A test setup was designed to apply cyclic torque load to CFDST columns. As shown in Figure 3, the test setup was mainly composed of top girder, steel base, actuator and rigid link. The upper and lower end plate of CFDST specimens were respectively connected with the top girder and the steel base through the high-strength bolts, and pretension was applied on the high-strength bolts to ensure that no relative sliding occurred between the end plates of specimens and test setup. The rigid link was used to fix the top end of specimens. One end of the rigid link is connected with the middle part of the top girder through a universal hinge and the other end is hinged with the base. Cyclic torque load on CFDST specimens was applied through the top girder by actuator.

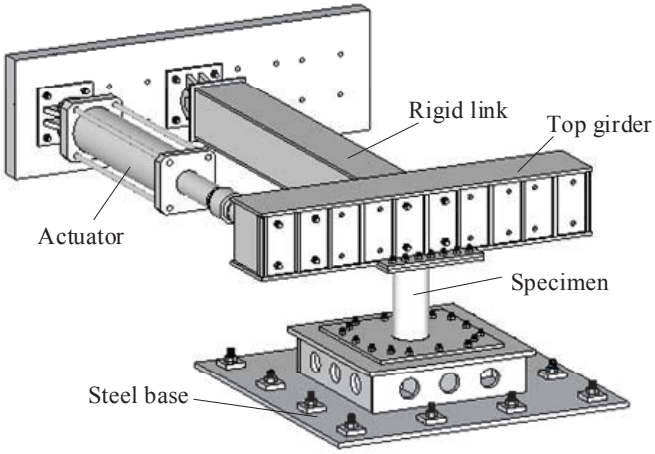

Figure 3: Test setup

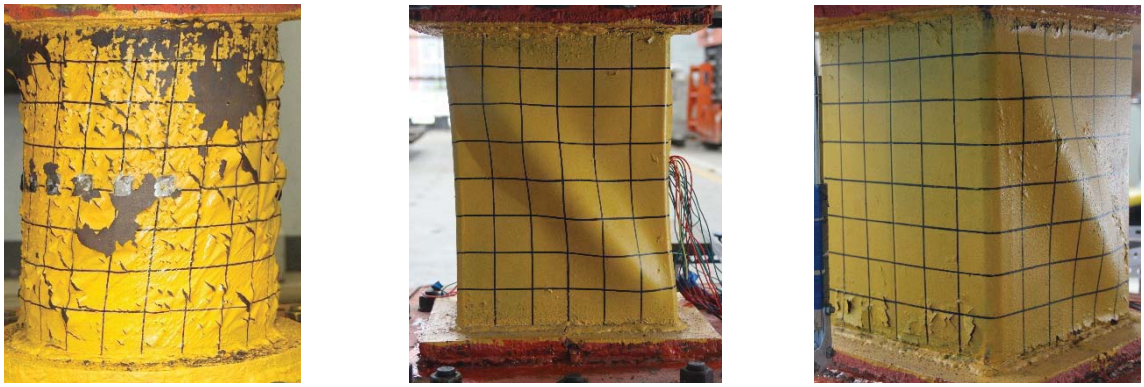
2.3 Test results and analysis

The typical failure mode of CFDST specimens with three section types are shown in Figure 4. For circular section CFDST specimens, when the cyclic pure torsional load was applied, the maximum circumferential shear stress (τ) of sandwich concrete of circular section CFDST specimens initially occurred on the outer edge. When the maximum shear stress or the maximum tensile stress reached the concrete tensile strength, the sandwich concrete cracked. Outer and inner steel tube of CFDST specimens can be regarded as a circular thin-walled steel tube. Under cyclic pure torsional load, the maximum principal tensile stress (σ_1) and the maximum principal compressive stress (σ_3) of hollow thin-walled steel tube element along the directions of 45 ˚ and 135 ˚, as shown in Figure 5. Generally, the hollow thin-walled steel tube under cyclic pure torsional load was more easily buckling to inside of section than buckling to outside of section. Buckling of outer steel tube of CFDST specimens was constrained by sandwich concrete, and the material strength of the outer steel tube can be fully utilized. The constraint effect of sandwich concrete on inner steel tube was weakness, and the inner steel tube of CFDST specimens under cyclic torque load was prone to occur local buckling.



(a) Circular section (b) Rectangular section (c) Square section

Figure 4: Local buckling of specimens

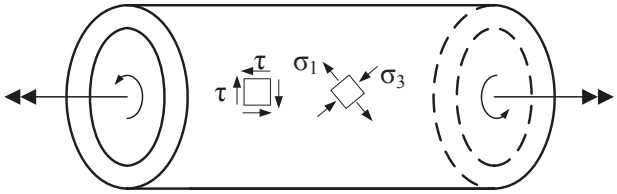


Figure 5: Stress diagram of circular section CFDST specimens

For square and rectangular section CFDST specimens, the maximum circumferential shear stress (τ) and the maximum principal stress (σ_1, σ_3) of the square and rectangular section CFDST columns appear initially at the middle of long edge. When the maximum shear stress or the maximum tensile stress reaches the tensile strength of sandwich concrete, cracks appeared on sandwich concrete. Under cyclic pure torsional load, the maximum principal tensile stress (σ_1) and the maximum principal compressive stress (σ_3) of hollow thin-walled steel tube element along the directions of 45 ˚ and 135 ˚, as shown in Figure 6. Generally, the hollow thin-walled steel tube with square or rectangular section under cyclic pure torsion was more easily buckling to inside the section. Because of the sandwich concrete constrained the buckling deformation of outer steel tube of CFDST columns with square or rectangular section, the strength of outer steel tube can be fully utilized. Obviously, the sandwich concrete of CFDST columns with square or rectangular section had limited constraint effect on inner steel tube.

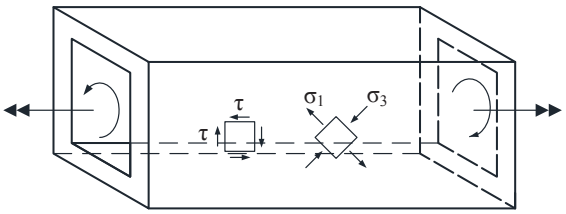

Figure 6: Stress diagram of CFDST with square and rectangular section

The torsional moment versus rotation angle hysteresis loops of CFDST columns with circular, square and rectangular section were in plump shapes, as shown in Figure 7. It means that the CFDST columns have a perfect behavior under cyclic pure torque load. There is no significant decline in the torsional moment versus rotation angle skeleton curves of circular section CFDST columns, as shown in Figure 8(a). The torsional moment versus rotation angle

skeleton curves of square and rectangular section CFDST columns declined significantly after the peak torsional capacity appeared, as shown in Figures 8(b) and (c). The key mechanical characteristic data of torsional moment versus rotation angle skeleton curves of CFDST column specimens were extracted, as shown in Table 3. The yield point of specimens can be defined according to literature [9]. The rotational ductility coefficient μ_θ is the ratio of the ultimate torsional angle θ_u to the yield rotation angle θ_y, which is an important index to measure the inelastic deformation capacity of members. The performance of CFDST columns improved with the increase of the value of μ_θ. T_p is the peak value of the torsional moment. The ultimate torsional angle θ_u refers to the maximum torsion angle subjected to a load larger than 85% of the ultimate bearing capacity or the torsion angle at the end of the test. The overall performance of CFDST columns with circular section under cyclic pure torsion load was better than CFDST columns with square and rectangular section.

3 FEA MODEL AND ANALYSIS

3.1 FEA model

A “shell-solid” finite element analysis (FEA) model was established to investigate the behaviour of CFDST columns under pure torsion. In this model, both the steel tubes were discretized by 4-node thin shell elements, and sandwiched concrete was discretized by 8-node brick elements. The element meshes for circular, square, rectangular section and boundary

conditions are shown in Figure 9. The contract property between steel tubes and sandwiched concrete was considered. In normal direction, hard contract is applied, and in the tangential direction penalty friction formulation is adopted. The friction coefficient for the FEA model is 0.6.

In order to simulate cyclic strengthen behaviour of steel tubes under cyclic torsion, the Ramberg-Osgood constitutive relation curve of structural steel Q235B under cyclic load in reference [10], E=2.06×10^{5}Mpa, K=1.065, n=0.104, as following:

$$x=y+(y/K)^{1/n} \tag{1}$$

$$x=\varepsilon/\varepsilon_y \tag{2}$$

$$y=\sigma/\sigma_y \tag{3}$$

The stress-strain relation presented by Han et al. [11] was used to simulate the plastic behaviour of core concrete in CFDST under cyclic torsion, is shown as following:

$$\begin{aligned} y &= 2x - x^2 && (x \le 1) \\ y &= \frac{x}{\beta_0 \cdot (x-1)^{\eta} + x} && (x > 1) \end{aligned} \tag{4}$$

Where:

$$x = \varepsilon / \varepsilon_0 \quad , \quad y = \sigma / \sigma_0$$

$$\sigma_0 = f_c'$$

$$\varepsilon_0 = \varepsilon_c + 800 \cdot \xi^{0.2} \cdot 10^{-6}$$

$$\varepsilon = (1300 + 12.5 f_c') \cdot 10^{-6}$$

$$\eta = \begin{cases} 2 & (\text{CFST with circular section}) \\ 1.6 + 1.5 / x & (\text{CFST with square section}) \end{cases}$$

$$\beta_0 = \begin{cases} \left(2.36 \times 10^{-5}\right)^{\left[0.25+(\xi-0.5)^7\right]} \cdot (f_c')^{0.5} \times 0.5 \ge 0.12 & (\text{CFST with circular section}) \\ \dfrac{(f_c')^{0.1}}{1.2\sqrt{1+\xi}} & (\text{CFST with square section}) \end{cases}$$

3.2 Analysis and discussion

The measured torsional moment (T) versus rotation angle (θ) skeleton curves are compared with the result calculated from the FEA model, as shown in Figure 10. It can be found that, the calculated results obtained from FEA model were in good agreement with test result from initial loading to peak loading stage. The elastic stiffness predicted by FEA model and test results of CFDST with rectangular section are in good agreement, generally. Due to the space between bolt and bolt hole wall and larger torsional moment, the elastic stiffness predicted by FEA model with circular and square section were larger than test results. The peak torsional moment predicted by FEA model (T_{uc}) are compared with the measured results (T_{ue}) in Table 4. In this paper, on the torsional moment (T) versus rotation angle (θ) curves calculated by the FEA model, the torsional moment corresponding to the measured peak displacement was taken as peak torsion moment.

3.3 Typical failure mode

Figure 11 shows the predicted typical failure modes of inner steel tubes of CFDST columns subjected to pure torsion. It can be seen that the failure modes of inner steel tube predicted by FEA model and test result are in good agreement, respectively. Inward local buckling was obvious for the inner steel tubes of rectangular and square CFDST columns, while no obvious buckling occurred on inner steel tube of circular CFDST columns. Figure 12

shows that the shear stress of sandwiched concrete of CFDST columns distributed Symmetrical.

4 DESIGN METHOD

The torsional bearing capacity of CFDST columns were mainly provided by sandwich concrete, inner steel tube and outer steel tube [12]. It is assumed that the design method of torsional bearing capacity of CFDST members as following:

$$T_{uc}=T_c+T_{so}+T_{si} \tag{5}$$

Where, T_c, T_{so} and T_{si} are torsional moment carried by sandwich concrete, outer steel tube and inner steel tube, respectively.

The sandwich concrete can be considered as plain concrete. The design method of the torsional bearing capacity of sandwich concrete can be calculated by the torsional bearing capacity formula of plain concrete. Because of outer steel tube and inner steel tube have a confined effect on the sandwich concrete, regardless of the reduction of the tensile strength of the concrete, the design method of the torsional bearing capacity of sandwich concrete is as follows:

$$T_c=f_t W_t \tag{6}$$

For square section

$$W_t=b_h^2\cdot(3h_h-b_h)/6-(b_h-2t_w)^2\cdot(3h_w-(b_h-2t_w))/6 \tag{7}$$

For circular section

$$W_t=\pi(d_o^3-d_i^3)/12 \tag{8}$$

Due to the confined effect caused by sandwich concrete, it is assumed the steel tubes under torque load can fully developed plasticity, and the outer steel tube and the inner steel tube are thin-walled closed-section steel tubes. The design method of torsional bearing capacity of the outer steel tube and the inner steel tube are as follows:

$$T_{so}=2A_0t_o\tau_{oyv} \tag{9}$$

$$T_{si}=2A_0t_i\tau_{iyv} \tag{10}$$

Where, $\tau_{oyv}=0.58f_{oyv}$ and $\tau_{iyv}=0.58f_{iyv}$ are shear strength of outer steel tube and inner steel tube, respectively. t_o and t_i are wall thickness of outer steel tube and inner steel tube. A_0 is the area enclosed by centre line of wall thickness of steel tube.

The calculated result and the test results in literature [12] are compared in Table 5. It can be found that, the calculated result is in good agreement with test result. Also, the calculated results are more conservative and safety.

Section type	No.	T_{ue} (kN·m)	T_{uc} (kN·m)	T_{uc}/T_{ue}	Section type	No.	T_{ue} (kN·m)	T_{uc} (kN·m)	T_{uc}/T_{ue}

Table 5: Test result and simplified model result

The constitutive relationship of structural steel under cyclic load was studied by Shi et al [10]. The results show that the cyclic load can increase the strength of steel by nearly 20% in the range of common strain.

The yield load calculated by theoretical formula is compared with test results in Table 6. It can be found that, generally good agreement is obtained between the calculated results and test results. In Table 6, T_{ye} is the average value of absolute value of positive and negative yield load. Tensile strength of sandwich concrete can be calculated by $f_t=0.395f_{cu}^{0.55}$.

5 CONCLUSION

In this paper, six concrete-filled double skin steel tube (CFDST) specimens subject to cyclic pure torsion loading were tested. The cyclic performance of CFDST columns was investigated. The main conclusions can be obtained as follows:

(1) The sandwich concrete had a significant impact on the CFDST columns under torsion load and the sandwich concrete changed the failure mode of outer steel tubes of CFDST columns.

(2) The overall performance of circular section CFDST columns under cyclic pure torsion loading was better than square and rectangular section CFDST columns.

(3) A “shell-solid” finite element analysis (FEA) model was established, and the validated FEA model can accurately simulate the behaviour of CFDST columns.

(4) A simplified theoretical model and design method were proposed to calculate the torsional bearing capacity of CFDST columns under pure torsion loading, the experimental and finite element comparative analysis results show that the simplified theoretical design method can predict the torsion capacity of CFDST columns effectively.

Keywords: Masonry tower, Operational modal analysis, Model updating, Fragility functions.

Abstract. *Masonry towers are widespread ancient constructions, located even in seismic zone. The assessment of their seismic capacity is a required task owing to the vulnerability and predisposition to suffer damage. Slender structures are also involved in peculiar dynamic behavior, like torsional mode shapes and acceleration amplification at height. The accuracy of the seismic response prediction depends by the knowledge of geometry, masonry properties and constraint boundary conditions, frequently uncertain. The authors investigated the seismic behavior of a tower, the St.Silvestro belfry in L'Aquila (Italy). The St.Silvestro complex was hit by the 2009 earthquake. The rehabilitation works was finalized to mitigate the vulnerabilities of the masonry complex. The results of operational modal lead to the updating of a finite element model, in terms of dynamic properties. The seismic performance of the belfry are assessed in terms of probability of collapse and revealed through fragility curves.*

1 INTRODUCTION

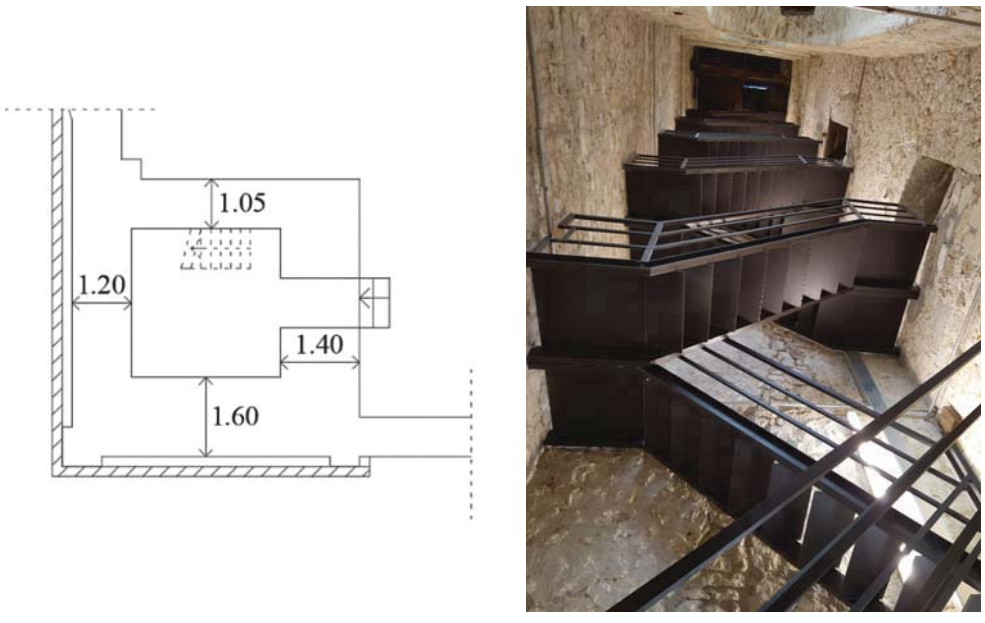
Masonry towers (MTs) are cultural buildings disseminated in urban contest, even in areas with high seismic hazard, isolated or included in the clustered buildings. In ancient times, MTs were conceived to withstand only gravity loads. Their vulnerability under horizontal loads is ascribed to the brittleness of the masonry and the geometric configuration. The poor quality of the masonry combined with the specific vertical configuration yields considerable tensional state at the basement, seismic amplification at height and dynamic phenomena which are uncommon for ordinary masonry constructions. Furthermore the geometric irregularities could worse the damage patterns and surrounding buildings could modify the seismic response, reducing the slenderness. Nevertheless, the induced damages by seismic events provide information about their dynamic behavior. Generally, the most frequent response of the steam of MTs is exhibited in local mechanisms, like overturning. While the upper part of the tower is involved in the rotation and sliding of the pillars, causing cracks in the arches, due to the lack of tie rods or hooping ties, slender pillars and roof too heavy and/or thrusting. Nevertheless, several structural configurations could modify the failure modes, worsening a damage pattern or causing specific cracks. The analysis could include the whole of the structural parameters to foresee a realistic response, on which the protection measures could evaluated. A strategy to reduce the uncertainties of the unknown parameters is a deep investigation, through a complete diagnostic and a critical analysis. Unfortunately, the knowledge is not feasible owing to the lack of historical data and the impossibility of invasive and destructive test. But a meaningful strategy to foresee a realistic structural response is the development a synergic integration between numerical and experimental analysis. To this aim, Operational Modal Analysis (OMA) is a powerful method that allows the investigation of modal parameters in a non-invasive way. The authors performed several studies on the seismic behavior of a masonry tower, the St.Silvestro belfry. The operational modal analysis and the numerical modeling are performed. In this paper the actual dynamic response of the belfry is investigated through the OMA. After that, the seismic performance, in terms and the derivation of fragility curves, are evaluated on a refined finite element model of the structure.

2 THE INVESTIGATED CASE STUDY: ST.SILVESTRO BELFRY IN L'AQUILA

2.1 Description of the building

St.Silvestro complex is a monumental building, situated in L'Aquila (Italy), built between XIII and XIV century, during the dominance of the king Federico II. The interior is divided in three naves of which the length of the central is twice of the lateral ones. Ogival arches separate the naves and support a masonry wall with a thickness of 80 cm and a height of 5 meters. The symmetric facade has a large Gothic window. While, the belfry is located in the right side of the church façade and it is as long as the lateral nave. It presents a rectangular plan with 5.5 and 6.9 meters per sides. The height of the tower is 33 m. A steel staircase arrives at the bell cell, characterized by slender masonry piers and large windows. The thickness of the masonry changes in correspondence with each wall: 1.05, 1.20, 1.40 and 1.60 m. The complex was built in local masonry [1], with irregular units arranged in irregular texture, namely "Apparecchio Aquilano".

Figure 1: Panoramic view of St.Silvestro church.



(a) (b)

Figure 2: Cross-section of the masonry tower (a) and the detail of the steel staircase inside the bell tower (b).

2.2 Suffered damage and underwent restorations

During the earthquakes swarm in 2009, the bell tower exhibited a local response. In particular, the visible damage pattern identified two overturning mechanism, like marked in red in Fig.3. The first mechanism involved the entire MT in a composed overturning around a cylindrical hinge located at the basement.

Figure 3: Crack scenario and schematisation of collapse mechanisms of the bell tower after the earthquakes (from the Fine Art Authority on-line site).

The second mechanism involved the upper part of the belfry in an overturning around a cylindrical hinge located at the gutter of the church (at 10.20 meters from the basement). These kinds of seismic response are a peculiar dynamic behavior of historical buildings. In fact, the lack of connection wall-to-wall and floor-to-wall is the main structural feature that induces a local response, as out of plane mechanism of the walls. Monumental buildings are often characterized by poor quality of masonry due to decay and arrangement over time, leading to a local collapse, even earlier to exhibit a out of plane response.

Based on the surveyed damage, the restoration of the St.Silvestro belfry focused on the repair of damage, closing the cracks by horizontal stone connections and injections. Whereas the reinforcement was finalized to assign a box-like behavior. Inserted steel rods avoided the out of plane response, recovering the lack of connection. From a visual inspection, it is noted that the position of the steel rods is close to an old installation in wood realized in a past restoration. In fact, due to high seismic risk of L'Aquila, the use of the wood pervaded noble and poor buildings as anti-seismic timber devices [2].
Moreover, the reinforcement ensured the enhancement of the mechanical properties of the masonry thanks grout injections, respecting the architectural criteria.

3 APPRAISAL OF THE ACTUAL PERFORMANCE OF THE BELFRY

3.1 In situ dynamic investigation

The appraisal of the performance of monumental buildings, including masonry towers, requires a deep knowledge of the structural system, in order to achieve a high level of accuracy. The recourse to specific test ensures the characterization of the building. Non destructive test, like visual and non invasive inspections, are not always able to grasp the unknown parameters. For example, the reliability of the thermal camera is related to the thermal equilibrium of the wall. Whereas destructive test could be compromise the architectural value of the component of the building. Others methods rely on the identification of the dynamic properties of the structure in its in-situ condition whether the architectural value of monumental buildings or the utilization of the infrastructure requires non destructive test methods. A powerful on site dynamic investigation is the Operational Modal Analysis (OMA) technique. Among the algorithms in time domain, the Stochastic Subspace Identification (SSI) method is used for the estimate of modal parameters from Output Only measurements. The SSI method is classified as Covariance-Driven Stochastic Identification (Cov-SSI) and Data-Driven Stochatsic Subspace Identification (DD-SSI), that was generalized to a reference-based version (SSI-cov/ref) by Peeters and De Roeck [3].
The dynamic campaign on St.Silvestro belfry was performed on December 2019, in order to investigate the structure response under ambient vibration measurements. The setup of the campaign involved 10 biaxial accelerometers, of which 2 accelerometers provided a reference location [4], while the other 7 were placed in the inferior levels in several measurement points, as displayed in the layout depicted in Fig.4. The data were sampled at a rate of 250 Hz. The cut-off frequency of the anti-aliasing filter was set to 20 Hz. The number of samples was set to N=720000, which resulted in a measurement time of 1 hour. Data from multi-setup measurements, with 4 setups, were then merged following the approach recalled in [5]. Two modes arise from the stabilization diagram and revealed translation shapes, as reported in Fig.5.

3.2 Numerical modelling

The dynamic response of the St.Silvestro belfry is evaluated also through a numerical analysis. Two different structural models were adopted. A model, with bi-dimensional finite elements, was developed aimed to reproduce the refinement behavior of the belfry, used for the model updating. An equivalent frame model, with a one-dimensional finite element, was performed to overtake the computational burden of non-linear analysis. The finite elements consisted of four frames, with an equivalent section with each wall, resorting to lumped plasticity [6]. A rigid-perfectly plastic behavior with final brittle failure was assigned to all plastic hinges. The whole structure has been assumed fixed to the foundation, considering the soil-structure as

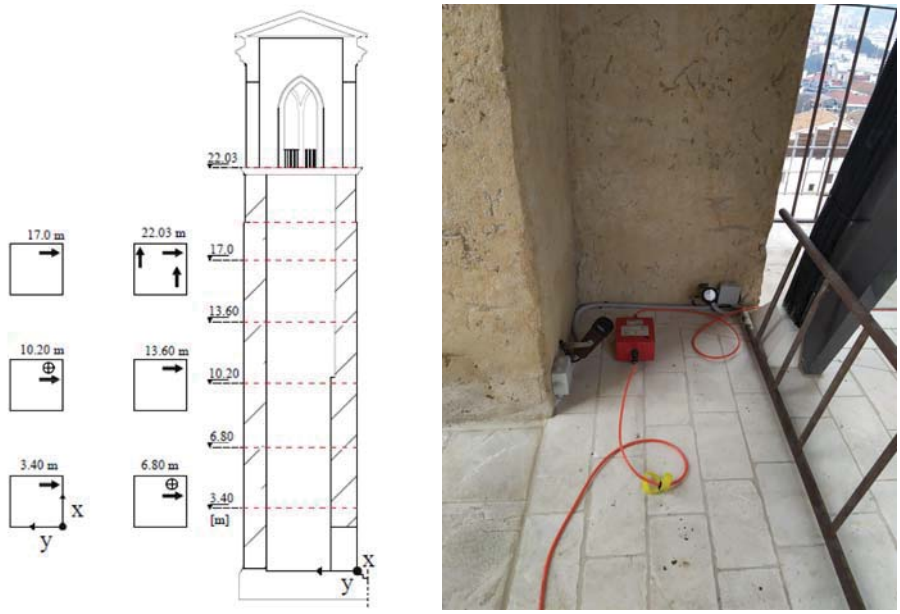


Figure 4: Experimental setup, showing the position of the accelerometers along the height of the tower. On the right: a sensor placed on the the top of the bell tower, at the height of 22,03 m.

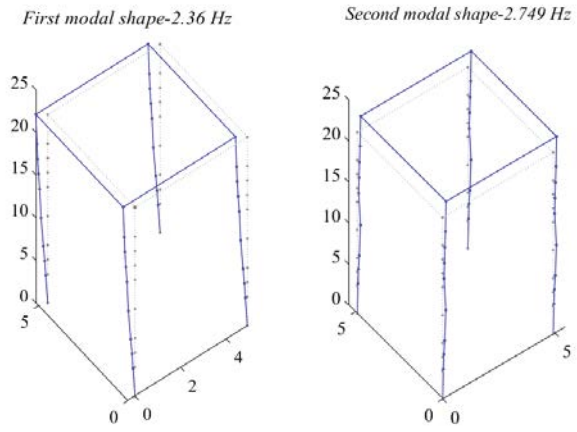

(a) (b)

Figure 5: First two experimental mode shapes deriving from OMA.

negligible. The neighboring church was included in the model by non-linear springs. The mechanical parameters of the reinforced masonry are assigned starting from the value reported in the Italian Standard Code[7] for unreinforced masonry, as reported in Table 1, and applying the corrective factor for the restoration measure carried out.

Table 1: Mechanical parameters of irregular stone masonry.

Irregular stone masonry	2	0.043	1230	410	21

Starting from numerical results, the model updating was carried out.

3.3 Model updating of modal properties

The model updating aims to correct the finite element model by processing the results from dynamic test on the structure. To measure the distance between the estimated modal parameters and the numerical ones, the following objective function is used [8]:

$$C = \sum_{i=1}^{M} \gamma_i \left(\frac{\omega_i^m - \omega_i^c}{\omega_i^m} \right)^2 + \beta \sum_{i=1}^{M} (1 - diag(MAC(\Phi_i^m, \Phi_i^c))) \tag{1}$$

where the apex $(*)^m$ indicates a measured variable, the apex $(*)^c$ a calculated variable, Φ_i is the mode shape vector, M is the number of modes, MAC is the modal assurance criterion [9], while γ_i and β are weighting factors. The weighting factors are set equal to one.

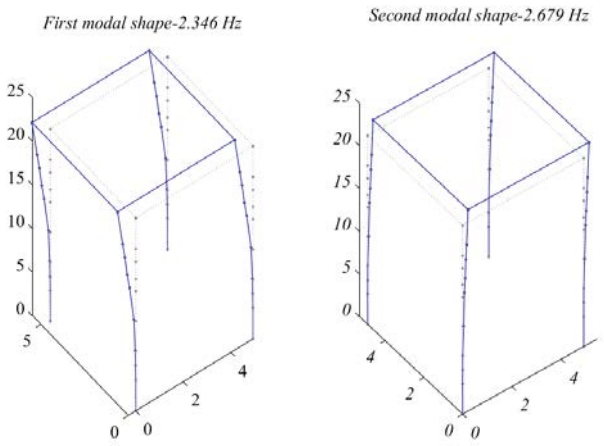

Figure 6: (a) First mode shape from model updating; (b) Second mode shape from model updating

The model updating was performed with the aim to detect the elastic modulus E of the masonry. According to the Italian Guidelines, an acceptable range for the modulus E value was investigated. The optimization led to a value of E for the walls in x direction equal to 3540 MPa, while the modulus for the y direction was identified to be equal to 3360 MPa [10]. The evaluated MAC takes the value equal to 0.78 for the first mode and to 0.88 for the second one, ensuring a consistent correspondence. The other values are negligible.

3.4 Derivation of fragility functions

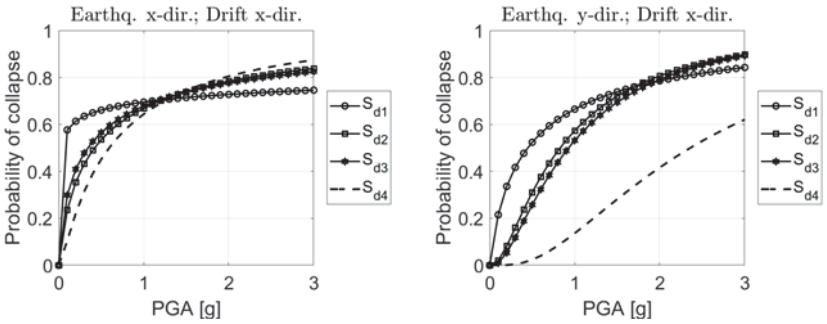
The seismic performance of the belfry, after the restoration, are estimated through fragility function. The probability of collapse of the structure is evaluated, for four limit states of interest, as a function of ground motion intensity measure, IM [11], which, in this paper, is the PGA itself. The occurrence or non occurrence of collapse is defined by the exceeding of a given displacement, for a given set of ground motion and dynamic structural analysis results. A lognormal cumulative distribution function is used for fitting the fragility function based on data collected from non linear dynamic analysis [11]:

$$P(C|IM = x) = \Phi\left(\frac{ln(x/\theta)}{\beta}\right) \tag{2}$$

where $P(C|IM = x)$ is the probability that a ground motion with $IM = x$ will cause the structure to collapse; Φ is the standard normal cumulative distribution function (CDF); θ is the median of the fragility function (the IM level with 50% probability of collapse); and β is the standard deviation of ln IM (sometimes referred to as the dispersion of IM). Since the truncated incremental analysis was carried out, an alternative procedure [11] to estimate the parameters θ and β is followed, obtained by varying the parameters until a certain likelihood function is maximized. Specifically, the parameters are obtained by maximizing the logarithm of the following likelihood function:

$$\{\hat{\theta}, \hat{\beta}\} = argmax_{\hat{\theta},\hat{\beta}} \sum_{j=1}^{m} \left[ln\Phi\left(\frac{ln(IM_i/\theta)}{\beta}\right)\right] + [n-m]\, ln\left[1 - \Phi\left(\frac{ln(IM_{max}/\theta)}{\beta}\right)\right] \tag{3}$$

where $\hat{}$ denotes an estimated parameter, $\Phi()$ the standard normal distribution PDF, n the number of ground motion used in the analysis, m the number of m ground motions that caused collapse at IM levels lower than IM_{max}, $\Phi()$ the standard normal distribution CDF. The parameters of Eq.(3) are estimated for each of the earthquake recordings. The resulting two parameters of the fragility function, representative of all considered seismic scenarios, are obtained taking the mean of all the couples of parameters estimated from each truncated incremental dynamic analysis. Fig.7 shows the obtained fragility functions, for the x direction, that reveals the high-



(a) (b)

Figure 7: Fragility curves of the numerical model of the masonry tower.

est value of probability of collapse due to the significant drifts in its direction of application. The in-homogeneous structural characteristics, in terms of the mechanical parameters and horizontal restrains, gives rise to the different probabilities of collapse. In detail, the restoration

works foresaw a different improvement of the mechanical property of the masonry, assigning different value of the elastic modulus and the strength resistance of the masonry. In addition, the horizontal constraint provided by the church is not the same between the two direction due to the different stiffness and connection of the adjacent masonries. Nevertheless, a further deep characterization is required in order to grasp the boundary conditions accurately.

