, 0.75s, 1s and 1.25s being respectively 44mm, 32mm, 25mm and 22mm. The wave shape was the most stable one when wave maker was initially launched, then the new wave was taken to break gradually due to the reflection of the previous wave in the water tank, and therefore, the experimental results should be tested in the beginning of the step of wave generation for the loading states that involve waves.

As the lower edge of the air outlet of the wind tunnel is 10cm higher than the still water level in the water tank, current field and wave field could not be affected individually by wind field when wind tunnel is running stably (Figure 2a). For wind-current, wind-wave and wave-current loading states, the three loading states can be performed by combining wind loading and current loading, wind loading and wave loading, wave and current loading. For the wind-

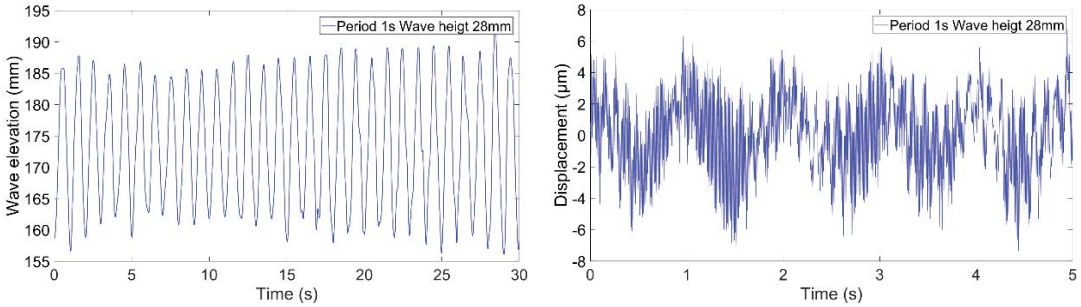
current-wave loading states, the wind field should be first flow in the velocity range of 7.5m/s to 20m/s until a stable state, then, current field is adjusted in the speed range of 0.3m/s to 0.8m/s up to its steady stage and finally wave field is provided in the periods of 0.5s, 0.75s and 1.0s.

3 EXPERIMENTAL RESULTS

Aiming to investigate the effect of various marine loadings on the dynamic characteristics of offshore wind turbine towers during construction, during the present experimental test the following loading states had been separated into four groups a) wind-wave; b) wind-current; c) wind-wave-current; d) wave-current.

3.1 Wind, wave and current

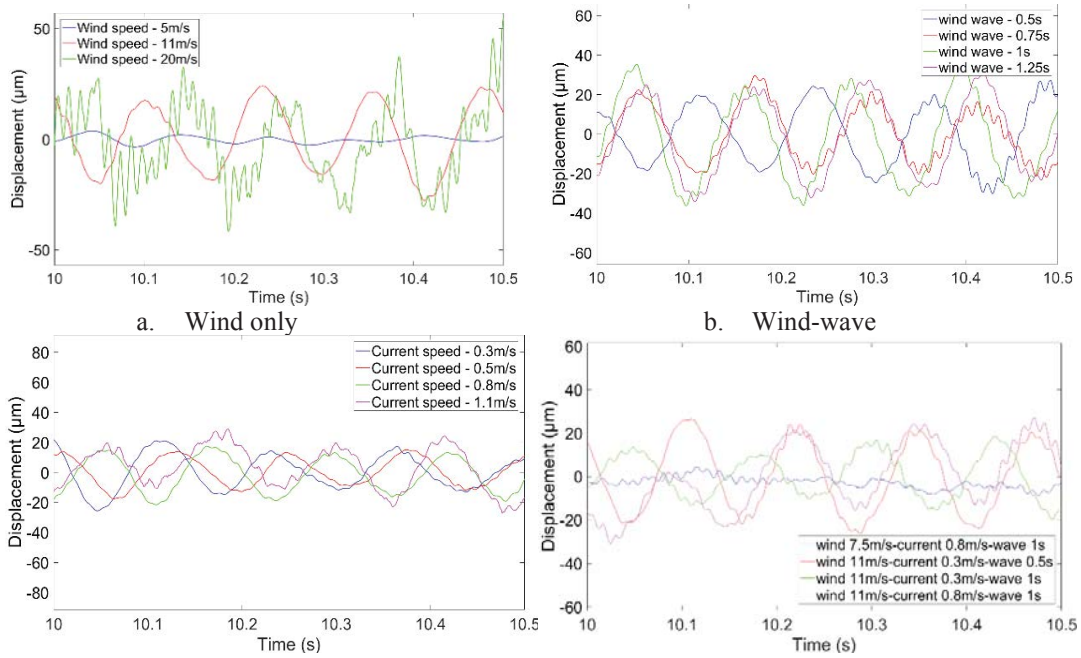
For the loading states of wind only, wind-wave, wind-current and wind-wave-current, the wind speed was gradually increased in the range of 5m/s to 28m/s. In each case, the velocity, acceleration and displacement at points A, B and C were respectively measured in the steady wind field. For the current only, its speed is set in a uniform speed at one loading state varying from 0.3m/s to 2m/s. For wave only, the still water level was 30cm. For each loading case, the period of wave maker is first determined at 0.4s, 0.5s, 0.75s, 1s and 1.25s, and then the wave height had been monitored by wave gauge. Figure 3 shows time histories of wave elevations and displacement responses when wave period is 0.75s and wave height is 28mm. According to Figure 3a, for wave height 28mm, the wave period is 1s. According to Figure 3b, it can be observed that as there are two peaks and one valley within each second, the time histories of displacement response exhibit periodicity and the respective periods are equal to the input period of the wave maker.



a. Time histories of wave elevations b. Time histories of displacement responses

Figure 3 Time histories of wave elevations and displacement response of the model under wave only at period of 1s and at wave height of 28mm

The displacement response of the tower model at point C under various loading states is depicted in Figure 4. According to Figure 4, there is regular dynamic response of the tower under wind speeds of 11m/s in the four loading states. Specifically, for the loading states of wind only, the regular dynamic response of the tower at point C exists only at wind speed 11m/s. For the loading of wind-wave and wind-current, the regular dynamic response of the tower under low current speeds and low wave periods respectively are depicted in Figures 4b and 5c, where the dynamic response of the tower becomes irregular gradually as soon as the current speed and the wave period increase. For the loading states of wind-wave-current, the regular dynamic response of the tower under the combination of low current speed and low wave period still occur, they however disappear as soon as current speed and wave period increase. For the loading states of wave only and current only, the dynamic responses of the tower were both irregular in the present experiment.

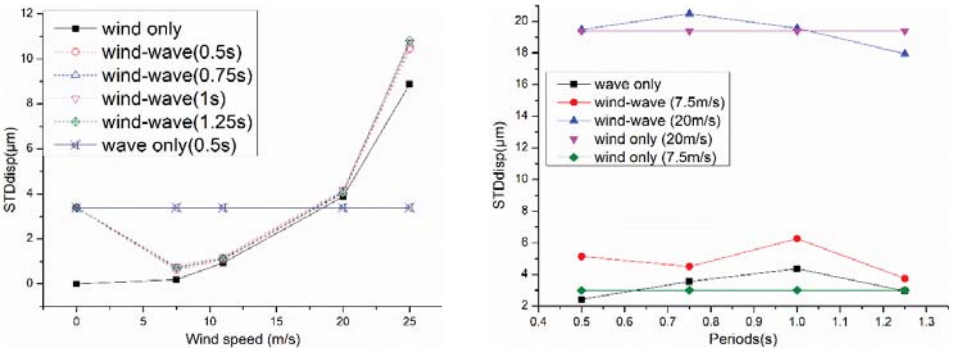


a. Wind only b. Wind-wave

c. Wind-current d. Wind-wave-current

Figure 4 Displacement response of the tower model at point C under various loading states

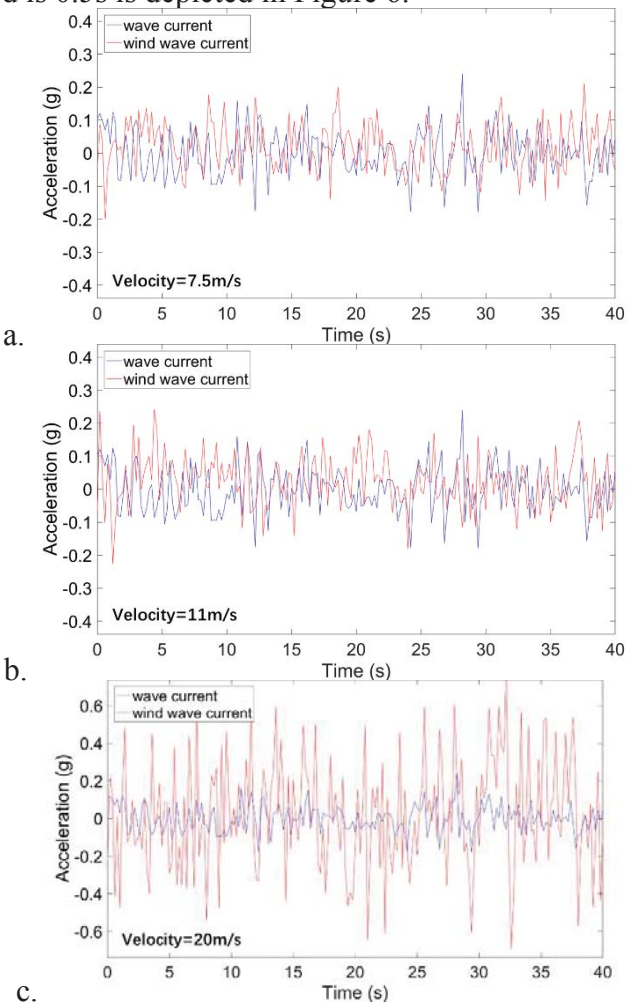
For the wind-wave loading cases, wind loading was chosen at wind speeds of 7.5m/s, 11m/s, 20m/s and 25m/s and the wave maker produced wave loadings at the periods of 0.5s, 0.75s, 1s and 1.25s with wave heights 44mm, 32mm, 28mm and 22mm respectively. Figure 5 shows the standard deviation of the displacement of the tower model at various wind speeds under wind only, wave only and wind-wave at various periods of 0.5s, 0.75s, 1s and 1.25s. According to Figure 5a, the standard deviation of the displacement of the tower model declines when wind speed increases from 0m/s to 7.5m/s, and the standard deviations of the displacement of the tower model are less than that of tower model under wave only. Then the standard deviation of displacement of tower model rises with wind speed increasing being greater than that of the tower model under wave only. Therefore, it is concluded that wave loading dominates the structural responses of tower model at a low wind speed loading state, whilst wind loading controls the structural responses of tower model at a high wind speed. Figure 5b provides the standard deviation of the displacement of the tower model under various loading states at wind speeds 7.5m/s and 20m/s and at periods 0.5s, 0.75s, 1s and 1.25s. Thus, for the 7.5m/s wind loading case, wave significantly affects the dynamic responses, whilst for the 20m/s wind loading case, wind predominantly controls the dynamic response of the monopile with the wave period varying. For the loading case of wind-current, a similar tendency can be observed where current only affects the dynamic response of the tower at low wind speed, whilst wind controls the dynamic response of the tower in the case that wind speed increases.



a. STD displacement versus wind speed b. STD displacement versus periods

Figure 5 Standard deviation of the model displacements under wind only, wave only and wind-wave

For the wind-wave-current loading state, wind loadings correspond to wind speeds of 7.5m/s, 11m/s and 20m/s, current loadings are set at current velocities of 0.3m/s, 0.5m/s and 0.8m/s, wave loadings are provided at wave periods of 0.5s, 0.75s and 1s. The wind field first runs at a stable state and then, current field is stabilized and at a final stage the wave field is made by using wave maker. Acceleration response of model under wind-wave-current and wave-current loading states at wind speed of 7.5m/s, 11m/s and 20m/s when current speed is 0.3m/s and wave period is 0.5s is depicted in Figure 6.



a.

b.

c.

Figure 6 Accelerations of the tower model under wind-wave-current and wave-current loading states

It was found that the combination of wave and current action only affects the dynamic response of the model in a low and medium wind speed; for a strong wind speed, wind still controls the dynamic responses of the tower.

3.2 Wave and current

With reference to the loading states of wave and current, loading states including wave only, current only and wave-current were considered to study the effect of wave and current on the dynamic response of the model. In this loading case, the current speed was 0.3m/s, 0.5m/s, 0.8m/s and 1.1m/s respectively and wave periods were set at 0.5s, 0.75s, 1s and 1.25s.

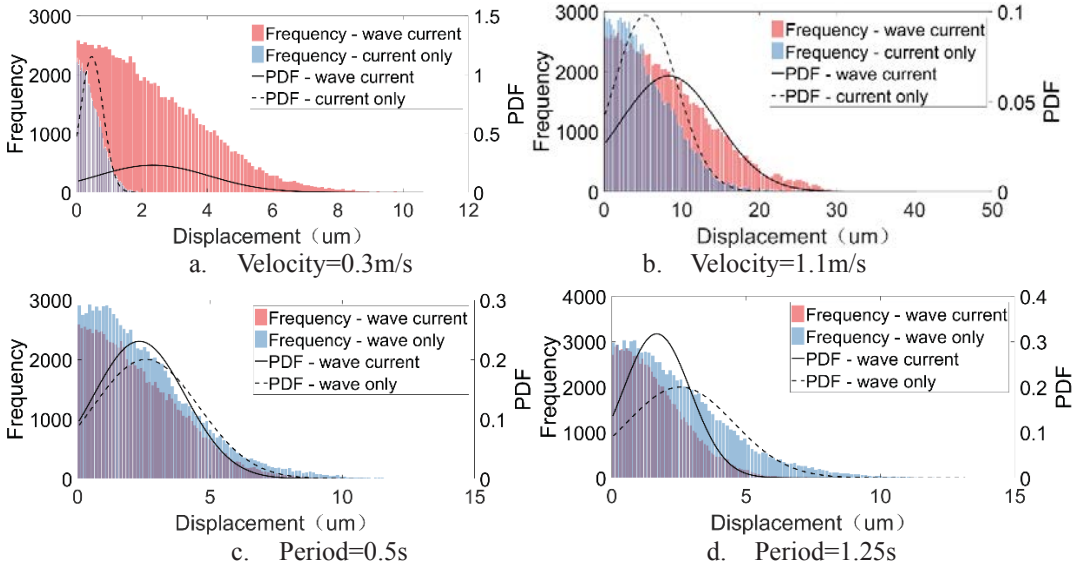


Figure 7 Probability characteristics of the displacements at point C under current speeds of 0.3m/s and 1.1m/s (wave period=0.5s) and wave periods of 0.5s and 1.25s (current speed=0.3m/s)

The probability characteristics of the displacements at point C under current speeds of 0.3m/s and 1.1m/s and wave period of 0.5s and 1.25s appear at Figure 7. The frequency in these figures is the number of any displacement value of the tower under various loading states. For the loading case at current speed of 0.3m/s, the probability function of displacement of the model under wave-current ranges in a wider displacement amplitude than that of the tower model under current only (shown in Figure 7a), which means that the wave dominates the structural response of the tower at this low current speed.

For the loading case at current speed of 1.1m/s, displacement amplitudes under wave-current and current only increase whilst probability functions move closer in the sense that current field principally controls the dynamic response of the monopile at current speed of 1.1m/s. According to Figures 7c and 7d, the value of displacements of the tower under wave only can always surpass that of the tower model under current-wave with the wave period increasing from 0.5s to 1.25s, the two PDFs only move slightly each other which indicate that wave period increase could not affect very significantly the dynamic response of the tower model under wave-current loading state.

4 NUMERICAL SIMULATION

4.1 Loadings

In marine environment the offshore monopile wind turbine towers during the erection stage are subjected to wind, current and wave loadings.

4.1.1 Wind and current loading

Wind loading can be applied to the tower wall as pressure around the tower cross section. The wind flow created at the wind tunnel is a uniform wind field at different wind speeds and the wind pressure on the tower model is related to the wind speed based on the Bernoulli equation as follows:

$$P_w = 0.5\rho_a v_a^2 \tag{1}$$

where P_w is the wind pressure, ρ_a is the air density (1.25kg/m^3) and v_a is the wind speed.

According to EN 1991-1- 4 [3], the external wind pressure corresponds to different profiles with reference to the circular cylinder. Reynolds number are respectively given by the equation:

$$R_e = vD/\nu \tag{2}$$

where R_e is the Reynolds number, v is the fluid speed, D is the diameter of the tower and ν is the kinematic viscosity of fluid.

With reference to the current loading, this is transferred into pressure according to the Bernoulli equation:

$$P_c = 0.5\rho_w v_c^2 \tag{3}$$

where P_c is the current pressure, ρ_w is the water density (1000kg/m^3) and v_c is the current speed.

4.2.2 Wave loading

For the wave loading, this is obtained by the Morrison's equation as the offshore monopile is a slender cylindrical structure fixed in the seabed. According to Morrison's equation [4],

$$dF = \rho_w \frac{\pi D^2}{4} dz C_M a + \frac{\rho_w}{2} C_D D dz |u| u \tag{4}$$

where wave moves along the x-direction as shown in Figure 2, a and u is the acceleration and the velocity of undisturbed wave in x-direction, respectively. C_M and C_D are respectively the mass and the drag coefficient for a smooth tubular section (respectively 2.0 and 1.2 in this experiment). For the situation of finite water depth, u and a can be obtained as the equations (5) and (6) [5]:

$$a = \omega^2 A \frac{coshk(y+h)}{sinhkh} \cos(\omega t - kx) \tag{5}$$

$$u = \omega A \frac{coshk(y+h)}{sinhkh} \sin(\omega t - kx) \tag{6}$$

$$\lambda = \frac{g}{2\pi} T^2 tanh \frac{2\pi}{\lambda} h \tag{7}$$

where $\omega=2\pi/T$, $k=2\pi/\lambda$, T is the period of the wave, λ is the wave length, A is the amplitude of the wave, t is the time, x is the wave motion direction, y is the vertical coordinate and its positive direction is upwards from water level to the tower top, h is the water depth in the water tank equal to 1.6m in this experiment and g is the gravitational acceleration.

4.2 Validation of the numerical model

The wind turbine tower model was created by the finite element software ABAQUS using the S4R shell element [6]. The tower was considered as fixed at its bottom and manufactured by Q235 steel. Its density and elastic modulus were respectively 7.85g/cm^3 and 206GPa and the Poisson's rate is 0.3. Wind, current and wave loading profiles of the offshore wind turbine tower are shown in Figure 8. In this model, as wind and current loadings are applied as uniform velocity on the slender cylindrical tower structure for each loading state, according to the equations (1, 3), the wind loading can be simplified in accordance to the inventory data [3, 7] and the current loading can be simplified as shown in Figure 8. In the tests the wind speed

was kept in the range of 7.5m/s to 20m/s, therefore, the Reynolds number of wind field varies from 0.5×10^5 to 1.5×10^5 being less than 2.0×10^5. The current speeds were varying from 0.3m/s to 2m/s in the Circulating Water Tank during the test. According to equation (2), the Reynolds numbers of current range from 0.3×10^5 to 2×10^5. Therefore, according to the inventory data [3, 4, 5], the distributions of wind and current load coefficients around the circumference can be divided into four parts. The angles of the wind pressure and current pressure around the circumference of the tower cross section were respectively decided to be 60°, 85°, 130° and 85° in this loading states as shown in Figure 8. The wind pressure had been simplified into uniform pressure along the tower height over the water level as wind field is applied as one constant velocity in a stepwise way whilst the current pressure was considered as uniform pressure along the tower height under the water level. For the wave loading, it had been considered as a periodic compressive loading applied on the half section of the tower wall under the water level as shown in Figure 8.

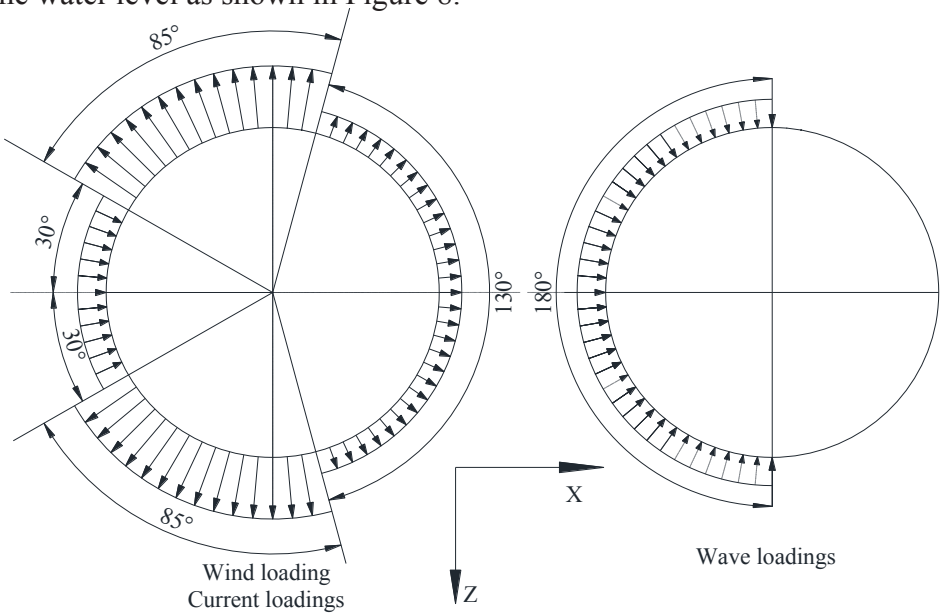

Figure 8 Wind, current and wave loading profile of offshore wind turbine tower

For the loading states of wind speed of 11m/s, current speed of 0.3m/s and wave periods of 0.5s and wave elevation of 44mm, the corresponding wind pressure, current pressure and wave force are calculated by the equations (1)-(7), and therefore, the displacement response at point C of the tower model under wind, current and wave loadings can be obtained from the numerical model. Figure 9 depicts the laboratory test and the numerical results with reference to the displacements at point C of the tower. It is noted that a good agreement between numerical and experimental results had been achieved.

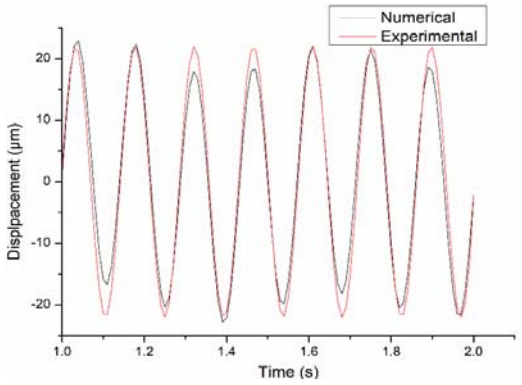

Figure 9 Comparison of time histories of displacement responses of the tower model at point C

5 CONCLUSIONS

In the present paper a Wind Tunnel and Circulating Water Channel was employed to study the dynamic response of offshore wind turbine tower during the erection stage in a marine environment. In this experiment, the loading states of wind-wave, wind-current, wave-current and wind-wave-current were applied to explore their effect on the dynamic response of the offshore tower model. To this end, the later with a geometrical scaling of 1:75 was manufactured and tested under wind, wave and current loadings. Three points A, B and C had been chosen to measure the velocity, displacement and acceleration respectively under the aforementioned selected loading cases. The numerical model of the monopile under wind, wave and current was validated by comparing its results with the experimental ones.

According to the laboratory test results, for the wave loading at low periods and current loading at low speeds, the dynamic response of the monopile under wind-wave, wind-current still occurs regularly, and the dynamic response of the tower is only slightly affected by the wave loading at high periods and current loading at high speeds under the wind speed of 11m/s. For the wind-wave-current loading case, the effect of combination of wave and current on the dynamic response of the tower is significant as displacements of the tower happen irregularly with the wave period and current speed increase. The loading states of wind-wave, wind-current, wind-wave-current and wind only control the dynamic response of the tower as soon as the wind speed increases. For the loading states of wave-current, the effect of the current loading is more significant than that of wave loading on the dynamic response of the tower. Therefore, current loading should not be ignored when the dynamic response of offshore towers in the marine environment is investigated.

Keywords: Offshore wind turbines, Hurricane, Dynamic responses, Spatial distribution

Abstract. *During extreme tropical cyclones such as hurricanes and typhoons, although offshore wind turbines (OWTs) are parked and feathered to mitigate loads on the turbine blades, failures may happen to OWTs due to hurricane induced environmental loads or errors of the control systems. In this study, attempts are made to investigate the spatial distributed characteristics of hurricane induced response of OWTs considering the influence of the misalignment between local wind and wave. The dynamic responses of the jacket supported OWT are computed via implementing coupled aero-servo-hydro elastic analysis based on the hurricane-related wind and wave fields. Parametric models are adopted to simulate the spatial dependent turbulent wind fields and uni-directional irregular wave fields induced by hurricanes. Based on a series of coupled aero-servo-hydro elastic analyses, the spatial distributed characteristics of dynamic response such as tower-top and platform displacement, structural stress in tower and substructure and axial force on cross-section of the legs are investigated by comparing their maximum, mean and standard deviation values. In addition, focusing on the points where maximum responses occur, the time history curves of response are obtained and analyzed to illustrate their temporal characteristics.*

1 INTRODUCTION

As a widely concerned renewable energy, offshore wind energy undoubtedly provides a solution to the environmental problems encountered in the process of energy utilization. However, the harvest of wind resource is companied with potential risks due to extreme tropical cyclones such as typhoons and hurricanes. In southeast coastal area of China where many offshore wind farms are located, there is a high risk that OWTs are exposed by tropical cyclones. From 2003 to 2008, a number of wind turbine failure cases during tropical cyclone activities were reported and attracted the attention of some scholars [1-3]. These failure events all happened to onshore wind turbines in the Asia-Pacific region and can be characterize as structural failure and blade failure. According to Li's study [3], the cause of the failures during hurricane events are correlated with extreme wind speed, drastic change of wind direction, intense turbulence in the inflow wind and fail of control system. During hurricane events, extreme wind and waves are generated causing the bearing loads more complicated than that on onshore wind turbines, which may lead to failures of OWTs although there is no record of these events.

Based on the above considerations, environmental loads due to hurricanes should be considered in the design future turbines. One of the major problems in analyzing the characteristics of OWT response caused by hurricanes is modelling spatio-temporal correlated wind and wave fields. In the past few decades, some sophisticated numerical models such as WAVEWATCH III, UMCM and SWAN [4-6] have been used to predict the wind and wave within hurricanes based on the physics of wave generation. However, due to the high computational cost and limited resolution, these numerical models are not appreciable for the dynamic analysis of OWTs. To this end, some parametric models were proposed to characterize hurricane generated wind and waves. For hurricane wind field model, Holland model [7] has been extensively used to characterize the hurricane radial profiles due to its simplicity and effectiveness. Some other parametric models for hurricane winds have been proposed taking into account the effect of surface friction and storm translation [8-11]. Attempts have also been made to provide parametric wave models generated by hurricanes [12-19]. The spatial distributed characteristic of significant wave height and local wave directions are investigated in these works.

Inspired by the failure cases of wind turbines reported before (although these failure events all happened to onshore wind turbines), the control system, turbine parking strategy and blade azimuthal configuration have vital influence on the aerodynamic load of a wind turbine. Kim and Manuel [5] investigated the hurricane induced loads on a monopole supported 5-MW OWT with considerations for nacelle yaw and blade pitch control and validated the most unfavorable yaw angle during hurricanes. For OWTs supported by substructures such as jackets and tripods, the structural bearing capacities are different when being loaded in different directions. Wei et al [20] investigated the bearing capacities of a jacket supported OWT in different directions. The lowest loading capacity at 45° is verified based on a static nonlinear pushover analysis of the jacket structure under wind and wave loads. Furthermore, attentions have been paid to hurricane risk assessment of OWTs and directional effects of environmental loads on OWTs [21-23].

In summary, the wind fields and wave fields induced by hurricanes are spatial distributed due to the characteristics of hurricane wind and physical mechanism of wave generation. Therefore both the amplitude and the direction of environmental loads vary with the spatial location. Despite the studies above, limited studies have been conducted on characteristics of hurricane induced dynamic response of jacket supported OWTs focusing on the spatial correlated wind and wave fields generated by hurricanes.

2 MODELING OF WIND AND WAVE INDUCED BY HURRICANES

The dynamic responses of OWTs depend on the environmental loading which is remarkably correlated with the wind fields and wave fields induced by hurricanes. However, due to the movement and intensity variation of storm, the hurricane induced wind fields and wave fields evolve over time. Therefore, the wind speed or the wave elevation at any specified point can be modeled as non-stationary processes. Despite the time-varying characteristics, the wind speed or the wave elevation can be characterized by stationary processes during a short interval (10 min) based on the slow-change characteristic of hurricane wind fields. Thus, parametric models are adopted to simulate the spatial dependent wind field and wave field during hurricanes.

2.1 Modeling of hurricane wind

The near-surface hurricane wind field, namely the mean wind speed at height of 10 m can be decomposed into an axisymmetric component of the storm vortex and an axially asymmetric component of the surface background wind [11]. The schematic for calculation of the near-surface hurricane wind at any specified point is shown in Figure 1. As is defined in Figure 1, storm track is assumed to be aligned with the horizontal axis and the storm center is fixed to the coordinate origin. r and φ are radial distance from storm center to observation point P and azimuth of vector OP which is defined counter-clockwise from the horizontal axis. The coordinate of the observation point P is $\left(X_P, Y_P\right)$, where Y_P represents the offset distance of point P from the storm track; X_P represents the horizontal distance of point P from the storm center O. The near-surface hurricane wind speed equals the vector sum of the component of the storm vortex and the component of the surface background wind. Meanwhile, a deceleration effect and a rotational effect are caused by the surface friction therefore the gradient wind and background wind should be modified by reduction factor (α_r and α_t) and rotation angle (α and β).

$$\vec{U}=\alpha_r\vec{V}_r+\alpha_t\vec{V}_t \tag{1}$$

Where $\vec{U}$ is the mean wind speed at height of 10 m; α_r and α_t are surface wind reduction factor (SWRF) of gradient wind speed V_r and background wind speed V_t.

In the present study, the gradient wind and the background wind are converted to the surface level with SWRF $\alpha_r=0.8$ and $\alpha_t=0.5$. The rotation angle of background wind $\beta=20^\circ$ while the rotation angle of gradient wind α is given by the National Weather Service's expression [8]

$$\alpha=\begin{cases}10^\circ\left(1+r/R_m\right), 0\le r<R_m\\ 20^\circ+25^\circ\left(r/R_m-1\right), R_m\le r<1.2R_m\\ 25^\circ, r\ge 1.2R_m\end{cases} \tag{2}$$

Where R_m is radius to maximum wind.

The value of the axisymmetric component of the storm vortex can be calculated based on the Holland model [7].

$$V_r(r)=\left\{\left(\frac{R_m}{r}\right)^B \frac{100B\Delta P\exp\left[-\left(\frac{R_m}{r}\right)^B\right]}{\rho}+\frac{r^2 f_c^2}{4}\right\}^{0.5}-\frac{f_c r}{2} \tag{3}$$

Where ρ is air density; $f_c = 2\Omega\sin\Phi$ is the Coriolis parameter, in which $\Omega = 7.292\times10^{-5}$ and Φ is lattice; ΔP is central pressure deficit; B is the Holland parameter which is determined as

$$B=\frac{V_m^2 e\rho + f_c V_m R_m e\rho}{100\Delta P} \tag{4}$$

Where e is base of natural logarithms; V_m is maximum mean wind speed.

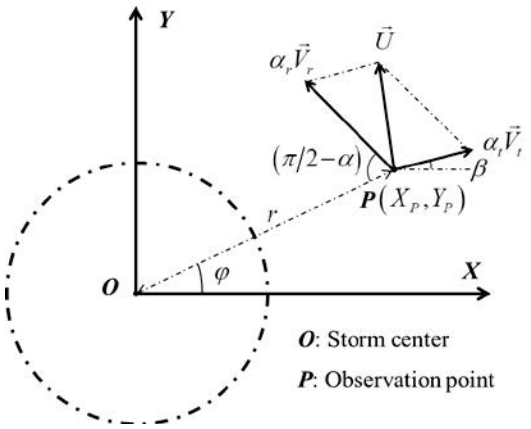

Figure 1: Schematic for calculation of the near-surface hurricane wind at any specified point

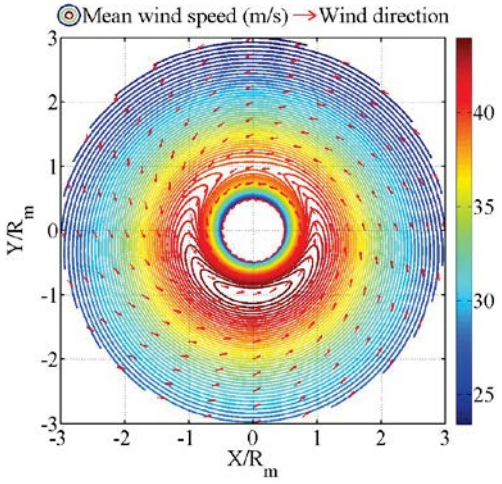

Figure 2: Contour of hurricane wind field at height of 10 m

Parameters	values
Latitude	30.8 deg
Storm central pressure deficit	52 mb
Radius to maximum winds	74 km
Forward movement speed	4.5 m/s
Air density	1.15 kg/m^3

Table 1: Parameters of a measured hurricane

Using the hurricane wind model mentioned above, the spatial distribution of mean wind speed at height of 10 m can be simulated according to the parameters of a measured hurricane listed in Table 1. The contour of hurricane wind field at height of 10 m is shown in Figure 2.

As is shown in Figure 2, due to the background wind, a peak occurs at the point where $r = R_m$ and $\varphi = 270^\circ$.

2.2 Modeling of hurricane wave

In early studies, wind generated seas are characterized by wave spectra based on measured data which are related with the steady wind speed over the sea [24, 25]. However, during meteorological forcing events such as tropical clones, hurricanes and typhoons, destructive waves are generated by time-varying wind fields correlated with the vortex structure. To this end, the concept of an extended fetch was proposed by Young [12-14] to reflect to the relationship between significant wave height, maximum wind velocity in the storm and velocity of the forward movement of the storm. More recently, fetch- or duration-limited wave growth functions [16-19] have been proposed according to the datasets from the National Aeronautics and Space Administration (NASA) and National Oceanic and Atmospheric Administration (NOAA) combined hurricane hunter missions during Bonnie 1998 [15, 26] and Ivan 2004 [27]. The fetch-limited wave growth function can be expressed as:

$$\begin{cases} H_s = 8.10\times10^{-4} U_{10}^{1.19} x_\eta^{0.405} \\ T_p = 9.28\times10^{-2} U_{10}^{0.526} x_\omega^{0.237} \end{cases} \tag{5}$$

Where H_s is significant wave height; T_p is spectral peak wave period; U_{10} is mean wind speed at height of 10 m; x_η and x_ω are effective fetch corresponding to H_s and T_p respectively.

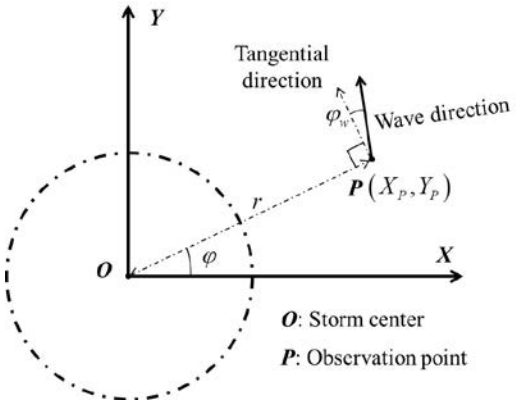

Figure 3: Schematic of azimuthal dependent wave direction

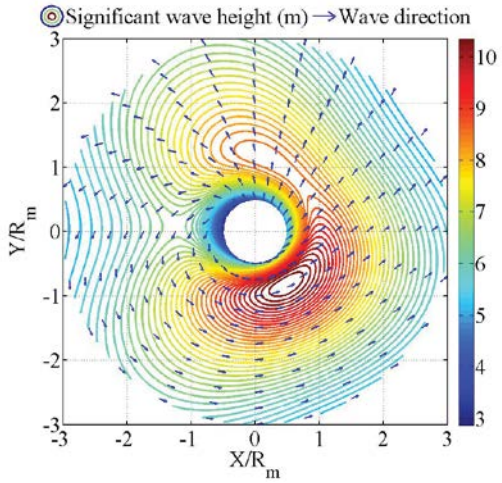

Figure 4: Contour of significant wave height

In this model, the variables x_η and x_ω in fetch-limited wave growth function as well as the angle between wave direction and tangential direction φ_w are azimuthal dependent as is shown in Figure 3. In Figure 3, the storm track is assumed to be aligned with the horizontal axis and the storm center is fixed to the coordinate origin. The detailed method to determine these variables can be found in Hwang's studies [18, 19]. In present study, Hwang's model was adopted to simulate hurricane wave field according to the hurricane wind field presented

in Section 2.1. The spatial distributed significant wave height, spectral peak wave period and directions of wind and waves are shown in Figures 4-6.

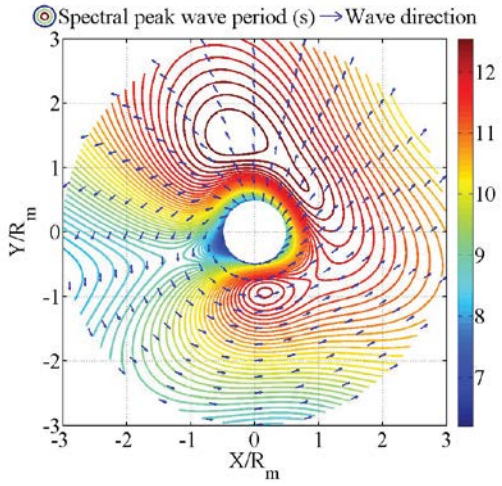

Figure 5: Contour of spectral peak wave period

3 NUMERICAL SIMULATION

3.1 Modeling of OC4-jacket OWT

In this study, a jacket design, namely OC4-jacket is considered to support the NREL 5-MW baseline turbine [28, 29]. The main dimensions and properties of OC4-jacket and NREL 5-MW baseline turbine are listed in Table 2. The schematic of the OC4-jacket support structure is shown in Figure 7. As shown in Figure 7, the supporting structural system of OC4-jacket is designed to be deployed in the site with 50-m water depth with the rotor-nacelle assembly (RNA) being mounted 90 m above mean sea level (MSL). In order to realize the rigid connection between tower and substructure, a rigid platform is employed. Moreover, the effect of nonlinear soil-pile interaction is neglected, in other words, the 4 legs of the jacket are assumed clamped at the seabed.

To simulate the parked wind turbine during hurricanes, the turbine blades were pitched to 90 and the RNA was yawed to be aligned with the local wind direction (shown in Figure 8). As a compromise of save computing cost, the wind turbine was assumed to be located within the range of $0.5R_m \sim 3.0R_m$ from the storm center.

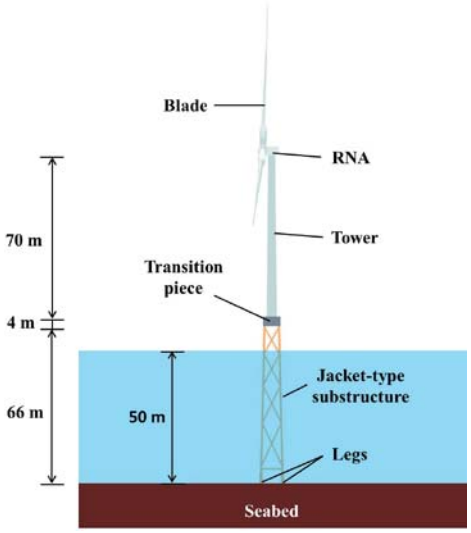

Figure 7: Schematic of an OC4-jacket OWT

3.2 Environmental loads

The inflow wind can cause aerodynamic load on OWTs including drag and lift force on blades and drag force on towers. With the hurricane wind field determined in Section 2.1, the Frøya wind profile and spectral model [30] were adopted to calculate the time series of inflow wind speed at different locations. The Frøya wind profile is expressed as

$$\overline{u}\left(z\right)=U_{ref}\left(1+0.0573\sqrt{1+U_{ref}}\right)\ln\left(z/H_{ref}\right) \tag{6}$$

Where $\overline{u}\left(z\right)$ is mean wind speed at height z; U_{ref} is the 1-hour mean wind speed at H_{ref}, $H_{ref}=10\,\mathrm{m}$.

The Frøya spectral model was developed for neutral conditions over water in the Norwegian Sea. It can be expressed as

$$S_u\left(f\right)=\frac{320\left(\frac{U_{ref}}{10}\right)^2\left(\frac{z}{10}\right)^{0.45}}{\left(1+\tilde{f}^{\,n}\right)^{\frac{5}{3n}}} \tag{7}$$

Where $n=0.468$ and

$$\tilde{f}=172f\left(\frac{z}{10}\right)^{2/3}\left(\frac{U_{ref}}{10}\right)^{-0.75} \tag{8}$$

In practice, blade element momentum (BEM) theory is one of most commonly used methods for calculating aerodynamic load on wind turbine blades. According to this method, two-dimensional airfoil tables of lift and drag coefficient are included as a function of the angle of attack, thus a set of equations can be iteratively solved for the induced velocities on each blade element. For parked turbines, the rotor wake/induction effects can be ignored. Thus, the aerodynamic load on blades and tower can be directly calculated based on the tables of lift and drag coefficient and instantaneous inflow wind speed.

The hydrodynamic load on OWTs is related to local wave kinematics. The linear Airy wave theory [31] is used to predict the kinematics of two-dimensional waves of small height in deep water. In order to reflect the stochasticity of sea states, irregular waves can be modelled as the linear superposition of sinusoidal wave components. Thus, the distribution of wave energy at different frequencies is characterized by specifying a wave spectrum. For a developing sea, the JONSWAP (the Joint North Sea Wave Project) spectrum was proposed and adopted by IEC standard [25, 32]. The IEC JONSWAP spectrum is expressed as

$$S_{JS}\left(f\right)=0.3125H_s^2T_p\left(\frac{f}{f_p}\right)^{-5}\exp\left[-1.25\left(\frac{f}{f_p}\right)^{-4}\right]\left(1-0.287\ln\gamma\right)\gamma^{\exp\left[-0.5\left(\frac{\frac{f}{f_p}-1}{\sigma}\right)^2\right]} \tag{9}$$

Where $S_{JS}\left(f\right)$ is IEC JONSWAP spectrum; f_p is spectral peak wave frequency, $f_p=1/T_p$; $\sigma=0.07$ for $f\le f_p$, $\sigma=0.09$ for $f>f_p$; γ is peak-shape parameter:

$$\gamma\begin{cases}5, \dfrac{T_p}{\sqrt{H_s}} \le 3.6 \\ \exp\left(5.75-1.15\dfrac{T_p}{\sqrt{H_s}}\right), 3.6 < \dfrac{T_p}{\sqrt{H_s}} \le 5 \\ 1, \dfrac{T_p}{\sqrt{H_s}} > 5\end{cases} \tag{10}$$

Based on the wave kinematics determined by JONSWAP spectrum as a function of significant wave height H_s and spectral peak wave period T_p, the wave force on slender members can be calculated by Morison's equation [33]

$$f_H = f_D + f_I = \frac{1}{2}C_D\rho_w D\left(u_x - \dot{x}\right)\left|u_x - \dot{x}\right| + C_M\rho_w\frac{\pi D^2}{4}\frac{\mathrm{d}u_x}{\mathrm{d}t} - \left(C_M - 1\right)\rho_w\frac{\pi D^2}{4}\ddot{x} \tag{11}$$

Where f_H is hydrodynamic force of a small size cylinder per unit length; f_I and f_D are the inertia force and drag force per unit length; C_M and C_D are the inertia coefficient and drag coefficient; u_x is the horizontal velocity component of water particle; ρ_w is water density; D is the diameter of cylinder; $\mathrm{d}u_x/\mathrm{d}t$ is the horizontal acceleration component of water particle; $\dot{x}$ and $\ddot{x}$ are the horizontal velocity component and horizontal acceleration component of the cylinder.

3.3 Dynamic analysis

The structural response of OWTs subjected to simultaneous wind and wave is nonlinear and influenced by the interaction of aerodynamic, hydrodynamic, structural, operational, and geotechnical effects. The open-source software for turbine dynamic simulation, FAST [34], developed at National Renewable Energy Laboratory (NREL) are used in calculating the structural response of OWTs subjected to simultaneous wind and wave, where aerodynamic load and hydrodynamic load are obtained as described in previous steps. In this case, six 700-s simulations were conducted assuming that the OWT is located in different positions within the range of $0.5R_m \sim 3.0R_m$ from the storm center with the first 100 s of dynamic responses removed.

Through numerical calculation, the maximum, mean, and standard deviation values of dynamic responses in key components were extracted. To reveal spatial distributed characteristics of dynamic response, the contour of maximum dynamic responses with respect to normalized spatial coordinates X/R_m and Y/R_m were obtained and analyzed.

Assuming that the storm intensity and the forward movement speed of the storm remains constant, the spatial distributed hurricane wind and wave field can be converted to time varying hurricane wind and wave field. As the storm track is aligned with the horizontal axis and the storm center is fixed to the coordinate origin, the observation point *P* moves in the negative direction of the horizontal axis with an offset distance Y_P. Thus, the time series of mean wind speed, significant wave height and maximum value of dynamic response can be obtained by extracting points from contours of dynamic response on line $Y = Y_{P\max}$. It should be noticed that $Y_{P\max}$ is offset distance of the point where maximum response occurs (Fig 9 (a)).

4 RESULTS AND ANALYSIS

4.1 Tower-top and platform displacement

Figure 9 shows contours of maximum, mean and standard deviation value of tower-top displacement and platform displacement. In Figs 9 (a-f), $d_{T\max}$, $d_{T\text{mean}}$, d_{TSTD} , $d_{P\max}$, $d_{P\text{mean}}$ and d_{PSTD} stand for maximum tower-top displacement, mean tower-top displacement, standard deviation of tower-top displacement, maximum platform displacement, mean platform displacement and standard deviation of platform displacement respectively. As is shown in Figure 9 (c-d), being the reflection of hurricane wind field, $d_{T\text{mean}}$ and $d_{P\text{mean}}$ have almost the same characteristic in spatial distribution. In addition, $d_{T\max}$, d_{TSTD}, $d_{P\max}$, and d_{PSTD} have similar characteristic in spatial distribution: the maximum value locates at the same point where $r = R_m$ and $\varphi = 255^\circ$. The point of maximum displacement has an offset distance $Y_{P\max} = -71.48$ .This is mainly because aerodynamic load has dominant effect on tower-top displacement and platform displacement. Apart from the mean response determined by mean wind load, the azimuth of the maximum response is affected by dynamic response which is related to dynamic loads and structural resistance.

The time history of normalized mean wind speed U_{10} , significant wave height H_s and maximum displacement $d_{\max}$ at the point of maximum displacement are shown in Figure 10. From Figure 10, the maximum displacement occurs near the eyewall after the wind speed reaches the peak value. In addition, similar to the time history curve of mean wind speed, the time history curve of maximum displacement shows unimodal characteristic. However, even if the aerodynamic load has dominant effect on tower-top displacement and platform displacement, the time history curve of maximum displacement is asymmetric while the time history curve of mean wind speed is of high symmetry due to the low forward movement speed of the storm. This phenomenon is correlated with non-axisymmetry of supporting substructure and temporal correlated wind-wave misalignment angle.

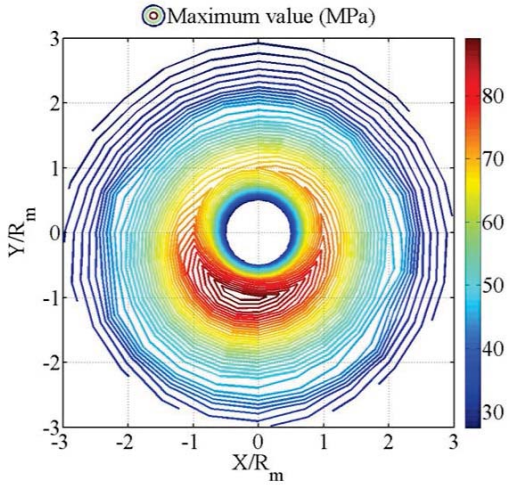
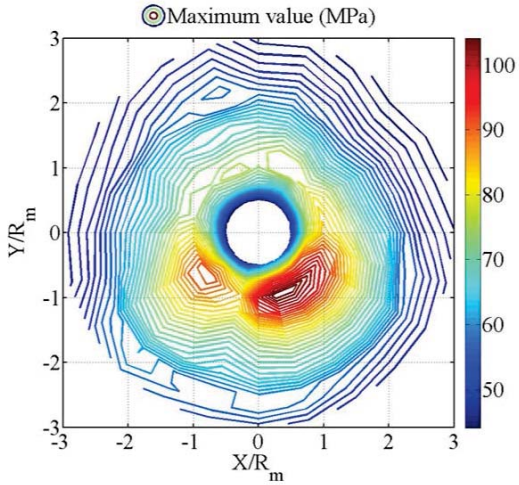
4.2 Stress in tower and substructure

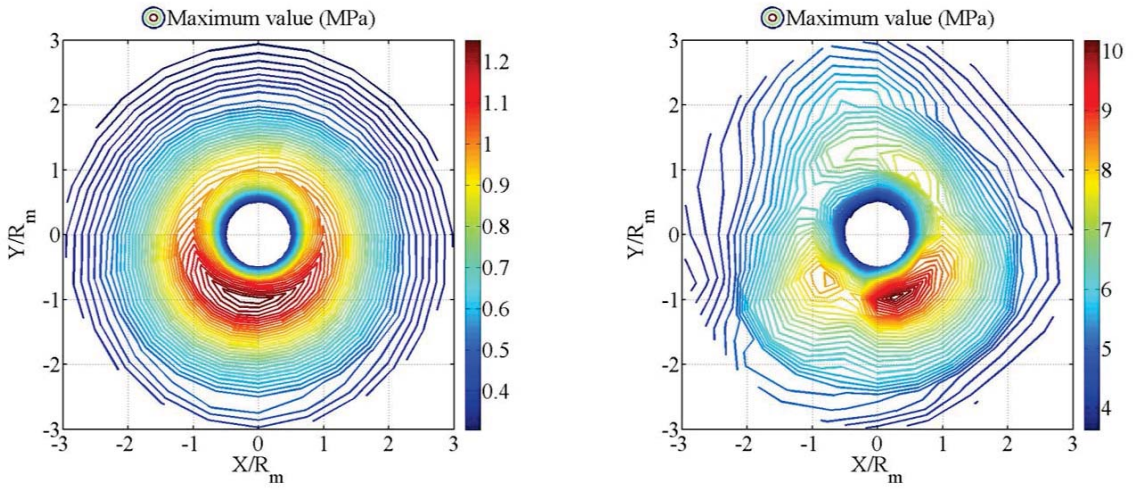
Contours of maximum normal stress and maximum shear stress in tower and substructure are shown in Figure 11 (a-d). In Figure 11 (a-d), $\sigma_{NT\max}$, $\sigma_{NJ\max}$, $\sigma_{ST\max}$ and $\sigma_{SJ\max}$ stand for maximum tower normal stress, maximum normal stress in substructure, maximum tower shear stress, maximum shear stress in substructure respectively. From Figure 11 (a-d), the distribution characteristic of $\sigma_{NT\max}$ and $\sigma_{ST\max}$ are similar to those of $d_{T\max}$. However, $\sigma_{NJ\max}$ and $\sigma_{SJ\max}$ show different characteristic in spatial distribution. The maximum value of $\sigma_{NJ\max}$ and $\sigma_{SJ\max}$ can be found at the point where $r = R_m$ and $\varphi = 285^\circ$. This point is almost coincident with the point where maximum significant wave height occurs. Meanwhile, another peak of $\sigma_{NJ\max}$ and $\sigma_{SJ\max}$ locates near the point where maximum value of $d_{T\max}$ occurs. Therefore, conclusion can be made that the maximum values of $\sigma_{NJ\max}$ and $\sigma_{SJ\max}$ should be attributed to hydrodynamic load while the maximum values of $\sigma_{NT\max}$ and $\sigma_{ST\max}$ should be attributed to aerodynamic load.



(a) $\sigma_{NT\max}$



(b) $\sigma_{NJ\max}$



(c) $\sigma_{ST\max}$ (d) $\sigma_{SJ\max}$

Figure 11: Contours of maximum normal stress and maximum shear stress in tower and substructure

According to the same method above, we can obtain the time history curves of normalized maximum normal stress $\sigma_{N\max}$ and normalized maximum shear stress $\sigma_{S\max}$ at the points where maximum values occur (shown in Figures 12-13). It should be noted that the maximum normal stress and maximum shear stress do not locate at the same point. Thus, the time history curves of normalized mean wind speed U_{10} and significant wave height H_s at corresponding points are shown in Figures 12-13. As Figures 12-13 show, the time history curves of normalized maximum normal stress $\sigma_{N\max}$ and normalized maximum shear stress $\sigma_{S\max}$ are bimodal with the maximum values occur before the arrival of minimum distance to storm center. With the intensity of hydrodynamic loads at their maximum values, the points of maximum response coincide with the points of maximum significant wave height.

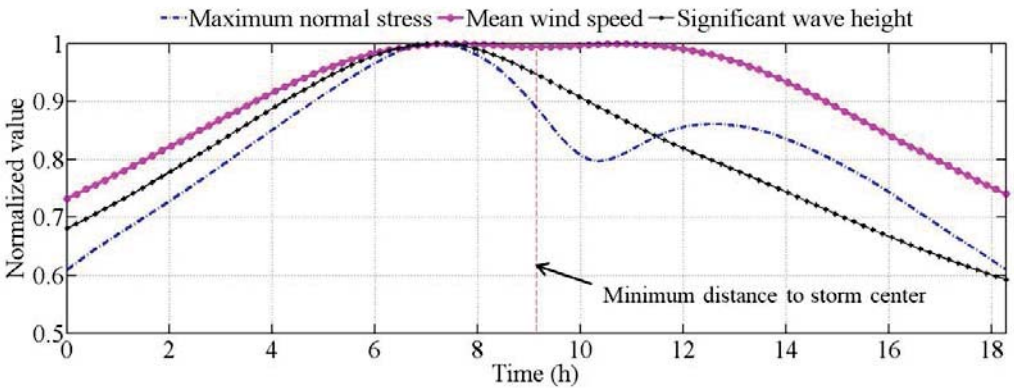


Figure 12: Time history of normalized mean wind speed, significant wave height and maximum normal stress

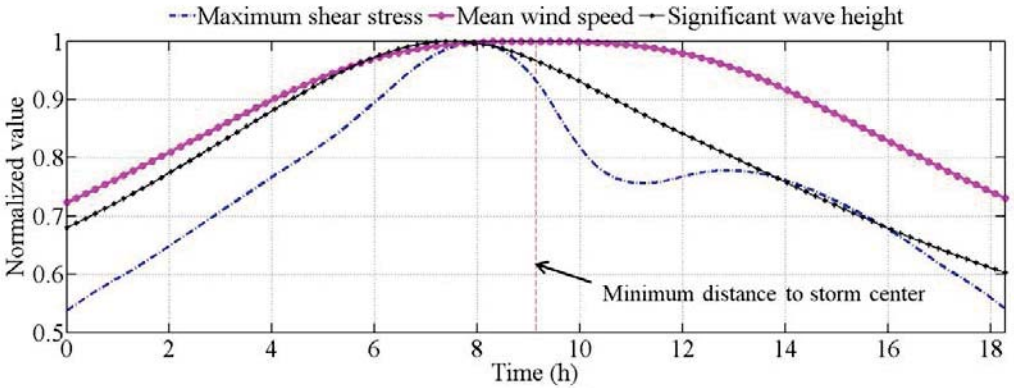

Figure 13: Time history of normalized mean wind speed, significant wave height and maximum shear stress

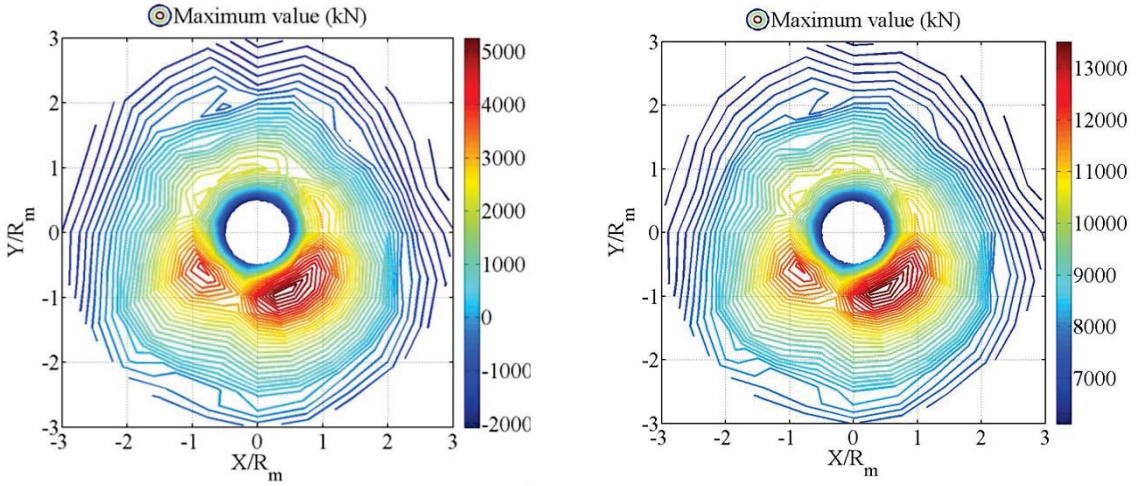
4.3 Uplift and downward axial force on legs

A part from the failure induced by excessive displacement and structural stress, the ultimate limit state of an OWT can also be determined by foundation uplift and yielding of underlying soil. Therefore, the contours of maximum uplift axial force $N_{U\max}$ and downward axial force $N_{D\max}$ on legs were checked (shown in Figure 14). From Figure 14 (a-b), the distribution characteristic of $N_{U\max}$ and $N_{D\max}$ are same as those of $\sigma_{NJ\max}$ and $\sigma_{SJ\max}$ except that the maximum values of $N_{U\max}$ and $N_{D\max}$ locate at the same point.



(a) $N_{U\max}$ (b) $N_{D\max}$

Figure 14: Contours of maximum uplift axial force and downward axial force on legs

The time history of normalized maximum uplift axial force $N_{U\max}$ and downward axial force $N_{D\max}$ at the points where maximum values occur are shown in Figure 15. From Figure 15, the time history of normalized maximum uplift axial force $N_{U\max}$ and downward axial force $N_{D\max}$ are bimodal in shape with the maximum values occur before the arrival of mini-

mum distance to storm center. Except for the specific value, the time history curve of $N_{U\max}$ shows the same trend as that of $N_{U\max}$.

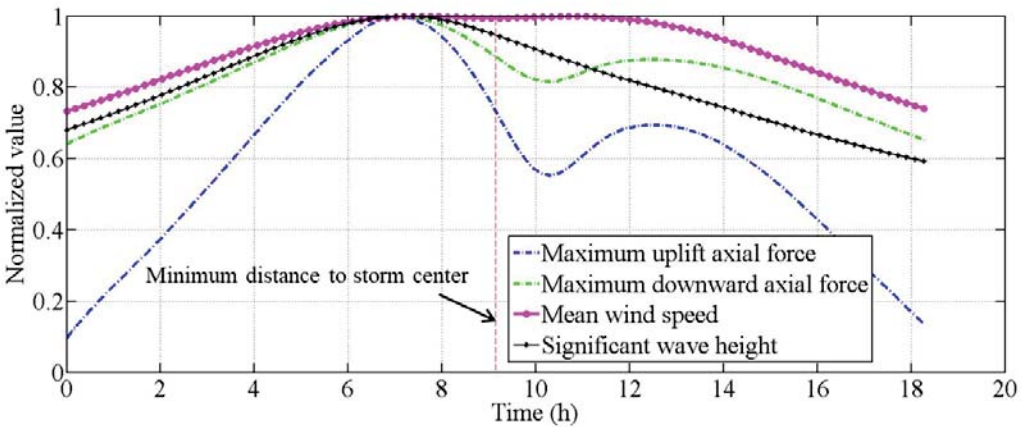


Figure 15: Time history of normalized mean wind speed, significant wave height, maximum uplift axial force and maximum downward axial force

5 CONCLUSIONS

In this paper, a series of coupled aero-servo-hydro elastic analyses have been conducted to investigate the spatial distributed characteristics of hurricane induced response of OWTs , by checking the tower-top and tower base displacement, normal stress and shear stress in tower and substructure , uplift and downward axial force of legs, etc. From this study, the following conclusions can be drawn:

(1) As tower-top and platform displacement are dominated by aerodynamic load, the spatial distribution and time history curve of maximum displacement show similar characteristics as mean wind speed. The maximum displacement occurs near the eyewall where the time history curve of maximum displacement shows unimodal characteristic. Moreover, time history curve shows that the maximum displacement occurs before the arrival of minimum distance to storm center.

(2) For structural stress, the spatial distributions of maximum normal stress and shear stress in tower show different characteristics from those in substructure. The spatial distributions of maximum normal stress and shear stress in tower are similar to those of maximum tower-top displacement while the maximum normal stress and shear stress in substructure can be found at the point near the point of maximum significant wave height. Besides, even if the time history curves of mean wind speed and significant wave height are unimodal in shape, the time history curves of normalized maximum normal stress and normalized maximum shear stress are bimodal with the maximum values occur before the arrival of minimum distance to storm center

(3) Being dominantly affected by hydrodynamic load, the spatial distributions of maximum uplift axial force and downward axial force share the same characteristic with those of maximum normal stress and shear stress in substructure. In addition, the time history curves of normalized maximum uplift axial force and downward axial force are bimodal in shape with the maximum values occur before the arrival of minimum distance to storm center.

Keywords: Wind energy, Horizontal-axis wind turbine blades, Random aerodynamics modeling, Stochastic flutter

Abstract. *The problem of flow-induced stability of wind turbine blades has been recognized by the literature for quite some time. Traditionally, the issue of flutter for a standard-size wind turbine blade has been avoided either because the rotor's operational angular speeds are low, or the blades are appropriately parked during high-wind events. Nevertheless, it has been recently shown that critical flutter rotor speed can still be an issue during operational stages for very long blades, such as the ones typical of off-shore wind turbines [1]. In these cases, the flutter probability, influenced by various sources of uncertainty, can be non-negligible from the point of view of structural reliability. Consequently, it is of interest to examine the non-deterministic flutter problem along with the prediction of the flutter probability.*

In contrast with previous work on the estimation of flutter probability of wind turbine blades, this study proposes a new, theoretically-based and numerically-implemented model to identify the conditions for stochastic stability of wind turbine blades. The model is based on implementation of stochastic calculus methods. Dynamic stability in a non-deterministic context depends on a specific definition. In the context of long-span bridge aerodynamics this problem has been examined in the recent past through implementation of the theory of (largest) Moment Lyapunov Exponent for dynamical systems, which may be used to test the statistical moment stability. The same approach is utilized in this paper to formulate and solve a suitable reduced-order model of the blade dynamics. The model is inspired by an analogous model used for rotorcraft stability under inflow turbulence perturbations [2, 3]. Soil-structure interaction and its effects on the stability of the blades, for example simulated through imperfect boundary conditions at the root, are not addressed in the manuscript but may be included in future formulations.

Description of the model will be presented, followed by results and discussion. Numerical results analyze the flutter of the reference NREL (National Renewable Research Laboratory) 5-MW wind turbine blade.

1 INTRODUCTION

Flow-induced stability of wind turbine blades has been examined by researchers for several years [4-6]. The issue of flutter for a standard-size wind turbine blade has been avoided either because the rotor's operational angular speeds are low, or the blades are appropriately parked when high wind speeds are observed. This author has recently demonstrated that critical flutter rotor speed can still be an issue during operational stages for very long blades, such as the ones employed for last-generation off-shore wind turbines [1]. In fact, flutter probability, influenced by various sources of uncertainty, can be of the order of 10^{-4} to 10^{-3}, a non-negligible value from the point of view of structural reliability. Consequently, it is of interest to examine the non-deterministic flutter problem along with prediction of flutter probability.

Contrary to ongoing work on the estimation of flutter probability of wind turbine blades [7, 8], this paper examines a new model to identify the conditions for stochastic stability of the rotor blades. The model is based on implementation of stochastic calculus methods [9] and stochastic dynamic stability, which depends on its definition (e.g. almost-sure stability, etc. [10, 11]). In the context of long-span bridge aerodynamics this problem has been examined [12] through implementation of the theory of (largest) Moment Lyapunov Exponent (MLE) for dynamical systems, which may be employed to study statistical moment stability [10]. The same approach is utilized in this paper to formulate and solve a surrogate, reduced-order model that mimics the blade dynamics. The model is derived from an analogous model used for rotorcraft stability under inflow turbulence perturbations [2, 3]. A short description of the model is presented in the next section, followed by preliminary results and brief discussion.

The issue of soil-structure interaction and its effects on the stability of the blades, for example simulated through imperfect boundary conditions at the root, is not addressed in the manuscript. For example, an indicative study that considers soil-structure interaction effects on the reduction of offshore wind turbine stochastic response due to a series of flaps installed on the rotor blades is discussed, for example, by Thakur et al. [13]. Formulation of this effect is not included herein and will possibly be considered in future studies.

2 THEORETICAL BACKGROUND

Figure 1 illustrates a schematic of a wind turbine blade of length R, i.e. its radius measured from the rotor plane center, rotating at an angular speed Ω (rad/s). Inflow conditions are also displayed. The generic cross section of the blade is located at a distance x from the rotor center. The figure also explains two main differences compared to standard aeroelastic theory of translating airfoil wings [14]: the reference inflow speed is not constant but linearly varies along the axis x; the reference chord length of each section of the blade also varies depending on the cross-section's geometry. Consequently, standard flutter theory cannot be used.

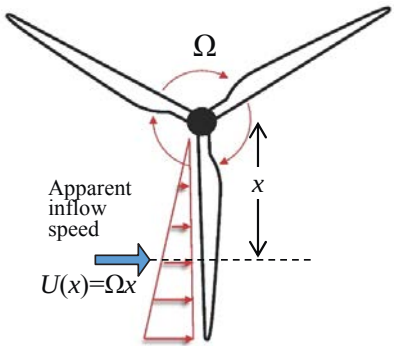

Figure 1: Schematic of rotating wind turbine blade with indication of relative inflow velocity $U(x)$ with $0 \leq x \leq R$.

Equations of motion are based on a continuous formulation of loads and response along blade's longitudinal axis x. The model exploits the model by Hodges and Dowell [15] and previous results [1]. The reference inflow velocity $U(x)$ is defined under the condition of "still-air" wind, i.e. blades rotate at no wind speed, and zero initial twist. This hypothesis is acceptable since inflow velocity is mainly controlled by blade rotation and attached flow conditions are needed to ensure that standard aeroelastic formulation can be applied.

The dynamic response of the blade is represented by modal superposition of the flap-wise, bending deflections h and torsional angles α, rewritten in terms of dimensionless time $\tau=t\omega_{0j}$ (with ω_{0j} a reference frequency) and span-wise coordinate $\eta=x/R$ as:

$$h(\eta,\tau)=\sum\nolimits_q \xi_q(\tau)c_o h_q(\eta)\approx \xi_j(\tau)c_0 h_j(\eta) \tag{1}$$

$$\alpha(\eta,\tau)=\sum\nolimits_q \xi_q(\tau)\alpha_q(\eta)\approx \xi_k(\tau)\alpha_k(\eta) \tag{2}$$

In the previous equation modal superposition is employed, with c_0 a reference chord length of the blade and $h_q(\eta)$, $\alpha_q(\eta)$ dimensionless mode shape functions of generic mode q. If flutter analysis is restricted (truncated) to the combination of a reference flap-wise mode (bending only, jth mode with natural angular frequency ω_{0j}) and torsional mode (torsional only, kth mode with angular frequency ω_{0k}), the two-mode reduced order model equations of the blade rotating at angular rotor speed Ω are, in dimensionless form:

$$\xi_j''(\tau)+2\zeta_j\xi_j'(\tau)+\xi_j(\tau)+\varepsilon_j\chi^2\xi_j(\tau)=Q_j(\tau)\Big/\left(\omega_{0j}^2 I_{0j}\right) \tag{3}$$

$$\xi_k''(\tau)+2\zeta_k\Delta\omega\xi_k'(\tau)+\left(\Delta\omega\right)^2\xi_k(\tau)+\varepsilon_k\chi^2\xi_j(\tau)=Q_k(\tau)\Big/\left(\omega_{0j}^2 I_{0k}\right) \tag{4}$$

In the previous equations the flap-wise mode j is taken as the reference and the flutter frequency ratio is defined as $\chi=\Omega/\omega_{0j}$, whereas the modal frequency ratio is $\Delta=\omega_{0k}/\omega_{0j}$. The derivation with respect to dimensionless time $\tau=t\omega_{0j}$ is designated by the prime symbol; the terms ε_j and ε_k indirectly measure the effects of the centrifugal forces on the rotating blade. The generalized forces Q_j and Q_k are computed according to unsteady aeroelastic airfoil theory via indicial functions [16], i.e. the Wagner function describing the (C) circulatory flow effects [17], and accounting for (NC) non-circulatory effects [18, 19]. It is interesting to note that using the standard dimensionless time $s=Ut/c$ (with U tangential inflow speed and c chord length, Fig. 1) is unsuitable for the purposes of derivation of a closed-form equation, since this quantity varies with x and depends on each specific blade cross section. Furthermore, since the relative tangential speed U varies along x, the convolution integral needed by the unsteady aeroelastic force formulation cannot be resolved in closed form. Therefore, the exponential term of the indicial function in the R.T. Jones' formula [17] below:

$$\Phi(s)=1-\sum\nolimits_{r=1,2} c_r\left\{\mathrm{e}^{-d_r s}\right\} \tag{5}$$

with c_r and d_r being suitable constants and s dimensionless time, must be represented by Taylor series to enable model derivation. The order of the Taylor series expansion of $\Phi(\tau)$ is N. After suitable manipulation, the generalized force of the reference flap-wise mode j is:

$$\frac{Q_j(\tau)}{\left(\omega_{0j}^2 I_{0j}\right)}=\Gamma_j^C C_L^*\left\{\begin{array}{l}\dfrac{\Phi_0 c_0}{2R\chi}G_{h_jh_j}^{(-1)}\xi_j'+\displaystyle\sum_{n=0}^{N}\frac{G_{h_jh_j}^{(n)}}{n!}\left(\frac{2R\chi}{c_0}\right)^n\left[c_1 d_1^{n+1}+c_2 d_2^{n+1}\right]\hat{\mu}_{ae,j}^{(n)}\\ +\Phi_0 G_{h_j\alpha_k}^{(0)}\xi_k+\displaystyle\sum_{n=0}^{N}\frac{G_{h_j\alpha_k}^{(n+1)}}{n!}\left(\frac{2R\chi}{c_0}\right)^{n+1}\left[c_1 d_1^{n+2}+c_2 d_2^{n+2}\right]\hat{\nu}_{ae,j}^{(n)}\end{array}\right\}+\Gamma_j^{NC}\left\{\begin{array}{l}G_{h_jh_j}^{(-1)}\xi_j''+\dfrac{R\chi}{c_0}G_{h_j\alpha_k}^{(-1)}\xi_k'\\ -\dfrac{a}{2}G_{h_j\alpha_k}^{(m)}\xi_k''\end{array}\right\} \tag{6}$$

In the previous equation the first set of braces is related to the C terms of the lift force whereas the second one to the NC, "added mass" effect. The quantity C_L^* is the derivative of the lift coefficient with respect to angle of attack (assumed as a constant along the blade), Γ_j^C and Γ_j^{NC} are dimensionless modal inertias, $G_{hj\alpha k}^{(.)}$ are "modal integral" terms. Finally, $\hat{\mu}_{ae,j}^{(n)}$ and $\hat{\nu}_{ae,j}^{(n)}$ are "partial" aeroelastic states. A similar expression can be derived to describe the generalized force of the mode k; it is not shown for the sake of conciseness.

Following previous work [12], propagation of aeroelastic load uncertainty that accounts for wind tunnel errors and modeling simplifications, is enforced by perturbing the term d_r (with r=2) of $\Phi(\tau)$ as $d_2 = d_{2m} + \delta_2$ with d_{2m} being its mean value and δ_2 a zero-mean random error parameter. The previous equations can be re-cast into a stochastic differential system, Itô-type, depending on a dimensionless scalar Wiener process $B(\tau)$ [9]. This vector equation includes the effect of random error δ_2 by state augmentation, as follows:

$$\mathrm{d}\,\mathbf{Z}(\tau) = \mathbf{a}_{NL}(\mathbf{Z}(\tau))\,\mathrm{d}\,\tau + \sqrt{2\pi}\,\mathbf{d}_u\,\mathrm{d}\,B(\tau) \tag{7}$$

In the previous equation, the drift function $\mathbf{a}_{NL}$ is nonlinear because of δ_2 whereas the diffusion vector $\mathbf{d}_u$ is zero since the forcing function is aeroelastic, i.e. turbulence effects are neglected in this first implementation. The previous equation is solved numerically through Euler-Monte Carlo algorithm, i.e. through sampling [12]. The pth order MLE is approximated, with time τ_l sufficiently large, as:

$$\Lambda_{\Xi}(p) = \lim_{\tau\to\infty} \log\left(\mathrm{E}\left[\left\|\Xi(\tau)\right\|^p\right]\right)\Big/\tau \approx \log\left(\mathrm{E}\left[\left\|\Xi(\tau_l)\right\|^p\right]\right)\Big/\tau_l\,, \tag{8}$$

and with $\Xi = [\xi_j, \xi_k, \mathrm{d}\xi_j/\mathrm{d}\tau,\ \mathrm{d}\xi_k/\mathrm{d}\tau]^T$.

3 EXAMINATION OF TAYLOR SERIES REPRESENTATION OF AIRFOIL INDICIAL FUNCTION

The derivation of the surrogate model requires the representation of the circulatory aeroelastic load, i.e. indicial function [Eq. (5)] by Taylor series expansion. A parametric study is carried out to examine the influence of the expansion order N on the accuracy of the representation. Apart from Eq. (5) (R.T. Jones' formula [17]) the use of the rational function below, as a first approximation to Eq. (5), has also been considered [16]:

$$\Phi(s) \approx \Phi_{\mathrm{rf}}(s) = \frac{s+2}{s+4} \tag{9}$$

The generalized aeroelastic force [Eq. (6)] in the proposed formulation strictly depends on the first derivative of Φ (or Φ_{rf}) with respect to dimensionless time s. The derivatives of Eqs. (5) and (9), using the Taylor expansion truncated at order N, respectively become

$$\frac{\mathrm{d}\,\Phi}{\mathrm{d}\,s} = \sum_{r=1,2} c_r d_r \left\{\mathrm{e}^{-d_r s}\right\} \approx \sum_{r=1,2} c_r d_r \left\{\sum_{n=0}^{N} \frac{(-s)^n (d_r)^n}{n!}\right\}, \tag{10}$$

$$\frac{\mathrm{d}\,\Phi_{\mathrm{rf}}}{\mathrm{d}\,s} = \frac{2}{(s+4)^2} \approx 2\left\{\sum_{n=0}^{N} (-1)^n (n+1)\, 4^{-(n+2)} s^n\right\} \tag{11}$$

Eq. (11) is obtained by suitable expansion of the expression $(s+4)^{-2}=y^{-2}$.

Figure 2 presents the results of this parametric study. In Figure 2a, the two expressions of the indicial functions, Eq. (5) and Eq. (9), are depicted; the main difference is related to the

range of dimensionless time larger than 4. Figure 2b examines the ability of the Taylor expansion to replicate the first derivative of the indicial function, $d\Phi/ds$ or $d\Phi_{rf}/ds$. The Taylor expansion in Eq. (10) is truncated at order N=5 whereas the one in Eq. (11) at order N=30.

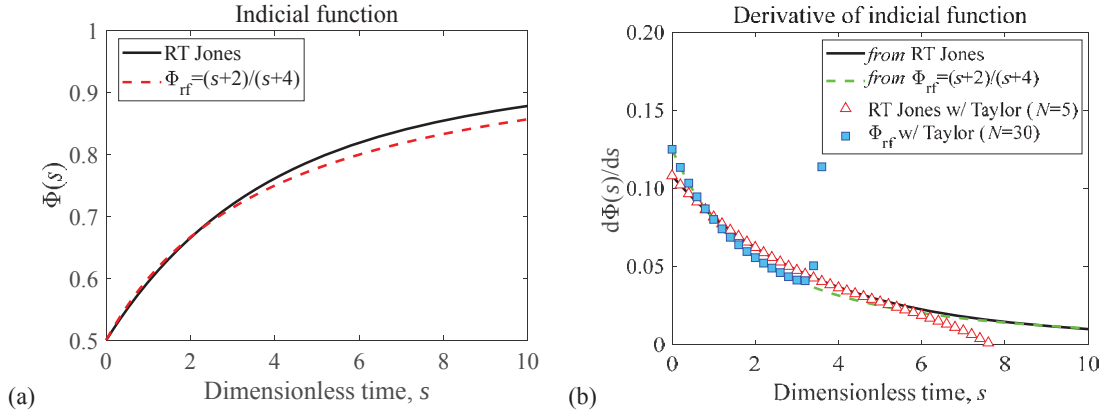

Figure 2: Taylor series representation of airfoil indicial function as a function of expansion order N - RT Jones' formula vs. rational function formula; (a) indicial function $\Phi(s)$, (b) first derivative of indicial function $d\Phi/ds$.

Even though the R.T. Jones' formula has been criticized since it may lead to less accurate results for large s [16], Figure 2b suggests that the ability of replicating the derivative of the function $d\Phi/ds$ is achieved with a lower order N. This feature is preferable from the point of view of the derivation of the surrogate model since N controls the number of partial aeroelastic states, $\hat{\mu}_{ae,j}^{(n)}$ and $\hat{\nu}_{ae,j}^{(n)}$, and consequently the complexity of the model in Eq. (7). Therefore, Eq. (10) is employed as the basis for the expression in Eq. (6).

4 SIMULATION RESULTS

The stochastic coupled-mode flutter of the NREL 5-MW wind turbine blade is examined (rotor radius R=61.5 m). The main structural and aerodynamic properties are derived from the literature [20]. The reduced-order model in Eq. (6) is based on the third flap-wise mode (mode j, natural frequency 4.34 Hz) and the first torsional mode (mode k, natural frequency 5.39 Hz) [1, 20]. Figure 3 illustrates the mode shapes of the two fundamental modes, employed for flutter analysis; in the panels both flap-wise (h) and torsional modal components (α) are displayed; edge-wise terms (p) are not shown.

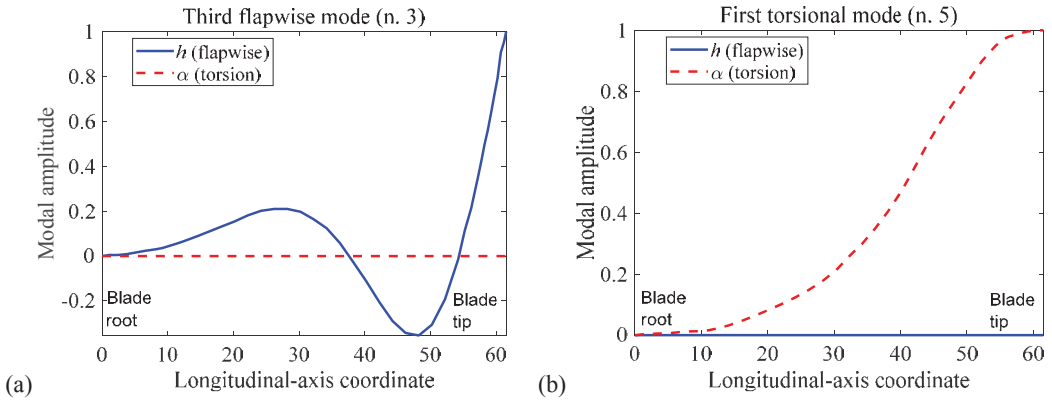

Figure 3: Mode shapes of the two fundamental modes used for flutter analysis; (a) third flap-wise mode (mode j), (b) first torsional mode (mode k). Data are derived from [1, 20].

The edgewise component (p) was neglected in the model. Modal similarity is evident from the panels, confirming that modal integrals $G_{hj\alpha k}^{(\cdot)}$ are non-zero and are responsible for the aeroelastic coupling.

The deterministic flutter problem is solved by setting δ_2=0; the system in Eq. (7) becomes linear in terms of state vector **Z** and flutter is examined by computing the system's eigenvalues as a function of Ω or χ, and by locating zero-damping critical condition. Results are illustrated in Figure 4. The critical flutter rotor speed is estimated as 16.7 rpm (against 20.7 rpm found in previous work [6]). The flutter frequency is 4.5 Hz (against 3.6 Hz). Differences are attributed to the fact that flutter solution of the NREL 5-MW wind turbine blade is also influenced by the 2nd flap-wise mode, neglected in this formulation. Furthermore, a constant C_L^* is employed in Eq. (5), whereas the lift slope varies along x as the cross section of the blade changes [20]. Results are, however, acceptable in the context of this simulation.

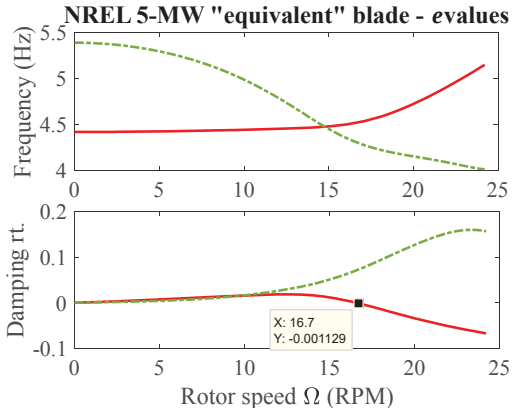

Figure 4: Eigenvalue analysis of the NREL 5-MW wind turbine blade; 3rd flap-wise mode (solid line) and 1st torsional mode (dashed-dotted line) as a function of angular rotor speed Ω (rpm). Flutter solution is highlighted; a positive damping rt. (ratio) in the figure is related to a stable system.

Figure 5 illustrates the stochastic flutter analysis of the system by presenting the estimation of Eq. (8) through numerical solution of Eq. (7) at Ω=16.94 rpm. The example includes non-zero random initial conditions and modeling error δ_2 in the aeroelastic loading of about 8% with respect to the nominal value d_{2m}.

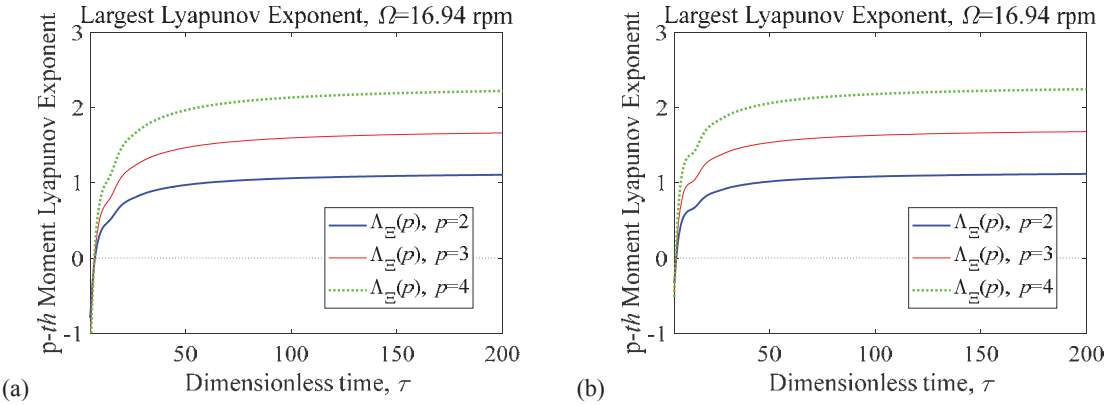

Figure 5. Stochastic flutter analysis of the NREL 5-MW wind turbine blade with random d_2; initial random conditions with (a) moderate zero-mean amplitudes, $E[\xi_{j0}^2]=E[\xi_{k0}^2]=0.01$; (b) large amplitudes, $E[\xi_{j0}^2]=E[\xi_{k0}^2]=0.10$.

Non-zero initial conditions are necessary to examine the onset of stochastic flutter. Two cases are presented: small initial dimensionless modal amplitudes with zero mean and variances $E[\xi_{j0}^2]=E[\xi_{k0}^2]=0.01$, and moderate amplitudes with $E[\xi_{j0}^2]=E[\xi_{k0}^2]=0.10$. The figure confirms that, since the stochastic problem is non-linear, it is amplitude dependent. In particular, for both small and moderate initial amplitudes an unstable system is obtained at Ω=16.94 rpm (negative MLE, asymptotically) suggesting that introduction of modeling error in the loading leads to a de-stabilizing effect in comparison with Figure 4.

5 DISCUSSION AND CONCLUSIONS

The study has demonstrated that it is possible to derive an analytical, closed-form formulation to describe the dynamics of rotating wind turbine blades under the influence of wind loads, contaminated by modeling variability and simplifications. The proposed formulation was employed to examine stochastic flutter of a reference offshore wind turbine blade. Numerical results (Figure 5) are, however, influenced by the solution algorithm, which may numerically introduce an unstable behavior. This aspect requires additional investigation. More discussion and a more detailed parametric investigation, by varying the properties of the input random variables, will be necessary in the future along with soil-structure interaction.

Keywords: Windenergy, Rotorblade, High-Fidelity, Model Updating

Abstract. *Within the context of the "SmartBlades2"-project, a wind turbine rotor blade was designed and extensively tested. The rotor-blade uses a lightweight composite structure and bend-twist coupling. The bend-twist coupling facilitates a passive load-reduction by changing the angle of attack under load. Due to a high sensor-density of 265 accelerometers in the experimental modal test of the blade, the sophisticated structural dynamics of the model are captured. Apart from the commonly measured first flapwise-, edgewise-bending and torsion mode, 35 modes up to a frequency of 60 Hz are identified. Unlike in many other wind turbine rotor blade investigations, the Finite Element (FE) model uses shell elements instead of beam elements and is directly based on production drawings. This experimental and simulative setup is particularly relevant, since a significant number of mode shapes exhibit a distinct local behavior which was in previous studies not accounted for. The differences between experimental and simulated results are minimized using computational model updating procedures. In this case-study, two formerly underrepresented aspects of the updating of large-scale FE models are examined. One is the use of different parameterizations and the other is the possibility of insufficient experimental data. The parametrizations are based on well-established criteria like error-localization and sensitivity. Moreover, the updating is performed with different (i.e. reduced) subsets of the modal data and the results are then compared to the model updating results achieved with the entire dataset. This in-depth investigation of the model updating of a composite structure allows the deduction of general guidelines in the model updating of industrial-sized FE models.*

1 INTRODUCTION

1.1 Model updating of rotor blades

In recent years a large number of wind-turbines were installed [14, 16, 19]. While the total installed power increased significantly, the output per wind turbine was also improved. This was reached by a number of measures. Aside from higher towers and efficiency improvements of the drivetrain, one important aspect is the aerodynamic improvement of the rotor blade [27]. Two closely related main trends govern this aerodynamic improvement. One is the aerodynamic optimization of the shape of the blade, and the other is the increasing length of the blades [15, 17, 27].
In general the aerodynamic optimization of the blade leads to mechanically more complex behavior [26]. The mechanical behavior of optimized rotor blades can, unlike the behavior of previously designed rotor blades not sufficiently be described with simple beam theory and requires more sophisticated models [25]. In addition to this, longer blades lead to higher loads and therefore a more considerate mechanical approach becomes necessary.
The wind turbine rotor blade that will be investigated in the following was designed with the intention of a geometrical bend-twist coupling to passively reduce loads during operation. Modal data from experimental vibration testing and finite element (FE) simulations usually lead to different results. In order to get reliable experimental data, various measures were taken [18]. To get an overview of the structural behavior, broadband random excitation signals are used. To check for specific properties, this is followed by tuned sine excitation. Different excitation levels are chosen, to identify possible nonlinearities. The modal parameters from all excitation runs (high force, low force, random, sine sweep - each in edge-wise as well as flap-wise direction) are compared with each other to extract the ”best” modes for the experimental modal model. Modeling errors in simulations can be classified in three main categories: idealization errors, discretization errors and erroneous parameters assumptions [22]. Neither idealization errors nor discretization errors are within the scope of conventional computational model updating [22]. Assuming these errors are negligible, a tuning (updating) of the parameters, so that similar results are achieved is reasonable [5]. The model updating is relying on previously acquired high-fidelity test-data described in [11, 13] and an existing FE model of the wind turbine rotor blade [30, 31]. From Figure 1 an impression of the fixed-free experimental set-up as well as the corresponding FE model can be gained. The model updating in this study is achieved

a) rotor blade attached to test-rig b) FE model of rotor blade and test-rig

Figure 1: Experimental setup and FE model

with FEMtools and MSC Nastran.
A simulation model that closer resembles reality will allow for better strain and deflection predictions and therefore offers several advantages. In operations, having better strain estimates leads to better fatigue and life-cycle estimations. Furthermore structural improvements of the mechanical behavior of new blades in the future can be based on a more precise predecessor model. This allows for reduced security margins, as the certainty in the mechanical behavior

of the precursor is higher. Increasing the validity of the deflection predictions enables better assessment of loads on the blade as well as on the entire wind turbine. Finally having more accurate deflection predictions also leads to better estimates of the output electrical power.
Numerous publications deal with iterative gradient-based model updating in the aerospace sector whereas only a few publications deal with the model updating of wind turbine blades. One reason for that appears to be, that the security requirements in the aerospace industry are higher than in the wind turbine industry. This is reflected in the certification process. Ground Vibration Tests are necessary for new aircraft prototypes, whereas they are not explicitly recommended for new wind turbine blades [2]. In this context the following publication presents a case study of the updating of a helicopter frame [22], [6] describes the updating of a full scale aircraft and among many others [7, 12, 21, 28] deal with small scale model updating problems. MOGRAVE and FRIBERG treat both a small scale and an industrial sized example [21]. Herein small refers to the dimensions of the model and not necessarily to the number of elements in the FE model. In recent years, some authors dealt with model updating of wind turbine blades. Amongst them [8, 9, 29] focused on a few modes and static deflection data. LUCZAK et al. investigated a blade section and chose a response surface based approach, that led to slightly improved correlation between test and analysis [20]. GROSS et al. updated a small scale wind turbine rotor blade (i.e. small in terms of rotor length) iteratively and sensitivity based [10]. The wind turbine rotor blade is tested under different boundary conditions. The exact improvements achieved with the model updating in terms of correlation between measured and simulated mode shapes remain unclear. In [5] the importance of having fewer parameters than responses and thus creating an (over-) determined system of equations is underlined. While DASCOTTE acknowledges the advantages of such a parameterization, the benefits of using more parameters than responses are described [1].

1.2 Methodology and Structure

The aim of this work is to improve and validate an existing FE model which is directly based on production drawings. In order to achieve this, high fidelity experimental results are used. A brief overview over the existing theoretical foundation for the techniques used in this work is given in Section 2. After an initial comparison of experimental and simulated results, it becomes apparent, that the compliance of the test-rig used during the experiments is non negligible, the model is thus (successfully) manually adapted (Section 3). The global similarity between experimental and simulated results ought to be minimized by adapting material parameters, while reflecting the true properties of the material as close as possible. This is firstly examined with the full set of sensors. A particular focus is laid on minimizing differences between experimental and simulated eigenfrequencies. Furthermore, two different parameterizations are investigated. These parameterizations are used and compared with respect to their advantages and disadvantages (Section 4.1). The parameterization which yields better results is used in the following computational model updating of the wind turbine rotor blade with subsets of sensors. The results of this are compared to the reference case that uses a full set of sensors (Section 4.2). Due to the comprehensive previously acquired experimental data [11], the updated wind turbine rotor blade models can be validated by changing the respective boundary conditions to ”free-free” and comparing the results to the respective experimental data set (Section 4.3). In Section 5 the results are summarized and an outlook is given. Section 6 acknowledges the support of different partners, without whom this study would not have been possible. The present work relies on a previously created simulation-model [30] as well as experimental data [11, 13] and is directly based on the study described in [18].

2 Iterative gradient-based model updating

The exact relation between changes in physical quantities like mass and stiffness (i.e. parameters) and the resulting changes in modal properties (i.e. responses) is simple to derive for very small systems but becomes increasingly difficult and practically impossible for industrial sized models. In light of this, the functional relation between parameters and responses is approximated with a TAYLOR series limited to the first two terms

$$\boldsymbol{r}_{\text{fe}}\left(\boldsymbol{p}\right) = \boldsymbol{r}_{\text{fe}}\left(\boldsymbol{p}_{\text{n}}\right) + \underbrace{\left.\frac{\partial \boldsymbol{r}_{\text{fe}}}{\partial \boldsymbol{p}}\right|_{\boldsymbol{p}=\boldsymbol{p}_{\text{n}}}}_{:=\boldsymbol{S}} \left(\boldsymbol{p} - \boldsymbol{p}_{\text{n}}\right). \tag{1}$$

In this $\boldsymbol{r}_{\text{fe}}$ is the response dependent on the parameters. Responses are chosen by the analyst and comprise (in the context of this work) of mode shapes and derived metrics, eigenfrequencies, mass and center of gravity resulting from the simulation model. $\boldsymbol{p}$ are the parameters (e.g mass and stiffness) and $\boldsymbol{p}_{\text{n}}$ are the parameter values at which the TAYLOR series is evaluated. $\boldsymbol{S}$ stands for the sensitivity of the numerical model. Evaluating $\boldsymbol{r}_{\text{fe}}$ at, yet to determine, new parameter values $\boldsymbol{p}_{\text{n+1}}$, the difference between experimental and numerical responses is

$$\boldsymbol{\varepsilon} = \boldsymbol{r}_{\text{exp}} - \boldsymbol{r}_{\text{fe}}\left(\boldsymbol{p}_{\text{n+1}}\right) \tag{2}$$

using the TAYLOR series for $\boldsymbol{r}_{\text{fe}}\left(\boldsymbol{p}_{\text{n+1}}\right)$ leads to the error term

$$\boldsymbol{\varepsilon} = \underbrace{\boldsymbol{r}_{\text{exp}} - \boldsymbol{r}_{\text{fe}}\left(\boldsymbol{p}_{\text{n}}\right)}_{:=\Delta\boldsymbol{r}} - \boldsymbol{S}\underbrace{\left(\boldsymbol{p}_{\text{n+1}} - \boldsymbol{p}_{\text{n}}\right)}_{:=\Delta\boldsymbol{p}}. \tag{3}$$

The objective function is then defined as

$$J(\Delta\boldsymbol{p}) = \boldsymbol{\varepsilon}^T\boldsymbol{W}_r\boldsymbol{\varepsilon} + \Delta\boldsymbol{p}^T\boldsymbol{W}_p\Delta\boldsymbol{p}. \tag{4}$$

It is dependent on the parameter changes $\Delta\boldsymbol{p} = \left(\boldsymbol{p}_{\text{n+1}} - \boldsymbol{p}_{\text{n}}\right)$. By additionally introducing diagonal weighting matrices for the parameters ($\boldsymbol{W}_p$) and the responses ($\boldsymbol{W}_r$) confidence in both experimental results and numerical model assumptions can be expressed [1]. The weighting matrices furthermore have a regularizing effect, which is comparable to a TIKHONOV-regularization [5]. Minimizing (4) leads to the calculation formulae for the new parameter $\boldsymbol{p}_{\text{n+1}}$ as defined in [1] and given in the following. According to DASCOTTE [1], if the number of parameters is less than or equal to the number of responses the new parameter values are calculated as

$$\boldsymbol{p}_{\text{n+1}} = \boldsymbol{p}_{\text{n}} + \left(\boldsymbol{W}_p + \boldsymbol{S}^T\boldsymbol{W}_R\boldsymbol{S}\right)^{-1}\boldsymbol{S}^T\boldsymbol{W}_R\Delta\boldsymbol{r}, \tag{5}$$

if the number of parameters is larger than the number of responses the new parameters are calculated with the equation

$$\boldsymbol{p}_{\text{n+1}} = \boldsymbol{p}_{\text{n}} + \left(\boldsymbol{W}_P\right)^{-1}\boldsymbol{S}^T\left(\boldsymbol{W}_R^{-1} + \boldsymbol{S}\boldsymbol{W}_P^{-1}\boldsymbol{S}^T\right)^{-1}\Delta\boldsymbol{r}. \tag{6}$$

2.1 Unification of measurements and simulations

In preparation of the updating, measurements and simulations have to be unified in many respects, which will be described in the following. Within this work all mode shapes (i.e experimental mode shapes $\boldsymbol{\psi}_r$ and simulated mode shapes $\boldsymbol{\phi}_r$) are scaled to largest component one. In the following damping is not considered and therefore the numerically calculated mode

shapes are entirely real valued. As the blade is lightly damped [18] using the magnitude and an appropriate sign for the experimental results as described in [1] is reasonable. In order to compare measurements and numeric calculations a common set of measurement points and degrees of freedom (DOFs) must be chosen. The numeric results can be reduced to the measurement points and DOFs, or the measurements can be expanded to the numerical calculated points and degrees of freedom. Expanding the measurement results implies interpolation between measurement points and can for example be achieved with the system equivalent reduction and expansion process (SEREP as described in [24]). To reduce the simulation results, the measurement points of the structure are mapped to nearby FE nodes. This means, that the results at DOFs, that are not close to a measurement point are omitted. As there are usually significantly more nodes than measurement points, the number of deleted results is large. The results (i.e. mode shapes) will be reduced to the measurement points.

2.2 Metrics for comparison

After measurements and simulations are unified, the similarity of measurement and simulation results can be quantified. This similarity quantification is helpful in the manual model adaptation and necessary for the computational model updating procedure. In the computational model updating select pairs are formed between experimental modes and simulated modes that have a high initial congruence.
In the derivation of most metrics, model assumptions and mathematical properties, like mass orthogonality or linear independence of eigenvectors are exploited. While the indicators described hereafter are rather similar, an important distinction is whether they refer to every DOF or they are giving a value for all DOFs. The same normal mode shapes have to be collinear and different mode shapes must be orthogonal with respect to the mass matrix [3]. This is supposed to be true for (normalized) experimental modes, numerical modes and between numerical and (normalized) experimental modes. Due to inaccurate and incomplete measurements, this relation is in practice not entirely fulfilled. Besides using Mass $\boldsymbol{M}$ as a weighting factor one can also directly check the orthogonality of mode shapes. The Mass Matrix $\boldsymbol{M}$ can (like any model of the real world) only be approximately correct. It is therefore reasonable to use no weighting factor instead of using a potentially wrong weighting factor. One then calculates the modal-assurance-criterion (MAC) for the simulated mode $\boldsymbol{\phi}_k$ (with the numbering k) and the experimental mode $\boldsymbol{\psi}_m$ (with the numbering m):

$$\mathrm{MAC}(\boldsymbol{\phi}_k, \boldsymbol{\psi}_m) = \frac{\left(\boldsymbol{\phi}_k^T \cdot \boldsymbol{\psi}_m\right)^2}{\left(\boldsymbol{\phi}_k^T \cdot \boldsymbol{\phi}_k\right)\left(\boldsymbol{\psi}_m^T \cdot \boldsymbol{\psi}_m\right)}. \tag{7}$$

The resulting value is 100 % for collinear modes and 0 % for orthogonal modes [1]. MAC values between simulated mode shapes of the same simulation are, as MAC value between experimental mode shapes of the same dataset, referred to as AUTOMAC values. As a measure of orthogonality for every degree of freedom l, over N mode shapes (with the numbering k) the coordinate-modal-assurance-criterion (COMAC) is introduced [1]

$$\mathrm{COMAC}(l) = \frac{\left(\sum_{k=1}^{N} (\boldsymbol{\phi})_k^l \, (\boldsymbol{\psi})_k^l\right)^2}{\left(\sum_{k=1}^{N} (\boldsymbol{\phi})_k^l \, (\boldsymbol{\phi})_k^l\right)\left(\sum_{k=1}^{N} (\boldsymbol{\psi})_k^l \, (\boldsymbol{\psi})_k^l\right)}. \tag{8}$$

The COMAC gives a sum (and therefore allows for fast checks) for multiple modes. The COMAC takes values between zero and one hundred percent. For brevity, the percentage signs are oftentimes omitted in the following.

3 Comparison of initial results and manual model adaptation

In Figure 2 the eight initially paired mode shapes are shown. In this figure, the experimental results are shown in red, while the simulated results are shown in blue. Their medium MAC value of 92 and medium frequency deviation of 8.8 % is detailed in Figure 6. It is noteworthy that mode shape 2.) has a MAC value of 98 inspite of its dissimilar appearance in Figure 2 2.). This is due to the fact, that sensors in edge-wise direction are only installed on the leading edge (Fig. 13 2.)), therefore the test-model (red) is not deformed in edge-wise direction at the other positions. It becomes apparent, that for all mode shape pairs apart from the first one, the experimentally determined eigenfrequency is higher than the simulated eigenfrequency. Furthermore the overall MAC values are high, but decrease slightly for modes with higher frequency.

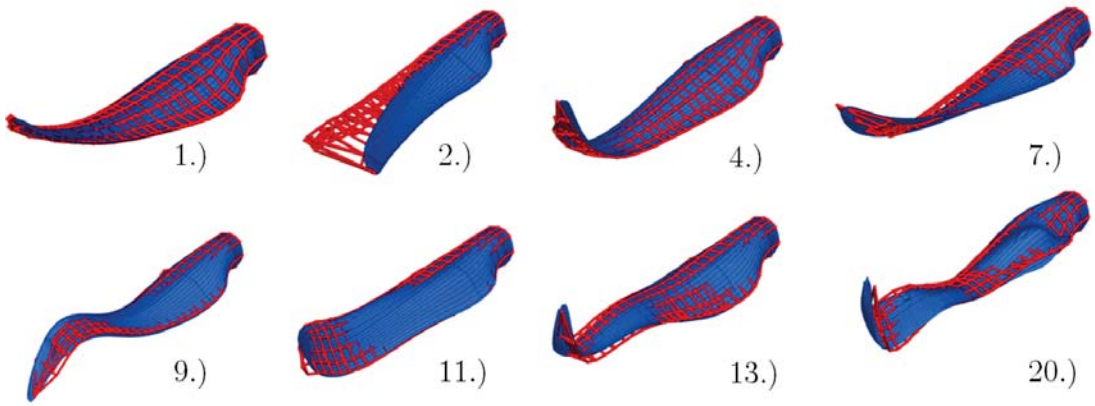

Figure 2: Initially paired mode shapes (numbered according to experimental mode shape number)

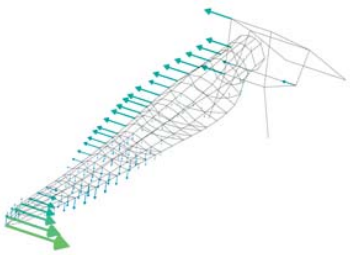

Figure 3: rig-mode at 7.2 Hz

The blade is tested while being clamped to a test-rig Figure 5 a). In a first approach a fixed-boundary condition is applied (i.e. displacement and rotations in all directions are suppressed) at the first nodal line on the blade root. An inspection of the COMAC values displayed in Fig. 4 a) and Fig. 4 b shows, that the local correlation gets significantly lower towards the root of the blade. Herein the gray markers indicate COMAC values below 50. In Figure 3 the first (experimental) rig-mode is depicted. Since this is the fifth experimental mode, it is concluded that the compliance of the test-rig is non negligible and therefore an FE model of the test-rig is created. The FE model of the blade is then rigidly attached to the FE model of the test-rig. The test-rig is made out of steel. The exact sort of the steel is unknown to the authors, S335 with its properties given in e.g. [4] is used in the model. To efficiently simulate the behavior of the test-rig, small features, like chamfers, holes and bolts are removed from the model. The simplified geometry of the test-rig is shown in Figure 5 b. Based on the simplified geometry, with unstructured meshing an FE model that consists of 58398 CTETRA-elements is constructed. The test-rig is estimated to have total mass of 23.5 tons. Removing holes, bolts and chamfers leads to an increase in mass of 1.5 tons and an (not quantified) increase in stiffness. The test-rig is fixed to the ground at four corner points with threaded rods. Nonetheless, the test-rig is assumed to move in lateral direction. This assumption is backed by the width of the support surface of the H beam (as depicted in the bottom

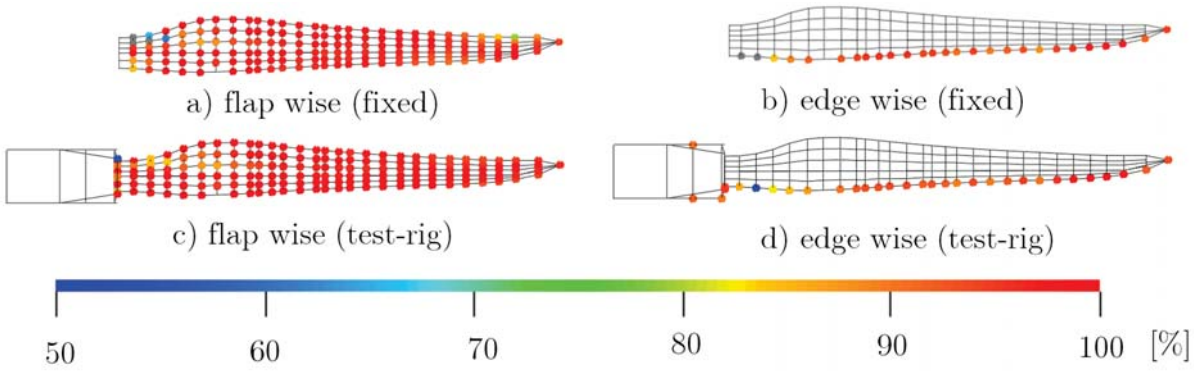

Figure 4: COMAC for 8 initially paired mode shapes

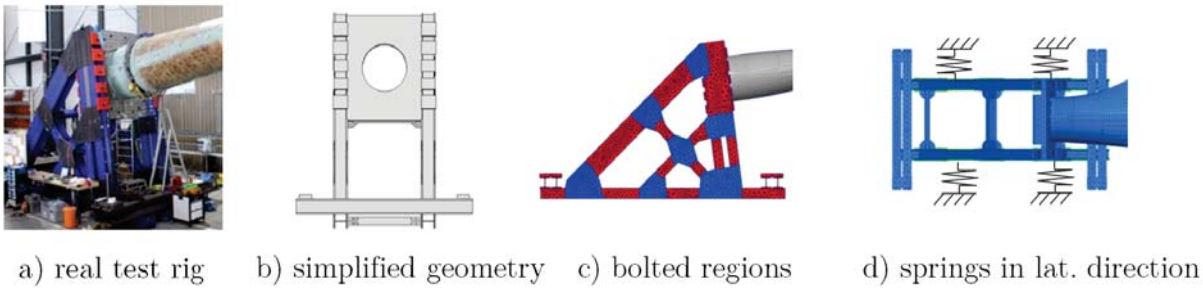

Figure 5: Test-rig: from reality to FE-model

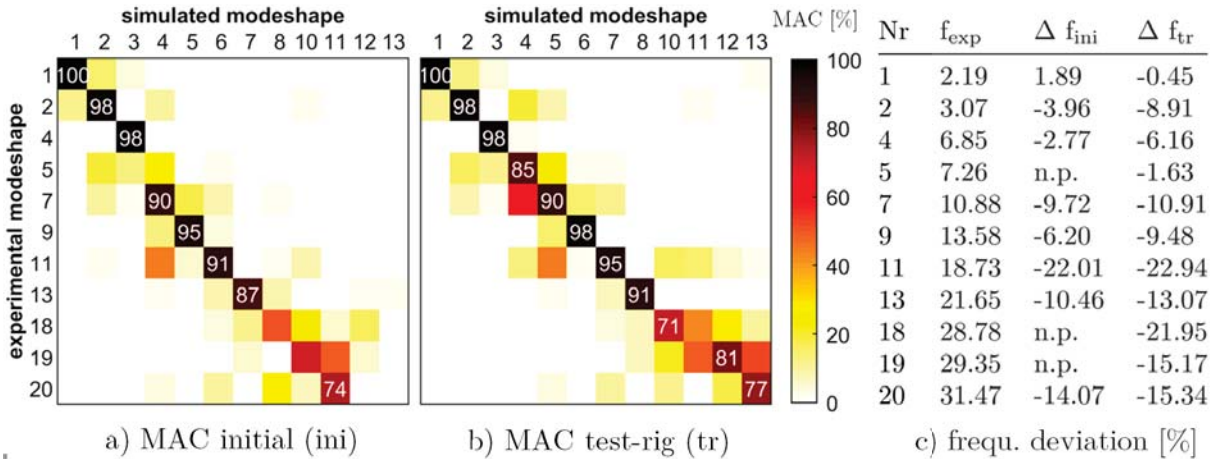
of Fig. 5 a) and Fig. 5 b)) on which the test-rig stands (1 cm for each surface, therefore 4 cm in total). This assumed lateral movement is described in the model, by attaching springs in lateral direction at every node on the bottom surfaces of the H beams (as symbolized in Fig. 5 d). The spring constants as well as the stiffness of the test-rig in areas of bolted connections shown in blue in Figure 5 c) are adjusted to reproduce the first rig-mode. With a stiffness reduction in these areas to 10 % of the nominal stiffness, a MAC value of 85 % and a frequency deviation of 1.64 % deviation is reached for the simulated mode and the experimental mode displayed in Figure 3. Furthermore, significantly higher COMAC values are reached for the initially paired mode shapes in both flap wise (Fig. 4 c)) and edge wise direction (Fig. 4 d)). Since the COMAC is calculated over all initially paired mode shapes, the increased COMAC values indicate, that the test-rig describes the reality more closely, than a fully fixed boundary condition. In Figure 6, MAC values as well as frequency deviations between simulated and experimental results for both the initial configuration (i.e. fully fixed) and the configuration with the auxiliary test-rig are shown. From this, it becomes clear, that the simulation model with the auxiliary test-rig not only leads to increased MAC values (compared to the initial configuration) but also three mode shapes (5.) 18.) 19.)) that where previously not paired (n.p.) and are now paired. Despite the slightly increased deviations in eigenfrequency for the model with the auxiliary test-rig (Fig. 6 c)), the overall similarity between experiment and simulation is increased with the above described manual model adaptation.

