PREFACE

This volume contains the full-length papers accepted for presentation at the XI International Conference on Structural Dynamics EURODYN 2020, streamed online from Athens, Greece on November 23-26, 2020.

EURODYN Conference Series is organized under the auspices of the European Association of Structural Dynamics (EASD). EASD was founded in 1990 as a joint European initiative of experts in Structural Dynamics, with the purpose of sponsoring and overseeing the organization of the EURODYN conferences, scheduled to take place with a three-year interval. The first EURODYN Conference was held in Bochum in 1990, organized by the founding president of EASD Prof. Wilfried Krätzig. Following Bochum, the conferences were held in Trondheim (1993), Florence (1996), Prague (1999), Munich (2002), Paris, (2005), Southampton (2008), Leuven (2011), Porto (2014), Rome in 2017 and this year in Athens, the city where the EURODYN 2020 conference would have taken place in June 2020.

In view of the first signs of the COVID-19 pandemic at the beginning of this year, we were forced to postpone the conference dates at the end of November 2020. This was expected to give the opportunity to the participants to attend the conference either physically or remotely. Unfortunately, and contrary to what we had all anticipated, the COVID-19 was still around at the end of June 2020, and hence we were left with no other choice but to abandon the idea of a physical conference and organize a fully online event. This transition was very painful and created many administration complications. Nevertheless, EASD and the organizing committee have seen this sanitary crisis as an opportunity to organize a different type of event and to propose a new approach for scientific collaboration and communication that respects both the legacy of the conference series and the health of the members of the European Community of Structural Dynamics.

EURODYN conferences have been established as the top scientific events in the area of theoretical, numerical and experimental Structural Dynamics worldwide and are highly-anticipated every three years by the international community of Structural Dynamics. For the 2020 edition of EURODYN series, more than 1000 abstracts were submitted, of which 830 were selected for presentation and among them 400 full-length papers were accepted for publication in the EASD Open Access Procedia, indexed by Scopus Database.

The editors of this volume would like to thank all authors for their contributions. Special thanks go to the 88 colleagues who were involved in the organization of 38 Minisymposia and to the reviewers who contributed to the scientific quality of this e-book with their work.

We would particularly like to thank the Members of the EASD Executive Board, and especially Álvaro Cunha, the President of EASD, Guido De Roeck, the Honorary Chairman of EURODYN 2020 and Fabrizio Vestroni the Chair of the EURODYN 2017, for their valuable advice, suggestions and interest, during the three-year preparation period of EURODYN 2020. Their contributions were significant to the successful outcome of this undertaking.

Manolis Papadrakakis

Michalis Fragiadakis
National Technical University of Athens, Greece

Costas Papadimitriou
University of Thessaly, Greece

ACKNOWLEDGEMENTS

The conference organizers acknowledge the support towards the organization of the "XI International Conference on Structural Dynamics", to the following organizations: European Association for Structural Dynamics (EASD), Greek Association for Computational Mechanics (GRACM), Hellenic Society for Earthquake Engineering (HSEE), School of Civil Engineering, National University of Athens (NTUA).

Plenary, Semi-Plenary Speakers and Minisymposia Organizers

We would also like to thank the Plenary and Semi-Plenary Speakers and the Minisymposia Organizers for their help in the setting up of a high standard Scientific Programme.

Plenary Speakers: Geert Degrande, Tracy Kijewski-Correa, Yi Qing Ni

Semi-Plenary Speakers: Eleni Chatzi, Joel P. Conte, Geert Lombaert, Andrei Metrikine, Sotirios Natsiavas, Filippo Ubertini

MS Organizers: I. Antoniadis, M. Arnst, K. Bakalis, B. Balachandran, C.C. Baniotopoulos, M. Barbato, J. Beck, M. Beer, G. Bonnet, C. Borri, C. Boutin, L. Bruno, E. Caetano, F. Casciati, C.A. Castiglioni, E. Chatzi, A. Cicirello, F. Clementi, D. Clouteau, J. Conte, M. Corradi, A. Cunha, G. De Roeck, G. Degrande, V. Denoël, D. Duhamel, J. Edelmann, D. Forcellini, A. Formisano, F. Foti, M. Fragiadakis, V. C. Fragkoulis, V. Fragkoulis, C. Gentile, R. Ghanem, D. Giagopoulos, A. Giaralis, P.B. Gonçalves, R. Höffer, A. Kanyilmaz, I. A. Kougioumtzoglou, S. Lenci, G. Lombaert, F. Magalhães, C. Maniatakis, E. Marino, T. Mazilu, C. E. N. Mazzilli, V. Melissianos, A. Metrikine, A.V. Metrikine, G. Milani, I.P. Mitseas, B. Moaveni, C. Moutinho, H. Mouzakis, H. P. Mouzakis, G. Müller, J. Naprstek, S. Natsiavas, P. Omenzetter, C. Papadimitriou, M. Papadrakakis, I. Papaioannou, A. Pavic, F. Pellicano, F. Perotti, M. Ploechl, I. Psycharis, G. Rega, J. Rodellar, E. Sapountzakis, J-F. Semblat, V. Sepe, C. Soize, S. Sorokin, C. Spyrakos, A. Taflanidis, F. Tubino, D. Vamvatsikos, K.N. van Dalen, P. Van den Broeck, K. Van Nimmen, M. Vasta, P-M. Vasta, I. Vayas, D. Wagg, K. Worden, W.M. Zhai

Acknowledgements..... iv

Contents..... viii

VOLUME I

Minisymposia

MS 1: ADVANCES IN COMPUTATIONAL STRUCTURAL DYNAMICS 1
Organized by B. Balachandran, D. Duhamel, D. Giagopoulos, S. Natsiavas

MS 2: NON-LINEAR DYNAMICS 180
Organized by J. Naprstek, G. Rega

MS 3: DYNAMIC BUCKLING 468
Organized by P.B. Gonçalves, F. Pellicano, C. E. N. Mazzilli

MS 4: DYNAMICS OF COMPOSITE MATERIALS 482
Organized by G. Bonnet, C. Boutin, S. Lenci

MS 5: DYNAMIC FLUID-STRUCTURE INTERACTION 621

MS 6: VEHICLE DYNAMICS 669
Organized by M. Ploechl, J. Edelmann

MS 7: SYSTEM IDENTIFICATION AND DAMAGE DETECTION 785
Organized by E. Chatzi, G. De Roeck

MS 8: STRUCTURAL HEALTH MONITORING 1053
Organized by J. Conte, A. Cunha, G. Lombaert, B. Moaveni, P. Omenzetter, C. Papadimitriou

MS 9: STRUCTURAL CONTROL 1408
Organized by F. Casciati, J. Rodellar

MS 10: ADVANCES ON INERTER-BASED STRUCTURAL VIBRATION CONTROL 1501
Organized by A. Giaralis, A. Taflanidis

MS 11: BRIDGE DYNAMICS 1586

MS 12: FOOTBRIDGE VIBRATIONS 1731
Organized by E. Caetano, F. Tubino, P. Van den Broeck, K. Van Nimmen

MS 13: HUMAN INDUCED VIBRATIONS IN FLOORS, STAIRCASES AND STADIA 1896
Organized by L. Bruno, A. Pavic

MS 14: WIND INDUCED VIBRATIONS OF SLENDER STRUCTURES AND FATIGUE 1944
Organized by V. Denoël, F. Foti, F. Perotti

MS 15: DYNAMICS OF ON- AND OFF-SHORE WIND ENERGY STRUCTURES (WES) 2113
Organized by C. Borri, E. Marino, C.C. Baniotopoulos, R. Höffer, F. Magalhães

MS 16: VIBRATION-BASED ASSESSMENT AND SHM OF CULTURAL HERITAGE STRUCTURES 2244
Organized by C. Gentile

MS 17: VIBRATIONS DUE TO CONSTRUCTION AND INDUSTRIAL ACTIVITIES 2407
Organized by C. Moutinho

VOLUME II

Minisymposia

MS 18: VIBRO-ACOUSTICS 2427
Organized by S. Sorokin

MS 19: BLAST AND IMPACT LOADS 2521

MS 20: MOVING LOADS 2585
Organized by T. Mazilu, A.V. Metrikine, K.N. van Dalen, W.M. Zhai

MS 21: TRAFFIC INDUCED VIBRATIONS 2680
Organized by G. Degrande, G. Lombaert, G. Müller

MS 22: DYNAMIC SOIL-STRUCTURE INTERACTION AND WAVE PROPAGATION 2782
Organized by D. Clouteau, A. Metrikine, G. Müller, J-F. Semblat

MS 23: ASSESSMENT OF INDUSTRIAL STRUCTURES AND INFRASTRUCTURE UNDER NATURAL HAZARDS 3043
Organized by K. Bakalis, V. Melissianos, D. Vamvatsikos

MS 24: SEISMIC PROTECTION OF STEEL STRUCTURES BY MEANS OF DISSIPATIVE SYSTEMS AND COMPONENTS 3079
Organized by C.A. Castiglioni, A. Kanyilmaz, I. Psycharis, H. P. Mouzakis, I. Vayas

MS 25: EXPERIMENTAL EARTHQUAKE ENGINEERING 3174
Organized by M. Fragiadakis, H. Mouzakis

MS 26: UQ AND PROBABILISTIC LEARNING IN COMPUTATIONAL DYNAMICS 3403
Organized by M. Arnst, R. Ghanem, C. Soize

MS 27: STOCHASTIC DYNAMICS AND RELIABILITY ANALYSIS OF STRUCTURAL AND MECHANICAL SYSTEMS UNDER ENVIRONMENTAL EXCITATION 3438
Organized by M. Barbato, M. Vasta

MS 28: UNCERTAINTIES ON MATERIALS AND ENVIRONMENTAL LOADS 3519
Organized by M. Barbato, V. Sepe, P-M. Vasta

MS 29: BAYESIAN UPDATING, FILTERING AND INVERSION FOR DYNAMIC SYSTEMS 3558
Organized by J. Beck, A. Taflanidis, I. Papaioannou

MS 30: RECENT ADVANCES IN PERFORMANCE-BASED ENGINEERING AND DESIGN OF STRUCTURES AND CIVIL INFRASTRUCTURE SYSTEMS SUBJECTED TO SINGLE OR MULTIPLE HAZARDS 3607
Organized by M. Barbato, J. Conte

MS 31: EUROPEAN ETN "DYNAMIC VIRTUALISATION: MODELLING PERFORMANCE OF ENGINEERING STRUCTURES" (DYVIRT) 3803
Organized by M. Beer, V. Fragkoulis, D. Wagg, K. Worden

MS 32: COMPUTATIONAL METHODS FOR STOCHASTIC DYNAMICS 3921
Organized by M. Beer, V. C. Fragkoulis, I. A. Kougioumtzoglou, I.P. Mitseas

MS 33: NUMERICAL SIMULATIONS FOR EARTHQUAKE-RESILIENT SYSTEMS 3939
Organized by D. Forcellini

MS 34: VIBRATION ABSORPTION 4069
Organized by I. Antoniadis, E. Sapountzakis

MS 35: NEW TRENDS IN THE COMPUTATIONAL AND EXPERIMENTAL STRUCTURAL DYNAMICS FOR THE PRESERVATION OF HISTORICAL MASONRY STRUCTURES IN SEISMIC AREAS 4200
Organized by F. Clementi, A. Formisano, G. Milani

MS 36: DAMPING MODELLING AND EXPERIMENTS 4349
Organized by A. Cicirello

MS 37: CONSERVATION, RETROFIT AND STRENGTHENING OF EXISTING STRUCTURES: INNOVATIONS IN APPLIED METHODS AND MATERIALS 4358
Organized by M. Corradi, C. Maniatakis, C. Spyrakos

MS 38: GENERAL SESSION ON STRUCTURAL DYNAMICS, STABILITY AND VIBRATIONS 4418
Organized by G. De Roeck, M. Fragiadakis, C. Papadimitriou, M. Papadrakakis

CONTENTS

VOLUME I

Minisymposia

MS 1: ADVANCES IN COMPUTATIONAL STRUCTURAL DYNAMICS

A MODE MATCHING TECHNIQUE FOR THE SEISMIC RESPONSE OF LIQUID STORAGE TANKS INCLUDING SOIL-STRUCTURE INTERACTION 1
Apostolos Tsouvalas, Timo Molenkamp, Khairina Canny, David Kroon, Marco Versluis, Yaxi Peng, Andrei Metrikine

APPLICATION OF THE WAVE FINITE ELEMENT METHOD TO MULTI-SPAN BRIDGES 15
Gabriele Paratore, Tien Hoang, Gilles Foret, Maria Pina Limongelli, Denis Duhame

A VARIATIONAL APPROACH TO ASYNCHRONOUS TIME-INTEGRATION OF STRUCTURAL DYNAMICS PROBLEMS IN THE CONTEXT OF FETI AND SPURIOUS OSCILLATIONS ON THE INTERFACES 26
Andreas Seibold, Daniel Rixen

DEVELOPMENT AND VALIDATION OF A MULTIBODY DYNAMICS MODEL FOR THE ASSESSMENT OF THE SEISMIC RETROFIT POTENTIAL OF BRIDGE EXPANSION JOINTS 44
Michael Tahedl, Andreas Taras, Fredrik Borchsenius, Daniel Rill

AN DELAYED FREQUENCY PRECONDITIONER APPROACH FOR SPEEDING-UP FREQUENCY RESPONSE COMPUTATION OF STRUCTURAL COMPONENTS 56
Guilherme Jenovencio, Arul Sivasankar, Zeeshan Saeed, Daniel Rixen

NONLINEAR FORCE LAW SELECTION AND PARAMETER UPDATE FOR A CANTILEVER BEAM WITH PERIODICALLY REPEATED IMPACTS 68
Alexandros Arailopoulos, Dimitrios Giagopoulos

SIMULATION-LEAN TRAINING-SETS FOR HYPER-REDUCTION OF PARAMETRIC GEOMETRIC NON-LINEAR STRUCTURES 80
Christian H. Meyer, Daniel J. Rixen

REGULARIZATION METHOD TO INCLUDE MATERIAL SOFTENING IN FIBER BEAM-COLUMN ELEMENTS FOR SEISMIC PERFORMANCE ASSESSMENT OF STEEL FRAMES 93
Sebastián Pozo, Bryam Astudillo, Esteban Samaniego, Francisco Flores

EFFICIENCY OF 1D CNNS IN FINITE ELEMENT MODEL PARAMETER ESTIMATION USING SYNTHETIC DYNAMIC RESPONSES 108
Mohammad Almutairi, Onur Avci, Nikolaos Nikitas

INFLUENCE OF SLENDERNESS RATIO IN THE MODAL ANALYSIS BY ANALYTICAL FORMULATION 121
Jonas Falcão, Rodolfo Carvalho, Renan Ribeiro, Ledymar Moreno, José De Brito

ON SPACE-TIME FORMULATIONS IN STRUCTURAL MECHANICS USING THE PROPER GENERALIZED DECOMPOSITION 136
Franz Bamer, Nima Shirafkan, Abdelbacet Oueslati, Marcus Stoffel, Géry De Saxcé, Bernd Markert

ISOGEOMETRIC COLLOCATION METHODS FOR THE DYNAMICS OF THREE-DIMENSIONAL GEOMETRICALLY EXACT BEAMS 154
Enzo Marino, Josef Kiendl, Laura De Lorenzis

ANALYTICAL-NUMERICAL MODELING OF FLEXIBLE PYLONS FOR STRUCTURAL HEALTH MONITORING 168
George D. Manolis, Georgios Dadoulis, Stylianos Pardalopoulos, Kosmas Dragos

MS 2: NON-LINEAR DYNAMICS

NONLINEAR DYNAMICS OF A NEGATIVE STIFFNESS OSCILLATOR: EXPERIMENTAL IDENTIFICATION AND MODEL UPDATING 180
Dario Anastasio, Alessandro Fasana, Luigi Garibaldi, Stefano Marchesiello

GEOMETRICALLY NONLINEAR FORCED VIBRATIONS OF MULTIPLE-STEPPED EULER-BERNOULLI BEAMS 193
Issam El Hantati, Ahmed Adri, Hatim Fakhreddine, Said Rifai, Rhali Benamar

NONSMOOTH MODAL ANALYSIS WITH BOUNDARY ELEMENT METHOD 205
Tianzheng Lu, Mathias Legrand

SUBSONIC STALL FLUTTER ANALYSIS IN 2D BLADE CASCADE USING HYBRID BOUNDARY ELEMENT METHOD 213
Chandra Shekhar Prasad, Ludek Pesek

GEOMETRICALLY NON-LINEAR FREE AND FORCED VIBRATION OF C-F-C-F RECTANGULAR PLATE AT LARGE TRANSVERSE AMPLITUDES 225
Abdelfattah Majid, El Mehdi Abdeddine, Khalid Zarbane, Zitouni Beidouri

NONLINEAR LONGITUDINAL FREE VIBRATION OF UNIFORM RODS AND RODS WITH SECTIONS VARYING EXPONENTIALLY 239
EL Mehdi Abdeddine, Abdelfattah Majid, Zitouni Beidouri, Khalid Zarbane

DYNAMIC RESPONSE OF TWO INTERACTING EXTENSIBLE BARS IN FRICTIONAL CONTACT 252
Timo Molenkamp, Athanasios Tsetas, Apostolos Tsouvalas, Andrei Metrikine

NUMERICAL STUDY OF DYNAMIC PROPERTIES OF A SELECTED MATERIAL LAYER OF BULLETPROOF SHIELDS 265
Miroslaw Bocian, Krzysztof Jamroziak, Maciej Kulisiewicz, Joanna Pach, Dariusz Pyka

MEASUREMENTS OF NONLINEAR VIBRATIONS OF A BEAM SUBJECTED TO TWO BROADBAND CORRELATED RANDOM EXCITATIONS 273
Sébastien Talik, Maxence Claeys, Jean-Pierre Lambelin, Jean-Jacques Sinou

VIBRATION POWER FLOW TRANSMISSION BETWEEN NONLINEARLY COUPLED OSCILLATORS WITH DUAL FORCE EXCITATIONS 283
Baiyang Shi, Chendi Zhu, Jian Yang

STOCHASTIC DYNAMICAL RESPONSE OF A NON-SMOOTH DYNAMICAL SYSTEM UNDER FILTERED WHITE NOISE 290
Saeed Gheisari Hasnijeh, Arvid Naess

A NEW TIME INTEGRATION SCHEME IN MULTIBODY DYNAMICS INVOLVING FRICTIONAL IMPACT BASED ON A RETURN MAP TO NON-FLAT CONFIGURATION MANIFOLDS 303
Elias Paraskevopoulos, Panagiotis Passas, Sotirios Natsiavas

COMPUTING BACKBONE CURVES FOR NONLINEAR OSCILLATORS WITH HIGHER ORDER POLYNOMIAL STIFFNESS TERMS 318
Ayman Nasir, Neil Sims, David Wagg

TOWARD A SYSTEMATIC CONSTRUCTION OF THE BASIS FOR NONLINEAR GEOMETRIC REDUCED ORDER MODELS 335
X.Q. Wang, Marc Mignolet

NONLINEAR VIBRATIONS OF AN ELASTIC PLATE ON A VISCOELASTIC FOUNDATION MODELLED BY THE FRACTIONAL DERIVATIVE STANDARD LINEAR SOLID MODEL 355
Marina V. Shitikova, Anastasiya I. Krusser

NONLINEAR HARDENING BEHAVIOR OF A HELMHOLTZ RESONATOR 369
Emmanuel Gourdon, Alireza Ture Savadkoohi, Claude-Henri Lamarque

EMPIRICAL EXPRESSION PREDICTING SEISMIC DISPLACEMENT OF SANDY SLOPES IN GREECE IN TERMS OF SOIL PROFILE TYPE USING NON-LINEAR DYNAMIC STICK-SLIP ANALYSIS 382
Loukas C. Katsenis, Constantine A. Stamatopoulos, Vassilis P. Panoskaltsis

SUPPRESSION OF CLASSICAL FLUTTER OSCILLATIONS IN BLADED WHEEL USING INNER DAMPING EFFECT 401
Ludek Pesek, Pavel Snabl, Ch. S. Prasad

THE THEORY OF BODY COLLISIONS IN ROLLING THROUGH GEOMETRY, KINEMATICS AND DYNAMICS OF BILLIARDS 412
Katica Hedrih

THE EFFECT OF BUILDING'S RESPONSE ON THE FRAGILITY OF FREESTANDING SYMMETRIC OR ASYMMETRIC CONTENTS 451
Spyridon Diamantopoulos, Michalis Fragiadakis

MS 3: DYNAMIC BUCKLING

PARAMETRIC INSTABILITY OF PULTRUDED FIBER-REINFORCED POLYMER COLUMNS UNDER AXIAL HARMONIC FORCING 468
Julio C. Coaquira, Daniel C.T. Cardoso, Paulo B. Gonçalves, Diego Orlando

EFFECTS OF INITIAL GEOMETRICAL IMPERFECTIONS ON DYNAMIC STABILITY OF CIRCULAR CYLINDRICAL PANELS 476
Frederico Silva, Wanclaine Vaz, Paulo Gonçalves

MS 4: DYNAMICS OF COMPOSITE MATERIALS

ON THE WAVE DYNAMICS OF MICROSCALE BISTABLE TENSEGRITY STRUCTURES 482
Andrea Micheletti, Zacharias Vangelatos, Narinder Singh, Costas P Grigoropoulos, Fernando Fraternali

PIECEWISE CONSTRUCTION OF WAVE DISPERSION CURVES IN ELASTIC PERIODIC NETWORKS BY ASYMPTOTIC MULTI-SCALE APPROACH 489
Antoine Rallu, Claude Boutin, Stéphane Hans

DEVELOPMENT OF FREQUENCY CURVES FOR CROSS-LAMINATED TIMBER (CLT) FLOORS USING DYNAMIC STIFFNESS METHOD 502
Miroslav Marjanović, Verica Jugović, Marija Nefovska-Danilović

ANALYTICAL SOLUTIONS FOR THE FLEXURAL NATURAL VIBRATION OF THE COMPOSITE GIRDERS WITH CORRUGATED STEEL WEBS 510
Yunsheng Li, Chaoxing Liu, Qingnian Dai, Yanling Zhang

METAMATERIALS WITH FIBERS OF ELLIPTIC CROSS-SECTION 520
Guy Bonnet, Vincent Monchiet

A TWO MODE NON-UNIFORM APPROXIMATION FOR AN ELASTIC ASYMMETRIC SANDWICH 528
Mohammed Alkinidri, Julius Kaplunov, Ludmila Prikazchikova

MODELING OF CFRP STRUCTURES USING MODEL UPDATING TECHNIQUES AND EXPERIMENTAL MEASUREMENTS 536
Ilias Zacharakis, Dimitrios Giagopoulos, Ioannis Zyganitidis, Alexandros Arailopoulos, Olga Markogiannaki

VIBRATION ANALYSIS OF LAMINATED COMPOSITE CYLINDRICAL SHELLS WITH VARIOUS FIBRE ORIENTATIONS ... 551
Chendi Zhu, Baiyang Shi, Chen Zhou, Jian Yang

ACOUSTIC WAVES IN HOMOGENIZED FLUID-SATURATED DEFORMING PERIODIC SCAFFOLDS UNDER PERMANENT FLOW 562
Eduard Rohan, Robert Cimrman, Salah Naili

A NEW ANALYTICAL METHOD FOR FREE VIBRATION ANALYSIS OF SANDWICH BEAMS 578
Lhoucine Boutahar, Zakaria Ibnorachid, Khalid El Bikri

HOMOGENIZED MODEL OF UNCONVENTIONAL DYNAMIC BEHAVIOUR OF PERIODIC PLATES AND EXPERIMENTAL COMPARISONS 589
Pascal Fossat, Claude Boutin, Mohamed Ichchou

A DISCRETE-TO-CONTINUUM APPROACH TO FREQUENCY BANGAPS IN 1D BIATOMIC METAMATERIALS 604
L. Placidi, A. Amendola, M. Miniaci, F. Fraternali

INDUCING DISPERSION CURVES WITH NEGATIVE GROUP VELOCITY IN INERTIALLY AMPLIFIED PHONONIC CRYSTALS THROUGH THE APPLICATION OF AN EXTERNAL STATE OF PRESTRESS 612
M. Miniaci, M. Mazzotti, A. Amendola, F. Fraternali

MS 5: DYNAMIC FLUID-STRUCTURE INTERACTION

SUSCEPTIBILITY OF U-PROFILES WITH DIFFERENT GEOMETRY AND POROSITY TO GALLOPING 621
Stanislav Hračov, Michael Macháček

THE EFFECT OF FOLDING WINGTIPS ON THE FLIGHT DYNAMICS OF AN AIRCRAFT WITH ELASTIC WING 631
Davide Balatti, Hamed Haddad Khodaparast, Michael Friswell, Marinos Manolesos, Mohammadreza Amoozgar
NONLINEAR STRUCTURAL BEHAVIOUR OF AN ARCH DAM UNDER STATIC AND DYNAMIC LOADS 640
Carla Ferreira, Helena Barros

A NEW OPEN SOURCE SOLVER FOR MODELLING FLUID-STRUCTURE INTERACTION: CASE STUDY OF A POINT-ABSORBER WAVE ENERGY CONVERTER WITH POWER TAKE-OFF UNIT 657
Bonaventura Tagliafierro, Rosario Montuori, Ioannis Vayas, Pablo Ropero, Alejandro Crespo, Jose Domınguez, Corrado Altomare, Giacomo Viccione, Moncho Gomez Gesteira

MS 6: VEHICLE DYNAMICS

SPEED DISTRIBUTION ON ROAD TEST SECTIONS FOR THE NEED OF PROFILE GROUND TESTING OF SPECIAL WHEELED VEHICLES 669
Mariusz Kosobudzki

TMEASY 6.0—A HANDLING TIRE MODEL THAT INCORPORATES THE FIRST TWO BELT EIGENMODES 676
Georg Rill

OPTIMIZATION OF NONLINEAR QUARTER CAR SUSPENSION-DRIVER SEAT MODEL USING GA BASED PID CONTROLLER 690
Omar El-Mezayen, Mustafa Qasem, Hesham Ibrahim, Nora Merabet, Zakaria.Elnaggar

ENHANCING ROAD – VEHICLE BEHAVIOR BY IMPLEMENTING ACTIVE - CONTROLLED DRIVER SEAT COMBINED WITH SEMI-ACTIVE GROUND HOOK SUSPENSION SYSTEM 705
Mohamed Ezzat, Hesham Ibrahim, Zakaria Elnaggar, Nora Merabet, Mohamed Salama

AUTO-SAPIENS, AN EXPERIMENTAL AUTONOMOUS DRIVING SYSTEM 718
Maicol Laurenza, Gianluca Pepe, Antonio Carcaterra

IDENTIFICATION OF NONLINEAR ROAD-VEHICLE DYNAMIC BEHAVIOR USING AUTOREGRESSIVE TECHNIQUE ….734
Mohab Anwar, Mostafa Tamer, Mohamed Tawfik, Hesham Ibrahim

EFFICIENT METHODS TO ASSESS LINEAR AND NON-LINEAR AUTOMOTIVE PLATOON CONTROL STABILITY AND PERFORMANCE …… 748
Christian Kalteis, Sebastian Thormann, Alexander Schirrer, Stefan Jakubek

ANALYSIS OF AUTOMOBILE BRAKE CREEP GROAN VIBRATIONS: TEST RIG EXPERIMENTS IN COMPARISON TO FINITE ELEMENT SIMULATIONS …… 758

Simone Castelli, Andrea Belleri, Alessandra Marini, Babak Moaveni

TOWARDS STRUCTURAL HEALTH MONITORING BASED RISK BASED INSPECTION PLANNING FOR OFFSHORE WIND TURBINE SUPPORT STRUCTURES 1230
Simon Tewolde, Ruediger Höffer, Inka Mueller

INVESTIGATION OF EFFICIENT MODAL IDENTIFICATION OF BRIDGES USING BAYESIAN INFERENCE 1242
Yoshinao Goi, Chul-Woo Kim

VIBRATION-BASED STRUCTURAL HEALTH MONITORING OF A REINFORCED CONCRETE BEAM SUBJECT TO VARYING AMBIENT TEMPERATURES USING BAYESIAN METHODS 1254
Patrick Simon, Ronald Schneider, E. Viefhues, S. Said, Ralf Herrmann, Matthias Baeßler

MONITORING MONOPILE PENETRATION THROUGH MAGNETIC STRAY FIELD MEASUREMENTS 1272
Peter Meijers, Apostolos Tsouvalas, Andrei Metrikine

MITIGATION OF ENVIRONMENTAL VARIABILITIES IN DAMAGE DETECTION: A COMPARATIVE STUDY OF TWO SEMI-SUPERVISED APPROACHES 1281
Artur Movsessian, Bilal Ali Qadri, Dmitri Tcherniak, David Garcia Cava, Martin Dalgaard Ulriksen

IMPLEMENTING A STRUCTURAL HEALTH MONITORING SYSTEM USING DIGITAL MODELS OF THE BAM LARGE DROP TEST FACILITY IN HORSTWALDE 1293
Ralf Herrmann, Falk Hille, S. Said, Jens Sterthaus, Karsten Müller, Thomas Quercetti, Frank Wille, J.-A. Paffenholz, Matthias Baeßler

APPLICATION OF A CLASSIFICATION ALGORITHM TO THE EARLY-STAGE DAMAGE DETECTION OF A MASONRY ARCH 1305
Alberto Barontini, Maria Giovanna Masciotta, Paulo Amado Mendes, Luís Ramos, Paulo Lourenço

VIBRATION-BASED DAMAGE DETECTION APPLIED TO A CONCRETE ARCH-DAM 1315
Sérgio Pereira, Filipe Magalhães, Álvaro Cunha, Jorge Gomes, José Lemos

A FULLY AUTOMATED OMA PROCEDURE WITH ADAPTIVE TRACKING OF LONG-TERM MONITORING DATA: AN APPLICATION TO MASONRY TOWERS 1325
Giacomo Zini, Michele Betti, Gianni Bartoli

VIBRATION-BASED ANOMALY DETECTION USING SPARSE AUTO-ENCODER AND CONTROL CHARTS 1335
Rafaelle Finotti, Carmelo Gentile, Flávio Barbosa, Alexandre Cury

DESIGN OF A MONITORING SYSTEM FOR A LONG-SPAN SUSPENSION BRIDGE: OPTIMAL SENSOR PLACEMENT ……..1348
Øyvind Wiig Petersen, Ole Øiseth, Gunnstein Thomas Frøseth

COMPARISON OF ALTERNATIVE DYNAMIC VIBRATION MITIGATION APPROACHES FOR WIND TURBINE TOWERS …….. 1358
Konstantinos A. Kapasakalis, Pyros-Orfeas N. Bollano, Evangelos J. Sapountzakis, Ioannis A. Antoniadis

AN INTEGRATED MONITORING STRATEGY FOR CURRENT CONDITION ASSESSMENT OF HISTORIC BRIDGES …. 1373
Gabriele Ravizza, Rosalba Ferrari, Egidio Rizzi, Vasillis Dertimanis, Eleni Chatzi

APPLICATION OF WAVELET SYNCHRO-SQUEEZED TRANSFORM (WSST) METHOD TO RAILWAY BRIDGE HEALTH MONITORING …… 1388
Neda Mostafa, Richard Loendersloot, Dario Di Maio, Tiedo Tinga

DETECTION OF CLAMPING FORCE LOSS IN BOLTED JOINTS OF RAIL SUPPORTS IN CONSIDERATION OF CHANGING AMBIENT TEMPERATURE …… 1397
Anna-Lena Dreisbach, Volkan Yokaribas, Gerhard Dietrich, Daniel Sahm, Daniel Pak, Claus-Peter Fritzen

MS 9: STRUCTURAL CONTROL

NUMERICAL PERFORMANCE EVALUATION OF A BI-DIRECTIONAL ROLLER SEISMIC ISOLATION BEARINGS …..… 1408
Ricardo González, Nelson Ortiz-Cano, Andrés Nieto-Leal, Carlos Gaviria-Mendoza

CONTROL LAW AND ACTUATOR CAPACITY EFFECT ON THE DYNAMIC PERFORMANCE OF A HYBRID MASS DAMPER; THE CASE OF ROTTWEIL TOWER …… 1422
Lefteris Koutsoloukas, Nikolaos Nikitas, Petros Aristidou, Christian Meinhardt

DOUBLE TUNED MASS DAMPER INERTER FOR SEISMIC RESPONSE REDUCTION OF STRUCTURES …… 1433
Mahdi Abdeddaim, Salah Djerouni, Abdelhafid Ounis, Nassim Djedoui

OPTIMAL FEEDBACK CONTROL LAW FOR VISCOELASTIC MATERIALS WITH MEMORY EFFECTS …… 1445
Gianluca Pepe, Elena Paifelman, Antonio Carcaterra

OPTIMAL DAMPER DISTRIBUTIONS IN SHEAR FRAMES CONSIDERING SOIL CONDITIONS …… 1459
Ersin Aydin, Baki Ozturk, Osman Sivrikaya

A LOCAL ACTIVE NOISE CONTROL SYSTEM BASED ON A NONLINEAR SENSING TECHNIQUE FOR YACHT APPLICATIONS …… 1475
Dimitrios Mylonas, Alberto Erspamer, Andreas Paradisiois, Christos Yiakopoulos, Ioannis Antoniadis

TUNING STRATEGIES AND PLACEMENTS FOR DISTRIBUTED MULTIPLE TUNED MASS DAMPERS FOR WIND-INDUCED VIBRATION CONTROL IN HIGH-RISE BUILDINGS …… 1491
Ahmed Abed, Oum El Khaiat Moustachi

MS 10: ADVANCES ON INERTER-BASED STRUCTURAL VIBRATION CONTROL

OPTIMUM DESIGN OF A TUNED-INERTER-HYSTERETIC-DAMPER (TIHD) FOR BUILDING STRUCTURES SUBJECT TO EARTHQUAKE BASE EXCITATIONS 1501
Predaricka Deastra, David Wagg, Neil Sims

RESPONSE CONTROL OF BUILDINGS USING TMDI UNDER WIND AND EARTHQUAKES 1510
Said Elias, Rajesh Rupakhety, Simon Olafsson

SUPPRESSION OF VIBRATION TRANSMISSION BETWEEN OSCILLATORS COUPLED WITH AN INERTER-BASED JOINT 1521
Zhuang Dong, Jian Yang, Han Meng, Dimitrios Chronopoulos

SEISMIC PROTECTION OF MULTI-STOREY ROCKING STRUCTURES WITH INERTERS 1529
Rodrigo Thiers-Moggia, Christian Málaga-Chuquitaype

THE EFFECTS OF PARASITIC MASS ON THE PERFORMANCE OF INERTER-BASED DYNAMIC VIBRATION ABSORBERS 1545
Hakan Dogan, Neil Sims, David Wagg

VIBRATION CONTROL OF STEEL LIQUID STORAGE TANKS EQUIPPED WITH INERTER-BASED ISOLATION SYSTEMS 1556
Daniele Zahedin Labaf, Maurizio De Angelis, Daniele Pietrosanti

INERTER-BASED VIBRATION ABSORBERS FOR ROTATING WIND TURBINE BLADES 1568
Zili Zhang

MOTION CONTROL PERFORMANCE OF TUNED MASS DAMPER INERTER (TMDI) IN CONTINUOUS WHITE-NOISE EXCITED CANTILEVERED BEAMS WITH VARIOUS SHAPES 1576
Zixiao Wang, Agathoklis Giaralis

MS 11: BRIDGE DYNAMICS

EXPERIMENTAL STUDY OF RAILWAY BRIDGES OF SEVERAL STRUCTURAL TYPOLOGIES 1586
Pedro Galvín, Emma Moliner, Antonio Romero, María Dolores Martínez-Rodrigo

DYNAMIC RESPONSE OF CORRUGATED STEEL CULVERTS FOR RAILWAY LINES 1613
Andreas Andersson, Raid Karoumi

DYNAMIC SOIL-STRUCTURE INTERACTION IN RESONANT RAILWAY BRIDGES WITH INTEGRAL ABUTMENTS 1625
Abbas Zangeneh, Andreas Andersson, Costin Pacoste, Raid Karoumi

A NEW APPROACH TO MODELLING ROCKING MOTION OF POST-TENSIONED SEGMENTAL COLUMNS 1634
Ehsan Ahmadi, Mohammad Kashani

STOCHASTIC DYNAMIC ANALYSIS OF HIGH-SPEED MAGLEV GUIDEWAY COUPLED SYSTEM CONSIDERING VEHICLE PARAMETER 1642
Peng Zhang, Zhi-wu Yu, Jian- feng Mao

RAIL-BRIDGE INTERACTION EFFECTS IN SINGLE-TRACK MULTI-SPAN BRIDGES. EXPERIMENTAL RESULTS VERSUS NUMERICAL PREDICTIONS UNDER OPERATING CONDITIONS 1652
María D. Martínez-Rodrigo, Pedro Galvín, Emmanuela Moliner, Antonio Romero

VERTICAL COUPLING EFFECT OF THE BALLASTED TRACK ON THE DYNAMIC BEHAVIOR OF MULTITRACK RAILWAY BRIDGES COMPOSED BY ADJACENT DECKS 1666
Emmanuela Moliner, Antonio Romero, J.C. Sanchez-Quesada, María Dolores Martínez-Rodrigo, Pedro Galvín

DISPLACEMENT BASED ANALYSIS AND DESIGN OF ROCKING BRIDGES 1680
Michalis F. Vassiliou, Natalia Reggiani Manzo

SEISMIC PERFORMANCE OF BRIDGES ISOLATED WITH DCFP DEVICES 1704
Paolo Castaldo, Guglielmo Amendola, Diego Gino, Elena Miceli

MEASUREMENTS OF AMBIENT VIBRATIONS FOR A CABLE-STAYED BRIDGE INCLUDING THE SOIL-FOUNDATION SYSTEM 1722
Vanni Nicoletti, Davide Arezzo, Sandro Carbonari, Francesca Dezi, Fabrizio Gara

MS 12: FOOTBRIDGE VIBRATIONS

PERFORMANCE OF INERTIAL MASS CONTROLLERS FOR ULTRA-LIGHT FOOTBRIDGES: A CASE STUDY 1731
Carlos M. C. Renedo, Iván M. Díaz, Justin M. Russel, Stana Živanović

INTERVAL SERVICEABILITY ASSESSMENT OF FOOTBRIDGES 1747
Roberta Santoro, Alba Sofi, Federica Tubino

CLOSED—FORM SOLUTION OF THE RESPONSE OF SINGLE PEDESTRIAN INDUCED LOAD FOR CLAMPED—CLAMPED BRIDGES 1756
Daniel Colmenares, Andreas Andersson, Raid Karoumi

NUMERICAL VALIDATION OF THE GENERALISED EQUIVALENT SPECTRAL MODEL THROUGH CROWD DYNAMICS SIMULATIONS 1769
Fiammetta Venuti, Federica Tubino

VALIDATION OF A NOVEL VIRTUAL REALITY PLATFORM FOR INVESTIGATING PEDESTRIAN-PEDESTRIAN INTERACTION IN THE CONTEXT OF STRUCTURAL VIBRATION SERVICE ABILITY 1777
Artur Adam Soczawa-Stronczyk, Mateusz Bocian

MEASURING THE DYNAMIC RESPONSE OF A LIVELY FOOTBRIDGE TO AMBIENT AND WALKING EXCITATION 1791
Alfredo Cigada, Carmelo Gentile, Giulia Lastrico, Maria Gabriella Mulas

DYNAMIC PROPERTIES OF TWO PEDESTRIAN WOODEN BRIDGES INCLUDING SEASONAL EFFECTS 1805
John Hallak Neilson, Aida Ibisevic, Hasanhüseyin Ugur, Jean-Marc Battini, Roberto Crocetti, Costin Pacoste, Maria D. Martinez-Rodrigo

EVALUATION OF HUMAN INDUCED VIBRATIONS IN KJÆRRA BRIDGE 1814
Thomas Tenev, Ole Andre Kristiansen, Emrah Erduran

PERFORMANCE OF BIODYNAMIC MODELS TO REPRESENT THE ACTION OF A PEDESTRIAN IN THE VERTICAL DIRECTION 1824
Rafaela Silva, Roberto Pimentel, Aleksandar Pavic

PEDESTRIAN LATERAL FOOT PLACEMENT AND LATERAL DYNAMIC INSTABILITY OF BRIDGES 1835
Mateusz Bocian, Jeremy Burn, John Macdonald

MOTION-BASED DESIGN OF ACTIVE TUNED MASS DAMPERS TO CONTROL PEDESTRIAN-INDUCED VIBRATIONS IN FOOTBRIDGES UNDER UNCERTAINTY CONDITIONS 1844
Javier Fernando Jiménez-Alonso, Jose Manuel Soria, Carlos Martín de la Concha Renedo, Francisco Guillen González

CONTACT FORCE RECONSTRUCTION ON VIBRATING SURFACES 1854
Jeroen Van Hauwermeiren, Katrien Van Nimmen, B. Vanwanseele, Peter Van den Broeck

AN OPEN ACCESS BENCHMARK DATASET ON PEDESTRIAN-INDUCED VIBRATIONS COLLECTED ON THE EEKLO FOOTBRIDGE 1866
Peter Van den Broeck, Jeroen Van Hauwermeiren, Katrien Van Nimmen

IDENTIFICATION OF HUMAN-STRUCTURE INTERACTION BASED ON FULL-SCALE OBSERVATIONS 1874
Katrien Van Nimmen, Jeroen Van Hauwermeiren, Peter Van den Broeck

A NOVEL METHOD FOR INDIRECT MEASUREMENT OF GROUND REACTION FORCES ON VIBRATING STRUCTURES 1883
Andrei Firus, Roman Kemmler, Hagen Berthold, Steven Lorenzen, Jens Schneider

MS 13: HUMAN INDUCED VIBRATIONS IN FLOORS, STAIRCASES AND STADIA

SIMPLIFIED COMPUTATION OF TIMBER FLOOR VIBRATIONS LEVEL DUE TO HUMAN ACTIVITIES 1896
Thomas Catterou, Jean-Baptiste Castaing, Patrice Garcia

SYSTEM IDENTIFICATION OF HUMAN LEG SPRING STIFFNESS DURING RHYTHMIC JUMPING ON A PERCEPTIBLY MOVING SURFACE 1913
Rory White, Nicholas Alexander, John Macdonald

ENVIRONMENTAL IMPACT OF STRUCTURAL MODIFICATIONS IN OFFICE FLOORS TO SATISFY VIBRATION SERVICEABILITY 1924
Márcio S. Gonçalves, Aleksandar Pavic

ANALYSIS THE LATERAL VIBRATION SERVICEABILITY OF TEMPORARY GRANDSTAND AND HUMAN COMFORT BASED ON EXPERIMENT 1932
Suhui Yu, Jian Yuan, Wei Wang, Chengqiang Gao, Weili Wang, Cong Liu

MS 14: WIND INDUCED VIBRATIONS OF SLENDER STRUCTURES AND FATIGUE

LARGE-SCALE AEROELASTIC TESTING TO INVESTIGATE THE RESILIENCY OF TRANSMISSION INFRASTRUCTURE TO HURRICANE STORMS 1944
Ziad Azzi, Amal Elawady, Arindam Chowdhury

A STUDY ON THE EVALUATION OF WIND INDUCED VIBRATION IN LONG-SPAN SUSPENSION BRIDGES WITH ARTIFICIAL NEURAL NETWORKS 1958
Dario Fernandez, Aksel Fenerci, Ole Øiseth

AUTHORIAL METHOD OF EVALUATING VIBRATIONAL COMFORT OF OCCUPANTS OF HIGH-RISE BUILDINGS BASED ON AEROELASTIC MODEL TESTS 1968
Aleksander Pistol, Łukasz Flaga, Piotr Krajewski, Andrzej Flaga

WIND TUNNEL TESTS ON MOTION-INDUCED VORTEX VIBRATION 1988
Kazutoshi Matsuda, Kusuo Kato, Nade Cao

DYNAMIC STUDY OF PORT CRANES SUBJECTED TO STOCHASTIC WIND ACTIONS 2001
Luigi Solazzi

ON THE VALIDATION AND USE OF A SIMPLIFIED MODEL OF AEOLIAN VIBRATION OF OVERHEAD LINES FOR PARAMETRIC STUDIES 2011
Emmanuel Cieren, John Redford, Maxime Guéguin, Olivier Allix, Christine Yang, Fikri Hafid, Jean-Michel Ghidaglia

FATIGUE LIFE ESTIMATION CONSIDERING THE QUASI-PERIODIC CROSS-WIND RESPONSE OF SLENDER STRUCTURES IN THE LOCK-IN RANGE 2022
Francesca Lupi, Ruediger Höffer, Hans-Jürgen Niemann

MODELING THE INTERACTION OF GALLOPING AND VORTEX INDUCED VIBRATION FOR STEEL-CONCRETE COMPOSITE BRIDGES IN LAUNCHING PHASE 2040
Cong Chen, Niccolo Wieczorek, Julian Unglaub, Klaus Thiele

WIND TUNNEL VIV TESTING OF HELICAL STRAND CABLE MODELS 2054
Arsenii Trush, Stanislav Pospíšil, Hrvoje Kozmar

NUMERICAL AND EXPERIMENTAL STUDY OF A SLENDER CATENARY BRIDGE WITH A NOVEL TENSIONING SYSTEM 2063
Gergely Szabó, Gábor Hochrein

PREDICTION OF THE WIND-INDUCED FATIGUE OF SLENDER STRUCTURES 2077
Michela Damele, Maria Pia Repetto

A STOCHASTIC AND CONTINUOUS MODEL OF AEOLIAN VIBRATIONS OF CONDUCTORS EQUIPPED WITH STOCKBRIDGE DAMPERS 2088
Francesco Foti, Vincent Denoël, Luca Martinelli, Federico Perotti

ENHANCED SERVICE ABILITY PERFORMANCE IN WIND-EXCITED TALL BUILDINGS EQUIPPED WITH OPTIMAL TUNED MASS DAMPER INERTER VIA TOP-STOREY SOFTENING 2103
Zixiao Wang, Agathoklis Giaralis

MS 15: DYNAMICS OF ON- AND OFF-SHORE WIND ENERGY STRUCTURES (WES)

DYNAMICS OF TENSEGRITY SOLAR FAÇADES OPERATING AS MECHANICAL ENERGY HARVESTERS 2113
Raffaele Miranda, Enrico Babilio, Narinder Singh, Diana P. Villamil, Filipe Santos, Fernando Fraternali

TALL OFFSHORE STEEL WIND TURBINE TOWERS UNDER WIND CURRENT AND WAVE LOADING: AN EXPERIMENTAL AND NUMERICAL STUDY 2123
Yu Hu, Jian Yang, Charalampos Baniotopoulos, Xinger Wang, Xiaowei Deng

SPATIAL DISTRIBUTED CHARACTERISTICS OF DYNAMIC RESPONSE OF JACKET SUPPORTED OFFSHORE WIND TURBINES SUBJECTED TO HURRICANE INDUCED ENVIRONMENTAL LOADS 2134
Bowen Jiang, Qingshan Yang, Guoqing Huang, Min Liu

SURROGATE MODEL FORMULATION FOR STOCHASTIC FLUTTER ANALYSIS OF WIND TURBINE BLADES UNDER UNCERTAIN AERODYNAMICS LOADS 2151
Luca Caracoglia

A SYSTEMATIC INVESTIGATION OF COMMON GRADIENT BASED MODEL UPDATING APPROACHES APPLIED TO HIGH-FIDELITY TEST-DATA OF A WIND TURBINE ROTOR BLADE 2159
Johannes Knebusch, Janto Gundlach, Yves Govers

PLATFORM OPTIMIZATION OF LARGE FLOATING OFFSHORE WIND ENERGY STRUCTURES 2175
Giulio Ferri, Enzo Marino, Claudio Borri

DYNAMIC FIELD DATA FROM OFFSHORE MONOPILE WIND TURBINES – ASSESSMENT OF NATURAL FREQUENCIES AND DAMPING 2181
Karin Norén-Cosgriff, Amir M. Kaynia

MONITORING OF OFFSHORE WIND TURBINES UNDER WAVE AND WIND LOADING DURING INSTALLATION 2189
Aljoscha Sander, Christian Meinhardt, Klaus-Dieter Thoben

EXPERIMENTAL EVALUATION OF BENDING MOMENTS AT THE TOWER OF AN ONSHORE WIND TURBINE 2206
João Pacheco, Francisco Pimenta, Álvaro Cunha, Filipe Magalhães

WIND TURBINE ROTOR BLADE VIBRATION – APPLICATION OF TWO ALTERNATIVE MODAL DECOMPOSITION PROCEDURES ……2219
Evgueni Stanoev

MS 16: VIBRATION-BASED ASSESSMENT AND SHM OF CULTURAL HERITAGE STRUCTURES

STATISTICAL PROCESS CONTROL PROCEDURES FOR ONLINE DAMAGE DETECTION OF A MONUMENTAL MASONRY PALACE: THE CONSOLI PALACE IN GUBBIO, ITALY …… 2244
Enrique García Macías, Filippo Ubertini

EFFECT OF NOISE IN THE TIME-FREQUENCY ESTIMATE OF THE PERIDYNAMIC BOND ELASTIC CONSTANT PARAMETER …… 2260
Gaetano Miraglia, Rosario Ceravolo, G. Coletta

DYNAMIC MODELLING OF TRAM-INDUCED VIBRATION ON THE TEMPLE OF MINERVA MEDICA IN ROME …… 2266
Fernando Saitta, Sara Forliti, Alessandro Colucci, Angelo Tatì, Ivan Roselli

ENHANCED CONTINUOUS DYNAMIC MONITORING OF A COMPLEX MONUMENTAL PALACE THROUGH A LARGER SENSOR NETWORK …… 2275
Alban Kita, Ilaria Venanzi, Nicola Cavalagli, Enrique Garcia-Macias, Filippo Ubertini

FE MODEL UPDATING OF MASONRY TOWERS: MODELING AND NUMERICAL ISSUES …… 2285
Riccardo Mario Azzara, Maria Girardi, Cristina Padovani, Daniele Pellegrini, Leonardo Robol

INFLUENCE OF IMPORTANT STRUCTURAL STRENGTHENING ON THE DYNAMIC PROPERTIES OF A MASONRY ARCH BRIDGE …… 2299
Chiara Pepi, Nicola Cavalagli, Massimiliano Gioffrè, Vittorio Gusella

A MULTIDISCIPLINARY APPROACH INTEGRATING GEOMATICS, DYNAMIC FIELD TESTING AND FINITE ELEMENT MODELING TO EVALUATE THE CONSERVATION STATE OF THE GUIMARÃES CASTLE'S TOWER KEEP …… 2310
Luis Javier Sánchez-Aparicio, Maria Giovanna Masciotta, Daniele Pellegrini, Borja Conde, Maria Girardi, Cristina Padovani, Luis Ramos, Belén Riveiro

ENVIRONMENTAL EFFECTS ON THE DYNAMIC CHARACTERISTICS OF A HISTORIC CATHEDRAL …… 2323
Carmelo Gentile, Antonello Ruccolo

A DAMAGE LOCALISATION PROCEDURE FOR MASONRY TOWERS BASED ON FREQUENCY DATA …… 2338
Paolo Borlenghi, Carmelo Gentile, Antonella Saisi

MODAL PARAMETERS IDENTIFICATION ON ENVIRONMENTAL TESTS OF ANCIENT BELL TOWERS AND VALIDATION OF THEIR NUMERICAL MODELS …… 2355
Francesco Clementi, Gianluca Standoli, Ersilia Giordano, Angela Ferrante, Stefano Lenci

MEASUREMENTS OF THE COLOSSEUM RESPONSE TO ENVIRONMENTAL ACTIONS …… 2367
Fabrizio Vestroni, Adriano De Sortis, Annamaria Pau

ASSESSMENT OF THE TRM REINFORCEMENT OF WINDOWED MASONRY WALLS THROUGH OMA IDENTIFICATION 2377
Salvador Ivorra, Domenico Camassa, David Bru, Ignacio Gisbert, Anna Castellano, Aguinaldo Fraddosio, Mario Daniele Piccioni

MODAL IDENTIFICATION OF THE SAN FRANCESCO CHURCH IN PISA, ITALY 2386
Emanuele Lorenzo, F. Canessa, Giuseppe Chellini, Anna De Falco, Carlo Resta, E. Savelli, Giacomo Sevieri

DYNAMIC ANALYSIS OF THE INTERACTION BETWEEN BELLS AND MASONRY STRUCTURES 2400
David Bru, Salvador Ivorra, Michele Betti, Gianni Bartoli, F. Javier, Baeza F. Borja Varona

MS 17: VIBRATIONS DUE TO CONSTRUCTION AND INDUSTRIAL ACTIVITIES

REDUCING IMPACT OF VIBRATIONS FROM COMPACTION ON SLOPE STABILITY 2407
Jörgen Johansson, Joonsang Park, Christian Madshus, Carl Wersäll

VOLUME II

Minisymposia

MS 18: VIBRO-ACOUSTICS

A COUPLED MODELLING APPROACH FOR THE FAST COMPUTATION OF UNDERWATER NOISE RADIATION FROM OFFSHORE PILE DRIVING 2427
Yaxi Peng, Apostolos Tsouvalas, Andrei Metrikine

WAVE-RESOLVING AIRCRAFT FUSELAGE MODEL FOR CABIN NOISE PREDICTIONS UNDER DISTRIBUTED FLUID LOADINGS 2437
Christopher Blech, Sabine C. Langer

NUMERICAL EVALUATION OF THE SOUND TRANSMISSION OF A STRUCTURAL SYSTEM WITH ATTACHED NOISE CONTROL TREATMENTS USING STATISTICAL ENERGY ANALYSIS 2446
Thaynan Oliveira

BAND STRUCTURE OF ELASTIC BODIES WITH PERIODIC NONLOCALITIES 2457
A. S. Rezaei, S. V. Sorokin, F. Mezzani, A. Carcaterra

GLOBAL LONG WAVE APPROXIMATIONS FOR ELASTIC WAVE GUIDES 2464
Kirill Cherednichenko, Julius Kaplunov, Danila Prikazchikov, Leyla Sultanova

A NOVEL VIEW ON THE COMPOSITION OF ENERGY FLOW IN MULTI-MODAL WAVEGUIDES 2475
Lasse S. Ledet, Sergey V. Sorokin

ACOUSTIC BLACK HOLE PROFILE OPTIMIZATION 2482
Horia Cornean, Sergey Sorokin, Benjamin Støttrup

NOISE REDUCTION USING THE CONCEPT OF ACOUSTIC BLACK HOLES DESIGNED BASED ON MODAL ANALYSIS 2489
Bjørnar Saurdal, Daniel Villadsen, Sergey Sorokin, Lasse Ledet

OPTIMIZATION OF PERFORMANCE OF WAVEGUIDES USING THE WAVE FINITE ELEMENT METHOD 2497
Peter Broberg, Mikkel Steffensen, Sergey Sorokin, Lasse Ledet

FAST FREQUENCY SWEEPS FOR UNBOUNDED MEDIA: AN EFFICIENT PERFECTLY MATCHED LAYER FINITE ELEMENT FORMULATION 2508
Romain Rumpler, Antoine Vermeil de Conchard, Huina Mao

MS 19: BLAST AND IMPACT LOADS

IMPACT DAMAGE CHARACTERIZATION AT RC PLATES WITH PLANAR TOMOGRAPHY AND FEM 2521
Deborah Nerger, Robabeh Moosavi, Franz Bracklow, Marcus Hering, Tino Kühn, Manfred Curbach, Falk Hille, Andreas Rogge

MODEL REDUCTION FOR STRUCTURES SUBJECTED TO BLAST LOADING BY USE OF DYNAMIC SUBSTRUCTURING 2544
Linus Andersson, Peter Persson, Kent Persson

2DOF BLAST ANALYSIS OF BUILDINGS 2565
Sander Meijers, Peter Flink, Harm Kraaijenbrink, Meindert Wiersma

PROTECTION OF MASONRY STRUCTURES AGAINST EXPLOSIONS APPLYING LAYERS OF TEXTILE REINFORCED MORTAR 2573
Leonidas Alexandros Kouris, Georgios Valsamos, Savvas Triantafyllou, Vasileios Karlos, Daniel A. Pohoryles, Dionysios A. Bournas, Martin Larcher, Folco Casadei

MS 20: MOVING LOADS

SIMPLIFIED DYNAMIC RESPONSE ANALYSIS OF A RAILWAY BRIDGE CONSIDERING SOIL-STRUCTURE INTERACTION 2585
Christoph Adam, Benjamin Hirzinger

DYNAMIC AMPLIFICATION FACTORS FOR ULTRA-HIGH-SPEED HYPERLOOP TRAINS: VERTICAL AND LATERAL VIBRATIONS 2594
Ehsan Ahmadi, Mohammad Kashani, Nicholas Alexander

MOVING LOAD ON AN ELASTIC HALF-SPACE COATED WITH A THIN VERTICALLY INHOMOGENEOUS LAYER 2601
Saad Althobaiti, Vladimir Bratov, Ali Mubaraki, Danila Prikazchikov

VERIFICATION OF THE VALIDITY OF THE IMPACT FACTOR USED IN THE DESIGN OF PC SLEEPERS 2612
Shintaro Minoura, Tsutomu Watanabe, Kodai Matsuoka, Kenji Narita

DYNAMIC RESPONSE OF SINGLE AND MULTI-SPAN BEAMS UNDER A MOVING LOAD USING DYNAMIC STIFFNESS FORMULATIONS AND GALERKIN'S METHOD 2621
Baran Bozyigit, Sinan Acikgoz, Yusuf Yesilce

THE IN-PLANE STEADY-STATE RESPONSE OF A RING IN RELATIVE MOTION TO A CONSTANT LOAD 2631
Tao Lu, Apostolos Tsouvalas, Andrei Metrikine

TRAIN-WEIGHT-IN-MOTION IDENTIFICATION MEASURING TIME-HISTORIES OF RAIL STRAINS 2638
Annamaria Pau, Fabrizio Vestroni

DYNAMIC EFFECT OF TRAINS WITH ARTICULATED COACHES AND JACOBS BOGIES WITH INTEGER WHEELBASE RATIOS 2646
Pedro Museros, Andreas Andersson, Raid Karoumi

ANALYSIS OF VIBRATIONS INDUCED BY PROXIMATE MASSES TRAVERSING A BEAM SUPPORTED BY A FINITE DEPTH FOUNDATION WITH PARTIAL SHEAR RESISTANCE 2658
Zuzana Dimitrovová

THEORETICAL ASSESSMENT OF VERTICAL INTERACTION BETWEEN A WHEELSET AND TRACK: INFLUENCE OF THE TRACK DAMPING MODEL 2667
T. Mazilu, M.A. Gheți

MS 21: TRAFFIC INDUCED VIBRATIONS

REDUCING VIBRATIONAL IMPACT LATERAL OF A RAILWAY TRACK ON AN URBAN DEVELOPMENT PROJECT 2680
Felix Mertens, Thomas Jaquet

IMPROVED FLOATING SLAB TRACK PERFORMANCE BY ON TOP INSTALLED TUNED MASS DAMPER 2688
Thomas Jaquet, Wang Bo

A MIXED-FRAME-OF-REFERENCE MODEL FOR RAILWAY INDUCED SOIL-STRUCTURE VIBRATION INTERACTION 2700
Paulius Bucinskas, Evangelos Ntotsios, David Thompson, Lars Andersen

THE USE OF MULTIPLE MODELS TO ANALYSE RAILWAY TRACK GROUND DYNAMICS 2718
Panudech Chumyen, David Connolly, Kaitai Dong, Pedro Costa, Paulo Soares, Peter Woodward

OURS - INTRODUCING THE DUTCH FORMAL MODEL FOR RAILWAY VIBRATION 2729
Arnold Koopman

SUBSOIL MODELLING FOR RAILWAY INDUCED VIBRATIONS 2740
Bruno Zuada Coelho, Sven Lentzen, Maarten Pronk, Dirk de Lange, Eleni Smyrniou, Marc Hijma

NUMERICAL ASSESSMENT OF THE INFLUENCE OF BALLAST HETEROGENEITIES ON THE DYNAMIC BEHAVIOR OF RAILWAY TRACKS 2763
Hadrien Pinault, Etienne Balmes, Elodie Arlaud, Régis Cottereau

MITIGATION OF VIBRATION INDUCED BY RAILWAY TRAFFIC USING GRANULAR BARRIERS 2775
Patryk Dec, Régis Cottereau, Baldrik Faure

MS 22: DYNAMIC SOIL-STRUCTURE INTERACTION AND WAVE PROPAGATION

SCATTERING OF ELASTIC WAVES BY TRANSVERSELY ISOTROPIC SPHERE 2782
Ata Jafarzadeh, Peter D. Folkow, Anders Boström

A 2.5D FEM-BEM-MFS METHODOLOGY FOR SOIL-STRUCTURE INTERACTION PROBLEMS IN LAYERED HALF-SPACES 2798
Hassan Liravi, Robert Arcos, Dhananjay Ghangale, Jordi Romeu

A NEW SEMI-ANALYTICAL APPROACH FOR DYNAMIC PILE-SOIL INTERACTION PROBLEM 2807
Kenny Conto, Robert Arcos, Cecília Parente, Pedro Alves Costa, Jordi Romeu

STRUCTURE-SOIL-STRUCTURE INTERACTION ANALYSIS FOR REINFORCED CONCRETE FRAMED STRUCTURES 2817
Reine Fares, Maria Paola Santisi d'Avila, Anne Deschamps, Evelyne Foerster

COUPLED ITM-FEM APPROACH FOR THE ASSESSMENT OF THE MITIGATION EFFICIENCY OF FINITE AND INFINITE OPEN TRENCHES AND SOFT FILLED BARRIERS 2827
Julian Freisinger, Gerhard Müller

SOIL-STRUCTURE INTERACTION OF AN END-BEARING PILE FOUNDATION: DESIGN OF AN EXPERIMENTAL CASE STUDY 2846
Freddie Theland, Jean-Marc Battini, Costin Pacoste, Geert Lombaert, Stijn François, Peter Blom, Fanny Deckner

VIBRATIONS OF RECTANGULAR FLEXIBLE FOUNDATION ON HALFSPACE 2857
Marko Radišić, Mira Petronijević, Gerhard Müller

THE EFFECTS OF MODEL ASSUMPTIONS ON THE DYNAMIC IMPEDANCE FUNCTIONS OF A SHALLOW FOUNDATION 2868
Johan Lind Östlund, Andreas Andersson, Mahir Ülker-Kaustell, Jean-Marc Battini

ANALYSIS OF SEISMIC METASURFACES USING SPECIALISED ASYMPTOTIC MODELS FOR RAYLEIGH WAVES 2882
Peter Wootton, Julius Kaplunov, Danila Prikazchikov

INCREMENTAL DYNAMIC ANALYSES OF BRIDGE PYLONS WITH CONSIDERATION OF THE EFFECT OF SURFACE WAVES 2893
Charisis Chatzigogos, Kristel Meza Fajardo

TRANSIENT ANALYSIS IN HALF-SPACE COMBINING IGA AND THE PERFECTLY MATCHED LAYER METHOD 2909
Arturo Méndez Salas, Margarita Chasapi, Sven Klinkel

NUMERICAL WAVENUMBER INTEGRATION FOR 2.5D WAVE EQUATION SOLUTION 2919
Joonsang Park, Karin Norén-Cosgriff, Amir M. Kaynia

USE OF THE DOMAIN REDUCTION METHOD TO SIMULATE THE SEISMIC RESPONSE OF AN EXISTING STRUCTURE PROTECTED BY RESONATING UNIT CELL METAMATERIALS 2926
Constantinos Kanellopoulos, Boris Jeremić, Ioannis Anastasopoulos, Božidar Stojadinović

THE EFFECT OF SOIL LIQUEFACTION ON THE SEISMIC PERFORMANCE OF A TYPICAL PORT QUAY WALL 2939
Stella Karafagka, Stavroula Fotopoulou, Anna Karatzetzou, Georgia Kroupi, Kyriazis Pitilakis

A 2.5 DIMENSIONAL INDIRECT TREFFTZ METHOD TO MODEL LINEAR ELASTIC SOILS 2955
Hannes Englert, Fei Qu, Gerhard Müller

MITIGATION OF GROUND VIBRATION FROM PILE DRIVING BY CIRCULAR ARRAYS OF RIGID BLOCKS PLACED ON THE GROUND SURFACE 2966
Lars Vabbersgaard Andersen, Peter Persson, Andrew T. Peplow

TIME DOMAIN BEM-FEM COUPLING FOR SEISMIC SOIL-STRUCTURE INTERACTION ANALYSES CONCEIVED FOR AN ANSYS-MATLAB WORKFLOW 2985
Francesca Taddei, Bettina Chocholaty, Gerhard Müller

EXPERIMENTAL IDENTIFICATION OF THE DYNAMIC BEHAVIOUR OF PILE-SOIL SYSTEM INSTALLED BY MEANS OF THREE DIFFERENT PILE-DRIVING TECHNIQUES 3005
Athanasios Tsetas, Sergio S. Gomez, Apostolos Tsouvalas, Kees van Beek, Faraz S. Tehrani, Evangelos Kementzetzidis, Federico Pisano, Ahmed Elkadi, Maxim Segeren, Timo Molenkamp, Andrei V. Metrikine

DEVELOPMENT OF A METAMATERIAL PERIODIC FOUNDATION FOR SEISMIC PROTECTION 3016
Ahmad Saoud, Ahmad Omar, Diogo Queiros-Conde

GENERATION OF ARTIFICIAL ACCELEROGRAMS CONSISTENT WITH EARTHQUAKE-INDUCED GROUND MOTIONS 3027
Federica Genovese, Giuseppe Muscolino, Giovanni Biondi, Ernesto Cascone

MS 23: ASSESSMENT OF INDUSTRIAL STRUCTURES AND INFRASTRUCTURE UNDER NATURAL HAZARDS

FULL SCALE DYNAMIC TESTING OF WALL PANEL CONNECTIONS FOR PRECAST INDUSTRIAL BUILDINGS 3043
Ilaria Venanzi, Laura Ierimonti, Filippo Ubertini, Annibale Luigi Materazzi, Leonardo Casali, Giuseppe Paci

GROUND MOTION MODEL FOR SEISMIC VULNERABILITY ASSESSMENT OF PROTOTYPE INDUSTRIAL PLANTS 3053
Chiara Nardin, Rocco Di Filippo, Roberto Endrizzi, Igor Lanese, Fabrizio Paolacci, Oreste Salvatore Bursi

SIMPLIFIED ESTIMATION OF DESIGN FAULT DISPLACEMENT FOR BURIED PIPELINES AT FAULT CROSSING 3067
Vasileios Melissianos, Dimitrios Vamvatsikos

MS 24: SEISMIC PROTECTION OF STEEL STRUCTURES BY MEANS OF DISSIPATIVE SYSTEMS AND COMPONENTS

INNOVATIVE DISSIPATIVE DEVICES WITH TENSEGRITY ARCHITECTURE AND SUPER ELASTIC BEHAVIOUR FOR THE SEISMIC PROTECTION OF STRUCTURES 3079
Narinder Singh, Ada Amendola, Filipe Amarante Dos Santos, Gianmario Benzoni, Fernando Fraternali

EARTHQUAKE EFFECTS ON LOW PROFILE CONTAINER CRANE WITH SEISMIC ISOLATION DEVICE 3086
Luigi Solazzi

STEEL TRUSS BRIDGE WITH BUCKLING RESTRAINED DAMPER UNDER SEISMIC LOADING 3097
Purevdorj Sosorburam, Eiki Yamaguchi

MONOTONIC AND CYCLIC BEHAVIOUR OF THE BEAM-TOCOLUMN JOINTS OF THE “FUTURE” MOCKUP 3107
Roberto Tartaglia, Mario D'Aniello, Raffaele Landolfo

DAMAGE-AVOIDANCE STEEL ROCKING FRAMES WITH BUCKLING-ENABLED COMPOSITE BRACING 3117
Leena Tahir Kibriya, Christian Málaga-Chuquitaype, Mohammad Mehdi Kashani

OPTIMIZATION OF DISSIPATIVE REPLACEABLE LINK FRAMES BY ELASTIC HIGH STRENGTH STEEL COUPLING BEAMS 3127
Marius Pinkawa, Cristian Vulcu, Benno Hoffmeister, Markus Feldmann

USE OF HIGH-STRENGTH STEEL FOR MULTI-CRITERIA OPTIMIZATION OF DISSIPATIVE DEVICES 3144
Silvia Caprili, Ivan Panzera, Walter Salvatore

ENHANCED STRUCTURAL RESILIENCE THROUGH THE USE OF "LEAF-SPRING" COLUMNS AND REPLACEABLE DISSIPATIVE COMPONENTS 3154
Cristian Vulcu, Marius Pinkawa, Aurel Stratan, Benno Hoffmeister

MS 25: EXPERIMENTAL EARTHQUAKE ENGINEERING

EXPERIMENTAL INVESTIGATION OF THE INFLUENCE OF TENSILE STRAIN ON THE CRACKING OF R/C VERTICAL STRUCTURAL ELEMENTS 3174
Theodoros A. Chrysanidis, Vassilis P. Panoskaltsis

EVALUATION OF CRACKING BEHAVIOR OF R/C VERTICAL COMPONENTS REINFORCED WITH VARYING LONGITUDINAL REINFORCEMENT RATIOS 3186
Theodoros A. Chrysanidis, Vassilis P. Panoskaltsis

GRAPHENE-RUBBER LAYERED COMPOSITES FOR SEISMIC ISOLATION 3198
Maria Rosaria Marsico, Julián Mauricio Londoño Monsalve

CYCLIC PERFORMANCE OF WIND TURBINE TOWER WITH CONCRETE FILLED DOUBLE SKIN STEEL TUBES SECTION UNDER TORSION..... 3204
Yu-HangWang, Shu-Qi Wang, Guo-Bing Lu, Ji-Ke Tan

THE ST. SILVESTRO BELFRY IN L'AQUILA: FROM THE REHABILITATION WORKS TO THE ACTUAL PERFORMANCE IN TERMS OF DYNAMIC PROPERTIES AND FRAGILITY FUNCTIONS ESTIMATION 3218
Ilaria Capanna, Riccardo Cirella, Angelo Aloisio, Rocco Alaggio, Franco Di Fabio, Massimo Fragiacomo

OUT-OF-PLANE SHAKING TABLE TESTS ON DUTCH BUILDING PRODUCTS 3228
Alexander Johannes Bronkhorst, C.P.W. Geurts

AN EXPERIMENTAL STUDY ON THE RELATIONSHIP BETWEEN EARTHQUAKE DAMAGE AND THE NATURAL FREQUENCY OF WOODEN HOUSE 3245
Kazuhiro Hayashi, Ariyoshi Yamada, Yoshiyuki Komiya

PERFORMANCE OF A LINEAR SOLUTION FOR APPROXIMATING NONLINEAR RESPONSE OF REINFORCED CONCRETE STRUCTURES SUBJECTED TO EARTHQUAKE SHAKING 3251
Kevin Kariuki, Tarjei Heen, Lars Halvor Kaasa, Amir Massoud Kaynia

BEHAVIOUR OF REINFORCED CONCRETE STRANDS DURING TENSION TEST INSPECTED WITH DIC 3261
Haukur Eiriksson, Bjarni Bessason

REVIEW OF SITE EFFECT MODELING METHODS CONSIDERING EXPERIMENTAL GEOPHYSICAL DATA 3274
Rita Abou-Jaoude, Nisrine Makhoul, Jean-Alain Fleurisson, Alexandrine Gesret

HYBRID COLLAPSE TEST OF STEEL COLUMNS WITH NONLINEAR FRAME SUBSTRUCTURING AND FORCE REDISTRIBUTION 3291

Keywords: underwater noise, offshore pile driving, vibro-acoustics, noise propagation, offshore wind.

Abstract. *This paper presents a computationally efficient modelling approach for the prediction of underwater noise radiation from offshore pile driving. A near-source module is adopted to capture the interaction between the pile, fluid and soil, which is based on a previously developed semi-analytical vibro-acoustic model. This module primarily aims at modelling the sound generation and propagation in the vicinity of the monopile. The Green's tensor for an axisymmetric ring source in a horizontally stratified acousto-elastic half-space emitting both compressional and shear waves is derived using the normal modes and branch line integrations. The boundary integral equations are then formulated based on the reciprocity theorem, which forms the mathematical basis of the far-from-source module for the propagation of the wave field at large radial distances. The complete noise prediction model comprises the two modules, which are coupled through the boundary integral formulation with the input obtained from the near-source module. Model predictions are benchmarked against measurement data from an offshore installation campaign.*

1 INTRODUCTION

The anthropogenic noise generated during the installation of the foundation piles for offshore wind farms has raised serious concern over environmental issues. The underwater noise pollution can endanger the lives of marine mammals and fishes [1]. Under the strict environmental regulations imposed by the government in many countries, the offshore industry strives to keep the noise levels to within acceptable limits. To assess the noise levels to be expected and control the hydro-sound emission, underwater noise predictions are required prior to the offshore installation of piles in most projects.

Over the last decades, modeling of the underwater noise generated by offshore pile driving has been studied extensively. Reinhall and Dahl [2] firstly proposed a coupled Finite Element (FE) and Parabolic Equation (PE) model for the prediction of underwater noise for offshore pile driving. The former method (FE) aims at generating the noise in the vicinity of the pile, while the latter one (PE) focus on the long-range propagation of the sound field. The coupling is achieved via a vertical array of phased point sources from FE results. Lippert and Estorff [3] presented a coupled FE and wavenumber integration model and investigated the influence of uncertainties in the sediment parameters through Monte-Carlo simulations. A theoretical benchmark case was then examined by various models discussed in [4]. Similar to [2], a two-step approach is adopted in most available models mentioned in [4, 3, 5] with a FE model to capture the vibration of the pile and a sound propagation model to propagate the field at larger distances (from the pile).

A semi-analytical approach for the prediction of underwater noise from pile driving was developed by Tsouvalas and Metrikine [6] based on a mode-matching technique. In contrast to most of the aforementioned models, this model additionally captured the characteristics of more complex seabed conditions with the soil being described as a three-dimensional elastic continuum. This allows one to examine the influence of the seabed properties on the noise generation and transmission.

In this paper, the authors present a coupled modelling approach for the noise prediction by impact piling with the focus being placed on a computationally efficient approach for the propagation of the sound field at large distances. The method extends the earlier works [7] by a far-range propagation module. The complete model comprises two modules: i) a near-source module aiming at the accurate description of the pile-water-soil interaction together with the sound generation and propagation in the pile vicinity [6], and ii) a far-from-source module aiming at the propagation of the wavefield at larger distances. The input to the far-from-source module is provided by the near-source module through the boundary integral formulation.

Section 2 introduces the mathematical statement of the problem together with the solution technique. In section 3, an experimental benchmark case is presented and measurement results are compared to model predictions. Finally, section 4 gives an overview of the main conclusions of the paper.

2 THEORY

The complete vibro-acoustic model for noise prediction in impact piling is shown in Fig.1. The pile is modelled as linear elastic thin shell occuping the domain $0 \leq z \leq L$. A vertical force $F(t)$ is applied at the top side of the pile. The ocean environment is modelled as an acousto-elastic layered waveguide. The fluid is modelled as a three-dimensional inviscid compressible medium with a compressional wave speed c_f and a density ρ_f occupying the domain $z_0 \leq z \leq z_1$ and $r \geq R$. The soil is described as a three-dimensional horizontally stratified elastic

continuum. Each soil layer is characterised by its density ρ_j, the compressional and shear wave speeds $c_{p,j}$ and $c_{s,j}$, and the compressional and shear damping coefficients $\alpha_{p,j}$ and $\alpha_{s,j}$, respectively. In the near-source module, the soil occupies the domain $z \geq z_1$ and is terminated at a large depth $z = H$ with a rigid boundary which has been shown not to affect the pile vibrations and noise generation in the vicinity of the pile [6]. In the far-from-source module, the soil extends to infinity in the vertical direction to accurately capture the energy loss mechanisms at larger distances from the pile.

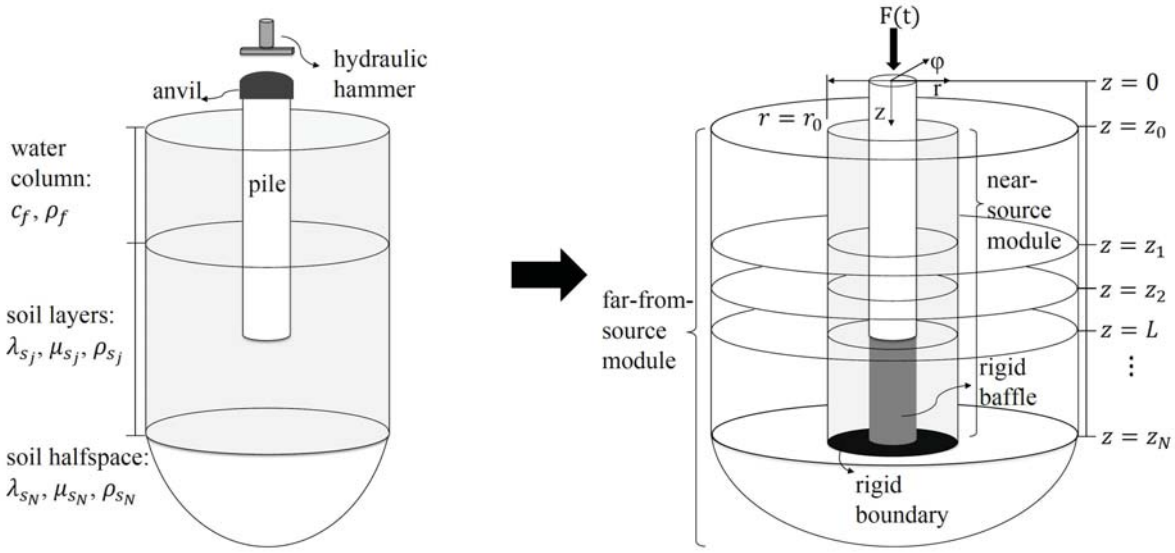

Figure 1: Geometry of the complete system (left) and the coupled modelling approach (right).

2.1 Governing equations

The equations of motion of the pile-soil-water system read [7]:

$$\mathbf{L}\,\mathbf{u}_p + \mathbf{I}_m\,\ddot{\mathbf{u}}_p = -\left[H(z-z_0) - H(z-L)\right]\,\mathbf{t}_s + \mathbf{f} \tag{1}$$

$$G_j\,\nabla^2\mathbf{u}_s^j + (\lambda_j + G_j)\,\nabla\nabla\cdot\mathbf{u}_s^j - \rho_j\ddot{\mathbf{u}}_s^j = \mathbf{0} \tag{2}$$

$$\nabla^2\phi_f(r,z,t) - \frac{1}{c_f^2}\ddot{\phi}_f(r,z,t) = 0 \tag{3}$$

In the equations above, $\mathbf{u}_p = [u_{p,z}(z,t)\ u_{p,r}(z,t)]^{\mathrm{T}}$ is the displacement vector of the mid-surface of the shell, $\mathbf{u}_s^j(r,z,t) = \left[u_{s,z}^j(r,z,t)\ u_{s,r}^j(r,z,t)\right]^{\mathrm{T}}$ is the displacement vector of each solid layer and $\phi_f(r,z,t)$ is a velocity potential introduced for the description of the fluid. The operators $\mathbf{L}$ and $\mathbf{I}_m$ are the stiffness and modified inertia matrices, respectively [6]. The vector $\mathbf{t}_s$ represents the boundary stress vector that takes into account the reaction of the soil and fluid surrounding the shell at $z_0 < z < L$. Naturally, in the domain $z_0 < z < z_1$ this reflects only the normal pressure exerted by the fluid normal to the surface whereas for $z > z_1$ both shear and normal stresses are present. The functions $H(z - z_i)$ are the Heaviside step functions which are used here to account for the fact that the soil and the fluid are in contact with a segment

of the shell in correspondence with Fig.1. The vector $\mathbf{f} = [f_{rz}(z,t)\ f_{rr}(z,t)]^{\mathrm{T}}$ represents the externally applied force on the surface of the shell.

A set of boundary conditions and interface conditions are formulated as follows for $r \geq R$:

$$p_f(r, z_0, t) = 0 \tag{4}$$

$$\sigma^1_{s,zz}(r, z_1, t) + p_f(r, z_1, t) = 0,\ \sigma^1_{s,zr}(r, z_1, t) = 0,\ u^1_{s,z}(r, z_1, t) - v_{f,z}(r, z_1, t) = 0 \tag{5}$$

$$\sigma^{j+1}_{s,zi}(r, z_j, t) - \sigma^{j}_{s,zi}(r, z_j, t) = 0,\ u^{j+1}_{s,i}(r, z_j, t) - u^{j}_{s,i}(r, z_j, t) = 0\,,\ 2 \leq j \leq N-1,\ i = z, r \tag{6}$$

$$u^N_{s,r}(r, z_N, t) = u^N_{s,z}(r, z_N, t) = 0 \tag{7}$$

where $p_f(r, z, t)$ indicates the pressure in the fluid, $\sigma^j_{s,zi}(r, z, t)$ represents the stresses in the soil at the corresponent layer j. In addition to Eqs. (4–7), the radiation condition needs to be satisfied at $r \to \infty$. In the far-from-source module, the boundary conditions at $z = z_N$ are substituted by the radiation condition at $z \to \infty$, which indicates that the bottom soil is modelled as elastic half-space.

2.2 Solution to the coupled problem

The complete solution to the coupled vibroacoustic problem consists of two modules: (i) the near-source module aiming at the noise generation and propagation in the vicinity of the pile; and (ii) the far-from source module aiming at propagating the field at larger distances from the pile.

2.2.1 Near-source module

The near-source module is based on a three-dimensional vibroacoustic model developed by Tsouvalas and Metrikine [6]. The module captures the characteristic of dynamic interactions between the pile and the surrounding media. A modal decomposition is applied both for the shell structure and the acousto-elastic waveguide as:

$$\begin{aligned}
\tilde{u}_{p,k}(z, \omega) &= \sum_{m=1}^{\infty} A_m\, U_{km}(z)\,, \\
\tilde{\phi}_f(r, z, \omega) &= \sum_{p=1}^{\infty} C_p\, H_0^{(2)}(k_p r)\, \tilde{\phi}_{f,p}(z)\,, \\
\tilde{\phi}_s(r, z, \omega) &= \sum_{p=1}^{\infty} C_p\, H_0^{(2)}(k_p r)\, \tilde{\phi}_{s,p}(z)\,, \\
\tilde{\psi}_s(r, z, \omega) &= \sum_{p=1}^{\infty} C_p\, H_1^{(2)}(k_p r)\, \tilde{\psi}_{s,p}(z)\,,
\end{aligned} \tag{8}$$

in which the subscripts p, f, s indicate the pile structure, fluid and soil, respectively, k refers to the displacement components r and z, the index $m = 1, 2, ..., \infty$ represents the mode number.

$H_n^{(2)}$ denotes the n^{th}-order Hankel function of the second kind which ensures that the radiation condition at $r \to \infty$ is satisfied at all times. The expressions for the displacement and the pressure/stress fields can be obtained through Helmholtz decomposition by substituting the potential functions. The coefficients C_p with $p = 1, 2, ..., \infty$ are the unknown modal amplitudes. The coefficients A_m are the modal amplitudes to be determined by solving the coupled problem. The terms k_p denote the horizontal wavenumber obtained by the formulation of the eigenvalue problem of the acousto-elastic region [8]. A system of infinite algebraic equations to the unknown coefficients C_p can be obtained [7]:

$$\sum_{q=1}^{\infty} C_q \left(L_{qp} + k_q \, H_1^{(2)}(k_q R) \, \Gamma_q \, \delta_{qp} - \sum_{m=1}^{\infty} \frac{R_{mq} \, Q_{mp}}{I_m} \right) = \sum_{m=1}^{\infty} \frac{F_m \, Q_{mp}}{I_m} \tag{9}$$

The coefficients of the shell structure are given by:

$$A_m = \frac{F_m + \sum_{p=1}^{\infty} C_p \, R_{mp}}{I_m} \tag{10}$$

The terms L_{qp}, Γ_q, Q_{mp}, R_{mp} and I_m are computed given the expressions in [6], which are omitted here for brevity. The eigenproblem of the shell and the surrounding acousto-elastic medium can be solved independently, which provide flexibilities in examining various configurations of the system.

2.2.2 Far-from-source module

To propagate the axisymmetric disturbances radiated from the pile into the surrounding medium, Green's tensors for a ring source emitting both compressional and shear waves are first derived. Assuming that a ring source is positioned at $\boldsymbol{r}_0 = (r_0, z_0)$, the wave equation in the Fourier-Hankel domain reads [9]:

$$\left[\frac{d^2}{dz^2} + k_{z,\xi}^2 \right] \hat{\Phi}_{\Xi,\xi}^{g}(k_r, z; r_0, z_0, \omega) = \frac{J_0(k_r \, r_0)}{2\pi} \, \delta(z - z_0) S_{\beta}^{\xi}(\omega) \tag{11}$$

in which ξ indicates the type of the sources considered; "f" being a fluid source, "p" a compressional source, and "s" being a shear source. The subscript Ξ represents the position of the receiver in the layered medium. $S_{\beta}^{\xi}(\omega)$ represents the source strength, which will be determined based on a unit impulse in β direction at source point $\boldsymbol{r}_0$ as discussed in section 2.2.3.

The solutions to Eq.(11) for the displacement potentials $\hat{\Phi}_{\Xi,\xi}^{g} = [\hat{\phi}_{f,\xi}^{g}, \hat{\phi}_{s,\xi}^{g}, \hat{\psi}_{s,\xi}^{g}]$ in the wavenumber domain are first derived for an acousto-elastic layered half-space. Applying the inverse Hankel transform yields:

$$\tilde{\Phi}_{\Xi,\xi}^{g}(\boldsymbol{r}; \boldsymbol{r}_0, \omega) = -\frac{1}{2} \int_{-\infty}^{+\infty} (S_{\beta}^{\xi}(\omega) \frac{e^{-\mathrm{i}k_{z,\xi}|z-z_0|}}{4\pi \mathrm{i} k_{(}z,\xi)} + A_{\xi}^{1} e^{\mathrm{i}k_{z,\xi}z} + A_{\xi}^{2} e^{-\mathrm{i}k_{z,\xi}z}) J_0(k_r \, r_0) H_0^{(2)}(k_r \, r) k_r dk_r \tag{12}$$

For $z \geq z_N$, $A_{\xi}^{1} = 0$ to ensure that the downward propagating waves *leave* the soil half-space without reflection. Upon substitution of the Eq.(12) into Eqs.(4–6), it becomes clear that the kernels in the integral representations need to be satisfied. This yields a linear algebraic system of equations with unknowns A_{ξ}^{1} and A_{ξ}^{2}. Once the amplitude coefficients are solved for every

k_r, the Green's tensor for any configuration of compressional or shear source potentials can be obtained.

To evaluate the wavenumber integral given by Eq.(12), the complex contour integration technique is applied. The solution can be expressed as a summation of a finite number of (normal) modes supplemented by Ewing-Jardetsky-Press (EJP) branch line integrations. The final expression of the Green's tensor in modal summation for the acousto-elastic domain considered here reads:

$$\begin{aligned}\tilde{\Phi}^{g}_{\Xi,\xi}(r,z;r_0,z_0;\omega) &= -\pi i \sum_{m=1}^{M}\left[\frac{\hat{\Phi}^{g,num}_{\Xi,\xi}(k_r,z;r_0,z_0)}{f'(k_r)} J_0(k_r\, r_0) H_0^{(2)}(k_r r) k_r\right]^{(m)} \\ &+ \frac{1}{2}\int_{\alpha+\beta} \hat{\Phi}^{g}_{\Xi,\xi}(k_r,z;r_0,z_0) J_0(k_r\, r_0) H_0^{(2)}(k_r r) k_r dk_r\end{aligned} \tag{13}$$

in which $\hat{\Phi}^{g,num}_{\Xi,\xi} = [\hat{\phi}^{g,num}_{f,\xi}, \hat{\phi}^{g,num}_{s_j,\xi}, \hat{\psi}^{g,num}_{s_j,\xi}]$ denotes the numerator of the solutions of the potential functions in Hankel domain. The characteristic equation $f(k_r)$, being the determinant of the coefficient matrix, is used to determine the horizontal wavenumbers $k_r^{(m)}$.

2.2.3 Direct boundary element integral

The direct boundary element method (BEM) is adopted in this model to couple the near-source and far-from-source modules. The solution of the wavefield in both acoustic and elastodynamic field employs Somigliana's identity in elastodynamics and Green's third identity in potential theory [9-11]. The boundary data is specified from the near-source module on a cylindrical surface at $r = r_0$ from the pile, i.e. section 2.2.1, are used as input to the far-from-source module via the BEM.

The fundamental solutions of Green's displacement tensors $\widetilde{U}^{\Xi\xi}_{\alpha\beta}(\boldsymbol{r},\boldsymbol{r}_0,\omega)$ are derived from the potential functions [12] given the receiver point at $\boldsymbol{r} = (r,z)$ (in medium Ξ) in α-direction due to a unit impulse at source $\boldsymbol{r}_0 = (r_0,z_0)$ (in medium ξ) in β-direction:

$$\begin{aligned}\widetilde{U}^{s\xi}_{\alpha\beta}(\boldsymbol{r},\boldsymbol{r}_0,\omega) &= \nabla\tilde{\phi}^{g}_{s_j,\xi}(\boldsymbol{r},\boldsymbol{r}_0,\omega) + \nabla\times W, \quad W = -\frac{\partial\psi^{g}_{s_j,\xi}(\boldsymbol{r},\boldsymbol{r}_0,\omega)}{\partial r} \\ \widetilde{U}^{f\xi}_{\alpha\beta}(\boldsymbol{r},\boldsymbol{r}_0,\omega) &= \nabla\tilde{\phi}^{g}_{f,\xi}(\boldsymbol{r},\boldsymbol{r}_0,\omega)\end{aligned} \tag{14}$$

For the elastic domain, the Green's stress tensors $\widetilde{T}^{\Xi\xi}_{\alpha\beta}(\boldsymbol{r},\boldsymbol{r}_0,\omega)$ related to $\widetilde{U}^{\Xi\xi}_{\alpha\beta}(\boldsymbol{r},\boldsymbol{r}_0,\omega)$ can be obtained through substitution of Eq. (14) into the constitutive equations [12]. The fundamental solution pair $\{\widetilde{U}_{\alpha\beta},\widetilde{T}_{\alpha\beta}\}$ can be obtained once the unknown source strengths $S^{\xi}_{\beta}(\omega)$ are determined. By employing the Green's displacement tensors in Eq.(14), the traction vector can be expressed through stress tensor as,

$$\tilde{\tau}_i = \tilde{\sigma}_{ij} n_j \tag{15}$$

where $\tilde{\tau}_i$ is the traction vector in i direction, n_j is the unit normal vector at the boundary. The condition of a unit impulsive load can be applied in the β-direction at the source $\boldsymbol{r} = \boldsymbol{r}_0$ by setting, :

$$\begin{bmatrix}\tilde{\tau}_\beta \\ \tilde{\tau}_\alpha\end{bmatrix} = \begin{bmatrix}\delta(\boldsymbol{r}-\boldsymbol{r}_0) \\ 0\end{bmatrix} \tag{16}$$

The solution of Eq.(16) yields the coefficients $S^{p}_{\beta}(\omega)$ and $S^{s}_{\beta}(\omega)$.

For the acoustic domain, the conventional boundary integral representation is the Helmholtz integral in terms of pressure or displacement potential. By taking the directional derivative of the displacement potential as stated in Eq.(14), the boundary integral formulation for the displacement can be obtained directly by setting $S^f(\omega) = 1$, which is analogous to the integral formulation in the soil.

By utilizing Betti's reciprocal theorem in elastodynamics [10] and Green's theorem for acoustic problem [11], the complete solution for the acousto-elastic domain reads:

$$\begin{aligned}\tilde{u}_\alpha^\Xi(\boldsymbol{r}) = &\sum_{\beta=r,z}\int_{S^s}\left(\widetilde{U}_{\alpha\beta}^{\Xi s}(\boldsymbol{r},\boldsymbol{r}_0,\omega)\cdot\tilde{t}_\beta^{\boldsymbol{n}}(\boldsymbol{r}_0,\omega) - \widetilde{T}_{\alpha\beta}^{\boldsymbol{n},\Xi s}(\boldsymbol{r},\boldsymbol{r}_0,\omega)\cdot\tilde{u}_\beta(\boldsymbol{r}_0,\omega)\right)dS_0^s(\boldsymbol{r}_0)\\ &+\int_{S^f}\left(\widetilde{U}_{\alpha r}^{\Xi f}(\boldsymbol{r},\boldsymbol{r}_0,\omega)\cdot\tilde{p}(\boldsymbol{r}_0,\omega) - \widetilde{T}_{\alpha r}^{\boldsymbol{n},\Xi f}(\boldsymbol{r},\boldsymbol{r}_0,\omega)\cdot\tilde{u}_r(\boldsymbol{r}_0,\omega)\right)dS_0^f(\boldsymbol{r}_0),\quad \boldsymbol{r}\in V\end{aligned} \tag{17}$$

where $\boldsymbol{n}$ is the outward normal to the cylindrical boundary. The superscripts of the Green's tensors, "f" and "s" indicate fluid and soil domains, respectively.

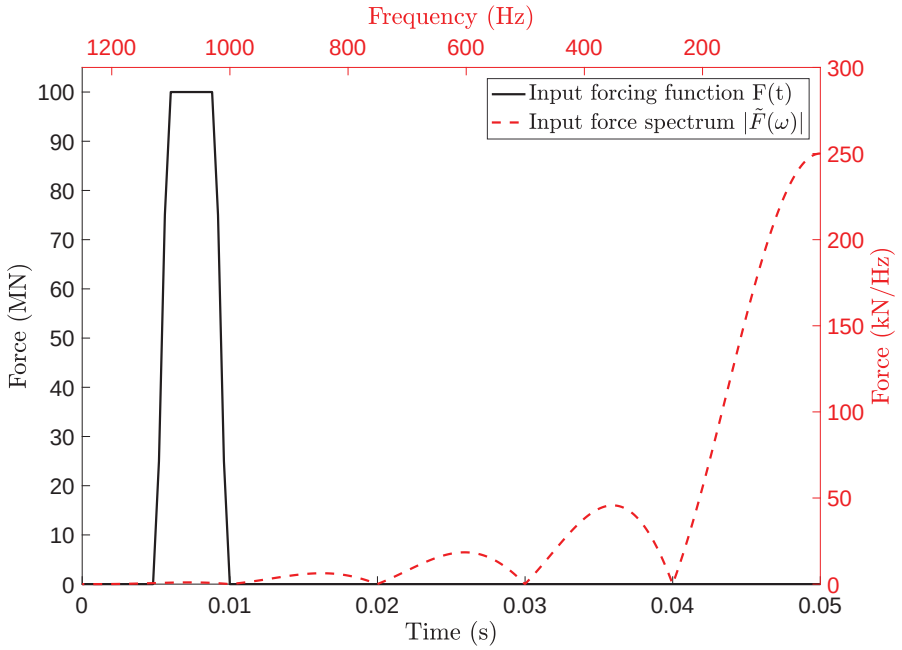

Figure 2: Input forcing function.

3 VALIDATION CASE STUDY

In order to validate the model, a benchmark case is considered with the measurement data recorded at offshore wind farm BARD Offshore 1 [5]. The material properties and the geometry of the model are given in Table 3 [5]. The seabed in the model consists of a thin marine sediment layer overlaying a stiffer soil half-space. The actual penetration depth of the pile was around 20 m. The pile was driven by a hydraulic hammer. The time signature of the applied force is the one shown in Fig.2, which generates approximately 1370 KJ blow energy into the system. The frequency spectrum is also given in Fig.2.

The peak pressure level (L_{peak}) and the sound exposure level (SEL) of receiver points at radial distances up to 1500m are shown in Fig.3. As can be seen, the difference between the

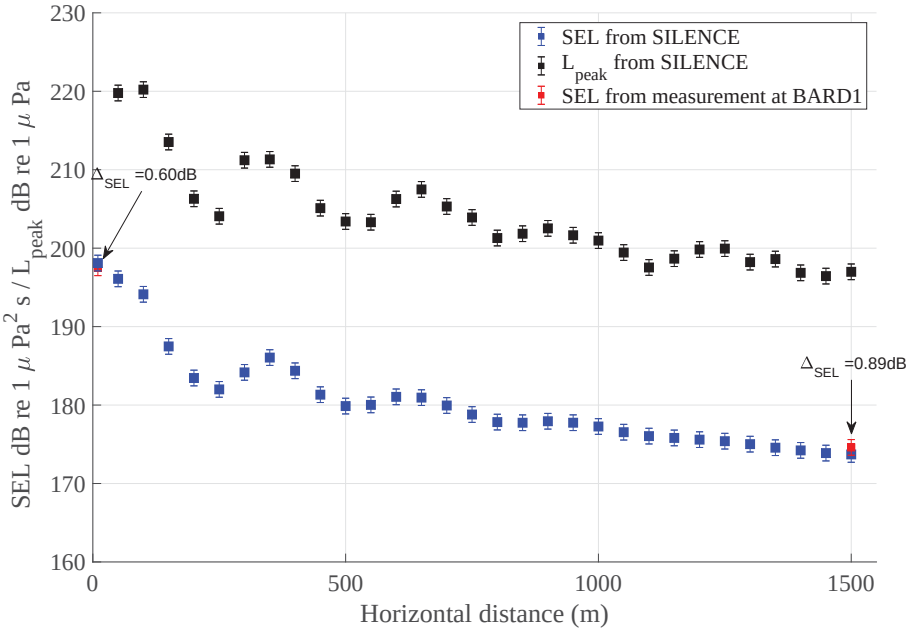

Figure 3: Comparison of SEL and L_{peak} at several radial distances from the pile and 2 m above the seabed.

Parameter	Pile	Parameter	Fluid	Upper soil	Bottom sediment
Length[m]	85	Depth [m]	40	2	48
Density [kg/m^3]	7850	ρ[kg/m^3]	1000	1888	1908
Outer diameter [m]	3.35	c_L [m/s]	1500	1705	1725
Wall thickness [mm]	70	c_T [m/s]	-	186	370
Final penetration depth [m]	20	α_p $[dB/\lambda]$	-	0.91	0.88
Maximum Blow Energy [kJ]	1370	α_s $[dB/\lambda]$	-	1.86	2.77

Table 1: Basic input parameters for the simulations.

predicted SEL and the measured values are 0.60 dB and 0.89 dB at 10m and 1500m radial distances from the pile respectively. The SEL indicates the averaged amount of energy radiated into the surrounding media and L_{peak} evaluates the impulsiveness of the pressure waves from the pile. The results verify the validity of the developed model, which can provide predictions that lies within the accuracy of the measurement equipment ($\pm$ 1 or 2 dB).

Figure 4 shows the pressure levels (dB re $1\mu Pa^2$/Hz) in 1/3-octave bands at various radial distances from the pile. Assuming that the energy in all the defined bandwidths (one-third octave) results from an effective source, the bandwidth energies add directly to give the total energy in one frequency band. The derivation of the sound pressure level in the unit of dB re 1 $\mu Pa^2 s^{-1}$ reads:

$$\mathrm{SPL}_{1/3-octave} = 10\log_{10}\sum_{i=m}^{n}\left(\frac{|\tilde{p}_i(\omega)|^2}{p_0^2}\right) \tag{18}$$

As can be seen in Fig.4, the spectrum shows that most of the energy is distributed at low frequencies, which is consistent with the 1/3-octave band spectrum obtained by measurement data and numerical results from FE-PE model in [5].

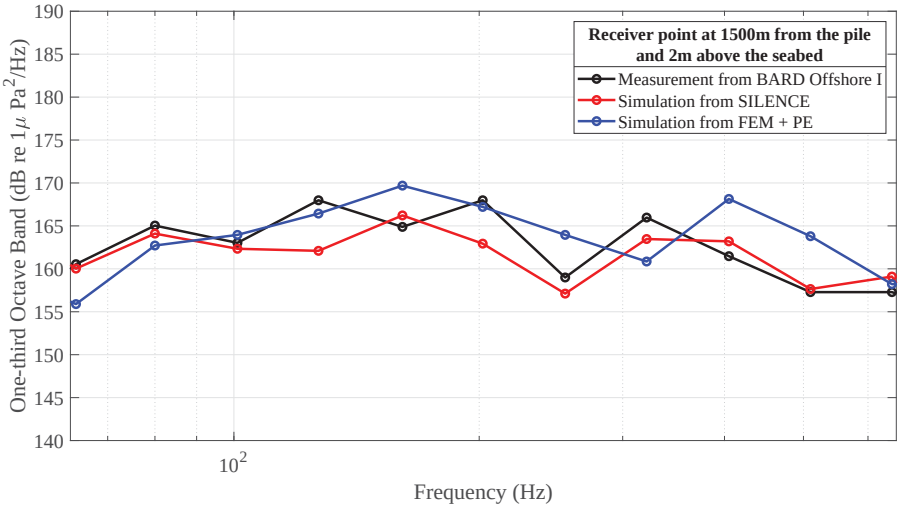

Figure 4: One-third octave band spectrum for a point positioned 2m above the seabed in the fluid and at r = 1500m from the pile.

4 CONCLUSIONS

The paper presents a computationally efficient coupled approach for noise predictions by offshore pile driving. The mathematical background of the generation and propagation of the sound field is given and the adopted method of solution is described. The direct boundary integral equation (BIE) formulation is adopted to propagate the radiated wave field from the near-source module to larger distances. A numerical analysis of a benchmark case is conducted, which verifies the validity of the model for the prediction of underwater noise from offshore pile driving. In the future, model predictions will be benchmarked against both numerical model predictions and available data from other measurement campaigns published in the scientific literature.

5 ACKNOWLEDGEMENTS

The authors gratefully acknowledge the China Scholarship Council (CSC) for financing this research project on the development of a generic underwater noise prediction model for offshore activities.

WAVE-RESOLVING AIRCRAFT FUSELAGE MODEL FOR CABIN NOISE PREDICTIONS UNDER DISTRIBUTED FLUID LOADINGS

Christopher Blech and Sabine C. Langer

TU Braunschweig
Institute for Acoustics
Langer Kamp 19
c.blech@tu-braunschweig.de

Keywords: cabin noise, aircraft, modelling, finite element method, seat, acoustic impedance

Abstract. *For the development of future passenger aircraft comprising novel technologies and designs, a reduction of cabin noise is one major aim. An analysis of the aircraft cabin sound pressure levels can be achieved by mechanical models. In opposite to energy-based methods, wave-resolving models allow a detailed investigation of distributed fluid loadings and the wave propagation within the fuselage. A turbulent boundary layer loading on the outer skin of the aircraft is investigated exemplary. As the loading bring along a specific footprint on the aircraft skin and the model resolves the bending waves, the load input can be applied directly. Besides the outer skin, the aircraft fuselage model considers the stiffeners, the insulation, the inner cabin lining and the cabin fluid of the entire cabin. Each part is validated separately and included in the aircraft fuselage model. The structural and fluid domains are fully coupled and discretised with finite elements using 2D shells and 3D continua resulting in millions of degrees of freedom. The simulation shall not model a specific aircraft, but rather demonstrate on the example of a generic research aircraft the crucial modelling and solving aspects of typical aircraft parts. Within this contribution, a section of the fuselage is presented having a specific focus on the cabin fluid modelling. The damping characteristics of the seats are considered by impedance boundary conditions within the 3D fluid domain and compared to a homogenising approach using a frequency-dependent damping loss factor. The necessary input parameters are measured in a reverberation chamber having available an aircraft seat bench. The numerical comparison of the modelling approaches in the fuselage model shows that local differences can be expected but in general the SPL is decreasing similarly with increasing frequency.*

1 INTRODUCTION

Facing an increasing demand for mobility, the number of flights is expected to raise significantly in future. Many passengers are exposed to cabin noise during flights. Under high noise levels, health and comfort issues may occur. A simulation of cabin sound pressure levels in early design stages can help to avoid a high exposure by integrating sound reduction measures if necessary.

Based on preliminary aircraft design data as provided in the Collaborative Research Center 880 [1], a wave-resolving fuselage model can be derived. The modelling of structure-borne sound waves in the primary and secondary structure and the fluid waves in the insulation and the cabin itself allows a detailed analysis of the sound transfer paths. As waves in all domains are considered, sound reduction measures like, e.g., acoustic black holes and their placement can be studied directly without any assumptions on their efficiency. Discretising and solving the model delivers the sound pressure level (SPL) distribution in the cabin under certain loads. Fluid loads like jet noise or the turbulent boundary layer (TBL) bring along a characteristic footprint on the outer skin. Only a correct consideration of phase differences and amplitudes of such loads ensure a precise prediction of cabin noise. Especially for novel aircraft concepts, resulting sound sources are not known and may be assessable through complex simulations. In [2], e.g., the cabin noise due to jet noise is investigated for a comparison of an UHBR engine with a conventional engine. The model is extended by a TBL load in [3] suggesting that this load might be one of the dominating loads in aircraft with UHBR engines.

However, appropriate modelling assumptions for all fuselage parts are required in order to receive reasonable responses in the cabin. The cabin fluid itself including seats and passengers is expected to play a major role in the entire model. Hence, a comparison of models of different complexity is aimed for in this contribution. Simple approaches considering a homogenised cabin fluid offer a simple and fast modelling procedure. A detailed consideration of seats is more complex but may offer crucial quality differences in the model. A boundary element solution of an aircraft passenger cabin is applied in [4] to the cabin fluid of an aircraft segment. The numerical model is compared to experiments – differences are mainly attributed to the neglected influence of the surrounding structure. In the model applied here, all surrounding structures are considered. Qualitatively, in [4], the numerical sound pressure distribution near the seats matched experimental results under a consideration of impedance boundary conditions for the seat surfaces. Hence, this shall be the local approach applied here within the fuselage model described in the next section.

2 FUSELAGE MODEL

The preliminary design data by the design tool PrADO [1, 5] within the CRC 880 provides a dimensioning of the entire primary structure of a virtual research aircraft for 100 passengers. For the purpose of cabin noise simulations, these information on materials, thickness distribution and cross-sections are automatically transferred into a finite element shell model of the outer skin, the stiffeners and the floor section. In Fig. 1, the FE model of the fuselage is shown. Basically, the model underlies the assumptions of linearity and symmetry. For simplicity, a small model with three seat-rows is applied in this study. Curved sandwich plates fixed to the stiffeners are considered as typical inner sidewall and ceiling panels with a constant thickness of 0.01 m. An aramid honeycomb core is homogenised to a 3D continuum meshed by 27-node quadratic hexahedrons while a glass-fibre-reinforced plastic layer is modelled at each side by shell elements perfectly fixed to the honeycomb core.

The double wall gap between outer skin and inner cabin linings is filled by glass wool. The fibres material is considered as homogenised 3D equivalent fluid volume meshed by hexahedrons as well. The passenger cabin itself is basically filled by air with typical density, temperature and humidity values of the cabin air in cruise. Different modelling approaches for the cabin fluid volume including damping, reflection and refraction of the aircraft seats shall be in focus of this contribution. As visible in Fig. 1, seat domains are already separated in groups in order to apply different modelling approaches keeping the finite element mesh unchanged.

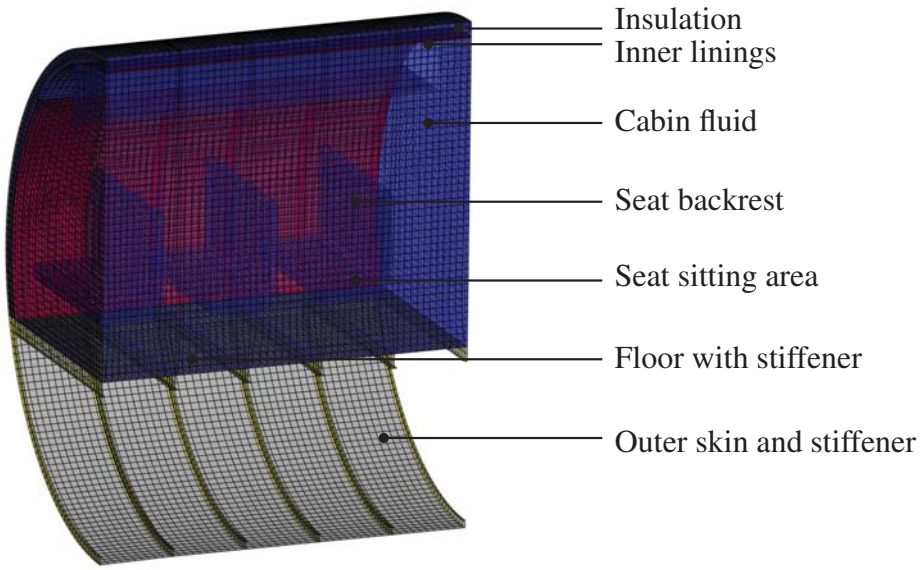

Figure 1: Meshed fuselage section model including structural and fluid domains; Symmetry boundary conditions are applied.

Fluid and structural domains are strongly coupled resulting in a total computational cost of $7.3\,\mathrm{min}$ per frequency step[1]. As exemplary load for a comparison of the cabin models, an artificially generated TBL load is considered as described in detail in [3].

3 MODELLING ASPECTS IN THE PASSENGER CABIN

In previous studies of the aircraft model from Sec. 2 which can be found in [2, 6, 3], a homogeneous constantly damped Helmholtz fluid domain is considered according to Eq. 1. A constant complex speed of sound $\underline{c}$ is applied for the entire fluid in order to consider the damping properties of seats and passengers. $\underline{p}$ is the sound pressure, ω is the angular frequency and $\mathbf{x}$ is the location in the aircraft cabin.

$$\nabla^2 \underline{p}(\mathbf{x},\omega) + \frac{\omega^2}{\underline{c}^2}\underline{p}(\mathbf{x},\omega) = 0 \tag{1}$$

$\underline{c}$ is calculated according to Eq. (2) by use of the fluid loss factor η_f and the imaginary unit i [7].

$$\underline{c}^2 = c^2\,(1 + i\eta_f) \tag{2}$$

[1]Using the direct MUMPS solver and the institute's in-house code elPaSo at 20 cores on the phoenix cluster of TU Braunschweig

In order to assess the consideration of $\underline{c} = const$, the model complexity is increased in this contribution. As the surrounding structures of the cabin (sidewall panels, floor) are considered with material damping properties in the model, the seats and the passengers are mainly expected to influence the cabin fluid domain. For the purpose of experimental studies on the damping characteristics of seats, three aircraft seats are available which are shown in Fig. 2 (a). As sketched in Fig. 2 (b), each seat is transformed to simplified cornered domains and considered as separate block in the FE model. Two approaches are investigated: A frequency-dependent loss factor and an introduction of surface impedances for the seat rows.

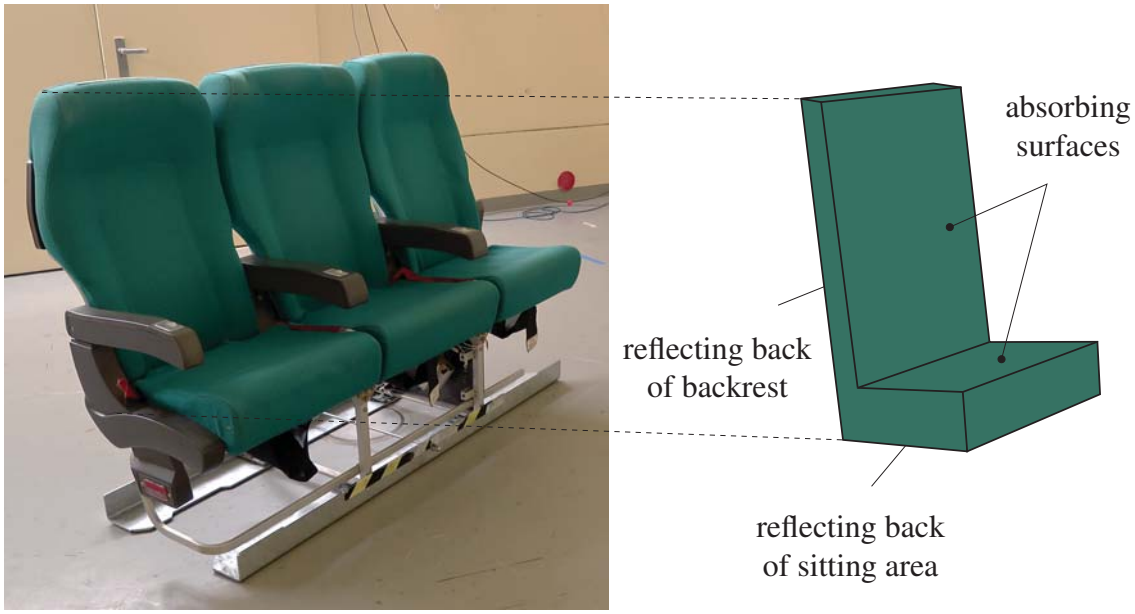

Figure 2: (a) Aircraft seats in reverberation chamber and (b) sketch of simplified seat assembly.

A first extension of the previous model is a consideration of a **frequency-dependent loss factor** $\eta_f(f)$ leading to a frequency-dependent speed of sound $\underline{c}(f)$ (Eq. (2)). The frequency-dependent parameter is yielded by measurements. The reverberation time $T_r(f)$ is measured in a reverberation chamber resulting in the equivalent absorption area $A_t(f)$ according to DIN ISO 354 [8] for the three seats shown in Fig. 2. The equivalent absorption area of three seats is linearly scaled to 100 seats which neglects any influences between seat rows. The effect of passengers has been studied as well, but the change of $A_t(f)$ is not significant. For the equivalent absorption area with 100 seats $A_{t,100}(f)$, the reverberation time $T_{r,\mathrm{cabin}}$ is calculated according to Eq. 3 [8] inserting the properties of the passenger cabin.

$$T_{r,\mathrm{cabin}}(f) = \frac{55.3 V_{\mathrm{cabin}}}{\left(A_{t,100}(f) + 4 V_c m_{\mathrm{cabin}}(f)\right) c} \tag{3}$$

$V_{\mathrm{cabin}} = 118\,\mathrm{m}^2$ is the fluid volume in the cabin and $m_{\mathrm{cabin}}(f)$ is the air absorption coefficient. Finally, $\eta_{\mathrm{cabin}}(f)$ is related to $T_{r,\mathrm{cabin}}(f)$ as given in Eq. (4) [9] with frequency f.

$$\eta_{\text{cabin}}(f) = \frac{2.2}{f T_{r,\text{cabin}}(f)} \tag{4}$$

In Fig. 3, the resulting loss factor is shown. In the low frequency range ($< 250\,\text{Hz}$), a homogenised loss factor of $3\,\%$ can be expected by the seat cushions. With increasing frequency, the loss factor decreases to $1\,\%$ damping at $1000\,\text{Hz}$. As most passenger cabins are similarly designed, a transferability of these results is expected to a certain extent.

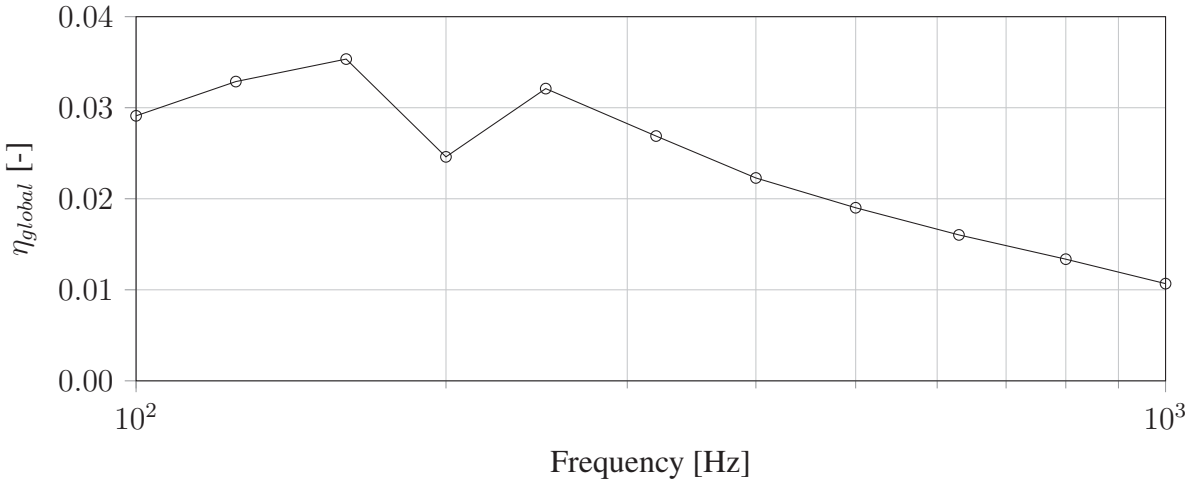

Figure 3: Homogenised loss factor in the cabin with volume $V_c = 118\,\text{m}^2$ for 100 passengers based on measurement of the reverberation time of three seats.

The second approach is similar to the above described approach by [4] – an acoustic **surface impedance** $\underline{Z}_a$ according to Eq. 5 [10] is placed in the fluid domain for the seat's backrest and the sitting area. The seat positions are given by the preliminary design data.

$$\underline{Z}_a(f) = \frac{\underline{p}(f)}{\underline{v}_n(f)} \tag{5}$$

The impedances are experimentally determined in the reverberation chamber as well. By placing an intensity probe near the surface, $\underline{p}$ and $\underline{v}$ are calculated on the basis of the two pressure signals and the cross-correlation of these. This way, the impedances of the surfaces (backrest and sitting area) are approximately given. The results for the $\underline{Z}_a$ are depicted in Fig. 4. In the low frequency range ($< 250\,\text{Hz}$), the values show high variations which is consistent with findings in [11]. In these frequency ranges, rather a smoother curve is expected which can be shown by comparing with porous material models or impedance tube measurements. With increasing frequency, the real part of the impedance converges to the impedance of air (blue curve) which is physically reasonable as the absorption performance of the seat cushion is expected to increase with reduced wave lengths.

As shown in Fig. 5 (b), the meshed cabin fluid volume assigned to the seat row is substituted by the surface impedance. This means, the finite elements in these regions are removed introducing a reflecting surface at the back of each seat cushion besides the impedance at the front of each seat cushion (backrest and sitting area). For the homogenised approach (Fig. 5 (a)), the mesh is the same including the filled gap. Here, no reflecting boundaries are introduced.

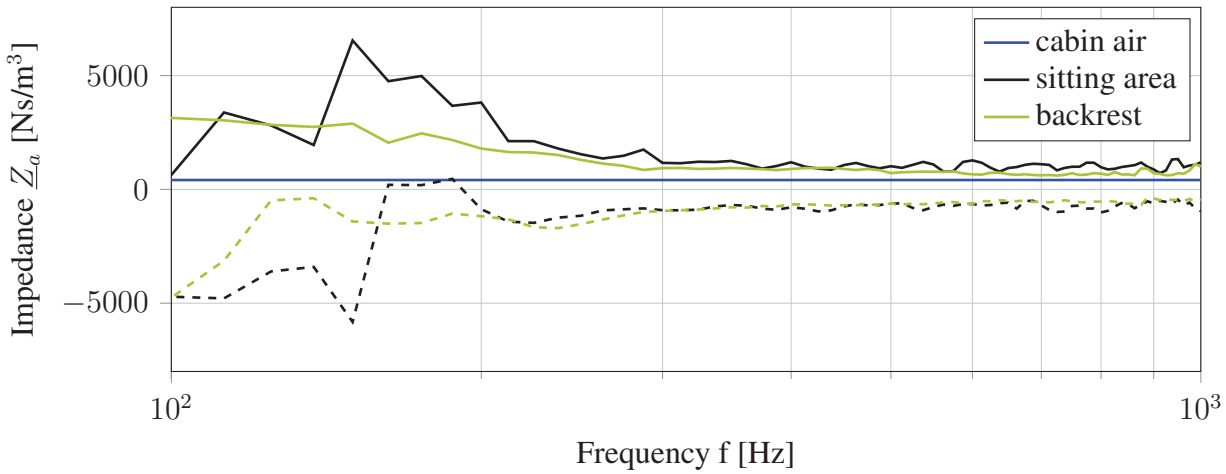

Figure 4: Acoustic impedances measured near the seat surfaces; The dotted lines are the imaginary parts.

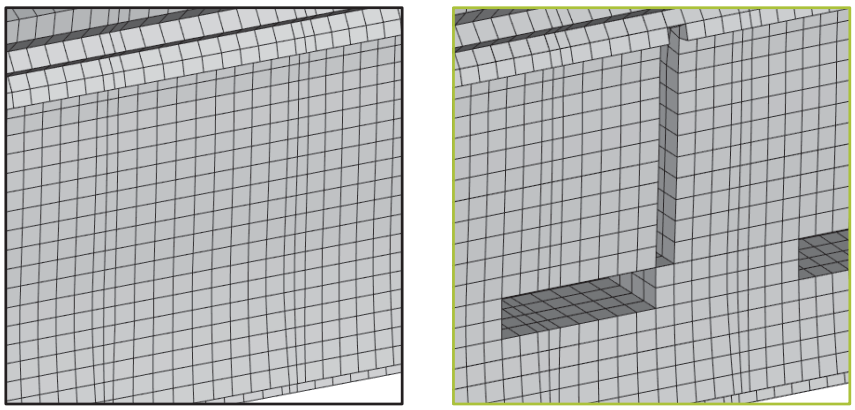

Figure 5: (a) Continuous mesh for homogenised approach; (b) Removed elements in seat region.

By removing the elements in the cabin fluid domain for the seat model, the computational costs are reduced by 17 % in comparison to the homogenised approach. Of course, the modelling effort is higher as the seat volumes must be considered in the model. In the vicinity of the sidewall panels, the meshing procedure is slightly more complex.

4 RESULTS

In Fig. 6, the SPL is plotted for the two described modelling approaches. The position corresponds to the seat in the central row near the sidewall panel. The height is chosen in accordance with a typical passenger ear height. Basically, the two SPL curves are similarly decreasing over frequency and show comparable basic sound levels. The overall damping characteristics seem similar as the dynamics of both curves is comparable as well. For a fast comparison of aircraft configurations (e.g. in third octave bands), the global loss factor may be appropriate in order to save modelling effort and avoid further mistakes during the introduction of impedances and reflecting boundaries. Furthermore, the impedance approach brings along several assumptions

like one impedance value at normal sound incidence which requires a more critical interpretation of results.

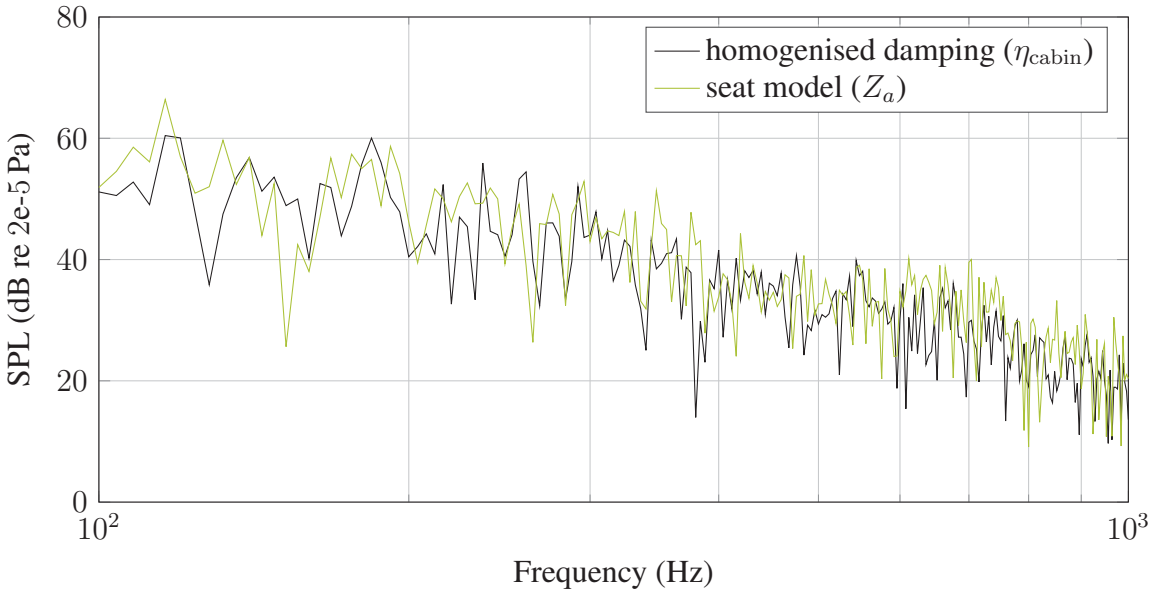

Figure 6: Sound pressure level at central seat position near the sidewall panel under TBL load with two different modelling approaches for the cabin.

Having a closer look, some resonances occur in both approaches (e.g. around 300 Hz and 530 Hz) but in most frequency regions there are local differences up to 10 dB and slightly more resonances in the response of the seat modelling approach. In the case of the local seat model, standing waves between seat rows and acoustic effects near seats can occur besides global resonances of the entire cabin fluid. In Fig. 7, pressure distributions in a cabin slice are shown for several frequencies. For the global pressure distribution at 168 Hz, for instance, only a slight distortion of the global shape is observed. For shapes in longitudinal direction as, e.g. seen at 184 Hz, the backrests of the seats seem to have a major influence. Furthermore, as it can be observed at 232 Hz, local effects (here below the seat sitting area) occur.

Concluding the results, detailed seat models seem necessary for applications or analyses which require a knowledge of local effects. For a rough and global comparison of the sound pressure levels, a global loss factor is appropriate. For active sound reduction measures, like noise cancelling in aircraft cabins, these local information are crucial and a seat model must be considered. Also, for a detailed investigations of tonal components like propeller noise, a seat model should be preferred in order to cover local effects at specific frequencies which might interfere with the tonal noise transferred into the cabin.

5 CONCLUSION

In this contribution, the SPL in an aircraft cabin is simulated using a finite element model of a typical fuselage section under an artificially generated TBL load. A comparison of two different modelling approaches is conducted – a homogenised damping loss factor for the entire cabin fluid is compared to a local modelling of seats introducing local impedances for the seat cushions. Both input parameters are frequency-dependent and received by measurements of a real seat bench. The resulting SPL at one passenger ear delivers comparable results regarding

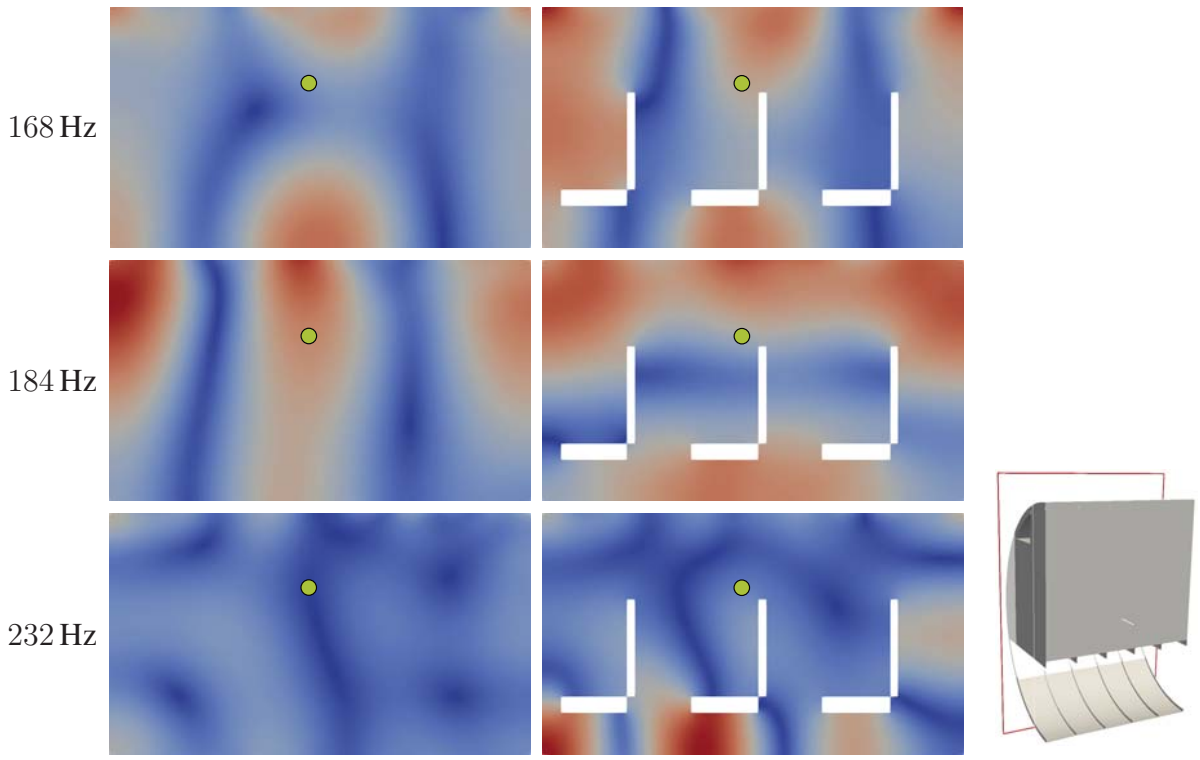

Figure 7: Qualitative pressure distribution in slices of the passenger cabin fluid; Each row refers to one example frequency with identical contour map ranges per row; The evaluation position for Fig. 6 is indicated by the green dots.

basic sound levels and damping performances over frequency. A detailed comparison of the pressure distribution in the cabin shows local effects at and between seat rows which lead to differences up to 10 dB in the model response.

For studies in future, a consideration of few tria elements in the volume mesh and non-coincident meshes in general may reduce the modelling effort. In addition, a consideration of porous material domains for the seat cushions might be a third approach. Furthermore, an experimental setup without surrounding aircraft parts seems reasonable in order to validate the local approach using impedances and reflecting backs of the seats. Finally, a more precise measurement of the seat impedances, especially for lower frequencies, is aimed for in future.

6 ACKNOWLEDGEMENT

The authors would like to thank the Collaborative Research Center 880 (Sonderforschungsbereich 880) of the German Research Foundation (Deutsche Forschungsgemeinschaft) and its graduate research program Graduate College for the financial support.

Special thanks go to the German Aerospace Center (DLR) Braunschweig for providing the aircraft seats and to the Physikalisch-Technische Bundesanstalt (PTB) Braunschweig for conducting measurements in their reverberation chamber.

Keywords: Vibroacoustics, Noise Control, Statistical Energy Analysis, Numerical Modeling.

Abstract. *Acoustical and structural systems are often found in engineering, whose importance of dynamic responses to random excitation is extended to high frequencies. On vibroacoustics, the prediction of the sound transmission loss and damping of a structural element in full spectral range is important for design purposes in many areas, like the automotive and aerospace industry. In the context of noise control, Statistical Energy Analysis (SEA) coupled with the Transfer Matrix Method (TMM) is widely used in high-frequency modeling of multilayered systems. Two mechanisms are involved in the application of a noise control treatment: the sound insertion loss (IL) and the damping loss factors of the equivalent systems. The first one is related to the transmission loss (TL) of the layers and, conceptually, is defined as the ratio between the acoustic TL of an treated panel over the TL of the panel without the attached treatment. The second one is related to the dissipative part that imposes acoustic or structural damping to the medium in contact with the treatment surfaces. This work presents a theoretical review involving the SEA approach coupled with the TMM for modeling the Sound Transmission Loss of treated subsystems. Additionally, implementing strategies are presented for considering this kind of wave approach in a SEA model. The results obtained from the SEA-Toolbox, a new open-source code developed in this project, are compared with experimental data.*

1 INTRODUCTION

Acoustical and structural systems are often found in engineering, whose importance of dynamic responses to random excitation is extended to high frequencies. Examples of such situations include:

- The structural response of an aerospace payload in flight;
- The vibration result of a structure under diffuse field conditions;
- The calculation of sound pressure into a car;
- The dynamical analysis of an aircraft structure (fuselage) due to jet noise and other dynamical sources;
- The sound transmission between partitions in a building;
- The knowledge of marine structures excited by intense vibration.

Statistical Energy Analysis (SEA) can be used for modeling a given system as an interaction of modes associated with isolated parts of the system (subsystems), considering each mode group as a single-degree-of-freedom oscillator described by the average energy response. The responses are obtained from the analysis of the energy distribution through the system, excited by a power source. This technique is based on the power balance equations for each mode group [1].

Some hypotheses are assumed in the determination of a model in SEA. The most important is that the vibration energy varies from one subsystem to another with a rate proportional to the difference between the modal energy and the proportionally dissipated energy within each subsystem. Another important hypothesis assumes weak coupling between subsystems. The weak coupling condition is valid if the internal dissipation of the subsystem is more important than the coupling path in the total loss of energy. It makes the ratio between the coupling factors and the internal dissipation factors considerably less than 1. Thus, the energy flow between the subsystems may be based on the difference between the energies of the decoupled subsystems [2, 3]. Additionally, it is important to ensure that the input powers are uncorrelated, and they can be simply summed. It guarantees the linearity of the equations that govern the SEA problem.

This paper concerns on the presentation and validation of the SEA Toolbox, an open source code that has been developed in the present project. In this version, the main connection types are implemented between beams, plates and acoustic subsystems. From the coupling between SEA and the Transfer Matrix Method (TMM) [4, 5], it is also possible to model plates and cavities with attached noise control treatments. An overview concerning the implementation of the method is presented and the Transmission Loss of treated subsystems obtained from the in-house code is compared with experimental data collected from the bibliography [6].

2 FUNDAMENTALS

In SEA the system is divided into physical elements in which the vibroacoustic characteristics, such as damping, excitation and coupling properties, can be considered similar. Subsystems directly excited by external sources will transmit a portion of energy to the others by means of coupling characteristics. The main mechanism in SEA is based on the relationship between power inputs and outputs from each subsystem. Figure 1 shows a simple problem of sound transmission loss in the SEA point of view.

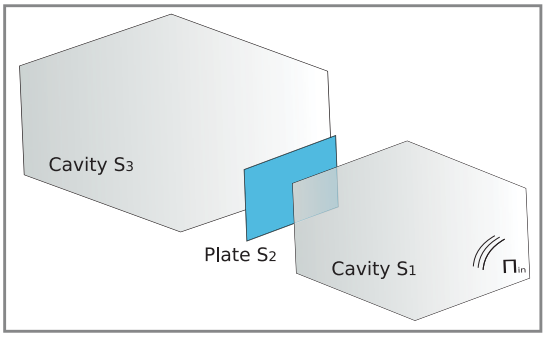

Figure 1: Example of a sound transmission loss problem.

Figure 1 shows the coupling of 3 SEA subsystems. However, it is common to have more robust models with a high number of elements. Considering a subsystem i coupled to a number of n subsystems, the power flow is [1, 2]

$$\Pi_i^{in} = \Pi_i^{\text{absorbed}} + \sum_{j \neq i}^{n} \Pi_{i;j}^{\text{transmited}} \ . \tag{1}$$

Equation (1) shows that there are a dissipated portion of the input power into a subsystem (controlled by the dissipation loss factor) and a transmitted portion of this power, controlled by the coupling loss factors. The transmitted powers by the coupling between subsystems will depend on the radiation characteristics and differences between the environments.

Considering a 3-subsystems problem, where the subsystem 1 is excited by an input power, as shown in Figure 1, the power flow can be illustrated by Figure 2.

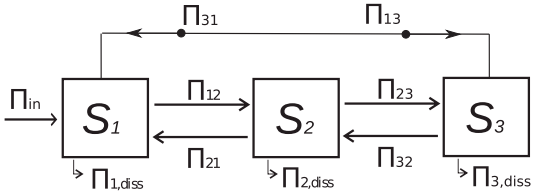

Figure 2: SEA flow for the cavity-plate-cavity problem.

It is possible to obtain the equations of the power flow illustrated in Figure 2, for each subsystem, as

$$\begin{aligned}
&\text{Subsystem 1:} && \Pi_{in} + \Pi_{21,trans} + \Pi_{31,trans} = \Pi_{1,diss} + \Pi_{12,trans} + \Pi_{13,trans} \\
&\text{Subsystem 2:} && \Pi_{12,trans} + \Pi_{13,trans} = \Pi_{2,diss} + \Pi_{21,trans} + \Pi_{31,trans} \\
&\text{Subsystem 3:} && \Pi_{23,trans} + \Pi_{13,trans} = \Pi_{3,diss} + \Pi_{31,trans} + \Pi_{32,trans} \ .
\end{aligned} \tag{2}$$

The power Π is related to the energy from

$$\Pi_i = \omega \eta_i E_i \ , \tag{3}$$

where ω is the angular frequency, η is the loss factor and E is the energy of a subsystem. Then, the dissipated power and the transmitted power will be given by

$$\Pi_{i,diss} = \omega \eta_{i,diss} E_i \qquad [i = 1, 2, 3] \ ; \tag{4}$$

$$\Pi_{ij,trans} = \omega \eta_{ij} E_i \qquad [i \neq j]. \tag{5}$$

being η_{ij} the coupling factor between the subsystems i and j.

Substituting Equation (4) and (5) into (2), the following linear system is obtained

$$\omega \begin{bmatrix} \eta_{1,diss} + \eta_{12} + \eta_{13} & -\eta_{12} & -\eta_{13} \\ -\eta_{21} & \eta_{2,diss} + \eta_{21} + \eta_{23} & -\eta_{23} \\ -\eta_{31} & -\eta_{32} & \eta_{3,diss} + \eta_{31} + \eta_{32} \end{bmatrix} \begin{Bmatrix} E_1 \\ E_2 \\ E_3 \end{Bmatrix} = \begin{Bmatrix} \Pi_{in} \\ 0 \\ 0 \end{Bmatrix} . \tag{6}$$

It can be observed that the SEA method is based on the resolution of linear systems for calculating the energy for each subsystem. The determination of damping variables for more complex systems is based on theoretical models or from direct experimental data. However, if the modal density of the subsystems involved in the problem are known, the coupling loss factor in one direction is required, and the following consistency ratio is valid to complement the damping matrix

$$n_i \eta_{ij} = n_j \eta_{ji} \ , \tag{7}$$

where n_i e n_j are the modal densities of the subsystems i and j, respectively. Theoretical models for the modal densities of flat plates and rectangular cavities can be found in [1, 3].

For the problem illustrated in Figure 1, the mean square value of the pressure inside the cavities $p_i^2 = E_i \rho_i c_i^2 / V_i$ can be recovered from the solution, with ρ_i being the fluid density, c_i the sound velocity and V_i the volume of the cavity $i = 1, 3$. The transmission loss of the partition can be calculated as [7]

$$TL = 10 \log_{10} \left(\frac{p_1^2}{p_3^2} \right) + 10 \log_{10} \left(\frac{S}{A_{eq}} \right) \ , \tag{8}$$

where $A_{eq} = 4 \omega V_3 \eta_{3,diss} / c_3$ is the equivalent absorption area of the reception cavity and S is the area of the panel.

2.1 The cavity-plate-cavity connection

The coupling between the three subsystems showed in Figure 1 is controled by diferent propagation paths. The most important ones are controled by the resonant and non-resonant sound transmission. The first one is affected by the radiation capacity of the structural system and is important in frequencies above the coincidence spectral region of the plate. On the other hand, the non-resonant path is controled by the mass of the structure and it is important for global responses below the coincidence frequency [8]. The radiation loss factor that models the connection between plate s and cavity a is given by

$$\eta_{sa} = \eta_{rad} = \frac{\rho_a c_a S_s}{\omega M_s} \sigma_{rad} \, , \tag{9}$$

with ρ_a being the fluid density, c_a the fluid sound velocity, S_s the area of the partition, M_s the structural mass and σ_{rad} the radiation efficiency of the structural system that can be recovered in theoretical models as that one proposed by Leppington [9]. The non-ressonant loss factor that models the coupling between two cavities i and j is

$$\eta_{ij} = \eta_{mass} = \frac{c_i A_i \tau_m}{4\,\omega\, V_i} \ , \tag{10}$$

where A is the total surface area, V is the volume of the cavity and τ_m is the mass controled transmission coefficient of the system. In this work, the field incidence transmission coefficient presented in [8] was used.

2.2 Noise control treatments modeling using transfer matrices

Multilayer panels are often used in the context of noise control. The mechanisms involved in the application of a noise control treatment (NCT) on a face of a structural system are: the sound insertion loss (IL) that can change the acoustic radiation and the mass law transmission of the structure, the sound absorption seen by the acoustic medium in contact with the surface of the treatment and the added structural damping. The methodology of the Transfer Matrix Method (TMM) [4] is based on the theory of plane wave propagation in a given layer. The material of each layer is assumed homogeneous, transversely isotropic and the surface of the treatment is considered infinite in this formulation. Figure 3 shows an incident plane acoustic wave upon a media with thickness h, at an incident angle θ.

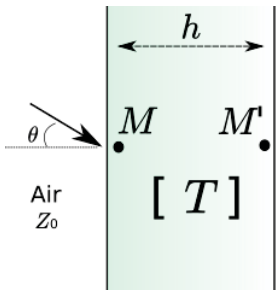

Figure 3: Ilustration of an infinite extent layer on the Tranfer Matrix Method.

The sound propagation inside the layer is represented by a transfer matrix T such that

$$V(M) = [T]V(M') \ , \tag{11}$$

where V is a vector containig the response for each degree of freedom of the media at the points M and M' set close to the foward and the backward of the layer [4]. The matrix T depends on the physical propierties as well as the thickness of the medium. If considering the layer illustrated in Figure 3 as an equivalent fluid, the vector $V = \{p, v\}^{\mathrm{T}}$ is composed by the pressure and the particle velocity. The transfer matrix T^f, in this case, is given by

$$[T^f] = \begin{bmatrix} \cos(k_x h) & \mathrm{j}\,\frac{\omega\rho_0}{k_x}\sin(k_x h) \\ \mathrm{j}\,\frac{k_x}{\omega\rho_0}\sin(k_x h) & \cos(k_x h) \end{bmatrix} \ , \tag{12}$$

where $k_x = \sqrt{k_c^2 - k_0^2 \sin^2(\theta)}$ is the longitudinal component of the wavenumber into the layer, k_c being the propagating wavenumber of the material, k_0 and ρ_0 the wavenumber and density

of the air. The continuity between adjacent layers is applied and a global transfer matrix $[T_g]$ is constructed according to the references [4] and [5]. The acoustic properties depend on the surface impedance computed from the ratio between pressure and velocity $p(M)/v(M)$, obtained from the solution of a linear system $V = [T_g]^{-1}\{F\}$.

2.2.1 Insertion Loss (IL) from the TMM

The Insertion Loss is defined as the ratio between the acoustic TL of a panel with the attached treatment over the TL of the unteated panel. This parameter can be calculated from the TMM simulation if considering a semi-infinite fluid as the boundary condition. The insertion coefficient IC will be given by

$$IC(\omega) = \frac{\int_0^{\theta_f} |T_{NCT}(\omega,\theta)|^2 \sin(\theta)\cos(\theta)\mathrm{d}\theta}{\int_0^{\theta_f} |T_{bare}(\omega,\theta)|^2 \sin(\theta)\cos(\theta)\mathrm{d}\theta} \ , \tag{13}$$

where θ_f is the final incidence angle, T_{NCT} and T_{bare} are the transmission coefficients of the treated and untreated infinite extent systems, respectively. In order to solve this problem, the bare panel is considered as the first solid layer in the TMM simulation. The insertion loss $IL(\omega) = -10\log_{10}(IC(\omega))$ is recovered from the insertion coefficient. Finally, the insertion loss from TMM is applied as a scaling factor to the radiation and the mass law coupling loss factors in the SEA problem [5], then

$$\eta_{rad} = \eta_{rad}\, IC(\omega) = \eta_{rad}(10^{-IL(\omega)/10}) \ ; \tag{14}$$

$$\eta_{mass} = \eta_{mass}\, IC(\omega) = \eta_{mass}(10^{-IL(\omega)/10}) \ . \tag{15}$$

With *SEA-Toolbox*, it is possible to model equivalent fluids, solids and poroelastic materials, over the incidence range from 0 to $\pi/2$.

3 METHODOLOGY

The present study consists of testing the functionality of Statistical Energy Analysis coupled with the Transfer Matrix Method for Transmission Loss problems. The SEA simulation of two acoustic cavities with a multilayered partition was done and the obtained results were compared with experimental data extracted from reference [6]. The experimental study was developed at the Laboratory of Vibration and Acoustics of the Federal University of Santa Catarina - Brazil and folowed the guidelines of the ISO 10140-2 standard [7]. Kulakauskas [6] presented a numerical and experimental evaluation of the sound transmission loss for single and double-wall setups using different porous samples.

In this work, the single and double-wall setups were reproduced in the new open-source code (*SEA-Toolbox*) using two different porous samples, considering the SEA implicit approach. It means that the multi-layer structures were represented by applying the obtained Insertion Loss from the TMM analysis to the SEA coupling factors (see Equations 9 and 10), as illustrated in Figure 4.

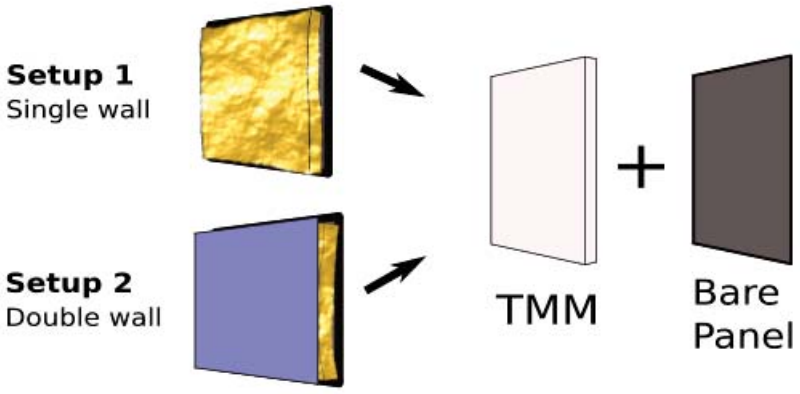

Figure 4: Ilustration of the simulated systems.

Based on the experimental procedure, the porous samples were modeled as simply supported limp fibers. The Johnson-Champoux-Allard model [10, 11] was used for the characterization of the fluid part in addition to the equivalent density calculated from the simplification of the Biot's Theory for low-stiffness framed materials [4]. This approach avoids artificial clamping between the plate and the porous material, but in case of using the full Biot's Theory (poroelastic material), an air gap should be applied between the structure and the foam to simulate the cited mounting condition. The properties for the solid structures and fibers considered in this work are presented in Table 3.

Table 1: Material properties of the setups considered in this work.

	Solid		**Porous**	
	Plate 1	**Plate 2**	**Material A**	**Material B**
Thickness h [mm]	1.0	0.5	50	58
Young's Modulus E [Pa]	71E9		-	-
Poisson's ratio ν [-]	0.33		-	-
Density ρ [kg/m^3]	2700		27	9.6
Flow Resistivity σ [kN/m^4]	-		5	38.72
Porosity ϕ [-]	-		0.89	0.92
Tortuosity α_∞ [-]	-		1.37	1.06
Viscous charac. length Δ [μm]	-		213	37
Thermal charac. length Δ' [μm]	-		288	148

As already mentioned, the SEA simulation consists of 3 subsystems illustrated by Figure 1. The emission (S1) and reception (S3) cavities have a volume of 147.54 m^3 and 199.0 m^3, based on the dimensions of the experimental reverberant chambers [6]. The total surface area A_1 and perimeter P_1 of the cavity S1 are 190 m^2 and 70.44 respectively. For the cavity S3, these geometrical dimensions are $A_3 = 210$ m^2 and $P_3 = 72.0$ m. The total surface area of the bare panel is $S_2 = 1.0$ m^2. An acoustic power source of 1 Watt was applied in the S_1 subsystem. The total mean absorption of the non-treated surfaces of the cavities was considered 1%, as well as the dissipation loss factor of the solid plate.

A propagation way that can be important in experimental procedures is the leakage due to the mounting conditions. According to Beranek [8], this phenomena causes a reduction in the

Insertion Loss that can be simply modeled as

$$\Delta IL_L = IL_s - IL_L \approx 10\log_{10}(1 + \beta\, 10^{TL_s/10}) \tag{16}$$

where IL_s and IL_L are the insertion losses of the sealed and leaky systems, TL_s the transmission loss of the system and β is the leak ratio factor. Experimentally, the influence of this phenomena becomes more important in high frequencies [6]. In this paper, the application of the model presented in Equation 16 was evaluated in the Transmission Loss of the double wall systems, considering $\beta = S_{leak}/S_{plate} = 2.0\,\mathrm{E} - 6$. The determination of S_{leak} was done by adjusting experimental data. The analyses are presented in Section 4.

4 RESULTS

The results were obtained in one third-octave band, from 250 Hz to 8000 Hz. Although the damping of the subsystems in contact with the surfaces of the NCT can be changed when applying the noise control treatment, these parameters are not important for this work. Since the treated acoustic surface is too small if compared to the total surface area of the reception cavity, the mean absorption of the subsystem 3 would not be significantly altered in this scenario. On the other hand, the loss factor of the structural system can be important for the sound transmission on frequencies above the critical frequency ($\approx$ 12 kHz) for this panel. Therefore, the Insertion Loss (IL) of the treatment is the only parameter that contributes significantly to the numerical transmission loss of the complete system. Figure 5 shows the infinite size insertion loss for the single and double-wall setups, considering the Material A and Material B, obtained from the Transfer Matrix Method.

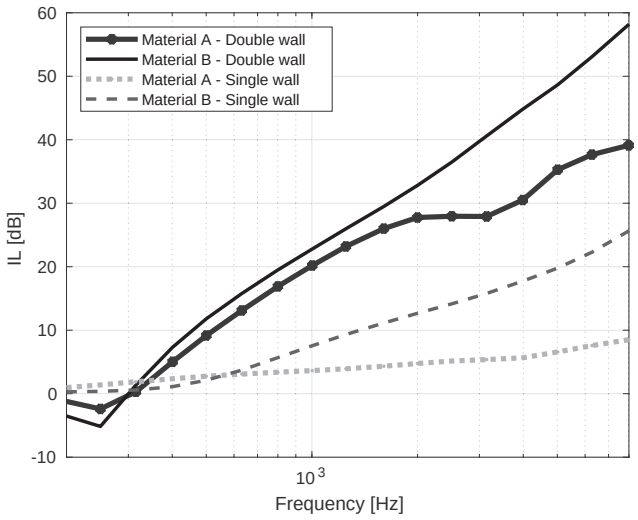

Figure 5: Insertion Loss obtained from the TMM for the studied systems.

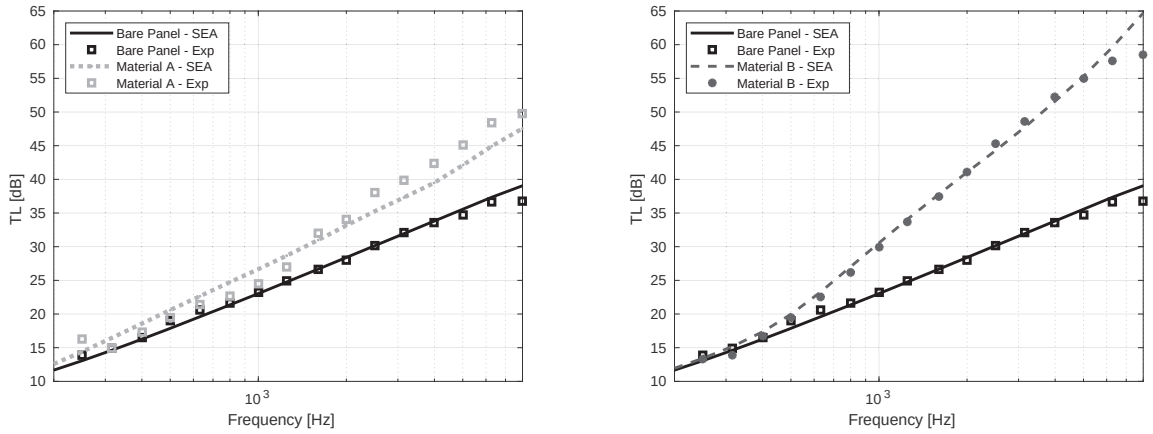
It can be noticed in Figure 5 that the formulation of transfer matrices is capable of capturing the poor performance of the double-wall configuration in frequencies below the resonance of the spring-mass system ($f \approx 300$ Hz), represented by a negative value of the IL. The results also show the importance of the flow resistivity parameter for improving the Insertion Loss of the system, which is expected since this parameter controls the barrier capacity of the porous material. The Insertion Loss was applied to the coupling factors, as presented in Equations 10

and 9. The Transmission Loss results calculated for the single-wall configurations (plate + porous) are presented in Figure 6.



(a) Material A (b) Material B

Figure 6: Sound Transmission Loss obtained for the single-wall configurations.

Figure 6 shows good agreement between numerical and experimental data for the considered single-wall systems, which indicates the efficiency of the presented modeling approach for flat structures. It can be noticed in the obtained result for Material B the drop of TL in high frequency that probably occurs due to the leakage of the sound wave in the experimental condition. This characteristic is more evident in Figure 7, that brings the collected Transmission Loss for the double-wall setups (plate - porous - plate) with and without the leakage correction applied to the numerical data.

Figure 7 shows that the greater the complexity of the multilayers, the more difficult it becomes to obtain a perfectly sealed condition from an experimental point of view. It can be seen in Figures 7 (a) and 7 (c) that the experimental TL of the different systems converges in high frequencies even though it does not occur when the same samples were used in the single-panel setups. It suggests greater importance of leaks in the double wall configurations. Although adjusting the parameter β imposes uncertainties, Figures 7 (b) and 7 (d) shows that the use of a model for considering this propagation path is necessary when the presence of leaks becomes evident in the experimental results. Nevertheless, the method of SEA/TMM can be a useful tool when due care is taken.

5 CONCLUSIONS

This paper presented an overview of the transmission loss characterization of multilayered structures using Statistical Energy Analysis and the Transfer Matrix Method. The Insertion Loss of the treated systems was calculated by using the TMM and applied to the coupling loss factors of the SEA matrix. Additionally, a model for leaks was presented and applied to the TL results for simulating experimental conditions of a double-wall system composed by plate-porous-plate. The results obtained from the $SEA - Toolbox$, an open-source code developed in the present project, demonstrated good agreement with experimental data.

Keywords: Long-range interactions, Periodic nonlocality, Wave propagation, Metamaterials, Floquet theorem.

Abstract. *Investigating the status of travelling waves in systems integrated with periodic means of distant communication, and the possibility of obstructing the energy flow carried via coupled modes, are of interest. The governing system of linear differential equations with periodic coefficients gives the possibility to adopt Floquet theorem, as a powerful framework, to identify the location of stop band frequencies. The generation of gaps in the band structure of the system owing to the newly launched periodic long-range channels is shown. The likelihood of pulling the first stopband to lower frequency bands as a major demand, is examined by raising some assumptions.*

1 INTRODUCTION

The analysis of waves travelling in periodic arrays has grabbed the attention of many researchers over the past few decades, and direct application in electromagnetism and acoustics have been the keynote to most of the investigations. The existence of bandgaps in the band structure of the mechanical systems, within which the transmission of energy is prohibited, is significantly important due to the problems frequently faced in real-life, such as discomforting noise in cars and noise-related health concerns.

In principle, the repetition of subunits with a certain pattern gives birth to some gaps in the band structure of the system [1]. The characteristics of the stopbands, including the width and the location, are totally dependent upon the type of subunits. Several studies concerning the analysis of the vibro-acoustic behaviors of structures composed of periodic attachments, have been conducted [2-4]. Recently, the acoustic metamaterials, typically made of thin-walled segments integrated with simple mechanical subunits such as spring and dampers, have been in the center of attention. A sizable number of studies [5, 6] are devoted to fully describe the features of the foregoing periodic configurations including the effect of resonator type and its placement on the band structure of the array. Although subunits mostly act locally, cases might be imagined in which the distant action between two or several points forms the force exerted by the element. To clarify the effect of nonlocalities on the status of travelling, a handful of investigations have been carried out [7-9]. For instance, in Ref. [9] the arising propagation regimes in a newly proposed waveguide in which distant particles may communicate remotely, is investigated, as the emergence of hypersonic group velocity under certain circumstances.

Although nonlocalities can adopt any topology, one may assume them to be distributed periodically. The recently developed mechanisms are, indeed, new paths for energy transmission through the system. The combination of nonlocality and periodicity might be a fruitful design which guarantees the born of gaps in the band structure of the system as well as other potential phenomena. To put it differently, the coincidence of periodicity and long-range interactions could deliver peculiar behaviors under particular conditions. The potential latent qualities offer the opportunity to tackle problems encountered in the vibro-acoustic field including achieving the ultra-low-frequency bandgaps, which is a hugely demanding task among the academics.

The inclusion of the periodic nonlocalities within the domain of a conventional system, alters the dynamics of the structure, and thereby a strong modification in the behavior of waves travelling through the domain. Using Floquet theorem, a structured investigation of the dependence of the system's response upon the intensity of the long-range effects is presented.

2 THEORY AND FORMULATION

This work investigates the dynamics of a periodic structure, as in Figure 1, composed of an infinite axisymmetric cylindrical shell. Besides, spring-like links let distant points interacting with each other. The inclusion of the periodically allocated axial connections generates new dynamic effects in the dynamic performance. The global dynamic response, by the displacements $\bar{u}(x,t)$ and $\bar{w}(x,t)$ along the axis and along the transverse direction, respectively, is associated by the following coupled differential equations:

$$\begin{aligned} \frac{Eh}{1-\nu^2}\left(\frac{d^2\bar{u}}{dx^2}+\frac{\nu}{R}\frac{d\bar{w}}{dx}\right) &= \rho\frac{d^2\bar{u}}{dt^2} \\ \frac{Eh}{1-\nu^2}\left(\frac{h^2}{12}\frac{d^4\bar{w}}{dx^4}+\frac{\bar{w}}{R^2}+\frac{\nu}{R}\frac{d\bar{u}}{dx}\right) &= \rho\frac{d^2\bar{w}}{dt^2} \end{aligned} \tag{1}$$

with $\rho, E, R, h,$ and ν being the mass density, Young's modulus, radius, thickness and Poisson's ratio, respectively. The nondimensional forms become:

$$\begin{aligned} \frac{d^2u}{dX^2} + \Omega^2 u - \nu \frac{dw}{dX} = 0 \\ \nu \frac{du}{dX} + w + \frac{h^2}{12R^2}\frac{d^4w}{dX^4} - \Omega^2 w = 0 \end{aligned} \tag{2}$$

$X = x/R$ denoting the nondimensional axial coordinate, $u = \bar{u}/R$ and $w = \bar{w}/R$ the nondimensional axial and bending displacements, are introduced. $\Omega = \sqrt{(1-\nu^2)\rho R^2 \omega^2/E}$ is the nondimensional frequency. In the correspondent structure, the energy is carried out via coupled modes due to the coupling between the axial and bending terms in the equations of motion. This may be perceived by inspecting Eq. (2) where both u and w are present in both equations indicating the link between the extensional and flexural modes.

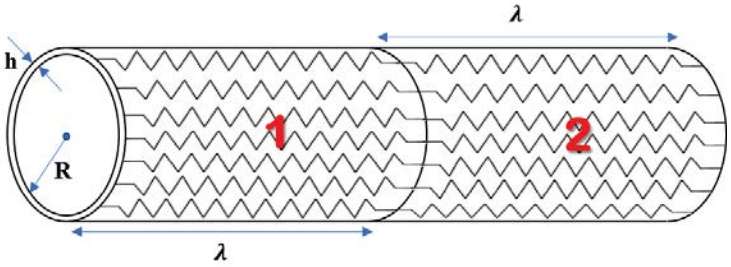

Figure 1: A periodicity cell of a cylindrical shell with periodic nonlocalities

Using modal coefficients τ_i, the general solution for the system of equations (2) is:

$$\begin{aligned} w = \sum_{i=1}^{6} \bar{w}_i \, e^{jk_i x} \\ u = \sum_{i=1}^{6} \tau_i \, \bar{w}_i \, e^{jk_i x} \end{aligned} \tag{3}$$

k_i $(i = 1, 2, \dots, 6)$ are the roots of the dispersion relation for a homogenous and isotropic axisymmetric cylindrical shell. Given the above expressions for the displacements u and w, 24 equations, in total, are necessary to fully characterize the kinematics of both segments. However, only twelve of them are self-sufficient and the rest are indeed connected to the independent ones by the modal coefficients. The modal coefficients are:

$$\tau_i = \frac{j\nu k_i}{k_i^2 - \Omega^2} = j\frac{1 + \frac{h^2 k_i^4}{12R^2} - \Omega^2}{\nu k_i} \tag{4}$$

where j is the imaginary unit. Considering a unit cell of the system, which contains two equivalent shell segments coupled with periodic nonlocalities of stiffness k, the interface conditions between the neighboring segments 1 and 2, in the nondimensional form, are:

$$\begin{aligned} w_1\big]_{X=\lambda} &= w_2\big]_{X=\lambda} \\ \left.\frac{dw_1}{dX}\right|_{X=\lambda} &= \left.\frac{dw_2}{dX}\right|_{X=\lambda} \\ \left.\frac{d^2w_1}{dX^2}\right|_{X=\lambda} &= \left.\frac{d^2w_2}{dX^2}\right|_{X=\lambda} \\ \left.\frac{d^3w_1}{dX^3}\right|_{X=\lambda} &= \left.\frac{d^3w_2}{dX^3}\right|_{X=\lambda} \\ u_1\big]_{X=\lambda} &= u_2\big]_{X=\lambda} \end{aligned} \tag{5}$$

$$\left.\frac{du_1}{dX}\right|_{X=\lambda} + \nu w_1\big]_{X=\lambda} = \left.\frac{du_2}{dX}\right|_{X=\lambda} + \nu w_2\big]_{X=\lambda} + \hat{k}\left[u_1\big]_{X=\lambda} + u_2\big]_{X=\lambda} - \left(u_1\big]_{X=0} + u_2\big]_{X=(1+\gamma)\lambda}\right)\right]$$

where $\hat{k} = kR(1-\nu^2)/E$ denotes the nondimensional spring stiffness. $\lambda = l_1/R$ and $\gamma = l_2/l_1$ are nondimensional length parameters. The above conditions are referring to the continuity of axial and bending displacements, the slopes dw/dX, the flexural moments d^2w/dX^2 and bending forces d^3w/dX^3 at the interface. Besides, the condition regarding the continuity of the axial force, is modified by an additional term $\hat{k}[u_1]_{X=\lambda} + u_2]_{X=\lambda} - \left(u_1]_{X=0} + u_2]_{X=(1+\gamma)\lambda}\right)]$, which brings into the system the effects induced by nonlocalities. To proceed with the analysis, six more equation are required, which are obtained by considering the Floquet periodicity conditions, as:

$$\begin{aligned} w_1]_{X=\lambda/2} &= \Gamma\, w_2]_{X=(1+\gamma/2)\lambda} \\ \left.\frac{dw_1}{dX}\right|_{X=\lambda/2} &= \Gamma \left.\frac{dw_2}{dX}\right|_{X=(1+\gamma/2)\lambda} \\ \left.\frac{d^2w_1}{dX^2}\right|_{X=\lambda/2} &= \Gamma \left.\frac{d^2w_2}{dX^2}\right|_{X=(1+\gamma/2)\lambda} \\ \left.\frac{d^3w_1}{dX^3}\right|_{X=\lambda/2} &= \Gamma \left.\frac{d^3w_2}{dX^3}\right|_{X=(1+\gamma/2)\lambda} \\ u_1]_{X=\lambda/2} &= \Gamma\, u_2]_{X=(1+\gamma/2)\lambda} \\ \left.\frac{du_1}{dx}\right|_{X=\lambda/2} + \nu w_1]_{X=\lambda/2} &= \Gamma\left(\left.\frac{du_2}{dx}\right|_{X=(1+\gamma/2)\lambda} + \nu w_2]_{X=(1+\gamma/2)\lambda}\right) \end{aligned} \tag{6}$$

Here Γ is a standard parameter describing the phase shift in a periodic array [10]. The relations in (6) compare the state vector of neighboring segments. It is apparent how the state vector gets modified from one cell to the next by the parameter Γ. Considering $\Gamma = e^{jK_B}$ with K_B being the Bloch parameter, two possibility for its value may be imagined: real-valued K_B, hence $|\Gamma| = 1$, suggests the propagation is allowed in the structure, complex valued K_B, inducing $|\Gamma| \neq 1$, disclosed the impossibility to project the state vector of one segment on the neighboring, implying the existence of stopband frequencies. Note that, once Γ is defined, its value is constant for any selected periodicity cell. A sixth-order transcendent equation associated with the described system is of the form:

$$\Gamma^6 + A_1\left(\Omega,\hat{k}\right)\Gamma^5 + A_2\left(\Omega,\hat{k}\right)\Gamma^4 + A_3\left(\Omega,\hat{k}\right)\Gamma^3 + A_4\left(\Omega,\hat{k}\right)\Gamma^2 + A_5\left(\Omega,\hat{k}\right)\Gamma + 1 = 0 \tag{7}$$

The above polynomial is the nontrivial solution of a system of equations obtained from the combination of Eqs. (5) and Eqs. (6). Eq. (7) proclaims the existence of three pair of roots possibly determining the energy transmission across the domain. Note that, the coefficients in the preceding equation may not be explicitly extracted and values of Γ are individually calculated for a given frequency Ω.

3 RESULTS AND DISCUSSION

This section is devoted to investigating the band structure of an unbounded axisymmetric cylindrical shell in the presence of periodic nonlocalities governed by the nondimensional stiffness $\hat{k}$. The analysis of the trend of Γ with respect to the nondimensional frequency Ω unveils the existence of several bandgaps induced by the introduction of periodic nonlocalities, occurring whenever $|\Gamma| \neq 1$, spread along the entire frequency domain. Since the bandgaps usually get smaller, the higher the frequency, only the first two bandgaps are here illustrated in Figures (2a) and (2b). In fact, energy transmission is not permitted about $\Omega = 0.96$ (see Figure (2a)) and $\Omega = 1.23$ (see Figure (2b)), where $|\Gamma|$ may adopt any value but unity. Evidently, the first gap is significantly broader with respect to the second one of the widths 0.006.

The figure implicitly points to the fact that the long-range interactions are conveniently beneficial for blocking the energy paths no matter it is being carried by extensional or bending modes.

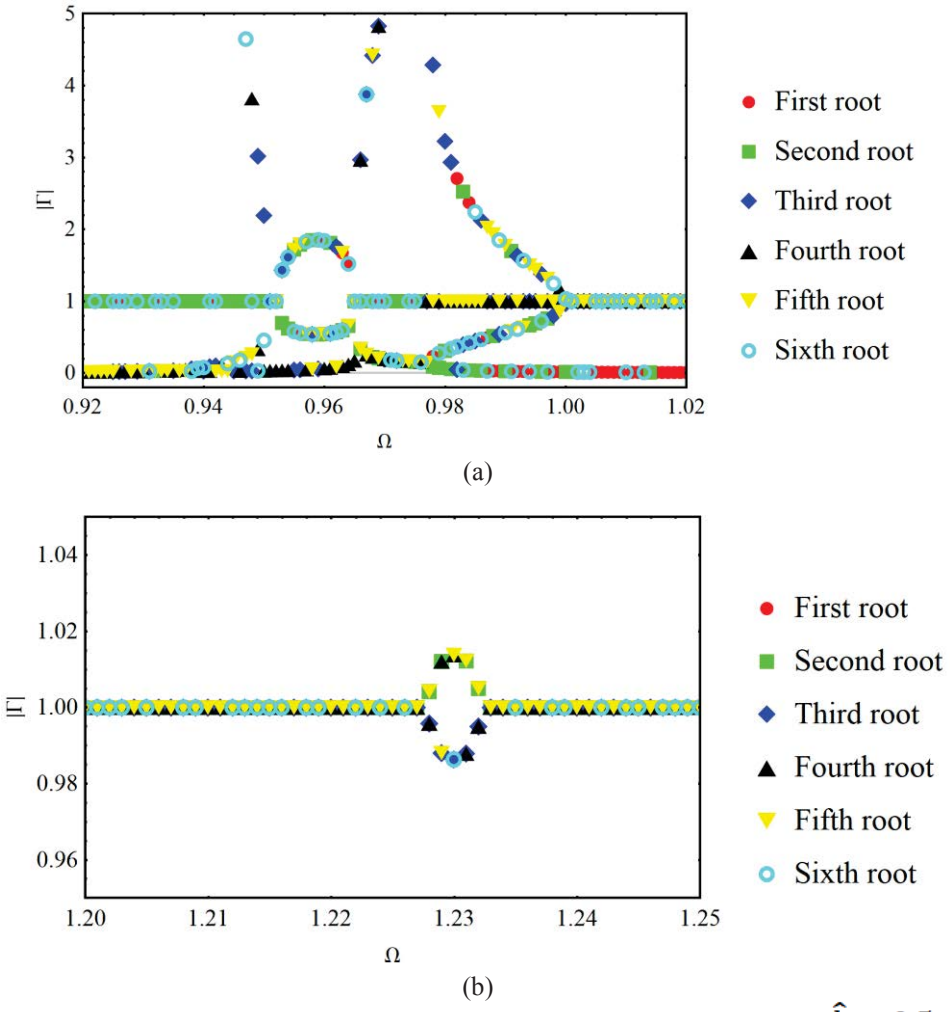

Figure 2: Band structure of an axisymmetric cylindrical shell with periodic nonlocalities ($\hat{k} = 0.5,\ \eta = 0.02$) a) First gap b) Second gap

According to Eq. (2), the response of the system is dependent upon the thickness-radius ratio η=h/R; therefore, the effect of this parameter may sensibly influence the location and the width of the gaps dramatically. Considering other parameters to be fixed as ν=0.3, γ=1, λ=1 and k̂=0.5, for four different value of η, the location of the stopbands is given in Table 1.

η	First gap	Second gap
0.005	$0.94895 < \Omega < 0.95495$	$0.96295 < \Omega < 0.96895$
0.01	$0.94895 < \Omega < 0.95795$	$0.98695 < \Omega < 0.98995$
0.015	$0.94995 < \Omega < 0.96195$	$1.12195 < \Omega < 1.12595$
0.02	$0.95195 < \Omega < 0.96495$	$1.22695 < \Omega < 1.23295$

Table 1: The low-frequency bandgaps in an axisymmetric cylindrical shell with periodic nonlocalities

To extract what is brought in the table, a narrow band $\Omega < 1.5$ is taken into account. Although the change in η roughly influences the width of the gaps, for the case of first stopband, a quite wider gap is met as this ratio increases. In fact, the left border of both gaps is pulled towards higher frequencies as the thickness-length ratio rises. Obviously, the origin of

these gaps may be simply explained by the decoupling of the flexural and longitudinal modes, which are integrated because of the Poisson's ratio and the further discussion is held for the future works.

The frequency dependence of $|\Gamma|$ is demonstrated in Figure 3, for two values of the non-dimensional stiffness, namely $\hat{k} = 0.2$ shown in black and $\hat{k} = 0.5$ in red. Two distinct patterns are observed: those points which resemble non-flat curves are originated from the real roots of Eq. (7), and the roots constructing the flat lines i.e. $|\Gamma| = 1$, are referring to pass band frequencies. Based on the figure, the right border of the stopband, the frequency at which the stop band vanishes, moves towards higher frequencies for higher values of $\hat{K}$. The emerging frequency (seed of the stopband) picks a slightly higher value with respect to the frequency associated with the system having less stiff external links. Given the circumstances, a wider gap is attained.

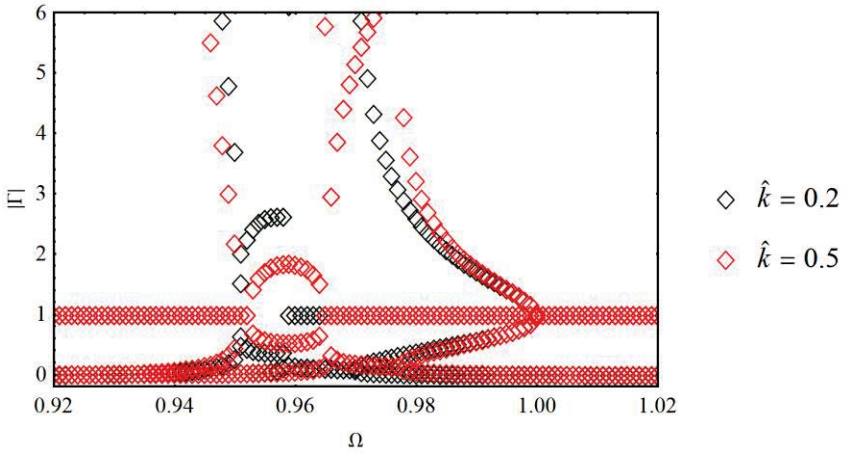

Figure 3: Band structure of an axisymmetric cylindrical shell with periodic nonlocalities for two different values of nondimensional stiffness $\hat{k}$

4 CONCLUSION

To identify the band structure of a hollow axisymmetric cylindrical shell with periodic long-range links embedded, Floquet analysis is carried out. The structure is composed of equivalent shell segments and equivalent axial links, which connect the interface of one pair of segments to the next. To simplify the analysis, the axial links are assumed to be simple extensional springs by which the interaction of distant points is made possible. The results suggest the generation of bandgaps in the band structure of the system and the occurrence of this phenomena may be attributed to the newly introduced periodic external links. Parametric studies show that the major gap (first one) becomes wider as stronger external connections are implemented. Moreover, the presented mathematical formulation shows the possibility of attenuating the flexural and extensional energy owing to solely axial nonlocalities.

Keywords: Long wave, high frequency, uniformly asymptotic, thin layer.

Abstract. *It is well known that the long-wave approximations for thin elastic structures can be separated into local low-frequency and high-frequency ones. The former are given by more conventional plate and shell theories justified near zero frequency, whereas the latter correspond to 2D equations valid over the vicinities of thickness resonances. In this contribution, we develop a more general long-wave procedure for a broad band surface loading resulting in 2D equations involving transcendental expressions of the spectral frequency parameter. These equations are reduced to the aforementioned local approximations in the vicinities of zero and thickness resonance frequencies. As an example, SH waves in a layer loaded along its faces are considered. Comparison with the exact solution of the problem is presented. Similar global approximations could also be constructed for periodic media, due to the analogy for asymptotic schemes for thin and periodic structures.*

1 INTRODUCTION

Dynamic asymptotic theories for thin elastic structures have been investigated in great detail, see e.g. books [6, 15], and references therein. The most focus traditionally has been on low-frequency dynamics corresponding to both classical and refined models, e.g. see [5, 11]. High-frequency long wave approximations got less attention. Nevertheless, the initial efforts in this area [1, 3] later on have found various implementations for fluid-loaded, pre-stressed, layered and curved structures, as well as for thin coating and interfacial layers modelled by imposing Dirichlet, Neumann and mixed boundary conditions along the faces, e.g. see [7, 8, 12, 13, 14, 17, 18, 19, 20].

At the same time, all the mentioned low- and high-frequency long-wave approximations are local ones in a sense, that their range of validity is restricted to the vicinities of zero and thickness resonance frequencies, respectively. Although their interaction was analysed for initial value problems for thin plates [10, 16], a non-local long-wave model covering a broad frequency range has not been developed yet. The previous consideration in [2] studying forced vibrations under arbitrary high-frequency loading did not take into account the peculiarities of near-cut-off behaviour and consequently has not resulted in a lower dimensional partial differential equations of motion.

Below we attempt to derive a non-local long-wave approximation oriented to a broad band surface loading for the simplest setup of anti-plane problem in elasticity for a thin layer with clamped lower face and a prescribed time-harmonic shear force on the upper face. The normalised vibration frequency is assumed to be of order unity meaning that the focus is not on the vicinity of a single chosen thickness resonance frequency as it has been usually done, but on a family of thickness resonances; it is obvious that the clamped lower face does not support low-frequency vibrations. Straightforward asymptotic scheme leads to a 1D differential equation in which the spectral parameter is transcendentally dependent on the vibration frequency, in contrast to all the above mentioned previous considerations on the subject. Various limits of the derived approximations are tackled, including its near- and outside cut-off behaviours. Comparisons with the exact solution and the known approximate results are presented.

2 STATEMENT OF THE PROBLEM

Consider an anti-plane problem of elasticity for a thin isotropic layer, such that the displacements $u_1 = u_3 = 0$ and $u_2 = u_2(x_1, x_3, t)$, see Fig. 1. The governing equations of motion and constitutive relations are given by

$$\sigma_{12,1} + \sigma_{23,3} = \rho u_{2,tt}, \qquad \sigma_{12} = \mu u_{2,1}, \qquad \sigma_{23} = \mu u_{2,3}, \tag{1}$$

where comma denotes differentiation with respect to appropriate spatial or time variable, and ρ and μ are volume mass density and the shear modulus, respectively.

Boundary conditions are taken in the form

$$\begin{aligned} &\sigma_{23} = P, \qquad x_3 = -h, \\ &u_2 = 0, \qquad x_3 = 0. \end{aligned} \tag{2}$$

The exact solution may be easily written for the case of harmonic loading, as well as the associated dispersion relation, see Appendix for more detail.

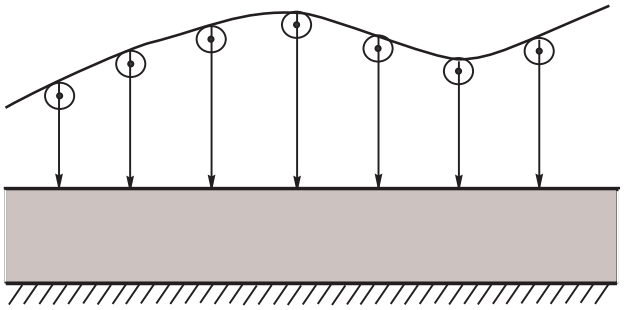

Figure 1: Statement of the problem.

3 ASYMPTOTIC ANALYSIS

The focus is on the long-wave regime, i.e. it is assumed that the thickness of the layer h is small compared to the typical wavelength l, therefore, a small parameter ε is

$$\varepsilon = \frac{h}{l} \ll 1. \tag{3}$$

Then, following the conventional asymptotic integration procedure, the dimensionless variables and parameters are introduced

$$\xi_1 = \frac{x_1}{l}, \qquad \xi_3 = \frac{x_3}{h}, \qquad K = kh, \qquad \Omega = \frac{\omega h}{c_2}, \tag{4}$$

along with the scaling

$$u_2 = hu_2^*, \qquad \sigma_{12} = \varepsilon\mu\sigma_{12}^*, \qquad \sigma_{23} = \mu\sigma_{23}^*, \qquad P = \mu p^*, \qquad \Omega \sim 1, \tag{5}$$

where the quantities with asterisks are assumed to be of the same asymptotic order.

Note that in what follows the time-harmonic motion is assumed, with the factor $e^{-i\omega t}$ omitted for brevity. Using (5), the governing equations (1) are rewritten as

$$\varepsilon^2\sigma_{12,1}^* + \sigma_{23,3}^* + \Omega^2 u_2^* = 0, \qquad \sigma_{12}^* = u_{2,1}^*, \qquad \sigma_{23}^* = u_{2,3}^*, \tag{6}$$

together with boundary conditions (2) represented as

$$\begin{aligned} &\sigma_{23}^* = p^*, \qquad \xi_3 = -1, \\ &u_2^* = 0, \qquad \xi_3 = 0. \end{aligned} \tag{7}$$

We proceed with expanding the scaled displacement and stress components as asymptotic series

$$\begin{pmatrix} u_2^* \\ \sigma_{12}^* \\ \sigma_{23}^* \end{pmatrix} = \begin{pmatrix} u_2^{(0)} \\ \sigma_{12}^{(0)} \\ \sigma_{23}^{(0)} \end{pmatrix} + \varepsilon^2 \begin{pmatrix} u_2^{(1)} \\ \sigma_{12}^{(1)} \\ \sigma_{23}^{(1)} \end{pmatrix} + ... \tag{8}$$

Therefore, at leading order we have

$$\sigma_{23,3}^{(0)} + \Omega^2 u_2^{(0)} = 0, \qquad \sigma_{12}^{(0)} = u_{2,1}^{(0)}, \qquad \sigma_{23}^{(0)} = u_{2,3}^{(0)}, \tag{9}$$

which leads to

$$u_{2,33}^{(0)} + \Omega^2 u_2^{(0)} = 0 \tag{10}$$

subject to the leading order boundary condition

$$u_2^{(0)} = 0, \qquad \xi_3 = 0. \tag{11}$$

Taking into account boundary condition (11) the solution of (10) is given by

$$u_2^{(0)} = C_1(\xi_1)\, \sin(\Omega\xi_3), \tag{12}$$

hence,

$$\sigma_{12}^{(0)} = \frac{dC_1}{d\xi_1} \sin(\Omega\xi_3), \qquad \sigma_{23}^{(0)} = C_1 \Omega \cos(\Omega\xi_3). \tag{13}$$

As may be seen from (12), the corresponding leading order dispersion relation has a term of $\cos\Omega$ degenerating at the cut-off frequencies, see (22) below, hence, consideration of the next order corrector is required.

At next order we have

$$\sigma_{12,1}^{(0)} + \sigma_{23,3}^{(1)} + \Omega^2 u_2^{(1)} = 0, \qquad \sigma_{12}^{(1)} = u_{2,1}^{(1)}, \qquad \sigma_{23}^{(1)} = u_{2,3}^{(1)}. \tag{14}$$

Therefore, from (14) and taking into account $(13)_1$, we obtain

$$u_{2,33}^{(1)} + \Omega^2 u_2^{(1)} = -\frac{d^2 C_1}{d\xi_1^2} \sin(\Omega\xi_3), \tag{15}$$

from which, in view of the boundary condition at $\xi_3 = 0$,

$$u_2^{(1)} = C_3(\xi_1)\, \sin(\Omega\xi_3) + \frac{\xi_3}{2\Omega} \frac{d^2 C_1}{d\xi_1^2} \cos(\Omega\xi_3). \tag{16}$$

Thus, the two-term expansions for the displacement u_2^* and stress σ_{23}^* follow from (8), (12) and (16) as

$$u_2^* = A(\xi_1) \sin(\Omega\xi_3) + \varepsilon^2 \left(\frac{\xi_3}{2\Omega} \frac{d^2 A}{d\xi_1^2} \cos(\Omega\xi_3) \right) + O(\varepsilon^4), \tag{17}$$

and

$$\sigma_{23}^{*} = A(\xi_1)\Omega\cos(\Omega\xi_3) + \varepsilon^2\left(\frac{1}{2\Omega}\frac{d^2A}{d\xi_1^2}\left[\cos(\Omega\xi_3) - \xi_3\Omega\sin(\Omega\xi_3)\right]\right) + O(\varepsilon^4), \quad (18)$$

where $A(\xi_1) = C_1(\xi_1) + \varepsilon^2 C_3(\xi_1)$.
Then, from boundary condition $(2)_1$ the relation between the load and displacement is

$$p^{*} = A\Omega\cos(\Omega) + \frac{\varepsilon^2}{2\Omega}\frac{d^2A}{d\xi_1^2}\left(\cos(\Omega) - \Omega\sin(\Omega)\right) + O(\varepsilon^4). \quad (19)$$

This may be rewritten in dimensional form as

$$h^2\frac{d^2A}{dx_1^2} + f(\Omega)A = g(\Omega)\,\frac{P}{\mu}\,, \quad (20)$$

where

$$f(\Omega) = \frac{2\Omega^2}{1 - \Omega\tan\Omega}, \qquad g(\Omega) = \frac{f(\Omega)}{\Omega}. \quad (21)$$

Thus, the derived approximation is in a sense global over the long-wave region, complementing the previous local long-wave high-frequency theories applicable in the vicinity of a single chosen cut-off frequency [6], however at a cost of a more sophisticated dependence on the spectral parameter $f(\Omega)$.

4 DISCUSSION

Let us compare the obtained approximate results with the exact solution displayed in the Appendix. Let us first examine the dispersion relations. The exact form of the dispersion relation becomes from (A.6) as

$$K^2 = \Omega^2 - \Omega_n^2, \quad (22)$$

which gives the cut-offs at $K = 0$ as $\Omega = \Omega_n$ or $\cos\Omega = 0$.

On setting $A = Ue^{ikx_1} = Ue^{iK\varepsilon^{-1}\xi_1}$ and $P = 0$ in (19), we have

$$K^2 = f(\Omega), \quad (23)$$

with $f(\Omega)$ defined in (21).

Note that (23) naturally gives the same cut-off frequencies as (22), associated with discontinuities of $\tan\Omega$. Indeed, since $\tan\Omega \sim (\Omega_n - \Omega)^{-1}$ in the near cut-off vicinity $\Omega^2 - \Omega_n^2 \ll 1$, the leading order term in the series of (23) around the cut-offs coincides with (22), i.e.

$$\frac{2\Omega^2}{1 - \Omega\tan\Omega} \sim \frac{(\Omega + \Omega_n)\Omega}{1 - \Omega_n(\Omega_n - \Omega)^{-1}} \sim \Omega^2 - \Omega_n^2. \quad (24)$$

At the same time, the form of (23) suggests the approximation will blow up in the vicinity of the roots of the transcendental equation $\tan\Omega = \Omega^{-1}$, which moves the wave number K outside of the long-wave range of validity $(K \ll 1)$. A confirmation of the above may be readily observed from the following illustration, see Fig. 2.

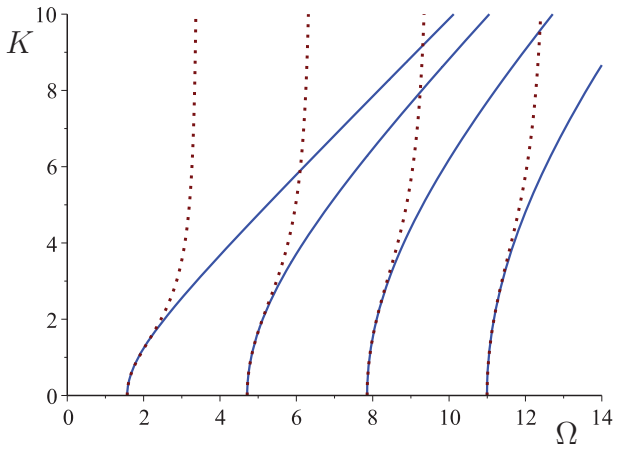

Figure 2: Dispersion curves: comparison of the exact solution (22) (blue solid curves) and approximation (23) (dotted lines).

The first four harmonics of the exact dispersion relation (22) depicted in Fig. 2 by blue solid lines, are compared with their approximation provided by formula (23) shown by dotted lines. On the contrary to known "local" polynomial approximations valid within the vicinity of a given cut-off frequency, see e.g. [6], the approximation derived in the present contribution, involving trigonometric functions of frequency, are "non-local", thus providing approximation in a broad range of frequencies.

Let us now compare the solutions of the forced problem. On setting $A = Ue^{ikx_1}$ and making use of (4) and (5), the exact and approximate displacements follow from (A.3) and (19) as

$$u_2^{ex} = \frac{P_0 h}{\mu} \frac{1}{\sqrt{\Omega^2 - K^2}\cos\sqrt{\Omega^2 - K^2}} \sin\left(\sqrt{\Omega^2 - K^2}\xi_3\right), \tag{25}$$

and

$$u_2^{as} = \frac{P_0 h}{\mu} \frac{1}{\Omega\cos\Omega - \dfrac{K^2}{2\Omega}(\cos\Omega - \Omega\sin\Omega)} \sin\left(\Omega\xi_3\right), \tag{26}$$

respectively, with the factor $e^{i(kx_1-\omega t)}$ omitted for brevity. It is clear that as $K \to 0$, the argument of sine function in (25) coincides with that of (26). Moreover, straightforward Taylor expansion of $\sqrt{\Omega^2 - K^2}\cos\sqrt{\Omega^2 - K^2}$ in (25) around $K = 0$ gives the

appropriate denominator in (26). Moreover, outside the vicinity of cut-offs a simpler approximation is possible as

$$u_2^{as} = \frac{P_0 h}{\mu} \frac{1}{\Omega \cos \Omega} \sin\left(\Omega \xi_3\right), \tag{27}$$

whereas in the vicinity of the cut-offs $|\Omega - \Omega_n| \ll \varepsilon$ we have (similar to [6])

$$u_2^{as} = \frac{P_0 h}{\mu} \frac{2(-1)^{n+1}}{K^2 - (\Omega^2 - \Omega_n^2)} \sin\left(\Omega \xi_3\right). \tag{28}$$

The comparison of the exact solution (25) with the approximations (26), (27) and (28) are presented in the following Figs. 3 and 4.

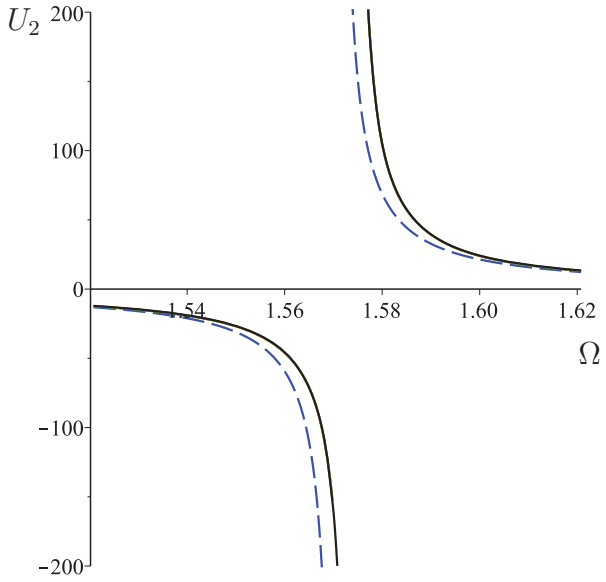

Figure 3: Comparison of the exact solution (25) and its approximations (27), (26) and (28) in the vicinity of the first cut-off frequency.

Fig. 3 demonstrates the variation of the scaled displacement on the upper surface

$$U_2 = \frac{\mu}{P_0 h} u_2\big|_{x_3=-h} \tag{29}$$

on the frequency in the vicinity of the first thickness resonant frequency $\Omega_1 = \pi/2$. The calculations are performed for $K = 0.1$. It may be clearly observed that the elementary leading order approximation (27) shown by dashed line is not capturing the true resonance, confirming its validity outside the cut-off vicinity. At the same time, the approximation (26), and its simplified version aimed at the vicinity of the cut-off frequency

(28), are virtually indistinguishable from the exact solution (25) in the above-mentioned vicinity. Indeed, the three solid lines merge together.

An even more pronounced behaviour may be seen in the following Fig. 4, showing variation of the scaled displacement U_2 on the wave number in case of the exact solution (25) and approximations (27), (26) and (28). The calculations are performed for the frequency value close to the first thckness resonant frequency, i.e. $\Omega - \Omega_1 = 0.1$. As before, the approximations (26) and (28) are extremely close to the exact solution (25), all shown by solid lines, but virtually indistinguishable. At the same time, the rough approximation (27) depicted by dashed line obviously cannot take into account the resonant nature in K, since it is independent of the wave number. This confirms the importance of the differential terms in (20), following from the asymptotic analysis for correctors.

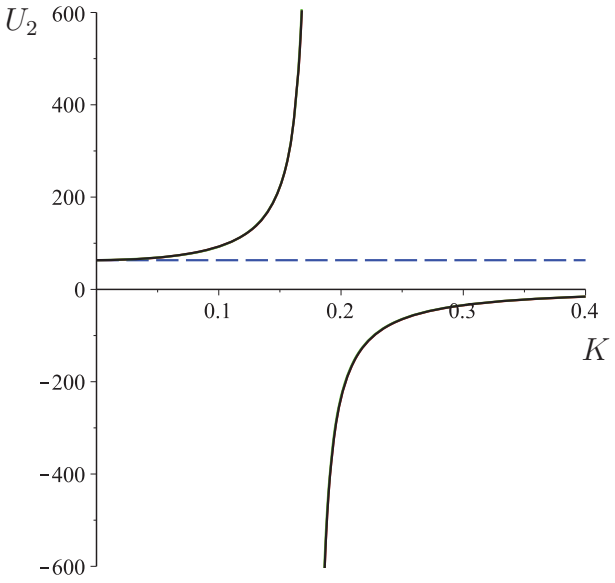

Figure 4: Comparison of the dependence of the exact solution (25) and its approximations (27), (26) and (28) on the wave number.

5 CONCLUSION

The derived long-wave equation (20) with a transcendental dependence of the spectral parameter is valid over a broad frequency band. This equation was implemented to analyse free and forced vibrations. As expected, it involves both the local high-frequency approximations valid near the thickness resonances (28), as well as a simple approximation (27) of the forced amplitude outside the latter. Comparison with the exact solution demonstrates that the obtained equation is robust over the whole long-wave range failing at short-wave domain which is generally not typical for surface loading

of thin structures. The developed methodology has a potential to be extended to more general setups, including plane and 3D problems with boundary conditions along the faces, supporting not only considered long-wave high-frequency vibrations, but also low-frequency ones. Finally, we note that a hierarchy of h-dependent effective hyperbolic problems with sharp-norm estimates for the difference between the appropriate solutions could be obtained using the mathematically rigorous approach in [4].

APPENDIX. EXACT SOLUTION FOR TIME-HARMONIC LOADING

Equations (1) imply a conventional wave equation for the non-zero displacement

$$u_{2,11} + u_{2,33} = \frac{1}{c_2^2}\, u_{2,tt}, \tag{A.1}$$

where $c_2 = \sqrt{\mu/\rho}$ is the shear wave speed. We focus on the time-harmonic load of the form and the corresponding anzats for the solutions

$$P = P_0 e^{i(kx_1 - \omega t)}, \qquad u_2 = U f(kx_3) e^{i(kx_1 - \omega t)}, \tag{A.2}$$

where k and ω stand for the wave number and frequency. On substituting (A.2) into (A.1) and satisfying the conditions (2), we obtain

$$u_2 = \frac{P_0}{\mu k \alpha \cos(k\alpha h)}\, \sin(k\alpha x_3)\, e^{i(kx_1 - \omega t)}, \tag{A.3}$$

where

$$\alpha = \sqrt{\frac{\omega^2}{k^2 c_2^2} - 1}. \tag{A.4}$$

The corresponding dispersion relation maybe trivially derived from the solvability of the homogeneous boundary value problem $(P = 0)$, taking the form

$$k\alpha \cos(k\alpha h) = 0, \tag{A.5}$$

implying non-trivial eigensolution for the displacement u_2 for

$$k\alpha h = \Omega_n = \frac{(2n-1)\pi}{2}, \quad n \in \mathbf{N}. \tag{A.6}$$

Keywords: Energy Flow, Essential state variables, Forces & displacements

Abstract. *In waveguide theory calculating the energy flowing through the guide is often of prime interest and especially within elastodynamics the energy partition between the different transmission paths such as axial, torsion, shear etc. is also of interest. In this paper, we show that the definition of state variables is not unique which make conclusions on energy partition between the various transmission paths somewhat ambiguous. On the other hand, we show that for the various definitions of state variables they all have in common what we denote essential state variables which is the part of the states variables that is responsible for the transmission of energy. The essential variables, therefore, correspond to what can be interpreted as the unique, or essential, part of any definition of the state variables. To illustrate this we use an infinite elastic plate strip simply supported at the edges as an example.*

1 INTRODUCTION

Calculating and interpreting the energy flow in a waveguide provides valuable insight into the behaviour of a waveguide and, at times, reveal interesting phenomena such as tunnelling effects, dominant transmission paths and near field re-distribution of energy between components of the waveguide e.g. between fluid and structure. This topic of energy and transmission path analysis within waveguide theory has become more or less a standard subject. However, there are equally interesting phenomena hidden in the total energy flow that are yet unresolved. For instance, in [1] it was shown how waves in orthotropic shells emit more energy in one direction than the other. Even for symmetric waveguides, where the energy is split into equal shares, there are still open questions such as which sub-components of the force and displacement fields are responsible for energy transmission through the waveguide. A deeper understanding of these issues is the subject of this paper.

For the waveguide governed by a self-adjoint operator, it is not surprising that the total energy flow varies much with frequency, however, it is not so obvious that only specific, or essential, terms of the forces and displacements contribute to the energy flow. Effectively, this negates the need for all remaining, or non-essential, terms and quite surprisingly also negates the effect of Poisson's ratio. This makes calculation of the total energy flow for all such waveguides indisputably simple.

While it is known from [2] that non-essential terms of forces and displacements all contribute to the energy flowing through individual transmission paths, the total energy flowing through the waveguide is completely independent of these, [3]. Showing this constitutes one of the main objectives of this paper. Furthermore, the non-essential terms of the forces are sensitive to the method of derivation, or rather the definition of the state variables. It makes the definition of transmission paths and the energy partition in them somewhat ambiguous. Fortunately, each definition contains the essential part which alone is responsible for the energy flow while the non-essential part can be attributed to the ambiguity. This novel view on the composition of energy flow constitutes the essence of the paper. To clarify this novel view, wave propagation in an infinite straight plate strip is considered.

The paper is structured as follows: In Sec. 2 the governing equations and definition of energy flow for the elastic plate strip are presented. In Sec. 3 two definitions of forces are shown for the example and in Sec. 4 the derivation of the essential state variables from the two definitions is shown. This section we also discuss a generalisation of the formulation of the total energy flow. Finally, Sec. 5 summarizes the results reported in the paper.

2 ENERGY FLOW IN WAVEGUIDES

In classical textbooks wave propagation in elastic solids, dispersion of waves and the energy flow through such waveguides are usually the main scope of the analysis. Moreover, we usually prefer to split the energy flow into its physical constituents (transmission paths) in terms of pairs of state variables e.g. we look at the energy propagating in shear, torsion etc. Thus, we define our state variables as the kinematic states (displacement and rotation) and the associated states of forces/moments, which essentially make up the total energy flow in a waveguide. However, as we shall see shortly the definition of these state variables is non-unique and therefore, particularly in the near-field, the energy distribution will depend on the choice of definition.

To illustrate this we use the infinite simply supported plate strip as an example i.e. we impose boundary conditions $w(x, y, t) = M_y(x, y, t) = 0$, at $y = 0$ and $y = L$. The Equation of Motion

(EoM) within the standard Kirchhoff plate theory is given as

$$D\nabla^4 w(x,y,t) + \rho h \frac{\partial^2}{\partial t^2} w(x,y,t) = q(x,y,t) \tag{1}$$

where $D = \dfrac{Eh^3}{12(1-\nu^2)}$, ρ is density, h the plate thickness, E Young's modulus, ν Poisson's ratio, $w(x,y,t)$ the transverse displacement of the plate strip and $q(x,y,t)$ a distributed driving force.

The solution to this problem is standard and hence all details are omitted. The displacement field is given as

$$w(x,y,t) = W \sin\left(\frac{m\pi}{L} y\right) \exp(kx - i\omega t) \tag{2}$$

where $m \in \mathbb{N}$ is the integer order of the wavenumber in coordinate y, k is the wavenumber in the propagation direction x, ω is the angular frequency, W the amplitude, L the width of the strip and $i = \sqrt{-1}$ the complex operator. (x,y,t) will be omitted in what follows.

Substituting this ansatz into the Equation of Motion with $q = 0$ gives the dispersion equation

$$D\left(k^4 - 2\frac{m^2\pi^2}{L^2}k^2 + \frac{m^4\pi^4}{L^4} - \frac{\rho h}{D}\omega^2\right) = 0 \tag{3}$$

from which we can find the wavenumbers as

$$k_1 = -\sqrt{\left(\frac{m\pi}{L}\right)^2 + \sqrt{\frac{\rho h \omega^2}{D}}} \qquad k_2 = \sqrt{\left(\frac{m\pi}{L}\right)^2 - \sqrt{\frac{\rho h \omega^2}{D}}} \tag{4}$$

where k_1 are evanescent waves and k_2 propagating waves if $\left(\frac{m\pi}{L}\right)^2 < \sqrt{\frac{\rho h\omega^2}{D}}$. Note that since the waveguide is symmetric we consider the right-going waves.

The solution to the inhomogeneous problem with $q \neq 0$ can be obtained straightforwardly, see e.g. [4]. From the inhomogeneous solution we can then easily deduce the state variables (generalised moment, shear force, rotation and displacement) and formulate components of the total energy flow propagating via the different transmission paths, [5].

Following [5] the time-averaged energy flow is defined as in Eq. (5).

$$N = -\frac{1}{2}\mathrm{Re}\left[\int_\Gamma \mathbf{Q} \cdot \left(\frac{\partial}{\partial t}\mathbf{U}\right)^* \mathrm{d}\Gamma\right] \tag{5}$$

where $\mathbf{Q}$ and $\mathbf{U}$ are the state variables on vector form, $\cdot$ the scalar product, Re is the real part, * the complex conjugated and Γ the cross-section of the waveguide.

For the plate strip with $\exp(-i\omega t)$ the formula expands to

$$N(x) = -\frac{\omega h}{2}\mathrm{Im}\left[\int_0^L Q w^* + M\gamma^* \mathrm{d}y\right] \tag{6}$$

where $\gamma = \frac{\partial}{\partial x} w$.

3 AMBIGUITIES IN STATE VARIABLES OF WAVEGUIDES

As already mentioned the definition of state variables in e.g. dynamics of thin plates and shells, is not unique and depends on the applied derivation methodology. Obviously, it does not alter the results in terms of total energy flow but does, however, alter the near-field energy distribution in the individual transmission paths and therefore slightly distorts conclusions of the near-field energy partition. Let us consider the different formulations of state variables for a plate strip.

State variables from infinitesimal volume equilibrium Probably, the most common way of deriving the state variables is to consider an infinitesimal element subjected to stresses and strains and require equilibrium thereof. Doing so, we arrive at the EoM from Eq. (1) and the state variables (relevant for the energy flow in the propagation direction x) given as in Eq. (7), [6].

$$\begin{aligned} \gamma_x &= \frac{\partial w}{\partial x} & \gamma_y &= \frac{\partial w}{\partial y} & M_{xy} &= -D(1-\nu)\frac{\partial^2 w}{\partial x \partial y} \\ M_x &= -D\left(\frac{\partial^2 w}{\partial x^2} + \nu \frac{\partial^2 w}{\partial y^2}\right) & Q_x &= -D\left(\frac{\partial^3 w}{\partial x^3} + \frac{\partial^3 w}{\partial y^2 \partial x}\right) \end{aligned} \tag{7}$$

Except for a few changes in sign convention we arrive at the same result coming from the variational principle, [6].

State variables from Equation of Motion On the other hand, we may also derive the state variables directly from the EoM. To do this we consider the homogeneous EoM in Eq. (1) formulated for $w^{(j)}$ and multiply it by the solution $w^{(n)}$. Then, through *'by parts integration'* following [6], we arrive at

$$\gamma = \frac{\partial w}{\partial x} \qquad M = D\left(\frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial y^2}\right) \qquad Q = D\left(\frac{\partial^3 w}{\partial x^3} + \frac{\partial^3 w}{\partial x \partial y^2}\right) \tag{8}$$

Even from this derivation, we would see that there are several ambiguities in the definition of state variables as they can be derived differently depending on the sequence of *'by-parts integration'*.

The first and, likely, most notable difference between the two formulations of the state variables is the lack of M_{xy} and Poisson's ratio in Eq. (8). Thus, it is indeed far from obvious that no matter which pairs of state variables are substituted into Eq. (5) the total energy flow remains the same. However, the reason why these state variables can be so different and yet still satisfy the same equations was pointed out in [3]. It is because they all have essential state variables in common, while all non-essential terms cancel completely in the reciprocity relation.

4 ESSENTIAL STATE VARIABLES

The essential state variables are not always easily derived and to accomplish this task the reciprocity relation should be used. So before deriving the essential state variables we need to derive the relation between total energy flow and reciprocity since the purpose is to show that the essential state variables constitute the energy-carrying terms.

The reciprocity relation is essentially a product of the state variables from one solution, (n), of the EoM with the state variables from another solution, (j). The inhomogeneous reciprocity

relation associated with the state variables from Eq. (8) is thereby given as

$$\int_\Gamma \left[Q^{(n)}w^{(j)} - Q^{(j)}w^{(n)} + M^{(j)}\gamma^{(n)} - M^{(n)}\gamma^{(j)}\right] \mathrm{d}\Gamma = \int_V qw^{(n)}\mathrm{d}V \tag{9}$$

Although, we proceed with Γ in the following it does in this case reduce to $\int_\Gamma [\quad] \mathrm{d}\Gamma = \int_0^L [\quad]_{x=a}^{x=b} h\mathrm{d}y$.

Then following [5] or [3] we multiply by $-i\omega$, consider only the real parts, take the time average and after some straightforward algebra we arrive at

$$-\frac{\omega}{2}\mathrm{Im}\int_\Gamma \left[Q^{(n)}w^{(j)^*} - Q^{(j)}w^{(n)^*} + M^{(j)}\gamma^{(n)^*} - M^{(n)}\gamma^{(j)^*}\right] \mathrm{d}\Gamma = -\frac{\omega}{2}\mathrm{Im}\left[\int_V qw^{(n)^*}\mathrm{d}V\right] \tag{10}$$

where we immediately notice that the right-hand-side equals the total injected energy, [5], and therefore the left-hand-side must equal the total energy flow through the waveguide and is therefore equivalent to Eq. (5).

Moreover, it was shown in [3] that if n and j are single modes the reciprocity relation in Eq. (9) obeys bi-orthogonality and the left-hand-side is therefore non-zero only when $n = -j$ (where $-j$ means the opposite going wave of j i.e. $k^{-j} = -k^j$). For the inhomogeneous case where each solution, (n) and (j), is an eigenfunction expansion, bi-orthogonality of Eq. (9) converts the reciprocity relation to a quantity for which superposition applies (cross-terms cancel) and thereby proving that the total energy flow in Eq. (10) is a linear quantity. Then, the energy flow in multi-modal waveguides may be calculated straightforwardly as

$$N = -\frac{1}{2}\mathrm{Re}\left[\sum_{n\in\mathbb{N}}\int_\Gamma \mathbf{Q}^{(n)} \cdot \left(\frac{\partial}{\partial t}\mathbf{U}^{(n)}\right)^* \mathrm{d}\Gamma\right] \tag{11}$$

i.e. all cross-products of the state variables' expansions cancel completely. Here (n) counts only propagating waves. See details in [3].

Besides, it was also shown in [3] that Eq. (9) has both spatially invariant real and imaginary parts. It is essential for deriving the modal amplitudes related to the inhomogeneous problem. This immediately leads to a generalised expression for energy flow, while the conventional definition from [5] – Eq. (5), retains only a spatially invariant real part. For details see [3].

4.1 Reciprocity – State variables from equilibrium

As it has already been shown that the reciprocity relation is closely related to the total energy flow we may continue and manipulate the reciprocity relation to simplify the energy expression. Thus, let us consider instead the homogeneous reciprocity relation for the state variables from the equilibrium derivation in Eq. (7). In this case reciprocity is formulated as in Eq. (12), see [6], and for simplicity we consider n and j to be single modes.

$$\int_\Gamma \left[-M_x^{(n)}\gamma_x^{(j)} + M_x^{(j)}\gamma_x^{(n)} - M_{xy}^{(n)}\gamma_y^{(j)} + M_{xy}^{(j)}\gamma_y^{(n)} + Q_x^{(n)}w^{(j)} - Q_x^{(j)}w^{(n)}\right] \mathrm{d}\Gamma = 0 \tag{12}$$

Then, by substituting the state variables into the reciprocity relation using the notation: $\frac{\partial^3 w^{(n)}}{\partial x^3} \equiv w_{xxx}^{(n)}$ and omitting D we get

$$\begin{aligned}\int_\Gamma \big[\left(w_{xx}^{(n)} + \nu w_{yy}^{(n)}\right) w_x^{(j)} - \left(w_{xx}^{(j)} + \nu w_{yy}^{(j)}\right) w_x^{(n)} + (1-\nu)w_{xy}^{(n)}w_y^{(j)} - (1-\nu)w_{xy}^{(j)}w_y^{(n)} \\ - \left(w_{xxx}^{(n)} + w_{xyy}^{(n)}\right) w^{(j)} + \left(w_{xxx}^{(j)} + w_{xyy}^{(j)}\right) w^{(n)}\big] \mathrm{d}\Gamma \quad = 0\end{aligned} \tag{13}$$

and further, substituting the solution from Eq. (2) into the latter we get

$$\int_\Gamma \Big[k^{2(n)}k^{(j)} - k^{2(j)}k^{(n)} - k^{3(n)} + k^{3(j)} + \frac{m^2\pi^2}{L^2}\left[-\nu k^{(j)} + \nu k^{(n)} + (1-\nu)k^{(n)} - (1-\nu)k^{(j)} + k^{(n)} - k^{(j)}\right]\Big] \mathrm{d}\Gamma = 0 \tag{14}$$

from which we see that the bracket must satisfy the equation (for $n \neq -j$, [3]) and we get

$$k^{2(n)}k^{(j)} - k^{2(j)}k^{(n)} - k^{3(n)} + k^{3(j)} + 2\frac{m^2\pi^2}{L^2}\left[k^{(n)} - k^{(j)}\right] = 0 \tag{15}$$

By keeping track of the origin of each cancelled and remaining term we may deduce the essential state variables which are identical to those derived from the EoM in Eq. (8) – For example we see that the first term $k^{2(n)}k^{(j)}$ from Eq. (15) arises from $w_{xx}^{(n)}w_x^{(j)}$ in the first term in Eq. (13) which in turn belongs to $M_x^{(n)}$ and $\gamma_x^{(j)}$, respectively. The second term comes from $M_x^{(j)}$ and $\gamma_x^{(n)}$ and so on. The terms in the last bracket of Eq. (15), however, come from $M_{xy}^{(n)}\gamma_y^{(j)}$.

Then, by comparing the different state variables from, respectively, Eq. (7) and (8) it becomes obvious that it is only the product of the essential part of the forces with the essential part of the kinematic variables that are responsible for the propagation of energy and thus Poisson's ratio is seen to not affect the total energy flow. We may also note that cancellation of the non-essential parts are obvious only in the reciprocity relation while in the conventional definition of total energy flow from Eq. (6) the cancellation is indeed not obvious and here rely, somewhat, on cancellation of numerical values.

Plate in polar coordinates Another interesting example in terms of ambiguous definitions of state variables is a plate in polar coordinates with direction of propagation in r. In this example, the state variables derived from equilibrium and the variational principle are not identical as in the case of the strip. Furthermore, although the EoM is the same for the plate and the plate strip the essential state variables are different as the last terms in Eq. (15) with the factor $2\frac{m^2\pi^2}{L^2}$ in front vanishes for the plate.

4.2 From reciprocity relation to dispersion equation

Besides a close relationship between the total energy flow and the reciprocity relation, there is also a close relation between reciprocity and the dispersion relation from Eq. (3). To show this we take the reduced reciprocity relation from Eq. (15) and multiply by $(k^n + k^j)$ to get

$$k^{4(j)} - k^{4(n)} - 2\frac{m^2\pi^2}{L^2}\left(k^{2(j)} - k^{2(n)}\right) = 0 \tag{16}$$

which in comparison with the dispersion equation is seen to correspond exactly to the dispersion equation formulated for k^n subtracted the dispersion equation for k^j. In other words, we can express the reduced reciprocity relation, which is associated with the total energy flow, directly from the dispersion equation by taking the difference of two different solutions (n and j), divide by $(k^n + k^j)$ and integrate over the contour (cross-section), Γ. Thus, we can deduce, directly from the EoM, the essential state variables.

5 CONCLUSIONS

In this paper, we have shown that there exist several definitions of state variables depending on which methodology is used to derive the governing equations. These definitions slightly distort the view on energy partition between transmission paths. It is shown explicitly here that each of these definitions consist of what we denote a non-essential and an essential part where the non-essential part can be attributed to the various definitions (the ambiguity) while the essential part alone is responsible for the energy transfer through the waveguide. This novel view on the energy flow in waveguides using essential state variables suggests that the energy partition between the transmission paths might be better defined using the essential variables as they are consistent (unique) throughout the various definitions. Finally, the essential state variables also make up the energy balance in Eq. (10) which can be interpreted as a generalised formulation of the energy flow defined in [5] as it has both spatial and temporal invariant real and imaginary parts.

Keywords: Acoustic Black Holes, Optimization, Calculus of Variations

Abstract. *The effectiveness of a one-dimensional acoustic black hole has often been characterized by its reflection coefficient R and its so-called normalized wave number variation, both of which depend on the height profile of the beam. The underlying assumptions of existence of acoustic black holes require the normalized wave number variation to be small. In this work, we consider an acoustic black hole with fixed parameters of geometry (i.e. length, maximal and minimal height) and pose the variational problem of finding a height profile which minimizes R under the additional constraint of keeping L^{2n} norm of the normalized wave number variation small, since for large n this norm approximates a point-wise estimate. Using the method of Lagrange multipliers, we solve this variational problem and prove that the optimal profile is one of three different types. These profile types can be seen as direct generalizations of the well-researched profile $h(x) = \epsilon x^2$. In the limiting case $n \to \infty$, we obtain closed form expressions for the optimal profiles as well as the corresponding reflection coefficient and the normalized wave number variation. Furthermore, we compare numerically the performance of the optimal profiles and profiles previously considered in the literature. In this comparison, we demonstrate that for comparable reflection coefficients the normalized wave number variation of the optimal profile is far superior to the other profiles.*

1 INTRODUCTION

In [10] M. Mironov showed that if the height of a plate goes sufficiently smoothly to 0 at the edge then bending waves does not reflect from this edge. In particular, Mironov considered a height profile near the edge of the plate given by $h(x) = \epsilon x^m$, for $m \geq 2$ and ϵ small. In reality an edge truncation is always present and in [10] Mironov also demonstrated how a truncation of the edge (see Figure 1) can lead to increased reflection. To combat this problem many different approached have been considered [1, 3, 6–8] and numerous experiments and practical applications have been proposed [3–5, 9, 12].

In this paper we consider the optimal choice of height profile h for acoustic black holes with fixed parameters of geometry. In particular, we will formulate a variational problem for the optimality of a profile and solve this using the method of Lagrange multipliers. In the literature different choices of profiles have been considered. These profiles include $h(x) = \epsilon x^m$ [3,6–8,10,12], $h(x) = \epsilon \sin^m(x)$ [8], and $h(x) = \epsilon x^m + h_0$ [1,11]. Especially noteworthy for our purpose is [11] in which multi-objective optimization algorithm was employed to numerically find an optimal profile of the form $h(x) = \epsilon x^m + h_0$ for an acoustic black hole. Note that our approach to finding optimal profiles is purely analytical and as opposed to [11] we do not restrict our attention to one particular type of profile.

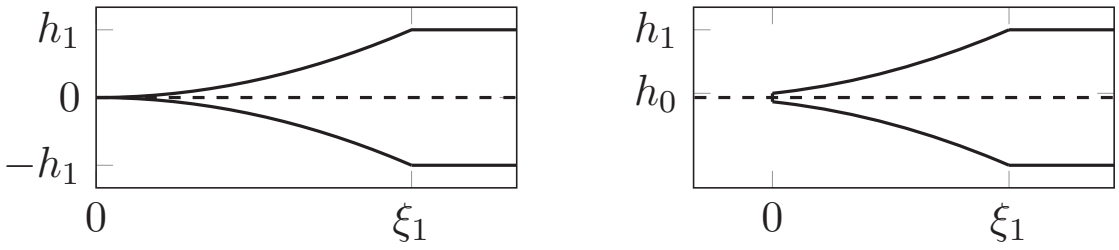

Figure 1: Non-truncated profile (left) and truncated profile (right).

2 SETTING AND PROBLEM STATEMENT

We consider an Euler-Bernoulli beam with *local* wave number given by the equation

$$(k(x))^4 = \frac{12\rho\omega^2}{Eh^2} = \frac{12\omega^2}{c^2h^2(x)}, \tag{1}$$

where $c = (E/\rho)^{1/2}$ is the speed of dilatation wave velocity in beams [7, 8]. We assume a time dependence $e^{-i\Omega t}$ and take energy dissipation into consideration, i.e. $E = E_0(1 - i\eta)$ for some $\eta > 0$. The reflection coefficient of an acoustic black hole, situated between x_0 and x_1 is defined as

$$R = \exp\Big(-2 \int_{x_0}^{x_1} \mathrm{Im}(k(x))\, \mathrm{d}x \Big), \tag{2}$$

under the assumption that the following geometrical acoustics validity condition is satisfied

$$\left| \frac{1}{k^2} \frac{\mathrm{d}k}{\mathrm{d}x} \right| \ll 1, \tag{3}$$

see e.g. [1, 7, 8, 10]. The left hand side of (3) is often referred to as the normalized wavenumber variation (NWV) [1]. The condition (3) has been suggested to be satisfied when the NWV is less that 0.3 [2].

For the rest of this paper we consider dimensionless variables and denote dimensional variables with a tilde. We want to construct an acoustic black hole in the interval $[0, \xi_1]$. We construct a symmetric acoustic black hole (cf. Figure 1) and hence we denote half the maximal (minimal) height by h_1 (h_0). We assume that $h_1 = 1$ and $h_0 \in (0, 1)$, see Figure 1. Additionally, $h(\xi)$ denotes the half beam height at ξ and Ω denotes the dimensionless frequency.

The equivalent problem in dimensional variables is to consider an interval $[\tilde{x}_0, \tilde{x}_1]$ and a function $\tilde{h}$ such that $\tilde{h}(\tilde{x}_0) = \tilde{h}_0$, $\tilde{h}(\tilde{x}_1) = \tilde{h}_1$, and $\tilde{h}(\tilde{x})$ is the half height of the beam at $\tilde{x} \in [\tilde{x}_0, \tilde{x}_1]$. Transformation to non-dimensional variables is done by the formulas

$$h(\xi) = \frac{\tilde{h}(\tilde{x}_0 + \xi\tilde{h}_1)}{h_1}, \quad k(\xi) = \tilde{k}(\tilde{x}_0 + \xi\tilde{h}_1)\tilde{h}_1, \quad h_0 = \frac{\tilde{h}_0}{\tilde{h}_1}, \quad \xi_1 = \frac{\tilde{x}_1 - \tilde{x}_0}{\tilde{h}_1}, \quad \Omega = \frac{\tilde{\omega}\tilde{h}_1}{\tilde{c}},$$

where $\tilde{\omega}$ is the dimensional angular frequency and $\tilde{c}$ it the dimensional longitudinal wave velocity and $\tilde{k}$ is the dimensional local wave number.

Our aim is to find a profile h which minimizes R in (2) while (3) hold. However, for simplicity we will approximate the pointwise bound in (3) with a bound of the L^{2n} norm of the NWV for large n. By noting that R is minimized by maximizing the integral on the right hand side of (2) and using a first order approximation to the non-dimensional form of k in (1) we arrive at the following isoperimetric variational problem: *Given $\eta, \Omega_0 > 0$ find, for every $n \in \mathbb{N}$, a curve h_n which maximizes the functional*

$$h \mapsto \int_0^{\xi_1} \frac{12^{1/4}\Omega_0^{1/2}}{\sqrt{2}h^{1/2}(\xi)} \frac{\eta}{4} \, \mathrm{d}\xi \tag{4}$$

subject to the boundary conditions

$$h_n(0) = h_0, \quad \text{and} \quad h_n(\xi_1) = 1, \tag{5}$$

and the additional constraint that

$$\int_0^{\xi_1} \Big(\frac{\sqrt{2}}{2 \cdot 12^{1/4}\Omega_0^{1/2}} \frac{h_n'(\xi)}{h_n^{1/2}(\xi)} \Big)^{2n} \, \mathrm{d}\xi = L \tag{6}$$

for some $L \ll 1$.

We refer to Ω_0 as the design frequency.

3 RESULTS

By using the method of Lagrange multipliers together with a convenient scaling and the notation $\delta = (-\lambda)^{-1/(2n)}$ we find that a solution to our isoperimetric problem must maximize

$$h \mapsto \int_0^{\xi_1} b\frac{1}{h^{1/2}(\xi)} - \frac{(h'(\xi))^{2n}}{h^n(\xi)} \, \mathrm{d}\xi, \tag{7}$$

where $b = (2\delta)^{2n} 12^{(2n+1)/4} \Omega_0^{n+1/2} \frac{\eta}{8}$. Hence any solution must satisfy the Euler-Lagrange equation

$$h'(\xi) = (2n-1)^{-1/(2n)} (a h^n(\xi) - b h^{n-1/2}(\xi))^{1/(2n)}, \quad \xi \in (0, \xi_1), \tag{8}$$

where a is some constant which must be determined so that the boundary conditions (5) holds. Note that by considering a sequence of oscillating functions with increasing frequency it follows that (7) does not have a minimizer.

3.1 The case $b = 0$

The case $b = 0$ is uninteresting from a practical perspective since it corresponds to minimizing the NWV without any regards for the reflection coefficient. Nevertheless it turns out to be interesting when considering the literature on acoustic black holes. When $b = 0$ the function

$$h(\xi) = \left(\left(1 - \sqrt{h_0}\right)\frac{\xi}{\xi_1} + \sqrt{h_0}\right)^2 \tag{9}$$

is the unique solution to (8) satisfying (5) for all $n \in \mathbb{N}$. This is a generalization of the profile $h(x) = \epsilon x^2$ (which has been used extensively in the literature, see e.g. [1, 4, 7, 8, 10, 11]). Indeed when converting this profile to non-dimensional variables it solves (9) if and only if $\tilde{h}_0\tilde{x}_1^2 = \tilde{h}_1\tilde{x}_0^2$.

3.2 The case $b > 0$

When $b > 0$ solving (8) leads to two possibilities. Specifically, for every $n \in \mathbb{N}$ there exists a number b_n such that:

1. If $b \leq b_n$ there exists a unique $a \geq bh_0^{-1/2}$ such that (8) has a unique $C^\infty([0, \xi_1], [h_0, 1])$ solution satisfying (5).

2. If $b > b_n$ there exists a unique $\xi(b) \in [0, \xi_1]$ and a function $h_b \in C^\infty([\xi(b), \xi_1], [h_0, 1])$ satisfying (8) with the boundary conditions $h_b(\xi(b)) = h_0$ and $h_b(\xi_1) = 1$ such that

$$h(\xi) = \begin{cases} h_0, & \text{if } 0 \leq \xi \leq \xi(b), \\ h_b(\xi), & \text{if } \xi(b) < \xi \leq \xi_1 \end{cases}$$

   is a $C^1([0, \xi_1], [h_0, 1])$ and piecewise $C^\infty([0, \xi_1], [h_0, 1])$ solution to (8).

Note that in both cases the solution must be found numerically as no closed form expression exist. Therefore it is unclear how to choose the parameters δ and n in practical applications.

The parameter n should be large to ensure that the left hand side of (6) approximates a point-wise estimate. By taking n to infinity we obtain the following: If $\Omega_\infty = \left(\frac{1-\sqrt{h_0}}{12^{1/4}\delta\xi_1}\right)^2$, then:

(a) If $\Omega_0 < \Omega_\infty$ then no optimal profile exists.

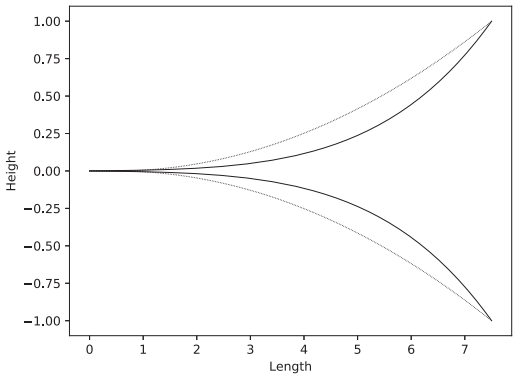
(b) If $\Omega_0 \geq \Omega_\infty$ then the optimal profile is given by

$$h(\xi) = \begin{cases} h_0, & \text{if } 0 \leq \xi \leq \xi_\infty, \\ \left(12^{1/4}\delta\Omega_0^{1/2}(\xi - \xi_1) + 1\right)^2, & \text{if } \xi_\infty < \xi \leq \xi_1 \end{cases} \tag{10}$$

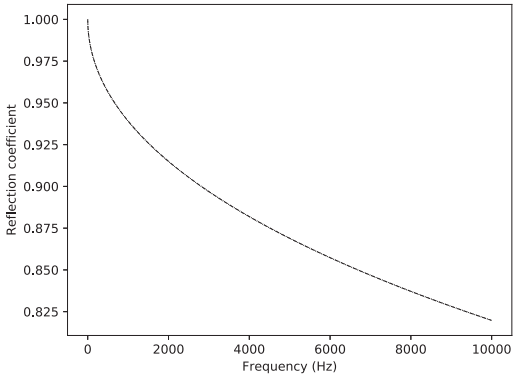
   where $\xi_\infty = \xi_1 - \frac{1-\sqrt{h_0}}{12^{1/4}\delta\Omega_0^{1/2}}$.

Note that h is a continuous function with a discontinuity in the first derivative at ξ_∞. Furthermore, the simple expression for h makes it possible to determine both R and the NWV explicitly. The NWV for the optimal profile in (10) is given by

$$\left|\frac{1}{k^2}\frac{\mathrm{d}k}{\mathrm{d}\xi}\right| = \begin{cases} 0, & \text{if } 0 \leq \xi \leq \xi_\infty, \\ \sqrt{2}\delta\left(\frac{\Omega_0}{\Omega}\right)^{1/2}, & \text{if } \xi_\infty < \xi \leq \xi_1, \end{cases} \tag{11}$$



(a) The classical (solid) and optimal (dotted) profile of Section 4.



(b) Reflection coefficients for the profiles in Figure 2a. The same line specefications as in Figure 2a have been used.

Figure 2: Classical and optimal profile and their corresponding reflection coefficients.

and the reflection coefficient for the profile in (10) is

$$R = \exp\Big[\frac{\eta\Omega^{1/2}}{2\sqrt{2}}\Big(\frac{\ln h_0}{2\delta\Omega_0^{1/2}} - \frac{12^{1/4}\xi_\infty}{h_0^{1/2}}\Big)\Big]. \tag{12}$$

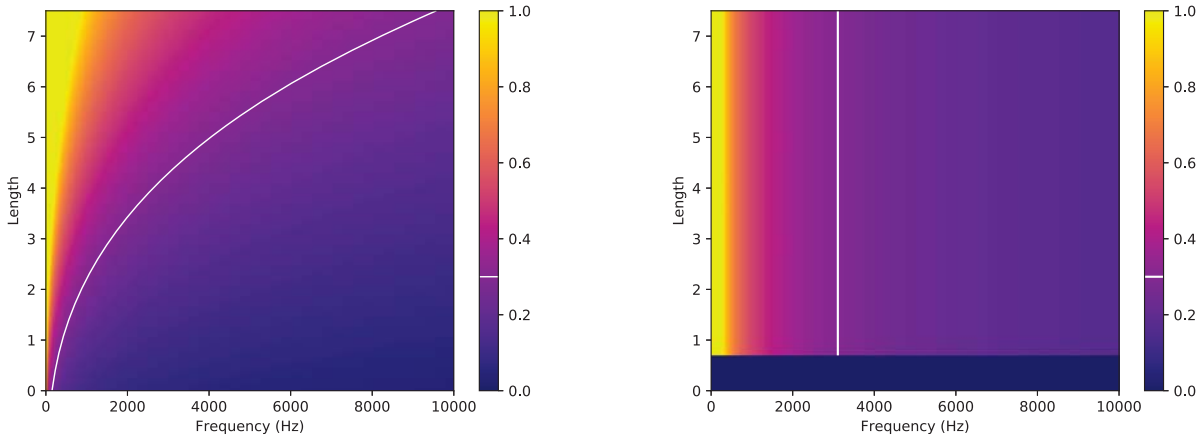
One strength of the optimal profile in (10) is that its NWV becomes a piecewise constant function of ξ. Hence to make the NWV small it suffices to consider sufficiently large Ω. For example, it is clear that if $\delta = \sqrt{2}/5$ then we have NWV< 0.4 when $\Omega > \Omega_0$. This is not the case for e.g. profiles of the form $h(x) = \epsilon x^m$ with $m > 2$ cf. Section 4.

4 NUMERICAL EXPERIMENTS

In [1] it was demonstrated that increasing m for profiles like $\tilde{h}(\tilde{x}) = \epsilon\tilde{x}^m$ decreases the reflection coefficient but increases the NWV. In this section we demonstrate numerically the difference between an acoustic black hole with profile $\tilde{h}(\tilde{x}) = \epsilon\tilde{x}^m$ for $m = 5$ and the profile in (10). We consider the following dimensional parameters: $\tilde{x}_0 = 5$cm, $\tilde{x}_1 = 20$cm, $\tilde{h}_0 = 0.00195$ cm, $\tilde{h}_1 = 2$cm, $\tilde{c} = 3000$m/s. Furthermore, we assume that the loss factor is $\eta = 0.01$ and let $\delta = \frac{\sqrt{2}}{5}$. We then find Ω_0 such that the optimal profile given by (10) has reflection coefficient similar to that of the non-optimal profile (see Figure 2b). The difference in the shape of the profile (see Figure 2a) leads to the vastly different NWV for the two profiles (see Figure 3). Note that the NWV of the "classical" profile is larger than 0.3 somewhere in the acoustic black hole at most of frequencies considered.

5 CONCLUSIONS

In the present paper the choice of optimal height profile for a one-dimensional acoustic black hole with fixed parameters of geometry has been considered. By regarding the reflection coefficient R as a functional defined on the possible height profiles we have posed the variational problem of minimizing R subject to the constraint that the L^{2n} norm of the NWV equals some small constant. By solving this problem we obtain, that the optimal profile can be of three types: a quadratic polynomial, a smooth function (which has to be determined numerically), or a C^1 function which is comprised of a constant part equal to the minimal height and a smooth part. In the limiting case $n \to \infty$, there is essentially one solution: a continuous piecewise smooth



(a) NWV for the classical profile in Figure 2a.

(b) NWV for the optimal profile in Figure 2a.

Figure 3: NWV for the profiles of Figure 2a.

function comprised of a constant part equal to the minimal height and a quadratic part. In fact, we obtain simple expressions for both the quadratic part and the length of the constant part. We have shown that this can be seen as a generalization of the well-known profile $h(x) = \epsilon x^2$. We have numerically compared this optimal profile in the limiting case to a profile of the form $h(x) = \epsilon x^m$ for $m > 2$. This shows that at similar reflection coefficients the NWV differs vastly. For the optimal profile the NWV becomes small for large frequencies but for the other profile NWV is large for most of the frequencies considered.

Abstract. *The classical theory of acoustic black holes (ABHs) is quite complex with its application being limited to simple plates and beams. The aim of this paper is to promote ABHs for the community of engineers well familiar with finite element analysis (FEA). Firstly, a validation of FEA as a tool to analyze and design ABHs is done by conventional FE studies replicating experiments, which have already been conducted. Then the concept of modal analysis-based design of ABH is proposed and verified by means of harmonic analysis (both using standard ANSYS software). As the damping layer is an essential part of any real fabricated products utilizing the ABH effect, the influence of its size and thickness are studied by the means of FEM and compared to what has been found in earlier experiments.*

1 INTRODUCTION

ABHs are power-law wedges used to achieve efficient damping of waves. The power-law wedges are described by $h(x) = \varepsilon x^m$, where ε is the wedge parameter and m is the power-law exponent, $m \geq 2$. Under such circumstances, the wave speed gradually decreases and the wave stops in the limit of $h \to 0$ where the height is zero, see Fig. 1, and hence, is not reflected but trapped. However, real fabricated wedges have truncations and it has been shown that the introduction of such truncations only reduce the reflection coefficient to about 50-70%, [1], making them practically useless as ABH dampers. It has been shown, on the other hand, that placing a damping layer in the ABH at the tip of the wedge can reduce the reflection coefficient to only 1-3%, meaning that almost all of the wave energy is absorbed by the damping layer, [1].

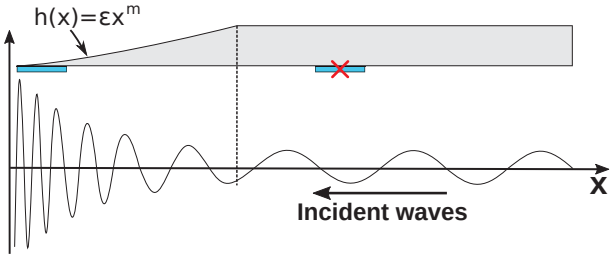

Figure 1: Illustration of the wave as it approaches the tip of the wedge.

The idea of the ABH is illustrated in Fig. 1 i.e. when a wave travelling through the plate reaches the ABHs the wave speed gradually slows down due to the gradual decrease in height, which causes the wavelength to decrease and the amplitude to increase. Thus, by placing a damping layer at the tip where the wavelength is short and the response is high, an efficient damping of the wave energy can be achieved. If, on the other hand, the damping layer is placed outside the ABH, where the wavelength is long and the energy is less concentrated, the damping layer has little to no effect. Thus, as the ABHs rely on sufficiently small wavelengths in the damping layer zone, ABHs are indeed mostly effective at higher frequencies, as also confirmed in literature, [2]. Likewise, it has been shown in [3] that damping layers do not need to cover the entire ABH area but covering just a small area may in fact be more efficient, see e.g. Fig. 6. It was also shown that at higher frequencies a larger damping area was required to retain the strong effect of the ABH which may be somewhat counter intuitive.

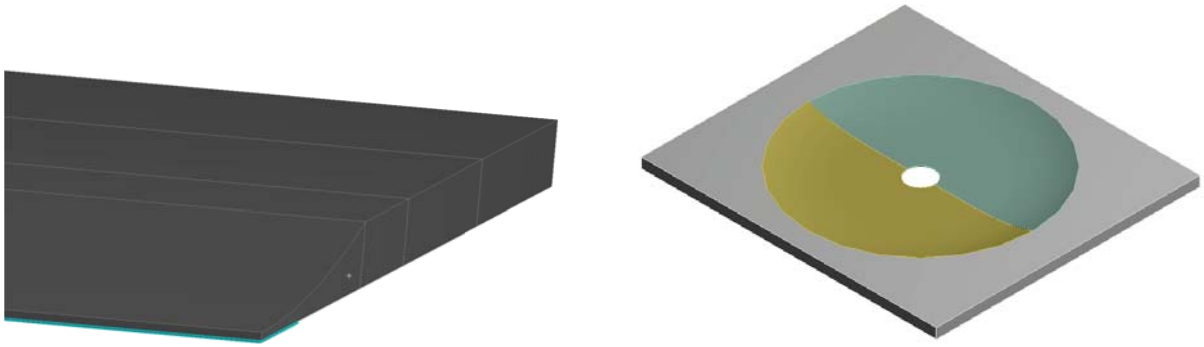
In this paper, we begin with simulations conducted using a commercial FEA program on cases, which have already been investigated experimentally by others. This is done to investigate the capability of the FEA program to simulate the ABH effect. Next, we implement ABHs in a physical product in FEA, and interestingly, it is found that design of ABHs can be done using modal analysis alone. The performance of the ABHs can, to some degree, be predicted from the eigenmodes as the damping effect proves to be strongly related to localization of the eigenmodes. This also explains why ABHs are more effective at higher frequencies. Therefore, ABHs of arbitrary shapes have also been tested as they do not need to be circular.

2 ACOUSTIC BLACK HOLES USING FINITE ELEMENT ANALYSIS

ABH theory is typically associated with infinite structures and incident waves while FEA is concerned with finite structures and therefore standing waves. Likewise the experimental work on ABH done in [2] was also based on finite structures with no attempt to make anechoic terminations and thus the effects observed here should be reproducible using e.g. FEA. Thus, to verify the ability of the commercial FE program ANSYS to capture the effect of a plate with ABHs, harmonic analysis has been conducted on cases from [4, 5], which involves both 1D and 2D examples. In [5], several configurations of plates with 2D ABHs are presented, but for brevity, only one of them is presented here. The cases presented here are seen in Fig. 2.

2.1 FEA setup

Meshing has been done following the guidelines from *ANSYS* and the damping layer has density of 1160 $\frac{kg}{m^3}$, stiffness equal to 0.1 of the plate material, [2], Poisson's ratio of 0.48, thickness of 0.2 mm, and a loss factor of 0.4 according to [2, 4, 6]. For the 1D example in Fig. 2, a unit force was applied transversely on the rear edge, while the transverse surface velocity response was measured on a line on top of the uniform section of the plate. Similarly for the 2D case, transverse loading and response measurements were done on two opposite edges of the plate.

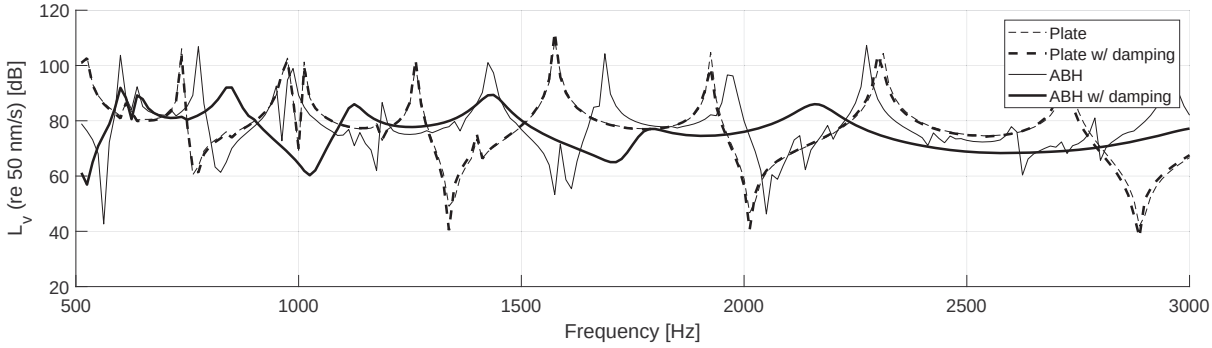


(a) (b)

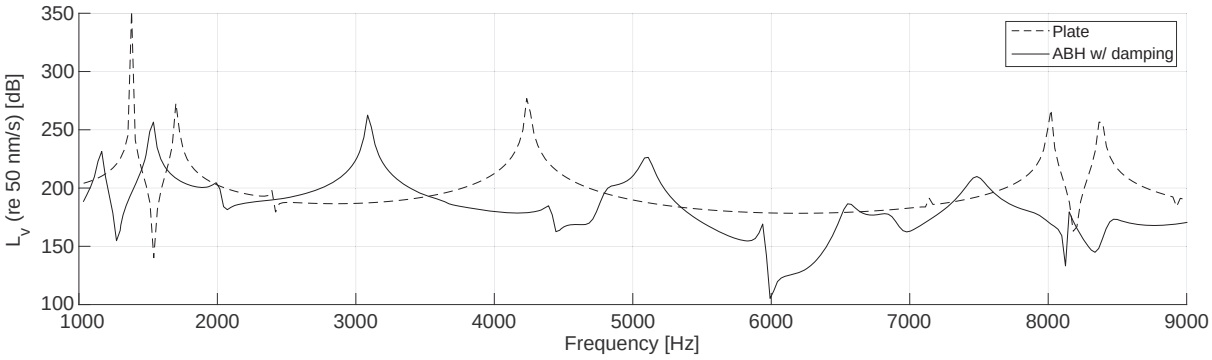
Figure 2: a) 1D ABH at the end of a plate. b) 2D ABH on a plate. Both in free conditions.

2.2 Harmonic analysis of acoustic black holes

The results from the replicated experiments on plates with 1D and 2D ABHs are plotted in Fig. 3.



(a)



(b)

Figure 3: a) Results from analysis of 1D ABH. b) Results from analysis of 2D ABH. Velocities in dB following ISO 1683, [7].

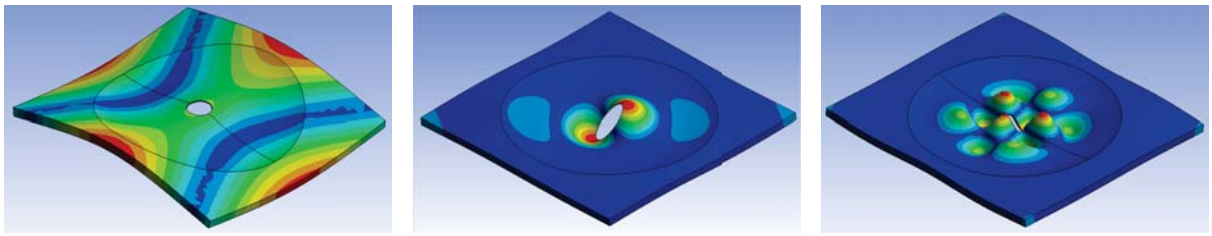
As can be seen in Fig. 3a, the unmodified plate with a damping layer has almost no effect on the response as mentioned in Sec. 1, while the introduction of ABHs without damping just shifts the eigenfrequencies, but does not significantly damp the response as the reflection coefficient remains within 50-70%, according to Sec. 1. The combination of an ABH with a damping layer, however, damps the response significantly and damping is seen to increase with increasing frequency as also discussed in Sec. 1. This is also observed for the 2D example in Fig. 3b.

In conclusion, we see similar tends of the ABH as those observed in experiments and the ABH theory in Sec. 1 when using standard harmonic analysis. Furthermore, in both graphs, we see that the dB-response is reduced significantly: for the 1D case in Fig. 3a about 20 dB and for the 2D case close to 100 dB.

2.3 Modal analysis of acoustic black holes

From the analyses done in Sec. 2, it has been found that the observed phenomena of the 1D and 2D ABHs, can actually be very well explained through simple modal analyses. In Fig. 4, we see selected eigenmodes from the modal analysis and immediately note that in terms of eigenmodes, the ABHs simply cause the eigenmodes at higher frequencies to localize in the center of the hole. This readily explains why ABHs work only at sufficiently high frequencies but also why adding a damping layer significantly improves the performance. Thus, localizing 'all' higher order modes in one location obviously makes damping by a small damping layer in the ABH very efficient for broad band excitation, in accordance with Sec. 1. Further, we see

that the lower order modes remain global and are thus less affected by the ABH. However, the wave speed still decreases in the ABH and some energy can be damped even at lower frequency as we shall see in Sec. 3.

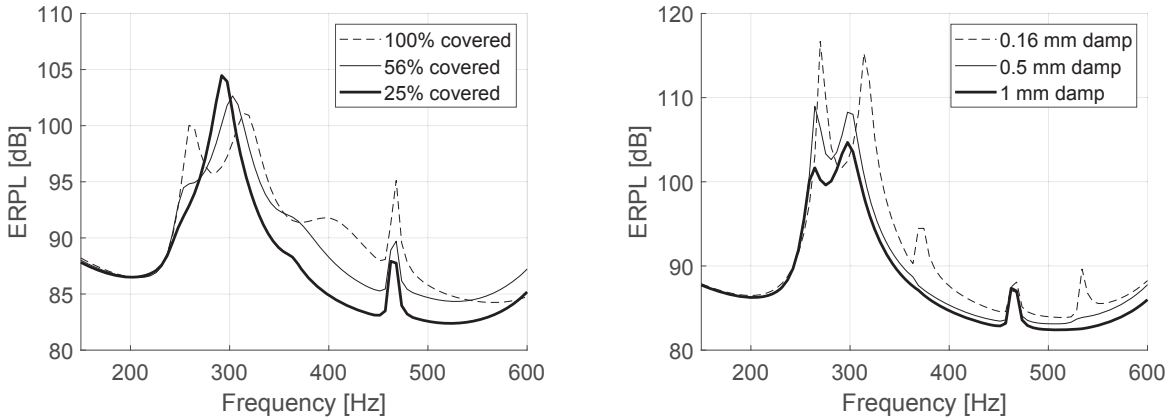


(a) (b) (c)

Figure 4: a) Global eigenmode at 770 Hz. b) Localized eigenmode at 2790 Hz. c) Localized eigenmode at 8165 Hz.

Furthermore, comparing Fig. 4b and 4c we can readily explain the counter intuitive phenomenon that for higher frequencies the localized eigenmodes become spatially less compact and thus require a larger damping layer, as also observed in experiments see e.g. Sec. 1.

Indeed, choosing the right damping layer thickness and size is not trivial. From Fig. 5a, we see that a low coverage can be desirable for these low frequencies, although the peak at 300 Hz is slightly higher for lower coverage. Considering 5b, it is seen that a thicker damping layer lowers the ERPL response, as expected. Therefore, it is believed that a thick and low coverage damping layer would be the optimal design.



(a) (b)

Figure 5: a) Comparison of damping layer coverage of the ABH. Layer thickness 1 mm. b) Comparison of damping layer thickness. Coverage of ABH: 25%. ERPL (Equivalent Radiated Power Level) is used. Test case: Circular ABH from Fig. 4.

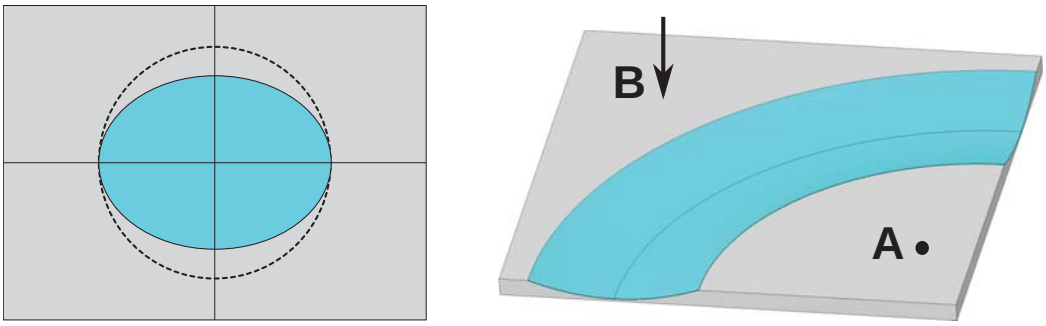
In conclusion, ABHs cause the eigenmodes to localize, thereby producing a large response in a small area, which can then be damped efficiently using only a small patch of damping layer. Thus, for a desired frequency range, the ABH can be designed based on a simple modal analysis and moreover the size of the damping layer be determined by matching the size of the spatially largest mode shape in the spectrum, which will typically be the last mode in the desired range.

At lower frequencies, however, the ABH have only little effect, but as this is usually interesting from a industrial viewpoint this will be the main interest in the following section.

3 ACOUSTIC BLACK HOLES OF ARBITRARY SHAPES

As we have shown in the previous section, the ABH can be evaluated and designed directly from modal analysis, we no longer confine ourselves to think of ABH as wedges or circular holes, nor are we strictly confined to power-laws (though they may likely be the most efficient ones) as long as we ensure localization of the eigenmodes. Therefore, we consider instead arbitrarily shaped ABHs (with power-laws) and study how they perform compared to the regular circular ABHs.

In this paper, two ABHs of 'arbitrary' shape have been considered. The first one is an elliptically shaped ABH, as a simple idea to reduce the size of the ABH without compromising the effect of the ABH, see Fig. 6a. This shape could also be tailored to match specific eigenmodes or shapes of an industrial product. The other type is an acoustic black 'moat', where a power-law profile is swept along a path to create a type of insulator, tailored to a specific lower order eigenmode. The purpose is to prevent waves generated at the source point B, from reaching the receiver point A, see Fig. 6b.



(a) (b)

Figure 6: Conceptual illustrations of arbitrary ABH. a) Elliptical ABH. b) Acoustic black 'moat' with a receiver (A) and source point (B).

To compare the performance of the arbitrarily shaped ABHs, a traditional circular one is used as benchmark. This ABH corresponds to the dotted circle in Fig. 6. For consistency, all ABHs are 100% covered with a 1 mm damping layer. Additionally, these ABHs have been implemented in a physical product and analyzed using the FEA approach elaborated in Sec. 2. The circular, elliptical and moat ABH cover, respectively 56%, 48% and 34% of the total surface area of the product. Further, the material properties have been changed to those of the physical product, which compared to steel, is much more compliant. Furthermore, the frequency range of interest is 150-600 Hz, which is indeed in the low frequency range even for this compliant material.

In Fig. 7, we see that all three cases reduce the ERPL by about 20 dB, even in this lower frequency range. Further, we note, interestingly enough, that the moat performs surprisingly well given a coverage of only 34% compared to the benchmark, which covers 56%. The elliptical ABH (with 48% coverage) also outperforms the circular one. This may be explained by the location and dimensions of the ellipsoid, which has been designed to match a specific mode shape.

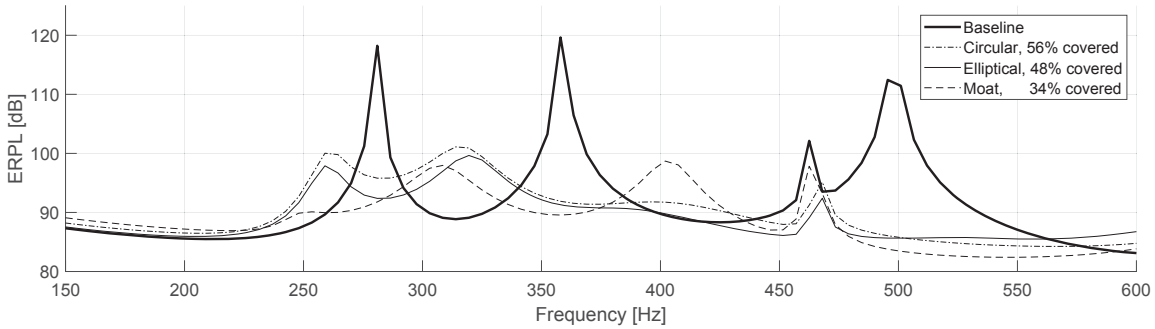


Figure 7: Comparison of ERPL, for the baseline design, a circular ABH, an elliptical ABH, and the acoustic black 'moat'.

Upon closer inspection of the eigenmodes of the moat, it can be seen from Fig. 8 that it does in fact act as an eigenmode-insulator, where the energy is sufficiently damped in the moat before it 'reaches' and excites the mode. The reason for this is explained by the decrease in wave speed, elaborated in Sec. 1. In conclusion, we have shown that we can, even at lower frequencies, benefit from the ABH concept even without having strict localization of the modes, simply by tailoring the ABH shapes to match the modes we are trying to damp, or 'protect', from the source. Thus, we have shown that we can benefit greatly from arbitrarily shaped ABHs designed based on modal analysis.

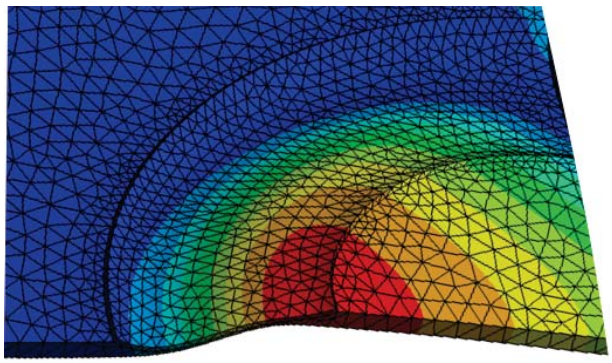

Figure 8: Lower order eigenmode for the acoustic black moat.

4 CONCLUSION

In this paper, we demonstrate that design of acoustic black holes can be done through standard finite element modal analysis of a structure with ABH through the eigenmodes. Further, the phenomena found in experiments conducted by various authors, may conveniently be explained by localization of eigenmodes. If the eigenmodes are not localized, the size of the ABH generally needs to be increased. Respectively, we have shown that the damping layer only needs to cover the area, where the given eigenmodes are localized, as a larger damping layer will have only an insignificant effect. Since localization of eigenmodes has been shown to be the key for designing efficient ABHs, it has been proposed that the shape of the ABHs does not need to be circular, which certainly allows for more freedom in design. This has also led to think of ABHs as moats, e.g. 'insulators' to protect a 'receiver' from a 'source'. This significantly widens the possibilities of using ABHs in industrial applications.

Abstract. *A classical problem in the design of periodic waveguides is to get stop bands at desired frequencies. In this paper, the problem is addressed by use of optimization within the Wave Finite Element Method (WFEM). Typically, today optimization for stop bands is done using stochastic optimization due to the 'semi-discrete' behavior of the objective function. This method, in-line with previous work, is used as benchmark. This is compared to another method which handles the 'semi-discrete' behavior by a simple manipulation of the objective function into being continuous. This is a novel method that allows for fully gradient based optimization to be used. By comparing the continuous objective function with the benchmark method, it is found, that the continuous objective function outperforms the benchmark, in terms of computational speed and robustness.*

1 INTRODUCTION

This paper is concerned with the general case of wave propagation in waveguides with complex geometry, where analytical solutions might not be available. To accommodate this, we use the wave finite element method (WFEM) which is a well-established numerical method for solving wave propagation problems of complex waveguides, and is described in numerous references, [1–4]. In WFEM a finite waveguide is modelled as being infinite through periodicity by use of continuity and periodicity conditions. Analysis of periodic structures is concerned with Bloch's parameter, K_B, which is a complex number, describing the phase change (Re$\{K_B\}$) and attenuation (Im$\{K_B\}$) of a wave over a unit cell. A description of analysis of periodic structures can be found in classical text such as [5]. To obtain wavenumbers in WFEM, Bloch's parameter is divided with the length of the unit cell. In this paper, however, only Bloch's parameter is of interest. Description of the WFEM is out of scope for this paper, but is described in detail in e.g. [2].

Periodic waveguides have the ability of attenuating waves at certain frequencies, following the phase-closure principle, [6]. This is also known as stop bands. For the industrial partner, Grundfos A/S, the main issue, that can be alleviated by stop bands, is the propagation of waves from pumps into a system, causing noise or damage. It is thus relevant to investigate how stop bands in periodic structures can be moved to or created at desired frequencies. By employing optimization on a parametric model of a waveguide, it is possible to tailor the performance of a waveguide to include stop bands at desired frequencies. In literature, this has been done by use of a stochastic optimization scheme and subsequent gradient based optimization on an analytical model of a waveguide in [7], by use of a pure stochastic optimization on a WFEM model in [8] and a genetic algorithm on an analytical model of a composite in [9]. Common for all papers is that they use zero order optimization algorithms. One of the main pit falls of zero order algorithms is increased computational time for problems involving many design variables. The scope of this paper is to present a novel method for optimization in WFEM using fully gradient based optimization.

The paper is structured as follows; In Sec. 2, optimization of the waveguides is described. This includes a benchmark method based on previous work from literature and a novel method. In Sec. 3, the optimization is carried out on two different examples. Finally, Sec. 4 will contain a discussion on the advantages of using the new method instead of the benchmark method.

2 OPTIMIZATION ON A WFE MODEL

In the optimization it is desired to maximize the attenuation of waves at desired frequencies, hereinafter denoted target frequencies, by including stop bands in a frequency range, corresponding to e.g. the operating frequency range of a pump.

From the WFE program a $2m \times n$ array, $\mathbf{K_B}$, is obtained. This array contains Bloch's parameter for n target frequencies and m different types of waves. To maximize the attenuation at all target frequencies with respect to all wavemodes of interest, corresponds to maximizing the absolute value of the imaginary part of $\mathbf{K_B}$. Mathematically this can be expressed as,

$$\min_{\mathbf{x}} \quad f(\mathbf{x}) = \max[-|\text{Im}\{\mathbf{K_B}\}|] \tag{1}$$

In Eq. (1), $\mathbf{x}$ is the vector of design variables that is put into the WFE model. The problem with the formulation of the objective function from Eq. (1), is that it has a 'semi-discrete' behavior, meaning that gradient information is only available at some points in the frequency spectra, see Fig. 1, where e.g. no gradient information is available at 0-1 kHz and 2-4 kHz. To overcome

this problem literature, [7–9], suggests that a stochastic algorithm must be applied before a gradient based optimization can be carried out. The issue with this method is that the stochastic algorithm is computationally heavy, when there is a large number of design variables, and needs several reruns to ensure robustness.

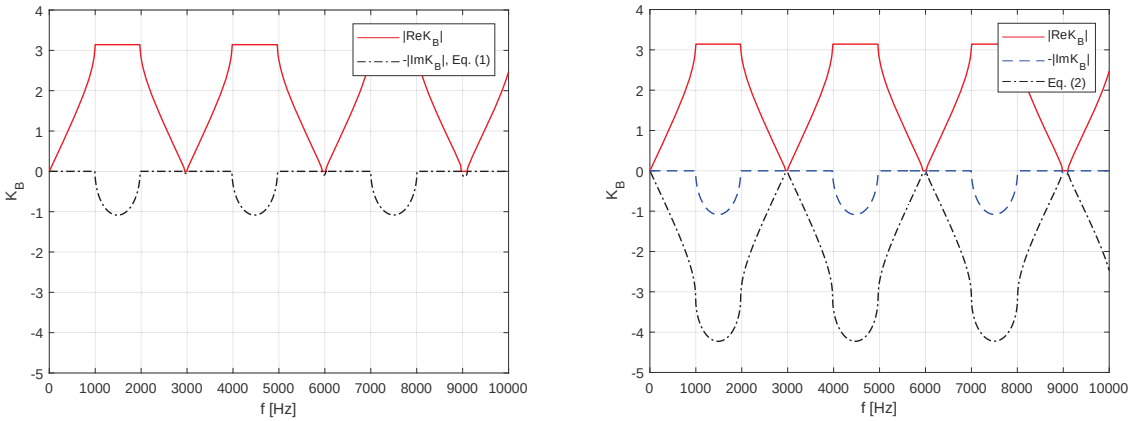

Figure 1: Illustration of the 'semi-discrete' behavior corresponding to Eq. (1) (left) and a function, which is C^1 continuous at almost all frequencies corresponding to Eq. (2) (right). The dispersion diagram is obtained for a two volume functionally graded material model, see Sec. 3, with only propagating longitudinal waves considered.

These issues can be overcome, by a simple manipulation of the objective function as proposed here. This method contains a formulation which is the summation of the real and imaginary part of the complex Bloch parameter. The real and imaginary part of the Bloch parameter is alternating C^1 continuous, and summation of them will yield an expression continuous almost everywhere, see Fig. 1. The continuous problem may thus be formulated as,

$$\min_{\mathbf{x}} \quad f(\mathbf{x}) = \max[-w_1|\mathrm{Im}\{\mathbf{K_B}\}| - w_2|\mathrm{Re}\{\mathbf{K_B}\}|] \tag{2}$$

where w_1 and w_2 are weights for the imaginary and real part, respectively.

Through the rest of this paper, optimization on the objective function in Eq. (1) will be denoted formulation 1, while optimization on the objective function in Eq. (2) will be denoted formulation 2 and will be benchmarked against formulation 1. The controlled random search (CRS) algorithm, [10], is used as the stochastic optimization scheme, in-line with [7], and the sequential quadratic programming algorithm (SQP), [11], instead of the method of moving asymptotes (MMA), for the gradient based optimization. The sensitivities are calculated numerically by use of forward difference approximation. Further, when optimizing with respect to a target frequency range, the frequency range is discretized into a sufficient number of discrete frequencies. To overcome the inherent problem of non-differentiability in the min-max problem of minimizing Eq. (1) and Eq. (2), bound formulation is used, when multiple target frequencies ($n > 1$) and wavemodes ($m > 1$) are considered, [12].

3 EXAMPLES

To compare formulation 2 with the benchmark formulation, two different 1-dimensional examples are considered. The first example is optimization of a waveguide, that consists of elements with fixed geometry and discretely functionally graded material properties. The second example is optimization of a waveguide, consisting of a bi-material composite with fixed

material properties and variable geometry. For both examples optimization is targeted for respectively maximum attenuation at a single target frequency, maximum attenuation at a target frequency range and maximum attenuation at multiple target frequencies. The focus of the optimization is on longitudinal propagating waves. Optimization using formulation 1 is carried out four times to ensure robustness, as the algorithm is stochastic, [7]. Only the solution with the highest attenuation level is presented in the following. For formulation 2, the optimization is made with different weighings. Not all solutions are presented.

3.1 Functionally graded material

In this example, optimization is carried out on a model consisting of n volumes of size 1m×1m×1m, see Fig. 2. Each volume has constant material properties given by the relation,

$$\begin{aligned} E_i &= E_A + x_i(E_S - E_A), \quad i = 1, 2, .., n \\ \rho_i &= \rho_A + x_i(\rho_S - \rho_A), \quad i = 1, 2, .., n \end{aligned} \tag{3}$$

where E_A and ρ_A are the material properties for aluminum, and E_S and ρ_S the material properties for steel, see Tab. 1. x_i are the design variables and have upper and lower bound, $0 \leq x_i \leq 1$. This means that there is an abrupt change in material properties at the volume

Material	Young's modulus E	Poisson's ratio ν	Density ρ
Aluminum	69 GPa	0.30	2700 kg/m^3
Steel	210 GPa	0.30	7800 kg/m^3

Table 1: Material properties used for the functionally graded materials.

boundaries which is needed for the travelling waves to be reflected and stop bands to be created. An industrial application for this example could be an element consisting of sintered metals with changing porosities which would result in this form of functionally graded materials.

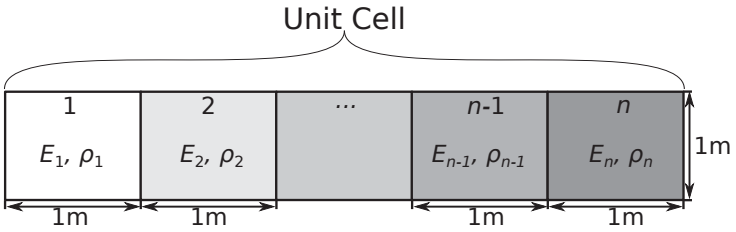

Figure 2: Illustration of the model consisting of n volumes of functionally graded material. Each volume has the dimensions 1m×1m×1m.

For a two volume model, it is the stiffness ratio between the two volumes that determines the stop bands. The stop bands evolve from the critical frequencies or 'seeds' of stop bands, which is described in [13]. The critical frequencies are dependent on the parameter $\tau = \frac{c_1 L_2}{c_2 L1}$, where c_i and L_i is the speed of sound and length of each volume. As the length of each element is fixed and the speed of sound remains constant, it is not possible to change the critical frequencies, see Fig. 1. Optimization is therefore carried out on a model consisting of 8 volumes, as this increases the mobility of the critical frequencies and thus stop bands.

The optimization is carried out for several target frequencies, see Tab. 2, and the starting guess for formulation 2 is a homogeneous material distribution, i.e. $x_i = 0.50$. The optimization for a desired stop band at frequency 2150 Hz, shows that formulation 1 finds a minimum with an

Formulation	x_{min}	f_{min}	Attenuation	Time [s]	nFunEval	w_1	w_2
		Target frequency: 2150 Hz					
1	[0.01, 0.01, 0.92, 0.92, 0.01, 0.01, 0.89, 0.92]	-0.23	0.23	5176	1804	-	-
2	[0.92, 0.01, 0.92, 0.92, 0.01, 0.92, 0.92, 0.01]	-0.15	0.15	1308	389	100	1
		Target frequencies: 275-400 Hz					
1	No solution found	-	-	-	-	-	-
2	[0.00, 1.00, 0.00, 0.90, 0.70, 1.00, 0.00, 0.00]	-1.12E+03	0.13	627	151	1	10
		Target frequencies: 500 Hz, 1000 Hz, 1500 Hz, 2000 Hz, 2500 Hz					
1	No solution found	-	-	-	-	-	-
2	[0.92, 0.01, 0.92, 0.01, 0.92, 0.92, 0.92, 0.24]	-5.02	0.00	533	160	100	1

Table 2: Results for optimization of the eight elements model for various target frequencies. Attenuation describes the lowest attenuation of target frequencies.

attenuation level just above formulation 2, but takes approximately 4 times as long. The result from the optimization, for a stop band in the frequency range 275-400 Hz for formulation 2, are shown in Fig. 3. From the table, it is seen that formulation 1 fails at finding a minimum, while formulation 2 finds a minimum. This is because there is a low number of possible solutions that produce a stop band at this frequency range, which makes the probability for the CRS algorithm to 'guess' a solution lower. In Tab. 2 the results are shown for a desired stop band at

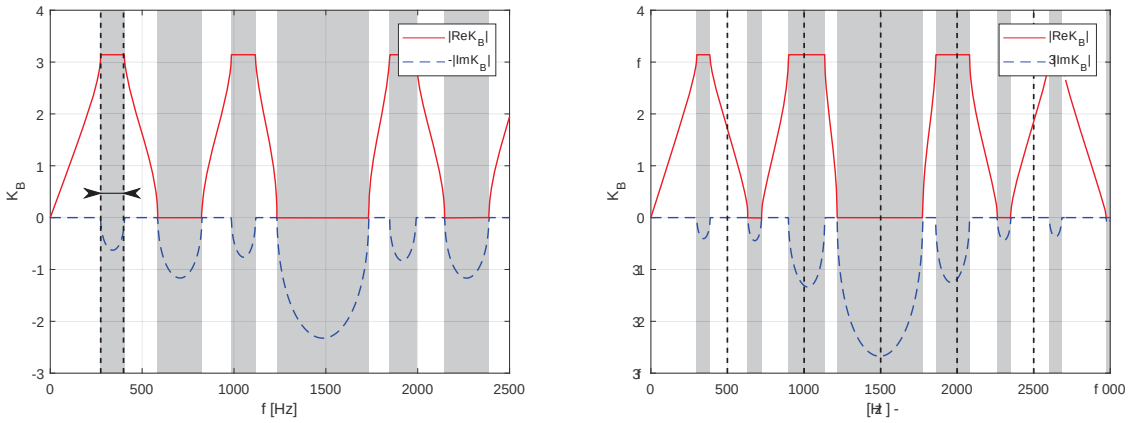

Figure 3: Results with a target frequency range of 275-400 Hz (left) using formulation 2. Results for target frequencies 500, 1000, 1500, 2000 and 2500 Hz using formulation 2 (right). Gray areas indicate stop bands.

500, 1000, 1500, 2000 and 2500 Hz, which corresponds to a fundamental frequency of 500 Hz and its first four harmonics. Formulation 1 fails to find a solution, while formulation 2 finds a solution where some of the target frequencies are, however, not placed in a stop band, see Fig. 3. This result highlights an important property of formulation 2; that it is capable of finding a solution where only some target frequencies are in stop bands, because it might be impossible to place all target frequencies in stop bands for the given mobility. Formulation 2, thus, gives a 'compromise' solution, while formulation 1 gives an 'all or nothing' solution. This implies that formulation 2 is more robust, as it always finds a solution.

3.2 Bi-material composite

This example consists of optimization of a composite consisting of two different materials. The model used is sketched in Fig. 4. The model consists of n layers of repeating fiber and

matrix material, with the material properties listed in Tab. 3. The length of the model is $L = 1$ m and the cross sectional area is $A = 1\text{m}\times 1\text{m}$. The design variables used in this case are the length of the material layers, x_i, where $i = 1, 2, .., n$, while the total length of the layers are constrained by,

$$\sum_{i}^{n} x_i = 1 \tag{4}$$

This means that only $n - 1$ design variables are independent. The lower bound for the design variables are $x_i \geq 0.01$. The starting guess for formulation 2 is in all cases an evenly distributed thickness of all layers, i.e. $x_i = 1/n$. This example is tested for a two and six layer model. The dispersion diagram for the starting guess for these models, are shown in Fig. 5. As the starting guess in both cases are evenly distributed layer thicknesses, one could expect the dispersion diagrams to be identical. However, this is not the case, as seen in Fig. 5, due to the constraint on the length of the model.

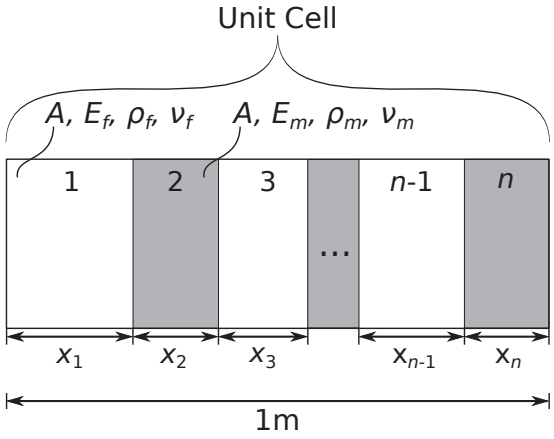

Figure 4: Illustration of the bi-material composite consisting of n repeating layers (left). The length of the composite must sum to 1 m and the cross sectional area is 1 m^2.

Material	Young's modulus E	Poisson's ratio ν	Density ρ
Fiber	72.35 [GPa]	0.22	2500 [kg/m^3]
Matrix	4.09 [GPa]	0.38	1272 [kg/m^3]

Table 3: Material properties used for the composite.

For the two layer model ($n = 2$), the optimization is carried out for a single target frequency at 5000 Hz with different weightings, and a target frequency range at 4000-6000 Hz. The results are listed in Tab. 4. For a target frequency at 5000 Hz the resulting dispersion diagrams for both formulations are shown in Fig. 6. As is observed from the results, the desired frequency is placed in a stop band by use of both formulations. Formulation 2 is as high as 5.2 times faster than formulation 1 depending on the chosen weighing. It is seen that the weight w_1 can be increased to decrease the computational time, but at some values of w_1, local minima may be found, as is the case for $w_1 = 10$ in Tab. 4. Fortunately, the speed is increased when $w_1/w_2 \to \infty$ in which case formulation 2 approaches formulation 1, which is indeed the main objective of the optimization, i.e. to maximize attenuation. Formulation 1 finds a minimum with a slightly higher attenuation and broader stop band than formulation 2. However, the solution

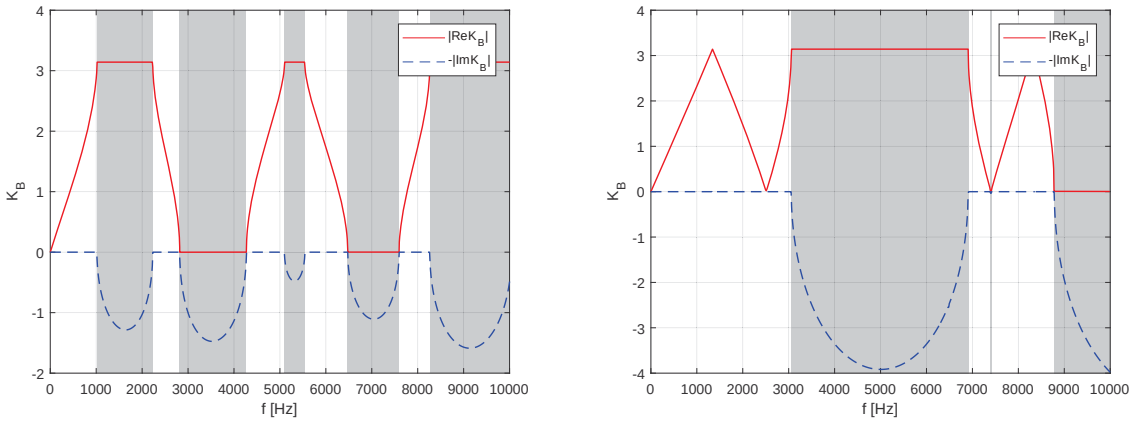

Figure 5: Dispersion diagram for the starting guess (equal volume fiber and matrix) for the two layer model (left) and for the six layer model (right). Gray areas indicate stop bands.

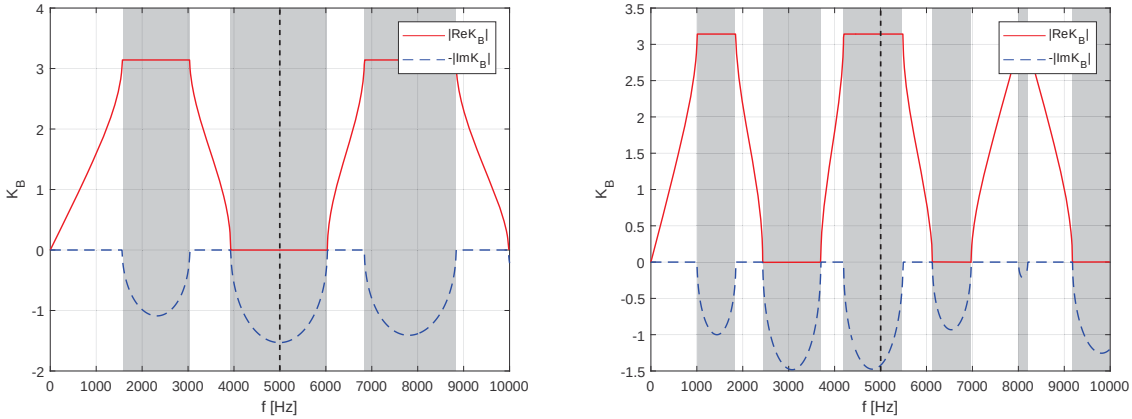

Figure 6: Results with a target frequency at 5000 Hz. (left) shows the dispersion diagram for results obtained using formulation 1 and (right) the results for formulation 2 with weights $w_1 = 100,\ w_2 = 1$. Gray areas indicate stop bands.

Formulation	x_{min}	f_{min}	Attenuation	Time [s]	nFunEval	w_1	w_2
Target frequency: 5000 Hz							
1	0.89	-1.53	1.53	659	222	-	-
2	0.38	-2.29	1.43	396	126	1	1
2	0.12	-0.89	0.97	217	71	10	1
2	0.37	-1.44	1.42	126	41	100	1
Target frequencies: 4000-6000 Hz							
1	0.89	-0.39	0.39	915	276	-	-
2	0.86	-0.24	0.00	218	74	1	1

Table 4: Results for optimization of the two layer composite for various target frequencies. Attenuation describes the lowest attenuation of target frequencies.

found for formulation 2 is closer to the starting guess, see Tab. 4, and thus tries to widen the nearest stop band instead of shifting. This means that formulation 2 finds a minimum, with less change of the original structure, discussed further in Sec. 4. The results for the optimization for a desired stop band at the frequency range 4000-6000 Hz is shown in Fig. 7. Formulation

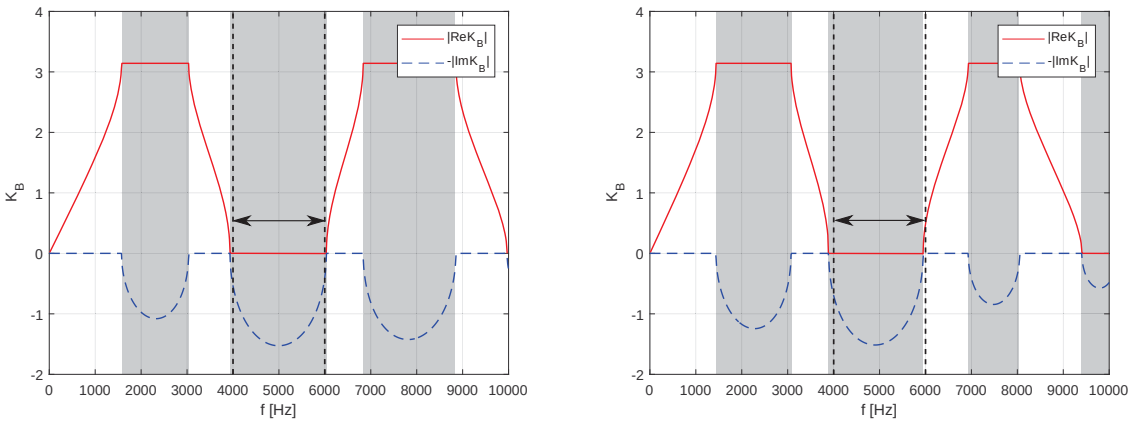

Figure 7: Resulting dispersion diagram for optimizing the two-layer composite for a desired stop band at 4000-6000 Hz, using formulation 1 (left) and formulation 2 (right). The arrow indicates the placement of the desired stop band and the gray areas indicate stop bands.

1 finds the same minimum for a single frequency at 5000 Hz and a frequency range at 4000-6000 Hz. The minimum found by formulation 2 is approximately the same as the one found by formulation 1, but it is slightly offset from the target frequency range, see Fig. 7. This could be fixed by proper weighting. From the results it is observed that by optimizing with respect to a frequency range, formulation 2 is capable of shifting stop band and finding the same minimum as for formulation 1. Formulation 2 thus outperforms formulation 1, in the sense, that it can find the same minimum as formulation 1 but at a much lower computational cost. Furthermore, it shows that formulation 2 is more versatile than formulation 1, because it is able to find different solutions to a single target frequency and a target frequency range.