4 FINAL REMARKS

A procedure for a reliable assessment of seismic response of a masonry tower is performed. The case study investigated is St.Silvestro belfry, located in the centre of L'Aquila and damaged by 2009 earthquake. By discussing the restoration works, the numerical and operational modal results, the paper aims at offering a reliable approach to obtain the seismic response with its confidence intervals. The prediction of the seismic performance of masonry towers is an tricky task, owing to the lack of the building knowledge. In order to overcome the uncertainties, an integrated approach between numerical and experimental analysis is a powerful procedure, as discussed in this paper. The experimental campaign has investigated the modal parameters of the St.Silvestro belfry. In particular OMA has allowed the evaluation of frequencies and modal shapes, taking into account the influences of neighboring construction, else uncertain. The model updating has founded the correspondence between the experimental data and numerical results. After that, the correct actual modal behavior is assessed. Furthermore the numerical model has yielded the seismic behavior in terms of fragility functions. Hence the integrated approach is capable to predict the seismic performance and the damage during the service condition or future earthquakes accurately, on which monitoring and retrofitting could be designed.

5 ACKNOWLEDGEMENTS

The geometric survey and additional information of the monumental complex of St.Silvestro were found on the online site of Fine Art Authority.

Keywords: Shaking table tests, one-way bending, unreinforced masonry, timber frame supported straw block wall

Abstract.

A shaking table experiment was performed to study the influence of several building products on the out-of-plane behavior of load-bearing walls in one-way bending. The products that were investigated are a high-strength mortar (Remix/Strating), a mortar-less dry-stacked masonry system (ClickBrick), a renovation anchor tie system (Fischer), and compressed straw blocks supported by a timber frame (Straw Blocks). The results obtained for the specimen with these products were compared to tests performed on two cavity wall specimen (R1 and R2) constructed from materials typically applied in Dutch masonry buildings. The results show that the test specimen with the ClickBrick dry-stacked system and the specimen with the Fischer renovation anchor have a larger flexibility than specimen R1 and R2. The Remix/Strating specimen with high-strength mortar displayed linear elastic behavior up to larger peak table accelerations than specimen R1 and R2, suggesting an improvement in the damage resistance. The Straw Blocks specimen could not be tested up to failure due to the limitations of the table; linear elastic behavior was observed until PTA = 1.2 g in the ground floor configuration and PTA = 0.7 g in the first floor configuration.

1 INTRODUCTION

Gas extraction in the province of Groningen in the North of the Netherlands has resulted in induced earthquakes in this region. The strongest event was the Huizinge earthquake (16th of August 2012) with a magnitude $M_w = 3.6$. The largest PGA level measured in this event was about 0.1 g. Although the magnitude of these earthquakes is relatively low, there is a risk for the building stock [1] because a large portion of the buildings in this region consist of unreinforced masonry (URM) and was not designed for seismic loads.

Until recently, little was known about the seismic performance of Dutch URM buildings. An extensive testing campaign by EUCentre and the TU Delft [2] on some typical Groningen buildings and building components has provided a better understanding on the performance of the more earthquake-prone buildings. This campaign has provided a basis for assessment of the existing building stock. Still, relatively little is known about the seismic performance of other (new) building products used in Dutch construction. Companies active in the construction industry wish to have a better understanding of the performance of their products under earthquake loading.

Various studies on the effect of earthquakes on masonry buildings, e.g. [3-6], found that damage to and failure of these buildings often has to do with the out-of-plane behavior of the load-bearing walls. Depending on the boundary conditions, different failure patterns can occur. Figure 1 shows two types of failure patterns that are often observed in buildings. The pattern in Figure 1 (left) is known as one-way bending failure. This is common in long walls or walls without support on both sides. The pattern in Figure 1 (right) is two-way bending failure, which occurs in walls where all sides are supported.

The out-of-plane behavior of masonry walls has been studied quite extensively. Doherty [7] performed shaking table tests on URM wall specimen to study the rocking and collapse behavior of a one-way spanning wall. Vaculik [8] studied the dynamic behavior of half-scale walls in two-way bending; an extensive shaking table test program was performed on 5 specimen in which the changes in properties (effective stiffness, natural frequency and damping) were monitored in detail. A detailed study of the influence of the top and bottom boundary condition was made by Dazio [9]. The results of this study showed that besides the slenderness and overburden load, the boundary conditions play an important role in the out-of-plane behavior of masonry walls.

Relatively few studies have been performed on the out-of-plane behavior of cavity walls. As part of the testing campaign by EUCentre [2], Graziotti et al [10] performed shaking table tests on the one-way bending behavior of cavity walls. They investigated the influence of the number of anchor ties, and made a comparison with the out-of-plane behavior a single leaf wall. They found that for all cavity walls the horizontal displacements of the inner and outer leaf were the same, even for the specimen with a small number of ties (2 ties/m^2).

To obtain a better understanding of the seismic performance of some building products applied in the Netherlands, an experimental shaking table test campaign was performed. The one-way out-of-plane bending behavior of various load-bearing walls including those building products was investigated with a similar experiment setup as developed by Graziotti et al [10].

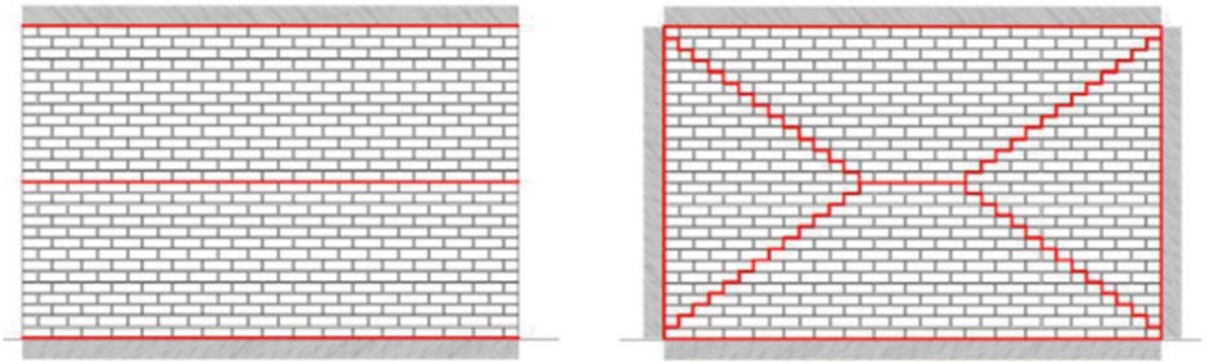

Figure 1: Damage patterns for (left) one-way bending and (right) two-way bending, after Graziotti et al. [7].

Five different cavity wall specimen and one wall specimen of compressed straw blocks supported by a timber frame were tested. Two cavity wall specimen (R1 and R2) were constructed from materials typically applied in Dutch masonry buildings. The products applied in the other specimen are a high-strength mortar (Remix/Strating), a dry-stacked masonry system (Click-Brick), a renovation anchor tie system (Fischer), and compressed straw block system supported by a timber frame (Straw Blocks).

Chapter 2 explains the setup of the shaking table experiment, and describes the various test specimen that were tested. Chapter 3 presents and discusses some of the results obtained for the various wall specimen. Chapter 4 gives the conclusions of this work.

2 EXPERIMENT

This chapter describes the setup of the experiment, the applied signals and the procedure. More detailed information can be found in [11-14].

2.1 Test setup

The tests were carried out on a uniaxial shaking table shown in Figure 2. The table has an area of 2 m x 3 m and a weight of 3.5 ton. The hydraulic actuator is controlled with the Moog test software package Integrated Test Suite.

Figure 2 shows the setup of the experiment. A triangular support frame (A) was placed behind the test specimen to support the top boundary condition. The natural frequency of the support frame is 25 Hz, to ensure an acceleration signal at the top of the specimen similar to the table acceleration in the frequency range of interest (0 – 20 Hz). A steel beam (B) is placed on top of the test specimen; the beam is connected with a hinge to the support frame. On both sides of the test specimen a beam (C) extends from the support frame. This beam catches the top beam (B) when the test specimen fails. The top beam (B) is pulled down with a predefined force by means of a spring construction (D) on both sides of the specimen. The force exerted by the springs represents the building mass on top of the wall. The applied force was dependent on the test configuration and the specimen, par. 2.5 specifies the applied forces. The aluminum frame (E) is used for laser sensors to measure the displacements of the test specimen during the tests. A similar frame is placed on the inside of the test specimen.

Figure 2: Overview photo of the test set-up with some components highlighted: the support frame (A), the upper beam (B), the support structure for the upper beam (C), the prestressing structure (D) and the laser frame (E).

2.2 Test specimen

A total of 6 different wall specimen were tested; 5 specimen were URM cavity walls, one specimen was a straw block wall supported by a timber frame. Figure 3 shows pictures of one of the cavity wall specimen and of the straw block timber frame specimen. All test specimen were constructed on a concrete block (1.47 m wide, 0.4 m deep and 0.2 m high). The global dimensions and weight (excluding concrete block) of the test specimen are given in Table 1. The cavity between inner and outer leaf was 80 mm for all cavity wall specimen.

The load-bearing inner leaf of the 5 cavity wall specimen was built with white calcium silicate (CS16) bricks in stretcher bond and Remix/Sakrete mortar (adhesive strength 0.45 N/mm^2). The calcium silicate stone is 214 mm wide, 102 mm deep and 72 mm high. All cavity wall specimen had an inner leaf of 32 layers with six and a half stretchers per layer.

Two cavity wall specimen were made of materials typically applied in Dutch masonry buildings, these specimen are referred to as Reference 1 and 2 (R1 and R2). Specimen R1 had an outer leaf of solid clay bricks (2.1 kg per brick). The outer leaf of specimen R2, consisted of perforated clay bricks (1.7 kg per brick). Both solid and perforated brick are 209 mm wide, 99 mm deep and 50 mm high. The outer leaves of specimen R1 and R2 consisted of 43 brick layers, with six and a half stretchers per layer. The Remix BM2 M5 mortar (adhesive strength 0.2 N/mm^2) was used in the outer leaves of both specimen. The inner and outer leaf of R1 and R2 were connected by L-shaped anchor ties (4.3 anchors per m^2) of type UNI-L (32512).

Figure 3: Front view and side view of one of the URM cavity wall specimen (top) and of the straw block timber frame specimen (bottom).

Test specimen	Description	Dimensions [m]	Mass [kg]
Reference 1 (R1)	URM cavity wall - solid brick outer leaf	2.68 x 1.46 x 0.28	1390
Reference 2 (R2)	URM cavity wall - perf. brick outer leaf	2.68 x 1.47 x 0.28	1318
Fischer	URM cavity wall - renovation anchor ties	2.68 x 1.46 x 0.28	1296
Remix/Strating	URM cavity wall - high-strength mortar	2.67 x 1.47 x 0.28	1397
ClickBrick	URM cavity wall - dry-stacked masonry	2.67 x 1.47 x 0.28	1160
Straw Blocks	Straw single wall - timber frame support	2.70 x 1.40 x 0.40	193

Table 1: Description, dimensions (height, width and thickness) and mass (excluding concrete base) of the test specimen.

The Fischer test specimen was constructed of the same materials as specimen R2, except for the anchor ties. The inner and outer leaf of this specimen were connected by Fischer renovation anchors, type VBS-8x225 A4. These anchors were inserted after construction of the cavity wall without the UNI-L anchor ties.

The Remix/Strating specimen was also constructed of the same materials as specimen R2, except for the mortar in the outer leaf. The outer leaf was built with a high-strength Remix/Sakrete mortar, with an adhesive strength of 0.5 N/mm^2.

The ClickBrick specimen had an outer leaf of ClickBrick stones. These perforated stones (240 mm wide, 100 mm high and 90 mm deep) are stacked dry; the stones are interconnected by means of metal clips. The top 3 of the 27 layers of stones were also glued together with a sealant. The inner and outer leaf were also connected with the UNI-L anchor ties.

The Straw Blocks specimen consisted of compressed straw blocks, supported by a wooden frame. The test specimen consisted of two elements of 0.7 meter wide. The two elements are connected by means of rods across the width of the test piece. At the bottom of the element, the wooden frame is attached to the concrete block by means of four M16 bolts.

2.3 Instrumentation

Figure 4 shows the sensor positions on the test specimen. Acceleration measurements (blue squares) were performed on the concrete block (a1) and the top beam (a32). Accelerations were also measured at 3 positions over the height on the inner (a32 – a35) and outer leaf (a29 – a31) of the specimen. Displacements of the test specimen relative to the shaking table were measured with lasers at the indicated positions d17 – d27 (yellow rectangles) in Figure 4. All sensors were sampled with a frequency of 500 Hz. The data was filtered with an eight-order Butterworth filter with a lowpass frequency of 50 Hz.

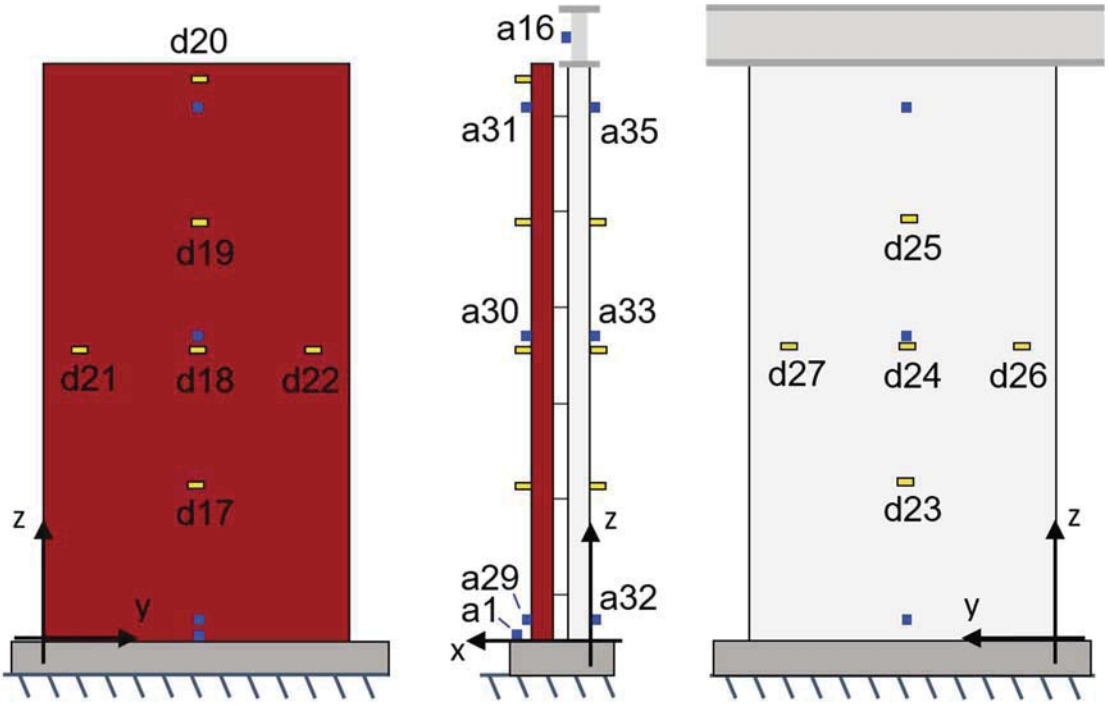

Figure 4: Schematic representation of the front, side and rear view of the test specimen with lasers (yellow) and accelerometers (blue) on the outer leaf (red) and the inner leaf (white), the concrete block and the top beam.

2.4 Signals

Figure 5 shows the earthquake signals applied in this experiment. These signals were also used in shaking table tests on masonry cavity walls by Graziotti et al. [10]. Graziotti et al. [10] [15] selected the Gr-1 signal based on research by Crowley et al. [16] on representative signals for Groningen earthquakes. The Gr-2 signal was created by Graziotti et al. [15] using the finite element package TREMURI for a 2-storey building; the Gr-1 signal was imposed at the level of the foundation of the building model and the Gr-2 signal was registered at the first floor.

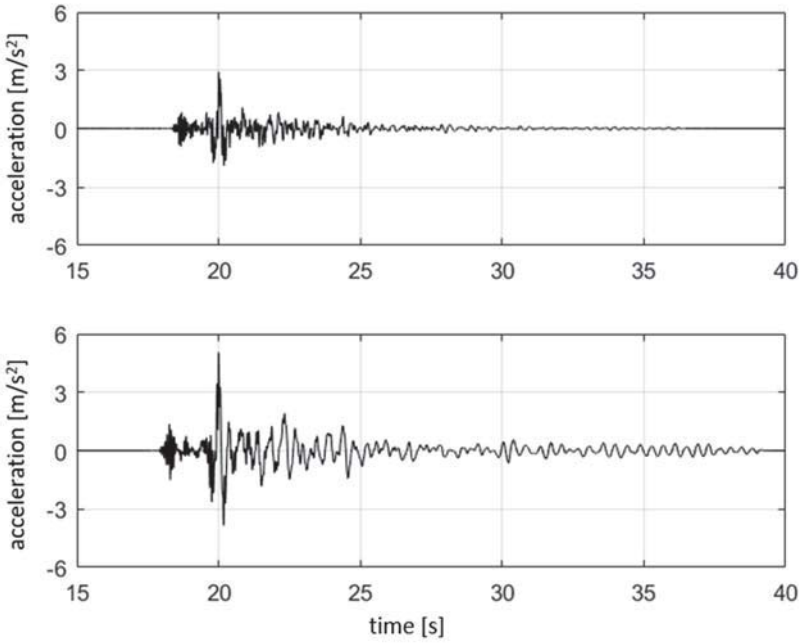

Figure 5: The earthquake signals applied in the shaking table tests (top) Gr-1 and (bottom) Gr-2. The presented signals represent the SF = 100% signals.

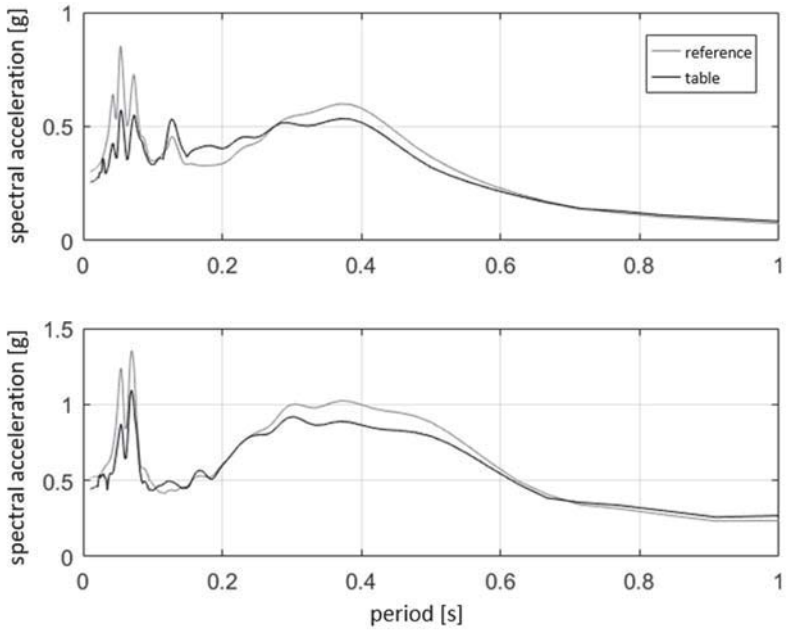

Figure 6: The response spectra (determined with 5% damping) of test signal (top) Gr-1 and (bottom) Gr-2. The presented spectra represent the SF = 100% spectra.

Figure 6 shows the desired (reference) and realized (table) response spectra of the Gr-1 and Gr-2 100% signals. For periods between 0.02 s and 1 s, the maximum difference between the reference and the table spectrum was 30%.

2.5 Test sequence

The tests on each specimen were performed in two phases, with two different test configurations:

1. Ground floor configuration
   An overburden load was applied to the top of the test specimen that is representative for a wall element on the ground floor of a 2-storey building (19 kN for the cavity wall specimen and 6.3 kN for the Straw Blocks specimen). In this configuration, the Gr-1 signal was simulated on the table.
2. First floor configuration
   The overburden load was reduced to a representative load for a wall element on the first floor of a 2-storey building (9 kN for the cavity wall specimen and 3 kN for the Straw Blocks specimen). In this configuration, the Gr-2 signal was simulated on the table.

In both configurations, the peak table acceleration (PTA) of the signal simulated on the table was gradually increased. The applied increase is indicated with a scaling factor (SF), with SF = 100% corresponding with the signals presented in Figure 5. Several tests were performed at each scaling factor. Table 2 gives the average PTA over all tests performed at a certain scaling; between brackets the standard deviation is specified.

Damage inspections were performed at regular intervals throughout the test program. In each inspection the specimen were examined visually; pictures were taken of both sides of the test specimen.

To prevent damage to the instrumentation, the lasers and acceleration sensors were removed when relative displacements larger than 1 cm were measured.

Table 2: Overview of tests on the wall specimen with signal Gr-1 and Gr-2 at different scales (SF). Several tests were performed at each intensity scale; the average PTA and standard deviation (between brackets) are specified.
* Additional ground floor configuration tests were performed on the Straw Blocks specimen up to SF = 500%.
Additional information on the test programs can be found in [11-14].

3 RESULTS AND DISCUSSION

This chapter presents and discusses results on the peak displacements measured on the inner and outer leaf of the specimen and the regular damage inspections performed in-between signal tests. Other results obtained on the changes in the effective stiffness and the natural frequency with increasing shaking intensity can be found in [11-14].

3.1 Ground floor configuration results

Figure 7 shows the measured maximum and minimum displacement in the middle of the inner and outer leaf of the test specimen against the peak table acceleration (PTA). A trend line (black dotted line) is fitted on the measured data for which PTA $\leqslant$ 0.2 g. This trend line is used to assess at which PTA the peak displacements in the middle of the specimen exceed this linear trend, which is an indication for changes in the properties of the specimen.

Figure 7(a) shows that for specimen R1 the peak displacement is larger than this linear trend for PTA > 0.4 g. Although this non-linear behavior can be an indication for damage accumulation in the specimen, no damage was observed in the inspections until test SF = 300% (PTA = 0.71 g). Note that the peak displacement that occurred during the test with SF = 300% is not plotted in Figure 7(a), because it was greater than the measurement range of the lasers.

Figure 7(b) shows the peak displacements of specimen R2. For peak table accelerations up to 0.4 g, the linear trend observed between peak displacements and PTA has the same slope as that observed for specimen R1. For PTA > 0.4 g, the peak displacements observed in specimen R2 remain relatively close to the linear trend. This indicates smaller changes in the properties of specimen R2, and suggests less damage accumulation than in specimen R1. No damage was observed in the ground floor configuration inspections performed on this specimen.

The peak displacements of the Fischer specimen, shown in Figure 7(c), follow a linear trend up to a PTA = 0.5 g. For a given PTA, the measured peak displacements are about a factor 2 greater than those observed for specimen R1 and R2. This suggests the out-of-plane bending stiffness of the Fischer specimen is smaller than that of R1 and R2. This could be the result of the more flexible connection between the inner and outer leaf due to the rubber plug applied in the renovation anchor. Because of the large displacements, the ground floor configuration tests on this specimen were stopped after the tests performed at a PTA = 0.5 g (SF = 200%).

Figure 7(d) shows the peak displacements of the Remix/Strating specimen with increasing PTA. The minimum and maximum displacement follow a linear trend up to a PTA = 0.6 g. This linear trend has the same slope as the trends observed for test specimen R1 and R2.

The peak displacements of the ClickBrick specimen, shown in Figure 7(e), follow a linear trend up to a PTA = 0.5 g. For PTA > 0.3 g, the peak displacements of the outer leaf are slightly (~0.3 mm) larger those of the inner leaf. This is probably due to the greater flexibility of the outer leaf, which mainly gets its stiffness from the clip elements between the dry-stacked stones.

The results of the Straw Blocks specimen are shown in Figure 7(f). Because of the linear elastic behavior of the specimen for the tests up to SF = 300%, additional tests were performed up to SF = 500% (not specified in Table 2, see [14] for detailed information). Figure 7(f) shows the peak displacements follow a linear trend up to PTA = 1.2 g. The slope of this trend is smaller than the slopes observed for specimen R1 and R2.

Apart from specimen R1, no visual damage was observed in the damage inspections performed in the ground floor configuration setup. Figure 8 shows no damage was observed on the outer leaf of specimen R1 up to inspection 5; after the test at SF = 300% a crack was observed near the middle of the R1 specimen, see Figure 8(c).

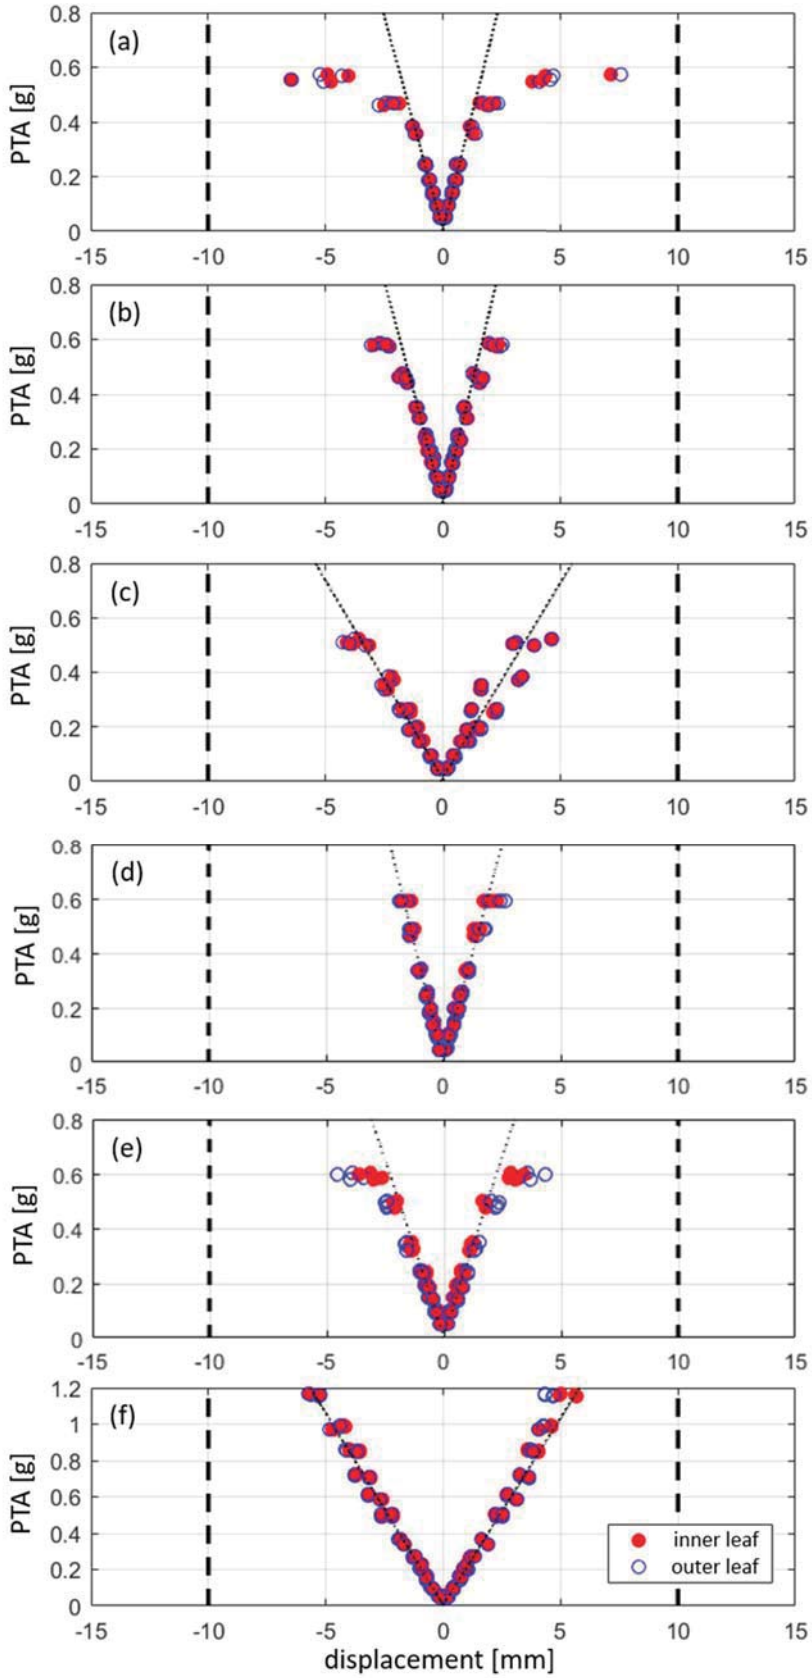

Figure 7: Peak displacement middle test specimen versus peak table acceleration (PTA) for Gr-1 signals: (a) R1, (b) R2, (c) Fischer, (d), Remix/Strating, (e) ClickBrick, and (f) Straw Blocks. The black broken line indicates the measurement range of the lasers; the black dotted line is a fitted line on the data with PTA $\leqslant$ 0.2 g.

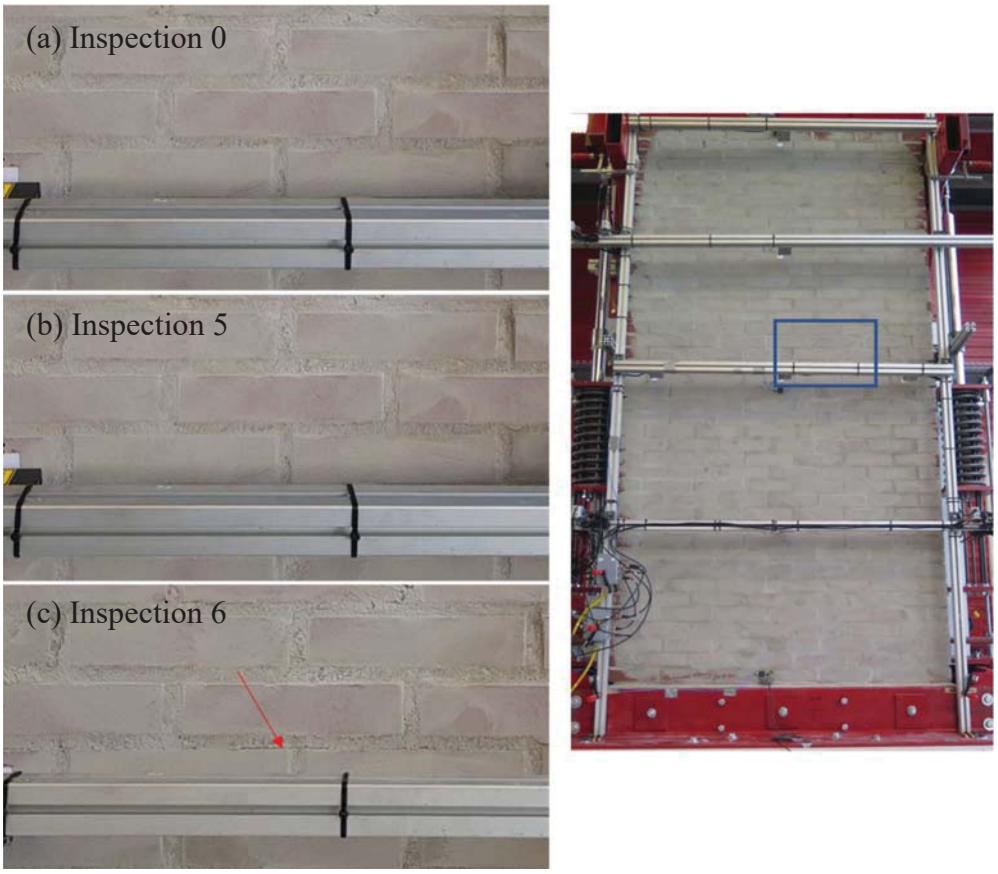

Figure 8: Pictures of the specified zone on specimen R1 (blue frame) in subsequent damage inspections: (a) inspection 0, (b) inspection 5, and (c) inspection 6. The red arrow indicates observed damage (hairline fracture).