4 Computational Model updating

In order to further improve the global similarity between simulated and experimental results the model of the blade is computationally updated as described in the following. In this process the above described auxiliary model of the test-rig is used but not further adapted.



Nr	f_{exp}	Δf_{ini}	Δf_{tr}
1	2.19	1.89	-0.45
2	3.07	-3.96	-8.91

20	31.47	-14.07	-15.34

Figure 6: MAC and deviation in eigenfrequency for initial and manually adapted model

4.1 Updating based on full set of sensors - reference configuration

4.1.1 Responses

The magnitude of the relative deviation in eigenfrequency $|\Delta f| = |(f_{fe}\text{-}f_{exp})/f_{exp}|$ between a simulated (fe) and an experimental mode (exp) is used as one measure for pairing respective modes. This is due to the fact that, in conjunction with similar mode shapes, this deviation is a good indicator of similarity and therefore helps in relating models in terms of their dynamic behavior. In the following, experimental and simulated modes are considered to be paired, if they have MAC value above 70 % and an absolute frequency deviation of less than 30 %.
As responses MAC values (11) and frequency deviations (11) of paired mode shapes as well as the center of gravity (1) in spanwise direction (COG) and the mass (1) are used. This results in a total number of 24 responses. The responses are weighed differently. The diagonal response weighting matrices $\boldsymbol{W}_R$ are built from the weights as given in the following. The frequency responses are, as oppose to all other responses which are given a weighting of 1, given different weights in the objective function (Tab. 4.1.1). Responses with higher weights are emphasized in the objective function, while responses with a lower weight are not. The weighting is based on the premise, that in the updating of this rotorblade, large initial discrepancies in frequency (in particular for torsional modes) ought to be minimized, while mode shape correlation should improve.

Table 1: response weighting

Experimental Mode Shape	1.)	2.)	4.)	5.)	7.)	9.)	11.)	13.)	18.)	19.)	20.)
frequency weighting	1	2	1	1	2	1	4	1	2	2	4

4.1.2 Initial sensitivities

To tune the global dynamic behavior of the simulation model, two types of parameters are used. A scaling factor on the membrane stiffness as well as a scaling factor on the density. In preparation of the parameterization, sensitivities are calculated for every shell element with respect to each response. The summed normalized initial sensitivities are displayed in Figure

7. Herein the scale is limited to allow the detection of relevant regions. For a small number of elements the magnitude of the sensitivities is larger than shown in Figure 7. With this, it becomes apparent that different regions are particularly sensitive. It is worth noting, that apart from the areas marked in red and blue in Figure 7, the beginning of the spar (not visible in the figure) is highly sensitive to changes in density as well as in membrane stiffness.

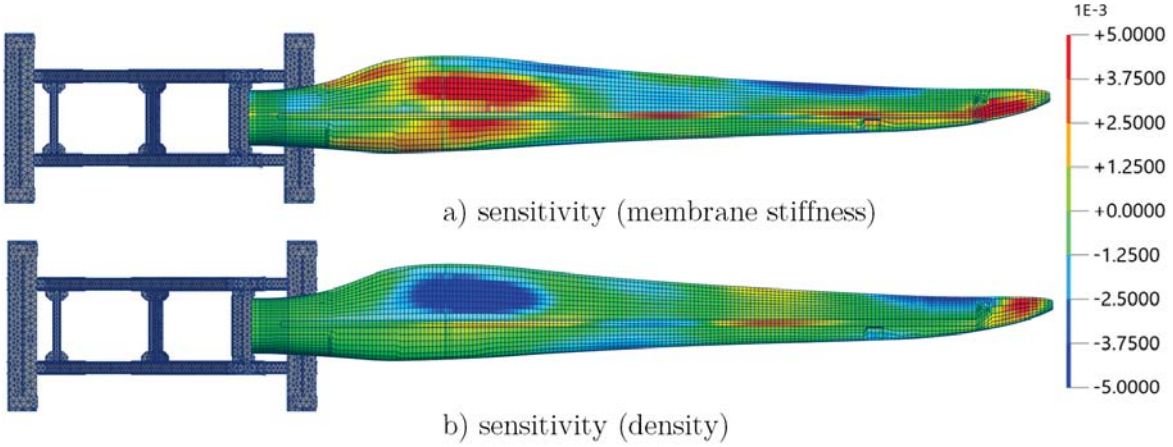

Figure 7: Initial summed normalized sensitivities (limited scale)

4.1.3 Parameterization

The model is parameterized in two different ways. In the first approach 12 design fields are used. Using one scaling factor on the membrane stiffness and one scaling factor on the density as parameters for each design field leads to 24 parameters in total. The design fields are equally spaced from root to tip and numbered consecutively from left to right, beginning in the upper left and ending in the lower right (Fig. 8 a)). The spar is included in the lower 6 design fields (i.e. design field number 7 to design field number 12). In the second approach 40 design fields as shown in Figure 8 b) are used and numbered according to the same scheme as in the other parameterization. Additionally 19 design fields are equally spaced along the spar (from root to tip) leading to a total number of 59 design fields and thus 118 parameters. The first parameterization has the advantage of using the same number of parameters (24) as responses (24) and therefore leading to a determined system of equations. In spite of this drawback, the parameterization with 118 parameters has the advantage of a finer spatial resolution and furthermore accounts for differences in sensitivities on the spar as oppose to the outer hull of the blade. Since the second parameterization uses fewer responses than parameters, the parameter changes are additionally constrained to their initial value in order to ensure a deterministic updating procedure. Because the model is directly based on production drawings, the maximum

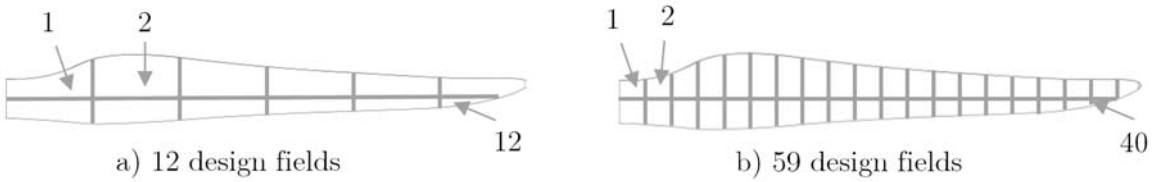

Figure 8: Design fields leading to parameterizations

parameter change is set to 15%. While the exact number is based on engineering judgment, the general limitation of parameter changes is due to the notion, that the updated model should not just reproduce the experimental results but also reflect the true material properties as close as possible [23]. The parameter change per iteration is limited to 0.5 % in order achieve a smooth convergence of parameters. All parameters are weighed equally with a value of 1 (i.e. $\boldsymbol{W}_P$ is the identity matrix). This is due to the fact, that there is no indication of particular uncertainty on select parameters.

4.1.4 Adaptations

The parameters are adjusted in 150 iteration steps. The final parameter values are shown in Figure 9. Both models are adapted similarly. This is particularly the case for the membrane stiffness (Fig. 9 c), Fig. 9 d)) where the membrane stiffness in large regions is increased by the set maximum of 15 %. Figure 9 b) shows, that the density at the tip of the blade is changed significantly differently in the two neighboring design fields 19 and 20. The discrepancy of more than 20 % shows that using a finer spatial resolution is particularly reasonable in this area. Furthermore, the differences between the adaptations of the spar as oppose to the outer hull of the blade (Figure 9 b) Figure 9 d)) indicates, that the sensitivities throughout the updating process differed. Since, in the parameterization with 12 design fields, the spar is included in the design fields towards the leading edge, the adaptations to the spar shown in Fig. 9 a) b) are equal to the respective parameter changes for the outer hull of the blade. Figure 10 shows

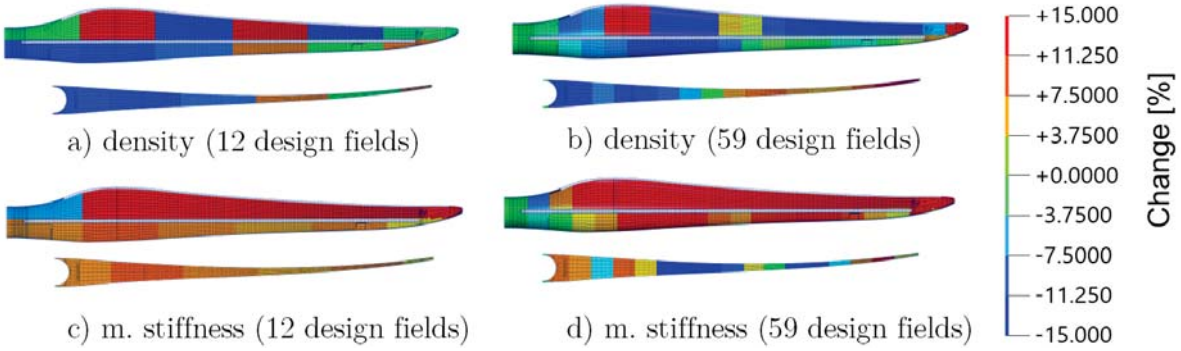

Figure 9: Parameter adaptations after 150 iteration steps

the parameter evolution over 150 iteration steps. Numerous parameters are increased to the set magnitude limit of 15% change after a comparatively small number of iterations. Besides this, parameters do not visibly change slope of change (i.e. parameters that decrease in the beginning continue to decrease and parameters that increase in the beginning continue to increase).

4.1.5 Results

Oposing Figure 6 and Figure 11 highlights, that updating the FE model (while using the FE model of the test-rig) leads to increased MAC values and decreased frequency deviations. Figure 11 a) and b) show that the MAC values are improved with both parameterizations. The parameterization with 118 parameters leads to an (overall) higher similarity (i.e. increased MAC values and decreased frequency deviations) than the parameterization with 24 parameters (Fig. 11) . From Figure 12 it becomes clear, that the parameter adaptations lead to an improvement

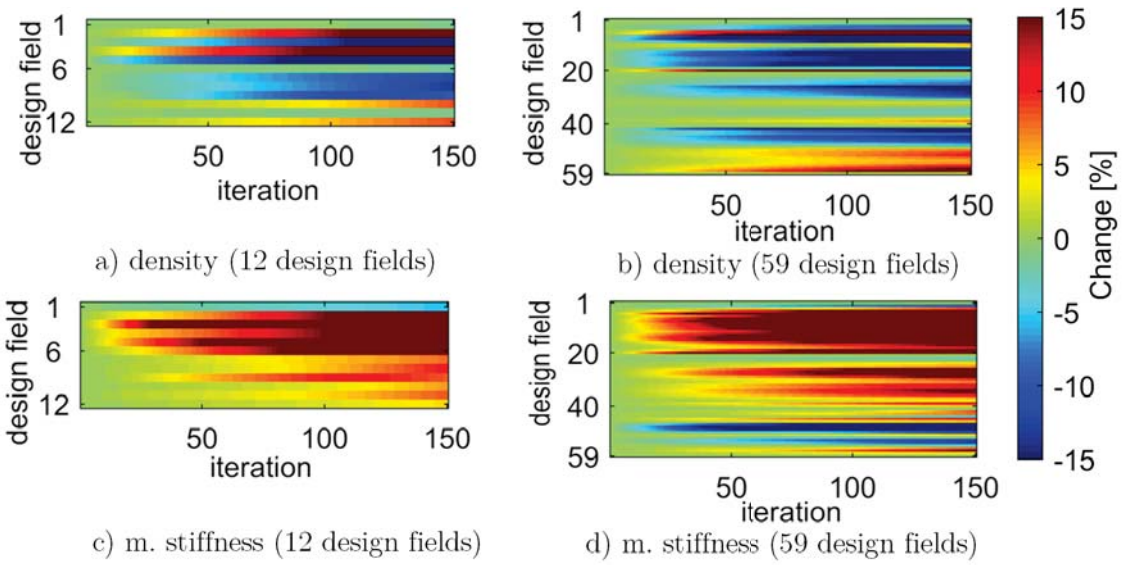

Figure 10: Evolution of iteratively adapted parameters

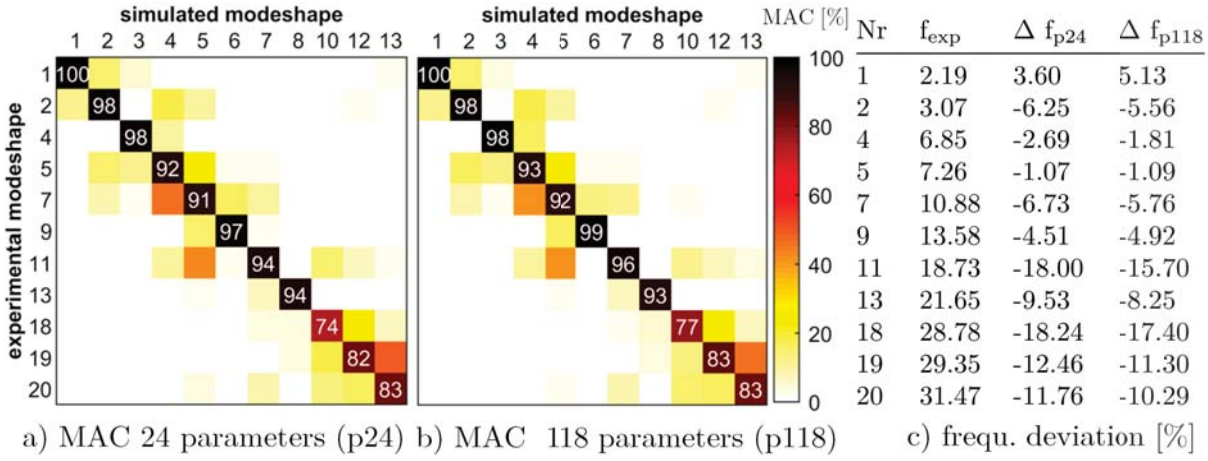

Nr	f_{exp}	Δf_{p24}	Δf_{p118}
1	2.19	3.60	5.13
2	3.07	-6.25	-5.56

20	31.47	-11.76	-10.29

Figure 11: MAC and deviation in eigenfrequency for updated models

in mean MAC value and decreasing discrepancy in frequency. Furthermore Figure 12 shows, that these similarity indicators are better for the parameterization with 118 parameters than for the parameterization with 24 parameters. It ought to be noted, that, while frequency deviations are still decreasing after iteration 100 mean MAC values are slightly deteriorating.

4.2 Updating based on reduced set of sensors

The updating with the reduced set of sensors uses the sensor locations shown in Figure 13 and is performed with the second parameterization (i.e. 118 parameters), which yielded better results in the reference case. The updating is performed with different sets of sensors selections. While the number of sensors used in the updating is reduced, the modal model is not changed, i.e. the modal identification is not repeated with the reduced sensor sets. The full set of sensors is displayed in green in the upper part of Figure 13. The total number of paired sensors on the wind turbine rotor blade and the test-rig is 272, 237 sensors are in flap wise direction while 35 are in edge wise direction (at the leading edge). The number of sensors is iteratively reduced. In each step one sensor is removed based on the notion, that the sum over the off-diagonal values of

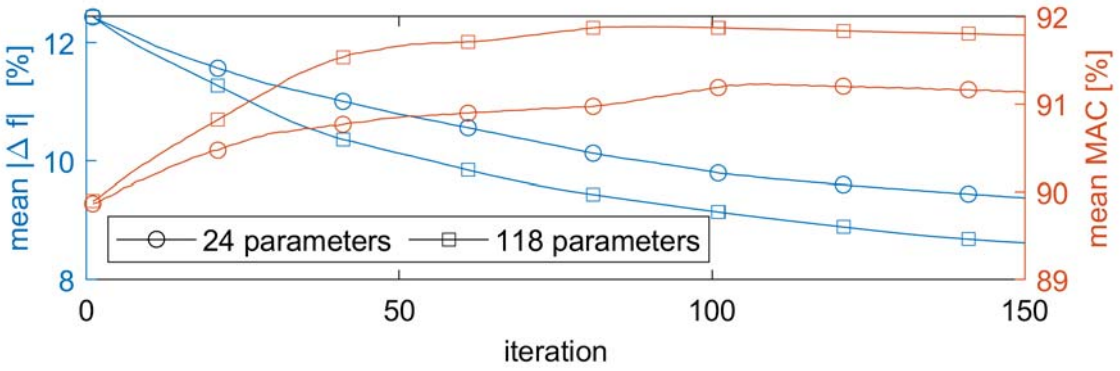

Figure 12: Evolution of medium MAC value and frequency deviation

the AUTOMAC-matrix for the Finite-Element (FE) mode shapes 1 to 20 evaluated at the sensor positions is minimized. Three configurations with reduced sensor sets will be investigated. The number of sensors is reduced to 1/2 (red. sens (1/2)), 1/4 (red. sens. (1/4)) and 1/8 (red. sens. (1/8)). The remaining sensors for these configurations are marked on the lower test-model in Figure 13. In the first configuration, sensors are located at all color-marked positions (red. sens (1/2)), the second configuration uses only the sensors at the positions marked in yellow and red (red. sens. (1/4). The third configuration uses only sensors at the locations marked in yellow (red. sens (1/8)). From Figure 14 it becomes clear, that potentially hard to distinguish mode shapes e.g. 11 and 12 are hard to distinguish for all configurations. Overall the AUTOMAC matrices lead to the impression, that most mode shapes up to the 20th mode are well distinguishable for all configurations. The evolution of the mean similarity indicators

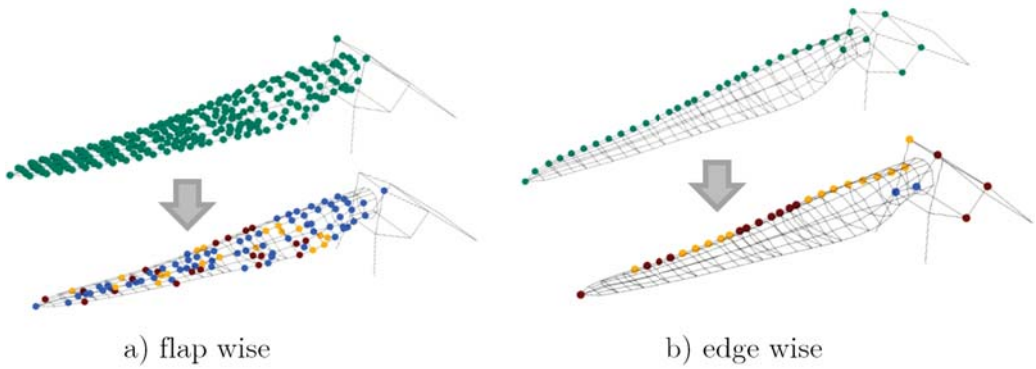

Figure 13: Full and reduced sensor selection

for the updating of these reduced configurations are displayed in Figure 15. It becomes clear, that the frequency discrepancy for all reduced sensor configurations is minimized as well as for the full sensor configuration. In contrast to this, the MAC improvements for the reduced configurations (red. sens. (1/4) and (red. sens. (1/8))) are smaller than for the full set of sensors or nonexistent (red. sens. (1/2)).

4.3 Verification

The boundary condition of the updated models is changed to ”free-free” and compared to the experimental ”free-free” modal-data described in [11]. An overview of these verification results can be gained from Figure 16. In this, the similarity metrics are calculated for mode

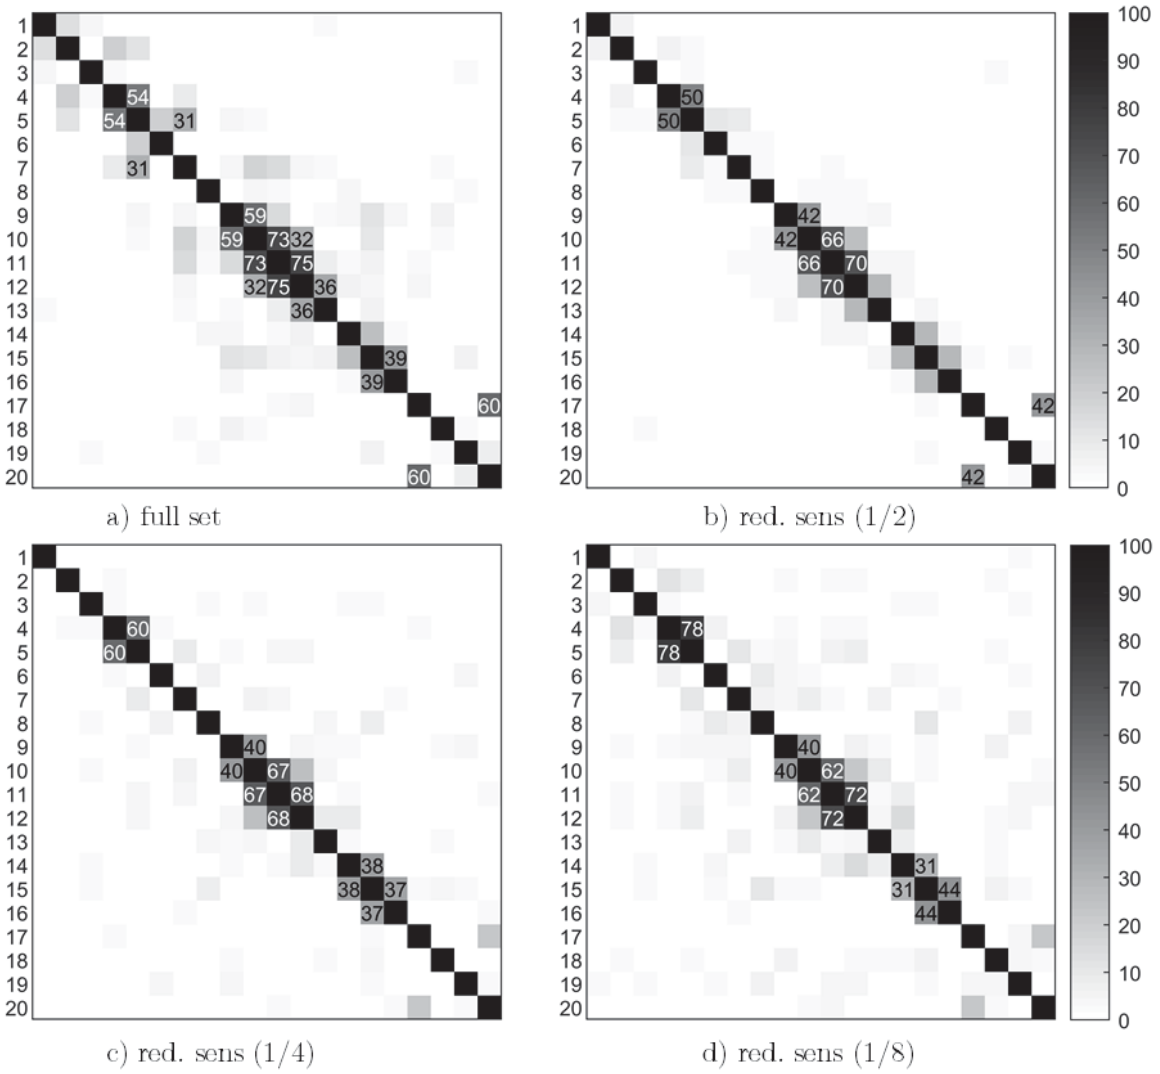

Figure 14: FE-AUTOMAC matrices in [%] evaluated for full and reduced sensor sets

shape pairs that occur in all configurations. It becomes clear, that the mean frequency deviation is improved for all configurations and all mean MAC values are marginally aggravated. The improvements are slightly better in terms of the MAC values for the parameterization with 24 parameters as oppose to the parameterization with 118 parameters. With respect to the mean frequency deviation, the parameterization with 118 parameters leads to slightly better results.

5 Summary and Outlook

In the present work, several aspects of the model updating of an industrial-sized FE model of a wind turbine rotor-blade were investigated. The more accurate representation of the boundary condition by creation of an auxiliary FE model led to the largest improvement in MAC values and slightly worsened the frequency deviation. In this case study, a parameterization with a number of parameters that exceeds the number of responses led to better results, than a parameterization in which the number of parameters is equal to the number of responses (Fig. 11). Furthermore it was shown, that with a reduced number of sensors, the frequency deviation can be minimized well, while the correlation of the MAC values was not significantly improved

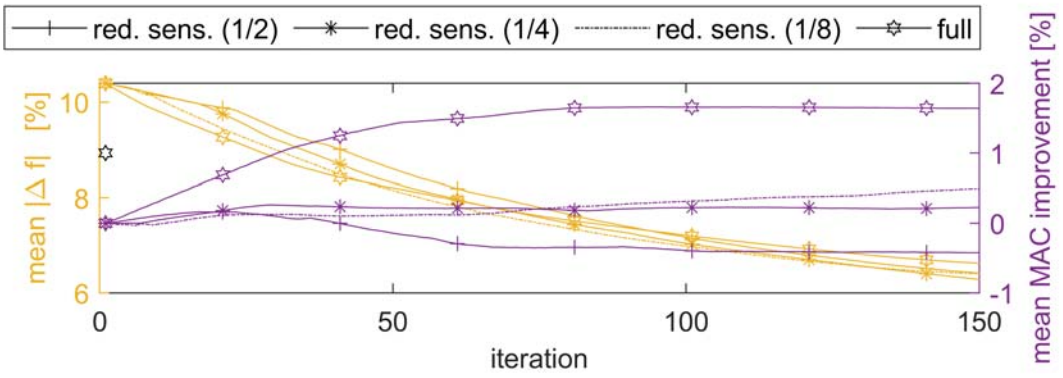

Figure 15: Evolution of similarity criteria for reduced sensor sets

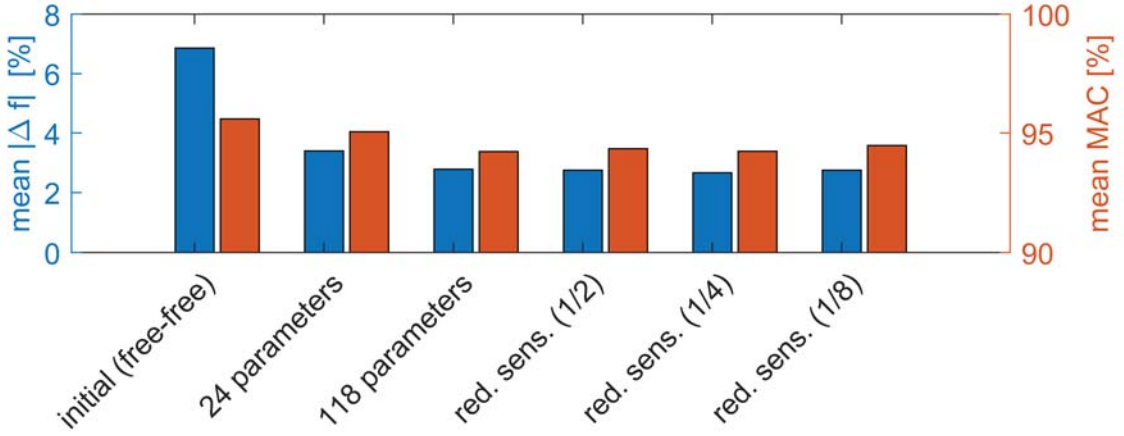

Figure 16: Verification of Updating results under altered boundary condition

(Fig. 15). The evolution of parameters showed no obvious ripple effects, which indicates, that the step-size for the parameter adjustments was chosen to be small enough. A large number of parameters was at the set global limit of 15%. Relevant parameter changes where observed for almost all parameters. While the observed improvements are in line with the focus on decreasing frequency deviations, it becomes apparent, that the parameter adaptations do not fully represent the true material characteristics. In light of this, future works should use different parameterizations and judge the respective results. If mode shape correlation improvements are of interest, a large number of sensors should be used. The effects of response-weighting are assumed to be relevant and will be examined in future works.

6 Acknowledgments

This publication relies upon previous works especially [11, 13, 18] and was partially funded by the German Federal Ministry for Economic Affairs and Energy (BMWi) in the SmartBlades2 project (0324032A-H). The authors are much obliged to all members of the DLR modal test team. The updating procedure was implemented within FEMtools (Dynamic Design Solutions) with the very appreciated technical assistance of its leader Eddy Dascotte.

Keywords: Floating Offshore Wind Turbines, Semisubmersible platform, 10MW Wind Turbines, Large floating platform, Platform optimization.

Abstract. *The increasing demand of energy is leading to continue innovation in the renewable energy sector. Wind energy harvesting hit a milestone placing wind farm offshore, firstly in shallow water, using fixed bottom supporting technologies and now moving to deep sea areas, where floating platforms are needed. With floating technologies, construction and service costs exponentially grow; therefore, structural and mechanical optimizations have a primary role in the design of a floating offshore wind turbine (FOWT). Optimizations may involve the stabilizing principle, platform shape and size, mooring lines geometry and positioning. In the present work, attention is focused on structural aspects and an optimization procedure for a large wind turbine supported by semisubmersible-like platforms is proposed. In this study, platform is optimized with the intent to enhance the structural performances of the whole system.*

.

1 INTRODUCTION

Floating Offshore Wind Turbines (FOWT) are complex structural systems exposed to multiple stochastic loading conditions. Optimal platform design is crucial to ensure appropriate reliability levels at the lowest possible cost. Past studies compared different platform stability classes. Wayman and Sclavounos [1] investigated stability and response of a barge-like platform and a Tension Leg Platform (TLP). They developed a simplified Frequency Domain (FD) model to evaluate the coupling interaction between the wind turbine and the floating system. With the increasing of rotor size, above 200m diameter and 10MW rated power, rational upscaling technique [2] based on power ratios were adopted to directly design platforms for larger turbines. New typologies of platforms, for example the tri-spar floater [3], have also been studied. However, there is still lack in design optimization for such large turbines. Brommundt et al. [4] performed a design optimization on mooring lines of a 5MW FOWT for two targeted environmental conditions. Karimi et Al. [5] performed a multi-objective design optimization of a 5MW WT supported by a semisubmersible platform and a TLP. Both cost and structural performances were considered as targets. Optimization is usually performed in the frequency domain, with the overall objective of reducing cost and increasing structural performances. Design variables are usually the geometrical properties of the platform, whereas a widely adopted objective function is the nacelle acceleration Response Amplitude Operators (RAO).

In the present work, the optimal dimensions of a semisubmersible-like platform, similar to the OC4 NREL platform [6], but suitable for a 10MW WT are investigated. The analysis is performed in the frequency domain, adopting a validated in-house developed model [7] coupled with FAST-v7 [8]. The effect of the mooring lines and the wind turbine are accounted for through additional mass, damping and stiffness matrices computed through a linearization analysis performed with FAST.

In the following, firstly the adopted FD model is briefly described. Then, results obtained from a parametric study of a semisubmersible platform suitable for a 10 MW WT are presented and compared with an upscaled 10 MW WT model [2]. In conclusion, future developments for a wider FD-based optimization procedure will be presented.

2 FREQUENCY DOMAIN MODEL

FOWTs can be analysed either in the time domain or in the frequency domain. In the first case, nonlinear dynamic interaction of the whole structure with wind, waves and control system can be possibly captured. Moreover, the time domain approach allows to simulate extreme load conditions, such as breaking waves impacts [9], [10], shutdown, or system failure. In an optimization context, where a large number of simulations are required, the time domain approach may lead to an unaffordable computational cost. FD models neglect or approximate nonlinear effects and allow to consider only steady load conditions. Despite these simplifications, their efficiency may still offer valuable guidance in the pre-screening phase of an optimization-based design. Most of the proposed FD approaches superimpose the turbine contribution in terms of mass, damping and stiffness matrices to the hydrodynamic contribution due to the floating platform. The description of the FD model adopted in this work, together with a code-to-code verification using benchmark results obtained from time domain simulations [11] [12], is available in [7]. The ANSYS AQWA potential solver [13] is adopted to evaluate radiation/diffraction hydrodynamic contributions to the equation of motion of the floating platform, while Morison's equation [14] is used for slender elements. The model considers approximated nonlinear viscous drag term and heave plates damping.

Mooring lines and wind turbine contribution to the equation of motion are evaluated through a linearization analysis around the operational point performed with FAST_v7. The linearized equation of motion is solved for the six rigid body platform degrees of freedom (DoFs). Finally, the RAOs are calculated.

3 10MW FOWT OPTIMIZED SEMISUBMERISBLE PLATFORM

In this section, a new semisubmersible-like platforms, suitable for the 10 DTU WT [15] is studied. The effect of two key design variables, namely the outer column diameter d and platform radius r (Figure 1), on the dynamic response of the platform is investigated.

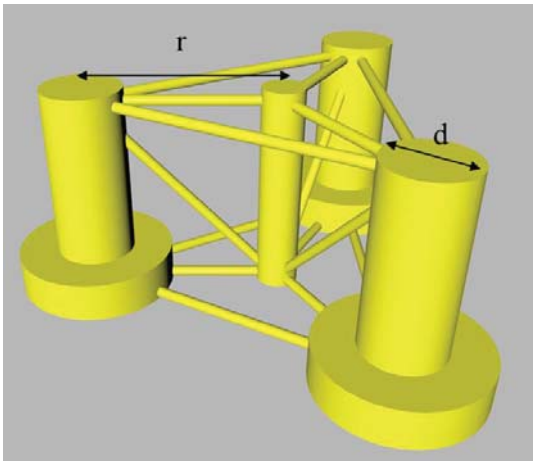

Figure 1: Semisubmersible-like platform design viariables.

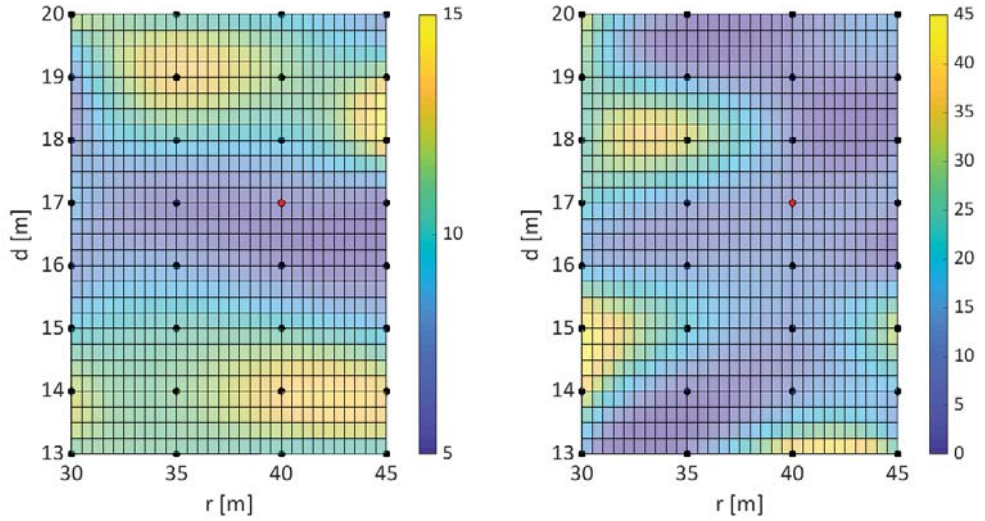
The ratio between heave plates and side columns diameters is set to 2. Heave plates length is set to 6m. Draft is kept constant to 28m by modifying the concrete ballast.

The length of the mooring lines is rearranged to maintain the same stiffness matrix on the whole set of possible solutions [7]. Eight different column diameters and platform radii are chosen in order to create a grid of 32 combinations. The grid spacing for d and r are 1 m and 5 m, respectively. The results for all 32 combinations are then interpolated using spline surfaces. Although only parked state condition is presented in this paper, for each combination (d, r), the mean pitch rotation angle is checked as to whether it is suitable for a power production state. A rotation of 5° is considered the maximum allowable pitch angle [1].

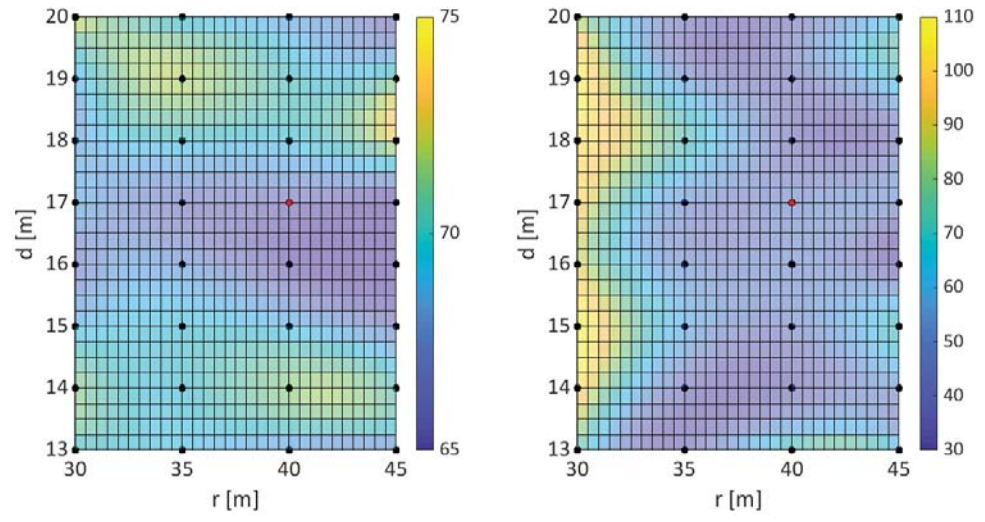
Two quantities of heave and pitch motions are chosen as target to be minimized: RAO peaks and integral RAO in the range of frequency excited by the constant 1 m^2/Hz white noise (0 to 0.2 Hz). Both heave and pitch are also indicators of turbine performance as discussed in [12] and [1]. Results are presented in Figures 2-5 and compared with those of an upscaled platform from the 5MW DeepWind semisubmersible (identified by a red dot in Figures 2 and 3). Heave and pitch RAO peaks for the investigated platforms are presented in Figure 2. From Figure 2a, a minimum region of heave RAO peak (parked case) can be identified for outer columns diameter between 16-17m and for almost all platform radii considered. Figure 2b presents the pitch RAO peaks (parked state). The minimum region between 13 m and 14 m for the column diameters and a platform radius of 35 m has to be discarded since the maximum allowable pitch angle of 5° is violated. A minimum region for a smaller and lighter solution with respect of the upscaled one (marked as a red dot in the figure) can be found between 16 m and 17 m for the column diameters and a platform radius of 35 m. Platforms with 16–17 m column diameters and 35 m radii appear to be the best choice, which minimizes both heave and pitch peaks.



(**a**) (**b**)

Figure 2: Parked condition; RAO peaks of heave (m/m) (a) and pitch (deg/m) (b). Red dots refer to the upscaled configuration.

In Figure 3, RAO integrals of heave (Figure 3a) and pitch (Figure 3b) DOFs are presented. Figure 3a and 3b reveal a lower minimum region between 16 m and 17 m for the outer column diameters. Local maxima in the bottom and upper part of the domain are caused by an increasing of the eigenfrequency peak and by heave–pitch coupling.



(**a**) (**b**)

Figure 3: Parked condition; RAO integral of heave (a) and pitch (b). Red dots refer to the upscaled configuration.

Considering the platforms analysed, and that the platform response in pitch would affect more the fatigue behaviour of both turbine tower and mooring lines than the response in heave, the configuration with a 16 m column diameter and 35 m platform radius is preferred to the 17 m, 35 m.

In Table 4, the numerical values of the RAO peaks of the upscaled and the optimized platform are compared. As it is possible to observe, a low reduction is achieved in surge because

the dynamic behaviour is mainly dominated by mooring lines, which are not optimised in this study.

	Surge Peak	Heave Peak	Pitch Peak
Upscaled	26.12	14.74	15.31
Optimised	24.08	7.27	9.62
Reduction [%]	7.78	50.69	37.12

Table 4. Comparisons of RAO peak values between the upscaled and optimised platforms.

4 CONCLUSION AND FUTURE WORKS

In the present work, a frequency domain optimization procedure for a semisubmersible-like platform is discussed. The optimized procedure is performed by considering 2 variables, namely the outer columns diameter d, and the platform radius r. An optimal configuration is achieved for d=16m and r=35m. Future works will be focused on considering more variables, such as draft and heave plates height. Moreover, different targets to be minimized will be considered, such as nacelle acceleration RAO and the difference between the platform draft windward and the local free surface wave elevation [16]. This is a fundamental quantity that must be considered to prevent bottom-slamming and, therefore, to reduce fatigue loads on mooring lines and turbine tower. To increase the efficiency of the optimization procedure, the next step will be the evaluation of multidimensional fitted functions for the hydrodynamic parameters (added mass, radiation damping and diffraction forces). This procedure will allow not to call the potential flow solver at every run in the optimization algorithm, leading to a drastic reduction of the computational time. The proposed procedure is also enforced by the fact that the hydrodynamic parameters are relatively smooth functions as it is possible to see in Figure 4.

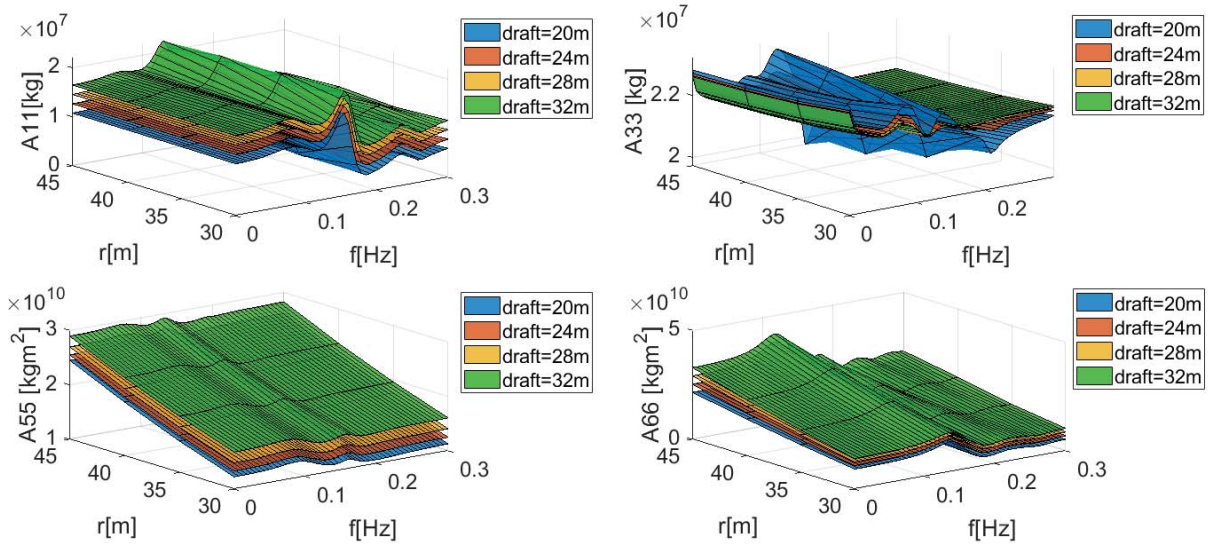


Figure 4: Added mass coefficients for a semisubmersible-like platform of 14 m side column diameter, varying platform radius (y axis), frequency (x axis) and platform draft from 20 m to 32 m.

DYNAMIC FIELD DATA FROM OFFSHORE MONOPILE WIND TURBINES – ASSESSMENT OF NATURAL FREQUENCIES AND DAMPING

Karin Norén-Cosgriff[1] and Amir M. Kaynia[1]

Keywords: offshore wind energy; pile foundation; measurements; acceleration; strain; natural frequencies.

Abstract. *The dynamic characteristics of offshore wind turbines are heavily affected by the ambient excitations (e.g. wave excitations and wind excitations) and nonlinear soil behaviour. For monopile structures, the fatigue design for the wind and wave loading is one of the most important problems to consider. Since the fatigue damage is sensitive to the foundation stiffness and damping, increasing the accuracy of analysis tools used in the design and optimization process can improve the reliability of the design and reduce conservatism, thereby leading to a more cost-efficient design. In this context, analysis of field data is important for calibrating and verifying purposes.*

This paper presents analysis of measured accelerations and strains in two offshore wind turbines in the North Sea with monopile foundations. One of the turbines is in a site that is dominated by sand and the other by clay. Field data during idling conditions, collected over long periods of operation, are analysed and the natural frequencies and estimates of damping are determined. Further, the effect of load (wave, wind and dynamic bending moment) on the natural frequencies is investigated and clear correlation between load level and natural frequency is demonstrated, which points to the importance of soil nonlinearity.

1 INTRODUCTION

According to [1] soil structure interaction (SSI) effects can reduce the fixed-base fundamental frequency more than 15% in the frequency range above > 0.25 Hz. Therefore, analysis tools need to include an accurate description of the soil. In this context, analysis of field data is important for calibrating and verifying purposes. However, only measurements from a few installations are reported in the literature. Some of these are mentioned below.

In [2] analyses of more than 1500 "rotor-stop" tests performed on offshore wind turbines founded on monopiles in four wind parks are described. In [3] analyses of measurement data from one offshore wind turbine structure on a monopile foundation in Horns Reef II wind farm are presented. In [4] results are presented from analyses of 'rotor stop' tests performed on one offshore wind turbine on a monopile in Burbo Banks wind farm. Research in [5] presents results from a load measuring campaign on one offshore wind turbine on a monopile in Horns Rev 1 Wind Farm. Studies carried out in [6] report measurements of overall damping from "rotor-stop" test in the Horns Rev 1 and the Burbo offshore wind farms. Finally, [7] and [8] present data from a long-term monitoring campaign and overspeed stops performed at the Belwind wind farm.

In the present study, analyses of measurement data from two wind farms in the North Sea with monopile foundations are presented. Measured acceleration and strain data collected over several periods of idling conditions are analysed. The objectives of these analyses are twofold. First, to determine the natural frequencies to be used in validation of developed foundation models, and second, to observe any sensitivity of the measured natural frequencies to the intensity of loading, which in turn would point to the role of soil nonlinearity. This paper describes the analyses performed at these sites and the main results.

2 SITE CONDITIONS, TURBINE STRUCTURE AND INSTRUMENTATION

Both sites are located in the North Sea. The ground conditions at the first site are sand-dominated, while the second site is predominantly clay. Measurement data from one tower at each site are used in this study. The tower at the sandy site is equipped with strain gauges at four levels on the inner wall of the monopile (MP) and the inner wall of the transition piece (TP). In this study, measured vertical strain in TP are analysed and in addition, information about wind speed from measurement at the tower is used. The tower at the clayey site is equipped with horizontal and vertical accelerometers close to the tower bottom, and strain gauges at several levels in the tower, the transition piece and the monopile. In this study, measured accelerations in the horizontal X and Y directions and foundation vertical strain are analysed. In addition, information about wind speed and wind direction measured at the tower are used. For both sites, information about significant wave height (Hs) and wave direction are collected from nearby metmasts. For the sandy site, no information about nacelle direction was available from measurements at the tower due to sensor error. The nacelle direction is therefore assumed to be about equal to the wind direction measured at the nearby metmast. Figure 1 shows the monopiles and the location of the instruments. Table 1 gives further information about the sites, the installations and the instrumentation. For the clayey site, for which both strain and accelerometer data are available, the determination of natural frequencies and damping are based on acceleration, since these data have the best quality. For the sandy site, the determination of the natural frequencies and damping are based on measured strain. Assessment of load through dynamic bending moment, is based on measured strain for both sites.

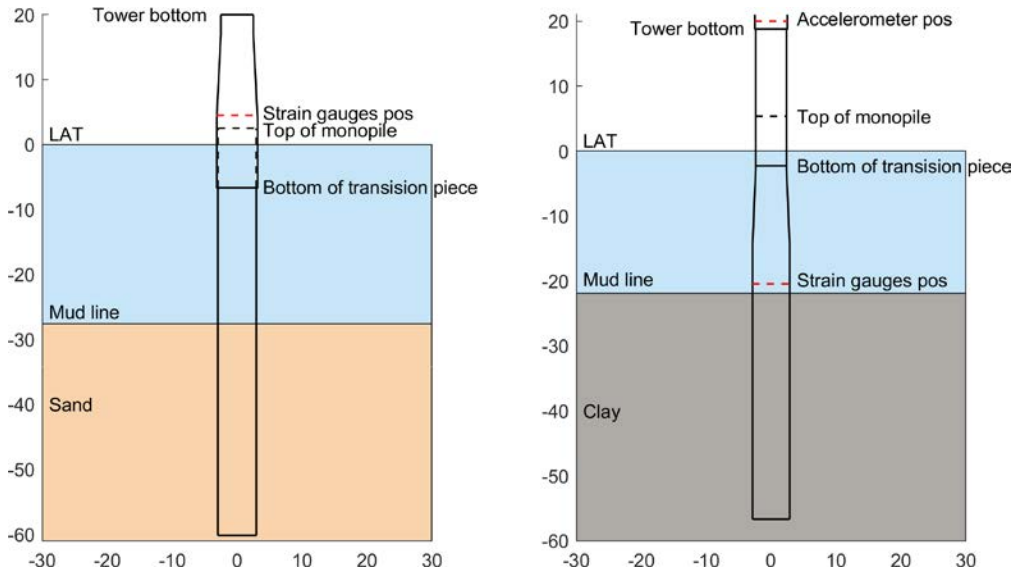

Figure 1: Ground conditions, monopile layout and sensor location, left: sandy site, right: clayey site.

	Site 1	Site 2
Ground conditions	Sand dominated	Clay dominated
Water depth	27 m	22 m

Monopile diameter	5.95 m	5.70 m
Instrumentation	4 vertical strain gauges in TP EL +4.5	3 vertical strain gauges in MP EL -20.45. 1 horizontal (X and Y) accelerometer in tower El +20
Sampling frequency	10 Hz	25 Hz

Table 1: Ground conditions, OWT and instrumentation

3 WIND AND WAVE INFORMATION

The response in idling periods are more affected by the foundation stiffness and damping than the response during production, which is primarily influenced by aerodynamic damping and stiffness. Therefore, the focus in this study is on idling periods. For the sandy site, the turbine is idling throughout all time periods from which data were received, while for the clayey site, the turbine is idling in between periods of production. Some of these idling periods lasted only a few minutes, while others lasted for several days. For data used in this study, a requirement is set for a minimum idling period of 24 minutes, with the first and last two minutes discarded to avoid influence from start-up and shut-down of the turbine. Figure 2 shows the distribution of the analysed time periods over wind speeds, wave heights, and wind and wave directions, described as averages in 20-minutes periods. The length of the red bins in the Rose diagrams corresponds to the number of 20-minutes periods with this observation, e.g. about hundred 20-minutes periods with wind direction between 265 and 270 degree for the sandy site.

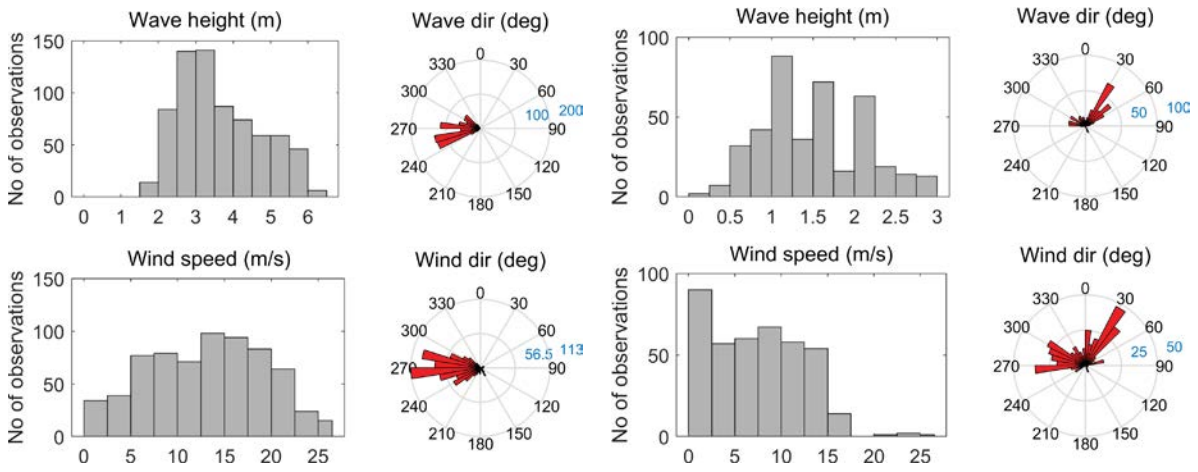

Figure 2: Distribution of average (in 20-minutes periods) wind speed, wave height and wind and wave direction for the analysed time periods, left: sandy site, right: clayey site.

4 DETERMINATION OF NATURAL FREQUENCIES

The natural frequencies are determined using the following FFT based methodology:

- The idling periods are divided into 20-minutes segments and FFT is performed on each segment using a 10-minutes analysis period and 50 % overlap, resulting in one Power Spectrum Density (PSD) for each segment with a frequency resolution of 0.0017 Hz.
- To determine the overall natural frequencies, an average PSD is calculated from all PSDs for the individual time periods, and the natural frequencies are identified from the peaks in the average PSD.
- To study a possible effect of the load on the natural frequencies, the first natural frequencies are determined from the PSDs for all individual 20-min segments and plotted against average wind speed, wave height and calculated dynamic bending moment in the respective 20-min period. Averaging by use of overlaps have the disadvantage of reducing the frequency resolution. Therefore, each determination of the first natural frequency in this part of the study is based on results from FFT analysis of 20-minutes segments without averaging.

The response of an offshore wind turbine is directional dependent due to the thrust on the rotor [3], i.e. there may be a small difference in the natural frequencies in the yaw direction (Fore-aft) and perpendicular to yaw direction (Side-side). Before applying the above methodology, the two directions are therefore analysed separately by transforming the measured accelerations and strains to a local coordinate system determined by the nacelle direction using the following equation:

$$\begin{bmatrix} Side-side \\ Fore-aft \end{bmatrix} = \begin{bmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{bmatrix} \begin{bmatrix} X \\ Y \end{bmatrix} \quad (1)$$

where θ is the nacelle direction from North-Y.

Figure 3 shows the overall PSD (average of PSDs from all 20-min periods) with the identified natural frequencies below 2 Hz. The first bending modes can be seen at 0.30 Hz and 0.33 Hz and the second bending modes at 1.70 Hz and 1.59 Hz for the sandy and clayey sites respectively. The peaks in between the 1st and second bending modes are believed to correspond to blade bending modes.

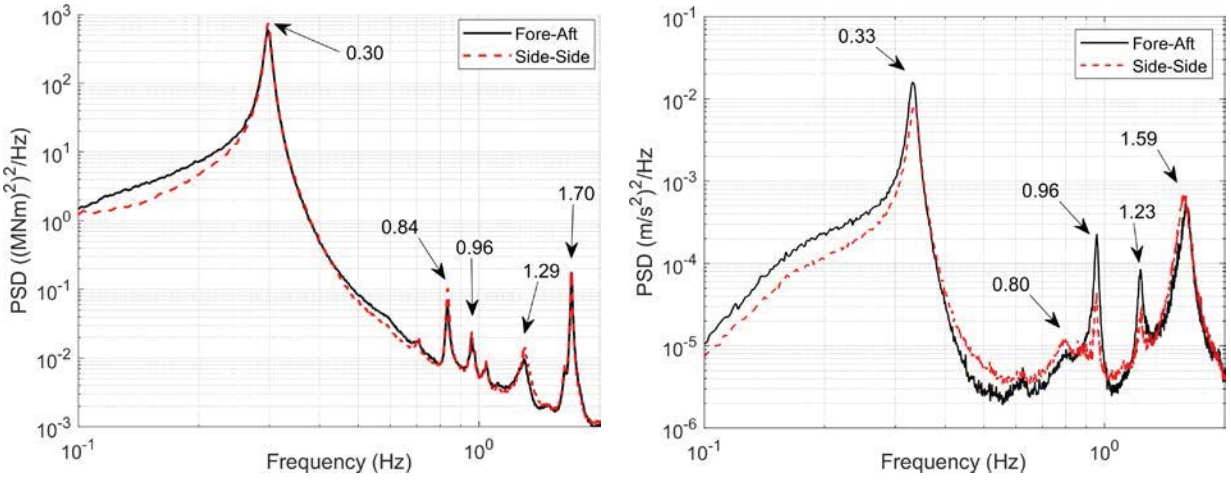

Figure 3: Overall PSD (average of all 20-min periods) with identified natural frequencies below 2 Hz, left: sand dominated site, right: clay dominated site.

Figure 4 shows the first natural frequencies in fore-aft and side-side direction determined for all individual 20-min segments and plotted versus load, i.e. wind speed, significant wave height and total dynamic bending moment (calculated from measured strain) for the two sites. Linear fits to data are also shown in the figures.

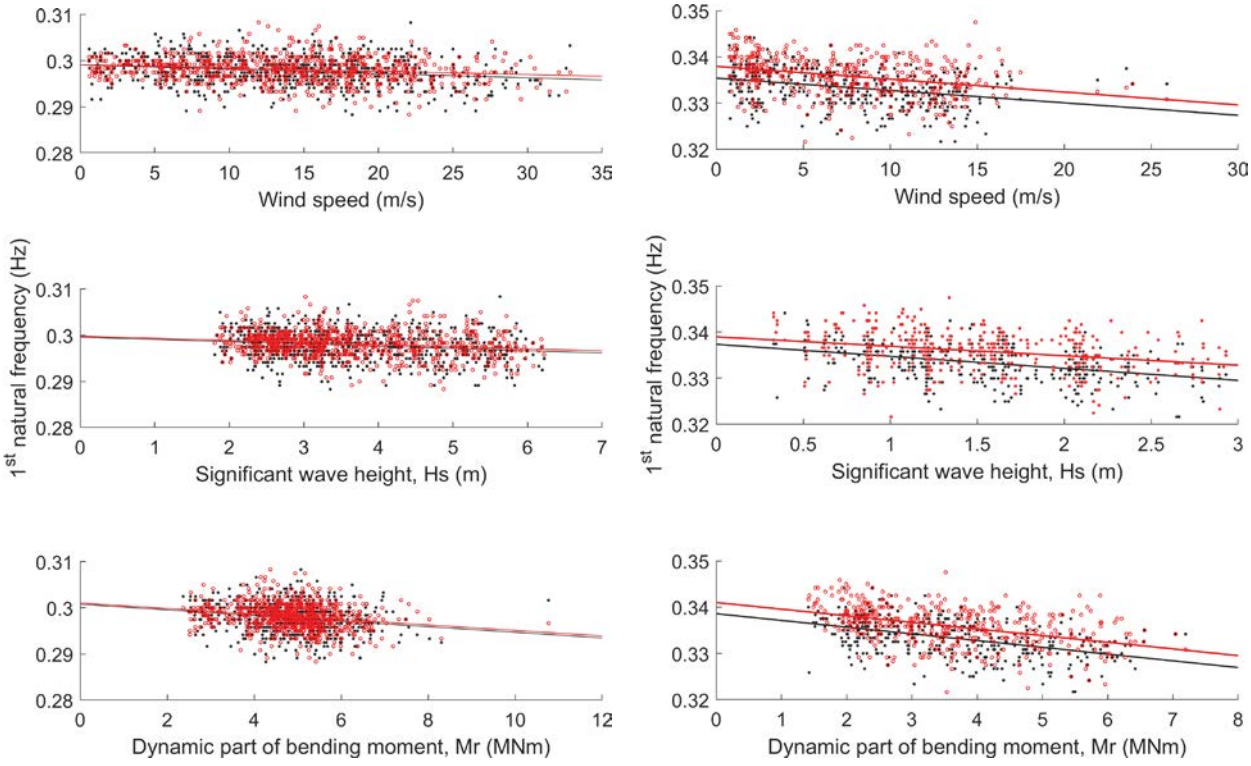

Figure 4: First natural frequency from FFT in side-side direction (red) and fore-aft direction (black) plotted against wind speed, wave height and total dynamic bending moment, left: sandy site, right: clayey site.

The results show that the first natural frequency decreases with increased load, which points to influence of soil nonlinearity. This is most evident for first natural frequency plotted versus the bending moment, which directly represents the load acting on the monopile.

However, Figure 4 also shows quite a large spread in data at the same time as the variation in the natural frequencies with load is very small. To reduce the spread of data and get a clearer trend, it may be considered to increase the frequency resolution by extending the length of the time series used in the FFT. Nevertheless, the wind and wave load are changing with time and the variation in load for each observation will therefore increase if the length of the time series are increased. As an alternative, other methods such as the time domain Multichannel AutoRegressive Moving Average (MARMA) method may be used to yield more accurate spectra with higher resolution compared to FFT. Further, Figure 4 shows that the two modes for the sandy site are not resolved. Methods like MARMA, which are based on analysis of the covariance function and takes advantage of cross information between all channels, will also be much better at identifying closely spaced natural frequencies compared to the FFT method. The MARMA method was successfully tried in the current study and resulted in a clear separation between the two modes and less spread in data compared to FFT.

5 ASSESSMENT OF DAMPING

Damping can be assessed from the measured data both in the frequency domain and in the time domain. Common for all methods is that they estimate the overall damping of the system, which for the first bending modes consists of a combination of aerodynamic damping, damping due to constructive devices, such as a tuned mass dampers, and additional damping, e.g. structural, hydrodynamic and soil damping [8]. When the turbine is parked or idling the aeroelastic damping is very low and it is therefore disregarded in this study.

In the frequency domain, the half-power bandwidth method can be used to estimate the damping ratio. By assuming that the damping ratio ζ is small (less than about 10%), the damping ratio is estimated using the following equation:

$$\zeta \approx \frac{f_2 - f_1}{2f_n} \tag{2}$$

where f_2 and f_1 are the upper and lower half-power frequencies, and f_n is the natural frequency.

For structures with closely spaced modes, possible mode coupling may lead to errors in the damping estimate [9]. For Offshore wind turbine (OWT) structures on monopiles, the first modes in the fore-aft and side-side direction are very closely spaced and a mode coupling is therefore possible. If mode coupling occurs, vibrational energy will be transferred from the highest to the lowest damped mode [2]. Damping determined with the half power bandwidth method should therefore only be considered as estimates of the real damping. Further, to obtain reasonably good estimate of the damping, it is important that the frequency resolution is fine enough for the shapes of the peaks to be correctly represented in the PSD, since a too coarse resolution will make the peaks wider and lower and hence over-estimate the damping. On the other hand, averaging is necessary to obtain peaks smooth enough such that the half power bandwidth method can be applied. In this study the half power bandwidth method is applied to the overall PSD as shown in Figure 3. A single degree of freedom (SDOF) system is fitted to the measured PSD by use of least squares estimation in the frequency range from f_1 to f_2. The damping is thereafter determined from the parameters of the SDOF system. Table 2 tabulates the first natural frequencies and overall damping ratios in fore-aft and side-side direction.

Direction	Sandy site		Clayey site	
	f_n (Hz)	ζ	f_n (Hz)	ζ
Fore-aft	0.298	0.019	0.333	0.021
Side-side	0.298	0.017	0.336	0.025

Table 2: First natural frequencies ($f_{n)}$ and damping ratio (ζ) determined by the half-power bandwidth method

The measurements at the clayey site show a larger overall damping than at the sandy site. It is assumed that the difference in damping ratio between the two sites is due to the differences in soil properties. However, the tower at the sandy site is equipped with a tuned mass damper, which contributes to the overall damping, while the tower at the clayey site has no damper. Therefore, the real difference in damping between the two sites is probably larger than shown in Table 2. The estimated damping ratios in Table 2 are somewhat lower than reported from rotor stop tests in [4] and [2]. However, in [10] even lower damping ratios was reported from an overspeed test when the tuned mass damper in top of the tower was turned off.

6 CONCLUSIONS

In this study, the first natural frequencies and associated damping are determined from measured dynamic field data from two wind farms in the North Sea with monopile foundations. At the first site, the ground conditions are dominated by sand, and at the second by clay. Only measurement data from periods when the turbines are idling are included in the analyses.

A clear correlation is demonstrated between load level and frequency, which points to the importance of soil nonlinearity. The estimated damping ratio for time periods when the turbine is idling is about 1.7-2.5 %, with higher damping for the clayey site compared to the sandy site. The estimated damping ratios are somewhat lower than reported from other field tests.

ACKNOWLEDGEMENTS

This study was performed with support from the research project REDWIN (Reducing cost of offshore wind by integrated structural and geotechnical design), funded by the Research Council of Norway, Grant Agreement 243984. This support is highly appreciated.

Keywords: oscillations, offshore installation, tuned mass damper

Abstract. *During the single blade installation of offshore wind turbines, relative motion between the blade root and turbine hub can cause a delay in the progression of the installation. This contribution presents the results of a monitoring campaign conducted during the installation of an offshore wind park in the North Sea. The campaign covered different states of the turbines: without rotor blades, with rotor blades, without supplementary damping system and with an installed, tuned mass damper system. The objective of the campaign was to determine the dynamic behaviour of the turbines in correlation with wind and wave data and to determine modal parameters. Accordingly, the turbines have been instrumented with sensors to record accelerations at three different positions. The modal parameters were then obtained using SSI/FDD algorithms. Structural damping is additionally determined with an RDM algorithm, and the results are being compared. The analysis of the data will be presented, including the different stages of the structural damping and the corresponding changes in movement patterns. The results shall be used to verify the load models and the predicted response of the structure.*

1 INTRODUCTION

Offshore wind turbines are steadily increasing in size in order to meet the rising demand for green electricity. This increase in accompanied with increasing water depths of offshore wind farms. Additionally, monopiles have become the economic foundations of choice. This current state of offshore wind farms results in eigenfrequencies between 0.2 Hz and 0.3 Hz, making the offshore wind turbines more susceptible for wind and wave induced loads. The response of these turbines is dependent on geometrical as well as structural parameters, among which the structural damping is essential for fatigue loads. Therefore it is of paramount importance to accurately predict the damping of a turbine in the design phase. Offshore wind turbines have generally a low damping ratio, with typical values around 1 %. Different types of damping can be distinguished in a offshore wind turbine: structural, soil, hydrodynamic and aerodynamic damping. Additionally, for a fully operational turbine, a directional dependency of their structural behaviour due to the damping effect of aerodynamic thrust generated by the blades can be observed. Hence, side-side deflection is in general more prone to large deflection amplitudes.

Damgaard et al. (2013) [1] and Guillaume et al. (2013) [2] used acceleration measurements conducted on operational wind turbines to calculate structural damping for the different modes of tower oscillations seen in offshore wind turbines. Both oscillations due to rotor stop tests as well as oscillations under ambient conditions proved to be sufficient to get accurate enough estimates of damping ratios. As the different modes of a wind turbine are spaced very close to each other, a coupling of the two lowest eigenmodes can be assumed and therefore pure fore-aft and side-side modes are not to be expected as energy will be transformed from one mode to another. This can results in a orbit like motion, where the turbines switches oscillation directions. In order to reduce fatigue loads and subsequently increase reliability, different types of damping systems have been proposed to reduce loads in offshore wind turbines, among which are: passive, semi-active and active tuned mass dampers (TMD), tuned liquid column damper, viscous fluid dampers & magnetorheological dampers [3].

Brodersen et al. [4] investigated an active tuned mass damper implemented into HAWC2 simulations, exploring the influence of the damper on structural responses. They showed, that fore-aft oscillations behave differently compared to lateral oscillations as the blades act as 'aerodynamic dampers'. They concluded, that an active tuned mass damper needs less mass to achieve high damping, however, the damper needs to be properly tuned in order to achieve maximum efficiency. A limiting factor of the active mass damper is the displacement velocity of the damper's mass. The authors address the tuning problem, by presenting a tuning algorithm. However, external loads in offshore wind turbines are complicated by wind-wave misalignment. One mitigation might be a tuned mass damper. Steward and Lackner [5] used simulations to demonstrate that an optimally tuned mass damper can reduce fore-aft and side-side fatigue loads by 5 % and 40 % respectively for the 5 MW NREL Turbine. These results were obtained by implementing a custom-written extension of FAST to include the modelling of TMDs. The authors further investigated two different orientation patterns of the TMDs. They conclude, that TMDs are cost-efficient and simple and conclude, that due to reduced loads, an increase in reliability can be expected.

Oscillations are not only critical regarding fatigue loads; relative motion between rotor hub and blade root during single blade installation can cause severe delays and thus increase cost significantly. Relative motion can be cause by aerodynamically induced movement of the blade dangling from the crane hook or by tower oscillations which in turn are caused by wind and wave loading and are thus a stochastic processes by nature. Recent work has investigated the

aerodynamic behaviour of turbine blades during craning operations in order to better understand limitations imposed by external factors such as wind speed and direction. For wind speeds between 8 - 12 m/s single blade installation was found to be feasible [6]–[9].

Jiang et al. [10] modelled the overall system consisting of a Tower-Nacelle-Hub assembly subjected to metocean loads as well as a blade under wind loading during single blade installation using HAWC2. Adapting a custom, integral criteria to assess likelihood of an installation attempt to succeed. The authors concluded, that during the final mating process between blade root and hub, tower oscillations are more dominant than blade root movements if significant resonance responses of the structure due to wave loading are present. Subsequently Jiang (2018) [3] proposed to use TMDs during the installation of offshore wind turbines at the tower top of an offshore wind turbine to reduce relative motion between blade root and nacelle hub [3]. Adapting the simulations from the previous study, the author found a 50 % reduction in relative motion when only considering the hub movement and an overall reduction of 30 % when considering both hub and blade root motion. First to demonstrate the theoretical application of an TMD for single blade installation.

Within this work, we present first measurements of a tuned mass damper used to reduce tower oscillations during single blade installation in the North Sea. Different states of the turbine undergoing installation were monitored: Tower (T), Tower, Nacelle and Hub (TNH) and Tower, Nacelle and Hub with the blades added consecutively (TNHB1, TNHB2 and TNHB3, where the number corresponds to the number of blades installed). The objective of the campaign was to monitor overall dynamic system behaviour and to obtain modal parameters.

2 MATERIAL AND METHODS

2.1 Wind farm details

A wind farm consisting of 32 multi-megawatt offshore wind turbines was installed during the time period of one year in the North Sea. The turbines have a hub height of approximately 110 m and were installed using a state of the art installation jack-up unit (IJU). The turbines are of hard-soft type and were installed in water depths between 35 m and 40 m.

The general installation procedure is as follows: (1) the IJU reaches the installation site, jacks up and connects to the previously installed transition piece atop the monopile with a gangway. (2) Following preparation on the transition piece, the tower is lifted from the IJU and placed on the transition piece. (3) The tower is followed by the nacelle-hub assembly. (4) If the conditions are favourable the blades are then installed using a specialized yoke, henceforth denoted as single blade installation tool (SBIT) with a net mass of approx. 70 t. (4.1) The SBIT is hooked onto the crane and grabs a blade from the blade rack aboard the IJU. (4.2) The SBIT and the blade are lifted to hub height and slowly manoeuvred such that the blade main axis and the generator axis are perpendicular towards each other. (4.3) Using a guiding pin, the blade root is then slowly mated with the hub flange. This processes is then repeated for each blade. It is within this phase of installation, where relative motions between blade root and hub must be at a minimum.

As this process is highly sensitive to relative motions between blade root and rotor hub a tuned mass damper was installed inside the nacelle. The TMD has two degrees of freedom and a damping mass of 10 tonnes. Using spring elements and viscous damping, the TMD was tuned to match the eigenfrequency of the turbines during single blade installation.

As the tuned mass damper was only available during the second half of the installation campaign, measurements of single blade installation with and without a TMD were conducted.

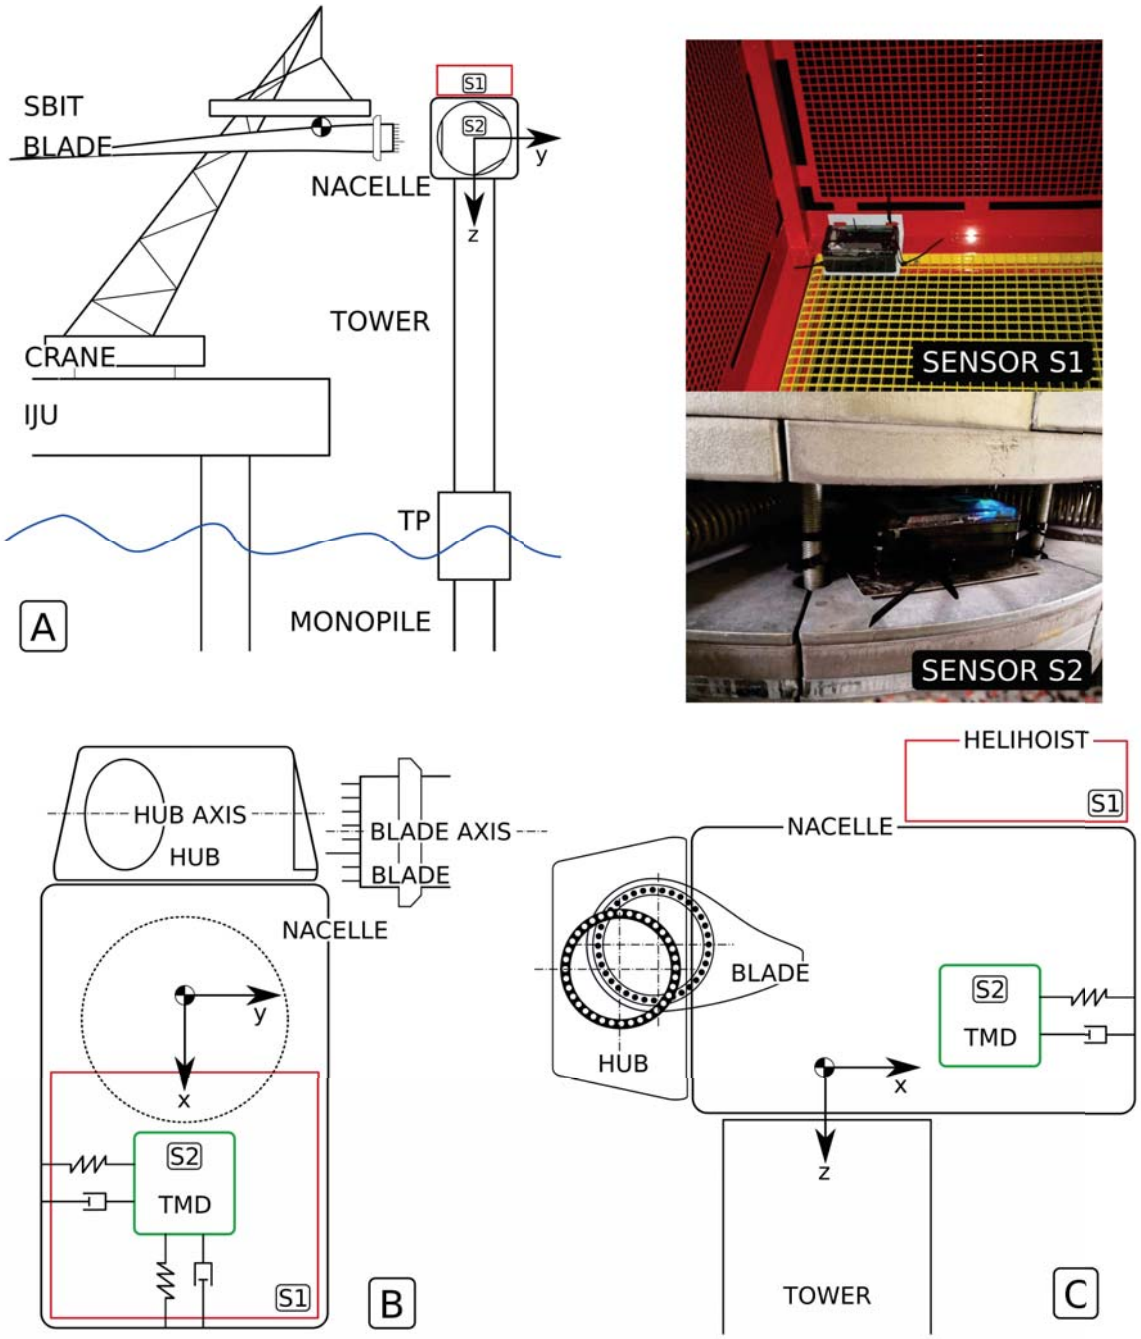

Figure 1: Typical setup of a single blade installation. (A) Installation Jack Up Unit (IJU) next to the Tower-Nacelle-Hub Assembly with the blade being attached to a Single Blade Installation Tool (SBIT), typically a yoke-like structure. The red square indicated the helicopter hoisting platform. S1 and S2 correspond to the sensors used within this study to determine dynamic behaviour of the turbine. (B) Top view of the single blade installation process. The green structure represents the tuned mass damper, deployed during single blade installation. (C) Side view of the installation process. Upper right figures: Sensors S1 and S2 mounted on the helicopter hoisting platform and the tuned mass damper respectively.

2.2 Measurements

In order to monitor the dynamic behaviour of the turbines during installation, custom build sensor boxes were deployed at two different positions: one sensor box is placed on the topmost position of the nacelle: the helicopter hoisting platform (short: helihoist). A second sensor box is placed on the tuned mass damper during installations where a tuned mass damper was present.

Sensor boxes contained a lead battery and electronics in a water proof containment (box) with a weight of approximately 3 kg and the measurements of 0.2 m x 0.06 m x 0.1 m. A LSM9DS1 (SparkFun Electronics, Colorado, USA) 9-Degrees-of-Freedom inertial measurement sensor capable of measuring linear acceleration, linear angular acceleration and the magnetic field was combined with a GPS-Sensor (GP-20U7; SparkFun Electronics, Colorado, USA), providing accurate time stamps as well as altitude information to form the sensory core of the sensor boxes. A real time clock (RS3231) provided back up temporal information in case of lack of GPS signal. A 32 GiB micro-SD-Card was used to store measurements. As a microcontroller, an ESP32 (Espressif Systems, Shanghai, China) was used. A sample frequency of 33 Hz was used, yielding accurate temporal resolution while allowing for good battery run time.

A LiDAR aboard the IJU provided high spatial and temporal resolution wind field information (measurement return period 1 s / 1 Hz). Additionally, a wave buoy in the vicinity of the installation site provided wave data, including significant wave height, peak period, zero upcrossing period and wave direction. The measurement return period was 30 min. / 0.00055 Hz.

In total, 15 turbines without a TMD and 4 turbines with a TMD were monitored during installation.

2.3 Data processing

All data post-processing has been implemented utilizing Python3 as well as it's rich set of scientific data analysis frameworks. As a fundamental data structure Pandas DataFrames (version 0.24.2) [11] was used. Numerical calculations were carried out using NumPy version 1.16.4 [12] and SciPy, version 1.3.0 [13]. All figures were generated using Matplotlib version 3.1.0.

Post-processing of measurement data starts with the subtraction of the mean for each acceleration component. Accelerations were then resampled using a linear interpolation scheme to a constant frequency of 30 Hz and filtered using a Butterworth Bandpass filter of third order. Lower and upper cut off frequencies were set to 0.1 and 1 Hz respectively. Accelerations were then integrated twice to yield velocity and position of the sensors during installation. Integration was carried out by applying a second order trapezoid scheme utilizing SciPy's integation module.

Based upon the positional vector, the instantaneous tower deflection D was calculated:

$$D = \sqrt{x^2 + z^2} \tag{1}$$

Where x and z are the instantaneous position vector components. The second component of the positional vector has been omitted, as it is aligned parallel to the tower axis and therefore it's contribution to the tower top deflection can be neglected.

To obtain a measure for the current state of the turbine and to allow for correlations with environmental data, 10 minute means of D were calculated, denoted as D_{10}. To maintain OEM privacy, all data has been normalised by the turbine tower diameter d_T, such that: $d = D/D_T$

and $d_{10} = D_{10}/D_T$. To further enhance privacy all dates presented in this study have been reset such that all measurements start at 01.01.1970 at 00:00 UTC. Temporal information is therefore only relative.

Wind data was binned into 10 minute windows and the window average was calculated. For wave measurements, data was first upsampled to 10 minute periods utilizing a forward interpolation scheme and subsequently merged with the wind data. Figure 2 depicts the data processing steps.

Figure 2 shows the data processing pipeline. Raw data is resampled, filtered and integrated twice to yield both velocity and position of the sensor in space and time. Using the postion vector, the deflection of the Nacelle can be calculated by employing Equation 1. Combining these measurements with metocean data and applying temporal averaging allows for scatter plots of mean deflection and metocean parameters such as significant wave height.

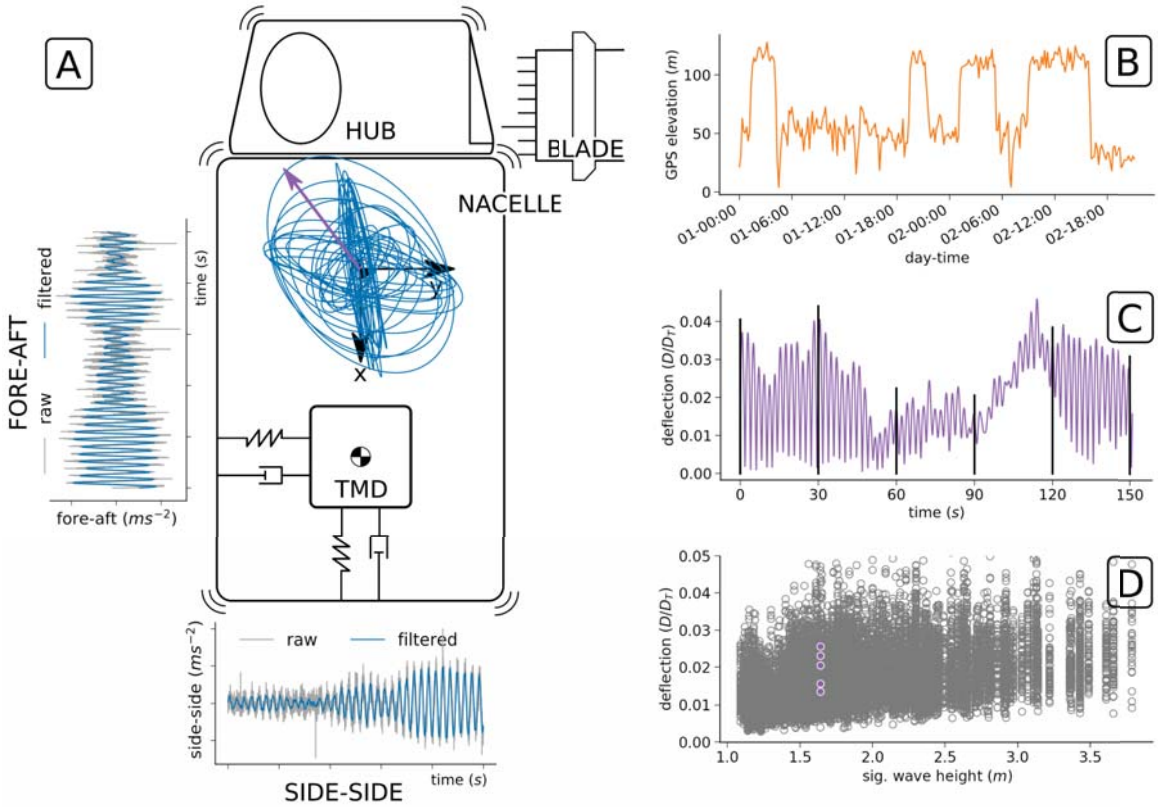

Figure 2: Data acquisition and processing: (A) Fore-aft and side-side accelerations are recorded by the sensors, resulting in a trajectory which can swiftly change direction. (B) GPS-Profile of the single blade installation process captured by another sensor mounted on the single blade installation tool. This allowed accurate tracking of the process in both space and time. (C) Integration of accelerations yields the trajectory of the orbit, from which the absolute deflection, a measure of how much the nacelle diverges from its base position can be obtained. (D) Applying a 60 s average of the deflection allows for the correlation of the deflection with external parameters, such as sig. wave height or wind speed.

2.4 Modal parameters

The monitoring campaign, which covered the states where the tuned mass damper system was either disabled (blocked) or activated was also used to identify the effectiveness of the TMD system by continuously determining the overall structural damping of the Tower-Nacelle-Hub assembly. To determine the structural damping ratio from the accelerations with unknown input (output only data), system identification techniques are applied such as the Random Decrement Method (RDM) as well as Stochastic Subspace Identification (SSI) and Enhanced Frequency Domain Decomposition (EFFD).

Random Decrement Method Figure 3a schematically shows the principle behind the random decrement method. Based on the assumption that the random excitation consists of a deterministic component which corresponds to free vibration terms and a random component which corresponds to forced vibrations, the random part can be eliminated by averaging a large number of blocks extracted from the time domain signal with a length τ. The blocks are chosen with the help of a threshold level. The Random Decrement Signature (RDS) (Figure 3b and Figure 3c) results the averaged time segments and the resulting damping ratio can be derived from the logarithmic decrement whereas the quality of the RDS strongly depends on the selection of the segment duration τ and the threshold y_S.

The random decrement method has been approved for system identification analyses of structures and buildings ([14]–[16]). Since the results of the damping are depending on the threshold and the segment duration, these parameters were varied to gain stochastic certainty. A window length of 2 and 3 periods (based on the determine natural frequency of the main structure) was analysed as well as a threshold level of 30 %, 50 % and 60 % of the max value of the investigated time history.

Figure 3b and Figure 3c show exemplary random decrement signatures from which the structural damping of the TNH was determined by analysing the decaying curve. This process was automated and applied for the complete time series that were recorded.

Operational Modal Analysis The stochastic subspace identification method is considered as a robust output-only identification technique compared to other available methodologies [17]. SSI algorithms identify a stochastic state-space model of the structure. The resulting model can then be translated into a more convenient structural model form for engineering interpretation of the results. The state-space model can be related to both modal model and Finite Element (FE) model formulations. The method works in the time domain and is based on a state space description of the dynamic problem assuming a linear behavior of the structure and a time-invariant dynamic response of the system due to a white-noise excitation. The system identification results at different model orders are compared to distinguish true structural modes from spurious modes in so-called stabilization diagrams. The time domain based SSI technique together with additional techniques such as the Enhanced Frequency Domain Decomposition (EFDD) techniques are often combined in algorithms for commercial Operational Modal Analysis software packages. The EFDD method relies on computation of response spectra. Long records are, therefore, required to keep low the error on spectrum estimation and to extract modal parameters in a reliable way. The software ARTEMIS from SVIBS (Structural Vibration Solutions) was used to identify the vibration modes of the TNH and to determine the structural damping. The results are plotted as stabilization cards and the estimated modal parameters are listed together with information about the probabilistic uncertainty.

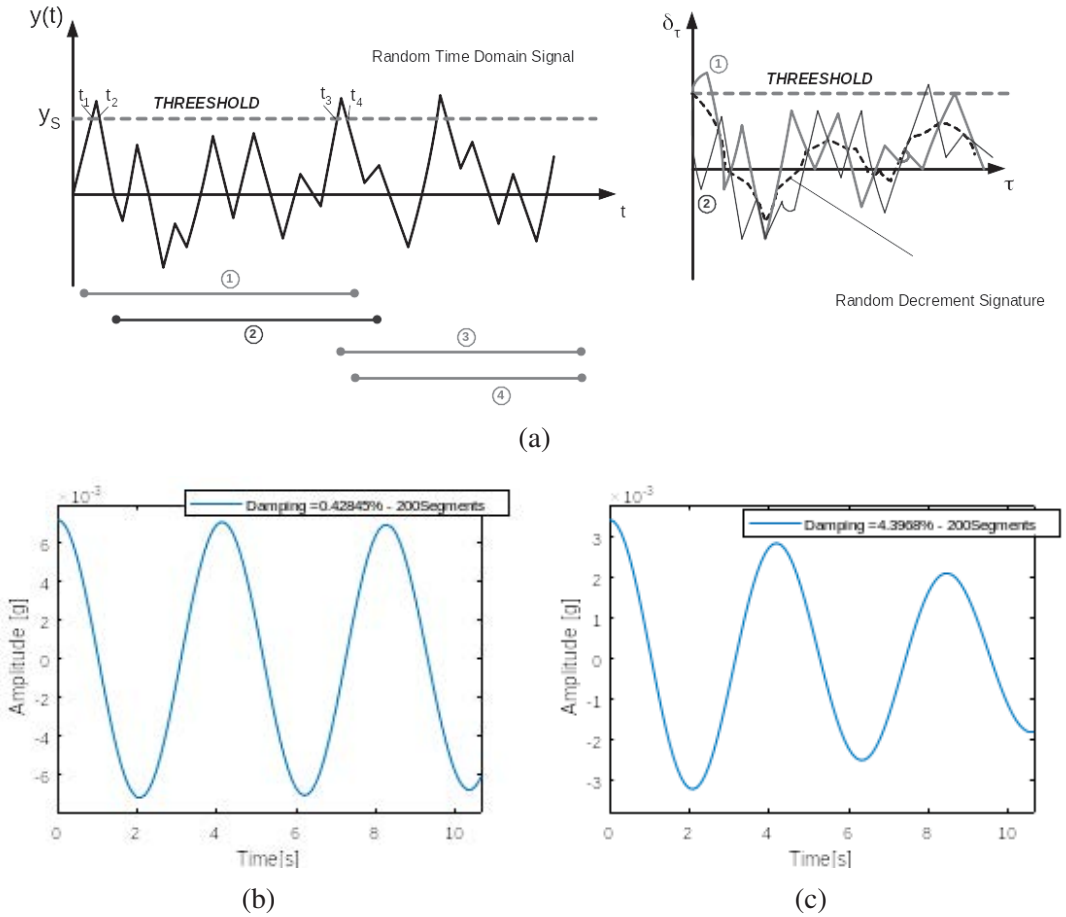

Figure 3: Principle of the Random Decrement Method (a). (b) Random Decrement Signature (RDS) of a 10 minute time history segment with blocked TMD – (c) (RDS) of a 10 minute time history segment with activated TMD

Identification of TMD parameters A two-measuring point acquisition, for which the vibrations of the wind turbine tower structure and the vibrating mass of the TMD are recorded can be used to determine the TMD parameters. But since this method will only provide the absolute vibrations of main structure and TMD a certain post-processing effort is required. Direct information regarding the relative TMD displacements can be gained when the relative vibrations of the TMD mass in addition to the vibrations of the main structure are getting obtained to derive the TMD parameters directly.

3 RESULTS

3.1 Nacelle deflections during single blade installation

Figure 4 shows exemplary two time series of nacelle deflection during the installation of two offshore wind turn turbines during single blade installation, where one turbine was equipped with a tuned mass damper. Both instantaneous deflection as well as the 10 min. mean of the deflection is shown (white line). A black horizontal line indicates the limit for single blade installation as learned during previous installations. For the installation without a TMD (Figure 4a), this limit is exceeded multiple times, Though the 10 min. average remains well below the limit. The time series shown starts after the finalised nacelle installation, spans an intermediate time period of about two hours within which the single blade installation tool (yoke) is picked up by the crane and then includes the three consecutive blade installations. Total blade installation spanned approx. 62 h with installation attempts made at each window where the deflection dropped below 3 % tower diameter. Six attempts at blade installation were made, for each blade two, where each of the first attempts failed.

During single blade installation with a TMD (Figure 4b) deflection was almost entirely above the threshold. With the beginning of the blade installation, the TMD was activated. This is indicated by the hatched area. An immediate response in nacelle deflection can be observed with the instantaneous deflection dropping below the installation limit with the exception of four spikes. The 10 min. mean of the nacelle deflection assumes a near constant value at when compared to the prior time period. The total blade installation installation duration was approx. 13 h, a significant reduction when compared to the previous installation duration without a TMD. To compare the two installations and to correlate the observed behaviour with metocean parameters, time series were divided into 10 min. segments and a temporal average was applied. This is shown in Figure 4c, where the 10 min. mean nacelle deflection is shown for the two previous installations as a function of the significant wave height.

During the installation without a TMD, significant wave height was between 0.75 m and 1.8 m. For the installation with a TMD, the wave range was between 1.25 m and 1.9 m. A clear reduction in mean deflection can be observed. Furthermore, while for the installation without a TMD mean deflection spread for a constant sig. wave height, spreading is significantly reduced with a TMD present.

Figure 5 shows 10 min. mean deflections for all captured installations with (red) and without (blue) a TMD present. The 10 min. mean deflection as a function of the significant wave height (Figure 5a), the wave peak period (Figure 5b) and the 10 min. mean wind speed (Figure 5c) are shown. Additionally, to give a simple model, a linear function is fitted using linear regression to both data sets.

The linear functions for both installations with and without TMD converge at a min. mean deflection of 0.5 %. For the installations with the TMD activated, the slope of mean deflection with significant wave height and wind speed is greatly reduced compared to the installations without a TMD present. As in Figure 4c, the spreading for a given wind speed Figure 5c or wave height Figure 5a is reduced as well. No clear correlation between mean deflection and wave peak period can be observed.

Figure 5: Scatter diagrams for the 10 min. mean deflection as a function of significant wave height H_S (a), wave peak period T_P (b) and the 10 min. mean wind speed U (c). Red indicates installations without a tuned mass damper (TMD), blue corresponds to installations with an active TMD.

3.2 Modal parameters

Figure 6 shows recorded time series of fore-aft and side-side accelerations of the wind turbine in different configurations (TNH, THNB1, TNHB2 and TNHB3) as well as the corresponding spectrograms (lower row, left and right hand side) which show the Auto Power Spectra of 10 minute - time segments plotted vs. the entire time of the monitoring campaign for the examined structure. The spectrogram not only indicates the times of the rotor blade installation for which a shift of the natural frequency can be detected but also the reduced acceleration values of the Auto-Power-Spectra and the much wider peaks indicating the increase of structural damping.

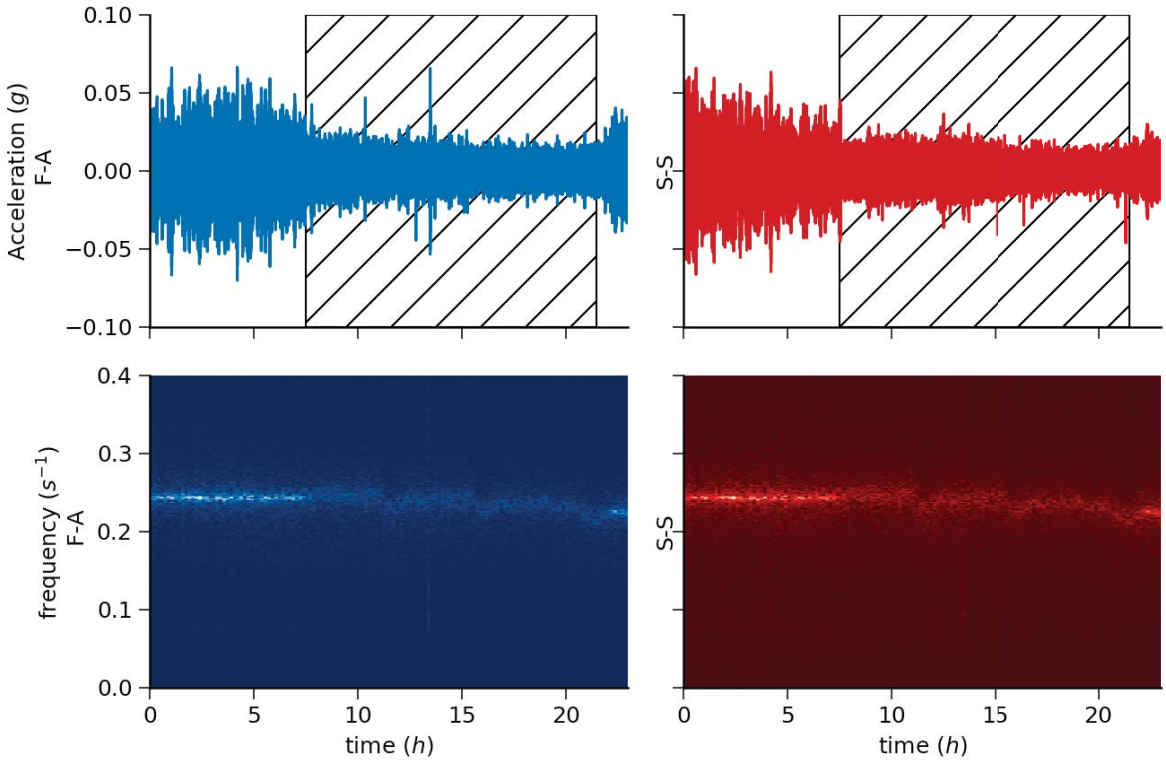

Figure 6: Top: Measured acceleration time series (fore-aft and side-side direction) of the wind turbine tower with Nacelle during single blade installation. The hatched area indicates the TMD being unlocked, resulting in an immediate reduction in accelerations. Bottom: Spectrogram (APS for 10 min time segments vs. recorded time). With each installed blade, a shift in frequency can be observed.

Figure 7 shows the determined damping ratios for time series with a length of 10 minutes, obtained via RDM. The time periods for which the TMD has been activated can clearly be identified. With the TMD deactivated, the damping ratio remains mostly below 1 %. With the activation of the TMD, damping ratio increases to values between 2 % and 4 %.

Figure 8a and Figure 8b show the resulting stabilization diagrams for a time period with blocked TMD and with activated TMD. It can be seen that for the state with blocked TMD the identified modal parameters coincide with structural damping determined with the Random Decrement Method. The damping estimation with the SSI algorithm revealed smaller structural damping ratios than determined with the RDM (TMD active: 2,52 %, no TMD: 0.57 %).

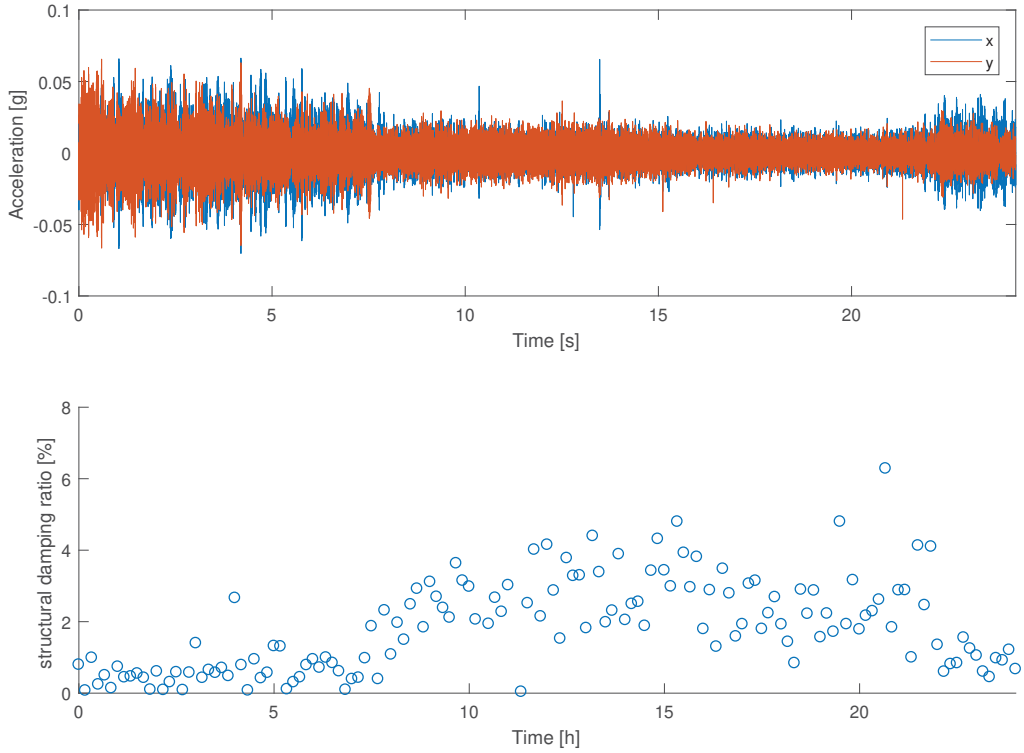

Figure 7: Above: Measured acceleration time histories of the wind turbine tower with Nacelle during rotor blade installation (x: fore-aft and y: side-side). Below: Determined Structural Damping ratio for time segments of 10 minutes using the Random Decrement Method

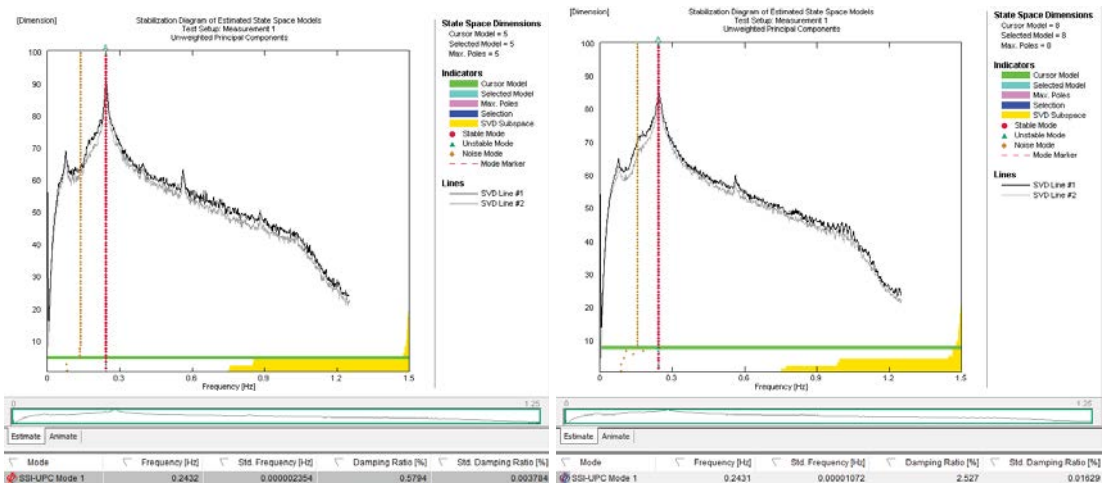

(a) (b)

3.3 Behaviour of the Tuned Mass Damper

Figure 9 shows the FFT spectra of 5 minute time segments of the accelerations measured at he nacelle (left) and the TMD mass (right). Initially (Time $\leq$ 1h) the FFTs of the Nacelle and the TMD mass show the same acceleration amplitudes and similar narrow peaks, which indicates, that the TMD is blocked. Later the FFT spectra of the Nacelle shows much smaller acceleration amplitudes with wider peaks, indicating that the TMD is active.

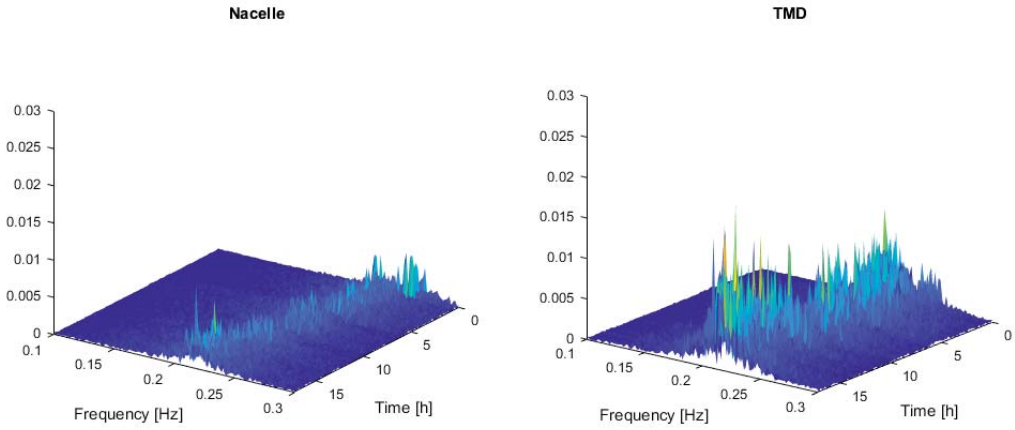

Figure 9: FFT Spectra of the acceleration time histories (5 minute segments) at Nacelle and TMD mass plotted for the entire monitoring time

The transfer function (shown for the measured accelerations of the nacelle in Figure 10) corresponds to a Frequency Response Function of the TMD system without the interaction with the main structure. From this function the tuning frequency and TMD damping ratio can is obtained by comparison with a single-degree of freedom approximation.The tuning frequency is 0.227 Hz while the TMD damping ratio is determined to be 10 %.