The next optimization case is for a six layer model. The optimization is carried out for a single target frequency at 2000 Hz and multiple target frequencies with harmonics hereof, i.e. 2000 Hz, 4000 Hz, 6000 Hz, 8000 Hz and 10000 Hz. The results are listed in Tab. 5. The results for a single target frequency at 2000 Hz are shown in Fig. 8. Approximately the same

Formulation	x_{min}	f_{min}	Attenuation	Time [s]	nFunEval	w_1	w_2
Target frequency: 2000 Hz							
1	[0.01, 0.25, 0.01, 0.01, 0.67]	-1.50	1.50	2078	619	-	-
2	[0.01, 0.12, 0.01, 0.01, 0.68]	-1.49	1.47	598	209	100	1
Target frequencies: 2000 Hz, 4000 Hz, 6000 Hz, 8000 Hz and 10000 Hz							
1	[0.27, 0.04, 0.08, 0.22, 0.38]	-6.70	0.89	3566	1007	-	-
2	[0.66, 0.08, 0.01, 0.01, 0.06]	-1.17	0.97	734	240	20	1

Table 5: Results for optimization of the six layer composite for various target frequencies. Attenuation describes the lowest attenuation of target frequencies.

minimum is found for both formulations. Interestingly, it is observed that x_2 in formulation 1

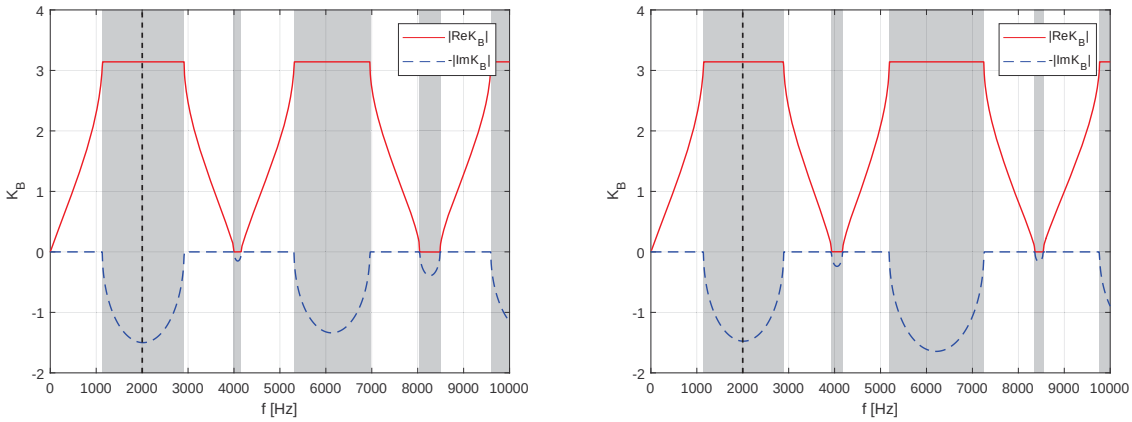

Figure 8: Resulting dispersion diagram for the six layer composite after optimizing for a stop band at 2000 Hz using formulation 1 (left) and formulation 2 (right). Gray areas indicate stop bands.

is approximately twice as large as in formulation 2. This implies, that x_2 in this case is actually irrelevant for the generation of the stop band at 2000 Hz, and hence we see that there exists several almost 'identical' solutions as mentioned in Sec. 3.1. The computational time is still higher for formulation 1, but it is observed that going from 1 to 5 design variables, the computational time for formulation 2 have increased by approximately a factor 5, while it is approximately only a factor 3 for formulation 1. The reason is that there are several solutions that makes a stop band at 2000 Hz. The probability of the CRS algorithm to find a minimum, therefore, significantly increases. For a stop band at target frequencies 2000 Hz, 4000 Hz, 6000 Hz, 8000 Hz and 10000 Hz, the results are shown in Fig. 9. As observed, both formulations finds a minimum that places all the desired frequencies in a stop band. Because less solutions exists for stop bands at these frequencies, the solution time for formulation 1 is much higher than for formulation 2, and in two of the four reruns formulation 1 failed to find a solution. Thus, to retain robustness, the stochastic optimization scheme must have more mobility, i.e. a high number of solutions. Furthermore, formulation 2 finds a minimum with a slightly higher attenuation. This again indicates, that for optimization problems with only few solutions, formulation 2 is indeed superior both on speed and robustness.

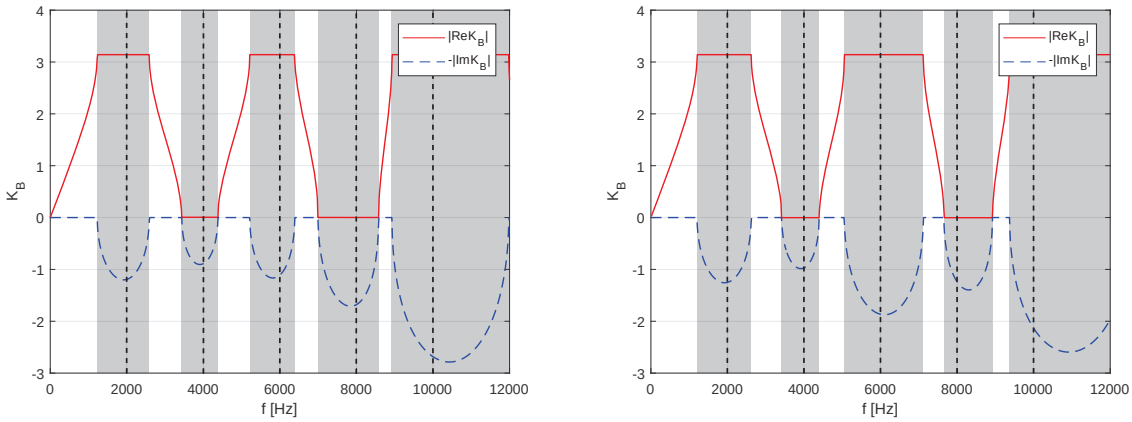

Figure 9: Resulting dispersion diagram for the six layer composite after optimizing for a stop band at 2000 Hz, 4000 Hz, 6000 Hz, 8000 Hz and 10000 Hz using formulation 1 (left) and formulation 2 (right). Gray areas indicate stop bands

4 DISCUSSION

Formulation 1 has the advantage, that if it finds a minimum, all desired frequencies will always be in a stop band. This is due to the stopping criteria for the CRS algorithm, ensuring that all found starting guesses are in a minimum, [7; 10]. The drawback of this, however, is that, if there is only a few number of solutions to the problem, the computational time of the CRS algorithm will increase. Another drawback is that the optimization has to be carried out several times to ensure the robustness of the algorithm, which is increasing the computational time even more. For optimization problems involving a lot of design variables, formulation 1 would thus be most impractical.

The advantages of formulation 2 is that it is much faster than formulation 1. In the examples studied, formulation 2 uses as low as $1/5$ of the time of formulation 1. If analytical expressions can be found for the design sensitivity analysis, this can be reduced even further. Another advantage of formulation 2 is that it gives a compromise if a solution, which has stop bands at all target frequencies, does not exist. This can be improved even further by introducing different weights on the target frequencies, such that the formulation will find the best compromise solution. According to the authors wishes, formulation 2 is thus more robust than formulation 1. The drawback of formulation 2 is, that specific weights are needed for different cases, which increases the computational time as multiple reruns are needed. As multiple reruns also are needed for formulation 1, to ensure the robustness, formulation 2 still outperforms formulation 1 in terms of computational time. One major difference between formulation 1 and 2 is that formulation 2 typically finds the closest local minimum, while formulation 1, due to the CRS algorithm, tends to find a 'more global' minimum with larger attenuation. This, however, can result in large changes in the waveguide optimized compared to the starting guess. In the case of waveguides of the industrial partner, a global minimum is not be desired, as long as there are no constraints on static performance. The reason is, that a global minimum often results in large ratios of stiffness between two elements, which will compromise the structural integrity. If constraints on static performance are added to the optimization problem, a global minimum is desired. However, when introducing constraints on static performance, another analysis is needed for each iteration, which would increase the computational time significantly. As no constraints are introduced in this paper, a minimum that ensures stop bands at the target frequencies with minimal change to the starting guess is desired. This means, that the solutions obtained by formulation 2 are likely better in a structural sense, as changes to the original structure are smaller. The work presented in this paper is work in progress and further improvements to formulation 2 are currently being investigated.

5 CONCLUSION

This paper is concerned with periodic waveguides modelled by the WFEM and two different methods for optimization of the waveguide is tested. One is a conventional benchmark which has a 'semi-discrete' behavior, causing lack of gradient information, and is optimized by a zero-order algorithm (CRS) and subsequent gradient based optimization, in-line with earlier work done by other authors. The other is a novel method which uses manipulation of the objective function such that it becomes continuous with gradient information available. Both methods has been tested on two 1-dimensional examples; one with the design variables associated with material properties in a functionally graded material, and one with the design variables associated with length of layers in a bi-material composite. From the results it was found that the new method solves the problem much faster and is indeed more robust than the benchmark method.

Keywords: Perfectly Matched Layer, Finite Element Method, Exterior Acoustics, Fast Frequency Sweeps, Unbounded Domains

Abstract. *Effective treatment of unbounded domains using artificial truncating boundaries are essential in numerical simulation including unbounded media, such as in the scope of exterior acoustics, sound transmission calculations, ... Among these, Perfectly Matched Layers (PML) have proved to be particularly efficient and flexible, as well as relatively easy to implement using the Finite Element Method (FEM). However, an efficient handling of frequency sweeps is not trivial with such absorbing layers since the formulation inherently contains coupled space- and frequency-dependent terms. Using the FEM, this may imply generating system matrices at each step of the frequency sweep. In this contribution, an approximation is presented in order to allow for efficient frequency sweeps, for instance using Padé-based methods as extensively used by the authors in previous contributions. The performance and robustness of the proposed approximation is presented on an acoustic cases. A generic, robust way to truncate the acoustic domain efficiently is also proposed, tested on a range of test cases and for different frequency regions. It is shown that the approximation, based on a sub-interval approximation of a tuning parameter in the frequency range of interest, provides consistently very good results, close to the costly, original formulations. An a priori estimate of a robust choice for this tuning parameter is also introduced, together with a set of empirical recommendations associated with mesh size, domain size and truncation.*

1 INTRODUCTION

Modelling and simulation of propagating waves in an unbounded domain are necessary in a wide range of disciplines such as acoustics, electromagnetism, solid and fluid mechanics, quantum mechanics, as well as study of earthquakes, water waves propagation, soil-structure or water-structure interaction, *etc.* In a computational environment, such as the Finite Element Method (FEM), the associated models imply a truncation of the unbounded domain with the treatment of artificial boundaries in order to avoid spurious reflections of the outgoing waves within the studied domain. Both for time- and frequency-domain analyses, the accuracy of these non-reflecting conditions under various problem configurations is fundamental. For time-harmonic problems [1], these conditions may be referred to in different ways in the literature, but can generally be classified into three broad families: Absorbing Boundary Conditions (ABCs) [2–7], Infinite elements [8–10], or Absorbing layers such as the Perfectly Matched Layer (PML) [11].

Over the past few decades, several improvements have been brought to these techniques. However, due mostly to complementary strengths and weaknesses, at times problem- and physics-dependent, none of these families has been established as the default option in order to model unbounded media, when considering a range of criteria such as accuracy, computational cost, robustness, and ease of implementation.

Appreciated for their flexibility (suited for a wide range of problems, e.g. including corners or low-incidence outgoing waves, generally less case-dependent performance, and well-suited for standard finite-element implementation [12–14]), PMLs are in focus in the present contribution. Their performance is however largely dependent on their thickness and on the choice of the decay parameter. The latter, due to its dependence on the mesh, on the size of the layer and on its position, may not always be tuned optimally. In short, PMLs require to define and discretize an additional domain whose size and mesh naturally strongly impact the performance and accuracy [15].

In view of the study of propagation of acoustic waves from structures into unbounded acoustic domains, frequency sweeps are an essential part of computational acoustics. However, neither ABCs nor PMLs are naturally adapted to such frequency sweep calculations via the FEM due to their coupled dependence on space and frequency. This dependence requires an update of the assembled system matrices at each frequency step, which has to be performed in a non-trivial way in order to avoid the high computational cost associated with re-assembling these matrices at each step. Furthermore, this coupled dependence on space and frequency makes these formulations difficult to be introduced in the scope of fast frequency sweep techniques, such as the Padé-approximant-based methods widely used by the authors in previous contributions [16,17]. The present contribution details an approximation which allows a frequency-independent generation of the system matrices, but also enables the straightforward use of Padé-based fast frequency sweep techniques for exterior acoustic calculations using the FEM.

First, a selection of PML formulations is presented in view of highlighting the chosen candidate for robust and efficient frequency sweeps, to be combined with Padé-based fast frequency sweep techniques. Then, a simple approximation is introduced, by imposing a piece-wise constant frequency approximation allowing for band-wise frequency-independent system matrices. The impact of this approximation and the choices of band-wide constant frequency parameters is subsequently evaluated on a 2D exterior acoustic case for various frequency ranges. Finally, a tuning procedure of this approximation frequency is proposed.

2 Cartesian Perfectly Matched Layer formulation

In order to take advantage of the geometric versatility of Perfectly Matched Layers as a non-reflecting boundary treatment, several formulations, using a range of different coordinates systems, have been proposed for unbounded wave propagation problems. From the original contribution by Berenger, for the Maxwell system in rectilinear coordinates [11], numerous formulations are available in the literature in order to respond to a range of more specific cases. The approach has been adapted for several types of physical problems, including acoustics [14, 18, 19], among others. The present contribution focuses on an approximation of the unbounded PML formulation initially proposed by Bermúdez $et\ al.$, in [14], for 2D Cartesian problems, enabling its use for fast frequency sweep techniques [20, 21]. In this sense, it relates to the contribution by Lenzi *et. al.* [22], however aiming at an arguably simpler implementation. In order to assess the accuracy of the approximation proposed, it is initially tested against the original, non-approximated, Cartesian coordinate formulation on the same application as presented in [14]. Adapting the approximation to a curvilinear coordinates formulation, though not the focus of this paper, is a natural extension of the present contribution. The problem formulation and its associated approximation are summarized in this section, after the formulation in [14].

2.1 Cartesian formulation

A general problem description is provided in order to introduce the 3D Cartesian formulation of the PML. As presented in Figure 1, the problem consists of a truncated infinite domain Ω_{T}, such that

$$\Omega_{\mathrm{T}} = \left\{(x, y, z) \in \mathbb{R}^3 : |x| \leq L_{\mathrm{T}x}, |y| \leq L_{\mathrm{T}y}, |z| \leq L_{\mathrm{T}z}\right\}.$$

This truncated domain contains an inner acoustic fluid domain Ω_{F} such that

$$\Omega_{\mathrm{F}} = \left\{(x, y, z) \in \mathbb{R}^3 : |x| \leq L_{\mathrm{F}x}, |y| \leq L_{\mathrm{F}y}, |z| \leq L_{\mathrm{F}z}\right\},$$

surrounded by a PML layer Ω_{A} such that $\Omega_{\mathrm{A}} = \Omega_{\mathrm{T}} \setminus \Omega_{\mathrm{F}}$. The interface between the acoustic domain Ω_{F} and the PML layer Ω_{A} is referred to as Γ_{I}, and the outer boundary of the truncated infinite domain as Γ_{D}. An acoustic velocity source is introduced within the acoustic domain, defined by its velocity amplitude g along the normal $\mathbf{n}_{\mathrm{S}}$ to the boundary Γ_{S}.

Following the formulation presented by Bermúdez $et\ al.$ in [14] for a 2D case, the amplitudes of the acoustic pressure fluctuations in the acoustic domain Ω_{F}, denoted p_{F}, and in the PML

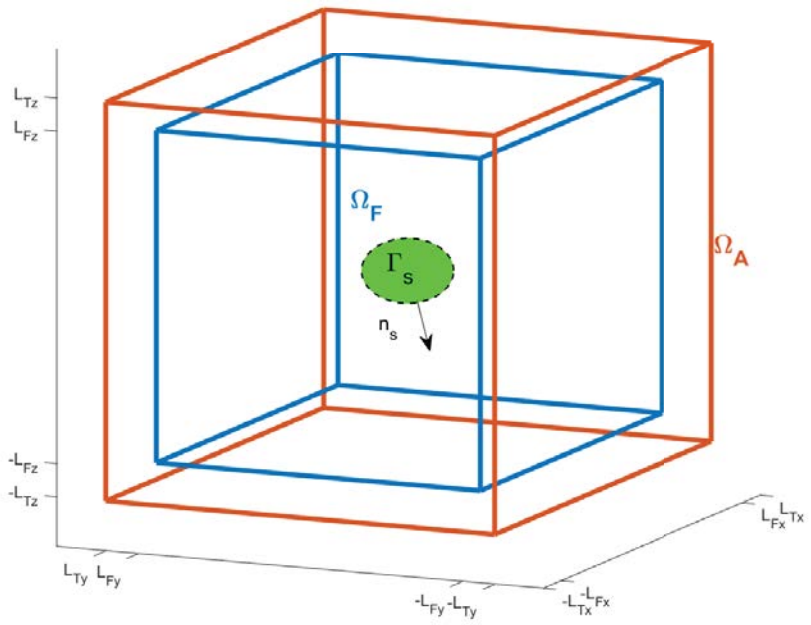

Figure 1: Cartesian PML on 3D scattering problem.

layer Ω_{A}, denoted p_{A}, are solution of the following set of equations:

$$\begin{cases} \Delta p_{\mathrm{F}} + k^2 p_{\mathrm{F}} = 0 \text{ in } \Omega_{\mathrm{F}} \\ \dfrac{\partial p_{\mathrm{F}}}{\partial \mathbf{n}_{\mathrm{S}}} = g \text{ on } \Gamma_{\mathrm{S}} \\ \dfrac{1}{S_x}\dfrac{\partial}{\partial x}\left(\dfrac{1}{S_x}\dfrac{\partial p_{\mathrm{A}}}{\partial x}\right) + \dfrac{1}{S_y}\dfrac{\partial}{\partial y}\left(\dfrac{1}{S_y}\dfrac{\partial p_{\mathrm{A}}}{\partial y}\right) + \dfrac{1}{S_z}\dfrac{\partial}{\partial z}\left(\dfrac{1}{S_z}\dfrac{\partial p_{\mathrm{A}}}{\partial z}\right) + k^2 p_{\mathrm{A}} = 0 \text{ in } \Omega_{\mathrm{A}} \\ p_{\mathrm{F}} = p_{\mathrm{A}} \text{ on } \Gamma_{\mathrm{I}} \\ \dfrac{\partial p_{\mathrm{F}}}{\partial x} + \dfrac{\partial p_{\mathrm{F}}}{\partial y} + \dfrac{\partial p_{\mathrm{F}}}{\partial z} = \dfrac{1}{S_x}\dfrac{\partial p_{\mathrm{A}}}{\partial x} + \dfrac{1}{S_y}\dfrac{\partial p_{\mathrm{A}}}{\partial y} + \dfrac{1}{S_z}\dfrac{\partial p_{\mathrm{A}}}{\partial z} \text{ on } \Gamma_{\mathrm{I}} \\ \dfrac{\partial p_{\mathrm{A}}}{\partial \mathbf{n}_j} = 0 \text{ on } \Gamma_{\mathrm{D}},\ j \in \{x, y, z\} \end{cases} \tag{1}$$

where S_x, S_y, and S_z are decay functions defined in Eqs (3)-(5), and the $\mathbf{n}_j$ are associated with the outer normal unit vectors to the boundary surfaces. For the sake of clarity, the operator $\dfrac{\partial \cdot}{\partial \square}$ is denoted $\partial_{\square} \cdot$ in the following.

Standard arguments in the finite element framework lead to the following discrete problem,

after the weak statement from the strong form of the problem in Eq. (1),

$$\int_{\Omega_\mathrm{T}} \frac{S_y S_z}{S_x} \partial_x p^h \, \partial_x u^h \, x \, y \, z + \int_{\Omega_\mathrm{T}} \frac{S_x S_z}{S_y} \partial_y p^h \, \partial_y u^h \, x \, y \, z + \int_{\Omega_\mathrm{T}} \frac{S_x S_y}{S_z} \partial_z p^h \, \partial_z u^h \, x \, y \, z - \int_{\Omega_\mathrm{T}} S_x S_y S_z k^2 p^h u^h \, x \, y \, z = \int_{\Gamma_\mathrm{S}} g u^h \, \mathrm{S} \tag{2}$$

for all functions u^h, continuous and piecewise linear in Ω_T. The decay functions may be expressed as

$$S_x(x) = \begin{cases} 1, & |x| < L_{\mathrm{F}x} \\ 1 + \dfrac{\sigma}{ik}\gamma(x), & L_{\mathrm{F}x} \leq |x| < L_{\mathrm{T}x} \end{cases} \tag{3}$$

$$S_y(y) = \begin{cases} 1, & |y| < L_{\mathrm{F}y} \\ 1 + \dfrac{\sigma}{ik}\gamma(y), & L_{\mathrm{F}y} \leq |y| < L_{\mathrm{T}y} \end{cases} \tag{4}$$

$$S_z(z) = \begin{cases} 1, & |z| < L_{\mathrm{F}z} \\ 1 + \dfrac{\sigma}{ik}\gamma(z), & L_{\mathrm{F}z} \leq |z| < L_{\mathrm{T}z} \end{cases} \tag{5}$$

where $L_{\mathrm{F}x}$, $L_{\mathrm{F}y}$, $L_{\mathrm{F}z}$ correspond to coordinates referring to inner boundaries of the PML layer and $L_{\mathrm{T}x}$, $L_{\mathrm{T}y}$, $L_{\mathrm{T}z}$ to outer boundaries (see Fig. 1). σ is a decay parameter and $\gamma(x)$, $\gamma(y)$ and $\gamma(z)$ are functions of the space variables, driving the shape of the decay functions. They may take several forms (e.g. constant, linear, quadratic, rational), see *e.g.* [14,23]. In the preliminary implementations leading to this contribution, three common forms have been investigated and are further commented upon in the following. Given a coordinate u associated with one of the axes of the Cartesian coordinate system considered here, *i.e.* $u \in \{x, y, z\}$, these selected functions, for the three chosen PML formulations, may be expressed as

$$\mathsf{PML}_1 : \gamma(u) = \left(\frac{u - L_{\mathrm{F}u}}{L_{\mathrm{T}u} - L_{\mathrm{F}u}} \right), \tag{6}$$

$$\mathsf{PML}_2 : \gamma(u) = \left(\frac{u - L_{\mathrm{F}u}}{L_{\mathrm{T}u} - L_{\mathrm{F}u}} \right)^2, \tag{7}$$

$$\mathsf{PML}_\infty : \gamma(u) = \left(\frac{1}{L_{\mathrm{T}u} - u} \right). \tag{8}$$

Beyond the choice of γ function for the PML formulation, the tuning of the σ parameter is yet another critical aspect to consider, in particular for the PML_1 and PML_2 formulations. For the unbounded formulation PML_∞, Bermúdez *et al.* proposed in [14] a value of the decay parameter, such that $\sigma = 1$, making it a robust, parameter-free formulation. Furthermore, it was shown that this formulation is better suited to absorb outgoing waves on a scattering problem than those associated with the linear and quadratic cases, PML_1 and PML_2 respectively, even when optimal values of σ are available analytically for these cases. Similar conclusions were drawn by Rabinovich *et al.*, in [23], given constant, linear and quadratic decay functions on a very different set of test cases.

Given the ease of tuning for the σ parameter and the robustness of the unbounded formulation in a wide range of cases, this PML_∞ formulation is primarily investigated in the present contribution.

After discretization, the weak form of Eq. (2) leads to a Finite Element (FE) system of the form

$$[\mathbf{K} - k^2\mathbf{M}]\mathbf{p} = \mathbf{f}, \tag{9}$$

where $\mathbf{f}$, the right-hand side (RHS) vector, includes the source terms imposed as Neumann boundary conditions on Γ_S. $\mathbf{K}$ and $\mathbf{M}$ are, following a Galerkin approach, formed by the contributions from elementary matrices $\mathbf{K}^e$ and $\mathbf{M}^e$, respectively, given by

$$\begin{aligned}\mathbf{K}^\text{e}_{ij} = &\int_{\Omega_e} \frac{S_y S_z}{S_x} \partial_x N_i^T \, \partial_x N_j \, \Omega + \int_{\Omega_e} \frac{S_x S_z}{S_y} \partial_y N_i^T \, \partial_y N_j \, \Omega \\ &+ \int_{\Omega_e} \frac{S_x S_y}{S_z} \partial_z N_i^T \, \partial_z N_j \, \Omega,\end{aligned} \tag{10a}$$

$$\mathbf{M}^\text{e}_{ij} = \int_{\Omega_e} (S_y S_z S_x) N_i \, N_j \, \Omega, \tag{10b}$$

$$\mathbf{f}^\text{e}_j = \int_{\Gamma_\text{S}} g N_j \, \text{S}, \tag{10c}$$

where the N_i correspond to the nodal finite element basis of an isoparametric FE formulation and Ω_e to the associated elementary domains.

Obviously, the rational forms involved in the elementary integration associated with the elementary matrices $\mathbf{K}^e$, in Eq. (10a), combining the 3D Cartesian expressions of the decay functions given in Eq. (3)-(5), imply non-separated space-frequency expressions. It implies, in turn, frequency-dependent elementary matrices, critically impacting the efficiency of typical frequency sweeps for acoustic applications. The following section therefore introduces considerations in order to perform frequency-independent integrations of the elementary matrices, leading to formulations suited for the use of fast frequency sweep techniques for exterior acoustics, as previously discussed by the authors [24, 25].

2.2 Approximation for efficient frequency sweep

In order to separate the frequency and space variables, in view of the elementary integrations to be performed in Eq. (10a), several approximations may be sought in the form, for instance, of polynomial expansions with respect to the frequency. The simplest form consists in choosing a constant value such that $f = f^*$, in the terms $\dfrac{1}{S_u}$, $u \in \{x, y, z\}$.

In the Perfectly Matched Layer domain Ω_A, this leads to approximated expressions such that

$$\frac{1}{S_u} \sim \frac{1}{1 + \frac{\sigma}{ik^*}\gamma(u)}, \qquad u = x, y, z, \tag{11}$$

where k^* corresponds to a constant value of the wave number, typically chosen within the range of interest. This may imply piece-wise approximations for a given broad frequency range of interest, which, as further detailed in the result Section 3, may match the need to adapt the FE mesh for frequency sub-intervals in view of the trade-off between accuracy and efficiency.

A number of options have been tested in order to evaluate the potential of such an approximation, i.e. setting $f = f^*$ constant only for some of the S_u terms, since only the denominator

terms in (10a) are critical in order to be able to perform frequency-independent integrations within each element. The simplest, and potentially most severe approximation to be tested, corresponds to setting such constant wavenumbers in all the S_u terms involved in the weak form of the problem, both in Eq. (10a) and Eq. (10b). Interestingly, having provided a satisfying degree of accuracy, and often better accuracy than the other combinations tested, this simple approximation, practical from an implementation point of view, is the focus of the analyses conducted in the following sections.

3 RESULTS AND DISCUSSION

3.1 Definition of the numerical test case

In order to have a reference solution which may be compared to results of the literature, the different formulations are tested on a bi-dimensional test case proposed by Bermúdez $et\ al.$ in [14]. As may be seen in Figure 2, this case corresponds to a scattering problem where the center of the domain is limited by a circle of unitary radius with a totally reflecting boundary. The solution of this problem, with a point source located at (x_0, y_0), is given by

$$p(x,y) = \frac{i}{4}\mathcal{H}_0^{(1)}\left(k\sqrt{(x-x_0)^2+(y-y_0)^2}\right), \tag{12}$$

where $\mathcal{H}_0^{(1)}$ is the Hankel function of the first kind, of order 0.

Note that in Figure 2, the notations used in the original contribution, a and b, correspond to $L_{\mathrm{F}x}$ and $L_{\mathrm{F}y}$ defined in Section 2.1, respectively, and a^* and b^*, to $L_{\mathrm{T}x}$ and $L_{\mathrm{T}y}$, respectively. N stands for the mesh refinement, in Figure 2, where $N = 2$ corresponds to 2 rectangular elements in the thickness of the layer.

Figure 3 introduces the solution of the real pressure field of this scattering problem for two frequencies chosen arbitrarily: $f = 20$ Hz and $f = 1$ kHz.

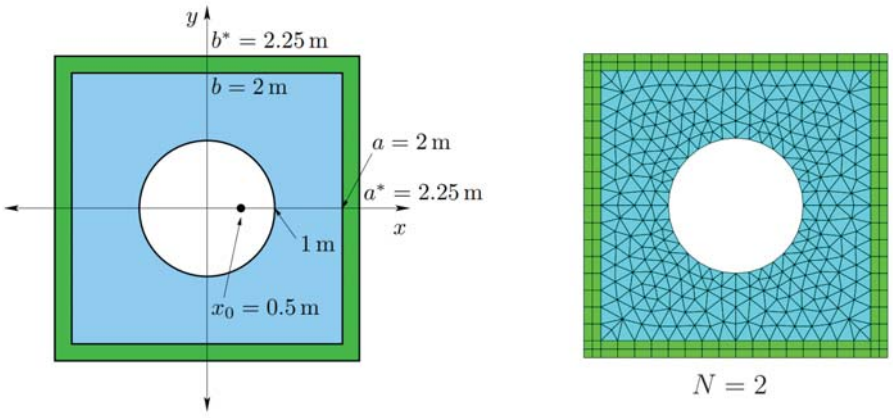

Figure 2: Bermúdez $et\ al.$ Scattering Problem [14].

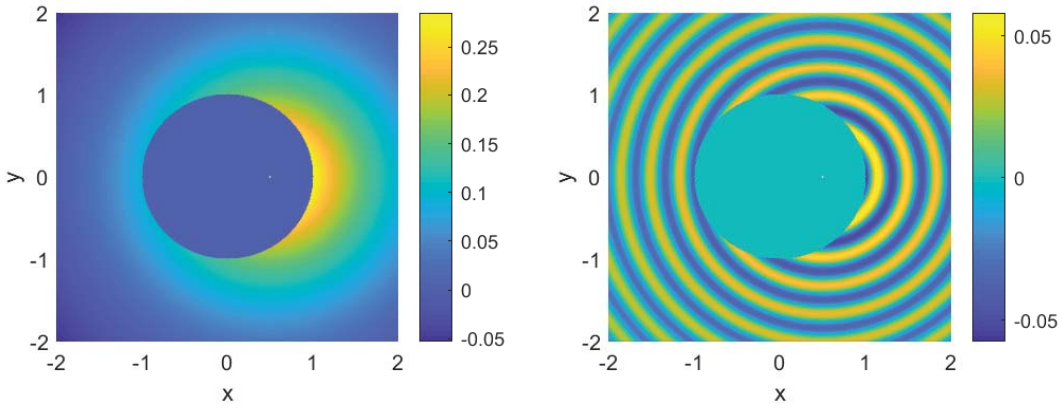
3.2 Illustration of the approximation

The behaviour of the PML approximation proposed here, with respect to the choice of k^*, is tested on the Bermúdez $et.\ al.$ test case. For this purpose, the pointwise L^2-error with respect to the analytical solution of Eq. (12) is used. For each choice of $f^* = \frac{c_0 k^*}{2\pi}$ in the frequency range of interest, the mean of these L^2-errors over the whole frequency range is calculated.

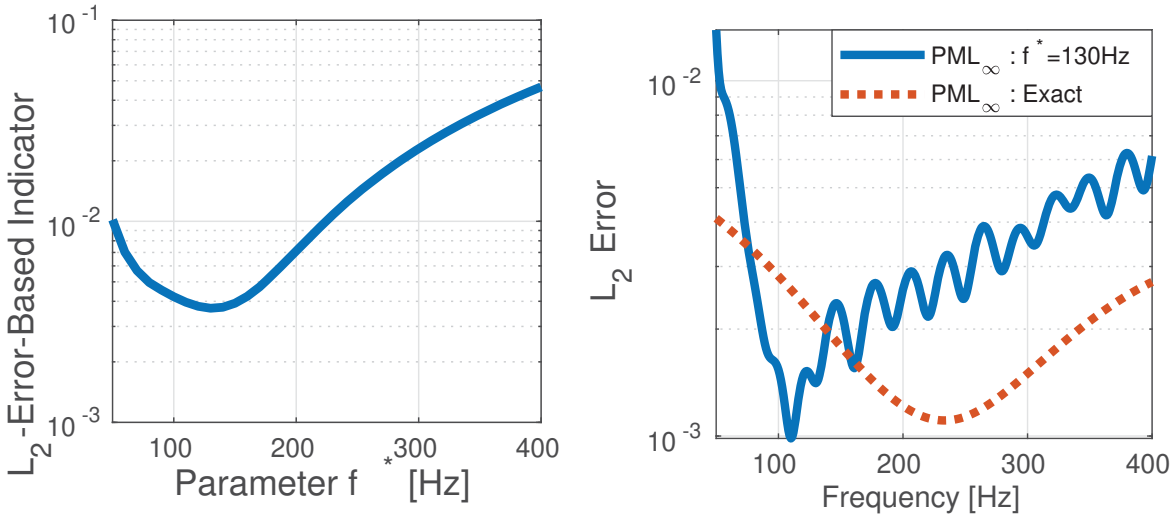


(a) $f = 20$ Hz (b) $f = 1$ kHz

Figure 3: Acoustic pressure field (real part) for the Bermúdez *et al.* scattering problem.

In this way, scanning all frequencies in the range of interest for each chosen value of f^*, an error estimate assessing the quality of the choice is obtained. The outcome of this procedure is presented in Figure 4a in the frequency range $[50 - 400]$ Hz.

In this case the optimal frequency minimizing the error indicator is found to be of $f^* = 130$ Hz. Figure 4b shows the frequency sweep obtained for this choice of $f^* = 130$ Hz, together with the results obtained with the non-approximated PML formulation. Note that the solutions are obviously the same for the value $f = f^*$. In this case, the value of this parameter has a



(a) (b)

Figure 4: Impact of the tuning of f^* on the accuracy of the PML approximation: (a) Error with respect to f^*; (b) Comparison with the original PML formulation.

significant impact on the accuracy of the approximation, which leads to the question of choosing an optimal value for a problem without a known analytical solution, a point considered in the following Section.

3.3 A priori indicators for f^*

In the process of attempting to locate, at least qualitatively, the optimal range for f^*, it seems sensible to consider the impact of the f^*-approximation on the decay functions in Eqs. (3)-(5). One suggestion to do so, is to connect f^* to the frequencies which allow to minimize the error between the approximate functions $1/S^*$ or S^*, and the exact ones $1/S$ or S, respectively. This assumption emerges from the fact that, in Eq. (2), the functions $1/S$ are impacting the integrations leading to the PML terms in the $\mathbf{K}$ system matrix, while the functions S are impacting the integrations leading both to PML terms in the $\mathbf{K}$ and the $\mathbf{M}$ system matrices. These reference approximation frequencies may be introduced as

$$f_{\mathrm{S}}^* = \quad argmin_f \left(||S_x - S_x^*||_{L_2} \right), \tag{13}$$

$$f_{1/S}^* = \quad argmin_f \left(\tfrac{1}{S_x} - \tfrac{1}{S_x^*}_{L_2} \right). \tag{14}$$

Provided a systematic and reliable truncation of the PML layers, as proposed and further detailed in Ref. [25], the use of the above a priori approximation indicators is evaluated for different frequency ranges on the selected test cases.

3.4 Approximation of the Bermúdez $et.\ al.$ test case

In order to evaluate the accuracy of the approximation and the impact of the choice of f^*, a number of calculations are performed, for different frequency ranges, and for varying values of f^*. Figure 5 shows the results of these calculations. The calculations are performed in the range $[20, 1000]$ Hz in order to limit the computational burden, given that several sweeps are to be calculated. The size of the domain, the thickness of the layer and the mesh size are defined according to the lowest and the highest frequencies of the range considered, as further detailed in Ref. [25]. In order to limit the computational burden, as realistically done for larger applications, the calculations in the full frequency range of interest are divided into sub-intervals such that the ratio between the upper and lower frequencies remains reasonably small. Three frequency intervals are therefore considered in this range, taking for bounds of these intervals the approximate rule $f_{\mathrm{max}} \leq 10 \cdot f_{\mathrm{min}}$. Note that although two intervals only are necessary in this case, the following intervals are chosen in order to test several configurations for the choice of f^*: $[20, 100]$ Hz, $[50, 400]$ Hz and $[100, 1000]$ Hz.

The Figures 5a, 5c, and 5e plot a measure of the error with respect to the choice of f^*. The same error measure as in Fig. 4a is used here. The impact of the approximation may thus be evaluated for different frequency ranges. The vertical lines correspond to the estimates calculated as detailed in Eqs. (13) and (14). These plots highlight that for most cases or frequency ranges, there may be an optimal value for f^* in order to minimize the approximation error. In connection with this, the *a priori* indicators detailed in Eqs. (13) and (14) seem to provide a fair estimate for a sensible choice of such approximation frequency. In particular, in this case, the estimate according to Eq. (13) clearly provides a higher weight to the low frequencies, as more severely exhibited by the optimal values for this case. It is not surprising that this estimate doesn't necessarily provide the optimal value for f^*, since minimizing the error between the approximate and the exact functions in Eqs. (13) and (14), does not imply optimizing the absorption performance of the PML. Another observation from these plots is that the narrower the frequency range (in term of ratio f_{max}/f_{min}), the less important the impact of the value of f^* on the results. A trivial approach to the problem would therefore be to chose narrower intervals with optimal mesh sizes, and to choose an approximation frequency close to a quarter or third of the frequency span.

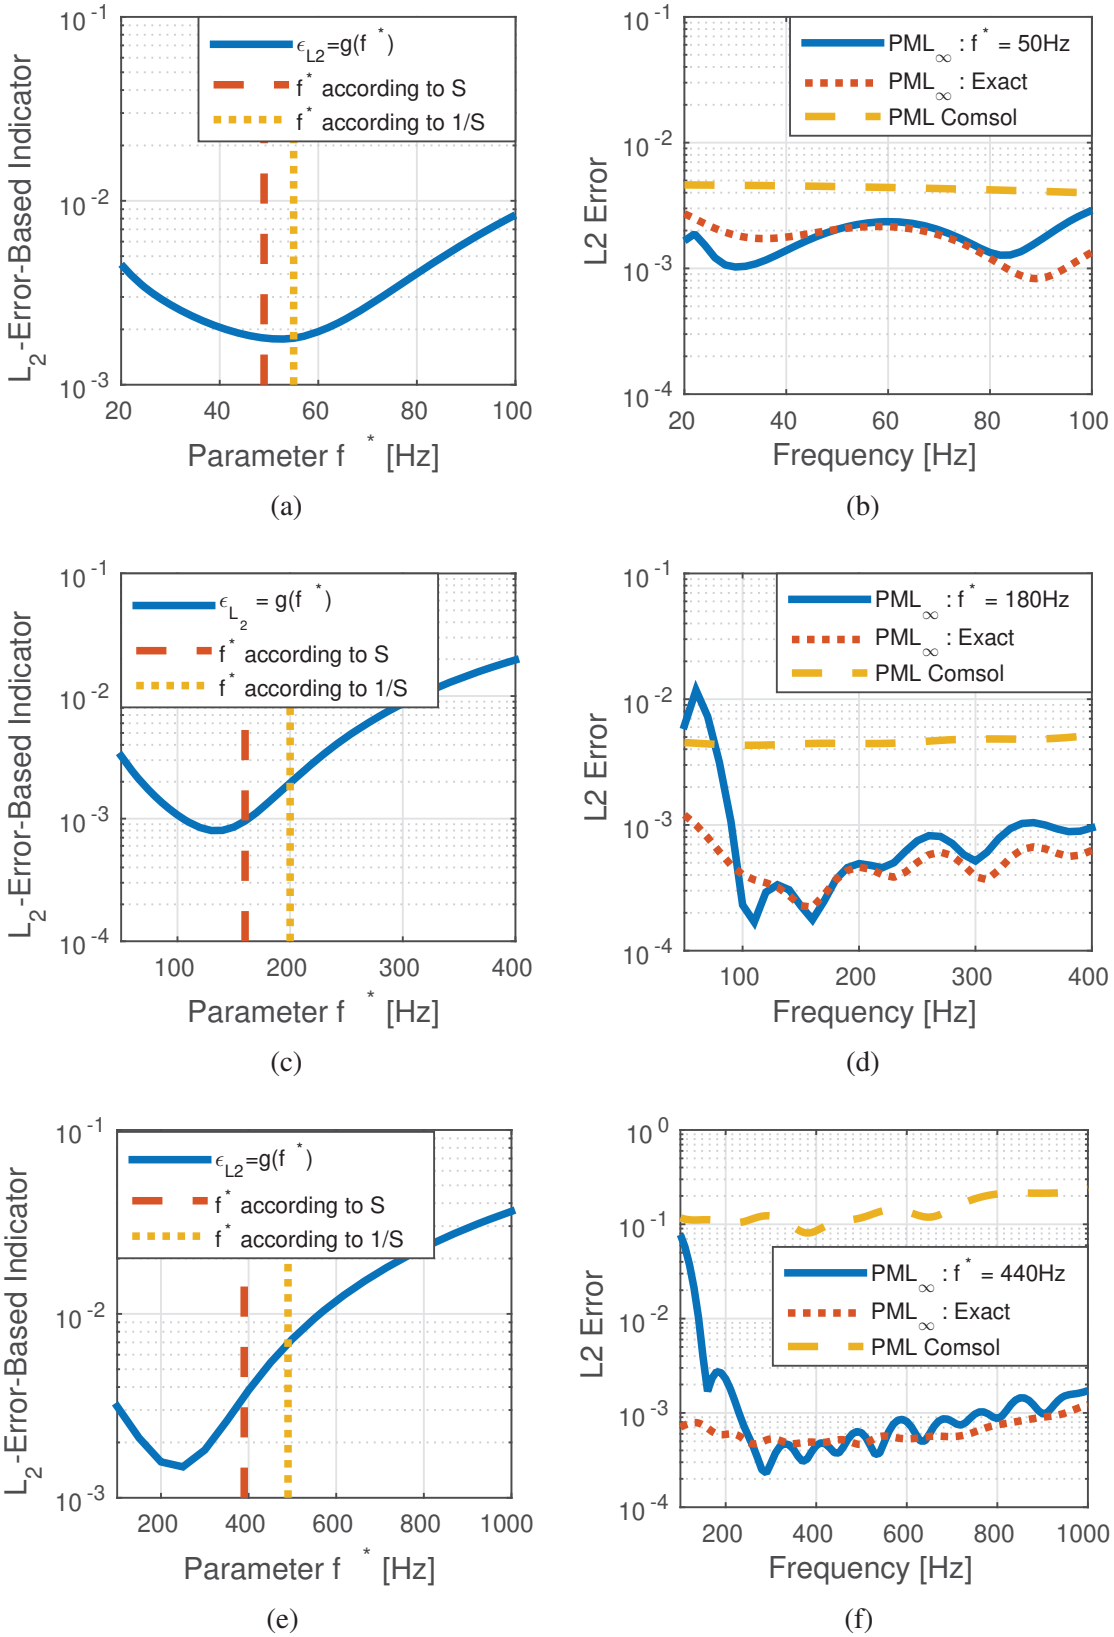


Figure 5: **Bermúdez *et. al.* test case**: Impact of the choice of f^* for different frequency ranges (left), and comparison of the error with the f^*-approximation, the original PML, and the COMSOL implementation (right).

The Figures 5b, 5d, and 5f plot the comparison between the error from the frequency sweep performed without the approximation (*i.e.* updating the assembly of the system matrix $\mathbf{K}$ in Eq. (9)), and the frequency sweep with the approximation where f^* is set as the arithmetic average of the indicators in Eqs. (13) and (14). For the sake of comparison with a commercial implementation, a reference calculation using COMSOL and its implementation of a rational PML formulation [26], with the same discretization and geometry, is also added for this test case. First, although the *a priori* estimate of a suitable value for f^* does not provide the optimal choice, the accuracy of the approximation is overall quite good. It is also noteworthy that the truncation approach detailed in Ref. [25] seems quite robust for all frequency ranges, since the error is kept low for all three plots. Finally, the approximated solution using the approach proposed in this contribution provides, overall, a better accuracy than the reference COMSOL implementation, for this specific case and problem definition (mesh, domain truncations, ...). Despite the value for f^* not being optimal, thus implying in this case a sharp increase of the error in the low-frequency end of the intervals, the maximum error observed for the approximated formulation remains in the range of the lowest error for the reference calculation. These observations may of course be case-dependent, and one may argue that the reference calculation may have the potential to be improved by tweaking the set of parameters available for that specific PML formulation. The objective is however here to estimate the robustness of the proposed approximation with as little prior knowledge about the problem of interest as possible, hence avoiding any specific tuning as available in COMSOL.

4 CONCLUSIONS

In this paper, a simple yet robust approximation of the unbounded PML formulation introduced by Bermúdez *et. al.* [14] is introduced in order to allow for the possibility of computationally efficient and accurate frequency sweeps. The proposed approximation provides results close to the original formulation while enabling for the FE system matrices to be generated once only during the initial assembly step. It is however shown that a tuning of the f^* approximation frequency is necessary for each frequency sub-interval of interest.

An *a priori* estimate of a robust choice for the value of this parameter is therefore proposed. It relies on a cost-effective minimization of the difference between the approximate and exact PML functions. It is shown that the resulting choice provides sensible approximations for the test case considered.

Abstract. *Prediction of dynamic effects of reinforced concrete structures under impact loading is a technical challenge. This is a consequence of the great variability of the physical properties resulting from the wide adaptability of reinforced concrete and a consequence of the wide range of impact loading. Experiments and numerical investigations are normally used on a small scale to address the problem. In this paper, impact tests on reinforced concrete plates with the lateral dimensions of 1.5 m x 1.5 m and a thickness of 30 cm are presented. In bending reinforcement, besides the velocity two properties are varied, the diameter and the spatial distribution of the rebars. Experiments are performed at the Otto-Mohr-Laboratory of the Institute of Concrete Structures of the Technische Universität Dresden. Due to the accelerated fall of the impactor the velocity ranges between 20 and 70 m/s. In addition to the measured quantities such as bearing forces, accelerations are also measured at 4 different positions on and under the plate, as well as the deflection at several positions. The measured data are used for the analysis of the damage form and the numerical examinations with the program Ansys Autodyn and the material model after Drucker-Prager. Numerical investigations support the tests, with detailed analysis of individual effects. These numerical computations and the planar tomographic investigations were carried out at BAM in Berlin. With the help of planar tomographic evaluation, the damaged structure is made visible and compared with the numerical results. Influences of the bending reinforcement are explained on the basis of damage evaluation in the local area and on selected measured values. In addition to the test evaluation, the tomographic and numerical methods are presented.*

1 INTRODUCTION

Reinforced concrete (RC) is used as a construction material in a wide range of applications in the building industry. This great variability of applications is reflected in the range of physical properties. Due to the variability of the physical properties it is still an engineering challenge to meet all necessary requirements for predicting dynamic effects in structural reinforced concrete members under impact loading. The damage behaviour of RC structures depends on various parameters and cannot be predicted exactly. There are several empirical formulas that give a prognosis for the penetration depth and the minimum thickness of the concrete layer to avoid perforation [1, 2]. Some formulae are anchored in codes of practice and can be used for initial analyses and verification [3]. However, often the real structural behavior is only approximated.

In addition to the analytical approaches, experiments are performed. These are often carried out in a small scale. For example, in [4] RC columns are investigated under hypervelocity impact (500–1700 m/s). In [5] - [9] investigations on impact damage on plates due to small projectiles and cylinders at high velocity (70–500 m/s) are presented. Large-scale tests were carried out with different boundary conditions (target size and shape, impactor velocity and shape) for example at Sandia Laboratories [10, 11], at the VTT (summarized among others in [12]) or [13].

Numerical investigations are performed to investigate parameter studies or to study structures that cannot be investigated destructively. Furthermore, it is possible to implement experiments that are otherwise not or very difficult to realize. Examples can be found at [14] - [18].

Not only the load and its temporal course are relevant for the test evaluation, as described e.g. by [19] and [20]. Also the local damages are interesting. Furthermore, there are many factors that influence the post-impact behaviour, such as the bond properties between concrete and steel. This leads to different damage characteristics due to the impact [2].

Most studies are focussing on investigations of detailed damage analysis after an impact is in the speed range above 100 m/s.

This paper presents some results of a study on damage of plates impacted by moderate impactor velocities. The impact damage was caused by an accelerated fall of the impactor on reinforced concrete plates (1.5 m x 1.5 m). The test setup should be comparable to a part of the scenario of an impact of an aircraft engine. The physical properties of the plates (concrete strength, plate thickness, degree of reinforcement) and the impact properties (energy, weight, speed) were varied.

To identify and characterize the internal crack structures of the RC plates, the innovative planar tomographic method was applied on a unique tomography laboratory test stand. Possible damages, such as cracks, scabbing and spalling, are made visible during the tomographic reconstruction. Numerical simulations are used to identify the physical effects.

2 EXPERIMENTAL INVESTIGATIONS

The experiments were carried out at the Otto-Mohr-Laboratory of the Institute of Concrete Structures of the Technische Universität Dresden. The drop tower facility, which was available for this purpose, was built in a former project part and can be used in two different configurations. In the freefall mode, the impactor moves due to a sledge-rail construction. Through gravity and in dependence of the height of fall, the energy and velocity of the impactor can be controlled. In contrast to this, the impactor in the ballistic configuration is accelerated by air pressure and a guided impact of the plate is realized with a pipe (Figure 1) [21]. At first, the influence of external (impact energy, impactor size) and internal parameters (plate geom-

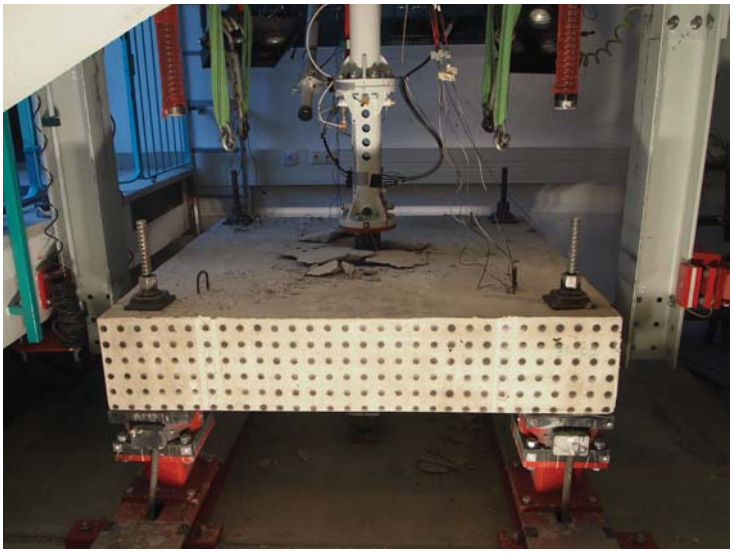

Figure 1: Experimental setup of an accelerated impact test

etry, concrete quality, reinforcement parameters) was investigated in free-fall tests and a first damage analysis was carried out [22, 19, 23]. Currently, a comprehensive investigation of the internal parameters takes place with accelerated experiments. Four test series are planned for this purpose (Figure 2). First of all, experiments with different plate thicknesses were carried

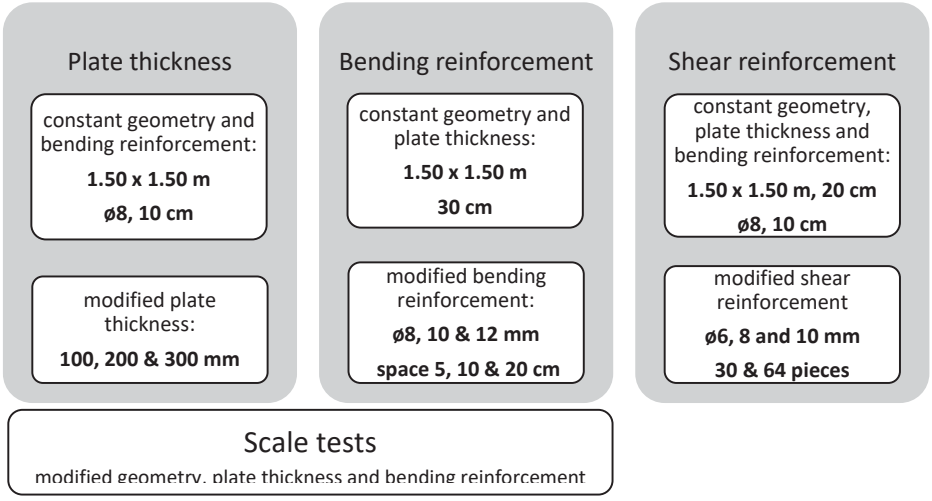

Figure 2: Planned test series

out. Therefore 15 plates with a geometry of 1.50 m x 1.50 m and a thickness of 10, 20 and 30 cm were tested with different velocities. All test specimens were made of concrete C35/45 and reinforcement ø8 with a spacing of 10 cm. These tests are the foundation for further investigations [24].

In the context of a further series of tests, the influence of bending reinforcement variations was investigated. Next to the the diameter, also the influence of the space between the reinforcementbars was examinated. In total, 32 plates with a geometry of 1.50 m x 1.50 m and a thickness of 30 cm were made. With a previous plate series include the reinforcement combinations therefore configurations of ø8 with a spacing of 5 and 20 cm as well as ø10 and ø12

with a spacing of 5, 10 and 20 cm. Four plates per configuration were loaded by impactors with different velocities and compared with the 30 cm thick samples (ø8–10 cm) from the plate thickness variation test series. In total, nine different bending reinforcement configurations could be realized.

Table 1 shows for each specimen (series & number) the respective reinforcement parameters (steel diameter d_r and spatial distribution of the rebars a_r). V_{imp} represents the velocity of the impactor measured in the experiments and I_{imp} the impulse resulting from multiplication of the velocity with the impactor mass.

Table 1: Test properties of all plates of the reinforcement variation, sorted by the diameter (d_r) of the reinforcement bars and its spatial distribution (a_r)

For all experiments, a 38 cm long steel impactor with a mass of 21.66 kg was used. For the impactor tip, a flat shape was chosen. In addition to the support forces and displacements, especially accelerations on the top on rear side of the plates were also measured (Figure 4). To evaluate the plate's damage, the weight of the test specimen was determined before and after the test and the masses of the fragments on the top (spalling) and under the plate (scabbing) were measured (Figure 3). After the experiments, the specimens were cut in the middle and the punching cones were investigated in the cross section. A computer tomographic examination was also carried out (see section 3).

3 PLANAR TOMOGRAPHY AND CRACK DETECTION

Planar tomography measurements were performed in the High Energy X-ray Laboratory (HEXY Laboratory) at the Federal Institute for Materials Research and Testing in Berlin (BAM). The manipulator can be controlled by 13 axes, 9 linear and 4 rotational axes, which ensures a different movement of X-ray source, object and detector for 3-dimensional investigations (CT and laminography) (Figure 5). The dimensions of the object can be up to 4 m in length, 1.5 m in height and 2 t in weight. A betatron, an electron accelerator, with an acceleration voltage of 7.5 MV is used. With this energy it is possible to radiate through concrete with a thickness of 0.3 m. The image data was recorded with a high-resolution matrix detector (DDA: Digital Detector Array) from PerkinElmer (XRD1620).

Due to the large dimensions of the concrete plates, the scanning method had to be adapted. With the new method a total of 4392 projections with 2048 x 2048 pixels each can be scanned. The total recording time for half a plate is 17 hours. The volume data of the investigated object are reconstructed using a fast shift-average algorithm [25]. The resulting three-dimensional volume is composed of voxels (a 3D equivalent of a pixel) with a side length of 0.5 mm in lateral direction and 1.5 mm in depth direction of the plate. This resolution allows the visualization of cracks with a minimum width of 0.5 mm.

The methodology of crack detection and segmentation is further explained in [26]. Data in STL format are generated from the segmented cracks in order to compare them with the exported data from the numerical simulations. STL data are a standard format for STereoLithography and contains all necessary geometric information. Figure 6 shows the visualization of the crack structure projected onto a layer of the tomographic data.

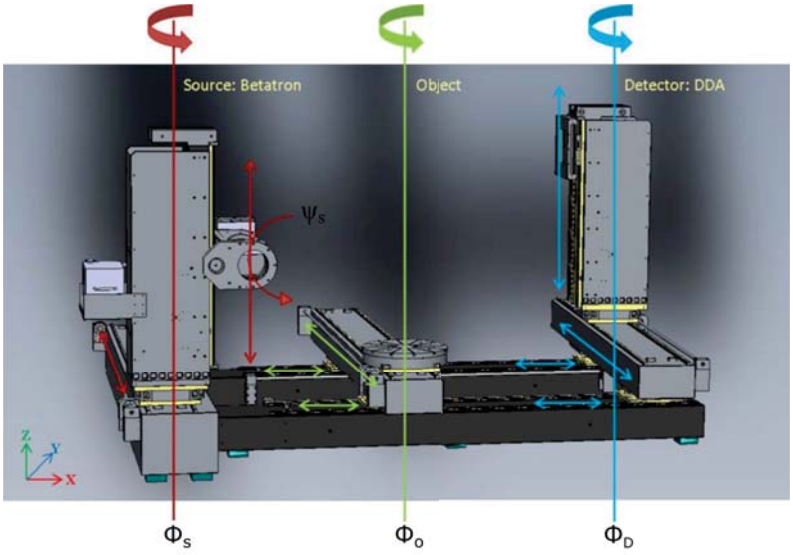

Figure 5: Schematic structure of the HEXY lab with its source, object, detector and its rotational axes [26]

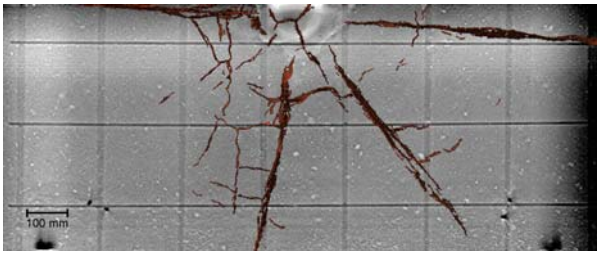

Figure 6: Visualization of the crack map (orange colored) projected on a layer of the tomographic data (gray colored)

4 NUMERICAL SIMULATION

For a numerical analysis the real system is simplified and transferred into a simulation model. The continuous body is reduced to small finite elements. Depending on the selection of the element type the nodes are generated. At each individual node the momentum balance equation is solved in the form of the weak differential equation of second order (Equation 1).

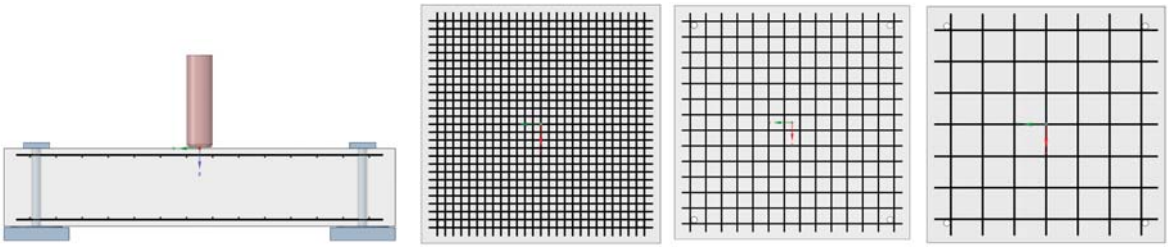
$$\mathbf{M}\ddot{u}(t) + \mathbf{C}\dot{u}(t) + \mathbf{K}u(t) = \mathbf{P}(t) \tag{1}$$

In Equation 1, $\mathbf{M}$ is the mass matrix, $\mathbf{C}$ is the damping matrix and $\mathbf{K}$ is the stiffness matrix of the system. $\mathbf{P}$ describes the externally acting time-variable forces. $u(t)$ describes the deformation which is also dependent on time.

In the explicit solution approach, the current status (time step n) of the deformation, acceleration and stress at each node of the system is determined first. From this, the deformations and velocities of the next time step (n+1) will be derivate. After calculating the internal forces and stresses of the time step (n+1) using the velocity, the external forces will be determined. Accelerations will be get from th forces and are the initial values for the next time step (n+2). This cycle is iteratively be going through until the last time step of the numerical simulation [27].

The impact test is modeled as a full model (Figure 7) with the program Ansys Autodyn. The bearings, the impactor and the plate are described with solids, whereas the rebars are modeled

with line elements. Automatic meshing takes place with a specified element edge length. Hexahedron were primarily used for the solids and beams for the line elements. The given edge length for the bearings is 20 mm and for the other components 10 mm. Thus, the system has 750,000–790,000 nodes and 730,000–810,000 elements when meshed.



(a) (b) (c) (d)

Figure 7: Side view of the model with the bearings, the plate, the impactor and the reinforcement (a), top view of the plate with the spatial distribution of the reinforcement bars: 5 cm (b), 10 cm (c) and 20 cm (d)

The impactor velocity was determined in the test from the measured data and was initially applied to the modeled impactor. The surfaces of the bearings are assumed to be fixed. Another fixed contact (contact = bonding) is defined between the plate and the four bearings. The impactor hits the center of the plate, whereby the contact is assumed to be frictionless. Previous comparative computations with the friction coefficient of 0.8 determined from the tests showed no relevant difference in the simulation. A reason is presumably the short contact time between impactor and plate. The rebars are modeled into the plate in a smeared pattern and the contact behaviour is defined as 'body interaction, type = reinforcement'. According to this formulation, the reinforcement bars are modeled as line bodies which are tied to each element they intersect.

An elastic material model was used for the structural steel components, since no significant damage to the components was detected during the tests. Concrete is described with the nonlinear material model 'Beton NL'. This model is freely available in the Ansys material library and is based on the strength description according to Drucker-Prager (DP).

The description of the failure surfaces according to Drucker-Prager is an extension of the description according to von Mises and is similar to that of Mohr-Coulomb under certain conditions, [28, 29, 30].

The failure criterion (Equation 2)

$$f(I_1, J_2) = \alpha I_1 + \sqrt{J_2} - k = 0 \tag{2}$$

mit

$$p = -\frac{1}{3} I_1 \tag{3}$$

$$\sigma_{eff} = \sqrt{3 J_2} \tag{4}$$

$$k = f(\varepsilon_{ij}^p) \tag{5}$$

$$d\varepsilon_{ij}^p = d\lambda \frac{\partial g}{\partial \sigma_{ij}} \overset{\text{assoz.}}{=} d\lambda \frac{\partial f}{\partial \sigma_{ij}} \tag{6}$$

is described with the first invariant of the volumetric stress tensor I_1, the second invariant of the deviational stress tensor J_2, the hardening rule k and a material parameter α for the compaction

path. p describes the pressure. σ_{eff} represents the effective or von Mises equivalent stress. ε^p describes the plastic strains in the object. Equation 6 is called flow rule. The derivative of a plastic potential $g(\sigma_{ij})$ multiplied by a proportionality factor $d\lambda$ represents the rule for the kinematic description of inelastic deformation, which is associative according to Drucker and Prager.

For the description of the piecewise linear yield surface of concrete under compression, the points P_i (pressure p / yield stress Y) in the meridian plane can be determined from measurements and comparisons with triaxial tests, see Figure 8. In [30], the appendix is a very extensive summary of about 13 international studies of triaxial tests with variing concrete strength which helps to identify the yield surface of concrete. Further material parameters for the model de-

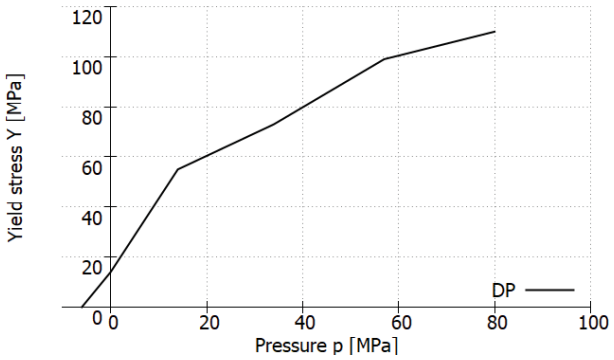


Figure 8: Failure surface after DP as a projection in a meridian plane based on the used test material

scription are shown in table 2. The material parameters for the tested plates are specified in a range. They refer to two different test sets: the plate thickness variation [24] and the bending reinforcement variation described in section 2. These data were used to calibrate the model. Only the tensile strength was adjusted so that the value is outside the range of the test data.

Properties	FEM	Test
Density	2250 $\mathrm{kg/m^3}$	2204–2279 $\mathrm{kg/m^3}$
Young's modulus	32200 MPa	27300–35700 MPa
Poisson's ratio	0.2	0.2
Maximum tensile pressure	6 MPa	2.82–4.58 MPa
Fracture energy Gf	100 $\mathrm{J/m^2}$	

Table 2: Material parameters of the numerical model and the range of the tested data of about 9 series (plate thickness variation [24] and reinforcement variation. The properties are named as in the Ansys program.

Figure 9 shows the process of numerical evaluation of the damage based on the damage structure. The computations were carried out without element erosion (Figure 9a). Using the parameter 'user defined result: damageall', the damage is displayed smeared. The result is shown per element as probability based on the user defined material failure (Figure 9b). For further comparison, elements with a value exceeding 0.93 are isolated and extracted (Figure 9c). This corresponds to a damage probability of 93%. In the SpaceClaim module of Ansys, the data set (STL format) is manually cleaned, replacing failed elements and re-meshing the surface (Figure 9d).

5 EVALUATION

In the following, damages in selected form (penetration depth, total degree of damage, quantity of cracks and impact area) with different emphasis (d_r = const. and a_r = const.) are to be examined on the tested plates. Furthermore, crack structures are evaluated based on tomographic data and comparisons with the numerical results. The bearing forces, the acceleration and the deformation data of the tests are compared with those of the numerical simulations using a plate series.

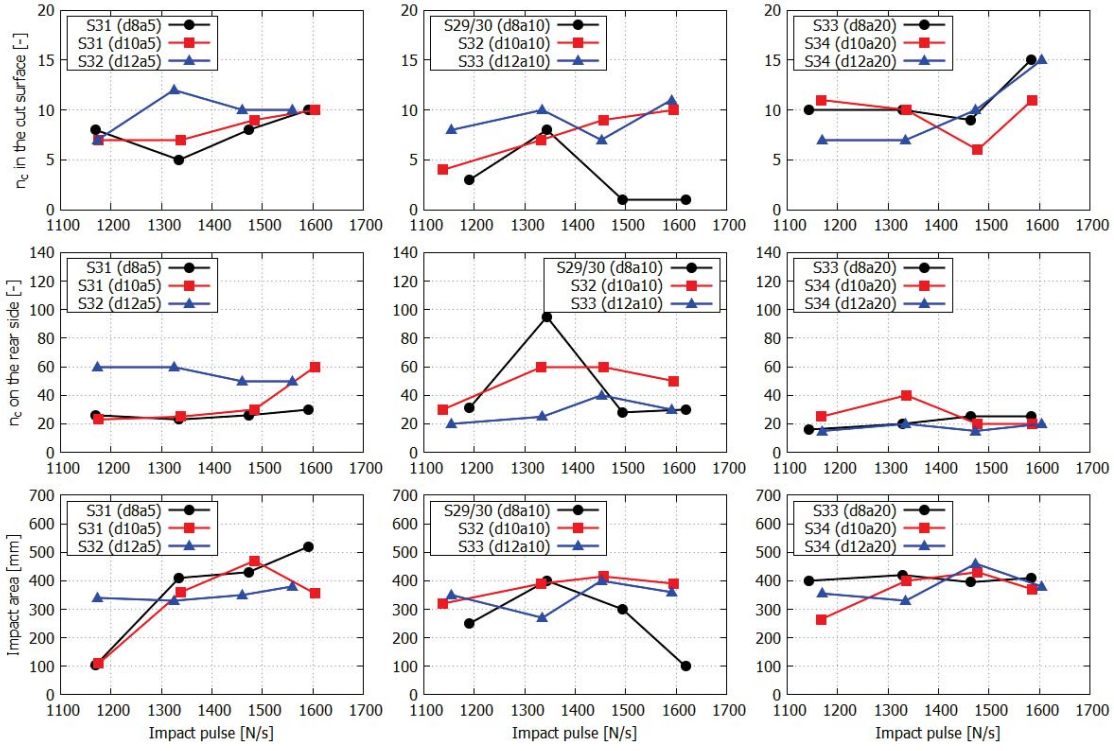

Figure 10: Visualization of the number of cracks (n_c) in the middle cut surface of the plate (top row), number of cracks on the half rear side (middle row) and the diameter of the damaged area of the front side of the plate (bottom row) in series with constant spatial distribution and varying rebar diameter

In Figures 10 and 11, the upper row shows the number of cracks (n_c) in the cut surface and

the middle row shows the cracks on the half rear side, both w.r.t. the impact pulse. In the bottom row, the diameter of the damaged area on the top side of the plate w.r.t. the impact pulse is presented. Cracks are counted as those that can be detected without using tools. This corresponds in some cases to a crack width of 0.1 mm. Every single crack was counted, which results in a large number for some plates.

The impactor mass was identical for all tests of series S29 to S34, see section 2. Therefore, for visualization it makes no difference whether the results are displayed w.r.t. the impact pulse or the impact velocity. For better comparison with other tests the impact pulse was used here.

Three series are compared in each presentation. These differed in the reinforcement's diameter (d = 8/10/12 mm) or it's spatial distribution (a = 5/10/20 cm). Despite of the parameters of the different series, the color representation is identical. The series with the smallest size of the varying parameter is colored black and circles are used for value marking. The series with the middle parameter is colored red and marked with squares, and the series with the highest parameter is colored blue and marked with a triangle.

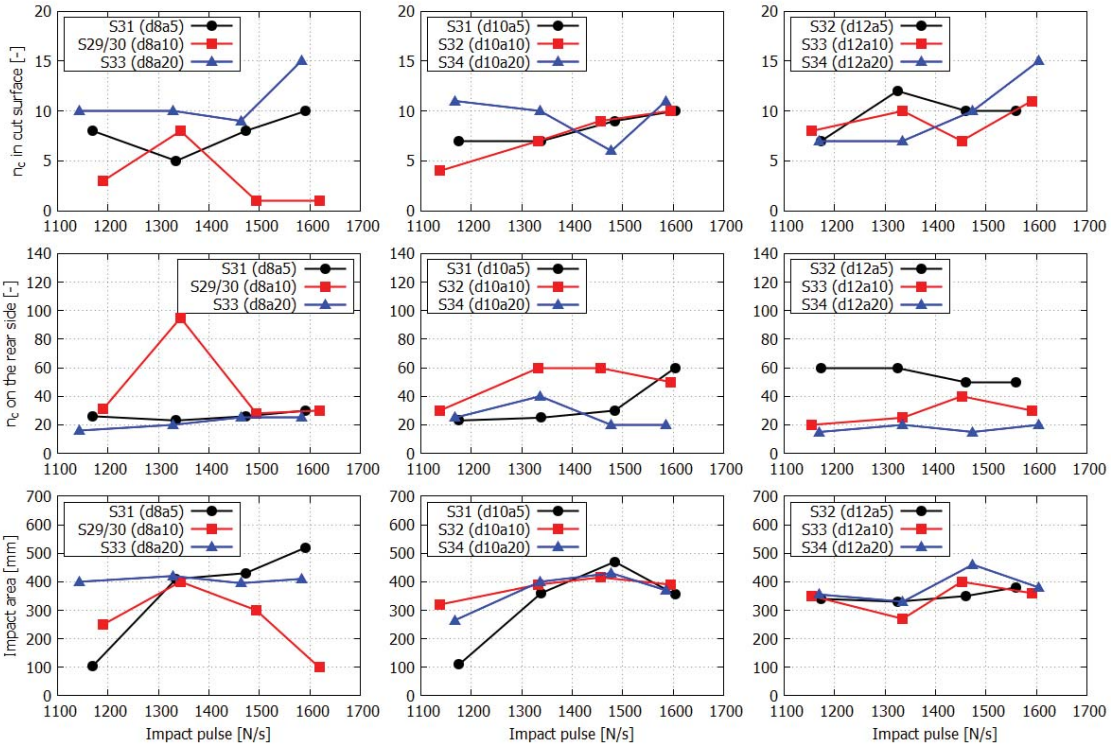

Figure 11: Visualization of the number of cracks in the middle cut surface of the plate (top row), number of cracks on the half rear side (middle row) and the diameter of the damaged area of the front side of the plate (bottom row) in series with varying spatial distribution and constant rebar diameter

In Figure 10, the series are sorted by the spatial distribution of the rebars. In each column, the spatial distribution remains constant and the diameter of the bars varies. In Figure 11, the comparison is the other way round. In the columns, the diameters of the bars remain constant and the spatial distribution varies. The aim is to obtain an overall comparison of the crack damage and to identify potential correlations.

For all combinations, the number of detected cracks is approximately in the same range and, with a few exceptions, increases with rising impact velocity. The number of cracks in the cut surface (upper row in each case) is currently not related to the number of cracks varying with the diameter or the distance between the bars. A similar conclusion can be drawn about the number of cracks on the half underside of the damaged plate.

In the following passages, the individual diagrams are explained in more detail.

At a constant distance of 5 cm, the 'curve' with the bar diameter of 12 mm behaves differently than expected (Figure 10, left diagram). In the comparison above, the plates with medium impact pulse show more cracks than the other plates. In the middle diagram, the whole series (S32 with d = 12 mm and a = 5 cm) shows more cracks. In the lower diagram, the diameter of the damaged surface on the upper side is plotted. In this series the plate with the lowest impact pulse has a much larger damaged area than the other series. With increasing velocity of the impactor, however, this changes slightly. In the three diagrams, the other two series (S31 with d = 8 mm and S31 with d=10 mm) are close together. A possible connection between impact area and number of cracks on the rear side cannot be recognized. At higher velocities the plates of the series S31 display a larger damaged area than that of S32. However, the number of cracks does not increase as expected.

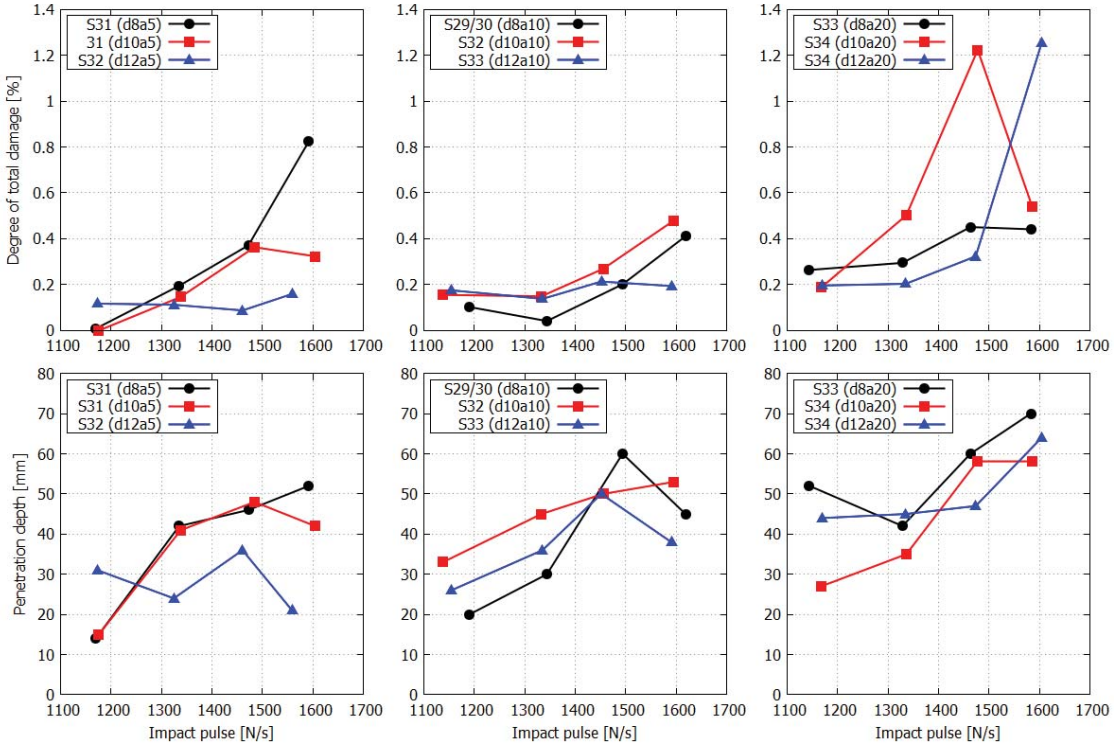

Figure 12: Degree of damage and penetration depth in the series with constant spatial distribution and varying rebar diameter

When comparing the series with constant rebar distance of 10 cm, the series S32 with d = 10 mm and S33 with d = 12 mm are relatively close to each other and show similar behaviour with increasing impact pulse. The series 29/30 with a bar diameter of 8 mm is the exception. A plate of this series with an impact pulse of about 1350 N/s is more damaged by cracks than the other plates of this series. The other three plates of this series are of about the same amount. A further remarkable difference to the two series S32 and S33 is the impact area.

With increasing velocity, the area is significantly smaller than the other plates of the series under the same experimental conditions. In the right column of Figure 10, all results of the plates are close together.

When comparing the series with constant diameter (see Figure 11) of 8 mm, the results of the individual plates differ from each other. When comparing the series with constant diameter of 10 mm and 12 mm, most results are again relatively close. Even if the individual results are not similar in every diagram, the behavior of the individual curves is relatively similar.

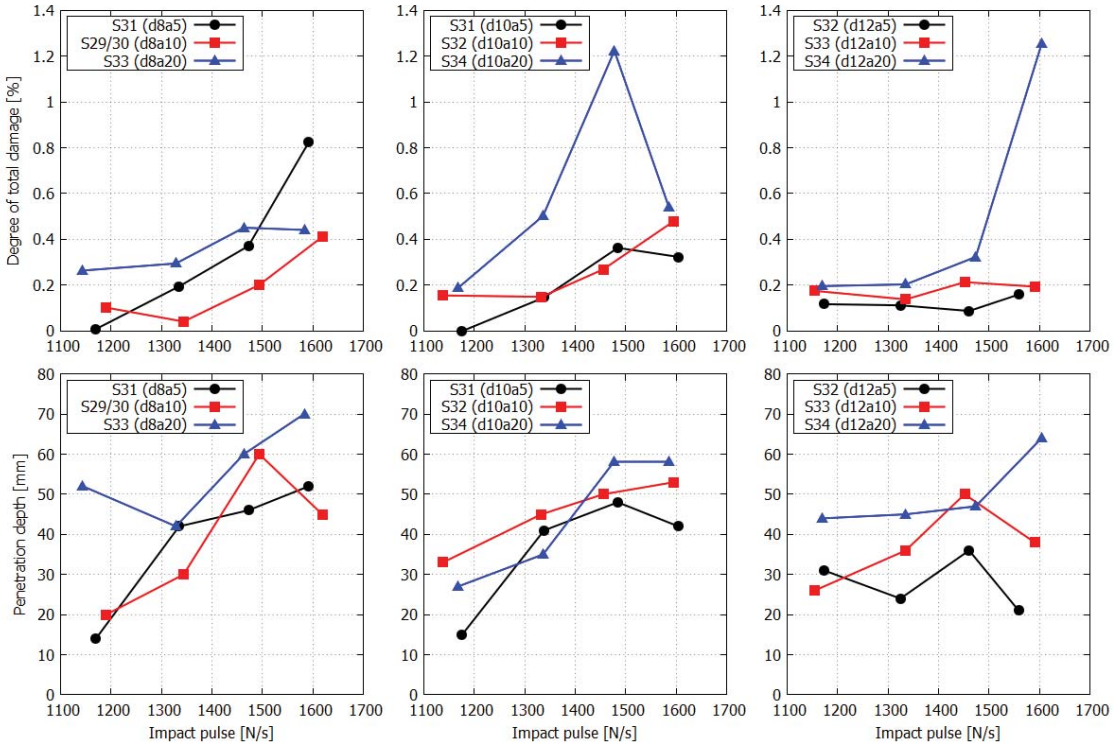

Figure 13: Degree of damage and penetration depth in the series with varying spatial distribution and constant rebar diameter

In the Figures 12 and 13, the total damage and penetration depth is given by the impact pulse. The total damage in this illustration is the ratio of the damaged material to the total volume of the plate and is calculated based on the weight loss. Analogous to the comparisons of the number of cracks, the exceptions to the results in individual series can be observed here.

The results of the series with constant distance a = 5 cm with respect to the impact area can be seen in the total damage and in slight variance in the values of the penetration depth, see Figure 12. When comparing the series with a spatial distribution of 10 cm, the results of the individual series are similar to each other, except for series 29/30 (d = 8 mm and a = 10 cm). The differences in the results of the series with 20 cm bar spacing were greater than expected after considering the previous results. With relatively minor crack damage and small impact area, the results of penetration depth and material loss show a high degree of damage.

Comparing the series with constant diameter (Figure 13), again the two series (S32 with d = 12 mm and a = 5 cm, and S29/30 with d = 8 mm and a = 10 cm) are an exception in the analysis of the results. The results of the series S31 and S33 with a constant diameter of d = 8 mm show expected results for the total damage and the penetration depth. In the S29/30 series, the impact area decreases with higher impact pulses, but the total damage increases.

When evaluating the results with constant diameter of d = 10 cm, the results of the series S31 with a = 5 cm and S32 with a = 10 cm can be explained. The results of series S34 with a = 20 cm cannot be concluded from the previous results. Similarly, this applies to the series with a bar diameter of 12 mm. Here it concerns the series S32 with a = 5 cm and S34 with a = 20 cm.

All the comparisons described here concerning damage (Figures 10 to 13) are based on a relatively small amount of tests. In total, 36 plates were examined. With the varying parameters of impact velocity, rebar diameter and their spatial distribution, one plate per constellation was tested. The individual damage characteristics examined will probably not show a large scattering width per parameter constellation, but it is exactly this scattering width and the reproducibility of damage caused by an impact that is not known.

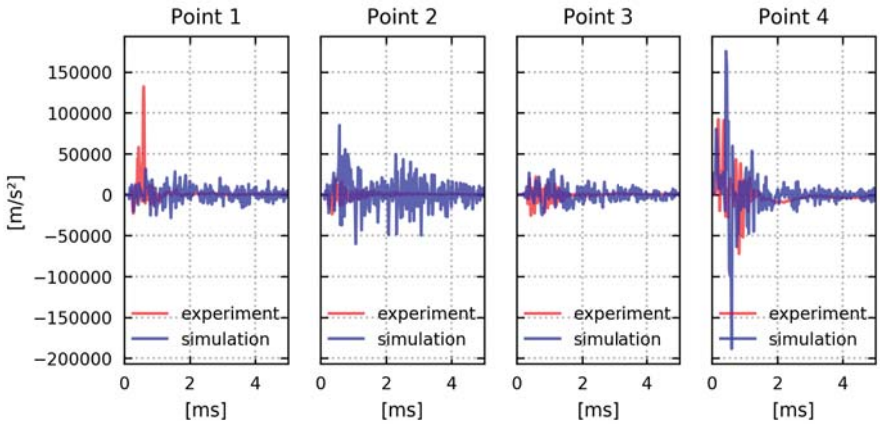

Figure 14: Visualization of the acceleration data in $[\mathrm{m/s^2}]$ comparing the test data with the numerical results of the plate S31P01 for the first 5 milliseconds at 4 measuring positions

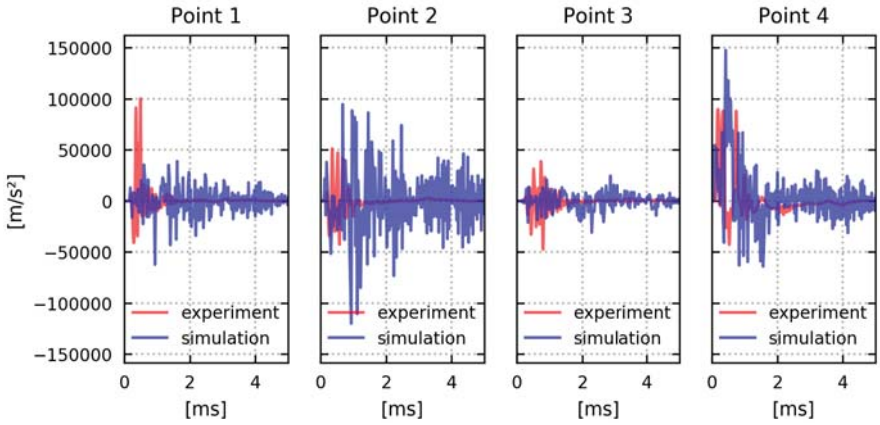

Figure 15: Visualization of the acceleration data in $[\mathrm{m/s^2}]$ comparing the test data with the numerical results of the plate S31P02 for the first 5 milliseconds at 4 measuring positions

The acceleration data were recorded at four positions on the plate, with three sensors mounted on the front and one sensor on the back (Figure 4). The measured data contain a time intervall of 2s. In the diagrams of Figure 14 bis 17, the measured values from the tests are only plotted for the first 5 milliseconds per plate compared to the numerical results based on the used time intervall of the numerical computations. Point 1 corresponds to measuring point ACC1, Point

2 correnspondsto ACC2 and so on. From the acceleration curve w.r.t. the time in every measuring position at every plate, it can be seen that the plate is damped faster than the numerical simulation. Further comparison have to be carried out with all measured data of all plates.

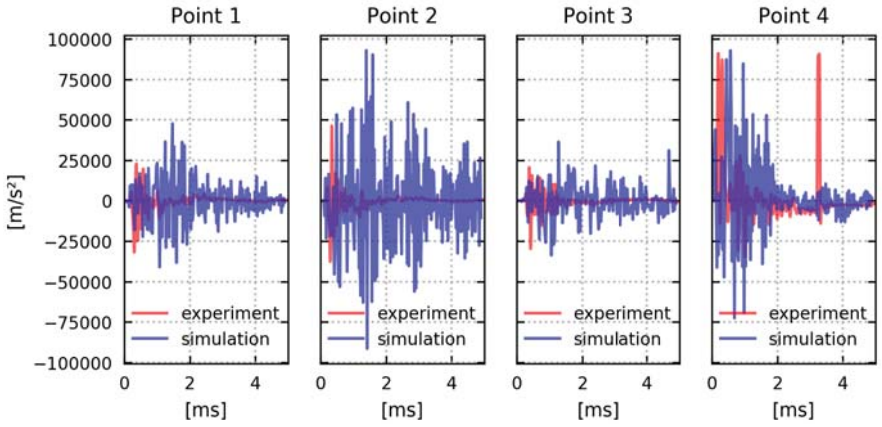

Figure 16: Visualization of the acceleration data in $[\mathrm{m/s^2}]$ comparing the test data with the numerical results of the plate S31P03 for the first 5 milliseconds at 4 measuring positions

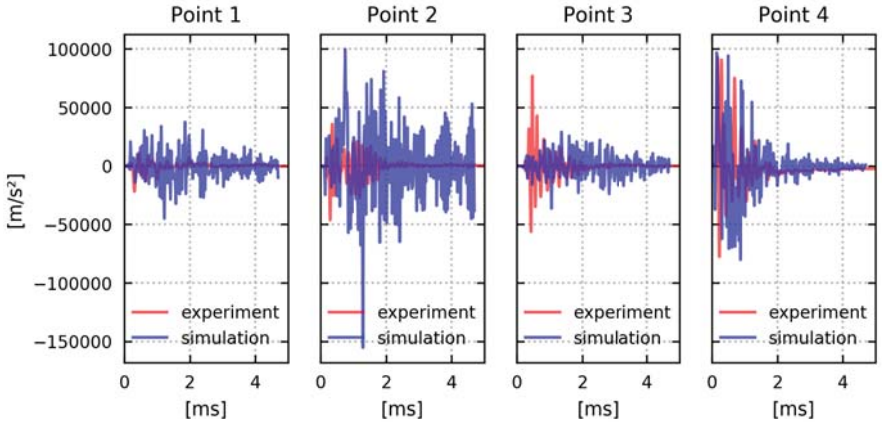

Figure 17: Visualization of the acceleration data in $[\mathrm{m/s^2}]$ comparing the test data with the numerical results of the plate S31P04 for the first 5 milliseconds at 4 measuring positions

In Figure 18, the maximum bearing force measured on the load cells in the tests with the results of the FEM is compared. Analogous to the previous comparisons, the results here are shown with constant bar diameter (left column) or constant spatial distribution (right column) w.r.t. the impact pulse. As in the previous figures, the colouring is black with circles as the second parameter increases, then red with squares and blue with triangles as marking of the measured data. The results from the numerical computations are colored the same. The measured values are marked with crosses for better differentiation.

The maximum forces in the bearings are mostly of the same order of magnitude. In the numerical results, the variance between the individual plates is much smaller than in the tested plates. Further investigations will follow, in which the relationship between the damage and the bearing reaction will also be investigated over time.

Figure 19 displays a selection of the analyzed tomographic results. Not all 36 plates of the reinforcement variation were examined. Here, 4 plates of the series 29/30 with a diameter of

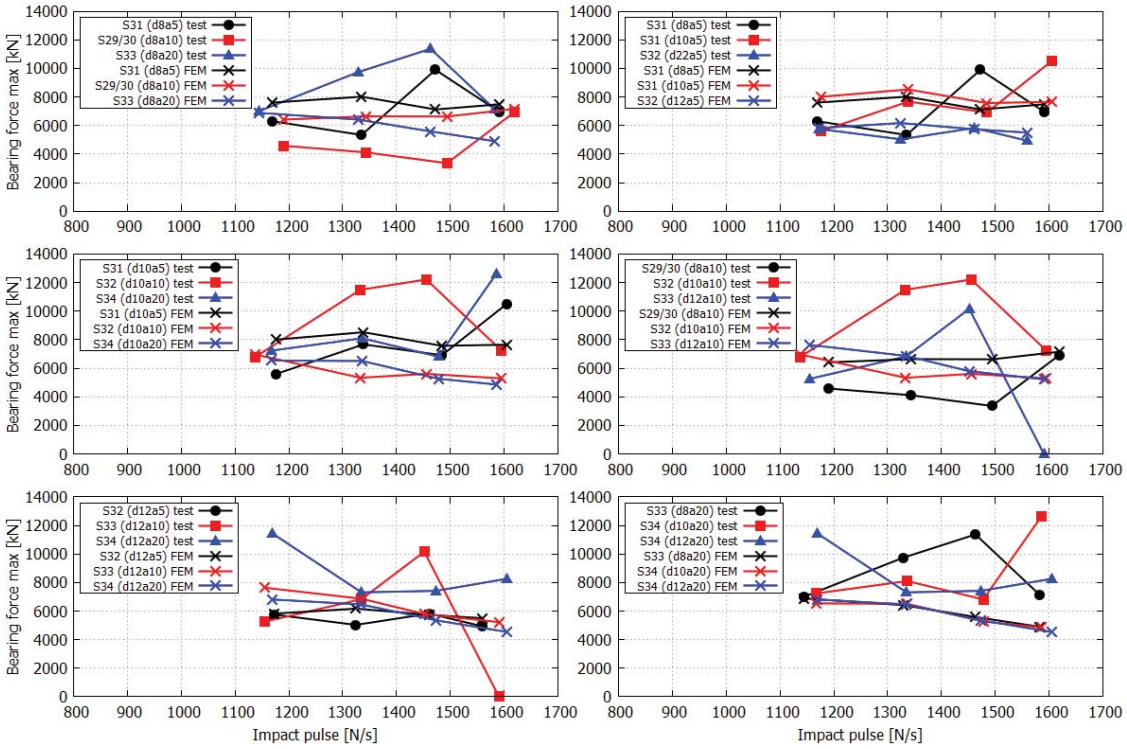

Figure 18: Visualization of the maximum bearing forces on the load cells comparing the test data with the numerical results

8 mm and a spatial distribution of 10 cm are compared to a plate of the series S31 (d = 8 mm and a = 5 cm) and two plates of the series S33 (d = 8 mm and a = 20 cm). In Figure 20, three plates with a spatial distribution of 20 cm and varying bar diameter are compared.

The crack maps (orange-red colored) were generated and in this case mapped to a layer of the radiated plate (gray colored). On some plates, the reinforcement bars are clearly visible (black colored). Only half plates are shown. The upper edge of each plate image corresponds to the middle cut edge of the entire plate. Due to the resolution, hairline cracks and cracks running diagonally into the material are not completely detected.

In table 3, the calculated damage degrees are shown. For a better allocation, the table lists the designation (series and plate), the rebar diameter (d_r), the spatial distribution of the rebars (a_r) and the impact pulse (I_{imp}). The total damage (dod total) is calculated from the material loss normalized to the mass of the total plate. The crack damage is calculated analogously from the crack volume normalized to the total volume. The identified crack volume from the tomographic data is calculated similar to the FEM damage maps. Both degrees of damage are evaluated separately and are based on different forms of damage (spalling and scabbing for one and crack volume for the other). In further steps, the crack maps are compared with the numerically computed damage maps in order to be able to configure the numerical parameters better for the future, also with regard to the damage. In this paper this takes place on the photos of the damaged plates, as shown in the Figures 21 to 23.

Table 3: Summary of the degree of crack damage (dod crack) and total damage (dod total) combined with the test parameters, like rebar diameter (d_r), the spatial distribution (a_r) and the impact pulse (I_{imp})

In the Figures 21 to 23, the results of the numerical simulations are compared to the crack patterns of the plates. On the left side, there is the middle cut surface, and on the right side, there is the half rear side of the plate, where the lower edge of the figure corresponds to the cut edge. The 4 plates of each series are shown sorted from top to bottom according to the impact velocity.

The cracks in the photos are highlighted in black and the spalling and scabbing in red. On

the photos, the individual cracks, the punching cone and the size of the impact area can be seen. The damage patterns of the FEM illustrate the probable damage due to the impactor. A blue coloring corresponds to a probability of 0%. The color gradient goes from blue to green to yellow to red. A red coloring corresponds to a probability of 100% damage of the element. The comparison of the representations (photo and FEM) indicates the difficulty of simulating crack structures if the damage level changes rapidly.

The material model was calibrated on previous plate experiments [21, 22, 19, 24]. The previous plates were not varied in the reinforcement parameters. The diameter remained constant 8 mm and the spatial distribution was 10 cm. For this reason, the correlation between the numerical data of the present plates and the experimental data in this series is better than for the others. Further refinements in the material model and in the contact modeling regarding the influence of the reinforcement will follow.

For a global evaluation of the damage, the external damage and the internal crack structures are of interest. In most cases, the cracks on the rear side of the plate between the numerical investigation and the damaged plate are identical. Difficulties occur in the case of spalling, since they do not appear in the numerical damage analysis. Due to the way the bearing is modeled, the damage to the bearing locations in the numerical model is unusually large.

The conformity of the cracks in the cut surface is less than that of the rear side of the plate. The impact velocities using in the tests are selected in such a way that, if possible, no bending failure and no perforation occurs. The damage area with cracks along the reinforcement and a punching cone due to the high compression force are in the focus. These patterns can be seen on the photos and in the numerical simulation. When comparing the photos with the numerical plots, not all computations show a match of the crack path. In contrast to the tests, the numerical results are reproducible and the models show no imperfections within the material.

In summary, the agreement is better for the plates with a distance of 10 cm than with a smaller or larger distance. The sensitivity of numerical modeling in this context is different from that of the experiments. In the experiments, there is still a lack of studies on the reproducibility of damage in order to be able to define a scattering width.

6 CONCLUSION

- With this variation of the reinforcement parameters, a large number of effects of local damage due to an impact was shown. In all series of reinforcement variation, the increase of damage with the impact velocity is clearly visible. Correlations between individual measured values and the structural behavior of the components were described.

- Further effects that concern the individual damage characteristics must be investigated more intensively. For example: What is the relationship between crack structure, impact area and reinforcement parameters? What about the reproducibility of damage? How large is the scatter range of the damage characteristics?

- The wide range of experiments and the detailed documentation is advantageous for further numerical investigations.

- It was shown that, the evaluation with the help of the combination of methods (direct analysis, tomography and FEM) can illustrate and explain many effects. The results of the combination of the evaluation methods tomography and numerics were presented using crack maps. In both methods, the structures were analyzed with the focus on damage. The damaged structure was identified and extracted. In further investigations the combinability of the tomographic data with the numerical results will be evaluated.

7 ACKNOWLEDGMENT

We thank the technical staff, especially Marcel Grunwald, for his support in the HEXY Lab. This work was funded by the German Federal Ministry of Economic Affairs and Energy under grant number 1501542 on the basis of a decision by the German Bundestag.

Keywords: Dynamic substructuring, Blast loading, Direct time-integration, Beam frame structure

Abstract. *In the present study, strategies are developed to enable time-efficient models for structures subjected to blast loading, appropriate for use in a structural design process. Dynamic substructuring is employed to obtain reduced models with localized nonlinearities, such as predefined plastic hinges in a beam–column structure. The parts of the substructures that remains linear elastic are modeled by Ritz-vectors whereas parts with a nonlinear response are retained as physical degrees-of-freedom. Furthermore, a time-stepping method is presented that is shown to be suitable for reduced models including local and predefined rigid–plastic behavior. The proposed methodology is applied and demonstrated in a numerical example of a concrete frame structure. Both the well-established Craig-Bampton method and reduction bases enriched by so-called correction modes are evaluated. For the load case studied, it is shown that the standard Craig-Bampton technique is suitable for reducing the substructures. Furthermore, it is shown that only a few Ritz-vectors are needed to sufficiently describe the deformation of the structure. However, additional modes are needed to ensure an accurate representation of the interface forces between the substructures.*

1 INTRODUCTION

Simplified models, such as equivalent single-degree-of-freedom (SDOF) systems, are often used for design of concrete members subjected to blast loading, an approach proposed already in the mid-1960s [1]. When this simplified approach is used for studying individual structural members, the supporting global structure is often considered as rigid and thus represented by prescribed displacement boundary conditions in the local response analyses. Hence, if a global response analysis is required it is in general performed in a subsequent stage, where the reaction forces computed in the local analyses are applied on the global structure. Such a procedure can be suitable if the stiffness and/or mass of the global structure are relatively large. However, in cases where the structural member is stiff and heavy, or even integrated as a part of the global lateral load-bearing structure, it can be necessary to employ a model of the coupled system. Furthermore, it can be necessary to include higher order modes to accurately capture the force transmitted between individual members and the global structure, in particular if the structure is subjected to a pulse with short duration and large peak pressure, as e.g. discussed in [2].

The dynamic response of a structure can e.g. be computed by use of a nonlinear finite element (FE) model, including the members subjected to external loading and the supporting global structure. However, the design of concrete structures subjected to blast loading is often an iterative process, where the cross-section dimensions and the amount and arrangement of bending reinforcement affect the dynamic response. Therefore, simplified and computationally efficient models are key in the conceptual design phase.

In the present study, strategies are developed to enable time-efficient models for structures subjected to blast loading, appropriate for use in a structural design process. More specifically, reduced models with localized nonlinearities, such as predefined plastic hinges in a beam–column structure, are obtained by use of dynamic substructuring (DS) (for an overview of DS techniques see e.g. [3,4]). Hence, parts that remains linear elastic are reduced and modeled by Ritz-vectors whereas the degrees-of-freedom (DOFs) included in parts with a nonlinear response are retained as physical DOFs. Furthermore, a time-stepping scheme is presented that is shown to be suitable for reduced models including local and predefined rigid–plastic behavior, such as frame structures with plastic hinges.

2 SIMPLIFIED MODELING OF CONCRETE STRUCTURES SUBJECTED TO BLAST LOADING

As for dynamic loading in general, the design of concrete structures subjected to blast loading can be challenging due to that the response is affected by the structure's mass, stiffness and strength. Hence, a modification of the dimensions, the amount and/or arrangement of reinforcement must, in general, be verified by an updated dynamic response analyses. Furthermore, a nonlinear response analysis is often required. The kinetic energy induced by the external pressure is converted into elastic and plastic strain energy, and if the plastic dissipation is omitted in the analysis the response can be inaccurate, e.g. resulting in a very conservative design. Therefore, simplified nonlinear SDOF models are often employed to evaluate the response of individual structural members.

In addition to the design of individual members, the global structure must be designed to resist progressive collapse and to ensure lateral stability. If a nonlinear response analysis is required for studying the global response, it is in general not straight-forward to construct a simplified model. Hence, a more refined nonlinear FE model of the whole structure can be necessary.

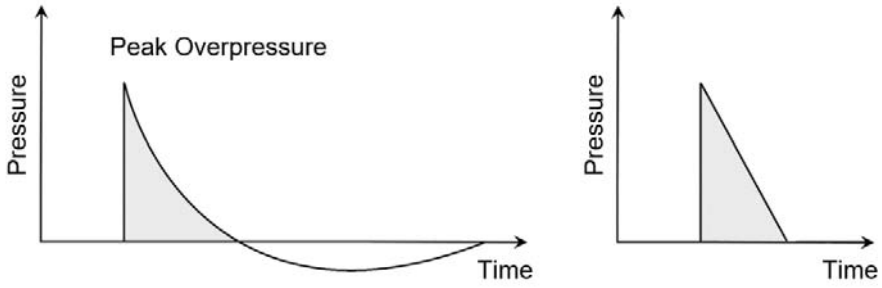

Figure 1: Typical (left) and idealized (right) blast pressure–time history.

2.1 Impulse pressure due to unconfined explosion

An unconfined explosion located on the ground surface results in a ground reflected shock wave that moves radially away from the center of the explosion [5]. If the explosion center is reasonable far from a structure, the pressure acting on the structure can be approximated by a uniform pressure. Upon impact, the initial wave is reinforced and reflected. The reflected impulse pressure acting on the structure is characterized by a very short duration and large peak pressure. For design purposes, the reflected impulse can, in general, be replaced by an equivalent triangular pulse, as shown in Figure 1. The actual duration is then replaced by a fictitious duration, computed from the peak reflected pressure and the reflected impulse.

2.2 Reduced models for design of concrete members

To ensure an adequate design of concrete members, such as beams and plates, subjected to blast loading, both the local response and the semi-global response (i.e. the global response of an individual member) must be considered. Hence, concrete members must be designed to resist local failure modes, such as punching shear failure, scabbing, spalling and penetration. Further, the shear force capacity and rotation capacity must be sufficiently large. Thus, it is crucial to ensure sufficient ductility and to avoid brittle failure modes.

A common procedure when evaluating the semi-global response of beams and plates is to set up an equivalent elasto-plastic SDOF system, where the yield force is derived from the ultimate moment capacity [1]. In fact, the yield force corresponds to the ultimate load, which implies that the maximum shear force in the dynamic response analysis is equal to the shear force given by a static yield line analysis. As e.g. shown in [2], the shear force computed using this simplified approach might be underestimated due to the neglection of higher order modes. Nonetheless, the approach can be reasonably accurate and in accordance with several design codes, such as UFC [5].

Using a simplified equivalent SDOF system implies that the position of the yield lines and/or plastic hinges can by assumed in accordance with a static yield line analysis, where the spatial load distribution correspond to the spatial distribution of the impulse pressure. This assumption is also the basis in the modeling strategies developed in Sections 3 and 4. However, it should be noted that this approach is primarily intended to be used in a conceptual design phase, i.e. a full nonlinear analysis can be necessary to verify the final design.

3 DYNAMIC SUBSTRUCTURING OF STRUCTURES WITH PLASTIC HINGES

By use of dynamic substructuring (DS) the aim is to efficiently compute the dynamic response of a structure by subdivision of the structure into substructures. Solving several substructures can be computationally less expensive than solving one large system. Moreover, DS can be employed to reduce systems with localized nonlinearities, such as predefined plastic

hinges in a beam–column structure. The parts of the structure that remains linear elastic is then reduced and modeled by Ritz-vectors whereas the DOFs included in parts with a nonlinear response are retained as physical DOFs.

In most DS techniques reduction is performed on the substructure level. Hence, the substructure displacements $\mathbf{u}^{(s)}$ are represented by a reduced set of coordinates $\mathbf{q}^{(s)}$, given by

$$\mathbf{u}^{(s)} = \mathbf{T}\mathbf{q}^{(s)} \tag{1}$$

where superscript *s* is the substructure label and $\mathbf{T}$ is a $n^{(s)} \times m^{(s)}$ transformation matrix, whose columns are Ritz-vectors, or so-called component modes. Depending on the DS technique, the reduced vector $\mathbf{q}^{(s)}$ can include physical master (or boundary) DOFs and/or generalized coordinates. Typically, $m^{(s)} << n^{(s)}$.

A FE formulation of a substructure leads to a linear equation of motion of the following form:

$$\mathbf{M}^{(s)}\ddot{\mathbf{u}}^{(s)} + \mathbf{C}^{(s)}\dot{\mathbf{u}}^{(s)} + \mathbf{K}^{(s)}\mathbf{u}^{(s)} = \mathbf{p}^{(s)} \tag{2}$$

where $\mathbf{p}^{(s)}$ is a $n^{(s)} \times 1$ substructure load vector and $\mathbf{M}^{(s)}$, $\mathbf{C}^{(s)}$ and $\mathbf{K}^{(s)}$ are the $n^{(s)} \times n^{(s)}$ substructure mass, damping and stiffness matrices, respectively. By inserting Equation (1) in (2) and pre-multiplying with $\mathbf{T}^{\mathrm{T}}$ the reduced subsystem is given by:

$$\widetilde{\mathbf{M}}^{(s)}\ddot{\mathbf{q}}^{(s)} + \widetilde{\mathbf{C}}^{(s)}\dot{\mathbf{q}}^{(s)} + \widetilde{\mathbf{K}}^{(s)}\mathbf{q}^{(s)} = \tilde{\mathbf{p}}^{(s)} \tag{3}$$

where

$$\widetilde{\mathbf{M}}^{(s)} = \mathbf{T}^{\mathrm{T}}\mathbf{M}^{(s)}\mathbf{T}, \qquad \widetilde{\mathbf{C}}^{(s)} = \mathbf{T}^{\mathrm{T}}\mathbf{C}^{(s)}\mathbf{T}, \qquad \widetilde{\mathbf{K}}^{(s)} = \mathbf{T}^{\mathrm{T}}\mathbf{K}^{(s)}\mathbf{T}, \qquad \tilde{\mathbf{p}}^{(s)} = \mathbf{T}^{\mathrm{T}}\mathbf{p}^{(s)} \tag{4}$$

The size of the reduced system matrices $\widetilde{\mathbf{M}}^{(s)}$, $\widetilde{\mathbf{C}}^{(s)}$ and $\widetilde{\mathbf{K}}^{(s)}$ is thus $m^{(s)} \times m^{(s)}$ and the reduced load vector $\tilde{\mathbf{p}}^{(s)}$ is $m^{(s)} \times 1$ (to simplify the notation the superscript *s* will be left out until Section 3.3, on substructure coupling procedures). The substructures are then reassembled to form a reduced model of the full coupled system, why DS is sometimes referred to as Component Mode Synthesis (CMS).

Arguably the most straight-forward methods within DS are the so-called condensation methods, where only physical master DOFs are included in $\mathbf{q}$. The most common condensation method is Guyan reduction, also referred to as static condensation due to that inertia effects are ignored [6]. The Guyan transformation matrix is given by

$$\begin{bmatrix}\mathbf{u}_i \\ \mathbf{u}_b\end{bmatrix} = \begin{bmatrix}-\mathbf{K}_{ii}^{-1}\mathbf{K}_{ib} \\ \mathbf{I}_{bb}\end{bmatrix}\mathbf{u}_b = \begin{bmatrix}\boldsymbol{\Psi}_{ib} \\ \mathbf{I}_{bb}\end{bmatrix}\mathbf{u}_b = \mathbf{T}_{\mathrm{G}}\mathbf{q} \tag{5}$$

where the subscripts *i* and *b* denotes the *interior* and interface *boundary* DOFs, $\mathbf{T}_{\mathrm{G}}$ is the Guyan transformation matrix and $\mathbf{q}$ contains the physical boundary DOFs. The columns of the transformation matrix are the so-called constraint modes, obtained by prescribing a unit displacement for a boundary DOF, while the interior DOFs are force-free and the other boundary DOFs are held fixed. Using this approach, "exact" results are achieved for static loading. However, due to neglected inertia effects the accuracy can be expected to decrease with an increasing forcing frequency.

Using a similar procedure but replacing the stiffness matrix with the dynamic stiffness matrix, exact result can instead be achieved for a certain forcing frequency, often referred to as dynamic reduction. There are also other more sophisticated condensation methods, such as Improved Reduction System (IRS) and System Equivalent Reduction Expansion Process (SEREP),

where the number of exact resonances is less or equal to the number of boundary DOFs [7]. However, using condensation methods, it is not possible to both obtain a reduced model that is "statically complete" (i.e. a basis for all possible deformations that result from loading at the substructure boundary nodes) and at the same time keeping exact resonances. To achieve this, a CMS approach is required that uses generalized coordinates representing the amplitudes of additional Ritz-vectors.

Several CMS techniques have been developed since the 1960s, which can be divided into *fixed-interface* and *free-interface* methods. The most popular approach, a fixed-interface method, is CMS by Craig-Bampton (C-B), developed in the late 1960s [8]. The C-B method combines fixed-interface normal modes with so-called constraint modes, see further Section 3.1. Free-interface methods, using so-called free-interface component modes, were developed by MacNeal, Rubin and Craig and Chang in the 1970s [9,10,11]. In addition, another free-interface method, the dual Craig-Bampton method, was proposed in the early 2000s which, in contrast to the other free-interface methods, preserves the sparsity of the system matrices [12].

Reducing a structure with plastic hinges, it is important to employ a DS technique where the physical boundary DOFs, namely the rotational DOFs at the plastic hinges, are retained. Therefore, the CMS method proposed by Craig and Chang is excluded due to an assembling procedure that removes the physical boundary DOFs. The dual C-B method is an interesting approach since the interface forces are kept as DOFs in the assembled system. However, this method produces negative eigenvalues which make a stable time integration impossible [13] (an approach to overcome this issue is e.g. proposed in [13], unfortunately this approach includes removing all physical DOFs).

Apart from retaining the physical boundary DOFs at the plastic hinges, the plastic deformations of the assembled system must be resolved. Hence, the reduced subsystems should be "statically complete" and rigid body modes of the subsystems should be included in the reduction basis. Using the C-B method, the rigid body modes are not explicitly included in the reduction basis. However, the rigid body modes are spanned by the constraint modes. In fact, the set of constraint modes is a basis for all possible deformations that result from loading at the substructure boundary nodes [14]. In addition to the C-B method, the free-interface methods by MacNeal and Rubin retains the physical boundary DOFs in the assembled system and explicitly includes the rigid body modes in the reduction basis.

In summary, either the fixed-interface C-B method or the free-interface methods by MacNeal and Rubin are judged to be the most suitable methods for reducing a beam–column structure including predefined plastic joints. A free-interface approach can be expected to be more accurate upon yielding, i.e. when the joint stiffness is zero, whereas a fixed-interface approach can be expected to be more accurate when the joints are fixed, i.e. when yielding does not occur. Based on this observation it is assumed that the classic C-B approach, which preserves the sparsity of the system matrices, is the preferred choice.

3.1 Craig-Bampton method

The Craig-Bampton method combines the retained physical DOFs with generalized coordinates corresponding to the amplitudes of so-called fixed-interface normal modes. Neglecting damping the partitioned mass and stiffness matrices can be written as:

$$\begin{bmatrix} \mathbf{M}_{ii} & \mathbf{M}_{ib} \\ \mathbf{M}_{bi} & \mathbf{M}_{bb} \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{u}}_i \\ \ddot{\mathbf{u}}_b \end{bmatrix} + \begin{bmatrix} \mathbf{K}_{ii} & \mathbf{K}_{ib} \\ \mathbf{K}_{bi} & \mathbf{K}_{bb} \end{bmatrix} \begin{bmatrix} \mathbf{u}_i \\ \mathbf{u}_b \end{bmatrix} = \begin{bmatrix} \mathbf{p}_i \\ \mathbf{p}_b \end{bmatrix} \tag{6}$$

By setting the boundary displacements to zero in Equation (6), the fixed-interface normal modes are obtained by the generalized eigenvalue problem:

$$\left(\mathbf{K}_{ii} - \omega_j^2 \mathbf{M}_{ii}\right)\left\{\boldsymbol{\phi}_i\right\}_j = 0 \tag{7}$$

where $\mathbf{K}_{ii}$ and $\mathbf{M}_{ii}$ are the interior stiffness and mass matrices. The eigenvectors are normalized so that $\boldsymbol{\Phi}_{ii}{}^{\mathrm{T}}\mathbf{M}_{ii}\boldsymbol{\Phi}_{ii} = \mathbf{I}_{ii}$, where $\boldsymbol{\Phi}_{ii}$ is the complete set of fixed-interface normal modes. The physical coordinates can then be represented as:

$$\begin{bmatrix}\mathbf{u}_i \\ \mathbf{u}_b\end{bmatrix} = \begin{bmatrix}\boldsymbol{\Phi}_{ik} & \boldsymbol{\Psi}_{ib} \\ \mathbf{0}_{bk} & \mathbf{I}_{bb}\end{bmatrix}\begin{bmatrix}\mathbf{q}_k \\ \mathbf{u}_b\end{bmatrix} = \mathbf{T}_{\text{C-B}}\mathbf{q} \tag{8}$$

where the subscript k denotes the kept fixed-interface normal modes, $\mathbf{T}_{\text{C-B}}$ is the Craig-Bampton transformation matrix, $\mathbf{q}_k$ is the generalized coordinates and $[\boldsymbol{\Psi}_{ib} \quad \mathbf{I}_{bb}]^{\mathrm{T}}$ is the constraint mode matrix, equivalent to the Guyan reduction basis. Hence, the Craig-Bampton method can be interpreted as an extension of the Guyan reduction where the neglected inertia terms are compensated by including a set of fixed-interface normal modes.

3.2 Craig-Bampton with Modal Truncation Augmentation

The fixed-interface normal modes included in the C-B reduction basis can be augmented by so-called high order static correction modes, which can be interpreted as a form of generalization of the Guyan static modes. The C-B method with so-called Modal Truncation Augmentation (MTA) is presented in [15].

If the internal forces are zero, the top row of Equation (6) can be rewritten as:

$$\mathbf{M}_{ii}\ddot{\mathbf{u}}_i + \mathbf{K}_{ii}\mathbf{u}_i = -\mathbf{M}_{ib}\ddot{\mathbf{u}}_b - \mathbf{K}_{ib}\mathbf{u}_b \tag{9}$$

Hence, the substructure can be considered excited by imposed displacements on its boundary. Further, the internal displacements can be approximated as

$$\mathbf{u}_i = \mathbf{u}_{i,\text{stat}} + \mathbf{y} \tag{10}$$

where $\mathbf{u}_{i,\text{stat}} = -\mathbf{K}_{ii}{}^{-1}\mathbf{K}_{ib}\mathbf{u}_b$ is the quasi-static solution modified by the second term $\mathbf{y}$ to obtain the dynamic response, i.e. similarly to the well-established mode acceleration method, e.g. described in [16]. By inserting Equation (10) into Equation (9) the dynamic response of the relative solution is given by

$$\mathbf{M}_{ii}\ddot{\mathbf{y}} + \mathbf{K}_{ii}\mathbf{y} = -\mathbf{M}_{ii}\ddot{\mathbf{u}}_{i,\text{stat}} - \mathbf{M}_{ib}\ddot{\mathbf{u}}_b = \mathbf{Y}\ddot{\mathbf{u}}_b \tag{11}$$

where $\mathbf{Y} = \mathbf{M}_{ii}\mathbf{K}_{ii}{}^{-1}\mathbf{K}_{ib} - \mathbf{M}_{ib}$, which can be interpreted as inertia forces associated to static modes [15]. This procedure can be continued by replacing $\mathbf{y}$ with a quasi-static solution and a dynamic correction. Hence, a recursive procedure is obtained, indicating that the dynamic response can be approximated as

$$\mathbf{u}_i \approx -\mathbf{K}_{ii}{}^{-1}\mathbf{K}_{ib}\mathbf{u}_b + \sum_{j=1}^{n}\left(-\mathbf{K}_{ii}{}^{-1}\mathbf{M}_{ii}\right)^{j-1}\mathbf{K}_{ii}{}^{-1}\mathbf{Y}\frac{\mathrm{d}^{2j}\mathbf{u}_b}{\mathrm{d}t^{2j}} \tag{12}$$

where n is the number of static corrections.

According to Equation (12) a dynamic response analysis is not included in the approximation. However, if a dynamic analysis including k eigenmodes has been performed, part of the corrections is already considered. The expression for the higher order corrections can then be rewritten as:

$$\mathbf{u}_{i,cor.j} \approx \left(\mathbf{K}_{ii}^{-1} - \sum_{r=1}^{k} \frac{\boldsymbol{\phi}_r \boldsymbol{\phi}_r^{\mathrm{T}}}{\omega_r^2} \right) \left(-\mathbf{M}_{ii} \mathbf{K}_{ii}^{-1} \right)^{j-1} \mathbf{Y} \frac{\mathrm{d}^{2j} \mathbf{u}_b}{\mathrm{d}t^{2j}} \tag{13}$$

where we use that the inverse of the stiffness matrix can be expressed as

$$\mathbf{K}_{ii}^{-1} = \sum_{r=1}^{N} \frac{\boldsymbol{\phi}_r \boldsymbol{\phi}_r^{\mathrm{T}}}{\omega_r^2} = \sum_{r=1}^{k} \frac{\boldsymbol{\phi}_r \boldsymbol{\phi}_r^{\mathrm{T}}}{\omega_r^2} + \sum_{r=k+1}^{N} \frac{\boldsymbol{\phi}_r \boldsymbol{\phi}_r^{\mathrm{T}}}{\omega_r^2} \tag{14}$$

where N is the total number of eigenmodes, and $\boldsymbol{\phi}_r$ and ω_r is the eigenmode and eigenfrequency for mode r. Hence, the space already spanned by the fixed-interface normal modes is removed from the corrections. The total response is then given by

$$\mathbf{u}_i \approx \sum_{r=1}^{k} \boldsymbol{\phi}_r q_r + \sum_{j=0}^{n} \mathbf{u}_{i,cor.j} \tag{15}$$

where $\mathbf{u}_{i,cor.0} = -\mathbf{K}_{ii}^{-1} \mathbf{K}_{ib} \mathbf{u}_b$. Furthermore, the amplitudes $\frac{\mathrm{d}^{2j} \mathbf{u}_b}{\mathrm{d}t^{2j}}$ can be treated as separate DOFs, i.e. instead of high order corrections the modal basis is augmented by high order correction *modes*, also referred to as force-dependent Ritz-vectors or Krylov vectors. Hence, the j-th order correction modes is given by:

$$\mathbf{x}_{i,cor.j} = \left(\mathbf{K}_{ii}^{-1} - \sum_{r=1}^{k} \frac{\boldsymbol{\phi}_r \boldsymbol{\phi}_r^{\mathrm{T}}}{\omega_r^2} \right) \left(\mathbf{M}_{ii} \mathbf{K}_{ii}^{-1} \right)^{j-1} \mathbf{Y} \tag{16}$$

Note that the number of vectors generated in each iteration equals the number of boundary DOFs, why the subspace spanned by the generated vectors is sometimes referred to as a block-Krylov subspace [14]. The static correction modes are both mass- and stiffness-orthogonal to the fixed-interface normal modes. However, they are not mutually orthogonal. This can e.g. be achieved by solving a small eigenvalue problem:

$$(\mathbf{X}_{cor}^{\mathrm{T}} \mathbf{K} \mathbf{X}_{cor}) \mathbf{Z} = (\mathbf{X}_{cor}^{\mathrm{T}} \mathbf{M} \mathbf{X}_{cor}) \mathbf{Z} \boldsymbol{\Lambda} \tag{17}$$

where $\mathbf{X}_{\mathrm{cor}}$ is the correction mode matrix. The eigenvectors are normalized so that $\mathbf{Z}^{\mathrm{T}} \left(\mathbf{X}_{\mathrm{cor}}^{\mathrm{T}} \mathbf{M} \mathbf{X}_{\mathrm{cor}} \right) \mathbf{Z} = \mathbf{I}$ and the orthonormal basis of the correction vectors is then given by $\tilde{\mathbf{X}}_{\mathrm{cor}} = \mathbf{X}_{\mathrm{cor}} \mathbf{Z}$. The relation between the substructure physical DOFs and the reduced coordinate is then given by

$$\begin{bmatrix} \mathbf{u}_i \\ \mathbf{u}_b \end{bmatrix} = \begin{bmatrix} \boldsymbol{\Phi}_{ik} & \tilde{\mathbf{X}}_{cor} & \boldsymbol{\Psi}_{ib} \\ \mathbf{0}_{bk} & \mathbf{0}_{bn} & \mathbf{I}_{bb} \end{bmatrix} \begin{bmatrix} \mathbf{q}_k \\ \mathbf{q}_n \\ \mathbf{u}_b \end{bmatrix} = \mathbf{T}_{\mathrm{C\text{-}B,cor}} \mathbf{q} \tag{18}$$

where $\mathbf{q}_n$ is the amplitudes of the correction modes and $\mathbf{T}_{\mathrm{C\text{-}B,cor}}$ is the C-B transformation matrix augmented by correction modes.

Using the above procedure, correction modes are generated based on interface excitation. Using a similar procedure, the correction modes, or so-called force dependent Ritz-vectors, can also be generated based on external loads applied to the substructure interior DOFs.

3.3 Substructure coupling procedures

Since the physical boundary DOFs are preserved in the C-B reduction process the assembly method is straight-forward, hence each substructure can be treated as a super-element. However, the substructures can either be assembled by eliminating one set of interface DOFs, a so-called *primal* assembled system, or so that all interface DOFs are preserved, a so-called *dual* assembled system.

The block diagonal system matrices for a structure consisting of N_s substructures are given by

$$\mathbf{M} = \text{diag}(\mathbf{M}^{(s)}), \qquad \mathbf{C} = \text{diag}(\mathbf{C}^{(s)}), \qquad \mathbf{K} = \text{diag}(\mathbf{K}^{(s)}) \tag{19}$$

where **M**, **C** and **K** have size $n \times n$ and the superscript s is the substructure label. The equation of motion can then be written as

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{C}\dot{\mathbf{u}} + \mathbf{K}\mathbf{u} = \mathbf{p} \tag{20}$$

where **u** is the $n \times 1$ global displacement vector, including all DOFs at the interfaces between substructures. Assuming compatible meshes, constraints enforced between substructures for individual DOF pairs, e.g. $u_i^{(s_1)} = u_j^{(s_2)}$, can be written in matrix form:

$$\mathbf{B}\mathbf{u} = \mathbf{0} \tag{21}$$

where the constraint matrix **B** is a signed Boolean matrix with size $m \times n$, where m is the number of constraints and n is the total number of DOFs.

As e.g. shown in [3], a primal assembly can be enforced by using the so-called Boolean localization matrix **L**, found by computing the null-space for **B**, i.e.

$$\mathbf{L} = \text{Null}(\mathbf{B}) \tag{22}$$

The relation between the global displacement vector and a displacement vector with a unique set of interface DOFs, $\mathbf{u}_P$, is then given by

$$\mathbf{u} = \mathbf{L}\,\mathbf{u}_P \tag{23}$$

By inserting Equation (23) in Equation (20) and pre-multiplying with $\mathbf{L}^T$ the equation of motion for the primal assembled system is given by

$$\mathbf{M}_P\ddot{\mathbf{u}}_P + \mathbf{C}_P\dot{\mathbf{u}}_P + \mathbf{K}_P\mathbf{u}_P = \mathbf{p}_P \tag{24}$$

where

$$\mathbf{M}_P = \mathbf{L}^T\mathbf{M}\mathbf{L}, \qquad \mathbf{C}_P = \mathbf{L}^T\mathbf{C}\mathbf{L}, \qquad \mathbf{K}_P = \mathbf{L}^T\mathbf{K}\mathbf{L}, \qquad \mathbf{p}_P(t) = \mathbf{L}^T\mathbf{p} \tag{25}$$

The number of DOFs in the primal assembled system is thus $n_P = n - m$ and, accordingly, the size of $\mathbf{M}_P$, $\mathbf{C}_P$, $\mathbf{K}_P$ is $[n_P \times n_P]$ and $\mathbf{p}_P$ is $[n_P \times 1]$.

Instead of eliminating one set of DOFs, a dual assembled system can be achieved by enforcing the interface constraints using Lagrange multipliers $\boldsymbol{\lambda}$. The system of equations can then be written as

$$\begin{bmatrix} \mathbf{M} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{u}} \\ \boldsymbol{\lambda} \end{bmatrix} + \begin{bmatrix} \mathbf{C} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \dot{\mathbf{u}} \\ \boldsymbol{\lambda} \end{bmatrix} + \begin{bmatrix} \mathbf{K} & \mathbf{B}^T \\ \mathbf{B} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \mathbf{u} \\ \boldsymbol{\lambda} \end{bmatrix} = \begin{bmatrix} \mathbf{p} \\ \mathbf{0} \end{bmatrix} \tag{26}$$

thus, preserving all interface DOFs [17]. Note that $\boldsymbol{\lambda}$ can be interpreted as an interface force vector, i.e. the forces required to enforce equal displacements for interface DOF pairs.

A dual assembled system can also be enforced using the penalty method, e.g. expressed as

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{C}\dot{\mathbf{u}} + (\mathbf{K} + \alpha \mathbf{B}^T\mathbf{B})\mathbf{u} = \mathbf{p} \tag{27}$$

where α is the penalty stiffness, chosen sufficiently large so that $\mathbf{Bu} \approx \mathbf{0}$ [17]. Note that this approach corresponds to adding stiff springs between the constrained DOFs.

The preferred assembly method, or constraint enforcement method, depend on several factors such as the analysis type, the output data of interested, etc.

4 TIME-STEPPING METHOD FOR STRUCTURES WITH RIGID–PERFECTLY PLASTIC JOINTS

Simplified models are often used for design of concrete structures where linear elastic beam elements are combined with predefined discrete plastic hinges, approximated as rigid–perfectly plastic. To enforce a rigid–perfectly plastic coupling between two DOFs, namely the rotational DOFs at the plastic hinges, one alternative is to utilize the penalty method, i.e. by introducing a stiff elastic–perfectly plastic rotational spring. However, one obvious problem when using the penalty method is to choose a suitable penalty stiffness—if it is too low, the results will be inaccurate and if it is too large, the system equations will be ill-conditioned with respect to inversion. Furthermore, the highest eigenfrequency of the system can be expected to increase significantly, which can result in a very small critical time increment size in conditionally stable time integration schemes.

Another alternative is to set up a dual assembled system according to Equation (26) and setting a maximum value, corresponding to the plastic moment, for the Lagrange multipliers. The Lagrange multipliers will then be either known, i.e. treated as external forces equal to the plastic moments, or unknown. However, ensuring stability for a system including Lagrange multipliers, for so-called Differential-Algebraic Equations (DAEs), is often found to be problematic in direct time integration of dual assembled systems. For example, a standard Newmark time integration scheme, assuming constant average accelerations, is in this case unconditionally unstable. However, methods to ensure stability exist, see e.g. [18]. Nonetheless the available time integration schemes are somewhat limited.

Instead of using a pure dual or primal formulation, a methodology is proposed where the system is reassembled when yielding of the rigid–perfectly plastic hinges starts or stops. Such a procedure implies that the nonlinear analysis is performed as a series of linear analyses. Hence, the plastic hinges are either modeled as fixed by eliminating one of the rotational DOFs or as external moments applied on both rotational DOFs at the plastic hinges. This approach can be expected to be particularly suitable for systems consisting of reduced substructures, with a limited number of plastic hinges. The critical time increment is then related to the highest eigenfrequency of the assembled substructures, which in turn have already been reduced by a modal truncation on the substructure level, removing the high frequency content. Furthermore, high frequency noise induced by penalty elements is avoided.

4.1 Time-stepping algorithm

Starting with the system in Equation (20), a $m \times n$ signed Boolean matrix $\mathbf{B}$ can be constructed to define all the interface couplings between the substructures. The couplings can either be fixed constraints or rigid–perfectly plastic couplings. The matrix is then partitioned as:

$$\mathbf{B} = \begin{bmatrix} \mathbf{B}_r \\ \mathbf{B}_c \\ \mathbf{B}_y \end{bmatrix} \tag{28}$$

where $\mathbf{B}_r$ defines m_r constraints (or boundary conditions) that are not limited by a yield force, e.g. the translational DOFs at a plastic hinge, $\mathbf{B}_c$ defines the m_c rigid–plastic couplings not yielding and $\mathbf{B}_y$ defines the m_y rigid–plastic couplings currently yielding. Hence, the Boolean matrices $\mathbf{B}_c$ and $\mathbf{B}_y$ must be updated in a time-stepping scheme. The constraints defined by $\mathbf{B}_r$ are enforced using a primal formulation before the time-stepping is initialized, hence by eliminating m_r interface DOFs. The equation of motion for the assembled system can then be written as

$$\widehat{\mathbf{M}}\ddot{\mathbf{u}}_r + \widehat{\mathbf{C}}\dot{\mathbf{u}}_r + \widehat{\mathbf{K}}\mathbf{u}_r = \hat{\mathbf{p}} \tag{29}$$

where

$$\widehat{\mathbf{M}} = \mathbf{L}_r^{\mathrm{T}}\mathbf{M}\mathbf{L}_r, \qquad \widehat{\mathbf{C}} = \mathbf{L}_r^{\mathrm{T}}\mathbf{C}\mathbf{L}_r, \qquad \widehat{\mathbf{K}} = \mathbf{L}_r^{\mathrm{T}}\mathbf{K}\mathbf{L}_r, \qquad \hat{\mathbf{p}} = \mathbf{L}_r^{\mathrm{T}}\mathbf{p} \tag{30}$$

and where the Boolean localization matrix $\mathbf{L}_r = \mathrm{Null}(\mathbf{B}_r)$. To simplify the implementation the eliminated DOFs are then removed from the matrices $\mathbf{B}_c$ and $\mathbf{B}_y$, i.e. by removing the corresponding m_r columns containing zeros. The size of the updated matrices $\widehat{\mathbf{B}}_c$ and $\widehat{\mathbf{B}}_y$ is then $m_c \times (n - m_r)$ and $m_y \times (n - m_r)$, respectively. At the initial stage, the couplings defined by $\widehat{\mathbf{B}}_c$ is enforced in the same manner by computing $\mathbf{L}_c = \mathrm{Null}(\widehat{\mathbf{B}}_c)$. At each time increment $t^{(i)}$, the interface forces $\boldsymbol{\lambda}^{(i)}$ is computed from the expression

$$\widehat{\mathbf{B}}_c^{\mathrm{T}}\boldsymbol{\lambda}^{(i)} = \hat{\mathbf{p}}^{(i)} - \widehat{\mathbf{M}}\mathbf{L}_c\ddot{\mathbf{u}}_c{}^{(i)} - \widehat{\mathbf{C}}\mathbf{L}_c\dot{\mathbf{u}}_c{}^{(i)} - \widehat{\mathbf{K}}\mathbf{L}_c\mathbf{u}_c{}^{(i)} \tag{31}$$

where the relation $\mathbf{u}_r = \mathbf{L}_c\mathbf{u}_c$ has been applied. If the interface force for a coupling is larger than the specified yield force, the Boolean matrices $\widehat{\mathbf{B}}_c$ and $\widehat{\mathbf{B}}_y$ are updated, i.e. the row in $\widehat{\mathbf{B}}_c$ defining the coupling is moved to $\widehat{\mathbf{B}}_y$. Thereafter, the system is reassembled by computing the localization matrix $\mathbf{L}_c = \mathrm{Null}(\widehat{\mathbf{B}}_c)$ and applying it to Equation (29). The couplings currently yielding are then considered by adding the yield forces as external loads, hence

$$\mathbf{L}_c^{\mathrm{T}}\widehat{\mathbf{M}}\mathbf{L}_c\ddot{\mathbf{u}}_c{}^{(i)} + \mathbf{L}_c^{\mathrm{T}}\widehat{\mathbf{C}}\mathbf{L}_c\dot{\mathbf{u}}_c{}^{(i)} + \mathbf{L}_c^{\mathrm{T}}\widehat{\mathbf{K}}\mathbf{L}_c\mathbf{u}_c{}^{(i)} = \mathbf{L}_c^{\mathrm{T}}\left(\hat{\mathbf{p}}^{(i)} - \widehat{\mathbf{B}}_y^{\mathrm{T}}\mathbf{f}_y\right) \tag{32}$$

where $\mathbf{f}_y$ is a $m_y \times 1$ vector containing the specified yield forces. Unloading of the m_y couplings currently yielding is detected by checking the relative velocity sign, i.e. if

$$\mathrm{sign}\left(\left\{\widehat{\mathbf{B}}_y\dot{\mathbf{u}}_r{}^{(i)}\right\}_j\right) \neq \mathrm{sign}\left(\left\{\widehat{\mathbf{B}}_y\dot{\mathbf{u}}_r{}^{(i+1)}\right\}_j\right) \tag{33}$$

where subscript j denotes an element of the column vector $\widehat{\mathbf{B}}_y\dot{\mathbf{u}}_r$. If unloading occurs, the system is updated by moving rows from $\widehat{\mathbf{B}}_y$ to $\widehat{\mathbf{B}}_c$, computing the localization matrix $\mathbf{L}_c = \mathrm{Null}(\widehat{\mathbf{B}}_c)$ and applying it to Equation (29).

The time integration between the system updates can be performed in a standard manner by the Newmark-β method, as e.g. described in [19]. However, for a nonlinear system including both elastic and plastic deformations it is convenient to use incremental quantities,

$$\Delta\mathbf{u}^{(i)} = \mathbf{u}^{(i+1)} - \mathbf{u}^{(i)}, \quad \Delta\mathbf{u}^{(i)} = \mathbf{u}^{(i+1)} - \mathbf{u}^{(i)}, \quad \Delta\ddot{\mathbf{u}}^{(i)} = \ddot{\mathbf{u}}^{(i+1)} - \ddot{\mathbf{u}}^{(i)}, \quad \Delta\mathbf{p}^{(i)} = \mathbf{p}^{(i+1)} - \mathbf{p}^{(i)} \tag{34}$$

In fact, the time-stepping algorithm is constructed so that the computed incremental displacements are always transformed and appended to $\mathbf{u}_r$, thus

$$\mathbf{u}_r{}^{(i+1)} = \mathbf{u}_r{}^{(i)} + \mathbf{L}_c \Delta\mathbf{u}_c{}^{(i)} \tag{35}$$

Consequently, the displacement vector need not to be transformed at the system updates. Merging DOF pairs in couplings where yielding is stopped would certainly be an ambiguous operation, since the displacement in each DOF in general will differ.

Upon yielding, the system is updated so that couplings where yielding is initiated are released. The interpretation of this update is straight-forward since the initial state of the physical quantities (i.e. displacements, velocities, accelerations) in the new configuration is well defined by the previous state. If yielding is stopped, rigid couplings are enforced by eliminating one set of interface DOFs. The velocities for the constrained DOFs are by definition equal when unloading is detected and it is thus straight-forward to eliminate one set of DOFs. The initial acceleration in the updated system is computed as

$$\ddot{\mathbf{u}}_c{}^{(i)} = \left(\mathbf{L}_c^{\mathrm{T}}\widehat{\mathbf{M}}\mathbf{L}_c\right)^{-1}\mathbf{L}_c^{\mathrm{T}}\left(\hat{\mathbf{p}}^{(i)} - \widehat{\mathbf{B}}_y^{\mathrm{T}}\mathbf{f}_y - \widehat{\mathbf{C}}\dot{\mathbf{u}}_r{}^{(i)} - \widehat{\mathbf{K}}\mathbf{u}_r{}^{(i)}\right) \tag{36}$$

Note that the time increment between system updates, $\Delta t^{(i)} = t^{(i)} - t^{(i-1)}$, is zero. Hence, the velocities and deformations are equal in increment i and $i - 1$. However, the accelerations are changed at the system updates in accordance with Equation (36). Even though an instantaneous change of the accelerations might seem unreasonable, this is a consequence of the unphysical assumption of a perfectly rigid connection, which however can be a very useful approximation; in particular when modeling plastic hinges in beam–column structures. Furthermore, it should be noted that both the strain and kinetic energy is preserved.

4.2 Remarks on performance and accuracy

In contrast to a conventional implicit direct time integration, the proposed time-stepping scheme, as presented above, is a non-iterative procedure. However, in general an adjustment of the last increment size before a system update is needed to ensure that the system is updated just before yielding start or stop. This adjustment can be set up in an iterative fashion.

If the system consists of reduced substructures the critical time increment, in a conditionally stable time integration scheme, can be expected to be reasonably large since the high frequency content has been removed in the reduction process on the substructure level. The time increment size prescribed in the analysis is then instead governed by the precision of the requested time-histories. Consequently, the Newmark parameters can be optimized to increase the analysis accuracy (or performance) rather than to ensure stability. For example, setting the parameters to $\beta = 1/12$ and $\gamma = 1/2$ ensures forth-order accuracy and $\beta = 0$ and $\gamma = 1/2$ enables the explicit central difference scheme [19]. Furthermore, if the system at hand is relatively small and if the number of system updates can be assumed rather limited, the critical time increment can be updated based on an eigenvalue analysis of the updated system. However, an alternative is to prescribe a conservative time increment and thereby skip this check.

5 NUMERICAL EXAMPLE: CONCRETE FRAME SUBJECTED TO BLAST LOADING

A concrete frame structure subjected to blast loading is studied to demonstrate the discussed substructuring and time-stepping method. The dynamic response is computed using a simplified two-dimensional model, suitable in a conceptual design phase. Various strategies to reduce the model by use of DS are investigated, both in terms of accuracy and computationally efficiency (i.e. number of DOFs). Focus is primarily on evaluating DS techniques applied to the lateral load-bearing structure that is not subjected to external loading, i.e. the supporting structure consisting of the horizontal beam and the right column, as shown in Figure 2a. The dynamic response is computed using the time-stepping scheme proposed in Section 4. Furthermore, the highest eigenfrequency, which is related to the critical increment size in conditionally stable time-integration schemes, is evaluated for the reduced models.

The concrete frame is subjected to a uniformly distributed reflected impulse pressure of 1500 Pa·s, as shown in Figure 2a. The pulse is approximated by an equivalent triangular pulse with a fictitious duration of 10 ms and a peak reflected pressure of 300 kPa at $t = 0$ s. The length of the frame members is 3 m and the cross-section width and height, for the columns as well as the horizontal beam, are 1000 mm and 200 mm, respectively. Young's modulus for concrete is set to 32 GPa and the density for reinforced concrete is set to 2500 kg/m^3. The ultimate moment capacity for the columns and the horizontal beam is set to 60 kNm.

5.1 Frame structure model reduced by dynamic substructuring

The frame structure is analyzed with a two-dimensional beam model. The positions of possible plastic hinges are predefined and approximated as five discrete rigid–perfectly plastic joints, as shown in Figure 2b. Yielding of the frame corners are approximated by one distinct plastic hinge, i.e. Joints 3 and 4, respectively. However, it should be noted that a more accurate approximation can be achieved by modeling the corners as separate substructures. Moreover, several effects are neglected in the analysis, e.g. catenary effects, reduced stiffness due to concrete cracking etc. Nevertheless, the model is suitable for studying different DS techniques and to evaluate the efficiency of the proposed time-stepping method.

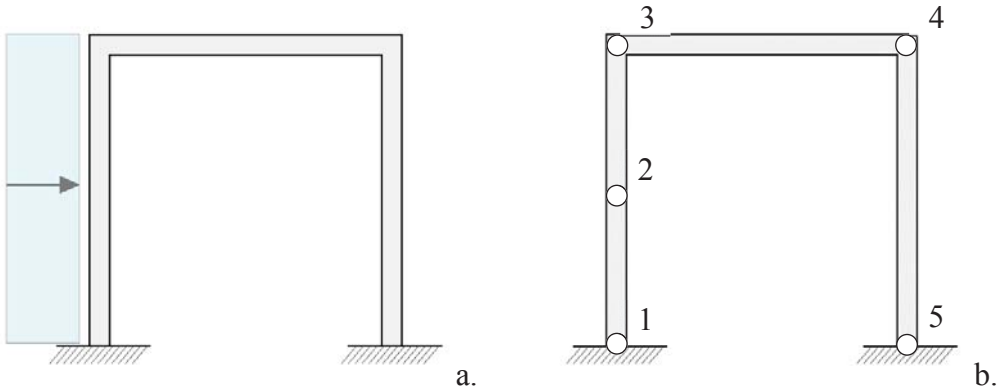

Figure 2: Concrete frame structure subjected to blast loading (a) and locations and labeling of plastic hinges (b).

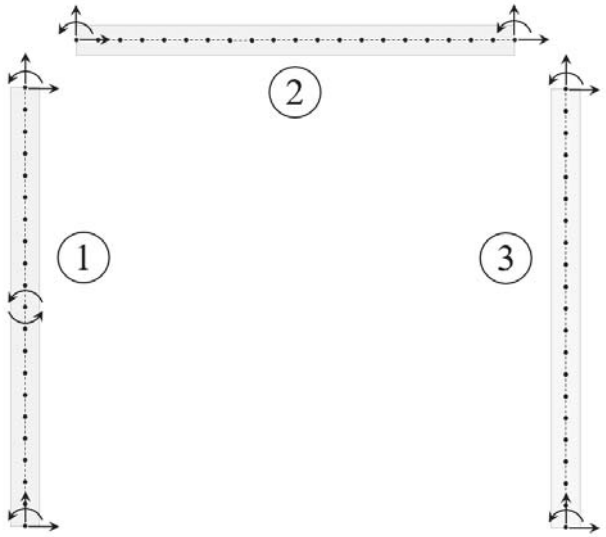

Figure 3: Boundary DOFs and numbering of substructures.

The structure is divided into three substructures, as shown in Figure 3. Each substructure is modeled by 20 Euler–Bernoulli two-node beam elements. Six interface DOFs are retained for Substructures 2 and 3, namely the translational and rotational DOFs at the beam ends. By selecting these boundary DOFs, the fixed-interface normal modes will be the exact mode-shapes of a fixed–fixed beam. Further, eight boundary DOFs are retained for Substructure 1, namely the translational and rotational DOFs at the top and bottom and the rotational DOFs at the joint positioned at midspan. By selecting these boundary DOFs the fixed-interface normal modes will include the exact symmetric modes for a fixed–fixed beam, whereas the antisymmetric modes will be affected by the constrained rotational DOFs at midspan. The fixed-interface normal modes and the constraint modes included in the reduction basis for Substructure 1 is shown in Figures 4 and 5. Note that the antisymmetric modes for a fixed–fixed beam are not excited by a uniformly distributed load. However, since Substructure 1 is not fully supported at the top, some antisymmetric normal modes (modes 2, 5 and 8) are included in the reduction basis.

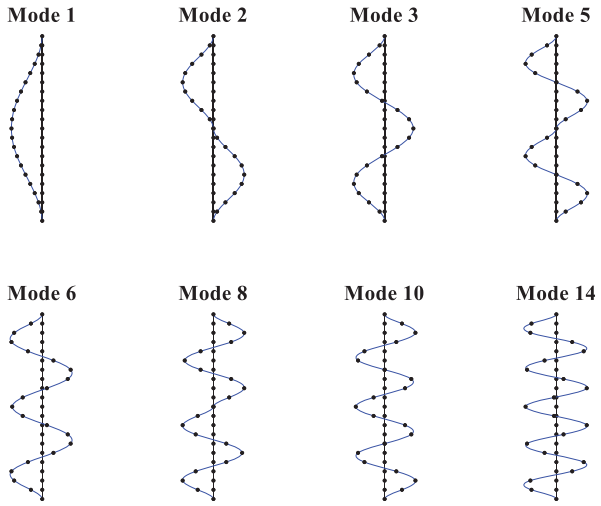

Figure 4: Substructure 1 – fixed-interface normal modes.

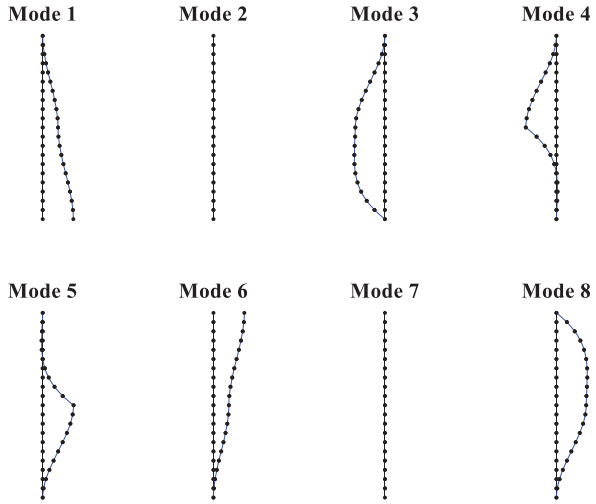

Figure 5: Substructure 1 – constraint modes.

During a dynamic response analysis, the predefined plastic hinges can be either fixed or free, i.e. non-yielding or yielding. A total of five predefined plastic hinges are included in the model, which implies that a response analysis can include up to ten different system configurations. However, to get a rough estimate of the reduced model accuracy two configurations are evaluated—where all joints are either fixed or free, respectively.

The eigenfrequencies for the assembled reduced systems are evaluated by computing the so-called normalized relative frequency difference (NRFD), given by $\text{NRFD} = \left| f_i^{red} - f_i^{full} \right| / f_i^{full}$, that relate the eigenfrequencies of the reduced system to those of the full system. As previously described, the reduction basis for Substructure 1 includes the fixed-interface normal modes and constraint modes shown in Figures 4 and 5, respectively. Five different reduction bases for Substructures 2 and 3 are evaluated. Using a standard C-B approach, reduction is performed including two or four fixed-interface normal modes. Furthermore, reduction bases including two or four correction modes, as described in Section 3.2, are evaluated. The correction modes are generated based on the constraint modes associated to the rotational boundary DOFs at the beam ends. Hence, two modes are generated by computing a set of first-order correction modes and two additional modes are generated by computing a set of second-order correction modes. In addition, the accuracy of a reduction basis including both four fixed-interface normal modes and two first-order correction modes is evaluated. The analyzed models are summarized in Table 1.

Model name	Normal modes	Correction modes[1]	No of DOFs[2]
Mode 1-2	1, 2	-	19
Cor. 1st	-	2 × 1st	19
Mode 1-4	1, 2, 3, 4	-	23
Cor. 1st, 2nd	-	2 × 1st + 2 × 2nd	23
Mode 1-4, Cor.1st	1, 2, 3, 4	2 × 1st	27
Full model	-	-	177

[1] Correction modes associated to rotational boundary DOFs.
[2] Total number of DOFs for model with fixed joints.

Table 1: Normal modes and correction modes for Substructures 2 and 3.

The computed NRFD values are shown in Figures 6 and 7. As shown in the figures, at least, the first seven free and fixed global modes, respectively, are well-described by all the evaluated reduced models; measured as NRFD < 1 %. However, to increase the precision for higher order modes, the constraint modes in Substructures 2 and 3 need to be complemented by at least four modes. However, increasing the number of fixed-interface normal modes and/or correction modes in the reduction basis result in additional generalized DOFs in the reduced system, hence, increasing the computational cost. Moreover, the accuracy when using correction modes and normal modes are comparably, as long as the same number of modes are included in the reduction basis.

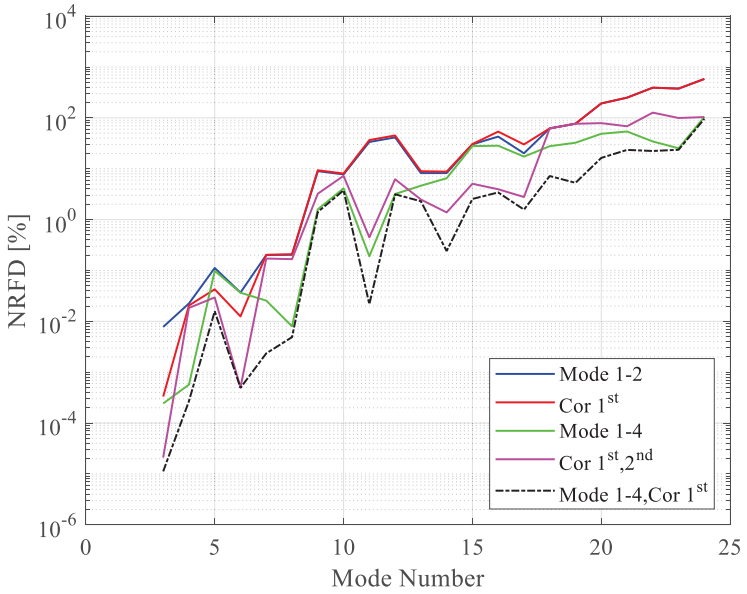

Figure 6: NRFD values for systems with unconstrained rotations at joints.

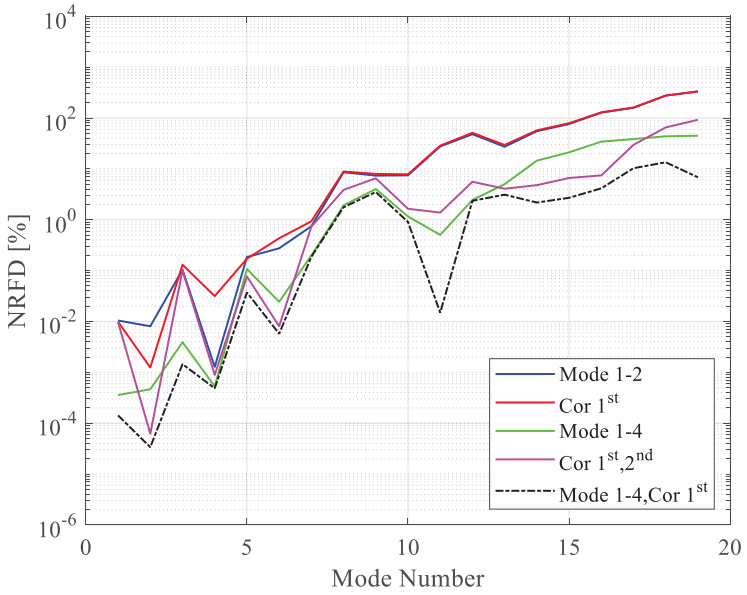

Figure 7: NRFD values for systems with constrained rotations at joints.

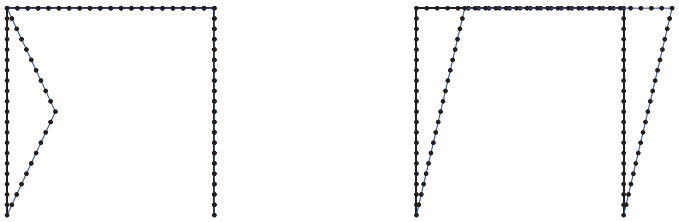

Figure 8: Failure modes spanned by rigid body modes.

Note that the NRFD value is not computed for the first two eigenmodes for the systems with free rotations at the joints. This is due to that the first two modes are rigid body modes with zero frequency. By properly scaling of the rigid body modes, the failure modes, shown in Figure 8, are obtained.

5.2 Dynamic response analysis and results

The dynamic response is computed for the reduced system where the reduction basis for Substructures 2 and 3 includes four normal modes and two first order correction modes. Again, the reduction basis for Substructure 1 includes the normal modes and constraint modes shown in Figures 4 and 5, respectively. The reduced model has a total of 27 DOFs in the initial stage, i.e. when the plastic hinges are fixed, whereas the full model has a total of 177 DOFs. The response is computed using the time-stepping scheme presented in Section 4. Direct time-integration is performed using the Newmark method, with parameters $\beta = 1/12$ and $\gamma = 1/2$ that result in a conditionally stable integration scheme with forth order accuracy [19]. The critical time increment is computed as $dt_{crit} = 2.45/\omega_{max}$. The analysis is performed with a time increment $dt = dt_{crit}/10$ and the analysis time is set to 150 ms.

Snapshots of the deformed shape during the first 50 ms is shown in Figure 9. As shown in the figure, the response of the left column during the first, approximately, 10 ms is similar to that of a fully supported fixed–fixed column due to the inertia of the supporting horizontal beam.

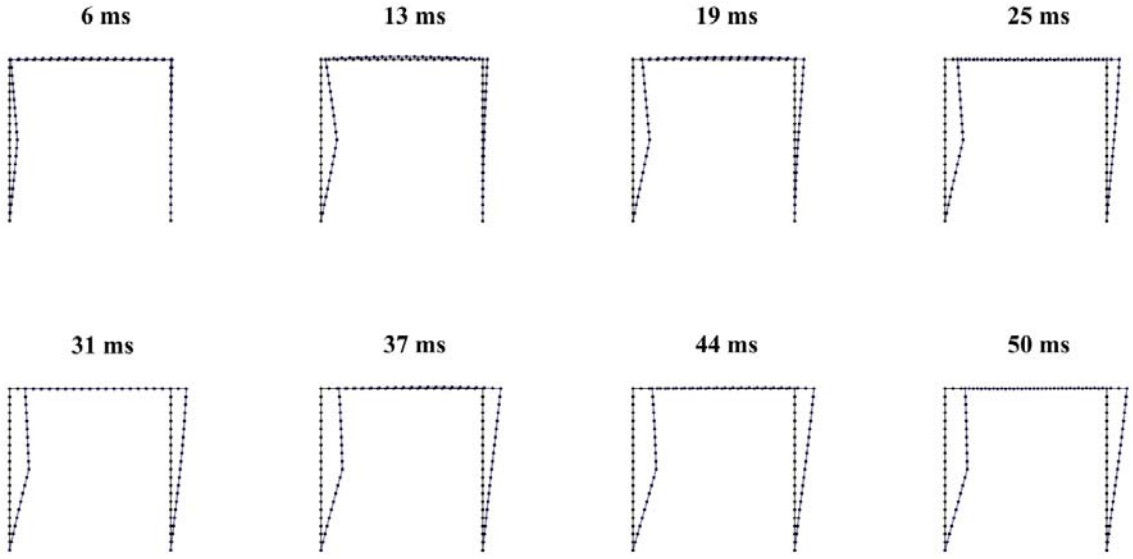

Figure 9: Snapshots of the deformed shape during the first 50 ms. The deformation is scaled by a factor of 15.

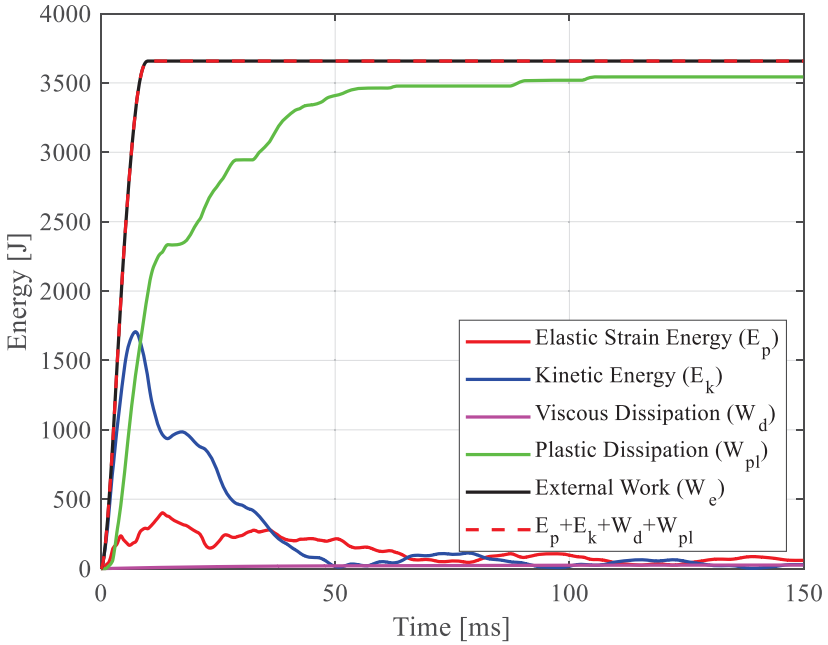

Figure 10: Elastic strain and kinetic energy, plastic and viscous dissipation and external work for the reduced system.

As shown in Figure 10, the energy induced by the external impulse pressure is mainly dissipated by plastic deformations, i.e. by rotation of the predefined plastic hinges. A low Rayleigh beta damping is included in the analysis by setting $\mathbf{C} = 10^{-5} \cdot \mathbf{K}$. As shown in the figure, the viscous dissipation is almost zero.

The relative rotation of the plastic hinges is shown in Figure 11. As shown, most of the plastic dissipation is due to plastic rotation in Joints 1 and 2. The rotation computed with the full model is shown in light gray color. As shown in the figure, the response is almost identical to that of the reduced model. Note that the relative rotation of the plastic hinges is an important parameter in a design calculation, which should not exceed the rotation capacity of the cross-section.

The horizontal displacement at Joints 2 and 4 is shown in Figure 12. The displacement is very close to the displacement computed with the full model. The fundamental eigenfrequency for the non-yielding frame structure is 11.7 Hz, corresponding to a period of 1/11.7 = 85 ms. Clearly, the displacement after approximately 50 ms can essentially be described by the fundamental mode and a plastic displacement.

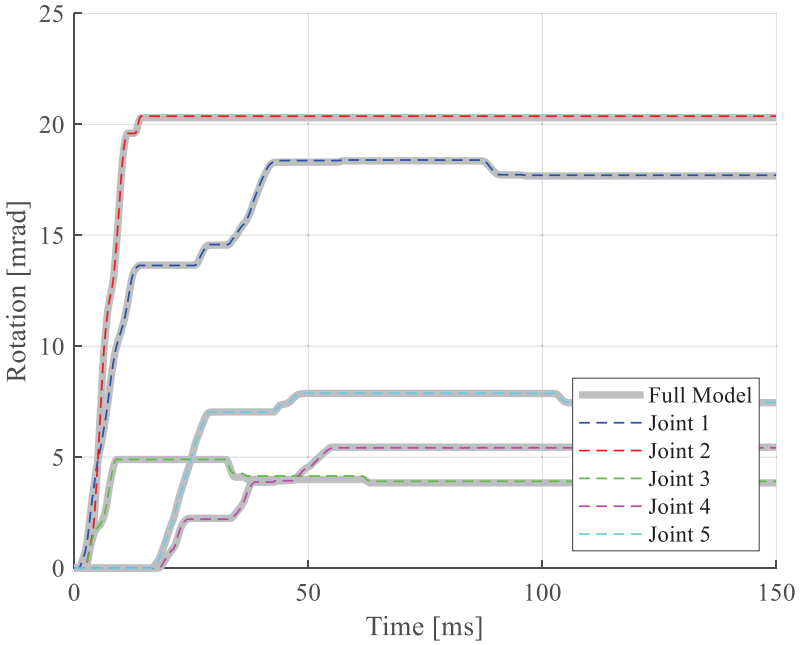

Figure 11: Relative rotations at Joints 1–5, positioned according to Figure 2b.

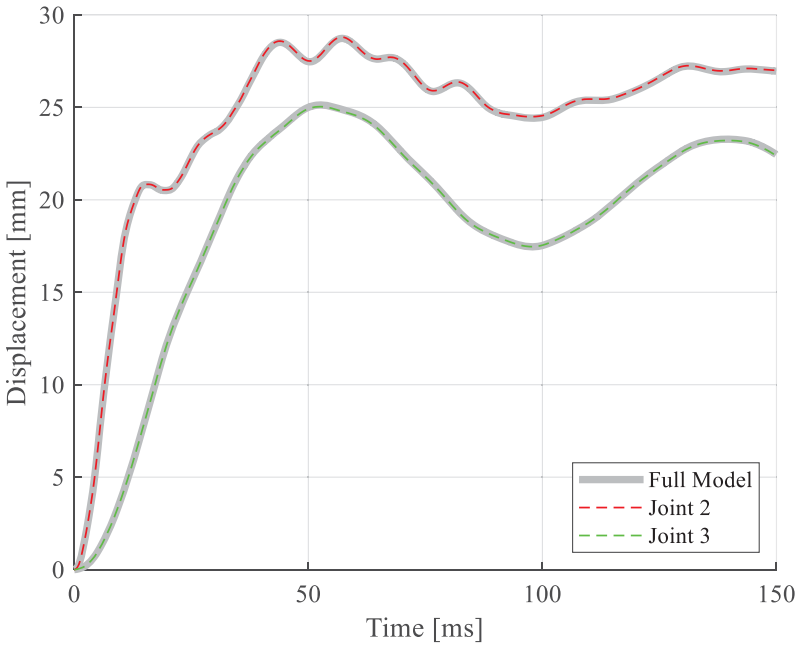

Figure 12: Horizontal displacements at Joints 2 and 3, positioned according to Figure 2b.

If a suitable reduction basis is applied to Substructure 1, to properly describe the application of the external pressure, the global displacements can be well-described by only including two fixed-interface normal modes (or correction modes) for Substructures 2 and 3, as indicated by Figures 11 and 12. However, a more refined reduction basis is needed to properly describe the reaction and interface forces between the substructures. The influence of the reduction basis on the horizontal interface force in Joint 4 is shown in Figure 13. As shown, the constraint modes need to be complemented by at least four modes to obtain a reasonable accurate response. The

accuracy for the models reduced by using fixed-interface normal modes and correction modes, respectively, are comparable. Hence, the correction modes are then the preferred choice since the generation of these modes are less computationally expensive (in this simple example, however, the computational cost of generating either normal modes or corrections modes is negligible).

The critical time increment in a conditionally stable direct time integration method is inversely proportional to the highest eigenfrequency. Consequently, a reduction of a system that removes the high frequency content can result in a more computationally efficient analysis. To get an estimation of how much the eigenfrequency is affected by the reduction bases studied herein, the highest eigenfrequency is computed for the initial state of the reduced systems, i.e. when all joints are fixed.

The highest eigenfrequency of the reduced models including two and four fixed-interface normal modes in the reduction bases for Substructure 2 and 3 is 4.2 kHz and 4.3 kHz, respectively. The highest eigenfrequency when using two and four correction modes is 4.2 kHz and 4.4 kHz, i.e. almost equal to the eigenfrequencies obtained when using normal modes. However, the highest eigenfrequency in the reduced models is in this case most likely governed by Substructure 1, reduced by a more refined reduction basis.

For the reduced model including four fixed-interface normal modes and two first-order correction modes the highest eigenfrequency is 4.7 kHz. In comparison, the highest eigenfrequency of the full model is 74.5 kHz, i.e. a factor of 74.5/4.7 ≈ 16. Furthermore, the highest eigenfrequency for a reduced system where the rigid–perfectly plastic joints are modeled using penalty elements, with a stiffness 10 times the mean stiffness of the corresponding entries in the unreduced stiffness matrix, is 64.4 kHz. Hence, for the model studied herein, the number of time increments can be decreased by a factor 64.4/4.7 ≈ 14 by avoiding penalty elements.

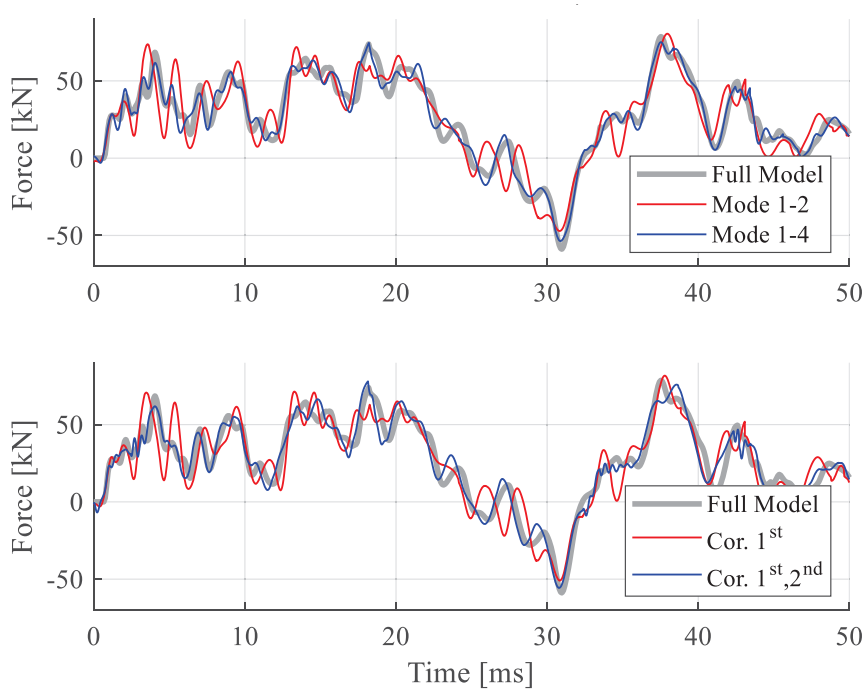

Figure 13: Horizontal interface force at Joint 4.

6 CONCLUSIONS

In the study, strategies are developed to enable time-efficient models for concrete frame structures subjected to blast loading, appropriate for use in a structural design process. Dynamic substructuring is employed to obtain reduced models with localized nonlinearities, such as predefined plastic hinges in a beam–column structure. The parts of the substructures that remains linear elastic are modeled by Ritz-vectors whereas parts with a nonlinear response are retained as physical degrees-of-freedom. Furthermore, a time-stepping scheme is presented that is shown to be suitable for reduced models including local and predefined rigid-plastic behavior.

The proposed methodology is applied and demonstrated in a numerical example of a concrete frame structure. The standard Craig-Bampton method that uses fixed-interface normal modes and constraint modes is evaluated. Furthermore, reduction bases augmented by so-called correction modes are investigated. Various reduction bases are evaluated for the substructures included in the supporting structure, i.e. the substructures that are not subjected to external loading. Two correction modes or two standard fixed-interface normal modes are sufficient to describe the displacement and relative rotations at the plastic hinges. However, to obtain an acceptable accuracy of the interface forces between the substructures, at least four correction modes or four standard fixed-interface modes are needed. For the studied load case, the accuracy when using correction modes and fixed-interface normal modes are comparable.

Moreover, the highest eigenfrequency for the reduced systems, which is related to the critical increment size in conditionally stable direct time integration methods, is evaluated. It is shown that a reduction of the studied model by use of dynamic substructuring can increase the critical time increment by a factor of approximately 16. Furthermore, it is shown that by enforcing a rigid–plastic behavior using the proposed time-stepping scheme, the critical increment size can increase by a factor of approximately 14 compared to a modeling approach where the rigid–plastic behavior is enforced using penalty elements.

The present methodology can be extended further to, for example, consider large deformations and failure, e.g. by considering the rotation capacity of the cross-sections. Furthermore, the methods can be applied and evaluated for larger and more complex structures, e.g. three-dimensional beam–column structures. Also, a more refined modeling approach for frame corners can be investigated, where the corner itself is treated as a separate substructure.

Abstract. *Blast loading on buildings may originate from various sources and may be redefined during the lifetime of a building. The blast response of buildings is roughly governed by the response of the façade and the main load bearing structure. While a full FEM analysis in the time domain can provide reliable and accurate results for the building response in detail, a quick assessment based on lumped masses is preferred in many cases in practice, either related to early design stages, decision making or to validation of sophisticated models. In such classical single or multi degree-of-freedom approaches the façade and main load bearing structure can be clearly distinguished. In practice both components are usually dealt with individually, conveniently ignoring the effect of the response of the former on the blast load on the latter component. Early graphical tools for the incorporation of non-linear effects have been widely used. Here the results of time-domain analyses of an elasto-plastic 2-degree-of-freedom system in terms of ductility demand are shown and compared to those of corresponding single-degree-of-freedom systems. Explicit results for the interaction of façade members and main load bearing members are obtained and shown for various configurations. It is concluded that representation of structural systems by individual single-degree-of-freedom systems in blast analysis is generally conservative for façade members, but can be unconservative for the main load bearing structure. In practical cases this underestimation is not likely to exceed 10%.*

1 INTRODUCTION

While nowadays non-linear finite element (FEM) analysis can be used to accurately evaluate the impact of blast loading on buildings, still simple analysis of individual structural members represented as single-degree-of-freedom (SDOF) systems is common in engineering practice. Such simple analysis is useful in early design stages and in the validation phase of the more complex calculations. Graphs for the evaluation of ductility demand of non-linear SDOF systems were already presented by Biggs [1] in 1964. However, the assessment of individual members without consideration of their dynamic interaction with other members or the main load bearing structure may entail significant errors. A logical step to assess these errors is to expand the SDOF lumped approach to a non-linear 2-degree-of-freedom (2DOF) system, see Figure 1, bridging the gap between simple SDOF and sophisticated FEM analysis. The first degree-of-freedom (DOF) represents the member that is struck by the blast first, while the second DOF represents its supporting structure.

The blast response of a non-linear 2DOF system is determined by five independent variables, as opposed to two independent variables in a non-linear SDOF system. Furthermore, a 2DOF system is essentially not different from multiple degree-of-freedom systems, i.e. FEM models, while the latter are more difficult to interpret. 2DOF Systems can be easily recognised in buildings, e.g. façade and main load bearing structure or glass panels and supporting mullions. Therefore, the 2DOF system is eligible for assessing the accuracy of SDOF approaches. This will be elaborated in the next sections with focus on ductility demand.

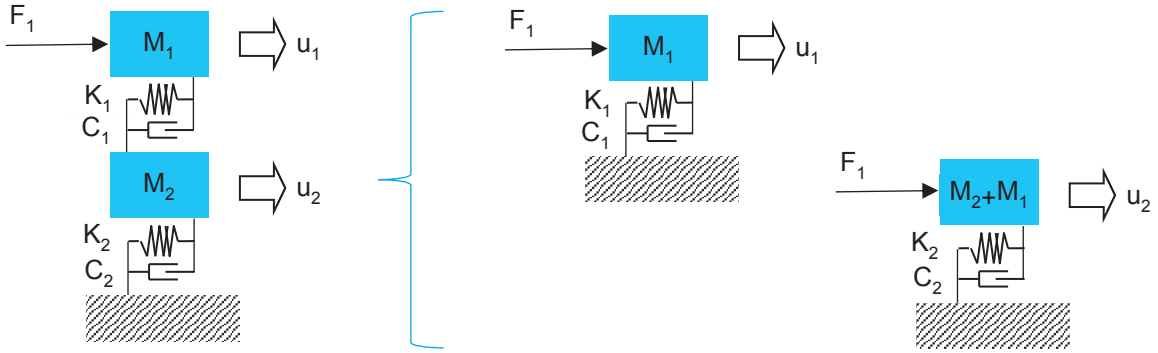

Figure 1: A 2-degree-of-freedom system (left) and its decomposition into two individual single degree-of-freedom systems (right).

2 2DOF SYSTEM FOR BLAST ANALYSIS

The dynamic response of a 2DOF system, as depicted in Figure 1, to a shock wave [1, 2] is governed by:

$$\begin{bmatrix} M_1 & 0 \\ 0 & M_2 \end{bmatrix} \begin{Bmatrix} \ddot{u}_1 \\ \ddot{u}_2 \end{Bmatrix} + \begin{bmatrix} C_1 & -C_1 \\ -C_1 & C_1 + C_2 \end{bmatrix} \begin{Bmatrix} \dot{u}_1 \\ \dot{u}_2 \end{Bmatrix} + \begin{bmatrix} K_1 & -K_1 \\ -K_1 & K_1 + K_2 \end{bmatrix} \begin{Bmatrix} u_1 \\ u_2 \end{Bmatrix} = \begin{Bmatrix} F_1 f_1 \\ 0 \end{Bmatrix} \quad (1)$$

with mass, damping and stiffness coefficients denoted by M_i, C_i and K_i respectively, where i is the related DOF. In order to assess the amount of interaction between the two DOFs that would be overlooked in case of SDOF modelling, a dynamic force is applied only to DOF 1 of the 2DOF system. For blasts this is often simplified as a triangular force-time diagram. The initial (maximum) external force is denoted by F_1 and the function defining its linear decay over duration t_d is denoted by f_1. The last equation is set up for absolute displacements u_i. It is convenient to write the dynamic response in terms of relative displacements w_i:

$$\begin{bmatrix} M_1 & M_1 \\ 0 & M_2 \end{bmatrix} \begin{Bmatrix} \ddot{w}_1 \\ \ddot{w}_2 \end{Bmatrix} + \begin{bmatrix} C_1 & 0 \\ -C_1 & C_2 \end{bmatrix} \begin{Bmatrix} \dot{w}_1 \\ \dot{w}_2 \end{Bmatrix} + \begin{bmatrix} K_1 & 0 \\ -K_1 & K_2 \end{bmatrix} \begin{Bmatrix} w_1 \\ w_2 \end{Bmatrix} = \begin{Bmatrix} F_1 f_1 \\ 0 \end{Bmatrix} \tag{2}$$

where $w_1 = u_1 - u_2$ and $w_2 = u_2$. Symmetry of the matrices can be restored by adding the first row to the second, which yields:

$$\begin{bmatrix} M_1 & M_1 \\ M_1 & M_2 + M_1 \end{bmatrix} \begin{Bmatrix} \ddot{w}_1 \\ \ddot{w}_2 \end{Bmatrix} + \begin{bmatrix} C_1 & 0 \\ 0 & C_2 \end{bmatrix} \begin{Bmatrix} \dot{w}_1 \\ \dot{w}_2 \end{Bmatrix} + \begin{bmatrix} K_1 & 0 \\ 0 & K_2 \end{bmatrix} \begin{Bmatrix} w_1 \\ w_2 \end{Bmatrix} = \begin{Bmatrix} F_1 f_1 \\ F_1 f_1 \end{Bmatrix} \tag{3}$$

Next, the following non-dimensional variables for time t and displacements w_i are introduced, similar to Biggs [1]:

$$\begin{aligned} \tau &= \frac{t}{T_1} \\ \mu_i &= \frac{w_i}{w_{i,el}} \end{aligned} \tag{4}$$

where μ_i is in fact the ductility demand, $w_{i,el}$ the elastic limit displacement and T_1 is the natural period of the upper SDOF subsystem (refer to Figure 1). If damping is neglected, it can then be derived that:

$$\begin{bmatrix} \frac{1}{4\pi^2} & \frac{1}{4\pi^2} \\ \frac{a}{4\pi^2} & \frac{a(b+1)}{4b\pi^2} \end{bmatrix} \begin{Bmatrix} \ddot{\mu}_1 \\ \ddot{\mu}_2 \end{Bmatrix} + \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \begin{Bmatrix} \mu_1 \\ \mu_2 \end{Bmatrix} = \begin{Bmatrix} \frac{F_1}{R_1} g_1 \\ \frac{F_1}{R_2} g_1 \end{Bmatrix} \tag{5}$$

where the stiffness and mass ratios have been introduced as:

$$\begin{aligned} a &= \frac{K_1}{K_2} \\ b &= \frac{M_1}{M_2} \end{aligned} \tag{6}$$

and plastic resistances as:

$$R_i = K_i w_{i,el} \tag{7}$$

Function $f_1(t)$ has transformed into $g_1(\tau)$ and still describes the linear decay of the shock load. The choice of T_1 for the normalisation of time could also have been T_2, which would lead to a similar result. So, it follows from equation 5 that the blast response of a 2DOF system to a shock wave is completely described by five independent non-dimensional variables: τ, F_1/R_1, F_1/R_2, a and b. Consequently, the maximum response depends on t_d/T_1, F_1/R_1, F_1/R_2, a and b. The last three are additional to the ones already defined by Biggs [1].

The response of the 2DOF system is analysed and subsequently the responses of two individual SDOF systems as shown in Figure 1. These SDOF systems are a decomposition of the 2DOF system and represent practical modelling approaches to the primary (DOF 1) and secondary (DOF 2) load resisting structure. Their natural frequencies are related as follows:

$$\begin{aligned} {f_{2DOF}}^2 &= \tfrac{1}{2} {f_1}^2 \frac{b}{a} \left(\frac{a(b+1)}{b} + 1 \pm \sqrt{\left(\frac{a(b-1)}{b} + 1 \right)^2 + 4\frac{a^2}{b}} \right) \\ {f_2}^2 &= {f_1}^2 \frac{b}{a(b+1)} \end{aligned} \tag{8}$$

and the two mode shapes of the 2DOF system can be written as:

$$\left\{ \begin{matrix} 1 \\ 1 - \frac{1}{2}\frac{b}{a} \left(\frac{a(b+1)}{b} + 1 \pm \sqrt{\left(\frac{a(b-1)}{b} + 1 \right)^2 + 4\frac{a^2}{b}} \right) \end{matrix} \right\} \tag{9}$$

The analysis results of these 2DOF and SDOF systems are presented in the next section.

3 DUCTILITY DEMAND IN 2DOF VERSUS SDOF SYSTEMS

The ductility demand as calculated for SDOF systems which are members of a larger structure, is expected to be different from the one calculated using a sophisticated FEM model with many DOFs. This higher complexity is represented here by a 2DOF system and the ductility demand for each of the two DOFs is compared between the 2DOF system and the SDOF system. This is shown here by means of contour plots of the maximum ductility ratio μ_i, i.e. ductility demand, resulting from 2DOF analysis divided by the maximum ductility ratio resulting from SDOF analysis, see Figure 2 to Figure 5. This means that a value smaller than unity in the contour plots indicates conservative design in case of an SDOF approach, and a value greater than unity indicates unconservative design in case of an SDOF approach. The contour plots are a function of t_d/T_1 and a for constant F_1/R_1, F_1/R_2 and b. If necessary, ratio t_d/T_1 can be readily converted to ratio t_d/T_2 based on equation 8:

$$\frac{t_d}{T_1} = \frac{t_d}{T_2}\sqrt{\frac{a(b+1)}{b}} \tag{10}$$

Since in reality always some damping is present, a small amount of damping, i.e. 2% of critical, has been specified in the calculations for practical purposes. The corresponding damping matrix has not been set up based on modal damping, but rather as a non-proportional damping matrix (refer to equation 1) where the damping coefficients are 2% of the critical damping coefficients of the individual SDOF systems.

Furthermore, economical blast design usually corresponds to resistance F_1/R_1 ratios greater than unity and in practice also the stiffness ratio a is usually greater than unity. In case of vehicle bombs [3] the duration of the blast is mostly shorter than the natural period of the glazing [4], so that the ratio t_d/T_1 is smaller than unity. Depending on the level of aggregation in the 2DOF representation, the mass ratio b may be smaller than unity (e.g. façade and building core) or approximately unity (e.g. glass panels and mullions). Therefore, contour plots are presented here for the constants as listed in Table 1 only, but many more have been generated and interpreted for F_1/R_1 and F_1/R_2 in the range (0.7,…,1.4) and b in the range (0.1,…,10).

Case	Resistance ratio F_1/R_1	Resistance ratio F_1/R_2	Mass ratio b
1	1.4	1.0	0.1
2	1.4	1.0	1.0
3	1.4	1.4	0.1
4	1.4	1.4	1.0

Table 1: Considered cases for evaluation of the ductility demand in a 2DOF system compared to individual SDOF systems.

The numerical solutions have been obtained by a Newmark time stepping scheme with parameters $\beta = 0.25$ and $\gamma = 0.5$, providing unconditional numerical stability. Time steps were constant per analysis and set to the smaller of 1/10th of the lower natural period and 1/50th of the blast duration. The number of time steps per analysis was set to fully cover the blast duration or the upper natural period, whichever was greater. The elasto-plastic response was dealt with by Newton-Raphson iterations with a tolerance of 10^{-4} within each time step.

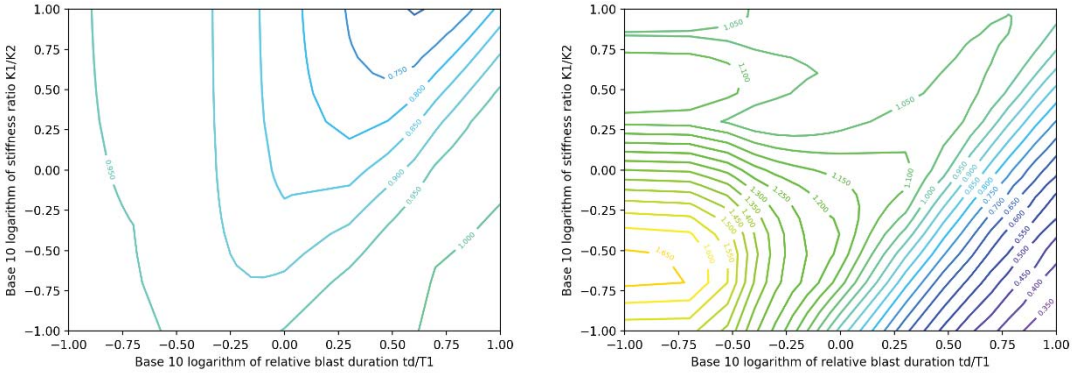

Figure 2: Ductility demand resulting from 2DOF analysis divided by ductility demand resulting from SDOF analysis at DOF 1 (left) and DOF 2 (right) for case 1 (F_1/R_1 = 1.4, F_1/R_2 = 1.0, b = 0.1).

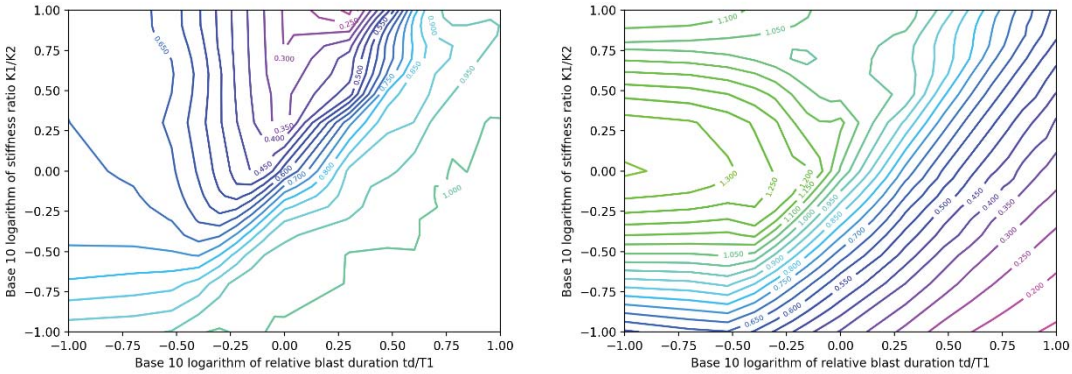

Figure 3: Ductility demand resulting from 2DOF analysis divided by ductility demand resulting from SDOF analysis at DOF 1 (left) and DOF 2 (right) for case 2 (F_1/R_1 = 1.4, F_1/R_2 = 1.0, b = 1.0).

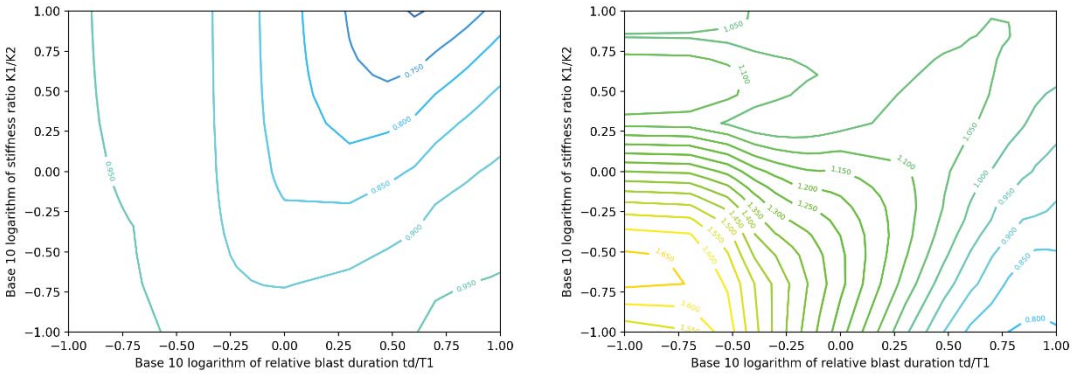

Figure 4: Ductility demand resulting from 2DOF analysis divided by ductility demand resulting from SDOF analysis at DOF 1 (left) and DOF 2 (right) for case 3 (F_1/R_1 = 1.4, F_1/R_2 = 1.4, b = 0.1).

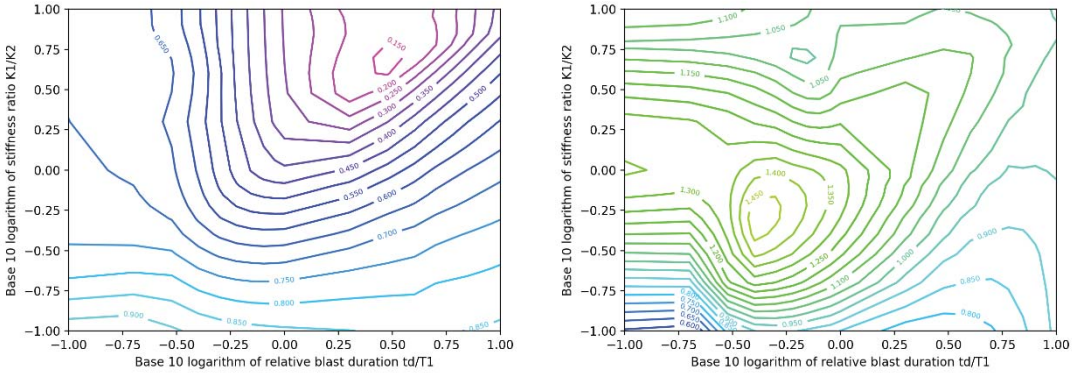

Figure 5: Ductility demand resulting from 2DOF analysis divided by ductility demand resulting from SDOF analysis at DOF 1 (left) and DOF 2 (right) for case 4 (F_1/R_1 = 1.4, F_1/R_2 = 1.4, b = 1.0).

Figure 2 to Figure 5 show that the ductility demand of DOF 1 is always conservatively estimated by an SDOF approach, however this is not a general rule (after inspection of other plots not presented here). Apparently, 2DOF analysis may return only 15% of the ductility demand calculated by SDOF analysis of DOF 1 in some cases. On the other hand, SDOF analysis of DOF 2 roughly tends to produce unconservative results for stiffness ratios a of 1.0 and less and t_d/T_1 ratios smaller than 1.0. It appears that SDOF analysis of DOF 2 may underestimate the ductility demand by 66% in some cases, e.g. for stiffness ratio a = 0.2 and relative blast duration t_d/T_1 = 0.1 in Figure 2 and Figure 4. It should be noted that structures with stiffness ratio a of 1.0 or less are rare cases in practice.

Underestimating the DOF 2 response might not frequently occur in building design. Considering the practical case of glass façades [4] with relative resistances F_1/R_1 = 1.4 and F_1/R_2 = 1.4, mass ratio b = 1.0 (Figure 5), stiffness ratio a = 7.0 and relative blast duration t_d/T_1 = 0.1, this underestimation of DOF 2 is reduced to 8% and the ductility demand of DOF 1 in 2DOF analysis is 69% compared to the one in SDOF analysis. This is shown in the time domain in Figure 6 and Figure 7. Such deviations can be considered fair in early design stages or FEM model validation stages. Note that, obviously, 2DOF analysis and SDOF analysis of DOF 2 (as defined in Figure 1) produce the same results if the stiffness ratio $a \gg 1.0$.

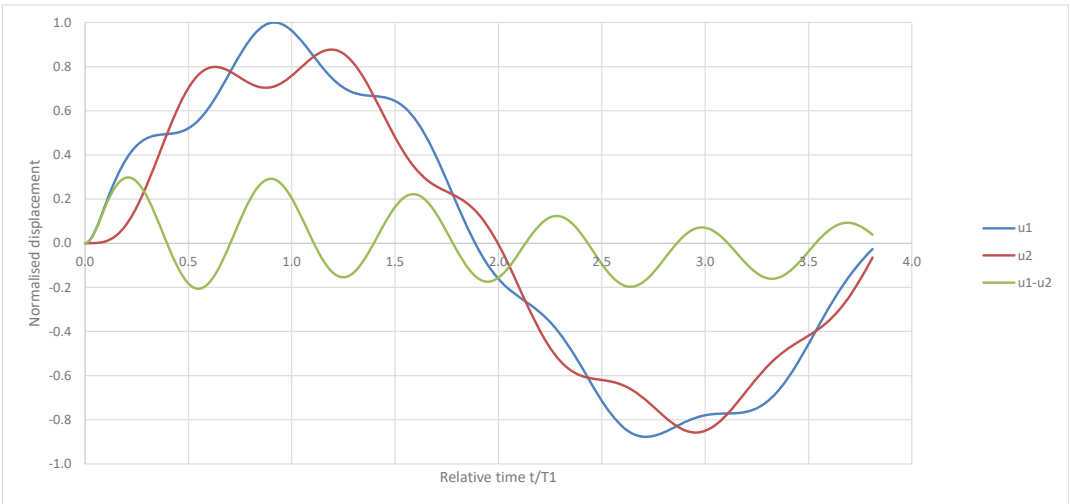

Figure 6: Normalised displacements of the 2DOF system showing the interaction of DOFs for the practical case of F_1/R_1 = 1.4, F_1/R_2 = 1.4, b = 1.0, stiffness ratio a = 7.0 and relative blast duration t_d/T_1 = 0.1.

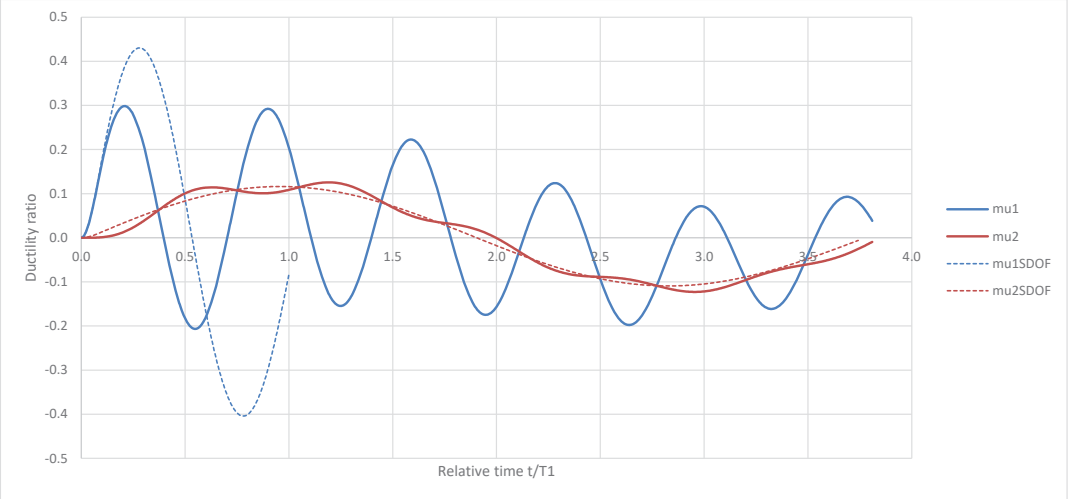

Figure 7: Ductility ratios according to 2DOF (solid lines) and SDOF analysis (dashed lines) for the practical case of $F_1/R_1 = 1.4$, $F_1/R_2 = 1.4$, $b = 1.0$, stiffness ratio $a = 7.0$ and relative blast duration $t_d/T_1 = 0.1$.

Ductility ratios greater than unity (plasticity) and more discrepancy at DOF 2 between 2DOF and SDOF approaches are observed e.g. in the rare case of stiffness ratio $a = 0.2$ combined with relative resistances $F_1/R_1 = 1.4$ and $F_1/R_2 = 1.4$, mass ratio $b = 0.1$ (Figure 4) and relative blast duration $t_d/T_1 = 0.4$. This is further shown in Figure 8 and Figure 9, where it can be seen that the ductility ratio at DOF 2 is actually 150% of the value calculated with an SDOF approach.

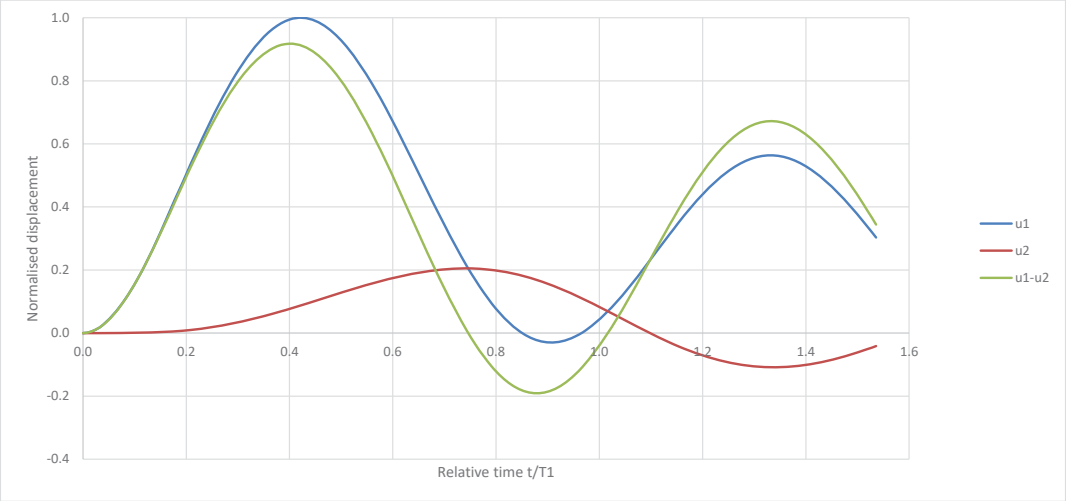

Figure 8: Normalised displacements of the 2DOF system showing the interaction of DOFs for the rare case of stiffness ratio $a = 0.2$ combined with $F_1/R_1 = 1.4$, $F_1/R_2 = 1.4$, $b = 0.1$ and relative blast duration $t_d/T_1 = 0.4$.

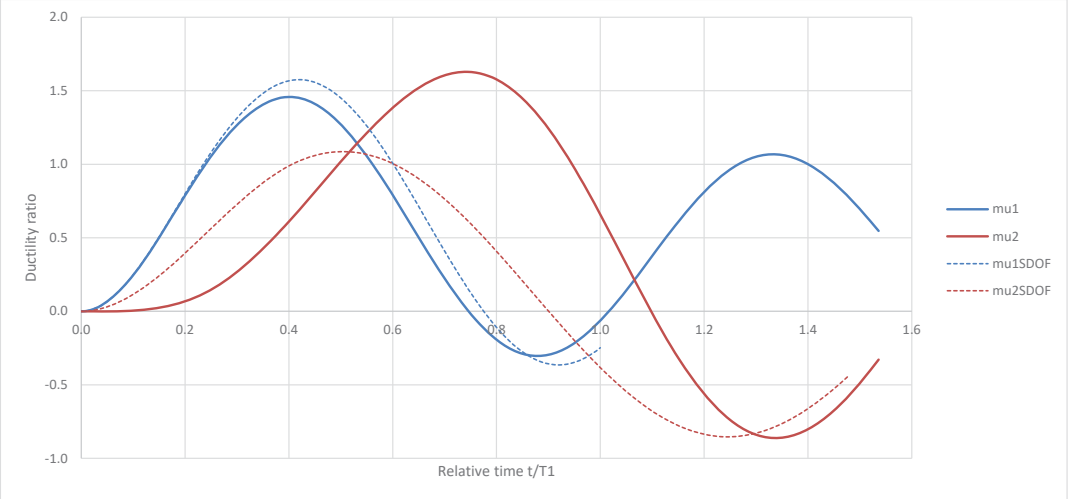

Figure 9: Ductility ratios according to 2DOF (solid lines) and SDOF analysis (dashed lines) for the rare case of stiffness ratio $a = 0.2$ combined with $F_1/R_1 = 1.4$, $F_1/R_2 = 1.4$, $b = 0.1$ and relative blast duration $t_d/T_1 = 0.4$.

4 CONCLUSION

In engineering practice frequent use is made of single-degree-of-freedom (SDOF) approaches to blast-resistant design and evaluation of buildings, either in concept design or in validation of sophisticated finite-element models. While this approach is simple and fast, the omission of the dynamic interaction with other structural members obviously entails some inaccuracy. This inaccuracy has been assessed here by means of a 2-degree-of-freedom (2DOF) system. It appeared that if the member that is struck by the blast first is analysed as an SDOF system, its calculated response in terms of ductility demand will be conservative in most cases. However, the response of the member or structural system that supports this primary system, if calculated using an SDOF approach, may be significantly underestimated in theory. In practical cases some underestimation of its structural response may occur, although this is not likely to exceed 10%.

Keywords: Textile reinforced mortar, Blast loads, Explicit model, Experimental calibration

Abstract. *The protection of masonry walls against blast-induced loads by using textile-reinforced mortar (TRM) is investigated herein. Typically the consequences to a structure from explosions (either intentional or accidental) may range from total or partial building collapse due to the direct release of energy to injuries and fatalities due to the created debris. Masonry elements are of stiff and brittle nature and demonstrate considerable resistance in medium-sized compressive loads but degrade dramatically for stronger loads and impacts under tensile stresses. TRM constitutes a novel composite, using open-mesh textiles made from fibre rovings, which has been proven effective as strengthening material to carry the tensile stresses of out-of-plane inertial loading, while satisfying the necessary compatibility, reversibility and durability requirements for masonry buildings. Retrofitting of existing structures with the use of TRM can substantially increase their strength and deformation capacity, providing a sufficient protection to the occupants from blast loads. It should be noted that improving the deformation capacity of masonry can increase the gravitational load bearing capacity of the structure and minimise second order phenomena during a blast event. In this work, we propose a numerical method to accurately predict the various structural effects of explosions on masonry. The focus is to evaluate the developed damage due to impulsive loads and investigate the enhancement of the global dynamic response of a masonry wall before and after retrofitting. Masonry consists of brick units surrounded by mortar joints. The brittle behaviour of this two-phase material is modelled in the EUROPLEXUS explicit finite element code for fast transient phenomena, in complex three-dimensional fluid-structure systems. The performance of masonry is described using plasticity laws for the constituent elements and damage for softening. Geometric non-linearity effects accounting for large displacements and large rotations are also considered. The numerical response is validated using out-of-plane experiments of masonry walletes.*

1 INTRODUCTION

Strong blasts and impact loads on structures result in cracking, fracture, diffusion of debris and may lead to their total or partial collapse. The main cause of injuries and fatalities after the impact of a blast wave on a structure is mainly attributed to the impact of the resulting structural fragments and debris on the occupants [1]. While structural integrity cannot be entirely ensured, damage control can be achieved by applying strengthening techniques. A description of the applied loads on structures due to external explosions is available in [2]. However, in the case of large and complex structures, where shadowing and channeling phenomena take place, advanced numerical modelling techniques are required [1,3] to accurately estimate the effect of strengthening on the dynamic response of the structure.

Masonry walls are amongst the most common building components; they can be distinguished in load bearing and non-load bearing elements as in the case of infill walls in reinforced concrete frame buildings. Masonry walls demonstrate a stiff and brittle nature and, even when designed as non-structural elements, they influence to a great extent the structure's response to external or internal explosions. Few studies are available in the literature for simulating textile reinforced mortar (TRM) strengthened masonry structures under seismic loads, and very limited information exists on the modelling of masonry subjected to blast loads and the simulation of the strengthening. The reason of scarce numerical models of TRM strengthened masonry is the presence of four different materials (brick units, mortar, textile, matrix) and their complicated interactions that give rise to numerous and complex damage modes. These necessitate fine resolutions that render numerical simulation a computationally intensive procedure. Therefore, several simplifications need to be performed in order to strike the right balance between the amount of numerical analysis and exhaustive material characterisation tests.

Focusing only on the TRM external layer, the influence of the imperfections of the in-plane position of the textile, i.e., a curved layer of the textile inside the matrix, on its tensile behaviour was studied in [4] using two-dimensional finite element (FE) models. In this, the mortar was simulated using plane stress elements whereas truss elements were used for the textile. As expected, the higher the imperfect and non-straight placement of the textile in the matrix the higher the change of the stiffness of the TRM. To reduce computational costs, reduced order macro-modelling approaches for TRM strengthened masonry walls were presented based on 2D planar models including either a homogenised non-linear (NL) material calibrated to experimental responses [5,6] or different materials for bricks and mortar [7]. The plane elements can overlap and a perfect bond between the masonry, the inorganic basis and, the textile was assumed [8]. In [9], the authors used fully bonded shell elements for the bricks and the mortar and linear elements arranged in a grid for the TRM; the NL material laws were calibrated using experimental data.

Kyriakides et al. [10] performed an experimental campaign and a corresponding numerical investigation studying the out-of-plane and retrofitting of masonry with an external coat made of steel fibres sprayed in a cementitious mortar, the so-called engineered cementitious composite (ECC), with or without a two-dimensional steel textile [11]. The modelling considers brick units and mortar joints separately simulated, whereas a second more simplified approach merges the two materials while maintaining the interfaces between the homogenised elements to simulate the interaction. A perfect bond between the reinforcement and the inorganic matrix is assumed in both models. Moreover, elastoplastic elements are introduced to simulate the interaction between the coat and the masonry.

Unreinforced masonry walls subjected to blast loads have been investigated both experimentally and numerically. A study investigating masonry materials under high strain rate conditions and their influence on the structural behaviour under blast shows that the strain rate effect has

a substantial impact [12]. Large unreinforced masonry walls 2m × 2m fixed at their base have undergone blast loads up to collapse and the resulting reflected peak pressures have been determined in [13]. A homogenisation model with strain rate effect has been developed for impact loads on unreinforced masonry walls in [14]. A study concerning masonry loaded by near filed detonations investigated the question of fragmentation of masonry [15]. A review of the available numerical models for masonry structures experiencing blast loads can be found in [16].

In [17–19], the effect of impact loads on masonry stack specimens strengthened with composites has been investigated both experimentally and numerically. The finite element simulation was performed on the basis of an implicit dynamic analysis procedure considering material failure via a smeared cracking model and loss of cohesion at the interfaces. The efficiency of elastomeric materials for strengthening masonry walls against blast loads has been investigated in [20]. The masonry specimens are ¼ scaled and made of concrete blocks while the strengthening process involved spraying with a polyurea liner. Single degree of freedom (SDOF) models have been used to simulate masonry performance and estimate their damage producing P-I curves [21].

This study develops a nonlinear FE model in EUROPLEXUS [22], an explicit code, to investigate the strengthening of masonry structural elements using TRM against blast loads.

2 EXPERIMENTAL CAMPAIGN

2.1 Test design and set-up

The test campaign conducted in [23], studying the out-of-plane response of masonry piers strengthened with external layers of TRM in the tension side was simulated in the present study. Kariou et al. 2018 [23] tested a series of eighteen specimens in three-point bending as presented in Figure 1, including two control specimens (unstrengthened). The load is increasing monotonically at the mid-span of the masonry piers which have 18 courses of bricks units in a stretcher bond (Figure 1).

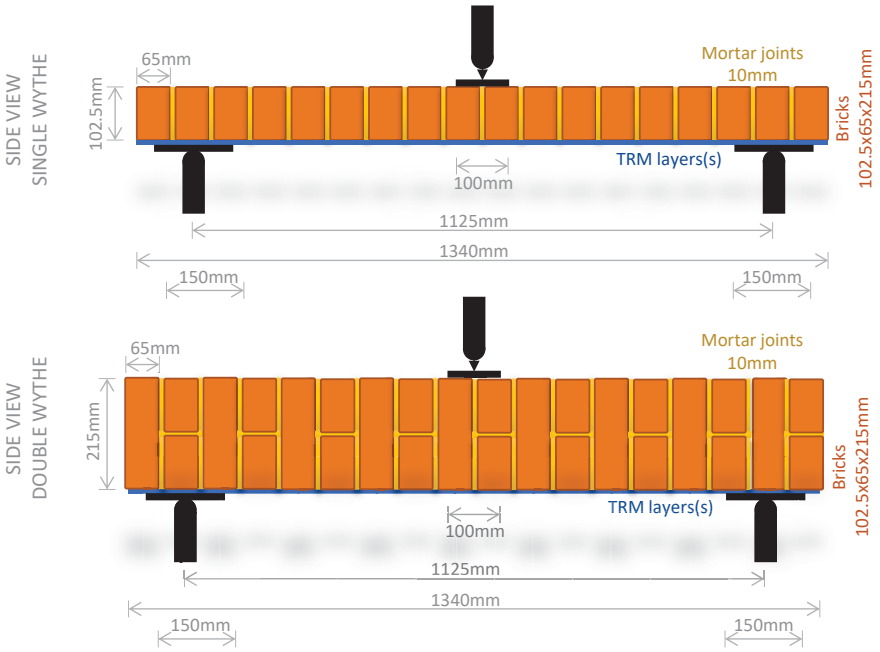

Figure 1. Test set-up and dimensions.

Mortar joints were approximately 10 mm thick, and the specimens' dimensions were 1.34 m long × 0.44 m wide. Wall thickness was a parameter under investigation and therefore, the eight single wythe piers (S) were 0.1025 m thick, while the eight double wythe piers (D) were 0.215 m thick as they include one head mortar joint. Three different fibres were used: (i) carbon (C), (ii) glass (G) and (iii) basalt (B). In this study, only the carbon textile is investigated. Details about the epoxy resin and the impregnation process can be found in [23]. The thickness of the coat is 3 mm for the one-layer carbon textile.

2.2 Material properties

The masonry walls were built using solid clay bricks 65 mm high and with bed face dimensions 215 × 102.5 mm and a mortar with a mix ratio of 1:4 (cement: sand) by volume. The mortar used for the matrix of TRM is made of cement mixed with polymers at a ratio 8:1 while the water to material weight ratio was kept at 0.23.

Material	Strength [MPa]	Elastic modulus [GPa]	Thickness [mm]
Masonry	9.7	2.5	102.5/215
Reinforcing mortar (matrix)	6.0	0.8	3.0
Carbon (C)	3800	225	0.097

Table 1. Material properties: elastic modulus (GPa), strength (MPa) and thickness (mm).

The masonry's vertical Elastic modulus and nominal strength are equal to 2.5 GPa and 9.7 MPa, respectively, estimated from the mean of three compression tests of masonry wallettes [24]. The matrix mortar compressive strength was found 6.0 MPa. Three different composite textiles have been used: (i) carbon with a nominal thickness 0.097 mm, glass with a nominal thickness 0.044 mm and basalt (coated textile) with a nominal thickness 0.037 mm. Measured material properties for all materials are provided in Table 1.

2.3 Test results

Masonry walls usually experience two predominant failure modes or a combination of the two: (i) textile failure (TX), or (ii) masonry failure (MR). The textile failure can occur either as fibre breakage (FB), or textile debonding (DB) and slippage (SL). Masonry failure can be either flexural with vertical cracks (FL), shear with diagonal cracks (SD) or shear sliding of the bricks on the mortar joints (SV) due to loss of bonding. In both cases (i.e. fibres and masonry) a combination of the failure modes is possible. The specimens retrofitted with carbon TRM failed in textile slippage (single wythe specimen) and textile rupture (double wythe specimen).

3 NUMERICAL MODELLING FOR BLAST LOADING

Finite element analysis has been performed to verify the quasi-static experimental results and then obtain a qualitative assessment of the performance of the specimen under blast loading. The simulations herein are carried out using the explicit finite element solver EUROPLEXUS [22] jointly developed by the French Commissariat à l'Energie Atomique et aux Energies Alternatives (CEA Saclay) and the European Commission's Joint Research Centre (JRC Ispra). The main application domain of the software is numerical simulation of fast transient phenomena including non-linear effects, such as explosions and impacts in complex three-dimensional fluid structure systems and therefore, suits perfectly for the masonry blast analysis applied here.

3.1 Numerical setup

The numerical model of the masonry wall was discretized by 8-node linear brick elements with reduced integration to avoid locking phenomena. A uniform element size of 1cm was opted for to also resolve the mortar joints, see Figure 2. The TRM layer has been modelled with 4-node shell elements with 6 DOFs per node, 4 integration points in the plane and 5 integration points through the thickness. A similar element size of 1cm has been employed for the TRM layer which is sharing common nodes with the masonry wall in order to take into account the bonding between the two different components. The specimen was constrained along the vertical direction (parallel to the load) at the support locations. For the quasi-static tests the load has been implemented somewhat faster (constant velocity of 0.05m/s), using time scaling which implies that the simulation run during a shorter time interval than the duration of the physical process of the test. Time scaling increases the strain rates in the structure, therefore rate-sensitivity has been deactivated from the constitutive model.

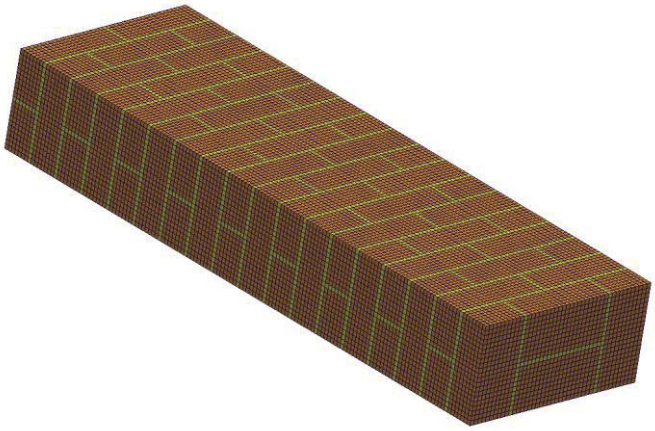

Figure 2. Numerical model of the masonry wall.

3.2 Blast load

An idealized form of a blast pressure-time curve at a certain distance from the detonation point and without intermediate obstacles is presented in Figure 3. The shock wave first reaches the point under consideration at the arrival time t_a (which includes the time of the detonation itself). The pressure reaches its maximum value p_{max} (peak-overpressure) almost instantly and starts decaying until it reaches the ambient pressure p_0 (in most cases the atmospheric pressure) within time t_d, called the positive phase duration. The pressure continues to drop below the ambient pressure reaching its minimum value p_{min}, and then starts to rise again reaching the ambient pressure within time t_n, known as the negative phase duration. The exponential decay of the pressure-time history is represented through the modified Friedlander equation [25], that describes the rate of decrease of the blast pressure values. Depending on the distance of the obstacle from the detonation point and the mass of the explosive charge, the desired parameters (time of arrival, pressure magnitudes, duration and impulses) can be defined using the graphs included in [26].

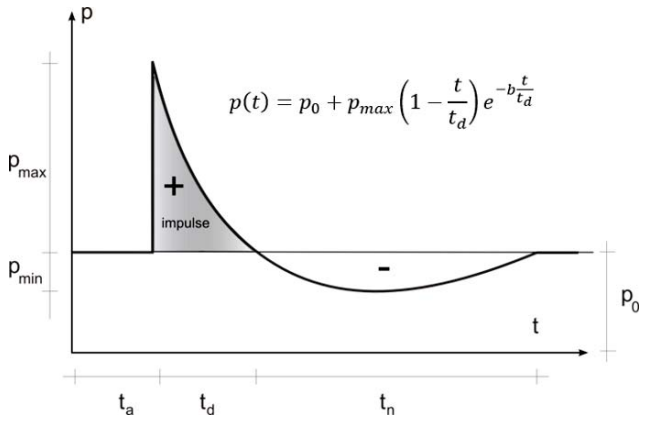

Figure 3. Idealized form of pressure-time history due to explosion (Friedlander equation [25]).

3.3 Material properties and modelling considerations

The response of a perfectly bonded TRM strengthened masonry is generally assumed to be trilinear [27] as shown in Figure 4, where the three subsequent phases I, II_a and II_b are characterised by the moduli E_1, E_2 (=0) and E_3, which can be further simplified to a linear one neglecting the first two phases. However, a complex interaction process between filaments, yarns, the matrix, and the masonry takes place which results in a macroscopic debonding and an uneven stress distribution of the fibres microscopically. To this end an estimation of an 'effective' elastic modulus is opted for in this study, calibrated from the experimental results. The definition of the effective strain is as follows:

$$\varepsilon_{eff} = \varepsilon + \varepsilon_{bond} \tag{1}$$

where ε_{bond} is the macroscopic 'strain' defined as the ratio of the slip to the length of the roving. The TRM coat is modelled assuming only the textile; to this end, the effect of the matrix is introduced as an initial increased stiffness applying the rule of mixtures to reflect its 'presence' prior to cracking and loss of tensile capacity.

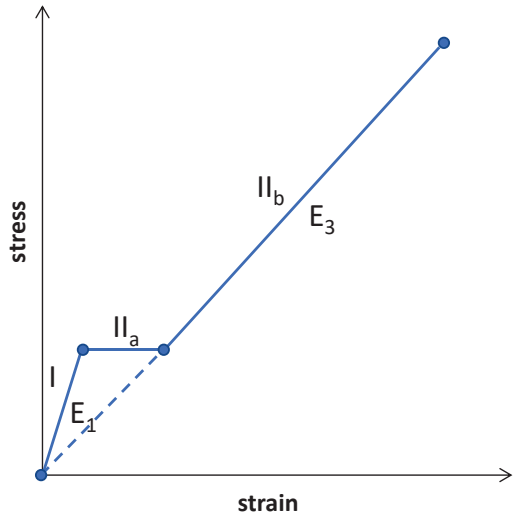

Figure 4. Typical trilinear stress-strain curve of TRM and a simplified linear one [28].

The mortar and the bricks exhibit a brittle behaviour, therefore a three-invariant cap model with mixed hardening has been used [29]. It includes strain rate sensitivity and isotropic damage,

and has been successfully employed in previous studies representing concrete structures [30]. For the TRM layer a Von Mises material law has been used, where elasto-plasticity with isotropic hardening is implemented via a radial return algorithm.

Failure was modelled using element erosion (element excluded from the calculation for the remaining period) that is triggered when all the integration points in the respective element reach a critical value related with the constitutive law. For the brittle material law, the volumetric plastic strain has been used as a failure criterion, while the threshold has been defined after appropriate parametric studies. For the TRM, a criterion based upon the principal strains has been engaged. The criterion is active when the hydrostatic stress is positive (traction), while when the hydrostatic stress is negative (compression) failure is inactive.

4 MODEL CALIBRATION AND BLAST ANALYSES

4.1 Calibration of the proposed model

The numerical model and the assumptions described in Section 3 are applied to the masonry single and double wythe specimens of the experimental campaign presented in Section 2 to calibrate the effective material properties. The calibrated material properties for both specimens retrofitted with a carbon TRM layer are presented in Table 2 and Table 3. It is noted that a uniform weight is applied to all materials as the analysis is explicit. Masonry and mortar joints are modelled using a concrete NL material law applying a Drucker-Prager strain threshold [22].

Material	Density [kg/m³]	Young modulus [GPa]	Poison ratio	Compressive strength [MPA]	Tensile strength [MPa]	Volumetric strain threshold
Brick	2000	6	0.3	15	1.5	0.2
Mortar	1800	0.4	0.2	5	0.5	0.1

Table 2. Material parameters for brittle constitutive law.

Density [kg/m³]	Young modulus [GPa]	Poison ratio [-]	Elastic limit [MPA]	Ultimate stress [MPa]	Ultimate strain [%]
3650	225	0.2	250	1600	1.5

Table 3. Effective material parameters for the carbon TRM layer.

The calibration of the effective material parameters for the carbon textile is shown in Table 3 and the comparison between analytical and experimental results are presented in Figure 5 where an excellent matching is observed. Failure is calibrated with high accuracy in both cases as well as the initial stiffness. A reasonably small variation of the stiffness is observed for the double wythe masonry specimen which can be attributed to local aleatory bonding imperfections.

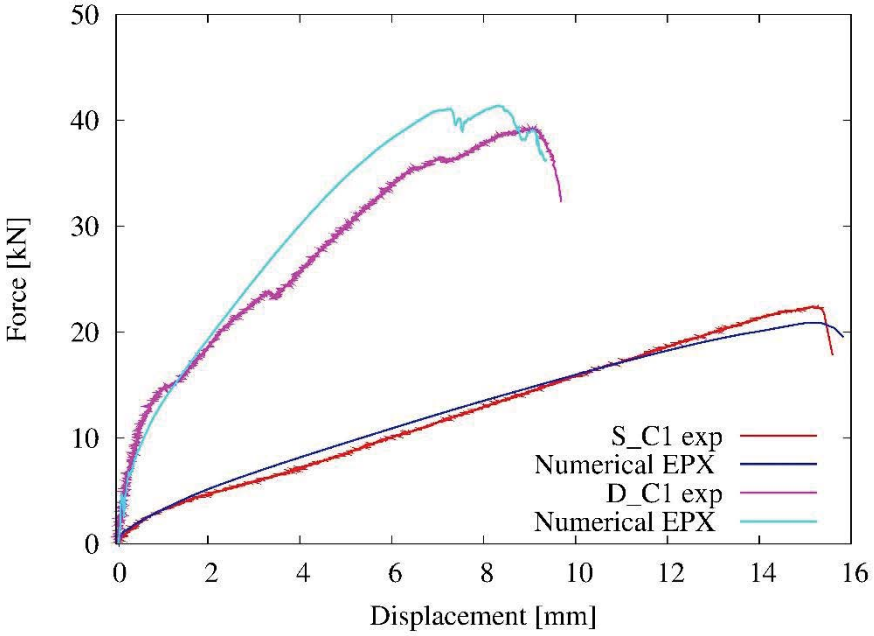

Figure 5. Comparison between experimental results of single (S_C1) and double wythe (D_C1) masonry and numerical model (EPX).

Moreover, comparing the failure mode and the crack propagation among the experimental specimens and the numerical models show a reasonably accurate coincidence as depicted in Figure 6.

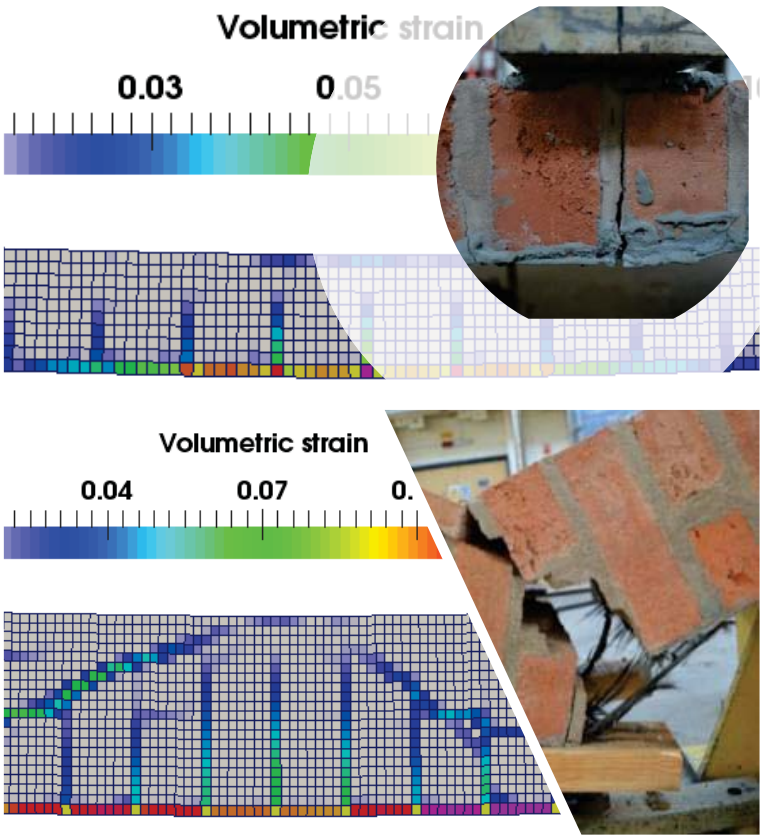

Figure 6. Failure mode of experimental specimens and analytical representation.

4.2 Application of blast loading

A hemispherical blast wave produced from a 80 kg TNT charge at a standoff distance of 5m has been considered to impinge the upper surface of the wall. This scenario implies a Hopkinson-Cranz scaled distance of 1.16 $m/kg^{1/3}$ according to the following Equation:

$$Z = {}^{R}/_{\sqrt[3]{W}} \tag{2}$$

where R is the standoff distance and W is the charge mass.

The materials comprising the masonry wall behave differently under impulsive loading when compared to static or quasi-static loading, due to the effect of the increased strain-rates. Figure 7 presents the comparison of the masonry wall response under blast loading with and without TRM enhancement. The magenta coloured zones indicate the eroded elements after reaching their maximum limit. More accurate representation of the crack propagation needs finer discretisation, but the current one is sufficient to extract qualitative conclusions.

The additional TRM layer appears to prevent the extensive cracking of the mortar. In fact, the opening of the mortar bed joints in the middle zone due to tensile failure is prevented allowing for an additional masonry arch mechanism to develop which, however, is still far from high plastic strains. This additional arch mechanism appears with a moderate diagonal cracking and a compression zone in the middle mortar head joints. Moreover, this mechanism relieves part of the stress and strain tension at the supports.

Monitoring of the number of the failed elements for each case, reveals that the TRM enhanced wall has 20% less eroded elements that is a clear indication of damage reduction. The TRM is not exfoliated, keeping together the individual components of the wall, a characteristic that can contribute towards the reduction of the potential flying debris and their lethal consequences, and thus, increase substantially the safety of the structure.

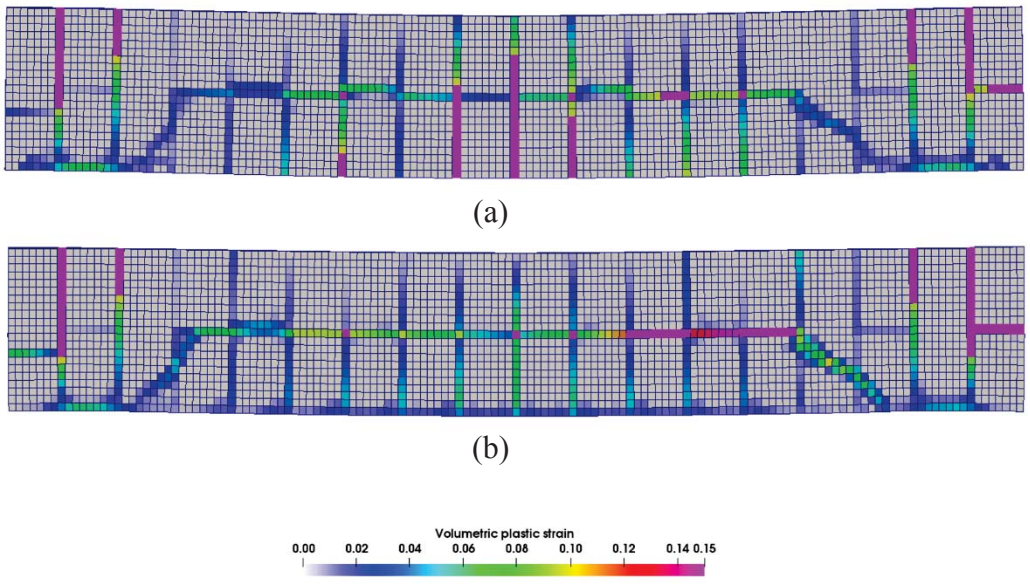

Figure 7. Damage states for: (a) unreinforced masonry, and (b) retrofitted masonry with TRM.

5 CONCLUSIONS

- A model for unreinforced masonry and masonry strengthened with TRM has been developed in an explicit FE code.

- The material models of the simulation have been calibrated using static out-of-plane experiments.
- The materials strain rate effect due to the impulsive loading has been estimated from the literature.
- Unreinforced and retrofitted masonry piers using one layer of carbon textile in inorganic cement-based matrix (TRM) have been exposed to blast loads.
- Application of one layer of TRM (using carbon textile in inorganic matrix) can substantially increase the capacity against impact and blast loads.
- Flying debris is expected to be substantially reduced and thus, increase the occupant safety.

Keywords: Bridge dynamics, Maximum bridge acceleration, Soil-structure interaction, Approach and departure phase.

Abstract. *Based on a simple mechanical model, the dynamic response of a railway bridge crossed by a high-speed train is analyzed. The bridge structure is represented by an Euler-Bernoulli beam resting at both ends on spring-damper elements, which model the viscoelastic flexibility of the soil below the bridge foundations. The train is simplified by its axle loads, which cross the beam at constant speed. The influence of the train on the structure during the approach phase and after departure is considered. In an application example the effect of the train speed, the subsoil conditions and the type of train on the peak acceleration of a ballasted bridge is studied.*

1 INTRODUCTION

The bridge structures along high-speed rail lines can be excited to resonance at critical speeds of the crossing train. Resonance leads to considerable acceleration responses of the bridge deck, which has a negative effect on the stability of the ballast bed and the track quality [1]. As a result, the intervals for track maintenance and track servicing must be reduced in order to maintain ongoing operation at the intended operating speed. Consequently, Eurocode 1 [2] specifies limit values for the maximum bridge acceleration, which is for ballasted bridges 3.5 m/s^2 and for non-ballasted bridges 5.0 m/s^2. Such resonance phenomena should be already identified at the planning stage. Therefore, a sufficiently accurate computational prediction of the dynamic bridge response is of great importance in this phase.

The analysis of the structural response is generally based on a mechanical model. For the problem soil-bridge-train interaction, various modeling strategies with varying degrees of detail can be found in the literature [3]. In the more complex models, the bridge structure is converted into a three-dimensional finite element model and the train is represented as a multi-body system [4]. In simple cases, the structure is represented as a beam, which is dynamically loaded by the static axle loads of the passing train [5]. The majority of studies neglect the flexibility of the soil under the bridge bearings and only very few studies (e.g. [6, 7]) deal with the effect of soil-structure interaction on the dynamic bridge response. The soil can be represented simplified by discrete spring-damper elements [8] below the supports.

In this contribution a simple model recently proposed by the authors [9] is used to efficiently predict the dynamic response of a bridge exposed to high-speed trains. The structure is modeled as an *Euler-Bernoulli* beam, whose viscoelastic supported bearings capture the behavior of the soil below the foundations. As a novelty, the approach presented in [9, 10] is used to take into account the effect of the train on the response of the structure while approaching and leaving the bridge. The train is represented in simplified form by the static axle loads moving at the speed of the train. The response of the non-classically damped beam is found by complex modal analysis. For an example problem the influence of the soil-structure interaction on the dynamic response of the bridge structure is studied.

2 MODELING STRATEGY

2.1 Bridge structure, foundation and subsoil

A slender single-span bridge with a constant cross-section over its span L is considered. The bridge structure can be sufficiently accurately represented as an *Euler-Bernoulli* beam with bending stiffness EI and mass per unit length ρA. The lumped masses m located at both beam ends represent the mass of the bridge foundations and the mass of the soil above the foundations. The half-space below the vertically excited rigid foundations is simplified by means of spring-damper elements [11], which are located under the bridge bearings in the model, see Figure 1. Assuming that the half-space is homogeneous, the spring stiffness k and the viscous damping parameter c of these elements are estimated in the present study on the basis of the *Wolf* cone model [12],

$$k = \frac{\rho_b c_w^2 A_0}{z_0} \,, \quad c = \rho_b c_w A_0 \tag{1}$$

where

$$z_0 = \frac{\pi}{4} (1 - \nu) \left(\frac{c_w}{c_s} \right)^2 \tag{2}$$

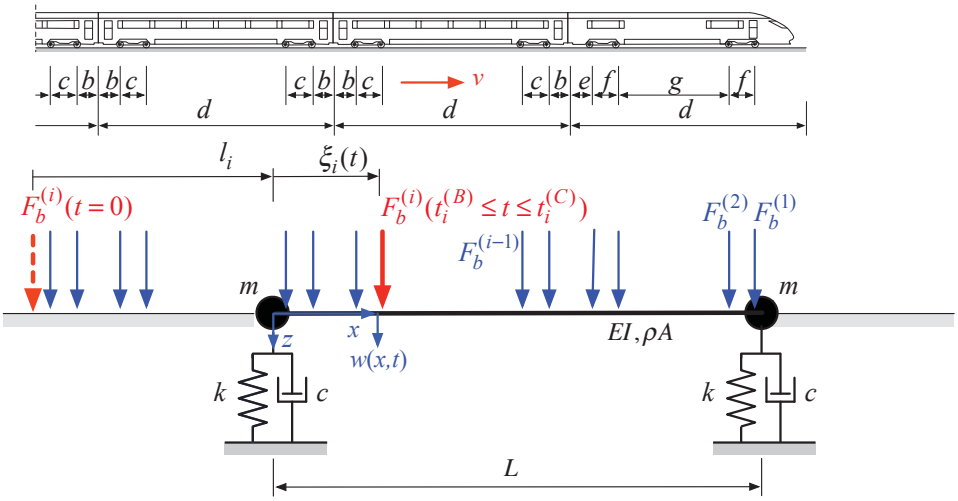

Figure 1: Idealization of the train as a sequence of moving static axle forces and bridge model; from [9].

ρ_b is the density of the soil, A_0 the contact area of the foundation, and $c_s = \sqrt{G/\rho_b}$ the shear velocity with G denoting the shear modulus. For soils with a *Poisson*'s ratio $\nu \le 1/3$, c_w corresponds to the compression velocity,

$$c_w = \sqrt{\frac{E_s}{\rho_b}} \quad , \quad \nu \le 1/3 \tag{3}$$

with the constrained modulus E_s, which is related to the shear modulus G through $E_s = 2G(1-\nu)/(1-2\nu)$.

The time history t of the vertical displacement $w(x,t)$ of the *Euler-Bernoulli* beam at position x satisfies the following partial differential equation [13],

$$\rho A \ddot{w}(x,t) + EI w_{,xxxx}(x,t) = p(x,t) \tag{4}$$

The corresponding boundary conditions of the present beam problem read as [10, 13],

$$\begin{aligned} m\ddot{w}(0,t) + kw(0,t) + c\dot{w}(0,t) + EIw_{,xxx}(0,t) = 0 \ , \ w_{,xx}(0,t) = 0 \\ m\ddot{w}(L,t) + kw(L,t) + c\dot{w}(L,t) - EIw_{,xxx}(L,t) = 0 \ , \ w_{,xx}(L,t) = 0 \end{aligned} \tag{5}$$

The load function $p(x,t)$ in the equation of motion Eq. (4) accounts for the effect of the moving train. It is composed of three portions [9],

$$p(x,t) = p_b(x,t) + p_0(x,t) + p_L(x,t) \tag{6}$$

where $p_b(x,t)$ captures train load when moving on the bridge, $p_0(x,t)$ represents the effect of the train in the approach phase, and $p_L(x,t)$ in the departure phase when the train has already left the bridge. In contrast to a vertically immovable bridge (i.e. on rigid ground), the two contributions $p_0(x,t)$ and $p_L(x,t)$ must be taken into account for this flexibly supported bridge, as described below.

2.2 Train model

2.2.1 Train on the bridge

Since the rail vehicles are generally low tuned, according to Eurocode [2] for the estimation of the dynamic bridge response a train with N_w wheel sets may be described by its N_w static

axle loads $F_b^{(i)}$, $i = 1, ..., N_w$ moving at the train speed v, as shown in Figure 1. If the speed v is constant, the load function $p_b(x,t)$ on the bridge can be expressed as follows [3],

$$p_b(x,t) = \sum_{i=1}^{N_w} F_b^{(i)} \delta(x - \xi_i)[H(t - t_i^{(B)}) - H(t - t_i^{(C)})] \tag{7}$$

The *Dirac* delta function $\delta(x - \xi_i)$ represents the i-th axle load $F_b^{(i)}$ at $\xi_i = vt - l_i$, with l_i denoting the initial position of the force at time $t = 0$ (cf. Figure 1). The *Heaviside* functions H describe the arrival of this force on the bridge at time $t_i^{(B)} = l_i/v$ or its departure at time $t_i^{(C)} = (l_i + L)/v$.

2.2.2 Approach and departure phase of the train

In the common models of viscoelastically supported beam bridges, the beam is suddenly loaded when the i-th axle load of the train is applied. Since the deflection of the beam is still zero when the load arrives at the bridge, an inertial force is suddenly generated which counteracts this axle load. However, the acceleration jump in the model associated with this inertial force has no physical background, but is only caused by the insufficient model, which ignores the approach and departure phase of the train. An appropriate model must consider the lowering of the bridge foundation caused by the deformation of the ground and track when the train approaches the bridge. The acceleration jump is then avoided in the analysis.

The model proposed recently by the authors [9] assumes that at time $t_i^{(A)} = (l_i - L_0)/v$ at the distance L_0 from the left support the i-th static axle load $F_b^{(i)}$ of the train induces the single force $P_0^{(i)}(t)$ at this support. $P_0^{(i)}(t)$ increases linearly with time $t - t_i^{(A)}$ from zero. At time $t_i^{(B)} = l_i/v$ the axle load $F_b^{(i)}$ reaches this support, where $P_0^{(i)}(t_i^{(B)}) = F_b^{(i)}$. This model is based on the assumption that the axle load $F_b^{(i)}$ in the approach phase crosses a rigid massless beam of length L_0, which is simply supported on the left and elastically supported on the right by the soil spring of stiffness k, as shown in Figure 2(a). The force $P_0^{(i)}$ thus represents the quasi-static reaction force of this beam at the flexible support due to the load $F_b^{(i)}$ moving at constant speed. The effect of the N_w axle loads on the left support can be combined to form the total force $P_0(t)$ as [9],

$$p_0(x,t) \equiv P_0(t) = \delta(x) \sum_{i=1}^{N_w} F_b^{(i)} \left(1 + \frac{vt - l_i}{L_0}\right) \left[H(t - t_i^{(A)}) - H(t - t_i^{(B)})\right] \tag{8}$$

The *Dirac* delta function $\delta(x)$ indicates the position of $P_0(t)$ at $x = 0$, i.e. at the left bridge bearing. The ith axis load $F_b^{(i)}$ is activated at the time $t_i^{(A)}$ by the *Heaviside* function $H(t - t_i^{(A)})$, and is deactivated at the time $t_i^{(B)}$ by the *Heaviside* function $H(t - t_i^{(B)})$ when entering the left bridge bearing.

If at time $t_i^{(C)} = (l_i + L)/v$ the axle load $F_b^{(i)}$ leaves the bridge, the force $P_L^{(i)}(t_i^{(C)}) = F_b^{(i)}$ is applied to the right support, which then decreases linearly with increasing distance of $F_b^{(i)}$ until it is zero at time $t_i^{(D)} = (l_i + L + L_L)/v$. L_L represents the influence length behind the bridge. Mathematically, the total force $P_L(t)$ at the right bridge bearing is expressed as [9],

$$p_L(x,t) \equiv P_L(t) = \delta(x - L) \sum_{i=1}^{N_w} F_b^{(i)} \left(1 - \frac{vt - l_i - L}{L_L}\right) \left[H(t - t_i^{(C)}) - H(t - t_i^{(D)})\right] \tag{9}$$

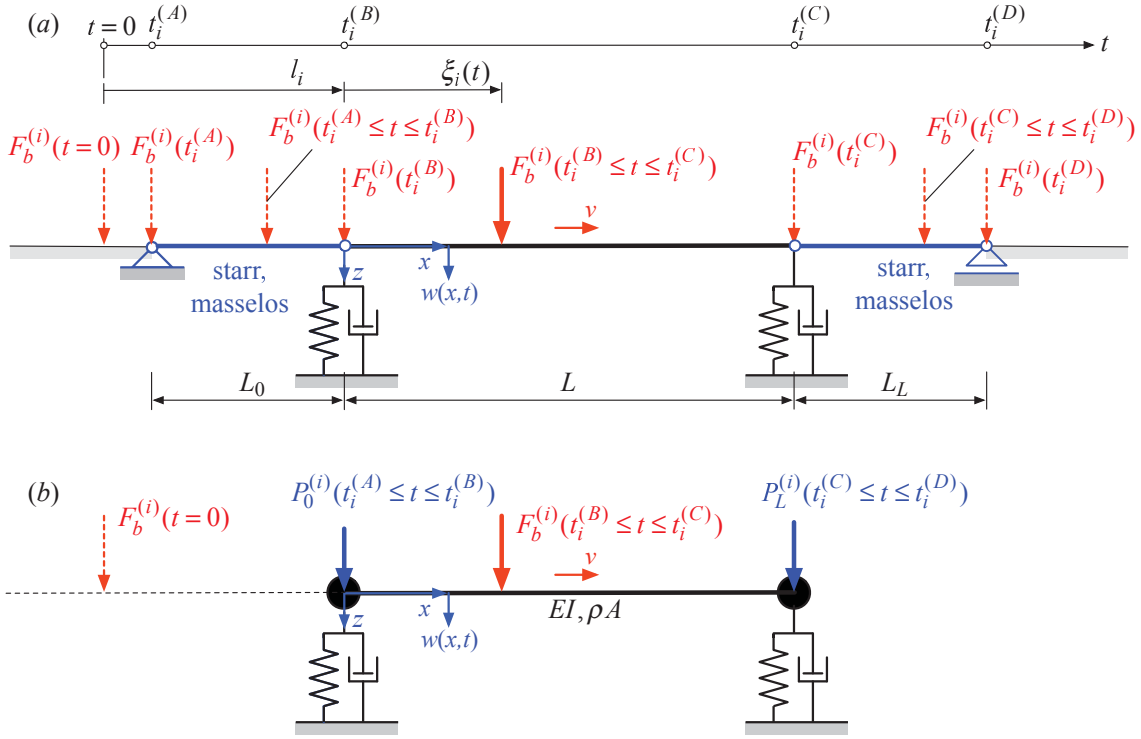

Figure 2: (a) Basic idea of considering the approach and the departure phase of the train, visualized for the ith axle load, whose position is shown at different time instants. (b) Implementation of the approach and departure condition on the viscoelastic supported beam model; modified from [9].

Figure 2(b) illustrates the load on the beam induced by the i-th moving axle load $F_b^{(i)}$. In the approach phase in the period $t_i^{(A)} \leq t \leq t_i^{(B)}$ the force $P_0^{(i)}$ is applied to the left support, in the period $t_i^{(B)} \leq t \leq t_i^{(C)}$ the force $F_b^{(i)}$ crosses the bridge and in the departure phase $P_L^{(i)}$ is applied to the right support.

3 ANALYSIS OF THE STRUCTURAL RESPONSE

The *Euler-Bernoulli* beam described by the equation of motion Eq. (4) is non-classically damped due to the non-classical boundary conditions Eq. (5). Therefore only a complex modal analysis leads to the decoupling of the modal equations. For the complex analysis the equation of motion is transferred to the state space. For details it is referred to [9, 10].

4 APPLICATION

4.1 Bridge and soil parameters

A single-span ballasted steel railway bridge with a span of $L = 21$ m is considered, see also [9]. The corresponding beam model has a bending stiffness of $EI = 2.6 \cdot 10^{10}$ Nm^2 and a mass per unit length of $\rho A = 7083$ kg/m. The modal damping coefficients $\widetilde{\zeta}_r = 0.5\%$, $r = 1, 2, \ldots$ of the vertically immovable steel structure (i.e. the base is rigid) are assumed to be equal to 0.5% according to Eurocode 1 [2]. In contrast, in the viscoelastically supported bridge models the modal damping coefficients for the steel structure are only half of the value proposed in Eurocode 1 [2], i.e. $\widetilde{\zeta}_r = 0.25\%$, because the effect of radiation damping is captured by the viscous dampers.

Five homogeneous soils of different stiffness are considered, whose soil parameters (con-

strained modulus E_s, *Poisson*'s ratio ν, mass density ρ) are summarized in Table 1 [9, 10]. Soil 1 with the lowest stiffness corresponds to a medium stiff soil and soil 5 to a stiff soil (rock). Since the required contact area A_0 of the foundations depends on the soil stiffness (i.e. the stiffer the soil the smaller the required area), the product of the base area of the foundation A_0 and the root of the constrained modulus of the soil E_s is kept constant when determining k and c, i.e. $A_0\sqrt{E_s} = 2.289 \cdot 10^4$ $\sqrt{\text{N}}$m. The foundations are assumed to have the same mass for all soils considered, i.e. $m = 1.5 \cdot 10^5$ kg.

	E_s [MN/m^2]	ν [-]	ρ [kg/m^3]	k [N/m]	c [kg/s]
1	200	0,30	2263	5,895·10^8	1,089·10^6
2	250	0,28	2300	7,662·10^8	1,098·10^6
3	300	0,26	2333	9,495·10^8	1,106·10^6
4	400	0,25	2367	1,284·10^9	1,114·10^6
5	500	0,25	2400	1,605·10^9	1,121·10^6

Table 1: Soil parameters and corresponding parameters of the spring-damper elements [9]

4.2 Maximum dynamic bridge response

In the following, the maximum dynamic response of the bridge subjected to the Austrian high-speed train Railjet and the Intercity-Express train ICE 3, respectively, is studied. The Railjet train with the maximum speed of $v_{max} = 280$ km/h consists of two powercars and twice six wagons with a total length of $L_{train} = 205.4$ m and 56 axles. The considered ICE 3 train is composed of two units (i.e. 16 cars) with a total length of $L_{train} = 400$ m and has 64 axles. The maximum speed of the ICE 3 train is 330 km/h. The amplitude and distances of the axle loads for the Railjet train can be found in [14] and for the ICE 3 train in [15].

As already described in the introduction, in general the maximum acceleration of the bridge deck is decisive for the assessment of the reliability of the bridge structure exposed to high-speed trains. Therefore, in a series of analyses, the acceleration response of the beam model under the effect of the axle loads of the considered trains is computed, increasing in each analysis the speed v stepwise by $\Delta v = 0.1$ m/s. The response is approximated by seven modes. Additionally, the deflection w_r of the beam model is also determined, which is the vertical displacement $w(x,t)$ minus the rigid body displacement due to the lowering of the supports,

$$w_r(x,t) = w(x,t) - \frac{(w(0,t) + w(L,t))}{2} \tag{10}$$

A previous convergence study [9] has shown that the influence length before and after the bridge of $L_0 = L_L = 20$ m is sufficient. Plotting the maximum bridge acceleration a and the maximum deflection w_{rel}, respectively, observed in the period $T = (l_1 + L_{train} + L_0 + L + L_L)/v$,

$$\begin{aligned} a(v) &= \max\{|\ddot{w}(x,t,v)| : 0 \le x \le L, 0 \le t \le T\} \\ w_{rel}(v) &= \max\{|w_r(x,t,v)| : 0 \le x \le L, 0 \le t \le T\} \end{aligned} \tag{11}$$

against the train speed v, yields the response spectra of the bridge structure induced by the Railjet train (Figure 3) and the ICE 3 train (Figure 4), respectively. In the Figures 3 and 4 the maximum accelerations are shown on the left and the maximum deflections on the right. The maximum spectral values occur at the critical speeds $v_l^{(r)}$ (also referred to as resonance speeds), which

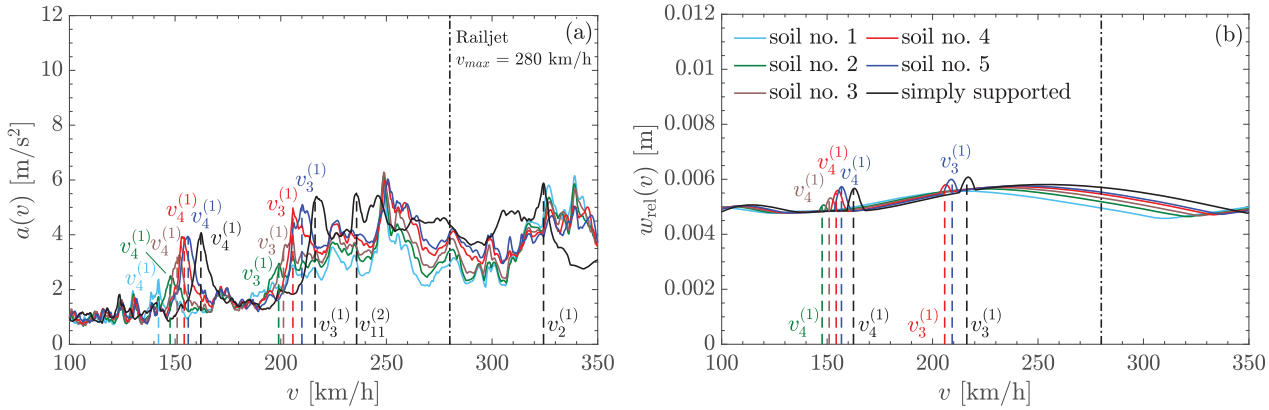

Figure 3: (a) Maximum acceleration and (b) maximum deflection of the bridge with respect to the speed of the Railjet train for different subsoil conditions.

are defined as [3] $v_l^{(r)} = df_r/j,\ j = 1, 2, 3, ...$ These resonance phenomena are a consequence of the excitation of the structural modes by the moving axle loads with constant distance d. f_r denotes the r-th natural frequency of the bridge and j is an integer variable. The distance d, which corresponds to the car length, is 26.5 m for the Railjet train and 24.78 m for the ICE 3 train.

As can be seen from Figure 3, the first two main resonance speeds $v_4^{(1)}$ and $v_3^{(1)}$ of the Railjet train in the ranges between 150 to 160 km/h and 200 to 230 km/h are a consequence of the excitation of the fundamental mode. The decrease of the soil stiffness is accompanied by a reduction in the fundamental frequency and consequently in the corresponding critical speeds. Thus, for the simply supported beam (rigid soil) the critical speed $v_4^{(1)}$ is 162.4 km/h, but for the structure on medium stiff soil 1 only $v_4^{(1)} = 142.2$ km/h. In the first case the maximum acceleration is $a(v_4^{(1)}) = 4.08$ m/s^2, in the latter case only $a(v_4^{(1)}) = 2.37$ m/s^2.

According to Figure 3(a), for the simply supported beam on rigid soil as well as for the structure on soils 4 and 5 at critical speeds $v_4^{(1)}$ and $v_3^{(1)}$ the acceleration threshold for ballasted bridges according to the Eurocode 1 [2] of 3.5 m/s^2 is exceeded. This is due to the low first mode damping for this combination of structure and soil properties. From this figure two main effects of the soil-structure interaction can already be seen. The critical speeds become smaller with lower soil stiffness, but at the same time the corresponding maximum accelerations are reduced because the overall damping increases. In contrast to the acceleration spectra, which show numerous local peaks, a minor amplification of the maximum deflection is only observed at the previously mentioned resonance speeds, as shown in Figure 3(b). However, these amplifications are not critical.

As the spectra of Figure 4(a) shows, the ICE 3 train induces resonance accelerations for all subsoil conditions that are a multiple of the acceleration threshold of 3.5 m/s^2. The critical speeds of the ICE 3 train, at which this limit acceleration is exceeded, start at about 220 km/h. These critical speeds excite the first and second mode ($v_2^{(1)}$, $v_{10}^{(2)}$, $v_{11}^{(2)}$) of the simply supported structure (on rigid soil), and the first and fourth mode ($v_2^{(1)}$, $v_{10}^{(4)}$) of the beam on flexible subsoil, as can be seen from Figure 4(a). As observed, the rigidly supported bridge model exceeds for the first time the limit acceleration of 3.5 m/s^2 at the speed $v_{11}^{(2)} = 220$ km/h, which is at a lower speed than with the models with flexible soil. The largest maximum acceleration of 9.6 m/s^2 occurs at $v_2^{(1)}$ of the model with soil 5, because the damping of the first mode is smaller with this model than with the simply supported beam. The deflection, on the other hand, is significantly

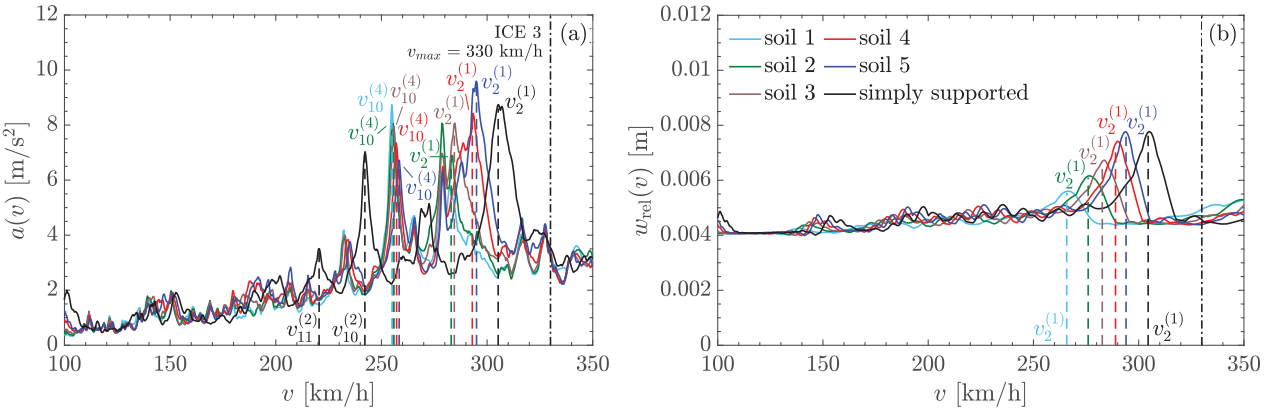

Figure 4: (a) Maximum acceleration and (b) maximum deflection of the bridge with respect to the speed of the ICE 3 train for different subsoil conditions.

increased by the ICE 3 train only at the critical speed $v_2^{(1)}$, see Figure 4(b).

5 CONCLUSIONS

The results of this study on the soil-bridge-train system are based on a simplified model in which the structure is represented as a beam, the subsoil as spring-damper elements below the bearings, and the train as moving axle loads. A corresponding consideration of the approach phase and the departure phase of the train is decisive for physically meaningful outcomes of this model.

This study shows the influence of soil-structure interaction on the numerically predicted acceleration response of a bridge structure exposed to a high-speed train. In general, the maximum accelerations become smaller due to the radiation damping of the ground. In many cases the resonance speeds are also reduced as the fundamental frequency of the bridge decreases due to the decreasing overall stiffness. As in the case of the considered bridge crossed by the ICE 3 train, additional resonance peaks can occur when taking into account the soil-structure interaction, since additional modes emerge in the interacting system due to the flexibility of the soil.

Keywords: Hyperloops, Ultra-high-speed trains, Dynamic amplification factors, Vertical and lateral vibration

Abstract. *The ultra-high-speed (UHS) Hyperloop is the next-generation mode of passenger/freight transportation, and is composed of a tube or a system of tubes through which a pod travels free of friction. The entire system must be supported by piers (multi-span viaducts), where the tubes act as the bridge deck. The UHS moving Hyperloops can exert large dynamic effects to the supporting pier-deck system both vertically and laterally. Particularly, asymmetric Hyperloop loading can generate significant lateral vibrations. Therefore, for safe design of a bridge pier-deck system for UHS trains, it is of great importance to explore dynamic interaction of bridge deck and piers under UHS moving Hyperloops. Hence, this paper analytically summarizes the dynamic amplification factors of the Hyperloop-deck-pier system for vertical and lateral vibrations. It was found that the UHS Hyperloop trains result in higher dynamic effects compared to the high-speed trains.*

1 INTRODUCTION

The Hyperloops suggested initially by Tesla, and later by TransPod, are ultra-high speed (UHS) trains that move and transport passengers at (UHSs) [1]. As shown in Figure 1, the train travels inside a vacuum tube (continuous beams) free of air resistance and friction. In addition, this UHS idea uses magnetic levitation and linear accelerators to push the train forward. The suggested operating speed of these trains are around 970 km/h, with a maximum

speed of 1200 km/h. This compares with mean operating speed of 270km/h for high-speed (HS) trains.

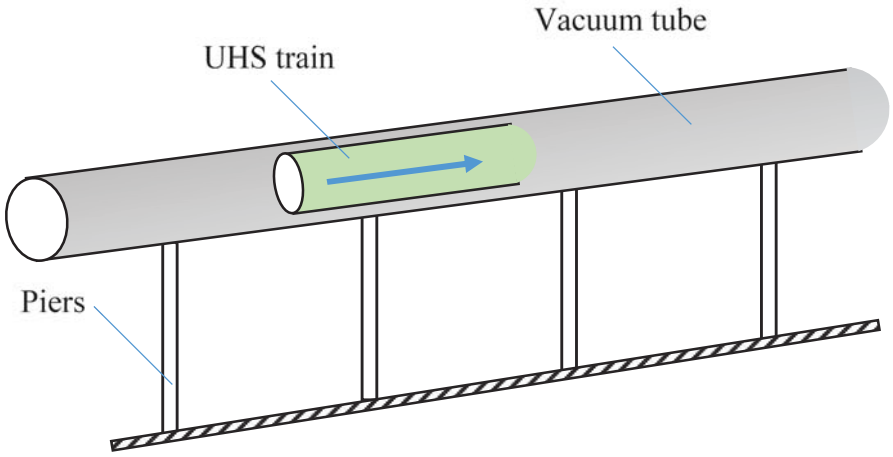

Figure 1: Preliminary concept of Hyperloop trains.

The present UK network rail guideline for design and assessment of bridge structures [2] does not take into account dynamic effects of moving loads for train speeds less than 160 km/h or vertical dynamic amplification factor (DAF) of 1. Nonlinear analysis of existing UK railway bridges also recommends that dynamic effects of train loading are very pronounced for train speeds over 160 km/h [3, 4]. Eurocode EN 1991-2 [5] recommends similar vertical DAFs for train speeds below 200 km/h. However, for train speeds higher 200 km/h, Eurocode EN 1991-2 [5] suggests further advanced dynamic analysis to determine vertical DAFs.

Analytical approaches for moving load problems are very appropriate for parametric analyses. However, it should be noted that all moving force problems cannot be analytically described and more rigorous numerical approaches are necessary to calculate dynamic effects of moving loads [6]. Dynamic effects of moving loads can be substantial particularly for HS trains. Thus, DAFs are defined as dynamic-to-quasi static peak deflection due to the dynamics of moving loads. A solid literature review on DAFs of road bridges for vertical motion can be found in [7]. Currently, there is lack of sufficient knowledge on the UHS Hyperloop trains, and hence, no design recommendations exist to design bridges and accommodate the next-generation UHS transport system. Therefore, this study summarizes DAFs of Hyperloop train-bridge-pier systems for vertical and lateral vibrations already published in [8, 9].

2 ANALYTICAL MODELLING

In this section, the equations of motion of a train composed of a set of moving masses traveling at any speed across a continuous beam of any span length with any number of spans is analytically studied. Consider a set of moving masses traveling at some group velocity V across a continuous beam of n spans of length L as illustrated in the Figure 2. The beam has a uniform mass per unit length m and flexural rigidity EI_b. In addition, for lateral vibration, lateral flexural rigidity of each column (bridge pier) of height h is EI_c. Small deflection theory and linear elastic analysis are used to formulate the lateral motion of the deck. Torsional and vertical oscillations are also ignored in this analysis.

To derive governing equations of vertical and lateral motions of the bridge deck, the Lagrangian formulation is used. The kinetic energy of the system is composed of kinetic energy of the beams and of the moving trainset, and the potential energy of the system includes the internal flexural strain energy of the beam and the external work done by the gravitational load of the train for vertical vibration. However, for lateral vibration due to vertical moving

load eccentricity, the flexural energy of the laterally deformed cantilever piers is also added to the potential energy. Then, the minimization of action principle is employed to derive equations of vertical and lateral motion separately:

$$\left(M_{ij}^{b,v}+M_{ij}^{t,v}\right)\ddot{Z}_i+C_{ij}^{v}\dot{Z}_i+K_{ij}^{v}Z_i=F_j^{t,v} \tag{1}$$

$$\left(M_{ij}^{b,l}+M_{ij}^{t,l}\right)\ddot{Y}_i+C_{ij}^{l}\ddot{Y}_i+\left(K_{ij}^{b,l}+\eta K_{ij}^{c}\right)Y_i=F_j^{t,l} \tag{2}$$

Equations (1) and (2) are respectively for vertical and lateral vibrations; *M, C* and *K* are mass, damping and stiffness matrices respectively; superscripts *b*, *t*, *v*, and *l* stand for beam, train, vertical and lateral; η is the pier-to-deck stiffness ratio; *Z* and *Y* are non-dimensional vertical and lateral deflections:

$$Z=gz/\omega_{1v}^2;\qquad Y=gy/\omega_{1l}^2 \tag{3}$$

where ω_{1v} and ω_{1l} are the first natural frequencies of the unloaded bridge respectively for vertical and lateral motions. For more information on the parameters and assumptions taken, you can see [8, 9].

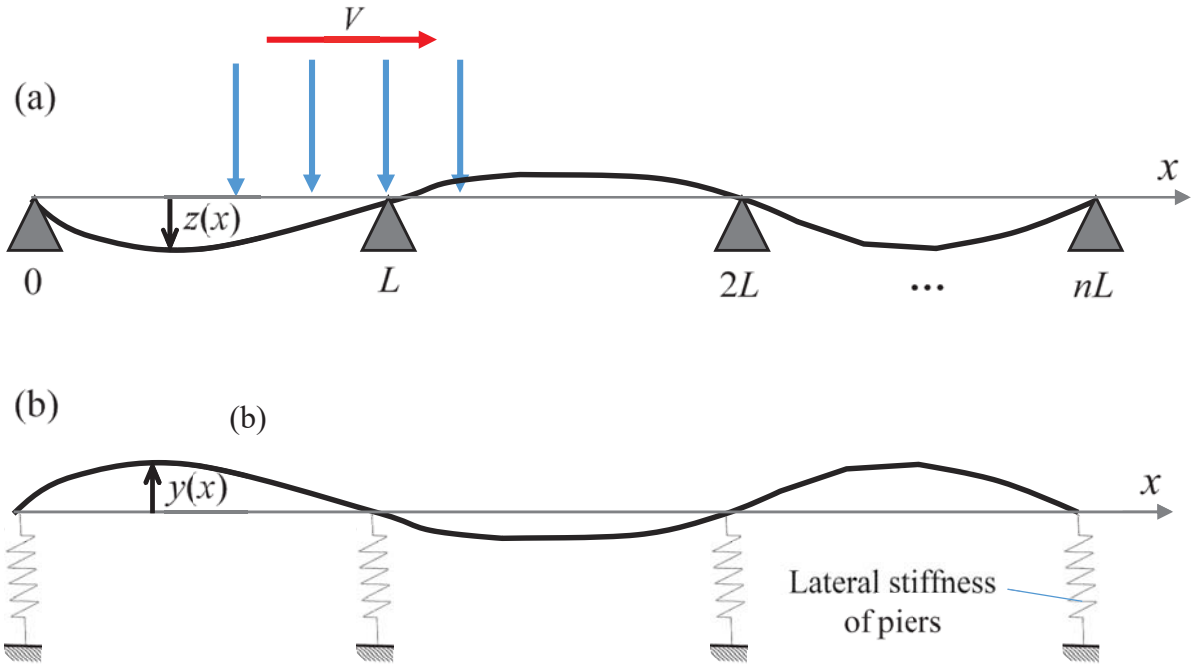

Figure 2: A train set of moving point masses traveling across an *n* span continuous beam: (a) vertical vibration, and (b) lateral vibration.

3 DYNAMIC AMPLIFICATION FACTORS

To study the effects of moving train on vertical and lateral motions of the pier-deck system, dynamic amplification factor (DAF), η, is determined and compared for a wide range of key parameters, $\eta = y_d^{max}/y_s^{max}$ where y_d^{max} and y_s^{max} are dynamic and quasi-static vertical/lateral deflections. The key parameters of the bridge deck-pier systems are: (1) vertical/lateral non-dimensional speed, $\Omega = \pi V/\omega_1 L$, (2) number of spans of length *L*, *n* (3) single train-to-single span bridge mass ratio, α, and (5) the spacing ratio between moving loads to span length, *s*.

Figure 3 shows the effects of single span to multi-span beams on dynamic amplification factors for both vertical and lateral motions. Vertical and lateral DAFs are plotted versus non-dimensional speed for single-span to 5-span beams. This figure is for case of single moving

mass on a continuous beam. The results show a clear maximum which increases for higher number of spans for vertical vibration. For lateral vibration, the increase in the peak is far less than the vertical motion. The increase in the peak is because of the train loading being in contact with the beam for more cycles of loading. The, the higher the number of span is, the more dominant the resonant response is. The peak speed limits for HS trains and Hyperloop trains form regions for lateral vibration as the natural frequency of the unload bridge changes for different number of spans for the lateral motion. It is desirable that the current maximum speed for HS trains is below this resonance.

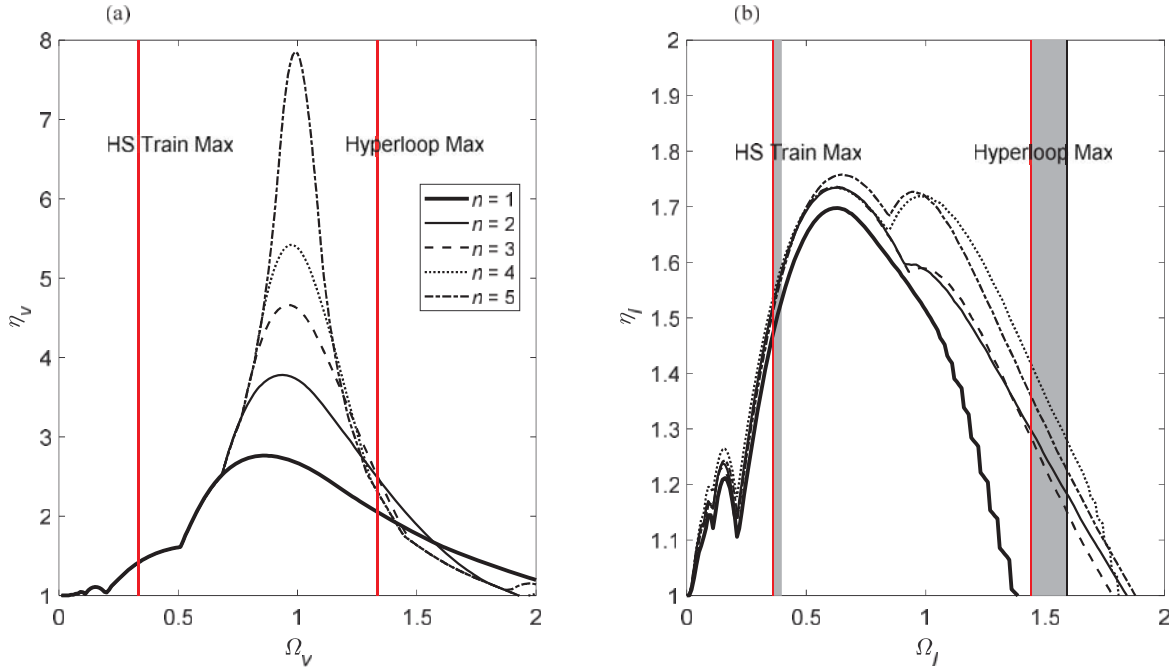

Figure 3: Dynamic amplification factors for single mass crossing multi-span continuous beam: (a) vertical vibration, and (b) lateral vibration.

Figure 4 illustrates vertical and lateral DAFs of a beam with different train-to-bridge mass ratios, α. Different train-to-bridge mass ratios show difference between a moving force (very small mass ratio, $\alpha = 0.01$) and a moving mass (larger mass ratios, $\alpha = 0.1$, 0.5, and 1.0). The maximum speed limits for HS trains and Hyperloop trains are constant for both lateral and vertical motions as the natural frequency of the unload bridge remains unchanged for different mass ratios. At $\alpha = 0.01$, there is a very small difference between moving force and moving mass problems, and for higher mass ratios, this difference becomes far more significant. It is worth noting that as the mass ratio increases, the lateral DAF does so. Moreover, the maximum vertical and lateral DAFs shift toward lower non-dimensional speed with the increase of mass ratio. Comparison of the vertical DAF range with those pf lateral motion shows that DAFs of vertical vibration are much larger than those from lateral vibration. This was expected as the magnitude of bridge lateral vibration due to the train loading eccentricity is much smaller than the vertical vibration of the bridge. Figure 5 illustrates vertical and lateral DAFs versus non-dimensional speed and spacing for a train of 9 equidistance masses. In the case where s is zero, a single moving mass travels the bridge while for $s = 0.25$, the mass of each moving load is divided by 9. The maximum vertical and lateral DAFs are roughly similar to a single moving mass case ($s = 0$). Further, the speed at which the maximum vertical and lateral DAFs occur depends on the spacing ratio. As spacing ratio increases, the maximum lateral DAF moves towards higher non-dimensional speeds for both vertical and lateral

vibrations. For normal HS trains, this is very desirable as it pushes the resonance further away from their operating speed limit. However, for Hyperloop trains, it is adverse as this effect pushes the resonance close to their operating speed limit.

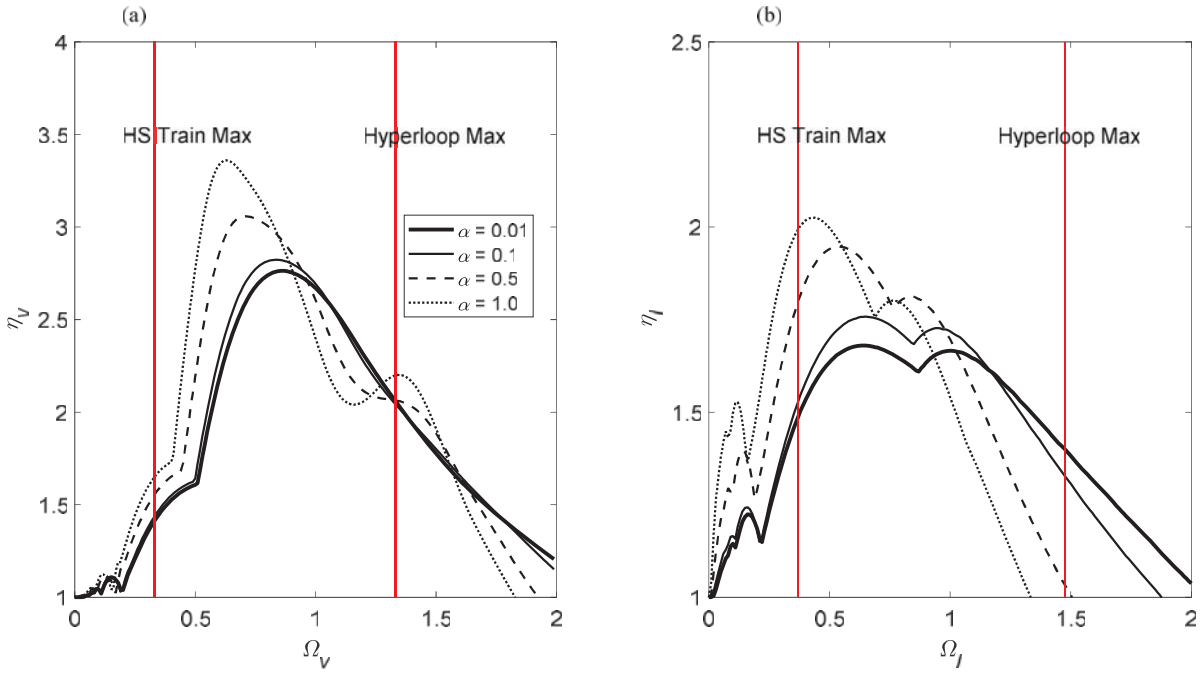

Figure 4: Dynamic amplification factors for different mass ratios, α: (a) vertical vibration, and (b) lateral vibration.

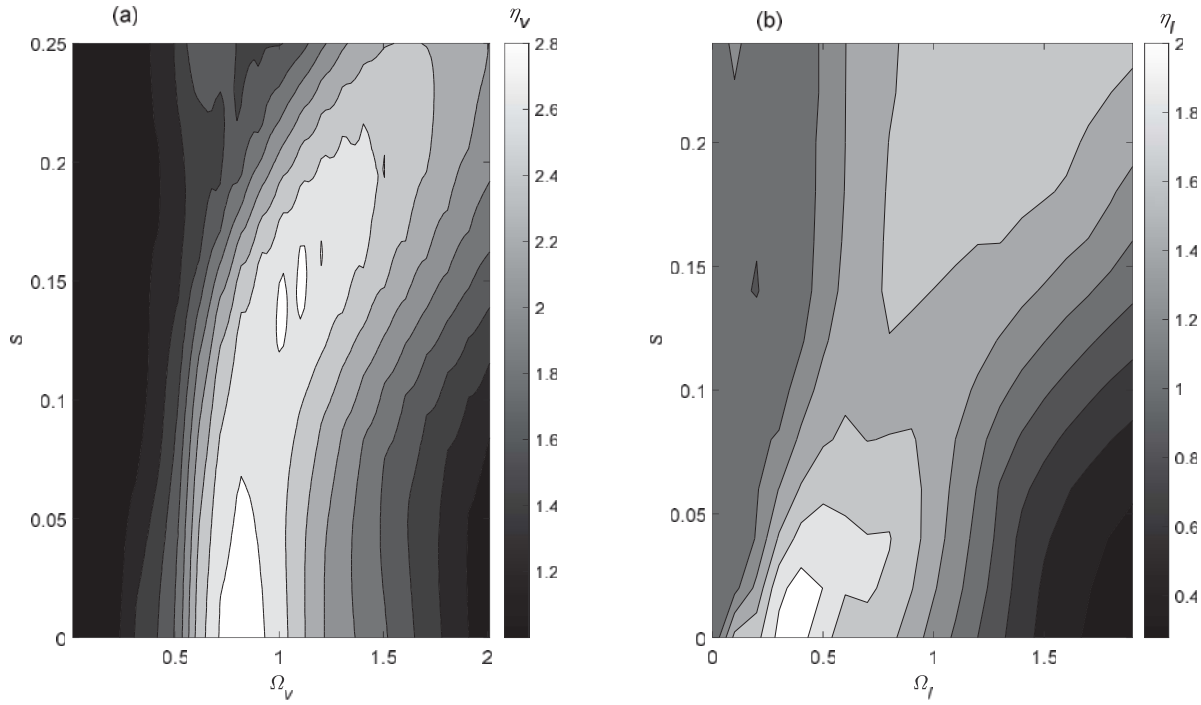

Figure 5: Dynamic amplification factors for different loading spacing values, s: (a) vertical vibration, and (b) lateral vibration.

From Figures 3 and 4, it is easy to understand that the DAFs at the operating speed limit can be used to design the structural system. This is correct for the HS train as the maximum DAF occurs for its maximum operating speed. However, for the Hyperloop train, the max DAF occurs below its max operating speed and all DAFs up to its maximum operating speed have to be taken into account. This is because there are bound to be accelerations, decelerations, emergencies and faulty trains and the designed structural system must be able to safely support all those speeds up to its maximum operating one.

4 CONCLUSIONS

This study addresses and summarizes the Dynamic amplification factors of Hyperloop trains for both vertical and lateral vibrations. It was found that the vertical and lateral DAFs of the system are highly dependent on the train speed, number of spans, train-to-bridge mass ratio, and train loading spacing. The DAFs of the lateral vibration are much smaller than the vertical vibration. Therefore, this work highlights the significance of vertical and lateral vibrations of the Hyperloop train-bridge-pier systems which needs be considered in future design guidelines. Given the significantly large dynamic amplification factors of the vertical vibration, it is necessary to highly stiffen the bridge spans and incorporate large damping in the form of viscous and tuned mass dampers.

Keywords: Moving load, asymptotic model, Rayleigh wave, inhomogeneous, thin coating.

Abstract. *The study is focussed on the near-critical regimes of the moving load on a coated elastic half-space. The material properties of the coating are assumed to be depending on the vertical coordinate. The analysis relies on the hyperbolic-elliptic formulation for the Rayleigh wave induced by prescribed surface loading, containing an elliptic equation for the elastic potential governing its decay over the interior, and a singularly perturbed wave equation on the interface between the layer and the substrate. This scalar formulation allows significant simplifications, including in particular, classification of the near-resonant regimes. The method of fictitious absorption is then used in order to incorporate the effect of poles, associated with the radiation of energy from the moving source. Finally, numerical illustrations of results for several types of vertical inhomogeneity are presented.*

1 INTRODUCTION

Moving load problems on elastic structures have been studied for around a century now, see e.g. [12], [25] and possess important industrial applications, in particular, in high-speed train operation [4]. Solution for steady-state regime of a moving load on an elastic half-space has been first presented in [6], see also [14]. Moving load on a coated half-space has been seemingly first considered by [2]. More realistic modelling motivates development of studies oriented to dynamics of multi-layered and vertically inhomogeneous half-space, see e.g. [15] and [22].

At the same time, sophisticated structure of the exact solution stimulates development of effective approximations. In view of the well-known fact of the Rayleigh wave speed being the critical speed of the moving load, the near-resonant formulation for surface wave field, allowing explicit solutions seems a prospective approach. The current work is based on the long-wave asymptotic formulation presented in [7], which has been applied to problems on a moving load for elastic half-space [17, 10, 8, 26], see also [18] for a more systematic exposition of the methodology of hyperbolic-elliptic models for surface waves. Recent advances of the approach include in particular extensions incorporating the effects of anisotropy [13] and pre-stress [21], composite models for elastic layers [9], as well as development of seismic meta-surfaces [29] and the second-order refined model [30].

The described asymptotic model [18] is focused on the contribution of the Rayleigh wave to the overall dynamic response. It is derived as a slow-time near-resonant perturbation of the self-similar solution by [5] and hence allows reduction of the vector problem of elasticity to a scalar problem for the Laplace equation in respect of the longitudinal elastic potential, with the boundary condition on the surface presented in the form of the forced wave equation. In case of the coated half-space the presence of the layer is reflected by the appropriate pseudo-differential operator, thus, the boundary condition describing the near-surface dynamics is a singularly perturbed wave equation, see e.g. [7].

The focus of the current contribution is on the near-resonant steady-state regimes of a moving line load on a half-space coated by a vertically inhomogeneous thin coating. The corresponding extension of the hyperbolic-elliptic model has been recently suggested in [24]. The study of a singularly perturbed hyperbolic equation at the interface allows classification of the regimes of the moving load, pointing out typical behaviours depending on the speed of the load and the combinations of material parameters.

The paper is organized as follows. The problem is formulated in Section 2. The analytic treatment of the pseudo-differential equation on the interface between the layer and the substrate and classification of regimes of the moving load is carried out in Section 3. Finally, numerical illustrations of the results are presented in Section 4.

2 FORMULATION OF THE PROBLEM

Consider a linearly isotropic, elastic half-space over the domain $-\infty < x_1, x_2 < \infty$ and $x_3 \geq 0$, coated by a thin layer of thickness h described by $-\infty < x_1, x_2 < \infty$ and $-h \leq x_3 \leq 0$, see Fig. 1.

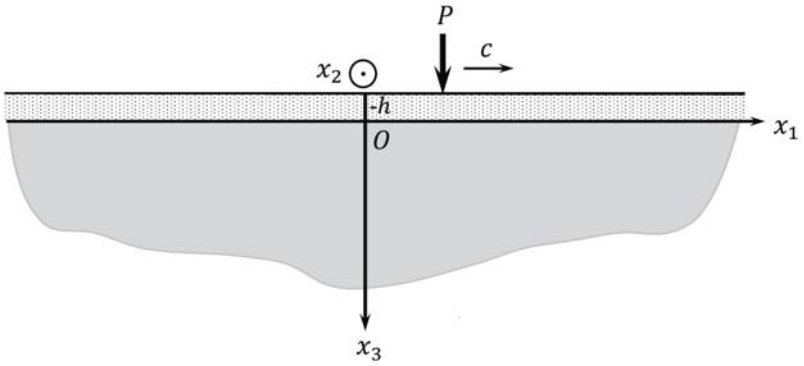

Figure 1: Moving load on a coated elastic half-space.

The properties of the coating are assumed to be dependent on the transverse variable x_3, so that

$$\lambda_c = \lambda(x_3), \quad \mu_c = \mu(x_3), \quad \rho_c = \rho(x_3) \tag{1}$$

denote the Lamé elastic parameters and volume mass density, respectively. The substrate is assumed homogeneous, with the associated material parameters given by λ_s, μ_s and ρ_s. The governing equations of motion and the constitutive relations of linear isotropic elasticity are conventionally written as

$$\sigma^q_{ij,j} = \rho_q u^q_{i,tt}, \qquad \sigma^q_{ij} = \lambda_q u^q_{k,k} + \mu_q \left(u^q_{i,j} + u^q_{j,i}\right), \tag{2}$$

where σ^q_{ij} and u^q_i $(i,j = 1,2,3)$ are the Cauchy stress and displacement components of the coating and substrate $(q = c, s)$, comma indicates differentiation with respect to appropriate spatial or time variable, and the Einstein summation convention is adopted. Here we restrict the consideration to plane-strain formulation, for which $u^q_2 = 0$ and the components $u^q_1 = u^q_1(x_1, x_3, t)$ and $u^q_3 = u^q_3(x_1, x_3, t)$ are independent of x_2.

The loading on the surface of the coating is prescribed in the form of a line vertical force P, moving at a constant speed c, hence the boundary conditions are written as

$$\sigma^c_{31} = 0, \qquad \sigma^c_{33} = P_0\, \delta\left(x_1 - ct\right), \qquad \text{at} \quad x_3 = -h, \tag{3}$$

see Fig.1. Perfect bonding on the interface is assumed, giving $(m = 1, 3)$

$$u^s_m = u^c_m, \qquad \sigma^s_{3m} = \sigma^c_{3m}, \qquad \text{at} \quad x_3 = 0. \tag{4}$$

Below, the long-wave assumption is adopted, i.e.

$$\epsilon = \frac{h}{L} \ll 1, \tag{5}$$

where L is the typical wave length.