3.2 First floor results

Figure 9(a) shows the measured maximum and minimum displacement in the middle of test specimen R1. Up to a peak table acceleration (PTA) of 0.2 g, the peak displacements of specimen R1 follow a linear trend with PTA. For a PTA > 0.2, the peak displacements are larger than this linear trend. In the tests with a PTA = 0.4 g (SF = 100%), a crack formed in the outer leaf at about ¾ of the height of the specimen ($z / h \approx 0.75$). Figure 10(c) shows a picture of the crack (top red arrow) that was observed in damage inspection 8 after this test. In addition to this new crack, the original crack had visibly increased (bottom red arrow), as can also be seen in Figure 10(c). The specimen failed in the third test at SF = 150%. The results of these tests are not presented in Figure 9(a) because the peak displacements exceeded the measurement range of the lasers.

The peak displacements measured on specimen R2 follow a linear trend up to 0.3 g. From a PTA = 0.4 g the peak displacements become slightly larger than this trend; in the tests with a PTA = 0.6 g, the peak displacements increase sharply. The first damage was observed in the inspection after this test, see Figure 10(e). The results of the tests at SF = 170% (PTA ≈ 0.7 g) are not shown because the displacements were larger than the measurement range of the lasers. After two tests at 170%, another damage inspection was carried out. In addition to an increase in the original crack formation at $z / h \approx 0.6$, a new crack was created at $z / h \approx 0.75$. The specimen failed after the third test at 170%.

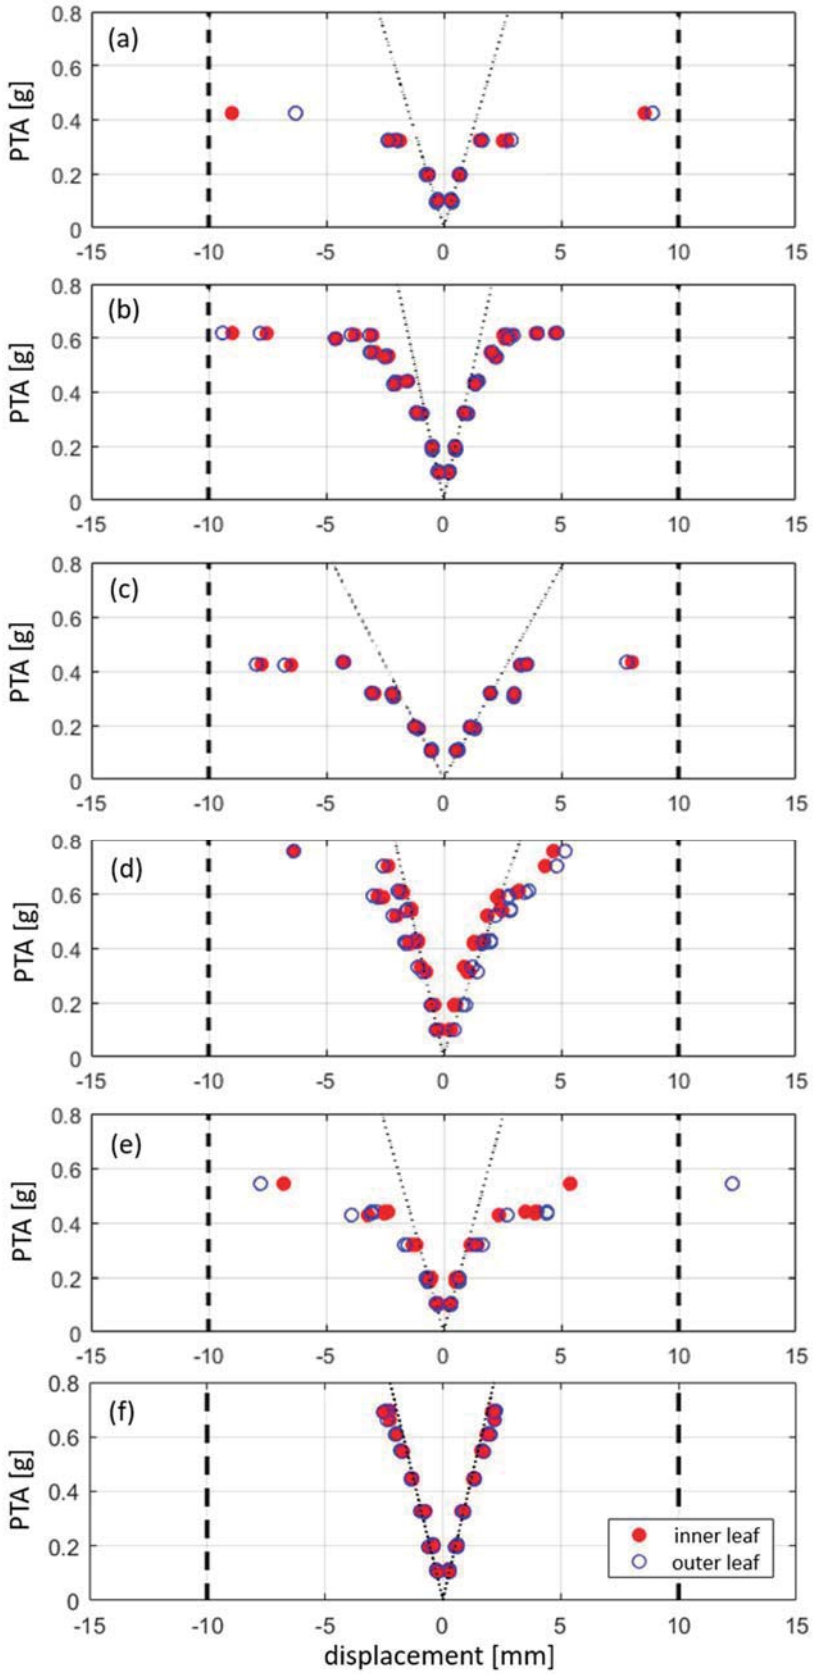

Figure 9: Peak displacement middle test specimen versus peak table acceleration (PTA) for Gr-2 signals: (a) R1, (b) R2, (c) Fischer, (d), Remix/Strating, (e) ClickBrick, and (f) Straw Blocks. The black broken line indicates the measurement range of the lasers; the black dotted line is a fitted line on the data with PTA $\leqslant$ 0.2 g.

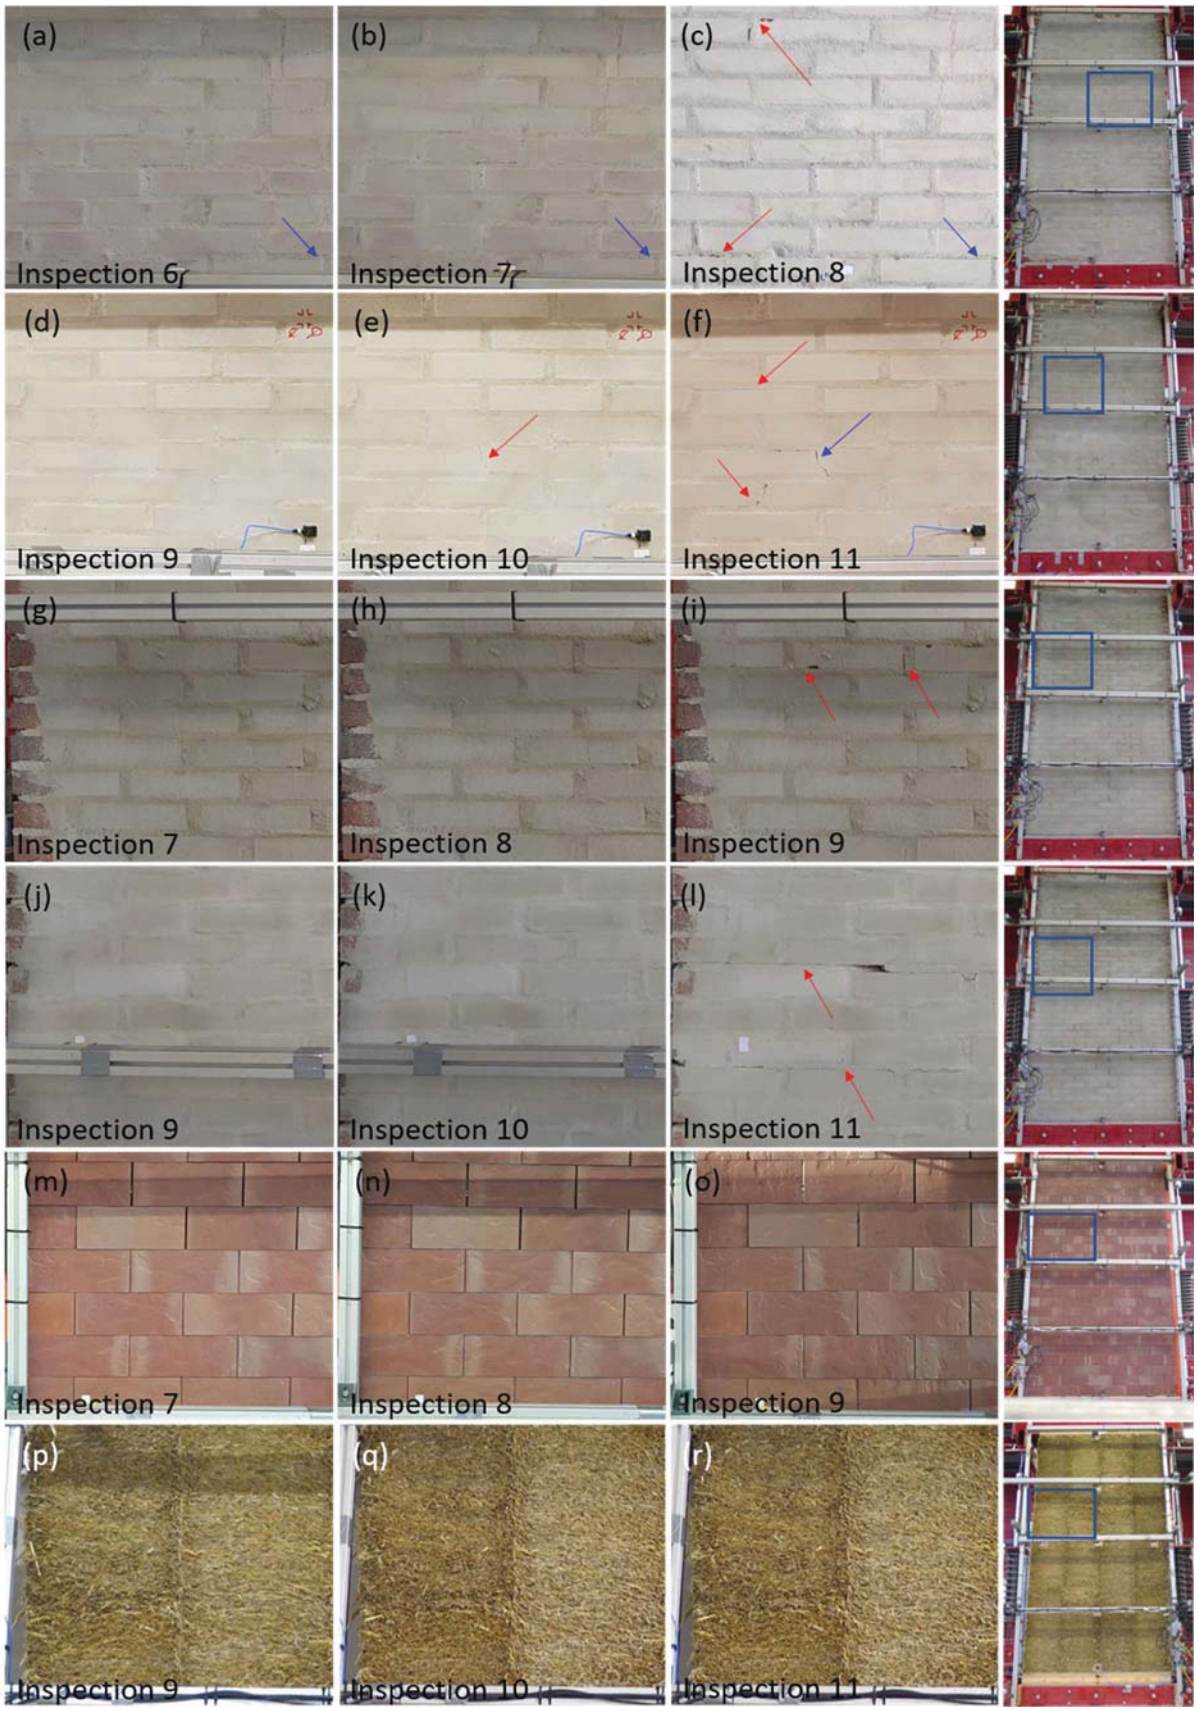

Figure 10: Pictures taken of the indicated zones in subsequent inspections on specimen (a-c) R1, (d-f) R2, (g-i) Fischer, (j-l) Remix/Strating, (m-o) ClickBrick and (p-r) Straw Blocks in the specified inspections. The red arrow indicates observed new damage, the blue arrow indicates damage also observed in an earlier inspection.

Figure 9(c) shows the peak displacements of the Fischer specimen with increasing PTA. The minimum and maximum displacement follow a linear trend up to a PTA = 0.2 g. In the tests with PTA = 0.4 (SF = 100%), a clear increase in peak displacement can be seen. However, no damage was observed in inspection 8 after these tests. Damage was observed after the first test with SF = 130%; damage inspection 9 was performed immediately after this test. Figure 10(i) shows cracking at z / h ≈ 0.75, indicated with red arrows. The Fischer specimen failed in the third test with SF = 130%.

The peak displacements of the Remix/Strating specimen are shown in Figure 9(d). The minimum and maximum displacement follow a linear trend up to a PTA ≈ 0.5 g. The peak displacements deviate from the linear trend from a PTA = 0.6 g. Visual damage was observed after the third test at SF = 170%; Figure 10(l) shows cracks at z / h ≈ 0.5 and z/h ≈ 0.6. The Remix/Strating specimen failed in the subsequent test at SF = 170%. The results of the Remix/Strating specimen indicate that the application of the high-strength mortar in the outer leaf increases the damage resistance.

Figure 9(e) shows the peak displacements of the ClickBrick specimen. The minimum and maximum displacement follow a linear trend up to a PTA ≈ 0.3 g. From a PTA ≈ 0.4 g, a clear increase in peak displacement is seen. However, no visual damage was observed in any of the inspections on the ClickBrick specimen. The test specimen failed in the third test at SF = 150%.

Figure 9(f) shows the peak displacements of the Straw Blocks specimen with increasing PTA. The minimum and maximum displacement follow a linear trend until the last test at SF = 170% (PTA = 0.7 g). The Straw Blocks test specimen showed no damage after completion of the tests in the first floor configuration.

4 CONCLUSION

This paper presented some of the results of an experimental study on the out-of-plane one-way bending behavior of load-bearing walls with various building products. Products that were investigated are a high-strength mortar (Remix/Strating), a mortar-less dry-stacked masonry system (ClickBrick), a renovation anchor tie system (Fischer), and a compressed straw block system (Straw Blocks). The results obtained for the specimen with these products were compared to tests performed on two cavity wall specimen (R1 and R2) constructed from materials typically applied in Dutch masonry buildings.

At shaking intensities with PTA < 0.4 g (ground floor configuration) both reference specimen R1 (solid brick outer leaf)) and R2 (perforated outer leaf) had the same linear elastic peak displacement response in the middle of the specimen. For larger PTA, specimen R1 displayed significantly larger peak displacements than R2. This indicates smaller changes in the properties of specimen R2, and suggests less damage accumulation.

The peak displacements of the Fischer specimen (renovation anchor) were about a factor 2 greater than those observed for specimen R1 and R2. This indicates the out-of-plane bending stiffness of the Fischer specimen is smaller than that of R1 and R2. The rubber plug applied in the renovation anchor might result in a more flexible connection between the inner and outer leaf, resulting in a lower out-of-plane bending stiffness.

The Remix/Strating specimen displayed linear elastic behavior up to a PTA ≈ 0.5 g in the first floor configuration. This result indicates an improvement of the damage resistance of the cavity wall compared to specimen R1 and R2, due to the high strength mortar applied in the outer leaf.

The peak displacements of the outer leaf of the ClickBrick specimen were slightly larger those of the inner leaf. This is probably due to the greater flexibility of the outer leaf, because

of the flexible clip elements between the dry-stacked stones. Although the specimen exhibited significant non-linear behavior from a PTA of 0.4 g in the first floor configuration, no damage was observed in the damage inspections up to failure.

The Straw Blocks specimen could not be tested up to failure due to the limitations of the table; linear elastic behavior was observed until a PTA = 1.2 g in the ground floor configuration and a PTA = 0.7 g in the first floor configuration.

For future work it is recommended to investigate the influence of specimen and record-to-record variability on the findings of the current study.

ACKNOWLEDGEMENTS

This work is part of the research project “Beoordelingskader voor herstel en versterking bij aardbevingen” which was performed by TNO in cooperation with Strating, Remix Droge Mortel, FeNB2, Fischer, Straw Blocks Systems, Wienerberger, BuildinG, and EPI-Kenniscentrum. Keywords: E-defense, High seismic grade, Primary natural frequency, Amplitude dependent, Damage evaluation

Abstract. *The 1995 Kobe earthquake and the 2011 Tohoku megathrust earthquake caused catastrophic consequences to a large number of wooden houses. A quick damage evaluation of houses in a disaster-stricken area is important to avoid confusion after an earthquake. In recent years, several methods have been examined to monitor aseismic performance of wooden houses, aiming at detecting damage by measuring changes in the dynamic characteristics of buildings before and after an earthquake, such as natural periods.*

In 2019, a shaking table test of a full-scale wooden house was conducted at E-Defense, NIED. The test specimen was a frame-type three-story wooden house (Japanese seismic grade index: 3). In the three directional shaking table test, the main excitation consisted of six JMA Kobe waves and four JR Takatori waves at different amplitudes. The maximum horizontal acceleration of each of the excitations ranged from 1.79 m/s2 to 14.43 m/s2. In the experiment, damage to the specimen gradually increased at each shaking. Eventually, the maximum story drift angle of the first story reached 1/19.

The authors examined the relationship between earthquake-induced damage and the reduction of natural frequency by microtremor measurement. In the experiment, the natural frequency of the wooden houses showed an insignificant decrease within the maximum story drift angle of 1/300 or less. A significant reduction of the primary natural frequency occurred after the drift angle exceeded 1/50 and the house was damaged to some extent. Even in the ultimate state where the maximum story drift angle exceeded 1/20, the primary natural frequency was 60% or larger than the original state.

1 INTRODUCTION

The 1995 Kobe earthquake [1] and the 2011 Tohoku earthquake [2] caused catastrophic consequences to many wooden houses. A quick damage evaluation of houses in a disaster-stricken area is important to minimize confusion after an earthquake. In recent years, several methods have been examined to monitor aseismic performance of wooden houses, aimed at detecting damage by measuring changes in the dynamic characteristics of buildings before and after an earthquake, such as natural periods [3, 4].

In this paper, the authors examined the relationship between earthquake-induced damage and the reduction of natural frequency by microtremor measurement based on the experimental results of a shaking table test of a full-scale wooden house.

2 E-DEFENSE SHAKING TABLE TEST

E-Defense of NIED (National Research Institute for Earth Science and Disaster Resilience, Japan) is the world's biggest shaking table (15m x 20m), and can precisely reproduce three-dimensional ground motion, such as that recorded at the Kobe Earthquake, with a test model of 1,200 tf on the shaking table.

2.1 Specimen

In 2019, a shaking table test of full-scale wooden houses was conducted at E-Defense. Two 3-story wooden houses were used for the test (see Figure 1): an adopted Post and Beam (P&B) structure, and a Shear-Wall (SW) structure. Both were built following the generic construction methods of Japanese Grade-3 index buildings (these seismic performances are 1.5 times the required level of the Japanese design code). The house's outer wall, interior, kitchen, bathroom, furniture and fixtures were prepared for the test, in addition to its structural members. This paper only discusses the P&B specimen. As shown in Figure 2, the base-isolation system was installed under the RC footing of the P&B specimen.

Figure 2 shows a plan view of each floor. As shown in Figure 2, seismographs and micrometers were placed on the 1st and 3rd floor.

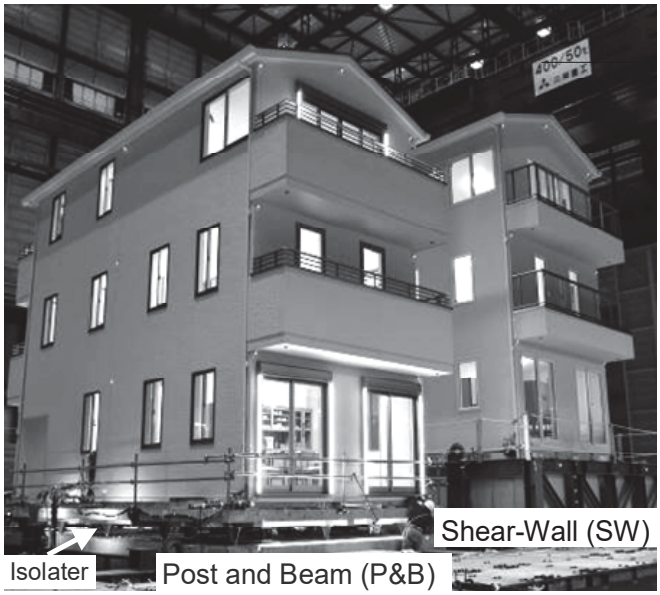

Figure 1: Two 3-story wooden houses.

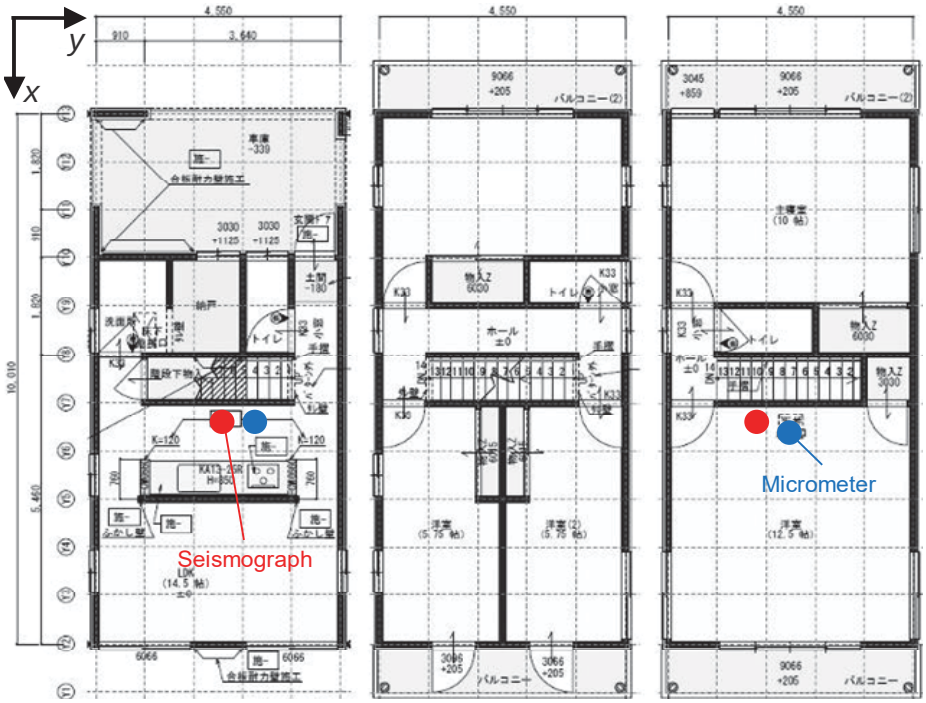

(a) 1st Floor (b) 2nd Floor (c) 3rd Floor

Figure 2: Plan view of P&B specimen.

2.2 Input waves

The shaking table test was programmed to impose gradually progressive damage to the wooden houses using input waves of gradually increasing amplitude. A total of six JMA Kobe waves (see Figure 3) of different amplitudes and four JR Takatori waves (see Figure 4) were used. The maximum horizontal acceleration of each main excitation ranged between 1.79 m/s^2 to 14.43 m/s^2. Table 1 shows the maximum acceleration for each excitation.

In the excitation I to VI, the base-isolation system was functioning. The device was then removed, and the footing of specimen was fixed to the shaking table.

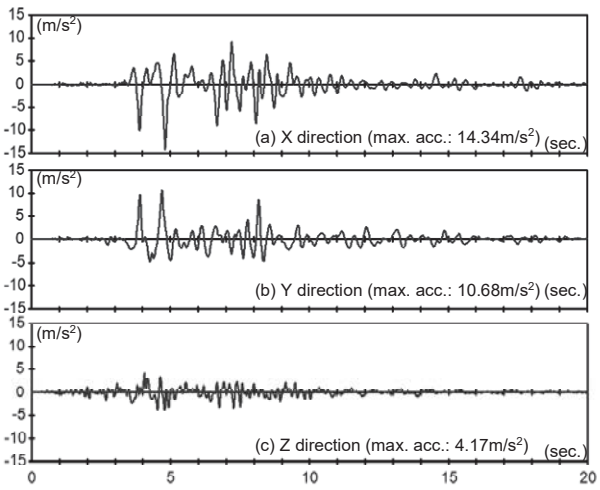

Figure 3: JMA Kobe Wave 100% (Excitation IX).

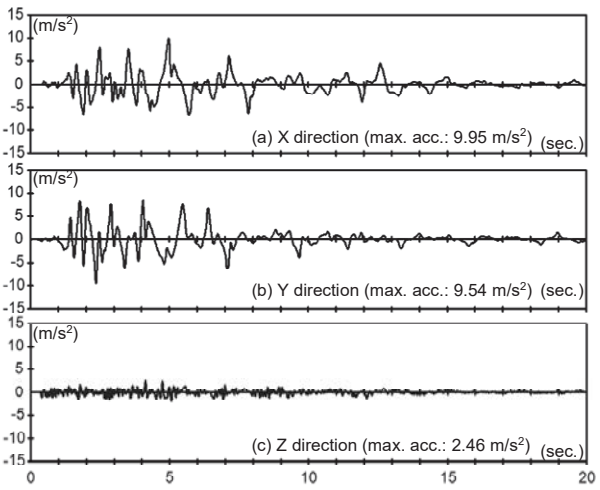

Figure 4: JR Takatori Wave 100% (Excitation X).

Table 1: Example of the construction of one table.

Excitation Number	Input Wave	Maximum Acceleration (m/s^2)			Footing	Maximum Story Drift Angle (1st story)		Microtremor Measurement
		X dir.	Y dir.	Z dir.		X dir.	Y dir.	
I	JMA Kobe 25%	2.21	1.90	0.87	Base isolation	1 / 1,250	1 / 1,111	(1) Original
II	JMA Kobe 50%	5.15	4.24	1.94		1 / 833	1 / 909	
III	JR Takatori 25%	1.87	1.79	0.38		1 / 1,250	1 / 1,250	
IV	JR Takatori 50%	4.10	4.16	0.90		1 / 769	1 / 588	(2) After Excitation IV
V	JMA Kobe 100%	14.43	11.02	4.15		1 / 588	1 / 400	
VI	JR Takatori 100%	962	9.19	2.56		1 / 400	1 / 313	
VII	JMA Kobe 25%	2.22	1.90	0.78	Fixed	1 / 769	1 / 526	(3) After Excitation VI
VIII	JMA Kobe 50%	5.06	4.28	1.82		1 / 145	1 / 128	
IX	JMA Kobe 100%	14.34	10.68	4.17		1 / 27	1 / 49	
X	JR Takatori 100%	9.95	9.54	2.46		1 / 19	1 / 36	(4) After Excitation X

2.3 Microtremor measurement

As shown in Table 1, microtremor measurements were taken four times. The first measurement (1) was performed before Excitation I. At this time, the specimen was non-damage (original condition). The second measurement (2) was after Excitation IV, and the third measurement (3) was after Excitation VI. Thus far, the specimen was a base-isolation system. The last measurement (4) was conducted after all the shaking table tests. This measurement results included the damage to the specimen that occurred after the footing was fixed to the shaking table.

2.4 Damage to the wooden house

In Table 1, the maximum story drift angle (SDA) of the test specimen (1st story) during the main excitation is shown. Until excitation IV (JMA Kobe 25%, 50%, and JR Takatori 25%, 50%), the maximum story drift angle was 1/500 or less, indicating an elastic behaviour. In excitation VI (JR Takatori 100%), the maximum story drift angle exceeded 1/400. The interior wall cloths were partially cracked, although the degree level of plasticization was not high. The base-isolation system of the specimen was functioning normally. In excitation IX and X (JMA Kobe 100% and JR Takatori 100%), the maximum story drift angle exceeded 1/50, and significant damage occurred, as shown in Figure 5.

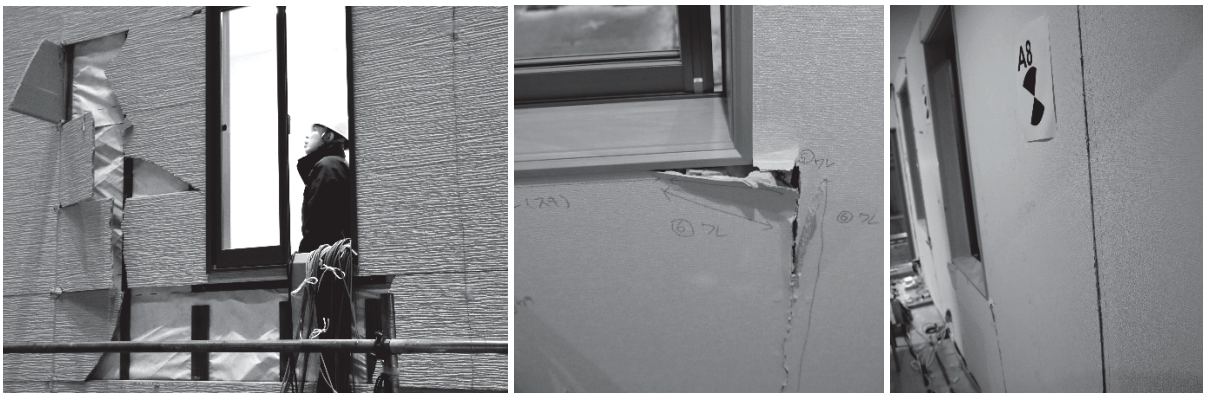

Figure 5: Damage of test specimen.

3 RESULTS OF MICROTREMOR MEASUREMENT

Figures 6 and 7 show the transfer function between 3rd floor acceleration response and 1st floor. Figure 6 is the *X* direction (the long side of the test specimen), and Figure 7 the *Y* direction (the short side). Red lines show the microtremor measurement (1), blue lines show the measurement (3), and purple lines show the measurement (4). In a non-damage condition (the original), the natural frequencies (the peak amplitude of the transfer function) of the test specimen were: *X* direction, 6.18 Hz, *Y* direction, 4.81 Hz. After Excitation VI, when the maximum story drift angle reached 1/400 to 1/313, the natural frequencies changed to 5.86 Hz (95% of the original) and 4.71 Hz (98%). In this range, the variations of natural frequencies were small, even though the test specimen (wooden house) was damaged. After Excitation X when the maximum story drift angle exceeded 1/50, the natural frequencies decreased to 3.86 Hz (62% and 80% of the original).

Figures 8 show the natural frequency - the maximum story drift angle relationship. In the experiment, the natural frequency of the wooden houses showed an insignificant decrease within the maximum story drift angle of 1/300 or less.

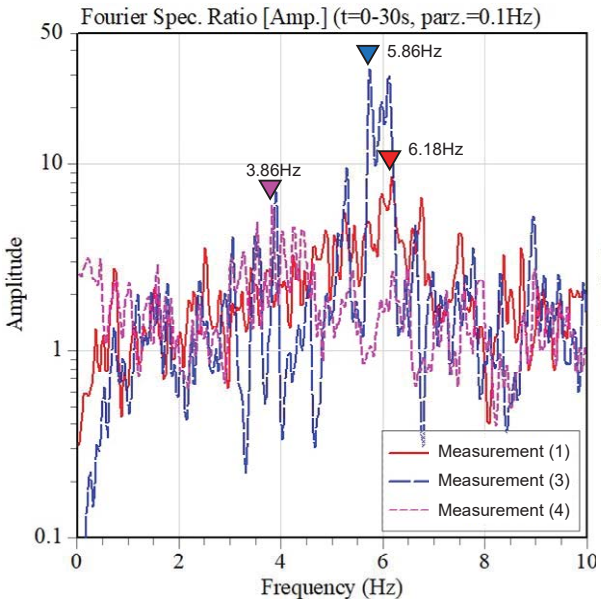

Figure 6: Transfer function of *X* direction.