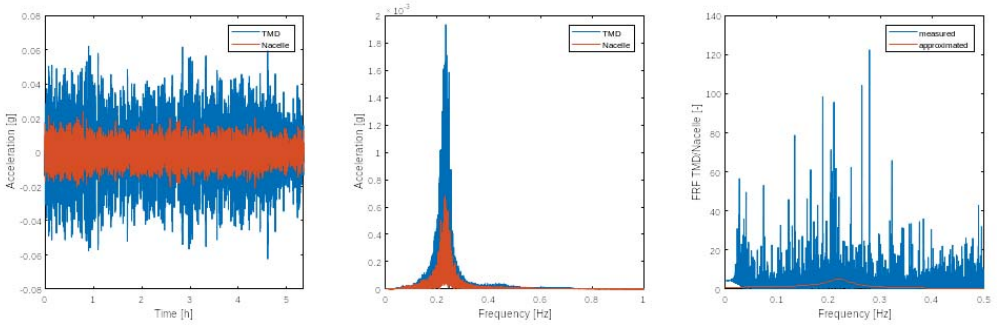

Figure 10: Left: Recorded Time Histories of the accelerations at Nacelle and TMD – Center: FTT Spectra of the entire time – Generated Transfer function and approximated signle degree of freedom - frequency response function with a tuning frequency of 0.227 Hz and a TMD damping ratio of 10 %.

4 DISCUSSION

The results presented here indicate that a TMD might indeed be a cost-effective and robust measure to improve single blade installation. However, much remains to be learned about the correlations and causalities of observed effects during single blade installation. While the measurements showed, that relative motions are indeed driven by wind and waves, the strong correlation between wind and waves - at least in the North Sea - does not allow to discern whether one of the two loads is the main driver.

While the TMD reduced deflections by more than 50 % compared to deflections observed during installations without a TMD at similar sea states other factors may still have a significant influence on the success of the single blade installation process. Among these are wind loads on the blade lifting device, wave loads on the ship and human influence as the installations are carried out manually. Structural damping increased significantly, independent on calculation method. Nevertheless more measurement with a higher precision are needed to gain more insight into the dynamic behaviour of offshore wind turbines in general and during installation in particular.

Apart from a reduction in relative motion and an increase in structural damping, the tuned mass damper increases the predictability of turbine behaviour during planning and execution of single blade installation and thus leads to a significant reduction in (financial) project risk.

Furthermore, the reduction in relative motion also leads to a reduction in HSE risks as well as a reduction in component damage. The unpredictable nacelle motions during the mating of the blade root and the hub pose a significant risk to technicians and can also lead to collisions between the hub/nacelle and the blade/lifting device.

While intended as a cost-efficient manner of measuring in dynamic behaviour of the turbines during installation, it has become apparent, that the MEMS-based sensor devices are fully capable of measuring relevant parameters with the needed precision and therefore present a novelty as well. In future studies the data obtained during this measurement campaign should be used to verify design load models as well as structural responses obtain via numerical simulations.

With regards to the operational modal analysis: a trial to determine the frequency response function for shorter time periods and detect variations of the TMD parameters with varying excitation levels and characteristics was not possible, since the time periods have to be long enough to generate the transfer function for TMD and Nacelle. While measuring the accelerations of the vibrating mass of a TMD system only provides an absolute vibration value, the direct acquisition of the relative displacement between TMD mass and main structure enables to determine the resulting TMD displacement directly but again not the TMD parameters such as tuning frequency and damping. To assess these values a comparison with a calculation model is still required.

We hypothesize, that the success rate of single blade installation is also dependent on the direction of oscillations, e.g. the shape of the orbit. This has yet to be investigated in future studies, where installation times should be correlated not only with nacelle deflection but also deflection direction and changes thereof.

Keywords: Wind turbine, Continuous monitoring system, Fatigue assessment, Strain gauge

Abstract. *The main goal of the WindFarmSHM research project is the development, validation and optimization of a monitoring strategy to be applied at the level of the wind farm, which should be able to evaluate the structural condition of a set of wind turbines and their consumed fatigue life. The accomplishment of this goal implies the development of an experimental campaign, the construction of numerical models and the implementation of new data processing methodologies.*

The experimental campaign is being performed at Tocha wind farm (an onshore wind farm located in Portugal) and includes the monitoring of three wind turbines, loaded by winds with different turbulence intensities motivated by the neighboring wind turbines, during a period of about 2 years. The instrumentation includes strain gauges, clinometers and accelerometers distributed in the tower and rotor.

As a first step in the development of tools to assess the fatigue condition of wind turbine towers, this work describes the data processing needed to obtain an accurate experimental estimation of the bending moments applied in the tower of the already fully instrumented wind turbine (WT1) and the validation of the obtained results using complementary monitoring components.

The experimental results reported in this contribution are also being used for calibration of advanced numerical models developed in FAST, which are very relevant for a better understating of the experimental data.

1 INTRODUCTION

Wind energy has experienced a truly remarkable evolution during the last two decades in terms of installed capacity and technological developments. In the EU, wind was the fastest growing energy source between 2005 and 2017, surpassing coal in 2016 as the second largest total installed power generation capacity [1]. 2017 was a record year for onshore and offshore installations that grew, respectively, 14.3% and 101% compared to 2016. It is expected that this capacity will continue to grow and that it will even double in a minimum interval of 10 years (taking the most optimistic forecast) [2].

Based on this scenario, it is possible to identify some of the present challenges, highlighting the concerns of the wind operators that need to manage the existing infrastructure Wind turbines were designed to operate 20 years, so it is estimated that about one half of the accumulated capacity currently installed in the EU will reach the end of design life in 2030 [2]. It is therefore essential to create a regulatory framework that defines the rules for the actions to be taken when the expected design life of the structures is exhausted.

Considering this background, the main goal of the WindFarmSHM research project is the development, validation and optimization of new methodologies to continuously assess the structural elements of wind turbines: tower, blades and foundation. This implies the development of innovative algorithms for data processing in order to:

i) Evaluate the remaining fatigue life of the main structural components based on the direct measurement of strains with strain gages, curvature measurements using pairs of clinometers or/and adopting a virtual sensors approach [3, 4];

ii) Extrapolate results obtained for instrumented wind turbines to non-instrumented wind turbines of the same wind farm, using SCADA data.

As a first step, this work describes the methodology and its validation for experimental estimation of the bending moments applied in the tower.

2 TOCHA WIND FARM

Tocha wind farm is located in the central region of Portugal approximately 3 km from the coastline, inserted in a coastal area with plain sandy terrain. It consists of five VESTAS wind turbines, model V100 with 1.8 MW of rated power, totaling 9.0 MW of installed power. This wind farm is owned by EDP Renewables and started its operation in May 2012.

Figure 1 shows the geographic location of the wind farm, the distribution of the five wind turbines (identified with numbers that will be used throughout this work)

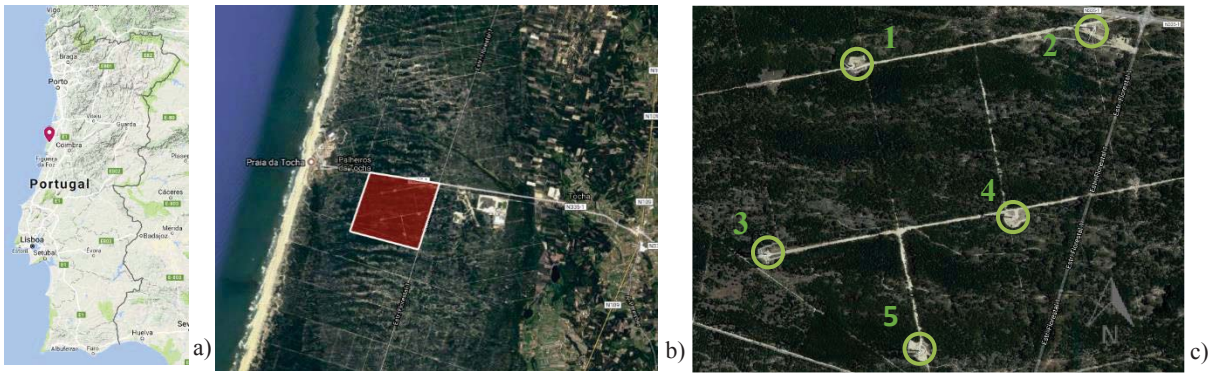

Figure 1: Tocha wind farm: a) Geographic location in Portugal [5]; b) Implantation area [6]; c) Wind turbines [7].

The Vestas V100-1.8 MW is a wind turbine designed for low wind onshore sites, so it features a larger rotor diameter, enabling it to deliver higher output at low wind speeds. It is a 3-bladed upwind turbine with a rotor diameter of 100 m (sweep an area of 7850 m^2) and a generator rated at 1.8 MW. The turbine operates at variable speeds from 9.3 to 16.6 rpm with a pitch control system. The hub is placed at a height of 95 m and is supported by a steel tower, of variable diameter, composed of four segments that are linked by bolted connections. Since the soil is sand, the steel tower is connected to a 14 by 14 m concrete slab supported by sixteen concrete piles with 1 m diameter.

As show in Figure 2, the power production increases gradually from cut-in wind speed (4 m/s) to rated wind speed (12 m/s) and is stable up to cut-out wind speed (20 m/s).

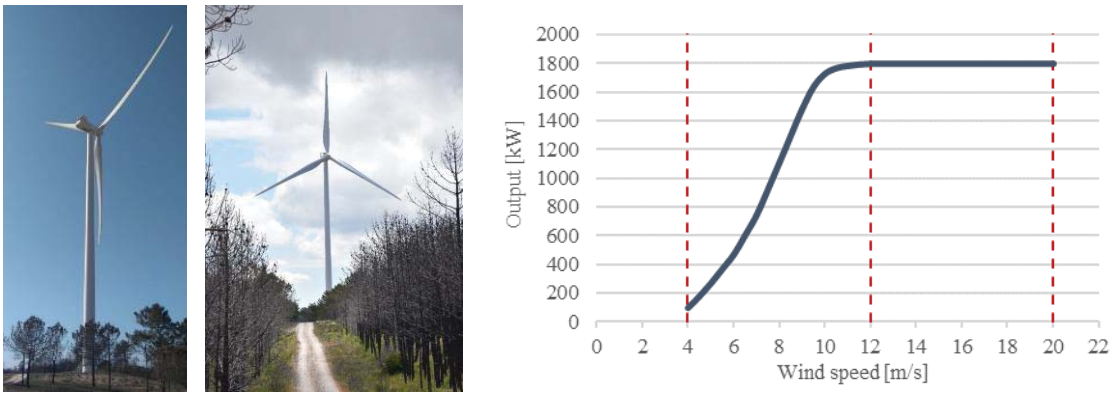

Figure 2: Wind turbines at Tocha wind farm and power curve of V100-1.8MW (https://en.wind-turbine-models.com).

3 MONITORING SYSTEMS

The experimental campaign in Tocha wind farm involves the simultaneous monitoring of several wind turbines during a period of about two years, which includes three instrumentation layout. However, only the tower monitoring systems comprehending acceleration and strain recording installed in wind turbine 1 are briefly described in this paper. A detailed description of the Tocha wind farm experimental campaign as well as some preliminary results can be found in [8].

The accelerations measurement system installed in the tower is based on a central acquisition system to witch all sensors are connected. It is composed by six force-balance accelerometers distributed along the tower height, measuring accelerations along two orthogonal horizontal directions at three sections, according to the scheme presented in Figure 3. In order to limit the length of the GPS signal cable (GPS antenna located in the nacelle), the central acquisition system (KMI) is located at the top platform, around 87 m.

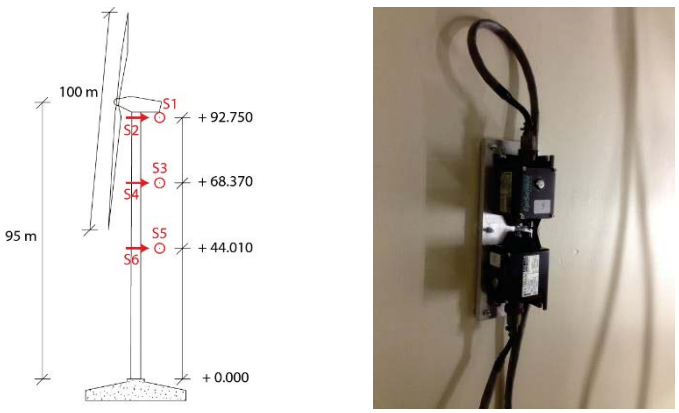

Figure 3: Sections instrumented with force balance sensors accelerometers (left). Photo of the force balance sensors (right).

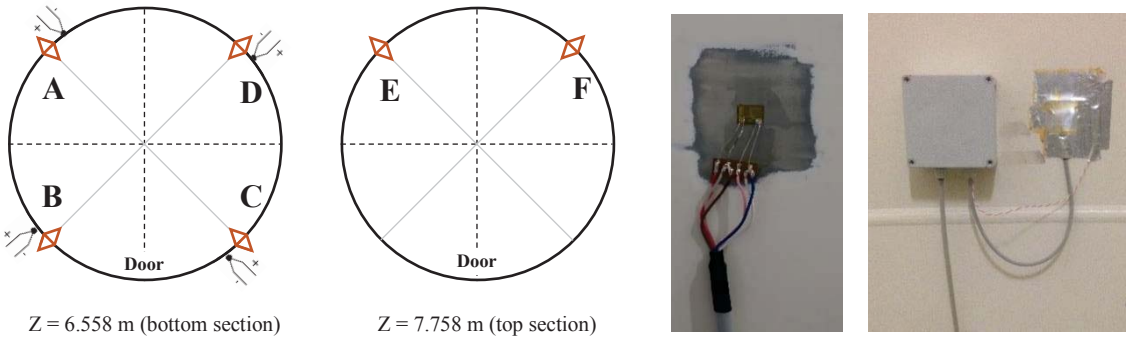
In order to evaluate alternative procedures for estimating static and dynamic bending moment diagrams along the tower, two alternative monitoring systems were considered: using strain and rotation measurements (not covered in this work), combined with accelerometers.

The strains system is composed of six 2D rosette strain gages, which measure the strain in two orthogonal directions and four temperature sensors Pt100.

In order to estimate the static bending moments diagram along the entire length of the tower the six strain gauges are distributed in two cross sections: four sensors at 6.5 m from the base of the tower (bottom section) and two sensors at 7.7 m (top section) as shown in Figure 4. The four temperature sensors are located in the bottom section, next to the strain gauges.

As will be demonstrated in the next section, measuring deformation in the direction perpendicular to the tower axis and temperatures is important to allow the evaluation of alternative procedures to minimize the influence of temperature on the measured longitudinal deformations.



Z = 6.558 m (bottom section) Z = 7.758 m (top section)

Figure 4: Locations of the strain gages (◊) and temperature sensors ( ); photo of a 2D rosette strain gage before protection; and photo of the strain rosette and temperature sensor after protection and box for signal conditioning.

These two monitoring components are connected to a National Instruments digitizer and processor, installed at the base of the tower. The acquisition frequency is 50 Hz for the strains measurements and 1 Hz for temperature measurements. A program developed in LabView for this specific application ensures data acquisition and recording.

Figure 5 shows the position of the strain gauges and clinometers along the vertical alignment formed by strain gauges A and E.

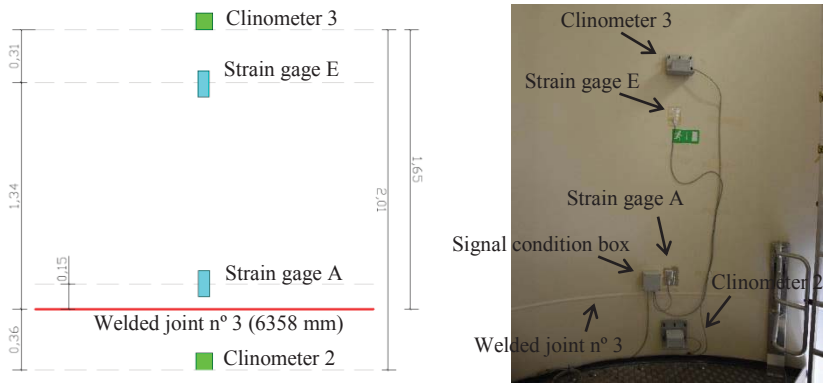


Figure 5: Scheme and photo of the position of the clinometers and strain gauges along the same vertical alignment.

In order to process the data collected from the described monitoring systems, it is essential to have SCADA data that accurately characterize the environmental and operational conditions of the wind turbine. In this study, the owner of the wind farm provides SCADA data with two types of sample rates: mean, maximum and minimum values from 10 min periods (SCADA 10 min) and data with a sampling interval of 15 sec (SCADA high resolution), of several operational and environmental parameters.

The data acquired with a higher sampling frequency is very useful as it allows accurately monitoring the rapid variations of some parameters, such as wind speed and direction, rotor speed, yaw angle and blades pitch angle, which is not possible to follow from the average values.

As shown in the Table 1, the monitoring of the tower is composed by three independent monitoring systems that adopt different timing protocols. In this way, it is necessary to synchronize all these systems in a common time frame to permit the join processing of different sensors datasets.

Acquisition system	Sensors type	Timing protocols
KMI	Force-balance Accelerometers	Global Positioning System time (GPS)
cRIO	Strain gauges Clinometers Temperature	Internal clock
SCADA	SCADA sensors	Network Time Protocol (NTP)

Table 1: Summary of installed monitoring systems at the tower of WT1 and corresponding timing protocols.

Global Positioning System time protocol was chosen as the reference from which all other systems were synchronized, so the force-balance accelerometers system is the reference time.

The synchronization of the cRIO acquisition system was performed by comparing the time series of extensions with the time series of accelerations measured by the force-balance sensors (Figure 6 left). The delay between the two systems identified over time is variable due to the limited accuracy of the internal clock of the cRIO system, so the time shift between the two systems is continuously updated. In a second phase, in order to make this synchronization

mora accurate are easy to automate, a low cost accelerometer placed next to one of the force balance sensors was connected to the cRIO.

The synchronization of SCADA data was performed by comparing the evolution of the yaw angle (SCADA high resolution) with the time series of strains over a variation of yaw angle of the nacelle (the eccentricity of the nacelle and rotor mass generates a sinusoidal signal in the strains gauges as shows in Figure 6 right). A constant delay of approximately 50 seconds was observed between the two systems.

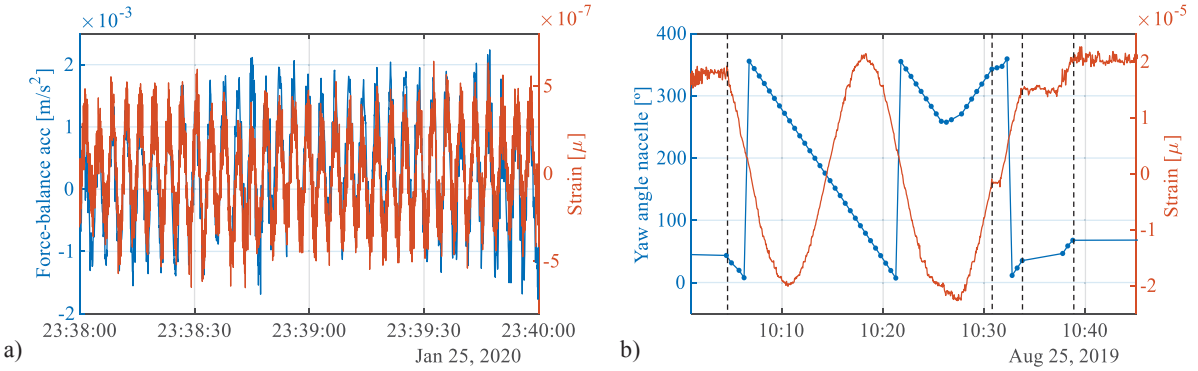

Figure 6: Synchronization of the monitoring systems: a) KMI (force-balance S3) and cRIO (strain gauge B) ; b) cRIO (strain gauge A) and SCADA (yaw angle) (the vertical dashed lines correspond to the singular points used for synchronization).

4 PROCESSING METHODOLOGY, CALIBRATION AND VALIDATION

Strain gauges are very sensitive sensors and many factors can easily preclude accurate measurements. All potential sources of errors need to be identified and it is necessary to implement a methodology for the signal processing according to the precision of the intended results.

Thus, the experimental determination of bending moments in the tower requires the acquired raw data to be pre-processed to obtain the real deformation. In the present application, as a first trial, the methodology presented in [9] with some upgrades is being followed. In a general way, this methodology consists of the following three steps: i) correction of the effect of temperature on strain gauges; ii) signal correction based on the average value of the extensions recorded on diametrically opposed sensors; iii) signal calibration according to guideline [10]. In the following sections, the steps of the implemented methodology are presented and validated.

4.1 Orientation Calibration

The first step is to determine the exact position of the sensors in the instrumented section of the tower (despite the care used in the sensor gluing there are always inaccuracies in sensor position), taking into account a local coordinate system where the y-axis coincides with the position of the entrance door. The nacelle angle defines the fore-aft and site-side axis for which the bending moments will be estimated.

As shown in Figure 7, the full rotation of the nacelle generates a sinusoidal signal in the strains gauges due the eccentricity of the nacelle and rotor mass. The values of the yaw angle for which the minimum value of the signals occurs correspond to the radial position of each sensor. In a good installation, the maxima and minima of diametrically installed sensors

should happen for the same time instant and for that same time instant the other two sensors should be close to zero. Please note that the strains presented in Figure 7 were pre-processed to have zero mean.

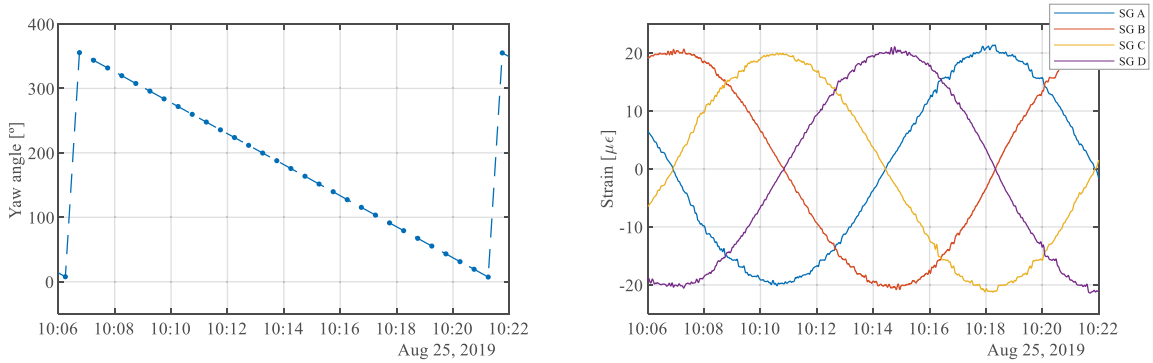

Figure 7: Yaw angle nacelle (left) and strain gauges signals (right) during nacelle full rotation at Aug 25, 2019 (see sensor positions in Figure 4 and Figure 5).

4.2 Correction of temperature effects

Many factors can easily distort strain measurements, but temperature is the most frequent source of errors. Temperature can influence the measurement of strains in two ways: thermal output and non-linear temperature gradient.

Thermal output is caused by variation of the electrical resistivity of the grid conductor with temperature and the differential thermal expansion between the grid conductor and the steel of the tower. This effect is minimized using the thermal output compensation curve provided by the manufacturer and the temperature measured on the steel surface.

The local heating of the sun can also influence the measured strains, as the temperature gradient may become non-linear. This parasite strains are minimized by averaging the two signals provided by the gauge couple installed at 180°.

Strain gauges are connected to the acquisition system using a ¼-bridge configuration with three wires in order to avoid effects of temperature on the cables.

In order to demonstrate in a practical example the influence of the temperature on the strain measurements, Figure 8 a) represents four strain signals measured at the bottom section, after being zeroed during the nacelle full rotation performed at around 07:00 (without compensation of the temperature effects). The same signals but with temperature effects minimized is shows at Figure 8 b). Comparing these figures, it is observed that in the first one the signals provided by the gauge couple installed at 180° are not perfectly symmetric, whereas in the second there is a perfect symmetry with respect to the x axis.

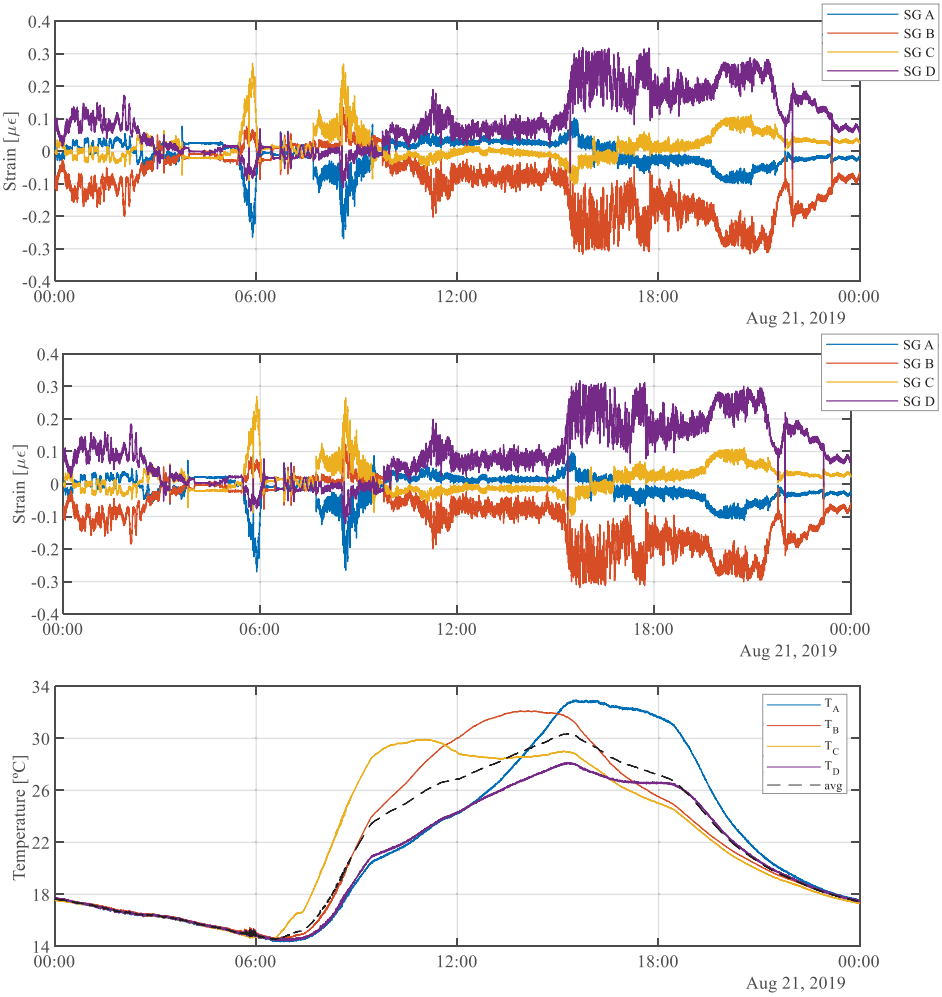

Figure 8: Daily temperature effects on strains measurements at the bottom section: a) Strains signals zeroed during the nacelle rotation; b) Strains signals zeroed during the nacelle rotation with compensation of the temperature effects; c) Temperature measurements

4.3 Drift correction

A significant drift is observed on the strains signals over time [11]. The correction of this drift is based on the procedure defined by the International Electrotechnical Commission (IEC) standards called calibration check [10]. The mean of the signals generated by yawing the nacelle through 360º represents the zero point (Figure 7).

A total of 10 full rotation of the nacelle, that met all the requirements, were observed in the period of 01-Aug-2019 to 01-Dez-2019 and were used to the calibration process (Figure 9).

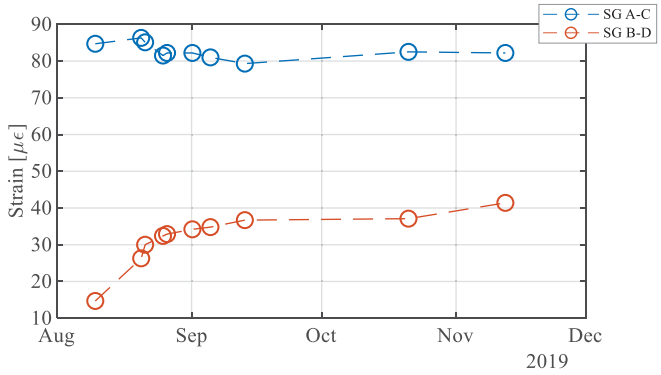

Figure 9: Mean value of the full rotation signals observed at August-2019 to December-2019 (see sensor positions in Figure 4 and Figure 5).

It appears that in the first months the drift remains close to 85 με for couple A-C. For the couple B-D, there is an initial 15 με drift with a linear evolution up to about 35 με over the first month. In the following months, the drift remains approximately constant.

4.4 Amplitude validation

The last validation consists of checking if the values of the strains measured in the structure and processed according to the procedure just presented correspond to real values of deformation of the structure due to applied loads.

In this sense, the average values of strains observed in all the recorded 10 min setups (total of 14720 setups) are shown in the Figure 10 as a function of the yaw angle. These values are compared with the theoretical strain curve that would be obtained for the maximum thrust force applied at the rotor level. It should be noted that the maximum drag force applied at the hub level is approximately 280 kN (calculated from the drag coefficients presented in [12]).

There is a good agreement between theoretical and experimental values. However, it should be noted that maximum strain values are not obtained for all directions. This is because prevailing conditions of wind action exist. These results also allow validating the calibration of the sensor orientation in section 4.1.

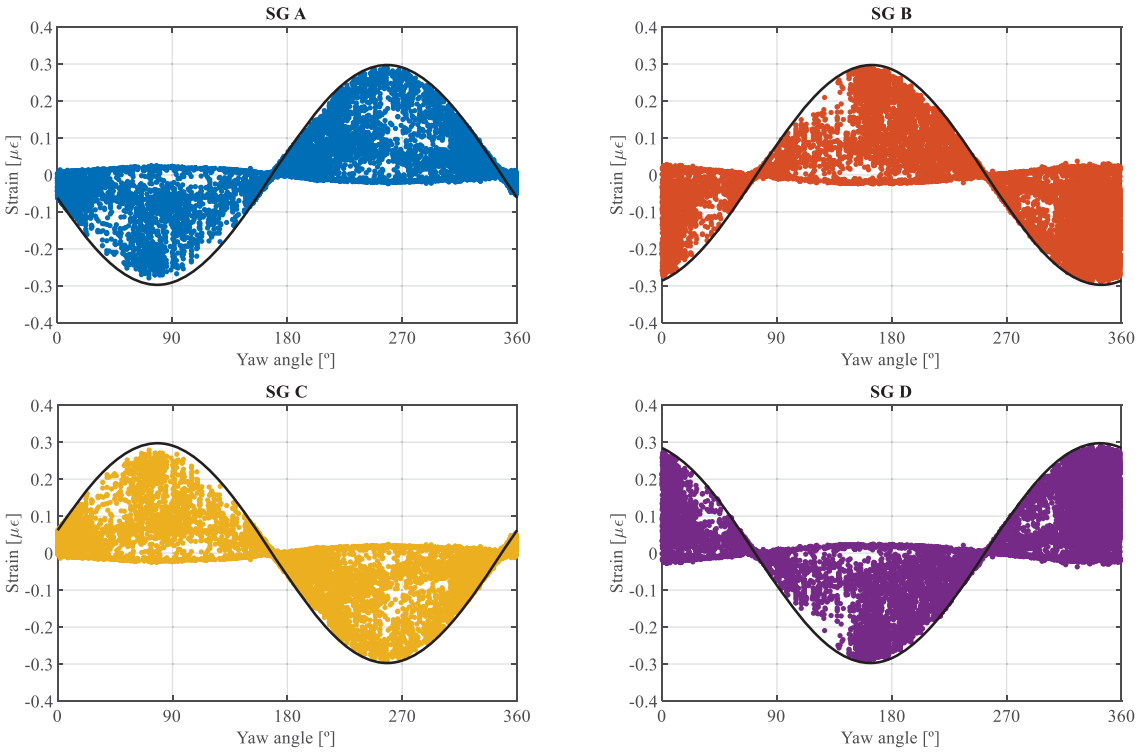

Figure 10: Average measured strains of strain gauges A, B, C and D (August-2019 to January-2020).

The bending moments estimated from the measurement of strains were also compared with those that can be obtained from the measurement of accelerations. Considering a rotor stop event (in which only the first vibration mode of the tower explains the structure's response) the displacement of the tower at the level of the accelerometer S1 was determined by double integration of the acceleration (Figure 11 left). Using a stiffness matrix provided by a simple numerical model developed in Robot [13], it was possible to determine the equivalent modal force applied at the S1 sensor level and the associated bending moment at the section instrumented with strain gages. The method followed to determine the response of structures in displacement from the measurement of accelerations is further developed in [3, 4].

For the same rotor stop event the strain time series measured at strains gauge D is represented in Figure 11 right.

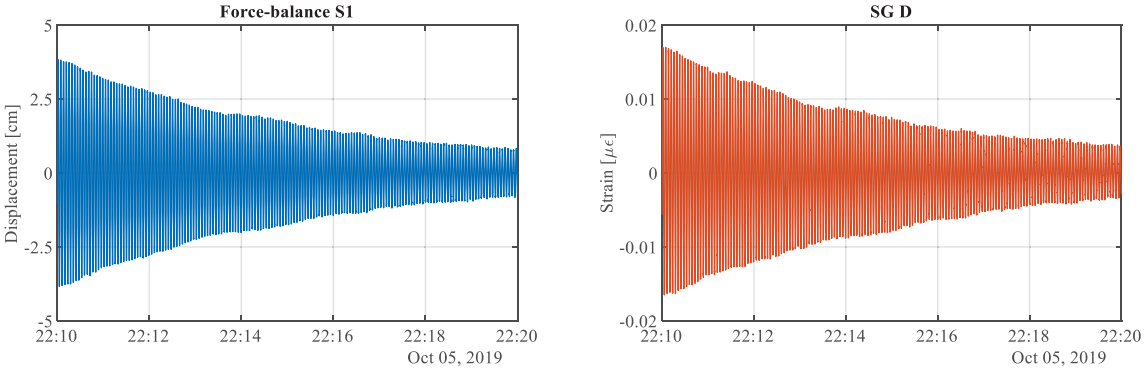

Figure 11: Rotor stop event on Oct, 5 2019: Time series of displacements at the top of the tower estimated from accelerations measured at sensor S1 (left) and strains at strain gauge D (right)

The bending moments at the base of the tower estimated from accelerations and strains are shown in the Figure 12. There is an excellent similarity between the bending moments estimated with the two methods. The error is less than 10% and can be explained by the difficulty in accounting for the exact stiffness of the tower.

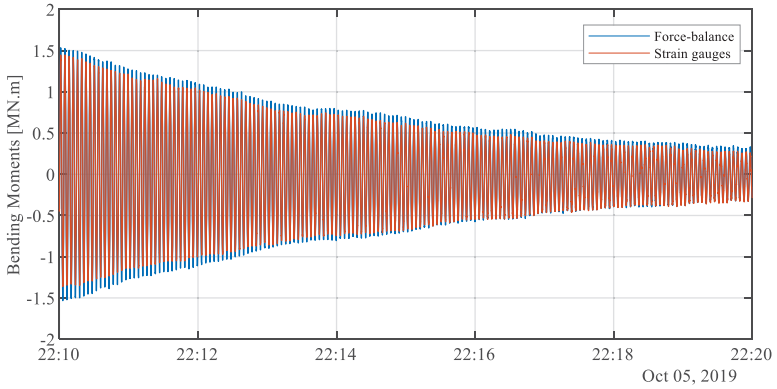

Figure 12: Bending moments at the base of the tower estimated from accelerations and strains time series.

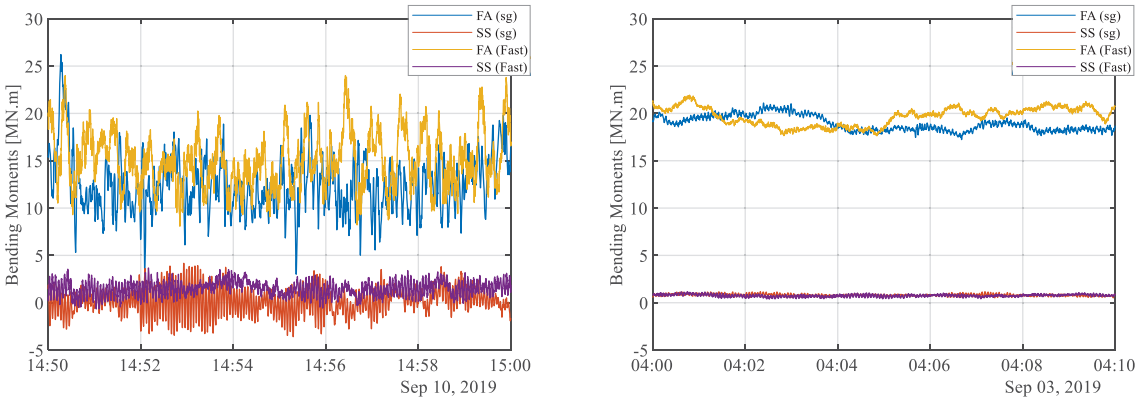
5 RESULTS

After the calibration and validation of the methodology to estimate the bending moments at the base of the tower, some final results are presented.

Applying the described data processing to the recorded series, in Figure 13 the temporal evolutions of the bending moments observed in the bottom instrumented section are presented, for the two main directions, considering two alternative turbine operation scenarios. The experimental results are compared with numerical counterparts, obtained from a model developed in FAST [14] and calibrated using the methodology described in [15].

It is possible to verify a good agreement between the numerical and experimental results. It should be noted that the simulated wind loads respect the mean and standard deviations observed in the field measurements, but the time series are different. In both analyzed situations, the mean values and scatter of the FA bending moments are very similar.



Rotor speed = 14.9 rpm; Wind speed = 13.0 m/s; TI = 14.6 %
$M_{FA,sg}$ = 12524 kN; $M_{FA,Fast}$ = 15043 kN

Rotor speed = 13.0 rpm; Wind speed = 7.9 m/s; TI = 4.4 %
$M_{FA,SG}$ = 18922 kN; $M_{FA,Fast}$ = 19684 kN

Figure 13: Experimental and numerical bending moments time series for FA and SS directions in the bottom instrumented section of the tower considering two operating conditions (TI: turbulence intensity; M_{xx}: bending moment average).

A very interesting in wind turbine towers is to express the evolution of the stresses as a function of wind speed. Figure 14 shows the 10 min average bending moment at the tower base for the fore-aft direction versus the 10 min average wind speed provided by the SCADA system during normal operation, considering different turbulence intensities.

Despite the short period of analysis, the results are quite promising. The drag force that is acting on the rotor and is responsible for the tower deflection is reduced above 10 m/s due the starting of the pitch control to keep the lift force and rotor speed constant. It is also verified that for wind speeds between 8 and 12 m/s the bending moment decreases as the turbulence intensity increases.

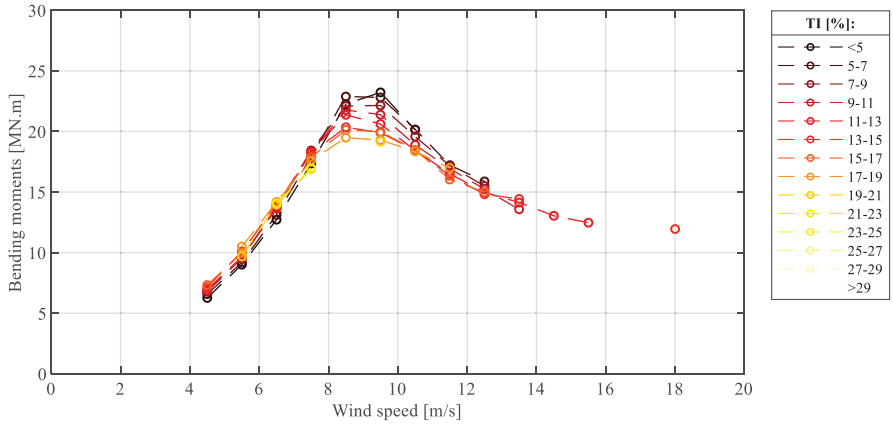


Figure 14: 10min average bending moment at the tower base for fore-aft direction versus the 10min average wind speed during normal operation, considering different turbulence intensities (August-2019 to January-2020).

6 CONCLUSIONS

This paper presents the methodology followed for the experimental evaluation of bending moments at the tower of a wind turbine. The quite extensive monitoring camping that is being conducted in Tocha wind farm is described, with particular attention for the strains monitoring system.

Special attention is given to the signal processing of the strain gauges, taking into account that temperature is known to be the major cause of signal perturbation. In this way, it is presented a procedure to minimize de daily temperature effects and also the long-term effects on the strain gauges. The post-processed strain signal are validated with theoretical and other experimental results.

Although the amount of data is still small, the results obtained are very promising. They are the starting point for fatigue calculation under development.

WIND TURBINE ROTOR BLADE VIBRATION – APPLICATION OF TWO ALTERNATIVE MODAL DECOMPOSITION PROCEDURES

Evgueni Stanoev[1]

University of Rostock, Albert-Einstein-Str. 2, 18059 Rostock, Germany
e-mail: evgueni.stanoev@uni-rostock.de

Keywords: modal decomposition, complex eigenvalue problem, vibration of wind turbine rotor blade, non-proportional damping

Abstract: *Two alternative modal decomposition procedures are applied to the vibration of a generic WT rotor blade, subjected to wind thrust loads. The first one, published first in [7] and [16], is based on a state-space-formulation of the equations of motion with symmetric damping matrix, which represents non-proportional damping. By use of the complex right eigenvectors of the associated quadratic eigenvalue problem a modal transformation matrix in real space is assembled, combining two complex transformations. The proposed procedure retains all common advantages of the classic modal decomposition of the equations of motion.*

The second applied procedure, known as a "phase synchronisation method", is presented in [14], [15]. The equations of motion here are formulated in the Lancaster state space form. Beside this the associated complex conjugated eigenvector and eigenvalue pairs are combined in separated modal resp. spectral matrices – this is another major difference to the first procedure. The assembling of the final real-space transformation matrix is based on the notion of "phase synchronization". The development of both procedures is described briefly, differences and advantages are discussed and pointed out in details.

Both presented methods are demonstrated on numerical example - vibration of a wind turbine rotor blade subjected to wind thrust loads. The presumed symmetric non-proportional damping matrix is derived by an aerodynamic damping approach, applied on the level of the differential equations of the beam element.

1 INTRODUCTION

The solution of the classic linear eigenvalue problem, associated to the equations of motion of multi-degree-of-freedom-systems (MDOFS), consists of real eigenvalues (natural frequencies) and real eigenvectors. The inclusion of viscous damping in the equations of MDOFS leads to a quadratic eigenvalue problem with corresponding complex conjugate pairs of eigenvalues and eigenvectors.

Starting point of our considerations are the equations of motion of a damped MDOFS in configuration space

$$\boldsymbol{M}\ddot{\boldsymbol{V}} + \boldsymbol{D}\dot{\boldsymbol{V}} + \boldsymbol{K}\boldsymbol{V} = \mathbf{p}(t)\ , \tag{1.1}$$

where $\boldsymbol{M}, \boldsymbol{D}$ and $\boldsymbol{K}$ are, respectively the (n x n) mass, damping and stiffness matrix, and $\boldsymbol{V}, \dot{\boldsymbol{V}}, \ddot{\boldsymbol{V}}$ are respectively the (n x 1) displacement, the velocity and the acceleration vectors and **p**(t) is the (n x 1) excitation vector.

In structural mechanics problems the matrices $\boldsymbol{M}, \boldsymbol{D}$ and $\boldsymbol{K}$ are considered to be real, symmetric and positive definite, excluding the presence of rigid body modes. In the classic modal analysis $\boldsymbol{D} = \mathbf{0}$, in this case Eq. (1.1) can be decoupled by use of the real right eigenvectors $\mathbf{X}_j$ of the undamped system:

$$\left(\lambda_j^2\, \boldsymbol{M} + \boldsymbol{K}\right) \mathbf{Q}_j = \mathbf{0} \tag{1.2}$$

In the case of classically damped system with $\boldsymbol{D} \neq \mathbf{0}$ Eq. (1.1) can also be decoupled by the real eigenvectors of the undamped system. According to [2] the necessary and sufficient condition for classical damping is:

$$\boldsymbol{D}\boldsymbol{M}^{-1}\boldsymbol{K} = \boldsymbol{K}\boldsymbol{M}^{-1}\boldsymbol{D} \tag{1.3}$$

The proportional damping assumption

$$\boldsymbol{D} = \alpha\boldsymbol{M} + \beta\boldsymbol{K}\ , \tag{1.4}$$

the so-called *Rayleigh damping*, is a particular case of classic damping – Eq. (1.4) satisfies the condition (1.3).

The associated quadratic eigenvalue problem to Eq. (1.1) is

$$\left(\boldsymbol{M}\lambda_j^2 + \boldsymbol{D}\lambda_j + \boldsymbol{K}\right)\boldsymbol{Q}_j = \mathbf{0} \tag{1.5}$$

where

$$\lambda_j = \alpha_j + i\omega_{Dj} \ \rightarrow\ \boldsymbol{Q}_j\ ; \qquad \overline{\lambda}_j = \alpha_j - i\omega_{Dj} \ \rightarrow \overline{\boldsymbol{Q}}_j \tag{1.6}$$

are complex conjugate eigenvalues with associated complex eigenvector pairs $\boldsymbol{Q}_j, \overline{\boldsymbol{Q}}_j$.

This paper presents the simpliest variant of a general modal decomposition method, presented in some variants in [7] and [16]-[19]. The method is used to transform in real-space the equations of motion of multi-degree-of-freedom-systems (MDOFS) with symmetric damping matrix, representing non-proportional damping. The equations of motion are stated in state-space formulation. The variant, presented in Section 3, is described in comparison with a similar technique for decoupling of non-classically damped system equations, referred to as *phase synchronization*, presented in earlier publications [4], [14], [15]. This approach has been described in [13] and [14] for free and forced vibrations in configuration space formulation. In [15] it has been shown the interpretation of the decoupling transformation by phase synchronization on the basis of state space formulation.

The problem of decoupling the homogenous problem in Eq. (1.5) can also be addressed as a reduction of the quadratic pencil $Q(\lambda) = \boldsymbol{M}\lambda^2 + \boldsymbol{D}\lambda + \boldsymbol{K}$. In [8], [9] and [4], [5] have been proposed the notion of *structure-preserving transformations* in diagonalizing $Q(\lambda)$. In [15] it has been shown the interpretation of the decoupling transformation by phase synchronization on the basis of state space formulation, under the assumption that all the eigenvalues λ_j , $\overline{\lambda}_j$ are complex and distinct.

In order to introduce to the method presented in Section 3, we will first briefly review in Section 2 the phase synchronization procedure on the basis of state space formulation according to [14], [15].– for the case of forced vibrations with n distinct complex conjugated eigenvalues λ_j.

2 THE PHASE SYNCHRONIZATION PROCEDURE IN STATE SPACE

All eigenvalues λ_j , $\overline{\lambda}_j$ in Eq. (1.6) are supposed to be complex conjugated and distinct, i.e. the quadratic eigenvalue problem is non-defective.

First of all, Eq. (1.1) should be written in state space in the *symmetric Lancaster form*, see [12]:

$$\begin{bmatrix} \boldsymbol{D} & \boldsymbol{M} \\ \boldsymbol{M} & \end{bmatrix} \begin{bmatrix} \dot{\boldsymbol{V}} \\ \ddot{\boldsymbol{V}} \end{bmatrix} + \begin{bmatrix} \boldsymbol{K} & \\ & -\boldsymbol{M} \end{bmatrix} \begin{bmatrix} \boldsymbol{V} \\ \dot{\boldsymbol{V}} \end{bmatrix} = \begin{bmatrix} \mathbf{p}(t) \end{bmatrix} \tag{2.1}$$

The associated state space eigenvalue problem takes the form

$$\left(\begin{bmatrix} \boldsymbol{D} & \boldsymbol{M} \\ \boldsymbol{M} & \end{bmatrix} \lambda_j + \begin{bmatrix} \boldsymbol{K} & \\ & -\boldsymbol{M} \end{bmatrix} \right) \begin{bmatrix} \boldsymbol{X}_j \\ \lambda_j \boldsymbol{X}_j \end{bmatrix} = L(\lambda_j) \begin{bmatrix} \boldsymbol{X}_j \\ \lambda_j \boldsymbol{X}_j \end{bmatrix} = \mathbf{0}$$

$$\rightarrow \begin{bmatrix} \boldsymbol{K} & \\ & -\boldsymbol{M} \end{bmatrix} \begin{bmatrix} \boldsymbol{X}_j \\ \lambda_j \boldsymbol{X}_j \end{bmatrix} = -\lambda_j \begin{bmatrix} \boldsymbol{D} & \boldsymbol{M} \\ \boldsymbol{M} & \end{bmatrix} \begin{bmatrix} \boldsymbol{X}_j \\ \lambda_j \boldsymbol{X}_j \end{bmatrix} \tag{2.2}$$

The symmetrically linearized pencil $L(\lambda_j)$ is referred to as the *Lancaster structure*.

A first complex modal transformation is defined by

$$\begin{bmatrix} \boldsymbol{V} \\ \dot{\boldsymbol{V}} \end{bmatrix} = \begin{bmatrix} \boldsymbol{X} & \overline{\boldsymbol{X}} \\ \boldsymbol{X}\boldsymbol{\Lambda} & \overline{\boldsymbol{X}}\,\overline{\boldsymbol{\Lambda}} \end{bmatrix} \begin{bmatrix} \boldsymbol{a} \\ \boldsymbol{b} \end{bmatrix} \tag{2.3}$$

where

$$\boldsymbol{a} = [a_1 \quad a_2 \quad \cdots \quad a_n]^T, \quad \boldsymbol{b} = [b_1 \quad b_2 \quad \cdots \quad b_n]^T \tag{2.4}$$

are new complex modal coordinates,

$$\boldsymbol{X} = [\boldsymbol{X}_1 \quad \boldsymbol{X}_2 \quad \cdots \quad \boldsymbol{X}_n], \quad \overline{\boldsymbol{X}} = [\overline{\boldsymbol{X}}_1 \quad \overline{\boldsymbol{X}}_2 \quad \cdots \quad \overline{\boldsymbol{X}}_n] \tag{2.5}$$

are modal matrices built by the complex $\boldsymbol{X}_j$ resp. the conjugate complex eigenvectors $\overline{\boldsymbol{X}}_j$, and

$$\boldsymbol{\Lambda} = \mathrm{diag}[\lambda_1, \lambda_2, \cdots, \lambda_n], \quad \overline{\boldsymbol{\Lambda}} = \mathrm{diag}[\overline{\lambda}_1, \overline{\lambda}_2, \cdots, \overline{\lambda}_n] \tag{2.6}$$

are the associated spectral matrices. The transformation (2.3) implies that the j-th damped mode of vibration $\boldsymbol{s}_j(t)$ is expressed as a linear combination

$$\boldsymbol{s}_j(t) = \boldsymbol{X}_j \underbrace{\left(c_j e^{\lambda_j t}\right)}_{a_j} + \overline{\boldsymbol{X}}_j \underbrace{\left(\overline{c}_j e^{\overline{\lambda}_j t}\right)}_{b_j} \tag{2.7}$$

The eigenvectors $\mathbf{X}_j, \overline{\mathbf{X}}_j$ may be normalized with respect to the mass matrix $\boldsymbol{M}$, which leads to the relationships

$$\begin{aligned} &2\lambda_j \mathbf{X}_j{}^T \boldsymbol{M} \mathbf{X}_j + \mathbf{X}_j{}^T \boldsymbol{D} \mathbf{X}_j = 2i\omega_{Dj} = \lambda_j - \overline{\lambda}_j \quad \text{resp.} \\ &2\lambda_j \overline{\mathbf{X}}_j{}^T \boldsymbol{M} \overline{\mathbf{X}}_j + \overline{\mathbf{X}}_j{}^T \boldsymbol{D} \overline{\mathbf{X}}_j = -2i\omega_{Dj} = \overline{\lambda}_j - \lambda_j \end{aligned} \tag{2.8}$$

Substitute Eq. (2.3) into (2.1) and pre-multiply by $\begin{bmatrix} \boldsymbol{X} & \overline{\boldsymbol{X}} \\ \boldsymbol{X}\boldsymbol{\Lambda} & \overline{\boldsymbol{X}}\,\overline{\boldsymbol{\Lambda}} \end{bmatrix}^T$ to obtain

$$\underbrace{\begin{bmatrix} \boldsymbol{X} & \overline{\boldsymbol{X}} \\ \boldsymbol{X}\boldsymbol{\Lambda} & \overline{\boldsymbol{X}}\,\overline{\boldsymbol{\Lambda}} \end{bmatrix}^T \begin{bmatrix} \boldsymbol{D} & \boldsymbol{M} \\ \boldsymbol{M} & \end{bmatrix} \begin{bmatrix} \boldsymbol{X} & \overline{\boldsymbol{X}} \\ \boldsymbol{X}\boldsymbol{\Lambda} & \overline{\boldsymbol{X}}\,\overline{\boldsymbol{\Lambda}} \end{bmatrix}} \begin{bmatrix} \dot{\boldsymbol{a}} \\ \dot{\boldsymbol{b}} \end{bmatrix} + \underbrace{\begin{bmatrix} \boldsymbol{X} & \overline{\boldsymbol{X}} \\ \boldsymbol{X}\boldsymbol{\Lambda} & \overline{\boldsymbol{X}}\,\overline{\boldsymbol{\Lambda}} \end{bmatrix}^T \begin{bmatrix} \boldsymbol{K} & \\ & -\boldsymbol{M} \end{bmatrix} \begin{bmatrix} \boldsymbol{X} & \overline{\boldsymbol{X}} \\ \boldsymbol{X}\boldsymbol{\Lambda} & \overline{\boldsymbol{X}}\,\overline{\boldsymbol{\Lambda}} \end{bmatrix}} \begin{bmatrix} \boldsymbol{a} \\ \boldsymbol{b} \end{bmatrix} = \begin{bmatrix} \boldsymbol{X}^T \mathbf{p}(t) \\ \overline{\boldsymbol{X}}^T \mathbf{p}(t) \end{bmatrix}$$

$$\begin{bmatrix} \boldsymbol{X}^T \boldsymbol{D} \boldsymbol{X} + 2\boldsymbol{\Lambda}(\boldsymbol{X}^T \boldsymbol{M} \boldsymbol{X}) & \\ & \overline{\boldsymbol{X}}^T \boldsymbol{D} \overline{\boldsymbol{X}} + 2\overline{\boldsymbol{\Lambda}}\left(\overline{\boldsymbol{X}}^T \boldsymbol{M} \overline{\boldsymbol{X}}\right) \end{bmatrix} \begin{bmatrix} \dot{\boldsymbol{a}} \\ \dot{\boldsymbol{b}} \end{bmatrix} + \begin{bmatrix} \boldsymbol{X}^T \boldsymbol{K} \boldsymbol{X} + \boldsymbol{\Lambda}(\boldsymbol{X}^T \boldsymbol{M} \boldsymbol{X})\boldsymbol{\Lambda} & \\ & \overline{\boldsymbol{X}}^T \boldsymbol{K} \overline{\boldsymbol{X}} + \overline{\boldsymbol{\Lambda}}\left(\overline{\boldsymbol{X}}^T \boldsymbol{M} \overline{\boldsymbol{X}}\right)\overline{\boldsymbol{\Lambda}} \end{bmatrix} \begin{bmatrix} \boldsymbol{a} \\ \boldsymbol{b} \end{bmatrix} = \begin{bmatrix} \boldsymbol{X}^T \mathbf{p}(t) \\ \overline{\boldsymbol{X}}^T \mathbf{p}(t) \end{bmatrix} \tag{2.9}$$

Accounting for the normalization (2.8), the left side of Eq.(2.9) can be reformulated:

$$\begin{bmatrix} \boldsymbol{\Lambda} - \overline{\boldsymbol{\Lambda}} & \\ & \overline{\boldsymbol{\Lambda}} - \boldsymbol{\Lambda} \end{bmatrix} \begin{bmatrix} \dot{\boldsymbol{a}} \\ \dot{\boldsymbol{b}} \end{bmatrix} + \begin{bmatrix} \left(\overline{\boldsymbol{\Lambda}} - \boldsymbol{\Lambda}\right)\boldsymbol{\Lambda} & \\ & \left(\overline{\boldsymbol{\Lambda}} - \boldsymbol{\Lambda}\right)\overline{\boldsymbol{\Lambda}} \end{bmatrix} \begin{bmatrix} \boldsymbol{a} \\ \boldsymbol{b} \end{bmatrix} = \begin{bmatrix} \boldsymbol{X}^T \mathbf{p}(t) \\ \overline{\boldsymbol{X}}^T \mathbf{p}(t) \end{bmatrix} \tag{2.10}$$

The state space form (2.1) is now decoupled in the complex form (2.10). Note that although Eq. (2.1) has been decoupled in state space, the new introduced complex variables $\begin{bmatrix}\boldsymbol{a}\\ \boldsymbol{b}\end{bmatrix}$, see Eq. (2.3), cannot be classified as displacements and velocities.

In the next step a purely real 2n-dimensional vector $[\boldsymbol{x}^T \quad \boldsymbol{y}^T]^T$ is defined:

$$\begin{bmatrix}\boldsymbol{x}\\ \boldsymbol{y}\end{bmatrix} = \begin{bmatrix}\boldsymbol{I} & \boldsymbol{I}\\ \boldsymbol{\Lambda} & \overline{\boldsymbol{\Lambda}}\end{bmatrix}\begin{bmatrix}\boldsymbol{a}\\ \boldsymbol{b}\end{bmatrix} \tag{2.11}$$

The inverse relationship of (2.11) is

$$\begin{bmatrix}\boldsymbol{a}\\ \boldsymbol{b}\end{bmatrix} = \begin{bmatrix}\boldsymbol{I} & \boldsymbol{I}\\ \boldsymbol{\Lambda} & \overline{\boldsymbol{\Lambda}}\end{bmatrix}^{-1}\begin{bmatrix}\boldsymbol{x}\\ \boldsymbol{y}\end{bmatrix} = \underbrace{\begin{bmatrix}\left(\overline{\boldsymbol{\Lambda}}-\boldsymbol{\Lambda}\right)^{-1}\overline{\boldsymbol{\Lambda}} & \left(\boldsymbol{\Lambda}-\overline{\boldsymbol{\Lambda}}\right)^{-1}\\ \left(\boldsymbol{\Lambda}-\overline{\boldsymbol{\Lambda}}\right)^{-1}\boldsymbol{\Lambda} & \left(\overline{\boldsymbol{\Lambda}}-\boldsymbol{\Lambda}\right)^{-1}\end{bmatrix}}_{\boldsymbol{S}}\begin{bmatrix}\boldsymbol{x}\\ \boldsymbol{y}\end{bmatrix} = \boldsymbol{S}\begin{bmatrix}\boldsymbol{x}\\ \boldsymbol{y}\end{bmatrix} \tag{2.12}$$

The reason of the definitions (2.11) and (2.12) is better clarified by looking at Sec. 3, Eq. (3.2), (3.4), (3.19).

Finally, we substitute Eq.(2.12) into (2.10) and then pre-multiply the resulting equation by $\boldsymbol{S}^T$ to obtain the real-space relationship (2.13)

$$\underbrace{\begin{bmatrix}\left(\overline{\boldsymbol{\Lambda}}-\boldsymbol{\Lambda}\right)^{-1}\left(-\overline{\boldsymbol{\Lambda}\boldsymbol{\Lambda}}+\boldsymbol{\Lambda}\boldsymbol{\Lambda}\right) & \boldsymbol{I}\\ \boldsymbol{I} & \boldsymbol{0}\end{bmatrix}}_{\begin{bmatrix}\boldsymbol{D_1} & \boldsymbol{I}\\ \boldsymbol{I} & \boldsymbol{0}\end{bmatrix}}\cdot\begin{bmatrix}\dot{\boldsymbol{x}}\\ \dot{\boldsymbol{y}}\end{bmatrix} + \underbrace{\begin{bmatrix}\left(\overline{\boldsymbol{\Lambda}}-\boldsymbol{\Lambda}\right)^{-1}\left(\overline{\boldsymbol{\Lambda}}\,\boldsymbol{\Lambda}\,\overline{\boldsymbol{\Lambda}}-\boldsymbol{\Lambda}\,\overline{\boldsymbol{\Lambda}}\,\boldsymbol{\Lambda}\right) & \boldsymbol{0}\\ \boldsymbol{0} & -\boldsymbol{I}\end{bmatrix}}_{\begin{bmatrix}\boldsymbol{\Omega_1} & \boldsymbol{0}\\ \boldsymbol{0} & -\boldsymbol{I}\end{bmatrix}}\cdot\begin{bmatrix}\boldsymbol{x}\\ \boldsymbol{y}\end{bmatrix} = \underbrace{\begin{bmatrix}\left(\overline{\boldsymbol{\Lambda}}-\boldsymbol{\Lambda}\right)^{-1}\left(\overline{\boldsymbol{\Lambda}}\boldsymbol{X}^T-\boldsymbol{\Lambda}\overline{\boldsymbol{X}}^T\right)\mathbf{p}(t)\\ \left(\overline{\boldsymbol{\Lambda}}-\boldsymbol{\Lambda}\right)^{-1}\left(\overline{\boldsymbol{X}}^T-\boldsymbol{X}^T\right)\mathbf{p}(t)\end{bmatrix}}_{\begin{bmatrix}\boldsymbol{T_1}^T\,\mathbf{p}(t)\\ \boldsymbol{T_2}^T\,\mathbf{p}(t)\end{bmatrix}} \tag{2.13}$$

where $\boldsymbol{D_1}, \boldsymbol{\Omega_1}, \boldsymbol{T_1}$ and $\boldsymbol{T_2}$ are real-space matrices (what can easy be checked):

$$\boldsymbol{D_1} = \left(\overline{\boldsymbol{\Lambda}}-\boldsymbol{\Lambda}\right)^{-1}\left(-\overline{\boldsymbol{\Lambda}\boldsymbol{\Lambda}}+\boldsymbol{\Lambda}\boldsymbol{\Lambda}\right) = -diag\left[\lambda_1+\overline{\lambda}_1,\cdots,\lambda_j+\overline{\lambda}_j,\cdots,\lambda_n+\overline{\lambda}_n\right] = -diag\left[2\alpha_1,\cdots,2\alpha_j,\cdots,2\alpha_n\right] \tag{2.14}$$

$$\boldsymbol{\Omega_1} = \left(\overline{\boldsymbol{\Lambda}}-\boldsymbol{\Lambda}\right)^{-1}\left(\overline{\boldsymbol{\Lambda}}\,\boldsymbol{\Lambda}\,\overline{\boldsymbol{\Lambda}}-\boldsymbol{\Lambda}\,\overline{\boldsymbol{\Lambda}}\,\boldsymbol{\Lambda}\right) = diag\left[\lambda_1\overline{\lambda}_1,\cdots,\lambda_j\overline{\lambda}_j,\cdots,\lambda_n\overline{\lambda}_n\right] = diag\left[\alpha_1^2+\omega_{D1}^2,\cdots,\alpha_n^2+\omega_{Dn}^2\right] \tag{2.15}$$

$$\boldsymbol{T_1} = \left(\boldsymbol{X}\overline{\boldsymbol{\Lambda}}-\overline{\boldsymbol{X}}\boldsymbol{\Lambda}\right)\left(\overline{\boldsymbol{\Lambda}}-\boldsymbol{\Lambda}\right)^{-1} \tag{2.16}$$

$$\boldsymbol{T_2} = \left(\overline{\boldsymbol{X}}-\boldsymbol{X}\right)\left(\overline{\boldsymbol{\Lambda}}-\boldsymbol{\Lambda}\right)^{-1} \tag{2.17}$$

Eq. (2.13) is the transformed uncoupled real-space form of the original equations of motion (2.1), the introduced n-dimensional vector $\boldsymbol{x}$ can be referred to as modal coordinates. The matrix equation (2.13) can be solved by expressing $\boldsymbol{y}$ from the second equation, see Eq. (2.19), and replacing it in the first one to get

$$\ddot{\boldsymbol{x}} + \boldsymbol{D_1}\dot{\boldsymbol{x}} + \boldsymbol{\Omega_1}\boldsymbol{x} = \boldsymbol{T_1}^T\,\mathbf{p}(t) + \boldsymbol{T_2}^T\,\dot{\mathbf{p}}(t) \tag{2.18}$$

Eq. (2.18) represents n uncoupled single-mass oscillator equations, which can be solved numerically by any time step integration operator. Having the time series $\boldsymbol{x}(t)$, $\dot{\boldsymbol{x}}(t)$ and $\ddot{\boldsymbol{x}}(t)$, the modal coordinates $\boldsymbol{y}(t)$ can be expressed from Eq. (2.13) to:

$$\boldsymbol{y} = \dot{\boldsymbol{x}} - \boldsymbol{T_2}^T\,\mathbf{p}(t) \tag{2.19}$$

The relationship between the modal coordinates $\begin{bmatrix} \boldsymbol{x} \\ \boldsymbol{y} \end{bmatrix}$ and the original state space variables $\begin{bmatrix} \boldsymbol{V} \\ \dot{\boldsymbol{V}} \end{bmatrix}$ from (2.1) can be derived by combining the first complex transformation (2.3) with the complex transformation introduced by (2.12):

$$\begin{bmatrix} \boldsymbol{V} \\ \dot{\boldsymbol{V}} \end{bmatrix} = \begin{bmatrix} \boldsymbol{X} & \overline{\boldsymbol{X}} \\ \boldsymbol{X}\boldsymbol{\Lambda} & \overline{\boldsymbol{X}}\,\overline{\boldsymbol{\Lambda}} \end{bmatrix} \begin{bmatrix} \boldsymbol{a} \\ \boldsymbol{b} \end{bmatrix} = \begin{bmatrix} \boldsymbol{X} & \overline{\boldsymbol{X}} \\ \boldsymbol{X}\boldsymbol{\Lambda} & \overline{\boldsymbol{X}}\,\overline{\boldsymbol{\Lambda}} \end{bmatrix} \begin{bmatrix} \boldsymbol{I} & \boldsymbol{I} \\ \boldsymbol{\Lambda} & \overline{\boldsymbol{\Lambda}} \end{bmatrix}^{-1} \begin{bmatrix} \boldsymbol{x} \\ \boldsymbol{y} \end{bmatrix} \tag{2.20}$$

The upper half of (2.20) is

$$\boldsymbol{V} = \left(\boldsymbol{X}\overline{\boldsymbol{\Lambda}} - \overline{\boldsymbol{X}}\boldsymbol{\Lambda}\right)\left(\overline{\boldsymbol{\Lambda}} - \boldsymbol{\Lambda}\right)^{-1}\boldsymbol{x} + \left(\overline{\boldsymbol{X}} - \boldsymbol{X}\right)\left(\overline{\boldsymbol{\Lambda}} - \boldsymbol{\Lambda}\right)^{-1}\boldsymbol{y} = \boldsymbol{T_1 x} + \boldsymbol{T_2 y} \tag{2.21}$$

and accounting for Eq.(2.19):

$$\boldsymbol{V} = \boldsymbol{T_1 x} + \boldsymbol{T_2}\left(\dot{\boldsymbol{x}} - \boldsymbol{T_2^T}\,\mathbf{p}(t)\right) \tag{2.22}$$

By use of Eq. (2.19) the real-space solution (2.20) can be rewritten in state space form:

$$\begin{bmatrix} \boldsymbol{V}(t) \\ \dot{\boldsymbol{V}}(t) \end{bmatrix} = \begin{bmatrix} \boldsymbol{X} & \overline{\boldsymbol{X}} \\ \boldsymbol{X}\boldsymbol{\Lambda} & \overline{\boldsymbol{X}}\,\overline{\boldsymbol{\Lambda}} \end{bmatrix} \begin{bmatrix} \boldsymbol{I} & \boldsymbol{I} \\ \boldsymbol{\Lambda} & \overline{\boldsymbol{\Lambda}} \end{bmatrix}^{-1} \begin{bmatrix} \boldsymbol{x}(t) \\ \dot{\boldsymbol{x}}(t) - \boldsymbol{T_2^T}\,\mathbf{p}(t) \end{bmatrix} \tag{2.23}$$

The inverse transformation of (2.23) is

$$\begin{bmatrix} \boldsymbol{x}(t) \\ \dot{\boldsymbol{x}}(t) \end{bmatrix} = \begin{bmatrix} \boldsymbol{I} & \boldsymbol{I} \\ \boldsymbol{\Lambda} & \overline{\boldsymbol{\Lambda}} \end{bmatrix} \begin{bmatrix} \boldsymbol{X} & \overline{\boldsymbol{X}} \\ \boldsymbol{X}\boldsymbol{\Lambda} & \overline{\boldsymbol{X}}\,\overline{\boldsymbol{\Lambda}} \end{bmatrix}^{-1} \begin{bmatrix} \boldsymbol{V}(t) \\ \dot{\boldsymbol{V}}(t) \end{bmatrix} + \begin{bmatrix} \mathbf{0} \\ \boldsymbol{T_2^T}\,\mathbf{p}(t) \end{bmatrix} \tag{2.24}$$

3 MODAL ANALYSIS PROCEDURE BASED ON THE STIFFNESS NORMALIZED RIGHT EIGENVECTORS

In this section is described a procedure, similar to the phase synchronization method in state space formulation, presented in Sec. 2. We will consider the case of forced vibrations with n distinct complex conjugated eigenvalues λ_j, see Eq. (3.12), what is the most relevant case in structural mechanics based on finite element formulation. The detailed development of the procedure differs in some points from the decomposition method based on the *Lancaster form* (2.1). The description of the differences in details, compared to the development steps in Section 2, aims to outline the structural mechanics background of the utilized mathematical transformations.

In order to derive the modal transformation for a MDOFS we will first consider the viscously damped single-degree-of-freedom-system (SDOFS).

3.1 The single mass oscillator

The equation of motion of a SDOFS is written in the extended form

$$\underbrace{\begin{bmatrix}1 & \\ & -\omega^2\end{bmatrix}}_{\boldsymbol{m}}\underbrace{\begin{bmatrix}\ddot{v}(t)\\ \dot{v}(t)\end{bmatrix}}_{\dot{\boldsymbol{q}}}+\underbrace{\begin{bmatrix}2\eta\omega & \omega^2\\ \omega^2 & \end{bmatrix}}_{\boldsymbol{k}}\underbrace{\begin{bmatrix}\dot{v}(t)\\ v(t)\end{bmatrix}}_{\boldsymbol{q}}=\underbrace{\begin{bmatrix}p(t)\\ \end{bmatrix}}_{\boldsymbol{p}}$$

$$\boldsymbol{m}\dot{\boldsymbol{q}}+\boldsymbol{k}\boldsymbol{q}=\boldsymbol{p} \tag{3.1}$$

where $\ddot{v}$ is acceleration, $\dot{v}$ – velocity, $v(t)$ – displacement, $\omega=\sqrt{\frac{k}{m}}$ – free vibration frequency and $\eta=\frac{c}{2m\omega}$ – Lehr's damping ratio.

The corresponding quadratic eigenvalue problem leads to two complex conjugate right eigenvectors $\boldsymbol{q}_j$, $(j=1,2)$

$$\dot{\boldsymbol{q}}+\underbrace{(\boldsymbol{m}^{-1}\boldsymbol{k})}_{\boldsymbol{a}}\boldsymbol{q}=\boldsymbol{0}\ \rightarrow\ \boldsymbol{q}_1=\begin{bmatrix}\lambda_r+\ i\lambda_i\\ 1\end{bmatrix},\ \boldsymbol{q}_2=\begin{bmatrix}\lambda_r-\ i\lambda_i\\ 1\end{bmatrix} \tag{3.2}$$

where $\lambda_r=-\eta\omega=\alpha$, $\lambda_i=\omega\sqrt{1-\eta^2}=\omega_D$ are the real resp. imaginary part of the associated complex conjugate eigenvalues $\left(\lambda=\lambda_r+i\lambda_i,\ \overline{\lambda}=\lambda_r-i\lambda_i\right)$.

The eigenvectors $\boldsymbol{q}_j$ are normalized with respect to the stiffness matrix $\boldsymbol{k}$, Eq. (3.1), and denoted by $\boldsymbol{\varphi}_j$:

$$[\boldsymbol{q}_1\quad\boldsymbol{q}_2]^T\cdot\boldsymbol{k}\cdot[\boldsymbol{q}_1\quad\boldsymbol{q}_2]=\begin{bmatrix}h_{11} & \\ & h_{22}\end{bmatrix}\quad\rightarrow\ \boldsymbol{\varphi}_j=\frac{\boldsymbol{q}_j}{\sqrt{h_{jj}}}\qquad(j=1,2) \tag{3.3}$$

The (2 x 2) modal matrix $\boldsymbol{\varphi}$, associated to the eigenvalue problem (3.2), is cast:

$$\boldsymbol{\varphi}=[\boldsymbol{\varphi}_1\quad\boldsymbol{\varphi}_2] \tag{3.4}$$

The normalization (3.3) leads to the orthogonality relationships (3.5), (3.6):

$$\boldsymbol{\varphi}^T\,\boldsymbol{m}\,\boldsymbol{\varphi}=\boldsymbol{\varphi}^T\begin{bmatrix}1 & \\ & -\omega^2\end{bmatrix}\boldsymbol{\varphi}=\begin{bmatrix}-\frac{1}{\lambda} & \\ & -\frac{1}{\overline{\lambda}}\end{bmatrix}\ \leftrightarrow\ (\boldsymbol{\varphi}^T)^{-1}\begin{bmatrix}-\frac{1}{\lambda} & \\ & -\frac{1}{\overline{\lambda}}\end{bmatrix}\boldsymbol{\varphi}^{-1}=\begin{bmatrix}1 & \\ & -\omega^2\end{bmatrix} \tag{3.5}$$

$$\boldsymbol{\varphi}^T\,\boldsymbol{k}\,\boldsymbol{\varphi}=\boldsymbol{\varphi}^T\begin{bmatrix}2\eta\omega & \omega^2\\ \omega^2 & \end{bmatrix}\boldsymbol{\varphi}=\begin{bmatrix}1 & \\ & 1\end{bmatrix}\ \leftrightarrow\ (\boldsymbol{\varphi}^T)^{-1}\begin{bmatrix}1 & \\ & 1\end{bmatrix}\boldsymbol{\varphi}^{-1}=\begin{bmatrix}2\eta\omega & \omega^2\\ \omega^2 & \end{bmatrix} \tag{3.6}$$

In Sec. 3.2 there will be used the analytical expression for the inverse of the complex modal matrix $\boldsymbol{\varphi}(\omega,\eta)$:

$$\boldsymbol{\varphi}^{-1}=\frac{1}{2\sqrt{1-\eta^2}}\begin{bmatrix}W_2-iW_1 & Q+iP\\ W_2+iW_1 & Q-iP\end{bmatrix} \tag{3.7}$$

where

$$W_1=\sqrt{\omega\sqrt{1-\eta^2}\left(1-2\eta\sqrt{1-\eta^2}\right)},\quad W_2=\sqrt{\omega\sqrt{1-\eta^2}\left(1+2\eta\sqrt{1-\eta^2}\right)} \tag{3.8}$$

$$P=\omega\left(W_2\sqrt{1-\eta^2}-\eta W_1\right),\qquad Q=\omega\left(W_1\sqrt{1-\eta^2}+\eta W_2\right) \tag{3.9}$$

3.2 Modal transformation of the MDOFS equations

At first the equations of motion (1.1) are recast to first order equations in state space:

$$\underbrace{\begin{bmatrix} \boldsymbol{M} & \\ & -\boldsymbol{K} \end{bmatrix}}_{\boldsymbol{M_G}} \underbrace{\begin{bmatrix} \ddot{\boldsymbol{V}} \\ \dot{\boldsymbol{V}} \end{bmatrix}}_{\dot{\boldsymbol{Q}}} + \underbrace{\begin{bmatrix} \boldsymbol{D} & \boldsymbol{K} \\ \boldsymbol{K} & \end{bmatrix}}_{\boldsymbol{K_G}} \underbrace{\begin{bmatrix} \dot{\boldsymbol{V}} \\ \boldsymbol{V} \end{bmatrix}}_{\boldsymbol{Q}} = \underbrace{\begin{bmatrix} \boldsymbol{p}(t) \\ \end{bmatrix}}_{\boldsymbol{P}} \tag{3.10}$$

where $\boldsymbol{M_G}$ and $\boldsymbol{K_G}$ are, respectively the (2n x 2n) symmetric generalized mass and the generalized stiffness matrices. The formulation in state space (3.10) doesn't use the Lancaster form (2.1), but retains the symmetry in the generalized matrices.

The associated quadratic eigenvalue problem can be written in the 2n-dimensional form

$$\left(\lambda_j \boldsymbol{M_G} + \boldsymbol{K_G}\right) \begin{bmatrix} \lambda_j \boldsymbol{X}_j \\ \boldsymbol{X}_j \end{bmatrix} = \boldsymbol{0} \tag{3.11}$$

where

$$\lambda_j = \lambda_{rj} + i\lambda_{ij} \;\rightarrow \begin{bmatrix} \lambda_j \boldsymbol{X}_j \\ \boldsymbol{X}_j \end{bmatrix}, \quad \overline{\lambda}_j = \lambda_{rj} - i\lambda_{ij} \;\rightarrow \begin{bmatrix} \overline{\lambda}_j \overline{\boldsymbol{X}}_j \\ \overline{\boldsymbol{X}}_j \end{bmatrix}, \quad (j = 1, \dots, n) \tag{3.12}$$

are the corresponding n complex conjugate eigenpairs. Each j[th] eigenvector-pair $\left(\boldsymbol{X}_j, \overline{\boldsymbol{X}}_j\right)$ can be normalized (index (j) omitted) with respect to the general stiffness matrix $\boldsymbol{K_G}$:

$$\begin{bmatrix} \lambda \boldsymbol{X} \\ \boldsymbol{X} \end{bmatrix}^T \begin{bmatrix} \boldsymbol{D} & \boldsymbol{K} \\ \boldsymbol{K} & \end{bmatrix} \begin{bmatrix} \lambda \boldsymbol{X} \\ \boldsymbol{X} \end{bmatrix} = A + iB \;\rightarrow\; \boldsymbol{\Phi} = \frac{\boldsymbol{X}}{\sqrt{A+iB}} = \boldsymbol{\Phi_r} + i\boldsymbol{\Phi_i} \tag{3.13a}$$

$$\begin{bmatrix} \overline{\lambda \boldsymbol{X}} \\ \overline{\boldsymbol{X}} \end{bmatrix}^T \begin{bmatrix} \boldsymbol{D} & \boldsymbol{K} \\ \boldsymbol{K} & \end{bmatrix} \begin{bmatrix} \overline{\lambda \boldsymbol{X}} \\ \overline{\boldsymbol{X}} \end{bmatrix} = A - iB \;\rightarrow\; \overline{\boldsymbol{\Phi}} = \frac{\overline{\boldsymbol{X}}}{\sqrt{A-iB}} = \boldsymbol{\Phi_r} - i\boldsymbol{\Phi_i} \tag{3.13b}$$

Due to the normalization (3.13a-b) the orthogonality relationships (3.14), (3.15) hold – expressed in terms of the j[th] eigenvector-pair (index (j) omitted):

$$\begin{bmatrix} \lambda \boldsymbol{\Phi} & \overline{\lambda \boldsymbol{\Phi}} \\ \boldsymbol{\Phi} & \overline{\boldsymbol{\Phi}} \end{bmatrix}^T \begin{bmatrix} \boldsymbol{M} & \\ & -\boldsymbol{K} \end{bmatrix} \begin{bmatrix} \lambda \boldsymbol{\Phi} & \overline{\lambda \boldsymbol{\Phi}} \\ \boldsymbol{\Phi} & \overline{\boldsymbol{\Phi}} \end{bmatrix} = \begin{bmatrix} -\frac{1}{\lambda} & \\ & -\frac{1}{\overline{\lambda}} \end{bmatrix} \tag{3.14}$$

$$\begin{bmatrix} \lambda \boldsymbol{\Phi} & \overline{\lambda \boldsymbol{\Phi}} \\ \boldsymbol{\Phi} & \overline{\boldsymbol{\Phi}} \end{bmatrix}^T \begin{bmatrix} \boldsymbol{D} & \boldsymbol{K} \\ \boldsymbol{K} & \end{bmatrix} \begin{bmatrix} \lambda \boldsymbol{\Phi} & \overline{\lambda \boldsymbol{\Phi}} \\ \boldsymbol{\Phi} & \overline{\boldsymbol{\Phi}} \end{bmatrix} = \begin{bmatrix} 1 & \\ & 1 \end{bmatrix} \tag{3.15}$$

Then the (2n x 2n) complex modal matrix $\boldsymbol{\Phi_G}$ can be built up:

$$\boldsymbol{\Phi_G} = \begin{bmatrix} \lambda_1 \boldsymbol{\Phi}_1 & \overline{\lambda}_1 \overline{\boldsymbol{\Phi}}_1 & \cdots & \lambda_n \boldsymbol{\Phi}_n & \overline{\lambda}_n \overline{\boldsymbol{\Phi}}_n \\ \boldsymbol{\Phi}_1 & \overline{\boldsymbol{\Phi}}_1 & \cdots & \boldsymbol{\Phi}_n & \overline{\boldsymbol{\Phi}}_n \end{bmatrix} \tag{3.16}$$

Note the difference to the form of Eqs. (2.3), (2.5) – the complex eigenvectors $\boldsymbol{X}$ and the conjugated complex $\overline{\boldsymbol{X}}$ are split, but in (3.16) they remain in pairs.

By the aid of the modal matrix $\boldsymbol{\Phi_G}$ and with account for (3.14), (3.15), the modal decomposition of the equations of motions (3.10) is performed to:

$$\underbrace{\boldsymbol{\Phi}_G^T \begin{bmatrix} \mathbf{M} & \\ & -\mathbf{K} \end{bmatrix} \boldsymbol{\Phi}_G}_{\begin{bmatrix} -\frac{1}{\lambda} & & \\ & \cdots & \\ & & -\frac{1}{\overline{\lambda}_n} \end{bmatrix}} \dot{\mathbf{A}} + \underbrace{\boldsymbol{\Phi}_G^T \begin{bmatrix} \mathbf{D} & \mathbf{K} \\ \mathbf{K} & \end{bmatrix} \boldsymbol{\Phi}_G}_{\begin{bmatrix} 1 & & \\ & \cdots & \\ & & 1 \end{bmatrix}} \mathbf{A} = \boldsymbol{\Phi}_G^T \begin{bmatrix} \mathbf{p}(t) \\ \end{bmatrix} \tag{3.17}$$

where the new complex modal coordinates **A** are introduced by Eq. (3.18):

$$\begin{bmatrix} \dot{\boldsymbol{V}} \\ \boldsymbol{V} \end{bmatrix} = \boldsymbol{\Phi_G}\, \boldsymbol{A}(t) = \boldsymbol{\Phi_G} \begin{bmatrix} a_1(t) & b_1(t) & \cdots & a_n(t) & b_n(t) \end{bmatrix}^{\boldsymbol{T}} \tag{3.18}$$

According to the assembly of the global modal matrix $\boldsymbol{\Phi_G}$ in (3.16), the complex coordinates (a_j, b_j) in the definition (3.18) remain in pairs, corresponding to the eigenvalue pair $(\lambda_j, \overline{\lambda}_j)$, whereas in the definition (2.4) in Sec. 2 they are separated. In comparison to the analogous decoupling transformation (2.10) the uncoupled modal equations (3.17) have – due to the normalization (3.13) – a very clear and more simple form of the modal stiffness matrix (equal to unity matrix) and of the modal mass matrix (equal to the inverse spectral matrix).

In a next step a second transformation of the complex modal equations (3.17) will be introduced in order to get $(j = 1, \ldots, n)$ uncoupled single oscillator equations in real space. The complex modal coordinates $[a_j \quad b_j]^T$, Eq. (3.18), will be replaced by new real coordinates $[x_j \quad y_j]^T$ for each j-th eigenpair, introduced by the definition:

$$\begin{bmatrix} a_j(t) \\ b_j(t) \end{bmatrix} = \left(\boldsymbol{\varphi}^{(j)}\right)^{-1} \begin{bmatrix} x_j(t) \\ y_j(t) \end{bmatrix}, \qquad \begin{bmatrix} \dot{a}_j \\ \dot{b}_j \end{bmatrix} = \left(\boldsymbol{\varphi}^{(j)}\right)^{-1} \begin{bmatrix} \dot{x}_j(t) \\ \dot{y}_j(t) \end{bmatrix} \tag{3.19}$$

Taking into account (3.19), the modal equations (3.17) can be transformed **in pairs** into the real form of SDOFS-equation (index (j) omitted), with regard to the inverse relationships (3.5), (3.6):

$$\begin{array}{cccccc} \underbrace{(\boldsymbol{\varphi}^T)^{-1} \begin{bmatrix} -\frac{1}{\lambda} & \\ & -\frac{1}{\overline{\lambda}} \end{bmatrix} \boldsymbol{\varphi}^{-1}}_{\begin{bmatrix} 1 & \\ & -\omega^2 \end{bmatrix}} & \cdot \begin{bmatrix} \dot{x} \\ \dot{y} \end{bmatrix} & + & \underbrace{(\boldsymbol{\varphi}^T)^{-1} \begin{bmatrix} 1 & \\ & 1 \end{bmatrix} \boldsymbol{\varphi}^{-1}}_{\begin{bmatrix} 2\eta\omega & \omega^2 \\ \omega^2 & \end{bmatrix}} & \cdot \begin{bmatrix} x \\ y \end{bmatrix} & = & \underbrace{(\boldsymbol{\varphi}^T)^{-1} \begin{bmatrix} \lambda \boldsymbol{\Phi}^T \boldsymbol{p}(t) \\ \overline{\lambda} \overline{\boldsymbol{\Phi}}^T \boldsymbol{p}(t) \end{bmatrix}}_{\begin{bmatrix} g(t) \\ h(t) \end{bmatrix}} \end{array} \tag{3.20}$$

Note that the matrix $(\boldsymbol{\varphi})^{-1}$ can be expressed according to Eq. (3.7)-(3.9) simply by the real and imaginary parts $(\lambda_{rj}, \lambda_{ij})$ of the corresponding eigenvalue pair $(\lambda_j, \overline{\lambda}_j)$.

Combining the two complex transformations (3.18), (3.19), a new (2n x 2n) transformation basis **Y** can be defined:

$$\begin{bmatrix} \dot{\boldsymbol{V}} \\ \boldsymbol{V} \end{bmatrix} = \boldsymbol{\Phi_G} \underbrace{\begin{bmatrix} \left(\boldsymbol{\varphi}^{(1)}\right)^{-1} & & \\ & \cdots & \\ & & \left(\boldsymbol{\varphi}^{(n)}\right)^{-1} \end{bmatrix}}_{\boldsymbol{\Psi}^{-1}} \underbrace{\begin{bmatrix} x_1 \\ y_1 \\ \cdots \\ x_n \\ y_n \end{bmatrix}}_{\mathbf{X}} = \underbrace{(\boldsymbol{\Phi_G} \boldsymbol{\Psi}^{-1})}_{\mathbf{Y}} \mathbf{X} = \mathbf{Y}\, \mathbf{X} \tag{3.21}$$

Finally, by the aid of the relationship (3.21), see also (3.17) and (3.20), the equations of motion (3.10) can be transformed into n real uncoupled SDOFS block equations as follows:

$$\underbrace{\mathbf{Y}^{\mathrm{T}}\cdot\begin{bmatrix}\mathbf{M} & \\ & -\mathbf{K}\end{bmatrix}\cdot\mathbf{Y}}_{\begin{bmatrix}1 & & & & \\ & -\omega_1^2 & & & \\ & & \cdots & & \\ & & & 1 & \\ & & & & -\omega_n^2\end{bmatrix}}\cdot\underbrace{\begin{bmatrix}\dot{x}_1\\ \dot{y}_1\\ \cdots\\ \dot{x}_n\\ \dot{y}_n\end{bmatrix}}_{\dot{\mathbf{x}}}+\underbrace{\mathbf{Y}^{\mathrm{T}}\cdot\begin{bmatrix}\mathbf{D} & \mathbf{K}\\ \mathbf{K} & \end{bmatrix}\cdot\mathbf{Y}}_{\begin{bmatrix}2\eta_1\omega_1 & \omega_1^2 & & & \\ \omega_1^2 & 0 & & & \\ & & \cdots & & \\ & & & 2\eta_n\omega_n & \omega_n^2\\ & & & \omega_n^2 & 0\end{bmatrix}}\cdot\underbrace{\begin{bmatrix}x_1\\ y_1\\ \cdots\\ x_n\\ y_n\end{bmatrix}}_{\mathbf{x}}=\underbrace{\mathbf{Y}^{\mathrm{T}}\cdot\begin{bmatrix}\mathbf{p}\\ \end{bmatrix}}_{\begin{bmatrix}g_1\\ h_1\\ \cdots\\ g_n\\ h_n\end{bmatrix}} \tag{3.22}$$

It can be shown that the **Y**-matrix and all „load"-vector component $[g(t) \quad h(t)]^T$ in Eq. (3.22) are purely real. After component multiplication of the analytically expressed terms of $\boldsymbol{\Phi_G}$ and of $\boldsymbol{\Psi^{-1}}$ all imaginary parts cancel each other, see details in [16], [19].

The components of two columns in the real-space matrix **Y**, belonging to the j[th] eigenvector-pair, may be denotes as

$$\mathbf{Y}=\begin{bmatrix}\cdots & \mathbf{Y}_{\mathrm{x1}}^{(\mathrm{j})} & \mathbf{Y}_{\mathrm{y1}}^{(\mathrm{j})} & \cdots\\ \cdots & \mathbf{Y}_{\mathrm{x2}}^{(\mathrm{j})\mathbf{V}} & \mathbf{Y}_{\mathrm{y2}}^{(\mathrm{j})} & \cdots\end{bmatrix} \tag{3.23}$$

Analytical expressions for the components in (3.23) can be derived as functions of the corresponding ω, η and the real and imaginary parts of the $\boldsymbol{\Phi}_j$, accounting also for (3.7)-(3.9), (index (j) omitted):

$$\mathbf{Y}_{x1}^{(\mathrm{j})}=\frac{\omega}{\sqrt{1-\eta^2}}\left[\left(-\eta\,W_2+\sqrt{1-\eta^2}\,W_1\right)\boldsymbol{\Phi}_{\mathbf{r}j}-\left(\eta\,W_1+\sqrt{1-\eta^2}\,W_2\right)\boldsymbol{\Phi}_{\mathbf{i}j}\right]$$
$$\mathbf{Y}_{y1}^{(\mathrm{j})}=\frac{\omega^2}{\sqrt{1-\eta^2}}\left[\left(-\eta\,Q-\sqrt{1-\eta^2}\,P\right)\boldsymbol{\Phi}_{\mathbf{r}j}+\left(\eta\,P-\sqrt{1-\eta^2}\,Q\right)\boldsymbol{\Phi}_{\mathbf{i}j}\right]$$
$$\mathbf{Y}_{x2}^{(\mathrm{j})}=\frac{1}{\sqrt{1-\eta^2}}\left[W_2\boldsymbol{\Phi}_{\mathbf{r}j}+W_1\boldsymbol{\Phi}_{\mathbf{i}j}\right]$$
$$\mathbf{Y}_{y2}^{(\mathrm{j})}=\frac{\omega}{\sqrt{1-\eta^2}}\left[Q\boldsymbol{\Phi}_{\mathbf{r}j}-P\boldsymbol{\Phi}_{\mathbf{i}j}\right] \tag{3.24a-d}$$

Similarly, the two components of the associated "load" vector are analytically:

$$g(t)=\frac{\omega}{\sqrt{1-\eta^2}}\left[\left(-\eta\,W_2+\sqrt{1-\eta^2}\,W_1\right)\boldsymbol{\Phi}_{\mathbf{r}j}^{\mathbf{T}}-\left(\eta\,W_1+\sqrt{1-\eta^2}\,W_2\right)\boldsymbol{\Phi}_{\mathbf{i}j}^{\mathbf{T}}\right]\mathbf{p}(t)$$
$$h(t)=\frac{\omega^2}{\sqrt{1-\eta^2}}\left[\left(-\eta\,Q-\sqrt{1-\eta^2}\,P\right)\boldsymbol{\Phi}_{\mathbf{r}j}^{\mathbf{T}}+\left(\eta\,P-\sqrt{1-\eta^2}\,Q\right)\boldsymbol{\Phi}_{\mathbf{i}j}^{\mathbf{T}}\right]\mathbf{p}(t) \tag{3.25a-b}$$

3.3 Comparison to the "phase synchronization" procedure

The transformation in Sec.2, analogously to (3.19), is given by Eq. (2.12). The advantage of the (2 x 2) transformation used in (3.20) is that it is done on the level "SDOFS-equation", employing stiffness normalization for the modal matrix **φ** – see Eq.(3.3). In contrast to this in the relationship (2.12) a (2n x 2n) matrix $\begin{bmatrix}\boldsymbol{I} & \boldsymbol{I}\\ \boldsymbol{\Lambda} & \overline{\boldsymbol{\Lambda}}\end{bmatrix}$ has to be inverted. Besides the analytical

inversion of the simple (2 x 2) matrix $\boldsymbol{\varphi}^{(j)}$ in (3.7), the definition (3.19) seems quite natural in order to transform the complex modal equations (3.17) back to the real form of uncoupled SDOFS – as seen in (3.20).

The mechanical reason of the relationship (2.11) and the inverse form (2.12) is clarified by looking at the eigenvectors (3.2) of the SDOFS. Due to the inverse order of displacements and velocities $\begin{bmatrix} \boldsymbol{V} \\ \dot{\boldsymbol{V}} \end{bmatrix}$ in the Lancaster form (2.1) in compare to the formulation (3.10), the meaning of the modal coordinates (x_j, y_j) here is interchanged, compare Eq. (2.18) and (3.27).

3.4 Solution of the modal equations and back transformation

Each SDOFS block equation in (3.22) can be solved eliminating the modal coordinate x_j to obtain the usual form of the SDOFS equation of motion (index (j) omitted):

$$x(t) = \dot{y} + \frac{1}{\omega^2} h(t) \tag{3.26}$$

$$\ddot{y}(t) + 2\eta\omega\, \dot{y}(t) + \omega^2 y(t) = g(t) - \frac{2\eta}{\omega} h(t) - \frac{1}{\omega^2} \dot{h}(t) \tag{3.27}$$

A usual numerical step-by-step integration of Eq. (3.27) yields the modal response $y_j(t)$, the modal coordinate $x_j(t)$ is calculated then according to (3.26). The back transformation to the original 2n state variables $\begin{bmatrix} \dot{\boldsymbol{V}}(t) \\ \boldsymbol{V}(t) \end{bmatrix}$ is done by superposition in accordance to (3.21) of the modal time series $x_j(t),\ y_j(t)$ (assembled in $\boldsymbol{X}$, Eq. (3.22)).

The final SDOFS equations from type (3.27) for each j-th eigenpair can be rebuilt in the uncoupled diagonal form (2.18) for the MDOFS – note that $y(t)$ in (3.27) corresponds to $x(t)$ in (2.18). The right sides of both equations clearly correspond to each other.

4 NUMERICAL APPLICATION TO A ROTOR BLADE VIBRATION

The numerical example considers the vibrations of a generic rotor blade subjected to wind thrust load. The equations of motion in the Lancaster form (2.1) and in the state space form (3.10) are solved applying resp. the "phase synchronization" technique, described in Sec.2 , and the proposed modal decomposition method in Sec. 3. In both cases have been employed only the first four lowest natural frequencies and the associated four complex eigenmodes.

4.1 Structural data, geometry and loads

All structural data for the reference rotor blade – geometry, mass, stiffness data etc. - have been taken from [23]. The blade model with 288 DOF is built by 48 beam elements, the over-all blade length is 63 m. The finite element stiffness and mass matrices are calculated on the base of numerical integration of the system of differential equations for the Bernoulli-beam, see detailed description of the employed transfer matrix method in [21].

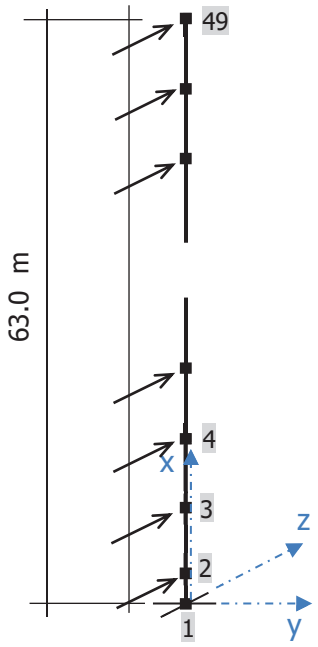

Figure 1: Rotor blade beam model subjected to wind loads

4.2 Wind loads

The wind speed time series $u(t)$, see Fig. 2, used for calculation of the wind thrust force, is an arbitrary 25-sec-cut from a real 10-min wind speed record in an offshore location in Baltic sea. This time series is used to calculate in a simple way realistic wind thrust loads. They are calculated on the basis of the formula for the aerodynamic lift force per unit length of an aerofoil, see [1] p.59:

$$L = \frac{1}{2}\rho \cdot ch(r) \cdot W^2 \cdot C_L \tag{4.1}$$

where:
- W : air velocity relative to the aerofoil
- ρ : air density = 1.225 [kg/m^3]
- $ch(r)$: chord length of the aerofoil
- C_L : lift coefficient $C_L = 2\pi\,\alpha = 2\pi\left(\frac{\pi}{180}6.0\right) = 0.658$, with an assumed constant AoA $\alpha = 6.0$ [deg]

The air velocity W in Eq. (4.1) is the vector sum of the circumferential speed Ωr (with assumed $\Omega = 12$ rpm after the initial four seconds) and the wind speed u, incident on the rotor plane in accordance with the Betz-theory:

$$W = \sqrt{(\Omega\, r)^2 + \left(\frac{2}{3}u\right)^2} \qquad \text{where } \Omega = \left(\frac{12}{30}\pi\right) \text{ in [rad/s]} \tag{4.2}$$

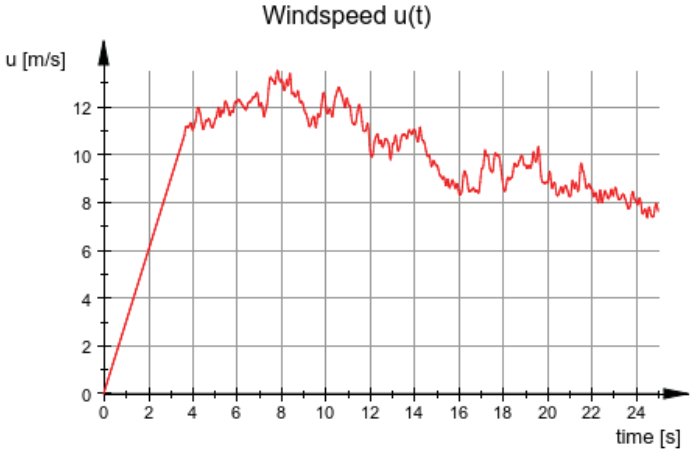

Fig. 2 Wind speed time series

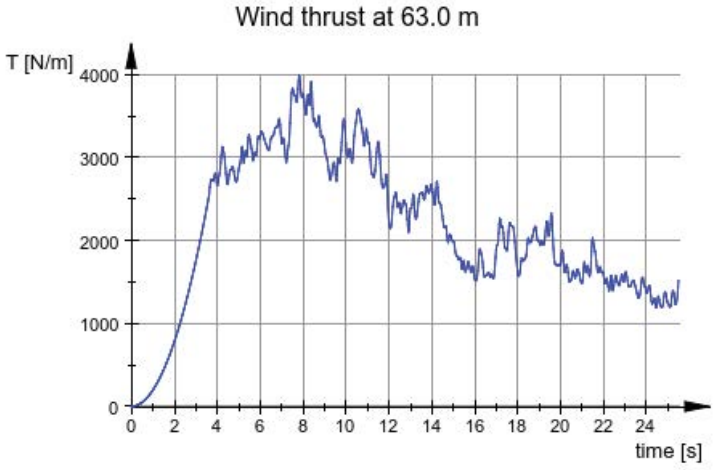

Fig. 3 Wind thrust T(t) on the rotor blade tip at 63.0 m

The resulting wind thrust loads $\mathrm{T}(t)$ per unit length along the x-axis of the rotor blade have been determined as function of the wind speed $u(t)$, see Fig. 3. In the structural model the wind thrust loads are acting as summarized nodal forces – see Fig. 1.

4.3 The non-proportional damping approach

For both procedures, the one described in Sec.2 and the modal decomposition method in Sec. 3, was applied the same system damping matrix. The matrix ***D*,** see Eq. (2.1) and (3.10), which represents non-proportional damping, has been assembled including an stiffness proportional damping part and an aerodynamic damping part.

In order to determine the first damping part the lowest four free-vibration frequencies and associated periods for the undamped system are calculated first to

$$\begin{aligned} f_1 &= 0.6722\ [s^{-1}] & T_1 &= 1.488\ [s] \\ f_2 &= 1.0934\ [s^{-1}] & T_2 &= 0.915\ [s] \\ f_3 &= 1.9177\ [s^{-1}] & T_3 &= 0.521\ [s] \\ f_4 &= 3.9647\ [s^{-1}] & T_4 &= 0.252\ [s] \end{aligned} \tag{4.3}$$

With an assumed damping ratio $\eta = 0.008$ for the first natural period T_1, see [1], p. 249, the stiffness-proportional damping part of $\boldsymbol{D}$, see Eq. (1.4), has been calculated:

$$\boldsymbol{D_p} = \beta\, \boldsymbol{K} \quad , \quad \beta = \frac{2\eta}{\omega_1} = \frac{\eta\, T_1}{\pi} = 0.00379[s] \tag{4.4}$$

The second aerodynamic damping part $\boldsymbol{D_a}$ of the system damping matrix is derived on the basis of a simple approach for the aerodynamic damping coefficient per unit length, given in [1], p. 247:

$$c(r) = \frac{1}{2}\rho \cdot\ \Omega r\ \cdot ch(r) \cdot \frac{dC_L}{d\alpha} \quad \left[\frac{kg}{s}\frac{1}{m}\right], \quad \text{where} \quad \frac{dC_L}{d\alpha} = 2\pi \tag{4.5}$$

The damping coefficients $c(r)$ along the x-axis, which represent the aerodynamic damping, are active for vibration in flapwise direction (z-direction in Fig. 1). In Eq. (4.6) are plotted the calculated $c(r)$-values for the last 12 points along the rotor axis.

r [m]	ch(r) [m]	$c(r)$ [kg/s/m]
56.7	2.28654	783.731
57.7	2.22487	776.044
58.7	2.11651	751.041
59.2	2.03366	727.789
59.7	1.93071	696.783
60.2	1.81172	659.315
60.7	1.68083	616.763
61.2	1.5422	570.555
61.7	1.39997	522.167
62.2	1.25829	473.127
62.7	1.12132	425.014
63.0	1.04312	397.265

(4.6)

Using the relationship (4.5), the damping matrix $\boldsymbol{D_a}$ for the Bernoulli-beam element is derived by analogy with the method used to derive the finite element mass matrix in [21]. The final symmetric system damping matrix $\boldsymbol{D} = \boldsymbol{D_p} + \boldsymbol{D_a}$ is assembled in the usual finite-element manner.