We consider the steady-state problems focusing on the near-resonant regimes, when the speed of the moving load is close to that of the resonant Rayleigh wave c_R in the substrate, namely

$$\left| \frac{c}{c_R} - 1 \right| \ll 1. \tag{6}$$

Then, the contribution of the Rayleigh wave to the overall dynamic response is dominant compared to that of body waves, hence, the hyperbolic-elliptic model for the Rayleigh wave is applicable.

The corresponding asymptotic formulation for a vertically inhomogeneous coated half-space has been recently proposed in [24], extending the previous results in [7]. Within this framework, efficient boundary conditions are derived by means of the asymptotic integration technique, see e.g. [11] and [19], then serving as a starting point for slow-time perturbation procedure.

For the current problem, the proposed model for surface wave contains an elliptic equation for the interior $x_3 > 0$

$$\frac{\partial^2 \phi}{\partial x_3^2} + \alpha_R^2 \frac{\partial^2 \phi}{\partial x_1^2} = 0, \tag{7}$$

where ϕ is the longitudinal Lamé elastic potential in the substrate and

$$\alpha_R = \sqrt{1 - \frac{\rho_s c_R^2}{\lambda_s + 2\mu_s}}. \tag{8}$$

The boundary condition at $x_3 = 0$ is given by a singularly perturbed 1D hyperbolic equation

$$\frac{\partial^2 \phi}{\partial x_1^2} - \frac{1}{c_R^2} \frac{\partial^2 \phi}{\partial t^2} - bh \sqrt{-\frac{\partial^2}{\partial x_1^2}} \left(\frac{\partial^2 \phi}{\partial x_1^2} \right) = -\frac{1 + \beta_R^2}{2\mu B} P_0 \, \delta(x_1 - ct), \tag{9}$$

where

$$B = \frac{\alpha_R}{\beta_R} \left(1 - \beta_R^2\right) + \frac{\beta_R}{\alpha_R} \left(1 - \alpha_R^2\right) - 1 + \beta_R^4, \qquad \beta_R = \sqrt{1 - \frac{\rho_s c_R^2}{\mu_s}}, \tag{10}$$

and the constant b is given by

$$b = \frac{(1 - \beta_R^2)}{2\,\mu\,B} \left[\tilde{\rho}\, c_R^2 \, (\alpha_R + \beta_R) - \beta_R \, \tilde{\gamma} \right], \tag{11}$$

with the integral quantities accounting for vertical inhomogeneity

$$\tilde{\gamma} = \frac{4}{h} \int_{-h}^{0} \frac{\mu_c \left(\lambda_c + \mu_c\right)}{\lambda_c + 2\mu_c} \, dx_3, \qquad \text{and} \qquad \tilde{\rho} = \frac{1}{h} \int_{-h}^{0} \rho_c \, dx_3. \tag{12}$$

It is worth noting that the pseudo-differential operator $\sqrt{-\frac{\partial^2}{\partial x_1^2}}$ is an essential feature of the problem, associated with the dispersion of waves within the coating layer. Moreover, the sign of the coefficient b is associated with the sign of the group velocity in the long-wave limit, see [28] for more detail.

Once the longitudinal potential ϕ is determined from the scalar formulation (7), (9), the transverse potential ψ may be found as its harmonic conjugate, see e.g. [18], originating from [5]

$$\psi\left(x_1, \beta_R x_3, t\right) = \frac{2\alpha_R}{1+\beta_R^2} \, \phi^*\left(x_1, \beta_R x_3, t\right), \tag{13}$$

where the asterisk denotes the Hilbert transform.

Now, the boundary value problem (7), (9) may be rewritten in the moving coordinate system $(\xi, x_3) = (x_1 - ct, x_3)$, hence the steady-state limit is governed by

$$\frac{\partial^2 \phi}{\partial x_3^2} + \alpha_R^2 \frac{\partial^2 \phi}{\partial \xi^2} = 0, \tag{14}$$

subject to

$$\eta \frac{\partial^2 \phi}{\partial \xi^2} - b\, h \sqrt{-\frac{\partial^2}{\partial \xi^2}} \left(\frac{\partial^2 \phi}{\partial \xi^2}\right) = -\frac{1+\beta_R^2}{2\mu B} \, P_0 \, \delta(\xi) \qquad \text{at} \qquad x_3 = 0, \tag{15}$$

where

$$\eta = 1 - \frac{c^2}{c_R^2}.$$

3 ANALYSIS ON THE INTERFACE

Let us concentrate on the analysis of equation (15) on the interface $x_3 = 0$. Note that on setting $h = 0$ the problem formulation (14), (15) will reduce to that for an uncoated elastic half-space which is the leading order Taylor expansion of the exact solution [6], for more details see [18].

Another observation which immediately follows from (15) is the presence of two small parameters, a geometric one, associated with the long-wave approximation, as well as η corresponding to the near-resonant vicinity.

Now, let us introduce the dimensionless coordinate $\zeta = \left|\frac{\eta}{b}\right| \frac{\xi}{h}$ along with a scaled quantity

$$\chi = -\frac{2\mu\, B\, b\, h}{(1+\beta_R^2)\, P_0} \frac{\partial^2 \phi}{\partial \xi^2}. \tag{16}$$

Then, the equation (15) takes the form

$$\text{sgn}\,(b\,\eta)\ \chi - \sqrt{-\frac{\partial^2}{\partial \zeta^2}}\,(\chi) = \delta(\zeta), \tag{17}$$

The solution of the latter can be obtained by using the Fourier integral transform

$$\chi = \frac{1}{2\pi} \int\limits_{-\infty}^{\infty} \frac{e^{i\omega\zeta}\, d\omega}{\text{sgn}\,(b\,\eta) - |\omega|}. \tag{18}$$

From (18) it may be observed that the analysis splits in two sub-cases, depending on the value of $\text{sgn}\,(b\,\eta)$.

3.1 SUB-CASE 1: NO POLES ON THE REAL AXE

Consider first the situation $b\eta < 0$, in which

$$\chi = \frac{1}{2\pi} \int_{-\infty}^{\infty} \frac{e^{i\omega\zeta}\, d\omega}{-1 - |\omega|} = \mathcal{F}\,(|\zeta|)\,, \tag{19}$$

where

$$\mathcal{F}\,(x) = \frac{1}{\pi}\,[\text{si}(x)\sin x + \text{Ci}(x)\cos x]\,, \tag{20}$$

with si and Ci denoting the sine and cosine integral functions, respectively, i.e.

$$\text{si}(x) = -\int\limits_{x}^{\infty} \frac{\sin t}{t}\, dt, \qquad \text{Ci}(x) = -\int\limits_{x}^{\infty} \frac{\cos t}{t}\, dt,$$

see e.g. [1]. Note that this case occurs either in the the sub-Rayleigh regime $(c < c_R)$ with local minimum of the phase velocity at the Rayleigh wave speed $(b < 0)$, or in the super-critical regime $(c > c_R)$ combined with local maximum of the phase velocity $(b > 0)$, for more detail see [7].

3.2 SUB-CASE 2: POLES ON THE REAL AXE

The second sub-case $b\eta > 0$ of poles on the real axis of the integral (18) may be treated using the limiting absorption principle, see e.g. [27, 16].

In case of the sub-critical regime $(c < c_R)$, when $(b > 0)$, formula (18) yields

$$\chi = \frac{1}{2\pi} \int_{-\infty}^{\infty} \frac{e^{i\omega\zeta}\, d\omega}{1 - |\omega|} = -2\, H\,(-\zeta) \sin\zeta + \mathcal{F}\,(|\zeta|)\,, \tag{21}$$

whereas in the case of the super-Rayleigh regime $(c > c_R)$ the solution becomes

$$\chi = 2\, H\,(\zeta) \sin\zeta + \mathcal{F}\,(|\zeta|)\,, \tag{22}$$

with $\mathcal{F}$ defined in (20) and $H(\zeta)$ denoting the Heaviside function.

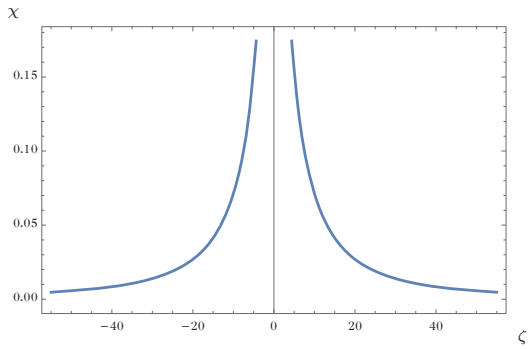
4 NUMERICAL RESULTS

In this section, the illustrations of the obtained results are presented. We consider the dependence of the Young's modulus E_c of the coating layer on the vertical coordinate x_3 of exponential form, see e. g. [22]

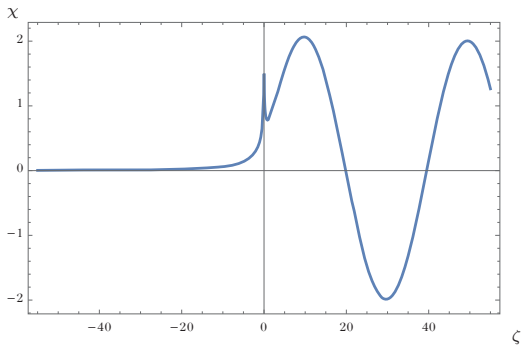
$$E(x_3) = E_c\, e^{\beta\, x_3}, \;\; \beta = \frac{1}{h} \ln\!\left(\frac{E_s}{E_c}\right), \tag{23}$$

providing a smooth variation from the value E_c on the surface of the coating to the Young's modulus E_s of the homogeneous substrate. In the computations below we also take $h = 1$ and assume constant mass densities $\rho_c = \rho_s = 1$, and Poisson's ratios $\nu_c = \nu_s = 0.25$, with the sub-Rayleigh and super-Rayleigh regimes computed for $c = 0.9\, c_R$, and $c = 1.1\, c_R$, respectively.

Consider first the case of a relatively hard coating layer, when $E_c/E_s = 10$. The associated graphs in Fig. 2 show the dependence of the quantity χ on the scaled moving coordinate ζ. In this case, the constant b may be computed using (11), resulting in $b \approx -1.32$. In Fig. 2(a) the super-Rayleigh regime is depicted $(\eta > 0)$, corresponding to the case of no poles in (18), whereas Fig. 2(b) illustrates the sub-Rayleigh regime $(\eta < 0)$, clearly showing the effect of poles in (18) for positive ζ, i.e. radiation of energy in front of the moving source.



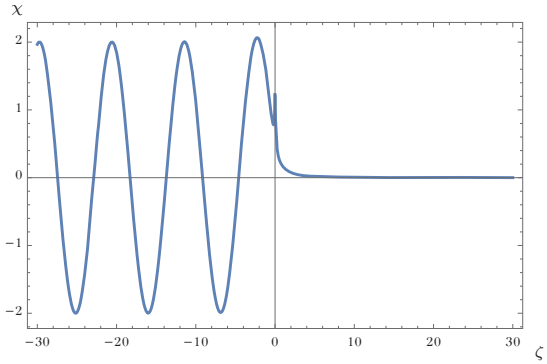
(a) $\eta > 0$.



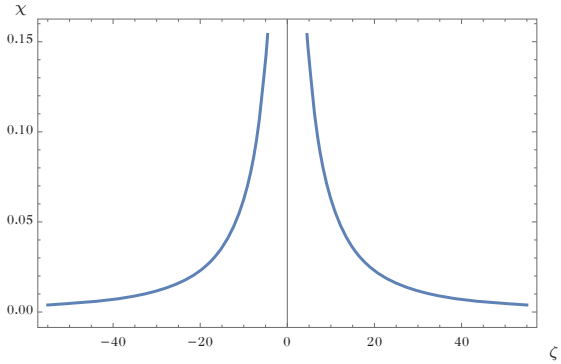
(b) $\eta < 0$.

Figure 2: Dependence of the quantity χ on the moving coordinate ζ for the case of softening within the layer $(E_c/E_s = 10)$.

The following Figs. 3 (a) and (b) illustrate another typical scenario, when the coating layer is relatively soft compared to the substrate and stiffens gradually with depth, when $E_c/E_s = 0.1$. The calculation of the constant b according to (11) gives $b \approx 0.276$. The plots in Fig. 3(a) and 3(b) show the variation of the quantity χ on the moving coordinate ζ. Now, the energy radiation behind the moving load is observed in the super-Rayleigh regime in Fig. 3 (a).



(a) $\eta > 0$.



(b) $\eta < 0$.

Figure 3: Dependence of the quantity χ on the moving coordinate ζ for the case of hardening within the layer $(E_c/E_s = 0.1)$.

5 CONCLUSIONS

The steady-state problem for a moving line load on a half-space coated by a thin vertically inhomogeneous layer has been analysed. The hyperbolic-elliptic formulation for the Rayleigh wave field allowed an explicit solution, as well as a clear classification of the regimes.

Further possible developments include addressing transient problems [17], generalizations to coatings with more sophisticated mechanical properties, taking into account

the effects of viscosity, curvature, long-wave high-frequency waves [20], as well as a more general treatment of a vertically inhomogeneous half-space, see e.g. [3]. We also mention potential applications for seismic metabarriers [23]

Keywords: PC sleeper, Impact load, On-site measurement, Wheel load, Railway track

Abstract. *The purpose of this study is to identify the actual load environment of train loads acting on PC sleepers in order to perform effective maintenance and optimize design of PC sleepers. In Japan, the design load for PC sleepers is calculated by multiplying the static wheel load by impact factor, which is a factor for considering the impact load (generally 2.0) and this value has been conventionally used since the beginning of the use of PC sleepers in Japan. However, considering the improvement of current track and vehicle maintenance technology, it is considered that wheel flats and track irregularities that cause impact loads have been reduced. Therefore, it is necessary to identify the impact factor based on the field tests. In this study, the wheel load was measured in the long rail section of the conventional line, and the actual condition of the impact factor was investigated. As a result, the current impact factor 2.0 is in a safer side to freight trains. Furthermore, for commuter trains, we confirmed that the impact factor for the static design wheel load in Japan (generally 80kN) can be lower than the current value.*

1 INTRODUCTION

PC sleepers are an essential component that contributes to the safety, stability and high-speed transportation of modern railways. PC sleeper is a component made of prestressed concrete which is laid under the rails of railway track. Its main role is to keep the distance between the two rails constant and to properly distribute the load of the passing train transmitted through the rails to the gravel called ballast. In addition to PC sleepers, there are wooden sleepers and iron sleepers. PC sleepers have advantages such as mass production and high durability.

Figure 1 shows an example of a PC sleeper laid on a railway track in Japan. Although there are differences in the distance between rails (track gauge) and the size of PC sleepers, the structure of railway track is generally the same throughout the world. Mass introduction of PC sleepers in Japan began around the 1960s and the cumulative number the cumulative number of installations has exceeded 39.5 million only for Japanese National Railways (JNR) and JR companies which took over most of the assets of the JNR after privatization. The life expectancy of PC sleepers is usually 50 years. However, in recent years, PC sleepers which exceeded this life expectancy have also increased and studies for appropriate maintenance and replacement guidelines have been promoted [1][2].

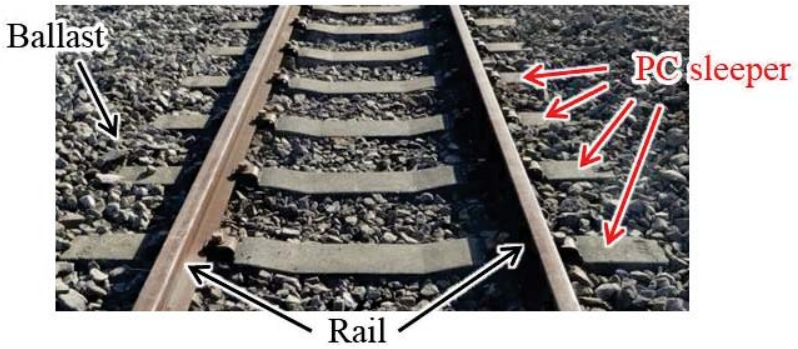

Figure 1: Example of a PC sleeper laid on a railway track

Figure 2 shows the method of design of PC sleepers in Japan. The PC sleeper is designed so that the PC sleeper does not crack under a predetermined design load. In Japan, the design load for PC sleepers is calculated by multiplying the train load transmitted via wheels (static wheel load) by impact factor, which is a factor for considering the impact load (generally 2.0) [3]. However, this value has been conventionally used since the beginning of the use of PC sleepers in Japan. The impact load is generated by unevenness of the wheel (wheel flat) and irregularities [4]. Since the track and vehicle maintenance technology advance in recent years, it seems that wheel flats and track irregularities causing impact loads have been reduced compared to the past time. Therefore, the value of this impact factor may not be in accordance with the actual situation. In order to evaluate the remaining life and to make an optimal design of track members such as PC sleepers, it is required to properly understand the load condition.

In this study, the wheel load was measured in the long rail section of the conventional line, and the actual condition of the impact factor was investigated.

Design load = static wheel load × impact factor (2.0) × dispersion dactor (0.5)

Figure 2: Method of design of PC sleepers in Japan

2 ON-SITE MEASUREMENT

2.1 Target site and PC sleeper

Figure 3 shows the track conditions of measurement site and Figure 4 shows the type 3 PC sleeper which is installed the site. The measurement site is a straight continuous welded rail section. The rail used in the site is a "60kg N-rail", which is specified in Japan industrial standards (JIS). The target PC sleeper is a "Type 3 PC sleeper" specified in JIS. This type of PC sleeper is for a straight section and a curved section with a radius of 800m or more, and is one of the most popular PC sleepers Japan. The No. 3 PC sleeper is designed under the condition of a design wheel load of 160kN with the impact factor of 2.0. The default interval of PC sleepers in the target section is 41 sleepers per 25m, but the each interval between sleepers varies by several tens of mm.

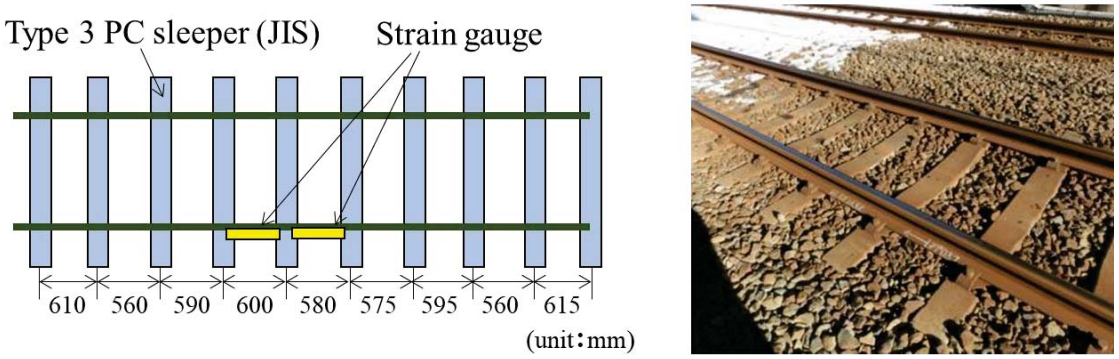

Figure 3: conditions of measurement site

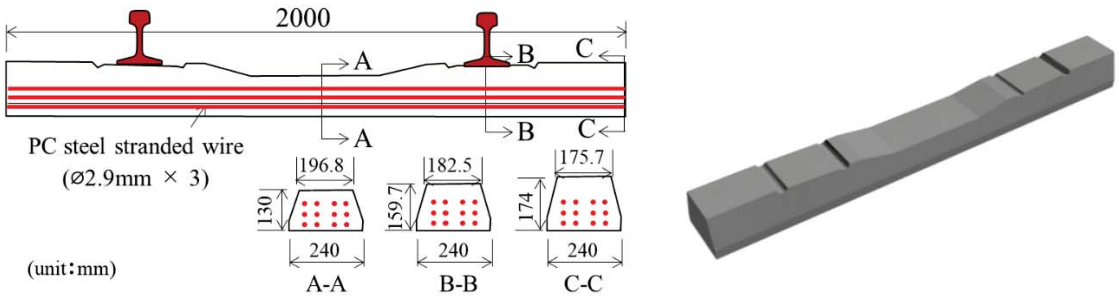

Figure 4: Type 3 PC sleeper

2.2 Measurement method

Figure 5 shows the method of measuring wheel load. In this measurement, a strain gauge for measuring the wheel load was attached to the side surface of the rail. The wheel load was measured by converting the measured strain. A piezoelectric accelerometer was installed on a PC sleeper about 30m away from the measurement point in the direction of train arrival, and used it as a trigger to start measurement. The strain gauge was connected to the National Instruments modules and stored in a PC via a LAN cable. The sampling rate was 10kHz. The recording program was constructed by LabVIEW. In this measurement, wheel load of both commuter trains and freight trains were measured. The measurement period is 50 days in total, and the number of measurement cases is 6042 for commuter trains and 2107 for freight trains.

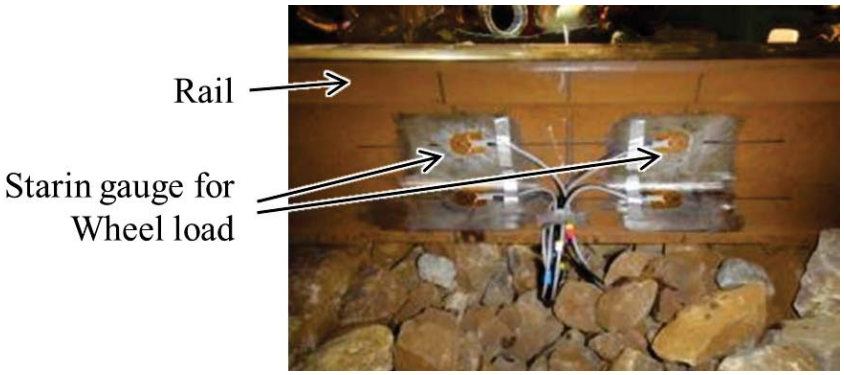

Figure 5: Sensor for measuring wheel load

3 MEASUREMENT RESULTS

Figure 6 shows the time-series data of the measured wheel load, and Figure 7-9 shows the wheel load of commuter train for each time. The data in Figure 9 is obtained by averaging wheel load for every 30 minutes. The average wheel load is 51.9kN for commuter trains and 87.2kN for freight trains, and the maximum wheel load is 105.9kN for commuter trains and 154.0kN for freight trains. The wheel load of commuter trains on weekdays tends to increase at commuter hours, from around 7:00 to 8:00 and from 18:00 to 20:00. On holidays, wheel load of commuter trains tends to increase around 16:30. According to Figure 9, the wheel load at around 18:00, which is the maximum on weekdays, was 1.15 times larger the wheel load at around 14:00 on weekdays, the wheel load at around 16:30, which is the maximum on holydays, was 1.13 times larger than that at 14:00.

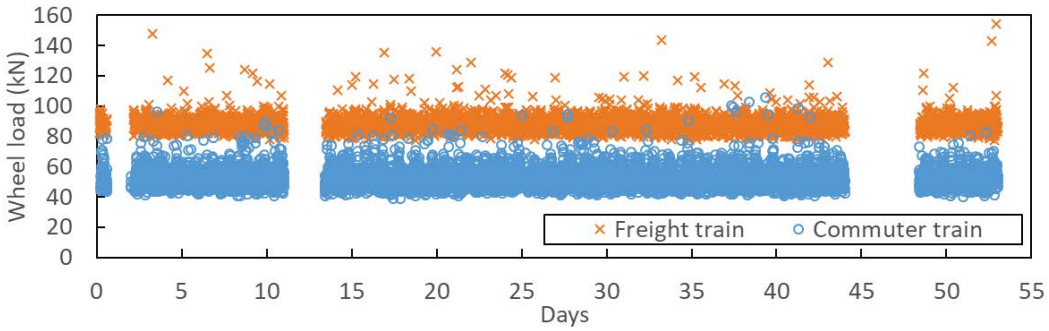

Figure 6: Time-series data of the measured wheel load

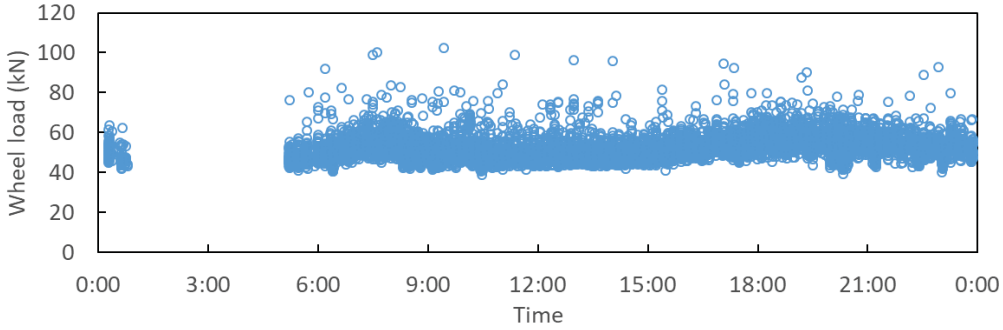

Figure 7: Wheel load for each time (Weekdays)

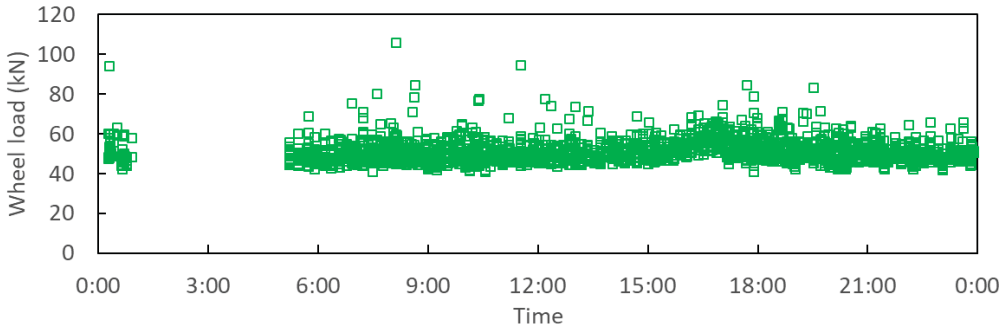

Figure 8: Wheel load for each time (Holydays)

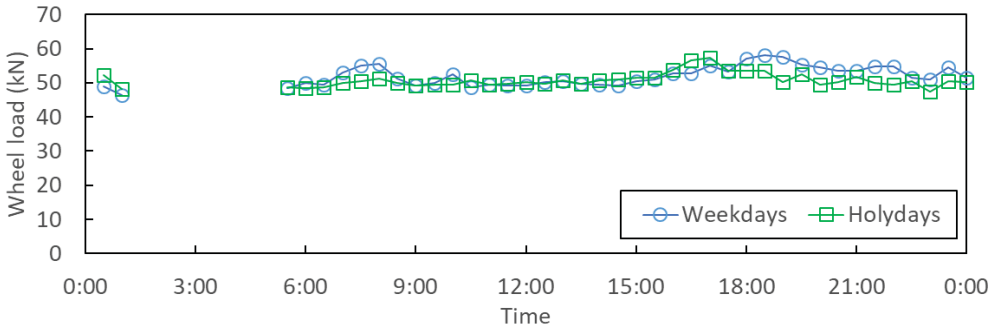

Figure 9: Wheel load for each time (averaging wheel load for every 30 minutes)

Figure 10 shows the minimum, average, and maximum values of wheel load measured by each trains in order to evaluate the variation of the wheel load in the same train. The minimum and average values of the wheel load of each train is similar value, but the maximum wheel load varies widely. From this, there is a possibility that a significant wheel load is caused by a wheel flat generated on a specific train.

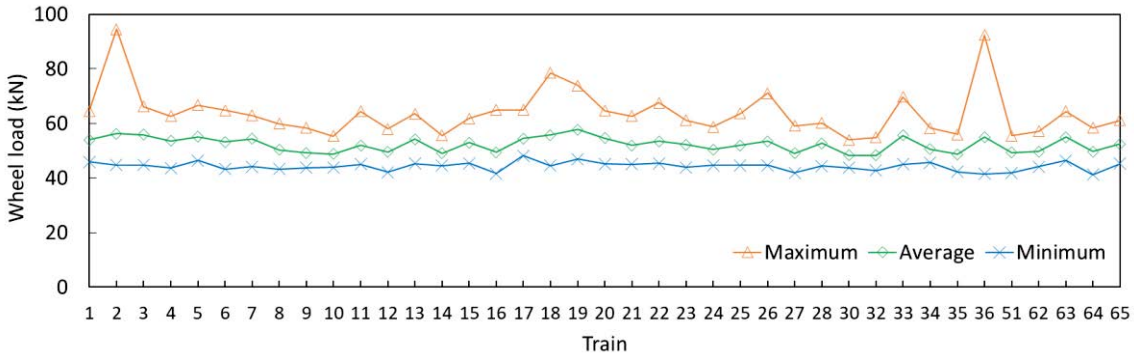

Figure 10: Wheel load measured by each trains

Figure 11-12 shows the probability distribution of wheel loads for commuter and freight trains. The same graph also shows a probability density function following a log-normal distribution. From this graph, the measured wheel load generally followed a log-normal distribution. The mode of wheel load for commuter trains was 48-49kN, and the mode of wheel load for freight trains was 88-89kN.

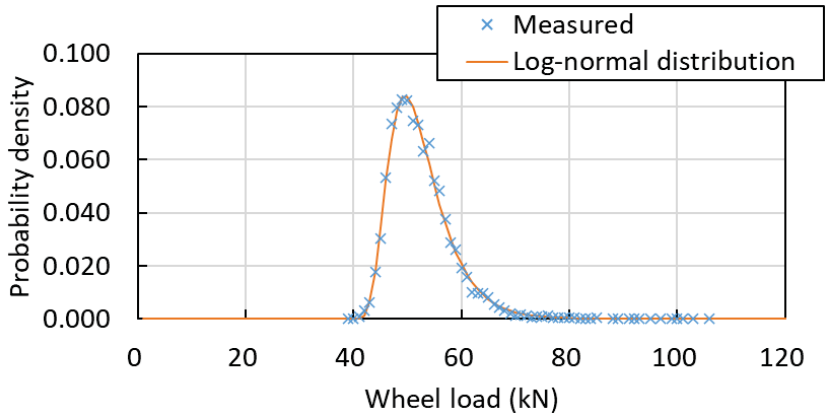

Figure 11: Probability distribution of wheel loads for commuter train

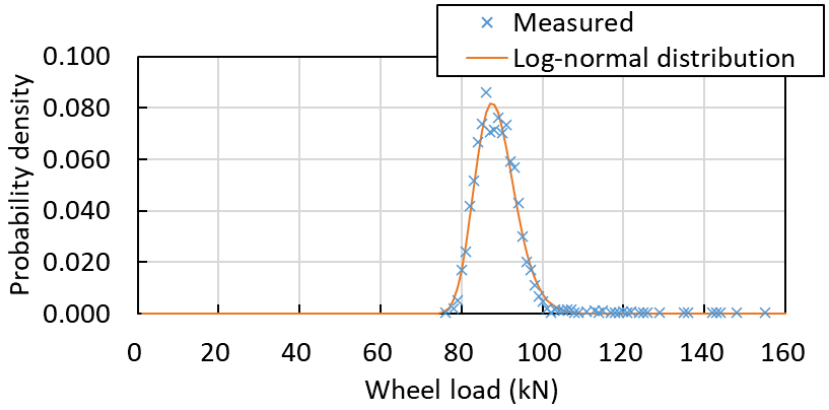

Figure 12: Probability distribution of wheel loads for freight train

Figure 13-16 shows the excess probabilities of measured wheel load and impact factor. The excess probability obtained from the probability density function following a lognormal distribution was also shown in the figure. From figure 13 and figure 14, it is confirmed that

wheel load of commuter train measured in the field test exceeding 90kN are approximately 0.1% or less, which is significantly smaller than the design wheel load considering the impact load (160kN). Similarly, when converted wheel load to an impact factor for a static wheel load of 80kN, impact factor which exceeds 1.2 are 0.1% or less. The main reason for this is the weight of the vehicle of a recent commuter train is lighter than the designed wheel load. For freight trains, percentage of wheel load which exceeds 140kN is less than 0.1%, and also impact factor which exceeds 1.8 is less than 0.1%, which is close to the value used in the design (2.0). In addition, the excess probability distribution of commuter trains roughly matches the excess probability by the log-normal distribution. On the other hand, for freight trains, the log-normal distribution underestimated the excess probabilities especially in the region where the wheel load was more than 110kN. This means that commuting trains run only the same type of train and the variation of train speed passing the site is relatively small. Whereas, for of freight trains, there are many types of locomotives and freight wagons, and the variation in passing speed is larger than the commuter train.

4 CONCLUSION

The purpose of this study is to identify the actual load environment of train loads acting on PC sleepers in order to perform effective maintenance and optimize design of PC sleepers. In the study, the wheel load was measured in the continuous welded rail section of the conventional line, and the actual condition of the impact factor was investigated. The conclusions obtained are as follows.

- The maximum wheel load measured in the study is 105.9kN for commuter trains and 154.0kN for freight trains.
- On weekdays, the average wheel load during commuting hours was 1.18 times higher than the wheel load measured during the daytime.
- The impact factor of 2.0, which has been used in the design of the PC sleeper, is generally appropriate for freight trains. However, for commuter trains, the design wheel load was large compared to the measured wheel load.
- For commuter trains, the probability of occurrence of the wheel load considering the impact load could be roughly estimated by log-normal distribution. Based on this, it can be used for future design and prediction of fatigue life.

Keywords: Dynamic stiffness method, Bernoulli-Euler beam, Free vibration, Moving load, Multi-span beam

Abstract. *This paper is concerned with the dynamic response analysis of single and multi-span beams under moving point loads. The Dynamic Stiffness Method (DSM) is used to calculate the mode frequencies and shapes of single, two and four-span Bernoulli-Euler beams. The exact mode shapes obtained from dynamic stiffness formulations are used to derive generalized mass, stiffness and force terms for normal modes using Galerkin's method. This enables efficient and accurate calculation of the time-history response of the investigated structures. This is demonstrated by comparing the results from this study with advanced finite element simulations of the same problem from the literature. The results validate the accuracy of this approach and demonstrate how this technique can be used to model dynamic amplification of bridges under the influence of moving loads.*

1 INTRODUCTION

The dynamic response of structures assembled from beam elements under moving loads is commonly encountered in bridge engineering applications. Fryba's textbook [1] summarises the pioneering work carried out on the dynamic behaviour of beams under moving loads. This includes analytical and computational work carried out on the response of solitary beams with different moving loads (e.g. point loads and sprung masses) and boundary conditions (simple or fixed supports), as well as work on more complex beam assemblies (e.g. frame structures and curved beams). For complex structures assembled from multiple beams, the free vibration characteristics of the system play an important role in reliable prediction of time-history response. Therefore, it is important to perform free vibration analysis of beam assembly systems accurately and use these to predict the dynamic response.

There has been significant research activity in the last few decades on simulating the response of beam assemblies to moving loads. For instance, Henchi et al. [2] applied the DSM to free vibration and time-history analyses of multi-span Bernoulli-Euler beams under moving load by using a fast Fourier transform (FFT) approach. Ichikawa et al. [3] combined direct integration method and analytical solutions to obtain the dynamic response of multi-span Bernoulli-Euler beams under a moving mass. Mahmoud [4] investigated the effects of cracks on the dynamic response of simply supported Bernoulli-Euler beams subjected to a concentrated moving load. Uzzal et al. [5] obtained the dynamic response of an infinite Bernoulli-Euler beam resting on a Pasternak foundation under the influence of a moving load. Mazilu [6] investigated the dynamics of infinite beams on bilinear viscoelastic foundation under constant and harmonic moving loads by using Bernoulli-Euler beam theory (BET). Beskou and Muho [7] investigated the dynamic response of a simply supported Bernoulli-Euler beam resting on a Winkler foundation considering a moving load on its surface with variable speed. Yang and Wang [8] performed time-history and stability analysis of an inclined beam subjected to a moving vertical concentrated load by using BET. Dynamic behaviour of various types of Timoshenko beams under moving loads and different boundary conditions were also investigated [9-12]. Kim and Lee [13] applied modified spectral element method (SEM) to the time-history analysis of single and multi-span Timoshenko beams and the results were presented in comparison with finite element method (FEM) results.

In this study, a simple approach is used to predict the dynamic response of multi-span beams under moving loads. In particular, continuous parameter models and DSM are used to identify mode frequencies and shapes of assembled structures. These exact mode shapes are then used to derive the dynamic time history response of the structure under the influence of moving loads using Galerkin's method. The use of theoretically exact mode frequencies and shapes for complex assemblies allow capturing the dynamic response efficiently and accurately. To demonstrate this, free vibration analyses of single, two and four-span Bernoulli-Euler beams are performed. First five natural frequencies and mode shapes are presented for all models. Then, time-history responses under a load moving with a constant speed are calculated for the single and two-span beams. Additionally, for the four-span beam model, an accelerating concentrated load is considered. The natural frequencies and time-history responses are compared to published studies from the scientific literature for validation purposes. The conclusion section summarizes the findings and provides a brief discussion on extending these models to simulate dynamic amplification in bridges.

2 FREE VIBRATION RESPONSE

The single, two and four span Bernoulli-Euler beams presented in Figure 1 are considered in this study. In Figure 1a, x describes the local beam coordinate, $S(t)$ is current position of the

load, *P* is a concentrated load, *v* is the velocity of this load, *t* is time and *a* is the constant acceleration of the load. For this preliminary study, the following assumptions are made: i) The behaviour of beams is linear elastic, ii) the material of beams is isotropic, iii) damping is neglected, and iv) axial deformations of the beam are not considered.

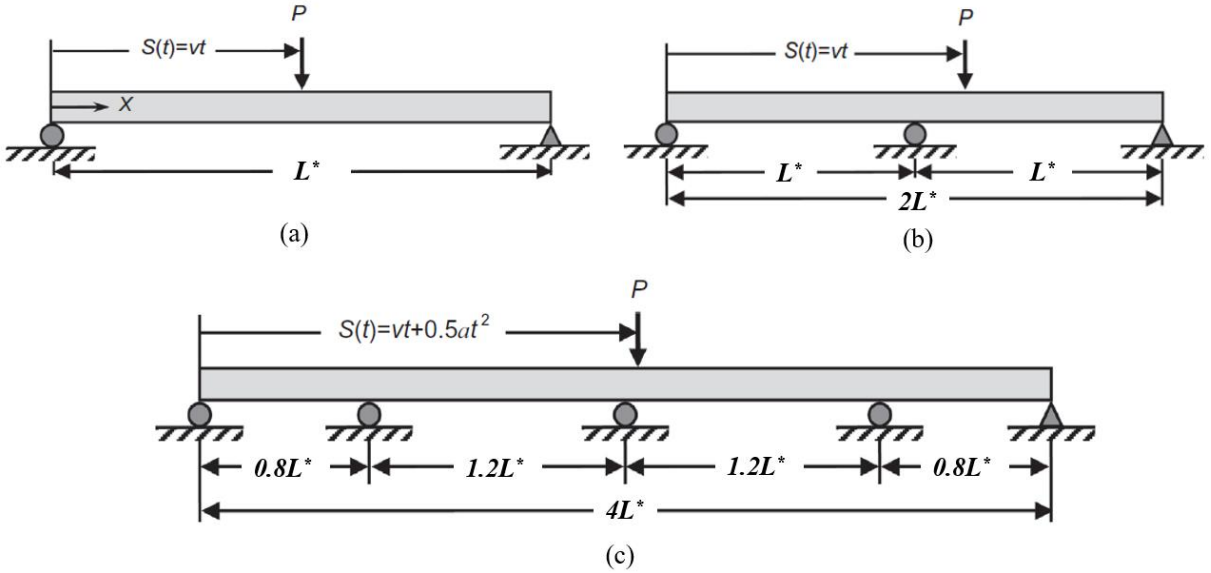

Figure 1: (a) Single-span Bernoulli-Euler beam under moving load (b) Two-span Bernoulli-Euler beam under moving load (c) Four-span Bernoulli beam under accelerating load [13]

The governing equation of motion of a single Bernoulli-Euler beam in free vibration can be written as [14]:

$$EI\frac{\partial^4 y(x,t)}{\partial x^4}+\bar{m}\frac{\partial^2 y(x,t)}{\partial t^2}=0 \tag{1}$$

where *y(x,t)* is transverse displacement function of the beam, $\bar{m}$ is mass per unit length, *E* is modulus of elasticity, *I* relevant area moment of inertia. If the bending motion of the beam is harmonic, Eq.(2) is obtained by applying the separation of variables method:

$$\frac{d^4 y(x)}{dx^4}-\frac{\bar{m}\omega^2}{EI}y(x)=0 \tag{2}$$

where ω is natural circular frequency.

It is assumed that the solution to Eq.(2) is of the form:

$$y(x)=\{C\}e^{isx} \tag{3}$$

where $\{C\}$ is a vector of integration constants, *s* represents the characteristic roots of equation and *i* is the imaginary number.

Substituting Eq.(3) into Eq.(2) leads to the following solutions for the transverse displacement and cross-section rotation functions in Eqs.(4) and Eq. (5), respectively:

$$y(x)=(C_1e^{is_1x}+C_2e^{is_2x}+C_3e^{is_3x}+C_4e^{is_4x}) \tag{4}$$

$$\theta(x)=(is_1C_1e^{is_1x}+is_2C_2e^{is_2x}+is_3C_3e^{is_3x}+is_4C_4e^{is_4x}) \tag{5}$$

where C_1, C_2, C_3 and C_4 are integration constants.

Bending moment function *M(x)* and shear force function *T(x)* can then be defined as follows:

$$M(x) = (EIs_1^2 C_1 e^{is_1 x} + EIs_2^2 C_2 e^{is_2 x} + EIs_3^2 C_3 e^{is_3 x} + EIs_4^2 C_4 e^{is_4 x}) \tag{6}$$

$$T(x) = (EIis_1^3 C_1 e^{is_1 x} + EIis_2^3 C_2 e^{is_2 x} + EIis_3^3 C_3 e^{is_3 x} + EIis_4^3 C_4 e^{is_4 x}) \tag{7}$$

In order to determine the eigenmodes of the assembled beam structure, its dynamic stiffness matrix needs to be assembled. To do this, the dynamic stiffness matrix of a single span element first needs to defined. This is achieved by the following procedure described below [15]:

i) a closed form solution for the free vibration problem is obtained, using Eqs. (2) – (3);

ii) the nodal degrees of freedom and forces are determined in terms of the natural vibration frequencies and boundary conditions;

iii) a frequency dependent dynamic stiffness matrix of the element is formulated by relating generalized nodal forces to generalized nodal displacements.

Following this procedure, the nodal degrees of freedom of the element and the arbitrary integration constants can be written in matrix form follows:

$$\delta = \begin{bmatrix} y_0 & \theta_0 & y_L & \theta_L \end{bmatrix}^T \tag{8}$$

$$\{C\} = \begin{bmatrix} C_1 & C_2 & C_3 & C_4 \end{bmatrix}^T \tag{9}$$

where $y_0 = y(x=0), \theta_0 = \theta(x=0), y_L = y(x=L), \theta_L = \theta(x=L)$. Here, L represents the length of a Bernoulli-Euler beam element. The nodal force vector (F) is given in Eq.(10) as:

$$F = \begin{bmatrix} T_0 & M_0 & T_L & M_L \end{bmatrix}^T \tag{10}$$

The sign convention utilised for the displacements and forces is shown in Fig. 2.

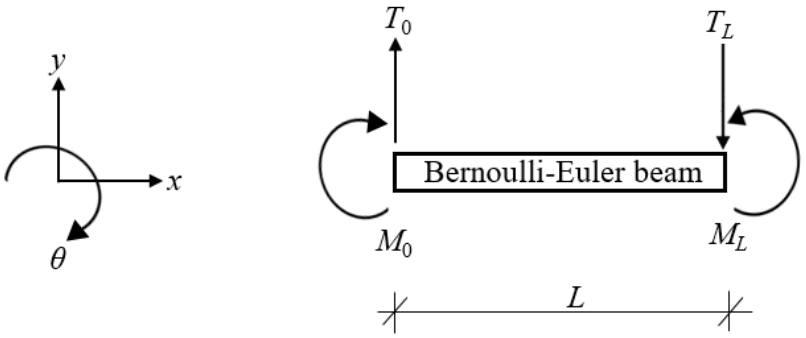

Figure 2: Positive sign convention for displacements and forces for a Bernoulli-Euler beam

The relations of $\delta = \Delta C$ and $F = \kappa C$ are obtained by using Eqs.(8-10) where Δ and κ represent coefficient matrices. Using these, the dynamic stiffness matrix of the single-span beam model is constructed by establishing a relationship between δ and F as follows:

$$F = \kappa(\Delta)^{-1}\delta \tag{11}$$

$$K^* = \kappa(\Delta)^{-1} \tag{12}$$

where K^* represents the dynamic stiffness matrix of the single-span Bernoulli-Euler beam.

The global dynamic stiffness matrix of the two-span and four-span beam models are obtained by assembling dynamic stiffness matrices from each element using standard assembly procedures:

$$\begin{Bmatrix} F_1 \\ F_2 \\ F_3 \\ . \\ . \\ . \\ F_j \end{Bmatrix}_{j\times 1} = \left[DSM_{glob} \right]_{j\times j} \begin{Bmatrix} \delta_1 \\ \delta_2 \\ \delta_3 \\ . \\ . \\ . \\ \delta_j \end{Bmatrix}_{j\times 1} \tag{13}$$

where j equals to the number of nodes multiplied by 2. Correspondingly, F_i and δ_i are the jth nodal force and degree of freedom of the system, respectively, and DSM_{glob} represents global dynamic stiffness matrix of the whole vibrating system. The DSM_{glob} is reduced to $DSM_{glob,red}$ matrix by removing rows and columns of inactive degrees of freedom according to displacement constraints arising from the boundary conditions.

The natural frequencies of the assembled structure are obtained by equating the determinant of the global dynamic stiffness matrix $DSM_{glob,red}$ to zero. A standard root finding algorithm (based on an iterative bisection approach) is used for obtaining the natural frequencies. This allows the calculation of the mode shape of each element of the structure for a given natural frequency. These are then normalized in a consistent manner, considering compatibility between nodal displacements and rotations to obtain the mode shape of the whole structure.

3 MOVING LOAD RESPONSE

The differential equation of a single Bernoulli-Euler beam element subjected to a moving concentrated load can be written as [4]:

$$EI\frac{\partial^4 y(x,t)}{\partial x^4} + \bar{m}\frac{\partial^2 y(x,t)}{\partial t^2} = P\delta^D\left(x - S(t)\right) \tag{14}$$

where δ^D is the Dirac delta function. Galerkin's method can be used to minimize the error in satisfying Eq.(14) with the following expansion for $y(x,t)$ [16]:

$$y(x,t) = \sum_{n=1}^{\infty} y_n(x) q_n(t) \tag{15}$$

where n is mode number, $y_n(x)$ and $q_n(t)$ are a chosen set of functions which approximate the eigenmodes and generalized displacements of the system, respectively. These need to satisfy boundary conditions of the model. When the chosen eigenmode functions are exact and orthogonal, Galerkin's method yields exact results. In this paper, the exact mode shape $y_n(x)$ of the whole structure is obtained from continuous parameter models using DSM, following the procedures discussed in the previous section.

Substituting Eq.(15) into (14) and assuming normal modes, Eq.(16) is obtained.

$$\bar{m}^* \ddot{q}_n(t) + k^* q_n(t) = Q(t) \tag{16}$$

In Eq.(16), $\bar{m}^*$ is generalized mass, k^* is generalized stiffness and $Q(t)$ is generalized force which are defined as follows [4]:

$$\bar{m}^* = \int_0^L y_n(x)^2 dx;$$

$$k^* = \int_0^L EI\left(\frac{d^2 y_n(x)}{dx^2}\right)^2 dx; \tag{17}$$

$$Q(t) = \int_0^L P\delta^D\left(x - S(t)\right) y_n(x) dx = P y_n\left(S(t)\right)$$

By using Eqs.(16) and (17), the dynamic response of the single-span beam can be obtained in terms of the generalized displacements for each vibration mode. Then, by using Eq. (15), the displacements at any desired location on the beam can be determined. For the two and four span beams, Eq.(17) is used to calculate generalized mass, stiffness and force values for each span separately. Then, these values are summed to obtain the total generalized mass, stiffness and force terms.

4 NUMERICAL CASE STUDY

To illustrate the numerical modelling procedure, the response of simple beam assemblies from the scientific literature will be discussed in this section. The following material and geometric properties are considered for each span of the model [13]: $L^* = 4$ m, width × height of the cross-section: 0.06 m × 0.02 m, unit weight of the beam: 7850 kg/m^3, $E = 2\times10^8$ kN/m^2.

In the free vibration analysis part of numerical case study, the first five natural frequencies and mode shapes are obtained by using DSM. Table 1 compares the first five natural frequencies of single, two and four-span beam models determined in this study to detailed finite element simulations conducted in an earlier study [13]. A very good agreement is observed where the maximum relative error between the results is less than 1%. It should be noted that the results from [13] are based on Timoshenko beam theory. However, as the cross-section of the beam is thin, the effects of rotational inertia and shear deformations are negligible. The accompanying mode shapes for single, two and four-span beam models are presented in Figure 3(a)-(c).

Model	Method	1st mode	2nd mode	3rd mode	4th mode	5th mode
Single-span beam	DSM	17.8047	71.2787	160.2420	284.8747	445.1167
	[13]	17.9755	71.8935	161.7267	287.4325	448.9480
	Error (%)	0.95	0.86	0.92	0.89	0.85
Two-span beam	DSM	17.8047	27.8143	71.2187	90.1361	160.2420
	[13]	17.9755	28.0796	71.8935	90.9805	161.7267
	Error (%)	0.95	0.94	0.94	0.93	0.92

	[13]	15.2254	21.8059	35.0013	37.3130	58.2663
	Error (%)	0.95	0.95	0.94	0.94	0.94

Table 1: First five natural frequencies (rad/sec) and relative errors for single-span, two-span and four-span beam model

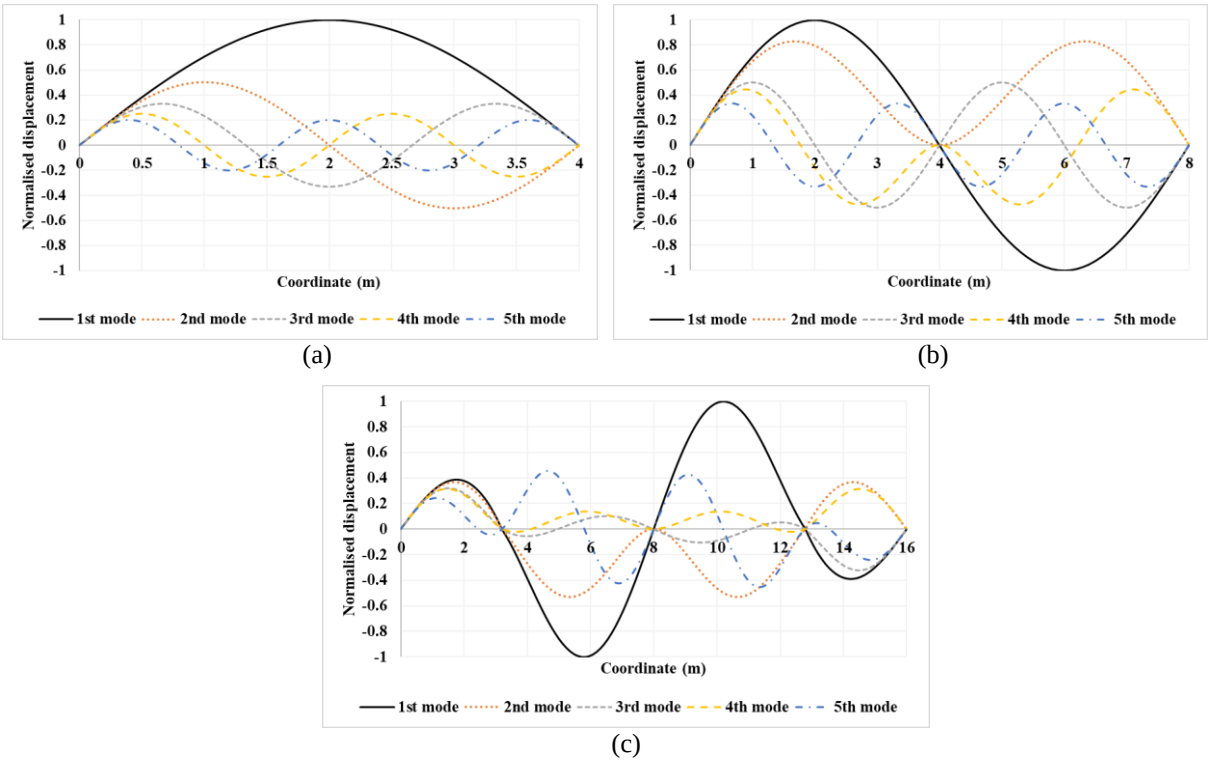

Figure 3: First five mode shapes of (a) Single-span Bernoulli-Euler beam model (b) Two-span Bernoulli-Euler beam model (c) Four-span Bernoulli beam model

After obtaining exact mode shapes, the dynamic response of the beam models can be calculated by using Eqs.(16)-(17). In this study, Eq.(16) is solved numerically using the ode45 function in Matlab, which is based on an explicit Runge-Kutta formulation [17]. The time-history responses of single and two-span Bernoulli-Euler beams under loads moving at constant velocity are presented in Figures 4 and 5. Both figures show the displacement at the middle of the first span. For the single span in Figure 4, accurate results could be achieved by considering only a single vibration mode. In contrast, for the two-span beam in Figure 5, the first two modes need to be considered to achieve good agreement with the published results.

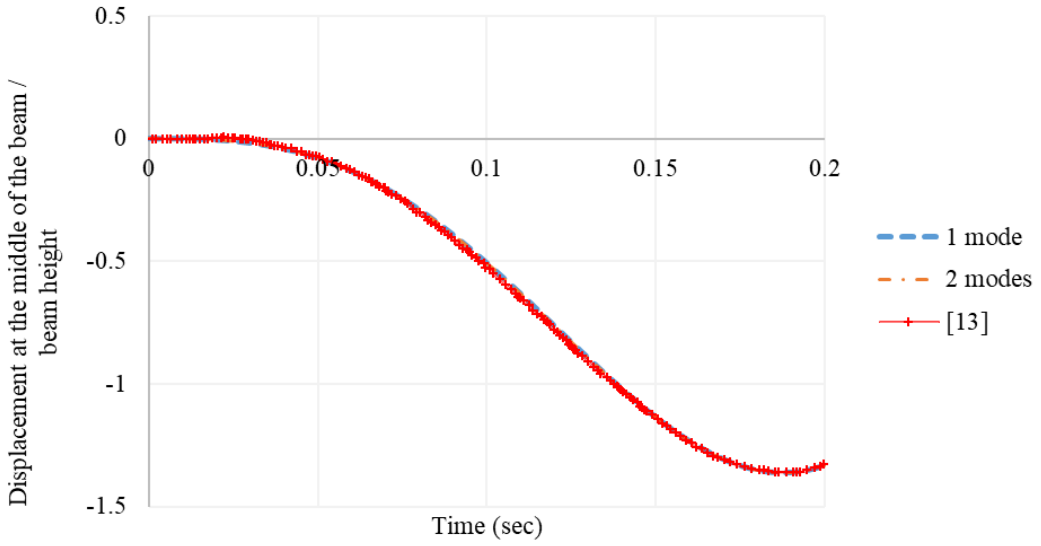

Figure 4: Time-history response of single-span beam model taking v = 20 m/s, P = 100 N

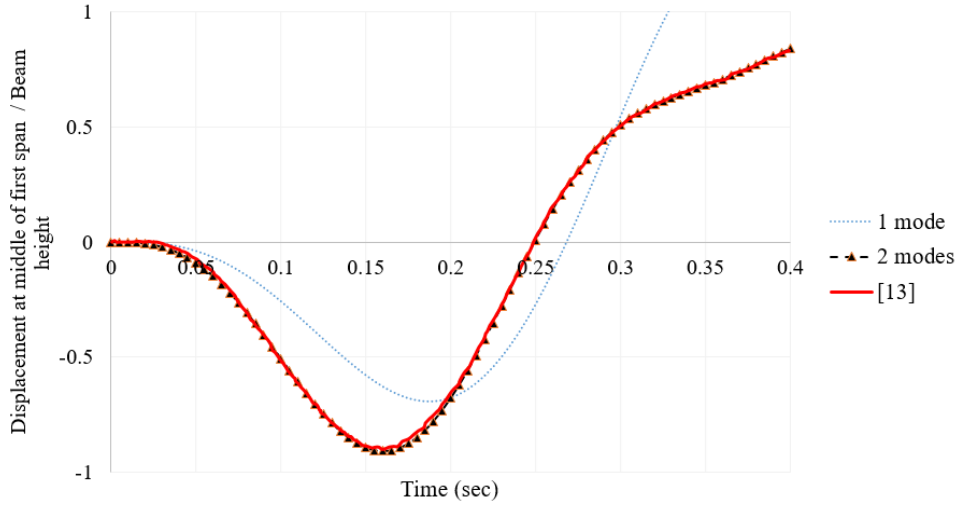

Figure 5: Time-history response of two-span beam model taking v = 20 m/s, P = 100 N

The proposed approach can also be used to calculate the dynamic response of beams under accelerating concentrated loads. Figure 6 shows the displacement time history at the middle of the second span of the four-span beam for an accelerating load. In this case, at least the first four modes need to be taken into account to capture the dynamic time history response of the multi-span beam structure accurately.

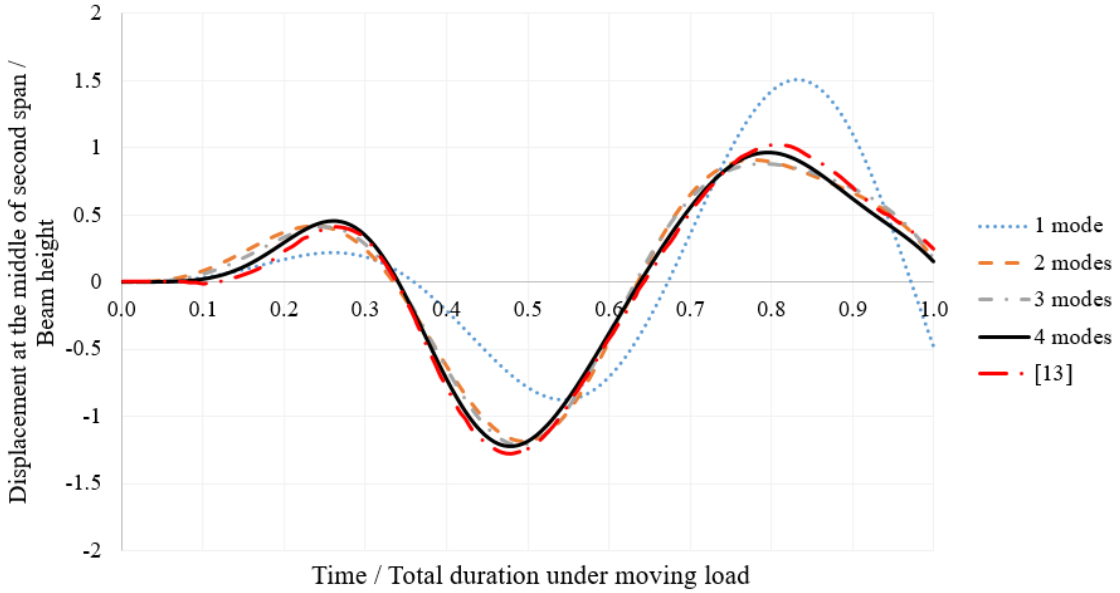

Figure 6: Time-history response of four-span beam model taking v = 20 m/s, a = 10 m/s^2 and P = 100 N

5 CONCLUSIONS

- In this paper, the dynamic stiffness approach, which is based on theoretically exact mode shapes, is combined with Galerkin's method for time-history response analysis of Bernoulli-Euler beams under moving loads. This enables the study of complex beam assemblies under the influence of moving loads in a computationally efficient manner.
- To demonstrate the numerical method, single, two and four-span beam models were considered for free vibration and dynamic response analysis under a concentrated moving load. Moving loads with constant velocity or constant acceleration have been considered.

- The estimation of natural frequencies and mode shapes from the DSM method demonstrate excellent agreement with detailed finite element simulations from the published literature.
- The time-history responses under the influence of moving load also demonstrate excellent agreement. The results show that increasing span number increases the number of modes that should be taken into account to achieve sufficient accuracy.
- The proposed approach is rigorous but simple. It can be easily extended to account for more advanced beam models (considering shear deformability) and geometries (e.g. arch frames) to investigate dynamic amplification in bridges under the influence of moving loads. This requires conducting a DSM analysis and using the identified mode shapes to calculate generalized mass, stiffness and force values to simulate the time history response of the structure.

Abstract. *Ring-like structures are very commonly used in civil, mechanical and aerospace engineering. Typical examples of such structures are components in turbomachinery, compliant gears, conventional pneumatic tires and more recent non-pneumatic tires, to name a few. In this paper, a ring on elastic foundation is considered. The foundation, modelled as distributed springs, connects the inner surface of the ring to an immovable axis. Focus is placed on the in-plane response of the ring subjected to in-plane load only. A high-order ring model, which accounts for the through-thickness variations of displacements is adopted for the study. Two loading situations of a ring structure are of interest in practice: (i) a stationary ring subjected to a circumferentially moving constant load; and (ii) a rotating ring under a stationary constant load. For the first situation, it is well-known that resonances occur when the rotational speeds of the load satisfy certain conditions. In a series of recent investigations, such resonance speeds have been predicted for a rotating ring subjected to a stationary load. In this paper the case of the rotating ring under a stationary constant load and that of a stationary ring subjected to a moving load are compared in terms of their resonance speeds, as well as the steady-state responses for various parameters. It is found that these two cases are distinguishable even for system parameters which result at similar critical speeds.*

1 INTRODUCTION

The in-plane vibration of rings is a classical problem in solid mechanics due to the broad applications of ring-like structures in practice. It is usually the case that the ring and the load acting on it are in relative motion. Two particular situations, namely a stationary ring subjected to a circumferentially moving load (hereafter it is termed as moving load case) and a rotating ring under a stationary load (hefeafter it is termed as rotating ring case) are commonly encountered in engineering. Despite the absence of consensus on the existence of resonances of a rotating ring subjected to a stationary load with constant magnitude [1, 2], a seemingly conclusive result has been obtained in [3] according to which resonance can occur in rotating rings. Modes which are stationary as observed in a space-fixed reference system, are excited by the load [4] when a ring rotates at high speeds, resulting in a steady-state response which is time-invariant to a space-fixed observer. The experimental evidence of such a response is the occurrence of the so-called "standing waves" in rolling tires [5]. Similar wave phenomena have been reported in soft calenders of paper machines [6]. On the contrary, there is no doubt in the literature that resonances of a stationary ring subjected to a circumferentially moving constant load occur when the rotational speeds of the load equal to one of the natural frequencies divided by the corresponding mode number. Investigations of the steady-state responses in such a case can be found in [6, 7].

To what extent the moving load case and the rotating ring situation can be treated as equal is of interest and some deliberations on the topic can be found in the literature. It is concluded in [6] that the effect of rotation is negligible and the rotating ring under stationary load and stationary ring under moving load can be treated as equal. In this work, the steady-state deflection patterns of the ring when the speed of the relative motion is lower and higher than the minimum resonance speed are investigated for both moving load and rotating ring cases. The high-order model adopted from [3] is employed to simulate the in-plane response of rings on elastic foundation in relative motion with a load. The primary aim is to critically study the earlier suggested equivalence between the two cases. The responses of the two cases are compared in terms of their resonance speeds, as well as the steady-state responses for various parameters. It is shown that these two cases need to be distinguished especially when the foundation stiffness is relatively large.

2 HIGH-ORDER RING MODEL

A ring on elastic foundation subjected to a point load is shown in Fig. 1. The ring and the load are in relative motion with Ω_r being the rotating speed of the ring and Ω_p the velocity of the load. The inner surface of the ring is connected to an immovable axis by distributed radial springs k_r and circumferential springs k_c. The in-plane radial and circumferential displacements of the ring are designated by $w(z,\theta,t)$ and $u(z,\theta,t)$. A space-fixed coordinate system (r,θ) is adopted to describe the motions of the ring. It is assumed that the mean radius of the ring is R. An auxiliary coordinate z is introduced as $z = r - R$. The material properties of the ring are: the density ρ, Young's modulus E, shear modulus G, Poisson's ratio ν, Lamé constants λ and μ. The dissipation in the ring material is considered by replacing E by $E^* = E(1 + \zeta \mathrm{d}/\mathrm{d}t)$ in which ζ is a loss factor of the material. In addition, A is the cross-sectional area, I is the cross-sectional moment of inertia, b is the width of the ring. A constant point load $P(t) = P_0$ is applied on the outer surface of the ring.

The high-order model of the ring developed in [3] is employed. Plane strain configuration is assumed for the model. The external load is incorporated in the governing equations by the

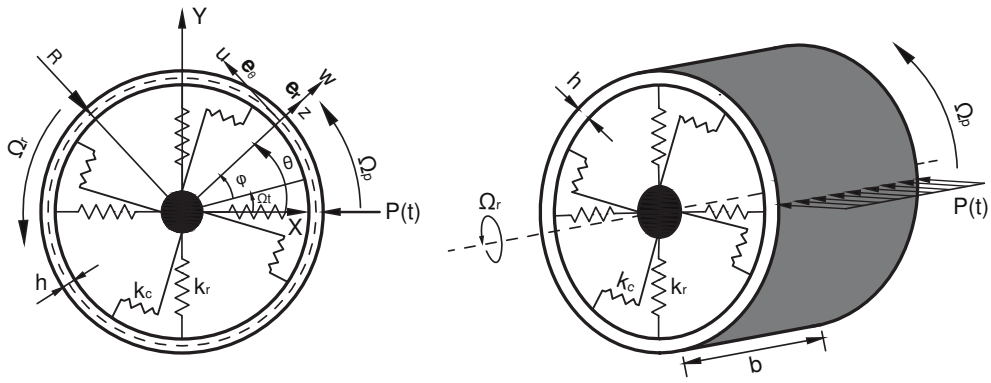

Figure 1: An elastic ring on elastic foundation in relative motion with a point (line) load. Ω_r and Ω_p are the rotational speeds of the ring and the load, respectively: left figure for front view; right figure for side view.

Hamilton's principle. One is referred to [8] for details of the derivation procedure. According to [3], the displacement fields are expressed as polynomial functions of the ring thickness z:

$$w(z,\theta,t) = \sum_{l=0}^{l=N_1} w_l(\theta,t)\, z^l,\; u(z,\theta,t) = \sum_{q=0}^{q=N_2} u_q(\theta,t)\, z^q \tag{1}$$

in which l, q are integers and $l \geq 0$, $q \geq 0$. N_1 and N_2 are the orders of the polynomials of the displacement fields. Assuming a radial point load of constant amplitude is applied on the outer surface of a rotating ring, the equations of motion that govern the small vibrations of the ring around the static equilibrium in the radial direction are:

$$\begin{aligned} &\int_{\frac{-h}{2}}^{\frac{h}{2}} (\mathrm{I}_1^{\mathrm{lin}}\, z^l)\, \mathrm{d}z + \rho \int_{\frac{-h}{2}}^{\frac{h}{2}} \left(r(\dot{v}_1 + \Omega_r\, v_1' - \Omega_r\, v_2) z^l\right) \mathrm{d}z + \left(f_1^{\mathrm{lin}} - f_2^{\mathrm{lin}}(-1)^l\right) \left(\frac{h}{2}\right)^l \\ &= -\left(\frac{h}{2}\right)^l P(t)\delta(\theta) = -\left(\frac{h}{2}\right)^l P_0\, \delta(\theta), \quad (l = 0,1,2,3...N_1). \end{aligned} \tag{2}$$

The dimension of P_0 is N.m^{-1} and δ is the Dirac delta function.

The linearised equations of motion of a rotating ring in the circumferential direction are:

$$\begin{aligned} &\int_{\frac{-h}{2}}^{\frac{h}{2}} (\mathrm{I}_2^{\mathrm{lin}}\, z^q)\, \mathrm{d}z + \rho \int_{\frac{-h}{2}}^{\frac{h}{2}} \left(r(\dot{v}_2 + \Omega_r\, v_2' + \Omega_r\, v_1) z^q\right) \mathrm{d}z + \left(f_3^{\mathrm{lin}} - f_4^{\mathrm{lin}}(-1)^q\right) \left(\frac{h}{2}\right)^q = 0, \\ &(q = 0,1,2,3...N_2). \end{aligned} \tag{3}$$

The details of the governing equations including the expressions for $\mathrm{I}_1^{\mathrm{lin}}$, $\mathrm{I}_2^{\mathrm{lin}}$, $f_1^{\mathrm{lin}} - f_4^{\mathrm{lin}}$ and the velocities v_1 and v_2 of a differential element of the ring in radial and circumferential directions in the left-hand side of Eqs. (2-3) can be found in [8]. For the case of a stationary ring subjected to a circumferentially moving load of constant amplitude, the governing equations can be obtained by setting Ω_r and the static equilibrium to zero on the left side of Eqs. (2-3) and altering $P_0\, \delta(\theta)$ to $P_0\, \delta(\theta - \Omega_p t)$ on the right-hand side of Eq. (2).

The following dimensionless parameters are introduced [3]:

$$k = \sqrt{I/A},\; \bar{k} = k/R,\; \bar{\gamma} = n\,\bar{k},\; \bar{\omega} = \omega\, k/c_0,\; \bar{v}_{(r,p)} = R\,\Omega_{(r,p)}/c_0,\; \bar{k}_{(r,c)} = k_{(r,c)}k^2/(Eh), \tag{4}$$

where $c_0 = \sqrt{E/\rho}$ is the speed of the longitudinal wave in the rod, $I = bh^3/12$ is the cross section area moment of inertia and $\bar{k}$ is the non-dimensional radius of gyration. $\bar{\theta} = \theta/\bar{k}$ and $\tau = c_0 t/k$ are the dimensionless angle and temporal variables, respectively. $\bar{P} = P_0\,\bar{k}/(Eh)$ is the dimensionless load amplitude.

3 MOVING LOAD VERSUS ROTATING RING

The load speeds causing resonance of a stationary ring subjected to a constant point load moving circumferentially are well known [7], namely $\Omega_p = \omega_n/n$ in which n is the circumferential mode number and ω_n is the nth natural frequency of the ring. The minimum resonance speed (the critical speed) is the lowest value of ω_n/n. Resonance speeds of a rotating ring subjected to a stationary constant load satisfy the condition $\bar{\omega}_n = 0$ in which $\bar{\omega}_n$ is the natural frequency calculated in a space-fixed reference system [3]. By substituting $\bar{\omega}_n = 0$ into the frequency equation [3], one can solve for resonance speeds for each circumferential wavenumber.

Theoretically, resonances of the moving load case always exist. However, in practice the load speed can not always reach the resonance speeds, especially for stiff rings since their resonance speeds are high. On the contrary, resonance occurs only for certain parameters of a rotating ring subjected to a stationary load of constant magnitude. Specifically, resonances of a rotating ring may only occur for relatively soft rings. For example; for a ring made of steel, resonance speeds do not exist for the rotating ring case whereas resonance speeds of such a ring for the moving load case do exist but are extremely large. One needs to bear in mind that if a ring is stiff, the responses of the ring for the rotating ring and moving load cases are similar. The reason is that in the operational speed range, the translational rigid-body like motion governs the response in both cases. Thus, only soft rings are considered in this section because resonance speeds exist for such rings for both moving load and rotating ring cases.

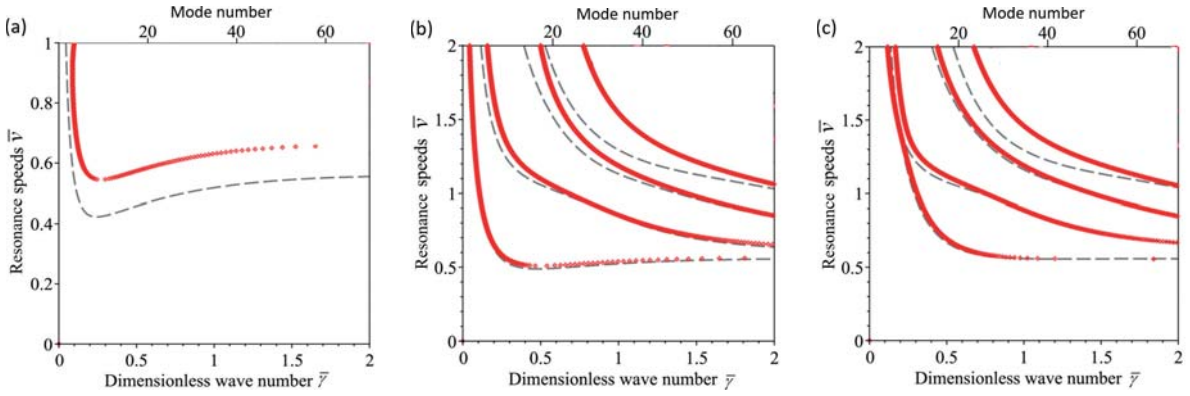

Figure 2: Comparison of resonance speeds, $h/R = 0.1, \bar{k}_c = 0.1$ using the high-order model with increasing stiffness of radial springs. Grey dashed line for moving load case; Red dotted lines for rotating ring case: (a) $\bar{k}_r = 0.001$; (b) $\bar{k}_r = 0.01$; (c) $\bar{k}_r = 0.1$.

3.1 Comparison of resonance speeds between both cases for relatively soft rings

Fig. 2 shows the comparisons of resonance speeds, as functions of the mode number, between moving load and rotating ring case with different values of the foundation stiffness. Since high-order theory is used, there are several curves representing higher order motions of the ring. In the figure, the lower abscissa in each plot is the dimensionless wavenumber, whereas the upper abscissa is the corresponding discrete circumferential mode number n. All the chosen

parameters represent relatively stiff foundation (soft ring) configuration since only in this case resonance speeds of rotating rings exist.

In Fig. 2 the upper limit of the plots is set at $\bar{v} = 1$ and therefore only the lowest branch of resonance speeds is shown. The reason is that at higher speeds, the predictions of other branches are not accurate since the rotation-induced hoop tension is approaching unrealistically high value. Generally, rotation stiffens the ring, therefore, the resonance speeds of rotating rings are larger than those in the moving load case as shown in Fig. 2(a). With increasing $\bar{k}_r$, the resonance speeds for the two lower branches of both cases become close as shown in Figs. 2(b)(c). For the two higher branches of resonance speeds, the differences are still large. The minimum resonance speed in Fig. 2 is a critical speed at which a wave-like steady-state deformation pattern is initiated. For the parameters shown in Figs. 2(b)(c), the critical speed converges to the Rayleigh wave speed with increasing wavenumber and a Rayleigh wave resonance is expected when a stationary constant load is applied [6].

3.2 Steady-state response for soft rings on stiff elastic foundation

The steady-state responses of a ring in relative motion to a constant point load is investigated in this section for a soft ring. The parameters are chosen the same as in Fig. 2(b). For this set of parameters, resonance speeds in the two cases are close, especially for the lower order motion. The dynamic responses are derived using the so-called "method of the images" described in [7, 8].

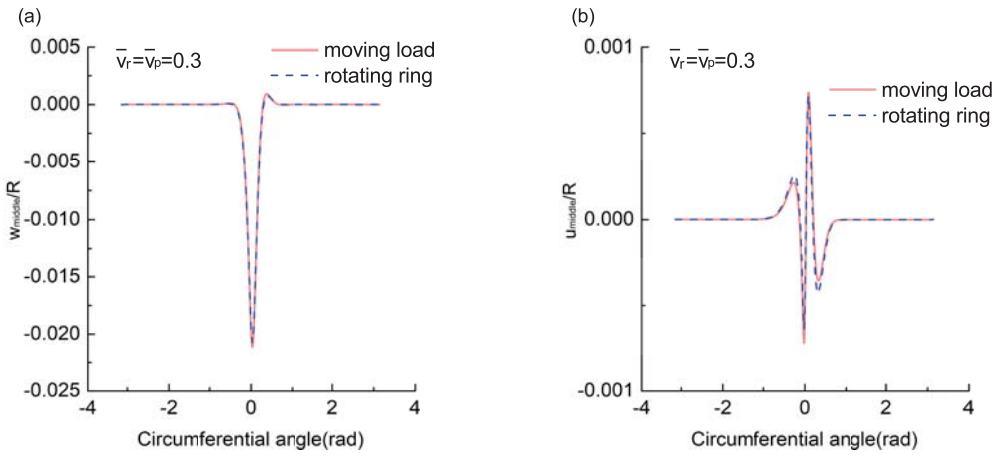

Figure 3: Displacements at the middle surface of the ring for $\bar{v}_r = \bar{v}_p = 0.3$, $\bar{k}_r = 0.01$, $\bar{k}_c = 0.1$, $\zeta = 0.002$, $\bar{P} = 0.002$: (a) Normalised radial displacement; (b) Normalised circumferential displacement.

As shown in Fig. 2(b), the minimum resonance speed in both cases is the same, namely $\bar{v}_{cr} \approx 0.5$. Therefore, two velocities of the relative motion are chosen: $\bar{v}_r = \bar{v}_p = 0.3$ as a sub-critical speed and $\bar{v}_r = \bar{v}_p = 0.7$ as a super-critical one. Fig. 3 shows the displacements (normalized with respect to the ring radius at the middle surface) at the middle surface of the ring for the two cases. It can be seen that the responses are very close. In this case, the stiffening effect due to rotation for the rotating ring case is not obvious. When the speeds increase, for the rotating ring case, the static expansion due to rotation becomes large, resulting in high hoop tension. This tension stiffens the ring, especially it suppresses the radial displacement of the rotating ring comparing to the moving load case as shown in Fig. 4(a) for the super-critical case $\bar{v}_r = \bar{v}_p = 0.7$. However, the stiffening effect is not obvious on the circumferential displacement

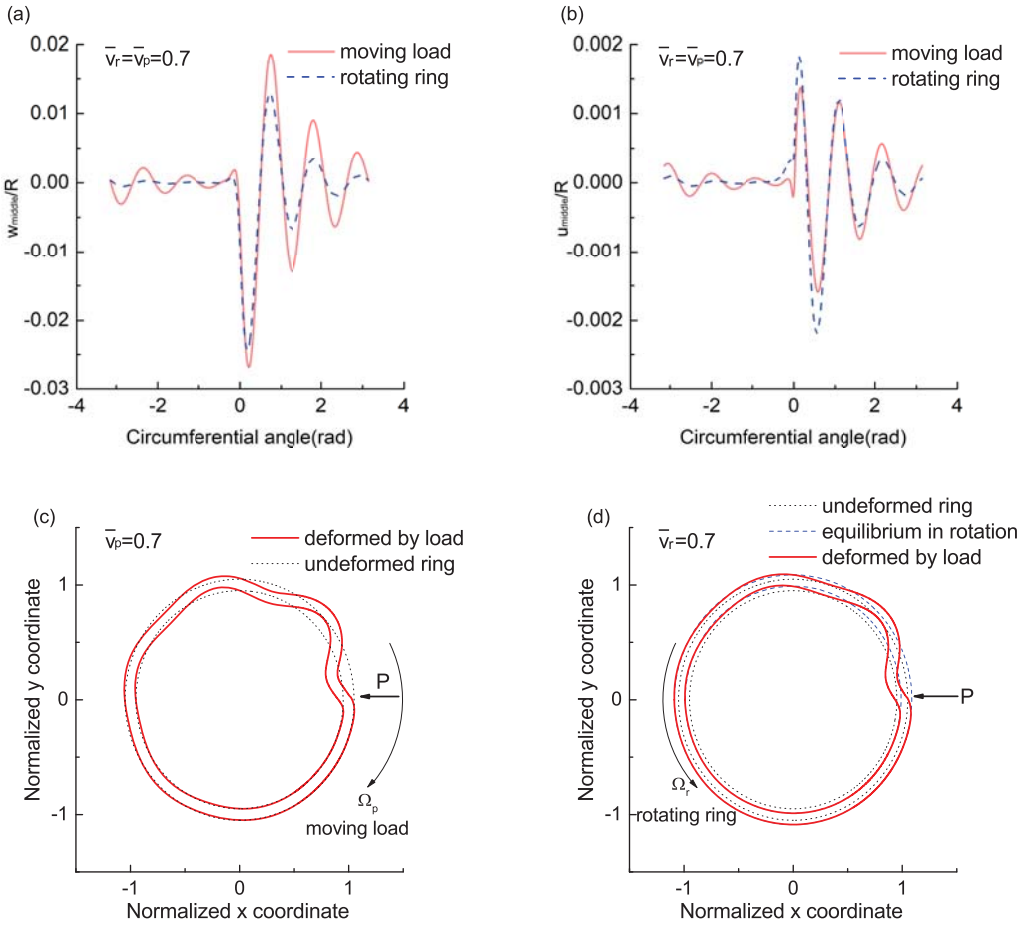

Figure 4: Displacements at the middle surface of the ring for $\bar{v}_r = \bar{v}_p = 0.7$, $\bar{k}_r = 0.01$, $\bar{k}_c = 0.1$, $\zeta = 0.002$, $\bar{P} = 0.002$: (a) Normalized radial displacement; (b) Normalized circumferential displacement; (c) Ring deformation, moving load; (d) Ring deformation, rotating ring. The ring deformations are scaled by 5.

(Fig. 4(b)). In Figs. 4(c)(d), the ring deformations in both cases are illustrated. Besides the different patterns, the rotating ring shows static radial expansion caused by rotation. In addition, the effect of damping is more pronounced in the rotating ring case as the displacements decay fast along the circumference away from the loading point.

3.3 Maximum deflection of the ring versus velocity

The maximum displacement at the middle surface ($D_{\max}$ is defined as $\max\{\sqrt{{w_0}^2+{u_0}^2}\}$ in which w_0 and u_0 are the radial and circumferential displacements at the middle surface, respectively) for a ring with the same parameters as used in section 3.2 is shown in Fig. 5(a). For the chosen parameters, the resonance speeds of both cases are quite similar as shown in Fig. 2(b). However, the responses are different under the same load as shown in Fig. 5(a), especially when the relative speeds between the load and the ring exceed the minimum resonance speed. For rotating ring case, the rotation of the ring stiffens the ring, resulting in smaller responses. In Figs. 5(b) and (c), the maximum middle surface displacements in the radial and circumferential directions are demonstrated, respectively. It can be seen that the responses are mainly governed by the radial motion. To conclude, for the moving load and rotating ring cases which have similar resonance speeds, their responses are in large disagreement at higher speeds of the

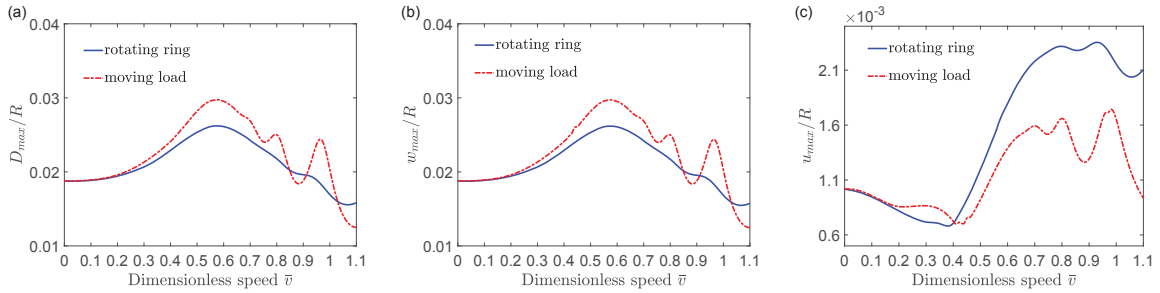

Figure 5: Comparison of maximum deflection at the middle surface versus velocity, $\bar{k}_r = 0.01$, $\bar{k}_c = 0.1$: (a) $D_{\max}$; (b) maximum radial displacement; (c) maximum circumferential displacement.

relative motion between the load and the ring.

4 CONCLUSIONS

The equivalence of the rotating ring under a stationary constant load case and a stationary subjected to a moving constant load case are discussed by comparing their resonance speeds, as well as the steady-state responses. It is found that these two cases need to be distinguished even for system parameters which result in similar critical speeds. The moving load on stationary ring and the rotating ring under stationary load cases can only be considered equivalent when the relative speeds between the ring and the load are low or the responses are mainly governed by the $n = 1$ mode. First, if resonance speeds exist, these can be very different in the two cases under consideration, which will result in different dynamic responses. Second, even for system parameters which result in similar critical speeds, the responses under the same load can be different due to the rotation effects.

Keywords: load identification, rail monitoring, rail strains.

Abstract. *This paper deals with the identification of the weight of a train in motion, based on the measurement of the time-history of the response in terms of strains at the foot of the rail. The direct problem is initially addressed: the response of a rail modelled as a one-dimensional Euler-Bernoulli beam with constant properties, resting on a linear elastic foundation with viscous damping and subjected to a Dirac delta load travelling at constant speed is considered. For the model described, a closed-form expression of the solution can be obtained, which permits to investigate the sensitivity of the response to the main mechanical parameters. Analytical strains are compared to their experimental counterpart, showing their practical ability to describe the real phenomenon. As a second step, the inverse problem consisting in the identification of the loads for a given time-history of measured strains is addressed. The solution of the inverse problem is set up as a minimization problem whose objective function is based on the difference between experimental and model time-histories of strains. This inverse problem is nonlinear, and its solution can be pursued by the Newton method, which requires recursive application of a linearized expression for the evaluation of the optimal parameters. The Bayesian formulation enables to investigate identifiability of parameters and minimum number of measurements, and leads to conclude that the identification process must begin with an improving of the interpretative model. This model updating can be achieved by evaluating the model parameters, using the time-history of a train whose weight is known. After that, the actual identification of the loads can be performed. The procedure proposed is applied to experimental strains recorded at the foot of a rail on a stretch of line run by a locomotor moving at a low constant speed. The identified loads were in good agreement with the expected value, with errors smaller than 4%.*

1 INTRODUCTION

Increased standards of safety in railway transport require awareness of the loads actually travelling on railway lines, in particular when freight trains running. This enables to timely schedule maintenance and monitor rail wear, as well as to check unbalanced loads which can affect vehicle safety, and requires the development of methods for the identification of travelling loads. This paper deals with the identification of the weight of a train in motion, based on the measurement of the time-history of the response in terms of strains at the foot of the rail.

To solve this inverse problem, it is first useful to address the direct problem. Here, the rail is modelled as a one-dimensional Euler-Bernoulli beam with constant geometrical and mechanical properties, resting on a linear elastic foundation with viscous damping and subjected to a Dirac delta load travelling at constant speed. The same model was used in the past to describe the response of rocket test tracks [1] and train tracks [2]. This model has proved its ability to describe the real experimental response and, since it enables obtaining a closed-form solution, it is used here as a reference model, enabling to investigate the response sentitivity to the main mechanical parameters. More complex models involving 2D descriptions of the elastic foundation were also proposed [3], but they seem not suitable for this inverse problem.

On accepting the simplified modelling of the travelling load as a Dirac delta, its identification involves the evaluation of its amplitude only. We approach this inverse problem using an estimator which minimizes the difference between the experimental response and the response provided by the described mechanical model of the rail. An overview of the different approaches presented in the literature for the solution of load identification problems can be found in the work by Ouyang [4]. Among these, it is worth citing the approach proposed by Trujillo and Busby [5], based on dynamic programming, not only the forcing term which provides the best match is sought, but also that which has a certain degree of smoothness according to Tikhonov's regularization. An application of dynamic programming to train load identification is presented by Zhu et al. [7]. Among other possible approaches, Ronasi et al. [6] calculate the minimum of an objective function measuring the distance between experimental and analytical data. In the framework of an algebraic solution, Meli and Pugi [8] made hypotheses to simplify the load time-histories and adopted a multibody model for the railway vehicle. We develop here a load identification procedure within the framework of a Bayesian approach, also addressing problems of optimal choice of parameters and measurements [9, 10, 11]. Based on the results obtained from the investigation of the Fisher matrix, we were able to conclude that the load identification problem can be better formulated in two steps. The first step consists in a model updating performed on the grounds of the knowledge of the response to a known load. The second step is the actual load identification.

Experimental tests were used for validation: they consist of field measurements of the rail strain time-histories due to the transit of a two-axis locomotor at low speed.

2 DIRECT PROBLEM

The rail is represented as a plane beam with constant geometrical and mechanical properties resting on a linearly elastic foundation with viscous damping, and subjected to a Dirac delta load of amplitude P moving at constant speed v. On setting E the Young's modulus of the cross section, I its moment of inertia, the solution to this problem in terms of transverse displacement w as a function of time t and space z can be written in closed form:

$$w(z,t) = \begin{cases} \frac{P}{EI}\left(\frac{e^{(z-vt)k_3}}{(k_3-k_4)(k_3-k_1)(k_3-k_2)} + \frac{e^{(z-vt)k_2}}{(k_2-k_4)(k_2-k_1)(k_2-k_3)}\right) & z \leq 0 \\ -\frac{P}{EI}\left(\frac{e^{(z-vt)k_4}}{(k_4-k_3)(k_4-k_2)(k_4-k_1)} + \frac{e^{(z-vt)k_1}}{(k_1-k_3)(k_1-k_2)(k_4-k_1)}\right) & z > 0. \end{cases} \quad (1)$$

where k_1, k_2, k_3 and k_4 are wavenumbers. The time-history of the response at $z = 0$ for $P = 1$ N resulting from Equation (1) is represented in terms of curvatures $\chi(z,t) = \partial^2 w/\partial z^2$ in Figure 1, for different speeds and damping. Curvature is the observed quantity, since in the experimental tests we will measure the strain at the foot of the rail, which is tied to the curvature by the linear relation $\epsilon = h_G \chi$, valid under the hypothesis of small displacements, with h_G distance between the center of mass of the cross-section and the foot of the rail. Figure 1a shows that, for speeds of 28 km/h, approximately corresponding to 0.1 of the critical speed v_{cr}, the dependence of the maximum amplitude on damping is very limited. The critical speed $v_{cr} = (4kEI/(\rho A)^2)^{1/4}$, with k stiffness of the soil, ρ mass density, and A area of the cross-section, is the lowest speed at which a free wave can propagate in the rail [1]. When the speed increases, the response is no longer symmetric, and the maximum amplitude more and more depends on the train speed (Figure 1b). When the speed equals the critical velocity, a resonance occurs: the maximum response increases and strongly depends on damping (Figure 1c).

Figure 2a shows the analytical time-history of the strains due to a series of ten Dirac loads with P=78400 N, which is approximately the load insisting on one wheel of an unalden ETR324, obtained using Equation 1 for a travelling speed of 28 km/h. Figure 2 b reports, for comparison, the experimental time-history of an ETR324, travelling at around 30 km/h. The pattern of the time-history obtained from the model satisfactorily agrees with the time-history observed experimentally.

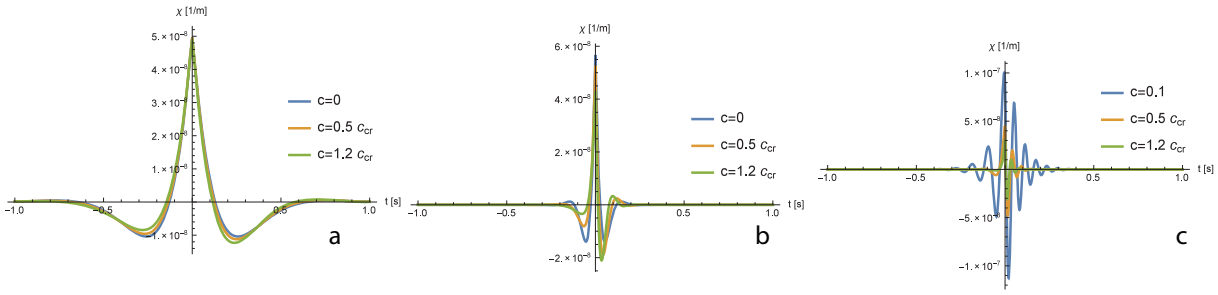

Figure 1: Time-histories of curvatures for different values of damping and speed: 28 km/h=$0.1v_{cr}$ (a), 140 km/h=$0.5v_{cr}$ (b), 280 km/h=v_{cr} (c). $c_{cr} = 2(k\rho A)^{1/2}$

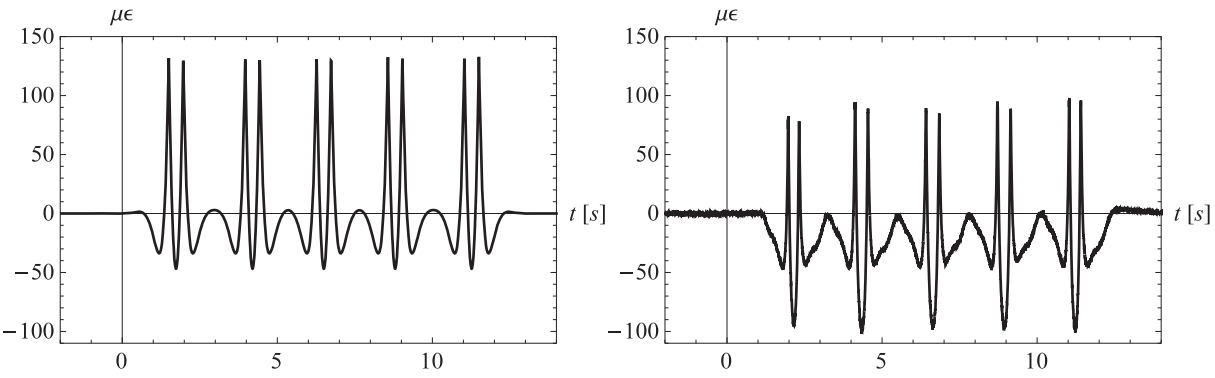
3 INVERSE PROBLEM

The goal of the solution of the inverse problem consists in the identification of the amplitude of the Dirac deltas representing train loads. It must be considered that the model contains several parameters, whose values may be more or less uncertain, and that have an influence on the result of the load identification. Some parameters are mechanical and geometrical characteristics of the model, that is ρA, EI, k, c, while others concern the load: P and v. We will be dealing with recordings made at low speed, therefore we will assume $c = 0$, and, also, that v is known, since it is easily measurable. The vector of unknown parameters will be $\mathbf{x} = \{\rho A, EI, k, P\}^T$.

Let us call $\boldsymbol{\epsilon}(\mathbf{x})$ the vector of observed quantities as a function of the vector of parameters $\mathbf{x}$, and $\mathbf{z}$ the vector of corresponding measured quantities, that is, the time-discretized experimental



a) b)

Figure 2: Analytical (a) and experimental (b) microstrain time-histories of an ETR324.

response at a given location. The vector of observed quantities is an m-element vector $\boldsymbol{\epsilon}(\mathbf{x}) = \{\epsilon_1(\mathbf{x}), ...\epsilon_m(\mathbf{x})\}$, whose i-th element represents the strain at a given abscissa and at the i-th time instant.

Within a Bayesian approach, parameters are random variables, and measured quantities satisfy the relationship

$$\mathbf{z} = \boldsymbol{\epsilon}(\mathbf{x}) + \mathbf{n} \tag{2}$$

where $\mathbf{n}$ is a vector of stochastic noise, independent of $\mathbf{x}$. Assuming a multivariate normal distrubution for $\mathbf{x}$ and $\mathbf{n}$, and being $\mathbf{S_x}$ and $\mathbf{S_n}$ the covariance matrices of the initial estimate of the parameters and of the noise, respectively, the maximum of the probability $p(\mathbf{x}|\mathbf{z})$ is attained for the optimal $\hat{\mathbf{x}}$ of $\mathbf{x}$ which minimizes the objective function:

$$l(\mathbf{x}) = \frac{1}{2}[\mathbf{z} - \boldsymbol{\epsilon}(\mathbf{x})]^T \mathbf{S_n}^{-1}[\mathbf{z} - \boldsymbol{\epsilon}(\mathbf{x})] + \frac{1}{2}(\mathbf{x} - \mathbf{x}_0)^T \mathbf{S_x}^{-1}(\mathbf{x} - \mathbf{x}_0). \tag{3}$$

Assuming that the initial estimate $\mathbf{x}_0$ is not too far from $\hat{\mathbf{x}}$, a linearization of the relationship between observed quantities and parameters provides a recursive formula whose iterative application enables to reach the minimum of the objective function:

$$\hat{\mathbf{x}} = \mathbf{x}_0 + (\mathbf{H}^T \mathbf{S_n}^{-1} \mathbf{H} + \mathbf{S_x}^{-1})^{-1} \mathbf{H}^T \mathbf{S_n}^{-1} (\mathbf{z} - \boldsymbol{\epsilon}(\mathbf{x}_0)), \tag{4}$$

where $\mathbf{H}$ is the sensitivity matrix whose components are $H_{ij} = \partial \epsilon_i / \partial x_j$, and $\mathbf{S} = (\mathbf{H}^T \mathbf{S_n}^{-1} \mathbf{H} + \mathbf{S_x}^{-1})^{-1}$ is the a posteriori covariance matrix. Within this linearized framewok, the Hessian matrix associated to $l(\mathbf{x})$ is $\mathbf{H}_e = \mathbf{H}^T \mathbf{S_n}^{-1} \mathbf{H} + \mathbf{S_x}^{-1}$, whose first term is the Fisher or information matrix $\mathbf{A} = \mathbf{H}^T \mathbf{S_n}^{-1} \mathbf{H}$.

Figure 3a reports the time-history of the change of the curvature for a 10% variation of each of the three model parameters EI, ρA and k. These time-histories are, in practice, the columns of the sensitivity matrix each multiplied by the variation of the related parameter, and divided by h_G. Figure 3a shows that the parameters which play the most important role are EI and k, while ρA has a scarce influence. Identifiability is the actual possibility to determine a single set of optimal parameters $\hat{\mathbf{x}}$ such that the objective function is at a minimum. Some information about it is provided by $\mathbf{H}$, whose rank indicates the maximum number of identifiable parameters: in

our case, the rank of $\mathbf{H}$ is 3, independently of the number of time samples, which are as many as the rows of the sensitivity matrix.

More precise information on the choice of parameters and measurements is provided by the Fisher matrix, which must be invertible for the solution (4) to be calculated. The list of its eigenvalues can put the parameters, or more often, their linear combination, in order of importance. This is displayed by the shape of the eigenvectors, which enables to point out possible coupling between parameters. Observing the eigenvectors of the Fisher matrix, which are reported in Figure 3b, it can finally be concluded that the parameters EI and k are coupled, while ρA is an independent parameter with scarce influence on the response, in fact, it is associated with the smallest eigenvalue and the related eigenvector has only the first component different from zero. In such situation, it seems to be appropriate to obtain the solution of the inverse problem in two steps: first the optimal parameters EI and k are sought using the response to a known load, then the updated model is used to determine the amplitude P, the real unknown of the problem.

The Fisher matrix also provides information on the choice of measurements by means of its Fisher inflow, which is the value of the terms on the principal diagonal as a function of the number of measurements. In fact, on assuming that $\mathbf{S_n}$ is a diagonal matrix, that is the noise is uncorrelated, the terms on the principal diagonal can be written as: $A_{ii} = \sum_k (\sigma_k^4)^{-1} (\partial \epsilon_k / \partial x_i)^2$. Since the summation occurs over the time instants, in the limit of the time instant between two samples tending to zero, it is obtained $A_{ij} = (1/T) \int_0^T (\sigma^4)^{-1} (\partial \epsilon / \partial x_i)^2 dt$, where T is the duration of the phenomenon. The terms on the principal diagonal of the Fisher matrix provide then an approximation of this integral, and tend to stabilize when the sampling frequency is sufficient, indicating that further samples do not provide further information. This is shown in Figure 4 a and b, where also the trace of $\mathbf{A}$ is reported, showing that a number of 40 measurements will provide a stable estimate of the covariance matrix, for our purposes, with a variation smaller than 5% for an increase of the number of measurements.

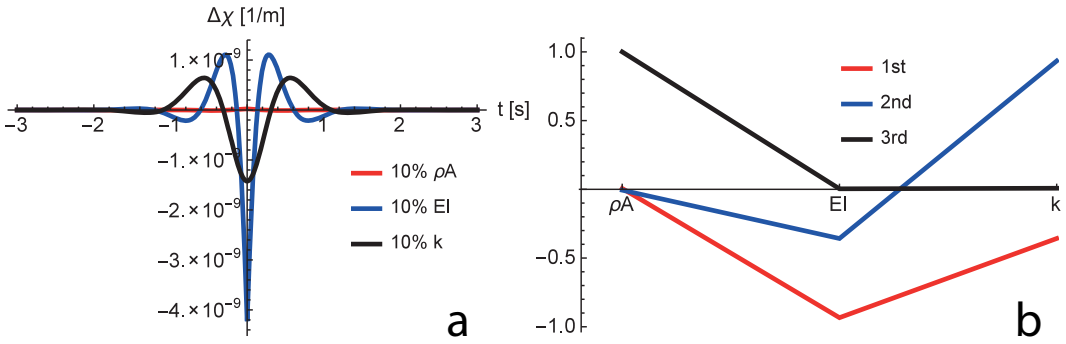


Figure 3: Time-histories of the change of curvature for a 10% variation of mechanical parameters (a) and eigenvalues of the Fisher matrix (b).

As proposed, we proceed to the identification of EI and k using 40 samples of a pseudo-experimental time-history generated by a known load. In the absence of noise and starting from initial parameters with a 30% error, we obtain convergence to the exact values within five iterative applications of Equation 4, according to the Newton method. The objective function is smooth and has a unique minimum, as it is shown in Figure 5. Using the identified parameters, if we proceed to the identification of the load, we obtain the exact value with a single application of Equation (4), in fact, since the dependence of the response on P is linear, Equation (4)

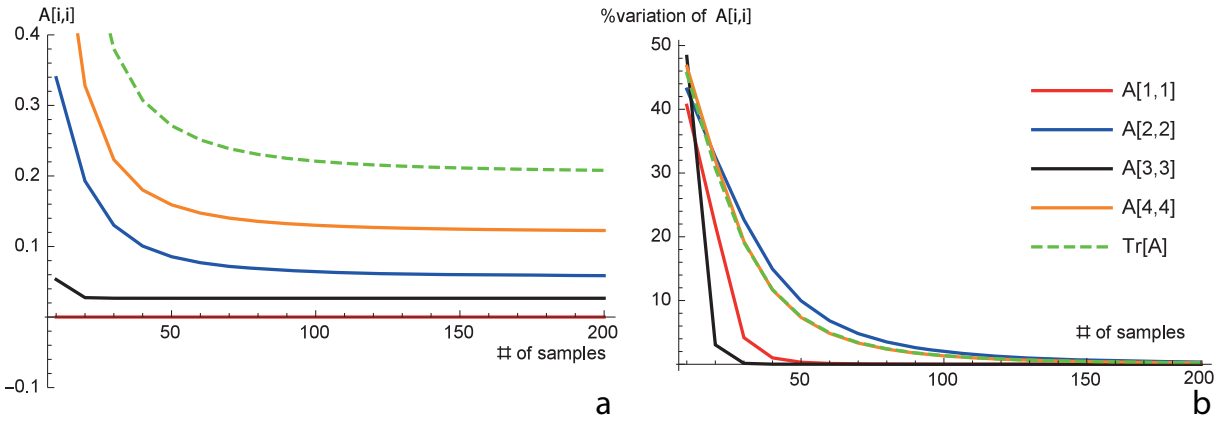

Figure 4: Fisher inflow and trace of the Fisher matrix (a), and % variation of their values (b) as a function of the number of samples.

does not constitute an approximation when the unknown parameter is P. It is instead an exact relationship, which does not requires iterations.

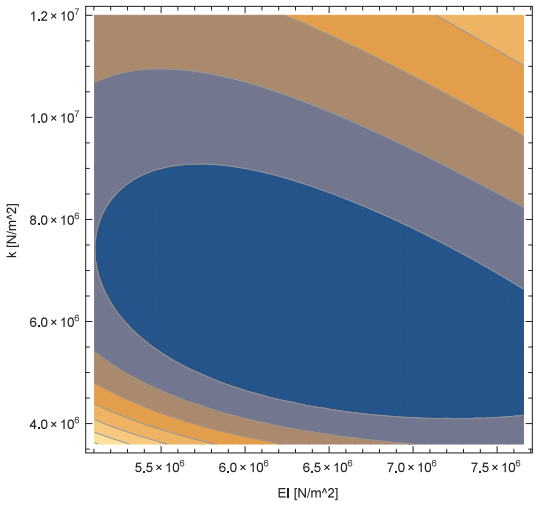

Figure 5: Contourplot of the objective function for pseudo-experimental data in the absence of error.

4 EXPERIMENTAL RESULTS

The procedure proposed is applied to experimental strains recorded at the foot of a rail on a stretch of line run by a locomotor moving at low constant speed. The weight of the locomotor is known and equal to 154.22 kN, so that two time-histories are firstly used to identify the soil stiffness. The resulting objective function is reported in Figure 6a, showing a distinct minimum. Then, a total of 10 locomotor transits with different constant speeds in the range 5-25 km/h were investigated. The updated model was used to identify the loads considered, at this stage, as unknowns, and the resulting identified values are reported in Table 1. These loads are in good agreement with the expected ones, with a mean error of 3.82%. The dispersion of errors, varying from -10.3 to 3.6%, can be ascribed to the simple interpretative model and to the the fact that experimental measurements were performed on one rail only, disregarding possible unbalance of the load. Figure 6b shows the comparison between the experimental time-histories of strains and those obtained from the updated model and the identified loads.

transit	1	2	3	4	5
weight	154.68	144.29	138.28	155.35	154.44
error [%]	0.3	-6.4	-10.3	0.7	0.14
transit	6	7	8	9	10
weight	155.46	144.63	157.71	142.73	159.73
error [%]	0.8	-6.2	2.3	-7.5	3.6

5 CONCLUSIONS

- We applied an approach for the identification of travelling loads of freight trains based on the minimization of the difference between the experimental time-history of strains at the base of the rail and their analytical counterpart. The model describing the response is a one-dimensional Euler-Bernoulli beam resting on a linearly elastic soil. The load is modelled as a Dirac delta load travelling at constant speed, whose amplitude is unknown and is the final goal of the identification procedure.

- As a result of a sensitivity analysis, among the model parameters, the soil and the beam stiffness resulted to be the most relevant, while damping was proved to be not significant for an appropriate description of the response in range of speeds away from the critical value. The procedure of identification is then performed in two steps, first updating the model using the response to a known load, then identifying the intensity of travelling loads.

- Experimental field tests were performed, in which the strains at the foot of the rail due to the transit of a locomotor at low speed were recorded. Making reference to the known loads, the model was updated by identifying the optimal value of the soil stiffness and, afterwards, used as interpretative model to identify the weight of the locomotor, now assumed as unknown. The loads were then identified with satisfactory accuracy, with a mean error smaller than 4%.

6 ACKNOWLEDGEMENTS

The authors would like to thank the company Ace System for collaboration in performing the experimental tests. This work was partially funded by PRIN 2015.

Keywords: Railway bridge, high-speed train, bogie wheelbase, train spectrum.

Abstract. *This paper deals with the dynamic response of railway bridges traversed by articulated trains, specifically the interaction effect between the coach length D and bogie distance d_{BA}. Current design code EN 1991-2 stipulate that the ratio D/d_{BA} should not be close to an integer value, but no further guidance is given. By using train signatures and a so-called bogie factor, the combined effect is illustrated in a non-dimensional domain. The results are also presented by realistic examples which show that integer ratios of D/d_{BA} are not necessarily worse than non-integer ratios. This is further confirmed by a parametric study of simply supported beams and ranges of train parameters according to EN 1991-2 Annex E.*

1 INTRODUCTION

Excessive vibrations may occur in railway bridges if the load frequency coincides with the natural frequency of the bridge. In the design of railway bridges, especially on high-speed lines, the dynamic response is analysed using a set of universal trains, named as HSLM in EN 1991-2 [1]. These train load models were developed within ERRI D214.2/RP6 [2] and should also cover ranges for different real trains, as defined in EN 1991-2 Annex E. Excessive vibrations are likely to occur at resonance, where the load frequency depends on the axle spacings or any of its integer multiples.

This paper focus specifically on the articulated train (AT) with *jacobs bogies*, where the coach length D and bogie distance d_{BA} are the main parameters. In EN 1991-2 Annex E it is stipulated that D/d_{BA} should not be close to an integer value. No further guidance is given on how close to an integer value such ratio is allowed, or how to assess its effect. The main aim of this study is therefore to explore the interaction effect between D and d_{BA} in terms of the resulting dynamic response. This is done by a parametric study of simply supported bridges and a non-dimensional approach based on train signatures and a so-called bogie factor, further explained in this paper.

2 MOTIVATION OF THE RESEARCH

A typical example is presented first, in order to motivate the reasons for this investigation. Let a theoretical simply supported (S-S) railway bridge have first natural frequency $n_0 = 7.0\,\mathrm{Hz}$, which is a usual value for spans between some 12.5 and $30\,\mathrm{m}$. Consider also an AT (see Figure 1) with characteristic distances $D = 18\,\mathrm{m}$ (carriage length) and $d_{BA} = b = 3\,\mathrm{m}$ (bogie wheelbase) travelling over the bridge. For the moment, the presence of the power cars (1) in Figure 1 is ignored, and it is admitted that all passenger coaches of type (2) and (3) have the same distances D and b. These hypotheses allow one to focus on the possible resonant coupling caused by integer values of the D/b ratio.

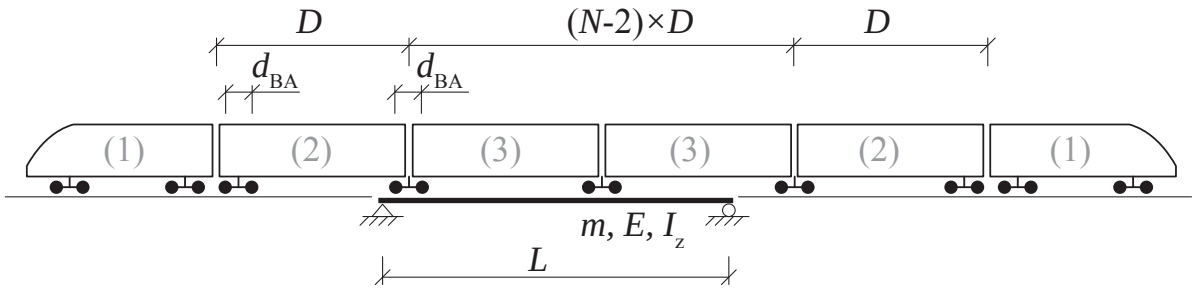

Figure 1: Articulated train passing over a S-S bridge.

Any mode of vibration of the bridge that is excited by the passing train will remain in *free vibration* once the train has left the bridge. The passage of each axle load generates such kind of free vibrations, that will accumulate with the free vibrations generated by the subsequent passing loads, in a way that may lead to (i) resonance in the case of in-phase addition, (ii) cancellation if the addition is in counter-phase, or (iii) addition to some intermediate degree in the rest of cases. If damping were absent, which is only possible from a theoretical point of view, resonance and cancellation phenomena would be ideally perfect for axle loads of equal

intensity adding in-phase or counter-phase, respectively. All these aspects were dealt with in depth in previous research works [3].

The relevance of an eventual integer value of D/b is apparent: in a two-axle bogie, if the vibrations of the second axle add in phase with those of the first axle, this means that the time interval b/V, where V is the speed of the train, is an integer multiple of the period T of the vibration mode of interest. For the fundamental mode, this entails

$$b/V = n/n_0 \qquad n = 1, 2, 3, \ldots \tag{1}$$

In equation (1) $n = 1$ is referred to as the *first bogie resonance*, while for $n = 2, 3, \ldots$ one speaks of *second resonance*, *third resonance*, etc. With the values presented above, one gets

$$V_{n=1} = \frac{b\, n_0}{1} = \frac{3 \cdot 7}{1} = 21\,\mathrm{m/s} = 75.6\,\mathrm{km/h} \tag{2}$$

It is apparent that for speeds equal to integer fractions of $75.6\,\mathrm{km/h}$, one will get the second, third, etc. resonances of the bogie. Because of damping, the amplitude of the resulting vibration from each of them will decrease as n increases. Moreover, speeds around $75.6\,\mathrm{km/h}$ are nowadays considered low speeds, and particular bridge vibration problems are not expected in regular operation of railway vehicles at such speeds.

In the sample case presented here, when the first resonance of the bogie takes place, then also a *sixth* resonance of the carriage takes place, because, in a way analogous to equation (2), one has, for characteristic distance $D = 18\,\mathrm{m}$:

$$V_{n=6} = \frac{D\, n_0}{6} = \frac{(6 \cdot 3) \cdot 7}{6} = 21\,\mathrm{m/s} = 75.6\,\mathrm{km/h} \tag{3}$$

Of course, if damping were high enough, such *sixth sub-harmonic* of the carriage resonance would have little effect, but it should also be born in mind that damping can be higher or lower depending on the bridge type and condition.

For free vibrations to accumulate, cancellation of the vibration mode (for each axle) must not take place [4], [3]. Therefore, the nondimensional speed K must be different from $1/(2i+1)$ if the bridge is S-S, of span equal to L. Integer i is referred to as the *order of the cancellation of the influence line*, since it yields the order of the corresponding zeros of the free vibration amplitude response (see figure 2 in reference [3]). Consequently, the condition to be verified to avoid cancellation is as follows:

$$K = \frac{V}{2n_0 L} \neq \frac{1}{2i+1} \quad i = 1, 2, \ldots \tag{4}$$

With the reference data employed above, cancellation would happen at $75.6\,\mathrm{km/h}$ for the spans listed in Table 1. So, one can select a span equal to $L = 15\,\mathrm{m}$ and be sure that is neatly far from cancellation, and indeed very close to a point of maximum free vibration. In such case, the addition of successive axle loads will lead to a *maximum resonance* phenomenon (see section 4 in reference [3]).

Figure 2 shows the response of the above described bridge under the circulation of a series of $2k = 20$ loads, arranged in $k = 10$ equidistant bogies with two loads $P = 170\,\mathrm{kN}$ in each bogie. The linear mass of the bridge is set to $m = 12\,\mathrm{t/m}$, which is a realistic value for a concrete, single-track, beam bridge of $15\,\mathrm{m}$ span, and damping ratio is $\zeta = 1.0\%$. Damping

i	1	2	3	4	5	6	7
$L(\mathrm{m})$	4.5	7.5	10.5	13.5	16.5	19.5	22.5

Table 1: Span lengths for i-th cancellation of the 1^{st} mode at $75.6\,\mathrm{km/h}$ in a S-S bridge with $n_0 = 7.0\,\mathrm{Hz}$.

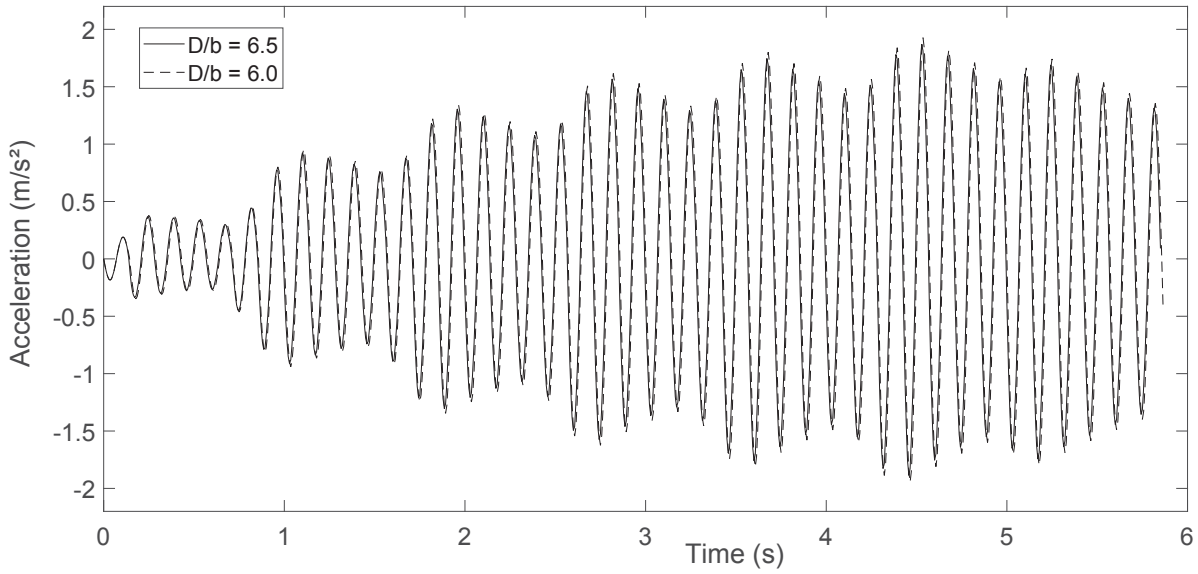

Figure 2: Time-history response of a S-S bridge under a sequence of 10 equidistant, two-axle bogies with $D = 18\,\mathrm{m}$, and $P = 170\,\mathrm{kN}$. $L = 15\,\mathrm{m}$, $n_0 = 7.0\,\mathrm{Hz}$, $m = 12\,\mathrm{t/m}$, $\zeta = 1.0\%$. $b = 3\,\mathrm{m}$ for the dashed line; $b = 2.769\,\mathrm{m}$ for the solid line.

should probably be somewhat higher for a bridge of such span, but the vibration effects will be better illustrated with the selected value.

Figure 2 shows a response that is clearly resonant, with six cycles between maximum peaks as expected from equation (3). Two time series are displayed: the dashed line corresponds to a slightly higher response, obtained with $b = 3\,\mathrm{m}$, so that $D/b = 6.0$; conversely, the solid line has been obtained with $b = 2.769\,\mathrm{m}$, which leads to $D/b = 6.5$. It should be noticed that in the latter case, the $D/b = 6.5$ ratio is *as far as possible* from being integer, but still the observed resonant response is almost identical in both cases. So the following question arises: From the point of view of bridge vibrations, is it reasonable to consider that ATs where $D/b = D/d_{BA}$ is close to integer are more critical than others? This question is dealt with in greater detail in the following sections.

3 NONDIMENSIONAL APPROACH BASED ON TRAIN SIGNATURE AND BOGIE FACTOR

3.1 Signature of a set of equidistant loads

Based on superposition of effects in linear regime, in reference [2] the following approach was presented for the computation of the acceleration level in a S-S bridge due to the passage of a train:

$$a_{max} = \Gamma_{max}(mL, \zeta, K) \cdot G(F_i, d_i, \lambda, \zeta) \tag{5}$$

where the term $G(F_i, d_i, \lambda, \zeta)$ is the *signature* or *train spectrum* for a series of loads F_i with spacing d_i measured from the first load ($d_1 = 0$). The wavelength $\lambda = VT$, where T is the period of the vibration mode, and $\Gamma_{max}(mL, \zeta, K)$ is the influence line for the fundamental mode of a S-S bridge. Because the influence line will vary between different types of structures, it is convenient to keep it as a separate factor, as in equation (5). In so doing, one can concentrate in the values of the signature; those values depend only on damping and the train type for each wavelength. Plots as a function of wavelength will then provide a quick view of the phenomena involved.

In reference [5], a new expression of the signature is presented for a group of k equidistant, unit loads:

$$\begin{aligned} G_E(k, \Lambda, \zeta) &= k \qquad \text{if } \zeta = 0 \text{ and } \Lambda = 1, 1/2, 1/3, ...\text{(resonance)} \\ G_E(k, \Lambda, \zeta) &= \sqrt{\frac{\sigma^{2(1-k)} f_k(\sigma, \Lambda)}{f_1(\sigma, \Lambda)}} \qquad \text{otherwise.} \end{aligned} \tag{6}$$

where

$$\begin{aligned} f_k(\sigma, \Lambda) &= (1 + \sigma^{2k} - 2\sigma^k \cos(2k\pi/\Lambda)) \\ \sigma &= e^{\zeta 2\pi/\Lambda} \geq 1 \\ \Lambda &= \lambda/D = VT/D \end{aligned}$$

and $f_1 = f_k(k = 1)$. Such expression can be computed very efficiently because it neither involves summations of out-of-phase loads, nor it involves taking the maximum among *subtrains* as prescribed in [2]. Conversely, it has the disadvantage that the power cars are not taken into account. The nondimensional wavelength Λ represents the fraction of D travelled in one period of the free vibration.

In order to get the complete signature for a series of carriages supported on bogies as it is usual in an AT, one has to multiply the signature given in equation (6) by the *bogie factor* or bogie spectrum. This factor is also introduced as a function of a nondimensional wavelength in reference [5], as explained next.

3.2 Bogie factor

The bogie factor is a multiplying function that can vary in the interval $[0, 2]$, and provides an exact, equivalent amplitude of the effect of two consecutive loads separated by distance $b = d_{BA}$. The equivalence is established in terms of the addition of the free vibrations created by each of the two loads, when they pass over a flexible structure at speed V:

$$\begin{aligned} f_B(\mu, \zeta) &= \sqrt{1 + e^{-\zeta 4\pi/\mu} + 2e^{-\zeta 2\pi/\mu} \cos(2\pi/\mu)} \\ \mu &= \lambda/b = VT/b \end{aligned} \tag{7}$$

In the same way that $\Lambda = 1/n_D = 1, 1/2, 1/3, ..$ implies resonance or sub-resonance or order n_D associated to distance D (carriage resonance), $\mu = 1/n_b = 1, 1/2, 1/3, ..$ implies resonance or sub-resonance of order n_b associated to distance b (bogie resonance). Also, when $\mu = 2, 2/3, 2/5, ..$ bogie cancellation occurs. Conversely, above $\mu = 2.0$, $f_B \to 2.0$ monotonically, in a way similar to the signature in equation (6), which tends to kF when $\Lambda \to \infty$ (F is the value of the constant axle loads different from unity).

In case of bogie resonance, integer ratios $D/b = l$ would lead to

$$\Lambda = \frac{VT}{D} = \frac{VT}{b} \cdot \frac{b}{D} = \frac{1}{n_b} \cdot \frac{1}{l} = \frac{1}{n_D} \tag{8}$$

As it is apparent, $n_D = n_b \times l$ is integer and (higher order) resonance of the carriage would also be induced. For this reason, the D/b integer ratios may initially be considered more aggressive, as explained in previous section.

3.3 Combined effect of signature and bogie factor

The signature or spectrum of a set of k two-axle bogies of constant loads F can be obtained exactly by multiplication of F times equations (6) and (7). Such signature will represent the vibration coupling of a series of carriages of an AT, where the power cars are neglected and all carriages are assumed to have constant length D. Therefore, the main coupling phenomenon between D and b can be analysed at once.

The signature can be suitably plot as a function of Λ and μ. In such approach it is convenient to realise that any constant ratio $\eta = D/b$, will lead to a inclined line in the $[\Lambda, \mu]$ plane, since

$$\mu = \frac{VT}{b} = \frac{VT}{D} \cdot \frac{D}{b} = \Lambda \cdot \eta \tag{9}$$

Therefore, in log-log axis the lines corresponding to constant η ratios will appear as inclined parallel lines, as shown in Figure 3. The upper limits in Figure 3 are set by considering that $n_0 = 7.0\,\mathrm{Hz}$, $V_{\text{max}} = 350\,\mathrm{km/h}$, $D_{\text{min}} = 18\,\mathrm{m}$ and $b_{\text{min}} = 2.5\,\mathrm{m}$, which are all usual values for high-speed articulated trains. Damping has been neglected, which leads to maximum values of the spectrum equal to 20, since the number of unit loads in the trainset is $2k = 20$.

In Figure 3 the three inclined lines correspond to $\eta = D/b$ equal to $5.5, 6.0$ and 6.5. It is seen that the critical point (where $\Lambda = 1/6$ and $\mu = 1$) reaches a maximum amplitude of 20 for $D/b = 6.0$, but the amplitudes for $D/b = 5.5$ and $D/b = 6.5$ are very similar. This is the theoretical explanation to the very small difference in the amplitude of vibrations levels displayed in Figure 2.

The peak response in Figure 2 can be also analysed for a wider range of speeds, as it is shown in Figure 4, where sub-resonances of the carriage are visible for $n_D = 2$ at $226.8\,\mathrm{km/h}$ to $n_D = 8$ at $56.7\,\mathrm{km/h}$, except for $n_D = 3$ that cancels exactly (indeed it cancels *twice*: $i = 2$ in equation 4, and also $\mu = 2$).

All predictions from Figure 3 are confirmed in Figure 4. The highest peak for the sixth sub-resonance corresponds to $D/b = 6$, while the other two curves give very similar response in this case, even if they are as far as possible from being integer. Besides, the peaks for the eighth, seventh and second sub-resonances are higher for $D/b = 6.5$, while the peaks for the fourth and third sub-resonances are higher for $D/b = 5.5$.

The conclusions of the studies presented in this section are generalised next for a wide ensemble of S-S bridges and articulated trains that cover the vast majority of cases of interest.

4 PARAMETRIC STUDIES

4.1 Hypotheses and methods

In order to confirm that integer values of D/b are not necessarily more aggressive than non-integers as regards the coupling of carriage-induced and bogie-induced vibrations, a comprehensive parametric study has been carried out with the following characteristics.

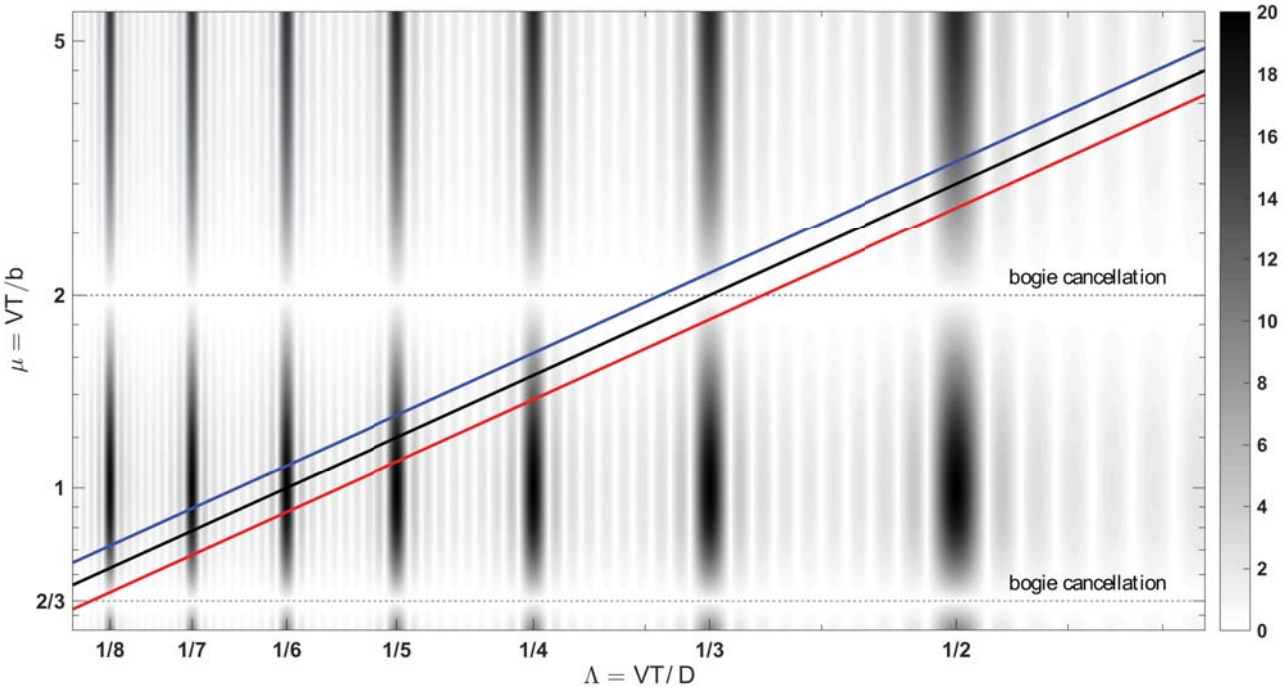

Figure 3: Signature of a sequence of $k = 10$ equidistant, two-axle bogies of unit loads (log-log axis). Red, black and blue lines correspond to $\eta = D/b$ equal to 5.5, 6.0 and 6.5, respectively.

Prestressed bridges of S-S type on rigid supports are analysed under sequences of $(10-1) = 9$ carriages supported on equidistant bogies. Therefore, $k = 10$ as in Figure 4 and each train has 20 constant, concentrated loads travelling at a constant speed V.

According to Table 2, the carriage length D is varied in a discrete manner from $18\,\mathrm{m}$ to $27\,\mathrm{m}$ in steps of $0.5\,\mathrm{m}$, in line with the limits in Annex E from EN1991-2 [1]. Providing that the bogie wheelbase b is limited to the interval $[2.5\,\mathrm{m}, 3.5\,\mathrm{m}]$ as stated also in Annex E from [1], the number of combinations of D and b that can produce integer ratios is limited to 51 different cases. Such cases are shown in Table 2, particularly in the two columns headed by symbol b; the integer $D/b = l$ value for each case is also shown in the corresponding row.

Also in Table 2, 51×2 bogie wheelbases are gathered where D/b is as far as possible from being integer. For instance, in the first row of the table, $D/b = l = 6$ for $D = 18\,\mathrm{m}$ corresponds to $b = 3\,\mathrm{m}$, while $b^- = 3.273\,\mathrm{m}$ corresponds to a smaller ratio $D/b = 6 - 0.5 = 5.5$. Analogously, $b^+ = 2.769\,\mathrm{m}$ corresponds to a larger ratio $D/b = 6 + 0.5 = 6.5$.

It can be seen in Table 2 that some of the values of b^- and b^+ lie outside the interval $[2.5\,\mathrm{m}, 3.5\,\mathrm{m}]$, but such interval is never exceeded by more than $9\,\%$, so the values in the table can be deemed acceptable for the purpose of this study.

Spans from $L = 5\,\mathrm{m}$ and $L = 30\,\mathrm{m}$ have been analysed under the action of such 51×3 trains, and the response under the trains with integer D/b values (column b) has been compared with the one due to the trains with non-integer D/b values (columns b^- and b^+). Damping values for the prestressed bridges have been selected according to [1]. Clearly, the possible carriage-bogie resonant coupling situation would take place for $n_D = n_b \times l$, as explained from equation (8) in section 3.2. In such case, the *resonance order for the carriage* (*length*) is a multiple of the *resonance order for the bogie* (*wheelbase*).

If the speeds involved were to be close to $200\,\mathrm{km/h}$ or higher, which is the usual range

Table 2: Definition of 51×3 ATs for the parametric study.

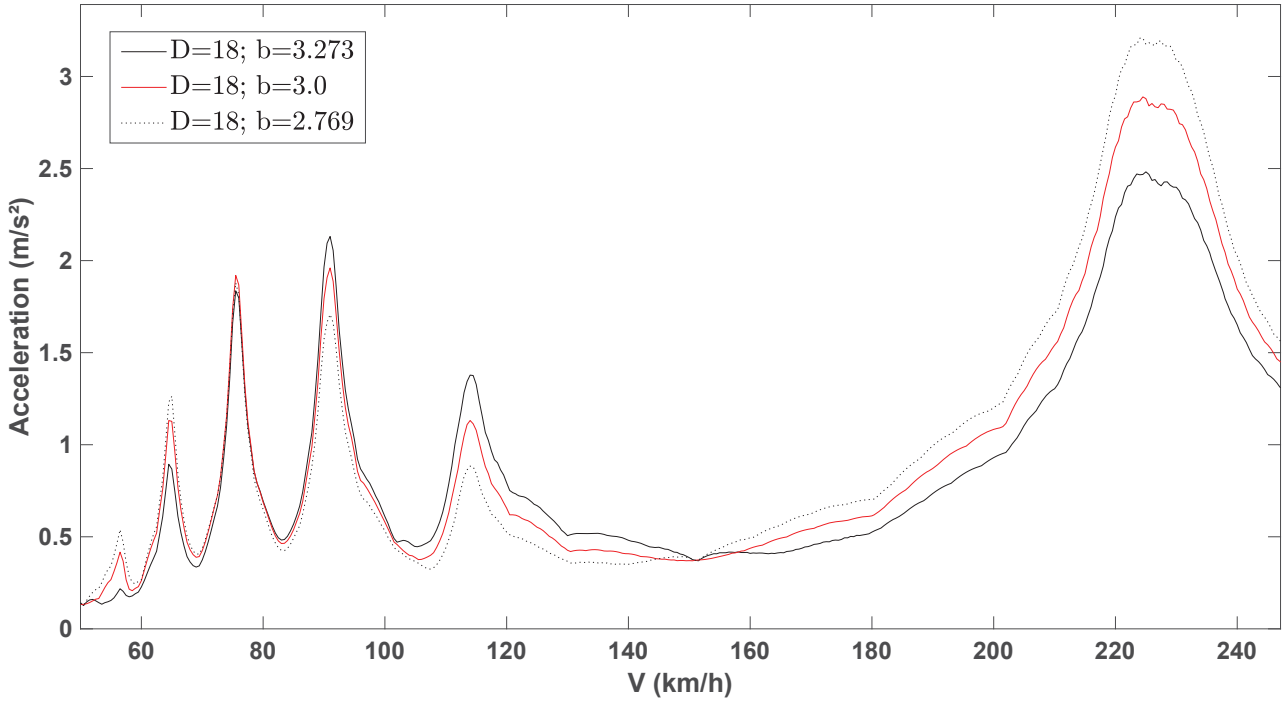

Figure 4: Acceleration envelope for a sequence of $k = 10$ equidistant, two-axle bogies of $F = 170\,\mathrm{kN}$. Values of b corresponding to $\eta = D/b$ equal to $5.5, 6.0$ and 6.5.

for dynamic analysis, $n_b \geq 2$ would correspond to very stiff elements and/or higher modes of frequencies above some $30\,\mathrm{Hz}$, for $b \in [2.5\,\mathrm{m}, 3.5\,\mathrm{m}]$. Moreover, $n_b \geq 3$ would correspond to frequencies above $45\,\mathrm{Hz}$, approximately. These are not the cases of main interest for the present study, which is focussed in the behaviour of principal structural elements. With such perspective, and given that for speeds lower than $200\,\mathrm{km/h}$ vibrations have traditionally not been considered a key concern in railway bridges [6], such cases will be left out of this study; accordingly, the resonance order of the bogie will be limited to $n_b = 1$. However, a closer nondimensional analysis such as the one presented in Figure 3 reveals that the conclusions for $n_b = 1$ and $n_b = 2$ are very similar.

Because resonance is a consequence of the addition of free vibrations, for a relevant resonant peak to occur the speeds of the trains must be carefully chosen in order to avoid cancellations of the influence line, as prescribed by equation 4. Therefore, the values of nondimensional speed $K = \hat{K}_i$ selected for the analysis can be taken as the average ones for every two consecutive cancellations, *i.e.*:

$$\hat{K}_i = \frac{V}{2n_0 L} = 0.5\left(\frac{1}{2i+1} + \frac{1}{2i+3}\right) \quad i = 1, 2, \ldots \tag{10}$$

Equation (10) yields nearly maximum free vibrations for each speed range between cancellations. In addition to those values $\hat{K}_i$, also one extra point has been selected above the first cancellation, named as $\hat{K}_1^m = 0.386$ in reference [3]. Only the fundamental mode of vibration has been considered, since the addition of free vibrations for every mode obeys the same physical rules that the addition for the fundamental mode. As for the integration of the equations of motion, Duhamel's integral has been used throughout.

From previous considerations, it is clear that each train with a $D/b = l$ integer ratio will

present maximum response when $n_D = n_b \times l = 1 \times D/b$. Consequently, the sub-resonances for $\Lambda = 1/n_D = b/D$ from Table 2 are the ones to be analysed. This objective has been accomplished by selecting 41 different, equally spaced speed values between $\Lambda = 1/(n_D + 0.5)$ and $\Lambda = 1/(n_D - 0.5)$, which captures the resonant peak with the required precision.

The frequency of the bridges has been taken from the lower bound of the frequency band in section 6.4.4 from [1]. This only entails that the nominal speed depends linearly on such frequency for the analyses, but it does not affects the spans involved.

The spans are selected to avoid resonance, by using the values $\hat{K}_i$ obtained previously. Because sub-harmonic n_D is the mid-point of the speed range for each analysis, then $V_{target} = n_0\, D/n_D$ is such mid-point. Given the definition of K, it is straightforward to obtain the associated span for each possible $\hat{K}_i$, which should lie within the range $L \in [5\,\mathrm{m}, 30\,\mathrm{m}]$, or is otherwise discarded. This procedure follows the concept of the maximum resonance described in section 4 of reference [3]:

$$L = \frac{D}{2\,\hat{K}_i\, n_D} \tag{11}$$

A total of 442 spans can be derived from the procedure explained above, which cover in a nearly continuous fashion the full range $L \in [5\,\mathrm{m}, 30\,\mathrm{m}]$, with very few minor exceptions that stem from the discretisation procedure adopted in the different ranges of parameters.

4.2 Results and discussion

Figures 5 and 6 summarise some of the main results of the parametric study. In each figure, the horizontal axes are merely counters of the number of different speeds (41) and number of different spans (442). The vertical axis shows the normalised maximum acceleration for every speed, obtained from time-histories of accelerations similar to the one in Figure 2.

The normalisation procedure is as follows. First, the analyses for wheelbase b corresponding to $D/b = l$ integer ratios are run and, for each span L_k, the maximum resonance acceleration is computed ($a^b_{max}(L_k)$, where $k = 1, 2, \ldots 442$). Then, the response envelope for span L_k is divided by $a^b_{max}(L_k)$ and represented in Figure 5; therefore, the maximum value of all curves for every span in Figure 5 is equal to unity. Since the response values at minimum and maximum speeds display variations among different spans that render the plot too jagged, the spans have been rearranged with a view to give an appearance as smooth as possible.

Second, the analyses for wheelbase b^- corresponding to $D/b = l - 1/2$ non-integer ratios are run and, for each span L_k, the maximum resonance acceleration is normalised against the value $a^b_{max}(L_k)$ previously computed. In such way, the maxima of the curves for every span in Figure 6 are not equal to unity, but only slightly smaller. This phenomenon was previously demonstrated to happen for a particular case in Figure 4 (sixth sub-resonance).

From Figures 5 and 6 the comparison of maximum response values for each span has been carried out. In so doing, the conclusion is that the largest observed difference is $4.2\,\%$, which is caused by the difference between b and b^-. A similar comparison has also been carried out among the results corresponding to b and b^+, which produces a largest difference of $3.2\,\%$.

In conclusion, the parametric study conducted here shows that the peak response of sequences of equidistant bogies where D is a multiple of b is not significantly larger than for sequences of bogies where the ratio D/b is as far as possible from being integer, when the first resonance case of the bogie n_b is considered.

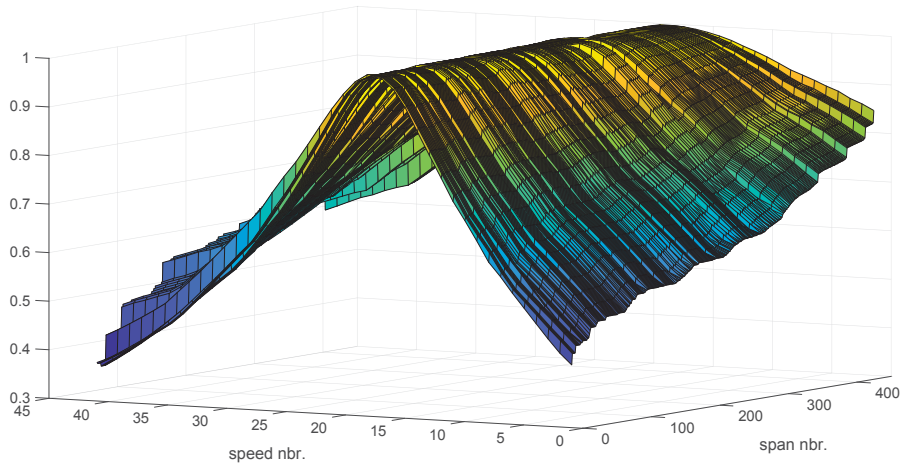

Figure 5: Envelope of maximum normalised accelerations for wheelbase b, corresponding to $D/b = l$ integer ratios.

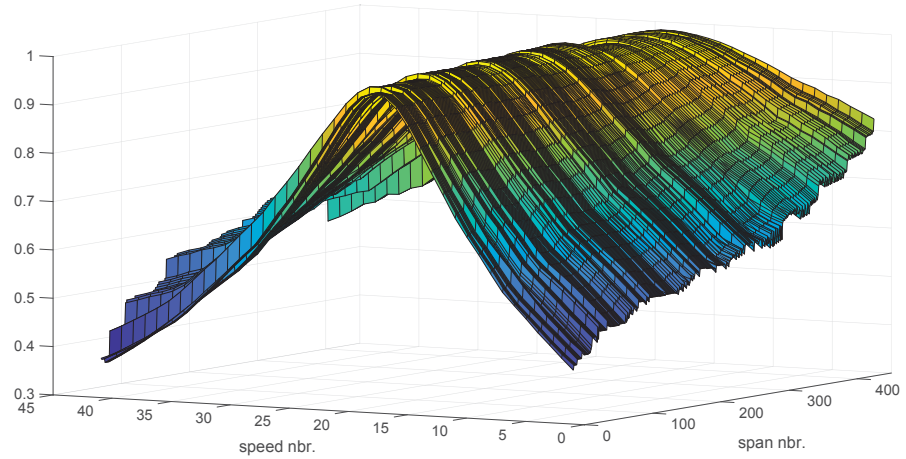

Figure 6: Envelope of maximum normalised accelerations for wheelbase b^-, corresponding to $D/b = l - 1/2$ non-integer ratios.

5 CONCLUSIONS

The coupled resonance effect of sequences of equidistant *Jacobs bogies* has been analysed in this article. The following conclusions can be drawn from the analyses carried out in this research work:

- The addition of the free vibrations created by series of $2k$ constant loads arranged in two-axle bogies that travel through a flexible structure can be carried out in an exact manner, by means of the multiplication of the signature (or spectrum) of a series of k equidistant loads times the signature of the bogie (*bogie factor*). Closed-form expressions for such signatures are summarised in this paper, and were either introduced or discussed in previous works [5].

- The multiplication of the signature of a series of k equidistant loads times the bogie factor yields the signature of an *articulated train* (power cars are neglected). Such signature can be represented in two-dimensional contour plots as a function of normalised wavelengths.

- The two-dimensional signature of the articulated train shows that the response of a train where the ratio between carriage length D and bogie wheelbase b is an integer value l is critical for sub-resonance order $1/l$, in case of first resonance of the bogie wheelbase.

- Both from a theoretical perspective as well as from a comprehensive parametric study, it has been shown that actual articulated trains (as described in Annex E from EN 1991-2) are not significantly more critical when D/b takes integer values than if such ratio is non-integer. This situation has been examined thoroughly for the first resonance of the bogie wheelbase.

- A closer analysis to the two-dimensional signature of the articulated train demonstrates that the preceding conclusions are also valid for the second resonance of the bogie wheelbase, which takes place at half the speed of the first one.

6 ACKNOWLEDGEMENTS

This research was partially developed during a stay performed by Pedro Museros at the *KTH Royal Institute of Technology*, within the Division of Structural Engineering and Bridges (Stockholm, Sweden). The financial support of the *Generalitat Valenciana*, through the program BEST2019 for research stays (*Subvenciones para estancias de personal investigador doctor en centros de investigación radicados fuera de la Comunitat Valenciana*), as well as the permission obtained from the *Universitat Politècnica de València* to carry out such stay, are gratefully acknowledged.

Keywords: Moving masses, foundation with partial shear resistance, unsteady solution, semi-analytical methods, dynamic amplification due to proximity

Abstract. *In this paper, analysis of vibrations induced by proximate moving masses traversing a beam supported by a finite-depth foundation with partial shear resistance is presented. This model is simple enough to be handled by semi-analytical approaches and has a counterpart in modal expansion, which is suitable for finite beams [1]. The model can acceptably approximate vibrations recorded experimentally as shown in [2] and provides results sufficiently close to the ones obtained on more sophisticated models [3].*

The semi-analytical analysis is based on developments related to massless foundation presented in [4-7]. The method is extended, and additional aspect of dynamic amplification due to the proximity of moving masses are included. Final solution is presented in convenient form where most terms are analytical, and thus can be easily evaluated. This form also clearly identifies each part contribution. Main part of the solution is harmonic, composed from steady and unsteady parts of the solution. The unsteady part needs identification of induced frequencies. These frequencies are also important indicators of the onset of instability of the moving masses. Generally insignificant transient part of the solution has to be obtained numerically.

The possibility of analysing same situation on finite beams is very important for results validation. In addition, because it is easy to determine vibration modes for beams with abrupt change in foundation stiffness, this additional feature can also be analysed.

The main new contribution of this paper is detailed analysis of dynamic amplification effects due to masses proximity and conclusion that, as far as the instability is concerned, its onset is not influenced by increasing number of masses.

1 INTRODUCTION

In recent years, due to increased computational power, there is a tendency to overlook analytical and semi-analytical solutions, despite their inherent and undoubtable advantages. Nevertheless, at the same time, this computational facility also amplified possibility of symbolic and high-precision calculation with adaptable number of digits precision. This way, after numerical identification of exact values of some key parameters, final results can be presented as closed-form formulas, evaluable in places of interest without the full-time history, and without the necessity of testing discretization parameters ensuring the results convergence.

The aim of this contribution is to fill the gap in available semi-analytical solutions related to wave propagation induced by moving loads, with practical applications of high-speed rails. Many works over the years were directed to moving force problems with a beam as a guiding structure, placed on simplified foundation models. However, when there is no inertia in the moving system, then there is a lack of dynamic interaction and important issues like instability of the moving object are completely hidden. Either inertia is considered in the supporting structure or not, in case of longitudinally homogeneous structure the solution related to moving force with constant velocity rapidly achieves its steady-state form. In case of linearity, superposition is possible.

When inertia is added to the moving object, the problem becomes inherently non-linear and therefore the question of proximate moving objects is relevant and important from a practical point of view. There are several published works on similar subjects, but the question of proximity is rarely considered.

In [7], some preliminary results related to the effect of proximity of two moving masses travelling over an infinite beam supported by a two-parameter visco-elastic foundation are presented. It was concluded that is it possible to define two limiting distances between the masses, identifying an interval for which full solution is strictly necessary. For higher distances, i.e. when masses are sufficiently apart, the error introduced by results superposition is negligible; while when masses are very close to each other, it would be better to replace the two masses by one single doubled mass. It was also concluded that these limiting distances can be determined from analysis of induced frequencies and the corresponding amplitudes. In addition, it was shown that the instability region is not affected in an undamped case and the onset of instability occurs exactly at the critical velocity, as for one moving mass.

In [2] it was proven that the classical critical velocity related to moving force on an infinite beam is not realistic. It was also shown that quite satisfactory foundation model can be obtained by considering finite depth foundation with partial shear resistance. Then the critical velocity is determined as a function of the mass ratio defined as square root of the ratio of the beam mass over the dynamically activated foundation mass. Such simplified model gives quite a good approximation of the full more sophisticated models as shown in [3].

It is therefore interesting to see how the preliminary conclusions from [7] will be affected by more realistic foundation model. In Section 2 the model under consideration is described. Some indications about the way how the semi-analytical solution is obtained are given in Section 3. Numerical results are presented in Section 4 and the paper is concluded in Section 5.

2 MODEL SPECIFICATIONS

In this paper it is assumed that a homogeneous beam is placed either on massless two-parameter visco-elastic foundation or on a foundation with finite depth and partial shear resistance under plan strain condition. The beam is subjected to two moving masses, acted on by constant force with harmonic component each. Both masses are moving at a constant velocity and the contact between the beam and each mass is rigid. The influence of the distance

between these masses is subject of analysis. The model is depicted in Figure 1. Part a) is showing the massless foundation and part b) the foundation with finite depth.

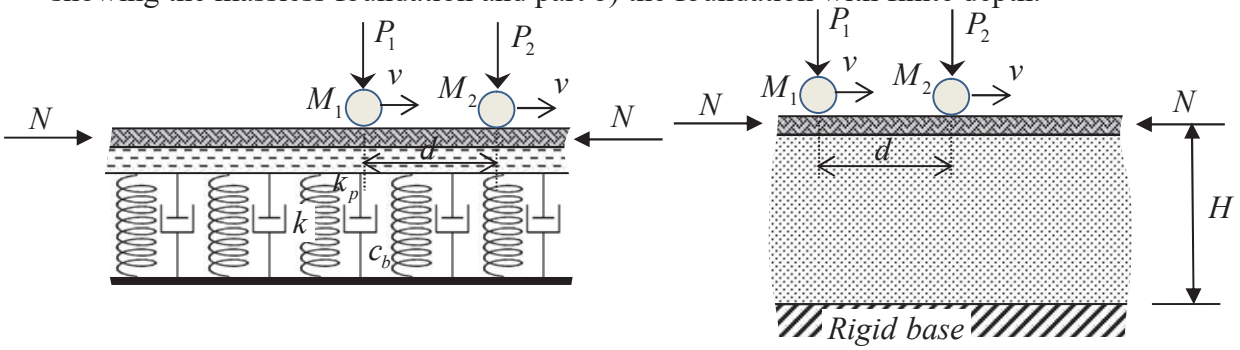

Figure 1: The model under consideration with supporting medium as: a) massless two parameter visco-elastic foundation; b) finite-depth foundation with partial shear resistance under plane strain condition.

It is further assumed that at zero time the beam is at rest and all deflections are measured from static position of the involved parts, excluding from further analysis beam and foundation weight. As the problem has applications in railways, the moving force acting on the point mass may not be coincident with the mass weight. The beam will be treated according to the Euler-Bernoulli theory. Foundation model, as described in [1-3], corresponds to a foundation strip of a finite width b and a finite depth H under plane strain condition and with neglected horizontal displacements, however, the shear resistance is included in its simplified form by the part of the shear stress coming from vertical displacements. This means that in finite element models, the foundation can be modelled by plane strain continuum without horizontal displacements.

3 GOVERNING EQUATIONS AND THE SOLUTION METHOD

The solution method follows the previous publications by this author. The governing equation for determination of the beam deflection field $w(x,t)$ reads:

$$EIw_{,xxxx}(x,t)+Nw_{,xx}(x,t)+mw_{,tt}(x,t)+c_b w_{,t}(x,t)+p(x,t)=F(x,t) \tag{1}$$

where EI, m, and N stand for the bending stiffness and mass per unit length of the beam, and a normal force acting on the beam normal axis. c_b is the coefficient of viscous damping, $p(x,t)$ is the foundation pressure and $F(x,t)$ is the loading term. x is spatial coordinate and t is the time. Derivatives are designated by the respective variable in subscript position, preceded by a comma. The foundation pressure in case of two parameter foundation is given by

$$p(x,t)=kw(x,t)-k_p w_{,xx}(x,t) \tag{2}$$

where k and k_p are Winkler's and Pasternak's moduli of the foundation. In case of foundation of finite depth, dynamic equilibrium in the vertical direction of the foundation has to be solved to determine the foundation pressure. In such a case

$$(\lambda+2\mu)u_{z,zz}(x,z,t)+\mu u_{z,xx}(x,z,t)=\rho u_{z,tt}(x,z,t) \tag{3}$$

where $u_z(x,z,t)$ is the vertical displacement field in the foundation and z is the vertical downward oriented spatial coordinate. Further:

$$\lambda=\lambda_0(1+c_f\bullet_{,t}),\ \mu=\mu_0(1+c_f\bullet_{,t}) \tag{4}$$

where c_f is the coefficient of viscous damping of the foundation and λ_0, μ_0 are basic values of Lame's constants. After determination of the displacement field, using also the boundary condition that states zero displacement at the bottom of the foundation depth and the interface condition establishing that the beam deflection is equal to the soil deflection on the top, foundation pressure is calculated from basic equation of elasticity.

The loading term is in both cases reads:

$$\begin{aligned} F(x,t) &= \left(P_{1c} + P_{1a}\sin\left(\omega_{f1}t + \varphi_{f1}\right) - M_1 w_{01,tt}(t)\right)\delta(x - x_1) \\ &+ \left(P_{2c} + P_{2a}\sin\left(\omega_{f2}t + \varphi_{f2}\right) - M_2 w_{02,tt}(t)\right)\delta(x - x_2) \end{aligned} \tag{5}$$

where, according to Figure 1, M_1 and M_2 are the rear and front mases, respectively, and

$$P_1 = P_{1c} + P_{1a}\sin\left(\omega_{f1}t + \varphi_{f1}\right),\ P_2 = P_{2c} + P_{2a}\sin\left(\omega_{f2}t + \varphi_{f2}\right) \tag{6}$$

P_{1c}, P_{2c} designate the constant forces; P_{1a}, P_{2a} are the amplitudes of the harmonic components, ω_{f1}, ω_{f2} are forced frequencies and φ_{f1}, φ_{f2} are phases of the harmonic terms. δ is the Dirac delta function, marking location of the load at positions x_1 and x_2. As rigid contact is assumed, then

$$w_{01}(t) = w(x_1,t) = w(vt,t),\ w_{02}(t) = w(x_2,t) = w(d + vt,t) \tag{7}$$

For proper problem statement, initial conditions must also be stated. It is assumed for the beam that

$$w(x,t)\big|_{t=0} = 0,\ w_{,t}(x,t)\big|_{t=0} = 0 \quad \forall x \tag{8}$$

and also, for the foundation that at zero time there are no initial displacements or velocities in the full domain. Boundary conditions are defined as

$$w(x,t) = 0,\ w_{,x}(x,t) \quad \forall t, x \to \pm\infty \tag{9}$$

It will be important to validate the final solution with solution on finite beams. In such a case, the boundary conditions must be altered. The advantage of the foundation model with finite depth specified above is that it can be conveniently represented on finite beams by separation in vibration modes, as shown in [1]. This is particularly advantageous, because in moving inertial object problems, where the supporting structure is composed of a beam on a foundation, there is an intimate connection between finite and infinite beams. Therefore, results obtained on finite beams are very good approximation of the infinite scenario, as already demonstrated in [4-7]. For finite beams it is necessary to start actuation of the load further from the initial support, to eliminate its influence. This also means that the most convenient supports can be used. These are undoubtably simple supports due to analytical version of the vibration modes described by numerically stable sine function without involvement of hyperbolic ones. Then the boundary conditions are

$$w(x,t)\big|_{x=0} = 0,\ w_{,xx}(x,t)\big|_{x=0} = 0,\ w(x,t)\big|_{x=L} = 0,\ w_{,xx}(x,t)\big|_{x=L} = 0 \quad \forall t \tag{10}$$

where L is the beam length.

Basic steps to be followed to obtain for solution on finite beams are presented in [1, 7]. In [7] construction of time dependent matrices is given. In [1] is it explained and proven how to determine vibration modes and how to define the orthogonality condition for the case of foundation with finite depth. The loading term is the same as for the massless foundation.

Disadvantage of the solution on finite beams is that quite a high number of modes must be used for good approximation of the results, which is particularly aggravated in the case of finite-depth foundation. Due to the moving inertial terms, equations in modal space are coupled, which makes the numerical solution of the modal coordinate computationally demanding. Nevertheless, it is possible to reorganize the terms in governing time-dependent matrices in a way that the computational effort is significantly reduced. The advantage of solution on finite beams is that it inherently includes all parts of the solution from the very beginning, therefore vibration patterns are not reduced directly to the steady-state solution as would result from the double Fourier transform. This way it forms convenient form for validation of infinite beams, where vibration patterns are considered also from the very start.

Solution on finite beams is conveniently rescaled to dimensionless parameters, which have same base for both types of foundations due to the possibility of introduction of an equivalent Winkler constant for the finite-depth foundation

$$k=\frac{\left(\lambda_0+2\mu_0\right)b}{H},\ \chi=\sqrt[4]{\frac{k}{4EI}},\ w_{st}=\frac{P\chi}{2k},\ v_{cr}=\sqrt[4]{\frac{4kEI}{m^2}}=\frac{1}{\chi}\sqrt{\frac{k}{m}} \tag{11}$$

Further in Eq. (11): χ is the inverse of the characteristic length, w_{st} is the maximum static displacement exhibited by the beam under constant still force P when the beam is supported by Winkler foundation characterized by modulus k. v_{cr} is the critical velocity related to the same case, but with the force moving by constant velocity. These values can be used to define dimensionless velocity α, time τ, spatial coordinate ξ and displacement, respectively

$$\alpha=\frac{v}{v_{cr}},\ \tau=\chi v_{cr}t=t\sqrt{\frac{k}{m}},\ \xi=\chi x,\ \widehat{w}=\frac{w}{w_{st}} \tag{12}$$

It is useful to remark that α=1 does not necessarily mean critical velocity of the problem, because even for massless foundation, the true critical velocity of the problem depends on the effect of the normal force and Pasternak's modulus, and in the case of foundation with finite depth, the critical velocity depends also on the mass ratio R

$$R=\sqrt{\frac{\rho bH}{m}} \tag{13}$$

where ρ is the soil density.

Basic steps for solution on infinite beams follow [1,4-6]. It is convenient to introduce the moving coordinate, and then in Eq. (12), instead of fixed coordinate x, r=x-vt is used. Final solution is presented as a sum of the steady-state solution, the unsteady harmonic solution and the transient vibration. As in previous works, the transient part can be mostly disregarded and affects the solution in initial times to force the full solution to match the initial conditions.

Main equation that determines the induced frequencies necessary for the unsteady part is

$$\left(\pi-2\eta_{M_1}q^2K\left(0,q\right)\right)\left(\pi-2\eta_{M_2}q^2K\left(0,q\right)\right)-4\eta_{M_1}\eta_{M_2}q^4K\left(\widehat{d},q\right)K\left(-\widehat{d},q\right)=0 \tag{14}$$

where q is the unknown complex induced frequency and $\widehat{d}=d\chi$ is the dimensionless distance between the masses. Further in Eq. (14):

$$K\left(\xi,q\right)=\int_{-\infty}^{\infty}\frac{\mathrm{e}^{\mathrm{i}\xi p}\mathrm{d}p}{D\left(p,q\right)},\ \eta_{M_1}=\frac{M_1\chi}{m},\ \eta_{M_2}=\frac{M_2\chi}{m} \tag{15}$$

Polynomial expression from Eq. (15) is given by

$$D(p,q) = p^4 - 4p^2\left(\eta_N - \eta_S + \alpha^2\right) - 4q^2 + 8\alpha pq + 8\mathrm{i}\,\eta_b\left(q - \alpha p\right) + 4 \tag{16}$$

for massless foundation. For foundation with finite depth the formulation is the same, only the effect of Pasternak modulus is removed, and the last number 4 is replaced by

$$4\eta_d \bar{C}_f / \tan\left(\bar{C}_f / \eta_d\right) \tag{17}$$

Formulations for other parameters can be consulted in previous author's works.

4 EXAMPLES

In this section, vibrations induced by two masses of equal value acted on by constant forces of equal value and without harmonic component are analysed. At first, a case with massless foundation is shown. As an example, the case with input data given in [4], where it is designated as Case 1, is used. In Figure 2 deflections of the contact point are plotted with respect to the dimensionless time. It is assumed that the masses are distanced by $\widehat{d} = 2\chi$.

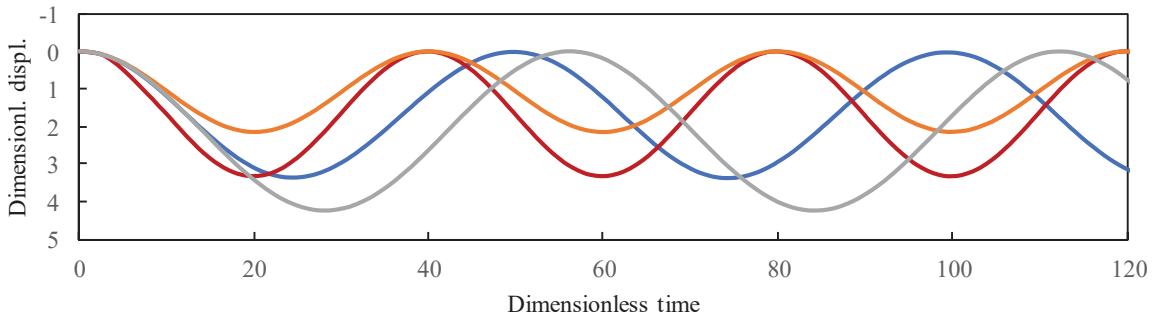

Figure 2: Deflections of the contact point of the rear mass with respect to dimensionless time for massless foundation (orange: one moving mass, grey: solution for doubled force and mass, red: approximate solution obtained by superposition, blue: correct solution).

The results in Figure 2 clearly show that, in case of proximate masses, superposition cannot be used. It is seen that the red line, which corresponds to the results superposition, is quite deviated from the blue one. Moreover, it exhibits the same frequency as one single mass. Full solution represented by the blue line is getting closer to the grey one obtained for the doubled mass and force with decreasing distance between the masses. It is important to remark that for the sake of comparison same static displacement as of one single force is used to scale the grey line results, because it was also used for the other results.

Next case is related to foundation with finite depth, mass ratio R=2 is selected. Results presented were obtained on finite beams. For the sake of simplicity, the number of foundation modes was reduced to one. For the correct solution more modes should be used, nevertheless, the general tendencies are the same. At first, foundation with no shear resistance is examined. This means that the foundation acts as a set of closely located columns with no mutual interaction. This is similar to Winkler's foundation, but here, mass inertia of the foundation is activated in the vertical direction. In Figures 3-5 deflection of the contact point is plotted for both masses, orange curve is for the front mass and the blue one for the rear mass. Effect of distance between mases is analyzed. In the first case, shown in Figure 3, the distance is very low. Both deflections are very similar and with almost steady amplitude. In Figure 4, deflections look like there were out of phase and thus the amplitude is also almost steady. Nevertheless, when the distance between the masses is between these two values, like in Figure 5, it is

seen that the dynamic interaction is affecting the amplitudes; firstly the rear mass is dominant, then the front mass is dominant and then they switch their roles again. Such dynamic interaction is very strong and can be deduced from the values of the induced frequencies.

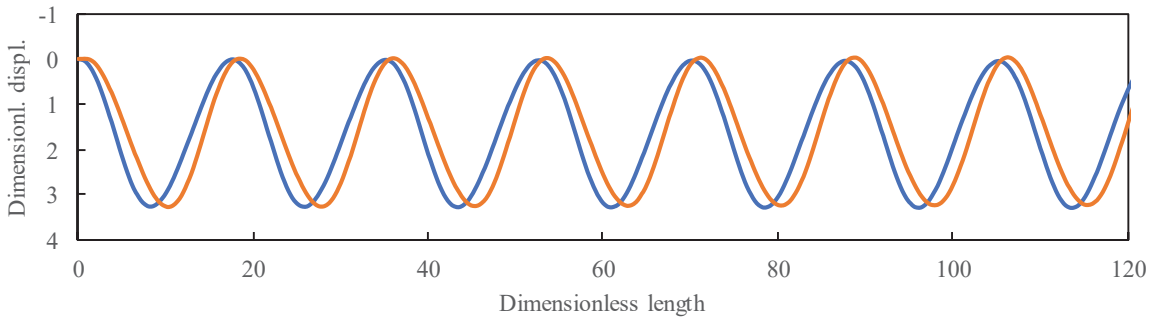

Figure 3: Deflections of the contact points of two masses distanced by $\hat{d} = 2\chi$ with respect to the dimensionless length (orange: front mass, blue: rear mass).

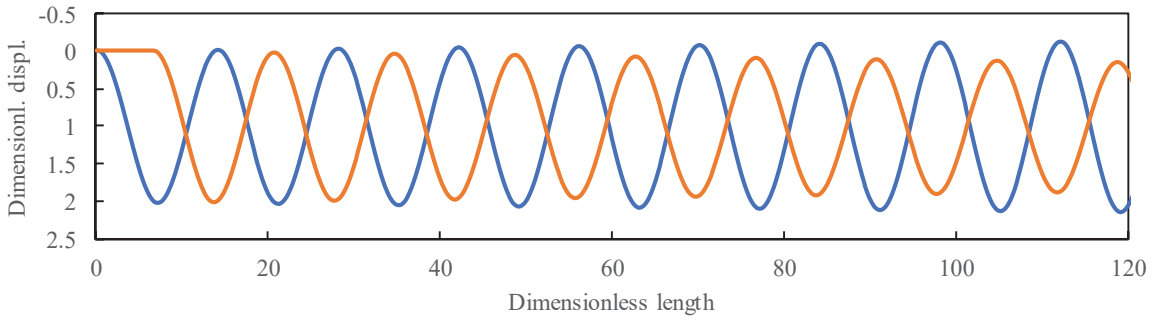

Figure 4: Deflections of the contact points of two masses distanced by $\hat{d} = 15\chi$ with respect to the dimensionless length (orange: front mass, blue: rear mass).

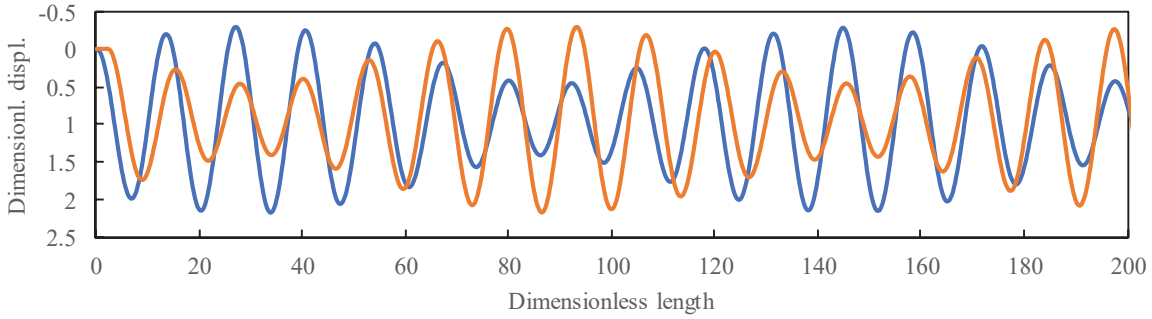

Figure 5: Deflections of the contact points of two masses distanced by $\hat{d} = 5\chi$ with respect to the dimensionless length (orange: front mass, blue: rear mass).

Finally, the influence of the shear resistance of the foundation on the dynamic interaction described above is analyzed. By increasing the shear resistance, it is seen that the dynamic interaction is reduced and the effect on the amplitudes is not so pronounced. This is shown in Figure 5 where three cases are plotted at the same time. They are for ϑ_s=0; 0.2 and 0.4, where

ϑ_s is defined as the ratio of the velocity of propagation of the shear waves in the foundation over the critical velocity. The larger ϑ_s the more moderate influence on the amplitudes.

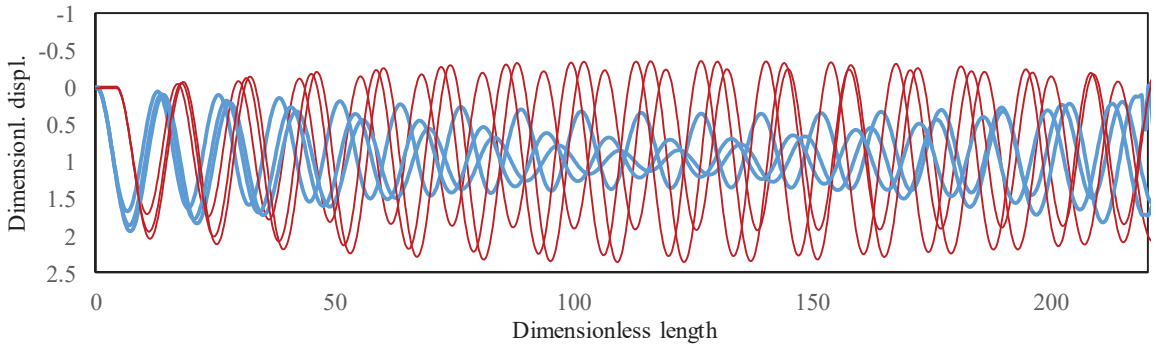

Figure 6: Deflections of the contact points of two masses distanced by $\widehat{d} = 10\chi$ with respect to the dimensionless length (red: front mass, blue: rear mass); different cases are for $\vartheta_s = 0; 0.2; 0.4$.

Together with the analysis of induced frequencies, the onset on instability and its relation the critical velocity was examined. As expected, the instability can take place only in the subcritical range, nevertheless, the critical velocity must be considered in the form as proven in [1-3].

5 CONCLUSIONS

In this paper it is shown how proximity of moving masses affects the beam deflection shape and what differences can be observed in vibration patterns when solution on massless two-parameter visco-elastic foundation and the one on finite-depth foundation with partial shear resistance are compared. Besides the confirmation of strong non-linearity of the problem itself which is demonstrated by impossibility of results superposition of proximate masses, it is shown that in the case of foundation with finite depth, additional frequency is controlling the vibration amplitudes. This effect can be reduced by increasing the shear resistance of the foundation.

Quite obvious conclusion was confirmed, namely, when masses are sufficiently apart, the results superposition is generally acceptable, but when masses are very close, it would be better to replace them by one load with doubled mass and force. The correct solution involving directly both masses is necessary only when masses are at an intermediate distance. In addition, it was shown that the instability region is not affected and in an undamped case, the onset of instability occurs exactly at the critical velocity, as for one moving mass.

The paper demonstrates that by using semi-analytical solutions, several analyses on the quality of the vibrations induced by the moving loads can be performed quickly and accurately without testing numerical convergence of discretized models. This way, it is possible to obtain straightforwardly accurate results in dimensionless forms, and thus encompassing in few graphs results related to all possible parameter combinations.

Keywords: wheelset, track, hysteretic model, viscous model, receptance, contact force

Abstract. *The paper presents a comparative analysis of the wheelset/track vertical interaction considering two track damping models, the hysteretic model and viscous model, respectively. To this end, a simple track model consisting in two independent infinite Euler-Bernoulli beams, each of them resting on a foundation with two elastic layers and an inserted inertial layer is used. The wheelset model has asymmetrical structure such as a driving wheelset. The axle is modelled using a free-free Euler-Bernoulli beam, and the wheels and driven wheel are considered rigid bodies. Regarding the parameters of the track model, given the values of the elastic foundation with hysteretic damping, the values of the parameters for the viscous damping model are calculated by applying the least square method in terms of rail receptance at acting point. The stiffnesses and damping constants of the viscous damping model minimize the sum of squared residuals, where the residual is the difference between the receptance modulus of the hysteretic model, and the receptance modulus of the viscous model at a certain angular frequency. Receptance modulus calculated with the viscous damping model matches the receptance derived from the hysteretic model excepting a limited frequency range around the antiresonance frequency of the rail. For simplicity, wheelset/track interaction is modelled applying the moving irregularity model. Interaction between wheelset and track is analyzed based on the numerical results. It is shown that the contact force predicted with the viscous damping model elastic overestimates the results delivered by the hysteretic damping model around the bounce-roll natural frequencies of the wheelset/track system. On the other hand, the results produced by the two models are in satisfactory agreement at lower and higher frequency.*

1 INTRODUCTION

The study of the wheel-rail interaction based on theoretical models is important in order to find solutions to many practical problems such as: rolling noise, rail corrugation and wheel out-of-roundness, ballast settlement etc.

Two kind of track models are used in numerical simulations depending on the track structure and frequency range: infinite beam on continuous elastic foundation [1] and infinite beam on discrete foundation, respectively [2]. In this context, the damping model of the track plays a role, since it has a strong impact on the magnitude of the wheel/rail contact force. From this perspective, the hysteretic and viscous damping models are the most common used due to their simplicity for the rail pad and ballast [3, 4].

Viscous damping model is a linear one and can be applied in both frequency and time-domain. However, the accuracy of the numerical simulations is affected by the fact that the dynamic stiffness increases with the frequency. Hysteretic damping model provides a better agreement with the test results – the dynamic stiffness doesn't depend on frequency, but it can be applied in the frequency-domain only [5]; it doesn't satisfy the causality requirement [6].

Despite the shortcomings mentioned above, the two damping models will still be used in the wheel/rail problem and the question is what kind of results we should expect when using one or the other. To answer this question, a theoretical investigation regarding the influence of the track damping model - hysteretic versus viscous - upon the magnitude of the interaction between a wheelset and track in the presence of the irregularities of the rolling surfaces is presented in this paper.

For simplicity, simple models for track and wheelset have been adopted: two infinite continuous beams on independent elastic foundation for track model and free-free beam with attached rigid bodies for wheelset model.

Values of the parameters of the viscous damping model are derived from those of the hysteretic damping model parameters applying the least square method regarding the difference between the rail receptance modulus at acting point calculated with the hysteretic damping model and the rail receptance modulus at acting point derived from the viscous damping model.

To evaluate the magnitude of the wheelset/tract interaction, the power spectral density (PSD) of the irregularities of the rolling surfaces are calculated starting from rail roughness limit spectrum [7].

Finally, the wheelset/track interaction is analyzed in terms of the PSD of the wheel/rail contact forces and wheel/rail displacements.

2 WHEELSET/TRACK MODEL

Fig. 1 shows the model of the interaction between a wheelset and track when the rolling surfaces exhibit small irregularities - roughness.

The wheelset is considered as an asymmetrical structure, corresponding to a driving wheelset, and consisting of two wheels and a driven gear rigidly fixed on the axle. The axle is modelled using a uniform free-free Euler-Bernoulli beam of $2l$ length, EI_a bending stiffness, where E is Young's modulus and I_a is the moment of inertia of the cross-section, and of m_a is the mass per length unit. The wheels and driven gear are considered rigid bodies of M_w mass and J_w mass moment of inertia for wheels, and M_g mass and J_g mass moment of inertia for the driven gear. Distance between wheels is $2e$ and the distance between a wheel and the corresponding axle end is a. The drive gear is located at the distance b from the left end of the axle.

Equation of motion for the driving wheelset is

$$EI_a \frac{\partial^4 w_a(y_a,t)}{\partial y_a^4} + M_w \left[\frac{\partial^2 w_a(a,t)}{\partial t^2} \delta(y_a - a) + \frac{\partial^2 w_a(l-a,t)}{\partial t^2} \delta(y_a - l + a) \right] -$$
$$J_w \left[\frac{\partial^3 w_a(a,t)}{\partial y_a \partial t^2} \delta'(y_a - a) + \frac{\partial^3 w_a(l-a,t)}{\partial y_a \partial t^2} \delta'(y_a - l + a) \right] + \quad (1)$$
$$M_g \frac{\partial^2 w_a(b,t)}{\partial t^2} \delta(y_a - b) - J_g \frac{\partial^3 w_a(b,t)}{\partial x \partial t^2} \delta'(y_a - b) +$$
$$m_a \frac{\partial^2 w_a(y_a,t)}{\partial t^2} = -Q_1(t)\delta(y_a - a) - Q_2(t)\delta(y_a - l + a),$$

where $w_{ao}(y_a, t)$ is the axle displacement in the cross section at the distance y_a from the left end of the axle at the t time moment and $Q_{1,2}(t)$ are the dynamic components of the wheel/rail contact.

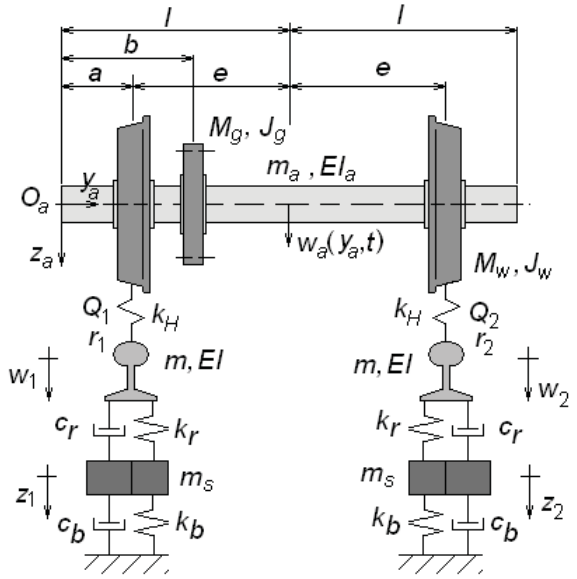

Fig. 1. Wheelset/track model.

Using the modal analysis method, the axle deflection becomes

$$w_a(y_a,t) = w_{ao}(t) + (y_a - l/2)\theta_{ao}(t) + \sum_{n=1}^{\infty} Y_n(y_a) T_n(t) \quad (2)$$

where $w_{ao}(t)$ and $\theta_{ao}(t)$ represent the axle motions as rigid body, and $T_n(t)$ and $Y_n(y_a)$ are the time coordinate and the eigenfunction of the n^{th} elastic vibration mode.

In the following, the axle motion is described by the rigid vibration modes and the first two elastic vibration modes. In this context, Eq. (1) transforms into the below matrix equation

$$\mathbf{M}\ddot{\mathbf{q}} + \mathbf{K}\mathbf{q} = \mathbf{Q}, \quad (3)$$

where $\mathbf{q} = [w_{ao}\ \theta_{ao}\ T_1\ T_2]^T$ is the column vector of the modal coordinates, **M** and **K** are the inertia and stiffness 4×4 matrix and **Q** is the column vector of the four modal forces.

When the steady-state harmonic behaviour is considered (frequency-domain), Eq. (3) becomes

$$\left(-\omega^2\mathbf{M}+\mathbf{K}\right)\bar{\mathbf{q}}=\bar{\mathbf{Q}}\,, \tag{4}$$

where $\bar{\mathbf{q}}=\left[\,\bar{w}_{ao}\quad \bar{\theta}_{ao}\quad \bar{T}_1\quad \bar{T}_2\,\right]^T$ is the column vector of the complex amplitude of the modal coordinates and $\bar{\mathbf{Q}}$ is the column vector of the complex amplitudes of the modal forces.

Solving Eq. (4), the complex amplitudes of the axle displacements at the two wheels may be calculate

$$\bar{w}_{a1,2}=\bar{w}_{ao}\mp e\bar{\theta}_{ao}+\sum_{n=1}^{2}Y_n(y_{an})\bar{T}_n \tag{5}$$

where $y_{a1,2}=l\mp e$.

After some calculations, it holds

$$\begin{aligned}\bar{w}_{a1}&=-\left(\bar{\alpha}_{11}\bar{Q}_1+\bar{\alpha}_{12}\bar{Q}_2\right)\\ \bar{w}_{a2}&=-\left(\bar{\alpha}_{21}\bar{Q}_1+\bar{\alpha}_{22}\bar{Q}_2\right),\end{aligned} \tag{6}$$

where $\bar{\alpha}_{ij}$ with i,j = 1,2 is the axle receptance corresponding to the i wheel due to the unit harmonic force acting at the j wheel, and $\bar{Q}_{1,2}$ is the complex amplitude of the wheel/rail harmonic force.

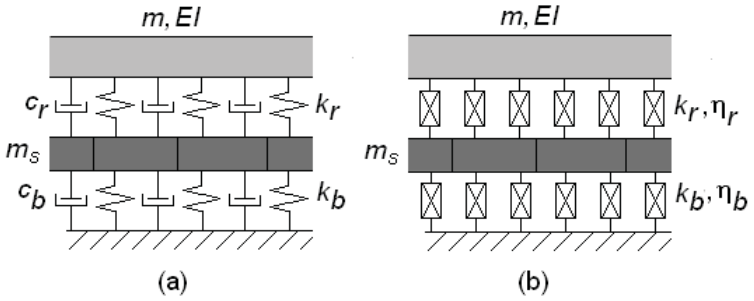

Fig. 2. Track model: (a) viscous damping; (b) hysteretic damping.

Ignoring the weak coupling between the two rails dynamics via sleepers, and the effect of the equidistant supports represented by sleepers, the track model is reduced to two identic infinite Euler-Bernoulli beams, each of them supporting on continuous foundation including two elastic layers and an intermediate inertial layer. The beams model the rails, and the continuous foundation introduces the elasticity of the rail pads and the ballast and the inertia of the sleepers. Such track model can be applied up to 6-700 Hz [7].

Regarding the damping of the track model, two kind of models are taken into consideration, viscous damping model and hysteretic damping model (fig. 2).

Parameters for the track model are the bending stiffness of the rail EI, where E is Young's modulus and I is the moment of inertia of the rail cross-section, the rail mass per unit length m, the railpad stiffness and damping constant per unit length k_r and c_r, the sleeper mass per unit length m_s, the ballast stiffness and damping constant per unit length k_b and c_b; the stiffnesses and damping constants correspond to the visco-elastic model for the foundation.

The track model with viscous damping can be applied in both time and frequency-domain and the equations of motion are given below.

Equations of motion for the time-domain:

$$\begin{aligned} &EI\frac{\partial^4 w_{1,2}(x,t)}{\partial x^4}+m\frac{\partial^2 w_{1,2}(x,t)}{\partial t^2}+c_r\left(\frac{\partial w_{1,2}(x,t)}{\partial t}-\frac{\partial z_{1,2}(x,t)}{\partial t}\right)+\\ &+k_r\left[w_{1,2}(x,t)-z_{1,2}(x,t)\right]=Q_{1,2}(t)\delta(x)\\ &m_s\frac{\partial^2 z_{1,2}(x,t)}{\partial t^2}+c_r\left(\frac{\partial z_{1,2}(x,t)}{\partial t}-\frac{\partial w_{1,2}(x,t)}{\partial t}\right)+c_b\frac{\partial z_{1,2}(x,t)}{\partial t}+\\ &+k_r\left[z_{1,2}(x,t)-w_{1,2}(x,t)\right]+k_b z_{1,2}=0. \end{aligned} \tag{7}$$

where $w_i(x,t)$ is the i rail displacement and $z_i(x,t)$ is the i sleeper displacement.

Equations of motion in the frequency-domain

$$\begin{aligned} &EI\frac{\mathrm{d}^4\overline{w}_{1,2}}{\mathrm{d}x^4}+\left(-\omega^2 m+k_r+i\omega c_r\right)\overline{w}_{1,2}-\left(k_r+i\omega c_r\right)\overline{z}_{1,2}=\overline{Q}_{1,2}\delta(x)\\ &\left[-\omega^2 m_s+k_r+k_b+i\omega\left(c_r+c_b\right)\right]\overline{z}_{1,2}-\left(k_r+i\omega c_r\right)\overline{w}_{1,2}=0. \end{aligned} \tag{8}$$

where the notations with bar are complex amplitudes, and $i^2=-1$.

When the hysteretic damping model is considered, the parameters for the two elastic layers are: k_r and k_b – the stiffness for the rail pad and ballast, η_r – the loss factor of the rail pad and η_b – the loss factor for the ballast.

Equations of motion of the track model with hysteretic damping can be written in the frequency-domain only

$$\begin{aligned} &EI\frac{\mathrm{d}^4\overline{w}_{1,2}}{\mathrm{d}x^4}+\left[-\omega^2 m+k_r\left(1+i\eta_r\right)\right]\overline{w}_{1,2}-k_r\left(1+i\eta_r\right)\overline{z}_{1,2}=\overline{Q}_{1,2}\delta(x)\\ &\left[-\omega^2 m_s+k_r\left(1+i\eta_r\right)+k_b\left(1+i\eta_b\right)\right]\overline{z}_{1,2}-k_r\left(1+i\eta_r\right)\overline{w}_{1,2}=0. \end{aligned} \tag{9}$$

The rails displacements at the acting points (x=0) are

$$\overline{w}_{1,2}=\overline{\alpha}_r\overline{Q}_{1,2}, \tag{10}$$

where $\overline{\alpha}_r$ is the rail receptance calculated for the section of the unit harmonic force.

Wheel/rail contact forces can be calculated applying linearized Hertz's contact theory

$$Q_{1,2}=k_H\left(w_{a1,2}-w_{1,2}-r_{1,2}\right), \tag{11}$$

or, for the frequency-domain,

$$\overline{Q}_{1,2}=k_H\left(\overline{w}_{a1,2}-\overline{w}_{1,2}-\overline{r}_{1,2}\right), \tag{12}$$

where $r_{1,2}$ are the rolling surfaces irregularities and k_H stands for the Hertzian contact stiffness.

Inserting Eqs. (6) and (10) in Eq. (8), it holds

$$\begin{aligned} &\left(\overline{\alpha}_{11}+\overline{\alpha}_r+\overline{\alpha}_H\right)\overline{Q}_1+\overline{\alpha}_{12}\overline{Q}_2=-\overline{r}_1\\ &\overline{\alpha}_{21}\overline{Q}_1+\left(\overline{\alpha}_{22}+\overline{\alpha}_r+\overline{\alpha}_H\right)\overline{Q}_2=-\overline{r}_2, \end{aligned} \tag{13}$$

where $\bar{\alpha}_H = 1/k_H$ is the receptance of the wheel/rail contact.

Problem solution is as follows:

- contact forces

$$\bar{Q}_1 = \frac{-\bar{r}_1(\bar{\alpha}_{22}+\bar{\alpha}_r+\bar{\alpha}_H)+\bar{\alpha}_{12}\bar{r}_2}{(\bar{\alpha}_{11}+\bar{\alpha}_r+\bar{\alpha}_H)(\bar{\alpha}_{22}+\bar{\alpha}_r+\bar{\alpha}_H)-\bar{\alpha}_{12}\bar{\alpha}_{21}}$$
$$\bar{Q}_2 = \frac{-\bar{r}_2(\bar{\alpha}_{11}+\bar{\alpha}_r+\bar{\alpha}_H)+\bar{\alpha}_{21}\bar{r}_1}{(\bar{\alpha}_{11}+\bar{\alpha}_r+\bar{\alpha}_H)(\bar{\alpha}_{22}+\bar{\alpha}_r+\bar{\alpha}_H)-\bar{\alpha}_{12}\bar{\alpha}_{21}} \quad (14)$$

- wheelset displacement at wheels level

$$\bar{w}_{a1} = \frac{\left[\bar{\alpha}_{11}(\bar{\alpha}_{22}+\bar{\alpha}_r+\bar{\alpha}_H)-\bar{\alpha}_{12}\bar{\alpha}_{21}\right]\bar{r}_1+\bar{\alpha}_{12}(\bar{\alpha}_r+\bar{\alpha}_H)\bar{r}_2}{(\bar{\alpha}_{11}+\bar{\alpha}_r+\bar{\alpha}_H)(\bar{\alpha}_{22}+\bar{\alpha}_r+\bar{\alpha}_H)-\bar{\alpha}_{12}\bar{\alpha}_{21}}$$
$$\bar{w}_{a2} = \frac{\left[\bar{\alpha}_{22}(\bar{\alpha}_{11}+\bar{\alpha}_r+\bar{\alpha}_H)-\bar{\alpha}_{12}\bar{\alpha}_{21}\right]\bar{r}_2+\bar{\alpha}_{21}(\bar{\alpha}_r+\bar{\alpha}_H)\bar{r}_1}{(\bar{\alpha}_{11}+\bar{\alpha}_r+\bar{\alpha}_H)(\bar{\alpha}_{22}+\bar{\alpha}_r+\bar{\alpha}_H)-\bar{\alpha}_{12}\bar{\alpha}_{21}} \quad (15)$$

- rails displacement at acting points

$$\bar{w}_1 = \bar{\alpha}_r \frac{-\bar{r}_1(\bar{\alpha}_{22}+\bar{\alpha}_r+\bar{\alpha}_H)+\bar{\alpha}_{12}\bar{r}_2}{(\bar{\alpha}_{11}+\bar{\alpha}_r+\bar{\alpha}_H)(\bar{\alpha}_{22}+\bar{\alpha}_r+\bar{\alpha}_H)-\bar{\alpha}_{12}\bar{\alpha}_{21}}$$
$$\bar{w}_2 = \bar{\alpha}_r \frac{-\bar{r}_2(\bar{\alpha}_{11}+\bar{\alpha}_r+\bar{\alpha}_H)+\bar{\alpha}_{21}\bar{r}_1}{(\bar{\alpha}_{11}+\bar{\alpha}_r+\bar{\alpha}_H)(\bar{\alpha}_{22}+\bar{\alpha}_r+\bar{\alpha}_H)-\bar{\alpha}_{12}\bar{\alpha}_{21}}. \quad (16)$$

In the following section, the same roughness is considered on the two wheel/rail pairs.

3 NUMERICAL APPLICATION

In this section, the parameters corresponding to the wheelset of the electric 060 EA locomotive in service on CFR (Romanian Railway) are considered. The values of these parameters are as follows: m_a= 244,4 kg/m, E = 210 GPa, I_a = 7.7136□10-5 m^4, 2l = 2.11 m, a = 0,305 m, b = 0.52 m, e = 0.75 m, M_w = 500 kg, J_w = 48.8 kgm^2, M_g = 550 kg (including the part of the gear housing resting on the axle), J_g = 17.7 kgm^2.

To point out the impact of the track damping model upon the assessment of the wheelset/track interaction, the hysteretic damping model is considered as reference and two kind of rail pad are considered: stiff rail pad with the stiffness of 350 MN/m and soft rail pad with the stiffness of 60 MN/m (both per half sleeper). Loss factor of the rail pad is η_r = 0.25. The other parameters of the track model are: rail mass per length unit of 60 kg/m, the inertia moment of the rail cross-section of 3.055□10^{-5} m^4, half sleeper mass of 132 kg, ballast stiffness corresponding to a half sleeper 50 MN/m, ballast loss factor of 1.00 and the sleeper bay of 0.55 m. Values per length unit for the rail pad and ballast stiffness are obtained by dividing the stiffness per half sleeper to the sleeper bay. Similar, the sleeper mass per length unit is calculated. The wheel/rail contact stiffness is k_H = 1.5 GN/m.

Figure 3 shows the receptance of the wheelset calculated at the two wheels when the harmonic unit force acts on left/right wheel. The receptance at the left wheel ($\bar{\alpha}_{11}$) is lower than the right wheel receptance ($\bar{\alpha}_{22}$) due to the inertial influence of the driven gear and housing gear which are mounted next to the left wheel. The natural frequencies of the wheelset bending modes taken into consideration in the model are at 86.5 and 187.3 Hz. The

left wheel receptance has antiresonance frequencies at 83.8 and 186.8 Hz, and the right wheel receptance, at 84.8 and 181.3 Hz. The cross-receptance of the wheelset ($\bar{\alpha}_{12} = \bar{\alpha}_{21}$) reflects the coupling between the vibration modes of the wheelset.

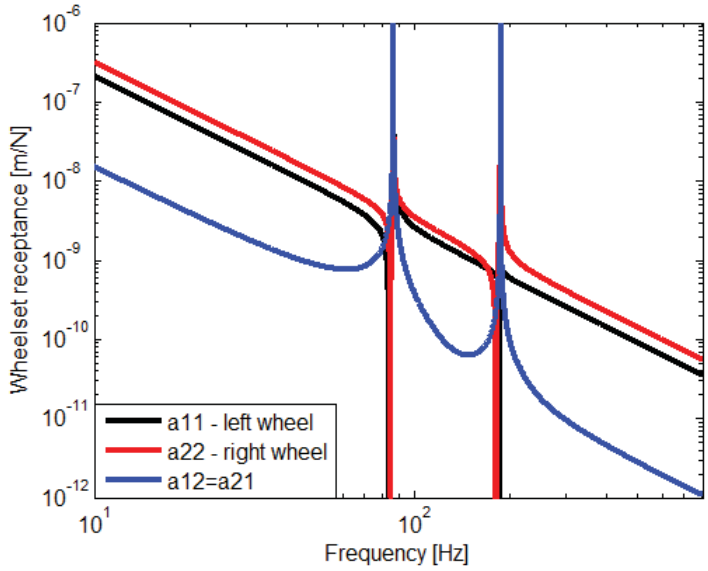

Fig. 3. Receptance of the wheelset calculated at each wheel.

The values of the parameters for the viscous damping model are calculated by applying the least square method in terms of rail receptance at acting point. The stiffnesses and constants damping of the viscous damping model minimize the sum of squared residuals, where the residual is the difference between the receptance modulus of the hysteretic model, and the receptance modulus of the viscous model at a certain angular frequency,

$$S(k_{rv}, c_{rv}, k_{bv}, c_{bv}) = \sum_{\omega_{min} \le \omega_i \le \omega_{max}} \left(\left|\bar{\alpha}_{rh}(\omega_i)\right| - \left|\bar{\alpha}_{rv}(\omega_i)\right| \right)^2 , \tag{17}$$

where the index *h* or *v* denotes the hysteretic damping model or the viscous damping model, and ω_{min} and ω_{max} are the limits of the angular frequency range.

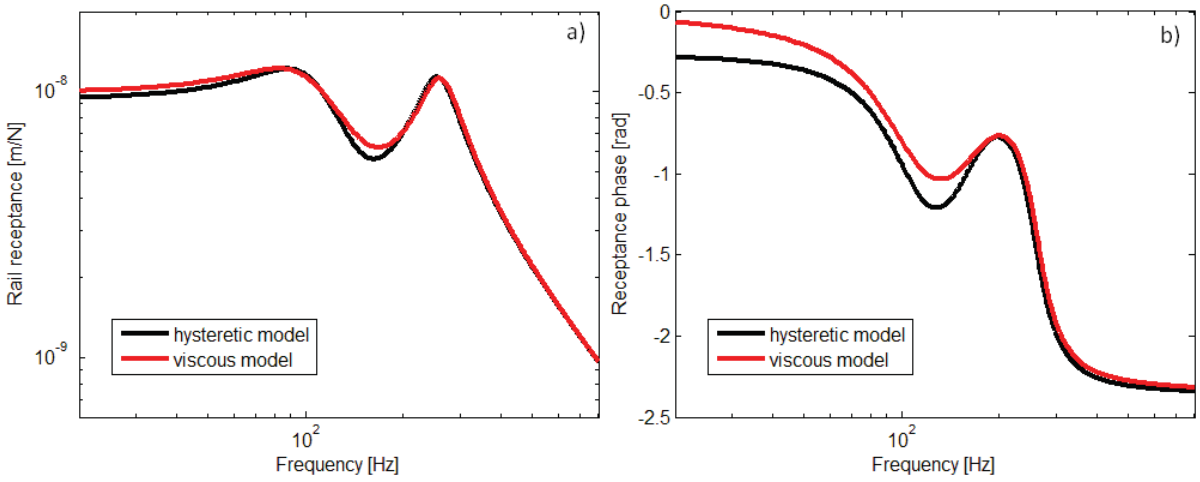

Fig. 4. Rail receptance for soft rail pad: a) receptance modulus; b) receptance phase.

Optimal parameters values can be found by setting the gradient to zero or by mapping the S function using the numerical calculation. Applying former approach, the results are displayed in Figs 4 and 5 for soft and stiff rail pad.

In Fig. 4, the optimal parameters values per half sleeper for the viscous model are: k_{rv} = 70.33 MN/m, c_{rv} = 7.596 kNs/m or ζ_r = 0,0788, k_{bv} = 68.77 MN/m, c_{bv} = 82.15 kNs/m or ζ_b = 0.4327, where the damping ratio for rail pad, ζ_r, and for the ballast, ζ_b, are defined as

$$\zeta_r = \frac{c_{rv}}{2\sqrt{k_{rv}m}}, \qquad \zeta_b = \frac{c_{bv}}{2\sqrt{k_{bv}m_s}}.$$

The rail receptance exhibits two peaks corresponding to the natural frequencies of the track, one at 86.2 Hz, and the other one at 244.7 Hz, and a deep at 145.9 Hz – the anti-resonant frequency due to the dynamic absorber effect produced by sleeper. The results derived from the viscous damping model well matches the results from hysteretic damping model, excepting the range around the anti-resonant frequency, where the maximum error can reach about 10 %.

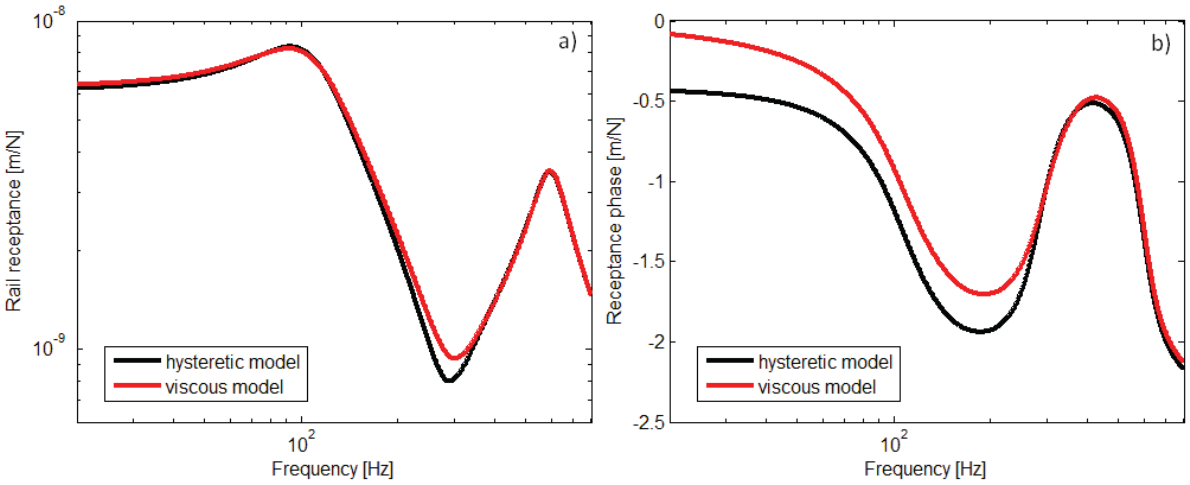

Fig. 5. Rail receptance for stiff rail pad: a) receptance modulus; b) receptance phase.

In the stiff rail pad case, the optimal parameters values per half sleeper for the viscous model are: k_{bv} = 374.28 MN/m, c_{rv} = 20.415 kNs/m or ζ_r = 0,0788, k_{bv} = 76.500 MN/m and c_{bv} = 76.500 kNs/m or ζ_b = 0.4327. Track natural frequencies take the frequency of 87.6 Hz and 581.7 Hz, respectively. The anti-resonant frequency is 278.1 Hz. The viscous damping model ensures results very close to those of the hysteretic damping model, especially around the natural frequencies of the track and at higher frequencies. However, there is a narrow frequency interval around the anti-resonance frequency where the errors are bigger. Receptance phase from the viscous damping model shows significant difference at lower frequencies in relation to that obtained from the hysteretic damping model.

The roughness of the rolling surfaces can be represented as the power spectral density function depending on the wave number. Starting from the rail roughness limit spectrum (fig. 6), power spectral density function can be derived considering the fourth-power dependence like in ref. [9] and adding a linear term in numerator

$$S(\Omega) = \frac{A + B\Omega}{\Omega^n}, \; \Omega_{j-1} < \Omega < \Omega_j, \tag{18}$$

where Ω is the wave number, A [rad^{n-1}/m^{n-3}] and B [rad^{n-2}/m^{n-4}] – constants, Ω_{j-1} and Ω_j are the limit frequencies delimiting a 1/3 octave interval and n is an exponent ($n = 4$).

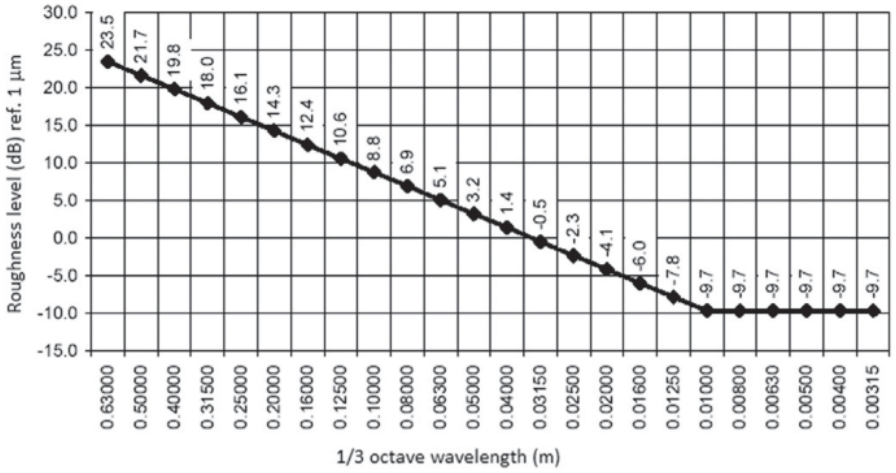

Fig. 6. Roughness limit spectrum [8].

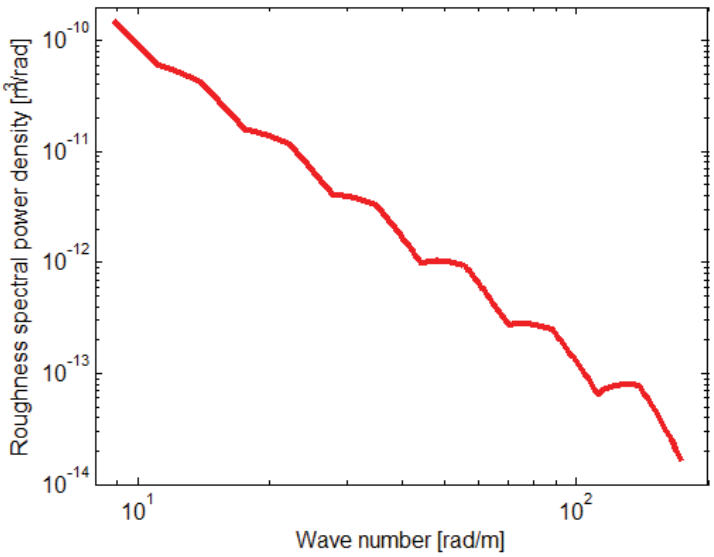

Fig. 7. Spectral density spectrum of the roughness.

Fig. 7 shows the power spectral density of the roughness of the rolling surfaces derived from the limit spectrum of the roughness, which has been extended from the wavelength of 0.63 m to the wavelength of 2 m in order to cover the lower frequencies.

When the wheelset travels along the track with the speed V, the power spectral density of the rolling surfaces roughness becomes ω dependent function, where $\omega = V\Omega$ is the angular frequency,

$$G(\omega) = \frac{S(\omega / V)}{V} = \frac{A + B\omega / V}{V(\omega / V)^n}. \tag{19}$$

The wheel/rail displacement power spectral density (PSD) can be calculated applying the following equation

$$G_{w_{a1,a2},w_{1,2}}(\omega)=\left|\bar{H}_{w_{a1,a2},w_{1,2}}(\omega)\right|^2 G(\omega)\,, \tag{20}$$

where $\bar{H}_{w_{a1,a2},w_{1,2}}(\omega)$ is the frequency response function of the wheel/rail displacement.

Similar, PSD of the contact force can be obtained

$$G_{Q_{1,2}}(\omega)=\left|\bar{H}_{Q_{1,2}}(\omega)\right|^2 G(\omega)\,, \tag{21}$$

where $\bar{H}_{Q_{1,2}}(\omega)$ is the frequency response function of the wheel/rail contact force.

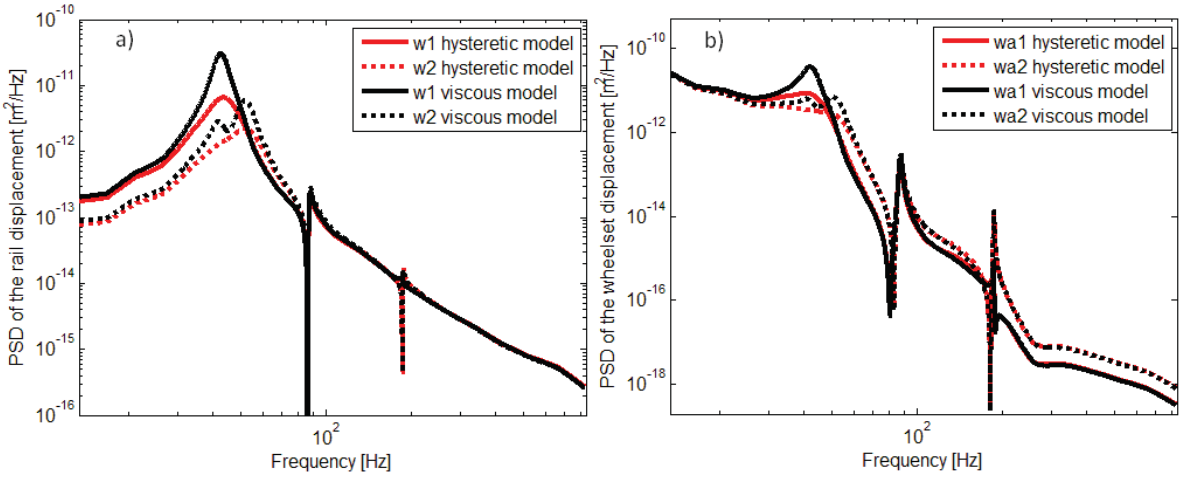

Fig. 8. PSD of the wheel/rail displacement at 30 m/s– soft rail pad.

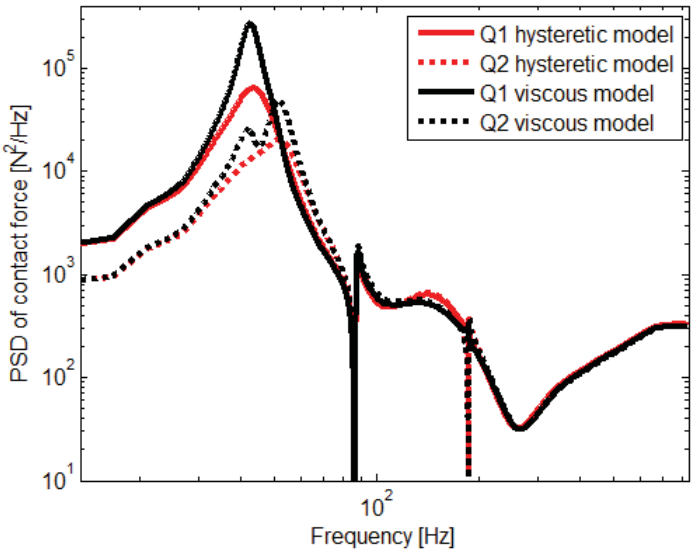

Fig. 9. PSD of the wheel/rail contact force at 30 m/s– soft rail pad.

Figs 8 and 9 shows the PSD of the wheel/rail displacements and contact force for both track damping models considering that the wheelset is moving along a track with soft rail pad at 30 m/s. Wheelset/track dynamics exhibits two resonance frequencies in the interval of 35-50 Hz (depending on the damping model) due to the bounce and roll motions of the wheelset on the track. However, instead of two peaks corresponding to the two resonance frequencies,

the PSD calculated with the hysteretic damping model shows one peak for the left wheel (at lower frequency) and other one for the right wheel (at higher frequency) due to the damping. When the viscous damping model is used, the left wheel has one peak, and the right wheel shows two peaks. It can be observed that the left side of the wheelset/track system vibrates more intense at low frequency due to the higher inertia. In general, the results obtained with the two damping models are close, but a significant difference can be identified in the range of resonance frequencies due to wheelset bounce-roll on the track.

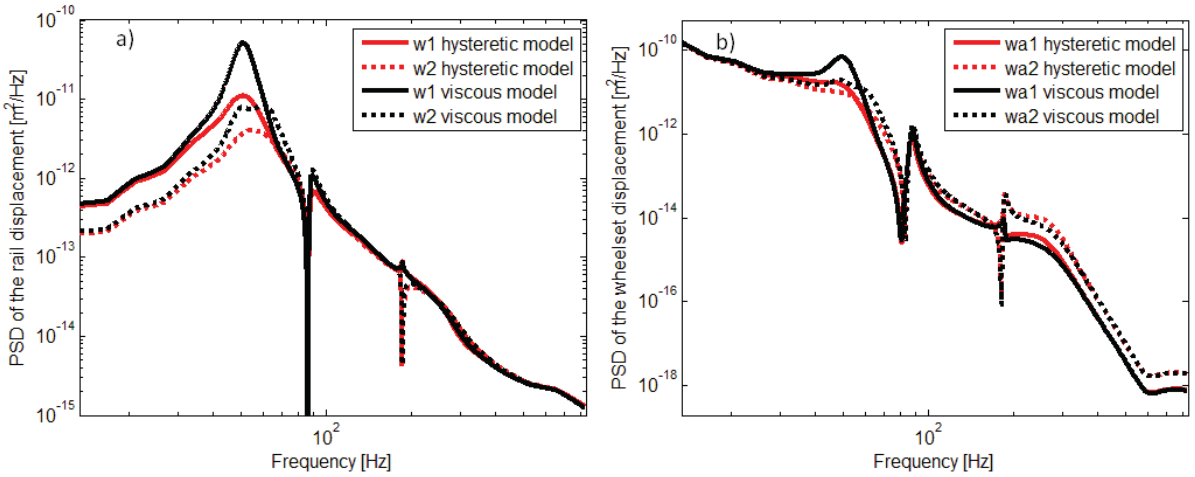

Fig. 10. PSD of the wheel/rail displacement at 30 m/s– stiff rail pad.

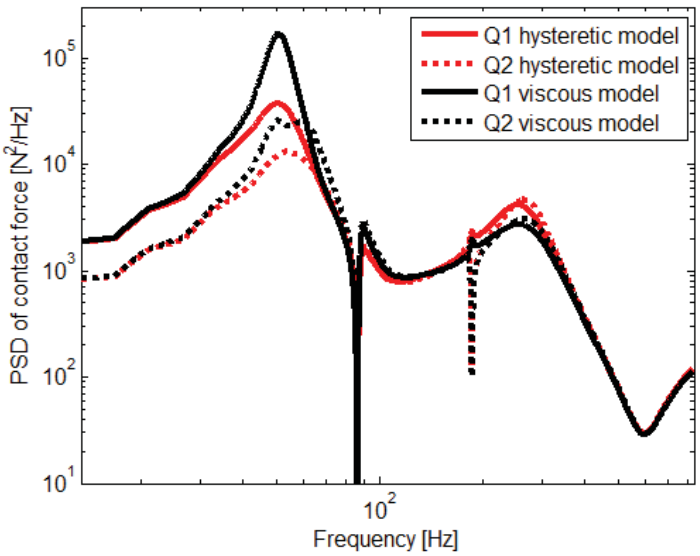

Fig. 11. PSD of the wheel/rail contact force at 30 m/s– stiff rail pad.

Similar comments can be drawn from the Figs 10 and 11 which show the results for the case of the track with stiff rail pad.

4 CONCLUSIONS

Theoretical investigation of the interaction between a wheelset and track is interesting from many practical reasons.

From the track modelling perspective, the most used damping models are the hysteretic and viscous models.

It was shown that the values of the parameters of the track model with viscous damping can be determined applying the least squares method to obtain the best approximation of the rail receptance given by the track model with hysteretic damping.

The results regarding the wheelset/track interaction in the presence of rolling surface irregularities calculated with the track model with viscous damping approximate well the results provided by the track model with hysteretic damping especially at lower and higher frequencies than the resonant frequencies due to the bounce-roll motion of the wheelset on track.

However, the viscous damping model overestimates the magnitude of the rail/wheel interaction in relation to the results obtained with the help of the hysteretic damping model in the range of resonant frequencies due to the bounce-roll motion of the wheelset on the track.

Keywords: Structural Dynamics, Traffic-induced Vibrations, Ground Vibrations

Abstract. *Perceptible vibration effects in adjacent buildings due to passing trains on a near-by track are usually expected in distances lower than one-hundred meters. Railway vibrations in distances of more than two-hundred meters are generally not considered to be a relevant emission source which could affect the living conditions in planned buildings of urban development projects.*

This paper focuses on a real-estate project in a German city to develop a new residential district with an almost identical structural design. Surprisingly, after completion of the first buildings in distances even further away than two-hundred meters to the next railway track, residents on higher floors complained about shaking ceiling lamps and substantially shocks in their apartments.

As a first approach, long-term monitoring revealed building vibrations with higher vibration velocity peaks, which can also be categorized perceptible for humans. The vibrational source could be identified quickly by frequently passing freight trains on the faraway track. A further aspect of the monitored data showed that the discomforting situation was caused by horizontal building movements in a low-frequency domain, especially on higher floors. To solve this vibrational problem, the dynamic behavior of the already constructed buildings, as well as the characteristic of the wave-propagation on the terrain, were measured.

Freight train induced horizontal vibrations correspond to the horizontal eigenmodes of the constructed buildings and amplifies the vibration level within the structure significant. In the early stage of the project, optimization of the construction has been required to detune the dynamic properties of planned buildings from the train vibrations. The paper represents the vibrational situation described above, the detailed numerical studies to find the critical points of the building design as well as the optimization process of the building structure.

Furthermore, this example should also give a short guideline on how the unintended effect of an increased vibrational impact lateral of a railway track can be avoided in future urban development projects.

1 INTRODUCTION

Perceptible vibration effects in adjacent buildings due to passing trains on a nearby track are usually expected in distances lower than one hundred meters. Railway vibrations in distances of more than two hundred meters are generally not considered to be a relevant emission source which could affect the living conditions in planned buildings of urban development projects.

This paper focuses on a real-estate project in a German city to develop a new residential district with almost identical building design. Surprisingly, after the construction of the first buildings in distances of more than two hundred meters to the next railway track, residents on higher floors complained about shaking ceiling lamps and substantially shocks in their apartments.

Studies and detailed investigations were launched to improve the vibrational situation for further planned buildings and give a short guideline of how the unintended effect of an increased vibrational impact can be reduced for future urban development projects.

2 URBAN DEVELOPMENT PROJECT

The project area is subdivided into several sections and located on sandy soil in a larger distance from the next railway line (see Figure. 1). The building design mainly consists of multistory buildings with five to six floors. The construction process started on the opposite side of the track and evolved spatially towards the track over several years.

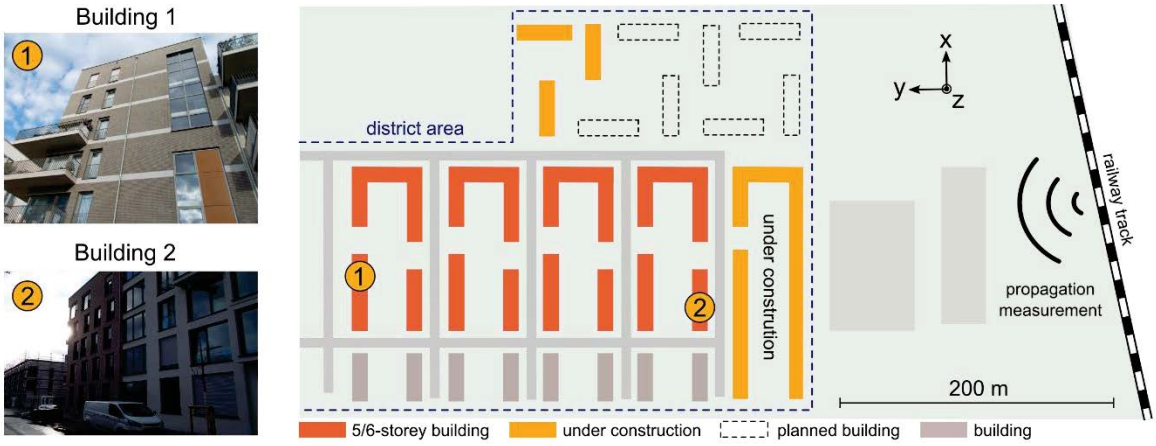

Figure 1: Building design and layout of the district area. The distance between the railway track and district area accounts for more than 200 meters.

A potential impact due to traffic vibrations on planed buildings is usually estimated in a preliminary stage of an urban development project. In the case of floor vibrations and secondary airborne sound, the attenuation of shock waves over distances of one hundred meters is commonly sufficient to avoid disruptive vibrations inside of living spaces.

However, residents on the upper floor in *Building 2* in even more than two hundred meters to the next railway track complain about perceptible shocks in their apartments especially during the night times.

3 VIBRATION MONITORING

Long-Term monitoring in *Building 2* revealed higher vibration velocity peaks which can also be categorized as perceptible (see Figure. 2). The vibrational source could be quickly identified by frequently passing freight trains on the faraway track.

A further aspect of the monitored data revealed that the discomforting situation is caused by horizontal building movements in a low-frequency range at around 4 Hz, especially on higher floors. Floor vibrations in vertical direction were not monitored during the corresponding events.

A more detailed monitoring-study in the apartments revealed up to 60 passing freight-trains in the night and 100 during the daytime. The relevant frequency-weighted velocity values for night and day do not exceed the requirements of the underlying vibrational standards [1].

However, more detailed investigations of the vibrational phenomena were launched to improve the living situation for future residents on higher floors of further planned buildings in the district area.

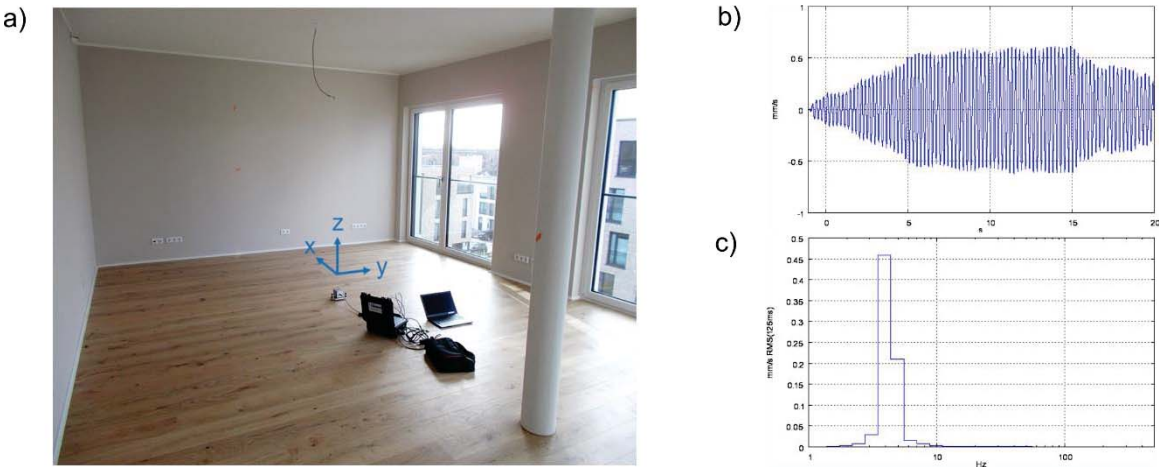

Figure 2: a) Vibration monitoring in an upper floor apartment of Building 2. b) - c) Monitored data in the time and frequency domain reveal horizontal building oscillations in the y-direction with vibration velocities of v_{max} = 0,63 mm/s and v_{rms} = 0,46 mm/s at 4 Hz.

4 FREIGTH TRAIN VIBRATIONS AND WAVE PROPAGATION

Ground vibrations of freight trains in the immediate range of the railway track and the wave-propagation on the terrain were measured. The averaged vibration spectra of freight trains are depicted in Figure 3 as 1/3 octave band values.

A combination of the driven train velocity, the weight and bogie spacing of freight-wagons as well as irregularities of the track superstructure lead to shock wave vibrations in a low-frequency regime laterally to the track. Additionally, sandy soils represent an ideal propagation medium for Rayleigh waves having longer wavelengths within a range of 20 to 40 meters.

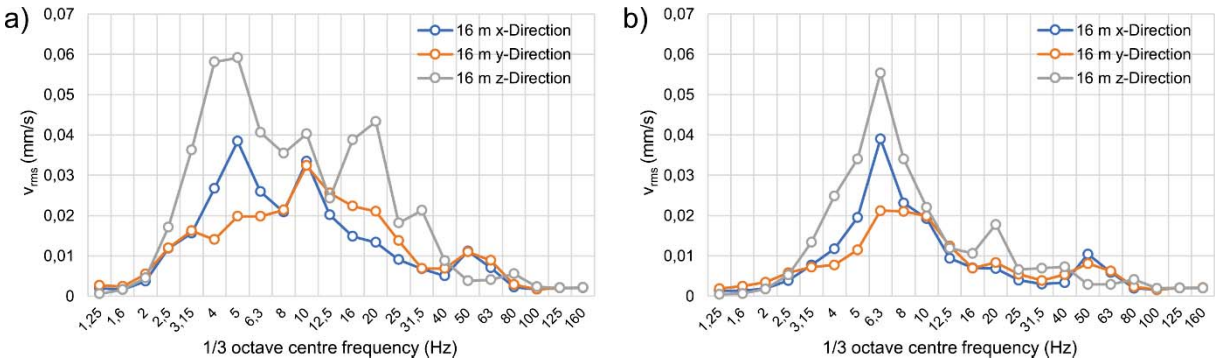

Figure 3: a) – b) Ground vibrations (averaged 1/3 octave values) of freight trains on track 1 (left) and track 2 (right) in the immediate range (16 m) of the railway track.

The reduction exponents of wave propagation on the terrain are depicted in Figure 4. For the purpose of interpretation, these exponents are summarized into three categories. The frequency domains relate to vibrational effects of building dynamics, floor vibrations and secondary airborne sound

On the basis of this rough interpolation, it is evident that the district area is exposed by low-frequency Rayleigh waves. Vibration components in the horizontal and vertical direction are present below the ground level [2]. Instead, higher frequency ranges reveal larger attenuations and corresponding vibrational effects in distant apartments are not estimated.

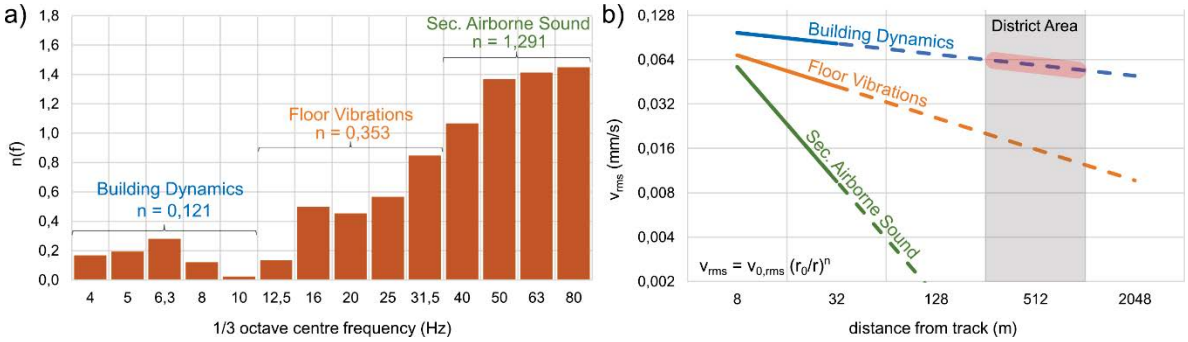

Figure 4: a) Reduction exponents n(f) for the wave propagation in sandy soil. b) Rough interpolation of the vibrational impact on the district area regarding building dynamics (red), vertical floor vibrations and secondary airborne sound.

5 DYNAMIC RESPONSE OF THE BUILDING STRUCTURE

In the next step, the dynamic response of the building structure on the horizontal wave excitation is examined. Vibration sensors were placed on various floors from the basement to the top level. The principal setup and basic concept for detection and interpretation of horizontal oscillations are described in Figure 5. Two different buildings were selected for closer examination (see Figure 1).

Building 1 is subdivided into six floors above the basement. The exterior wall construction consists entirely of reinforced concrete and a wall thickness of 0.2 meters. *Building 2* has one floor less and the exterior wall is executed in the masonry of calcareous sandstone.

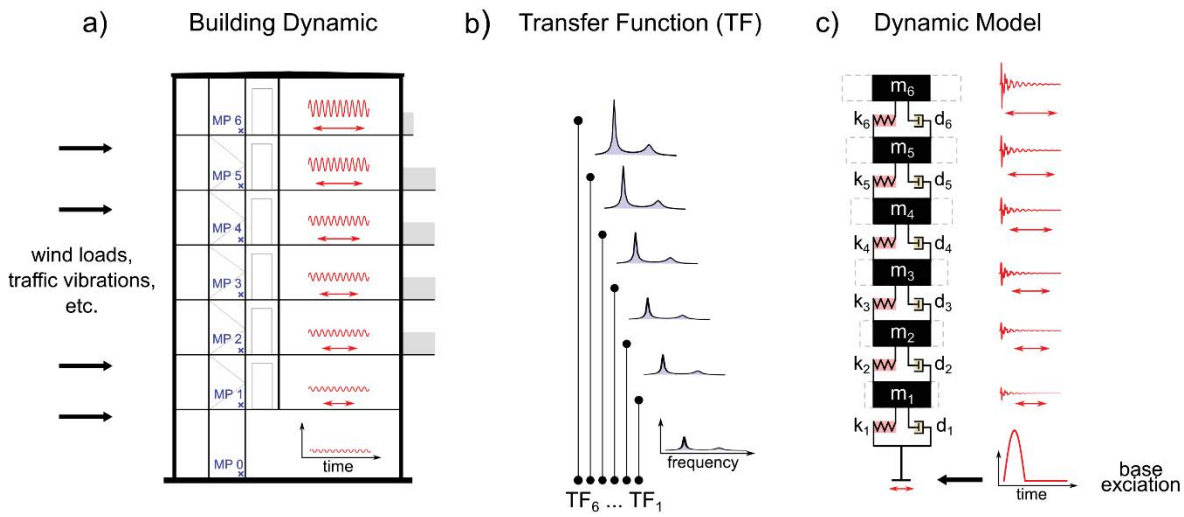

Figure 5: a) – b) Principal set up to detect horizontal transfer functions TFi which represents the dynamic response of the building structure on external excitations. c) A simple dynamic model to emulate the dynamic behavior of bearing structures.

The transfer functions TF_i from the basement to of each floor are plotted in Figure 6 a) and b). In addition, Figure 6 c) shows the transfer behavior derived from the dynamic model. The parameters for stiffness *k* and mass *m* of the coupled system have been tuned to reach an eigenfrequency of around 4 Hz. A numerical method was used to calculate the temporal development of the system [3].

The magnification factors for lateral vibrations of the building structures are depicted in Figure 7. In addition, the model-like behavior for different attenuation ratios ξ of around 1,3%, 2,5% and 5% of the mass oscillations are plotted.

In contrast to the dynamic response of *Building 1* in Figure 7 a), the model-like behavior does not fit well with the transfer magnification of *Building 2* in Figure 7 c). *Building 1* exhibits a better-natured transfer behavior due to its constructive design. Structural damping in between 2,5% and 5% match with the expected attenuation for structures of reinforced concrete [4]. Larger amplification within the structure of *Building 2* in y-direction leads to rocking movements and a higher vibration level on the upper floors.

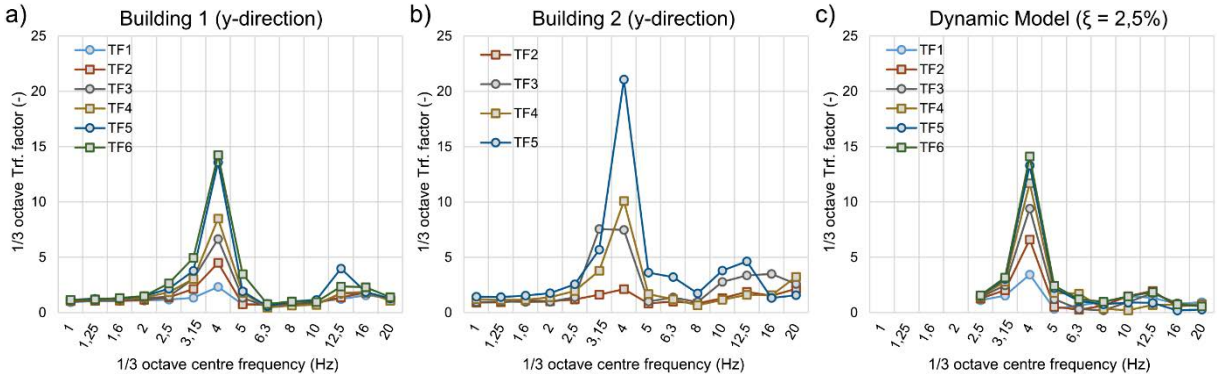

Figure 6: a) – b) Transfer functions TF_i of Building 1 and Building 2 in y-direction. c) Numerical results of the dynamic model with an attenuation ratio of about 2,5% for mass oscillations m_i. (model parameter: $m_i = 1$ to, $k_i = 1100$ kN/m, $d_i = 21.75$ kNs/m).

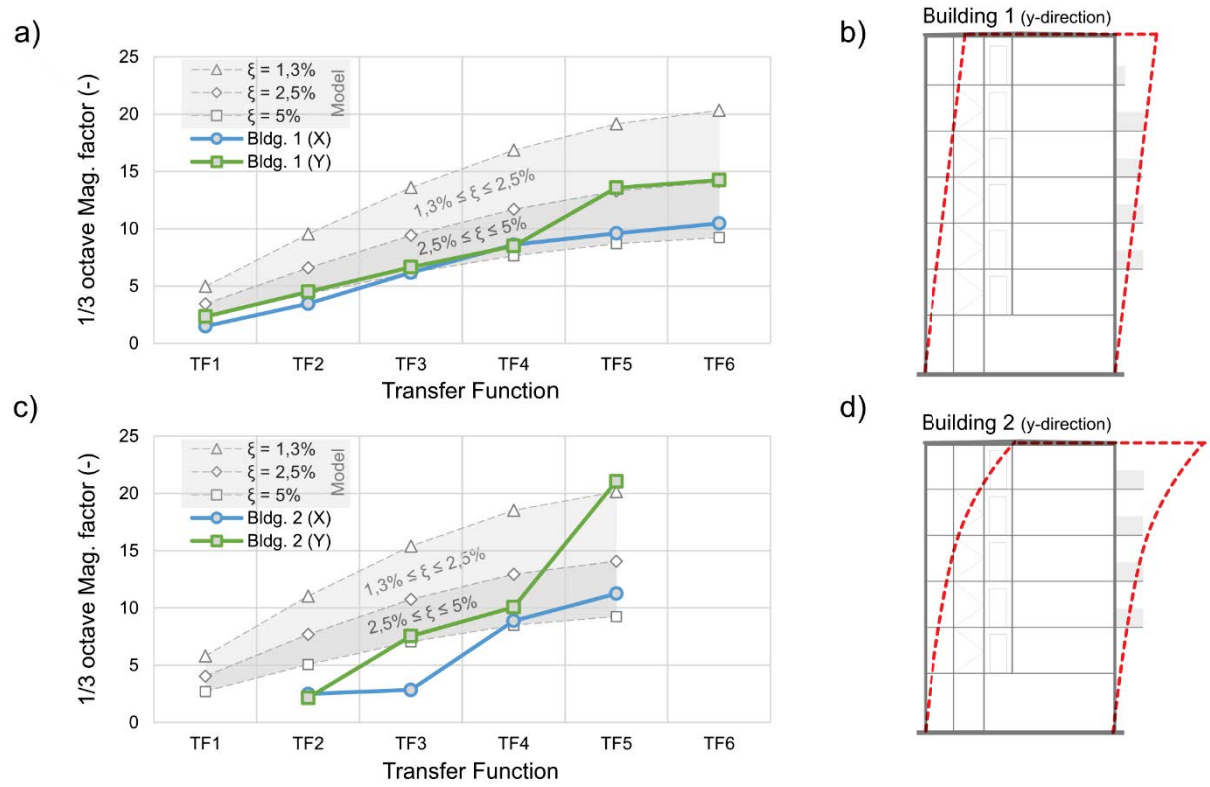

Figure 7: a), c) 1/3 octave magnification factors of Building 1 and Building 2. Besides, numerically gained results from the dynamic model and for different attenuation ratios are depicted. b), d) represent the horizontal deflection of the building schematically.

In summary, disruptive vibrations on upper floors in *Building 2* are caused by an interaction between freight-train vibrations at the track, wave propagation in sandy soils as well as the horizontal oscillation amplification within the building structure which is partially made of calcareous sandstone. A stiffer design should increase structural stability and lead to a model-like response.

On the basis of this knowledge gained, a more detailed FEM study was targeted to improve the dynamic performance of the structural design and to find an optimized constructive design for the district area the dynamic performance of the structural design and to find an optimized constructive design for the district area.

6 OPTIMIZED BUILDING DESIGN

Future area development involves the construction of further multi-story buildings. Fundamental measures to improve the vibrational situation for the whole area could be implemented at the railway track as well as on the propagation path between track and buildings.

An upgrade of the train track and strengthening of the railway superstructure could reduce vibrations at the track. A subterraneous curtain on the path works as a propagation barrier, but these options appeared to be unrealistic due to long approval processes, technical reasons, and economic inefficiency.

Modal analysis in the low-frequency range in Figure 8 reveals basic movement patterns of the building structure in a horizontal direction. The eigenfrequency of Rocking modes matches the experimental results and corresponding resonance magnifications should be minimized.

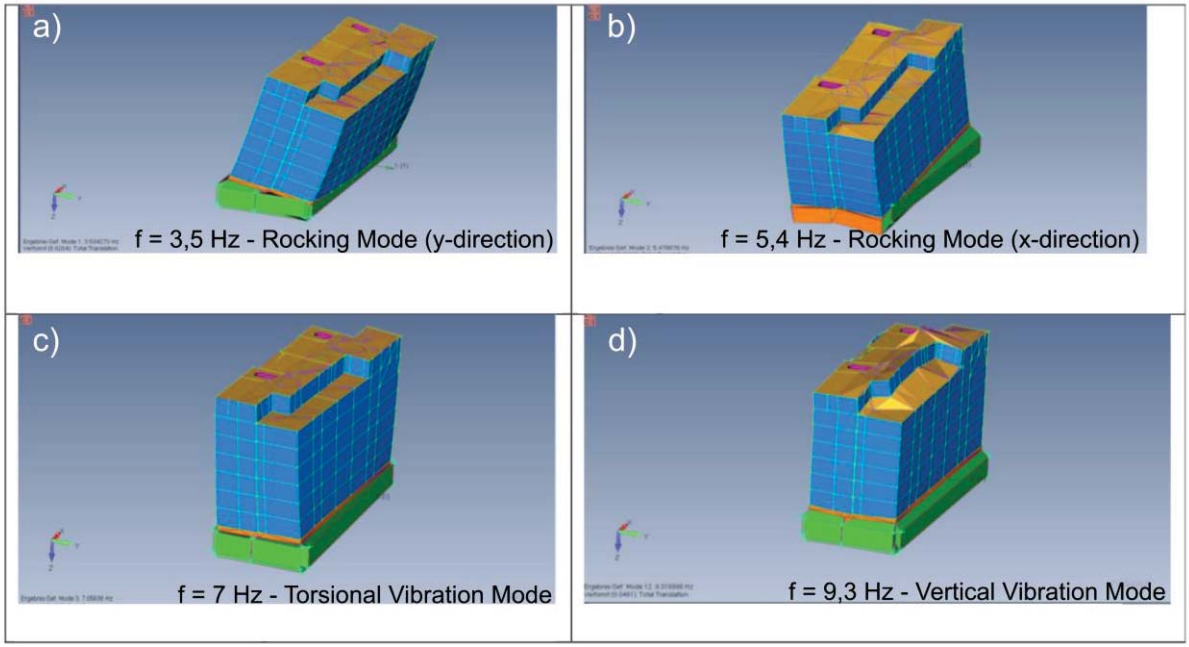

Figure 8: Modal analysis of the building structure having regard to the sandy foundation. a) - b) Rocking modes match with the experimental results and cause horizontal movement patterns. c) – d) In addition, torsion and vertical modes are present in the low-frequency range.

A detailed FEM study instead was launched which is based upon the prior approach. The structural building design and foundation soil were modeled in FEM and a detailed analysis of the building dynamics depending on its parameter was conducted.

Figure 9 depicts the transfer behavior of a construction made of calcareous sandstone (blue). Besides a shift towards higher eigenfrequencies, a stiffer wall construction of a thickness of 0.2 meters (red) made of reinforced concrete leads to a transfer reduction of 33%. These numerical gained results match the experimental results in Figure 7. Furthermore, an increased exterior wall thickness of 0.3 (yellow) meter only reduces the amplification by 40%.

As a result, a stiffer wall construction of thickness 0.2 meter represents a cost-effective solution to reach a reduced vibration level within planned apartments on higher floors.

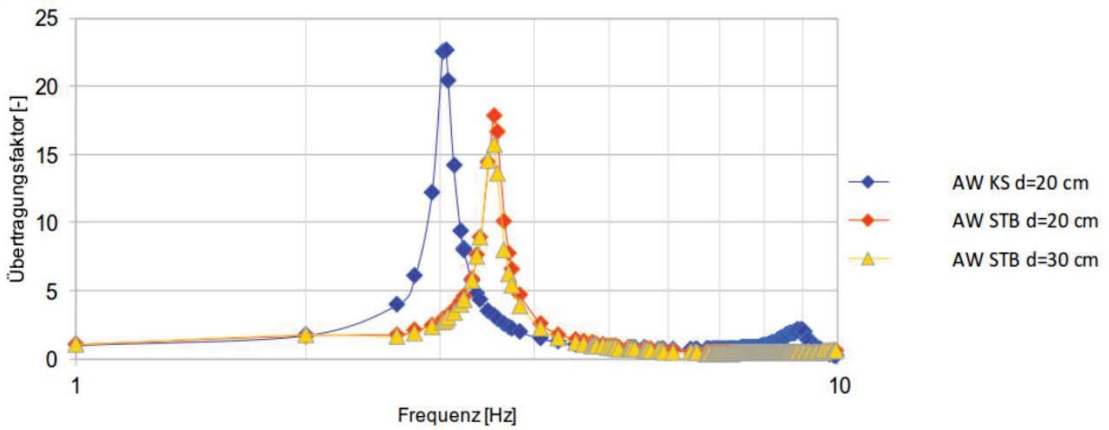

Figure 9: Transfer functions for three different constructive building designs derived from FEM. The transfer behavior for an exterior wall made of calcareous sandstone (blue), reinforced concrete wall of thickness 0.2 meters (red) and 0.3 meters (yellow).

7 SUMMARY

Shock-waves from the faraway railway track lead to horizontal oscillations of the building structure. Buildings are exposed by low-frequency Rayleigh waves which match with the Rocking modes of the constructional design. The design leads to higher amplification of the vibration level within the structure.

The dynamic response of two different constructional designs exhibits that the structural stability of the exterior wall construction is decisive for the amount of amplification within the structure. The optimized structure was determined within a FEM model. A reinforced concrete wall can reach a cost-effective reduction of the vibration level in contrast to a masonry construction of calcareous sandstone.

In general, this case-study indicates, that the constructional design of planned buildings should be investigated more precisely if dynamical risk factors like soft ground, higher building constructions, and a low-frequency shock-wave exposition lateral of a railway track occur.

Keywords: Floating Slab Track, Tuned Mass Damper, Viscous Damper, Insertion Gain

Abstract.
Floating Slab Track (FST) are proven to provide the best mitigation for railway vibration. The inertia of the floating slab balances the excitation of the train pass. Floating Slab on discrete bearing usually provides a system frequency lower than 10 Hz. Although the system frequency is low, FST shows at higher modes, especially in the typical ground-borne noise frequency band of about 63 Hz smaller performances as normally expected. Higher modes of the slab itself amplify train vibration because these modes will not be damped adequately by the support bearings or springs. The solution is an on these specific disturbing frequencies tuned TMD mounted on top of the slab, which balances this problem expertly. The case study at the Metro line 4 shows the application of this combined mitigation measure.

1 INTRODUCTION

In China, the metro network has been rapidly expanded over the past 15 years. A wide variety of noise and vibration measures were also applied in order to protect nearby residential houses. In particular, mass-spring-systems (MSS) were completed in many urban areas in China. An MSS supported by steel springs is a standard mitigation measure in China now. In some areas of the line, however, these systems did not show the isolation effect in practice that could theoretically be expected. This may be due to mistakes during the design phase or construction phase.

2 VIBRATION ATTENUATION BY FLOATING SLAB TRACK

There is no doubt that the best performances in terms of vibration attenuation can be achieved by floating slab track systems if they are well designed by experienced engineers. These mass-spring-systems (MSS) consist of floating slabs with the rails mounted on top. The slabs

are usually constructed of reinforced concrete. Together with the dead load of rails, sleepers and fastenings (and the ballast, if any), they form dynamically active masses that are isolated from the sub-structure by elastic mounts which may be of rubber, elastomeric material or steel. The performance of an MSS depends on a number of factors. Besides the vertical tuning frequency, the bending natural frequencies of the slabs are of significant importance. In addition, the system damping, as well as the stiffness of the sub-structure, has a clear influence. Finally, the success of an MSS can also depend on the dynamics of the tunnel itself. In certain cases there is little advantage to be obtained by using a medium-frequency (say above 15 Hz) floating-slab track construction in railway tunnels. Since the tuning frequency depends on the static spring deflection, it is obvious that the spring stiffness is the most important issue. Fig. 2 shows the transmissibility factor VF over the tuning factor η. The tuning factor is defined as the ratio of the excitation frequency f divided by the natural frequency f_0. It clearly shows that the attenuation of vibration transmission takes place only if the factor is beyond the value of $\sqrt{2}$. There is no reduction of dynamic forces possible when the natural frequency (= tuning frequency) of an MSS is close to or above the relevant excitation frequencies. For an undamped single degree of freedom system (SDOF), the dynamical amplification V being the ratio between dynamic and static force equals:

$$V = \sqrt{\frac{1 + 4D^2\eta^2}{(1-\eta^2)^2 + 4D^2\eta^2}}$$

With
η = f/fo
D = Damping

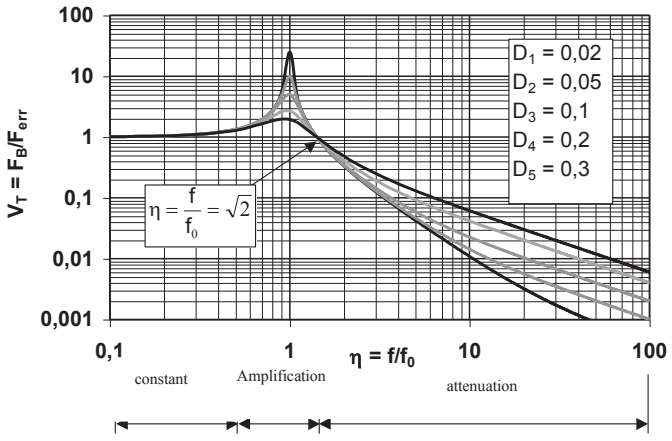

Figure 1: transmissibility curve depending on the damping

Typical vibration frequencies induced by trains are found in a range of 10 - 80 Hz. The frequency spectra usually reveal a concentration of higher peaks in the 60 Hz area, e.g. due to wheel-rail interaction. However, quite often there are high vibration levels between 10 and 30 Hz as well.

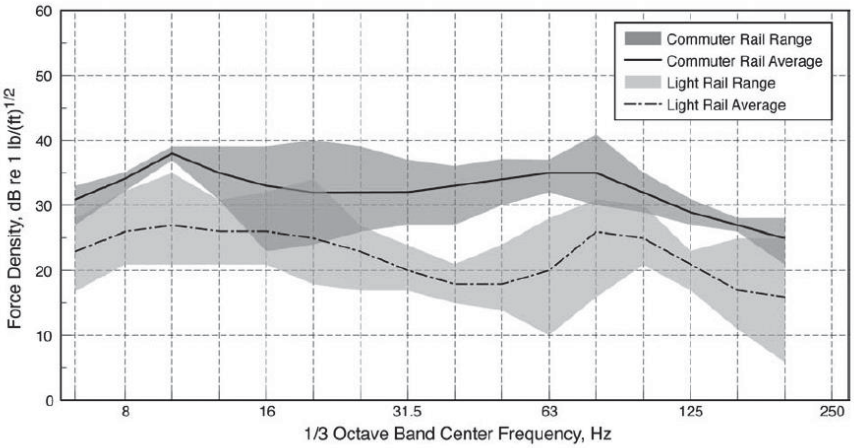

Figure 2: Force density levels for Commuter Train and LRT

In the case of a standard track bed, these frequencies might cause severe vibration problems in nearby buildings showing resonance frequencies just in that range.

A' low-tuned ' mass-spring-system on steel springs can be relied on to provide a tuning frequencies 4 to 10 Hz. Since the tuning frequency of a floating slab track is so important, it has to be explained how it is defined. As a first approach, the extension of the slab can be neglected and all spring stiffnesses of a direction can be united as one common spring. This results in a single-mass-system with 6 degrees of freedom. With respect to the direction of the dominant train excitations, the vertical translation natural frequency is the most relevant one, here referred to as the 'tuning frequency'. A linear spring elasticity provided, the tuning frequency f0 of the non-damped system can easily be calculated by the following simplified equation:

$$f_0 = \frac{5}{\sqrt{\delta_{[cm]}}}(Hz) \qquad \text{with} \quad \delta = \frac{F}{k_z}$$

Although the actual correlations are much more complex, the tuning frequency can be used to evaluate the efficiency of a floating trackbed system at a first view.
Sometimes the non-suspended part of the rolling stock is added to the mass leading to a lower tuning frequency. This part is usually chosen as 10% to 15% of the axle loads contributing to the sprung system.
A more realistic result is achievable by modeling the slab according to the Finite- Element-Method (FEM). In this case, the flexural modes of the slab are taken into consideration. This is of special importance when the 1.-order bending natural frequency of a slab is in the same range as the tuning frequency resulting in coupled modes. The tuning frequency will be shifted, and a diminished tuning factor might result in a reduction of the isolation efficiency of the system.

Vertical Loading	Dynamic Factor	Phi = 1.3 (multiplying the static load and considering the dynamic of a rolling stock)

Horizontal Loading	Curve	$P_H = P \cdot \frac{v^2 \cdot f}{127 \cdot r}$
	Nosing	30 - 100 kN
	Braking	25% of vertical loading

Table 1: Usual train loading for the FST design

3 DESCRIPTION OF THE METRO LINE

The metro line 4 in a Chinese city with a total length of about 42 km was inaugurated in 2017. This line goes from North to South and connects residential areas downtown. The line is constructed as a bored tunnel with a China typical inner diameter of 5.4 m. The tunnel depth is in the range of -20 m (T/R). The subsoil condition is mostly soft clay. Due to the close vicinity between Metro line and dwelling areas and also the very soft soil condition the need for mitigation measures can be normally expected. At the residential area, the predicted vibration level was 72 dB > 62 dB (accepted value for residential buildings).

Figure 3: *Alignment of Metro Line 4 and affected residential buildings*

区域 Applicable Zone	昼间 Daytime	夜间 Nigthtime
特殊住宅区 Special Residential Area	65	62
居住、文教区 Residential &Cultural&Education Area	65	62
居住、商业混合区，商业中心区 Mixed Zone&Bussiness Center District	70	67
工业集中区 Industrial Concentration District	75	72
交通干线道路两侧 Both Sides of Traffic Trunk Road	75	72

Table 2: Accepted limits according to JGJ/T170-2009, Aw= 65 dB (aref=1e-6 m/s)

Due to the predicted vibration level, an FST on steel spring with a system frequency of f=10 Hz was required. Spring supported Floating Slab Tracks are the common mitigation measure in China to attenuate Noise & Vibration from Metro lines.

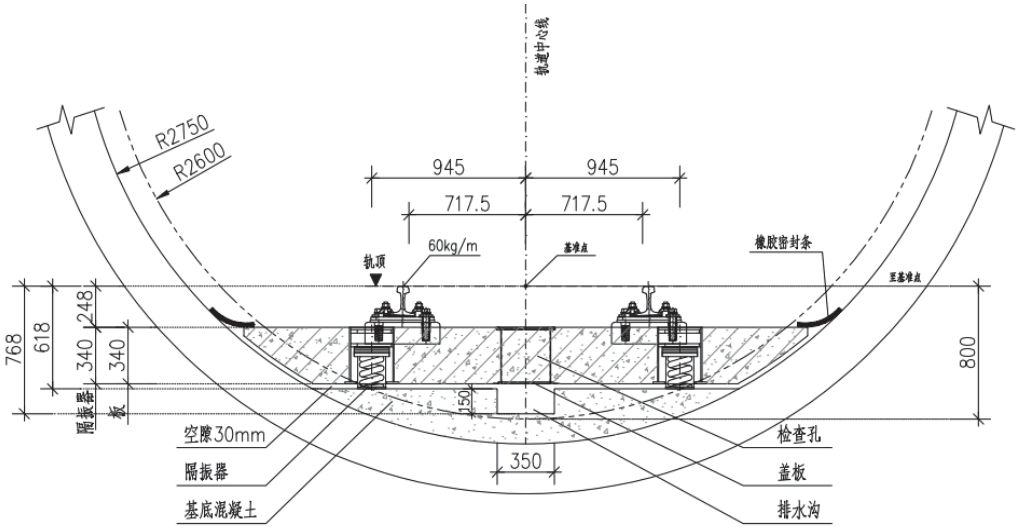

Figure 4: Cross Section of the installed Floating Slab Track

Although an FST on springs was installed the residentials complain about noticeable rumbling noise during the train pass-by. A comprehensive measurement campaign was carried out to identify the reason for the rumbling noise. The measured spectrum at the tunnel wall and within the residential building clearly shows a main peak in the spectra at the 63 Hz 1/3 octave band. The installed FST on springs was not able to mitigate significantly the vibration from the wheel/rail interaction.

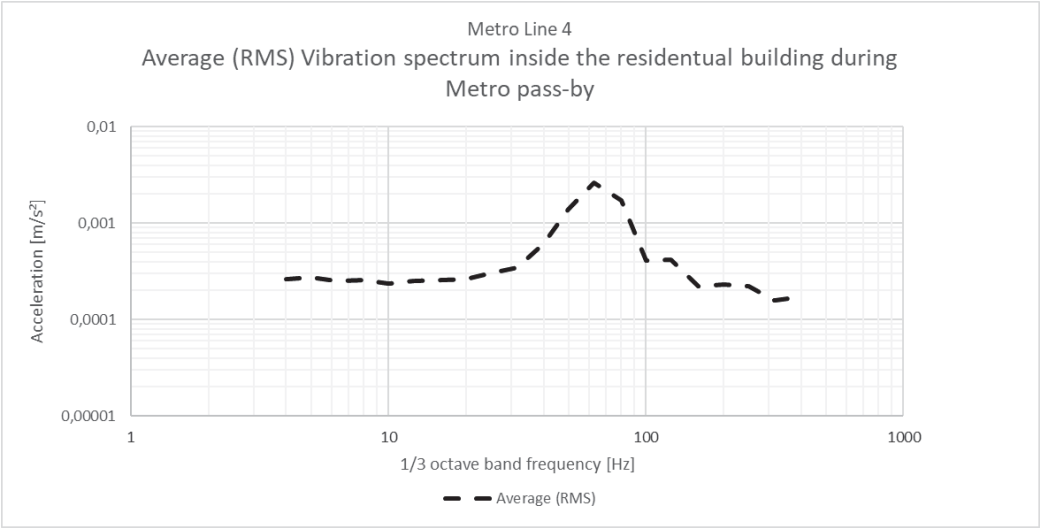

Figure 5: Vibration spectrum inside the affected building on the second floor

Measurements at the tunnel wall confirmed the results of the buildings. Due to the rail wheel interaction, a major peak at 63 Hz on the slab and at the tunnel wall is visible.

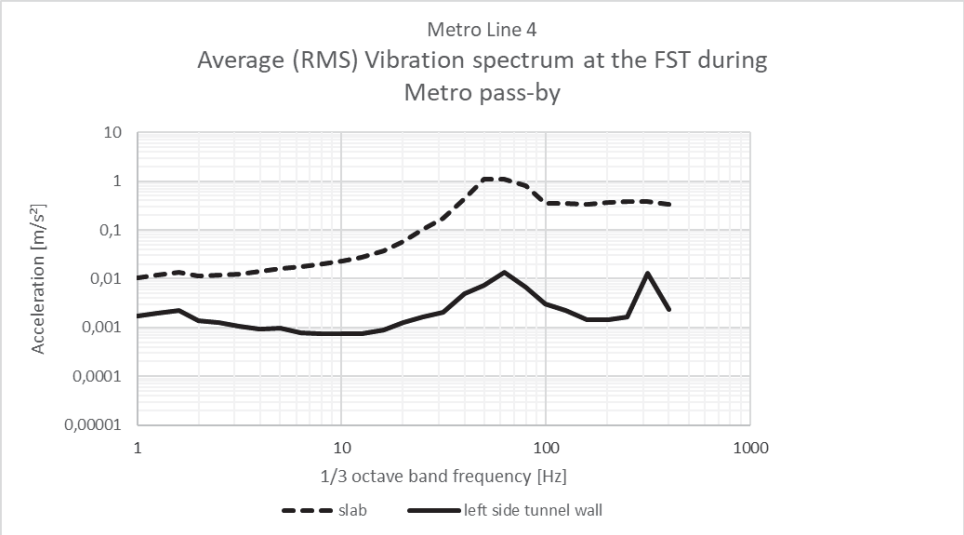

Figure 6: Measured vibration at the tunnel

4 POTENTIAL MITIGATION MEASURES

4.1 Damping of the FST

In order to mitigate the vibration level at 63 Hz, several options were investigated. Damping is an essential factor for all mitigation systems. At railways systems, the standard mitigation materials provide hysteretic and viscous dampers.
The introduction of more viscous damping into the spring cans would increase the damping but would also result in a higher system frequency due to the stiffening effect of the viscous liquid. Real viscous dampers provide only at low frequencies < 10 Hz enough damping, therefore higher structural modes usually are not damped by viscous dampers.

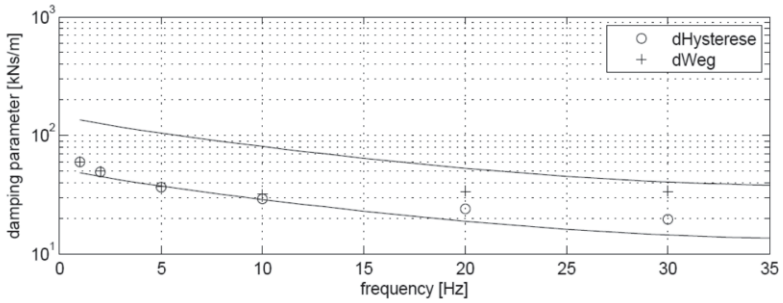

Figure 7: Typical damping behavior of a viscous damper (real measurement)

A theoretical analysis of the expected vibration level at the tunnel wall for an FST with ideal viscous damping and the consideration of the real damping can be seen in figure 8.

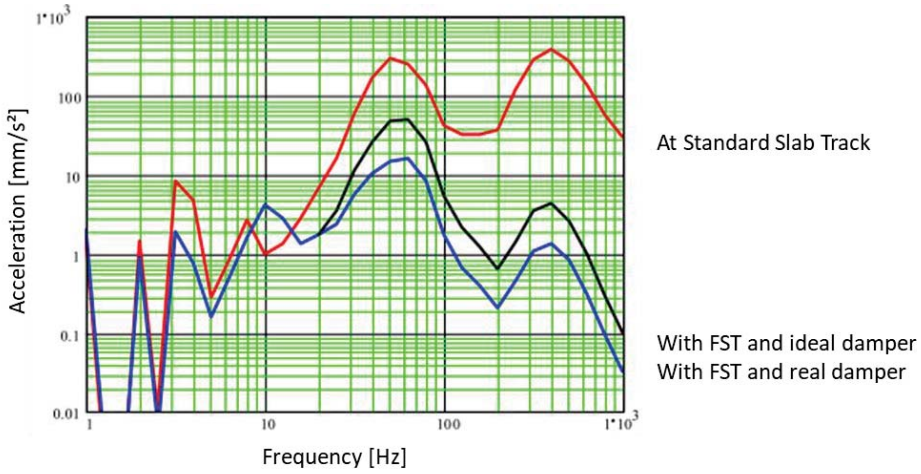

Figure 8: Calculated vibration level at the tunnel wall depending on the applied damping model

4.2 Lower FST system frequency

A lower support frequency can increase the mitigation effect. FST on springs allows due to the permanent access from above to change the springs easily. Softer ones can replace the current springs. Due to the given dimensions, spring stiffness can be varied in the range of +- 20%, which means approx. 10% lower system frequency. It has to be checked whether softer springs would also in compliance with the permissible deflection of the FST (e.g. effect on rail stress) and the static design pf the slab itself (e.g. installed reinforcement).

4.3 Application of a Tuned Mass Damper

A standard method of introducing damping or balancing forces is the application of so-called Tuned Mass Damper (TMD). Excitation forces are compensated by mass forces so that parts of the structure (main construction) remain almost at rest in a certain frequency range. In vibration damping, an additional oscillator consisting of mass and stiffness (undamped absorber) or of mass, stiffness, and damping (damped absorber) is attached to the main structure to be calmed.

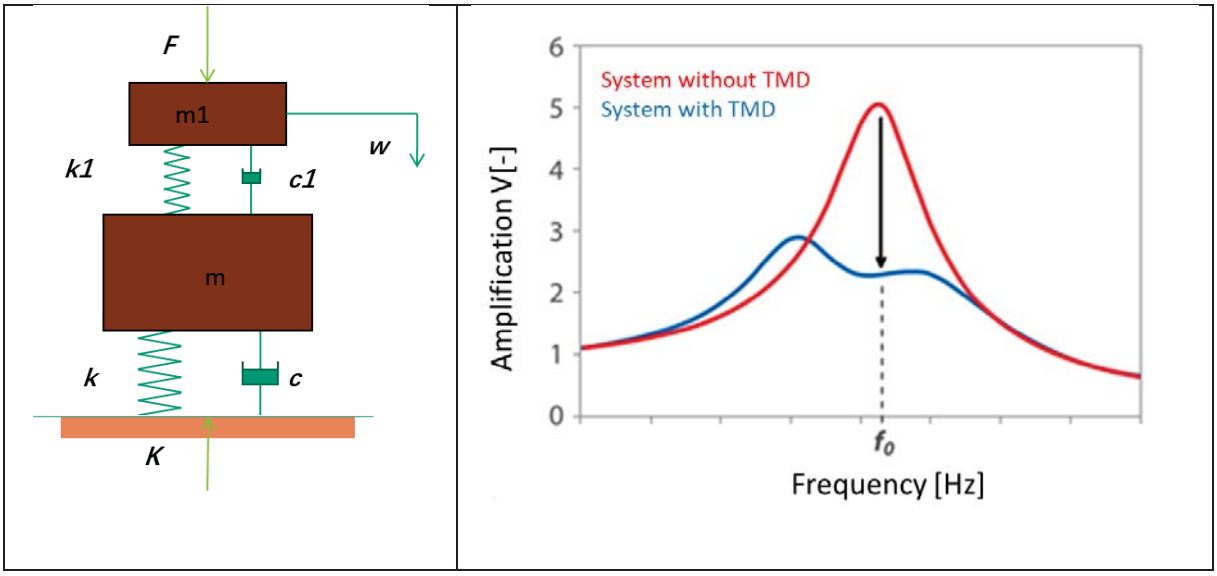

Figure 9: Structure with a Tuned Mass Damper

The undamped absorber is usually used for stationary harmonic oscillation problems, where the absorber natural frequency T is tuned to the excitation frequency. Theoretically, the vibration amplitudes of the main system can be reduced to zero if no damping is present.

For stationary broadband excitation, which is essential in the range of a natural system frequency, the use of an optimally damped absorber is useful. The natural frequency and the damping ratio D_{opt} of the optimally damped absorber can be designed according to [Petersen] with the mass ratio as follows

According to Den Hartog

$$\mu = \frac{m_T}{m}$$

$$\omega_T = \sqrt{k_T/m_T}$$

$$\omega_{T,opt} = \omega \sqrt{\frac{1}{1+\mu}}$$

$$D_{opt} = \sqrt{\frac{3\mu}{8(1+\mu)^3}}$$

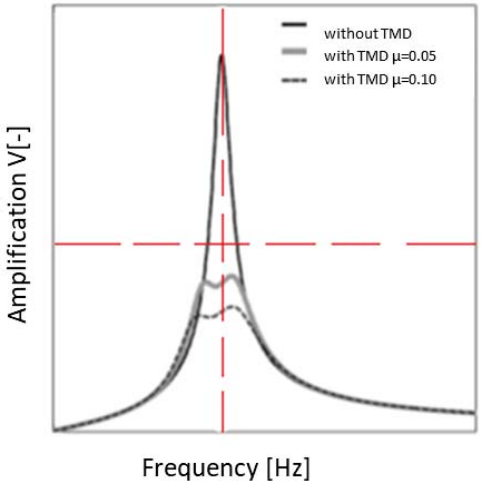

Figure 10: Effect of the TMD mass on the primary system

The above figure shows the effect of an optimally damped absorber with different mass ratios. In order to achieve enough vibration reduction, mass ratios of 0.05 to 0.15 are recommended. The analysis of a 63 Hz TMD leads to the following results:

- The insertion gain can be improved at 63 Hz (from 10 Hz to 65 Hz) with the disadvantage of lower mitigation between 70 and 100 Hz.
- A reduction of -6 dB can be achieved in the 63 Hz 1/3 octave band
- A weakly damped TMD has a stronger narrowband effect.
- The double-weight absorber performs twice as strong and more broadband.
- Minimum damping of 15% is recommended to ensure reliable TMD amplitudes and transmitted forces

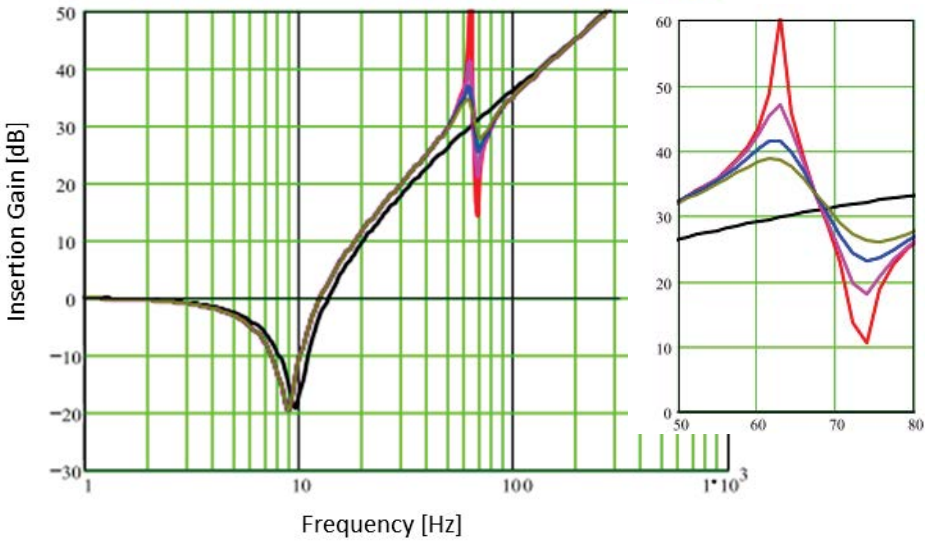

Figure 11: Calculated Insertion Gain for an FST/TMD combination

5 PREFERRED SOLUTION (COMBINED FST / TMD APPLICATION)

Due to the advantages of the TMD compared to the other options, it was decided to continue with the design of the TMD. The following requirements have to be considered to ensure the absolutely safe operation of the track line.

- A low profile of the TMD, it must be designed in between the rails
- No coverage of drainage checking holes
- No obstruction of rescue vehicles

These requirements result in a compact TMD design. The TMD consist mainly of steel plates supported by rubber strips. The system frequency can be adjusted by the specific bedding modulus of the strips and the related strip size. Metal brackets prevent the steel plates from lifting off. A total of 100 m per direction was equipped with these TMD.

Host frequencies	10 Hz (vertical FST system frequency) / 63 Hz (rail / wheel interaction)
Total length of equipped FST per direction	100 m
Number of TMD	88
Installation time per TMD	2 h
TMD Mass	970 kg
Mass ratio	0,15
1. TMD frequency (Theory, Measured)	8.74 Hz / 12.5 Hz
1. TMD Damping (Optimum/ Measured)	18.9 % / 15%
2. TMD frequency (Theory, Measured)	48 Hz / 50 Hz

Table 3 Overview of the design parameter

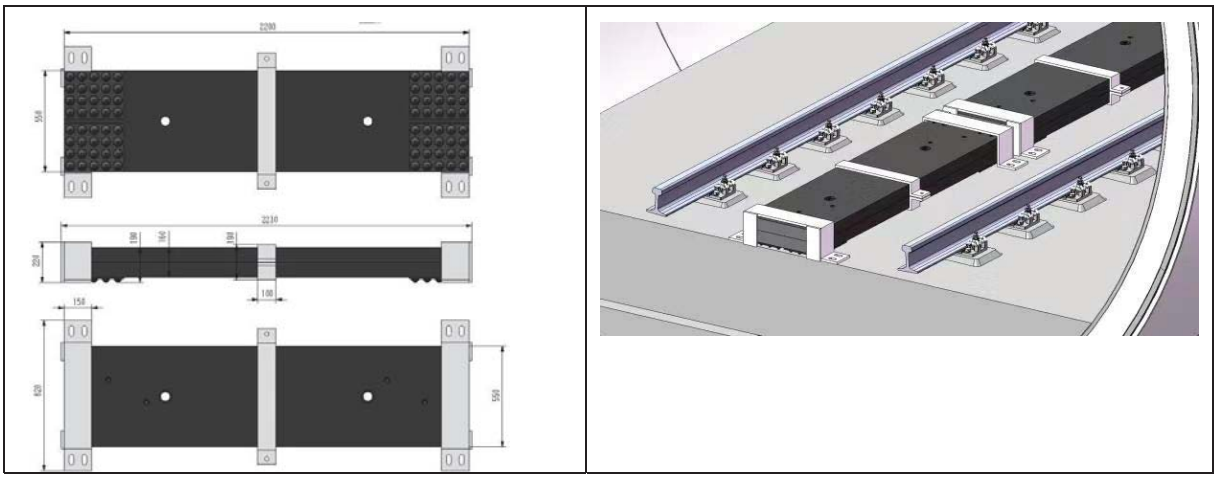

Figure 12: Design of TMD on top of the floating slab track

Figure 13: Installed TMD on the FST

6 ON-SITE RESULTS

Vibration measurements have been performed to check the performance of the installed TMD. In particular, the vibration level at the rail, on the slab, at the TMD, and at the tunnel wall was measured before and after the installation of the TMD. Simultaneously also measurement in residential buildings nearby has been carried out. It was figured out that the effect of the TMD on the tunnel wall vibration shows only low mitigation but measurements within the building show the expected reduction. The TMD itself shows peaks at its eigenmodes which reveals the operation of the TMD itself during train pass-by.

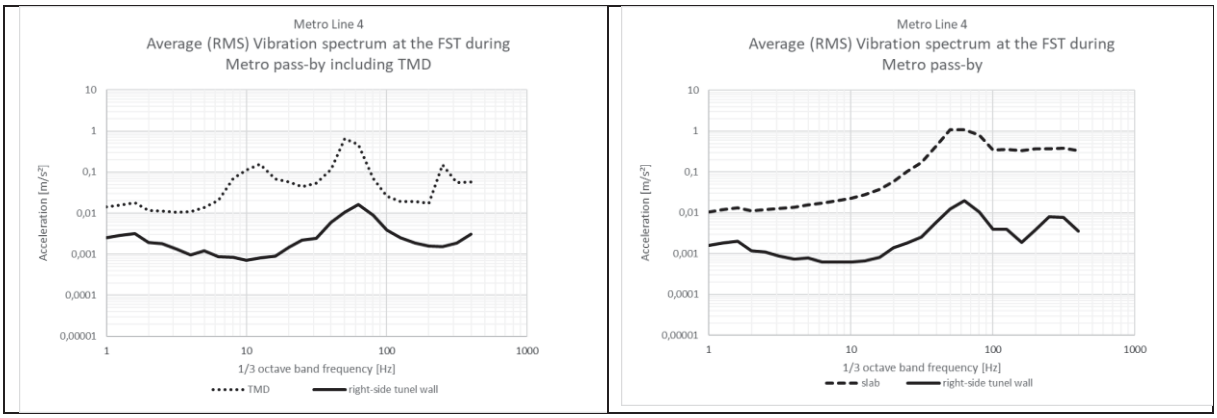

Figure 14: Vibration Level at the tunnel site with and without TMD

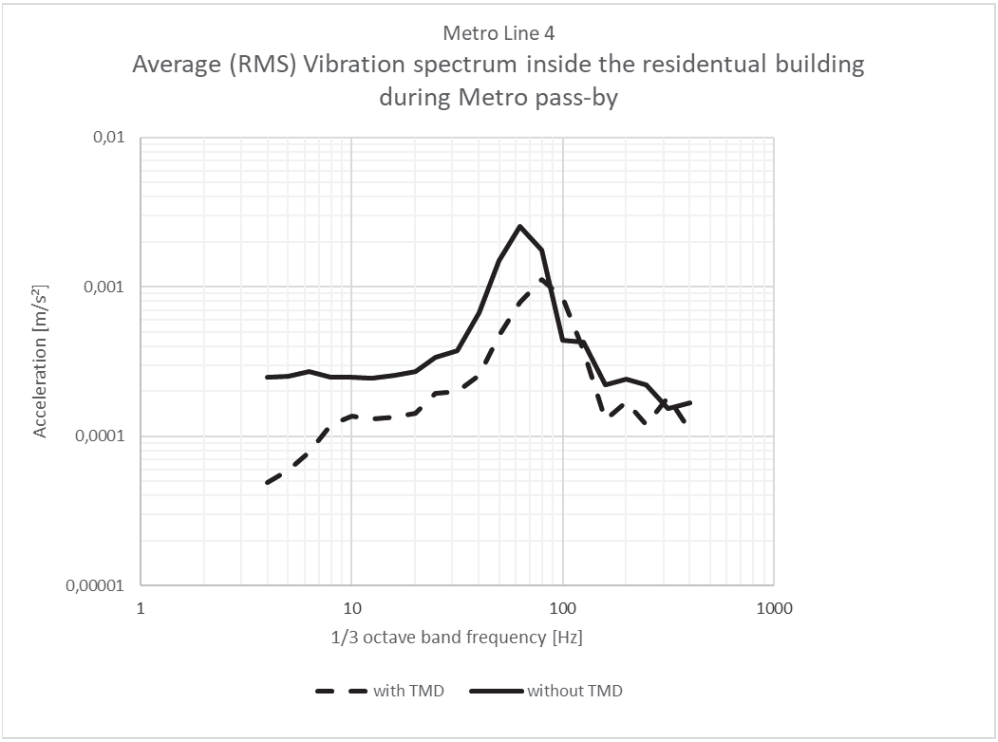

Figure 15: Measured vibration level inside the building with and without TMD

A noticeable reduction mainly at the 63 Hz (1/3 octave band frequency) was measured and confirmed the balancing effect of the TMD on the vibration level. The mitigation effect is even a little bit higher and might result due to the additional inertia of the TMD mounted on the FST.

7 CONCLUSION

Floating Slab Track (FST) are proven to provide the best mitigation for railway vibration. The inertia of the floating slab balances the excitation of the train pass. Floating Slab on discrete

bearing usually provides a system frequency lower than 10 Hz. Although the system frequency is low, FST shows at higher modes, especially in the typical ground-borne noise frequency band of about 63 Hz smaller performances as normally expected. A TMD mounted on top of the slab and tuned on these specific disturbing frequencies can balances this problem expertly. The Case Study at the Metro Line 4 in a Chinese city shows clear vibration mitigation in nearby residential housings due to the installed TMD over 100 m track length.

- The theoretical analysis shows a reduction of – 6dB at the 63 Hz 1/3 octave band. On-site measurements show in the nearby residential housel a slightly higher mitigation effect compared to the theory. The reason might be due to a higher inertia effect of the TMD.
- The design has to consider the requirement/clearance of the track
- Minimum damping of 15% is recommended to ensure reliable TMD amplitudes and transmitted forces
- A TMD mass ratio of 15% is recommended

Keywords: Soil-structure interaction, train induced vibration, mixed frame of reference

Abstract. *When modelling the railway induced vibration in a building, three main aspects of the problem have to be considered: the vibration generation at the moving vehicle-track interaction points, the vibration propagation in the underlying infinite soil, and the vibration reception inside the building. This study proposes a computational modelling approach for predicting the full vibration propagation path from the train vehicles up to the building structure. The method includes a moving train model that is directly coupled to a stationary building structure, with interaction between them through the underlying soil using a single step solution procedure. A semi-analytical model is utilized to model the soil to which rigid objects and structures modelled by finite elements (FE) are coupled. The system is excited by a multi-body vehicle model passing over an irregular track. The proposed modelling approach uses the frequency-domain solution with some parts, such as the railway track, formulated in the moving frame of reference (FOR) and other parts, such as building structures, formulated in a fixed FOR. The coupling terms between the two FORs are found by utilizing an analytical formulation of receptance between the two FORs. It is shown that due to the coupling between the fixed and moving FORs, the previously uncoupled discrete frequencies become coupled through the other FOR as a result of the Doppler effect and wave scattering. Two solution procedures of the full system are proposed: partial coupling, where some secondary effects from reflected waves propagating through soil are disregarded, and full coupling, where the vehicle, track, soil and structure are modelled as a fully coupled system. Both proposed solution procedures offer a single-step approach for solving the whole system in the frequency-spatial domain. The application of the model is demonstrated and validated in two example cases: one analyzing a simple building structure near a railway track, using the partial coupling solution procedure, and another analyzing the behaviour of a vehicle model passing over a rigid block embedded inside the soil, using the full coupling solution procedure.*

1 INTRODUCTION

One of the important environmental impacts of existing and future railway lines occurs due to the ground-borne vibration induced by the trains. When a train runs on the track, its wheels induce vibration in the track structure. This vibration then propagates through the ground into nearby buildings where it is perceived either directly, due to motion of floors and walls, or indirectly as re-radiated noise. This causes disturbance to occupants, potential loss of building functionality (e.g. interference with sensitive equipment), loss of real estate value and, in worst case, leading to structural damage.

The impact of railway-induced vibrations has been investigated since the beginning of the previous century and much work has been done to understand and simulate the dynamic interactions between the train, track, tunnel (for underground railways) and ground resulting in models which can predict ground-borne vibration around the railway system. The exact propagation mechanism of environmental vibration is an extremely complex phenomenon, and thus proper evaluation of its effects is difficult. Several different numerical models have been developed for predicting vibration from surface and underground railways in the last few decades. They are mainly based on numerical or semi-analytical methods. Each approach has its own merits. Semi-analytical models are simpler, requiring less input parameters, but they are not able to represent the full details of a given situation. Conversely, numerical models can represent more detailed geometry but require a larger number of input parameters and greater computational effort. The results are then specific to this particular situation and cannot be generalized easily. There are also important limitations in the use of either type of model, due to the modelling simplifications and parameter uncertainty. A comprehensive overview of the state of the art on railway-induced ground vibration models and the underlying excitation mechanisms can be found in [1].

When modelling the environmental vibration in a building induced by railway traffic, three main parts of the problem need to be considered: the vehicle-track system which is the vibration source, the underlying soil through which the vibration propagates, and the building structure which is the vibration receiver. Ideally, all the parts would be combined into a single model, including all coupling terms. However, due to complex analytical formulation needed and the limitations of computational models, this is rarely performed. Most often, parts of the model are coupled together; for example, a coupled vehicle-track-soil model is calculated, and the obtained results propagate to the building structure [2 - 9]. This way, the secondary coupling terms are excluded from the system, such as the effect of the building structure to the response of the track and the vehicle. This is acceptable, as these coupling terms do not influence the system significantly [10]. For example, Fiala et al. [2] used a two-step approach to obtain the response of a building structure by splitting the problem into a vehicle-track-soil source model and a structure-soil receiver model. With a similar approach, François et al. [3] studied road-traffic-induced vibration. The work also proposed a methodology to exclude the soil-structure interaction problem for cases of soft structures resting on stiff soils. A so-called sub-modelling technique was proposed by Hussein et al. [6], where the response of the soil surface from a tunnel structure was modelled using the 'pipe-in-pipe' model [11] to find the response of a 2D frame. An almost identical system assembly method was also used by Lopes et al. [5]; however, the soil surface response from a tunnel structure was modelled using a 2.5D FEM-PML (perfectly matched layers) model and a 3D building structure was analyzed. In [9], Kuo et al. use a similar numerical approach and the model developed in [10] to investigate the effect of dynamic soil characteristics, surface foundation type, and building geometry on the building's response to railway induced vibrations and compare with the FRA empirical adjustment factors [12].