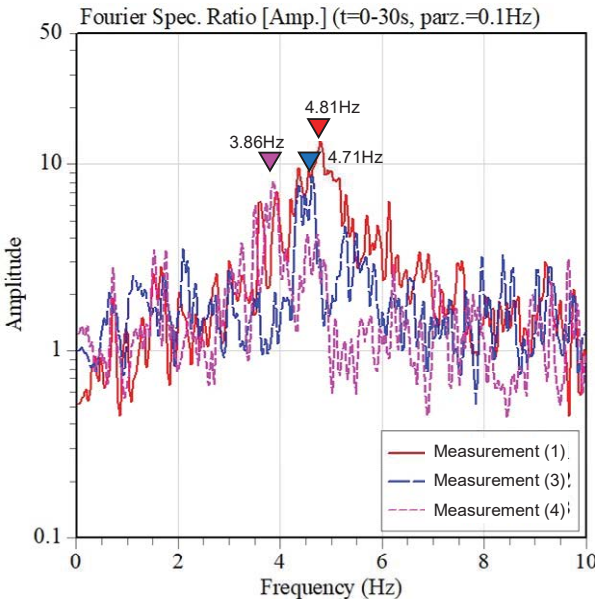

Figure 7: Transfer function of *Y* direction.

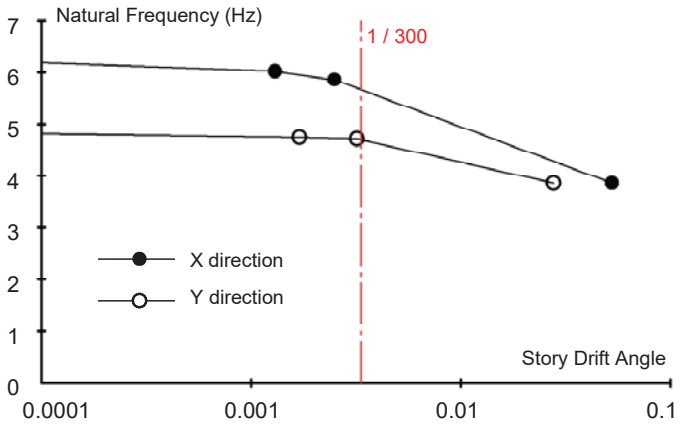

Figure 8: Natural Frequency - Maximum Story Drift Angle Relationship.

4 CONCLUSIONS

This paper examined the relationship between earthquake-induced damage and the reduction of natural frequency by microtremor measurement based on a shaking table test of a full-scale wooden houses conducted at E-Defense, NIED. The excitation consisted of six JMA Kobe waves and four JR Takatori waves at different amplitudes. In the experiment, damage to the specimen gradually increased at each shaking. Eventually, the maximum story drift angle of the first story reached 1/19.

The natural frequency of the wooden houses showed an insignificant decrease within the maximum story drift angle of 1/300 or less. A significant reduction of the primary natural frequency occurred after the drift angle exceeded 1/50, and the house was damaged to some extent. Even in the ultimate state where the maximum story drift angle exceeded 1/20, the primary natural frequency was 60% or larger than the original state.

Abstract. *Nonlinear Time History Analyses (NTHA) are generally regarded as the most accurate way of predicting the dynamic response of a structure to a given seismic ground motion. However, these types of analyses are computationally demanding and require proper software. The aim of this paper is to investigate the feasibility and accuracy of an Equivalent Linear analysis (ELA) where material nonlinearity is accounted for through an iterative procedure with the use of secant stiffnesses. The method is applied to one of the pylons of a major suspension bridge recently designed in Chile. For comparative purposes, two models are created in the open-source framework OpenSees: 1) a full nonlinear fiber model where nonlinear material behaviour is accounted for through distributed plasticity, and 2) an elastic model where the element flexural stiffnesses are updated using the ELA method. The analyses are carried out for seven earthquake time histories. The results show that the ELA is able to reproduce the maximum forces in the structure with a satisfactory accuracy. However, the method is not able to capture regaining of stiffness once cracks are closed due to cyclic responses.*
For further verification, several pushover analyses are also conducted on both models with the inertial forces extracted from the most unfavourable time-steps in the nonlinear time domain analysis. The pushover analysis verifies that the ELA method is capable of predicting the structural response up to the point of yielding of the steel reinforcement or crushing of the concrete. Nevertheless, the method is fairly accurate in identifying possible plastic hinges, and to some degree, assessing the ductility of the structure.

1 INTRODUCTION

Large suspension bridges are particularly susceptible to earthquake excitation due to their slender configurations. When built in seismic active areas, earthquake induced forces often become the most prominent design criteria, thus accurately capturing this effect during design calculations are of top priority. This is no exception for the Chacao Bridge, which upon completion will connect the island of Chiloé to the Chilean mainland. The suspension bridge spans approximately 2750 meters, divided into two main spans of 1155 and 1055 meters supported by three pylons. The Norwegian consultant company Aas-Jakobsen participated in the international design team tasked with designing the bridge. One of the firm's task was design of the bridge pylons. The northern and southern pylons consist of two pylon legs connected by three girders, all of which are made from hollow Reinforced Concrete (RC) sections. With the bridge located in one of the most seismic active regions in the world, namely the subduction zone between the Nazca Plate and the South American Plate [1, 2], a complete time history analysis (THA) was deemed necessary to predict the structures response to a seismic event. The analysis was carried out in RM-Bridge [3] with seven ground motion records corresponding to a seismic event with a return period of 1030-years (Maximum Probable Earthquake) [4].

Although widely recognised as an accurate way of capturing the behaviour of structures subjected to cyclic dynamic forces [5], running a full NTHA on large structures such as the Chacao Bridge quickly becomes a momentous task and convergence is not guaranteed. If, however, the sections of the structure are expected to exceed their elastic domain during an seismic event, the forces resulting from an THA may be too conservative since the ductile behaviour of the structure is not captured [6].

To cope with the issue of overestimating forces when designing the Chacao Bridge pylons, an iterative procedure was proposed, hereby referred to as the ELA. First, the nonlinear moment-curvature relation was calculated for each section in the Finite Element (FE) model. Then, a series of elastic THAs was carried out using the same ground motion record. Following each analysis, the largest absolutes moment for each section was obtained and used together with the appropriate moment curvature relation to determine the secant stiffness of that section. A new elastic model with updated stiffness properties was then established. When the flexural stiffnesses of the sections converge after a number of THAs, the nonlinear material response of the structure is considered approximately captured. The final iteration with converged stiffness properties will therefore in principal have the same resulting forces as those following a full NTHA. An elastic analysis with secant stiffnesses is allowed by the AASHTO Seismic Design Manual, as long as the distribution of forces are verified to be consistent with expected nonlinear behaviour [7]. The use of cracked stiffness properties is also recommended by the Eurocode 8 when performing a linear elastic analyses [8]. However, it appears that little attention has been paid to investigate the consistency between the two methods. A comparative study was therefore conducted using the South Pylon of the Chacao Bridge. A FE model with linear elastic elements was developed in OpenSees [9], onto which the ELA could be conducted. A second model with nonlinear material properties was used as a baseline. Finally, multiple pushover analyses were performed for further verification of the methods capabilities.

2 MODEL DESCRIPTION

2.1 OpenSees Model

The FE model of the South Pylon in this study was established in the open source software framework OpenSees [9]. The geometry and material properties of the models were based on

the RM-Bridge model previously created by Aas-Jakobsen during the design of the Chacao Bridge with minor modifications. The suspension cables were simplified as springs at the top of each pylon leg. Additionally, the foundation SSI-matrices were simplified by neglecting off-diagonal terms and modelling the remaining parts as linear springs.
For the comparative purpose of this study, two models were established; a model with nonlinear material properties using the fiber section functionality provided in OpenSees and a linear elastic model. The nonlinear fiber model utilized the built-in material models *Concrete02* [10] and *Steel02* [11] for the concrete and reinforcement fibers, respectively. The moment-curvature relations used in the ELA were obtained with the same material models. The chosen material parameters are summarized in Tables 1 and 2.

Parameter	Symbol	Value
Expected maximum compressive strength	f_{pc}	58.5 MPa
Initial modulus of elasticity	E_{cm}	32.1 GPa
Strain at maximum compressive strength	ε_{c0}	3.64 ‰
Ultimate compressive strength	f_{pcu}	49 MPa
Ultimate compressive strain	ε_{cu}	5 ‰
Expected tensile strength	f_t	4.05 MPa
Tensile softening stiffness	E_{ts}	4.41 MPa
Ratio between unloading and initial slope	λ	0.5

Table 1: *Concrete02* material parameters.

Parameter	Symbol	Value
Expected yield strength	f_y	470 MPa
Young's modulus	E_s	200 GPa
Yield strain	ε_y	2.35 ‰
Strain hardening ratio	b	0.06
Isotropic hardening parameter	a_1	0
Isotropic hardening parameter	a_2	1
Isotropic hardening parameter	a_3	0
Isotropic hardening parameter	a_4	1
Asymptote parameter	R_0	0.20
Asymptote parameter	cR_1	0.925
Asymptote parameter	cR_2	0.15

Table 2: *Steel02* material parameters.

P-Δ transformation was applied in order to capture nonlinear geometry effects, with the pylon carrying gravity loads from the bridge deck in addition to its self weight resulting in severe compression forces. Damping was included as Rayleigh damping, with a chosen target damping ratio of 5 % for the two fundamental modes in the longitudinal and transverse directions of the bridge.

2.2 Model verification

As the discretization of the fiber section is important for the performance of both the full nonlinear analysis and the ELA method, a study on discretization was conducted to decide on the appropriate average size of the concrete fibers in the pylon. The study was performed by calculating the moment-curvature diagrams for representative sections along the pylon with varying axial forces. The results revealed that a mesh consisting of 25×10 concrete fibers per side of each pylon leg element was sufficiently accurate without restricting the efficiency of the analyses, as seen in Figure 1.

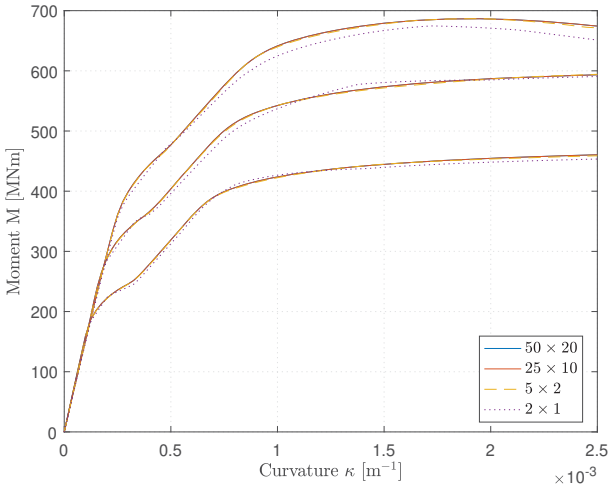

Figure 1: Moment-curvature relations for different meshing and axial load.

The modal properties of the two models were compared to verify that their initial stiffnesses and therefore initial dynamic properties would be similar. The mean deviation of modal periods for the first 20 modes is 1.26%, with a maximum deviation of 2.15% in mode number 20. This was deemed sufficiently accurate to assume similar initial behaviour between the models under both static and dynamic loading.

3 ANALYSIS PROCEDURE

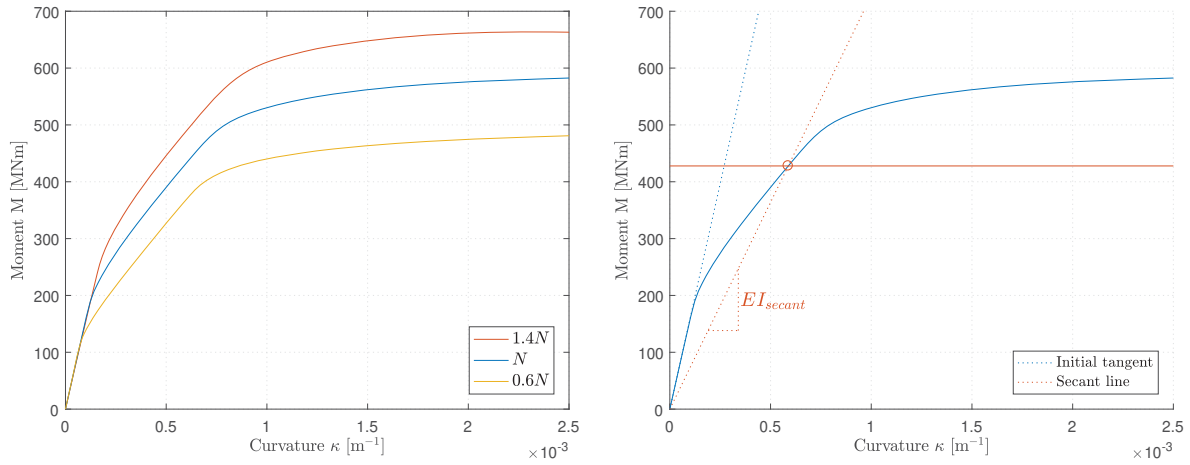
3.1 Equivalent Linear Analysis

The algorithm for the ELA was developed using a combination of the THA solver in OpenSees and MATLAB for post-processing data. The method is largely based on nonlinear moment-curvature relations for the RC sections, so these are initially computed by performing a section response analysis for each fiber section in OpenSees. Since this relation depends on axial force, seen in Figure 2a, a series of different scaling of the gravity load was applied so that each element had a number of moment-curvature diagrams associated with it. The stiffness properties of the initial linear elastic elements were taken as the slope of the tangent at the origin for the corresponding moment-curvature relations with unit gravity load. A full transient THA was then conducted in OpenSees using the the linear elastic model and Newmark's constant average acceleration method as time-stepping scheme. The selected ground motion was applied in both horizontal directions with a time step of 0.01 seconds. Data regarding forces, acceleration and displacements was recorded during the analysis and upon completion written to text files. MATLAB was then invoked to post process the results. For each element, MATLAB scripts obtained the maximum moment about both principle axes along with the corresponding axial forces. The

updated stiffness about each axis was then obtained by finding the intersection point between the moment and the appropriate moment-curvature relation, as shown in Figure 2b. By making use of the relation

$$EI = \frac{M}{\kappa} \tag{1}$$

where M and κ is the moment and curvature about the section axis, the secant stiffness was taken as the slope of a line going through the origin and the intersection point. Since the axial load changes for each iteration during the procedure, the intersection point was linearly interpolated between existing curves, enveloping moment-curvature relations so to avoid recomputing these for each iteration.



(a) Effect of compressive load for M-κ relation.

(b) Secant line in M-κ relation.

Figure 2: Determination of secant line using moment.

The updated stiffness for each element was taken as the mean between the newly acquired and previous value, to ensure smoothness during the scheme. A new linear elastic model with updated stiffness properties was then created. If the newly obtained stiffness values differed significantly from the previous ones, another iteration was initiated using the updated model. The iterations continue until the change in all element stiffnesses falls below a given convergence threshold.

3.2 Pushover Analysis

The pushover analyses were conducted with inertial forces as basis for the load distribution. For each critical element, e.g. base elements in the pylon legs or cross-beams, the total acceleration in each node was retrieved for the time-step where the maximum bending moment appeared for that element. The different total acceleration profiles were then multiplied with the mass matrix to obtain the inertial forces which were set as the load level for load factor $\lambda = 1$. The obtained distributions were then scaled from $\lambda = 0$ until the solution failed to converge. This procedure was conducted on both the full nonlinear model, as well as the one using the ELA iteration scheme.

4 ANALYSIS RESULTS

4.1 THA

The results from the time history analyses show that in general the ELA method was able to capture maximum bending moments in critical sections of the pylon. Table 3 summarizes the maximum forces in selected elements of the pylon, averaged over all seven ground motions for both the initial elastic model and the reduced stiffness model obtained through ELA. The average reduction ratios from the initial stiffness of the elements are also included in the table. The moments are normalized by the bending moment values following the NTHA by using the formula

$$M^* = \frac{M}{M_{fiber}} \tag{2}$$

Element	Ratio	$M^*_{y,initial}$	$M^*_{y,final}$	$M_{y,fiber}$ [MNm]
4101	0.63	1.12	1.06	338
4103	0.80	1.11	1.03	274
4106	0.99	1.10	0.96	187
4112	0.99	1.04	1.21	92
4115	0.82	1.10	1.11	192
4120	1.00	1.04	1.03	53
4501	0.31	1.27	1.03	185
4701	0.35	1.13	1.01	137

Table 3: Summary of average normalized bending moments about the bridges transverse axis.

Figure 3 and 4 plot the displacement and moment response histories of the full nonlinear fiber model, the initial elastic model and the converged model using the ELA for one of the input ground motions. The maximum bending moment response for each model is highlighted in the plot. Figure 5 shows the maximum absolute value of the bending moments at the base of the pylon normalized against the bending moment response of the fiber section model, with the average values across all seven ground motions plotted at the bottom.

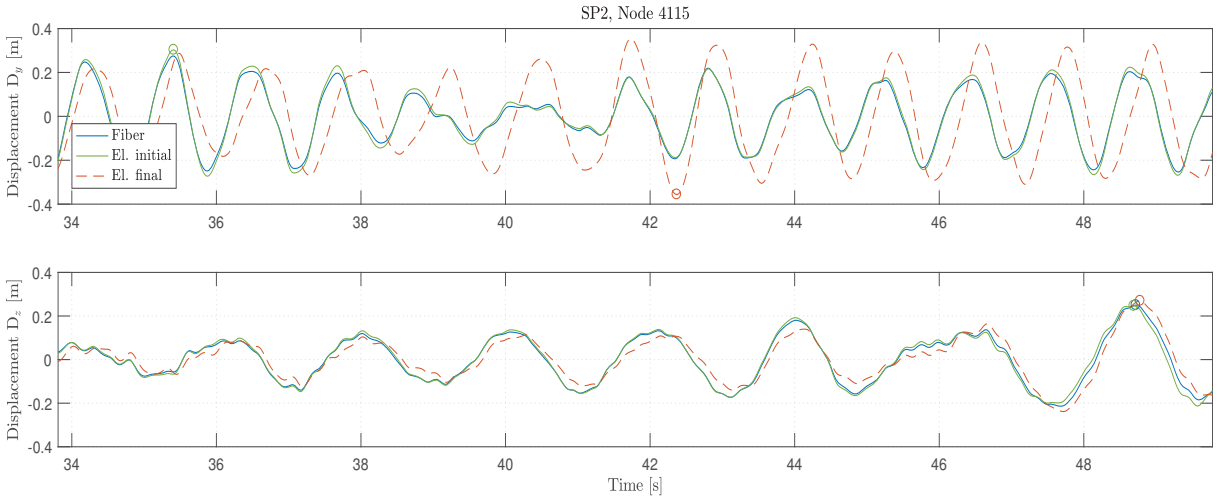


Figure 3: Displacement response history of upper part of pylon.

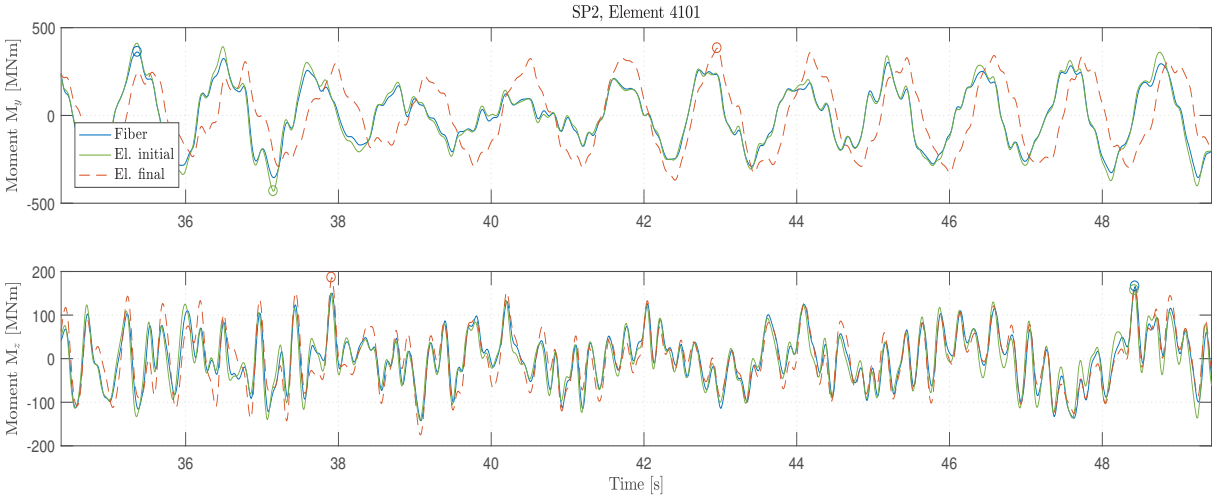

Figure 4: Moment response history in base of pylon.

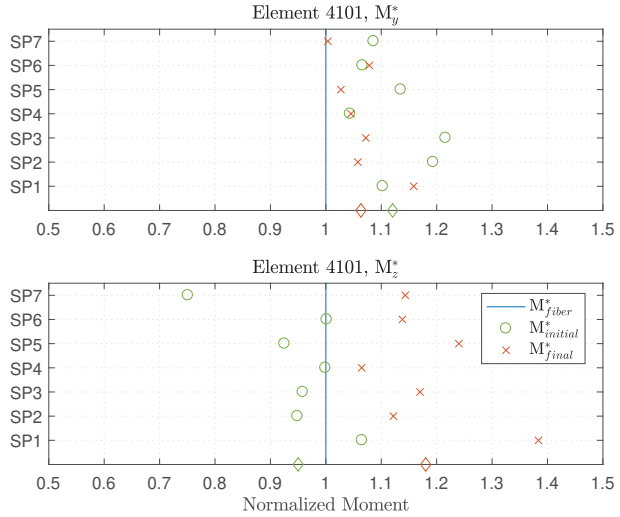

Figure 5: Moment response history of element 4101.

When studying the time histories for the various input ground motions, it is clear that in the ELA performed well in approximating the bending moments in the pylon. From Table 3, the largest deviation between the final iteration of the ELA and the full nonlinear model was 21%, which occurs in element 4112. A possible reason for the deviation in this element is the combination of low bending moment levels and large deflections in this particular area of the pylon. This in turn means that the forces and therefore reduction ratios are largely governed by the stiffness of the remaining elements of the pylon and consequentially second order geometrical effects plays a significant role. This effect can also be seen in the bottom part of Figure 5, where the M_z values appear quite spurious, and are in general larger for the final iteration of the model based on the ELA than the model with initial stiffnesses. This is a general trend in areas with small bending moments and can be attributed to second order geometrical effects.

For the remaining elements listed in the table, the largest deviations were in the range of 1-11%, which from an engineering point of view is acceptable for an approximate method. For the displacement time histories, the model using the ELA was slightly shifted in its response compared to the model with initial stiffnesses and the full nonlinear model. This is is explained

by the fact that the stiffness of the various elements in the ELA model are based on the largest forces throughout the response history. The ELA model also does not include closing of cracks which in sum yields a lower stiffness and therefore larger, phase-shifted displacements.

4.2 Pushover analysis

The pushover analyses conducted in this study served as a foundation for verifying the results from the THAs, as well as a separate examination for comparing the response of structures using the ELA and nonlinear material models. Figure 6 plots the load-displacement pushover curve for the analysis L1, while Figure 7 plots the moment distributions for load factor $\lambda = 1$ and $\lambda = 1.5$ where the latter is the load factor where the model using the ELA failed to converge. Analysis L1 corresponds to the inertial force level and distribution which yields the largest bending moments at the base of the western pylon leg, that is, element 4101. The results for the base and upper part of the pylon are summarized in Table 4.

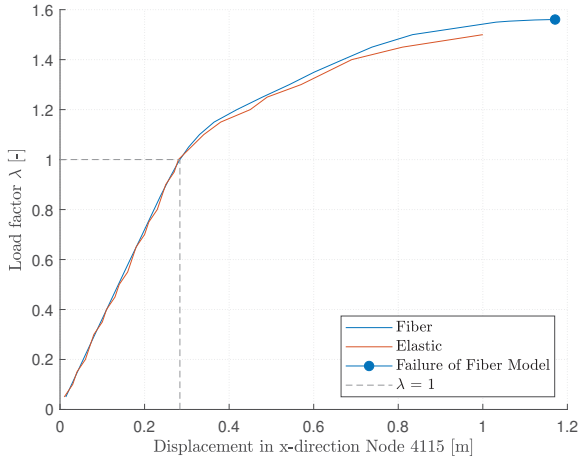

Figure 6: Force-displacement pushover curve for analysis L1.

When transient and cyclic effects are excluded, the pushover analyses shows the ELAs ability of accurately approximating the nonlinear model during static analysis. The various pushover analyses conducted demonstrate that the ELA performed well both up to the load level retrieved from the THAs and beyond. For design purposes, pushover analyses performed on models with the ELA method can be used to predict the location of possible plastic hinges. It can also be implemented to control safety factors for given load levels from transient analyses.

Element	Ratio $\lambda = 1$	$M^*_{\lambda=1}$	Ratio $\lambda = 1.5$	$M^*_{\lambda=1.5}$
4101	0.95	0.99	0.47	1.03
4201	0.95	1.00	0.47	1.04
4115	0.92	1.02	0.47	1.05
4215	0.93	1.01	0.31	1.04

Table 4: Summary of critical element for pushover analysis L1.

5 CONCLUSION

The goal of this study has been to assess if the the secant stiffness can provide a reasonable approximation to the nonlinear material behavior of structures. By assessing the forces succeeding ELAs and comparing these to the forces following full NTHAs, several remarks can be made. For the majority of elements the approximation of forces is satisfactory, especially for those enduring large moments during the THA. There are however anomalies where the ELA increases the gap between responses which may be rooted in the shortcomings of the method. Unlike a full NTHA, the ELA is not able to take effects such as cyclic degradation, closing of cracks and dissipation of energy due to cracking of the concrete into consideration. Further, since the stiffness reduction developments occur independent of each other during each iteration, information regarding interaction between elements is lost.The consequence of this is an overall softer structure, with certain unpredictable properties. Rather than using the stiffness values obtained following the ELA, it is proposed to use these as guidelines for creating new ones. By selecting stiffnesses enveloped by the initial and reduced values, more towards the latter, overestimation of stiffness reduction is counteracted. The resulting structure will then inherit a realistic crack distribution. The quality of the nonlinear approximation was confirmed by pushover analyses, where the ELA was capable of accurately producing similar bending moment and deflection patterns as the nonlinear fiber model. When reaching load levels where post-yield capacity was expected, the ELA produced bending moments with slightly higher values in the elements experiencing the largest stiffness reductions. This is due to how the ELA obtains secant stiffnesses for moments close to the section's ultimate capacity.

Overall, the ELA has proven to be a valid alternative to a full nonlinear analysis. The method is also code-compliant as it satisfies the requirements from both Eurocode 8 and the AASHTO Guide Specifications for LRFD Seismic Bridge Design with regards to providing results that are consistent with expected nonlinear material behaviour.

6 ACKNOWLEDGMENTS

This paper is partly based on the MSc thesis of the first two authors in the Department of Structural Engineering at the Norwegian University of Science & Technology (NTNU) [12]. These authors would like to thank Aas-Jakobsen for providing the neccecary resources for preparing this paper, as well as their general support for this study.

Abstract. *Knowledge about the plastic behaviour of steel bars in reinforced concrete (RC) structures is important, especially for seismic design. The paper presents the results of experimental tests where the main aim was to observe the plastic deformations, interaction and bond-slip of reinforcement bars inside concrete strands. In standard tests of reinforcement bars the gauge length is 5d (i.e. five times the diameter of the bar). The tests on the concrete strands revealed that a length of 5d is not representative for the actual section length of the reinforcement bar, which develops free length inside the tested concrete strands that is longer than 5d.*

1 INTRODUCTION

Destructive testing of RC elements includes the risk of damaging conventional meters and sensors that are directly connected to the specimens. A non-contact optical technique known as Digital Image Correlation (DIC) is an alternative method where this risk is not a problem. The main principle of the DIC-method is to use camera and take continuously photos with short time interval of the test specimen during the loading of the test specimen. Digital image correlation technique is then used to match a selected facet on pictures taken of the surface of the test specimen before and after each load step, i.e. between pictures in the series, and thus follow the deformations throughout the entire test. The method can detect deformations anywhere on the surface of the specimen which is facing the camera. Meaning that "meters" can be located afterwards anywhere on the test specimen's surface, which is very convenient for crack development in concrete and necking in reinforcement bars in long test specimens.

The DIC technology has been applied for more than three decades. It was originally proposed by a group of researchers at the University of South Carolina, USA, early in the 1980s [1, 2]. Since then the method has been developed and refined and the algorithms have been improved [3, 4]. Improvements in digital camera technology in recent decades, e.g. higher resolution, have facilitated improvements in DIC analysis. The accuracy of the DIC analysis depends on the resolution of the camera used, the distance from camera to specimen, and by the fines and details of the pattern on the surface of the test specimen. The quality of the processing algorithms and software used to correlate the images is also very important.

The knowledge of how plastic deformations develop and how interaction and bond-slip of reinforcement bars inside concrete elements develop under seismic action is essential for rational and economical seismic design of RC structures. Number of experimental and analytical studies of bond slip in RC elements exists in the literature [5, 6, 7]. Some more recent studies have used the DIC technique in investigating bond slip [8, 9].

In this paper the results of experimental tests using DIC technique are presented where the main aim was to study the plastic deformations, interaction and bond-slip of reinforcement bars inside concrete strands. Prior to the testing of the strands, novel uniaxial DIC tests were done on long unboned reinforcement bars, i.e. bars without concrete confinement, in order to get basic information on both longitudinal and lateral plastic deformations of long ribbed steel bars [10]. The test results of the long steel bars help to explain the observed behaviour of the bond slip in the RC strands.

2 TEST SPECIMENS AND TEST SETUP

2.1 Reinforcement bars

Prior to the testing of the concrete strands, tests were made on eight reinforcement bars alone (i.e. not inside concrete) with the same length as the bars inside the concrete strands [10]. Six of the bars had thickenings at the ends and two of them were without thickenings (Table 1).

The reinforcement bars had a characteristic yield strength of min 500MPa and a strain at max stress of min 7.5% according to class C in Eurocode 2 [11]. The bars had two rows of transverse ribs and two longitudinal ribs. All the bars fulfilled the demands concerning strength, strain and geometry according to Eurocode 2 [11] and EN 10080:2005 [13].

The reinforcement bars were washed with hydrochloric acid (HCl), primed with a thin layer of matte white spray paint and finally marked manually with a black pen (Fig. 1).

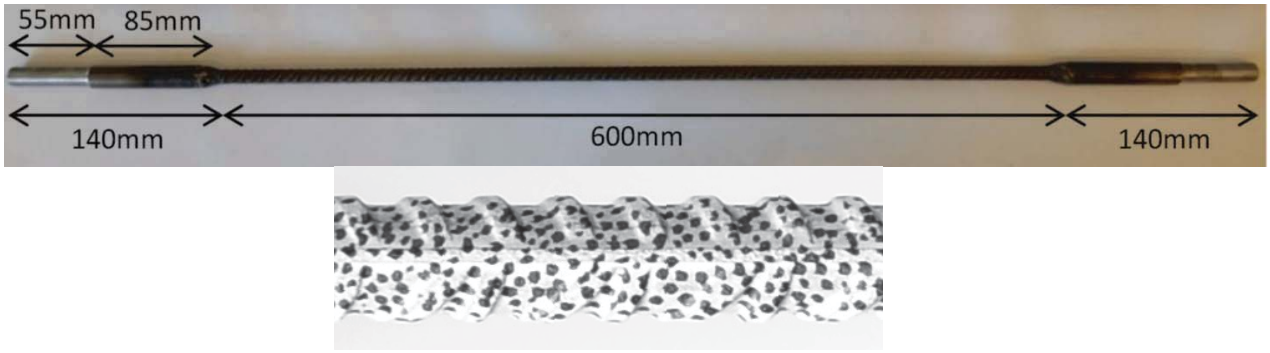

Figure 1: (a) Reinforcement bar (10mm) with thickenings at both ends that were used in two of the concrete strand test specimens. (b) The surface of the bars that were tested alone (Table 1) were dotted with black dots for the DIC analysis.