4.4 Rotor blade vibration applying the phase synchronization procedure

The equations of motion in the form (2.1) will be transformed employing only the first four eigenvalues and the associated eigenmodes. The first four lowest angular eigenfrequencies ω_{Dj} of the damped system and the corresponding damping ratios η_j are calculated to

$$\omega_{Dj} = \begin{pmatrix} 4.1399 \\ 6.8696 \\ 12.001 \\ 24.883 \end{pmatrix} \qquad \eta_j = \begin{pmatrix} 0.20484 \\ 0.013013 \\ 0.076374 \\ 0.047186 \end{pmatrix} \tag{4.7}$$

The first four complex conjugate eigenvalue pairs from Eq. (2.2) are combined in the two spectral matrices, see Eq. (2.6):

$$\boldsymbol{\Lambda} = \begin{pmatrix} -0.8664 + 4.14\,\mathrm{i} & 0 & 0 & 0 \\ 0 & -0.0894 + 6.87\,\mathrm{i} & 0 & 0 \\ 0 & 0 & -0.9192 + 12.0\,\mathrm{i} & 0 \\ 0 & 0 & 0 & -1.175 + 24.88\,\mathrm{i} \end{pmatrix} \tag{4.8a}$$

$$\overline{\boldsymbol{\Lambda}} = \begin{pmatrix} -0.8664 - 4.14\,\mathrm{i} & 0 & 0 & 0 \\ 0 & -0.0894 - 6.87\,\mathrm{i} & 0 & 0 \\ 0 & 0 & -0.9192 - 12.0\,\mathrm{i} & 0 \\ 0 & 0 & 0 & -1.175 - 24.88\,\mathrm{i} \end{pmatrix} \tag{4.8b}$$

The corresponding (288x4) mass normalized modal matrix $\boldsymbol{X} = [\boldsymbol{X}_1 \quad \boldsymbol{X}_2 \quad \cdots \quad \boldsymbol{X}_n]$ – Eq. (2.5), is computed to (here only the first twelve rows are printed):

$$[\boldsymbol{X}_1 \quad \boldsymbol{X}_2 \quad \boldsymbol{X}_3 \quad \boldsymbol{X}_4] = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & -0.02737 - 3.329\,10^{-13}\,\mathrm{i} & 0 & -0.03778 + 1.558\,10^{-12}\,\mathrm{i} \\ -0.03531 + 0.0008951\,\mathrm{i} & 0 & -0.04235 - 0.001384\,\mathrm{i} & 0 \\ 0 & 0 & 0 & 0 \\ 0.001415 - 9.58\,10^{-5}\,\mathrm{i} & 0 & 0.004074 - 4.16\,10^{-5}\,\mathrm{i} & 0 \\ 0 & -0.0007704 - 1.154\,10^{-15}\,\mathrm{i} & 0 & -0.002819 + 1.155\,10^{-13}\,\mathrm{i} \\ 0 & 0 & 0 & 0 \\ 0 & -0.0276 - 3.332\,10^{-13}\,\mathrm{i} & 0 & -0.03863 + 1.593\,10^{-12}\,\mathrm{i} \\ -0.03573 + 0.0009239\,\mathrm{i} & 0 & -0.04357 - 0.001372\,\mathrm{i} & 0 \\ 0 & 0 & 0 & 0 \\ 0.001415 - 9.605\,10^{-5}\,\mathrm{i} & 0 & 0.004076 - 4.245\,10^{-5}\,\mathrm{i} & 0 \\ 0 & -0.0007704 - 6.286\,10^{-16}\,\mathrm{i} & 0 & -0.002819 + 1.171\,10^{-13}\,\mathrm{i} \end{pmatrix} \tag{4.9}$$

The two (8 x 8) system matrices in the modal uncoupled equations of motion (2.13) are

$$\begin{bmatrix} \boldsymbol{D_1} & \boldsymbol{I} \\ \boldsymbol{I} & \boldsymbol{0} \end{bmatrix} = \begin{pmatrix} 1.733 & 0 & 0 & 0 & 1.0 & 0 & 0 & 0 \\ 0 & 0.1788 & 0 & 0 & 0 & 1.0 & 0 & 0 \\ 0 & 0 & 1.838 & 0 & 0 & 0 & 1.0 & 0 \\ 0 & 0 & 0 & 2.351 & 0 & 0 & 0 & 1.0 \\ 1.0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1.0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1.0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1.0 & 0 & 0 & 0 & 0 \end{pmatrix} \tag{4.10}$$

$$\begin{bmatrix} \boldsymbol{\Omega_1} & \boldsymbol{0} \\ \boldsymbol{0} & -\boldsymbol{I} \end{bmatrix} = \begin{pmatrix} 17.89 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 47.2 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 144.9 & 0 & 0 & 0 & -5.457\,10^{-12} & 0 \\ 0 & 0 & 0 & 620.5 & 0 & 0 & 0 & -3.638\,10^{-12} \\ 1.758\,10^{-12} & 0 & 0 & 0 & -1.0 & 0 & 0 & 0 \\ 0 & 2.648\,10^{-13} & 0 & 0 & 0 & -1.0 & 0 & 0 \\ 0 & 0 & -2.425\,10^{-12} & 0 & 0 & 0 & -1.0 & 0 \\ 0 & 0 & 0 & -4.678\,10^{-12} & 0 & 0 & 0 & -1.0 \end{pmatrix} \tag{4.11}$$

The "right side" vector in the final uncoupled modal equations (2.18) have been calculated as a function of the wind speed time series $u(t)$:

$$\boldsymbol{T}_1^T\,\mathbf{p}(t) + \boldsymbol{T}_2^T\,\dot{\mathbf{p}}(t) = \begin{pmatrix} -19.32\,u^2 \\ -1.951\,u^2 \\ -2.096\,u^2 \\ -0.5554\,u^2 \end{pmatrix} + \begin{pmatrix} 0.02013\,u \\ -1.743\,10^{-12}\,u \\ -0.1791\,u \\ 8.235\,10^{-12}\,u \end{pmatrix} \tag{4.12}$$

The modal vibrations $x_j(t), y_j(t),\ (j = 1,..,4)$ and the resulting time series for the original DOF in the next figures has been determined in the time 0… 25[sec], the time step length for the applied Newmark integration method is 0.02434 s.

The resulting time series of the modal coordinates are shown exemplarily in Figs. 4, 5 and 6.

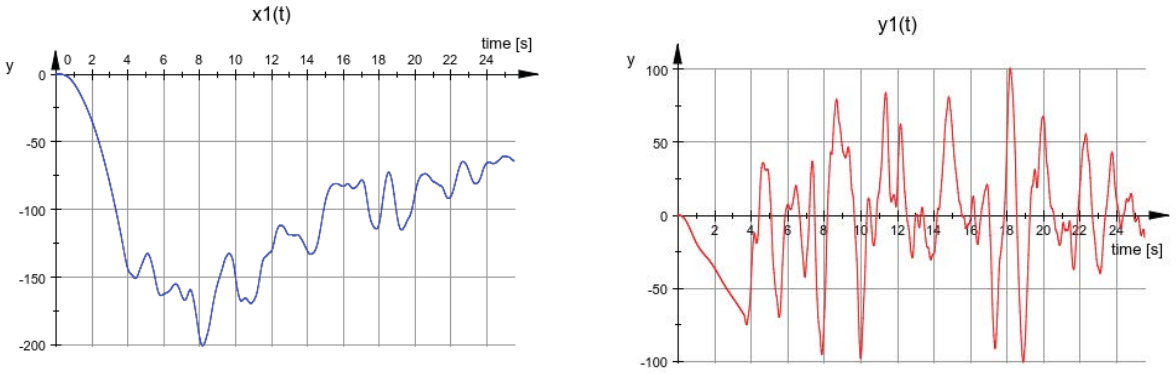

Fig. 4 Time responses of the modal coordinates $x_1(t), y_1(t)$

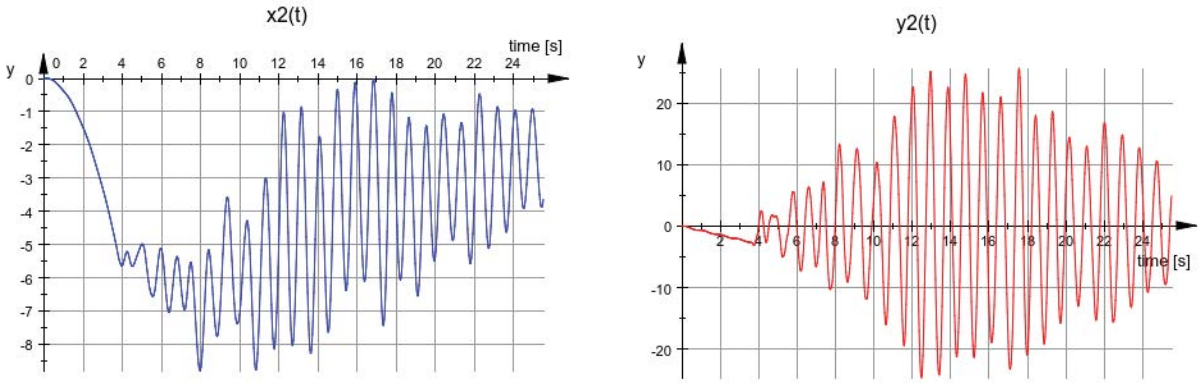

Fig. 5 Time responses of the modal coordinates $x_2(t), y_2(t)$

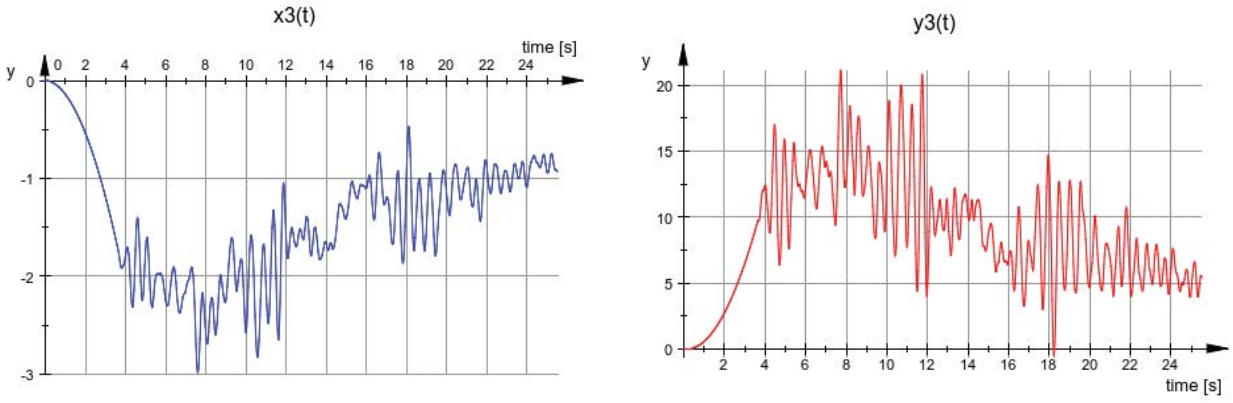

Fig. 6 Time responses of the modal coordinates $x_3(t), y_3(t)$

The back transformation of the modal vibrations to the original DOF in accordance to Eq. (2.23) is done by means of the (576 x 8) real-space transformation matrix, shown in Eq.(4.13) (only the first 18 rows are printed, they correspond to the displacements $\boldsymbol{V}(t)$):

$$\begin{bmatrix} \boldsymbol{X} & \overline{\boldsymbol{X}} \\ \boldsymbol{X}\,\boldsymbol{\Lambda} & \overline{\boldsymbol{X}}\,\overline{\boldsymbol{\Lambda}} \end{bmatrix} \begin{bmatrix} \boldsymbol{I} & \boldsymbol{I} \\ \boldsymbol{\Lambda} & \overline{\boldsymbol{\Lambda}} \end{bmatrix}^{-1} =$$

$$\begin{pmatrix}
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & -1.195\,10^{-5} & 0 & 4.859\,10^{-5} & 0 & 1.98\,10^{-16} & 0 & 1.203\,10^{-16} \\
-4.156\,10^{-6} & 0 & 1.647\,10^{-5} & 0 & -6.979\,10^{-8} & 0 & 1.503\,10^{-8} & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
4.858\,10^{-6} & 0 & -1.916\,10^{-5} & 0 & 8.122\,10^{-8} & 0 & -1.715\,10^{-8} & 0 \\
0 & -1.396\,10^{-5} & 0 & 5.623\,10^{-5} & 0 & 8.828\,10^{-17} & 0 & -7.181\,10^{-17} \\

0 & -2.848\,10^{-5} & 0 & 0.000111 & 0 & 1.755\,10^{-16} & 0 & -1.417\,10^{-16}
\end{pmatrix}$$

(4.13)

The total time responses for the original state variables $\boldsymbol{V}(t)$, $\dot{\boldsymbol{V}}(t)$, obtained by a back transformation according to Eq. (2.23), are plotted in Figs. 7-9 for the two bending directions at the rotor blade tip.

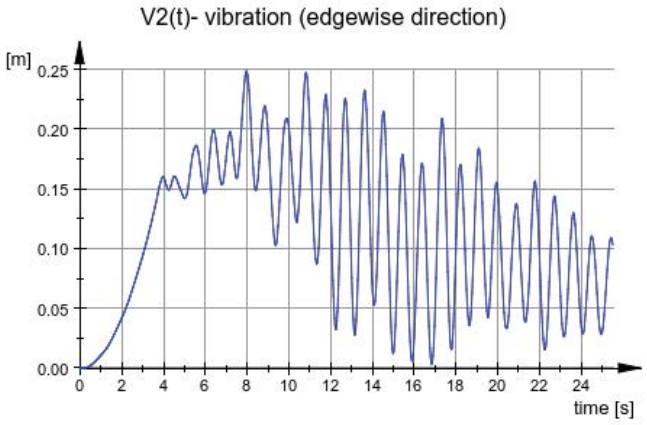

Fig.7 Total vibration $v_2(t)\ [m]$ (in y-direction, see fig.1) at the rotor blade tip - node #49

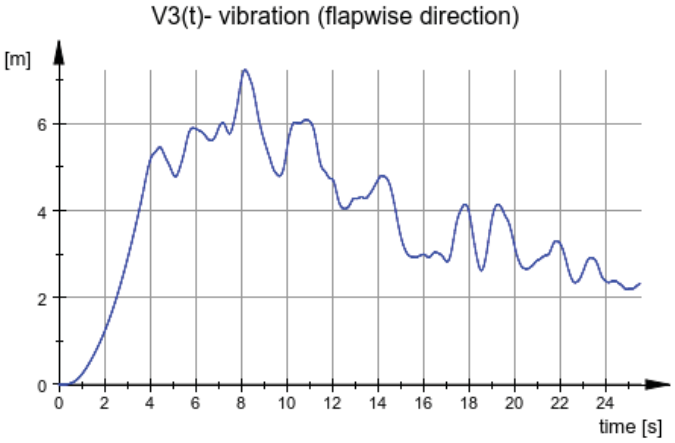

Fig. 8 Total vibration $v_3(t)$ $[m]$ (in z-direction, see fig.1) at the rotor blade tip - node #49

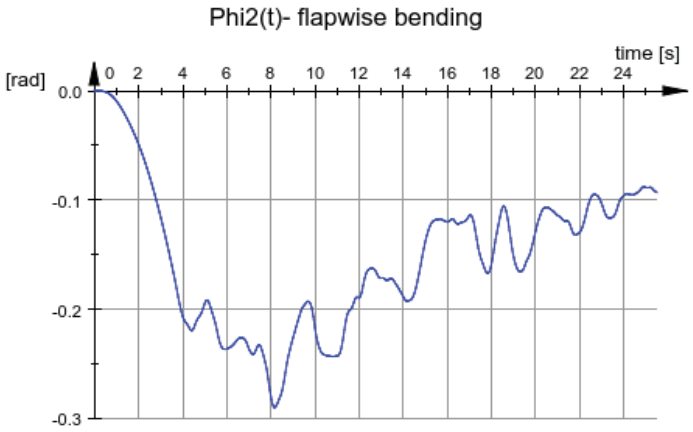

Fig. 9 Total bending angle $\varphi_2(t)$ [rad] (about y-axis, see fig.1) at the rotor blade tip - node #49

4.5 Application of the proposed new modal procedure

In this section the modal procedure based on the stiffness normalized eigenvectors, Sec. 3, is applied to the equations of motion (3.10) for a rotor blade. The geometry, structural data, wind thrust loads and the assembly of the system damping matrix for the rotor blade are described in Sec. 4.1-4.3.

Starting point for the calculations is the eigenvalue problem (3.11). The first four complex conjugate eigenvalue pairs of the matrix $\left(\boldsymbol{M_G}^{-1}\boldsymbol{K_G}\right)$ are

$$\begin{pmatrix} -0.86636+4.13985\,\mathrm{i} \\ -0.86636-4.13985\,\mathrm{i} \\ -0.0894045+6.86957\,\mathrm{i} \\ -0.0894045-6.86957\,\mathrm{i} \\ -0.919237+12.0008\,\mathrm{i} \\ -0.919237-12.0008\,\mathrm{i} \\ -1.17544+24.8831\,\mathrm{i} \\ -1.17544-24.8831\,\mathrm{i} \end{pmatrix} \tag{4.14}$$

The number of modes considered in the modal transformation is limited to the first four eigenvector pairs. Exemplarily the 1-th and the 3-th complex eigenvector pairs are plotted in Fig.10 resp. Fig. 11. Due to the 288 DOF of the beam model, Fig.1, the (576x8) modal matrix $\boldsymbol{\Phi_G}$ with stiffness normalized eigenvectors – Eq.(3.16), is computed to (here only the first twelve rows are printed)

$$\begin{pmatrix}
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 2.28\,10^{-6}+2.28\,10^{-6}\,i & 2.28\,10^{-6}-2.28\,10^{-6}\,i & 0 & 0 & -4.87\,10^{-6}-4.87\,10^{-6}\,i & -4.87\,10^{-6}+4.87\,10^{-6}\,i \\
9.37\,10^{-7}+1.08\,10^{-6}\,i & 9.37\,10^{-7}-1.08\,10^{-6}\,i & 0 & 0 & -2.35\,10^{-6}-2.4\,10^{-6}\,i & -2.35\,10^{-6}+2.4\,10^{-6}\,i & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
-1.1\,10^{-6}-1.26\,10^{-6}\,i & -1.1\,10^{-6}+1.26\,10^{-6}\,i & 0 & 0 & 2.73\,10^{-6}+2.79\,10^{-6}\,i & 2.73\,10^{-6}-2.79\,10^{-6}\,i & 0 & 0 \\
0 & 0 & 2.66\,10^{-6}+2.66\,10^{-6}\,i & 2.66\,10^{-6}-2.66\,10^{-6}\,i & 0 & 0 & -5.64\,10^{-6}-5.64\,10^{-6}\,i & -5.64\,10^{-6}+5.64\,10^{-6}\,i \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 5.65\,10^{-6}+5.65\,10^{-6}\,i & 5.65\,10^{-6}-5.65\,10^{-6}\,i & 0 & 0 & -1.19\,10^{-5}-1.19\,10^{-5}\,i & -1.19\,10^{-5}+1.19\,10^{-5}\,i \\
2.33\,10^{-6}+2.68\,10^{-6}\,i & 2.33\,10^{-6}-2.68\,10^{-6}\,i & 0 & 0 & -5.79\,10^{-6}-5.92\,10^{-6}\,i & -5.79\,10^{-6}+5.92\,10^{-6}\,i & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
-1.68\,10^{-6}-1.93\,10^{-6}\,i & -1.68\,10^{-6}+1.93\,10^{-6}\,i & 0 & 0 & 4.15\,10^{-6}+4.23\,10^{-6}\,i & 4.15\,10^{-6}-4.23\,10^{-6}\,i & 0 & 0 \\
0 & 0 & 4.06\,10^{-6}+4.06\,10^{-6}\,i & 4.06\,10^{-6}-4.06\,10^{-6}\,i & 0 & 0 & -8.47\,10^{-6}-8.47\,10^{-6}\,i & -8.47\,10^{-6}+8.47\,10^{-6}\,i
\end{pmatrix} \tag{4.15}$$

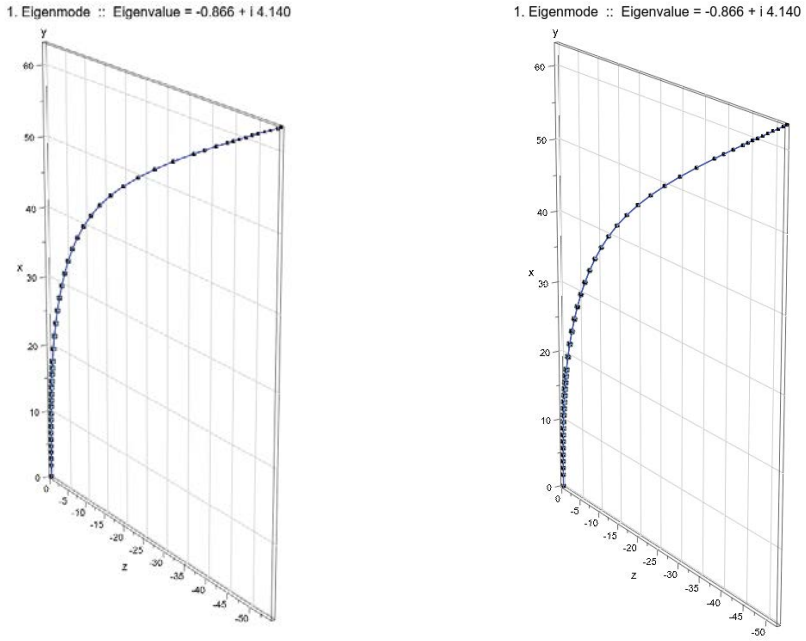

Fig. 10 Real (left) and imaginary (right) part of the 1-th complex eigenvector pair (associated eigenvalue $\lambda = -0.8664 \pm i\,4.140$)

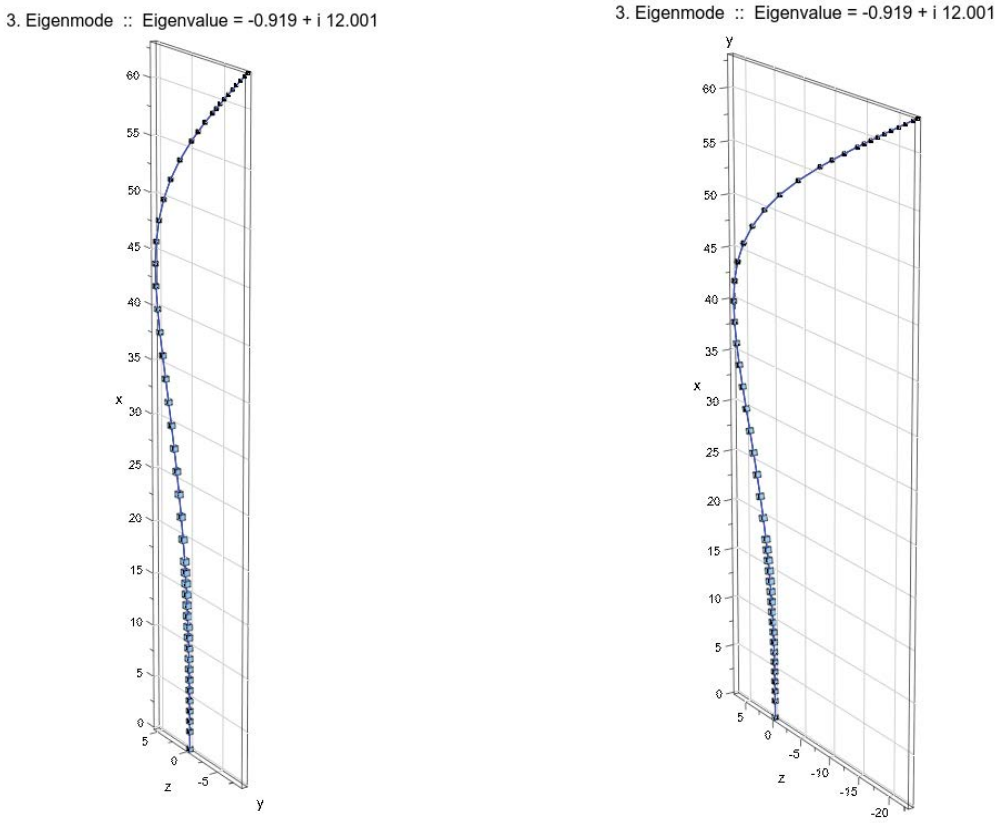

Fig. 11 Real (left) and imaginary (right) part of the 3-th complex eigenvector pair (associated eigenvalue $\lambda = -0.919 \pm i\ 12.001$)

The matrix $\boldsymbol{\Psi}^{-1}$ is calculated for the case of four involved eigenmodes according to Eq. (3.21), (3.7)-(3.9):

$$\boldsymbol{\Psi}^{-1} = \begin{bmatrix} \left(\boldsymbol{\varphi}^{(1)}\right)^{-1} & & & \\ & \left(\boldsymbol{\varphi}^{(2)}\right)^{-1} & & \\ & & \left(\boldsymbol{\varphi}^{(3)}\right)^{-1} & \\ & & & \left(\boldsymbol{\varphi}^{(4)}\right)^{-1} \end{bmatrix} =$$

$$\begin{pmatrix} 1.2302 - 0.80443\,i & 4.396 + 4.396\,i & 0 & 0 & 0 & 0 & 0 & 0 \\ 1.2302 + 0.80443\,i & 4.396 - 4.396\,i & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1.3275 - 1.2934\,i & 9.0041 + 9.0041\,i & 0 & 0 & 0 & 0 \\ 0 & 0 & 1.3275 + 1.2934\,i & 9.0041 - 9.0041\,i & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1.8648 - 1.5994\,i & 20.909 + 20.909\,i & 0 & 0 \\ 0 & 0 & 0 & 0 & 1.8648 + 1.5994\,i & 20.909 - 20.909\,i & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 2.612 - 2.3763\,i & 62.2 + 62.2\,i \\ 0 & 0 & 0 & 0 & 0 & 0 & 2.612 + 2.3763\,i & 62.2 - 62.2\,i \end{pmatrix} \tag{4.16}$$

Finally, according to Eq. (3.21) and (3.24), the (576x8) real transformation matrix **Y** is computed, see Eq. (4.17). Here are plotted the first 18 rows starting with row #289 – this part of **Y** corresponds to the $\boldsymbol{V}(t)$-vector of displacements.

$$\mathbf{Y} = \begin{pmatrix}
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0.000012 & 0 & 0 & 0 & -0.000049 \\
0 & 4.0\,10^{-6} & 0 & 0 & 0 & -0.000016 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & -5.0\,10^{-6} & 0 & 0 & 0 & 0.000019 & 0 & 0 \\
0 & 0 & 0 & 0.000014 & 0 & 0 & 0 & -0.000056 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0.00003 & 0 & 0 & 0 & -0.000119 \\
0 & 0.00001 & 0 & 0 & 0 & -0.000041 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & -7.0\,10^{-6} & 0 & 0 & 0 & 0.000029 & 0 & 0 \\
0 & 0 & 0 & 0.000021 & 0 & 0 & 0 & -0.000084 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0.000055 & 0 & 0 & 0 & -0.000217 \\
0 & 0.000019 & 0 & 0 & 0 & -0.000075 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & -0.00001 & 0 & 0 & 0 & 0.00004 & 0 & 0 \\
0 & 0 & 0 & 0.000028 & 0 & 0 & 0 & -0.000111
\end{pmatrix} \tag{4.17}$$

The time-dependent "load" vector in the final uncoupled modal equations (3.22) is calculated to be a function of the wind speed time series, see Fig. 2:

$$\begin{bmatrix} g_1(t) \\ h_1(t) \\ \cdots \\ g_4(t) \\ h_4(t) \end{bmatrix} = \mathbf{Y}^{\mathrm{T}} \cdot \left[\mathbf{p}\right] = \begin{pmatrix} 19.36\,u^2 \\ 0.1812\,u^2 \\ 1.951\,u^2 \\ 0 \\ 1.929\,u^2 \\ -12.95\,u^2 \\ 0.5554\,u^2 \\ 0 \end{pmatrix} \tag{4.18}$$

The (4x4) mass, damping and stiffness matrices of the four final uncoupled modal equations from type (3.27) are resp.

$$\begin{pmatrix} 1.0 & 0 & 0 & 0 \\ 0 & 1.0 & 0 & 0 \\ 0 & 0 & 1.0 & 0 \\ 0 & 0 & 0 & 1.0 \end{pmatrix}, \begin{pmatrix} 1.733 & 0 & 0 & 0 \\ 0 & 0.1788 & 0 & 0 \\ 0 & 0 & 1.838 & 0 \\ 0 & 0 & 0 & 2.351 \end{pmatrix}, \begin{pmatrix} 17.89 & 0 & 0 & 0 \\ 0 & 47.2 & 0 & 0 \\ 0 & 0 & 144.9 & 0 \\ 0 & 0 & 0 & 620.5 \end{pmatrix} \tag{4.19}$$

Compare the numerical evaluations (4.10), (4.11) of the final modal equations from type (2.18) to the final equations (4.19) now – evidently both modal procedures leads to the same final uncoupled modal equations. The Same applies for the "load vectors" in (4.12) resp. (4.18).

Due to the equal final modal equations, as seen above, the time responses of the modal coordinates $y_j(t), x_j(t),\ (j = 1, \ldots, 4)$ are exactly the same. Exemplarily the $y_1(t), x_1(t)$ vibrations are plotted in Fig.12. Compare to Fig. 4 to note the interchanged meaning of y_1 and x_1 in this case, as already mentioned in Sec. 3.3.

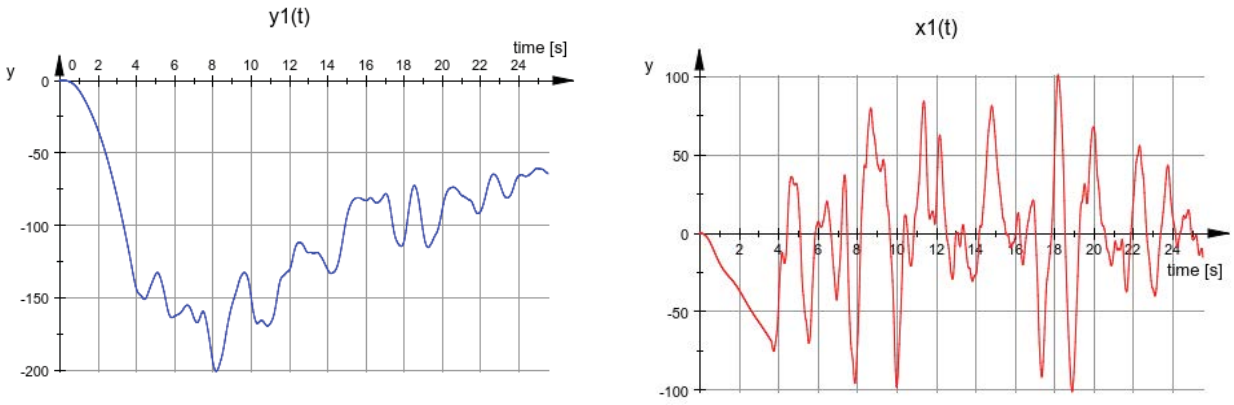

Fig. 12 Time responses of the modal coordinates $y_1(t), x_1(t)$

By a back transformation according to Eq. (3.21) the total responses $\boldsymbol{V}(t)$ is obtained. As a matter of course, all vibration plots in this case are exactly the same like in Figs. 7-9. Exemplarily the plots analogously to Figs. 7,8 is shown in Fig. 13.

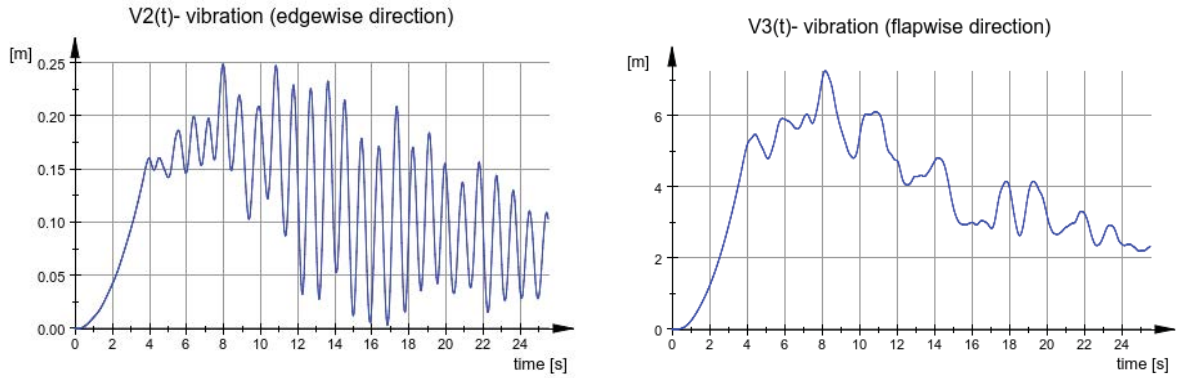

Fig. 13 Total vibrations $v_2(t), v_3(t)$ $[m]$ (y- and z-direction, see fig.1) at the rotor blade tip - node #49

For the sake of validation, the classic equations of motion (1.1) for the rotor blade model were calculated by direct time integration. The parameters used for the applied unconditionally numerically stable Newmark integration method are $\alpha = 0.5,\ \beta = 0.25$. The resulting flap- and edgewise vibrations are practically identical to the vibrations shown in Fig.13.

5 CONCLUSIONS

- The modal decomposition procedure, described briefly in Sec. 2, is well known from the literature, see [13] – [15]. Without any explanations of the notion of "phase synchronization", the presented algorithm leads, starting with a modal transformation in complex space, to an uncoupled, real-space form of modal equations.
- In the proposed modal procedure, presented in Sec. 3, the transformation matrix is assembled employing the right complex conjugate eigenvector pairs, normalized on the SDOFS level and on MDOFS level with respect to the corresponding stiffness matrices.

The real-space modal transformation matrix **Y**, Eq. (3.23), (3.24a-d), is developed by combining of two complex transformations, resulting from the eigenvalue problem of the SDOFS and the MDOFS. There are shown and discussed some advantages and differences in comparison with "phase synchronization" method, Sec. 2, which is based on the "Lancaster" state space form of the equations of motion. The proposed procedure is derived in a quite natural way, but it doesn't base on the notion of "phase synchronization". Both procedures lead in the final form to same uncoupled real-space modal equations, as shown in the numerical example in Sec.4.

- One restrictive condition has to be accounted for: both considered modal procedures implies the existence of distinct complex conjugated eigenvalues, at least for the first lowest natural frequencies.
- Application of the "phase synchronization" and the proposed method implies availability of reliable professional eigensolver software for complex eigenvalue problems. Numerical problems for both procedures in especially this first basic step are to be probably expected in real-life structural models with a high number of DOFS. Another important algorithmic aspect to be accounted for is the assumed order of the eigenvalues and eigenvectors in each complex conjugate pair, Eq. (1.6), (3.12). All complex eigenvectors in the $\boldsymbol{\Phi_G}$ -matrix should be ordered in this way, see Eq. (3.16).
- One important advantage of the classic modal decomposition of the equations of motion is retained in both considered procedures - an uncomplete modal transformation may be performed by use of a few *(k << n)* eigenmodes to get *k* uncoupled SDOFS block equations in real space. This leads with sufficient numerical accuracy to the total time response of all original *n* DOF – as shown in the numerical examples in Sec. 4, employing only the first four complex eigenvalues and associated eigenmodes.
- The presented rotor blade vibration should only be a qualitative demonstration of the numerical performance of both presented modal procedure. For any quantitative conclusions about possible numerical limitations more tests and case studies should be done in future.
- In the numerical example in Sec. 4 was applied a simple approach for the aerodynamic damping in the beam element model. It was used mainly in order to create a symmetric damping matrix on the finite element level, which leads together with the assumed stiffness proportional damping to the damping matrix incorporating non-proportional damping.
- The real-space modal transformation (3.21) could be applied for description of the elastic deformation of a rotor blade beam model, as a part of the multi-body simulation of a wind turbine. In compare to the classic modal superposition, the proposed procedure operates by double number of modal coordinates - (x_j, y_j) , assembled in the modal coordinates vector $\boldsymbol{X}$. The formulation of the integral terms of the mass matrix and the general inertia forces for the flexible rotor blade body by use of this modal transformation is an interesting topic to be investigated in further research.

Keywords: Damage identification, Historic buildings, Structural health monitoring, Automated modal identification, Control chart, Machine Learning.

Abstract. *This paper proposes a new semi-supervised two-class pattern classification method for early damage detection of structures. The proposed approach comprises five consecutive steps, including the (i) collection of data samples representing the healthy condition of the structure (training period); (ii) clustering analysis; (iii) outliers elimination; (iv) pattern recognition using local Principal Components Analysis; and (v) pattern classification through control charts. The effectiveness of the proposed approach is demonstrated through two different case studies. These include a benchmark beam simulation model, and the Consoli Palace in Gubbio (Italy). The latter has been monitored for two years using a long-term vibration-based monitoring system, and represents an extraordinary example of a stiff masonry building with complex environmental effects. Analyses and discussion are presented covering the effects of differing structural/environmental behaviour regimes, the presence of outliers in the training period, and the effectiveness of different control charts.*

1 INTRODUCTION

The heightened awareness about the importance of the conservation of heritage structures has fostered the implementation of numerous Structural Health Monitoring (SHM) systems in recent years [14, 9, 5, 10]. In particular, ambient vibration-based SHM systems are becoming particularly popular owing to their capability of performing a non-destructive assessment of the structural integrity with minimum architectural impact and without affecting the normal operating conditions of structures [2, 4, 15]. Through Automated Operational Modal Analysis (A-OMA) techniques, such systems allow the tracking of the modal features of structures and, in turn, it is possible to detect damage-induced anomalies and so enable the decision-making of condition-based rehabilitation [17, 18]. Nevertheless, the development of efficient SHM methodologies for early damage detection still remains an open and active research area.

Specifically, the SHM of masonry structures is specially challenging due to the complex dependence of their intrinsic stiffness on environmental factors (mainly temperature and humidity), often resulting in different behaviour regimes [7, 5, 10]. This is the case, for instance, of masonry structures experiencing freezing conditions during the winter, when the icing of pore water in masonry leads to a dramatic change in temperature/stiffness relationship. Such environmental effects induce both daily and seasonal fluctuations in the modal features of structures, which usually mask damage-induced anomalies. In this regard, the application of advanced statistical process control procedures becomes imperative for early damage detection [3].

In this line, this paper presents a new semi-supervised two-class pattern classification method for early damage detection of structures. The proposed approach comprises five consecutive steps, including the (i) collection of data samples representing the healthy condition of the structure (training period); (ii) clustering analysis; (iii) outliers elimination; (iv) pattern recognition using local Principal Components Analysis; and (v) pattern classification using control charts. The effectiveness of the proposed approach is evaluated through two different case studies. These include a benchmark beam structure model, and the monumental Consoli Palace in Gubbio (Italy). The palace has been continuously monitored since July 2017 with a low-cost mixed static/dynamic/environmental long-term monitoring system [10]. In this work, the monitoring data of three high-sensitivity accelerometers and two thermocouples recording ambient vibrations and environmental temperatures are exploited. On this basis, the resonant frequencies of the palace have been identified and tracked using an A-OMA technique based upon the Covariance-based Stochastic Subspace Identification method (COV-SSI). The experimentally identified resonant frequencies are selected as damage-sensitive features, and the effectiveness of the proposed damage detection approach is evaluated considering artificial damage in the shape of frequency decays. The Consoli Palace represents an exceptional example of a stiff masonry building. Due to the low excitation levels in the building, the identified resonant frequencies present an elevated number of outliers that hinder the damage detection tasks. Additionally, the complex geometry of the palace and its connection with the adjoining buildings originates the existence of highly non-linear environmental effects, making it an outstanding benchmark structure for testing the proposed damage detection approach.

2 TWO-CLASS PATTERN CLASSIFICATION METHOD FOR DAMAGE DETECTION

This paper proposes a five step pattern classification algorithm for two-class damage detection as sketched in Fig. 1. The proposed approach comprises: (I) Characterization of the healthy condition of the structure with an initial training period; (II) Clustering analysis to identify the

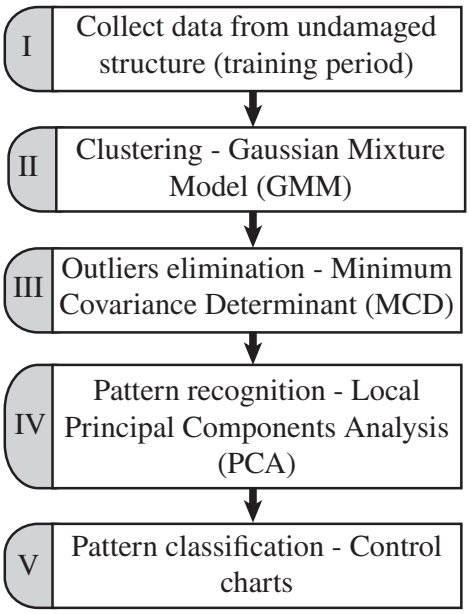

Figure 1: Flow chart of proposed two-class pattern classification algorithm for damage detection.

presence of multiple environmental regimes; (III) Outliers elimination; (IV) Pattern recognition through local PCA; and (V) Patter classification using control charts.

Let us consider that the SHM system performs an automated identification of m resonant frequencies f_i, $i = 1, \ldots, m$ as damage sensitive features. For notational convenience, let us denote the features at an instant n in vector form as $\mathbf{x}_n = \left[f_{(1,n)}, \ldots, f_{(m,n)}\right]$. We assume that the SHM system identifies a total of N sets of modal features, so the observation matrix $\mathbf{Y} \in \mathbb{R}^{N \times m}$ is constructed by collecting the features vectors by rows. In order to statistically characterize the healthy condition of the structure, a subset of tp data samples are selected as the training period. This must be long enough to cover the full range of environmental conditions (both daily and seasonal fluctuations), and typically a one-year period is assumed adequate. Note that the observation matrix $\mathbf{Y}$ represents a multivariate data set which, in principle, is composed of non-linear data.

2.1 CLUSTERING - GAUSSIAN MIXTURE MODEL

In order to take into account different environmental mechanisms, the damage sensitive features in the training period are clustered into different data sets using a GMM model. This approach assumes that the probability density function $p(\mathbf{x})$ of the data set in the training period $\mathbf{X}$ (in general, non-normally distributed) can be represented as a linear superposition of K Gaussian components as [1]:

$$p(\mathbf{x}) = \sum_{k=1}^{K} \pi_k \mathcal{N}\left(\mathbf{x} \,|\boldsymbol{\mu}_k, \boldsymbol{\Sigma}_k\right). \tag{1}$$

Each component of the mixture is defined as a Gaussian distribution $\mathcal{N}\left(\mathbf{x} \,|\boldsymbol{\mu}_k, \boldsymbol{\Sigma}_k\right)$ with mean and covariance matrix denoted by $\boldsymbol{\mu}_k$ and $\boldsymbol{\Sigma}_k$, respectively. The parameters $\boldsymbol{\pi} = [\pi_1, \ldots, \pi_K]^{\mathrm{T}}$ in Eq. (1) are called the mixing coefficients, and they range between 0 and 1 ($0 \leq \pi_k \leq 1$) and sum to one ($\sum_{k=1}^{K} \pi_k = 1$). The model parameters, $\boldsymbol{\mu}_k$,$\boldsymbol{\Sigma}_k$ and π_k, are fitted by minimizing the

log-likelihood function:

$$\ln p(\mathbf{X}\,|\boldsymbol{\pi},\boldsymbol{\mu},\boldsymbol{\Sigma}) = \sum_{n=1}^{t_p} \ln \left\{ \sum_{k=1}^{K} \pi_k \mathcal{N}\left(\mathbf{x}_n\,|\boldsymbol{\mu}_k,\boldsymbol{\Sigma}_k\right) \right\}. \tag{2}$$

The maximum likelihood solution for the parameters ($\boldsymbol{\mu}$,$\boldsymbol{\Sigma}$ and $\boldsymbol{\pi}$) is estimated using the iterative Expectation-Maximization (EM) algorithm. In the expectation (E) step, the parameters (initial guess at the beginning) are held fixed and the posterior probability of assigning $\mathbf{x}_n$ to the k's cluster is given by the so-called responsibilities $\gamma(z_{nk})$ as:

$$\gamma(z_{nk}) = \frac{\pi_k \mathcal{N}\left(\mathbf{x}_n\,|\boldsymbol{\mu}_k,\boldsymbol{\Sigma}_k\right)}{\sum_{j=1}^{K} \pi_j \mathcal{N}\left(\mathbf{x}_n\,|\boldsymbol{\mu}_j,\boldsymbol{\Sigma}_j\right)}, \tag{3}$$

where z_{nk} is an element of a K-dimensional binary random variable $\mathbf{z}$ with a 1-of-K representation. Only one element in $\mathbf{z}$ is equal to 1 and all other elements are 0.

Then, in the maximization (M) step, the parameters are re-estimated using the posterior probability calculated in the previous E step as follows:

$$\boldsymbol{\mu}_k^{new} = \frac{1}{N_k} \sum_{n=1}^{t_p} \gamma(z_{nk}) \mathbf{x}_n, \tag{4}$$

$$\boldsymbol{\Sigma}_k^{new} = \frac{1}{N_k} \sum_{n=1}^{t_p} \gamma(z_{nk}) \left(\mathbf{x}_n - \boldsymbol{\mu}_k^{new}\right) \left(\mathbf{x}_n - \boldsymbol{\mu}_k^{new}\right)^{\mathrm{T}}, \tag{5}$$

$$\pi_k^{new} = N_k/N, \quad N_k = \sum_{n=1}^{t_p} \gamma(z_{nk}). \tag{6}$$

The log-likelihood in Eq. (2) can then be evaluated. Convergence of either the parameters of the log likelihood is checked, and if the criteria are not satisfied, the process is iterated using the updated data values until the criteria are met. Once the K clusters have been defined in the training period, new data samples are assigned to the cluster with the least Mahalanobis distance.

2.2 OUTLIERS ELIMINATION

The Minimum Covariance Determinant (MCD) method [8] is used to minimize the effect of outlier measurements in the training population. The MCD method seeks a sample subset within a multivariate dataset that minimizes the covariance matrix. Specifically, the MCD method is applied in this work to every cluster identified in the training period. Consider an arbitrary cluster $\mathbf{C} = \{\mathbf{x}_1, \ldots, \mathbf{x}_d\}$ containing d samples, and let $H_1 \subset \{1, \ldots, d\}$ be an h-subset, that is $|H_1| = h$. Being $\boldsymbol{\mu}_1$ and $\boldsymbol{\Sigma}_1$ the empirical mean and covariance matrix of the data in H_1, the Mahalobis distances of all the data samples in the cluster read ($\det(\boldsymbol{\Sigma}_1) \neq 0$):

$$d_1(i) = \sqrt{\left(\mathbf{x}_i - \boldsymbol{\mu}_1\right)^{\mathrm{T}} \boldsymbol{\Sigma}_1^{-1} \left(\mathbf{x}_i - \boldsymbol{\mu}_1\right)} \quad \text{for} \quad i = 1, \ldots, d. \tag{7}$$

Now take H_2 another h-subset such that $\{d_1(i); i \in H_2\} := \{(d_1)_{1:d}, \ldots, (d_1)_{h:d}\}$ where $(d_1)_{1:d} \leq (d_1)_{2:d} \leq \ldots \leq (d_1)_{d:d}$ are the ordered distances, and compute $\boldsymbol{\mu}_2$ and $\boldsymbol{\Sigma}_2$ based on H_2. Then $\det(\boldsymbol{\Sigma}_2) \leq \det(\boldsymbol{\Sigma}_1)$ with equality if and only if $\boldsymbol{\mu}_2 = \boldsymbol{\mu}_1$ and $\boldsymbol{\Sigma}_2 = \boldsymbol{\Sigma}_1$. This process, also known as C-step, can be iteratively repeated. If $\det(\boldsymbol{\Sigma}_2) = 0$ or $\det(\boldsymbol{\Sigma}_2) = \det(\boldsymbol{\Sigma}_1)$, the

algorithm stops; otherwise, another C-step is run yielding $\det(\boldsymbol{\Sigma}_3)$, and so on. The sequence $\det(\boldsymbol{\Sigma}_1) \geq \det(\boldsymbol{\Sigma}_2) \geq \det(\boldsymbol{\Sigma}_3) \geq \ldots$ is nonnegative and hence must converge, so there must be an index s such that $\det(\boldsymbol{\Sigma}_s) = 0$ or $\det(\boldsymbol{\Sigma}_s) = \det(\boldsymbol{\Sigma}_{s-1})$. In this work, the fast implementation of the MCD method proposed by Rousseeuw and Driessen [16] has been implemented. The dimension h of the subsets has been selected as $0.8d$. Once the algorithm converges, a certain percentage of the samples with the largest Mahalanobis distances with respect to the converged sample subset are considered as outliers and eliminated.

2.3 PRINCIPAL COMPONENTS ANALYSIS

Once the detected outliers have been eliminated from the clusters, pattern recognition using PCA is conducted for every cluster in the training period. Principal Component Analysis consists of a double change of coordinates, where the original data are first projected in the vectorial space generated by the principal components (PCs) and then remapped back to the original space by retaining only some of the PCs. Let us denote the matrix of observations $\mathbf{X}_{c_k} \in \mathbb{R}^{n_{c_k} \times m}$ in an arbitrary cluster c_k ($k = 1, \ldots, K$) of size n_{c_k} and $\mathbf{X}^*_{c_k} \in \mathbb{R}^{n_{c_k} \times m}$ a matrix whose columns are the centred variables $\mathbf{x}^*_j$ (i.e. $x^*_{ij} = x_{ij} - \overline{x}_j$, where $\overline{x}_j$ denotes the mean value of the observations on variable j). Then, the eigendecomposition of the covariance matrix $\boldsymbol{\Sigma}$ reads:

$$\boldsymbol{\Sigma} = \left(\mathbf{X}^*_{c_k}\right)^{\mathrm{T}} \mathbf{X}^*_{c_k} = \mathbf{U}_{c_k} \mathbf{S}^2 \mathbf{U}^{\mathrm{T}}_{c_k}, \tag{8}$$

where $\mathbf{U}_{c_k} \in \mathbb{R}^{n_{c_k} \times n_{c_k}}$ is the so-called loading matrix. The eigenvalues of the covariance matrix contained in the diagonal matrix $\mathbf{S}^2$ represent the variance contributions of each PC. Assuming that the PCs providing the largest contributions to the variance represent the effects of environmental and operational factors, it is possible to find an approximation $\widehat{\mathbf{X}}^*_{c_k}$ isolating such factors through dimensionality reduction. This can be done by retaining only the first l columns of matrix $\mathbf{U}_{c_k}$ in Eq. (8) into a rectangular reduced loading matrix, $\widehat{\mathbf{U}}_{c_k} \in \mathbb{R}^{l \times m}$. Hence, matrix $\widehat{\mathbf{X}}^*_{c_k}$ is estimated as:

$$\widehat{\mathbf{X}}^*_{c_k} = \mathbf{X}^*_{c_k} \widehat{\mathbf{U}}_{c_k} \widehat{\mathbf{U}}^{\mathrm{T}}_{c_k}, \tag{9}$$

which represents the backward transformation of the original observations in $\mathbf{X}^*_{c_k}$ from a reduced space of the l PCs to the original one. Since the transformation in Eq. (9) provides a representation of the environmental/operational effects, matrix $\widehat{\mathbf{U}}_{c_k}$ allows to predict the resonant frequencies of the structure beyond the training period.

2.4 CONTROL CHARTS

Once the transformation matrices $\widehat{\mathbf{U}}_{c_k}$ are obtained for all the identified clusters c_k ($k = 1, \ldots, K$) in the training period, it is possible to compute a matrix of predicted resonant frequencies $\widehat{\mathbf{Y}} \in \mathbb{R}^{N \times m}$ throughout all the monitoring period. Since the statistical models used to construct $\widehat{\mathbf{Y}}$ are fitted using the training period representing a baseline in-control population where the structure is assumed to remain healthy, the appearance of damage can be inferred from the detection of anomalies in the residual error matrix $\mathbf{E} \in \mathbb{R}^{N \times m}$ computed as:

$$\mathbf{E} = \mathbf{Y} - \widehat{\mathbf{Y}}. \tag{10}$$

Assuming that $\widehat{\mathbf{Y}}$ reproduces the part of the variance in the resonant frequencies related to environmental/operational changes, $\mathbf{E}$ only contains the residual variance stemming from iden-

tification errors, un-modelled environmental/operational effects, and structural defects. Therefore, the presence of damage in the shape of anomalies in the time series of $\mathbf{E}$ can be revealed through control charts. These furnish time series of certain statistical distances between the distribution of the residuals contained in $\mathbf{E}$ and the in-control data base. Specifically, two different control charts are used in this work, including the Hotelling (T^2) and Multivariate Exponentially Weighted Moving Average (MEWMA) control charts. The statistical distances handled by these control charts are positive by definition, so an in-control region can be specified by an interval [0,*UCL*]. The upper control limit (*UCL*) can be estimated as the statistical distance attaining a certain confidence (exceeding) level α in the training database. In this light, the appearance of out-of-control processes violating the in-control region may indicate the appearance of damage.

- *Hotelling's* T^2: The Hotelling's T^2 control chart [6] is defined as:

$$T_i^2 = r\left(\overline{\mathbf{E}} - \overline{\overline{\mathbf{E}}}\right)^{\mathrm{T}} \boldsymbol{\Sigma}_0^{-1}\left(\overline{\mathbf{E}} - \overline{\overline{\mathbf{E}}}\right),\ i = 1, 2, \ldots, N/r, \tag{11}$$

  where r is an integer parameter referred to as subgroup size, $\overline{\mathbf{E}}$ is the mean of the residuals in the subgroup of the last r observations, while $\overline{\overline{\mathbf{E}}}$ and $\boldsymbol{\Sigma}_0$ are the mean values and the covariance matrix of the residuals statistically estimated in the training period.

- *Multivariate Exponentially Weighted Moving Average (MEWMA)*: Originally proposed by Lowry *et al*. [12], the MEWMA control chart represents an intermediate solution between the T^2 and the MCUSUM control charts. Alike the MCUSUM control chart, the MEWMA method also accounts for the information from past observations, although it gives weights decreasing in a geometric progression from the most recent observation to the first one. The statistical distance used in the MEWMA control chart reads:

$$MEWMA_i = \left(r\,\mathbf{z}_i^{\mathrm{T}}\boldsymbol{\Sigma}_{z_i}^{-1}\mathbf{z}_i\right)^{1/2},\ i = 1, 2, \ldots, N/r, \tag{12}$$

  with

$$\begin{aligned} \mathbf{z}_i &= \lambda\left(\overline{\mathbf{E}} - \overline{\overline{\mathbf{E}}}\right) + (1-\lambda)\mathbf{z}_{i-1}, \\ \boldsymbol{\Sigma}_{z_i} &= \lambda\frac{1-(1-\lambda)^{2i}}{2-\lambda}\boldsymbol{\Sigma}_0, \end{aligned} \tag{13}$$

  where λ is a smoothing constant with $0 \leq \lambda \leq 1$. Practically, the most often used value of λ is 0.1.

3 CASE STUDIES

To illustrate the capabilities of the proposed approach for early-damage detection, two case studies are examined in this section. The first one is a numerical beam model which is subjected to changing temperature conditions and varying mass distribution. The second one is a real-life case study, the Consoli Palace in Gubbio (Italy), which was monitored for almost two years.

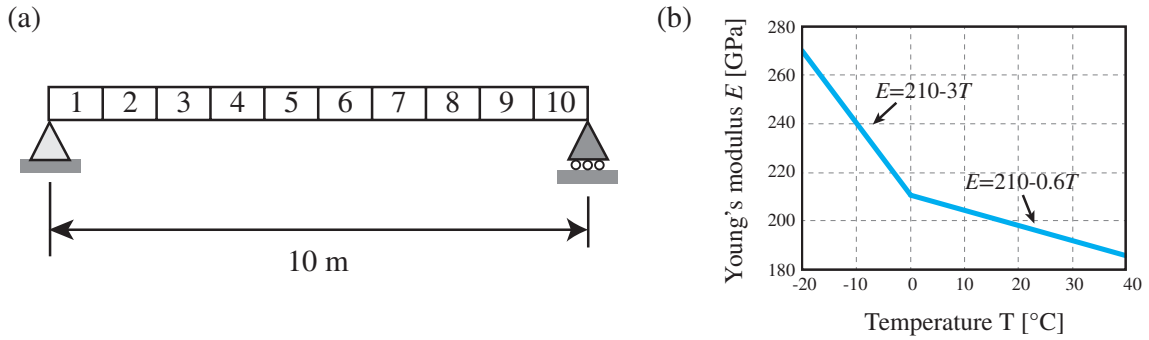

Figure 2: Beam structure model (a) and variations of Young's modulus with temperature for the beam structure model (b).

3.1 Beam structure model

The first case study is the benchmark beam model previously reported in references [11, 20] and sketched in Fig. 2 (a). The model consists of a 10 m long simply supported beam defined by ten 2-nodes beam-bending elements of 1 m each. The beam has constant cross-section, inertia and mass density of 0.08 m^2, 0.0006 m^4, and 7850 kg/m^3, respectively. The Young's modulus of the beam is assumed to be temperature dependent according to the bi-linear relationship shown in Fig. 2 (b).

The first four natural frequencies of the beam are used as damage sensitive features. In particular, seven consecutive set ups are analysed as summarised in Table 1. The training period is defined by the first two data sets (UC-1 and UC-2). The first one includes 800 and 420 observations with temperatures between 0°C and 40°C and between -20°C and 0°C, respectively. In addition, a random variation of $\pm 10\%$ in the mass density of the beam is also considered in order to include some randomness in the observations. The second data set has 400 observations for temperatures between 0°C and 40°C and 210 between -20°C and 0°C. In this case, a larger variation in density of $\pm 25\%$ is considered as a way of simulating the presence of outlier measurements. Afterwards, five damage cases with increasing severities (25%, 30%, 35%, 40% and 45%), labelled from DC-1 to DC-5 in Table 1, are considered. Specifically, damages are simulated through reductions in the bending stiffness of the 4th element. Data from each damaged case are obtained considering 200 samples with temperatures ranging between 0°C and 40°C, and 100 samples between -20°C and 0°C. Moreover, each element is assumed to have a $\pm 10\%$ random variation in density.

	UC-1		UC-2		DC-1		DC-2		DC-3		DC-4		DC-5	
Samples	800	420	400	210	200	100	200	100	200	100	200	100	200	100
ΔT^a	T_1	T_2	T_1	T_2	T_1	T_2	T_1	T_2	T_1	T_2	T_1	T_2	T_1	T_2
$\Delta\rho^b$ [±%]	10	10	25	25	10	10	10	10	10	10	10	10	10	10
Damage^c [%]	0	0	0	0	25	25	30	30	35	35	40	40	45	45

[a] T_1: [0°C,40°C], T_2: [-20°C,0°C].
[b] *$\Delta\rho$ denotes the relative variation of the mass density of the beam.*
[c] *Damage severity defined as a reduction of the bending stiffness of the 4th element.*

Table 1: Data samples considered in the beam structure model.

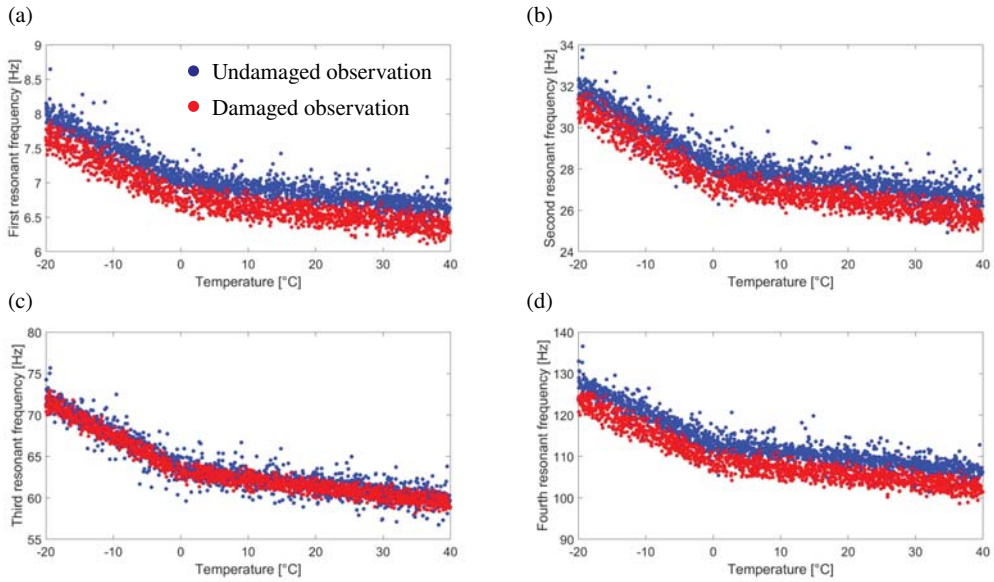

Figure 3: Plot of temperature versus (a) first natural frequency, (b) second natural frequency, (c) third natural frequency and (d) fourth natural frequency of the beam structure model.

of beam structure model. It is interesting to note that the damaged and undamaged observations intermix and can be hardly distinguished from one another in the third resonant frequency. The third mode is relatively insensitive to the presence of damage since the fourth element is located near a node of this mode. In the rest of the modes, some of the damaged observations cluster together with the undamaged cases, specially in the space containing the outlier measurements. Therefore, these outliers need to be identified and removed from the database before applying damage detection methods. To do so, the proposed approach sketched in Fig. 1 is applied herein. Firstly, the GMM model is applied to differentiate the two different environmental regimes in the time series of resonant frequencies. The result, shown in Fig. 4, shows that the GMM model can accurately separate between resonant frequencies obtained with temperatures ranging between -20°C and 0°C (Cold observations) and between 0°C and 40°C (Hot observations). Afterwards, the outliers detection algorithm previously overviewed in Section 2.2 can be applied independently to each cluster. In particular, a percentage of 30% of the data samples with the largest Mahalanobis distances according to Eq. (7) are considered as outliers. The result of the outliers elimination algorithm applied to the training period (UC-1 and UC-2) is shown in Fig. 5. It can be seen that most of the detected outliers surround the clean measurements.

Then, a PCA model can be fitted using the clean training database. In this case, one single PC sufficed to explain more than 95% of the variance of the resonant frequencies in the two clusters. The comparison between the predictions of the resonant frequencies by the PCA model and the numerical ones is presented in Fig. 6. The low scatter of the points around the diagonal line corroborates that the PCA model is formed with accuracy. This model can now be used to detect the appearance of damage beyond the training period according to the approach previously presented in Section 2.3. Specifically, Fig. 7 shows the Hotelling's control charts obtained without applying (a) and applying (b) the outliers elimination algorithm. The effect of the presence of outliers in the training period is clearly exemplified in Fig. 7 (a). In this graph, the presence of outliers between the observation numbers 1020 and 1830 lead to a large UCL (confidence level 95%) and corrupts the estimation of the mean vector $\overline{\overline{\mathbf{E}}}$ and covariance matrix

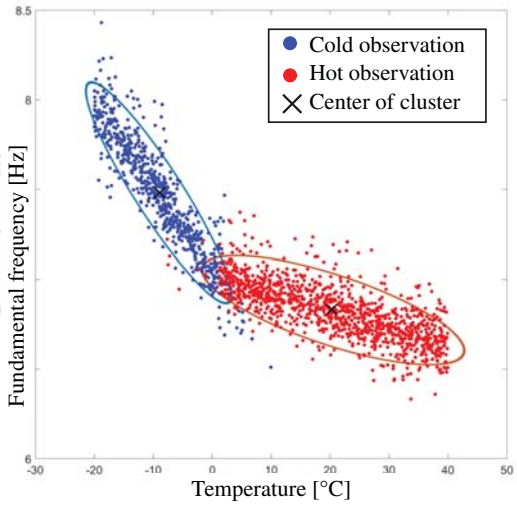

Figure 4: Cluster of the first resonant frequency with temperature of the beam structure model using GMM.

of the residuals $\boldsymbol{\Sigma}_0$ in the training period. This hinders the detection of mild damage severities, not being possible the identification until the damage severity of 35%-40%. Conversely, the control chart in 7 (b) shows that the outliers elimination algorithm effectively eliminates most of the outliers in the observation numbers between 1020 and 1830. This leads to a considerably smaller UCL and better estimation of $\overline{\overline{\mathbf{E}}}$ and $\boldsymbol{\Sigma}_0$. This allows to accurately detect all the damaged cases.

3.2 Consoli Palace

The Consoli Palace (Fig. 8 (a)), located in the city of Gubbio in Italy, was erected between 1332 and 1349 and currently hosts the Civic Museum of Gubbio. The palace is 60 m high, including a bell-tower and a panoramic loggia, and has a rectangular plan of about 40×20 m. Within the framework of the Horizon 2020 European HERACLES project (2016-2018, heracles-project.eu), a permanent SHM system has been installed in the Consoli Palace since July 2017. Specifically, three PCB 393B12 accelerometers (A1, A2 and A3) were deployed on the roof level of the palace, as well as two K-type thermocouples to monitor the environmental temperature. The sensors are connected to a NI CompactDAQ-9132 data acquisition system with NI 9234 and NI 9219 acquisition modules for accelerations and temperatures, respectively. Ambient accelerations and temperatures were respectively sampled at 100 Hz and 0.1 Hz and stored in consecutive separate files containing 30 min-long recordings. The data files were sent online through the Internet to a remove server, where an in-house code for the management of integrated SHM systems called MOSS was used for automated SHM of the palace.

Figure 9 shows the time series of identified resonant frequencies using an automated version of the SSI-COV. Specifically, five modes corresponding to Fx1 (first global bending mode in the $x-$direction), Fy1 (first global bending mode in the $y-$direction), L1 (first order local mode related to the interaction between the palace and the bell-tower), T1 (global torsional mode), and L3 (third order local mode) were tracked in the Consoli Palace. For more specific information on the adopted A-OMA technique and identification results of the Consoli Palace, readers may

refer to references [13, 19, 10]. It is interesting to note that local sudden increases in the resonant frequencies were found during the time period from February 25$^{\text{th}}$ to March 1$^{\text{st}}$ 2017. Freezing air temperatures were registered during these days, thereby such increases are conceivably due to the formation of ice in the micro porosity of the mortar joints and the consequent stiffening effect.

Figure 10 plots the fundamental frequency versus environmental temperature throughout the training period of one year. In this figure, the presence of freezing conditions is evident in the shape of hasty frequency increases. Moreover, it is noted that the frequency-temperature relationship is not linear, but describes a non-linear behaviour with certain hysteresis. Such a behaviour may be due to the intricate geometry and distribution of volumes of the palace, which presumably originate the presence of complex temperature/humidity gradients throughout the building. In this case, the use of clustering approaches for the discrimination of different environmental regimes becomes imperatives. Specifically, two different GMM models have been investigated, one using 5 clusters in Fig. 10 (a) and a second one only using 2 clusters in Fig. 10 (b). It is noted that the database corresponding to the frequencies under freezing conditions is well captured by both modes. Additionally, it is interesting to note that the GMM model with the largest number of clusters differentiate four clusters in the frequency-temperature hysteresis cycles. Two clusters (cyan and blue) collect the data samples with minimum/maximum temperature values, while two other clusters (green and red) separate the two branches closing the hysteresis cycles. This fact may indicate the existence of distinct cooling and heating mechanisms.

Once the tracked resonant frequencies have been classified into clusters, the outliers elimination algorithm is applied to the database of the training period. Specifically, a percentage of 5% of the data samples with the largest Mahalanobis distances have been eliminated. Additionally, since freezing conditions are only observed in a poorly populated cluster, all the samples corresponding to this cluster have been dismissed. The resulting clean training population has been used to construct the statistical models and so eliminate the effects of environmental factors. Specifically, the GMM model in Fig. 10 (a) has been used to build a four-member PCA model. In all the the sub-models, only 2 PCs have been retained since they sufficed to explain more than

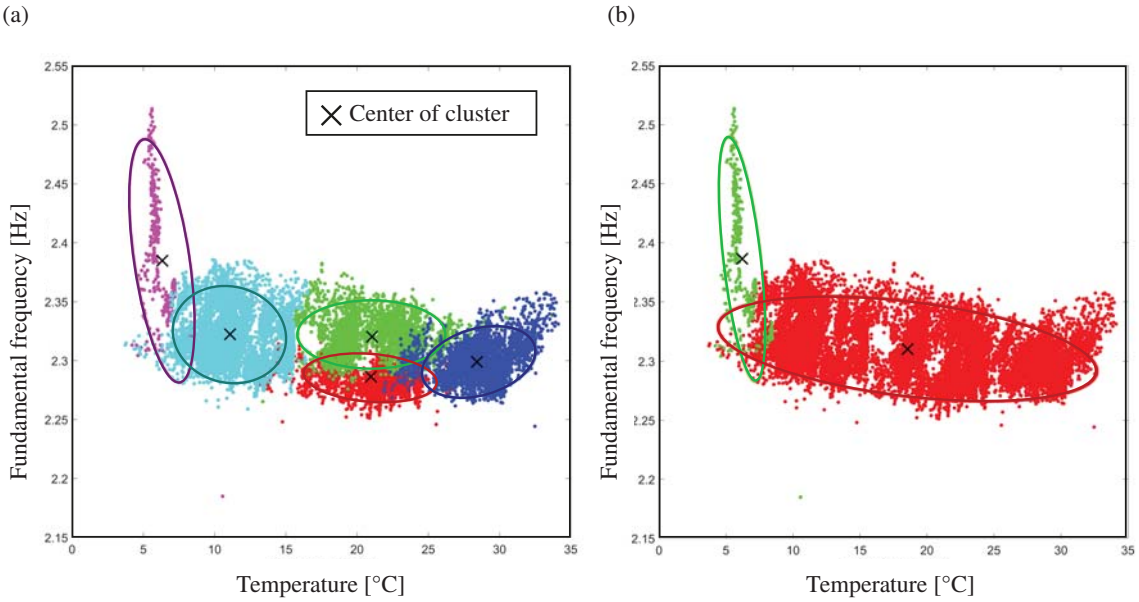

Figure 10: Clustering results of the resonant frequencies of the Consoli Palace using the GMM model considering five clusters (a) and two clusters (b).

95% of the variance of the resonant frequencies of the clusters. On the other hand, for comparison purposes, the GMM model in Fig. 10 (b) has been used to construct an AutoAssociative Neural Network (AANN) [3]. This model is also known as non-linear PCA, and its architecture consists of three hidden layers: mapping, bottleneck, and de-mapping. In this particular work, the mapping, bottleneck, and de-mapping layers have been defined with 5, 3, and 5 neurons, respectively. Hyperbolic tangent sigmoid transfer functions have been selected, and the AANN has been trained using the Levenberg-Marquardt back-propagation method. AANNs have been reported to outperform standard PCA models when dealing with non-linear correlations, so their ability to reproduce the non-linear behaviour observed in Fig. 10 is tested herein by considering the two-cluster GMM model in Fig. 10 (b).

Figures 11 and 12 present the control charts obtained using the PCA and the AANN models, respectively. In these figures, two different cases are analysed, namely the experimentally identified resonant frequencies (undamaged) and a test case including artificial damage. Specifically, the remaining monitoring time after the training period has been divided into three segments, and frequency decays have been applied to the fundamental frequency in the last two segments. The artificial frequency decays have been selected as 0.4% (mild) and 1% (moderate). Additionally, the results obtained using the Hotelling and the MEWMA control charts are also reported. It is noted in all the undamaged cases using the Hotelling's control chart that, although the UCL has been estimated for a confidence level of 95% (5% of outliers), the percentage of outliers is consistently greater than 10% beyond the training period. This fact may indicate limitations of the regression models, frequency tracking errors, or an insufficient training period. Moreover, it is also noticeable that the MEWMA control chart is more sensitive to shifts in the mean values of residuals. Let us focus first on the results obtained with the PCA model in Fig. 11. It is observed that the percentage of outliers in the damaged sections of the Hotelling's control chart goes from 10% and 15.6% (undamaged) to 16% ($\Delta Fx1 = -0.4\%$) and 41.3% ($\Delta Fx1 = -1.0\%$). That is to say, frequency decays of $\Delta Fx1 = -0.4\%$ and $\Delta Fx1 = -1.0\%$ lead to increases in the number of out-of-control samples of 16.0% and 164.74%, respectively. On the other hand, the number of outliers in the damaged sections of the MEWMA control chart

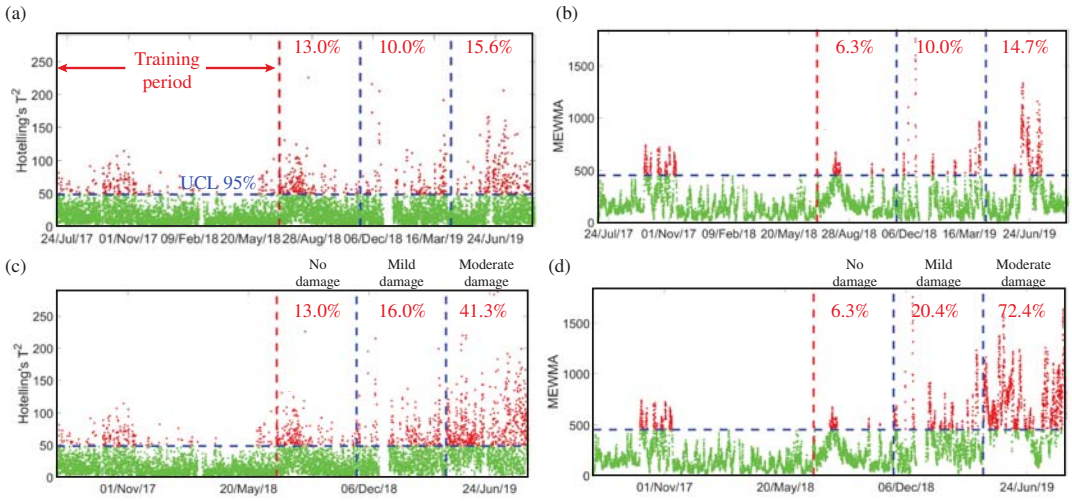

Figure 11: Control charts of the undamaged resonant frequencies of the Consoli Palace (a,b) and considering artificial damages (c,d) using the PCA regression model. The results are obtained using the Hotelling (a,c) and the MEWMA (b,d) control charts ($r = 4$).

goes from 10.0% and 14.7% to 20.4% ($\Delta Fx1 = -0.4\%$) and 72.4% ($\Delta Fx1 = -1.0\%$), that is increases of 104% and 392.517%, respectively. With regard to the results obtained using the AANN model in Fig. 12, it is observed that the number of outliers in the undamaged cases is in general larger that those obtained by the PCA model. This fact may indicate that, despite the superior capability of the AANN model to reproduce non-linear correlations, the consideration of one single cluster for non-freezing conditions may be insufficient. Furthermore, the incorporation of artificial damage in this case leads to increases of -1.89% ($\Delta Fx1 = -0.4\%$) and 219.11% ($\Delta Fx1 = -1.0\%$) in the Hotelling's control chart, and 15.33% ($\Delta Fx1 = -0.4\%$) and 184.43% ($\Delta Fx1 = -1.0\%$) in the MEWMA control chart. Note that even a decrease in the number of outliers is found in the Hotelling's control chart for a mild damage severity. Therefore, it can be concluded that this second model cannot be used to detect early-stage faults, and a larger number of clusters would be necessary to improve its efficiency.

4 CONCLUSIONS

This paper has presented a new semi-supervised two-class pattern classification method for early damage detection of structures. The proposed approach comprises five consecutive steps, including the (i) collection of data samples forming the training period; (ii) clustering analysis using the GMM method; (iii) outliers elimination using the MCD method; (iv) pattern recognition using local Principal Components Analysis; and (v) pattern classification using Hotelling and MEWMA control charts. The effectiveness of the proposed approach has been demonstrated through two different case studies, including a benchmark numerical beam structure and the Consoli Palace in Gubbio (Italy). The presented results and discussion have demonstrated the importance of outliers elimination for the correct statistical analysis of the training population and the construction of statistical models for the elimination of environmental effects. The complex relationships between the resonant frequencies and environmental temperature in the Consoli Palace have highlighted the importance of performing clustering analysis, so that local statistical models can be constructed for the different structural/environmental behaviour regimes.

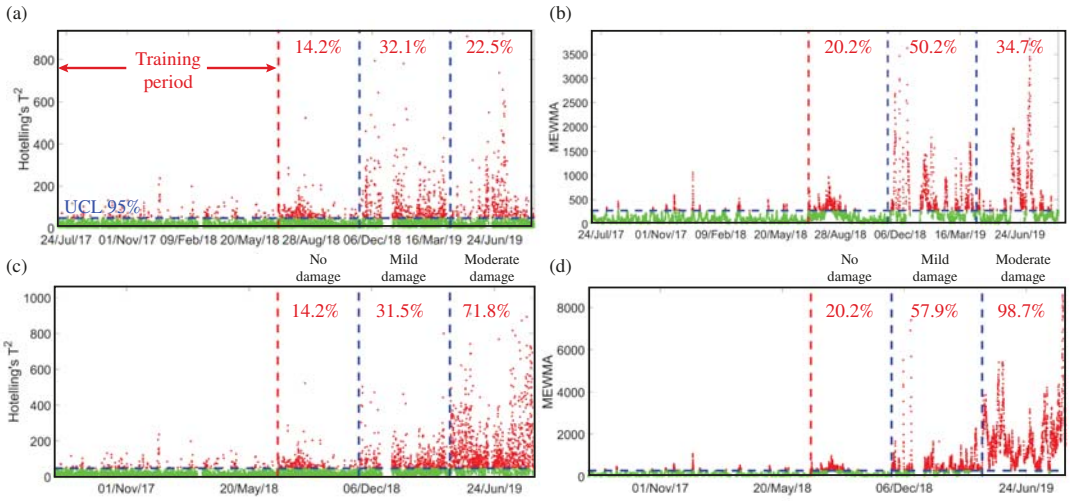

Figure 12: Control charts of the undamaged resonant frequencies of the Consoli Palace (a,b) and considering artificial damages (c,d) using the ANN regression model. The results are obtained using the Hotelling (a,c) and the MEWMA (b,d) control charts ($r = 4$).

Abstract. *The Peridynamic (PD) theory is a modern nonlocal (nonlinear, elastic /inelastic, without/with memory) theory able to deal with long-range forces and discontinuity in materials. For this reason the theory is suitable for the monitoring of masonry structures. Starting from a special case of PD formulation, named Bond-Based Peridynamic (BBPD), a feature obtained by the idealization of real systems with BBPD is used for SHM purposes: the bond elastic constant parameter. To characterize the damage (i.e. permanent deterioration of material and/or geometric properties of the systems) occurring in systems idealized with PD models, a joint time-frequency direct estimate of the parameter values is performed using a Short Time Fourier Transform (STFF) of the systems response and the input acceleration at the base of the systems. The method is applied numerically and the effect of noise in the time-frequency evaluation of the parameter values is analyzed. The study concludes that PD can provides simply and strong information on the health of simulated systems, allowing at the same time an easy and scalable parametrization of civil, especially masonry, structures, while the bond elastic constant parameter can be used for the damage characterization, i.e. to detect, quantify and localize the damage in a generic system.*

1 INTRODUCTION

A modern nonlocal theory of continuum established in early 2000 by Stewart Silling [1], [2] and Silling et al. [3], named *Peridynamic* (PD), is recently attracting attention in the field of computational mechanics. The theory replaces the partial differential equations of the classical continuum theory with integral, spatial, equations. This allows to easily overcome problems related to the representation of discontinuities in the matter, which can rise during damage (e.g. cracks), where the differential formulations are not defined. A comprehensive literature review of Peridynamic applications and uses can be found in [4]. Basically, PD theory found its principle in the forces-interaction (*bonds*) of points. The matter is divided in infinitesimal portions characterized by their mass and volume. Each point *k* is then supposed to interact with its neighbours inside a region. The collection of all the points inside this region is named *family* of *k*. The family of *k* is in turn characterized by the *horizon*, i.e. the maximum distance for which the interaction between *k* and the other points of a body occurs. The horizon define the locality of the behaviour of a system; the smaller the horizon the more local the behaviour will be. For further insight on PD theory and its fundamental literature one can refer to the book of Madenci and Oterkus [5].

Despite the huge amount of literature on PD theory and its applications, and the emerging literature on damage simulation in PD, studies on the use of PD theory as a paradigm of SHM are still missing. In particular an interesting field of research in this perspective is the identification of PD model parameters for the damage detection of structural systems, in support to the SHM of the built environment. In this direction, an interesting reference work is the study of Ibrahim [6] on fracture mechanics, which assessed the recent advances of Structural Life Assessment (SLA) and explained the differences between SLA and SHM in PD [4].

On this perspective, the equations of motion written with a special case of PD formulation, the Bond-Based PD (BBPD) [1], reveal a new feature that can be used as control parameter in the monitoring of civil structures. The feature can be extracted thanks to the PD integral equations of motion, which directly relate the internal material state (e.g. internal force field, etc.), with the structural response (e.g. displacements, etc.). This feature is called *bond elastic constant*, and its value should decrease with damage.

In the paper, the method for a direct time-frequency estimate [7], [8], [9] of the values of the bond elastic constant over the joint Time-Frequency (TF) domain is proposed [10] for a single bond, using time-history variables (e.g. displacements, accelerations, etc.) (see Section 2). The method is then demonstrated in Section 3 with numerical simulations on a case study: a single bond is here used to monitor the health of an idealized Single Degree of Freedom (SDOF) system connected to the ground. Conclusions are finally drawn in Section 4.

2 DIRECT TIME-FREQUENCY ESTIMATE OF BOND CONSTANT

The linearized micro-linear viscoelastic BBPD equation of motion can be written in standard form as (bold is herein used for vectors, bold capital for matrices and italic for scalars):

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{C}\dot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) = \mathbf{z}(t)$$

$$\mathbf{M} = \begin{bmatrix} \mathbf{M}_k & \mathbf{O} & \cdots \\ \mathbf{O} & \ddots & \cdots \\ \vdots & \vdots & \ddots \end{bmatrix}; \ \mathbf{C} = \begin{bmatrix} \sum_{\substack{j=1 \\ j\neq k}}^{K} \mathbf{C}_{kj} & -\mathbf{C}_{kj} & \cdots \\ -\mathbf{C}_{kj} & \ddots & \cdots \\ \vdots & \vdots & \ddots \end{bmatrix}; \ \mathbf{K} = \begin{bmatrix} \sum_{\substack{j=1 \\ j\neq k}}^{K} \mathbf{K}_{kj} & -\mathbf{K}_{kj} & \cdots \\ -\mathbf{K}_{kj} & \ddots & \cdots \\ \vdots & \vdots & \ddots \end{bmatrix} \tag{1}$$

where:

$$\begin{gathered}\mathbf{M}_k = m_k \mathbf{I}_3 \\ \mathbf{C}_{kj} = \nu_{kj} \mathbf{K}_{kj} \\ \mathbf{K}_{kj} = c_{kj} V_j V_k \boldsymbol{\Xi}_{kj} \\ \boldsymbol{\Xi}_{kj} = \frac{\boldsymbol{\xi}_{kj} \left(\boldsymbol{\xi}_{kj}{}^{\mathrm{T}}\right)}{\left\|\boldsymbol{\xi}_{kj}\right\|^3} \\ c_{kj} = \begin{cases} c_{kj} \text{ if } \left\|\boldsymbol{\xi}_{kj}\right\| \leq h \\ 0 \text{ if } \left\|\boldsymbol{\xi}_{kj}\right\| > h \end{cases} \\ \boldsymbol{\xi}_{kj} = \mathbf{x}_j - \mathbf{x}_k \end{gathered} \tag{2}$$

In equations (1) and (2) $\mathbf{x}_k = (x_{k,X}, x_{k,Y}, x_{k,Z})^{\mathrm{T}}$ are the coordinates X, Y, Z of point k, c_{kj} is called bond elastic constant, and h is the horizon. V_j and V_k are the volumes associated to the points j and k respectively while ν_{kj} is a bond damping constant; m_k is the mass associated to the point k, $\mathbf{I}_3$ is a 3x3 identity matrix and $\mathbf{O}$ is a 3x3 zero matrix. K is the number of points used to discretize the system. Finally, $\mathbf{u}(t)$ and $\mathbf{z}(t)$ denote the displacement vector and the external force vector respectively, being t the time variable.

The linearized equations of motions can be written in expanded form for each point k as:

$$\begin{gathered}\sum_{\substack{j=1 \\ j \neq k}}^{K} \left[c_{kj} \left(\frac{V_j V_k}{m_k} \frac{\left(\boldsymbol{\xi}_{kj} \left(\boldsymbol{\xi}_{kj}{}^{\mathrm{T}}\right)\right)}{\left\|\boldsymbol{\xi}_{kj}\right\|^3} \boldsymbol{\eta}_{kj} + \nu_{kj} \frac{V_j V_k}{m_k} \frac{\left(\boldsymbol{\xi}_{kj} \left(\boldsymbol{\xi}_{kj}{}^{\mathrm{T}}\right)\right)}{\left\|\boldsymbol{\xi}_{kj}\right\|^3} \dot{\boldsymbol{\eta}}_{kj} \right) \right] = \mathbf{n}_{k,e}(t) \\ \mathbf{n}_{k,e}(t) = -\mathbf{a}_k(t) + \ddot{\mathbf{u}}_k(t) \\ \boldsymbol{\eta}_{kj} = \mathbf{u}_j(t) - \mathbf{u}_k(t) \end{gathered} \tag{3}$$

where $\mathbf{u}_j(t)$ and $\mathbf{u}_k(t)$ are the coordinates X, Y, Z of displacement at point j and k, while $\mathbf{a}_k(t)$ are the coordinates X, Y, Z of the external acceleration at point k. If we write the equations (3) for two points (the first representing the ground and the second representing a SDOF) relativized with respect the response of the first point, we have:

$$c_{21} \left(\frac{V_1 V_2}{m_2} \frac{\left(\boldsymbol{\xi}_{21} \left(\boldsymbol{\xi}_{21}{}^{\mathrm{T}}\right)\right)}{\|\boldsymbol{\xi}_{21}\|^3} \boldsymbol{\eta}_{21} + \nu_{21} \frac{V_1 V_2}{m_2} \frac{\left(\boldsymbol{\xi}_{21} \left(\boldsymbol{\xi}_{21}{}^{\mathrm{T}}\right)\right)}{\|\boldsymbol{\xi}_{21}\|^3} \dot{\boldsymbol{\eta}}_{21} \right) = -\ddot{\mathbf{u}}_1(t) + \ddot{\mathbf{u}}_2(t) \tag{4}$$

In the assumption of all the geometrical quantities known and supposing to know the mass and damping term, we can estimate the time-frequency values of the bond elastic constant as:

$$\begin{gathered} c_{21,d}(f,t) = \frac{\mathrm{T}_{Re}\left(n_{21,d}(t)\right) \mathrm{T}_{Re}\left(n_{2,e,d}(t)\right) + \mathrm{T}_{Im}\left(n_{21,d}(t)\right) \mathrm{T}_{Im}\left(n_{2,e,d}(t)\right)}{\mathrm{T}_{Re}\left(n_{21,d}(t)\right)^2 + \mathrm{T}_{Im}\left(n_{21,d}(t)\right)^2} \\ \mathbf{n}_{21}(t) = \frac{V_1 V_2}{m_2} \frac{\left(\boldsymbol{\xi}_{21} \left(\boldsymbol{\xi}_{21}{}^{\mathrm{T}}\right)\right)}{\|\boldsymbol{\xi}_{21}\|^3} \boldsymbol{\eta}_{21} + \nu_{21} \frac{V_1 V_2}{m_2} \frac{\left(\boldsymbol{\xi}_{21} \left(\boldsymbol{\xi}_{21}{}^{\mathrm{T}}\right)\right)}{\|\boldsymbol{\xi}_{21}\|^3} \dot{\boldsymbol{\eta}}_{21} \\ \mathbf{n}_{2,e}(t) = -\ddot{\mathbf{u}}_1(t) + \ddot{\mathbf{u}}_2(t) \end{gathered} \tag{5}$$

where $c_{21,d}(f,t)$ is the time-frequency estimate of the bond elastic constant obtained with the observations along the direction d (i.e. X, Y, or Z) and the real and imaginary parts of the assumed linear Time-frequency Distribution (TFD), $T_{Re}()$ and $T_{Im}()$, respectively.

3 NUMERICAL APPLICATION

In order to study the effect of noise on the identification of the bond elastic constant, this section demonstrates the identification procedure reported in Section 2 applied on signals corrupted by adding to the original signals, the 7% of uncorrelated random time-histories extracted from Gaussian distributions having the same variance of the uncorrupted signals. The east-west record of the Loma-Prieta earthquake of the October 17, 1989 in the Santa Cruz Mountains (https://it.mathworks.com/help/matlab/matlab_prog/loma-prieta-earthquake.html, sampled at 200 Hz, has been used as input acceleration applied to the assumed SDOF, which was simulated numerically in this section. For the simulation, the following values were assumed:

- $\mathbf{x}_1=(0,0,0)^T$ m;
- $\mathbf{x}_2=(1,0,0)^T$ m;
- $V_1=V_2=1$ m^3;
- $m_2=1$ kg;
- $\nu_{21}=0.0036$ s.

Then, in order to simulate the occurrence of a low level of damage, potentially mistaken for noise in signals, the bond elastic constant has been reduced of a 0.002% each time instant, starting from 16.23 s up to 17.23 s, bringing to a total reduction of about 9.52% in 1 second (corresponding to a reduction in the value of the natural frequency of 4.88%). Figure 1 depicts the imposed acceleration at the base of the SDOF and the acceleration response of the SDOF, while Table 1 reports the reference values of bond elastic constant before and after the application of damage. The explicit forward-backward Euler time integration algorithm has been used to solve the nonlinear dynamic analysis, as suggested by [5].

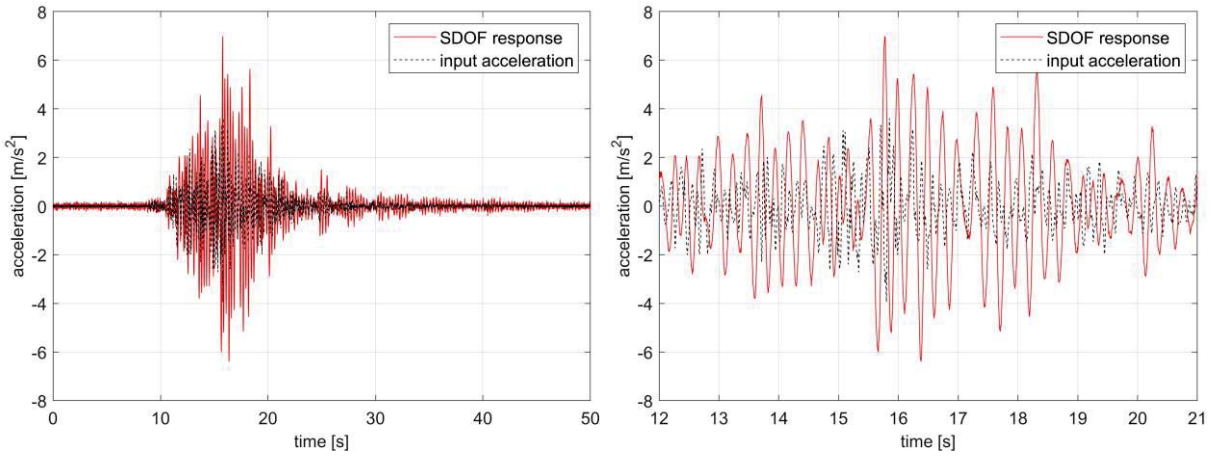

Figure 1: Accelerations obtained from the simulation (left) and zoom of the signals between 12 and 21 s (right).

c_{21} [N/m^6] before damage	c_{21} [N/m^6] after damage
636	575.462

Table 1: Reference values of bond elastic constant before and after the application of damage.

After having simulated the system, the identification procedure described in Section 2 has been applied. The TFD were calculated with a STFT using a periodic Hanning window over 128 points. The following page focuses on the discussion of the results of the procedure.

Figure 2 depicts the estimated bond elastic constant in the case of signals corrupted by 7% of uncorrelated Gaussian noise functions. From the figure is possible to conclude as the parameter estimate is mostly corrupted for joint time-frequency values that are not excited enough. This results is quite interesting because shows as the time-frequency estimate may be used as a tool to identify a time-frequency subdomain that brings the higher quantity of information in the reproduction of a specific signal. In particular, the high frequency values bring to overestimate the true values of the parameters, while the low frequencies bring to underestimate the true c_{21}. Then, it is worth noting that because very high and very low values of the bond elastic constant are associated to low values of probability, the definition of the time-frequency subdomain containing the higher quantity of information is also possible in case of lack of information on the real values of c_{kj}. From Figure 2 it is also possible to note as the estimated values of c_{21} in the area of high information content are almost close to the reference values reported in Table 1, also in case of corrupted signals.

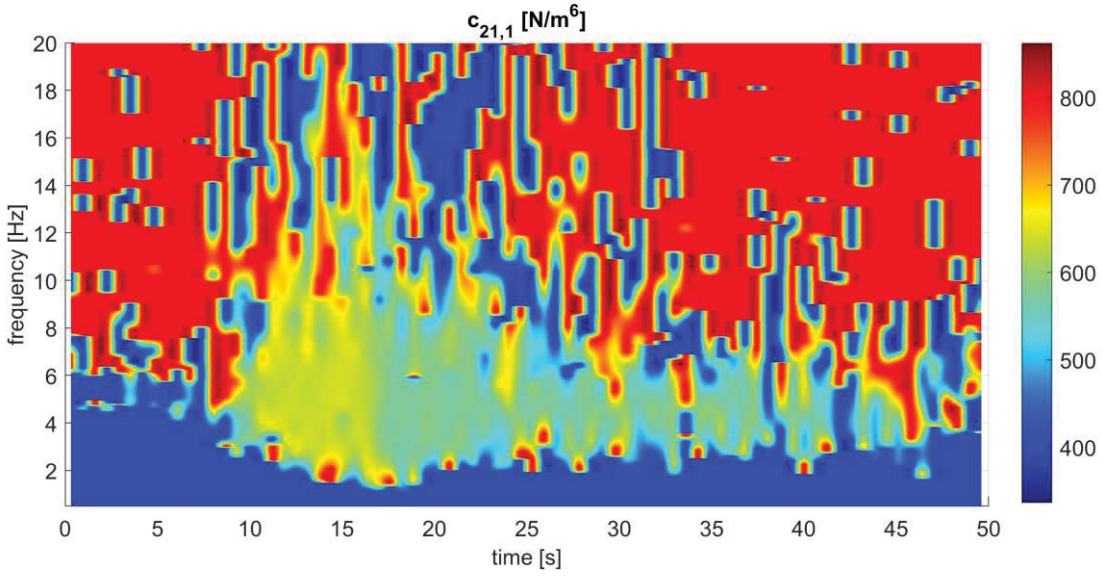

Figure 2: Time-frequency estimate of the bond elastic constant value.

4 CONCLUSIONS

Peridynamic can provides simply and strong information on the health of simulated systems. In the paper, a method to identify the *bond elastic constant* parameter of PD, over the time-frequency domain, has been proposed. The method has been demonstrated numerically on a nonlinear SDOF, whose simulated records has been corrupted by noise. The main results of the analysis are reported hereinafter:

- The method was able to estimate a correct parameter value also in presence of corrupted signals;
- The time-frequency estimate of the parameter reveals the definition of a time-frequency subdomain where the higher quantity of information for a system is located, making its use a potential instrument to define, for example, time-frequency filters specific for a given system.

Finally, it is worth mentioning that given the original aim of PD theory (emulating discontinuities and long-range forces in materials), masonry structures could greatly benefit from this PD idealization, as they are incline to crack under strong external actions, such as those ones due to earthquake.

Abstract. *The passage of trams in urban areas is a source of cyclic vibration which can induce damages in buildings close to the track. This aspect is even more relevant in the case of historical buildings and monuments because of their intrinsic fragility and the importance of preserving them as unaltered as possible for the next generations. In this framework, the purpose of this paper is the development of a mathematical modelling, based on experimental measurements, for the numerical simulation of vibration due to tram passages close to the so-called temple of Minerva Medica in Rome. The vibration signals were recorded at some points on ground level and on the structure by the use of GPS synchronized seismographs equipped with triaxial velocimeters. By means of spectral analysis of the acquired data, time windows associated to each tram passage have been assumed as stochastic nonstationary processes characterized in terms of energy and dominant frequencies by an evolutionary power spectral density. The signals acquired at different points due to the same passage define a multivariate process. The model would like to allow the simulation of the input at the base of the monument and the evaluation, through finite element analysis, of the exposure of the structure to cyclic stresses under different amplitudes highlighting the probability and location of damages in time.*

1 INTRODUCTION

Existing monuments in urban areas are subjected to more and more vibration cycles related to the increase in traffic of the last decades. Vibrations induce stresses which could lead to accumulation of micro-damages in time. Therefore, the exposure for a long time of such structures to cyclic loads could be dangerous in the perspective of their conservation.

In this paper a method is presented for the simulation of vibration induced by tram passages near a monument, in order to evaluate the load cycles on the structure, resorting to stochastic dynamics and experimental measurements. In more detail, a relevant case study, the so-called Temple of Minerva Medica in Rome, probably a nymphaeum of an extra-urban residence, was chosen for its peculiarities, i.e. the closeness with tramways, as well as with the main Rome's railway station. The monument was the subject of many studies for its dynamic characterization, before ([1],[2]) and after [3]-[7] the last major rehabilitation intervention that was carried out in 2012-2013. In [7] it was found a much higher effect of the tram passages in the close road with respect to that of the railway trains, whose vibration is more damped. In this context, the recent vibration measures on soil and structure where used to define the model. At each tram passage the acquired time histories in many points served to derive evolutionary spectral densities of the non-stationary processes. The method proposed in [8] is adopted, which in turn integrates the theory of evolutionary processes due to Priestley [9]. In the proposed approach the simulation procedure is particularized to multivariate processes, as was done for stationary cases in [10].

2 THE TEMPLE OF MINERVA MEDICA IN ROME

The temple (Fig. 1) was erected in the 4th century and today is close to the main railway station in Rome. The main chamber is decagonal with a diameter of 25 m and height of about 24 m (originally 32 m, after partial collapse of the dome). Openings are present in the chamber walls at the first level, whereas at the base there are nine apses and the main entrance.

Figure 1: View from South of the Temple of Minerva Medica. The two tramways can be seen (bottom left).

The structure was initially built in *opus latericium*, which was a common construction technique of that time, based on the use of Roman bricks and mortar. As the building started presenting structural problems, in the following centuries the construction was restored and

reinforced. In this context, interventions in *opus mixtum* of tuff bricks and Roman bricks were carried out. In particular, most niches were closed and some walls with the function of buttresses were added on the southeast side of the monument, which testify that a certain structural weakness of this part already arose in ancient times. Also, some major restoration interventions were carried out in the past. In 1846 first floor arcade of the southeast side was reconstructed, while the upper floor arcade of the southeast side was reconstructed in the years 2012-2013.

Close to the building there is the main roman railway station. In addition, the tramways are very close to the South-West side of the building and the effect of tram passages has been shown to be more dangerous for the monument than that of the railway.

3 DYNAMIC MODELLING OF TRAM PASSAGES

3.1 Experimental measurements of vibrations

Several velocity time histories were acquired in different measurement campaigns, in many points on soil and structure. Herein, only data acquired in July 2019 were used. Moreover, only tri-axial signals in point P (Fig. 2) at the base are considered with the purpose of the procedure set-up.

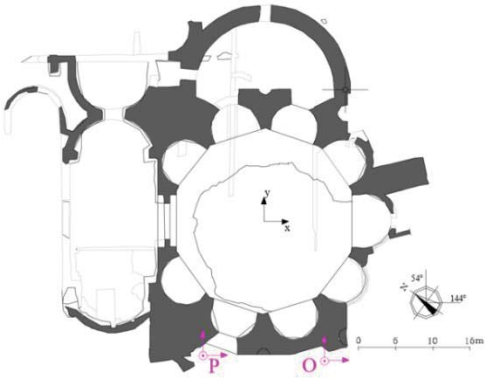

Figure 2: Acquisition points at the base of the structure.

3.2 Mean time arrivals of tram

The simulation of train arrivals in each direction can be obtained by means of a Poisson distribution with parameter λ, defined as follows:

$$p(N,t) = \frac{e^{-\lambda t}(\lambda t)^N}{N!} \tag{1}$$

By means of the data collected in about three hours of experimental measurements, the parameter λ =0.0029 s^{-1} was estimated during day.

3.3 Spectral representation of each passage event

Time histories acquired for 30 passages, 15 per each direction, were used for the definition of evolutionary spectral densities. In more detail, in this initial study the three components recorded in only one point at the base of the structure have been used. In addition, only one direction of tram movement is considered.

Short-time Fourier Transform (SFT) with a window-squared function *h(t)* was adopted [8]:

$$f(t,\omega) = \int_{-\infty}^{\infty} x(\tau)h(t-\tau)e^{-i\omega\tau}d\tau \tag{2}$$

The evolutionary spectral densities have been estimated as follows:

$$S_{x_i x_j}(t,\omega) = E[\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} x_i(\tau_1)x_j^*(\tau_2)h(t-\tau_1)h(t-\tau_2)e^{-i\omega\tau_1}e^{i\omega\tau_2}d\tau_1 d\tau_2] \quad (3)$$

in which $x_i(t)$ and $x_j(t)$ are two signals recorded in different points in space or simply two components at the same points. In this preliminary work only the three components at one point are considered. Therefore spectral density matrix is defined as $\mathbf{S}(t,\omega)=S_{x_i x_j}(t,\omega)$ (i,j=1,..,3). The cross spectra are complex quantities. However, $\boldsymbol{S}$ is Hermitian, so the eigenvalues are real.

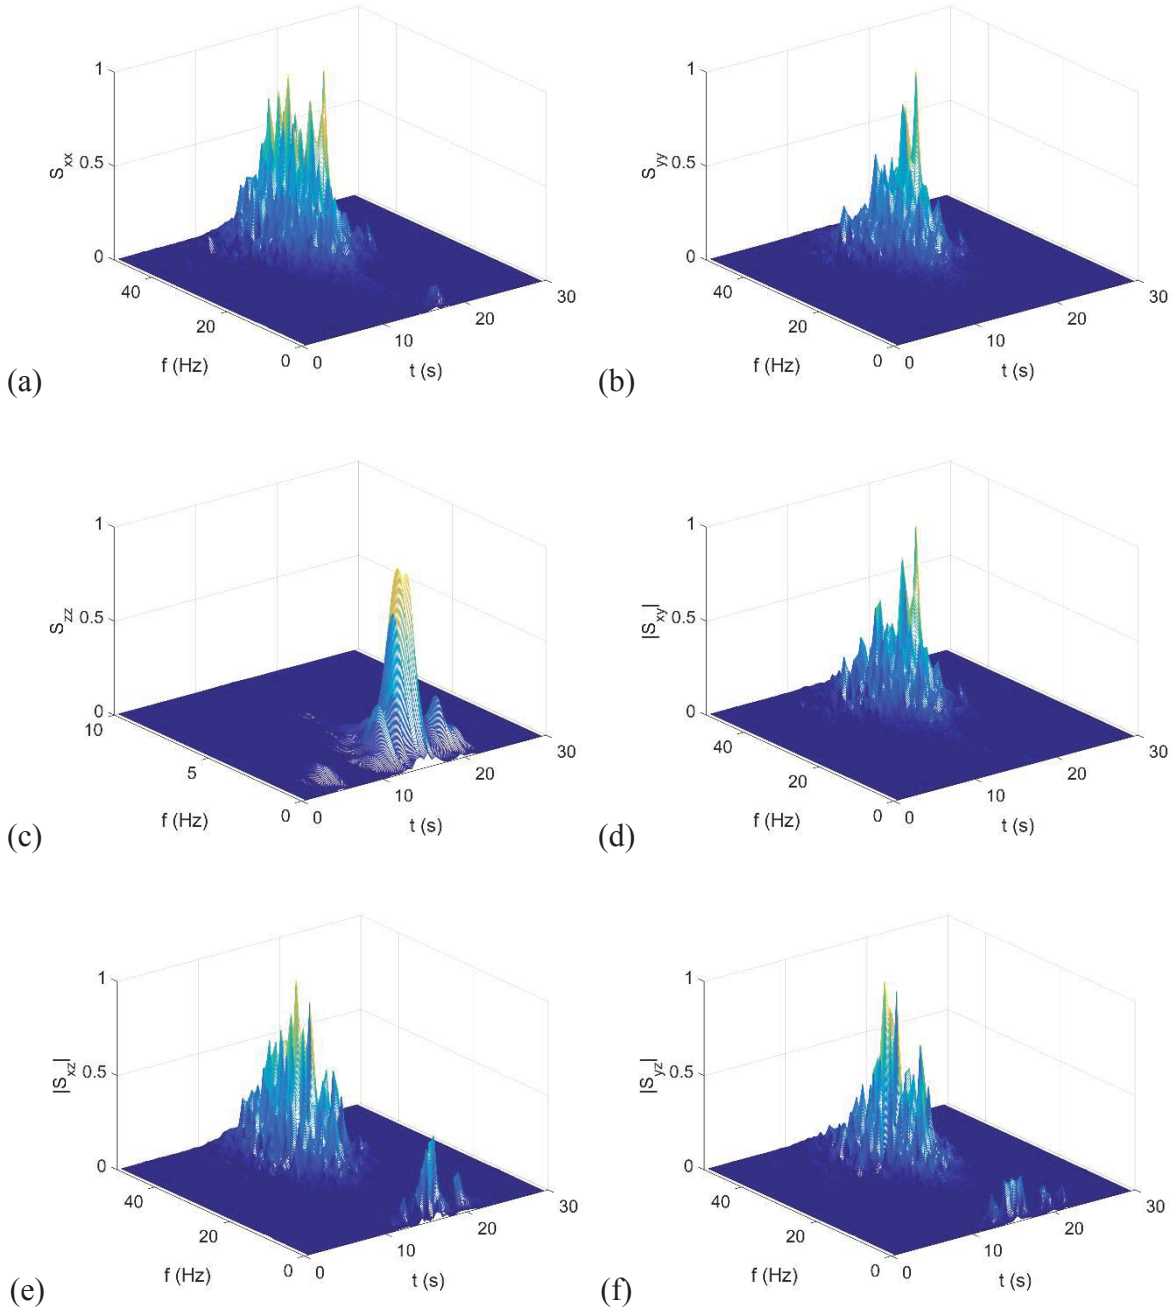

Figure 3: Normalized evolutionary spectral densities, direct (a)-(c) and absolute value of the cross-spectra (d)-(f).

Figs. 3a-f show the obtained spectra, normalized to have unitary maximum amplitude. In the case of cross-spectra which are complex, the absolute value is reported. In addition, the frequency f=$\omega/2\pi$ is considered. Horizontal components present the major energy content at high frequency values, in the range 20-45 Hz, whereas the vertical component has relevant amplitudes for frequencies lower than 5 Hz.

3.4 Simulation

The simulation is performed in the framework of stochastic multivariate processes. In analogy with stationary cases [10], according to [8], with some modification to take into account that eigenvectors are complex, the following simulation formula can be applied:

$$\boldsymbol{x(t)} = \sum_{j=1}^{3} \boldsymbol{X_j(t)} \tag{4}$$

$$\boldsymbol{X_j(t)} = \boldsymbol{2\sum_{k=1}^{N} \mathrm{Re}\left[\psi_j(\omega_k, t)\right] \sqrt{\Lambda_j(\omega_k, t)\Delta\omega} \left[\cos\left(R_{kj}^{(j)}\omega_k t\right) - \sin\left(I_{kj}^{(j)}\omega_k t\right)\right]} \tag{5}$$

Given that $\boldsymbol{S}$ is Hermitian, its eigenvalues are real and eigenvectors respect the following equations: $\boldsymbol{\Psi^* S \Psi = \Lambda}$ and $\boldsymbol{\Psi^* \Psi = I}$. In the previous equations $\boldsymbol{I}$ denotes the identity matrix, the asterisk denotes the transpose and conjugate of the matrix, $\boldsymbol{\Psi}$ is the matrix whose columns are the complex eigenvectors of $\boldsymbol{S}$, and $\boldsymbol{\Lambda}$ is the diagonal matrix of real eigenvalues.