The aim of this work is to model the full vibration propagation path from the vehicle up to the building structure. The proposed method includes a moving vehicle model that is directly coupled to a stationary building structure, with interaction between them through the infinite underlying soil, without needing a multiple step solution. At the same time, the method offers a relatively quick and flexible solution procedure. A fully 3D system is modelled, with structures modelled using FE, allowing a wide variety of configurations. To limit the computational times needed, the semi-analytical soil formulation is utilized, with a surface railway track, using the model originally proposed by Sheng et al. in [13, 14] and later extended in [15]. A multi-body vehicle model passing over an irregular track excites the system. The work introduces an approach of solving the coupled vehicle-track-soil-building system using a single step solution procedure. Two system assembly and solution methods are presented: *partial coupling* and *full coupling*. With the *partial coupling* procedure disregarding some effects caused by the reflected waves for a more computationally efficient solution, and the *full coupling* procedure including all the coupling terms. Additionally, the methodology for modelling rigid objects and FE structures interacting with the soil is described with its implementation into the proposed solution approaches. To show the capabilities of the proposed modelling approach two example cases are analyzed: (i) for a simple building structure near a railway track, using the partial coupling solution procedure, and (ii) the behaviour of a vehicle model passing over a rigid block embedded inside the soil, using the full coupling solution procedure.

2 SEMI-ANALYTICAL SOIL MODEL

A semi-analytical soil model is used in the present work. The model utilizes a well-known approach based on an analytical solution to the Green's function in the frequency-wavenumber domain. For the linear hysteric half-space $z \leq 0$, the displacement field in time–space domain can be obtained using a convolution integral:

$$u_i(x,y,z,t) = \int_{-\infty}^{t}\int_{-\infty}^{0}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} g_{ij}(x-x',y-y',z,z',t-t')\, p_j(x',y',z',t')\, \mathrm{d}x'\, \mathrm{d}y'\, \mathrm{d}z'\, \mathrm{d}t' \quad (1)$$

where the Green's function g_{ij} relates the displacement component u_i at the point (x, y, z) and time t to the loads p_j applied in direction j at all positions and times up to and including the time t. The soil is assumed invariant and infinite in both horizontal directions, while the material properties vary over depth due to stratification.

The Green's function is challenging to find analytically in time-space domain for a layered half-space. Thus, a triple Fourier transformation can be performed, transforming the two horizontal coordinates into the wavenumbers k_x andk_y, and time into the circular frequency ω. By introducing a discretization into a number of depths z_n, $n = 1,2,3,\ldots,N_z$, Eq. (1) simplifies into

$$\bar{U}_i(k_x,k_y,z,\omega) = \sum_{n=1}^{N_z} \bar{G}_{ij}(k_x,k_y,z,z_n,\omega)\, \bar{P}_{n,j}(k_x,k_y,\omega) \quad (2)$$

where $\bar{U}$ and $\bar{G}_{ij}$are components of the displacement vector and the Green's function tensor, respectively, in the frequency-wavenumber domain. After the discretization over depth, $\bar{P}_{n,j}$ signifies the traction applied on a horizontal interface placed at the depth z_n. In the following, upper case symbols indicate Fourier transforms with respect to time, whereas overbar indicates Fourier transforms with respect to the horizontal spatial coordinates.

There are two major approaches used to assemble multiple soil layers and express analytically the Green's functions $\bar{G}_{ij}$ appearing in Eq. (2): the flexibility approach and the stiffness

approach. The flexibility approach is based on the original work proposed by Thomson [16] and Haskell [17]. The stiffness approach was introduced by Kausel and Roësset [18] and extends the original transfer matrix, as derived in [16, 17] by reordering it into a stiffness expression equivalent to those used in the FEM, assuming that the interface between two layers is interpreted as a connecting node. Multiple layers can be assembled by overlapping the stiffness matrices at the connecting interfaces.

In this work, both methods have been utilized: the flexibility approach with numerical stabilization for the fixed FOR soil model and the stiffness approach for the moving FOR model. The reason that the flexibility approach is used for the fixed FOR and the soil-structure interaction is because it enables the application of structure-to-soil interaction forces without increasing the size of the involved matrices (that is always six by six) for foundations that are embedded in the ground (i.e. piled foundations). For the moving FOR problem, only the Green's functions for a surface load (i.e. the track) are needed and thus the stiffness approach is used which is free of numerical instabilities at higher frequencies, that are more prominent due to the moving of the load. Any instabilities occurring in the flexibility approach are dealt using stabilization techniques that are based on the orthonormalization method [19] and by splitting very thick layers (if any) into multiple smaller layers with the same material properties.

After the displacements in the frequency-wavenumber domain are obtained, a double inverse Fourier transformation is performed into frequency-space domain

$$U_{\mathrm{f}\,i}(x_{\mathrm{f}}, y, z, \omega_{\mathrm{f}}) = \frac{1}{4\pi^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\overline{U}_i(k_x, k_y, z, \omega_{\mathrm{f}})\,\mathrm{e}^{\mathrm{i}(k_x x_{\mathrm{f}} + k_y y)}\,\mathrm{d}k_x\,\mathrm{d}k_y. \tag{3}$$

This equation is used when both the load and the response in a fixed FOR is considered. The load is applied at a circular frequency ω_{f} and coordinate x_{f}, with subscript 'f' indicating a fixed FOR. Here, the inverse Fourier transformation can be carried out in semi-discrete form by adopting polar coordinates, since the integration with respect to the azimuthal angle can be done in closed form, leading to Bessel functions in the components of the Green's function.

When the whole system is considered in a moving FOR, the Green's function and, at the same time, the response in the frequency-wavenumber domain lose the polar symmetry around the origin of the wavenumber domain, compared to a purely fixed FOR. Hence, a fully discrete inverse Fourier transformation from wavenumber domain into spatial domain is necessary. Assuming that a load is moving in the positive x-direction, the frequency used to compute the Green's function becomes wavenumber dependent. In that case, the inverse double Fourier transformation into frequency–space domain is defined as

$$U_{\mathrm{m}\,i}(x_{\mathrm{m}}, y, z, \omega_{\mathrm{m}}) = \frac{1}{4\pi^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\overline{U}_i\big(k_x, k_y, z, \omega_{\mathrm{m}} - k_x v\big)\mathrm{e}^{\mathrm{i}(k_x x_{\mathrm{m}} + k_y y)}\,\mathrm{d}k_x\,\mathrm{d}k_y \tag{4}$$

where v is the velocity at which the moving FOR travels through the fixed FOR. Subscript 'm' indicates values in the moving FOR.

Since the methodology presented in this work uses both moving and fixed FOR, a mixed FOR is used, where the displacement response observed in a fixed FOR from a load applied at a stationary point in the moving FOR and vice versa are needed in order to obtain the coupling terms between the two FORs.

Following a similar analysis with [13], the displacements $U_{\mathrm{f}\,i}$ at x_{f} for fixed FOR from a harmonic moving load of circular frequency ω_{m} can be expressed as

$$U_{\mathrm{f}\,i}(x_{\mathrm{f}}, y, z, \omega_{\mathrm{m}}, \omega_{\mathrm{f}}) = \frac{1}{v}\mathrm{e}^{\mathrm{i}\beta x_{\mathrm{f}}}\frac{1}{2\pi}\int_{-\infty}^{\infty}U_i\big(\beta, k_y, z, \omega_{\mathrm{m}} - \beta v\big)\mathrm{e}^{\mathrm{i}k_y y}\mathrm{d}k_y\,,\ \ \beta = \frac{\omega_{\mathrm{m}} - \omega_{\mathrm{f}}}{v} \tag{5}$$

where ω_f is the receiving frequency at the fixed FOR.

Alternatively, using an equivalent analysis for a stationary harmonic load of circular frequency ω_m received in a moving FOR at $x_\mathrm{m} = x_\mathrm{f} - vt$ the displacements $U_{\mathrm{m}\,i}$ can be expressed as:

$$U_{\mathrm{m}\,i}(x_\mathrm{m}, y, z, \omega_\mathrm{f}, \omega_\mathrm{m}) = \frac{1}{v}\mathrm{e}^{\mathrm{i}\beta x_\mathrm{m}}\frac{1}{2\pi}\int_{-\infty}^{\infty} U_i(\beta, k_y, z, \omega_\mathrm{f})\mathrm{e}^{\mathrm{i}k_y y}\mathrm{d}k_y\,, \qquad \beta = \frac{\omega_\mathrm{m} - \omega_\mathrm{f}}{v}. \quad (6)$$

Comparing Eqs. (5) and (6) it is evident that the expressions are equivalent. That is, the displacements originating from a moving source and observed in a fixed FOR are equivalent to the displacements caused by a stationary source and observed in a moving frame:

$$U_{\mathrm{m}\,i}(x_\mathrm{m}, y, z, \omega_\mathrm{f}, \omega_\mathrm{m}) = U_{\mathrm{f}\,i}(x_\mathrm{f}, y, z, \omega_\mathrm{m}, \omega_\mathrm{f}) \quad (7)$$

given that the horizontal coordinates x_m and x_f have the same numerical value. In practice, this means that only Eq. (5) or Eq. (6) needs to be evaluated. Then the integral part of the equation is reused for the other FOR combination, with changed *x*-coordinate.

3 STRUCTURES INTERACTING WITH SOIL IN A SINGLE FRAME OF REFERENCE

To couple the semi-analytical soil model to a FE model of one or more structures, a dynamic stiffness matrix of the soil is established. Firstly, the desired geometry of the soil-structure interface is discretized into a number of 'soil–structure interaction' (SSI) nodes. The response is requested at a range of 'observation' nodes. The dynamic stiffness matrix is established using the SSI nodes, which is then coupled to structures and used to obtain the system displacements.

To establish the dynamic stiffness matrix of the soil, a global flexibility matrix relating all the degrees of freedom is needed. For a three-dimensional case, each SSI node has three degrees of freedom. Therefore, the receptance matrix $\mathbf{R}_{\mathrm{ss}}(\omega)$, also called the flexibility matrix, is a square matrix with three times more rows and columns than the number of nodes in the system. To create the receptance matrix, a unit harmonic load $\bar{P}_{0,s_j}$ is applied to a single degree of freedom, s_j, and the resulting displacements are observed at all SSI degrees of freedom, including the loaded one. The procedure is repeated for every degree of freedom in the system. This way, the receptance relating all degrees of freedom to the loaded degree of freedom is established. The receptance between degrees of freedom $s_i$and s_j is found as

$$R_{s_i,s_j}(\omega) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \bar{G}_{d_i d_j}(k_x, k_y, z_{n_i}, z_{n_j}, \omega)\,\hat{\bar{P}}_{n_j,s_j}(k_x, k_y, \omega)\,\mathrm{e}^{\mathrm{i}\left(k_x(x_{n_i}-x_{n_j})+k_y(y_{n_i}-y_{n_j})\right)}\,\mathrm{d}k_x\,\mathrm{d}k \quad (8)$$

where $\hat{\bar{P}}_{n_j,s_j}(k_x, k_y, \omega)$ is the double spatial Fourier transform of a distributed harmonic load $\hat{P}_{n_j,s_j}(x, y, \omega)$ of unit magnitude acting within the frequency domain at the depth z_{n_j} in degree of freedom s_j. The same procedure can be performed in both fixed and moving FORs. The obtained results are placed in a single column of the receptance matrix and the process is repeated for every degree of freedom. Assuming there is a total of S SSI degrees of freedom in the system, the assembled receptance matrix becomes:

$$\mathbf{R}_{\mathrm{ss}}(\omega) = \begin{bmatrix} R_{s_1,s_1}(\omega) & R_{s_1,s_2}(\omega) & \cdots & R_{s_1,s_S}(\omega) \\ R_{s_2,s_1}(\omega) & R_{s_2,s_2}(\omega) & \cdots & R_{s_2,s_S}(\omega) \\ \vdots & \vdots & \ddots & \vdots \\ R_{s_S,s_1}(\omega) & R_{s_S,s_2}(\omega) & \cdots & R_{s_S,s_S}(\omega) \end{bmatrix}. \quad (9)$$

The receptance matrix can be established for the moving and fixed FORs. However, only in the fixed FOR, the matrix is symmetric, assuming that the applied load $\hat{P}_{n_j,s_j}(x,y,\omega)$ is the same for all degrees of freedom. If no external structures are connected to the semi-analytical soil model, it is possible to apply the loads and obtain the system displacements $\mathbf{U}_\mathrm{s}$ directly as

$$\mathbf{U}_\mathrm{s}(\omega) = \mathbf{R}_\mathrm{ss}(\omega)\,\mathbf{P}_\mathrm{s}(\omega) \tag{10}$$

where $\mathbf{P}_\mathrm{s}$ is the vector of load magnitudes. It is implied here that the load acting in degree of freedom s_j has a spatial distribution defined by $\hat{P}_{n_j,s_j}$ and a magnitude defined by element j of $\mathbf{P}_\mathrm{s}$.

3.1 FE models interacting with the soil

To couple the soil model with an FE model of one or more structures, the dynamic stiffness matrix of the soil $\mathbf{K}_\mathrm{ss}(\omega)$ is needed. It can be obtained by inverting the receptance matrix. Including the dynamic stiffness matrix $\mathbf{K}_\mathrm{FE}$ of the FE model the dynamic stiffness in the single frame of reference (SFOR) can be assembled as:

$$\mathbf{K}_\mathrm{SFOR}(\omega) = \begin{bmatrix} \mathbf{K}_\mathrm{ss}(\omega) + \mathbf{K}_\mathrm{FE}^\mathrm{ss}(\omega) & \mathbf{K}_\mathrm{FE}^\mathrm{sn}(\omega) \\ \mathbf{K}_\mathrm{FE}^\mathrm{ns}(\omega) & \mathbf{K}_\mathrm{FE}^\mathrm{nn}(\omega) \end{bmatrix} \tag{11}$$

where superscript ‘s’ denotes the degrees of freedom through which the FE model interacts with the soil, while superscript ‘n’ denotes the degrees of freedom that are internal to the FE model. Combinations of superscripts ‘sn’ and ‘ns’ denote the coupling terms. Due to symmetry of the FE system matrices, $\mathbf{K}_\mathrm{FE}^\mathrm{ns}(\omega) = [\mathbf{K}_\mathrm{FE}^\mathrm{sn}(\omega)]^\mathrm{T}$. In addition, the matrix $\mathbf{K}_\mathrm{FE}^\mathrm{sn}(\omega)$ is usually sparsely populated.

The displacements of the system can then be obtained by solving the system of equations:

$$\mathbf{K}_\mathrm{SFOR}(\omega)\,\mathbf{U}_\mathrm{SFOR}(\omega) = \mathbf{P}_\mathrm{SFOR}(\omega). \tag{12}$$

To obtain the displacements of the observation degrees of freedom, a flexibility matrix relating the SSI and observation degrees of freedom is needed. Assuming that the numbering of observation degrees of freedom is stored in a set $o = \{o_1, o_2, \ldots, o_O\}$ with the number of degrees of freedom being O, the flexibility matrix will have O rows and S columns. The flexibility matrix for observation degrees of freedom is assembled as:

$$\mathbf{R}_\mathrm{os}(\omega) = \begin{bmatrix} R_{o_1,s_1}(\omega) & R_{o_1,s_2}(\omega) & \cdots & R_{o_1,s_S}(\omega) \\ R_{o_2,s_1}(\omega) & R_{o_2,s_2}(\omega) & \cdots & R_{o_2,s_S}(\omega) \\ \vdots & \vdots & \ddots & \vdots \\ R_{o_O,s_1}(\omega) & R_{o_O,s_2}(\omega) & \cdots & R_{o_O,s_S}(\omega) \end{bmatrix}. \tag{13}$$

To find the displacements of the observation nodes, the observation flexibility matrix $\mathbf{R}_\mathrm{os}$ is multiplied by the soil displacements at the SSI degrees of freedom $\mathbf{U}_\mathrm{s}$, which are extracted from the whole system displacement vector $\mathbf{U}_\mathrm{SFOR}$:

$$\mathbf{U}_\mathrm{o}(\omega) = \mathbf{R}_\mathrm{os}(\omega)\,[\mathbf{R}_\mathrm{ss}(\omega)]^{-1}\,\mathbf{U}_\mathrm{s}(\omega) = \mathbf{R}_\mathrm{os}(\omega)\,\mathbf{K}_\mathrm{ss}(\omega)\,\mathbf{U}_\mathrm{s}(\omega). \tag{14}$$

3.2 Rigid structures interacting with the soil

The semi-analytical soil model allows also modelling of completely rigid objects interacting with the soil. This is useful when modelling structures that are much stiffer than the surrounding material, for example building foundations. To create a three-dimensional rigid object, the object shape is discretized into a number of SSI nodes. The global flexibility matrix is created in

the same way as in the previous subsection and inverted to obtain the dynamic stiffness matrix. However, condensation of the stiffness matrix must be performed in order to reduce the system such that the response can be determined in terms of the rigid body modes rather than the original degrees of freedom of the SSI nodes. This is achieved by assuming that SSI nodes belonging to the same rigid object are fixed relatively to each other and move together with the degrees of freedom of a reference master node that defines the motion of the rigid object. In principle, the master node can be placed at any position. However, it is most conveniently placed in the point at which coupling to an FE model should be done. That is, for example, in the centre of the topside of a footing. In the most common three-dimensional case, separate SSI nodes have three degrees of freedom each, i.e. three lateral displacements, while each rigid object has six degrees of freedom: three for lateral displacements and three additional rotational degrees of freedom of the reference node. For a single rigid object composed of a number of SSI nodes, the transformation matrix $\mathbf{T}_{0,i}$ is created. Multiple rigid objects can also be a part of the same system. The global transformation matrix for a system with N rigid objects can be assembled as:

$$\mathbf{T}_\mathrm{s} = \begin{bmatrix} \mathbf{T}_{0,1} & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \mathbf{T}_{0,2} & \cdots & \mathbf{0} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{0} & \mathbf{0} & \cdots & \mathbf{T}_{0,N} \end{bmatrix}. \tag{15}$$

The system can also contain non-associated ‘free’ SSI nodes, which are not part of any rigid object. In that case, the local transformation matrix for such nodes will be the identity matrix with the same number of rows and columns as the number of degrees of freedom associated with the free node.

To obtain the condensed stiffness matrix of the soil, , the dynamic stiffness matrix of the soil $\mathbf{K}_{\mathrm{ss}}(\omega)$ is modified:

$$\mathbf{K}_\mathrm{s}(\omega) = [\mathbf{T}_\mathrm{s}]^\mathrm{T}\, \mathbf{K}_{\mathrm{ss}}(\omega)\, \mathbf{T}_\mathrm{s}. \tag{16}$$

The matrix can then be coupled to FE structures in the same way as described previously. Due to condensation of some SSI nodes, Eq. (14) is also modified by introducing the transformation matrix

$$\mathbf{U}_\mathrm{o}(\omega) = \mathbf{R}_{\mathrm{os}}(\omega)[\mathbf{R}_{\mathrm{ss}}(\omega)]^{-1}\, \mathbf{T}_\mathrm{s}\, \mathbf{U}_\mathrm{s}(\omega) = \mathbf{R}_{\mathrm{os}}(\omega)\mathbf{K}_{\mathrm{ss}}(\omega)\mathbf{T}_\mathrm{s}\, \mathbf{U}_\mathrm{s}(\omega). \tag{17}$$

3.3 Vehicle, railway track and wheel-rail interaction

The system is excited by one or more vehicles travelling across a railway track. The vehicles can be modelled using various multibody systems, with varying complexity, depending in the application case. Vehicles are only modelled in two dimensions and only the vertical wheel-rail interaction forces are considered. The dynamic stiffness matrix of the vehicle $\mathbf{K}_{\mathrm{vv},i}(\omega_\mathrm{m})$ is created in a moving FOR by combining the vehicle stiffness, damping and mass matrices. If multiple vehicles are needed, it is assumed that there is no direct interaction between vehicles and the dynamic stiffness matrix becomes:

$$\mathbf{K}_\mathrm{v}(\omega_\mathrm{m}) = \begin{bmatrix} \mathbf{K}_{\mathrm{vv},1}(\omega_\mathrm{m}) & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \mathbf{K}_{\mathrm{vv},2}(\omega_\mathrm{m}) & \cdots & \mathbf{0} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{0} & \mathbf{0} & \cdots & \mathbf{K}_{\mathrm{vv},I}(\omega_\mathrm{m}) \end{bmatrix}. \tag{18}$$

Here it is assumed that there is a total number I of vehicles in the system. Further, there is no coupling between separate vehicles through the vehicle stiffness matrix, i.e. each car of a train acts like a separate vehicle.

A layered track structure containing the rails, rail-pads, sleepers and ballast is used. It is coupled to the underlying soil in the frequency-wavenumber domain as described in [15]. By using the stiffness matrix for the rails $\mathbf{K}_\mathrm{r}(\omega_\mathrm{m})$ and the diagonal stiffness matrix $\mathbf{K}_\mathrm{H}$ for the wheel-rail contact interaction the coupled vehicle–track system response from a unit amplitude unevenness is given as:

$$\begin{bmatrix} \mathbf{K}_\mathrm{v}^{\mathrm{uu}}(\omega_\mathrm{m}) & \mathbf{K}_\mathrm{v}^{\mathrm{uw}}(\omega_\mathrm{m}) & \mathbf{0} \\ \mathbf{K}_\mathrm{v}^{\mathrm{wu}}(\omega_\mathrm{m}) & \mathbf{K}_\mathrm{v}^{\mathrm{ww}}(\omega_\mathrm{m}) + \mathbf{K}_\mathrm{H} & -\mathbf{K}_\mathrm{H} \\ \mathbf{0} & -\mathbf{K}_\mathrm{H} & \mathbf{K}_\mathrm{r}(\omega_\mathrm{m}) + \mathbf{K}_\mathrm{H} \end{bmatrix} \begin{Bmatrix} \mathbf{U}_\mathrm{v}^{\mathrm{u}}(\omega_\mathrm{m}) \\ \mathbf{U}_\mathrm{v}^{\mathrm{w}}(\omega_\mathrm{m}) \\ \mathbf{U}_\mathrm{r}(\omega_\mathrm{m}) \end{Bmatrix} = \begin{Bmatrix} \mathbf{0} \\ K_\mathrm{H}\,\mathbf{d}(\omega_\mathrm{m}) \\ -K_\mathrm{H}\,\mathbf{d}(\omega_\mathrm{m}) \end{Bmatrix} \tag{19}$$

where $\mathbf{d}(\omega_\mathrm{m}) = \exp\left(\frac{\omega_\mathrm{m}}{v}\,\mathbf{x}_\mathrm{w}\right)$ is the vector containing the unit unevenness for all wheel positions $\mathbf{x}_\mathrm{w}$ in the moving FOR. In Eq. (19), the vehicle degrees of freedom are split into two parts: those relating to the wheels, denoted with the superscript ‘w’, and those that are not coupled to the track, denoted with superscript ‘u’. It is assumed that each vehicle wheel has the same linearized Hertzian spring stiffness K_H when calculating the acting forces. Solving Eq. (19) for the unknown displacement vector $\mathbf{U}$ produces the system behaviour. Note that in this case, the effects of external structures coupled to the railway track through the soil are not accounted for.

The stiffness matrix for the rails in Eq. (19) can be found by inverting the flexibility matrix $\mathbf{R}_\mathrm{rr}(\omega_\mathrm{m})$ relating the rail displacements between all vehicle wheel sets positions is constructed. This is achieved in a similar manner as described in the previous section, assuming a single degree of freedom of a rail in a moving FOR for every wheel. The matrix is later used to establish the stiffness matrix of a coupled-domain stiffness matrix.

4 ASSEMBLY AND SOLUTION OF GLOBAL SYSTEM

Parts of the model described in the previous sections are combined into a single global system. The resulting system combines parts formulated in a moving FOR, such as the vehicle and the track, and parts formulated in the fixed FOR, such as the structures interacting with the soil. To couple the two FORs together, the relation described in Section 2 is used. For this purpose, the receptance matrix $\widetilde{\mathbf{R}}_\mathrm{sr}$, providing the interaction between the degrees of freedom of the rails and the degrees of freedom of the soil, is established. The matrix $\widetilde{\mathbf{R}}_\mathrm{sr}$ couples the moving and fixed FORs, and it is therefore dependent on two frequencies: ω_m and ω_f. The tilde indicates that the quantity is defined in the mixed FOR.

4.1 Partly coupled global system

The flexibility matrix, assembled in the fixed FOR and connecting all the degrees of freedom interacting with the soil, is added to the system. Using the created matrices, the full flexibility matrix for the so-called ‘global’ (indicated by subscript ‘g’) system can be constructed

$$\widetilde{\mathbf{R}}_\mathrm{g}(\omega_\mathrm{m}, \omega_\mathrm{f}) = \begin{bmatrix} \mathbf{R}_\mathrm{rr}(\omega_\mathrm{m}) & \widetilde{\mathbf{R}}_\mathrm{rs}(\omega_\mathrm{f}, \omega_\mathrm{m}) \\ \widetilde{\mathbf{R}}_\mathrm{sr}(\omega_\mathrm{m}, \omega_\mathrm{f}) & \mathbf{R}_\mathrm{ss}(\omega_\mathrm{f}) \end{bmatrix}. \tag{20}$$

If no rigid bodies are present in the soil model, the global flexibility matrix may be inverted to obtain the stiffness matrix of the global system $\widetilde{\mathbf{K}}_\mathrm{g}(\omega_\mathrm{m}, \omega_\mathrm{f})$. When the system contains rigid objects, which are formulated as described in Section 3.2, the global stiffness matrix can be constructed using the global transformation matrix

$$\mathbf{T}_{\mathrm{g}} = \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{T}_{\mathrm{s}} \end{bmatrix} \tag{21}$$

where $\mathbf{I}$ is the identity matrix with dimensions equal to the number of rail degrees of freedom. It is assumed that there are no rigid bodies modelled in the moving FOR. In theory, it is possible to model rigid bodies in both the moving and the fixed FORs, given that the reference nodes for these bodies are not shared between the two FORs.

After the stiffness matrix of the system has been obtained, the vehicle and the FE structures can be also added to the global system. The governing equation for partial coupling in the mixed FOR becomes:

$$\widetilde{\mathbf{K}}(\omega_{\mathrm{m}}, \omega_{\mathrm{f}})\widetilde{\mathbf{U}}(\omega_{\mathrm{m}}, \omega_{\mathrm{f}}) = \widetilde{\mathbf{F}}(\omega_{\mathrm{m}}, \omega_{\mathrm{f}}) \tag{22}$$

where

$$\widetilde{\mathbf{K}}(\omega_{\mathrm{m}}, \omega_{\mathrm{f}}) = \begin{bmatrix} \mathbf{K}_{\mathrm{v}}^{\mathrm{uu}}(\omega_{\mathrm{m}}) & \mathbf{K}_{\mathrm{v}}^{\mathrm{uw}}(\omega_{\mathrm{m}}) & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{K}_{\mathrm{v}}^{\mathrm{wu}}(\omega_{\mathrm{m}}) & \mathbf{K}_{\mathrm{v}}^{\mathrm{ww}}(\omega_{\mathrm{m}}) + \mathbf{K}_{\mathrm{H}} & -\mathbf{K}_{\mathrm{H}} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & -\mathbf{K}_{\mathrm{H}} & \widetilde{\mathbf{K}}_{\mathrm{g}}^{\mathrm{rr}}(\omega_{\mathrm{m}}, \omega_{\mathrm{f}}) + \mathbf{K}_{\mathrm{H}} & \widetilde{\mathbf{K}}_{\mathrm{g}}^{\mathrm{rs}}(\omega_{\mathrm{f}}, \omega_{\mathrm{m}}) & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \widetilde{\mathbf{K}}_{\mathrm{g}}^{\mathrm{sr}}(\omega_{\mathrm{m}}, \omega_{\mathrm{f}}) & \widetilde{\mathbf{K}}_{\mathrm{g}}^{\mathrm{ss}}(\omega_{\mathrm{m}}, \omega_{\mathrm{f}}) + \widetilde{\mathbf{K}}_{\mathrm{FE}}^{\mathrm{ss}}(\omega_{\mathrm{f}}) & \mathbf{K}_{\mathrm{FE}}^{\mathrm{sn}}(\omega_{\mathrm{f}}) \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{K}_{\mathrm{FE}}^{\mathrm{ns}}(\omega_{\mathrm{f}}) & \mathbf{K}_{\mathrm{FE}}^{\mathrm{nn}}(\omega_{\mathrm{f}}) \end{bmatrix} \tag{23}$$

and

$$\widetilde{\mathbf{U}}(\omega_{\mathrm{m}}, \omega_{\mathrm{f}}) = \begin{Bmatrix} \widetilde{\mathbf{U}}_{\mathrm{v}}^{\mathrm{u}}(\omega_{\mathrm{m}}, \omega_{\mathrm{f}}) \\ \widetilde{\mathbf{U}}_{\mathrm{v}}^{\mathrm{w}}(\omega_{\mathrm{m}}, \omega_{\mathrm{f}}) \\ \widetilde{\mathbf{U}}_{\mathrm{g}}^{\mathrm{r}}(\omega_{\mathrm{m}}, \omega_{\mathrm{f}}) \\ \widetilde{\mathbf{U}}_{\mathrm{g}}^{\mathrm{s}}(\omega_{\mathrm{m}}, \omega_{\mathrm{f}}) \\ \widetilde{\mathbf{U}}_{\mathrm{FE}}^{\mathrm{n}}(\omega_{\mathrm{m}}, \omega_{\mathrm{f}}) \end{Bmatrix}, \qquad \widetilde{\mathbf{F}}(\omega_{\mathrm{m}}, \omega_{\mathrm{f}}) = \begin{Bmatrix} \mathbf{0} \\ K_{\mathrm{H}}\mathbf{d}(\omega_{\mathrm{m}}) \\ -K_{\mathrm{H}}\mathbf{d}(\omega_{\mathrm{m}}) \\ \mathbf{0} \\ \mathbf{0} \end{Bmatrix}. \tag{24}$$

The superscripts relate to the degrees of freedom of: ‘w’-wheels, ‘r’-rails, ‘s’-soil in the fixed FOR, ‘n’-parts of FE structures not coupled to the soil and ‘u’-vehicles uncoupled from the track (e.g. the vehicle body). Vectors $\widetilde{\mathbf{U}}_{\mathrm{v}}$, $\widetilde{\mathbf{U}}_{\mathrm{g}}$ and $\widetilde{\mathbf{U}}_{\mathrm{FE}}$ store the displacements for the vehicle, global railway track–soil system and the FE structure, respectively.

After the system has been solved, the displacement for the observation degrees of freedom in the fixed FOR can be obtained. When the displacements for both the global and the observation degrees of freedom have been obtained, the effects from J_{m} discrete excitation frequencies ω_{m} can be added together to obtain the total response in the fixed FOR:

$$\mathbf{U}_{\mathrm{FE}}(\omega_{\mathrm{f}}) = \frac{1}{2\pi}\sum_{j=1}^{J_{\mathrm{m}}} \widetilde{\mathbf{U}}_{\mathrm{FE}}\left(\omega_{\mathrm{m},j}, \omega_{\mathrm{f}}\right) D(k_{\mathrm{m},j})\, \Delta k_{\mathrm{m}} \tag{25}$$

where $D(k_{\mathrm{m},j})$ is the rail unevenness obtained from a power spectral density (PSD) according to the wavenumber $k_{\mathrm{m},j}$, and Δk_{m} is the wavenumber step size.

The time-domain response for the degrees of freedom associated with the fixed FOR can be obtained by performing an inverse discrete Fourier transformation of the displacements $\mathbf{U}_{\mathrm{FE}}(\omega_{\mathrm{s}})$:

$$\mathbf{u}_{\mathrm{FE}}(t) = \frac{1}{2\pi}\sum_{j=1}^{J_{\mathrm{f}}} \mathbf{U}_{\mathrm{FE}}\left(\omega_{\mathrm{f},j}\right)\mathrm{e}^{\mathrm{i}\,\omega_{\mathrm{f},j}\,t}\,\Delta\omega_{\mathrm{f}} \tag{26}$$

where J_{f} is the number of discrete frequencies in the fixed FOR. Note that J_{f} and J_{m} need not be equal. However, the step sizes $\Delta\omega_{\mathrm{f}}$ and Δk_{m} must be small enough, and the number of frequencies J_{f} and J_{m} large enough, to ensure proper discretization of peaks in the loads and resonances

of the system while, at the same time, avoiding violation of the periodicity inherent in the frequency-domain solution.

4.2 Fully coupled global system

Using the matrices already created for the previously described solution procedure, it is also possible to assemble a fully coupled global system. Such a system will account for the frequency spreading of the reflected waves due to the Doppler effect and might be useful for certain cases where the full coupling between the vehicle (the source) and the structures (the receivers) cannot be discarded. In such a system, the previously uncoupled frequencies in a single FOR are now coupled through the other FOR and the matrix $\mathbf{K}_{\mathrm{g}}$ will be fully populated. The system can be solved by applying loads in either FOR or both FORs at the same time. However, the computation of the fully coupled system is an extremely computationally demanding process, which involves double inversion of very large matrices. Thus, it should only be used when the secondary coupling effects are an important factor.

5 VALIDATION AND APPLICATIONS

The methodology described in this paper is validated by comparisons with other state-of-the-art computational approaches. By considering a system with no structures or rigid objects interacting with the soil, the described system assembly and solution procedures provide identical results to the approach provided by Sheng et al. in [13, 14]. This is expected, as the proposed method here utilizes the same vehicle-track-soil interaction model, and, with no other structures interacting with the soil, the coupling terms cancel out. Modelling of rigid objects interacting with the soil was validated by comparison with BE and FEM-PML models. It was determined that the semi-analytical model provides a very good match, especially with the FEM-PML model, where even the secondary coupling terms show very good agreement. To demonstrate the capabilities of the proposed fully-coupled modelling approach, an example case was set up where the modelled structure is close to the railway track.

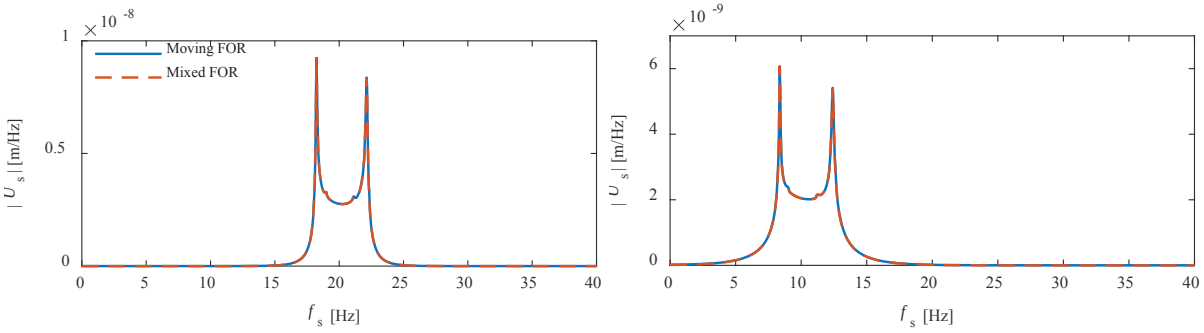
5.1 Coupling between moving and fixed frames of reference

In order to validate the coupling terms between the two FORs and especially the symmetry between when a load is applied in the moving FOR and the displacements observed in a fixed FOR and vice versa, two test cases were set up. The proposed mixed-FOR model was simplified by removing the railway track, the vehicle and the FE/rigid structures interacting with the soil. This way, the effects of a single load with a single excitation frequency acting directly on the soil surface can be observed. The ground was modelled as a homogenous elastic half-space of dense sandy-type soil, with 250 MPa Young's modulus, 0.25 Poisson's ratio, 2000 kg/m^3 mass density and 0.05 loss factor. A stationary point in the fixed FOR was placed 3 m from the line along which the load was moving.

A moving vertical load with constant speed v and frequency f_{m} was modelled. The vertical displacements were observed within a fixed FOR for a range of frequencies f_{f}. The system was modelled using the simplified mixed-FOR model. For the analysed case, only the coupling terms between the moving and the fixed FORs, as described in Section 2, have an effect for the obtained results. For comparison, a full model was established, modelled only in the moving FOR, using the semi-analytical approach.

Using the created model, the displacement field of the soil surface in the moving FOR and within the time domain was obtained for a single excitation frequency. Then, a time signal for displacements of an observation point moving through the displacement field with speed $-v$ was found, considering that for every time step the position of the observation point changed.

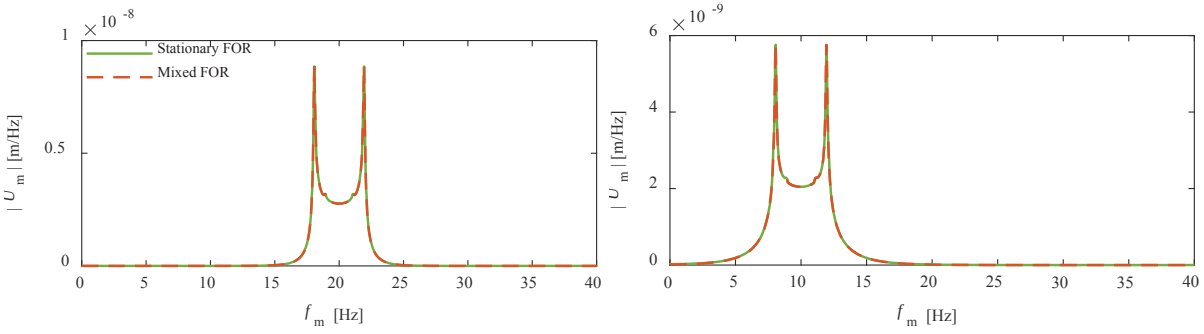
Fourier transforming the obtained time signal into frequencies f_s, the displacement spectra for a stationary observation point was obtained. Two combinations of speed and frequency in the moving FOR were investigated: Case 1 with $v = 20$ m/s and $f_m = 20$ Hz, and Case 2 with $v = 40$ m/s and $f_m = 10$ Hz. The comparison of both approaches are shown in Figure 1 where it can be seen that the two approaches agree, confirming the analytical derivation presented in Section 2.



(a) (b)

Figure 1: Displacements in a fixed FOR from a unit load applied in a moving FOR: (a) $v = 20$ m/s and $f_m = 20$ Hz; (b) $v = 40$ m/s and $f_m = 10$ Hz.

A similar validation example was created to analyse the coupling between a load in a fixed FOR and the resulting displacements in a moving FOR. Here, the mixed FOR model was compared to a full solution formulated only in a fixed FOR. In the same way as for the previous validation case, using the full model, the displacement field of the soil surface was found in time domain. Then the vertical displacements for a moving observation point were obtained by changing the position of the point for every time step. Fourier transforming the time-domain response for frequencies f_m, the displacement spectra for a moving observation point were obtained. Two combinations of speed and stationary frequency were again investigated: Case 1 with $v = 20$ m/s and $f_s = 20$ Hz; Case 2 with $v = 40$ m/s and $f_s = 10$ Hz. Results of both approaches are given in Figure 2. Once again, the results agree well, this time confirming the derivation given in Section 2.



(a) (b)

Figure 2: Displacements in a moving FOR from a unit load applied in a fixed FOR.: (a) $v = 20$ m/s and $f_s = 20$ Hz; (b) $v = 40$ m/s and $f_s = 10$ Hz.

Comparing the two validation examples, it is evident that the response spreads out through the observer frequencies due to the Doppler effect, independently of which FOR the load was

applied in. The range of affected frequencies dependent on the speed of the moving FOR. However, a load applied in the fixed FOR produces two symmetric peaks around the excitation frequency, when observed in a moving FOR, while a load applied in a moving FOR produces two peaks in the fixed FOR. Further, comparing the results of Case 1 for both cases, it can be observed that the result in Figure 4 at $f_s = 20$ Hz and the result in Figure 5 at $f_m = 20$ Hz show exactly the same response. This confirms the symmetry between the two FORs implied by Eq. (7). The same result is obtained by comparing the responses of Case 2 for both cases.

5.2 Validation of the modelling approach

To validate the modelling approach presented in this paper, it was compared to a sub-modelling technique, as described in [6]. A similar modelling approach was also used in [5]. In both cases the sub-modelling approach was used to model an underground railway tunnel with a vehicle travelling through it, in turn exciting a building structure above the soil. However, the solution procedure can also be applied to surface railways and the system analysed in this work. The method uses the free-field displacements of the soil caused by a passing vehicle, which are later modified by introducing the building structure. Ensuring equilibrium and compatibility between the degrees of freedom connecting the building and the soil, a solution for the building displacements can be found.

Comparing the methodology proposed in this work with the sub-modelling technique, it becomes evident that the basic parts used for both solution procedures are identical. For example, the free-field displacements from a moving load used in the two-step approach are identical to the flexibility matrix used here. However, the assembly and solution of the full system is somewhat different, with the proposed methodology allowing a wider range of applications, such as modelling rigid inclusions or allowing a two-way coupling between the two FORs. Further, the sub-modelling technique, as applied in this work, is a two-step solution approach, as the wheel-rail interaction forces are obtained in the moving FOR before being used to obtain the displacements in the fixed FOR.

As, both approaches use the same basic parts, it is relatively easy to compare them. For comparison, a building structure, with six columns supporting two floors was used. The building is facing the railway track with its narrow side, which is 8 m wide, and the building is supported by two columns at either side. The length of the building is 10 m in the direction orthogonal to the track. In addition to the four columns placed at the corners, a column is placed in the middle of each of the longer sides. Each storey is 4 m high. The whole building structure is constructed from concreate with a Young's modulus of 30 GPa, a Poisson's ratio of 0.15, a mass density of 2400 kg/m3, and loss factor of 0.03. The columns have square cross-sections, with one side equal to 0.3 m, while the floors are 0.25 m thick slabs. Since the sub-modelling technique cannot directly model rigid objects, a flexible slab footing lies underneath the whole building with the same thickness as the building floors. 3D beam elements were used to model the columns, using Euler-Bernoulli beam theory to account for bending. The floors and the foundation slab of the building were modelled using Mindlin-Reissner shell elements, accounting for bending as well as shear. All FE parts of the model were discretized with mesh size of 0.5 m, resulting in 4841 degrees of freedom in the system.

The soil is modelled as a half-space of sand, with the same properties as in Section 5.1. Both systems were excited by a single passing vehicle, travelling at 40 m/s, exposed to a unit rail unevenness, with a 4 m wavelength corresponding to an excitation frequency of 10 Hz. For analysis, only a single excitation frequency is used, as the effects from multiple excitations

frequencies are just added together due to the principal of superposition. Thus, a single excitation frequency is enough to evaluate how well both models perform. The test case is illustrated in Figure 3.

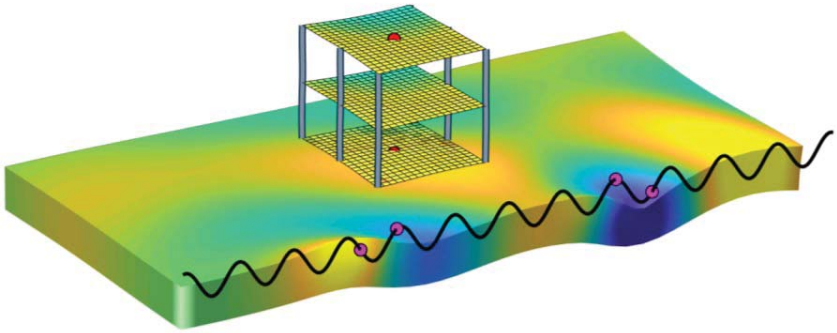


Figure 3: Investigated case for validating the modelling approach. The vehicle is travelling from left to right, with magenta nodes indicating the wheel positions. The red nodes indicate the observation points, while the shades of colour indicate the vertical displacements (bright yellow is up, dark blue is down). Track unevenness is not scaled.

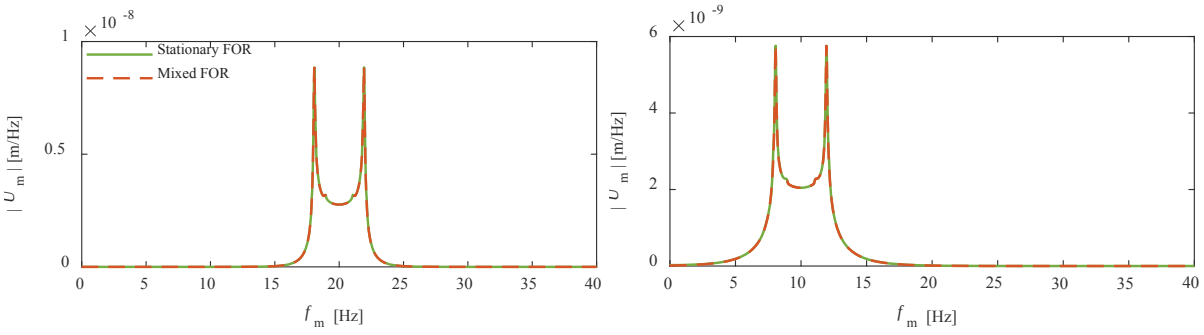
Figure 4 shows the displacements of the building structure obtained at the centre of the ground floor and the second floor where both approaches provide almost identical results, showing that the proposed method is performing well. At the same time, almost identical results indicate that the back-coupling of the building structure to the railway track is insignificant. Thus, for at least for the considered case, there is no significant difference whether on or the other approach is considered.



(a) (b)

Figure 4: Displacements in a moving FOR from a unit load applied in a fixed FOR.: (a) $v = 20$ m/s and $f_s = 20$ Hz; (b) $v = 40$ m/s and $f_s = 10$ Hz.

5.3 Fully coupled system

A fully-coupled system solution approach might be necessary in cases where the modelled structures are close to the railway track, introducing a significant change of dynamic stiffness along the track. In that case, the re-scattered waves can have an effect on the vehicle behaviour and the obtained wheel-rail interaction forces. Problems where these effects are important could include modelling of tunnels underneath buildings, railway stations and various structures nearby the tracks. Several such cases have been investigated by Coulier et al. [20], finding that while the axial loads are not effected significantly, the vibration insertion gain for source–receiver transmission can be affected up to 10 dB, when using a fully coupled solution procedure.

Another set of problems could include the sudden change of stiffness underneath the track, e.g. when a concreate passage is constructed underneath the railway track.

To examine such a case, a test case was set up modelling a single vehicle traveling across a railway track, as shown in Figure 5. The speed of the vehicle was 40 m/s. The vehicle and the track properties are given in Tables 1 and 2. The soil was modelled as a 5 m layer of soft clay sitting over a stiffer half-space of sand. The clay had a Young's modulus of 80 MPa, a Poisson's ratio of 0.48, a mass density of 2100 kg/m3, and a loss factor of 0.05. The underlying sand had the same properties as in Section 5. Underneath the track, at a depth of 1 m, a rigid block was embedded within the soil. The block was centred at the position, where the travelling vehicle centre line was located at time 0. The block was modelled as a 2D plate, placed in the horizontal plane with one side equal to 2 m. It was discretized into 36 discretization nodes, with three degrees of freedom per node. The system was excited by the deadweight of the vehicle only applied at $f_{\mathrm{m}} = 0$ Hz, with no excitation from the rail unevenness. The system was assessed by the fully-coupled modelling approach. As only the quasi-static effects of the vehicle were modelled, the considered frequency ranges are reduced. The one-sided frequency range of the moving FOR was 0-30 Hz, and the one-sided frequency range of the fixed FOR is 0-25 Hz. In the computation, negative as well as positive frequencies were considered for either FOR, and each range was split into 200 discrete frequencies.

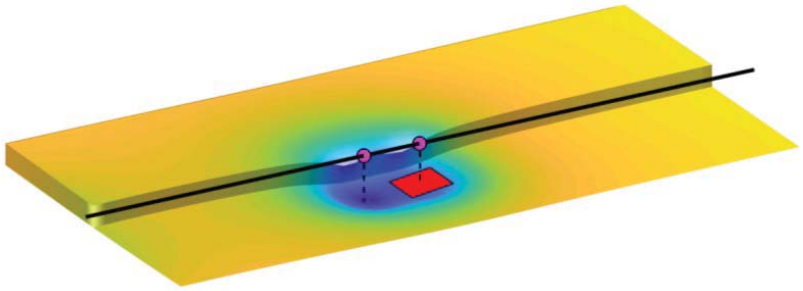


Figure 5: Vehicle passing over a buried rigid block, at an instance where the leading wheel of the vehicle is directly above the centre of the rigid block. The vehicle is travelling at 40 m/s from left to right. The black line indicates the vehicle traverse line, with the magenta nodes indicating the positions of the vehicle wheel sets. Only the two wheel sets of the front bogie are shown.

Rail mass per unit length	60.0 kg/m
Rail bending stiffness	$6.4 \cdot 10^6$ N/m^2
Rail loss factor	0.01
Railpad stiffness	$5.0 \cdot 10^8$ N/m
Railpad loss factor	0.1
Sleeper spacing	1 m
Sleeper mass per unit length	542.0 kg/m
Ballast vertical stiffness	$4.64 \cdot 10^9$ N/m^2
Ballast mass per unit length	1740 kg/m
Ballast loss factor	0.04
Track width	3.2 m

Table 1: Railway track properties.

Figure 6 shows the velocities obtained for the vehicle in the moving FOR as well as the rigid block in the fixed FOR. It can be observed that the vehicle passing over a rigid block introduces a significant excitation into the system, with the rigid block as well as the vehicle reacting to the passage. In this system, the observed excitation of the vehicle is purely due to the weak

coupling effects that are disregarded in the two-step procedure. The waves generated by the passing vehicle are scattered by the rigid block in the fixed FOR and in turn excite a range of frequencies in the moving FOR. These effects would not be accounted for when the weak coupling between the vehicle and structures is not modelled.

Mass of car body	40000 kg
Mass of bogie	5000 kg
Mass of wheel set	1800 kg
Car body pitch moment of inertia	$2.0 \cdot 10^6$ kg·m^2
Bogie pitch moment of inertia	6000 kg·m^2
Primary suspension stiffness	$2.4 \cdot 10^6$ N/m
Secondary suspension stiffness	$6.0 \cdot 10^5$ N/m
Primary suspension damping	$30 \cdot 10^3$ N·s/m
Secondary suspension damping	$20 \cdot 10^3$ N·s/m
Distance between bogies' centers	19.0 m
Distance between bogie's wheels sets	2.7 m
Herztian constant	$5.14 \cdot 10^{-8}$

Table 2: Vehicle properties.

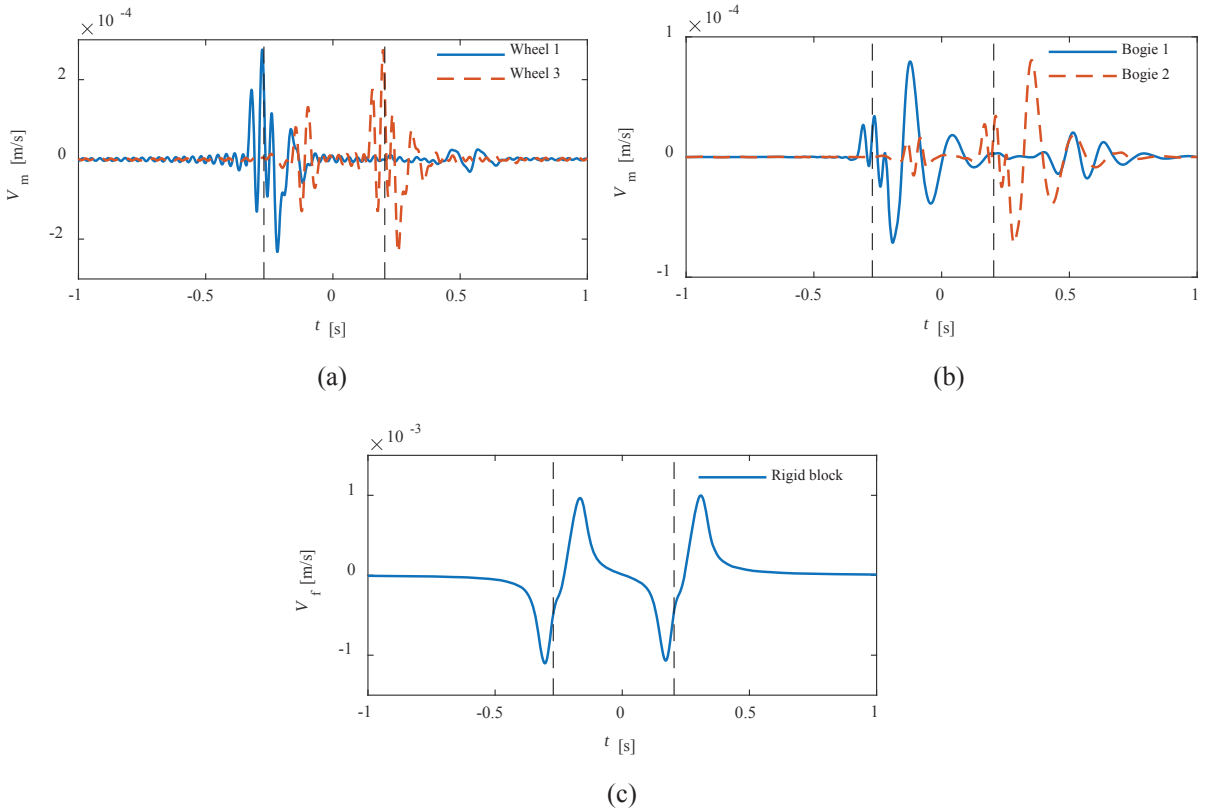

Figure 6: Vertical velocities for parts of the vehicle (in moving FOR) and the rigid block underneath the track (in fixed FOR). The vertical dashed black lines indicate time instance when the first and third vehicle wheels are directly above the centre of the rigid block. The response is shown for: (a) the first and the third vehicle wheels; (b) both vehicle bogies; (c) rigid block underneath the track.

From the wheel velocities shown in Figure 6(a), it can be seen that both leading wheels of separate bogies produce very similar results. However, the excitation due to the first wheel passage over the rigid block generates a wave that excites the third vehicle wheel, even before

it reaches the rigid block. A similar effect is also observed after the third wheel passes over the rigid block, where the generated wave travels forward and excites the first vehicle wheel. A very similar behaviour is also observed on the bogies. When comparing these secondary excitations, it can be seen that the reaction of the third wheel due to the first wheel passage is higher than the excitation of the first wheel due to third wheel passage. This is due to the Doppler effect of the wave travelling through the rail, as the third wheel is travelling towards the wave propagating form the first wheel, while the wave generated by the third wheel must 'catch up' to the first wheel. From the rigid block displacements, it can be observed that the largest velocities are reached just before the leading wheel of a bogie reaches the centre of block. Interestingly, to obtain the same displacements of the rigid block, a fully-coupled system solution approach is unnecessary, as the partly coupled solution provides results that are almost identical. For the analysed case, it can beconcluded that the fully coupled solution approach is only necessary if the vehicle behaviour is of interest, for example for assessment of driver and passenger comfort, or if the track and wheel wear is to be assessed.

6 CONCLUSIONS

- The paper introduced a new modelling approach for the estimation of environmental vibration resulting from railway traffic. A model of a coupled vehicle-track-soil-building system was introduced with two approaches proposed for assembly and solution of the whole system: the partly-coupled approach and the fully-coupled approach. Both solution approaches use a single step procedure with one approach considering a fully-coupled system, while the other approach discards some secondary coupling effects for a more computationally efficient solution procedure.
- A semi-analytical model was utilized to model the soil to which rigid objects and structures modelled by the FE were coupled. The proposed modelling approach uses the frequency-domain solution with some parts, such as the railway track, formulated in the moving FOR and other parts, such as building structures, formulated in a fixed FOR. The coupling terms between the two FORs are found by utilizing an analytical formulation of receptance between the two FORs. It has been established that due to the coupling between the fixed and moving FORs, the previously uncoupled discrete frequencies become coupled through the other FOR as a result of the Doppler effect and wave scattering. Thus, additional consideration is needed when modelling such systems.
- The proposed methodology is a robust approach that does not suffer from numerical instabilities, due to the usage of frequency domain solutions. A wide range of cases can be assessed, including the modelling of rigid objects in or on the ground and flexible structures modelled by the FEM, interacting with the soil. Using the proposed partly-coupled solution approach, the computations can be easily parallelized, thus providing a relatively fast and efficient computational method. Further, the suggested fully-coupled solution procedure is useful in cases where the weak coupling between the vehicle and structures cannot be discarded.
- The analytically derived coupling terms between the two FORs were validated by comparing with models formulated in a single FOR. Further, the partly coupled solution procedure of the full system was compared to a solution procedure in which the weak coupling is completely discarded. The two solution procedures have been found to provide almost identical results, validating the proposed partly coupled solution procedure while, at the same time, indicating insignificant back-coupling in the considered case.

- To demonstrate the capabilities of the numerical model and the potential of the fully-coupled solution procedure, the response of a vehicle passing over a buried rigid block was investigated. It was been found that the fully coupled solution procedure can predict the weak coupling effects between the vehicle and the structure, producing a vehicle response distributed through frequencies, when the load is applied only at a single frequency. Thus, in the present example, the modes of the vehicle were excited parametrically by the waves scattered from the rigid inclusion as a result of the passing deadweight of the vehicle.

Keywords: High-speed railway, Track-ground dynamics behaviour, Analytical modelling, Numerical Modelling, Critical Velocity

Abstract. *With the increases in train speed in recent decades, it is important to define the track-ground critical velocity to prevent high track dynamic amplification. This is affected by wave propagation in the soil layers and track supporting the moving load. Therefore, this paper investigates the important variables that influence the critical velocity and dynamic amplification based on three case studies of track-ground dynamic problems, which are: the presence of low stiffness soil layer, track shakedown and soil improvement. Three modelling strategies (analytical, hybrid analytical-numerical and 2.5D numerical) are used to analyse the different track-soil problems. The findings provide a better understanding of critical velocity and dynamic amplification. These are useful when considering a new track-ground design or improving the existing railway lines.*

1 INTRODUCTION

In recent decades, global railway transportations put a great effort into providing the service with higher train capacity and faster journey time; thus, the increase of operational train speed is required. This can bring the problems to engineering practice when the increased train speed approaches to the critical velocity of the track-ground system. By definition, the critical velocity is the minimum threshold speed of the moving and non-oscillating load that wave commences propagation within the supporting track-ground ([1], [2], [3],[4], [5]).

At critical velocity, high levels of dynamic track-ground amplification occur and lead to the accelerated track degradation, including the elevated ground-borne vibration in the free-field ([6], [7]). These phenomena are undesirable on the railway line because they directly concern the safety risk and require the various expensive and advanced solutions to remediate [8]. To prevent such negative impacts, it is essential to define the influential variables related to track-ground dynamics issues, in particular, critical velocity and dynamic amplification. This is because the behaviour and response of track-ground dynamics can become more significant when experiencing high-speed moving load [9].

Existing railway standards for high-speed track attempt to consider the track behaviour and using a basic function of static response and speed to calculate dynamic response [10]. However, this concept is insufficient to achieve an accurate assessment of the complexity of wave propagation within track and soil because of the variety of track types and ground conditions.

Several models have been developed and proposed in the literature, aimed to investigate the dynamic track behaviour due to the moving load. Basically, [11] used analytical methods to model the problem by considering the moving load over an elastodynamic medium. With this approach, the dispersion characteristics of track and ground can be analysed, and the critical velocity can also be derived from the dispersion curves ([12],[13]). Better than the pure analytical simulation, the problem has been modelled semi-analytically ([14],[15]) where the analytical methods are applied for only track structure whereas the 3D soil is simulated using the Green's functions in terms of wavenumber-frequency domain [16]. These simulations are useful to achieve a better understanding of the relationship between moving speed and dynamic displacement amplification while the computation requirements are relatively low. However, when the track structures are more complex, they are still unable to overcome those limitations and complexities.

Alternatively, the 2.5D model has been developed which assumed the track as an invariant structure in the direction of train passage. With this simulation, the number of degrees of freedom are reduced by discretising the track into 2D slices and then capture the response in 3D using a transform ([6],[17],[18], [19],[20]). This is beneficial because it is capable of analysing a relatively complex track and soil conditions, with much lower run times compared to 3D model [21]. For the non-repetitive geometry (for example, transition zones or singular defects), 3D modelling has become an attractive alternative, presenting with a series of brick elements for individual track-ground components. Thus, ensuring the more accurate results in stress and strain field ([22], [23],[24],[25]).

In this paper, the effect of track-soil problems (a presence of low-stiffness soil layer, track shakedown and soil improvement) on dynamic track-soil behaviour, particularly, dynamic amplification and critical velocity will be investigated and analysed. Due to the complexity of such problems, track and soil geometry can be considered repetitive. Therefore, an analytical, semi-analytical and 2.5D numerical model are sufficient to perform the analysis above. The remaining sections of this paper are arranged in order as follow. In section 2, three modelling approaches are described. The modelling analysis of three track-soil problems will be presented in section 3.

2 MODELLING STRATEGIES

In this paper, three different approaches have been developed individually to analyse each problem. The detail of each modelling strategy is described as follows.

Strategy 1 (Analytical): As outlined in [13], analytical expressions are used to compute the dispersion relationship between track and ground. Once the dispersion curves have been plotted, the critical velocity can be identified. For example, the track and soil dispersion curve in terms of wavenumber and phase velocity, as shown in Figure 1, derived from the concrete slab track model with two-layered soil support. Both sub-figures point out that the critical velocity occurs at the intersection point between track and soil dispersion line. For phase velocity, it is straightforward to read to critical velocity, whereas the calculation is required for wavenumber representation, using the frequency divided by wavenumber.

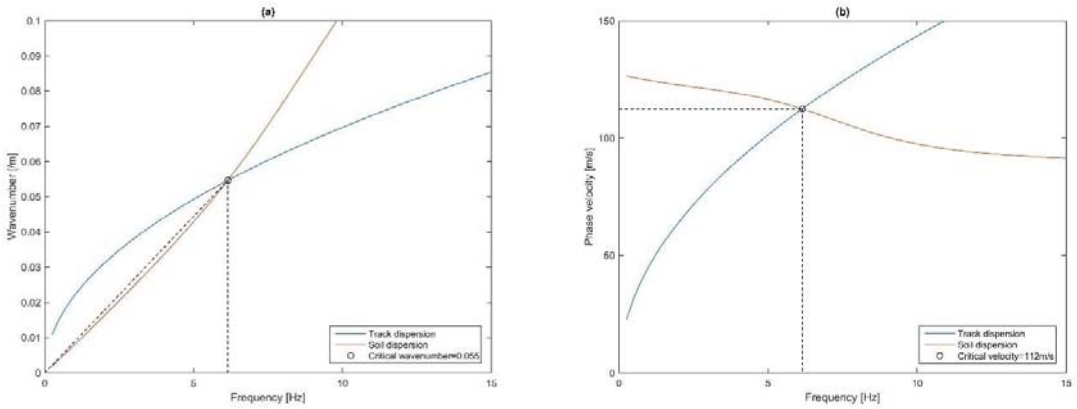

Figure 1: Dispersion relation (a) Wavenumber (b) Phase Velocity

Strategy 2 (Semi-analytical): The track and soil are modelled separately using different methods. An analytical approach is applied to model the track while the ground is modelled using the thin-layer element method (TLM). The thin-layer element and Green's function of soil are used to compute the equivalent soil stiffness in the wavenumber-frequency domain, and such stiffness is then used within a track model to compute the coupled track-ground response, as shown in Figure 2 [26].

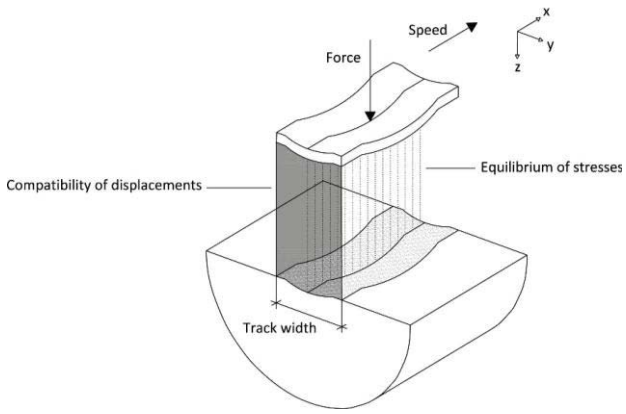

Figure 2: Track-ground interface of a semi-analytical model

Strategy 3 (2.5D numerical): The 2D geometry of track and soil structure are defined using eight-node quadratic finite elements and solving in the frequency domain Absorbing bounda-

ries are created to alleviate the reflection at boundaries, as presented in Figure 3, and the transform is then used to capture the 3D response ([18],[27]).

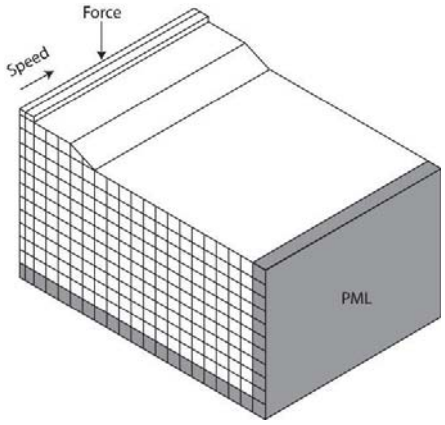

Figure 3: Simplified model of 2.5D modelling method

3 MODELLING ANALYSIS

3.1 Modelling parameters

To generate less complicated models and simulations, only slab track is used throughout this paper, with the properties as shown in Table 1. For the soil properties, Young's modulus is varied in each section depending upon the purpose of informing discussion, and the Poisson's ratio and density are constant at 0.35 and 2000 kg/m3 respectively. Regarding the analysis layout, the soil problem with low stiffness magnitude are presented first, followed by the track shakedown, and remediation solutions for soil are given in the last section.

Component	Properties	Value
Rail	Bending stiffness (Nm^2)	$1.29x10^7$
	Mass (kg/m)	120
Railpad	Stiffness (N/m)	$5x10^8$
	Damping (Ns/m)	$2.5x10^5$
Slab	Height of slab (m)	0.35
	Young's modulus (MPa)	30,000
	Half-track width (m)	1.25
	Density (kg/m^3)	2500

Table 1: Track material properties

3.2 Low stiffness soil layers

In general, the stiffness of soil stratum increases with depth because of the historical earth pressure. An example of dispersion curves for the typical soil layers, which the upper layer contains low stiffness soil (30, 75 and 100 MPa) overlying high stiffness soil (150 MPa) are illustrated in Figure 4(a). It is seen that the soil phase velocity is relatively low when the small magnitude of soil stiffness occurs. In contrast, with the natural processes [28] or localised soil improvement [26], the low-stiffness layers can arise below the top surface zones, possibly causing an increase in soil phase velocity. To illustrate the effect of this scenario on track and

earthwork design, the example of an upper layered soil with 100 MPA stiffness and 6m depth overlying an infinite thickness of soil layer with 50 MPA stiffness is generated. The result of the relationship between train speed and maximum rail displacement is shown in Figure 4(b). It is seen that two peaks occur at similar speeds to the shear wave velocities of two different soil layers. The first peak can be defined as critical velocity which the elastodynamic wave energy commences propagating in low-stiffness layers and the train moving speed is located at the second peak with the highest dynamic amplification. Apart from the theoretical impact, it also affects the engineering practice because the expensive and advanced solutions are required for soil improvement.

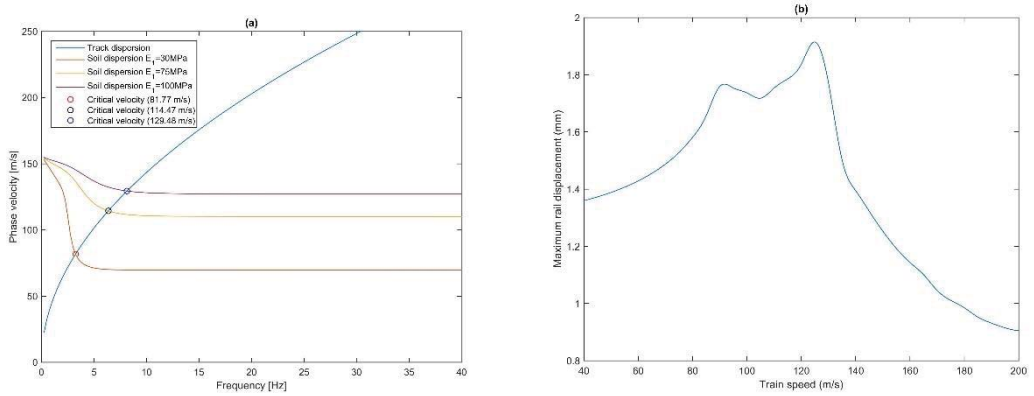

Figure 4 : A presence of low stiffness soil layer: (a) dispersion curves when low-stiffness overlying high-stiffness, (b) Maximum rail displacement curve when low-stiffness underlying high-stiffness

3.3 Track shakedown

With the repeated passages of moving train, track deformations can be both elastic and plastic. Its response can be classified into three main stages: elastic, elastic shakedown, cyclic plasticity and ratcheting depending on moving train loading as presented in Figure 5 ([29],[30],[31]).

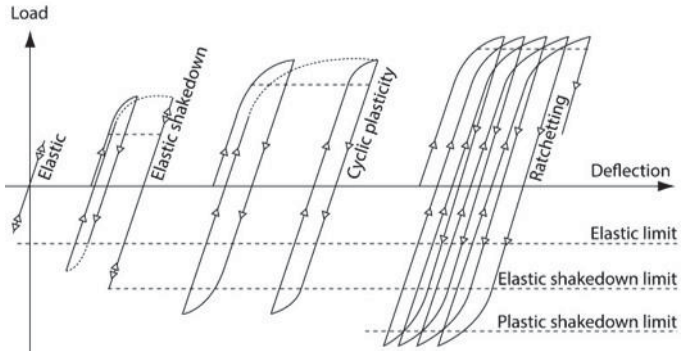

Figure 5: Elastic- Perfectly Plastic behaviour during cyclic loading

For the early stage of elastic, this happens when the train loading is low and does not exceed the elastic yield limit. The permanent track settlement does not appear because the track behaviour is fully elastic with no accumulated strain.

The more adverse stage is elastic shakedown. When train loading is high and exceeds the elastic yield limit for initial train passages, the track will settle with the short period and then return to elastic. The additional train passages at the same loading have no significant impact

on the permanent settlement unless the train loading increase. The reason is that the total stress field (resulting from the combination between the accumulated remaining stress during the initial load cycles, incremental stress from train loading and at-rest stress field) does not affect the yield limit.

The last stage is cyclic plasticity and ratcheting, which is the most critical scenario because the permanent strains occur during each train passage due to the very high train loading exceeding the elastic limit. Such strains, then, induce the instability of track permanent deformation, leading to the increased permanent settlement and ultimate failure.

Regarding the stage of track deformations above, it points out that the elastic shakedown stage plays an important role in track failure because the failure will occur when train loading equal or exceed the elastic shakedown limit. The influential factor for defining this limit are the material properties of track & subgrade, loading aspects (for example, speed and geometry) and level of track dynamic during train passages. To investigate the relationship between the elastic shakedown limit and train speed, an example of the homogenous ground with Young's modulus of 71 MPA and varying friction angle, ϕ = 20˚-35 ˚ are created [32]. The results are plotted, as presented in Figure 6. It is seen that the elastic shakedown limit tends to decrease when the train speed increase for all varying friction angles and the minimum value of shakedown limit can be found at critical speed of 116 m/s. Therefore, the track failure can occur at equal to higher than this speed. However, the analysis above is based on a single moving load, and if considering full train geometries, the shakedown limit will likely be reduced.

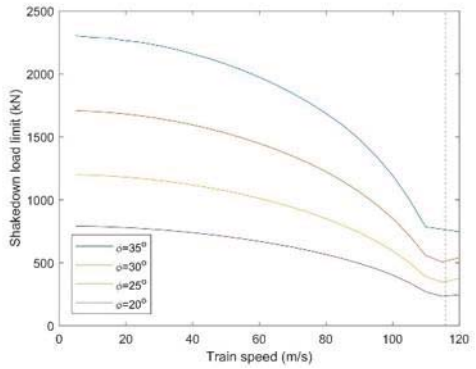

Figure 6: The relationship between train speed and elastic shakedown limit

3.4 Soil improvement

As mentioned in section 3.2, sandwiched low stiffness layers can cause the multiple dynamic amplification factor (DAF) peak generation and significant stiffness contrast. This is challenging to find out the reasonable solutions that can increase the soil stiffness while the cost is needed to be optimised. Therefore, in this section, two main solutions will be considered and discussed.

- Soil replacement

  This is the fundamental practice to improve the soil stiffness by replacing the existing softer soil with the stiffer soil throughout the localised layer. The challenging tasks are to determine the optimisation between the magnitude of stiffness improvement and replacement depth, with respect to construction cost.

  To illustrate this, the example of an original homogenous half-space soil with the stiffness of 45 MPa is created. Then, the soil is locally stiffened by varying five discrete depths (1 to 5 m) and three stiffer magnitudes (100, 200 and 300 MPa). After

simulating the model, the results of all variation cases are plotted, as shown in Figure 7. It is seen that the improvement depth and stiffness magnitude have a non-linear relationship with track deflection. When considering the improvement depth of 1 m, only 300 MPa of stiffness results in lower rail displacement compared with the benchmark case with no improvement (see the dashed line in Figure 7). The reasons are that the train speed is higher than the critical velocity of the original soil, including the increased stiffness shifts the DAF peak closer to train speed [26].

Apart from at 1 m depth above, it is seen that the lower deflections occur when the stiffness magnitude increase. Interestingly, the complex relationships between improvement depth and magnitude stiffness are found at a different level of deflections. For example, 1 m of 300 MPa improvement presents a similar displacement as 2m of 100 MPa, as well as 2 m of 300 MPa and 5 m of 100 MPa. Therefore, to maximise performance and minimise cost, different combinations of both variables are essential to be considered.

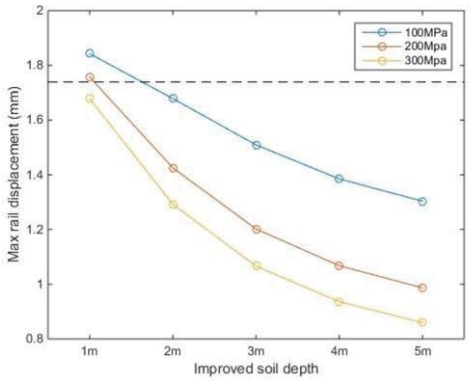

Figure 7: Soil replacement optimisation considering improvement depth and stiffness magnitude

- Discrete soil stiffening

In contrast with soil replacement, soil can be stiffened discretely by either placing stone columns or performing jet grouting. To investigate the performance of both methods, two-layered soil models are created with the thickness of 4 m and 102 MPa of stiffness for the upper layer while the infinite depth of lower layer is modelled with 468 MPa. Then, nine stone columns with diameter of 0.8 m and a stiffness of 160 MPa were placed at the top layers with 1.6 m of spacing while the jet grouting was performed at five locations at 3.48 m of spacing in top layer with 0.7 m of diameter and stiffness of 1 GPa for another model as shown in Figure 8.

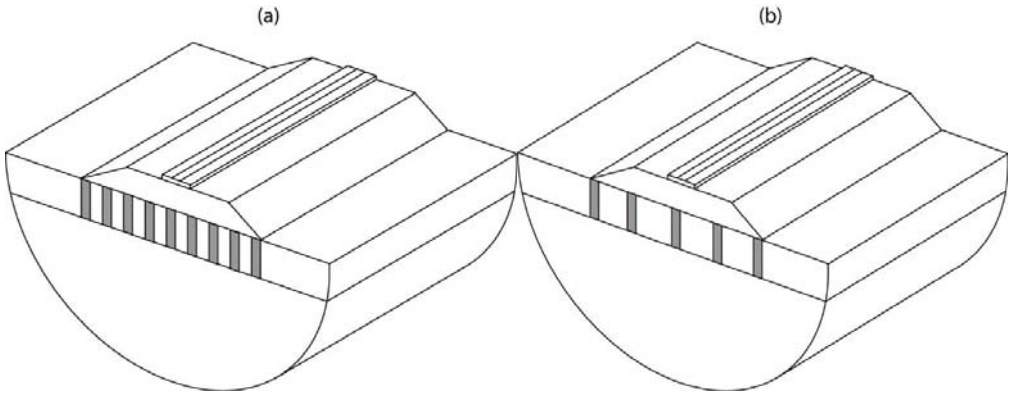

Figure 8 : Discrete soil stiffening model (a) stone column, (b) jet grouting

The results of dynamic amplification for both methods, including the non-improvement case (considered as benchmark case) are plotted, as shown in Figure 9. Such curves from two methods have been normalised as regard to the static displacement of the benchmark. When considering dynamic amplification aspect, using stone column and jet grouting provides a benefit of 12% and 39% respectively compared to the benchmark. Besides, both methods also offer an advantage on critical velocity, 7% when using stone column and 22% for jet grouting. However, these benefit can be affected if the quantity, dimension and stiffness of stone column and jet grouting are changed. Therefore, these three variables above are required to consider when optimising cost and performance of these two methods.

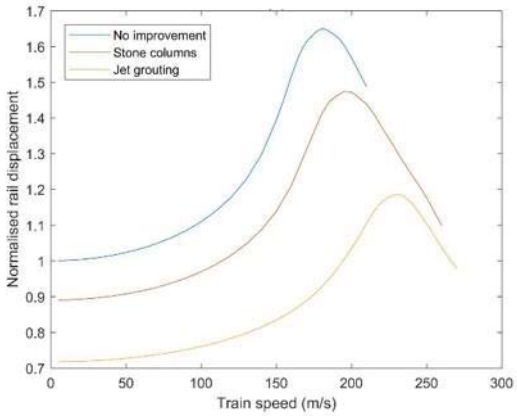

Figure 9: Normalised rail displacement curve when using a stone column and jet grouting

4 CONCLUSION

This paper aims to analyse the dynamic behaviour due to various track and soil problems which involve low-stiffness soil layers, track shakedown and soil improvement. Three types of modelling strategies which consist of analytical, semi-analytical and 2.5D numerical model are developed individually to simulate an example for each problem.

The analysis shows that the presence of sandwiched low stiffness layers can result in a higher level of complexity of soil wave dispersion, with respect to critical velocity. For track shakedown issue, it is found that the elastic shakedown limit is considered as an important factor for the likelihood of track failure due to train loading. Besides, the shakedown limit is highly sensitive when train speed increase. Soil improvement is also examined with two remediation solutions which are soil replacement and discrete soil stiffening. For soil replace-

ment, an improvement depth and stiffness magnitude of replacing soil are essential variables for optimisation of the cost and performance. The relationship between these two variables and track deflection are both non-linear. Lastly, the stone column and jet grouting are considered as discrete soil stiffening method. Two solutions can increase the critical velocity and reduce the dynamic amplification, while jet grouting has a more significant impact on such parameters compared to the stone column.

OURS – INTRODUCING THE DUTCH FORMAL MODEL FOR RAILWAY VIBRATION

Arnold Koopman

Level Acoustics & Vibration
De Rondom 10, Eindhoven, The Netherlands
e-mail: arnold@levelav.nl

Keywords: Railway, Vibration, Modeling, Emission, Measurement

Abstract. *Assessment of environmental vibration of railway lines can take many forms, often depending on the skills and tools of whoever carries it out. In order to protect stakeholders from this arbitrariness and to reduce assessment costs, the Dutch government has commissioned the design and implementation of a screening model for railway vibration. After a study on the state-of-the-art of different methods a methodology has been chosen. This has been carried out and the model is now taken into service.*

In our state of the art study we found that the best approach is to combine a database of vibration forces of different train types for different soil conditions with a numerical model of the soil and an analytical model of the building. This is also given by the type of data that is usually available in environmental impact studies. Key parts are the existence of an extensive soil database in the Netherlands as well as a 6-monthly update of the track geometry. An important issue we addressed was controlling train-track-soil interaction in such a hybrid model given the soft soils that are typical for the Netherlands. We also gave a thorough treatment of all the variations and uncertainties.

What is achieved now is a model where users input general information like geometry of the track and the types, speeds and number of trains into the model. The model itself collects detailed information from various databases, builds an FEM model and runs its calculations resulting in expected exposure values and their bandwidth. Validation will show to what extend this model can be used.

This paper focusses on the schematization of the problem and the measurement of vibration forces.

1 INTRODUCTION

Current procedure in The Netherlands for environmental vibration impact studies of railway projects is the common three step approach: 1. scoping (setting a distance contour around the project and finding relevant buildings); 2. screening (identifying possible exceedance of criteria); 3. detailed predictions (targeting identified locations). As the third step can be quite costly, a good screening procedure is very important. As most projects involve existing lines (to be upgraded), measurements as a central part of the screening is a possibility and in fact the main method right now. Any model to replace that should at least deliver the same quality, in terms of the avoidance of false positives (wrongly identifying buildings) and false negatives (missing the right buildings). It implies that the model should be especially at his best around the criteria levels and that the model should provide information about its reliability, for users to make it possible to choose the level of certainty that suits their purpose. Another important requirement is that it does not need more input than is available in a screening phase. A nice to have for a screening model is that it is also of use for detailed predictions, for instance by allowing parts of the screening model to be replaced by alternative modelling. That way a detailed study can focus on a part without the burden of building a complete alternative model.

A state of the art study [1] learned that such a model, applicable to typical Dutch soils (ranging from very soft to sandy), is not readily available nor can be easily derived from existing similar models. For instance: an existing Dutch commercial screening model[1], completely based on empirical data, lacks information about its reliability. The Swiss model VIBRA-2 is not applicable to soft soils. Current procedures involving the combination of a train-track-soil model, a ground-propagation model and a building response model require too much details.

The models that are available, according to the state of the art study, fall into three categories:

1. Empirical models. They often offer solutions for the complete problem: source, soil propagation, building response. However they lack known reliability and cannot be transposed from their empirical base to other soils, trains, etc.
2. Detailed models. They offer only solutions for parts of the problem: either the source, or a part of the propagation. Their use requires input that is often not available during screening.
3. Machine learning models. As with empirical models loads of measurement data are statistically treated but instead of deriving closed expressions or look-up tables, networks (neural nets, random forests, etc.) are trained on it. They require a quantity and quality of empirical data that is not yet available in The Netherlands.

It has become clear that any new screening model would involve a combination of models. Empirical models suit the level of detail during screening, detailed models make it possible to transpose the empirical models, statistics is needed to learn about the resulting reliability.

2 SCHEMATIZATION OF *OURS*

OURS[2] is built up like noise models used for environmental assessment:

- The source part is empirical
- The propagation part is detailed

[1] VibraDyna, Movares

[2] OURS is an acronym, *Ontwikkeling Uniform Rekenmodel Spoortrillingen*, which is Dutch for "development of a uniform calculation model for railway vibration"

- The building response is empirical/detailed

Different from noise models is that the propagating medium, the soil, influences both the source and the building response. The detailed soil module therefore also feeds into the source module and the building module.

Similar to noise models, each part of problem is described in the frequency domain. Modules generate octave band spectra with mid frequencies 2, 4, 8, 16, 32 and 63 Hz. The main metrics that the model needs to produce are of a peak nature: Vmax and Vtop. They are the maximum over a week of the maximum of each pass-by. The model works with an average over a week of the root-mean-square of each pass-by. This supports the use of spectral analysis. The peak metrics are derived afterwards based on statistical assumptions about the distribution of the vibration amplitude during a pass-by and the distribution of peak levels among pass-bys.. That procedure is already in use for common railway vibration measurements in the Netherlands [2].

2.1 Source

The kinetic energy of the forward moving train is the actual source of environmental vibration. Irregularities, like track unevenness, track stiffness variation, discontinuities, wheel out of roundness, etc. transform part of this energy into propagating waves. Quasi static excitation caused by the moving axle load only lead to propagating waves above a certain critical speed but also generate a near field below that speed which for soft soils can be considerable. The mechanics of the train, the track and local soil influence how much power is injected into the ground and at which frequencies. OURS does not model all that in detail. Instead, the combined source mechanisms are modelled as one “equivalent” point force on the track, equivalent in the sense that it generates the same vibration levels at a given distance, of 25 meter, from the track. The assumption is that the source power is proportional to the square of the excitation force of the train-track system on the soil.

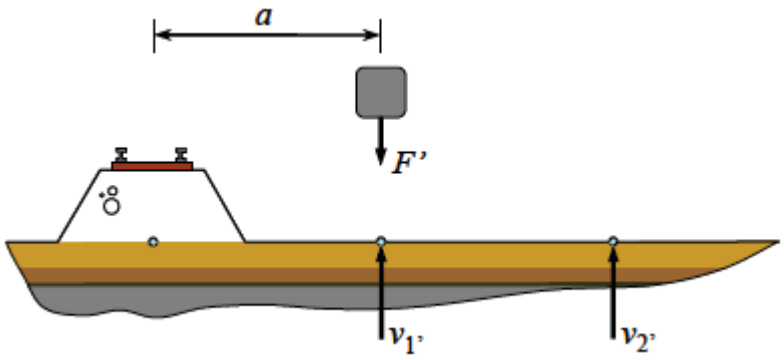

Figure 1: Measurement procedure for use of the equivalent force characterization of a railway track. Using a drop weight the transfer mobility from point 1 to point 2 is measured. Assuming translational symmetry of the ground and regarding the embankment as part of the source, that transfer mobility is taken to be valid also for the train-track system towards point 1.

The distance of the evaluation point (distance *a* in Figure 1) is determined from a sensitivity study performed by Hoving [3]. In that study, a physically complete, though simplified numerical model of the train-track-soil system is set up to determine the minimal distance *a* where the transfer mobility from track to point 1 is not influenced by the train and the track. That distance can be considered the border between source and propagation path and the evaluation point for an equivalent force method.

A drop weight generating a force F on point 1, 25 meter from the track, leads to a velocity response v of point 2 at a distance of 25 meter from point 1. The ratio is the transfer mobility over 25 meter, denoted by Y_{25}:

$$Y_{25} = \frac{v_2}{F_1} \tag{1}$$

Assuming translation invariation, Yo also describes the transfer mobility from a point directly under the embankment to point 1. Measuring the velocity at point 1 during a train passby, a force can be calculated that is characterizes the active train-track-system as a source equivalent to a drop weight:

$$F_{eq} = \frac{v_1}{Y_{25}} \tag{2}$$

The force levels are determined from in situ measurements. How this is done precisely is described in chapter 3. It leads to a database of force spectra for a range of train types, with different speeds, on certain measurement locations. This database constitutes the main part of the source module of OURS. However, this is not enough for describing the source.

Equivalent forces are characteristic for the measurement circumstances under which they are determined: of course train speed and track conditions, but also soil conditions. An algorithm is needed to transpose the measurement data to different conditions. For train speed, that can be a simple case of interpolation between measurement data, given that sufficient speed variation is available in the database. For track conditions, the force can be scaled, given that condition measurements from monitoring trains are available. However, for the embankment as well as for soft soils there is a problem that cannot be solved as easily.

When the receiving system, especially the soil, is relatively soft, the assumption that the source power is proportional to the excitation forces breaks down. The relative mobilities of source system and receiving system influence the actual power injection. This interaction has to be taken into account. In structural acoustics, this is done by introducing a coupling function that is dependent on de mobilities of the subsystems. For railways lines this is difficult: the two dimensional interface between the subsystems complicate the coupling function and complicate the measurement of the needed mobilities.

For OURS, a more simple approach is chosen to take the influence of the soil on vibration generation into account. For each type of train, the equivalent force is determined on two very different soils: a very stiff one and a very soft one. The soil mobility of each of those two locations, already needed to determine forces from measured velocities, become part of the source description. For any location where a prediction is needed, the equivalent fore is determined by interpolation between the two measurement sites based on the mobility of the prediction site. The latter mobility is determined by the same module that calculates the ground propagation.

The interpolation parameter that weights the relative contribution of the soft soil measurements and the stiff soil measurements is determined as follows:

$$s_i = \frac{-\lg(\hat{Y}^{\square}_{25,i}\hat{Z}^{\square}_{25,i,\downarrow})}{\lg(\hat{Z}^{\square}_{25,i,\uparrow}/\hat{Z}^{\square}_{25,i,\downarrow})} \tag{3}$$

In this formula, Z with an arrow up is the transfer impedance (reciprocal of the transfer mobility) of the stiff soil and Z with the arrow down likewise for the soft soil, i is the index for fre-

quency bands, Y_{25} is the calculated transfer mobility of the soil. Given that soil mobilities can differ by an order of magnitude or more, a logarithmic scaling is chosen.

For a certain situation to be evaluated, the equivalent force of a train can thus be calculated from the measured equivalent forces at two sites:

$$F_{eq} = s_i \cdot F_{z,i,\uparrow} \left(\frac{v}{v_{\uparrow}}\right)^{n_{\uparrow}} + (1 - s_i) \cdot F_{z,i,\downarrow} \left(\frac{v}{v_{\downarrow}}\right)^{n_{\downarrow}} \quad (4)$$

In this formula, V stands for the train speed. The exponent n for the influence of the train speed on the equivalent force is also determined at the two measurement sites, each with their own appropriate reference speed (being the median speed at that location).

2.2 Ground propagation

A rather unique opportunity for soil characterization, needed for any propagation model, is the availability in The Netherlands of an extensive and continuously growing database of cone penetration tests (CPT's). For about 80% of the railway system, at least one CPT is available within 600 meter distance. This trove of input data makes it feasible to employ a detailed numerical model. Chosen is to start with implementing a 2D axial symmetric finite element method. Possibly this will be accompanied in the future by a full 3D FEM implementation, for instance for assessing tracks not on grade, mitigation measures, etc.

After drawing from the CPT database, a 2D FEM is built, meshed and solved in the frequency domain. This automated process is implemented into OURS and does not require any commercial FEM code.

The ground module generates transfer functions, for use of calculating the decay over distance as well as point mobilities. These point mobilities are used for taking soil-structure interaction into account, for the source as well as for the building. For the source, the calculated mobility amplitude is used to interpolate between the measured ground mobilities in the source database (see paragraph 2.1). For the building, the calculated complex mobility is combined with a calculated complex building mobility to determine a coupling function (see paragraph 2.3). Also, at the position of the building, the speed of the incoming waves, of whatever nature, is determined for use of the building response.

Choosing a 2D solution over 3D has the benefit of fast calculation but has the drawback that the actual 3D geometrical decay is not represented fully in the 2D solution. This is remedied by imposing the missing extra dimension afterwards.

Choosing to describe the soil with a 2D model in the frequency domain has the drawback that the moving load effect cannot be represented correctly. The near field decay related to the pass-by of an axle cannot be determined from a transfer function. This can be helped by treating the moving load effect completely separately in the time domain, adding axle loads to the source database and using the FEM representation for static deflection tests. This is not implemented in OURS yet.

The ground module is described in more detail in another paper of this Proceedings.

2.3 Building response

The assessment of environmental vibration mainly involves annoyance. To a lesser degree, for railway vibration, structural damage is also an aspect to be accounted for. According to the Dutch regulation [4] in use for annoyance, vibration possibly leading to annoyance is evaluated at the floors of buildings. Vibration possibly leading to structural damage is evaluated at the foundation of the building, according to a generally excepted guideline [5]. In ei-

ther case, a building response model is needed and should take account of soil – structure interaction. To calculate vibration levels on floors, the dynamics of the building structure as well as those of the floors need to be described.

The building response module of OURS is an analytical model in the frequency domain. It takes in information about the nature of the structure and the floors as well as the point mobility and the wave speed in the ground as a function of frequency. From that input, it calculates transfer functions from a green field soil to the foundation and to the floors.

A more detailed description is outside the scope of this paper.

3 MEASUREMENT METHOD FOR SOURCE DESCRIPTION

3.1 General

In OURS, a train type is described by at least two locations, each delivering an equivalent force and the mobility of the soil on which this force is measured. Force and mobility are octave spectra. The mobility is a transfer mobility over 25 meter, determined from a drop weight test. The force is the root-mean-square (rms) of the ground velocity during pass-by, on 25 meter distance from the track, divided by the mobility.

To reduce the influence of varying soil conditions at the measurement location as much as possible, the following precautions are made:

- locations on one side of a track are used with an area of about 200 meter by 200 meter that only contain grass land, without ditches or elevations
- 9 vibration measurements points are used, each at least 2D, preferably 3D. The horizontal of a 2D sensor is oriented towards the source (track or drop weight), a horizontal of the 3D sensor is oriented towards the track.
- for placing the measurement equipment, first the top layer, often about 25 cm, is removed

The drop weight test is performed at each of the 9 measurement points, not only to then later average mobilities, but also to identify possible deviated local soil conditions, to be taken into account during post processing.

To reduce the influence of variation between trains of the same type, at least 50 pass-by's are required, which are averages later. In practice, the measurements continue for at least 2 weeks.

To determine train type and track number a webcam is used and software is trained on the resulting images. To determine train speed a speed radar is installed.

3.2 Measurement procedure

At each measurement location, after careful selection of such a location, the following procedure is followed.

1. A mesh of 3x3 of 50 by 50 meter is set out on 25 meter from the nearest rail of a railway track. See Figure 2.
2. At the 9 mesh points vibration equipment is installed. After removal of the top layer, first a sufficiently stiff plate (first mode>160 Hz, size 30 cm x 30 cm) is positioned and on top of that the sensor is placed. The hole is covered to avoid sensor excitation by rainfall.
3. Webcam and speed radar are installed close to the track and set to run and save continuously.
4. The area is closed down: no cattle or farming or humans allowed.

5. Triggered by a pass-by, full time signals of all 9 points are collected and saved with a pretrigger and posttrigger of 2 seconds.
6. After at least two weeks of measurements, at the last two days a drop weight of at least 300 kg is brought and used to perform the mobility measurements. The drop weight is equipped with an accelerometer to determine the excitation force. The weight is dropped on a plate of about 1 m^2, near each of the 9 measurement points. At least 6 drops at each point: 3 at maximum impulse and 3 at 30% of maximum impulse. Each time the full time signals of all measurement points are collected. In addition to the 9 fixed vibration sensors, there are 4 1D vibration sensors that accompany the drop weight and are positioned around it.
   At least 8 seconds of signal, including a pretrigger of 1 second, is recorded.

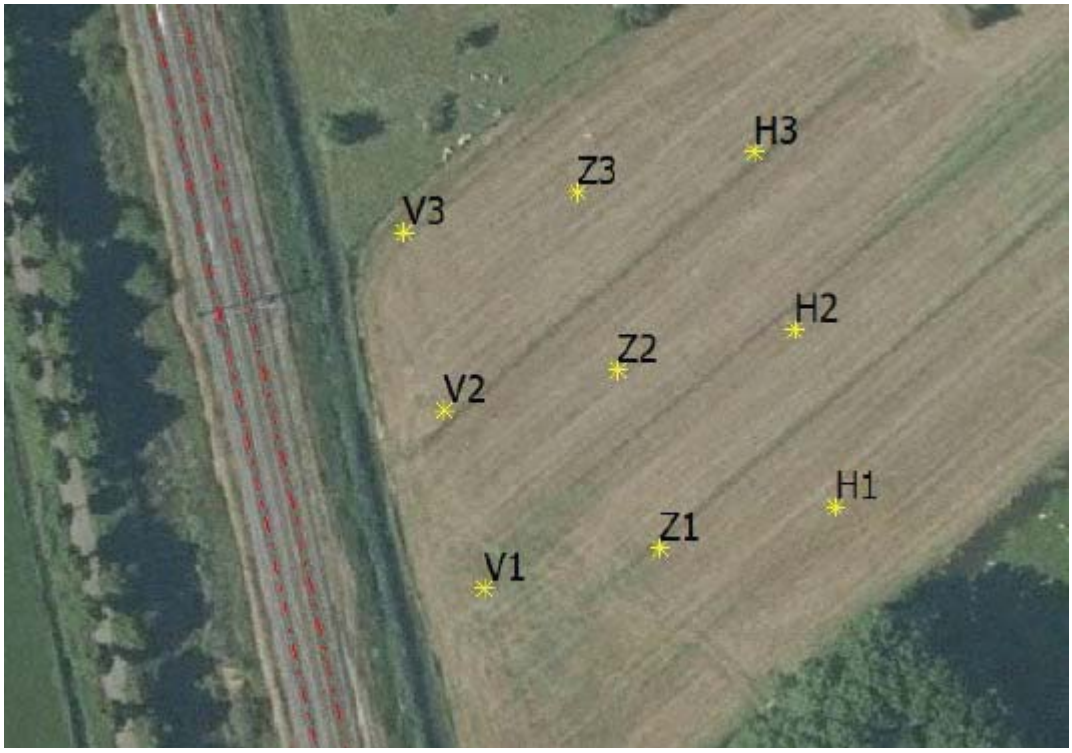

Figure 2: Measurement grid, next to the track. The lines V, Z and H are on a distance of resp. 25, 50 and 75 meter from the nearest rail

The equipment needs to fulfill the next requirements:

- Vibration measurement equipment must fulfill the requirements according to the Dutch guideline SBR B [6] (a.o.: measurement range of 1 to 80 Hz, with a resolution of 0.01 mm/s). The four extra sensors placed around the drop weight need to have a resolution of 0.001 mm/s.
- For the pass-by measurements, the sample frequency is at least 500 Hz. Synchronization between the sensors of 1 second is sufficient.
- For the drop weight measurements, the sample frequency is at least 1000 Hz and all sensors need to be in sync.
- The drop weight should be able to generate a maximum impulse of at least 1000 Ns.

3.3 Post process procedure

First the drop weight tests are processed.

- For each drop, the time signals of the four “traveling” sensors are averaged to one signal.
- For each drop weight test location, the transfer function estimate from the accelerometer on the drop weight to each of the measurement channels is determined. Preferably the estimate is based on a pwelch procedure.
- If in the field accelerometers instead of velocity sensors are used, the transfer functions are divided by the angular frequency.
- The transfer functions are divided by the mass of the drop weight, resulting in a mobility.
- The transfer functions are spectrally averaged to octave band spectra.
- Along with the transfer function estimate, the coherence is determined. The coherence can turn out to be insufficient for large parts of the spectrum, for instance because the drop weight bounces too much or local deformation of the soil underneath the drop weight plate occurs. In that case, instead of determining transfer function estimates, each measurement channel is filtered to octave bands and spectra are generated bases on the root-mean-square of the full signal. The mobilities are derived from the ratio of the spectra, after corrected for drop weight mass. If in the field accelerometers are used, the time signals are first integrated.
- For each test location, the point mobilities (derived from the 4 traveling sensors) is compared to the mobility derived from the vertical direction of the field sensor at that location to investigate the validity of the field sensor. In case of a considerable deviating spectrum, that sensor is removed from all measurements, including the pass-by’s.
- The 9 point mobilities are also compared mutually to find outliers to be removed from all measurements.
- From the remaining mobilities, all the 25-m “neighbor” mobilities for the vertical direction are selected. The inverse is taken to yield the impedance. These impedances are averaged, thus resulting in what is called, in OURS, Zo. Multiplication of Zo with a velocity measurement on a 25 meter distance gives an equivalent force.
- From the neighbor mobilities the horizontal in the direction of the drop weight is divided by its vertical. These are averaged, resulting in what is called, in OURS, Yratio. That parameter is used to derive a vertical force to horizontal velocity mobility from Zo.

Then the pass-by’s are processed.

- The time signals are put through an octave filter bank.
- The signals, including the original unfiltered one, are further treated according to SBR B: the frequency weighting related to human perception is applied in the time domain, the signal is convoluted with an exponential filter with a decay time of 1/8 second, resulting in a DC signal.
- For each channel from the unfiltered but SBR-B treated signal the moment that the maximum (called “Veff,max” by SBR-B) occurs is determined. For that moment and 5 seconds (±2.5 seconds) around it, the root mean square of the octave filtered and SBR-B treated time traces is determined. This results in what is called, in OURS, a Vrms,5s per octave band per measurement point per vibration direction per pass-by.
- The decay over distance, from 25 to 50 and 75 meters from the track, for the vertical and the horizontal vibration directions, is determined by curve fitting an exponential decay on each pass-by and average the results.

- The Vrms,5s spectra are multiplied with correction spectrum that accounts for the amount that the local track geometry deviates from the Dutch mean as determined by the most recent visit from a track monitoring train.
- Using the distance decay, the Vrms,5s on 50 and 75 meter are translated to a prospected spectrum at 25 meter. For multiple tracks, pass-by's on the tracks further from the field are translated to the first track, using that same distance decay relation.
- Each Vrms,5s is multiplied with Zo to yield an equivalent force spectrum.
- Per type of train, all force spectra of that type are collected to fit the exponential of the relationship between train velocity and equivalent force. This exponential becomes part of the source database.
- After applying train speed correction, for each type of train all equivalent force spectra are averaged, yielding Feq, which becomes part of the source database.

4 MEASUREMENT RESULTS

In 2018, specialists from the company Cauberg-Huygen have carried out source measurements at 3 locations in the Netherlands: Best, Schalkwijk and Nijkerk. Best and Nijkerk are chosen for their stiff soil (sandy), Schalkwijk for its very soft soil (clay).

From this experience, some lessons are learned. One involves the drop weight. Applying an elastic layer under a drop weight is an often used method to skew the excitation spectrum. Varying that layer makes it possible to "scan" a considerable frequency range. Eventually it turned out, for this procedure, that just using one very stiff rubber (of unknown Youngs's modulus though) is sufficient.

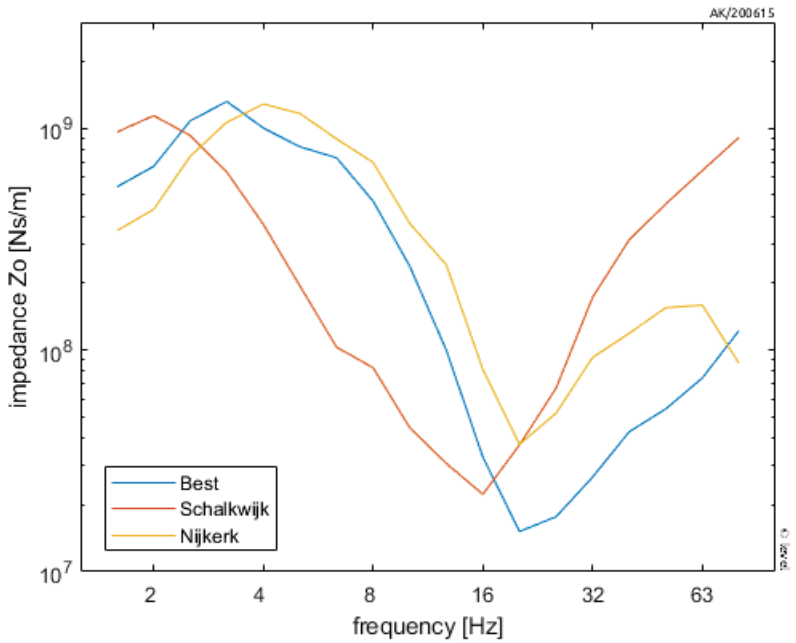

Figure 3: Impedance over 25 meter Zo, as determined by drop weight tests on three different locations in The Netherlands. The variation coefficient in each band is about 30%.

Some results are presented in figures 3, 4 and 5. First the measured impedances are shown. For the purpose of investigation, the impedances are evaluated for third octaves instead of octave. Around 8 Hz, an important frequency for railway vibration on soft soils, the difference between the stiff soils and the soft soil is an order of magnitude. Around 63 Hz, the soft soil has a much higher impedance over 25 meter.

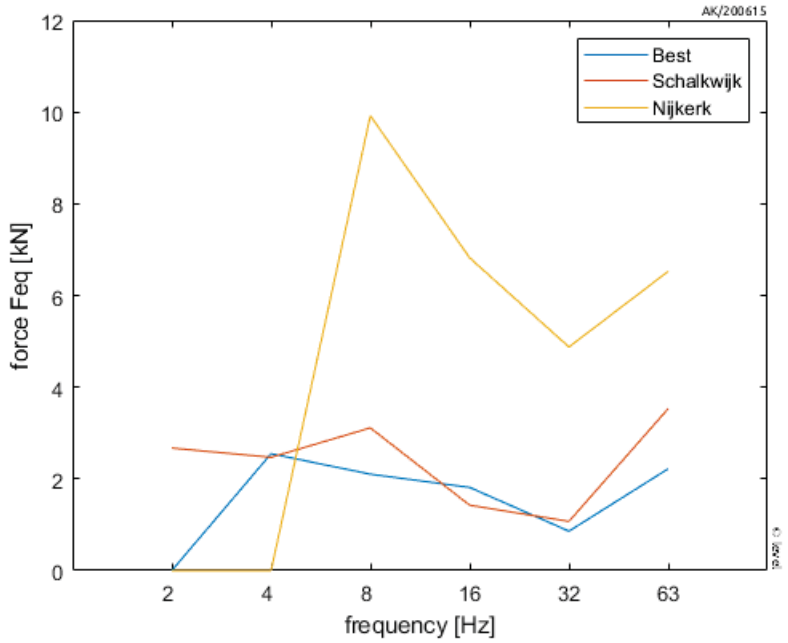

Figure 4: Equivalent force of a VIRM passenger train at 135 km/hr as determined on three different locations. The variation coefficient in each band is about 30%.

The equivalent force for a very common and very significant train type, the double deck passenger train VIRM, is shown in 4, for each of the three locations. It illustrates the influence of the soil on the equivalent force. Remarkable is that for the main part of the frequency range, not the one soft location but one of the two stiff locations stands out: Nijkerk. From a stiffer soil higher forces are expected so the current assumption is that it is actually the other stiff location, Best, that is deviating from expectations. Either way, these results are not fully explained yet and are still under investigation.

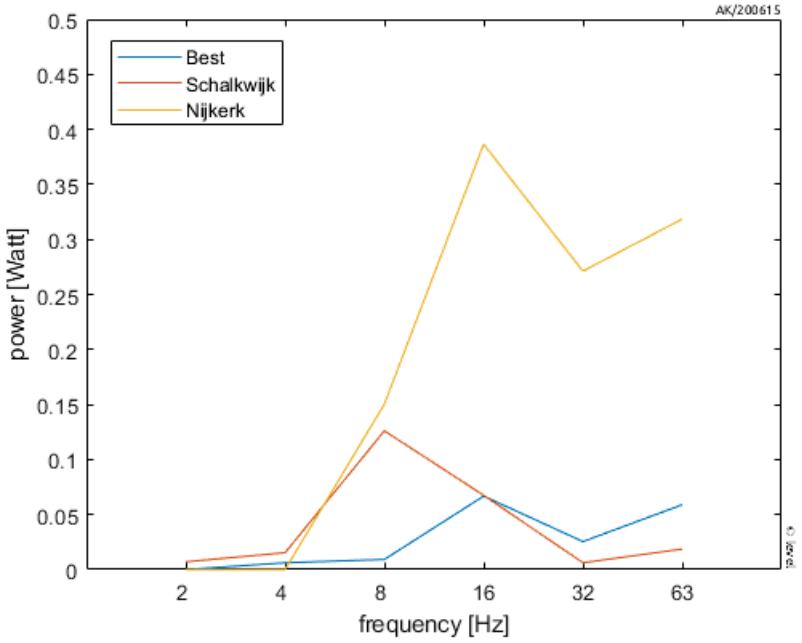

Figure 5: Power, injected into propagating waves, by VIRM passenger trains with a speed of 135 km/hr, on three different locations. The variation coefficient in each band is about 50%.

Finally, the power injected into propagating waves is determined from the equivalent force and resulting response at 25 meters from the track. It illustrates the influence of the soil on injected power and therefor the need to incorporate the soil influence into a source characterization. Again, Nijkerk stands out. This can partially be explained by the high forces that are generated there. Schalkwijk shows why 8 Hz is such an important frequency for soft soils: most of the power is in that octave band. It can be explained by the relatively low soil impedance there which leads to a stronger coupling with the train-track system.

5 CONCLUSIONS

This paper describes the physical schematization that OURS uses to describe the generation and propagation of railway vibration. An important aspect is the influence of the stiffness of the soil on the vibration generation. This led to a measurement procedure that is described in this paper. That procedure has been carried out at three locations, to fill the source database of OURS.

The measurement results show that the injected power indeed depends on the soil conditions and that the equivalent force as a descriptor of a source is only valid under similar soil impedances.

Two similarly stiff locations generate different injected and different equivalent forces though. This is not understood yet.

The full implementation of OURS, the installer as well as all the code, which is released under an open source license, can be found on Github [7].

6 ACKNOWLEDGEMENTS

This work is commissioned by the Dutch Ministry of Infrastructure and Watermanagement to the National Institute for Public Health and the Environment (RIVM) and carried out in a consortium of RIVM, Deltares, DGMR, Cauberg-Huygen, Movares and Level Acoustics & Vibration.

Abstract. *Nuisance due to railway induced vibrations has been receiving increased attention in the Netherlands, as a recent study has found that a significant part of the population living in the vicinity of railway tracks in the Netherlands, experiences excessive vibrations levels. As a result, the Dutch government has commissioned the design and implementation of a screening model for the estimation of railway induced vibrations at a network level. Within this screening model, attention has been paid to the characterisation of the subsoil. This paper focuses on the methodology developed to perform a semi-stochastic subsoil characterisation, based on publicly available datasets for the Netherlands. The method uses a countrywide cone penetration test database and the Dutch geomorphological map to define, at a specific location, a set of possible subsoil schematisations, their likelihood of occurrence, and the corresponding subsoil parameters. The effect of soil variability on the vibration levels is assessed by computing the transfer function at different distances from the source. The transfer functions are computed with a newly developed finite element model kernel. The kernel is optimised to specifically compute layered half-spaces. The results show that the subsoil schematisation plays a significant role on the vibration level, which shows that it is paramount to perform a correct characterisation of the subsoil when trying to estimate induced vibration.*

1 INTRODUCTION

Railway induced vibrations are found to cause public nuisance to inhabitants living on the vicinity of railway tracks. In the Netherlands it is estimated that 20% of the inhabitants living within 300m of a railway track experience severe nuisance due to railway induced vibrations [27].

In order to better characterise the environmental levels of exposure to railway induced vibrations the Dutch government has commissioned a screening model. In 2016 the desire for a robust calculation model was expressed by the minister of the Ministry of Infrastructure and the Environment (currently the Ministry of Infrastructure and Water Management). In response the Dutch National Institute for Public Health and the Environment (RIVM) started a project to answer the following questions:

1. What is the quality of available calculation methods?
2. Can the available methods be improved?
3. What calculation model could best be developed that is suited for railway induced vibrations in the Netherlands?

In an inventory on the state-of-the-art of railway induced vibration models [8], 17 calculation models were considered (10 foreign and 7 domestic). The main conclusion of this study was that none of these models were directly suited to be used in the Netherlands, but a combination of methods could be applied to create a calculation method that fits the requirements for accuracy and reproducibility.

The lead to the development of a new screening model : OURS (a detailed description of the model can be found in [13]). At the heart of the OURS model lies the soil independent source characterisation as developed in [26]. This enables the generation of a database with source parameters that only depend of parameters such as train speed, weight and wagon types. Once a database is filled, then the source terms are convoluted with the transfer admittance through the soil and the vibration levels can be predicted at the foundation of the buildings.

One of the major components of admittance modelling corresponds to the subsoil modelling. Even in countries with abundant information about the subsurface, such as the Netherlands, the data density is in most cases not high enough for reliable deterministic subsoil schematisations. The challenge is to produce a reliable subsoil schematisation and parametrisation, with the available information.

The development of OURS screening model had the following requirements:

- The method needs to be applicable in the entire county;
- The method needs to provide unique response (independent of the user);
- The method needs to provide, for a specific location, subsoil layering and subsoil parameters (Young modulus, soil density, Poisson ratio and damping ratio).

During the past years, a methodology has been developed for flood defences [10] that uses subsurface build up scenarios to characterise the subsurface for a certain assessment. This approach combines data from e.g. boreholes, cone penetration test (CPTs) and geological maps with expert knowledge about the natural pattern in the build-up of the subsurface. The result

is a stochastic subsoil schematisation that, at a certain location, provides the possible subsoil schematisations and its likelihood of occurrence.

Although this methodology has successfully been adopted in flood defences, it cannot be translated into the current project, as it requires expert knowledge in order to derive the subsoil schematisations. The proposed methodology for OURS uses the concepts defined in the flood defences methodology, such as the concept of subsoil scenario [10], but the derivation of the subsoil scenarios is purely based on public datasets.

The second major component of the development of the admittance modelling consists of the creation of a finite element analysis (FEA) kernel. The admittance can be modelled using several methodologies. One of the fastest options is to deploy a semi-analytical description of a layered halfspace. However, the flexibility of such a model is very low. It can only be used in very homogeneously distributed layers. A slightly slower, and a more flexible option are Boundary Element models (BEM). This is a fully numerical method in which only the enclosing surfaces of the layers are discretized. When introducing many thin layers or irregularities, the BEM methods becomes slower. The most flexible and unfortunately slowest option corresponds to Finite Element Method (FEM). In FEM the complete soil domain under consideration has to be discretised. This generally leads to a large number of unknowns to be solved. However, the system of equations to be solved is sparse (in contrary to BEM) and when deploying an explicit scheme to solve the differential equations, only a diagonal matrix has to be inverted.

The major advantage of using FEM is its flexibility. Although it is not foreseen within the scope of this project, it should be easy to improve the method to also model e.g. countermeasures to prevent nuisance. Only FEM is able to easily model these geometric constructs.

This paper the methodology for subsoil modelling and admittance computation in OURS and it is organised as follows: section 2 describes the principles of subsoil modelling, section 3 presents the development of the FEM kernel for the analysis, and section 4 illustrates the application of the methodology in a case study.

2 SUBSOIL MODELLING

2.1 Public datasets for subsoil modelling

The model for the subsoil schematisation and parametrisation developed for OURS has been developed with the following public datasets:

- The Netherlands Hydrological Instrument (NHI);
- Geomorphological map;
- Cone Penetration Test (CPT).

The following sections show the description of these different datasets, and its interpretation (when applicable).

2.1.1 NHI dataset

In the Netherlands the NHI [3] provides the targeted water level for the entire country. This information is used to compute the phreatic level depth, z', and therefore estimate the vertical effective stresses, σ'_{v0}, which are of importance to perform the subsoil schematisation and parametrisation (see Section 2.2.2).

Figure 1 illustrates the targeted water level for the Netherlands. This value is displayed in NAP level (Normaal Amsterdams Peil), which corresponds to the reference surface for vertical positions for the Netherlands. From the Figure 2 it follows that the east and southeast part of the Netherlands have a higher target water level than the western part. This is related to the higher elevation of this region.

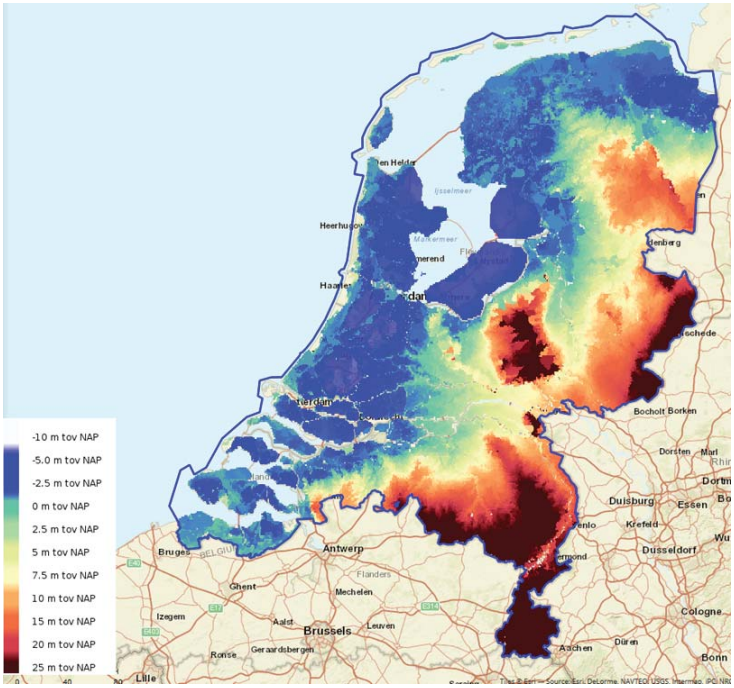

Figure 1: Yearly targeted ground water level for the Netherlands [3].

2.1.2 Geomorphological map

In the Netherlands the geomorphological map has been developed by the Wageningen Environmental Research (Alterra). This map is freely available through PDOK [21]. The geomorphological map provides a detailed overview of the altimetry, origins and formations of the Dutch subsoil (e.g. moraines, river valleys; old river beds), as well as abnormal geological depositions and elevation details. Moreover, the geomorphological map provides information about active geomorphological processes, such as dune formation due to aeolian transport and sedimentation and erosion along rivers and tidal processes.

Figure 2 illustrates the geomorphological map of the Netherlands. Each colour corresponds to an independent geomorphological entity. These geomorphological entities can be interpreted as geological formations that have a similar build-up process. From the figure it follows that the eastern part of the Netherlands has more complex morphology than the western part. Areas as Flevoland have little variability, as they are the result of land reclamation activities.

2.1.3 CPT tests

The CPTs tests are generally the main information used to perform the subsoil schematisation and parametrisation in geotechnical engineering, therefore have been adopted as the main dataset for the development of the subsoil modelling in OURS.

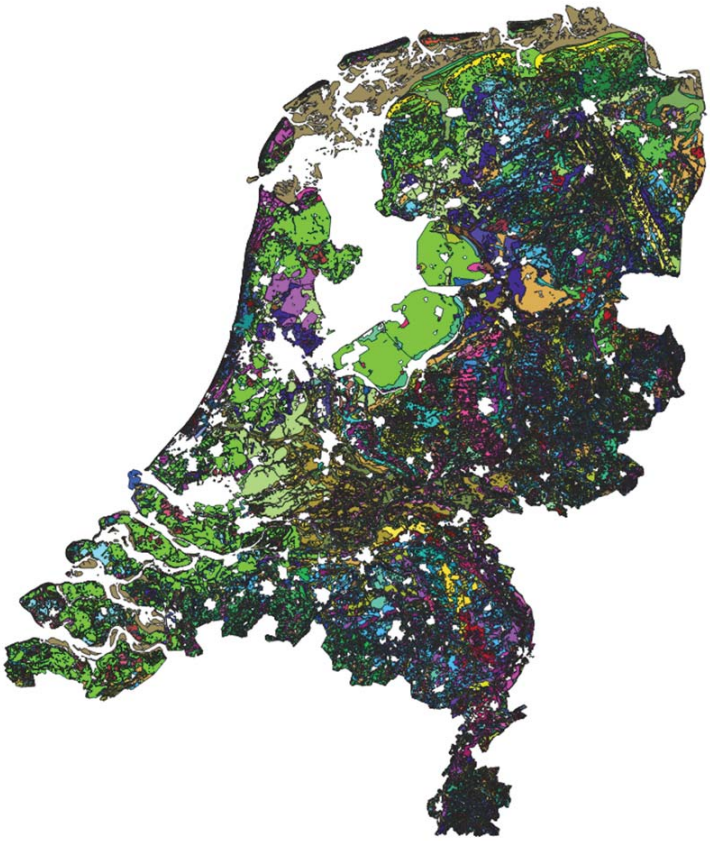

Figure 2: Geomorphological map of the Netherlands [21].

In the Netherlands a public database containing CPTs is freely available (BRO: Basisregistratie Ondergrond [2]), and it is maintained by the Dutch government. This database is being continuously updated with new CPT data, as in the Netherlands it is compulsory to add the CPTs tests into the BRO database for projects funded by the public works.

Figure 3 shows the CPT dataset available in the BRO (February 2020), alongside with the Dutch railway network. In total there are 97732 CPTs tests. It follows that the Randstad has a higher density of CPT tests than the rest of the Netherlands. Nevertheless, the amount of CPT tests will increase with time, as more data will become available in the BRO, which will lead to an overall increase in the density of CPT tests across the country.

2.2 CPT interpretation

2.2.1 CPT: subsoil layering definition

The CPT tests were used to perform the subsoil layering definition. This layering was performed in accordance to the methodology presented in Robertson and Cabal [23]. This is the most established classification system for soils found in literature. This methodology for the calculation is described in Procedure 1.

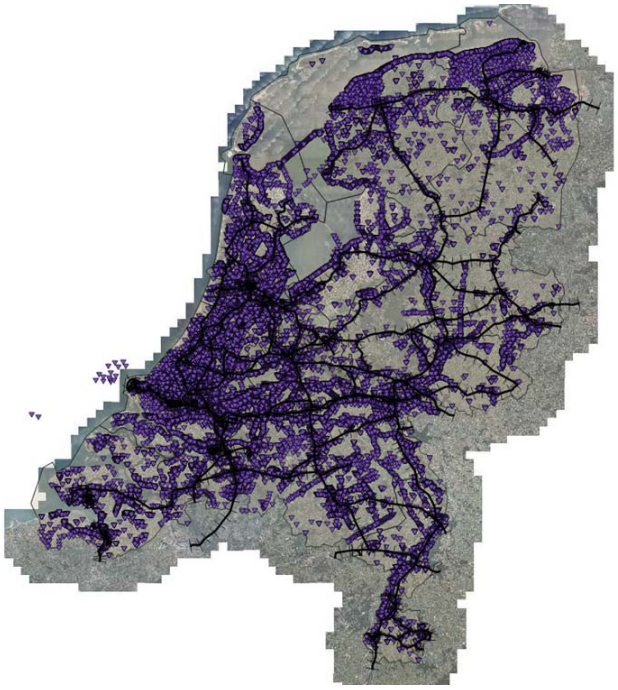

Figure 3: Overview of the CPT distribution in the Netherlands [2]. ▼ represents a CPT and $\neq$ the Dutch railway network.

Procedure 1

1. Read CPT file from BRO
2. Read phreatic level from NHI
3. Compute soil volumetric weight (see Section 2.2.2)
4. Compute total and effective stresses
5. Compute lithology according to [23]

2.2.2 CPT: subsoil parametrisation

For the analysis of wave propagation problems, not only the subsoil layering is of importance, but also the geomechanical parameters associated with each layer. In the model of OURS the wave propagation analysis is done by means of FEA, which has the following geomechanical parameters as input: soil density, ρ; Poisson ratio, ν; small strain shear modulus, G_0; and damping ratio, D_r. Table 1 provides the overview of the correlations used to estimate the geomechanical parameters. Further information about the choice of the correlations, and parameters can be found in [22].

Different correlations exist to establish the relation between CPT data and soil volumetric weight, γ. In OURS the correlation proposed by Lengkeek *et al.* [15] was adopted. This consists of a specific correlation developed for the Netherlands, based on the interpretation of 300 CPT tests, that accounts for the very soft and highly organic soils, typical of the region.

Very little literature is available on the correlation between CPT testing and Poisson ratio. However, this parameter does not vary greatly [14]. From the literature [7, 24, 11, 16] it follows

Property	Correlation	Note
volumetric weight γ	$\gamma = \gamma_{ref} - \beta \cdot \frac{\log\left(\frac{q_{t,ref}}{q_t}\right)}{\log\left(\frac{R_{f,ref}}{R_f}\right)}$	from [15]
soil density ρ	$\rho = \frac{\gamma}{g}$	-
Poisson ratio ν	0.495	clay / loam undrained behaviour
	0.25	silty / sandy clay
	0.3	silty sand
	0.3	sand
	0.375	dense sand
shear wave velocity v_s	$v_s = \sqrt{10^{0.55 \cdot IC + 1.68} \cdot \left(\frac{q_t - \sigma_{v0}}{Pa}\right)}$	from [23]
small strain shear modulus G_0	$G_0 = \rho / v_s^2$	-
damping ratio D_r	$D_r = 2.512 \cdot \left(\frac{\sigma'_{v0}}{Pa}\right)^{-0.2889}$	peat [30]
	$D_r = 0.8005 + 0.0129 \cdot I_p \cdot OCR^{-0.1069} \cdot \left(\frac{\sigma'_{v0}}{Pa}\right)^{-0.2889} \cdot (1 + 0.2919 \ln f)$	clay [6]
	$D_r = 0.55 \cdot C_u^{0.1} \cdot D_{50}^{-0.1069} \cdot \left(\frac{\sigma'_{v0}}{Pa}\right)^{-0.05}$	sand [18]

Table 1: Overview of the correlations for CPT interpretation.

that several authors provide a range of admissible values for the Poisson ratio in the different types of soils.

The value of the shear modulus G depends on the level of shear strain experienced by the soil. For problems involving wave propagation through the subsoil it is generally assumed that the material behaves in elastic regime and that the strain levels are very small. The shear deformations are the result of particle distortion rather than sliding and rolling between particles. Such deformation is almost linearly elastic. This behaviour can be quite accurately simulated by means of the small strain shear modulus, G_0, which is the shear modulus that is mobilised at very small strains [9]. Most of the correlations between CPT and small strain shear modulus are performed through the shear wave velocity, v_s. In OURS the adopted correlation for the shear wave velocity is one proposed by Robertson and Cabal [23], as it is a very well established correlation, and has the advantage of being an universal correlation for all the different soils types.

The value of the damping ratio, D_r, similarly to the shear modulus, is related to the shear strain level. However, while the shear modulus decreases with the increase of the shear strain, the damping ratio increases with the increase of the shear strain. This is related to the dissipation of energy due to hysteretic damping [20]. The damping ratio is estimated for very small shear strains, the reasoning being the same as presented before for the shear modulus. The correlation used to compute the damping depends on the type of soil material.

2.3 Scenario schematisation

2.3.1 Methodology for subsoil scenario schematisation

The methodology devised for the subsoil schematisation was based on the methodology that has been developed for flood defences in the Netherlands [10].

For flood defences, the subsoil is schematised by dividing the subsurface into build-up scenarios that characterise the subsurface for a certain assessment (e.g. macrostabilily, piping). This approach combines data from e.g. boreholes, CPTs and geological maps with expert knowledge about the natural pattern in the build-up of the subsurface. This is relevant, because it important the order of deposition of the sediments (e.g. sediments deposited in a dynamic river-mouth area or at the bottom of the sea). The environment in which the sediments were deposited gives information about what build-up to expect, how much variability is possible, over what distances relevant changes in build-ups can occur and what are the expected geotechnical properties.

One of the requirements for the development of OURS is that the methodology is independent of expert knowledge, so that at any given location the results are always the same, independently from the user.

In order to achieve this, the methodology proposed in [10] for flood defences has been modified. The concept of subsoil scenarios with a defined probability of occurrence remains, however the methodology for its derivation has been modified.

The subsoil scenarios have been computed by combining the information of the geomorphological map with the CPT tests. At the analysis location (x,y) all the CPT tests are gathered for all the geomorphological entities that are in the vicinity of the analysis location (600 m). Each geomorphological entity is a different subsoil scenario (with a probability of occurrence), and the soil properties for the scenario are derived from all the CPT tests that are contained in the geomorphological entity.

In order to keep the FEA computations into a reasonable computational time the scenarios were schematised with a minimum layer thickness of 0.5 m. This means, that layers that are thinner than 0.5 m are merged together. This method is further elaborated in Procedure 2.

Procedure 2

1. Define circle with a radius of 600 m, with centre at the railway analysis location
2. Intercept circle with geomorphological map
3. Identify all the geomorphological entities contained in the interception
4. Read and process all CPTs within each geomorphological entity
5. Read and process remaining CPTs contained in the circle that are not part of any geomorphological entity
6. Schematise in scenarios
   (a) Each geomorphological entity is considered one scenario
   (b) If there is a region in the circle without a geomorphological entity, this region is also considered a scenario
   (c) The probability of occurrence of each scenario is the ratio between the area of the geomorphological entity within the circle and the area of the 600 m radius circle
7. Perform interpolation at the house analysis location. The interpolation is performed to determine the geomechanical properties of each scenario at the analysis point. The interpolation is performed by means of the inverse distance method

Figure 4 shows this procedure in a schematic example. In this example three scenarios: exist Scenario 1, that corresponds to Geomorphological #1 (containing CPT1, CPT2 and CPT3), Scenario 2, that corresponds to Geomorphological #2 (containing CPT6 and CPT7) and Scenario 3 with corresponds to the remaining part of the circle without a geomorphological entity (containing CPT 4 and CPT5).

The geomechanical properties of each scenario will be calculated by interpolating the CPTs contained within each scenario at the calculation point.

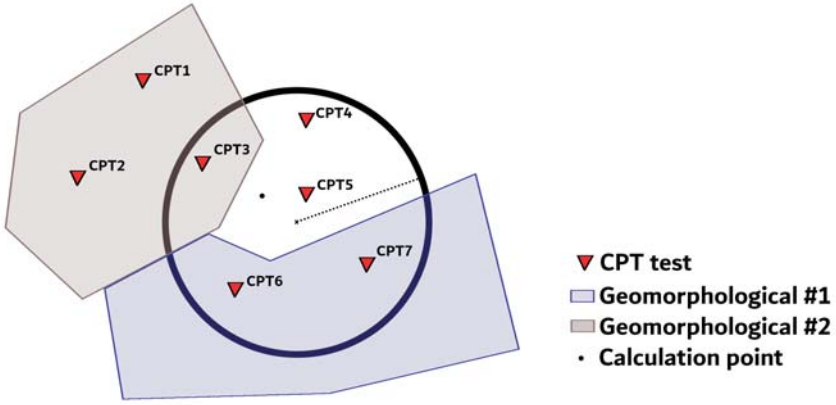

Figure 4: Example of the subsoil scenario schematisation.

The variability in the subsoil parameterisation has been done following the methodology first proposed by Vanmarcke [28], and further developed for the specifics of the Dutch situation by Calle [4].

The methodology is derived from a time series analysis, in which a time varying signal is assumed as one realisation from a stationary stochastic function. Signal characteristics, such as scale of fluctuation and irregularities, are determined by means of the autocorrelation function.

The method is based on the assumption that that at each location (x,y) along the line infrastructure (e.g. dike, road, railway) the spatial variability along the horizontal directions can be described as the random fluctuation, in relation to the average value along the vertical direction. In other words, the average value is random at each location in the (x,y) plane and it is assumed as a stochastic function with average value and standard deviation. These average and standard deviation are called regional parameters, and correspond to the representative values for the soil layer within the area of interest (local fluctuations within a layer, z direction, are averaged out). On the model schematisation of OURS the material parameterisation corresponds to the regional parameters.

3 FINITE ELEMENT ANALYSIS

There is a multitude of options to determine the admittance spectra of a layered half space. The fastest option consists of analytical models. However, analytical models are not flexible enough to eventually simulate mitigation techniques to reduce the vibration levels. On the other end of the spectrum the numerical methods (especially FEM), offer a slow but very flexible alternative.

The modelling of mitigation techniques does not lie within the scope of this project. However, in order to account for the future developments of the model, it is chosen to implement a FEM methodology to determine the admittances.

Within the scope of this project it is sufficient to implement an axisymmetric FEM procedure. Axisymmetric FEM models are impractical when modelling mitigation techniques (which are generally not axisymmetrically oriented around the source of vibrations. However, axisymmetric FEM models do require a similar infrastructure as 3D FEM models do, and thus it can easily be upgraded to a 3D environment.

Further constraints are imposed to the choice of the transmission model by the geometrical dimensions and the maximum frequencies in which the admittances are determined. The admittances are to be determined within a maximum range of 150m to 200m with soils characterised to a depth of 50m. The maximum required frequency is set at 80Hz to 100Hz. These numbers determine whether the system matrices of the FEM model can be assembled and kept in RAM, or be only directly translated into force vectors each time step in an explicit procedure. With these dimensions the system matrices of the axisymmetric models can easily be determined once and stored in RAM. This is determinative for the implemented solving procedures.

When eventually switching to 3D FEM models, the solving procedures need to be adapted. In this light an explicit procedure and an optimal assemblage procedure are developed which can be used when implementing 3D models.

3.1 Finite Element formulation

Several Finite Elements have been implemented in the code. There is naturally an axisymmetric element to determine the stiffness, mass and damping of the soil. There are also elements that determine the stiffness and the damping and the so-called infinite boundaries. For efficiency

reasons the equations have been incorporated analytically on finite element level. This is made possible by assuming that all elements constitute a rectangular geometry. The numerical equations are first fully written out and after summarising all terms, the number of floating point operations are reduced. The resulting analytical equations are rather lengthy and they are therefore not presented in this paper. The resulting number of floating point operations per element are roughly equal to the implementation of the axisymmetric iso-P elements in commercially available explicit software packages. The present element is based on incompatible modes which offers the advantage of a locking free behaviour. The aforementioned iso-P elements suffer greatly from locking (i.e., added parasitic non-physical stiffness caused by improper interpolation of the displacement strains) and this is generally alleviated by reducing the order of numerical integration. The downside of low-order numerical integration is the exhibition of so-called zero energy or hourglass modes. These modes, which consume no energy hence the name, add a zig-zag form of displacements to the solution and are generally battled by adding a numerical damping to the solution procedure.
By analytically incorporating the incompatible mode or Enhanced Assumed Strain element [25], the need of adding artificial damping can be circumvented without consuming additional CPU time.

3.1.1 Axisymmetric stiffness matrix

The strain and stress component vectors of an axisymmetric elements are defined in Voigt notation as

$$\boldsymbol{\varepsilon} = \begin{Bmatrix} \varepsilon_{rr} \\ \varepsilon_{zz} \\ \varepsilon_{\varphi\varphi} \\ 2\varepsilon_{rz} \end{Bmatrix}, \quad \boldsymbol{\sigma} = \begin{Bmatrix} \sigma_{rr} \\ \sigma_{zz} \\ \sigma_{\varphi\varphi} \\ \sigma_{rz} \end{Bmatrix}, \tag{1}$$

where φ denotes the hoop direction.
The strain and stress vector are coupled by the constitutive equations. In this case the linear elastic-isotropic Hooke's law is chosen

$$\boldsymbol{\sigma} = \frac{E}{(1+\nu)(1-2\nu)} \begin{bmatrix} 1-\nu & \nu & \nu & 0 \\ \nu & 1-\nu & \nu & 0 \\ \nu & \nu & 1-\nu & 0 \\ 0 & 0 & 0 & \frac{1-2\nu}{2} \end{bmatrix} \boldsymbol{\varepsilon} = \boldsymbol{D}\boldsymbol{\varepsilon}, \tag{2}$$

where E is the Young's modulus, and ν is the Poisson ratio.
The strain components are kinematically linked to the displacements as

$$\varepsilon_{rr} = \frac{\partial u_r}{\partial r},\ \varepsilon_{rr} = \frac{\partial u_r}{\partial r},\ \varepsilon_{rr} = \frac{\partial u_r}{\partial r}, \text{and } \varepsilon_{rr} = \frac{\partial u_r}{\partial r}. \tag{3}$$

The displacements $\boldsymbol{u}(\xi,\, \eta)$ within the element are interpolated with bilinear interpolation shape functions $H_I(\xi,\, \eta)$

$$\boldsymbol{u}(\xi,\, \eta) = \begin{Bmatrix} u_r(\xi,\, \eta) \\ u_z(\xi,\, \eta) \end{Bmatrix} = \sum_{I=1}^{4} H_I(\xi,\, \eta)\, \boldsymbol{u}_I, \tag{4}$$

where the index I denotes the node number of the element and

$$H_I(\xi,\, \eta) = \frac{1}{4}(1+\xi_I\xi)(1+\eta_I\eta). \tag{5}$$

In order to alleviate the locking effect, the strain components are enhanced with so-called incompatible modes [25] as

$$\boldsymbol{\varepsilon}\left(\xi,\,\eta\right)=\boldsymbol{B}\left(\xi,\,\eta\right)\boldsymbol{u}_I+\boldsymbol{M}\boldsymbol{\alpha}, \tag{6}$$

where $\boldsymbol{B}$ is the so-called strain-displacement matrix resulting from the above kinematic expressions. The enhanced strain components are determined as $\boldsymbol{M}\boldsymbol{\alpha}$, where

$$\boldsymbol{M}=\begin{bmatrix} \xi-\bar{\xi} & 0 & 0 & 0 & 0 \\ 0 & \eta-\bar{\eta} & 0 & 0 & 0 \\ 0 & 0 & \xi-\bar{\xi} & \eta-\bar{\eta} & 0 \\ 0 & 0 & 0 & 0 & \xi\eta\dfrac{J\left(\xi,\,\eta\right)}{r\left(\xi,\,\eta\right)}J\left(0\right) \end{bmatrix} \tag{7}$$

The element averaged coordinates are denoted with a bar $\left(\bar{\xi},\,\bar{\eta}\right)$, and J is the determinant of the Jacobian matrix

$$\boldsymbol{J}=\begin{bmatrix} \dfrac{\partial r}{\partial\xi} & \dfrac{\partial z}{\partial\xi} \\ \dfrac{\partial r}{\partial\eta} & \dfrac{\partial z}{\partial\eta} \end{bmatrix} \tag{8}$$

THe additional enhanced strain components should not generate additional internal work. Therefore

$$\int_V\boldsymbol{\sigma}^T\boldsymbol{M}\boldsymbol{\alpha}\,dV=0 \tag{9}$$

It can be shown that the above interpolation matrix $\boldsymbol{M}$ fulfils this constraint.
The internal virtual work δW^i can be expressed in terms of the stiffness matrix $\boldsymbol{K}^\alpha$ as

$$\delta W^i=\int_V\delta\boldsymbol{\sigma}\cdot\boldsymbol{\varepsilon}\,dV=\delta\begin{Bmatrix}\boldsymbol{u}\\ \boldsymbol{\alpha}\end{Bmatrix}^T\begin{bmatrix}\boldsymbol{K}^e & \boldsymbol{L}^T\\ \boldsymbol{L} & \boldsymbol{Q}\end{bmatrix}\begin{Bmatrix}\boldsymbol{u}\\ \boldsymbol{\alpha}\end{Bmatrix}=\delta\boldsymbol{q}^T\boldsymbol{K}^\alpha\boldsymbol{q} \tag{10}$$

where

$$\boldsymbol{K}^e=\int_V\boldsymbol{B}^T\boldsymbol{D}\boldsymbol{B}\,dV,\;\boldsymbol{L}=\int_V\boldsymbol{M}^T\boldsymbol{D}\boldsymbol{B}\,dV,\;\boldsymbol{Q}=\int_V\boldsymbol{M}^T\boldsymbol{M}\boldsymbol{B}\,dV \tag{11}$$

The coefficient vector $\boldsymbol{\alpha}$ is constant within one finite element and discontinuous across the element border. Therefore these degrees of freedom can be statically condensated on element level, and the element stiffness matrix $\boldsymbol{K}$ becomes

$$\boldsymbol{K}=\boldsymbol{K}^e-\boldsymbol{L}^T\boldsymbol{Q}^{-1}\boldsymbol{L} \tag{12}$$

Due to the static condensation the above type of EAS finite elements (Enhanced Assumed Strain) is numerically very expensive in the assembling process. The advantage of these elements is that they lack any kind of locking. The cheapest of avoiding locking is by introducing mixed integration schemes, such as SRI (Selective Reduced Integration), which dictates that the shear terms in the internal virtual work are integrated with a reduced Gauss quadrature scheme. One of the disadvantages is that the finite element suffers from hourglassing caused by the incapability of capturing the strain energy in these so-called hourglassing deformation modes of the element. In the present code the EAS formulation does not produce unacceptably large CPU times, because:

- The matrices are only assembled once, and

- The assemblage is optimised by constructing $\boldsymbol{K}$ with an analytical expression
- This is possible, since all finite elements are rectangularly shaped
- The finite elements in one column of one layer are described by the same stiffness matrix

3.1.2 Axisymmetric mass matrix

The construction of the mass matrix $\boldsymbol{M}$ is more straightforward than the construction of the stiffness matrix. The mass matrix should represent the kinetic virtual work δW^k as

$$\delta W^k = \int_V \rho \delta \boldsymbol{u} \cdot \ddot{\boldsymbol{u}} \, dV = \delta \boldsymbol{u}^T \boldsymbol{M} \ddot{\boldsymbol{u}} \tag{13}$$

With the interpolation function of Eq. 5 the construction of the mass matrix $\boldsymbol{M}$ is fully defined. Usually a full integration scheme iwth four integration points n at ξ_n, $\eta_n = \pm\sqrt{1/3}$ is deployed. However, when the integration points are located at the nodal positions ξ_n, $\eta_n = \pm 1$ then a diagonalized or lumped mass matrix is generated. This matrix could alternatively be constructed by summing all columns j in each row i of the original (or consistent) mass matrix and by replacing the respective diagonal component with the result

$$M_{lumped,ij} = \delta_{ij} \sum_{j=1}^{all} M_{consistent,ij} \tag{14}$$

The application of the lumped mass matrix in a explicit central difference method leads to a very efficient implementation.

3.1.3 Axisymmetric damping matrix

In dynamic analysis of FEM models, the treatment of damping has to be considered carefully. The standard case of viscous damping (i.e., velocity proportional damping) leads to frequency dependent behaviour. A common methodology is to apply Rayleigh damping, by constructing the damping matrix $\boldsymbol{C}$ from a mass proportional part and a stiffness proportional part

$$\boldsymbol{C} = \alpha \boldsymbol{M} + \beta \boldsymbol{K} \tag{15}$$

The resulting damping ratio ζ then becomes

$$\zeta = \frac{\alpha}{2\omega} + \frac{\beta\omega}{2} \tag{16}$$

which is dependent on the circular frequency ω. Alternatively, the Caughey damping could be deployed as viscous damping model [1]. However, this leads to a fully occupied damping matrix (a lot of RAM is needed), and it requires the determination of all eigenmodes (a lot of CPU time is needed at assemblage).
As the input data of the soil properties assumes frequency independent damping, hysteretic damping seems to be the appropriate choice here. Hysteretic damping is described by assuming a complex Young's modulus leading to a certain amount of phase difference between the displacements and the resulting elastic reaction forces

$$E^{tot} = E\,(1 + i\eta) \tag{17}$$

For relatively small amount of damping (up to 15 % damping ratio) the hysteretic damping η is related to the viscous damping ratio ζ as

$$\eta = 2\zeta \tag{18}$$

to simulate a comparable amount of energy loss per cycle. The hysteretic damping matrix $\boldsymbol{C}_{hyst}$ can now easily be constructed as

$$\boldsymbol{C}_{hyst} = \eta \boldsymbol{K} \tag{19}$$

In the frequency domain analysis, modelling hysteric damping is straightforward. In the time domain analysis special attention has to be given to describing the complex part of the reaction forces. The hysteretic damping force $\boldsymbol{F}^d$ is computed as

$$\boldsymbol{F}^d = i\boldsymbol{C}_{hyst}\boldsymbol{u} \tag{20}$$

The hysteretic damping matrix is thus multiplied with a vector $i\boldsymbol{u}$ which is in phase with the velocity vector (i.e., in the same multi-dimensional direction), but which has the same length as the displacement vector. Therefore the hysteretic damping forces can be obtained as [19]

$$\boldsymbol{F}^d = \boldsymbol{C}_{hyst}\frac{\|\boldsymbol{u}\|}{\|\dot{\boldsymbol{u}}\|}\dot{\boldsymbol{u}} \tag{21}$$

3.1.4 Infinity boundary elements

In order to simulate infinite boundaries are characterised by the fact that elastic waves (primary and secondary) move from the interior to the exterior only. This can be simulated by absorbing the incoming wave energy. For the primary waves this is best approximated by imposing a normal stress σ as [17]

$$\sigma = \rho\, V_P \dot{u}_n \tag{22}$$

and for the secondary waves this is best approximated by imposing a shear stress τ as

$$\tau = \rho\, V_S \dot{u}_t \tag{23}$$

Here V_P and V_S are the wave velocities of the primary and the secondary waves [5]

$$V_P = \sqrt{\frac{E\,(1-\nu)}{(1+\nu)\,(1-2\nu)\,\rho}},\; V_S = \sqrt{\frac{E}{2\,(1+\nu)\,\rho}} \tag{24}$$

and $\dot{u}_n$ and $\dot{u}_t$ are the velocity components normal and tangential to the infinite boundary, respectively. The damping force $\boldsymbol{F}^c$ is expressed in terms of an infinite damping matrix $\boldsymbol{C}^\infty$ as

$$\boldsymbol{F}^c = \boldsymbol{C}_n^\infty \dot{\boldsymbol{u}}_n + \boldsymbol{C}_t^\infty \dot{\boldsymbol{u}}_t = \boldsymbol{C}^\infty \dot{\boldsymbol{u}} \tag{25}$$

where the force vector is constructed as the surface integral of the stresses and therefore

$$\boldsymbol{C}_n^\infty = \int_A^\infty \rho\, V_P\, dA,\; \boldsymbol{C}_t^\infty = \int_A^\infty \rho\, V_S\, dA \tag{26}$$

The integrals are numerically evaluated by Gauss integration over two integration points. The final result is expressed and implemented as an analytical/parametric equation.
The disadvantage of solely applying dashpots at the infinity boundaries, is that the model can

potentially become statically underdetermined. Therefore it is suggested that an additional stiffness needs to be introduced at these boundaries. It is found that the following additional stresses have minimal contribution to wave reflection [12]

$$\sigma = \frac{\rho V_P^2}{2R} u_n, \ \tau = \frac{\rho V_S^2}{2R} u_r \tag{27}$$

where R denotes the distance to the source of excitation. The elastic force $\boldsymbol{F}^k$ is expressed in terms of an infinite stiffness matrix $\boldsymbol{K}^\infty$ as

$$\boldsymbol{F}^k = \boldsymbol{K}_n^\infty \boldsymbol{u}_n + \boldsymbol{K}_t^\infty \boldsymbol{u}_t = \boldsymbol{K}^\infty \boldsymbol{u} \tag{28}$$

where the force is constructed as the surface integral of the stresses and therefore

$$\boldsymbol{K}_n^\infty = \int_A^\infty \frac{\rho V_P^2}{2R} \, dA, \ \boldsymbol{K}_t^\infty = \int_A^\infty \frac{\rho V_S^2}{2R} \, dA \tag{29}$$

3.2 Solving the system of equations

The equation to be solved reads

$$\boldsymbol{M}\ddot{\boldsymbol{u}}\left(t\right) + \boldsymbol{C}^\infty \dot{\boldsymbol{u}}\left(t\right) + \left[\boldsymbol{K} + \boldsymbol{K}^\infty + i\boldsymbol{C}_{hyst}\right] \boldsymbol{u}\left(t\right) = \boldsymbol{F}^{ext}\left(t\right) \tag{30}$$

where $\boldsymbol{F}^{ext}\left(t\right)$ denotes the time dependent externally applied force vector. This equation is solved either in the frequency domain as a harmonic response analysis, or in explicitly in the time domain by the central difference method.
At the basis of the harmonic response analysis lies the decomposition of the linear response into multiple and independent exp-functions of circular frequency ω

$$\boldsymbol{u}\left(\omega\right) = \hat{\boldsymbol{u}} \exp i\omega t, \ \boldsymbol{F}^{ext}\left(\omega\right) = \hat{F}\hat{\boldsymbol{F}} \exp i\omega t \tag{31}$$

where $\hat{\boldsymbol{u}}$ is the vector of amplitudes, $\bar{\boldsymbol{F}}$ is the normalised excitation vector, $\hat{F}$ is the force amplitude and i is the complex unit. With this decomposition the equation to be solved becomes

$$\left[-\omega^2 \boldsymbol{M} + i\omega \boldsymbol{D}^\infty + \boldsymbol{K} + \boldsymbol{K}^\infty + i\boldsymbol{C}^\infty\right] \hat{\boldsymbol{u}} = \hat{F}\bar{\boldsymbol{F}} \tag{32}$$

Introducing the system matrix $\boldsymbol{A}$ representing the bracket terms on the left-hand side, it follows

$$\frac{\hat{\boldsymbol{u}}\left(\omega\right)}{\hat{F}\left(\omega\right)} = \boldsymbol{A}^{-1}\bar{\boldsymbol{F}} \tag{33}$$

The code is developed in Python and the Pardiso solver is used to solve the equation directly. The Python interface to Pardiso (i.e., pyPardiso) only support real matrices and therefore the solution vector $\hat{\boldsymbol{u}}$, the complex system matrix $\boldsymbol{A}$ and the external force vector are extended as

$$\hat{\boldsymbol{u}}^* = \begin{Bmatrix} \hat{\boldsymbol{u}}_{real} \\ \hat{\boldsymbol{u}}_{imag} \end{Bmatrix}, \ \boldsymbol{A}^* = \begin{bmatrix} \boldsymbol{A}_{real} & -\boldsymbol{A}_{imag} \\ \boldsymbol{A}_{imag} & \boldsymbol{A}_{real} \end{bmatrix}, \ \bar{\boldsymbol{F}}^* = \begin{Bmatrix} \bar{\boldsymbol{F}}_{real} \\ \bar{\boldsymbol{F}}_{imag} \end{Bmatrix} \tag{34}$$

Solving the system of equations explicitly with the central differences method is based on the Taylor series approximation of the first and the second derivative

$$\dot{\boldsymbol{u}}^{n+\frac{1}{2}} = \frac{\partial \boldsymbol{u}^{n+\frac{1}{2}}}{\partial t} = \frac{\boldsymbol{u}^{n+1} - \boldsymbol{u}^n}{\Delta t}, \ \ddot{\boldsymbol{u}}^n = \frac{\partial^2 \boldsymbol{u}^n}{\partial t^2} = \frac{\boldsymbol{u}^{n+1} - 2\boldsymbol{u}^n + \boldsymbol{u}^{n-1}}{\Delta t^2} \tag{35}$$

where n is an index to a position in time, and Δt is the time increment with which the differential equation of motion is integrated through time.
With the aforementioned approximation of the hysteretic damping, the system of equations to be solved becomes

$$\ddot{\boldsymbol{u}}^n = \boldsymbol{M}^{-1}\left(\boldsymbol{F}^{ext,n} - \left(\boldsymbol{K} + \boldsymbol{K}^{\infty}\right)\boldsymbol{u}^n - \boldsymbol{C}_{hyst}\frac{\|\boldsymbol{u}\|}{\|\dot{\boldsymbol{u}}\|}\dot{\boldsymbol{u}}^{n-\frac{1}{2}} - \boldsymbol{C}^{\infty}\dot{\boldsymbol{u}}^{n-\frac{1}{2}}\right) \tag{36}$$

In linear systems the central difference scheme becomes unconditionally stable when

$$\Delta t \leq \frac{2}{\omega_{n,max}} \tag{37}$$

where $\omega_{n,max}$ denotes the maximum undamped eigenfrequency of the system. However, due to the approximation of the hysteretic damping, this conditions has proven not to be strict enough. In general the above maximum time increment has to be reduced by a factor of 0.6.

3.3 Verification

One of the undertaken verification cases consists of the calculation of the compliance of a rigid disk with a radius of 1 m on a 20 m thick homogeneous layer of soil with non-reflecting boundary conditions at $r \to \infty$, see Figure 5.

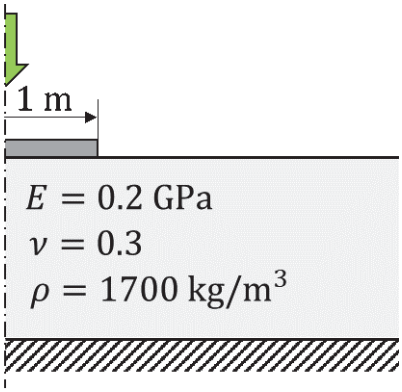

Figure 5: Illustration of the verification case

The soil is excited dynamically by applying a vertical force on the circular rigid disk. A damping of 5 % is assumed and the maximum frequency is set to 100 Hz. The infinitely stiff disk is modelled by coupling the underlying soil nodes in vertical direction to one degree of freedom.
The compliance experienced by the disk is computed with both the central difference method as well as the harmonic response analysis. The results are compared with those obtained by the semi-analytical Wolf model [29]. It is shown (see Figure 6) that the harmonic response analysis agrees well with the results obtained with the Wolf model. In amplitude the central difference method agrees well with the Wolf model. The agreement is less when comparing the phase. It should be noted though that only the amplitude results are relevant for the calculations of the train induced vibrations.

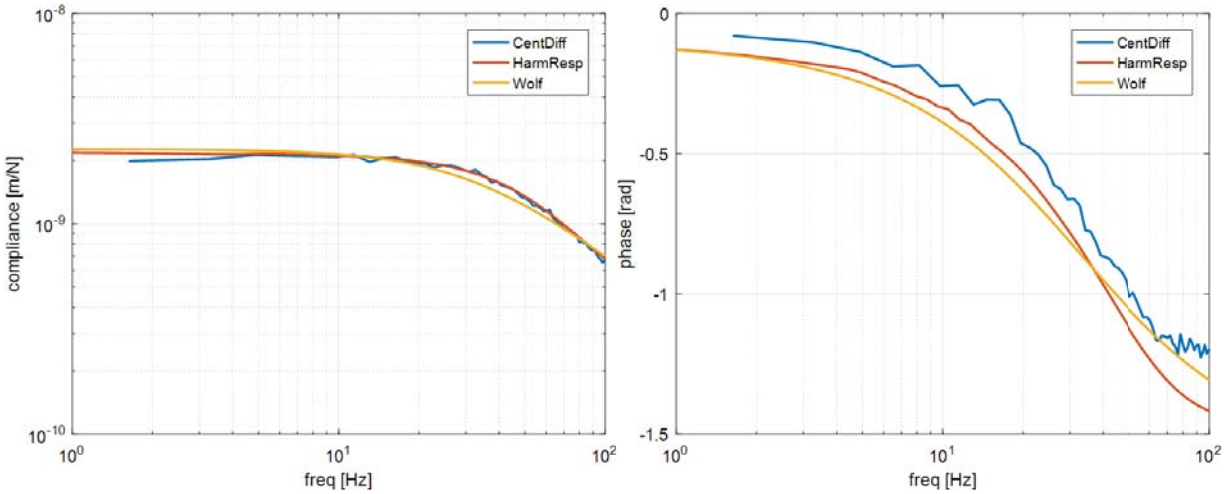

Figure 6: Results of the verification case

4 CASE STUDY

In order to illustrate the proposed methodology for subsoil modelling and FEA admittance calculation, the model developed for OURS has been applied to two locations in the Netherlands: Delft and Tilburg.

Figure 7 shows the subsoil scenario schematisation for the two locations. It follows that the subsoil schematisation in Delft exhibits more variable than the subsoil schematisation in Tilburg. Although for both locations 4 scenarios exist, the variability in the build-up layer formation is bigger in Delft. For Tilburg the subsoil consists of two soil types, sand and sand mixtures, while in Delft it consists of at least six different soil types, ranging from sand to clay layers.

The location in Tilburg is dominated by two scenarios (scenario 3 and 4) that together form 96 % probability of occurrence. The location in Delft is dominated by three scenarios (scenarios 2, 3 and 4 form 99 % probability of occurrence).

The subsoil parametrisation is illustrated in Figure 8 for both locations. Although all geomechanical parameters have a mean and standard deviation, the figure only shows the mean value, for the sake of readability. Similarly to the layering schematisation, the location in Delft exhibits more variation in the geomechanical parameters than the location in Tilburg.

Figure 10 shows the vertical and radial admittance results for both locations at three different distances from the source: 10, 50 and 100m. The results for all the different scenarios are represented as well as the results for the weighted mean admittance. As it would be expected, the admittance is found to reduce with the distance from the source.

The results are also different for the two locations. For Delft it is found that the admittance is constant for the point located at 10m from the source, but for the points further away from the source (50 and 100m) the admittance exhibits a linear reduction with the frequency, i.e. the admittance attenuates linearly with the frequency. This behaviour is less visible in Tilburg. This is related with the presence of soft soil layers in Delft, that cause an higher attenuation of the high frequencies.

Figure 10 shows the mean vertical and radial admittance obtained for the two location. It is clear that the admittance attenuates with the distance, in the entire frequency range.

5 CONCLUSIONS

This paper presented the methodology developed in OURS to model the subsoil and compute the admittance, between source and receiver.

The subsoil modelling is done by combining public datasets to provide a semi-stochastic subsoil schematisation and parametrisation. The admittance is computed by means of a FEA kernel that has been develop to optimise calculation speed.

The application of the methodology of OURS has been illustrated in two locations (Delft and Tilburg).

Keywords: Ballasted track, Heterogeneous medium, Periodic structures, Model reduction.

Abstract. *In most numerical models of railway tracks, the ballast (i.e. the granular layer in which the sleepers lie) is modeled by a homogeneous medium. This assumption allows an easier implementation within a Finite Element (FE) code, yet may not be justified. In fact, considering the results of in-situ measurements, the global response of the track varies significantly before and after ballast tamping, even at low frequencies (< 100 Hz). After having analyzed these experiments, this paper proposes to include in a track model a heterogeneous medium for the ballast, fully compatible with the FE framework. Samples of random fields (previously fitted to Discrete Elements simulations) are taken for the mechanical properties of the ballast layer. Because the heterogeneous properties require a refined mesh, a model reduction strategy is then proposed to ensure a reasonable computation cost: a learning procedure to construct a reduced basis from several heterogeneous samples. Finally, time-based computations on the track model are performed. It is shown that the heterogeneity does not significantly alter the global response of the track below 30 Hz, yet generates local modifications which are relevant to characterize for the track settlement analysis.*

1 INTRODUCTION

The majority of railway tracks are nowadays ballasted, i.e. covered by a layer of a granular material (typically 0.3 m thick) composed of coarse crushed stone of calibrated size [1]. The main roles of the ballast layer are to transfer the dynamic load caused by the train to the soil and provide elasticity and vibration damping, while facilitating maintenance and water draining. Like other granular materials, ballast mechanical behaviour is not fully understood yet and subject of much research [2–4].

Characterizing the dynamic behavior of the ballast is an industrial issue for the conception and the maintenance of railway tracks. The experimental approaches are mainly a triaxial test on a ballast sample [5] or a full-scale model in laboratory [6, 7]. However, these experiments have a limited range of study due to the boundary conditions of the model and are costly to set up. Thus, numerical studies of railway ballast are also frequent. An extensive approach consists in modeling every ballast grain and the interactions between them (contact, friction, impact...). This method is known as Discrete Element Method (DEM), and is mainly implemented in NSCD (Non-Smooth Contact Dynamics) codes [8–10] or in Molecular Dynamics [11]. However, this granular approach requires huge computational power (a week per computation for [8]), is limited to low frequencies (< 40 Hz) and to a small sample of ballast, and is not easily coupled with soil Finite Element (FE) models.

When a larger scale study is required and lower computational cost desired, continuous models of the railway track are prefered. The ballast layer is then considered as a homogeneous medium, and FE approches are considered [12–19]. These models are coupled with soil behaviour or even train dynamics. To reduce the computational cost, model reduction strategies are accessible, with a periodicity assumption along the track axis [12, 18, 19]. The ballast layer mechanical behavior is often considered linear elastic, yet a non-linear approach is used by Alves Costa et al. [15].

The objective of this paper is to determine the frequency range of influence of the heterogeneity of the ballast layer, neglected without proof in classical FE approaches. A heterogeneous track model has been developed by Abreu Corrêa and al. [20]. The idea of this model consists in mapping the ballast mechanical properties from a sample of 3D random fields. The result is a deterministic model where the mechanical properties at each integration point are different. In [20], the resolution is made by Spectral Element Method (SEM), which is well-suited for large-scale problems especially in seismic wave prediction [21]. The model has been compared successfully to an equivalent DEM model solved by NSCD. However, this approach has not been yet extensively studied in a full-scale track model, which is one purpose of this paper. Another issue of [20] is the high computational cost required.

The first section of this paper will motivate the study of heterogeneous ballast by presenting experimental results. The global responses of the track after ballast tamping, with and without dynamic stabilization, are compared. In a second section, the model from [20] is adapted to a piecewise periodic reduced FEM model, first developped by Arlaud et al. [18]. The influence of the heterogeneity can thus be studied with a much smaller computation cost. In a third part, hammer impact and pass-by of vehicles are simulated for the heterogeneous track model and compared to a homogeneous one.

2 OBSERVATION OF THE EFFECT OF BALLAST HETEROGENEITY

According to standard maintenance operations on French ballasted tracks, the ballast layer is mechanically packed under sleepers by a tamping machine and then stabilized by a dynamic stabilizer. To assess the efficiency of these operations, a track survey was carried out in Évres, Grand Est region, France, on the East-European High Speed Line (EE-HSL) linking Paris and Strasbourg. Two areas distant of 50m were surveyed before and after tamping. Only the second zone was stabilized.

A vertical accelerometer is placed at the end of a bi-block sleeper (blue dot on figure 1) and the rail is excited by an instrumented hammer (red star). The hammer and the accelerometer are synchronized, and the measurements are sampled at a sampling frequency of 16 kHz.

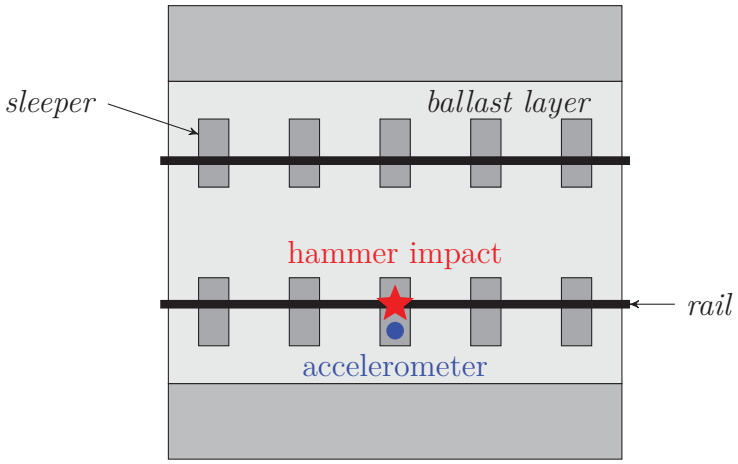

Figure 1: Scheme of the receptance test on a high-speed line.

20 hammer strokes were recorded and the *receptance* is post-processed, i.e. the transfer between the vertical displacement of the sensors $u_z(t)$ and the force exerted by the hammer $f(t)$:

$$R(\omega) = \frac{U_z(\omega)}{F(\omega)} \ . \tag{1}$$

The main interest of this survey is that all frequencies are excited at a similar level by the hammer. The 20 tests are highly repeatable, thus the mean value of these tests will be considered. The coherence between the signals of the sensor and the hammer was above 90% only above 20 Hz. As the focus of this study is only medium frequencies, the results are shown in figure 6 between 20 and 200 Hz.

Before ballast tamping (dotted line in figure 6), the receptances of the two zones have a similar shape with a very broad peak and a identically decreasing phase until 80 Hz, but a very different magnitude (around 60 %), even if the zones are as close as 50m. After ballast tamping, the magnitudes have similar levels, increased 5 times compared to magnitude before tamping. However, without dynamic stabilization (plain blue curve in figure 6), an additional peak appears at 80 Hz. These experiments show that the the ballast layer settlement can then have a high impact on the magnitude level.

These observations are a clear motivation to study the impact of the ballast heterogeneity (mean stiffness and variability), within a numerical model.

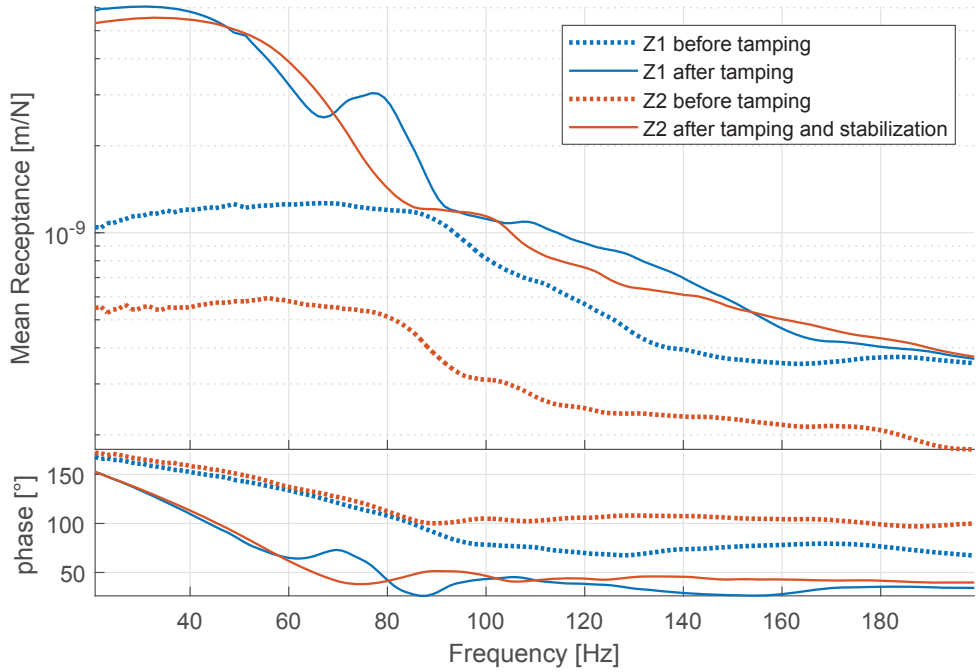

Figure 2: Receptance of the track on two zones (Z1 in blue and Z2 in orange) before (dotted lines) and after ballast tamping (plain lines). On Z1, only ballast tamping is done, on Z2, ballast tamping and dynamic stabilization.

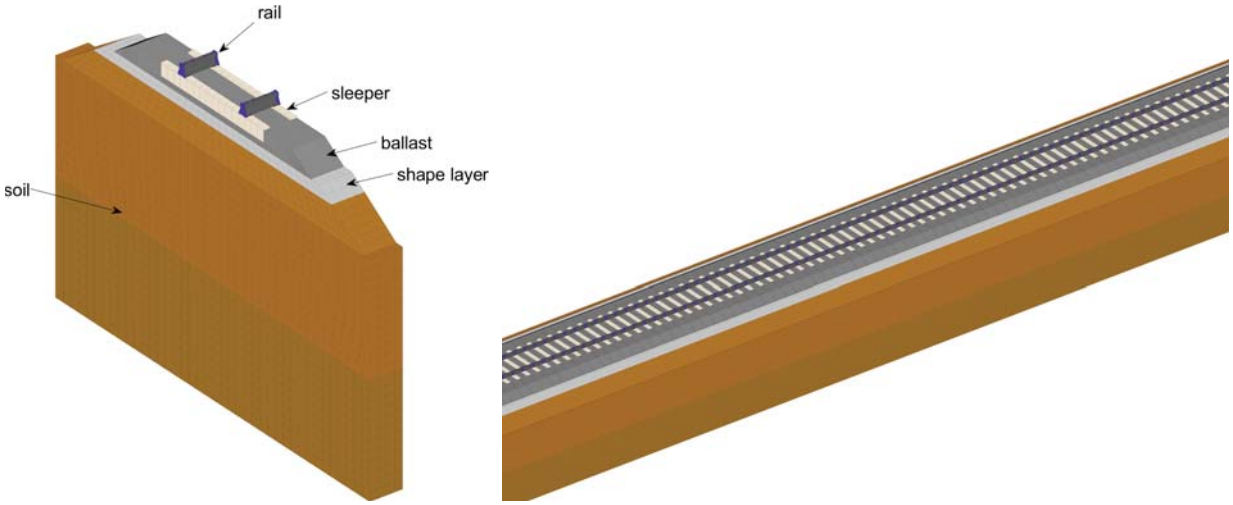
3 REDUCED TRACK MODEL WITH HETEROGENEOUS BALLAST

3.1 Meshing of the slice model

A geometrically periodic track model is considered, adapted from [18]. A reference cell Ω_0 of width $x_0 = 60$ cm, the distance between two sleepers as shown on figure 3, is meshed with hexahedral quadratic elements. The mesh size is defined to ensure 6 nodes per wavelength for the shortest shear wave propagating in the track.



(a) Reference cell. (b) Closeup to periodic track structure.

Figure 3: 3D view of the periodic track model.

To build a heterogeneous model for the ballast layer, the following procedure is used

1. 3D periodic random fields are generated for the density ρ, the bulk modulus $K = \frac{E}{3(1-2\nu)}$ and shear modulus $G = \frac{E}{2(1+\nu)}$ (where E and ν are respectively the Young modulus and Poisson ratio). The choice of these mechanical parameters ensures real-valued shear and pressure wave velocities. These fields are not correlated, and follow a log-normal distribution, ensuring positive values, with parameters taken from table 1. They are efficiently generated with a spectral method proposed by Shinozuka and Deodatis [22]. For example, the density random field $\rho[x]$ is calculated from

$$\rho[x] = \mathbb{E}_\rho(x) + 2\sum_{n=1}^{N_{\text{rand}}} \zeta_n \sqrt{\mathbb{S}_\rho(n\Delta k)\Delta k}\cos(n\Delta k x + \varphi_n), \tag{2}$$

where $\mathbb{E}_\rho$ and $\mathbb{S}_\rho$ are the expectation and autocorrelation of ρ, ζ_n standard normal fields, φ_n uniform fields on $[-\pi\ \pi]$ and Δk the step in wavenumber. The correlation model for each field between the 3 directions of space is chosen gaussian, only determined by a correlation length λ_{corr}, equal to 7 cm. These values are taken from [20], and were identified to a DEM simulation.

Property	**Mean value**	**Standard deviation**
Bulk modulus K	139 MPa	417 MPa
Shear modulus G	104 MPa	312 MPa
Density ρ	1700 kg/m^3	5100 kg/m^3

Table 1: Properties of the heterogeneous beam.

2. Samples of these random fields are generated. A 3D view of a sample of the density field in a block of size $0.25\times0.25\times0.6$ cm^3 is presented in figure 4. The isosurfaces are represented for 80% and 99% of the maximal density. This representation highlights harder points (in red) included in a softer medium (transparent). The periodicity of the field ensures the continuity of the mechanical properties by taking only $\Delta k = \frac{2\pi}{x_0}$ in equation (2).

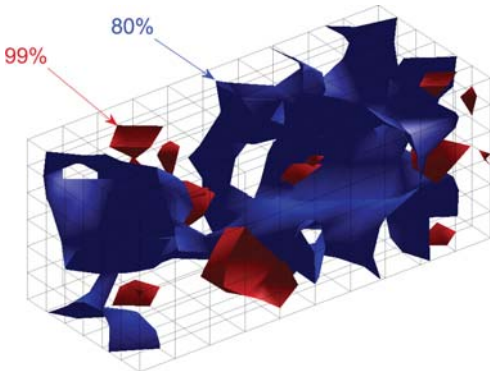


Figure 4: Sample of 3D random field for density. Isosurfaces for 80% and 99% of maximal density are plotted respectively in blue and red.

3. The values of the sample generated in a block bigger than the ballast layer are interpolated linearly at the integration points of the mesh. In order to keep a good representativeness, the mesh in the ballast layer is refined down to $\frac{\lambda_{\text{corr}}}{3}$. This refined

mesh is connected with the coarser mesh with Multiple Point Constraint (MPC): the refined surface of the ballast is forced to have the displacement of the surface below.

The pad between the sleeper and the rail is 9 mm thick, and has a dynamic stiffness of 180 kN/mm. As a volumic element, it is modeled with an anistropic behavior, with an equivalent stiffness 100 times higher in the vertical direction and a damping ratio of 20%.

Finally, every other part of the track model has linear elastic behavior shown in table 2. For the reduction phase, an hysteretic damping model is used by taking a complex modulus $E^* = E\,(1 + i\eta)$. For time simulations, an equivalent viscous model is built. The natural soil has been chosen with an artificially low density to avoid unwanted soil modes. A clear perspective is to include PML elements to model properly the radiation of waves in the soil.

Part	E [MPa]	ν [-]	G [MPa]	ρ [kg/m^3]	η [%]
Under ballast layer	360	0.35	133	1700	7
Shape layer	544	0.35	201	2000	1
Embankment	1290	0.3	496	1990	1
Natural soil	67	0.3	26	1.8	10
Sleeper	$3 \cdot 10^4$	0.25	$1.2 \cdot 10^4$	2400	0
Rail	$2.1 \cdot 10^5$	0.285	$8.2 \cdot 10^4$	7800	0

Table 2: Properties of the homogeneous track components (in order: Young modulus, Poisson ratio, shear modulus, density, damping ratio).

3.2 Building of reduced heterogeneous slice models

The implementation and validation of the reduced methodology used in this paper is fully detailed in [23]. A summary is presented here for reference.

At the end of the meshing phase, the matrix problem in the reference cell Ω can be expressed after assembly as

$$\left(-\omega^2\,[M] + [K]\right)\{q(\omega)\} = [b]\,\{f(\omega)\}\ , \tag{3}$$

where $[M]$ is the mass matrix, $[K]$ the stiffness matrix (taken with complex values $E(1+i\eta)$ to include damping behavior), $\{q\}$ the displacement at the Degrees of Freedom (DOF), and $[b]\,\{f\}$ the external forces applied to the track (contact force of train wheels for example).

When expressing the problem in the wavenumber domain at a fixed wavenumber $\kappa_0 = \frac{x_0}{\lambda_0}$ (where λ_0 is the wavelength), the periodicity condition between Ω_0 and its adjacent cell can be expressed as

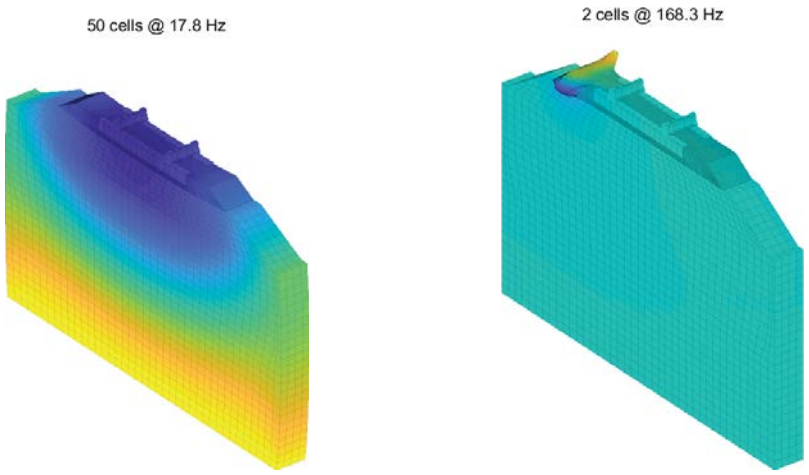
$$[c(\kappa_0)] \begin{Bmatrix} \mathrm{Re}\left(Q(\kappa_0,\omega)\right) \\ \mathrm{Im}\left(Q(\kappa_0,\omega)\right) \end{Bmatrix} = \{0\}\ , \tag{4}$$

where matrix $[c]$ is independent of frequency. Then the constrained problem can be written as

$$[T_c]^T \begin{bmatrix} Z & 0 \\ 0 & Z \end{bmatrix} [T_c] \begin{Bmatrix} \mathrm{Re}\left(Q_c\right) \\ \mathrm{Im}\left(Q_c\right) \end{Bmatrix} = [T_c]^T \begin{bmatrix} b & 0 \\ 0 & b \end{bmatrix} \begin{Bmatrix} \mathrm{Re}\left(F\right) \\ \mathrm{Im}\left(F\right) \end{Bmatrix}\ , \tag{5}$$

where $[T_c]$ is a basis of the kernel of $[c]$, and $\{Q_c\}$ the reduced coordinated such as $\{Q\} = [T_c]\{Q_c\}$. The equation (5) can be solved by a classical modal approximation [24], after having computed the modes $\left(\{\phi_j(\kappa_0)\}, \omega_j(\kappa_0)\right)_j$ of the structure Ω_0 for each κ_0.

The key proposition of the reduction procedure is to compute the modes only for few κ ($\kappa = \frac{1}{2}, \frac{1}{5}$ and $\frac{1}{50}$ cell^{-1} in this paper), considering that the modes vary slightly as a function of κ. The main contributing modes for these 3 values of κ are selected with a Singular Value Decomposition (SVD) procedure. Adding the static contribution, and after some manipulations to ensure the periodicity of the selected modes, the reduced basis for the slice (noted $[T]$) is constructed. As examples, two chosen modes are presented in figure 5: a global bending mode (a) for $\kappa = \frac{1}{50}$ cell^{-1} and $f = 17.8$ Hz, and a local ballast shoulder mode (b) for $\kappa = \frac{1}{2}$ cell^{-1} and $f = 168.3$ Hz. The name '*local*' denotes that only a small portion of the track is moving.



(a) Global track bending mode. (b) Local ballast shoulder mode.

Figure 5: Examples of slice modes selected during the learning phase. Blue corresponds to minimal value of vertical displacement, yellow to the maximal value.

This procedure is performed for three different samples of the ballast layer and the final reduced basis is the result of the SVD for all samples. Then, problem (5) can be expressed and solved in reduced coordinates (208 DOF per slice) instead of physical coordinates (464,919 DOF), thus reducing the computational cost by a factor of more than 2000.

3.3 Assembly of the track from slice models

At this step, heterogeneous slice models have been constructed. However, if one of this slice model is repeated to assemble the track model, the track will remain periodic, which is not the case in reality, with a full random ballast layer.

To avoid this issue, the second key proposition is to consider for each repetition of the slice mesh a random combination of the heterogeneous models. First, reduced matrices $[M_a]$ and $[K_a]$ are assembled by selecting only elements that have homogeneous properties (i.e. the whole track except the ballast layer). These matrices are independent of the heterogeneous sample. Similarly, reduced matrices $[M_{b,j}]$ and $[K_{b,j}]$ are assembled from elements with heterogeneous properties, for each sample j. To obtain the reduced matrices

$[M_n]$ and $[K_n]$ of the n-th slice of the track model, a random combination of coefficient $\left(\alpha_j^n\right)_j$ such as $\sum_j \alpha_j^n = 1$ is sampled with a uniform law on [0 1]

$$[M_n] = [M_a] + \sum_j \alpha_j^n \, [M_{b,j}] \ , \qquad [K_n] = [K_a] + \sum_j \alpha_j^n \, [K_{b,j}] \ . \tag{6}$$

With this procedure, each slice of the assembled track model is different, though taken from the same reduced basis. The numerical gain is even more dramatic between a full 3D track model of 100 slices (more than 40 millions of DOF), and the reduced model (12,880 DOF), i.e. a reduction of a factor more than 3000.

Moreover, to avoid reflection of waves at the end of the track model, the 3 first and 3 last slices are modified to include a damping gradient. If α is the desired damping (here $\alpha = 0.1$), the real-valued part of the stiffness matrix $[K_j]$ of the j-th slice of the 3 edge slices is substituted by the damping matrix $\mathrm{i}\omega\frac{j\alpha}{3}\,[K_j]$ ($j = 3$ corresponding to the first or last slice of the track). The mass matrix $[M_j]$ is untouched.

4 NUMERICAL SIMULATION RESULTS

4.1 Simulation of hammer impact on a track

The first study case is a simulation of the impact experiment presented in section 2. A track of 60 m (i.e. 100 slices) is modeled with the procedure described in section 3. Following the setup in figure 1, an impact is applied on the exterior rail in the middle of the model (i.e. 30 m from the edges or in the 50th slice) and the displacement is measured on the sleeper. The impact is modeled by a Ricker impulse of time 10 ms, with a weight of 10 kg. The temporal integration is done by a Newmark implicit scheme with a time step of $\delta t = 1$ ms and a simulation time of $t_f = 0.8$ s. The receptance (defined in equation (1)) is computed and shown in figure 6. The heterogeneous track model is compared for reference to a homogeneous model, constructed from the same mesh and reduction procedure with the mean values for ballast properties (see figure 1).

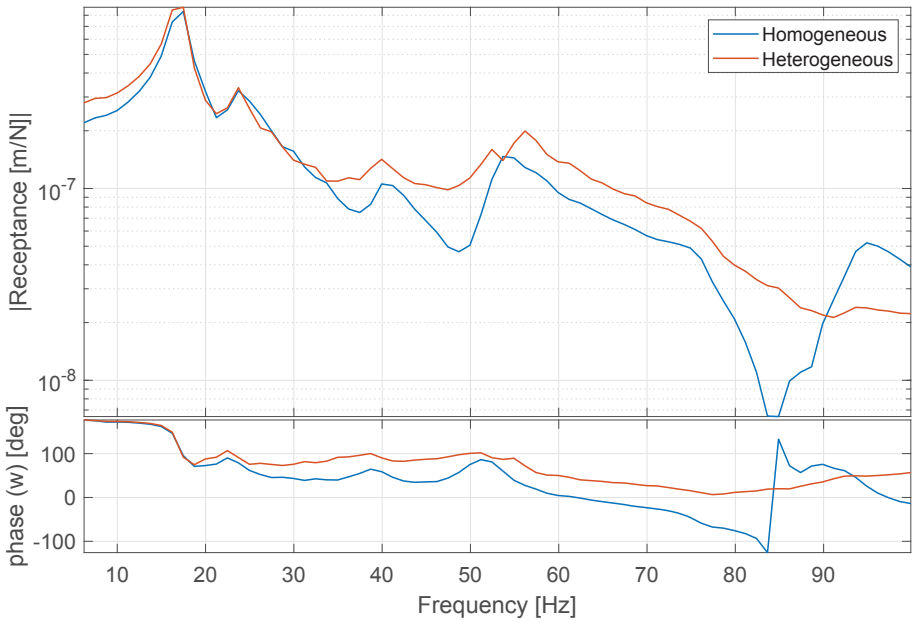


Figure 6: Computed receptance of the track for a heterogeneous model (plain orange curve), and for a homogeneous model (dotted blue curve).

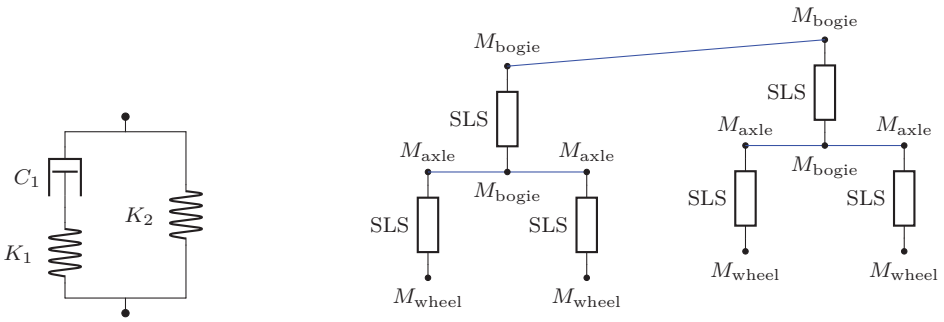
It can be seen that the receptance is very similar at low frequencies (until 25 Hz), especially the phase. The static level (around 0 Hz) is increased by 30%, i.e. 30% softer, which can be explained by a local difference in properties of the ballast layer under the considered sleeper of the heterogeneous model. At higher frequencies (> 25 Hz), the difference is more noticeable. In particular, the peak at 55 Hz is split into two for the heterogeneous model, and the anti-resonance at 83 Hz is shifted to higher frequencies.

This first simulation shows that the difference generated by the heterogeneity of the ballast layer can be non-negligible for higher frequencies than 30 Hz. An immediate continuation of this work is to analyze the discrepancies between impacts at different position in the same track model, and between several track models constructed from different random samples.

4.2 Simulation of bogie pass-by

Another simulation of interest for railway engineering is the pass-by of a vehicle on the track. As a first approach, the pass-by of a single bogie is considered. The bogie is modeled by a assembly of Standard Linear Solid (SLS) models (composed of two springs $K_1 = K_2 = 1.226 \cdot 10^6$ N/m and a damper $C_1 = 10^3$ Ns/m) and beams (represented in blue in figure 7) which have the properties of steel (as the rail in table 2). The masses for the wheels are $M_{\text{wheel}} = 595.5$ kg, for the axles $M_{\text{axle}} = 1024$ kg, and for the bogie $M_{\text{bogie}} = 6780$ kg. These values are representative of a French high speed train. The contact on the rail between the vehicle model and the track model is performed with a functional gap force representation.



(a) SLS (Standard linear solid model). (b) Scheme of the bogie model (beams in blue).

Figure 7: Scheme of the vehicle used in the simulation.

In the simulation (at a time step of $\delta t = 0.1$ ms), the bogie passes by at $v_0 = 80$ km/h on a 60 m track (i.e. 100 slices) with heterogeneous ballast. The displacement of the 5 middle sleepers (48th to 52th slices) is measured and plotted in figure 8 for the heterogeneous and homogeneous track. The 5 curves are superimposed to show dispersion, with a rescaled time axis $\left\{t_j^*\right\} = \{t\} + \frac{jx_0}{v_0}$.

The displacement for the heterogeneous model is lower than for the homogeneous model, and the spread is bit wider. This means that this zone of the heterogeneous ballast is globally stiffer than the homogeneous properties. This seems to be contradictory to the result for the impact simulation (see figure 6), where it is softer. However, the excitation is very different between both simulations: for the impact, all frequencies are equivalently excited on a small portion of ballast below the concerned sleeper, and

for the bogie pass-by, the excitation is dominated by low frequencies and a larger portion of ballast (around 5 sleepers) are excited. It is possible that the mean stiffness of the ballast layer excited by the impact is lower than the mean properties, but the mean stiffness of the ballast layer excited by the bogie pass-by is higher. This is a first effect of heterogeneity, which would not be represented by a fully homogeneous track model.

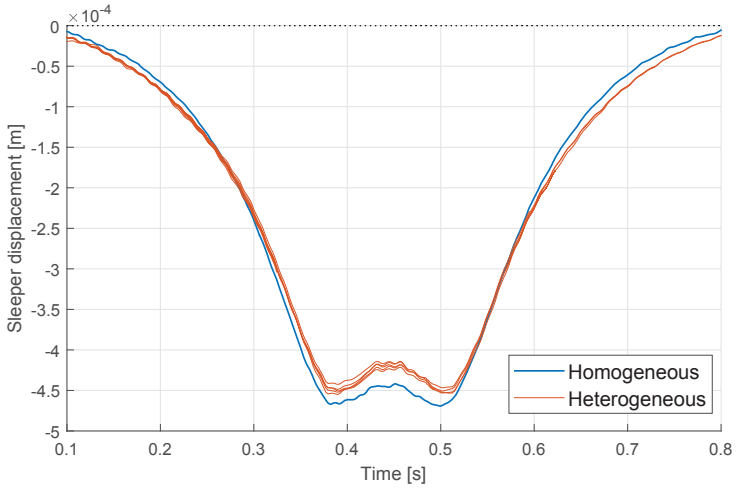


Figure 8: Displacement on 5 consecutive sleepers for a homogeneous (in blue) and heterogeneous track model (in orange), with a rescaled time axis.

The second noticeable effect is the dispersion of the displacement at a pass-by. For the homogeneous model (blue curve in figure 8), the displacement curves on 5 consecutive sleepers are near identical (0.17% of standard deviation from the mean value). This observation validates that the bogie simulation is at an established regime. For the heterogeneous model (orange curve), the displacement curves have a 16 times higher dispersion (2.8%), which is visible by the spread of the curves at the minimum values. This second effect is explained by the local discrepancies of ballast properties, and is also not captured by a homogeneous track model.

5 CONCLUSION

In this paper, the construction of a heterogeneous track model has been presented. The ballast layer is modeled by a heterogeneous, continuous medium whose mechanical properties are taken randomly. A reduced basis for the slice models is constructed from modes computed at few wavenumbers. The slices are then combined randomly to obtain a track model where the ballast layer has lost periodicity. Two type of simulations have been introduced: a hammer impact which excites the track at all frequencies and thus gives an estimation of the critical frequencies, and a vehicle pass-by which is the design case for railway engineering. These first simulations highlight the dispersion added by the heterogeneity, which cannot be obtained from a homogeneous model.

A first clear perspective is to better characterize this dispersion by considering several randomly generated tracks, simulating impacts at different positions along the track, and passages at different speeds. A second development is to add absorbing boundaries (PML) to the soil edges to take into account the radiation in our model. In particular, the remaining effect of heterogeneity while taking into account the radiative behavior of the soil should be checked.

Abstract. *This paper presents the experimental and numerical evaluation of the barrier's efficiency to mitigate vibration induced by railway traffic. A full-scale in situ experimental setup in France for trains passages on a commercial track is presented. The performance to mitigate vibration of both open and in-filled trench with different materials for different size of trenches is investigated. A numerical model is also introduced in order to understand the phenomena involved and to enable improvements to the design of the barriers to be proposed. A moving load representing a train pass-by is considered. Under the assumptions of linearity and periodicity the response induced by a train pass-by can be reconstructed from the response of a single bogie on a single sleeper.*

1 INTRODUCTION

Railway traffic induces vibrations that can be detrimental to industrial activities and cause annoyance to people in the neighboring buildings. One method to mitigate these waves is to use open trenches or soil barriers (filled trenches). Main conclusions of previous studies about trenches and fill materials of different types highlight that open trenches isolate better than barriers [4] and that trench depth is the main controlling parameter of efficiency [2]. However, the depth of open trenches is limited by stability : rainwater filling, risk of collapse. The use of filling materials improves the stability of the barrier but reduces it efficiency. A main parameter of the efficiency of the barrier is the impedance ratio between soil and the barrier. In this paper, we will study different filling materials and different configurations of the barrier.

First, the experimental campaign that is being set up in France to study the efficiency of the barriers for different parameters of the barriers is presented. Then, a numerical model will be used to understand the details of the experiments and to enable improvements to the design of the barriers to be proposed.

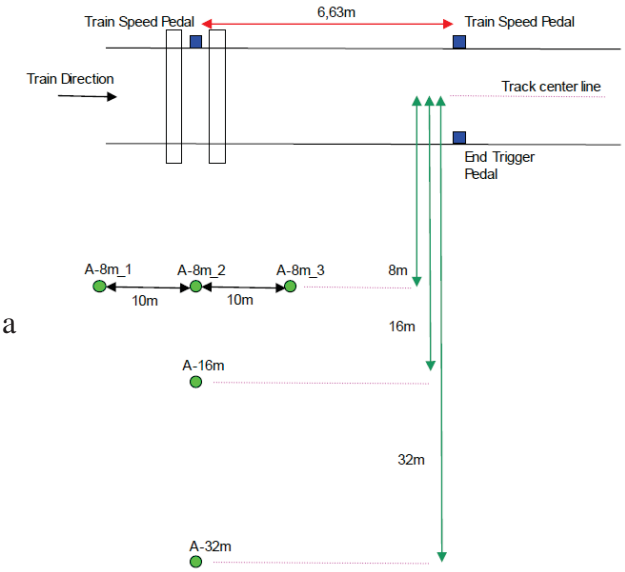
2 EXPERIMENTAL SETUP

With the increase in rail traffic the problems related to noise and vibrations have started to be largely studied. Within the framework of the European research and development project RIVAS, SNCF has carried out a measurement compaign to assess the influence of solutions to reduce vibrations generated by rail traffic. Another experimental campaign is being set up to characterize the efficiency of a barrier on the transmission path to mitigate railway waves. The frequencies of interest are in the range of 10-250 Hz. The test site selected to test the barrier is the same that has been used for RIVAS project. It is located in Florange, France. The track is used for commercial purposes and trains running on this track are TER (Regional Express Trains) and Intercity trains. About ten trains run on this track every day.

2.1 Description of the measurements

Before any works are carried out, a characterization of track and soil is required. The tested site has been already partially characterized during experiments realized for the RIVAS project. As the roughness is the source of vibrations induced at the wheel/rail contact, measurements of rail roughness were realized. Accelerometers were installed on the track and in the soil at 8 m, 16 m and 32 m from the track as presented Fig. 1. Using hammer impacts on the rail and receivers in the soil measurements of track receptances and track/soil transfer functions were realized. The soil/soil transfert functions are estimated from excitations from hammer strikes on an aluminum plate. Others experiments such as for instance the MASW (Multiple Analysis of Surface Waves) to deduce shear wave velocity variations in the soil are carried out to determine soil's properties.

Two areas are defined: a reference section and a test section in which barriers is dug. Measurements are performed for three configurations: before any works, for open trenches and for trenches filled with a different materials. The repeatability of the measurements are verified by comparison of acquisitions results for the same type of trains. Barriers are 20 m long. The first one will be 5 m deep and 3 m wide and the second one 3 m deep and 5 m wide. About fifty acquisitions in each configuration are performed.



a

Figure 1: Position of receivers in the soil

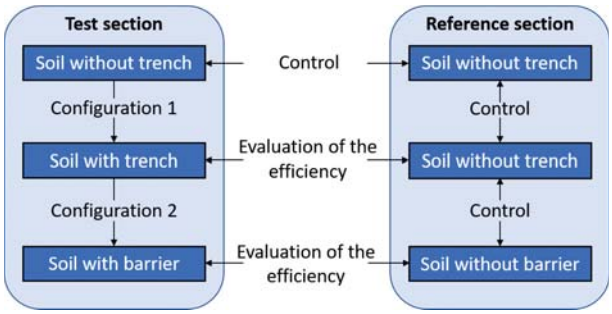


Figure 2: Principle of the test section

2.2 Usefulness of measurements

Before any works are carried out, acquisitions in both areas are compared in order to verify that the responses of the soil for a passing train are similar. The influence of the trench and the barrier on the vibration field is evaluated using the insertion losses defined by :

$$IL(\mathbf{x},\omega) = 20\log_{10}\left|\frac{\hat{a}_Z^{ref}(\mathbf{x},\omega)}{\hat{a}_Z^{Trench}(\mathbf{x},\omega)}\right| \tag{1}$$

where $\hat{a}_Z^{ref}(\mathbf{x},\omega)$ is the vertical acceleration at the reference section and $\hat{a}_Z^{Trench}(\mathbf{x},\omega)$ is the vertical acceleration at the test section. The test section has two functions : to be a reference in the estimation of barrier efficiency and to ensure that the zone was not affected by works in the test section (Fig. 2).

These experiments allow to compare the efficiency of an open trench with these of a barrier, but also to the influence of parameters such as depth, width of the trench and the filling material.

3 WAVE PROPAGATION PROBLEM IN THE PRESENCE OF A BARRIER FOR A MOVING LOAD

In this section, a numerical model is used to understand the phenomena observed during the experiments and propose improvements to the design of the barrier. First, the numerical model is introduced. Then, the modeling of the source is presented. A moving load representing a train pass-by is considered. We show that the response induced by a passing train can be reconstructed from the response of a single bogie on a single sleeper under the assumptions of linearity and periodicity (sleepers spaced regularly). Signals corresponding to a dynamic loading can be easily introduced. Simulations are realized in the time domain.

3.1 Description of the model

Wave propagation problems are solved using the SEM software developed in partnership by CentraleSupelec, Institut de Physique du Globe de Paris and the Commissariat à l'Énergie

Atomique et aux énergies alternatives. SEM is a 3D solver based on the spectral element method (Komatitsch et al. [5] or Cohen [1]). The spectral element method is Finite Element Method (FEM) that uses Lagrange polynomials of high order. The nodes of the Lagrange polynomials are those of the Gauss-Lobatto-Legendre (GLL) quadrature.

A simple model of the track has been considered in this study. Indeed, only the soil, the ballast layer and the sleepers are taken into account (see Fig. 3). In this part, all materials are

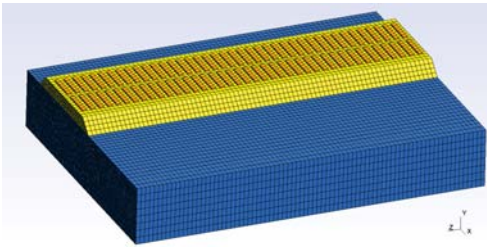

Figure 3: 3D model of the track

assumed to be isotropic linear elastic and follow the Hooke's law. The sleepers are regularly spaced every 0.6 m.

An explicit time scheme is used to solve the problem of wave propagation, the time step Δt is calculated in SEM from the courant number $C < 1$ by :

$$\Delta t = C \frac{\min \Delta x_{nodes}}{c_{p,max}} \tag{2}$$

where $\min \Delta x_{nodes}$ is the minimum distance between two nodes and $c_{p,max}$ is the maximum velocity of materials considered in the model. Then, the time step will be very small for a small mesh or too high velocities.

3.2 Response to a train pass-by obtained from the response of a single bogie

The train is modeled as a set of 13 bogies with different weights. Vibrations produced by a train pass-by can be separated into a quasi-static and dynamic excitation. The quasi-static excitation is related to the static components of the moving axles loads whereas the dynamic excitation is related to the wheel/rail interaction. For a train passing at a speed lower than the wave speed in the soil, vibrations induced by the dynamic excitation are higher than those induce by the quasi-static excitation [8]. For barriers close to the track, the vibration produced by a quasi-static load must be taken into account. The moving axle load can be decomposed in the time domain into a static component and a dynamic component [7].

Under the assumptions of linearity and periodicity, the acceleration at a point $\mathbf{x}$ due to a quasi-static load of a passing train is equal to the sum of accelerations produced by the pass-by of each bogie. It is given by:

$$a_{\text{Train}}(\mathbf{x}, t) = \sum_{k=0}^{12} a_{Bk}(\mathbf{x}, t) = \sum_{k=0}^{12} \alpha_k a_B(\mathbf{x}, t + \tau_k) \tag{3}$$

where a_{Bk} is the acceleration produced by the bogie B_k, τ_k the time delay of the k-th passing bogie with respect to the first one, α_k is the ratio of the weight of bogie k with respect to bogie

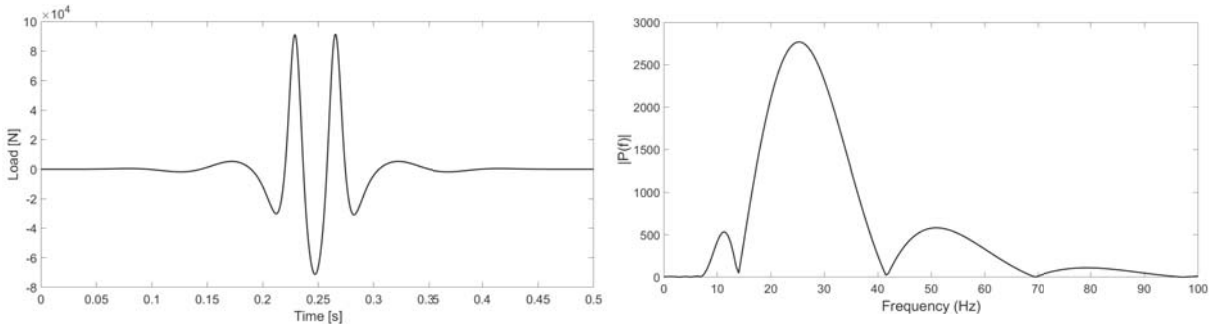

Figure 4: (Left) Loading time function on a single sleeper (Right) Fourier Transform of the loading.

0, $\alpha_0 = 1$, and $a_B = a_{B0}$. The spectrum of a train pass-by is thus given by :

$$\hat{a}_{\text{Train}}(\mathbf{x}, \omega) = \sum_{k=0}^{12} \hat{a}_{Bk}(\mathbf{x}, \omega) = \hat{a}_B(\mathbf{x}, \omega) \sum_{k=0}^{12} \alpha_k \exp(i\omega\tau_k) \tag{4}$$

where $\hat{a}_B$ is the spectrum of the first bogie. The spectrum due to a quasi-satic excitation for a full train can then be analytically calculated from the spectrum of a single passing bogie.

The input force representing the quasi-static load of a bogie is determined using the approach of Hoang et al. [3]. The rail is modeled as an Euler-Bernoulli beam, supported by a periodic elastic support modeling the rail pads on the sleepers. The total force applied on the beam can be expressed as a function of the moving load and reaction forces of sleepers (Fig. 4). By performing a double Fourier transform in time and space of the vertical displacement u_z, given by a dynamic equation, an analytical expression of the 2D-Fourier transform is obtained. The estimation of the dynamic excitation for an axle due to track unevenness characterized by its power spectral density is presented in [7]. The contribution of the dynamic excitation has not been taken into account yet.

For a point force of constant amplitude moving at constant sub-Rayleigh speed along an ideally flat surface of an elastic half-space there are only quasi-static localized displacements moving along with the force that are generated and no elastic waves [6]. However Rayleigh waves are generated if the railway is supported by sleepers. The Fig. 5 presents displacement induced in the soil by a bogie pass-by on 100 sleepers. Three waves can be identified: a

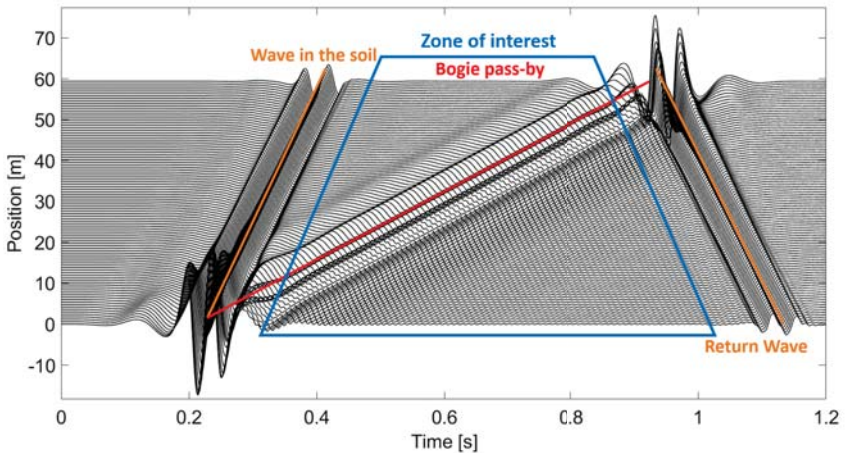

Figure 5: Displacement in the soil obtained for a simulation with 100 sleepers.

wave propagating in the soil at the Rayleigh waves velocity, a wave corresponding to the bogie

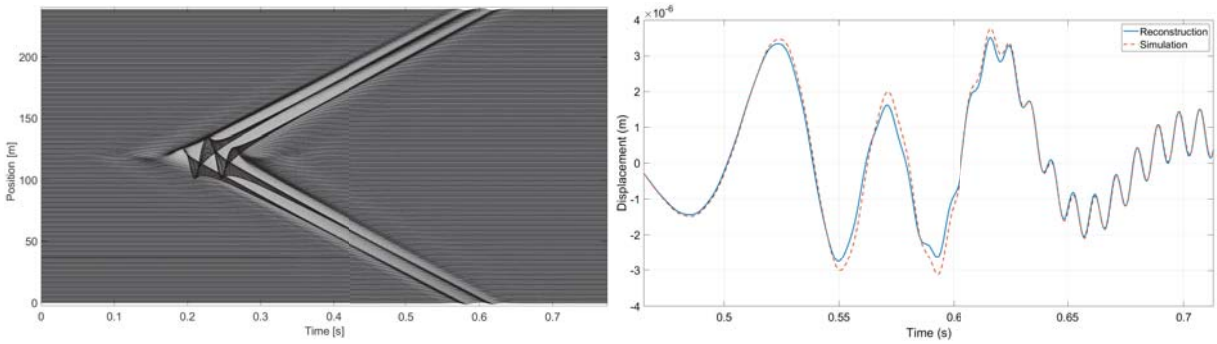

Figure 6: (Left) Displacements (magnified by 5e5) in the soil for a bogie loading on a single sleeper (Right) Reconstructed and simulated displacements in the soil for a bogie pass-by through the simulated domain.

pass-by and a return wave in the soil. The wave in the soil and the return wave appear in the simulations because of the limited size of the track. The loading is applied from the first to the last sleeper and there is no time history of the loading neither before nor after the simulated time. Then, the load on the first bogie generates one wave in the soil and another one which corresponds to the bogie pass-by. The signal of interest is obtained after the removal of these two waves. Oscillations can be seen after the bogie pass-by. They correspond to interference between the displacement induced by a load on one sleeper and displacements induced by loads on the following sleepers. So since there is no loading history above the simulated domain the wave in the soil induced by a load on the last sleeper doesn't interfere with any other wave and a return wave appears in our simulation.

The acceleration at point x for a moving bogie at speed v can be reconstructed from the acceleration measured in sensors distributed along the track with the same periodicity d that sleeper and excited by a non-moving loading applied on only one sleeper using formula :

$$a_B(x,t) = \sum_{k\in\mathbb{Z}} a_0\left(x - kd, t - k\frac{d}{v}\right) \tag{5}$$

where $a_0(x,t)$ is the acceleration at point x at time t produced by a loading at point x_0 at instant t_0. In order to be able to carry out this reconstruction it is necessary to simulate a bogie loading on one single sleeper for a great number of sleepers. The simulation is realized for 40 sleepers. Assuming that wave form are conserved and that the only difference between measurements is in their amplitudes, results are extrapolated beyond the simulated domain. The Fig. 6 (Left) represents the displacement in the soil for a bogie loading on a single sleeper. The reconstructed displacements for a moving bogie along the track are presented in the Fig. 6 (Right). The reconstructed displacements (bleu line) are in good agreement with displacements obtained from the simulation (orange dashed line) of a bogie pass-by.

4 CONCLUSION

A planned experience that aims to evaluate the efficiency of a barrier on the transmitted waves induced by a railway traffic was presented. Different sizes of trenches and materials will be tested. Concerning numerical simulations, they will be used to understand the phenomena that occur on the experiments. The use of a single bogie loading on only one sleeper allowed to reduce the numerical costs. The response of the passing bogie and the spectrum of the train pass-by can then be reconstructed from the simulation results of only a standing bogie in one sleeper.

SCATTERING OF ELASTIC SH WAVES BY TRANSVERSELY ISOTROPIC SPHERE

Ata Jafarzadeh[1], **Peter D. Folkow**[1], **and Anders Boström**[1]

Keywords: Scattering, Transversely isotropic, Sphere, SH waves, $\mathbf{T}$ matrix.

Abstract. *The scattering by a transversely isotropic sphere in a three-dimensional, homogeneous, isotropic and infinite elastic medium is considered. The problem is a scalar one and is phrased as a scattering problem for an incident SH elastic waves propagating in the direction parallel to the axis of material symmetry. The elastodynamic equations inside the sphere are transformed to spherical coordinates and the displacement field is expanded in associated Legendre functions in the polar coordinate and powers in the radial coordinate. This leads to recursion relations for the expansion coefficients inside the sphere. Using the boundary conditions on the surface of the sphere results in a system of equations for all the expansion coefficients for the fields outside and inside the sphere. As a result, the transition ($\mathbf{T}$) matrix elements are calculated and given explicitly for low frequencies.*

1 INTRODUCTION

Scattering of a wave by a single obstacle has been of much interest in physics and mathematics. This includes the study of scattering for acoustic waves, electromagnetic waves, and elastic waves, where the latter are of interest in this article. There is a wide body of literature on elastodynamic wave scattering in isotropic media. In the treatise on theoretical physics, Morse and Feshbach include several aspects of continuum mechanics and elastic wave propagation [1]. A comprehensive overview of scattering of acoustic, electromagnetic and elastic waves is presented in a unified way by de Hoop [2] and Varadan et al. [3]. However, there exist many natural and synthetic materials, which are not isotropic. This may be fibers in a composite, the grains in a metal, or, on a larger scale, natural soils and rocks or an anisotropic formation in the ground. If the materials are anisotropic the classical series expansion methods for circles and spheres are not applicable any longer and the problem becomes more complicated.

The study of waves in unbounded or semi bounded anisotropic media has mostly been treated in Cartesian and cylindrical coordinates. It is then straightforward to investigate the propagation of waves in layered media. For bounded anisotropic media, where the present focus lies, not so much has been done by analytical methods. However, spherically and cylindrically anisotropic obstacles have been considered by some authors [4–8]. For the case when the obstacle is anisotropic in Cartesian coordinates most interest seems to arise for electromagnetic problems, not mechanical ones. Thus, Wu and Ren [9] investigate the scattering by an anisotropic circle in an isotropic medium using cylindrical wave functions in anisotropic electromagnetic media. Similar wave functions have been used to treat the scattering by a sphere, and to derive the null field approach ($\mathbf{T}$ matrix method) [10–12]. The basic idea in the derivation of these wave functions is a plane wave expansion that is transformed into polar or spherical coordinates, which leads to quite complicated expressions involving integrals that have to be computed numerically. It seems that the method has not been used for mechanical scattering problems. Zharnikov and Syresin [13] develop a very different approach which leads to a Riccati equation for the impedance operator, and they determine the modes in an anisotropic elastic waveguide. Recently, investigations have been performed for scattering of elastic waves by anisotropic obstacles in the 2D case for an orthotropic circle for incident SH waves [14] and P-SV waves [15], using the same type of method as in the present article.

In this paper the scattering problem is considered for a single transversely isotropic spherical obstacle contained in a three-dimensional, homogeneous, isotropic and infinite elastic medium. This is a problem that finds applications in particle composites and in grain scattering in metals (see Boström and Rudá [16]). This canonical problem is here investigated in the simplest case with an incident plane SH wave propagating in the z direction which is scattered by a transversely isotropic sphere with the axis of material symmetry perpendicular to the xy plane (see Figure 1). Therefore, the problem becomes rotationally symmetric and the displacement and stress fields are independent of the azimuthal angle φ. Based on the polarization of the incident wave the problem reduces to a scalar one, relating only to motion in the azimuthal φ direction. The first step is to state the elastodynamic equations in spherical coordinates which leads to expressions containing trigonometric functions in the polar θ coordinate. Expanding the displacement field in associated Legendre functions in θ leads to coupled ordinary differential equations which can be solved by a power series expansion in the radial r coordinate. An expansion in the spherical vector wave functions outside the sphere is employed and using the boundary conditions on the surface of the sphere results in a system of equations for all the expansion coefficients of the fields outside and inside the sphere. The method is in particular well

suited for low frequencies and in this case it is possible to give the elements of the transition matrix in simple analytical form. Some numerical examples are given showing the scattered wave in the far field.

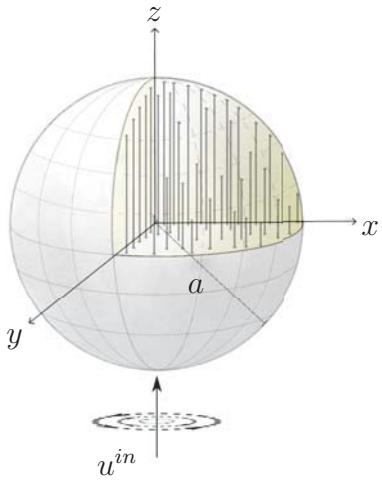

Figure 1: Transversely isotropic sphere with radius a, and incident torsional wave.

2 STATEMENT OF PROBLEM

Consider an anisotropic sphere with radius a surrounded by a homogeneous isotropic elastic infinite medium with density ρ and Lamé parameters λ and μ. Due to the geometry of the problem, it is convenient to use spherical coordinates (r, θ, φ). Considering a time harmonic situation and suppressing the time factor $e^{-i\omega t}$, it is convenient to introduce the spherical vector wave functions of the surrounding medium [3]

$$\boldsymbol{\psi}^0_{1\sigma ml}(r,\theta,\varphi) = \frac{1}{\sqrt{l(l+1)}}\nabla\times\left(\boldsymbol{r}j_l(k_sr)Y_{\sigma ml}(\theta,\varphi)\right) = j_l(k_sr)\boldsymbol{A}_{1\sigma ml}(\theta,\varphi), \tag{1}$$

$$\begin{aligned}\boldsymbol{\psi}^0_{2\sigma ml}(r,\theta,\varphi) &= \frac{1}{\sqrt{l(l+1)}}\nabla\times\nabla\times\left(\boldsymbol{r}j_l(k_sr)Y_{\sigma ml}(\theta,\varphi)\right)\\ &= \left(j_l'(k_sr)+\frac{j_l(k_sr)}{k_sr}\right)\boldsymbol{A}_{2\sigma ml}(\theta,\varphi)+\sqrt{l(l+1)}\frac{j_l(k_sr)}{k_sr}\boldsymbol{A}_{3\sigma ml}(\theta,\varphi),\end{aligned} \tag{2}$$

$$\begin{aligned}\boldsymbol{\psi}^0_{3\sigma ml}(r,\theta,\varphi) &= \left(\frac{k_p}{k_s}\right)^{3/2}\frac{1}{k_p}\nabla\left(j_l(k_pr)Y_{\sigma ml}(\theta,\varphi)\right)\\ &= \left(\frac{k_p}{k_s}\right)^{3/2}\left((j_l'(k_pr)\boldsymbol{A}_{3\sigma ml}(\theta,\varphi)+\sqrt{l(l+1)}\frac{j_l(k_pr)}{k_pr}\boldsymbol{A}_{2\sigma ml}(\theta,\varphi)\right).\end{aligned} \tag{3}$$

Here the first index 1, 2 and 3 on the wave functions indicates SH, SV and P waves, respectively. The spherical harmonics $Y_{\sigma ml}(\theta,\varphi)$ are defined as

$$Y_{\sigma ml}(\theta,\varphi) = \sqrt{\frac{\epsilon_m(2l+1)(l-m)!}{4\pi(l+m)!}}P_l^m(\cos\theta)\left\{\begin{array}{c}\cos m\varphi\\ \sin m\varphi\end{array}\right\}, \tag{4}$$

where $P_l^m(\cos\theta)$ is an associated Legendre function of order $m = 0, 1, 2, ..$ and degree $l = m$, $m+1, m+2, ...$, which has the following definition in terms of the Legendre polynomial

$$P_l^m(x) = (-1)^m(1-x^2)^{\frac{1}{2}m}\frac{d^m P_l(x)}{dx^m}. \tag{5}$$

In eq. (4), $\sigma = e$ for the upper row which is even with respect to φ or $\sigma = o$ for the lower row which is odd with respect to φ. ϵ_m is the Neumann factor, $\epsilon_0 = 1$ and $\epsilon_m = 2$ for $m = 1, 2, 3, ...$ The upper index 0 on the wave functions denotes that they are regular containing spherical Bessel functions j_l, while outgoing waves containing spherical Hankel functions of the first kind $h_l^{(1)}$ are denoted by an upper index $+$. The longitudinal and transverse wave numbers are $k_p = \omega\sqrt{\rho/(\lambda+2\mu)}$ and $k_s = \omega\sqrt{\rho/\mu}$, respectively. Finally, the vector spherical harmonics $\boldsymbol{A}_{\tau\sigma ml}(\theta,\varphi)$, $\tau = 1, 2$ and 3, form a vector basis system for vector-valued functions on the unit sphere which are mutually orthonormal and are defined as

$$\begin{aligned}
\boldsymbol{A}_{1\sigma ml}(\theta,\varphi) &= \frac{1}{\sqrt{l(l+1)}}\nabla\times(\boldsymbol{r}Y_{\sigma ml}(\theta,\varphi)) \\
&= \frac{1}{\sqrt{l(l+1)}}\left(\boldsymbol{e}_\theta\frac{1}{\sin\theta}\frac{\partial}{\partial\varphi}Y_{\sigma ml}(\theta,\varphi) - \boldsymbol{e}_\varphi\frac{\partial}{\partial\theta}Y_{\sigma ml}(\theta,\varphi)\right), \\
\boldsymbol{A}_{2\sigma ml}(\theta,\varphi) &= \frac{1}{\sqrt{l(l+1)}}r\nabla Y_{\sigma ml}(\theta,\varphi) \\
&= \frac{1}{\sqrt{l(l+1)}}\left(\boldsymbol{e}_\theta\frac{\partial}{\partial\theta}Y_{\sigma ml}(\theta,\varphi) + \boldsymbol{e}_\varphi\frac{1}{\sin\theta}\frac{\partial}{\partial\varphi}Y_{\sigma ml}(\theta,\varphi)\right), \\
\boldsymbol{A}_{3\sigma ml}(\theta,\varphi) &= \boldsymbol{e}_r Y_{\sigma ml}(\theta,\varphi).
\end{aligned} \tag{6}$$

Usually it is necessary to have the traction vector on a surface for applying boundary conditions. The traction vector $\boldsymbol{t}^{(r)}$ on the spherical surface $r = a$ with normal $\boldsymbol{e_r}$ is needed to solve the scattering problem, and can be derived directly from the displacement field $\boldsymbol{u}$ by

$$\boldsymbol{t}^{(r)} = \boldsymbol{e}_r\lambda\nabla\cdot\boldsymbol{u} + \mu\left(2\frac{\partial\boldsymbol{u}}{\partial r} + \boldsymbol{e}_r\times(\nabla\times\boldsymbol{u})\right), \tag{7}$$

The first vector wave function (SH waves) and its traction only depend on the first vector spherical harmonic while the second and third wave functions (P-SV waves) only depend on the second and third vector spherical harmonics. Therefore, the scattering problem can be solved for SH waves and P-SV waves separately.

The scattering problem for an incoming wave scattered by the sphere is determined by the constitutive and governing equations inside the sphere (as described later) and the boundary conditions on the sphere, which here are taken as continuity of displacement and traction. Solving the problem, the scattering by the sphere can be represented by the transition ($\mathbf{T}$) matrix which gives the relation between the expansion coefficients of the scattered waves and incoming waves. The incoming and scattered waves can be expanded in the vector wave functions

$$\boldsymbol{u}^{in}(\boldsymbol{r}) = \sum_{\tau\sigma ml} b_{\tau\sigma ml}\boldsymbol{\psi}^0_{\tau\sigma ml}(\boldsymbol{r}), \tag{8}$$

$$\boldsymbol{u}^{sc}(\boldsymbol{r}) = \sum_{\tau\sigma ml} g_{\tau\sigma ml}\boldsymbol{\psi}^+_{\tau\sigma ml}(\boldsymbol{r}), \tag{9}$$

where the expansion coefficients of the incoming wave $b_{\tau\sigma ml}$ can be regarded as known and the expansion coefficients of the scattered wave $g_{\tau\sigma ml}$ are to be determined. The $\mathbf{T}$ matrix is defined as the linear relation between $b_{\tau\sigma ml}$ and $g_{\tau\sigma ml}$

$$g_{\tau\sigma ml} = \sum_{\tau'\sigma'm'l'} T_{\tau\sigma ml,\tau'\sigma'm'l'} b_{\tau'\sigma'm'l'}. \tag{10}$$

Inside the sphere the material is assumed to be transversely isotropic with density ρ_1, such that the axis of anisotropy is perpendicular to the xy plane. Therefore, the constitutive equations in Cartesian coordinates are

$$\begin{Bmatrix} \sigma_{xx} \\ \sigma_{yy} \\ \sigma_{zz} \\ \sigma_{yz} \\ \sigma_{zx} \\ \sigma_{xy} \end{Bmatrix} = \begin{bmatrix} C_{11} & C_{12} & C_{13} & 0 & 0 & 0 \\ C_{12} & C_{11} & C_{13} & 0 & 0 & 0 \\ C_{13} & C_{13} & C_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & 2C_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & 2C_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & C_{11}-C_{12} \end{bmatrix} \begin{Bmatrix} \epsilon_{xx} \\ \epsilon_{yy} \\ \epsilon_{zz} \\ \epsilon_{yz} \\ \epsilon_{zx} \\ \epsilon_{xy} \end{Bmatrix}. \tag{11}$$

The equations of motion in spherical coordinates inside the sphere are

$$\frac{\partial\sigma_{rr}}{\partial r} + \frac{1}{r}\frac{\partial\sigma_{r\theta}}{\partial\theta} + \frac{1}{r\sin\theta}\frac{\partial\sigma_{\varphi r}}{\partial\varphi} + \frac{1}{r}\left(2\sigma_{rr} - \sigma_{\theta\theta} - \sigma_{\varphi r} + \cot\theta\sigma_{r\theta}\right) = -\rho\omega^2 u_r, \tag{12}$$

$$\frac{\partial\sigma_{r\theta}}{\partial r} + \frac{1}{r}\frac{\partial\sigma_{\theta\theta}}{\partial\theta} + \frac{1}{r\sin\theta}\frac{\partial\sigma_{\theta\varphi}}{\partial\varphi} + \frac{1}{r}\left(\cot\theta\left(\sigma_{\theta\theta} - \sigma_{\varphi\varphi}\right) + 3\sigma_{r\theta}\right) = -\rho\omega^2 u_\theta, \tag{13}$$

$$\frac{\partial\sigma_{\varphi r}}{\partial r} + \frac{1}{r}\frac{\partial\sigma_{\theta\varphi}}{\partial\theta} + \frac{1}{r\sin\theta}\frac{\partial\sigma_{\varphi\varphi}}{\partial\varphi} + \frac{1}{r}\left(3\sigma_{\varphi r} + 2\cot\theta\sigma_{\theta\varphi}\right) = -\rho\omega^2 u_\varphi, \tag{14}$$

where the strains ϵ_{ij} in spherical coordinates are

$$\begin{aligned} \epsilon_{rr} &= \frac{\partial u_r}{\partial r}, \quad \epsilon_{\varphi\varphi} = \frac{1}{r\sin\theta}\frac{\partial u_\varphi}{\partial\varphi} + \frac{\cot\theta}{r}u_\theta + \frac{u_r}{r}, \\ \epsilon_{\theta\theta} &= \frac{1}{r}\frac{\partial u_\theta}{\partial\theta} + \frac{u_r}{r}, \quad \epsilon_{\theta\varphi} = \frac{1}{2r}\left(\frac{\partial u_\varphi}{\partial\theta} - \cot\theta u_\varphi + \frac{1}{\sin\theta}\frac{\partial u_\theta}{\partial\varphi}\right), \\ \epsilon_{\varphi r} &= \frac{1}{2}\left(\frac{1}{r\sin\theta}\frac{\partial u_r}{\partial\varphi} + \frac{\partial u_\varphi}{\partial r} - \frac{u_\varphi}{r}\right), \quad \epsilon_{r\theta} = \frac{1}{2}\left(\frac{\partial u_\theta}{\partial r} - \frac{u_\theta}{r} + \frac{1}{r}\frac{\partial u_r}{\partial\theta}\right). \end{aligned} \tag{15}$$

By using the transformation of the stresses and strains between Cartesian and spherical coordinates the stress-strain relations in spherical coordinates become

$$\begin{aligned} \sigma_{rr} = &\left(\alpha_1 + 2\alpha_2\right)\epsilon_{rr} + \alpha_1\epsilon_{\theta\theta} + \left(\alpha_1 - \beta_2 + \beta_3\right)\epsilon_{\varphi\varphi} - 2\beta_1\left(\epsilon_{rr}\cos 2\theta - \epsilon_{r\theta}\sin 2\theta\right) \\ &- \beta_3\left(\epsilon_{\varphi\varphi}\cos 2\theta\right) + \beta_2\left(\left(\epsilon_{rr} - \epsilon_{\theta\theta}\right)\cos 4\theta - 2\epsilon_{r\theta}\sin 4\theta\right), \end{aligned} \tag{16}$$

$$\begin{aligned} \sigma_{\theta\theta} = &\left(\alpha_1 + 2\alpha_2\right)\epsilon_{\theta\theta} + \alpha_1\epsilon_{rr} + \left(\alpha_1 - \beta_2 + \beta_3\right)\epsilon_{\varphi\varphi} + 2\beta_1\left(\epsilon_{\theta\theta}\cos 2\theta + \epsilon_{r\theta}\sin 2\theta\right) \\ &+ \beta_3\left(\epsilon_{\varphi\varphi}\cos 2\theta\right) + \beta_2\left(\left(\epsilon_{\theta\theta} - \epsilon_{rr}\right)\cos 4\theta + 2\epsilon_{r\theta}\sin 4\theta\right), \end{aligned} \tag{17}$$

$$\begin{aligned}\sigma_{\varphi\varphi} = &(\alpha_1 + 2\alpha_2 + 2\beta_1 + \beta_2)\,\epsilon_{\varphi\varphi} + (\alpha_1 - \beta_2 + \beta_3)\,(\epsilon_{\theta\theta} + \epsilon_{rr}) \\ &+ \beta_3\,((\epsilon_{\theta\theta} - \epsilon_{rr})\cos 2\theta + 2\epsilon_{r\theta}\sin 2\theta)\,,\end{aligned} \tag{18}$$

$$\sigma_{\theta\varphi} = \alpha_3\epsilon_{\theta\varphi} + \beta_4\,(\epsilon_{\theta\varphi}\cos 2\theta + \epsilon_{\varphi r}, \sin 2\theta)\,, \tag{19}$$

$$\sigma_{\varphi r} = \alpha_3\epsilon_{\varphi r} - \beta_4\,(\epsilon_{\varphi r}\cos 2\theta - \epsilon_{\theta\varphi}\sin 2\theta)\,, \tag{20}$$

$$\begin{aligned}\sigma_{r\theta} =&2\alpha_2\epsilon_{r\theta} + \beta_1\,((\epsilon_{\theta\theta} + \epsilon_{rr})\sin 2\theta) + \beta_3\,(\epsilon_{\varphi\varphi}\sin 2\theta) \\ &+ \beta_2\,((\epsilon_{\theta\theta} - \epsilon_{rr})\sin 4\theta - 2\epsilon_{r\theta}\cos 4\theta)\,,\end{aligned} \tag{21}$$

where

$$\begin{aligned}&\alpha_1 = \frac{1}{8}(C_{11} + 6C_{13} + C_{33} - 4C_{44}), \quad \alpha_2 = \frac{1}{8}(C_{11} - 2C_{13} + C_{33} + 4C_{44}), \\ &\beta_1 = \frac{1}{4}(C_{11} - C_{33}), \quad \beta_2 = \frac{1}{8}(C_{11} - 2C_{13} + C_{33} - 4C_{44}), \quad \beta_3 = \frac{1}{2}(C_{12} - C_{13}), \\ &\alpha_3 = \frac{1}{2}(C_{11} - C_{12} + 2C_{44}), \quad \beta_4 = \frac{1}{2}(C_{11} - C_{12} - 2C_{44}).\end{aligned} \tag{22}$$

Here, $\alpha_1, \alpha_2, \beta_1, \beta_2$ and β_3 are five linearly independent coefficients that are sufficient to describe the transversely isotropic medium. However, for simplicity, two more coefficients α_3 and β_4 are defined for the case of incident SH waves. They can easily be written in terms of the other coefficients

$$\alpha_3 = 2\alpha_2 + \beta_1 - \beta_3, \qquad \beta_4 = 2\beta_2 + \beta_1 - \beta_3. \tag{23}$$

In the isotropic limit $\beta_i = 0, i = 1, 2, 3, 4$, $\alpha_1 = \lambda_1$ and $\alpha_3 = 2\alpha_2 = 2\mu_1$, with μ_1 and λ_1 being the Lamé parameters of the sphere, and eqs. (16) to (21) reduce to the isotropic case.

3 SCATTERING OF INCIDENT TORSIONAL WAVES

The simplest form of the defined scattering problem occurs for a plane SH wave (or torsional wave) propagating parallel to axis of material symmetry in the z direction. Due to the uncoupling of the SH waves, the displacement field outside the sphere can be written in terms of the first spherical vector wave function (eq. (1)). Such a rotationally symmetric incident wave together with the symmetrical geometry of the media simplify the problem to an axisymmetric situation. Consequently, the displacement and stress fields are φ independent and the vector wave function only consists of $m = 0$ terms (which only have an even part $\sigma = e$). For such an incident plane wave the displacement field outside the sphere, which can be divided into incident and scattered waves, only consists of displacement in the azimuthal direction and is from eqs. (8) and (9)

$$u_\varphi^{in}(r,\theta) = \sum_{l=1}^{\infty} b_{1l}\boldsymbol{\psi}_{1e0l}^0(r,\theta)\cdot\boldsymbol{e}_\varphi = \sum_{l=1}^{\infty} b_{1l}w_l j_l(k_s r)P_l^1(\cos\theta), \tag{24}$$

$$u_{\varphi}^{sc}(r,\theta)=\sum_{l=1}^{\infty}g_{1l}\boldsymbol{\psi}_{1e0l}^{+}(r,\theta)\cdot\boldsymbol{e}_{\varphi}=\sum_{l=1}^{\infty}g_{1l}w_{l}h_{l}^{(1)}(k_{s}r)P_{l}^{1}(\cos\theta), \tag{25}$$

where $w_l=\sqrt{(2l+1)/(4\pi l(l+1))}$.

The radial traction outside the sphere is equal to zero for the r and θ directions and it only has a φ component which is derived from eq. (7) for the incident and scattered waves

$$\begin{aligned}\sigma_{\varphi r}^{in}&=\sum_{l=1}^{\infty}b_{1l}\mu r w_{l}\frac{d}{dr}\left(\frac{j_{l}(k_{s}r)}{r}\right)P_{l}^{1}(\cos\theta),\\ \sigma_{\varphi r}^{sc}&=\sum_{l=1}^{\infty}g_{1l}\mu r w_{l}\frac{d}{dr}\left(\frac{h_{l}^{(1)}(k_{s}r)}{r}\right)P_{l}^{1}(\cos\theta).\end{aligned} \tag{26}$$

In order to find the linear relation between g_{1l} and b_{1l}, the continuity conditions on the surface of the sphere must be applied, and eqs. (12) to (14) must be satisfied inside the sphere. Since there is only traction and displacement components in the φ direction and they are φ independent as well, substituting eqs. (19) and (20) into eq. (14) and using the strain relation in spherical coordinates (eq. (15)) lead to the following partial differential equation to be satisfied inside the sphere

$$\begin{aligned}&\frac{\partial^{2}u_{\varphi}}{\partial r^{2}}+\frac{2}{r}\frac{\partial u_{\varphi}}{\partial r}+\frac{1}{r^{2}}\nabla_{p1}^{2}u_{\varphi}+\beta\cos 2\theta\left[-\frac{\partial^{2}u_{\varphi}}{\partial r^{2}}+\frac{2}{r^{2}}u_{\varphi}+\frac{1}{r^{2}}\nabla_{p1}^{2}u_{\varphi}\right]\\&\quad+\beta\sin 2\theta\left[\cot\theta\left(\frac{1}{r}\frac{\partial u_{\varphi}}{\partial r}-\frac{2}{r^{2}}u_{\varphi}\right)+\frac{\partial}{\partial\theta}\left(\frac{2}{r}\frac{\partial u_{\varphi}}{\partial r}-\frac{1}{r^{2}}u_{\varphi}\right)\right]+k^{2}u_{\varphi}=0,\end{aligned} \tag{27}$$

where $\beta=\beta_4/\alpha_3$ is a measure of the degree of anisotropy, with $\beta=0$ in the isotropic case, $k=\omega\sqrt{2\rho_1/\alpha_3}$ is the wave number in the anisotropic sphere determined with the mean stiffness of the sphere $\alpha_3/2$, and

$$\nabla_{pm}^{2}=\frac{\partial^{2}}{\partial\theta^{2}}+\cot\theta\frac{\partial}{\partial\theta}-\frac{m^{2}}{\sin^{2}\theta}. \tag{28}$$

The differential equation for the Legendre functions of order m can be written in terms of this operator

$$\nabla_{pm}^{2}P_{l}^{m}(\cos\theta)+l(l+1)P_{l}^{m}(\cos\theta)=0. \tag{29}$$

Due to the appearance of ∇_{p1}^2, it is useful to expand the displacement field inside the sphere in terms of the associated Legendre functions of order 1

$$u_{\varphi}(r,\theta)=\sum_{l=1}^{\infty}f_{l}(r)P_{l}^{1}(\cos\theta). \tag{30}$$

Substituting eq. (30) into eq. (27) and using multiple angel formulae for trigonometric functions and the differential equation for the associated Legendre function of order 1 (eq. (29)) lead

to the following relation

$$\sum_{l=1}^{\infty}\Bigg[P_l^1(\cos\theta)\left[(1+\beta)f_l''(r)+\frac{2}{r}f_l'(r)-\left(l(l+1)+\beta\left(2-l(l+1)\right)\right)\frac{1}{r^2}f_l(r)\right]$$
$$+P_l^1(\cos\theta)\cos^2\theta\left[2\beta\left(-f_l''(r)+\frac{1}{r}f_l'(r)-l(l+1)\frac{1}{r^2}f_l(r)\right)\right] \tag{31}$$
$$+\frac{dP_l^1(\cos\theta)}{d\cos\theta}\sin^2\theta\cos\theta\left[2\beta\left(-\frac{2}{r}f_l'(r)+\frac{1}{r^2}f_l(r)\right)\right]+k^2f_l(r)P_l^1(\cos\theta)\Bigg]=0,$$

where a prime denotes differentiation with respect to r. Equation (31) contains terms including multiplication of the associated Legendre functions and trigonometric functions. However, it is convenient to write them in terms of orthogonal functions. For this purpose, the following recursion relations can be used

$$\begin{aligned}(l-m+1)P_{l+1}^m(x)&=(2l+1)xP_l^m(x)-(l+m)P_{l-1}^m(x),\\(-1)^m(1-x^2)\frac{dP_l^m(x)}{dx}&=lxP_l^m(x)-(l+m)P_{l-1}^m(x).\end{aligned} \tag{32}$$

It can be concluded that

$$\begin{aligned}\cos^2\theta P_l^1(\cos\theta)&=c_{1l}P_l^1(\cos\theta)+c_{2l}P_{l+2}^1(\cos\theta)+c_{3l}P_{l-2}^1(\cos\theta),\\\frac{dP_l^1(\cos\theta)}{d\cos\theta}\sin^2\theta\cos\theta&=s_{1l}P_l^1(\cos\theta)+s_{2l}P_{l+2}^1(\cos\theta)+s_{3l}P_{l-2}^1(\cos\theta),\end{aligned} \tag{33}$$

where

$$\begin{aligned}c_{3l}&=\frac{l(l+1)}{(2l+1)(2l-1)},\qquad c_{2l}=\frac{l(l+1)}{(2l+1)(2l+3)},\qquad c_{1l}=\frac{l-1}{l}c_{3l}+\frac{l+2}{l+1}c_{2l},\\s_{3l}&=(l+1)c_{3l},\qquad s_{2l}=-lc_{2l},\qquad s_{1l}=\frac{l-1}{l}s_{3l}+\frac{l+2}{l+1}s_{2l}.\end{aligned} \tag{34}$$

Consequently eq. (31) turns into

$$\sum_{l=1}^{\infty}\left[P_l^1(\cos\theta)R_{1,l}(r)+P_{l+2}^1(\cos\theta)R_{2,l}(r)+P_{l-2}^1(\cos\theta)R_{3,l}(r)\right]=0, \tag{35}$$

which is an expansion only in terms of the associated Legendre functions. It is noted that there is coupling between different degrees of the associated Legendre functions. Here

$$\begin{aligned}R_{1,l}(r)&=(1+\beta-2\beta c_{1l})f_l''(r)+2(1+\beta c_{1l}-2\beta s_{1l})\frac{1}{r}f_l'(r),\\&\quad+\left(r^2k^2-l(l+1)-\beta\big(2-l(l+1)\big)-2\beta c_{1l}l(l+1)+2\beta s_{1l}\right)\frac{1}{r^2}f_l(r),\\R_{2,l}(r)&=-2\beta c_{2l}f_l''(r)+2\beta(c_{2l}-2s_{2l})\frac{1}{r}f_l'(r)+2\beta\big(-l(l+1)c_{2l}+s_{2l}\big)\frac{1}{r^2}f_l(r),\\R_{3,l}(r)&=-2\beta c_{3l}f_l''(r)+2\beta(c_{3l}-2s_{3l})\frac{1}{r}f_l'(r)+2\beta\big(-l(l+1)c_{3l}+s_{3l}\big)\frac{1}{r^2}f_l(r).\end{aligned} \tag{36}$$

Using the orthogonality of the Legendre functions, the following relation must be satisfied inside the sphere for all values of $l=1,2,3,...$ with the condition $f_0(r)=f_{-1}(r)=0$,

$$R_{1,l}(r)+R_{2,l-2}(r)+R_{3,l+2}(r)=0. \tag{37}$$

This is a system of coupled ordinary differential equations for the functions $f_l(r)$. To solve this system of equations, $f_l(r)$ are expanded in power series in r. In order to achieve a solution that is analytical at the origin, the functions $f_l(r)$ must behave as r^l when r approaches the origin and must also contain only even or odd powers of r. Thus, the following series expansion can be made

$$f_l(r) = \sum_{j=l,l+2,\ldots} q_{j,l} r^j. \tag{38}$$

Inserting eq. (38) into eq. (37), results in

$$\sum_{j=l,l+2,\ldots} \left[\left(q_{j,l} M_{1j,l} + q_{j,l+2} M_{2j,l} + q_{j,l-2} M_{3j,l} + q_{j+2,l} k^2 \right) r^{j-2} \right] = 0, \tag{39}$$

where

$$\begin{aligned} M_{1j,l} =& \frac{(j + j^2 - l(1+l))\,(-3 + 4l + 4l^2 + 3\beta)}{-3 + 4l + 4l^2}, \\ M_{2j,l} =& -\frac{2\,(6 + 5l + l^2)\,(3 + j^2 + 4l + l^2 + 2j(2+l))\;\beta}{(3+2l)(5+2l)}, \\ M_{3j,l} =& -\frac{2\,(j^2 - 2j(-1+l) + (-2+l)l)\,(2 - 3l + l^2)\,\beta}{3 - 8l + 4l^2}. \end{aligned} \tag{40}$$

Finally, the linear independence of the powers of r leads to the following equation for all $l = 1, 2, ..,$ and $j = l, l+2, ..,$ with the condition $q_{j,l} = 0$ for all $j > l$

$$q_{j,l} M_{1j,l} + q_{j,l+2} M_{2j,l} + q_{j,l-2} M_{3j,l} + q_{j+2,l} k^2 = 0. \tag{41}$$

This system of equations can be used to determine all $q_{j,l}$ for $j = l+2, l+4, ..$ in terms of $q_{l,l}$. Thus the solution inside the sphere is complete and only contains the unknown coefficients $q_{l,l}$.

Furthermore, for solving the scattering problem, the continuity conditions at the boundary of the sphere must be considered. Substituting the expanded displacement field into the constitutive relation (eq. (20)), the following stress inside the sphere is evaluated

$$\begin{aligned} \frac{2}{\alpha_3}\sigma_{\varphi r} = \sum_{l=1}^{\infty} & (1+\beta)\left(f_l'(r) - \frac{f_l(r)}{r} \right) P_l^1(\cos\theta) - 2\beta\cos^2\theta P_l^1(\cos\theta) f_l'(r) \\ & - 2\beta \frac{dP_l^1(\cos\theta)}{d\cos\theta} \sin^2\theta \cos\theta \left(\frac{f_l(r)}{r} \right), \end{aligned} \tag{42}$$

which again contains terms including multiplication of trigonometric and Legendre functions. However, in order to apply the continuity condition it is convenient to derive the stress inside the sphere in terms of the associated Legendre functions of order 1, the same as the one outside the sphere. Therefore using the same recursion relations as eq. (33) the stress inside the sphere can be rewritten

$$\begin{aligned} \frac{2}{\alpha_3}\sigma_{\varphi r} = \sum_{l=1}^{\infty} & \left[(1+\beta)\left(f_l'(r) - \frac{f_l(r)}{r} \right) - 2\beta\left(c_{1l} f_l'(r) + s_{1l} \frac{f_l(r)}{r} \right) \right] P_l^1(\cos\theta) \\ & + \left[-2\beta\left(c_{3l} f_l' + s_{3l} \frac{f_l(r)}{r} \right) \right] P_{l-2}^1(\cos\theta) \\ & + \left[-2\beta\left(c_{2l} f_l'(r) + s_{2l} \frac{f_l(r)}{r} \right) \right] P_{l+2}^1(\cos\theta). \end{aligned} \tag{43}$$

Considering the expansion of $f(r)$ in terms of powers as in eq. (38), the stress becomes

$$\frac{2}{\alpha_3}\sigma_{\varphi r} = \sum_{l=1}^{\infty} \sum_{j=l,l+2,\ldots} \Big[q_{j,l} N_{1j,l} + q_{j,l+2} N_{2j,l} + q_{j,l-2} N_{3j,l} \Big] r^{j-1} P_l^1(\cos\theta), \tag{44}$$

where

$$\begin{aligned} N_{1j,l} &= \frac{3 + 9\beta - 2l(2+3\beta) - 2l^2(2+3\beta) + j\left(-3 + 4l + 4l^2 + 3\beta\right)}{-3 + 4l + 4l^2}, \\ N_{2j,l} &= -\frac{2(3 + j + l)\left(6 + 5l + l^2\right)\ \beta}{(3+2l)(5+2l)}, \\ N_{3j,l} &= -\frac{2(2 + j - l)\left(2 - 3l + l^2\right)\beta}{3 - 8l + 4l^2}. \end{aligned} \tag{45}$$

Due to the orthogonality of the associated Legendre functions, the boundary condition for the displacement on the surface of the sphere $r = a$ for $l = 1, 2, ...$, gives from eqs. (24), (25), (30) and (38)

$$\sum_{j=l,l+2,\ldots} q_{j,l} a^j = b_{1l} w_l j_l(k_s a) + g_{1l} w_l h_l^{(1)}(k_s a). \tag{46}$$

The stress boundary condition likewise gives from eqs. (26) and (44)

$$\begin{aligned} \sum_{j=l,l+2,\ldots} \Big[q_{j,l} N_{1j,l} + q_{j,l+2} N_{2j,l} + q_{j,l-2} N_{3j,l} \Big] a^{j-1} =& \gamma r b_{1l} w_l \frac{d}{dr}\left(\frac{j_l(k_s r)}{r}\right)\Big|_{r=a} \\ &+ \gamma r g_{1l} w_l \frac{d}{dr}\left(\frac{h_l^{(1)}(k_s r)}{r}\right)\Big|_{r=a}, \end{aligned} \tag{47}$$

where $\gamma = 2\mu/\alpha_3$ is the ratio of the stiffness outside the sphere and the mean stiffness inside the sphere. These equations together with eq. (41) are sufficient to find all the unknowns g_{1l} and $q_{j,l}$ expressed in terms of the incident wave coefficients b_{1l}. Therefore, the solution outside the sphere in the isotropic medium can be derived using eqs. (24) and (25)

$$u_\varphi(r,\theta) = \sum_{l=1}^{\infty} \Big(b_{1l} j_l(k_s r) + g_{1l} h_l^{(1)}(k_s r) \Big) w_l P_l^1(\cos\theta). \tag{48}$$

Here the coefficients g_{1l} of the scattered field are to be determined by using the derived system of equations, where the expansion coefficients of the incoming field are known. For incident plane SH wave, the b_{1l} are

$$b_{1l} = i^l \sqrt{2\pi(2l+1)}. \tag{49}$$

4 THE RAYLEIGH LIMIT

A scattering problem can be simplified by considering extreme values of the geometrical or physical parameters that enter the scattering process. For instance, when the size of the sphere is much smaller than the wavelength of the incident wave, or in other words, when the sphere disturbs only a small fraction of the full incident plane wave, only lower degrees of the scattered wave are significant. This is known as low-frequency scattering, also known as the Rayleigh

limit. For such a problem, the interior displacement field can be expanded to a specific (low) order j_{max} and the regularity condition requires that $l_{max} \leq j_{max}$. Here, $j_{max} = l_{max} = 4$ is considered. The problem can be decoupled into $l = 1, 3$ and $l = 2, 4$. For the $l = 1, 3$ part the following equations are derived from the continuity conditions given in eqs. (46) and (47)

$$q_{1,1}a + q_{3,1}a^3 = b_{11}w_1 j_1(k_s a) + g_{11}w_1 h_1^{(1)}(k_s a), \tag{50}$$

$$q_{3,3}a^3 = b_{13}w_3 j_3(k_s a) + g_{13}w_3 h_3^{(1)}(k_s a), \tag{51}$$

$$\begin{aligned}\frac{2}{5}(5+3\beta)q_{3,1}a^2 - \frac{24}{5}\beta q_{3,3}a^2 =& b_{11}\gamma a w_1 \frac{d}{dr}\left(\frac{j_1(k_s r)}{r}\right)\Big|_{r=a} \\ &+ g_{11}\gamma a w_1 \frac{d}{dr}\left(\frac{h_1^{(1)}(k_s r)}{r}\right)\Big|_{r=a},\end{aligned} \tag{52}$$

$$\begin{aligned}-\frac{8}{15}\beta q_{3,1}a^2 + (2 - \frac{6}{5}\beta)q_{3,3}a^2 =& b_{13}\gamma a w_1 \frac{d}{dr}\left(\frac{j_3(k_s r)}{r}\right)\Big|_{r=a} \\ &+ g_{13}\gamma a w_3 \frac{d}{dr}\left(\frac{h_3^{(1)}(k_s r)}{r}\right)\Big|_{r=a},\end{aligned} \tag{53}$$

which contains the five unknowns $g_{11}, g_{13}, q_{1,1}, q_{3,1}$ and $q_{3,3}$. The additional equation needed comes from eq. (41) which is zero identically for $l = 1, j = 1$ and $l = 3, j = 3$, and is as follows for $l = 1, j = 3$

$$k^2 q_{1,1} + 2(5+3\beta)\beta q_{3,1} - 24\beta q_{3,3} = 0. \tag{54}$$

For solving the system of equations, it is convenient to use the series expansion of the spherical Bessel and Hankel functions, where at low frequencies two terms at most are sufficient. Solving the system of equations the $\mathbf{T}$ matrix is derived based on eq. (10) for elements relating to SH waves ($\tau = 1$) and for $m = 0, \sigma = e$ and different values of l. These matrix elements are simply denoted $T_{ll'}$ and has the following value for T_{11}

$$T_{11} = -\frac{ik_s^3 a^5(-k^2 + \gamma k_s^2)}{45\gamma} = -\frac{ik_s^5 a^5}{45}(1 - \frac{\rho_1}{\rho}). \tag{55}$$

As $l = 1$ corresponds to a rigid body rotation at low frequencies, this element only depends on the density of the sphere, not on the stiffness properties of the sphere. Consequently, this element is identical to the one for an isotropic sphere with the same density.

The $l = 2, 4$ part gives

$$q_{2,2}a^2 + q_{4,2}a^4 = b_{12}w_2 j_2(k_s a) + g_{12}w_2 h_2^{(1)}(k_s a), \tag{56}$$

$$q_{4,4}a^4 = b_{14}w_4 j_4(k_s a) + g_{14}w_4 h_4^{(1)}(k_s a), \tag{57}$$

$$(1-\beta)q_{2,2}a-\frac{1}{7}(-21+5\beta)q_{4,2}a^3-\frac{40}{7}\beta q_{4,4}a^3 = b_{12}\gamma a w_2\frac{d}{dr}\left(\frac{j_2(k_sr)}{r}\right)\Bigg|_{r=a} + g_{12}\gamma a w_2\frac{d}{dr}\left(\frac{h_2^{(1)}(k_sr)}{r}\right)\Bigg|_{r=a}, \tag{58}$$

$$-\frac{24}{35}\beta q_{4,2}a^3+(3-\frac{9}{7}\beta)q_{4,4}a^3 = b_{14}\gamma a w_4\frac{d}{dr}\left(\frac{j_4(k_sr)}{r}\right)\Bigg|_{r=a} + g_{14}\gamma a w_4\frac{d}{dr}\left(\frac{h_4^{(1)}(k_sr)}{r}\right)\Bigg|_{r=a}, \tag{59}$$

which contains five unknowns $g_{12}, g_{14}, q_{2,2}, q_{4,2}$ and $q_{4,4}$. The additional equation from eq. (41) for $l=2, j=4$ is

$$k^2q_{2,2}+2(7+\beta)\beta q_{4,2}-40\beta q_{4,4}=0. \tag{60}$$

The result of solving the system of equations for the first $\mathbf{T}$ matrix element T_{22} (using the asymptotic form of the spherical Bessel and Hankel functions) is

$$T_{22}=-\frac{ik_s^5a^5(\beta+\gamma-1)}{45(\beta-4\gamma-1)}. \tag{61}$$

In the isotropic limit $\beta=0$ and $\gamma=\mu/\mu_1$, this is in agreement with the corresponding isotropic $\mathbf{T}$ matrix element.

To determine other elements of the $\mathbf{T}$ matrix $T_{ll'}$, it is necessary to truncate the expansion of the displacement field inside the sphere at l_{max} in which $l_{max}>l+2$ and $l_{max}>l'+2$, since there is coupling between the $l, l-2$ and $l+2$ degrees of the associated Legendre functions inside the sphere. For instance to evaluate T_{13}, T_{31} and T_{33}, $l_{max}\geq 5$ must be considered. Expanding the displacement field inside the sphere to $j_{max}=l_{max}=5$, the following result for the $\mathbf{T}$ matrix elements is obtained

$$\begin{aligned}
T_{11} =& -\frac{ik_s^5a^5}{45}(1-\frac{\rho_1}{\rho}) \\
&+\frac{ik_s^3a^7}{23625}\left(125k_s^4-\frac{175k^2k_s^2}{\gamma}+\frac{k^4\left(-70\beta^2+87\beta\gamma+5(7+3\gamma)(2+5\gamma)\right)}{\gamma^2L_1}\right), \\
T_{13} =& T_{31}=\frac{i4\sqrt{2}k^2k_s^5a^7}{1125\sqrt{7}}\frac{\beta}{L_1}, \quad T_{33}=-\frac{i2k_s^7a^7}{7875}\frac{5\left(-1+\beta^2\right)+(5+3\beta)\gamma}{L_1}, \\
T_{22} =& -\frac{ik_s^5a^5(\beta+\gamma-1)}{45L_2}+\frac{ik_s^5a^7}{189}\frac{3k^2\gamma+k_s^2\left(\beta^2-5\gamma^2-\beta(2+\gamma)+\gamma+1\right)}{L_2^2},
\end{aligned} \tag{62}$$

where

$$L_1=2\left(-1+\beta^2\right)-(5+3\beta)\gamma, \qquad L_2=\beta-4\gamma-1, \tag{63}$$

This is all $\mathbf{T}$ matrix elements that are of order $(k_sa)^5$ and $(k_sa)^7$, higher order elements are all smaller, going at least as $(k_sa)^9$.

5 Numerical Results

The numerical implementation is straightforward, the only parameter to check is the truncation j_{max} and l_{max}. The validity of the computations can be checked in three ways. The first is to look at the special case of isotropy and this is exactly fulfilled as the method reduces to the standard separation-of-variables solution for this case. The other two is to check the T matrix for symmetry and "hermicity" [17], which are both only valid for lossless media, i.e. real stiffnesses. Symmetry is due to reciprocity and is exactly fulfilled in the Rayleigh limit and more or less exactly fulfilled numerically. "Hermicity" is due to energy conservation and this gives the following relation for the T matrix (in matrix notation)

$$T^{\dagger}T = -\mathrm{Re}T \tag{64}$$

where the dagger denotes the Hermitian conjugate (taking both the transpose and the complex conjugate). This is a very good nonlinear check (but of course it is only necessary, not sufficient). This check is not possible to apply in the Rayleigh limit as the leading order terms are all imaginary and the leading order real terms are much smaller and are thus not calculated. For higher frequencies it is possible to perform this check numerically and this has been done with a very satisfactory result. For $k_s a = 5$, for instance, this relation is satisfied to 4 digits when the truncation $j_{max} = 20, l_{max} = 10$ is used and to 7 digits for $j_{max} = 24, l_{max} = 12$.

One physical quantity that is often calculated is the far field amplitude which is defined according to

$$u^{sc} = F(\theta)\frac{e^{ik_s r}}{k_s r}, \tag{65}$$

where the asymptotic behaviour of the spherical Hankel function for the scattered field is used and the far field amplitude is

$$F(\theta) = \sum_{l=1} i^{l+1} g_{1l} w_l P_l^1(\cos\theta). \tag{66}$$

For numerical illustration, the absolute value of the far field amplitude for cases with the material of the sphere denser and stiffer than the surrounding is calculated. Therefore, $\rho_1/\rho = 2$ and $\gamma = 0.2$ is assigned for all cases. The degree of anisotropy is given by the parameter $\zeta = (C11 - C12)/(2C44)$, which is the quotient between the two shear stiffnesses inside the sphere. The frequency is specified by the parameter $k_s a$. The computations are performed both numerically and in the Rayleigh limit to order $(k_s a)^5$ and $(k_s a)^7$.

First the validity of the Rayleigh limit is examined for an anisotropic sphere with stiffness quotient $\zeta = 0.2$. Figure 2 shows the normalized far field amplitude of the sphere in the $\theta = 3\pi/4$ direction as a function of frequency. As the T matrix goes as $(k_s a)^5$ for low frequencies the normalization is $F(3\pi/4)/(k_s a)^5$. The Rayleigh limit with only $(k_s a)^5$ is shown dashed and with including $(k_s a)^7$ is shown dash-dotted, and the numerical result with $j_{max} = 24, l_{max} = 12$ is shown dotted. These are also compared with the far field amplitude of the isotropic sphere when $\zeta = 1$ (full-drawn). A good agreement between the Rayleigh limit and the numerical result is observed for low frequencies (approximately $k_s a < 0.3$ by considering $(k_s a)^5$ terms and $k_s a < 0.8$ by including $(k_s a)^7$ terms). Also, the effect of anisotropy is considerable even for low frequencies.

To illustrate the effect of anisotropy, Figure 3 shows a polar plot (for $0 \leq \theta \leq \pi$) of the absolute value of the far field amplitude of the anisotropic sphere for $k_s a = 2$ and different

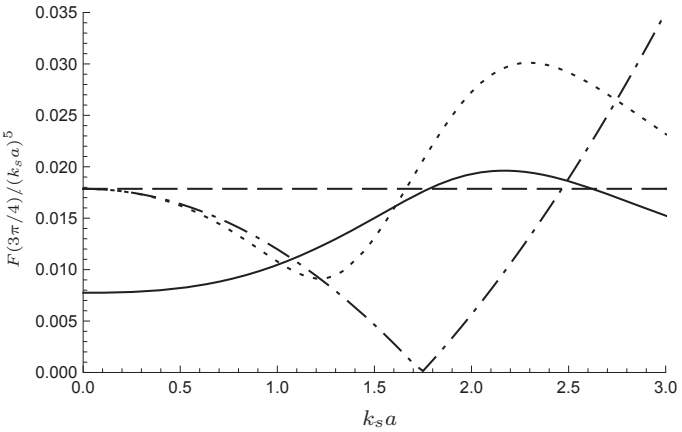

Figure 2: The normalized far field amplitude as a function of frequency $k_s a$ in the $\theta = 3\pi/4$ direction for the density ratio $\rho_1/\rho = 2$ and stiffness ratio $\gamma = 0.2$. Curves are given for a transversely isotropic sphere with stiffness quotient $\zeta = 0.2$, both with numerical computations (dotted) and in the Rayleigh limit (two curves, one with only $(k_s a)^5$ terms (dashed) and one with including also $(k_s a)^7$ terms (dash-dotted)). Also the result for an isotropic sphere ($\zeta = 1$, full-drawn) is included.

values of the stiffness quotient: $\zeta = 10$ (full-drawn), 2 (dashed), 0.5 (dotted), 0.1 (dash-dotted). This is also compared with the isotropic case (i.e. $\zeta = 1$) on the left side of the figure. Figure 4 illustrates the same situation for the higher frequency $k_s a = 5$, which shows somewhat stronger effects due to the anisotropy.

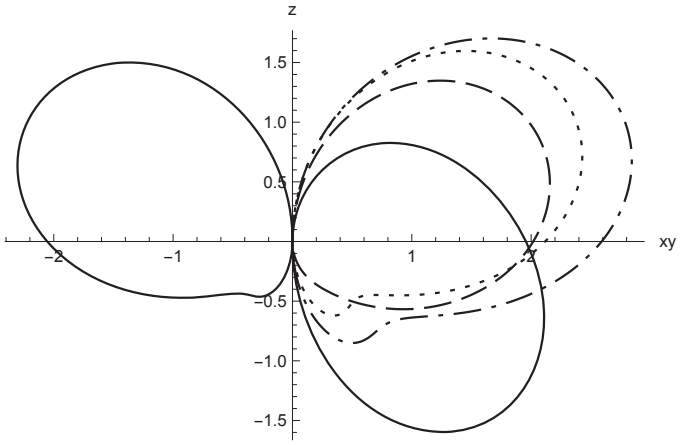

Figure 3: The far field amplitude for the frequency $k_s a = 2$, density ratio $\rho_1/\rho = 2$ and stiffness ratio $\gamma = 0.2$ for the isotropic sphere ($\zeta = 1$) on the left side and transversely isotropic sphere with stiffness quotient $\zeta = 10$ (full-drawn), 2 (dashed), 0.5 (dotted), 0.1 (dash–dotted), on the right side.

6 CONCLUSIONS

The scattering problem for a transversely isotropic sphere inside an isotropic medium for an incident SH wave in the z direction is considered. Transformation of the constitutive equations from Cartesian to spherical coordinates results in complicated expressions for the equations of motion and stresses inside the sphere. Expanding the displacement field in associated Legendre functions of order 1 in θ and power series expansions in r, leads to recursion relations for the expansion coefficients that couple different polar degrees (in contrast to an isotropic sphere where there is no such coupling). Applying the boundary conditions on the sphere the $\mathbf{T}$ matrix elements can be obtained. Explicit expressions are obtained for the $\mathbf{T}$ matrix elements for low

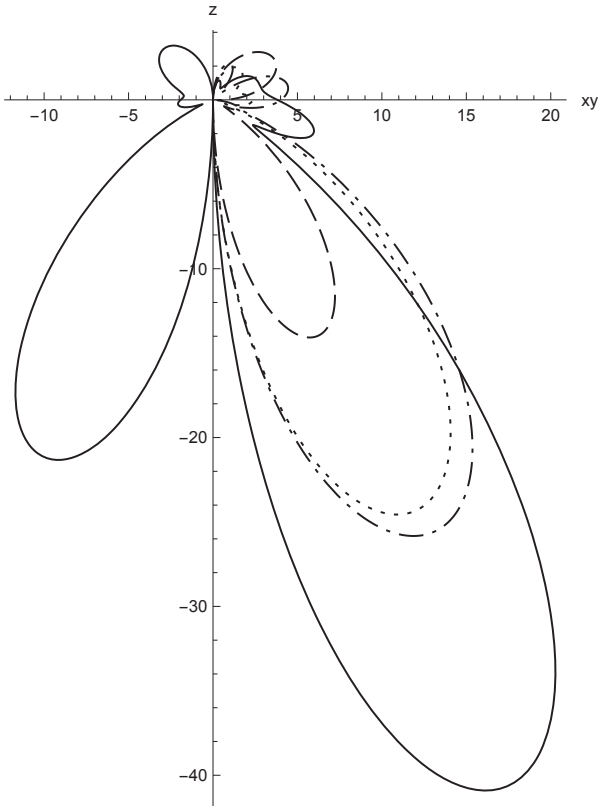

Figure 4: The far field amplitude for the frequency $k_s a = 5$, density ratio $\rho_1/\rho = 2$ and stiffness ratio $\gamma = 0.2$ for the isotropic sphere ($\zeta = 1$) on the left side and transversely isotropic sphere with stiffness quotient $\zeta = 10$ (full-drawn), 2 (dashed), 0.5 (dotted), 0.1 (dash–dotted), on the right side.

frequencies.

The present calculations for the SH waves in low frequencies are of limited interest as these $\mathbf{T}$ matrix elements are not of leading order (the P-SV waves are expected to behave as $(ka)^3$ as they do in the isotropic case). However, the present article also includes the necessary expressions for the stresses expressed in spherical coordinates for the general case. The present approach is applicable to this general case as well and such work is in progress.

The calculated $\mathbf{T}$ matrix elements can be used for various purposes. One important application is in the estimation of damping and phase velocities in polycrystalline materials, typically metals. The grains in such materials are far from spherical, but at low frequencies (when the grains are much smaller than the wavelength) the grain shape is not very important as the scattering is mainly a volume effect. For damping calculations in 2D this approach has been shown to give excellent agreement with FEM computations (Boström and Rudá [16]).

Keywords: Method of fundamental solutions, elastodynamics, soil-structure interaction, railway tunnels, layered half-space.

Abstract. *In this paper, a new prediction methodology to deal with longitudinally invariant soil-structure interaction problems in elastodynamics is presented. The method uses the finite-element method to model the structure, the boundary-element method to model the local soil surrounding the structure and the method of fundamental solutions to model the wave propagation through the soil. All those methods are formulated in the two-and-a-half-dimensional domain. The methodology is firstly verified in the framework of a homogeneous half-space system by comparing the results of the current method with those computed by the semi-analytical solution of this problem. Secondly, the methodology is verified against a two-and-a-half-dimensional finite element-boundary element approach, for two calculation examples: a tunnel embedded in a homogeneous half-space and a tunnel embedded in a layered half-space. This comparison also shows that this novel methodology reduces the computational costs of such simulations without compromising the accuracy of the results. The increase on the computational efficiency is due to the use of the method of fundamental solutions to account for the wave propagation in the medium, and it is even higher when the number of evaluations points increases.*

1 INTRODUCTION

In the framework of soil-structure interaction problems, some structures can be considered as longitudinally invariant systems that can be assessed by two-and-half-dimensional approaches. Structures like at-grade railway tracks [4], tunnels [1], roads [2] or bridges [3] are some examples of soil-structure problems where the structure can be modelled as longitudinally invariant system. A review of the literature indicates that there are several works that contributed to the study of this kind of soil-structure interaction problems. Among them, coupled 2.5D finite element-boundary element methodology (2.5D FEM-BEM) is a well-known numerical approach for the assessment of the soil-structure interaction problems. François et al. [2] presented a 2.5D FEM-BEM model in frequency domain. They proposed this method to study the wave propagation in soil induced by railway or road traffic using this method. Galvín et al. [4] used the same method to analyse two different applications: a ballasted track over a layered half-space and a tunnel embedded in a layered half-space. Lopes et al. [5] proposed an alternative method where a 2.5D FEM with 2.5D perfect matched layers (PML) is used to assess the ground-borne vibration response of a building. Later, the re-radiated noise inside the building was investigated using a 2.5D MFS in acoustics weakly coupled with the building vibration field obtained with the method presented in [5] [6]. More recently, Ghangale and his colleagues [7] presented a method for the prediction of the energy flow radiated by underground railway infrastructures based on a 2.5D FEM-BEM method to model the tunnel and the locally surrounding ground and on the semi-analytical solutions of a cylindrical cavity to model the wave propagation on the soil.

The MFS is a collocation method which approximates the solution within an elastic medium employing a combination of fundamental solutions of the medium governing equations. It is specially interesting for dealing with wave propagation problems in unbounded or partially unbounded domains. Its application is based on a distribution of collocation points, which evaluates the boundary conditions at discrete positions, and on a distribution of source points (or virtual forces, in elastodynamic problems), which are obtained by complying the boundary conditions at the collocation points. The collocation points are located on the boundary and the source points outside the domain. Godinho et al. [11] presented two-dimensional FEM-MFS modelling approach for these types of problems. An extension of this to longitudinally invariant systems was presented by Amado-Mendes and his colleagues [1], where a methodology that models the structure using 2.5D FEM and the surrounding soil with 2.5D MFS is proposed. For many years, it has been a concern of the researchers to find the optimal distance between collocation and source points, particularly in complicated shapes. An incorrect selection of this distance may lead to large errors of the numerical method [9]. Besides, it should be noted that the amount of source points affects the numerical convergence and stability of the results [10].

In this study, a 2.5D FEM-BEM-MFS method in frequency domain is presented. The 2.5D FEM-BEM is used to obtain the displacement field on the boundary and the 2.5D MFS is used as a post-processing tool to obtain the displacement and traction fields on the soil from the displacement field on the soil-structure interaction boundary. The main novelty of the current method is, thus, the way MFS is applied, which leads to two global benefits. On the one hand, the application of this methodology results to an increase of the computational efficiency of the method respect to traditional 2.5D FEM-BEM approaches and this is mostly significant when many evaluator points are to be analysed. On the other hand, a significant difference between the work of Amado-Mendes et al. [1] and the current method is related about how the dynamic stiffness matrix of the soil at the soil-structure interaction boundary is obtained.

2 Description of the methodology

In this study, the calculations are performed in two general steps. Firstly, the displacements on the boundary are computed through a 2.5D FEM-BEM method. In this 2.5D FEM-BEM approach, the FEM is used to model the structure and the BEM is used to model the locally surrounding soil. The formulation of the 2.5D FEM-BEM used here is based on [2]. The response of the soil-structure system can be calculated by

$$\left[\mathbf{K}_0 - \mathbf{i}k_x\mathbf{K}_1 + {k_x}^2\mathbf{K}_2 + \bar{\mathbf{K}}_s - \omega^2\mathbf{M}\right]\bar{\boldsymbol{U}} = \bar{\boldsymbol{F}}, \tag{1}$$

where $\mathbf{K}_0$, $\mathbf{K}_1$, $\mathbf{K}_2$ and $\mathbf{M}$ are the stiffness and mass matrices related to the 2.5D FEM domain, $\bar{\mathbf{K}}_s$ is the dynamic stiffness matrix of the soil obtained by 2.5D BEM model, k_x is the longitudinal wavenumber and ω is the angular frequency. Moreover, $\bar{\boldsymbol{U}}$ and $\bar{\boldsymbol{F}}$ are the vectors of displacements and applied external forces along the mesh of the structure, respectively. Thus, the displacements $\bar{\boldsymbol{U}}_{\boldsymbol{b}}$ on the boundary can be extracted from $\bar{\boldsymbol{U}}$.

Secondly, the displacement and traction fields in the soil are calculated using a 2.5D MFS for elastodynamics. For this aim, the displacements on the boundary ($\bar{\boldsymbol{U}}_{\boldsymbol{b}}$) are considered as the boundary conditions of the MFS. Then, the virtual source strengths can be computed as

$$\bar{\boldsymbol{S}}_v = \bar{\mathbf{H}}_{cs}^{-1}\bar{\boldsymbol{U}}_c, \tag{2}$$

where $\bar{\boldsymbol{S}}_v$ is the vector of virtual source strengths, $\bar{\mathbf{H}}_{cs}$ represents the matrix of displacement Green's functions on the collocation points due to the virtual sources and $\bar{\boldsymbol{U}}_c$ represents the displacements at the collocation points. If the collocation points are considered to be directly the nodes of boundary mesh, $\bar{\boldsymbol{U}}_c = \bar{\boldsymbol{U}}_b$. If the configuration is different, the displacement in the collocation points $\bar{\boldsymbol{U}}_c$ should be obtained by interpolation along the boundary from $\bar{\boldsymbol{U}}_b$. In this study, the Green's function are computed by the ElastoDynamics Toolbox for MATLAB [8]. Given the source strengths, the displacement and traction fields can be calculated as

$$\bar{\boldsymbol{U}}_f = \bar{\mathbf{H}}_{fs}\bar{\boldsymbol{S}}_v, \quad \bar{\boldsymbol{T}}_f = \bar{\mathbf{H}}_{fs}^{\tau}\bar{\boldsymbol{S}}_v, \tag{3}$$

where $\bar{\mathbf{H}}_{fs}$ and $\bar{\mathbf{H}}_{fs}^{\tau}$ represent the source-evaluators Green's functions for displacements and tractions, respectively, and $\bar{\boldsymbol{U}}_f$ and $\bar{\boldsymbol{T}}_f$ stand for the displacement and traction of the evaluation points, inside the domain.

In order to improve the computational efficiency of the method, a mapping technique is used. In this technique, the Green's displacement and Green's traction fields are calculated for the unique values of the sources depth and relative distances of the source-receiver points. Then, these Green's functions are mapped into the original configuration of sources and evaluation points by performing the required coordinate rotations [7].

3 Verification of the method for a homogeneous half-space problem

The proposed method is firstly verified for a solid cylinder with a radius of 3 m embedded in a homogeneous half-space, a system illustrated in Fig. 1. In order to compare with the semi-analytical solutions of a homogeneous half-space for verification purposes, the solid cylinder is assumed to be defined by the exact same mechanical parameters than the soil. The mechanical parameters of the soil are defined in Table 1. The vertical displacements obtained with the new

method are plotted against the results obtained by the semi-analytical solution of the problem and by the 2.5D FEM-BEM approach for a wavenumber of 0.1 rad/m. Results of this verification are shown in terms of displacement Green's functions in the wavenumber-frequency domain, presented in dB based on reference of 10^{-12} m/(N/m).

Type	E [MPa]	ρ [kg/m^3]	ν	Damping
Cylinder	108	1800	$1/3$	0.05
Soil	108	1800	$1/3$	0.05

Table 1: Mechanical parameters of the solid cylinder and the soil.

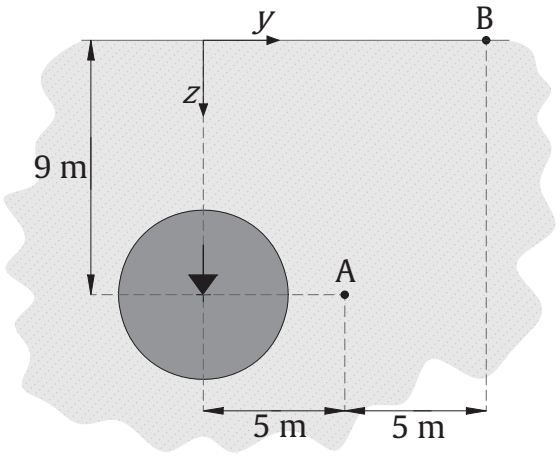

Figure 1: Geometry of the system studied, based on a solid cylinder in a homogeneous half-space. A and B represent the field points on the soil where the results will be obtained. The input vertical force applied at the center of the cylinder is represented by a big arrow.

According to the results presented in Fig. 2, very good agreement of the results is observed between the three methods compared. The results of the current method and those obtained by 2.5D FEM-BEM method are almost exactly matched. However, a slight difference can be observed between the results of the proposed method and semi-analytical solution, particularly at frequencies higher than 60 Hz, due to the mesh size.

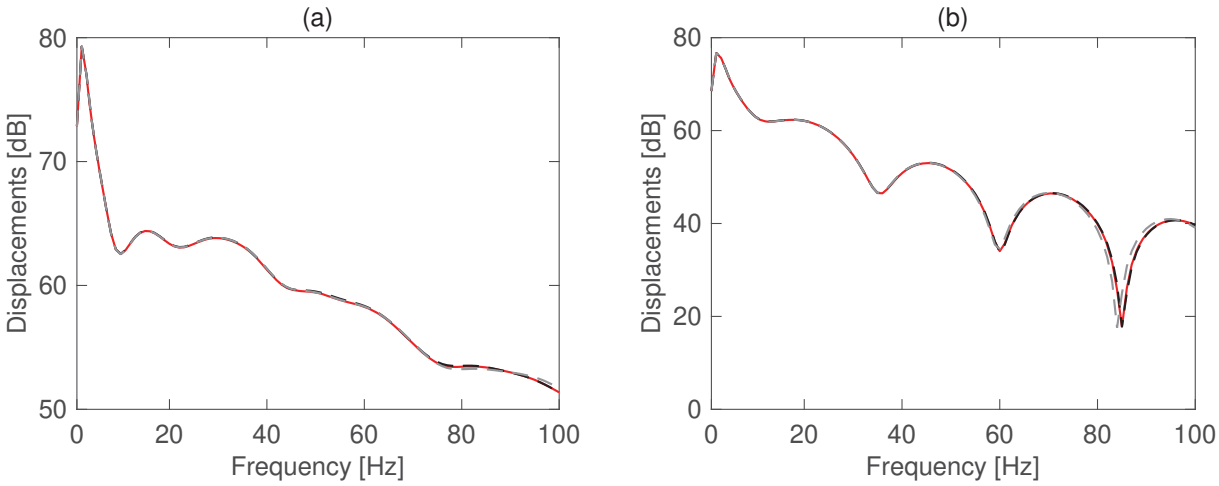

Figure 2: Vertical displacement Green's functions at evaluation points A (a) and B (b). Methods: 2.5D FEM-BEM (solid red line), 2.5D FEM-BEM-MFS (dashed black line) and semi-analytical solution (dashed gray line).

4 Verification of the method for the case of a tunnel embedded in a half-space

In this section, the methodology is verified against a 2.5D FEM-BEM approach, for two calculation examples: a tunnel embedded in a homogeneous half-space and a tunnel embedded in a layered half-space. In these examples, the comparison is done in terms of the displacement Green's function due to a vertical force applied in the bottom of the tunnel and for the wavenumber of 0.1 rad/m. The mechanical parameters of the soil and tunnel are presented in Table 2 and Table 3 for the homogeneous and layered half-space cases, respectively. In the example of a tunnel embedded in a layered half-space, the soil is divided into three layers.

Type	E [MPa]	ρ [kg/m^3]	ν	Damping
Tunnel	31000	2500	0.2	0.001
Medium	108	1800	$1/3$	0.05

Table 2: Mechanical parameters of the tunnel and the soil for the homogeneous half-space case.

Type	E [MPa]	ρ [kg/m^3]	ν	Thickness [m]	Damping
Tunnel	31000	2500	0.2	–	0.001
Soil layer 1	50	1900	0.3	4	0.05
Soil layer 2	180	1980	0.3	9	0.05
Soil layer 3	400	2050	0.3	∞	0.05

Table 3: Mechanical parameters of the tunnel and the soil for the layered half-space case.

4.1 A tunnel embedded in a homogeneous half-space

The application of the methodology for a tunnel embedded in a homogeneous half-space is studied. As shown in Fig. 3, a tunnel embedded in a homogeneous half-space at a depth of 9 m

from the ground surface is assumed. The external radius and the lining thickness of the tunnel are 3 m and 0.3 m, respectively. A single vertical point load is considered to be acting on the bottom surface of the tunnel. Two evaluation points, one on the near field (A), one in the far field (B) are assumed in the soil. The vertical displacements obtained by the proposed methodology are compared with those obtained by the 2.5D FEM-BEM approach. This comparison is shown in Fig. 4, where the left graph represents the vertical displacements in the point A and right figure denotes the vertical displacements at point B.

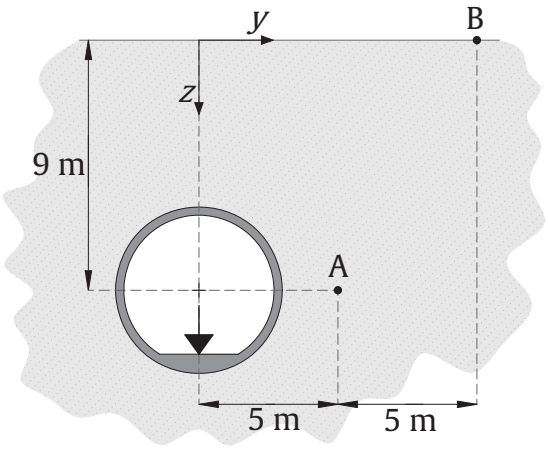

Figure 3: Geometry of the second system studied, based on a tunnel embedded in a homogeneous half-space. A and B represent the field points on the soil where the results will be obtained. The input vertical force is represented by a big arrow.

As presented in Fig. 4, the vertical displacements obtained by the 2.5D FEM-BEM-MFS are in a very good agreement with respect to those obtained with the 2.5D FEM-BEM approach.

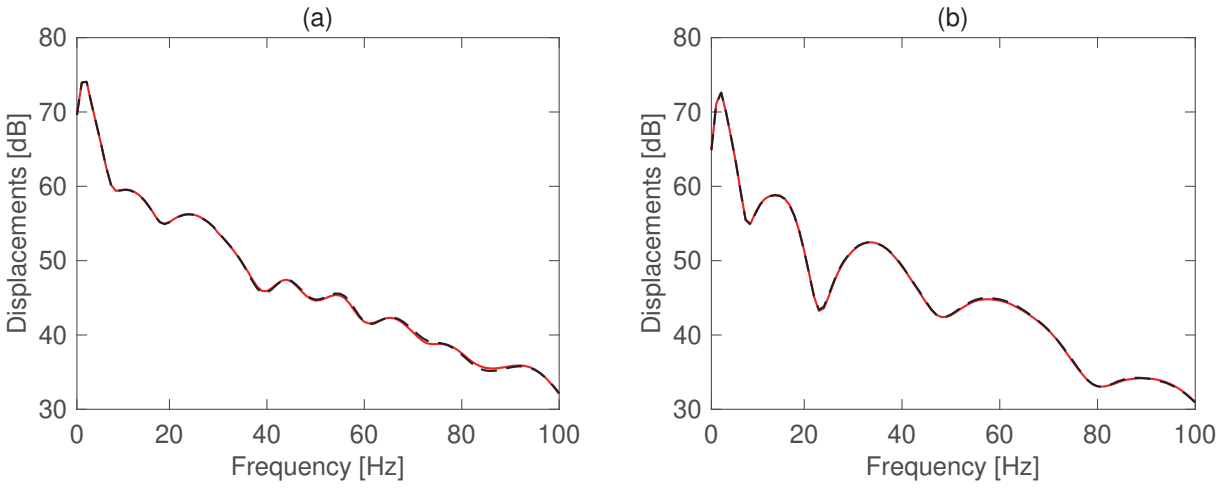

Figure 4: Vertical displacement Green's functions for the system in Fig. 3. Methods: 2.5D FEM-BEM (solid red line) and 2.5D FEM-BEM-MFS (dashed black line).

4.2 A tunnel embedded in a layered half-space

In order to investigate the performance of the method for a tunnel embedded in a layered half-space, another example is presented in this section. As can be observed in Fig. 5, a tunnel structure is located in the second layer and two field points are assumed in the soil (A and B). The geometry of the tunnel is the same as previous example.