Test and bar no.	Diameter (mm)	Free length (mm)	Resolution of pictures (pixels/mm)	(mm/pixel)	Remarks
2.1, 2.2, 2.3, 2.4	10	775	9.01	0.111	Thickening at the ends
3.1, 3.2	10	775	7.43	0.135	Thickening at the ends
4.1, 4.2	10	775	7.43	0.135	No thickenings

Table 1: Overview of the reinforcement bars tested alone (i.e. not inside concrete), where the bars are numbered with the test number followed by a running number. The free length is the visible part of the bars between the grips of the testing machine.

2.2 Concrete strands

Tests were made on four concrete strands with a dimension of 100x100x740mm with one 10mm ribbed reinforcement bar located at the centre (Fig. 2, Table 2). The reinforcement ratio is 0.79%. The concrete had a cylinder compressive strength of 32MPa and an axial tensile strength of 23MPa. The concrete strands were primed and dotted the same way as the reinforcement bars (Fig. 2)

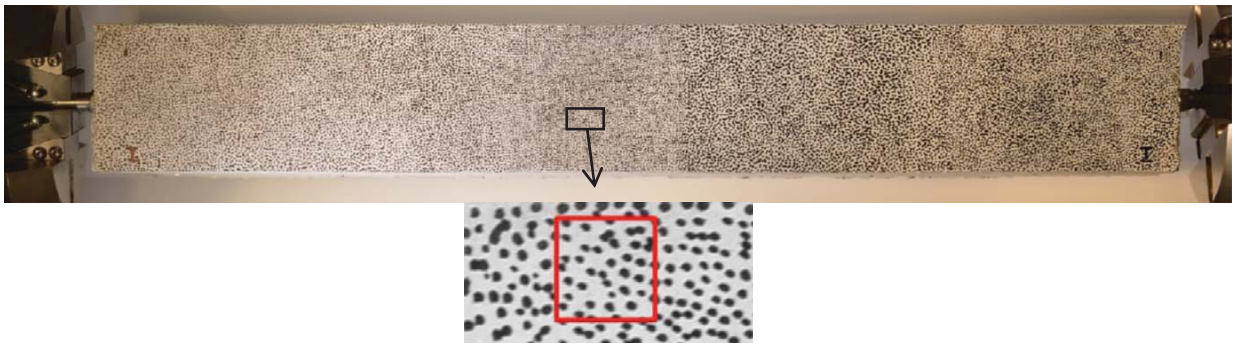

Figure 2: Concrete strand with ribbed reinforcement bar at centre (the test specimen on the picture is located vertically in the testing machine, but is here shown horizontally). The side that is facing the camera is dotted with black dots for the DIC analysis. The size of the dots can be seen inside the red box which is 10x10mm at size.

Concrete strand no.	Width (mm)	Length (mm)	Bar diam. (mm)	Resolution of pictures (pixels/mm)	(mm/pixel)	Remarks
1, 2, 3, 4	100x100	740	10	8.78	0.114	Bar in strands 1 & 2 had thickening at the ends

Table 2: Overview of the concrete strands tested.

Two of the concrete test specimens (strands 3 and 4) had a normal reinforcement bar, but the other two (strands 1 and 2) were equipped with bar with thickenings at the ends. The thickenings secured that the in-elastic behavior of the bars took place inside the concrete, as the stress in the thickenings was in the elastic state during the test. The thickenings consist of steel rods with a 16mm diameter that were welded to the reinforcement bars (end to end). The diameter was reduced to 14mm on the outermost 55mm so they fitted into the grips of the testing machine (Fig. 1).

2.3 Test setup, hardware and software

All tests (i.e. bars alone and the concrete strands) were executed in an Instron testing machine with a capacity of 500kN. A 500kN load cell was used to measure the applied load. The test setup for the concrete strands is shown on Fig. 3 and the test setup for the reinforcement bars alone was identical. The tests were executed in a displacement controlled mode at a speed of 0,1mm/sec. The elastic stress rate in the bars (in tests for bar alone) was within given limits in EN ISO 6892-1:2009 [12]. Pictures were taken with one second interval, but not all the pictures were though used in the DIC analysis. The number of pictures used in each DIC analysis was in the range 164-203. One camera with 36-megapixel resolution was used in the tests. A monitor showing the jack load was located close to the specimen and visible on all photos and was used for synchronisation of the load with the DIC analysis.

In DIC analysis "subsets", each including a different random pattern, are defined and tracked as the specimen moves and deforms. The displacement of the centre of each subset is given in the output results. The size of the subsets must be defined in harmony with the resolution of the pictures and the applied pattern, where several dots are needed inside each subset. Generally, the size of the subsets in this study was in the range of 1.0×1.0mm to 3.4×3.4 mm for the reinforcement bars and 13.8×13.8mm for the concrete strands. The software DaVis 8 from LaVision [14] was used in the DIC analysis.

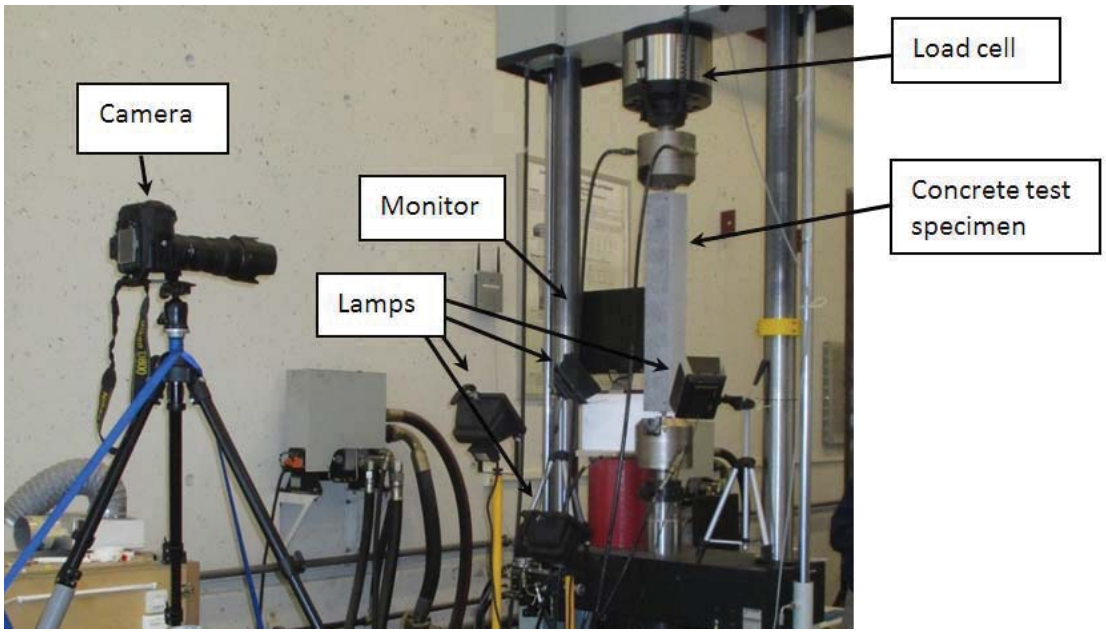

Figure 3: Test setup with one camera on a tripod, four lamps and a monitor.

3 TEST RESULTS

3.1 Test of reinforcement bars

The standard uniaxial stress-strain curves for steel bars are based on laboratory tests of bars with 5d gauge length, where d is the diameter of the steel bar [11, 12]. Because the DIC analysis is executed after the test, the location of the gauge segment can be decided after the test, symmetric about the neck. The gauge length can also be different from 5d. In the test series of 170-600 mm long reinforcement bars the following gauge lengths were used: 1d, 3d, 5d and 10d [10]. The stress-strain curves for these gauge lengths were identical all the way to the max stress, but after that the segment including the neck dominated the strain development. As both the uniaxial and lateral strain was measured, the Poisson's ratio could be determined. The Poisson's ratio increased rapidly during the yielding phase to 0.44-0.49 and was constant all the way to rupture. The bars developed a yielding plateau where the yielding propagated from one end of the bar to the other (Lüder's behaviour [15]) on approximately 1d long segment at a time.

In Fig. 4 strain-vs-picture (corresponds to strain-vs-time) and stress-vs-picture curves for twelve 50mm long side-by-side segments are shown. Note that the stress-vs-picture curve is scaled down by 5000 in order to fit into the graph. The outermost segments (segment 1 and 12) included the welding at the thickenings. The following notes 1-5 are marked on the graph on Fig. 4:

1. Up to picture no. 20 the bar is in the elastic range.
2. Between pictures no. 20-40 the stress-curve has a bending shape that begins at approximately 400MPa. The bending shape is a result of yielding in segments 1 and 12 in the bar at the welds (i.e. the strain on the vertical axis increases rapidly in segments 1 and 12). The heat from the execution of the welds resulted in lower yield stress in the bar at the welds and in a different yield behaviour (bend shape instead of a yielding plateau).
3. Between pictures no. 40-75 the stress-curve is horizontal, i.e. yielding plateau. The yielding strain can be observed as vertical jump in the strain curves beginning with segment 2. When segment 2 stops yielding segment 3 takes over and so in continues in a numeric order to the last segment 11[10]. I.e. the yielding-front propagates from one end of the bar to the other, known as Lüder's behaviour [15].
4. Between pictures 75-155 the whole bar goes through a strain hardening process.
5. Between pictures 155-164 necking occurs in segment 1, i.e. the bar fails at the weld in segment 1. All the bars with thickenings failed in the bar at the weld.

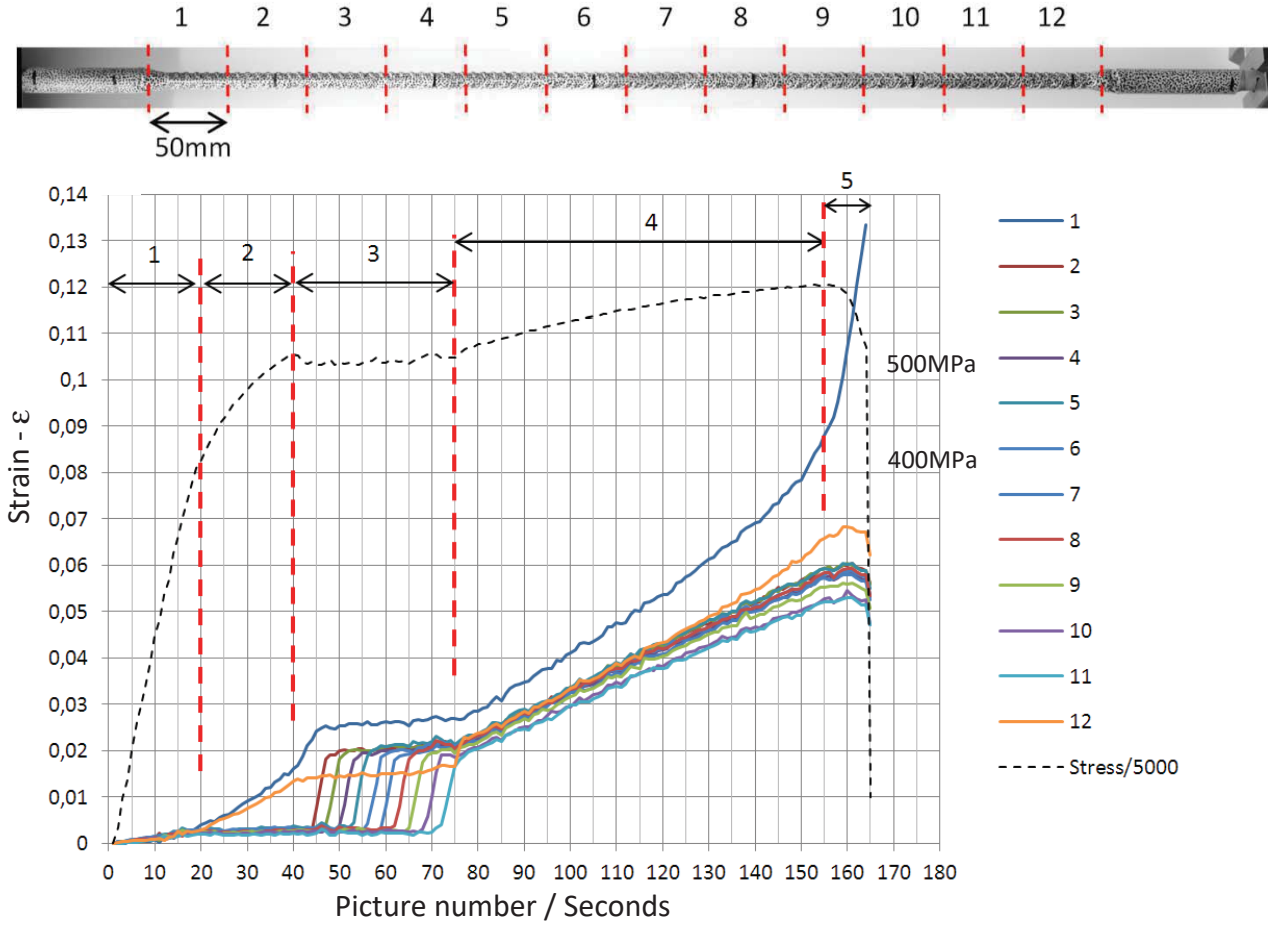

Figure 4: The strain development in twelve 50mm long side by side segments numbered 1-12 as a function of the picture number for reinforcement bar no. 2.1 with thickening at the ends. The segments including a weld are number 1 and 12. The stress in the bar is also shown as a function of the picture number scaled down by 5000 in order to fit into the graph.

Classical stress-strain diagrams for each segment are shown on Fig. 5 and as before segments 1 and 12 show different behaviour from the other segments.

The graph on Fig. 6 shows a stress-strain curve for bar 2.1 that is with thickening at the ends and for bar 4.1 that is without thickenings. Both curves are for gauge segments that includes the neck. The stress-strain curves for all the other bars included in the test (Table 1) are identical to the ones shown on Fig. 6. The heat from execution of the weld is affecting the stress-strain behaviour in the segments including the weld, but not the other segments, as can be seen on the strain-curves for all twelve segments for bar 2.1 on Fig. 4 and on the stress-strain curves on Fig. 5. Firstly, it affects the yielding behaviour as the curve starts bending at approximately 400MPa, instead of following a straight line to the yielding plateau, like segments 2-11 for bar 2.1 on Fig. 5. Secondly, the stress-strain curves are much shorter, so both the max stress and the failure occurred much earlier/at lower strain, in the segments including the weld than the others not including a weld. As can be seen on the graph on Fig. 6 the strain at max stress is though fulfilling the demand of 7.5% elongation for reinforcement bar in class C [11]. Segment 1 on Fig. 4 and Fig. 5 is the same as the one used to present bar 2.1 on Fig. 6 (shown as blue curve on all the graphs). The strain curves for the other segments not including a weld (i.e. segments 2-11) only reached 5-6% strain when segment 1, that included the neck, failed (Fig. 4 and 5).

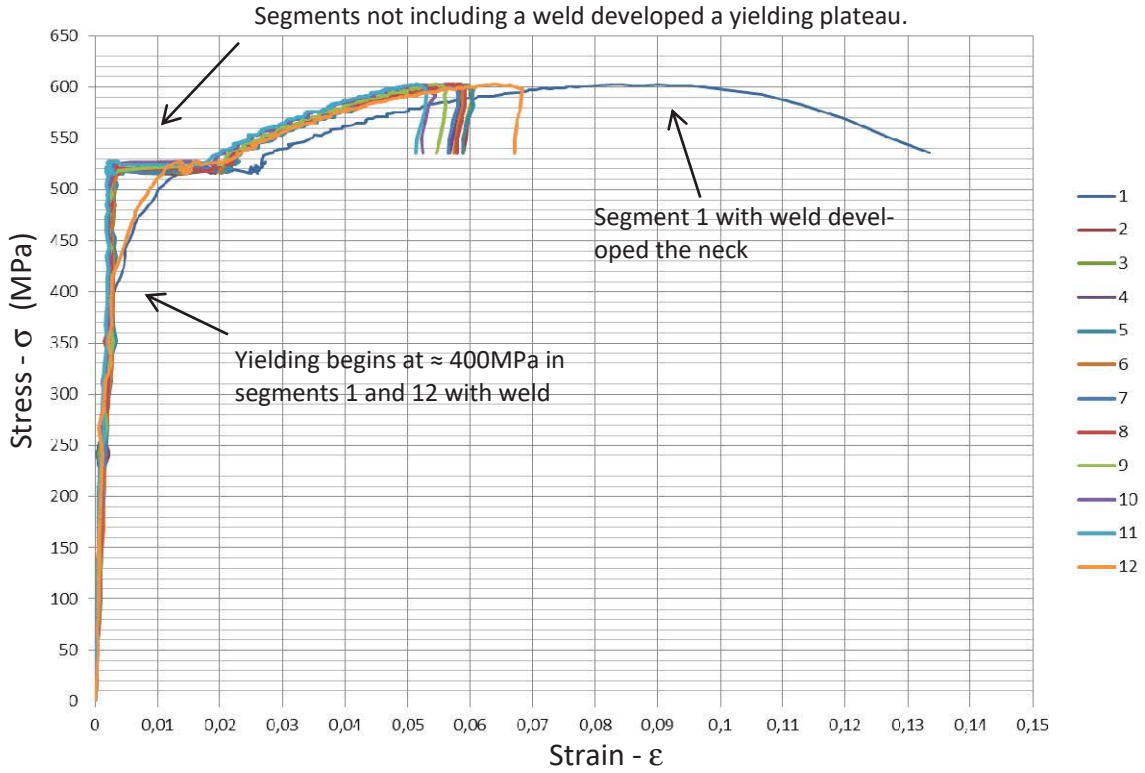

Figure 5: The stress curve and the twelve strain curves in bar 2.1 on graph 4 are here shown together as stress-strain curves. The segment including the neck finished the stress-strain development while the other segments stopped. Segments 1 and 12 including a weld started yielding at app. 400MPa and had a curved shape and a small yielding plateau, while the other segments not including a weld developed a yielding plateau.

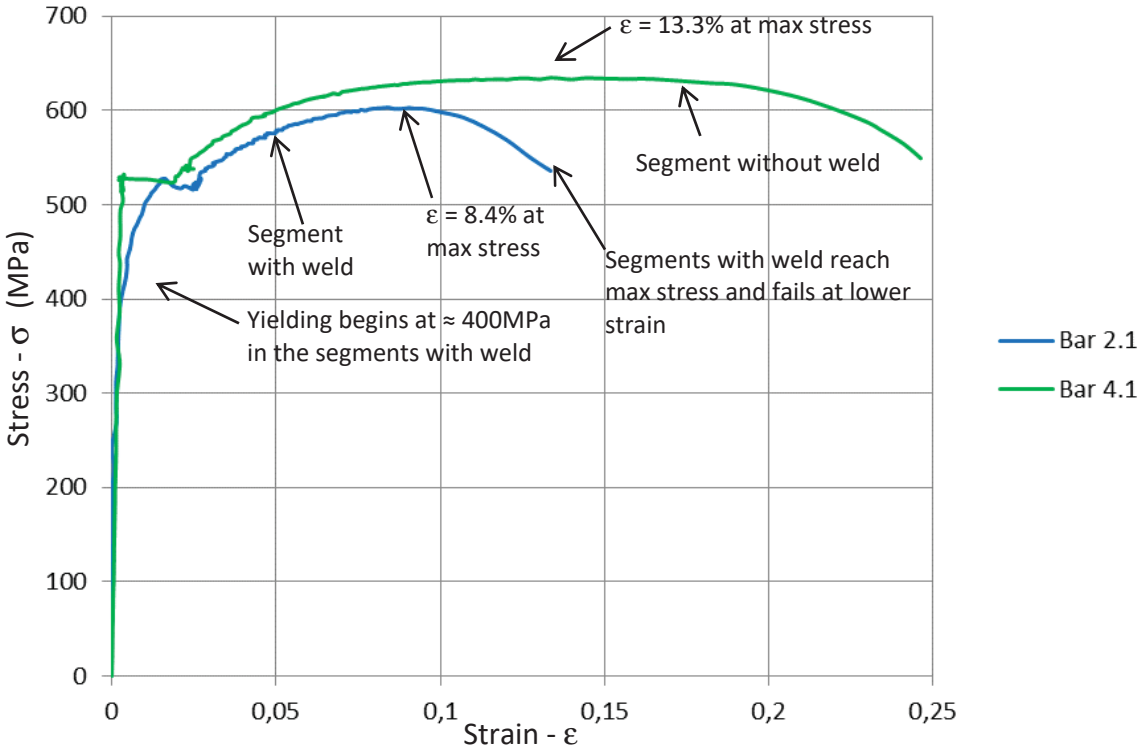

Figure 6: Stress-strain curves for bar 2.1 with thickenings and bar 4.1 without thickenings, where both gauge segments included the neck. The heat from the execution of the welding affects the stress-strain behaviour of the segment including the weld.

3.2 Test of concrete strands

The development of the crack widths and the strain across the cracks was determined on the surface of the test specimens facing the camera. The gauge length was decided to be 50mm as for the reinforcement bars, i.e. five times the diameter of the reinforcement bar inside the concrete. As the DIC analysis was performed after the test the gauge segments could be located with the crack in the centre. Eleven points on each side of the crack were used to determine an average crack width and average strain (Fig. 7).

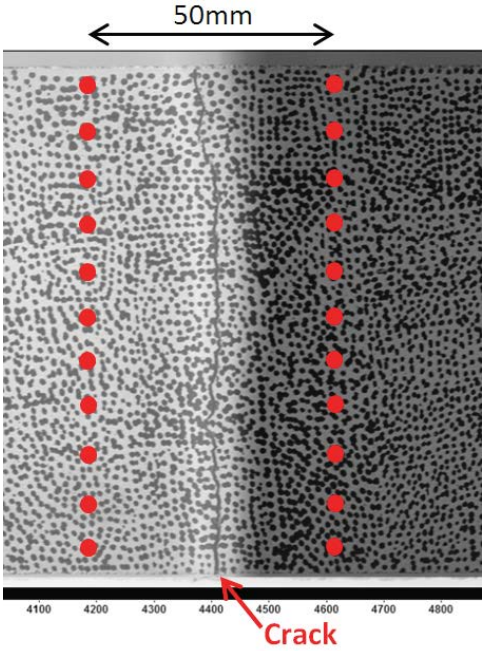

Figure 7: Eleven points on each side of the crack (red dots) were used to determine average values for the crack width and the strain across the crack.

Concrete strand no. 1 was the only specimen that developed two cracks (Fig. 8). No other damage was observed in the concrete. The reinforcement bar ruptured inside the concrete strand at the welding at top, which was confirmed by smashing the concrete with a hammer after the test. The outstanding part of the bar/thickening moved 15mm out of the concrete at the top, but no movement of the bar/thickening at the bottom was observed.
Concrete strand no. 2 developed one crack (Fig. 8). No other damage was observed in the concrete. The reinforcement bar ruptured inside the concrete strand at the welding at top, which became obvious after the test when the bar that was inside the smaller concrete part was easily pulled out of the concrete with bare hands (Fig.8). No movement of the outstanding part of the bars/thickenings was observed.
Concrete strand no. 3 developed one crack (Fig. 8). As expected in strands with reinforcement without thickening at the ends, damage of the concrete at top and bottom was observed. The top of the concrete strand splitted and punching failure was observed at both end surfaces. The bar ruptured at the top, outside the concrete.
Concrete strand no. 4 developed one crack (Fig. 8). As expected in strands with reinforcement without thickening at the ends, damage of the concrete at top and bottom was observed in form of punching failure at both end surfaces. The bar ruptured at the top, outside the concrete.

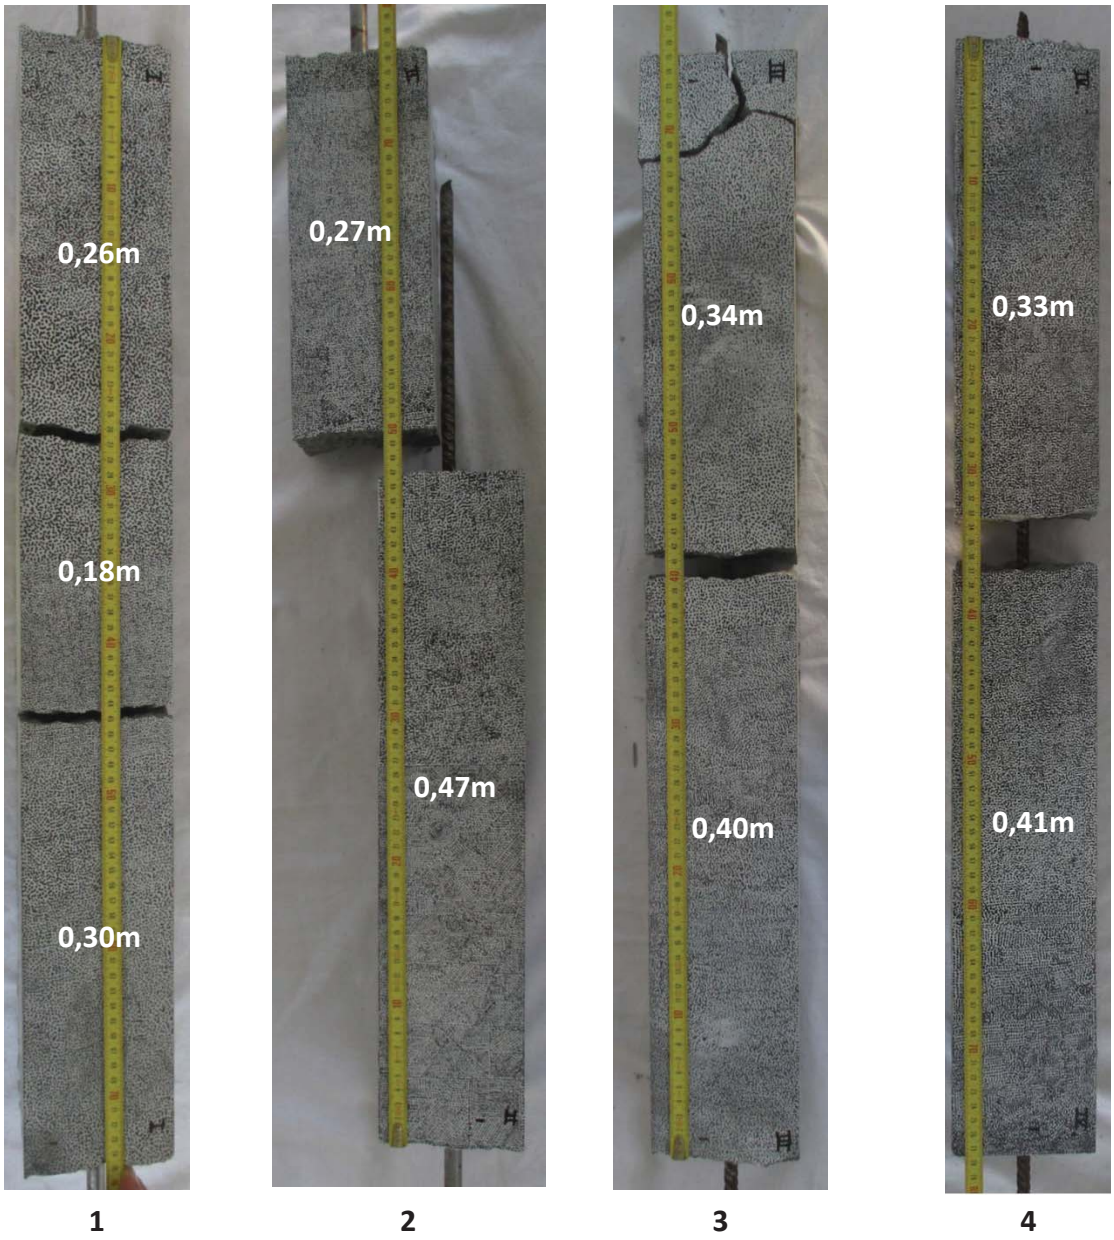

Figure 8: Side view of all four concrete strands after the test, facing the same way as during the test. Test specimen 1 and 2 developed no failures at the ends as the reinforcement had thickenings at the ends. The reinforcement ruptured inside the concrete. Test specimen 3 and 4 had no thickenings in the reinforcement and therefore they developed some failure at the ends. The reinforcement ruptured outside the concrete.

The development of the crack width (w in mm) and the applied axial jack force (P in kN) in the four concrete strands as a function of the displacement of the jack (u in mm) is shown in Fig. 9. In all cases the cracks opened simultaneously with the load drop in the force and in the case of concrete strand 1 there occurred two load drops, one for each crack. As can be seen on the development of the cracks in concrete strand 1 and 2, where the bars have thickening at the ends, the curves show a very steady increase of the crack width, compared with concrete strand 3 and 4 (Fig. 9). The reason is that all the yielding elongation in the bar in strands 1 and 2 happens inside the concrete, while the elongation of the bar outside the concrete is not contributing to the crack width in strands 3 and 4. The curves for the crack width in strands 3 and 4 are therefore not as steady.

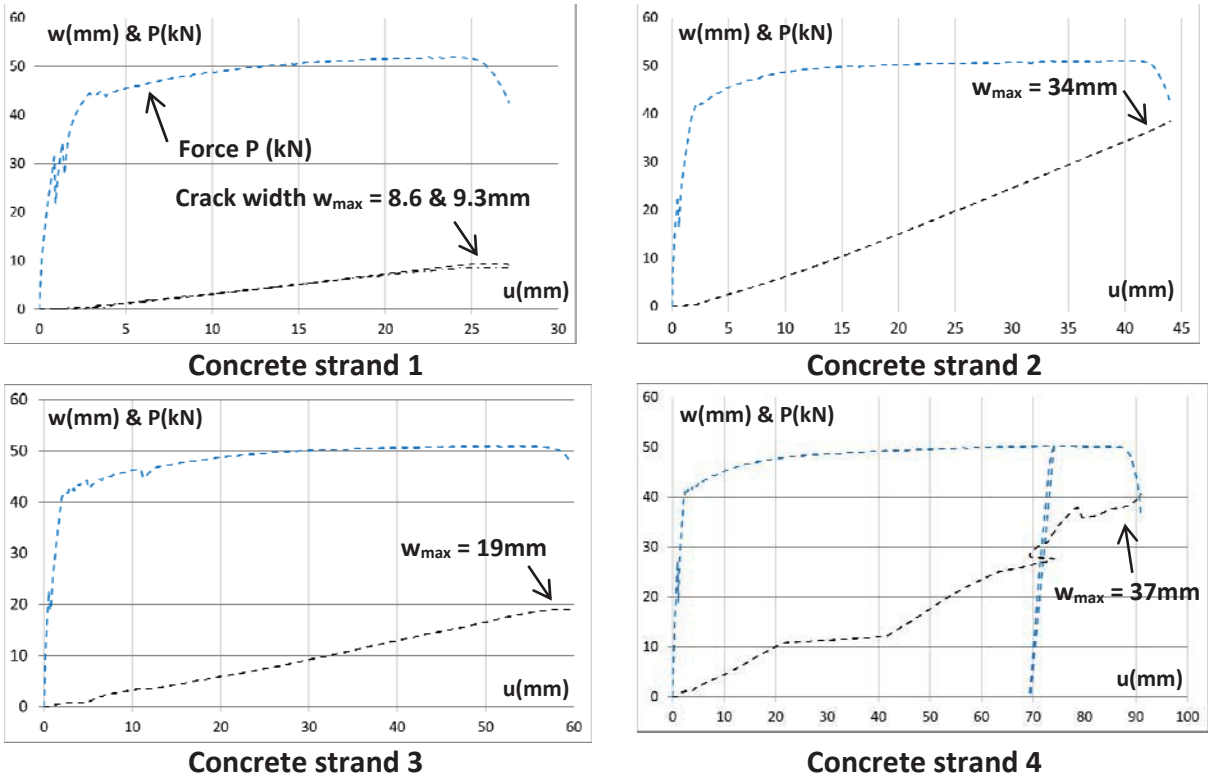

Figure 9: The development of the crack width (w in mm) in the four concrete strands as a function of the displacement of the jack (u in mm). The force in the jack (P in kN) is also on the graph.

In concrete strand 1 the crack width in both cracks starts descending at the same time the force starts descending. The reason is that the bar ruptured in the top weld and the outstanding part of the bar/thickening moved out of the concrete. That is not the case in concrete strand 2 as the crack width continues to increase during the descending part of the force (necking in the bar). The reason is that the necking of the bar occurred completely inside the concrete and contributed to the crack width.