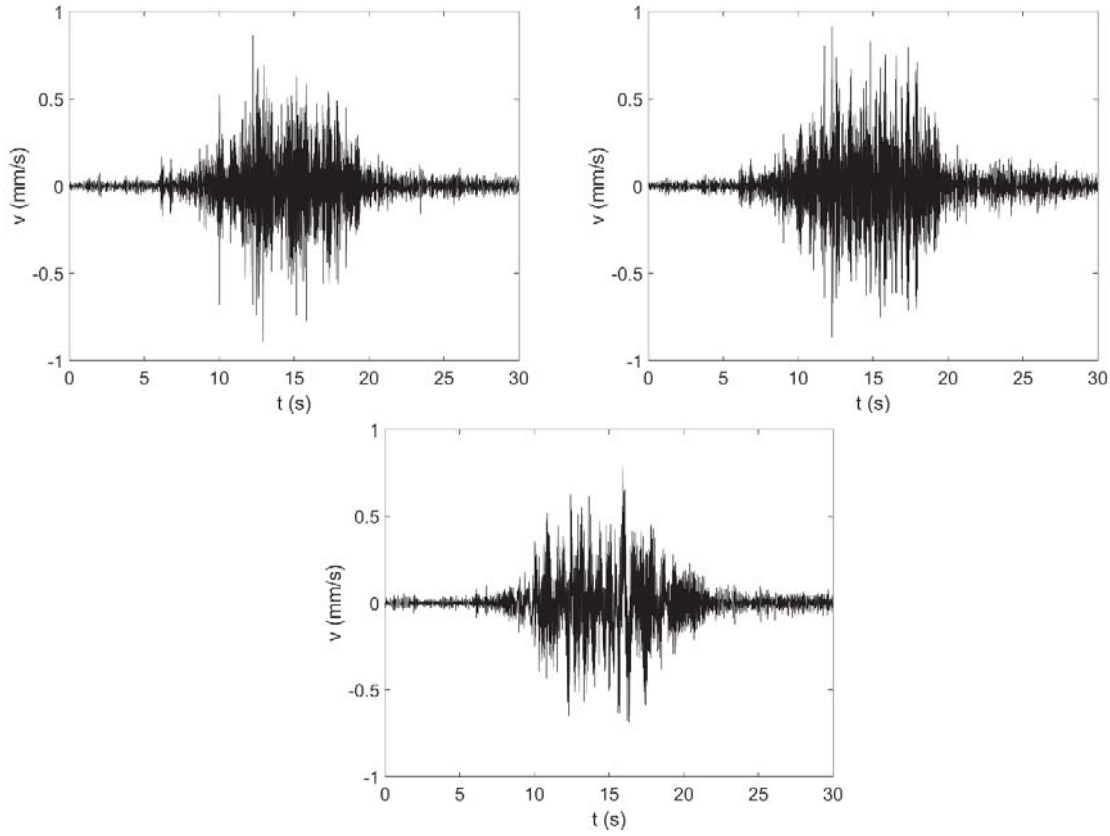

Figure 4: Time histories at one measurement point for one tram passage.

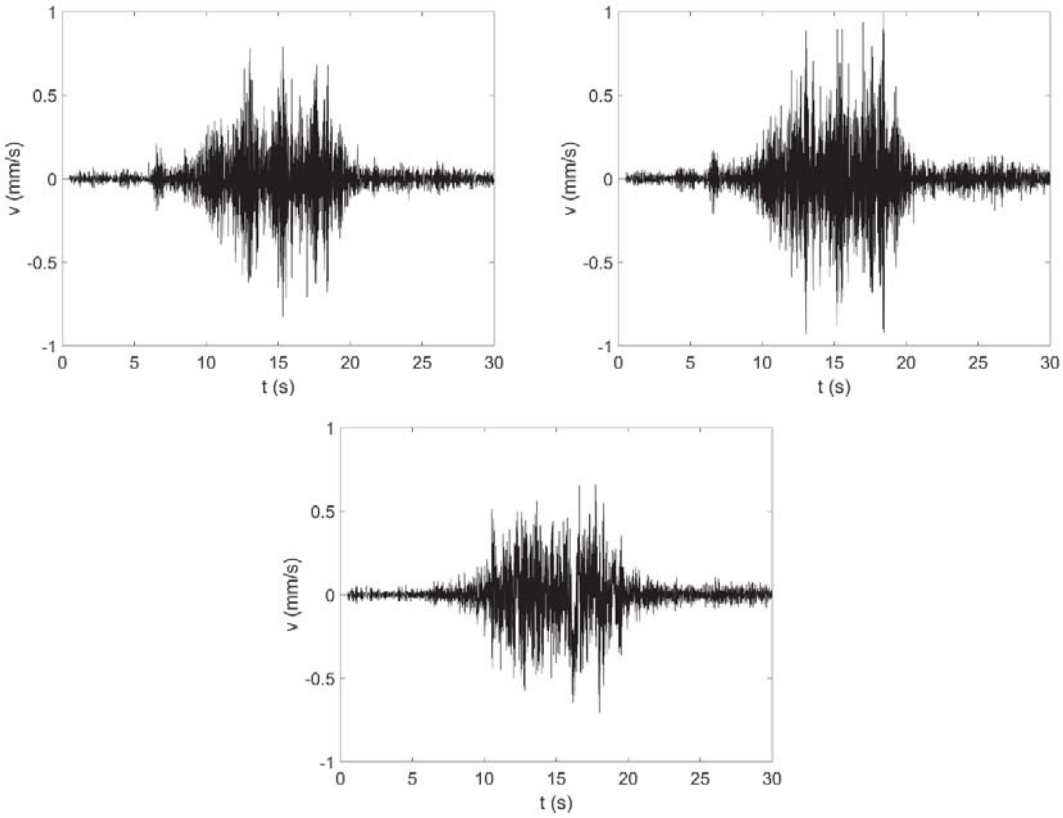

Figure 5: Simulated three-component time history.

Figs. 4 show the time histories acquired at point P of Fig. 2 in one passage event. Figs. 5 show the simulated time histories, which take into account the frequency content and time evolution obtained from 15 tram passages.

4 FINITE ELEMENT MODEL AND STRESS SIMULATION

A finite element model has been developed in Midas Gen code (Fig. 6). The geometry of the monument was largely deduced by laser scanning technique.

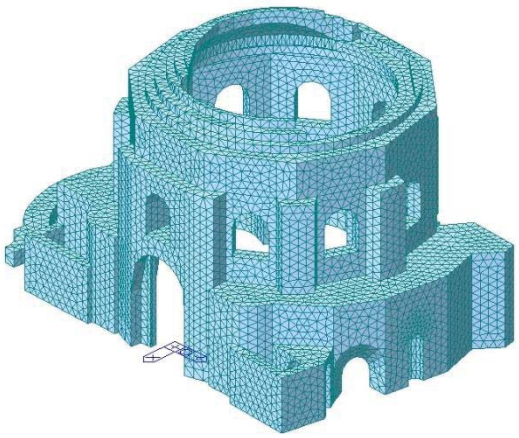

Figure 6: View of the model.

From the initial point cloud, horizontal sections of the monument were obtained and used as

reference to define the volume. 72980 solid elements were used for meshing. The material has been modeled as homogeneous and isotropic with the following parameters: unit weight of 18 kN/m^3, Poisson ratio of 0.2 and 744 MPa of Young modulus. The material properties were calibrated through model updating according to the frequencies obtained through experimental results of ambient vibration testing of the monument [3]. Figs. 7 show the first two modal shapes (f_1=2.070 Hz and f_2=2.392 Hz).

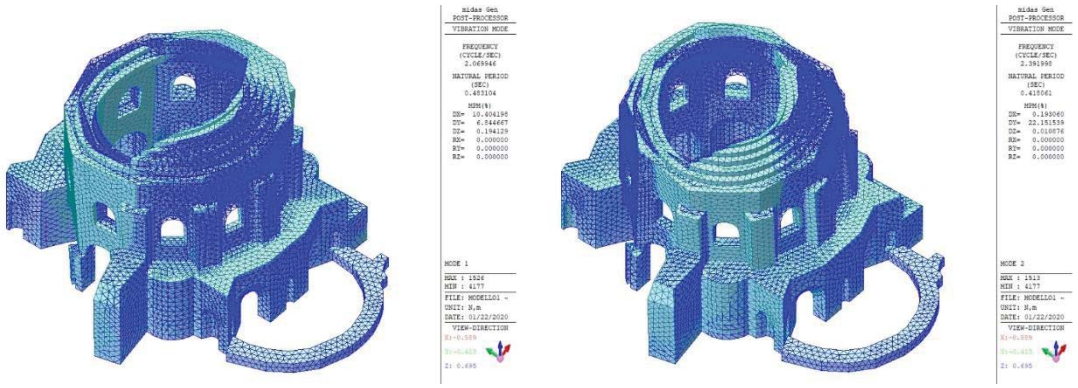

Figure 7: First two modal shapes.

The model has been excited by means of base acceleration obtained by derivative of the simulated time histories of velocity. In order to reduce the order of the model, Ritz vectors were used considering accelerations in three orthogonal directions. Modes up to frequency of about 70 Hz were retained to well describe the spectra content.

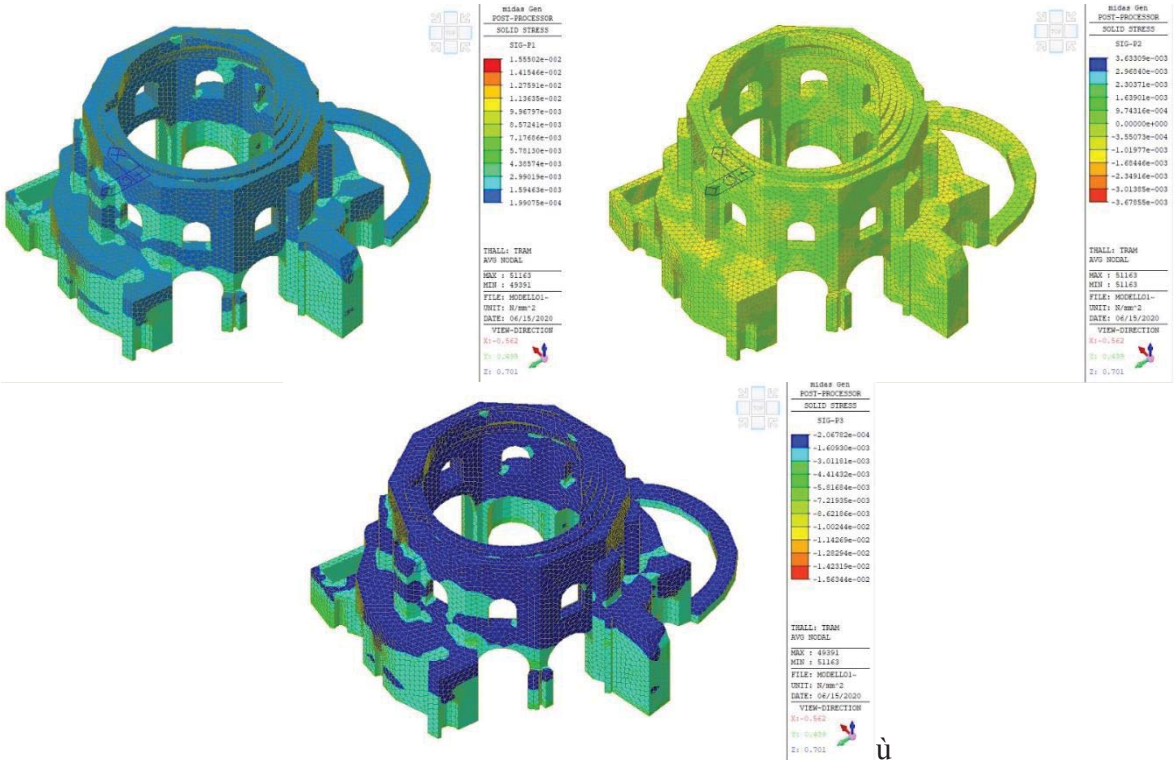

Figure 8: Principal stresses under simulated time accelerations.

Figs. 8 show the principal stresses evaluated on the structure. This preliminary model will be improved considering more than one measurement point to capture the effect of the distance from the tramway and evaluate stresses with a multi-point base input.

5 CONCLUSIONS

A procedure for modelling the vibration due to train passages in the proximity of monuments is proposed in this paper. Resorting to stochastic dynamics, evolutionary spectral densities of each passage event can be defined for each measurement point, as well as the mean time arrival of trams. In this way, time histories of velocities are simulated reflecting time evolution and frequency content of the measure data. In this work the method is applied for data recorded at the base of the Temple of Minerva Medica in Rome. Only one tramway, the closest to the monument, with trams passing in North-West direction, is considered as a preliminary study, defining the mean time arrival of the trains, as well as the evolutionary spectra. Simulation of triaxial velocities in one point is proposed as well as the stress evaluation on the structure. The work would be completed considering more measurement points on the soil, so to have different distances from the tramway and the possibility of simulating a multi-point input on the structure. In this way, load cycles could be evaluated highlighting the portions of the structure much prone to damages.

Keywords: Architectural heritage, Seismic assessment, Dynamic monitoring, Damage detection, Preventive conservation.

Abstract. *After recent seismic events in Italy (Umbria-Marche 1997, L'Aquila 2009, Emilia 2012, Central Italy seismic sequence 2016), there has been a growing scientific interest on the preventive conservation of historic monumental buildings. In this regards, vibration-based low-cost and non-destructive Structural Health Monitoring (SHM) systems provide very useful information on the structural behavior. This information includes both global and local mechanisms and results in more accurate seismic assessments and effective retrofits, also allowing detection of small structural damages developing after far-field earthquakes.*

This paper presents the ongoing research activities regarding the SHM of the Consoli Palace in Gubbio, Italy. A simple and low-cost mixed static-dynamic long-term SHM system has been active since July 2017 with the main purpose of detecting damage-induced anomalies in the time series of the amplitudes of the two major cracks existing in the building and the variation of natural frequencies of global and local vibration modes. The system comprised two crack meters, two temperature sensors and three high sensitivity accelerometers, the latter finalized at the continuous modal identification and modal tracking of the building for damage detection purposes through statistical process control tools. Recently, the SHM system has been integrated with additional sensors, and now comprises 12 accelerometers on three levels of the palace that allow a more detailed detection of the possible vibration modes' variations, 4 crack meters to monitor the openings of two additional cracks and 4 thermocouples to more accurately remove thermal effects by accounting for the effects of the different solar radiation on the buildings' façades. The paper presents preliminary considerations about the first results of the new larger sensor network, including (i) a discussion on the role of an enriched identification of the mode shapes, (ii) a preliminary assessment of environmental effects on modal properties of the structure, both the natural frequencies and mode shapes, and (iii) considerations on the removal of such environmental effects and damage detection based on novelty analysis. The differences between previous and new results and the advantages of the adoption of a larger sensor network are highlighted.

1 INTRODUCTION

Masonry structures, such as towers, palaces and churches, constitute an important part of Cultural Heritage (CH) buildings in Europe, whose preventive conservation against material degradation and natural hazards can be regarded as a societal priority, as well as a scientific and technical challenge. Within the Italian context, most of these buildings are especially exposed to seismic risk, as a consequence of the high seismic hazard of most of the Italian territory and their high seismic vulnerability. This has also been dramatically testified by recent Italian earthquakes, such as those occurred in Emilia in 2012 [1] and Central Italy in 2016-2017 [2], just to mention the most recent ones.

Ambient Vibration Tests (AVT) and Operational Modal Analysis (OMA) [3, 4], as well as long-term vibration-based SHM, are becoming especially popular in application to CH structures, owing to their fully non-destructive and non-invasive nature. Literature counts several applications of vibration-based SHM methods to slender masonry towers based on the continuous identification of natural frequencies from in-service response data collected by a few sensors deployed on the upper part of the structure [5, 6, 7]. In this context, any damage or change in the structural behavior is automatically detected in the form of anomalies in time series of continuously identified natural frequencies, typically using multivariate statistical analysis methods, while the damage localization task can be addressed by solving an inverse problem, with the purpose to identify damage-induced local changes in equivalent elastic properties of the masonry [6, 8]. While suited for slender structures, vibration-based SHM methods are not directly applicable to stiffer masonry buildings, such as churches and palaces, where a mixed static-dynamic monitoring approach is often more informative, using measurements of strains, deformations, tilts and crack amplitudes to derive static signatures [9, 10, 11, 12, 13].

The Consoli Palace is the most representative monument of the medieval town of Gubbio, Italy, and is located in the heart of its historical center. Several studies have been carried out on the Consoli Palace in the framework of Horizon 2020 European HERACLES (HEritage Resilience Against CLimate Events on Site) project, devoted to enhancing the resilience of historic buildings against harmful events [13, 14, 15, 16, 17]. The palace has been under continuous monitoring since July 2017 using a simple mixed static and dynamic long-term SHM system. To the best of the authors' knowledge, the Consoli Palace can be regarded as the first (or one of the first) example(s) in the scientific literature, in which continuous long-term modal identification and SHM based on frequency tracking has been applied to the case of a stiff masonry palace, with the purpose of early detecting any damage or change in its structural behavior following an earthquake, whereby the existing literature limits to slender structures such as towers [5, 6, 7, 18, 19], churches and/or cathedrals [20, 21].

2 THE SHM DAMAGE-DETECTION ALGORITHM

The adopted vibration-based SHM method consists of a Multiple Linear Regression (MLR) model to remove the effects of changes in environmental and operational conditions from time series of natural frequencies and of a control chart based on T^2-statistic to detect deviations from normal conditions possibly related to a structural damage. Tracked modal frequencies are collected in an observation matrix, $\mathbf{Y} \in \mathbb{R}^{n \times N}$, where n is the number of identified frequencies and N is the number of observations. Quantities contained in matrix $\mathbf{Y}$ are affected by

changes in environmental conditions and cannot be directly used as damage sensitive features. Instead, quantities contained in a residual error matrix, $\mathbf{E} \in \mathbb{R}^{n \times N}$, are used for this purpose and computed as

$$\mathbf{E} = \mathbf{Y} - \hat{\mathbf{Y}} \tag{1}$$

where $\hat{\mathbf{Y}}$ are modal frequencies independently estimated through a proper statistical model. Under the assumption that such a model can reproduce the part of the variance in frequency estimates that is associated with changes in environmental and operational conditions, the error matrix only contains the residual variance in the data associated with errors in output-only modal identification and with un-modeled environmental and operational effects on modal frequencies. If a damage pattern develops, this affects data contained in $\mathbf{Y}$ but not those in $\hat{\mathbf{Y}}$. It follows that $\mathbf{E}$ contains quantities that are feasible for damage detection purposes. After computing matrix $\mathbf{E}$ in Eq. (1), a damage condition is identified as an anomaly in the residual errors, under the assumption that damage induces a change in the distribution of $\mathbf{E}$. To this aim, the classic statistical process control tool named *Novelty Analysis* is adopted. It consists of the use of control charts based on properly defined statistical distances or, in other words, on an index able to flag relevant natural frequency shifts (see Fig.1). A well known quantity used for this purpose in SHM is the Hotelling or Shewhart T^2-statistical distance [22], defined as

$$T^2 = r \cdot (\overline{\mathbf{E}} - \overline{\overline{\mathbf{E}}})^T \cdot \Sigma^{-1} \cdot (\overline{\mathbf{E}} - \overline{\overline{\mathbf{E}}}) \tag{2}$$

where r is an integer parameter, referred to as *group averaging size*, $\overline{\mathbf{E}}$ is the mean of the residuals in the subgroup of the last r observations, while $\overline{\overline{\mathbf{E}}}$ and Σ are the mean values and the covariance matrix of the residuals, respectively. Both $\overline{\overline{\mathbf{E}}}$ and Σ are statistically estimated in a reference period, called the *training period* (denoted as t_t), during which the structure is in the healthy state, i.e. it can be considered undamaged and experiences the normal environmental and operational conditions. An anomaly in the data is identified in the form of an outlier in the observed values of the residual errors, which is a value of the statistical distance which lies outside fixed control limits. Changes in T^2 are therefore likely to occur after a seismic event, evidencing the development of a damage pattern in the structure.

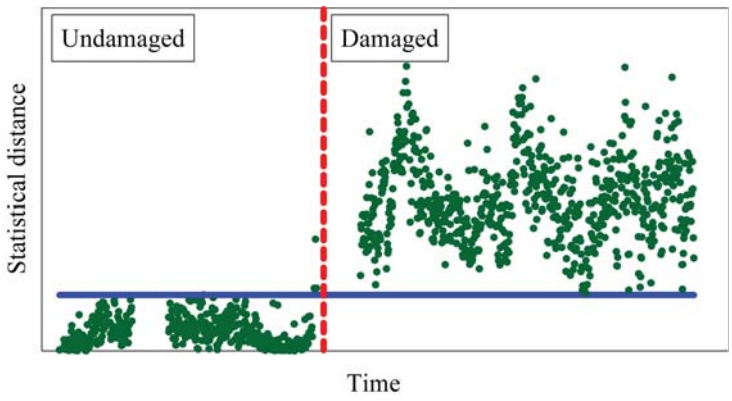

Figure 1: A typical example of control chart.

3 THE CONSOLI PALACE

The Consoli Palace is a very iconic masonry building in the medieval town of Gubbio, Italy. Built in gothic style between 1332 and 1349, it hosted the Consuls who were elected to control both legislative and executive branches of the government of the City. Since 1909 the building has been functioning as the Civic Museum, with a rich collection of art masterpieces, including the Iguvine Tablets dating back to the ancient Umbrian civilization.

AVTs have been carried out in May 2017 allowing identification of the first six modes of vibration within the range from 0 to 10 Hz: three involve vibration of the overall building, being two global flexural modes and one torsional mode, whereas the remaining three modes consist of mixed and/or local modes related to the dynamic interaction between the Palace and the small bell-tower placed on its top.

Significant thermal effects on both crack amplitudes and natural frequencies of the Consoli Palace have been investigated during the first year of monitoring. Negative linear correlations between crack amplitudes and temperature have been observed, while correlations between natural frequencies and temperature are also negative but sometimes non-linear. Also, the simultaneous recordings of static and dynamic data have allowed improving the statistical model used for the prediction of natural frequencies, by including the crack data as predictors, in addition to temperature data as generally found in the literature. More information can be found in [13].

3.1 The monitoring system

A mixed static-dynamic monitoring system has been active since July 2017. It is composed of:

- Three high sensitivity uni-axial piezoelectric accelerometers model PCB 393B12 (10 V/g sensitivity and $\pm$ 0.5 g measuring range) deployed on the roof of the Palace.
- Two crack meters (Linear Variable Displacement Transducers-LVDTs S-Series model with measurement range from 0 to 50 mm and resolution $<0.3\mu$m) permanently installed across two major cracks in the upper portion of the structure and related to possibly activating failure mechanisms, aimed at monitoring their possible opening and closing.
- Two temperature sensors (K-type thermocouples) installed close to each LVDT, in order to measure the surface temperature of the wall aiming at observing its influence on the evolution of the cracking pattern, as well as on global vibration modal properties.
- One data acquisition system (NI cDAQ-9132) with a remote connection to a data analysis server located in the Laboratory of Structural Dynamics of the University of Perugia.

Further details on the monitoring system can be found in [13].

Considering a continuous monitoring period from July 2017 to February 2020, data analysis can be synthesized in Fig.2: (i) results of modal identification and frequency tracking are presented in Fig. 2a, (ii) the recorded time series of crack amplitudes and temperature data are plotted in Figs. 2b, c. Plots versus the most correlated temperature are shown on the right side

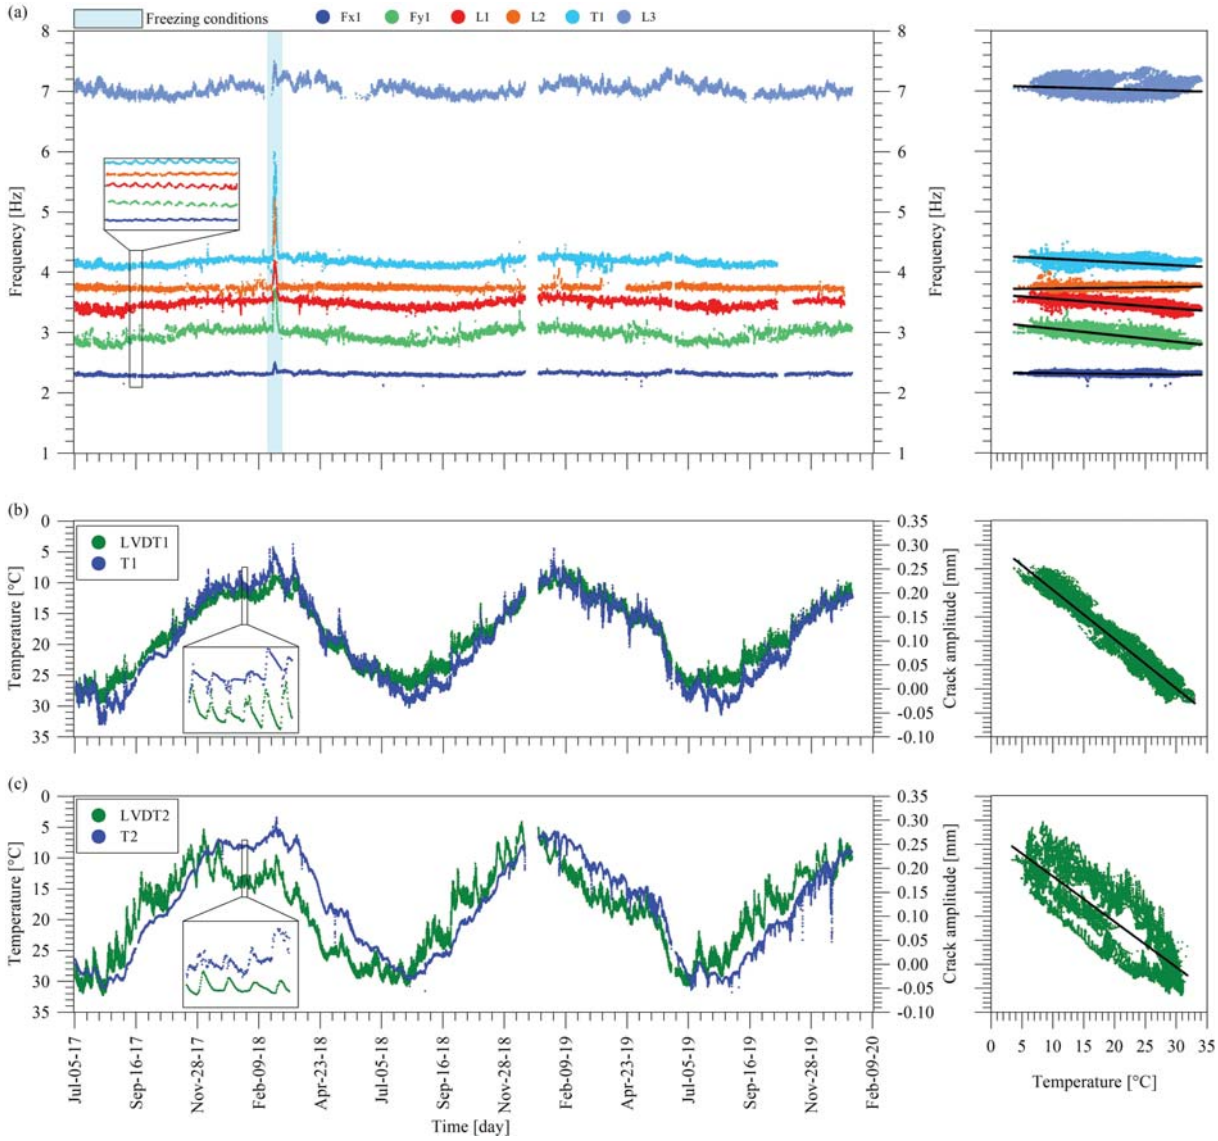

Figure 2: Time series of identified natural frequencies using automated SSI (a) and time evolution of the two monitored crack amplitudes and temperature data of Consoli Palace during more than two years of continuous monitoring (b-c). Their correlation with temperature data is also plotted.

of the figure. These results show that modal tracking is possible with an acceptable continuity for all natural frequencies of the six vibration modes. Also, their seasonal variations and daily fluctuations are evident. However, there are some continuously tracking difficulties. Some natural frequencies are not consistently identified, e.g. Fy1 global and L2 local modes of vibration, exhibiting lower identification success ratios, which might be associated to a lower traffic excitation during night hours, as well as to difficulties in modal tracking due to poor information on the mode shapes which are essential to correctly classify identified poles as belonging to this or that structural mode.

As an alternative solution, a denser sensor network could overcome many of the abovementioned shortcomings of the actual monitoring system.

4 THE NEW PROPOSED MONITORING SYSTEM

The SHM system has been recently enlarged with additional sensors, as depicted in Fig. 3. It now comprises a total of:

- Twelve accelerometers deployed on three levels of the palace that allow a more detailed detection of the possible vibration modes' variations: A1-A3 on the roof are the same sensors as in the previous system, A4-A6 in the Nobili hall, A7-A9 deployed in the Arengo hall and A11, A12 located on the roof and monitoring the top movements of the East and West façades, respectively.
- Four crack meters-LVDTs to monitor the openings of two previous (LVDT1 and LVDT2) and two additional cracks (LVDT3 and LVDT4).
- Four temperature sensors (K-type thermocouples) installed close to each LVDT, allowing a better thermal effects removal by accounting for the effect of the different solar radiation on the North and South façades.
- The same data acquisition system (NI cDAQ-9132) with a remote connection to the laboratory server.

The higher number of accelerometers and their deployment in three levels along the height contributes to improving modal tracking. For instance, natural frequencies of modes Fy1 and L2 can be tracked more regularly. Most importantly, an enriched identification of the mode shapes is considered. In fact, mode shapes can be identified continuously in time and the evolution of Modal Assurance Criterion (MAC) values, calculated with respect to the mode shapes of the calibrated numerical, is possible. On the other hand, considering the characterization of environmental parameters, a more accurate investigation of their effects on modal properties of the structure can be carried out with additional temperature sensors, not limiting it to the natural frequencies but also considering the mode shapes. Two additional crack meters are

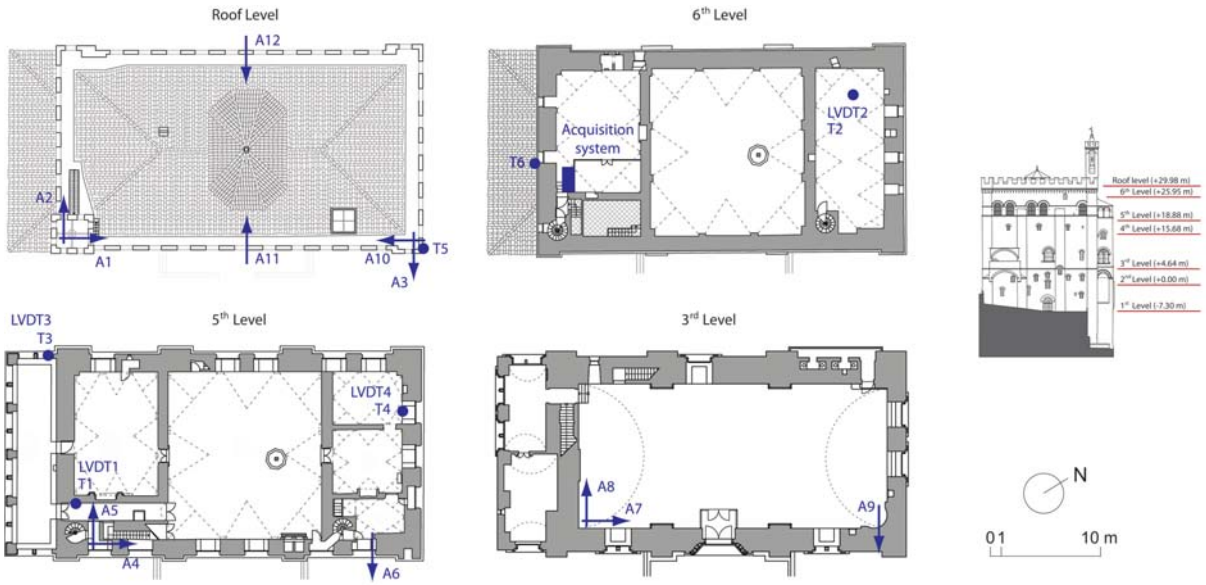

Figure 3: Layout of the new larger sensor SHM network recently installed on the Consoli Palace: (i) 12 accelerometers, (ii) 4 LVDTs, (iii) 4 K-type thermocouples and (iv) the data acqusition system.

installed, considering the main possibly activating failure mechanisms: (i) the overturning of the loggia on the South side of the Palace and (ii) the overturning of the northern part of the West façade. LVDT3 is located in correspondence of a new investigated crack pattern, related to the first mechanism, while LVDT4 is positioned in the medium-lower part of the crack of the North façade, already monitored in the upper level by LVDT2, related to the second mechanism. Finally, after the removal of the environmental effects, damage detection based on novelty analysis can be carried out using the information on variations of both natural frequencies and mode shapes, as well as crack amplitudes. In this context, the purpose of this new larger SHM system is a more accurate early detection of damage-induced anomalies in the time series of the natural frequencies of global and local vibration modes, as well as in the time series of the amplitudes of the major cracks existing in the building.

Based on the very first monitoring days, the differences between previous and new results are under specific attention, highlighting the advantages of the adoption of a larger sensor network. The monitoring data analysis has been carried out using an ad hoc created software tool, called MOSS, allowing continuous automated OMA and damage detection for SHM. The code allows for automatically managing data recordings of ambient vibrations and environmental variables. It also includes multiple regressive models for conducting damage identification, as well as a package of surrogate modeling. A user-friendly graphical interface of the MOSS software is shown in Fig. 4. More information can be found at https://shmlab.weebly.com/ (Research area).

5 CONCLUSIONS

The ongoing research activities regarding the mixed SHM of a monumental palace, the Consoli Palace in Gubbio, Italy, have been presented. A simple and low-cost mixed static-dynamic long-term SHM system has been active from July 2017 to February 2020. A new larger sensor SHM network has been recently installed in the Consoli Palace.

The main advantages of the new system are summarized below:

- An improved natural frequencies tracking and continuous identification of mode shapes.
- A more accurate characterization of environmental parameters and investigation of their effects on the modal properties of the structure.
- A more in-depth investigation of the major crack patterns by using additional crack meters and temperature sensors close to them.
- A more accurate earthquake-induced damage detection based on novelty analysis using the information on variations of both natural frequencies and mode shapes, as well as crack amplitudes.

Keywords: Dynamic monitoring, soil-structure analysis, model updating

Abstract. *The goal of this paper is to investigate the role of soil-structure interaction in modeling the dynamic behavior of masonry towers. The study, conducted on the bell tower of the Basilica of San Frediano in Lucca (Italy), is based on both experimental and numerical results. The former were collected during an experimental campaign carried out on the tower using seismometric stations, while the latter have been obtained via the modal analysis and model updating procedures implemented in the finite element code NOSA-ITACA. Combining experimental and numerical outcomes made it possible to assess the influence of the soil, modeled as a system of elastic springs, on the natural frequencies of the tower. Finite element models of the tower have been calibrated by taking the presence of the adjacent church into account and choosing different unknown parameters, including the soil stiffness.*

1 INTRODUCTION

Finite element (FE) model updating techniques are based on solution of a constrained minimum problem, in which the objective function is generally expressed as the discrepancy between experimental and numerical natural frequencies and mode shapes [1]. Wide application of these techniques to heritage structures is quite recent [2], [3], [4].

An efficient algorithm for model updating based on a modified Lanczos projection strategy and a trust-region scheme has been implemented in NOSA-ITACA, free software developed in house by ISTI-CNR and successfully applied to several case studies [5, 6]. Besides reducing the overall computation time of the numerical process and enabling accurate analysis of large-scale models with little effort, the proposed algorithm allows for obtaining information on both the reliability of the solution and its sensitivity to noisy experimental data.

Recent studies have shown that soil-structure interaction should be taken into account in studying the dynamic behavior of masonry structures [7], [8], [9], [10], [11], [12]. Stemming from the results of a continuous monitoring campaign conducted by the authors on the San Frediano belfry in the historic center of Lucca [13], this paper is aimed at investigating how this interaction influences the results of model updating.

In [13] FE model updating of the tower was conducted, by taking the presence of the adjacent church into account via suitable boundary conditions and considering the tower clamped at the base. In the present paper, the soil-structure interaction is studied by applying at the structure's base a system of elastic springs whose stiffness is varied in order to represent different soil types [14]. Two models of the tower have been analyzed: in the former the tower is free, and the influence of the church neglected, while in the latter the presence of the lateral walls of the church is modelled via elastic springs. The influence of soil stiffness on the tower's natural frequencies has been investigated and the model updating procedure implemented in NOSA-ITACA [5], [6] has been applied to determine the optimal mechanical properties of the tower-springs system.

2 FE MODEL UPDATING

Numerical modeling of a structure is usually characterized by several uncertainties regarding the properties of the constituent materials, the constraining effect of the adjacent buildings, boundary conditions, local soil conditions, etc. Model updating is a procedure aimed at determining some unknown parameters of a FE model in order to match the experimental and numerical dynamic properties of a structure (frequencies and mode shapes) [1]. Assuming that the stiffness and mass matrices of a structure discretized into finite elements depends on a parameter vector x varying in a p-dimensional box Ω, we want to determine the optimal value of x that minimizes, within the box Ω, the objective function

$$\phi(\mathrm{x}) = \sum_{i=1}^{q} w_i^2 [\, f_i^{exp} - f_i(\mathrm{x})]^2, \tag{1}$$

where f_i^{exp} and $f_i(\mathrm{x})$ are the q experimental and numerical frequencies to match (with q not less than p). In particular, numerical frequencies $f_i(\mathrm{x})$ are calculated by solving a generalized eigenvalue problem involving the stiffness matrix K(x) and mass matrix M(x) depending on the parameter vector x. Scalars w_i are the weight that should be given to each frequency in the optimization scheme; in order to obtain satisfactory accuracy on the frequencies, w_i is usually chosen as equal to the inverse of the experimental frequency.

The numerical procedure for model updating, described in detail in [5, 6], has been implemented in the NOSA-ITACA code, a finite element software package developed in house by

ISTI-CNR [15], for performing modal analyses [16] and managing the large-scale problems encountered in applications.

The algorithm implemented in the code is based on construction of local parametric reduced-order models embedded in a trust-region scheme for solving the constrained minimum problem. In particular, the algorithm exploits the structure of the stiffness and mass matrices and the fact that only a few of the smallest eigenvalues have to be calculated in order to solve the problem.

3 THE SAN FREDIANO BELL TOWER

The bell tower of the Basilica of San Frediano (Figure 1), dating back to the 11th century, is one of the best preserved in Lucca's historic center. The tower, whose geometry is sketched in Figure 2 and described thoroughly in [13], is 52 m high, with walls varying in thickness from about 2.1 m at the base to 1.6 m at the top. The San Frediano Basilica adjoins the tower on two sides for about 13 m of its height. The masonry constituting the tower appears to be made of regular stone blocks at the base, while quite homogeneous brick masonry is visible in the upper sections, apart from the central part of the walls, where the masonry between the windows is made up of stone blocks.

In the period 2015-2017 the tower was instrumented with four SARA tri-axial seismometric stations, each made up of a SL06 24-bit digitizer and a SS20 seismometer (electrodynamic velocity transducer, 2.0 Hz eigenfrequency), made available by the Arezzo Seismology Observatory (INGV). The instruments were arranged on the San Frediano bell tower adopting different sensors layouts and data recorded were analyzed via the Covariance Driven Stochastic Subspace Identification method (SSI/Cov) [17], [18] implemented in the MACEC code [19].

Table 1 reports the mean values of the first five frequencies calculated using data recorded in August 2016, with a sampling frequency of 100 Hz. The first and second frequencies correspond to flexural mode shapes along the X and Y direction, respectively. The third frequency is likely related to a torsional mode shape. The last two frequencies correspond once again to flexural model shapes. More details on mode shapes are given in [13].

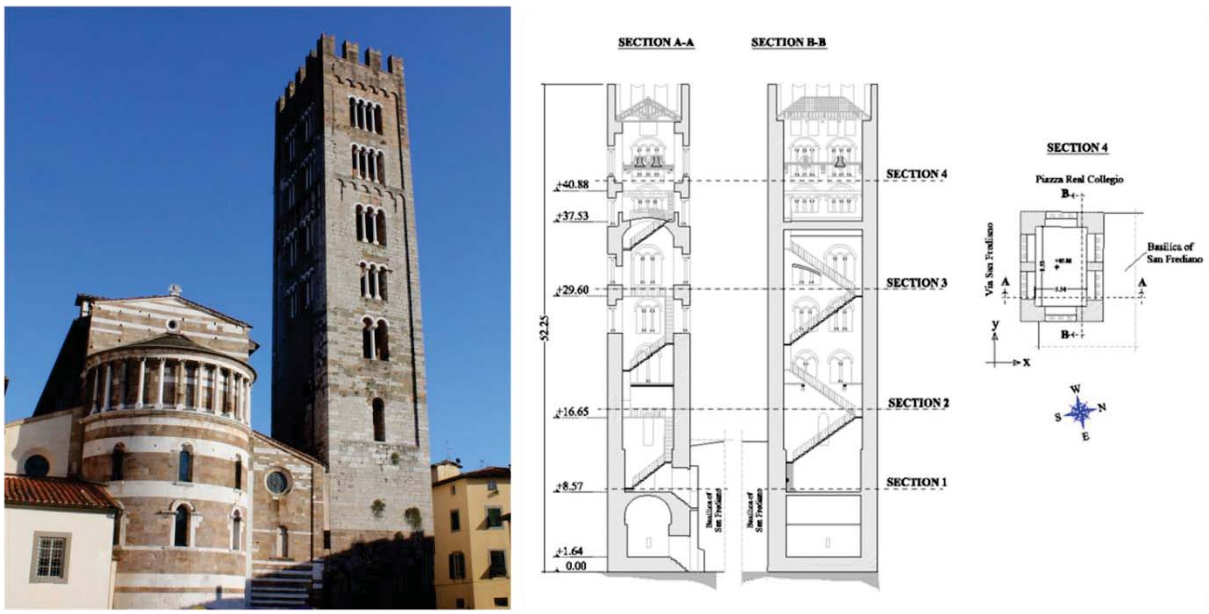

Figure 1: The San Frediano bell tower.

	Frequency [Hz]
Mode 1 (Bending X)	1.11
Mode 2 (Bending Y)	1.39
Mode 3 (Torsional)	3.45
Mode 4 (Bending X)	4.64
Mode 5 (Bending Y)	5.37

Table 1: The first five frequencies of the San Frediano bell tower.

3.1 FE modeling, modal analysis and model updating

This section is devoted to the modal analysis of the bell tower. All numerical analyses presented in this paper have been conducted via the NOSA–ITACA code [5], [6], [16], [15].
The San Frediano bell tower has been discretized into 45935 brick and 673 beam and truss elements (element n. 8, 9 and 35 in [15]) with 60228 nodes, as shown in Figure 2. Beams have been used to model the steel tie rods and the wooden roof elements, while trusses are used for the springs at the base, according to the Winkler model for the soil [14] and to model the adjacent building. In particular, two models have been considered: in the former (Model 1) the presence of the church is neglected, while in the latter (Model 2) elastic spring have been applied 12.50 m above the base to account for the church's adjacent walls (red springs along X and magenta springs along Y in Figure 2). In both cases horizontal displacements of the base are prevented and vertical displacement is constrained by the presence of elastic springs under the tower's base (green in Figure 2).
The masonry has been modeled as an isotropic linear elastic material with Poisson's ratio $\nu = 0.2$, mass density $\rho = 2000$ kg/m^3, and Young's modulus E_m varying from 2.0 GPa to 10.0 GPa. Figures 3 to 7 show the first five frequencies of Model 1 as functions of E_m, with the soil stiffness k_w taking values between 4800 and 128000 kN/m^3, corresponding respectively to loose and dense sand [14]. As expected, for fixed k_w, the frequencies are increasing functions of Young's modulus. The first and second frequencies remain strictly below the corresponding experimental frequencies, likely due to the fact that the real system is considerably stiffer than its numerical model. For fixed E_m, the frequencies increase as soil stiffness k_w increases, but this rise becomes less evident as Young's modulus increases; for example, the first frequency increases by about 44% when E_m=2 GPa and k_w ranges from 4800 kN/m^3 to 128000 kN/m^3, while for E_m=10 GPa the growth of the first frequency is on the order of 18.5%. Furthermore, there is visibly greater influence of the soil stiffness on the two first bending frequencies than on higher-order ones. With respect to the experimental mode shapes, the MAC values [18] are consistently greater than 0.9, and their variation with soil stiffness is not appreciable.

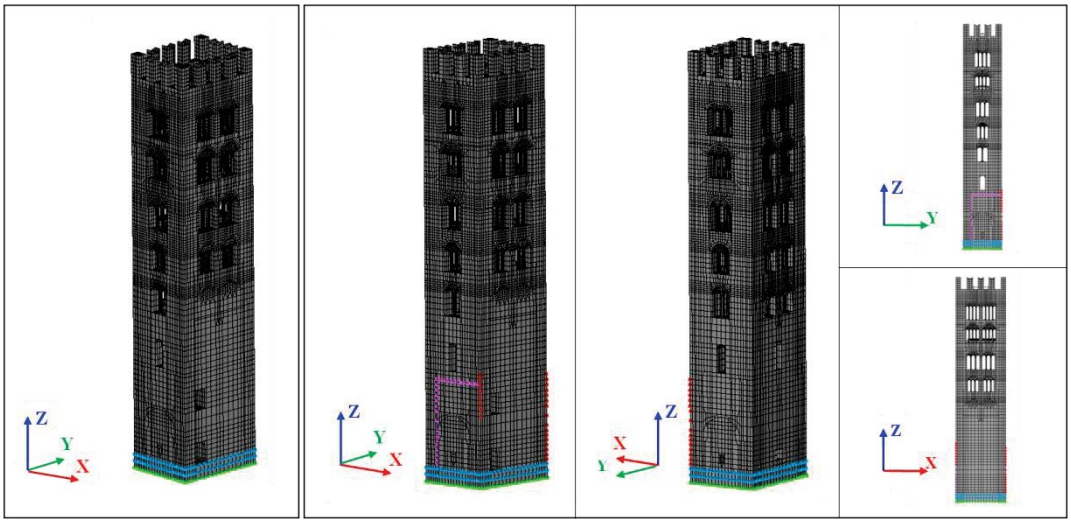

Figure 2: FE discretization of the San Frediano bell tower, model 1 (left) and model 2 (right). In model 1 and model 2 the soil is modeled as vertical springs (green) and the displacements along X and Y are prevented at the base (cyan). In model 2 the presence of the adjacent church is modeled as springs along X (red) and Y (magenta).

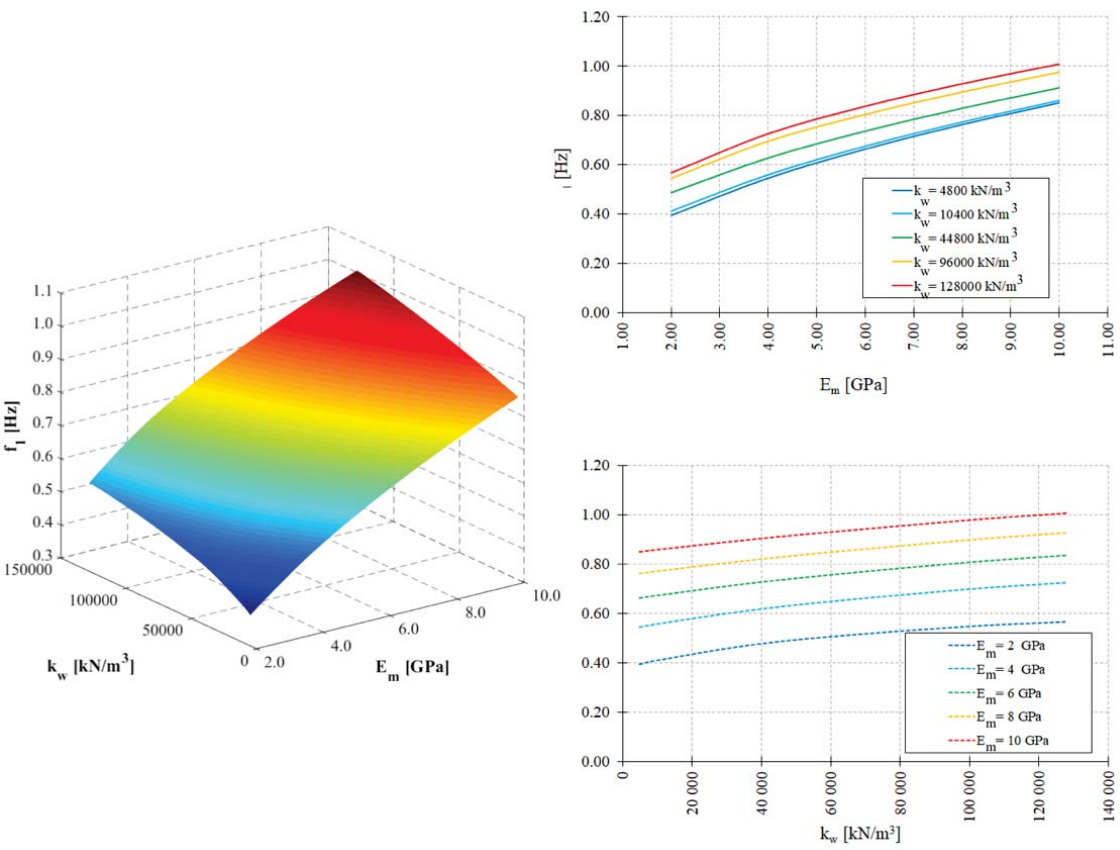

Figure 3: Model 1, first frequency as a function of Young's modulus E_m and soil stiffness k_w.

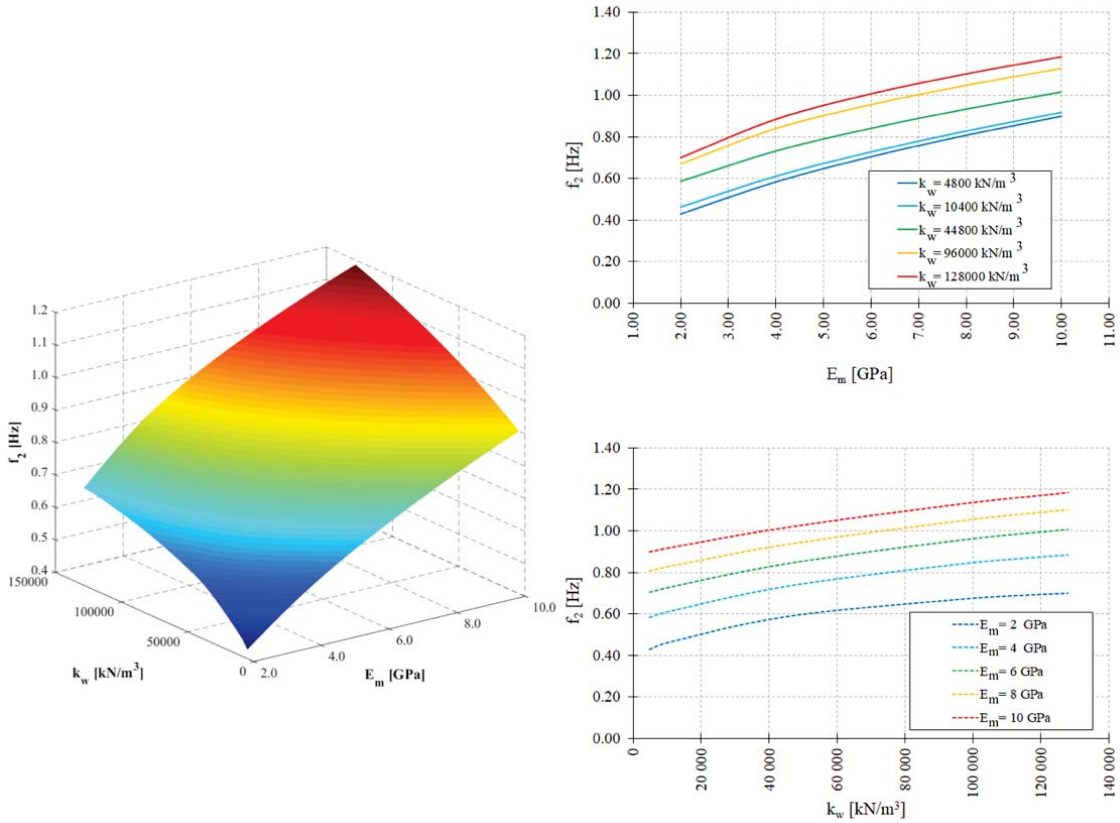

Figure 4: Model 1, second frequency as a function of Young's modulus E_m and soil stiffness k_w.

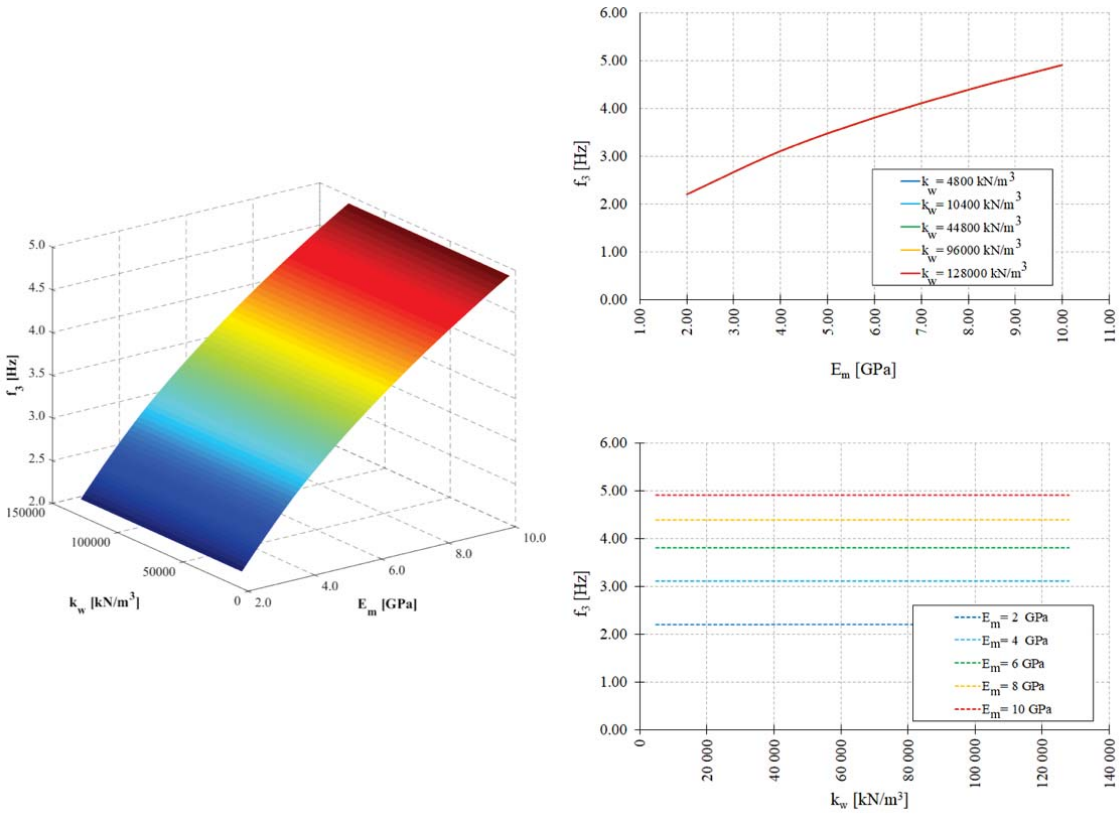

Figure 5: Model 1, third frequency as a function of Young's modulus E_m and soil stiffness k_w.

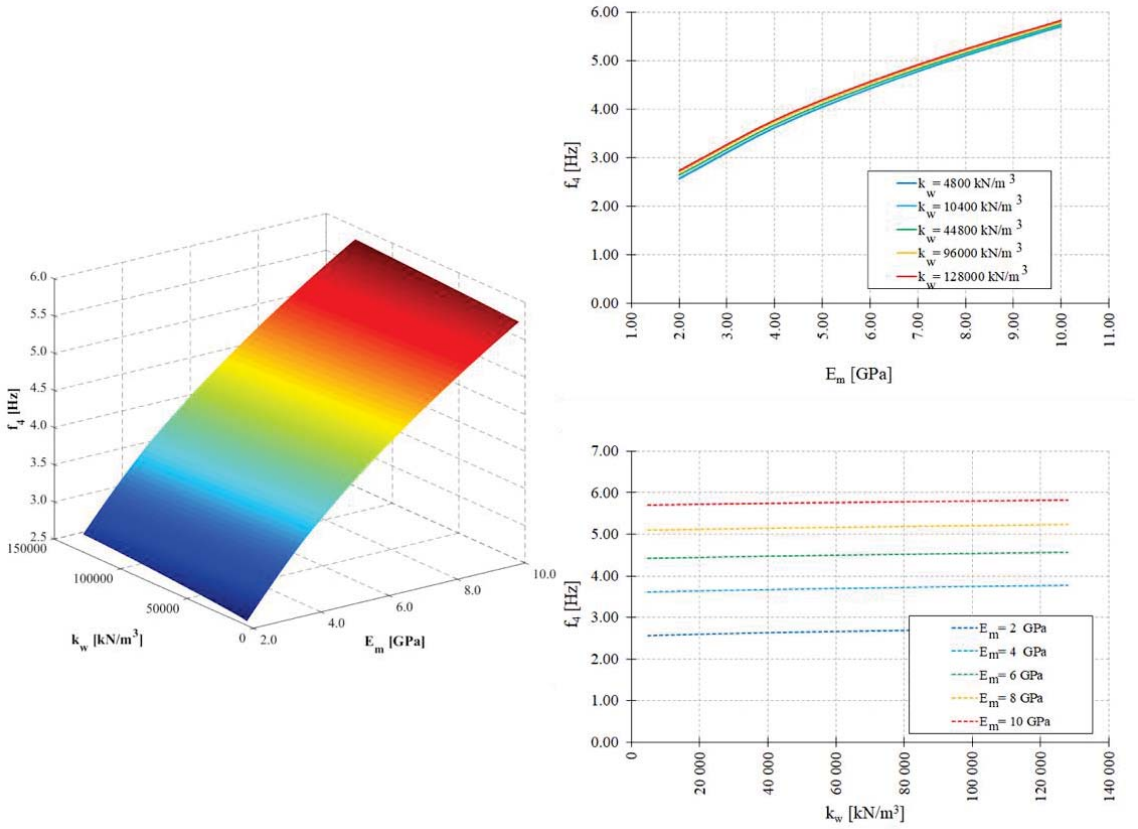

Figure 6: Model 1, fourth frequency as a function of Young's modulus E_m and soil stiffness k_w.

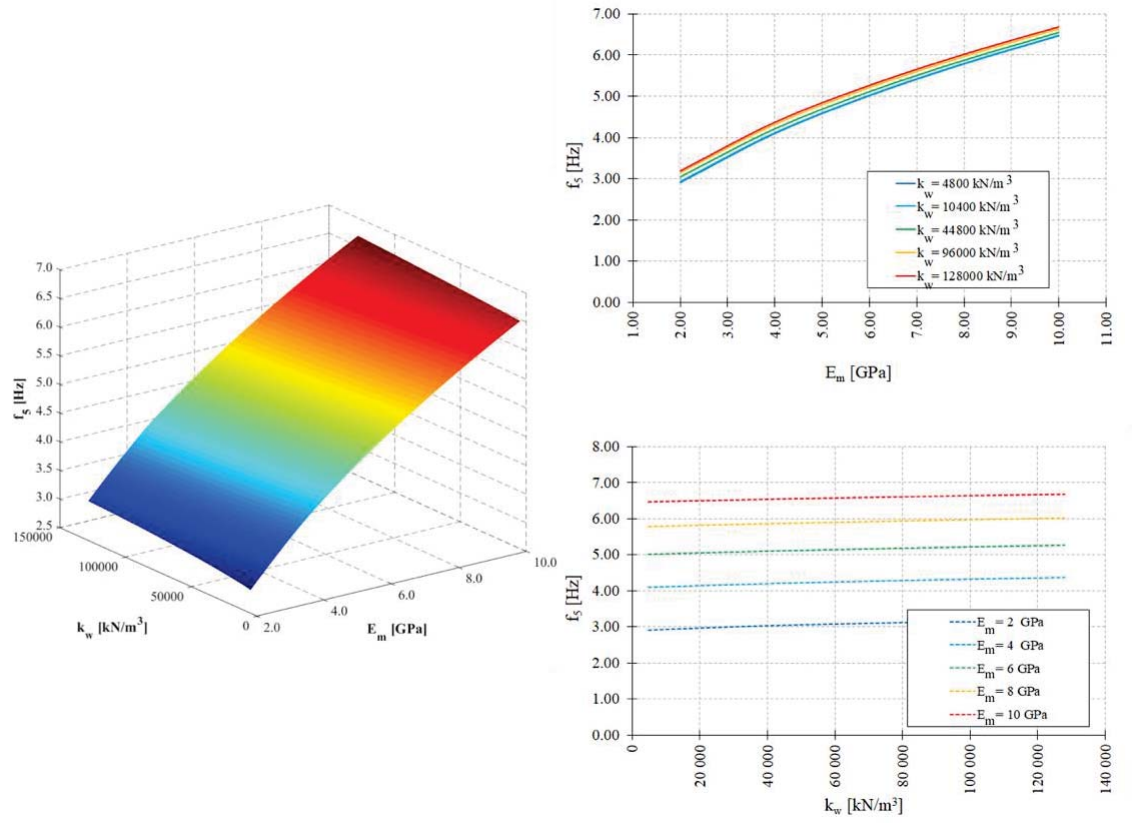

Figure 7: Model 1, fifth frequency as a function of Young's modulus E_m and soil stiffness k_w.

The model updating procedure described in [5] and [6] is conducted on Model 1 considering the unknown parameters masonry's Young's modulus E_m [GPa] and the soil stiffness k_w [kN/m^3] ranging in the intervals

$$E_m \in [1.0, 10.0] \text{ GPa}, \qquad k_w \in [4800.0, 128000.0] \text{ kN/m}^3. \tag{2}$$

The procedure provides the following values

$$E_m^{opt} = 6.61 \text{ GPa}, \quad k_w^{opt} = 1.28\ 10^5 \text{ kN/m}^3, \tag{3}$$

with k_w^{opt} coinciding with the right end of the interval in (2). The corresponding numerical frequencies and the relative errors with respect to the experimental frequencies are summarized in Table 2.

	Exp. freq. [Hz]	Num. freq. [Hz]	Relative error [%]
Mode 1	1.11	0.87	21.62
Mode 2	1.39	1.04	25.18
Mode 3	3.45	3.99	-15.65
Mode 4	4.64	4.78	-3.02
Mode 5	5.37	5.51	-2.61

Table 2: The first five numerical frequencies of Model 1 corresponding to the optimal values in (3) with the relative errors with respect to the experimental values.

The errors shown in the Table demonstrate that Model 1 is not able to capture the dynamic response of the real system.

Model 2 differs from Model 1 in that elastic springs are now applied 12.50 m above the base to account for the adjacent church walls. Let us fix the elastic constants of the springs: k_X = 7.75 10^7 N/m for the springs along X (red in Figure 2) and k_Y = 1.5 10^8 N/m for the springs along Y (magenta in Figure 2). These constants have been determined by considering the presence of the adjacent church, whose walls have a shear stiffness of about 2.4 10^9 N/m in the Y direction and 1.89 10^9 N/m in the X direction. As for the church's constituent material, a shear modulus of 1.25 GPa and a Poisson's ratio of 0.2 have been assumed [20].

Figures 8 to 12 show the first five frequencies of Model 2 as functions of E_m and soil stiffness k_w. Dashed lines represent the experimental frequency values.

As in Model 1, for fixed k_w, the frequencies are increasing functions of Young's modulus and for fixed E_m the frequencies increase with increasing soil stiffness k_w. However, in this case the growth is more or less steady; for example, the first frequency increases by about 6.45% when E_m=2 GPa and the value of k_w is increased from e 4800 kN/m^3 to 128000 kN/m^3, while for E_m=10 GPa the corresponding increase is about of 5.84%.

In this case, unlike in Model 1, the five frequencies of the tower are less influenced by soil stiffness. In fact, the tower's bending stiffness is mainly influenced by the constraint of the adjacent walls, while the vertical deformability of the soil under the base seems to make a negligible contribution to the overall deformability of the system. In this case, also unlike in Model 1, the experimental frequency values intercept the surfaces of the numerical frequencies, thus indicating that Model 2 can provide a good approximation of the actual dynamic behavior of the tower.

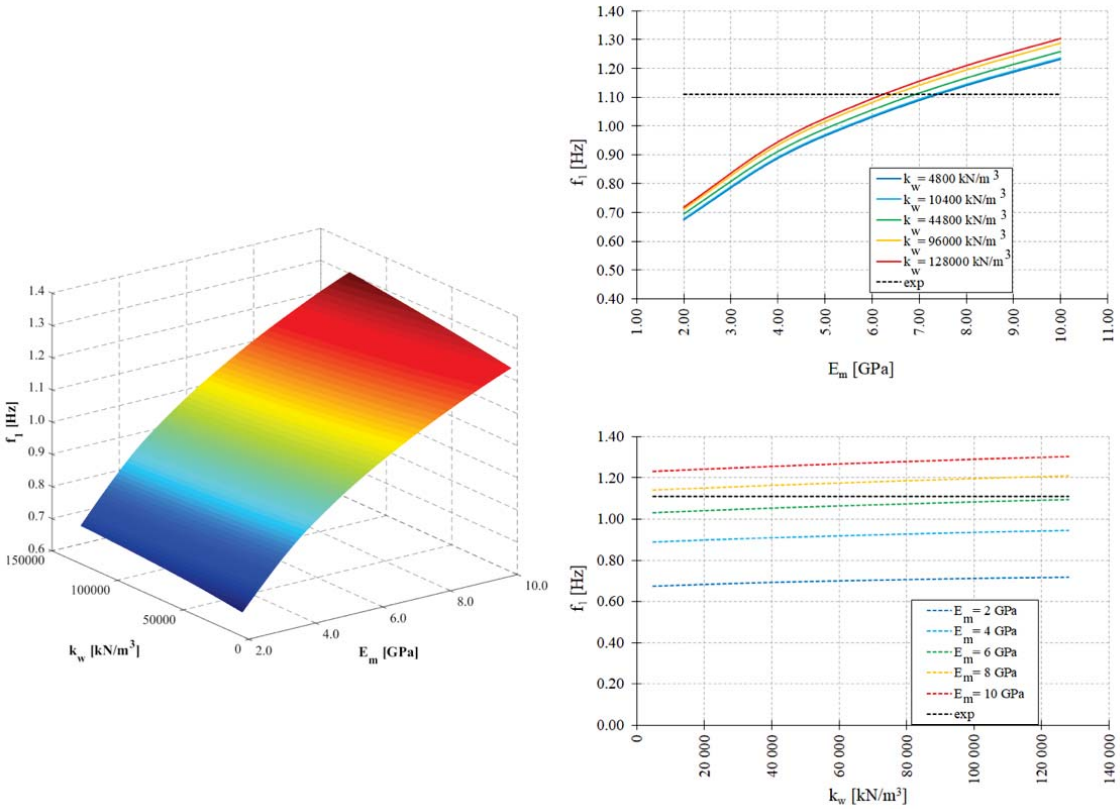

Figure 8: Model 2, first frequency as a function of Young's modulus E_m and soil stiffness k_w.

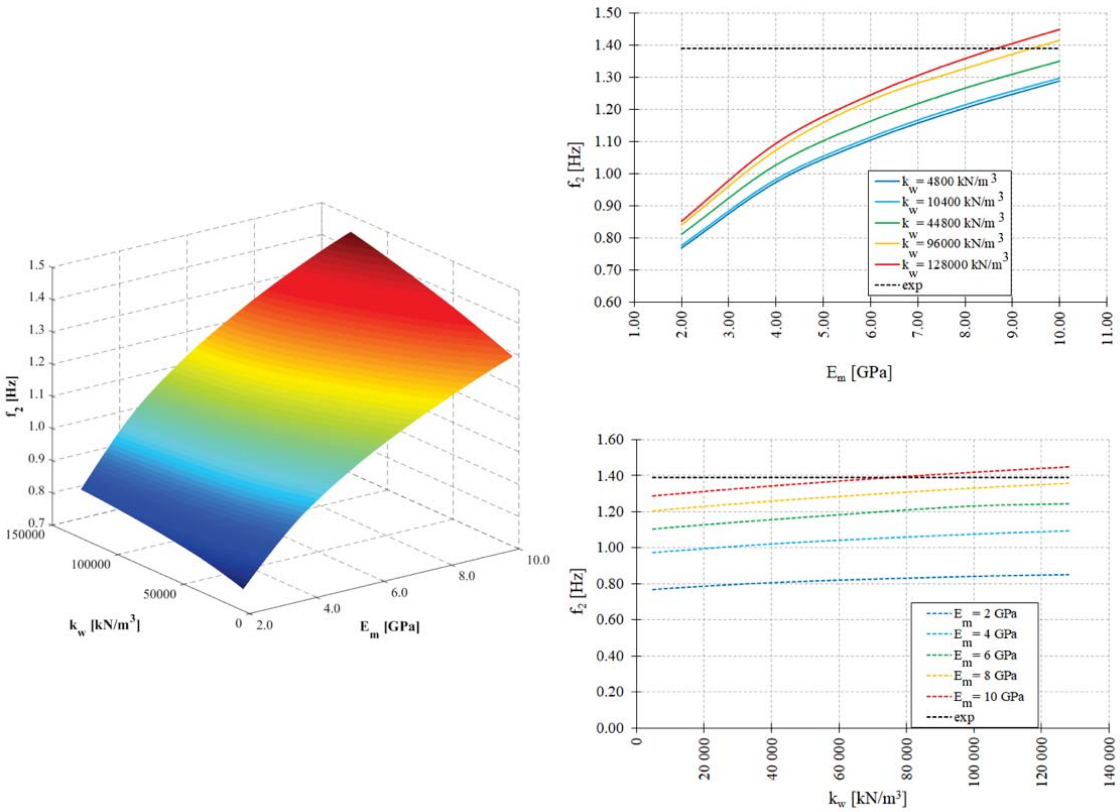

Figure 9: Model 2, second frequency as a function of Young's modulus E_m and soil stiffness k_w.

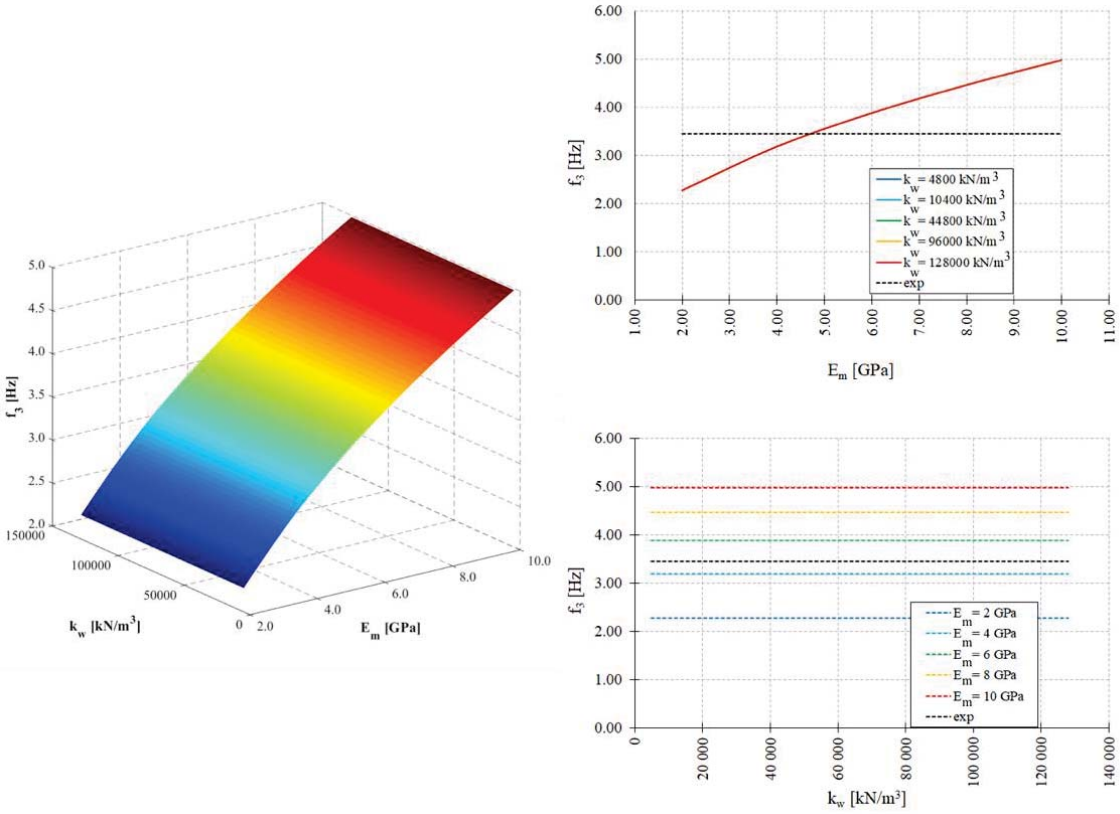

Figure 10: Model 2, third frequency as a function of Young's modulus E_m and soil stiffness k_w.

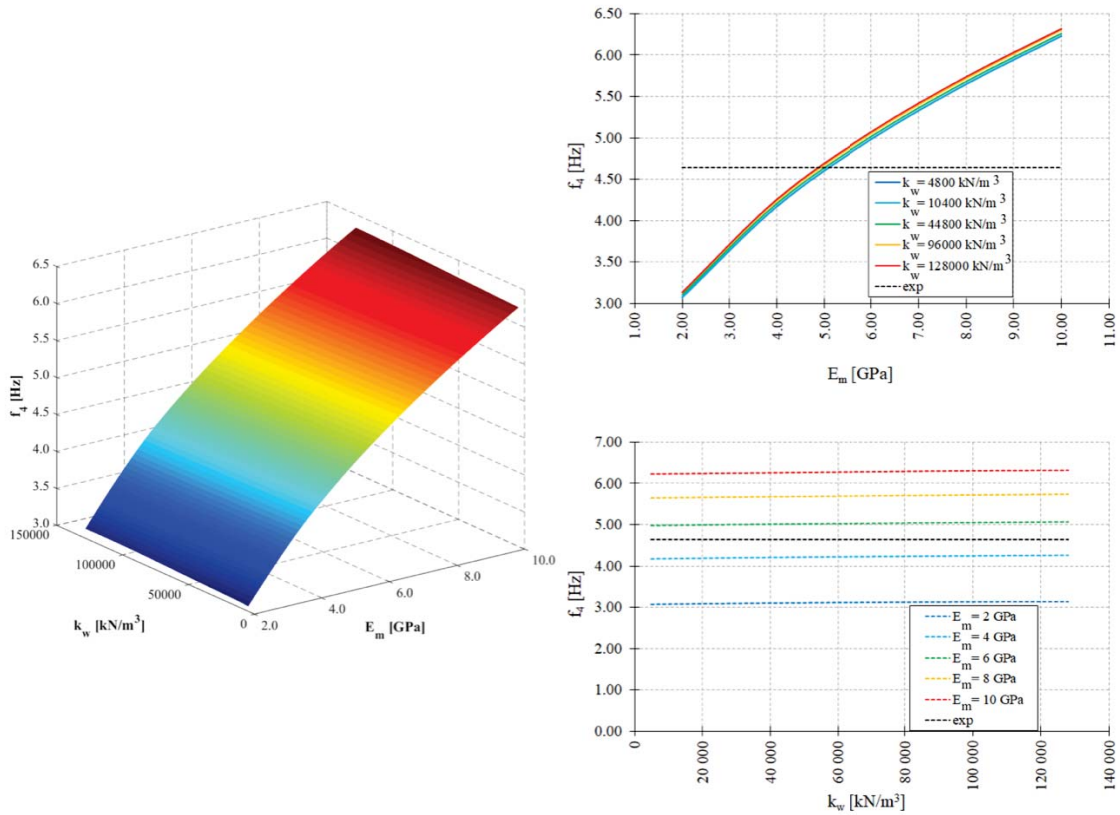

Figure 11: Model 2, fourth frequency as a function of Young's modulus E_m and soil stiffness k_w.

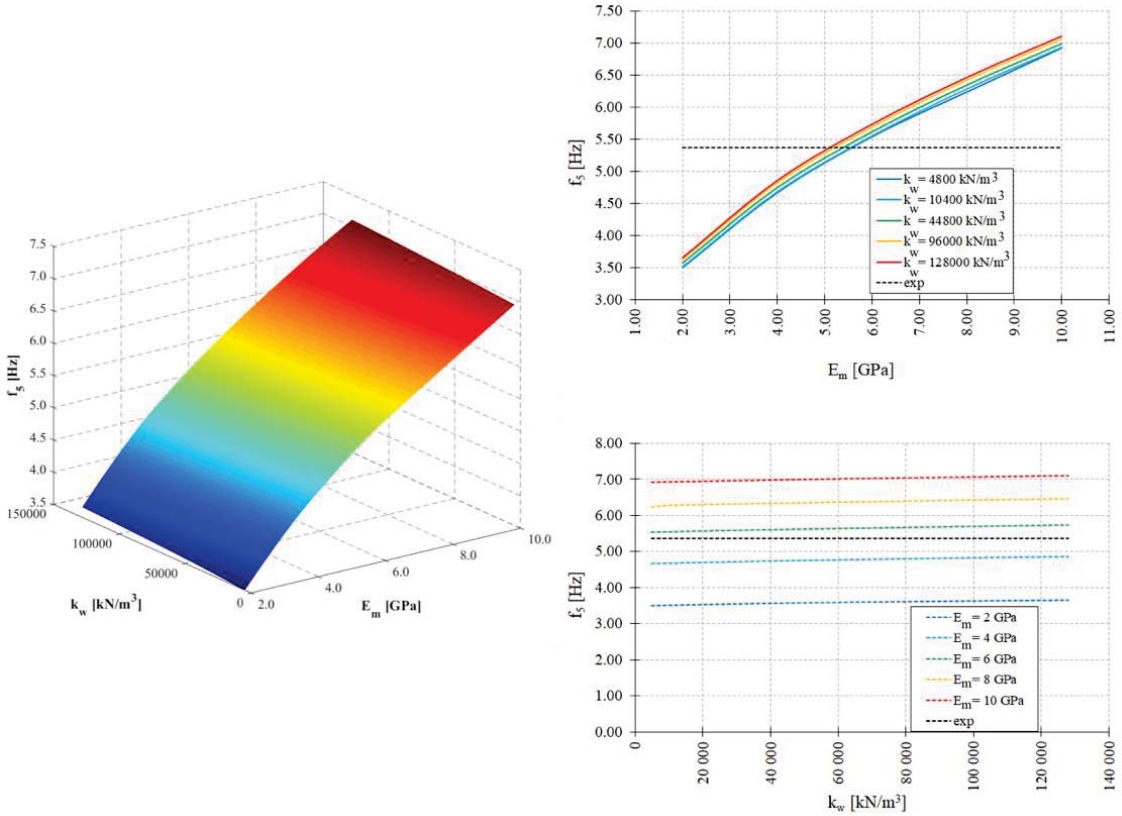

Figure 12: Model 2, fifth frequency as a function of Young's modulus E_m and soil stiffness k_w.

The results of the model updating procedure conducted on Model 2, for E_m [GPa] and k_w [kN/m^3] varying in the intervals given in (2), as in the case of Model 1, are the following

$$E_m^{opt} = 5.327 \text{ GPa}, \qquad k_w^{opt} = 1.28\ 10^5 \text{ kN/m}^3, \tag{4}$$

with k_w^{opt} coinciding with the right end of the interval in (2). The corresponding numerical frequencies and the relative errors with respect to the experimental frequencies are summarized in Table 3.

	Exp. freq. [Hz]	Num. freq. [Hz]	Relative error [%]
Mode 1	1.11	0.98	11.71
Mode 2	1.39	1.29	7.19
Mode 3	3.45	3.65	-5.80
Mode 4	4.64	4.64	0.0
Mode 5	5.37	5.71	-6.33

Table 3: The first five numerical frequencies of Model 2 corresponding to the optimal values in (4) with the relative errors with respect to the experimental values.

The errors in this case are still consistent, but lower (about one half) than those shown in Table 2 for Model 1.

Finally, if model updating is performed considering as unknown parameters E_m, k_w and the elastic constants k_{X1}, k_{X2} and k_Y of the lateral springs as well, for k_{X1}, k_{X2} and k_Y [N/m] varying in the interval [1.0 10^8, 7.0 10^{21}], then the optimal values are

$$E_m^{opt} = 4.53 \text{ GPa}, \quad k_w^{opt} = 0.69389\ 10^5 \text{ kN/m}^3, \quad k_{X1}^{opt} = k_{X2}^{opt} = k_Y^{opt} = 3.5\ 10^{21} \text{ N/m}. \tag{5}$$

The corresponding numerical frequencies and the relative errors with respect to the experimental frequencies are reported in Table 4.

	Exp. freq. [Hz]	Num. freq. [Hz]	Relative error [%]
Mode 1	1.11	1.13	-1.80
Mode 2	1.39	1.39	0.0
Mode 3	3.45	3.50	-1.45
Mode 4	4.64	4.97	-7.11
Mode 5	5.37	6.05	-12.66

Table 4: The first five numerical frequencies of Model 2 corresponding to the optimal values in (5) with the relative errors with respect to the experimental values.

For the sake of comparison, we recall the results obtained in [13] considering the tower clamped at the base and assuming that the horizontal displacements of the points adjacent to the church (magenta and red points in Figure 2) are prevented. The model updating conducted in [13] with E_m as the unknown parameter yielded the following optimal value

$$E_m^{opt} = 4.20 \text{ GPa}, \tag{6}$$

and the frequencies reported in Table 5.

	Exp. freq. [Hz]	Num. freq. [Hz]	Relative error [%]
Mode 1	1.11	1.18	-6.31
Mode 2	1.39	1.43	-2.88
Mode 3	3.45	3.37	-2.32
Mode 4	4.64	4.93	-6.25
Mode 5	5.37	6.00	-11.73

Table 5: The first five numerical frequencies of the tower clamped at the base with the horizontal displacements prevented [13] corresponding to the optimal value in (6) with the relative errors with respect to the experimental values.

Thus, a comparison of Table 4 to Table 5 shows that taking into account both the deformability of the adjacent constraints and the soil–structure interaction allows for appreciably fine-tuning the model and improving the simulation of the experimental results.

4 CONCLUSIONS

This paper is devoted to studying the effects of soil deformability and adjacent buildings on the dynamic behavior of masonry towers. The investigation relies on the use of some experimental results collected during a long-term dynamic monitoring campaign on the San Frediano bell tower in Lucca and an automated model updating procedure implemented in the NOSA-ITACA code.

The paper shows that soil stiffness can significantly affect the dynamic behavior of isolated towers, while in the case of towers connected to other buildings, the model's global stiffness is very sensitive to the kind of connection with the adjacent structures. The use of automated model updating procedures can help fine-tune the FE model, and enables estimating the stiffness of both the soil and the lateral constraints.

Keywords: Masonry arch bridge, Ambient Vibration Tests, Finite Element Analysis.

Abstract. *This paper presents the preliminary results of an ongoing research on a masonry arch bridge in the neighborhood of Todi (Umbria, Italy). Forced and ambient vibration tests (AVTs) were carried out in year 2016 on the masonry arch bridge. High-sensitivity piezoelectric accelerometers, a laser vibrometer and a radar interferometer were used to record the structural response. The structure exhibited typical mechanical deterioration phenomena: longitudinal cracks below the vault, material detachment in the voussoir as well in the spandrel wall and damage of the abutments. The damage level of the masonry was even worsened by vegetation grown between the cracks of the stones. The Enhanced Frequency Domain Decomposition (EFDD) method was used to identify the experimental natural frequencies and mode shapes. The experimental modal properties were finally used to calibrate an accurate Finite Element (FE) numerical model developed using a photogrammetric survey based on high-resolution images provided by UAV (Unmanned Aerial Vehicle) . In 2017 a restoration process was started aimed to strengthen the tested structure. The experimental tests were repeated at the end of the restoration process. In particular, AVTs were carried out using high-sensitivity accelerometers located in the same positions used before the restoration process. In this paper, the comparison of the natural frequencies and the vibration modes, obtained be-fore and after the restoration process, is presented in order to discuss the effect of severe dam-age on the masonry arch bridge. Furthermore, this comparison is used to gather information on the effect of the restoration activities on the dynamic properties of the masonry arch bridge. The obtained results are crucial for calibrating suitable numerical models in both the different stages using a multidisciplinary approach, which uses UAV technology and photogrammetry techniques.*

1 INTRODUCTION

Masonry arch bridges are one of the most common structural typology present in the world-wide cultural heritage. Today many of these ancient constructions are characterized by severe damage conditions due to natural hazards, foundation settlements and inherent degradation with time resulting in loss of strength, stiffness and physical properties [1, 2, 3, 4]. All these factors can affect negatively the structural performance of this kind of constructions often requiring repair and/or strengthening. Over the past decades a large number of experimental studies have been devoted to the investigation of the effectiveness of different strengthening works applied to ancient masonry building but only limited studies used full-scale structures.

Finite element (FE) models can be considered as a predominant tool to investigate the structural performance of historic masonry structures and several contributions can be found in literature [5, 6]. In spite of this, the numerical modeling of historic masonry structures is still a challenging task since they may be characterized by a significant level of complexity in terms of geometry, existing damage and mechanical properties [7, 8, 9, 10]. Modern survey technique such as terrestrial laser scanning and photogrammetry can be suitably used for describing accurately the geometric complexity of the structural members and the irregularities consisting in lacking material volumes due to a severe damage [11, 12, 13]. The proper estimation of the mechanical properties can be performed by means of expensive and invasive procedures, often impossible to be carried out [13]. For this reason, AVTs can be used to extract data on the modal properties of the tested structures [14, 15, 16, 17] and the unknown numerical model parameters can be estimated by solving optimization procedures aimed at minimizing the distance between the model predicted and the measured modal parameters [18, 19, 20, 21, 22, 23, 24].

This work presents the results of an ongoing research on a masonry arch bridge in the neighborhood of Todi (Umbria, Italy). The bridge is characterized by an irregular segmental arch, with a span and a rise higher than 10 m and 4 m, respectively. The structure exhibited typical mechanical deterioration phenomena consisting in cracks below the vault, material detachment in the side walls and the arches and damage of the West and east abutment. The damage level of the masonry was even worsened by vegetation grown between the cracks of the stones (Figure 1(a-b)). In 2017 a restoration process was started mainly consisting in a conservative restoration of the walls (cleaning, coating and grouting) and the planking level and a structural reinforcement of the vault and the masonry walls (Figure 2(a-b)).

The main purpose of this research is to determine the strengthening effects on the dynamic

Figure 2: Images of the historic masonry arch bridge after the strengthening: general view of the South side (a) and wall (b).

properties of this full-scale severely damaged masonry structure before and after strengthening. AVTs were carried out on Case A (i.e. severely damaged bridge) and Case B (i.e. strengthened bridge). Two FE models were developed starting from the digital geometric survey: one derived from photogrammetric survey that accurately describes the damage state (lack of material) and one regularizing the surfaces describing the post-strengthening state. The modal properties identified from both numerical models and the experimental works are compared highlighting the effect of important structural strengthening on the dynamic properties accounting for an accurate geometric description of the geometric irregularities due to severe damage.

2 EXPERIMENTAL MEASUREMENTS

The dynamic characterization of the masonry arch bridge before and after strengthening has been performed by Enhanced Frequency Domain Decomposition (EFDD) [25, 26] using vibration response in operating conditions and classical contact measurements. For the sake of clarity in the following the experimental results obtained before and after strengthening will be referred to as ”Case A”and ”Case B”, respectively.

2.1 Case A: AVTs for severely damaged masonry bridge

AVTs were carried out on the severely damaged masonry arch bridge in 2016 [28]. The dynamic response of the tested structure was measured using nine uni-axial accelerometers (model PCB 3939B12, 10 V/g sensitivity) located in different positions in order to obtain three different setups, to be used for the identification of vertical, horizontal and torsional vibration modes. The three sensor layouts are reported in Figure 3(a-b-c). Three sensors were installed at the keystone section of the arch to be used as a reference system for the analysis: two sensors were placed in the South side, giving measurements in both vertical and transversal directions while the third sensor was placed in the North side giving measurements in the vertical direction (red arrows in Figure 3(a-b-c)).

The testing methodology consisted in three different measurements, each recording 900 s time series with a sampling frequency of 1653 Hz, which is the minimum sampling frequency available for the used system, NI 9234 module with cDAQ 9188, due to inner anti aliasing filter. Since the power spectral density matrix estimated from the raw acceleration data showed a sig-

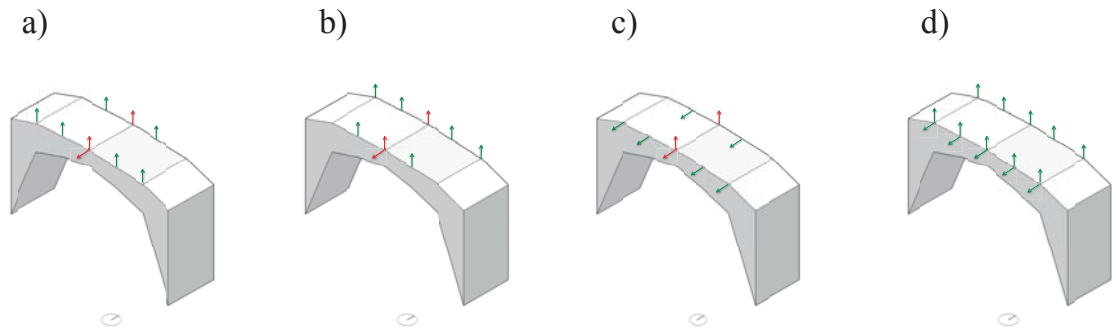

Figure 3: AVTs before strengthening: accelerometers arrangement used in Setup#1 (a), Setup#2 (b) and Setup#3 (c). Accelerometers arrangement for the AVTs after strengthening (d). Reference sensors are indicated in red.

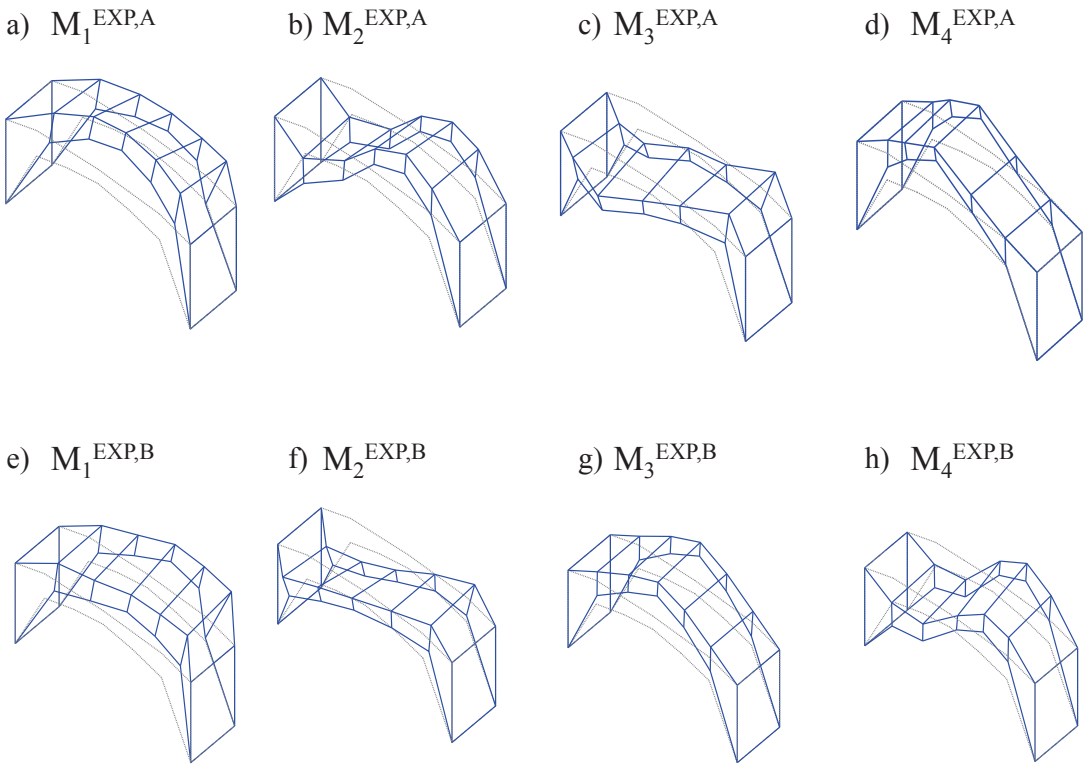

Figure 4: First four vibration modes of the masonry arch bridge before (a-d) and after (e-h) strengthening.

nificant frequency content between zero and 20 Hertz, the recorded data were downsampled to 27.55 Hz, offsets and drifts were removed. A low pass filter of order 3 with a cut-off frequency equal to 27.548 Hz was also applied.

The obtained natural frequencies are summarized in Table 1 and the corresponding vibration modes are reported in Figure 4(a-d). The The first four vibration modes are satisfactory identified from the AVTs. Two Out-of-Plane (OoP) modes ($M_1^{EXP,A}$, $M_3^{EXP,A}$) and two In-Plane (IP) modes ($M_2^{EXP,A}$, $M_4^{EXP,A}$) can be distinguished. Some modes present nearly symmetric configuration ($M_1^{EXP,A}$, $M_4^{EXP,A}$), while others are antisymmetric ($M_2^{EXP,A}$, $M_3^{EXP,A}$).

Given a set of experimental modal vectors it is possible to estimate the auto-MAC matrix

Table 1: Modal features obtained from experimental tests before strengthening.

Mode	$f[Hz]$	Mode's type
$M_1^{EXP,A}$	8.77	1^{st} OoP-Symmetric
$M_2^{EXP,A}$	13.93	1^{st} IP-Antisymmetric
$M_3^{EXP,A}$	14.72	2^{nd} OoP-Antisymmetric
$M_4^{EXP,A}$	17.76	2^{nd} IP-Symmetric

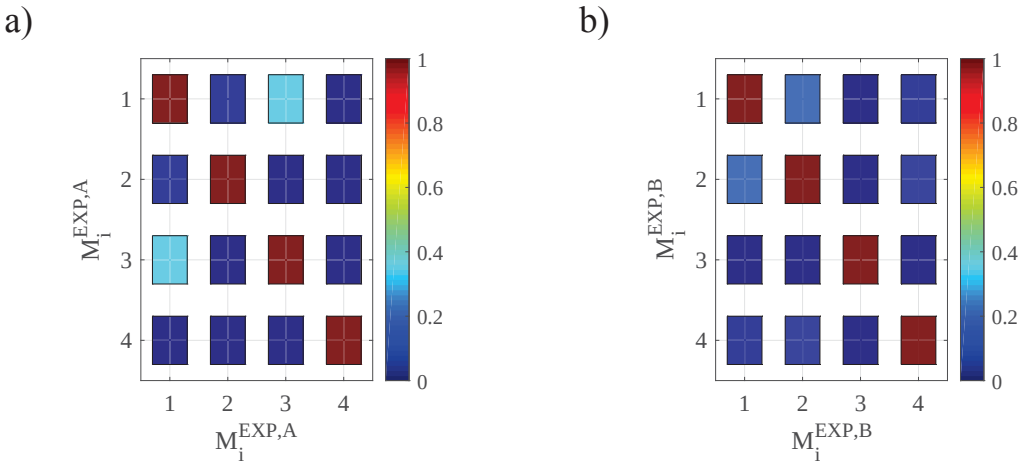

Figure 5: Components of the auto-MAC matrix evaluated on the identified natural mode shapes before (a) and after (b) strengthening.

[27], whose components are the auto-MAC numbers. The auto-MAC numbers are able to measure the degree of correlation between pair of modal vectors, assuming values equal to 1 or 0 for perfect correlation or no correlation, respectively. The auto-MAC numbers are very sensitive to the load non-stationarities and to the noisy reference modal vector. For this reason the auto-MAC is used in order measure the quality of the measurements. The optimal auto-MAC matrix should be characterized by values equal to one on the diagonal and zero otherwise. In this case study, the diagonal terms in diagonal auto-MAC matrix are equal to 1 since each modal vector is paired with itself, while the out-of-diagonal components are not all equal to 0 (Figure 5(a)). It should be noted that the auto-MAC number between the two OoP modes is higher than 0.4, that can be due the low level of vibrations and the related noise in the reference modal vectors, as well as to the combination process of three different setups.

2.2 Case B: AVT for strengthened masonry arch bridge

AVTs were carried out on the strengthened masonry arch bridge in 2017. The dynamic response of the tested structure was measured using fifteen uni-axial accelerometers (model PCB 3939B12, 10 V/g sensitivity).

Accelerometers were placed on both sides of the deck giving measurements in both vertical and transversal direction according to Figure 3(d). The testing methodologies consisted in two different measurements, each recording 1800 s time series with a sampling frequency of 200 Hz. Since the power spectral density matrix estimated from the raw acceleration data showed a significant frequency content between zero and 40 Hertz, the recorded data were downsampled to 50 Hz and offsets and drifts were removed.

Table 2: Modal features obtained from experimental tests after strengthening.

Mode	$f[Hz]$	Mode's type
$M_1^{EXP,B}$	10.96	1^{st} OoP-Symmetric
$M_2^{EXP,B}$	17.78	2^{nd} OoP-Antisymmetric
$M_3^{EXP,B}$	22.62	1^{st} IP-Symmetric
$M_4^{EXP,B}$	32.48	2^{nd} IP-Antisymmetric

The obtained natural frequencies are summarized in Table 2 and the corresponding vibration modes are reported in Figure 4(e-h). The first four vibration modes are satisfactory identified from the AVTs. Two Out-of-Plane (OoP) modes ($M_1^{EXP,B}$, $M_2^{EXP,B}$) and two In-Plane (IP) modes ($M_3^{EXP,B}$, $M_4^{EXP,B}$) can be distinguished. Some modes present nearly symmetric configuration ($M_1^{EXP,B}$, $M_3^{EXP,B}$), while others are clearly antisymmetric ($M_2^{EXP,B}$, $M_4^{EXP,B}$). Figure 5(b) show the auto-MAC matrix characterized by diagonal elements equal to 1 with the out-of-diagonal components all lower than 0.20 indicating good quality measurement.

2.3 Comparison

Figure 6 (a) compares the vibration modes obtained from the AVTs before and after strengthening in terms of MAC matrix. The MAC matrix has a similar meaning of the auto-MAC: the MAC matrix components are the MAC numbers estimated from each pair of vibration modes obtained from the experimental measurements carried out before and after strengthening. The diagonal MAC terms are equal to zero with the exception of the MAC value of the pair given by the first OoP symmetric mode $M_1^{EXP,A}$ and $M_1^{EXP,B}$ (equal to 0.6). The MAC value of the pair given by $M_2^{EXP,A}$ and $M_4^{EXP,B}$ (IP-Antisymmetric) is equal to 0.83; the MAC value of the pair given by $M_3^{EXP,A}$ and $M_2^{EXP,B}$ (OoP-Antisymmetric) is equal to 0.56 and finally the MAC value of the pair given by $M_4^{EXP,A}$ and $M_3^{EXP,B}$ (IP-symmetric) is equal to 0.86. This indicates a shift between the natural frequencies and the corresponding vibration modes caused by the the mass and the stiffness change due to the important structural strengthening.

Figure 6 (b) compares the natural frequencies identified by the measurements before and after strengthening in terms of percentage relative differences $\Delta = (f_i^{EXP,B} - f_i^{EXP,A})/f_i^{EXP,B} \times 100$. These percentage differences have been estimated reordering the natural frequencies such that they correspond to the same mode shape using the maximum MAC number. It should be noted that an increase of the natural frequencies higher than 15 % occur in all cases, with a maximum percentage difference higher than 55 % occurring for the IP-Antisymmetric mode shape (i.e. $f_2^{EXP,A}$ and $f_4^{EXP,B}$).

3 FINITE ELEMENT ANALYSIS

Two preliminary FE models have been set up in ABAQUS [29] environment in order to numerically reproduce the modal behavior of the tested structure before and after strengthening.

The first numerical model will be referred to as "Model A" and it corresponds to the severely damage state (Figure 7(a)). The geometry was carefully defined based on a photogrammetric survey provided by drones as an assembly of five main substructures, namely the arches, the vault, the side walls, the filling and the gallery. It should be noted that the photogrammetric based survey provided an accurate representation of the bridge geometry with respect to its external envelope, allowing to model some important details, such as the lack fo materials in the spandrel, the abutments and the arches. All these volumes were modeled extruding the hole profile obtained from the survey with a constant depth. The initial mechanical characteristics

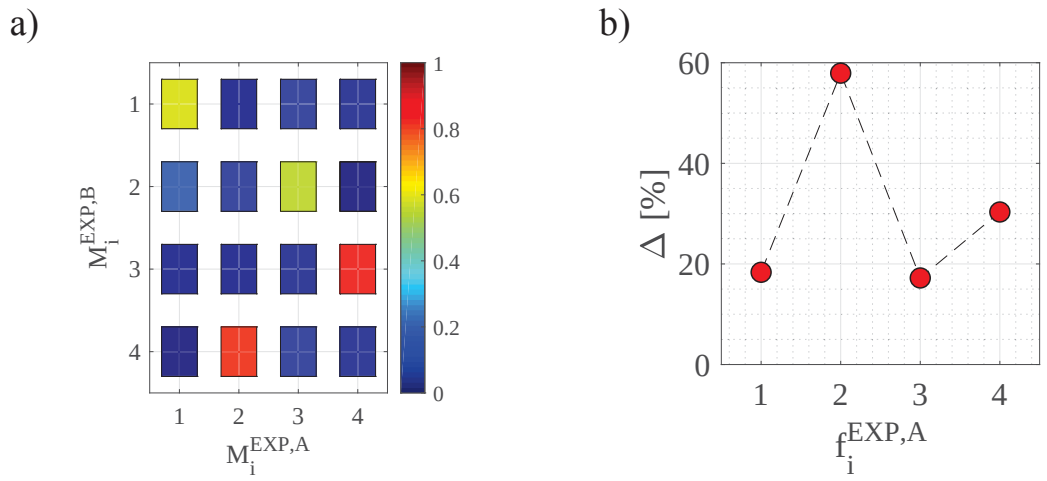

Figure 6: Comparison between the experimental results obtained before and after strengthening: MAC matrix (a) and percentage relative difference in terms of modal frequencies (b).

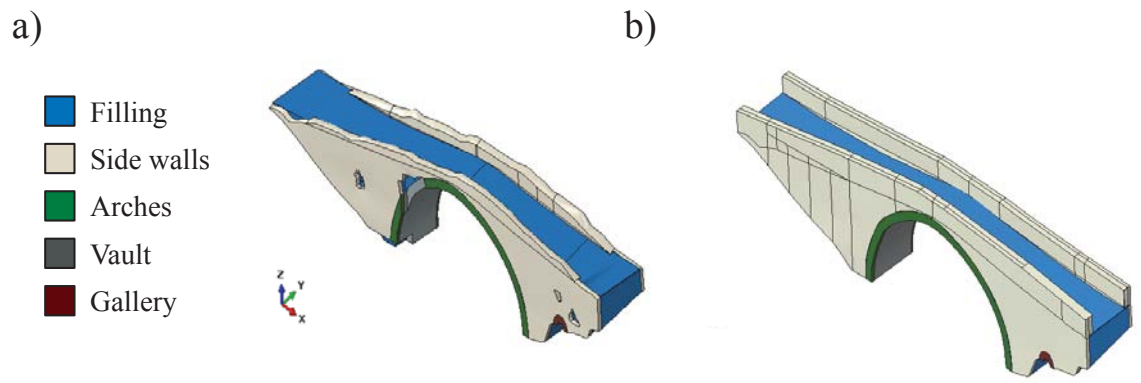

Figure 7: 3D FE models before and after strengthening: Model A (a) and Model B (b).

of all the five substructures are selected according to the prescription of the recent Italian instructions [30, 31, 32]. Table 3 provides a summary of the of the main mechanical properties of the chosen materials in terms of Young's modulus E and mass density ρ. The Poisson's ratio was taken constant for all the materials with a value equal to 0.2. The second numerical model will be referred to as "Model B" and it corresponds to the strengthened state (Figure 7(b)). The geometry was obtained regularizing the external surfaces of Model A. In this case the initial mechanical characteristics of all the five substructures are set according to the prescription of the recent Italian instructions multiplied by a coefficient α, able to account for the good condition of the mortar (Table 3).

The first four mode shapes of the masonry arch bridge in its severely damaged state are shown in Figure 8(a-d). It is worth noting that the second and the third numerical mode shapes ($M_2^{FEM,A}$ and $M_3^{FEM,A}$) are inverted with respect to the experimental modes. This is mainly due to the geometric irregularities considered in the detailed FE model and to the severely damaged state of the vault with several cracks and lacking material. Table 4 compares the natural frequencies identified by the Model A with the measured ones in terms of relative differences

Table 3: Mechanical parameters of the materials used in the FE models: elastic moduli E, mass density ρ and correction coefficient α.

Structural Part	$E[MPa]$	$\rho[t/m^3]$	α
Arches	2800	2.2	1.2
Vault	2400	2.2	1.2
Side walls	1230	2.0	1.4
Filling	870	1.9	1.5
Gallery	1500	1.8	1.5

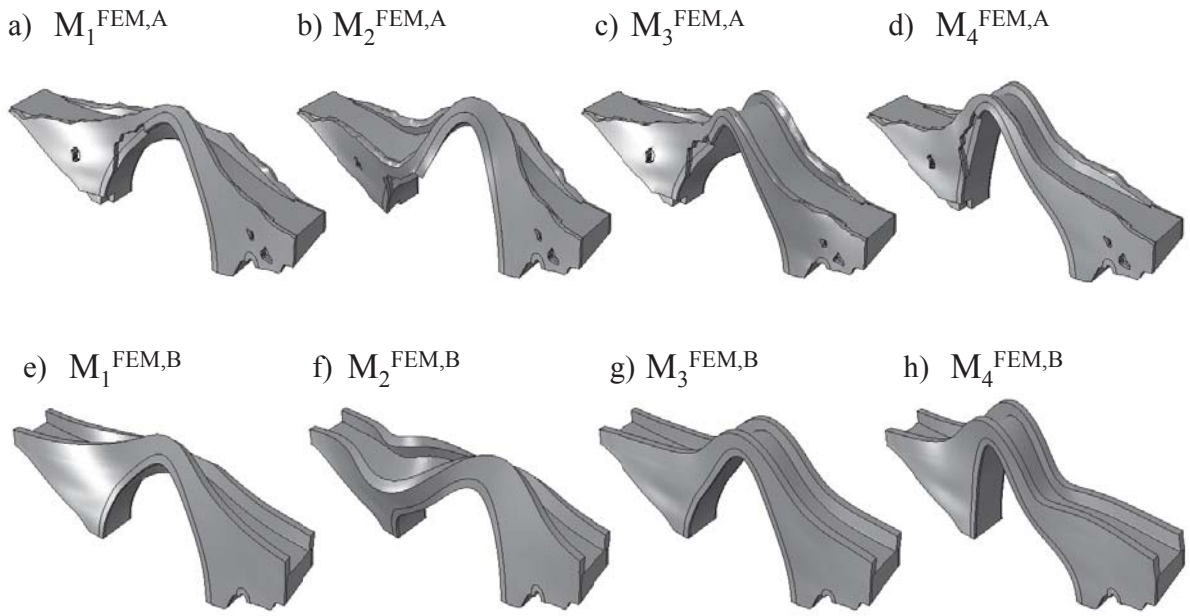

Figure 8: First four numerical mode shapes of the masonry arch bridge estimated from the FE models before (a-d) and after (e-h) strengthening .