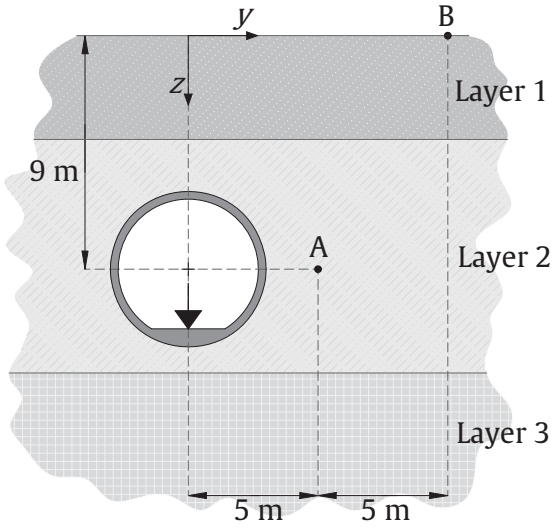

Figure 5: Geometry of the third system studied, based on a tunnel embedded in a layered half-space. A and B represent the field points on the soil where the results will be obtained. The input vertical force is represented by a big arrow.

The results confirms that the proposed methodology can be used for the case of layered half-space. Based on Fig. 6, the results of the current methodology are again consistent with the results of the 2.5D FEM-BEM approach. However, a slight difference can be observed at frequencies higher than 60 Hz for the point A.

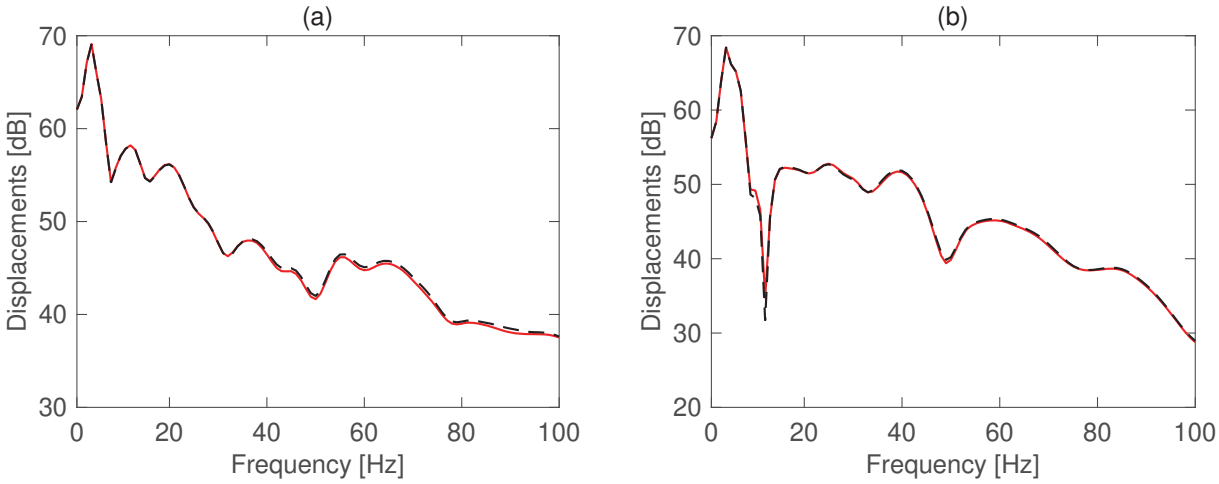

Figure 6: Vertical displacement Green's functions for the system in Fig. 5 at evaluation points A (a) and B (b). Methods: 2.5D FEM-BEM (solid red line) and 2.5D FEM-BEM-MFS (dashed black line).

5 CONCLUSIONS

In this study, a methodology is presented to deal with longitudinally invariant soil-structure interaction problems in elastodynamics. The methodology is firstly verified for the case of a solid cylinder embedded in a homogeneous half-space, having the structure and the soil the same mechanical parameters. Then, the performance of the model is investigated by presenting two calculation examples; a tunnel embedded in a homogeneous half-space and a tunnel embedded in a layered half-space. The results obtained for the three cases studied confirm that the accuracy of the new 2.5D FEM-BEM-MFS method is in agreement with those obtained by 2.5D FEM-BEM, especially in the far field results. Furthermore, the inclusion of the MFS as a post-processing tool has found to be very simple to be implemented. However, it is also found, as was expected, that the accuracy of the 2.5D FEM-BEM-MFS strongly depends on the accuracy of the boundary conditions obtained by 2.5D FEM-BEM method. Moreover, the displacement and traction Green's functions in the field points can be obtained in x, y and z directions. However, in this paper, only the vertical displacements are presented.

The accuracy of the results can be improved considerably by controlling the robustness of the method. To do so, a check point can be assumed in the domain and the distance between virtual sources and collocation points can be optimised by minimising the relative error between the current method and 2.5D FEM-BEM approach at this control point.

Keywords: Dynamic pile-soil interaction, Pile foundations, substructuring method.

Abstract. *This paper proposes a new semi-analytical approach for the computation of the dynamic response of a pile embedded in a half-space when it is subjected to a vertical harmonic load applied at the pile head or to loading from an incident wave field. The proposed approach considers the soil as an elastic half-space medium. In order to capture all essential dynamic behaviour of the pile-soil interaction avoiding large computational efforts, the system is modelled using the substructuring method in which the displacements and forces in a set of uniformly distributed points along the pile shaft are compatibilized with another set of coupling points in the soil also uniformly distributed along the virtual interaction area between the pile and the soil. The paper aims to study the accuracy and computational efficiency of this approach in comparison with two other methodologies: a numerical approach based on axisymmetric finite elements and perfect-matched layers, and against the approximate analytical approach based on linear elasticity developed by Novak. These comparisons reveal that the dynamic response for driving-point, far-field or incident wave-field problems can be predicted with acceptable accuracy and computational efficiency when the number of interaction points in the system increases.*

1 INTRODUCTION

Ground-borne vibration is an important cause of annoyance to nearby buildings inhabitants, malfunction on precision devices in surrounding facilities or even structural damage. These negative effects occurs when the ground-borne vibration incident wave-field excites the building structure through its foundations, being piled foundations one of the most common types. There are different models used to study the dynamic response of a single pile embedded in a half-space, which can be classified into three broad groups [6]. First group is based on the dynamic Winkler foundation approach, attributed as earliest building foundations dynamic models. In that method, the soil medium is modelled by infinitesimally, thin, independent, horizontal layers, meaning that waves can be only propagated in horizontal direction. This approach is adopted in the Novak's benchmark research [10], where the dynamic response of single piles is found throughout an Euler-Bernoulli beam and axial rod models of the pile for the lateral and vertical responses, respectively, which include the soil reaction directly in their differential equations of motion. The second type of methods are based on modelling the soil as an elastic medium. They are proposed to account for wave propagation in the soil in all directions. A relevant model of this method was presented by Kaynia and Kausel [3], where a general formulation for the prediction of the dynamic response of single piles and pile groups embedded in a layered half-space is presented. In this method the soil is also modelled as an elastic half-space while the piles are modelled as Euler-Bernoulli beams and axial rods. Furthermore, forces and displacements of each substructure (soil and pile) are compatibilised in a set of coupling points in order to compute the response of the system. These coupling points are defined when the whole traction acting on the virtual soil-pile interface is segmented along the pile shaft. Where, each segment is identified by a node and placed in its center. Therefore, each node represents either the load acting on the lateral surface of the pile (called barrel load distribution), or the load which is related to the pile-tip surface (called disk load distribution). Recently, the PiP model developed by Forrest [2] was adapted by Kuo et al. [7, 8] in order to create a three-dimensional single-pile dynamic model, which is formulated in the wavenumber domain and uses mirror-image sources to simulate a half-space and the finite length of the piles. Ntotsios et al. [11] developed two methods for the dynamic response of piled foundations where the approach for the coupling technique is similar to the one proposed by Kaynia in [3]. Euler beam and axial rod formulations are again used to model the pile. The dynamic compatibility between the pile and the soil is performed by distributing the displacements and forces in discrete points along the pile shaft over an annulus on the soil, with mean radius equal to the pile radius and a thickness of one-tenth of that, except for the pile-tip, where the distribution is done over a circular disk with the same radius than the pile. On their first method, the response of the soil is computed using the thin layer method (TLM), while in the second approach, the boundary element method (BEM) is used to model the soil medium with the pile cavity. Finally, numerical approaches are also an interesting modelling option for piled foundations. With the finite element method (FEM) [5, 4], the non-linear behaviour of the soil and its interaction with the pile can be introduced. However, the computation of FEM models requires large computational efforts, mostly when high frequency analysis is performed. Furthermore, the FEM applied to wave propagation problems in the soil requires the implementation of energy-absorbing boundaries to simulate an unbounded medium [1]. The BEM is another alternative to be used for this type of problems in order to model the soil, where the use of energy-absorbing boundaries is not required.

In some piled foundation problems where only the pile-driving response is required, the Winkler foundation approach could be enough to compute the dynamic response. When the soil

response is required or when the coupled response between piles is desired to be computed, the low accuracy of this method for these problems releases the numerical approach as the most suitable method to compute the dynamic response without decreasing accuracy. However, the usage of these methods is usually complex and they inherently have high computational requirements. For these reasons, the aim of this paper is presenting a new semi-analytical approach for the computation of the dynamic response of a single pile embedded in a half-space when it is subjected to a vertical harmonic load applied at the pile head or to the action of an incident wave-field. The benefits are its computational efficiency keeping high accuracy levels and the simplicity of its implementation in a computer algorithm, becoming a suitable tool for design use by practising engineers.

2 SINGLE PILE-SOIL MODEL

The current section starts describing the assumptions adopted in the present work. Then, the resulting formulation of the pile-soil model presented here is described. This pile-soil model is mainly constructed using dynamic substructuring techniques. Thus, the dynamic behaviour of each substructure (the pile and the soil) is analysed separately to be later assembled using a coupling procedure. The assumptions followed here are:

- The pile is assumed to be perfectly elastic and it is modelled as a structural column member for the axial response. Lateral motion is not considered in the present work.
- The soil is considered to be a perfectly elastic homogeneous half-space.
- The non-linear effects associated to the soil-pile contact interaction, high strain levels or liquefaction of the soil are neglected.
- The coupling of sub-systems is performed in the basis of equilibrium of forces and compatibility of displacement conditions.

Fig. 1 illustrates the system of a single piled foundation embedded in a homogeneous half-space, which is the problem considered in this study. The system is subjected to a external time-harmonic vertical point load applied either at the pile head or on the soil. In the framework

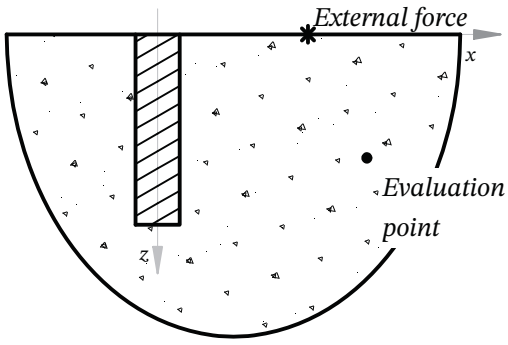

Figure 1: Single pile model.

of dynamic substructuring, the coupling between the pile and the soil is proposed to be done in a set of uniformly distributed coupling points. To do so, the soil-pile interaction traction,

distributed along the the soil-pile interface, is divided into $N+1$ segments (see Fig. 2a) and each of these segments is identified by its corresponding node, placed at the centre of each segment, at the pile shaft. First N nodes are related to the segments of traction acting on the lateral soil-pile surface (barrel loads, see Fig. 2b) while the segment associated to the node $N+1$ refers to the traction acting on the pile-tip (disk load, see Fig. 2c). Therefore, soil-pile interaction will be performed at those points, called coupling points, in where the force equilibrium and compatibility of displacement conditions are complied. The resulting compatibility equations are:

$$\mathbf{P}_p^c + \mathbf{P}_s^c = 0, \tag{1a}$$

$$\mathbf{U}_p^c = \mathbf{U}_s^c. \tag{1b}$$

where

$$\mathbf{P}_p^c = \begin{bmatrix} P_p^{c_1} & P_p^{c_2} & \dots & P_p^{c_{N+1}} \end{bmatrix}^{\mathrm{T}}, \tag{2a}$$

$$\mathbf{P}_s^c = \begin{bmatrix} P_s^{c_1} & P_s^{c_2} & \dots & P_s^{c_{N+1}} \end{bmatrix}^{\mathrm{T}}, \tag{2b}$$

$$\mathbf{U}_p^c = \begin{bmatrix} U_p^{c_1} & U_p^{c_2} & \dots & U_p^{c_{N+1}} \end{bmatrix}^{\mathrm{T}}, \tag{2c}$$

$$\mathbf{U}_s^c = \begin{bmatrix} U_s^{c_1} & U_s^{c_2} & \dots & U_s^{c_{N+1}} \end{bmatrix}^{\mathrm{T}}. \tag{2d}$$

The subscripts described in equations of the current section are referred to the corresponding substructure of the system (s, soil or p, pile). Coupling points, evaluation point or external force are referred by the superscripts c, e and f, respectively. Thus, in Eq. (1), $\mathbf{P}_p^c$ and $\mathbf{P}_s^c$ represent the vectors of vertical interaction forces acting on the pile and the soil, respectively (Eq. (2a),(2b)), while, $\mathbf{U}_p^c$ and $\mathbf{U}_s^c$ are referred to the vector of vertical displacements at the coupling points of the pile and soil, respectively (Eq. (2c),(2d)).

2.1 Response due to an external force applied in the pile head

Based on the dynamic system presented in the previous section, the displacements at the coupling points when the system is excited by an external vertical force applied in the pile head can be written as

$$\mathbf{U}_p^c = \mathbf{H}_p^{cf} F_p + \mathbf{H}_p^c \mathbf{P}_p^c, \tag{3a}$$

$$\mathbf{U}_s^c = \mathbf{H}_s^c \mathbf{P}_s^c, \tag{3b}$$

where the $\mathbf{H}_p^c$ and $\mathbf{H}_s^c$ represents the receptance matrices of the pile and the soil, respectively, at the coupling points, having a dimension of $(N+1) \times (N+1)$. The vector $\mathbf{H}_p^{cf}$ represent the receptance of the coupling points due to the external force F_p, which is applied at the pile head. Thus, the interaction forces at the coupling points in the pile can be obtained combining Eq. (3) with Eq. (1), that is

$$\mathbf{P}_p^c = -(\mathbf{H}_p^c + \mathbf{H}_s^c)^{-1} \mathbf{H}_p^{cf} F_p. \tag{4}$$

Finally, if the dynamic response of the system is required at the pile head, its driving-point response U_p is expressed by Eq. (5a), while if the evaluation points is placed on the soil, then its responses U_s is defined by Eq. (5b).

$$U_p = \mathbf{H}_p^{ec} \mathbf{P}_p^c + H_p^{ef} F_p, \tag{5a}$$

$$U_s = -\mathbf{H}_s^{ec} \mathbf{P}_p^c, \tag{5b}$$

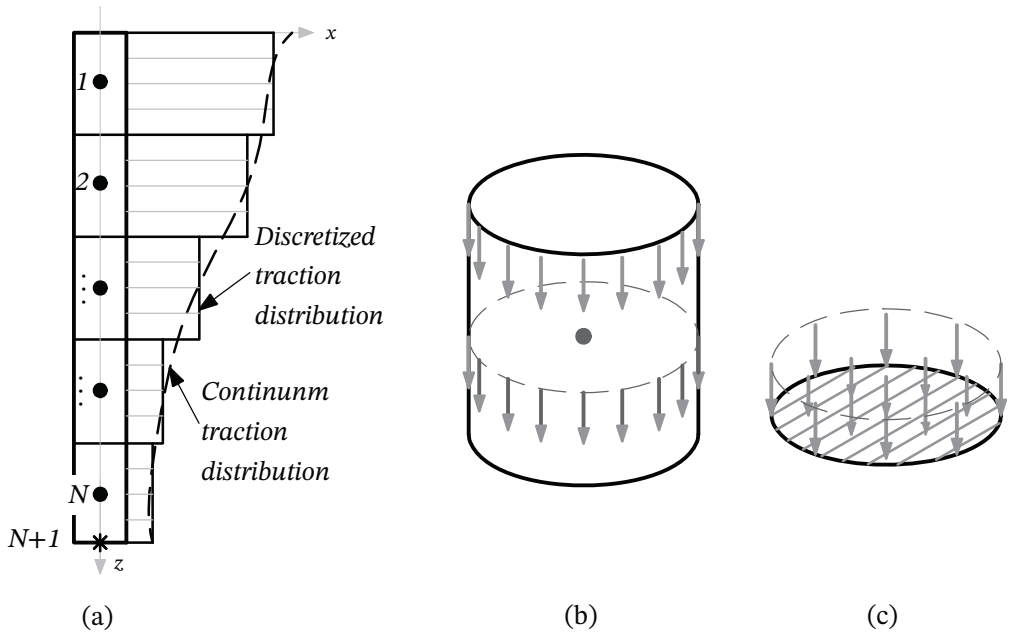

Figure 2: Discretisation of the pile-soil interaction traction (a), where segment from 1 to N represent to barrel type loads (black dots representing the coupling points) while the last segment $N+1$ depicts the disk type load (coupling point represented by star dot). Continuum barrel traction for the firsts N segments (b). Continuum disk traction for the last segment $N+1$ (c).

where $\mathbf{H}_p^{ec}$ and $\mathbf{H}_s^{ec}$ refers to the vector of receptances relating the response in the evaluation point, placed at the pile head or at the soil, respectively, due to the interaction forces $\mathbf{P}_p^c$, while the H_p^{ef} is the receptance of the evaluation point due to the external force F_p applied in the pile.

2.2 Response due to an external force applied in the soil

In the previous section, the system was subjected to an external force placed at the pile head. In the current section, the response of the pile to an incident wave-field due to an external vertical point load in the soil is formulated. In this case, the displacements in the coupling points in the point of view of the pile and the soil are

$$\mathbf{U}_p^c = \mathbf{H}_p^c \mathbf{P}_p^c, \tag{6a}$$

$$\mathbf{U}_s^c = \mathbf{H}_s^{cf} F_s + \mathbf{H}_s^c \mathbf{P}_s^c, \tag{6b}$$

respectively, being F_s the force applied on the soil and $\mathbf{H}_s^{cf}$ the receptance matrix that relates the displacement at the coupling points with the applied external force. Therefore, the corresponding interaction forces of the system are equal to:

$$\mathbf{P}_p^c = (\mathbf{H}_p^c + \mathbf{H}_s^c)^{-1} \mathbf{H}_s^{cf} F_s. \tag{7}$$

Thus, the dynamic response of the pile at the pile head U_p under an incident wave-field produced by F_s is given by:

$$U_p = \mathbf{H}_p^{ec} \mathbf{P}_p^c. \tag{8}$$

2.3 Soil receptance matrices

In order to compute the soil receptance matrices appearing in the previous sections, the soil-pile interaction traction in the point of view of the soil is discretised in a set of N_s uniformly

distributed points placed along the virtual pile perimeter for each pile segment, as shown in Fig. 3. This can be seen as a discretised form of the method proposed by Kaynia and Kausel [3]. The corresponding receptance matrix associated to all these points $\mathbf{H}_{sg}^{c}$ of $M \times M$ dimensions,

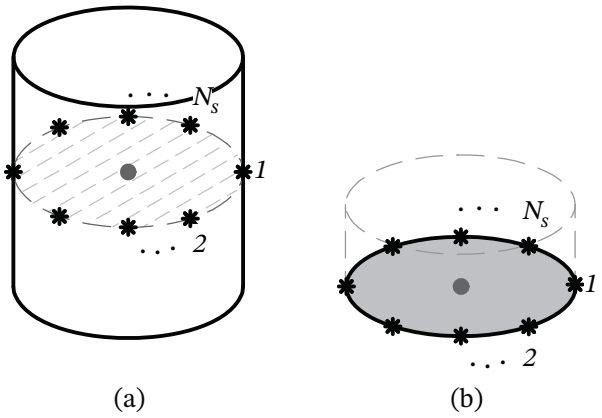

Figure 3: Traction segment discretised into N_s points for a: a) barrel type traction element. b) disk type traction element.

being $M = (N+1)N_s$, can be condensed into $\mathbf{H}_{s}^{c}$ by the expression:

$$\mathbf{H}_{s}^{c} = \mathbf{W}_d \mathbf{H}_{sg}^{c} \mathbf{W}_f \tag{9}$$

where $\mathbf{W}_d$ is the matrix which condense all N_s displacement values of each segment into a corresponding equivalent displacement. The matrix $\mathbf{W}_f$ applies the same concept for the case of the interaction forces. In both cases, this research is developed assuming a uniform distribution. Similarly, when an external force is applied in the soil, this procedure can be extended to compute the soil receptance matrix $\mathbf{H}_{s}^{cf}$. Finally, The Green's functions of the soil required to construct $\mathbf{H}_{sg}^{c}$ and the remaining soil receptances are computed using the ElastoDynamics Toolbox for MATLAB [12], which uses the direct stiffness matrix method to deal with wave propagation problems in horizontally layered media.

2.4 Pile receptance matrices

The receptance matrices related to the pile can be found assuming that the pile can be modelled as a simple rod structural member. Thus, the differential equation for the axial vibration of the pile in the time domain is described as

$$m_p \frac{\partial^2 u_z}{\partial t^2} - E_p A_p \frac{\partial^2 u_z}{\partial z^2} = 0. \tag{10}$$

In Eq. (10), the mass per unit of length is defined by m_p, while A_p and E_p are the cross-section area and the elastic modulus of the pile, respectively. Therefore, if an external force F_z is applied at the pile in some position z_1 of its shaft, the solution of Eq. (10) in the frequency domain for free-free rod is given by

$$\frac{U_z(z)}{F_z} = -\frac{\cos(\alpha z)[\cos(\alpha z_1) + \sin(\alpha z_1)\tan(\alpha L)]}{E_p A_p \alpha \tan(\alpha L)} \qquad 0 \quad \leq z \leq z_1, \tag{11a}$$

$$\frac{U_z(z)}{F_z} = -\frac{\cos(\alpha z_1)\cos(\alpha z)}{E_p A_p \alpha \tan(\alpha L)} - \frac{\cos(\alpha z_1)\sin(\alpha z)}{E_p A_p \alpha} \qquad z_1 \leq z \leq L, , \tag{11b}$$

$$\alpha = \frac{m_p \omega^2}{A_p E_p}, \tag{12}$$

in where L is the total length of the pile and ω is the circular frequency in which the dynamic analysis is performed.

3 COMPARISON OF THE MODEL

In this section, the accuracy of the new semi-analytical approach is analysed in order to demonstrate its applicability in different pile problems. The methods presented for the comparison are the new semi-analytical approach, the extended Novak approach [10] proposed by Kuo [7, 8] and an axisymmetric FEM-based approach with perfect matched layers (aFEM-PML). The aFEM-PML is based on an axissymmetric version of the method presented by [9] considering eight-noded square elements of 25 cm of side. In the extended Novak approach, the approximate far-field response using the Novak approach is obtained by the assumption that only cylindrical SV-waves can spread from the pile through the soil and just in radial direction [7, 8]. The parameters used to compute the results are as following: the pile has a length of $L = 20$ m and radius $r_p = 0.354$ m and it is made of concrete with density $\rho_p = 2800$ kg/m^3, Young's modulus $E_p = 40$ GPa, Poisson's ratio $\nu_p = 0.3$ and hysteretic damping ratio $\beta = 0.01$; while the soil is modelled as a homogeneous half-space elastic medium with density $\rho_s = 2250$ kg/m^3, shear modulus $G_s = 90$ MPa, Poisson's ratio $\nu_s = 0.4$ and hysteretic damping ratios for S- and P-waves equals to $D_s = 0.03$, $D_p = 0.03$, respectively. Furthermore, the range of frequency considered to perform the comparison is from 1 Hz to 80 Hz.

Plots in Fig. 4 show the driving-point response of the pile head. These responses are computed using different values of N and N_s and the results are compared with the outcomes from the Novak method. In this figure, a poor agreement in the response is observed when the pile has $N = 5$ coupling points, as shown in Fig. 4a, where the difference between the two methods rise until 11 dB over the frequency range of 80 Hz. Likewise, if the the number of coupling points is increased to $N = 10$ or $N = 15$ (see Fig. 4b and Fig. 4c) the response of the system presents a good agreement respect to results obtained by the Novak method (less of 2dB of variation) furthermore, the response computed by the current approach shows a smooth curve for the whole range of frequency. Finally, high accuracy is achieved (0.6 dB of variation) when the new semi-analytical method is applied with $N = 25$ coupling points, see Fig. 4d. This can be also seen in Fig. 5a, where the results obtained with the aFEM-PML method are also added in the comparison.

In Fig. 5, the new method is compared with the Novak and the aFEM-PML methods in terms of the response at the soil due to the action of a vertical harmonic force at the pile head. The response in the soil has been computed at the ground surface and at distances of 5 m, 10 m and 20 m from the pile shaft. For this comparison, the new method is applied assuming $N = 25$ and $N_s = 4$. It is observed that the Novak method shows large discrepancies with respect to the aFEM-PML model, mostly at large distances from the pile. That is due to the assumption adopted by Novak in his model and the consequent inaccuracy of the wave-spreading equations [7] in where the wave propagation in the soil due to the axial pile action is assumed to be based only on SV-waves. By other hand, the new semi-analytical model shows less than 2 dB, 1.5 dB and 1 dB of variations in comparison with the aFEM-PML method when the evaluation point and the pile shaft are at a distance of 5 m, 10 m, and 20 m, respectively. This shows that the agreement in the results for axial vibrations is good in the whole frequency range of interest.

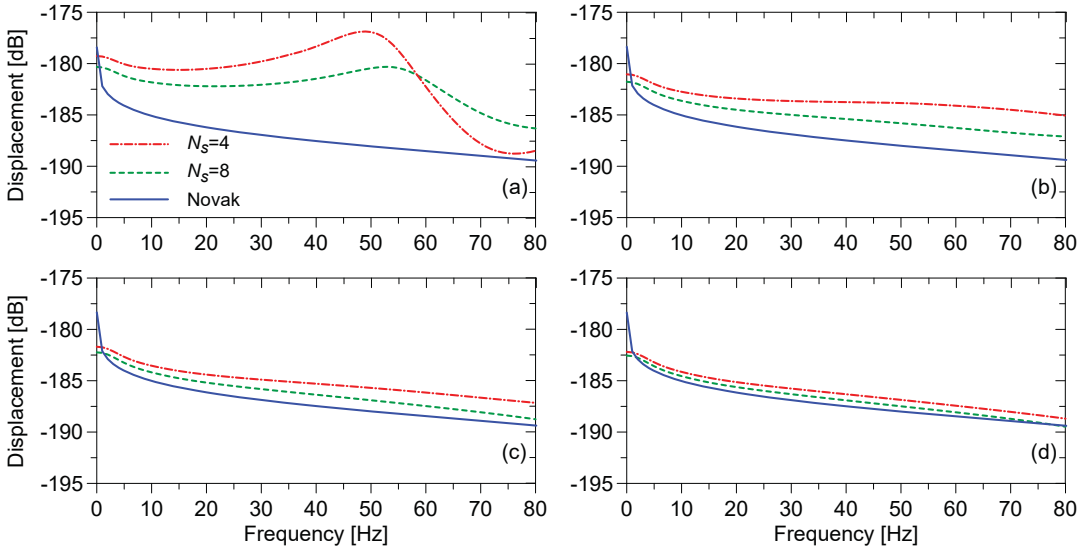

Figure 4: Driving-point response in dB (with a reference of 1 m/N). Cases: $N = 5$ (a), $N = 10$ (b), $N = 15$ (c) and $N = 25$ (d) coupling points.

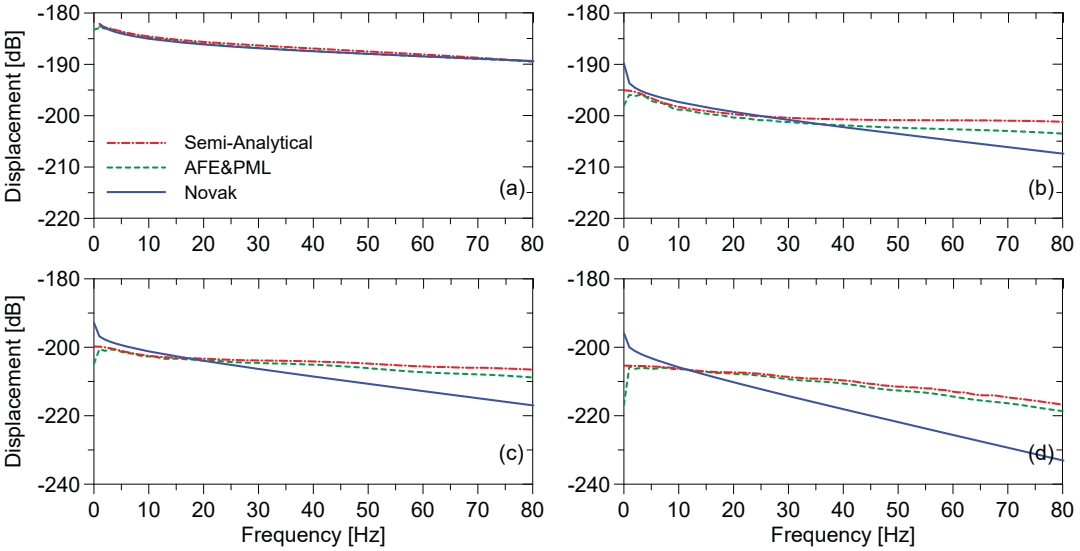

Figure 5: Displacement response in dB (with a reference of 1 m/N) due to an external force applied at the pile head considering with $N = 25$ and $N_s = 4$ for the semi-analytical approach. Cases: Driving-point response (a); response at 5 m (b); response at 10 m (c); and response at 20 m (d).

4 CONCLUSIONS

In this paper, a new semi-analytical modelling approach for the dynamic response of a single pile embedded in a half-space is presented. This new semi-analytical model captures the driving-point response of the pile reasonably well, with some differences at high frequencies (less than 1.5 dB) when the results obtained are compared against the Novak's method [10]. That agreement is obtained when the number of coupling points is equal to 25 and when the number of points used to discretise the traction distribution of each segment is eight. If the number of coupling points is less than 25, the differences in the dynamic response are high for the whole range of frequency.

When the response of the soil due to a force in the pile is required, the results obtained with the new approach present a good agreement in comparison with the aFEM-PML model. The aFEM-PML is an accurate numerical model that requires considerable computational costs, while the new approach is able to reach similar levels of accuracy using quite less resources and time, due to its semi-analytical nature. Novak method, in contrast, is showing a poor agreement with respect to the aFEM-PML method, an expected result due to simplifications on soil modelling inherent to the Novak's method. It can be concluded, then, that the new proposed semi-analytical method can provide accurate results on the soil response, being this feature of the method a significant benefit with respect to Novak's method.

Keywords: Structure-soil-structure interaction, seismic wave propagation, 3D finite element model.

Abstract. *The seismic response of buildings is generally obtained by modeling structures as isolated from surroundings. However, the structural vibration contributes through the soil to the excitation of adjacent structures and vise-versa. In this research, the structure-soil-structure interaction (SSSI) is studied questioning the influence of an adjacent construction, whose interference passes through the soil. Beneficial and detrimental cases are distinguished.*

The one-directional three-component wave propagation in a T-shaped soil profile (1DT-3C) is adopted as modeling technique to explore the effects of coupling seismic site effects, due to the local soil stratigraphy, with the SSSI, taking into account the foundation deformability and rocking. A three-dimensional model of each structure is adopted to estimate the seismic response taking into account the different mode shapes. This approach allows an easy analysis of SSSI to inspire the design of seismic risk mitigation tools and urban organization.

The seismic response of a reinforced concrete framed structure is numerically simulated by accounting for the effect of an adjacent structure in the linear elastic regime, in both cases of seismic loading exciting the target structure or the adjacent structure. The target to adjacent structure fundamental frequency ratio, is adopted as a key parameter influencing the SSSI phenomenon. In some cases, the effect of the adjacent structure resonance is more detrimental to the target structure than its own resonance as a single building. In other cases, a beneficial effect is obtained by the presence of the adjacent structure. The obtained results can be extended to understand the effect of an adjacent vibration control device.

1 INTRODUCTION

Nowadays, constructions tend to be built more closely to save space especially in big cities, although building codes still consider purely isolated structures in the design phase.

Structure-soil-structure interaction (SSSI) investigations to understand the effect of a nearby building have been undertaken by Luco and Contesse [1] using a two-dimensional analytical model. The effects of an existing second structure are more important for the case of a stiffer structure located close to a more deformable one. In particular, in case of resonance of the stiffer structure, its seismic base motion is significantly different from the one obtained when ignoring the 2nd nearby more deformable structure.

Warburton et al. [2] have found, through an analytical study, that the unexcited mass affects only slightly the response of the excited mass. On the other hand, the unexcited mass is largely influenced by the excited mass even for significant inter-distance. When the adjacent mass has no more influence (increasing inter-distance), the soil-structure interaction (SSI) increases with decreasing soil frequency.

A parametric numerical analysis undertaken by Aldaikh et al. [3], for three adjacent oscillators coupled through the soil, showed that there are detrimental and beneficial configurations of dynamic characteristics of buildings adjacent to the building under consideration. The authors considered that a central building is much more influenced by two adjacent buildings than when there is only one adjacent building. Regardless of the earthquake event features, the interaction generally amplifies the seismic energy seen by a building with two adjacent taller buildings. On the other hand, the effect of two adjacent slightly lower buildings was beneficial in their study.

Mizuno [4] has experimentally observed the SSSI with the consequent variation and possible increase of the structural response caused by the radiation waves from a nearby structure. Moreover, the excitation of a nearby structure induces energy dissipation. Under ambient vibration, the response of the building having low fundamental mode becomes larger than that of a single building, while the response of the building having high natural modes has an opposite trend.

Trombetta et al. [5] investigate the SSSI by centrifuge tests. During strong shaking, SSSI is found to be less significant; this could be due to a combination of superstructure yielding and saturation of footing forces. Consequently, from a design perspective, the results suggest that SSSI effects should be considered for low-to-moderate levels of earthquake shaking.

Nateghi and Rezaei-Tabrizi [6] use a two-dimensional FE model to study the nonlinear dynamic response of two adjacent tall framed buildings. When the soil and structure fundamental modes are close, the interaction between adjacent structures increase the nonlinear response, so it cannot be neglected.

According to Vicencio and Alexander [7], SSSI effects increase when considering loose soil and closely spaced buildings. The most adverse effects on building displacement occur when there is a big difference of height between the adjacent buildings. Moreover, soil nonlinearity can modify SSSI effects in adverse or beneficial way, so it should be accounted for. The nonlinear SSSI response acceleration is amplified for the case of a lower building flanked by a taller one; a beneficial effect can occur for the taller building but this reduction is not assured for the entire range of aspect ratios.

Exploiting SSSI, a device called vibration barrier (ViBa) behaving as an oscillator is proposed by Cacciola et al. [8]. The ViBa is able to reduce the seismic energy on its neighborhood structures and their seismic response. Tombari et al. [9] shows a reduced structural seismic response using a ViBa buried in the soil.

In this research, a parametric analysis is carried out to investigate the interference of an adjacent structure (AS) in the seismic response of a target structure (TS). The modeling technique proposed by Fares et al. [10] is adopted, consisting of a one-directional three-component seismic wave propagation in a T-shaped soil domain (1DT-3C).

2 1DT-3C WAVE PROPAGATION MODEL FOR SSSI

The soil basin is assumed as horizontally layered and infinitely extended. Shear and pressure waves propagate vertically from the top of the underlying elastic bedrock to the soil surface. The one-directional propagation of a three-component seismic wave in a T-shaped soil domain, assembled to one or more 3D building, is modeled in a finite element (FE) scheme, as proposed by Fares et al. [10]. A fully 3D soil domain is modeled until a fixed depth h, where SSI is not negligible. A one-dimensional model is then used for deeper layers, until the underlying elastic bedrock, represented by dashpots.

The soil domain area A is selected as the smallest for which the peak of the building base to bedrock transfer function corresponds to the soil column fundamental frequency in the free-field case (Santisi d'Avila and Lopez-Caballero [11]). Depth h is defined by a preliminary analysis defining the variation in stresses and strains in the soil due to SSI, compared with the free-field case (Fares et al. [10]). A constraint equation is assigned to condense out the degrees of freedom at the base of the 3D soil domain to those at the top of the unit area soil column. No strain variation is considered in the horizontal directions and, for this reason, a periodic lateral boundary condition is imposed at the lateral boundary surfaces.

The 3D frame structure is modeled using Timoshenko beam elements. The building shallow foundation is rigidly connected to the soil, node-by-node. The rotational degrees of freedom of nodes at the base of building columns are blocked. The damping due to structural and non-structural elements is taken into account by the damping submatrix related to the building that is assumed as mass and stiffness proportional, according to Rayleigh approach [12].

The discrete dynamic equilibrium equation is solved directly for the assembly of soil-foundations-structures (Figure 1). The dynamic process is solved step-by-step by the implicit Hilber-Hughes-Taylor algorithm [13]. Numerical damping is provided by the α-method using the parameters $\alpha = -0.1$, $\beta = 0.25(1-\alpha)^2 = 0.3025$ and $\gamma = 0.5 - \alpha = 0.6$ that guarantee an unconditionally numerical stability. The time step is automatically selected in the range between 10^{-4} s and the time step used for the input signal sampling. More details about the model are given by Fares et al. [10].

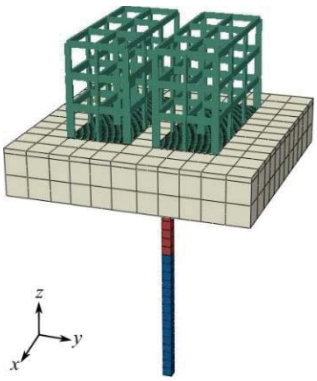

Figure 1: 1DT-3C model for structure-soil-structure interaction analysis.

3 INPUT DATA

A parametric analysis is carried out to study the influence of an AS on the dynamic response of a TS for various target to adjacent structure frequency ratio f_{TS}/f_{AS}, in linear elastic regime.

3.1 Soil profiles

Two soil profiles are used for the analysis, whose stratigraphy and mechanical parameters are given in Table 1. The profile shear velocity v_s is selected to obtain ground types C and D according to the Eurocode 8 classification [14]. The density ρ and the compressional wave velocity v_p are calculated according the relationships proposed by Boore [15]. Soil properties are assumed constant in each soil layer.

A squared soil area $A = 25\ \text{m} \times 25\ \text{m}$ is selected. A 3D soil domain is modeled until a depth $h = 5\ m$, that corresponds to the interface between the first and second soil layer, and a 1D model is used in deeper soil layers.

		Profile C $v_{s30} = 225\ \text{m/s}$, $f_s = 2.0\ \text{Hz}$			**Profile D** $v_{s30} = 173\ \text{m/s}$, $f_s = 1.5\ \text{Hz}$		
Depth	**Thickness**	**ρ**	**v_s**	**v_p**	**ρ**	**v_s**	**v_p**

15	10	1930	210	1347	1930	170	1275
30	15	1930	250	1417	1930	180	1293
>30		2100	1000	2449	2100	1000	2449

Table 1: Stratigraphy and mechanical properties of the analyzed soil profiles.

3.2 Reinforced concrete framed buildings

Five 3D framed structures are modeled. The number of stories is determined in order to obtain various building fundamental frequencies (Table 2). The floor area is defined arbitrarily because it has a negligible influence on the building fundamental frequency.

The column orientation and the floor plan dimensions are indicated in Figure 2. The structural elements size is given in Table 3. The load (sum of dead and live ones) is $700\ \text{kg/m}^2$. It is distributed on beams in x-direction, according to their influence area, as mass per unit length. The inter-story height is 3.2 m. All the analyzed buildings have a translational motion as first mode shape, in y-direction.

Building	**Floors**	**Floor plan**	**Frequency** Hz
1	3	b	4.6
2	3	a	3.8
3	5	b	2.6
4	5	a	2.2
5	7	a	1.5

Table 2: Fundamental frequency of fixed-based framed structures, corresponding to a translational mode shape in y-direction.

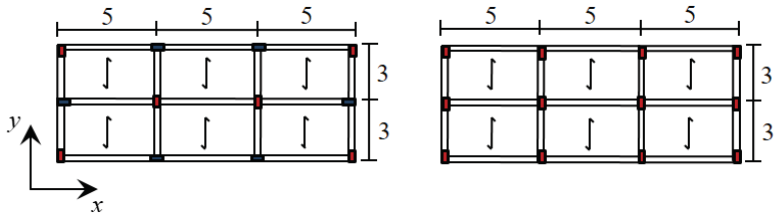

Figure 2: Floor plans of the analyzed buildings in the cases of same (a) and different (b) inertia to horizontal motion in the two orthogonal directions x and y. The buildings have the same floor dimensions but different column orientation.

	Buildings 1-2		Buildings 3-4		Building 5

2	30×70	30×70	30×70	30×70	30×70	30×70
3	30×60	30×60	30×60	30×60	30×60	30×60
4			30×60	30×60	30×60	30×60
5			30×60	30×60	30×60	30×60
6					30×60	30×60
7					30×60	30×60

Table 3: Dimensions of rectangular cross-section beams for the analyzed buildings.

The concrete mechanical properties considered are the elastic compression modulus $E_c = 31220\ \mathrm{N/mm^2}$ and the Poisson ratio $\nu_c = 0.2$. For reinforced concrete (RC) beam elements, it is assumed a shear correction factor $\chi = 0.857$, a density $\rho = 2500\ \mathrm{kg/m^3}$ and a damping ratio $\zeta = 5\%$. The foundation, embedded in the soil, is a RC slab which is 16 m long, 7 m wide and 0.5 m deep.

Each of the five framed buildings in Table 2 are assembled with the two T-shaped soil profiles described in Table 1. Moreover, 25 models are obtained, for each soil profile, where each building (Table 2) is close to a similar building and to the others. The distance between the shallow foundations in y-direction (Figure 1) is assumed to be equal to 0.1 m. The SSSI analysis is compared to the single building case (SSI). The models produced when assuming as TS, the building with fundamental frequency $f_{TS} = 1.5$ Hz, are shown in Figure 3.

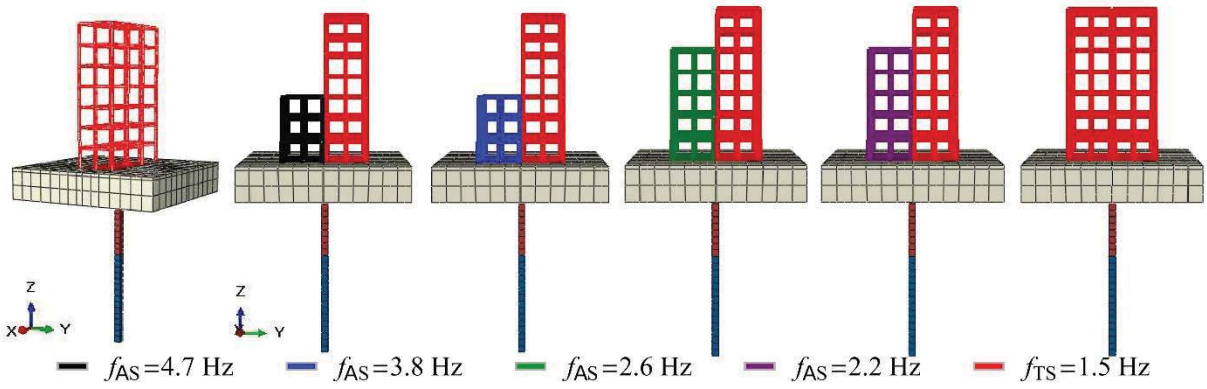

Figure 3 Soil-building systems for SSSI analysis, compared with SSI analysis (left). This figure represents the case where the target structure has fundamental frequency $f_{TS} = 1.5$ Hz.

3.3 Synthetic narrow-band seismic loading

The seismic loading is applied at the soil-bedrock interface in terms of viscous force, proportional to the motion velocity. In this research, a synthetic wavelet is used as input motion for the SSSI analysis, whose predominant frequency corresponds to the building fundamental mode.

The incident motion at the soil-bedrock interface is expressed in terms of velocity [16] as:

$$v_0(t) = v_{0\max}/2\left[1+\cos\left(2\pi f_q/n\,(t-t_0)\right)\right]\cos(2\pi f_q(t-t_0)) \qquad (1)$$

The motion duration is $2t_0$, where $t_0 = n/(2f_q)$ is the time of peak envelope, the predominant frequency is f_q and $n = 5$ is the number of cycles. The incident motion amplitude $v_{0\max}$ corresponds to a peak acceleration $a_{0\max} = 0.1\ \mathrm{m/s^2}$. The loading is applied in the y-direction (Figure 1).

4 SSSI ANALYSIS

In a first part of this parametric analysis, the seismic response of a TS is investigated in the case where the seismic loading excites its fundamental frequency f_{TS}. This means that the synthetic signal has predominant frequency $f_q = f_{TS}$. The ratio between the peak accelerations for SSSI and SSI analyses (a_{SSSI}/a_{SSI}), obtained at the top of the TS, with respect to the TS to AS fundamental frequency ratio f_{TS}/f_{AS}, is shown in Figure 4 for the two selected soil profiles.

At the resonance ($f_q = f_{TS}$), the response for a stiffer TS is not affected by the presence of the AS: it is similar to the single building case. On the contrary, when the AS is stiffer, the TS response is reduced by 30%, compared with the single building case.

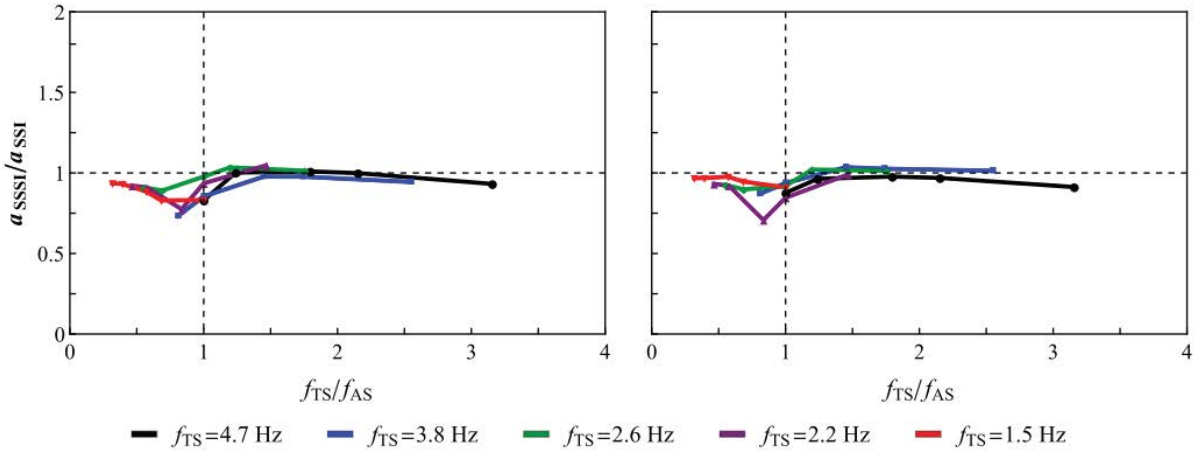

Figure 4: Ratio between the peak acceleration at the top of the target structure (TS) in a SSSI analysis and that in a SSI analysis (single excited building) versus the target to adjacent structure fundamental frequency ratio f_{TS}/f_{AS}, at the resonance of the TS ($f_q = f_{TS}$): soil profile having natural frequency $f_s = 1.5$ Hz (left) and $f_s = 2$ Hz (right).

In a second part of this analysis, the seismic response of a TS is investigated in the case where the seismic loading excites the fundamental frequency f_{AS} of the AS. This means that the synthetic signal has predominant frequency $f_q = f_{AS}$. Figure 5 presents the ratio between the SSSI and SSI peak accelerations (a_{SSSI}/a_{SSI}), obtained at the top of the TS, with respect to the TS to AS fundamental frequency ratio f_{TS}/f_{AS}, for the two selected soil profiles.

At the resonance of the AS ($f_q = f_{AS}$), when the TS is stiffer, its response is increased up to 50% due to the presence of an AS, compared to the single building case. In this situation, the

TS, as a single building, is also loaded by an input signal exciting the fundamental frequency f_{AS} of the AS. On the contrary, when the AS is stiffer, the TS response is reduced by 25%, compared with the single building case.

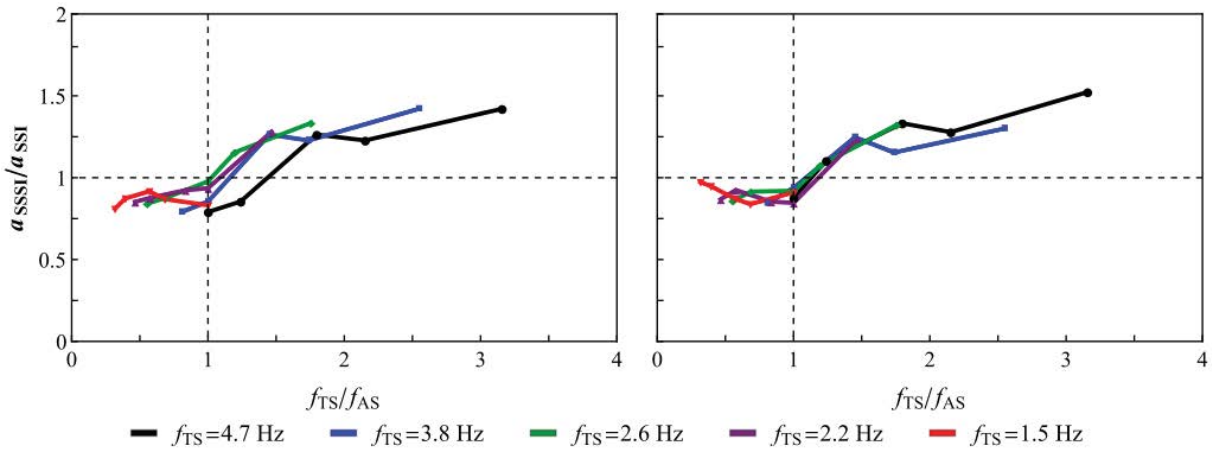

Figure 5: Ratio between the peak accelerations at the top of the target structure (TS) for SSSI (with adjacent strure AS) and SSI (single excited building) analyses when the AS is excited at its resonant mode ($f_q = f_{AS}$), vs. the TS to AS fundamental frequency ratio f_{TS}/f_{AS}, considering two soil profiles with different natural frequencies (left: $f_s = 1.5$ Hz; right: $f_s = 2$ Hz).

The TS response for SSSI analysis is then compared in both cases of TS and AS resonance (Figure 6). The TS response is higher at its resonance than at the resonance of the AS, except in the case of stiffer TS having fundamental frequency close to that of the AS. The TS response at its resonance is lower than at the resonance of the AS, for target to adjacent frequency ratio f_{TS}/f_{AS} in the range $[1 - 1.5]$.

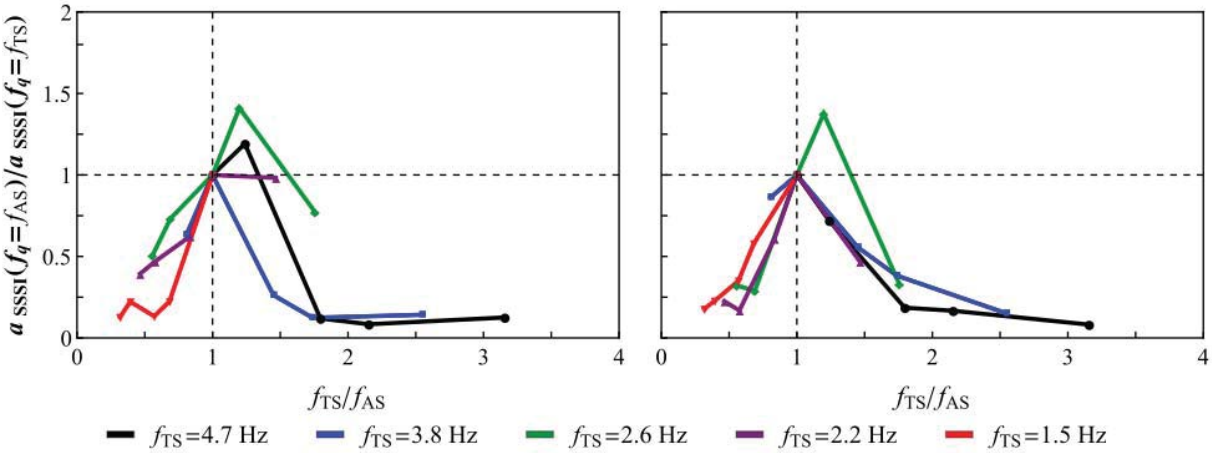

Figure 6: Ratios between the peak accelerations at the top of the TS for SSSI and SSI analyses when the AS is excited at its resonant mode, vs. the TS to AS fundamental frequency ratio f_{TS}/f_{AS}, considering two soil profiles with different natural frequencies (left: $f_s = 1.5$ Hz; right: $f_s = 2$ Hz).

The TS seismic response is compared for both cases: at its resonant mode ($f_q = f_{TS}$) as a single building and at the AS resonant mode ($f_q = f_{AS}$). In the first case (TS as a single building at resonance), TS response is generally higher than in the latter case except when the TS is stiffer with fundamental mode close to the AS one (Figure 7). However, the TS response for

the second case (resonance of an AS) is higher for TS to AS frequency ratio f_{TS}/f_{AS} in the range $[1-1.5]$.

These results are useful to identify the range of fundamental modes which a vibration reduction device should have to produce to obtain a beneficial effect in the vicinity of a TS.

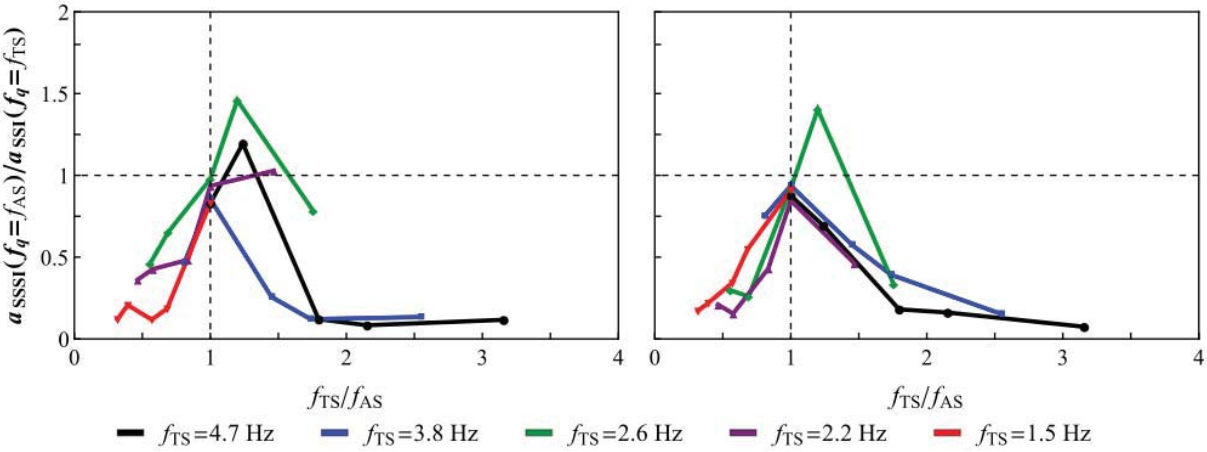

Figure 7: Ratio between the peak accelerations at the top of the TS for a SSSI analysis when the AS is excited and for a SSI analysis (single excited TS building), vs. to the TS to AS fundamental frequency ratio f_{TS}/f_{AS}, considering two soil profiles with different natural frequencies (left: $f_s = 1.5$ Hz; right: $f_s = 2$ Hz).

5 CONCLUSIONS

A parametric study has been carried out to investigate the effect of an adjacent structure (AS) on the seismic response of a target structure (TS). The seismic response is analyzed in the case of a single TS and in the presence of a nearby one.

The 1DT-3C wave propagation approach allows simulating the response of soil and structures to a three-component seismic motion, in a finite element scheme, accounting for foundation deformability, rocking effect, soil-structure interaction and interaction between close structures. Two reinforced framed structures having shallow foundation are assembled with a T-shaped soil domain.

In a structure-soil-structure interaction (SSSI) analysis, each building is modeled as close to a similar building and to others having various height and fundamental frequency. A similar trend is obtained for the seismic response of all the analyzed structures.

In this research, the focus is put on the TS top response. The variation of the peak acceleration versus the TS to AS fundamental frequency ratio is investigated, for SSSI and SSI analyses.

When the TS is stiffer, at its resonant mode, the response is not modified by the presence of the AS: it is similar to the single building case. On the contrary, at the AS resonant mode, the TS response is amplified due to the presence of an AS, compared to the single building case.

When the AS is stiffer, the TS response is reduced compared to the single building case in both cases of resonance (for TS and AS).

When comparing the TS response in both cases (TS or AS resonance), the acceleration at the top of the TS structure is higher for the TS resonance case when it is modeled as single building, except when considering a stiffer TS with fundamental mode close to the AS one. In this case of stiffer TS having fundamental frequency close to that of the AS, the highest response of the TS is obtained when it is modeled nearby the AS structure, at the resonance of the AS structure.

The proposed approach for SSSI analysis can be used to identify the range of fundamental modes which a vibration reduction device should have to produce to obtain a beneficial effect in the vicinity of a TS.

Keywords: Soil Dynamics, Soil-Structure-Interaction(SSI), Integral Transform Method, Finite Element Method, Wavenumber-Frequency Domain, Vibration Mitigation

Abstract. *In order to determine the wave propagation in unbounded media considering the interaction of structures with the soil and thus also their influence on the resulting wave field, an appropriate model is necessary. A efficient approach to account for the infinite extension of the soil by the analytical solutions of the Integral Transform Method (ITM) and for the irregular geometries of the structures by the Finite Element Method (FEM) is presented. The coupled ITM-FEM approach is applied for the assessment of the mitigation efficiency of infinite open or infilled trenches using a computationally profitable 2.5D approach. For spatially limited trenches a complete three dimensional model is used. Amplitude reduction factor and insertion loss are calculated for different combinations of soil and barrier material. The accuracy of the method is shown by comparison to analytical solutions and literature results.*

1 INTRODUCTION

In the modern urban environment, vibrations are caused by a variety of sources such as rail and road traffic, industrial- or construction machinery. These vibrations are transmitted into the soil causing disturbances in adjacent structures and annoyance of nearby residents. In order to attenuate the disrupting effects, mitigation measures can be installed at the source or the receiving structure. However, as a big part of the vibratory energy is transported by Rayleigh waves propagating in an area close to the ground surface, introducing suitable wave barriers in the transmission path leads to an appropriate reduction in the amplitude of the elastic waves on the side of the barrier averted from the source. Usually both, open and soft or stiff infilled trenches act as vibration isolating screens by reflecting and diffracting the incident waves.
A comprehensive amount of studies on the mitigation efficiency of open and infilled trenches can be found in literature. First field tests on the screening effect of rectangular open and bentonite filled trenches were conducted by Dolling [1]. Further measurements were performed by Woods [2], who clearly distinguished between active isolation, installing the open trench in the near field very close to the source, and passive isolation placing the trench in the far field, where the Rayleigh wave dominates the wave field. Numerical studies investigating the amplitude reduction of Rayleigh waves by open or concrete filled trenches using the Finite Element Method (FEM) in the frequency domain were presented by Segol et al. [3] and Haupt [4]. Later, the Boundary Element Method (BEM) was employed by Emad and Manolis [5] as well as Beskos et al. [6], Dasgupta et al. [7], Leung et al. [8], who used it to investigate the efficiency of open and infilled trenches due to harmonic sources. Ahmad and Al-Hussaini [9] performed an extensive parametric study on the effects of the dimensions and the filling material of trenches and barriers situated in a homogeneous as well as a layered soil. To be able to include more complex barrier and source compositions, still satisfying the radiation condition for infinite media, different FEM-BEM formulations were developed and used to predict the reduction of ground vibrations by wave barriers due to moving loads [10, 11, 12]. Mitigation measures aiming on the reduction of railway induced vibrations can be assumed to be longitudinally invariant. Coulier et al. [13] and François et al. [14] used a coupled 2.5D FEM-BEM approached based on [15] to investigate the effect of soft and stiff wave barriers, open trenches and subgrade stiffening next to the track.
In this paper an efficient domain decomposition method to model the three dimensional Soil-Structure-Interaction (SSI) is presented using a coupled Integral Transform Method (ITM) - Finite Element Method approach. The infinite soil is described by the analytical solutions of the ITM avoiding any non-physical reflections at artificial boundaries, whereas the FEM is used to model structures of more complex geometry and material distribution. Fully or partially embedded cylindrical or spherical cavities can be modeled, thus enabling the coupling of finite or longitudinally invariant structures within a matching FEM subsystem.
The outline of the paper is as follows. In section 2 firstly the fundamental solutions are introduced and superposed in order to obtain the stiffness matrix of the ITM subsystems in the respective reference system. Subsequently the dynamic stiffness of the FEM subsystems is presented, followed by the coupling of the substructures. A validation of the proposed method is shown in section 3 by comparison with the analytical solution of the homogeneous halfspace. In section 4, a 2.5D ITM-FEM approach is used to model infinite open trenches and infilled barriers. First, the results for a concrete filled trench and subgrade stiffening next to the track are checked against literature results. Second a comparison of the mitigation efficiency of very

soft or stiff barriers and an open trench is presented. Furthermore a 3D ITM-FEM model is used to investigate the screening efficiency of a spatially limited open trench for different load positions and frequencies. Finally the results for the length invariant open trench are directly opposed to those for the finite open trench.

2 ITM-FEM FORMULATION FOR ELASTODYNAMICS

2.1 Fundamental solutions

The dynamic behavior of an linear elastic, homogeneous and isotropic continuum can be described by the Lamé differential equation, which consists of three coupled partial differential equations

$$\mu u^i|^j_j + (\lambda + \mu)\, u^j|^i_j - \rho \ddot{u}^i = 0 \tag{1}$$

with the displacement field u^i, the Lamé constants μ and λ and the density ρ. Using a Helmholtz decomposition $u^i = \Phi|^i + \Psi_l|_k\, \varepsilon^{ikl}$ and thereby expressing the displacement field by the sum of the gradient of a scalar field Φ and the rotation of a vector field $\mathbf{\Psi}$, the system of equations turns into three decoupled wave equations in dependency of the wave velocities of the compressional c_p and the shear wave c_s (setting $\Psi_z = 0$ cp. [16]).

$$\Phi|^j_j - \frac{1}{c_p^2}\ddot{\Phi} = 0 \qquad\qquad \Psi_i|^j_j - \frac{1}{c_s^2}\ddot{\Psi} = 0 \tag{2}$$

The fundamental solutions for the systems halfspace, fullspace with cylindrical cavity and fullspace with spherical cavity are derived from (2) transforming the equations into the appropriate basis and then applying the respective local and non-local boundary conditions.

The system halfspace is solved in Cartesian coordinates (x, y, z) by using a threefold Fourier transform into the wavenumber-frequency domain (k_x, k_y, z, ω). Thus the coupled partial differential equations can be transformed into three decoupled ordinary differential equations that can be solved analytically with an exponential approach [17]:

$$\hat{\Phi} \;= A_1\, e^{\lambda_1 z} + A_2\, e^{-\lambda_1 z} \tag{3}$$

$$\hat{\Psi}_\alpha = B_{\alpha 1}\, e^{\lambda_2 z} + B_{\alpha 2}\, e^{-\lambda_2 z} \tag{4}$$

with $\alpha = x, y$, $\lambda_1 = \sqrt{{k_x}^2 + {k_y}^2 - k_p^2}$, $\lambda_2 = \sqrt{{k_x}^2 + {k_y}^2 - k_s^2}$ and $k_p = \frac{\omega}{c_p}$, $k_s = \frac{\omega}{c_s}$.

The system fullspace with cylindrical cavity is solved in cylindrical coordinates (x, r, φ) under application of a Fourier transform with respect to $x \circ\!\!-\!\!\bullet\, k_x$ and $t \circ\!\!-\!\!\bullet\, \omega$ as well as performing a Fourier Series expansion along the circumferential direction $\varphi \to n$. Furthermore the vector field $\mathbf{\Psi} = \Psi \mathbf{g}^1 + \chi|^j \varepsilon_{ij1} \mathbf{g}^i$ is expressed by two independent scalar fields. The respective system of equations is solved with Hankel functions of first and second kind [18]:

$$\hat{\Phi}\,(k_x, r, n, \omega) = C_{1n}\, H_n^{(1)}\,(k_1 r) + C_{4n}\, H_n^{(2)}\,(k_1 r) \tag{5}$$

$$\hat{\psi}\,(k_x, r, n, \omega) = C_{2n}\, H_n^{(1)}\,(k_2 r) + C_{5n}\, H_n^{(2)}\,(k_2 r) \tag{6}$$

$$\hat{\chi}\,(k_x, r, n, \omega) = C_{3n}\, H_n^{(1)}\,(k_2 r) + C_{6n}\, H_n^{(2)}\,(k_2 r) \tag{7}$$

with ${k_1}^2 = {k_p}^2 - {k_x}^2$ respectively ${k_2}^2 = {k_s}^2 - {k_x}^2$.

The system fullspace with spherical cavity is solved in spherical coordinates (r, φ, ϑ). All quantities on the spherical boundary are transformed into series of spherical harmonics $(\varphi, \vartheta \to$

$m, l)$ and a Fourier transform into the frequency domain is carried out. Thus the wave equations are solved in the (r, m, l, ω) domain by spherical Hankel functions of first and second kind [19]:

$$\hat{\Phi}\left(r, m, l, \omega\right) = C_{1lm}\; h_m^{(1)}\left(|k_p| r\right) + C_{4lm}\; h_m^{(2)}\left(|k_p| r\right) \tag{8}$$

$$\hat{\psi}\left(r, m, l, \omega\right) = C_{2lm}\; h_m^{(1)}\left(|k_s| r\right) + C_{5lm}\; h_m^{(2)}\left(|k_s| r\right) \tag{9}$$

$$\hat{\chi}\left(r, m, l, \omega\right) = C_{3lm}\; h_m^{(1)}\left(|k_s| r\right) + C_{6lm}\; h_m^{(2)}\left(|k_s| r\right) \tag{10}$$

For all three systems local stress boundary conditions are applied respectively on the halfspace surface Λ, the cylindrical cavity surface Γ_c or the spherical cavity surface Γ_s. Additionally employing the Sommerfeld radiation condition [20] the vector of unknown coefficients $\mathbf{C}_i$ can be determined for each system separately and the stresses and displacements due to unit load states at the surfaces can be calculated by $\hat{\boldsymbol{\sigma}}_i = \hat{\mathbf{K}}_i \mathbf{C}_i$ and $\hat{\mathbf{u}}_i = \hat{\mathbf{H}}_i \mathbf{C}_i$, where $i = hs, c, s$ stands for the different fundamental systems and $\hat{\mathbf{K}}_i$, $\hat{\mathbf{H}}_i$ are the matrices including the fundamental solutions, kinematic and material relations linking the unknowns with the stresses and the displacements. A detailed derivation of the solutions of the fundamental systems as well as the matrices for the calculation of the $\hat{\boldsymbol{\sigma}}_i$ and $\hat{\mathbf{u}}_i$ can be found in [21, 22] and [23].

2.2 Superposition of fundamental systems

The superposition of two of the fundamental systems each is now used to satisfy the boundary conditions of the complete system at both surfaces. Therefore the halfspace is superposed with the fullspace with cylindrical cavity resulting in a halfspace with cylindrical cavity. Furthermore the halfspace is superposed with the fullspace with spherical cavity to obtain the system of a halfspace with spherical cavity. For this reason fictitious surfaces $\delta\Lambda$ resp. $\delta\Gamma_j$ (with $j = c, s$ for the cylinder resp. the sphere) are introduced into the fundamental systems allowing a superposition at the common surfaces as depicted in Figure 1. Thus, loading the halfspace with unit stress states $\hat{\boldsymbol{\sigma}}_\Lambda$ at Λ for each wavenumber combination (k_x, k_y), the stresses $\hat{\boldsymbol{\sigma}}_{\delta\Gamma_j}^{(\Lambda)}$ at the fictitious surface $\delta\Gamma_j$ can be determined. The other way round, the stresses $\hat{\boldsymbol{\sigma}}_{\delta\Lambda}^{(\Gamma_j)}$ at $\delta\Lambda$ due to unit stress states $\hat{\boldsymbol{\sigma}}_{\Gamma_j}$ at Γ_j for each of the respective series members (n resp. m, l) can be calculated. The sum of the stresses at Λ and Γ_j has then to be equal to the external loads $\hat{\boldsymbol{p}}_\Lambda$ and $\hat{\boldsymbol{p}}_{\Gamma_j}$ acting on the complete system. Thus the scaling factors $\mathbf{C_{ITM}}$ for the unit stresses and the

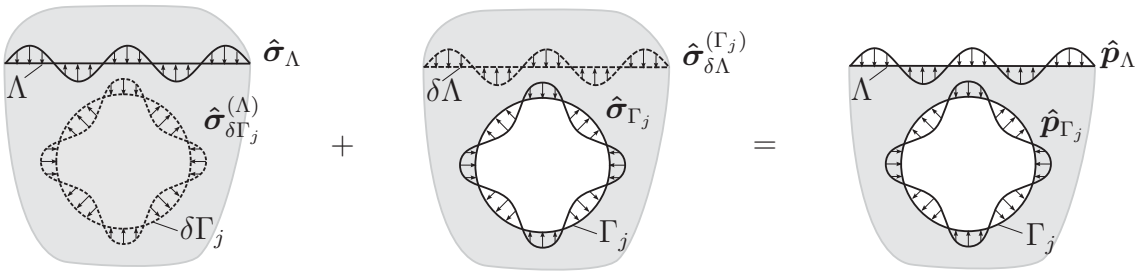

Figure 1: Fictitious surfaces and stresses at the surfaces due to unit stress states.

stresses at the fictitious boundaries, gathered in $\hat{\mathbf{S}}_{\mathbf{ITM}}$, can be determined in dependency of the total external load $\hat{\mathbf{P}}_{\mathbf{ITM}}$ on Λ and Γ_j as:

$$\mathbf{C_{ITM}} = \hat{\mathbf{S}}_{\mathbf{ITM}}^{-1} \hat{\mathbf{P}}_{\mathbf{ITM}} \tag{11}$$

Subsequently, also the resulting displacements $\hat{\mathbf{u}}_{\mathbf{ITM}}$ at Λ and Γ_j can be calculated from the displacements due the unit stresses, gathered in $\hat{\mathbf{V}}_{\mathbf{ITM}}$, scaled with the amplitudes $\mathbf{C}_{\mathbf{ITM}}$:

$$\hat{\mathbf{u}}_{\mathbf{ITM}} = \hat{\mathbf{V}}_{\mathbf{ITM}}\, \mathbf{C}_{\mathbf{ITM}} \tag{12}$$

Combining equations (11) and (12) the stiffness matrix $\hat{\mathbf{K}}_{\mathbf{ITM}} = \hat{\mathbf{S}}_{\mathbf{ITM}} \hat{\mathbf{V}}_{\mathbf{ITM}}^{-1}$ of the ITM subsystem for a halfspace with cylindrical or spherical cavity is obtained giving a direct relation between the displacements and the external loads:

$$\underbrace{\begin{bmatrix} \hat{\mathbf{K}}_{\mathbf{\Lambda\Lambda}_{\mathbf{ITM}}} & \hat{\mathbf{K}}_{\mathbf{\Lambda\Gamma}_{\mathbf{j\,ITM}}} \\ \hat{\mathbf{K}}_{\mathbf{\Gamma}_{\mathbf{j}}\mathbf{\Lambda}_{\mathbf{ITM}}} & \hat{\mathbf{K}}_{\mathbf{\Gamma}_{\mathbf{j}}\mathbf{\Gamma}_{\mathbf{j\,ITM}}} \end{bmatrix}}_{\hat{\mathbf{K}}_{\mathbf{ITM}}} \underbrace{\begin{pmatrix} \hat{\mathbf{u}}_{\mathbf{\Lambda}_{\mathbf{ITM}}} \\ \hat{\mathbf{u}}_{\mathbf{\Gamma}_{\mathbf{j\,ITM}}} \end{pmatrix}}_{\hat{\mathbf{u}}_{\mathbf{ITM}}} = \underbrace{\begin{pmatrix} \hat{\mathbf{P}}_{\mathbf{\Lambda}_{\mathbf{ITM}}} \\ \hat{\mathbf{P}}_{\mathbf{\Gamma}_{\mathbf{j\,ITM}}} \end{pmatrix}}_{\hat{\mathbf{P}}_{\mathbf{ITM}}} \tag{13}$$

The systems halfspace with cylindrical or spherical indentation can be derived analogously by shifting the cavity to the halfspace surface. Further details can be found in [24].

2.3 Finite Element Implementation

The FEM structures that shall be coupled to the previously introduced ITM subsystems need to match with the shape of the respective cavity surface Γ_j. Therefore the dynamic stiffness matrix of a FEM mesh with a cylindrical and a spherical outer boundary have to be computed. Applying the 2.5D approach, the stiffness of the halfspace with cylindrical cavity was calculated in the (k_x, ω) domain. This allows to represent the 3D response on a two dimensional mesh. Thus quadrilateral finite elements with linear shape functions are used to discretize the cross section of the FEM substructure. However, the FEM formulation has to be adopted to the wavenumber frequency domain as presented in [18]. To enable a direct stiffness coupling with the ITM later on, the nodes need to be equally distributed along the cylindrical boundary.
For the spherical FEM structure usual three dimensional, eight node solid elements can be used and the dynamic stiffness matrix is computed in Cartesian coordinates and in the frequency domain as well (x, y, z, ω). The FEM nodes on the spherical boundary must be situated on the intersections of latitudes and longitudes to be able to transform the FEM stiffness matrix into the basis of the ITM subsystem for the coupling. Thereby the z-coordinates of the latitudes are chosen as the Gauß points along the diameter and the longitudes are equally distributed along the circumference [22].

$$\begin{bmatrix} \bar{\mathbf{K}}_{\mathbf{\Gamma}_{\mathbf{j}}\mathbf{\Gamma}_{\mathbf{j_{FE}}}} & \bar{\mathbf{K}}_{\mathbf{\Gamma}_{\mathbf{j}}\mathbf{\Omega}_{\mathbf{FE}}} \\ \bar{\mathbf{K}}_{\mathbf{\Omega\Gamma}_{\mathbf{j_{FE}}}} & \bar{\mathbf{K}}_{\mathbf{\Omega\Omega}_{\mathbf{FE}}} \end{bmatrix} \begin{pmatrix} \bar{\mathbf{u}}_{\mathbf{\Gamma}_{\mathbf{j\,FE}}} \\ \bar{\mathbf{u}}_{\mathbf{\Omega}_{\mathbf{FE}}} \end{pmatrix} = \begin{pmatrix} \bar{\mathbf{P}}_{\mathbf{\Gamma}_{\mathbf{j\,FE}}} \\ \bar{\mathbf{P}}_{\mathbf{\Omega}_{\mathbf{FE}}} \end{pmatrix} \tag{14}$$

2.4 Coupling of Substructures

The coupling of the ITM and the FEM substructure is carried out at the cylindrical respectively the spherical boundary of the substructures. On the coupling surface the continuity of displacements as well as the equilibrium of forces are used as transition conditions. As reference system for both cases the basis of the ITM subsystem is chosen. Therefore the dynamic stiffness matrix of the cylindrical FEM subsystem on Γ_c needs to be transformed into the (k_x, r, n, ω) domain by applying a twofold Fourier transform as well as a Fourier series expansion along the circumference. The spherical FEM structure is transformed into the (r, m, l, ω) domain by transforming the dynamic stiffness on Γ_s into spherical coordinates, conducting a Fourier transform into the frequency domain and developing it into series of spherical harmonics. The FEM

formulation inside the structure Ω is kept in the (x, y, z, ω) domain.

$$\begin{bmatrix} \hat{\mathbf{K}}_{\mathbf{\Lambda\Lambda_{ITM}}} & \hat{\mathbf{K}}_{\mathbf{\Lambda\Gamma_{j_{ITM}}}} & 0 \\ \hat{\mathbf{K}}_{\mathbf{\Gamma_s\Lambda_{ITM}}} & \hat{\mathbf{K}}_{\mathbf{\Gamma_j\Gamma_{j_{ITM}}}} + \hat{\mathbf{K}}_{\mathbf{\Gamma_j\Gamma_{j_{FE}}}} & \bar{\mathbf{K}}_{\mathbf{\Gamma_j\Omega_{FE}}} \\ 0 & \hat{\mathbf{K}}_{\mathbf{\Omega\Gamma_{j_{FE}}}} & \bar{\mathbf{K}}_{\mathbf{\Omega\Omega_{FE}}} \end{bmatrix} \begin{pmatrix} \hat{\mathbf{u}}_{\mathbf{\Lambda_{ITM}}} \\ \hat{\mathbf{u}}_{\mathbf{\Gamma_j}} \\ \bar{\mathbf{u}}_{\mathbf{\Omega_{FE}}} \end{pmatrix} = \begin{pmatrix} \hat{\mathbf{P}}_{\mathbf{\Lambda_{ITM}}} \\ \hat{\mathbf{P}}_{\mathbf{\Gamma_j}} \\ \bar{\mathbf{P}}_{\mathbf{\Omega_{FE}}} \end{pmatrix} \tag{15}$$

3 VALIDATION

The systems halfspace with partly embedded cylindrical or spherical cavity are verified in this section by a comparison with the analytical solution of a homogeneous halfspace. Therefore in the coupled ITM-FEM system the cavity is homogeneously filled with finite elements. Same material parameters are chosen for the FEM substructure and the surrounding soil modeled by the ITM. The system is excited by a vertical harmonic load with $f = 12$ Hz at the halfspace surface $\hat{\mathbf{P}}_{\mathbf{\Lambda}}$ with block size 2x2 m and amplitude $P_0 = 1 \frac{\mathrm{N}}{\mathrm{m}^2}$ at $y_{\mathrm{load}} = -10$ m outside of the FEM inclusion with radius $R = 4$ m. (Figure 2). The soil material parameters are chosen as Soil A given in Table 2.

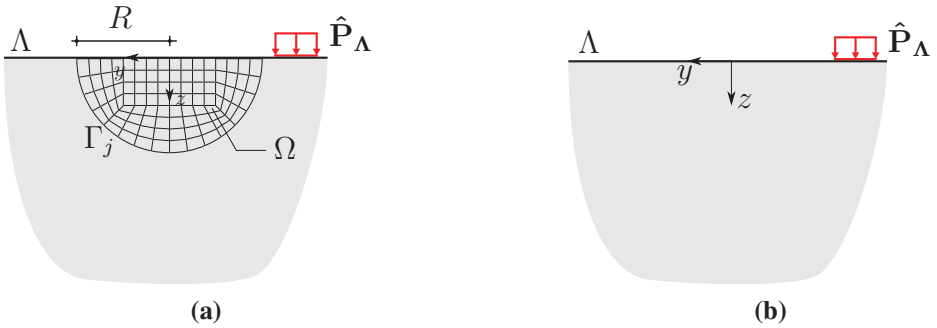

Figure 2: Setup for comparison of coupled ITM-FEM system (a) with analytical solution for homogeneous halfspace (b).

The results for the absolute value of the vertical displacement on the halfspace surface are presented normalized with the load resultant in Figure 3. A very good agreement of the coupled ITM-FEM approach with the benchmark solution can be stated for both, the 2.5D and the 3D model.

4 NUMERICAL RESULTS

4.1 Infinite open trenches and infilled barriers (2.5D)

In this section numerical results for length invariant open trenches and infilled barriers are presented applying the proposed 2.5D ITM-FEM approach for a halfspace with cylindrically shaped FE substructure. Firstly the results gained with the proposed methodology for a concrete filled trench are compared with those available in published literature. Second the effect of subgrade stiffening as wave impeding barrier is shown followed by a comparison of the mitigation efficiency and the mechanism of action of open trenches and soft or stiff barriers.

Concrete filled trench

In this example the Rayleigh wave diffraction by a rectangular trench, infilled with concrete, in the transmission path, as depicted in Figure 4a, is investigated with the ITM-FEM approach. The results are compared with those obtained by Haupt [4] with the FEM, and Beskos et al. [6] with a constant element based BEM implementation. As the literature results were calculated for a 2D case, the ITM-FEM solution was also done only for wavenumber $k_x = 0$, which means constant conditions in longitudinal direction x. A vertical harmonic load with amplitude $P_0 = 1\ \frac{\mathrm{N}}{\mathrm{m}^2}$ and a width of $b_{\mathrm{y,load}} = 2\ \mathrm{m}$ is applied at a distance of $y_{\mathrm{load}} = -16\,\mathrm{m}$ from the trench with a frequency of $f = 30\ \mathrm{Hz}$ resulting in a Rayleigh wavelength of $\lambda_r = 3.18\ \mathrm{m}$. The width and depth of the barrier were chosen to $w_{\mathrm{tr}} = 1.25$ m and $d_{\mathrm{tr}} = 3.25$ m, prescribed by the FE discretization. Therefore the normalized dimensions result to $W_{\mathrm{tr}} = 0.39$, $D_{\mathrm{tr}} = 1.02$ and $L_{\mathrm{load}} = 5.03$, which almost coincide with the dimensions used in [4, 6]. The further discretization and geometry parameters are given in Table 1 as well as the material parameters of the soil (Soil B) and the concrete filling (Infill A) in Table 2.

Table 2: Material parameters of different soils and infill materials

In Figure 4b the amplitude reduction factor A_r for the absolute value of the vertical displacement $|u_z(x = 0, y, z = 0, \omega)|$ at the halfspace surface is shown at $x = 0$ over the dimensionless distance y/λ_r. A_r is defined as the amplitude in presence of the trench $|u_{z,\mathrm{tr}}|$ divided by the amplitude in absence of the trench $|u_{z,\mathrm{ref}}|$. Thus values of A_r smaller than one mean a reduction of the vibration amplitudes of $(1.0 - A_r) \cdot 100$ percent. Significant amplifications are observed

in front of the trench caused by the constructive or destructive interference of the incident and reflected Rayleigh waves due to their phase difference [9], which is indicated by the peak distances being very close to $\lambda_r/2$. On the load remote site, a substantial amplitude reduction due to the concrete barrier of $50-70\%$ is achieved. A very good agreement between the literature results and the ITM-FEM approach can be stated.

Subgrade stiffening as wave impeding barrier

In this section the 2.5D ITM-FEM approach is used to investigate the efficiency of subgrade stiffening as mitigation measure in the transmission path. The setup depicted in Figure 5a is adopted from Coulier et al. [13], who used a 2.5D FEM-BEM methodology to analyze subgrade stiffening next to the track for the mitigation of railway induced vibrations. A block of stiffened soil (Infill B) with a width and depth of $w_{\mathrm{tr}} = d_{\mathrm{tr}} = 2$ m located within a homogeneous halfspace (Soil C) is investigated. The discretization parameters are given in Table 1. The material parameters for the surrounding and the stiffened soil, leading to the same wave velocities as in [13], are presented in Table 2. A quadratic, harmonic block load with $P_0 = 1\ \frac{\mathrm{N}}{\mathrm{m}^2}$ and a width of $b_{\mathrm{x,load}} = b_{\mathrm{y,load}} = 1$ m is applied at a distance of $y_{\mathrm{load}} = -6$ m from the barrier. The absolute value of vertical displacements and the insertion loss $\bar{\mathrm{IL}}_z$ over the total surface were evaluated for the reference case $|u_{\mathrm{z,ref}}|$ without subgrade stiffening and the situation in presence of the stiffened block $|u_{\mathrm{z,tr}}|$. Therefore positive values of the insertion loss

$$\bar{\mathrm{IL}}_z(x, y, z = 0, \omega) = 20 \log_{10} \frac{|u_{\mathrm{z,ref}}|}{|u_{\mathrm{z,tr}}|}\ [\mathrm{dB}] \tag{16}$$

indicate a reduction compared to the reference case without mitigation measure.

Coulier et al. [13] showed by an investigation of the insertion loss in the wavenumber-frequency domain, that the block of stiffened soil can act as a wave impeding barrier. Considering the stiffened block as infinitely long Timoschenko beam, it was demonstrated that the wave impeding effect depends strongly on the relation of the projection of the Rayleigh wave length in the soil in longitudinal direction λ_x and the free bending wave length in the beam λ_b. The transmission of plane waves in the soil with $\lambda_x < \lambda_b$ is impeded, as the response of the

beam is then dominated by its bending stiffness and the amplitude decreases proportionally to k_y^{-4} for a given frequency.

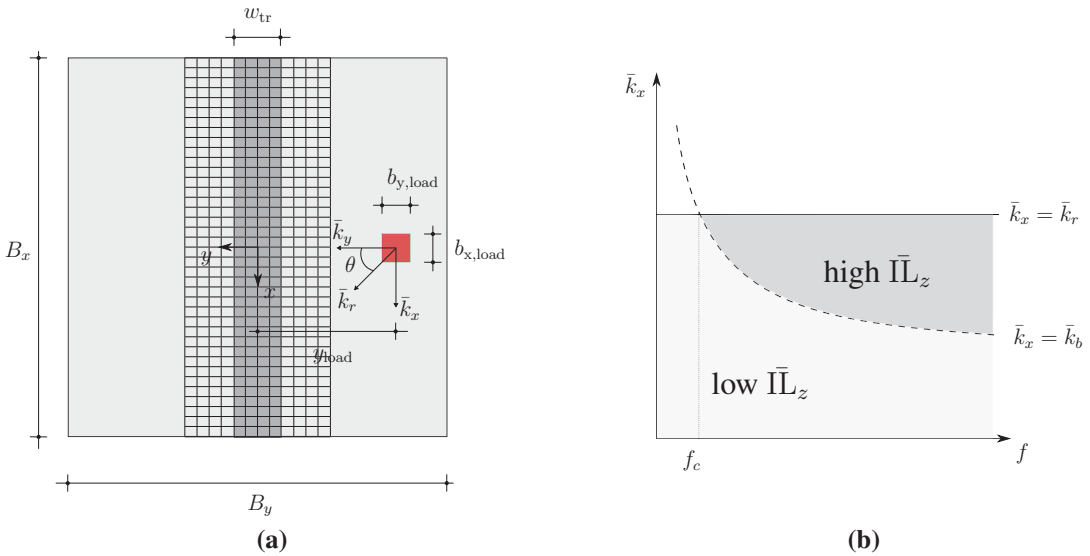

Figure 5: (a) Topview of setup for comparison of coupled ITM-FEM system with 2.5D FEM-BEM model of Coulier et al. [13]. (b) Schematic sketch of the dispersion curves of the free bending wave in a Timoschenko beam and the Rayleigh wave in a homogeneous halfspace.

Figure 5b shows a schematic sketch of the insertion loss $\bar{\mathrm{IL}}_z(\bar{k}_x, y, z = 0, \omega)$ over the dimensionless wavenumber $\bar{k}_x = k_x c_s/\omega$ and the frequency f as presented in [13]. A high insertion loss is obtained for wavenumbers $\bar{k}_x$ smaller than the dimensionless Rayleigh wavenumber $\bar{k}_x = \bar{k}_r = c_s/c_r$ and bigger than the free bending wavenumber $\bar{k}_b$. The contribution of wavenumbers $\bar{k}_x > \bar{k}_r$ to the total response and especially the response in lateral direction is quite limited. This is due to the fact, that the value of the transfer function of a homogeneous halfspace in the wavenumber frequency domain for wavenumbers $k_x^2 + k_y^2 > k_r^2$ is quickly decreasing with increasing wavenumbers and thus, as the propagation direction in the $x-y$ plane is given by $\theta = \tan^{-1}(\bar{k}_x/\bar{k}_y)$, for $\bar{k}_x > \bar{k}_r$ the waves traveling in y-direction have only comparatively small amplitudes. The propagation direction of the Rayleigh wave, which makes up the largest part of the overall response results as $\theta_r = \sin^{-1}(\bar{k}_x/\bar{k}_r)$. For wavenumbers $\bar{k}_x < \bar{k}_b$ follows $\lambda_x > \lambda_r$ and thus the Rayleigh wave is able to propagate through the stiffened block with low transmission loss, whereas for $\bar{k}_x > \bar{k}_b$ the waves are impeded by the barrier because λ_x gets smaller than λ_b. Therefore a critical frequency f_c, when the mitigation measure becomes effective, can be determined by the intersection of the Rayleigh wave and the free bending wave dispersion curves [13]:

$$f_c = \frac{c_r^2}{2\pi}\sqrt{\frac{\rho A}{EI}}\sqrt{\frac{E\mu\kappa}{(E-\rho c_r^2)(\mu\kappa-\rho c_r^2)}} \tag{17}$$

where E is the Young's modulus, μ the shear modulus, ρ the density, A the cross sectional area and I the moment of inertia of the beam. κ is the shear coefficient and can be set to $\kappa = 5/6$ for rectangular cross sections. c_r is the Rayleigh wave velocity in the soil. This critical frequency strongly depends on the stiffness contrast between the soil and the block of stiffened soil. Thus subgrade stiffening is more effective in soft soils. For the given material parameters the critical frequency results to $f_c = 12.37$ Hz.

The propagation direction of the Rayleigh waves is given by θ_r. Beyond a critical angle of $\theta_c = \sin^{-1}(\bar{k}_b/\bar{k}_r)$ and assuming $\omega > \omega_c$, the wavenumbers $\bar{k}_x$ are bigger than $\bar{k}_b$ and thus $\lambda_x < \lambda_b$ holds. Therefore the impinging plane waves with $\theta > \theta_c$ are impeded by the barrier. The critical angle in dependency of the frequency is given by [13] as:

$$\theta_c(f) = \arcsin\left(c_r \sqrt{\rho \left(E + \mu\kappa \pm \sqrt{(E-\mu\kappa)^2 + \frac{4E(\mu\kappa)^2 A}{\rho I(\omega/2\pi)^2}} \right) (2E\mu\kappa)^{-1}} \right) \tag{18}$$

Figure 6a and 6c show the real part of the vertical displacement $u_z(x, y, z = 0, \omega)$ due to a harmonic load with $f = 5$ Hz $< f_c$ for the reference case and the case when subgrade stiffening was applied. The Rayleigh wave length λ_r is much larger than the depth of the barrier and thus a significant part of the Rayleigh wave is able to pass beneath it. For all waves impinging at the stiffened block, $\bar{k}_x > \bar{k}_b$ holds and therefore they are not impeded. The wave field in both cases is very similar and the corresponding insertion loss $\bar{\mathrm{IL}}_z$ in Figure 6e is almost zero over the whole surface. The real part of the vertical displacements for a excitation frequency of $f = 30$ Hz $> f_c$ is shown in Figure 6b and 6d. In the reference case cylindrical wave fronts are observed, whereas, if subgrade stiffening is applied, the wave field is not cylindrical anymore due to the interaction of the barrier and the soil. All waves hitting the barrier at an angle greater than the critical angle θ_c are impeded, leading to a significant reduction of vibrations in the areas with $\theta > \theta_c$. Hence, large values of the insertion loss, partly exceeding $10\,\mathrm{dB}$, are observed there. The critical angle, which results to $\theta_c = 43.26°$ at $f = 30$ Hz, is sketched in Figure 6f.
However, below the critical angle the amplitude reduction is rather small due to the relatively shallow barrier (only $0.32\,\lambda_r$ at $f = 30$ Hz) and the not so pronounced stiffness contrast between the barrier and the soil. Although lines of increased $\bar{\mathrm{IL}}_z$ can be observed in this area due to the partial destructive interference caused by the phase shift of the waves passing below the barrier and the waves transmitted through the barrier with much higher wave velocity, which appears mainly for thick barriers of lower depth [25]. For larger depth of the barrier and an increased stiffness contrast also for angles $\theta < \theta_c$ a significant reduction can be achieved, as more reflections occur at the left face of the barrier and less vibrations are transmitted. Furthermore a smaller part of the Rayleigh wave passes below the barrier. On account of this in the following section the mitigation efficiency for an open trench, a soft and a stiff barrier are compared, assuming adequate dimensions and a sufficient stiffness contrast.

Stiff and soft barriers vs. open trench

The vibration screening efficiency of open trenches massively depends on the trench depth. A satisfactory screening efficiency of $A_r < 0.25$ can be achieved for depths d_{tr} greater than about $1.2\lambda_r$ of the soil [2]. Due to stability reasons the construction of ideal open trenches with vertical sides is limited to shallow depths. For this reason, trenches are often filled with soft material that must be able to withstand the horizontal soil stresses while still providing adequate insulation [26]. Open trenches achieve their vibration reduction effect by the reflection of the incident Rayleigh waves. As no energy can be transferred across the open trench the vibration reduction usually is higher than for infilled trenches, where a part of the wave energy is transmitted through the barrier. If a very soft infill material is used the behavior of the filled trench resembles that of open trench [27], which also yields for the mitigation efficiency.
However, the physical mechanism, which is responsible for the vibration reduction changes, when it comes to stiff barriers. Additionally to the reflected and transmitted Rayleigh waves,

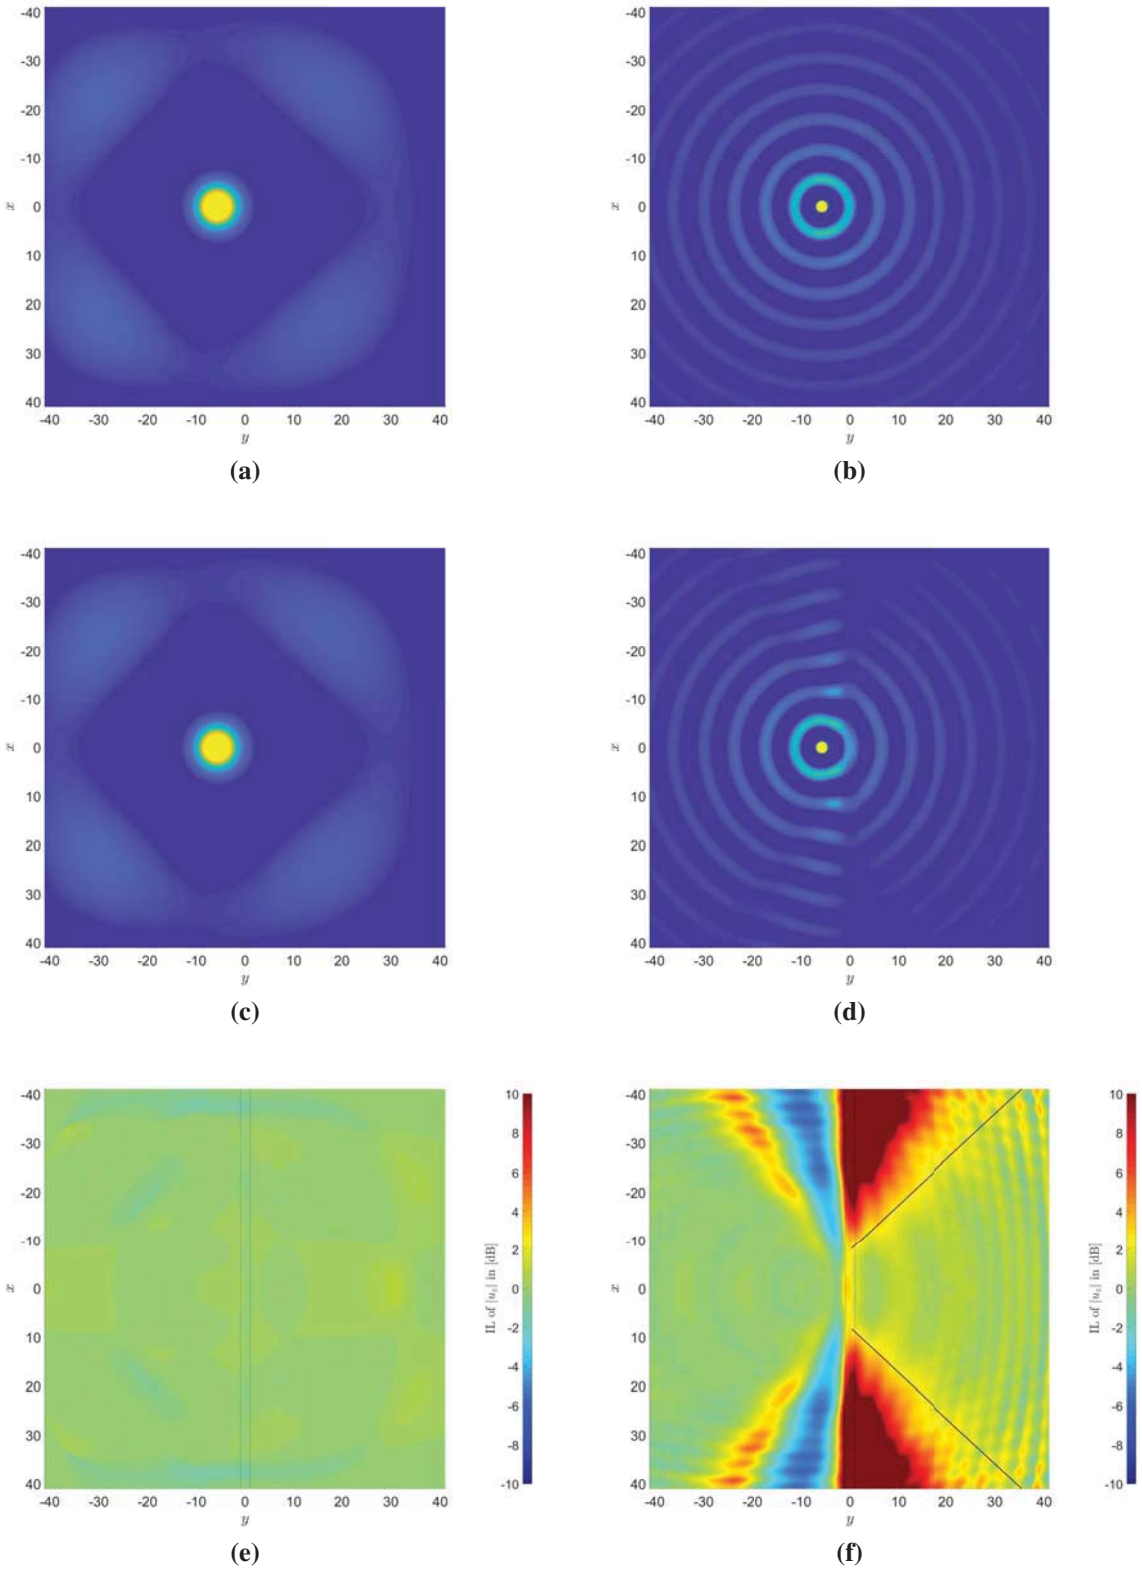

Figure 6: Real part of the vertical displacement $u_z(x, y, z = 0, \omega)$ due to harmonic excitation with block load at $y = -6$ m in the reference case (a,b) and in the case with subgrade stiffening (c,d) as well as the corresponding insertion loss $\bar{\mathrm{IL}}_z$ (e,f). Left column for $f_c > f = 5$ Hz and right column for $f_c < f = 30$ Hz.

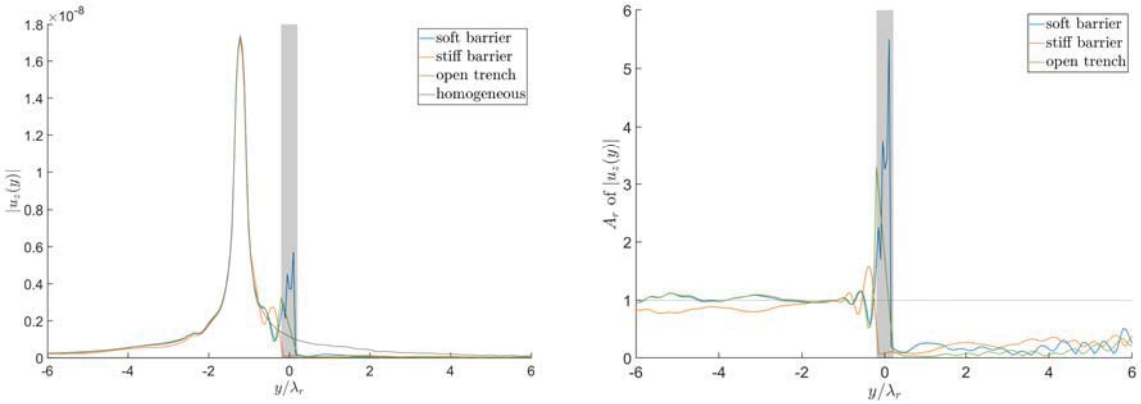
the presence of the barrier gives rise to body (P- and S-) waves, that are also reflected and transmitted [9]. Furthermore body waves radiating downward the barrier occur, acting like a new wave source at the lower end of the stiff barrier, emitting body waves into the interior of the halfspace [25]. This transformation of Rayleigh waves into body waves is called mode conversion. The screening effect of a stiff barrier with adequate depth therefore is partly based on the reflection of the Rayleigh waves and partly on its transmission into the interior of the halfspace. For fixed dimensions, the decisive parameter for the vibration mitigation efficiency of a stiff barrier is the stiffness difference between soil and infilled trench rather than the impedance [13]. The material damping of the infill material has no significant effect on the on the screening performance [28]. Therefore, very stiff barriers in relatively soft soils have a mitigation efficiency close to that obtained by an open trench [14].



(a) **(b)**

Figure 7: (a) Absolute value of vertical displacement $|u_z(x = 0, y, z = 0, \omega)|$ due to harmonic excitation with $f = 20$ Hz by a 1x1 m block load at $y_{\text{load}} = -4$ m for soft barrier, stiff barrier, open trench, homogeneous halfspace and (b) the corresponding amplitude reduction factor A_r. The gray bar indicates the area enclosed by the open trench resp. the barrier.

Figure 7a shows the vertical displacement $|u_z(x = 0, y, z = 0, \omega)|$ for an extremely stiff (Infill C) and a very soft (Infill D) barrier as well as an open trench and the reference case of a homogeneous halfspace (Soil A). The material properties of the barriers and the soil are given in Table 2, the used discretization in Table 1. Again a 1x1 m block load with $P_0 = 1\ \frac{\text{N}}{\text{m}^2}$ located at $y_{\text{load}} = -4$ was chosen. For the excitation frequency of 20 Hz, λ_r results to 3.3 m and therefore the normalized dimensions of the trench respectively the barrier account for $D_{\text{tr}} = 1.2$ and $W_{\text{tr}} = 0.4$. The soft barrier and the open trench show large displacement amplitudes at the load sided edge, whereas in case of the stiff barrier the deformation is almost zero. This also reflects in the amplitude reduction factor depicted in Figure 7b, exhibiting $A_r \gg 1$ for the open trench and the soft barrier and a very small A_r for the stiff barrier. Behind the trench a significant reduction of vibrations is observed for all three cases, albeit the open trench performs best over the largest part of the considered range.
This tendency is also visible in Figures 8(a,c,e), where the amplitude reduction factor A_r over the surface with dimensions normalized by λ_r is depicted. In the graphs, the area occupied by the barrier is marked by the white lines. The open trench shows the greatest reduction effect over the entire area on the load averted side. Nearly the same pattern of A_r develops on the load facing side for the open trench and the soft filled barrier, which can be explained by the similar physical mechanism for the vibration screening, relying almost solely on the reflection of the impinging Rayleigh waves.

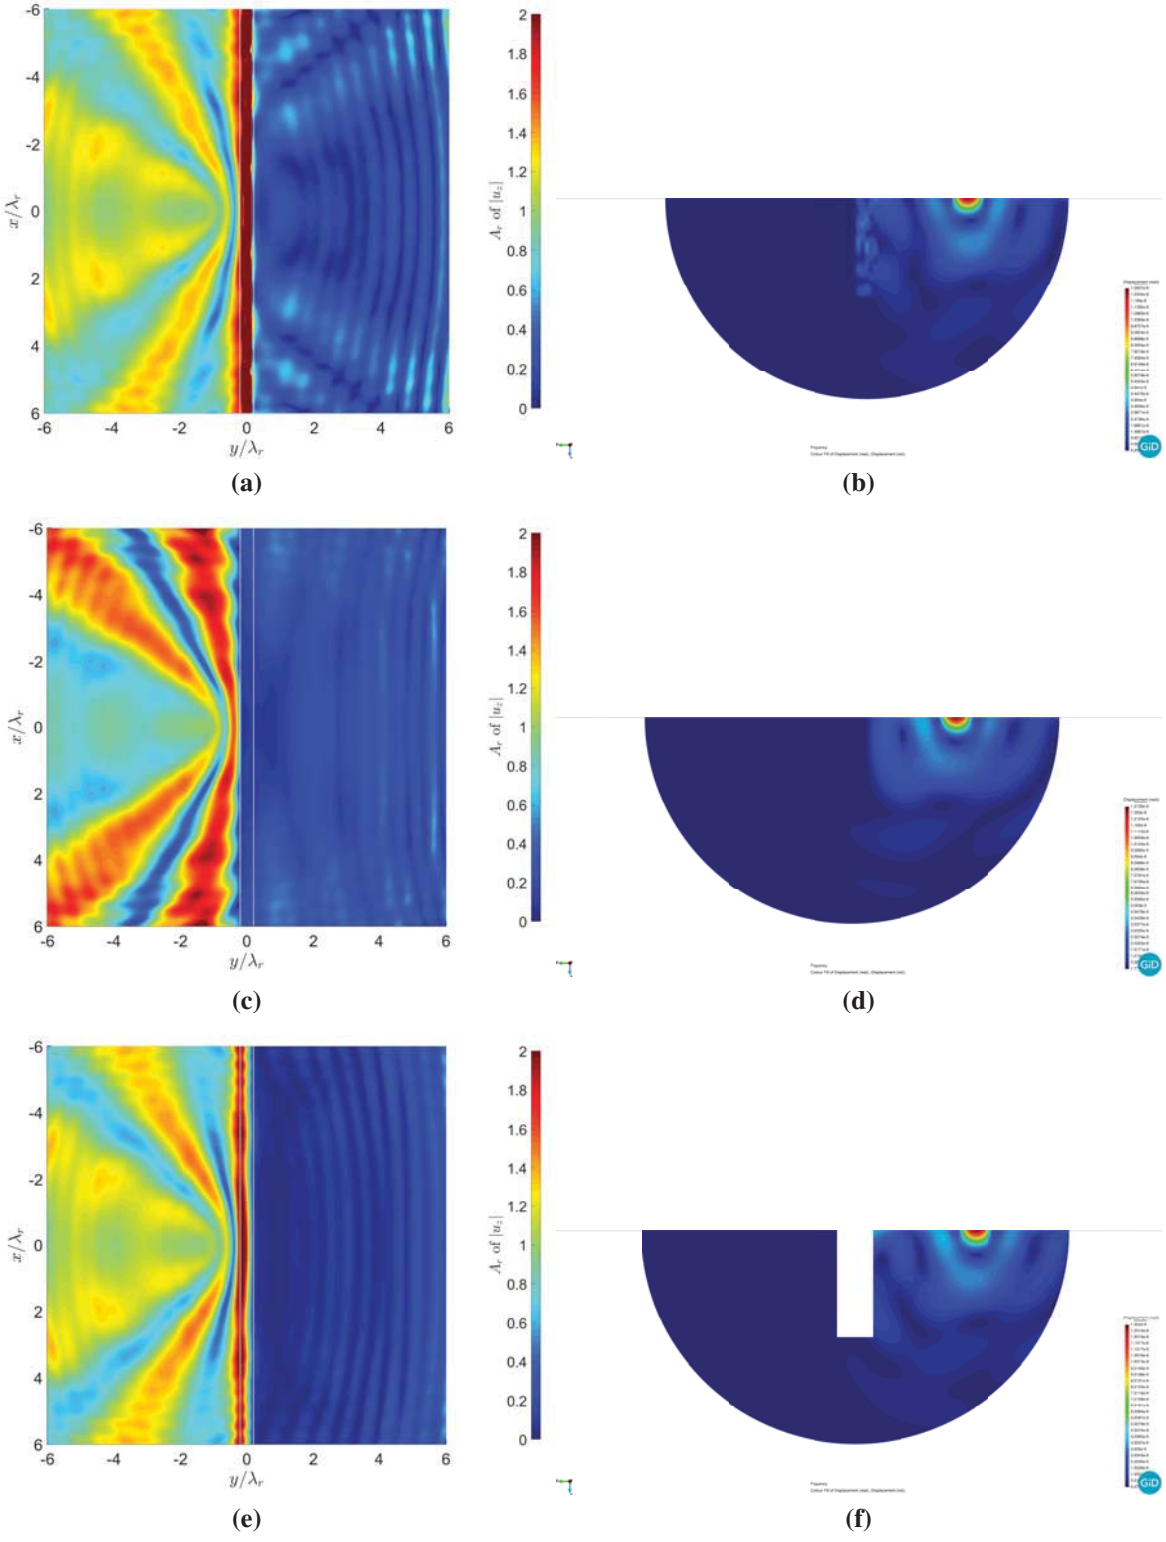


Figure 8: Left column: Amplitude reduction factor A_r, right column: Resultant of displacements $\mathbf{u}(x, y, z, \omega) = \sqrt{u_x^2 + u_y^2 + u_z^2}$ for (a,b) soft barrier, (c,d) stiff barrier and (e,f) open trench.

However, in case of the stiff barrier, due to the very different ratio of wave velocities in the soil and the barrier compared to the soft infill material as well as larger amount of mode conversion, a very different interference pattern of the reflected waves occurs before the bar-

rier. Moreover, in Figures 8(b,d,f) the pseudo resultant of the displacements $\mathbf{u}(x, y, z, \omega) = \sqrt{u_x^2 + u_y^2 + u_z^2}$ within the FEM substructure is illustrated for all three cases in a section at $x = 0$. In the considered frequency range the wave lengths in the soil are considerably larger than the barrier width and thus impose their displacements to the barrier quasi statically [14]. It is clearly visible that with the soft filling material, large deformations occur at the edge and within the barrier, similar to the limit case of the reflection of the incident waves at the free end, as for an open trench. In contrast the stiff barrier shows no deformation at all and therefore almost acts as fixed boundary [11].

4.2 Finite open trench (3D)

Unlike the previously presented 2.5D approach, dealing with infinitely long mitigation measures in longitudinal direction, the 3D approach allows the investigation of spatially limited open trenches or barriers, closer to practical applications. For the length invariant structures the energy transmission is restricted over the whole length, whereas in case of finite vibration shielding measures much more complex wave interference phenomena occur, as additionally to the lower trench end diffraction effects arise also at side edges [7]. Thus, regions with reduced or increased vibration amplitudes on the ground surface can clearly be observed as depicted in Figures 10c and 10d.

For the investigation of the finite open trench, the three dimensional ITM-FEM approach is applied, whereby the open trench is modeled within the half spherically shaped FEM substructure as displayed in Figure 9. A radius of $R = 6$ m was chosen for the sphere and a open trench with $d_{\mathrm{tr}} = 3.8$ m, $w_{\mathrm{tr}} = 1.2$ m and $l_{\mathrm{tr}} = 4.8$ m included. A total region of $B_x = B_y = 64$ m was investigated using $N_x = N_y = 2^7$ Fourier series members on the halfspace surface as well as $N_l = 40$ longitudes and $N_m = 20$ latitudes for the discretization of the sphere, leading to a finite element size of $d_{x,\mathrm{FE}} = d_{y,\mathrm{FE}} = 0.6$ m along the surface. The Material properties of Soil A, given in Table 2, were used for the calculations. In the FEM subsystem solid elements

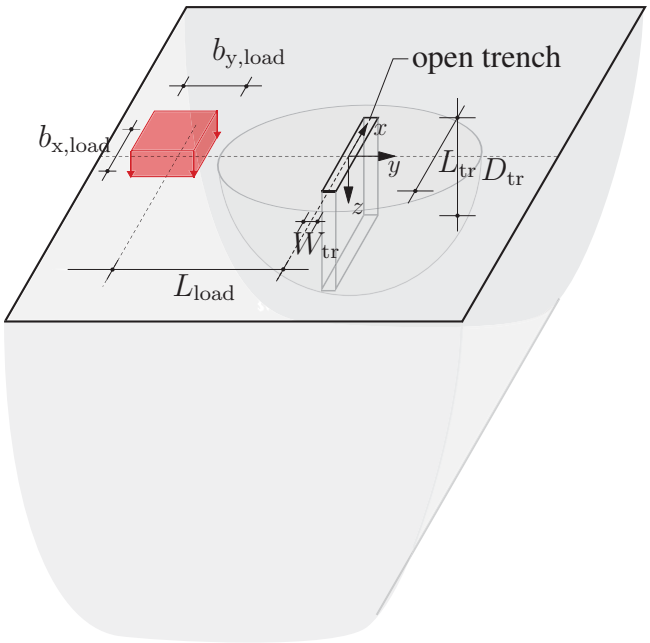

Figure 9: Sketch of the three-dimensional ITM-FEM system for the vibration isolation by an finite open trench.

with linear shape functions were used, which, in general, are not as accurate as higher order elements, if it comes to stress concentrations or detailed results for the displacement amplitude in the near field around the load are of interest. However, for the assessment of the vibration mitigation efficiency, the response behind the trench is more important than the deformation of the trench itself or the stress concentrations around it [7]. Therefore satisfactory precision is reached for the investigated problem, using the ITM-FEM approach.
In the following sections the influence of the trench length and depth as well as the distance of the load from the trench is investigated and finally compared to results obtained for the infinite trench.

Variation of the excitation frequency

Figure 10a shows the absolute value of the vertical displacements at $x = 0$ over the y due to a harmonic $1.2\,\mathrm{x}\,1.2$ m block load located at $y_{\mathrm{load}} = -3$ m with excitation frequencies of 12 Hz and 22 Hz. The corresponding amplitude reduction factor A_r is depicted in Figure 10b. As the frequency changes, also the Rayleigh wavelength and therefore the relative dimensions of the open trench vary. At $f = 12$ Hz, λ_r results in 5.5 m and thus $D_{\mathrm{tr}} = 0.69$, $W_{\mathrm{tr}} = 0.22$ and $L_{\mathrm{tr}} = 0.87$, whereas for $f = 22$ Hz the Rayleigh wave length is $\lambda_r = 2.9$ m and thereby $D_{\mathrm{tr}} = 1.31$, $W_{\mathrm{tr}} = 0.41$ and $L_{\mathrm{tr}} = 1.65$. The amplitude reduction for 12 Hz, depicted in Figure 10e, is rather limited as a significant part of energy passes below the open trench. With increasing frequency the penetration depth of the Rayleigh wave reduces and therefore the mitigation efficiency rises, as can be seen in Figure 10f showing A_r for an excitation frequency of 22 Hz. Amplifications of the displacement amplitudes can be observed in front of the trench and at the sides as well as a reduction behind the trench. For small ratios $l_{\mathrm{tr}}/\lambda_r$ amplifications occur also directly behind the open trench, a phenomenon which was also observed by Woods [2] experimentally. Due to the small trench length, especially for lower frequencies, the waves travel around the trench thereby causing this amplifications, as can clearly be seen in Figure 10c. With increasing dimensionless length and depth the mitigation efficiency rises and thus the shadow zone enlarges and gets more defined.

Variation of load position

Dolling [1] showed that above a certain trench length the shielding effect no longer changes significantly and concluded that an radiation angle of $45° - 56°$ leads to an effective vibration reduction. Also Woods [2] found that larger trenches are required at greater distance from the source to achieve a certain amplitude reduction. Therefore in this section the variation of the load position with a fixed open trench length, depth and width is investigated as depicted in Figure 11a. This leads to a variation of the radiation angle

$$\alpha = \tan^{-1}\left(\frac{L_{\mathrm{tr}}/2}{L_{\mathrm{load}} - W_{\mathrm{tr}}/2}\right) \tag{19}$$

of the waves on the open trench of $45°$ for $y_{\mathrm{load}} = -3$ to $10°$ for $y_{\mathrm{load}} = -14$ and therefore a different shielding zone and mitigation efficiency. Figure 11b shows the amplitude reduction factor $A_r(x = 0, y, z = 0, \omega)$ for load positions $y_{\mathrm{load}} = -3,\ -8,\ -14$ due to an excitation with $f = 22$ Hz. With increasing y_{load} the amplitude reduction at some distance behind the trench decreases substantially, which fits well to Woods's [2] statement, that the screening efficiency is larger, if the trench is positioned close to the source.

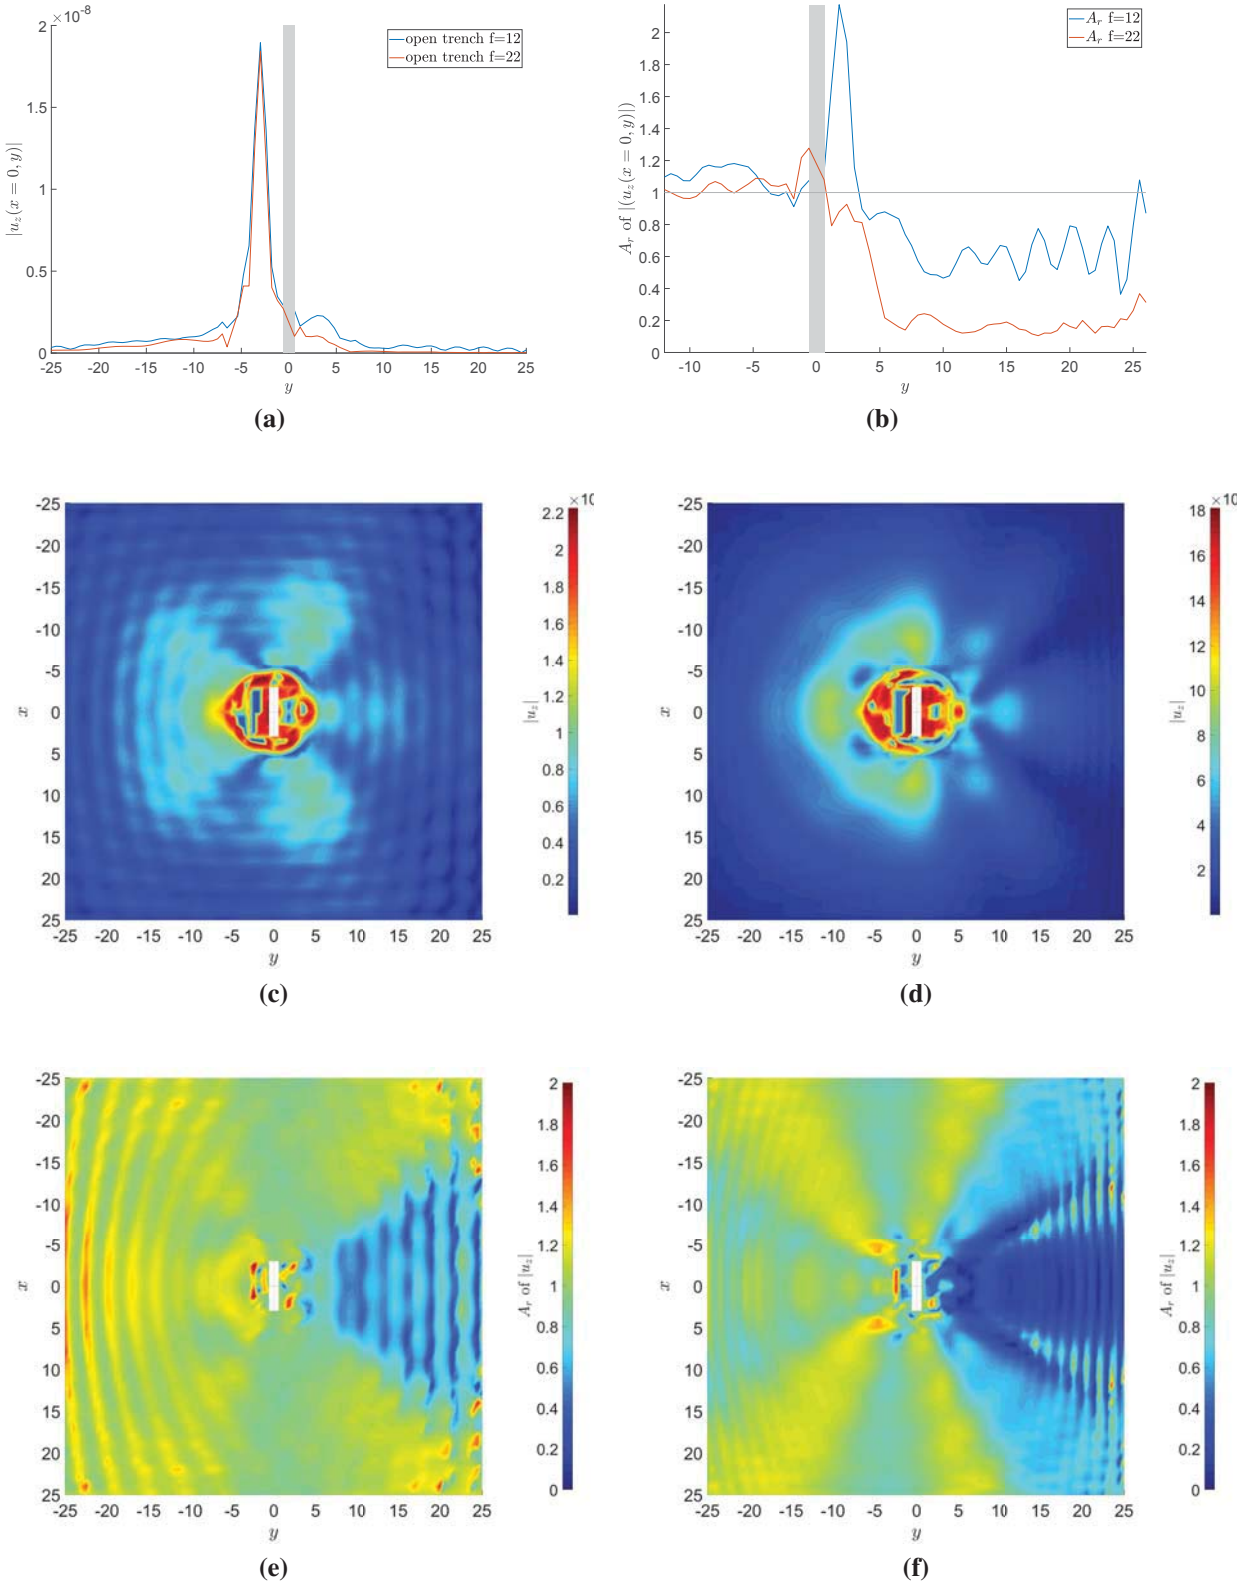

Figure 10: (a) Absolute value $|u_z(x = 0, y, z = 0, \omega)|$ and (b) corresponding A_r. (c,e) Real part of the vertical displacement $u_z(x, y, z = 0, \omega)$ and A_r of $|u_z(x, y, z = 0, \omega)|$ for $f = 12$ Hz and (d,f) for $f = 22$ Hz.

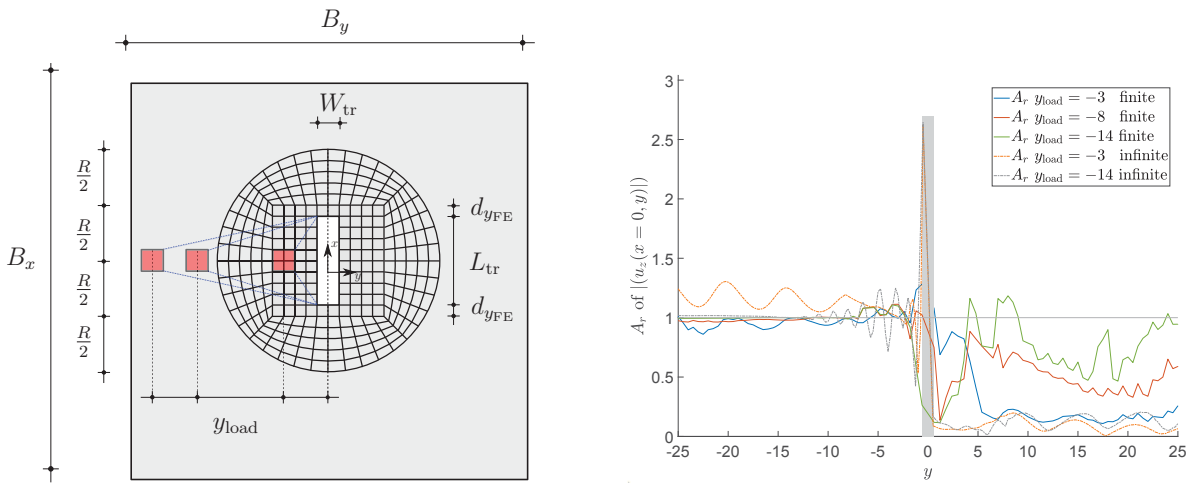

Figure 11: (a) Setup for variation of load position and radiation angle (blue lines). (b) Amplitude reduction factor A_r of $|u_z(x = 0, y, z = 0, \omega)|$ for different load positions y_{load} for the finite and the infinite open trench.

This is further confirmed, when the amplitude reduction factors for different load positions considering the infinitely long trench is opposed to the ones obtained for the finite open trench as depicted also in Figure 11b as well. The variation of A_r due to different load positions is very small for the length invariant open trench because the radiation angle is not relevant in this case, as there is no possibility for the waves to travel around open trench. A more exposed peak in front of the trench can be observed in the 2.5D case because a bigger part of the incoming waves is reflected leading to a lower A_r over the whole length behind the trench.

5 CONCLUSIONS

In this paper a coupled Integral Transform Method - Finite Element Method approach for the Soil Structure Interaction of length invariant (2.5D) and finite (3D) structures has been presented. Therefore fundamental solutions of the Lamé differential equation were superposed in order to gain the systems halfspace with partially or fully embedded cylindrical or spherical cavity. At the cavity boundaries a FEM substructure is coupled to the ITM using a direct stiffness coupling by enforcing the continuity of displacements and the equilibrium of forces. The proposed methodology was validated by comparison with the analytical solution of a homogeneous halfspace for the 2.5D and the 3D approach.
Within the FEM region, structures with more complex geometry and material distribution can be modeled. This was used to investigate the vibration reduction efficiency of longitudinally infinite open trenches and barriers with soft or stiff infill material. The normalized depth of the barrier and the stiffness contrast between infill material and soil are found to be the most important parameters for the performance of the screening measure. More shallow barriers with less pronounced stiffness contrast, as in case of subgrade stiffening, act as wave impeding barrier up from a critical frequency and provide a significant insertion loss within an area delimited by a critical angle. For deeper stiff or soft filled barriers with distinct stiffness contrast the performance is similar to an open trench.
In case of spatially limited open trenches also the dimensionless length plays an important role. As diffraction occurs at the sides of the trench additionally to the bottom, more complex wave interference patterns occur. The radiation angle and therefore the distance of the source from the trench has fundamental impact on the mitigation efficiency, which is not the case for length invariant trenches.

Abstract. *The construction of apartment and office buildings close to road or rail traffic is becoming more frequent in urban areas. These sites are however prone to issues of disturbing vibrations in nearby buildings induced by traffic. In Sweden, designing building foundations with pre-fabricated end-bearing concrete piles is often a necessary and economical measure when soil conditions are poor. Although pile groups have been studied extensively in the context of seismic analysis, there are limited experimental results on the response of end-bearing pile groups due to ground vibration evoked by sources acting on the soil's surface. This paper presents the design of an experimental case study of an end-bearing pile group, aimed at validating models for predicting vibration levels in piled buildings. The test site is presented with results from geotechnical and geophysical site investigations. The experimental setup is outlined, describing measurements taken at each stage of construction of the pile group. Results from numerical simulations demonstrate a different behaviour of the pile group in comparison to an equally large surface foundation.*

1 INTRODUCTION

The densification of the urban environment drives the desire to build on previously unused land close to railway lines or heavily trafficked major roads. When utilizing land close to traffic lines for apartment or office buildings, the risk for comfort disturbing vibrations induced by traffic becomes imminent. Therefore, assessment of expected vibration levels should be carried out prior to construction. In the Stockholm area, and in many other regions in Sweden, the railway network is partially constructed in areas with relatively shallow glacial clay deposits overlaying a high quality bedrock. On such sites, end-bearing pre-fabricated concrete piles are commonly used when constructing building foundations. Soil-structure interaction of different types of pile foundations has been extensively analysed in the literature through numerous numerical models and experiments. However, the vast majority of experimental studies available in the literature have mainly been focused on the local behaviour of floating piles and pile groups. There is limited experimental data presented in the literature on the response of end-bearing pile groups, and especially considering the response due to distant sources acting on the ground surface. Moreover, most studies consider only the narrow frequency range of interest in earthquake engineering, and there are few studies covering the full frequency range 1–80 Hz, relevant for the analysis of traffic induced vibrations [5].

This paper presents the design of an experimental case study with the purpose of validating prediction models for the transmission of vibrations through soil to end-bearing pile foundations. The experiment concerns the dynamic response of a 2×2 pile group with pre-fabricated end-bearing concrete piles subjected to controlled dynamic excitation in the frequency range 1–80 Hz. The experiment is performed in phases of staged construction at a site with a minimum of outside disturbance, allowing to isolate the influence of the addition of the foundation to the site. To determine the ability of numerical models to capture the influence of the embedment in the soil on the bending behaviour of the piles, and thereby the kinematic interaction, measurements are performed at various depths along the center lines of the piles. The objective of the paper is to document and motivate the design of the proposed experiment. The site is presented in section 2 with the identified soil properties obtained from site investigations. Section 3 describes the measurement setup, the geometry of the test foundation and the data to be acquired. Section 4 presents numerical predictions of the expected response of the pile foundation. Finally, section 5 concludes the paper.

2 MEASUREMENT SITE

2.1 Location

The measurement site is located in Brottby, about 40 km north of Stockholm, Sweden, at a remote field that has not been cultivated for more than five years. There is a small private road adjacent to the site and a single inhabited house close by. Thereby, the experimental environment is considered to have a high degree of control while maintaining realistic field conditions. An overview of the site is presented in fig. 1.

2.2 Stratification

An extensive geotechnical site characterization has been performed at the site, consisting of weight probing, bedrock probing, cone peneration tests (CPT) and laboratory testing of undisturbed soil samples. The soil profile at the site consists of a top 1 m thick layer of stiff dry-crust clay, a 3.5 m body of soft clay and 2 m layer of moraine on top of a stiff bedrock. A summary

Figure 1: Overview of the experimental site in Brottby outside of Stockholm.

of the clay profile properties obtained from laboratory measurements of the clay is presented in table 1 and the interpreted soil profile is presented in fig. 2, where the points and depths of investigation are indicated.

Table 1: Clay soil properties obtained from laboratory measurements.

2.3 Dynamic soil properties

The small strain dynamic properties that characterise the mechanical behaviour of the soil are the soil density ρ, P- and S-wave velocities C_{p} and C_{s} and the corresponding damping ratios β_{p} and β_{s}. The soil density of the clay is obtained directly from the laboratory measurements, while the underlying moraine and bedrock densities are assumed using typical values used in geotechnical design. The P- and S-wave velocities of the soil are estimated from in-situ and laboratory testing. Material damping ratios are assumed equal for P- and S-waves and are estimated from the geophyscial tests. The oedometer and triaxial aparatuses used in the laboratory testing were additionally equipped with bender elements (BE), allowing to determine S-wave velocities of undisturbed soil samples reloaded to their in-situ stress states. The material samples were taken at point 13 in fig. 2, where the pile group is constructed. In addition to the laboratory measurements, in-situ testing has been performed by means of two seismic cone penetration tests (SCPT) carried out at points 13 and 8 in fig. 2, a seismic refraction test and spectral analysis of surface waves (SASW) based on the vertical acceleration responses of the soil along a line between points 9 and 12 in fig. 2. The seismic refraction test yields estimates of P-wave velocities while the SCPT and SASW tests yield S-wave velocities. However, P-wave velocities

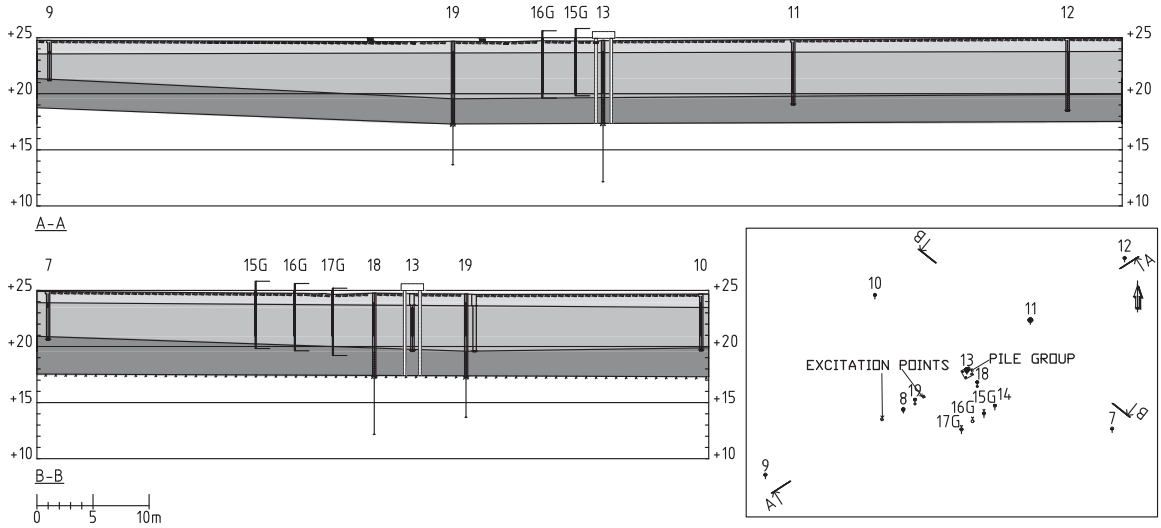

Figure 2: Geotechnical investigation points (numbered) in topview (down-right corner) and sections with shading indicating the interpreted stratification at the site with moraine (bottom), clay (mid-layer) and dry-crust and topsoil (top-layer). The position of the pile group and excitation points on the soil surface are indicated in relation to the investigation points.

are assumed uniform below 1 m depth, due to the full saturation of the clay. A summary of the estimated small-strain dynamic properties of the profile based on the aforementioned tests is presented in table 2.

3 EXPERIMENTAL SETUP

The investigation concerns a 2×2 pile group constructed of prefabricated concrete piles with a square 235×235 mm cross section, illustrated in fig. 3. The pile cap is cast so that it is slightly elevated from the ground. Thereby, only the piles are in contact with the soil. The four plies are driven to bedrock at a depth of approximately 6.5 m and are separated by a distance of 1365 mm. To enable measurements to be performed at depth, a $\varnothing 76$ mm plastic pipe is cast along the center line of each pile. To replicate the case of vibrations induced by nearby sources at the surface, two positions on the surface with a distance 10 and 20 m to the front of the pile cap are considered. At each position, a concrete foundation of dimension 0.5×0.5×0.2 m is cast

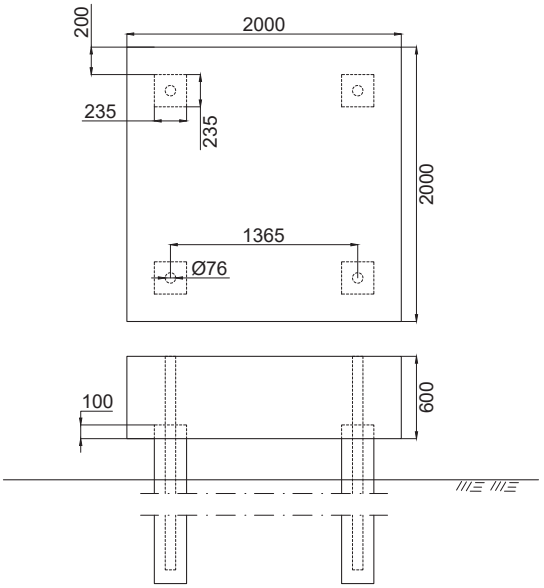

Figure 3: Dimensions in millimetres of the case-study pile foundation.

in place to allow for dynamic excitation (see fig. 5b). Accelerometers are mounted at the soil's surface in the vertical direction and in the horizontal direction, aligned with the propagation path between the excitation points and the construction site. Additional sensors are placed symmetrically at a distance 20 m perpendicularly from the line between the excitation points, to serve as reference points to control for temporal variations in between measurements. Figure 4 presents an illustration of the setup.

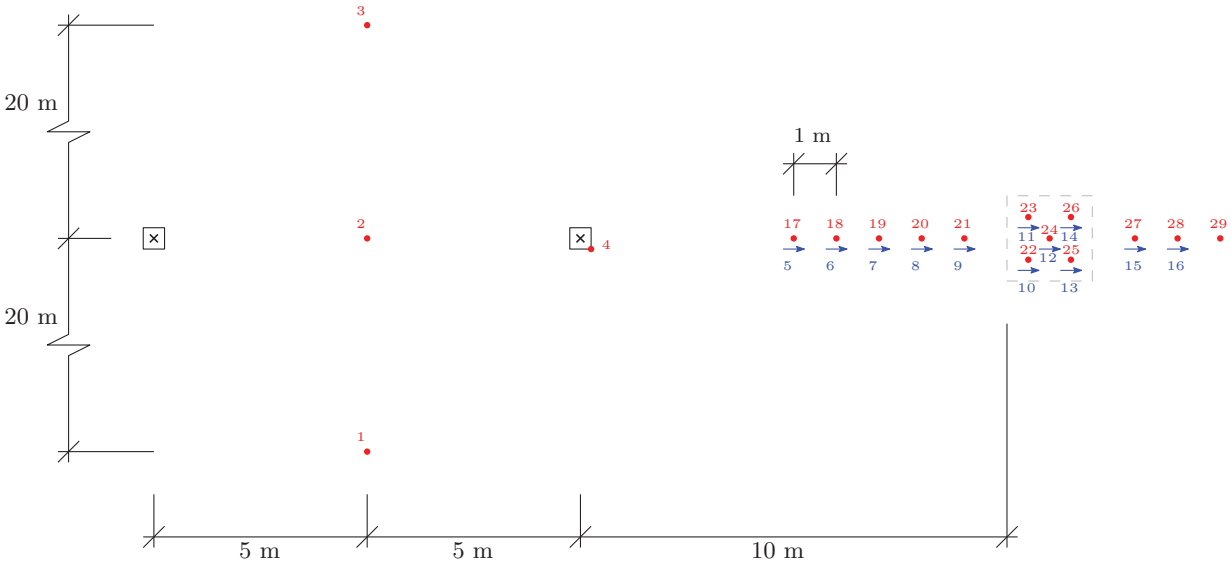

Figure 4: Measurement setup in Brottby. Excitation positions are indicated by an $\times$, vertical measurement channels by a dot and horizontal channels by an arrow.

To reduce the uncertainty regarding the stiffness of the piles, an experimental modal analysis test has been carried out in the factory after the casting of the piles, suspending one of the piles in flexible springs to simulate free-free boundary conditions. In order to identify the material

properties of the reinforced concrete beam, the experimentally obtained natural frequencies and bending modes are matched with an analytical model of the free-free beam. The model updating yield an equivalent modulus of elasticity $E_{\mathrm{p}} = 39$ GPa with a Poisson's ratio $\nu_{\mathrm{p}} = 0.2$ and density $\rho_{\mathrm{p}} = 2400$ kg/m^3 for the concrete piles.

3.1 Dynamic measurements

The dynamic force is applied to the soil by means of a Wölfel BD.5 inertial shaker. The inertial shaker supplies a constant amplitude force over a frequency range 0.5–200 Hz with harmonic or band-limited noise excitation. Thereby, possible non-linearities can be investigated for the frequency band of interest by varying the excitation amplitude. The shaker is firmly mounted on the cast in place concrete foundations by means of threaded fittings. Additionally, an impact sledgehammer Dytran 5803 series is used for impact testing whenever mounting the shaker in place is infeasible, e.g. when determining pile impedances. The responses on the soil's surface are measured by 20 PCD 393A03 and 9 PCB 393B31 accelerometers, with sensitivities 1 and 10 V/g, respectively. The more sensitive sensors are used for the most distant vertical measurements. The accelerometers are mounted on aluminium pickets with a curciform section of dimensions $40 \times 40 \times 300$ mm and are shown mounted in the soil in fig. 5c. The soil-picket-sensor dynamic system is verified experimentally to have a natural frequency well above the frequency band of interest (1-80 Hz) when mounted at site, according to the recommendations given by Degrande et al. [2] and Hunaidi and Rainer [4]. After installation of the sensor pickets in the ground, they are left in place to ensure that the position and mounting is the same in between measurement sessions. Responses in the piles at depth are measured with sensors attached to a pneumatic device, equipment originally designed for seismic exploration in boreholes (see e.g. [8]). The cavity along the centreline of the piles makes it possible to mount the sensors at arbitrary depth, allowing to determine the frequency response at any number of measurement points along the piles with a limited amount of sensors.

3.2 Measurements at different phases of construction

For the purpose of response prediction, it is desirable to relate the foundation response to the free-field response measured at the surface prior to installation of the foundation. As the dynamic behaviour of the system is modified at each phase of construction, the influence of the piles and the interaction through the union of the pile tops in the pile cap are tracked by performing response measurements at three different stages of construction (with reference to fig. 6):

1. At the soil surface prior to construction due to distant excitation (P_1) from L =10 and 20 m.
2. On the pile tops and in the surrounding soil due to excitation of the piles in three directions (P_2) as well as excitation vertically (P_1) from the two distances $L = 10$ and 20 m.
3. On the pile cap and in the surrounding soil due to excitation of the pile group in three directions (P_2) as well as distant vertical excitation (P_1) for $L = 10$ and 20 m.

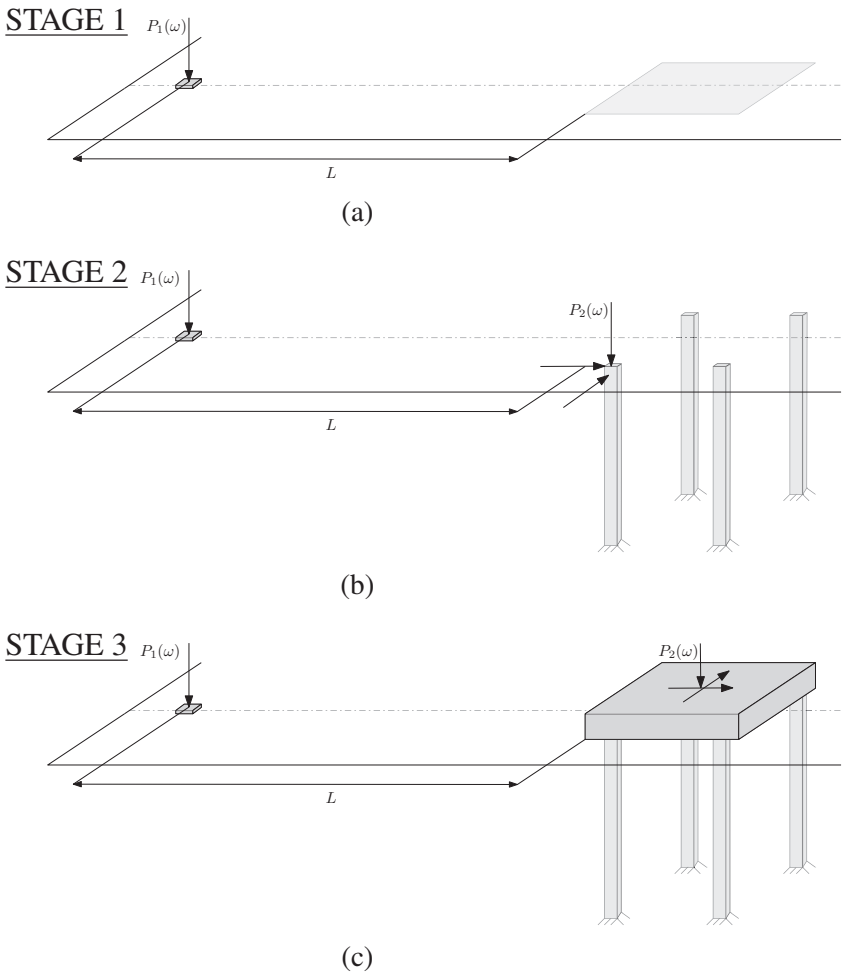

Figure 6: Illustration of the measurements during the different construction stages (a) in the free field, (b) where only piles are installed and (c) where the full pile group is constructed.

Measuring at the different phases of construction of the foundation allows to extract the responses and impedances of the individual piles and the impedance of the pile group when joined

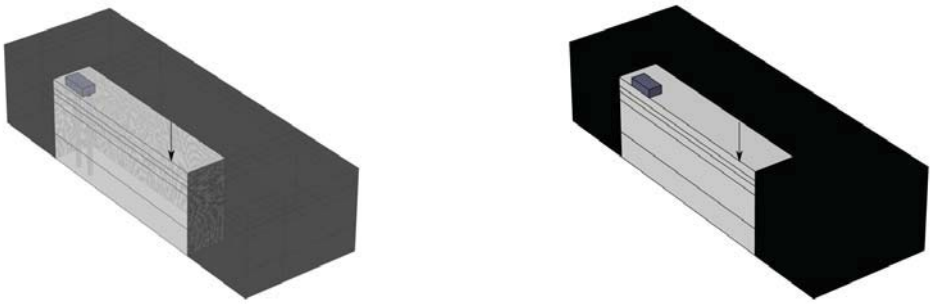
through the cap. This way, data is collected at each step in the construction process whenever additional complexity is added to the system. Thereby, model validation can be performed at each stage of construction. Furthermore, prediction methods using the information acquired in the first or second construction stage to make predictions of the joined pile group's behaviour can be analysed and evaluated. Such methods can be purely empirical models or hybrid models that merge experimental data and numerical predictions, e.g. the strategy followed by François et al. [3] using the method of joining subsystems [6], where hybrid predictions are made based on experimentally obtained pile top impedances and pile top responses due to distant excitation, in combination with a numerical model of the structure joining the pile tops.

4 NUMERICAL PREDICTIONS

To assess the experimental setup, preliminary numerical simulations are performed using a numerical model of the site and the pile group. A comparison is made to the case where instead of a pile foundation, a surface foundation of the same size as the pile cap is considered. Additionally, the corresponding response at the free ground surface at the position of the foundation is considered as a reference to both cases, highlighting the differences of the responses of the two foundation types in relation to the measured velocity at the free surface.

4.1 Numerical model

Simulations are conducted based on the assumption of small strains, so that the soil can be considered linear elastic. A finite element model is constructed to simulate the response of the pile group due to dynamic excitation using the software `Comsol Multiphysics`. The model is composed of solid elements to model both the pile group and the soil. The pile group material properties are set to the experimentally identified ones presented in section 3. The soil layer material properties are defined in accordance with table 2, except for the bedrock which is replaced by a fixed boundary condition. As the problem is symmetric along the path between the source and the receiver, a symmetry condition is applied. The radiation condition is fulfilled by using Perfectly Matched Layers (PML), applied in a zone closest to the boundary in fig. 7, attenuating any outgoing waves before hitting the fixed outer boundary of the model. The PML stretch functions are defined in accordance with the ones proposed by Basu and Chopra [1] and have been verified to efficiently absorb outgoing waves when compared to Green's functions of the profile, corresponding to the exact solutions of a point load, computed with the Direct stiffness method using the Matlab toolbox EDT [7].

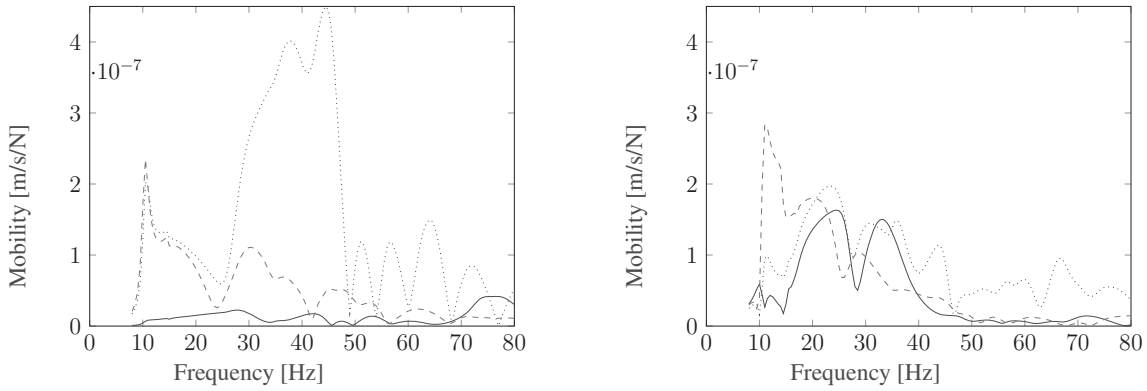


(a) (b)

Figure 7: Geometry of single symmetric finite element model of the (a) pile foundation and (b) surface foundation. The arrow indicates the position and direction of the applied load at the offset 10 m and the outer black partitions of the model correspond to the zone of Perfectly Matched Layers (PML).

4.2 Simulation results

The vertical and horizontal responses of the pile- and surface foundation due to a vertical point load applied at the soil surface at a 10 m distance are compared to the responses at the free surface corresponding to the mid-point of the foundations. Figure 8 compares the velocity responses of the reference points for all three cases. The surface foundation amplifies both the vertical and horizontal responses in the lower frequency range, while acting as a filter at higher frequencies where the dimensions of the foundation are comparable to the wavelengths of the surface waves.



(a) (b)

Figure 8: Velocity response at a 10 m distance from the source at the free surface (dotted line), mid-point surface foundation (dashed line) and mid-point pile cap (solid line) in the (a) vertical direction and (b) horizontal direction.

The pile group, on the other hand, presents a different behaviour, where the vertical response in the lower frequency range is suppressed, while a higher response is found in the frequency range 70–80 Hz, compared to the surface foundation. The horizontal motion of the pile group shows a similar response as the free surface in the frequency range 10–40 Hz. The horizontal

motion of the surface foundation shows a similar trend as the vertical motion, where an amplification of the response is found for lower frequencies while higher frequencies are attenuated.

5 CONCLUSION

Traffic induced vibrations are becoming a concern when constructing apartment or office buildings in the vicinity of major roads or railway lines. When building on sites with poor soil conditions, pre-fabricated concrete piles are an economical choice for constructing the foundation. Although many different modelling approaches exist for making predictions of the response of piled foundations, there is a lack of experimental evidence of the ability to predict the response of end-bearing piles when subjected to distant excitation on the soil's surface.

The design of an experimental campaign investigating the dynamic response of a pile group due to small strain incident loading is presented. The aim of the experiment is to validate models used for the prediction of traffic induced vibrations in buildings. The experiment is conducted at a remote site in the vicinity of Stockholm, where no outside disturbance or construction activity is present. The site's soil profile consists of a shallow layer of soft clay on top of a bottom layer of moraine resting on a high quality bedrock. Multiple geophyscial tests are performed, yielding dynamic soil parameters used as input for model predictions. At this site, a 2×2 concrete pile group is constructed using conventional pre-fabricated concrete piles, joined by a $2 \times 2 \times 0.6$ m concrete pile cap.

Controlled dynamic excitation is applied at the construction site from distances of 10 and 20 m at different stages of construction. Measurements are taken at the undisturbed soil surface before construction, after the piles are driven and finally when the pile tops are joined in the pile cap. Responses are measured along the propagation path in the soil, along the center line of the embedded piles and on top of the pile cap. Numerical simulations of the experimental setup show a different behaviour of the pile group compared to a surface foundation of the same dimensions, demonstrating that the foundation type has a large influence on the transmission of vibrations for the proposed setup.

6 ACKNOWLEDGEMENTS

This work is supported by the Development Fund of the Swedish Construction Industry, SBUF. The funding for experiments and site investigations is received from Vinnova, the Richertska foundation and Trafikverket. The financial support is gratefully acknowledged. The authors would like to thank the Swedish Geotechnical Institute (SGI) for assisting with the laboratory analysis of the soil samples.

Keywords: Integral Transform Method, Dynamic Stiffness Method, Fourier Transforms, Modal Superposition Method, Substructure Method

Abstract. *A semi-analytical method deals with vertical vibrations of a massive, flexible rectangular foundation smoothly jointed to an elastic, homogeneous halfspace is presented. The method is based on the solution in frequency domain that represents a combination of the Integral Transform Method (ITM) used for the soil and the Dynamic Stiffness Method (DSM) used for the foundation. The coupling of the foundation and the soil is established using the modal superposition technique. The influence of the foundation mass and the foundation stiffness on the response of the system is analyzed. The accuracy of the results obtained by using the proposed technique is also discussed.*

1 INTRODUCTION

The dynamic response of rigid foundations on the elastic halfspace has been investigated extensively since the beginning of the last century [1]. The assumption that the foundation is rigid simplifies the solution. However, it is not applicable in the general case, since foundations exhibit flexural behavior. The response of the flexible foundation-soil system is affected by many factors, such as the foundation-soil stiffness ratio, the load distribution, the foundation mass, etc. The studies of the dynamic response of flexible foundations are mostly performed using a combined finite element method and Green's function [2, 3, 4, 5, 6, 7]. This is a computationally demanding approach, especially in the high frequency range. A more efficient technique is the one based on modal analysis that uses free vibration mode shapes of a plate and the modal stiffness matrix of the soil. This technique is used by Chen and Hou [8] to solve the problem of vibrations of circular flexible foundation. It requires the usage of the Bessel functions and the closed form stiffness matrices for wave propagation problems in layered media.

In this paper the solution for vertical vibrations of rectangular flexible foundations smoothly jointed to an halfspace is obtained. The Integral Transform Method (ITM) [9, 10], used to compute impedance functions of the soil, is combined with the Direct Stiffness Method (DSM) [11, 12], used to calculate the dynamic stiffness of the foundation plate, to obtain the response of flexible surface foundation in the frequency domain.

The ITM is based on solving Lamé's differential equations of motion, decoupling them using the Helmholtz decomposition and transforming them from partial to ordinary differential equations by a threefold Fourier Transform. The ordinary differential equations are solved in the transformed wavenumber-frequency domain by taking into account the boundary conditions of the system. The solution is transferred in the original space-time domain by using threefold inverse Fourier Transform.

The DSM is based on the exact solution of the governing differential equations of motion in the space-frequency domain. Consequently, the dynamic stiffness matrix of the element is frequency dependent. It can be developed explicitly for one-dimensional beam elements and Levy-type plates. In the case of plates with arbitrary boundary conditions, the plate displacements are presented in infinite series form, and the boundary problem is solved using the Projection method [15].

The soil-foundation interaction problem (FSI) is solved using the substructure approach and the modal superposition technique [8, 13, 14].

The proposed method is used to analyze the influence of the foundation mass and the foundation stiffness on the response of the system. Both perfectly flexible massive foundation and massive rigid foundation are analyzed. The obtained results are compared with the results from the literature.

2 FORMULATION OF THE PROBLEM

The formulation is derived by observing a steady state vertical vibrations of a rectangular flexible foundation on the surface ($z = 0$) of an elastic, homogeneous and isotropic half-space, Figure 1. It is assumed that the foundation behaves as a Kirchhoff plate and that the contact between the foundation and the soil is smooth. The foundation-soil system represents the assemblage of two substructures, namely the soil and the foundation. The solution is obtained using the substructure approach, i.e. each medium is considered separately and finally combined taken into account the equilibrium and compatibility conditions at the contact surface. In order to reduce the numerical effort the modal superposition is introduced. The displacement

field of the foundation is represented by a set of modal coordinates corresponding to free vibration mode shapes of a rectangular plate, while the influence of the soil reaction forces on the foundation is considered by introducing modal soil impedance functions. The response of the system is obtained in the frequency domain, (x, y, ω). Regarding the steady state analysis, the ω variable is omitted in the notation of the functions.

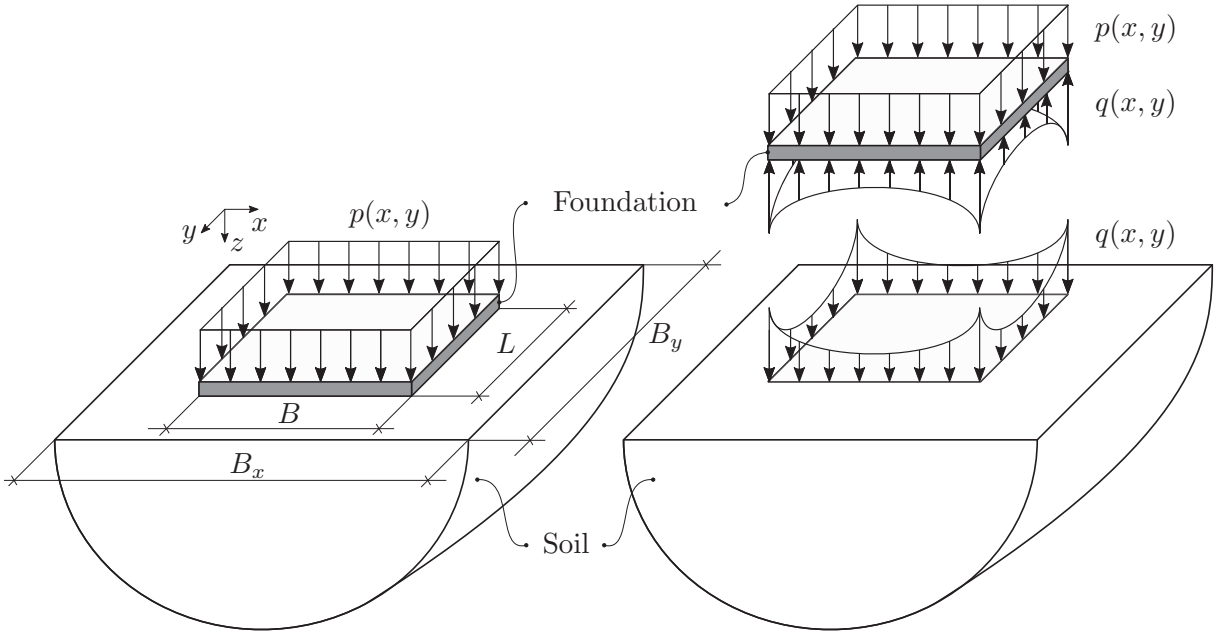

Figure 1: Disposition of the problem.

The differential equation of the problem in (x, y, ω) domain is given by

$$D\left(\frac{\partial^4 w(x,y)}{\partial x^4} + 2\frac{\partial^4 w(x,y)}{\partial x^2 \partial y^2} + \frac{\partial^4 w(x,y)}{\partial y^4}\right) - \rho h \omega^2 w(x,y) = p(x,y) - q(x,y) \tag{1}$$

where ω is the excitation frequency, D denotes the bending stiffness of the plate, $w(x, y)$ is the displacement field, ρ is the material density and h is the thickness of the plate. The bending stiffness of the Kirchhoff plate is defined as

$$D = \frac{Eh^3}{12(1-\nu^2)} \tag{2}$$

where E is Young's modulus, ν is Poisson's coefficient of the foundation. The functions $w(x, y)$, $p(x, y)$ and $q(x, y)$ are the transverse deflection of the foundation, the vertical load and the soil reaction, respectively. They can be expanded in a series of free vibration modes as follows:

$$w(x,y) = \sum_{n=0}^{N} Y_n \phi_n(x,y) \tag{3}$$

$$p(x,y) = \sum_{n=0}^{N} P_n \phi_n(x,y) \tag{4}$$

$$q(x,y) = \sum_{n=0}^{N} Q_n \phi_n(x,y) \tag{5}$$

where ϕ_n represents the orthonormalized mode shape of the foundation for the n^{th} mode and Y_n , P_n and Q_n are modal coefficients:

$$Y_n = \int_{x=0}^{B} \int_{y=0}^{L} w(x,y)\phi_n(x,y)dxdy \tag{6}$$

$$P_n = \int_{x=0}^{B} \int_{y=0}^{L} p(x,y)\phi_n(x,y)dxdy \tag{7}$$

$$Q_n = \int_{x=0}^{B} \int_{y=0}^{L} q(x,y)\phi_n(x,y)dxdy \tag{8}$$

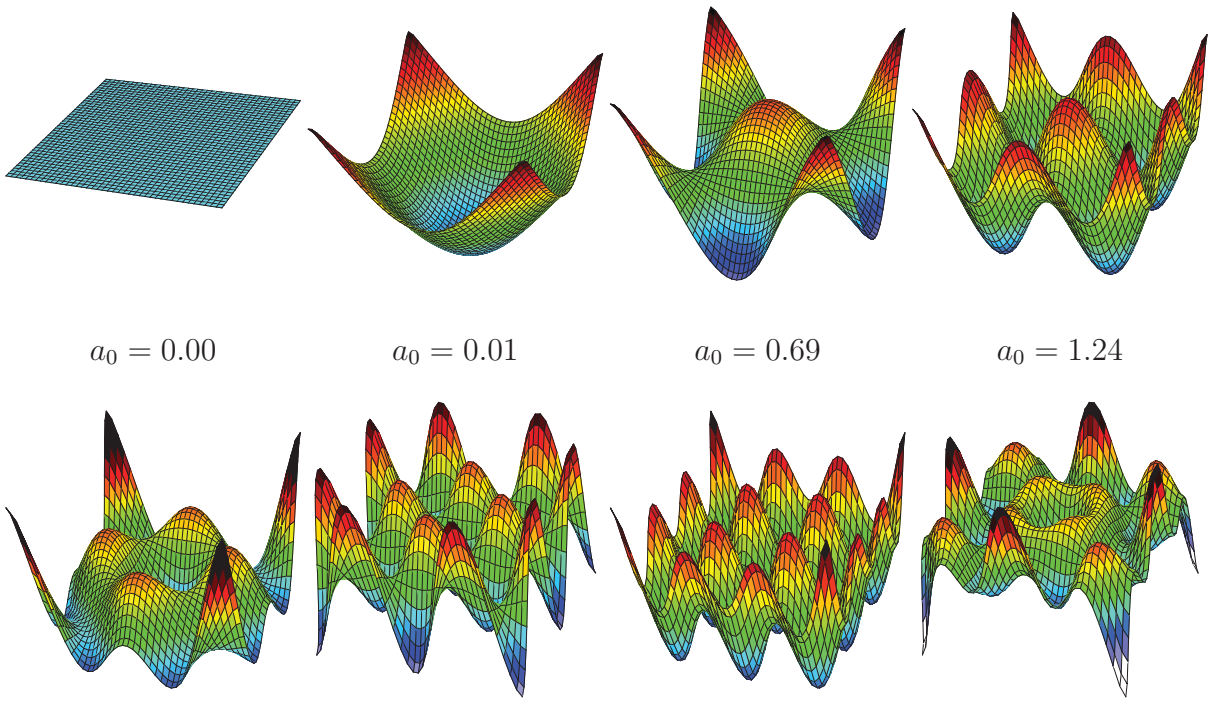
The mode shapes of the foundation are obtained for the case of free vibrations of the completely free plate, solving the eigenvalue problem by using the DSM [11]. The general solution of the problem is of the form

$$\phi_n(x,y) = e^{k_{xn}x}e^{k_{yn}y} \tag{9}$$

where k_{xn} and k_{yn} are wavenumbers in x and y direction, such that

$$k_{xn}^2 + k_{yn}^2 = \pm\omega_n\sqrt{\frac{\rho h}{D}} \tag{10}$$

and ω_n is the n^{th} natural frequency of the plate. The problem is solved by introducing an infinite series of base solution in the (k_x^2, k_y^2) plane [15]. Figure 2 shows the first eight mode shapes of a Kirchhoff plate. The first mode is a translational mode. Substituting equations (6) and (9) into



$a_0 = 0.00$ $a_0 = 0.01$ $a_0 = 0.69$ $a_0 = 1.24$

$a_0 = 1.75$ $a_0 = 2.96$ $a_0 = 3.05$ $a_0 = 3.54$

Figure 2: Free vibrations mode shapes of a rectangular foundation.

equation (1) gives

$$\sum_{n=0}^{N}\left(D(k_{xn}^4+2k_{xn}^2k_{yn}^2+k_{yn}^4)-\rho h\omega^2\right)\phi_n(x,y)Y_n=\sum_{n=0}^{N}\phi_n(x,y)P_n-\sum_{n=0}^{N}\phi_n(x,y)Q_n \quad (11)$$

Since the mode shapes ϕ_n are orthonormal, for a uniform mass distribution, equation (11) can be decoupled into N equations by multiplying with the mode shape ϕ_n and integrating over the area of the foundation. That gives the system of N equations, written in matrix form:

$$\left[D\left[\mathbf{k^4}\right]-\rho h\omega^2[\mathbf{I}]\right]\{\mathbf{Y}\}=\{\mathbf{P}\}-\{\mathbf{Q}\} \quad (12)$$

where $\{\mathbf{Y}\}$, $\{\mathbf{P}\}$ and $\{\mathbf{Q}\}$ are coefficient vectors of the modal displacement, the load and the soil reaction, respectively, $[\mathbf{I}]$ is the identity matrix and $[\mathbf{k^4}]$ is the pure bending wavemode wavenumber matrix of the plate

$$\left[\mathbf{k^4}\right]=\begin{bmatrix}0 & 0 & \cdots & 0\\ 0 & \rho h\omega_1^2 & & \vdots\\ \vdots & & \ddots & 0\\ 0 & \cdots & 0 & \rho h\omega_N^2\end{bmatrix} \quad (13)$$

where $\omega_1,\ldots,\omega_N$ are natural frequencies of the plate, obtained using the DSM [11].

Relation between displacements and soil reaction coefficient vectors can be defined as follows

$$[\mathbf{K_s}]\{\mathbf{Y}\}=\{\mathbf{Q}\} \quad (14)$$

where $[\mathbf{K_s}]$ is the modal impedance matrix of the soil, obtained using ITM [16]. Substituting (14) into (12) the equation of motion becomes

$$\left[D\left[\mathbf{k^4}\right]-\rho h\omega^2\left[\mathbf{I}\right]+\left[\mathbf{K_S}\right]\right]\{\mathbf{Y}\}=\{\mathbf{P}\} \quad (15)$$

Once the modal impedance matrix of the soil is formed, the displacement coefficient vector Y is obtained by solving the system of equations (14) and finally the displacement field $w(x,y)$ is obtained by using equation (3). To obtain the displacement field spectrum, the procedure should be repeated for every frequency ω in a desired frequency range. A computer program based on this formulation is developed in MATLAB [17]. In order to achieve numerical stability of the ITM, it is necessary to introduce a small damping into the system. This is accomplished by using a complex moduli

$$E^*=E(1+2i\xi) \quad (16)$$

$$G_s^*=G_s(1+2i\xi) \quad (17)$$

where G_s is soil medium shear modulus, i is imaginary unit and $\xi=1\%$ is the damping ratio.

3 NUMERICAL RESULTS

In order to investigate the influence of the mass and stiffness of the foundation on the response of the system it is good to rewrite equation (15) as

$$\left[\left[\mathbf{K_p}\right]+\left[\mathbf{K_m}\right]+\left[\mathbf{K_s}\right]\right]\{\mathbf{Y}\} \;=\; \{\mathbf{P}\} \quad (18)$$

$$(19)$$

where

$$[\mathbf{K_p}] = D\left[\mathbf{k^4}\right] \tag{20}$$

$$[\mathbf{K_m}] = -\rho h\omega^2\,[\mathbf{I}] \tag{21}$$

Two extreme cases are analyzed: a rigid foundation and a perfectly flexible foundation. The obtained results are presented in terms of main system parameters: the dimensionless stiffness ratio K, the dimensionless mass ratio M, the dimensionless frequency a_0 and the dimensionless response parameter - the displacement $\overline{\Delta}$ [7]

$$K = \frac{Eh^3(1-\nu_s)}{12(1-\nu^2)G_s(B/2)^3} \tag{22}$$

$$M = \frac{h\rho}{(B/2)\rho_s} \tag{23}$$

$$a_0 = \frac{\omega(B/2)}{c_s} \tag{24}$$

$$\bar{\Delta} = \Delta\frac{G_s(B/2)}{(1-\nu_s)\sum F_{ext}} \tag{25}$$

where ω is the excitation frequency, foundation parameters are: modulus E, Poisson's ratio ν, density ρ, thickness h, width B and soil medium parameters are: shear modulus G_s, shear wave velocity c_s, Poisson's ratio $\nu_s$and density ρ_s. A set of steady state analyses is performed, for $a_0 \in [0.1, 6]$ with an increment of 0.05.

In the case of rigid foundation ($K \geq 3.3$) the displacement field is uniform and spatially independent. The stiffness $[\mathbf{K_p}]$ vanishes since $[\mathbf{k^4}] = 0$. The usage of only the first, translational mode shape participates in the solution, $n = 0$. The system of equations (27) is reduced to a single equation:

$$(K_{s0} + K_{m0})Y_0 = P_0 \tag{26}$$

After obtaining Y_0 from equation (26) the response of the system is calculated as

$$\Delta = Y_0\phi_0 \tag{27}$$

The response of rigid foundation is analyzed for $M = 0$ and $M = 1$. The results are presented in Figures 3 and 4 in terms of absolute values of dynamic stiffness and dynamic flexibility of the system, respectively. Figure 3 shows the absolute values of the components of dynamic stiffness matrix: K_{m0}, K_{s0} and $K_{m0} + K_{s0}$. It is shown that the mass of the foundation decreases the stiffness of the system for $a_0 < 3$ and increases the stiffness of the system for $a_0 > 3$. Figure 4 shows the absolute values of vertical displacement $\overline{\Delta}$ of massive foundation $M = 1$ and the foundation without the mass $M = 0$. The vertical displacement of massive foundation is higher than the vertical displacement of massless foundation for $a_0 < 3$, while for $a_0 > 3$ is the opposite.

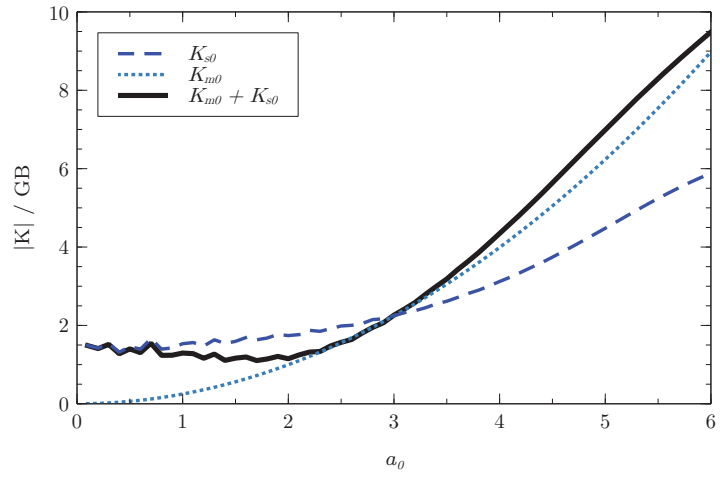


Figure 3: The influence of foundation mass on dynamic stiffness $[\mathbf{K}]$ of rigid foundation.

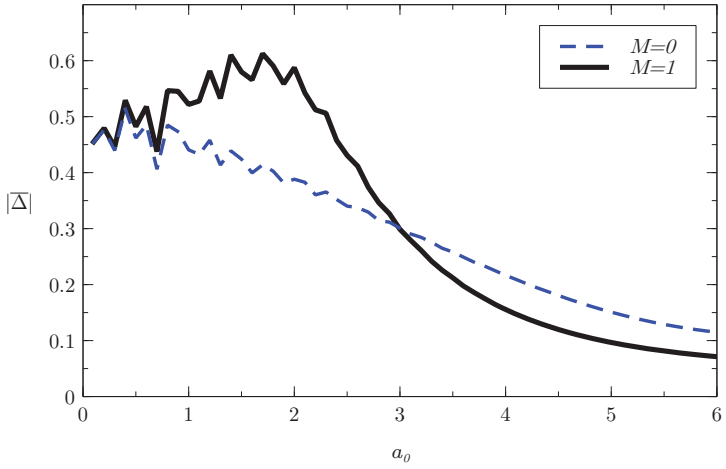

Figure 4: The influence of foundation mass on dynamic flexibility $\overline{\Delta}$ of rigid foundation.

In the second case a perfectly flexible massive foundation is analyzed, $K = 0$, $M = 1$. The influence of the number of mode shapes n on the response of the system is analyzed and compared with the results from the literature [7]. The first eight mode shapes, Figure 2, are taken into account. Absolute values of vertical displacement of the center of the foundation are shown in Figure 5. It is obvious that as the number of mode shapes increases the results converge. Six natural frequencies of the system are distinguished by using eight free vibration mode shapes of the plate, $n = 8$. The corresponding natural mode shapes of the system are shown in Figure 6. There is no resemblance between the natural mode shapes of the flexible foundation, 6, and the natural mode shapes of the flexible plate, 2.

The third and fourth natural frequency, $a_0 = 3.75$ and $a_0 = 4.15$, does not occur in the literature [7]. In the comparison with the rigid massive foundation, Figure 4, the flexible foundation performs similar within the frequency range $0 \leq a_0 \leq 2.5$. However, for $a_0 > 2.5$, the absolute displacement of the flexible foundation does not decrease with the frequency as in the case of rigid foundation.

The deviation of the results obtained using the proposed method is visible in figures 3, 4 and

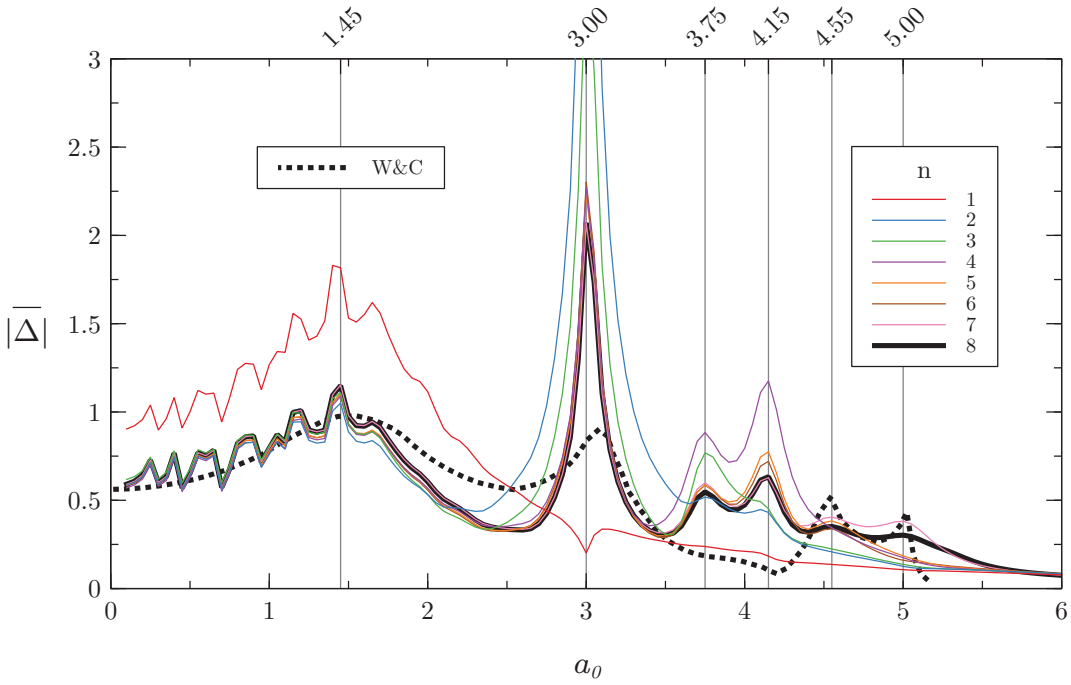

Figure 5: The influence of the number of mode shapes on the response of the system involving the flexible foundation, $K = 0$, $M = 1$, plotted against the results from the literature [7].

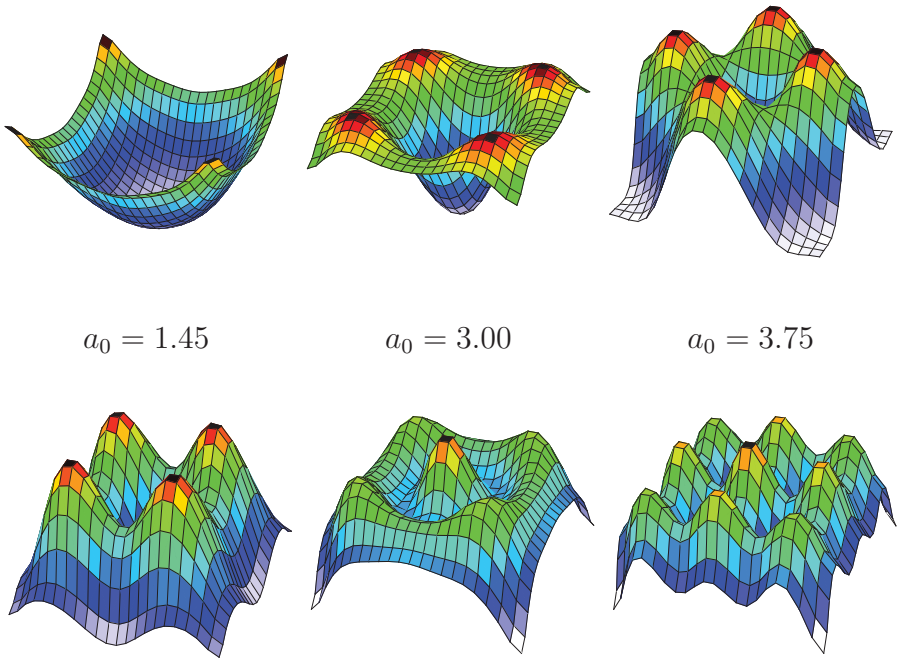
5 for $a_0 \in [0, 1.5]$. For small damping ratios, especially in the low frequency range, it is hard to avoid the aliasing effect of Fourier Transforms without a significant computational effort. The solution could be the application of the method of residue [18, 19] but this is still to be investigated.



$a_0 = 1.45$ $a_0 = 3.00$ $a_0 = 3.75$

$a_0 = 4.15$ $a_0 = 4.55$ $a_0 = 5.00$

Figure 6: Displacement shapes of the flexible foundation at characteristic peaks, $K = 0$, $M = 1$.

4 CONCLUSIONS

This paper presents a semi-analytical method for solving the problems of massive flexible rectangular foundations resting on the surface of the soil. It is a hybrid method based on coupling Dynamic stiffness method (DSM) and Integral transform method (ITM) using substructuring approach and modal superposition technique. Both DSM and ITM are based on the analytical solution of governing equations of motion in space-frequency or wavenumber-frequency domain. The presented study shows the differences between the analysis of a massive rigid and flexible foundation. In the case of rigid foundation, the influence of the mass could be added to the system separately, while in the case of flexible foundation, the analysis must be carried out simultaneously. The response of a perfectly flexible massive foundation is analyzed. Regarding the nature of the presented method, the number of mode shapes used for the calculation is important for the convergence of the results. The results of the analysis are compared with the results from the literature. More natural frequencies are discovered in the spectrum of vertical displacements of the foundation central point using the proposed method. The deviation of the results obtained using the ITM-DSM is visible in the low frequency range, $a_0 < 2.5$. The solution to this problem is discussed, and it is to be investigated.

Keywords: Dynamic impedance functions, Permanent load, Dynamic soil–structure interaction, Soil dynamics.

Abstract. *The effects of model assumptions on the dynamic impedance functions of shallow foundations are investigated using finite elements. The shallow foundations are considered massless and rigid and are positioned in strata of frictional soil on top of bedrock. Two studies are established. The first investigates the combined effects of model assumptions including the variation of modulus with depth, the embedment of the foundation, and permanent load acting on the foundation. The second study is a parametric analysis investigating the effects of permanent load considering strata with varying soil modulus coefficients and with varying soil depths. Functions describing the small-strain modulus and the modulus reduction of frictional soil are used in an iterative process to update the spatial modulus distribution of the soil due to the permanent load. The results show that model assumptions can have a large effect on the impedance functions. The static stiffness coefficients vary substantially, in some instances by more than 100 %. The impedance functions, normalized with the static stiffness coefficients, match each other well in the frequency range below the fundamental frequency. However, in the frequency range above the fundamental frequency, the normalized impedance functions differ substantially from each other. Further, the results show that the effect of the permanent load is largest in the case of shallow and stiff soil strata, both regarding normalized impedance functions as well as the static stiffness coefficient, which was increased up to 67 %. The variation in fundamental frequency is however small.*

1 INTRODUCTION

In the design of high-speed railway bridges, a dynamic assessment is required. The boundary conditions of these bridges are in many design situations modeled with fixed supports. However, the flexibility of the supports, due to the dynamic soil–structure interaction (SSI), may significantly change the dynamic properties of the bridges. One method of considering the SSI is by decoupling the models and calculating impedance functions. Instead of computing the complete soil–foundation–structure system, the model is decoupled and impedance functions are calculated from the soil–foundation subpart before being applied to the structure. This sub-structuring of the system enables faster calculations, especially at train loading analysis, as compared to the calculation of the complete system.

The impedance function is commonly expressed in complex numbers:

$$Z(\omega) = k_d(\omega) + i\omega c_d(\omega) \tag{1}$$

where k_d is the dynamic stiffness coefficient, c_d is the dashpot coefficient, ω is the cyclic frequency of excitation, and $i = \sqrt{-1}$.

Impedance functions have been published in many journal papers and are compiled in handbooks to give structural engineers simple tools to take SSI into account in design (see e.g. [1] or [2]). Although the studies given in the literature fully explore the effects of one or two of the specific features in each paper, when it comes to combinations of features that are not given in the literature, it may be difficult for the engineer to find the relevant model assumptions to use in a specific project and what consequences to expect. To fill that gap, this paper investigates the effects of the embedment of the foundation, the variation of the modulus with the depth, and the depth of the stratum on bedrock in different combinations. Further, the effects of applying a permanent load to the soil–foundation system and updating the spatial distribution of the modulus before performing linear dynamic analyzes are introduced.

The purpose of this paper is to show the effects of model assumptions on the dynamic impedance functions of shallow foundations. The article aims at filling the gap in the literature by investigating the combined effects of model assumptions from a practical point of view. Two main objectives of the study are defined. The first was to study the implications of model assumptions, including the embedment of the foundation, the variation of the modulus with the depth, and the permanent load. Impedance functions calculated from the models with varying levels of idealization are compared in the paper. The second objective was to quantify the influence of permanent load in relation to the soil modulus coefficient and stratum depth. A parametric study was performed for this purpose. To fulfill the objectives, numerical models using finite elements (FE) were created. The shallow foundation was assumed to be rigid and massless and was given a fixed geometry. The soil strata consisted of frictional soil supported by bedrock. Whereas the permanent load of the structure was included in the soil–foundation FE model in order to consider its effect on soil properties, the mass of the structure was not. This mass will be taken into account when the impedance functions are attached to the structure. The spatial variation of the modulus of elasticity caused by the permanent load was updated for each element, considering functions for the low-strain modulus and modulus reduction. Linear dynamic analyses were then performed on the updated models, and the impedance functions were calculated. The dynamic loading was assumed to affect the soil within the linear elastic range, and the impedance functions are valid in the serviceability limit state.

The soil and foundation parameters were chosen in the context of high-speed railway (HSR) bridges and Swedish soil conditions. Swedish geology is dominated by glacial soil masses

on top of high-quality bedrock [3]. At many locations, lodgment moraine overlays bedrock, possibly covered by clay or silt layers. For shallow strata consisting of frictional soil, shallow foundations may be suitable for HSR bridges. Such soil deposits are limited in depth, and the maximum depth considered in this study was assumed to be 8 m. The embedment depth of a foundation is typically determined by the frost-free depth, which in Sweden is considered at 1.1-2.5 m.

2 SOIL PROPERTIES

2.1 Small-strain shear modulus

The small-strain shear modulus of soil has been studied empirically by several authors for soil types ranging from cohesive to frictional, and many suggestions for formulas have been proposed [4–6]. Seed and Idriss [7] suggested a simplified formula for the small-strain shear modulus of frictional soil:

$$G_0 = K_0(\sigma')^d \tag{2}$$

where K_0 is the soil modulus coefficient, d is the stress exponent, and σ' is the mean effective stress. K_0 and d are soil type-specific constants. The Swedish design recommendations [8] have adopted this formula and adjusted it for Swedish conditions. In the recommendations, K_0 ranges from 15,000 to 30,000 where the first value corresponds to sand and the latter to crushed fill material. Furthermore, $d = 1/2$, and the stress is inserted in kPa.

The mean effective stress σ' can be subdivided into two additive parts. For frictional soil, the stress in the undisturbed in situ soil is commonly estimated by the confined effective stress based on the coefficient of lateral earth pressure [9]:

$$\sigma'_0 = \sigma'_v \frac{1+2k}{3} \tag{3a}$$

where this approximate relationship can be used:

$$k = 1 - \sin(\phi') \tag{3b}$$

Here, σ'_v is the effective vertical stress, k is the coefficient of lateral earth pressure, and ϕ' is the drained friction angle. Assuming no groundwater, the effective vertical stress σ'_v can be calculated with $\rho g z$ where ρ is the density, g is the gravity constant, and z is the depth from the soil surface. External load adds to σ' by the mean effective stress

$$\sigma'_{\mathrm{m}} = \frac{\sigma'_x + \sigma'_y + \sigma'_z}{3} \tag{4}$$

where σ'_x, σ'_y, and σ'_z are the effective normal stresses. Finally, the resulting stress becomes

$$\sigma' = \sigma'_0 + \sigma'_{\mathrm{m}} \tag{5}$$

2.2 Normalized modulus reduction

The reduction of modulus and increase of material damping ratio due to loading have been evaluated empirically in numerous studies for soil gradations ranging from cohesive to frictional soils [10–12]. In recent decades, researchers have aimed at collecting data from empirical studies and describing nonlinear relationships using statistical tools. In [13], a statistical analysis of empirical data from resonant column tests was conducted. This produced a set of 18 dimensionless parameters describing the normalized modulus reduction curves and material damping ratio

curves. The 18 parameters can be chosen to get either mean values or variances of the curves, and their values are dependent on the soil type. The normalized modulus reduction curve is calculated with

$$\frac{G}{G_0} = \frac{1}{1 + \left(\frac{\gamma}{\gamma_\mathrm{r}}\right)^a} \tag{6}$$

where γ is the current shear strain, γ_r is the reference shear strain, and a is the curvature coefficient. The formulas for γ_r and a are found in [13] and require, in addition to the 18 dimensionless parameters, the plasticity index, over-consolidation ratio, and stress in the soil. Only soils with gradations ranging from clay to sand were included. However, the difference in normalized modulus reduction curves between different gradations of frictional soils is relatively small [12, 14]. A comparison between the mean normalized modulus reduction curve of gravelly soils by Rollins et al. [12] and the corresponding curve for sand in [13] shows good agreement.

The shear strain can be calculated from the effective octahedral shear strain [15],

$$\gamma = \frac{\alpha}{3}\sqrt{(\varepsilon_x - \varepsilon_y)^2 + (\varepsilon_x - \varepsilon_z)^2 + (\varepsilon_y - \varepsilon_z)^2 + 6(\gamma_{xy}^2 + \gamma_{xz}^2 + \gamma_{yz}^2)} \tag{7}$$

where ε_i and γ_{ij} are components of the strain vector and $\alpha = 0.65$. This shear strain measure has been used in previous studies [16, 17].

3 NUMERICAL STUDIES

A fixed geometry of the foundation was used in all numerical simulations, and an overview of the FE model including the dimensions of the foundation is presented in Figure 1. The foundation was regarded as massless and rigid. The dimensions of the foundation are as follows: $L = 9.4$ m, $B = 3.3$ m, the thickness of the slab is 1.0 m, the length of the support wall is 7.0 m, and the thickness of the support wall is 0.9 m. H_1 is the soil depth underneath the bottom of the foundation, H_2 is the embedment depth and R is the radius of the FE model. The FE model is further described in section 4.1.

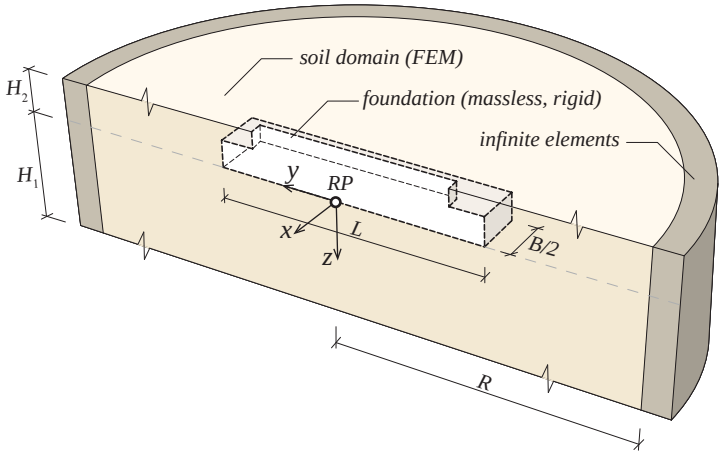

Figure 1: A cross-section of the finite element model.

The material properties of the soil were chosen from typical values of frictional lodgment moraine [18] and were assumed constant in all calculations. The following material properties were chosen for all cases: material damping ratio $\xi = 2.0$ %; density $\rho = 2000$ kg/m^3; Poisson's

ratio $\nu = 0.25$; friction angle $\phi' = 45$ deg; stress exponent $d = 1/2$, and gravity constant $g = 9.81$ m/s^2.

The permanent load was applied as a force P. In order to relate the load to the size of the foundation, the load is presented as a pressure q obtained from dividing the force P with the foundation's bottom surface area. The following values were taken: $q = (0, 220, 500)$ kPa. According to the Swedish design requirements, the upper limit on the pressure of shallow foundations on top of lodgment moraine on bedrock is 600 kPa [19].

The modulus at the surface of the stratum goes toward zero due to Eq. 2. This can cause poor conditioning of the elements because elements with high modulus are next to elements of low modulus, which can be particularly sensitive in the calculation of impedance functions from surface foundations. To avoid this, a lower limit for the modulus corresponding to the value at a depth of 0.2 m was chosen.

3.1 Model assumptions study

The effects of the model assumptions on the impedance functions were studied by investigating four cases as shown in Figure 2. It was decided that the fundamental frequency of all cases should be the same. This choice was made based on the fact that the behavior of the soil–foundation system is essentially different at frequencies below compared to above the fundamental frequency of the soil stratum, and fixing it was considered to be the best way to compare the models. In order to get the fundamental frequency of the homogeneous stratum to match the fundamental frequency of the stratum with a modulus varying with depth, the modulus value of the homogeneous soil stratum can be obtained by calculating an equivalent depth z_{eq} [20, 21]. z_{eq} determines the depth at which the equivalent modulus value G_{eq} of the modulus varying with the depth $G(K_0, \sigma'_0)$ is taken from. G_{eq} is then applied to the homogeneous stratum and the equivalent wave speed v_{eq} gives the fundamental period $T = 4H/v_{\text{eq}}$, where H is the total stratum depth. In this work, since $d = 1/2$ in Eq. 2, the equivalent depth was calculated to $z_{\text{eq}} = 0.64H$.

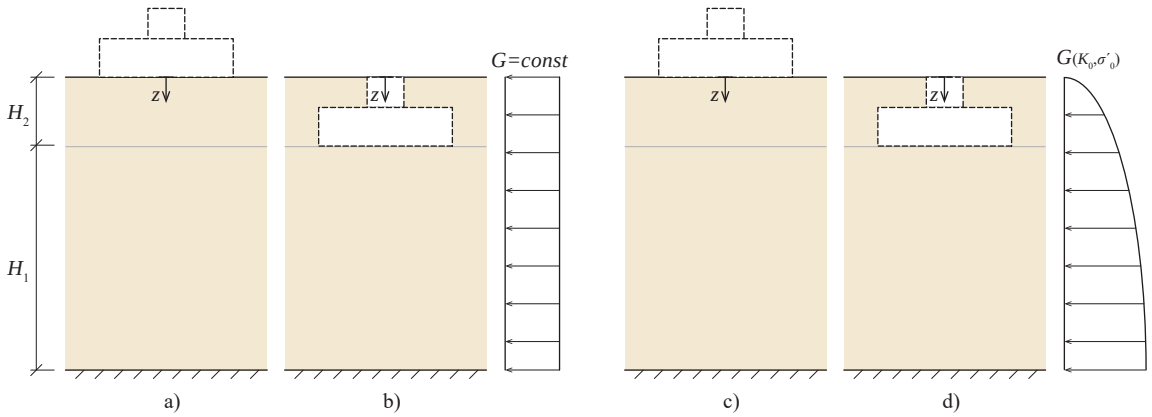

Figure 2: Cases considered in the model assumptions study.

The model assumption cases had the following properties:

- Case (a): A surface foundation on a stratum of homogeneous soil. No permanent load.
- Case (b): An embedded foundation in a stratum of homogeneous soil. No permanent load.

- Case (c): A surface foundation on a stratum with modulus varying with the depth. Includes permanent load P.
- Case (d): An embedded foundation in a stratum with modulus varying with the depth. Includes permanent load P.

The following parameters were chosen for all the models: $H_1 = 8$ m and $K_0 = 30{,}000$, corresponding to a deep soil stratum consisting of stiff lodgment moraine. The embedment depth was fixed at $H_2 = 1.6$ m. The modulus of Case (a) and Case (b) was calculated to G_{eq} = 240 MPa.

3.2 Parametric study

The effect of the permanent load was studied for the strata with varying depth H_1 and soil modulus coefficient K_0 in the parametric study. All the models had the configurations of Case (d) in Figure 2. Eighteen combinations were analyzed based on the following parameters: $q =$ (0, 220, 500) kPa, $H_1 =$ (2, 4, 8) m, and $K_0 =$ (15,000, 30,000). The embedment depth was fixed at $H_2 = 1.6$ m.

4 NUMERICAL MODEL

4.1 FE model

The numerical model of the soil–foundation system was created in the commercial FE software Abaqus [22], and an overview of the FE model is presented in Figure 1. The soil domain was created as a disk with a thickness equal to the stratum depth, and the bedrock was made infinitely stiff by constraining the bottom surface of the disk against translations. A void within the soil domain was created with the geometry of the embedded foundation. Then, rigid connections were applied to the surfaces of the soil facing the void linking them to a reference point (RP) positioned at the midpoint on the bottom surface. In the case of a surface foundation, no void was created and the single surface at the interface between soil and foundation was rigidly connected to the RP. Loading was applied and output was taken at the RP. The damping of the soil was applied as rate-independent structural damping which is incorporated in the complex modulus as $\boldsymbol{K}^* = \boldsymbol{K}(1 + i2\xi)$, where $\boldsymbol{K}$ is the stiffness matrix.

Quadratic tetrahedral solid elements were used. The mesh size at the center of the soil domain at the foundation was 0.25 m. From the center, the mesh size was gradually enlarged along the radius toward the boundary of the model. The radius of the model was R = 200 m. At the boundary, the mesh size was 20 m. Due to the gradual enlargement of the elements, the computational time was reduced without causing spurious waves that can occur due to large size differences between elements. Infinite elements [23] were attached to the outer surface boundary of the model domain.

4.2 Calculation procedure

The updating of the G-modulus in each of the elements due to permanent load and the calculation of impedance functions were performed as follows:

1. Initially, the unloaded modulus was assigned: Calculate σ_0' (Eq. 3) and G_0 (Eq. 2). In this state, $G/G_0 = 1$ (Eq. 6), and the shear modulus is $G = G_0$.
2. Apply permanent load P to the RP in Figure 1 and run a static analysis.

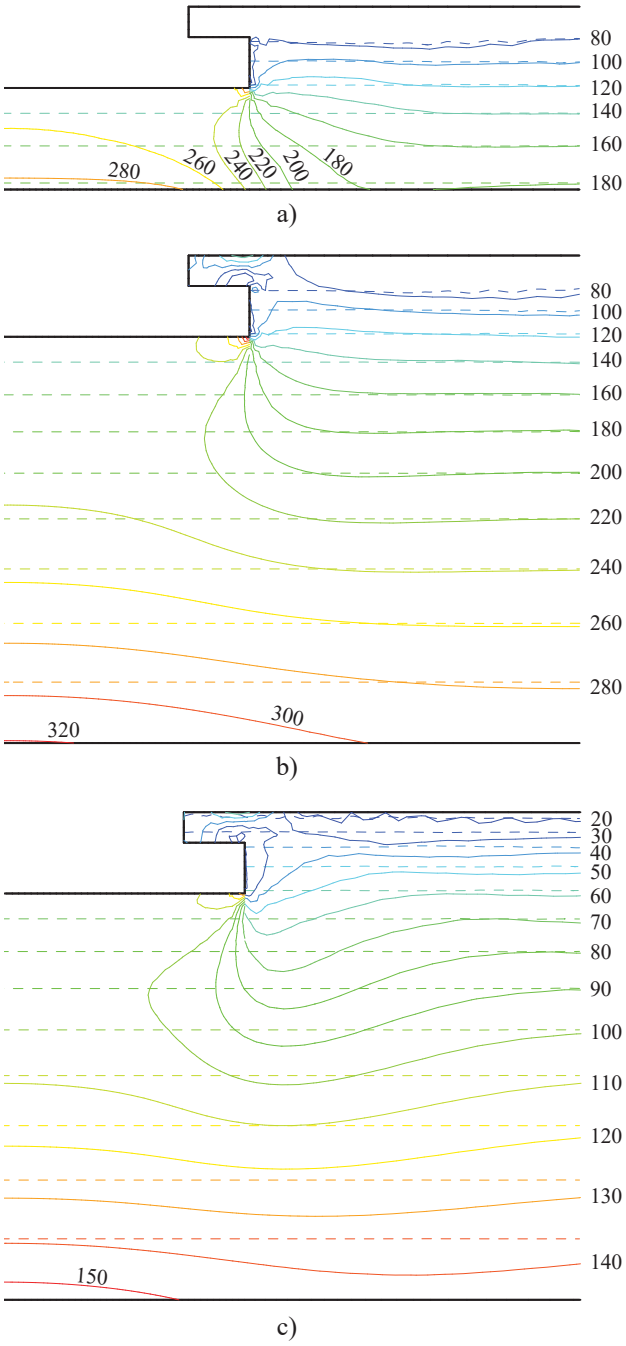

Figure 3: Updating of the shear modulus distribution due to permanent load. Values given in MPa. a) $H_1 = 2$ m, $K_0 = 30{,}000$, b) $H_1 = 8$ m, $K_0 = 30{,}000$ and c) $H_1 = 8$ m, $K_0 = 15{,}000$. Dashed lines: Unloaded soil. Solid lines: Updated soil.

3. Successively calculate: σ_0' (Eq. 3), σ_m' (Eq. 4), σ' (Eq. 5), G_0 (Eq. 2), γ (Eq. 7), and G (Eq. 6).

4. Repeat steps 2 and 3 until convergence of the distribution of shear modulus G is reached.

5. Calculate impedance functions.

Direct steady-state calculations were performed in order to obtain the impedance functions.

Harmonic unit loads were individually applied at the RP displayed in Figure 1 to each of the six degrees of freedom in a given frequency range. The compliance functions U were obtained from the model. The impedance functions were then calculated by the inverse of the compliance functions $Z = U^{-1}$. Only the values of the diagonal of the impedance function matrix were analyzed.

The converged distributions of the shear modulus for three of the models are shown in Figure 3, and the cuts are taken along the y–z plane. The models were configured as in Section 3.2 with $q = 220$ kPa. An increase of the permanent load results in two opposite effects on the modulus: an increase of G_0 due to the increase of σ' and a reduction by G/G_0 due to the increase of γ. In the volume between the foundation and the bedrock, the permanent load caused an increase in the modulus. The influence is large for shallow stratum depths. Just outside of this volume, the modulus can be either reduced or increased from permanent load depending on the stress–shear strain interaction.

5 RESULTS

The real part of the impedance function is denoted with $\mathrm{Re}(Z_j)$, whereas the imaginary part is denoted with $\mathrm{Im}(Z_j)$. The degrees of freedom are indicated by the subscript j and the coordinate axes are defined in Figure 1. The compliance functions, $|U_j|$, are denoted in the same way as the impedance functions and are given as absolute values. All functions are presented with the dimensionless frequency $a_0 = \omega w/v_{s,\mathrm{eq}}$ where $w = B/2$ and $v_{s,\mathrm{eq}} = \sqrt{G_{\mathrm{eq}}/\rho}$ is the equivalent shear wave velocity of the strata (without the influence of the permanent load). Impedance functions are normalized with the static stiffness coefficients $k_{j,\mathrm{stat}}$, and the compliance functions are normalized by the static displacements $u_{j,\mathrm{stat}}$.

5.1 Model assumptions study

The normalized impedance functions from the model assumptions study are presented in Figure 4 including the x and z degrees of freedom. The corresponding static stiffness coefficients are given in Figure 5. The following observations are made:

- The static stiffness coefficients range from 3 to 9 GN/m depending on the model case. The embedment of the foundation increases the static stiffness coefficient as compared to the static stiffness coefficient of the corresponding surface foundation, as shown by comparing Case (a) to Case (b), and Case (c) to Case (d). This is explained by the reduced distance to the bedrock. Strata with a modulus varying with the depth have lower static stiffness coefficients than strata with homogeneous modulus. This is evident when comparing Case (a) to Case (c) and Case (b) to Case (d). With increasing permanent load, the values of the static stiffness coefficients in Cases (c) and (d) are increased but they do not exceed the static stiffness coefficients of the homogeneous cases of (a) and (b).

- In the pre-resonance state, i.e. before wave propagations are initiated, the impedance functions are proportional to the static properties of the soil–foundation system. The normalized impedance functions can be described by a single degree of freedom system. The real part of this system is $(k_{j,\mathrm{stat}} - \omega^2 m_{j,\mathrm{stat}})/k_{z,\mathrm{stat}}$, where $m_{j,\mathrm{stat}}$ is the mass of the system, and the imaginary part is constant and is equal to $i2\xi$. The normalized impedance functions are thus very similar in the pre-resonance frequency range, however, they differ substantially at higher frequencies. In the post-resonant frequency range, the impedance is highly influenced by wave propagations and the single degree of freedom system can

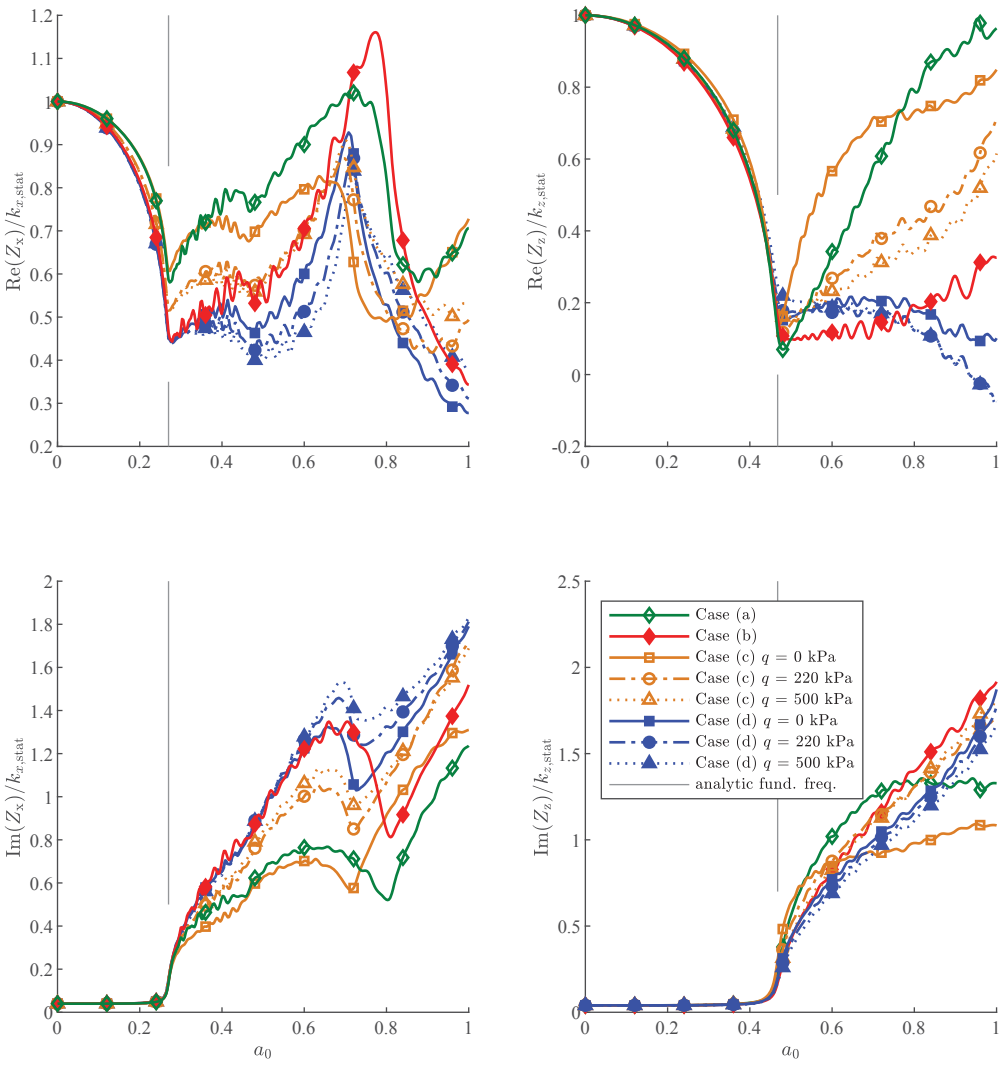

Figure 4: Normalized impedance functions from the model assumptions study.

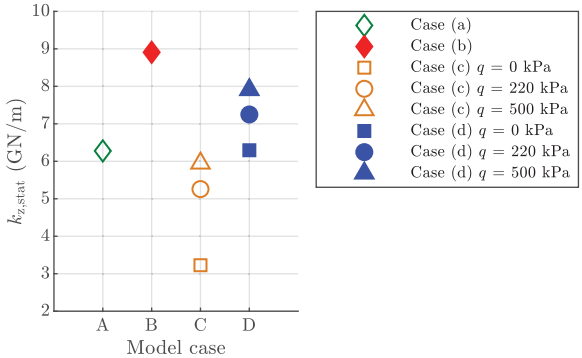

Figure 5: Static stiffness coefficients of the four model cases.

no longer describe the impedance functions. The imaginary part is increased significantly due to the radiation damping, and the differences in impedance between the cases are large.

- All cases had the same fundamental frequency which was also the same as the analytical fundamental frequency of the soil strata [20]. The fluctuations in impedance that can be observed for all cases at $a_0 \approx 0.7$ in the x-direction are due to the second mode of vibration of the soil, which for a homogeneous stratum has the natural frequency of three times the fundamental frequency according to $T_n = (4H/v)/(2n-1)$ were v is the wave speed and n is the mode number. The natural frequencies of the second mode for the strata with modulus varying with the depth are somewhat lower than the natural frequencies of the strata with homogeneous soil. The fundamental frequencies of the strata are not changed by the local influence that the permanent loads have on the soil moduli.

- For surface foundations on top of strata with modulus varying with the depth, as in Case (c), very low static stiffness coefficients are obtained with $q = 0$. This shows the consequences of omitting permanent load in combination with a very low modulus at the surface of the model. Adding the permanent load to Case (c) increases the static stiffness coefficient considerably. This effect is also shown for the normalized impedance functions, where an increase of the permanent load leads to a decrease of the real part of the impedance and an increase of the imaginary part.

5.2 Parametric study

Normalized impedance functions in the z-direction are presented in Figure 6. The static stiffness coefficients of each case, normalized with the static stiffness coefficients with q = 0 kPa, are given in Figure 7. The static stiffness coefficients with q = 0 kPa are given in Table 1 as a reference. Normalized compliance functions are presented in Figure 8. The following observations are made:

- For most cases, the static stiffness coefficient increases with the permanent load, in particular for shallow strata with a high soil modulus coefficient, see Figure 7. This can be explained by the high pressure and the small shear strain that mainly increase the modulus, see Figure 3 (a)–(b). The maximum increase of the static stiffness coefficient is 67 %. In the case of the deep strata with a low soil modulus coefficient ($H_1 = 8$ m and $K_0 =$ 15,000), the static stiffness coefficient decreases with an increased permanent load. The reduction is small (4 %) and is likely due to the high shear strains beside and under the foundation, which reduces the modulus (see Figure 3 (c)).

- In the pre-resonance frequency range, the system acts as a single degree of freedom system, as described in section 5.1. The real part of the normalized impedance can however be significantly influenced by the permanent load in this range, especially for shallower strata. This is clearly visible in Figure 6 in the case of H_1 =2 m where $(k_{j,\mathrm{stat}} - \omega^2 m_{j,\mathrm{stat}})/k_{z,\mathrm{stat}}$ is less steep for increasing permanent load, which is explained by a larger $k_{z,\mathrm{stat}}$ in relation to $m_{z,\mathrm{stat}}$. In the case of the deep soil, the effect of the permanent load on the pre-resonance impedance is low.

- In the frequency range above the fundamental frequency, the effect of the permanent load can lead to both an increase and a decrease of the normalized impedance at different

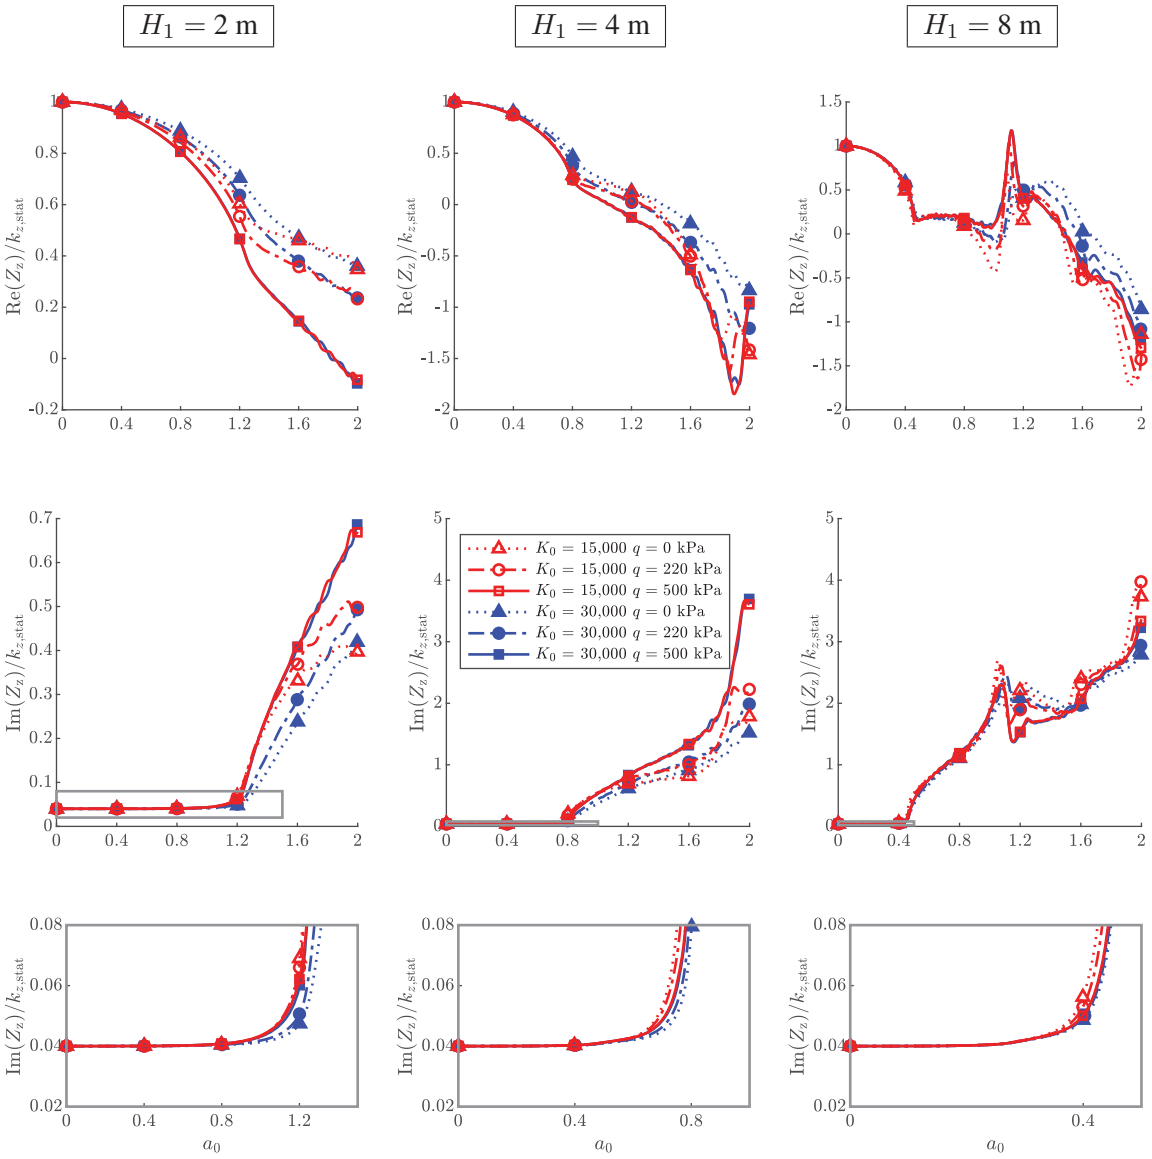

Figure 6: Normalized impedance functions and the effects of the permanent load.

K_0	H_1 (m)		
	2	4	8
15,000	5.7	4.0	3.1
30,000	11.4	7.9	6.3

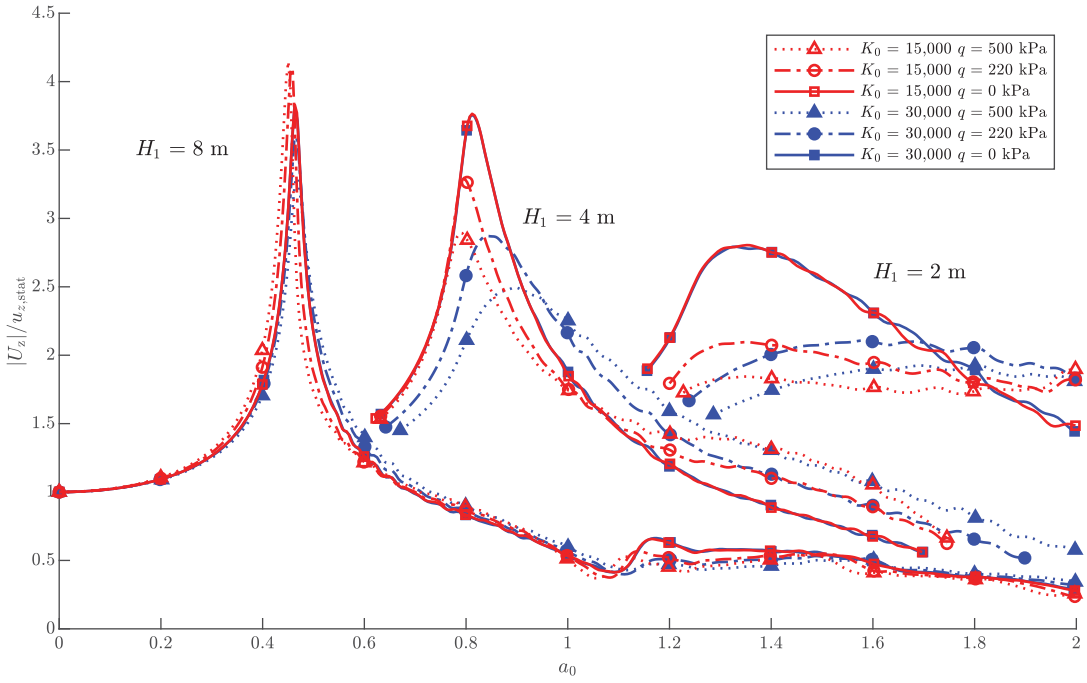

Figure 8: Normalized compliance functions from the parametric study.

frequency ranges. In the case of the shallower strata however, the real part of the normalized impedance is generally increased from the additional permanent load, whereas the imaginary part is decreased. Whereas the effect of the permanent load on the static stiffness coefficients can be quite large, the effect on the normalized impedance functions is relatively small, especially for the deeper strata and at lower frequencies.

- The effect of the permanent load on the fundamental frequency is small, see Fig 8. In the case of $K_0 = 15{,}000$, the fundamental frequency decreases with an increasing permanent load, whereas it increases in the case of $K_0 = 30{,}000$. The effect is smaller for deeper soil strata and increases with shallower depths. However, the variations of the fundamental frequency due to the permanent load are small when compared to the ones that are due to the stratum depth and the soil modulus coefficient.

- In most cases, the resonances of the normalized compliance functions decrease with an increasing permanent load, see Figure 8. The decrease is larger in the cases with stiffer and deeper soils. The resonance peaks for these cases are less distinct, whereas the resonance peaks become pointier for deeper and softer soils. The largest reduction of the normalized resonance peak is however observed in the case of the intermediate depth of $H_1 = 4$ m with a stiff soil $K_0 = 30{,}000$ and is 34 %. In the case of the soft and deep soil stratum ($H_1 = 8$ m with $K_0 = 15{,}000$), a small increase of the normalized resonance (8 %) due to the permanent load is observed.

6 CONCLUSIONS

The conclusions from the presented studies are summarized in the following main points:

1. The model assumptions can have a great influence on the impedance functions. The con-

sidered combinations of model assumptions produced normalized impedance functions that are similar in the frequency range below the fundamental frequency. However, in the frequency range above the fundamental frequency, the normalized impedance functions are very different. Further, the static stiffness coefficients of the models differ with more than 100 %.

2. The parametric study showed that the permanent load has a significant influence on the normalized impedance functions, especially in the cases of shallow soil strata with high soil modulus coefficients. In most of the cases, an increase of the permanent load leads to an increase of the static stiffness coefficient (with up to 67 %). However, in the case of the deep and soft soil, it leads to a small decrease of 4 %. The normalized impedance functions are in some cases relatively uniform, especially for the deeper strata.

3. The permanent load has a small effect on the fundamental frequency of the soil–foundation system.

Abstract. *Previous work has considered the effect that an array of periodic flexural resonators formed from Euler-Bernoulli beams attached to the surface of a linear elastic half-space has on Rayleigh wave propagation, using a specialised leading order asymptotic model for the Rayleigh-like wave motion induced by applied surface stresses. In this work we consider the same beam-like flexural resonators but instead apply a recently developed second order model as a correction to the leading order model. The higher order model is shown to be straightforward to apply and obtains an explicit dispersion relation, albeit one that is significantly less concise than obtained from the leading order model. This explicit dispersion relation is shown to give a significant improvement over the leading order model for cases with either a vertical or horizontal stress only, but not when a mixed stress is applied. As in previous work, special attention is devoted to the effect of various junction conditions between the half-space and resonators.*

1 INTRODUCTION

Recently, there have been several analytical [3, 6], numerical [5, 14], and experimental [2] studies on the use of sub-wavelength resonators for the control of surface waves on elastic substrates. Notable features of such resonant arrays include filtering, focusing, rainbow trapping, and mode-conversion of surface waves to bulk waves [4]. Numerical approaches are computationally intensive and require extensive GPU computing facilities [5], while complete analytical studies present their own significant challenges [6].

Unlike bulk waves, these surface waves do not have an explicit wave equation; they are instead 'hidden' through the equations of linear elasticity. This makes both finding the exact solution or undertaking numerical analysis for a system dominated by surface waves difficult. A leading order asymptotic model has been developed for the Rayleigh-type waves produced by forcing along the surface of a linearly elastic half space, relying on a slow-time perturbation procedure applied to the eigensolution expressed in terms of a single plane harmonic function, see [1, 12]. Within the described asymptotic formulation, the propagation of the Rayleigh wave along the surface is described by a hyperbolic equation, whereas the decay over the interior is governed by an elliptic equation for one of the elastic potentials. A systematic exposition of the asymptotic models for the Rayleigh and Rayleigh-type wave may be found in [11].

This model has been applied to multiple problems including moving loads [10, 8], surface arrays of rod-like resonators [7]. In each, the asymptotic model has produced a simple but remarkably accurate approximation of the exact solution. The formulation has also been recently extended to anisotropic media [13, 9].

While the asimptotic model for the Rayleigh wave has proven to give close representations of the exact solution in many cases, as the problems become more involved the deviation between the exact solution and result from the leading order model will increase. Previous consideration of a system of a surface array of beam-like resonators has shown notable deviations when there are stresses both parallel and perpendicular to the surface [15]. As such it is necessary to investigate this system further, making use of a newly developed higher order model [16].

2 PROBLEM STATEMENT

First we make use of the same system of flexural resonators introduced previously [15]. Shown in Figure 1, this consists of a periodic array of vertically arranged Euler-Bernoulli beams of length L and spacing l attached to the surface of a linearly elastic half-space.

Classically, these Euler-Bernoulli beams have governing equation

$$B_b I_b \frac{\partial^4 u_b}{\partial z^4} + M_b \frac{\partial^2 u_b}{\partial t^2} = 0, \tag{1}$$

where u_b is perpendicular displacement, B_b and M_b are the bending stiffness and mass

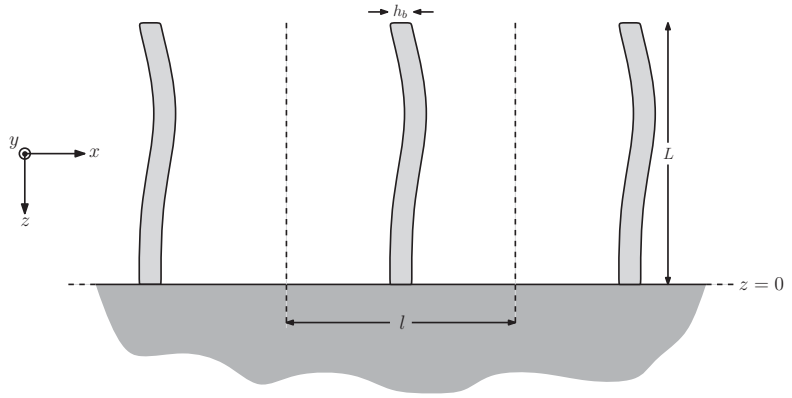

Figure 1: An array of beam-like resonators of length L and diameter h_b periodically attached with spacing l to the surface of a semi-infinite linearly elastic half space.

per unit length of the resonators respectively, and

$$I_b = \frac{\pi h_b^4}{64}, \quad B_b = \frac{E_b}{1-\nu^2} \tag{2}$$

where h_b is the diameter of a beam E_b and ν are the Young modulus and Poisson ratio respectively. This gives the dispersion relation as,

$$K = \left(\frac{64 M_R}{B_b \pi h_b^4}\right)^{\frac{1}{4}} \sqrt{\omega}. \tag{3}$$

In order to investigate the effect on the half-space, these resonators have boundary conditions for displacement, bending angle, bending moment and horizontal force respectively at $z = 0$,

$$u_b = u_1, \qquad \frac{\partial u_b}{\partial z} = \frac{\partial u_3}{\partial x} \qquad \frac{\partial \sigma_{33}}{\partial x} = -B_b \frac{\partial^2 u_b}{\partial z^2}, \qquad H = I_b B_b \frac{\partial^3 u_b}{\partial z^3}, \tag{4}$$

where the half-space displacement is $\mathbf{u} = (u_1, u_2, u_3)$, $\boldsymbol{\sigma}$ is the usual stress tensor and H is the out-of-plane force in the x-direction.

Since the width of each beam is much less than the separation length l we can assume to a good approximation that the stress from the beams will be distributed evenly.

2.1 ASYMPTOTIC MODEL

Suppose that waves are near the classical Rayleigh wave speed. Then a small parameter is defined by the difference between the wave speed c and the classical Rayleigh speed c_R, such that $|c - c_R| \ll 1$. For the sake of simplicity, below we focus on the plane-strain case. Then, at leading order, the elastic bulk has governing equations,

$$\frac{\partial^2 \phi}{\partial z^2} + \alpha_R^2 \frac{\partial^2 \phi}{\partial x^2} = 0, \qquad \frac{\partial^2 \psi}{\partial z^2} + \beta_R^2 \frac{\partial^2 \psi}{\partial x^2} = 0. \tag{5}$$

where ϕ and ϕ are longitudinal and shear displacement potentials respectively and,

$$\alpha(c) = \sqrt{1 - \frac{c^2}{c_1^2}}, \qquad \beta(c) = \sqrt{1 - \frac{c^2}{c_2^2}} \tag{6}$$

with $\alpha_R = \alpha(c_R)$, $\beta_R = \beta(c_R)$ and c_1, c_2 being the bulk longitudinal and shear wave speeds respectively.

Depending on whether the half-space is subject to a normal or tangential stress, we obtain different boundary conditions. In the case of a tangential stress at $z = 0$, $\sigma_{33} = 0$ and

$$\Box\psi = -\frac{1 + \beta_R^2}{2\mu B}\sigma_{31}, \tag{7}$$

while for a normal stress at $z = 0$, $\sigma_{31} = 0$ and

$$\Box\phi = \frac{1 + \beta_R^2}{2\mu B}\sigma_{33}, \tag{8}$$

where $\Box$ is the D'Alambertian operator

$$\Box = \frac{\partial^2}{\partial x^2} - \frac{1}{c_R^2}\frac{\partial^2}{\partial t^2},$$

and B is a material constant arising from the perturbation scheme, given by

$$B = \frac{\beta_R}{\alpha_R}(1 - \alpha_R^2) + \frac{\alpha_R}{\beta_R}(1 - \beta_R^2) - (1 - \beta_R^4). \tag{9}$$

Following the same approach as for the leading order model we obtain new second order boundary conditions. In the case of a normal stress, at $z = 0$,

$$\Box\phi_{,11} = \frac{1 + \beta_R^2}{2\mu B}\,\Box_1\sigma_{33} \tag{10}$$

and similarly for a tangential stress,

$$\Box\psi_{,11} = -\frac{1 + \beta_R^2}{2\mu B}\,\Box_1\sigma_{31}. \tag{11}$$

where the operator $\Box_1$ is defined as

$$\Box_1 = \frac{\partial^2}{\partial x^2} + A_R\Box$$

and the constant A_R is given by,

$$A_R = \frac{1 - \beta_R^2}{1 + \beta_R^2} + \frac{1}{4B}\left(2(1 - \beta_R^2)^2 + \frac{(\alpha_R^2 - \beta_R^2)^2}{\alpha_R^3\beta_R^3}\right). \tag{12}$$

3 NORMAL OR TANGENTIAL STRESS

Similar to the previous approach, we consider three distinct sets of junction conditions. The first two of these arrays, with simply supported and beam on a rail junction conditions, produce only a tangential and normal stress respectively.

3.1 SIMPLY SUPPORTED BEAMS

Begin the treatment of this array with simply supported beams. Then choose the junction conditions for simply supported connections to be,

$$u_b = u_1, \qquad -B_b \frac{\partial^2 u_1}{\partial z^2} = 0, \qquad H = I_b B_b \frac{\partial^3 u_b}{\partial z^3}, \tag{13}$$

which gives the horizontal stress on the half-space as as,

$$\sigma_{31} \approx \frac{H}{l^2} = B_b \frac{\pi h_b^4}{64 l^2} K^3 u_H \frac{\cos(KL)\cosh(KL) - 1}{\cosh(KL)\sin(KL) - \cos(KL)\sinh(KL)}, \tag{14}$$

Then introduce a scaled stress $\hat{H}$,

$$\frac{H}{l^2} = K^3 \hat{H} u_H = -k K^3 \hat{H} \beta_R \frac{1 - \beta_R^2}{1 + \beta_R^2} \psi, \tag{15}$$

where the full unimodal dispersion relation is

$$\begin{aligned} \left((\lambda + 2\mu)k^2\alpha^2 - \lambda k^2\right) \left(-\mu k^2 \left(1 + \beta^2\right) - k K^3 \hat{H} \beta\right) \\ = \left(2\,\mu k^2 \alpha + k K^3 \hat{H}\right) \left(-2\mu k^2 \beta\right). \end{aligned} \tag{16}$$

and the asymptotic dispersion relation is given by,

$$k^2 + k K^3 \hat{H}\ \beta_R \frac{1 - \beta_R^2}{2\mu B}\ - \frac{\omega^2}{c_R^2} = 0. \tag{17}$$

Following the same approach but for the higher order model yields,

$$k^3 + k^2 K^3 (A_R + 1) \hat{H}\ \beta_R \frac{1 - \beta_R^2}{2\mu B}\ - k \frac{\omega^2}{c_R^2} + K^3 A_R \hat{H}\ \beta_R \frac{1 - \beta_R^2}{2\mu B} \frac{\omega^2}{c_R^2} = 0. \tag{18}$$

The comparison of these dispersion relations is given in Figure 2. This plot shows a uniform improvement on the accuracy of the asymptotic model, becoming near indistinguishable to the full unimodal solution for lower frequencies. However, this improved accuracy comes at the cost of increased complexity in the dispersion relation; while the quadratic dispersion relation is less accurate, it yields a straightforward closed form solution. Although the new cubic dispersion relation still produces a closed form solution, it is more difficult to intuitively interpret.

3.2 BEAMS ON RAILS

Next take the junction conditions for connections of a beam moving freely on a rail

$$\frac{\partial u_b}{\partial z} = \frac{\partial u_3}{\partial x}, \qquad \frac{\partial \sigma_{zz}}{\partial x} = -B_b \frac{\partial^2 u_1}{\partial z^2}, \qquad I_b B_b \frac{\partial^3 u_\eta}{\partial \zeta^3} = 0, \tag{19}$$

so the vertical stress is given by,

$$\sigma_{33} \approx \frac{V}{l^2} = i\frac{K}{k}\frac{\pi h_b^2}{4l^2} B_b \, u_{V,x} \frac{1 - \cos(KL)\cosh(KL)}{\cosh(KL)\sin(KL) + \cos(KL)\sinh(KL)} \tag{20}$$

Introduce a scaled stress $\hat{V}$ defined by

$$\frac{V(x,y,t)}{l^2} = i\frac{K}{k}\hat{V} u_{V,x} = -iKk\hat{V}\frac{1-\beta_R^2}{2}\psi, \tag{21}$$

leading to the full unimodal dispersion relation,

$$\mu k^2 \left(1+\beta^2\right)\left(\lambda k^2 - (\lambda+2\mu)k^2\alpha^2 + kK\hat{V}\alpha\right) = 2\mu k^2 \alpha \left(-2\mu k^2 \beta + kK\hat{V}\right) \tag{22}$$

and the approximate dispersion relation,

$$k^2 - k\,\frac{\alpha_R}{\mu B} K\hat{V}\frac{1-\beta_R^2}{2} - \frac{\omega^2}{c_R^2} = 0. \tag{23}$$

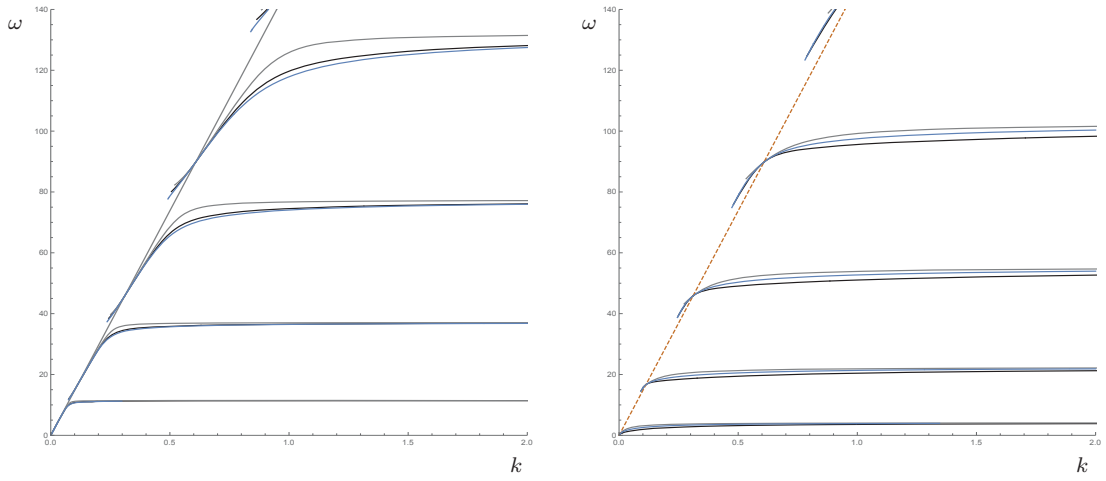

Figure 2: Dispersion curves (frequency ω vs. wavenumber k) for surface waves on the half-space coated with simply supported beam like resonators (left) and beam-like resonators on a rail (right). Solid blue lines show the full unimodal solution, solid black lines the higher-order asymptotic solution and solid gray lines the leading order asymptotic solution.

For the higher order model, using the same approach as before, we obtain the dispersion relation,

$$k^3 - k^2 \frac{\alpha_R}{\mu B} K(A_R + 1)\hat{V}\frac{1-\beta_R^2}{2} - k\frac{\omega^2}{c_R^2} - \frac{\alpha_R}{\mu B} K A_R \hat{V}\frac{1-\beta_R^2}{2} = 0. \tag{24}$$

The comparison of these dispersion relations is again given in Figure 2. Unlike the simply supported array, this plot does not show a uniform improvement for the full range of frequencies. It does, however, show greatly improved accuracy in the immediate vicinity of the Rayleigh line, in particular being much more accurate at predicting the locations of the band gaps. This is also again a cubic dispersion relation, with added complexity over the lower order model.

4 MIXED NORMAL AND TANGENTIAL STRESS

Finally we consider the case where all relevant quantities between the resonators and half plane are conserved. Matching all junction conditions (4) gives the multi-stress condition,

$$\begin{aligned} \sigma_{31} \approx \frac{H}{l^2} &= \frac{\pi h_b^4}{64 l^2} B_b K^2 (\xi u_{V,x} + K\eta u_H), \\ \sigma_{33} \approx \frac{V}{l^2} &= i\frac{\pi h_b^2}{4 l^2} B_b \frac{K}{k} (\zeta u_{V,x} + K\xi u_H), \end{aligned} \tag{25}$$

where,

$$\xi = \frac{\sin(KL)\sinh(KL)}{\cos(KL)\cosh(KL)+1}, \tag{26}$$

$$\eta = \frac{\cosh(KL)\sin(KL) + \cos(KL)\sinh(KL)}{\cos(KL)\cosh(KL)+1}, \tag{27}$$

$$\zeta = \frac{\cosh(KL)\sin(KL) - \cos(KL)\sinh(KL)}{\cos(KL)\cosh(KL)+1}. \tag{28}$$

This gives the full unimodal solution as

$$\begin{aligned} &\left(\mu k^2\left(1+\beta^2\right) + \frac{\pi h_b^4}{64 l^2} B_b k\left(K^3\beta\eta - K^2 k\xi\right)\right) \\ &\qquad = \left((\lambda+2\mu)k^2\alpha^2 - \lambda k^2 + \frac{\pi h_b^2}{4 l^2} B_b\left(K^2\xi - Kk\alpha\zeta\right)\right) \end{aligned} \tag{29}$$

However the existing asymptotic model is not formulated to account for both a normal and tangential stress. Naively combining the previous leading order asymptotic models yields the multi-stress model,

$$\Box\psi = -\frac{1+\beta_R^2}{2\mu B}\sigma_{31} - i\frac{\alpha_R}{\mu B}\sigma_{33}. \tag{30}$$

However, this new model inherits the assumption that at coincidence with the Rayleigh line the stresses tend to zero. This does not take into account for cross interaction between stress terms. Hence to find the predicted inaccuracy with the model at $c = c_R$ first assume that the stresses have the decomposition

$$\sigma_{31} = H_\phi \phi + H_\psi \psi, \qquad \sigma_{33} = V_\phi \phi + V_\psi \psi. \tag{31}$$

so that substitution into the classical Rayleigh denominator gives,

$$\begin{aligned} &-(1+\beta^2)^2 - 4\alpha\beta \\ &\quad = i\frac{2\beta}{\mu k^2} H_\phi + \frac{1+\beta^2}{\mu k^2} H_\psi - \frac{1+\beta^2}{\mu k^2} V_\phi + i\frac{2\alpha}{\mu k^2} V_\psi + \frac{H_\phi V_\psi - V_\phi H_\psi}{\mu^2 k^4} \end{aligned} \tag{32}$$

from which a leading order expansion about the Rayleigh line yields,

$$\left(k^2 - \frac{\omega^2}{c_R^2}\right)\psi = \frac{1+\beta_R^2}{2\mu B}\sigma_{31} + i\frac{\alpha_R}{\mu B}\sigma_{33} - \frac{V_\phi H_\psi - H_\phi V_\psi}{2\mu^2 B k^2}\psi. \tag{33}$$

and so at leading order we predict an inaccuracy of the order of $V_\phi H_\psi - H_\phi V_\psi$. Therefore when the two applied stresses are similar this will tend to zero, but will give a significant deviation when the stresses are more distinct.

The use of this new model gives the leading order asymptotic dispersion relation as,

$$\begin{aligned} 0 = {} & k^2\left(1 + \frac{1+\beta_R^2}{2\mu B l^2}\frac{\pi h_b^4}{64} B_b K^2 \frac{1-\beta_R^2}{2}\,\xi\right) \\ & - k\left(\frac{\alpha_R}{\mu B l^2}\frac{\pi h_b^2}{4} B_b K \frac{1-\beta_R^2}{2}\,\zeta - \frac{1+\beta_R^2}{2\mu B l^2}\frac{\pi h_b^4}{64} B_b K^3 \beta_R \frac{1-\beta_R^2}{1+\beta_R^2}\,\eta\right) \\ & - \left(\frac{\omega^2}{c_R^2} + \frac{\alpha_R}{\mu B l^2}\frac{\pi h_b^2}{4} B_b K^2 \beta_R \frac{1-\beta_R^2}{1+\beta_R^2}\,\xi\right). \end{aligned} \tag{34}$$

We can combine the higher order model in a similar way to produce a multi-stress model,

$$\Box\psi_{,11} = \Box_1\left(-\frac{1+\beta_R^2}{2\mu B}\,\sigma_{31} - i\frac{\alpha_R}{\mu B}\,\sigma_{33}\right), \tag{35}$$

which on substitution of the stresses yields the higher order dispersion relation,

$$
\begin{aligned}
0 = {} & k^4 \left(1 + (A_R+1)\frac{1+\beta_R^2}{2\mu B l^2}\frac{\pi h_b^4}{64} B_b K^2 \frac{1-\beta_R^2}{2}\,\xi\right) \\
& - k^3 (A_R+1)\left(\frac{\alpha_R}{\mu B l^2}\frac{\pi h_b^2}{4} B_b K \frac{1-\beta_R^2}{2}\,\zeta - \frac{1-\beta_R^2}{2\mu B l^2}\frac{\pi h_b^4}{64} B_b K^3 \beta_R \eta\right) \\
& - k^2 \left(\frac{\omega^2}{c_R^2} + (A_R+1)\frac{\alpha_R}{\mu B l^2}\frac{\pi h_b^2}{4} B_b K^2 \beta_R \frac{1-\beta_R^2}{1+\beta_R^2}\,\xi\right) \\
& + k^2 A_R \left(\frac{1+\beta_R^2}{2\mu B l^2}\frac{\pi h_b^4}{64} B_b K^2 \frac{1-\beta_R^2}{2}\,\xi\right)\frac{\omega^2}{c_R^2} \\
& - k A_R \left(\frac{\alpha_R}{\mu B l^2}\frac{\pi h_b^2}{4} B_b K \frac{1-\beta_R^2}{2}\,\zeta - \frac{1-\beta_R^2}{2\mu B l^2}\frac{\pi h_b^4}{64} B_b K^3 \beta_R \eta\right)\frac{\omega^2}{c_R^2} \\
& - A_R \left(\frac{\alpha_R}{\mu B l^2}\frac{\pi h_b^2}{4} B_b K^2 \beta_R \frac{1-\beta_R^2}{1+\beta_R^2}\,\xi\right)\frac{\omega^2}{c_R^2}.
\end{aligned}
\tag{36}
$$

This dispersion relation is shown with the leading order and full unimodal solutions in Figure 3. While the higher order model is a significant improvement over the leading order model, particularly for lower frequencies, both models show the same divergence from the unimodal solution at the Rayleigh line. While this inaccuracy can be calculated, this would significantly reduce the simplicity of the model.

Furthermore, this higher order dispersion relation is significantly more complicated than the leading order relation. While the quartic dispersion relation can still have a closed form solution, it will be significantly less concise or simple to interpret.

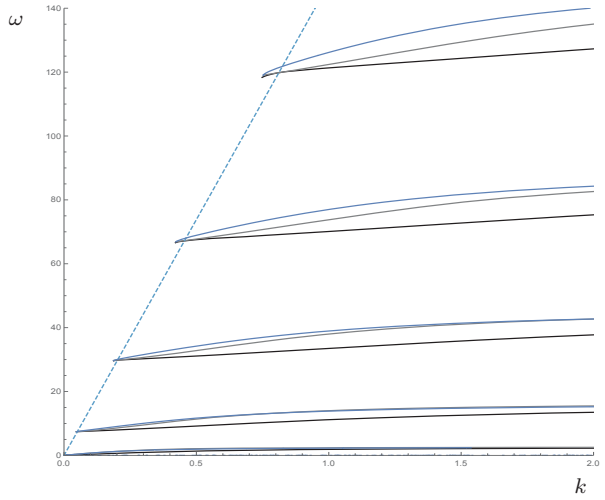

Figure 3: Dispersion curves (frequency ω vs. wavenumber k) for surface waves on the half-space coated with fully matched beam-like resonators. Solid blue lines show the full unimodal solution, solid black lines the higher-order asymptotic solution and solid gray lines the leading order asymptotic solution.

5 CONCLUSION

The refined model for Rayleigh waves has been successfully applied to the array of beam-like resonators for a range of junction conditions. While this showed a general improvement in accuracy compared to the leading order model, it also made the solutions obtained more complicated. This is particularly notable for the fully matched model where the increase in accuracy was only shown away from the Rayleigh line, where there is a fixed deviation from the unimodal solution. This deviation is fundamentally related to the formulation of the model and forms of the stresses so cannot be reduced by taking higher order models.

Overall, the results show the scope of the use of the higher order model. Accurate, closed form solutions in terms of scalar variables can be obtained for a significantly reduced amount of computing power. However, as the complexity of these systems increases, it may not be possible to produce closed form solutions.

Keywords: bridge pylon design, surface waves, nonlinear soil-structure interaction, surrogate models, incremental dynamic analyses

Abstract. *The impact of surface waves on long-period structures remains among the less well understood aspects in the earthquake-resistant design of civil structures. Surface waves are typically characterized by rich low-frequency content and long durations and accordingly they can be particularly damaging for long-period structures, such as high-rise buildings, bridge pylons, liquid storage tanks, telecommunication masts etc. It is understood that an insufficient seismic design may be obtained for this class of structures if the effect of surface waves is not taken into account in the definition of earthquake loading. The present paper proposes a concise surrogate mechanical model for the study of the seismic nonlinear response of bridge pylons with and without the consideration of the effect of surface waves on dynamic response. The model is fully parametrizable based on a reduced number of dimensionless parameters that allow generating a large set of different structural and foundation configurations. The model couples a multi-fiber beam model for the bridge pylon with a nonlinear macroelement for the pylon foundation, accounting for sliding, uplifting and partial or full loss of bearing capacity in the foundation soil. This coupled pylon-foundation model is subjected to three cases of record sets for performing Incremental Dynamic Analyses (IDA), in which the records may preserve or not the surface wave components in the horizontal and rotational degrees-of-freedom of the incident motion. The IDA methodology is exploited for presenting in a synthetic manner the overall dynamic response for two characteristic bridge pylon designs and for highlighting the situations in which the non-consideration of surface waves may indeed lead to an insufficient design.*

1 INTRODUCTION

A common assumption in normative seismic studies of civil structures is to establish ground motions (to be used as incident excitations at the foundation level) via 1D site response analyses, in which the vertical propagation of shear waves is studied along an idealized soil column (1D model). Despite its efficiency, this approach wipes out the effects of real 3D topography of the subsoil and, in particular, the eventual presence of surface waves (Rayleigh waves / Love waves). Surface waves are typically generated in geological settings such as sedimentary basins and are characterized by rich low-frequency content and long durations. For example, presence of Rayleigh waves in the incident motion will lead to an increase in horizontal spectral accelerations (translational component) in the low-frequency range and also will generate a rotational component that cannot be obtained via 1D site response analyses.

Notwithstanding the ubiquitous principle, already anticipated by Biot [1] in the 1930's (*cf*. Trifunac [2]) that under favorable conditions (long waves), rotational seismic motions are small and can be neglected, several recent strong earthquakes (*e.g*. Chi-Chi 1999, Chuetsu 2004, El Mayor 2010, Tohoku 2011) have revealed significant rotational motions related to the passage of surface waves. These motions can be detrimental for long-period structures such as high-rise buildings, bridge pylons and liquid storage tanks, to name the most important ones.

Available studies for assessing the impact of surface waves on long-period structures are rather scarce. In two recent papers [3], [4], Meza & Papageorgiou have studied the effect of surface waves on the response of tall buildings and have shown that Rayleigh waves can increase the damage levels in such structures because of period elongation due to nonlinear response, extended shaking duration and risk of resonance. Concerning the effect of surface waves on bridge pylons, Chatzigogos *et al*. [5] have recently proposed a simplified surrogate model with consideration of nonlinear response in the pylon and/or in the foundation. The model is used for studying different soil-pylon configurations and for quantifying the increase in seismic demand (with respect to several performance criteria) due to the consideration of surface waves.

The present paper aims to extend the initial results obtained by Chatzigogos *et al*. [5] by probing -in a more systematic way- the impact of surface waves on nonlinear response of selected soil-pylon configurations via the technique of Incremental Dynamic Analysis (IDA) [6]. IDA is by now a well-established method for gaining insight into nonlinear seismic response for increasing levels of shaking. The studied bridge pylons are subjected to various records of increasing intensity and this allows plotting Damage Measures (DM) of interest as functions of appropriately selected seismic Intensity Measures (IM). The analyses are performed with and without consideration of the surface wave component of the considered records and this allows quantifying the additional distress provoked by the incidence of surface waves.

2 SURROGATE MODEL FOR BRIDGE PYLONS

2.1 General principles

In the following, we concentrate on the study of bridge pylons as shown on Figure 1. The surrogate model proposed by Chatzigogos *et al*. [5] will be used hereafter for studying the response of two characteristic pylon configurations with the IDA methodology. The model is intended for studying the transverse dynamic response of single-branch pylons (piers) and it is formulated in 2D kinematics. The pier supports at its top a part of the bridge deck and the deck-pier connection is concretized via a local spring-dashpot element. The pier foundation is a shallow footing resting at the ground surface (the footing embedment is neglected). Basic features of the surrogate model are the following:

- *Consideration of full nonlinear pier response in bending*. This is achieved by discretizing the pier into 2-noded multi-fiber beam elements. The cross-section of the pier is equally discretized into a number of fibers that are assigned an appropriate 1D nonlinear law. For the application presented hereafter, the nonlinear model for the fibers will be a simple elastoplastic law, with initial elastic stiffness E_p, yield stress f_y and post-elastic stiffness $E'_p = \alpha_k E_p$ (α_k: proportionality constant). In terms of global behavior, parameters E_p and f_y give rise to yield bending moment $M_{p,y}$ and yield curvature κ_y of the pier section.
- *Nonlinear response at the foundation level*. This is achieved via a dedicated nonlinear foundation macroelement following Chatzigogos *et al*. [7]. This model is briefly presented in §2.3.
- *Translational and rotational seismic excitation*. The excitation is introduced as imposed displacement to a control point at the base of the model. Following [5], three scenarios will be studied hereafter: a) only horizontal excitation without surface wave effect, b) only horizontal excitation, enriched with surface wave effect and c) horizontal and rotational excitations with full consideration of surface wave effects. For simplicity, vertical component of seismic motion is neglected in the presented analyses.
- *Solution in time domain.* The resulting dynamic equilibrium equation is integrated in time domain using an unconditionally stable Newmark scheme under the assumption of small displacements. Calculations are run in the open-source FEM platform Code_ASTER [8].

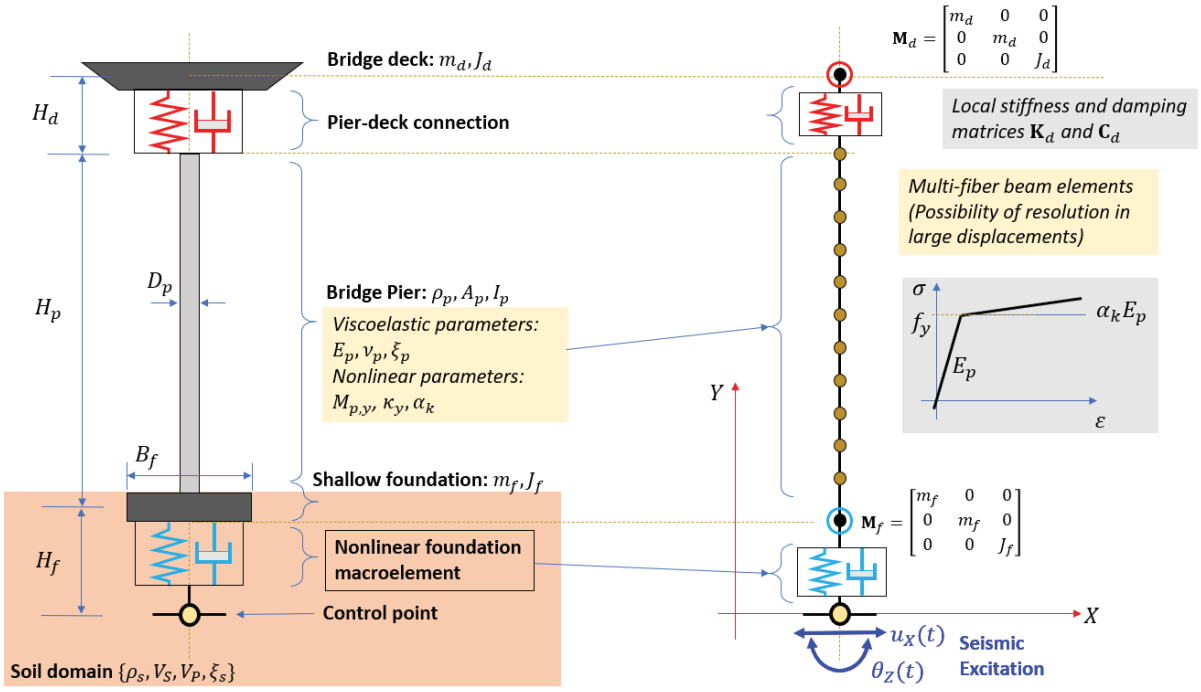

Figure 1: Surrogate model for studying the effects of surface waves on bridge pylons.

2.2 Geometric and mechanical characterization

The proposed surrogate model is intended for efficiently generating a large number of different pylon-foundation configurations, in the search for those cases that are particularly vulnerable in the incidence of surface waves. Each instance of the surrogate model can accordingly be obtained via a set of geometric and mechanical parameters that are organized into vector **a** that groups a limited number of dimensional parameters and into vector **b** that groups all other governing quantities that are either dimensionless or expressed as normalized parameters. In

the definition of governing model parameters, we use subscripts p, d, f and s to designate respectively the pier, the deck, the foundation and the soil. Normalized parameters are designated with a tilde (~).

The vector of dimensional parameters reads:

$$\mathbf{a}^{\mathrm{T}} = \{H_p, m_p, A_p, E_p, T_p, M_{p,y}, W_{\mathrm{tot}}\} \tag{1}$$

with the following definitions:

- H_p : height of bridge pier
- m_p : mass of bridge pier
- A_p: cross-sectional area of pier (considered uniform in the entire height)
- E_p : Young's modulus of bridge pier (initial elastic stiffness)
- T_p : fundamental period of vibration of the pier considering fixed-base conditions
- $M_{p,y}$: yield bending moment of pier section
- $W_{\mathrm{tot}} = g(m_p + m_d + m_f)$: total weight of the structure

The definition of the surrogate model is completed by 17 additional parameters that are either dimensionless or are normalized and are grouped in vector **b**, which reads:

$$\mathbf{b}^{\mathrm{T}} = \{\widetilde{H}_d, \widetilde{D}_p, \widetilde{H}_f, \tilde{B}_f, \widetilde{m}_d, \widetilde{m}_f, \tilde{J}_d, \tilde{J}_f, \xi_p, \xi_s, \nu_p, \nu_s, \tilde{\rho}_s, \tilde{V}_S, \widetilde{N}_{f,\max}, \tilde{V}_{f,\max}, \widetilde{M}_{f,\max}\} \tag{2}$$

with the following definitions:

- $\widetilde{H}_d = H_d/H_p$: normalized height of the bridge deck (form pier top to the center of gravity of bridge deck, *cf*. Figure 1)
- $\widetilde{D}_p = D_p/H_p$: normalized bridge pier diameter (or equivalent diameter for non-circular pier sections)
- $\widetilde{H}_f = H_f/H_p$: normalized foundation height (from pier base to the center of gravity of bridge footing)
- $\tilde{B}_f = B_f/H_p$: normalized characteristic footing dimension
- $\widetilde{m}_d = m_d/m_p$: normalized mass of bridge deck supported by the pier
- $\widetilde{m}_f = m_f/m_p$: normalized mass of bridge foundation
- $\tilde{J}_d = J_d/m_p H_p^2$: normalized rotational inertia of bridge deck
- $\tilde{J}_f = J_f/m_p H_p^2$: normalized rotational inertia of foundation
- ξ_p : critical damping ratio for the bridge pier (in the linear viscoelastic range)
- ξ_s : critical material damping ratio in the soil (in the linear viscoelastic range)
- ν_p : Poisson's ratio for the bridge pier
- ν_s : Poisson's ratio in the soil
- $\tilde{\rho}_s = \rho_s/(\frac{m_p}{A_p H_p})$: normalized soil mass density
- $\tilde{V}_S = V_S/(\frac{H_p}{T_p})$: normalized shear wave velocity (rigidity contrast between soil and structure)
- $\widetilde{N}_{f,\max} = N_{f,\max}/W_{\mathrm{tot}}$: maximum centered force supported by the foundation
- $\tilde{V}_{f,\max} = V_{f,\max}/W_{\mathrm{tot}}$: maximum horizontal force supported by the foundation
- $\widetilde{M}_{f,\max} = M_{f,\max}/M_{p,y}$: maximum overturning moment supported by the foundation

The above definitions for the pylon foundation imply that it is possible to determine dynamic impedance terms (computed at the fundamental SSI frequency of the pylon) assuming equivalent foundation dimension B_f and the homogenized linear viscoelastic soil domain with parameters $\{\rho_s, \nu_s, V_S, \xi_s\}$. For a surface footing (anticipating negligible off-diagonal impedance terms) and 2D kinematics, three stiffness terms $\{K_{NN}, K_{VV}, K_{MM}\}$ and the corresponding damping terms $\{C_{NN}, C_{VV}, C_{MM}\}$ are obtained.

2.3 Nonlinear foundation macroelement

An important feature of the proposed model is the use of a dedicated macroelement for description of nonlinear response at foundation level. The implemented foundation macroelement follows the formulation proposed by Chatzigogos *et al*. [7]. The foundation macroelement is an advanced link element that is placed at the base of the model and aims at reproducing nonlinear foundation response under earthquake action. The macroelement provides a phenomenological constitutive law for relating the increment of foundation displacements $\dot{\mathbf{u}}_f$ to the corresponding increment of work-conjugate force parameters $\dot{\mathbf{Q}}$. For obtaining the macroelement constitutive law, total displacement increment is decomposed into the linear elastic counterpart $\dot{\mathbf{u}}_{\text{lin}}$ that is computed from impedance terms, and counterparts for three independent nonlinear mechanisms: sliding ($\dot{\mathbf{u}}_{\text{sl}}$), foundation uplifting ($\dot{\mathbf{u}}_{\text{up}}$) and soil plasticity ($\dot{\mathbf{u}}_{\text{sp}}$). Total displacement increment $\dot{\mathbf{u}}_f$ thus reads:

$$\dot{\mathbf{u}}_f = \dot{\mathbf{u}}_{\text{lin}} + \dot{\mathbf{u}}_{\text{up}} + \dot{\mathbf{u}}_{\text{sl}} + \dot{\mathbf{u}}_{\text{sp}} \tag{3}$$

Each nonlinear mechanism is described independently by an appropriate model. In particular, sliding mechanism is described by the standard Coulomb friction criterion with a non-associative flow rule. Soil plasticity is described by a bounding surface hypoplastic formulation [10] that can easily be adapted to soil behavior (cohesive, frictional or combination of the two). Finally, uplift mechanism is described by a phenomenological nonlinear elastic model that respects the perfect reversibility of this mechanism and depends solely on foundation geometry. Coupling between nonlinear mechanisms is achieved by solving simultaneously the nonlinear equations of each mechanism (with only minor adjustments in the formulation of each mechanism) for the same force increment. A detailed presentation of the foundation macroelement model implemented in this study is provided in references [5] and [7].

3 STUDIED CONFIGURATIONS

The analyses presented hereafter are performed for two pylon configurations corresponding to two types of seismic design philosophy for the foundation. The first configuration corresponds to what would be a conventional design, in which the foundation is designed with an over-strength (in terms of overturning moment) with respect to the bending moment capacity at the pylon base. Such a design implies that damage will be concentrated at the base of the bridge pylon, while the foundation should exhibit a quasi-linear response.

In the second configuration, the foundation dimension is reduced, inviting for development of nonlinear response at the foundation level (via activation of sliding, uplifting and soil plasticity mechanisms). Such an "inversion" in conventional capacity-design of interacting foundation-superstructure systems has been proposed by many researchers (*e.g.* [12]) as a viable means of seismic protection of structures with an affordable scheme for foundation design. The price to pay is the irreversible foundation response and the pronounced displacements at the top of the pylon (due to uplifting and high foundation rotations) that must be shown to remain in acceptable limits.

Table 1 presents the geometric and mechanical parameters that define the two studied configurations. Given that the pier height is $H_p = 30$m, the configurations are designated "P30-Large" or simply P30L and "P30-Small" or simply P30S.

P30L exhibits a foundation with characteristic dimension $B_f = 11.0$m. For P30S, $B_f = 7.0$m. Table 1 provides the dimensional (vector **a**) and dimensionless parameters (vector **b**) defining the studied configurations. For convenience, Table 1 also provides the dimensional parameters corresponding to vector **b**.

Table 2: Additional geometric and mechanical parameters of studied bridge pier configurations.

It is interesting to note that the maximum foundation overturning moment is $M_{f,\max} = 133.7$MNm for P30L and only $M_{f,\max} = 34.5$MNm for P30S. Yield bending moment of the pier section is $M_{p,y} = 43.0$MNm for both configurations.

Tables 2(a) and 2(b) provide some additional parameters characterizing the two configurations. In particular, Table 2(b) provides the parameters for the definition of foundation macro-element, following [5] and [7].

4 RECORD SET FOR INCREMENTAL DYNAMIC ANALYSES

The implementation of IDA requires the definition of a concise set of seismic records that correspond to a prescribed earthquake scenario (defined, for example, by the couple {Magnitude, distance} and given geotechnical conditions). The number of records in this set must be large enough to cover uncertainties related to the obtention of a representative acceleration time history in terms of spectral accelerations, strong phase duration, characteristic intensity measures *etc*. In standard IDA applications (*cf*. [6]), calculations are performed for a set comprising at least 30 records. Once such a record set has been defined, uniform scaling is applied to all records to achieve a preselected range of values for one or more characteristic intensity measures. In most cases, scaling is performed with respect to PGA, but other intensity measures can be used, as for example, Arias intensity, CAV *etc*.

Notwithstanding the necessity of a dense record set compatible with a specific earthquake scenario, the following IDA implementations will be performed for a record set comprising 12 signals that have been obtained from different recent earthquakes exhibiting variable characteristics. This record set comes from the studies of Meza & Papageorgiou [3], [4] and, in the present context, offers the advantage that for the selected records, it has been possible to extract the surface wave components in the definition of the translational and rotational ground motions. Consequently, for the two degrees-of-freedom of interest for the presented analyses, three separate signals are provided:

a) total motion q_{tot}, which corresponds to what has been recorded *in situ*
b) extracted motion q_{SW}, which corresponds to the contribution of surface waves in the recorded motion
c) body wave motion q_{BW}, which is the motion exempt of the effect of surface waves ($q_{\mathrm{BW}} = q_{\mathrm{tot}} - q_{\mathrm{SW}}$); it is thus understood that q_{BW} comprises exclusively the effect of body waves

In the above definitions, we use q to designate generically either horizontal translation u or rotation θ about a horizontal axis (rocking). The signals are provided in terms of displacements; velocities and accelerations are obtained by differentiation. The method for extracting the surface wave component of the recorded signals has been exhaustively presented in [13] and [14].

Table 3 presents main properties and intensity measures of the selected records. For each record, we provide the seismic event of origin and some basic features (year, location, magnitude, depth), the time step dt used for definition of the provided signal and corresponding Nyquist frequency f_{N}. Then, for each of the two retained degrees-of-freedom (translation / rotation), Table 3 provides characteristic intensity measures for total motion q_{tot}, extracted motion q_{SW} and body wave motion q_{BW}, with $q \equiv u$ for horizontal translation and $q \equiv \theta$ for the rocking. The provided intensity measures are: a) maximum acceleration, b) maximum velocity, c) maximum displacement, d) Arias Intensity I_A, e) Cumulative Absolute Velocity CAV and f) effective duration t_f. Definition of I_A, CAV and t_f for rotational motions is extrapolated from corresponding definitions for translations.

The presented IDA analyses are performed for five PGA levels defined with reference to motions u_{BW} : The considered intensity levels are: {0.1g, 0.2g, 0.3g, 0.4g, 0.5g}. All other

motions are scaled accordingly so that the above PGA levels are assured for motion u_{BW}. Basic scaling factor as reported in Table 3, is the coefficient that multiplies the initial signal so that PGA of motion u_{BW} becomes equal to 0.1g.

Table 3: Record set for IDA: Intensity measures for translational and rotational components

Some additional comments deserve to be noted for the selected records:

- Motion u_{BW} is used as reference motion for scaling: this is the motion that would be felt by the structure if no effect of surface waves were to be considered for the translational component and if rocking (θ_{BW}) were to be neglected following Biot's principle. Incidence of surface waves will modify the horizontal motion from u_{BW} to u_{tot} ; moreover, it will induce the amplified rotational motion θ_{tot} (with respect to θ_{BW})
- The effective durations, especially for motion u_{tot}, are particularly large, with values that may exceed 4min at least for one record (CHB026: $t_f = 243$s). This is because emphasis is to be given in the surface wave component, which is characterized by low frequencies (below 1Hz) that tend to increase duration if several cycles are contained in the signal

- Accordingly, time step dt used for the definition of signals is rather large (ranging between 40msec and 70msec, with corresponding Nyquist frequencies f_N ranging between 7.5Hz and 16Hz). This implies that high-frequency content is poorly described in the signals but this is a deliberate choice for reducing the number of time steps and, accordingly, computational cost
- Total rotations θ_{tot} in the selected signals are rather limited and this is line with Biot's principle, which postulates quasi-negligible rocking motions. For example, record CHB026 presents $\max\{\theta_{tot}\} \approx$ 1e^{-05}rad, which after scaling for the highest intensity level ($\max\{\ddot{u}_{BW}\}$ = 0.5g) yields: $\max\{\theta_{tot}\} = 5\times16.68\times$1e^{-05}rad = 0.8mrad. This value corresponds to an imposed drift at the base of the pylon of only 0.8‰.

Figure 2 presents the response spectra of the 12 signals for motions u_{BW}, u_{tot} and θ_{tot} after scaling of u_{BW} to 0.1g. Characteristic frequencies of u_{BW} motions are contained between 0.5Hz and 4Hz. For u_{tot}, this interval increases from 0.2Hz to 4Hz with higher spectral accelerations, especially for the first characteristic peak of the spectrum. Characteristic frequencies for total rotations are between 2Hz and 8Hz. Finally, it is interesting to note that, although all u_{BW} motions are scaled at 0.1g, PGA values for u_{tot} may range from 0.1g to 0.15g, the difference highlighting the increase in PGA due to the surface wave component.

It is recalled that IDA analyses are performed for three hierarchical motion scenarios:

- Scenario 1: Only horizontal translation u_{BW} is applied at the pylon base
- Scenario 2: Only horizontal translation u_{tot} is applied at the pylon base - scenario 2 adds the translation surface wave effect with respect to scenario 1
- Scenario 3: Horizontal translation u_{tot} and rotation θ_{tot} are applied at the base - scenario 3 adds the total rotational effect with respect to scenario 2

5 IMPLEMENTATION AND RESULTS

5.1 Organization of computations and results

The computations required for IDA analyses are performed with open-source FEM platform Code_ASTER [8]. The total number of performed analyses is N = 2 pylon configurations × 3 excitation scenarios × 12 records × 5 intensity measures = 360 nonlinear analyses. The calculations are performed in time domain under the assumption of small displacements.

IDA analyses give rise to so-called IDA curves, which present the evolution of a given damage measure (DM) or performance criterion as function of a preselected intensity measure. Following [5], seven damage measures (DM) are used for producing IDA curves and probing the performance of bridge pylon in nonlinear range. The selected DMs are (acronyms are provided in parentheses):

1. Maximum total drift of the deck (MTD) that is obtained from the sum of three components: horizontal displacement of the foundation, foundation rotation and structural drift due to pier deformation
2. Maximum structural drift of the deck (MSD); this is the component of deck displacement which is due exclusively to pier deformation
3. Residual total drift of the deck (RTD); this is deck displacement obtained at the end of excitation. Assuming that pylon vibration has been completed at the end of nonlinear analysis, RTD corresponds to the irreversible components due to sliding and permanent rotation at the foundation and also due to permanent structural drift of the pier
4. Residual structural drift of the deck (RSD), which can be high if the pier response is strongly nonlinear
5. Maximum ductility demand (DD) obtained at the base of the pylon, defined as:

$$\mathrm{DD} = \max\left\{1;\ \frac{\kappa(t)}{\kappa_y}\right\} \tag{4}$$

   where $\kappa(t)$ the developed curvature at the pylon base and κ_y the yield curvature, corresponding to the first exceedance of yield stress in the outer fiber of pier section. If DD = 1, the response is elastic
6. Maximum moment (MM) developed at the base of the pier
7. Accumulated foundation settlement (FS) at the end of loading. Pronounced FS is an indicator of a bearing failure at the foundation, eventually combined with significant permanent rotation

The provided Damage Measures characterize the global behavior and allow identifying significant nonlinear response at the pier or at the foundation. Global parameters are MTD and RTD. Parameters pertaining to the superstructure are MSD, RSD, DD and MM. Finally, FS is an indicator of damage level at the foundation. In what regards the definition of intensity measures, we provide the IDA curve set pertaining to the basic IM used for scaling, which is PGA of motion u_{BW}.

5.2 IDA curves for global DMs

Figures 3 and 4 present the obtained IDA curves for the two global DMs, namely maximum total drift (MTD) and residual total drift (RTD) of bridge deck. For presentation of IDA curves, the same figure setup is always adopted. Each presented figure contains two plots: in the left side, results for P30S (small foundation) are plotted, in the right side for P30L (large foundation). IDA curves are plotted in space {DM, IM}, where horizontal axis corresponds to the studied DM and vertical axis to the selected IM, which is PGA of u_{BW} varying from 0.1g to 0.5g. Each plot contains the following data:

- The raw data from transient analyses corresponding to 3 scenarios, 5 intensity levels and 12 records. These data are plotted as grey circles; each plot contains 180 data points;
- For each excitation scenario, a statistical treatment allows plotting the median value together with 16% and 84% percentiles of studied DM as function of increasing IM. Median values are presented with continuous lines, percentiles are presented with dotted lines. Each excitation scenario is represented by a specific color. Scenario 1 (excitation with u_{BW}) is represented in blue; scenario 2 (excitation with u_{tot}) is represented in green;

scenario 3 (excitation with u_{tot} and θ_{tot}) is represented in red. In the following we may refer to scenario 1 as SC1 (respectively for 2 and 3). SC2-3 will indicate scenarios 2 and 3 together.

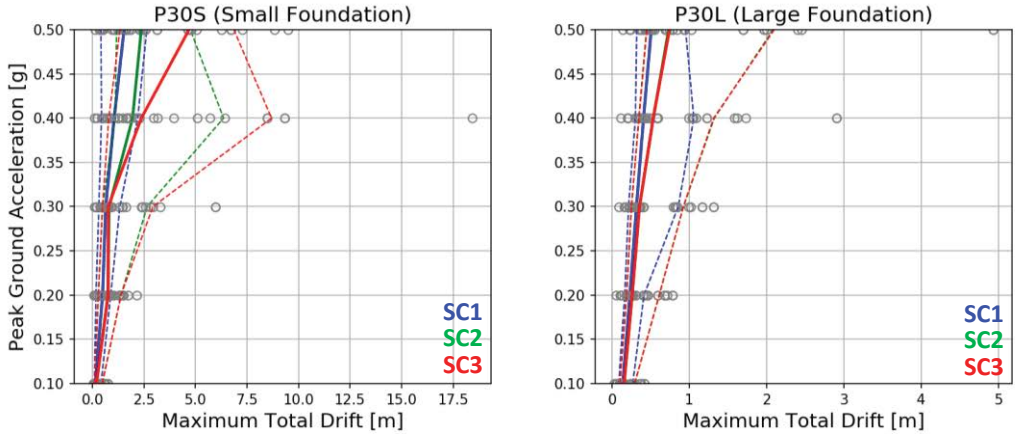

Figure 3: IDA curve for global parameter MTD (Maximum total drift)

IDA curves for global parameter MTD, as presented on Figure 3, indicate a sharp contrast in response for the two studied configurations. For P30S, maximal MTD can be as high as 17.5m for the most critical data point. Despite the fact that this is an isolated value, it certainly indicates development of a bearing failure mechanism at foundation level, accompanied by pronounced rotations. For P30L, maximal MTD is 5m and this is due to nonlinear pier response in bending. For P30S, median curves are all increasing with increasing IM and it is interesting to note that up to 0.30g, there is little difference between SC1 and SC2-3. Beyond 0.3g however, the difference between the three scenarios is more pronounced and one can notice an initial increase from SC1 to SC2, then an additional distress when passing to SC3. This indicates that both the total rotational component and the translational component of surface waves can have an impact on the response for very strong events, in case of yielding foundation systems. On the contrary, in P30L, median curves show a slight increase in MTD when passing from SC1 to SC2, but no additional distress when passing to SC3. Actually, SC3 curves are strictly superimposed to SC2 curves, implying that the consideration of θ_{tot} has no impact on the final result even for very high intensities. Finally, the extent of percentile curves is an indicator of variability in response. In P30S, SC2-3 present clearly larger variabilities than SC1 and this is due to highly nonlinear foundation response. For P30L, there is still a difference in variability between SC1 and SC2-3, but it is less pronounced.

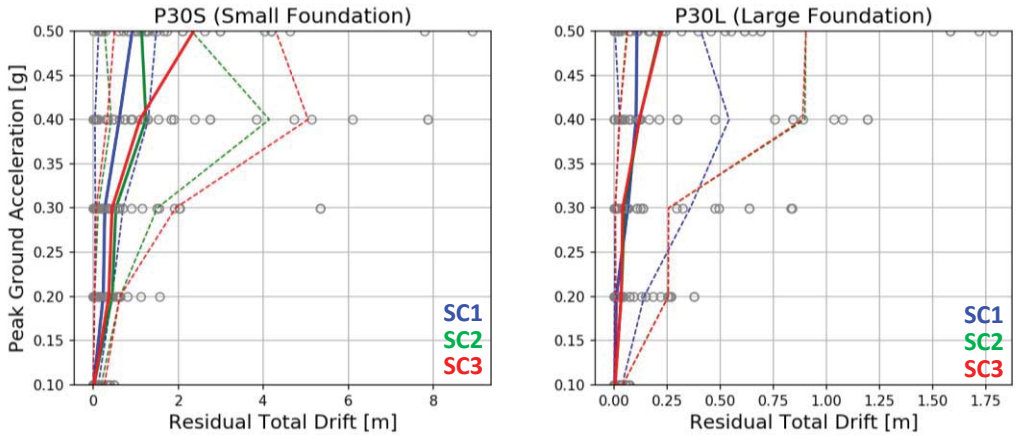

Figure 4: IDA curve for global parameter RTD (Residual total drift)

Figure 4 presents the obtained IDA curves for residual total drift (RTD). Again, the performance of P30S is much more critical than for P30L. The maximal obtained RTD value for P30S can be as high as 8m or more for a very strong earthquake and obviously this corresponds to a failure at foundation level that leads to non-tolerable residual displacements at bridge deck. In terms of mean values, it is interesting to note that SC1 leads to RTDs that increase slightly with intensity and remain less than 1m even at 0.50g. When the effect of surface waves is considered (SC2-3), RTD may be increased by factor 2 or more with respect to SC1. Rocking component (SC3) can lead to even higher RTD values for very strong events.

RTD evolution for P30L seems to remain independent of considered scenario for intensities up to 0.40g. It is needed to reach 0.50g to see a difference between SC1 and SC2-3. As for MTD, SC2-3 are strictly superimposed (both median and percentile curves are almost identical).

5.3 IDA curves for structural DMs

Figures 5 to 8 present IDA curves for four DMs pertaining to the response of the pier, namely maximum structural drift (MSD), residual structural drift (RSD), ductility demand at pylon base (DD) and maximum developed bending moment at the base (MM). All four DMs are clear indicators of the "isolation effect" offered by the reduced foundation design in P30S as compared to P30L.

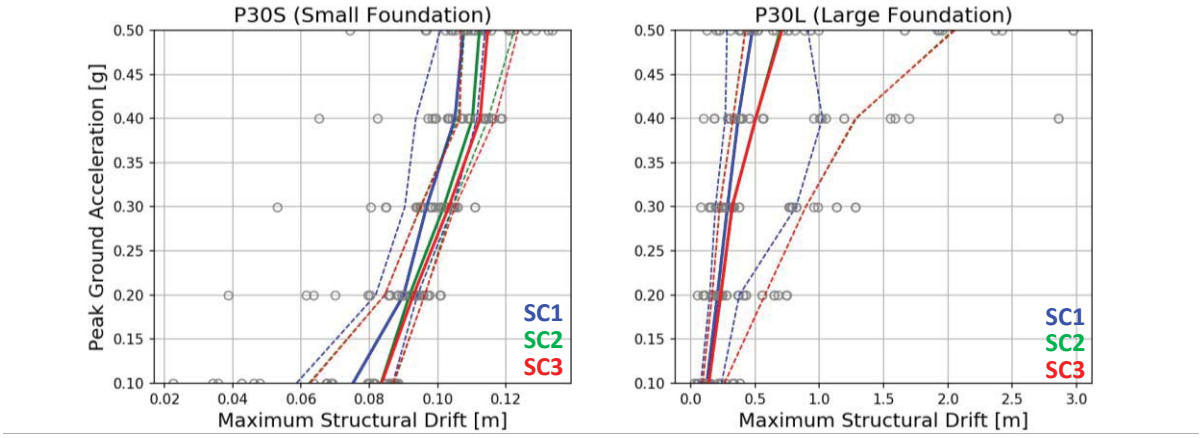

Figure 5: IDA curve for structural parameter MSD (Maximum Structural Drift)

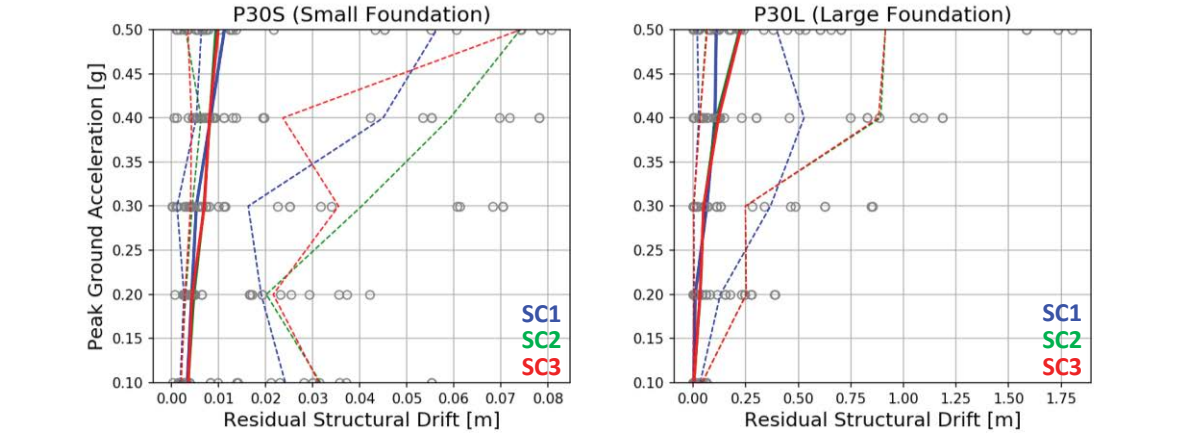

Figure 6: IDA curve for structural parameter RSD (Residual Structural Drift)

More specifically, Figure 5 presents IDA curves for maximum structural drift (MSD). For P30S, MSD values are limited, not exceeding 15cm for the most severe case in the data set. On

the contrary, MSD values for P30L can be as high as 3m (isolated data point). In terms of influence of surface waves, MSD increases slightly from SC1 to SC2 and then to SC3 for P30S for all intensities beyond 0.2g. In the case of P30L, SC2-3 are strictly superimposed (both median and percentile curves). The passage from SC1 to SC2 leads to an increase in distress, which is amplified as intensity increases.