As discussed earlier, another study of the reinforcement bars revealed a development of a yielding plateau where the yielding propagated from one end of the bar to the other. This was then followed by a strain hardening of the whole bar. It was also revealed that the stress-strain curves for gauge lengths in the range of 1d to 10d were identical all the way to the max stress [10]. These findings are important for the understanding of the behaviour of the bars inside the concrete together with the findings in this test, that gauge segments including a weld show different behaviour in the strain development, yield stress and max stress.

In concrete strand 1 and 2 the welds played a bigger role than anticipated in the beginning. The cracks occurred in some distance from the end of the concrete strand as expected, at the end of the transfer zone where the bond between the concrete and the reinforcement bar have transferred sufficient part of the tension force to the concrete, able to over win the tension strength in the concrete and create a crack. In the crack zone the reinforcement bar carries the whole force alone and there is the biggest stress in the bar. The bar starts yielding and because of the Poisson's ratio, which increases during the yielding phase to a value in the range of 0.44 to 0.49 [10], the bar also develops lateral contraction, affecting the bond between the bar and the concrete. The yielding of the bar propagated away from the crack in both directions and reached the weld at top in concrete strands 1 and 2 which failed. This became evident in the case of concrete strand 2 that the yielding is propagating along the bar all the way to the weld which failed and the reinforcement bar could after the test easily be pulled out of the top

concrete part with bare hands (Fig. 8). The bottom part of concrete strand 2 was cut into seven pieces whereof six of them were 50mm in length (Fig. 10). The bond between the reinforcement and the concrete was checked with a hammer. The reinforcement bar inside the two concrete pieces closest to the crack was very loose inside the concrete, while the third one had more resistance. The reinforcement bar inside the fourth piece barely moved when it was hit hard with the hammer and then not at all in concrete pieces number five and six. This indicates that the bar didn't yield all the way to the end of the bottom part of concrete strand 2. The length of the reinforcement bar belonging to the top part of concrete strand 2 (which was easily pulled out of the concrete with bare hands) is 200mm (Fig. 8) and if assumed that the reinforcement was loose inside concrete pieces no. 1 and 2 on Fig. 10 the total size of the free length is 300mm, i.e. 30d.

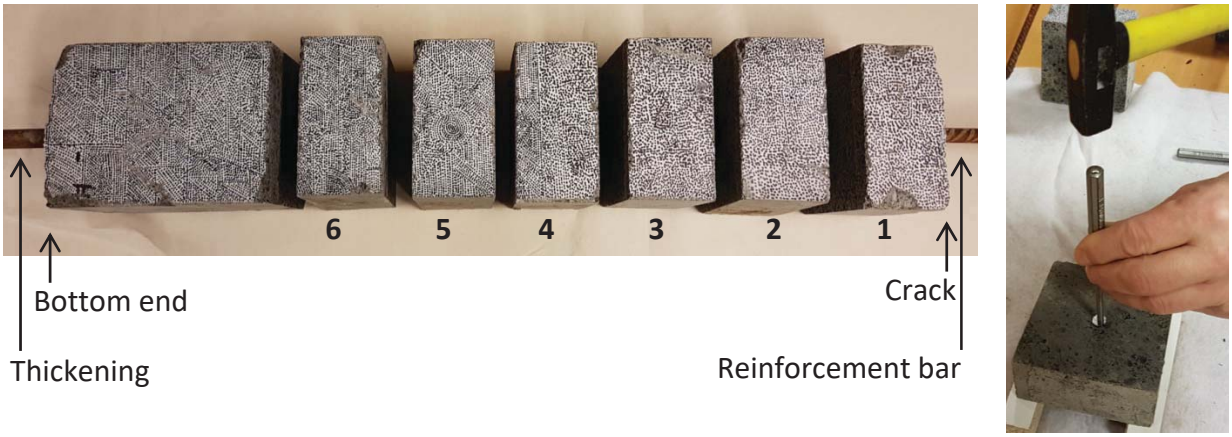

Figure 10: The bottom part of concrete strand 2 (see Fig. 8) was cut into seven pieces for comparison of the bond between the reinforcement and the concrete. The reinforcement in the two concrete pieces closest to crack where loose inside the concrete, but the resistance in the bar increased with the distance away from the crack. The resistance was checked with a hammer.

This simple test indicates that the reinforcement bars lose the bond to the concrete when the longitudinal strain together with the lateral strain increases. This also becomes evident when size of the crack widths is studied.

Concrete strands 1 and 2 have welds in the bars at the thickenings and the strain at max stress in the reinforcement bars is in the range of 8.4-13.3% according to the graph on Fig. 6, depending on whether the yielding occurs in a segment with or without a weld. When the yielding occurs along a long section, like described above, the total elongation of the bar is somewhere in the above-mentioned range, but is most likely closer to the latter value because the weld is only a small part of the total length of the bar that is yielding. Concrete strand 2 had a crack width of 34mm (Fig. 9) and by using the measured free length of 300mm, it results in a strain of 11.3%. By using that strain value for concrete strand 1, also having reinforcement bar with a weld that failed, it results in a free length of app. 8d for both cracks.

Concrete strands 3 and 4 had reinforcement bar without thickenings/welds and the strain can be assumed to be close to the latter strain value mentioned above, i.e. 13.3%. For a standard gauge length of 5d (50mm) it would result in a crack width of 6.7mm. Concrete strand 3 had a crack width of 19mm demanding a free length of 14d and app. 28d is needed for the 37mm crack width in concrete strand 4.

4 DISCUSSION AND CONCLUSIONS

In standard tests of reinforcement bars the gauge length is 5d, but the tests presented in this paper on concrete strands with one 10mm reinforcement bar in the centre, revealed that the free length of the reinforcement bars inside the concrete strands was in the range of 8d-30d. As the whole bar is active along the free length (not only in the vicinity of the neck) and the stress-strain behaviour of the reinforcement bars is the same up to max stress, even though the free length becomes larger than 5d, it results in a large plastic elongation in the uniaxial direction together with a lateral contraction of the bar of the size of 44-49% of the longitudinal strain. The ribs lose its grip on the concrete and the reinforcement bar becomes free inside the concrete. The actual free length becomes longer than 5d resulting in longer elongation of the bar (in mm) avoiding premature rupture of the reinforcement bar during earthquakes.

Abstract. *It is well known that seismic waves are affected by the geological nature of the different layers in which they propagate close to the surface. The various structural and topographic elements cause the incident signal to be reflected, refracted, or diffracted. As a result, the combination of those different waves modifies the spatial, spectral, and temporal characteristics of the wavefield. These phenomena are called site effects. Especially amplifications of the ground motion acceleration is observed, which may induce failure of the structures located on the surface, as well as slope instabilities. The spatial variability of the ground motion can be very significant over small distances, because of the changes in the geometry and the soil conditions. During the last years, many research works have been conducted through numerical simulations on simplified slope geometries in order to identify the effect of geological, topographic and input signal parameters on the amplification of the amplitude of seismic waves. However, the predictions resulting from the numerical simulations are often different from the field observations. So, this paper firstly presents an in-depth literature review about available methods to model site effects and their implications. Secondly, it also focused on results of existing works that benefit from experimental data in the analytical modeling; more especially works considering geophysical data obtained through H/V and MASW experiments are examined.*

1 INTRODUCTION

An earthquake is known by the shaking of the Earth surface, which may cause severe structural destruction and deaths. Energy is suddenly released in the Earth's lithosphere, creating seismic waves, that propagate to reach the surface.
During their journey to the surface, the seismic waves face different kinds of effects, that can modify the spatial, spectral and temporal characteristics of the signal such as its direction, amplitude, duration and frequency content ..., and therefore affect the ground motion. Those effects depend mainly on the complexity of the source mechanism, the path followed by the seismic waves and site effects close to the surface.
Speaking of site effects, seismic waves are affected by the geological structure of the soil in which they propagate. For example, when a seismic wave arrives at an alluvial basin, its propagation velocity decreases while the amplitude of its signal increases. As the geometry and conditions of a sedimentary layer vary over short distances, it means that the seismic signal may vary over small surfaces.
Despite all the harm and risks caused by such phenomena, it has been difficult so far to study the slope stability during dynamic events. In many research studies numerical simulations have been performed on simplified slope geometries (2D models), to identify the effect of geological, topographic and input signal parameters, on the amplification of the amplitude of seismic waves [1, 2, 3, 4, 5, 6]. Few studies have used more realistic geological and geomorphological site conditions (3D models) to compute ground motion amplifications due to surface topography [7, 8, 9].

Therefore, this paper presents an in-depth literature review about available methods to model site effect and its implications. It also focused on results of existing works that benefit from experimental data in the analytical modeling; more especially works considering geophysical data obtained through H/V and MASW experiments we analyzed.

2 SITE EFFECTS

During major historical earthquakes, different aspects of damages have been observed in various locations for the same event. The waves behavior and characteristics, and therefore the distribution of damage, were mainly controlled by the type of soil in which the seismic waves propagate. This phenomenon is commonly called as site effects.
Seismic site effects are related to the alteration of the seismic waves when they propagate close to the surface; seismic waves are trapped in sediment layers (softer layers), they are reflected and refracted on all the borders, edges, slopes and the bottom of sedimentary basin until they dissipate all their energy. That is why infrastructures such as buildings, bridges may be damaged due to the important spatial variability of the ground motion over very small distances.
Many observations around the world have shown that the amplification of a signal could reach 10 times the initial signal amplitude due to similar effects, and it mainly depends on the velocity contrast between the layers and the geometry of the basin [10]. Reflections and refractions also happen when seismic waves reach hills and mountains, which may induce failure of structures situated on the surface or slope instabilities.
Generally, two site effects are considered: the ones due to the geological nature of the soil and those due to the topography.

2.1 Geological site effects

Geological site effects caught the attention of researchers [11, 12, 13, 14] since the Mexico earthquake in 1985, when this large earthquake struck Mexico City with a moment magnitude of 8. Even though its epicenter was located along the Pacific Coast (more than 350 km far from Mexico-City), the city suffered major damage due to the large earthquake magnitude and its geological conditions, which consists of the ancient lake beds that Mexico City sits on. As usually observed, the acceleration amplitude strongly decreased with the distance from the epicenter (from 150 $\mathrm{cm/s^2}$ recorded at a station very close to the epicenter, to 18 $\mathrm{cm/s^2}$ at a station situated at 200 km from the epicenter), but locally increased a lot up to 170 $\mathrm{cm/s^2}$ when the seismic waves reached the alluvial deposit on which Mexico City has been founded: seismic waves have been trapped and they reached the resonance frequency of the site [15]. This was the first time where seismic site effects have been evidenced. Furthermore, a large number of the cities hit by earthquakes were damaged according to the geological and lithological nature of the soil, where they are constructed.

2.2 Topographical site effects

Different observations carried out in the past showed that seismic ground motion is affected by the variation of the site's topography. This hypothesis was presented by Levret et al. (1986) [16] to explain the damages observed in the village of Rognes in France located on a hill, during the Lambesc's earthquake in 1909. Other examples also show that damages were more severe on the crest of hills than on its bottom: San Fernando earthquake in 1971 [17], Whitter Narrow's earthquake (California) in 1987 [18], Chichi earthquake (Taiwan) in 1989, Northridge's earthquake (California) in 1994 [19, 20], Salvador earthquake in 2001, Sichuan earthquake (China) in 2008. One of the first topographic site effects was reported by Spudich et al. (1996) [20] who analyzed signals recorded in several seismological stations installed along Mount Tarzana slope in Los Angeles. They noticed high amplification of the seismic motion, caused by the Northridge earthquake aftershocks, between the crest and the bottom of the hill. Since then, many experimental studies [21, 22, 23, 24, 25, 26, 27, 28, 29, 20, 30, 31] were conducted to better understand the topographic site response. 2D & 3D numerical simulations [17, 32, 33, 34] showed a 30 to 100% increase in the amplification of the ground motion for frequencies between 2 and 5 Hz. There are many explanations for the causes of topographic site effects, and what may affect the wave:

- The interference between the slope of the hill and the incident angle of the wave, especially the SV waves [18, 29].
- The interference between the incident wave and the diffracted waves [29].
- The wave ray path along the topographic surface [35].

2.3 Site effects assessments

Site effects can be generally detected by the three following characteristics:

- The amplification of the ground in the subsurface layers.
- The resonant frequency.

- The length of the seismic ground motion.

Different approaches were developed over the years and three are frequently used to evaluate seismic site effects:

- The Horizontal to Vertical Spectral Ratio using Microtremors recordings at a single station (ambient noise) MHVSR [36], detailed in section 3.
- The Horizontal to Vertical Spectral Ratio using Earthquake data EHVSR [37], detailed in section 3.4.
- The Classical Spectral Ratio CSR [38], detailed in section 4.

The definition for each of the methods and their respective limitations are introduced in the following sections.

3 THE SINGLE STATION MHVSR ANALYSIS APPROACH

Ambient noise or microtremors were first investigated by Omori in 1908 [39] and caught the attention of Japanese researchers, especially after 1950. Measurement of microtremors was used to estimate geological conditions and mechanical properties of the subsurface materials. The application of microtremors was first proposed by Kanai & Tanaka in 1961 [40]. After that, several research investigations were conducted to evaluate its capacity in assessing the ground motion characteristics and the site response of sediment deposit [41, 42, 15, 43, 44].
The ambient noise is a mixture of various wave types, most of the time generated by sources located at the surface of the Earth or at the bottom of the sea. In other words, ambient noise is a constant vibration created by the combination of low-frequency $<$1Hz and 1Hz (ocean, meteorology, wind, etc...), and high-frequency $>$1Hz (human activities, machinery, etc...).

3.1 Nakamura method

To better understand whether microtremors are composed of body waves or surface waves, a series of theoretical and numerical studies were conducted by Nogoshi and Igarashi. Based on the theoretical HVSR of Rayleigh waves founded by Suzuki in 1933 [45] and the numerical analysis of Ohta in 1963 [46], Nogoshi and Igarashi concluded in a sequence of articles [47, 48], that a microtremor is caused by Rayleigh waves. This clarifies why they did not initiate the famous Nakamura method, also known as the horizontal to the vertical spectral ratio of microtremors MHVSR. Despite that some article are citing them as founders of the Nakamura method [49, 50, 51, 52], they did not describe the characteristics and the basics of the MHVSR technique. The confusion may be caused by the fact that the original papers of the japanese researcher Nakamura were published in Japanese [53]. The MHVSR method estimates the amplification, and the resonant frequency of the surface layer [54, 36] as explained by the Japanese researcher Yutaka Nakamura.

3.2 Empirical development and amplification estimation

The Japanese researcher Y. Nakamura tried to estimate the horizontal amplification of the ground motion by computing the ratio between the horizontal spectra of microtremors measured on soft soil (f) and bedrock (b) sites (base ground) H_f/H_b. Then he decided to use the vertical

components instead of horizontal ones V_f/V_b to eliminate as much as possible the peaks caused by Rayleigh waves, and, therefore, to point out the effect of shear waves. After this procedure, he defined the spectral amplitude ratio as the ratio between horizontal-motion spectral ratio and vertical-motion spectral ratio, both on-site and on bedrock

$$\frac{H_f/H_b}{V_f/V_b} \tag{1}$$

Based on different observations [36, 55, 56, 57], $H_b/V_b \simeq 1$, this means that the Nakamura method makes it possible to derive an estimation of the amplification characteristics and resonant frequency by only using either earthquake motion records HVSR or microtremors HVSR of the measurements at the ground surface [36][53].
After comparison with the results of different surveys and data, Nakamura obtained the following relationships between the averaged thickness and the averaged shear wave velocity of the subsurface layer (V_s) and the base ground (bedrock) (V_{sb}):

$$V_s = \frac{V_{sb}}{A} \tag{2}$$

$$h = \frac{V_{sb}}{4AF} \tag{3}$$

with A the peak amplification factor that occurs at or close to the resonant frequency F.

From equations 2 and 3, we obtain:

$$F_n = n(\frac{V_s}{4h}) \tag{4}$$

where n is an index designating the n^{th} mode of oscillation [58]. When n=0, we obtain the resonant frequency f_0 for the fundamental mode over a 1D medium.

Based on Molnar et al. (2018) [52], the microtremor HVSR was developed for several purposes such as:

- Identifying the presence of stiff layers.
- Estimating the depth of soil thickness h through the peak amplitude when assuming the value of V_s (equation 2) [44, 59, 60, 61].
- Identifying the lateral heterogeneities in the subsoil when the H/V curves present some peculiar shapes [62, 63, 64, 65].

3.3 Field data Collection

The MHVSR single station methodology is considered as a non-invasive and inexpensive easy method to apply for seismic site characterization. On the other hand, the field data collection of ambient noise should follow some rules to get more stable MHVSR and more precise curve peaks. Some of these rules consist of:

- Using a three-component velocimeter,

- Leveling the velocimeter on the surface, where the conditions represent a natural, free field ground characteristic,
- Placing the feet of the sensor directly onto the soft soil (vegetation should be removed),
- Protecting the sensor from direct wind [66],
- Collecting data on natural ground surfaces better than on surfaces constructed by man (pavement), which may alter the peak of the MHVSR [67] or over underground cavities (should be avoided otherwise it is recommended to take multiple recordings at different times),
- Conducting the recordings early in the morning, to minimize noise from human activities, and for enough duration (the lower frequency required, the greater the recording time and the larger time window should be) [68].

The data collected can be analyzed using the Geopsy software package (`www.geopsy.org`), according to the SESAME project recommendations, that standardized the H/V method [52].

3.4 H/V using earthquake data EHVSR

During the Field observations performed by [27, 29, 69], the horizontal component of the seismic ground motion was much more amplified than the vertical components. Sometimes, even the polarization of the seismic ground motion could be considered. For example, during the experimental studies on the hill in Tarzana California, the horizontal component perpendicular to the hill slope was more amplified than the parallel one [20, 70].
Thus, for this method, it is considered that only the horizontal component of the motion (SH waves) are affected by site effects at least for low frequencies. Therefore, the vertical components are considered as the reference of the ground motion. The fact that the EHVSR method does not require a reference station represents an advantage.
The experimental results issued by both H/V spectral ratio methods (EHVSR and MHVSR), present good agreements [71, 72, 73].

3.5 Interpretations and limitations of H/V

The H/V method has been mostly used until now to study the effects due to sediment-filled-valleys, and rarely used in determining the topographic site effects even if it produces satisfactory results. This technique allows the determination of the fundamental resonance frequency of the subsurface, but does not allow the determination of the level of amplification on a large band of frequencies.
Normally, with the absence of shear wave velocity inversions with depth, the plot of the H/V curves presents sharp clear peaks when the structure of the subsoil is flat (1D), and an amplitude equal to or higher than 1 in the entire frequency domain except around $2f_0$ (presence of Rayleigh waves). As mentioned in the previous paragraph, the sensitivity of the horizontal components to the geological and topographical changes in the medium, is greater than for the vertical ones. Therefore, the detachment of the horizontal and vertical components, having stratigraphic origins, is illustrated in the Fourier Spectra of the three components with an eye-shape [67] (black arrow in figure 1).
The latter helps us understand that narrow H/V peaks are artificial and not natural, or of anthropic origins, because they are not characterized by spectral eye-shapes [61]. Acquiring the

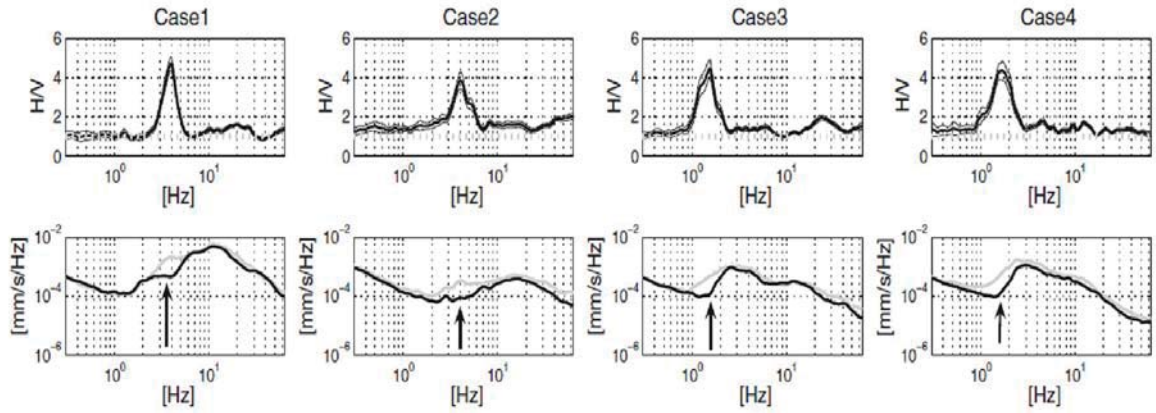

Figure 1: First row shows average H/V curves with the standard deviation with respect to the average. Second row shows average spectra (Z → black, EW → gray solid line, NS → gray dotted line). Stratigraphic columns are, for each site, from top to bottom: 1) Silt/igneous bedrock; 2) gravel/sedimentary bedrock; 3) clay/igneous bedrock; 4) clay/igneous bedrock [67].

data is a simple task, but the interpretation of their H/V curves poses several challenges at different levels. The peculiarity in the shape of H/V curves, such as broad peaks and plateau-like shapes and even amplitudes lower than 1, usually indicates a shear wave velocity inversion due the presence of cavities, stiff soil layer over softer soil, artificial soil, lateral heterogeneities, lateral sediment thickness variation (2D & 3D structures) and anthropic layers. An example is given in figure 2, of two H/V plots representing the different behavior of the curves depending on the site chosen to acquire the measurements.

Therefore, it is not wise to estimate a preliminary fundamental frequency just by applying the H/V technique. The application of complementary active or passive geophysical methods such as the multichannel analysis of surface waves (MASW), helps to avoid misinterpretations of the soil fundamental frequency [65, 61] and better evaluate the site effects.

Here are some examples on what could affect the H/V curves:
(1) Numerical simulations of microtremors on actual sedimentary basins (e.g. Santa Clara, Grenoble, Switzerland, Japan) were conducted, and the results showed a difference between the H/V peak frequency in a 3D velocity structure model and the fundamental frequency in a 1D velocity structure model. For 2D & 3D structures, the peak frequencies of the H/V curves are $\pm$ equal to 20 to 40% of the theoretical 1D resonant frequency (Equation 4) [75, 63, 64].
(2) In 2009, Castellaro and Mulgari [67] found that recording ambient vibrations with sensors placed on a concrete layer or asphalt, affects the H/V curves and alters the amplitude. This is in contradiction with the Site EffectS assessment using AMbient Excitations (SESAME) European project (`http://sesame-fp5.obs.ujf-grenoble.fr/index.htm`) recommendations [66]. The SESAME project present guidelines and recommend procedures for field data acquisition (ambient noise), processing and interpretation of the results using the H/V spectral ratio technique, and allows the measurement of ambient noise on artificial surfaces.

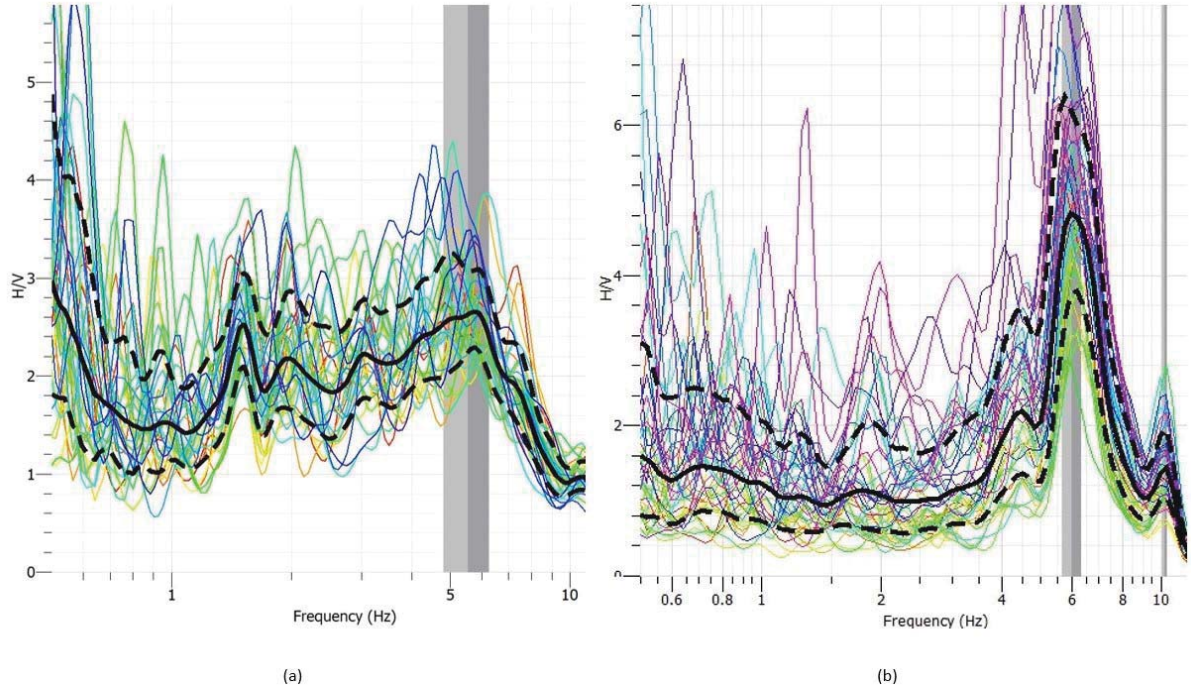

Figure 2: H/V preliminary results from recordings on two particular sites of Byblos in Lebanon. Colored plots refer to different profiles estimated for the different time windows, the black plot represents their average and the dashed ones represent the standard deviation with respect to the average. The grey area represents the averaged peak frequency and its standard deviation. (a) Ambient noise was recorded at a site laying on an anthropic layer with a moderate inclination of the subsoil (data recorded during our experimental/geophysical field mission in 2019). (b) Ambient noise was recorded at a site after the excavation of the anthropic layer. The Geopsy software was used to compute the H/V and to plot the curves [74].

4 THE CLASSICAL SPECTRAL RATIO

In addition to the microtremor HVSR and earthquake HVSR methods, we can distinguish another approach for the evaluation of site effects: The classical spectral ratio CSR [38].
This method consists in the calculation of the ratio between ground motion Fourier spectra recorded at a given site and at reference site . A seismic recording on a site i is represented in the frequency domain by:

$$S_i(f) = O(f) * P_i(f) * H_i(f) * I_i(f) \tag{5}$$

where O(f) represents the seismic source effect, P_i(f) the propagation path effects, H_i(f) the modification of the signal due to the characteristics of the soil on the subsurface, I_i(f) the response of the recording instruments and f is the frequency.
This equation shows all the effects that influence a seismic signal, that is why it becomes difficult, to separate site effects from other effects when the signal is recorded near the source. The spectral ratio of the different seismic signals recorded at two different sites (the study and the so called reference sites respectively) for the same seismic event, allows eliminating the seismic source effect, the propagation path effect and the response of the recording instruments as the distance between the site of study and the reference site is negligible compared to the epicenter

distance. The only remaining effect is the site effects:

$$\frac{S_{is}(f)}{S_{ir}(f)} = \frac{H_{if}(f)}{H_{ir}(f)} \tag{6}$$

where S_i is the Fourier transform of the signal recorded on the site of study and S_r is the Fourier transform of the signal recorded on the reference site.

This method presents some constraints:
(1) The necessity to find a reference site that is not affected by site effects. According to Chavez-Garcia et al.(1996) [37] and Lebrun et al. (1999) [71], the reference site station should be on the same geological layer (because, in this case, the same geological nature of the soil won't influence the amplification), and at a minimum distance of one wavelength from the topography. However, Sanchez-Sesma et Campillo (1991) [76] suggested choosing the reference site on the ground base (bedrock) that does not present any variation in topography and that is situated at a minimum distance of two times the horizontal dimension of the hill. Other studies [77, 57, 55] recommended choosing the reference site where the HVSR is close to unity at all frequencies. This kind of site reference could be hard to find, so we must select the best possible reference station [37].
(2) The source and the propagation path should be the same for the site being studied and the reference site, which is possible when the epicenter of the event is far enough from both stations (larger than five times the distance between the two stations).

These are the reasons why the CSR method is not very practical to perform, but it is still used in the evaluation of topographic site effects [77, 37, 71].

5 MULTICHANNEL ANALYSIS OF SURFACE WAVES (MASW)

Since a surface wave is frequency-dependent, the Multichanel Analysis of Surface Waves (MASW) method is based on the study of the dispersion of surface waves [78]. This technique is widely used to construct the subsurface Vs profile, obtained by inversion of surface-wave dispersion curves [79]. Two MASW techniques are used: active and passive [80], it depends on how the surface waves are generated. The passive MASW is based on measurements of ambient noise, whereas the active technique is based on generating surface waves using a sledgehammer or any other active seismic sources [81] and a linear receiver array of geophones, collecting data in a roll-along mode. The penetration depth of surface waves is usually limited at 30 m, because of frequency (wavelength) limitations, but this can varies with the site and type of active source used. The MASW data can be analyzed for example with the GEOPSY package (`www.geopsy.org`) using built-in tools to extract the dispersion curve (DC) and invert them.

For the deeper layers of the soil, when investigating is required, the microtremor array methods (MAM) can be used to resolve phase velocities of the lower frequency band (deeper part of the Vs profile) depending on the bandwidth of sources, resonant sensor frequency and the largest inter-station distances of the array. The successful results from (MAM) producing reliable dispersion curves have been accepted as an indirect proof for the assumption of surface wave predominance [49].

6 DISCUSSION AND CONCLUSIONS

This paper presents an in-depth literature review about available methods to model site effects and their implications. It presents results of existing works that benefit from experimental data in the analytical modeling and focuses on geophysical works obtained through H/V and MASW experiments.

It was noted that, microtremor recordings are a very good, easy and inexpensive technique for the estimation of site characteristics (resonant frequency and amplification thickness). Different studies showed a good agreement between numerical and experimental calculations, especially in urban zones. Therefore, it can be used to obtain a map of the fundamental resonant frequency of a city, in microzonation studies, especially in low seismic areas [82, 50, 83], and in the evaluation of site response. Even if the H/V method using ambient noise is considered easier, its application for the evaluation of topographic effects is still limited. Lebrun et al. (1999) [71] obtained consistent results with HVSR and CSR at low frequencies. Therefore, he confirmed the suggestion of Lermo et Chavez- Garcia (1993) [56] and Chavez-Garcia et al. (1996) [37], that it is possible to evaluate topographic site effects with the HVSR technique [84, 85]. Nevertheless, in this case, more experiments and 3D numerical modeling should be conducted to confirm their conclusions.
The application of multichannel analysis of surface waves (MASW) [78] is a powerful active source method for obtaining phase velocities for the high-frequency band. Thus, the dispersion curves obtained are used to provide Vs profiles that contain information on shallow sedimentary structures in a cost-effective and time-efficient manner.
Both the multichannel and single station methods have, when used alone, more limitations in comparison to their combined use. This is why the main goal is to combine the H/V spectral ratio from ambient noise (HVSR method) with the MASW technique to obtain reliable shear-wave velocity profiles of the subsurface down to bedrock. This combination allows deriving quantitative information on S-wave velocity sections for the study site. A similar combination of techniques is reported in the seismological literature by Scherbaum et al.(2003) [86] and Zor et al.(2010) [87].

The understanding and the usage of these different approaches, is still very important in the research domain to better evaluate experimentally and numerically the site effects. The implementation of these methods is in progress on the experimental site of Byblos in Lebanon. The purpose of the ongoing research work is to perform a careful comparison between results from numerical modeling of site effects and field observations and recordings on this experimental site. For this purpose, site investigations will allow acquiring the geological and seismic data necessary for the simulations and also to perform a microzoning on the site; semi-permanent equipment will be installed to record ground motions. The coherence of recorded signals will be evaluated using the Multichannel Analysis of Surface Waves and H/V ratio. Then, building a realistic model using the acquired experimental data, and a real topographic profile chosen from the Byblos region and conducting a numerical study using the Flac 2D/3D software, will allow comparing results from the numerical simulations with instrumental data. Combining experimental and numerical data for real sites instead of using simple parameters and geometries, makes this review and the research work in progress interesting, because the results will be more realistic in terms of spatial distribution of the soil movement, as well as the consequences in terms of amplification factors, slope stability, and building vulnerability.

7 ACKNOWLEDGMENTS

We are grateful to the following academic institutions: MINES-Paristech PSL University, Centre de Géosciences, Balamand University and Notre Dame University for supporting this research work, and to the SAFAR program (Campus France) for funding the first year of the PhD thesis.