$\Delta = (f_i^{EXP,A} - f_i^{FEM,A})/f_i^{EXP,A} \times 100$. Also in this case the natural frequencies are reordered such that that they correspond to the same mode shape accounting for the mode shape/natural frequency switching. It can be seen that the maximum relative difference occur for the second OoP-antisymmetric mode (i.e. $M_3^{EXP,A}$, $M_2^{FEM,A}$).

The first four mode shapes of the masonry arch bridge in its strengthened state are shown in Figure 8(e-h). Figure shows that the mode shapes obtained are the same of those obtained experimentally. Comparison of the numerically and experimentally identified natural frequencies are shown in Table 5 in terms of $\Delta = (f_i^{EXP,B} - f_i^{FEM,B})/f_i^{EXP,B} \times 100$. The maximum error between the natural frequencies is obtained for the second IP-antisymmetric mode, higher than 33 %.

Table 4: Comparison between experimental and initial numerical natural frequencies of Model A.

Mode	$f^{EXP,A}$	$f^{FEM,A}$	$\Delta[\%]$
1^{st} OoP-Symmetric	8.77	8.69	0.82
1^{st} IP-Antisymmetric	13.93	15.31	9.90
2^{nd} OoP-Antisymmetric	14.72	14.70	0.14
2^{nd} IP-Symmetric	15.76	16.01	1.53

Table 5: Comparison between experimental and initial numerical natural frequencies of Model B.

Mode	$f^{EXP,B}$	$f^{FEM,B}$	$\Delta[\%]$
1^{st} OoP-Symmetric	10.96	10.86	0.92
2^{nd} OoP-Antisymmetric	17.78	18.47	3.82
1^{st} IP-Symmetric	22.62	20.20	10.69
2^{nd} IP-Antisymmetric	32.48	21.69	33.22

4 CONCLUSION

The objective of this study was to carry out AVTs on the damaged and the strengthened full-scale masonry arch bridge in order to assess the effect of strengthening on the dynamic properties using both measurements and numerical analyses.

From the experimental measurements four natural frequencies were identified within the range $[8.77 - 17.76]$ Hz and $[10.96 - 32.48]$ Hz respectively for the severely damaged (Case A) and the strengthened (Case B) masonry arch bridge; further two IP and two OoP (symmetric and antisymmetric) vibration modes were identified in both cases. When the dynamic properties obtained from the measurements carried out in the two different cases are compared to each others two majors conclusions can be drawn: first, natural frequencies obtained in Case B were significantly higher than those obtained in Case A; second, after the strengthening the obtained vibration modes were more distinctive and natural frequency/vibration mode switchings were observed for the two IP modes and the second OoP antisymmetric mode.

The results obtained from the measurements were than compared to the results obtained from the numerical analysis starting from two different preliminary FE models: one able to describe the geometric irregularities due to the presence of existing damage and one describing the post strengthened state. It turns out the the adopted simulations are in both cases able to reproduce the modal behavior of the tested structure; natural frequencies and mode shapes match their experimental counterparts although in the post strengthened scenario the model predicted natural frequencies relative to the two IP vibration modes were significantly underestimated.

Keywords: Architectural heritage, geomatics, ambient vibration test, dynamic identification, model updating, numerical simulation

Abstract. *The development of realistic numerical models able to replicate as closely as possible the actual structural behaviour of heritage buildings is crucial for a thorough assessment of their structural performance against exceptional scenarios. In this regard, higher accuracy can be achieved by leveraging a multidisciplinary approach that integrates multiple contributions from different fields, such as geomatics, dynamics and computational modelling. In the present paper, this strategy is applied to the tower keep of the Guimarães castle, in Portugal, a masonry fortified structure dating back to the X century. Starting from an accurate laser scanner survey, a detailed numerical model has been created resorting to efficient algorithms able to represent complex situations. Furthermore, by exploiting the dynamic*

properties extracted from the processing of vibration data collected during field dynamic testing, the mechanical characteristics of the constituent materials of the tower have been estimated by means of a model updating technique embedded in a trust-region scheme implemented in the NOSA-ITACA code. The results obtained so far allowed to establish valuable baseline information that will be of pivotal importance to catch possible changes in the tower's response and to perform more in-depth structural analyses.

1 INTRODUCTION

Heritage structures represent a significant part of our built environment. Besides their cultural and social importance, historical buildings and sites are touristic attractions that positively impact the economy of the cities and countries in which they are located. Thus, the preservation of the built heritage is of primary concern at the local and global scale and goes beyond cultural requirements.

Since ancient constructions have been exposed to aging and deterioration phenomena for centuries, they are particularly vulnerable to new threats and damages. Material aging, pollution impact, long-term effects of ground subsidence, environmental vibrations and extreme events are just some of the main causes of damage in historical structures. If not detected in due time, damage can irreversibly impair the structural performance over time. However, the structural assessment of built heritage does conceal many challenges owing to the geometrical complexity characterizing age-old constructions, the heterogeneity of materials and building techniques adopted as well as the limited knowledge about past events and interventions that might have affected their actual conservation state [1].

In this context, preventive strategies based on regular condition surveys and periodic or continuous structural monitoring are fundamental to obtain a global insight into the behaviour of such non-conventional systems and promptly identify anomalies in order to plan in advance adequate corrective measures and ensure the good conservation of our built heritage [2], [3], [4]. At the same time, the complexity of old constructions requires the use of advanced tools for their accurate documentation and assessment, trying to improve the level of knowledge about the structure and to obtain reference information for post-event analysis in case of unexpected scenarios. A multidisciplinary approach integrating high-resolution surveys, field dynamic testing and finite element modelling is therefore necessary to achieve a full comprehension of historical buildings [5].

In the present work, this strategy is applied to an ancient masonry tower keep located in the hearth of the medieval castle of Guimarães, in Portugal. First, an accurate survey is performed using a terrestrial laser scanner in order to map the existing damages and develop an accurate 3D numerical model. Then, ambient vibration tests are carried out to extract meaningful information about the most significant dynamic parameters of the keep, namely frequencies, mode shapes and damping ratios. Finally, the experimental results are used to calibrate, through a model updating procedure based on a trust-region scheme [6], two refined FE models of the tower in order to estimate the mechanical characteristics of its constituent materials. Research is still in progress to achieve a very accurate simulation of the dynamic behaviour of the keep; however, the obtained results allowed to set baseline information that will be crucial to identify future deviations in the tower's response and to perform more advanced structural analyses.

2 FROM REALITY TO "AS-BUILT" CAD MODELLING

2.1 Guimaraes castle´s tower keep

Located in the historical center of the homonymous city (District of Braga, Portugal), the medieval castle of Guimarães is a five-sided polygonal military fortification erected during the X century (late Romanesque-early Gothic period) on a small hill formed from granite. The castle was primarily built to defend the Monastery of the city and its population from the attacks of Vikings and Moors, becoming nowadays a symbol of the Portuguese national identity. The construction is delineated by thick perimetral walls which give rise to a shape similar to a shield. Eight flanking towers (turrets) can be found along the walls, with height varying from 12 to 20 m. Turrets and walls surround and protect the inner military square together with the most prominent tower therein located: the central tower keep (Figure 1a). This free-standing structure, 25.86 m high and composed of four squared levels with an estimated area of 76 m^2 each, features massive bearing walls made of three-leaf regular granite masonry varying in thickness from about 1.98 m at the 1st floor, to 1.54 m at the 4th one, and is topped by battlements. Centrally, the construction has a squared granite pillar which tapers upwards from about 1.90 x 1.90 m^2 (base) to 1.20 x 1.20 m^2 (top). The pillar and the walls support the double-warped wooden floor of the different levels as well as the wooden trusses and rafters of the tiled four-pitched roof (Figure 1b).

a) b)

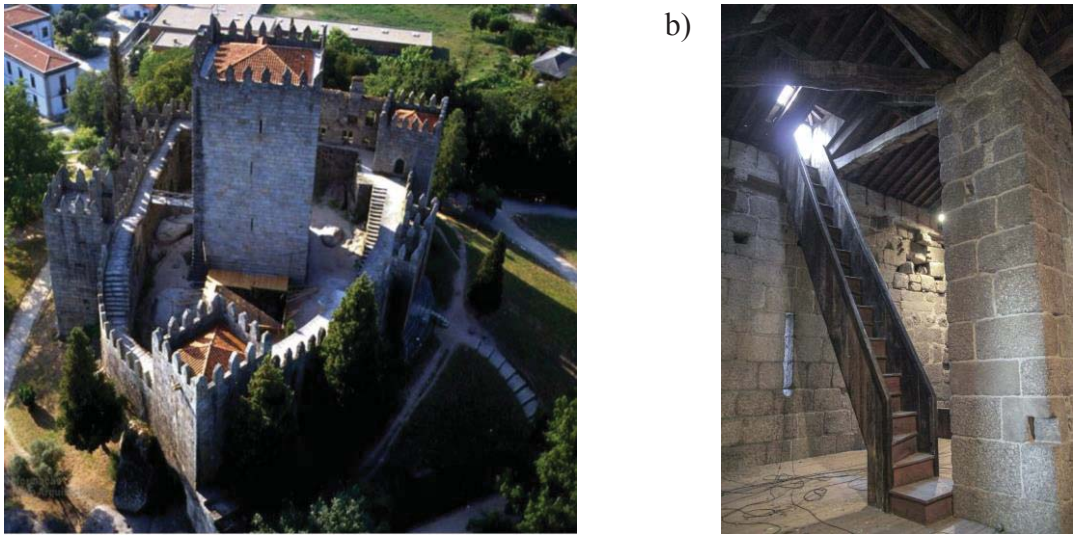

Figure 1: Guimaraes castle: a) outdoor view; and b) detailed view of the central pillar and roof trusses. (First photo source: http://www.monumentos.gov.pt/).

Concerning the state of conservation, the tower keep exhibits typical damages and deterioration processes: moist areas along the walls due to water infiltration and deficiencies in the drainage system; spread biological colonies, especially in the form of lichens, with high concentration on the most exposed parts; longitudinal cracks induced by the out-of-plane deformation of the main façade, likely due to the horizontal thrust of the timber roof structure.

2.2 3D digitalization via TLS technology

The geometrical configuration of the tower, with narrow spaces and unfavorable lighting conditions, made the Terrestrial Laser Scanner (TLS) device the best solution to digitalize the building. The light-weight TLS Faro Focus x330 ® was used for this purpose (Figure 2). Its most relevant features are summarized in Table 1.

Thirty-two scans were needed to capture the whole tower keep (Figure 2): i) eight scan stations to digitalize the façades; ii) sixteen stations to capture the indoor spaces; and iii) eight scans for the roof of the tower. It is worth noting that this large number of scans was due to the necessity of having a good overlap between scan stations in order to carry out a proper cloud-to-cloud alignment.

Specification	Value
Physical principle	Phase shift
Wavelength (nm)	1550
Measurement range (m)	0.60 to 330
Field of view (degrees)	300 V x 360 H
Nominal accuracy value at 25 m (mm)	± 2mm
Capture rage (pts/sec)	122,000 to 976,000
Spatial resolution at 10 m (mm)	6

Table 1: Technical specifications of the TLS Faro Focus.

a) b)

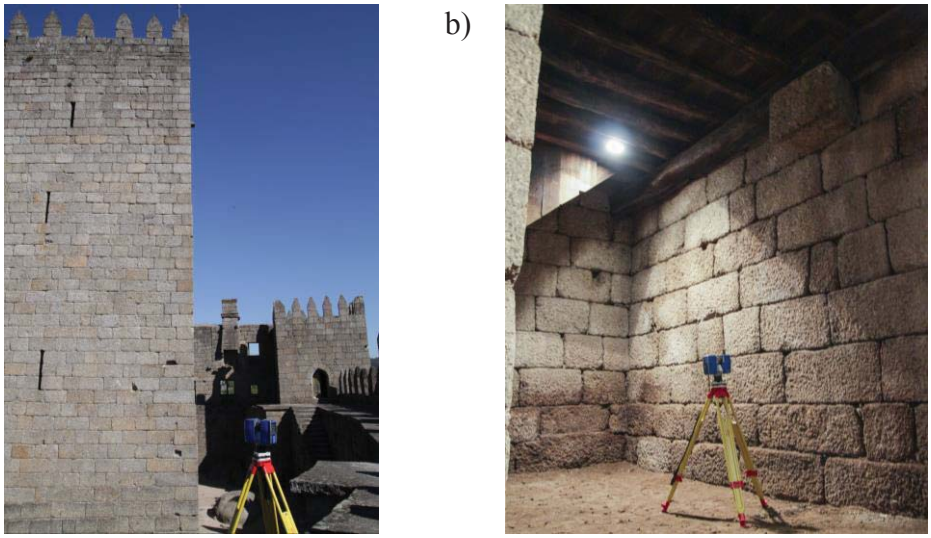

Figure 2: 3D digitization of the tower keep through TLS: a) outdoor; and b) indoor.

2.3 Point cloud processing

All the stations were aligned in a single coordinate system by means of the coarse-to-fine registration proposed in [7]. The approach begins with a pair-wise registration through the ICP (Iterative Closets Point) algorithm [8], followed by the Generalized Procrustes Analysis (GPA) [9], with the aim of minimizing the error accumulation among the different scans. As a result, a complete 3D point cloud of the tower was obtained, with an error of 0.003±0.002 m. The huge amount of captured data, counting about 410,982,656 points, demanded the application of a decimation filter for their manipulation; thus, a curvature-based filter with a threshold of 0.02 m was employed. This filter allows to decimate flat areas while maintaining all the details in curved areas (e.g. edges or timber elements). At the end of the decimation process, the final point cloud contained 32,449,888 points – barely 8% of the original one (Figure 3).

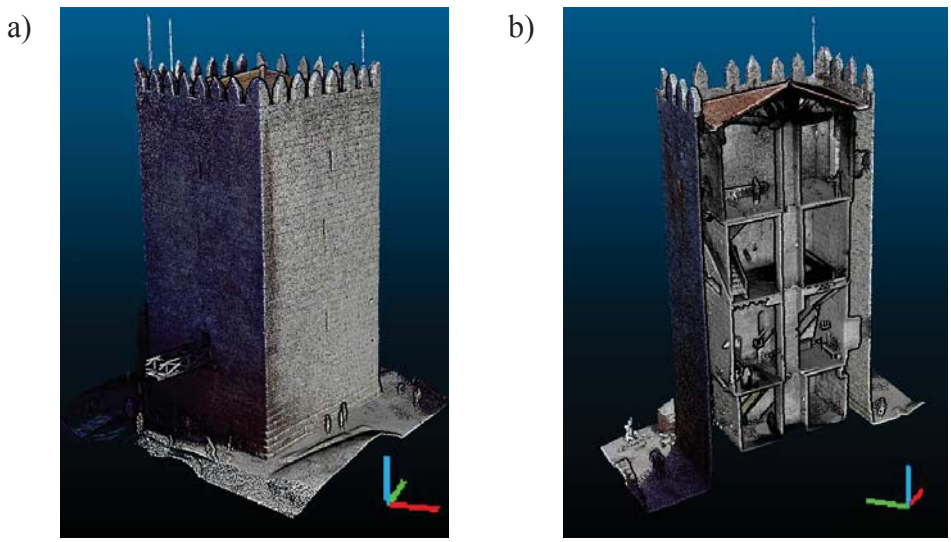

Figure 3: 3D point cloud of the tower keep: a) exterior view; and b) section crossing the center of the tower.

2.4 As-built modelling

As mentioned in Sub-Section 2.1, the main façade of the tower keep suffers visible out-of-plane deformations. With the aim of considering this outward displacement in the numerical analysis of the structure, an as-built CAD modelling stage was carried out, using the reverse engineering workflow proposed by [10]. The approach consists of the following steps: i) 3D Delaunay triangulation; ii) horizontal sections along the z-axis each 2.0 m; iii) b-spline vectorization of each section; iv) creation of surface between b-splines by means of Lofted surfaces; and v) refinement of the model through the use of Boolean operators (Figure 4).

In order to further simplify the subsequent numerical simulation, the timber structure of floors and roof was modelled by means of b-spline curves. To this end, several transversal sections along the different timber elements were extracted; then, a b-spline approximation was computed using as nodes the centroid of each section. This allowed to obtain an accurate as-built CAD model of the tower to be later used as geometrical base for defining the numerical mesh (see Sub-Section 4.2).

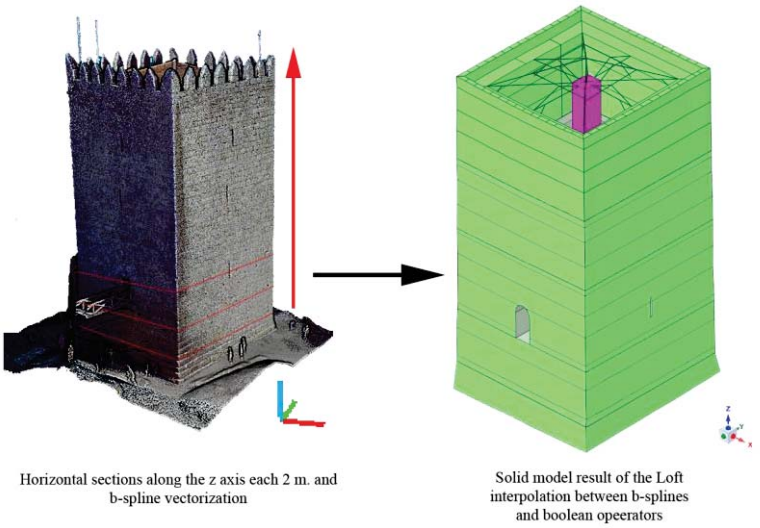

Figure 4: From the point cloud to the CAD model: graphical workflow.

3 OPERATIONAL MODAL ANALYSIS

3.1 Dynamic testing procedure

Dynamic testing can be considered as a global nondestructive tool since it allows to obtain real-time punctual checkups of the structural fitness just by deploying an array of sensors in the structure and recording the corresponding vibration response to random ambient excitations, without resorting to any invasive technique [11]. This aspect represents one of the major strengths of dynamic testing, making it play a leading role in the context of structural health monitoring of historical constructions. From the analysis of vibration signals, it is possible to estimate the dynamic properties of a structural system (frequencies, mode shapes and damping ratios) and use this information for different purposes, including the identification of anomalies and damage mechanisms, the assessment of strengthening needs or the calibration of realistic numerical models for in-depth structural analyses.

As for the Guimarães castle, the dynamic characterization of the tower keep was performed by Operational Modal Analysis (OMA), namely using output-only data acquired from the structure in operating conditions through classical contact vibration sensors. Eleven uniaxial piezoelectric accelerometers (model PCB 393B12, 10 V/g sensitivity, ±0.5 g dynamic range, 8 μg resolution) were distributed across the tower in order to measure its vibration response at strategic locations both in the bearing walls and the central pillar. The testing procedure consisted of two setups, each one recording 600 s acceleration time series sampled at 200 Hz from eleven measurement points; two accelerometers were kept on the top level as reference points for the analysis. In total, records from twenty DOFs (degrees of freedom) were acquired. The complete sensor layout is displayed in Figure 5.

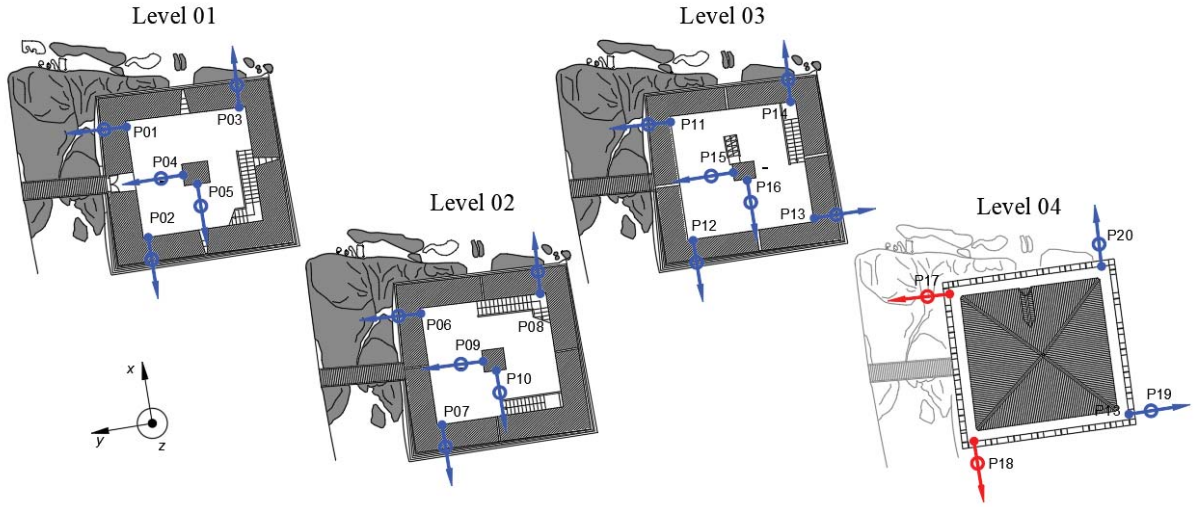

Figure 5: Sensor layout for the dynamic testing (reference sensors are indicated in red).

3.2 Data processing and results

The dynamic properties of the tower keep were estimated using two output-only dynamic identification techniques available in the commercial software ARTeMIS [12], i.e. the Enhanced Frequency Domain Decomposition (EFDD) and the Stochastic Subspace Identification with Extended Unweighted Principal Component (SSI-UPCX). Before elaboration, data were preliminary analyzed to remove trends, down-sample the signals and reduce leakage errors. Indeed, since the power spectral densities of the raw time histories displayed a significant frequency content in the range 2–15 Hz, all data were pre-processed with a decimation of order 5, passing from 102,400 to 20,480 of spectral resolution. Afterwards, both the afore-

mentioned modal estimators were applied, allowing to cross-validate the results of eight out of eleven vibration modes in the frequency and time domains.

The estimated natural frequencies and damping ratios are summarized in Table 2 together with the MAC values indicating the degree of similarity between corresponding mode shapes. Overall, eleven vibration modes were identified for the tower keep: two translation modes at 2.68 Hz (f_1) and 2.74 Hz (f_2) featuring in-phase modal components; one translation mode at 3.88 Hz (f_3) with out-of-phase modal components; one torsion mode at 4.81 Hz (f_4); two bending modes at 5.75 Hz (f_5) and 6.04 Hz (f_6); and five additional higher-order dominant bending modes at 7.22 (f_7), 7.98 (f_8), 9.23 (f_9), 10.22 (f_{10}) and 13.86 Hz (f_{11}).

	f_{EFDD} [Hz]	f_{SSI} [Hz]	$\|\Delta f\|$ [%]	ξ_{EFDD} [%]	ξ_{SSI} [%]	MAC
φ_1	2.67	2.68	0.37	0.66	1.13	0.98
φ_2	2.74	2.74	0.00	0.71	1.15	0.91
φ_3	3.88	3.88	0.00	1.22	1.41	1.00
φ_4	4.82	4.81	0.21	0.63	0.68	0.94
φ_5	5.38	5.75	6.43	0.78	1.99	0.57
φ_6	6.03	6.04	0.17	1.60	2.16	0.99
φ_7	7.16	7.22	0.83	0.51	1.97	0.48
φ_8	7.90	7.98	1.00	1.27	2.10	0.99
φ_9	9.21	9.23	0.22	0.65	2.22	0.98
φ_{10}	10.47	10.22	2.45	0.18	1.75	0.29
φ_{11}	13.91	13.86	0.36	0.38	1.53	0.92

Table 2: Experimental frequencies, damping ratios and MAC values (highlighted in grey the modal vectors featuring a low correlation).

Very low percentage errors in terms of frequency values are found comparing the two modal estimators, and consistent results are obtained as far as the damping ratios are concerned. It is also highlighted that, despite the inherent difficulties associated with the presence of closely spaced frequencies, a high correlation (MAC > 0.90) is found between all comparable vibration modes, except for modes 5, 7 and 10. Figures 6 and 7 show, respectively, the singular value decomposition (SVD) of the spectral density matrices and the first four estimated mode shapes.

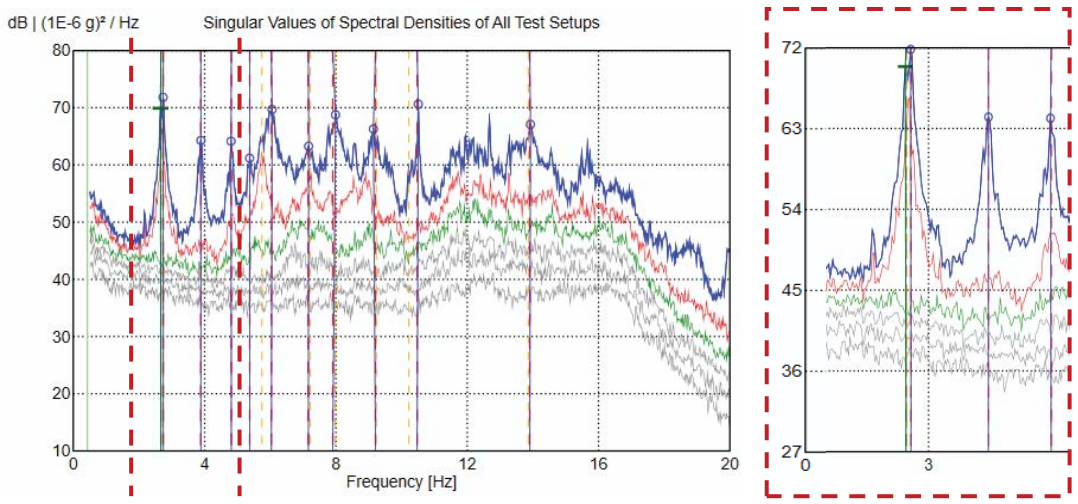

Figure 6: Singular value decomposition: peak picking of dominant frequencies.

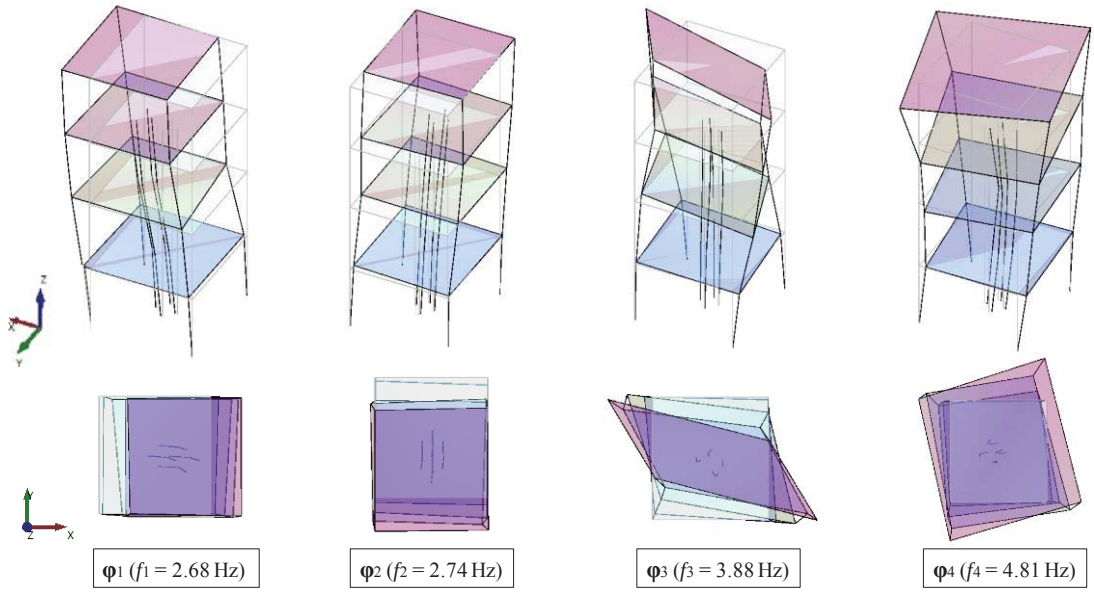

Figure 7: Experimental mode shapes of the tower keep (undeformed shape in light grey).

4 MODAL-BASED FINITE ELEMENT MODEL UPDATING

4.1 Model Updating

Model updating is a procedure aimed at calibrating an FE model in order to match the experimental and numerical dynamic properties (frequencies and mode shapes) of a structure [13]. It is an inverse problem based on modal analysis, which in turn relies on the solution of the generalized eigenvalue problem:

$$\mathbf{Ku} = \omega^2 \mathbf{Mu} \tag{1}$$

where $\mathbf{K}$ and $\mathbf{M} \in \mathrm{R}^{nxn}$ are the stiffness and the mass matrices of the structure discretized into finite elements; $\mathbf{u} \in \mathrm{R}^n$ is the vector of the degrees of freedom, with n being the total number of DOFs. The eigenvalue ω_i^2 is linked to the structure's frequency f_i by the relation $f_i = \omega_i/2\pi$ and the eigenvector $\mathbf{u}^{(i)}$ represents the corresponding mode shape.

The model updating problem can be reformulated as an optimization problem by assuming that the stiffness and mass matrices, $\mathbf{K}$ and $\mathbf{M}$, are functions of a parameter vector x varying in a p-dimensional box Ω. The goal is to determine the optimal value of x that minimizes, within the box Ω, the objective function $\phi(\mathrm{x})$ defined by:

$$\phi(\mathrm{x}) = \sum_{i=1}^{q} w_i^2 [\overline{f_i} - f_i(\mathrm{x})]^2 + w_{i+q}^2 [1 - \gamma_i(\mathrm{x})]^2 \tag{2}$$

where $\overline{f_i}$ and $f_i(\mathrm{x})$ are the q experimental and numerical frequencies to match, scalars γ_i are the square root of the modal assurance criterion (MAC) indicators [14] and measure the correlation between the i-th experimental mode shape and the corresponding numerical one, while scalars w_i encode the weight that should be given to each frequency and mode shape in the optimization scheme. Usually, to obtain relative accuracy on the frequencies, w_i is chosen equal to the inverse of the experimental frequency. As for the eigenmodes, weights are typi-

cally fixed to 0.1; this value respects the accuracy of the information retrieved from the identification phase, where, in general, eigenvectors are obtained with one magnitude lower accuracy than the corresponding frequencies.

The numerical procedure for model updating herein used to obtain the optimal values of the parameter vector x, and described in detail in [15], [6], is implemented in the NOSA-ITACA code [16], a finite element software developed in house by ISTI-CNR (www.nosaitaca.it). The algorithm is based on the construction of local parametric reduced-order models embedded in a trust region scheme for solving the constrained minimum problem. In particular, it exploits the structure of the stiffness and mass matrices and the fact that only a few of the smallest eigenvalues have to be calculated in order to solve the problem. This procedure reduces both the overall computation time of the numerical process and the user's effort.

4.2 FE Model Calibration

With the aim of understanding the dynamic behavior of the tower and the mutual interaction between wooden elements and masonry structure, two detailed FE models, hereinafter referred to as Model A and Model B, were created via the NOSA-ITACA code and calibrated using the experimental results presented in Section 3. The mesh of each model was obtained from the as-built CAD model described in Sub-Section 2.4. Aiming at exploiting all the defined geometrical features, a tetrahedral mesh algorithm with high-order elements was applied, making sure that the thickness of the walls was defined by at least two elements in order to be able to capture stress gradients correctly in future non-linear analyses.

Model A (Figure 8a) counted 220,854 DOFs and was composed of: 45,296 10-node isoparametric tetrahedral elements (element 27 of the NOSA-ITACA library) – used to model the walls and the central pillar of the tower; 1,457 3-node thick shell elements (element 26 of the NOSA-ITACA library) – employed to simulate the wooden slabs; and 1,542 beam elements (element 9 of the NOSA-ITACA library) – used to model the wooden beams of floors and roof. Model B (Figure 8b) was obtained from Model A by removing all shell and beam elements, and replacing them with equivalent masses (m_1, m_2, m_3, m_4).

The masonry was modeled as a homogeneous isotropic material with a Poisson's ratio ν=0.2 and a mass density ρ_m = 2600 kg/m^3 [17], [18]; whereas a Poisson's ratio ν=0.3 and a mass density ρ_w = 1000 kg/m^3 were adopted for the wood. The structure was assumed to be clamped at the base.

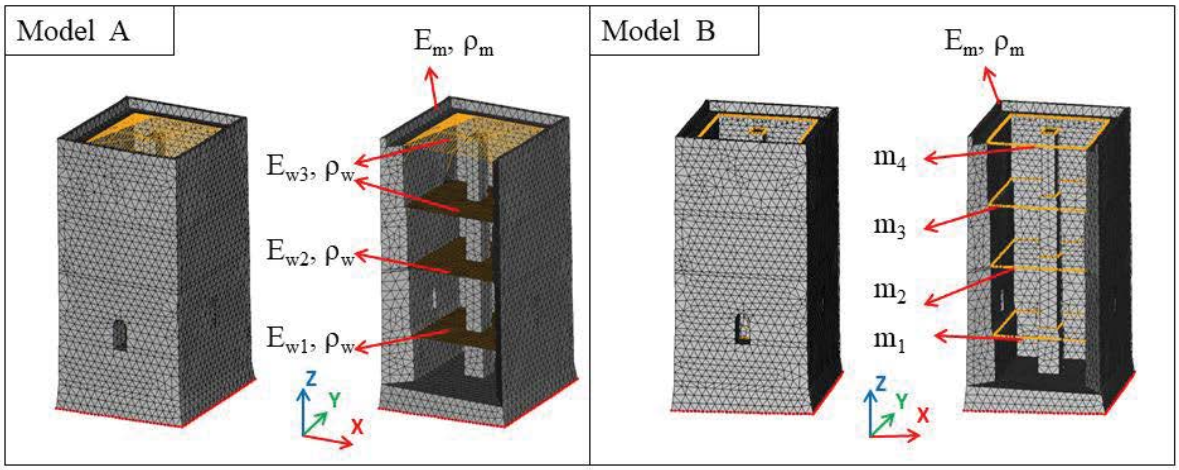

Figure 8: FE modelling of the tower keep: Model A and Model B.

As regards Model A, the numerical procedure recalled in Sub-Section 4.1 was employed to estimate the optimal values for the Young's moduli of masonry E_m, wooden slab and beams E_{w1}, E_{w2}, E_{w3}, assuming for the box Ω the following parameters bounds:

$$1000 \text{ MPa} \leq E_m \leq 8000 \text{ MPa}$$

$$100 \text{ MPa} \leq E_{w1}, E_{w2}, E_{w3} \leq 9000 \text{ MPa}$$

and trying to match the first four experimental frequencies and mode shapes of the tower. The parameter range for the wood material was chosen sufficiently large in order to take into account not only the uncertainties related to the knowledge of the mechanical characteristics of the material itself, but also the possible constraints between the wood elements and the masonry structure. The optimal mechanical parameters obtained through the model updating process are listed below:

$$E_m = 1686.5 \text{ MPa};\ E_{w1} = 290.66 \text{ MPa};\ E_{w2} = 454.76 \text{ MPa};\ E_{w3} = 890.92 \text{ MPa}$$

Table 3 summarizes the results of the optimization algorithm in terms of frequencies, absolute value of relative errors with respect to the experimental frequencies, and MAC values. The numerical mode shapes corresponding to the optimal values of the parameters are shown in Figure 9.

	Exp. [Hz]	Num. [Hz]	$\|\Delta\|$ [%]	MAC
f_1	2.68	2.51	6.34	0.98
f_2	2.74	2.61	4.74	0.99
f_3	3.88	4.26	9.79	0.69
f_4	4.81	4.80	0.21	0.62

Table 3: Model A – experimental frequencies, numerical frequencies, relative percentage errors, MAC values.

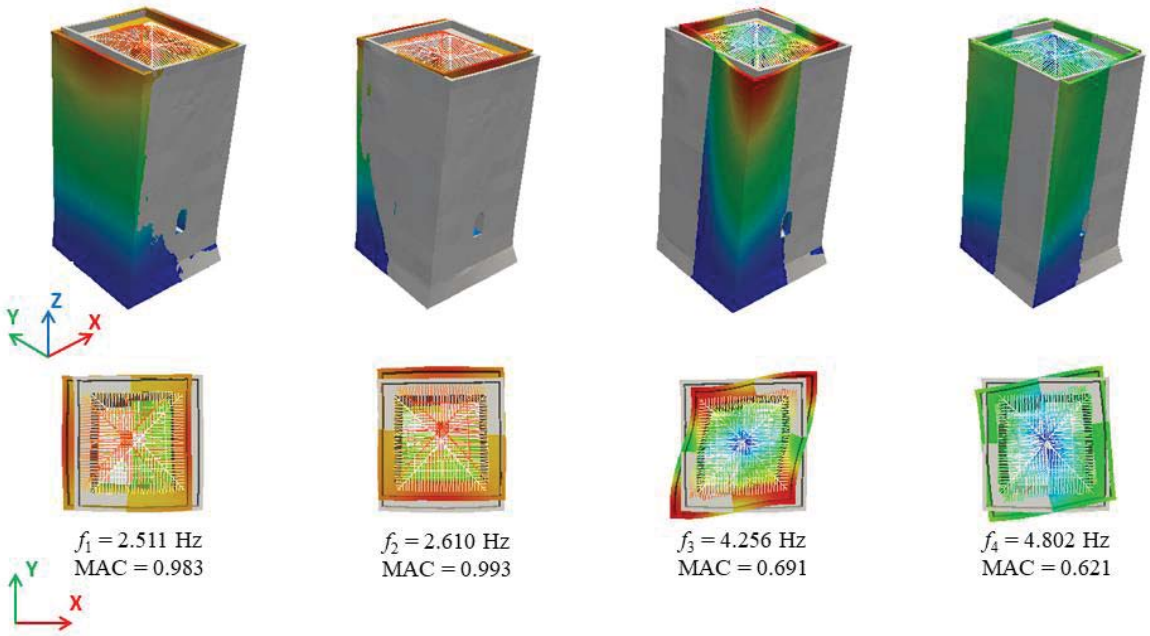

Figure 9: Model A – numerical mode shapes after the updating process (undeformed shape in grey).

In the attempt to improve the tuning with the experimental results, the same procedure was applied to Model B. In this case, the goal was to estimate the optimal values for the Young's modulus E_m and the mass density ρ_m of the masonry, assuming the following box Ω bounds for the parameters:

$$1000 \text{ MPa} \leq E_m \leq 8000 \text{ MPa}$$

$$2000 \text{ kg/m}^3 \leq \rho_m \leq 3000 \text{ kg/m}^3$$

The following parameter values were obtained through the optimization process:

$$E_m = 1955.8 \text{ MPa}; \qquad \rho_m = 2877.14 \text{ kg/m}^3$$

It is interesting to note that the updated Young's modulus and mass density obtained are consistent with the values reported in literature [17], [18].
The overall results in terms of frequencies, absolute value of relative errors between experimental and numerical frequencies, and MAC values are presented in Table 4, while the numerical mode shapes corresponding to the optimal values of the parameters are displayed in Figure 10.

	Exp. [Hz]	Num. [Hz]	$\lvert\Delta\rvert$ [%]	MAC
f_1	2.68	2.61	2.61	0.98
f_2	2.74	2.70	1.46	0.99
f_3	3.88	3.83	1.29	0.69
f_4	4.81	5.08	5.61	0.64

Table 4: Model B – experimental frequencies, numerical frequencies, relative percentage errors, MAC values.

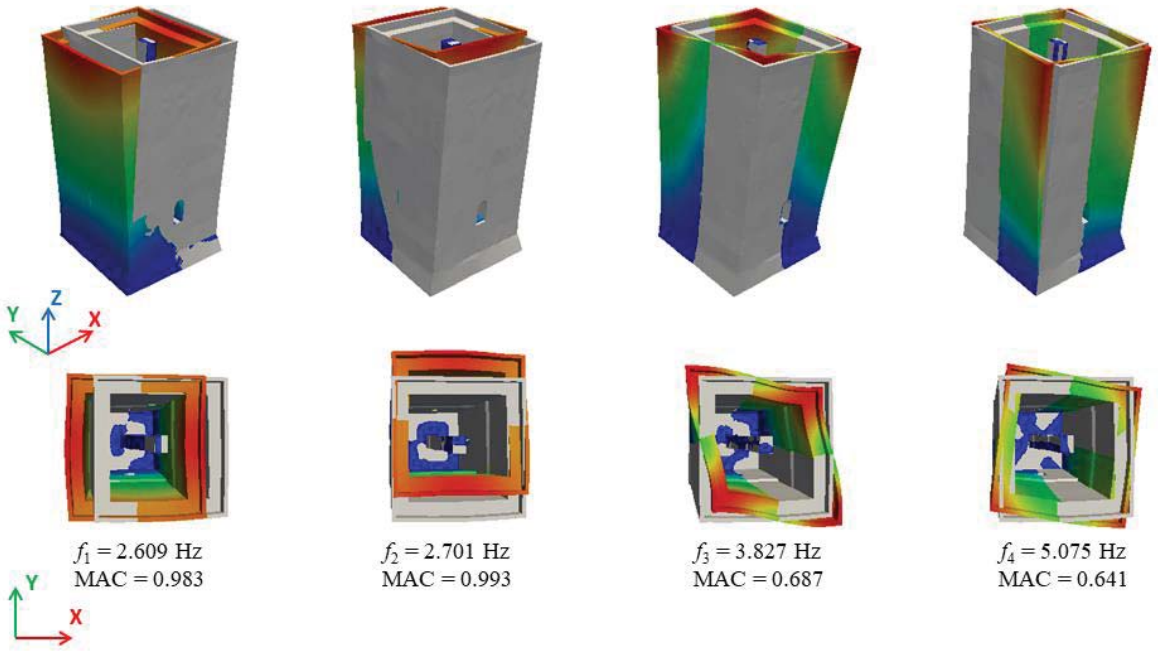

Figure 10: Model B – numerical mode shapes after the updating process (undeformed shape in grey).

Despite the similarities between numerical and experimental mode configurations, a high frequency percentage error is recorded for Model A. The comparison of the results with Model B shows that, if the wooden elements are not considered, the Young modulus of the masonry increases of about 15% and the mass density of nearly 10%; furthermore, the maximum relative error related to the two first frequencies decreases from 6.32% (Model A) to 2.65% (Model B). Regarding the MAC values, a good match between the two first experimental and numerical mode shapes is obtained for both models, while the third and fourth modal vectors are not very well approximated. Using an orthotropic material as done in [19] does not improve the numerical model, since the MAC value related to the third and fourth mode shapes remain unchanged.

5 CONCLUSIONS

The present paper aims to show the capabilities of an integrated and multidisciplinary approach to the complex problem of safeguarding heritage structures. The approach proposed here, encompassing digitalization, monitoring, numerical modelling and simulation, and relying on techniques and tools – either commercial or developed in house – at the disposal of the authors, is tested on the iconic tower keep of the Guimarães castle. The "laser acquisition – 3D digitalization – point cloud processing – CAD modelling – dynamic identification – finite element model updating" chain is described in all its steps, the ultimate goal being an accurate, fine-tuned numerical model of the tower. Such a digital counterpart of the real tower is of fundamental importance, since it constitutes the basis of any eventual finite element simulation aimed to predict the structural behavior of the tower under changing operational and environmental conditions.

Keywords: Automated modal identification, Cathedral of Milan, Condition-based maintenance, Continuous monitoring, Temperature

Abstract. *The maintenance and preservation of the Milan Cathedral is traditionally performed through well-established and time-scheduled programs of visual inspection and architectural restoration of surfaces, decorations, and statues in Candoglia marble. On the other hand, the structural condition assessment and preservation turns out to be a challenging task due to the dimensions and complexity of the building, the usual uncertainties on the material properties and also the difficulty in inspecting several structural elements. Therefore, a structural monitoring system was recently designed and installed in the Milan Cathedral to assist the condition-based structural maintenance of the monument. The monitoring system includes different sensing technologies to allow appropriate tracking of different long-term structural behavior. The dynamic monitoring of the horizontal response of selected piers is complemented by the static monitoring of the tilt of the same piers and of the strain in selected tie-rods. In addition, the indoor and outdoor environmental parameters are extensively measured as well.*

After a concise historic background on the historic monument and the description of the dynamic monitoring system installed in the Milan Cathedral, the paper focuses on the dynamic characteristics of the monument, that were identified in the first hours of continuous monitoring, Subsequently, the results of the first year of dynamic monitoring are presented and discussed, with special attention being given to the influence of environmental parameters on the variations observed in the resonant frequencies and mode shapes. In more details, the presented results highlight that: (a) 8 global vibration modes are automatically detected in the frequency range 1.0-5.0 Hz; (b) the variations observed in the resonant frequencies are mainly driven by temperature, with the effect of thermal changes being very peculiar; (c) the mode shapes and the related mode complexity do not exhibit appreciable fluctuations associated to the environmental changes, so that an appropriate strategy of SHM should be based also on the time invariance of those parameters.

1 INTRODUCTION

The Milan Cathedral is a world-wide known Heritage monument, whose structural construction took more than 4 centuries, from the apse erection in 1386 until the façade finalization in 1813 [1]. Subsequently, the architectural works continued until the installation of the last iron gate in 1965 and this year is usually indicated as the official completion of the building works. Since 1387 all operational aspects related to the construction, maintenance and restoration of the cathedral are managed by the historic Institution named *Veneranda Fabbrica del Duomo di Milano* [2] and denoted as *Fabbrica* in the following. After the construction of the main structures of the cathedral, the *Fabbrica* main mission moved to continuous inspection, maintenance and preservation of the monument, with those activities being especially related to surfaces, decorations and statues in Candoglia marble.

After the recent assessment of the state of preservation and the tensile force of the metallic tie-rods of the Milan Cathedral [3], the idea of adopting a Structural Health Monitoring (SHM) strategy has been taking shape to continuously assist the structural condition assessment and preservation of the monument. Consequently, a joint research started between the *Fabbrica* and Politecnico di Milano and a structural monitoring system [4] was designed and installed in the cathedral, with the objectives of providing the information needed for the condition-based structural maintenance and the creation of a large archive of experimental data useful to enhance the knowledge of the monument.

The long-term monitoring system [4], fully computer based and with efficient transmission of the collected data, includes static and dynamic measurements. The dynamic monitoring is performed through seismometers (electro-dynamic velocity sensors) installed at the top of 14 selected piers and at 3 levels of the main spire. The static monitoring system consists of: (a) bi-axial tilt-meters installed at the top of selected piers and at 3 levels of the main spire; (b) vibrating wire extensometers mounted on the tie-rods exhibiting tensile stress larger than 100 MPa [3]. Since both the long-term static behavior and the time evolution of dynamic signatures are expected to be sensitive also to environmental changes [5] and especially the temperature might affect the variation of structural parameters in masonry structures [6-11], the indoor and outdoor environmental parameters (temperature and humidity) are extensively measured to establishing correlations with the changes of structural parameters [4-11] and evaluating the risks for the preservation of the main artifacts present in the cathedral [12].

The present paper is mainly aimed at describing the monitoring system installed in the cathedral with emphasis on the dynamic measurements, the processing of the continuously collected time series and the automated extraction of dynamic signatures (i.e. resonant frequencies, mode shapes and mode complexity [13-14]). Since the dynamic response of the church is continuously collected in a well distributed measurement grid (27 channels of data), the features representative of structural condition should include the mode shapes and not only the resonant frequencies. The use of mode shapes and mode complexity within a SHM strategy conceivably exhibit advantages because those modal parameters might be less sensitive than resonant frequencies to exogenous factors and contain information also on the local structural behavior.

In more detail, the paper starts with a concise historic background of the Milan Cathedral and a brief description of the dynamic monitoring hardware and of the software tools developed to process the continuously acquired time series. Subsequently, the dynamic reference characteristics of the cathedral, that were identified in the first hours of dynamic monitoring, are presented and discussed. At last, the evolution in time of the environmental and modal parameters during the first year of monitoring is addressed and comments are given within a SHM perspective.

2 THE MILAN CATHEDRAL

The Milan Cathedral (Figs. 1-3) is the most representative landmark of the city of Milan and one of the largest masonry monuments ever built: the building spreads over an area of more than 10400 m^2, with a volume of about 300000 m^3, so that it is the second largest gothic cathedral in the world by volume and area.

The church exhibits a unique style of architecture, which is characterized by a fusion of European Gothic style and Lombardy tradition, also with the presence of neo-classic, neo-gothic and even renaissance influences, due to the long period required by the construction works. The church construction started in 1386 from the half-octagonal apse and East choir, and proceeded with the transept, the main dome, the *tiburio* (i.e., the prismatic structure with octagonal base, which is built around the main dome) and the main spire; subsequently, the five-nave structure over eight bays was built and finalized, in 1813, with a neo-Gothic façade. As previously pointed out, the inauguration of the last gate (January 6h, 1965) is generally assumed as the official ending of the monument building.

When compared with other gothic cathedrals, the Milan Cathedral exhibits a peculiar structural system, with metallic tie-rods being permanently installed under each vault (Fig. 2) and designed to exert an active part in resisting the lateral thrusts [3]. Historical documents [1] testify that the tension bars in the cathedral were permanently installed on the top of the piers during the construction, to reduce the horizontal thrust on the lateral buttresses, as those

buttresses were judged too slender by the French architect Jean Mignot. A total of 122 metallic tie-rods (Fig. 2) is nowadays present in the cathedral and most of them are the original elements dating back to the age of construction.

A longitudinal section of the Milan Cathedral is shown in Fig. 3. The overall dimensions of the Latin cross-shaped plan are about 66 m × 158 m (Fig. 4), with the aisles and the central naves spanning 9.6 m and 19.2 m, respectively.

(dimensions in m, courtesy of *Veneranda Fabbrica del Duomo di Milano*).

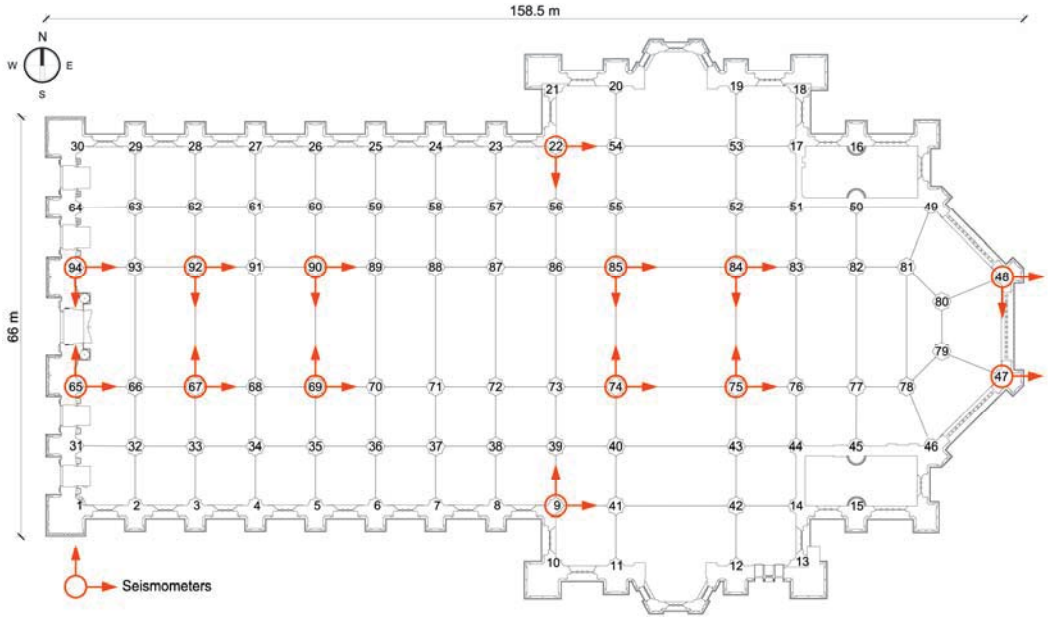

Figure 4: Plan of the Milan Cathedral (dimensions in m) and layout of the seismometers installed in the church.

3 DYNAMIC MONITORING SYSTEM AND DATA ANALYSIS

In order to characterize the health state of the Milan Cathedral and to address its condition-based structural maintenance, the following key parameters are continuously measured or identified from the measurements:

- Bi-axial tilt of the capital of selected piers (i.e., piers 31, 64, 69, 90, 11, 20, 74-75, 84-85 and 47-48 in Fig. 4) and main spire;
- Strain of tie-rods 28-62, 27-61, 26-60, 35-69, 25-59, 7-37, 9-39, 39-40, 56-55, 45-77, 38-72 and 87-57 (Fig. 4);
- Indoor and outdoor environmental parameters. The indoor temperature is measured in the same capitals where the tilts are recorded, whereas the humidity is measured in the neighborhood of instrumented ties. The outdoor parameters are collected through a weather station installed in the main spire;
- Resonant frequencies, mode shapes and damping ratios.

Due to the different technical characteristics of the various sensing devices and sampling rates of the data acquisition, two separated long-term monitoring systems, one static and one dynamic, were installed in the church. Strains, tilts and environmental data are collected at a rate of two samples per hour, whereas the dynamic monitoring is performed with a sampling frequency of 100 Hz. It is further noticed that the monitoring systems are fully computer based and their architecture has been established in order to minimize wiring, as well as the visual impact of the sensing devices inside the church.

The dynamic monitoring system is based on SARA SS45 seismometers (electro-dynamic velocity transducers). Since the electro-dynamic sensors are characterized by high sensitivity of 78 V/(m/s), un-necessity of powering and excellent performance in the low frequency range ($f \leq 100$ Hz), those transducers turn out to be especially suitable for the application in vibration testing or monitoring of civil engineering and cultural heritage [10] structures. The dynamic monitoring system consists of:

- 13 bi-axial seismometers and 1 mono-axial seismometer, installed at the top of selected piers inside the Cathedral (Fig. 4) and measuring the velocity in the two orthogonal N-S (transversal) and E-W (longitudinal) directions. The sensors installed on piers (94, 92, 90), (65, 67, 69), (22, 85, 84), (9, 74, 75) and (47, 48) are grouped and wired to five 24-bit digitizers SARA SL06. Each digitizer is equipped with A/D conversion system, 8 GB memory, synchronization by GPS, back-up battery and UMTS modem for data transfer;
- 3×3 mono-axial seismometers, installed at the same levels of the main spire hosting the biaxial tilt-meters belonging to the static monitoring. The three sensors installed at each level are wired to 24-bit digitizer, with the digitizers being connected to a switch for data transfer.

The velocity data are transferred in real time to the *Fabbrica* workstation and stored in separate files (in compressed mini-seed format) of 1 hour. Every hour, the automatic signal processing involves the following tasks: (a) pre-processing the raw data (to compensate the low-frequency attenuation of the sensor) using the SEISMOWIN commercial software (https://www.sara.pg.it/?lang=en) and subsequent saving of the time series in text format; (b) data analysis to extract the maximum and the root mean square values and creation of a file in Matlab (.mat) format; (c) low-pass filtering and down-sampling (to reduce the sampling frequency from 100 Hz to 20 Hz), and creation of a database of files for the application of the modal identification tools; (d) automated modal estimation and tracking.

After the automated modal parameter estimation, only the hourly evaluated features (i.e. the statistical characteristics of each dataset and the modal parameters) and a few time series corresponding to meaningful events are permanently stored in the *Fabbrica* archives and can be accessed through graphical and reporting tools. It should be noticed that similar tools allow the management and visualization of the static monitoring results.

The modal parameters of the cathedral and of the main spire are independently identified using a fully automated procedure, based on the covariance-driven Stochastic Subspace Identification (SSI-Cov) algorithm [15] and developed in previous research [16]. The length of the time window adopted in the automated identification was set equal to 1 h (3600 s). The automated procedure [16] involves the two main steps of modal parameters estimation (MPE) and modal tracking (MT).

The MPE is performed through an automatic interpretation of the stabilization diagram, based on the sensitivity of frequency and mode shape to the model order variation. For each dataset, after having filtered the spurious poles by checking the associated damping ratio and mode complexity value [13-14], the poles sharing similar frequencies and mode shapes are clustered together, and a set of representative modal parameters (i.e. resonant frequency, damping and mode shape) is estimated for each cluster. It is worth mentioning that the mode complexity is checked by averaging the information provided by both the Modal Phase Collinearity (MPC) [13] and Mean Phase Deviation (MPD) [13-14] through the Modal Complexity Index (MCI = 0.5 × [(1 − MPC) + (MPD/45°)], varying between 0 and 1, with 0 indicating a mono-phase behavior of the identified mode shape).

The MT, aimed at providing the time evolution of the parameters of each mode, is based on frequency and MAC [17] variation with respect to a pre-selected list of baseline modes. It is worth mentioning that this step is performed in an adaptive way, i.e. by updating the MAC and frequency variation threshold of each mode after a new dataset has been analyzed.

In the automated identification of the dynamic characteristics of the cathedral (27 channels of data, Fig. 4), the time lag parameter i was set equal to 60 and the data were fitted using stochastic subspace models of order n varying between 20 and 140; furthermore, in the noise modes elimination step, the maximum allowable damping ratio and MCI was set equal to 8% and 0.15, respectively.

4 DYNAMIC CHARACTERISTICS OF THE CATHEDRAL

The grid of seismometers permanently installed in the cathedral allowed the identification and fairly good spatial description of a relatively large number of key vibration modes. Typical results obtained on the first day of continuous monitoring, in terms of resonant frequencies and mode shapes, are shown in Fig. 5 (where the blue color refers to modes with dominant motion in the N-S direction and the red color refers to modes with dominant deflection in the E-W direction). The inspection of Fig. 5 allows the following comments:

(a) The lower two modes, as expected, are global sway modes of the cathedral along the transverse (N-S, f_{C1}=1.38 Hz, Fig. 5b) and longitudinal (E-W, f_{C2}=1.69 Hz, Fig. 5c) direction;

(b) The subsequent two modes (f_{C3}=1.96 Hz, Fig. 5d and f_{C4}=2.51 Hz, and Fig. 5e) involve dominant motion in the N-S direction and bending of the naves, with the deformed shapes being characterized by one and two changes of sign from apse to façade, respectively;

(c) The higher modes (Figs. 5f-i) are characterized by more complex mode shapes. For example, the 5th mode (f_{C5}=2.65 Hz, Fig. 5f) involves out-of-phase bending of the North and South naves, whereas the 6th mode (f_{C6}=2.76 Hz, Fig. 5g) involves out-of-phase motion of the façade and apse in the E-W direction;

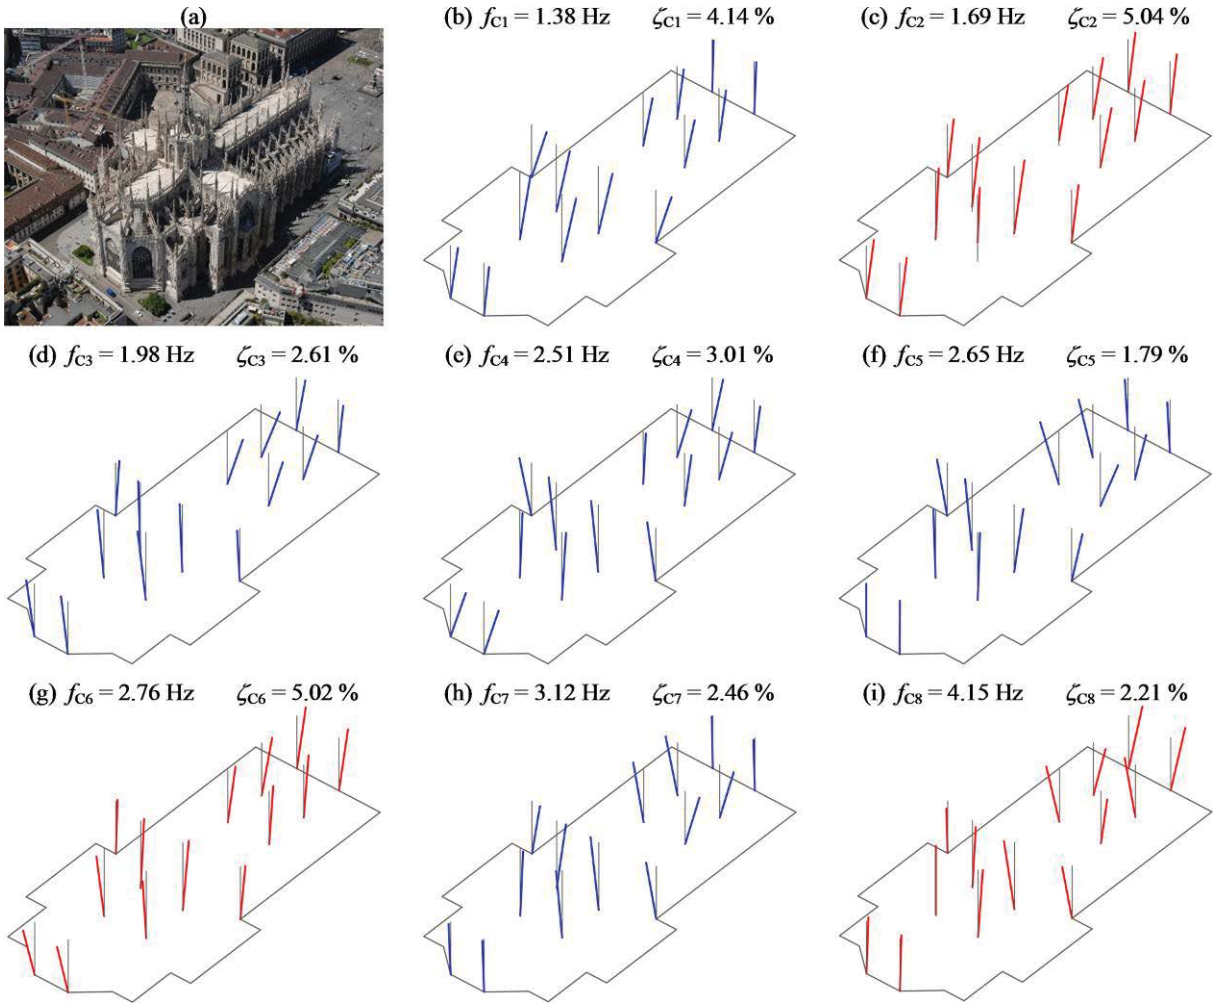

Figure 5: (a) Aerial view of the Milan Cathedral from apse and (b)-(i) identified vibration modes (17/10/2019, h 12:00–13:00).

(d) The N-S modes exhibit damping ratios varying from 1.79% (C5) to 4.14% (C1), whereas the damping of the E-W modes ranges between 2.21% (C8) and 5.04% (C2). It is further noticed that especially the damping of E-W modes seems to be larger than generally observed at the low level of ambient excitation existing on historical buildings.

5 SELECTED RESULTS FROM THE CONTINUOUS DYNAMIC MONITORING

The dynamic monitoring is active in the Milan Cathedral since October 19th, 2018. This section summarizes the main results obtained during the first year of monitoring (from 16/10/2018 to 15/10/2019) and, for the sake of consistency, only the experimental results collected in the cathedral are presented and discussed (with no comments being provided on the data measured on the main spire).

As usual for masonry buildings, the evolution in time of environmental parameters is firstly presented in order to understand the effects of changing environment on the variations observed in the natural frequencies and modal parameters.

5.1 Environmental parameters

As previously pointed out, a quite extended grid of temperature sensors and hygrometers has been installed inside the church, to support both the SHM program and the preservation of

the artifacts, which are kept inside the monument. The variation in time of the average indoor temperature and the outdoor temperature (measured by the weather station) is shown in Fig. 6a, whereas Fig. 6b refers to the average indoor humidity. The orange line in Fig. 6a presents the evolution of the outdoor temperature and highlights changes between −1.7°C and +35.4°C, with remarkable daily variations in sunny days. The corresponding variation of the average indoor temperature is represented by the red line in Fig. 6a and ranges between +8.8°C and +30.6°C: it is further noticed that the availability of a large number of temperature sensors in the church highlights [12] a low temperature gradient in space, with the difference between the extreme values not exceeding 0.5°C. Consequently, the low temperature gradient and the correlation coefficients (always larger than 0.99) between the measured temperatures allow to assume the average indoor temperature (Fig. 6a) as a representative quantity for the SHM correlations. A similar conclusion is drawn for the relative humidity, whose time series are highly correlated [4, 12] and exhibit correlation coefficients of the order of 0.90 or larger.

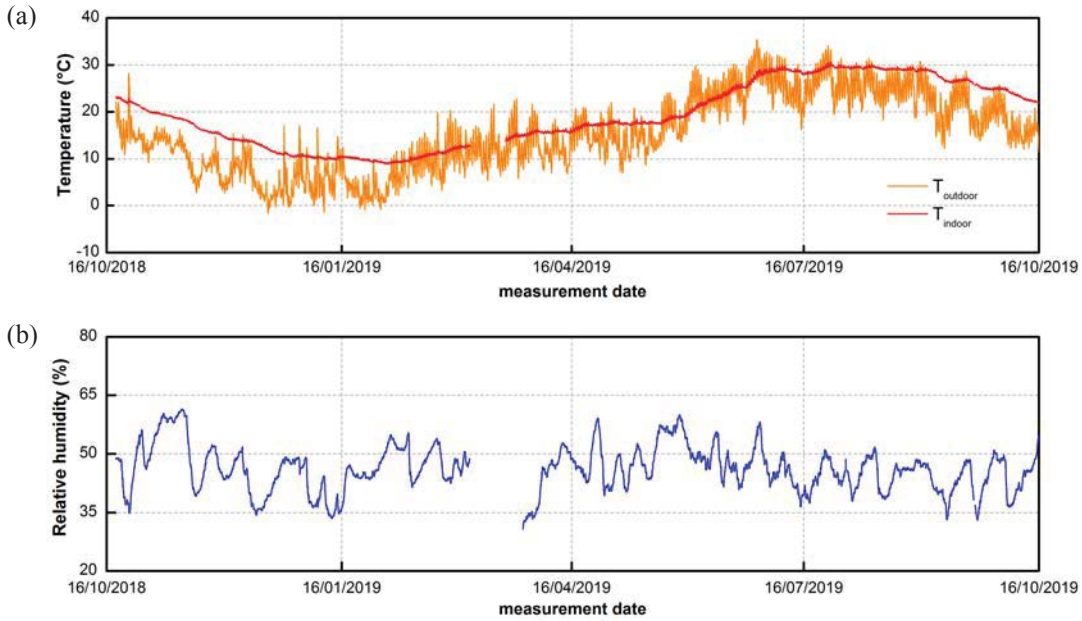

Figure 6: Evolution in time of: (a) average indoor temperature and outdoor temperature; (b) average indoor relative humidity.

5.2 Environmental effects on natural frequencies

The results of automated modal identification and frequency tracking during the first year of monitoring are exemplified in Fig. 7 for the lower 6 modes of the cathedral, exhibiting the higher identification rate. The complete results of automated OMA in terms of natural frequencies and damping ratios are summarized in Table 1 with some statistical information. In more details, Table 1 lists the identification rate, the mean value (f_{mean}) and the standard deviation (σ_f) of the automatically identified frequencies and their extreme values (f_{min}, f_{max}) as well as the mean value (ζ_{mean}) and the standard deviation (σ_ζ) of the damping ratio.

It should be noticed that the identification rate of the frequencies in Fig. 7 ranges between 99.8 % and 88.9 % (Table 1), whereas the higher two frequencies exhibit lower identification success ratios still allowing the tracking with an acceptable continuity.

As expected [5-11], Fig. 7 reveals clear long-term variations as well as daily fluctuations of natural frequencies, that are conceivably associated with changing temperature. In addition, the environmental effects turn out to be very distinctive and this peculiarity is understood, for

example, by carefully inspecting the time evolution of f_{C2} and f_{C4} in Fig. 7. Those modes, whose variation is quite easy to inspect in Fig. 7, are characterized by dominant motion in the longitudinal E-W (f_{C2}) and transverse N-S (f_{C4}) direction (Fig. 5).

Mode	Id. Rate	f_{mean} (Hz)	σ_f (Hz)	f_{min} (Hz)	f_{max}(Hz)	ζ_{mean} (%)	σ_ζ (%)
C1	99.8 %	1.383	0.011	1.359	1.423	3.73	0.24
C2	99.3 %	1.677	0.020	1.605	1.739	5.17	0.81
C3	99.3 %	1.993	0.015	1.956	2.059	3.24	0.42
C4	97.9 %	2.530	0.021	2.477	2.632	3.25	0.42
C5	96.4 %	2.668	0.021	2.609	2.757	1.42	0.32
C6	88.9 %	2.778	0.034	2.683	2.923	5.15	0.55
C7	71.4 %	3.170	0.051	3.066	3.383	2.56	0.53
C8	36.9 %	4.177	0.038	4.094	4.350	1.80	0.31

Table 1: Statistics of the natural frequencies and damping ratios identified in the first year of monitoring.

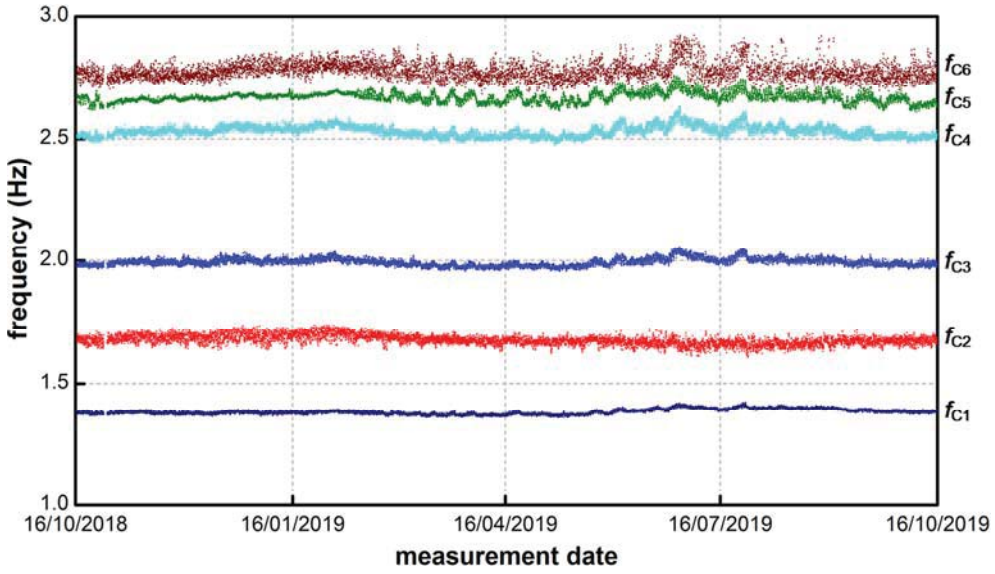

Figure 7: Variation in time of the natural frequencies of the lower 6 modes during the first year of monitoring.

Figure 7 highlights that the frequency of mode C2 clearly increases with decreased indoor and outdoor temperature (Fig. 6a) and decreases with increased temperature: this trend, which is exactly the opposite of what expected for masonry buildings [6-11], is confirmed by plotting the frequency f_{C2} versus the outdoor temperature (Fig. 8a), along with the best fit line: even if for a given temperature a quite remarkable frequency variation is observed, negative temperature correlation is exhibited by frequency f_{C2} during the entire monitoring period. It is worth mentioning that: (a) a negative frequency-temperature correlation is obtained with indoor average temperature and (b) the temperature effect on E-W mode f_{C6} is remarkably similar to what observed for mode f_{C2}, especially in the cold season (Fig. 7).

Even more complicated temperature-driven mechanisms characterize the variation of N-S modes: as shown in Fig. 7, the frequency f_{C4} tends to increase both in the cold and in the hot season and a similar trend is exhibited by N-S modes f_{C1}, f_{C3} and f_{C5}. The correlation between f_{C4} and the outdoor temperature is exemplified in Fig. 8b and, as it has to be expected, a non linear best fit line is obtained.

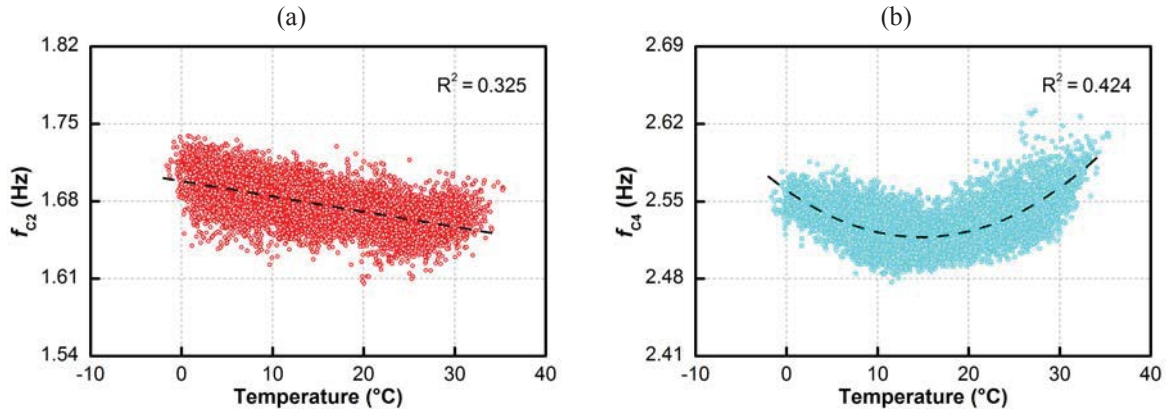

Figure 8: Correlation between outdoor temperature and identified natural frequencies: (a) f_{C2} and (b) f_{C4}.

It is further noticed that, during the cold season, a generalized (tensile) strain increase with decreased temperature is measured by the extensometers installed in the tie-rods [4]. Hence, the corresponding increased forces in the tension bars conceivably exert a stiffening action on the overall structure since the metallic tie-rods form a grid of stiffening elements spread over the entire cathedral (Fig. 2).

In summary, all natural frequencies of the cathedral exhibit a negative dependence on both indoor and outdoor temperatures in the cold season, whereas the correlation changes in the hot season, for the N-S modes only. The negative dependence of natural frequencies on temperature is a distinctive behavior of the Milan Cathedral, with this trend being very different from what generally reported in the long-term studies on masonry structures, either towers [6, 7, 10] or churches [6, 8-9]. Indeed, a negative frequency-temperature correlation is only reported in the literature for a monumental building [11], which is characterized by the presence of metallic tie-rods, as well.

In the authors' opinion, the complex dependence of natural frequencies on temperature observed in the Milan Cathedral results from two temperature-driven opponent effects: the stiffening exerted during the cold season by the increased tensile forces in the metallic grid of tie-rods and the usual thermal expansion of the masonry materials. The former effect turns out to be dominant in the cold season for all modes, whereas the latter tends to overcome in the hot season, for N-S modes.

Notwithstanding the complex temperature-driven behavior of the cathedral and the difference of trend exhibited by N-S and E-W modes, the removal of environmental effects can be performed, for example, by applying the principal component analysis (PCA) [18] to the frequency data collected during an appropriate training period. In the present application, the lower 6 modes (Fig. 7) were considered and the training period includes the first year of monitoring.

Since two latent sources of temperature-driven variability have been suggested by the previous analysis and those sources affect differently the N-S and E-W modes, the first four PCs are retained in order to establish the PCA-based model. As shown in Fig. 9, the PCA provides a very effective removal of the environmental effects.

Once the PCA-based prediction model has been established using the data collected during an appropriate training period, the occurrence of abnormal structural changes not observed during the training period is often detected by using the residual errors (i.e., the difference between the identified frequency and its prediction). Anomaly detection approaches might involve: (a) verifying that each prediction error does not exceed 95% confidence interval [19] or (b) using the prediction errors within the framework of statistical control charts (such as the well-known Hotelling's T^2 control chart [20]).

5.3 Mode shapes and mode complexity

As previously pointed out, a quite dense network of high quality seismometers is installed in the Milan Cathedral, so that the mode shape variations should be investigated with SHM purposes. Since the environmental changes affect almost uniformly any structural system, the mode shapes are supposed to be less sensitive [10] than natural frequencies to those changes. Consequently, if the mode shapes turn out to be approximately time-invariant during an appropriate observation period (including a statistically representative sample of environmental conditions), any subsequent variation in the mode shapes conceivably provides the evidence of a structural change [21]. On the other hand, even if mode shapes contain also local information on the structure, those parameters might exhibit low sensitivity to local structural changes.

The evolution during the first year of monitoring of the mode shape variation, in terms of MAC, is shown in Fig. 10 for the lower 6 modes. It should be noticed that the MAC index is computed between a pre-selected set of reference mode shapes (corresponding to the same set of baseline modes used in the automated procedure of modal identification, Fig. 5) and the currently identified mode shapes. Figure 10 highlights that the MAC values (i.e., the mode shapes) are approximately independent of temperature and time invariant, even if the standard deviation of the MAC tends to increase with the increasing mode order (i.e., with the increasing spatial complexity of the distribution of modal deformations, Fig. 5). Columns 2-4 of Table 2 summarize the statistical characteristics of the MAC in terms of average value (MAC_{mean}), standard deviation (σ_{MAC}) and minimum value (MAC_{min}).

The investigation on mode shape changes was carried out also by considering the mode complexity, through the MPC (i.e., the collinearity of the mode shape components of each single mode on a straight line in the complex plane). Figure 11 and columns 5-7 of Table 2 demonstrate that also the MPC measure of mode complexity [13] is approximately time invariant, even if the MPC values tend to depart from unity (perfect collinearity) and to exhibit an increased dispersion for the higher modes.

6 CONCLUSIONS

The paper focuses on the monitoring program of the Milan Cathedral. Special emphasis is given on the dynamic measurements, the automated extraction of modal signatures and the influence of environmental changes on the variations observed in the dynamic characteristics of the historic monument. Based on the results collected in the first year of monitoring (i.e., between 16/10/2018 and 15/104/2019), the following main conclusions can be drawn:

- The application of state-of-art tools for automated operational modal analysis allows accurate estimate and tracking of 8 resonant frequencies in the frequency interval 0-5 Hz.

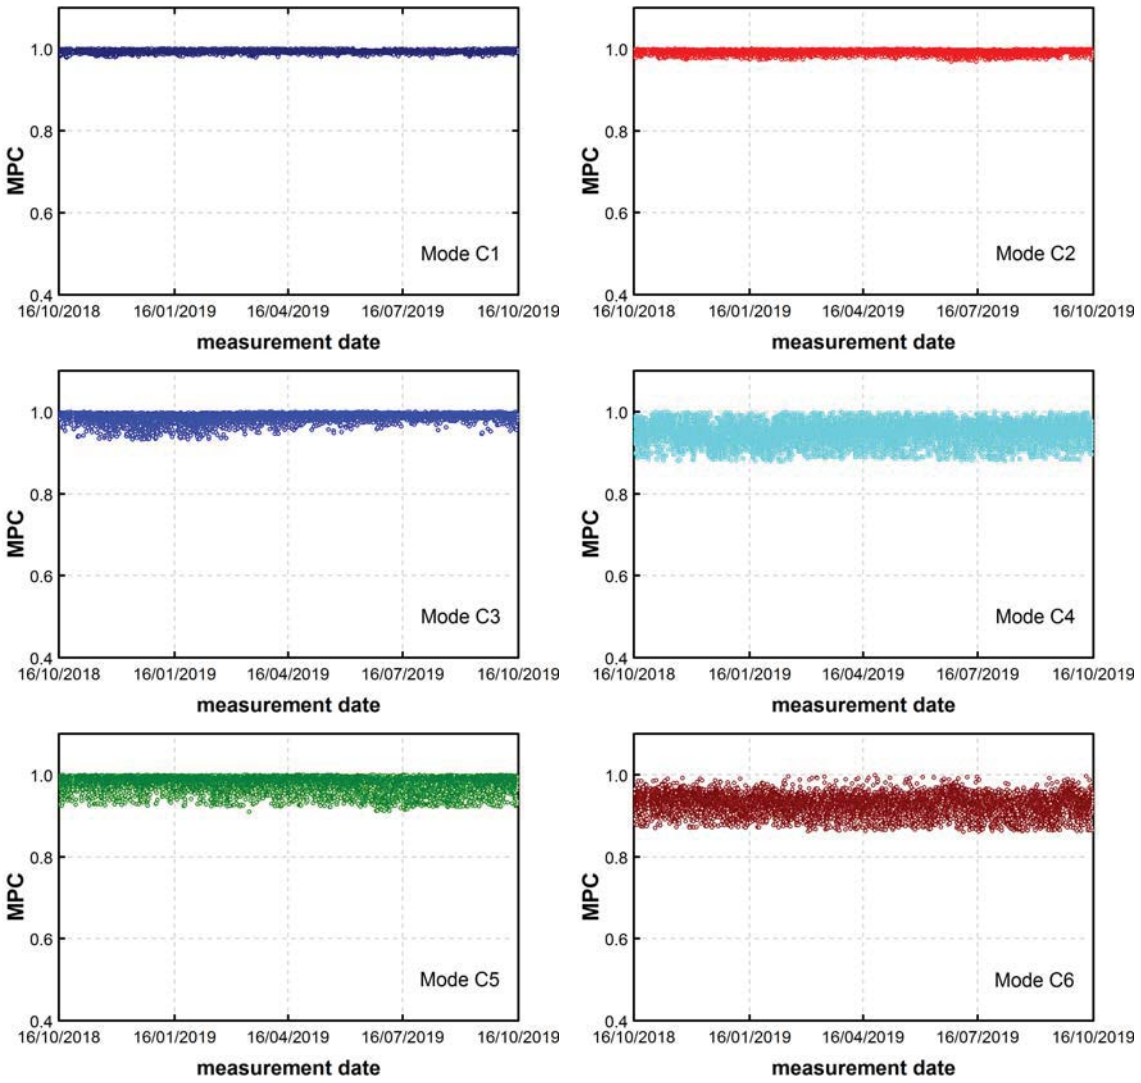

Figure 11: Variation in time of the MPC of the lower 6 modes during the first year of monitoring.

- The automatically identified modes involve dominant motion in the main transverse (N-S) and longitudinal (E-W) direction of the cathedral.
- The (outdoor and indoor) temperature turned out to be a dominant driver of the variations observed in the fluctuation of the resonant frequencies of all modes. The relative humidity seems to slightly affect only the frequency of the first mode [4].
- The frequency-temperature correlations reveal a distinctive trend, which is very different from what reported in almost all long-term studies on historic masonry structures. The natural frequencies of the cathedral exhibit a negative dependence on indoor and outdoor temperature in the cold season, whereas the correlation becomes positive in the hot season, for the N-S modes only.
- The complex dependence of natural frequencies on temperature observed in the Milan Cathedral conceivably results from two temperature-driven opponent effects: the stiffening exerted during the cold season by the increased tensile forces in the metallic tie-rods and the usual thermal expansion of the masonry materials. The former effect turns out to be dominant in the cold season for all modes, whereas the latter tends to rule the frequency variation of N-S modes in the hot season.

- PCA-based regression models are suitable to remove the environmental effects from natural frequencies.
- The mode shapes of the cathedral and the corresponding mode complexity (evaluated via MPC) do not exhibit appreciable fluctuations associated with the environmental effects, so that an appropriate strategy of SHM should be based also on the time invariance of modal deformations.

ACKNOWLEDGEMENTS

The support of *Veneranda Fabbrica del Duomo di Milano* and the precious co-operation of Francesco Canali is gratefully acknowledged. The authors would like to thank the technical staff of AGISCO and *Veneranda Fabbrica del Duomo di Milano* for mounting all monitoring devices, and the technical staff of SARA Electronics Instruments for the assistance during the installation and the initial operational setting of the seismometers.

Keywords: Masonry tower, Damage localization, Model updating, Operational Modal Analysis, Non-destructive test, Historical constructions

Abstract. *The structural health conditions of masonry towers can be monitored with a few dynamic sensors (e.g. accelerometers or seismometers) placed at the top of the structure. This cost-effective setup provides continuous and reliable information on the natural frequencies of the structure; however, to move from anomaly detection to localisation with such a simplified distribution of sensors, a calibrated numerical model is needed. The paper summarises the development of a Structural Health Monitoring (SHM) procedure for the model-based damage localisation in masonry towers using frequency data. The proposed methodology involves the subsequent steps: (i) preliminary analysis including geometric survey and Ambient Vibration Tests (AVTs); (ii) FE modelling and updating based on the identified modal parameters; (iii) creation of a Damage Location Reference Matrix (DLRM) from numerically simulated damage scenarios; (iv) detection of the onset of damage from the continuous monitoring system performed with state-of-art techniques, and (v) localisation of the anomalies through the comparison between the experimentally identified variations of natural frequencies and the above-defined location matrix, called DLRM. The proposed SHM methodology is exemplified on the ancient masonry tower of Zuccaro in Mantua, Italy. Pseudo-experimental monitoring data were generated and employed to assess the reliability of the adopted algorithm in identifying the damage location. The results show a promise toward the practical applications of the proposed methodology in the monitoring of real structures.*

1 INTRODUCTION

Within the context of Structural Health Monitoring (SHM) of masonry towers, recent experiences [1-4] provided the evidence that the installation of few high-sensitive accelerometers at the top of the structure, combined with automated modal identification tools, can reveal the onset of damage under changing environments. This cost-effective measurement setup provides continuous and reliable information on the natural frequencies of the structure; however, to move from anomaly detection to localisation with such a simplified distribution of sensors, a calibrated numerical model is needed.

One possibility for performing damage localisation of masonry towers is the use of the surrogate-based FE model updating based on cleaned observations [3]. Once the fluctuations from the environmental effects are removed from the identified natural frequencies, the FE model of the structure is updated each time a new observation is available. Consequently, abnormal changes in structural parameters are detected and correlated with their location; in this case, the localisation is performed among the areas involved in the updating. Another way to localise the damage, based on nonlinear dynamic analysis, is shown in [4]: once an anomaly is detected from the monitoring system, a non-linear dynamic analysis is performed with the recorded seismic sequence to identify the areas prone to damage. Subsequently, the frequency decays obtained from the FE analysis, and the one from the monitoring system are compared. The main limitation of the first approach is the detail of the localisation. At the same time, in the latter, the non-linear dynamic analysis is computationally expensive and based on numerous assumptions on material properties.

In the present study, a model-based damage localisation procedure based on previously computed damage scenarios is developed, to increase the capability of real-time damage evaluation after a seismic event. A FE model of the structure is employed to study how damage in a specific location affects the mutual variation between the natural frequencies; accordingly, a damage localisation algorithm based on natural frequency changes is proposed.

The procedure outlined in this paper is summarised in Fig. 1 and involves the following steps: (i) preliminary analysis including geometric survey and ambient vibration tests (AVTs); (ii) FE modelling and updating based on the identified modal parameters; (iii) creation of a Damage Location Reference Matrix (DLRM) from numerically simulated damage scenarios; (iv) detection of the onset of damage from the continuous monitoring system performed with state-of-art techniques, and (v) localisation of the anomalies through the comparison between the experimentally identified variations of natural frequencies and the DLRM location matrix.

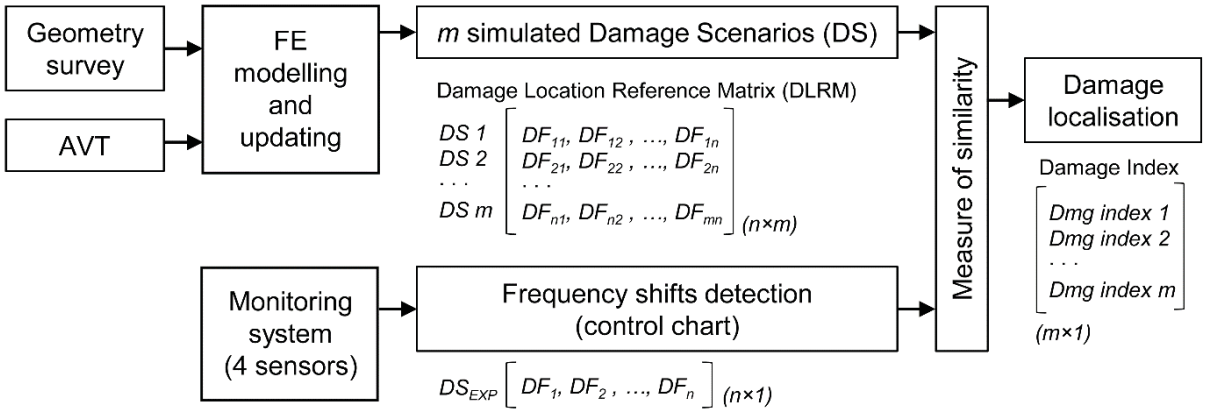

Figure 1: Damage localisation procedure for masonry towers based on the Damage Location Reference Matrix.

The proposed SHM methodology is exemplified on the ancient *Zuccaro*'s tower in Mantua, Italy. Firstly, documentary research, direct on-site inspections, AVTs and FE modelling and updating were performed and are fully reported in [5] and [6]. Subsequently, pseudo-experimental monitoring data are generated from the calibrated model and employed to assess the reliability of the adopted algorithm in identifying the damage location. It is worth mentioning that the investigated structure is of interest due to the quite large number of identified natural frequencies with only four seismometers and the peculiar shape of the last two modes representing a warping distortion of the cross-section.

2 THE DLRM APPROACH FOR DAMAGE LOCALIZATION

The developed DLRM approach is designed to give information on the damage location using only the measured changes in natural frequencies.

It is assumed that a monitoring system with few sensors is available so that the natural frequencies are continuously identified, the environmental effects are removed, and the occurrence of structural anomalies is detected through statistical tools, such as the control charts. Control charts are graphical representations of the evolution over time of a certain process with designed control limits to detect abnormal observations. For SHM purposes, the control limits are based on an initial training period when the structure is assumed to be undamaged. The successful use of control charts in damage detection of ancient constructions has been reported by different scholars [1, 4]. In this paper, the Hotelling multivariate control chart based on the T^2 statistic [7] is adopted.

From a calibrated numerical model, a series of damage scenarios are simulated, and the consequent variations of natural frequencies are collected in a matrix called DLRM. Through a comparison of similarity between the frequency variations in the DLRM and the ones detected from the cleaned observations of the continuous monitoring system, it is possible to locate in which area the anomaly appeared.

To clarify the working principles of the DLRM approach, the model of an idealised masonry tower is employed. Fig. 2 shows the geometry adopted and the *n* vibration modes involved. As demonstrated by different researches [1-4], the first torsion mode (T_1) and four bending modes (B) are often identified with the low-cost monitoring setup.

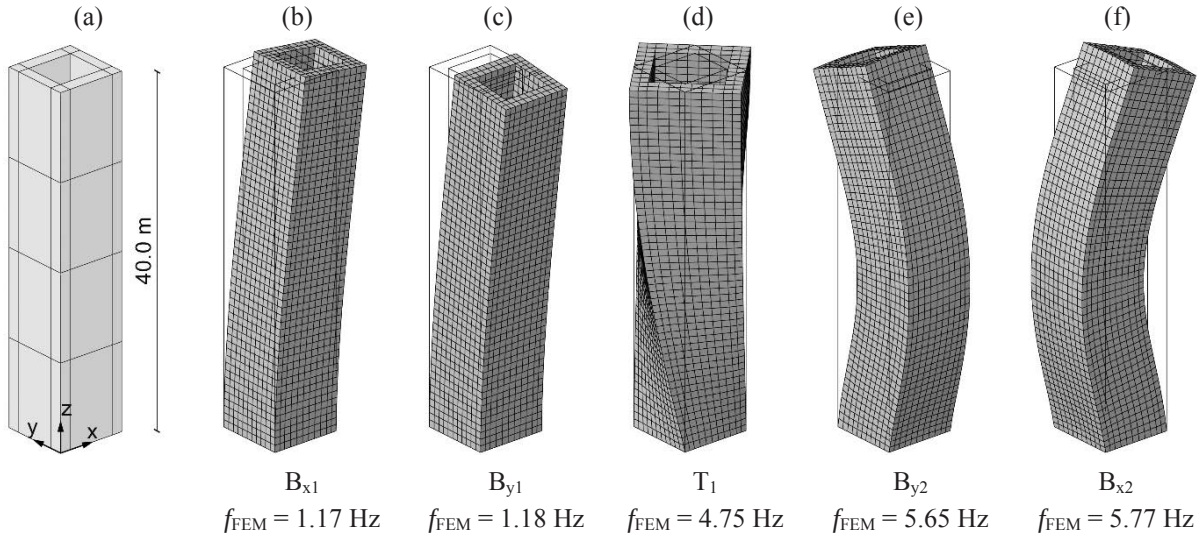

Figure 2: (a) Idealised tower geometry; (b-f) numerical vibration modes employed in the damage localisation.

2.1 Creation of the Damage Location Reference Matrix (DLRM)

The DLRM contains the *m* percentage of variation of the *n* considered natural frequencies. The creation of the DLRM is performed as follow:

(i) the previously calibrated FE model is divided into *m* elements (Fig. 2a), differentiating corners and walls in plan, and floors in height;
(ii) *m* eigenvalue analyses are performed reducing the elastic modulus of each element by a certain quantity (e.g. 40%);
(iii) the changes in the *n* natural frequencies are collected in an *n*-by-*m* matrix called DLRM.

The effects of the different Damage Scenarios (DSs) are measured through the percentage of frequency discrepancy, defined as follow:

$$DF_i = \frac{f_i^u - f_i^d}{f_i^u} \cdot 100 \tag{1}$$

where the *i-th* natural frequencies of the structure before and after the damage are represented by $f_i{}^u$ and $f_i{}^d$, respectively.

To give an example on how the location of damage influences the natural frequencies, Fig. 3 illustrates the comparison between the simulated DS of the idealised tower for the elements of two consecutive floors. The DSs are obtained reducing the elastic modulus of each element by the 40%. As presented in Fig. 1, the DSs are the rows of the DLRM.

From the analysis of this simplified application, it is possible to draw the following observations on the effectiveness of the localisation procedure using the frequency variations:

(a) The DS belonging to different floors gives in all cases different pattern of frequency variations (Fig. 3);
(b) The DS of the four corner elements belonging to the same level (Figs. 3a-b, bars with the same colour) gives the same frequency variations;
(c) The DS on the four wall elements belonging to the same floor (Figs. 3c-d, bars with the same colour) gives the same frequency variations when aligned on the same direction.

2.2 Model-based Damage localisation

Once the onset of damage is detected, it is possible to identify its location analysing the variation of natural frequencies. Comparing the frequency shifts obtained from the monitoring system with the *m* simulated damage scenarios, it is possible to locate the damage among the *m* elements previously identified. The Cosine Similarity is adopted to measure the similarity between the vector of the identified experimental frequency shifts ($\boldsymbol{DS}_{EXP}$) and the *m* vectors of the simulated damage scenarios ($\boldsymbol{DS}_j$):

$$\cos\theta_j = \frac{\boldsymbol{DS}_j \cdot \boldsymbol{DS}_{EXP}}{\left\|\boldsymbol{DS}_j\right\| \cdot \left\|\boldsymbol{DS}_{EXP}\right\|} \tag{2}$$

where θ_j is the *j*-th angle between the two vectors. In the present paper, the adopted Damage Index is expressed as follow:

$$Damage\ Index_j = (\cos\theta_j)^2 \tag{3}$$

where values close to 1 suggest a good correlation with the identified frequency shifts while values lower than 0.8 suggest a poor correlation. The *j*-th Damage Index is then plotted together with the corresponding *j*-th DS – representing the element location – (e.g. Fig. 4). The localisation is then performed considering the location associated with the higher Damage Index.

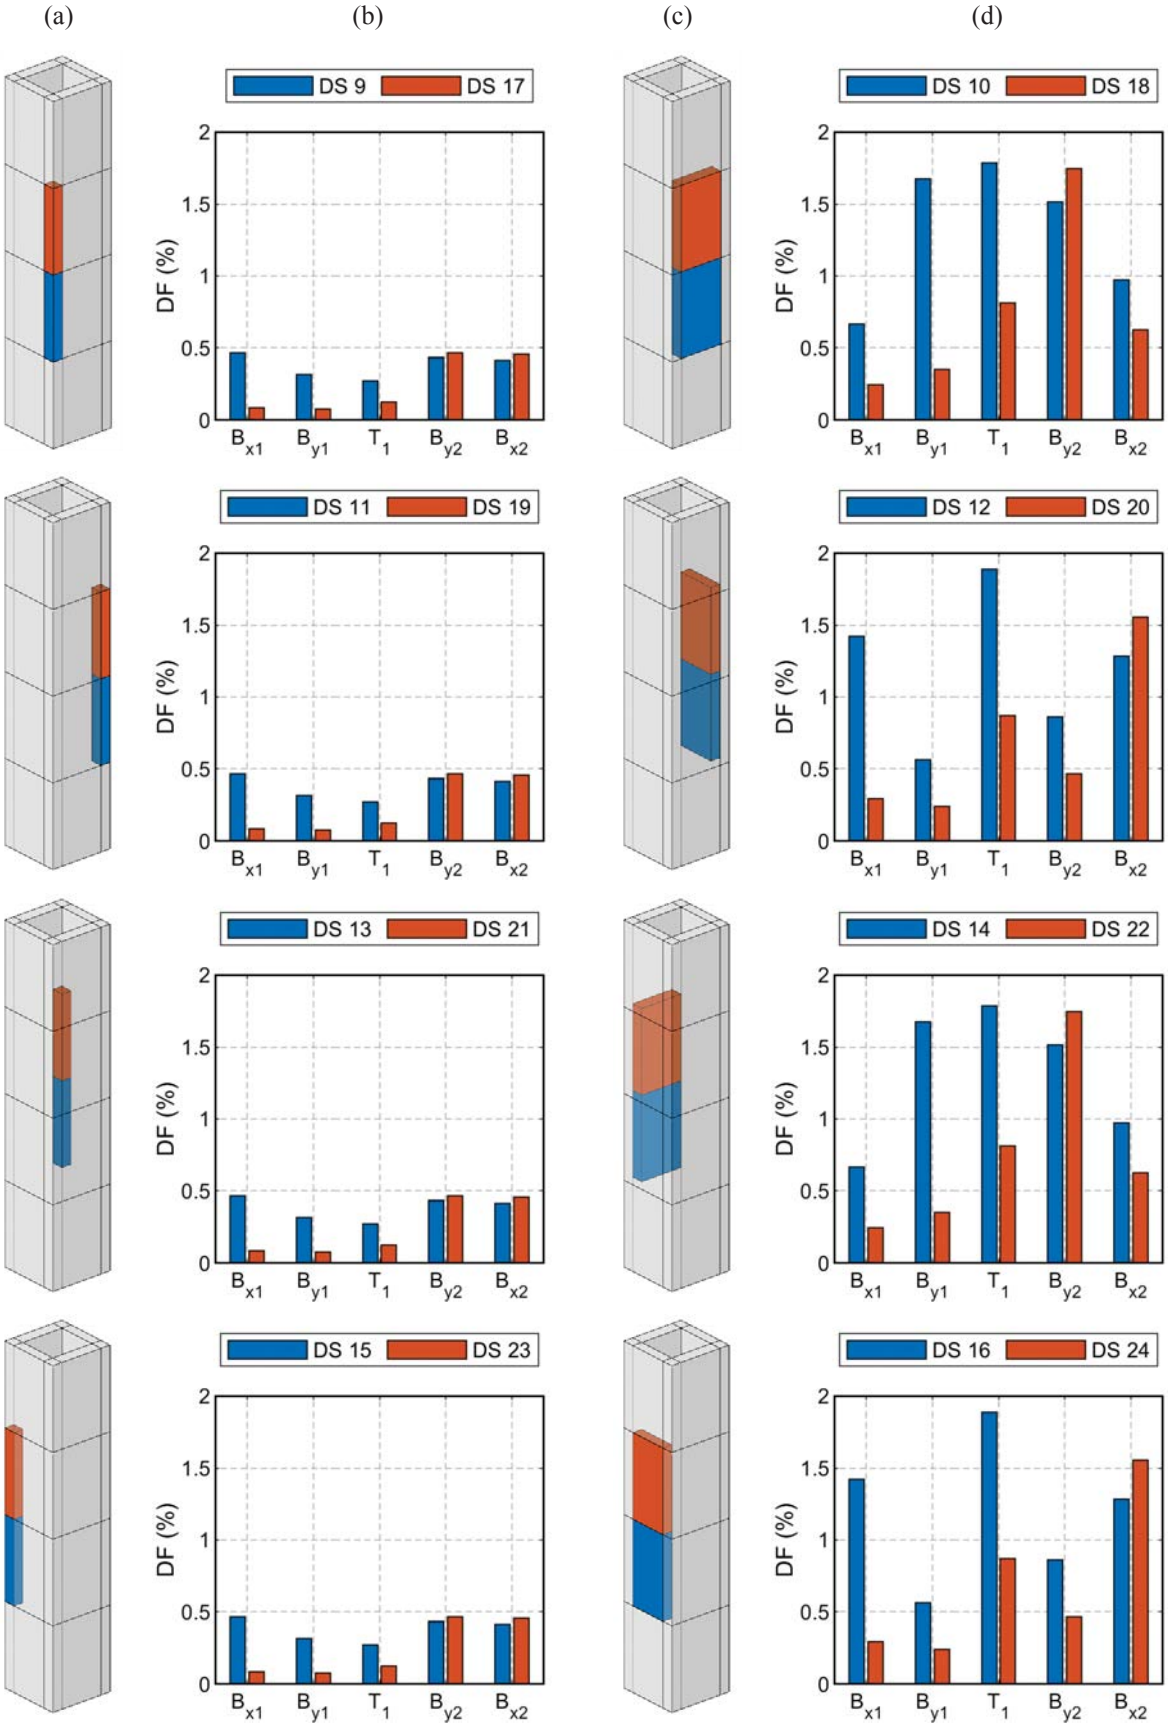

Figure 3: Comparison between the simulated Damage Scenarios (DS) of the first (a-b) and second (c-d) floor in terms of the discrepancy of frequency (DF, Eq. 1).

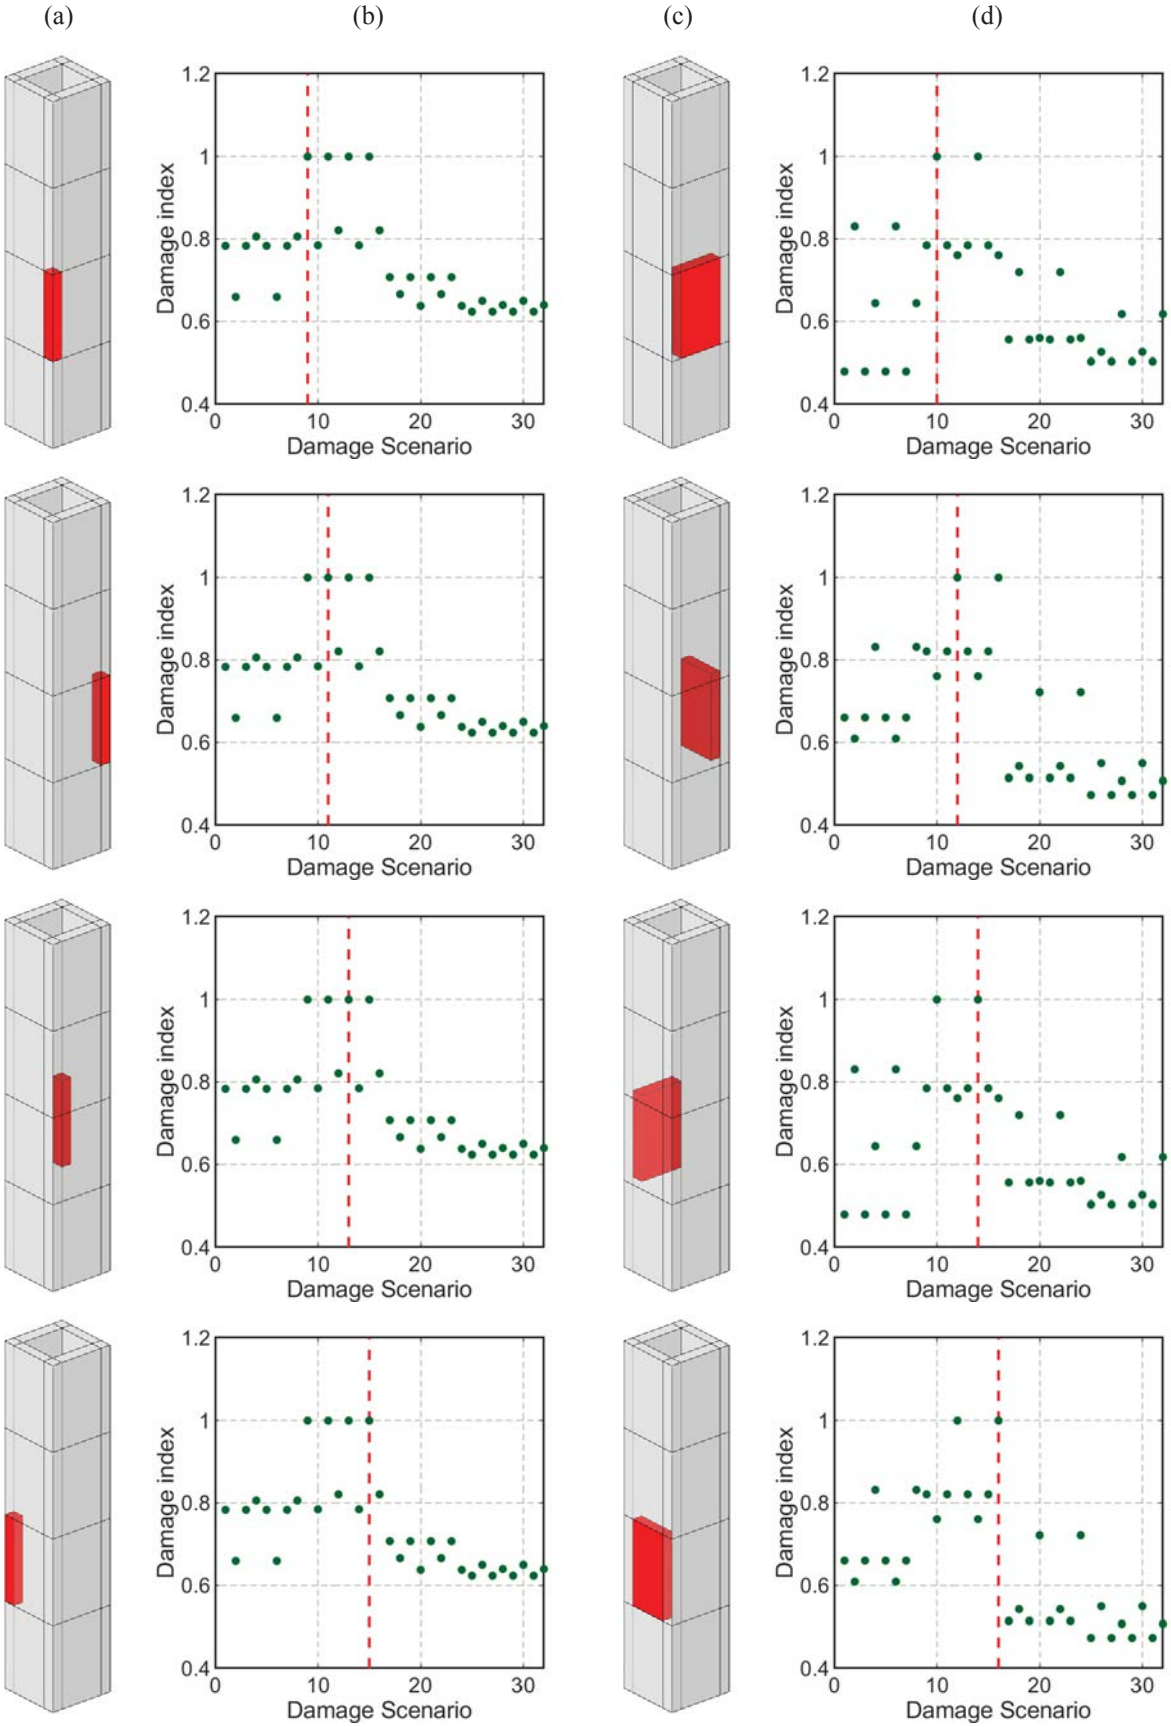

Figure 4: Localisation of simulated frequency shifts obtained by decreasing the elastic moduli of first-floor walls (c-d) and corners (a-b) by the 20% (the red dashed line represents the actual damage location).