Figure 6 presents IDA curves for residual structural drift (RSD). It is recalled that residual values are the ones obtained at the end of transient analysis and it is supposed that pylon vibration has been completed. For P30S, median RSD values on Figure 6 are less than 1cm and present significant variability: these values are actually "spurious" and originate from the fact that pylon vibration has not been perfectly dissipated by the final time step in transient analyses; if the analyses were to be continued further, RSD curves for P30S would be excepted to fall identically to zero. Results for P30L are almost identical to the results for RTD presented on Figure 4. This implies that RTD in case of P30L is only obtained from the structural component while the foundation contribution is negligible (as expected, since the foundation response is quasi-linear).

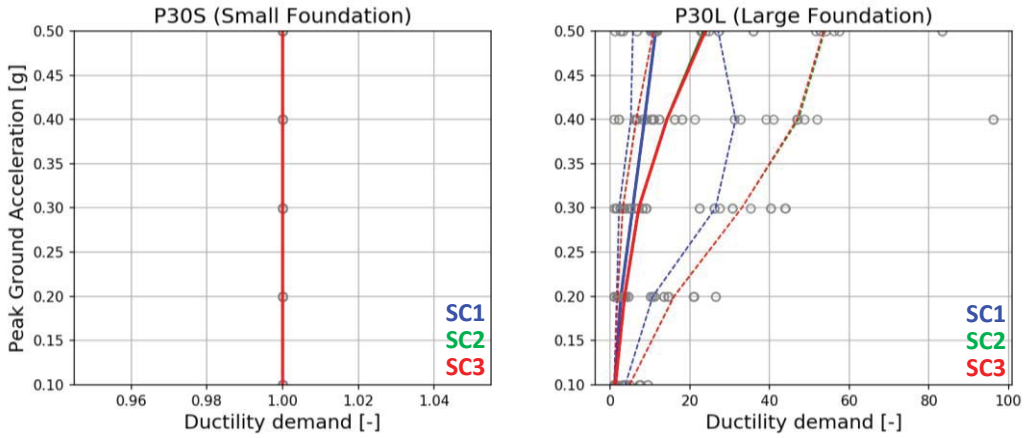

Figure 7: IDA curve for structural parameter DD (Ductility Demand at pier base)

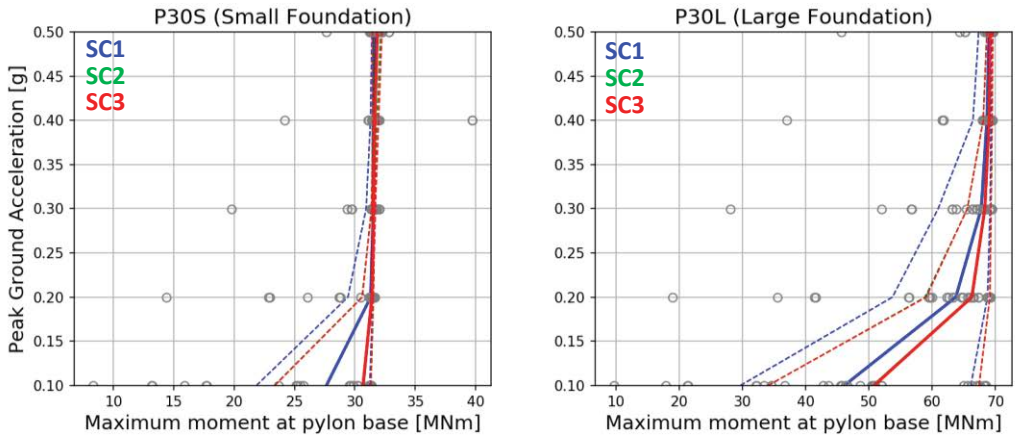

Figure 8: IDA curve for structural parameter MM (Maximum bending moment at pier base)

Figure 7 presents IDA curves for ductility demand (DD) at the pylon base. The result for P30S is very clear: all DDs are strictly equal to 1, which means that the pylon response remains elastic for all intensity levels. This a clear manifestation of the "capacity-design" approach, which guides all damage to a structural element (here, the foundation) and thus protects another structural element (here, the pier). In case of P30L, "capacity-design" is inversed. Consequently,

median DD curves at the pylon base are quickly raising with intensity level and may reach the value 10 for SC1 at 0.5g. The effect of surface waves increases even further median DD values, exceeding the value 20 at 0.5g. As in the previous cases for P30L, SC2-3 are superimposed: the effect of surface waves comes from the translational component. The rotational component induces no further distress on the system.

Figure 8 presents the obtained IDA curves for maximum bending moment developed at the pylon base (MM). An interesting feature of these curves is that, contrary to the previously examined DMs, here the variability is larger for smaller intensities. As IM is increased, IDA curves (both median and percentiles) tend asymptotically to a characteristic value. For P30S, this value is 34.5MNm (*cf*. Table 2b) and corresponds to the foundation overturning moment capacity. For P30L, this value is almost 70MNm and corresponds to the bending moment capacity of the pier. Recall, that for P30L, the overturning capacity at the foundation is 133.7 MNm (*cf*. Table 2b).

5.4 IDA curve for DMs pertaining to foundation response

As a final result, Figure 9 presents IDA curves for foundation settlement (FS), which is a performance indicator of foundation response. As expected, response for P30L is very favorable, with median settlements not exceeding 2cm for the strongest intensity level. The effect of surface waves is almost negligible and median curves for SC1 and SC2-3 are almost superimposed. On the contrary, the performance for P30S is -as expected- much more severe. Median settlements for SC1 are 0.25m at 0.5g but exhibit very high variability. Corresponding 84% percentile value is at least 4 times larger (>1.0m). The effect of surface waves almost doubles median FS for high intensities and one can observe a slight additional distress in passing from SC2 to SC3.

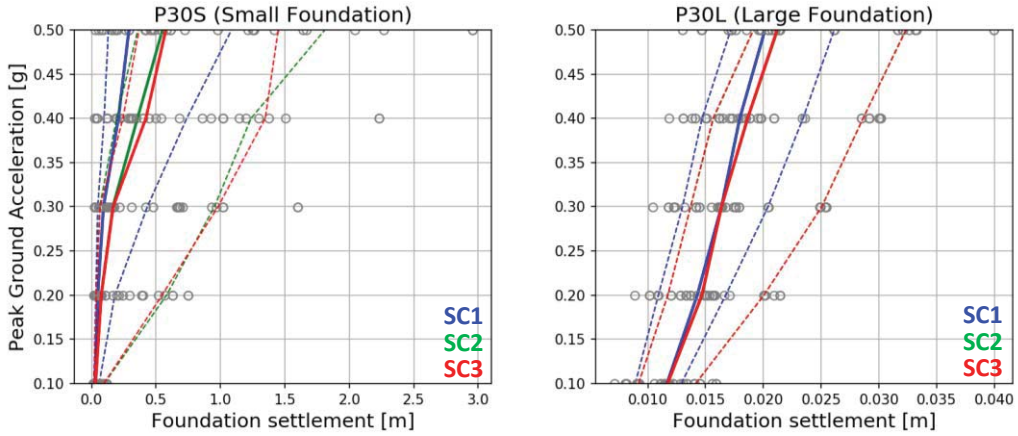

Figure 9: IDA curve for foundation parameter FS (accumulated Foundation Settlement)

6 CONCLUSIONS AND PERSPECTIVES

The present work has focused on the assessment of detrimental effects that surface waves may induce on bridge pylons. Two pylon configurations were studied, with emphasis on two variants for foundation design: a) conventional design, in which the foundation exhibits overstrength with respect to bridge pylon base section, b) inversed capacity-design, in which foundation dimension is reduced so as to concentrate nonlinear response at the foundation and thus protect the superstructure. The pylons have been studied via the IDA technique using a set of twelve records, in which it has been possible to isolate the effect of surface waves for horizontal translation and rocking. Basic conclusions of the study are the following:

- The detrimental effect of surface waves is mainly due to the horizontal motion component, at least for the record set used in this study. Even so, the effect of surface waves may lead to a significant increase in demand for both studied configurations. For the pylon with yielding superstructure, ductility demands at the pylon base section may be doubled due to surface waves. For the pylon with yielding foundation, foundation settlements may equally be doubled because of surface waves
- Detrimental effects of surface waves become more severe as seismic intensities increase. For seismic levels up to 0.20g, the response seems to be slightly altered by the incidence of surface waves
- An observable effect of the rocking motions has only been obtained for very high intensities and only for the configuration with yielding foundation. In the case of yielding superstructure, rocking motions have induced no further damage with respect to horizontal translations
- Bridge pylons designed with yielding foundations remain an interesting option for seismic design as a means for avoiding excessive damage in the superstructure. However, these systems seem to be more vulnerable to the effect of surface waves than conventional systems.

The presented results constitute the preliminary step for a detailed assessment of the effect of surface waves on bridge pylons within the framework or French research project ANR MODULATE. Prospective research works can focus on the following topics:

- A parametric investigation of a large number of pylon configurations (exploiting the proposed surrogate) model and confrontation with real cases
- Further IDA analyses and construction of fragility curves for record sets enriched with new records. As a matter of fact, one of the main objectives of the research project is to generate such records, both from post-processing of natural recordings and by large-scale numerical computations in realistic and canonical subsoil topographies. A further understanding is required as to the influence of rocking motions and as to how large rocking motions (induced by surface waves) can be. IDA analyses can further be investigated as to the selection of most relevant damage and intensity measures for the studied problem
- Last but not least, the studies can be extended to analyses for large displacements, which is a more rigorous hypothesis for systems near instability, foundation failure or extensive structural damage. Another possible extension is towards more realistic modeling of mechanical behavior in the concrete pier. Some selected pylon configurations can become the object of detailed 3D analyses.

7 ACKNOWLEDGEMENTS

This research work has received funding from the French National Research Project ANR MODULATE (2018 - 2022). More details and updates on ANR MODULATE can be accessed through the project website: https://modulate.brgm.fr.

Keywords: numerical methods, isogeometric analysis, dynamic analysis, finite element method, B-Splines, perfectly matched layer, elastic wave.

Abstract. *This contribution is concerned with a numerical approach to represent the elastic half-space subjected to dynamic forces. The proposed numerical solution is achieved by combining the advantages of the isogeometric analysis concept and the absorbing boundary technique, Perfectly Matched Layer (PML). Due to the nature of the half-space modeling, the attenuation or propagation of the wave motion to infinity as well as an optimal representation of the dynamic response of the media must be validated. Both conditions are needed to obtain acceptable results for dynamic analysis. In this contribution, the PML in combination with the B-Splines is adopted. On one hand, B-Splines is capable of describing more precisely the geometry, dynamic effects and the unknown field of the problem. On the other hand, the spurious reflections are avoided employing the PML method. This is defined using an artificial layer surrounding the computational domain. Using these two formulations, a better representation of the half-space domain can be achieved with less computational effort and higher accuracy. In order to evaluate the performance of this approach, a numerical example is presented for the 2D case considering a homogeneous linear elastic domain. The equation of motion is solved using the displacement-based formulation and approximated by an implicit time integration method. The variation of spatial and temporal refinement of the selected domain, the order of interpolation functions and geometrical properties of the absorbing layer are the considered aspects to investigate the performance of this approach. The results are also compared with the standard FEM.*

1 INTRODUCTION

The success for the representation of unbounded domains in transient analysis relies mainly in two aspects: the validation of the energy propagation and a well-representation of the wave. Depending on the considered problem, solution approaches are commonly based on numerical, analytical or semi-analytical methods.

In numerical methodologies, the most common practice to fulfill the first condition is imposing artificial conditions in order to imitate the behaviour of the far field. Among the most common techniques are those where mechanical methods based on spring and dash-pot models or sufficiently extended domains are used. There are others where preferably absorbing boundary conditions are imposed.

The Perfectly Matched Layer (PML) belongs to the last category. The particularity of PML is that the waves are attenuated inside of an artificial medium without generating any reflection during the transition at incidence plane, see Fig.1. This approach was introduced by Beregner in studies of the electromagnetic field to solve Maxwell's Equations [1].Afterwards this was extended for the modelling of other unbounded media, such as media in elastodynamics [2] [3]. This method has evolved considerably resulting in complex formulations where the equations to be solved include convolutional terms. Those formulations are efficient but certainly costly.

On the other side, not only the energy dissipation must be guaranteed but also the best way to depict the geometry problem and dynamic effects. The Finite Element Analysis is famous for its high potential to model complex media. However, a fine discretization is commonly needed to achieve the desired approximation of the solution. This fact is a major concern generally in time-domain analysis. Therefore, here, the isogeometric analysis is employed not only because of its easy way to catch the geometry but also because it avoids spurious results in dynamics analysis. For example, *optical branches* occurring in standard FEM for high order interpolation functions are eliminated using the IGA approach. The use of IGA has great advantages since the high order basis functions used in numerical analysis demonstrate superior approximation behaviour. That is basically because it possesses higher continuity in comparison with the standard FEA [4] [5]. The basis functions or B-Splines are used not only to depict the geometric but also to approximate the unknown field of the problem to be treated.

In this contribution, the Perfectly Matched Layer Method in combination with the isogemetric analysis (IGA-PML), is used primarily as twofold for unbounded media modelling. Firstly, the use of PML eliminates the influence of reflected wave coming back to the domain of interest. Secondly, isogeometric analysis is used to achieve a better representation of the wave propagating through the media and to capture PML effects all over the computational domain.

2 ISOGEOMETRIC ANALYSIS

The isogeometric analysis concept is an analysis procedure supported by a representation using CAD [4]. The basic idea is to define as good as possible a geometry model to be used in a direct way into an analysis model. The most common computational geometry technologies used for that purposes are the Non-Uniform Rational B-Splines (NURBS), however there are others approaches which can be employed instead. NURBS functions are a strong engineering design tool due to their capability to represent almost directly curved shapes. Other advantages for using NURBS as basis functions are their flexibility to reach a better refinement by knot insertion procedure, their C^{p-1} continuity for p-th order NURBS, and a higher continuity along the described geometry. This avoids some shortcomings in dynamic analysis due to the fact that no abrupt changes occur in the approximated geometry.

The parameter space using NURBS is determined by using patches instead of elements; therefore, the mapping itself is global to the whole patch. Regularly, the domain contained in each patch is homogeneous and uniform. For heterogeneous media additional patches can be added.

The NURBS basis funtions, based on B-Splines, are defined using the Cox-de Boor Recursion formula. For more details see [4], [5]. In case that $p = 1$, the B-Splines functions are the same like those used for standard piece-wise linear element functions. For higher order basis functions no similar equivalence is shown. Those functions are piece-wise non-negative through the domain. Another relevant aspect, and among the most important features of these functions, is the $p - 1$ continuous derivatives across the element boundary for each p^{th} order function.

In this contribution, a single patch is used to depict the geometry of the half-space containing the absorbing boundary layer. Then, the approximation of the geometry and the unknown filed are continuous along the domain of interest and the perfectly matched layer.

3 PERFECTLY MATCHED LAYER FORMULATION

The perfectly matched layer is an artificial absorbing boundary method, see Fig. 1. It is based on creating a layer surrounding the domain of interest where outgoing waves from the source are exponentially attenuated. This effect is achieved using *analytic continuation* to map the equation of motion into a complex plane [6]. This modification is accomplished by changing the coordinate system of the problem. Hence, spurious reflections are avoided at the interface between the layer and the domain with an additionally imposed attenuation along this layer. This PML approach is achieved in terms of a *complex coordinate stretching* but it is in fact mathematically equivalent to the original *split-field* and *perfectly matched anisotropic absorbers* approaches [7].

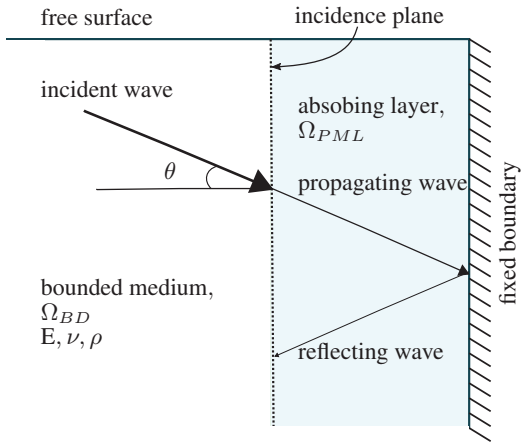

Figure 1: Scheme of perfectly matched layer method. θ denotes incidence angle of the wave.

Here, the complex coordinate stretching approach is adopted for a two dimensional case under plane strain motion. For more detailed information see e.g. [1],[2],[3],[8],[9].

PML equations are naturally developed in the frequency domain. For an elastic medium undergoing time-harmonic motion whose displacements of the form, $\mathbf{u}(\mathbf{x}, t) = \bar{\mathbf{u}}(\mathbf{x})\exp(i\omega t)$

the governing equations, without material damping and body forces, are

$$\begin{aligned} \text{div}\bar{\boldsymbol{\sigma}} &= \omega^2 \rho \bar{\mathbf{u}} \\ \bar{\boldsymbol{\sigma}} &= \mathbb{C}\bar{\boldsymbol{\varepsilon}} \\ \bar{\boldsymbol{\varepsilon}} &= \tfrac{1}{2}\left\{\text{grad}(\bar{\mathbf{u}}) + \text{grad}(\bar{\mathbf{u}})^T\right\}, \end{aligned} \tag{1}$$

where, $\bar{\boldsymbol{\sigma}}$ is the stress tensor, ρ material density, $\bar{\boldsymbol{\varepsilon}}$ contains the strains, $\mathbb{C}$ is the elasticity matrix, and ω is the angular frequency. These quantities are mapped into an orthogonal real coordinate system. The Eq.1 accepts body-wave solutions of the form,

$$\bar{\mathbf{u}}(\mathbf{x}) = \mathbf{q} e^{-ik_r \cdot \mathbf{x} \cdot \mathbf{p}}, \tag{2}$$

where, $\bar{\mathbf{u}}$ are the displacements at position vector $\mathbf{x}$, k_r is the wavenumber, $k_r = \omega / c_r$, with, c_r wave velocity for r-wave type: $r \in \{p, s\}$ for P and S-waves, respectively. $\mathbf{p}$ is unit vector for the propagation direction and $\mathbf{q} = \pm\mathbf{p}$ is the particle motion, see [2].

The wave described by Eq. 2 will travel without any variation or attenuation in an unbounded medium. With the intention of avoiding that effect, an additional attenuation is imposed to the wave response.

3.1 Complex stretch coordinate system

In order to impose the desired attenuation for outgoing waves, the wave equation solution is modified using a transformation into a complex coordinate system. This means that the dependent variable $\mathbf{x}$ is defined with a real and an imaginary part. A simple representation of this conversion is given as,

$$\lambda(\mathbf{x}) = \tilde{\mathbf{x}} = a(\mathbf{x}) - ib(\mathbf{x}). \tag{3}$$

If Eq.3 is used into Eq.2, replacing $\mathbf{x}$, the wave solution in Eq. 2 is transformed as,

$$\bar{\mathbf{u}}(\tilde{\mathbf{x}}) = \mathbf{q} e^{-ik_r \cdot \tilde{\mathbf{x}} \cdot \mathbf{p}} = \mathbf{q} e^{-ik_r \cdot (a(\mathbf{x}) - ib(\mathbf{x})) \cdot \mathbf{p}} = \mathbf{q} e^{-k_r b(\mathbf{x}) \cdot \mathbf{p}} e^{-ik_r a(\mathbf{x}) \cdot \mathbf{p}}. \tag{4}$$

The function $b(\mathbf{x})$ in Eq. 4 imposes an additional attenuation in the wave solution if it is bigger than zero but exponential amplification if it is smaller than zero [6]. In this paper, a and b functions are defined as $a(x_i) = 1 + f(x_i)/b_0 k_i$, and $b(x_i) = f_i(x_i)/b_0 k_i$, where $i \in \{1, 2\}$ defines the direction in which the wave is attenuated. The term b_0 is the characteristic length of the problem. The function $f_i(x_i)$ is called *attenuation function*. These functions impose the rate of attenuation at the position x_i. Evanescent and propagating waves are attenuated by $a(x_i)$ and $b(x_i)$, respectively. The Eq. 3 is considered for the determination of,

$$\tilde{x_i} = \int_0^{x_i} \lambda(\xi) \mathrm{d}\Omega_\xi, \tag{5}$$

where λ is the complex value coordinate stretching function. This relation implies the following mathematical change,

$$\frac{\partial \tilde{x_i}}{\partial x_i} = \lambda(x_i) \rightarrow \frac{\partial}{\partial \tilde{x_i}} = \frac{1}{\lambda(x_i)} \frac{\partial}{\partial x_i}. \tag{6}$$

Finally, the transformation of the coordinate system is done by applying Eq.6 into Eq. 1 for all $\partial / \partial x_i$. It results in,

$$\begin{aligned} \text{div}(\bar{\boldsymbol{\sigma}}\tilde{\boldsymbol{\Lambda}}) &= \omega^2 \rho \lambda_1(x_1) \lambda_2(x_2) \bar{\mathbf{u}} \\ \bar{\boldsymbol{\sigma}} &= \mathbb{C}\bar{\boldsymbol{\varepsilon}} \\ \bar{\boldsymbol{\varepsilon}} &= \tfrac{1}{2}\left\{\text{grad}(\bar{\mathbf{u}})\boldsymbol{\Lambda} + \boldsymbol{\Lambda}^T \text{grad}(\bar{\mathbf{u}})^T\right\} \end{aligned} \tag{7}$$

The terms $\tilde{\mathbf{\Lambda}}$ and $\mathbf{\Lambda}$ are called *stretch tensors* defined as,

$$\tilde{\mathbf{\Lambda}} = \begin{bmatrix} \lambda_2(x_2) & 0 \\ 0 & \lambda_1(x_1) \end{bmatrix}, \; \mathbf{\Lambda} = \begin{bmatrix} 1/\lambda_1(x_1) & 0 \\ 0 & 1/\lambda_2(x_2) \end{bmatrix} \tag{8}$$

The subindex 1 and 2 in Eq. 7 and 8 denotes the direction of attenuation, and

$$\bar{\boldsymbol{\sigma}} = \begin{bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{12} \end{bmatrix}, \; \bar{\boldsymbol{\varepsilon}} = \begin{bmatrix} \varepsilon_{11} \\ \varepsilon_{22} \\ 2\varepsilon_{12} \end{bmatrix} \tag{9}$$

The system of equations in 7 is formulated with respect to a rotated orthogonal system with basis $\mathbf{e}'_i$. Afterwards, these functions are mapped to the orthogonal basis system $\mathbf{e}_i$ using the rotated matrix $\mathbf{Q}$ whose components are $Q_{ij} = \mathbf{e}_i \cdot \mathbf{e}'_j$.

The time domain equations are obtained through the inverse Fourier transform of Eq. 7 after the change of basis. The resulting equations are,

$$\begin{gathered} \operatorname{div}\left(\boldsymbol{\sigma}\tilde{\mathbf{F}}^e + \mathbf{\Sigma}\tilde{\mathbf{F}}^p\right) = \rho f_m \ddot{\mathbf{u}} + \frac{c_r \rho}{b_0} f_c \dot{\mathbf{u}} + \frac{\mu}{b_0^2} f_k \mathbf{u} \\ \boldsymbol{\sigma} = \mathbb{C}\boldsymbol{\varepsilon} \\ \left(\mathbf{F^e}\right)^T \dot{\boldsymbol{\varepsilon}} \mathbf{F^e} + \left(\mathbf{F^p}\right)^T \boldsymbol{\varepsilon} \mathbf{F^e} + \left(\mathbf{F^e}\right)^T \boldsymbol{\varepsilon} \mathbf{F^p} + \left(\mathbf{F^p}\right)^T \mathbf{E} \mathbf{F^p} = \\ \frac{1}{2}\left\{ \left(\mathbf{F^e}\right)^T \left(\operatorname{grad} \dot{\mathbf{u}}\right) + \left(\operatorname{grad} \dot{\mathbf{u}}\right)^T \mathbf{F^e} \right\} + \frac{1}{2}\left\{ \left(\mathbf{F^p}\right)^T \left(\operatorname{grad} \mathbf{u}\right) + \left(\operatorname{grad} \mathbf{u}\right)^T \mathbf{F^p} \right\} \end{gathered} \tag{10}$$

The terms $\mathbf{F}^n$ and $\tilde{\mathbf{F}}^n$, assuming $n \in \{e, p\}$, contain the components of the stretching tensors for e, evanescent and p, propagating wave, see [3]. μ is the shear modulus, $\mathbf{E}$ and $\mathbf{\Sigma}$ are the integration of stresses and strains over the time, respectively. $\dot{\boldsymbol{\varepsilon}}$, $\dot{\mathbf{u}}$ and $\ddot{\mathbf{u}}$ is the derivative of strains, displacements and velocities with respect to time, respectively. The constants, f_m, f_c and f_k are,

$$\begin{aligned} f_m &= \left[1 + f_1^e(x'_1)\right]\left[1 + f_2^e(x'_2)\right], \\ f_c &= f_1^p(x'_1)\left[1 + f_2^e(x'_2)\right] + \left[1 + f_1^e(x'_1)\right] f_2^p(x'_2), \\ f_k &= f_1^p(x'_1) f_2^p(x'_2), \end{aligned} \tag{11}$$

where the quantities with prime denote the direction of attenuation in the orthogonal system with basis $\mathbf{e}'_i$.

4 NUMERICAL APPROXIMATION WITH B-SPLINES

The above mentioned equations are approximated in space and time by employing IGA and the Newmark's Method.

The weak form of the equations in 10 is obtained using an arbitrary test function, $\mathbf{v}$ and integrating the system throughout the computational domain Ω. The geometry and all unknown fields are approximated using NURBS basis functions such as,

$$\mathbf{u}^h(\xi, \eta) = \bar{\mathbf{N}}\mathbf{u}, \quad \mathbf{x}^h(\xi, \eta) = \bar{\mathbf{N}}\mathbf{x} \tag{12}$$

where, $\bar{\mathbf{N}} = \mathbf{N}(\xi)\,\mathbf{M}(\eta)$, with $\mathbf{N}$ and $\mathbf{M}$ containing the B-Splines basis functions for parametric directions, ξ and η, respectively. The superscript h indicates the approximated term.

The approximation in time is carried out with the Newmark's method. It is important to mention, that due to the nature of new quantities generated by the complex coordinate stretching, which associate the attenuation functions, the equation to be solved must be linearised at the time step t_{i+1}. Therefore, the Newton-Raphson method is employed to solve the system at each time step, Δt, confer e.g. [3]. Due to the use of Newmark's method, the system is solved through increments using an effective stiffness and forces. In piece-wise element representation, the effective stiffness matrix is,

$$\tilde{\mathbf{k}}^e_{i+1} = (\mathbf{k}^e + \bar{\mathbf{k}}^e) + \frac{\gamma}{\beta\Delta t}(\mathbf{c}^e + \bar{\mathbf{c}}^e) + \frac{1}{\beta\Delta t^2} \tag{13}$$

and effective vector of forces,

$$\tilde{\mathbf{p}}^e_{i+1} = \mathbf{m}^e\dot{\mathbf{u}}_{i+1} + \mathbf{c}^e\dot{\mathbf{u}}_{i+1} + \mathbf{k}^e\mathbf{u}_{i+1} + \mathbf{p}^e_{i+1} \tag{14}$$

where,

$$\begin{gathered}\mathbf{m}^e = \int_{\Omega^e} \rho f_m \bar{\mathbf{N}}\bar{\mathbf{N}}\mathrm{d}\Omega^e, \quad \mathbf{c}^e = \int_{\Omega^e} \frac{c_s\rho}{b_0} f_c \bar{\mathbf{N}}\bar{\mathbf{N}}\mathrm{d}\Omega^e, \quad \mathbf{k}^e = \int_{\Omega^e} \frac{\mu}{b_0^2} f_k \bar{\mathbf{N}}\bar{\mathbf{N}}\mathrm{d}\Omega^e \\ \bar{\mathbf{c}}^e = \int_{\Omega^e} \tilde{\mathbf{B}}\mathbb{C}\mathbf{B}^\epsilon \mathrm{d}\Omega^e, \qquad \bar{\mathbf{k}} = \int_{\Omega^e} \tilde{\mathbf{B}}\mathbb{C}\mathbf{B}^\rho \mathrm{d}\Omega^e\end{gathered} \tag{15}$$

The operators, $\mathbf{B}^\epsilon, \mathbf{B}^\rho$, and $\tilde{\mathbf{B}} = \mathbf{B}^e + \Delta t\mathbf{B}^p$, contain the derivatives of the basis functions modified by the components of the attenuation tensors, see [3]. The terms β and γ are constants of the Newmark's method. The element internal forces, $\tilde{\mathbf{p}}^e_{i+1}$ are expressed by,

$$\tilde{\mathbf{p}}^e_{i+1} = \int_{\Omega^e} \tilde{\mathbf{B}}^T \cdot \hat{\boldsymbol{\sigma}}_{i+1}\mathrm{d}\Omega^e + \int_{\Omega^e} \tilde{\mathbf{B}}^{p^T} \cdot \hat{\boldsymbol{\Sigma}}_{i+1}\mathrm{d}\Omega^e \tag{16}$$

with,

$$\begin{gathered}\hat{\boldsymbol{\Sigma}}_{i+1} = \hat{\boldsymbol{\Sigma}}_i + \Delta t\hat{\boldsymbol{\sigma}}_{i+1}, \\ \hat{\boldsymbol{\sigma}}_{t+1} = \mathbb{C}\hat{\boldsymbol{\varepsilon}}^h_{t+1}, \\ \hat{\boldsymbol{\varepsilon}}^h_{i+1} = \tfrac{1}{\Delta t}\left[\mathbf{B}^\epsilon\dot{\boldsymbol{u}}_i + \mathbf{B}^\rho\mathbf{u}_{i+1} + \tfrac{1}{\Delta t}\hat{\mathbf{F}}^\epsilon\hat{\boldsymbol{\varepsilon}}_i - \hat{\mathbf{F}}^\rho\hat{\mathbf{E}}_i\right]\end{gathered} \tag{17}$$

Being unique for each PML-element, the terms $\hat{\mathbf{F}}^\epsilon$ and $\hat{\mathbf{F}}^\rho$ contain only the components of the attenuation functions for evanescent and propagating waves, respectively.

The computational domain and the PML layer are defined in the same patch using B-Splines basis functions. Due to the influence of control points over each element for higher order, the standard PML technique is modified since the attenuation property can be activated directly before of the delimited physical border between the adjacent computational medium and absorbing layer. Let us set this assumption using Fig. 2. The right element is in charge to represent the absorbing layer, and the left two elements the bounded domain. Then, for linear order, the influence of absorbing property of the wave starts immediately at the boundary between the bounded and PML domain. This fact can change when higher order basis functions are employed, where the participation of attenuation functions also influences the control points belonging to the PML-Element allocated just before of the delimited boundary. This aspect is discussed further in the numerical application.

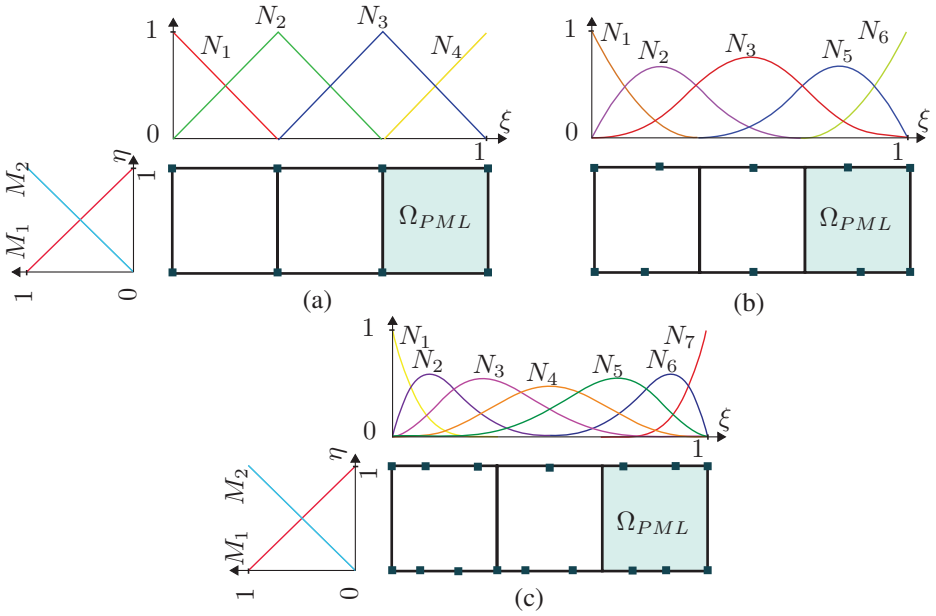

Figure 2: IGA-PML. Influence of basis functions in ξ parametric direction beyond the absorbing layer for order; (a) q =1 , (b) q =2, and (c) q =4. N_i and M_j are the basis functions along ξ- and η-parametric direction, respectively. Subscripts $i, j \in 1, 2, ..., N_{cp}$, where N_{cp} is the number of basis functions. Square dots are the control points.

5 NUMERICAL EXAMPLES

A 2D case for a band geometry is presented, see Fig 3. This is subjected at its left side to a sinusoidal time-dependent displacement, $u(t) = 0.01\sin(16\pi t)$ [m] for $t \in [0, 0.25]$ [s] and $u(t) = 0$ [m] for $t \in (0.25, 1.00]$ [s]. Its right side is fixed. The medium possesses a Young's moduls, $E = 10$ [kPa], density, $\rho = 10$ [kg/m^3] and Poisson's ratio, $\nu = 0$ [-]. No material damping is considered. The approximation of the geometry is based on the standard displacement based formulation using linear elements as reference solution. The density mesh in horizontal direction is quantified based on the wavelength, λ_ω, as, $\Delta x = \lambda_\omega/9$, see [10]. Δy=2 [m] since the wave only travels along x-direction. For this example, the incidence angle of propagating wave, θ is zero. The used time step is Δt =0.001 [s].

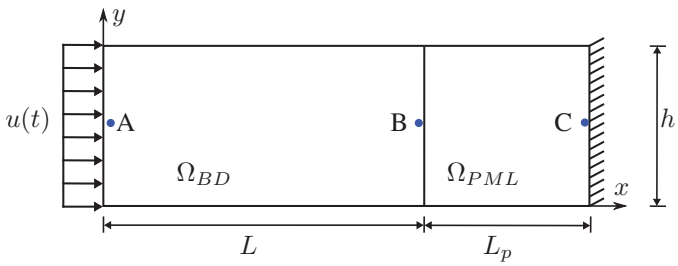

Figure 3: Band geometry. L=10 [m], and Lp=h=5 [m]. Ω_{BD} and Ω_{PML} are the bounded and PML layer domain, respectively. A, B and C are reference points.

The mesh density used in *IGA-PML* is the same as in the reference solution, FEM with Lagrange Interpolation Functions, but not the basis functions. The order of B-Splines basis functions, p and q, is the same in both parametric directions for *IGA-PML*, with $p = q$ =1, 2 and 4. As reference solution, the standard approximation used for the PML is also considered. The results are presented in Fig.4, 5 and 6, for the horizontal displacements of the system at

point A, B and C, see Fig. 3.

The displacements at point A, are shown in Fig.4. These are quite similar for all cases at $t < 0.6$[s]. By using the standard FEM, the system continues oscillating since no attenuating or absorbing boundary is used. In order to prevent this issue, the domain is usually extended.

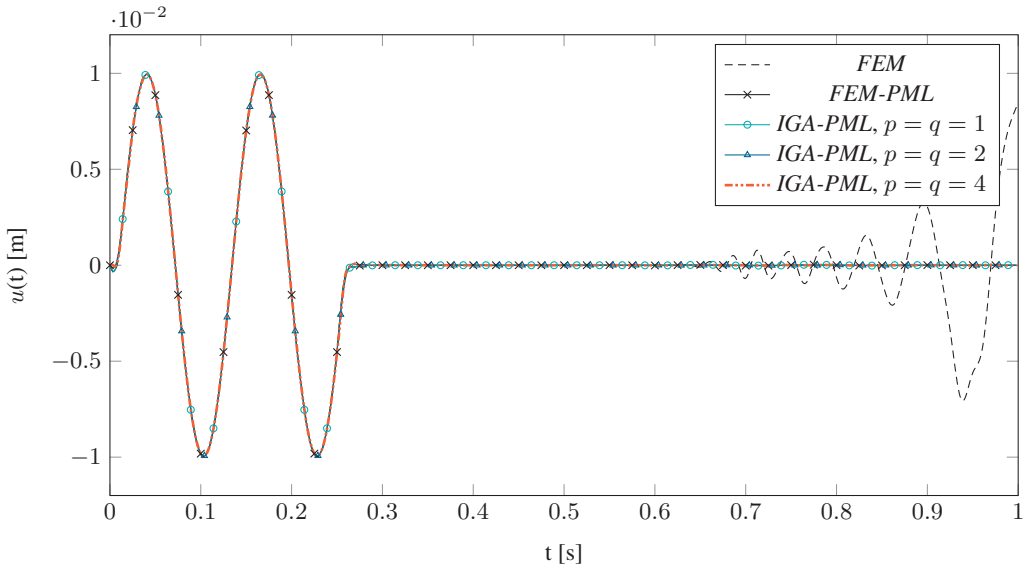

Figure 4: Horizontal displacement of system at point A (0.3 , 2.5) [m]

At the point B the wave amplitude is slightly attenuated in these cases where the PML method is used. However, this small difference could be neglected since all displacements are artificial beyond this point. Furthermore, this effect could be removed using a smaller integration step.

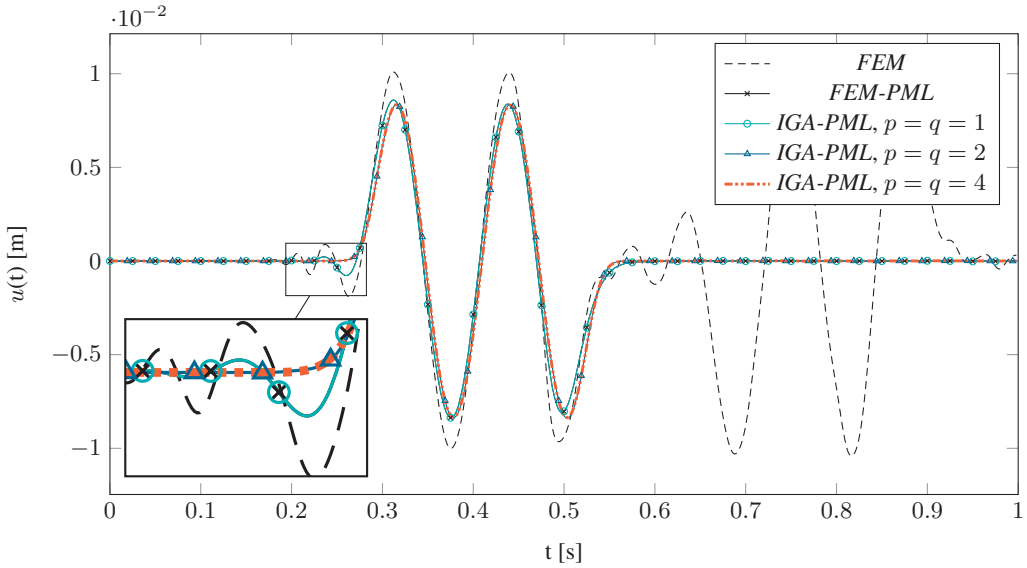

Figure 5: Horizontal displacement of system at point B (9.9 , 2.5) [m]

Another aspect to analyse in Fig.5 is the description of the wave. For the linear FEM, *FEM-PML*, and *IGA-PML*, it is noticed that the transition of the wave between 0.18 and 0.28 [s] has some small oscillations. These spurious effects are absent when higher order B-Splines basis

functions are used. This numerical error is commonly avoided when the mesh refinement is increased keeping a small time step calculation.

In Fig.6 the displacements, corresponding to point C, are plotted for *IGA-PML* of order $p = q =$1, 2 and 4. Even when these displacements are small in the range of $1.5\text{x}10^{-5}$ and $0.2\text{x}10^{-5}$ [m], there are still some differences when the order is increased. Presumably, this fact is due to the high-continuity presented in the basis functions.

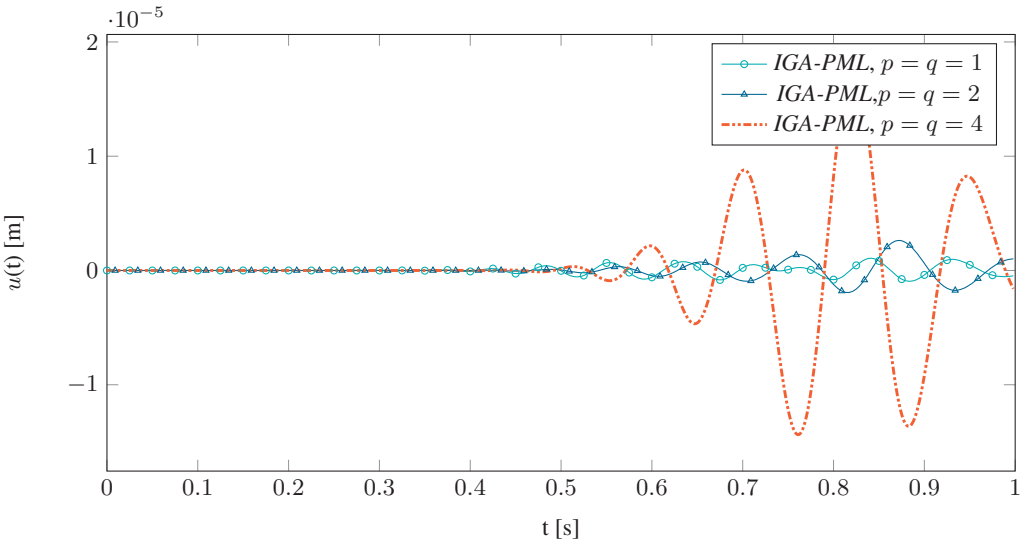

Figure 6: Horizontal displacement of system at point C (14.7 , 2.5) [m]

Additionally, the displacements using *IGA-PML* at different instants of the time calculation are plotted in Fig. 7. These figures correspond to the case with interpolation function of order, $p = q =$2. It is noticed that the displacements at the end of the calculation, Fig.7.d, are in general zero, but small displacements are presented. However, these could be neglected in comparison with the initial imposed displacement amplitude, see Fig. 4.

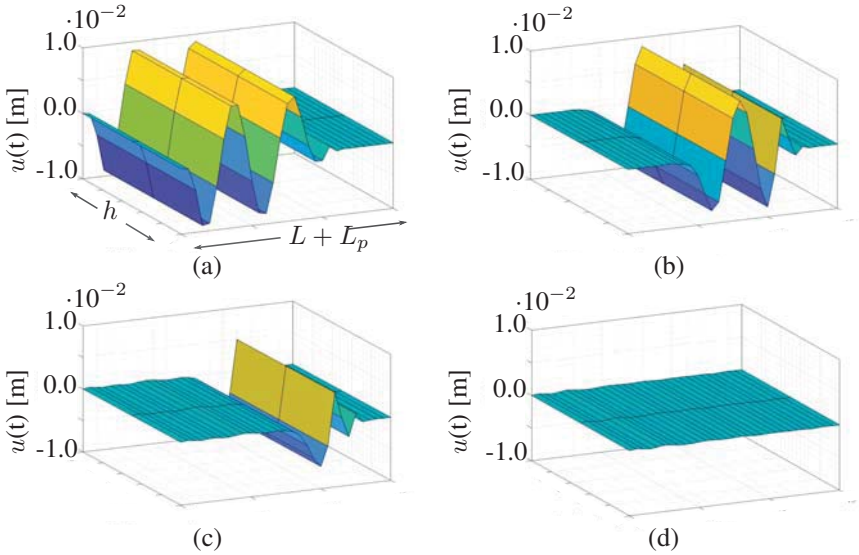

Figure 7: Displacement of horizontal degrees of freedom at: (a) $t = 0.25$, (b) $t = 0.38$, (c) $t = 0.50$, and (d) $t = 1.00$ [s]

6 CONCLUSIONS

- Combination of PML using high order basis functions based on IGA is carried out for two dimensional cases for elastic, homogeneous unbounded domains.
- The attenuation effects of the absorbing layer are slightly imposed just before the incidence border if mesh is considerably fine. However, an absorbing influence beyond the PML border can be expected when a coarse mesh is used. This assumption can be considered for further studies.
- The effects of the basis functions are tested near the fixed boundary where it is observed that, even when the displacements are minimal, the attenuation rate increases with higher order B-Splines basis functions, Fig.4.
- Due to discretization in time, the solution depends strongly on time step. The smaller this interval is, the better the wave approximation is for both FEM and IGA-PML.

Abstract. *In this study, we propose and implement a convergence scheme for the numerical wavenumber integration in the context of 2.5D FE solution and validate it through a numerical example. In brief, the scheme is to estimate the convergence based on the relative difference between two interpolations for a given set of wavenumbers, which is done iteratively by refining the wavenumber sampling until the relative difference becomes no greater than a specified value. We evaluate the performance and convergence of the numerical integration scheme by comparing the results of the responses of a tunnel in a layered ground due to a concentrated harmonic load using both a full 3D model and a 2.5D model, including computational time aspect. Finally, we consider applying the same scheme to other relevant numerical integrations.*

1 INTRODUCTION

Most problems in structural and soil dynamics are defined in 3D space. However, in a mathematical framework quite a few among those problems can be simplified in such a way that the geometry and material properties (i.e. density, stiffness, damping, etc.) of the media of interest are invariant along a particular axis. It is then possible to solve some of these 3D problems via the so-called 2.5D numerical approach (e.g. Galvin et al., 2010). For instance, wave propagation due to moving load along a tunnel structure built in layered soil media is a good example where the given geometry and material properties are often assumed constant along the track direction (Say y-axis), while they vary along the other two directions (x and z). Thanks to the y-direction invariance of both geometry and property, all the differentiations with respect to the y coordinate in the 3D wave equation can be replaced by the y-direction wavenumber (k_y) without any loss of accuracy in describing the features in the 3D problems. Then, as in discrete methods such as finite element (FE) method, the solution can be obtained by a spatial discretization only along the x- and z-axes, effectively reducing the number of degrees of freedom (DOF) to solve. On the other hand, this formulation requires that the resulting 2D FE equation be solved for many wavenumbers k_y in the FE context. This can be time-consuming but is still much less demanding than a full 3D FE analysis, provided that one employs a procedure that ensures efficient convergence of the associated wavenumber integration. Therefore, it is important to optimize the sampling and number of k_y's to solve so that one can calculate accurate and converged results, while the computational time is reasonable. Particularly for calculation of high frequency (~100Hz) dynamic response at far offset along the y-axis, the 2.5D FE solution indeed becomes essential in comparison to a full 3D FE solution due to the computational memory requirement.

In this study, we implement a convergence scheme for the numerical wavenumber integration in the context of 2.5D FE solution and validate it through a numerical example. In brief, the scheme is to estimate the convergence based on the relative difference between two interpolations (e.g. linear and spline) for a given set of wavenumbers, which is done iteratively by refining the wavenumber sampling until the relative difference becomes no greater than a specified value (e.g. 0.01). We discuss the performance and convergence of the numerical integration scheme by considering various aspects. At the end, we also discuss to apply the same scheme to other relevant numerical integrations e.g. wavenumber integration for the fully analytical solution.

All the FE calculations in the current study are performed by means of the commercial software *COMSOL Multiphysics*™. The relevant 2.5D wave equation is implemented and solved in the module of *2D Coefficient Form PDE*. In order to avoid artificial reflection from the computational domain boundary, a perfectly matched layer technique (Park and Kaynia, 2017) is deployed in the current study.

2 PROPOSED WAVENUMBER INTEGRATION METHOD

The numerical wavenumber integration is a common and necessary step in calculation of the analytical-solution for elastic wave propagation in layered media (e.g. Apsel and Luco, 1983; Park and Kaynia, 2018) to obtain dynamic response in the spatial domain from the wavenumber domain. There are two associated challenges: 1) handling of the pole singularities in the kernels of wavenumber integration; and 2) controlling of the convergence of numerical integration. The former challenge, which is the most critical in the analytical solution, is due to the extremely large and singular value of kernels at the propagation poles. A similar procedure for numerical wavenumber integration is required in the 2.5D FE solution. However, the challenge is related mainly to the convergence control, because the pole singularity doesn't exist or is not so strong

in the 2.5D FE solution. In the following, we discuss these features through an example of wave response in a homogeneous half-space.

Figure 1 compares two kernels calculated via a fully analytical solution (red thin solid line) by Park and Kaynia (2018) and the corresponding 2.5D FE solution (blue thick solid line). Both of the kernels are for the same homogeneous half-space subjected to a harmonic vertical load with frequency 100 Hz applied at the surface. The kernels are calculated exactly at the loading point. It is clearly shown in Figure 1 that the kernel of the 2.5D FE solution looks rather moderate without any strong singularity near the Rayleigh pole (black thin dashed vertical line). On the other hand, that of the analytical solution shows a strong and sharp singularity near the Rayleigh pole, subsequently requiring very-densely-sampled wavenumbers to calculate accurately. It is shown that the challenge in relation to the pole singularity is less significant (or almost negligible) in the 2.5D FE solution than the analytical solution. Therefore, it is expected that interpolation of the kernels of the 2.5D FE solution is feasible, even near the poles, which in turn can save significantly the computation effort in the 2.5D FE solution. Yet, we still need to make sure the convergence of the wavenumber integration by optimizing the sampling and number of wavenumbers to include into the 2.5D FE calculation.

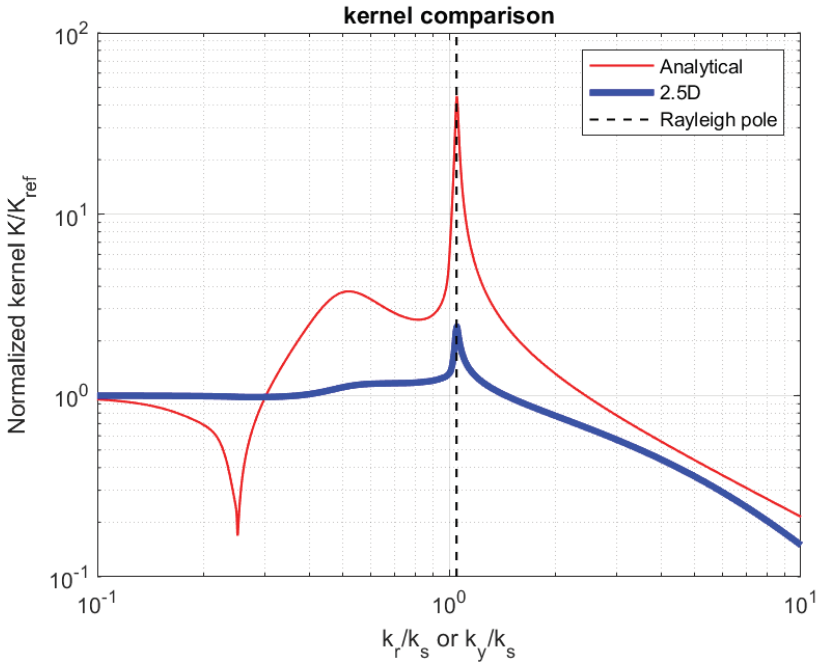

Figure 1. Comparison of two kernels calculated by means of analytical and 2.5D solutions, normalized with respect to the reference kernel calculated at the zero wavenumber. Note that the *x*-axis is the normalized wavenumber with respect to the shear wavenumber k_s; and k_r and k_y are the radial- and y-direction wavenumbers, respectively, used in the analytical and 2.5D FE solutions.

Based on the observations made through the example in Figure 1, we propose a convergence controlling scheme. The scheme a simple approach, consisting of the following steps:

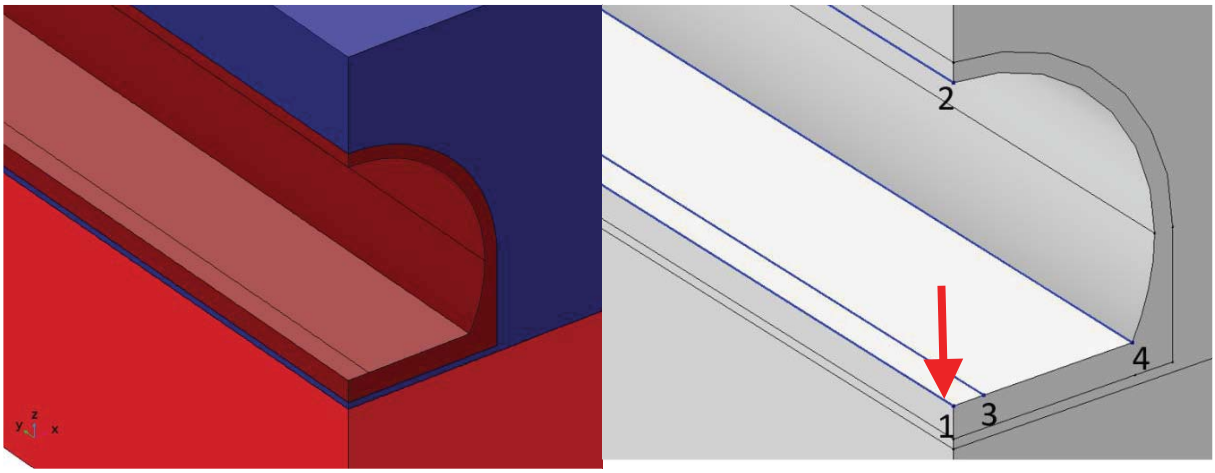
1. Initialize a wavenumber sampling of k=[0:Δk:k_{max}]. Here, k_{max} should be so large that the kernels at k_{max} is small enough. Note that as shown in Figure 1, the kernels decay quickly for k>$k_{Rayleigh}$. In addition, Δk could be large enough such that the total number of k's is no so high e.g. < 10. Alternatively, the sampling can be done logarithmically, while using the same k_{max}.
2. Calculate the kernels for the given wavenumber sampling k by 2.5D FE solution procedure.

3. Interpolate the kernels by means of two different interpolations (e.g. linear and spline).
4. Estimate the relative differences between the interpolated values of the two different interpolation methods at the middle points of individual wavenumber sampling intervals.
5. Collect the middle-point wavenumbers (say $k_{>0.01}$) where the relative differences are greater than a specified criterion (e.g. 0.01).
6. Re-calculate the true kernels for those collected middle-point wavenumbers $k_{>0.01}$ by 2.5D FE solution procedure.
7. Repeat Steps 3-6 by updating k with accumulatively adding $k_{>0.01}$, until $k_{>0.01}$ does not exist.

Once Step 7 above is completed, we perform an inverse Fourier transform from k_y-domain to y-domain in order to calculate the final wave response in the spatial domain. We have found through numerical experiments that the number of wavenumbers after Step 7 is around a few 100's. If, on the other hand, we in a brute force manner use an equally-spaced wavenumber sampling for k=[0,k_{max}], the total number of wavenumbers could be in the order of $>10^4$.

3 NUMERICAL EXAMPLES

We validate the wavenumber integration scheme proposed in the study by solving a simple example of a tunnel embedded in a two-layered soil medium. Figure 2(a) shows the full 3D model described with 2 symmetric planes used at x=0m and y=0m. The tunnel is located in the upper soil layer of 16m thickness, and the tunnel bottom is close to the lower bedrock layer of infinite thickness. The thickness of the tunnel wall varies between 0.6m to 1.0m along the perimeter, shown in Figure 2. The harmonic excitation load of 100 Hz is applied in the middle of the tunnel base and in the vertical direction, red arrow in Figure 2(b). The material properties and geometry in the example problem is shown in Table 1. In addition, Figure 2(b) shows four lines highlighted in blue, where we extract the displacement results and compare with a full 3D FE simulation. Figure 3(a) and (b) show the FE meshes used in calculation, respectively, for the 2.5D and 3D analyses. The numbers of DOFs used in each model are around 43×10^3 and 1250×10^3, respectively.

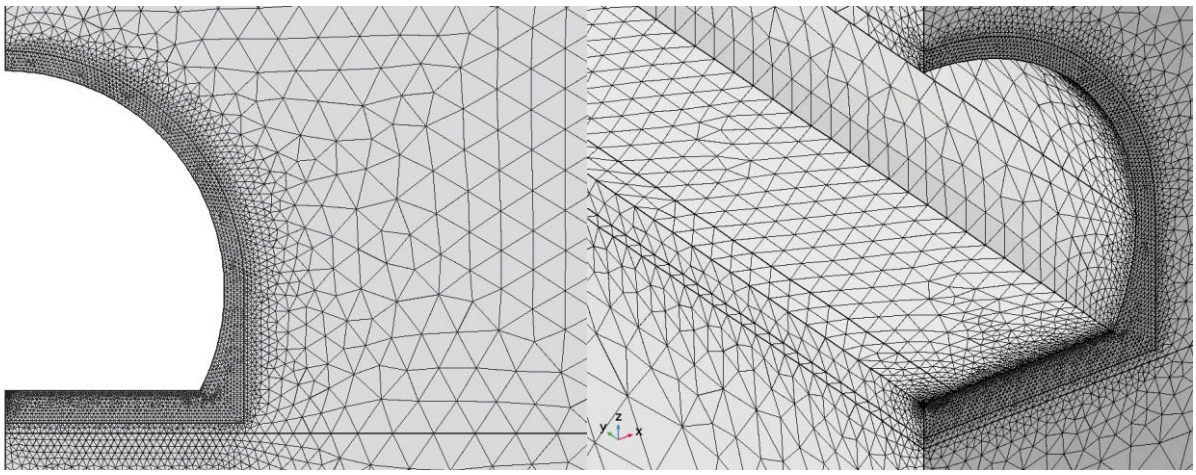


(a) (b)

Figure 2. (a) Example problem of a tunnel imbedded into two-layered soil medium (modelled with two symmetric planes at x=0m and y=0m); (b) 4 lines (blue) on the tunnel surface where responses are calculated and compared. Red arrow shows where the vertical point load of 100Hz is applied on Line 1.

Material	Density [kg/m^3]	Shear/Compression velocity [m/s]	Thickness [m]
Upper layer	1500	500/2000	16
Lower layer	3000	2000/4000	inf
Concrete tunnel	2300	2128/3475	0.6 (bottom: 1.0)

Table 1. Material properties and geometry in the example problem in analysis. A uniform viscous damping of 1% is applied to all the materials.



(a) (b)

Figure 3. FE meshes used: (a) for 2.5D simulation; (b) for 3D simulation

Figure 4 compares the two results of the 2.5D and 3D FE simulations, calculated along the 4 lines highlighted with blue lines in Figure 2(b). The solid and dashed lines are, respectively, for the 2.5D and 3D FE solutions, and the blue and red colors denote, respectively, the real and imaginary parts of the time-harmonic response. It is clearly shown that the agreement between the 2.5D and 3D FE simulations is perfect for Line 1, 3 and 4. Namely, the solid and dashed lines are exactly on the top of each other. The agreement for Line 2 (line along the tunnel crown) is also very good but not as much as the other lines, which is believed to have to do with the wavenumber sampling near the Rayleigh (or generally, wave propagation) pole(s). The improvement on this issue is under investigation.

It is mentioned earlier that k_{max} should be so large that the kernels at k_{max} is small enough, making sure that the numerical integration is converged. Furthermore, we have also found out that k_{max} depends on the relative position of (or distance between) load and receiver points. Figure 5 shows the normalized kernels for the four response lines in Figure 2(b) whose distances to the vertical load are different. Line 1 has zero distance to the load point, and Lines 3, 4 and 2 have 1m, 6m and ca 11m distance, respectively. It is easily noticed in Figure 5 that the decaying rate of the kernels is proportional to the distance between the load and response points. Therefore, we may conclude that the longer the distance is, the smaller k_{max} is needed.

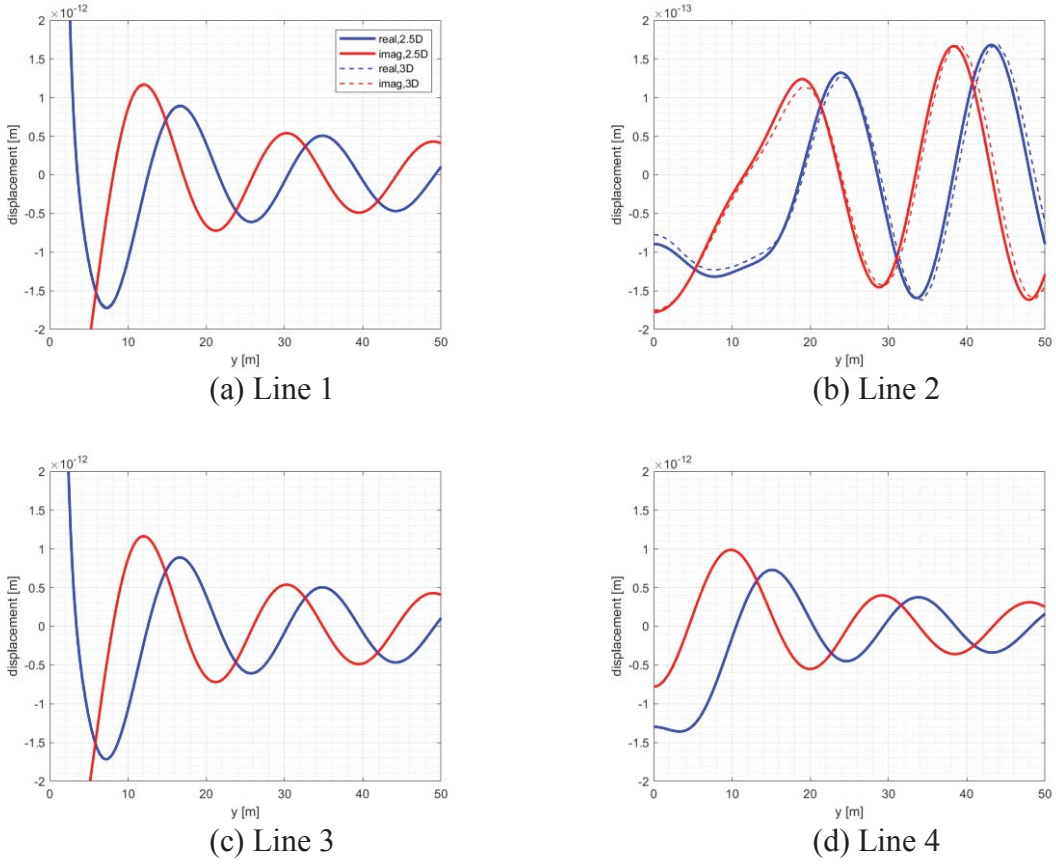


Figure 4. Comparison of 2.5D (solid lines) and 3D (dashed lines) simulation results in displacement along 4 lines on the tunnel surfaces (defined in Figure 2). Note that the Y-axis scale of Plot (b) is 10 time smaller than that of the other three plots.

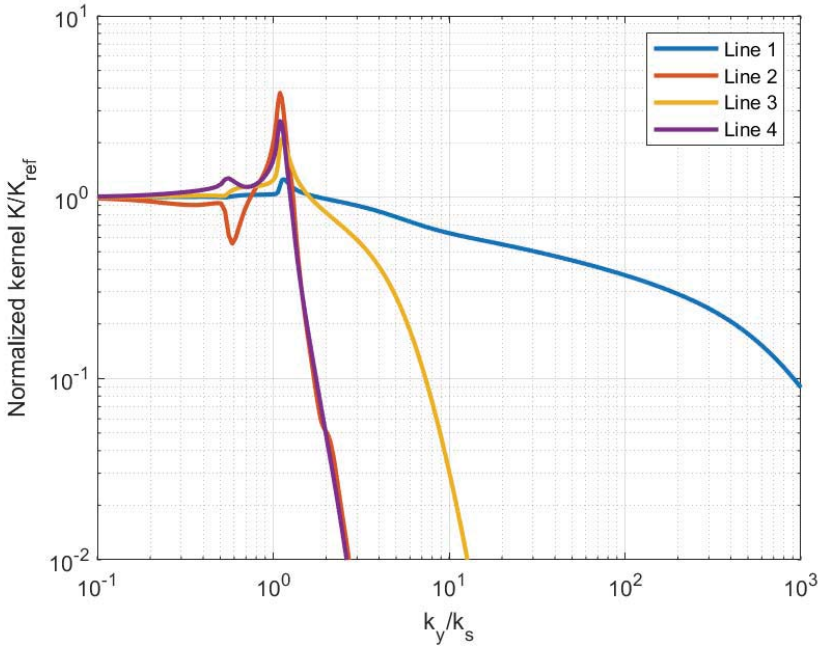

Figure 5. Comparison of kernels calculated for the four lines on the tunnel surfaces (defined in Figure 2). Note that the kernels are normalized with respect to the reference kernel calculated at the zero wavenumber. In addition, the *x*-axis is the normalized wavenumber with respect to the shear wavenumber k_s of concrete (~0.295).

4 CONCLUSIONS

In this study, we propose a simple scheme with which we can efficiently integrate the wavenumber integration in the context of 2.5D FE solution for a full 3D wave equation. The scheme consists of 7 steps and controls iteratively the convergence of the integration. The satisfactory performance of the proposed integration scheme is demonstrated by comparing the results of the responses of a tunnel in a layered ground due to a concentrated harmonic load using both a full 3D model and a 2.5D model. In addition to comparison of the displacements, information about computational time is provide. One of the key parameters in the proposed scheme is the maximum wavenumber to be used in the analysis (k_{max}). Analyses indicate that the longer the distance between load and response points, the smaller k_{max} is required.

Herein, we have applied successfully the proposed integration technique to the 2.5D FE wave equation. Nevertheless, it is worthwhile to mention that the same technique can also be applied to any numerical integration e.g. numerical wavenumber integration for the fully analytical solution by Park and Kaynia (2018), replacing a brute force integration with equally-spaced wavenumbers and saving computation time by >10 times. A related study is in progress.

Keywords: Domain Reduction Method; Seismic Metamaterials; Resonating Unit Cells; Dynamic Soil-Structure Interaction

Abstract. *Metamaterials have been successfully used during the past decade in the field of electromagnetism to control the propagation of electromagnetic waves. Interesting and possibly practically useful phenomena, such as negative refraction and generation of frequency bandgaps, may be induced in metamaterials. Recently, remarkable attempts have been made to bring this concept to the civil engineering scale in order to control the incoming seismic waves, mitigate their effects on structures and enhance seismic resilience of communities. A study on the potential of installing multiple resonating unit cells around an existing structure to improve its seismic performance is presented in this paper. Taking advantage of the 180^o phase difference that occurs right after the resonance of the unit cell masses, bandgaps can be generated at frequencies of interest for earthquake engineering applications. The Domain Reduction Method (DRM) is employed to realistically model the wave field (vertically propagating shear waves in this case). The model is verified and key features of DRM important for modeling the seismic response of metamaterials are exemplified.*

1 INTRODUCTION

Use of metamaterials to control the propagation of electromagnetic waves was initially proposed by Pendry et al. [1]. Since then, many researchers applied this concept in different science and engineering fields, where the wavelengths are orders of magnitude larger, as in the case of mechanical waves in solids. In particular, earthquake engineers have considered locally resonant metamaterials or resonating unit cells or resonators (multiple unit cells with a vibrating mass inside each one of them), embedded into the soil as the means to guide the incoming seismic waves in certain frequency ranges (i.e., wave lengths) away from the structure to be protected. Most of these studies ([2], [3], [4], [5]) have shown, either numerically or experimentally, that this is feasible for the case of surface waves. Such waves couple with the resonators and are transmitted downwards before reaching the structure.

However, as shown by Zaccherini et al. [6], in case of more realistic inhomogeneous soil layers with depth-increasing stiffness, the initially downward-transmitted waves will eventually bend upwards and travel back towards the ground surface. This implies that the successfully diverted surface waves (aiming to protect one structure) may cause additional damage to neighboring structures. Such unintended "transfer" of seismic risk needs to be thoroughly addressed if seismic metamaterials are to find their way into civil engineering practice.

Most importantly, only a few studies ([7], [8]) have dealt with the other critical seismic wave component: the body shear waves. In contrast to surface waves, body waves propagate almost vertically through the soil, inciting the structure from below. A debate on which waves (surface or body) are more destructive is still ongoing in the earthquake engineering community. However, with a realistic model of the seismic wave field generated by the rupturing seismic fault, the relative importance of the different types of seismic waves can be assessed based on the basis of sound seismic risk analysis principles.

This study employs the Domain Reduction Method (DRM) ([9], [10]) that realistically models both body and surface waves. The DRM is a Finite Element (FE) analysis method that aims at reducing a large computational domain that includes the entire problem (including the seismic fault, the bedrock, the soil, and the structure), to a much smaller computational domain that only includes local soil and structure, using appropriate boundary and initial conditions, and interface layers [11]. The energy generated by oscillations of the structure is radiated back into the domain and dissipated using so-called damping elements at the DRM model boundary. DRM enables accurate modelling of all 6 components of seismic waves.

The paper focuses on a 2D (plane strain) domain, vertically propagating horizontal shear waves, and a structure represented by an elastic single degree of freedom (SDOF) system responding to horizontal base excitation, and metamaterial resonators similar with those ones proposed by Colombi et al. [7]. The aim is to showcase the effectiveness of the DRM in modelling soil–structure–metamaterial seismic response. Emphasis is placed on the importance of model verification and validation, and the illustration of some of the most powerful and useful features of the DRM, as implemented in the Real-ESSI Simulator [12].

2 FINITE ELEMENT MODEL

The in-plane linear elastic FE modelling is conducted using the Real-ESSI Simulator [12], in which the DRM is already incorporated and can be easily applied. The FE model is illustrated in **Fig. 1**, where the DRM elements are highlighted with orange color. The FE model is part of a one-to-two orders of magnitude larger domain that includes the rock and the remaining soil through which the seismic waves propagate. The seismic motions are inserted into the FE model by applying "effective" forces on the DRM elements. To calculate these effective forces, one needs to calculate the displacement and acceleration time histories for each node of the DRM

elements using the free-field response of the larger domain and the known mass and elastic stiffness matrices of the FE model. This can be done either analytically ([13], [14]) or numerically, using one of the available commercial packages to calculate free-field response. This complex process is automated in Real-ESSI, obliviating the need to manually calculate the effective forces on DRM elements. In this way, the only necessary input is the acceleration and displacement time histories of the seismic motion.

A second important part of the FE model are the damping elements (shown with dark-grey color in **Fig. 1**), which surround the DRM elements (orange). Note the different damping ratio values assigned to the damper element zones on the sides and under the soil domain. The purpose of the damping elements is to damp out any waves generated by oscillations of the structure by artificially applying high values of Rayleigh viscous damping on such inciting waves. In the absence of a structure (free-field), the damping elements remain inactive, as there are no radiated waves entering their domain.

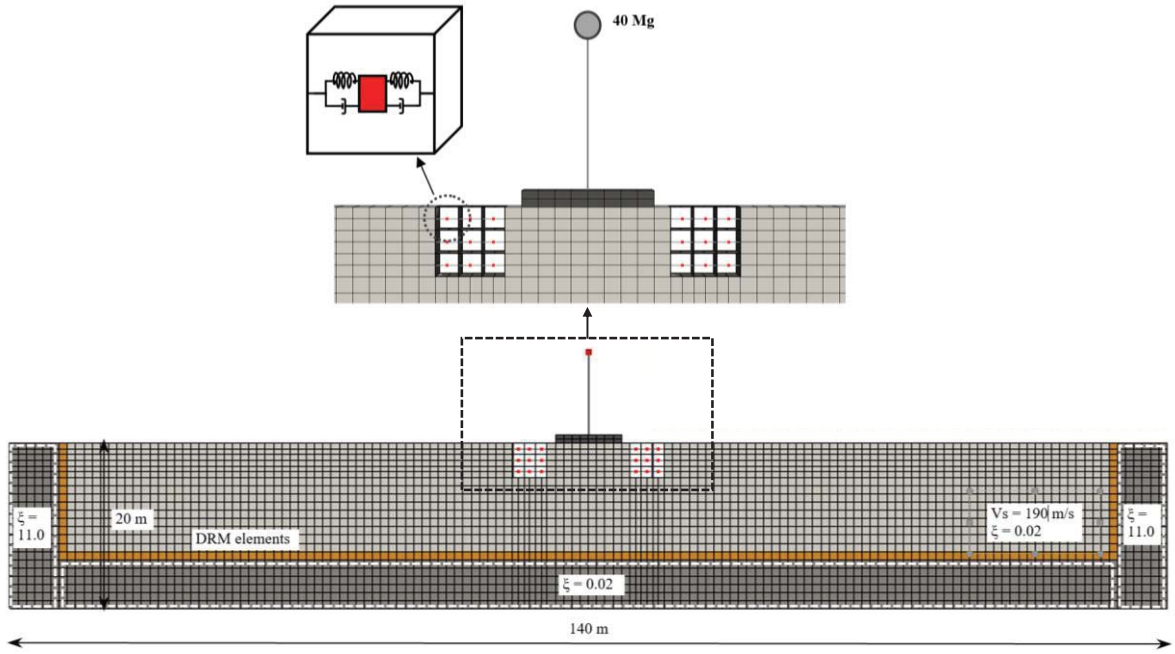

Fig. 1. Geometry of the FE model including the resonating unit cells and the structure.

2.1 Soil, structure, and metamaterial properties

A uniform and relatively soft soil layer of 20 m depth is considered, with V_s = 190 m/s (shear wave velocity), ν = 0.3 (Poisson's ratio), ρ = 1.6 Mg/m^3 (mass density), resting on rigid bedrock; the resulting horizontal natural period is 0.42 s. The soil is modelled using 8-node elastic solid brick elements (2D modelling with 3D elements, i.e. a 3D slice), sufficiently discretized to properly capture wave field response (at least 10-elements per wavelength [15], [16]). Since rigid bedrock is assumed at 20 m depth, the radiated waves from the structure and the resonators should not be damped out by the damping elements at the bottom of the model. In this particular case, radiated waves propagating to the bottom boundary of the FE model should get fully reflected back towards the ground surface, and continue propagating (downwards and upwards), until they gradually dissipate or get artificially damped out by the lateral damping elements (this is why ξ = 0.02 damping ratio is used for the damping elements in the horizontal zone under the soil, same as for the soil above, as shown in **Fig. 1**).

At this point, it should be noted that this is not how damping elements are supposed to be used. According to the DRM, damping elements should be used to damp out internally

generated and radiated waves, not allowing them to go back into the main domain. A deeper FE model would be required for this purpose, also including the rock layer above the DRM elements, so that any radiated waves would be naturally reflected at the soil–rock interface.

An idealized SDOF system is used to represent an existing shear building, lying on a rigid surface foundation of 8 m width, which is modelled with 8-node elastic brick elements. The SDOF system of 10 m height is modelled with elastic beam elements, assumed to be massless, and a 40 Mg lumped mass on top. The stiffness of the beam is defined, so that the resulting natural period of the SDOF system is 0.45 s. A Rayleigh viscous damping of 5% was assumed.

The resonating unit cells are placed at the sides of the structure, embedded into the soil. Each unit cell (18 in total), is a hollow reinforced concrete (RC) box, containing a mass element (at the centre), connected to the sides of the box through two pairs of springs and dashpots, as shown in **Fig.1**. The RC box is modelled with elastic shell elements of h = 0.2 m thickness, Young's modulus E = 25 GPa, v = 0.2, and ρ = 2.5 Mg/m^3, while a Kelvin-Voigt truss element is used to model each pair of springs and dashpots. The spring stiffness and the mass are determined so that the natural vibration period of each unit cell is 0.5 s – just above the 0.45 s period of the SDOF system (the reason of this selection will be explained in Section 2). Hence, assuming a mass of 2.5 Mg for each unit cell, the spring stiffness should be 197.4 kN/m. As discussed later on, the increase of the mass of the resonating unit cells leads to increase of their efficiency. Finally, a damping ratio of 6% is assumed for the unit cells.

Concerning the boundary conditions of the FE model, all degrees of freedom of the outer (lateral and bottom) boundaries of the damping elements are fixed. In addition, since a one-component ground motion excitation is employed (i.e., vertically propagating horizontal shear waves), the soil element nodes are allowed to move only horizontally. The same applies to the lumped mass at the top of the SDOF system and the vibrating masses inside the unit cells (i.e., no rotations or vertical motions are allowed). Finally, the foundation-soil and resonators-soil interfaces are modelled using full contact bonded elements.

2.2 Input motion

As shown in **Fig. 2**, the desired base excitation of the SDOF system is a Ricker pulse of 0.42 s period and 0.1 g peak amplitude. The input motion, applied on the DRM elements, is calculated to create such a wave field that will result in the targeted motion at the ground surface. Generation of the free-field wave field (by first performing deconvolution of the Ricker pulse down to the bedrock) to create the "effective" forces for the DRM elements is done automatically in Real-ESSI, using the analytical solutions described in [13] and [14].

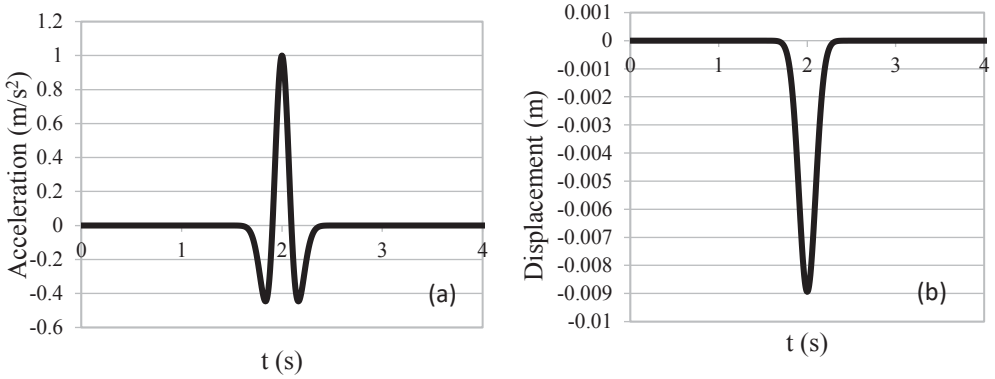

Fig. 2. Ricker pulse (0.42 s, 1 m/s^2): (a) horizontal acceleration; and (b) horizontal displacement time histories.

2.3 Verification of the FE model

2.3.1 Free-field response

The free-field model of **Fig. 3** is developed and used to verify that the excitation at the ground surface is, indeed, the targeted Ricker pulse of **Fig. 2**. The developed free-field model is exactly the same as before, but the SDOF structure and the resonating cells are removed. **Figure 4a** depicts the deformed FE mesh with superimposed horizontal displacement contours for $t = 2$ s. At this specific instant, the model surface attains the maximum negative displacement amplitude (-0.0089 m), as it should. Exactly the same deformed FE mesh is shown in **Fig. 4b**, but with exaggerated horizontal displacement scaling, to verify that the soil layer deforms in its first vibration mode shape, as it should, since the dominant period of the Ricker pulse (0.42 s) coincides with the natural period of the soil column (0.42 s).

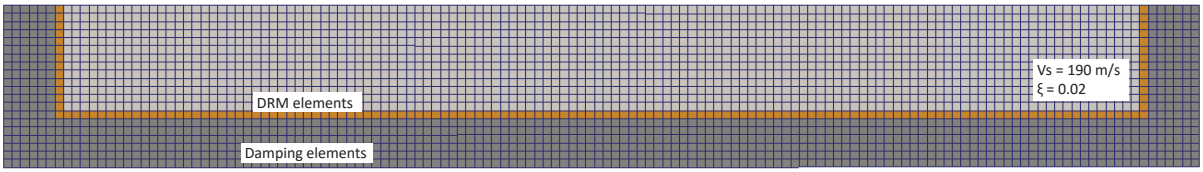

Fig. 3. FE model developed to verify the free-field response.

The effect of numerical damping is examined in more detail looking at the ground surface acceleration time histories (**Fig. 5**). Numerical damping can be tuned using the parameter γ of the Newmark integration method [17]. At this point, it should be noted that numerical damping has nothing to do with the physical damping mechanisms. Such *algorithmic* damping was introduced by Newmark [17] in order to damp out the non-realistic high frequencies stemming from model discretization. Such numerical damping should be employed cautiously, as its improper use could also damp out the real response of the model.

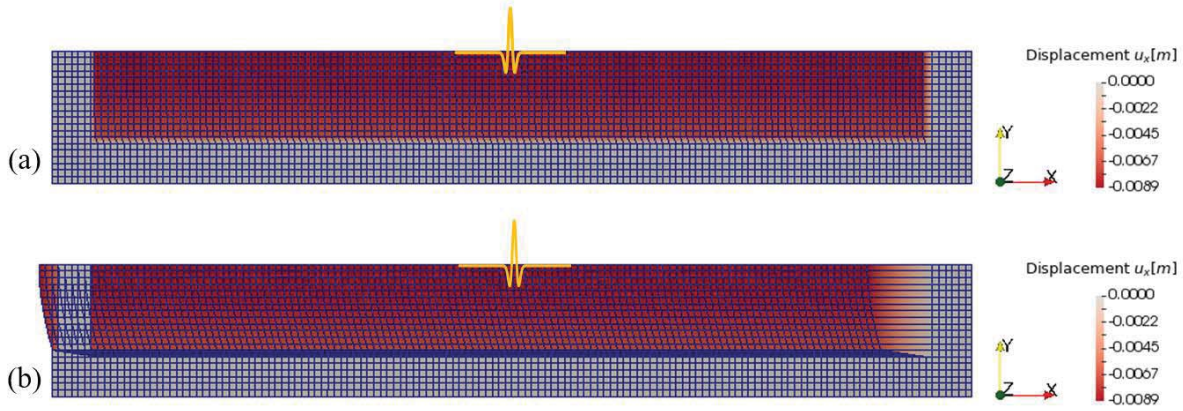

Fig. 4. Free field analysis – deformed FE mesh with superimposed horizontal displacement contours for $t = 2$ s: (a) consistent scaling; (b) exaggerated horizontal displacements.

As shown in **Fig. 5a**, in the absence of numerical damping ($\gamma = 0.5$), the targeted Ricker wavelet is "contaminated" by spurious oscillations after the main pulse. These oscillations vanish with a slight increase of numerical damping ($\gamma = 0.6$), while the main pulse remains unaffected (**Fig. 5b**). Further increase to $\gamma = 1.0$ leads to improper reproduction of the main pulse and to spurious oscillations (**Fig. 5c**). It is therefore essential to conduct a short sensitivity analysis at the beginning of a DRM study, to fine tune the necessary numerical damping. A

similar sensitivity analysis is conducted for the complete model (including the SDOF structure and the resonators), concluding that no numerical damping is necessary (i.e., $\gamma = 0.5$).

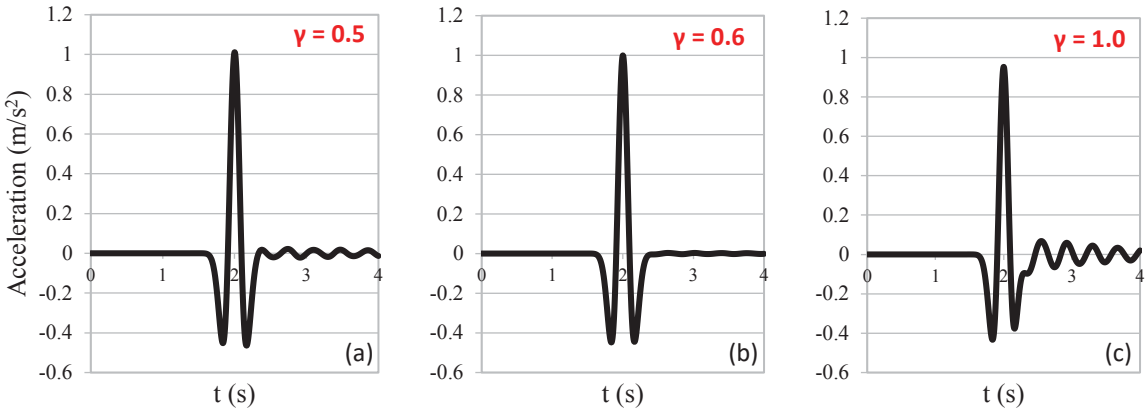

Fig. 5. Time histories of horizontal accelerations at the ground surface for three different values of numerical damping: (a) $\gamma = 0.5$ (no numerical damping); (b) $\gamma = 0.6$; and (c) $\gamma = 1.0$

2.3.2 Damping of the DRM elements

As previously discussed, since the damping elements at the bottom of the FE model are not active, waves radiated from the structure can propagate downwards and upwards, being reflected at the bottom boundary (bedrock) and at the ground surface, respectively. The same Rayleigh viscous damping ($\xi = 0.02$) is used for the soil and the damping elements under the DRM elements, while a higher ξ is employed for the lateral damping elements (**Fig. 1**).

A short sensitivity study is conducted to better understand the importance of damping elements. For this purpose, the Rayleigh viscous damping of all damping elements (including those under the DRM elements) is progressively increased until the response of the SDOF structure (in terms of horizontal accelerations at the mass) is not affected any more (**Fig. 6**). Such convergence is observed for $\xi = 9$ (900%), as the response remains unaffected with further increase of damping to $\xi = 11$ (1100%). This implies that, with $\xi = 9$, all radiated waves from the SDOF structure and the unit cell resonators are fully absorbed by the damping elements.

Figure 7 compares the response for $\xi = 11$ applied to all damping elements, to the case where the same high value of ξ is applied only to the lateral damping elements. The acceleration time histories at the top of the SDOF structure are shown in **Fig. 7a**. Except from the non-negligible difference between the two cases, it can also be observed that that the structural response becomes more intense when the radiated waves are fully absorbed, which is not intuitive. As discussed later on, this is attributed to the response of the resonating unit cells. The vibrating masses inside the unit cells are moving out-of-phase with respect to the SDOF structure. As a result, the radiated waves from the resonators, propagate downwards to bedrock, being reflected back towards the ground surface. And since they are out-of-phase, this leads to a decrease of the acceleration of the SDOF structure. This is why the accelerations of the SDOF structure increase when the radiated waves are damped out.

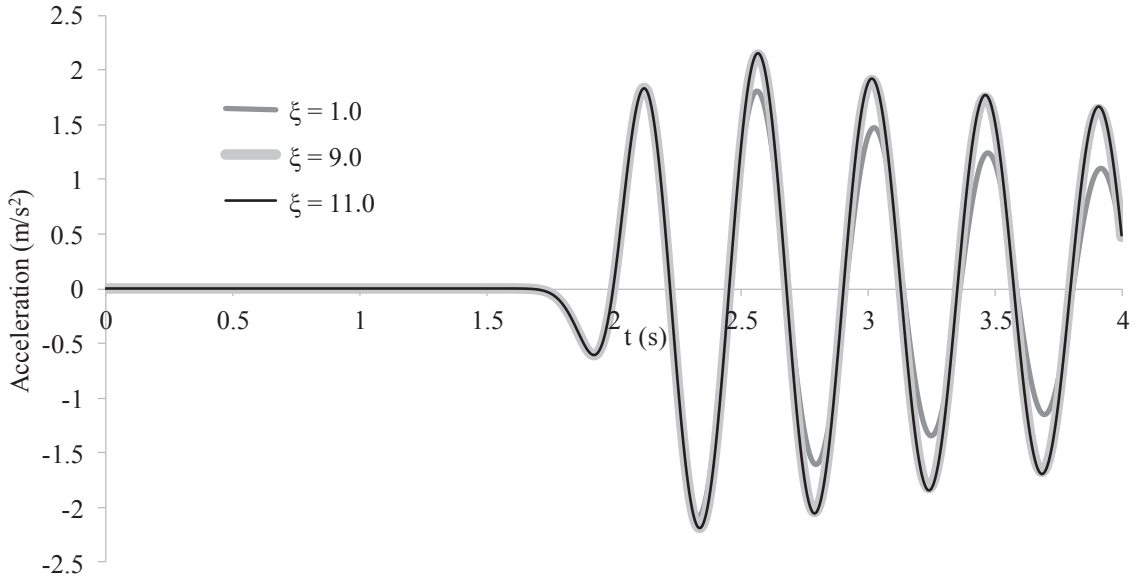

Fig. 6. Time histories of horizontal acceleration at the top of the SDOF structure for three different values of damping ratio (ξ = 1, 9, and 11) of the damping elements in the FE model.

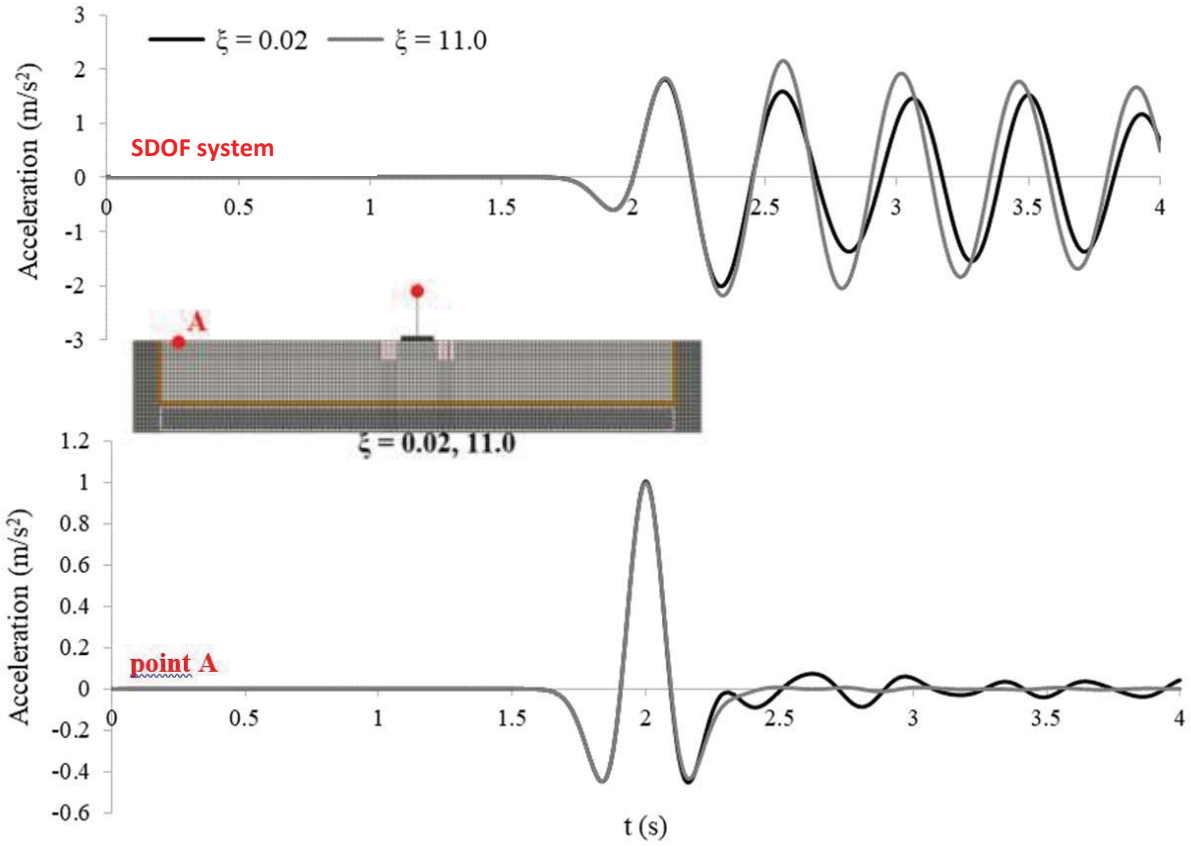

Fig. 7. Time histories of horizontal acceleration: (a) at the top of the SDOF structure; and (b) at the ground surface (point A). For the lateral damping elements, $\xi = 11$ (i.e., laterally propagating waves are fully absorbed); for the damping elements under the DRM elements (inside the white box of the embedded figure), $\xi = 11$ is compared to $\xi = 0.02$ (i.e., practically no damping).

Figure 7b offers a comparison of free-field ground surface accelerations (at Point A, away from the structure). When ξ = 11 for all damping elements, the response at point A is the targeted Ricker pulse (free-field response). However, when only the lateral damping elements are "active", the radiated, from the structure and the resonators, waves are not damped, leading to the development of spurious oscillations after the main pulse. These waves will eventually be damped out when they reach the lateral damping elements. Ideally, those waves should have been able to continue propagating sideways, as shown in **Fig. 8**. The latter plots the FE model strain energy density for four different snapshots, showing the waves, generated by the vibration of the SDOF structure and the resonators, travelling laterally.

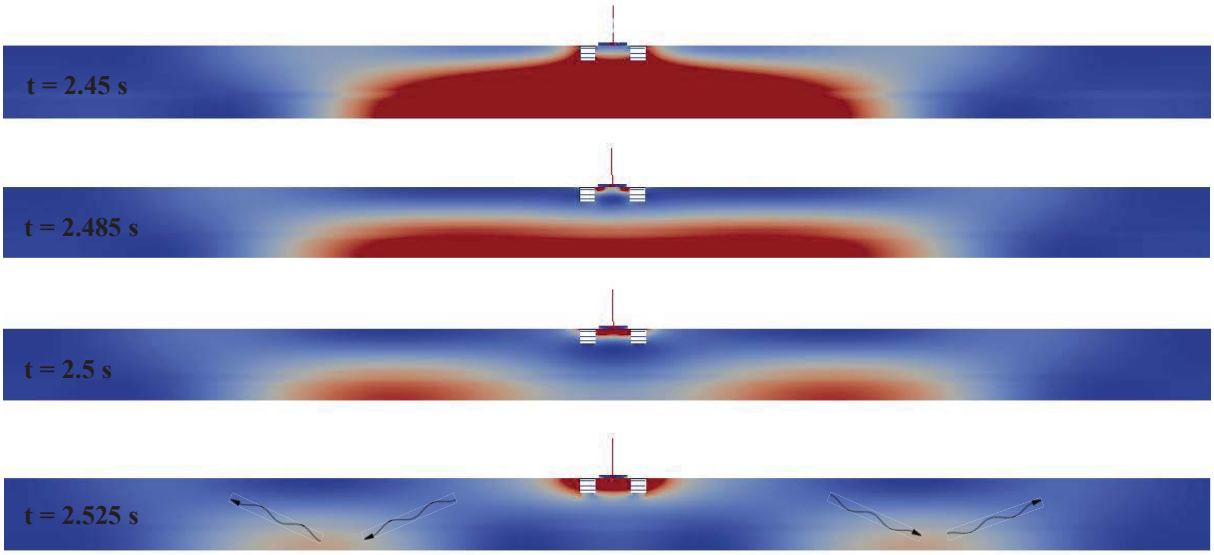

Fig. 8. Snapshots (t = 2.45, 2.485, 2.5 and 2.525 s) of strain energy density contours, showing the lateral propagation of waves radiated from the SDOF structure.

2.3.3 Lateral boundaries of the FE model

An additional sensitivity analysis is conducted to explore the effect of the FE model length. The length is gradually increased until the response of the SDOF structure is not affected any more. As shown in **Fig. 9**, this is achieved when the FE model length becomes equal to 780 m, as further increase to 880 m does not seem to cause any changes in response. This leads to an extremely large FE model, which may be computationally affordable in 2D, but not in 3D. However, faster wave attenuation in 3D along with additional damping due to material nonlinearities [18] may allow significant reduction of the required length.

3 RESULTS

Before presenting some of the key results, it is important to explain a simple property of resonating unit cells that leads to decreased accelerations in the surrounding soil and, consequently, to a reduction of the seismic response of the structure. When a SDOF system resonates under harmonic base excitation, it moves with a 90^o phase difference with respect to the excitation displacement signal. If the harmonic excitation frequency is slightly changed, the displacement phase difference will rapidly drop to 0^o or jump to 180^o, provided that the viscous damping ratio of the SDOF system is relatively low. In the FE model studied herein, the resonating unit cells have a slightly smaller resonant frequency (2Hz = 1/0.5s) than the SDOF structure (2.22 Hz = 1/0.45 s); the Ricker excitation is slightly larger (2.38Hz = 1/0.42 s). Thus, the resonant unit cell masses and the soil will move out-of-phase (with 180^o phase difference).

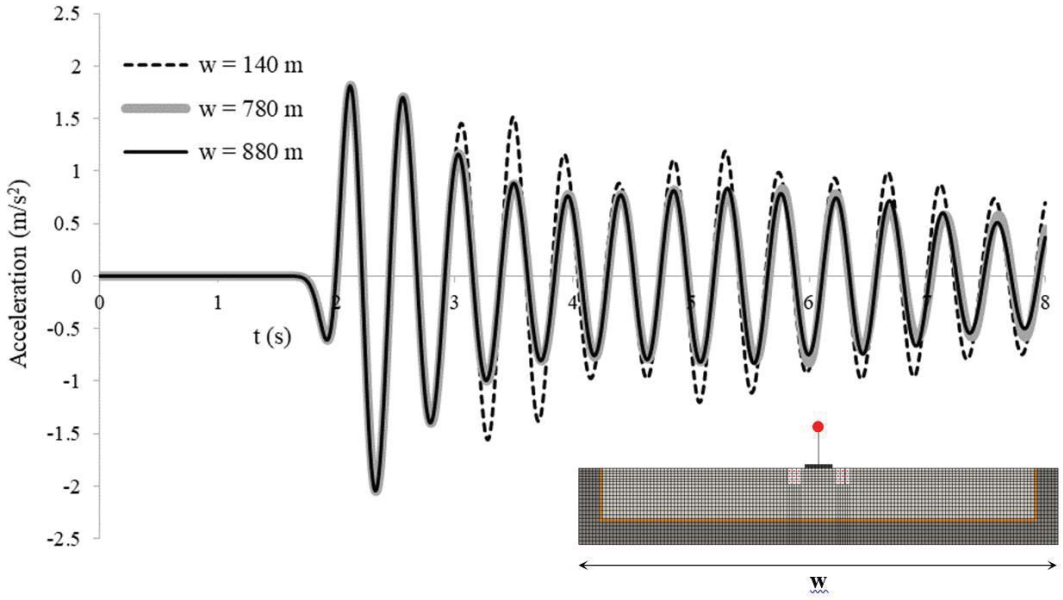

Fig. 9. Horizontal accelerations at the top of the SDOF structure for three different FE model lengths.

Such opposing motion will reduce the accelerations at the ground surface, leading to the desired reduction of the response of the SDOF structure. Out-of-phase resonator systems are more effective for continuous multi-cycle excitations, such as harmonics. The Ricker pulse was deliberately chosen (because of its similarity to the main pulse of recorded ground motions) to examine the efficiency of unit cell resonators for such short pulse signals.

Figure 10 compares the response of the SDOF structure, in terms of acceleration, with and without unit cell resonators. Two cases are examined with respect to the vibrating mass inside the unit cells: 2.5 Mg and 5 Mg. The corresponding stiffness of the unit cell springs is appropriately adjusted, so that their natural period remains 0.5 s. The peak response of the SDOF structure is barely affected by the unit cell resonators. A decrease in response can be observed only after the third cycle, revealing that the effectiveness of resonating unit cells increases with the number of excitation cycles.

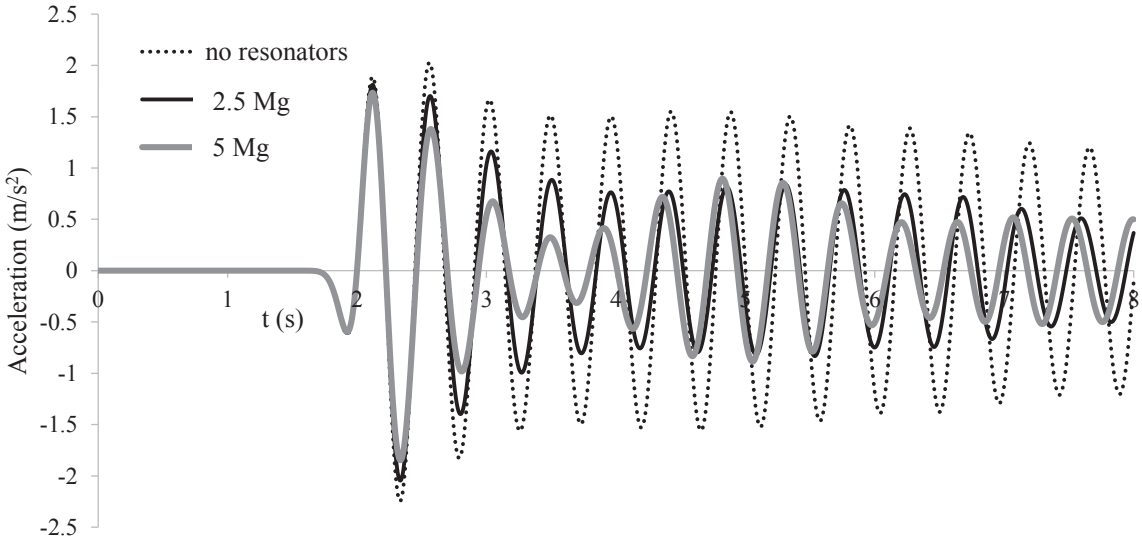

Fig. 10. Horizontal accelerations at the top of the SDOF structure with and without resonators. The vibrating mass in each unit cell is varied from to 2.5 Mg to 5.0 Mg.

Figure 11 compares the acceleration at the top of the SDOF structure to that of the unit cell vibrating mass (2.5 Mg). Right after the end of the transient part (Ricker pulse), both the building and the resonators experience free vibration. Since the mass of the SDOF structure (40 Mg) is approximately equal to the total mass of the resonators (18 x 2.5 Mg = 45 Mg), the inertia forces of the two system components (SDOF structure and resonators) will be proportional to their accelerations. The acceleration of the SDOF structure gradually decreases, reaching a minimum at t = 4 s, when the resonators are moving exactly out of phase. For t > 5 s, the acceleration of the resonators is significantly reduced due to their internal viscous damping (ξ = 0.06). After this point, the free-vibrating SDOF structure becomes the excitation source for the resonators, which are henceforth excited at the natural vibration period of the SDOF structure (0.45 s). And since their natural vibration period of 0.5 s is a bit longer, their masses are, again, going to move out of phase with the SDOF structure. In this way, the resonators continue playing a protective role, reducing the response of the SDOF structure.

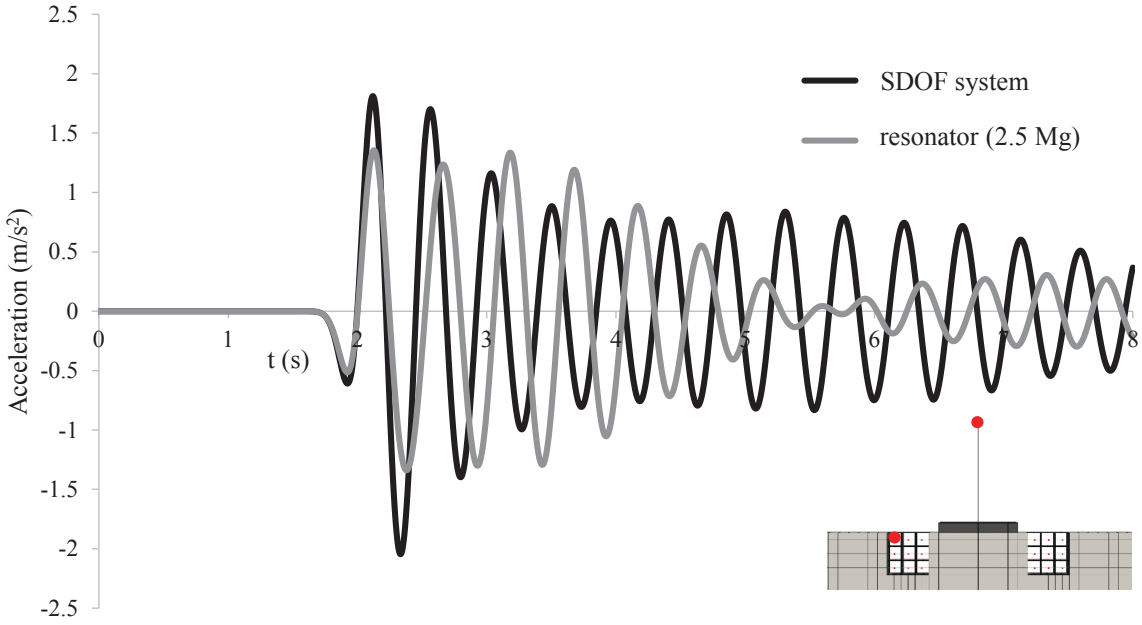

Fig. 11. Horizontal accelerations at the top of the SDOF system, compared to the mass of the top left resonator.

Figure 12 compares the horizontal displacement contours with and without resonators (of 2.5 Mg unit cell mass) for a snapshot at t = 3 s, when the systems are subjected to free vibration (same displacement scale factor). In the absence of resonators (**Fig. 12a**), the displacements are visibly larger compared to the case with 2.5 Mg resonators (**Fig. 12b**), both for the soil and the SDOF structure. Observe also that the unit cell masses are moving in the opposite direction to that of the SDOF structure, which explains their protective function.

4 CONCLUSIONS

The paper has presented a preliminary study on the potential of installing multiple resonating unit cells around an existing structure to improve its seismic performance. The following key conclusions are summarized as follows:

- The Domain Reduction Method (DRM) was used within the Real-ESSI Simulator to realistically model both body and surface waves in FE models, and investigate soil-structure-metamaterial interaction. Some of its powerful features, such as the possibility to damp out waves radiating from the vibrating structures, were demonstrated.

- The importance of conducting short sensitivity analyses to determine the parameters of the FE model was stressed. In this study, the sensitivity of the FE model to numerical damping and the length of the FE model were studied in detail. It was shown that (for this particular case) the lateral boundaries of the FE model should be placed at a considerable distance from the structure in order not to affect its response. It was also shown that adding numerical damping in the analysis to mitigate the spurious high-frequency response due to model discretization might also damp out real frequency components of response.
- The resonating unit cell metamaterials were effective in reducing the free-vibration response of an existing structure for the specific case analysed. It was shown that such metamaterials are effective thanks to the out-of-phase vibration of the unit cell masses with respect to the soil and the structure. This is achieved by tuning the resonator unit cell vibration periods to be slightly longer than the fundamental natural vibration period of the protected structure. Their effectiveness increases with increasing unit cell mass, provided they remain properly tuned.

Abstract. *Quay walls are one of the key elements of the port facilities. Experience obtained from past strong seismic events has demonstrated the increased seismic vulnerability of port facilities due to ground shaking as well as the important economic and societal losses (e.g. the 1995 Kobe earthquake. The most significant source of earthquake-induced damage to port facilities is the increase of induced earth pressures caused by inertial forces to the retained groundmass and by hydrodynamic force and pore-water pressure build-up in the saturated cohesionless soils that often prevail at coastal areas. This pressure build-up both in the back-fill and the foundation soil may increase the lateral pressures to quay walls and generate liquefaction effects at the foundation soil. The aim of this study is to investigate the influence of liquefaction on the seismic response of a typical port gravity quay wall resting on a potentially liquefiable soil. The analyses were conducted, under effective stresses using OpenSees. Comparative results highlighted the effect of liquefaction in modifying the ground motion and the quay wall dynamic response. The main conclusion of the comparative numerical study in a typical gravity quay wall is that while the impact of the liquefaction on the amplitude of the acceleration of the wall is negligible compared to the non-liquefaction case, the effect on the permanent seaward horizontal and vertical displacements of the wall is very important, almost doubled, increasing in that way considerably the vulnerability of the wall.*

1 INTRODUCTION

Ports are critical facilities that represent major part of regional, national and international transportation facilities, sometimes located in areas susceptible to liquefaction. As quay walls are of the most important assets of a port, they might be strongly influenced by liquefaction hazards. They are earth retaining waterfront gravity structures, parallel to the shoreline that create sufficiently deep vertical front in order to allow the approach, berthing, mooring, operations and maintenance of ships and vessels. Block-type quay wall is the simplest type of gravity quay wall, which consists of concrete blocks constructed on a layer of gravel or crushed stone [1]. The examples of recent devastating earthquakes in 1995 Kobe, Japan [2], 1999 Kocaeli, Turkey [1], 2007 Niigata-Chuetsu Oki, Japan [3], 2010 Maule, Chile [4], 2011 Christchurch, New Zealand [5] among others, indicated that port waterfront gravity structures are particularly susceptible to ground shaking and ground failure, including liquefaction and lateral displacement, which may result in high economic losses. Therefore, the investigation of the seismic response of waterfront gravity quay walls has become a concern to the scientific community as well as the waterborne transportation industry.

The seismic response and vulnerability of waterfront quay walls has already been studied using numerical soil-structure interaction methods [6-14]. Pitilakis and Moutsakis [6] analysed the seismic behaviour of a gravity retaining quay wall and compared it with field observations. Kakderi and Pitilakis [7] proposed seismic fragility curves for typical monolithic gravity quay walls, neglecting possible damages due to liquefaction effects. In the framework of UPGRADE research project [8] seismic fragility curves are proposed for typical block-type gravity quay walls, considering possible friction and displacements between the interfaces of the construction blocks, again neglecting liquefaction-induced damages. Alielahi and Moghadam [9] investigated the influence of quay wall hunch on the seismic fragility, ignoring also soil liquefaction. Kamalzadeh and Pender [10] investigated the static and dynamic response of a gravity retaining wall for different Ricker wavelet excitations.

Among the vulnerability studies of waterfront gravity structures considering liquefaction, Ichii [11-12] and Miraei and Jafarian [13] proposed analytical seismic fragility curves for gravity-type quay walls, while Calabrese and Lai [14] developed fragility functions for blockwork wharves using artificial neural networks, considering different geometries, type of failure mechanism and the effect of liquefaction occurrence. All these studies do not extensively examine the effect of soil liquefaction on the seismic response of gravity quay walls and its surrounding soil.

In this context the herein work presents a numerical investigation of the effects of liquefaction on the seismic response of a typical port gravity quay wall resting on a liquefiable soil. The analyses are conducted, under effective stresses using OpenSees, with the direct approach, where the soil and the structure response is coupled. We compare the response of the wall for a number of strong ground excitations when liquefaction is not allowed to the case when it may occur. The results are presented and discussed in terms of acceleration time histories at different locations on the wall and the soil, as well as in terms of the residual seaward displacement and the permanent vertical displacement of the quay wall.

2 FRAMEWORK APPROACHES AND NUMERICAL MODELLING

A typical port quay wall system is used founded on the same soil profile prone to liquefaction under strong seismic excitations. The potential effect of the liquefaction in the global seismic response of the gravity quay wall is studied considering a coupled soil-structure system under effective stress conditions, where in a first step we artificially don't allow the liquefaction to happen while in the second we allow it.

2.1 Selection of the soil and structure typology

A typical gravity wall section of the Port of Thessaloniki has been selected. Based on the available geotechnical information, N_{SPT} values and laboratory data [15-16], we define a soil profile representative of the port area of Thessaloniki, Greece (Figure 1). The fundamental period of the soil profile, T_o, is equal to 0.71s. The high liquefaction potential of the subsoil layers is estimated according to EC8 guidelines [17]. The soil formations susceptible to liquefaction are located from -3.0m to -18.0m consisting mainly of silty/clayey sands and non-plastic silts (ML-SM, ML-CL, SC-SM) with low N_{SPT} values. Owing to the rather high liquefaction susceptibility of the port area, the soil profile refers to ground type S, in accordance to EC8 soil classification scheme. The height of the quay wall is equal to 14.0m. Figure 2 shows the geometry of the quay wall and its surrounding back-filled and mound gravel. The soil layers, the quay wall and its surrounding gravel characteristics are analytically described in the following.

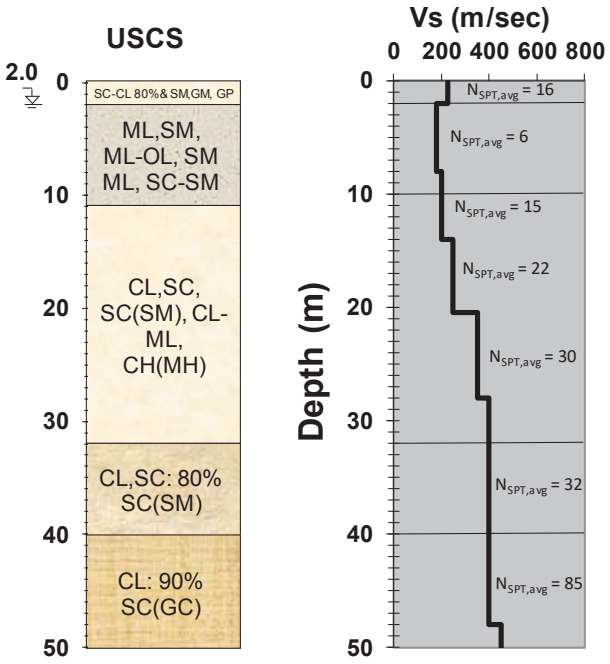

Figure 1: Representative soil profile with USCS classification as well as Vs profile and average N_{SPT} values.

2.2 Soil-structure modelling

Two-dimensional (2D) numerical simulation of the soil-structure system is conducted in OpenSees [18]. The soil grid adopted has a total length three times its depth to minimise wave reflections at the vertical boundaries. Thus, the dimensions of the soil model are 50.0m x 150.0m. Sufficiently dense discretization is achieved by using quadrilateral elements of 0.5m x 2.0m considering that the maximum frequency of interest is set to 10Hz, allowing an adequate number of elements to fit within the shortest wavelength of the propagating shear wave. Figure 3 illustrates the geometry of the finite element (FE) soil-structure model. The locations of the nodes at different sites of the soil model, namely A, B, C, D and FF (point at the free field surface), as well as at the top of the quay wall (W_T), used to capture the soil and quay wall seismic response are also shown.

The soil profile consists of different layers of cohesive and cohesionless soil materials (Figure 1), thus the soil model in OpenSees is divided into eight soil layers (Figure 3). Saturated unit weights are used for the soil below the ground water level (-2.0m), while nine-node

quadrilateral elements are used for the soil and the back-filled and mound gravel in the frame of effective stress analysis. Such elements are capable of simulating fluid-solid coupling during the earthquake excitation, based on Biot's theory of porous medium [19], as they have corner nodes with both displacement (u) and pore pressure (p) degrees of freedom and interior nodes with only two displacement degrees of freedom.

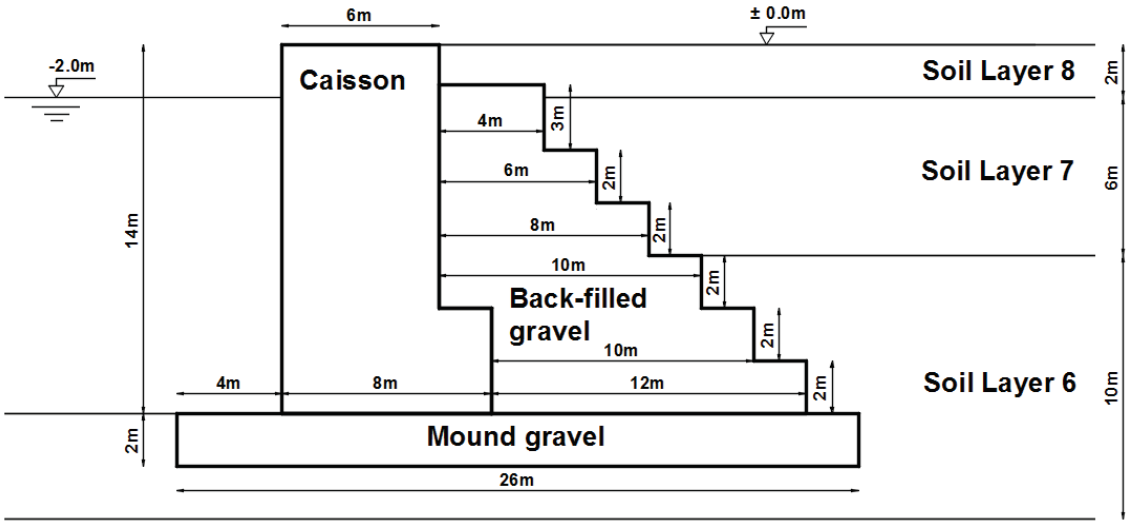

Figure 2: Geometry of the typical gravity quay wall and its surrounding back-filled and mound gravel.

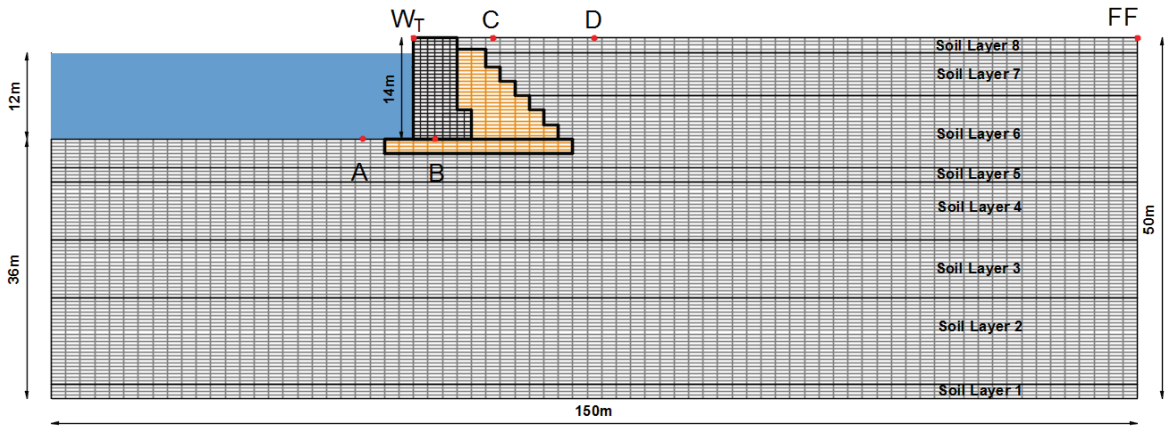

Figure 3: Geometry of the finite element soil-structure model along with the locations of the nodes used to capture the soil and quay wall seismic response.

The fully coupled (u-P) approach is applied, which can simulate permanent shear-strain accumulation in clean medium-dense cohesionless soils during liquefaction and dilation due to increased cyclic shear stiffness and strength. The constitutive model employed to describe the soil behaviour is based on Prevost's [20] multi-surface plasticity model, with some modifications by Yang [21]. During the application of the gravity load the material behaves in elastic range, while during the subsequent dynamic loading its response is elastic-plastic. To simulate the hysteretic behaviour of soil under cyclic loading, Prevost's [20] kinematic law is employed, therefore all yield surfaces correspond to stress space within the failure envelope [21-22] and comply with Masing loading-unloading-reloading criteria [23]. The cohesionless soil layers are simulated using the "PressureDependMultiYield02" elastic-plastic material in OpenSees. The yield function is assumed to follow the shape of the Drucker-Prager criterion and the yield surface is a function of cohesion and friction angle. Plasticity is expressed

through a non-associative plastic flow rule [22], capable of handling the contractive/dilative soil behaviour stimulated by shear loading to effectively depict the interaction between shear and volumetric responses. The cohesive soil layers are simulated with the "PressureIndependMultiYield" material in OpenSees, which describes an elastic-plastic material in which the volumetric stress-strain response is linear elastic and independent of the deviatoric response. This material simulates the monotonic or cyclic response of materials whose shear behaviour is insensitive to changes of the confinement pressure. The yield function is assumed to follow the Von Mises criterion and the yield surface is solely a function of the undrained shear strength. Plasticity, which exhibits only in the deviatoric stress-strain response, is defined via the multi yield surface plasticity model, with an associative plastic flow rule which considers that the incremental plastic strain vector is normal to the yield surface.

For each soil layer, the soil features are defined, namely the mass density (ρ), the shear wave velocity (V_s), the friction angle (φ) at the peak shear strength, the cohesion (c) and Poisson's ratio ν (taken equal to 0.35), while the reference low-strain shear (G_r) and bulk (B_r) moduli are computed. The mass density of the materials corresponds to the total mass densities, thus for the soil layers that overlay or underlay the groundwater table dry or saturated conditions should be reflected respectively. Table 1 summarizes the soil properties adopted for each soil layer. For soils susceptible to liquefaction, a set of parameters that describe and control the mechanism of the accumulation of completely plastic shear deformation caused by liquefaction, are also defined according to the proposed values of Yang et al. [24]. Regarding the gravel backfill, it is simulated employing the "PressureDependMultiYield02" material, where the mass density is set equal to 2.1 Mg/m^3 below the water table and 1.8 Mg/m^3 above the water table, while the friction angle φ, G_r and B_r are defined equal to 40^o, 189MPa and 567MPa respectively.

The quay wall is simulated using standard four-node plane strain quad elements 0.5m x 1.0m, with nodes that have only two translational degrees of freedom. It is noted that the quay wall is modelled as a monolithic component, neglecting the friction interfaces between the blocks forming the quay wall. The "*ElasticIsotropic"* material in OpenSees is used to model the quay wall, considering a Young's Modulus (E) equal to E=27000MPa, a mass density equal to ρ=2.4 Mg/m^3 and a Poisson's ratio equal to ν=0.2. No interface is considered between the quay wall and the surrounding soil material of the gravel backfill, while equal displacements are ensured between the quay wall and the backfill nodes.

Subsequently, the hydraulic boundaries of the model are also defined. As the ground water table is located at -2.0m depth, all the pore pressure nodes that lie above this level have their pore pressure degree of freedom fixed. This creates a water drainage path which allows the water to escape to the adjacent elements and ensures that no pore pressure is built up in the area above the groundwater table, thus it is maintained to zero. The same constrain is assigned to the nodes of the seabed which lie at the foot of the quay wall, as they are submerged beneath the water and to the backfill nodes which are in contact with the quay wall as well. The body of water and the dynamic effects it causes are incorporated into the model in a way that does not affect the effective stresses of the soil elements. The water forces are applied to the nodes of the seabed as vertical nodal masses. The water mass value for each of these nodes is derived by multiplying the half of the distance to adjacent nodes, the thickness of the elements this mass refers to, the depth of the water and the water's mass density. A similar process is followed to define the water forces applied at the vertical front face of the quay wall. In this case horizontal masses are assigned, calculated by applying a triangular distribution of the hydrostatic forces considering that the maximum depth is 12.0m.

Special boundary conditions are also assigned to ensure that free-field conditions exist at the lateral boundaries of the soil model and avoid the presence of wave reflections. In particu-

lar, the elements in the edge lateral columns of the mesh are given a significantly increased -practically infinite- thickness, so they appear to be adequately more massive than the rest of the elements in the interior of the mesh. In addition, periodic boundary conditions are achieved by bounding together the translational degrees of freedom for the nodes on either side of these lateral columns, so they perform equal displacements both in the horizontal and in the vertical direction. Finally, the soil grid is underlain by an elastic half-space, which stands for the finite rigidity of the underlying bedrock. A Lysmer and Kuhlemeyer [25] viscous damper is applied in the horizontal direction to the soil model base to account for the finite rigidity of the underlying half-space, setting a bedrock shear wave velocity equal to 750m/s and mass density equal to 2.2Mg/m^3. To define the Lysmer and Kuhlemeyer [25] dashpot, the viscous uniaxial material is used, which is described by the dashpot coefficient (c). The dashpot coefficient is calculated according to Joyner and Chen [26] by multiplying the underlying bedrock's mass density and shear wave velocity, as well as the base area of the soil to obtain the equivalent loading application throughout the site. To properly simulate the underlying elastic half-space necessitates that all the base nodes of the soil model are fixed against vertical translation only and left free to move in the horizontal direction while all are given equal horizontal displacements. Seismic energy dissipation during dynamic loading is accounted for by assigning mass and stiffness proportional Rayleigh damping with a damping ratio equal to 2.0%.

Layer Thickness (m)	Soil layer	Model	ρ (Mg/m^3)	G_r (MPa)	B_r (MPa)	φ (^{o})	c (kPa)

3 NUMERICAL ANALYSIS

3.1 Seismic input motion

A representative set of 15 earthquake records is selected from the European Strong-Motion Database. They are all referring to rock type or stiff soils (ground types A and B according to EC8 soil classification scheme) with magnitude (M_w) and epicentral distance (R) between

$5.5<M_w<6.5$ and $0<R<45$km, respectively. They are covering a wide range of peak ground acceleration (PGA) from 0.13g to 0.51g. The selection criterion is the average acceleration spectra of the set to be of minimal "epsilon" [27] at the period range $0.00<T<2.00$sec with respect to the corresponding 5% damped median plus 0.5 standard deviations spectrum defined based on the ground motion prediction equation (GMPE) by Akkar and Bommer [28]. The optimization procedure is performed using REXEL [29], that allows obtaining combinations of accelerograms, which on average are compatible to the reference spectrum. The list of the selected records is presented in Table 2, while Figure 4 shows the 5% elastic response spectra of the selected earthquake records and their mean elastic response spectrum compared to the corresponding median plus 0.5 standard deviations of Akkar and Bommer [28] spectrum. The matching is satisfactory. Among the selected time histories it is worth to notice that the frequency content of the Kalamata and Umbria Marche 2 earthquake records (ID 414 and 594 respectively) is quite distinct compared to the other records (Figure 4), as they are characterized by long-period pulses unlike the other high-frequency records.

Earthquake Name	Date	M_w	Fault Mechanism	Epicentral Distance [km]	$PGA_{initial}$ [m/s^2]	$PGA_{corrected}$ [m/s^2]	EC8 Site class	Waveform ID
Umbria Marche (aftershock)	6/10/1997	5.5	normal	5	1.838	2.060	A	651

Table 2: List of earthquake records used for the dynamic analyses.

These records are then filtered between 0.25 and 15 Hz, using a fourth-order bandpass Butterworth type filter. Baseline correction linear type is also applied. Table 2 presents also the values of $PGA_{corrected}$ obtained from the corrected accelerograms used for the analyses.

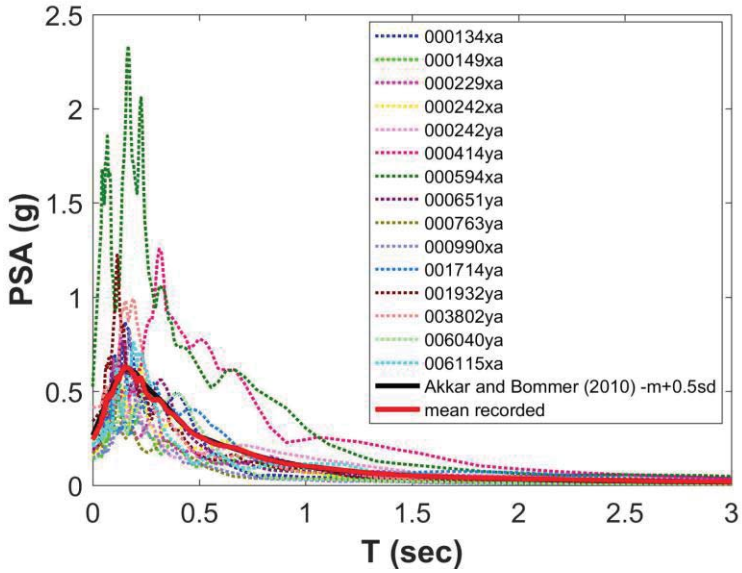

Figure 4: Elastic response spectra of the selected earthquake records and their mean elastic response spectrum in comparison with the corresponding median plus 0.5 standard deviations Akkar and Bommer [28] spectrum.

3.2 Comparative dynamic analysis

The effect of soil liquefaction on the seismic response of the typical gravity quay wall is illustrated below, conducting two sets of seismic analyses for the two conceptual modelling approaches using as input the earthquake records of Table 2. Layers of potential liquefaction are identified by the loss of effective confining stress (equal to zero) which is also verified by the corresponding stress-strain loops (e.g. at -15m depth at free field conditions as shown in Figure 5). Indicatively, Figure 5 presents the computed effective confinement profile and stress-strain hysteresis loops at specific depth for Kalamata earthquake motion (ID 414 record) for the two approaches, allowing or neglecting soil liquefaction.

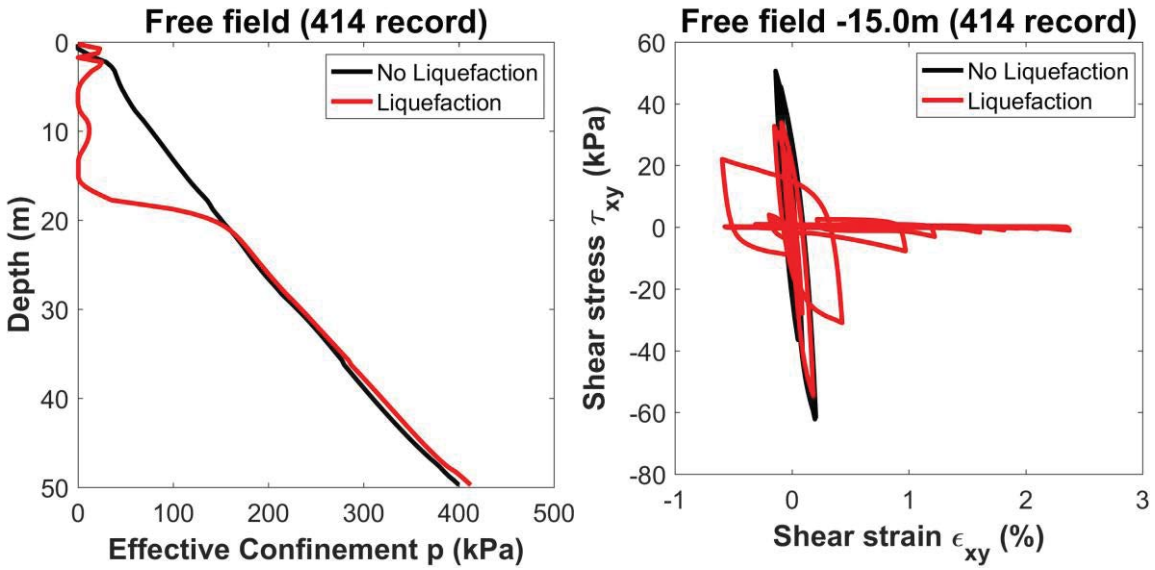

Figure 5: Effective confinement profile (left) and stress-strain hysteresis loops at -15.0m depth (right) for the ID 414 input motion at free-field conditions, for the liquefiable and the non-liquefiable cases.

For the case that we allow liquefaction to occur, the hysteresis loops corresponding to the time before the onset of liquefaction are smooth and are dominated by steeper slope, indicating greater values of the dynamic shear modulus which represents the shear stiffness of the soil, while after a specific point, a change in the pattern of the stress-strain loops is observed. Specifically, the circles are characterized by large shear strain amplitudes and adequately small shear stresses, leading to a radical decrease in the shear stiffness and accumulation of large shear strains (Figure 5).

The effect of liquefaction on the acceleration time histories and the frequency content of the motion at free field soil surface and on the quay wall is also examined. Indicatively, the acceleration time histories for the two considered approaches at the FF and the W_T for Kalamata (ID 414) and Ano Liosia (ID 1714) input motions, which are considered representative of the extreme and average response respectively, are presented in Figure 6 and Figure 7 respectively.

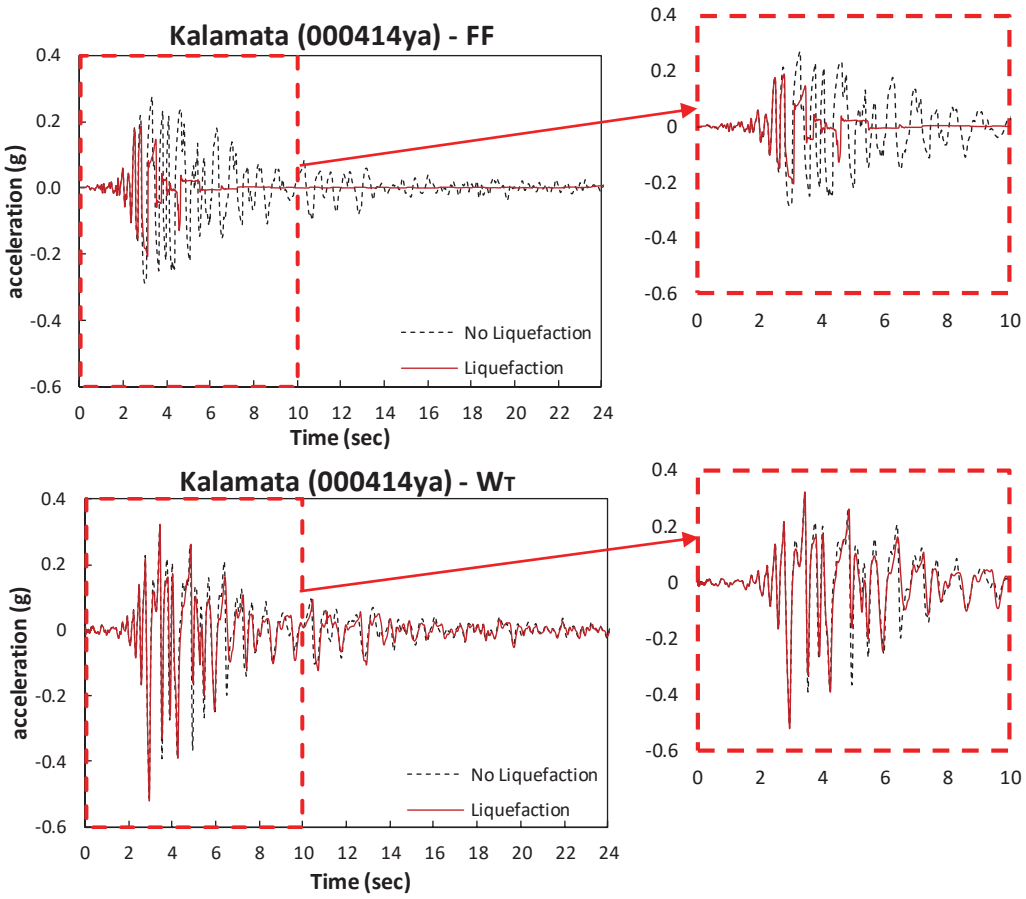

Figure 6: Comparison of the acceleration time histories computed at the free field conditions FF (top) and on the wall W_T (bottom) for the two approaches for Kalamata (ID 414) input motion.

Regarding the computed acceleration time history at the FF, as shown in Figure 6 (top) and Figure 7 (top) for Kalamata (ID 414) and Ano Liosia (ID 1714) input motions respectively, liquefaction apparition causes seismic energy dissipation and leads, as expected, to significant reduction in the strong ground motion duration. The amplitudes of the ground motion in the case where liquefaction occurs are decreased, compared to the corresponding values ignoring liquefaction. These trends are more pronounced for the lower-frequency Kalamata (ID 414) input motion while the Ano Liosia (ID 1714) input motion seems more representative of the average dynamic response.

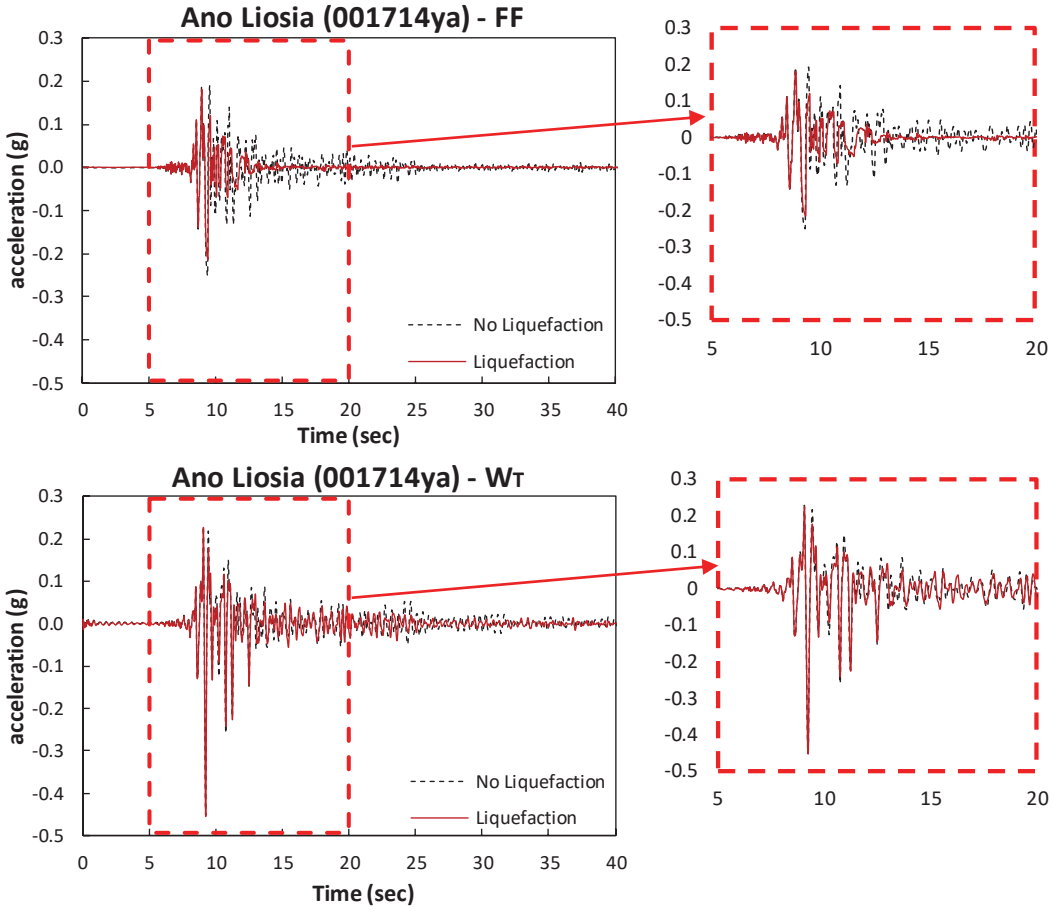

Figure 7: Comparison of the acceleration time histories computed at the free field conditions FF (top) and on the wall W_T (bottom) for the two approaches for Ano Liosia (ID 1714) input motion.

Contrary to the free field conditions it is observed (Figure 6 and Figure 7, bottom) that the liquefaction didn't alter the computed acceleration time histories on the top of the wall compared to the no-liquefaction case. Indicatively, computed acceleration time histories at different locations with the Kalamata (ID 414) and Ano Liosia records (ID 1714) used as rock input motion, are presented for the two approaches in Figure 8 and Figure 9. The reason of this phenomenon may be attributed to the oscillation of the rigid wall in a coupled system when receiving a rather similar seismic excitation at its base.

In Figure 10 we present the computed PGA values for all input motions used at the top of the wall (W_T) and at the different other locations i.e. FF, C and D. The computed residual seaward displacement and the permanent vertical displacement at the top of the quay wall are shown in Figure 11 for both approaches when allowing or restricting liquefaction. Moreover, to better understand the differences between the two approaches at the quay wall response in terms of displacements, the ratios of the permanent horizontal and vertical displacement values at the top of the wall (W_T) for the liquefiable case to the corresponding ones for the non-liquefiable case are also presented in Figure 12.

The main observation from the analyses of the PGA is that the computed values on the wall are getting large values independently of the presence or not of liquefaction and that the PGA values are progressively decreased with distance from the wall to the free field values (Figure 10 locations FF and D) due to the increase of the importance of liquefaction and non-

linear site effects. The closer we are to the wall the more the ground response is controlled by the oscillation of the wall itself. It should be also notified that the red points depict the results of the analysis for Umbria Marche 2 (ID 594) input motion where the analysis failed, and the results are presented only for completeness reasons. Moreover, for the liquefiable case at the FF (Figure 10, top-right) it is observed that for a PGA_{rock} value lower than approximately 0.2g there is still an amplification of the PGA relative to PGA_{rock}, while for PGA_{rock} values higher than 0.2g the PGA value of the seismic motion attenuates due to liquefaction. These observations are in accordance with the results of the study conducted from Lopez-Caballero and Modaressi Farahmand-Razavi [30].

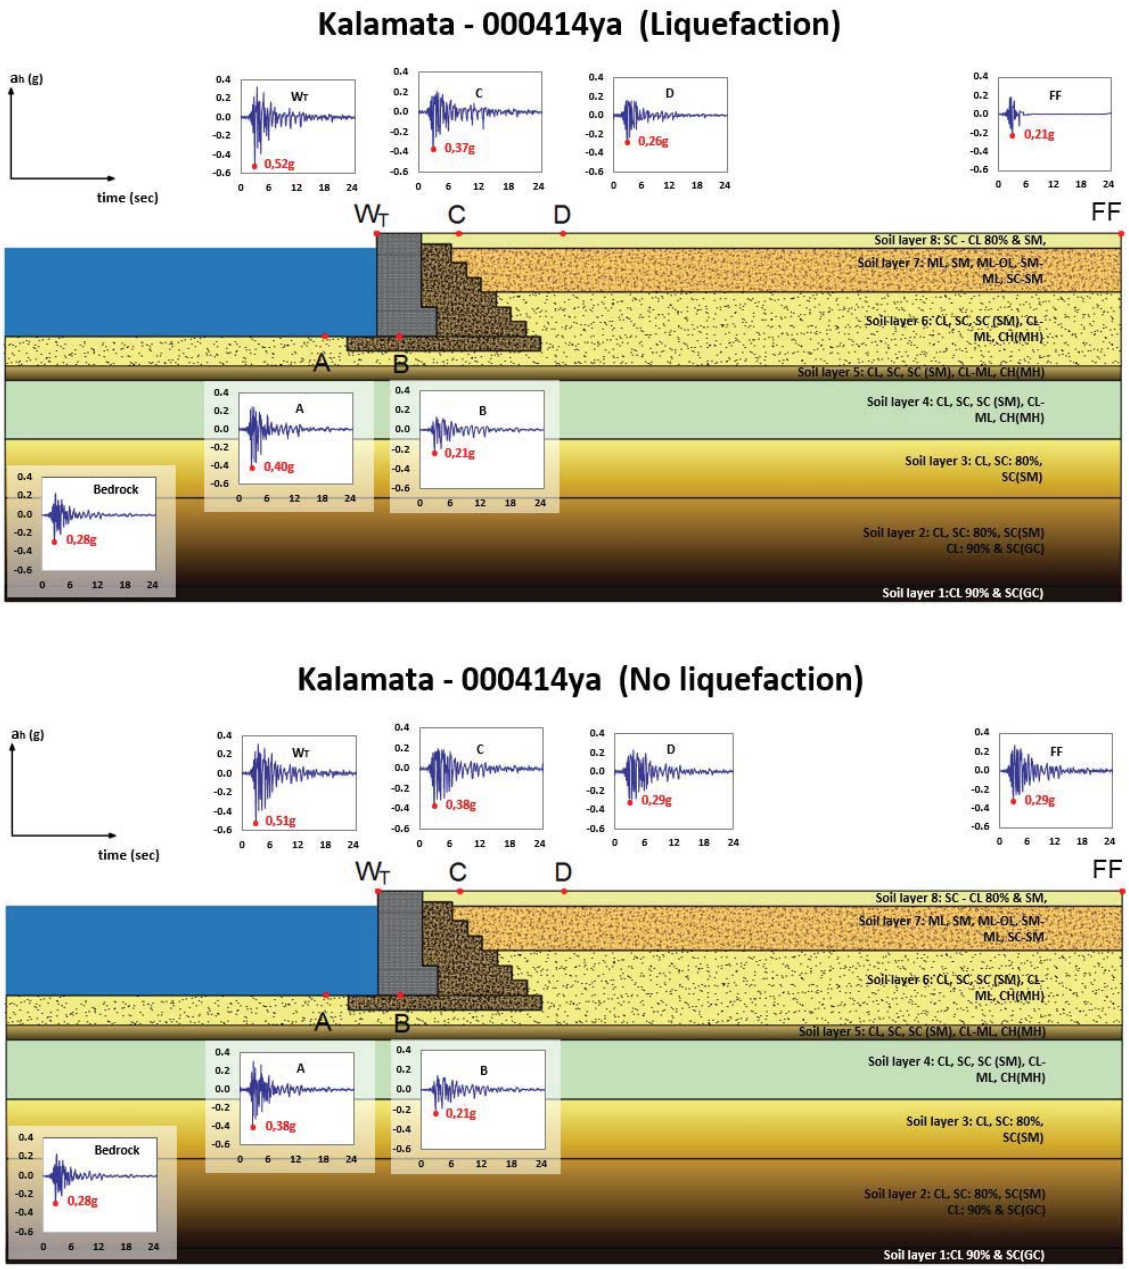

Figure 8: Acceleration time history response at the various sites of the model for Kalamata (ID 414) input motion allowing (top) or neglecting (bottom) liquefaction.

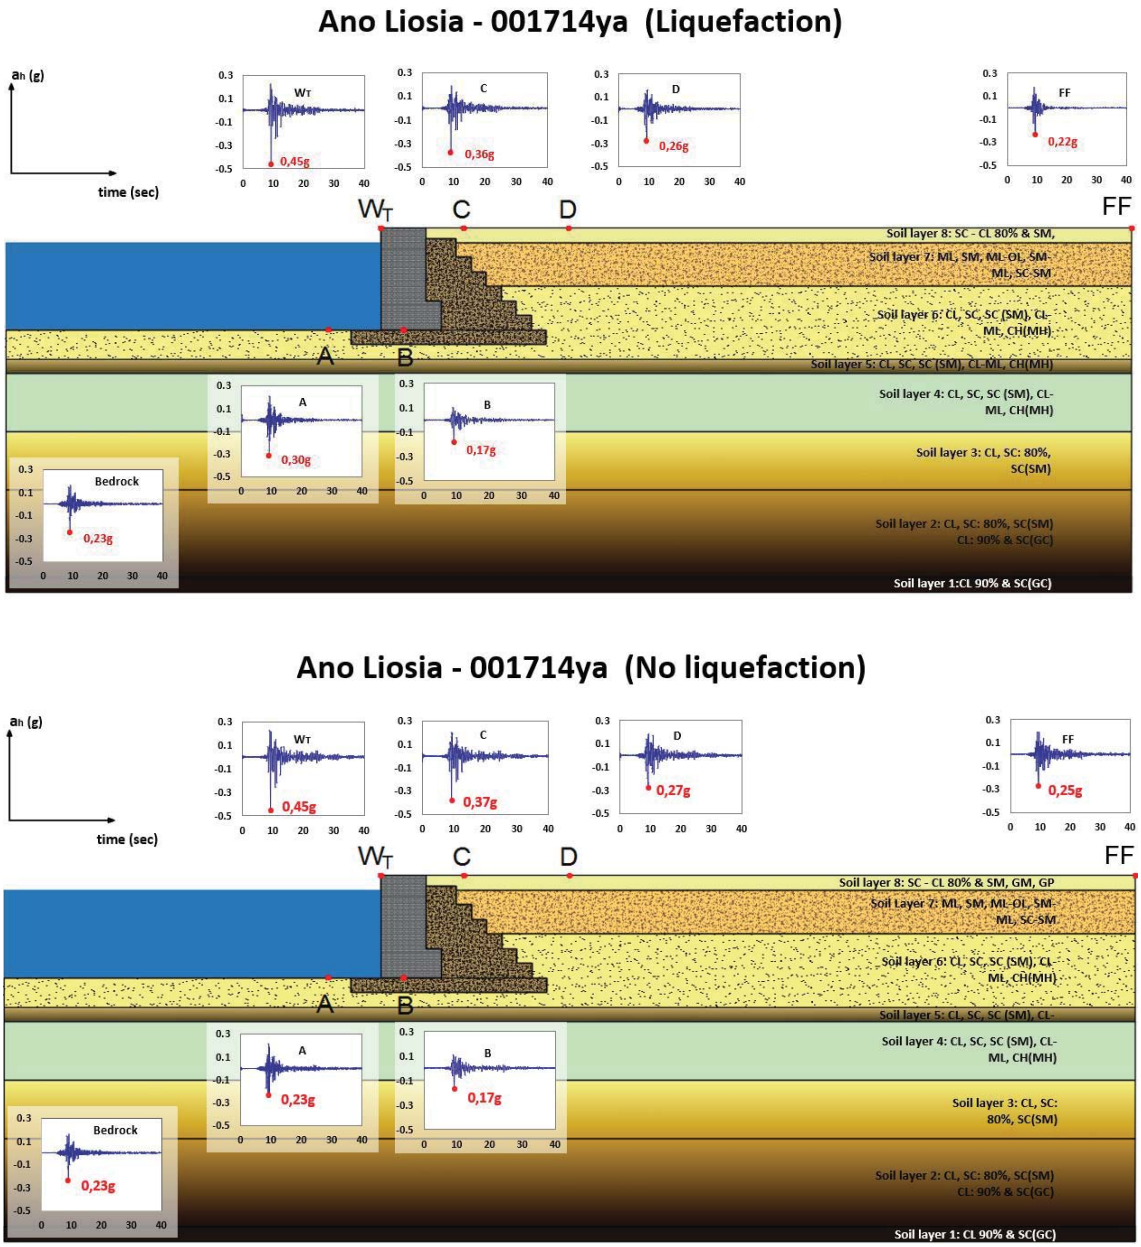

Figure 9: Acceleration time history response at the various sites of the model for Ano Liosia (ID 1714) input motion allowing (top) or neglecting (bottom) liquefaction.

Figure 11 presents the computed permanent horizontal and vertical displacements of the rigid wall, while in Figure 12 we present the ratio of the same displacements when considering the presence of liquefaction or not. It is clear that in the case of liquefaction the seaward permanent displacements of the wall are much higher, i.e. almost twice as high, compared to the non-liquefaction case, which nevertheless are not negligible. For example, for rock-basement excitations of 0.2g-0.3g the average value of the horizontal permanent displacement without liquefaction are of the order of 5 cm, and they are doubled in case liquefaction is considered. A similar trend is observed for the vertical displacements, where, however, the absolute and relative values are as expected lower compared to the horizontal displacements. More specifically, regarding the computed absolute displacement values, the permanent horizontal displacements vary from 2.3 cm to 60.3 cm when we consider soil liquefaction and from 1.9 cm to 31.9 cm when liquefaction is neglected, while the permanent vertical displacement val-

ues range between 2.1 cm and 17.8 cm for the liquefiable case compared to those of the non-liquefiable case that vary between 1.9 cm and 11.6 cm.

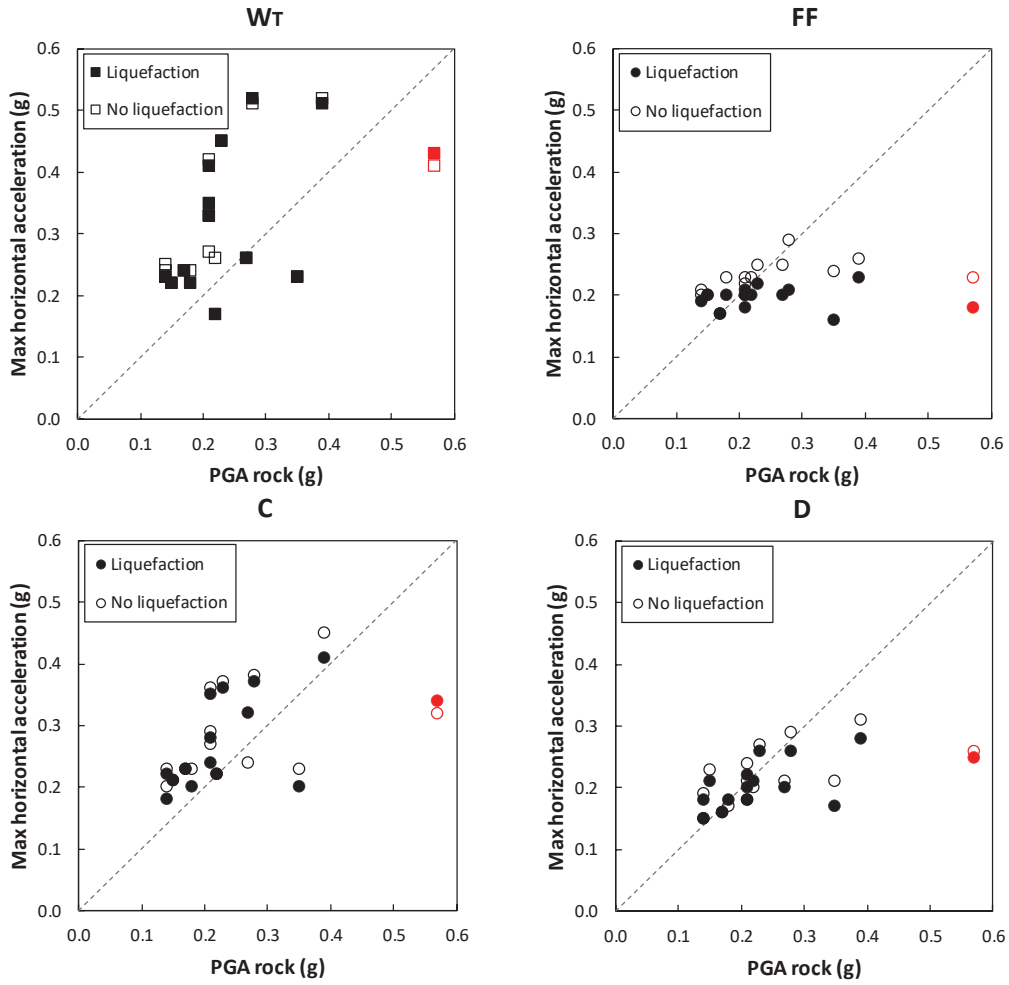

Figure 10: Maximum horizontal acceleration - PGA_{rock} pairs at different locations: W_T (top-left), FF (top-right), C (bottom-left) and D (bottom-right) for the two cases allowing (solid circles) or not liquefaction.

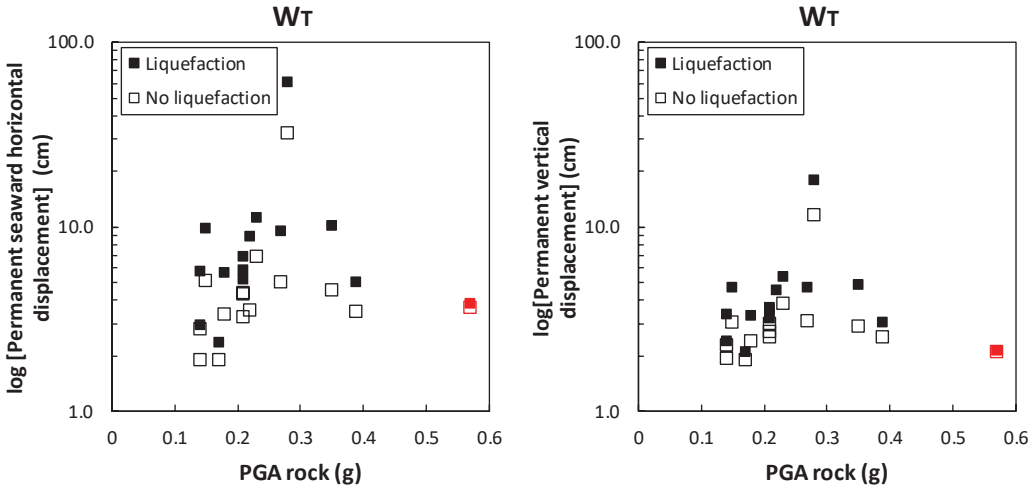

Figure 11: Permanent horizontal displacement (left) and permanent vertical displacement (right) variation with PGA_{rock} at the top of the wall (W_T) with (solid rectangles) and without liquefaction.

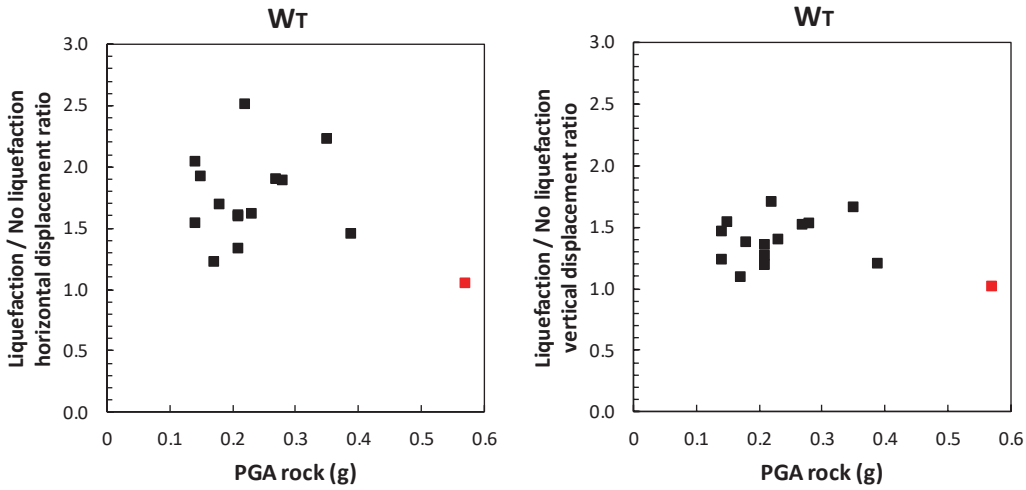

Figure 12: Ratios of the permanent horizontal (left) and vertical displacement (right) values computed at the top of the wall W_T for the liquefiable case to the corresponding ones for the non-liquefiable case.

According to PIANC [31], for gravity quay walls four damage states are defined (i.e. <1.5%, 1.5-5.0%, 5.0-10.0% and >15.0%) in terms of the normalized seaward displacement (horizontal displacements divided by the wall height), which is considered as an appropriate Damage Metric (DM) from the viewpoint of quay wall performance. In this study, the normalized seaward displacements vary from 0.23% to 6.03% when liquefaction is allowed and from 0.19% to 3.20% when liquefaction is neglected. Thus, for the liquefiable case the first three damage states could be reached, even without scaling of the records.

4 CONCLUSIONS

The influence of the liquefaction of the foundation soil on the seismic response of port gravity-type quay walls has been investigated for a typical structure of the Port of Thessaloniki. The numerical analysis has been conducted applying OpenSees with a set of 15 earthquake records having different amplitudes and frequency content, allowing or not liquefaction to occur. The main conclusion of the comparative study is that while the impact of the liquefaction on the amplitude of the acceleration of the wall is negligible compared to the non-liquefaction case, the effect on the permanent seaward horizontal and vertical displacements of the wall is very important, almost doubled, increasing in that way considerably the vulnerability of the wall. Further research is certainly needed to investigate and quantify the effects of liquefaction on the seismic response and vulnerability of a variety of port quay wall typologies and soil conditions, always prone to liquefaction under strong seismic ground motion excitations.

ACKNOWLEDGMENTS

This study was carried out in the framework of the ‘‘Resilient, system-wide seismic risk assessment of port facilities. Application to Thessaloniki Port system’’ RESPORTS project (http://resports.gr/), funded by the Hellenic Foundation for Research and Innovation (HFRI) and General Secretariat for Research and Technology (GSRT) under Grant Agreement No754.

Keywords: Indirect Trefftz Method, Wave Based Method, 2.5 Dimensional Problems, Soil-structure Interaction

Abstract. *This contribution presents a 2.5-dimensional, frequency domain approach to model linear elastic soils, based on Indirect Trefftz Elements. 2.5-dimensional solution procedures allow a convenient way to model structures that are periodic in one direction.*
The solution of the problem is carried out in the frequency domain. One dimension is transformed to the wave number domain using a Fourier Transformation. The problem is solved for each wave number separately and the results are reproduced by superposing the different wave number solutions. For each wave number, Indirect Trefftz Elements are used to solve the differential equation governing the considered problem, allowing to model problems with boundaries of moderate complexity. With the help of a Helmholtz decomposition, the Lamé differential equation is split up in its irrotational and solenoidal parts, with each of the fields approximated by a truncated set of wave functions. The used wave functions inherently satisfy the governing equation of the problem. Inter-element continuity is enforced using a Galerkin approach.
Compared to conventional Finite Element Approaches the method incorporates the wave characteristics of the solution directly since the shape functions are chosen as a linear combination of propagating and evanescent waves. Inclusion of radiating boundary conditions is straightforward. The resulting systems of equations are smaller as compared to Finite Elements, which can reduce solving time for the soil model effectively. As a drawback, the method suffers from matrices that are fully populated and include complex entries.

1 INTRODUCTION

Vibrations introduced by heavy machines or railway lines are transported through the soil and affect systems in the vicinity as for example adjacent structures. Resulting oscillations may cause inconvenience or even damage to the exited systems. Densification in urban areas has lead to an additional awareness for this mechanism and the requirement to limit those effects became even more present. Since reduction measures are preferably planed during the design process, the demand for a proper prediction of vibrations and their propagation using numerical simulations has steadily increased.

Classical FEM approaches suffer from reflections at artificial boundaries since only areas of limited size can be modeled. Different approaches have been developed to deal with the infinite extensions of the soil in the context of numerical simulations. Extensions to the FEM include Transmitting Boundaries (TB) [1], Perfectly Matched Layers (PML) [2] and the Thin Layer Method (TLM) within others. Fontara [3] investigates two different formulations of PML in the frequency domain.

Besides, coupled Finite Element - Boundary Element methods (FEM-BEM) are widely used, to model the semi infinite system [4]. Francois [5] presents a 2.5 dimensional FEM-BEM procedure for systems with invariant geometry in one dimension. The approach uses Green's functions of a layered halfspace for the BEM model. This avoids the requirement to mesh the free surface.

Another approach, the Integral Transform Method (ITM) is based on available analytical solutions in the frequency domain, making use of the characteristics of the wave components of those solutions for negative frequencies [6]. Frühe [7] developed a solution for a halfspace with cylindrical or spherical inclusion using the ITM to couple the different analytical systems. Hackenberg and Dengler [8] enhanced the ITM approach with a FE procedure for 2.5 dimensional problems. The infinite extension of the problem is handled using analytical solutions in the context of the ITM whereas those parts requiring a finer resolution are described by the FEM. The degrees of freedom of the FE mesh along the common boundary with the ITM domain are transformed in the wave number domain to couple the two subsystems in a direct manner. Hackenberg [9] and later Freisinger [10] expanded the method for 3-dimensional problems and evaluated the insertion loss of different structures.

Different publications refer to Trefftz [11] like methods to solve bounded and unbounded problems. Jirousek [12] introduced Hybrid Trefftz FEM elements for various applications. Different authors [13] extended this idea for an application to 2-dimensional dynamic soil problems in the frequency domain and developed Hybrid-Trefftz displacement or stress elements. Moldovan [13] extended those elements to be applicable to biphasic media.

The Wave Based Method (WBM) belongs to the family of Indirect Trefftz methods and has originally been introduced by Desmet [14] for acoustic problems to cover the so called mid frequency gap, where pollution effects and increasing numerical effort prevent the applicability of traditional element-based procedures as the FEM. It is a deterministic prediction method based on the ideas of Trefftz using propagating and evanescent waves to set up the approximation space. The WBM is based on a rather coarse discretization of the problem domain, using convex subdomains, as shown in figure 1. The method was extended to plate in membrane and plate bending problems ([15, 16]). Later Klanner [17] showed an application of the WBM for thick plates. A summary of current extensions to the method is given in [18].

Huybrechs [19] investigates the numerical behavior of WBM and its approximation space and proposes an oversampled collocation method rather than a weighted residual method to solve

the problem. He also states, that the used function set rather resembles a frame than a basis in a mathematical sense. An overview of different Trefftz Methods, with focus on the used approximation space is given in [20].
This work aims to give an application of the WBM to 2.5 dimensional soil problems, described by the Lamé equation. The idea is to develop a more flexible solution procedure with respect to geometric restriction of methods like the ITM, that is always limited to simple geometries, with analytical solutions being available. Nevertheless the presented procedure can still handle radiating boundaries or infinite extensions straight away.

In the first chapter the theory of 2.5 dimensional problems is described. A Helmholtz de-

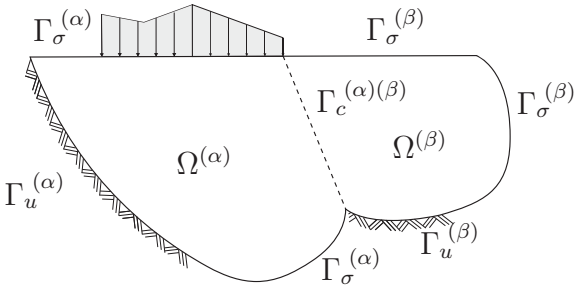

Figure 1: Concept of domain decomposition in the WBM

composition of the partial differential equation of the problem is given. The resulting three decoupled wave equations are used to define a suitable shape function approximation set in the frequency wave number domain (ω, k_x). After transformation the problem can be treated similar to conventional 2 dimensional approaches. In the next chapter the incorporation of the boundary residuals along real and artificial boundaries Γ, in the sense of a weighted residual approach is focused, followed by a short verification example and the conclusion.

2 2.5 DIMENSIONAL SOILS

The presented solution procedure handles systems with infinite extension in x-direction. Instead of solving the problem directly, a Fourier Transform (FT) of the considered system from time domain t to frequency domain ω and from the spatial coordinates x to the wave number domain k_x is carried out. Starting from a general 3-dimensional continua the governing equations are transformed in the frequency - wave number domain and solved for each frequency ω and wave number k_x separately. For the homogenous part of the resulting differential equation in the wave number frequency domain a Trefftz complete set of shape functions can be found, that spans the entire solution space and where each shape function itself inherently satisfies the underlying differential equation of the problem. A general shape function will be stated as $\mathrm{N}(x, y, z, t)$ in the following, here given in dependency of the time t and the spatial coordinates x, y and z. In a first step the FT with respect to time is carried out, defined by:

$$F(\omega) = \int_{-\infty}^{\infty} f(t) \cdot \mathrm{e}^{-\mathrm{i}\,\omega\, t}\, dt \tag{1}$$

The same procedure is repeated with respect to the spatial coordinate x:

$$F(k_x) = \int_{-\infty}^{\infty} f(x) \cdot \mathrm{e}^{-\mathrm{i}\, k_x\, x}\, dx \tag{2}$$

The transformed problem is solved using the shape functions $\hat{\mathrm{N}}(k_x, y, z, \omega)$, given in the k_x, y, z, ω domain. The same procedure is repeated for the inhomogeneous part of the differential equation. Therefore external loads are are also transformed to the k_x, y, z, ω domain, as shown in figure 2 for the spatial coordinate x.

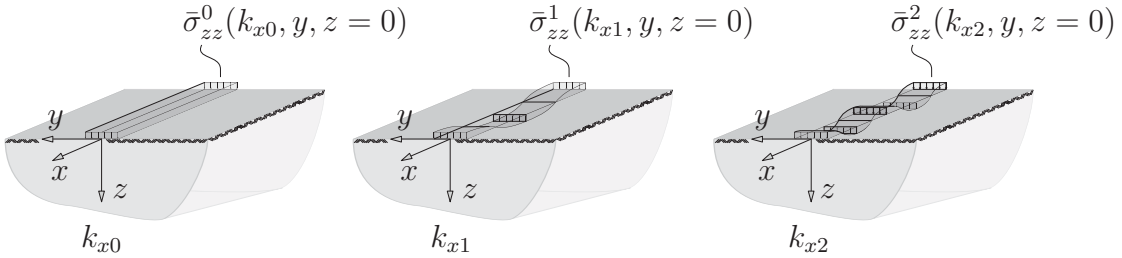

Figure 2: Concept of the Fourier Transform in x-direction for an external loading.

2.1 Governing Equations

The general problem is described by the Lamé Equation for 3-dimensional continua which is derived from the equilibrium,

$$\sigma^{ij}|_j + Q^i - \rho \ddot{u}^i = 0 \tag{3}$$

with the stress tensor σ^{ij}, internal volume forces Q^i and the inertia terms $\rho\ddot{u}^i$. Considering only the homogenous part of the equilibrium equation (3) and introducing the constitutive equation and the kinematic relations leads to the Lamé equation (4):

$$\mu u^i|^j_j + (\lambda + \mu) u^j|^i_j - \rho \ddot{u}^i = 0 \tag{4}$$

In the above equation a linear elastic, homogeneous, isotropic material descriptions has been used, with the Lamé constants λ and μ describing the material properties. Hysteretic damping effects are considered using a complex Young's modulus,

$$\underline{E} = E\left(1 + \mathrm{i}\,\mathrm{sgn}\left(\omega\right)\zeta\right) \tag{5}$$

with the imaginary unit $\mathrm{i} = \sqrt{-1}$ and the hysteretic damping ratio ζ.

2.2 Helmholtz Decomposition

The three coupled equations described by equation (4) can be transformed into linear independent equations using a Helmholtz decomposition. The solution of the Lamé equation can be written as the sum of a irrotational field given by the gradient of a scalar field Φ and a solenoidal field given by the rotation of a vector field $\mathbf{\Psi}$.

$$u^i = \Phi|^i + \Psi_l|_k \epsilon^{ikl} \tag{6}$$

This gives the following linearly independent wave equations.

$$\Phi|_j^j - \frac{1}{{c_p}^2}\ddot{\Phi} = 0 \qquad \text{with} \qquad c_p = \sqrt{\frac{\lambda + 2\mu}{\rho}} \tag{7}$$

$$\Psi_i|_j^j - \frac{1}{{c_s}^2}\ddot{\Psi}_i = 0 \qquad\qquad c_s = \sqrt{\frac{\mu}{\rho}}$$

Herein c_p denotes the compressional wave velocity and c_s the shear wave velocity respectively. The density of the soil is given by ρ. Applying the two-folded FT as mentioned in chapter 2 the wave equations can be written as Helmholtz equations

$$\left[-{k_x}^2 + {k_p}^2 + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}\right]\hat{\Phi}(k_x, y, z, \omega) = 0 \tag{8}$$

$$\left[-{k_x}^2 + {k_s}^2 + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}\right]\hat{\Psi}_1(k_x, y, z, \omega) = 0 \tag{9}$$

$$\left[-{k_x}^2 + {k_s}^2 + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}\right]\hat{\Psi}_2(k_x, y, z, \omega) = 0 \tag{10}$$

with the wave numbers $k_p = \frac{\omega}{c_p}$ and $k_s = \frac{\omega}{c_s}$.

2.3 Boundary Conditions

The boundary is defined by either Dirichlet boundary conditions with prescribed displacements (equation (21)), Neumann boundary conditions with prescribed stress (equation (22)) or mixed Boundary Conditions (equations (23)).
The physical quantities in the cartesian reference system are recovered from the potentials $\hat{\Phi}$ and $\hat{\mathbf{\Psi}}$ using the following relations:

$$\hat{u}_x = \mathrm{i}\, k_x\hat{\Phi} - \frac{\partial}{\partial z}\hat{\Psi}_2 \tag{11}$$

$$\hat{u}_y = \frac{\partial}{\partial y}\hat{\Phi} + \frac{\partial}{\partial z}\hat{\Psi}_1 \tag{12}$$

$$\hat{u}_z = \frac{\partial}{\partial z}\hat{\Phi} - \frac{\partial}{\partial y}\hat{\Psi}_1 + \mathrm{i}\, k_x\hat{\Psi}_2 \tag{13}$$

and similar for the stress components:

$$\hat{\sigma}_{xx} = (2\mu + \lambda)\left(\mathrm{i}\, k_x\, \hat{u}_x\right) + \lambda\left(\frac{\partial}{\partial y}\hat{u}_y + \frac{\partial}{\partial z}\hat{u}_z\right) \qquad \hat{\sigma}_{xy} = 2\mu \cdot \left(\frac{1}{2}\frac{\partial}{\partial y}\hat{u}_x + \frac{1}{2}\mathrm{i}\, k_x\hat{u}_y\right) \tag{14}$$

$$\hat{\sigma}_{yy} = (2\mu + \lambda)\left(\frac{\partial}{\partial y}\hat{u}_y\right) + \lambda\left(\mathrm{i}\, k_x\, \hat{u}_x + \frac{\partial}{\partial z}\hat{u}_z\right) \qquad \hat{\sigma}_{yz} = 2\mu \cdot \left(\frac{1}{2}\frac{\partial}{\partial z}\hat{u}_y + \frac{1}{2}\frac{\partial}{\partial y}\hat{u}_z\right) \tag{15}$$

$$\hat{\sigma}_{zz} = (2\mu + \lambda)\left(\frac{\partial}{\partial z}\hat{u}_z\right) + \lambda\left(\mathrm{i}\, k_x\, \hat{u}_x + \frac{\partial}{\partial y}\hat{u}_y\right) \qquad \hat{\sigma}_{xz} = 2\mu \cdot \left(\frac{1}{2}\frac{\partial}{\partial z}\hat{u}_x + \frac{1}{2}\mathrm{i}\, k_x\hat{u}_z\right) \tag{16}$$

All used boundary conditions require the evaluation of displacements or stresses in normal or in plane direction, with the normal vector of the boundary $\mathbf{n} = n_i \cdot \mathbf{e}^{\,i}$ and two perpendicular in plane vectors $\mathbf{t}_1 = t_{1\,i} \cdot \mathbf{e}^{\,i}$ and $\mathbf{t}_2 = t_{2\,i} \cdot \mathbf{e}^{\,i}$. Finally the cartesian components are transformed to the normal and in-plane components using tensor calculus:

$$\sigma_n = n_i \cdot \sigma^{ij} \cdot n_j \qquad \sigma_{t_1} = n_i \cdot \sigma^{ij} \cdot t_{1\,j} \qquad \sigma_{t_2} = n_i \cdot \sigma^{ij} \cdot t_{2\,j} \tag{17}$$

$$u_n = n_i \cdot u^i \qquad u_{t_1} = t_{1\,i} \cdot u^i \qquad u_{t_2} = t_{2\,i} \cdot u^i \tag{18}$$

For the sake of conciseness, the relations from equation (11) to (18) are replaced by a differential operator $\mathcal{L}_u(\hat{\mathrm{N}})$ for the displacements or $\mathcal{L}_\sigma(\hat{\mathrm{N}})$ for the stresses respectively.

3 THE WAVE BASED METHOD

To solve the problem for each combination of frequency ω and wave number k_x the Wave Based Method (WBM) is used. A Trefftz complete basis of the partial differential equation (PDE) is employed. The approximation space is formed by a truncated set of wave functions. To ensure convergence a non-convex domain Ω has to be split up into multiple convex subdomains $\Omega = \Omega^{(\alpha)} \cup \Omega^{(\beta)}$ as shown in figure 1. Since the used shape functions fulfill the differential equation of the problem by definition, the total residual of the approximate solution results only of the accumulated errors along the boundaries.

3.1 Field Variable Expansion

The approximate solution is recaptured using a superposition of the shape functions $\hat{\Phi}_i$, $\hat{\Psi}_{i1}$ and $\hat{\Psi}_{i2}$ multiplied with the yet still unknown weighting factors c_i.

$$\hat{\mathbf{u}} = \sum_{i=1}^{I} \mathcal{L}_{\mathbf{u}}(\hat{\mathrm{N}}_i) \cdot c_i + \sum_{j=1}^{J} \hat{\mathbf{u}}_{p,j} \quad \text{with} \quad \mathcal{L}_{\mathbf{u}}(\hat{\mathrm{N}}) = \begin{pmatrix} \mathcal{L}_{u_x}(\hat{\mathrm{N}}) \\ \mathcal{L}_{u_y}(\hat{\mathrm{N}}) \\ \mathcal{L}_{u_z}(\hat{\mathrm{N}}) \end{pmatrix} \tag{19}$$

External loads can either be applied along the boundaries or as external volume loads. The later are included using particular solutions functions for an infinite domain. In equation (19), $\hat{\mathbf{u}}_{p,j}$ refers to the displacement field of the particular solution due to the external volume load j.
The shape functions are chosen in accordance with [15], applying a suitable truncation rule for the maximum of the integer values p_k respectively s_k with $k = 1 \ldots 4$. The used shape functions are listed in table 1, where $p_l = 1, 2, \ldots, P_{l,\max} \in \mathbb{N}^+$ and $p_m = 0, 1, \ldots, P_{m,\max} \in \mathbb{N}$ with $l = 1, 2$ and $m = 3, 4$ and similar rules applied for s_k.

The wave numbers k_1 and k_2 used for the shape functions are defined in equation (20) as the projected components of the physical wave numbers k_p and k_s to the y-z-plane.

$$k_1{}^2 = k_p{}^2 - k_x{}^2 \qquad k_2{}^2 = k_s{}^2 - k_x{}^2 \tag{20}$$

3.2 Incorporation of Boundary Residuals

A single shape function by itself violates the boundary conditions of the problem, resulting in a residual term along the boundaries. In theory, due to the completeness of the solution space, the residual term vanishes if an infinite number of shape functions is used. The occurring residual terms are given in equations (21) to (23) with the terms $\bar{(*)}(\mathbf{x})$ describing the non

Irrotational scalar field $\hat{\Phi}$

Table 1: Shape functions

homogeneous part of the boundary condition.

$$\mathbf{R}_u^{(\alpha)}(\mathbf{x}) = \begin{cases} R_{u_n} &= \hat{u}_n(\mathbf{x}) - \bar{u}_n(\mathbf{x}) = 0 \\ R_{u_{t_1}} &= \hat{u}_{t_1}(\mathbf{x}) - \bar{u}_{t_1}(\mathbf{x}) = 0 \\ R_{u_{t_2}} &= \hat{u}_{t_2}(\mathbf{x}) - \bar{u}_{t_2}(\mathbf{x}) = 0 \end{cases} \quad \vee\, \mathbf{x} \in \Gamma_u \tag{21}$$

$$\mathbf{R}_\sigma^{(\alpha)}(\mathbf{x}) = \begin{cases} R_{\sigma_n} &= \hat{\sigma}_n(\mathbf{x}) - \bar{\sigma}_n(\mathbf{x}) = 0 \\ R_{\sigma_{t_1}} &= \hat{\sigma}_{t_1}(\mathbf{x}) - \bar{\sigma}_{t_1}(\mathbf{x}) = 0 \\ R_{\sigma_{t_2}} &= \hat{\sigma}_{t_2}(\mathbf{x}) - \bar{\sigma}_{t_2}(\mathbf{x}) = 0 \end{cases} \quad \vee\, \mathbf{x} \in \Gamma_\sigma \tag{22}$$

$$\mathbf{R}_{u\sigma}^{(\alpha)}(\mathbf{x}) = \begin{cases} R_{u_n} &= \hat{u}_n(\mathbf{x}) - \bar{u}_n(\mathbf{x}) = 0 \\ R_{\sigma_{t_1}} &= \hat{\sigma}_{t_1}(\mathbf{x}) - \bar{\sigma}_{t_1}(\mathbf{x}) = 0 \\ R_{\sigma_{t_2}} &= \hat{\sigma}_{t_2}(\mathbf{x}) - \bar{\sigma}_{t_2}(\mathbf{x}) = 0 \end{cases} \quad \vee\, \mathbf{x} \in \Gamma_{u\sigma} \tag{23}$$

For inter-element coupling the displacement field of element α is prescribed to element β and the stresses of element β to element α resulting in a additional residual term for each element.

3.3 Weighted Residual Formulation

By introducing the truncated set of wave functions as an approximate solution the residual terms along the boundaries do not disappear anymore, but can only be minimized in an integral sense, for example by using a weighted residual method. In the sense of a Galerkin procedure the same functions used for the approximation are used as weighting functions, denoted by $\delta(*)$.

$$\delta u_n = \sum_{i=1}^{K} \mathcal{L}_{u_n}(\mathbf{N}_i) \cdot \delta c_i \qquad \delta u_t = \dots \tag{24}$$

$$\delta \sigma_n = \sum_{i=1}^{K} \mathcal{L}_{\sigma_n}(\mathbf{N}_i) \cdot \delta c_i \qquad \delta \sigma_t = \dots \tag{25}$$

3.4 Solution and Post Processing

The weighted residual expression is evaluated along the complete boundary $\Gamma = \Gamma_\sigma \cup \Gamma_u \cup \Gamma_{u\sigma} \cup \Gamma_c$ and expressed in dependency of the defined boundary conditions as

$$-\int_{\Gamma_\sigma} \delta u_n \, R_{\sigma_n} + \delta u_{t_1} \, R_{\sigma_{t_1}} + \delta u_{t_2} \, R_{\sigma_{t_2}} \, d\Gamma_\sigma + \int_{\Gamma_u} \delta \sigma_n \, R_{u_n} + \delta \sigma_{t_1} \, R_{u_{t_1}} + \delta \sigma_{t_2} \, R_{u_{t_2}} \, d\Gamma_u \, ... = 0$$

which leads to the linear system of equations to be solved for the unknown contribution factors c_i:

$$\rightarrow \quad \delta \mathbf{c}^T \, (\mathbf{K}\,\mathbf{c} - \mathbf{f}) = 0 \tag{26}$$

The final physical values in the frequency-wave-number domain are reproduced using equation (19). After that an inverse FT with respect to time t and the spatial coordinate x is carried out in the sense of:

$$f(x,y,z,t) = \frac{1}{(2\pi)^2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \hat{F}(k_x,y,z,\omega) \cdot \mathrm{e}^{\mathrm{i}\,k_x x} \cdot \mathrm{e}^{\mathrm{i}\,\omega t} dk_x \, d\omega \tag{27}$$

4 NUMERICAL EXAMPLES

As a validation example a linear elastic homogenous soil is considered. The halfspace is loaded at the surface by a constant line loading. The calculated results are compared to a reference solution using the Fourier Transform (FT) of the load in spatial y-direction and the analytical response to each contribution in the wave number domain k_y. For the reference solution a repetition length of $B_y = 256\,[m]$ and $n = 4096$ Fourier terms are used. Due to comparability the example is solved for a uniform line loading with constants value in x-direction. An extension to different wave numbers k_x can be achieved using the procedure described in chapter 2. For the validation example a soil with the given parameters is used: elasticity modulus $E = 260 \cdot 10^5\,[\frac{N}{m^2}]$, Poisson ratio $\nu = 0.3$, density $\rho = 2000\,[\frac{kg}{m^3}]$ and hysteretic damping ratio $\zeta = 0.1$. The external loading at the halfspace surface is considered as an inhomogeneous Neumann boundary condition using equation (22) with constant value $\bar{\sigma}_n = 1[\frac{N}{m^2}]$.

The used decomposition for the WBM model is given in figure 3. Three coupled, convex subdomains are used to model the considered area. The chosen subdomains serve well to proof

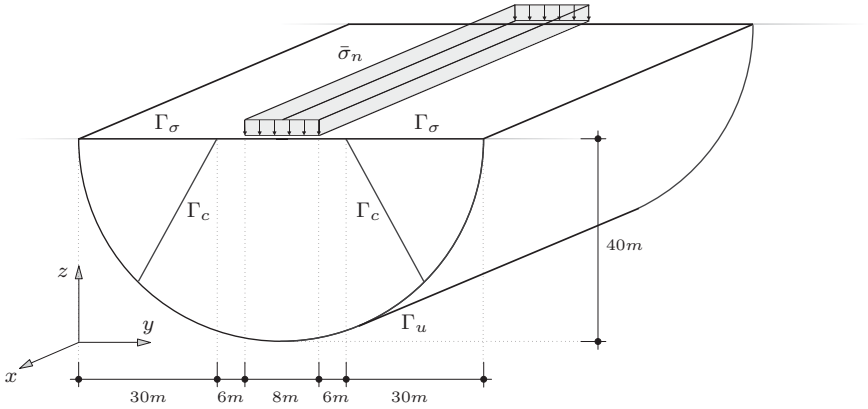

Figure 3: Validation example - Geometry and used decomposition into convex subdomains

inter-element continuity on the one hand side as well as the flexibility of the element boundary description on the other hand side. In this example, the dimensions of the modeled domain are chosen large enough that the effect of spurious reflections at the artificial exterior boundaries become small. Nevertheless they can not be neglected completely without further treatment. In the presented example this results in rather large relative errors for the left and right element at the surface. Figure 4 shows the results split up in real and imaginary part for a sample frequency

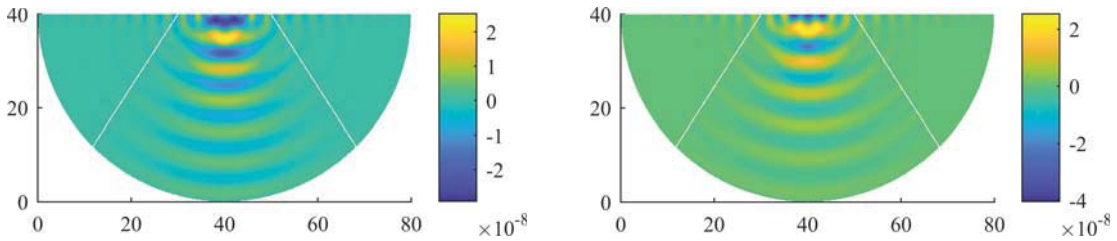

Figure 4: *(a)* Real part and *(b)* imaginary part of vertical displacements $u_z(x = 0)$ in $[m]$.

of $20\,[Hz]$. Figure 5 shows the results of the vertical displacement at the surface along a line $(x = 0, y, z = 40)$ for the given frequency of $20\,[Hz]$ comparing them against an ITM solution using the described FT of the load along the y-direction. Evaluating the relative error along the surface reveals the largest values at the beginning and end of the surface line load. This is not surprising due to the discontinuity of the boundary condition at exactly those positions.

5 CONCLUSION

The presented results show that the method can be adapted to model 2.5 dimensional soil problems and gives correct and precise results. Nevertheless the consideration of the semi infinite area should be included to avoid spurious reflections. This can be achieved by using a different set of shape functions for the exterior elements which is straight forward for the presented method. Furthermore special treatment of singularities as occurring at the beginning and end of the surface line load can enhance the numerical efficiency and convergence rate of the method significantly. Therefor particular solution functions for external loads as well as special

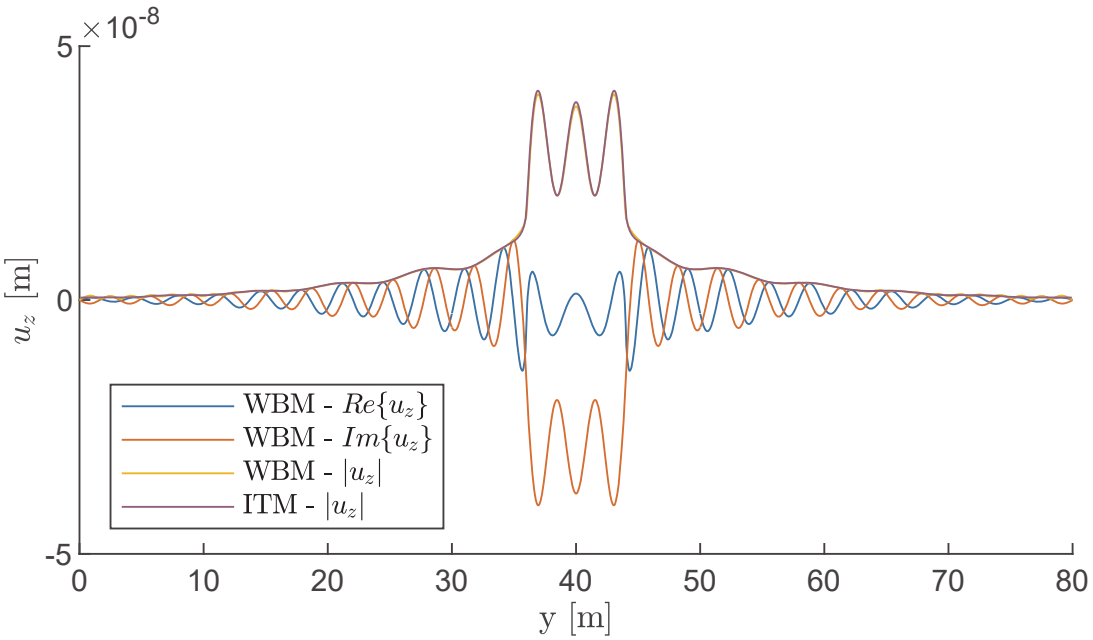

Figure 5: Vertical displacements u_z at surface $(z = 40, x = 0)$ for $20\,[Hz]$ *(yellow line)* and FT reference solution *(purple line)*

purpose functions for singularities due to the geometry of the problem should be developed in the future.

Keywords: Ground Vibration, Pile Driving, Layered Soil, Insertion Loss, Wave Impedance.

Abstract. *Ground vibration associated with pile driving causes annoyance to inhabitants of the neighbouring environment and may possibly lead to damage on existing structures in the proximity of a construction site. Vibration mitigation near the source can reduce the problem. The paper investigates the effect of circular arrays of blocks, placed on the ground surface around the position at which the pile is driven. A semi-analytical model of a layered soil has been used for the analysis, and the blocks have been modelled as monolithic structures, accounting for the full structure–soil–structure interaction. Two different sites have been studied: a layered soil with three metres of soft sand over a half-space of till, and a five metres deep layer of soft clay overlying a half-space of lime. The block arrays consist of one to three concentric rings with radii 4, 8, and 12 m, respectively. The rings contain 6, 12, and 24 blocks, respectively, and the size of the blocks have been scaled such that each ring has the same total mass. The pile has not been modelled explicitly; instead vertical excitation has been applied in different depts over a circular area corresponding to the cross section of a pile. For the considered cases it has been found that an array of blocks, shaped as a "Stonehenge", may provide significant mitigation of the ground vibration level in a receiver zone placed 20–40 m from the pile. When a load is applied within the soft topsoil layer, the array provides an insertion loss in the order of 5–20 dB, depending on the size of the blocks and the configuration of the arrays. For loads applied deeper in the soil, within the stiffer half-space, the insertion loss is small and may in some situations be negative. However, this must be seen in the context that the transfer mobility in the reference state without the blocks, i.e. the greenfield, is low when the load is applied within the stiff half-space.*

1 INTRODUCTION

Environmental vibration from construction activities in urban environments causes annoyance to inhabitants. Long term exposure to noise and vibration may even lead to health problems [1,2], and excessive vibrations can be the cause of damage to structures. Hence, controlling the level of vibrations in the built environment is important.

Several ideas have been proposed for the mitigation of ground vibration from various sources. For rail-traffic-induced vibrations, concepts such as barriers, trenches and soil stiffening [3], [4], or heavy masses placed along the track [5] have been demonstrated to reduce the ground vibration levels in the shielded zones behind the barriers. Also, sheet pile walls in various configurations have been proposed for vibration screening [6–8]. However, installing such barriers will itself cause vibration during the driving of the individual piles.

As an alternative to the continuous barriers, wave impedance blocks (WIBs) placed on the ground surface or embedded within the soil can be used for the reduction of ground vibration [9–11]. Masoumi et al. [12] reported an experimental validation of the mitigation provided by such systems. WIBs – or another change in geometry or material – can be placed in a periodic array. Following the original idea of Mead [13], wave propagation in certain frequency bands can thereby be reduced significantly, theoretically leading to the presence of stop bands (or band gaps) with no propagation of energy. In this context, Persson et al. [14] suggested the reshaping of a landscape into an array of hills and/or valleys, while Andersen [15] analysed the effect of linear arrays of embedded WIBs using a two-dimensional model. The study was later extended to finite arrays in three-dimensions [16–18]. Also, simplified models were proposed for fast, preliminary analysis of WIB arrays placed on the ground surface [19,20].

Returning to the particular vibration problem related to installation of piles, a thorough study on the wave propagation via the soil and into buildings, including the effect on the structure and the occupants, was conducted by Athanasopoulos and Pelekis [21]. More recently, the vibratory sheet pile driving was studied by Deckner et al. [22–24]. The vibrations transmitted via the ground carry most of the energy in the frequency range relevant for whole-body vibrations, i.e. in the range 1–80 Hz. Further, buildings (or structural elements such as floors or walls) may resonate at the excitation frequencies involved in vibratory or impact pile driving [21].

A means of mitigating the ground vibrations from pile driving is therefore beneficial but demands that it can be realized at a low cost and without causing additional vibration. The use of WIBs placed on top of the ground could provide an efficient solution, by using a system of large construction waste-bags or other types of containers that can be filled with locally available material (excavated soil, recycled concrete, etc.), the work involved in establishing the vibration mitigation system would be minimal. Based on this idea, the authors previously proposed the introduction of a circular array of WIBs placed around a vibration source acting on the ground surface [25]. Different configurations of the array were tested, using a semi-analytical model. The main findings were that the WIB arrays provided an insertion loss (IL) of up to 20 dB in the vertical ground vibration levels, defined as the mean value in the zone 20–40 m away from the source. The effect was particularly pronounced at frequencies just above cut-on for wave propagation in soft topsoil, where the vibration levels peaked in the reference case without the WIBs. Also, an array with a configuration mimicking that of Stonehenge (with large blocks in the centre ring and gradually smaller blocks in the surrounding rings) was in many situations found to be more effective than arrays with block of equal size in all rings.

However, whereas Andersen et al. [25] concluded that the circular WIB arrays may be efficient for ground vibration mitigation related to surface sources, no analyses of buried sources or pile driving were performed. This paper, on the other hand, has focus on the IL related to vibrations generated by excitation at various depths below the ground surface. The frequency

range 0–80 Hz has been considered, as this is relevant for whole-body vibration and for the first eigenmodes of typical building elements and resonance in soil layers. To allow a direct comparison with the earlier findings, it has been chosen to use the same soil stratifications, i.e. 3 m of soft sand over a till half-space (Case 1), and 5 m of soft clay over a lime half-space (Case 2). However, compared to [25], only the "Stonehenge" configuration of the WIB array has been analysed in the paper. Ideally, to study the vibration from pile driving, a numerical model should account for the nonlinear response of the pile–soil system as proposed, for example, by Rooz et al. [26]. However, for a conceptual feasibility study of the suggested mitigation strategy, we propose the use of a simplified methodology. Hence, a linear viscoelastic model is used for the ground, and the pile is not modelled explicitly. Instead, vibration sources at various depths in the ground are considered. During the driving process, a pile will transfer energy to the soil, partly along the shaft, and partly at the tip. The proposed model allows a quantification of the IL that can be achieved for the contributions at each separate depth, but because of the simplified modelling approach it cannot be used for the assessment of the overall vibration levels.

The remaining parts of the paper are structured as follows. First, Section 2 describes the computational model. Then, Sections 3 and 4 provide the results and a discussion of the IL achieved in Cases 1 and 2, respectively. Finally, the main conclusions and suggestions for further research are given in Section 5.

2 SEMI-ANALYTICAL MODEL FOR THE SOIL AND RIGID BLOCKS

2.1 Transfer-matrix method for a layered ground with embedded sources

The analyses concern the vibration propagation into the far field, and in the case of man-made vibration due to pile driving, the cyclic shear strain magnitudes are small enough that a linear viscoelastic behaviour of the soil can be assumed. With wavelengths much longer than the characteristic grain size, a solid continuum model can be applied. The half-space $x_3 \leq 0$ is considered, assuming the ground surface and any internal interfaces to be horizontal. Given the linearity and horizontal invariance of the problem, the displacement in direction i at any point (x_1, x_2, x_3) and time t can be found as

$$u_i(x_1, x_2, x_3, t) = \int_{-\infty}^{0}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{t} g_{ij}(x_1 - y_1, x_2 - y_2, x_3, y_3, t - \tau) \times p_j(y_1, y_2, y_3, \tau)\, \mathrm{d}\tau\, \mathrm{d}y_1\, \mathrm{d}y_2\, \mathrm{d}y_3, \qquad x_3 \leq 0\,, \quad (1)$$

where $g_{ij}(x_1 - y_1, x_2 - y_2, x_3, y_3, t - \tau)$ is the Green's function for the half-space, and $p_j(y_1, y_2, y_3, \tau)$ is the load applied at the position (y_1, y_2, y_3) and time τ.

The Green's function in the time–space domain cannot be found in closed form for a layered half-space. Instead, Eq. (1) is Fourier transformed into the frequency–horizontal wavenumber domain, arriving at the equation

$$\bar{U}_i(k_1, k_2, x_3, \omega) = \sum_{n=1}^{N_\mathrm{P}} \bar{G}_{ij}(k_1, k_2, x_3, y_{3n}, \omega)\, \bar{P}_j(k_1, k_2, y_{3n}, \omega). \quad (2)$$

$\bar{U}_i(k_1, k_2, x_3, \omega)$ is the triple Fourier transform of $u_i(x_1, x_2, x_3, t)$, while $\bar{P}_j(k_1, k_2, y_{3n}, \omega)$ is the triple Fourier transform of $p_j(y_1, y_2, y_3, \tau)$, and $\bar{G}_{ij}(k_1, k_2, x_3, y_3, \omega)$ is the triple Fourier transform of $g_{ij}(x_1 - y_1, x_2 - y_2, x_3, y_3, t - \tau)$. A discretization has been made in order to evaluate the contributions from a finite set of loads applied at the depths y_{3n}, $n = 1,2, \ldots, N_\mathrm{P}$. For each discrete depth that is not coinciding with an interface between two soil layers or the ground surface, an additional interface must be introduced in the model.

The material properties of each soil layer are defined in terms of the shear modulus G, Poisson's ratio ν, the mass density ρ, and the loss factor η. Thus, rate-independent hysteretic material damping is assumed, leading to a complex-valued dynamic stiffness of the soil. Next, for any combination of the source and receiver depths, x_3 and y_{3n}, the horizontal wavenumbers (k_1, k_2), and the angular frequency ω, an analytical solution for $\bar{G}_{ij}(k_1, k_2, x_3, y_{3n}, \omega)$ can be found by the layer transfer matrix-method proposed by Thomson [27] and Haskell [28]. The efficient implementation of Andersen and Clausen [29] has been used for the present analysis, augmented by the stabilization method proposed by Wang [30]. This allows a fast calculation of the response without necessitating a discretization over depth by the thin-layer method.

Once, $\bar{G}_{ij}(k_1, k_2, x_3, y_{3n}, \omega)$ and $\bar{P}_j(k_1, k_2, y_{3n}, \omega)$ have been evaluated for a given angular frequency, a double inverse Fourier transformation can be carried out with respect to k_1 and k_2 in order to obtain the solution in the frequency–space domain, $G_{ij}(x_1 - y_1, x_2 - y_2, x_3, y_3, \omega)$. In the present work, the load is assumed to be distributed uniformly over a circular horizontal area with a radius of $r_\mathrm{P} = 0.25$ m, corresponding to the cross section of the pile at a given depth. Hence, the load is axisymmetric. The same property applies to the Green's function, given the horizontal invariance of the stratification. This allows the double inverse Fourier transformation to be carried out in a semi-discrete manner with analytic transformation over the azimuth direction and discrete Fourier transformation in the radial direction. A discretization into 10 000 wavenumbers along the radial direction has been used, focussing on the range relevant to waves propagating in the layered medium, and Simpson integration has been applied for increased accuracy [29]. Since the frequency domain is considered in the present analyses, further inverse Fourier transformation into the time domain should not be carried out.

2.2 Rigid blocks interacting dynamically with the soil

An array with N_B rigid blocks is considered. The blocks are placed on the ground surface, and the dynamic soil–structure interaction (SSI) is modelled, discretizing the interface between each block and the soil into N_ssi points. The blocks have a rectangular footprint of 1 m × 2 m for the inner ring of the circular array, and smaller for the other rings. This footprint is discretized into 6 × 12 points. Around each of the SSI points, the traction is distributed uniformly over a circular area with the radius $r_\mathrm{ssi} = r_\mathrm{P} = 0.25$ m. Hence, the circular loaded areas have a small overlap, and a total of $N_\mathrm{SSI} = N_\mathrm{ssi} N_\mathrm{B} = 72 N_\mathrm{B}$ SSI points are present.

Unit loads will be applied, in turn, at a set of N_P source points. This adds N_P degrees of freedom (d.o.f.) to the problem. Thus, the model has $3N_\mathrm{P} + 3N_\mathrm{SSI}$ displacement d.o.f., leading to a global flexibility matrix $\mathbf{C}_\mathrm{SSI}(\omega)$, the elements of which are defined by the Green's function $G_{ij}(x_1 - y_1, x_2 - y_2, x_3, y_{3n}, \omega)$ that relates $U_i(x_1, x_2, x_3, y_{3n}, \omega_n)$ to $P_j(y_1, y_2, x_3, y_{3n}, \omega_n)$.

Since each rigid block has six d.o.f., $6N_B$ rigid-body modes exist for the array, in addition to the $3N_\mathrm{P}$ degrees of freedom associated with the source points. The relationship between the $3N_\mathrm{P} + 3N_\mathrm{SSI}$ d.o.f. and the $3N_\mathrm{P} + 6N_\mathrm{B}$ rigid-body modes is defined in terms of the matrix $\mathbf{U}_0$, and the dynamic stiffness matrix $\mathbf{D}_\mathrm{SSI}(\omega)$ for the reduced model can be found as

$$\mathbf{D}_\mathrm{SSI}(\omega) = \mathbf{U}_0^T \left(\mathbf{C}_\mathrm{SSI}(\omega)\right)^{-1} \mathbf{U}_0, \tag{3}$$

which has the dimensions $\left((3N_\mathrm{P} + 6N_\mathrm{B}) \times (3N_\mathrm{P} + 6N_\mathrm{B})\right)$. The displacement response at a set of receiver and observation points can finally be determined by postprocessing. Here, the donut-shaped area with inner radius 20 m and outer radius 40 m, centred at the load, is considered, using a pattern of nearly regular triangle with 0.5 m between the receiver points in the radial direction and approximately 1 m distance in the azimuthal direction. This provides 14 520 points in the receiver zone. Following the same discretization strategy, 4 921 observation points are present on the ground surface within the circular area inside the donut-shaped receiver zone.

2.3 Configurations of the rigid blocks and the loads

In the previous work by the authors [25], different configurations of circular WIB arrays were considered. Here, we shall only consider the so-called "Stonehenge" configuration. The WIBs are placed on the surface of the ground, forming one, two or three concentric rings. The radii are 4 m, 8 m, and 12 m, respectively, and the loads are applied at the centre of the rings at some depth below the ground surface. The reference point for each of the rigid blocks is placed at the centre of the rectangular base, i.e. in the centre of the SSI interface for each block. The number of blocks in Rings 1, 2 and 3 is 6, 12 and 24, respectively, as shown in Figure 1a.

The inner ring (Ring 1) serves as the reference in terms of block dimensions. As mentioned, the blocks in this ring have a rectangular footprint of the dimensions 1 m × 2 m. The shorter side length is in the radial direction, while the longer side length is tangential to the ring. Three different block heights are considered: 1 m, 2 m, and 3 m. The WIBs in Rings 2 and 3 are scaled uniformly in all directions, thus keeping the aspect ratio. The scaling factors $0.5^{1/3}$ and $0.5^{2/3}$ are used for the blocks in Rings 2 and 3, respectively, such that the total volume of the blocks in each ring will be the same. For example, with a height of 2 m and a mass density of 2 000 kg/m^3, corresponding to dense soil or granulated concrete, the mass of the blocks in Ring 1 is 4 000 kg each, while the individual blocks in Rings 2 and 3 have masses of 2 000 kg and 1 000 kg, respectively. Again, it is noted that such blocks could, for example, by realized by filling some type of containers with material that is already present at the construction site.

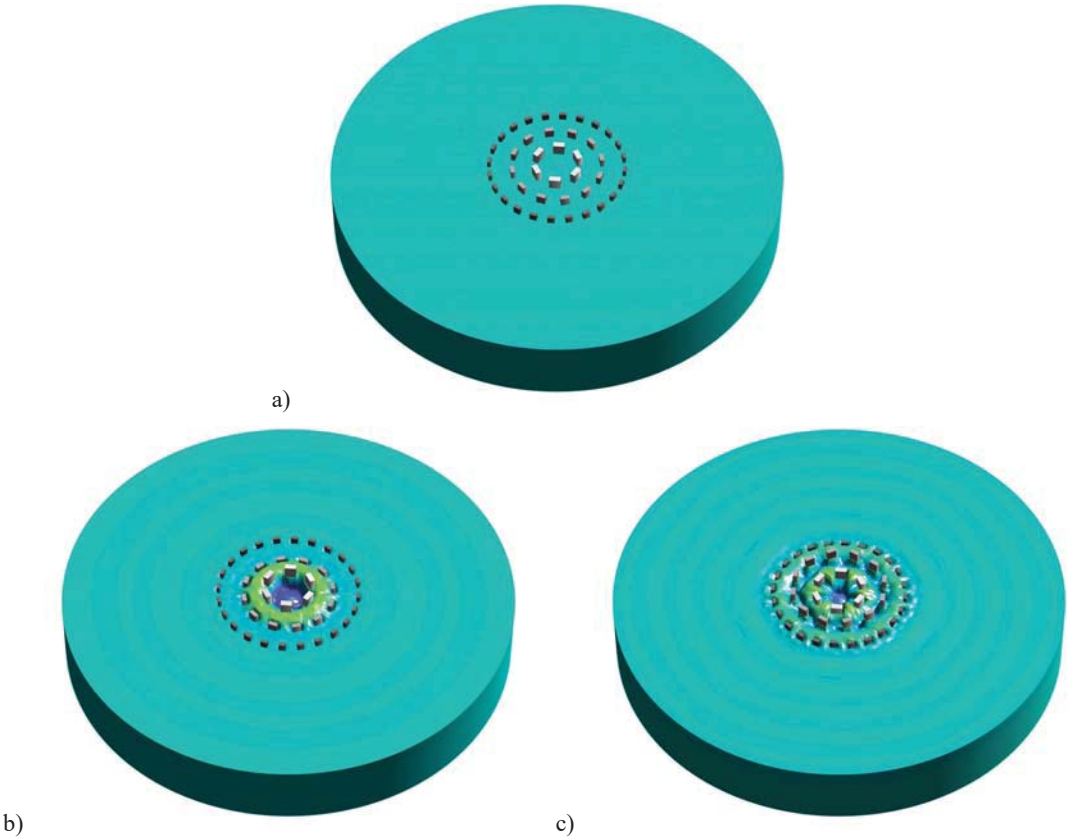

Figure 1: Model and example results: a) Configuration of the rigid blocks (WIBs) in the "Stonehenge" with three rings; b) ground vibration at 25 Hz; c) ground vibration at 30 Hz. The radii of the rings are 4 m, 8 m and 12 m, respectively, and the radius of the model is 40 m. The load is placed 2 m below the ground surface and applied vertically, uniformly distributed over a circular area with a radius of 0.25 m.

Figure 1b shows the ground displacement at 25 Hz due to a load applied 2 m below the ground surface and with three rings of WIBs placed in a "Stonehenge". The centre block height is 2 m, and the soil consists of 3 m of soft dry sand underlain by a till half-space (see Section 3, Table 1, for soil properties). Figure 1c shows the similar results at 30 Hz. At 25 Hz the displacement response is confined within the second ring, whereas large vibrations reach the third ring at 30 Hz. However, a clear effect is seen in the figure for both frequencies.

2.4 Insertion loss and transmission loss in the receiver zone

At any frequency, the vibration level in the receiver zone is influenced by 1) the source magnitude, geometry and position; 2) the transmission through the soil and any structures present within the close environment; and 3) the effect of the WIB array. A detailed discussion of the source is beyond the scope of the paper. However, assuming linear behaviour, the response scales linearly with the source magnitude. Further, as already mentioned, the load is applied uniformly on a circular area that could represent the cross section of a pile at a given depth.

Regarding the transmission of vibration through the soil, we assume that no obstacles or structures are present, except for the WIBs. The reference level (RL) for vibrations in the donut-shaped receiver zone is therefore taken as the level observed in the greenfield. In decibels, the RL for any point on the ground surface ($x_1, x_2, x_3 = 0$) and angular frequency ω is defined as

$$\mathrm{RL}_i^n(x_1, x_2, \omega) = 20\log_{10}\left(\left|U_i^{0n}(x_1, x_2, \omega)\right|\right) - 20\log_{10}(U_{\mathrm{ref}}). \tag{2}$$

Here $U_i^{0n}(x_1, x_2, \omega)$ is the ground surface displacement amplitude for a unit-magnitude (1 N) vertical distributed load applied around a source point at depth y_{3n}, and $U_{\mathrm{ref}} = 100$ pm. Only the vertical vibrations are considered. Thus, only $RL_3(x_1, x_2, \omega)$ is evaluated for the points within the receiver zone. Since a unit-magnitude load is applied, the RL may be regarded as a transfer mobility in dB for the layered ground.

The effect of a WIB array can be quantified in terms of an IL, defined as the difference in dB between the observed vibration levels before and after introducing the WIBs. Hence, a positive insertion loss implies a reduction in vibration level. For displacement component i, WIB configuration j, and pile (load) depth n, the IL is given as

$$\mathrm{IL}_i^{nj}(x_1, x_2, \omega) = 20\log_{10}\left(\left|U_i^{0n}(x_1, x_2, \omega)\right|\right) - 20\log_{10}\left(\left|U_i^{nj}(x_1, x_2, \omega)\right|\right), \tag{3}$$

where $U_i^{nj}(x_1, x_2, \omega)$ is the surface displacement amplitude obtained by applying the unit-magnitude load, i.e. the transfer mobility, after insertion of the WIB array. Again, only vertical vibration is considered, i.e. only $\mathrm{IL}_3^{nj}(x_1, x_2, \omega)$ is evaluated at the 3 780 receiver points.

To assess the importance of mitigation of ground vibration at a given frequency, it is necessary to study the RL and IL in combination. If the RL is high and the IL is low in a range of frequencies relevant to the generation of vibrations at the source, the received vibration level will be high. On the other hand, if the RL is low, a small (or even negative) IL can be tolerated, especially if the source level is also anticipated to be relatively low. This will form the basis for the discussion of the results presented in the following sections. As outlined in the introduction, two cases will be considered:

- Case 1: 3 m soft sand over a till half-space
- Case 2: 5 m soft clay over a lime half-space.

As a single measure of the RL and IL for different WIB arrays, the mean values of the RL and IL within the receiver zone will be used. The variation within the receiver zone is visualized by further calculating the 10% and 90% quantiles of the RL and IL.

3 CASE 1: 3 METRES OF SOFT DRY SAND OVER A HALF-SPACE OF TILL

The material properties for the soft sand layer and the underlying till half-space are given in Table 1. To examine the effect of the block height, three subcases are considered:

- Case 1.1: 1 m high blocks in Ring 1, and with either one, two or three rings
- Case 1.2: 2 m high blocks in Ring 1, and with either one, two or three rings
- Case 1.3: 3 m high blocks in Ring 1, and with either one, two or three rings.

It is noted that the blocks in Rings 2 and 3 will be smaller than those in Ring 1, as explained in Subsection 2.3 and shown in Figure 1a.

The blocks act as monolithic structures. The mass is proportional to the height, whereas the stiffness related to the soil–structure interaction is invariant to the block height. Hence, WIBs with different heights will resonate at different frequencies. This is even more pronounced for the pitch and rolling modes (or rocking) of the blocks, since a part of the rotational inertia scales with the cube of the height. Further, since the blocks in the Rings 1, 2 and 3 are not of the same size, the resonance frequencies will differ. The values are provided in Table 2, based on the static stiffness of the soil and the inertia of the blocks. It has been judged that the vertical vibration levels in the receiver zone are mainly influenced by the vertical motion (heave) of the blocks, their horizontal sliding, and their pitch rotation around the axis tangential to the perimeter of the ring. Hence, only the frequencies related to resonance in these modes are given.

An important observation can be made regarding the resonance frequencies in Table 2: they all lie in the frequency range 0–80 Hz, which is relevant to whole-body vibrations and building vibration. Further, this is the frequency range where most of the energy will be present in the excitation due to pile driving, and it may be expected that guided waves may be generated in the soft sand layer within this frequency range. The ratios between the resonance frequencies for the blocks and the cut-on frequencies for the layer waves can be expected to have an influence on the IL. Obviously, the mass of the WIBs will itself be important, since a heavier mass requires more energy to be moved.

The transfer mobility of the stratified soil, quantified in terms of the RL, depends strongly on whether the load is applied within the top layer of soft soil or within the underlying and much stiffer half-space. However, it has been found that the response is only marginally influenced by the relative depth of the load within the layer. Hence, to avoid an over-excessive number of figures, only two source points ($n = 2, 8$) will be considered, that is: $y_{3\,2} = -2$ m (which is inside the topsoil layer) and $y_{3\,8} = -8$ m (which is within the underlying half-space).

Soil layer (from top)	Shear modulus G [MPa]	Poisson's ratio ν [-]	Mass density ρ [kg/m^3]	Loss factor η [%]	Thickness h [m]
Sand, *soft, dry*	35.72	0.3330	1 553	4.50	3.0
Till (half-space)	500.0	0.3500	2 100	2.00	∞

Table 1: Soil properties for Case 1.

	Blocks in Ring 1			Blocks in Ring 2			Blocks in Ring 3		
	Heave	Sliding	Pitch	Heave	Sliding	Pitch	Heave	Sliding	Pitch

Table 2: Resonance frequencies (in Hz) of the blocks in Case 1.

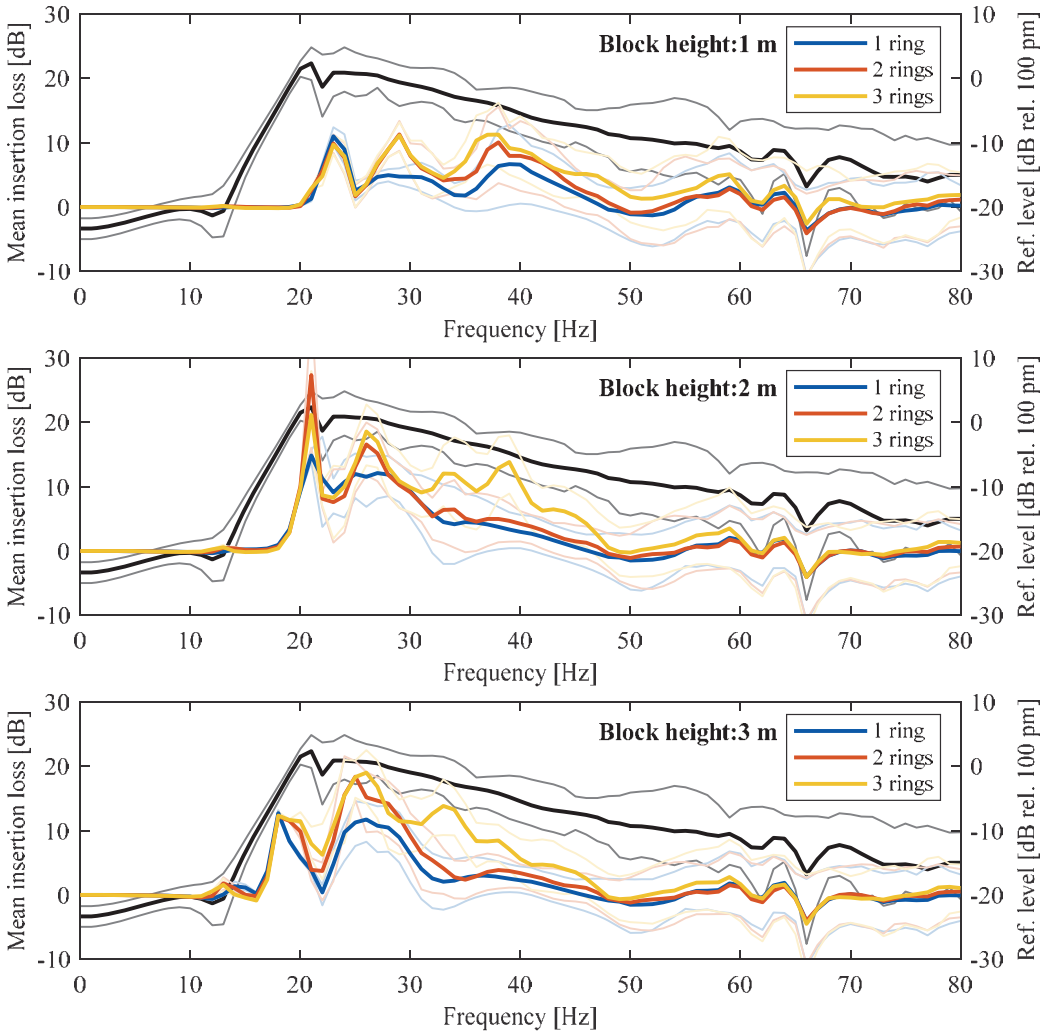

Figure 2: Mean ILs for the ground vibration within the donut-shaped surface area placed 20–40 m away from the centre of the load: Cases 1.1, 1.2, and 1.3, with the load acting 2 m below the ground. The black lines show the reference level of vibrations and the thin lines show the 10% and 90% quantiles of the respective quantities.

For the load depth of 2 m, Figure 2 shows the mean and the 10% and 90% quantiles of the RL (black lines) in Case 1. Further, the figure shows the mean and quantile values for the IL achieved with 1, 2 or 3 rings in the "Stonehenge" in Cases 1.1 (1 m high blocks in Ring 1), 1.2 (2 m high blocks in Ring 1), and 1.3 (3 m high blocks in Ring 1). For frequencies below 12.5 Hz, the RL is relatively small, about –22 dB rel. 100 pm. Then, within the interval 12.5–20 Hz, the RL increases to about 0 dB, indicating the presence of a cut-on frequency for wave propagation in the top layer at approximately 12.5 Hz. The shear wave velocity in the soft sand is about 150 m/s, which leads to a wavelength of 12 m at this frequency. Hence, the layer thickness matches with one quarter of a wavelength, which leads to resonance. From 20 Hz and up to 50 Hz, the RL decreases almost monotonously. This can be attributed to material dissipation and less constructive interference of waves. Beyond 50 Hz, where the shear wavelength becomes smaller than the layer thickness, the response varies differently.

For the various configurations of the WIB arrays, the IL peaks somewhere in the frequency range 18–38 Hz, with the exact position of the peak being dependent on the block height and

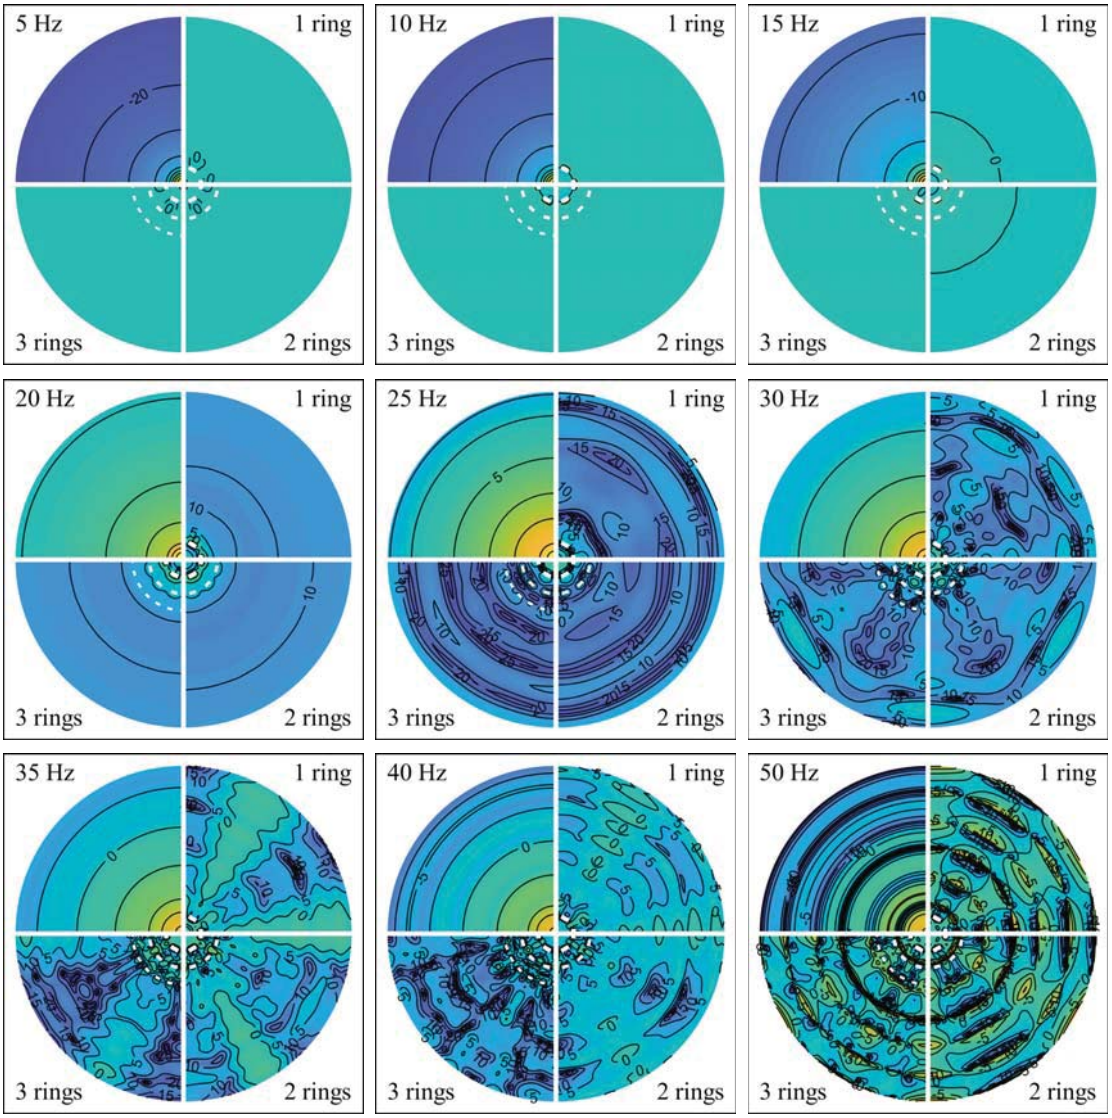

Figure 3: Contours of the reference vibration levels and ILs (in dB) for Case 1.2 with 1, 2, or 3 rings. The centre blocks are 2 m high and the vertical load is applied 2 m below the ground surface. Pale yellow/dark blue shades represent unfavourable/favourable values, respectively.

number of rings. In Case 1.1, with all three rings present, the IL is around 5–10 dB in the range 22–60 Hz, with some tips and dips. This configuration is more effective (providing higher IL than the other configurations) in the frequency range 35–80 Hz. The 1 m high blocks even provide a larger IL than the 2 or 3 m high blocks in the frequency range 45–60 Hz. However, a larger IL is obtained from 17 to 35 Hz in Cases 1.2 and 1.3. In most of the tested scenarios, the IL increases with the number of rings. As an exception, Case 1.2 is particularly effective around 21 Hz when only two rings are present. Also, in Cases 1.1 and 1.2, one ring of WIBs provides slightly higher IL than two or three rings around 23 Hz. Figure 3 shows the RL (top left quadrants of the subplots) and IL (remaining quadrants of the subplots) on the ground surface at nine selected frequencies for Case 1.2. The figure clearly shows that the array has limited effect for frequencies below 15–20 Hz. For frequencies higher than 25 Hz, the IL is subject to large variation within the receiver zone, which can also be seen from the quantile lines in Figure 2.

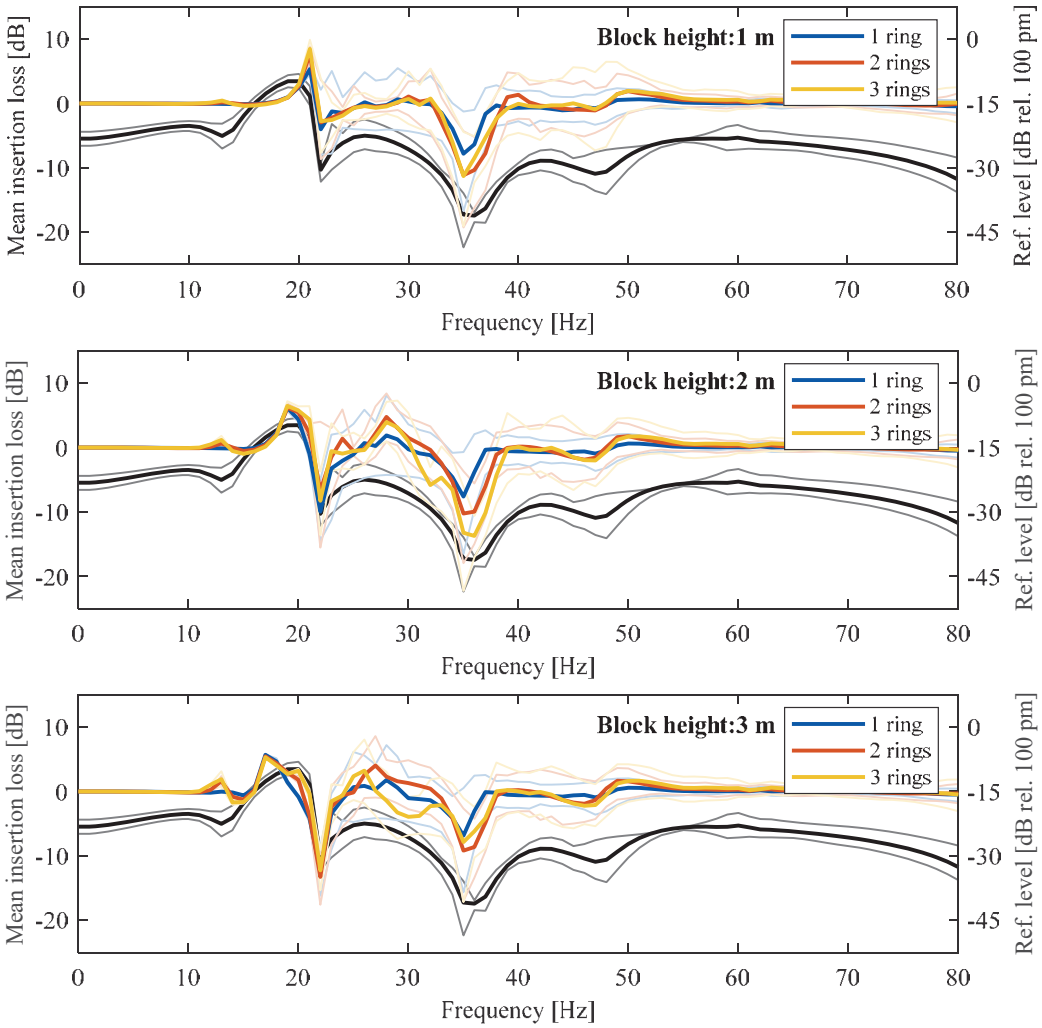

Figure 4: Mean ILs for the ground vibration within the donut-shaped surface area placed 20–40 m away from the centre of the load: Cases 1.1, 1.2, and 1.3 with the load acting 8 m below the ground. The black lines show the reference level of vibrations and the thin lines show the 10% and 90% quantiles of the respective quantities.

Figure 4 shows the mean and quantile values of the RL and IL in the receiver zone for Case 1 with the load applied at $y_{3\,8} = -8$ m. As an example of the local variations of the RL and IL within the receiver zone for this load depth, Figure 5 shows the results for Case 1.2, i.e. with a block height of 2 m in Ring 1. The WIB arrays have limited effect for frequencies below 15–20 Hz, similarly to the case with the load depth of 2 m. However, for the frequency range 12–55 Hz, the IL varies significantly and is, in some cases, negative, down to about –15 dB. The negative IL associated with the 2 and 3 m high blocks is more pronounced around 22 Hz, whereas the 1 and 2 m high blocks lead to lower IL around 35 Hz. However, with reference to Figure 2, this is where the higher IL is obtained when the load is applied at $y_{3\,2} = -2$ m.

Hence, a given configuration of the WIB array may provide a high IL in some frequency range when the load is applied at one depth, but it may be ineffective – or even amplify the ground vibration – in the same frequency range when the load is applied at another depth. A comparison of Figures 2 and 4 shows that the RL is about 20–30 dB lower when the load is applied at 8 m depth, compared to the load applied 2 m below the ground surface. This indicates

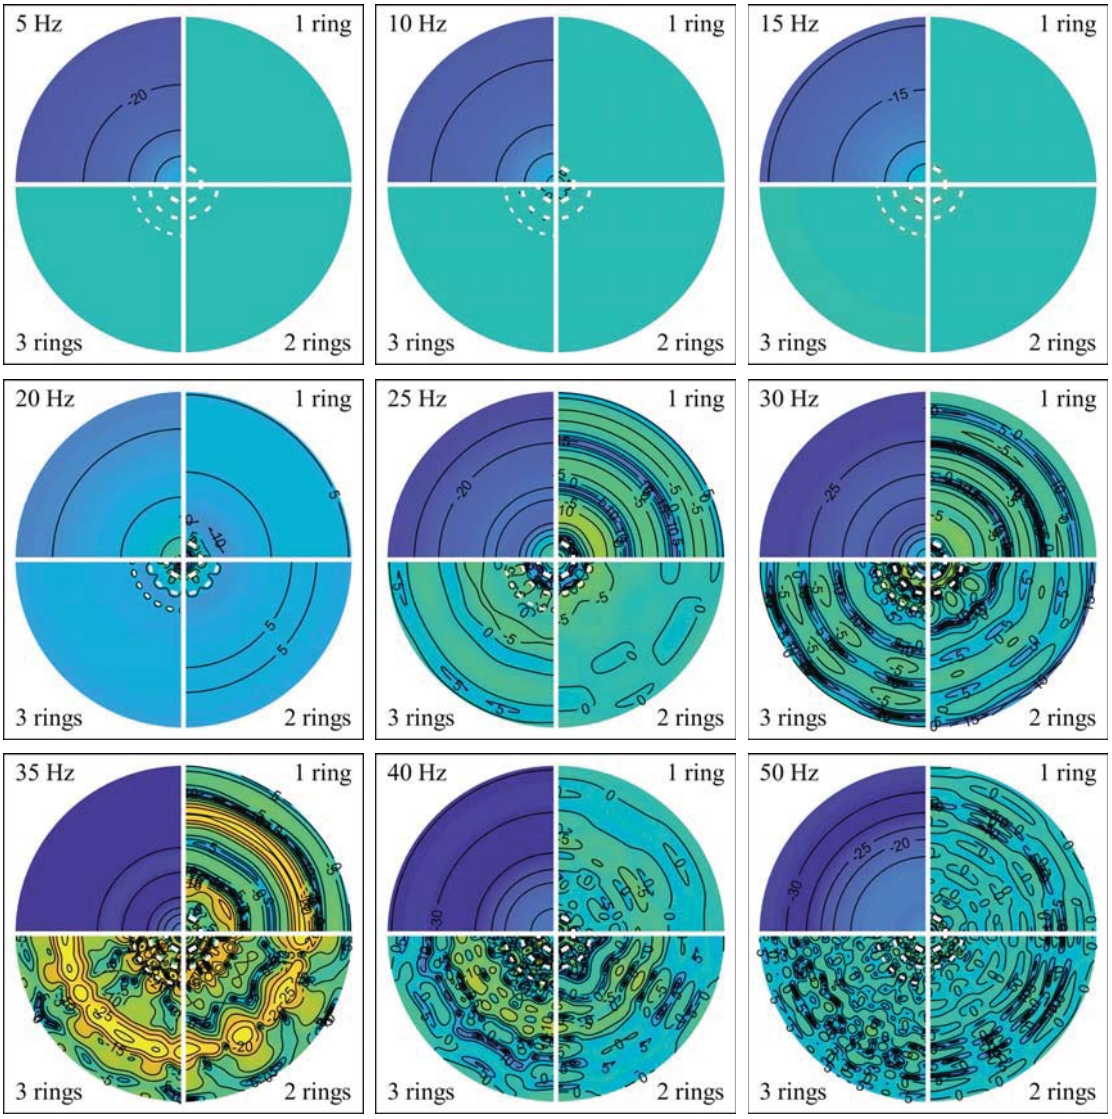

Figure 5: Contours of the reference vibration levels and ILs (in dB) for Case 1.2 with 1, 2, or 3 rings. The centre blocks are 2 m high and the vertical load is applied 8 m below the ground surface. Pale yellow/dark blue shades represent unfavourable/favourable values, respectively.

that the vibrations will not be trapped within, and guided by, the soft topsoil layer. In any case, the resulting vibration level in the receiver zone can be found as the RL minus the IL. Since the mean value of $\mathrm{RL}_3^8 - \mathrm{IL}_3^{8j}$ is well below zero for all considered frequencies, the poor performance of the WIB arrays for the deeper source has limited consequences for the overall quality of the mitigation technique. Instead, the WIB arrays imply a significant reduction of the vibration level when the load is applied within the soft top layer, exemplified by $y_{3\,2} = -2$ m. At these frequencies, the RL is around 0 dB. With reference to Table 2 and Figure 2, the larger values of IL_3^{2j} are present within the frequency range where the WIBs may resonate. Hence, depending on the soil stiffness, the WIBs can be designed to resonate in the frequency range for which a high IL is required. The size of the blocks and their the height relative to the footprint are design variables. To make adjustments on site, the height can be changed, e.g., by filling more soil or granulated concrete into containers, such as large construction waste-bags.

4 CASE 2: 5 METRES OF SOFT CLAY OVER A HALF-SPACE OF LIME

The site considered in Case 2 has a 5 m layer of soft wet clay underlain by a lime half-space. The material properties are given in Table 3, and it is noted that the clay is slightly softer than the sand considered in Case 1. Combined with the deeper top layer, this provides a lower cut-on frequency, around 7 Hz, compared to the cut-on frequency of 12.5 Hz in Case 1.

The resonance frequencies of the blocks within the WIB arrays can be found in Table 4. Notably, the resonance frequencies associated with the heave and pitch modes are higher than those in Case 1 (cf. Table 2), whereas the resonance frequencies related to sliding are lower. This can be explained by the soil deformation involved in the different modes of vibration. For the heave and pitch modes, the vertical motion of the SSI interfaces is important. Here, the impedance depends on the compressibility of the soil, which is low due to the high Poisson's ratio (0.4942) corresponding to nearly incompressible behaviour) compared to the Poisson's ratio in Case 1 (0.3330). On the other hand, the sliding mode is mainly influence by the shear stiffness, and since the shear modulus in Case 2 is about 10% lower than that in Case 1, the resonance frequency for the sliding mode can be expected to be lower as well.

Figure 6 shows the mean and quantile values of RL_3^2 and IL_3^{2j} (load placed at $y_{3\,2} = -2$ m) for Cases 2.1, 2.2, and 2.3, i.e. with block heights of 1 m, 2 m and 3 m, respectively, in Ring 1. Example results for the local variations within Case 2.3 are shown in Figure 7. Similarly, results for the load placed 8 m below the ground ($y_{3\,8} = -8$ m) are shown in Figure 8 and Figure 9.

For the load acting within the soft clay layer, 2 m below the ground surface, the reference vibration level within the receiver zone is small (about –45 dB) for frequencies below the cut-on frequency. A rapid increase in the RL can be seen from 7 Hz and up to about 14 Hz, where the TL has its maximum, around 7–8 dB. Beyond this peak, an almost linear monotonous decrease can be observed, reaching approximately –20 dB at 80 Hz.

The WIB arrays generally provide positive insertion loss when the load is placed at a depth of 2 m. With a block height of 1 m in Ring 1, the array delivers up to about 5–10 dB reduction in the vibration level within the receiver zone for the considered frequency range above 25 Hz. The effect of the second ring begins at around 30 Hz, and the third ring contributes to a further increase of the mean IL for frequencies above 35 Hz. The 2 m high blocks produce a mean IL comparable to that of the 1 m high blocks in most of the considered frequency range. As expected, a slight shift in the mean IL peaks towards lower frequencies can be seen. When the block height is further increase to 3 m, a significantly larger mean IL is obtained in the frequency range 18–25 Hz. The peak in the mean IL reaches 15 dB, independently of the number of rings in the array. However, the peak is slightly wider when two or three rings are present,

Soil layer (from top)	Shear modulus G [MPa]	Poisson's ratio ν [-]	Mass density ρ [kg/m^3]	Loss factor η [%]	Thickness h [m]
Clay, *soft, wet*	30.03	0.4942	1 694	4.50	5.0
Lime (half-space)	4 300	0.3500	2 100	2.00	∞

Table 3: Soil properties for Case 2.

	Blocks in Ring 1			Blocks in Ring 2			Blocks in Ring 3		
	Heave	Sliding	Pitch	Heave	Sliding	Pitch	Heave	Sliding	Pitch
Case 2.1	36.0	29.0	25.7	44.0	35.6	33.2	54.7	44.5	39.2
Case 2.2	25.4	20.5	9.85	31.1	25.2	12.9	38.7	31.4	15.0
Case 2.3	20.8	16.8	5.45	25.4	20.6	7.17	31.6	25.7	8.31

Table 4: Resonance frequencies (in Hz) of the blocks in Case 2.

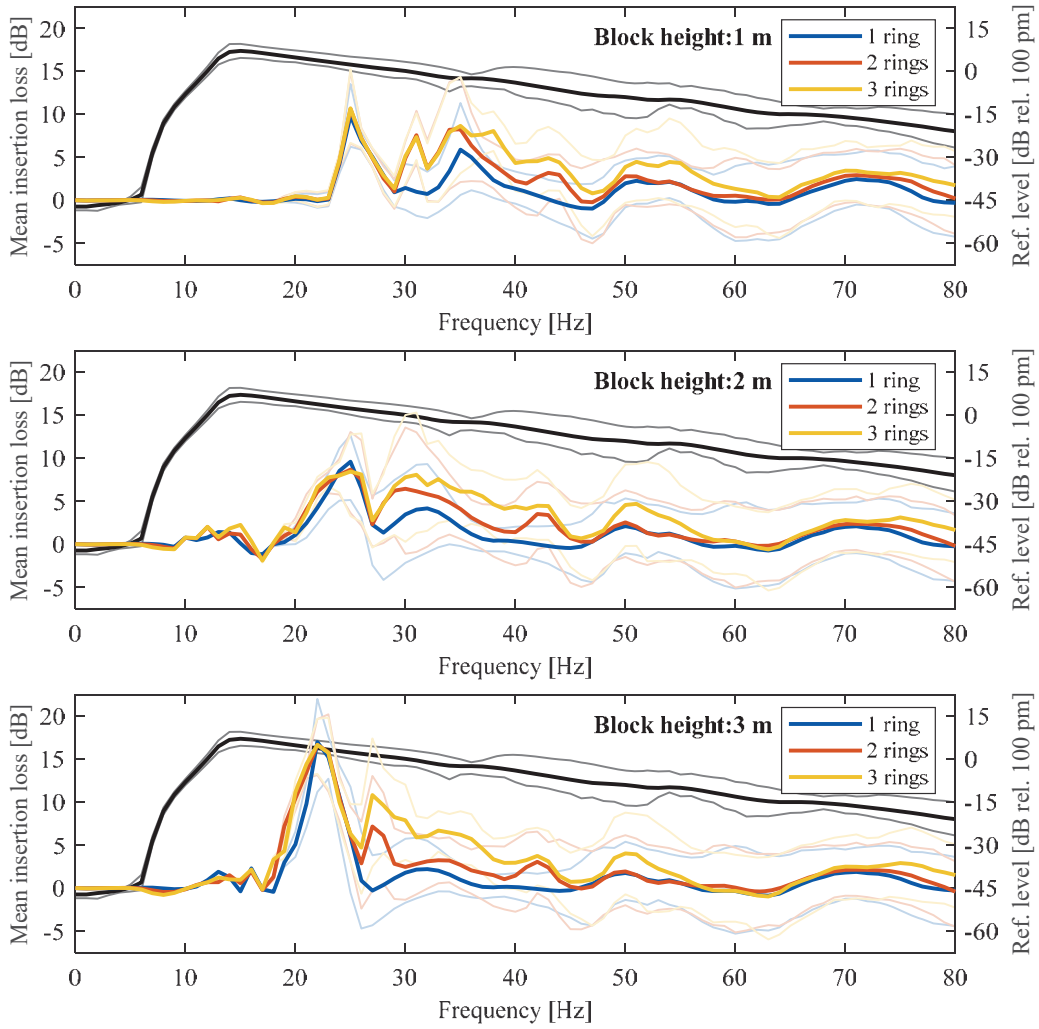

Figure 6: Mean ILs for the ground vibration within the donut-shaped surface area placed 20–40 m away from the centre of the load: Cases 2.1, 2.2, and 2.3 with the load acting 2 m below the ground. The black line shows the reference level of vibrations and the thin lines show the 10% and 90% quantiles of the respective quantities.

compared to the case with only one ring. For frequencies beyond 25 Hz, the ILs for Cases 2.1–2.3 are similar. Like it was found for Case 1, it can be observed that the WIB arrays have an effect in the frequency range where the WIBs may resonate.

The variations of the RL and IL produced by the 3 m high blocks (Case 2.3) are shown in Figure 7. Again, it is clearly seen that the effect of the WIB array is limited at low frequencies. The large IL observed around 18–25 Hz is also visible in this figure. However, even if the mean IL was previously found to reach nearly the same magnitude (15 dB), the subplots for the frequencies 20 and 25 Hz in Figure 7 show that the mean IL is the result of very different distributions for the array with only one ring versus the arrays with two or three rings. Especially, at 20 Hz the IL field is much more homogeneous and generally higher with two or three rings. This explains why the mean IL peak in Figure 6 is narrower for the array with one ring, and it also explains why the 10% and 90% quantile values are lower and higher, respectively, for one ring compared to two or three rings. Finally, at 30 Hz, zones with negative IL appear. A similar observation can be made for Case 1, with reference to Figure 3, where zones with negative IL

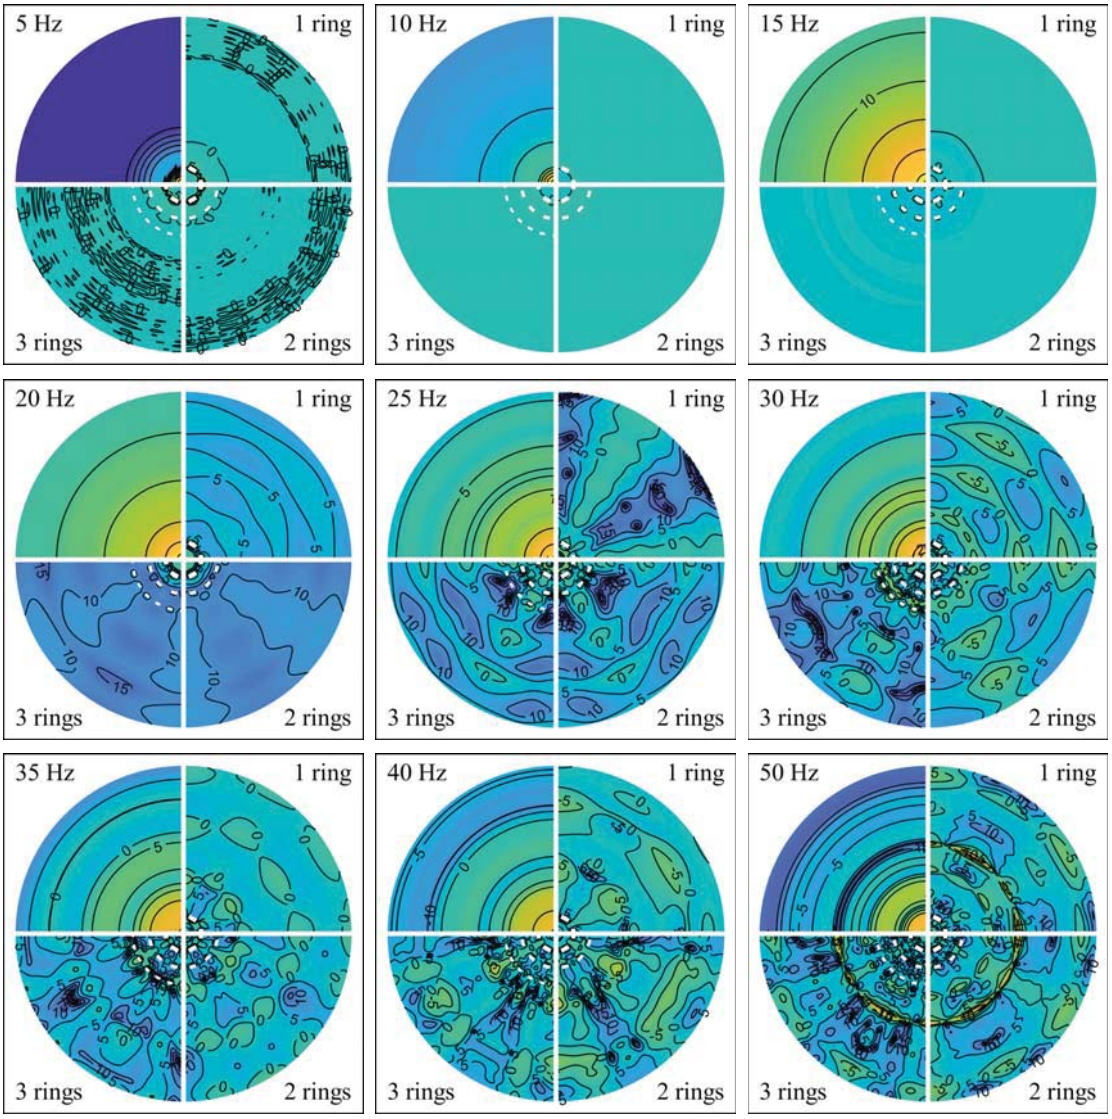

Figure 7: Contours of the reference vibration levels and ILs (in dB) for Case 2.3 with 1, 2, or 3 rings. The centre blocks are 3 m high and the vertical load is applied 2 m below the ground surface. Pale yellow/dark blue shades represent unfavourable/favourable values, respectively.

appear at 50 Hz. However, the mean IL is still positive at e.g. 50 Hz for both cases, when the load is applied 2 m below the ground surface (see Figures 2 and 4). For some higher frequencies, especially around 65 Hz in Case 1, a slightly negative mean IL is obtained. This should be seen in the context of the RL which is about 15–20 dB lower here compared to the maximum that occurs at around 20 Hz and 14 Hz in Cases 1 and 2, respectively. Further, the load spectra associated with pile driving can be expected to have less energy at higher frequencies.

Figure 8 shows the mean and quantile values of the RL and ILs in the receiver zone within Case 2, when the load is applied at 8 m depth. The RL is consistently below –35 dB rel. 100 pm in the entire frequency range relevant to whole-body vibration, i.e. up to 80 Hz. This is different when compared to Case 1, where an RL up to about –10 dB was obtained for frequencies slightly higher than the cut-on frequency of 12.5 Hz. A small local peak is also present in Case 2 for frequencies just above the cut-on frequency which is here around 7 Hz. However, this peak

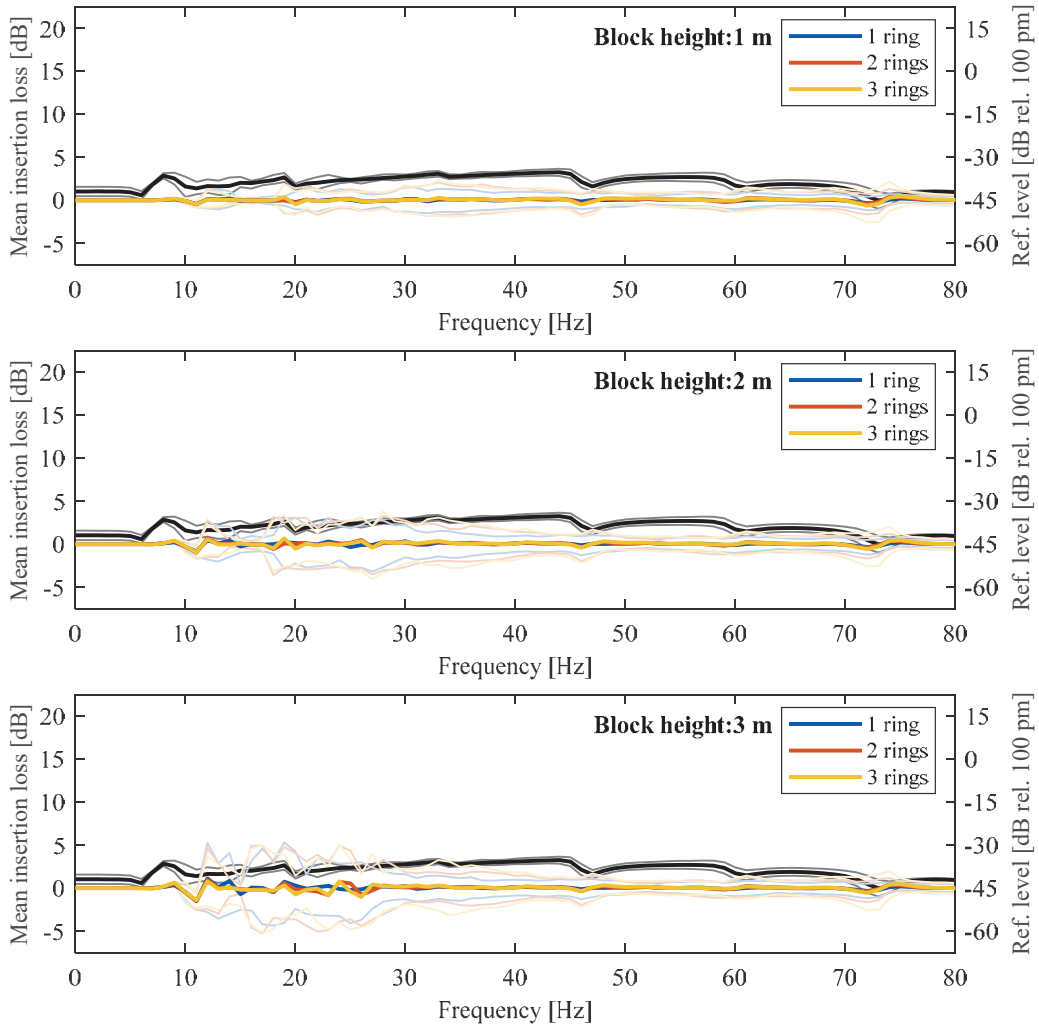

Figure 8: Mean ILs for the ground vibration within the donut-shaped surface area placed 20–40 m away from the centre of the load: Cases 2.1, 2.2, and 2.3 with the load acting 8 m below the ground. The black line shows the reference level of vibrations and the thin lines show the 10% and 90% quantiles of the respective quantities.

is much less pronounced, indicating that only a very small amount of the energy travelling within the ground enters the topsoil layer when the load is applied withing the lime half-space. This can be explained by the large impedance mismatch between the soft clay and the lime.

Compared to Case 1, more specifically by comparing Figures 4 and 8, it can be observed that the mean IL in Case 2 is nearly zero when the load is applied within the lime half-space, whereas some variation occurred in Case 1, when the load was applied within the till half-space. The very low impact of the WIB arrays on the IL can also be seen in Figure 9 which further shows that the number of rings has very limited influence. In Case 2 it is therefore even more pronounced, compared to Case 1, that the critical scenario will be related to loads applied within the soft topsoil. When the load acts within the deeper and stiffer soil, the transfer mobility to the ground surface is low.

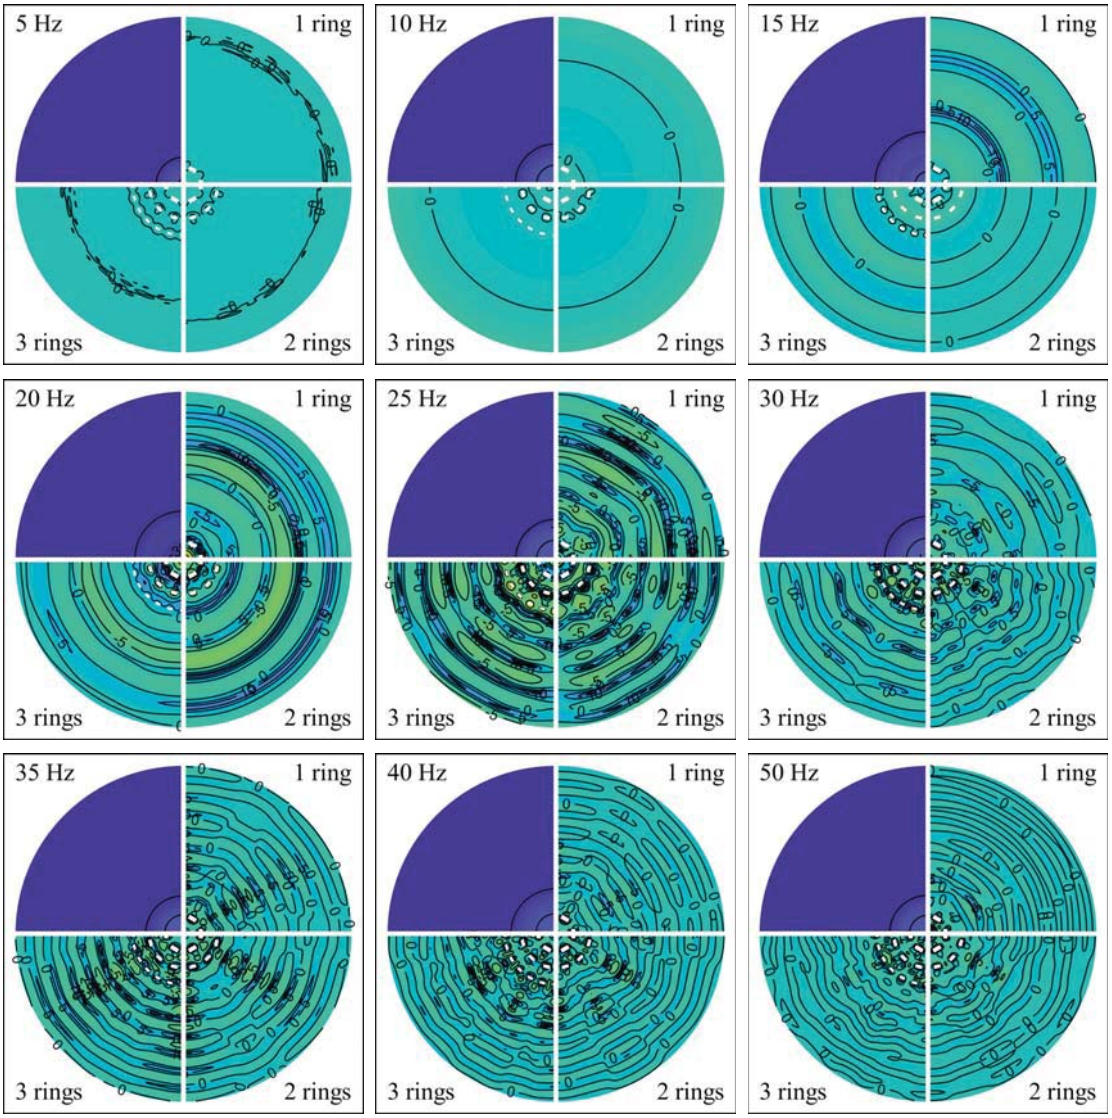

Figure 9: Contours of the reference vibration levels and ILs (in dB) for Case 2.3 with 1, 2, or 3 rings. The centre blocks are 3 m high and the vertical load is applied 8 m below the ground surface.

5 CONCLUSIONS AND SUGGESTIONS FOR FURTHER RESEARCH

Based on a semi-analytical model of a layered soil, the insertion loss provided by circular arrays of monolithic blocks placed on the ground surface has been studied. It has been found that blocks placed in a so-called “Stonehenge” configuration effectively reduce the ground vibration level in a receiver zone 20–40 m away from the position at which a pile is driven into the soil. For two different cases, both of which consider a soft topsoil underlain by a stiffer half-space, an insertion loss of about 5–20 dB can be obtained by using blocks that could, on a construction site, be made from appropriate containers infilled with excavated soil or some heavy construction waste material. Adding more rings of wave impedance blocks to the array

will in most cases increase the insertion loss, but with an optimal tuning of the resonance frequencies, a significant reduction in the vibration level in the receiver zone can be achieved, even with a single ring of blocks, demonstrating the large mitigation potential of the solution.

In the present analyses, the pile has not been modelled explicitly. Instead, loads have been applied at different depths, in the soft topsoil or in the stiff half-space. When a pile is driven, forces will be transferred to the surrounding soil simultaneously along the shaft and the at the tip. Depending on the relative strengths of the soil down along the pile, the excitations produced along the shaft or at the tip may dominated. However, this cannot be modelled correctly by a simple viscoelastic model. Further research on the energy transfer mechanism between the pile and the soil is proposed in order to achieve more detailed quantification of the overall mitigation potential of circular block arrays.

Further, based on the observation that the block arrays are effective within the frequency range where the blocks may resonate, an optimization of the individual blocks is proposed for a future study. This can be combined with the optimization of the full array, focussed on placing the blocks on the ground such that the interference pattern of the scattered waves leads to an overall minimization of the transfer mobility within a selected receiver zone and for a given range of frequency.

Despite the shortcomings of the computational model, and knowing that a further potential for optimization exists, this study shows promise for an innovative technique where mitigation is placed *on* the ground surface which inhibits the transmission of vibration from *within* the body of the ground. Within the context of ground vibration, the method established here could be expected to apply to other scenarios with different source characteristics, i.e. different pile-driving methods. Developed further there could also be potential to study various source-types such as blasting or shock-vibration.

Keywords: Soil-Structure Interaction, Boundary Element Method, Finite Element Method, BEM-FEM coupling, Time Domain.

Abstract. *In this contribution, we present the implementation of the coupling between the Finite Element Method (FEM) and the Boundary Element Method (BEM) in the time domain, for the analysis of the Soil-Structure Interaction (SSI) in the three dimensional space. The Boundary Element Method is based on the transient fundamental solutions for the half-space. The coupling between the BEM and the FEM is obtained using the soil's stiffness matrix and the soil reaction forces, which result from a convolution integral. The coupling is implemented linking the software MATLAB with the software ANSYS. The system of equations is solved in ANSYS and within the solution step MATLAB is activated to calculate the soil's stiffness matrix and the interaction forces at the interface between soil and structures at the current time step. Verification examples for static and dynamic cases are presented. A case study for a seismic excitation is presented to show the applicability of the proposed method.*

1 INTRODUCTION

The dynamic interplay between the buildings and the underlying soil is referred to as Soil-Structure Interaction (SSI). The soil acts both as a compliant support with a frequency-dependent flexibility and as a energy absorber, due to its infinite size. For certain combinations of buildings and soil, the SSI may lead to an amplification of the dynamic response w.r.t. the static response of the whole system, to a shift of the natural frequencies of the buildings and to a change in damping properties. Therefore, it is important to account for the dynamic behavior of the soil and its effect on the dynamic behaviour of the structures placed on it.. The main difficulty of simulating the SSI is related to the infinite size of the soil, for which the Sommerfeld radiation condition must be fulfilled.

Different methods exist to account for the SSI in seismic analysis of buildings, the most popular of which are the Finite Element Method (FEM), the Finite Difference Method (FDM) and the Boundary Element Method (BEM). A detailed state of the art can be found in [1].

For FEM the whole domain is discretised whereas in the BEM only the boundaries are divided into elements. Consequently, the dimension of the problem is reduced by one when using BEM. This leads to less necessary storage space. Moreover, the BEM can achieve higher accuracy for the results, since it uses fundamental solutions as weighting functions. These fundamental solutions fulfill exactly the boundary conditions.

Although research has been conducted on boundary elements since the 1960s, BEM is not as established as the FEM, mainly due to the fully populated system of equations generated by the BEM and the requirement of the existence of suitable fundamental solutions for the investigate soil systems (such as an homogeneous half space, a layered half space, etc...). Additionally, several commercial tools made the FEM user-friendly and versatile, while the BEM is rarely available as a ready-to-use black box. An extensive overview of the development of BEM can be found in [2].

The BEM for SSI can be used both in the Time Domain (TD) and in the Frequency Domain (FD), depending on the available fundamental solutions (also called Green's functions). The TD-BEM can be used for nonlinear problems and can lead to less computational effort for transient loads with a narrow frequencies spectrum. As a matter of fact, the transient fundamental solutions have a bounded support, while the FD fundamental solutions never vanish.

From general descriptions of the coupling of BEM and FEM for elastodynamics [3][4][5], the application to SSI problems was straightforward [6].

Further improvements of the BEM for SSI were achieved by using fundamental solutions for the half-space instead of the full space [7]. Depending on the given problem, the suitable fundamental solution can be chosen among the available ones [8] to optimize the computation. Several studies have been conducted on the topic of BEM for 2D- and 3D-structures in the time domain dealing with different issues, such as the choice of the suitable fundamental solutions (e.g. [9] and [10]) or the coupling of incompatible interfaces of BEM and FEM for 2D boundary elements ([11]).

Recently, Vasilev et al. [12] developed a hybrid computational tool, based on the FEM/BEM coupling. The hybrid numerical scheme is realized via the sub-structure approach, integrating the seismically active far-field geological media as a macro-finite element in the commercial program ANSYS. Here, they assume a plane strain state.

Galvin and Romero [13] developed a numerical tool *SSIFiBo* in MATLAB to study dynamic soil-structure interaction problems. The model is based on a three dimensional TD-BEM. This model allows computing structural forced-vibrations, as well as seismic responses.

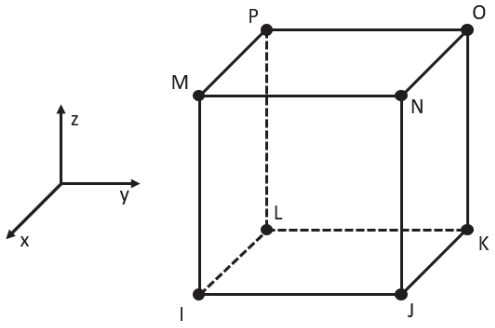

Figure 1: Notation of nodes for *SOLID185*, according to [18, p. 960]

Schepers [14] improved an existing customization of ANSYS [15] [16] [17] which allows FEM-BEM coupling of structures at the surface of an arbitrarily layered half-space, both in time and frequency domain.

In this work, we present the *Ssibefe* tool, a FEM-BEM coupling where the FEM subsystem (the building) is modeled using ANSYS and the BEM subsystem (the soil) is treated using MATLAB. The loading can be applied to the FEM elements and nodes and/or can be defined as a propagating transient plane wave in the soil with an arbitrary angle of incidence w.r.t the surface. Pre- and postprocessing is performed in ANSYS. The TD fundamental solutions for the homogenous half-space are taken from [8] and the procedure for the implementation is similar to the one described by [15], [16] and [17].

2 METHODS

2.1 MODELLING THE STRUCTURE WITH THE FINITE ELEMENT METHOD

The equation of motion for the structure reads:

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{C}\dot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) = \mathbf{P}(t) + \mathbf{Q}(t), \tag{1}$$

where $\mathbf{M}$ is the mass matrix, $\mathbf{C}$ the damping matrix, $\mathbf{K}$ the stiffness matrix, $\mathbf{u}(t)$ the displacements and $\mathbf{P}(t)$ the external loading. All the aforementioned vectors and matrices can be determined as usual by means of classical FEM formulations. The key vector in this formulation is the vector $\mathbf{Q}(t)$, which contains the soil reactions at the interaction nodes. This is unknown and represents the influence of the soil as nodal forces, which result from the contact pressure at the soil–structure interface. This can be computed with the BEM formulation, described in section 2.2.

The analysis of the finite system is done with the commercial software *Ansys Mechanical APDL 2019 R2*. The structure is modelled by 3D solid elements, specifically the *SOLID185*-elements, which consist of 8 nodes [18]. The arrangement of the nodes is depicted in fig. 1.

2.2 MODELLING THE SOIL WITH THE BOUNDARY ELEMENT METHOD

2.2.1 Theoratical Background

At the heart of the TD-BEM used here lies the transient fundamental solutions for the 3D the half space subjected to a vertical or horizontal unit point load on the surface, that changes

in time as a Heaviside function (s. annex A). These satisfy the traction-free condition at the surfaces of the soil and the Sommerfeld radiation condition.

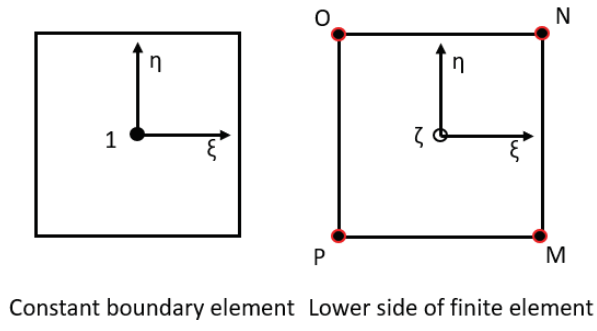
We start from the discretized form of the boundary integral formulation of the Lamé-Navier equation [19], in absence of body forces. At first the time dependency is not considered and will be treated separately in section 2.3. The displacements $\mathbf{w}^i$ at point i on the soil surface can be written as:

$$\mathbf{c}^i\mathbf{w}^i(\mathbf{x}^i) = \sum_{e=1}^{E}\sum_{n=1}^{N} \mathbf{q}_n^e \int_{S_e} \mathbf{N}_n \mathbf{g}(\mathbf{x},\mathbf{x}^i) dS - \sum_{e=1}^{E}\sum_{n=1}^{N} \mathbf{w}_n^e \int_{S_e} \mathbf{N}_n \mathbf{t}(\mathbf{x},\mathbf{x}^i) dS \tag{2}$$

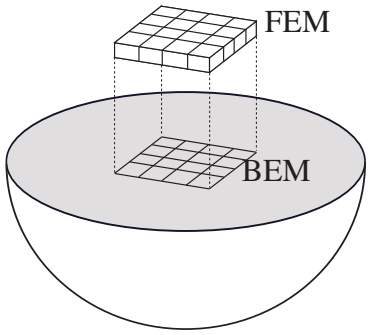
with

$\mathbf{g}(\mathbf{x},\mathbf{x}^i)$: fundamental solution for the displacements evaluated at point $\mathbf{x}^i$ for loads at $\mathbf{x}$
$\mathbf{t}(\mathbf{x},\mathbf{x}^i)$: fundamental solution for the tractions evaluated at point $\mathbf{x}^i$ for loads at $\mathbf{x}$
$\mathbf{q}_n^e$: nodal forces at point $\mathbf{x}^i$
$\mathbf{w}_n^e$: nodal displacements at point $\mathbf{x}^i$
$\mathbf{N}_n$: shape functions of nodes at point $\mathbf{x}^i$
$\mathbf{c}^i$: geometrical coefficient, which is related to the the position of the load and contains unitary values at the soil surface for a smooth boundary
N, E, S_e: number of nodes per element, number of elements and area of each element respectively.

We assume constant tractions on each boundary element. Therefore, each boundary element has only one node at the centre of the bottom surface of the coupled finite element. The elements are pictured in fig. 2a. Here, the red circled nodes define the contributing coupling nodes.



(a) Coupling nodes for constant shape functions.



(b) Coupling surface.

Figure 2: Coupling between soil and structure.

We consider Heaviside-time-varying unit forces for each nodal component of displacements and tractions. If the load position is located inside the domain, the stresses $\mathbf{t}(\mathbf{x},\mathbf{x}^i)$ on the surface are equal to zero and only the first part of the right side of eq. (2) will be considered in further derivations, leading to the following expression for the the displacements:

$$\mathbf{c}^i\mathbf{w}^i(\mathbf{x}^i) = \sum_{e=1}^{E}\sum_{n=1}^{N} \mathbf{q}_n^e \Delta\mathbf{G}_n^e \tag{3}$$

where

$$\Delta\mathbf{G}_n^e = \int_{-1}^{1}\int_{-1}^{1} \mathbf{N}_n(\xi,\eta)\mathbf{g}(\mathbf{x},\mathbf{x}^i(\xi,\eta))J(\xi,\eta)d\xi d\eta \tag{4}$$

Here, $J(\xi, \eta)$ denotes the determinant of the Jacobian for the transformation of coordinates from the original Cartesian to a local element reference coordinate system.

To obtain the flexibility matrix of the soil, the integral in eq. (3) is evaluated $(E \cdot N)^2$ times. The integral is performed for all the interaction nodes as an observation point and with the loading position being located on every interaction node (collocation point method). This leads to a matrix $\mathcal{G}^{ji}$, where the rows j indicate the loading position information whereas the columns i indicate the observation position information. Once the unitary coefficients $\mathbf{c}^i$ are included in the system matrix, eq. (3) can be written in matrix form as:

$$\mathbf{w} = \mathcal{G}\mathbf{q} \tag{5}$$

The fundamental solution $\mathbf{g}(\mathbf{x}, \mathbf{x}^i)$ is a antisymmetrical second order tensor, originally defined in cylindrical coordinates, as described in annex A:

$$\mathbf{g}^{\text{cyl}} = \begin{bmatrix} g_{rr} & 0 & g_{rz} \\ 0 & g_{\phi\phi} & 0 \\ g_{zr} & 0 & g_{zz} \end{bmatrix} \tag{6}$$

with $g_{zr} = -g_{rz}$. The transformation from cylindrical to Cartesian coordinates is performed according to [15] (s. annex B).

Following the suggestions in [20], if the loading point $\mathbf{x}$ coincides with the observation point $\mathbf{x}^i$, a $1/r$-singularity occurs. This integration is solved using a transformation to polar coordinates according to [21] (s. annex C).

Summarizing, eq. (5) says that the interaction of the soil with any other elastic body at its surface can be represented by integrals over the contact surface and a force-displacement relationship can be established to built the stiffness or flexibility matrix of the soil.

The fundamental solutions depend on the dimensionless time τ which in turn depends on on the time t. The time dependency will be treated in the next section.

2.3 Time discretization

According to [15], for the application of the proposed method in the time domain, the displacement at the current time depends on the current contact pressures and on its history and is obtained with a convolution integral. For a Heaviside loading function, the second Duhamel integral is performed:

$$\begin{aligned} \mathbf{w}(t) &= \mathcal{G}(t) \otimes \mathbf{q}(t) \\ \mathbf{w}(t) &= \mathbf{q}(0)\mathcal{G}(t) + \int_0^t \mathcal{G}(t-\tau)\frac{d\mathbf{q}(\tau)}{d\tau}d\tau = \int_0^t \mathcal{G}(t-\tau)\frac{d\mathbf{q}(\tau)}{d\tau}d\tau. \end{aligned} \tag{7}$$

The transient fundamental solutions are captured in the matrix $\mathcal{G}(t)$

$$\mathcal{G}(t) = \begin{bmatrix} \mathcal{G}_{xx}(t) & \mathcal{G}_{xy}(t) & \mathcal{G}_{xz}(t) \\ \mathcal{G}_{yx}(t) & \mathcal{G}_{yy}(t) & \mathcal{G}_{yz}(t) \\ \mathcal{G}_{zx}(t) & \mathcal{G}_{zy}(t) & \mathcal{G}_{zz}(t) \end{bmatrix}. \tag{8}$$

The integral is split into intervals of the length Δt. By calculating the mean of the upper and lower value, the soil displacements for the time step $i+1$ can be deduced

$$\mathbf{w}^{i+1} = \frac{\mathcal{G}^{i+1} - \mathcal{G}^{i}}{2}\cancelto{0}{\mathbf{q}^0} + \frac{\mathcal{G}^{i+1} - \mathcal{G}^{i-1}}{2}\mathbf{q}^1 + \ldots + \frac{\mathcal{G}^{1} - \cancelto{0}{\mathcal{G}^0}}{2}\mathbf{q}^{i+1} \tag{9}$$

Subsequently, the flexibility of the soil is obtained after inserting the following abbreviations valid for constant time step duration for the whole simulation

$$\begin{aligned} \mathbf{F}^i &= \frac{1}{2}\left(\mathcal{G}^{i+1} - \mathcal{G}^{i-1}\right) \\ \mathbf{F}^{cur} &= \frac{1}{2}\mathcal{G}^1 = \frac{1}{2}\mathcal{G}(\Delta t) \end{aligned} \tag{10}$$

and considering the initial condition $\mathbf{q}^0 = 0$ and the relation $\mathcal{G}^0 = 0$, which results from causality, the deformations of the soil yield

$$\mathbf{w}^{i+1} = \underbrace{\mathbf{F}^i\mathbf{q}^1 + ... + \mathbf{F}^1\mathbf{q}^i}_{\mathbf{w}^{hist}} + \mathbf{F}^{cur}\mathbf{q}^{i+1} \tag{11}$$

If, additionally, a seismic excitation $\mathbf{s}$ occurs, one has to substitute the absolute displacements at the interaction nodes $\mathbf{w}^{i+1}$ with the relative displacements $(\mathbf{w}^{i+1} - \mathbf{s}^{i+1})$ to get

$$\mathbf{w}^{i+1} = \mathbf{w}^{hist} + \mathbf{F}^{cur}\mathbf{q}^{i+1} + \mathbf{s}^{i+1} \tag{12}$$

3 Implementation of the coupling

First, interaction nodes are defined, which are located at shared surfaces of the structure and the soil.

Fig. 2b shows the coupling surface between BEM and FEM for a square foundation. Since the numbering of the nodes is different for the BEM and the FEM subsytem, different letters identify different quantities:

- $\mathbf{u}_I$: displacements of the structure according to the nodal ordering of FEM at the interaction surface
- $\mathbf{v}$: displacements of the structure for nodal ordering of BEM at the interaction surface
- $\mathbf{w}$: displacements of the soil for nodal ordering of BEM at the interaction surface

The transformation matrices $\mathbf{T_u}$ and $\mathbf{T_q}$ help to couple the displacements of the two subsystems at the interface. These matrices are described in annex D.

From eq. (12), the soil's contact pressure can be computed as

$$\mathbf{q}^{i+1} = [\mathbf{F}^{cur}]^{-1}(\mathbf{w}^{i+1} - \mathbf{w}^{hist} - \mathbf{s}^{i+1}) \tag{13}$$

To satisfy compatibility at the interaction surface the structural displacements must equal the soil's displacement

$$\mathbf{w}^{i+1} = \mathbf{v}^{i+1} = \mathbf{T}_u\mathbf{u}_I^{i+1} \tag{14}$$

The soil reaction forces at the FEM nodes result from the combination of eq. (14) with eq. (15) as

$$\mathbf{Q}_I^{i+1} = \mathbf{T}_q\mathbf{q}^{i+1} = \underbrace{\mathbf{T}_q[\mathbf{F}^{cur}]^{-1}\mathbf{T}_u}_{\mathbf{K}_{soil}^{cur}}\mathbf{u}_I^{i+1} - \underbrace{\mathbf{T}_q[\mathbf{F}^{cur}]^{-1}\mathbf{w}^{hist}}_{\mathbf{Q}_I^{hist}} - \underbrace{\mathbf{T}_q[\mathbf{F}^{cur}]^{-1}\mathbf{s}^{i+1}}_{\mathbf{Q}_I^{seism}}, \tag{15}$$

where $\mathbf{K}_{soil}^{cur}$ is the soil's stiffness matrix.

Therefore, the equation of motion of the coupled problem becomes

$$\begin{bmatrix} \mathbf{M}_{RR} & \mathbf{M}_{RI} \\ \mathbf{M}_{IR} & \mathbf{M}_{II} \end{bmatrix} \begin{pmatrix} \ddot{\mathbf{u}}_R^{i+1} \\ \ddot{\mathbf{u}}_I^{i+1} \end{pmatrix} + \begin{bmatrix} \mathbf{C}_{RR} & \mathbf{C}_{RI} \\ \mathbf{C}_{IR} & \mathbf{C}_{II} \end{bmatrix} \begin{pmatrix} \dot{\mathbf{u}}_R^{i+1} \\ \dot{\mathbf{u}}_I^{i+1} \end{pmatrix} + \begin{bmatrix} \mathbf{K}_{RR} & \mathbf{K}_{RI} \\ \mathbf{K}_{IR} & \mathbf{K}_{II} + \mathbf{K}_{soil}^{cur} \end{bmatrix} \begin{pmatrix} \mathbf{u}_R^{i+1} \\ \mathbf{u}_I^{i+1} \end{pmatrix} = \begin{pmatrix} \mathbf{P}_R^{i+1} \\ \mathbf{P}_I^{i+1} \end{pmatrix} + \begin{pmatrix} 0 \\ \mathbf{Q}_I^{hist} + \mathbf{Q}_I^{seism} \end{pmatrix} \tag{16}$$

where I indicated the degrees of freedom (DOFs) at the interaction nodes, whereas the remaining DOFs are marked with R.

The flexibility matrix of the soil $\mathbf{F}^i$ in eq. (10) has to be calculated for every time step to deduce the quantity $\mathbf{w}^{hist}$.