Keywords: Steel MRFs, Pushover analysis, Hybrid test, Steel tubular columns, Collapse

Abstract. *A hybrid test method that uses the nonlinear static (pushover) analysis to examine the static force-deformation response of building structures is presented. The ultimate performance of the columns at the base of steel moment-resisting-frames (MRFs) is evaluated experimentally considering force redistribution due to the failures of panel zones and beams. The test method combines static sub-structuring techniques and finite element analysis methods. The behavior of the steel MRF is simulated by the finite element analysis program ABAQUS, while the first story column is physically tested online. Three actuators are used to simulate the physical continuity between the analytical and experimental substructures by controlling the axial load, the drift angle, and the bending moment distribution along the column length. A square tubular steel column was tested as a part of a five-storey five-bay steel MRF. The frame was deformed to a roof drift equal to 12% using pushover analysis that incorporates a novel mixed force/displacement controlling algorithm. The measured storey drift for the tested column was almost 30.0%. The test system ensured realistic loading and boundary conditions to the column sub-structure, which was tested in full interaction with the MRFs until global frame collapse. The frame deformed in a collapse mechanism that involved the first two storeys.*

1 INTRODUCTION

In recent years, steel is becoming an increasingly popular construction material [1]. The benefits and reason for the increase in popularity include the speed of erection, reliability of components and high strength to weight ratio thus allowing smaller foundations. As a high-performance structural type, steel moment-resisting-frames (MRFs) usually constitute the main earthquake or wind resistant mechanism in multi-storey buildings [1]. In seismic design, the large inherent ductility of steel MRFs allows engineers to adopt larger behavior factors q (or reduction factors R) compared to other structural types, and potentially, steel MRFs can withstand multiple damages in members and connections when they are subjected to intense single or multiple hazard events. Nevertheless, the sudden failure of individual components increases force demands to the adjacent elements and leads to a significant internal force redistribution, which is not intended in the inelastic design.

When the columns of the first storey are design to be fixed to the foundation beam, they exhibit multiple failures such as yielding, local buckling, and fracture. Although evaluating the ultimate behavior of columns experimentally has been the main research topic for many years in the field [2-5], this has been mostly done by treating the column as an individual member with a given length. However, as far as the inelastic behavior of the framed structure is concerned in the preliminary design stage, local failures occurred in the column itself or in the neighboring components, such as beams, panel zones and connections [6] (Figure 1a) can define new loading boundaries to the original tested column length. As shown in Figure 1b, the moment at the top of the column subassembly which is initially considered to be zero (inflection point) in cantilever column tests can take positive or negative values depending on the failure level and failure sequences occurred in the column and the remaining structure.

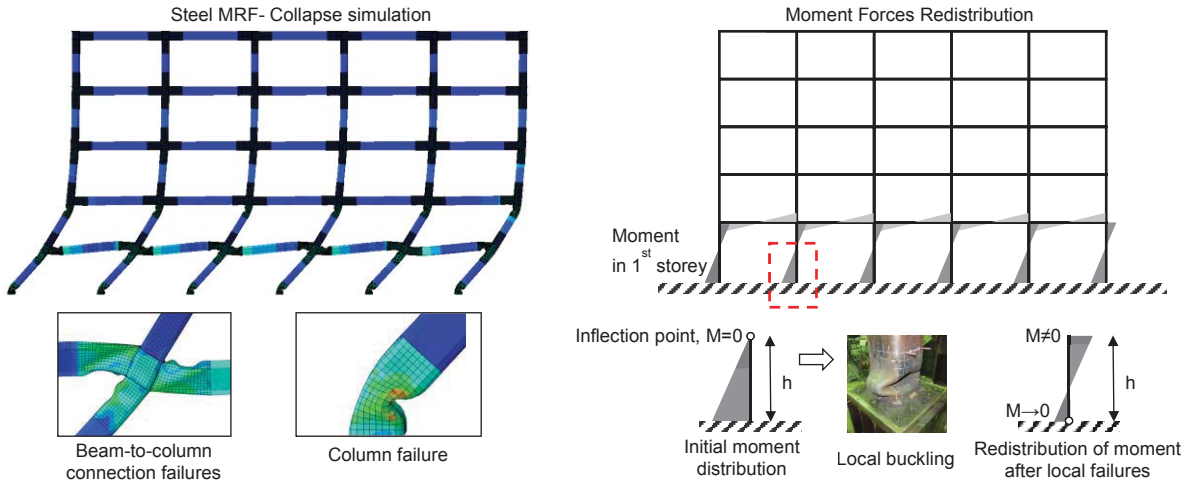

Figure 1: (a) Collapse simulation of a 5-storey 5-bay steel framed structure, local buckling failures in beams and columns [6]; (b) moment redistribution in columns at base after local buckling in beams and columns.

This paper develops an experimental platform for conducting column tests transferring the pragmatic loads and deformation demands to the column boundaries considering the inelastic behavior of the whole framed structure. To achieve this scope, a substructure-based hybrid test environment is developed for subjecting column specimens to collapse by performing in parallel an advanced inelastic static pushover analysis to building structure. The test method considers online updating of the model based on the experimental information. The redistribution of

force and ductility demands induced by the failures of the peripheral to the column building members is imposed by incorporating an appropriate number of loading jacks linked online to a finite element analysis performed in ABAQUS [7].

A square tubular column is physically tested to evaluate the proposed test platform. Three actuators that control the axial load, the moment at the column base and top, and the lateral deformations are used to simulate the physical continuity between the analysis frame and the test column. A MATLAB [8] user-subroutine interferes on the main control program and ABAQUS [7] to impose the target drift angle and loads to the column quasi-statically. The ultimate capacity of the column sub-structure is evaluated up to almost 30% storey drift, which corresponds to a roof drift equal to 12%. The test method is reasonable, and a smooth operation is achieved. By using the proposed test method, columns can be tested under various frame design parameters, and the collapse behavior of the column sub-structure and frame can be clarified with reasonable accuracy.

2 BUILDING STRUCTURE

The structure considered in this study is a moment-resisting-frame (MRF) of a prototype five-storey, five-bay steel office building designed based on the Japanese seismic design code [9, 10]. It has a rectangular floor plan with aspect ratio equal to 1.70. The longitudinal dimension L_X has length 32.0 m and five bays, while the transverse dimension L_Y has length 18.6m and three bays. In Figure 2a, the structural system of a typical floor plan is presented while in Figure 2b the elevation of the building is shown. The total building's height is 20.50 m. The structural system illustrated in Figure 2a consists of three planar moment resisting frames (MRFs) along the X axis and two planar MRFs along the Y axis. The building has square tube column sections (width×thickness: 500×22 in mm) and H beam sections (height×width×web thickness×flange thickness: 600×250×12×19 for the first three storeys and H-600×250×12×22 for the last two storeys). Grade of steels BCP325 and SN490B were adopted for columns and beams, respectively. The ultimate strength design of the building was achieved through a characteristic factor $D_s = 0.25$ (i.e., behavior factor $q = 4.0$), while the allowable strength and drift limitation requirement of 1 / 200 was satisfied for a base shear coefficient $C_0 = 0.20$. The period of the building is 0.94 sec along the X axis and 0.90 sec along the Y axis. A full description of the building can be found in [6].

3 ONLINE TEST METHOD

3.1 Concept

The concept of the test method is illustrated in Figure 3a and b. One plane steel MRF of the three along the X direction shown in Figure 1 is considered. The steel MRF is divided into two parts: (a) the analytical; and (b) the experimental substructure. The experimental substructures are the column at the building base while the rest structure consists the analytical substructure. The numerical model is created with the aid of the FEA software ABAQUS [7], which can capture with fair accuracy the non-linear behavior of frame components with ultimate failure that of local buckling. Details of the FEA model are given in a following subsection. The test of the column specimen is to acquire accurate information about the restoring forces and column stiffness. The restoring forces are applied to the numerical substructure to reproduce the restraint of the first story column.

In Figure 3b, the rotation and the moment at the column base are denoted by the letters θ_i and M_i, respectively. In the proposed on-line test method, the column bases are excluded from the frame model and replace by a non-linear rotational spring with constant $K_{rot,i}$. The column height is considered equal to the clear mid-height of the first storey. The axial force reaction and the moment of the column top, as obtained from the FEA for a given θ_i, are imposed to the column substructure by means of three jacks. The on-line test is conducted in many steps i. At each loading step, the restoring moment of the column substructure is measured experimentally (M_i) and is used along the corresponding θ_i to predict the spring constant $K_{rot,i+1}$ of the following step i+1 in the numerical model to reproduce the actual column restraint. The next analysis step is performed with the updated model. At the i+1 analysis step, the difference between the experimental and numerical M_i at the previous analysis step i, is imposed as external pseudo moment to compensate the over- or under-estimation of the column restraint. A restart procedure featured by the FEA is repeatedly used to accommodate the restored information of the hybrid test at each step operated by MATLAB main program developed in [11, 12].

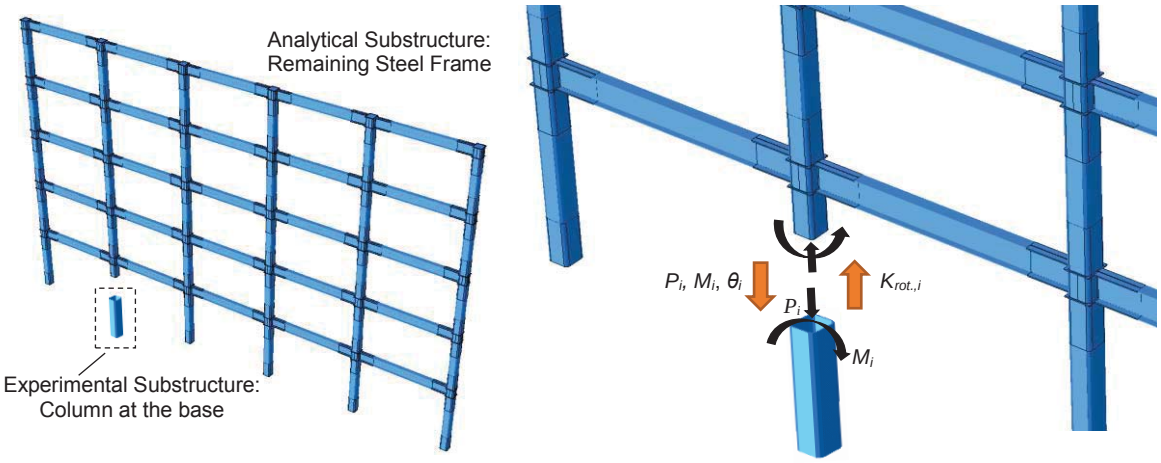

Figure 3 (a) Sub-structuring concept; (b) On-line update of column-frame boundary conditions.

3.2 Finite Element Model of the Analytical Substructure

The plane frame shown in Figure 3a was modelled by the finite element analysis software ABAQUS [7] using the fishbone sub-structuring technique [13]. The overall view and modelling details of the fishbone model is shown in Figure 4. The model developed is a mixed shell/beam element model that combines the powerful nonlinear S4R shell elements with beam-column elements. Shell elements were used in the critical regions of the building, such as beam-column connections, where strong geometrical nonlinearities (e.g., local buckling) are expected to take place. Beam-column elements were used for the remaining length of the beams and columns, which tend to remain mostly elastic. The inelastic behavior of column at the base is simulated through a non-linear moment-rotation spring. The spring constant is calculated using the experimental data at each restart analysis step, as discussed in the previous section.

For sufficiently small strains, steel is modeled as a linear elastic isotropic material with density ρ=7850 kg/m^3, modulus of elasticity E=205 GPa and Poisson ratio ν=0.3. For large strain analysis, the constitutive model used for steel includes pressure-independent plasticity with kinematic hardening. A strain hardening equal to 1.0% of the modulus of elasticity was assigned.

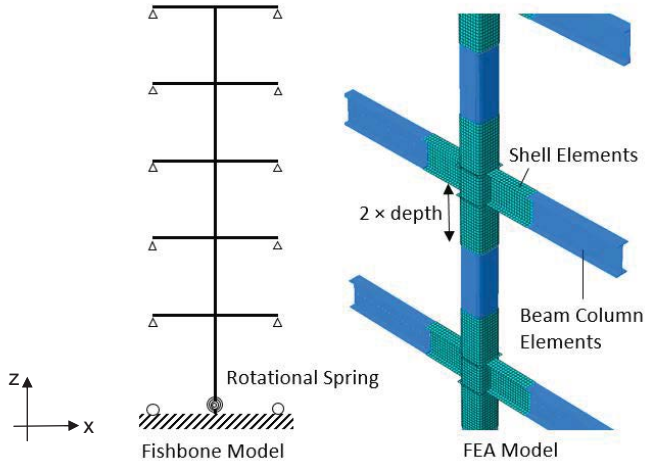

Figure 4 Fishbone model in ABAQUS [7].

3.3 Analysis

Static pushover analysis has been widely used in earthquake engineering and design of buildings, such as in the Capacity Spectrum Method (CSM) [14]. In general, pushover analysis is used for seismic evaluation of existing buildings and design verification for new construction in order to identify damage states and their correlation with the amplitude of the seismic ground motion. Among the advantages of the pushover analysis method are that it is simple, fast and provides all the capacity points of a structure until collapse [15, 16].

The force distribution that is applied to the structure in each increment of the static pushover collapse test is updated according to the first eigenmode of the structure. This eigenmode is calculated with the use of a shifted block Lanczos algorithm, similar to that developed and described in detail in [7, 17]. However, it is recognized that static analysis with force-control cannot be used to trace the descending branch of the structural response at large deformations. For the above reason, in this study the restart analysis is used only with general static analysis

with mixed force and displacement control. A full description of the inelastic pushover analysis platform used in present hybrid test can be found in [6].

3.4 Loading System and Test Substructure

Three hydraulic jacks ensure physical continuity between the analytical and experimental substructures by controlling axial loads, moments and column drifts. The test set-up is illustrated in Figure 5. One jack is placed vertically to impose the axial load (Jack 1: force control), while the other two are placed horizontally to apply the column rotations (Jack 2: displacement control) and moment at the column top (Jack 3: load control). The L-shaped element was designed to be as rigid as possible.

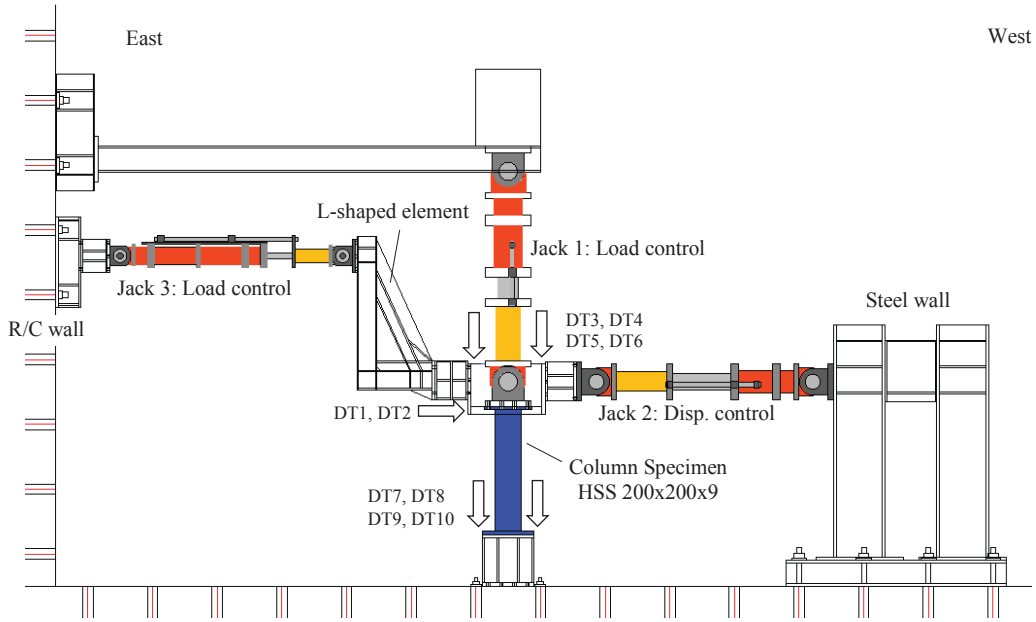

Figure 5 Test set-up for the online hybrid test.

Floor	Elastic Modulus [GPa]	Yield Stress (YS) [MPa]	Ultimate Stress (US) [MPa]	Stress at US	Elongation (%)
Flange	193	345	527	15.04	34.4
Corner	172	502	585	5.56	13.8

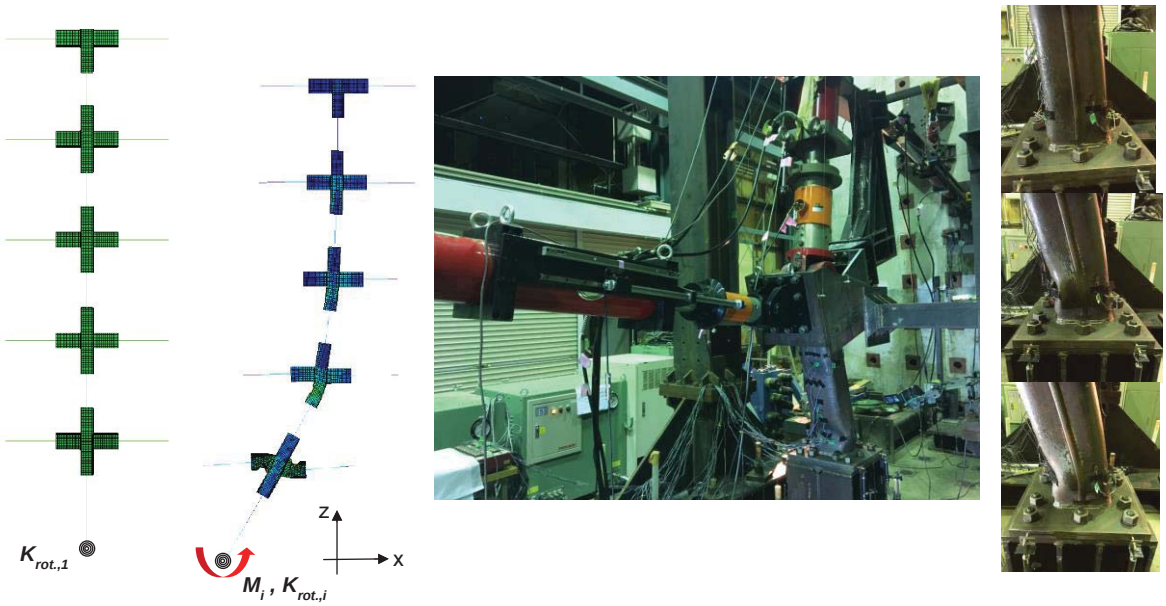
Table 1: Properties of column based on the coupon test results.

Linear displacement traducers (DT1 to DT10) were used to measure the rotation of the column top and basement as well as lateral story drifts. The column specimen had a square hollow structural steel (HSS) section with 200 mm width d, 9 mm thickness t and corner curvature r = 3.5t. The clear height of the column was equal to 802 mm while its total height measured from the column bottom to the middle point of the pin end of the vertical jack was equal to 1,030 mm. The column specimen was fabricated from a plate of conventional Japanese SN490 steel to realize equivalent behavior to BCP325 column in a small scale. Coupon tests were performed and material properties such as, elastic modulus, yield stress (YS), ultimate stress (US), strain measured at US, and rapture elongation are shown in Table 1.

4 TEST RESULTS

4.1 Overall Behavior

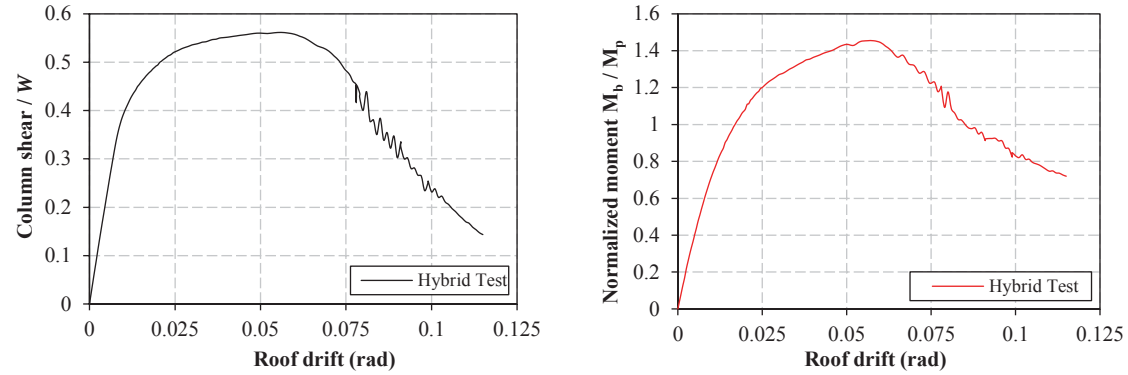
Figure 6 shows the hybrid static pushover collapse test. In Figure 6a the analytical substructures are illustrated at its both initial position and final position. The fishbone frame model deforms in a collapse mechanism that involves the first two stories. This collapse mechanism is identical with the one introduced in Figure 1a where the whole framed building was considered. The behavior of the column at base was investigated experimentally and the information was transferred to the analytical substructure through the hybrid simulation. In the fishbone frame model, active plastic hinge were formed at the column just below the panel zone of the second storey level and at the beam ends of the first storey. Figure 6b illustrates the overall view of the ultimate column deformation as controlled by the three jacks during the hybrid test. The progress of local buckling at the tested column is highlighted in Figure 6c.



(a) (b) (c)

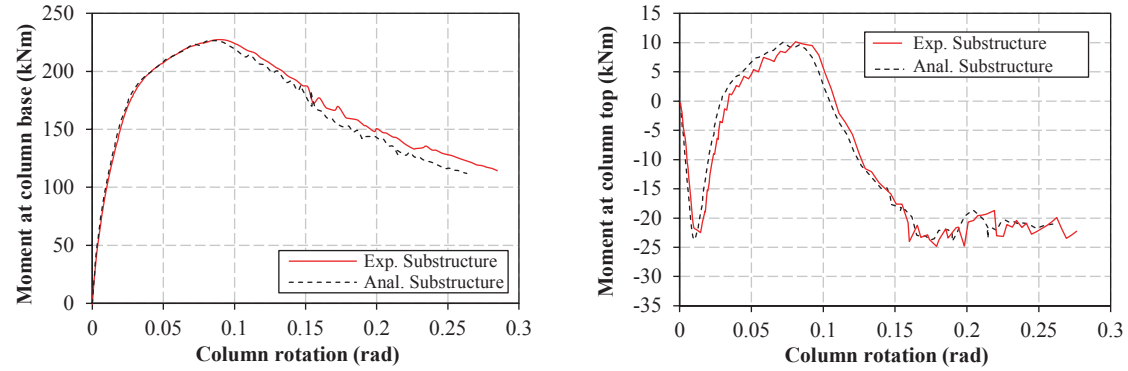
Figure 6 (a) Collapse simulation in Abaqus [7]; (b) column deformation controlled by the hybrid test set-up; (c) progress of local buckling during the test.

Figure 7a shows the pushover curve for building as obtained during the hybrid test. The period T of the fishbone frame model was 0.98 sec. The mode shape was [1.00; 2.13; 2.92; 3.54; 4.66] while the load proportion factor (LPF) during the test was [1.00; 1.78; 2.45; 2.97; 3.93]. The curve is presented in the typical fashion: total lateral force on the building (base shear force) normalized by the weight of the fishbone frame model on the vertical axis versus roof drift on the horizontal axis. The weight of the fishbone model W is equal to the total building's weight divided by three (number of the seismic resistant frames) and then divided by five for distributing equally the weight to the six columns. The building is seen to have an over-strength of more than 2 relative to its design base shear of 0.26W [7]. The pushover curve reaches 0.62W at a roof drift of 0.05 radians and then descends. The descending branch drops more steeply after reaching a roof drift of 0.07. Figure 7b shows the bending moment at the column base M_b against the roof drift. The M_b is normalized by the plastic moment of the square tubular column. The maximum $M_{b,max}$ was found to be 225 kNm at a roof drift of 0.06 radians. The calculated plastic moment M_p of the section is 155.60 kNm based on the flange yield stress (Table 1).



(a) (b)

Figure 7 (a) Pushover curve; (b) Bending moment at column base.



(a) (b)

Figure 7 Hybrid test consistency: (a) bending moment at column base M_b – column rotation; and (b) bending moment at column top M_t – column rotation.

4.2 Loading control

Figure 7a compares the bending moment at column base M_b – column rotation relationship between analytical and experimental substructures, while Figure 7b compares the bending moment at column top M_t – column rotation relationship in the same format. Based on these figures one can observe that the proposed hybrid simulation was successful in updating the analytical substructure based on the experimental values and vice versa. The moment distribution along the tested column was kept almost the same as the one determined in finite element analysis. All the jacks were synchronized accurately and effectively imposed the bending moments and rotations to the column specimen up to the very end of test. The variation of the bending moment at column top maintains the correct column curvature (single or double) as determined in frame analysis. The maximum $M_{t,max}$ was almost equal to -25 kNm, a value that corresponds to 11% of the maximum bending moment at column base ($M_{b,max}$ = 225 kNm).

5 CONCLUSIONS

A hybrid test method which uses the nonlinear adaptive static (pushover) analysis to evaluate the static force-deformation response of structures until collapse is presented. The method was validated on a five-storey five-bay steel moment-resisting frame (MRF) designed based on the Japanese seismic design code. Main conclusions of the present study are as follows:

- The hybrid test method uses finite element modelling methods for members and materials. Failures related to strength and stiffness reduction, such as shear inelastic deformation of panel zones and local buckling of beams, are captured with fairly accuracy. The load distribution transferred to the experimental substructure is updated accounting for the stiffness reduction.
- The analytical substructure is simplified further by adopting the fishbone modelling methods in order to reduce the computational time. The test system appears to ensure accurate loading and boundary conditions to the column test substructure. Overall, the fishbone model deformed in a similar way with the full five-storey five-bay MRF model. A collapse mechanism that involved the first two stories was observed.
- For the test substructure, a square tubular column located at the first storey of the frame was examined. The frame was deformed up to a 12% roof drift. The measured storey drift for the tested column was almost 30.0%. The maximum bending moment applied at column top was almost equal to -25 kNm, which is 11% of the maximum moment of the column ($M_{b,max}$ = 225 kNm).
- The building is seen to have an reserved capacity of more than 2 against its design base shear of 0.26W at the ultimate strength design. The pushover curve reaches 0.62W at a roof drift of 0.05 radians and then descends. The descending branch drops more steeply after reaching a roof drift of 0.07.

ACHNOWLEDGEMENTS

This work was supported by the New Exploratory Research Grant (2019H-04 / 3604835687) awarded to the first author by the Disaster Prevention Research Institute (DPRI). The authors are tankful to Nippon Steel Corporation for providing the column specimen. The authors are also grateful to Mr. Shingo Hamauzu, postgraduate of Kyoto University, and technicians of Structures Lab in DPRI for their valuable assistance. The research travel fund at University of Birmingham for conference attendance is gratefully acknowledged.

Keywords: Force vibration, frequency response function (FRF), OCXO high-precision synchronised wireless accelerometers, modal analysis

Abstract. *This paper describes an experimental validation of a novel FRF-based modal testing system designed to measure experimentally sway modes of tall timber and other building structures. The test uses a set of synchronised electrodynamic shakers and oven-controlled crystal oscillator (OCXO) high-precision synchronised wireless accelerometers for simultaneous force and response measurements. This modal testing system makes no use of cables or radio-waves to connect all accelerometers simultaneously with the multi-channel data acquisition system but provides a perfect synchronised measurement of a practically unlimited number of force and response channels. The system will be used to to estimate experimentally sway modes of as-built tall timber buildings. Therefore, the aim of this paper is to demonstrate the feasibility of the OCXO-based system in high-rise building FRF measurements. Two nominally identical FRF-based modal testing exercises were carried out on a 15-tonne laboratory-based test floor structure supported by 4 columns in order to measure its horizontal 'swaying' modes of vibration using: (1) a well-established and quality assured 'wired' system based on a 20-channel spectrum analyser, and (2) OCXO-based wireless system. It was shown that the two methodologies produce almost identical modal testing results and that the OCXO-based method is robust and reliable for field utilisation on high-rise buildings.*

1 INTRODUCTION

High-rise buildings dominate the skylines of many cities in the world, which have decided to go 'up' rather than 'out' to cope with transportation and other challenges facing their growing population. Vibration serviceability due to wind-induced lateral sway has become the de-facto governing design criterion for economically designed novel high-rise buildings above 50 m, dictating the size, shape and therefore cost of such structures. Damping ratios and natural frequencies of key modes of vibration that can be excited by wind are key modal parameters which are used in design to size the structure and predict wind-induced sway vibrations of tall buildings in service.

However, recent practice shows that damping and natural frequencies of tall buildings are also quite unreliable parameters to assume in design. Underestimation of the fundamental natural frequency of up to 50 % by the finite element model (FEM) relative to its experimental counterpart is common. The situation with damping ratios is similar or worse due to uncertainties in the values of modal damping ratios measured in as-built buildings. Natural frequencies and damping ratios in as-built tall building structures are essentially non-linear and amplitude dependent. To an extent where is currently not known, therefore, the traditional output-only ambient vibration testing (AVT) or ambient vibration survey (AVS) methods for their estimation based only on measured responses to unmeasured ambient excitation which vary with time are naturally producing estimates of modal parameters which vary from one block of data to another.

A standard input-output modal test (MT) or experimental modal analysis (EMA) where both the excitation force and the corresponding dynamic response are measured with the aim of experimentally estimating a structure's frequency response function (FRF) is a much more powerful tool to deal with structural non-linearities and uncertain modal parameters such as the natural frequency and damping. For many decades, EMA has traditionally dominated aerospace and automotive sectors, whereas AVT has been very much used in experimental dynamic testing of large civil engineering structures. This despite the fact that AVT generally has in principle inferior performance as to its quality of modal parameters relative to EMA.

The key reason for this situation are practical difficulties in exciting a tall building with a measurable force, causing a measurable response without damaging the building at the point of excitation. If this problem is overcome the next logistical complication is measuring such responses simultaneously throughout the building needed to estimate experimentally mode shapes and complete the set of four modal properties: natural frequencies, modal damping ratios, modal masses and mode shapes. Therefore, MT based on FRFs in tall buildings are practically non-existent in literature.

This paper describes novel FRF-based MT of sway modes of a large 15-tonne laboratory structure using a set of synchronised electrodynamic shakers and OCXO high-precision synchronised wireless accelerometers for simultaneous force and response measurements. This MT system makes no use of cables or radio-waves to connect response accelerometers simultaneously with the multi-channel data acquisition system and provides perfect synchronous measurement of practically unlimited number of force and response channels. The system will be used to estimate sway modes via FRF-based MT of as-built tall timber buildings.

This paper has five sections. After the introduction in Section 1, the test structure is described in Section 2. Section 3 describes the novel FRF-based modal testing set-up for the horizontal sway modes of the test structure. Section 4 then describes the results of the modal testing and their interpretation. Finally, Section 5 provides conclusions.

2 TEST STRUCTURE

The test structure was a reconfigurable floor panel weighing approximately 15 tonnes, with approximate dimensions 7.5 m×5 m, as shown in Figure 1a. The test structure was placed indoors in the laboratory of Vibration Engineering Section, University of Exeter, UK. This was one of five possible configurations of the test structure which can be re-configured into two full-scale footbridges spanning 15 m and three floor panels with a surface area of around 40-50 m^2 [2]. The floor plate structure made of 12 sandwich plate systems (SPS) panels was supported by of two main girders (UB 457×191×82 mm) and two secondary beams (UB 305×165×40 mm). M22 countersunk bolts were used to inter-connect the SPS panels with each other through steel strips (SP02 200×2279×12 mm) running under the panels, as shown in Figure 1d, and make them acting as a continuous plate supported by four edge beams (SB01 UC 203×203×46 mm), as shown in Figure 1c. Figure 1b shows the support detail used to transfer the loading from the floor panel to the column (SC01 UC 203×203×46 mm). The size and shape of this structure made it a perfect test bed to try the new wireless FRF-based modal testing technique to measure its sway modes of vibration.