The localisation procedure is exemplified on the model of the idealised tower. 8 frequency shifts are simulated reducing the elastic modulus of the 8 elements of the first floor by the 20% (Figs. 4a-c). The simulated DS_{EXP} are then compared with the *j*-th DS of the DLRM. The following observations can be drawn:

(a) As expected, it is not possible to distinguish between a DS on a corner element belonging to the same floor;

(b) Similarly, it is not possible to differentiate between the DS on wall elements belonging to the same level and same direction.

In conclusion, a numerical model of an idealised tower was employed to exemplify the application of the DLRM approach showing promising results. It should be noticed that increasing the number and the type (e.g. bending, torsion, or local) of vibration modes can substantially increase the effectiveness of the localisation capability of the proposed approach.

3 THE ZUCCARO'S TOWER: DESCRIPTION AND DYNAMIC TESTING

The *Zuccaro*'s tower of Mantua (Fig. 5), about 43 m high, is a historical defensive structure built in the Middle Ages [5]. The first record regarding its existence dates back to 1143. The few and small openings and the tower location at the limits of the city Middle Ages fortifications suggest its original defensive role. As shown in Fig. 5, the tower is nowadays included in a building aggregate, surrounded on three-sides by low-rise constructions.

The structure has an approximate squared plan with the side equal to 8.5 m. The load-bearing walls are built in solid brick masonry with a thickness ranging from 1.1 m at the base to 0.8 m at the top. A brick masonry cross vault is covering the ground floor, while a timber staircase is connecting the 8 timber floors distributed along the height of the structure (Fig. 7). It is worth mentioning that the roof and the timber floors were substituted after a fire occurred in 1979 and the related intervention – carried out in the 90s – involved the injection of expanding mortars in several areas.

Due to a large number of uncertainties regarding the evolution of the building and the effectiveness of strengthening interventions, an extensive investigation survey was recently carried out involving visual inspection and Ambient Vibration Testing (AVT). The results of the investigations are reported in [5] and [6]. The survey was aimed at providing details on the geometry of the structure, detect critical areas and irregularities, and identify the dynamic characteristics of the structure (i.e. natural frequencies and mode shapes).

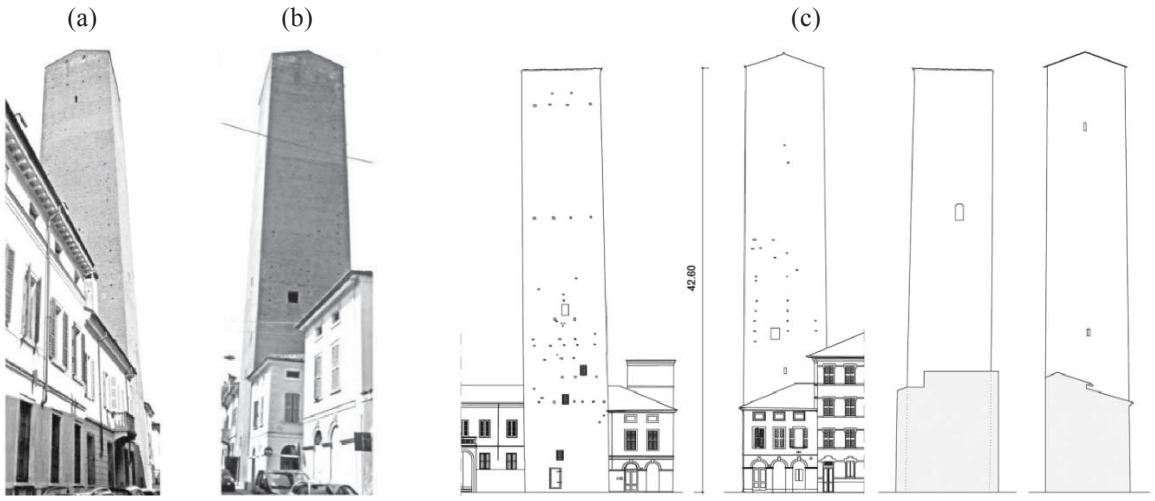

Figure 5: The *Zuccaro*'s tower: views from the west (a) and south corners (b); and geometric survey of the external fronts (c).

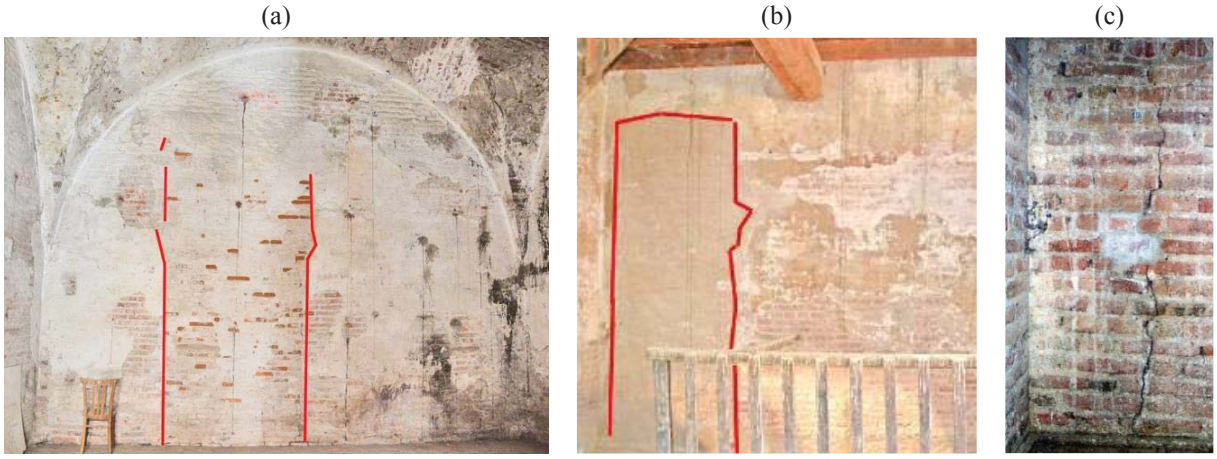

Figure 6: Details of masonry cracks and discontinuities: (a) ground floor, N-E front, (b) 1st floor, S-E front and (c) 3rd floor, S-W front.

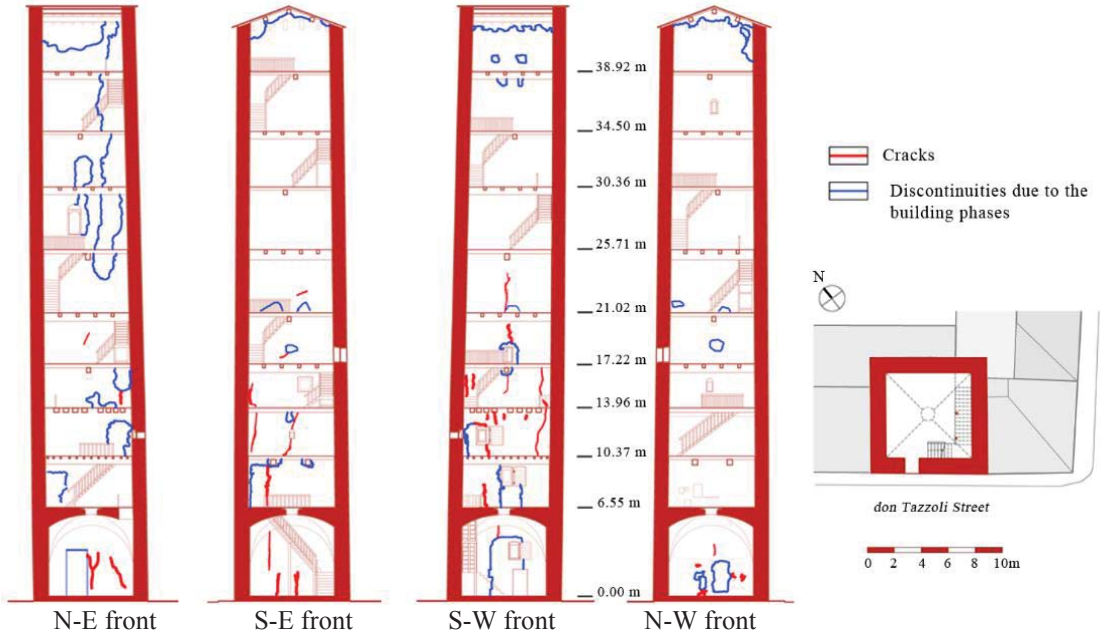

Figure 7: Section of the tower with the survey of the crack patterns and discontinuities due to different building phases.

3.1 On-site inspections

The accurate on-site inspections of the inner fronts of the tower are summarised in Fig. 7. From the stratigraphic survey, the discontinuities due to different building phases or local masonry reconstructions are identified. Furthermore, the on-site inspections highlighted the following aspects:

(a) Sharp discontinuities and deep cracks were found around the corner between the S-W and S-E walls (Fig. 6c) starting from the base up to 17.22 m;
(b) Some deep and thick cracks were identified on the cross vault at the ground level;
(c) The presence of large areas with fragmentary and non-homogeneous masonry was identified starting from the height of 21.0 m on the N-E front (Fig. 7);
(d) Extended dark areas resulting from the fire of 1979 were found in the inner walls.

3.2 Dynamic characteristics of the tower

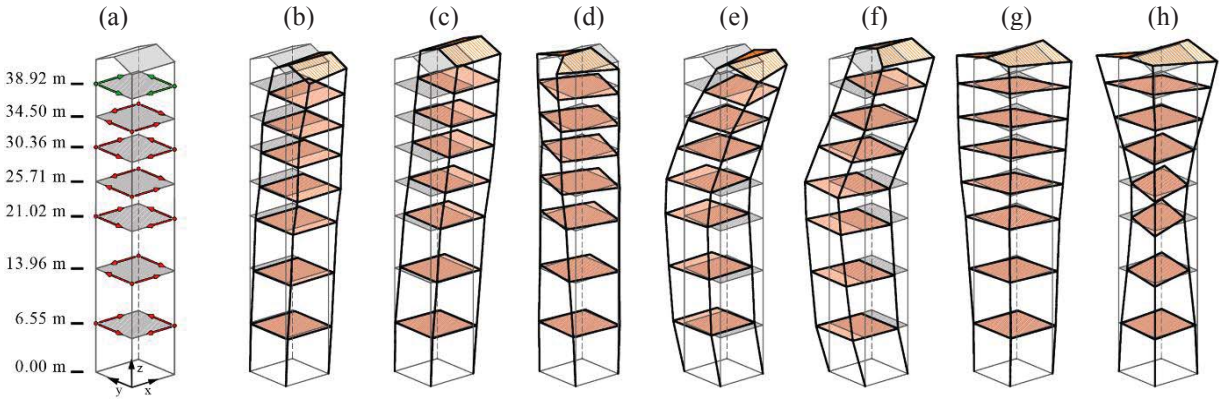
Two series of AVTs were conducted on the tower involving a different number of sensors. The first test (4 measuring channels) was performed between October 23rd and 24th, 2016 [6] with the twofold objective of identifying the vibration modes of the structure and evaluating the effectiveness of a 4-sensor setup for the future installation of a monitoring system. The second test (28 measuring channels) was performed between December 11th and 12th, 2017 [5] with the objectives of obtaining a complete representation of the mode shapes and roughly assessing the impact of temperature changes on natural frequencies.

During the first test, 2 bi-axial seismometers (electro-dynamic velocity transducers, SARA SS45) were positioned at the opposite corners of the top floor to measure the dynamic response of the structure under ambient excitations. During the second test, high-sensitivity accelerometers (sensitivity of 10 V/g; peak acceleration of 0.5 g) were employed to measure the response of the tower in 14 points belonging to 7 selected cross-sections (Fig. 8a).

The extraction of the modal parameters was performed with two well-known algorithms: the Frequency Domain Decomposition (FDD [8]) and the data-driven Stochastic Subspace Identification (SSI-data [9]). Both algorithms are available in the commercial software ARTeMIS [10]. Overall, 4 bending modes (B), 1 torsion mode (T) and 2 warping distortion modes (W) were identified in the frequency range of 0-9 Hz.

In the present paper only the results of the second test are reported and Fig. 8 summarises the modal parameters identified. The sequence of the first 5 modes is consistent with the results obtained in similar studies [3-4], whereas the last two modes appear to be very peculiar of the investigated structure. From the analysis of the identified dynamic characteristics, the following observations are drawn:

(a) Two closely spaced bending modes in opposite directions (B_{y1} and B_{x1}) are identified between 1.2 and 1.3 Hz;
(b) The third mode is a global torsion mode (T_1) followed by other two higher-order bending modes (B_{y2} and B_{x2});
(c) The last two modes (W_1 and W_2) are associated with cross-section distortion of first and second order. The peculiar shape of these modes is known as warping.
(d) Regardless of the differences in the external temperatures, an excellent correspondence between the first 5 vibration modes was found while W_1 and W_2 exhibit a stronger sensitivity to the environmental conditions.



Mode no.	B_{y1}	B_{x1}	T_1	B_{y2}	B_{x2}	W_1	W_2
f_{SSI} (Hz)	1.225	1.280	4.095	4.781	4.977	5.504	7.465

Figure 8: (a) Sensors layout of the AVTs of 11-12 December 2017 (T =2.4°C); (b)-(h) Identified vibration modes.

4 THE ZUCCARO'S TOWER: FE MODELLING AND UPDATING

The 3D model of the tower was developed with the FE code ABAQUS using the eight-node brick elements (C3D8). A relatively large number of elements were employed to obtain a regular distribution of masses, a good description of the opening distribution, and to avoid frequency sensitivity to mesh size. Overall, the numerical model consists of 10582 brick elements with 48438 degrees of freedom and an average mesh size of 0.5m (Fig. 9a).

Once the geometry of the numerical model is established, the selection of the structural parameters to be updated is the next key issue. To prevent the ill-conditioning of the inverse problem and to improve the robustness of the updated parameter estimates the number of updating variables was kept smaller than the experimental parameters used as targets and only the uncertain structural parameters were updated. Consequently, the following assumptions were adopted: (a) the effect of soil-structure interaction was neglected, and the tower was assumed pinned at the base; (b) a linear elastic orthotropic material was adopted for the brick masonry, with constant mass density and Poisson's ratio equal to 17 kN/m^3 and 0.15 respectively; (c) the shear modulus was considered equal to $G = \alpha \cdot E$, where E is the Young's modulus, and α is a constant multiplier.

In addition, to calibrate all the identified vibrations modes, the following aspects were considered:

(a) the presence of the building aggregate was modelled with a uniform distribution of linear elastic translational springs with constants k_x and k_y on the S-E side and N-E side, respectively;
(b) the masonry walls were divided into 2 regions with constant material properties based on successive modelling refinement involving different assumptions on the model uncertainties (the full process is described in [6]);
(c) the presence of timber floors was simulated with a series of rigid beams connected to the vertical walls using linear elastic springs (constant k_{RS}).

Overall, the number of updating parameters was equal to 6: 2 Young's moduli, the ratio α, and the springs constants k_x, k_y and k_{RS}.

The adopted FEMU procedure was implemented in MATLAB environment and it is based on the Douglas-Reid method [11] with the Particle Swarm Optimisation (PSO) algorithm [12]: the updating parameters are iteratively corrected in a constrained range until a stable minimum solution for an objective function is found. Particularly, the following objective function was adopted:

$$J(\boldsymbol{x}) = \frac{100}{n} \sum_{i=1}^{n} \left| \frac{f_i^{AVT} - \widehat{f}_i(\boldsymbol{x})}{f_i^{AVT}} \right| \tag{4}$$

where f_i^{AVT} is the i-th experimentally identified natural frequency and $f_i(\boldsymbol{x})$ is the i-th polynomial approximation [11] of the numerical natural frequencies, expressed as functions of the $\boldsymbol{x}$ updating parameters.

Tab. 2 lists the optimal estimates of the uncertain parameters of the model. The difference between the elastic modulus of the upper and lower part of the tower is motivated by the presence of fragmentary and non-homogeneous masonry starting from the height of 21.0 m (Fig. 7).

In conclusion, an excellent correlation between the numerical and experimental modal parameters is obtained, with the maximum frequency discrepancy (DF_{max}) being equal to 0.71%. Hence, the updated model is capable of accurately representing the experimentally identified modal parameters.

Mode no.	f_{SSI} (Hz)	f_{FEM} (Hz)	DF_i [%]	MAC
B_{y1}	1.225	1.226	-0.08	0.98

5 THE ZUCCARO'S TOWER: APPLICATION OF THE DLRM APPROACH

To test the capability of the proposed approach for the damage localisation in masonry towers, three damage scenarios (DS) were simulated, and pseudo-experimental monitoring data were generated for the *Zuccaro*'s tower. The previously updated numerical model was divided into 80 elements (Figs. 10a-b) – 8 elements per floor – to simulate the possible effect of local damages. Fig. 10 shows the selected elements, which belongs to different regions of the tower: lower (DS2), medium (DS44) and upper (DS74) parts.

The damages are simulated in a simplified way through a Young's modulus reduction by 30%. Fig. 11 shows the changes in natural frequencies generated by the three simulated DS. The maximum variation is obtained for the DS2 and it is equal to 0.47% on the first mode (B_{y1}) while in the other two cases the maximum variations are lower than 0.25%.

Since the installation of the monitoring system is ongoing, the monitoring data were generated from the experimentally identified natural frequencies. The environmental effects were not considered at this stage since the procedure is supposed to use the cleaned observations. Consequently, a normal distribution with a defined standard deviation was assumed for each frequency according to literature values (cleansed observations) [3].

Tab. 3 illustrates the adopted mean values and standard deviations for the pseudo-experimental monitoring data and reports the effects of the three DS on the 7 natural frequencies considered. It is worth noting that the DSs have comparable frequency shifts than the selected standard deviations (Tab. 3).

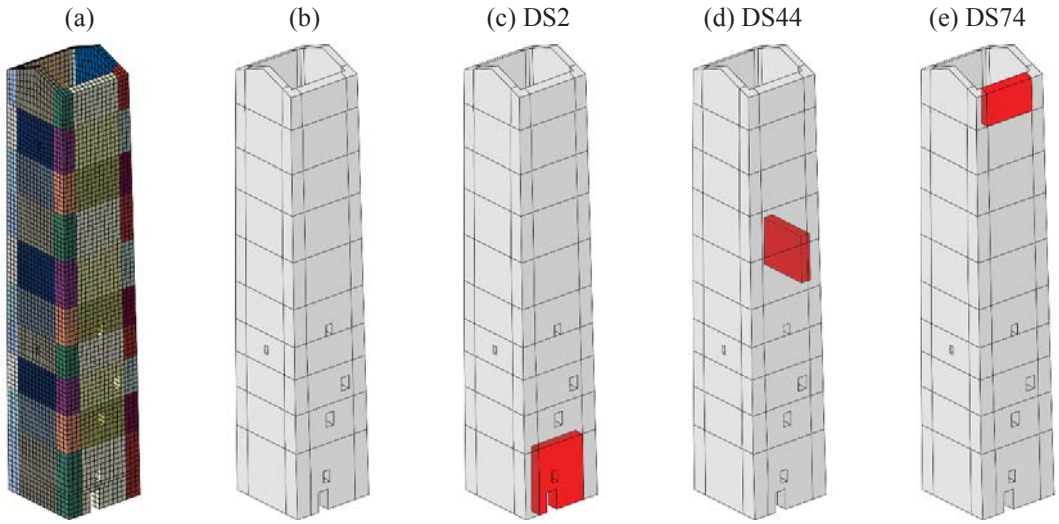

Figure 10: (a-b) FE model of the *Zuccaro*'s tower divided into 80 elements; (c-e) simulated damage scenarios.

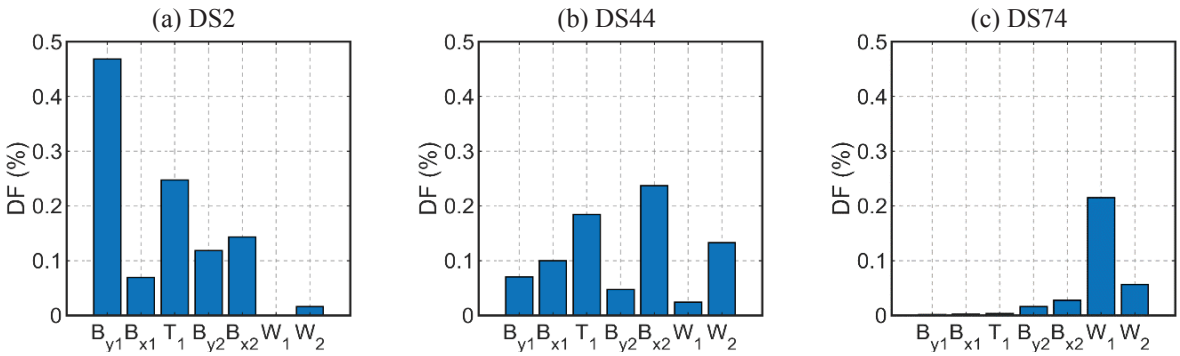

Figure 11: Comparison between the frequency shifts (DF, Eq. 1) of the three introduced damage scenarios.

	f_{mean} (Hz)	σ_f (Hz)	Δf_{DS2} (Hz)	Δf_{DS44} (Hz)	Δf_{DS74} (Hz)
B_{1y}	1.225	0.005	0.006	0.001	0.000
B_{1x}	1.280	0.005	0.001	0.001	0.000

B_{2y}	4.781	0.010	0.006	0.002	0.001
B_{2x}	4.977	0.012	0.007	0.012	0.001
W_1	5.504	0.020	0.000	0.001	0.012
W_2	7.465	0.030	0.001	0.010	0.004

Table 3: Statistic of the pseudo-experimental monitoring data with 3 simulated damage scenarios.

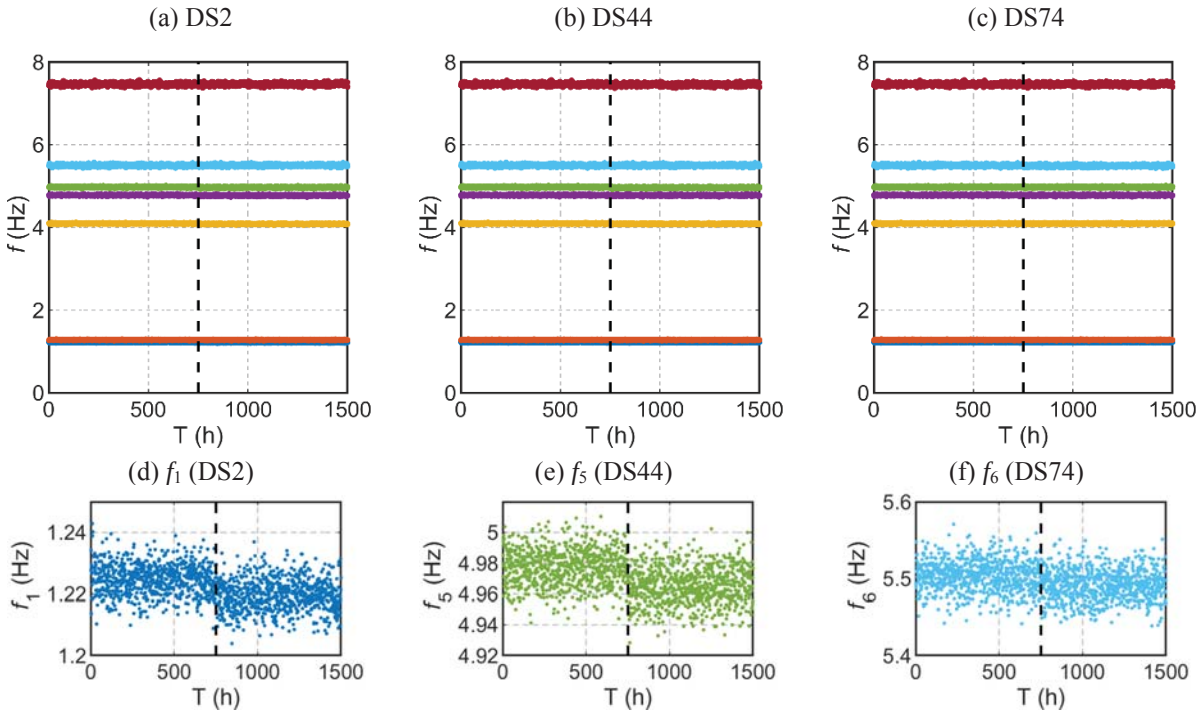

Figure 12: (a-c) Pseudo experimental monitoring data; (d-f) focus on the frequencies with the higher changes.

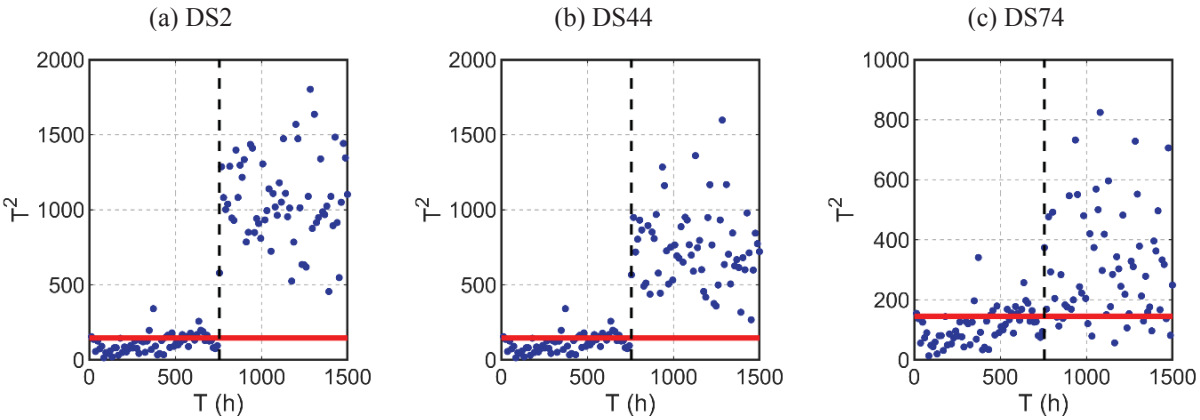

Figure 13: Damage detection through control charts for the 3 damage scenarios.

Overall, 1500 observations are generated (1 observation per hour), and the simulated frequency shifts are introduced in the middle of the generated time history (T=750h; Fig. 12). The frequency shifts are particularly visible on the first mode (B_{y1}; Fig. 12d) for the DS2 and on the fifth mode (B_{x2}; Fig. 12e) for the DS44. Conversely, the effects of the DS74 on f_6 (W_1; Fig. 12f) are less evident; in this case, the standard deviation for the mode W_1 is equal to 0.02 Hz while the considered frequency shift is equal to 0.01 Hz.

To detect the presence of structural anomalies on the generated monitoring data, the control charts based on T^2 – statistic are adopted [7]. A training period of 336 h (14 days) was employed to define the mean values of for the 7 natural frequencies. The residual errors between the mean frequencies of the reference period and the frequencies of each observation are used to define a multivariate control chart (Fig. 13) composed by subgroups of 12 h. The structural anomalies are detected each time an observation lays outside the control limit. The black dashed line in Fig. 13 represents the instance in which the DSs were introduced. Clearly, the three DS are associated with different DFs (see Fig. 11) and consequently the outliers on the control charts are more evident in the DS2 (Fig 13a) where the DFs are higher while are less emphasised in the DS74 (Fig 13c) where the DFs are lower.

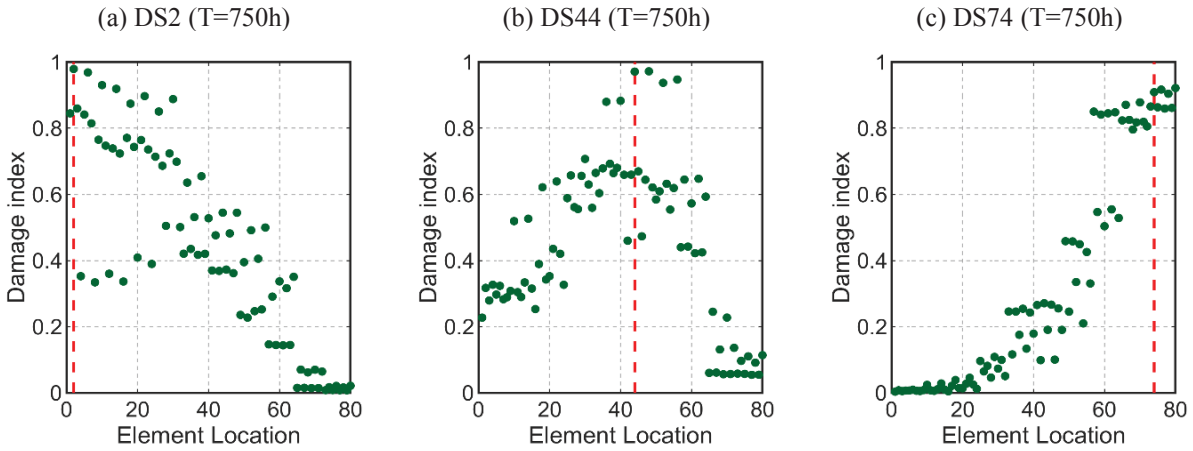

Figure 14: Damage localisation through the DLRM at the time T when the damage was introduced.

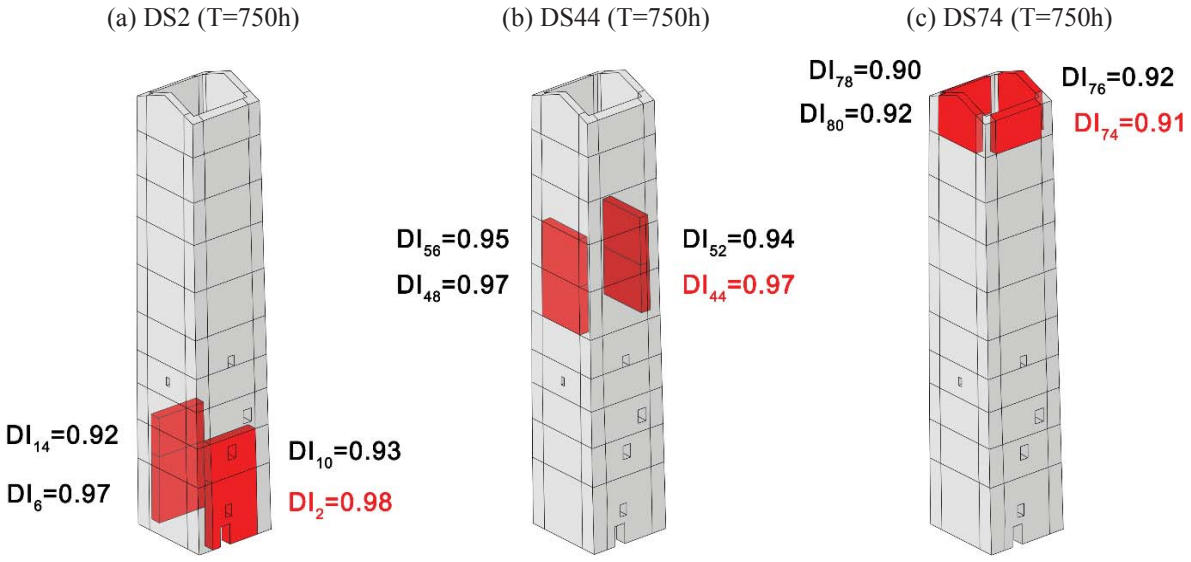

Figure 15: Elements with a damage index higher than 0.90 at the time T=750h (the DI coloured in red indicates the correct position of the simulated damage).

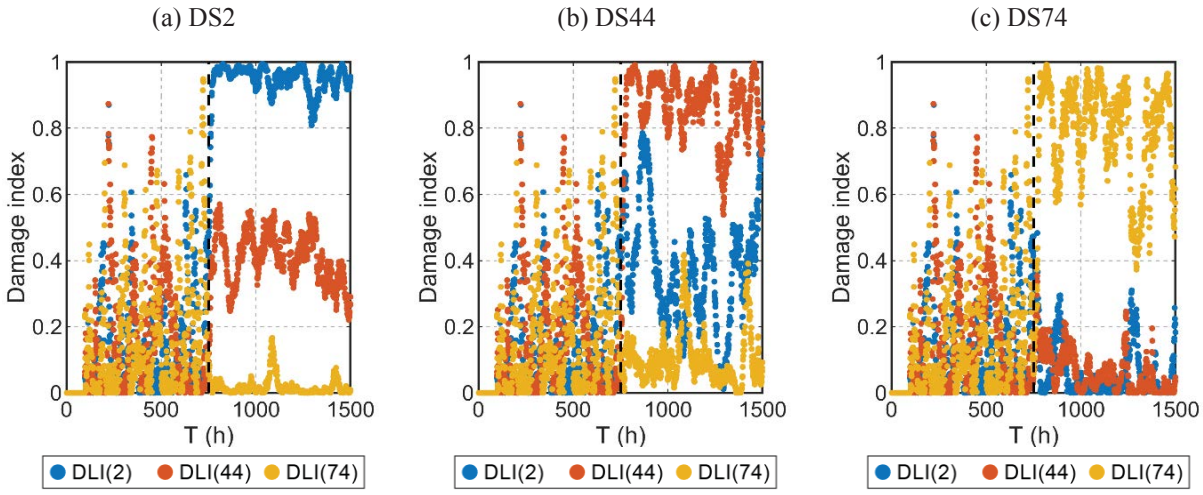

Figure 16: Comparison between the Damage Indexes of three elements over the entire monitoring period.

Once the onset of a damage is verified, the comparison between the pseudo-experimental frequency shifts and the computed DLRM is performed. The DLRM was previously generated from the updated FE model (Fig. 10a) following the procedure explained in Section 2; the adopted elastic modulus reduction was equal to the 50%.

The comparison between the pseudo-experimental frequency shifts and the computed DLRM is provided by Eq. 3 and the results at time T=750h – that is the time when the damage is detected from the control charts – are depicted in Fig. 14. The red dashed line represents the correct damage location while the green dots are the Damage indexes (DIs) of each element. The elements with higher DIs are more likely to be damaged. As it was in the detection stage, the localisation is more evident for DS2 and DS44 since the DFs are higher.

Fig. 15 illustrates the position of the elements with a Damage index higher than 0.90. The following observations can be drawn: (a) the DS2 is correctly localised in the lower part of the tower on the walls along the x-direction; (b) similarly, the DS44 is correctly localised among the 5th and 7th floors on the walls along the y-direction; (c) the DS74 is correctly localised in the top floor of the tower, but it was not possible to distinguish on which wall. Particularly, the localisation of the last DS relies on the induced frequency shift on mode W_1 (see Fig. 11c), which is associated with a cross-sectional distortion. Conversely, the other localisations rely also on bending modes (see Figs. 11a-b) which are characterised by a direction-dominated component of motion.

In conclusion, Fig. 16 illustrates the evolution over time of the DIs of three selected elements. Before the introduction of the structural anomaly at T=750h, the DIs are characterised by random variations; conversely, when the damage occurs, the DIs exhibit a much stable pattern. Notably, the stability is correlated with the magnitude of the frequency shift: bigger for DS2 and lower of DS74.

6 CONCLUSIONS

Prior research has demonstrated the effectiveness of damage localisation for masonry towers based on monitored frequency data and FE modelling [3-4]. In this study, further investigations are carried out to increase the capability of an accurate real-time damage evaluation. Accordingly, a model-based damage localisation procedure using previously computed damage scenarios and continuously identified natural frequencies is illustrated. The proposed approach is exemplified on the *Zuccaro*'s tower; an ancient masonry structure built in the Middle Ages in the city of Mantua, Italy

The results from the investigated structure suggest the following conclusions:

1) In masonry towers, and generally in slender structures, the mutual variation of natural frequencies caused by a structural damage is directly correlated with the damage location;
2) The simulated frequency shifts added to the pseudo-experimental monitoring data were detected and localised with the proposed approach;
3) A cost-effective monitoring setup composed by few sensors placed at the top of the structure and combined with an automated modal identification algorithm and a regression model to filter out the environmental effects can be used not only to detect but also to localise a structural damage.

Promising results suggest future applications of the methodology for monitoring real structures. To expand the capability of the proposed approach, further investigations with multiple damage scenarios should be performed.

ACKNOWLEDGEMENTS

Sincere thanks are due to M. Cucchi (LPMSC, Politecnico di Milano) and A. Ruccolo (PhD candidate, Politecnico di Milano) who assisted the authors in conducting the field tests.

Abstract. *Masonry towers are quite widespread in Europe and represent an important portion of the built heritage that must be preserved, especially in high-seismicity regions. Very often, such masonry towers exhibit unique peculiar morphologic and typological characteristics, which might affect their different structural behaviors under horizontal loads. For this reason, accurate knowledge of their dynamical parameters is useful for seismic assessment and the design of risk mitigation interventions.*

In this work, the opportunities provided by dynamic identification techniques for the non-destructive evaluation of heritage structures are discussed with a focus on different bell towers, located in the Marche region (Italy). All of them were stricken by a long seismic sequence (Center Italy earthquakes between August and October 2016), and are investigated in detail in order to have an insight into their dynamic behavior. Furthermore, the experimental investigations and the operational modal analysis results are presented, and they are useful for defining the Finite Element (FE) model of the towers with a continuum approach.

The monitoring system consists of several elements adequately connected. Many operative problems have conditioned the positioning of the instrumentation due to the limited accessibility of the structure, not only to the primary access but also to reach the top.

However, it has been possible to identify with certain confidence the first three frequencies of the towers and their corresponding mode shapes. The results carried out after the updating procedure may be considered very good. The material data values estimated in this way will constitute an important reference for the evaluation of the state of the building.

1 INTRODUCTION

Europe preserves a large part of the Earth's historical and artistic heritage, Italy is one of the European countries that owns the majority of historical buildings, especially palaces and churches. Because of its particular position, the nation is crossed by African and Euro-Asiatic tectonic plates, the seismic risk is very high and continuously endangers the historical structures [1–12]. One of the last examples is the recently Central Italy Earthquakes that hit the areas between Marche, Abruzzo and Umbria Regions causing widespread damages especially at the construction part of the cultural heritage, highlighting, once again, the necessity to find methodologies to take under control their health, in order to intervene before irreparable damages occur. Currently, the most appropriate technique to achieve this purpose is the Structural Health Monitoring (SHM) using the variation of structures dynamic characteristics as frequencies, damping and mode shapes. To obtain these data, accelerometric sensors are placed on specific points of the structure, in order to record, accelerometric time histories only from ambient noise. The data acquired are filtered and processed by appropriate techniques able to extract the dynamic information. These data can be used for two different purposes, depending on the acquisition duration: if there are acquired for a short period (Short-term monitoring) they can be used to identify the current building state and caliber a numerical model [7,13–16], whereas if there are acquired for a long period (Long-term monitoring), such as more than one year, they can be used to the damage identification [17–21], since, the variation of the dynamic characteristics are linked to stiffness or mass variations [22]. In this last case, particular attention must be paid to the ambient conditions because, as many studies showed, they can provoke variation in frequencies, some authors are looking for algorithms to delete them from the signals [23,24].

In this paper, the monitoring and the Finite Element Model (FEM) calibration are presented taking as a case study a complex composed by civic tower a palace and an arcade in Matelica, a village in the hinterland of Marche region Figure 1. This study wants to be an example of applicability the dynamic monitoring for protection of the heritage masonry constructions.

2 CASE STUDY

2.1. Historical development

At the start, the Governor's Palace was a porticoed structure used as delimitation between the plaza and the open-air market. This structure was destroyed during the gothic war.

The Civic Tower dates to the XII century, it was built on the ruins of a Romanesque structure, in 1209 it became the imperial lieutenant's residence. The actual configuration of the Governator's Palace goes back to 1284, by the work of the Benincasa da Firenze and Bruno da Fabriano. The gallery construction on the tower and the ogival windows closing occurred in the XIV century. In 1511 started the arcade construction, on the right side of the Palace, designed by Costantino and Giovan Battista da Lugano architects, and was initially used as a textile market (Figure 2). The structures were modified several times, between 1670-1830, when they were subjected to the first restoration interventions; however, at their end, the palace was declared unsafe for static problems. To improve the tower stability in 1893 its base was extended. Similar interventions aimed to improve the stability of all the components of the building continued until 1997 when a big restoration was carried out after the Umbria-Marche earthquake.

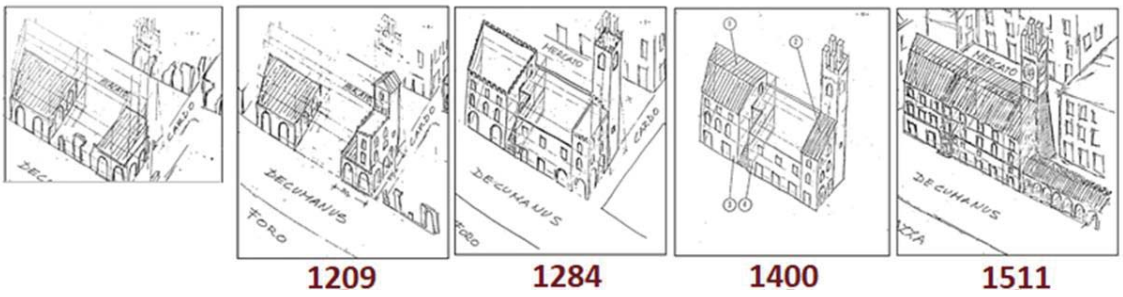

Figure 2 Historical evolution of the complex

2.2. Geometric survey

The palace has a rectangular plant of dimensions 13.30mx37.58m, it has three floors and a mezzanine between the ground and first floor. On the North-West side there is the Civic Tower, it has a rectangular plant 7.25mx7.45m and a height of 35m with eight levels divided by masonry and wood floors. The open gallery is on the North side of the palace. It has a rectangular plant characterized by 14 polygonal columns with ionic capitals that support round arches (Figure 3). The materials used are various. The most visible façades in the South and East are covered by regular masonry, whereas on the others are visible the irregular masonry Figure **1**. The masonry type present are uncut stone for the palace, uncut stone and solid blocks for the tower and solid bricks for the arcade. The roofs are made of wood trusses.

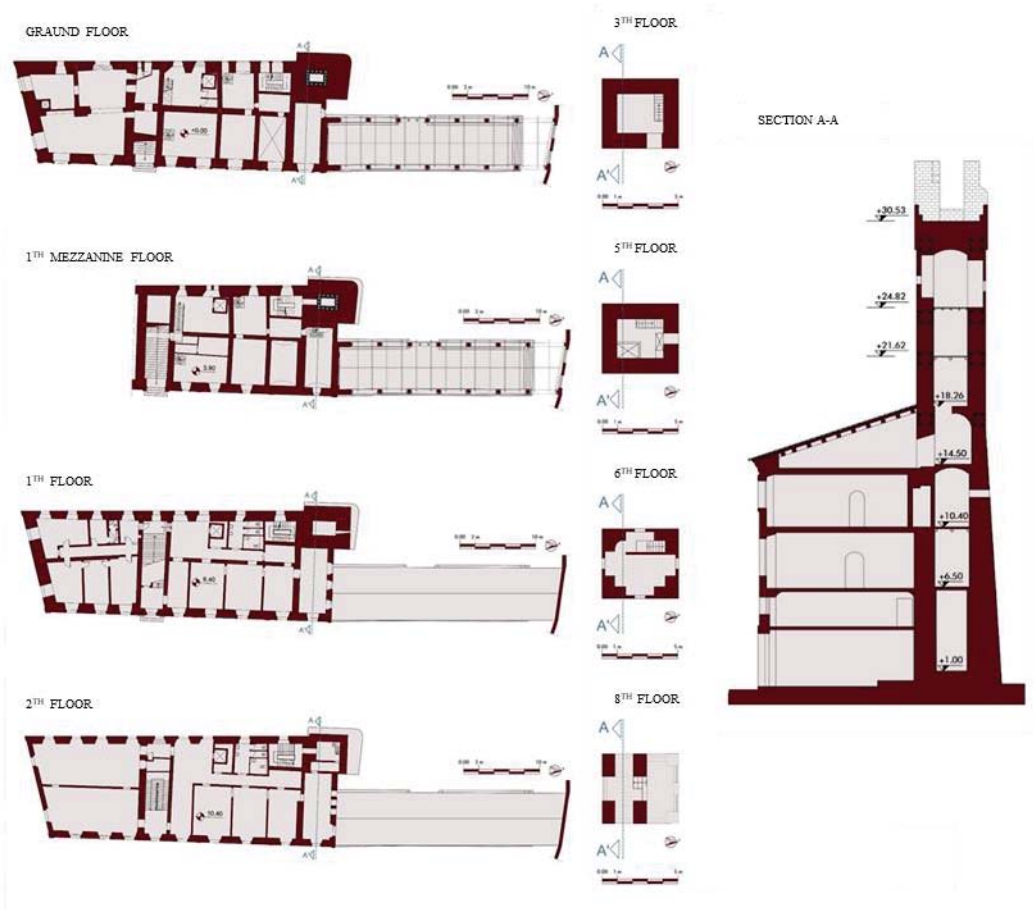

Figure 3 Geometrical configuration of the complex

3 DYNAMIC CHARACTERIZATION

3.1 Ambient Vibration Testing

The study of historical buildings structural behavior is usually carried out through linear or non-linear analysis on FEMs. Being the objective to represent the real structure behavior in the most accurate way, the realization of these Numerical Models (NMs) requires a deep knowledge of the structural parameters, such as materials properties, connections among elements, boundary conditions, etc. Among all the possible methodologies which allows to investigate structural properties, these case study has been approached through a method which has become very popular in the last few years, due to its non-invasiveness and the satisfactory results produced: Ambient Vibration Testing (AVT). This method is based on the monitoring of vibrations produces on the building by ambient effects (like wind, traffic…) and on the extraction of modal properties (natural frequencies, modal damping and mode shapes) from the analysis of these data through modal identification techniques. Then these properties are used to build an Experimental Model (EM), whose response is compared with that of the NM. An iterative process, which consists in the variation of the unknown parameters in the model, like Young Elastic Modulus E and material density ρ, is applied in order to obtain correspondence between both natural frequencies and associated mode shapes of the two types of models [25].

3.2 Monitoring equipment, sensors layout and data

Structural monitoring of the case study has been performed using a wired sensors network, composed of:

- four triaxial accelerometers of GEA System series, with a sensitivity of 1000 mV/g, a measurement range of ± 8g and A/D converter with a resolution of 24 bit;
- hub for synchronization;
- coaxial cables.

Sensors layout has been designed applying the concept of Optimal Sensor Placement (OSP) [26],so that, in the different layouts configured for the acquisitions, sensors have been placed in the most sensitive points of the building (in accordance with the possibility of reaching them), in order to better detect the translational and torsional components of the tower displacement [18]. In order to assure a rigid link between the selected point and the sensor epoxy resin has been used.

The monitoring activity of the tower has been conducted through 6 acquisitions, considering as many sensors layouts, which are shown in Figure 4. Data have been collected with a sample rate of 1024 Hz for periods which vary between 40 and 60 minutes, in order to satisfy Rodriguez condition [27].

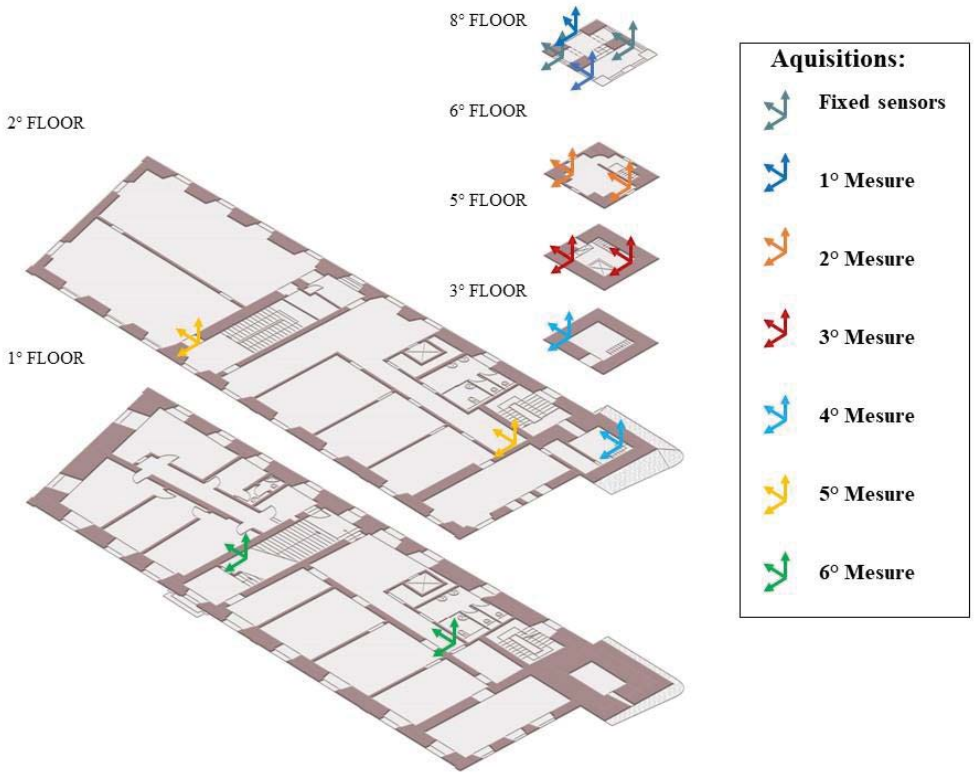

Figure 4 Sensors Layout

3.3 Operational Modal Analysis

3.3.1 OMA identification technique

The acquired data, after a filtering process, have been analyzed through modal identification techniques. Among these methodologies some operates in time domain, while others operate in the frequency domain. For the case study under exam, it was decided to apply a time domain technique, called Stochastic Subspace Identification (SSI) method [28]. This methodology consists in a conversion of the second order differential equation of motion into two first order equations, defined "state equation" and "observation equation", which, for a generic discrete time instant t = kΔt (where Δt is the sampling period and k ϵ N) can be written as:

$$\begin{aligned} \{\hat{x}_{k+1}\} &= [A]\{\hat{x}_k\} + [B]\{u_k\} \\ \{y_k\} &= [C]\{\hat{x}_k\} + [D]\{u_k\} \end{aligned} \tag{1}$$

where:

- $[A]$ is the matrix of input physical information;
- $[B]$ is the matrix of input statistical parameters;
- $[C]$ is the discrete output matrix;
- $[D]$ is the direct output transmission matrix;
- $x_k = x_k(\Delta t)$ is the discrete-time vector containing the sampled displacement and velocities;
- $\{y_k\}, \{u_k\}$ are the vectors of sampled input and output.

Other parameters describing the dynamic system are considered as deterministic and should not be subdued to the variations linked to excitation changes.

At this point, applying a Singular Value Decomposition (SVD) of the [A] matrix, the Eigenvalues, corresponding to the natural frequencies, and the correspondent Eigenvectors, which describe the mode shapes, are extracted.

For the examined case study, acquired data have been decimated into an interval of 12.5 Hz, in order to highlight the first five modes, mainly involving the tower, and their modal parameters. The values of natural frequencies and modal damping, for each mode, are reported in Table 1.

Mode	Frequency [Hz]	Damping [%]
1	1.923	0.679
2	2.007	0.873
3	5.058	2.931
4	6.531	1.569
5	7.629	2.705

Table 1 Modal parameters of Experimental Model

3.3.2 Preliminary FE model

The results of the investigation campaign, carried out to assess the geometrical characteristics of the building and to evaluate status of the materials, allowed to realize a preliminary non calibrated NM, created using Midas FEA© software.

This model, even if the analysis is principally focused on the tower behavior, represents the complete structure, composed of the main building, the tower and the open gallery, due to the importance of considering the effects of interaction between the tower and the connected building [29–31]. The internal elements, like floors and stairs, have been modeled in case they

significantly influence the stiffness of the structure, like in case of the concrete floors built after the restoration works, while, in case of secondary elements, they have been considered only as loads distributed on the walls. As concerns the modeling process, the geometries have been discretized through 4-nodes tetrahedral solid elements, while, for the material properties assigned to the meshes, they have been selected from the tables reported in the Italian Code [32,33], scaled with the appropriate factors to take into accounts the knowledge level (KL1). These preliminary parameters are reported in Table 2.

Position	Types	W [kN/m^3]	E [N/mm^2]
Open Gallery Base	Soft stone masonry	13-16	1440
Open Gallery Walls	Solid bricks masonry	18	1500
Wood	Wood	7.6	1100
Building interior Walls	Solid bricks masonry	18	1500
Interior Arch Walls	Solid bricks masonry	18	1500
Building Perimetric Walls	Rough-hewn masonry	20	1440
Tower Walls (1-2-3-5-6)	Rough-hewn masonry	20	1440
Tower Wall (4)	Rough-hewn masonry	20	1230
Tower Walls (7-8-9)	Solid bricks masonry	18	1500

Table 2 Material parameters of preliminary Numerical Model

The NM, built with these characteristics, has been analyzed using Lanczos method, and has shown the results reported in Table 3, where the values of natural frequencies associated to the first five modes are shown.

Mode	Frequency [Hz]	Damping [%]
1	1.731	5.000
2	1.764	5.000
3	4.953	5.000
4	6.264	5.000
5	7.667	5.000

Table 3 Modal parameters of preliminary Numerical Model

3.3.3 NM calibration

The calibration process of the NM model consists, as already said, in an iterative procedure in which some parameters considered unknown, in particular Young Elastic Modulus and density of materials, are modified, at each step of the procedure, in order to obtain a coincidence, or at least a maximum difference (Δf) of 5%, between the modal frequencies of the experimental and numerical models. Then, also the correspondence between the mode shape, associated to the same mode, is checked and validated, using the CrossMAC criterion [34]. This tool, which is applied in case of complex modes, provides an indication of the consistency of the modal vectors associated to the mode shapes obtained from different models. This indicator is calculated as the normalized scalar product of the modal vector for the r mode of analytical model $\{\varphi_A\}$, and the associated modal vector for the q mode of the test model $\{\varphi_X\}$:

$$MAC(r,q) = \frac{\left|\{\varphi_A\}_r^T\{\varphi_X\}_q\right|^2}{(\{\varphi_A\}_r^T\{\varphi_A\}_r)(\{\varphi_X\}_q^T\{\varphi_X\}_q)} \quad (2)$$

These scalar results are assembled in the CrossMAC matrix, whose optimal configuration is that of a principal diagonal with terms which are near or equal to 1 (which indicate good or perfect correspondence) and with terms outside of the diagonal which are near or equal to 0.

The first comparison in terms of frequencies between the EM and NM is shown in Table 4, which shows a too big difference in the values of frequencies associated to the first two modes.

Mode	Frequency EM [Hz]	Frequency NM [Hz]	Δf [%]
1	1.923	1.731	9.98
2	2.007	1.764	12.11
3	5.058	4.953	2.08
4	6.531	6.264	4.09
5	7.629	7.667	0.50

Table 4 Comparison of EM and preliminary NM modal frequencies

Better correspondence, instead, is obtained comparing the mode shapes, whose direction of displacement are coincident between EM and NM, being the first two mode translational respectively in Y and X direction, the third and the fifth are flexional in Y and X, respectively, while the fourth shows a distorting behavior (Figure 5).

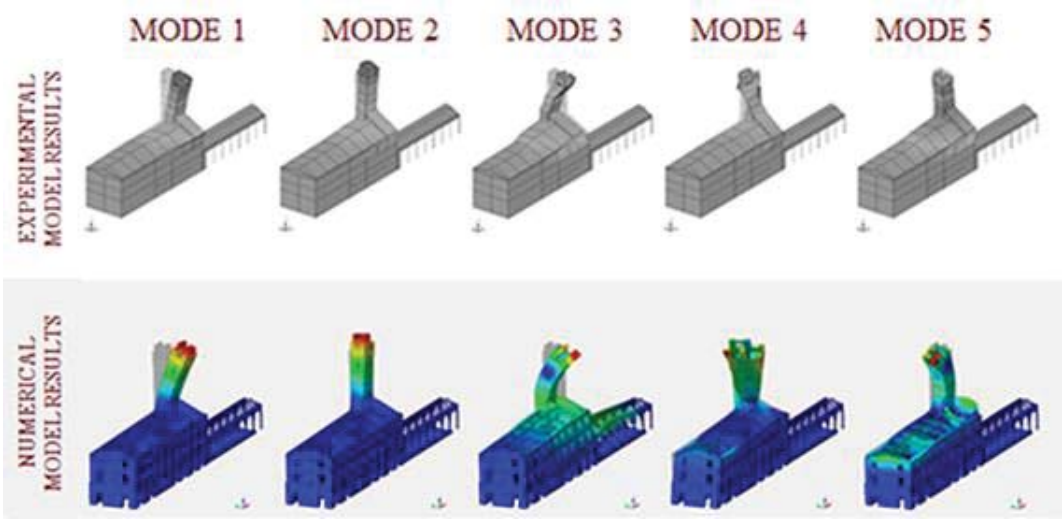

Figure 5 Comparison of mode shapes of preliminary NM and EM

The first step of parameter update has been operated only on the elastic modulus of the materials attributed to the tower elements. The criterion was to increase the stiffness of the element subjected to intervention in 2007 and decrease the density of some other elements, whose characteristics are inferior in respect of the previsions. The result of this operation comported a decrement of the frequencies values difference under the 5%, with the exception of the second mode.

In the second step, also the elastic modulus of elements which were not subdued to interventions has been increased, assuming that their deterioration was not as serious as thought at first. The result comported also a decrement of the difference in the values of frequency for the second mode under 5%.

In the last step it has been decided to intervene on the parameters associated to the building, dividing the perimetric walls in three sections, whose stiffness has been increased for the portion nearer the tower, and decreased for the other two parts. The results in terms of frequencies are reported in Table 5.

Mode	Frequency EM [Hz]	Frequency NM [Hz]	Δf [%]
1	1.93	1.88	2.59
2	2.01	1.92	4.48

3	5.06	5.31	4.94
4	6.53	6.77	3.68
5	7.63	7.82	2.49

Table 5 Comparison of modal frequencies of EM and calibrated NM

This modification allowed a better correspondence between mode shapes, as it is possible to see from Figure 6, and as attested in Table 6, where CrossMAC results are shown.

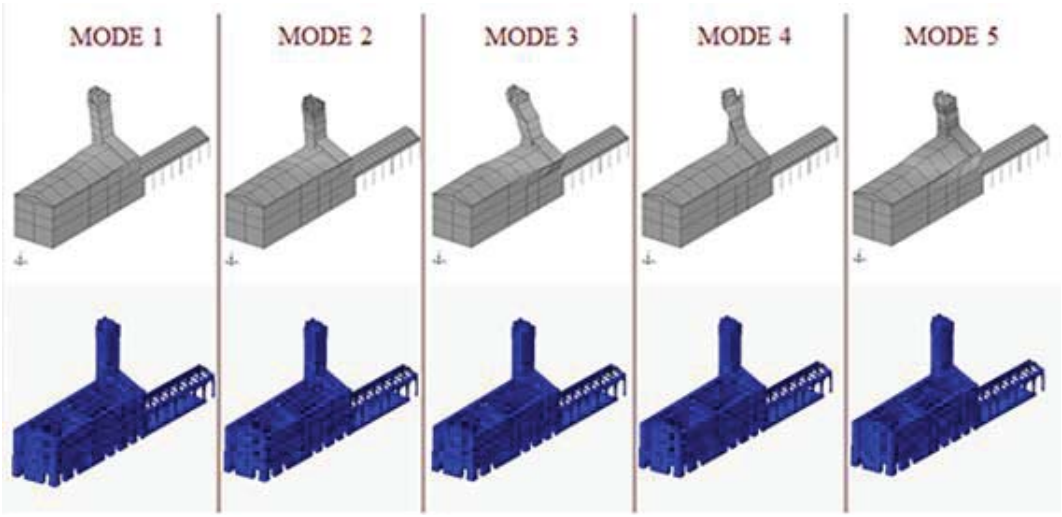

Figure 6 Mode shapes comparison after calibration

CrossMAC		EXPERIMENTAL MODEL				
		MODE 1 1.93 [Hz]	MODE 2 2.01 [Hz]	MODE 3 5.06 [Hz]	MODE 4 6.53 [Hz]	MODE 5 7.63 [Hz]
NUMERICAL MODEL	MODE 1 1.88 [Hz]	0.89	0.03	0.00	0.00	0.01
	MODE 2 1.92 [Hz]	0.00	0.98	0.01	0.04	0.02
	MODE 3 5.31 [Hz]	0.19	0.02	0.70	0.05	0.30
	MODE 4 6.77 [Hz]	0.00	0.02	0.00	0.81	0.16
	MODE 5 7.82 [Hz]	0.00	0.09	0.11	0.10	0.78

Table 6 Cross MAC after calibration

These results highlight the low level of interaction between the tower and the palace, whose dynamic behaviors do not influence each other so much, probably due to the different manufacturing and absence of linking elements. In particular, the disorganic movement of the tower, shown for the higher modes, and especially the distorting behavior of the fourth mode, can be linked to the sectional changes and to the variation of material properties. As concerns the damage propagation, the most damages zones are the ones with low values of Young Elastic Modulus.

4 CONCLUSIONS

The model updating process, operated for the tower and the rest of the Governor Palace structure, produced good results in terms of correspondence with the modal parameters and mode shapes extracted from EM. Moreover, it allowed the observation of an interesting

phenomenon in the tower dynamic behavior, such as the sectional distortion caused by the fourth mode.

Once again, dynamic monitoring and modal identification techniques, confirmed their effectiveness in the evaluation of dynamic behavior and consequently on the health status of historical structures, being the method non-invasive and allowing to produce accurate numerical models, which can be used implement rapid, localized and economically sustainable interventions.

Abstract. *The Colosseum is the most famous monument of ancient Rome. Differential settlements of its foundations, standing partly on alluvial deposits and partly on stiff soil, and various earthquakes are the main causes of collapses that give the Colosseum its present shape. In order to preserve the monument, a number of structural interventions were made during the 19th century. At present, the health status of the monument requires to be monitored against possible degradation phenomena. During the preliminary design stage of a new underground line crossing the center of Rome, at present under construction, further investigations on materials properties and dynamic features have been performed. In particular, twelve accelerometers on two vertical lines in the highest portion of the monument have been installed. In the present paper data gathered with this monitoring system for a long period of time gives the opportunity of a further insight into the health conditions of the structure. The vibration levels induced by road traffic during a long interval of time and frequencies and mode shapes of low modes are identified using ambient vibration. Both these results are compared with the outcomes of an experimental campaign of a few years ago. Finally, the dynamic behaviour recorded during the 2016-2017 Central Italy seismic sequence is analysed and discussed.*

1 INTRODUCTION

Structural Health Monitoring (SHM) has notably increased its importance in the last decades [1, 2, 3]. The spreading of this kind of activity is also due to the updating of instruments and the reduction of their cost; at the same time, theory and techniques of data processing have become more effective [4, 5, 6, 7, 8, 9]. In this field methods based on structural vibration and their evolution are well established, also because information easily obtained using environmental excitations happens to be effective in detecting structural deterioration. In the case of large structures and cultural heritage buildings, SHM should be a must. So, it is natural that the Colosseum, the most famous monument of ancient Rome, is the object of special attention by the Superintendent of Cultural Heritage with a series of activities.

A new underground line crossing the center of Rome, at present under construction [10], run tangentially to the Colosseum; during the design stage a wide campaign of experimental investigations on materials properties and dynamic features have been performed. Moreover, the monument has been instrumented in order to develop both static and dynamic monitoring. In particular, inclinometers and estensometers to measure displacements due to temperature changes and twelve accelerometers on two vertical lines in the zone with greatest height have been installed.

The slow movements produced by temperature induce deformations and stresses, with cycles which are repeated every year. The accelerometric registrations of the ambient vibrations permit to obtain the intrinsic dynamic properties of the structure with a twofold aim. First, the comparison and correlation between experimental modal parameters and those predicted by a finite element model enable us to identify or update an accurate model of the monument; this is an important item especially where buildings of historical interest are involved, since they are often characterized by complex geometry and heterogeneity of materials. Second, the evolution in time of the modal properties gives information on possible degradation phenomena.

In this paper the main attention is devoted to the dynamic response; in particular, the vibration levels induced by road traffic for a long time interval is examined, then ambient vibrations are used to identify frequencies and shapes of low modes by these incomplete data. These results are both compared to available data obtained by the authors during an experimental campaign of a few years ago. Finally, the dynamic response to the 2016-2017 Central Italy seismic sequence is analysed and discussed.

2 THE NEW UNDERGROUND LINE OF ROME

The severe conditions of the surface traffic in Rome highlighted the need to improve the public transportation network. The two existing underground Lines A and B did not reach all the sectors of the city and suburbs. The authority managing the underground lines decided, in such a context, to construct the new Line C crossing the Rome territory along the alignment NW-SE. Figure 1, just for the intermediate part of the line, denoted as Section T3, shows the interference of the new line with some of the most famous monuments in the world. Among the others, the underground line runs near the Colosseum. Further details can be found at [10].

During the design stage, several forecasting activities have been performed, in order to simulate the effects of the underground works and to estimate the possible impacts on the monuments. For the Colosseum, the effects were estimated as negligible and no special provisional measures were provided. Nevertheless, a comprehensive monitoring system has been deployed, in order to study the response of the structure before and during the underground construction.

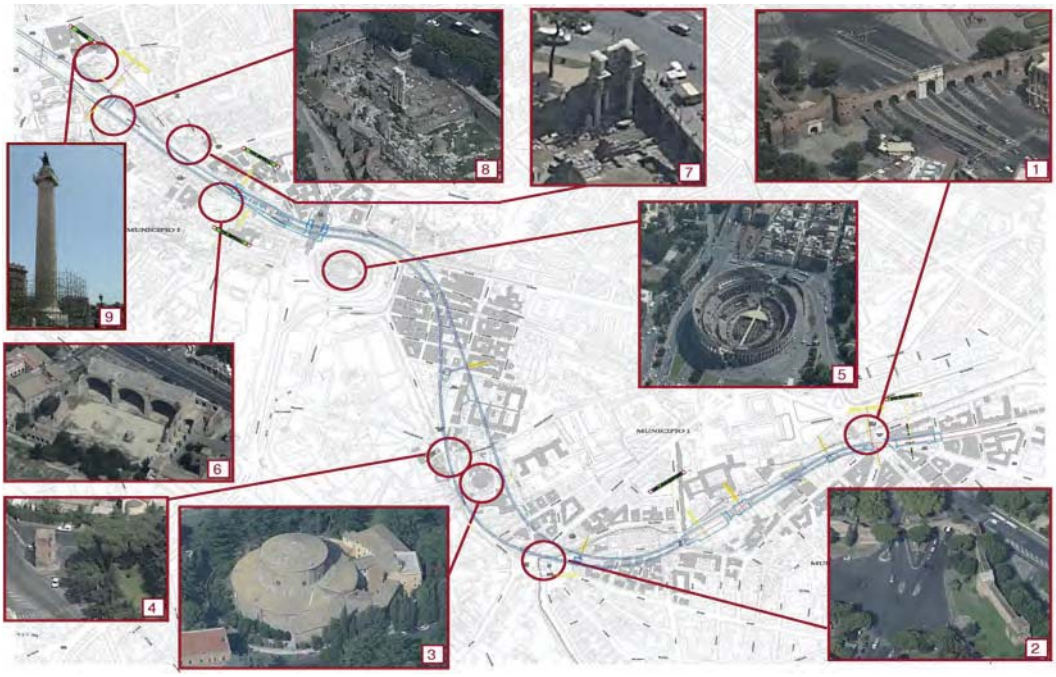

Figure 1: The Section T3 of the new Line C of Rome underground and the interference with monuments: 1) Porta Metronia, 2) Acquedotto Celimontano, 3) Basilica di S. Stefano Rotondo, 4) Porta Asinaria, 5) Colosseum, 6) Basilica di Massenzio, 7) Colonnacce, 8) Foro di Cesare, 9) Colonna Traiana.

3 DESCRIPTION OF THE MONITORING SYSTEM

A general description of the monitoring framework is reported in [11]. For the Colosseum, the monitoring system can be divided into 4 sections:

- topographic monitoring, aimed at gathering absolute displacements and rotations;
- geotechnical monitoring, aimed at gathering soil pore pressure and vertical and horizontal ground displacements;
- structural monitoring, divided into two subsections:

  - static monitoring, aimed at gathering structure and air temperatures, existing cracks openings, relative displacements, rotations;

  - dynamic monitoring, aimed at gathering structural accelerations and velocities.

The static monitoring is composed by 4 thermometers, 7 tiltmeters, 22 crackmeters and 12 wire-crackmeters. The dynamic monitoring is composed by 12 triaxial force-balance accelerometers, located along two vertical alignments, as reported in Fig. 2. The present paper is devoted to the analysis of dynamic measured quantities.

4 ANALYSIS OF DYNAMIC MEASUREMENTS

4.1 Road traffic

The main goal of the accelerometric monitoring system previously described is the survey of the vibration level during the construction of the underground line. Due to the presence of the monitoring system since the end of of 2014 and still functioning, both current vibration level

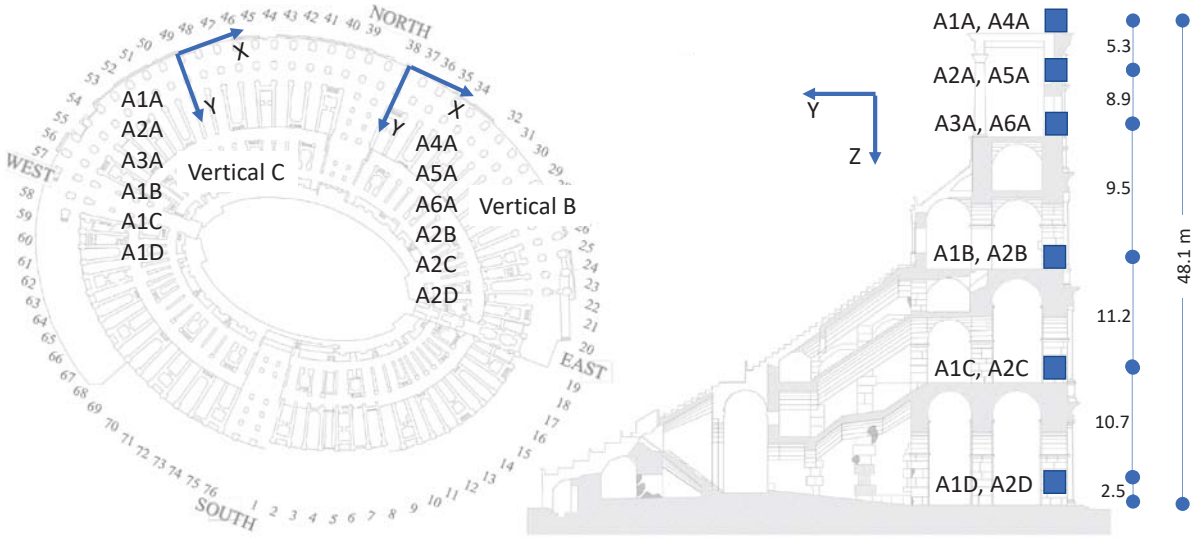

Figure 2: Locations of the accelerometric sensors and channels positive directions.

and peak values can be evaluated. A comprehensive analysis of data is outside the scope of the present paper, nevertheless a short discussion on the vibration level measured during one month (January 2020) is reported here; during this period the construction was inactive. Figure 3 shows the envelopes of the velocity recorded at the base and on the top in each direction. In vertical and circumferential directions at the base the maximum value of the velocity is about 0.15 mm/s, on top is about 0.5 mm/s, with smaller effective values respectively of about 0.02 mm/s at the base and 0.05-0.1 mm/s on top. In radial direction the maximum values of the velocity are similar, while the effective values are respectively of about 0.04 mm/s at the base and 0.15 mm/s on top. With reference to the time interval considered, the vibration level is very similar to that reported in [6] and it does not exceed the limit values reported in [12].

4.2 Modal analysis using ambient vibration

The experimental modal parameters have been evaluated in [6] using a large number of measurement points, under ambient vibration excitation. It was verified that the input at the base of the monument, in the frequency band 1-6 Hz, approximates a white noise. The experimental modal parameters were therefore derived from the response only, under the hypothesis of white noise excitation. In this condition, the output spectrum reaches a maximum at the natural frequencies, where the response of the structure peaks. The vibration frequencies of the first six modes, obtained in [6] by a singular value decomposition of the power spectral density matrix of the responses, are listed in Tab. 1.

Mode	1	2	3	4	5	6
Frequency [6]	1.03	1.30	1.49	1.60	1.66	1.75
Frequency (this study)	1.04	1.28	1.47	1.62	1.71	-

Table 1: Frequencies (Hz) of the first modes evaluated in [6] and in the present study.

Data recorded with the new monitoring system has been used to repeat the experimental modal analysis. In the present setup, few measurements are available, especially on the top

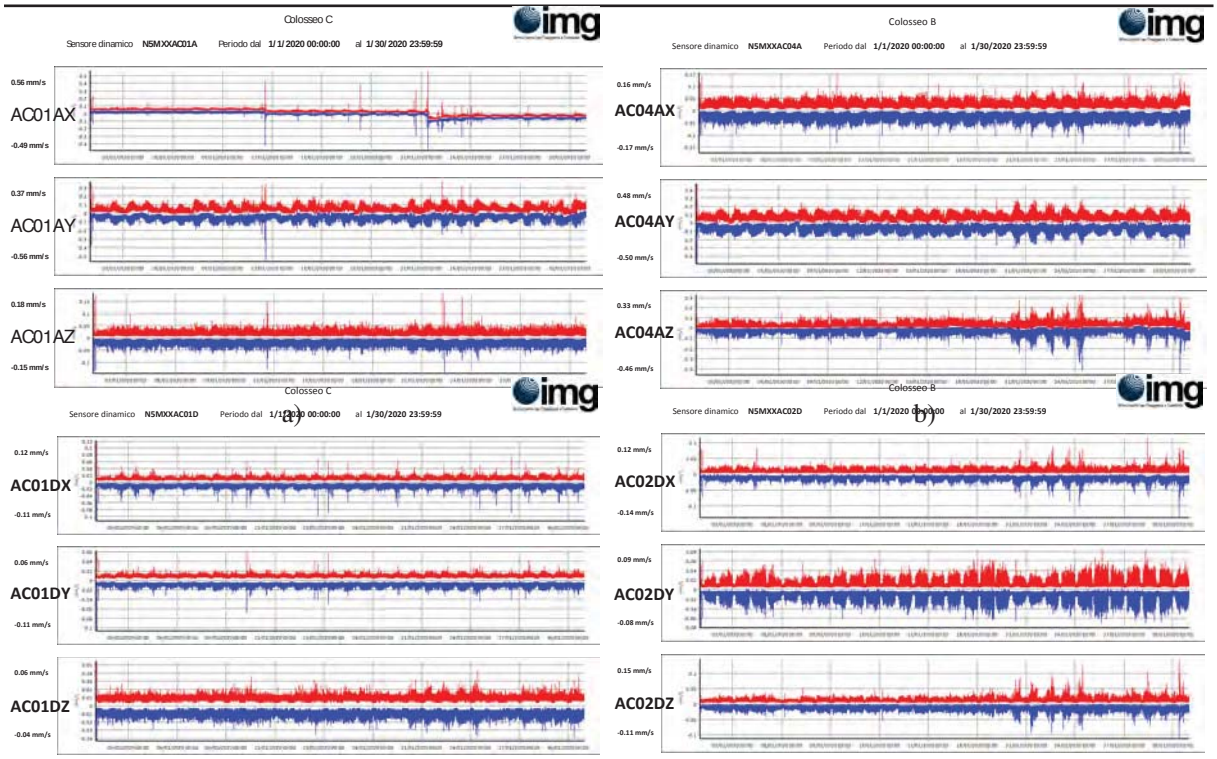

Figure 3: Velocity vibration levels (mm/s) measured during January 2020; a) sensor A1A (top level); b) sensor A4A (top level); c) sensor A1D (base level); d) sensor A2D (base level); for each sensor from top to bottom X (circumferential), Y (radial) and Z (vertical).

of the structure, thus it resulted rather difficult to detect the first two modes, which mainly involve points very far from the sensors. The same techniques applied in [6] have been used. Figure 4 shows the first two singular values of the power spectral density matrix of the response, where the modes identified are indicated with black circles. A comparison between the natural frequencies is reported in Tab. 1, showing a very good agreement. Also the components of the eigenvectors common to both [6] and present test setup have been compared, obtaining an acceptable agreement. Thus, with reference to this limited comparison, it can be argued that the dynamic characteristics of the structure appear stable.

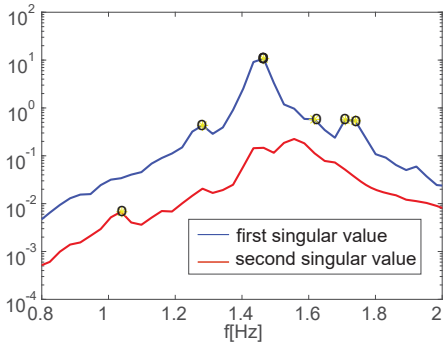

Figure 4: Singular value decomposition of the power spectral density matrix using data from ambient vibration.

Table 2: Events with magnitude $M_w > 5$ during the 2016-2017 Central Italy seismic sequence; the distances are computed between the epicenters and the Colosseum; $a_{b,t}$, $a_{b,r}$ and $a_{b,v}$ (measured in g*100) are the peak base accelerations recorded by the monitoring system respectively along the tangential, radial and vertical directions.

4.3 Response to 2016-2017 Central Italy seismic sequence

The measured response of a structure when it is impacted by a significant earthquake often furnishes significant information about its characteristics and health conditions [13, 14]. During 2016 and 2017, Central Italy has been interested by a significant seismic sequence. The accelerometric monitoring network was already deployed on the monument, thus several records of the structural response are available. Here, only events with magnitude greater than 5 have been considered. The main characteristics of these events are listed in Tab. 2. The epicenters are rather far from the Colosseum, with distances ranging from 92 to 122 km. The maximum value of the acceleration recorded at the base is about 0.01 g in the horizontal direction and 0.004 g in the vertical direction. The event that produced maximum accelerations at the base occurred on 2016, October 30, with a magnitude of 6.5 (event no. 5 in Tab. 2).

Figure 5 shows the 5% damping acceleration response spectra of event no. 5, as recorded at the monument base at two points in two directions. Modes 3 to 6 are located in the maximum amplification range of the spectra. In order to have a rough evaluation of the level of shaking, one could consider that, according to current seismic regulations, the 475-year return period site response spectrum on stiff soil has spectral ordinates respectively of 0.15, 0.23 and 0.1 g at 0, 0.5 and 1s. Thus, in terms of elastic response spectrum, event no. 5 produced about 1/10 of the spectral accelerations expected for the design earthquake.

Table 3 lists maximum accelerations recorded in radial directions. As expected, the peak values have been attained at the top level (about 0.09 g). It is interesting also to note that the dynamic amplification, i.e. the ratio between top and base peak accelerations, decreases when base peak acceleration increases. At any rate, the minimum dynamic amplification in radial direction is about 8.5. Thus, in the hypothesis of linear behaviour, a 475-year earthquake could lead to top accelerations up to about 1.3 g. This highlights the seismic vulnerability of the monument in its actual configuration, which probably requires a study for a mitigation intervention. In circumferential direction (Tab. 3) maximum accelerations of about 0.02–0.03 g have been recorded. Also in this direction the minimum amplification factor is about 3.6, a value rather common for masonry structures. Maximum recorded accelerations in vertical direction, not reported here, exhibits a minimum amplification factor of 2.4.

The configuration of the accelerometric monitoring system allows us to estimate a drift parameter that can be related to the strain level of the structure, i.e. the relative displacement between two sensors on the same vertical divided by their distance. Table 4 lists this quantity

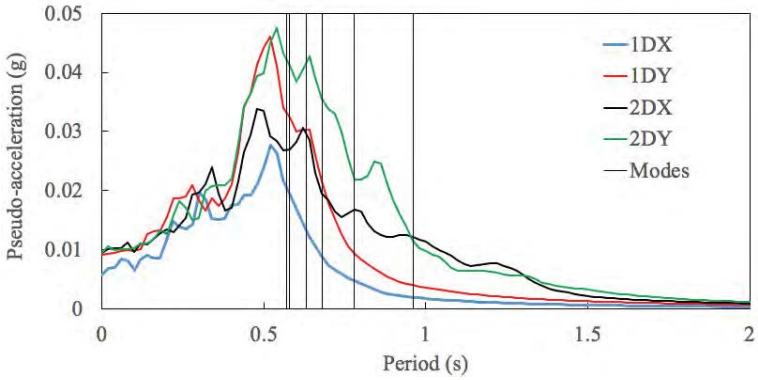

Figure 5: Response spectra at 5% damping of the accelerations recorded at the base during the event n. 5 of Tab. 2; the first letter A of the sensor labels is omitted; the directions X and Y are reported in Fig. 2; the vertical lines correspond to the first 6 modes of the structure.

for both horizontal directions. The graphical representation of Fig. 6 highlights that, in the plane of the facade, a strain concentration occurs on the third order of openings. In the out-of-plane direction, the upper part of the facade exhibits almost constant values. This behaviour is common to all 9 seismic events studied here. With reference to the strongest event no. 5 of Tab. 2, it was verified that the drift parameters of the upper sections are in phase and the maximum values are simultaneously attained, thus the behaviour is that of an almost rigid rotation. The rotation center is located at the base of the third order openings, which can be considered the most stressed part of the structure, both in plane and out of plane, during an earthquake.

5 CONCLUSIONS

The new Line C of Rome underground passes near the Colosseum. Owing to the historical renown of this ancient monument, the General Contractor, on behalf of Superintendent of Cultural Heritage, decided to perform a series of experimental activities to investigate its health conditions; in particular, static and dynamic instruments were used to monitor the structure before, during and after the underground construction.

In this study the focus was on five-year recordings of the dynamic quantities, accelerations and velocities, available to date, considering three different groups of results: the traffic induced vibration, the ambient vibration and the response to a recent seismic sequence in Central Italy.

As far as the velocities caused by the traffic, the levels of the results processed are very similar to those measured in a previous experimental campaign conducted by two of the authors in 2005, and, mainly, the maximum amplitude is below the levels known to cause damage, according to international guidelines.

As far as the ambient vibration, the procedures of the experimental modal analysis are used to identify frequencies and modes components at measurement points. Also in this case the dynamic properties obtained are in good agreement with those determined in 2005, leading to the preliminary conclusion that no overall deterioration phenomena recently occurred.

The registrations of accelerations produced by the seismic sequence of 2016-2017 in Central Italy are of some interest because they are the only available recordings of the earthquake effects on the monument. Notwithstanding the epicenter is far from the Colosseum, around 100 km, the measurements are sufficiently clear, with non-negligible response peaks. For the recorded earthquakes the maximum amplification of the spectrum is observed in a frequency band which

does not involve the first two modes of the monument, localized mainly at Valadier's and Stern's buttresses, which are the most dangerous. These results are important because they make it possible to use an updated finite element model to interpret these data and to predict the response to the expected earthquakes in Rome, evaluating the actual risk of the monument.

6 ACKNOWLEDGEMENTS

The experimental data have been made available by Metro C S.C.p.A., General Contractor of the Line C of the Rome Underground. The cooperation of Design Manager Eliano Romani and Dr. Ivan Mammone are gratefully acknowledged. Moreover, the valuable contribution of Eng. Matteo Ruggeri of IMG S.r.l. that manages the monitoring system is acknowledged.

Abstract. *Masonry constructions compose the majority of the Architectural Heritage world-wide, thus, their preservation is of great importance. Nevertheless, they usually show a great vulnerability to seismic and dynamic loads. Several reinforcement techniques can be used in order to improve their dynamic behaviour. The Textile Reinforced Mortar (TRM) material appears as very suitable, since it meets the requirements of compatibility and reversibility of the retrofitting. Moreover, it avoids some problems related to permeability. And strongly reduces adhesion and debonding issues. In this paper the effectiveness of the TRM reinforcement for dynamic loads for windowed brick masonry walls is evaluated through vibration testing and operational modal analysis. To this aim, two scaled brick masonry walls were built at the "Laboratorio de Grandes Estructuras" of the University of Alicante. Only one of them was reinforced with the TRM. Both were damaged with a cyclic in-plane lateral force for simulating damage due to seismic actions. Structural vibrations of the two walls were measured in the presence of a white noise excitation. Modal parameters were evaluated through Operational Modal Analysis (OMA) before and after the damage. Finally, changes in modal parameters due to damage were compared and investigated in both the unreinforced and reinforced cases. The results suggest that TRM reinforcement can be considered effective for improving the mechanical behaviour of a brick windowed masonry wall.*

1 INTRODUCTION

Masonry buildings represent a relevant part of constructions all around the world. Indeed, the majority of architectural heritage is made of masonry and a lot of new buildings are still built using masonry materials and traditional techniques. However, masonry buildings usually show a great vulnerability to seismic and dynamic loads [1], mainly due to the properties of the materials and to weak connections between horizontal and vertical structural elements [2-3]. Thus, in order to guarantee the stability and the integrity of the construction, it is of great importance to improve its mechanical behaviour through appropriate strengthening interventions. In addition, the reinforcement of masonry construction may be also aimed at repairing damages induced by unexpected static or dynamic loads, in particular earthquakes, that along with other causes can reduce the mechanical properties of masonry structural elements over time [4-6]. In this document, the assessment of the reinforcement of masonry walls in particular is addressed. Among possible reinforcement materials for masonry, in the recent past Fiber-Reinforced Polymer (FRP) composites [7-11] have been widely employed, but these composites show several drawbacks, mostly related to the stress-transfer mechanisms between reinforcement and masonry supports. More recently, another reinforcement material [12-13], the Textile Reinforced Mortar (TRM), has gained interest since it is particularly suitable for masonry constructions. Indeed, due to the presence of a mortar matrix instead of an epoxy one, it meets the requirements of compatibility and reversibility of the retrofitting. Moreover, it avoids some problems related to permeability and, above all, TRM strongly reduces adhesion and debonding issues. Finally, as it is shown in [14], TRM is effective in recovering the pre-damage stiffness of a scaled masonry building.

For the above, a detailed study on the effectiveness of TRM on different types of wall is of great interest. The main purpose of this study is the evaluation of the effectiveness of TRM reinforcement of a windowed brick masonry walls for dynamic loads. For this purpose, two distinct scaled brick masonry walls were built at the "Laboratorio de Grandes Estructuras" of the University of Alicante (Alicante, Spain). The two walls were constructed with the same geometrical features and with the same materials and technique in such a way that they have about the same mechanical characteristics. Only one of the walls was reinforced with the TRM. A vertical load was applied on both the two walls for reproducing real loading conditions of a bearing masonry wall. Both walls were damaged with a cyclic in-plane lateral force in order to simulate damage due to seismic actions. Finally, in order to evaluate the effectiveness of the TRM reinforcement for brick walls in the presence of windows, modal parameters of the two walls were evaluated through Operational Modal Analysis (OMA) before and after the damage by using ARTeMIS Modal commercial software. Indeed, since modal parameters are function of physical features like mass, stiffness and damping, it is well known that these parameters can be employed for structural assessment and damage identification [15-22].

2 MASONRY WALLS, REINFORCEMENT MATERIAL AND DAMAGE

The two windowed brick walls built for this study are shown in Figure 1a-b. The walls were built using clay bricks laid by means of 10 mm thick lime mortar joints adopting an English bond disposition. The geometric and mechanical characteristics of bricks and lime mortar are reported in Table 1. At the base, the walls were constrained through a steel plate and anchors to the strong floor of the laboratory in such a way that the lateral displacement is hindered. In order to simulate real loading conditions of a masonry wall, two vertical loads of 15000 daN were applied on two points (points P_1 and P_2 in Figure 1c). A steel beam allows for an approximately uniform distribution of the total load (30000 daN) applied on the top of the wall (Figure 1).

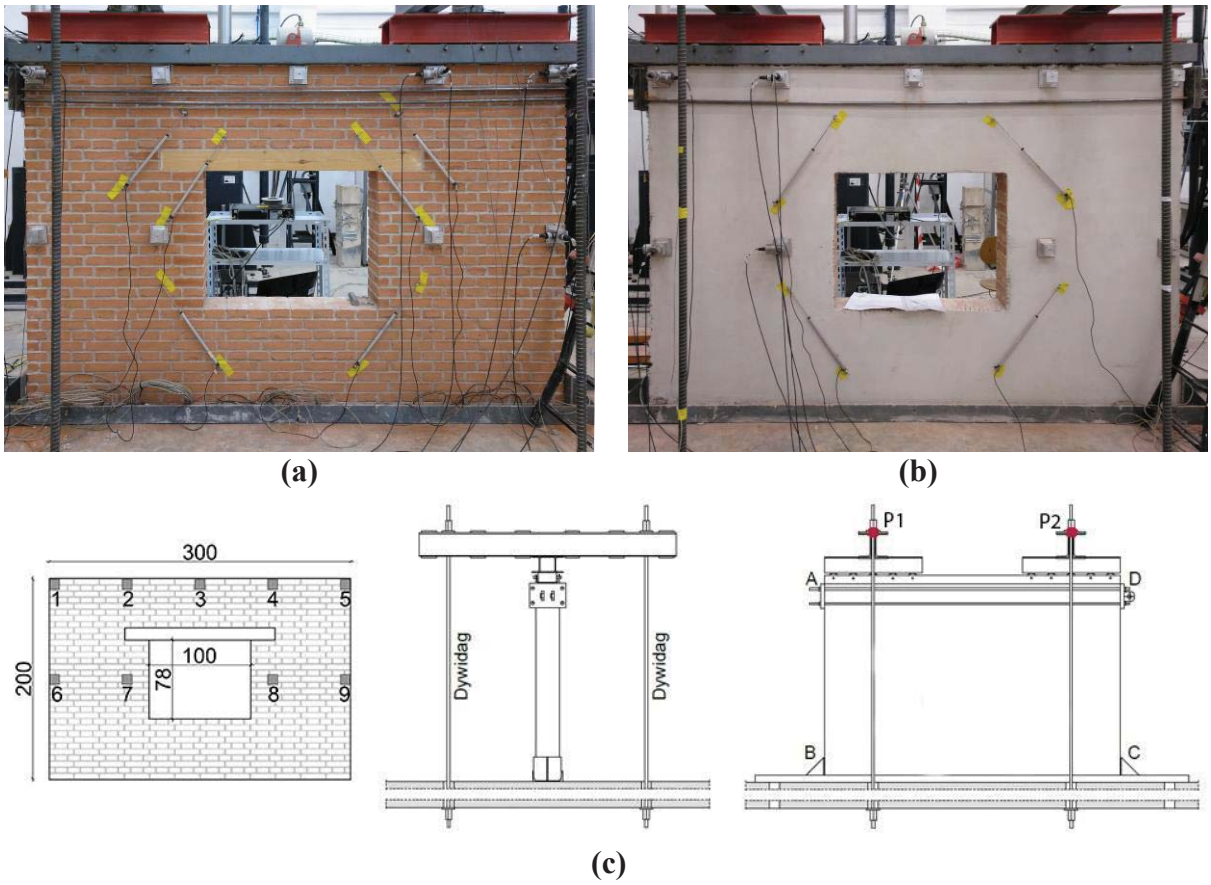

Figure 1: (a) Unreinforced and (b) reinforced windowed masonry walls in the undamaged state; (c) scheme of the experimental setup: preload device and anchorage system.

For the reinforced wall (Figure 1b), a 25x25 mm glass textile mesh embedded into a 10 mm thick cementitious mortar layer was applied on both the two lateral surfaces of the wall. Specifically, the application of the TRM reinforcement occurred in the following steps: (1) a 5 mm thick cementitious mortar layer was applied on the lateral surfaces of the wall; (2) a glass fiber textile grid was located on the cementitious layer; (3) the glass fiber grid was covered with 5 mm thick layer of the cementitious binder. It is worth noting that the first cementitious mortar layer allows for the bond between the masonry support and the glass fiber textile grid. The mechanical properties of the reinforcement are shown in Table 2.

Bricks		Lime mortar	
Dimensions (mm)	230 x 110 x 50	Compression strength at 28 days (MPa)	9.4
Compression strength (MPa)	17.20	Compression strength at 100 days (MPa)	10.1

Table 1: Geometric features and compression strength of bricks and lime mortar.

In order to simulate the effects of a high-intensity seismic action, both the two walls were damaged (Figure 2) by imposing a cyclic in-plane horizontal top displacement with increasing amplitude. Specifically, the horizontal displacement was determined by means of a hydraulic jack with a feedback system capable of producing a displacement control load test.

3 MODAL ANALYSIS

Vibration testing and Operational Modal Analysis (OMA) were carried out on the two walls in order to estimate their modal properties (natural frequencies, mode shapes and modal damping) both in the undamaged and damaged state. Schematically, modal properties were estimated in the following four cases: (1) unreinforced and undamaged wall; (2) unreinforced and damaged wall; (3) reinforced and undamaged wall; (4) reinforced and damaged wall. In each of these four cases, the response of the wall was experimentally monitored through accelerometers with respect to 18 DOF. Specifically, a grid of 9 points (Figure 1c) was defined on each wall and, for each point, the in-plane (x-direction) and out-of-plane (y-direction) vibrations were measured. A white noise excitation was generated through a shaker located in the middle of the top of each wall.

For data acquisition, 8 piezoelectric accelerometers of sensitivity 10 V/g, two signal conditioner model PCB 482A22 and two data acquisition devices model Kyowa PCD-320 were employed. The sampling frequency was set to 2000 Hz. Since only 8 accelerometers were available, the two accelerometers located at point 1 (in the x- and y-direction) were adopted as reference sensors. Consequently, it was possible to measure the response of the wall at the considered 18 DOF by three suitable arrangements of accelerometers, thus resulting in 3 data sets.

Finally, vibration data were processed by using the ARTeMIS Modal commercial software. In particular, the Enhanced Frequency Domain Decomposition (EFDD) method was employed for determining natural frequencies, mode shapes and modal damping.

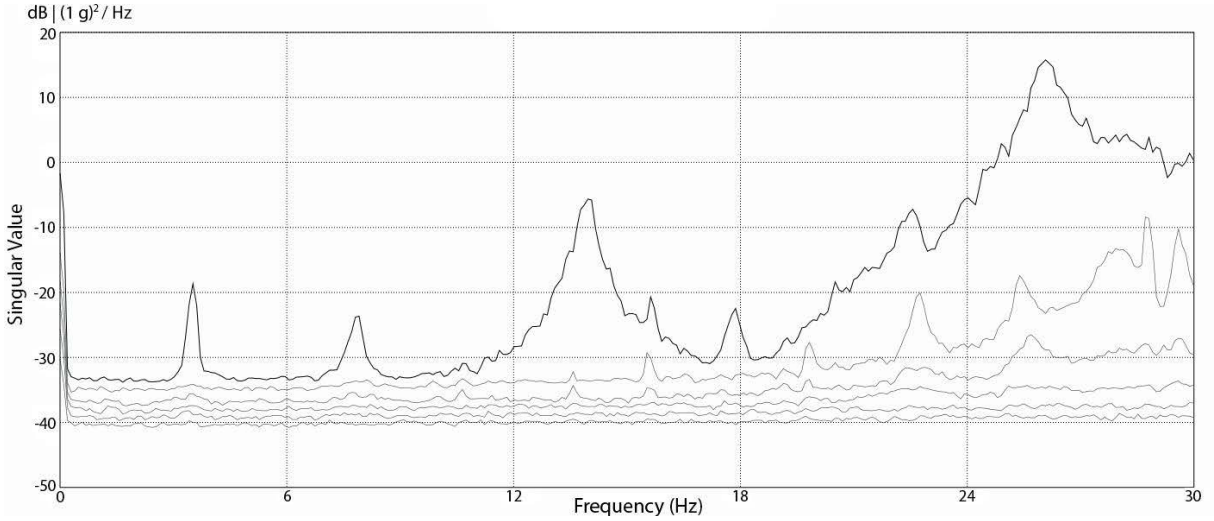

Figure 3: A typical Singular Value Plot obtained by processing acceleration data of the walls through the EFDD technique.

4 RESULTS

Figure 2 shows both the unreinforced and reinforced wall after the damage process. A classical damage pattern with diagonal cracks is visible for the two walls. The horizontal cracks of the reinforced wall are due to the presence of the glass textile grid. In the unreinforced wall, the cracks mainly follow mortar joints, except in some points where they cross one or more bricks. For the unreinforced wall the initial elastic stiffness was 25.2 kN/mm, the ultimate horizontal displacement was 22 mm and the ultimate horizontal load was 143 kN. For the reinforced wall the initial elastic stiffness, the ultimate horizontal displacement and the ultimate horizontal load were 28.7 kN/mm, 33 mm and 351 kN, respectively. Since the two walls were similar to each other, it is evident that the TRM reinforcement improves the stiffness of the wall, its ductility and its ultimate strength to horizontal cyclic loads, and thus to seismic actions.

Regarding operational modal analysis, the first three vibration modes for each wall were identified both in the undamaged and damaged case. Figure 3 shows a typical Singular Value Plot, in the frequency range from 0 to 30 Hz, obtained through the EFDD method. In Table 3, a comparison between natural frequencies estimated in the four cases above listed is reported. Both for the unreinforced and for the reinforced case a noticeable decrease of natural frequencies occurs with damage. In particular, comparing natural frequencies before, f_U, and after, f_D, the damage through the frequency discrepancy parameter $D_f = |(f_D - f_U)/f_U|$, for the unreinforced case a decrease of 24.09 %, 60.00 % and 31.42 % of the natural frequency of the first, second and third vibration mode, respectively, it is observed; the corresponding decreases for the reinforced case are of 44.05 %, 39.20 % and 45.42 %, respectively.

Mode no.	Unreinforced wall			Reinforced wall		
	f_U (Hz)	f_D (Hz)	D_f (%)	f_U (Hz)	f_D (Hz)	D_f (%)
1	5.276	4.005	24.09	6.300	3.525	44.05
2	15.829	6.331	60.00	12.891	7.838	39.20
3	22.415	15.372	31.42	25.551	13.947	45.42

Table 3: Natural frequencies estimated for the unreinforced and reinforced wall both in the undamaged (U) and damaged (D) state.

Since the natural frequency is related to the modal stiffness, a decrease of the natural frequency means that the damage has induced a reduction of the modal stiffness for all the three identified modes. In particular, in the unreinforced wall the damage has mostly affected the second mode, while in the reinforced case it has affected almost uniformly all the three modes. It suggests that the application of TRM reinforcement allows distributing on all vibration modes the negative effects of damage.

Furthermore, it can be observed that, except for the second vibration mode, the reinforced wall has natural frequencies slightly higher than those of the unreinforced wall. Since the two walls are similar to each other, this consideration, together with information about the initial elastic stiffness of the two walls above reported, allows arguing that the TRM reinforcement slightly increase the stiffness of the wall on which it is applied.

Finally, it is worth observing that, even though the ultimate load was much higher for the reinforced wall, the frequency decrease (i.e. the stiffness reduction) due to damage is comparable for the two walls. It means that TRM reinforcement limits the negative effects of the damage on the structural stiffness of the wall.

In Table 4 a comparison between the modal damping ratio estimated for the four considered cases is presented. Both for the unreinforced and for the reinforced case, an increase of modal damping ratio occurs with damage. Comparing modal damping ratio before, ς_U, and after, ς_D, the damage through the discrepancy parameter $D_\varsigma = \left|(\varsigma_D - \varsigma_U)/\varsigma_U\right|$, for the unreinforced case an increase of 1.00 %, 227.39 % and 12.16 % of the modal damping of the first, second and third vibration mode, respectively, it is observed. On the other hand, for the reinforced case an increase of 16.18 %, 87.87 % and 51.95 % of the first, second and third vibration mode, respectively, occur. Since the modal damping is related to energy dissipation, an increase in modal damping means that, as a result of the damage, the energy dissipation increase. As for natural frequencies, modal damping ratio values suggest that the application of TRM reinforcement allows distributing on more vibration modes the negative effects of damage. Indeed, considering the discrepancy parameter D_ς, in the unreinforced wall the damage has mostly affected the second mode, while in the reinforced case the effect is distributed on all the three vibration modes.

Mode no.	Unreinforced wall			Reinforced wall		
	ς_U (Hz)	ς_D (Hz)	D_ς (%)	ς_U (Hz)	ς_D (Hz)	D_ς (%)
1	1.608	1.624	1.00	1.922	2.233	16.18
2	0.449	1.470	227.39	0.907	1.704	87.87
3	0.625	0.701	12.16	0.793	1.205	51.95

Table 4: Modal damping ratio estimated for the unreinforced and reinforced wall both in the undamaged (U) and damaged (D) state.

The estimated mode shapes of the reinforced wall in the undamaged state are represented in Figure 4. The mode shapes estimated in the other three cases are similar. In order to quantitatively compare mode shapes, the Modal Assurance Criterion (MAC) values were calculated. In Table 5 and in Table 6 the MAC values respectively for the unreinforced and the reinforced wall are listed. It can be seen that for both walls, the mode shape of the second vibration mode, which is a bending mode, is the most affected by the damage. Considering the cracking pattern for the two wall (Figure 2), it could be explained by observing that, since the second vibration mode involves opposite transverse displacements of the two free vertexes of the wall (Figure 4b-4e), the friction at crack surface is emphasized for that vibration mode. Further-

more, it is worth observing that the MAC values for the unreinforced case are lower than those for the reinforced case. This can suggest that the TRM reinforcement reduces the negative effects of damage in terms of variation of mode shapes.

5 CONCLUSIONS

In this paper, the effectiveness of the TRM reinforcement on scaled windowed brick masonry wall is evaluated through vibration testing and Operational Modal Analysis. In particular, natural frequencies and modal damping are considered as parameters respectively related to the structural stiffness and the energy dissipation. In addition, for both the two walls, mode

shapes are investigated through the calculation of the MAC value both in the undamaged and the damaged state. The results show that, both for the unreinforced and for the reinforced case, for all the three identified modes there is a decrease of natural frequency and an increase of the modal damping. This means that after the damage there is a reduction of structural stiffness and an increase of energy dissipation, respectively. Furthermore, it can be seen that the damage affects the mode shapes mainly for the unreinforced case.

More specifically, the results suggest that the application of TRM reinforcement: (1) improves the stiffness of the wall, its ductility and its ultimate strength to horizontal cyclic loads; (2) allows distributing on more vibration modes the negative effects of damage related to both the structural stiffness and the energy dissipation; (3) limits the effects of damage on mode shapes. This last conclusion remarks that the reinforced wall has at the end of the test higher level of structural integrity than the unreinforced specimen. In conclusion, it can be argued that, with respect to horizontal cyclic load, like seismic actions, TRM reinforcement can improve the mechanical behaviour of windowed brick masonry walls.

Abstract. *The preservation of Cultural Heritage assets from natural and man-made disasters is of great importance for communities because of their architectural and social value. Lack of any hazard-resisting design, material typology and degradation due to ageing strongly affect the behaviour of Cultural Heritage assets. In this context, Structural Health Monitoring systems can help stakeholders to control the behaviour of heritage constructions, to improve the estimation of their residual life expectancy and to optimize maintenance and retrofitting interventions. This paper presents the preliminary results of the modal identification of the transept of San Francesco church in Pisa. An experimental campaign aimed at measuring the structural response under environmental vibrations was performed, and Operational Modal Analysis was applied to quantify modal properties (frequencies and mode shapes). Data were then used to calibrate the elastic parameters of a refined numerical model. Issues and practical considerations related to the design and installation of dynamic monitoring systems for complex masonry constructions (such as the one under investigation) were derived to provide practitioners with practical guidance.*

1 INTRODUCTION

Cultural Heritage (CH) assets represent a relevant economic resource because of cultural tourism, but their intangible value is also of primary importance since they play a fundamental role in fostering a community's sense of place and belonging. For these reasons, preservation of heritage constructions is a matter of primary importance, though current conservation efforts are too often limited to emergency measures, and designed without a comprehensive intervention plan [1].

In this context, Structural Health Monitoring (SHM) [2] systems can help stakeholders control the behaviour of heritage constructions, while improving the estimation of their residual life expectancy and optimizing maintenance and retrofitting interventions.