The structural displacements $\mathbf{u}_I^i$ at the interaction nodes are computed by ANSYS at every time step and used to compute the soil reaction forces at $i+1$. The soil stiffness is added to the structure's stiffness through a user-defined super-element in ANSYS (element type *MATRIX50*) and the soil reactions are applied as external loads at the interaction nodes. The master DOFs of the soil super-element are the DOFs of the coupling nodes of the FEM-structure at the soil surface. With this configuration the system can be solved with usual solution routines in ANSYS. An overall calculation sequence for the proposed scheme is given in annex E.

It is to highlight, that, if the soil properties, the discretization of the elements at the interaction surface and the time step remain unchanged, a new analysis with different parameters and seismic and/or external loading can be carried out reusing the same flexibility matrix. This leads to a relevant reduction of computational time.

An interactive connection between MATLAB and ANSYS is created through the toolbox *aaS* (ANSYS as a Server) and the Mechanical APDL preprocessor and solver are accessed directly through MATLAB.

4 VERIFICATION

For the verification, we present the dynamic analysis of a rigid square foundation loaded with a Heaviside point load at its center. After the oscillation has decayed, the static displacement can be observed, so that also the static flexibility of the system can be compared to literature values. The results are compared to the ones found in [16], although we assume a Poisson's ratio $\nu = 0.25$ for the soil, while the reference results are computed with $\nu = 0.33$. As an additional reference, the static flexibility in different directions is compared to the reference values given in [22, p. 43].

As the results are normalized w.r.t. the quadratic foundation geometry and to the soil properties, the foundation side length a, the foundation thickness h, the shear modulus of the soil μ_s and the soil density ρ_s can be chosen arbitrarily. The Poisson's ratio is given ($\nu_s = 0.25$). The other problem parameters are given in tab. 1. In order to simplify the invetsigation, the Poisson's ratio of the foundation is set equal to 0, but could take any arbitrary value.

The vertical displacement u_z due to a vertical load P_z, the horizontal displacement u_x due to a horizontal load P_x, the rotation ϕ_y due to a moment around the y-axis M_y, the rotation ϕ_z due to a torsional moment M_z and finally the rotation ϕ_y due to a horizontal load P_x are examined. The loading starts at $\tau = \frac{tc_s}{a} = 1$. Two cases are investigated shown in fig. 4:

- massless foundation: the response follows the shape of the variation in time of the loading until it reaches a state of rest at $\approx \tau = 3$.

Table 1: Problem properties of the verification case.

Foundation density	massless foundation: $\rho_f = 0$
	massive foundation: $\rho_f = \frac{\rho_s}{h}\sqrt{\frac{a^2}{\pi}}$
Young's modulus of the foundation	$E_f \approx \mu_s * 10^{11}$
Poisson's ratio of the foundation	$\nu_f = 0$
Poisson's ratio of the soil	$\nu_s = 0.25$

- massive foundation: the foundation oscillated around the static response and, eventually, approaches the static solution at different times τ for the different directions of loading.

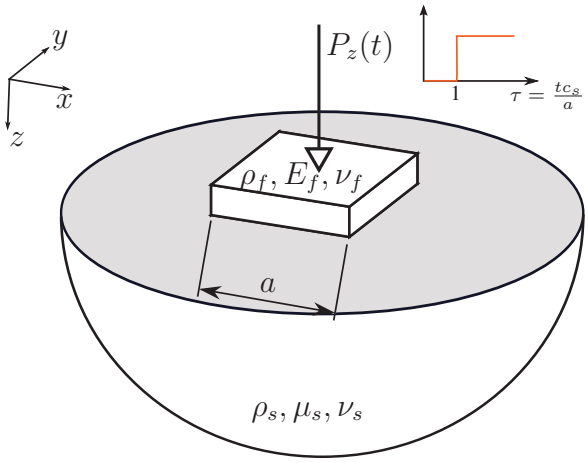


Figure 3: Verification case, shown for a vertical load.

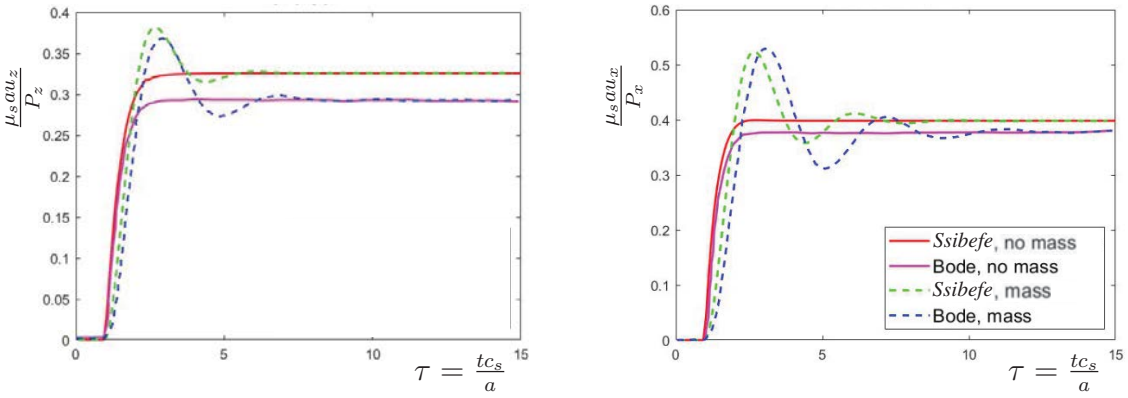
The foundation and the soil surface are discretised with 8×8 elements with the side length $l = a/8$. The time step size is chosen as $\Delta t = 0.75l/c_s$, where $c_s = \sqrt{\frac{\mu_s}{\rho_s}}$ is the shear wave velocity of the soil.

The static flexibility is deduced from the displacements at rest. These are then compared in tab. 2 to the results from [16, pp. 107-111] and from the static stiffness values in [22, p. 43].

	$\frac{\mu_s a}{P_z}u_z$	$\frac{\mu_s a}{P_x}u_x$	$\frac{\mu_s a^3}{M_y}\phi_y$	$\frac{\mu_s a^3}{M_z}\phi_z$	$\frac{\mu_s a^2}{P_x}\phi_y$
Ssibefe	0.326	0.398	1.551	1.050	0.067
Bode [16]	0.2951	0.379	1.419	0.940	0.064
discrepancy [%]	1.11	1.05	1.09	1.12	1.05
Wolf [22]	0.319	0.380	1.5	0.964	-

Table 2: Static flexibility of a rigid, massless foundation on a homogeneous half-space.

As can be observed in tab. 2, the results are in good agreement. Nevertheless, small discrepancies especially between [16] and the results from *Ssibefe* occur for all modes, because of the different Poisson's ratios used. This is also confirmed in fig. 4a and fig. 4b, which show the transient displacements for the vertical and horizontal case respectively. Considering the different Poisson ratios, the different methods show a satisfying agreement.



(a) Vertical displacement.

(b) Horizontal displacement.

Figure 4: Normalized displacements for a rigid square foundation subjected to a transient point load at the center in different directions.

5 SEISMIC APPLICATION OF THE *Ssibefe*

For the demonstration of the application of the *Ssibefe* for seismic problems, we present the dynamic analysis of an elastic cube of side length a resting on an elastic half space subjected to a seismic excitation resulting from an incident plane wave that propagates through the soil. Fig. 5 shows the investigated scenario.

Depending on the angle of incidence the wave, the direction of propagation and the time function, the seismic excitation at the interaction points $\mathbf{x}_I$ can be estimated according to eq. (17). The time function $s(t)$ of the plane wave can be chosen arbitrarily, from synthetic accelerogram to recorded data to analytical expressions. In this application, we assume a Ricker wavelet for the function $s(t)$, described by eq. (18) and plotted in fig. 6 for the specific loading parameters given in tab. 3.

$$\mathbf{s} = s\left(t - \frac{(\mathbf{x}_I - \mathbf{x}_0)^T \mathbf{n}}{c_{\text{ind}}}\right) \mathbf{s}_0 \tag{17}$$

$$s(t) = \left(1 - \pi^2 f_0^2 t^2\right) e^{\left(-\pi^2 f_0^2 t^2\right)} \tag{18}$$

The spectrum of the input is shown together with the output in fig. 9. In this application, the seismic wave propagates in the positive x-direction and the soil particles move along the x-axis, simulating a P-wave. The coordinates of the corner A of the building are $\mathbf{x} = [40\text{ m}, 5\text{ m}, 0\text{ m}]^T$ and the faces of the cubic building are oriented as the coordinate system.

The soil and structural properties are listed in tab. 5. The natural frequencies of the fixed-base cube are also given in tab. 4 for a better result interpretation. The element size is $l = 2.5$ m and the time step size is chosen equal to 0.025 s.

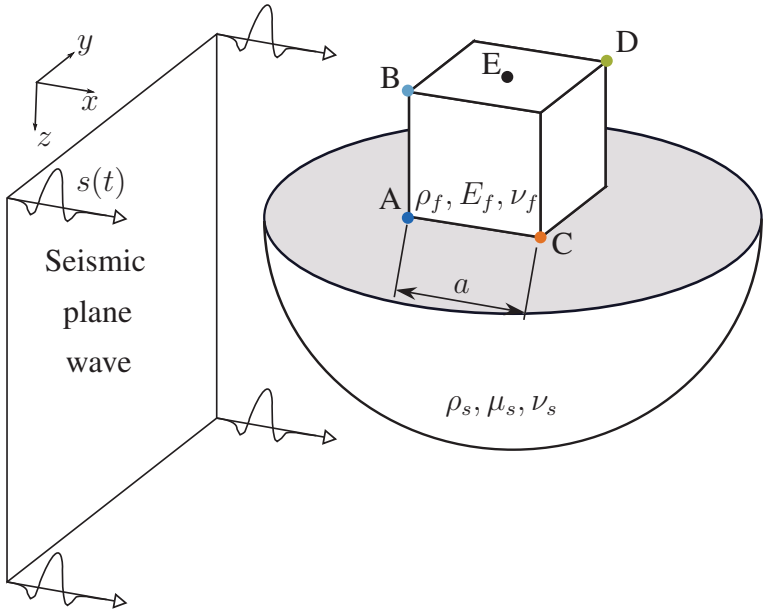


Figure 5: Building resting on an elastic half space subjected to a seismic excitation resulting from an incident plane wave that propagates through the soil.

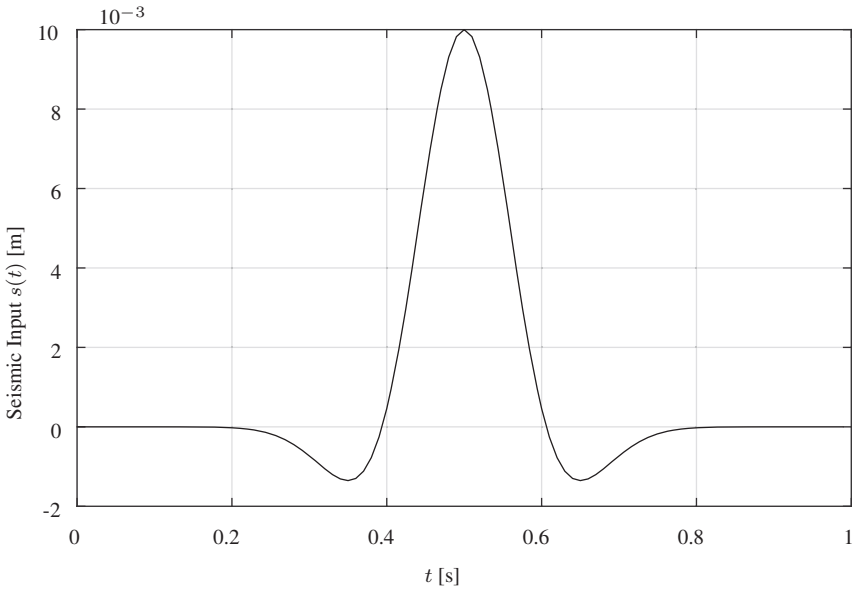

Figure 6: Time function of the seismic wave.

Table 3: Seismic load parameters.

Source position at $t = 0$	$\mathbf{x_0} = [0 \ 0 \ 0]^T$	[m]

1. axial	1.8322	[Hz]
2. bending x, y	2.0320	[Hz]
2. torsion/bending	2.5050	[Hz]
3. torsion/bending	3.0997	[Hz]
4. torsion/bending	3.1589	[Hz]
1. bending z	3.1680	[Hz]
2. axial/bending	3.5130	[Hz]

The results are compared to the ones obtained with the FEM/BEM coupling proposed by Bode [23], which runs on a ANSYS/FORTRAN Framework. The authors had the possibility to run the same identical example with both the existing framework [23] and the newly implemented *Ssibefe*. The only difference is the material damping in the soil, which we assumed equal to zero, while in Bode [23] it is small (0.1%) but not exactly zero. In the following discussion, only the horizontal displacements are shown, being those the largest. However, all the components of displacements and stresses can be computed.

Fig. 7 shows the horizontal displacements at the building base, at A and C. The delay of the wave arrival between the two points is correctly represented. Fig. 8 shows the horizontal displacements at the building top, at B and D and E. The spectra in fig. 9 show that the response at E is characterized by a natural frequency 0.6 Hz, which corresponds to the natural frequency of the 1st bending mode of the fixed-base building (0.76750 Hz) considering the influence of the soil. At the corners B and D also higher modes play an important role, as shown in fig. 9.

All the plots show good agreement between the reference results (Bode [23]) and the proposed results based on the *Ssibefe* tool. In general, there is a very slight difference of damping during the final oscillations, which leads to slightly different amplitudes and periods of oscillation. However, the difference can be neglected.

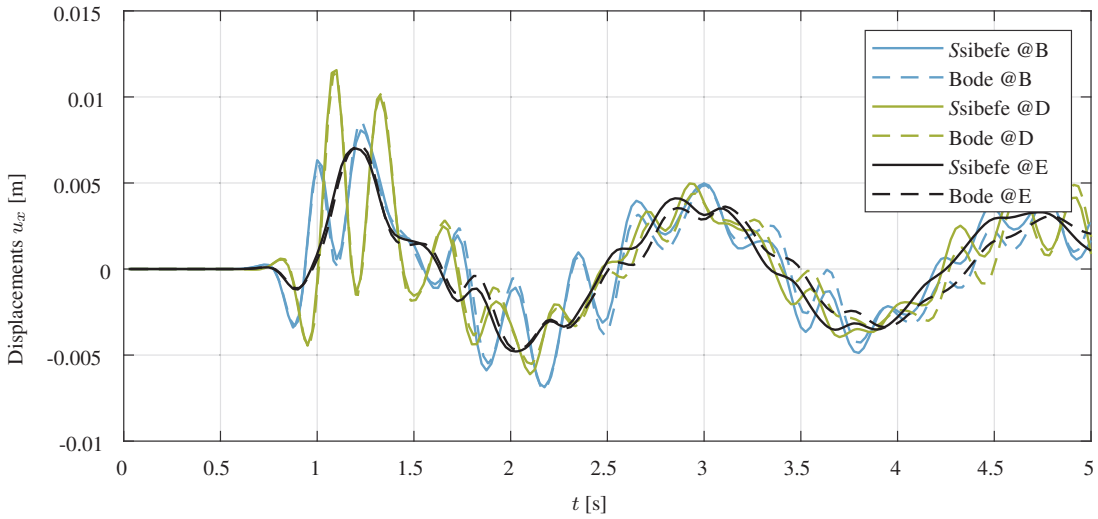

Figure 8: Horizontal displacements at the building top, at B and D and E.

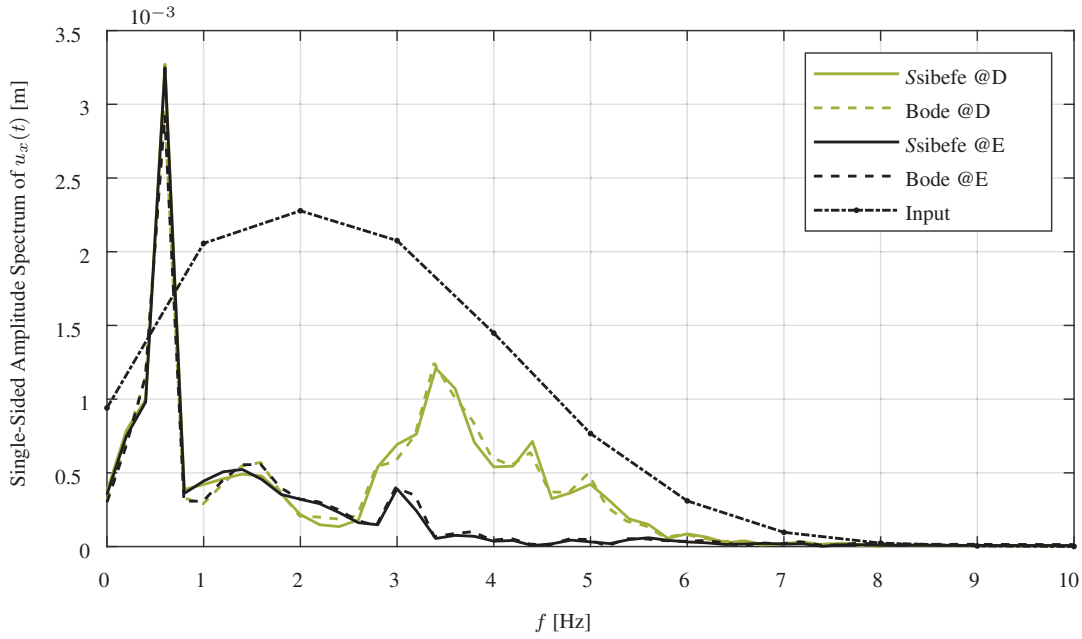

Figure 9: Spectra of the horizontal displacements at D and E, compared to the spectrum of the time function of the seismic wave.

6 CONCLUSIONS

In this contribution, we presented a new implementation of the coupling between the BEM and the FEM for soil-structure interaction problems, in the time domain. The developed computer tool *Ssibefe* is based on an interactive connection between MATLAB and ANSYS. The FEM part is generated through the ASNYS preprocessor, the soil reaction forces and the soil dynamic stiffness are computed with MATLAB functions based on the BEM formulation . The generated quantities are combined together into the coupled system of equations of the SSI system and the resulting system is solved with usual ASNYS solver routines. We presented the theoretical background of the methods and the time discretization approach. The tool can be used for both external loads on the structure and seimsic excitation. For the verification, we presented the dynamic analysis of a rigid square foundation loaded with a Heaviside point load at its center. The dynamic response as well as the static flexibility were compared to literature values, showing good agreement between the references and the results of the new implementation. Finally, we demonstrated the applicability of the *Ssibefe* tool for seismic problems, showing the dynamic analysis of an elastic cube of side length a resting on an elastic half space subjected to a seismic excitation resulting from an incident plane wave that propagates through the soil. The results match those from a reference software and show the potential of the proposed tool. Further developments of the *Ssibefe* tool will enable the consideration of layered soils, using fundamental solutions in the frequency domain, and additional forms of the seismic excitation.

Appendices

A Green's Functions

In this section the above mentioned fundamental solutions are shown [8, p.78-83].

A.1 Vertical load

$$r = \sqrt{x^2 + y^2} \quad \text{distance between loading and source point} \tag{A.1}$$

$$a^2 = \left(\frac{c_s}{c_p}\right)^2 = \frac{1-2\nu}{2(1-\nu)} \quad \text{ratio of s- and p-wave velocity} \tag{A.2}$$

$$\tau = \frac{t c_s}{r} \quad \text{dimensionless time} \tag{A.3}$$

$$H(t-t_0) = \left\{ \begin{array}{ll} 1 & t > t_0 \\ \frac{1}{2} & t = t_0 \\ 0 & t < t_0 \end{array} \right\} \text{Heaviside step function} \tag{A.4}$$

$$K(k) = \int_0^{\pi/2} \frac{d\theta}{\sqrt{1-k^2\sin(\theta)^2}} \quad \text{complete first elliptic integral} \tag{A.5}$$

$$\Pi(n,k) = \int_0^{\pi/2} \frac{d\theta}{(1+n\sin(\theta)^2)\sqrt{1-k^2\sin(\theta)^2}} \quad \text{complete third elliptic integral} \tag{A.6}$$

$$R(\xi^2) = (1-2\xi^2)^2 + 4\sqrt{\xi^2-1}\sqrt{\xi^2-a^2} = 0 \quad \text{Rayleigh function} \tag{A.7}$$

with $\xi = c_s/c$ a dimensionless wave slowness including the wave velocity c.

The Rayleigh function is further multiplied by $(1-2\xi^2)^2 + 4\sqrt{\xi^2-1}\sqrt{\xi^2-a^2}$ to obtain the bicubic equation

$$1 - 8\xi^2 + 8\xi^4(3-2a^2) - 16\xi^6(1-a^2) = 0 \tag{A.8}$$

For this equation the three roots $[\xi_1^2, \xi_2^2, \xi_3^2]$ are being calculated. The first two are non-physical values whereas $\xi_3 = c_s/c_r$ equals the ratio of shear and Rayleigh wave velocity. Due to considerations of real and complex roots of equation (A.8) the solutions of the half-space u_{zz} and u_{rz} are split into two domains ($\nu < 0.2631$ and $\nu > 0.2631$). Additionally, the numerical calculation of the first and third kind of the elliptic integral has to be implemented. This is done by adapting some parts but still applying the MATLAB code according to [8, pp. 250f.]. Further parameters are derived as follows

$$A_i = \frac{(1-2\xi_i^2)^2\sqrt{\|a^2-\xi_i^2\|}}{4(\xi_i^2-\xi_j^2)(\xi_i^2.-\xi_k^2)} \quad \xi_i \neq \xi_j \neq \xi_k \tag{A.9}$$

$$B_i = \frac{(1-2\xi_i^2)(1-\xi_i^2)}{(\xi_i^2-\xi_j^2)(\xi_i^2-\xi_k^2)} \quad \xi_i \neq \xi_j \neq \xi_k \tag{A.10}$$

$$k^2 = \frac{\tau^2 - a^2}{1-a^2} \tag{A.11}$$

$$n_i = \frac{1-a^2}{a^2-\xi_i^2} \tag{A.12}$$

$$C = \frac{(2\xi_3^2-1)^3}{1-4\xi_3^2+8(1-a^2)\xi_3^6} \tag{A.13}$$

$$Q_1(\tau) = 1 + 2z + \sqrt{z^2+z} \tag{A.14}$$

$$z = \frac{a^2-\xi_1^2}{\tau^2-a^2} \tag{A.15}$$

Important to notice is the fact that Q_1 should be replaced with $1/Q_1$ if $|Q_1| > 1$. With these definitions the displacements u_{zz} and u_{rz} can finally be obtained by

Case 1: $\nu < 0.2631$

$$u_{zz} = \frac{P(1-\nu)}{2\pi\mu r} \left\{ \begin{array}{ll} 0 & \tau < a \\ \frac{1}{2}\left[1 - \sum_{i=1}^{3} \frac{A_i}{\sqrt{\|\tau^2-\xi_i^2|}}\right] & a < \tau < 1 \\ 1 - \frac{A_3}{\sqrt{\xi_3^2-\tau^2}} H(\xi_3 - \tau) & \tau > 1 \end{array} \right\} \tag{A.16}$$

$$u_{rz} = \frac{P\tau}{8\pi^2\mu r} \left\{ \begin{array}{ll} 0 & \tau < a \\ \frac{1}{(1-a^2)^{3/2}} \left[2K(k) - \sum_{i=1}^{3} B_i \Pi(k^2 n_i, k)\right] & a < \tau < 1 \\ \frac{k^{-1}}{(1-a^2)^{3/2}} \left[2K(k^{-1}) - \sum_{i=1}^{3} B_i \Pi(n_i, k^{-1})\right] + \frac{2\pi C}{\sqrt{\tau^2-\xi_3^2}} H(\tau - \xi_3) & \tau > 1 \end{array} \right\} \tag{A.17}$$

Case 2: $\nu > 0.2631$

u_{rz} not available

$$u_{zz} = \frac{P(1-\nu)}{16\pi\mu r} \left\{ \begin{array}{ll} 0 & \tau < a \\ 8Re\left[\frac{(1-2\xi_1^2)^2(a^2-\xi_1^2)}{(\xi_1^2-\xi_2^2)(\xi_1^2-\xi_3^2)} \frac{1}{Q_1 - Q_1^{-1})}\right] + \frac{A_3}{\sqrt{\xi_3^2-\tau^2}} - 4 & a < \tau < 1 \\ \frac{2A_3}{\sqrt{\xi_3^2-\tau^2}} H(\xi_3 - \tau) - 8 & \tau > 1 \end{array} \right\} \tag{A.18}$$

A.2 Horizontal load

For a horizontal load the quantities u_{rx} and $u_{\theta x}$ are only known in case of the Poisson's ratio $\nu = 0.25$. Again some parameters have to be defined.

$$a_h = \frac{1}{3}\sqrt{3}, \quad \xi_1^2 = \frac{1}{4}, \quad \xi_2^2 = \frac{1}{4}(3-\sqrt{3}), \quad \xi_3^2 = \frac{1}{4}(3+\sqrt{3}) \tag{A.19}$$

$$C_1 = \frac{3}{4}\sqrt{3}, \quad C_2 = \frac{1}{8}\sqrt{6\sqrt{3}+10}, \quad C_3 = \frac{1}{8}\sqrt{6\sqrt{3}-10} \tag{A.20}$$

Subsequently, the displacements can be calculated

$$u_{rx} = \frac{P}{2\pi\mu r}\left\{\begin{array}{ll} 0 & \tau < a_h \\ \tau^2\left[\frac{C_1}{\sqrt{\tau^2-\xi_1^2}} - \frac{C_2}{\sqrt{\tau^2-\xi_2^2}} - \frac{C_3}{\sqrt{\xi_3^2-\tau^2}}\right] & a_h < \tau < 1 \\ 1 - \frac{2\tau^2 C_3}{\sqrt{xi_3^2-\tau^2}}[1-H(\tau-\xi_3)] & \tau > 1 \end{array}\right\} \tag{A.21}$$

$$u_{\theta x} = \frac{-3P}{8\pi\mu r}\left\{\begin{array}{ll} 0 & \tau < a_h \\ \left[\frac{1}{2} - \frac{4}{3}(C_1\sqrt{\tau^2-\xi_1^2} - C_2\sqrt{\tau^2-\xi_2^2} + C_3\sqrt{\xi_3^2-\tau^2})\right] & a_h < \tau < 1 \\ 1 - \frac{8}{3}C_3\sqrt{\xi_3^2-\tau^2}[1-H(\tau-\xi_3)] & \tau > 1 \end{array}\right\} \tag{A.22}$$

The above derived relations for the displacements due to horizontal and vertical loads are plotted while being scaled with the shear modulus μ and the distance r in the figures A.1 to A.4. For the later description via the tensor $\mathbf{g}$ according to [15], the quantities are written in a new notation, acconting for a changed coordinate system (the z-axis in the *Ssibefe* tool points downward while it was defined upward in [8]).

$$g_{zz} = u_{zz}, \quad g_{rz} = -u_{rz}, \quad g_{rr} = u_{rx}, \quad g_{\phi\phi} = -u_{\theta x}, \quad g_{zr} = u_{rz} \tag{A.23}$$

B Coordinate Transformation

The coordinate transformation

$$\mathbf{g}^{cart} = \mathbf{B}^T(\phi)\mathbf{g}^{cyl}\mathbf{B}(\phi) \tag{B.24}$$

can be accomplished by the rotation matrix

$$\mathbf{B}(\phi) = \begin{bmatrix} \cos(\phi) & \sin(\phi) & 0 \\ -\sin(\phi) & \cos(\phi) & 0 \\ 0 & 0 & 1 \end{bmatrix} \tag{B.25}$$

This leads to tab. B.1.

$g_{xx} = g_{rr}\cos^2(\phi) + g_{\phi\phi}\sin^2(\phi)$	$g_{xy} = (g_{rr} - g_{\phi\phi})\cos(\phi)\sin(\phi)$	$g_{xz} = g_{rz}\cos(\phi)$
$g_{yx} = g_{xy}$	$g_{yy} = g_{rr}\sin^2(\phi) + g_{\phi\phi}\cos^2(\phi)$	$g_{yz} = g_{rz}\sin(\phi)$
$g_{zx} = g_{zr}\cos(\phi) = -g_{xz}$	$g_{zy} = g_{zr}\sin(\phi) = -g_{yz}$	$g_{zz} = g_{zz}$

Table B.1: Green's functions in Cartesian coordinates.

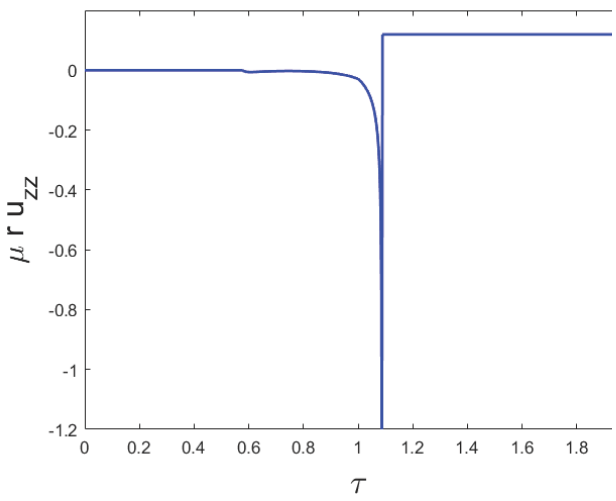

Figure A.1: Vertical displacement due to vertical load, $\nu = 0.25$.

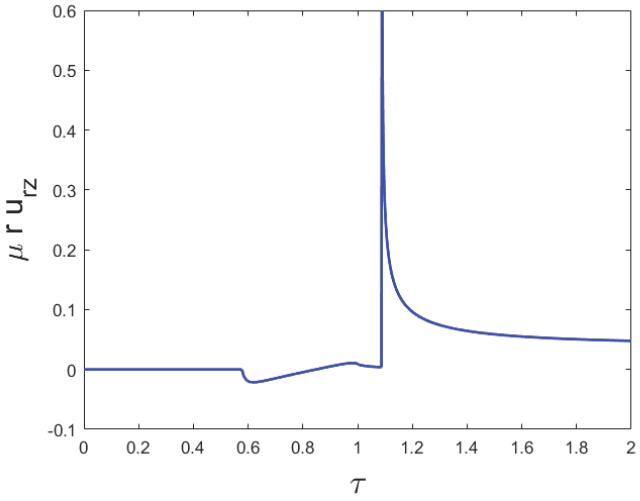

Figure A.2: Radial displacement due to vertical load, $\nu = 0.25$.

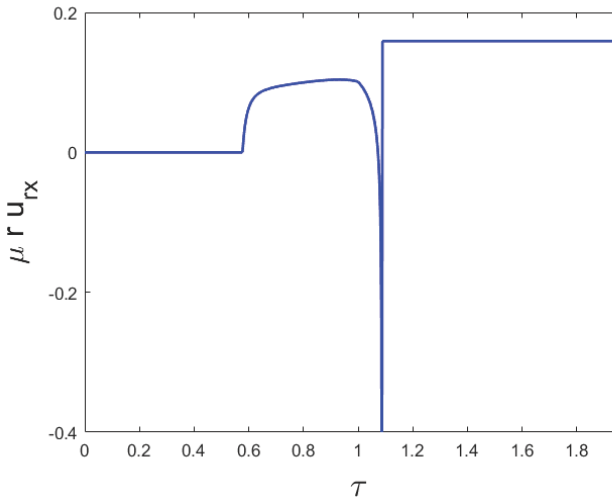

Figure A.3: Radial displacement due to horizontal load, $\nu = 0.25$.

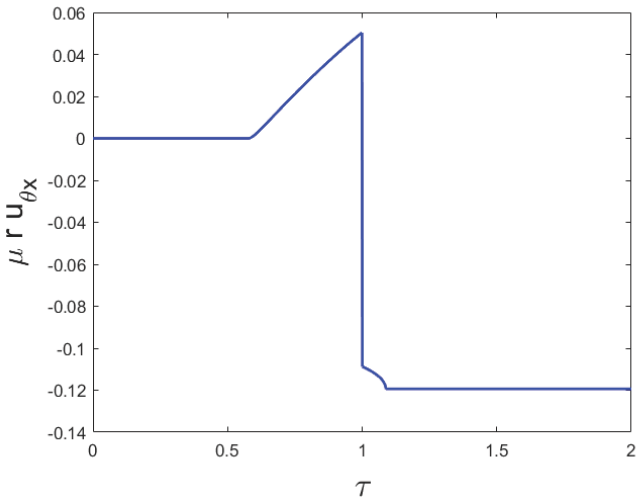

Figure A.4: Tangential displacement due to horizontal load, $\nu = 0.25$.

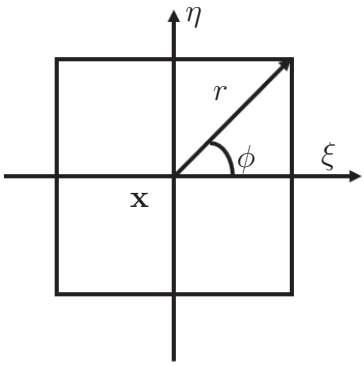

Figure C.1: Transformation to polar coordinates for constant boundary elements.

C Transformation to polar coordinates

To regularise the weak singularity of the integrand in eq. (4) a transformation to polar coordinates according to [21] can be used.

$$\Delta \mathbf{G}_n^e = \sum_{m=1}^{M} \sum_{k=1}^{K} \mathbf{N}_n(\xi_m, \eta_k) \mathbf{g}(r(\xi_m, \eta_k), \phi(\xi_m, \eta_k), t) J(\xi_m, \eta_k) W_m W_k \tag{C.1}$$

The coordinate system for constant elements is located in the centre of the element because the origin of the coordinate system should be at the loading node (see fig. C.1). The radius and the angle are adapted as follows

$$r(\xi, \eta) = \sqrt{\xi^2 + \eta^2} \qquad \phi(\xi, \eta) = atan2\left(\frac{\eta}{\xi}\right) \tag{C.2}$$

For the calculation of the Jacobian determinant changes of the partial derivatives occur

$$\begin{aligned} \frac{\partial r}{\partial \xi} &= \frac{\xi}{\sqrt{\xi^2 + \eta^2}} & \frac{\partial \phi}{\partial \xi} &= -\frac{\eta}{\xi^2 + \eta^2} \\ \frac{\partial r}{\partial \eta} &= \frac{\eta}{\sqrt{\xi^2 + \eta^2}} & \frac{\partial \phi}{\partial \eta} &= \frac{\xi}{\xi^2 + \eta^2} \end{aligned} \tag{C.3}$$

Except for these adaptations, formula (C.1) is valid for the constant elements as well. Since this regularisation approach led to the best results, it is used for all further calculations in this thesis.

D Transformation matrices from BEM to FEM

$$\mathbf{T}_u = \begin{bmatrix} [\mathbf{N}] & [\mathbf{0}] & [\mathbf{0}] \\ [\mathbf{0}] & [\mathbf{N}] & [\mathbf{0}] \\ [\mathbf{0}] & [\mathbf{0}] & [\mathbf{N}] \end{bmatrix} \tag{D.1}$$

with e.g.

$$\mathbf{N} = \begin{bmatrix} N_M & 0 & 0 & 0 & \dots \\ 0 & 0 & N_P & 0 & \dots \\ \dots & \dots & \dots & \dots & \dots \end{bmatrix} \tag{D.2}$$

$$\mathbf{T}_q = \mathbf{T}_u^T \mathbf{A} \tag{D.3}$$

with the matrix $\mathbf{A}$ which contains the element area as a diagonal matrix.

Keywords: Soil-structure interaction, pile driving, experimental testing, system identification, installation effects

Abstract. *A novel pile-driving technique, named Gentle Driving of Piles (GDP), that combines axial low-frequency and torsional high-frequency vibrations has been developed and tested recently. During the experimental campaign, several piles were installed onshore, making use of the GDP shaker. Besides those, a number of additional piles were installed using conventional pile-driving techniques, i.e. impact piling and axial vibratory driving. After the completion of the installation phase, the installed piles have been subjected to impact hammer tests with the following goals. First, the in–situ dynamic properties of the pile-soil system have been identified. Second, the post-installation soil state has been investigated, along with its evolution in time for each pile driving scenario. Preliminary analyses, of the data collected during the impact tests show dissimilar trends in the overall dynamic response between the piles installed with impact hammer and those installed with the axial and the GDP shakers.This observation suggests a difference in the post-installation dynamic behaviour of the pile-soil systems related to different pile-driving techniques. In this paper, a first attempt is made to identify the differences in the overall pile-soil dynamic behaviour of the piles installed by means of the three different pile-driving techniques.*

1 INTRODUCTION

The offshore wind industry plays a major role in the energy transition. Due to the sustainability targets set at international level, the installed capacity of offshore wind turbines is growing, leading to greater depths and distances to shore [7]. In that framework the foundations of offshore wind turbines are also affected by this consistent progression challenge. Monopiles are the most common foundations used for offshore wind turbines in shallow waters, like the North Sea [6]. Various alternative foundation concepts do exist, yet these substructures remain the most favorable choice due to simplicity of manufacture, ease of the installation procedure, robustness and proven reliability [1, 5].

Currently, impact pilling is the most common method for the installation of monopiles in the offshore environment [8]. However, the latter installation method engenders several issues that require further consideration. The major drawbacks are the high levels of noise generated during pile driving [9], which may be harmful for the aquatic species, and the large stresses developed at the pile head during hammer impact, that can reduce the structural life-time of the monopile due to fatigue [2]. Consequently, an alternative pile driving technique that can mitigate the noise emissions and does not peril the fatigue life of the structure, without compromise of the driving efficiency and the pile bearing capacity, has been a growing need. To that end, a novel pile-driving technique, named Gentle Driving of Piles (GDP), that aims to accomplish the stated objectives, has been recently developed. This technique is based on simultaneous application of low-frequency axial vibrations and high-frequency torsional vibrations at low amplitudes.

To test the novel pile driving technique, an experimental campaign was designed and executed in a site of medium to medium-dense sand. This experimental campaign encompassed the installation of several piles by means of three distinct pile driving techniques; namely, impact pilling, axial vibratory driving and GDP. Following the installation tests, that were concluded to be successful, further investigation was considered necessary to provide evidence that the bearing capacity and the dynamic properties of the pile-soil system have not been compromised and are within acceptable limits for operation. To this end, in the post-installation phase, lateral loading tests and impact tests with an instrumented hammer were conducted, in order to investigate further the effect of each installation method on the behaviour of the pile-soil system. More specifically, the response in operational conditions, the vibration characteristics and the temporal evolution of the dynamic properties of the pile-soil system are to be examined, in accordance with the aforementioned experimental tests. The present work is focused upon the instrumented hammer impact tests, in order to examine the dynamic behaviour of the installed piles in terms of prior- and post-loading response, temporal evolution of the system properties and influence of the respective installation method. At this point it was observed for the first time that the method of installation can have significant influence on the vibration characteristics of the system such as damping and dynamic stiffness.

This paper is structured as follows. In Section 2, the experimental tests and the identification procedure followed are described. Onwards, in Section 3 a collection of the most representative results are presented, along with some observations and relevant conclusions. In Section 4, the main conclusions accompanied by the research questions to be addressed in the near future are outlined.

2 EXPERIMENTAL TESTS AND IDENTIFICATION PROCEDURE

During the installation phase of the experimental campaign, several piles were installed by means of impact pilling, axial vibratory driving and GDP techniques. The dimensions of the

tests piles and the reaction pile are given in Table 1.

Pile Geometry	Test piles [m]	Reaction pile [m]
Length	10	10
Outer diameter	0.762	1.6
Wall thickness	0.0159	0.02

Table 1: Geometrical characteristics of the piles.

Evidently, since the main objective of the experimental campaign was the proof of concept of the GDP method, the majority of the piles were installed by means of the latter method. Furthermore, the rest of the piles in the experimental site were installed by impact and axial vibratory driving, the two conventional and currently most established installation methods [3]. The latter were mainly chosen to serve as reference cases, since they are vastly used in engineering applications and their features during and post-installation are considered to be known. The configuration of the installed piles is shown in Figure 1. The position of the 8 piles installed around the reaction pile is displayed, while the latter was used as a support for the post-installation lateral tests loading apparatus.

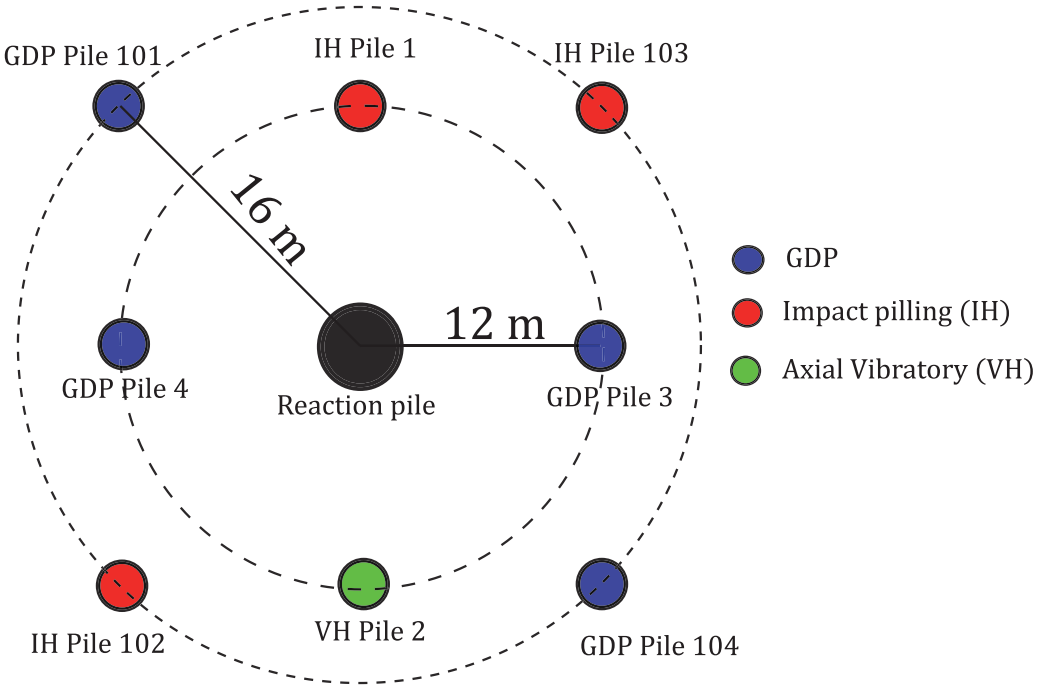

Figure 1: Pile layout

As already presented in Table 1, the test piles were 10 meters long, with final embedment depth of 8 meters. Accordingly, the height above the ground level was 2 meters, such that an adequate part of the pile could be used to mount the loading frame for the lateral loading tests.

2.1 Experimental set-up

In order to perform the impact hammer tests, 2 PCB tri-axial accelerometers and an instrumented impact hammer were used. The tests were performed on all the installed piles using the instrumentation set-up displayed in Figure 2.

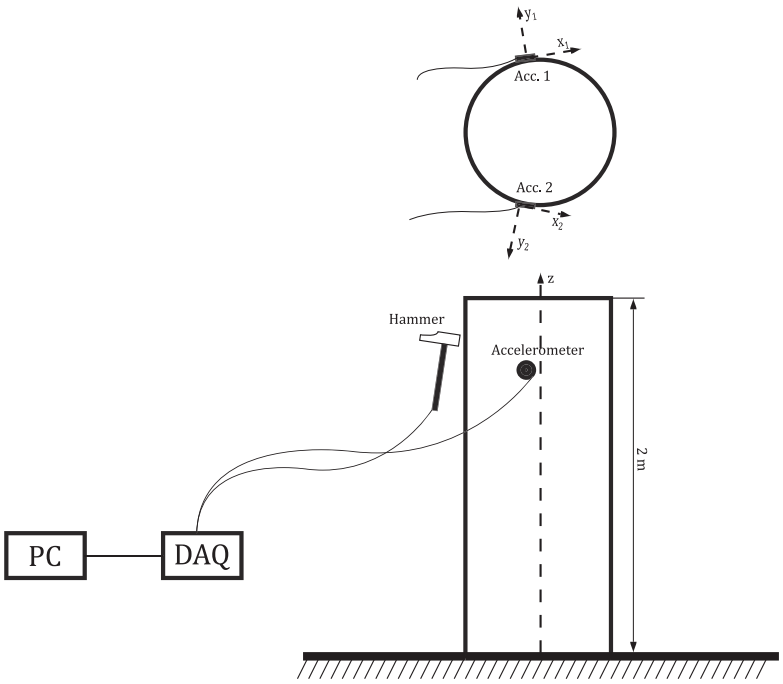

Figure 2: Experimental set-up and pile instrumentation

The instrumented hammer was used to excite the pile at two different locations and with different impact direction. First, the hammer was impacted horizontally, as shown in Figure 2 and at 1.5 meters above the ground surface. Each test was comprised of three distinct hits, in the same location and direction, in order to ensure the consistency of the measurements. In the same manner, hammer impact tests were repeated with an impact force applied along z-direction, at the top of the pile and in the same vertical line that the horizontal impacts were performed.

The accelerometers were mounted to the outer wall of the pile at the same height with the location of the horizontal hammer impacts, 1.5 meters from the ground surface. Acceleration data were registered in x, y and z directions simultaneously, with a sampling frequency that was set to 16 kHz for all tests.

During a period of two weeks, three hammer impact tests took place, one week apart from each other and in parallel with the lateral loading tests. The latter tests, conducted in parallel with the impact tests due to time constrains, were detrimental for the direct comparison of all the hammer tests, but did allow for a comparison of the installed piles in groups. Piles that were tested in analogous circumstances are grouped together and conclusions are drawn based on the features of each respective pile group.

In the present work two groups will be considered, one group including the four piles seen in Figure 1 at a radial distance of 16 meters from the reaction pile. These piles had been laterally loaded before the start of the impact hammer test, to mimic loading conditions similar to the ones encountered in offshore environments. This group was chosen on the basis that all piles had experienced lateral loading already and piles installed by two different techniques

comprise the first group, namely the impact-driven and the GDP piles. Thus, without drawing a conclusion with respect to the loading, the time evolution of the system properties and the effect of the installation method could be identified. The second group is comprised of two instrumented piles driven by axial vibratory driving and the GDP technique. At the first day of the hammer tests, both piles were not loaded, so a comparison was performed based on the data obtained from the testing on the first and last day of the experiments. In essence, the pre- and post-loading behaviours were compared, to showcase the effect of loading on the two piles driven with different techniques.

2.2 Identification procedure of the main system parameters

In this work, the half-power Band-width method (HPBW) is used to identify the main pile-soil system parameters. A natural frequency of the system can be obtained based on the location of a distinct peak in the acceleration frequency-response function (FRF) and its respective equivalent viscous damping ratio can be quantified accordingly.

The quality factor Q and the frequency ratio in resonance Ω_{res} of a damped system with viscous damping ratio ξ, are defined in a classical manner:

$$Q = \frac{\Delta\Omega_{\frac{1}{2}}}{\Omega_{\text{res}}} = \frac{\Omega^{+}_{\frac{1}{2}} - \Omega^{-}_{\frac{1}{2}}}{\Omega_{\text{res}}}; \quad \Omega_{\text{res}} = \sqrt{1-2\xi^2}, \tag{1}$$

in which $\Omega^{+}_{\frac{1}{2}}$ and $\Omega^{-}_{\frac{1}{2}}$ correspond to the frequencies at which the PSD function is half of the maximum value. A general expression for the damping ratio of a SDoF system can be obtained in terms of the quality factor, as follows [4]:

$$\xi = \frac{1}{\sqrt{2}}\sqrt{\frac{\sqrt{-Q^4+4Q^2+4}-2}{\sqrt{-Q^4+4Q^4+4}}} \tag{2}$$

Generally, for low-damped systems, it can be assumed that $Q << 1$. In these cases, the damping ratio can be approximated by the following expression:

$$\xi \approx \frac{1}{2}Q = \frac{\Delta\Omega_{\frac{1}{2}}}{2\Omega_{\text{res}}}. \tag{3}$$

This procedure is used in Section 3 to compute the selected natural frequencies and the equivalent damping ratios of the tested piles.

3 RESULTS

In the current section the power spectral density graphs (PSD) are presented for the selected 4 out of 8 piles, organized in a consistent manner as presented in subsection 2.1 to draw the relevant conclusions. The following graphs have been produced using the acceleration response measured along the y-direction of each sensor, during the lateral hammer impact tests, as shown in Figure 2. Each pair of simultaneous recordings for each hammer impact was averaged prior to signal analysis. Subsequently, the acceleration frequency-response functions from the 3 lateral hammer impacts per day were averaged. Finally, the averaged power spectral density S_{yy} of the pile-soil system at each day, for all responses and only lateral impacts, was obtained.

In Figure 3, the power spectral density for Pile IH-103, for each of the 3 testing days can be seen. Apparently, the PSD's of the three tests do not showcase significant deviation within the

testing period, while there exist some quite distinct peaks in the PSD of the system, which can be considered to correspond to resonant frequencies of the pile-soil system.

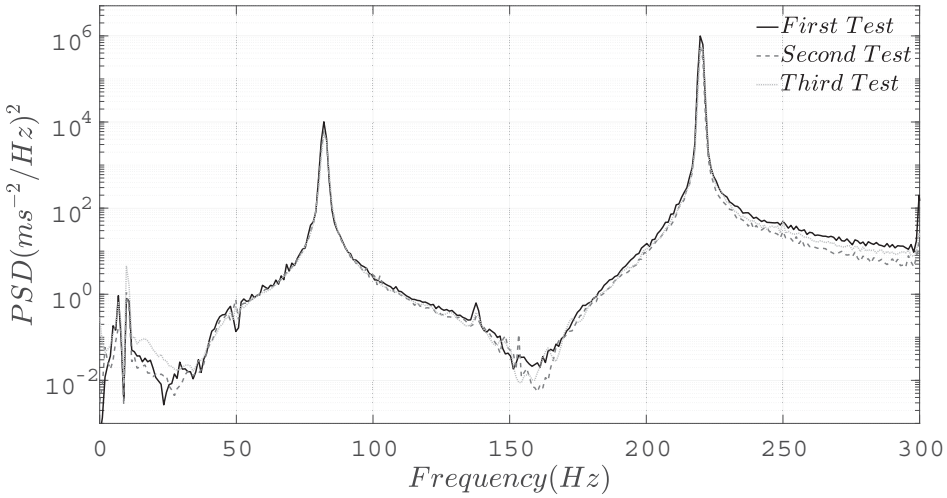

Figure 3: Power spectral density graphs for Pile IH-103 for all testing days

The PSD of the Pile GDP-101 can be seen in Figure 4. Similarly to Pile IH-103, Pile GDP-101 does not present significant alteration in its dynamic behaviour within the testing period.

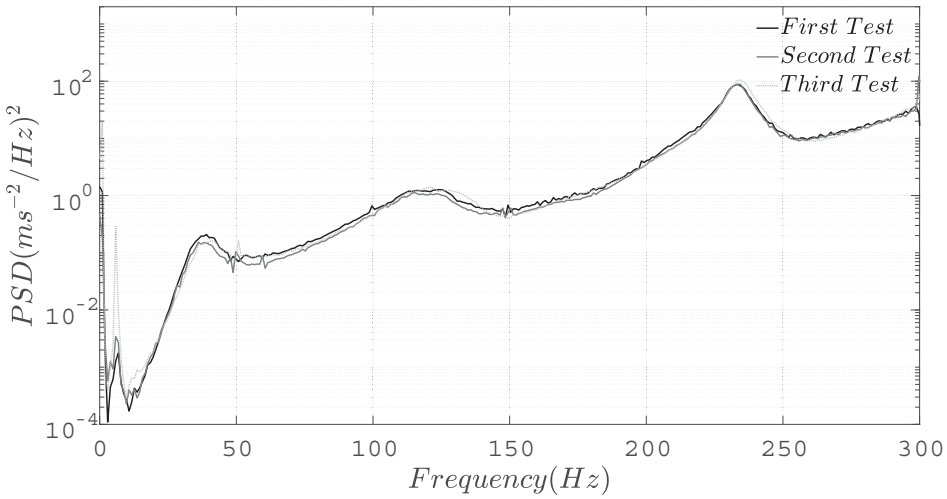

Figure 4: Power spectral density graphs for Pile GDP-101 for all testing days

To showcase the possible differences between the measured properties of the two systems, Figure 5 shows both PSDs of Pile IH-103 and Pile GDP-101, on the last testing day. It is evident that the responses of the two systems are quite dissimilar and though the time evolution of the properties of the two systems was shown to be insignificant in both cases. The difference in magnitude and mainly in the form of the PSDs is an indication of lower damping present in the pile-soil system of Pile IH-103. It needs to be noted that the piles have a structural dissimilarity. Specifically, all piles except the ones driven with impact piling, have a cap welded on the top of the pile, which was used to mount the axial vibratory and the GDP shaker. The effect of this

cap is not expected to be significant, but is still to be investigated. A final conclusion about the dynamic stiffness of the two systems can thus not be drawn at this stage. However, piles driven with the same installation method, all present identical behaviour. Thus, a consistent observation is made regarding the significant difference in the PSD magnitude and the damping ratio of the IH- and GDP-driven piles.

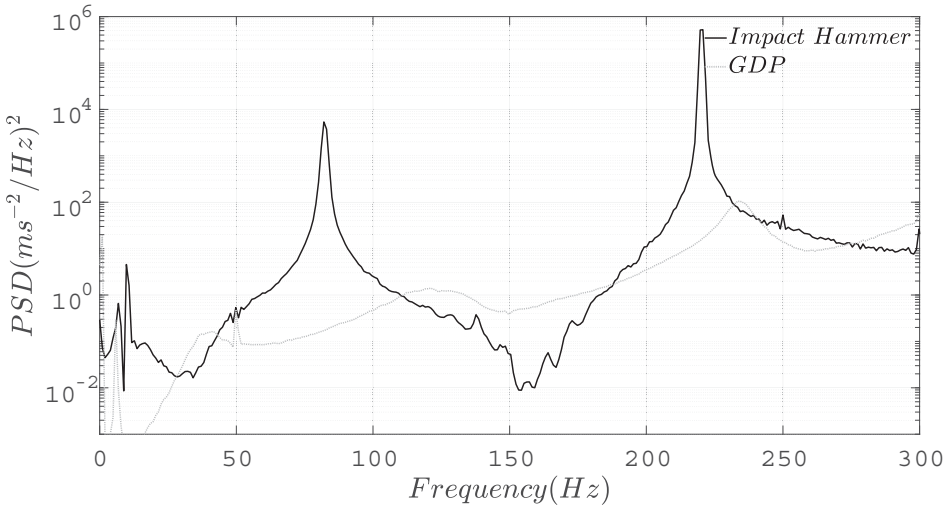

Figure 5: Power spectral density graphs for Pile IH-103 and Pile GDP-101 after the application of lateral loading

The HPBW method presented in Section 2.2 is used to quantify indicative vibration characteristics for Pile IH-103 and Pile GDP-101. In Figure 3, there are two distinct peaks observed in the same frequency and same amplitude for all the tests. Those two peaks are analyzed in Figure 3 and their corresponding natural frequencies ω_n and equivalent viscous damping ratios ζ_{eq} are presented in Fig. 6.

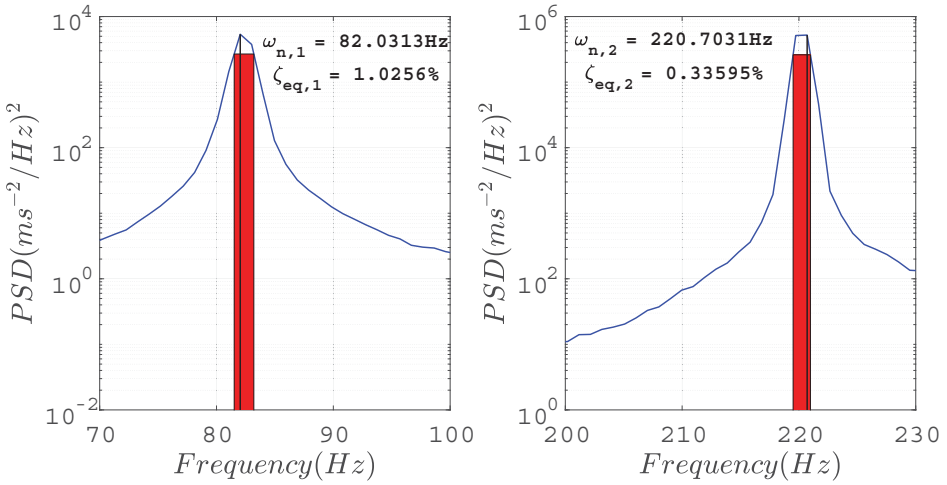

Figure 6: Identification of equivalent viscous damping ratio by the HBWM for Pile IH-103

In the same manner, for the PSDs presented in Figure 4 one peak can be clearly identified, that comprises also the fundamental frequency of the relevant time signal. Similarly to the IH-

103, the same identification procedure is followed and the respective natural frequency ω_n and equivalent viscous damping ratio ζ_n are given in Figure 7.

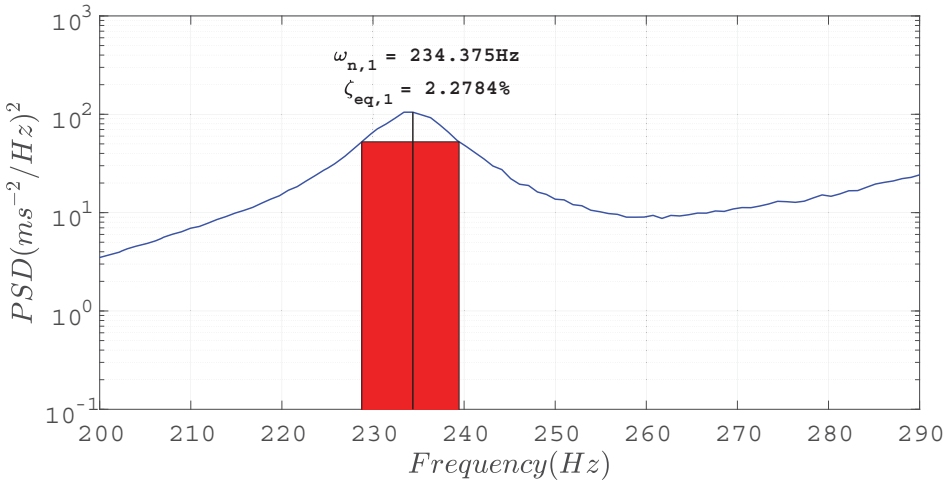

Figure 7: Identification of equivalent viscous damping ratio by the HBWM for Pile GDP-101

In continuation, the effect of the lateral loading is to be addressed by the PSDs of two piles, driven by axial vibratory and GDP techniques respectively. In Figure 8 the PSDs of Pile VH-2, installed with an axial vibratory hammer, are presented for the first and last day of the measurements, indicating prior and post-loading behaviour. The system characteristics, both in frequency and magnitude, indicate a decrease of dynamic stiffness after the application of lateral loading. As can be seen in Figure 8, the form of the PSD is preserved, but a shift to lower frequencies and an increase in magnitude take place, which both indicate a dynamic stiffness decrement. A multitude of reasons may have contributed to that observation, such as creation of a gap between the pile walls and the soil and degradation of the soil in the immediate vicinity of the pile.

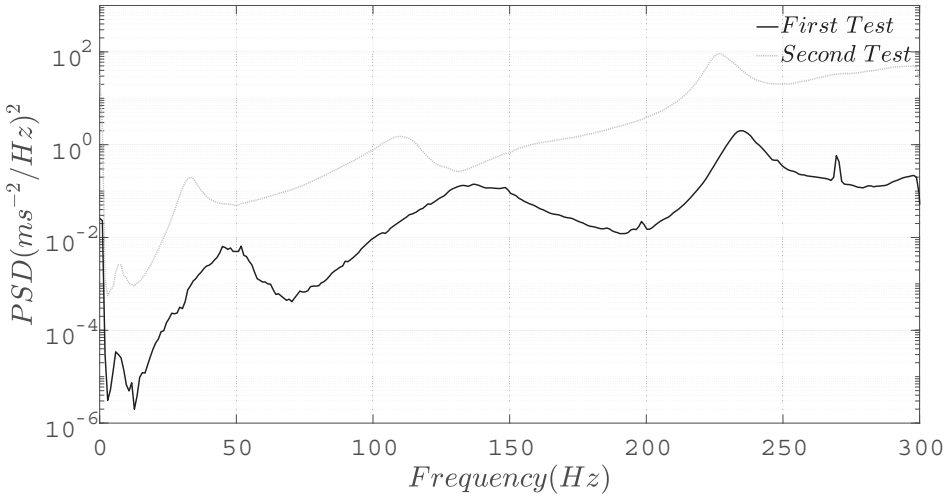

Figure 8: Power spectral density graphs for pile VH-2 in the first and last testing day

A qualitatively similar behaviour can be observed in Figure 9, which refers to Pile GDP-4.

Albeit, the shift of the PSD form with respect to the frequency is distinguished, no drop in the dynamic stiffness of the system, as was observed in the case of pile VH-2, is seen here.

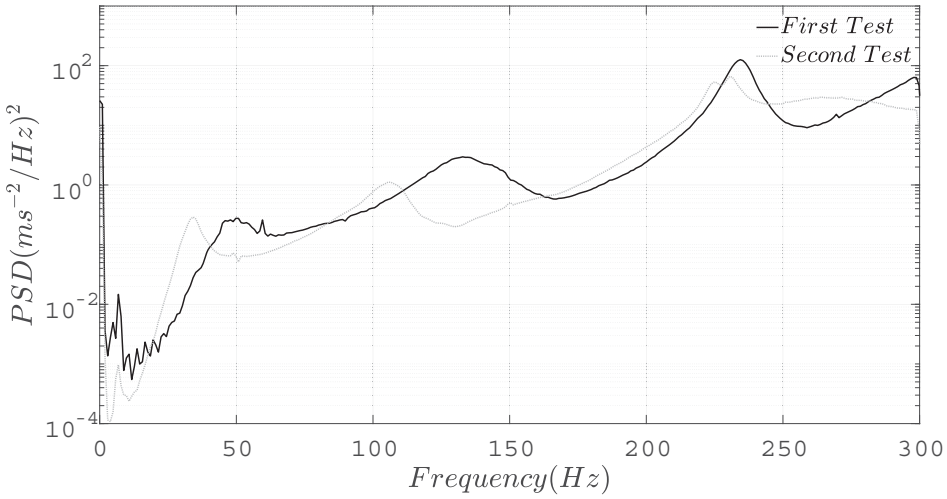

Figure 9: Power spectral density graphs for Pile GDP-4 in the first and last testing day

To investigate the latter observation, a PSD graph including both Pile VH-2 and Pile GDP-4 is presented in Figure 10. By inspection of this figure it can be inferred that the difference in pre- and post-loading behaviour is much greater in the Pile VH-2, compared to that of Pile GDP-4.

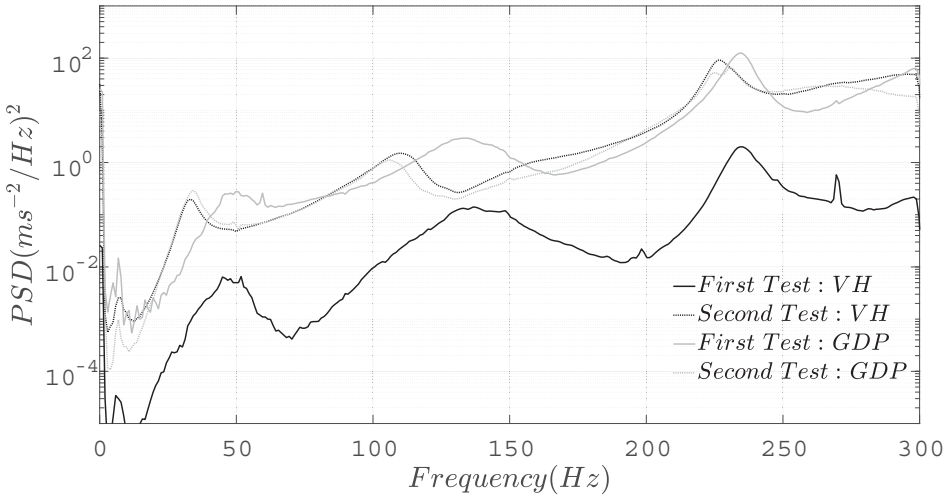

Figure 10: Power spectral density graphs for Pile VH-2 and Pile GDP-4 in the first and last testing day

4 CONCLUSIONS

To summarize, the work presented herein comprises a part of a test campaign, conducted in the context of investigating a novel pile driving method, namely the Gentle Driving of Piles (GDP). During the campaign, onshore installation of scaled piles by means of two conventional

pile driving methods, namely impact piling and axial vibratory driving and the novel GDP method was performed. The proof of concept was successfully accomplished indicating the potential of this novel method to fulfill the originally envisaged goals and motivations.

To realize these objectives, post-installation tests were conducted to examine the various aspects of the behaviour of the pile-soil system with respect to the reference cases of the conventional impact piling and axial vibratory driving. In this work, a part of the post-installation tests, namely impact tests with an instrumented hammer, is briefly discussed. Main objective of this work is to present a collection of selected results of these experimental tests, that can summarize and showcase the dominant trends observed in the majority of the data obtained. Final conclusions were not drawn, but mainly some indications, which will be used to guide a further investigation of the experimental data. A concise consideration of each respective case parameters, accompanied with numerical modeling and used in conjunction with all the available experimental results is intended with the aim to provide a better understanding of all the addressed techniques and predominantly of the GDP method.

Keywords: Periodic foundation, Metamaterial, Frequency band-gap, Attenuation, Seismic protection, Wave propagation.

Abstract. *One of the most recent and interesting research topics of structural seismic protection nowadays is the use of seismic metamaterials. The idea is based on the concept of phononic crystals or in another term the attenuation of propagating waves due to the periodic distribution of materials. There are different types of seismic metamaterials under study such as periodic void inclusion, periodic rigid inclusion, Metaforest that is considered as a natural seismic metamaterial and seismic isolation by using periodic foundation which is the subject and locus of this paper. Phononic crystals concept produces frequency band-gaps at different levels that are related to geometrical, physical and mechanical properties of arranged materials. Therefore, each propagating wave with a frequency within attenuation range will be blocked due to the local resonance phenomenon. The following research attempts to present the evolution of metamaterial periodic foundation system designed for seismic protection and the analysis of fundamental theory and methods of periodic materials. Finite element method is also employed and dynamic responses of a frame structure with periodic foundations are compared. Moreover, a parametric analysis is carried out to highlight on the influence of different geometrical, physical and mechanical parameters of the composite periodic foundation on the attenuation zone properties. In conclusion, this study proves that this seismic isolation concept has the potential to significantly reduce the seismic risk which in turn confirms the validity of the proposed metamaterial periodic foundation.*

1 INTRODUCTION

Natural disasters have been a threat to humanity with the support of industrial and urban evolutions that take place nowadays. One of the most significant catastrophes is a natural earthquake, taking into consideration its physical damages and human loss that it causes. Major research and studies have been implemented to discover the finest solutions to evade the chaos and crises left over by natural disasters, chiefly seismic ones. However, the most recent and interesting study is the propagating waves in periodic media that appeals to researchers' concern and generates approaches such as photonic crystals to alter the propagation of electromagnetic waves and phononic crystal for seismic protection. The end of 20th century witnessed the emergence of photonic crystals which comprise a periodic arrangement of materials with different dielectric properties that provide a dispersive medium to electromagnetic waves. Those materials highlight a frequency range called band gap, where electromagnetic waves cannot propagate. Photonic crystals' capability to manipulate electronic waves evokes suggestions to implement an analogous principle on propagating waves with different natures. Civil engineering researchers have applied that concept by changing scales on mechanical waves, such as sound waves or seismic waves which paves the route to broaden the notion of phononic crystal for seismic protection. The idea is based on the attenuation of propagating waves due to the periodic distribution of materials. There are different types of seismic metamaterials under study such as periodic void inclusion, periodic rigid inclusion, Metaforest (that is considered as a natural seismic metamaterial), and periodic foundation for seismic isolation which is the subject and locus of this paper. The addition of a flexible isolation system, such as rubber bearings, frictional/sliding bearings, and roller bearings, between the structure and the foundation, reduces the seismic effect on the structure and gives it a much lower fundamental frequency [12, 7, 3]. That system is the most prominent applied one in civil engineering for earthquake-resistant design to protect installations and buildings. The disadvantage of this strategy is that buildings usually have remarkably large horizontal displacements after an earthquake. To reduce those displacements, additional dampers are often required, which can lead to new problems [11, 9, 5]. Theoretically, researchers have proved the effectiveness of a phononic crystal in general and periodic foundation in particular to reach a new seismic isolation strategy.

This paper focuses on the development of metamaterial periodic foundation systems designed for seismic protection and the analysis of fundamental theory and methods of periodic materials. This research presents the design of a multidimensional composite periodic foundation for seismic isolation. It highlights on the influence of geometrical, phtysical and mechanical properties of periodic arrangements of materials on the band gaps properties. In addition, a study of the effectiveness of this approach at the strcutural scale will be shown.

2 Phononic Crystal

Phononic crystals are macroscopic materials blended with periodic distribution in one or many directions. Thus, they are able to block acoustic propagation in some directions and frequency ranges, by Bragg reflections or local resonance phenomenon of the periodic array's elements. Accordingly, the key of this concept is the frequency band gap.

2.1 Phononic Band Gap Structure

The aim of studies that treat the propagation of waves is to determine its behavior in terms of the relationship between the frequency and wave vector according to the other parameters in the medium of propagation. That relation is called a dispersion relation.

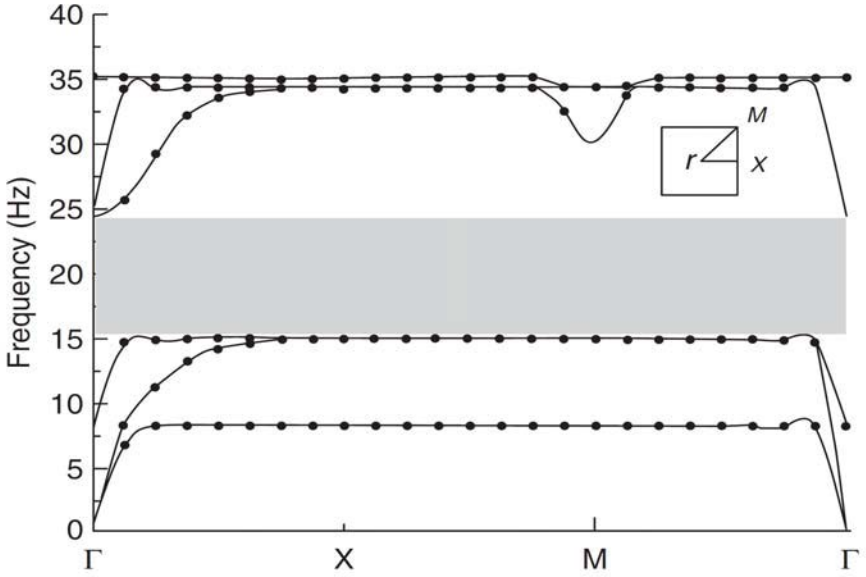

Figure 1: Dispersion relation between vectors and frequencies of waves [8].

Waves with frequencies that have no corresponding wave vector (K) on the abscissa cannot propagate in the periodic structure, since there are no corresponding modes which means these frequencies are inside the bandgap. The mechanism of forming the band gap is based on Bragg reflections due to the periodicity of crystal or the phenomenon of local resonance of resonators that are placed in protection systems.

2.2 Opening of Bandgap by Diffusion of Bragg

If the wavelengths (λ) of elastic waves are in the order of periodic structure's frequency, the bandgap is obtained due to Bragg reflection. You can distinguish between three different areas according to the value of the wavelength (λ) compared to the period of structure (a) [4].

- For $\lambda << a$: the wave propagates in a succession of media.
- For $\lambda >> a$: the wave is a little bit affected by structuring and it propagates in a homogeneous material.
- For $\lambda = a$: the wave is seriously affected by the periodicity of media. The propagation of waves is more complex than the previous cases.

2.3 Opening of Bandgap by Local Resonance

The appearance of bandgap of resonance is related to the fact that each resonator will trap a part of the energy of the transmitted wave, thus the stresses caused by the propagations of waves interact with the stresses of the resonance of resonators in anti-resonance frequency range, therefore the waves will be reflected. This association plays a key role in the presence or disappearance of a bandgap where wavelengths are far from the frequency of phononic Crystal [2].

3 Periodic Foundation and Theoretical Formulation

The two-dimensional (2D) periodic foundation consists of three materials with different geometrical, physical and mechanical properties of arranged materials. It consists of concrete plates

that have cylindrical or square steel inclusions surrounded by rubber, and they are periodically distributed in X and Y directions [6]. This type of foundation is a typical periodic foundation with local resonance. The basic idea of this new seismic isolation method is to replace the traditional solid foundation with the periodic foundation to reduce seismic risk.

3.1 Wave Equation

In a homogeneous medium, the equation of elastic wave propagation can be written in the form (Cheong et al [6]):

$$\rho\frac{\partial^2 u}{\partial t^2} = \nabla\cdot\left(\rho C_t^2\nabla u_i\right) + \nabla\cdot\left(\rho C_t^2\frac{\partial u}{\partial x_i}\right) + \frac{\partial}{\partial x_i}\left[\left(\rho C_l^2 - 2\rho C_t^2\right)\nabla\cdot u\right] \tag{1}$$

With i=1, 2, 3. For a 2D infinite system, the displacement vector $u_i = u(x, y)$ and the equation (1) will be:

$$\rho\frac{\partial^2 u}{\partial t^2} = \nabla_T\cdot\left(C_{44}\nabla_T u_i\right) + \nabla_T\cdot\left(C_{44}\frac{\partial u_T}{\partial x_i}\right) + \frac{\partial\left[\left(C_{11} - 2C_{44}\right)\nabla_T\cdot u_T\right]}{\partial x_i} \tag{2}$$

with $U_T = [u_x, u_y]$, $\nabla_T = \left[\frac{\partial}{\partial x}, \frac{\partial}{\partial x}\right]$,i=1,2

3.2 Periodic Boundary Conditions

The passage from one point of the array to another space of a mesh is translated by phase shift of $e^{i\overrightarrow{K_B}L}$. The calculation of the bandgaps of a periodic array is limited to the study of an elementary cell by applying periodic boundary conditions given by equation (4) below.

According to Bloch's theory [1], the solutions of the wave equation in the form of Floquet-Bloch can be written as:

$$u(r,t) = e^{i(k.r-wt)}.u_k\overrightarrow{r} \tag{3}$$

Where:
K: wave vector in the reciprocal space.
w: wave pulsation.
$u_k\overrightarrow{r}$ is on the same periodicity as the elastic parameters which is $u_k(r) = u_k(r + L)$
Thus,

$$u(r + L, t) = e^{i(k(r+L)-wt)}.u_k(r + L) = e^{ikL}.e^{i(k.r-wt)}.u_k(r) = u(r, t).e^{ikL} \tag{4}$$

4 Design and Development of Metamaterial Periodic Foundation

To apply phononic crystal concept for seismic protection, a bandgap in low frequency range (between 1 and 10Hz) should be found. Therefore, a local resonance phenomenon should be used in order to prevent seismic waves propagation in the sub-wavelnegth range [10].

4.1 Structure Configuration

The studied model is a 2D periodic foundation composed of a concrete matrix (a=1.4m) in which cylindrical steel inclusions (of radius r= 0,2m) are enrobed in rubber (of thickness e=0,2m). Each enrobed steel cylinder is considered as a resonator (figure 2), where every resonator absorbs the energy from wave at a frequency range located in the anti-resonance frequency range to reach an equilibrium between wave and resonators stresses, where the gap is observed

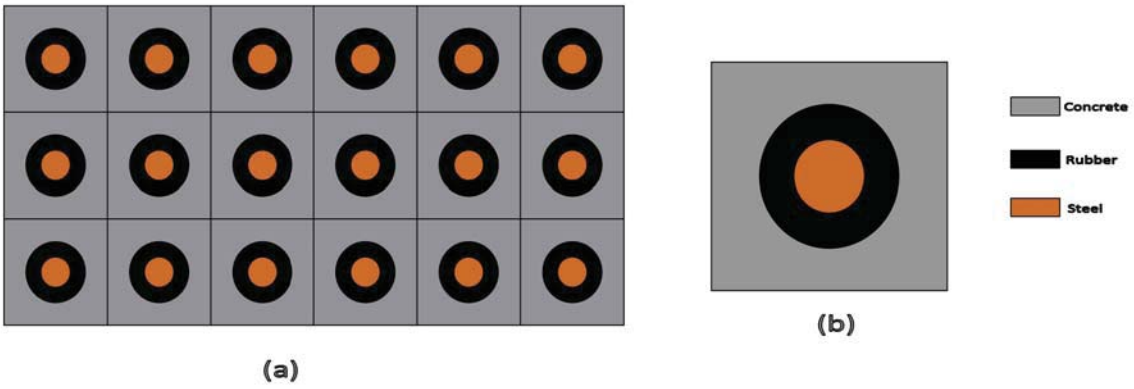

Figure 2: (a) plan (xy) section of periodic foundation, (b) plan (xy) section of the unit cell

4.2 Materials properties

The goal is to create a low frequency bandgap by using a local resonance phenomenon,which imposes the use of rubber material for the randall and steel or plumb material for the core, where the low rubber's elastic modulus and the high mass core allow this type of a resonator to resonate at low frequency

Materials	$\rho(Kg/m^3)$	E (GPa)	ν
Concrete	2450	28	0,3
Rubber	1300	$1{,}3 \cdot 10^{-4}$	0,463
Steel	7850	210	0,3
Plumb	11600	16,46	0,4

Table 1: Mechanical properties of used materials density ρ, elastic modulus E, Poisson's ratio ν.

4.3 Parametric Study

In this part, an elementary cell has been studied to determine the influence of the physical parameters (elastic modulus E, the density ρ and the Poisson's ratio ν) on the characteristics of the bandgap: the lower edge frequency (FEL), the upper edge frequency (UEF) and the width frequency deviation (FGW).

4.3.1 Numerical Model

The periodic structure is modeled with 2D plane deformation in Comsol Multiphysics software by implanting one cell. And, the finite element method is adopted to calculate structure's bandgap.

4.3.2 Boundary Conditions

The periodicity of the cells in the two directions (X, Y) are modelled by following Bloch's boundary conditions. The corresponding equations of Bloch's conditions are:

$$u_3 = u_1.e^{i.Kx.a}$$
$$v_3 = v_1.e^{i.Kx.a}$$
$$u_4 = u_2.e^{i.Ky.a}$$
$$v_4 = v_2.e^{i.Ky.a}$$

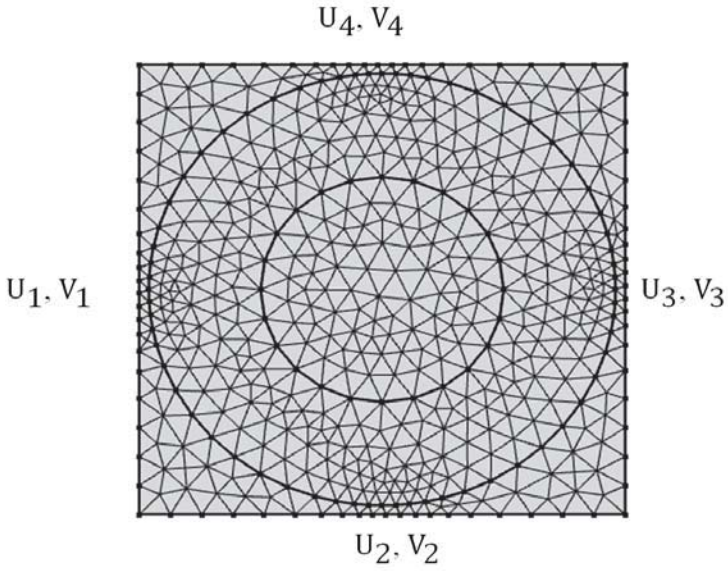

Figure 3: FE mesh and periodic conditions of a unit cell

4.3.3 Structure's Bands Calculation

The calculation of the dispersion curve is limited by the principal symmetric axes of the first Brillouin's zone. For every wave vector, the modes are calculated by using frequency analysis proposed by Comsol (figure 4).

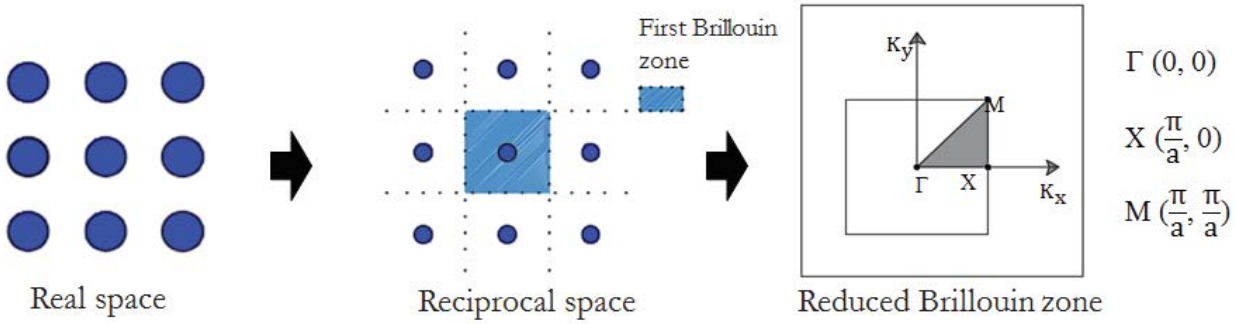

Figure 4: First irreducible Brillouin zone for a square periodic structure

Figure 5 shows the dispersion curve of model

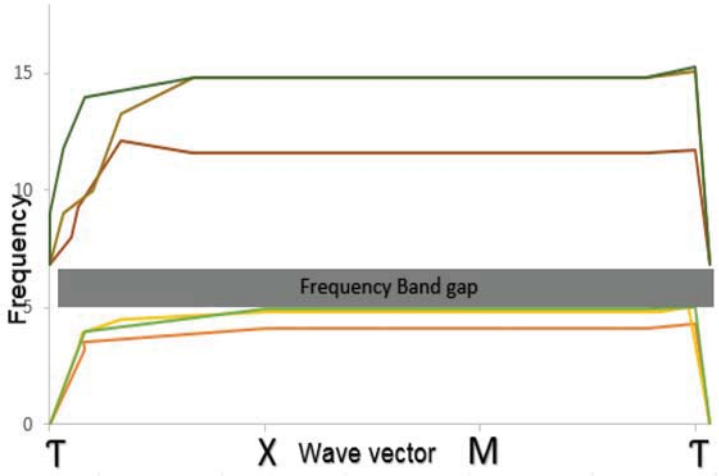

Figure 5: Dispersion cure of the periodic structure with reference properties

4.4 Results

The results indicate that the main physical parameters affecting the band gap properties are core density and rubber elastic modulus. The figures (6, 7) below show that LEF and UEF decrease and FGW increases when core density increases, and all characteristics of bandgap increase when rubber elastic modulus increases. These results demonstrate the important role of the low rubber elastic modulus on construction of periodic foundation with low frequency bandgap and the core density's effects to create low frequency bandgap.

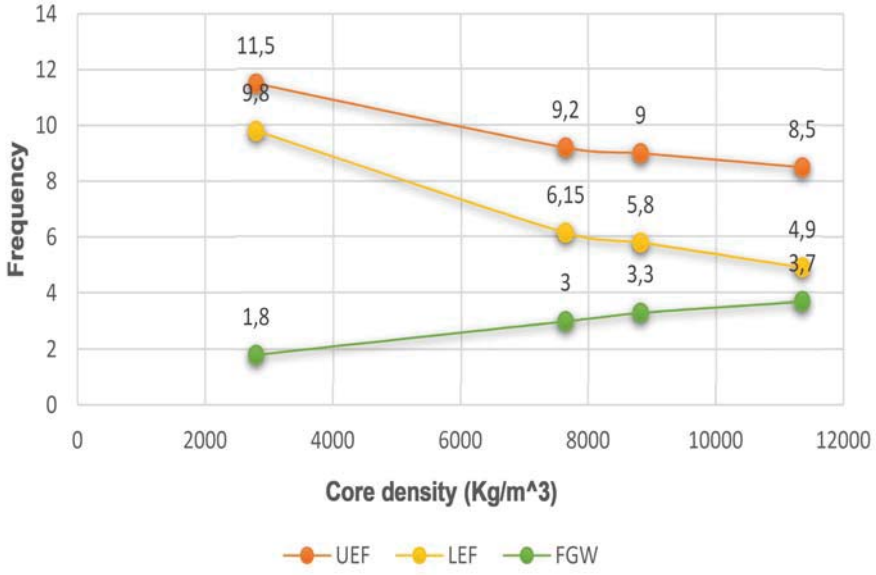

Figure 6: Core density Influence on bandgap's characteristics

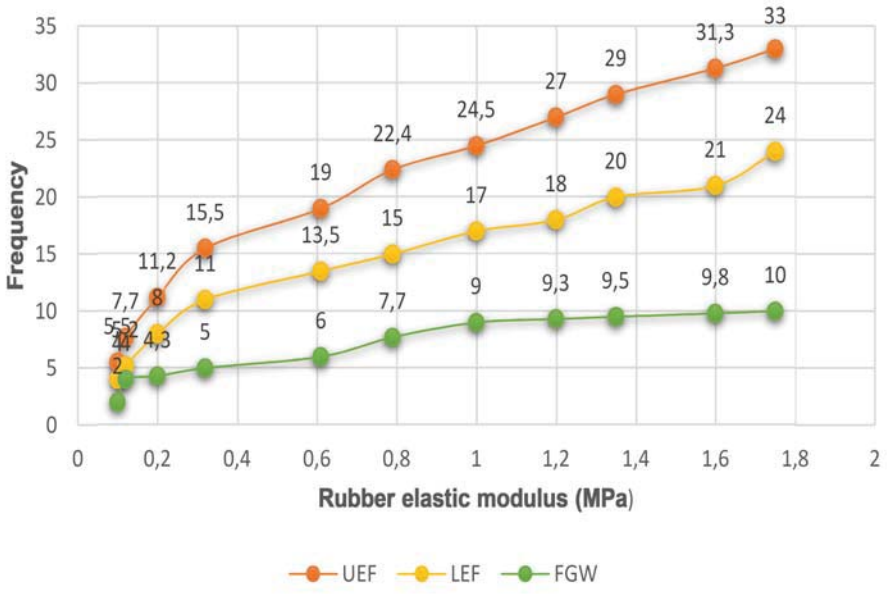

Figure 7: Rubber elastic modulus influence on bandgap's characteristics

5 Verification of the Effectiveness of a Metamaterial Periodic Foundation for Seismic Protection

In order to verify the effectiveness of periodic foundation, it is necessary to compare between the concrete base and periodic foundation. Thus, two models are built, one with a concrete base and the other with a periodic foundation. Both foundations have the same geometrical properties (3m*7 m*0.4m) and the same upperstructure which are composed of two storeys (3m*3.2m*2,9m).

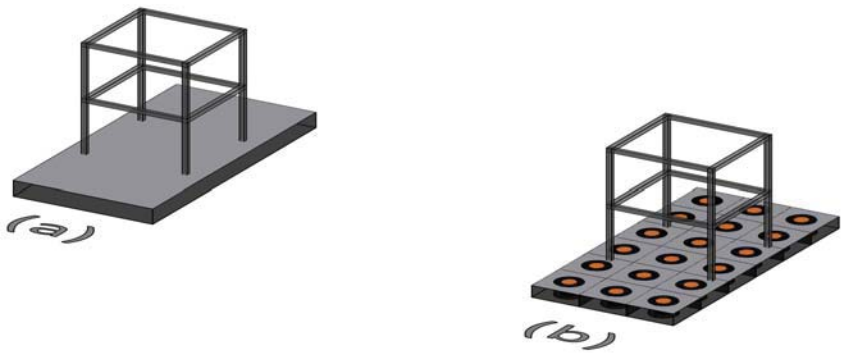

Figure 8: , Frame structure with (a) Concrete foundation (b) Periodic foundation,

The fundamental frequency of upperstructure is equal to 5.04 Hz, thus the cell's bandgap must cover its fundamental frequency. For this reason the following periodic foundation's cells properties (figure 9) have been adopted. These properties give a bandgap between [4.94; 6.8] Hz. Comsol Multiphysics software was used to create the finite element model adopted in this study with displacement conditions: zero displacement in the Z direction and 5cm of vibration amplitude with different frequencies in Y direction

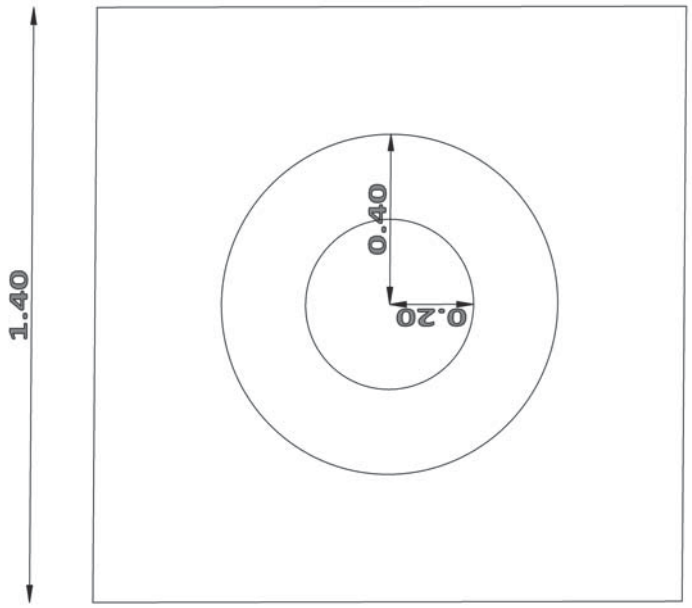

Figure 9: Dimension of periodic foundation's cell

5.1 Results and Analysis

The figure below shows the dynamic responses of the upperstructure and demonstrates the effectiveness of the periodic foundation in seismic isolation with reduction factor about 7 times inside the bandgap

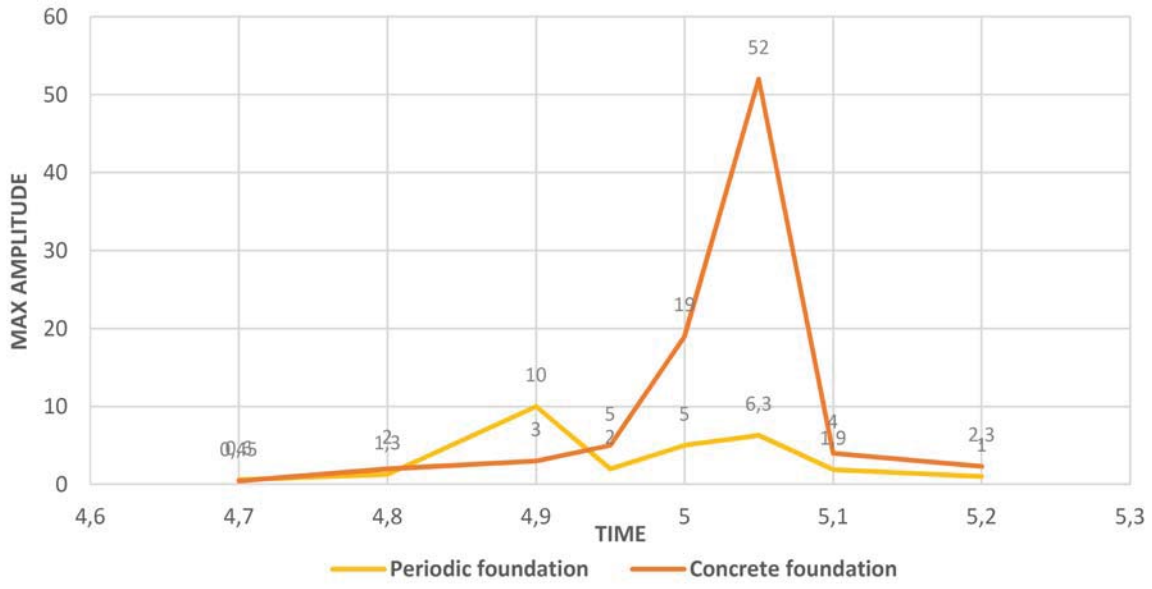

Figure 10: Relative displacement responses in Y direction for second story

6 CONCLUSIONS

The periodic distribution of materials provides itself with a new property, where it inhibits the propagation of elastic waves in the same directions and frequency ranges. These periodic materials are called phononic crystal. A big number of periodic structures is studied and all of these studies indicate the presence of bandgaps, where the waves cannot propagate.

In this paper, a periodic foundation based on local resonance phenomenon was investigated where the wavelengths of seismic waves are in order of a Kilometer. This research included a parametric study to determine the effect of the materials parameters on the bandgap which allowed us to deduce that the density of core and the elastic modulus of rubber are quite effective on bandgaps' characteristics. Moreover, a three-dimensional finite element structural model was used to validated the effectiveness of this periodic foundation approach in achieving its role as seismic attenuator in the desired frequency range [1 ; 10] Hz

Keywords: Artificial accelerograms, Fully non-stationary stochastic process, 1D Non-linear seismic site response analysis, Real ground motion records, Simulation.

Abstract. *Seismic response history analysis is the most significant approach for seismic analysis of structural and geotechnical systems, especially when nonlinearities are present. The main purpose of this analysis is the determination of the system response when it is subjected to a ground motion acceleration.*

Several approaches have been proposed to select the most appropriate seismic acceleration. The various approaches use, respectively: a) real accelerograms; b) synthetic accelerograms and c) artificial accelerograms. The artificial accelerograms for their versality are the most adopted. However, the main drawback of generated artificial accelerogram is the impossibility to take into account of both the time and frequency contents of real accelerograms when the spectrum compatibility is satisfied.

In this paper an alternative method is proposed. The proposed method requires the following steps: i) to select a target accelerogram; ii) to find a fully non-stationary model of earthquake ground acceleration such that the target accelerogram may be considered as one of its samples; iii) to evaluate the mean elastic spectrum of a set of generate fully non-stationary accelerogram samples; iv) to satisfy the compatibility of so determined elastic spectrum to elastic target response spectrum by means of an iterative procedure.

In order to quantify the influence of accelerogram models on the seismic response a non-liner geotechnical system is analysed. In particular, selected a target accelerogram recorded in a stiff soil, the response of a real soil deposit is evaluated assuming for the soil a non-linear one-dimensional (1D) model.

1 INTRODUCTION

A proper definition of the design seismic actions is a fundamental step in the dynamic analysis of structural and geotechnical systems as well as in dynamic soil-structure interaction problems. Seismic codes typically represent the earthquake-induced ground shaking in terms of pseudo-acceleration response spectrum. However, for strongly non-linear problems the use of the design response spectrum is improper and the selection of input motions to be used in non-linear dynamic analyses is required. In this framework, the increasing availability of strong motion records makes the use of *real accelerograms* an attractive option for a proper definition of the input motions [1] even if the results of the selection procedures are influenced by multiple sources of uncertainties related to the definition of the seismic hazard at the site of interest and to the criteria adopted to check the compatibility of the selected records with the frequency and energy content of a target motion expected at the site [2,3]. Despite different selection procedures have been proposed in the literature (e.g. [4,5,6]), depending on the characteristics of the expected target motion and on the adopted compatibility criteria, it may be impossible to select a suitable number of compatible accelerograms without applying large acceleration scale factors which distort the actual characteristics of selected motions leading to unrealistic inputs [2,3].

A suitable alternative for the definition of the input motion consist of sets of *synthetic accelerograms* obtained from seismological numerical models and accounting for site-to-source effects. The determination of the source parameters for previous earthquakes invariably carries a high degree of uncertainty, and the specification of these parameters to which the resulting ground motions can be highly sensitive for future earthquake scenarios can involve a significant degree of expert judgment [1].

Finally, *artificial accelerograms* generated using proper numerical procedures can be also adopted for engineering purposes. Traditionally, artificial accelerograms are generated to match a target response spectrum by obtaining a *power spectral density* (*PSD*) function from the target response spectrum and then to derive accelerogram samples as sinusoidal signals having random phase angles (see e.g. [7,8]). Recently it has been shown that the *artificial accelerograms* generated by applying the models proposed in the literature are not able to catch the up-crossing law of time axis, which is a measure of evolutionary frequency content of accelerograms in various seismological sites [9,10]. Moreover, it has been recognized that artificial accelerograms generated by applying stationary models, extensively adopted by International Seismic Codes, have an excessive number of cycles and consequently they possess unreasonably much higher energy content with respect to real ones [1,10].

In this vein, a new procedure for generating samples of a *fully non-stationary* zero-mean Gaussian process, having a target acceleration time-history as one of its own samples, is described in this paper. The procedure requires the following steps: i) select a target accelerogram; ii) find a *fully non-stationary* model of earthquake ground acceleration such that the target accelerogram may be considered as one of its samples; iii) generate a set of *fully non-stationary accelerogram* samples and evaluate their mean elastic response spectrum; iv) using an iterative procedure aimed to obtain the compatibility between this mean spectrum an that of the target accelerogram.

The reliability and the accuracy of the proposed procedure in generating sets of accelerograms with statistical characteristics similar to those of the target is also checked and discussed in the paper through a numerical application concerning 1D non-linear site response analysis. In this framework it is also shown that the proposed procedure is also able to catch both the time-varying amplitude and frequency content of the target accelerogram.

2 EVOLUTIONARY MODEL FOR EARTHQUAKE INDUCED GROUND ACCELERATION

According to the formulation recently proposed by the authors [9], the *fully non-stationary* model of earthquake ground acceleration is defined as the sum of zero-mean Gaussian *uniformly modulated* stochastic processes. Each *uniformly modulated* random process consists of the product of a positive deterministic *modulating function*, $a(t)$, and a stationary zero-mean Gaussian filtered sub-process, $X_k(t)$. The stochastic process so defined is able to catch simultaneously the time-varying intensity and the time-varying frequency content, although its component processes are individually *uniformly modulated*. Then, the *fully non-stationary* stochastic process $F_0(t)$, of time duration T_D, is here obtained by dividing the time interval $0 \div T_D$ in *n* contiguous time intervals of amplitude $\Delta T_k = t_k - t_{k-1}$ $(k = 1, 2 \cdots, n)$ and requiring that in each time interval the sub-process $X_k(t)$, possesses a unimodal *PSD* function, that is:

$$F_0(t) = \sum_{k=1}^{n} F_{0,k}(t) = a(t) \sum_{k=1}^{n} X_k(t)\, \mathbb{W}(t_{k-1}, t_k) \tag{1}$$

where $\mathbb{W}(t_{k-1}, t_k) = \mathbb{U}(t - t_k) - \mathbb{U}(t - t_{k-1})$ is the window function, with $\mathbb{U}(t)$ the unit step function. The one-sided *EPSD* function of the zero-mean Gaussian fully non-stationary process introduced in Eq.(1) results:

$$G_{F_0 F_0}(\omega, t) = \sum_{k=1}^{n} a^2(t)\, \mathbb{W}(t_{k-1}, t_k)\, G_{X_k}(\omega) \equiv \sum_{k=1}^{n} G_{X_k}(\omega, t) \tag{2}$$

Moreover, in the time interval $[t_{k-1}, t_k)$, the sub-process $X_k(t)$ is here characterised by the following one-sided *PSD* function:

$$G_{X_k}(\omega) = \beta_k^2 \left(\frac{\omega^2}{\omega^2 + \omega_{H,k}^2} \right) \left(\frac{\omega_{L,k}^4}{\omega^4 + \omega_{L,k}^4} \right) G_k^{(CP)}(\omega); \qquad k = 1, ..., n \tag{3}$$

where $\omega_{L,k}$ and $\omega_{H,k}$ are the *k*-th frequency control of the second order low pass and first order high pass Butterworth filters, respectively, $G_k^{(CP)}(\omega)$ is a unimodal one-sided *PSD* function, having unit area, which can be viewed as the linear combination of the displacement and velocity responses of a second-order oscillator subjected to two statistically independent Gaussian white noise processes [11]:

$$G_k^{(CP)}(\omega) = \frac{\rho_k}{\pi} \left(\frac{1}{\rho_k^2 + (\omega + \Omega_k)^2} + \frac{1}{\rho_k^2 + (\omega - \Omega_k)^2} \right); \qquad k = 1, ..., n \tag{4}$$

In equation (4) ρ_k and Ω_k are two free parameters. The first one is a circular frequency bandwidth, the second one is close enough to the predominant circular frequency of the *k*-th filtered stationary process. Finally, in Eq.(3) the coefficient β_k^2 is evaluated in such a way that the sub-process $X_k(t)$ possesses unit variance $\mathrm{E}\left\langle X_k^2(t) \right\rangle \equiv \sigma_{X_k}^2 = 1$. It is given in closed form solution as follows:

$$\beta_k^2 = \frac{2\, \bar{a}_k \bar{b}_k \left(\omega_{H,k}^4 + \omega_{L,k}^4 \right)}{\omega_{L,k}^3 \left(\bar{c}_k + \bar{d}_k + \bar{e}_k \right)} \tag{5}$$

where:

$$\begin{aligned}
\bar{a}_k &= \left(\rho_k^2+\Omega_k^2\right)^4 + 2\left(\rho_k^4 - 6\rho_k^2\Omega_k^2 + \Omega_k^4\right)\omega_{L,k}^4 + \omega_{L,k}^8;\\
\bar{b}_k &= \rho_k^4 + 2\rho_k^2\left(\Omega_k^2 - \omega_{H,k}^2\right) + \left(\Omega_k^2 + \omega_{H,k}^2\right)^2;\\
\bar{c}_k &= -2\,\bar{a}_k\,\rho_k\,\omega_{H,k}\,\omega_{L,k}\left(\rho_k^2 + \Omega_k^2 - \omega_{H,k}^2\right);\\
\bar{d}_k &= \left[\left(\rho_k^2+\Omega_k^2\right)^2\left(\rho_k^4 - 6\rho_k^2\Omega_k^2 + \Omega_k^4 + \omega_{L,k}^4\right) - \omega_{H,k}^2\left(\rho_k^2 - \Omega_k^2\right)\left(\left(\rho_k^2+\Omega_k^2\right)^2 + \omega_{L,k}^4\right)\right] \\
&\quad \times 2\omega_{L,k}\left(\omega_{H,k}^4 + \omega_{L,k}^4\right);\\
\bar{e}_k &= \sqrt{2}\,\bar{b}_k\,\rho_k\left\{\omega_{L,k}^2\left(\omega_{H,k}^2 - \omega_{L,k}^2\right)\left(\omega_{L,k}^4 + \rho_k^4 - 2\rho_k^2\Omega_k^2 - 3\Omega_k^4\right)\right. \\
&\quad \left. + \left(\omega_{H,k}^2 + \omega_{L,k}^2\right)\left[\rho_k^6 + \Omega_k^6 + 3\Omega_k^2\rho_k^2\left(\rho_k^2+\Omega_k^2\right) + \omega_{L,k}^4\left(\rho_k^2 - 3\Omega_k^2\right)\right]\right\}.
\end{aligned} \tag{6}$$

Scaling the *PSD* function (3) to have unit variance allows separating, in each time interval, the time variation in amplitude from the frequency content of the various segments of the stochastic process $F_0(t)$.

3 PARAMETERS ESTIMATION FROM A TARGET ACCELEROGRAM

The purpose of this section is to define a stochastic process $F_0(t)$ such that the target accelerogram, $\ddot{U}_g(t)$, may be considered as one of its samples. To do this the *modulating function* and the frequency content of the process $F_0(t)$ are estimated separately.

3.1 Estimation of modulating function

Let us consider a target accelerogram $\ddot{U}_g(t)$ of time duration T_D. To evaluate the *modulating function*, $a(t)$, the time interval $0 \div T_D$ is subdivided in three contiguous time intervals of amplitude $\Delta T_j = t_j - t_{j-1}$ $(j=1,2,3)$. The *modulating function* in the first time interval, $0 \le t < t_1$, is here assumed parabolically increasing from zero; while in the third time interval, $t_2 \le t \le T_D$, it is assumed exponentially decreasing. In the second time interval, $t_1 \le t < t_2$, a polynomial of *p*-th order to model the *modulating function* is adopted:

$$a(t) = \sum_{j=1}^{2} \bar{a}_j(t)\,\mathbb{W}(t_{j-1}, t_j) + a(t_2)\exp\left[\frac{(t-t_2)}{T_D - t_2}\ln\left(\frac{\left|\ddot{U}_g(T_D)\right|}{a(t_{n_a-1})}\right)\right]\mathbb{W}(t_2, t_3). \tag{7}$$

The parameter of the modulating function, $a(t)$, in the first two time intervals $[0, t_1)$,and $[t_1, t_2)$ are estimated by least-square fitting the expected energy of the fully non-stationary process to the energy of the target accelerogram. That is the following optimization problems is solved:

$$\begin{cases} \text{find } \alpha_1,\ \alpha_2,\cdots\ \alpha_p; \\ \text{minimising} \quad \int_{t_{j-1}}^{t_j}\left[E_{\ddot{U}_g}(t)-\int_{t_{j-1}}^{t}\left[a(t_{j-1})+\bar{a}_j(\tau)\right]^2 \mathrm{d}\tau\ \right]^2 \mathrm{d}t; \qquad j=1,2. \\ \text{such that} \quad \bar{a}_j(t)=\sum_{i=1}^{p}\alpha_i\,(t-t_{j-1})^i, \quad \bar{a}_j(t)\geq 0, \quad t_{j-1}\leq t<t_j; \end{cases} \tag{8}$$

where $a(0)=0$ and:

$$E_{\ddot{U}_g}(t)=\int_0^t \ddot{U}_{\mathrm{g}}^2(\tau)\,\mathrm{d}\tau \quad 0\leq t\leq T_D \tag{9}$$

is the cumulative energy function of the target accelerogram. Moreover, in the third time interval with $t\in[t_2,t_3\equiv T_D]$, the *modulating function* is approximated by an exponential decaying function whose coefficients are evaluated by imposing the continuity with the previous one and its decaying down to the absolute value, $\left|\ddot{U}_{\mathrm{g}}(T_D)\right|$, at the end of the target accelerogram:

$$a(t)=a(t_2)\exp\left[\frac{(t-t_2)}{T_D-t_2}\ln\left(\frac{\left|\ddot{U}_{\mathrm{g}}(T_D)\right|}{a(t_2)}\right)\right], \quad t_2\leq t\leq T_D. \tag{10}$$

3.2 Estimation of PSD function parameters

Since analysing the expected energy function of the fully non-stationary stochastic process $F_0(t)$, it is possible only to estimate the amplitude variation of the target accelerogram $\ddot{U}_{\mathrm{g}}(t)$, another criterion to estimate the variation of the frequency content of $F_0(t)$ must be established, such that $\ddot{U}_{\mathrm{g}}(t)$ may be considered as one of its samples. Once the time interval $0\div T_D$ is divided in *n* contiguous time intervals, this purpose is here achieved by capturing in the generic *k*-th time interval a group of seismic waves possessing the specific frequency distribution of the target accelerogram in the same time interval. To do this the spectral parameters, Ω_k, ρ_k, $\omega_{H,k}$ and $\omega_{L,k}$, appearing in Eq.(3), of the one-sided *PSD* function $G_{X_k}(\omega)$ of the stationary sub-process $X_k(t)$ must be appropriately estimated. In particular, the predominant circular frequency and the circular frequency bandwidth, are evaluated, respectively, as authors [9]:

$$\Omega_k\cong\frac{2\pi N_{0,k}^+}{\Delta T_k}; \quad \rho_k\simeq\frac{\pi N_{0,k}^+}{2\Delta T_k}\left[\pi-2\frac{N_{0,k}^+}{P_k}\right] \tag{11}$$

where N_0^+ and P_0 are the total number of *zero-level up-crossings* and the total number of *peaks* of target accelerogram. To complete the characterization of the one-sided *PSD* function $G_{X_k}(\omega)$, given in Eq.(3), the circular frequency control of two Butterworth filters $\omega_{H,k}$ and $\omega_{L,k}$ in all time intervals, $[t_{k-1},t_k)$, have to be estimated.

3.3 Fully non-stationary samples

Once the parameters characterizing the *fully-non stationary* zero-mean Gaussian process, $F_0(t)$, defined in Eq.(1), are estimated, it is easy to generate its samples in such a way that the selected target accelerogram can be considered as one of its own samples. Indeed, the *i*-th sample of the $F_0(t)$ stochastic process, containing in its set the target accelerogram $\ddot{U}_g(t)$, can be evaluated as:

$$F_0^{(i)}(t) = a(t)\sqrt{2\Delta\omega}\left[\sum_{r=1}^{m_N}\sin\left(r\,\Delta\omega t + \theta_r^{(i)}\right)\left(\sum_{k=1}^{n}\mathbb{W}(t_{k-1},t_k)\sqrt{G_{X_k}\left(r\,\Delta\omega\right)}\right)\right] \tag{12}$$

assuming a frequency increment $\Delta\omega = \omega_N / m_N = 0.1$, an upper cut-off circular frequency $\omega_N = 100$ rad/s, and the random phase angles, $\theta_r^{(i)}$, uniformly distributed over the interval $[0-2\pi)$. It follows $m_N = 1000$, and $\Delta t = \pi/(4\omega_N)$.

4 FULLY NON-STATIONARY SPECTRUM COMPATIBLE ARTIFICIAL ACCELEROGRAMS

In this section the *EPSD* of the fully non-stationary is modified to guaranty the spectrum compatibility of the sets of artificial accelerograms.
To reduce the gap between the elastic response spectrum of target accelerogram and the mean elastic response spectrum of artificial accelerograms an iterative procedure has to be implemented. The *EPSD* function (2) is rewritten as:

$$\begin{aligned}&\bar{G}_{F_0F_0}^{(j)}\left(\omega_k,t\right) = a^2(t)\bar{G}_0^{(j)}(\omega_k)\sum_{\ell=1}^{n}\mathbb{W}(t_{\ell-1},t_\ell)\,G_{X_\ell}\left(\omega_k\right);\\ &\bar{G}_{F_0F_0}^{(0)}\left(\omega_k,t\right) \equiv G_{F_0F_0}\left(\omega_k,t\right)\end{aligned} \tag{13}$$

In this equation $\bar{G}_0^{(j)}(\omega_k)$ is a corrective *PSD* function at the *j*-th iteration evaluated as follows [12]:

$$\bar{G}_{X_k}^{(j)}(\omega_k) = \bar{G}_{X_k}^{(j-1)}(\omega_k)\,\frac{S_e^{(T)}(\omega_\ell,\zeta_0)^2}{\bar{S}_e^{(j-1)}(\omega_\ell,\zeta_0)^2} \tag{14}$$

where $S_e^{(T)}(\omega_\ell,\zeta_0)$ is the elastic response spectrum of target accelerogram, $\bar{S}_e^{(j)}(\omega_\ell,\zeta_0)$ is the mean elastic response spectrum determined at the *j*-th iteration.

Notice that at first iteration it is assumed $\bar{G}_0^{(0)}(\omega_k) = 1$. Once the corrective *PSD* function is introduced, by using the original set of random phase angles, $\theta_r^{(i)}$, a new set of samples has to be calculated:

$$\bar{F}_0^{(i)}(t) = a(t)\sqrt{2\Delta\omega}\left[\sum_{r=1}^{m_N}\sin\left(r\,\Delta\omega t + \theta_r^{(i)}\right)\left(\sum_{\ell=1}^{n}\mathbb{W}(t_{\ell-1},t_k)\sqrt{\bar{G}_0^{(j)}(r\,\Delta\omega)G_{X_\ell}\left(r\,\Delta\omega\right)}\right)\right] \tag{15}$$

It has to be emphasized that the procedure should not be expected to be convergent at all selected control frequencies.

Moreover, it has been pointed out that it is not productive to iterate for more than about four cycles [12].
Obviously, by adopting the fully non-stationary process possessing, at the *j*-th iteration, the *EPSD* function (13), it is not possible to fully satisfy the energy content and the frequency content of target recorded accelerogram as well as the spectrum compatibility to its elastic response spectrum.
However, as will show in the next section, the proposed procedure furnishes a good compromise in satisfying these three aspects.

5 NUMERICAL APPLICATION

In order to highlight the reliability and the accuracy of the proposed procedure in generating sets of accelerograms with statistical characteristics similar to those of the target one, a numerical application concerning 1D non-linear site response analysis was used.
A comparison with the results obtained using a set of accelerograms generated using the stationary response spectrum compatible method [7] is also presented and discussed herein.

5.1 Target motion and site description

The target accelerogram consist of the N-S component of the ground motion recorded at Vasquez Rocks Park during the 1994 Northridge earthquake (M_w = 6.7). The recording stations is characterized by an average shear wave velocity in the upper 30 m equal to $V_{s,30}$ = 996 m/s and by a site-source distance R_{JB} = 23.1 km [13].
The ground motion, having an overall duration T_D = 36.6 s, was characterized by a peak ground acceleration a_{max} = 0.132 *g*, a *total* and *Arias intensity* equal to I_0 = 1.9 m^2/s^3 and I_A = 0.3 m/s, respectively, a significant strong motion duration (i.e. interval of time elapsed between the 5% and 95% of I_0) *SMD* = 7.3 s and a total number of *zero-level up-crossings* and of *peaks* equal to N_0^+= 196 and P_0 = 212, respectively.
The 1D site response analyses were carried out using the soil profile derived by [14] with reference to the port area of Tremestieri (Messina), located in the east cost of Sicily.
The shear wave velocity profile detected by a Cross Hole test in the upper 50 m, was interpolated using the following expression:

$$V_S(z) = V_{S0}\left(1+\alpha\frac{z}{H}\right)^m \tag{16}$$

with V_{S0} = 80 m/s, m = 0.5 and α = 50 and allowed to detect a seismic bedrock (V_s = 800 m/s) at a depth H = 99 m.
For this soil profile the average shear wave velocity is $\overline{V}_{S,H}$ =537 m/s and the fundamental period of elastic vibration is $T_{1,L}$ = 0.63 s.
For the site of interest, resonant column tests were also performed on soil samples retrieved at depths of 7, 13, 18.5 and 28.5 m.
The test results in terms of variation of the normalized shear modulus G/G_0 and of the damping ratio D with the shear strain amplitude γ, are plotted in Figure 1. The curves refer to effective vertical stresses σ_v' ranging from 100 to 300 kPa.

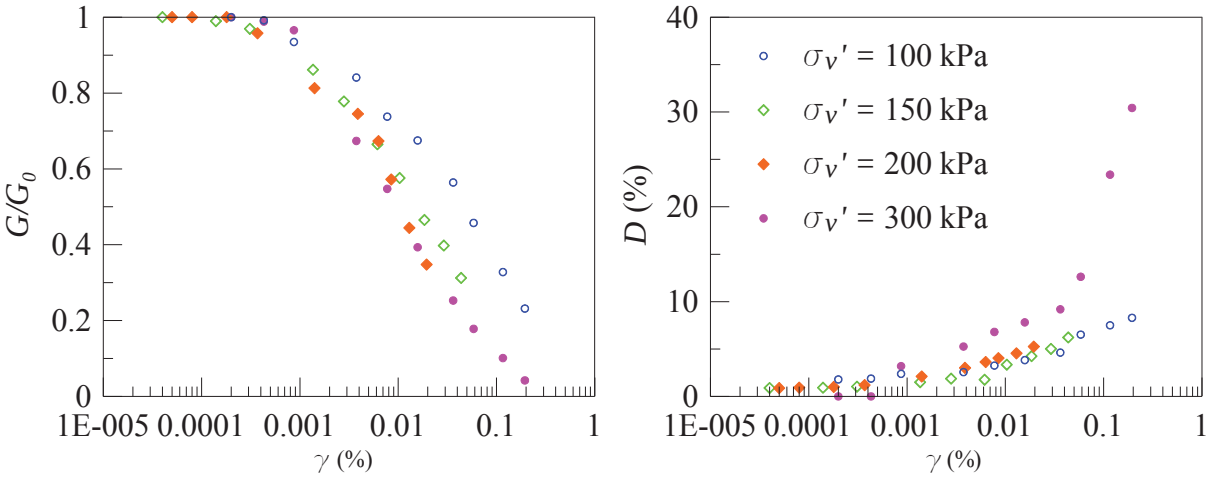

Figure 1: G/G0 – γ (a) and D – γ (b) curves evaluated or the site of interest.

5.2 Set of fully non-stationary accelerograms

Using the proposed procedure, a set of artificial accelerograms was generated using appropriate modulating and power spectral density functions which allowed to preserve the amplitude and the frequency content of the target motion.

To evaluate the *modulating function* $a(t)$, the time duration of the analysed accelerogram $0 \div T_D$, is divided in three time intervals, optimizing the choice of instants of passage from one time interval to adjacent ones (see e.g. [9]).

Figure 2 shows the absolute value of the target accelerogram together with the *modulating function* $a(t)$.

The parameters which characterise $a(t)$ are listed in Table 1, together with the values of the time instants t_1 and t_2, corresponding to the passage from one interval to another, the corresponding percentages of *total intensity* k_1% and k_2%, the order p of the polynomial in the second time interval, and the absolute value $|\ddot{U}_g(T_D)|$ at the end of the target accelerogram.

For the first two time-intervals, the polynomial coefficient α_i, obtained through the optimization procedure, are listed in Table 2.

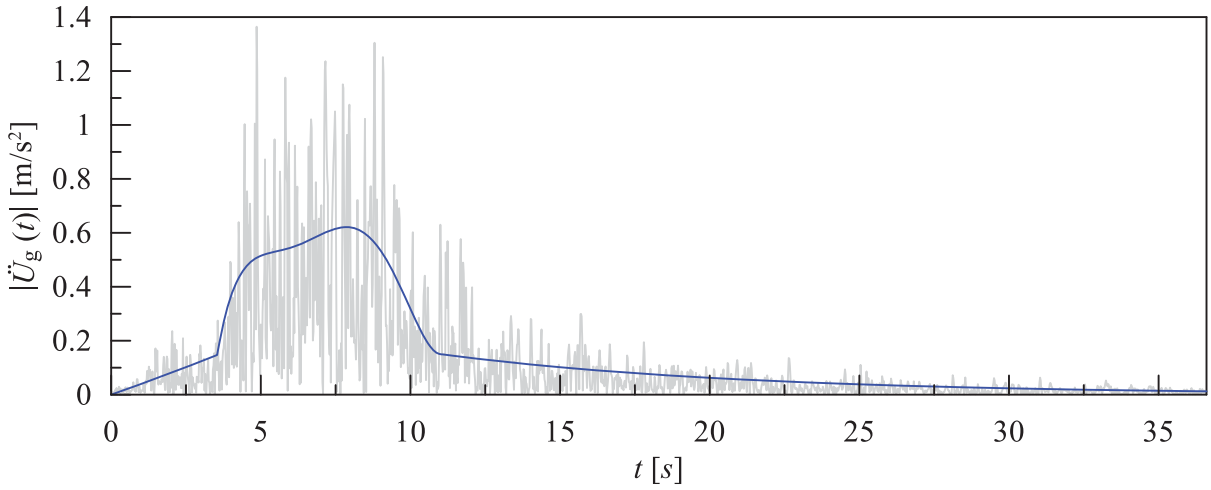

Figure 2: Absolute value of the analysed accelerograms and selected *modulating functions* $a(t)$.

t_1 [s]	t_2 [s]	k_1%	k_2%	p	$\lvert\ddot{U}_g(T_D)\rvert$ [m/s^2]
3.54	11.02	1	92	5	0.0123

Table 1: Parameters of the modulating function selected for the target accelerograms.

$0 \le t < t_1$		$t_1 \le t < t_2$				
α_1	α_2	α_1	α_2	α_3	α_4	α_5
0.039	$6.998 \cdot 10^{-4}$	0.641	-0.429	0.138	-0.020	$1.042 \cdot 10^{-3}$

Table 2: Polynomial coefficients [m/s^{i+2}] in the first two time-intervals of the modulating function.

The characterization of the *fully-non stationary* zero-mean Gaussian process $F_0(t)$ must be completed by estimating the predominant circular frequency Ω_k, and the bandwidth circular frequency ρ_k of the one-sided *PSD* function $G_{X_k}(\omega)$ of the stationary sub-process $X_k(t)$, according to Eq(11). As highlighted in [9], to obtain accurate results, the analysed accelerogram must be subdivided into many time intervals $\ddot{U}_{g,\ell}(t)$, each of which containing a number of *zero level up crossings* $N_{0,k}^+$ at least equal to one; consequently the target accelerogram is subdivided in 73 time intervals with a constant time step of 0.5 s. Through several numerical tests it was verified that the control frequencies of two Butterworth filters $\omega_{H,k}$ and $\omega_{L,k}$ can be assumed equal to $\omega_{H,k} = 0.1\,\Omega_k$ and $\omega_{L,k} = \Omega_k + 0.8\,\rho_k$, respectively. The parameters useful to the characterisation of the one-sided *PSD* function $G_{X_k}(\omega)$ are reported in Table 3.

Table 3: Main parameters of the one-sided *PSD* functions in the time intervals analysed.

Once the parameters characterizing the *fully-non stationary* zero-mean Gaussian process, $F_0(t)$, are estimated, according to Eq.(12), it is easy to generate its samples in such a way that the selected target accelerogram can be considered as one of its own samples.

A more complete comparison can be performed by evaluating, for the analysed accelerogram, the cumulative energy function $E_{\ddot{U}_g}(t)$ and the cumulative *zero-level up-crossing*

function $N_0^+(t)$, which count the number of *zero-level up-crossing* until the time *t*. These two functions are compared, for the analysed accelerogram, with the corresponding mean value functions obtained by calculating the average of the results of the set of artificial accelerograms samples.

In particular, in Figure 3a the cumulative energy function of the analysed target accelerogram is compared to that obtained as the mean value of 50 samples. In the Figure 3a the cumulative energy function confidence intervals, evaluated as the mean values plus/minus the corresponding standard deviation, are also plotted.

In Figure 3b the cumulative *zero-level up-crossing* function of target accelerogram is compared with the mean value function of 50 samples and the *zero-level up-crossing* function confidence intervals. In Figures 3a and 3b, the shaded areas represent the envelope of the maximum and minimum values of the cumulative energy function and the cumulative *zero-level up-crossing* function of the 50 generated samples, respectively.

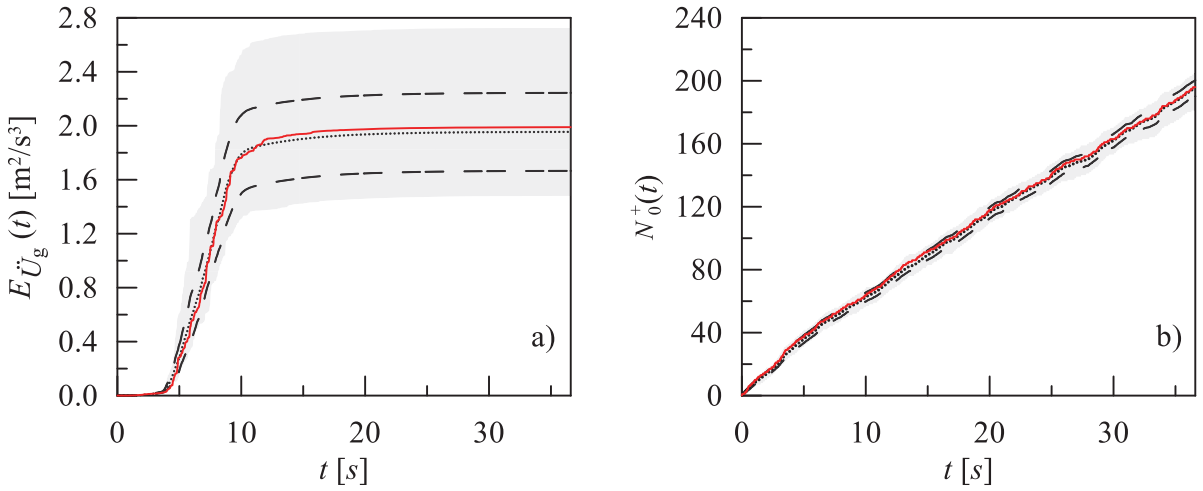

Figure 3: Comparison among the cumulative energy function a) and the cumulative zero-level up-crossing function b) of the selected accelerogram with statistics of the artificial ones: target function (red solid line); mean value function (black dotted line); mean value plus/minus standard deviation functions (black dashed lines); envelope of the maximum and minimum values of all samples (shaded area).

5.3 Set of Stationary accelerograms

A set of stationary spectrum compatible *artificial accelerograms* were also generated by applying the procedure proposed by [7]. According to this procedure the *PSD* function of the zero-mean Gaussian stationary process $G_{F_0F_0}^{(ST)}(\omega)$ is determined as follows:

$$G_{F_0F_0}^{(ST)}(\omega)=0, \quad 0\le\omega_\ell\le\omega_1;$$
$$G_{F_0F_0}^{(ST)}(\omega)=\frac{4\zeta_0}{\omega_\ell\pi-4\zeta_0\omega_{\ell-1}}\left[\left(\frac{S_e^{(T)}(\omega_\ell,\zeta_0)}{\eta_U(\omega_\ell,\zeta_0)}\right)^2-\Delta\omega\sum_{j=1}^{k-1}G_{F_0F_0}^{(ST)}(\omega_j)\right], \quad \omega_1<\omega_\ell\le\omega_N; \tag{17}$$

where $\omega_1\le 1\,(\text{rad/s})$ and ω_N (the cut off circular frequency) define the bounds of the existence domain of the *PSD* function $G_{F_0F_0}^{(ST)}(\omega)$, $\zeta_0=0.05$ is the damping ratio, $S_e^{(T)}(\omega_\ell,\zeta_0)$ is the target elastic pseudo-acceleration spectrum and $\eta_U(\omega_\ell,\zeta_0)$ is a peak factor

$$\eta_U(\omega_\ell,\zeta_0)=\sqrt{2\ln\left\{\frac{T_D\,\omega_\ell}{\pi}\left(-\ln 0.5\right)^{-1}\left[1-\exp\left[-q_U^{1.2}\sqrt{\pi\ln\left(\frac{T_D\,\omega_\ell}{\pi}\left(-\ln 0.5\right)^{-1}\right)}\right]\right]\right\}} \tag{18}$$

in which $q_U=0.246$ is the bandwidth factor. The samples of stationary Gaussian zero-mean process can be calculated by applying the following relationship:

$$\overline{\overline{F}}_0^{(i)}(t)=\sqrt{2\Delta\omega}\left[\sum_{r=1}^{m_N}\sin\left(r\,\Delta\omega t+\theta_r^{(i)}\right)\sqrt{G_{F_0F_0}^{(ST)}\left(r\,\Delta\omega\right)}\right] \tag{19}$$

5.4 Spectrum compatibility

To satisfy the spectrum compatibility between the mean elastic response spectrum of the 50 artificial fully non-stationary accelerograms and the elastic response spectrum of target accelerogram, the iterative procedure described in section 4 was applied.
In Figure 4a the average spectrum of the initial (*0*-th iteration) set of artificial accelerograms and of the samples generated after 4 iterations (*4*-th iteration), are compared with the target elastic pseudo acceleration response spectrum. In Figure 4b, the percentage deviation (*err*) between the target response spectrum and the mean of the response spectra generated by the *0*-th and *4*-th iterations are shown. The average spectrum of the set of artificial accelerograms generated by the stationary model and the correspondent deviation from the target response spectrum are also plotted in Figure 4a and in Figure 4b respectively.

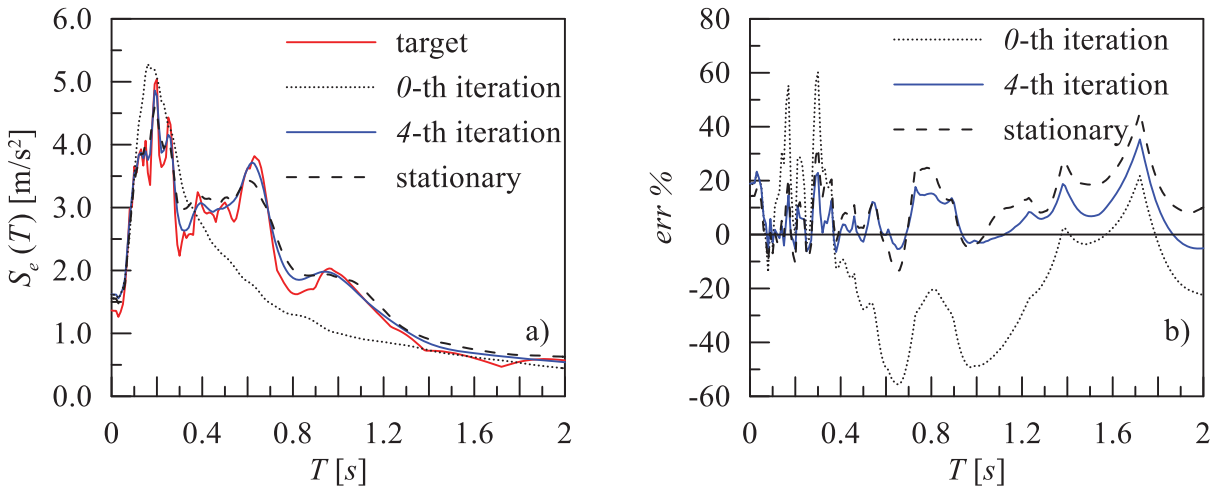

Figure 4: a) Target elastic response spectrum and mean elastic response spectra evaluated from 50 generated samples for the fully non-stationary model at the *0*-th and *4*-th iterations, and for stationary model; b) percentage errors among the target elastic response spectra and the mean ones.

In Figure 5 the time-history of the analysed target recorded accelerogram is compared with one sample of the fully non-stationary spectrum compatible accelerogram, $\overline{F}_0^{(i)}$, generate by means of Eq.(15), and one sample of the stationary spectrum compatible accelerogram $\overline{\overline{F}}_0^{(i)}$, generate by Eq.(19).

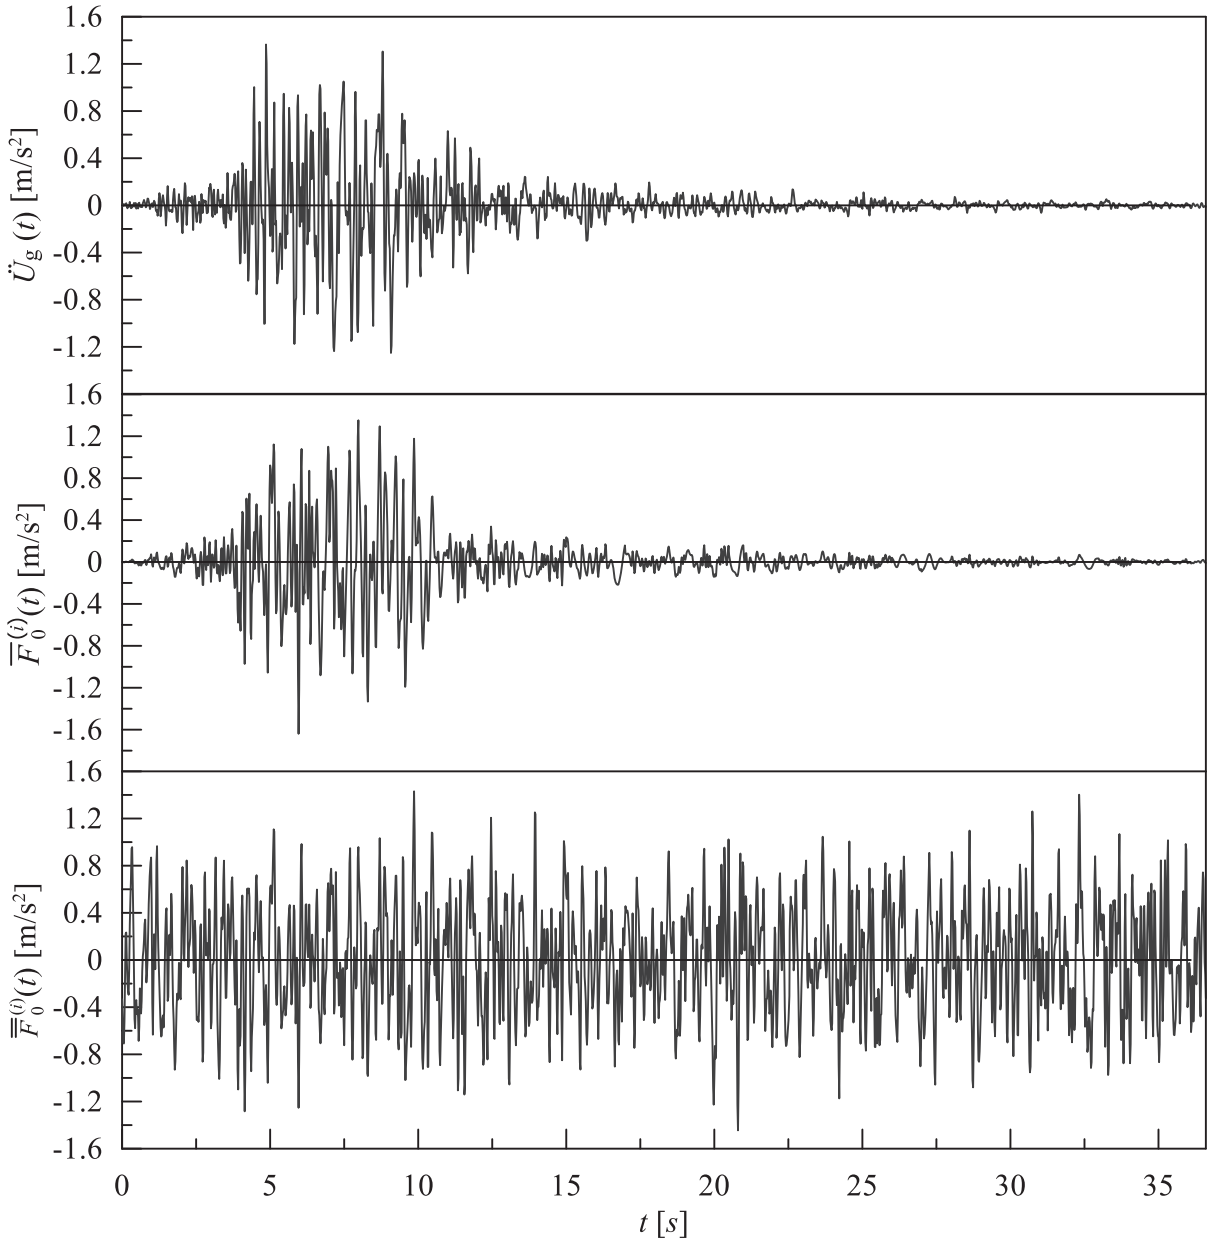

Figure 5: Comparison among the selected accelerogram and the corresponding *i*-th generated samples by the proposed fully non-stationary model $\overline{F}_0^{(i)}$ and the stationary model $\overline{\overline{F}}_0^{(i)}$.

The mean value of the cumulative *energy function* and the cumulative *zero level up crossing* function of the generated stationary samples are reported in Figure 6 with the corresponding functions obtained from the target and from the samples generated by applying the proposed fully non-stationary model.

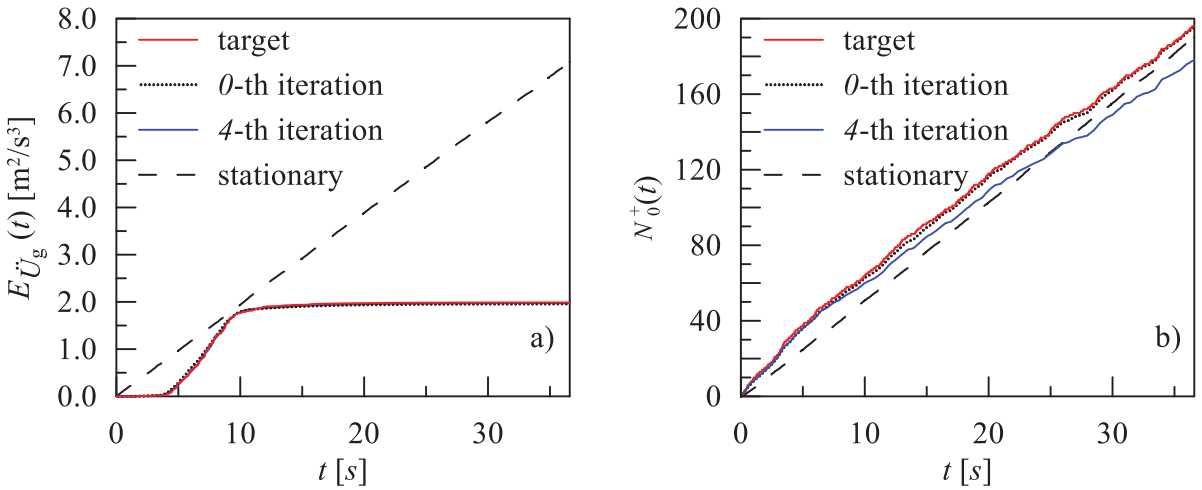

Figure 6: a) Comparison among the cumulative energy function of the target accelerogram and the mean cumulative energy functions of the fully non-stationary model, at the *0*-th and *4*-th iterations, and for stationary model; b) Comparison among the cumulative *zero level up crossing* function of the target accelerogram and the mean cumulative functions of the fully non-stationary model, at the *0*-th and *4*-th iterations, and for stationary model.

5.5 1D non-linear site response analyses

1D non-linear site response analyses were carried out through using the software Deepsoil vs. 6.1 [15]. The non-linear backbone formulation is described by the modified hyperbolic model MKZ developed by [16]. The hysteretic Re/Unloading Formulation, represented by the non-Masing model, is the MRDF-UIUC Pressure-Dependent Hyperbolic [17] model which leads to a simultaneous fit of modulus reduction and damping curves. In the analyses, the soil deposit is discretized in discrete 1 m layers having a soil unit weight γ = 19 kN/m^3 while the values V_b = 800 m/s and γ_b = 22 kN/m^3 are assigned to the shear wave velocity and unit weigh of the bedrock respectively.

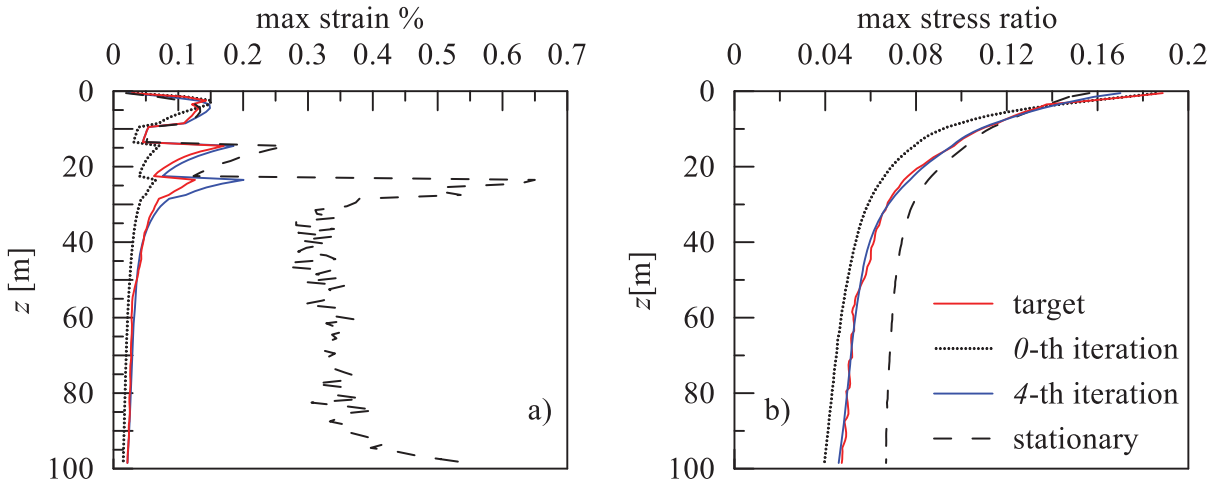

Figure 7: Profiles of peak shear strain (a) and peak stress ratio (b) computed for the target accelerogram (red line) and as the mean of the responses computed for each of the 50 spectrum-compatible stationary (dashed black line) and non-stationary (*0*-th and *4*-th iteration) artificial accelerograms.

The analysis results are presented in Figure 7 in terms of profiles of peak shear strains (Fig. 7a) and peak stress ratio (Fig. 7b) defined as the ratio between the peak shear stress, computed through the analysis, and the static effective vertical stress. Specifically, the Figure 7 shows the

profiles computed for the target accelerogram (continuous red line) and the profiles obtained as the mean of the responses computed for each of the 50 spectrum-compatible stationary (dashed black line) and non-stationary artificial accelerograms. In this latter case, the results refer to the average of the site responses computed for the initial (*0*-th iteration) set of artificial accelerograms and for the set obtained after *4* iterations of the procedure described in section 5.4 to achieve the spectral compatibility.
For both the peak strain and the peak stress ratio, it can be observed that, at all the depth (z), the response computed for the target accelerogram is in a good agreement with the average response predicted using the two sets (*0*-th and *4*-th iteration) of non-stationary accelerograms. Specifically, the effectiveness of the generation procedure described in this paper is clearly apparent from the comparison with the average response related to the set of spectrum-compatible non-stationary accelerograms (*4*-th iteration); in this case, differences between the average profile and the profile related to the target accelerogram less than 4% can be observed at all the depth with the only exception of the shallowest data ($z < 1$ m about) concerning the stress-ratio (Fig. 7b).
Conversely, larger differences are apparent between the profile related to the target accelerogram and the mean profile computed for the set of stationary spectrum-compatible accelerograms. These differences are more evident in terms of profile of peak strain (Fig. 7a) in the lower portion of the soil deposit. The differences in the computed profiles can be ascribed to the unreasonably much higher energy content which generally characterize artificial accelerograms generated by applying stationary models; as a consequence, these accelerograms are widely characterized by an excessive number of loading cycles in comparison with actual acceleration records [1] and by a very large strong motion duration (which is almost coincident with the total duration). These characteristics of the input motions lead to unacceptable errors in the prediction of the seismic response as a consequence of an overestimation of non-linear effects.
Accordingly, the need of procedures aimed to generate non-stationary ground motion to be used in non-linear seismic analysis is clearly apparent.

6 CONCLUSIONS

In this paper a procedure for generating fully non-stationary spectrum compatible artificial accelerograms has been proposed. In the procedure, the target accelerogram is subdivided in many contiguous time intervals in which appropriate unimodal Power Spectral density functions and modulating functions have been estimated to obtain cumulative energy and frequency content very close to the ones of the target accelerogram. To reduce the gap between the elastic response spectrum of the target accelerogram and the mean elastic response spectrum of fully non-stationary artificial accelerograms, an iterative procedure has been implemented.
A numerical application concerning 1D non-linear site response analysis showed that the use of artificial accelerograms generated by the proposed non-stationary spectrum compatible model leads to profiles of peak shear strain and peak stress ratio very close to that obtained using the target accelerogram as input motion. Contrary, the use of stationary accelerograms leads to results very far from those obtained using the target accelerogram as a consequence of a wrong estimate of the actual non-linear soil behaviour.
Finally, it has to be emphasised that the proposed method for generating fully non-stationary spectrum compatible accelerograms could represent a useful and promising tool in the analyses devoted to assess the seismic performance of structural and geotechnical systems through non-linear dynamic analyses.

Abstract. *During the recent seismic events in Italy (such as L'Aquila 2009, Emilia 2012 and the 2016 Central Italy seismic sequence), several damages and collapses were observed in precast reinforced concrete industrial buildings. Although reliable seismic design criteria are nowadays available for precast frame structures, recent earthquakes showed that the optimal design of the cladding-to-structure connections is yet to be solved. Currently, in the seismic design practice of precast structures, the panels are modeled as additional masses, without any stiffness contribution. Then, the capacity displacement of the designed connection is compared with its demand displacement. This design practice does not correctly reflect the actual behavior of the connection because, due to the configuration of the anchorage devices that exert friction and blockage effects, a force exchange can occur between the panels and the supporting beams. This was demonstrated by the surveys carried out after the seismic events, reporting several damages to traditional anchorage systems. In the context presented above, the research work is aimed at investigating the seismic behavior of the first prototype of an innovative cladding-to-structure connection for precast industrial buildings. The innovative device is capable to guarantee higher robustness with respect to the devices currently available on the market, especially when friction forces on the sliding cart are significant and is able to avoid jamming of the cart. Full scale experimental tests are carried out on a prototype precast building equipped with cladding panels. The system is forced by a vibrodyne mounted on the roof and providing an in-plane sinusoidal force along the direction of the panel. Tests are repeated with two different types of connection between the wall panels and the structure: a traditional one and an innovative one, showing the superior performance of the new type of connection in reducing the load transfer and avoiding damage to the panel and the beam even at large excitation levels.*

1 INTRODUCTION

Precast reinforced concrete technology is a construction method which gained success especially in industrial constructions and commercial buildings, due to the need of large spans and plan dimensions. The 2012 Emilia-Romagna earthquake (central Italy) highlighted the seismic vulnerability of these structures in terms of direct and indirect losses [1], focusing the attention on damage prevention methodologies for prefabricated structures [2, 3].
In particular, precast buildings can experience collapses or serious damages in structural and nonstructural elements, expecially due to the lack of adequate beams-to-columns and cladding-to-structure connections [4], demostrating an insufficient safety level against seismic actions [5]. Indeed, connections should be able to absorb the relative displacements due to cyclic seismic loading in order to avoid damage for both vertical and horizontal panels [6, 7].
In this framework, the research work is aimed at investigating the in-plane anchorage performance of an innovative cladding-to-structure connection device. The new device has a joint capable of rotating along the two principal directions, as well as sliding along the vertical and horizontal direction. It follows that, during the seismic event, the connection can perform a rotational-translational motion. The idea is to effectively decouple the movement between the panel and the structural element, overcoming the major limitations associated with traditional anchorage systems, such as deformability, friction force and jamming of the cart.

2 THE CASE STUDY

The case study is a prototype single-story building (Figure 1) with plan dimensions of 10.2 x 14.6 m and with a height of 11.0 m. The frame is composed by reinforced concrete columns with a rectangular cross section, prestressed I-shaped beams along the shorter side of the structure, and U-shaped precast roof beams along the longer side. A reinforced concrete cladding

Figure 1: The full scale prototype building.

panel can be mounted on the structure and is connected to a reinforced concrete support beam.

The connection between the panel and the support beam is realized by 4 steel plates, two on each side of the support beam, equipped with a hole to house a central connection pivot. The support beam, integral with the wall panel and the principal beam as well, allows to measure the cladding-to-structure force exchange through the displacements transducers installed on the steel plates. A vibrodyne is installed on the rooftop, capable of inducing a sinusoidal force to the structure, as better detailed in the next section.
Two different types of hammer-head strap devices are used to connect the cladding panel to the support beam: a traditional hammer-head strap (Figure 2a) and a first prototype of an innovative device (Figure 2b).
The traditional connection is composed by: a hammer-head strap whose head is connected to the panel in a vertically oriented C-shaped steel channel; a bolt and a toothed washer connected to the support beam through an horizontally oriented C-shaped steel channel. The basic idea is that the panel and the structure are rigidly connected through the two blocks (channels). One of the limitations associated with the use of a traditional non-seismic connection concerns the significant amount of force exchange between the panel and the structure, due to the friction exerted in the anchorage components which can lead to a collapse mechanism. In order to improve the anchorage performance, the innovative connection has a rotating pin near the panel coinciding with the vertical bolt which allows rotation to take place around the vertical axis passing through the bolt (yellow dashed line in Fig. 2b). Furthermore, a sliding block is installed on the support beam that allows the sliding movement as indicated by the red arrow in Fig. 2b).

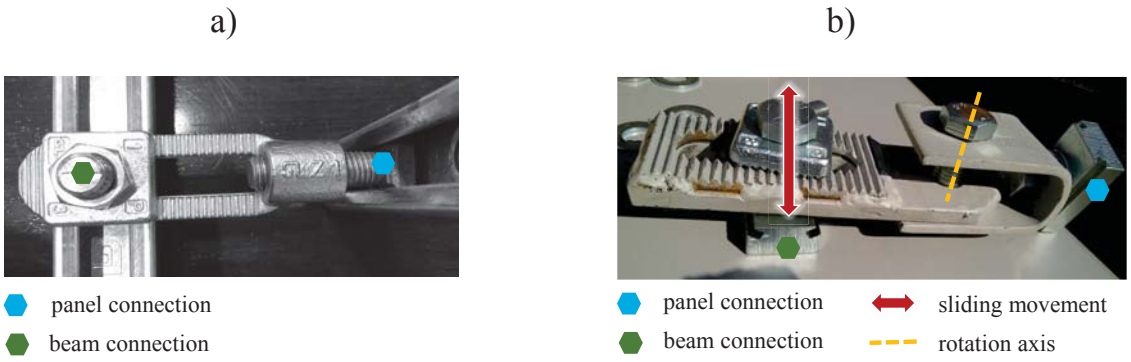

Figure 2: The tested connection devices: a) the traditional hammer-head strap; b) the first prototype of the innovative device.

3 EXPERIMENTAL SET-UP

The prototype building is instrumented with several types of sensors (Figure 3): n. 8 uniaxial piezoelectric accelerometers, model PCB393B12 with a sensitivity of 10 V/g, are located at the top of each column (A1-A8); n.2 accelerometrs (A9-A10) are installed on the support beam connecting the principal beam to the cladding panel; n. 2 accelerometers are positioned at the top of the cladding panel; n. 8 strain gauges are installed on the two faces of each steel plate (E1-E8 with reference to Figure 3) to measure the force exchange between the panel and the support beam. All the sensors are simultaneously acquired with the data acquisition (DAQ) system, model NIcDAQ9184, connected to the PC via Ethernet.

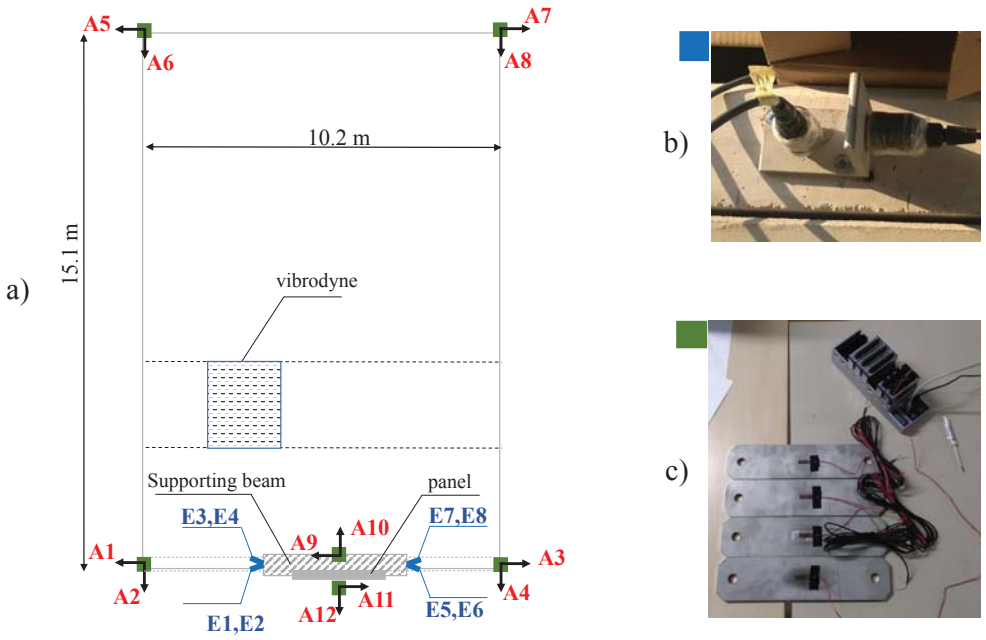

Figure 3: Sensors configuration: a) global configuration in plan; b) uniaxial accelerometers installed in two orthogonal directions; c) strain gauges installed in the steel plates to measure transmitted forces between cladding panel and structure.

The structure can be subjected to an harmonic force induced by a mechanical vibrodyne jointed to the rooftop in an eccentric position with respect to the geometric center of gravity. The vibrodyne is composed of two eccentric masses (70 Kg for each mass) whose movement induces the sinusoidal force in the horizontal direction.

4 PRELIMINARY ANALYSIS RESULTS

The experimental tests were carried out on July 3^{rd} and 5^{th}, 2019. The different configurations analyzed are:

- C1 - prototype building without the cladding panel.
- C2 - prototype building with the cladding panel connected through a traditional hammerhead strap connection.
- C3 - prototype building with the cladding panel connected through the innovative connection.

The response is measured by means of the accelerometers and displacement transducers as shown in Figure 3.

4.1 Ambient Vibration Test

In order to identify the structural dynamic properties of the prototype building, ambient vibration tests (AVTs) were carried out for the configurations C1 and C2, measuring micro tremors induced by ambient vibrations and daily activities. The data were recorded for a duration of 1 hour with a sampling frequency of 1652 Hz, which was down-sampled to 100 Hz. Figure 4 shows the normalized singular values (SV) of the spectral density matrix of all data

sets identified through the Frequency Domain Decomposition (FDD) approach with the indication of the first three principal vibration modes for configuration C1 (Figure 4a), configuration C2 (Figure 4b) and configuration C3 (Figure 4c). The vibration modes associated to the

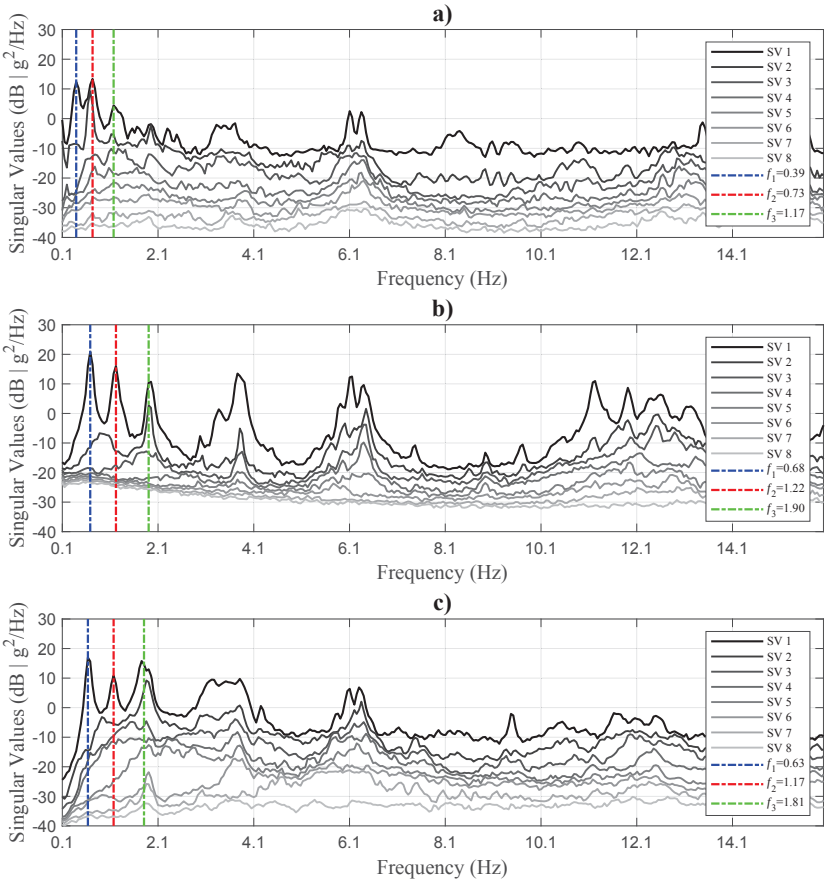

Figure 4: Singular values (SV) of the power spectral density matrix obtained from the AVT and identified resonant peaks of the first 3 modes: a) configuration C1, b) configuration C2, c) configuration C3.

first three principal vibration modes are presented in Figures 5-7. As regards configuration C1 (Figure 5), the first mode is flexural-torsional ($f_1 = 0.39$ Hz), the second is flexural-torsional ($f_2 = 0.73$ Hz) and the third one is purely torsional ($f_3 = 1.17$ Hz). As concerns configuration C2, from Figure 6 it can be observed that the first mode is flexural ($f_1 = 0.68$ Hz), the second is flexural-torsional ($f_2 = 1.22$ Hz) and the third is purely torsional ($f_3 = 1.90$ Hz). For further information, Figure 7 shows the first three principal vibration modes associated to configuration C3: the first flexural ($f_1 = 0.63$ Hz), the second flexural-torsional ($f_2 = 1.17$ Hz) and the third purely torsional ($f_3 = 1.81$ Hz). It is worth noticing that the different technologies used for the cladding-to-structure connection, i.e., configuration C2 vs configuration C3, does not significantly affect the evaluation of the principal vibration modes. Indeed, at low levels of vibrations the friction force exerted by the connection does not allow the sliding of the panel with a consequent similar dynamic behavior. In any case, slightly lower natural frequencies are observed using the innovative connection device, which is consistent with its mechanical behavior.

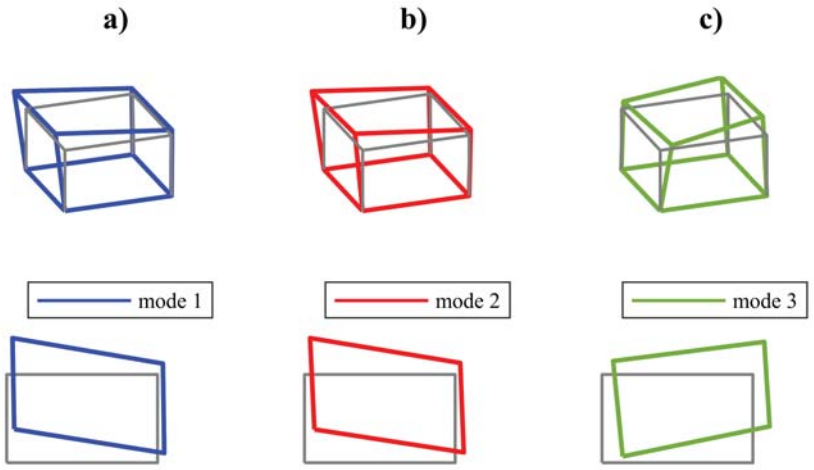

Figure 5: First three vibration modes obtained from the AVT for configuration C1.

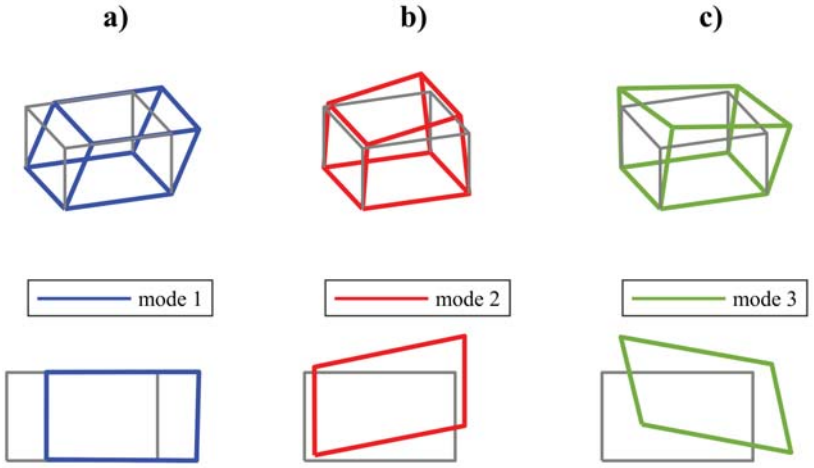

Figure 6: First three vibration modes obtained from the AVT for configuration C2.

4.2 Forced Vibration Tests

In this section some results of the forced vibration tests associated to configurations C1, C2 and C3 are presented. As an example, Figure 5 shows the horizontal lateral displacement evaluated for channels A1 and A2 for all the configurations. Displacement time histories were obtained by double integration of measured acceleration. In the case of configuration C1 (Figure 5a-b) the force induced by the vibrodyne has a maximum value of 3450 N. In the case of configuration C2 (Figure 5c-d) the force induced by vibrodyne has a maximum value of 8600 N, while in configuration C2 (Figure 5e-f) the maximum value corresponds to 5500 N.

The significant panel-to-structure force exchange reached with configuration C2 caused the partial damage of the traditional connection. This aspect is confirmed by analyzing Figure 6, which represents the mean value of the force measured during the tests by the strain gauges E1-E8 (Figure 3), suitably manipulated to reduce environmental effects (temperature and humidity)

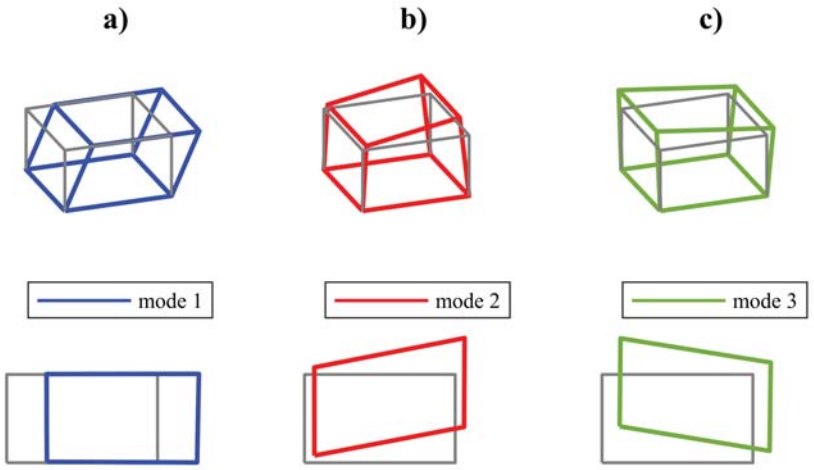

Figure 7: First three vibration modes obtained from the AVT for configuration C3.

and projected in the two main directions x and y. In particular, a Butterworth filter was used to clean up the signal. From the Figure it can be noted that the force exchange in the case of the traditional device is strongly higher (blue line) with respect to the case of the innovative device (red line).
Furthermore, Table 1 shows the maximum horizontal displacement (d) of the support beam and of the cladding panel corresponding to the maximum horizontal force provided by the vibrodyne considering configurations C2 and C3.
The experimental results confirm that force exchange between the panel and the structure due to the friction exerted between the anchorage components of the traditional connection device is not negligible, since it leads up to the connection collapse. Therefore, the reduced value of the cladding panel displacement associated to configuration C3 with respect to the support beam proves the superior performance of the new type of connection in reducing the load transfer and, consequently the in-plane movement of the panel, avoiding damages to the panel and the beam.
Results of forced vibration tests highlight the effectiveness of the first prototype of the innova-

Configuration	F_{max}	Support beam		Cladding panel	
	[N]	d_x [m]	d_y [m]	d_x [m]	d_y [m]
C2	8600	0.1954	0.1827	0.0479	0.0238
C3	5500	0.1390	0.0131	0.0018	0.0087

Table 1: Maximum horizontal displacement (d) of the support beam and of the cladding panel with the indication of the maximum horizontal force provided by the vibrodyne for C2 and C3 configuration.

tive device in improving the seismic behavior of the panel-to-structure connection for in-plane movement. Further prototypes, with optimized mechanical characteristics, will be tested considering both in-plane and out-of plane forces with the aim of improving robustness of the connection device against seismic loads.

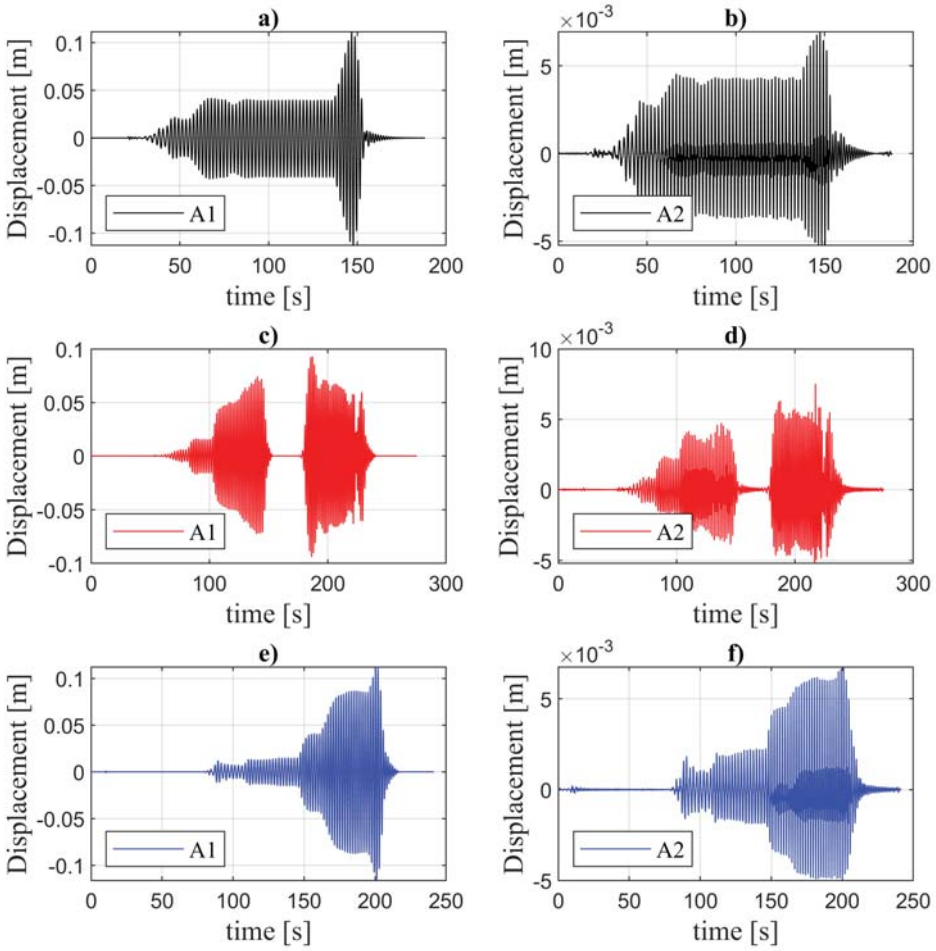

Figure 8: Horizontal displacements evaluated during the experimental tests: a) configuration C1 channel A1; b) configuration C1 channel A2; c) configuration C2 channel A1; d) configuration C2 channel A2; e) configuration C3 channel A1; f) configuration C3 channel A2.

5 CONCLUSIONS

The study has focused on the evaluation of the seismic behavior of the first prototype of an innovative connection between cladding panels and supporting structures. The main objective is to decouple the movement between the panel and the structure. For the purpose, a prototype building has been built and used to perform AVTs and forced vibration tests along the plane of the panel. The structural response has been measured by means of accelerometers and strain gauges. Both AVTs and force vibration tests were performed considering three different configurations: C1, C2 and C3. The anchorage performance of two types of systems (traditional vs innovative system) has been compared.

The effectiveness of the innovative device has been assessed by measuring the amount of force transmitted between the support beam and the cladding panel. On the one hand, the results of the experimental tests showed that the traditional device induces a not negligible force exchange between cladding panels and supporting beam. On the other hand, the first prototype of the innovative connection device considerably reduces the in-plane force transmission, decoupling

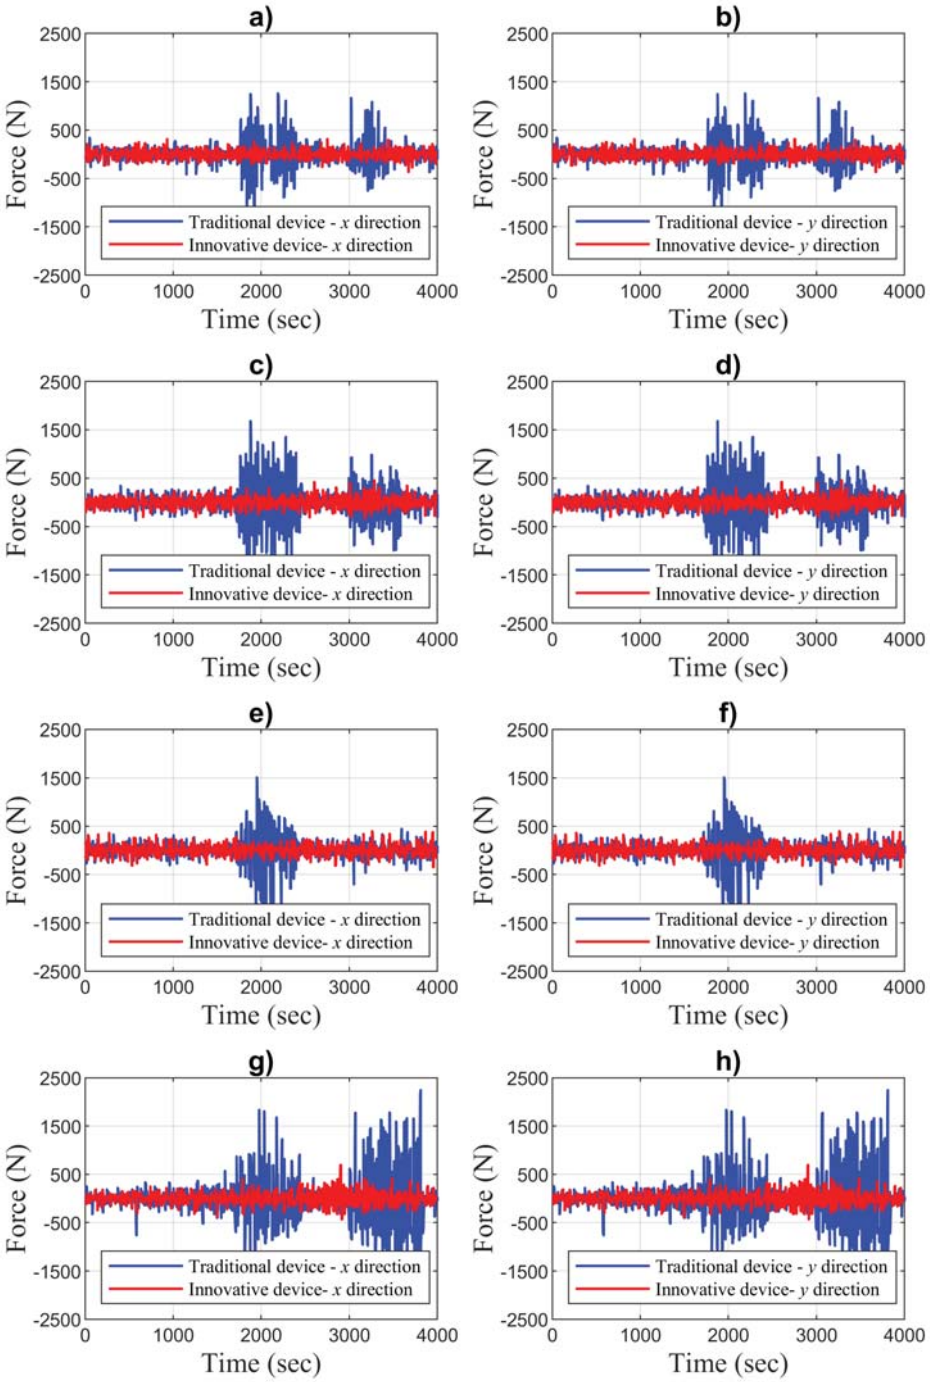

Figure 9: Panel-to-structure force exchange measured by the transducers for the traditional and innovative devices: a) Plate 1, *x* direction; b) Plate 1, *y* direction; c) Plate 2, *x* direction; d) Plate 2, *y* direction; e) Plate 3, *x* direction; f) Plate 3, *y* direction; g) Plate 4, *x* direction; h) Plate 4, *y* direction;.

more effectively the panel-structure movement. It follows that such a proposed design solution is promising towards an effective improvement of the seismic behavior of reinforced concrete precast structures, leading the way to further enhancements of the prototype device with the aim of considering both in-plane and out-of plane loads.

Ackowledgments

The Authors would like to acknowledge the support of the European social fund in the framework of POR FESR - Axis 8 - Seismic prevention and support for the recovery of the areas affected by the earthquake.

Keywords: Ground motion model, industrial plants, shaking table tests.

Abstract. *Relationships between seismic action, system response and relevant damage levels in industrial plants require a solid background both in experimental data, due to the high level of nonlinearity, and in knowledge of seismic input due to large uncertainty. Besides, risk and fragility analyses depend on the adoption of a huge number of seismic records usually not available in a site-specific analysis. In order to manage these issues and to gain knowledge on the definition of damage levels, limit states and performance for major-hazard industrial plant components, we present a possible approach and discuss results of an experimental campaign based on a real prototype industrial steel structure. The investigation of the seismic behaviour of the reference structure has been carried on through shaking table tests, focusing in particular on the structural or process-related interactions that can lead to serious secondary damages as leakage in piping systems or connections with tanks and cabinets. This has been possible thanks to the adoption of a ground motion model (GMM) able to generate a suite of synthetic time-histories records for specified site characteristic and earthquake scenarios. In fact, model parameters can be identified by matching the statistics of a target-recorded accelerogram to the ones of the model in terms of faulting mechanism, earthquake magnitude, source-to-site distance and site shear-wave velocity. Hence, the stochastic model, based both on these matched parameters and on filtered white-noise process, generates the ensemble of synthetic ground motions capable to capture the main features of real earthquake ground motions, including intensity, duration, spectral content and peak values. Finally, by means of the combination of a high-fidelity and a low-fidelity FE model as well as the stochastic input generated by a GMM, a seismic vulnerability assessment of both industrial components and the global structure can be carried out.*

INTRODUCTION

Between major natural hazard critical for industrial facilities, we can undeniably enlist seismic events. In fact, as well documented in literature - see [1]; [2]; [3] -, in these occurrence, industrial process plants have shown to be susceptible to experience significant damages both in primary structure and in secondary elements that usually constitute plant components and on which rely the operation of facilities.

Besides, as demonstrated by recent catastrophic events - like Tohoku earthquake in 2011 - and particularly stressed in the literature - see [4]; [5] - industrial facilities are especially vulnerable to those natural hazards which may trigger technological accidents: the so called NaTech events, i.e. Natural-Technological events. Therefore, there is a strong necessity to investigate interactions between primary structure and plant components, but also between the components among themselves, in order to avoid, as shown in previous references, serious consequences and critical secondary damages which, in addition to loss of production, also pose a danger to humans and the environment if hazardous substances are released due to leakages. In this perspective, the objective of the project SPIF, i.e. *Seismic Performance of Multi-Component Systems in Special Risk Industrial Facilities*, under the grant of European H2020 - SERA, *Seismology and Earthquake Engineering Research Infrastructure Alliance for Europe*, is to carry out a complete investigation of the seismic behaviour of industrial plants equipped with complex process technology by means of shaking table tests.

The case-test structure is a three-storey moment resisting steel frame with vertical and horizontal vessels and cabinets, arranged on the three levels and connected by pipes. The three levels are constructed as flexible diaphragm made of steel cross beams, partially covered with gratings. Tests are carried out without base isolation of the industrial structure. Furthermore, firmly anchored components are taken into account to compare their dynamic behavior and interactions with each other. Besides, the campaign structure is equipped with sensor systems integrated into the test structure itself for a rapid damage assessment.

Along with this line, the following paper focuses on the main aspects of investigation of seismic performances of a prototype steel-frame industrial plant, with a special focus on loss of containment (LoC) from bolted flange joints (BFJs), see [6], pipe bends and tee-joints, vessels' connections and anchorages. Therefore, seismic risk is evaluated through fragility curves analyses, according to [10] inside the framework of PBEE, [8].

In details, to take into account the variability of the seismic action and the high number of time histories needed, a GMM has been adopted, in order to generate a suite of synthetic time-histories records for specified site characteristic and earthquake scenarios, based on the results of a site-specific probabilistic seismic hazard analysis in severe seismic prone zone in Italy - PSHA, see [7].

Moreover, a faster-low (LF) and a refined high fidelity (HF) FE models are developed in order to represent the complexity of the experimental campaign with two different level of computational efforts and accuracy reproduced. The whole test campaigns provide then the necessary background to properly calibrate FE models. Therefore, in order to reduce the space of the GMM parameters, a global sensitivity analysis (GSA) over FE models is performed to assess the individual contributions of each input variables to the total variance of the model response. Finally, the LF model of the prototype industrial plant is adopted to perform a seismic fragility analysis with a cheaper computational effort demanded.

In sum, the paper is arranged into 6 main sections: the first section illustrates SPIF test structure, whilst the second one focuses on the characterization of the seismic input. The third

section presents the arrangement of the experimental campaign, in the fixed configuration. The fourth one deals with the description of the FE modelling of the primary structure and of the industrial components, such as pipes, bends and vessels. In the fifth section, we show the procedure in order to gain relevant seismic fragility curves both for components and the global system. In the last section, main conclusions are drawn and future developments are proposed.

THE SPIF STRUCTURE

The primary steel structure is a three storey moment resisting steel frame with flexible diaphragm made of crossbeams. The three dimensional primary steel structure is shown in Fig. (1). The ground-plan dimensions are 3.7 m x 3.7 m and the storey height is 3.1 m, which leads to a total height of 9.3 m. The rigid frame is simply supported on the reinforced concrete base plate and the crossbeams are hinged connected to the frame beams. In total four tanks are installed, two vertical tanks on the first level and two horizontal tanks on the second level. Furthermore one electrical cabinet is placed on the first level. Concerning piping system, the nominal pipe diameter is DN 100, with the exception of the suspended pipes on the third story that are DN 80. In addition, smaller single degree of freedom (SDOF) oscillators systems are installed on each of the three levels to investigate the structure component interaction for different periods in the linear and non-linear range.

(d) 3D back view.

Figure 1: Representation with quote of the prototype industrial plant for SPIF project: (a) top, (b) side and (c)-(d) 3D front and back views.

Besides, the test structure is equipped with a complex system of sensors which includes FBG

fiber optics sensors, for LoC and leakage detection, strain-gauges, LVDT and accelerometer in strategical positions, as shown for example in Fig. (2).

EXPERIMENTAL CAMPAIGN

Sequence and intensity levels of shaking table tests are performed so as to reach more severe damages or even collapses in components by passing from *fully operational* (OP) to *near collapse* (NC) limit states, or, as in case of major industrial plants, from *operating condition or design basis earthquake condition* (OBE) to *safe shutdown earthquake condition* (SSE). In particular, the first set of simulation tests are executed on the base isolated structure while the second set is run on the non-isolated configuration. In both configuration's setup, after tuning the shaking table, input signals are launched and then scaled with coefficient related to the probability of exceeding the seismic action, P_L, in T_L years other than the reference probability of exceedance P_{LR}, over the same T_L years, as reported in Tab. (2). In more details, according to

	Components EC8-4:(2.1.4)	**Buildings** EC8-4:(4.2.5)
Cl. I	0.8	0.8
Cl. II	1	1
Cl. III	1.2	1.2
Cl. IV	1.6	1.4

Table 1: Important class and coefficients according to EC8, Part 1 and Part 4.

the assumption during design phase of considering an importance factor γ_I equal to 1.0, it has been evaluated in Eq. (1) the ratio between the maximum allowed value of importance factor in case of components versus the assumed one, see Tab. (1): this ratio is then used as a scale factor in order to pass to a SLS *safe life limit state* for the structure and the equivalent OBE *operating condition or design basis earthquake condition* for pipe systems.

$$\gamma_I = \frac{1}{1.6} = 0.625 \tag{1}$$

Probability of Exceedance NTC18: 3.2.1			
OP	81	%	Fully Operational
DL	63	%	Damage Limit
SD	10	%	Significant Damage
NC	2.5	%	Near Collapse

Table 2: Probability of exceedance according to Italian Standards.

Then, according to EC8-Part 1: (2.1-4(P)Note), the value of the importance factor γ_I is obtained by the ratio between T_L and T_{LR}, i.e. time associated to the reference seismic action in order to achieve the same probability of exceedance in T_L years as in the T_{LR} years for which the reference seismic action is defined

$$\gamma_l = \left(\frac{T_{LR}}{T_L}\right)^{-1/k} with \quad k = 3 \tag{2}$$

as well as

$$\gamma_l = \left(\frac{P_L}{P_{LR}}\right)^{-1/k} with \quad k = 3 \tag{3}$$

again the needed factor with which multiply the reference seismic action. So, by referring to Italian codes in Tab. (2), importance factors for different limit states are evaluated and reported in Tab. (3), together with the reference peak ground acceleration of the spectra involved in the design phase. Main assumptions in order to evaluate proper spectra for the test structure were

	NC	**SD**	**DL**	**OP**	**units**
γ_I	1.000	0.625	0.541	0.498	[-]
a_{gR}	0.690	0.431	0.233	0.215	[g]
	SSE	**OBE**			

Table 3: Important coefficients and reference peak ground acceleration for different limit states.

in fact the following ones: · nominal life: 50 years; · soil type: C –T1; · damping: 5%; · peak ground acceleration: $a_{gR} = 0.69\,g$ and · importance class II.

Therefore, spectra-compatible accelerograms have been evaluated with a relative difference between matched and target spectra less than 10%. These accelerograms are assigned to both the configuration setup, i.e. structure with and without base isolation, with the 4 aforementioned different scale factors related to separated limit states.

Furthermore, for the isolated setup, natural records from PEER NGA-WEST2 database are selected, with the purpose of stressing the designed isolators. In particular, selection criteria were devoted to have a strong frequency content around the range of the working-isolated structure and to match the design spectrum. For this last point, it has been necessary to scale up the natural accelerogram selected with the first main issue, according to a scale factor derived as the ratio between maximum acceleration reached by the artificial seismic input and the natural one.

Then, in order to induce damage or collapse in previous analysed components, as, for example, leakage in selected flanges or collapse of vessel's footing, seismic records from ground

motion model are selected, thanks to the high variability of the ensemble site-characteristic generated. Hereafter, the main characteristics and peculiar aspects of the ground motion model are presented.

SEISMIC INPUT FROM GMM

Synthetic ground motions are employed in order to cover the range of IMs of interest and eventually obtain a sufficient large ensemble of time-histories for fragility curves analyses. Here, a synthetic ground motion model has been assumed in order to reproduce the spectral variability of recorded accelerograms. In particular, according to [9], with the purpose of calibrating the GMM for a specific geographical location and specific site characteristics, a PSHA deaggregation is performed. Along this line, in the assumption of far-field scenario, a severe seismic prone zone of central Italy is selected. Below, see Fig. (3), it is reported the main result of the probabilistic seismic hazard deaggregation analysis.

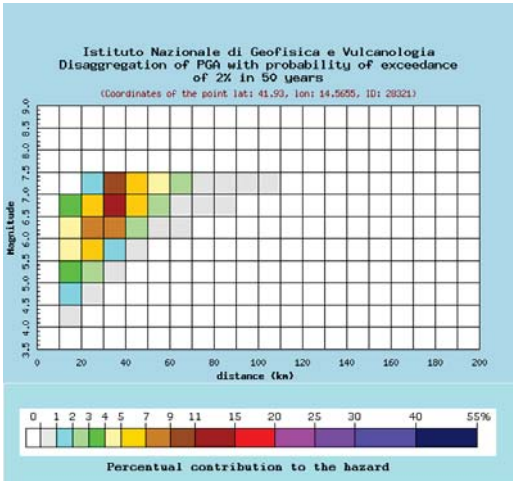

Figure 3: Probabilistic seismic hazard deaggregation analysis for Palmoli, Central Italy.

Moreover, the original recorded accelerograms are selected from the INGV site (http://www.ingv.it/) and ITACA - *Italian Accelerometric Archive* - Database, with the following criteria:

- fault to site distance $> 10\ km$;
- moment magnitude > 5.5;
- main shock seismic records only.

Besides, another core assumption, both in design of the structure and in selection of ground motions time histories, is correlated to the soil characteristics, that is assumed of type C according to European standards. Herein, in Tab. (4) compatible accelerograms are reported.

According to [11], GMM is defined in terms of a set of parameters based on ground motion properties with physical meaning, as reported in Tab. (4). The model is based on a modulated, filtered white-noise process and incorporates both temporal and spectral non-stationarities, as shown in Eq. (4)

$$a_g(t) = q(t,\alpha)\left[\frac{1}{\sigma_f(t)}\int_{-\infty}^{t} h(t-\tau,\lambda(\tau))\,\omega(\tau)d\tau\right] \tag{4}$$

	Earthquake Name	Station Name	$V_{S,30}[m/s]$	Distance fault-site $[km]$	Moment Magnitude $[M_w]$
1	IT-1979-0009-NORCIA	BVG	211	38	5,8
2	IT-1984-0004-LAZIO-ABRUZZO	CSN0	501	19,7	5,9
3	IT-1984-0004-LAZIO-ABRUZZO	PNT	325	26,8	5,9
4	IT-1984-0004-LAZIO-ABRUZZO	GRG2	187	49,1	5,9
5	IT-1984-0004-LAZIO-ABRUZZO	GRG1	192	49,1	5,9
6	IT-2009-0009-L-AQUILA	AVZ	199	35,1	5,5
7	IT-2009-0009-L-AQUILA	GSA	492	14,4	5,5
8	EMSC-20160824-CENTRAL-ITALY	TRE	353	45,3	6
9	EMSC-20160824-CENTRAL-ITALY	FOC	342	45,7	6

Table 4: Set of selected accelerograms from ITACA database.

where $\omega(\tau)$ is a white-noise process, while $\widehat{\alpha}$ is defined by means of

$$\widehat{\alpha} \, = \, arg \min_{\alpha} \left(\left| I_a \left(t_{45} \right) \, - \, \widehat{I}_a \left(t_{45} \right) \right| \, + \left| \left(t_{95} \right) \, - \, \widehat{I}_a \left(t_{95} \right) \right| \right) \tag{5}$$

It should be noticed that the modulating function $q(t, \alpha)$ completely defines the temporal characteristics of the process, whereas $h\left(t \, - \, \tau, \lambda(\tau)\right)$, denoting the impulse-response function IRF, and its time-varying parameters define the spectral characteristics of the process. In particular, IRF of a linear time-varying filter can be expressed as follows:

$$h\left(t \, - \, \tau, \lambda\left(\tau\right)\right) \, = \, f(\omega_f, \zeta_f) \tag{6}$$

where

$$\omega_f \, = \, \omega_{mid} \, + \, \omega'(t \, - \, t_{mid}) \tag{7}$$

Simulating process of GMM is then able to generate an ensemble of ground acceleration time-history similar to those illustrated in Tab. (4) for a given set of model parameters, as reported in Tab. (5).

Name	Distribution	Average Value	Units
I_a	Uniform	0,212	$[m/s]$
t_{mid}	Uniform	3,6	$[s]$
D_{5-95}	Uniform	8,8	$[s]$
ω_{mid}	Uniform	43,7	$[Hz]$
ζ_f	Uniform	0,25	$[-]$

Table 5: Distribution of stochastic GMM parameters.

Along this line, two main hyphotesis have been assumed: the first one is to consider parameters statistically independent; the second regards the choice of assuming uniform distributions in order to describe probability distribution of all the parameters, with the only exception of ω' that is assumed constant. Thus, in order to reduce the variability of the seismic input and to reduce the space of parameters, a set of 200 white-noises combining 200 accelerograms is performed on the LF model with a convergence check upon the third quartile of both spectral acceleration for $T_1 \, = 0.36 \, s$ and maximum displacement at top storey. Results are reported in Fig. (4) and Fig. (5) and indicate that at almost 100 of white-noises convergence is reached.

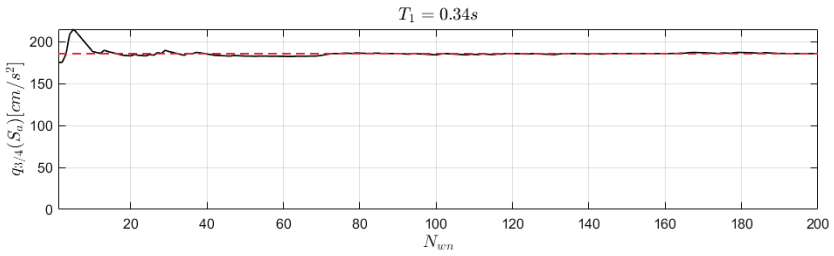

Figure 4: Check on number of white-noises N_{wn} at the third quartile for $S_a(T_1)$.

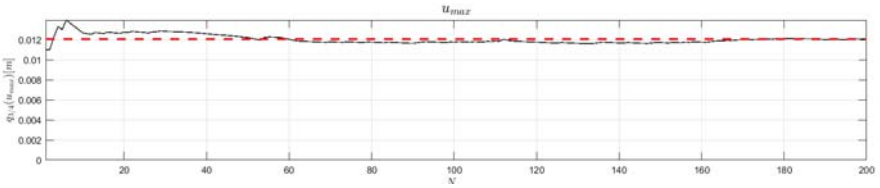

Figure 5: Check on number of white-noises N_{wn} at the third quartile for u_{max} at top storey.

THE FINITE ELEMENT MODEL

According to [9], one of the most important feature of a GMM is the possibility to study the structural response to earthquake with characteristics that are coherent with the site seismicity (e.g. fragility curves). The main disadvantage of this technique is the great number of non linear analysis necessary to take into account the variability of the seismic action. To overcome the numerical effort required in such procedure two model are needed.

First a low fidelity model (LF) that aims to reproduce the essential characteristics of the system with the smallest computational effort possible is developed. For our purposes this essential characteristics are: natural periods, base shear and behaviour of the major component such as tanks and piping system.

In a second phase an high fidelity model (HF) is introduced with the purpose to caught the behaviour of the structure in greater detail even with reference to the interaction between primary and secondary elements.

In the next section, only issues and principal techniques involved in the definition of LF and HF model of the isolators are discussed, while a general comment on the main differences between LF and HF model is briefly dwell.

Piping system

As can be seen in Fig. (1) the piping system is composed of straight pipes, bends, tee joint and BFJs. Since our purpose is to include in the model only the foundamental aspects of the structure, we firstly have to identify the most critical components for the LoC limit state. According to [14] there are only three possible failure modes for pipes: fracture due to excessive tensile loading, local buckling due to compressive action and low cycle fatigue. The first failure mode is prevent if the plastic deformation does not exceed the tensile strain limit ϵ_{Tu}, that the Author suggests to use a conservative value of 2%. Compressive failure is typical in pipe bends and the limit compression strain ϵ_{Cu} can be estimated from Eqn. (8)

$$\epsilon_{Cu} = 0.5 \cdot \left(\frac{t}{D}\right) - 0.0025 + 3000 \cdot \left(\frac{\sigma_h}{E}\right)^2 \tag{8}$$

Neglecting the effect of internal pressure, a value of 1% is found. Instead, the third failure

mode arises only if the component undergoes large plastic deformation several times. Thanks to results of preliminary analysis, it is possible to outline only two points (the nozzle in position 6 and the tee joint in position 5) with tension's value above yielding limit. To investigate the possibility of high stress level, those position are model with *shell finite elements*. It is important to notice LF model is an elastic one, since the structure is designed to remain elastic even under very high seismic shacking. In later analysis the elastic solution will be used as guide to choose significant ground motions to evaluate inelastic response of components. In conclusion, such level of deformation in pipes capable to induce failure seems to be unlikely. So, the weakest component for the LoC prevention are the BFJs. The model proposed by [15] is used to investigate the performance of the BFJs. This method is developed in the framework of the EN 1591-2009 and results in a linear domain like the one shown in Fig. (6). The BFJs are designed in accordance with EN 1591-2014 to ensure the performance level requested in two seismic condition:

- Operating condition basis earthquake **(OBE)**: it corresponds to an earthquake scenario, considering the seismic hazard of the site, that could reasonably affects the structure during his operating life time;
- Safe shut-down earthquake **(SSE)**: it corresponds to maximum ground motion for which some critical components of the plant must be designed to remain functional.

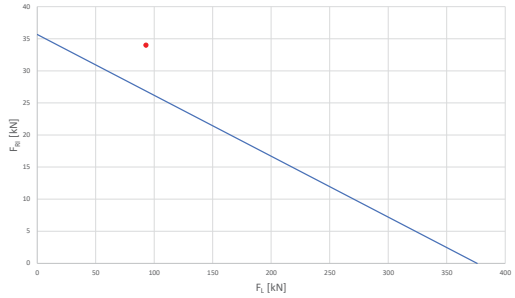

Figure 6: Example of leakage domain of the La Salandra model

To model the rest of the piping system in terms of mass and stiffness, several techniques are available. The easiest choice is to adopt beam element with reduced stiffness' value by means of flexibility factors. Codes provide an analytical formulation of these factors based on elasticity theory. Example of such factors, in the case of elbow element, are shown in equations below.

$$h = \frac{4 \cdot R \cdot e_n}{d_m^2} \tag{9}$$

$$k_B = \frac{1,65}{h} \tag{10}$$

In case of tee joint, no stiffness reduction is required. A more precise approach consist in the determination of flexibility factors for elbows derived from a FEA. In this case a FEM of pipe bends based on shell element is developed and moments are applied to one end. Then, by equating deflection of the FE model with an analogous system of beam deflection, it is possible to evaluate proper flexibility factors. According to [16] using this procedure flexibility factors

Flexibility factor		
Direction	UNI EN 13480-3	FEM
In plane	9.24	8.28
Out of plane	9.24	8.21

Table 6: Comparison between flexibility factor

Figure 7: FEM of a single elbow

for in plane and out of plane action can be found. The results of the two procedure are resumed in Tab. (6), while FE model employed is depicted in Fig. (7).

In this calculation, stiffening effects of pressure are neglected, since just few elbows are pressurized and with a negligible resultant effect caused by internal pressure.

The main hypothesis by referring to flexibility factor is that the ends of the elbow are free to ovalize. Thus, if this condition is not respected, a significant stiffening effect raise. In order to individuate those critical conditions, a parametric study is carried out with this scheme: a specimen made of two elbows (with direction specified in Tab. (7)) separated by a straight pipe is analysed. Several simulations are launched for increasing length of the central pipe from 200mm to 3000mm. During the simulation, two set of displacement are imposed to the specimen: a linear displacement parallel to the straight pipe and a rotation of one end. As a result mutual force to the imposed displacement are collected. For high length of central pipe, flexibility contribution for elbow is constant and the central pipe behaves like a beam with circular cross section. When the length of central pipe goes under a threshold value, a stiffening effect can be seen and also induce an error greater than 10%, compared to the equivalent beam behaviour. Thus, a cut-off length can be defined.

Bends scheme	Direction	L [mm]
L-R	Axial	450
	Bending	200
L-L	Axial	450
	Bending	300
L-U	Axial	450
	Bending	450

Table 7: Cut-off length

Looking at Tab. (7), it is possible to notice that in case of bending a cut-off length equal to $2,5D$ is adequate. This result are in good agreement with results of [16]. In the other cases, when forces are of primary importance, a greater value of $4D$ looks adequate.

FRAGILITY ASSESSMENT OF A STEEL STRUCTURE AND COMPONENTS

In this paragraph, a method for performing fragility assessment of components and structure is illustrated, based on the seismic response of the test structure on the LF model. In fact, by using outputs of the simulations, it is possible to evaluate fragility functions F_D defined as the conditional probability of an event - i.e. overpass a threshold for a certain damage state (D) - given the observation of an intensity measure (IM) which describes the seismic event, see [7] and [10].

$$F_D\left(im\right) \, = \, P\left[D \geq C_{LS} | IM \, = \, im\right] \tag{11}$$

So, it is clear the importance of the choice of both the intensity measure proper for the case-test and the definition of the damage state D and its class of limit state C_{LS}, seen as thresholds - [17].

The most popular procedure to compute fragility functions via time-history analysis can be summarized, according to [18] and [19], as follows:

- definition of a numerical model for the structure of interest, $y(t) \, = \, \mathcal{M}[\ddot{x}_g(t|IM \, = \, im); \theta_{\mathcal{M}(t)}]$ where $\mathcal{M}$ stands for the numerical model, $\theta_{\mathcal{M}}$ for a set of model parameters, and $\ddot{x}_g$ for the seismic input;
- selection of suitable IM and N ground motions of interest;
- selection of EDP of interest;
- definition of damage limit states D via EDP thresholds.

Given the N outcomes, it is common to assume a lognormal probability distribution for the random variable IM associated with the given damage state D. Then, the parameter of the lognormal can be estimated via the method of the maximum likelihood. However, one positive aspect of the likelihood function is that it can be written also for a generic probability density function $f(x;\theta)$, where θ is the set of parameter to be estimated. Thus, by dividing data into two groups, i.e. data that causes collapse and data that do not cause collapse, the likelihood function is given by:

$$\mathcal{L}\left(\theta\right) \, = \, \prod_{n=1}^{N} f\left(x;\theta\right)^{\overline{N}} \left[\, 1 \, - \, F\left(\overline{x};\theta\right)\right]^{\left(N \, - \, \overline{N}\right)} \tag{12}$$

or in logarithmic form

$$ln\mathcal{L}\left(\theta\right) \, = \, \sum_{n=1}^{N} f\left(x;\theta\right) \, + \, \left(N \, - \, \overline{N}\right) \left[\, 1 \, - \, F\left(\overline{x};\theta\right)\right] \tag{13}$$

and solution of the parameter can be found

$$\hat{\theta} \, = \, arg \min_{\theta} \left[-ln\mathcal{L}\left(\theta\right)\right] \tag{14}$$

CONCLUSIONS

In this paper, we investigate relationships between seismic action, system response and relevant damage levels in a prototype of an industrial plant. This has been possible by means of the development of a procedure that combines modeling of the industrial structure, in both primary and secondary elements, and selecting proper ground motion time histories for analyses. As a first step, we have defined a seismic scenario associated to a geographical site by means of a probabilistic seismic hazard analysis. Then, based on this analysis we provide an adequate seismic input employing a stochastic ground motion model calibrated against coherent natural seismic records. Successively, in order to select ideal signal causing desired damage in terms of limit states, a large set of synthetic time histories has been generated and assigned to a low fidelity finite element model. In particular, we focused on the modeling of secondary elements, such as elbows, tee-joints and bolted flange joints, i.e. critical elements within the steel structure. As a result, both the steel structure and relevant industrial components have been subjected to artificial spectrum-compatible and seismic records provided by a ground motion model. Thus targeted LS have been sought. Finally, we present the methodology to derive fragility curves based on the results of LF models.

Keywords: pipeline – fault crossing, fault offset hazard, simplified expressions

Abstract. *A set of simplified expressions are derived for estimating the design fault displacement for pipelines crossing active faults by considering alternative scenarios, seismicity levels, and the pertinent uncertainties. Buried steel pipelines are an efficient and safe means of oil and gas onshore transportation and provide a direct link between extraction, processing, and consumption of fuel. Hazardous materials are transported via pipelines and consequently, any pipe failure may have devastating consequences. In case of crossing an active tectonic fault, the pipeline may be subject to significant deformations and strains threatening its integrity in the event of an earthquake. Its design hinges on a single value of the fault displacement magnitude, typically estimated as a specific "safe" percentile (e.g., 84%) from the surface displacement distribution given a "maximum" magnitude, estimated from regression models parameterized on fault characteristics. This single-scenario-based approach can lead to either conservative or unconservative designs as the actual level of safety is unknown. Instead, Probabilistic Fault Displacement Hazard Analysis (PFDHA) can provide a robust probabilistic basis to determine design values corresponding to specified return periods, at the cost of requiring extensive seismological data that may be unavailable for every single major or minor fault that a transmission or distribution pipeline crosses. Herein, logic tree aggregation is employed to cater to different levels of data completeness and provide design-level fault displacement values that incorporate all pertinent uncertainties.*

1 INTRODUCTION

Onshore buried pipelines transporting oil and gas are vulnerable to seismically-induced permanent ground displacements, such as those resulting from seismic fault activation. Tectonic fault offset is the primary cause of earthquake-related catastrophic pipe failures [1]. The structural performance of buried pipes under faulting has drawn the attention of numerous researchers over the last decades, carrying out experimental, analytical, and numerical studies (e.g. [2]–[5]). However, in the vast majority of studies, fault offset is considered to be deterministic (i.e. a few rather arbitrary values are considered) or is estimated via empirical expressions that relate fault characteristics (e.g. earthquake magnitude, fault geometry, rupture length, etc.), such as those published by Wells and Coppersmith [6]. In the case of typical structures, such as building and bridges, numerous design codes, standards or guidelines are available to estimate the seismic loading for a predefined level of design hazard, typically as the result of probabilistic seismic hazard analysis. Contrarily, for buried pipelines, a single fault displacement magnitude is considered as the worst-case scenario, consisting of a postulated occurrence of an earthquake with a specific magnitude at a specific location. Consequently, pertinent uncertainties are disregarded, resulting in a hazard-independent estimation with an unknown level of conservatism.

The environmental, social, and economic repercussions of a potential pipeline failure call for the employment of state-of-the-art methods for the estimation of fault offset magnitude and therefore the design of pipelines at fault crossings. To achieve parity with the design standards for buildings and bridges, at the very least an approach is needed to set the design fault displacement for a pipeline at a pre-defined hazard level. Hence, a better balance between safety, capital/maintenance costs, and environmental responsibility can be attained. The appropriate such method is the Probabilistic Fault Displacement Hazard Analysis (PFDHA) that was introduced by Youngs et al. [7] for the seismic hazard assessment of the planned nuclear waste repository at Yucca Mountain, Nevada, USA.

Transmission and distribution pipelines form an extensive network, covering areas that range from a few hundred thousand square meters to entire countries. When seismic areas are traversed, crossing major or minor tectonic faults is almost inevitable. These faults might be active or inactive, or even not mapped due to inactivity during the last thousands of years. In case of crossing a major fault, this will be probably fully mapped and recorded, allowing the implementation of a full probabilistic hazard analysis (PFDHA) to account for all geotechnical and seismological parameters of the crossing. On the other hand, designers are aware that the latter is not the case for minor faults, typically being poorly mapped and recorded resulting in a minimum or even zero data availability. The problem is regularly treated based on a blend of expert opinion, engineering assumptions, and the implementation of empirical regression equations to calculate/estimate the design fault displacement. Thus, the aforementioned drawbacks of the deterministic approach are inflated again in the design. The present study stands as the first step to develop a set of simplified expressions for the estimation of fault offset magnitude for pipe – fault crossings, in case there is insufficient data. The expressions are derived from the statistical processing of PFDHA results taking into account typical values of the pertinent seismological parameters of the European area.

2 FAULT DISPLACEMENT HAZARD

2.1 Probabilistic Fault Displacement Hazard Analysis

The basis of Probabilistic Fault Displacement Hazard Analysis (PFDHA) was originally established by Youngs et al. [7] and later modified/improved, for example in [8]–[11]. The outcome of PFDHA is the mean annual frequency (MAF) of exceeding fault displacement levels

at a site by considering the fault geometry, the fault slip rate, the distribution of earthquakes, and the pertinent aleatory and epistemic uncertainties. PFDHA has been applied for the pipeline – fault crossing problem by the authors in [12], adopting the "earthquake approach" that is derived from the classic Probabilistic Seismic Hazard Analysis [13]. The "principal faulting" of PFDHA is considered under the assumption that the pipeline crosses a main fault, while distributed faulting issues are neglected. The fault displacement hazard estimation depends, among others, on the fault event rate, the maximum earthquake magnitude, the surface rupture length (SRL), the position of the rupture along the fault trace, and the position of the pipeline crossing site.

PFDHA for pipe – fault crossing site is essentially an application of the total probability theorem:

$$\lambda_D(d) = v \sum_i P(D > d|m_i) P_M(m_i) \tag{1}$$

where v is the mean annual rate (seismic rate) of all earthquakes above a minimum earthquake magnitude of engineering significance, following a Poisson model of occurrences, $P_M(m_i)$ is the probability of magnitude M falling within the i-th bin characterized by m_i at its center and is estimated using the Gutenberg-Richter bounded recurrence law [14]. $P(D>d|m_i)$ is the probability that the fault displacement D exceeds a defined value d at the crossing site, given an earthquake of magnitude m_i has occurred. Eq. (1) is applied for both the average fault displacement (AD) and the maximum fault displacement (MD) options of PFDHA, each one associated with a different fault displacement prediction equation, similar to a ground motion prediction equation of classic PSHA.

2.2 Hazard uncertainty

The identification and quantification of uncertainties is an integral part of seismic hazard analysis as the hazard curve is sensitive to the parameters adopted in the analysis. Any uncertainty can be incorporated in PFDHA. Uncertainties are classified into two main categories, namely aleatory and epistemic. Aleatory uncertainties are related to the inherent variability of nature, e.g. randomness in earthquake magnitude, fault displacement, etc., and are handled through sampling. Epistemic uncertainties are related to the incomplete understanding of nature and in time can be reduced with better observations, e.g. ground motion prediction equations. These uncertainties lead to alternative hazard curves and are handled through logic trees [15] by creating different models for input parameters and assigning weight factors to the tree branches. Weight factors represent the relative belief of the engineer in alternative models, without necessarily being frequency-based probabilities [16]. It is noted that there is no evidence (recorded data) for favoring the AD or MD approach of PFDHA. Thus, this option is considered as an epistemic uncertainty and is assigned a weight factor equal to 0.50 in a logic tree formulation.

3 METHODOLOGY OUTLINE

3.1 Parameters

The aforementioned formulation of fault displacement hazard estimation requires the following key input parameters:

- Seismic rate v of all earthquakes above magnitude 4.50 (minimum earthquake magnitude of engineering significance)
- Fault type (strike-slip, normal, reverse)

- Maximum earthquake magnitude (M_{max})
- b-value of the Gutenberg-Richter Bounded Recurrence Law [14] (slope of the curve)
- Fault length (LF) in km
- Pipe – fault crossing point (XL) that is the ration of the location of the crossing point to the closet fault edge to the fault length with $0 < XL \leq 0.50$

Specifically, the seismic rate according to Eq. (1) is an external multiplier of the seismic hazard calculations that are carried out separately for each fault type. On the other hand, for reasons of practicality, parameters M_{max}, b, FL, and XL are treated as discrete variables and are assigned indicative realistic values as per Table 1.

Parameter	Values
M_{max}	4.65, 5.00, 5.35, 5.65, 6.00, 6.35, 6.65, 7.00, 7.35, 7.75, 8.25
b	0.70, 0.90, 1.10
LF	10, 20, 50, 100, 150, 200
XL	0.10, 0.20, 0.30, 0.40, 0.50

Table 1: Parameters considered in fault displacement hazard estimation.

The range of b-values of the Gutenberg-Richter Bounded Recurrence Law [14] is from 0.70 to 1.10 for stable and active regions in Europe (EU SERA project, http://www.sera-eu.org/en/home/). The range of M_{max} values is 4.50 to 8.50, discretized in 11 bins with the bin centers listed in Table 1. Wells and Coppersmith [6] provide expressions that relate fault characteristics along with the pertinent limitations regarding the applicability of the expressions. Thus, in the case of normal/reverse fault, the maximum considered fault length (LF) is 100km (discretized in 4 values), while in the case of strike-slip fault it is 200km (discretized in 6 values).

3.2 Knowledge levels

Application of the full PFDHA framework, as described so far, necessitates seismological and geotechnical data that are not always available, for example, in case of minor faults or faults considered to be inactive. To account for input data incompleteness, the aim is to formulate pertinent expressions for the estimation of the design fault displacement for different levels of data availability, as presented indicatively in Table 2.

	Parameters				
Level	fault type	b	M_{max}	LF	XL
A	✓	✓	✓	✓	✓
B	✓			✓	✓
C				✓	✓
D / D1	✓			✓	
D / D2	✓		✓		
E / E1				✓	
E / E2			✓		

Table 2: Indicative levels of data knowledge for the pipeline – fault crossing site with reducing data availability from Level A to Level E.

The available data at each level reflects the objective difficulties in gathering all the necessary data. Assuming a minor fault, the length can be estimated by analyzing satellite images and determining then the fault crossing point. However, this fault might have been inactive for

a long period, and consequently estimating the maximum earthquake magnitude and the *b*-value of Gutenberg-Richter Law might not be possible.

The present study stands as the first step towards formulating simplified expressions for the estimation of the design fault displacement for pipelines crossing faults. The seismic rate v in Eq. (1) is assumed to be $v = 1$, reflecting areas of roughly moderate seismicity, namely areas where an earthquake of magnitude above 4.50 is expected once a year on average. Levels A and B of Table 2 are examined for all fault types, taking into account all the parameters of Table 1.

3.3 Design fault displacement

The typical return period of $T = 475$ yrs is considered in the current version of EN1998-4:2006 [17]. Structures of higher importance than the typical one (namely significance factor equal to one) are designed with seismic loads that are increased by multiplying with significance (or performance) factors higher than 1.00. More return periods and equivalent probabilities of exceedance (PoE) in 50 yrs are considered hereinafter (Table 3). In more detail, a return period of $T = 225$ yrs refers to low importance infrastructure (e.g., minor pipelines not carrying fuel), while $T = 975$ yrs and $T = 2475$ yrs are reserved for significant structures or infrastructure.

T	PoE in 50 yrs	MAF
225 yrs	20%	0.0045
475 yrs	10%	0.0021
975 yrs	5%	0.0010
2475 yrs	2%	0.0004

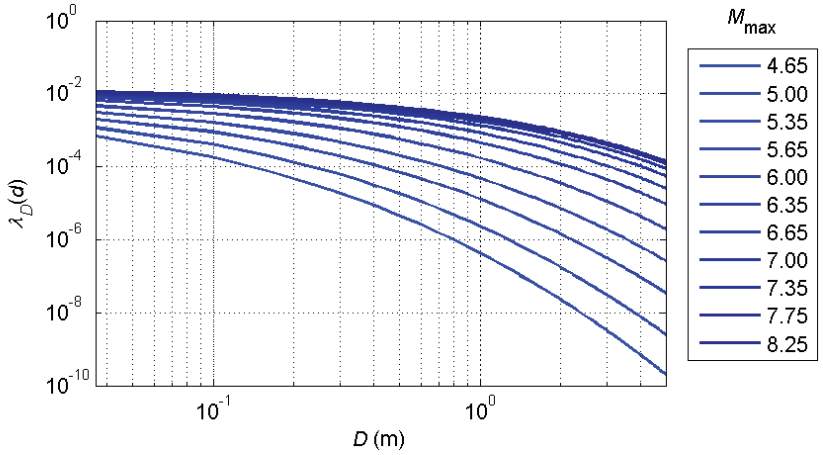
Table 3: Return periods (*T*) considered and equivalent probabilities of exceedance (PoE) in 50 yrs and corresponding mean annual frequencies (MAF).

4 LEVEL A

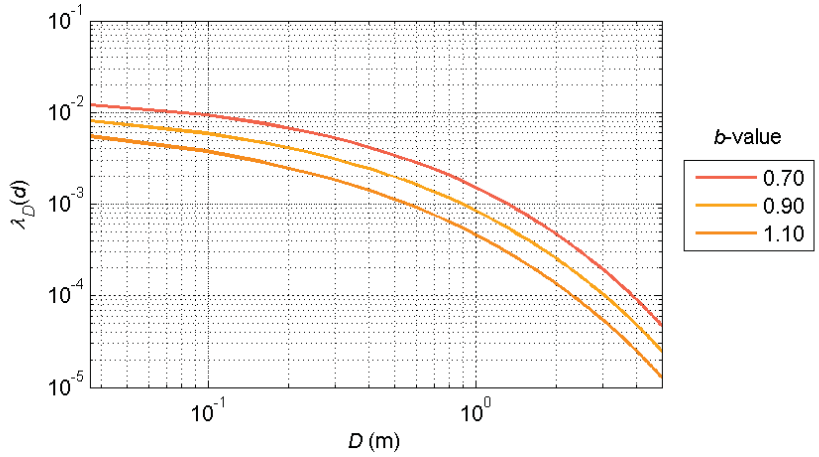
Level A of data knowledge is the one that requires all available data, namely fault type, *b*-value, magnitude M_{max}, fault length (*LF*), crossing point (*XL*). Considering all values of Table 1 for strike-slip, normal, and reverse fault type, PFDHA (section 2) is performed for all possible combinations of parameter values. In case of a strike-slip fault, the number of fault displacement hazard curves produced is equal to (11 values of M_{max}) × (3 *b*-values) × (6 values of *LF*) × (5 values of *XL*) = 990, while in case of normal and reverse fault the number of hazard curves is equal to (11 values of M_{max}) × (3 *b*-values) × (4 values of *LF*) × (5 values of *XL*) = 660. Then, to identify the effect of each parameter on the hazard curve, the case of normal faulting is examined in Figure 1 where in each case a single parameter is varied, while the other three are kept constant. The "anchoring" central set of parameter values for this example is $M_{max} = 6.65$, $b\text{-value} = 0.90$, $LF = 50\text{km}$, and $XL = 0.30$. The effect of maximum earthquake magnitude is evaluated in Figure 1(a), where for low fault offsets the range of MAFs is roughly from 10^{-3} to 10^{-2}, while for very high offsets this range is 10 times higher. In general, the increase of M_{max} leads to lower MAFs, indicating that a higher magnitude earthquake is rarer. Then, the effect of the Gutenberg-Richter *b*-value is examined in Figure 1(b), where the hazard curves for varying *b*-values are almost parallel to one another. The increase of the *b*-value leads to lower MAFs since the *b*-value is the slope of the curve that provides the "expected" future earthquake magnitude. Thus, a higher *b*-value implies that more low magnitude events "will occur" for each large magnitude event and consequently the overall rate of large magnitude events becomes lower.

The displayed behavior of the hazard curves for varying fault length in Figure 1(c) may seem peculiar, as longer faults may seem to underproduce small displacements. However, one should bear in mind that all curves are calculated for the same seismic rate $v = 1.00$ meaning that one event with magnitude $M \geq 4.50$ is expected on average per year. Thus, taking, for example, a small offset value of $d = 0.10\text{m}$, $\lambda(0.10\text{m}) = 0.0184$ for $LF = 10\text{km}$, while $\lambda(0.10\text{m}) = 0.0032$ for $LF = 100\text{km}$. The reason is that contrary to peak ground acceleration (PGA) or spectral acceleration $S_a(T_1)$ wave-propagation effects that affect points outside the immediate fault rupture, a fault offset cannot be recorded outside the rupture itself. Thus, on a longer fault, the many small events that could produce such a low value of $d = 0.10\text{m}$ actually happen away from the crossing point, reducing the corresponding MAF. When larger fault offsets are considered, larger magnitudes automatically come into play, rupturing larger segments of the fault to produce more frequent larger offsets. Thus, a fault length of 10km will very rarely produce a displacement of $d = 2\text{m}$, having a MAF of $\lambda \approx 10^{-5}$ versus a MAF of $\lambda \approx 1.5 \times 10^{-4}$ for the 100km fault.

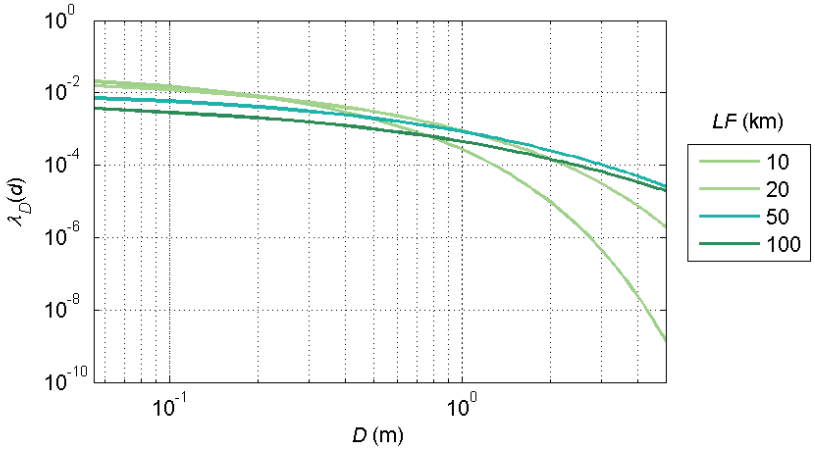
Finally, the effect of the crossing point location along the fault trace is examined in Figure 1(d). Youngs et al. [7] used normalized fault displacement data for the estimation of the conditional probability that the offset at a specific point will exceed a predefined value. The normalization is expressed as D/AD or D/MD where D is the fault offset, AD is the average fault displacement, and MD is the maximum fault displacement. Distributions of ratios D/AD and D/DD are expressed as a function of the crossing point x/LF (XL) with $f(D/AD$ or $D/MD|x/LF)$ being symmetric about a maximum value at $x/L = 0.50$. Thus, higher fault displacement is expected for values x/LF close to 0.50, as presented in Figure 1(d), where hazard curves for higher x/LF are parallelly "displaced" to lower MAFs.



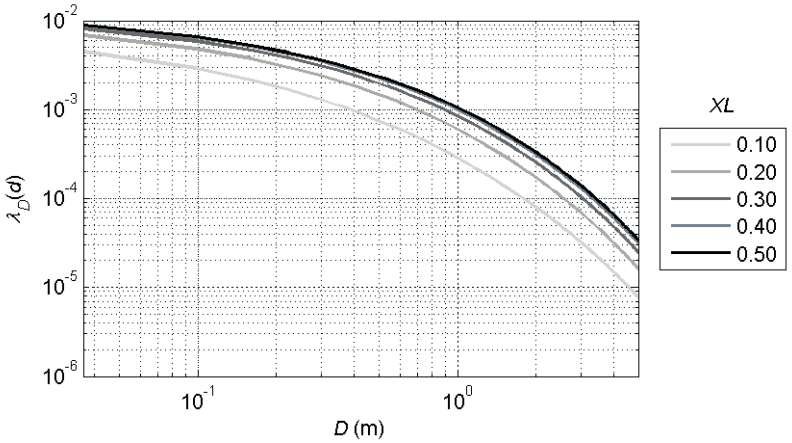
(a): varying magnitude M_{max}, b-value $= 0.90$, $LF = 50\text{km}$, and $XL = 0.30$



(b): $M_{\max} = 6.65$, varying b-value, $LF = 50$km, and $XL = 0.30$



(c): $M_{\max} = 6.65$, b-value $= 0.90$, varying LF, and $XL = 0.30$



(d): $M_{\max} = 6.65$, b-value $= 0.90$, $LF = 50$km, and varying XL

Figure 1: Fault displacement hazard curves on pipeline crossing site.

5 LEVEL B

In knowledge Level B, the maximum earthquake magnitude ($M_{\max}$) and the b-value are unknown variables, as presented in Table 2. The logic tree of Figure 2 is formulated to handle the unknown variables by assigning pertinent weight factors to the tree branches. The weight factors for the b-value are listed in Table 4 and are selected based on expert opinion for European sites.

parameter value	weight factor w_b
0.70	0.1585
0.90	0.6830
1.10	0.1585

Table 4: Level B – weight factors for the parameter *b*-value of Gutenberg-Richter Law [14].

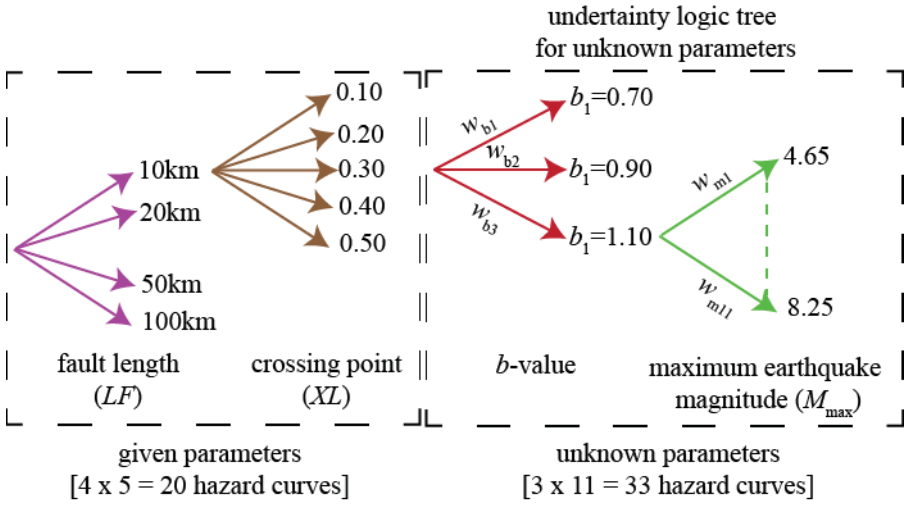


Figure 2: Logic tree formulation to handle unknown parameters in data knowledge Level B.

The weight factors for $M_{\max}$ are estimated based on the empirical expressions of Wells and Coppersmith [6]. The earthquake magnitude is normally distributed with respect to fault length (*LF*). The mean value of earthquake magnitude concerning *LF* and the corresponding standard deviation for each fault type are estimated after:

$$\text{Normal fault: } M_{mean} = 4.86 + 1.32\log_{10}(LF)\,,\sigma = 0.34 \tag{2}$$

$$\text{Reverse fault: } M_{mean} = 5.00 + 1.22\log_{10}(LF)\,,\sigma = 0.28 \tag{3}$$

$$\text{Strike-Slip fault: } M_{mean} = 5.16 + 1.12\log_{10}(LF)\,,\sigma = 0.28 \tag{4}$$

Thus, for every fault length considered, the mean earthquake magnitude is estimated using Eqs. (2)-(4). Then, the weight factor for each magnitude ($M_{\max}$) considered is evaluated as:

$$w_m = F(M_{\max}) = \Phi\left(\frac{M_{\max} - M_{mean}}{\sigma}\right) \tag{5}$$

In case of normal or reverse fault, following the procedure presented above along the logic tree of Figure 2 leads to the reduction of the total number of hazard curves (or combination of discrete parameter values) to consider from 660 to 20 [(4 values of *LF*) × (5 values of *XL*)], while in case of strike-slip fault the corresponding reduction is from 990 curves to 30 [(6 values of *LF*) × (5 values of *XL*)]. This reduction is simply achieved by summarizing the larger sample of hazard curves through the logic tree.

The next step in the process is to determine the fault offset values from each hazard curve that correspond to each return period of Table 3. The case of normal fault is illustrated in Figure 3, where the 20 hazard curves are plotted with solid lines and the 4 return periods under consideration are plotted with dashed horizontal lines. The grouping of hazard curves that is observed is related to the different fault lengths considered. In other words, the grouping of the

hazard curves is a combination of Figure 1(c) and Figure 1(d). The intersection of each horizontal line with a hazard curve provides a single point estimate of the fault offset, given the return period. Consequently, for each return period 20 fault offset values are estimated.

The fault displacement in meters with respect to fault length and crossing point can be estimated via the general function $d(LF, XL)$:

$$d(LF,XL) = p_{00} + p_{10}LF + p_{01}XL + p_{20}LF^2 + p_{11}(LF)(XL) + p_{02}XL^2 + p_{03}LF^3 + p_{21}(LF^2)(XL) + p_{12}(LF)(XL^2) \text{ (m)} \quad (6)$$

where p_{00}, p_{01}, …, p_{12} are the fitting coefficients. Evidently, to accommodate all observations on the relative significance of fault length (LF) and crossing point (XL), the length is captured with terms up to the third power, while for the crossing point, terms up to the second power are employed, including all interaction terms up to the third order. The resulting coefficients are listed in Table 5 for the normal fault, in Table 6 for the reverse fault, and in Table 7 for the strike-slip fault type. It is noted that Eq. (6) is applied for each return period of Table 3. Indicative results of the fitted surface for normal fault type and $T = 475$ yrs is shown in Figure 4. The root mean square error (RMSE), which is the standard deviation of the residuals (prediction errors), for each fitting is listed in Table 5 through Table 7, indicating that the error is at the order of a few centimeters, namely the data is very concentrated around the line of best fit. Finally, it is noted that the adjusted R-square is above 0.995 for all cases.

6 CONCLUSIONS

The estimation of design fault displacement for buried pipelines crossing active tectonic faults typically relies on regression equations, engineering assumptions, or expert opinion. Pipelines are structures of very high importance and consequently, it is deemed necessary to employ state-of-the-art probabilistic tools for the estimation of the design fault displacement. However, pipelines extend over hundreds or thousands of kilometers, crossing several major or minor, active, or potentially inactive tectonic faults. Thus, performing a full probabilistic hazard assessment of each fault crossing might not be possible or even desirable. Therefore, we presented a comprehensive first attempt to formulate simplified expressions for the calculation of the fault displacement.

The appropriate method for the seismic hazard assessment of fault is the Probabilistic Fault Displacement Hazard Analysis (PFDHA) that has been adjusted by the authors for buried pipeline – fault crossings. Considering a range of realistic values for the key input parameters of PFDHA, namely fault type, maximum earthquake magnitude, fault length, crossing point, and *b*-value for earthquake magnitude recurrence, analysis is carried out for all combinations of the input parameters. Results are then statistically processed by taking into account reduced levels of data knowledge, namely unknown parameters, to formulate simplified expressions that relate fault characteristics and fault offset, given the desired return period.

The developed simplified expressions are the first decisive step towards formulating a methodology for estimating the design fault displacement for pipeline – fault crossing considering different knowledge levels and with respect to the required return period. The proposed methodology aims at overcoming the typical drawbacks of the deterministic approach (regression equations, expert opinion, etc.), where pertinent uncertainties are disregarded, resulting in a hazard-independent estimation with an unknown level of conservatism.

Abstract. *The present paper deals with the design and the mechanical modeling of a seismic bracing system with tensegrity architecture, which operates as a lightweight mechanical amplifier for longitudinal displacements, efficiently limiting the inter-story drifts while dissipating energy. The proposed brace is based on a D-bar tensegrity structure with rhomboidal shape comprising Shape-Memory Alloy (SMA) tendons. The SMA tendons can develop austenitic-martensitic (solid to solid) phase transformations, which enable them to amplify the signals into wide super elastic hysteresis, while subjected to mechanical cycles, comprising strains up to ≈6-7%, with no residual deformations. The underlying concept of the proposed device is the use of SMA wire sections as the dissipating component, and some preliminary results have been presented in previous studies. Enhanced energy dissipation and re-centering capability of the current SMA-D-bar (SMAD) braces are illustrated by the seismic analysis of a benchmark structure. The efficiency of the designed bracing to minimize the seismic damage of the served structure paves the way for the development of advanced seismic energy dissipation systems incorporating tensegrity concepts and superelasticity.*

1 INTRODUCTION

Near field seismic vibrations are represented by pulses of short duration with extensive time periods with enormous peak ground speeds and accelerations [1]. Significant work in the field of seismic structure response control through passive energy dissipation devices (PEDs) has been outlined since previous two decades [2]. Which can be categorized into three different forms including semi-control, active and passive [3]. Passive control devices (passive energy dissipation devices (PEDD)) are considered to be the best in terms of efficiency, inexpensive and effective techniques to dissipate and eliminate the risk of seismic activity [4]- [6]. Permanent configuration of the energy dissipation devices in structure for the sole purpose of dissipation has been considered extremely effective which can dissipate significant seismic energy into other forms of energy thus reducing the risk of potential damage to the buildings [7]. Yet permanent devices are hard to fabricate and require a lot of resources to build them. In every field such as electrical, mechanical and civil engineering additive manufacturing has emerged as one of the basic and significant contributors. Due to its low cost and easy availability, the usability of the FDM (fused deposition modeling) has been enhanced since the last decade. Using the CAD (Computer Added Designs) packages, it has become possible to realize any pre-customized prototype and part with zero waste production technology [8]. To date, additive manufacturing has made a major contribution in the area of mechanical engineering. 3D printing has also shown its wide-spread use in the civil engineering sector. But very less research has been conducted in the field of additively manufactured seismic isolator. For civil / structural fields, this technology has been recognized far less. However, even after so much potential these technologies bring, these fields don't actually apply these technologies very often. Because most of the configurations were designed on site and in an industrial environment. But now several research works are being carried out to explore the effectiveness and feasibility of the additive manufacturing in civil engineering [9]- [12]. In present work an effort has been made to develop a tensegrity architecture based seismic isolator in which SMA wires were used as restitution elements and their response were observed in terms of amplification. Further, The main feature includes the use of additive manufacturing to prepare the linking components and the joints. The structure was developed using the commercial CAD program, and tested for prescribed motions that are expected to occur in structure during lateral force activity. Finally, the device was operated by implementing a customized NI based virtual interface. Furthermore, the presence of friction in joints can not be ruled out and the unaccounted dissipation of energy would also occur in joints. Which would also act as passive dissipation of energy in 3D printed bodies. In next sections, procedure for manufacturing such device has been discussed along with the testing and conclusions obtained from the research work.

2 MATERIALS AND METHODS

The main focus of this study was the development of an seismic bracing system with tensegrity architecture that could be helpful in seismic analysis of a structures . As mentioned in the previous section, the setup was intended to act as PED deviecs and SMA tendons were used as restitution elements. The dissipation of energy in buildings can be separated into two major categories, such as elastic dissipation and inelastic dissipation [13]. In this research work a system has been developed that relies on elastic dissipation mechanism such as PED devices. In Figure 1 various designs such as Diagonal 1(a) , Upper toggle 1(b), Chevron 1(c), Reverse toggle 1(d) and Scissor-jack 1(e) [14] have been shown.

The present study generalizes the Scissor-jack PED device shown in in Figure 1(e) bu de-

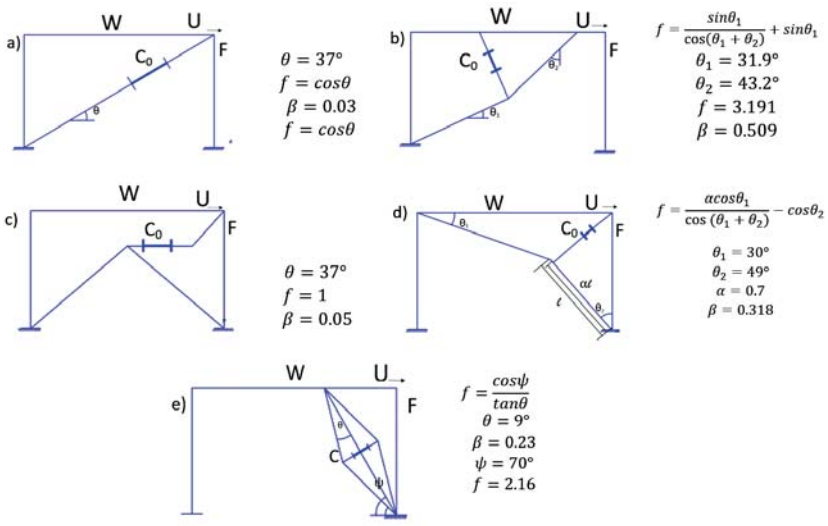

Figure 1: Different configurations of PED based systems [14]

signing a tensegrity structure with similar geometry, which is formed by a D-bar rhomboidal arrangement of four bars (blue solid elements in Fig. 2) connected each other through longitudinal and a transversal string/cable elements (red this elements in Fig. 2). This SMA-D-bar (SMAD) design allows the brace to produce stretching in the longitudinal string when it is loaded by a longitudinal force pointing upward, and, conversely, to produce stretching in the transverse string when it is loaded by a longitudinal force pointing upward (see also [15]).

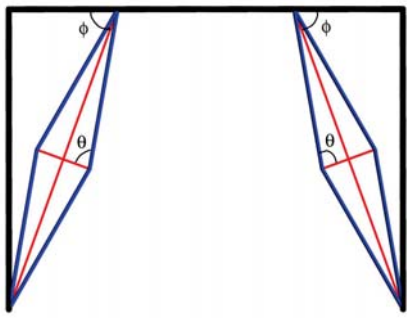

Figure 2: SMAD braces inserted into a frame structure

3 MECHANICAL MODELING

The SMAD bracing concept illustrated in Figure 2 is mechanically studied in terms of its displacement amplification and energy dissipation properties which could be very useful while assessing the seismic behavior of an earthquake-proof structure. The tensegrity-based SMAD brace is assumed to be in zero self-stress state while the structure has been assumed to be under zero external force P [15]. Because of the symmetry and loading condition of the SMAD brace, it is easy to observe that all the bars of such a structure bear an equivalent axial force N, which is assumed to be in compression. In addition, transverse SMA wires have been assumed to be carrying horizontal tensile force while vertical tensile forces are carried by the longitudinal SMAs. After assuming the forces in all the nodes, an equilibrium equation has been derived

(See Equation 1).

$$N = \frac{X}{cos\theta}, P = 2Xsin\theta - Y = Xtan\theta - Y \tag{1}$$

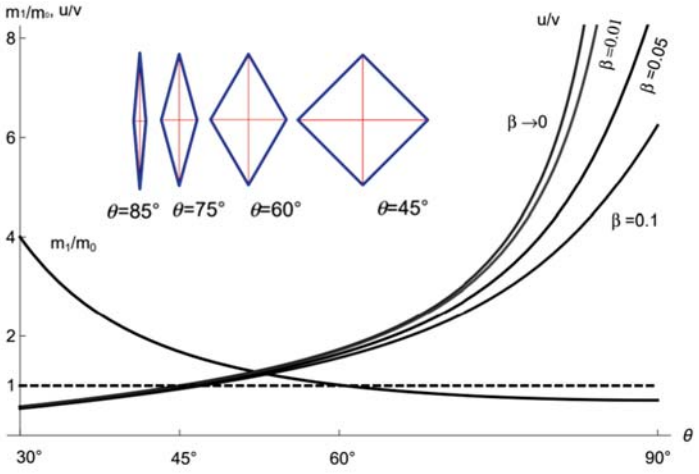

Figure 3: Displacement amplification response

When the bars acts as rigid bodies (since they feature axial stiffness much greater than the SMA wires), then the movement of SMAD brace can be described by Equation 2.

$$u/v = \left(\sqrt{4cos^2(\theta) - \beta(\beta - 4sin(\theta))} - 2cos(\theta)\right)/\beta \tag{2}$$

where *u, v and b* denote the longitudinal and the transverse displacements of the structure, and the length of the bars respectively. In the case where β approaches to 0, which shows nearly negligible movement of the brace from original position, Equation 2 converges to 'tan θ', where θ is angle of inclination. Figure 3 shows the various position of the SMAD braces at different angle of inclinations 'θ'. It has been observed that when θ approaches 90°, *u/v* ratio tends to achieve infinite values. Similarly at θ = 80° ratio becomes 5.67. Even at θ = 80° and β = 0.01, the *u/v* ratio experience a small change but with with substantially large value i.e., 5.26 (Fig. 3). In terms of the buckling load of the SMAD brace, it is useful to compare such a key mechanical parameter with that exhibited by a straight beam with length equal to the longitudinal size of the SMAD brace. Let us consider a SMAD brace with mass m_1 and straight beam with mass m_0, made of the same material, which feature the same buckling load. The analysis presented in Par. 3.3 of [16] allows us to conclude that such masses are related each other through the following equation

$$m_1/m_0 \; = \; (2\sin^5\theta)^{-\frac{1}{2}} \tag{3}$$

which gives $m_1/m_0 < 1$ for $\theta > 60.5$ degrees (Fig. 3). In particular, we observe that it results $m_1/m_0 \approx 0.73$ when $\theta = 80$ degrees (Fig. 3), which proves that tapered SMAD braces exhibit much higher buckling loads, over straight beams with equal mass. The mechanical modeling of the superelastic response of the SMA wires under stretching is given in Sect. 2.2 of Ref. [15], to which we refer the reader for details.

4 ANTI-SEISMIC BEHAVIOR

We wish now to study the seismic response of the SMAD-reinforced frame structure depicted in Fig. 2, by assuming the presence of hinged connections between the vertical columns and the horizontal beam, and at the basis of the columns. We let F denote the horizontal force acting on the frame, which is produced by a shaking excitation of the foundation structure, and let u_f denote the corresponding lateral displacement. As in [14], [15], the bars of the SMAD braces consist of TS 2×2×1/4' profiles, while the SMA strings are formed by strand comprising 12+6+1 SMA wires with 2mm diameter each [17]. The external frame has horizontal span of 2540 mm, and height of 1972 mm.The horizontal beam of the frame features a W8×21 profile, while the columns are made with W8×24 profiles [15]. Fig. 4 reports the F vs. u_F curves of frames reinforced with SMAD braces exhibiting different aspect angles ψ and θ, under of a dynamical displacement loading at the frequency of 4 Hz with maximum lateral displacement $u_F = 6$ mm. The results in Fig. 4 highlight the noticeable energy dissipation properties of the SMAD-reinforced brace, through superelastic response of the SMA strings/cables. Such a response does not induce appreciable permanent strains in the SMA cables [**?**], and therefore the SMAD-brace offers complete self-centering capabilities [18]- [19]. The additional results presented in Ref. [**?**] show that the non-invasive and self-centering SMAD braces feature energy dissipation capacity up to nearly 70% greater that that offerend by the schissor-jack device analyzed in [14].

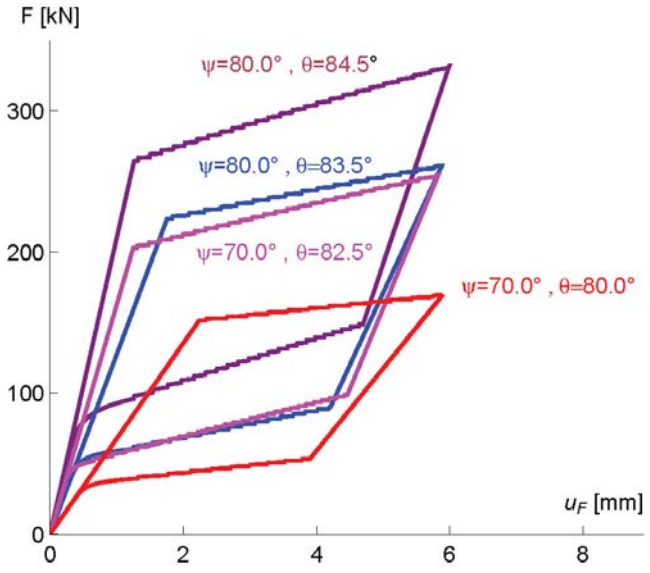

Figure 4: Force-displacement responses of a model frame reinforced with symmetrical SMAD braces.

5 CONCLUSIONS

The present paper has studied the seismic response of a tensegrity based bracing with superelastic tendons. This study showed that tensegrity inspires, light-weight bracings have a great potential in structural seismic protection. It can be clearly observed that compression efficiency of the proposed bracing is associated with a geometrical advantage, due to a metamaterial-type displacement amplification response. It has been shown that the proposed tensegrity bracing acts as a mechanical amplifier for longitudinal displacements, thus increasing the level of de-

formations experienced by the transverse SMA tendons, and the associated, superelastic energy dissipation. Based on the seismic vulnerability assessment it is possible to conclude that the proposed tensegrity-based bracings may successfully mitigate the earthquake induced damage in earthquake-proof structures, significantly reducing the probability of collapse under strong earthquakes [15]. Future work will include the experimental verification of the theoretical results presented in this work, to be conducted through structural identification procedures [20] on additively manufactured physical models of SMAD braces.

EARTHQUAKE EFFECTS ON LOW PROFILE CONTAINER CRANE WITH SEISMIC ISOLATION DEVICE

L. Solazzi

Department of Mechanical and Industrial Engineering
University of Brescia
Via Branze, 38 - 25123 Brescia (Italy)
luigi.solazzi@unibs.it

Keywords: crane, lifting equipment, earthquake actions, dynamic behavior, anti-seismic device, seismic design, seismic performance.

Abstract. *The focus of this research is to evaluate and compare the mechanical behaviour of a big ship to shore low profile container crane subjected to earthquake actions, with and without anti-seismic device applied to it. For this purpose, a specific machine was designed considering different load and geometrical configurations. Subsequently, the earthquake actions were studied. The different acceleration spectrums were established by Italian standards. The anti –seismic device was chosen to limit the crane displacement to not compromise the crane performance due, for example, to the increase of the payload swinging effect. The numerical results show that, for each load and geometrical configurations assumed, the anti-seismic device has a positive effect, it reduces the maximum stress values (about 20%). The dynamical crane behaviour is practically unchanged with the isolation device adopted, it was observed a small reduction of the natural frequencies values and a little increase of the magnitude of the maximum displacement. These results are valid also in case of dynamic action applied to the crane due, for example, to the trolley and payload movement.*

1 INTRODUCTION

The scope of this research it to analyze the dynamical behavior of the ship to shore low profile container crane, which is the popular crane utilized in the port for moving containers from the quay to the ship and vice versa. In particular, the object of this study is to analyze the seismic effects on crane considering the introduction of the anti-seismic devices. The crane can be subjected to many different actions: dead load and inertia actions [1,2,3,4], moving payload and trolley [5,6], impulse loading [7], wind [8,9,10], earthquake [11,12]. The earthquake actions can be very dangerous, in fact, for example during Kobe earthquake (17/1/1995) [13,14] different cranes collapsed causing considerable damage also on the economic point of view. In this case, the principal failure modes for these structures are local or global buckling phenomena.

This topic is very important, and so in [15], for example, are collected some recommendations for design these machines. Several papers report studies on this phenomenon [16] both experimental [17] and especially on scaled model [18,19]. From these study, different solutions were proposed to avoid the damage caused by the earthquake, introducing a seismic isolation [20,21,22].

The purpose of this research is a feasibility study of the crane with and without the anti-seismic devices in order to promote (if there are positive benefits) the implementation of these components to the crane to increase the safety factor for the whole crane.

2 SHIP TO SHORE LOW PROFILE

The object of this research is a big ship to shore low profile container crane. The main characteristics and geometrical dimensions are reported in the table 1 and in the figure 1.

Maximum payload	45000 kg
Lifting speed (unloaded)	35 m/min
Lifting speed (loaded)	85 m/min
Beam translation	30 m/min
Trolley translation	170 m/min
Bridge sliding	40 m/min

Table 1: Main crane performance.

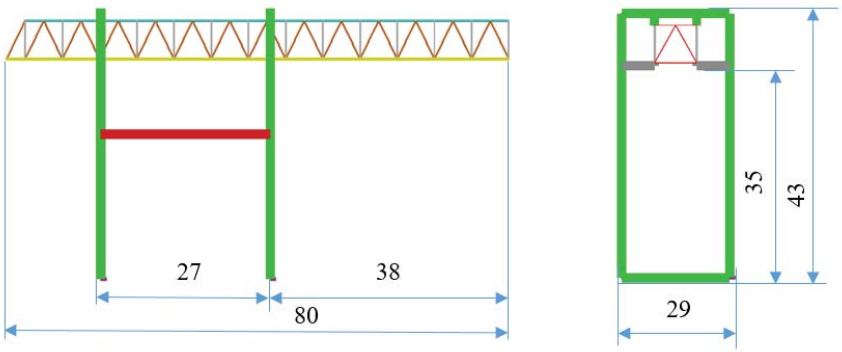

Figure 1: Main geometrical dimensions [m] for ship to shore low profile container crane.

2.1 Fem model

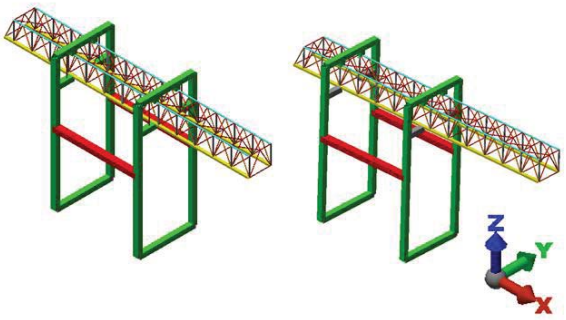

Figure 2 : Finite element crane model with the arm at sea side position and ground side position.

After preliminary analytical analyses, performed in order to design the main crane parts, a subsequent solid model and finite element analyses were carried out with the aim to study the crane mechanical behavior. Figure 2 shows the crane finite element model, which is composed of about 5000 quadratic beam elements and 8000 nodes.

The procedure adopted for dynamic analyses performed by finite element method technique (using Autodesk Simulation Software ®) is superposition modal method [23,24]. For this technique, the total mass involved for analyses is very important because it is correlated to the number of natural vibrational modes. Some standards adopt this value at least equal to 80% or more. In this research, the value adopted is equal to 90 % which corresponds about to the first 10 natural vibration modes.

2.2 Load conditions

The crane analyzed can assume different geometrical configurations and can be subjected to different load conditions. With the aim to analyze the machine, some of these configurations and actions were assumed as representative of the whole possibility of the working area and loads of the machine. They are:

1) arm completely out (sea side position) and unloaded structure;
2) arm completely out, sea side payload;
3) arm completely out, ground side payload;
4) arm in resting position, unloaded structure.

For each combination, three different analyses were performed. These analyses are:

a) linear static analysis;
b) modal analysis;
c) response spectrum analysis (assuming three different peak ground accelerations).

2.3 Response spectrum

The external actions induced by the earthquake were studied basing on the Italian Technical Standards 2008 (D.M. 14 Gennaio 2008), which are replaced by NTC 2018 (D. M. 17 Gennaio 2018) [25,26,27]; the acceleration spectrum is very similar to the Eurocode 8 Standard. Figure 3 shows an example of the accelerations spectra elaborated, which is equal for the two Italian standards adopted.

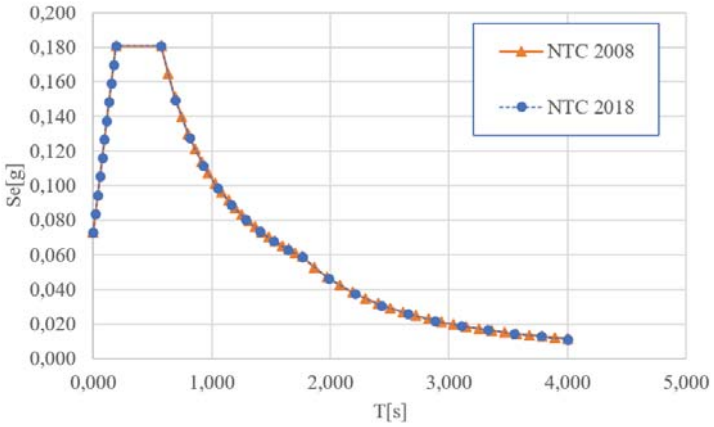

Figure 3: Comparison between acceleration spectra from NTC 2008 with that obtained by NTC 2018.

The earthquake analyses were performed considering three different "peak ground accelerations (PGA)", these values are PGA=0.15g, 0.2g and 0.35 g. In particular, the load spectra assumed refers to a very high earthquake action in specific South - Italian zone considering the structure life equal to 50 years.

.

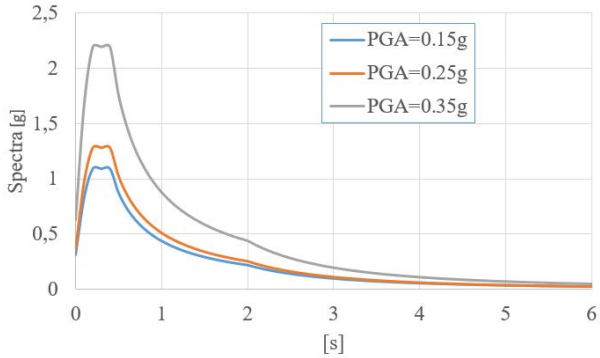

Figure 4: Three different load spectra applied to the ship to shore crane.

2.4 Results

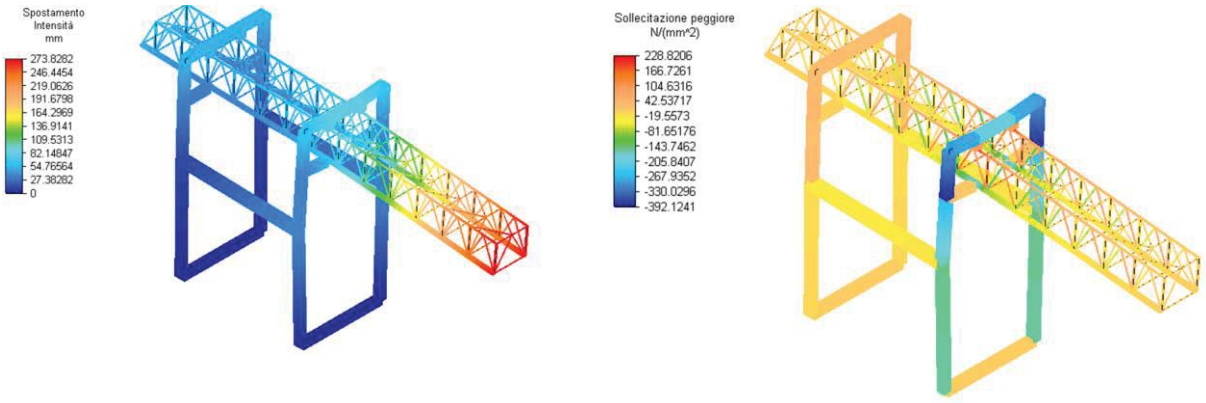

Figure 5: Stress and displacement in the second load condition (2,a).

Figure 5 shows the crane displacements and the stresses distribution in the second load condition, i.e. when the arm is positioned at sea side and the payload is applied at the end of the arm. The material assumed for crane design is a classical structural high strength steel (S460M or S460ML according to European standard EN 10025:2004) with the minimum yield strength equal to 460 MPa and tensile strength variable between 520 to 670 MPa. With this assumption, the safety factor is about 1.17, with respect to the yield strength and the ratio between the arm length and the maximum displacement that is about 300.

Table 2 shows the results from modal analyses for the same load condition. In particular, the table reports the first natural frequencies and the perceptual mass involved in the specific natural mode. The structure deformations are reported in the figure 6. The natural frequencies values are in agreement with the ones for this type of lifting machine [6,7,12].

Mode	Frequency [Hz]	%Mass X_direct.	%Mass Y_direct.	%Mass Z_direct.
1	0.213	0	50.51	0
2	0.409	0	49.05	0
3	0.416	99.29	0	0.09
4	1.07	0.33	0	33.59
5	1.18	0	0.03	0
6	2.64	0	0.01	0
7	3.97	0.01	0	48.34

Table 2: Main results from modal analyses in load condition 1,a).

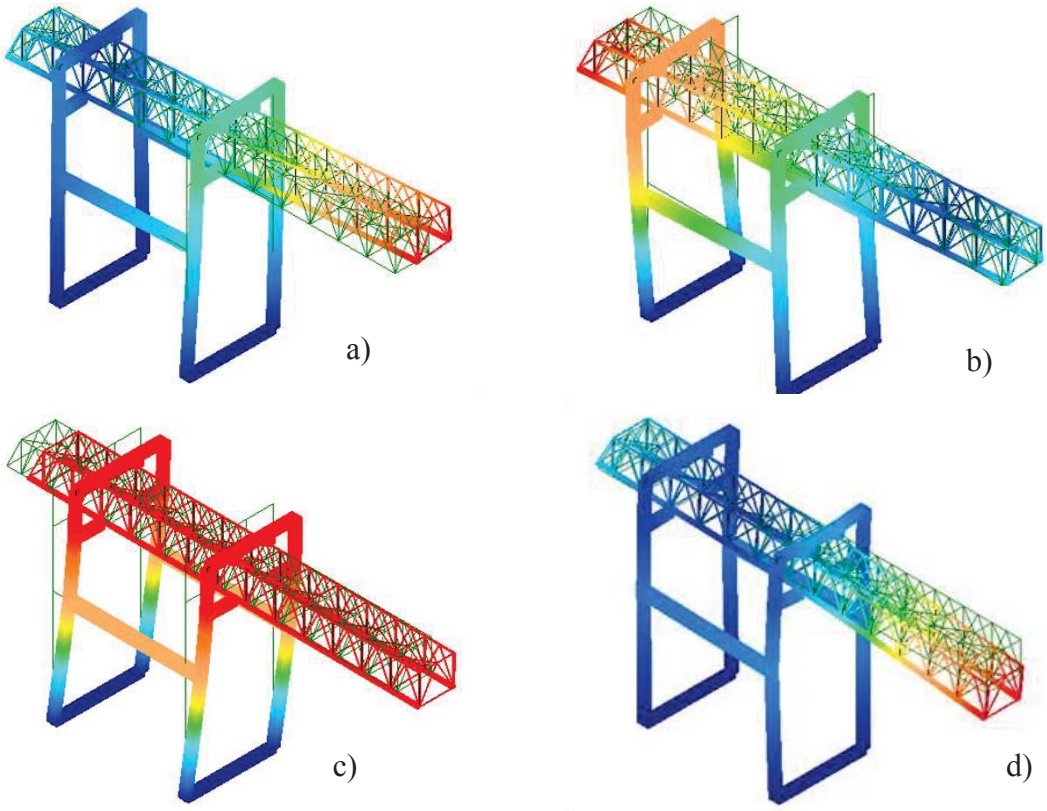

Figure 6: Crane displacement in corresponding of each vibration mode. a) 0.213 Hz, b) 0.409 Hz, c) 0.416 Hz) and d) 1.07 Hz.

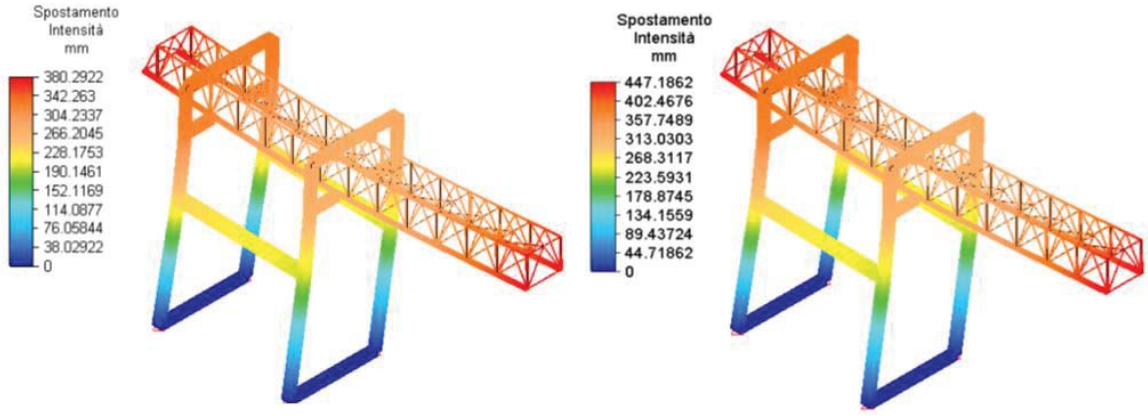

Figure 7: Crane displacements in the second load configuration assumed, subjected to PGA=0.15g and PGA=0.25g.

The modal results for other loads conditions are comparable with the previous reported. Figure 7 shows the displacement in the crane in the second load condition subjected to the load spectrum with PGA=0.15g. and with PGA=0.25g. It is important to underline that the crane trend deformation is obviously equal.

Table 3 reports the maximum displacement and the safety factor (respect to the yield strength) for the four load / geometrical conditions subjected to the static action and different earthquake magnitude.

	Load condition 1		Load condition 2		Load condition 3		Load condition 4	
PGA/Static	Max dis-placement [mm]	Safety factor	Max dis-placement [mm]	Safety factor	Max dis-placement [mm]	Safety factor	Max dis-placement [mm]	Safety factor
PGA=0.35g	902.6	0.56	764.2	0.54	750.7	0.54	828.1	0.61
PGA=0.25g	528.5	0.96	447.3	0.92	439.9	0.91	485.2	1.09
PGA=0.15g	449.3	1.15	380.5	1.09	373.9	1.08	412.4	1.22
STATIC	125.3	1.98	273.8	1.17	92.8	2.31	71.4	3.43

Table 3: Main results from static and earthquake analyses for different load conditions.

3 INTRODUCTION TO ANTI SEISMCI SYSTEM AND TECHNOLOGIES

As known, the anti-seismic system is a classical device mainly applied in the civil field; these components must dissipate the earthquake energy. In synthesis, the seismic isolation consists in decoupling the movement of the structure, usually only in horizontal plane, from that of the ground. This operation can be performed by inserting at the base an extremely flexible device and / or sliding ones or even rolling ones. With these components, the structure can move rigidly in the horizontal plane. The seismic dissipation consists in the insertion of several dampers in specific structure's points.

.

3.1 Choice criterion adopted

It is important to underline that the isolation device, adopted in order to reduce the stresses state magnitude on crane induced by earthquake, must not compromise the crane performance.

In another word, for example, it is important that the crane displacement isn't excessive to limit the increase of the pendulum load phenomenon, the time for load and unload the container, and so on. The finale product adopted (choose after several iterative analyses) consists of alternate layers of rubber and vulcanized reinforcement steel plate of limited thickness [28,29]. The commercial product reported in [30] can be applied to the cranes legs modifying the supports. The main parameter of this isolation device adopted is the horizontal stiffness, which is equal to 2kN/mm. This spring element was applied at the base of each crane leg.

After that the spring elements were included in the crane finite element model, the previous analyses were carried out again, in order to evaluate the seismic isolation device effects on the crane mechanical behaviour. The main results are reported in the table 4.

Table 4 shows the same results reported in the table 3 but in this case, the analyses consider the anti-seismic impact.

	Load condition 1		Load condition 2		Load condition 3		Load condition 4	
PGA/Static	Max displacement [mm]	Safety factor	Max displacement [mm]	Safety factor	Max displacement [mm]	Safety factor	Max displacement [mm]	Safety factor
PGA=0.35g	915.9	0.71	767.1	0.68	757.6	0.67	835.7	0.73
PGA=0.25g	536.7	1.20	450.3	1.10	443.9	1.14	489.7	1.24
PGA=0.15g	456.2	1.41	381.4	1.19	377.3	1.34	416.2	1.46
STATIC	125.8	1.98	274.5	1.21	92.8	2.31	72.1	3.49

Table 4: Main results from static and earthquake analyses for different load conditions.

4 INERTIA ACTIONS

As reported in the previous chapters, the implementation of the anti-seismic device reduces the maximum actions on the crane. Its effect is positive, in fact, it decreases the maximum stress values, avoid the possibility to make plastic hinge in the specific point of structure, reduce the overturning moment that can make the crane collapse and so on.

It is important to underline that the crane is subjected to many different inertia action induce by load and trolley movement as reported in the introduction paper. The maximum displacement and the payload oscillation must be limited in order to not increase, for example, the time for loading and unloading the container (for this specific crane). The choice of the anti-seismic device must take into account this phenomenon and so the apparatus adopted is a compromise between the positive effect (reduce the stress values) and the maximum crane displacement due to the trolley and payload movements.

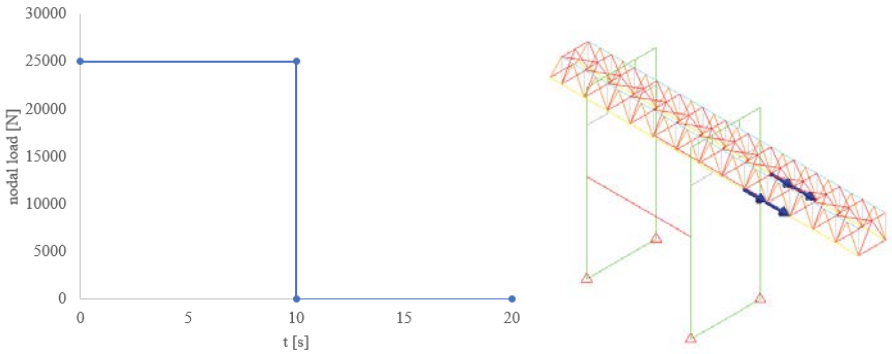

Figure 8: Trend of inertia action and schematic fem model.

This chapter reports the numerical results for the crane subjected to inertial action and compare the crane performance with and without the anti-seismic device applied to it. It is important to underline that, for this load condition reported, the main inertia actions are in the arm direction due to the trolley and the payload movements. For the study of this phenomenon, it was assumed that the inertia action is equal to 100000 N. This value corresponds to acceleration payload and trolley equal to a=2m/s2. The trend of this action is reported in figure 8 and it refers to start and stop the trolley movement.

Figure 9 reports the maximum crane displacement with and without the anti-seismic device.

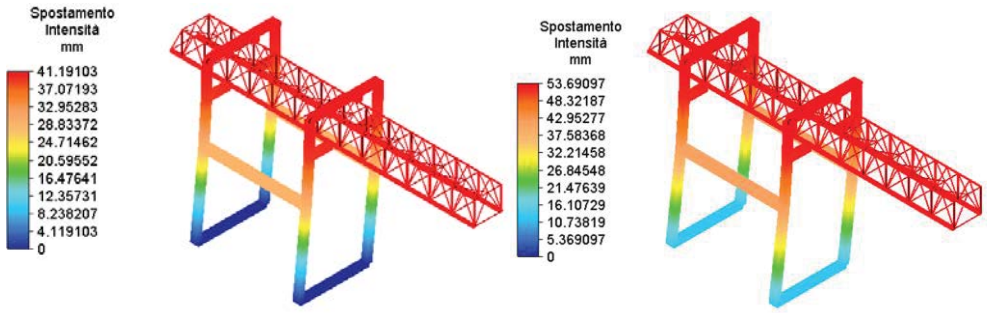

Figure 9: Maximum crane displacement a) without anti-seismic device and b) with it (in the static load applied).

Figure 10 shows the displacement trend in horizontal direction for crane with and without the anti-seismic device, subjected to the external action reported in figure 6.

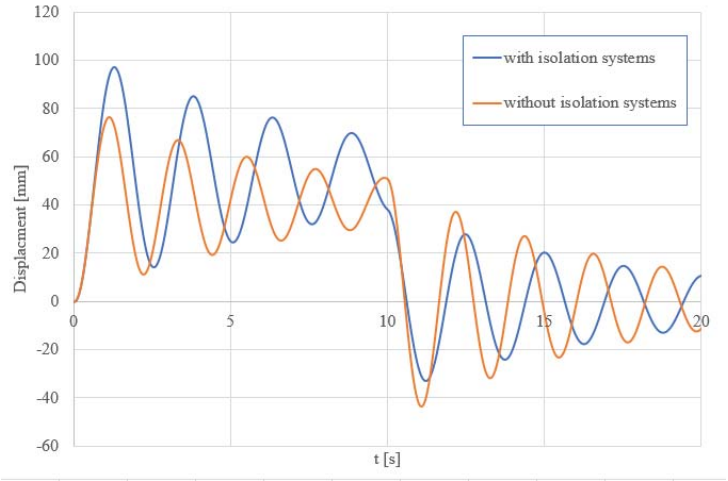

Figure 10: Crane displacement to the variable inertia action.

5 RESULTS

The main results of this research in order to evaluate the anti-seismic effects on the crane studied are reported in the previous tables and graphs and can be summarized with these points. The worst load condition is n°2 and corresponds to the arm at seaside position with payload (and trolley) applied at the end. With the minimum earthquake action (PGA=1.4), for all load conditions, the maximum stress value is near the material yield strength. The anti-seismic device reduces the maximum stress values and increases the safety factor about 20% especially in the case with the earthquake actions. In static load condition (for all configurations) the anti-seismic device shows a minimum and negligible effect. The variation in the natural frequencies values in the cases with and without isolation systems is negligible. In the

case of actions variable over time (like moving the payload), it is possible to observe an increase in the displacement value but this new trend can be easily taken into account to design the trolley movement control.

6 CONCLUSIONS

This research reports the main numerical results for a big ship to shore low profile crane with the seismic device applied at the crane base. The results of finite element analyses carried out show that the implementation of specific anti-seismic device caused a general lowering of the natural frequencies, that leads to maximum stress reduction and increase the displacements. However, the movements are not so high to prejudice the crane performance and usefulness of the isolation systems. With the specific isolation device implemented, the maximum displacements (for different geometrical and load conditions of crane) are comparable. It is very important to highlight that the final isolation system device chosen do not significantly increases the crane translation due to the inertial actions and so the crane performance in term of container movement per hour do not change. The different displacement trend can be easily implemented in the control system for the trolley movement in order to unchanged the crane productivity. The results of this feasibility study with the aim of implementing the isolation device to low profile container crane are encouraging. The research is still in progress in order to study both the crane mechanical behaviour subjected to earthquake with isolation device for different crane types, and the methodology adopted to choose the best isolation system device.

Keywords: Steel Truss Bridge, Seismic Performance, Buckling Restrained Damper, Nonlinear Dynamic Analysis

Abstract. *The buckling restrained bracing (BRB) is widely used to improve the seismic behavior of a building. It is employed for a bridge as well, but the application is very limited. The BRB device may also be used as a damper rather than the structural component or the bracing, in which case the device is called a buckling restrained damper (BRD). Yet, such application has not been explored much. There are quite a few bridges designed according to the old seismic design codes in Japan. Their seismic resistance may not be satisfactory for the current seismic design codes. Against this background, the behavior of a steel truss bridge under a large seismic load is investigated by nonlinear dynamic finite element analysis. Some members are indeed found possibly damaged in the earthquake. Retrofitting is therefore needed. To this end, the application of the BRD is tried in the present study. A parametric study on the seismic behavior of the truss bridge with the BRD is conducted by changing the length and the cross-sectional area of the yielding core of the BRD, to this end. The FEA show that the BRD surely improves the seismic performance of the truss bridge and with some BRDs, all the members could stay intact. The points to note for the application of the BRD are also revealed.*

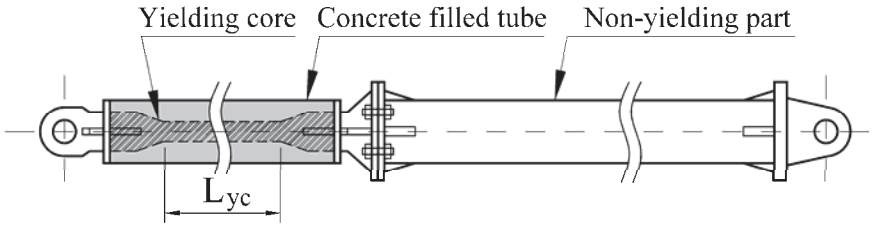

Figure 1: Buckling restrained damper (BRD).

1 INTRODUCTION

Many bridges were damaged by the earthquake in the past. The damage was investigated in the aftermath, and seismic design codes were upgraded whenever found necessary [1, 2]. It is noted that the 1995 Kobe Earthquake was the most influential in the revision of the Japanese seismic design codes.

New bridges are designed by the revised design codes. Existing bridges due to the old seismic design codes need be investigated to see if they satisfy the requirements of the revised seismic design codes. If the performance is not satisfactory, the bridge would be retrofitted.

There are various ways to improve seismic performance. One of the commonly employed methods is to install dampers. A typical type is a fluid viscous damper. For the building, the buckling restrained bracing (BRB) is getting popular [3]. It is basically a structural member, a bracing, and it undergoes plastic deformation in large seismic loading. Buckling is prevented by limiting the lateral displacement so that seismic energy is absorbed by the plastic deformation both in tension and compression. The application of the BRB to the bridge has been studied [4], yet it is still very limited.

The BRB device is not necessarily used just as a bracing; It could be used as a damper, which is then called a buckling restrained damper (BRD). In the present study, the application of the BRD is explored for retrofitting a truss bridge that does not satisfy the requirements of the current seismic design codes. A parametric study of the BRD is to be carried out to reveal its effectiveness on the seismic performance of the bridge.

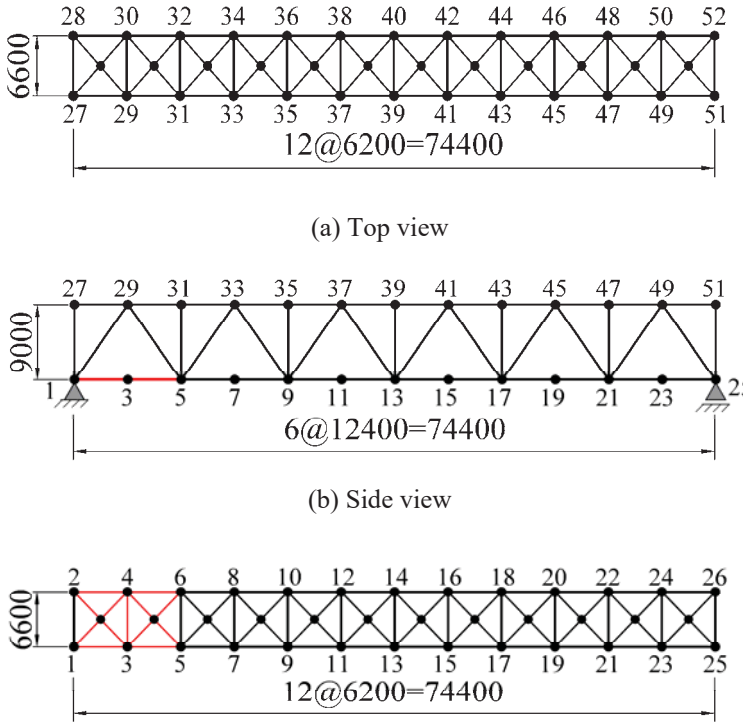
The BRD is illustrated in Figure 1. Only a part of the BRD undergoes plastic deformation and absorbs seismic energy. This part is called the yielding core. The remaining part stays elastic and its deformation is small. In this study, the latter is assumed rigid. The length and the cross-sectional area of the yielding core are treated as parameters and several values are given to them. For all the analyses, ABAQUS [5]is used.

2 SAFETY EVALUATION

2.1 Safety evaluation

A simply supported steel truss bridge is dealt with in the present study. Figure 2 shows the truss with node numbers. The node numbers at the centers of the lateral members are neglected for the sake of clarity. The dimensions of the cross sections and the steel grades are given in Table 1. The yield strengths σ_y of SM490Y and SM400 are 355 N/mm^2 and 235 N/mm^2, respectively. Young's modulus E of the steel is 2.0×10^5 N/mm^2, Poison's ratio is 0.3 and the mass density is 7.85 t/m^3. Beyond the yield strength, the steel shows elastic-plastic behavior, which is modelled as the von Mises material with the kinematic hardening rule. The tangent stiffness beyond the yield strength in uniaxial tension is assumed E/100.

The truss bridge is supported by the hinge at Nodes 1 and 2, while Nodes 25 and 26 are supported by the roller so that these nodes can move in the longitudinal direction. The bridge



(a) Top view

(b) Side view

(c) Bottom view

Figure 2: Truss bridge model (mm).

has a reinforced concrete deck of 10.60 m in width and 200 mm in thickness on the upper chords.

The damage in the concrete deck wouldn't be so serious in general and the repair wouldn't be so difficult if any. The deck is therefore treated as an elastic body for the sake of simplicity. Young's modulus of the concrete is 2.1×10^4 N/mm^2, Poison's ratio is 0.2 and the mass density is 2.35 t/m^3.

Damping factors are 2% for the truss members and 3% for the concrete deck. Rayleigh damping is employed. 3-D beam elements B33 are used for the truss members, and shell elements S4R are for the concrete deck. In total, 1180 beam elements and 168 shell elements are employed for modelling the truss bridge.

2.2 Seismic performance

The seismic behavior of the truss bridge under seismic loading is obtained by the nonlinear dynamic analysis. The seismic loading recorded in the 2005 Niigata-Ken Chuetsu Earthquake (Figure 3) is applied in the longitudinal direction.

Following Specifications for Highway Steel Bridges [6], the safety is judged by the following equations:

$$R_t = \sigma/\sigma_y \quad \text{under tension} \tag{1}$$

$$R_c = \sigma/\sigma_{cr} \quad \text{under compression} \tag{2}$$

where σ is the induced axial normal stress and σ_{cr} is the compressive strength. The violation of the inequality (1) indicates that the member yields; the violation of the inequality (2) implies that local buckling takes place.

Table 1: Truss member

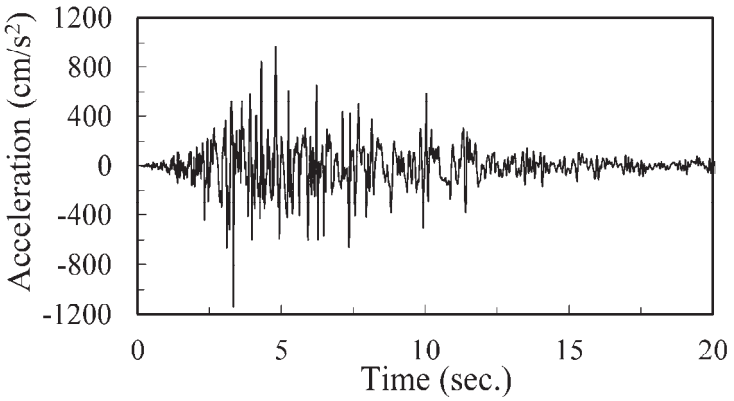

Figure 3: 2004 Niigata-Ken Chuetsu Earthquake.

The nonlinear dynamic analysis reveals that the members highlighted in red in Figure 2 would be possibly damaged, as the violation of Eq. (1) and/or Eq. (2) are/is found. The largest R_c is 1.21, which is observed in Members 1-3 and 2-4; the largest R_t is 1.07 which occurs also in Members 1-3 and 2-4.

3 INSTALLATION OF BRDS

3.1 BRD model and locations

For the yielding core of the BRD, LY225 is used. LY225 is a steel grade with Young's modulus 2.0×10^5 N/mm^2, Poisson's ratio 0.3 and the yield strength 225 N/mm^2. It exhibits the elastic-plastic behavior of the von Mises material with the kinematic hardening rule. The tangent stiffness beyond the yield strength in uniaxial tension is 3E/100.

The BRD is made in such a way that the buckling is prevented. Therefore, the yielding core is modeled by a single truss element T3D2.

Two BRDs are installed to the truss bridge near the lower chords possibly damaged. One end of one of the BRDs is set at the bridge abutment close to Node 1 and the other end is connected to Node 5. The other BRD is set between the bridge abutment close to Node 2 and Node 6.

3.2 Parametric study

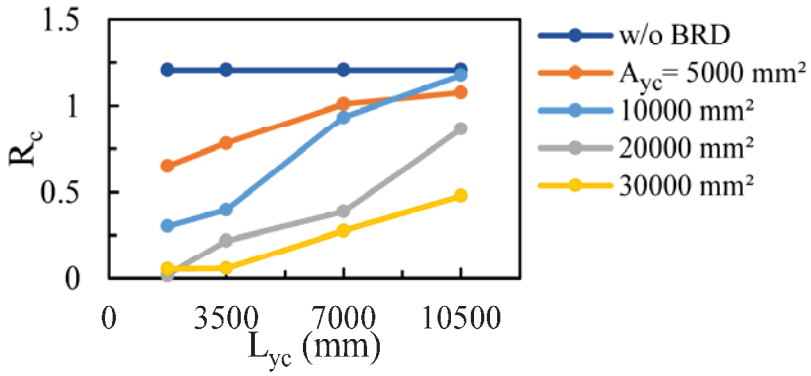
To study the effective use of the BRD, a parametric study is conducted. Two parameters are considered, the length of the yielding core L_{yc} and the cross-sectional area of the yielding core A_{yc}. Specifically, the following values are considered herein:

$$L_{yc} = 1750,\quad 3500,\quad 7000,\quad 10500 \text{ mm}$$
$$A_{yc} = 5000,\quad 10000,\quad 20000,\quad 30000 \text{ mm}^2$$

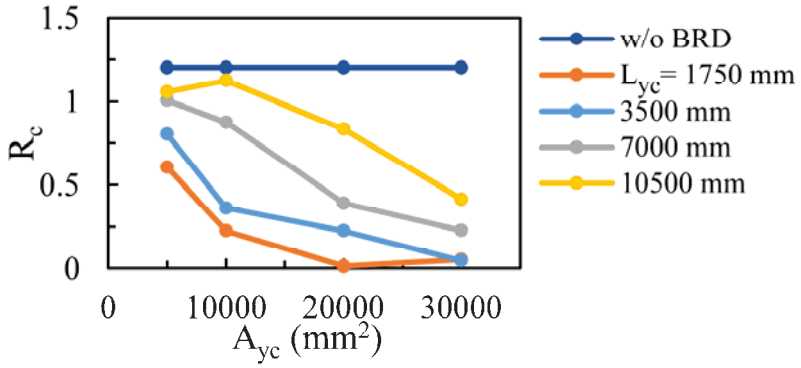
The combination of these values results in 16 different BRDs. The BRD is named using the values of the parameters. For example, the BRD with L_{yc} = 1750 mm and A_{yc} = 5000 mm^2 is called BRD 1750-5000.