Numerical models are commonly used as a tool to assess structural health of CH assets and to predict the buildings response to environmental conditions. Typical CH assets are characterized by the lack of any hazard-resisting design, materials of unknown properties and diffused degradation due to ageing. For this reasons, epistemic uncertainties regarding materials, geometry and boundary conditions [3, 4] strongly affect Finite Element (FE) model results.

Ambient vibration-based modal identification techniques are then key to record and derive information for both model parameter calibration and structural control. Being non-destructive, such techniques perfectly meet the well-known minimum intervention and reversibility criteria for CH assets [5]. Through dynamic identification, vibrational properties of the structure (natural frequencies, modal shapes and damping coefficients) can be deduced and compared to the ones obtained from numerical models [6, 7, 8].

In this paper we present the first steps towards the definition of a robust SHM system for masonry CH assets [10]. The San Francesco church in Pisa, Italy (Figure 1) was chosen as a case study, and dynamic measurements were performed to evaluate the response of its bell tower and transept to ambient vibrations.

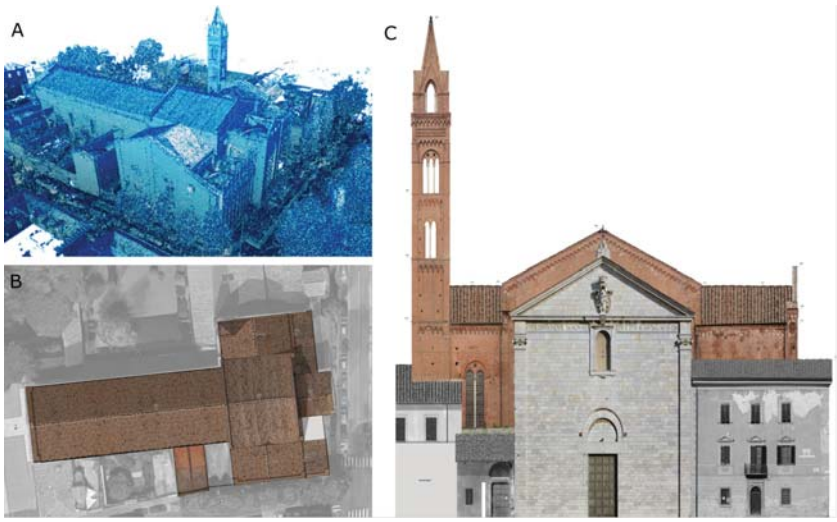

Figure 1: A) Point cloud survey; B) planimetry; C) façade of the San Francesco church.

The results were elaborated through Operation Modal Analysis (OMA) techniques [9] and used to identify natural frequencies and mode shapes. A preliminary dynamic identification of the bell tower alone provided first estimates for the constitutive parameters of the masonry walls. A FE model of the entire church was then built in order to preliminarily choose relevant

mode shapes involving the transept, and to design sensor positioning. After the experimental campaign, the same model was used to perform a manual mode-matching between numerical and experimental results.

2 THE SAN FRANCESCO CHURCH IN PISA

The construction of the San Francesco church in Pisa dates back to the 13^{th} century, and was executed under the direction of architect Giovanni di Simone [11]. It follows the traditional Franciscan canon of sobriety and humbleness, avoiding frescoes and limiting the use of marble to the façade (of later construction), preferring exposed brick on the exterior and painted plaster on the interior.

Its geometry (the nave measures 70.5 m x 17.7 m) makes it the second largest church in the city, after the Cathedral of Pisa. Its peculiarity is a "hanging" masonry tower, resting at a height of 12 m above ground level on two limestone cantilevers embedded in the north transept walls. The dynamic behaviour of the bell tower was already investigated during an experimental campaign in March 2019 by a research group from the University of Pisa lead by Prof. De Falco. The campaign's results are briefly recalled in the following.

A massive restoration work of the San Francesco church is currently underway, thus enabling the self-standing scaffolding system to be used during the dynamic experimental campaign herein presented. It is worth noting that the scaffolding system (Figure 2) is designed to have no contact with the structural system, so that it does not affect dynamic observations. Thanks to this, a diffuse network of sensors over most of the church's transept, including the highest portion of the walls, could be installed, thus obtaining significant data for modal identification.

Figure 2: Self-standing scaffolding system in the nave.

Plans of renovation also envisage the complete removal and restoration of the roof and of the supporting truss structures. This will allow a new experimental campaign to be performed in order to better evaluate the effect of roofing on the overall vibrational behaviour of the building.

3 EXPERIMENTAL CAMPAIGN ON THE BELL TOWER

On the 30^{th} March 2019, an experimental campaign was performed on the San Francesco bell tower in order to identify its modal properties. Accelerometers and velocimeters were placed at different positions along the tower's height (Figure 3), measuring its response to ambient

vibrations. Natural frequencies and mode shapes were derived using the software LMS Test.Lab 8 [12] to perform digital signal processing and to apply the PolyMax algorithm [13] to the data. The first three identified frequencies correspond to two flexural modes (1.10 Hz and 1.32 Hz) and a torsional one (3.55 Hz). Flexural modes are roughly aligned with the main diagonals of the bell tower's cross section.

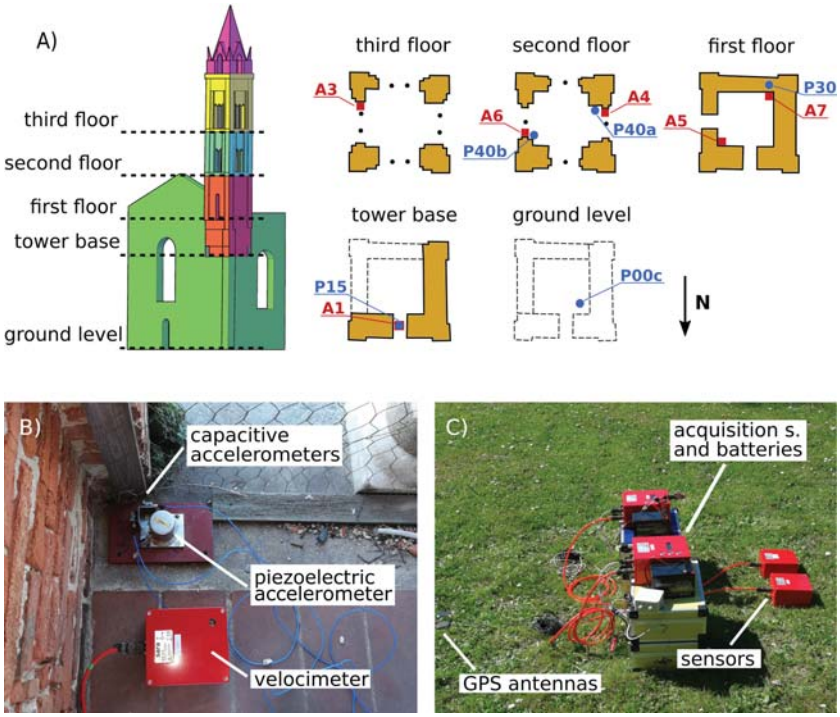

Figure 3: A) Sensor positioning along the bell tower. Accelerometers are indicated with the letter A, velocimeters with the letter P; B) employed sensors; C) velocimeter acquisition system.

A FE model was developed during this phase to simulate the masonry bell tower together with a limited portion of the neighbouring church walls (Figure 10). Experimental results were used to update the value of the elastic material properties of the model. The first three natural frequencies and mode shapes were matched with numerical ones (Figure 4) by varying the values of the Young's moduli of bell tower and church. Good accordance (less than 5% difference) between experimental and numerical data was finally reached for values of 1800 and 1300 MPa for the bell tower and church, respectively.

4 EXPERIMENTAL CAMPAIGN ON THE TRANSEPT

4.1 Instrumentation and acquisition

After the dynamic identification of the bell tower, an experimental campaign was carried out on the church's transept during December 2019 and January 2020. A network of accelerometers was used to record the building's response to ambient vibrations. Nine monoaxial capacitive accelerometers (*PCB DC capacitive accelerometers – Model 3701G3FA3G*) and six monoaxial piezoelectric accelerometers (*PCB ICP accelerometers – Model 393C*) from the Structural Laboratory of the University of Pisa were employed. Technical characteristics of the sensors are summarized in Table 1. Data were recorded and pre-processed through an acquisition system

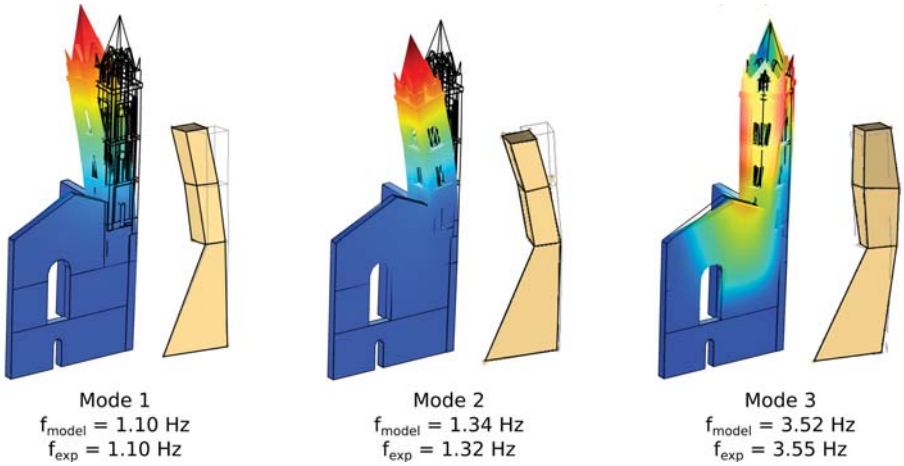

Figure 4: Mode matching for the bell tower.

(*LMS Scadas Mobile*) controlled by a dedicated application (LMS Test.Lab 8). Figure 5 shows the employed sensors and acquisition system.

PCB DC capacitive accelerometers model 3701G3FA3G	
Average sensitivity @ 30 Hz	1000 mV/g
Average eigenfrequency	540 Hz
Frequency range ($\pm$ 5 %)	0 to 100 Hz
PCB ICP piezoelectric accelerometers model 393C	
Average sensitivity @ 100 Hz	1000 mV/g
Average eigenfrequency	5.3 kHz
Frequency range ($\pm$ 5 %)	0.025 to 8¸00 Hz

Table 1: Technical characteristics of the employed sensors.

The sensors were assembled to create two- or three-directional measurement stations by fixing them to rigid metallic plates. Four different device configurations were adopted to perform three 30 minutes records with a sampling frequency of 256 Hz and 8-second average time windows.

Sensor layout was determined beforehand based on the results of a preliminary numerical model. Two main necessities had to be assessed:

1. to identify the modal properties of all reachable transept portions;
2. to gain insight regarding the influence of roof and supporting trusses on the vibrational behaviour of the connected walls.

Figures 6 and 7 show sensor positions, and Table 2 summarizes the configurations with the corresponding instrumented positions. Sensors in positions 1, 6, 8, 14 and 25 were used for each configuration, in order to be able to merge data from the different acquisitions.

Connection between sensors and acquisition system was achieved through cables ranging in length between 50 and 100 m on account of the church's geometry. This required careful

planning in the design of the experimental campaign, to make sure that as few accelerometers as possible had to be moved between a configuration and the following. Nevertheless, logistics often required long procedures, resulting even more complex since operations were carried out on the scaffolding.

Cable length, together with some electrical dissipations which may also have interacted with the scaffolding system, could have been the cause of issues concerning some of the sensors during measurements. This was particularly true in the case of capacitive accelerometers, which required an external power source and for which tripolar power cables were used. Some of the

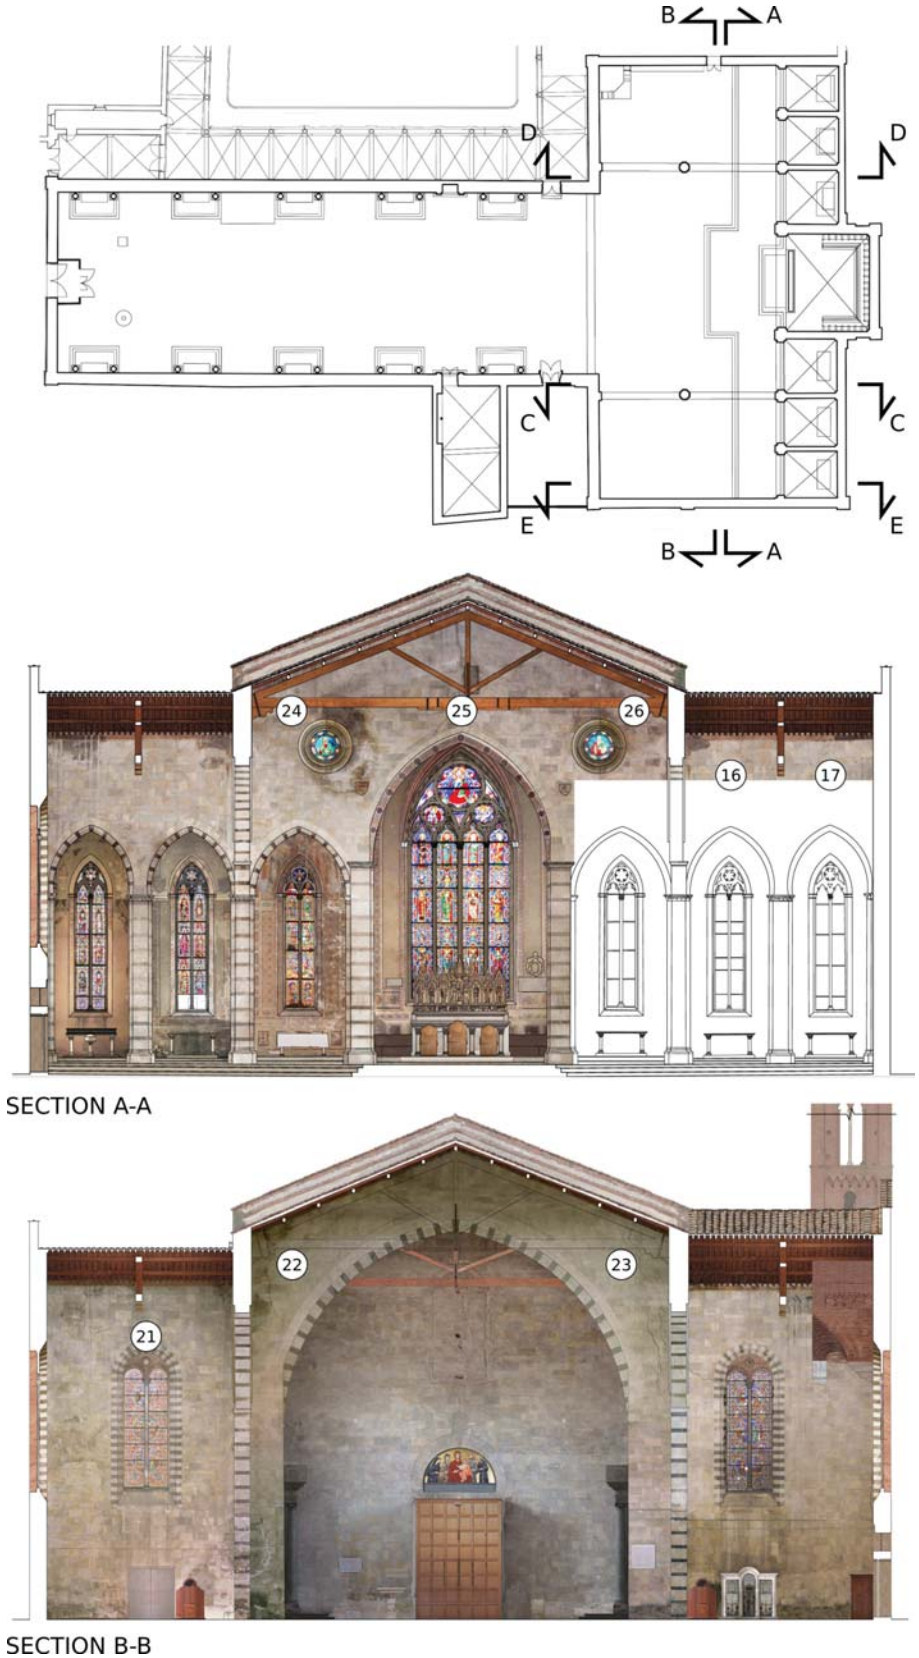

Figure 6: Sensor positioning. Church plan, section AA (east transept wall) and section BB (west transept wall). White portions were impossible to photograph.

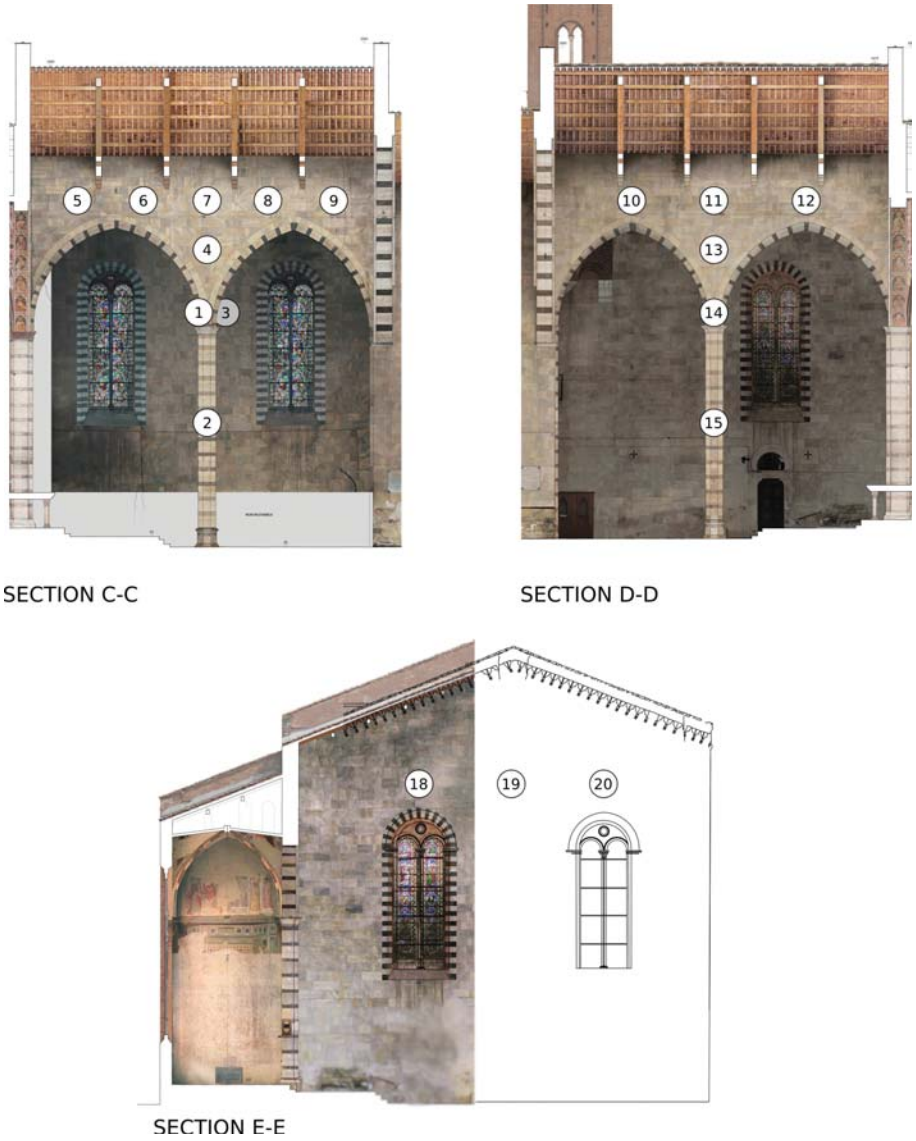

Figure 7: Sensor positioning. Section CC (south partition wall), section DD (north partition wall) and section EE (south transept wall). White portions were impossible to photograph.

longer cables, when used for sensors located closer to the acquisition system, had to be partially stored on cable reels. This may have worsened signal quality through induced electro-magnetic effects. Future testing may benefit from the use of piezoelectric accelerometers only, or from the use of capacitive accelerometers with better insulated cables.

4.2 Data elaboration and discussion

Data from accelerometers were processed using the software LMS Test.Lab, computing the Power Spectral Density function with Hanning windowing at 16768 spectral lines and 10% overlap. To perform a preliminary identification of peaks in the transept's frequency response, selected signals in the frequency domain were grouped based on sensor position: north and south partition walls and east, west and south transept walls. Figure 8 shows the resulting PSDs. Here, the different lines correspond to signals from accelerometers mounted on one wall, and measuring in orthogonal direction. Peaks have been identified through manual peak-picking.

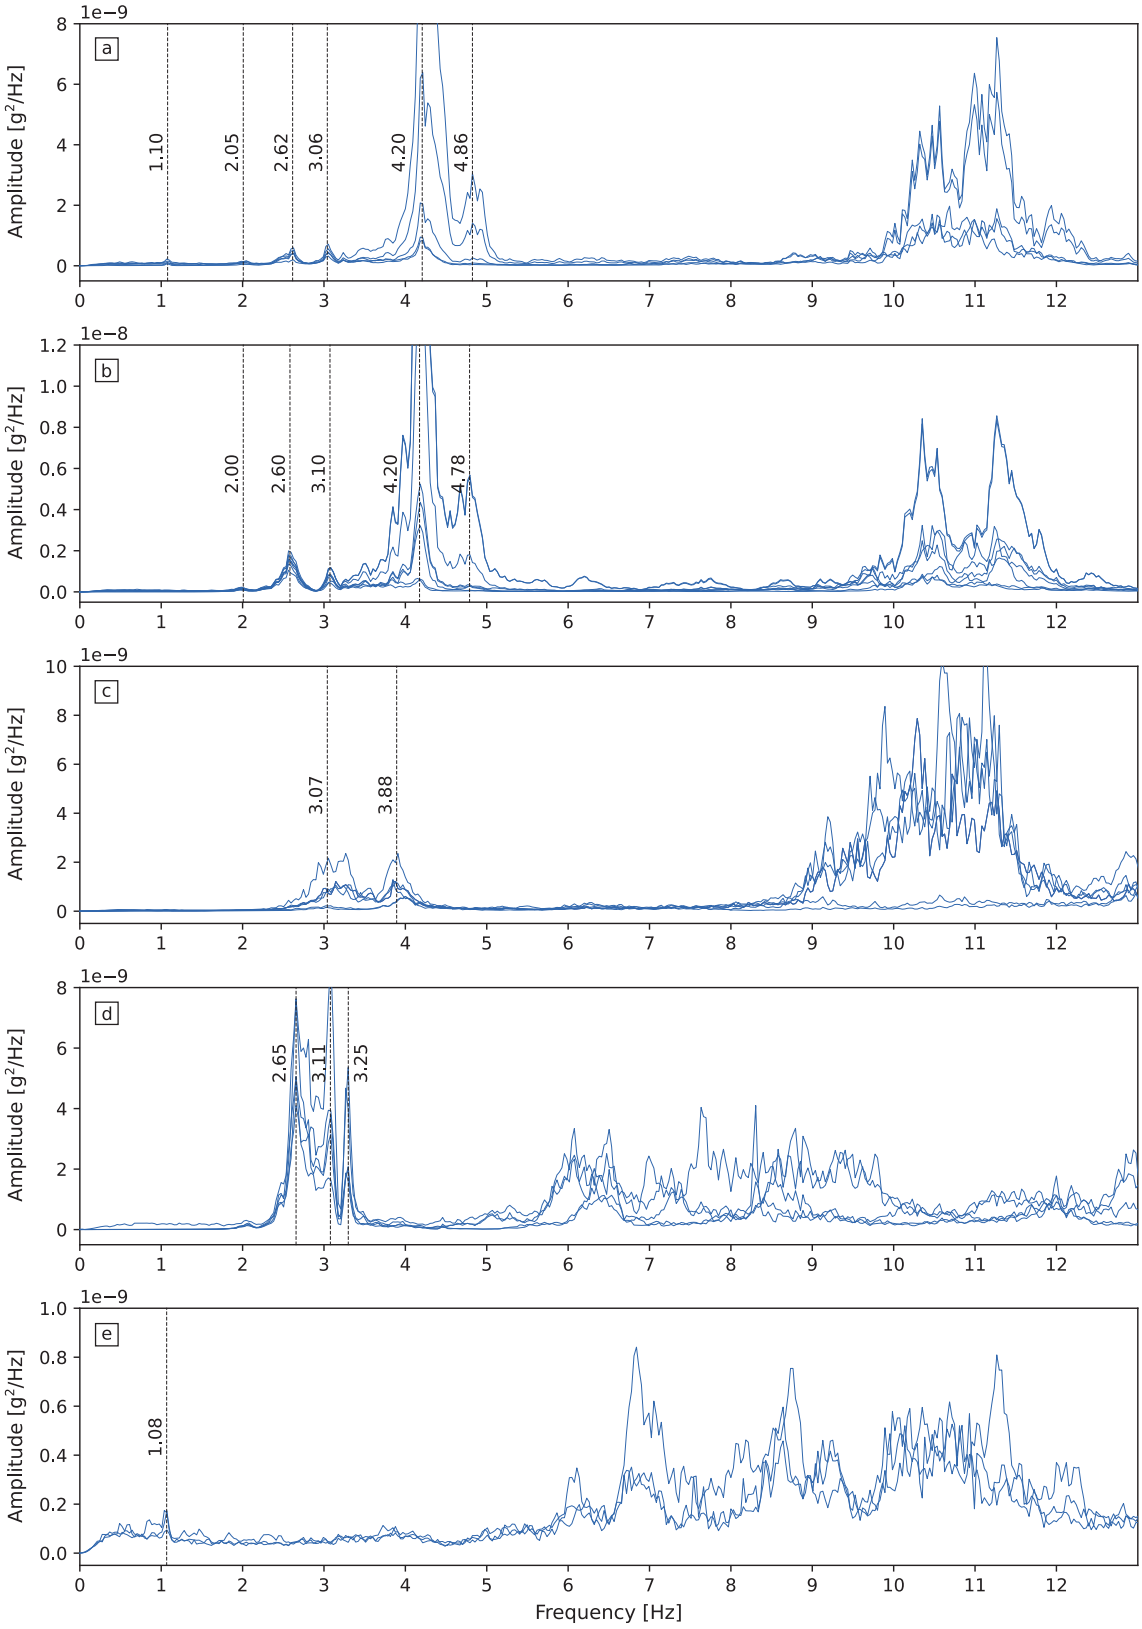

Figure 8: Power Spectral Density of signals recorded from sensors on different transept portions. a) North partition wall; b) south partition wall; c) east transept wall; d) west transept wall; e) south transept wall.

Some observations can be derived:

- frequency responses from the north and south partition walls are very similar. This could be expected since their geometry is roughly the same, even though boundary conditions differ significantly. The north wall is in fact contiguous to the bell tower and to an external vaulted cloister, while the south portion of the transept is free along its height and borders with adjacent roads.
- A peak corresponding to approximately 1.10 Hz can be recognized in the frequency responses of the north partition and west transept walls, and is absent from the response of other walls. This suggests that the first natural frequency of the bell tower, corresponding to its first flexural mode, was identified.
- The vibrational behaviour of the east transept wall is, as expected, quite different from the other walls. This is due to its being horizontally braced by several vaults that cover the altar and the chapels.
- The west transept wall is occupied for the most part by an archway that separates the transept from the nave, as can be seen in Figure 6. Unfortunately, the scaffolding system did not reach the arch's keystone, so that sensors were placed in positions very close to orthogonal walls. The frequency response shown in Figure 8 is detrimentally affected by the lack of sensors in the higher portion of the wall.

The PolyMax algorithm was applied to each single measurement run in order to identify natural frequencies which peaks may have been ignored during manual peak-picking, and the relative partial mode shapes. The results were then combined in LMS Test.Lab to construct global mode shapes, and a multi-run matrix was constructed, grouping together corresponding peaks from different runs (Table 3). Figure 9 shows the mode shapes identified with the PolyMax algorithm, on a simplified 80-point geometry of the church's transept. The northern portion is not shown, since it was not subjected to measurements.

	Configuration 1 [Hz]	Configuration 2 [Hz]	Configuration 3 [Hz]	Configuration 4 [Hz]
Mode 1		1.06	1.08	
Mode 2	2.01	2.00	2.00	
Mode 3	2.62	2.60	2.61	2.58
Mode 4	3.09	3.10	3.06	3.07
Mode 5			3.27	3.51
Mode 6	4.19	4.19	4.19	4.19
Mode 7	4.90	4.87	4.88	4.84
Mode 8	6.19	6.04	6.04	5.98
Mode 9			7.78	7.58
Mode 10	10.07	9.64	10.00	9.84
Mode 11		10.20	10.28	10.20
Mode 12	11.31		11.64	11.57

Table 3: Experimental natural frequencies of the transept.

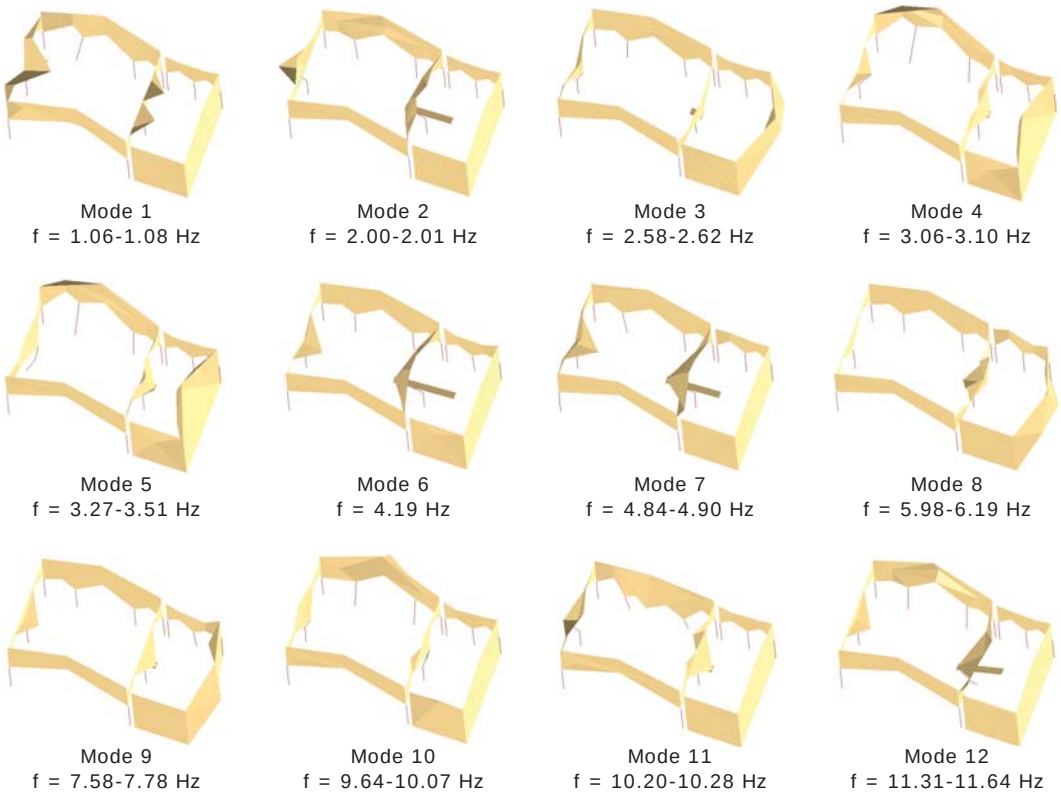

Figure 9: Experimental transept mode shapes extracted with PolyMax algorithm.

The identified mode shapes did not provide useful information regarding the influence of roof and supporting trusses. In particular, at this stage no conclusive answer can be given to the question regarding the eventual rigid-link effect exerted by the roofing system: while some of the mode shapes (e.g., modes 1, 2 and 4) show the two partitioning walls moving in phase, others (e.g., modes 6 and 7) clearly show them moving in opposition of phase. Further measurements, concentrating on the trusses' supports, will help to shed light on the matter.

5 FINITE ELEMENT MODEL

A FE model of the San Francesco church in Pisa was developed using the software Comsol Multiphysics 5.5 [14]. The church's geometry was obtained from a refined point cloud, resulting from a survey fieldwork with laser scanner (Figure 1A). The point cloud was imported in AutoCAD [15] and interpolating solids were defined to assembly the entire geometry of the church.

In Comsol Multiphysics, tetrahedral finite elements with Serendipity quadratic shape functions were used to define a mesh composed of 572991 elements, with maximum dimension set at 1.00 m (Figure 10). A cloister and part of the monastery are contiguous to the northern transept and nave walls (Figure 6). Their presence was considered using displacement boundary conditions to simulate the restraints they exert on the church. Since no conclusive observations could be made regarding the role of the roofing system in the dynamic characterization of the transept, trusses were included in the model because this was thought to represent the most "natural" choice. At this stage, values of Young's moduli for the church's and bell tower's masonry were estimated to be 1300 MPa and 1800 MPa respectively, in accordance with the previous

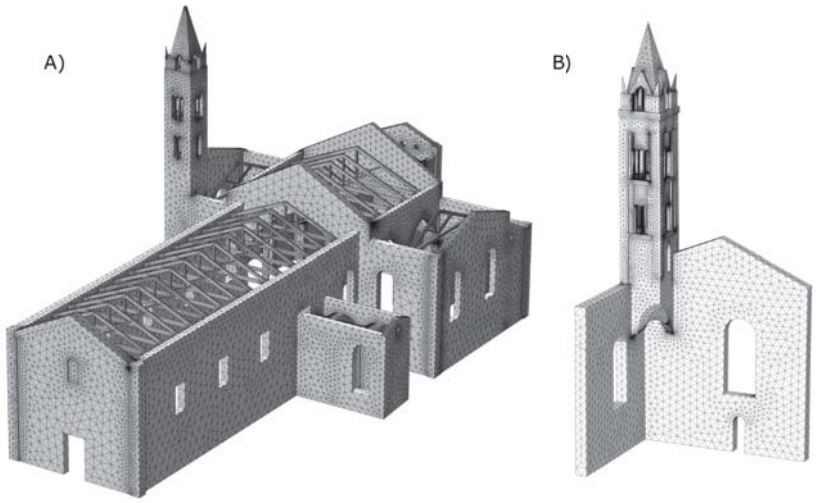

Figure 10: FE models. A) The church; B) preliminary model of the bell tower.

dynamic identification of the bell tower. An automatic updating procedure will be the object of further research work.

Modal analysis resulted in more than 150 mode shapes in the frequency range from 0 to 12 Hz, while only twelve were derived from data analysis (Table 3). Most of the former correspond to natural frequencies of the portions of the church which were not instrumented and therefore not identified, such as the nave and the altar chapels. Sensors used during the acquisition may have not recorded vibrations relative to mode shapes that were not triggered with enough energy by ambient noise.

Mode-matching was performed, and good accordance between experimental and numerical data was reached for some of the modes. Figure 11 shows modal shapes for modes 1, 2, 3 and 7 (according to numbering used in Table 3). Results of the FE model are compared with experimental data. The large number of numerical mode shapes, however, and the presence of many modes with very similar frequencies suggest the necessity to employ an automatic mode-matching procedure such as the Modal Assurance Criterion (MAC) [16]. For this reason, masonry constitutive parameters were not updated using experimental modal information in this case. This will instead be the topic of future research work.

6 CONCLUSIONS

This paper presents preliminary results of the modal identification of the San Francesco Church in Pisa, which is the first step towards the development of a robust SHM system for masonry CH assets. The church's bell tower and transept were subjected to dynamic testing, and operational modal analysis enabled the identification of a limited number of vibrational modes and frequencies. A FE model, preliminarily used to design instrumentation layout, was employed to perform mode matching between experimental and numerical mode shapes, using values for material constitutive parameters resulting from a previous experimental campaign on the bell tower. This first effort allowed us to expand our knowledge regarding practical problems and difficulties arising from performing dynamic testing on a complex structure such as the San Francesco church. Further experimentation will concentrate on specific substructures of the church, and on a dedicated investigation regarding the vibrational influence of roof and supporting trusses.

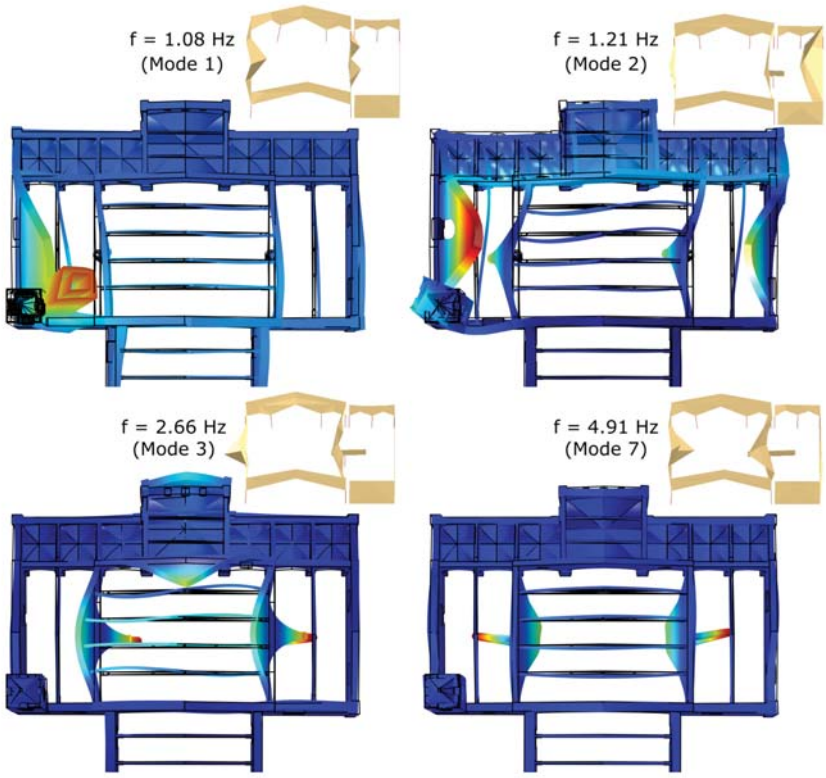

Figure 11: Mode shapes and natural frequencies from the FE model are shown and compared to mode shapes from the experimental campaign.

Keywords: Bell tower, Masonry, Dynamic, Damage

Abstract. *This research show the numerical and experimental results evaluated in the Fiesole bell tower in Italy. The aim of this investigation is to increase the knowledge related to the dynamic interaction between the vibration frequencies of the bells and the dynamic behavior of the masonry tower. In particular, in this paper the numerical evaluation focuses on the bell and tower interaction, taking into account the behavior of the tower as an exempt structure. In particular, the study was divided into several phases. The first phase consisted of the geometric definition of the structure, as well as the definition of the mechanical properties of the bells. In the second phase the dynamic properties of the structural system were evaluated and the numerical model was calibrated. In the third phase, lateral restrictions of the tower were released and a parametric study of the interaction of the dynamic forces of the bells with the tower was carried out. Based on these results, the velocity ranges, and swing amplitude of the bells, which could damage the tower, were evaluated according to DIN 4178-2005. The main results show that the biggest bell should not be used for velocity values near 41.53 rpm. regardless of the swing angle. Also, for smaller bells, swing angles between 50º and 95º and speeds between 25-40 rpm. should be avoided.*

1 INTRODUCTION

Masonry towers are very common buildings from the middle ages until now. In particular, many of them have bell towers at the top of the buildings. These bells have been used to advise the population of different events by means of the ringing of the bells [1]. In recent years, interest in the dynamic behavior of such structures has increased, especially through the use of monitoring techniques (structural health monitoring), reporting papers on vibration modes and frequencies [2, 3], as well as studies related to their seismic vulnerability [4]. On the other hand, several authors have published articles related to the dynamic forces generated by the bells ringing [5]. However, there are not many authors who analyze the behavior of these structures under loads in service, such as those due to the swing of the bells.

With the aim of increasing this field of knowledge, in this work the interaction between the vibration frequencies of the bells and the dynamic behavior of the masonry tower, under the consideration of structure exempt is evaluated. In particular, the study is divided into several phases. The first phase consisted of the geometric definition of the structure, as well as the definition of the mechanical properties of the bells. In the second phase the dynamic properties of the structural system are evaluated and the numerical model is calibrated. In the third phase, lateral restrictions of the tower are released and a parametric study of the interaction of the dynamic forces of the bells with the tower is carried out. Based on these results, the velocity ranges, and swing amplitude of the bells, which could damage the tower, are evaluated according to DIN 4150 [6].

2 CASE OF STUDY: FIESOLE BELL TOWER

The tower selected for the analysis is the Fiesole bell tower from the Cathedral of Fiesole (Italy), Figure 1. This structure is a hollow rectangular cross section of 5.10x4.10m². The thickness of the external wall is variable with height. From 0 to 7.25m the thickness of the wall is a constant value of 1m. The thickness for the next section of 15 m length is 0.85m. For the third section of 16m length, the thickness is 0.75m. Finally, for the last section from 38m to the crown at 39.65m, the thickness is equal to 0.25m. Regarding the openings in the external walls of the tower, there are no important elements, except for the access point at the base of the tower, and the openings located in the belfry, at 26.30m and 30.90m. Regarding the lateral constraints, there are tree lateral church walls connected on north, south and west sides with a thickness of 1m. In general, the material of the tower and lateral walls are irregular stone bricks with mortar.

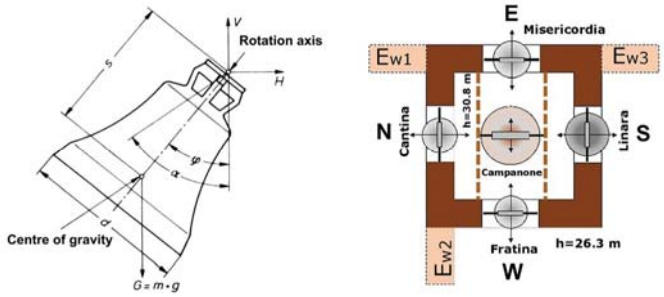

Figure. 2: Left: Simplified bell model. Right: Arrangement of the bells with their swing directions.

3 DYNAMIC BELL FORCES

The belfry of the tower shows five different bells, Figure 2. The first four, Fratina, Cantina, Misericordia and Linara, are located at 26.30m, and the weight of them is 2.452 kN, 2.256 kN, 3.237 kN and 4.395 kN. The last one is the Campanone, located at 30.90m and its weight is 7.142 kN. Table 1 shows the dynamic properties of the bells. These bells swing according to the Central European System [5]. Dynamic horizontal force of the bells, evaluated according of the German standard [10], Equation 1, depends on the mass of the bells, m, the swing velocity, Ω, the geometry coefficient, c, and the swing rotation angle, α. The c coefficient is a function of the inertia and the distance from the bell gravity center to the rotation axis of the bell. Finally, the effect of the rotation angle, α, Figure 2, is taken into account by means of the γ coefficient. Figure 3 shows an example of the dynamic force of the Campanone bell, and the harmonics components of this force. These harmonics change with the swing angle and velocity and they can interact with the vibration frequencies of the tower.

Bell	Geometry coefficient	Weight (kg)	Diameter (mm)	Swing velocity	Swing angle	Dynamic Horizontal Force (kN)
Campanone	0.76	728	1120	29.98	64	5.014
Linara	0.75	448	970	33.52	73	3.645
Misericordia	0.75	330	870	33.04	65	2.289
Cantina	0.75	230	780	34.47	72	1.838
Fratina	0.80	250	670	36.96	69	2.006

4 EXPERIMENTAL TEST

In order to analyze the dynamic properties of the tower six 393 PCB Piezotronics uniaxial accelerometers are placed at 30.9m and 38 m on the internal part of the tower East façade, in a triaxial configuration. By means of this test setup it is possible to evaluate the frequencies in E-W and N-S direction, Figure 2. The range of measurement for these devices is from 0.025 Hz to 800 Hz, with a voltage sensivity of 1V/g. Data acquisition hardware consist of a signal conditioner PCB 482A22 and a data logger HBM Spider8 (SR55). The sample frequency is 400 Hz. Two test are done. During the first one, a signal of 15 minutes is recorded, and the dynamic load used during this test is the ambient noise. In the second test, a signal of 6 minutes is recorded and the dynamic load used in this case is the horizontal force due to the swinging of the Misericordia bell with a swing angle and swing velocity equal to 100º and 30 rpm.

Mode		EFDD		CFDD		CVA	
-	plane	Hz	csv	Hz	csv	Hz	csv
1	zy (N-S)	0.87	*1.22*	0.89	*1.75*	0.86	*0.30*

EFDD: Enhanced Frequency Domain Decomposition; CFDD: Curve-fit Frequency Domain Decomposition; CVA: Canonical Variate Analysis.

Table 2: Statistical analysis of ambient vibration test.

Signals are analyzed using ARTeMIS software for OMA, and Matlab software. Signals are decimated from 400 Hz to 50 Hz, and filtered between 0.1 Hz to 20 Hz. Different techniques are used for the analysis. Table 2 shows the mean frequencies and the standard deviation values for the principal vibration modes according to the Enhanced Frequency Domain Decomposition technique (EFDD) and Curve-fit Frequency Domain Decomposition technique (CFDD) for the analysis in frequency domain, and the parametric technique Canonical Variate Analysis (CVA), for the analysis in time domain. Finally, the global damping of the structure is evaluated using de data of the second test and the logarithmic decay technique. Global damping value is equal to 1.5%, and it is very close to the proposed one by the standard DIN 4178 [7] for masonry buildings.

Finally, with the aim to evaluate the experimental results, the analytical first bending frequency is compared with the proposed in some standards. Table 3 shows the results for the NTC-08 [8], DPCM-11 [9] and NCSE02 [10]. In general, all the results are close to the experimental ones, and they are valid for a preliminary value. Moreover, the results for the Spanish standard shows the best results compared to the experimental data.

Direction	NTC-08	DPCM-11	NCSE-02	Experimental
-	Hz	Hz	Hz	Hz
E-W (zx)	1.307	1.407	1.116	0.976
N-S (zy)	1.307	1.407	0.979	0.873

Table 3: First bending frequency according to different standards.

Figure 5: Frequencies and modal shapes for bell tower without lateral restraints

5 DAMAGE EVALUATION DUE TO BELL SWING

A numerical model has been implemented with ANSYS software with the aim to evaluate the dynamic behavior of the tower, and the dynamic interaction between the tower and the bells. All the elements used are solid 186 elements. Perfect bonded contact is selected between the elements in contact with the tower. The analysis is divided in three phases. The first one consist of the numerical model calibration process. During this phase, a confined model is used, and the optimization process is done using genetic algorithm [11]. The parameters used in GA were, population of 20 chromosomes, elite count and crossover fraction equal to 10% and 80%, and 75 generations. Five variables are evaluated, three variables for the Elastic modulus of the three masonry confinement walls, one for the Elastic modulus of the main body of the tower, and finally, one more for the tower masonry self-weight. Relative error between numerical and experimental data for the first five vibration frequencies is used in the calibration process. Finally, the elastic modulus and the self-weight calibrated values for the tower are 2043 MPa and 1894 kg/m³, and the global error is equal to 3.31%. The second phase consist of the analysis of the bells swing velocity range that could generate resonance problems with the bell tower. In this phase and the next one, the numerical model used is the same as the calibrated one, but the lateral restriction are released. Figure 5 shows the first five modal shapes for the tower without lateral restraints. It has been selected the model without lateral restraints due to the aim of this research is focused on the dynamic interaction between the bell tower and the bells in case of analyzing the tower as exempt structure.

Regarding the critical bell swing velocity range, a preliminary analysis is done taking into account the relationship between the frequency of the tower and the harmonic of the horizontal bell force. Figure 6, shows the amplification factor for the normally used range of bell swing velocities. It is possible to evaluate that the critical bell swing velocities and harmonics for the

first and second mode are 29.34 rpm (1st harmonic) and 36.6 rpm (1st harmonic), for the third mode are 41.53 rpm (3rd harmonic) and 24.93 rpm (5th harmonic), for the fourth mode are 22.55 rpm (7th harmonic) and 31.56 rpm (5th harmonic), and finally, for the fifth mode are 21.2 rpm (9th harmonic), 27.26 rpm (7th harmonic) and 38.16 rpm (5th harmonic). Finally, in the third phase of this research, a parametric study of the interaction between the bell forces and bell tower is done. Figure 6 shows the normalized resultant velocity on the top of the tower for the swing velocities selected, and the normalized standard velocity limitation, for the different bells according to the standard DIN 4150 [6]. For these velocities, a swing angle from 50º to 170º and height equal to 30.9 m in E-W direction, is evaluated.

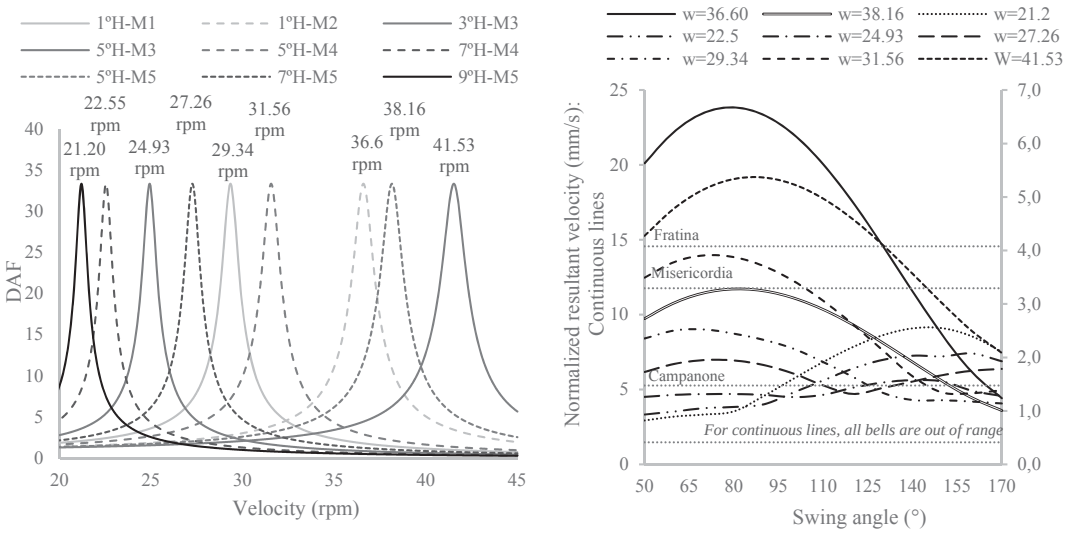

Figure 6: Left: Local sensitivity analysis of the dynamic interaction between bell tower frequencies and bell harmonics. Right: Maximum horizontal velocity of the last floor for bell loads.

The results show that for bells located at 30.9 m none of the three bells in E-W directions could be used for swing velocities equal to 36.60 rpm and 38.16 rpm, with maximum normalized horizontal velocities equal to 23.85 mm/s and 11.72 mm/s. Regarding the others bell swing velocities, for the same location and bell swing direction, it is possible to see that for bells similar to Fratina bell, swing velocity of 41.53 rpm and swing angle from 50º to 130º could damage the tower due to the interaction between the 1st harmonic bell force and the 2nd vibration mode of the tower. However, the results show that there are not resonance problems between the 3rd harmonic of the bell force and the 3rd vibration mode of the tower, although the relationship between these frequencies is close to one. From the point of view of bells similar to the Misericordia bell, damage bell swing velocities are 41.53 rpm and 31.56 rpm for bell swing angles lower than 150º or lower than 110º respectively. Regarding the interaction between the harmonics of the bell forces and the vibration frequencies of the tower for these bell velocities, the problem is focused between the 1st harmonics of the bell forces and the 2nd vibration mode of the tower. In this case the influence of the 3rd and 5th harmonics of the bell forces in the 3rd and 4th vibration mode of the tower is negligible. Finally, Campanone bell shows that only bell swing velocities lower than 25 rpm with bell swing angle lower than 125º could be used without damaging the tower. It is important to note the relevance, for these low bell swing velocities, of the interaction between the higher order harmonics and the higher vibration modes of the tower,

6 CONCLUSIONS

In this paper, the dynamic behavior and the interaction between the Fiesole bell tower and movements of the bells is evaluated. Fist, Operational Modal Analysis is used to evaluate the first five vibration frequencies of the tower by means of three different techniques, EFDD, CFDD, CVA. Second global damping of 1.5% is evaluated using logarithmic decay technique. Third, a numerical model is implemented using ANSYS commercial software, and variables such as bell swing velocity, bell swing angle, and bell dynamic properties are evaluated by means a parametric analysis. The results show that for any bell located at 30.9m height, velocities equal to 36.60 rpm and 38.16 rpm could damage the bell tower. In case of Campanone bell, bell swing velocities higher than 25rpm and bell swing angle higher than 125º could damage the tower. In conclusion, it can be argued that, the dynamic interaction between the bells movements and the bell tower can damage the Fiesole bell tower.

Keywords: Compaction, slope stability, non-linear soil, and equivalent linear frequency domain FE

Abstract. *A tsunami caused by a landslide caused extensive damage at Statland, Norway in 2014. The landslide was probably triggered by man-made vibrations. To understand better how vibrations from vibratory compaction affect slope stability, a frequency domain numerical tool (Comsol Multiphysics) has been extended to account for realistic non-linear soil behaviour. The tool is validated by comparison with field experiments of vibratory compaction. The non-linear analysis is believed to capture the essential behaviour of the vibratory compaction and the response of the slope. The numerical analysis and evaluations indicate vibratory compaction can have contributed to triggering the slide at Statland. To perform compaction in the vicinity of slopes with low stability near the shoreline with vibration susceptible soils we suggest: 1) using lighter equipment and/or higher loading frequencies or performing compaction without vibration, and avoiding excessive jumping of the vibratory roller drum; 2) applying thinner layers and more time between compaction passes, allowing for drainage of potential built up pore pressures; 3) monitoring slope horizontal and vertical displacements at some critical points; and 4) monitor pore pressures at critical points, if possible.*

1 INTRODUCTION

A landslide-induced tsunami caused extensive damage at Statland, Norway in 2014. Only luck prevented any fatalities. The investigation of technical cause [1] concluded the slide was likely triggered by vibratory compaction of a rockfill in the shoreline in connection with development and extension of a near shore recreation cottage area. For safer nearshore developments it is very important to understand better the processes involved in the landslide triggering.

Often ground conditions along the Norwegian fjords consist of loose soil deposits with silt and sensitive clays. In combination with artesian water pressure the stability of such shoreline submarine slopes can be very low. The combination of loose soil and low stability makes these slope extra vulnerable to vibrations.

A tentative procedure on how to account for cyclic- and dynamic effects during vibratory compaction near slopes with vibration sensitive material, was proposed [2]. However, such approach may not always be practical, especially in small projects. Therefore the possibility of establishing a vibration limit has also been investigated in [3]-[4]. Through linear elastic models accounting for soil non-linearity by an ad-hoc reduction of soil stiffness depending on the induced strains. Recently, an equivalent linear numerical tool has been developed which has been validated against data from compaction and pile driving vibration experiments [5]. This tool is applied to the Statland case to better understand how non-linear soil properties affect the dynamic response of the slope. The following section gives a brief description of vibration triggered landslides and soil compaction induced vibrations before describing the numerical model and results for the Statland case.

2 VIBRATION-TRIGGERED LANDSLIDES

It is commonly not considered likely for non-blasting construction vibrations to cause landslides. We have only found the following potential cases in the literature:

- The Trestyckevatten slide south of Uddevalla, Sweden in 1990 [6] was most likely triggered by a heavy vibratory roller which caused the failure of a berm designed to provide additional stability to an embankment for the E6 highway.
- The Åsele-slide in 1983, also in Sweden [7] caused the failure of a road embankment that was partially submerged due to filling up of hydro-electric reservoir. The slide was triggered by tractor- pulled 3.3 ton vibratory roller.
- The 1987 Lake Ackerman slide caused damage to Highway 94 in Michigan, USA [8]. Six 22-ton trucks with vibrator plates generating signals for a seismic refraction study triggered the slide. The road embankment consisted of hydraulic fill of loosely deposited sand. Hryciw et al. estimated the cyclic shear strains induced in the fill of up to 0.06%, which could be enough to generate pore pressure build up and cause failure in loose fine silty sand ([9], [10]).
- The 1994 Skagway landslide reported in [10] have similarities with the Statland case, however there is limited information on the road construction done shortly before the slide. It is not clear if compaction can have contributed to the landslide.

The above cases were all near shoreline submarine landslides with loose ground conditions. For landslides where rock blasting was a potential trigger, the slide occurred in combination with other adverse factor such as low stability prior to blasting, higher than normal ground water level due to high precipitation, artesian pressures, erosion at the slope base, temporary placement of fill masses, etc. In addition, the existence of thin sand or silt layers within the clay are

confirmed in many cases, and are hence assumed to have played a crucial role [12]-[13]. These adverse factors also play an important role, when construction vibrations induce landslides.

3 STATLAND LANDSLIDE

January 29, 2014, a submarine landslide and a resulting tsunami [14] caused damage to port facilities and nearshore infrastructure at Statland, in the county of Nord-Trøndelag, Norway. Some photos of the damage are shown Figure 1. The newly constructed road and part of an old molo was swept away by the landslide. Luckily no humans was in vicinity when the landslide occurred. The tsunami slammed into buildings many of which were totally or partially destroyed. The investigation of the possible slide causes [1] established the slide occurred an hour and half after the filling and compaction work was finished. It further concluded it was very likely the construction work triggered the slide.

Deltaic deposits have accumulated over years along the margin of Namsfjorden outside the small community of Statland. The deposits consist mainly of loose sands and silts overlaying marine and partly sensitive clays (quick clays). The soft and weak soil conditions result in very low static factors of safety for the partially submarine slope [1]. In addition, there are considerable amount of organic material down to depths of 14 m beneath the seabed [1], which originated from sawmill industry in the area during the last 120 years. The sedimentation rate in the area is estimated to be in the order of 12 cm/year. Thus, there are considerable amounts of material still undergoing consolidation.

Such loose silty soils are susceptible to strength degradation due to vibrations, and thus some preliminary analysis of the impact of vibratory compaction on the slope stability was performed in [1]. The analysis indicated that compaction may have contributed to slide triggering in combination with other factors such as low tide and low static stability.

Figure 1 Photos showing damage caused by the Statland landslide. The right hand side photos compare the situation before and after the landslide with yellow dashed line showing the shoreline after the slide.

4 VIBRATIONS FROM VIBRATORY ROLLERS

Ground vibration from vibratory rollers transmits large dynamic loads to the soil in order to compact the fill materials during construction. Such dynamic loads can possibly cause pore pressure build-up and reduce soil strength in vibration susceptible soils such as loose silt and sand, and sensitive clays. This should be considered when carrying out construction work near slopes with such soils. The strength reduction depends on soil conditions, cyclic load amplitude and number of load cycles.

Performing vibratory roller compaction according to guidelines such as the Norwegian standard NS 3458 involves passing over the same area sometimes up to 8 times with the roller. This means a soil element is exposed to a large number of vibration cycles. The number of cycles depends on the speed of the roller and the vibration frequency. Vibratory rollers have vibration frequencies typically between 20-40 Hz and, on some rollers, both the load amplitude and vibration frequency can be varied, depending on the type of soil and the thickness of the compacted layers. The speed of the roller is typically between 0.5 m/s to 1.5 m/s. E.g. for the case of the Statland landslide ([1]) a low estimate of number of cycles indicated the soil in the upper part of the slope had experienced several hundred cycles with strains large enough to build up pore pressure.

The vibration amplitude depends on the vibratory roller's dynamic behaviour and its interaction with the ground during the compaction process (see e.g.[14]and [16]). There are various vibration modes, changing from full contact between drum and the substrate, to the periodic loss of contact during normal operation, to a less desirable chaotic bouncing of the drum as shown in Figure 2. Bouncing occurs when the period for one cycle is longer than the time for loss of contact and is more common at larger load amplitudes and can cause increased vibration amplitudes.

Vibratory compactors can start bouncing when the compacted fill is becoming stiffer after a number of passes over the fill. When this happens the roller drum will lose contact with the soil during a longer part of each vibration cycle and therefor do not vibrate with the same frequency as the compacted fill and soil. When bouncing occurs the soil is subjected to load impulses with a frequency which can be closer to the soil deposit's natural vertical vibration frequency. This can lead to larger vibrations and possibly pore pressure build up further away from the roller. There may be a "double" resonance if the natural frequency of the vibratory roller and the underlying fill is close to the natural vibration frequency of the soil layers in the slope.

Full-scale tests of vibratory compaction [17], [18] indicate the largest vibration amplitude occurs when the drum vibration frequency is about twice of the natural vertical vibration frequency of the system consisting of the drum and underlying fill and soil as shown in Figure 6. This is interpreted as that every other cycle the roller is in the air, and every other cycle it "hits" the compacted fill and soil in phase with the natural vibration frequency between roller and fill.

Jumping reduces the compaction efficiency [17] and is undesired. Therefore, some modern vibratory roller have various types of automatic feedback control systems to avoid such jumping [12]. The jumping is reduced by changing drum vibration amplitude and/or frequency ([19]). Since jumping can cause larger vibrations it is also undesired with respect to slope stability and should be avoided. The lower graph in Figure 2 shows schematically the dynamic behaviour of a vibratory roller drum and the vibration frequency halving which can occur during jumping.

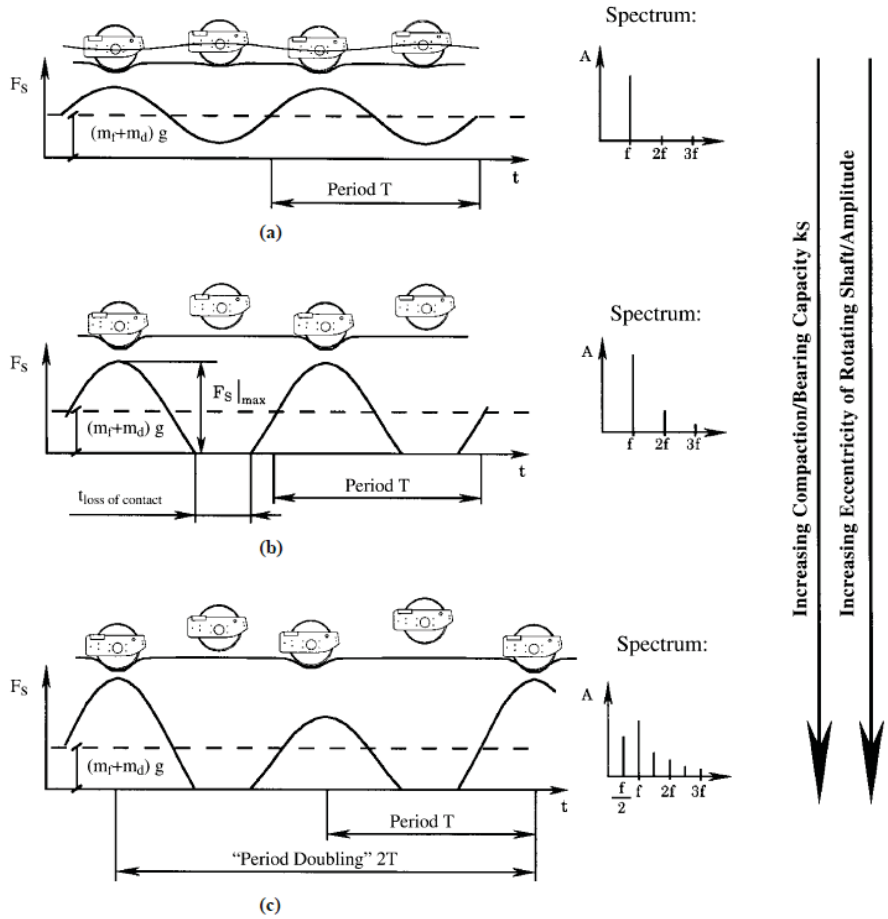

Figure 2 Dynamic behaviour of a vibratory roller drum, a) full contact, b) periodic loss of contact, and c) double-jumping. Spectrum show the period doubling when the drum jumps. From [19].

5 NUMERICAL METHOD

Numerical simulations of effects from vibro-compaction done earlier in [2]-[4] were based on linear elastic material properties. Soil nonlinearity (reduction of stiffness with increased loading) was accounted for by manually reducing the material stiffness in the regions subjected to the largest cyclic strains. Recently we implemented a new feature in Comsol Multiphysics [5], to account directly for soil nonlinearity by means of laboratory measured strain dependent secant stiffness and damping. This extended tool is described in the following sections. The analysis is done in the frequency domain which allows for an equivalent linear soil model to be used to iteratively account for soil non-linearity.

Modelling of nonlinear soil behaviour with the equivalent linear method originates from the analysis of earthquake induced ground vibrations [21][22]. With increasing cyclic strain, the secant soil stiffness decreases, and the damping increases as shown schematically in Figure 3. This behaviour is often represented by curves showing reduction of secant shear modulus and increase of damping as shown in Figure 4.

The input parameters in the model is the initial shear wave speed, mass density, and hysteretic damping. In the frequency domain analysis constant elastic parameters are used, and thus the nonlinear stress-strain variation cannot be followed. Therefore, for each loading frequency, the COMSOL solver iterates until there is shear modulus is compatible with the shear strain in an equivalent linear sense in the whole computational domain. The secant shear modulus and damping vary with the distribution of shear strain amplitude within the soil around the roller

drum. The secant shear modulus, G_s, is expressed as varying with the octahedral shear strain amplitude, γ, according to the hyperbolic relationship in Eq. (1).

$$G_s = G\frac{1}{1+\left(\frac{|\gamma|}{\gamma_{ref}}\right)^n} \tag{1}$$

where G is the initial shear modulus, n and γ_{ref} are material parameters. The octahedral shear strain, γ, is a complex variable when operating in the frequency domain, and therefore the equation was modified in COMSOL to use the amplitude of the shear strain. The material damping is modelled with a frequency independent damping, which is included in the soil stiffness by replacing the shear modulus with a complex shear modulus, $G_s^* = G_s(1+i2D)$, where, D is the material damping factor, and i the imaginary unit.

The above method is not restricted to the hyperbolic law in Eq. (1), other formulations such as presented in [23]-[26], or simple tabulated data points for shear strain versus G/G_s , or damping, for specific materials are also possible. The material damping for the current analysis were given as tabulated values.

The combination of a cyclic and an average shear stress, can have considerable effect on the cyclic stress-strain behaviour and damping [27]-[29], but these effects were not considered in this study. Though the nonlinear cyclic stress-strain and damping-strain behaviour of the clay, silt and sand materials differ to some extent, in this preliminary study, they were modelled with the same stiffness reduction and damping curves, based on the empirical equations in [23] with the soil index input parameters given in Table 1.

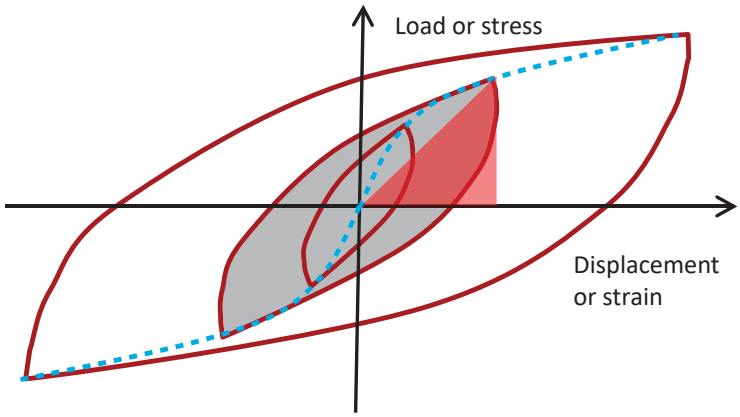

Figure 3 Schematic cyclic stress-strain loops for a soil element. The red triangle and the grey shaded loop shows the definition of elastic energy and hysteretic loss energy respectively in one cycle. The cyclic "back-bone" or "skeleton" curve which controls the shape of the hysteresis loops, is shown by the blue dotted line. Assuming a hyperbolic shape this line is given by Eq. (6).

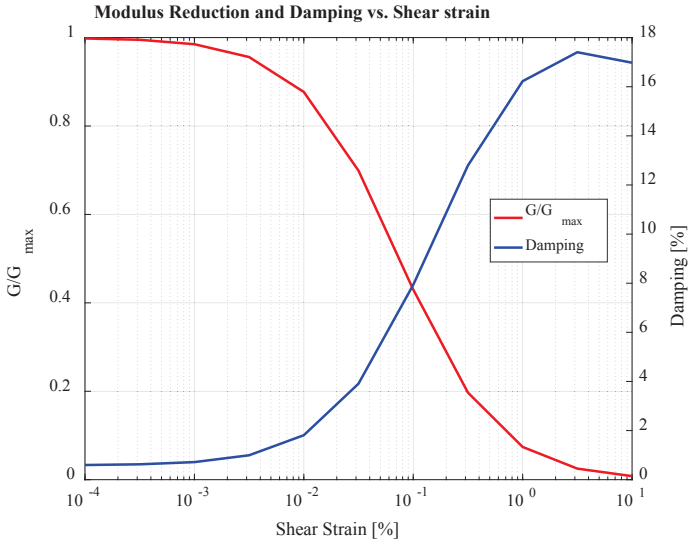

Figure 4 Shear Modulus reduction and damping versus shear strain used in COMSOL analysis.

Absorbing boundaries of the Perfectly Matched Layers (PML) type [30] are used to reduce unwanted wave reflections from the boundaries of the computation domain in the dynamic analysis. This also allows for modelling of radiation damping.

Since the soil strains become large near the vibratory roller it is important to have mesh element size fine enough to resolve the high strain and stress gradients. A comparison between *1st* and 2nd order elements are given in section 7.2. Also the element size should be small enough to resolve the wave lengths appearing for the various stress and strain conditions at the various frequencies analysed. In three dimensions it is most likely faster to adopt the mesh size according to the frequency, i.e. the higher frequency the finer the mesh. In 2D we have found for some models it was faster to use "brute force" and use the same fine mesh for all frequencies.

6 VALIDATION BY COMPARISON WITH FULL SCALE VIBRATORY ROLLER COMPACTION EXPERIMENTS

A qualitative comparison of the vibratory roller drum vertical displacement amplitude is shown in Figure 5. The left figure show measured response in the field [19] and the right figure show simulated response for 3D model as described in section 7, for several load amplitudes constant with frequency. The maximum applied load amplitude is 258 kN shown with light blue line with circle – marked 1 in the legend, the other curves are for lower load amplitudes as indicated by the numbers in the legend. The figure clearly demonstrates that the developed model is able to capture the resonance frequency reduction with increasing load amplitude as it appears due to resonance match with the roller vibration frequency. Some data points are missing in the computation due to lack of convergence in the solver which tends to appear at very large vibration amplitudes. Improved convergence can likely be achieved with a finer mesh.

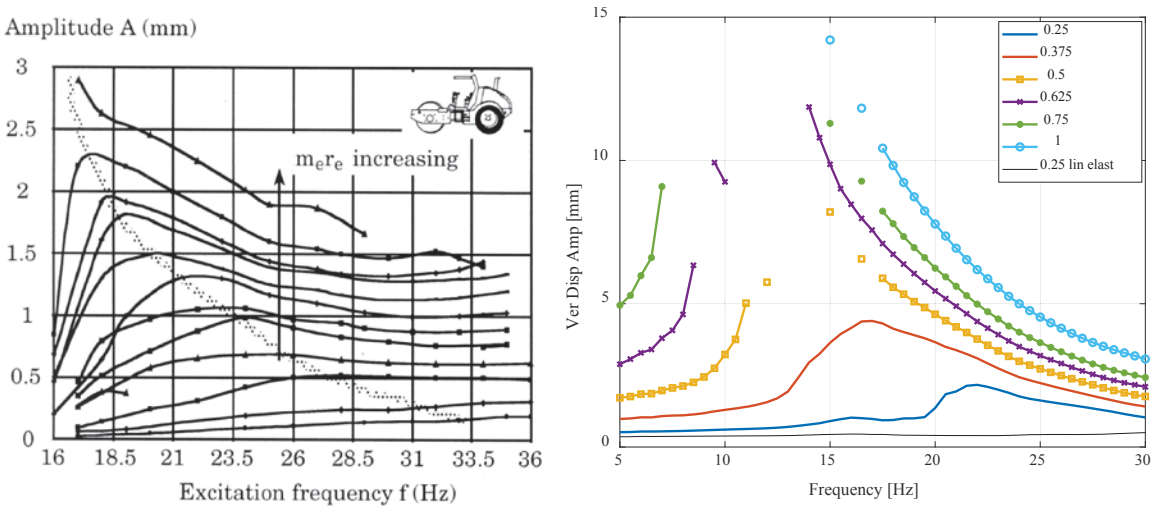

Figure 5 Qualitative comparison vibratory roller drum response to capture the change of resonance frequency due to increasing load amplitude. The left figure is from [19].

To demonstrate quantitatively the equivalent linear method can capture essential features of nonlinear dynamic soil behavior during vibratory compaction, we have compared numerical results with full-scale compaction experiments described in detail in [17] and [18], and in references therein. Several frequency sweep tests were run with the roller passing over an area being compacted. The vertical displacement amplitude of the roller during the sweep tests are shown in Figure 6 a). Within each pass over the compacted area, the frequency is "swept" from 15 to 35 Hz. With increasing number of passes of the vibratory roller, the frequency of the first peak found between 15 and 20 Hz increases due to increasing soil stiffness due to the effect of the compaction. The second peak in each curve at about 30 Hz is due to the drum is bouncing.

An axi-symmetric model was used for quick analysis of the vibro-compaction experiment. The drum, the compacted gravel layer and the underlying rock fill were modelled with 2nd order solid finite elements. Absorbing boundaries was applied on the outer and bottom boundary of the model. A stiff block with a mass of 7600 kg represents the roller drum. The vertical dynamic load on the drum, due to an eccentric moment of 7.3 kgm, is proportional to the square of the rotation frequency giving a load amplitude of 83 kN at 17 Hz increasing to 258 kN at 30 Hz. The depth to bedrock was assumed 5 m in the model.

To account for the densification during compaction, the model was run with different initial shear wave speeds in the gravel fill layer of 160, 180, 200 and 220 m/s. A Poisson's ratio of 0.3 was used in the gravel fill. The rock fill shear wave speed was assumed to vary linearly between from 220 m/s beneath the fill to 270 m/s at 5 m depth. The rock fill density and Poisson's ratio were set to 2000 kg/m^3 and 0.3 respectively.

To model the effect of soil nonlinearity on the response of the drum, the curves for shear modulus reduction and damping versus shear strain shown in Figure 3 were used for the gravel fill. For simplicity, the same curves were used for the rock fill as well.

Varying the initial shear wave speed from 180 m/s to 220 m/s gave a good match with the frequency variation of the first frequency peak observed in the experiment as can be seen in Figure 6 b). The 2nd response peak is due to bouncing of the drum and is not possible to account for in the numerical model due to assumption of full contact between drum and soil.

The experimental response amplitude at the higher frequency of 30 Hz, is not very much higher (~20%) than the response at 15 Hz. Thus the load amplitude experienced by the soil in the experiment when the drum vibrates with 30 Hz and bounces is likely not much larger than the one at 15 Hz.

The analysis show it is necessary to use a nonlinear soil behaviour to obtain a good match with the frequencies observed in the experiments. As shown in Figure 7 the computed shear modulus reduces to less than 10% of its initial value beneath the drum and the material damping factor exceeds 15%. There are many uncertainties in the non-linear modelling in terms of physical input parameters and the numerical model itself. However, the good match with experiments give confidence the method could be used for the analysis of vibro compaction near slopes and other related applications where the nonlinear soil behaviour is important, e.g. foundations subjected to large dynamic loads [5].

7 VIBRATION ANALYSIS OF THE STATLAND LANDSLIDE

7.1 Numerical model

A three-dimensional calculation model was established (shown in Figure 8) based on the 2D geometry used in the investigation of the cause of the slide [1]. The colours indicate the shear wave speed as determined from CPT tests made at the site, with interpretation based on empirical equations from [31]. A road was constructed by compacting a rock fill layer (upper most yellow layer) and replacing older loose fills (in turquoise). Older fill material which was not replaced is shown in light green. The old fill contains various materials such as wood chunks etc. The shear wave speed in the replaced masses and in old fills are based on NGI's experience with similar materials [1]. The bed rock is modelled linear elastic with an assumed shear wave speed of 2000 m/s (shown in blue). Above the bedrock there is loose recently deposited material consisting of sand, silt and quick clay with shear wave speeds decreasing with depth from over

200 m/s between of 2 m to 3 m depth beneath the sea floor to about 100 m/s at 25 m depth. This was modelled with three thicker layers in yellow, orange, and red with constant initial shear wave speeds of 150, 120 and 100 m/s respectively. The Poisson's value in the fill mass is set to 0.4 and in soil below ground water level 0.495. The water above the submerged part of the slope has not been modelled. For an analysed vibrating submerged foundation under similar conditions, the water was shown to increase both radiation damping and added soil mass [32][33], thus it will likely have an effect of the dynamic response of the slope, but it is neglected here.

There was no information available about stress-strain curves for the materials at the time of analysis, therefore for simplicity, in the current model the same relative shear modulus reduction versus strain curve was applied to both fill and natural soil. The natural soil is very loose and as such the modulus-reduction curve may give a too stiff response. However, the objective was to estimate the order of magnitude of the induced strains in the soil.

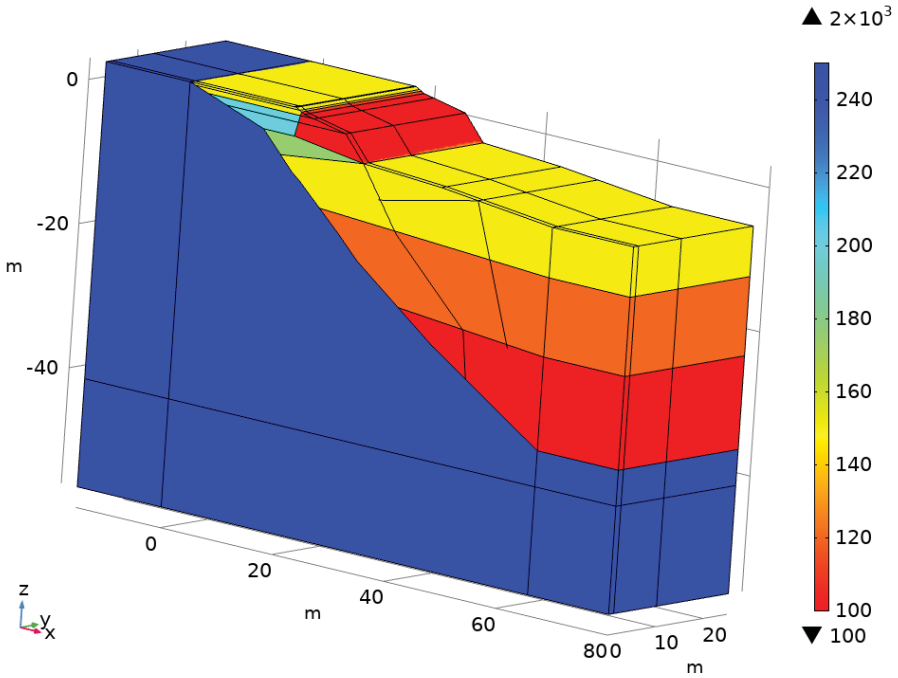

Figure 8 Model used for the vibration analysis of the Statland landslide case. Colours show shear wave speed in the fill and natural soils. The bedrock shear wave speed was set to 2000 m/s (shown in blue).

The vibratory roller used during the compaction work was a Volvo CE SD 115D with a 2.1 m wide and 1.5 m diameter drum. Further technical information about the vibro compactor is available in [34]. The part of the drum in contact with the soil is modelled as a 2.1 m long, 0.3 wide and 5cm thick, rigid plate placed close to the edge of the slope (as shown in Figure 10). The plate mass is equal to the dynamic mass of the whole drum, which was estimated to 3570 kg based on the nominal displacement amplitude of 1.92 mm and load amplitude of 257 kN at a vibration frequency of 30.8 Hz. The Young's modulus of the plate was set to a high value to simulate the drum to be very rigid. The load due to eccentric mass was applied uniformly on the plate and there is no slippage allowed between the plate and the soil. Most vibratory rollers can only operate within a few pre-set frequency values. Here we assumed the load is continuous in the range from 0-30 Hz and proportional to the square of the drum vibration frequency, similar to the load in the full-scale experiments [17].

The static stresses from the weight of the vibratory roller may somewhat increase the stiffness and strength of the soil beneath the drum, but this is not accounted for in analysis. The static load diminishes quickly with depth as opposed to the dynamic loads which penetrate

much deeper. As a verification, the static stresses in the model due to the weight of the plate have been compared with field measurement [35] of a similar vibro compactor. The stresses are of the similar magnitude. Analysis performed in connection with the validation showed the increase in static stress beneath the drum has little effect on the overall vibration response. It was checked by changing low strain shear wave speed with 25% in the layer closest to the drum resulting in 10% change in resonance frequency. This was considered to have little consequence for computing the dynamic effects of vibro compaction on slope stability.

7.2 Effect of soil non-linearity and frequency dependent load

The numerical 3D model is still under development with tuning of mesh size and discretization to handle the large strains in the vicinity of the drum. However, the numerical results are considered to still be informative for engineering purposes and are therefore presented here.

Figure 10 shows the vertical response of the drum with blue curves for a load increasing with the square of the vibration frequency from 10 kN at 5 Hz to 257 kN at 31 Hz. The peak response, taken as average of the two points on the plate, is 3.5 mm at 20 Hz for a load of 109 kN. The drum response increases rapidly when the load frequency approaches 20 Hz due to local resonance between the drum and soil immediately beneath it.

At 4 m below the drum and 10 m further out in the slope (locations indicated with arrows in Figure 10) the vibration amplitude (shown with green and red curve in Figure 9) increases when approaching 15 Hz, which appears to be the natural frequency of the slope. The vibration further away from the drum do not increase above 15 Hz even though the load amplitude and the drum response increases very much at that frequency. This is interpreted due to 1) the soil can only transmit a limited shear stress due to the non-linear soil behavior [31] and 2) the increasing dynamic resistance due inertia of the vibrating plate. This is also indicated by the maximum shear strain plots for 14 Hz and 20 Hz (Figure 10 and Figure 11). For vibration frequencies below 15 Hz there is very low shear strains except in the vicinity of the drum. For vibration frequencies of 20 Hz and above, the shear strain amplitude do not increase very much even though the load amplitude doubles from 20 Hz to 30 Hz. The shear strains reach values for which pore pressure build-up can be expected [9], particularly for a large number of cycles and if the soil cannot dissipate the pore pressure. Such built-up pore pressure may also spread to critical parts of the slope through permeable layers which often exist in quick clay deposits of this kind. ([36]).

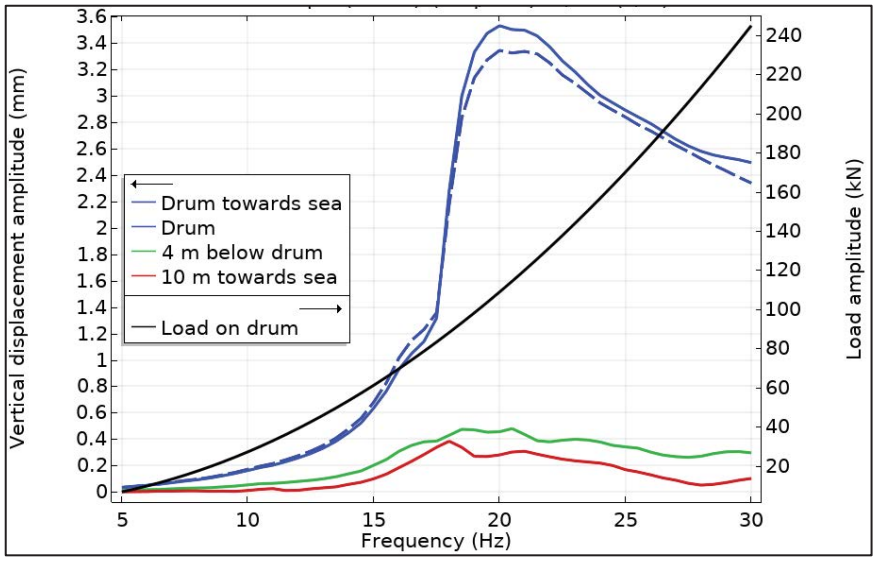

Figure 9 Vertical displacement amplitude (left axis) and load amplitude (right axis) versus loading frequency. Peak drum response at 20 Hz.

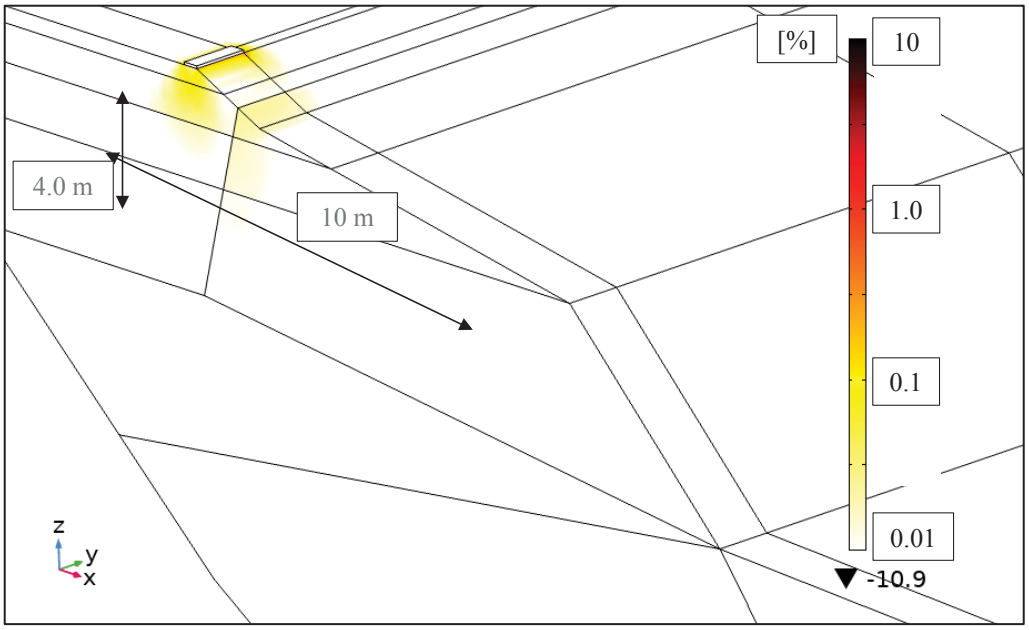

Figure 10 Maximum shear strain at 14 Hz for load amplitude of 53 kN. Colour scale is logarithmic from 0.01 % to 10% shear strain.

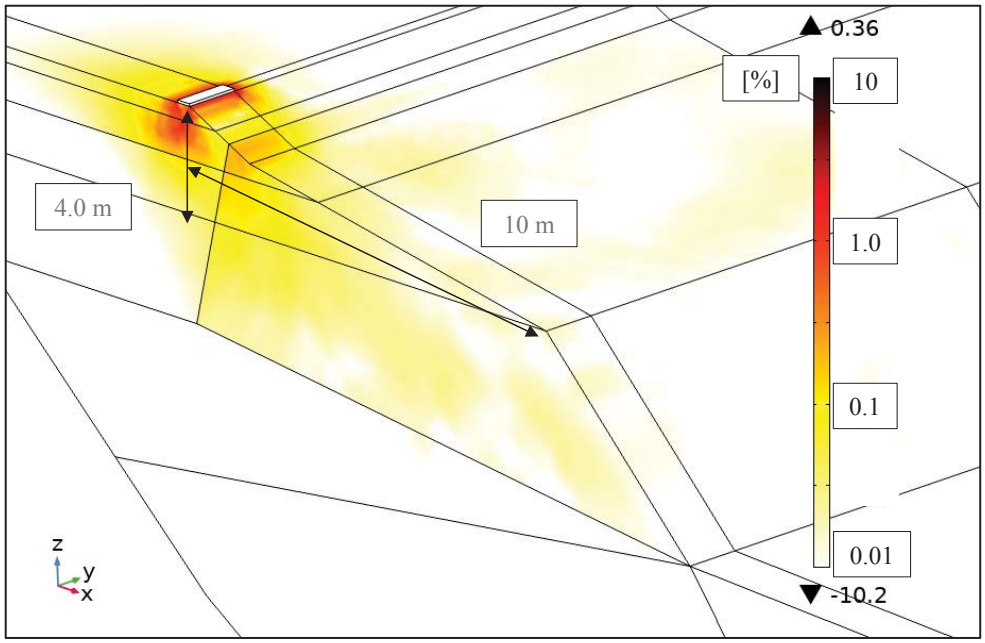

Figure 11 Maximum shear strain at 20 Hz. Colour scale is logarithmic from 0.01 % to 10% shear strain. At 10 m from the drum towards the slope the maximum shear strain reaches 0.025 %.

Using 2nd order elements allows improved capturing of large strain amplitudes around the vibrating plate (drum), and also reduces possible volumetric locking due to high Poisson's values in the submerged part of the slope. Figure 12 shows the response for the same model as in Figure 9, except for the use of 2nd order elements. The peak response of the drum now occurs at 15 Hz compared to 20 Hz for the model with linear element. The vibration amplitude of the drum is approximately the same as for 1st order elements with some increase to the sides of the drum due to local nonlinearity (see solid and dashed blue lines). However, the applied load amplitude on the drum is much lower with 61 kN at 15 Hz, compared to 109 kN at 20 Hz, which indicates the response is to stiff with the 1st order elements.

Using the 2nd order mesh discretization give a softer numerical behavior of the soil, and the frequency at the peak response of the drum-fill now coincides with the slope's natural vibration frequency of about 15 Hz. The vibration amplitude 4 m beneath and 10 m in front of the drum increase rapidly with frequency as shown with green and red curves in Figure 12. 4 m beneath the drum the maximum velocity amplitude is about 35 mm/s and 10 m towards the slope it is 20 mm/s. These velocity amplitudes correspond to shear strains high enough to cause pore pressure build up [9]. The double resonance, i.e. the coincidence of resonance frequency of the drum and compacted fill with the slope's natural vibration frequency likely have contributed to the relatively large shear strains induced.

The difference in response of the slope below and above the resonance frequency is also clearly seen in the plots of shear strains for 13 Hz and 16 Hz as shown in Figure 13 and Figure 14. Figure 14 shows a node-antinode wave pattern with regions of high shear strains surrounding areas with low shear strains.

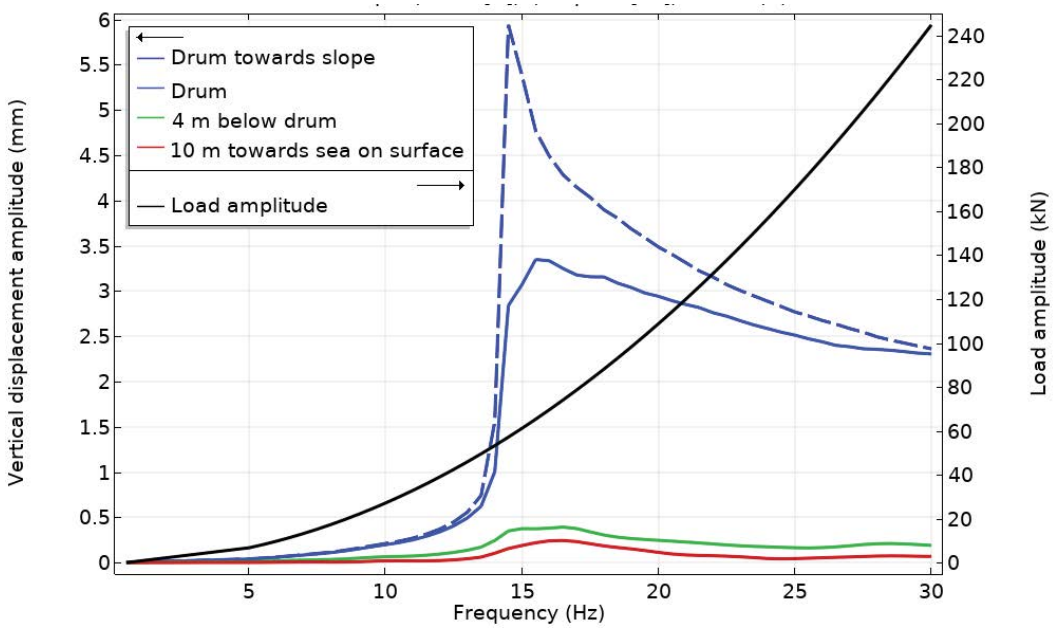

Figure 12 Vertical displacement amplitude (left axis) and load amplitude (right axis) versus loading frequency. Peak drum response at about 15 Hz.

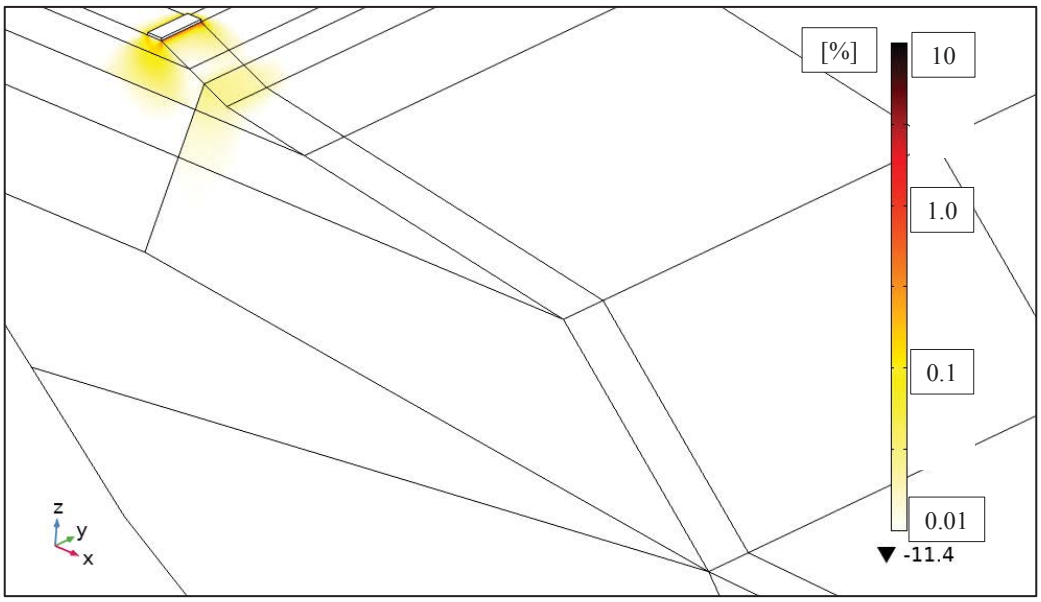

Figure 13 Maximum shear strain at 13 Hz for load amplitude of 46 kN. Colour scale is logarithmic from 0.01 % to 10% shear strain.

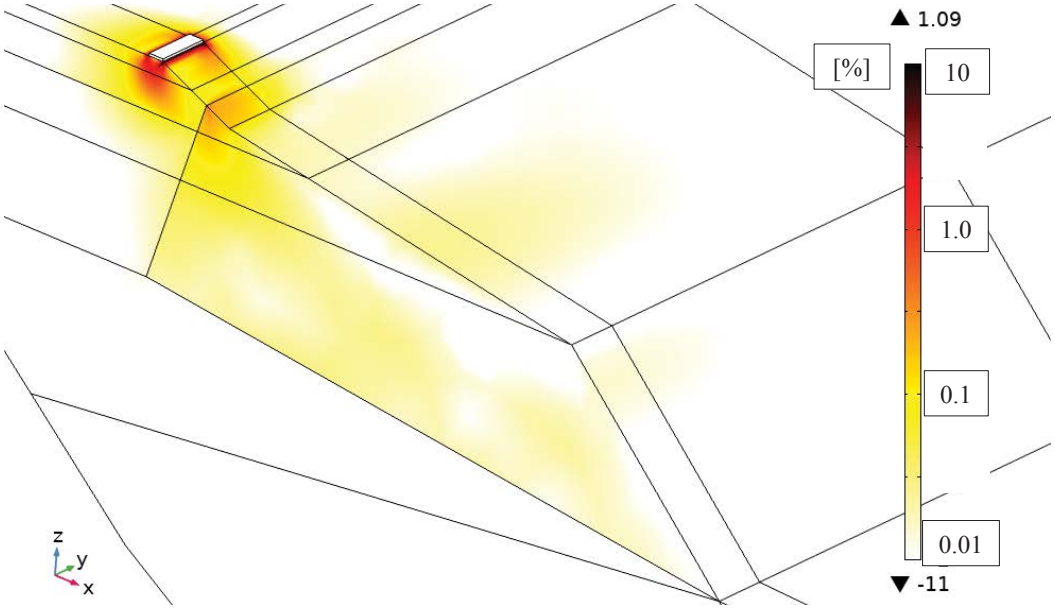

Figure 14 Maximum shear strain at 16 Hz. Colour scale is logarithmic from 0.01 % to 10% shear strain. At 10 m from the drum towards the slope the maximum shear strain reaches 0.025 %.

7.3 Effect of bouncing drum

To understand better the effect of a jumping drum on the slope stability and soil-nonlinearity we have compared the response for four different load amplitudes all at 15 Hz close to the natural frequency of the slope, at which vibrations can propagate out towards the slope surface. This comparison have so far only been done for 1st order elements, but give a qualitative indication.

Comparing static stress due to weight on the drum with dynamic stresses beneath it, indicates the drum may not be in contact with the soil in parts of the vibration cycle (i.e. it is bouncing). The non-contact situation starts at frequencies in the range 12-15 Hz in this analysis. The frequency range will vary with drum mass, load amplitude and the non-linear soil stiffness.

It is not fully correct to apply the equivalent linear method to the problem of a bouncing drum. However, the estimated vibration amplitudes are likely on the high side and thus it would be conservative to use the approach to estimate the effect of compaction on slope stability. As mentioned, the load acting on the drum is proportional to the square of the drum vibration frequency. Thus when the drum is bouncing, the load amplitude applied to the drum is controlled by the drum vibration frequency, even though the soil vibrates with a lower frequency.

The following analysis tries to capture the underlying mechanism causing the second vibration peak around 30 Hz as shown in Figure 6 a). A comparison of stiffness degradation at a vibration frequency of 15 Hz is given in Figure 15 a) - d) for load amplitudes of 67 kN (not bouncing), 101 kN (partial loss of contact), 134 kN (partial loss of contact) and 269 kN (double frequency bouncing at 30 Hz as shown in Figure 2 c) and in the experiment result Figure 6a). 269 kN is the load for a roller vibration frequency of 30 Hz.

For the lower load amplitude (67 kN) there is only stiffness degradation locally beneath the roller and some 30-40% reduction in the upper part of the old fill towards the sea. With increasing load amplitude, the stiffness reduction reaches deeper down, at 100 kN load the reduction is about 60% at a depth of 1.5 m. For a load of 134 kN the stiffness reduction is more than 60% down to 2-meter depth. For the large load amplitude of 269 kN the stiffness degradation is occurring in a larger soil volume down to some 4 meter depth and the old fill sustains larger stiffness degradation down to 2 meter depth.

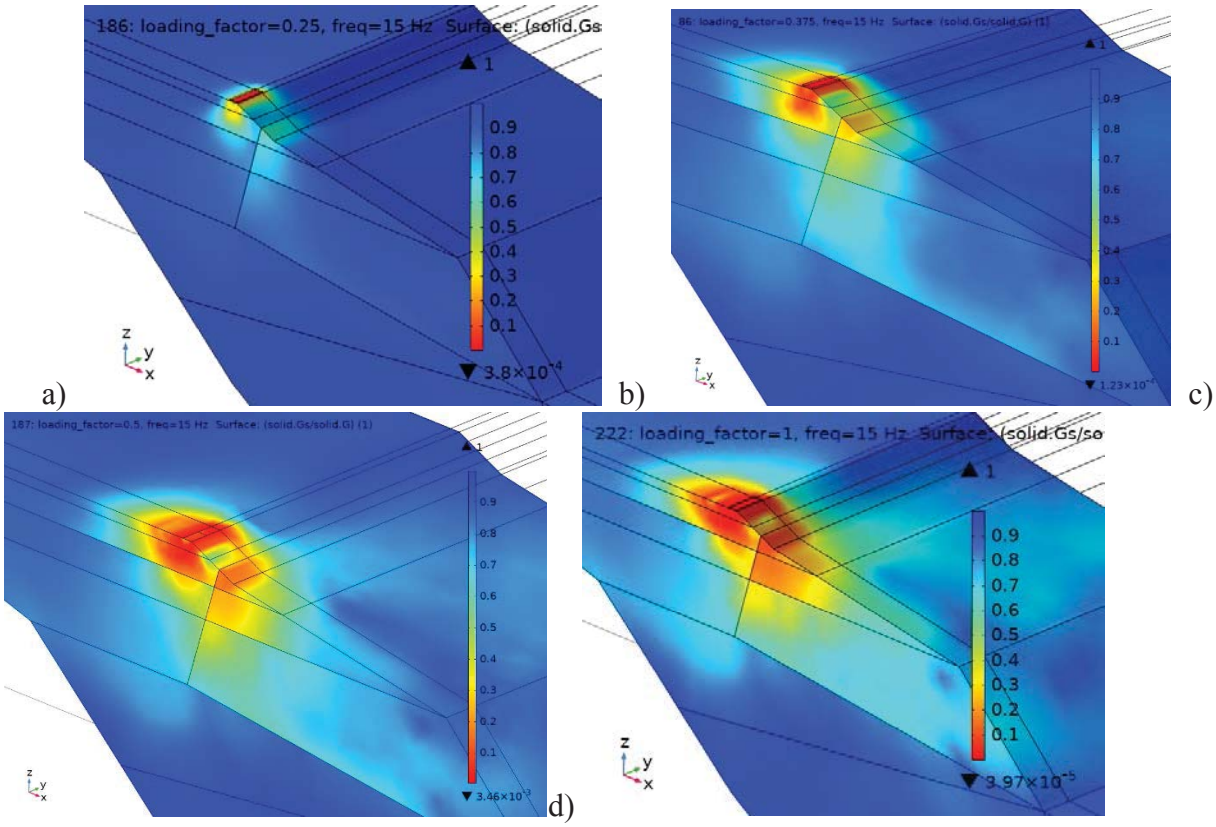

Figure 15 Reduction of shear modulus for a vibration frequency of 15 Hz for a load amplitude of 67 kN in a), corresponding to 25% of maximum load amplitude. In b) the load is 101 kN, in c) 134 kN and in d) the maximum load amplitude of 269 kN is applied.

8 DISCUSSION

There are usually many contributing factors when construction activities cause landslides. These could e.g. be unknown soil conditions, such as the presence of weak soil layers and artesian water pressures resulting in lower actual factors of safety than anticipated by the geotechnical engineer's stability analysis. In the case of vibratory compaction, one should consider the effect of increased weight from the fill, compaction induced increase in lateral pressures, and use of less heavy equipment [37]-[40].

Here we have to tried to understand how vibrations induced by compaction may affect the slope stability. The computed shear strains due to vibrations from compaction for the Statland case are large enough to cause pore pressure build up in the soft soil sediments [9]. Considering the very loose soil conditions as indicated by the post-slide investigation [1] it seems very likely the construction work caused the landslide and probably the vibratory compaction have contributed to the triggering. This confirms the conclusions in [1].

Vibrations were not measured for Statland case. Therefore it is not known how large the vibration amplitude was or how large the dynamic impact on the slope was. The analysis presented in this paper have tried to capture a range of possible load amplitudes and frequencies, to understand the effect of compaction on slope stability and if it is possible to establish a vibration limit to avoid slope failure. For practical reasons such limit values should be related to vibration measured on the ground surface. The vibration amplitude on the ground surface is very high near the vibratory roller, but attenuates quickly with distance. Since the roller is moving around when it operates it may be difficult to establish a vibration limit since the distance

to the roller is not known / varying all the time. Thus, the vibrations could be larger than measured by the vibration sensor. However, if one can measure vibrations on the ground surface at critical locations, e.g. on based slope stability analysis and tentatively keeping them lower than 20 mm/s it seems unlikely the vibrations could have negative effect on slope stability. In general, depending on the ground conditions and computed factor of safety for the slope stability, a slope can tolerate much larger vibration amplitudes than 20 mm/s.

The numerical analysis further indicate for a bouncing roller, i.e. the roller drum is fully in the air during every other soil vibration cycle, the effect on stiffness and strength degradation in the ground can be even larger. Thus avoiding bouncing of the drum is imperative when compacting in the vicinity of vibration sensitive soils. Many modern vibratory compaction rollers can sense and automatically reduce the jumping [15], [19].

The vibration frequency range of many vibratory rollers lies within a range such that when it bounces the frequency of impact on the ground may coincide with global natural vibration frequency of slopes. The performed numerical analysis indicates the global natural frequency of the slope is mainly controlled by the elastic shear wave speeds and geometry. The local soil-nonlinearity around the drum do not affect the global natural frequency. Further analysis is needed to understand the interplay ("double resonance") between the global natural frequency, the local natural frequency of the drum-soil, and how they are affected by soil nonlinear stiffness and slope geometry.

For load amplitudes large enough to cause jumping of the drum, the performed frequency domain analysis does not capture the partial or no-contact between the drum and the soil. Therefore the computed vibration amplitudes are likely on the high side. Further comparison with field measurements and non-linear time domain analysis are needed.

9 CONCLUSIONS AND RECOMMENDATIONS

The numerical analysis indicate vibratory compaction have possibly contributed to triggering the slide at Statland. The nonlinear analysis is believed to have captured the essential behaviour of the vibratory compaction and the response of the slope. The peak response at the frequency is close to the one stated by the operator of the vibratory roller and the manufacturer's data sheet.

To reduce the landslide risk during compaction work in the vicinity of slopes with vibration susceptible soils and low static stability near the shoreline the following is suggested

- Use less heavy equipment and/or higher loading frequencies or perform compaction without vibration. Avoiding excessive bouncing of the vibratory roller drum is imperative.
- Applying thinner layers and more time between compaction passes. Allowing for more time between placing of layers reduces the number of load cycles applied by the soil and allows for drainage of potential built up pore pressures both due to cyclic loading and due to static loading from weight of the fill.
- Monitor slope horizontal and vertical displacements at some critical points.
- Monitor pore pressures at critical points. Locations with artesian pressure have lower stability, any extra pore pressure from the compaction will reduce the stability of the slope.

10 ACKNOWLEDGEMENT

The financial support by the governmental research program "Natural Hazards: Infrastructure for floods and slides (NIFS)" and by the Norwegian Research Council through Remedy

project BegrensSkade II – Risk Reduction of Groundwork Damage Grant No. 267674, is gratefully acknowledged. The equivalent linear dynamic 3D tool sprung out of the collaboration with Prof. Staffan Hintze (NCC), Kenneth Viking (Swedish Transport Administration), and Fanny Deckner (GeoMind) financially supported by NCC and by the Development Fund of the Swedish Construction Industry, which is also highly appreciated.