3.3 Effectiveness

The nonlinear dynamic analysis of the truss bridge with the BRD is conducted. It is found that the BRD surely improves the seismic performance of the bridge. The improvement of R_c



(a) Influence of L_{yc}



(b) Influence of A_{yc}

Figure 4: Effectiveness of BRD (Member 1-3).

is summarized in Figure 4. Through the parametric study, the following observations are made:

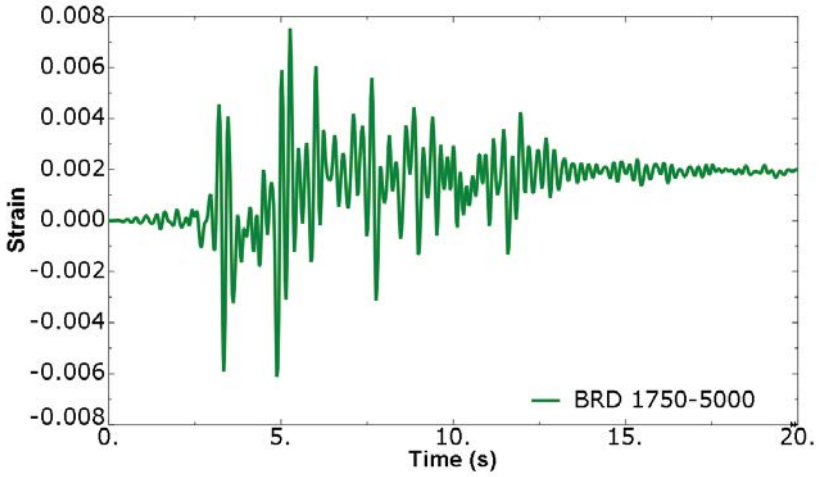
1. BRD is more effective with a shorter L_{yc};
2. BRD is more effective with a larger A_{yc};
3. The reduction in R_c is more pronounced than in R_t.

Obviously both parameters have a significant influence on the seismic performance of the truss bridge. However, the way they work is different.

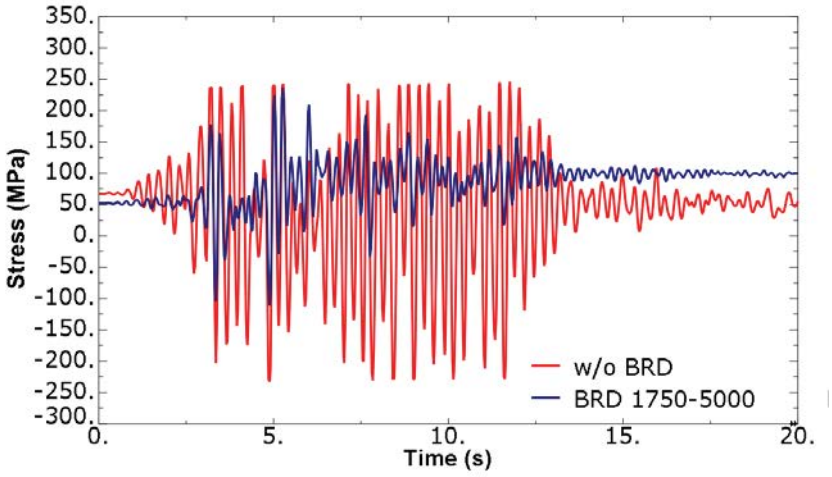
Figures 5 and 6 show the time-history response with the BRDs. Figures 5 is the result with BRD 1750-5000, and Figures 6 is with BRD 10500-30000. In the former, the BRD is effective because it is short while the latter is effective because the cross-sectional area is large. In both figures, the stress in the truss member is the normal stress in the axial direction in the upper flange.

BRD 1750-5000 undergoes plastic deformation and absorbs seismic energy. Large strain occurs. The stress in Member 3-5, inside the BRD range, is reduced. The stress in Member 5-7, outside the BRD range, increases a little.

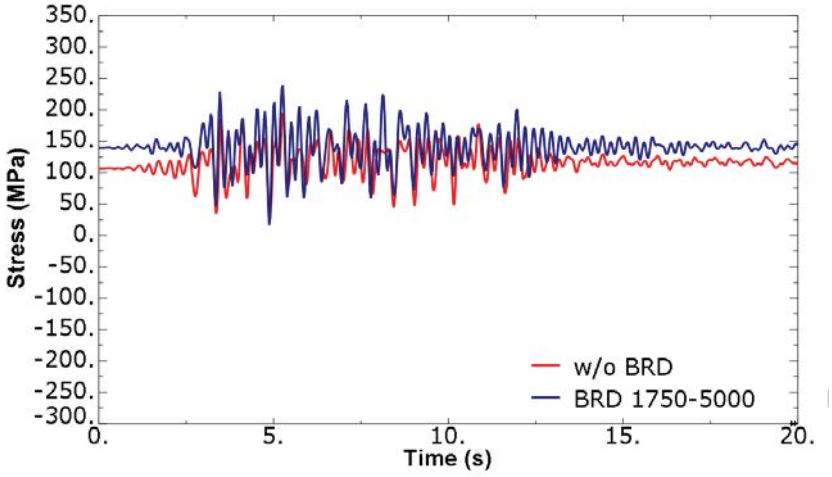
On the other hand, the strain in BRD 10500-30000 is small and the BRDs stay in an elastic state. Seismic energy is not absorbed at all. Yet the stress in Member 3-5 is reduced considerably, which is attributable to the large stiffness of the BRD. The significant increase in the stress in Member 5-7 is noted.



(a) Strain in yielding core

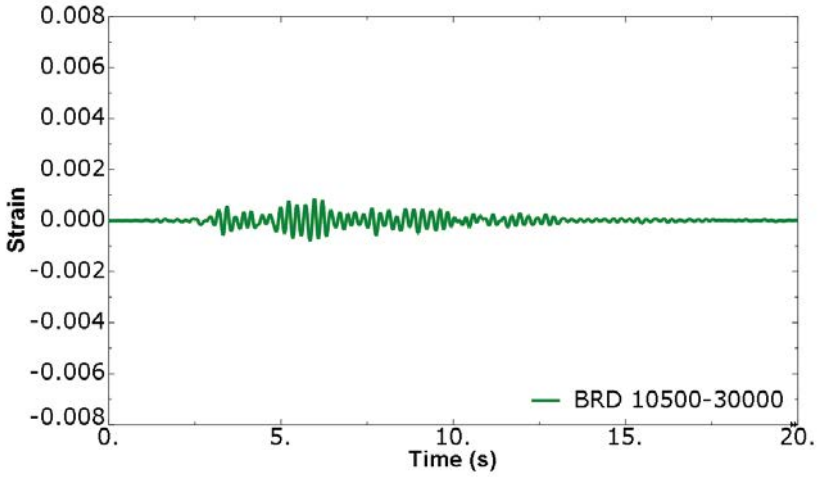


(b) Stress in Member 3-5

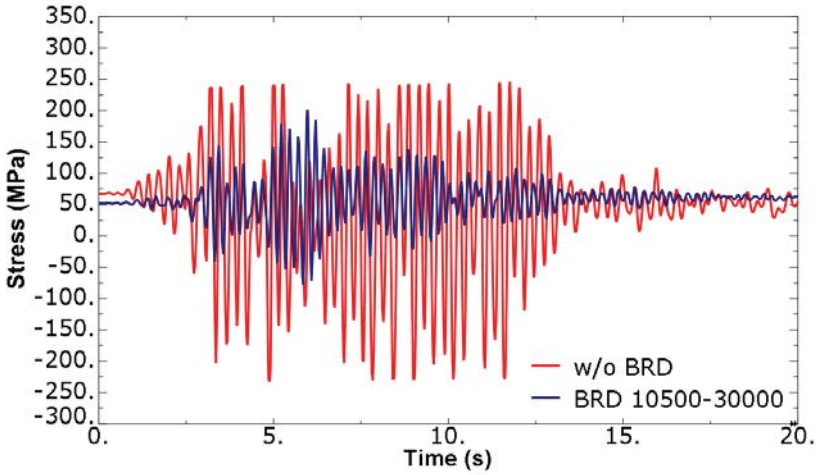


(c) Stress in Member 5-7

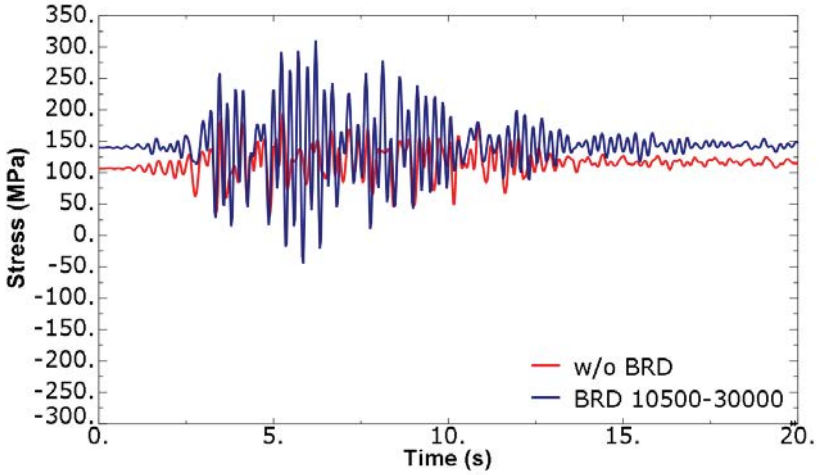
Figure 5: Seismic response with BRD 1750-5000.



(a) Strain in yielding core



(b) Stress in Member 3-5



(c) Stress in Member 5-7

Figure 6: Seismic response with BRD 10500-30000.

Table 2: Seismic performance of truss bridge.

(a) R_c

		A_{yc} (mm^2)			
		5000	10000	20000	30000
L_{yc} (mm)	1750	Intact	Intact	Intact	Intact
	3500	Intact	Intact	Intact	Intact
	7000	Damaged	Intact	Intact	Intact
	10500	Damaged	Damaged	Intact	Intact

(b) R_t

		A_{yc} (mm^2)			
		5000	10000	20000	30000
L_{yc} (mm)	1750	Damaged	Damaged	Intact	Intact
	3500	Damaged	Damaged	Intact	Intact
	7000	Damaged	Damaged	Damaged	Intact
	10500	Damaged	Damaged	Damaged	Damaged

Summary of the seismic performance is given in Table 2. "Damaged" indicates that some members violate Eq. (1) and/or Eq. (2). "Intact" means all the members satisfy Eqs. (1) and (2): with some BRDs, no damage would occur in this truss bridge.

4 CONCLUDING REMARKS

The BRB device was applied to the truss bridge as a damper. The nonlinear dynamic analysis of the truss bridge has revealed that the BRD could improve the seismic performance considerably. It was found that with the shorter length and the larger cross-sectional area, the BRD works more effectively. With proper BRDs, the truss bridge could stay intact even under rather large seismic loading.

Both the length and the cross-sectional area influence the seismic performance of the bridge. A short yielding core absorbs seismic energy, but it may undergo large strain repeatedly; Low-cycle fatigue may take place. A larger cross-sectional area of the yielding core reduces the stress in the member inside the BRD range while the stress outside the BRD range increase noticeably. Those negative aspects must be taken into account carefully in the application of the BRD.

Abstract. *The non-linear behavior of beam-to-column joints may significantly influence the seismic performance of steel moment resisting frames (MRFs). The current Eurocodes does not give detailed rules for seismic-resistant joints, but the next version of EN1998 will provide specific rules for pre-qualified joints whose background was matured within the RFCS research project "EQUALJOINTS". Recently the research project "FUTURE" has been approved within the "H2020-INFRAIA-01-2016-2017 Research Infrastructure for Earth-quake Hazard". In this project shake table tests will be carried out on a two-storey one bay MRF equipped with the beam-to-column joints prequalified according to EQUALJOINTS procedure, namely haunched joint, dog-bone and the extended stiffened joint. In this paper, the behaviour of joints under both monotonic and cyclic loads is investigated in order to verify the effectiveness of the design procedure. Parametric analyses were also carried out to investigate the influence of the finger shims on both non-linear behaviour of the joints. The results show that the design criteria are effective to guarantee the required performance of the joints and, despite the cumulative plastic deformation in the dissipative elements, the introduction of the finger shims are useful for the dismantling phase.*

1 INTRODUCTION

The seismic response of steel moment resisting frames (MRFs) is largely influenced by the behaviour of joints. At the current stage, EN1993-1-8 [1] does not give detailed rules for seismic-resistant joints. EN 1998-1 [2] allows using dissipative joints, provided that the design is supported by testing, which results in impractical solutions within the time and budget constraints of real-life projects. Even though the lack of analytical models to predict the joints behaviour to meet code requirements is more evident for dissipative beam-to-column connections, reliable design tools for non-dissipative connections are also necessary. These criticisms have been recently overcome for a set of bolted joints that were studied within the European research project "EQUALJOINTS" [5].

Steel MRFs are also sensitive to the combined effects of the coupling between vertical and horizontal components of earthquake ground motions [6-9]. Indeed, differently from far-field input, the combined components of strong earthquake motions may (i) change the axial forces in columns, (ii) increase bending moment and shear force demands in the connections, (iii) amplify plastic deformations, (iv) extend plastic hinge formations and (v) reduce the available ductility of dissipative zones.

Besides the joints and the effects induced by vertical ground motions (VGMs), also the design requirements of EC8 largely influence the response and the efficiency of steel MRFs. In particular, it is generally recognized that the drift limitations (i.e., damage limitation checks at serviceability limit state) often impose an increase of the lateral stiffness of MRF, hence the increase of beam and column sizes to satisfy such requirement typically results in significant design overstrength and non-economical solutions [9]. Indeed, EC8 compliant MRFs may be generally massive and expensive structures [10], due to the large consumption of steel. In addition, the larger are the beam-column shapes the more difficult and expensive is the manufacturing of the joints. Provided that the overall stability of the structure is guaranteed, the possibility to increase the drift limitations (e.g. from 0.75% up to 1.5% of the inter-storey height) can be beneficial to optimize the design and to improve the structural efficiency by reducing the design overstrength. This can be achieved through the application of special ductile claddings that are able to accommodate large interstorey drift ratios, higher than 1.5% [11]. The increase of lateral deformability may con-tribute to a greater sensitivity of the frames to P-Delta effects.

However, it is well recognized that the current EC8 provisions concerning the control of P-Delta effects is extremely conservative and excessively penalising for steel frames since it does not account for the material overstrength, the design over-strength and the hardening effects associated with redundancy and plastic redistribution [10].

In the light of the considerations discussed above concerning the criticisms of EC8, the European research project FUTURE (acronym of Full-scale experimental validation of steel moment frame with EU qualified joints and energy efficient claddings under Near fault seismic scenarios) has been recently financed. The main objectives of the project FUTURE are the investigation of seismic response of steel MRFs accounting for different types of prequalified beam-to-column joints as well as the role of ductile claddings under NF earthquakes. To this end, comprehensive shake table tests on specifically conceived mock-up have been planned. The mock-up is designed to be used in several experimental tests, after the substitution of damaged dissipative parts at the end of each them.

In this paper, the preliminary simulations to study

the influence of the finger shim plates on the monotonic and cyclic response of the beam-to-column joints of FUTURE mockup are presentented. This article is subdivided in three parts, as follows: in the first part some information about the project and the design of the

joints are reported; afterwards the modelling procedure is described. Finally, the results in terms of moment rotation curves and equivalent plastic deformations are reported.

2 THE FUTURE MOCKUP

The experimental mock-up is shown in Figure 1. The structure consists of a two storey steel MRF (5 m x 5 m) sub-structured from a reference archetype building. The mock-up is designed to detach and to replace easily all components that will experience plastic deformations, namely the column ends at the base level and the end portions of the beams with corresponding end-plate connections. The schematic view of reduced beam section (RBS), haunched (H) and extended stiffened (ES-E) are shown in Figure 2.

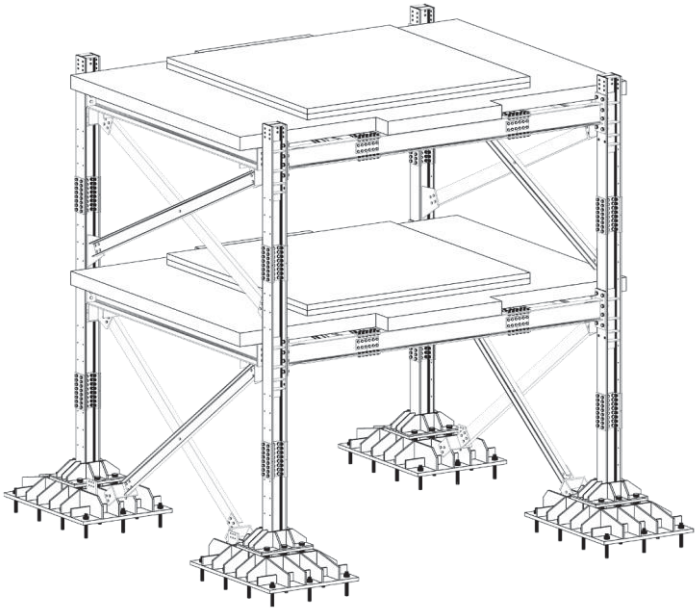

Figure 1: Experimental mock-up

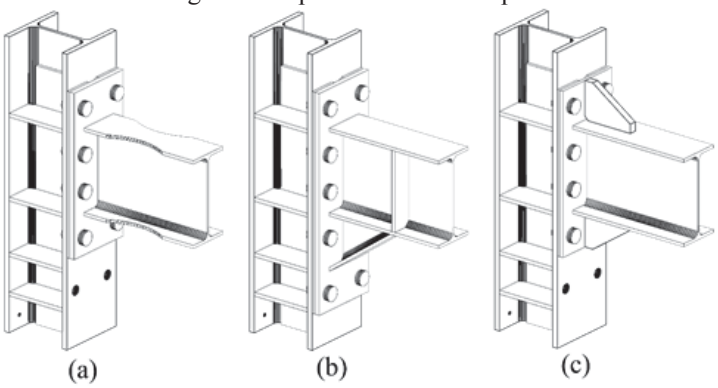

Figure 2: Investigated joints: a) Reduced beam section (RBS), b) Hunched (H) and c) Extended stiffened equal strength (ES-E)

3 THE INVESTIGATED BEAM-TO-COLUMN JOINTS

All investigated joints were designed according to the Equaljoints criteria [12]. In particular, the end-plate connections of haunched and RBS joints were designed as full-strength, namely to be stronger than the connected beam segment where plastic deformations are expected. ES joints were designed with equal strength connections, namely designed to guaran-

tee the contemporary yielding of both connection and beam. In addition, for all joint configurations the column web panel was de-signed to be stronger than the connected beam and connections in order to remain elastic during the whole experimental campaign. The capacity design requirements to obtain the required joint behaviour can be expressed by Eq. (1):

$$M_{wp,Rd} \geq M_{con,Rd} \geq M_{con,Ed} = \alpha \cdot (M_{B,Rd} + V_{B,Ed} \cdot s_h) \tag{1}$$

$$M_{wp,Rd} = V_{wp,Rd} \cdot z \tag{2}$$

In Equation 1, $M_{wp,Rd}$ is the flexural strength corresponding to the shear capacity of column web-panel (see Eq. (2), $V_{wp,Rd}$ is the column web shear resistance, z is the internal level arm, $M_{con,Rd}$ is the flexural strength of the connection zone, $M_{con,Ed}$ is the design bending moment at the column face, $M_{B,Rd}$ is the design bending strength of the beam, $V_{B,Ed}$ is shear force corresponding to the occurrence of the plastic hinge in the connected beam, s_h is the distance between the applied shear and the column face. α depends on the design performance level and it is given by $\gamma_{sh} \times \gamma_{ov}$ for the full strength joints, while equal to 1 for equal strength joints and to 0.8 for partial strength joints. (being γsh the hardening factor and γ_{ov} the ratio between the average and the characteristic yield stress of the steel) In the case of dissipative connections (i.e. equal and partial strength configurations), a further hierarchy criterion [12] was adopted in order to avoid the failure of the bolts, so that the design tensile strength of each bolt row should be larger than the strength of the connected plate accounting for both the random variability of its yield stress and the relevant strain hardening. This requirement is expressed by Eq. (3), being d the nominal bolt diameter, γ_{M0} and γ_{M2} the partial safety factors according to Eurocode 3.

$$t \leq \frac{0.42 \cdot d}{\sqrt{\gamma_{ov} \cdot \gamma_{sh}}} \cdot \sqrt{\frac{\gamma_{M0} \cdot f_{ub}}{\gamma_{M2} \cdot f_y}} \tag{3}$$

For each investigated joints two models were performed, namely one assumes the direct contact between the end-plate and the column flange and another con-siders the presence of finger shims that often are used for constructional reasons in the bolted beam-to-column joints (see Figure 3a).

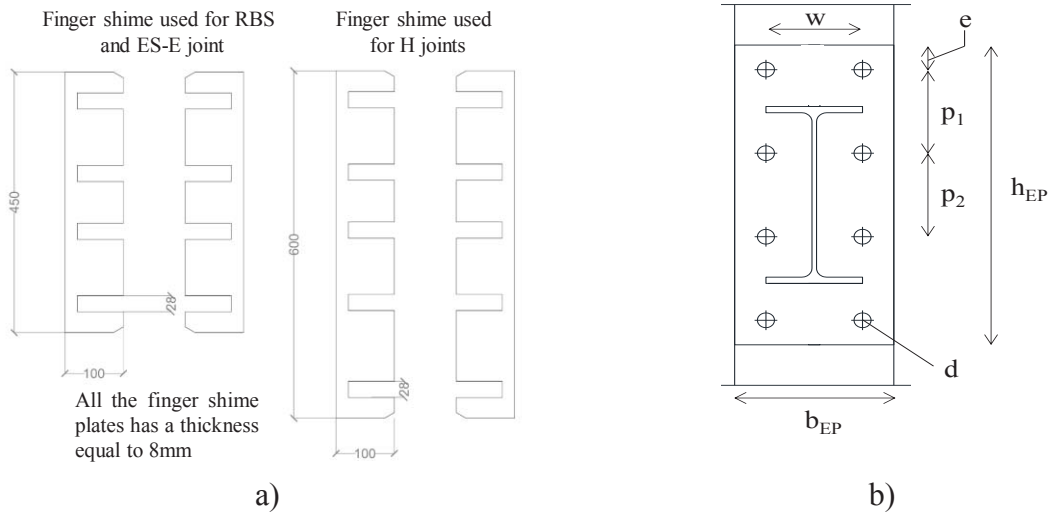

Figure 3: Geometric features of finger shims (a) and investigated connections (b).

The beam (IPE240A) and the column size (HEB200) are the same for all joint assemblies. Table 1 and Figure 3b reports the main geometrical features of all investigated joints. In addition, the rib introduced in the ES-E has a base of 135mm and a thickness of 15mm.

In the following, the results of both monotonic and cyclic analyses of each beam-to-column joint are reported in terms of moment rotation curves with also the distribution of the equivalent plastic deformation (PEEQ).

Joint Typologies	End plate			Bolts M16 grade 10.9				
	b_{EP}	h_{EP}	t_{EP}	d	e	p_1	p_2	w
	mm	mm	mm	mm	mm	mm	mm	mm

Table 1: Geometric features of the investigated joints

4 MODELLING ASSUMPTIONS

Finite element analyses (FEAs) were carried out using the finite element software ABAQUS 6.14 [13]; all details about the modelling procedure are reported in previous study of the Authors [14-17]. However, the main information about the modelling assumptions are summarized hereinafter.

All joints elements were discretized by C3D8I elements and a mesh sensitivity analyses was performed in order to choose the most appropriate mesh dimension (see Figure 4). The beam imperfections due to the mill tolerance allowed by EN 10034 (1993) were accounted for and applied to the model by scaling the deformed shape of associated buckling mode as shown in Tartaglia et al [15]. All assemblies are made by the European S355 steel with the exception of Grade 10.9 for the pre-loadable bolts. The stress-strain curves of the materials were obtained from coupon tests performed within the EQUALJOINTs research project. In the FE model, the Von Misses criteria and the combined (i.e. isotropic and kinematic) plastic hardening were assumed. The behaviour of bolts was modelled by multilinear force-displacement curve described by D'Aniello et al. [18]. To model the shank necking and the fracture in the threaded area the ductile damage was introduced in the model as proposed by Pavlovic et al [19]. The material of the welds was modelled by an elastic perfectly plastic constitutive law, with the yield stress equal to 460 MPa, which corresponds to an electrode grade A46 (as given by EN ISO 2560, 2009).

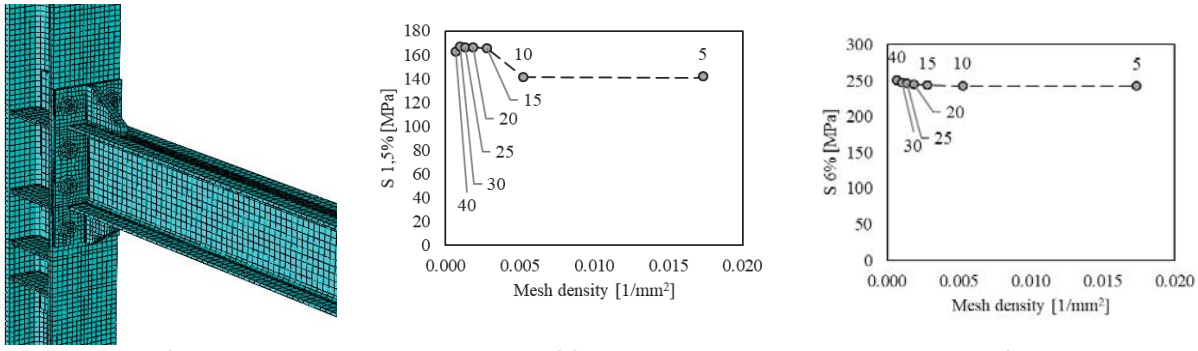

Figure 4: Example of the mesh on the ES-E joint Mesh (a) and mesh sensitivity analyses on the beam (b) and on the bolts (c).

5 RESULTS

5.1 Reduced beam section (RBS) joint

Figure 5 shows the results of both monotonic and cyclic analyses of RBS joints. The monotonic analyses were performed up to 10% of joint rotation while the AISC341 loading protocol was used for the cyclic simulations. Most of the plastic deformations are concentrated in the RBS section with the activation of a perfect plastic hinge leaving the connection almost elastic. However, some plastic deformation can be observed around the weld between the beam flange and the end-plate at a high level of imposed rotation (10%). The joints show a very ductile behaviour up to 6% of chord rotation with small decrease of resistance due to beam geometrical imperfections.

Comparing the results in terms of backbone curve no appreciable differences can be observed between the joints with and without finger shims. These considerations are also confirmed by the PEEQ distribution on both the investigated joints.

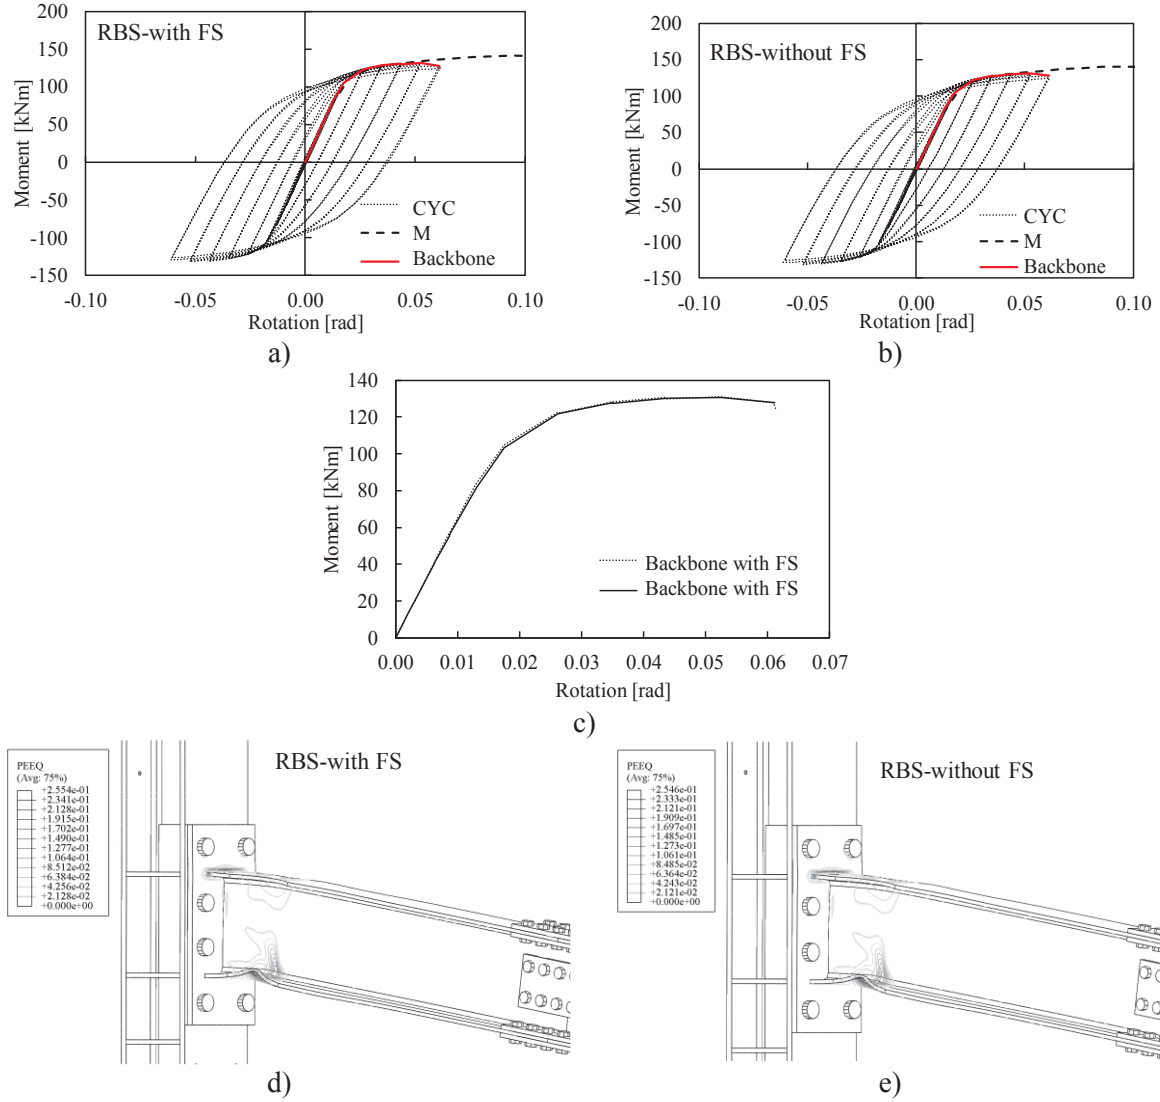

Figure 5: Monotonic and cyclic behaviour of RBS joints with and without finger shims.

5.2 Haunched joint

The results in terms of moment rotation curves and distribution of PEEQ for haunched joints with and without finger shims are summarized in Figure 6. As observed in the previous case also in haunched joints the plastic hinge forms at the extremity of the beam, leaving the connection and column web panel in elastic range. However, a larger reduction of resistance due to the beam flange local instability can be observed at 3.5% of rotation. The decrease of resistance is smaller than 20% at a 4% of rotation, hence these joints conform with both European and American requirements.

As in the previous case also for this type of connection no appreciable differences can be observed between the joints with and without the finger shims.

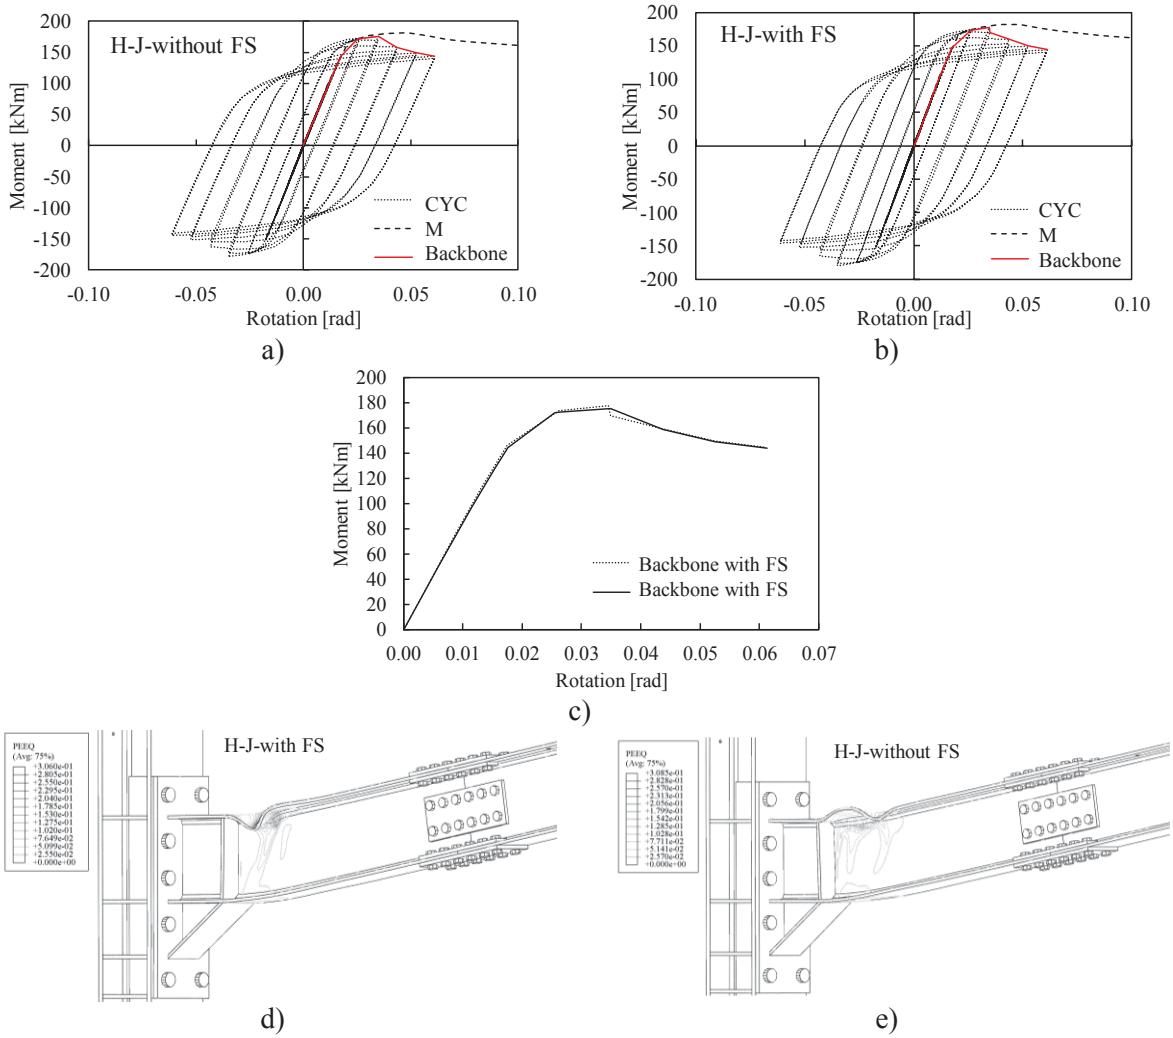

Figure 6: Monotonic and cyclic behaviour of haunched joints with and without finger shims

5.3 Extended stiffened equal strength (ES-E) Joint

Also the extended stiffened equal strength joints show a very ductile behaviour with plastic deformation in both beam and connection (see Figure 7).

Differently from the previous cases, the presence of finger shims gives some slight difference in terms of moment-rotation response curves, but negligible differences in terms of distribution of plastic deformations. The reason of such differences is mainly due to the longer

length of the bolt shanks in the joints with finger shims, which increases the deformability and the gap opening of the connection in its non-linear range.

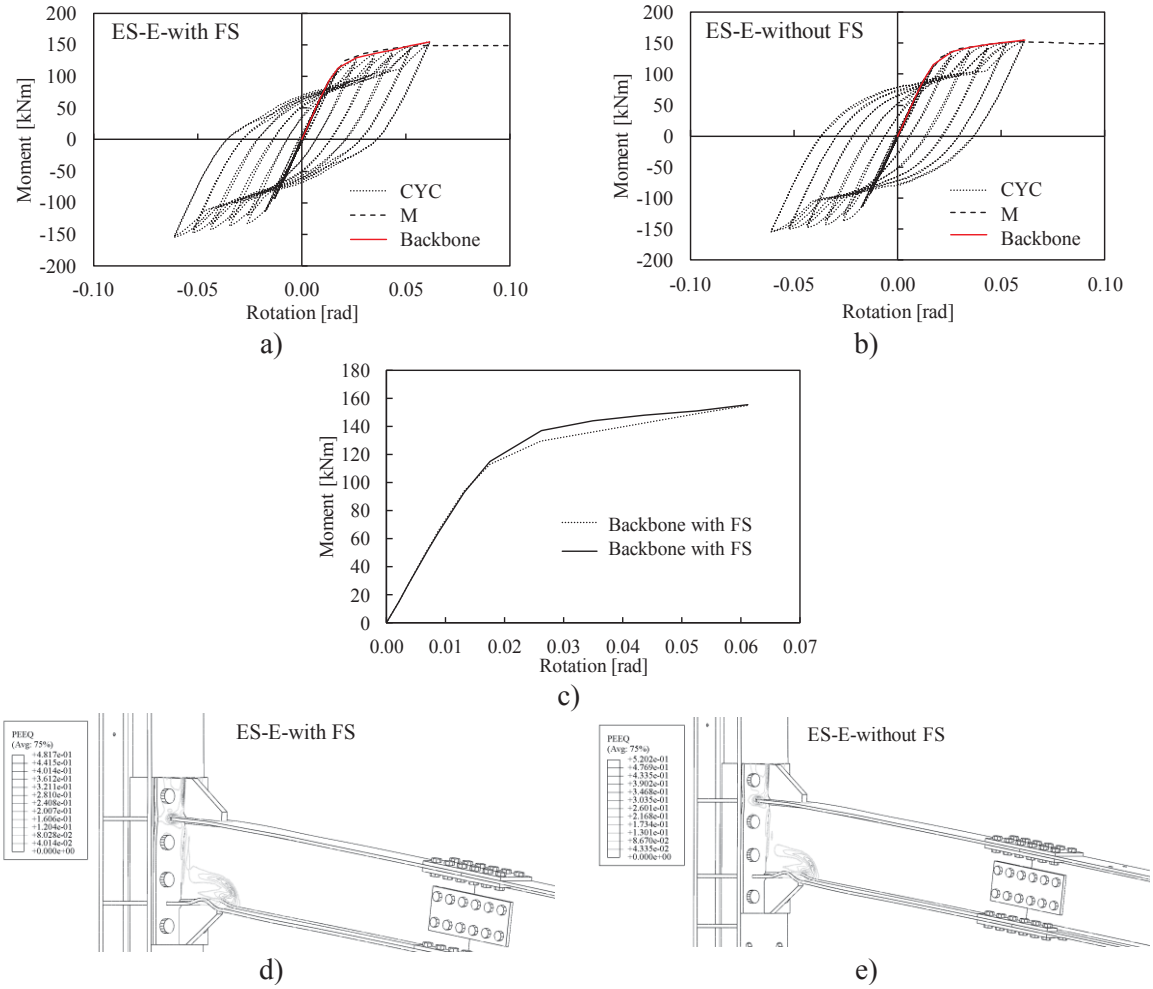

Figure 7: Monotonic and cyclic behaviour of ES-E joints with and without finger shims

6 CONCLUSIONS

The non-linear response and influence of finger-shim plates on three different beam-to-column joints configurations was investigated by means of finite element simulations. On the basis of the results, the following remarks can be pointed out:

- The bolted joint with reduced beam section ensures a very good ductile behaviour up to rotation of 6% without showing any resistance decrease. The performance of this type of joint is not influenced by finger shims.
- The haunched joint designed in accordance with the criteria developed within the Equaljoints research project allow to obtain a full rigid/full strength joint. The response is not affected by the introduction of the finger shim plates
- Differently from the previous cases, the influence of the finger shim plate can be observed for equal strength connection due to the larger deformability of the connection and some variation of the distribution of the contact forces when the connection opens. How-

ever, the presence of finger shims does not significantly modify the global performance of the joint.

Keywords: Buckling-enabled bracing, Damage-avoidance, Rocking frame, Steel buildings

Abstract. *The severe social and economic impacts of recent earthquakes have inspired a growing interest in smart structural systems that offer immediate post-disaster occupancy. Post-tensioned rocking frames are emerging damage-avoiding seismic-resistant structures that employ rocking joints at member connections (to avoid major damage to primary structural elements) and unbonded post-tensioned strands (to provide self-centring capability). Nevertheless, currently available passive load-resisting systems to control the peak structural responses in steel rocking frames rely on sacrificial yielding components that accumulate damage during strong dynamic action. This results in a system with limited durability and a requirement for regular maintenance throughout the building's lifetime. By contrast, the recently proposed Buckling-Enabled Composite Bracing (BECB) elements can provide a thorough damage-avoidance solution by means of carefully controlled elastic buckling behaviour. In these systems, compression-only elements with circular-arc-shaped cross-sections are incorporated into steel rocking frames as lattice bracing in order to improve their dynamic performance. The proposed system has been shown to perform successfully under static loading and discrete sine-sweep ground motions for single-storey rocking frames. This further examines this innovative concept by performing numerical investigations on three-storey four-bay post-tensioned steel rocking buildings under real earthquake ground motions. The performances of conventional moment frames (MRFs) and their rocking frame counterparts (RFs) with and without BECB elements are compared through numerical simulations. Glass-fibre reinforced polymer (GFRP) is selected for the BECB elements. Static Pushover, Discrete Sine-sweep and Incremental Dynamic (IDA) analyses are performed to evaluate the buildings' performances. Damage measures investigated include maximum inter-storey drifts and floor accelerations. It is demonstrated that BECB members enhance the dynamic response of steel rocking frames by significantly reducing maximum storey drifts and accelerations.*

1 INTRODUCTION

In response to the severe socioeconomic impacts of earthquakes [1], rocking self-centring frames that employ elastic gap-opening mechanisms at the column-foundation and beam-column interfaces, have been proposed as damage-limiting alternatives. These systems utilize unbonded post-tensioned tendons to tie members together and re-centre the structure to its plumb position after strong ground motion. This configuration effectively prevents yielding of primary structural members, but can lead to large storey drifts and accelerations. Therefore, sacrificial elements that dissipate modest amounts of energy through yielding (damage) are typically provided to stabilize the rocking response.

Research devising methods of enhancing earthquake resilience for rocking structures has spanned over the last decade [2, 3, 4, 5, 6, 7, 8, 9, 10, 11]. Particularly for self-centring steel frames, the use of yielding thin steel plate infill walls [12, 13, 14], buckling-restrained braces [15], yielding seat angles [16, 17], short axial yielding devices [18], yielding web hourglass pins [19], or beam web/flange friction devices [20, 21, 22] have been explored. Although these technologies are very effective in reducing peak response quantities, they all comprise of sacrificial and/or replaceable components that accumulate damage during strong dynamic action. This results in a system with limited durability, and a requirement for frequent inspections and maintenance. Furthermore, in spite the inclusion of these technologies, the structures often experience permanent post-earthquake damage and require significant repair or replacement.

In contrast, the recently proposed buckling-enabled composite bracing (BECB) elements can provide a thoroughly damage-avoidance solution [23, 24]. In these systems, shell-like elements with GFRP material properties, are employed to improve the dynamic performance of rocking steel frames through their elastic buckling properties. A curvature in the cross-section is provided to increase the section's buckling capacity. Single-storey post-tensioned steel rocking frames with BECB have been shown to perform successfully under numerical testing to static displacement cycles and discrete sine-sweep ground motions [23], demonstrating reduced peak responses, greater lateral-load resistance, and no damage accumulation compared to systems without BECB.

This paper builds on this innovative concept by performing numerical investigations on three-storey post-tensioned steel rocking buildings. The performances of conventional moment frames (MRFs) and their rocking frame counterparts (RFs) with and without BECB elements are compared through numerical simulations. Numerically-generated frequency response functions (FRFs) are examined. Incremental Dynamic Analyses (IDA) are performed to evaluate the buildings' performances [25]. Multiple damage measures are investigated, including maximum inter-storey drifts and floor accelerations. It is demonstrated that BECB enhances the static and dynamic performance of rocking frames by significantly reducing the storey drifts and accelerations without any damage accumulation. This study forms a strong foundation towards the provision of truly damage-avoidance solutions and supplies the tools for further investigations into practical design methods.

2 PROPOSED STRUCTURES

The 3-storey steel moment-resisting frame (MRF) proposed by the Structural Control Committee of the American Society of Civil Engineers [26] for the SAC Steel Project was selected as the benchmark building herein. The structure's geometric and member details are presented in Figure 1. The building has a total height of 11.88 m, and width of 36.6 m. It represents a typical low-rise structure with an aspect ratio of 0.33. The beams are made of 248

MPa steel while 345 MPa steel is employed for the columns. The seismic mass of the first and second levels is 9.57×10^5 kg and the third level is 1.04×10^6 kg.

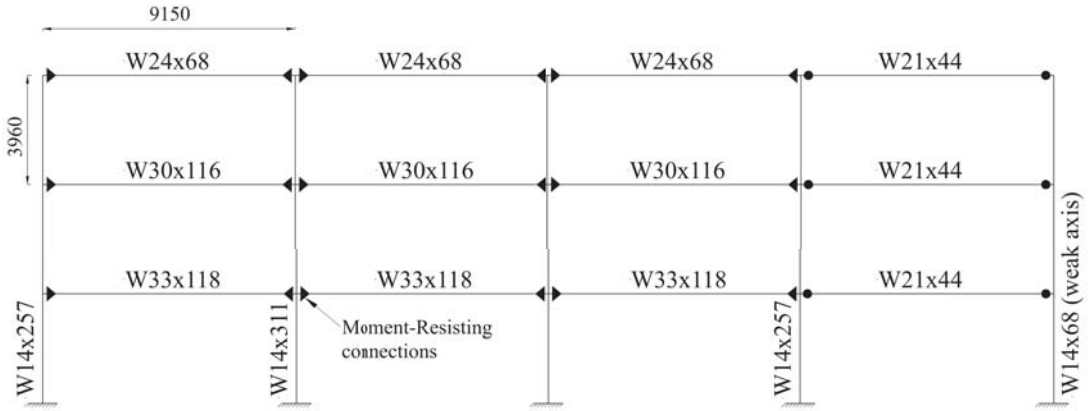

Figure 1: Three-storey, four-bay steel moment-resisting frame.

The rocking frame (RF) counterparts employed identical sections as the MRF with rocking connections at both the beam-column and column-foundation interfaces. To provide support for the BECB at ground level, a floor beam with section W33x118 was provided. A tendon cross section of 500 mm^2 was incorporated for the beams and columns. A view of the cross-section illustrating the geometric parameters of BECB member is presented in Figure 2 and the proposed configurations for the RF systems with BECB are presented in Figure 3.

For configuration 1, two sizes of BECB (8 elements in total) were incorporated in a single bay, including shorter members with dimensions of L (length) = 3.3 m, α (curvature) = 50◦, t (thickness) = 16 mm, r (radius) = 100 mm and longer members with L = 6.7 m, α = 50◦, t = 25 mm, r = 180 mm. For configuration 2 (C2), BECB elements were incorporated in two bays of the building. An isotropic elastic material with modulus 'E' of 18 GPa and Poisson's ratio 'μ' of 0.3 (GFRP) was used to simulate each BECB element in ABAQUS [27, 28] in order to obtain the respective buckling response.

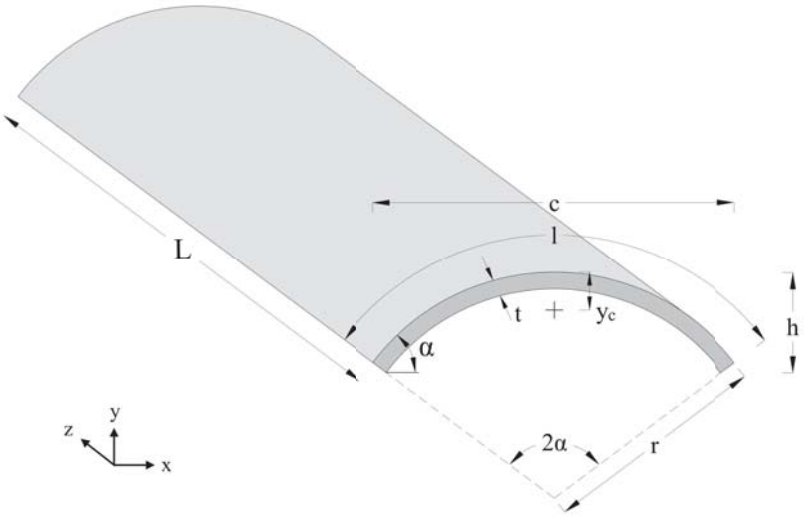

Figure 2: BECB element cross-section with geometric parameters.

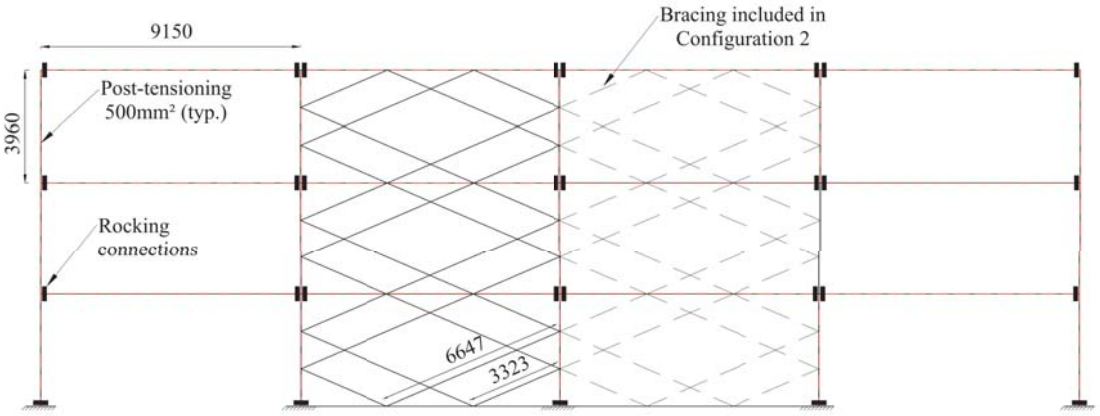

Figure 3: Three-storey, four-bay steel self-centring rocking frames with BECB in single and two bays (C2).

3 FINITE ELEMENT MODELLING

Four planar frames (MRF, RF, RF w/ BECB, and RF w/ BECB C2) with three-degrees-of-freedom per node were defined using the open source finite element framework OpenSees [29]. Force-based non-linear beam-column elements were used for beams and columns. A Steel01 material model was employed for the fibre sections with their respective yield strengths. Each section was discretized into 40 fibres and 2 force-based elements with 3 Gauss-Lobatto integration points per element. Geometric non-linearities were accounted for by means of a Corotational transformation. A constant stiffness proportional damping of 5% was specified for all models. All degrees of freedom for every structure were constrained at the foundation level to simulate a fixed base. Nodal masses were defined in the horizontal and vertical degrees of freedom, and lumped at the top of each column element. Beam gravity loads were applied as distributed loads along beam lengths.

The details of the rocking frames were simulated using the numerical modelling procedures proposed in [30]. The columns and tendons (beam and column) were modelled as continuous elements along the frame height and width. The post-tensioning tendons were modelled using Corotational Truss Elements with an initial stress uniaxial material (Steel02 material in OpenSees [29]). Zero-length gap elements (springs) were used to simulate the rocking surfaces. Elastic Perfectly Plastic material with no tension stiffness was defined for the gap element. The Lobatto integration scheme introduced in [31], was used to determine the distribution of the gap elements along member edges.

Elastic Bilinear uniaxial material was used to represent the pre to post-buckling behaviour of BECB. The MinMax uniaxial material [29] was used to define the failure envelope of the bracing members employing the fracture strain of GFRP [27]. Subsequently, the bracing members were represented as truss compression-only elements in the numerical models.

Static lateral loads were applied at the nodes assuming linear first-mode distribution. A displacement control strategy was used to perform the non-linear static analysis. Frequency response functions (FRFs) were generated using discrete sine-sweep input ground motions as originally proposed in [30]. MATLAB [32] was used to generate input harmonic base motions. Subsequently, Incremental dynamic analyses (IDA) were performed to evaluate the buildings' performances. The set of 22 far-field strong ground motion records from FEMA P695 (ATC-63) were selected for the analyses [33].

4 STATIC RESPONSE

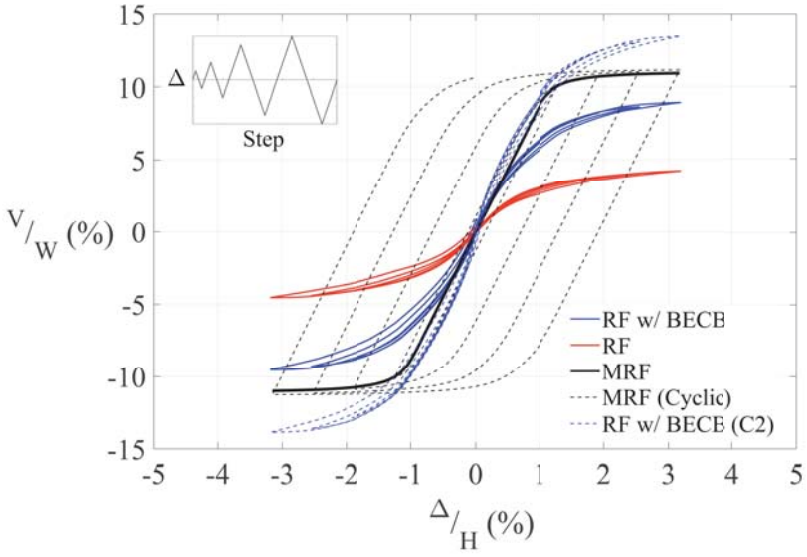

Figure 4: Static response comparison between moment-resisting frames (MRF) and rocking frames with and without BECB (RF w/BECB and RF w/BECB C2).

The results of the static analysis for the four buildings under consideration, are illustrated in Figure 4. This Figure plots the base shear 'V' against roof drift (Δ). The base shear 'V' was normalized using the total weight of each frame 'W'. Each frame configuration was subjected to a series of four horizontal cycles.

Figure 4 demonstrates that the bracing elements significantly increase the lateral load carrying capacity of both rocking frame configurations with BECB. The lateral resistance of the rocking frame without BECB (RF) was 55% lower than the moment-resisting frame (MRF). Rocking frame with BECB (RF w/BECB) exhibited a 30% increase in the lateral load resistance whereas configuration 2 showed a 63% increase compared to the RF. In comparison with the MRF, the lateral capacity of the RF w/BECB was 20% lower, whereas the RF w/BECB C2 was 15% higher. Additionally, Figure 4 demonstrates that all the RFs experienced zero residual drifts and damage accumulation, in contrast to the MRF.

5 FREQUENCY RESPONSE FUNCTIONS

A series of dynamic analyses were performed for low, medium, and high forcing amplitudes. The frequencies were normalized against the natural frequencies of the corresponding finite element models. The FRFs for all buildings are presented in terms of maximum storey accelerations in Figure 5. Moreover, the FRFs were utilized to identify the fundamental frequencies of the rocking building models using the maximum inflection points of the low-amplitude curves.

It can be observed from Figure 5 that the natural frequency of the MRF is 1 Hz, whereas the RF is 0.7 Hz. In comparison, the fundamental frequency of the RF w/ BECB and RF w/ BECB C2 are approximately 1.5 Hz and 2 Hz, respectively. Therefore, it is apparent that both configurations of the buckling-enabled braced frames are stiffer than their pure rocking frame counterpart. Contrary to the rocking structures, the fundamental frequency of the MRF is constant across all forcing amplitudes until yielding. It is also apparent that the RF has greater flexibility than its MRF counterpart, which is expected because of the increased storey displacements due to the gap-opening mechanisms and the absence of any lateral control device/mechanism.

Moreover, it can be observed that the maximum storey accelerations for the RF for high amplitude excitations is 55% greater than the MRF. The RF w/ BECB exhibited accelerations that were 25% higher than the MRF whereas the accelerations of RF w/ BECB C2 were very close (about 2-5% higher) to the MRF. Similarly, the RF w/ BECB showed a substantial reduction of upto 50% and the RF w/ BECB C2 of 35%, compared to the RF under medium to high amplitude excitations. Likewise, the maximum inter-storey drifts for RF were 40% higher than MRF. The RF w/ BECB 15% greater and RF w/ BECB C2 were 10% lower than MRF.

From the foregoing it is evident that steel rocking frames equipped with BECB result in significantly lower peak response quantities compared with systems without BECB and close to those exhibited by a conventional steel moment-resisting frame. Besides, BECB was also observed to enhance the overall stability of the rocking structure and numerical convergence during the analyses was achieved significantly quicker.

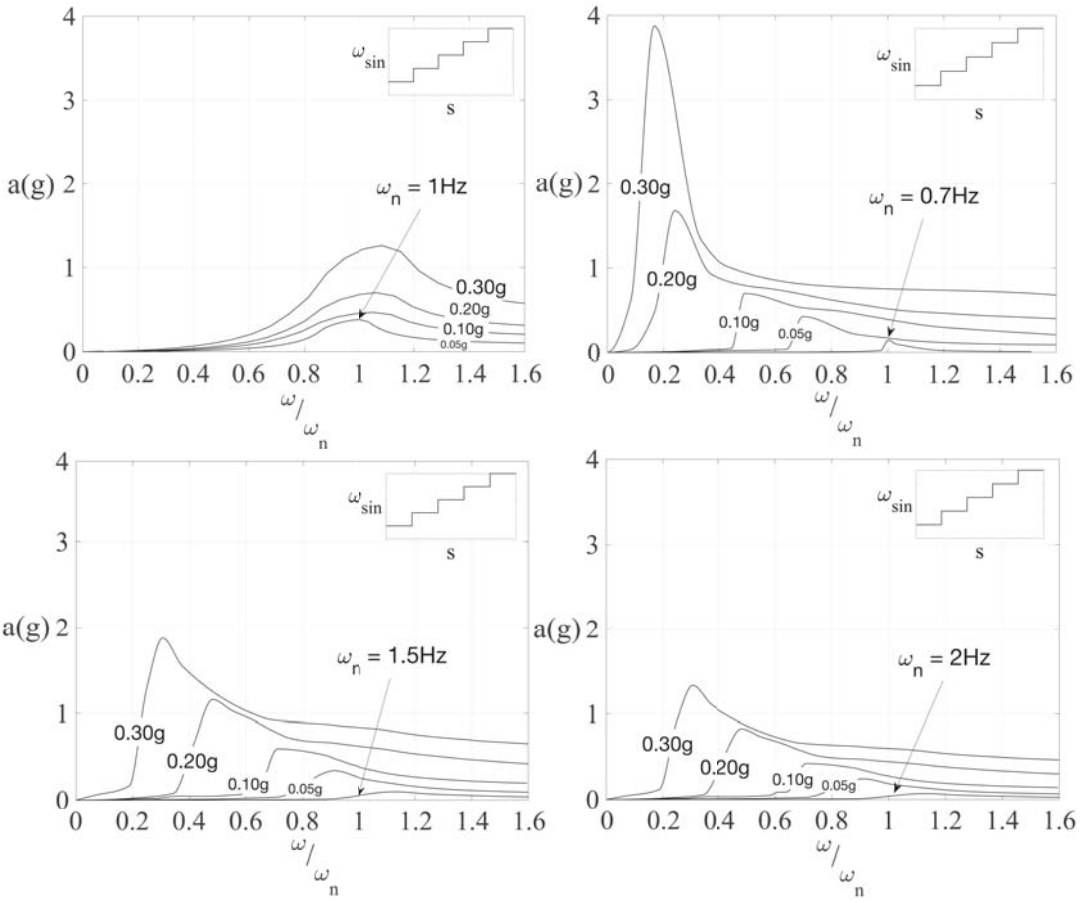

Figure 5: Frequency Response Functions (FRFs) for MRF (Top left), RF (Top right) RF w/ BECB (Bottom left), and RF w/BECB C2 (Bottom right).

6 INCREMENTAL DYNAMIC ANALYSIS

Previous sections have examined the static and dynamic behaviour of rocking steel frames equipped with BECB to conventional moment-resisting steel frames by subjecting them to idealized ground-motions. This section examines the effectiveness of the BECB by subjecting the buildings to a set of real earthquake records. To this end, the 22 far-field earthquake suite detailed in FEMA P695 and obtained from the Pacific Earthquake Engineering Research Center (PEER) database, were employed. The peak inter-storey drift ratio, was adopted as the damage measure (DM), while the spectral acceleration at the fundamental period of each re-

spective building, $Sa(T_1)$, was selected as the intensity measure (IM). The median (50^{th} percentile) IDA curves comparing the four buildings are presented in Figure 6.

It can be observed that the IDA curves of RF w/ BECB and RF w/ BECB C2 exhibited a higher elastic slope than the MRF, indicating a stiffer structure and hence lower relative displacements than MRF and RF. Likewise, the RF w/ BECB C2 remained in the elastic range for drifts of upto 4% whereas the elastic-plastic transition for the MRF was at the 2% ratio, with RF and RF w/BECB around 3%. Moreover, the MRF experienced softening after 2% drift and global collapse at approximately 10% drift. For the RF w/ BECB C2, softening was observed after yielding of the post-tensioning (at 4% drift) and this was followed by BECB fracture at 5% drift. Similarly, the RF w/ BECB building experienced first brace fracture at around 4% drift. The global collapse for RF w/ BECB C2 occurred at 7% drift. In contrast, the global collapse for the RF w/ BECB was at 5% and RF at 3%. It can also be observed that in the buildings with BECB, hardening occurred after BECB member buckling at 0.5% drift. The IDA curves of some records for the rocking frames displayed successive segments of softening and hardening behaviour (weaving) before final instability. This was more prominent for the RFs compared to other buildings.

In a practical setting, each building will be designed differently to satisfy similar demands and identical sections were used herein to allow a direct comparison of the structural responses. Furthermore, the proposed BECB system relies on controlled elastic buckling of GFRP members that do not accumulate plastic strains. Therefore, it is crucial that a compression-only response is ensured. A possible connection has been proposed in [23] between the BECB and the steel members. This was designed to allow a transfer of compressive forces during the lateral frame movement, causing the brace to buckle, while preventing tension stresses to be developed in the BECB. It is also important to mention that the proposed system is expected to remain elastic for typical recurrent lateral loads such as winds. Subsequently, the BECB members can be tuned to allow activation of the buckling response leading to a change in the dynamic behaviour only during periods of high demand.

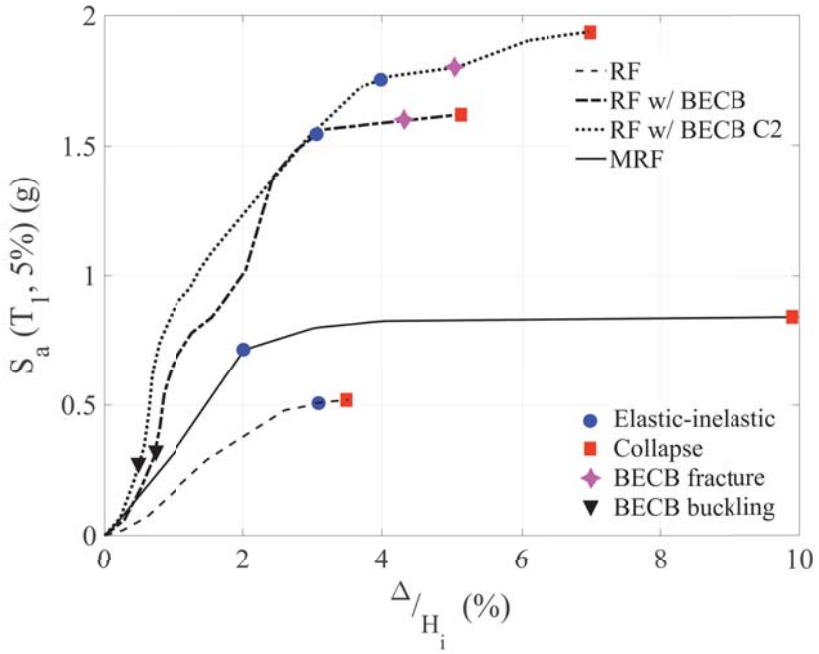

Figure 6 Summarized (50% fractile) IDA curves comparing the MRF, RF, RF w/BECB, and RF w/BECB C1 for 22 far-field earthquake records from FEMA P695 report.

7 CONCLUSIONS

Currently available lateral-load resisting systems for rocking frames comprise of replaceable yielding components that are damaged after strong motion leading to non-negligible maintenance costs and downtime. By applying the recoverable elastic buckling properties of the newly proposed bracing elements with circular-arc shaped cross-section this paper has demonstrated that a damage-avoidance rocking system can be achieved. The main research findings of this study are summarized below.

- In comparison with the moment-resisting frame, the lateral capacity of the rocking frame with BECB in two bays was 15% higher.
- Both configurations of the buckling-enabled braced frames were 1.5-2 times stiffer than their pure rocking frame and the moment-resisting frame buildings.
- The rocking frame with BECB in two bays exhibited maximum storey accelerations that were within 10% of the values experienced by the moment-resisting frame.
- The IDA curves of rocking frames with BECB displayed a greater elastic slope than the moment-resisting frame and pure rocking frame, indicating stiffer structures and hence lower relative displacements in the elastic range (for constant S_a).
- In the buildings with BECB, some hardening was observed after the initial BECB member buckling at an average of 0.5-1% drift ratios for the records considered.
- Both buildings with BECB remained elastic up to 3-4% drifts which are greater than the moment-resisting frame at 2% drift.
- The rocking frame with BECB employed in a single-bay experienced brace failure at 4% drift whereas the model with BECB in two bays exhibited the first brace fracture at 5% drift ratio.
- The pure rocking frame exhibited numerical non-convergence (collapse) at a drift ratio close to 4%. In contrast, the buildings with BECB collapsed at 5% and 7%, for each configuration respectively.
- The area between yielding and global instability was greater with the addition of BECB, compared to the pure rocking frame.

Keywords: Seismic design, FUSEIS system, dual system, dissipative replaceable beam links, coupling beams

Abstract. *The Dissipative Replaceable Link Frame (DRLF) is an innovative lateral load resisting system, recently developed, investigated, and further optimized in the European research projects FUSEIS, MATCH, INNOSEIS and DISSIPABLE. The system consists of two strong columns, which are rigidly interconnected by several horizontal beams, forming a vertical VIERENDEEL beam. The interconnecting beams are attached by a bolted head plate connection, making them easily detachable. As they are separated from the slab, they do not take part in the gravity load bearing function. The dissipative beam links being the only intended spots of inelastic action and therefore energy dissipation, plus being easily exchangeable because of their bolted connection and missing participation in the gravity load bearing paths, act as exchangeable seismic fuses during a strong earthquake. After such an event, exchanging the beam links is foreseen to bring the structure back to its undamaged pre-earthquake stage quickly. However, Eurocode 8 demands on damage limitation affecting non-structural components – like e.g. partition walls – might represent a tough requirement on global lateral stiffness of the Link Frame systems. For high buildings, displacement verifications often govern the design, similar as known for conventional Moment Resisting Frames (MRF). In order to overcome this restriction, in this paper, a solution to increase lateral stiffness of Dissipative Replaceable Link Frames is investigated: Keeping the connections of the regular gravity frame hinged, strong elastic steel coupling beams are introduced, connecting two adjacent Link Frames. These coupling beams are not intended to dissipate energy, but instead should remain elastic, in order to keep the whole building easily repairable, by restricting seismic damage to the Dissipative Replaceable Links. Moreover, such additional source of lateral stiffness is able to improve re-centering capability to diminish accumulation of residual displacements during an earthquake and further to re-center the building when the seismic fuses are replaced. In this paper, preliminary conclusions on the concept and performance of this innovative system under development in the ongoing project DISSIPABLE are presented.*

1 INTRODUCTION

The Dissipative Replaceable Link Frame (DRLF) is an innovative lateral load resisting system, which was initially developed and investigated in the European research project "FUSEIS - dissipative devices for seismic-resistant steel frames" [1]. The objective of the FUSEIS project was to overcome the drawback of non-repairability of traditional systems such as Moment Resisting Frames (MRF), Concentrically Braced Frames (CBF) or Eccentrically Braced Frames (EBF). While such conventional systems perform well during strong seismic events due to dissipation of a large amount of energy, however, they are not economically repairable after the design basis earthquake has struck the structure. Thus, usually the only available option is the demolishing of the damaged building and replacing it by a new one. To overcome this issue, within the FUSEIS project several innovative systems have been developed, where the dissipative elements called fuses are the only source of energy dissipation and above all are easily replaceable after an earthquake.

One of the investigated systems was the formerly called FUSEIS-1 system (see [1], [2], [3]), which in this paper is called Dissipative Replaceable Link Frame (DRLF). It was further developed and investigated within the MATCH [4] and INNOSEIS [5] projects, and is further enhanced within the ongoing DISSIPABLE [6] project.

The DRLF system consists of two strong columns, which are rigidly interconnected by several beams, forming a vertical VIERENDEEL beam. In order to be easily detachable, these interconnecting beams – the Dissipative Replaceable Links (DRL) – are attached by a bolted head plate connection. As they are not coupled with the slab, consequently, they are not a part of the gravity load bearing frame. Optimally, inelastic action is foreseen to take place solely in the Dissipative Replaceable Links (DRL). When achieving this, they can act as exchangeable seismic fuses during a strong earthquake. Being the only source of energy dissipation by design, along with the missing participation in the gravity load bearing paths and moreover their detachable connection design, exchanging the Dissipative Replaceable Links is foreseen to bring the structure back to its undamaged pre-earthquake stage quickly, without the need of rebuilding the whole structure.

Eurocode 8 [7] demands on damage limitation affecting non-structural components – like e.g. partition walls – represent a tough requirement on global lateral stiffness of such Dissipative Replaceable Link Frame systems. For high buildings, displacement verifications often govern the design. In this case, usually partial-strength moment connections may be introduced to the gravity load bearing frames, in order to increase global stiffness. However, this may result in damage of the gravity frame connections, which are usually not feasibly repairable, finally pre-venting full exploitation of the potentially excellent energy dissipation capacity of such a system.

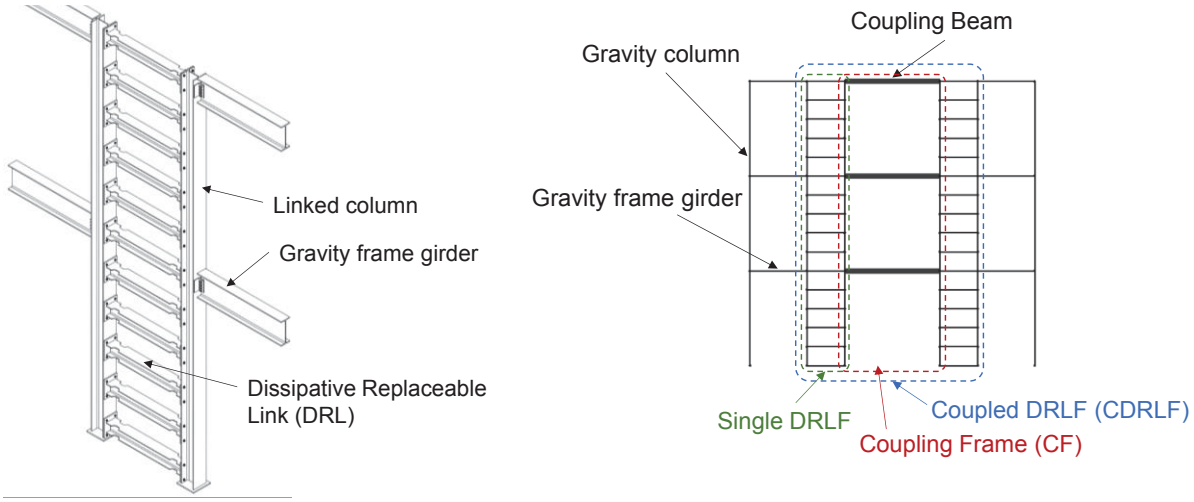
In this paper, an alternative solution of increasing lateral stiffness of Dissipative Replaceable Link Frame systems is investigated: Keeping the connections of the gravity frame hinged, strong elastic steel coupling beams are introduced, connecting two Dissipative Replaceable Link Frames. These coupling beams are not intended to dissipate energy, but instead should remain elastic, in order to keep the whole building easily repairable, by restricting seismic damage to the Dissipative Replaceable Link fuses only.

In the following, after a general introduction to the innovative concept of the Coupled Dissipative Replaceable Link Frame (CDRLF) system, two case studies of an 8-storey office building are presented. The first one, acting as 'reference system', is the already known Dissipative Replaceable Link Frame. Because the building is quite high, in total three bays with such frames were required, to comply with seismic requirements on stiffness. The second system, labelled as 'optimized system', introduced the concept of coupling beams. Consequently, only two bays

of DRLFs were needed. In a first step, the performance of both systems was assessed and compared via pushover analyses. Target displacements were derived based on the N2 method. Further on, for verification of the conclusions derived by the non-linear static analyses, dynamic time history analyses with seven recorded accelerograms have been conducted. The gain in performance achieved by the introduction of the coupling beams is discussed in terms of push-over curves, plastic mechanisms, inter-story drifts, residual displacements and repairability. It is demonstrated, how the optimized system is well able to comply with the foreseen performance targets.

2 DISSIPATIVE REPLACABLE LINK FRAMES

A schematic sketch of the Dissipative Replaceable Link Frame (DRLF) is shown in Figure 1, left panel. For high buildings, this type of system may have the issue of inherent flexibility, which is also a well-known issue for classical Moment Resisting Frames (MRF). Moreover, residual displacements may hinder the repairability performance target. In order to increase stiffness and re-centering capability, two of such frames might be connected by Coupling Beams, as shown in Figure 1, right panel. This combination results in the Coupled Dissipative Replaceable Link Frame (CDRLF). The lateral strength and stiffness of such a coupled frame is basically due to the frame action of the two single DRLFs as well as the Coupling Frame, which consists of the coupling beams and the strong columns, where the coupling beams are attached to. Thus, the internal strong columns contribute to both frames. The in total three frame actions act in series resulting in the global frame behavior (see Figure 2).



Dissipative Replaceable Link Frame (DRLF) Coupled Dissipative Replaceable Link Frame (CDRLF)

Figure 1: Single Dissipative Replaceable Link Frame (DRLF) (left) and two DRLFs coupled by elastic HSS Coupling Beams (CB) forming the Coupled Dissipative Link Frame (CDRLF) (right).

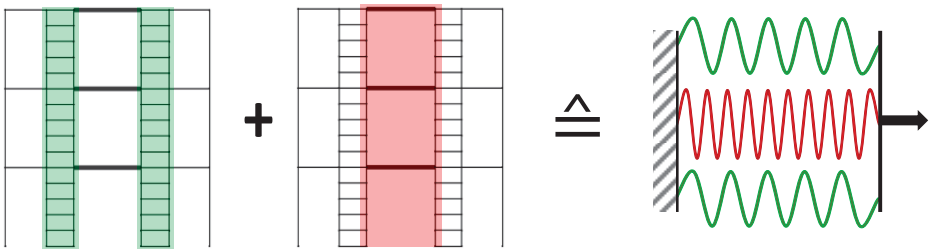


Figure 2: Two single Dissipative Replaceable Link Frames (DRLFs) and the Coupling Frame (CF) acting in series as resulting total lateral load resisting system.

The concept of coupling beams is a well-known one for linking two reinforced concrete shear walls. However, in this context, usually it are the coupling beams, which are foreseen to dissipate energy. See e.g. [8] for an innovative system of concrete shear walls connected via replaceable steel coupling beams. Contrary, in the scope of the research presented herein, the coupling beams need to remain elastic for the design basis earthquake (usually 10% in 50 years / 475 years return period). Therefore, the investigated innovative system could be best compared to dual frame systems, e.g. a combination of an EBF with a MRF, where the MRF is deemed to add stiffness and residual strength to the system, see e.g. [9].

Design equations for the DRLF have been developed in the FUSEIS [1] project and disseminated throughout the INNOSEIS [5] project. However, the coupling frame connecting two DRLF is a recently developed enhancement during the ongoing DISSIPABLE [6] project. Therefore, design equations and guidelines for the coupling frame are missing yet. For the time being, design verification by non-linear static (pushover) and/or response history analysis (RHA) is needed. Development of design guidelines is foreseen during the DISSIPABLE [6] project.

The coupling beams are suspected to high seismic strength demands. Moreover, once the beam links are plastified, the contribution of the Coupling Frame on the overall stiffness increases, further enlarging demands on coupling beams. Consequently, usually relatively high strength steels will be needed to be applied for these elements.

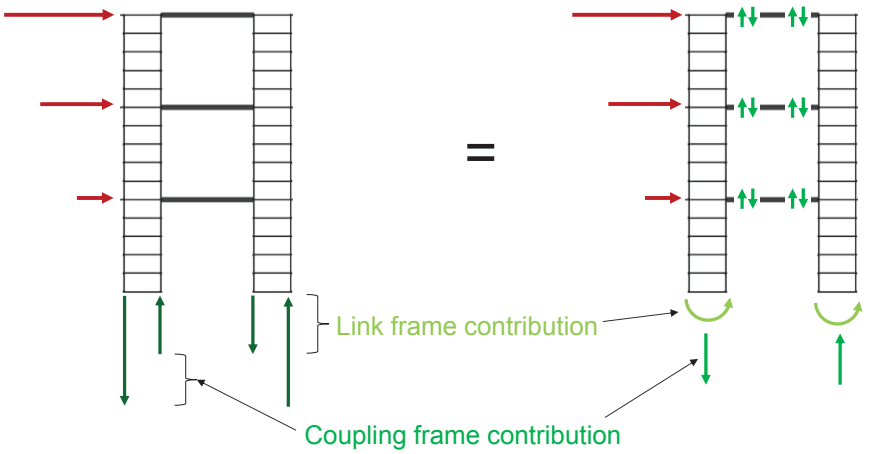

Figure 3: Load transfer and resistance contribution of the single DRLF and the CF.

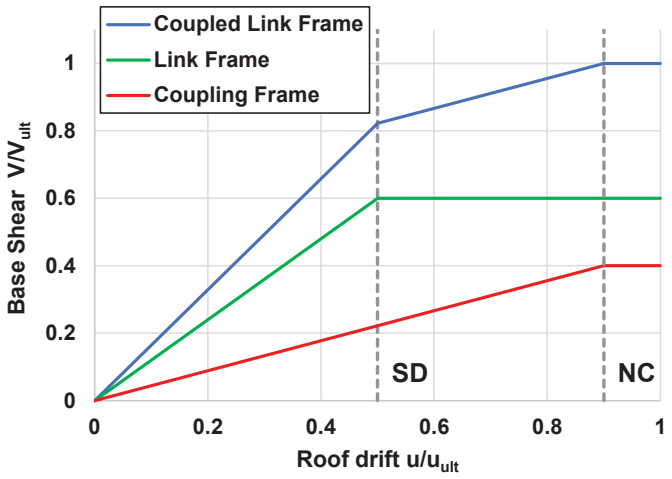

Figure 4: General behavior of the CDRLF and contribution of its single components.

The general design philosophy behind the CDRLF is summarized in Table 1. For frequent earthquakes, no damage shall occur to the overall lateral load resisting system. For the design basis earthquake, only the Dissipative Replaceable Links shall be damaged, while coupling beams are foreseen to remain elastic. Thus, the whole building results to be repairable, preventing its demolition. Only for very rare earthquakes, also the coupling beams are allowed to suffer damage, in order to prevent collapse of the building while sacrificing its reparability.

Possible design scenarios	10% in 10 yrs 95 yrs	10% in 50 yrs 475 yrs	2% in 50 yrs 2475 yrs
Performance target	No damage	Reparability	No collapse
Damage to dissipative links	No	Yes	Yes
Damage to coupling beams	No	No	Allowed
Reparability	---	Yes	No, if coupling beams damaged

Table 1: Design philosophy for the Coupled Dissipative Replaceable Link Frame (CDRLF).

3 CASE STUDY

To illustrate the concept of the CDRLF, in the following a typical 8-story office frame building has been designed in two different ways. In the first one, no coupling beams have been introduced, which rendered the system to be a DRLF. In the latter approach, the coupling frame effect was introduced, resulting in a CDRLF system.

The main dimensions of the initial situation used as starting point are shown in Figure 5. Firstly, the two designs have been conducted to satisfy seismic design requirements according to Eurocode 8 [7] regarding strength as well as stiffness. Table 2 shows an overview of the loads considered in design. Furthermore, the characteristics of the considered seismic action are summarized in Table 3.

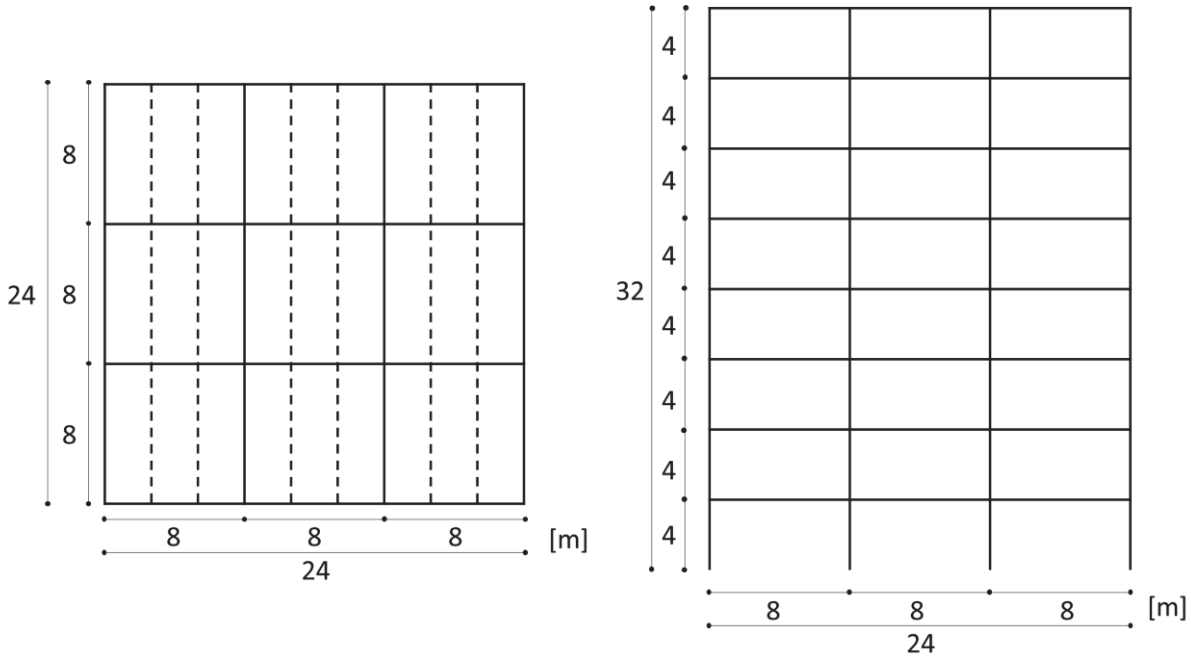

Figure 5: General floor plan and elevation of 8-story case study.

Design loads	Description	Load value
Dead loads	Composite slab and steel sheeting	2.75 kN/m²
Superimposed loads	Services, ceiling and raised floor	
	- intermediate floors	0.70 kN/ m²
	- top floor	1.00 kN/m²
	Perimeter walls	4.00 kN/m²
Live loads	Offices (Class B)	3.00 kN/m²
	Movable partitions	0.80 kN/m²

Table 2: Loading conditions used for design.

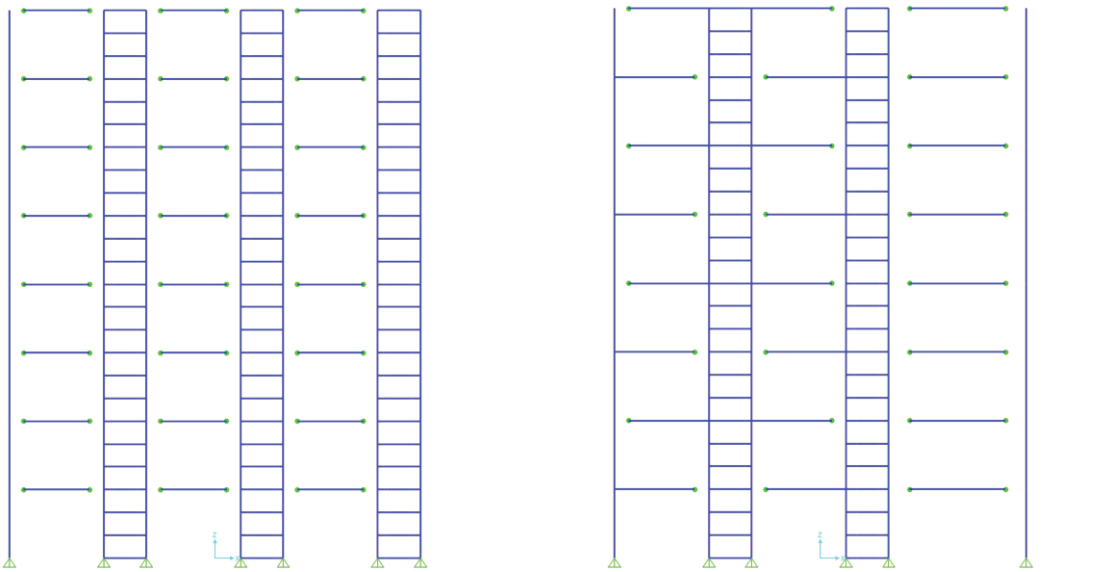
Seismic design action	Description
Peak ground acceleration	$\alpha_{gR} = 0.3g$
Importance factor (Class II)	$\gamma_I = 1.0$
Ground type	B ($S = 1.2$, $T_B = 0.15$ s, $T_C = 0.5$ s, $T_D = 2.0$ s)
Type of response spectrum	Type 1
Lower bound factor β	0.2
Behavior factor q	2.0 for the reference structural system 2.8 for the optimized structural system

Table 3: Seismic design action according to Eurocode 8.

Finally, the designs resulted in the following case study frames shown in Figure 6:

- Reference structural system: 2D frame with three Dissipative Replaceable Link Frames and pinned coupling beams (see Figure 6a), thus no coupling frame action;
- Optimized structural system: 2D frame with two Dissipative Replaceable Link Frames and two bays with coupling beams, for which alternating pinned/fixed connections were used (see Figure 6b); thus, the whole system is a Coupled Dissipative Replaceable Link Frame.

For a better understanding of the structural response, especially the influence and contribution of dissipative links and coupling beams, these two structural configurations were studied in detail by means of pushover and response history analyses.



(a) Reference system – 3 × DRLFs (all coupling beam ends are pinned)

(b) Optimized system – 2 × DRLFs + 2 × CFs (coupling beam ends alternating pinned and fixed)

Figure 6: Case study frames: (a) reference system; (b) optimized system.

The general properties for the case study frames are summarized in Table 4. The design and analyses were performed with RSTAB 8 [10] and SAP2000 [11]. Based on the presence of the reinforced concrete slabs, a rigid diaphragm constraint was considered for the nodes of each floor. The masses were calculated automatically from the applied gravitational loading on the structure. The importance of the second order effect was evaluated through the value of the inter-story drift sensitivity coefficient θ [12]. The coefficient θ was computed for each level, and the maximum value was found between $0.1 < \theta \leq 0.2$. Consequently, second order effects were considered in an approximate way by multiplying the design values of the demands with the following factor: $\alpha = 1/(1-\theta)$.

The cross-sections used for the lateral force resisting system of the reference and optimized structural systems are presented in Table 5. The design of the lateral force resisting system was governed by the deformation limitation (corresponding to the serviceability limit state – SLS, and/or to the ultimate limit state – ULS). In case of the optimized system, the coupling beams were modeled with alternating pinned/fixed connections with the aim to increase their flexibility and to avoid the formation of plastic hinges at serviceability limit state (SLS), ultimate limit state (ULS) and as much as possible at near collapse (NC) seismic intensity level. Beside the pinned/fixed connection solution, the coupling beams corresponding to floors 1÷4 were realized with S460 steel grade (Table 5). Reduced beam sections (RBS) were considered for the dissipative links for both structural systems. The P-Delta effect of the seismic masses that was not attributed to the frame was considered by employing a leaning column. The maximum usable behavior factor q was 2.0 for the reference system and 2.8 for the optimized system. Larger behavior factors were not exploitable (i.e. not needed), because stiffness requirements did not allow for a further decrease of cross sections.

Structural system	Reference	Optimized
Stories	8 @ 4 m	8 @ 4 m
Bays	3 @ (5.5 + 2.5 m)	2 @ (5.5 + 2.5 m) & 1 @ 8 m
Column base connection	pinned	pinned
Coupling beam connections	pinned at both ends	fixed at one end, pinned at the other end

Table 4: General properties of the case studies.

	Reference system (T_1=2.75 sec.)		Optimized system (T_1=2.56 sec.)

Table 5: Cross-sections of elements for the reference and optimized system.

4 SEISMIC PERFORMANCE EVALUATION

The seismic performance was evaluated through: (i) nonlinear static analyses (pushover) using the N2 method [13]; and (ii) nonlinear dynamic analyses (time-history). Both types of analyses were performed using SAP2000 [11] and considering the 2D structural configurations illustrated in Figure 6. The N2 method [13] was used for determining the target displacements and the state of the two structural systems corresponding to the three seismic intensity levels. The response under a set of seven recorded accelerograms was evaluated through time-history analyses.

4.1 Nonlinear static analyses

The N2 method, developed by Fajfar [13] and comprised in Annex B of EN 1998-1 [7], can be used to verify the seismic performance of buildings designed by current methods (i.e. response spectrum analyses). The method combines the nonlinear static analysis of a multiple degrees of freedom system (MDOF) with an analysis based on the response spectrum of a single degree of freedom system (SDOF). The lateral story forces were assumed to be proportional to the 1st mode of vibration. Furthermore, the structural performance was evaluated for the limit states shown in Table 6, where "a_{gr}" is the reference peak ground acceleration of *0.3g*, and "a_g" represents the peak ground acceleration for a specific earthquake level.

Limit state	Return period, [years]	Probability of exceedance	a_g/a_{gr}	a_g/g
Damage Limitation (DL / SLS)	95	10% / 10 years	0.5	0.15
Significant Damage (SD / ULS)	475	10% / 50 years	1.0	0.30
Near Collapse (NC)	2475	2% / 50 years	1.7	0.51

Table 6: Limit states and corresponding scaling factors for the seismic input.

For beams subjected to flexure, based on FEMA 356 [14] and Annex B of EN 1998-3 [15], the following acceptance criteria were considered corresponding to the rotation at DL, SD and NC: $1{\cdot}\theta_y$, $6{\cdot}\theta_y$ and $8{\cdot}\theta_y$, where θ_y is the yield rotation. The damage state conditions of the plastic hinges associated to three limit states are similar in both codes, and it can be assumed that Immediate Occupancy (IO) corresponds to Damage Limitation (DL), Life Safety (LS) stands for Significant Damage (SD), and Collapse Prevention (CP) relates to Near Collapse (NC).

The plastic hinge definitions for the Dissipative Replaceable Links (see Table 7) were based on the parameters reported in [2].

Point	$M/M_{pl,RBS}$	$\theta/\theta_{pl,,RBS}$	Acceptance criteria	
A	0	0	Limit state	($\theta/\theta_{pl,RBS}$)
B	1	0	IO	15
C	1.27	40	LS	20
D	0.6	40	CP	35
E	0.6	45		

Table 7: Non-linear hinge parameters considered for the Dissipative Replaceable Links.

From the nonlinear static analyses, a pushover curve (capacity curve) was obtained for each structure. Further, using the N2 method [13], the target displacements (D_t) were obtained for the two structural systems corresponding to each of the three seismic intensity levels (i.e. SLS, ULS, NC). The obtained target displacement values are summarized in Table 8. As can be observed, very similar values were obtained for the two structures.

	Limit state	a_g/a_{gr}	Reference structure	Optimized structure
D_t [m]	DL / SLS	0.5	0.157	0.157
	SD / ULS	1.0	0.314	0.315
	NC	1.7	0.533	0.535

Table 8: Target displacements of reference and optimized structures.

The outcomes of the nonlinear static analyses are shown in terms of: (i) capacity curve (base shear force vs. top displacement); (ii) the state of the lateral load resisting frames corresponding to the three seismic intensity levels (SLS, ULS, NC), i.e. at the computed target displacements. It is to be noted that the target displacements are marked on each capacity curve. The outcomes are presented for the following configurations: (i) Reference structure (see Figure 7); (ii) Optimized structure (see Figure 8).

Based on the state of each structural configuration (plotted for the three seismic intensity levels – SLS, ULS and NC), the following observations can be made:

- at SLS – both structural configurations were characterized by an elastic response;
- at ULS – the reference structure was characterized by an elastic response, while plastic hinges developed in the dissipative links at the first five stories of the optimized structure;
- at NC – both structural systems evidenced plastic hinge development in the dissipative links, but the rotations did not reach the life safety or collapse prevention levels; in case of the optimized structure, the coupling beams did not develop plastic hinges.

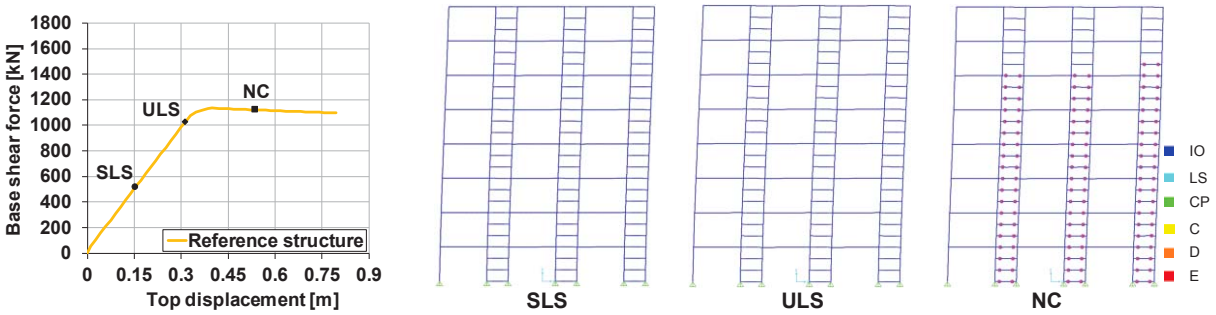

Figure 7: Reference structure: capacity curve and the state of the frame at the three seismic intensity levels – SLS, ULS, NC (i.e. a_g/a_{gr}=*0.5; 1.0; 1.7*).

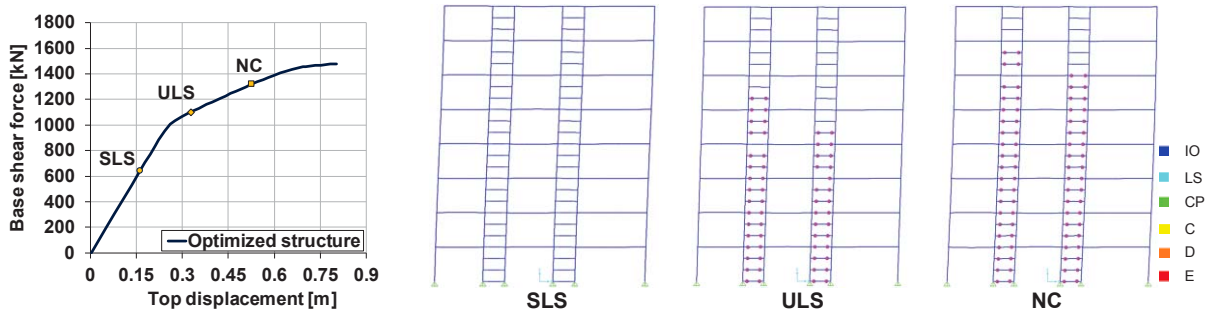

Figure 8: Optimized structure: capacity curve and the state of the frame at the three seismic intensity levels – SLS, ULS, NC (i.e. a_g/a_{gr}=*0.5; 1.0; 1.7*).

A comparison between the pushover curves of the two structural systems, i.e. reference and optimized, is shown in Figure 9a. As can be observed, the initial stiffness and the post-yield response of the two structural systems evidence some differences:

- The reference structure (for which the coupling beams were pinned at both ends) showed a relative lower initial stiffness. In the post yield region, the pushover curve was characterized by a horizontal tendency (i.e. large deformations with little decrease of force).
- In case of the optimized structure (for which the coupling beams were modeled with alternating pinned/fixed connections), the pushover curve evidenced a linear ascending tendency in the post yield region (i.e. capacity increases with the deformation).

The improved response of the optimized structures, i.e. bilinear shape with a linear ascending tendency in the post yield region, can be explained by examining the shape of the pushover curves of the two subsystems (i.e. coupling beam frames, dissipative link frames). Subsequently, the contribution of each of the two subsystems is illustrated in Figure 9b. Compared to the link-frame subsystems, the coupling beam frames are characterized by a linear-elastic response, with a lower stiffness and capacity. The linear-elastic response of coupling beam frames is therefore responsible for the linear ascending tendency in the post yield region of the optimized structural system and confirms the potential for improved performance and increased re-centering capacity.

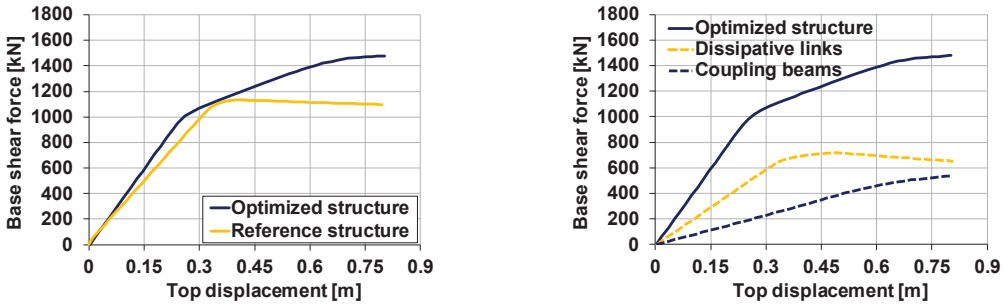

Figure 9: (a) Comparison between the pushover curves of the reference and optimized structural systems; (b) response/contribution of the dissipative link frames and coupling beam frames.

4.2 Nonlinear dynamic analyses

The two systems were further analyzed by means of dynamic time history analyses. A set of seven accelerograms matching the target spectrum has been chosen from the PEER NGA online ground motion database [16]. The scaling factors have been set such, that requirements according to the current draft of the revision of Eurocode 8 are met. These are as follows:

- Scaling factors not larger than *2.0*, nor smaller than *0.5*.
- The period range of interest has been set to $0.2 \cdot T_{1,min}$ to $1.5 \cdot T_{1,max}$, whereby $T_{1,min}$ and $T_{1,max}$ are the minimum and maximum fundamental periods of the considered frames.
- Within this period range, the ratio of mean to target spectrum should be within the range of *0.75* to *1.30*. Moreover, the average of this ratio over the considered period range should be larger than *0.95*. Also, for each individual spectrum the ratio should nowhere be below *0.5* within that range.
- Not more than two records of the same earthquake should be used.

The final suite of seven accelerograms is listed within Table 9. Each record can be correlated to the PEER data base with the Record Sequence Number (RSN). Figure 10 shows the target, mean and individual spectra along with a vertical line, indicating where the period range of interest begins. The first mode periods T_1 for the reference and optimized structure correspond to 2.75 s and 2.56 s, respectively. The 50%, 75% and 130% scaled target spectrum used for ground motion selection is also indicated in the figure.

#	RSN	Scale factor	R [km]	M	Earthquake name	Year	Station
1	6	1.11	6.1	6.95	Imperial Valley-02	1940	El Centro Array #9
2	15	1.95	38.7	7.36	Kern County	1952	Taft Lincoln School
3	20	1.32	26.9	6.5	Northern Calif-03	1954	Ferndale City Hall
4	30	1.65	9.6	6.19	Parkfield	1966	Cholame-Shandon #5
5	68	1.70	22.8	6.61	San Fernando	1971	Hollywood Stor FF
6	95	1.38	3.8	6.24	Managua Nicaragua-01	1972	Managua ESSO
7	96	1.85	4.7	5.2	Managua Nicaragua-02	1972	Managua ESSO

Table 9: Recorded acceleration time histories used for dynamic analyses.

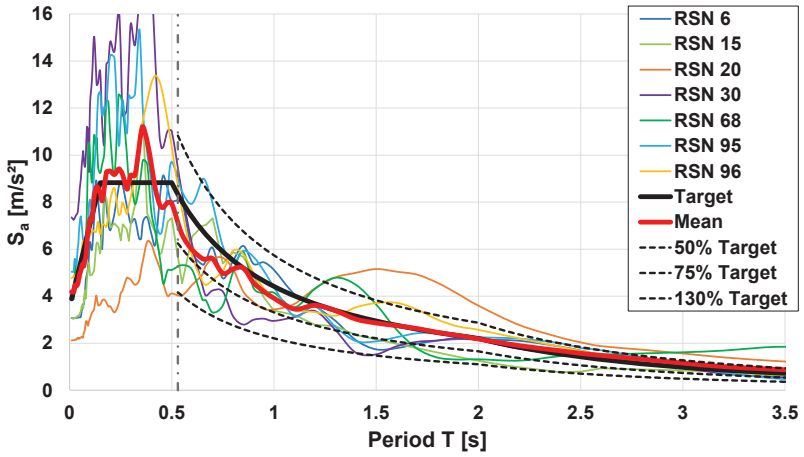

Figure 10: Elastic response spectra of mean and individual accelerograms compared to the target spectrum.

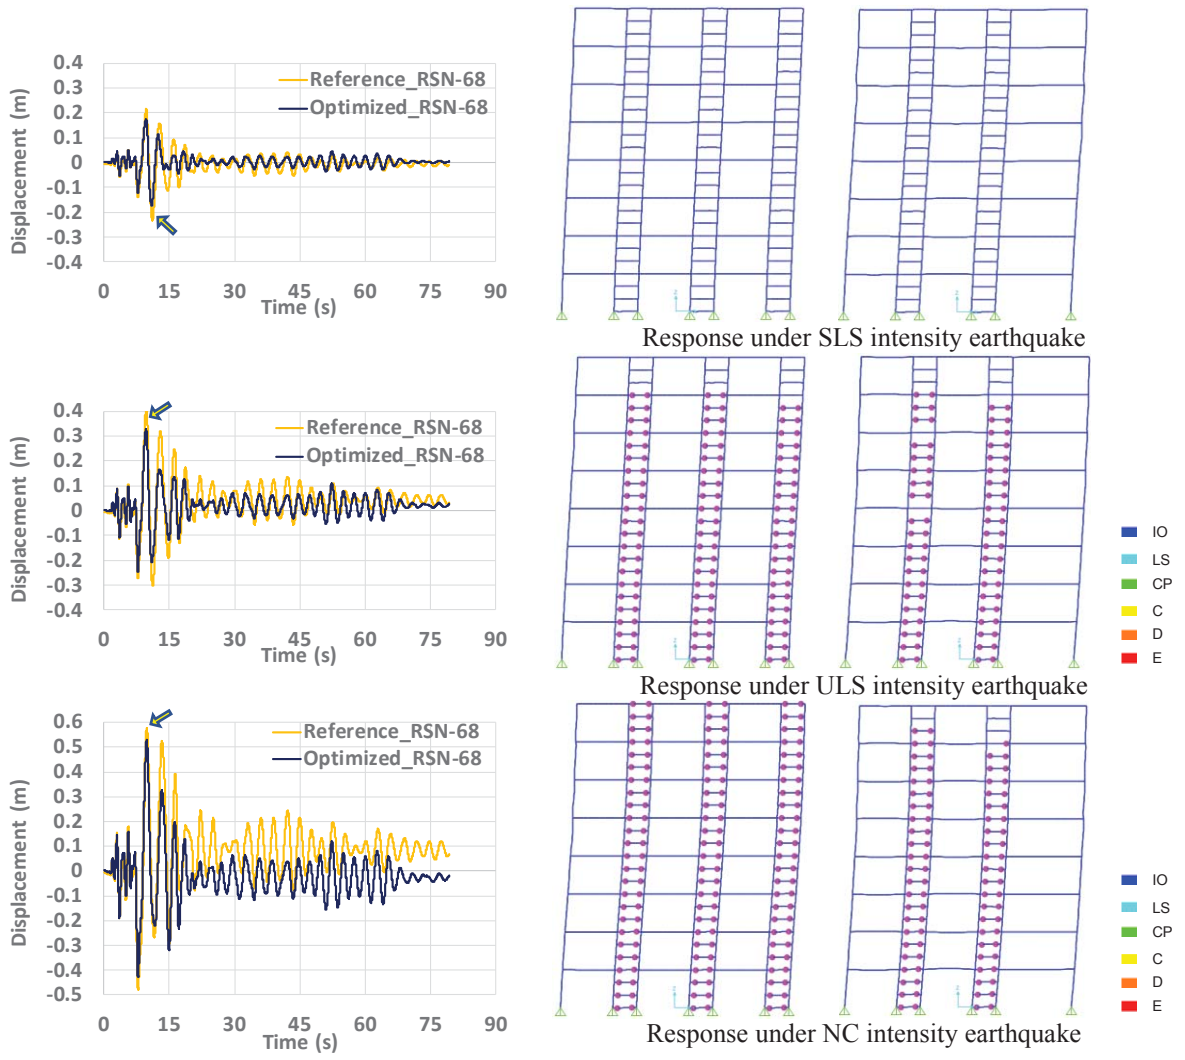
The outcomes of the time-history analyses are presented for both reference and optimized structural configuration in terms of: (i) comparison of the displacement at top floor; (ii) state of frame corresponding to the maximum displacement (i.e. scaled deformed shape with marked plastic hinges). Consecutively, the response under one of the seven accelerograms (i.e. *#5 – RSN 68*) at the three intensity levels (SLS, ULS and NC) is shown in Figure 11.

As can be observed, the time-history analyses evidenced the following:

- *at SLS (serviceability limit state – a_g/a_{gr}=0.5)*: ▪ plastic hinges did not develop in any of the two structural systems (reference or optimized); ▪ the comparison between displacements at top floor showed similar deformations – with slightly lower values corresponding to the optimized structure;
- *at ULS (ultimate limit state – a_g/a_{gr}=1.0)*: ▪ plastic hinges developed in the dissipative links (at seven out of eight stories) for both structural configurations; ▪ the comparison between displacements at top floor showed some differences, i.e. lower deformations corresponding to the optimized structure; ▪ the rotations within plastic hinges did not reach the life safety or collapse prevention levels;
- *at NC (near collapse – a_g/a_{gr}=1.7)*: ▪ a global plastic mechanism was evidenced with plastic hinges in the dissipative links for both structural systems; ▪ the comparison between displacements at top floor showed significant differences between the reference and optimized structure for five out of seven accelerograms which lead to residual deformations (i.e. *#1,3,5,6,7*); ▪ for both structural systems, the replaceable dissipative links did not evidence rotations corresponding to life safety or collapse prevention levels; ▪ the optimized structure evidenced plastic hinges in the coupling beams only for one out of seven accelerograms (i.e. *#3 – RSN 20*).



(a) Comparison of the response (b) Reference structure (c) Optimized structure

Figure 11: Outcomes of time-history analyses: (a) comparison of the response (top displacement vs. time); (b) & (c) state of reference and optimized structures.

The nonlinear dynamic analyses also allowed to evaluate the inter-story drifts corresponding to each: (i) structural configuration (reference / optimized); (ii) accelerogram (*#1 to #7*); (iii) seismic intensity level (SLS, ULS, NC).

Exemplarily, Figure 12 illustrates the inter-story drifts generated by one of the accelerograms (*#5 – RSN68*) within the two systems. In general, largest inter-story drifts occur at the mid-floors for the reference system, whereby the optimized system is characterized by larger drifts at the bottom and small ones at the top. Besides the lower floors, inter-story drifts tend to be less large for the optimized system compared to the reference structure.

The average of the maximum (+/-) inter-story drift values for the reference and optimized structures, corresponding to each seismic intensity level (SLS, ULS, NC), was computed from the outcomes of the set of seven selected accelerograms listed in Table 9. The average values summarized in Table 10 confirm the observations mentioned above regarding the minimum inter-story drifts also for other accelerograms. The maximum inter-story drifts occurred at 6^{th}÷7^{th} floor for the reference structure, respectively at 5^{th}÷6^{th} floor for the optimized structure.

In Figure 13 the average inter-story drifts between reference and optimized structure can be compared. Besides the first two floors, the optimized structure showed in general lower drifts. Moreover, the inter-story drift profile is more uniform throughout the height.

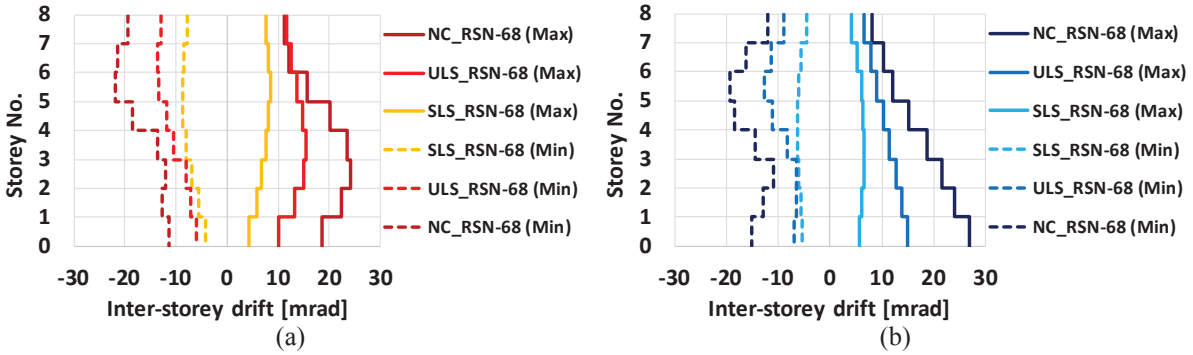


Figure 12: Inter-story drifts generated by *#5 – RSN68* within the corresponding structural systems: (a) reference structure; (b) optimized structure.

Story	Reference structure			Optimized structure			Ratio optimized/reference		
	SLS	ULS	NC	SLS	ULS	NC	SLS	ULS	NC
8	7.4	13.9	19.6	5.3	9.3	12.2	0.72	0.67	0.62
7	**7.7**	**14.5**	21.0	6.5	11.8	15.8	0.84	0.81	0.75
6	7.5	14.1	**21.5**	**7.1**	**13.2**	18.5	0.95	0.94	0.86
5	6.9	13.4	20.5	6.8	12.6	**18.6**	0.99	0.94	0.91
4	6.5	12.9	20.3	6.4	11.8	17.6	0.98	0.91	0.87
3	5.8	11.5	18.6	5.8	10.9	17.5	1.00	0.95	0.94
2	5.2	10.1	15.9	5.3	10.5	17.7	1.02	1.04	1.11
1	4.1	7.6	12.3	5.1	10.4	18.4	1.24	1.37	1.50

Table 10: Average of the maximum inter-story drifts [mrad] corresponding to the three seismic intensity levels (SLS, ULS, NC) and the two structural configurations (reference / optimized).

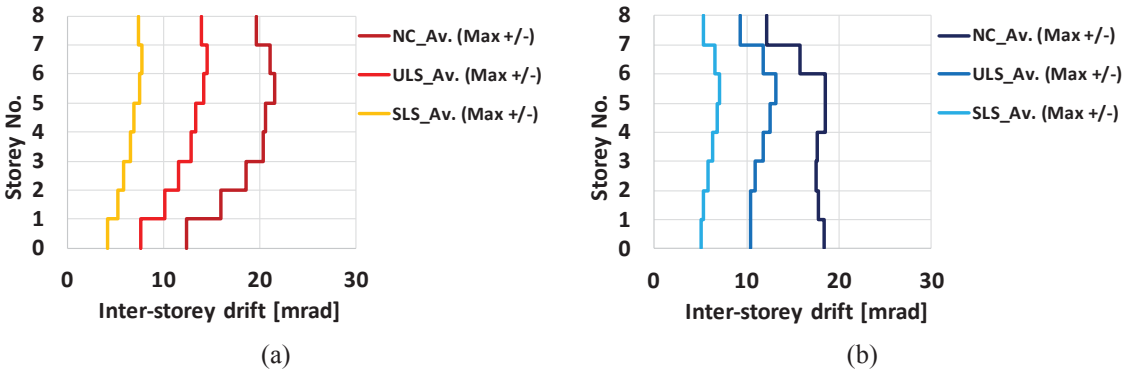

Figure 13: Average of the maximum (+/-) inter-story drifts corresponding to the three seismic intensity levels (SLS, ULS, NC) and the two structural configurations: (a) reference; (b) optimized.

The response of the two structural systems was evaluated by comparing the residual deformations. Figure 14 shows the residual deformation at the top floor corresponding to each of the seven accelerograms at NC intensity level for both structural configurations. As can be observed, the largest residual deformations were evidenced for *#3 – RSN 20*. Furthermore, for five out of seven accelerograms (*RSN 6 / 20 / 68 / 95 / 96*) the residual deformations of the optimized structure were approximately by two thirds lower compared to the reference structure.

Regarding the seismic performance and resilience of a structural system, some important aspects are represented by: (i) the possibility of structural repair; (ii) a low amount of residual deformations; (iii) the re-centering capability of the structure. Table 11: Reference vs. optimized structural configuration: fulfilment of resilience/seismic performance criteria shows an overview with regard to the fulfillment of the resilience and seismic performance criteria by the two structural systems (reference vs. optimized). Through the use of replaceable dissipative links, potentially both structural systems have the possibility to be repaired after a seismic event. In contrast to the reference structure (with relatively high residual deformations, and no re-centering capability), the optimized structural system fulfils all three criteria:

- *Structural repair* – through the use of replaceable dissipative devices;
- *Low residual deformations* – through the use of coupling beams of high strength steel and with alternating pinned/fixed connections (for an elastic response);
- *Re-centering capability* – by incorporating the two bays with coupling beams (of high strength steel and pinned/fixed connections) characterized by an elastic response, which will contribute to the structural re-centering during the replacement of the dissipative links.

	RSN_06	RSN_15	RSN_20	RSN_30	RSN_68	RSN_95	RSN_96
Reference	0.166	0.024	0.485	0.066	0.070	0.152	0.171
Optimized	0.050	0.024	0.099	0.048	0.021	0.055	0.041

Figure 14: Reference vs. optimized structural system: residual displacements at the top floor corresponding to each of the seven accelerograms (NC seismic intensity level).

Performance criterion	Reference structure	Optimized structure
Structural repair	***Yes***: both structural systems are generally reparable through the use of Dissipative Replaceable Links (DRL)	
Low residual deformations	***No***: the reference structure is characterized by relatively high residual deformations	***Yes***: the optimized structural system is characterized by a significant reduction of residual deformations, resulting from the use of the two bays with pinned-fixed coupling beams
Re-centering capability	***No***: the reference structure does not possess any worth mentioning re-centering capability	***Yes***: the optimized structure contains two bays with pinned-fixed coupling beams that responded elastically, and therefore, would contribute to the re-centering of the structure during the replacement of the dissipative links

Table 11: Reference vs. optimized structural configuration: fulfilment of resilience/seismic performance criteria.

5 CONCLUSIONS

The preliminary investigations on the newly developed CDRLF system within this paper show its general feasibility and potential of enhancing the already known DRLF system regarding stiffness increase and improved re-centering capability for mid to high rise buildings. Thus, it renders an alternative to application of partial-strength joints to the gravity load bearing frame of a system with DRLFs, as conventionally done for introducing additional stiffness. Main conclusions derived from the investigated case study are as follows:

- The design philosophy was shown to work effectively for the considered case study. Damage to coupling beams was not triggered up to NC and beyond, while almost all of dissipative links showed plastic response.
- The optimized system, two DRLFs with 'one end fixed – the other end hinged' coupling beams, showed a significant improvement over the reference system with three DRLFs.
- The improvement consists of:
  - the decrease in needed amount of DRLF bays (two compared to three),
  - an improved global force displacement relationship (introduced hardening slope after damage to dissipative links),
  - lower inter-story drifts,
  - noteworthy re-centering capability and, thus,
  - much lower residual displacements.
- This optimization results in a system that fully complies with the envisaged performance targets, which is repairability by restricting damage to dissipative replaceable links only, limiting of residual displacements and providing re-centering capability by the coupling beams.
- To achieve the performance targets – widespread damage to dissipative links before damage to coupling beams is triggered – a balanced stiffness distribution between the two DRLFs and the coupling frames is necessary. The coupling frame needs to be stiff enough, to increase noteworthy overall stiffness, but on the same time flexible enough, to prevent attraction of too much force, once the DRLFs soften du to energy dissipation.
- The balance of the stiffness was achieved by introducing a hinge at one end of each coupling beam.
- Sophisticated static nonlinear (pushover) are needed to assure that the foreseen performance targets are met. Simple application of current seismic design equations for designing the CDRLF system does not necessarily guarantee a well performing structure. Therefore, simplified design equations especially for the coupling beams are needed to ease application of the CDRLF system in practice.
- The strength design of the coupling beams might be challenging, especially when both coupling beam ends are designed to be fixed. Thus, often coupling beams in high strength steel will be required, as the increase of section size would jeopardize the need of a balanced stiffness distribution between DRLFs and CFs.

Finally, it can be stated that the CDRLF system is currently under investigation within the ongoing DISSIPABLE project. The study presented in this research shows promising results. A testing campaign consisting of hybrid tests on a 2D frame as well as shaking table tests on a 3D structure is underway. Eventually, the project consortium will deliver design guidelines along with a worked example.

6 ACKNOWLEDGEMENTS

Research leading to the innovative design concept presented in this paper has received funding in the framework of following European research projects: FUSEIS ("Dissipative Devices for Seismic Resistant Steel Frames"), MATCH ("Material Choice for Seismic Resistant Structures"), INNOSEIS ("Valorization of Innovative Anti-Seismic Devices") and DISSIPABLE ("Fully Dissipative and Easily Repairable Devices for Resilient Buildings with Composite Steel-Concrete Structures"). The financial contribution of the Research Fund for Coal and Steel (RFCS) of the European Community is gratefully acknowledged.

The second author was supported by the Alexander von Humboldt Foundation through a Research Fellowship for Experienced Researchers, which is also gratefully acknowledged.

Abstract. *Among the various strategies for the seismic protection of buildings, the use of passive devices based on energy dissipation through the development of plastic deformations represents a valid, simple and economic solution. During seismic events, damage is concentrated in correspondence of the dissipative elements which are thought to be replaced in the post-seismic phase in order to fully recover the initial capacity of the device and, therefore, to restore the original building behaviour. In this context, the adoption of steel devices has relevant impact and advantages on the overall building performance. In the present study, the implementation of a steel dissipative and replaceable device using High-Strength Steels (HSS) for the non-dissipative components was deeply analyzed, and results are briefly presented. The improvement due to HSS adoption accounted for the direct/short-term economic aspects (i.e. cost of the device, weight) and the indirect/long-term ones (i.e. seismic risk performance) within a multi-criterial optimization procedure.*

1 INTRODUCTION

In the last decades, with the aim of preventing damages on structures due to seismic events, several passive protection devices were developed exploiting different energy dissipation strategies such as friction, viscous, viscoelastic or plastic [1],[2]. Concerning dissipative plastic devices, the adoption of steel systems progressively diffused thanks to their optimal mechanical performance, lightness, workability and application versatility. Steel components can be connected through "*dry*" systems to structural elements, e.g. using bolted joints, and this can provide relevant advantages in the post-seismic phase allowing the easy replacement of the damaged components and providing the fully-recovery of the initial capacity.
In the present study, a steel Dissipative and Replaceable Device (in the following called DRD) developed within the research project DISSIPABLE "*Fully dissipative and easily reparable device for resilient buildings with composite steel-concrete structures"* funded by the Research Fund for Coal and Steel of European Commission and actually ongoing, is presented and deeply analysed. DRD's conception was developed as improvement of the existing INERD^{TM} connections, already proposed by [3]-[4]. Figure 1a shows the geometric configuration of the DRD device. Two pairs of plates (external and internal) are connected to the steel frame and braces within the structural configuration; the transversal *pin*, located between the plates, is the dissipative component devoted to absorb the relative displacements of the plates, developing plastic deformations and then dissipating the seismic energy stored during the earthquake; as visible, the pin is designed to be replaced after damages.

Respect to the previous configuration of the INERD^{TM} system, additional transversal spacers between plates were added to avoid transversal deformation, observed during cyclic experimental tests [5] (Figure 1b). Another relevant aspect concerns the accumulation of ovalization of plates' holes, causing pinching phenomena on the hysteretic cycle resulting in the reduction of the dissipative capacity of the system (Figure 1c).

a) b) c)

Figure 1: a) Configuration of DRD device; b) lateral deformation of plates in the INERD^{TM} system [5]; c) typical hysteretic behaviour of the DRD device.

The present work, as suggested by the project's guidelines, deeply investigates the possible use of high-strength steels (HSS) for the DRD realization: the impact of HSS in terms of overall cost/benefits over the whole life-cycle of hypothetical structures equipped with DRDs, in terms of both of direct (i.e. fabrication, installation, working) and indirect (i.e. the expected annual losses due to the seismic risk) costs' reduction was considered. Several different mechanical configurations of the devices, defined by varying both material and geometry, were studied through a parametric numerical and economic analysis. The following decision variables were adopted to carry out a multi-criterial optimization analysis aiming to determine the optimal design solution.

- Material's *cost* for device fabrication.
- Device's *weight*: including diseconomies of manufacture, transport, installation and load on the structures.
- *Dissipative capacity* of the device, in terms of energy dissipation with respect to the stiffness of the device.

2 THE USE OF HIGH STRENGTH STEEL

In last decades, the use of HSS progressively increased for the manufacturing of structural components; several countries started to elaborate and adopt standard provisions including HSS in the structural design [6]. However, currently, the application of HSS for the seismic design is limited by existing seismic design codes and constructional practice. Mild Steel (MS) is typically preferred since presenting a higher ductility and a higher dissipative capacity [7]. Besides, if the use of HSS can effectively reduce elements' sections since provided by higher strength, deformability problems can affect steel structures, highly limiting – from a practical point of view – the employment of those grades. If properly used, HSS can guarantee several advantages to seismic constructions:

- *Economic advantages*: increasing the strength, it is possible to reduce sections and therefore the self-weight of structures as well as costs for material, transportation, fabrication, assembling, processing and welding, overall management.
- *Structural safety*: self-weight's reduction leads to reducing the seismic mass. Therefore, excellent toughness proprieties guarantee higher safety level.
- *Architectural advantages*: the reduction of elements' size enables special aesthetical and elegant structural solutions.
- *Sustainability advantages*: the employment of lower materials' quantity leads to a lower use of resources, energy consumption, to the reduction of CO_2 emissions and of waste material during the whole life of the structure.

On the other hand, the cost of HSS is usually higher than the one associated to MS grades, increasing with the increase of the yielding strength; however, the costs' increase is lower respect to the increase of the strength performance [8]. This means that, for a *static* design, the adoption of HSS can be preferred to MS, but, in the case of seismic design (or even in the case of fire design [8]), due to the more brittle behavior of HSS, the lower resistance to crack propagation [9] and the higher sensitivity towards heating induced by processing (flame cutting, welding, flame straightening, etc.), usually MS is preferred to HSS.

3 PARAMETRIC ANALYSIS

Taking into consideration the structural performance of DRD previously defined, HSS can be used for the non-dissipative components (i.e. plates and stiffeners). Increasing the strength capacity of the plates, it is expected to achieve lower accumulation of plastic ovalization phenomena with the following increase of the overall dissipative capacity of the device. The HSS implementation can be assessed in parallel to the possible reduction of plates' thickness, then decreasing the resulting weight and costs of the system.

3.1 Definition of parametric configurations' set

The geometrical configuration of the DRD device considered is shown in Figure 2. The pin, with a shaped circular section, is located within the holes of the plates with a gap of 1.0 mm.

For the pin, S235 steel grade was selected in order to provide optimal ductility performance; for the plates, five different steel grades and three different thickness combinations were otherwise considered (respectively equal to 30/20 mm, 30/15 mm and 25/15 mm for the external/internal plates), globally resulting in 5x3=15 different possible configurations.

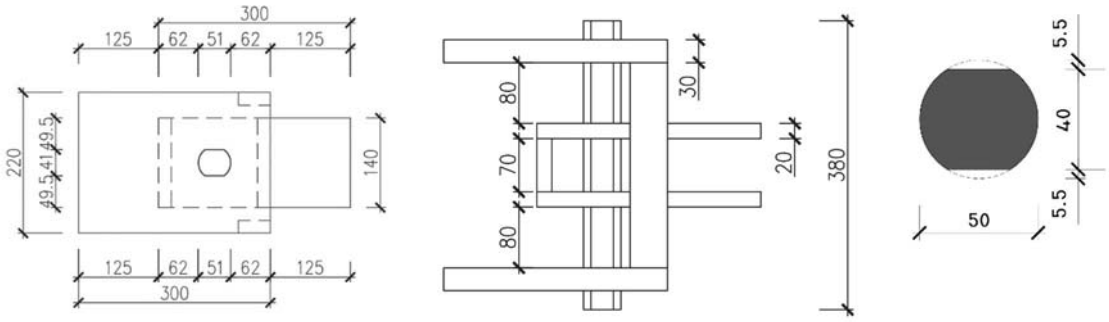

Figure 2: Geometrical configuration of the DRD.

Table 1 shows the five steel grades used for the plates, with indications concerning mechanical performance as suggested by EN10025-6-2004 [10] and estimated cost [€/kg], being f_y and f_u respectively the yielding and ultimate tensile strength, e_y and A the yielding and ultimate deformation. For the S235 used for the pin, the following values were adopted: f_y=215 MPa, f_u=360 MPa, A_g=0.40. In order to compare the results achieved by using HSS and ordinary MS, S355 steel grade was also considered. For the materials' cost estimation of Table 1 reference is made to [11], presenting the trend of the material cost (normalized to the one associated to S23) for each yielding stress of steel (Figure 3).

Steel grade	f_y [MPa]	e_y [-]	f_u [MPa]	A_g [-]	Cost [€/kg]	Weight [kg/m^3]
S355	355	0,0017	470	0,30	1,1549	7850
S500	500	0,0024	590	0,17	1,3434	7850
S620	620	0,0030	700	0,15	1,4994	7850
S690	690	0,0033	770	0,14	1,5904	7850
S890	890	0,0042	940	0,11	1,8504	7850

Table 1: Steel grades considered for optimization procedure.

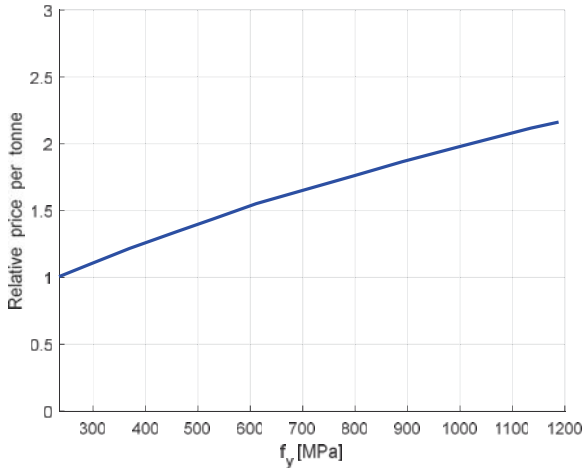

Figure 3: Steel material price vs yielding tension [11].

Cost vs yielding trend can be reliably approximated by equation (1), used for the evaluation of the costs presented in Table 1:

$$C(f_y) = 0.0013 \cdot f_y + 0{,}6934 \tag{1}$$

With the aim of assessing the practical application of the proposed solutions/combinations for the structural design, it was necessary to evaluate the connector-plate coupling as a "*pin*" connection, carrying out the resistance checks indicated by Eurocode 3 [12]. This highlighted that all the above-mentioned configurations satisfy all the requirements except for the bearing capacity of the internal plates, whose plasticization is therefore expected.

3.2 Numerical modelling of the DRD device

The numerical model of the DRD device was developed using the Finite Element (FE) software Abaqus® [13] basing on the model provided within the DISSIPABLE research project by the Instituto Superior Técnico (IST - Portugal), made available to the involved partners (Figure 4). Materials were represented through the used of elastic-plastic with isotropic-hardening law. A more refined mesh (cubic 4 mm sizes instead of 8 mm) was defined for the pin and the plates' portions close to it, providing better accuracy in the stress and strain distributions' calculation; element type selected was C3D4R. Contact between pin and plates was modelled as tangential "penalty" friction (with friction coefficient 0,45) and normal "hard" contact.

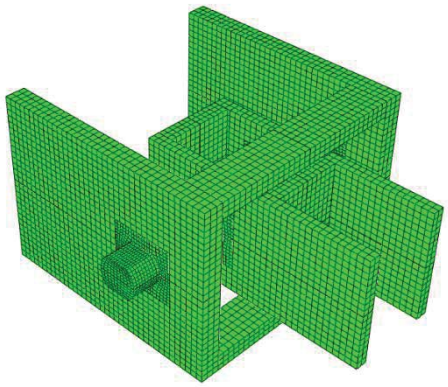

Figure 4: Numerical model of DRD developed with Abaqus ®.

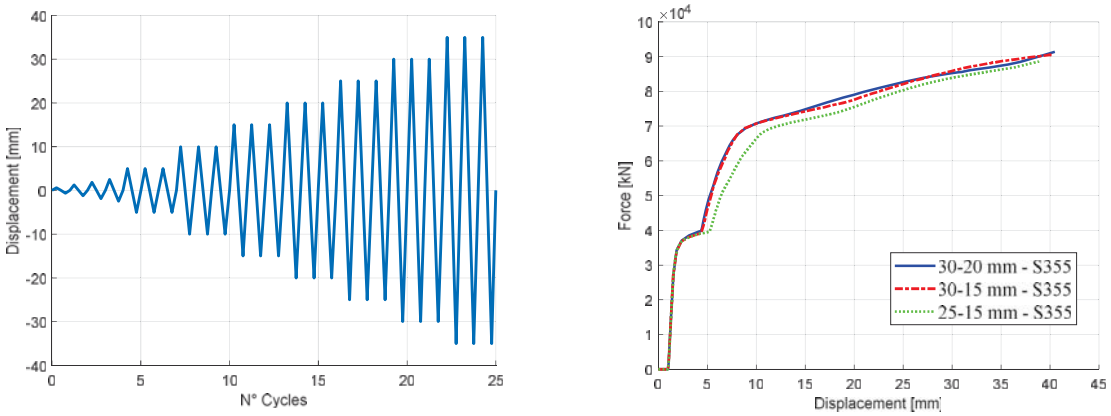
3.3 Execution of numerical analyses and results

Each configuration was tested under cyclic loading condition using incremental imposed displacement according to the ECCS protocol [14]; 25 cycles were performed, whose amplification trend is presented in Figure 5a. In order to make each configuration easily comparable to the others, an equivalent yielding displacement (e_y) equal to 2.5 mm was assumed. The execution of preliminary monotonic pushover analyses showed that resulting capacity curves are not strictly affected by the variability of the steel grade adopted or by the internal plates' thickness and, as visible from Figure 5b, resulting differences are very small. Cyclic analysis was the performed using Abaqus/Standard.

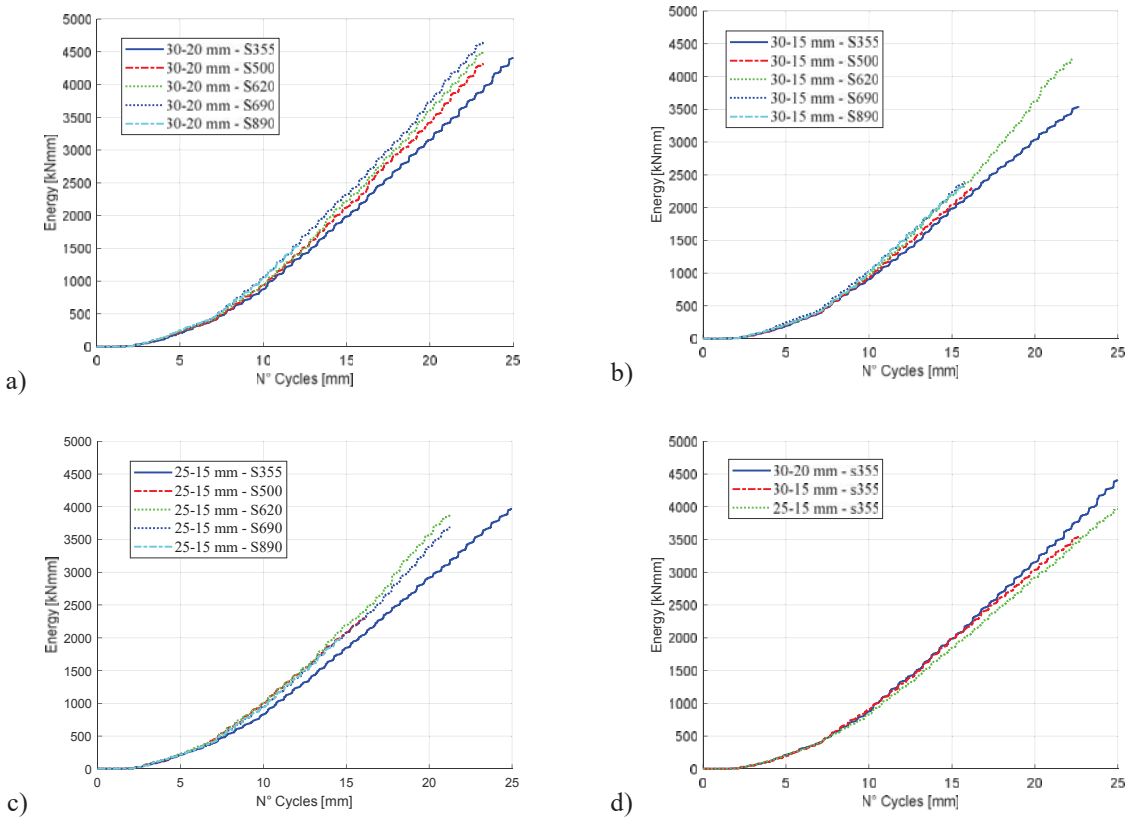
Figure 6-shows the trend of the energy dissipated by the device for each considered configuration. Energy (E_n) was evaluated in correspondence of each n-th load step by means of equation (2), being F_n and δ_n respectively the force and the displacement associated to each n-th cycle.

$$E_n = E_{n-1} + \frac{1}{2} \cdot (F_n - F_{n-1}) \cdot (\delta_n - \delta_{n-1}) \quad (2)$$



a) b)

Figure 5: a) Displacement history according to ECCS protocol; b) capacity curves for configurations with S355 and different thickness configurations (similar results for other steel grades were achieved)



a) b)

c) d)

Figure 6: Accumulated energy vs N° cycles for different thickness combinations: a) 30-20 mm; b) 30-15 mm; c) 25-15 mm; d) comparison for S355.

It can be observed how the relative trend of the different curves remains proportional to the progress of the load cycles: higher HSS grades show better results in terms of dissipated energy

and reduction of the pinching effect. The optimization comparison is carried out in relation to the 12th cycle, achieved for all the configurations without numerical convergence errors.

The dissipative capacity shall be appropriately analysed in relation to the device' stiffness, proportional to the seismic input energy entering the structure. Analytical relationships available [3]-[15] allow to evaluate the device's stiffness according to the characteristics of the pin only; however, as can be observed by the numerical results, relevant differences in the stiffness occurred varying the thickness of the plates. For this reason, the value of the total energy accumulated by devices was divided by the average value of the stiffness developed (K_n) by the selected configuration, evaluated for each step according to equation (3):

$$K_n = \frac{(F_n - F_{n-1})}{(\delta_n - \delta_{n-1})} \tag{3}$$

The weight, cost (normalized according to the most expensive configuration), dissipated energy, maximum stiffness, energy/stiffness ratio for each configuration are presented in Table 2.

Configuration	W [kg]	Cost [-]	Energy [kNmm]	K_n [kNmm]	Energy / K_n
S355_30/20	54,8	0,64	1335,220	59,04	22,62
S500_30/20	54,8	0,74	1407,283	59,04	23,84
S620_30/20	54,8	0,82	1392,881	59,04	23,59
S690_30/20	54,8	0,87	1555,155	59,04	26,34
S890_30/20	54,8	1,00	1533,460	59,04	25,97
S355_30/15	51,4	0,60	1301,158	57,78	22,52
S500_30/15	51,4	0,69	1391,148	57,78	24,08
S620_30/15	51,4	0,77	1415,064	57,78	24,49
S690_30/15	51,4	0,81	1492,313	57,78	25,83
S890_30/15	51,4	0,93	1488,243	57,78	25,76
S355_25/15	46,6	0,54	1243,519	53,16	23,39
S500_25/15	46,6	0,62	1436,039	53,16	27,01
S620_25/15	46,6	0,69	1441,435	53,16	27,12
S690_25/15	46,6	0,73	1389,082	53,16	26,13
S890_25/15	46,6	0,84	1399,892	53,16	26,33

Table 2: Summary table on the optimization aspects for each configuration.

It is possible to observe how the configurations having of 25-15 mm thickness combination, although provided by lower dissipative capacity respect to the 30-15 mm ones (the best combination for energy optimization was S690_30/20), show the least stiffness and therefore allow to achieve the higher Energy / K_n ratio. S620_25/15 configuration turns out to be the best.

4 OPTIMIZATION PROCEDURE

In order to consider together the three performance aspects previously mentioned (i.e. weight-W, cost-C, energy/stiffness ratio-R) a multi-objective performance index (I) was defined as the weighted sum of the three quantities, linearly normalized as shown in Table 3 (0 – best, 1 – worst):

$$I_i = p_W \cdot W_i + p_C \cdot C_i + p_R \cdot R_i \tag{4}$$

The weights associated to each of the three involved parameters, namely p_W, p_C and p_R, are related to the importance of each aspect within the decision-making process of optimization. These weights can then vary in relation to several factors such as the typology of the structure, its function, the events expected during its whole life cycle, etc. For simplicity, two decisional

scenarios were considered: the first (corresponding to the index I_1) where equal importance is given to each optimization parameter (p_W, p_C, $p_R = 0.333$) and the second (corresponding to the index I_2) where the weight parameter has been neglected ($p_W = 0.0$, p_C, $p_R = 0.5$).

The normalized values for the quantities and the resulting indexes are reported in Table 3.

Configuration	W	C	R	I_1	I_2
S355_30/20	1	0,22	0,98	0,73	0,60
S500_30/20	1	0,43	0,71	0,71	0,57
S620_30/20	1	0,61	0,77	0,79	0,69
S690_30/20	1	0,72	0,17	0,63	0,44
S890_30/20	1	1,00	0,25	0,75	0,63
S355_30/15	0,59	0,13	1,00	0,57	0,57
S500_30/15	0,59	0,33	0,66	0,53	0,49
S620_30/15	0,59	0,50	0,57	0,55	0,54
S690_30/15	0,59	0,59	0,28	0,49	0,43
S890_30/15	0,59	0,85	0,30	0,58	0,57
S355_25/15	0	0,00	0,81	0,27	0,41
S500_25/15	**0**	0,17	**0,02**	0,06	0,10
S620_25/15	0	0,33	0,00	0,11	0,16
S690_25/15	0	0,41	0,21	0,21	0,31
S890_25/15	0	0,65	0,17	0,27	0,41

Table 3: Results of the optimization procedure.

Both for first (I_1) and second (I_2) scenario, configuration S500_25/15 is able to optimize the multi-objective index, being also the lightest solution and the one characterized by the lower resulting cost; this can be then considered as the best configuration. Differently, the configuration S355_25/15 is the one able to optimize the cost (and the weight) but showing the most disadvantageous dissipated energy/mean stiffness ratio. From Table 3, it can also be observed the value of R, which is progressively optimized by increasing the steel grade.

5 CONCLUSIONS

In the present study, the possibility of implementing a dissipative and replaceable device (DRD) with the use of high-strength steel (HSS) was considered using different combinations of thickness for the plates (i.e. the non-dissipative components of the device). The economic and performance aspects of the device, as the weight, the material's cost and the dissipative capacity were evaluated with the support of numerical analyses within an overall optimization procedure. Results clearly indicate that the adoption of HSS can increase the dissipative capacity without thereby increasing, necessarily, the stiffness of the system: this is particularly advantageous in combination to small thicknesses, for which the weight and cost of the device are then optimized.

ACKNOWLEDGMENTS

The present work has been developed within the framework of the European research project DISSIPABLE funded by the RFCS (European Union's Research Fund for Coal and Steel) – Grant Agreement no. RFCS2017-800699.

Abstract. *The main challenges of the construction sector (at this point and in the coming decades) are: natural hazards, climate change, sustainability, competitiveness, technology take-up, in service performance, re-industrialization. Regarding natural hazards, the latest seismic events evidenced the need for more resilient earthquake-resistant structures. Justified by expensive repairs, downtime and/or building demolition – it has become a widely held belief that the ductility of a structure is not the final goal, and that preventing the loss of life is not sufficient for a modern structure. Consequently, the current study was launched with the aim of providing structural configurations and practical solutions for enhanced resilient and sustainable buildings and communities. In particular, the research aims at reducing the repair costs and downtime of a structure damaged by natural hazards (e.g. earthquakes) and, consequently, at providing a more rational design approach, with regard to sustainability. Both replaceable dissipative components and structural re-centering capabilities are addressed. In brief, the research activities consist in developing a set of bolted beam-to-column joints with replaceable dissipative components and investigating the applicability potential of innovative "leaf-spring" columns into building frames. The central idea of the current study is to combine and rigidly connect several columns in the shape of a "leaf-spring", and to benefit from the mechanical properties of such an innovative element. Primarily, the "leaf-spring" columns are aimed to provide the structure with re-centering capability and to improve the overall structural response. The current paper presents: (i) the aim, objectives and particularities of the current research; (ii) the outcomes of a case study (i.e. the design and seismic performance evaluation of standard vs. innovative structural configurations); (iii) a proposed solution for beam-to-column joints with replaceable components and for structural re-centering; (iv) the main conclusions and future research activities.*

1 INTRODUCTION

Advanced modern technologies have significantly pushed the development of our society. Yet, nature continues to offer proof of its unpredictable and destructive character. When subjected to natural hazards, buildings and other engineering structures should possess the ability to provide safety and stability. However, in the light of the latest seismic events, it has become clear that the current degree of seismic protection is unsatisfactory. This aspect was evidenced during recent earthquakes in: *Mexico* (*19.09.2017 - 7.1 M_w magnitude*), *Italy* (*24.08.2016 - 6.2 M_w*), *Nepal* (*25.04.2015 - 7.8 M_w*), *China* (*03.08.2014 - 6.3 M_w*), *Turkey* (*23.10.2011 - 7.2 M_w*), *Japan* (*11.03.2011 - 9.0 M_w*), *New Zealand* (*22.02.2011 - 6.2 M_w*), and *Chile* (*27.02.2010 - 8.8 M_w*). Under severe or even moderate earthquake activity, buildings have suffered extensive damage and even total collapse.

Buildings designed according to modern seismic codes are expected to exhibit a controlled ductile inelastic response during major earthquakes, implying extensive structural damage (see examples in Figure 1), along with, possibly substantial residual deformations. However, the structures might be difficult or uneconomical to repair due to the experienced damage and residual drifts and may need demolition and rebuilding.

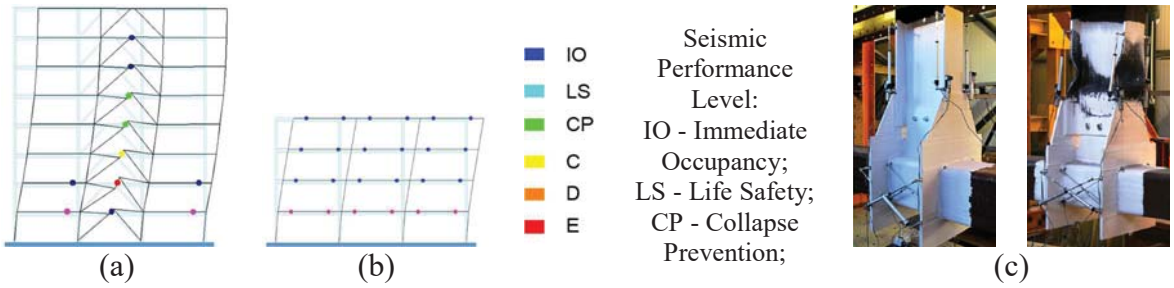

Figure 1: Examples of expected inelastic response of structural members: (a) dual eccentrically braced frame (D-EBF) with plastic hinges in shear links and beams; (b) moment resisting frame (MRF) with plastic hinges in beams; (c) beam-to-column joint (before and after test) with large plastic deformations in the dissipative zone [1]

The 2011 Christchurch (New Zealand) earthquake is a recent example of the necessity of more resilient earthquake resistant structural systems. Approximately 50% of the buildings in the central business district were declared unusable due to significant damage or due to proximity to dangerous and unsafe buildings, and nearly 1000 buildings were demolished [2]. The cost of rebuilding was estimated at $40 billion NZD (approx. 20% of New Zealand's GDP), without including the economic losses related to business downtime [2].

In order to reduce the structural damage caused by moderate to strong earthquakes, different strategies can be employed. The most sophisticated existing solutions are base isolation and the implementation of active and semi-active structural control [3]. Other strategies rely on supplementary damping through viscous, friction or yielding dampers. While some of these solutions are more efficient than others at reducing structural damage, all of them have the following disadvantages: specialized knowledge is required during design and erection; carefully carried out maintenance is needed; the initial cost is high. Another option implies a conventional structural design with replaceable dissipative members (easy to substitute after a moderate-to-strong earthquake), which will reduce the repair costs. An efficient system has to fulfil two requirements: (i) the inelastic deformation should occur only in removable elements; (ii) the damaged dissipative elements must be replaceable [15].

Self-centering systems, a relatively new concept, address the drawbacks of the conventional yielding systems, and have recently received much attention. A review is shown in [2]. Of sev-

eral practical applications, the following few are mentioned here: self-centering moment resisting frames (SC-MRFs) based on post-tensioned beam-to-column [4] and column base [5] connections, self-centering concentrically braced frames (SC-CBFs) [6], self-centering energy dissipative (SCED) bracing [7], steel self-centering devices (SSCDs) [8], and shape memory alloy self-centering buckling restrained braces (SC-BRBs) [9].

For a structure to be repairable, in addition to constraining the inelastic deformations to the removable dissipative members, any permanent (residual) drift needs to be eliminated, while providing a re-centering capability (in contrast to self-centering). Some of the most renowned removable dissipative component systems are: INERD connections [10], FUSEIS devices [11], buckling restrained braces (BRB) [12], steel plate shear walls (SPSW) [13], removable links in eccentrically braced frames (EBF) [14][15][16]. Beam-to-column joints with replaceable components were investigated as the following: (i) damage free joints with friction dampers [17]; (ii) joints with replaceable T-stub fuses [18][19] and yield-links [20][21][22][23][24][25][26].

Concepts as "re-centering capacity" and "removable dissipative element" were recently implemented in a dual structure, obtained by combining steel eccentrically braced frames (with removable bolted links) and moment resisting frames [27]. The easily replaceable bolted links provided the energy dissipation, while the more flexible, but still sufficiently stiff, moment resisting frames provided the necessary re-centering capability.

2 AIM AND OBJECTIVES OF THE CURRENT RESEARCH

The current research represents an attempt to face the challenges of the construction sector, and to respond to the vision documents from U.S. [28] and Europe [29]. Particularly, the current research has the aim to provide structural configurations and practical solutions for enhanced resilient and sustainable buildings and communities. The main objectives are:

- To look at the construction/deconstruction process from an open-minded perspective, and to propose solutions that provide enhanced resilience and sustainability, and that take into account also the concept of design for deconstruction;
- To develop a set of bolted beam-to-column joints with replaceable dissipative components;
- To investigate the applicability potential of "*leaf-spring*" columns in building frames;
- To investigate (experimentally and numerically) the behavior of joint assemblies with replaceable dissipative components undergoing large cyclic strains;
- To investigate the re-centering capability of frames equipped with "*leaf-spring*" columns;
- To provide a technical and economical comparison between a conventional, respectively a more resilient and sustainable structural system;
- To elaborate a set of design examples and to propose structural application schemes for the implementation of replaceable dissipative components and re-centering solutions.

3 CASE STUDY: STANDARD VS. INNOVATIVE STRUCTURAL SYSTEM

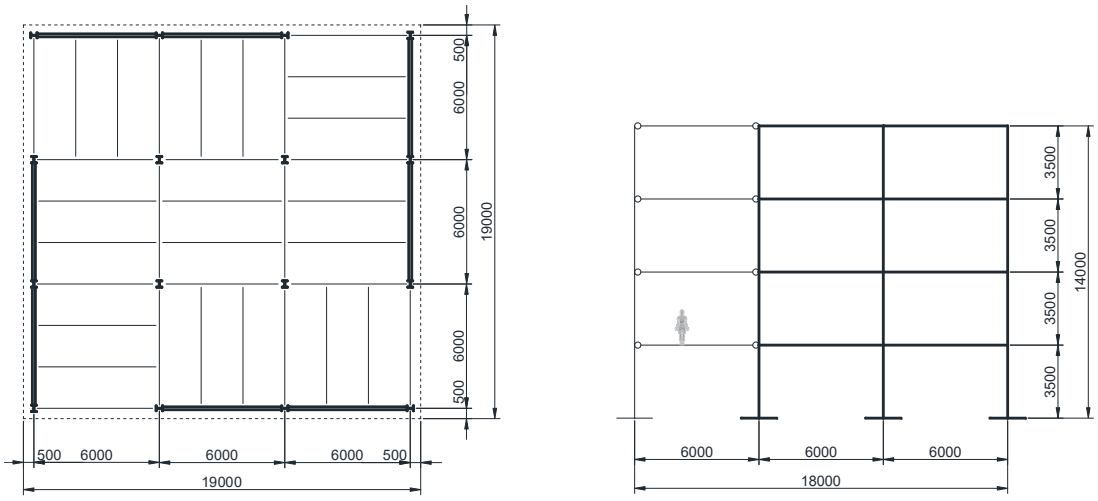
3.1 Structural configuration benchmark

For the development of a structural configuration benchmark, a representative 3D multi-story building configuration was selected. The following parameters were chosen considering as being representative for a 3D multi-story building located in a region with seismic hazard:

- Location: (a) Romania / Bucharest (Soft Soil); (b) Europe (Stiff Soil / Spectrum Type C)
- Building use: Office
- Structural type: Moment Resisting Frame (MRF)
- Number of stories: *4*

- Number of spans/bays: *3*
- Story height: *3.5 m*
- Span/bay length: *6.0 m*
- Outline of the slab: Exceeds the perimeter composed by the outer axes with *0.5 m*

The arrangement and dimensions of the structural configuration are illustrated in Figure 2. In particular, the floor layout with columns, main beams and secondary beams are shown in Figure 2a. Only the outer frames (illustrated in Figure 2b) act as lateral force resisting systems, while the internal structural system transfers the gravitational loading. Regarding the perimeter frames, only two of the three spans/bays are moment resisting. The obtained structural configuration is therefore symmetrical and has the same mechanical properties in both directions.



(a) (b)

Figure 2: Arrangement and dimensions (mm) of the structural configuration: (a) floor layout (with columns, main beams and secondary beams); (b) perimeter moment resisting frame

3.2 Characteristic values of actions

The *permanent actions* include the self-weight of the primary and supporting structure, as well as finishing elements connected with the structure:

- Uniform load acting on the slab: *5 kN/m²*
- Uniform load acting on the perimeter beams (from the glass façade): *3.5 kN/m*
- The weight of beams and columns is considered automatically within the analysis software

The *variable actions* acting on the slab, considering that the building is used for offices (category B), and including the equivalent load from partitioning walls, is:

- Uniform load acting on the slab at intermediate floors: *3.3 kN/m²*
- Uniform load acting on the slab at the top floor: *2.5 kN/m²*

The *seismic action* is defined for two soil conditions, and the following building data:

- Soil type (see the elastic and design spectra in Figure 3):
  - Soft soil (T_c*=1.6 sec.*): specific soil condition in Bucharest according to P100-2013 [31]
  - Stiff soil (T_c*=0.6 sec.*): soil type C according to EN 1998-1 [30]
- High seismic zone, considering a peak ground acceleration of: a_g*=0.3g*
- Importance of the building: office building, γ_I*=1.0 (→ a_g = 0.3×9.81 = 2.95 m/s²)*
- Behavior factor corresponding to moment resisting frames and high ductility class: *q=6.5*

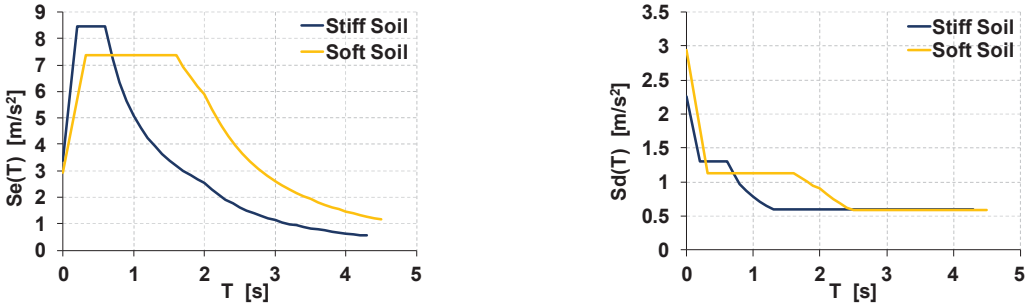


Figure 3: Soft & Stiff Soil: elastic and design spectrum for the horizontal components of the seismic action

3.3 Design of the standard structural configurations (MRF)

Two standard structural configurations were designed and analyzed with SAP2000 [32], i.e. one for soft and one for stiff soil. The structural configurations have a compact planar shape, the lateral force resisting system is placed symmetrically, and the reinforced concrete slab has a sufficient in plane stiffness in order to assure the diaphragm effect. The structural design was performed on 3D models (based on the layout illustrated in Figure 2), using a modal response spectrum analysis.

Based on the presence of the reinforced concrete slabs, a rigid diaphragm constraint was considered for the nodes of each floor. The outer columns were fully fixed at the base, and the connections between beam elements (fixed/pinned) were modelled according to the layout in Figure 2. The gravitational loads were applied on slabs (permanent and variable loads), and on the perimeter beams (permanent loads from the façade walls). The masses were calculated automatically from the applied gravitational loading on the structure. The beams were realized from S235 steel grade and the columns from S355 grade.

The modelling of global imperfections was performed based on the provisions from Section 5.3.2 of EN 1993-1-1 [33], i.e. through a system of equivalent lateral forces for each horizontal direction. The importance of the second order effects was evaluated through the value of the inter-story drift sensitivity coefficient (θ), which was determined according to Section 2.10 of [34], respectively Section 4.6.2.2(2) of P100-2013 [31]. The coefficient (θ) was computed for each level and each direction, and the maximum value was found between $0.1 < \theta \leq 0.2$. Consequently, the second-order effects were considered in an approximate way by multiplying the design values of the demands with the following factor: $\alpha = 1/(1-\theta)$.

The cross-section of elements for the lateral force resisting system of the standard designed structures (in Soft and Stiff Soil conditions) are presented in Table 1. The design of the lateral force resisting system was governed by the deformation limitation (corresponding to the serviceability limit state – SLS, and/or to the ultimate limit state – ULS).

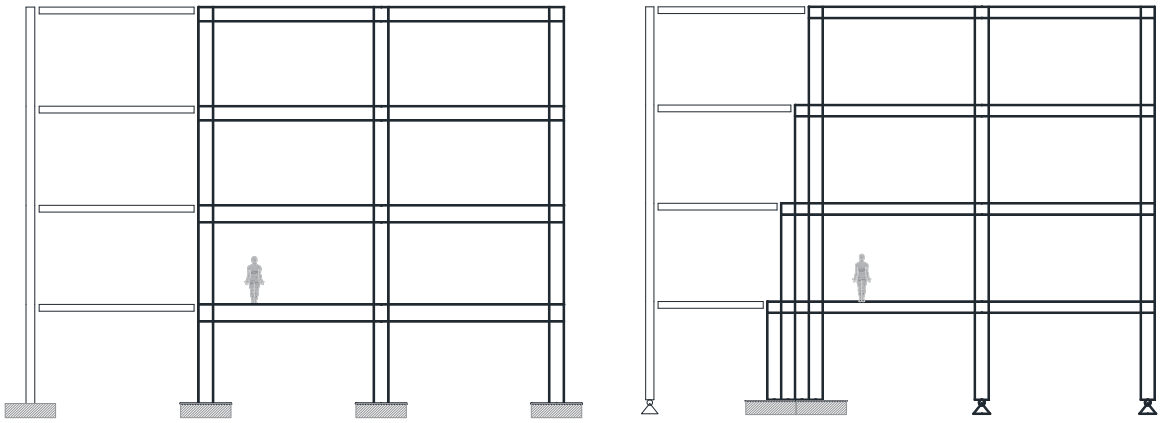
Standard structure located in Soft Soil conditions (T_1=0.751 sec.)			Standard structure located in Stiff Soil conditions (T_1=0.977 sec.)		
Floor	Beam	Column	Floor	Beam	Column
4	IPE-600	HEB-600	4	IPE-500	HEB-500
3	IPE-600	HEB-600	3	IPE-550	HEB-500
2	IPE-750x137	HEB-600	2	IPE-550	HEB-500
1	IPE-750x137	HEB-600	1	IPE-550	HEB-500

Table 1: Cross-section of elements for the standard lateral force resisting system – Soft & Stiff Soil conditions.

3.4 Structural configurations with Leaf Spring Columns (LSC)

3.4.1. Description of the concept

The idea within the current research is to rigidly combine several columns in the shape of a ”*leaf-spring*”, and to benefit from the mechanical properties of such an innovative element. In contrast to a standard moment resisting frame (see Figure 4a), which does not possess any noteworthy re-centering capability, an innovative structural system is proposed as part of the current research (see Figure 4b). In particular, the structural configuration is composed of: (i) a Moment Resisting Frame (MRF) that acts as a lateral load resisting system and as a seismic energy dissipation system (through the development of plastic hinges in beams); (ii) an innovative Leaf Spring Column (LSC) that acts as a lateral load resisting element, which will suffer only elastic deformations and will provide the re-centering capability of the structure.



(a) [MRF] (b) [MRF+LSC]

Figure 4: Structural configuration: (a) standard moment resisting frame (MRF); (b) innovative structural system, i.e. a moment resisting frame equipped with a “*leaf-spring*” column (MRF+LSC)

3.4.2. Design of the innovative structural configurations (MRF+LSC)

The “*leaf-spring*” column (LSC) is intended to be realized by joining and connection of several steel profiles in a progressive manner (see Figure 4b). The individual profiles of the LSC are to be connected in such way as to prevent the relative displacement between each other, and to work as a unitary element. Ongoing finite element analyses are devoted to the investigation of the performance of LSC’s with bolted/welded connection between profiles.

Considering the standard moment resisting frames with 6.0 m span/bay (Figure 4a and Table 1) as a starting point (reference system), two structural configurations were developed and modelled using LSC’s and moment resisting bays (as illustrated in Figure 4b and Figure 5). An offset of 250 mm (half of the HEB-500 column height) was defined for the beams in MRF bays (for both standard and innovative structures). Also, the same input data was considered with regard to the material properties, geometry, loading conditions and combinations.

Compared to the designed reference structures (with standard MRF’s), the new structural system (see Figure 5) has been adapted regarding the following aspects:

- *LSC*: one “*leaf-spring*” column was used for each perimeter frame using HEB-500 profiles for the structure in Soft soil, and HEB-400 profiles for the structure in Stiff soil;
- *Secondary beams*: the secondary beams were arranged parallel to the main beams (see the perimeter MRF’s in Figure 5 and layout in Figure 17); this new arrangement has the aim

to allow the replacement of the dissipative main beams (which will be positioned with a certain gap below the slab);

- *Material for LSC's*: as the "*leaf-spring*" columns are to remain in the elastic range, the use of S700 high strength steel (HSS) was essential, and therefore in case of unavailable profiles of such steel grade, these would be realized from welded plates of equivalent thickness;
- *Beams from MRF bays*: the cross-section of the beams in the MRF bays could be decreased;
- *Base connections for columns*: the base connections of the MRF columns was considered as pinned based on the observation that a fixed connection would not result in noteworthy benefit, and that the presence of the LSC's prevents the development of bending moment at the other column bases;

An overview of the structural configuration is shown in Figure 5: (i) 3D view; (ii) perimeter lateral load resisting frame [LSC+MRF]; (iii) location of the LSC's; (iv) connections at column bases; (v) connections for secondary beams and main beams; (vi) secondary beams oriented parallel to the main beams (that are part of the perimeter frames).

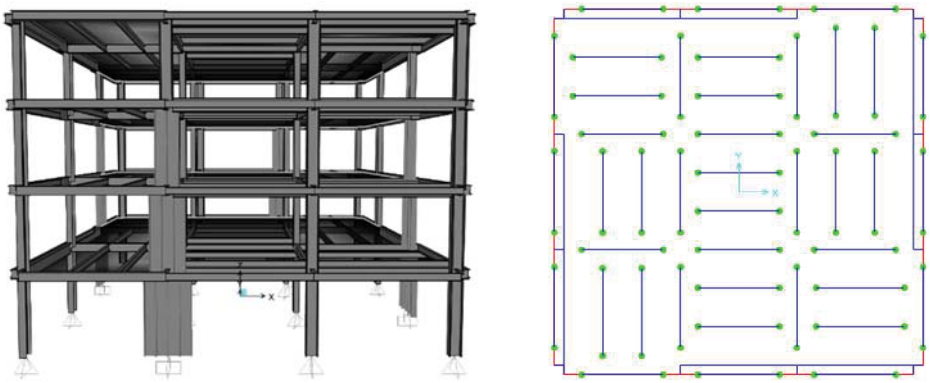


Figure 5: Proposed innovative structural configuration [MRF+LSC]: 3D view and floor layout (with connection characteristics for main and secondary beams)

The cross-section of elements for the lateral force resisting system of the designed innovative structures (in soft and stiff soil conditions) are presented in Table 2. As for the reference structure, the design of the lateral force resisting system was governed by the deformation limitation (corresponding to the serviceability limit state SLS, and/or the ultimate limit state ULS).

Innovative structure located in Soft Soil conditions (T_1=*0.711 sec.*)				Innovative structure located in Stiff Soil conditions (T_1=*0.966 sec.*)			
Floor	Beam	Column	LSC	Floor	Beam	Column	LSC

3	IPE-550	HEB-500	2 x (HEB-500)	3	IPE-450	HEB-400	2 x (HEB-400)
2	IPE-550	HEB-500	3 x (HEB-500)	2	IPE-450	HEB-400	3 x (HEB-400)
1	IPE-550	HEB-500	4 x (HEB-500)	1	IPE-450	HEB-400	4 x (HEB-400)

Table 2: Cross-section of elements for the innovative lateral force resisting system – Soft & Stiff Soil conditions.

3.4.3. Preliminary remarks regarding the use of LSC's

The particularities of standard moment resisting frames (i.e. design governed by deformation limitations, formation of plastic hinges in beams and at column bases) was confirmed during the design process of the two structural systems: standard [MRF] and innovative [MRF+LSC].

The state of a standard designed [MRF] system after a major seismic event would be characterized by large lateral deformations and yielded structural members (dissipative zones of the beams and the base of the columns). Such damages are usually very difficult to repair, making the demolition of the building and replacement by a new one the only available options.

The proposed innovative structural system (see Figure 4b and Figure 5), represents an important step forward towards the aim of providing structural configurations and practical solutions for enhanced resilient and sustainable buildings. From the design of the innovative structural system [MRF+LSC], the use of LSC's evidenced some advantages:

- It provided a change in the load transfer mechanism, i.e. compared to a standard [MRF] the lateral load was distributed among both LSC's and MRF bays;
- The LSC's acted like a "*leaf-spring*" – being characterized by elastic deformations (with a tendency to recover their initial un-deformed shape), and making them good candidates for providing structural re-centering capability;
- The use of LSC's and the change in the load transfer mechanism allowed reducing the cross section of beams and columns, as well as using pinned column base connections.

4 SEISMIC PERFORMANCE EVALUATION

The seismic performance was evaluated through: (i) nonlinear static analyses (pushover) using the N2 method [35]; and (ii) nonlinear dynamic analyses (time-history). Both types of analyses were performed using Sap2000 [31] and considering 3D structural configurations. However, for the current study the seismic action was applied only on "*x*" direction, and the deformations of the structure were blocked in "*y*" direction. Thus, 2D analyses were performed on the 3D structures that include two perimeter lateral load resisting frames on each direction.

4.1 Nonlinear static analyses

The N2 method, developed by Fajfar [35] and comprised in Annex B of EN 1998-1 [30], can be used to verify the seismic performances of buildings designed by current methods (i.e. spectral analysis). The method combines the nonlinear static analysis of a multiple degrees of freedom system (MDOF) with an analysis based on the response spectrum of a single degree of freedom system (SDOF). The lateral story forces were assumed to be proportional to the 1st mode of vibration. Furthermore, the structural performance was evaluated for the limit states shown in Table 3, where "a_{gr}" is the reference peak ground acceleration of *0.3g*, and "a_g" represents the peak ground acceleration for a specific earthquake level.

Limit state	Return period, [years]	Probability of exceedance	a_g/a_{gr}	a_g/g
Damage Limitation (DL / SLS)	95	10% / 10 years	0.5	0.15
Significant Damage (SD / ULS)	475	10% / 50 years	1.0	0.30
Near Collapse (NC)	2475	2% / 50 years	1.7	0.51

Table 3: Limit states and corresponding scaling factors for the seismic input.

For beams subjected to flexure, based on FEMA 356 [36] and Annex B of EN 1998-3 [37], the following acceptance criteria were considered corresponding to the rotation at DL, SD and NC: $1\theta_y$, $6\theta_y$ and $8\theta_y$, where θ_y is the yield rotation. The damage state condition of the plastic hinges (see the results of the structural analyses performed with Sap2000 [32]) associated to three limit states are similar in both codes, and it can be assumed that Immediate Occupancy

(IO) corresponds to Damage Limitation (DL), Life Safety (LS) stands for Significant Damage (SD), and Collapse Prevention (CP) relates to Near Collapse (NC).

From the nonlinear static analyses, a pushover curve (capacity curve) was obtained for each of the four structural configurations: (i) standard [MRF] in soft soil; (ii) innovative [MRF+LSC] in soft soil; (iii) standard [MRF] in stiff soil; and (iv) innovative [MRF+LSC] in stiff soil. Further, using the N2 method, the target displacements (D_t) were obtained for each of the four structural systems, and corresponding to the three seismic intensity levels (i.e. SLS, ULS, NC). Table 4 and Table 5 summarize the values of the computed target displacements corresponding to the standard and innovative structures located in soft and stiff soil, respectively.

	Limit state	a_g/a_{gr}	Standard structure: [**MRF**]	Innovative structure: [**MRF+LSC**]
	DL / SLS	0.5	0.09	0.09
D_t [m]	SD / ULS	1.0	0.17	0.19
	NC	1.7	0.30	0.32

Table 4: Target displacements of standard and innovative structures located in Soft Soil conditions

	Limit state	a_g/a_{gr}	Standard structure: [**MRF**]	Innovative structure: [**MRF+LSC**]
	DL / SLS	0.5	0.09	0.10
D_t [m]	SD / ULS	1.0	0.18	0.20
	NC	1.7	0.31	0.34

Table 5: Target displacements of standard and innovative structures located in Stiff Soil conditions

The outcomes of the nonlinear static analyses are shown in terms of: (i) capacity curve (base shear force vs. top displacement); (ii) the state of the perimeter lateral load resisting frame corresponding to the three seismic intensity levels – SLS, ULS, NC – i.e. at the computed target displacements. It is to be noted that the target displacements are marked on each capacity curve. The outcomes are presented for the following configurations:

- Figure 6 – Standard structure [MRF] located in Soft soil conditions;
- Figure 7 – Innovative structure [MRF+LSC] located in Soft soil conditions;
- Figure 8 – Standard structure [MRF] located in Stiff soil conditions;
- Figure 9 – Innovative structure [MRF+LSC] located in Stiff soil conditions.

Based on the state of each structural configuration (plotted for the three seismic intensity levels – SLS, ULS, and NC), the following observations can be made:

- at the SLS earthquake plastic hinges were developed in beams of both structural systems and soil conditions, but with rotations lower than the corresponding acceptance criteria;
- at ULS and NC earthquake plastic hinges developed in beams and at column bases for the standard MRF's (see Figure 6 and Figure 8), while for the innovative structures [MRF+LSC] – plastic hinges developed only in beams (see Figure 7 and Figure 9) as the column bases were pinned and only the LSC´s were considered with fixed connection; the plastic hinges from beams and/or columns did not reach rotations corresponding to life safety or collapse prevention criteria.

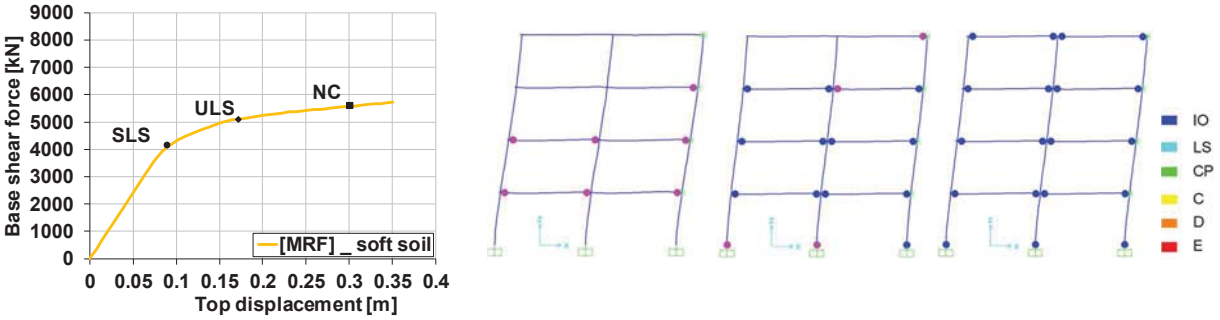

Figure 6: Standard structure located in Soft soil conditions: capacity curve (with marked target displacements) and the state of the perimeter lateral load resisting frame [MRF] at the three seismic intensity levels – SLS, ULS, NC (i.e. a_g/a_{gr}=*0.5; 1.0; 1.7*)

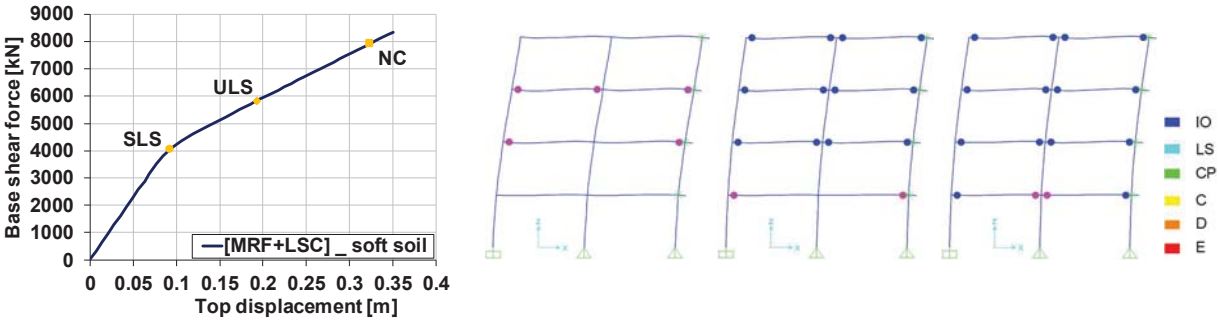

Figure 7: Innovative structure located in Soft soil conditions: capacity curve (with marked target displacements) and the state of the perimeter lateral load resisting frame [MRF+LSC] at the three seismic intensity levels – SLS, ULS, NC (i.e. a_g/a_{gr}=*0.5; 1.0; 1.7*)

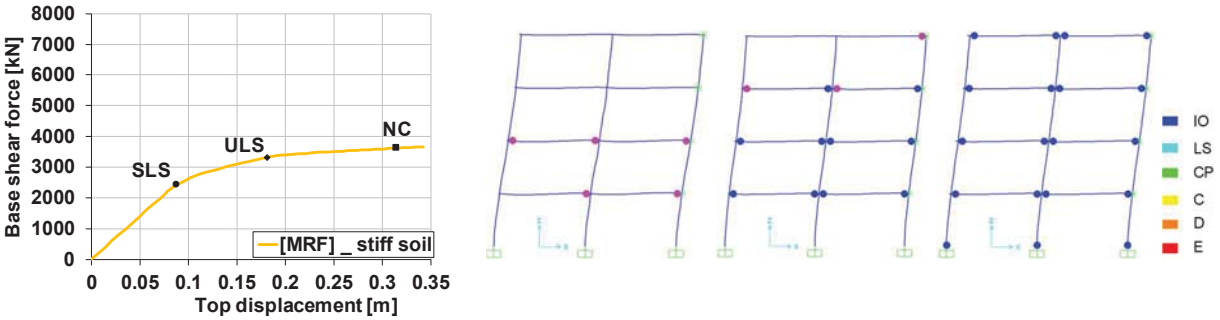

Figure 8: Standard structure located in Stiff soil conditions: capacity curve (with marked target displacements) and the state of the perimeter lateral load resisting frame [MRF] at the three seismic intensity levels – SLS, ULS, NC (i.e. a_g/a_{gr}=*0.5; 1.0; 1.7*)

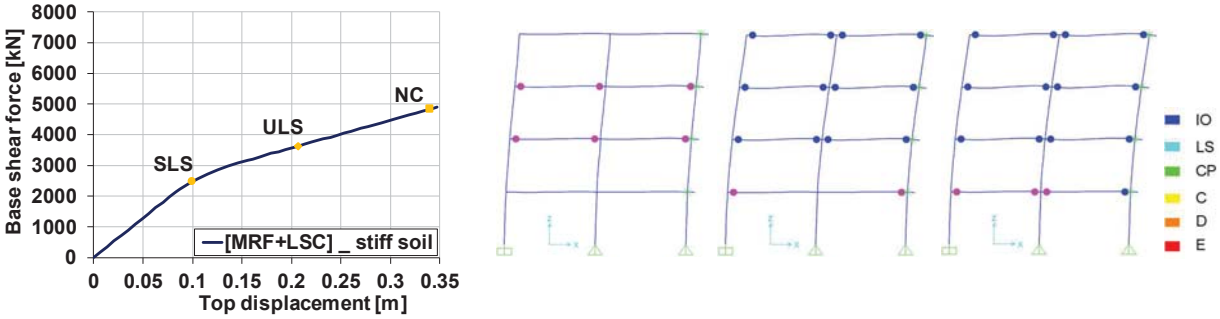

Figure 9: Innovative structure located in Stiff soil conditions: capacity curve (with marked target displacements) and the state of the perimeter lateral load resisting frame [MRF+LSC] at the three seismic intensity levels – SLS, ULS, NC (i.e. a_g/a_{gr}=*0.5; 1.0; 1.7*)

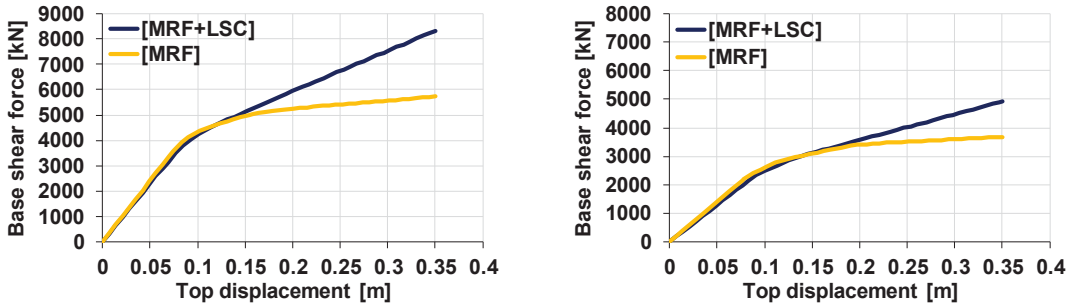
A comparison between the pushover curves of the two structural systems, i.e. standard [MRF] and innovative [MRF+LSC], designed for soft and stiff soil conditions – is shown in Figure 10. As can be observed, the initial stiffness of the two structural systems is similar, but the post-yield response is different:

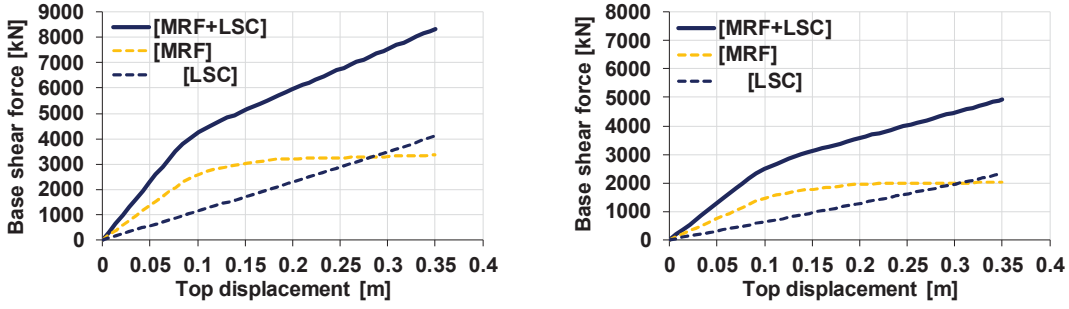
- In case of the standard structure [MRF], the pushover curve is characterized by a relative horizontal tendency (i.e. large deformations with little increase of force).
- In case of the innovative structure [MRF+LSC], the pushover curve is characterized by a linear ascending tendency (where the capacity increases with the deformation).



(a) (b)

Figure 10: Comparison between the pushover curves of the standard [MRF] and innovative [MRF+LSC] structural systems located in: (a) Soft soil conditions; (b) Stiff soil conditions

The improved response of the innovative structures, i.e. bilinear shape with a linear ascending tendency in the post yield region, can be explained by examining the shape of the pushover curves of the two subsystems (LSC's, MRF's with fixed columns). Subsequently, the contribution of each of the two subsystems is illustrated in Figure 11 for both soil conditions. Compared to the MRF subsystems, the LSC's are characterized by a linear-elastic response, with a lower stiffness and capacity (up to a *0.3 m* top displacement). The linear-elastic response of LSC's is therefore responsible for the linear ascending tendency in the post yield region of the [MRF+LSC] structural system and confirms the potential for the re-centering capacity.



(a) (b)

Figure 11: Contribution of the two subsystems (MRF & LSC) corresponding to the innovative structure located in: (a) soft soil conditions; (b) stiff soil conditions

The linear-elastic response of the LSC's modeled using beam elements was checked also using a more advanced finite element modeling procedure, i.e. a pushover analyses were performed on an LSC modeled with shell elements using Abaqus (v2019) platform [38]. The comparison between the capacity curves from Sap2000 [32] and Abaqus (v2019) [38] was very close, and confirmed the modeling procedure used for the current structural configurations. Further numerical studies will be devoted for a more detailed investigation of LSC's.

4.2 Nonlinear dynamic analyses

For the nonlinear dynamic analyses, two sets of seven artificial accelerograms were adopted. The elastic response spectrum of the selected accelerograms is compared in Figure 12 with the corresponding target spectrum (for soft and stiff soil). For soft soil conditions the first mode period for the standard, respectively innovative structure corresponds to: $T_{1\text{-}st}=0.751$ *sec*; $T_{1\text{-}inno}=0.711$ *sec*. Regarding stiff soil, the first mode period for the standard, respectively innovative structure corresponds to: $T_{1\text{-}st}=0.977$ *sec*; $T_{1\text{-}inno}=0.966$ *sec*.

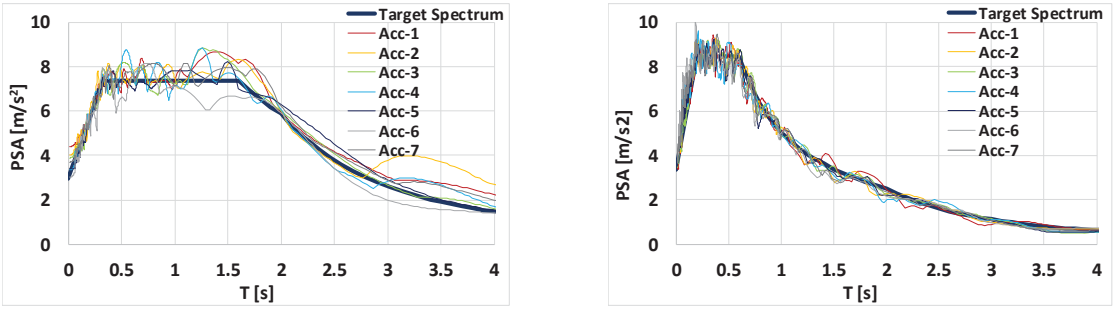


Figure 12: Elastic response spectrum of accelerograms compared to the target spectrum for Soft and Stiff Soil

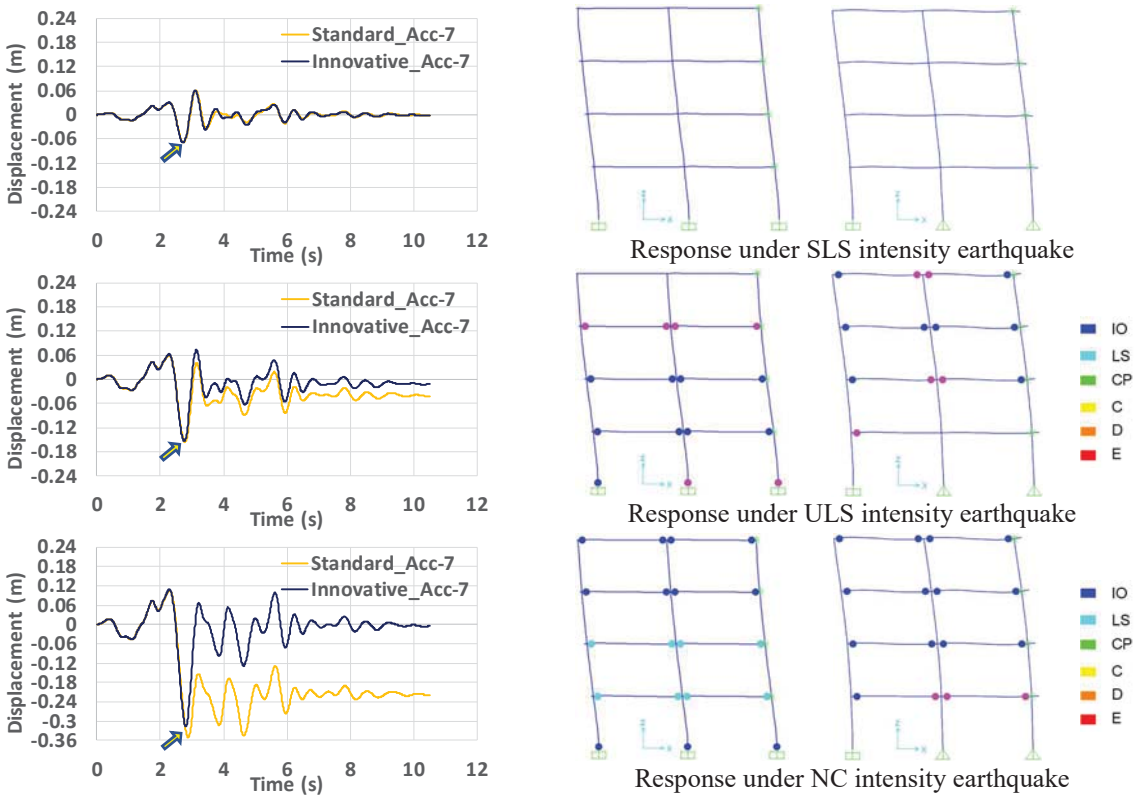
The outcomes of the time-history analyses are presented for both standard and innovative structural configuration in terms of: (i) comparison of the displacement at top floor; (ii) state of frame corresponding to the maximum displacement (i.e. scaled deformed shape with marked plastic hinges). Consequently, the response under one of the most severe accelerograms (i.e. *Acc-7_soft*; *Acc-7_stiff*) at the three intensity levels - SLS (serviceability limit state - $a_g/a_{gr}=0.5$), ULS (ultimate limit state - $a_g/a_{gr}=1.0$), and NC (near collapse - $a_g/a_{gr}=1.7$) - is shown in:

- Figure 13 for standard [MRF] and innovative [MRF+LSC] structures designed for soft soil;
- Figure 14 for standard [MRF] and innovative [MRF+LSC] structures designed for stiff soil.

The time-history analyses under *Soft Soil* conditions (see Figure 13) evidenced the following:

- *at SLS (serviceability limit state – $a_g/a_{gr}=0.5$)*: ▪ plastic hinges did not develop in any of the two structural systems (standard or innovative); ▪ the comparison between displacements at top floor showed almost identical deformations;
- *at ULS (ultimate limit state – $a_g/a_{gr}=1.0$)*: ▪ plastic hinges developed in beams (at three out of four stories) for both structural configurations; ▪ plastic hinges developed at the column bases of the standard structure corresponding to only one accelerogram (i.e. *Acc-7,* see Figure 13); ▪ the comparison between displacements at top floor showed differences with some residual deformations corresponding to the standard structure [MRF];
- *at NC (near collapse – $a_g/a_{gr}=1.7$)*: ▪ a global plastic mechanism was evidenced with plastic hinges in beams and at column bases for the standard [MRF], and with plastic hinges in beams for the innovative structural system [MRF+LSC]; ▪ the comparison between displacements at top floor showed significant differences between standard and innovative structure for five out of seven accelerograms that caused the development of plastic hinges at column bases in the standard [MRF] and which lead to residual deformations (i.e. *Acc-2,3,4,5,7*); ▪ only one case with residual deformations was evidenced for the innovative structural system (i.e. *Acc-6*), however these were not generated by plastic hinges at column bases, but by the plastic hinges in beams (that are planned to be replaceable); ▪ for the standard structure [MRF], the beams at the first two stories developed plastic rotations in the range of 0.021÷0.025 rad (*Acc-2*; *Acc-7* – see Figure 13), that exceeded the life-safety criteria, and which was not observed for the innovative structure [MRF+LSC].

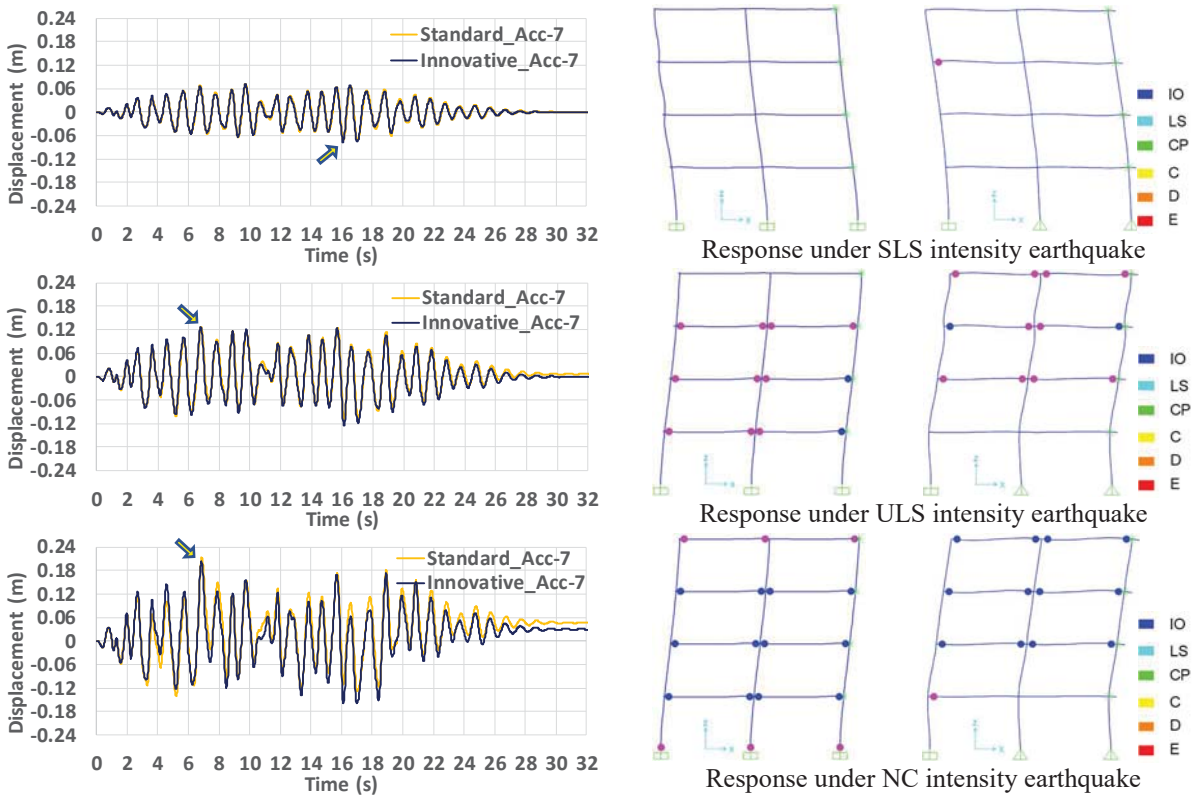


(a) Comparisson of the response (b) Standard structure (c) Innovative structure

Figure 13: Outcomes of time-history analyses for structures in Soft Soil conditions: (a) comparison of the response (top displacement vs. time); (b) & (c) state of standard [MRF] and innovative [MRF+LSC] structures

The time-history analyses under *Stiff Soil* conditions (see Figure 14) evidenced the following:

- *at SLS (serviceability limit state – a_g/a_{gr}=0.5)*: ▪ a minor plastic hinge developed in one beam corresponding to the innovative structure; ▪ the comparison between displacements at top floor showed almost identical deformations;
- *at ULS (ultimate limit state – a_g/a_{gr}=1.0)*: ▪ plastic hinges developed in beams (at three out of four stories) for both structural configurations, but the rotations did not reach the life safety (LS) level; ▪ no plastic hinges developed at the column bases; ▪ the comparison between displacements at top floor showed some differences, i.e. slightly lower deformations corresponding to the innovative structure;
- *at NC (near collapse – a_g/a_{gr}=1.7)*: ▪ a global plastic mechanism was evidenced in case of the standard structural system with plastic hinges in beams and at column bases, while in case of the innovative structure plastic hinges developed in all beams except at first floor; ▪ the comparison between displacements at top floor showed some differences, i.e. the innovative structure [MRF+LSC] evidenced lower deformations, but the differences were not in the same amount as observed for the structural system located in soft soil; ▪ the development of plastic hinges in beams and at column bases for the standard structure [MRF], respectively in beams for the innovative structure [MRF+LSC] lead to residual deformations, however with values lower than *5 cm*; ▪ the plastic hinges did not reach rotations corresponding to life safety in any of the two structural systems.

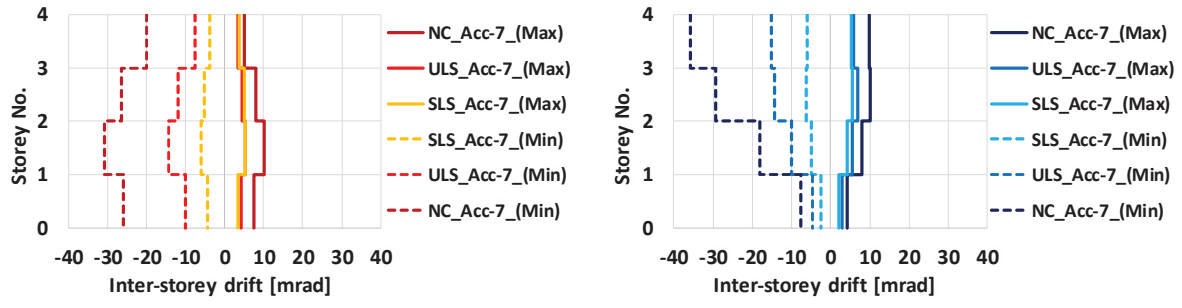


(a) Comparisson of the response (b) Standard structure (c) Innovative structure

Figure 14: Outcomes of time-history analyses for structures in Stiff Soil conditions: (a) comparison of the response (top displacement vs. time); (b) & (c) state of standard [MRF] and innovative [MRF+LSC] structures

The nonlinear dynamic analyses also allowed to evaluate the inter-story drifts corresponding to each: (i) structural configuration (standard / innovative); (ii) soil condition (soft / stiff); (iii) accelerogram (*Acc-1÷Acc-7*); (iv) seismic intensity level (SLS, ULS, NC). Figure 15 and Figure 16 illustrate the inter-story drifts generated by the two accelerograms (i.e. *"Acc-7_Soft", "Acc-7_Stiff"*) within the corresponding structural systems. The following observations can be made:

- the highest inter-story drift within the standard structure [MRF] occurred at the 2nd floor corresponding to both soil conditions and each of the three seismic intensity levels;
- the highest inter-story drift within the innovative structure [MRF+LSC] occurred at the 4th floor corresponding to both soil conditions and each of the three seismic intensity levels;
- the lowest inter-story drift was evidenced at the top floor for the standard structure [MRF], and at the 1st floor for the innovative structure [MRF+LSC];



(a) (b)

Figure 15: Inter-story drifts generated by *"Acc-7_Soft"* within the corresponding structural systems: (a) standard structure [MRF]; (b) innovative structure [MRF+LSC]

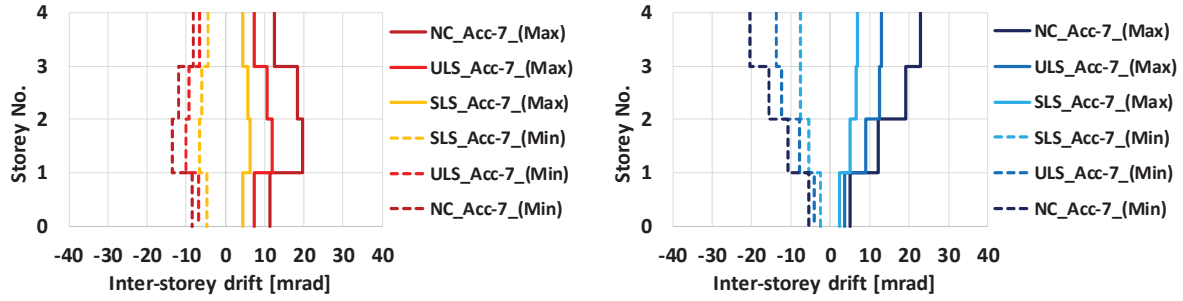


Figure 16: Inter-story drifts generated by *"Acc-7_Stiff"* within the corresponding structural systems: (a) standard structure [MRF]; (b) innovative structure [MRF+LSC]

An improved response of the innovative structures can be observed in Figure 15 and Figure 16 by comparison to the standard structures. In particular, the "*soft-story*" type of mechanism does not occur for the innovative structures, as the maximum (+/-) deformations occur at the top floor. Furthermore, the LSC's have a stiffening effect at the lower part of the structure.

The average of the maximum (+/-) inter-story drift values for the standard and innovative structures, corresponding to each seismic intensity level (SLS, ULS, NC), was computed from the outcomes of the two sets of seven accelerograms. The average values summarized in Table 6 for soft soil conditions and in Table 7 for stiff soil conditions, confirm the observations mentioned above also for other accelerograms.

Story	Standard structure [MRF]			Innovative structure [MRF+LSC]

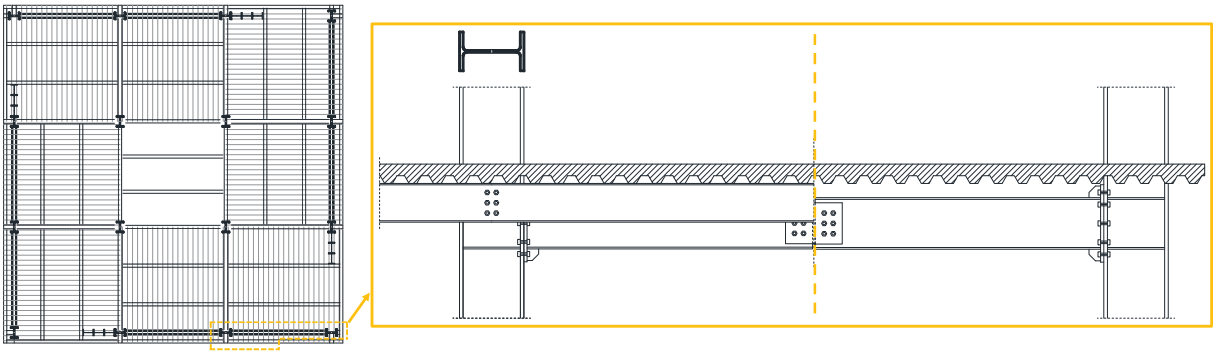
5 SOLUTION FOR THE REPLACEABLE DISSIPATIVE COMPONENTS

An efficient system has to fulfil two requirements: (i) the inelastic deformation should take place only in removable elements; (ii) the damaged dissipative elements must be replaceable. For a structure to be repairable, in addition to constraining the inelastic deformations to the removable dissipative members, any permanent (residual) drift needs to be eliminated, while providing a re-centering capability. As a result, the current study proposes the use of "*leaf-spring*" columns in order to prevent the formation of plastic hinges at the base of the columns,

and to provide the re-centering capability of the structure. In addition, the proposed solution for the replaceable dissipative components is illustrated in Figure 17, and consists of:

- Division of roles between frames, i.e. gravitational load resisting structure (the internal frames) / lateral load resisting structure (the perimeter frames);
- Rearrangement of secondary beams (see Figure 17a), i.e. with a parallel orientation to the main beams (i.e. those which are part of the lateral load resisting frame);
- Secondary beams from the façade are aimed to support the concrete slab and the façade elements (see Figure 17b);
- The replaceable dissipative components (i.e. the main beams) are to be decoupled from secondary beams and the concrete slab, and realized from two parts connected at mid span through a simple/continuous bolted connection (see Figure 17c).



(a) (b) (c)

Figure 17: Proposed solution for the replaceable dissipative components: (a) floor layout – with arrangement of columns / main beams / secondary beams / steel deck for the concrete slab; (b) secondary beams from the façade; (c) replaceable dissipative components (main beams decoupled from secondary beams and concrete slab).

The proposed solution for replaceable dissipative components has the following advantages:

- The dissipative components (i.e. the main beams) are easy to inspect and to replace as these are manufactured from two parts that can be individually dismantled, and the weight is reduced to half;
- Even though the replacement of the dissipative beams might take some effort, it is much more favorable compared to demolishing the building and constructing a new one;
- The beam-to-column joints can be designed as full-strength/full-rigid joints and detailed based on existing connection solutions in seismic regions.

6 CONCLUSIONS

The current research represents an attempt to face the challenges of the construction sector and to respond to the two vision documents from U.S. [28] and Europe [29]. In particular, the research aims at reducing the repair costs and downtime of a structure hit by natural hazards (i.e. earthquakes), and consequently at a more rational design approach in the context of sustainability. Both replaceable dissipative components and structural re-centering capability are being addressed. In brief, the research activities consist in developing a set of bolted beam-to-column joints with replaceable dissipative components and investigating the applicability potential of innovative "*leaf-spring*" columns into building frames.

A structural configuration benchmark was developed for a 3D multi-story building. In a first stage, two standard structural configurations with perimeter moment resisting frames (MRF's) were designed for soft and stiff soil conditions (with a PGA of a_g=*0.3g*). Using the standard

structures [MRF] as reference, a set of innovative structural configurations [MRF+LSC] were developed and designed for the same loading and soil conditions. The inelastic response of the structures was evaluated through nonlinear static (pushover) and dynamic (time-history) analyses. A detailed description of the seismic performance was presented in Section 4.1 and 4.2. In brief, both structural systems evidenced an appropriate seismic performance, i.e.:

- *at SLS*: an elastic response of the standard [MRF] and innovative [MRF+LSC] structures;
- *at ULS*: plastic hinges developed in beams (at three out of four stories) for both structural configurations, but the rotations did not reach the life safety (LS) level;
- *at NC*: ▪ a global plastic mechanism was evidenced with plastic hinges in beams and at column bases for the standard [MRF], respectively with plastic hinges in beams for the innovative structural system [MRF+LSC]; ▪ for the standard structure [MRF] in soft soil conditions, some plastic hinges in beams reached rotations corresponding to life safety.

From the design and investigation of the two structural configurations, the soft soil conditions proved to be a more severe loading case and lead to: (i) higher cross-section of members; (ii) larger inter-story deformations and displacements at top floor; (iii) higher rotations in plastic hinges (i.e. life safety level was reached in some plastic hinges).

From the design and analyses of the innovative structural system [MRF+LSC], the use of LSC's evidenced some advantages and/or improvement of the structural response:

- It provided a change in the load transfer mechanism, i.e. compared to a standard MRF, the lateral load was distributed among both "*leaf-spring*" columns and MRF bays;
- The LSC's were characterized by a linear-elastic response, with a lower stiffness and capacity (up to a *0.3 m* top displacement) compared to the MRF subsystem;
- The use of LSC's and the change in the load transfer mechanism allowed to reduce the cross-section of beams and columns from the perimeter lateral load resisting frames, and to use pinned connections for the base of the columns;
- An improved response of the innovative structures, i.e. capacity curve with a linear ascending tendency in the post yield region;

A solution was proposed for beam-to-column joints with replaceable dissipative components (see Section 5), that will be further investigated along with the novel "*leaf-spring*" columns. Based on the outcomes of the current study, it can be stated that, compared to the standard structure [MRF] which does not possess any noteworthy re-centering capability, the innovative structural system [MRF+LSC] evidenced an improved seismic performance and increased resilience. The proposed structural system [MRF+LSC] and joining solution have the following advantages and/or improvement of the structural response:

- The [MRF] subsystem is the main lateral force resisting component (especially at the top floors) and the main seismic energy dissipation system – see pushover curve in Figure 11;
- The [LSC] subsystem is the secondary lateral force resisting component (see Figure 11) and provides (through its elastic response) the re-centering capability of the structure;
- The [LSC] subsystem: (i) contributes to the stiffening of the structure at the lower part; (ii) allows to use simple connections for the other columns and to reduce the cross-sections of beams and columns; (iii) prevents the formation of plastic hinges at column bases;
- The dissipative components (i.e. the main beams) are easy to inspect and to replace, as these are manufactured from two parts that can be individually dismantled and the weight is reduced to half;
- Even though the replacement of the dissipative beams might take some effort, it is much more favorable compared to demolishing the building and constructing a new one;

- The beam-to-column joints can be designed as full-strength/full-rigid joints, and detailed based on existing connection solutions in seismic regions.

Within the current study, the innovative structural configurations contained one LSC for each perimeter lateral load resisting frame. Consequently, two LSC's acted on each of the two main directions. This resulted in high demands and the necessity of using profiles of S700 high strength steel (eventually profiles manufactured from welded S700 plates of equivalent thickness). In order to keep the LSC's in the elastic range, but without using profiles of high strength steel, another solution would be to re-design the innovative structures by considering additional LSC's. Thus, the demands within LSC's and on the foundations would decrease.

The ongoing and future research activities are devoted to further investigate the proposed solution for structural re-centering ("*leaf-spring*" columns – LSC's) and replaceable dissipative components. Advanced finite element numerical simulations and eventually experimental investigations will be carried out. Structural analyses will be performed considering natural ground motion records, as well as building configurations with additional stories. A technical and economical comparison between the conventional and the more resilient and sustainable structural system (with replaceable components and re-centering capability) will be performed.

Keywords: Tensile strain, Cracking, Structural elements, Width

Abstract. *The main objective of this research is to study the phenomenon of cracking in the vertical structural elements of R/C constructions, in particular the columns and the walls, and more particularly in the extreme regions of the walls, namely the boundary columns. Various parameters of the phenomenon of cracking will be studied, e.g. load influence, tensile strain, etc. It has to be noted the fact that load application is a monotonic axial tensile loading that simulates the strain condition that takes place at the boundary edges of reinforced concrete seismic walls. Specifically, this type of loading simulates the tensile loading that takes place during the first semi-cycle of loading under seismic dynamic events. Experimental research takes place by the construction and use of a group of 4 experimental specimens subjected to different degrees of elongation. This test group examines the tensile parameter and how it affects the cracking. The test specimens in question are all reinforced with the same longitudinal reinforcement ratio (4.02%) and subjected to tensile degrees 10‰, 20‰, 30‰ and 50‰. Significant conclusions are reached on cracking, e.g. its extent, the size of the cracks, their positions, minimum crack width, maximum crack width, average crack width, number of cracks, etc.*

1 INTRODUCTION

Several international researchers have explored the phenomenon of cracking in reinforced concrete structures [1]–[23]. Although most of the given structures are typically reinforced in two directions, most studies carried out worldwide to investigate the behaviour of cracking have involved uniaxially tensiled reinforced concrete members with reinforcement in only one direction. To date there is not yet a widely established and accepted methodology for predicting cracking characteristics, e.g. crack widths and spacings between cracks [7], [9], [10], [23]–[26]. In addition, most of the existing research conducted has been strictly limited to the state of the stabilized crack pattern only and does not involve cracking behaviour and crack characteristics deep in the yield region [27], [28].

In the framework of the current study, an experimental program has been conducted involving reinforced concrete members detailed in two directions using longitudinal rebars and transverse reinforcement in the form of ties. This is a common construction practice used in at least the vast majority of concrete structures. As per the results outlined within this work, cracking behaviour and the crack characteristics are discussed. Useful conclusions concerning cracking under different degrees of elongation are derived. The experimental procedure of the current study has taken place in Aristotle University of Thessaloniki at the Laboratory of Strength of Materials but the result analysis has taken place in Democritus University of Thrace.

2 EXPERIMENTAL PROGRAM

2.1 Detailing of Test Specimens

The current experimental program consists of four test specimens. The thickness of each specimen is 7.5 cm and the length of the cross-section is 15 cm. The ratio between the length and the thickness of the cross-sectional area is equal to 2, which is a typical ratio for constructing reinforced concrete columns. The total height of the test specimen is equal to 90 cm. Each of the four specimens is subjected to a uniaxial central tensile loading. The main test element is between the metal plates and its height is 64 cm (Figure 1).

Table 1 shows the geometrical and detailing characteristics of all four specimens. All four segments tested here have been worked on in two directions through deformed bars in terms of reinforcement. The reinforcement of each specimen simulates a typical reinforcement found in the reinforced concrete columns of typical construction buildings or in the confined boundaries of reinforced concrete seismic walls. The construction scale used to simulate typical columns or typical confined boundaries was equal to 1:3, which is commonly used for research purposes worldwide [29], [30].

The number of longitudinal bars is equal to four. Each bar is placed at each corner of the column specimen and has a diameter of 12 mm. The longitudinal reinforcement ratio is equal to 4.02%. The transverse reinforcement consists of transverse ties placed along the height of the prism. The centre-to-centre distance between two ties is about 3.3 cm and the diameter of each tie is 4.2 mm. The only variable differentiating specimens from each other is the tensile strain. The nominal tensile strain takes values equal to 10.00%, 20.00%, 30.00% and 50.00%. It is well known that in real constructions, tensile strains up to 30.00% have been observed [31], [32]. Also, modern seismic and concrete codes have related provisions allowing large tensile strains for reinforcement bars [33]–[37]. These are the reasons why such large tensile strains were chosen to be applied to the elements. There is also, of course, the research interest itself, in examining what happens to cracking characteristics strained to such extents and their behaviour when such large strains are observed.

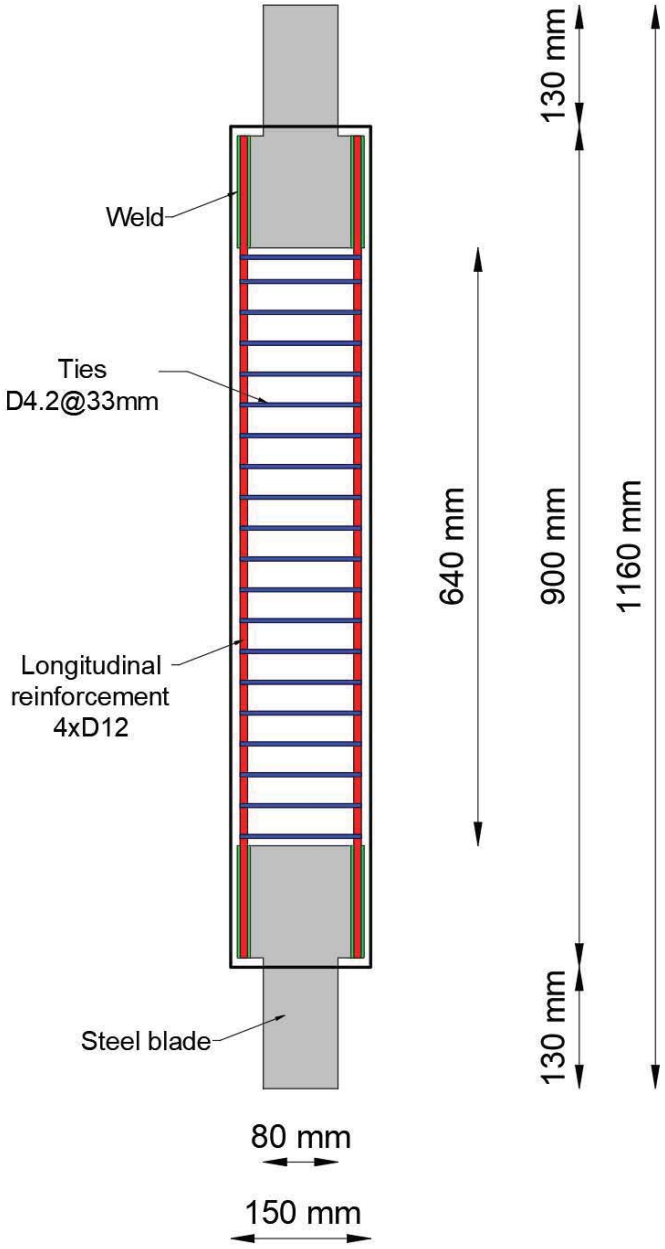

Figure 1: Vertical reinforcement layout for specimens.

N/A	Specimen name	Dimensions (cm)	Longitudinal reinforcement	Longitudinal reinforcement ratio [ρ_l] (%)	Transverse reinforcement	Nominal tensile strain (‰)
1	C-10	15x7.5x64	4xD12	4.02	D4.2@33 mm	10.00
2	C-20	15x7.5x64	4xD12	4.02	D4.2@33 mm	20.00
3	C-30	15x7.5x64	4xD12	4.02	D4.2@33 mm	30.00
4	C-50	15x7.5x64	4xD12	4.02	D4.2@33 mm	50.00

Table 1: Geometrical and detailed properties of element specimens

2.2 Loading Test Setup

A universal testing machine was used to apply the load. For example, for specimen C-20, the nominal degree of elongation is 20.00‰. Figure 2 displays the experimental configuration for imposing the tensile load. The rate of loading was slow, of the order of 4 mm/min, so no result was affected by the influence of the strain rate [38]–[40].

Figure 2: Loading test configuration.

3 RESULTS AND DISCUSSION

3.1 Experimental Findings

Figure 3 presents the change of tensile strain relative to the tensile load imposed on the test elements. It is obvious that specimens with a high nominal degree of elongation are subjected to high tensile strains too and vice versa. It is noted that the nominal degrees of tensile strain (10‰, 20‰, 30‰, 50‰) are slightly different from the residual actual tensile degrees, but these differences are small and negligible.

After conducting the experiments, different cracking formations and eventually cracking characteristics were noticed for each specimen. Figure 4 shows the state of each specimen after the end of the uniaxial tensile test. Cracks of small width are obvious for specimens with low degrees of tensile strain (10‰ and 20‰), while cracks of moderate and large width are present for specimens strained under larger degrees of elongation (30‰ and 50‰). It is apparent that the final cracking formation differs between the specimens, depending on the tensile strain they have sustained.

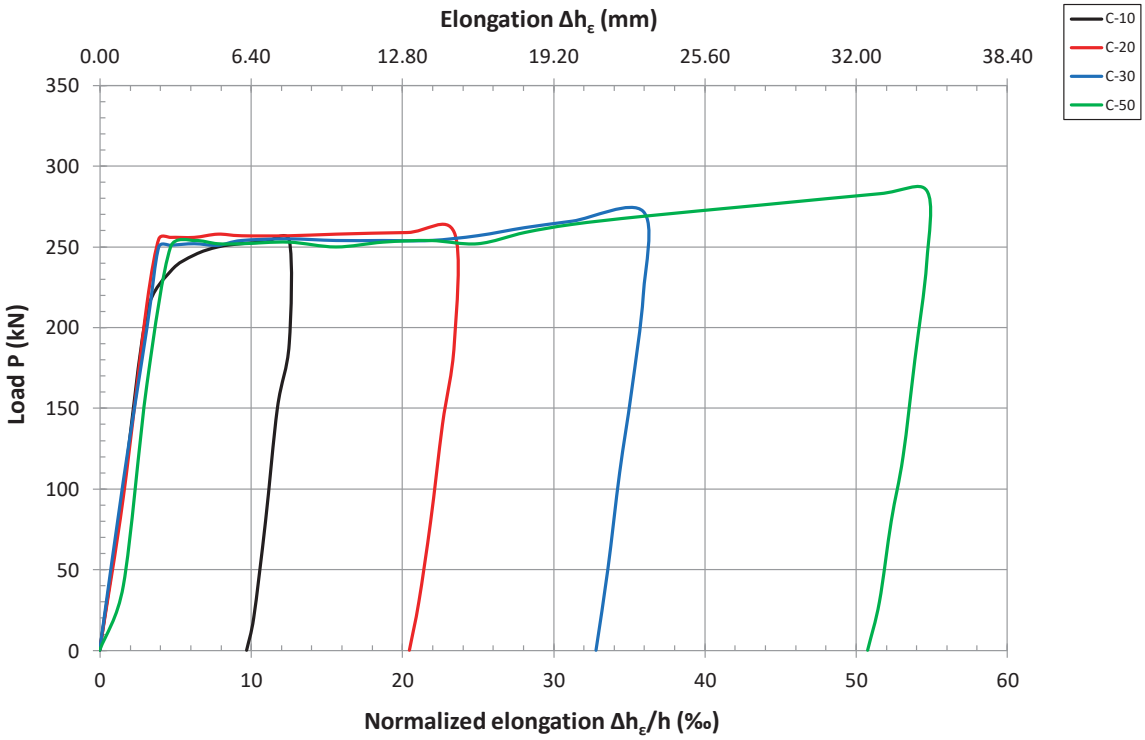

Figure 3: Diagram of tensile load versus elongation.

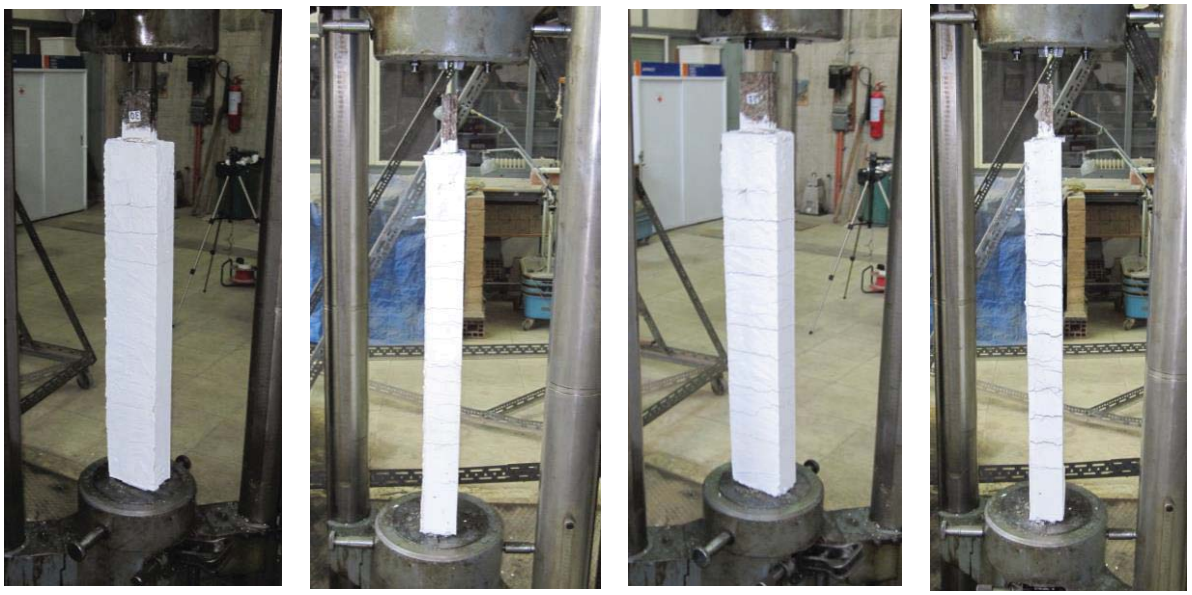

(a) **(b)** **(c)** **(d)**

Figure 4: Specimens after the uniaxial tensile test: (a) C-10, (b) C-20, (c) C-30, (d) C-50.

3.2 Analysis of Experimental Findings

The results of the analysis of the test findings for all segments are brought together in the following table and diagrams. Table 2 presents the width characteristics of the cracks. Figure 5 displays the variation of the crack width characteristics. Figure 6 – Figure 9 use bar charts to display the results for the same type of cracking characteristics, e.g. minimum width, average width, etc.

N/A	Specimen	Number of cracks [N]	Minimum crack width [W_{min}] (mm)	Maximum crack width [W_{max}] (mm)	Average crack width [W_{ave}] (mm)	W_{min}/W_{ave}	W_{max}/W_{ave}	W_{max}/W_{min}
1	C-10	5	0.6	1.5	1.100	0.55	1.36	2.50
2	C-20	9	0.5	2.0	1.256	0.40	1.59	4.00
3	C-30	10	1.0	2.9	1.810	0.55	1.60	2.90
4	C-50	11	2.1	3.8	3.064	0.69	1.24	1.81

Table 2: Crack width characteristics.

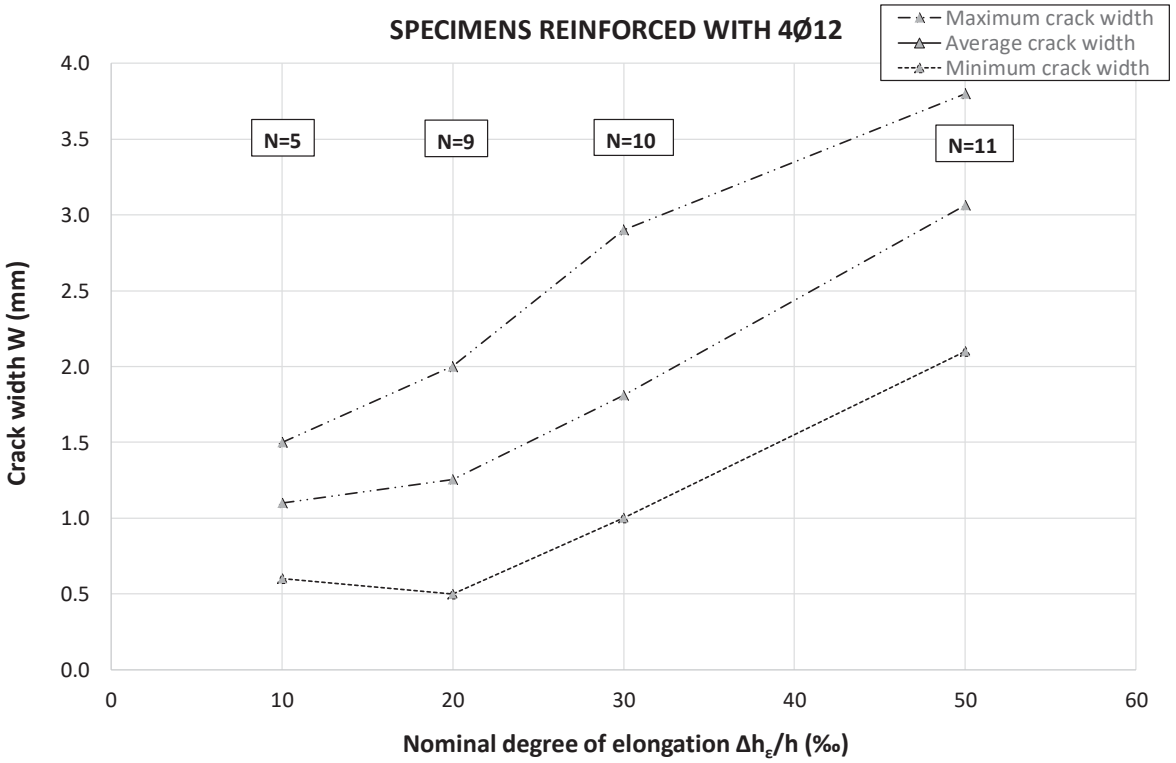

Figure 5: Change of crack width relative to the degree of elongation.

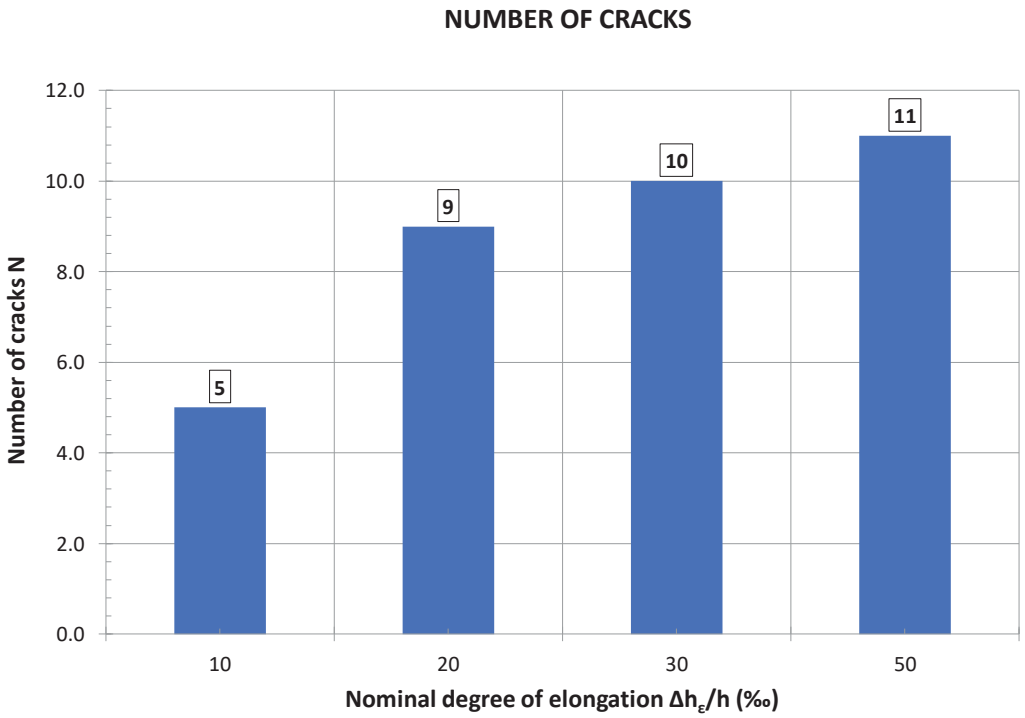

Figure 6: Bar chart of number of cracks regarding the degree of elongation.

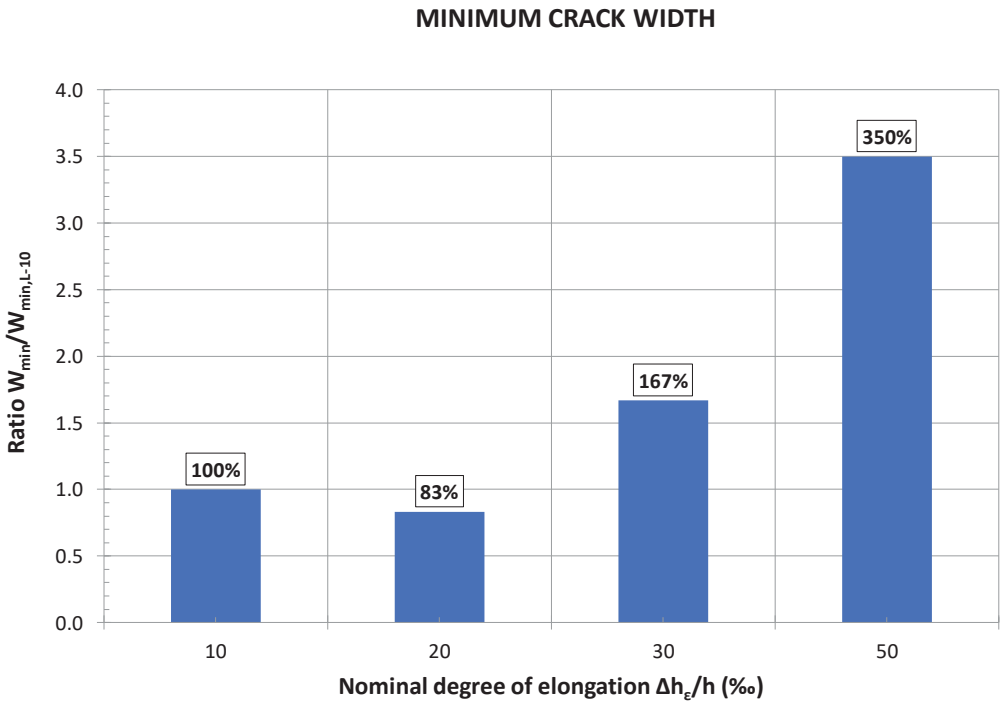

Figure 7: Bar chart of minimum crack width as a percentage of the minimum crack width of the reference specimen.

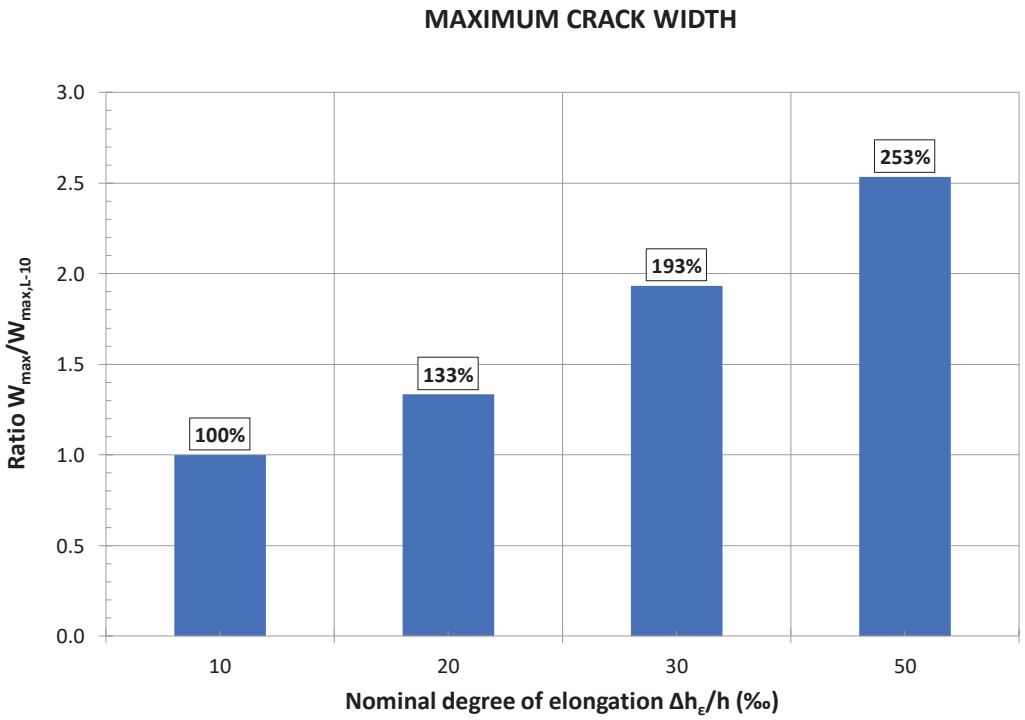

Figure 8: Bar chart of maximum crack width as a percentage of the maximum crack width of the reference.

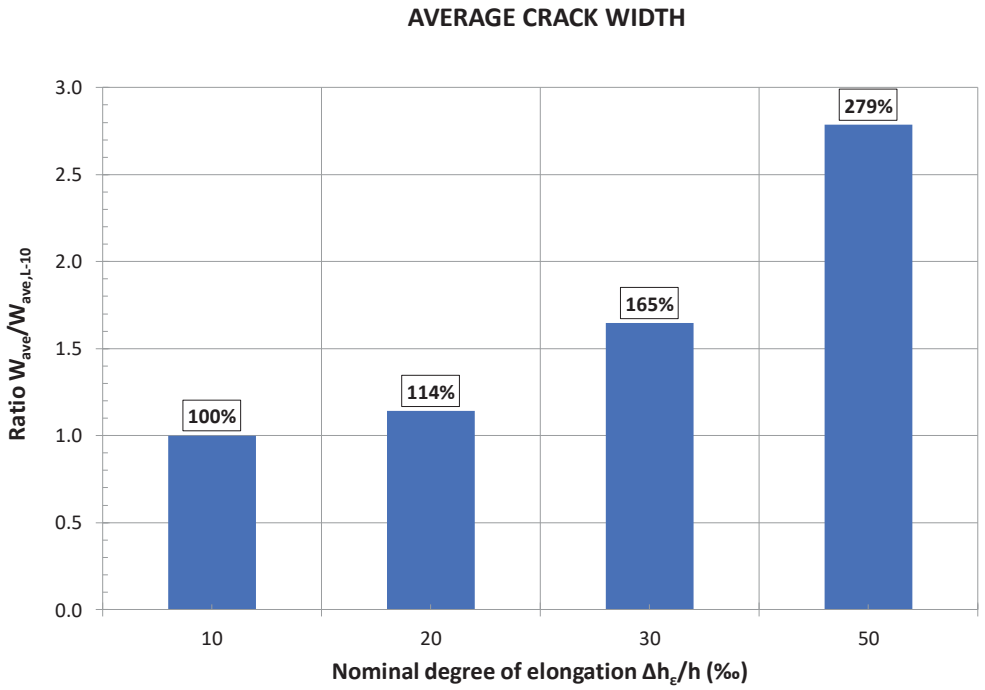

Figure 9: Bar chart of average crack width as a percentage of the average crack width of the reference specimen.

The experimental findings of the test elements were then analysed and evaluated:

1. Comparing the number of cracks formed with the tensile strain applied, it is obvious that the number of cracks formed increases with the increase of the degree of tensile strain applied (Table 2, Figure 6). For a better understanding of this phenomenon, more experiments concerning different longitudinal reinforcement ratios and arrangements of rebars need to be performed.
2. Comparing the crack width with the degree of elongation applied, it can be seen that the width becomes larger as the elongation degree sustained increases (Table 2, Figure 5). It is noteworthy that all types of crack width increase with the increment of the tensile degree – meaning the minimum, maximum and average crack width.
3. Specimen C-10 is characterized as the reference specimen. It is noticeable that although the normalized elongation (30‰) is three times greater for specimen C-30 compared to the elongation of the reference specimen (10‰), the increase of the minimum crack width is 1.67 times higher (167%). In all cases, the increase of their minimum crack width is smaller than the increase of the corresponding degree of elongation.
4. The increase of the average widths is smaller, too compared to the increase of normalized elongation, e.g., specimen C-30 displays a 165% increase in average crack width for a 300% elongation increase compared to the reference specimen.
5. The damage state of specimens indicates that cracks appear at or near to the tie positions (Figure 4). Thus, the presence of steel ties helps and promotes the disorganization of concrete around them.

4 CONCLUSIONS

This paper looks at four specimens to investigate cracking formation and behaviour in terms of the number of cracks and their width. The following conclusions are drawn:

1. The degree of tensile deformation holds a significant part in terms of the formation of cracks and their characteristics, e.g. the number of cracks formed and the width of cracks – whether considering the minimum, maximum or average value.
2. Higher degrees of elongation result in cracks with larger widths. Thus, the design of reinforced concrete structural components should take into account the degree of elongation because, as it is well known, large crack widths can lead to oxidization and deterioration of rebars and eventually affect structural safety.
3. The question arises of whether the longitudinal ratio or whether the arrangement of rebars plays an essential role, too. Further research is needed on the subject using test specimens with different longitudinal reinforcement ratios and arrangements. This will help to check the impact of the mechanical factor of reinforcement ratio has.

Keywords: Longitudinal ratio, Cracking, Spacing, Width

Abstract. *Cracking phenomenon in reinforced concrete members has troubled researchers and engineers worldwide due to the many mechanical parameters affecting this phenomenon. One such mechanical parameter is the longitudinal reinforcement ratio used for the detailing of vertical structural components in reinforced concrete structures. Although, the percentage of rebar content has been studied, it is the first time that cracking behavior is studied using varying ratios of rebars strained under a uniaxial tensile loading till a high degree of elongation found only at buildings sustained severe earthquake actions.*

This research is both experimental. For the experimental part, 8 test specimens in the form of R/C ties are used and strained using a monotonic uniaxial tensile loading simulating the tensile type of loading during the first cycle of dynamic seismic action. The first four test specimens are reinforced with longitudinal reinforcement ratio equal to 1.79% and the other four test specimens are reinforced with longitudinal reinforcement ratio equal to 3.19%. The test specimens are subjected to tensile degrees 10‰, 20‰, 30‰ and 50‰. Significant conclusions are reached concerning cracking behavior for different longitudinal ratios, e.g. number of cracks, crack width, crack spacing, etc.

1 INTRODUCTION

Cracking phenomenon and its characteristics has been explored by several researchers worldwide in reinforced concrete structures [1]–[23]. Although most of the given structures are typically reinforced in two directions, most studies carried out worldwide to investigate the behaviour of cracking have involved uniaxially tensiled reinforced concrete members with reinforcement in only one direction. To date there is not yet a widely established and accepted methodology for predicting cracking characteristics, e.g. crack widths and spacings between cracks [7], [9], [10], [23]–[26]. In addition, most of the existing research conducted has been strictly limited to the state of the stabilized crack pattern only and does not involve cracking behaviour and crack characteristics deep in the yield region [27], [28].

In the framework of the current study, an experimental program has been conducted involving reinforced concrete members detailed in two directions using longitudinal rebars and transverse reinforcement in the form of ties. The main aim of the present study is to investigate the influence of the longitudinal reinforcement ratio. As per the results outlined within this work, cracking behaviour and the crack characteristics are discussed. Useful conclusions concerning cracking under different longitudinal reinforcement ratios are derived. The experimental procedure of the current study has taken place in Aristotle University of Thessaloniki at the Laboratory of Strength of Materials and the result analysis has taken place in Democritus University of Thrace.

2 EXPERIMENTAL PROGRAM

2.1 Detailing of Test Specimens

The current experimental program consists of eight test specimens. The thickness of each specimen is 7.5 cm and the length of the cross-section is 15 cm. The ratio between the length and the thickness of the cross-sectional area is equal to 2, which is a typical ratio for constructing reinforced concrete columns. The total height of the test specimen is equal to 90 cm. Each of the eight specimens is subjected to a uniaxial central tensile loading. The main test element is between the metal plates and its height is 64 cm (Figure 1).

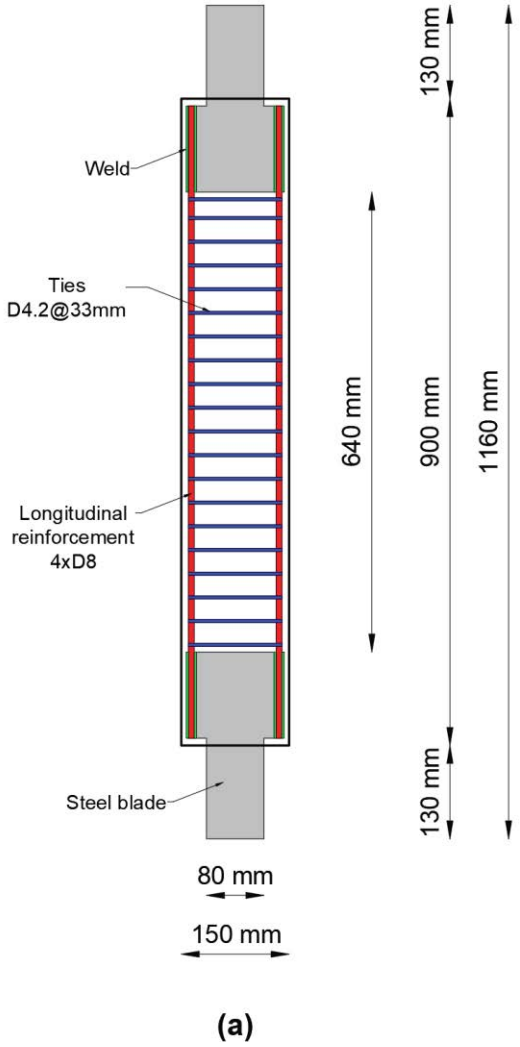

Figure 1: Vertical reinforcement layout for specimens reinforced with ratio equal to 1.79%.

Table 1 shows the geometrical and detailing characteristics of all eight specimens. There are two groups of test specimens. Each group consists of four test specimens. The reinforcement of each specimen simulates a typical reinforcement found in the reinforced concrete columns of typical construction buildings or in the confined boundaries of reinforced concrete seismic walls. The scale of construction used to simulate typical columns or typical confined boundaries was equal to 1:3, which is commonly used for research purposes worldwide [29], [30].

The number of longitudinal bars varies depending if the specimen belongs to the first group or the second group of test specimens. The longitudinal reinforcement ratio is equal to 1.79% for the first group of specimens and equal to 3.19% for the second group of specimens. The transverse reinforcement consists of transverse ties placed along the height of the prism. The axial distance between two ties is about 3.3 cm and the diameter of each tie is 4.2 mm. The only variable differentiating the two groups of specimens from each other is the longitudinal reinforcement ratio. The nominal tensile strain takes values equal to 10.00%, 20.00%, 30.00% and 50.00% for the four specimens of both groups. It is well known that in real constructions, tensile strains up to 30.00% have been observed [31], [32]. Also, modern seismic and concrete codes have related provisions allowing large tensile strains for reinforcement

bars [33]–[37]. These are the reasons why such large tensile strains were chosen to be applied to the elements. There is also, of course, the research interest itself, in examining what happens to cracking characteristics strained to such extents and their behaviour when such large strains are observed.

N/A	Specimen name	Length (cm)	Thickness (cm)	Effective height (cm)	Longitudinal reinforcement	Longitudinal reinforcement ratio [ρ_l] (%)	Transverse reinforcement	Nominal tensile strain (‰)
1	L-10	15	7.5	64	4xD8	1.79	D4.2@33 mm	2.75
2	L-20	15	7.5	64	4xD8	1.79	D4.2@33 mm	2.75
3	L-30	15	7.5	64	4xD8	1.79	D4.2@33 mm	2.75
4	L-50	15	7.5	64	4xD8	1.79	D4.2@33 mm	2.75
5	H-10	15	7.5	64	4xD8 + 2xD10	3.19	D4.2@33 mm	3.19
6	H-20	15	7.5	64	4xD8 + 2xD10	3.19	D4.2@33 mm	3.19
7	H-30	15	7.5	64	4xD8 + 2xD10	3.19	D4.2@33 mm	3.19
8	H-50	15	7.5	64	4xD8 + 2xD10	3.19	D4.2@33 mm	3.19

Table 1: Geometrical and detailed properties of prism specimens

2.2 Loading Test Setup

A universal testing machine was used to apply the load. For example, for specimen C-20, the nominal degree of elongation is 20.00‰. Figure 2 displays the experimental configuration for imposing the tensile load. The rate of loading was slow, of the order of 4 mm/min, so no result was affected by the influence of the strain rate [38]–[40].

Figure 2: Loading test configuration.

3 RESULTS AND DISCUSSION

3.1 Experimental Findings

Figure 3 presents the change of tensile strain relative to the tensile load imposed on the test elements for both groups of test specimens. It is obvious that specimens with a high longitudinal reinforcement ratio demand higher load values to be strained to the same degree of elongation compared to the specimens reinforced with low percentages of reinforcement.

After conducting the experiments, different cracking formations and eventually cracking characteristics were noticed for each specimen. Figure 4 shows the state of each specimen after the end of the uniaxial tensile test. Cracks of small width are obvious for specimens with low degrees of tensile strain (10‰ and 20‰), while cracks of moderate and large width are present for specimens strained under larger degrees of elongation (30‰ and 50‰). It is apparent that the final cracking formation differs between the specimens, depending on the tensile strain they have sustained.

Figure 4: Specimens after the uniaxial tensile test: (a) L-10, (b) L-20, (c) L-30, (d) L-50, (e) H-10, (f) H-20, (g) H-30, (h) H-50.

3.2 Analysis of Experimental Findings

The results of the analysis of the test findings for all segments are brought together in the following table and diagrams. Table 2 presents the width characteristics of the cracks. Figure 5 displays the variation of the crack width characteristics for low-reinforced specimens, while

Figure 6 displays the same but this time for high-reinforced specimens. Figure 7 uses bar charts to display the number of cracks formed for both groups of test specimens, while Figure 8 uses, again, bar charts to display this time the results for the average crack width for low and high reinforcement specimens.

N/A	Specimen	Number of cracks [N]	Minimum crack width [W_{min}] (mm)	Maximum crack width [W_{max}] (mm)	Average crack width [W_{ave}] (mm)	W_{min}/W_{ave}	W_{max}/W_{ave}	W_{max}/W_{min}
1	L-10	9	0.2	1.5	0.844	0.24	1.78	7.50
2	L-20	9	1.2	2.3	1.678	0.72	1.37	1.92
3	L-30	9	1.4	3.1	2.311	0.61	1.34	2.21
4	L-50	9	1.9	6.7	3.811	0.50	1.76	3.53
5	H-10	11	0.2	1.0	0.655	0.31	1.53	5.00
6	H-20	12	0.2	1.5	1.050	0.19	1.43	7.50
7	H-30	13	0.6	2.0	1.354	0.44	1.48	3.33
8	H-50	13	0.8	3.2	2.277	0.35	1.41	4.00

Table 2: Crack width characteristics.

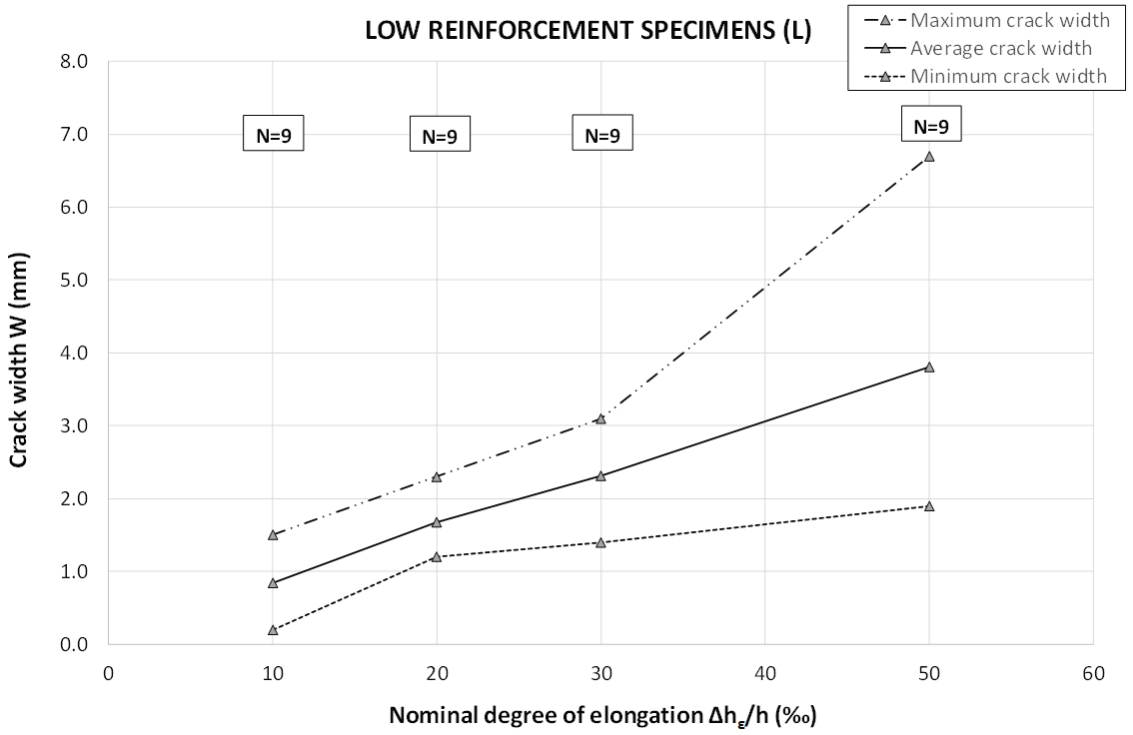

Figure 5: Change of crack width relative to the degree of elongation (low reinforcement specimens).

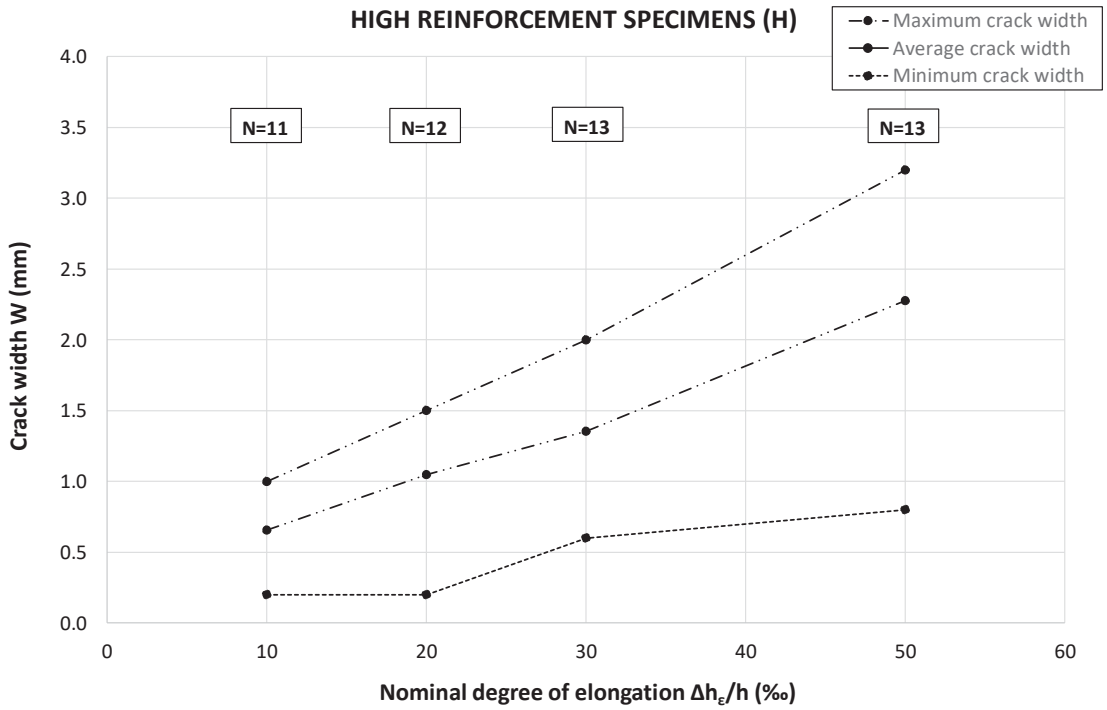

Figure 6: Change of crack width relative to the degree of elongation (high reinforcement specimens).

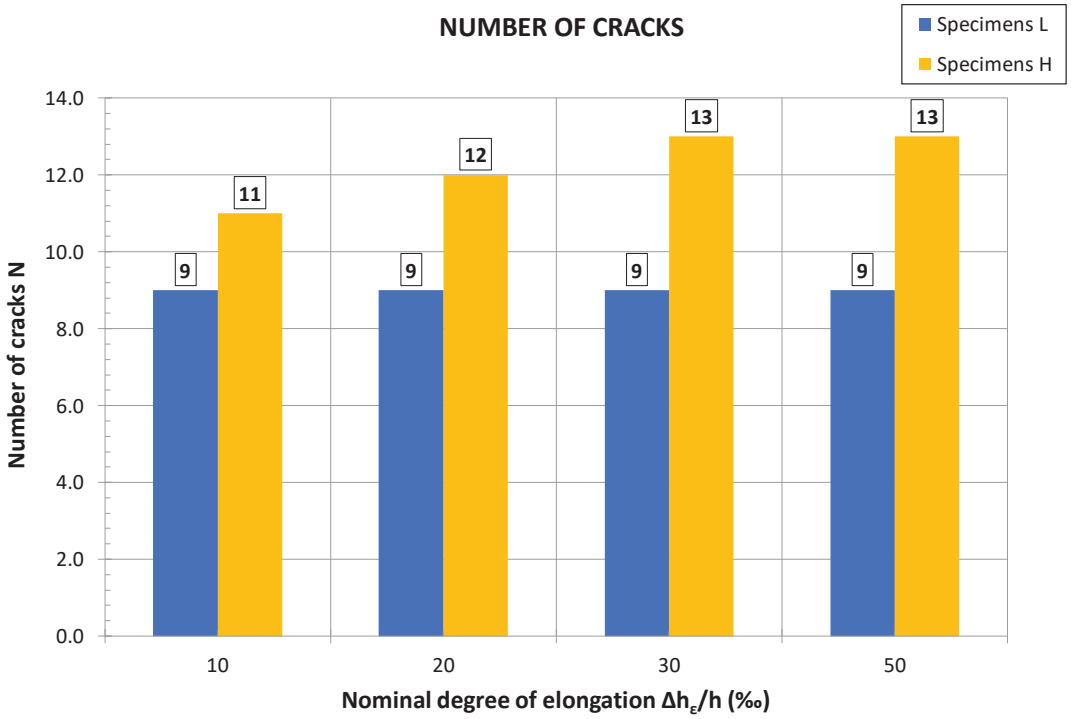

Figure 7: Bar chart of number of cracks regarding the degree of elongation.

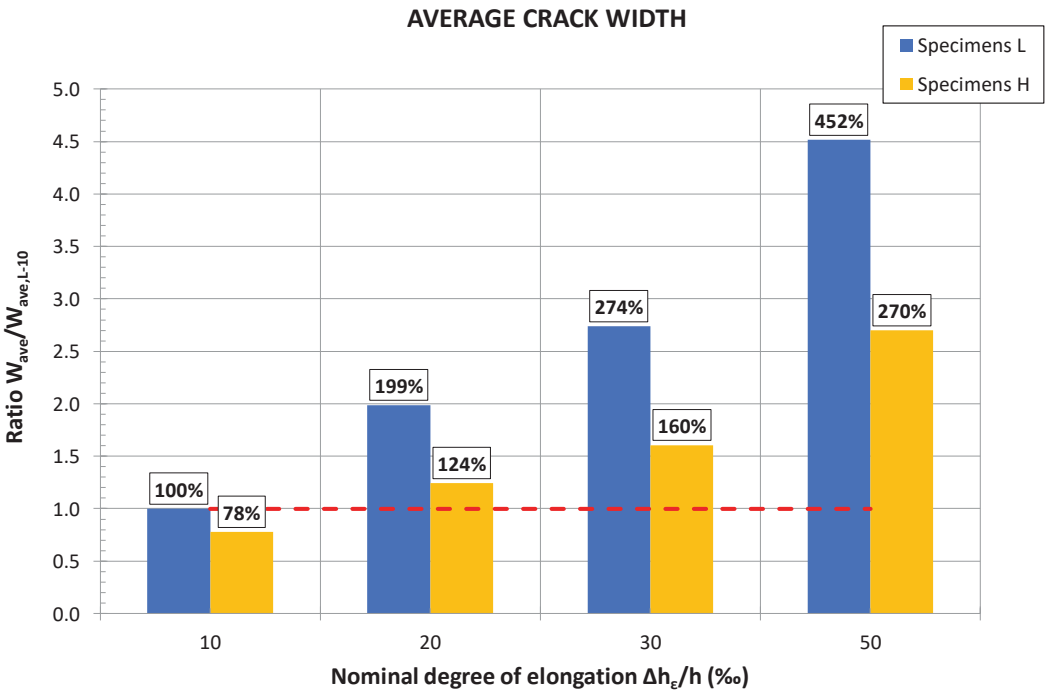

Figure 8: Bar chart of average crack width as a percentage of the average crack width of the reference specimen.

The analysis of the experimental findings of the tests conducted led to the following:

1. Comparing the number of cracks formed with the longitudinal reinforcement ratio used, it is obvious that the number of cracks formed increases with the increase of the longitudinal reinforcement ratio (Table 2, Figure 7). It seems that the presence of an increased percentage of rebars leads concrete to a larger disarrangement which results to an increased number of cracks formed throughout the height of the test specimens.
2. Comparing the average crack width with the percentage of longitudinal reinforcement utilized, it can be seen that the average width is larger for a smaller ratio of longitudinal reinforcement (Table 2, Figure 5).
3. Specimen L-10 is characterized as the reference specimen. It is noticeable that the normalized elongation (30‰) is three times greater for specimen L-30 compared to the elongation of the reference specimen (10‰) and the increase of the average crack width is 2.74 times higher (274%) compared to the average crack width of the reference specimen. In all cases, the increase of their average crack width follows closely the increase of the corresponding degree of elongation.
4. This is not true for the high reinforcement specimens. For the case of highly reinforced test specimens, it is obvious that although the normalized elongation (30‰) is three times greater for specimen H-30 compared to the elongation of the reference specimen (10‰), the increase of the average crack width is 1.60 times higher (160%). In all cases, the increase of their average crack width is smaller than the increase of the corresponding degree of elongation. This can be explained since the increment of the rebar content leads to an increment to the number of cracks

formed. Thus, a bigger number of cracks formed for the same tensile strain leads ultimately to smaller average crack width.

5. The damage state of specimens indicates that cracks appear at or near to the tie positions (Figure 4). Thus, the presence of steel ties helps and promotes the disorganization of concrete around them.

4 CONCLUSIONS

This paper looks at eight specimens to investigate cracking formation and behaviour in terms of the number of cracks and their average width. The following conclusions are drawn:

1. The degree of longitudinal reinforcement ratio used holds a significant part in terms of the formation of cracks and their characteristics, e.g. the number of cracks formed and the width of cracks.
2. Higher percentages of rebar ratio result in a higher number of cracks formed.
3. Higher longitudinal reinforcement ratios lead to smaller average crack widths. This fact should be taken into account when designing reinforced concrete structural elements since the width of cracks plays a crucial role to the duration of life of rebars.

Abstract. *In recent years, research has been conducted on the design and manufacture of lighter and low-cost seismic isolator devices. This include studies on elastomeric isolators made with alternative materials (e.g. glass or carbon fibre replacing steel sheets). Graphene-Reinforced Elastomeric Isolator (GREI) is proposed here to overcome the heavy weight and long manufacturing process of elastomeric isolators currently used.*
This manuscript presents an experimental dynamic analysis on rubber pads reinforced with a few layer graphene. Graphene deposition on rubber was achieved by a recently developed isopropyl alcohol assisted direct transfer method.
The experimental setup consisted of a single-degree-of-freedom mass-spring-damper system, with vertical load applied on tested specimens. Experimental modal analysis was performed and the mechanical properties essential to characterise the specimens were extracted from the measured frequency response function.
Results show that a few layer graphene transferred on a rubber pad increase vertical stiffness and damping of the graphene-rubber layered composite; this fosters the use of natural rubber in lieu of high damping rubber, saving the cost of reinforcing rubber with particulate fillers. Also, experimental results show that the mechanical properties of the graphene-rubber composite alter when varying the thickness of the graphene films transferred on rubber pads, stressing the sensitivity of the sample to the concentration of graphene.

1 INTRODUCTION

The concept of base isolation consists of interposing special devices such as elastomeric isolators between a structure and its foundation to decouple them. This layer gives the structure a fundamental frequency that is much lower than both its fixed-base frequency and the predominant frequency of the ground motion. Typical elastomeric isolators are made of alternate layers of steel and rubber and are used mainly in strategic and public buildings due to high cost of designing, production and installation. They are stiff vertically yet flexible horizontally and enable structures to survive potentially devastating seismic events. The primary weight in a steel-reinforced elastomeric isolator (SREI) is due to the reinforcing steel shims, which are used to provide the rubber-steel composite with high vertical stiffness. There is an on-going quest for new materials for elastomeric isolators which will result in highly efficient, ultra-lightweight and low-cost devices; this will extend the use of this technology to residential and commercial buildings, on a global scale.

Numerous studies have been conducted to investigate the dynamic behaviour of isolators reinforced with fibre sheets e.g. glass or carbon fibres (Fibre-Reinforced Elastomeric Isolators, FREI) [1-5]. However, aspects such as the design, the alignment and behaviour of the fibres, and the dependence of FREI to preloading history require further investigation.

An attractive alternative to using fibres to reinforce rubber is graphene. Graphene, a one-atom thick layer of carbon, is the strongest known material, which is also mechanically flexible. Many studies were conducted to determine the mechanical properties, electrical conductivity, gas permeability and thermal stability of this material; however, there are only a few works that incorporate graphene into elastomers. For instance, Prud'Homme et al. demonstrates the prominent potential of graphene in improving the mechanical properties of elastomers; Wu observed that graphene can be used to tune the vulcanization kinetics of rubbers [6-7].

The idea behind this research is to reinforce pure rubber with a few layer graphene and to create Graphene-Reinforced Elastomeric Isolator (GREI). This research also aims at exploiting the properties of graphene to enhance the damping of the graphene-rubber compound. Additional damping in the graphene-rubber compound will open the possibility of using pure rubber in lieu of high damping rubber; this will lead to save costs for reinforcing rubber with special particles and further reducing the cost of the devices. The dynamic response of square and circular graphene-rubber specimens with applied vertical load is investigated and experimental results are discussed.

2 SPECIMENS AND EXPERIMENTAL SETUP

In order to study the influence of the first shape factor, which is a dimensionless measure of the aspect ratio of the single layer of the elastomer, we have manufactured two sets of samples, with circular and square geometries.

Set 1 consists of three specimens. Specimen 1.1 is made of a square pure rubber pad 47 mm side and 15 mm thick; Specimen 1.2 is made of a square rubber pad 47 mm side and 15 mm thick with a circular thick layer of graphene on the top with diameter of 38 mm; and Specimen 1.3 is made of a square rubber pad 47 mm side and 15 mm thick with a circular thin layer of graphene on the top with diameter of 38 mm (Figure 1a).

Set 2 consists of two specimens made with nine circular pads of rubber each with diameter 47 mm and thickness 1.5 mm. Specimen 2.1 is made of nine pads of pure rubber bonded together using a cold vulcanizing agent. Specimen 2.2 is made of nine pads of rubber alternated to eight circular thin layers of graphene with diameter 38 mm (Figure 1b-c). Set 1 samples are

confined to two 72x72mm square steel plates 3 mm thick, while Set 2 samples are confined to two circular steel plates 3 mm thick with 72 mm diameter.

Graphene deposition on rubber was achieved by an isopropyl alcohol assisted direct transfer method [8]. To vary the thickness of the graphene films on rubber, multiple transfers of graphene films were used (i.e. 3 transfers for the thin films and 6 transfers for the thick films). The elastomer used in the samples is natural rubber with hardness 70° Shore A Degree, measured experimentally using a RS Pro digital durometer. The total height of the specimens is assumed equal to the thickness of the rubber that is 15 mm for Set 1 and 13.5 mm for Set 2 samples. Indeed, the thickness of a few layer graphene transferred on top of the rubber pad is negligible (a ten-layer graphene film is ~ 4.61 nm).

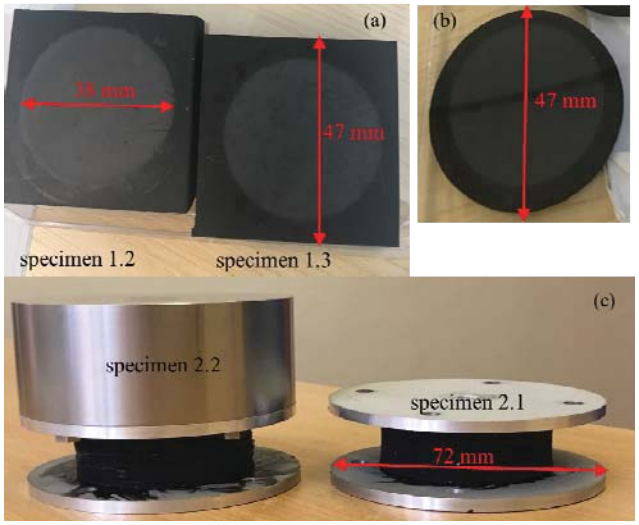

Figure 1: (a) Specimens 1.2 and 1.3 made of a square rubber pad 15 mm thick. (b) Circular sample 1.5 mm thick rubber pad with a few layer graphene on top. (c) Specimen 2.2 made of nine circular rubber pads with 1 kg applied vertical load; Specimen 2.1 made of nine circular rubber pads.

The experimental setup is shown in Figure 2 and can be seen as a single-degree-of-freedom (SDOF) mass-spring-damper system. A vertical SignalForce Shaker V20 applies dynamic loading to the bottom of the specimen. A load cell is attached to the bottom steel plate of each specimen to measure the vertical forces effectively transmitted from the shaker; gravity loads are applied on the specimens in the form of a solid stainless steel cylinder bolted to the upper steel plate (1 kg and 2 kg at a time). Two accelerometers were used to record accelerations at the top of the added mass (i.e. stainless steel cylinder) and at the bottom of the lower steel plate respectively. LABVIEW software was used to acquire and process experimental data.

Experimental modal analysis was performed and the dynamics of the system and the mechanical properties essential to characterize the specimens were extracted from the measured Frequency Response Function (FRF).

Vibration tests were also performed on one of the 3 mm steel plates alone to define its natural frequency and ultimately to assess any dynamic interaction with the dynamic behaviour of the graphene-rubber compound.

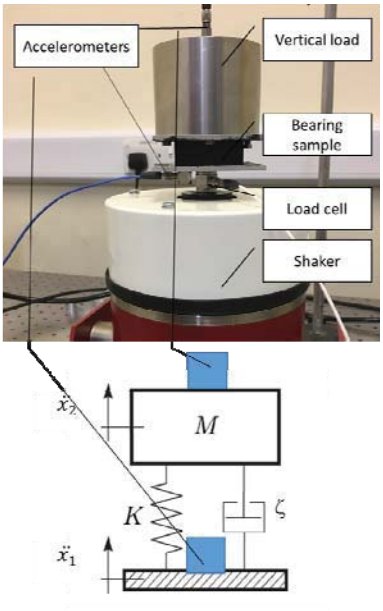

Figure 2: Experimental setup at the Dynamics Laboratory of the University of Exeter and corresponding SDOF mass-spring-damper system.

3 ANALYSIS

The natural frequency and damping of the specimens were initially estimated from the FRF using the peak-picking and half-power bandwidth methods. The vertical natural frequency of the three specimens is plotted in Figure 3, also showing that for exciting frequencies less than 250 Hz (i.e. a frequency ratio less than 0.7) the dynamic response of the specimens is disturbed by the dynamic response of the confining steel plates. FRFs show that the vertical natural frequency of the two specimens 1.2 and 1.3 made of a rubber pad and a few layer graphene on top (either thin or thick) is higher than the natural frequency of the specimen made of pure rubber (specimen 1.1). This result proves that specimens 1.2 and 1.3 are stiffer vertically than specimen 1.1, and that the increase in vertical stiffness is likely due to the added layers of graphene.

The damping ratios of the specimens 1.2 and 1.3 are higher (0.73% and 17% respectively) than that of the specimen 1.1. Such an increase in damping ratio is beneficial to base isolation systems, which typically employ high damping rubber elastomeric isolators (in which rubber is reinforced with particulate fillers) to provide additional damping. It follows that any increase in damping in the graphene-rubber compound (such as in specimens 1.2 and 1.3) would enable using low damping natural rubber and save the costs associated with filling rubber.

The natural frequency of the specimen made of nine rubber pads (specimen 2.1) was found to be higher than the frequency of the specimen made of rubber pads alternated with eight layers of graphene (specimen 2.2). Vertical natural frequency of Set 2 samples with vertical load 1 kg are depicted in Figure 4, also showing the transmissibility. As the natural frequency is lower in specimen 2.2 than in specimen 2.1, the vertical stiffness calculated experimentally is also lower in the graphene-reinforced rubber specimen compared to that in the specimen made of rubber pads only. Besides that, experimental results indicate a lower damping factor of the specimen reinforced with graphene compared to the damping factor of the specimen made of rubber pads only. Such a decrease of vertical frequency, vertical stiffness and damping factor in the specimen reinforced with graphene is likely due to an excessive quantity of

graphene present in the specimen 2.2, provoking loss of adhesion between layers of graphene-reinforced rubber and unexpected inner behaviour between the graphene particles.

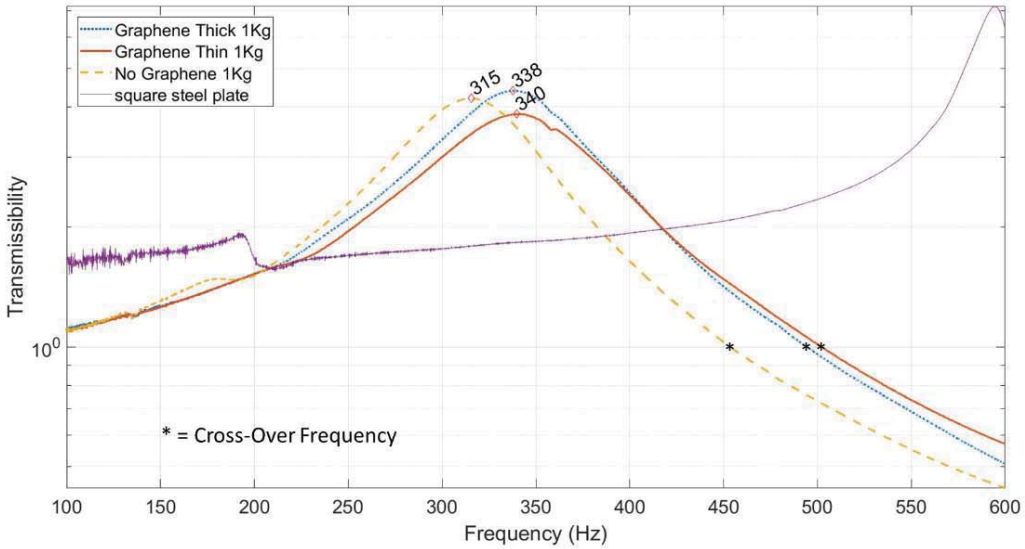

Figure 3: Set 1 samples with vertical load 1 kg: transmissibility and cross-over frequency at transmissibility T =1.

Research studies also demonstrated that strength in graphene-elastomer nanocomposite is sensitive to preparation techniques. It follows that the preparation of Set 2 specimens and their peculiar geometry (alternated layers of rubber and graphene) may have produced microstructural changes weakening the specimens and affecting their mechanical properties.

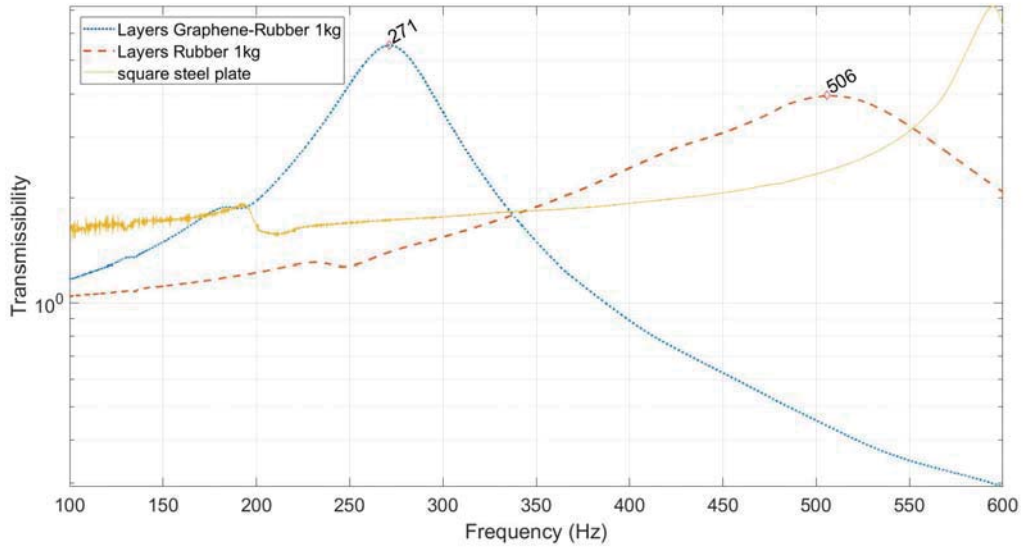

Figure 4: Transmissibility of Set 2 samples with vertical load 1 kg.

4 CONCLUSIONS

Experimental results show that by adding a few layer graphene the vertical stiffness and damping of Set 1 samples increase. In particular, the vertical stiffness increases by 15.7% when a thin layer of graphene is added on the top of a 15 mm thick rubber pad, and by 14.5% when a thick layer of graphene is added. It follows that a few layer graphene is a viable and low-cost alternative to reinforce elastomeric isolators and to replace heavy steel reinforcing

shims. Experimental results also show that a few layer graphene transferred on top of the specimen enhance the damping. They show an increase of 17.7% in the damping of the composite rubber-thin layer of graphene, and of 0.7% in the composite rubber-thick layer of graphene; hence natural rubber can be used in lieu of high damping rubber, saving the cost of reinforcing rubber with particulate fillers.

Results point out that an excessive concentration of graphene is detrimental to the mechanical properties of the samples, e.g. specimen 1.2 (with a thick layer of graphene) has lower vertical frequency and damping than specimen 1.3 (with a thin layer of graphene).

Unwanted behaviour of the rubber pad due to high concentration of graphene is evident from the experimental results on Set 2 samples too. The specimen made with nine rubber pads alternated with eight layers of graphene exhibits lower vertical stiffness and damping factor than the specimen made of nine rubber pads only. Eight layers of graphene worsen the performance of the rubber, although it is likely that less layers would enhance its mechanical properties, as it has seen in the response of specimen 1.3 with a thin layer of graphene on top. These results lay the foundation for expanding this research into seismic metamaterials and for investigating the optimal quantity of graphene to be transferred homogenously on the rubber pad that would enhance its mechanical properties.

Keywords: Concrete-filled double skin steel tube, cyclic performance, hysteretic behaviour, pure torsion

Abstract. *In order to investigate the cyclic performance of concrete-filled double skin steel tube columns (CFDST), tests of six CFDST specimens subject to cyclic pure torsion loading were carried out. Parameters being investigated include various section type, hollow ratios and steel ratios. Failure mode, ductility, hysteretic behaviour, bearing capacity and energy dissipation capacity were analysed. The experimental results show that the CFDST exhibit good cyclic performance, torsional bearding capacity and good energy dissipation. Besides, simplified calculation model was proposed to predict the ultimate torsion of CFDST, and good agreement between the proposed simplified calculation model and design methods proposed by Huang-Hong are achieved for the calculated results of the yield torsion of specimens. A finite element analysis (FEA) model was established to investigate the behaviour of CFDST, the results of FEA model were agreed well with test results in terms of the torsional moment (T) versus rotation angle (θ) curves.*

1 INTRODUCTION

Wind energy is a kind of clean renewable energy, wind power generation is the most widely used and the fastest-growing new energy generation technology. As a main load carrying structure in the wind turbine, the tower not only supports the weight of necelle and rotor, but also bears the wind load and dynamic load. Therefore, the tower plays an important role in the stable operation of the whole machine. Considering the principle of concrete-filled double skin steel tube (CFDST), a new type of CFDST composite tower for wind power tower structure is proposed in this paper, as shown in Figure 1. The upper part is a steel tower, and the lower part is the CFDST composite tower which is connected by the bolts. The inner and outer steel plates of CFDST composite tower are connected to the concrete by the studs to enhance the connection between steel plates and concrete.

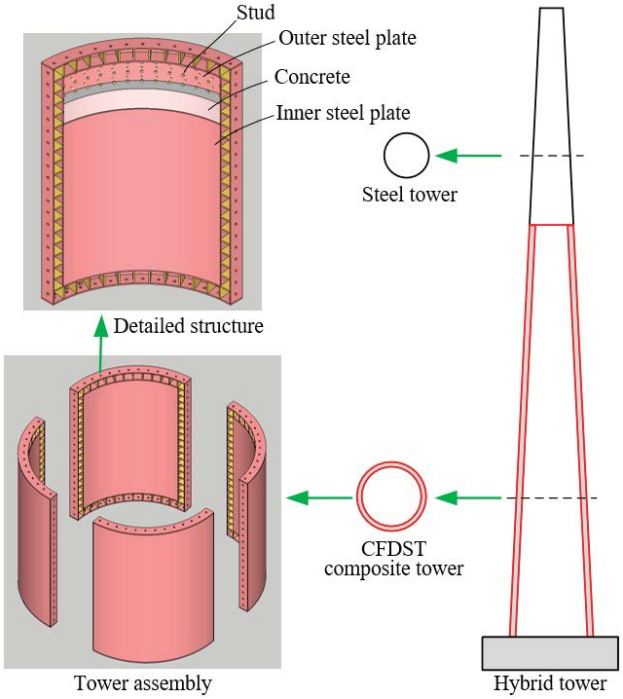

Figure 1: Schematic diagram of CFDST composite tower

In recent years, the overall reliability analysis and the axial compression test of components for the CFDST composite tower at the bottom has been carried out in literature [1]-[3]. The influence of different section number and diameter ratio of upper and lower sections on bearing capacity was obtained. It was pointed out that CFDST composite tower at the bottom was more suitable for high-power wind turbine. Han et al. [4]-[6] carried out axial compression and eccentric compression tests of CFDST columns by taking the ratio of diameter to thickness of steel tube, hollow rate, ratio of length to thickness and eccentricity as main parameters, and proposed practical calculation methods of bearing capacity for CFDST columns under axial compression and eccentric compression. Huang et al. [7]-[8] conducted an experimental study on the monotone torsional behaviour of four CFDST columns with square section and six CFDST columns with circular section, considering the steel content and hollow rate as the main parameters. The test results showed that the CFDST columns has good ductility and high bearing capacity.

However, there are few studies on the mechanical properties of CFDST columns and CFDST composite tower under cyclic torsional load. Therefore, through carrying out quasi-

static tests, this paper studies the cyclic performance of CFDST columns under torsion load. It provides reference for the research on torsional resistance and engineering design of CFDST composite tower.

2 EXPERIMENTAL INVESTIGATION

2.1 Specimens

Six specimens were designed to investigate the cyclic performance of CFDST under torque load, including two square section CFDST short columns, two CFDST rectangular section short columns and two circular section CFDST short columns. Parameters of specimens were hollow ratio and section type. All steel tubes were seamless steel tubes. The geometric dimensions of specimens are shown in Figure 2.

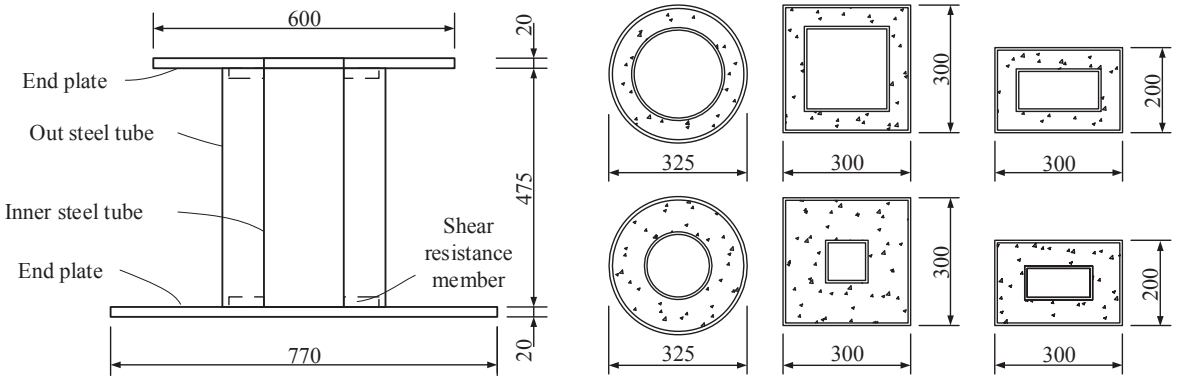

Figure 2: Geometric dimension of specimens

The steel tubes of specimens were welded on the end plates. In order to ensure sandwich concrete bearing torque load, four shear components were welded on the end plates. The sandwich concrete was poured into the space between outer steel tube and inner steel tube through the reserved holes in the upper end plate. The cubic concrete compressive strength f_{cu} are shown in Table 1. Mechanical properties of steel tubes (f_{yo}-yield strength of outer steel tube, f_{uo}-tensile strength of outer steel tube, E_{so}-Young's modulus of outer steel tube, f_{yi}-yield strength of outer steel tube, f_{ui}-tensile strength of outer steel tube, E_{si}-Young's modulus of outer steel tube) are shown in Table 2.