3 MODAL TESTING SETUP

The main purpose of this modal testing exercise was to prove the feasibility of the novel modal testing system which had to satisfy the following requirements:

1. Fast in-situ setting up; this was facilitated by using wireless accelerometers;

2. Suitable for modal testing to estimate horizontal sway modes; facilitated by electrodynamic shakers able to generate a full range of measurable excitation forces in the horizontal direction with sufficiently low frequency content, and

3. Ability to measure as precisely as possible modal damping ratios and investigate nonlinear behaviour; this was facilitated by SIMO (single-input multi-output) FRF-measurement and modal testing strategy.

The significant novelty of the wireless system was that both the force and acceleration responses were recorded simultaneously using oven controlled crystal oscillator (OCXO) technology [3] for synchronisation of otherwise disconnected channels for acquiring the excitation force (by measuring acceleration of the known shaker moving mass) and the corresponding structural response. The use of this high-precision OCXO-synchronized data acquisition system meant that there was no need for any wired or wireless radio (GPS, Wi-Fi, UWB, GMS, 3G/4G/5G, etc.) connection while acquiring fully synchronised force and structural response data enabling FRF estimation.

The key reason for the above requirements is that the system had to be deployable in fully operational tall timber buildings, so as little as possible disruption and safety considerations dictated the need for a system which is fast to set-up and does not need wires running across floor levels which are notorious time consuming to setup and potentially unsafe due to tripping hazard.

3.1 Test grid and setup

Figure 2 shows the test grid featuring 15 test points (TPs) used in the modal testing. At each TP Honeywell QA750 force balanced accelerometers were placed to measure positive acceleration in the positive x direction, as shown in Figure 2. Moreover, two APS Dynamics Inc. shakers (Model 400) were positioned both at TP11 (denoted with two magenta triangles), to excite the structure horizontally in the x direction at a single degree of freedom. Therefore, for the purpose of the FRF estimation, TP11 was chosen as a reference point.

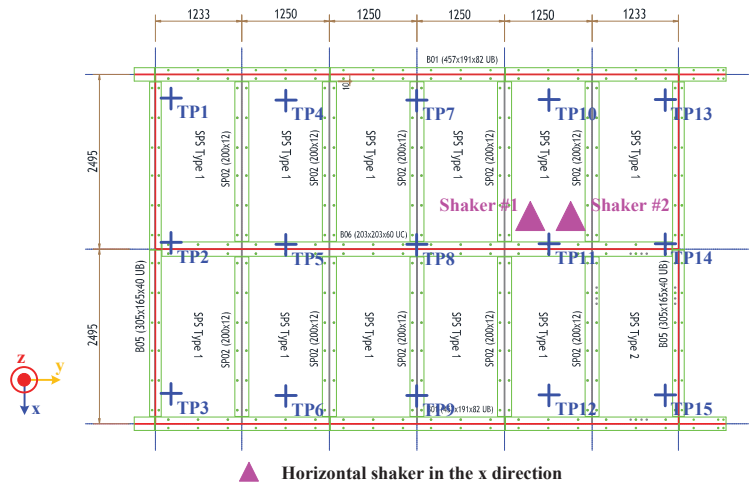

Figure 2: Test grid. Two horizontal shakers were positioned at TP11

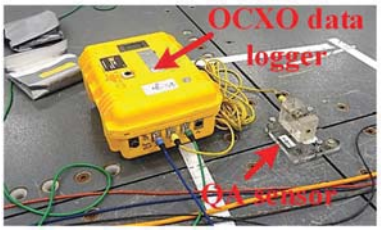
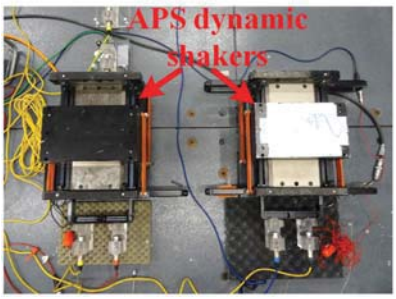
Figure 3a shows the test structure instrumented in the VES laboratory. The five yellow boxes are the OCXO-synchronised data loggers. Up to four horizontally positioned QA750 sensors, as shown in Figure 3b, were connected to the data logger.

(a) Photo of the test structure



(b) Photo of data logger (yellow box) with acceleration sensor



(c) Photo of two APS shakers

Figure 3: Photo of the test structure and equipment

Due to the limited number of the OCXO data loggers and accelerometers not all 15 test points and two shakers were possible to instrument with accelerometers at the same time. Therefore, the modal testing using the OCXO-based system was divided into acquiring two sets of FRF-data. The first set covered two shakers and 12 test points (TP1-12), and the second set covered again two shakers and the remaining three test points (TP13-15).

After finishing the OCXO-based input-output measurements, a well established and quality assured standard FRF-measurement method was used with the wired accelerometers in the measurement chain where the data acquisition and processing were done by a 20-channel Data Physics DP730 spectrum analyser (SA). This was done to obtain nominally identical FRF data for validation of the FRFs measured using the OCXO data loggers. Only excitation and response measurements pertinent to the x-direction (Figure 2) were carried out.

3.2 Methodology for measuring FRF data wirelessly

Figure 4 shows the block diagram representing the methodology of the OCXO and SA systems.

To run and control the 'wireless' FRF measurement using OCXO data loggers, a minimum wired system featuring SA was part of the measurement chain. This was done for two reasons:

1. To make use of the SA's ability to generate and post-process input-output data for a range of very useful excitation forcing functions traditionally used in FRF measurements (random, chirp, stepped sine and swept since, etc.), and

2. To quality assure OCXO-based FRF measurements considering that the OCXO data are not being monitored during the modal testing. Therefore, to check how the modal test

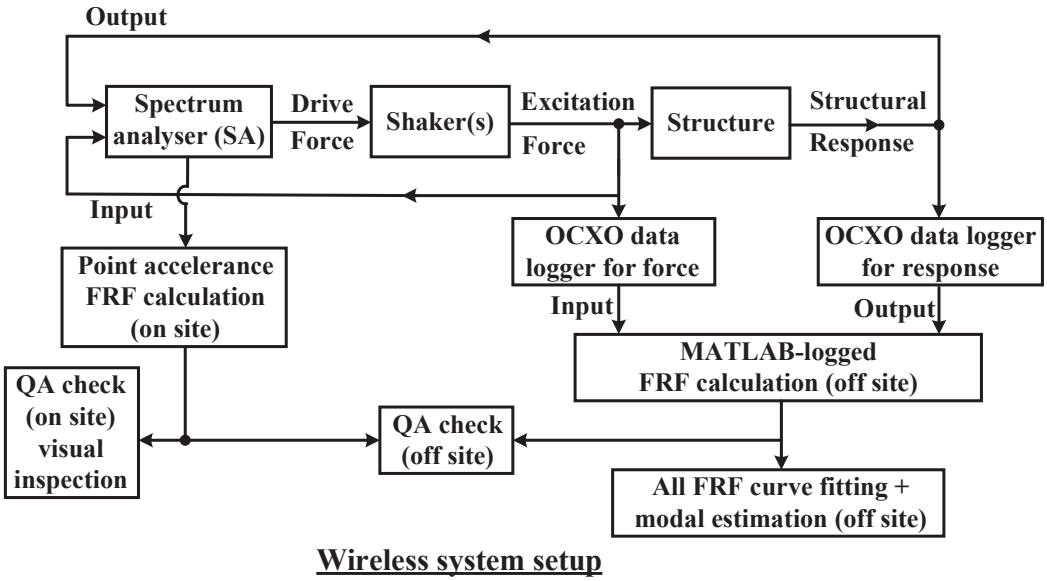


Figure 4: FRF-based modal testing scheme combining the 'wireless' OCXO-based measurement of FRFs across the whole structure with the limited 'wired' SA-based point-accelerance FRF measurement

was progressing a minimum wiring was used to measure only the point-accelerance FRF at TP11 using the SA in parallel with the OCXO system.

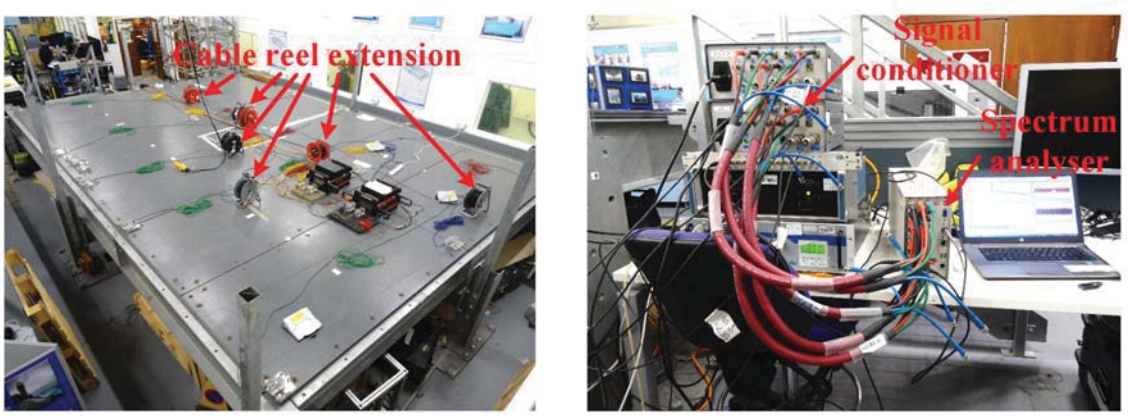
Such traditional SA-based FRF measurement was instantaneously available for visual inspection to determine if sufficient quality FRF data was being obtained and how many averages were used. The key underlying assumption was that the nominally identical OCXO-based FRF data, calculated using a different set of accelerometers just for the FRF point accelerance measurement, would - after post processing - produce the same FRF data as the SA-based counterpart. A key purpose of this testing exercise was to check if such assumption was correct. Normally, in point-accelerance FRF measurements pertinent to the building sway modes, the excitation shaker(s) and the data acquisition centre are very close towards the top of the building so there is no need for long wiring across several floor levels.

Therefore, at the reference test point, each of the two shakers had two sensors: one connected to the SA (wired) and the other to the OCXO data logger (wireless) (Figure 3c). In particular, one yellow OCXO box near TP11 and collecting the response data from that point and shakers acted as a 'master clock' for other OCXO boxes facilitating response measurements at other response points. This 'master clock' was then used synchronise other 'slave clocks' at the other locations. After the OCXO time synchronisation, each yellow box would have the same time clock a negligible delay of less than one micro-second was expected and the structural input-output measurement could start.

3.3 Methodology for measuring FRF data using wired system

Figure 5 shows photo of wired accelerometers at all 15 TPs featuring six 4-channel extension reels, external signal conditioners and DP730 spectrum analyser.

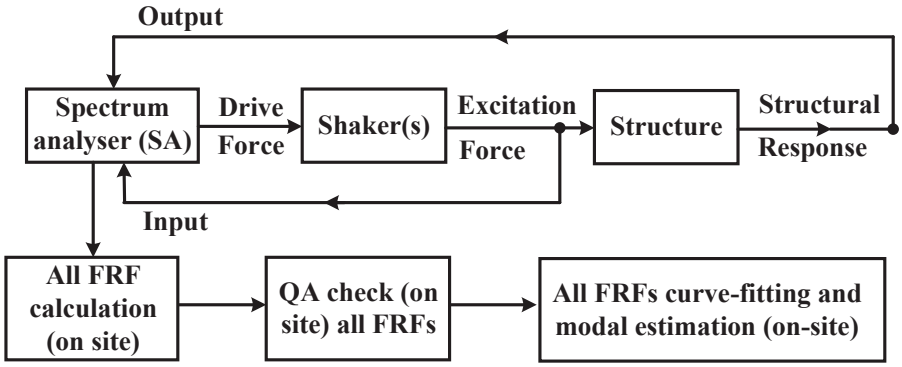
It can be seen that all connection cables and extension reel cables had to pass over the structure to the standard 20-channel SA-based data acquisition system. In a real building situation, cables from extension reels would run across many floors and over many floor levels making



(a) Photo of modal testing (b) Photo of data acquisition system

Figure 5: Modal testing setup up using a standard 'wired' SA-based setup

their safe installation in an operational building time consuming and overall management quite challenging from health and safety as well as efficiency points of view. Figure 6 shows a standard 'wired' FRF measurement setup.



Wired system setup

Figure 6: FRF-based modal testing scheme based on the standard 'wired' setup featuring SA-based measurement of all FRFs

4 FORCE AND ACCELERATION RESPONSE DATA PROCESSING, FRF CALCULATION AND CURVE FITTING, AND ESTIMATION OF MODAL PROPERTIES

Figure 7 shows two raw data sample histories (sample number on the horizontal axis and voltage amplitude on the vertical axis) pertinent to the acceleration of the shaker armature. These two sets of data were recorded using two accelerometers connected side by side to the shaker armature (Figure 3c), so they represent nominally the same information. However, the blue trace was acquired using the OCXO data logger, and the red trace using the SA data acquisition. Although the two traces are nominally identical there is an unknown time shift between them. Strictly speaking, the duration of the time shift is not needed considering that the OCXO boxes were all synchronised. However, as the OCXO system was new there was a need to validate it against the SA data which were treated as a 'gold' standard. For that, at the end of the random excitation driven by a signal from the SA, the shaker mass was moved

manually to create a clear 'reference event' which was then used to determine exactly the time delay between the OXCO and SA data. This was found to be consistent across all comparable sets of OCXO- and SA-recorded data pertinent to the point mobility measurements enhancing confidence in the OXCO-recorded data. This delay was used to shift all OXCO-recorded data to look like the SA-recorded data to enable easier visual comparison.

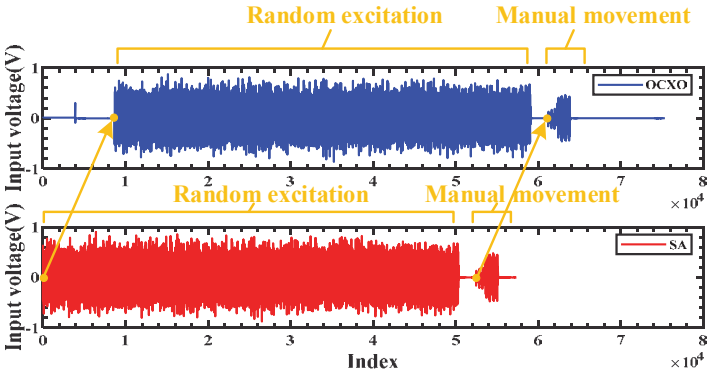


Figure 7: Comparison of the raw OCXO- and SA-recorded data pertinent to the shaker force measured by measuring acceleration of the known armature mass

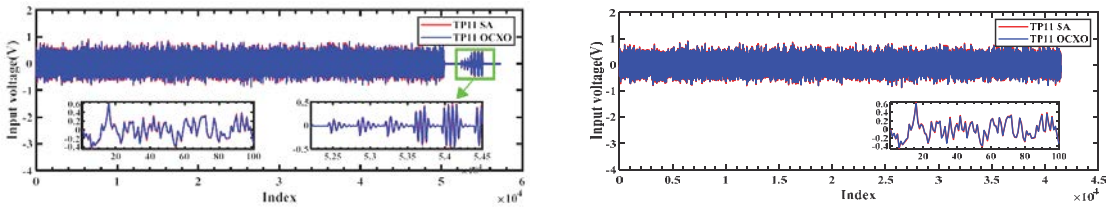
Figure 8 provides a visual comparison of such two sets of data. It can be seen that the two sets of data are very much identical for practical purposes which validated the OCXO-recoded data.

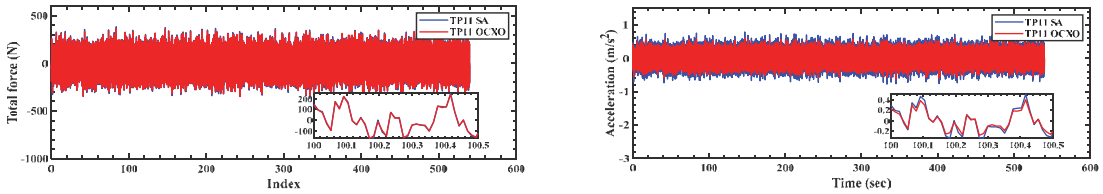


(a) Voltage time history showing the manual mass movement

(b) Voltage time history after removing the manual movement

Figure 8: The raw OCXO- and SA-recorded voltage data pertinent to the shaker force, plotted one above the other

The raw data was then converted into a time history and scaled. Figure 9 shows examples of the random excitation and response, using the two data acquisition systems.



(a) Total input force

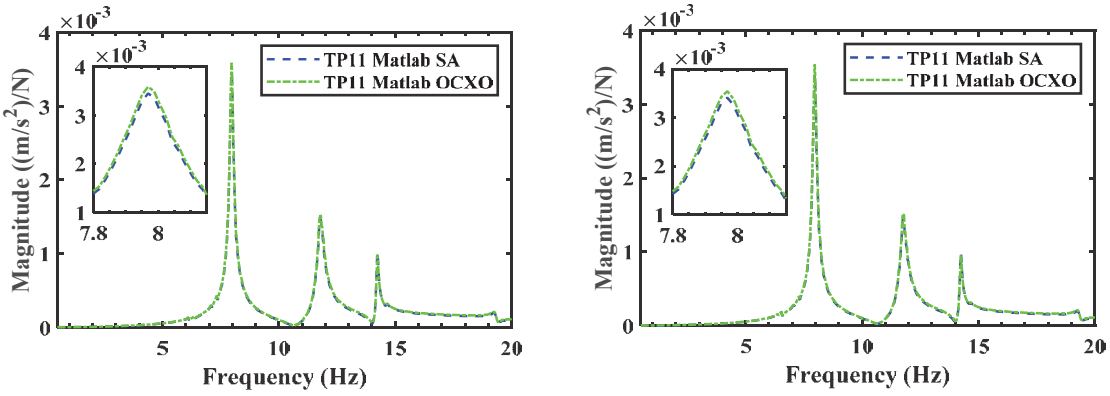
(b) Acceleration at reference point

Figure 9: Examples of total random excitation force (input) and the relevant acceleration at the refer-ence test point TP11

It can be seen that the two sets of overlaid time histories are very much identical with some negligible discrepancies appearing on the acceleration response data.

The FRF was calculated between the total input force and all measured acceleration responses at 15 test points. The total input force from the two simultaneously running shakers was obtained by simple summing of the two shaker random forces measured as each shaker was driven by the same random force signal generated by the SA, part of single-input multiple-output (SIMO) modal testing process. Therefore, in total, 15 FRFs were measured. In total, 4096 data blocks of 53 s duration were acquired. FRFs were estimated using 75 % overlap of the data blocks and a total of 100 averages in conjunction with the Hanning windowing. This yielded a frequency resolution of 0.01875 Hz.

Figure 10 shows the point-accelerance FRF measured at TP11 for the first 12 TPs (FRF set 1) and the remaining 3 TPs (set 2).

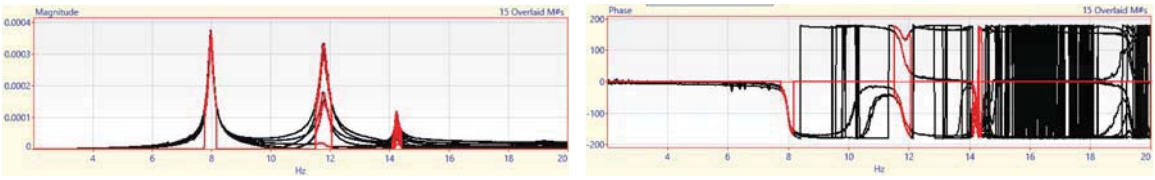


(a) Set 1 reference FRF (b) Set 2 reference FRF

Figure 10: Point-accelerance FRF magnitudes for FRF sets 1 and 2

Although measured at different times, assuming that the structure is linear and time-invariant those two reference FRFs should, of course, be identical, as they clearly very nearly are.

In addition, it can also be seen in Figure 10 that the SA- and OCXO-based measurements were consistent and for practical purposes identical. Therefore, the OCXO high-precision synchronised wireless system was proven to be of sufficient quality to carry out reliable FRF measurements. Using the 15 OCXO-measured FRFs, Figure 11 shows their magnitudes and phases, and the curve fitting results for the first three sway modes of vibration measured.



(a) FRF magnitude (b) FRF phase

Figure 11: All measured FRF magnitudes and phases (black traces), including the curve-fitting results (red traces)

FRF and curve-fitting data in Figure 11 indicates good quality of the data and fitting. The

curve-fitting used that the SIMO polynomial fitting ([4]). The lowest three modes identified in Figure 11 are shown in Figure 12.

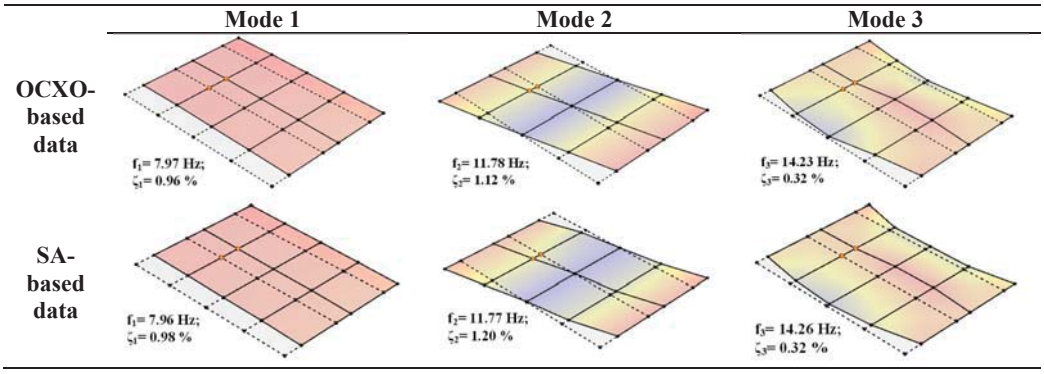


Figure 12: First three horizontal sway modes

The first mode at around 7.96 Hz is a clear sway in the x-direction, whereas the second mode at around 11.78 Hz is an antisymmetric twisting of the floor plate. The third mode at around 14.23 Hz implies an in-plane motion of the middle line engaging the 'strip' connection between the SPS plates in the horizontal direction. All three modes are logical for this type of structure.

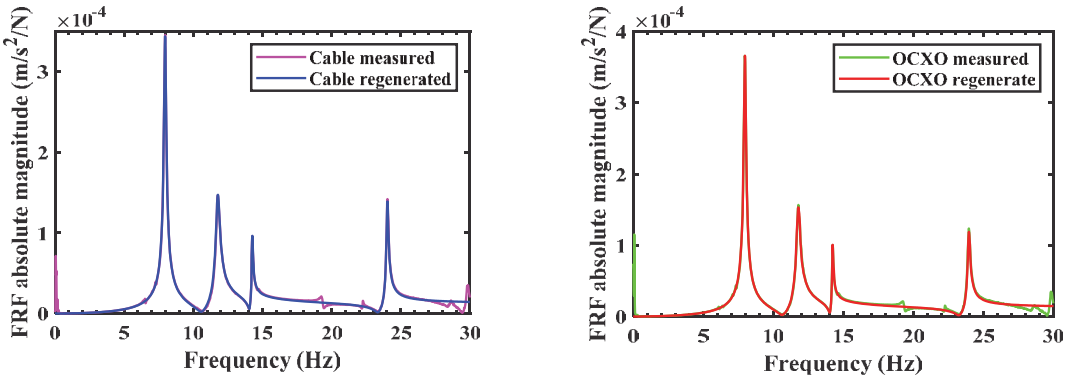
Table 1 summarises the modal properties of the structure using OCXO and SA systems. The relative errors of the natural frequencies and modal damping ratios were calculated and are also presented in Table 1.

Mode number	OCXO		Spectrum analyser		Relative error		MAC value
	Modal frequency (Hz)	Modal damping (%)	Modal frequency (Hz)	Modal damping (%)	Frequency (%)	Damping (%)	
1	7.97	0.96	7.96	0.98	0.17	2.25	0.994
2	11.78	1.12	11.77	1.20	0.08	6.29	0.976
3	14.23	0.32	14.26	0.32	0.19	2.91	0.957

Table 1: Comparison of OCXO and SA-based modal properties

The natural frequency error is smaller than 0.2 %, whereas the damping ratio has the maximum error of approximately 6 %. The table also gives the modal assurance criterion (MAC) value ([5]). The MAC calculation is used to compare the level of similarity of the two sets of mode shapes. For each pair of the SA- and OCXO-estimated mode shapes the MAC is almost 1, which means that the identified mode shapes are very similar, indeed. In conclusion, the SA- and OCXO-based data acquisition methods produced almost identical modal testing results validating the described OCXO-based 'wireless' methodology for the FRF data gathering.

Finally, Figure 13 shows measured and regenerated (using modal data for the first four estimated modes) point mobility FRFs at TP11 - for SA- and OCXO-based data acquisition systems.



(a) SA-based (b) OCXO-based

Figure 13: Point mobility FRFs at TP11 – Left: SA-based measured and regenerated; Right: - OCXO-based measured and regenerated

It can be seen that the measured and regenerated FRFs are very close indeed, validating again the OCXO-based approach.

5 CONCLUSIONS

This paper proposes a new methodology of using OCXO high-precision synchronised wireless accelerometers for FRF measurements. The aim was to demonstrate the feasibility of the OCXO-based system for use in high-rise building FRF measurement. Therefore, two nominally identical FRF-based modal tests were carried out on a 15-tonne laboratory-based test floor in order to measure its horizontal 'swaying' modes of vibration using:

1. A well-established and quality assured 'wired' system based on a 20-channel spectrum analyser, and;

2. OCXO-based wireless system.

It was shown that the two methodologies produce almost identical modal testing results and that the OCXO-based method is efficient robust and reliable for field utilisation on high-rise buildings.

Abstract. *This paper claims that a major source of error in Seismic Analysis of Structures is the assumptions used to scale up from component- to system-level behavior. It also claims that validation of numerical models should be performed statistically. As a statistical validation requires multiple virgin specimens, the paper suggests the use of a 3D printer to construct the reinforcement of microRC specimens (1:40) to be tested in a geotechnical centrifuge. It presents some first tests on gypsum-based microconcrete, additively manufactured rebars with diameters as low as 0.35mm, and small scale RC beams. The properties observed seem to resemble the ones of full scale RC components. Given the material properties, Opensees is able to accurately capture the behavior of the microbeam.*

1 INTRODUCTION

Structural models blatantly fail to blindly predict the response of shake table tests. This paper claims that the problem sources from the uncertainty/error introduced to scale up from the component-level cyclic to the system -level dynamic behavior of the problem. It also claims that the appropriate way to validate models in Earthquake Engineering is to perform multiple tests on virgin specimens under different ground motions, and to demand that the model predict the Cumulative Distribution Function (CDF) of the maxima of the response quantity of interest. Then manufacturing the virgin specimens becomes the constraint. Therefore, this paper suggests, that the specimens be constructed at a small scale (1:40) using an additive manufacturing technology to fabricate and place the reinforcement. A geotechnical centrifuge should be used to preserve similitude of stresses.

2 STATEMENT OF THE PROBLEM

Time history analysis is considered as the state of the art in modeling of the seismic response of RC structures. Its most widespread validation procedure is the test of predicting the response of an RC structure tested on a shaking table. However, blind prediction contests show that the contestants fail in predicting the response of the tested specimens with reasonable accuracy, even for structures much simpler than the ones constructed in practice, and even when the structural properties and measured excitation are given to the contestants [1].

For example, the simple RC model shown in Figure 1 (left) was tested on the shaking table of UCSD in 2010 under 6 ground motions [2-3]. A total of 41 expert teams (17 from professional practice and 24 from the academia) were invited to predict the response. The measured response and the prediction for the maximum top displacement are indicatively shown in Figure 1 (middle). There is a large dispersion of the numerical results and many predictions grossly underestimate or overestimate displacements. Interestingly, after the test series of the six earthquakes the column did not appear to have failed. However, only 14 out of 41 contestants predicted non-failure, while the rest predicted failure. Within the group that predicted failure, there was a large dispersion related to the mode of failure (Figure 1, right).

Panagiotou et al. 2010 [4] tested a full-scale 7-story building slice with a rectangular wall (Figure 2, left) under 4 ground motions. 21 teams were invited to predict the response. Indicative results for the absolute maximum displacement for the last excitation are shown in Figure 2 (right) (Panagiotou, Personal Communication). Again there is a large dispersion among the contestants and most of them fail to predict the response with a reasonable accuracy. In the context of post-Galileo science, the above indicative results directly question current analysis and design methods.

In order to track the main source of the error, one can break down the sources of error and uncertainty at 3 levels: Material, Component, and System Level. Given the behavior at each level, the engineer makes certain (good or bad) assumptions to level-up. For example, for given material properties in cyclic loading we use the beam theory and a set of assumptions for the interaction of rebars and concrete to reach the component level cyclic behavior.

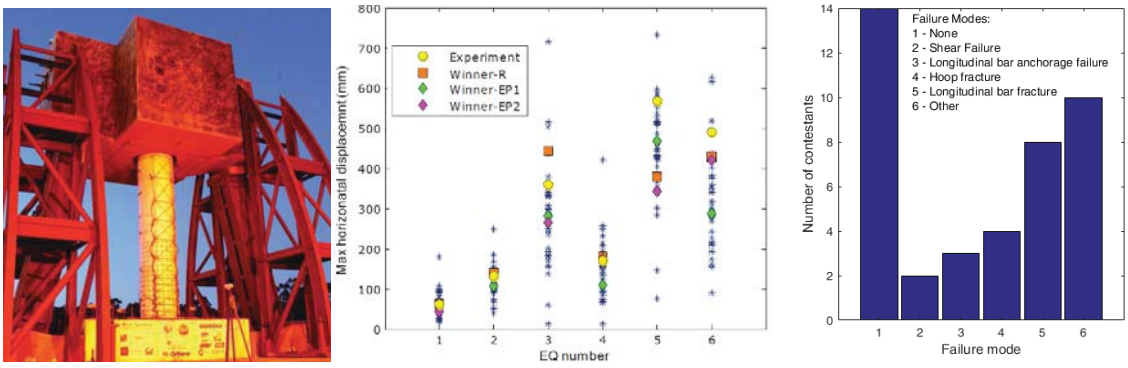

Figure 1. Left: Bridge column tested in UCSD [2]. Middle: Maximum top displacements predicted by the blind prediction contest contestants [3]. Right: Number of predictions for each of the six suggested failure modes [3]

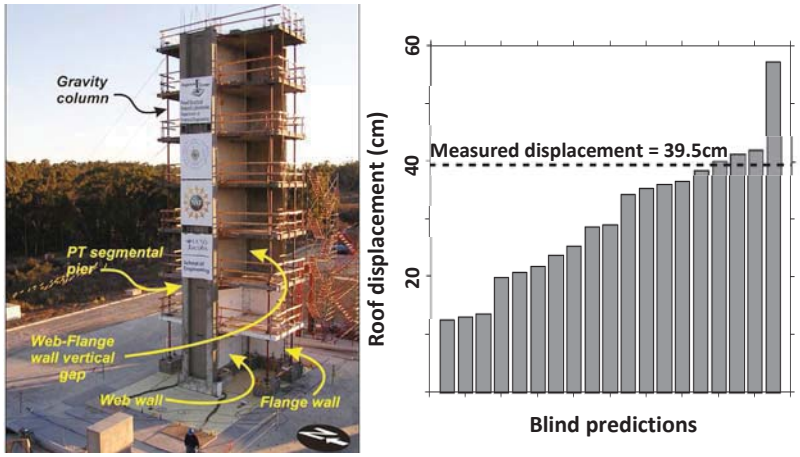

Figure 2. Left: Building slice tested on UCSD[5]. Right: Predictions of blind prediction contest (courtesy of Marios Panagiotou).

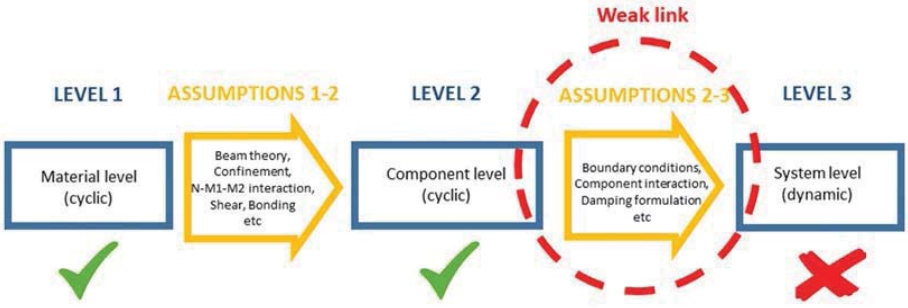

Figure 3. Schematic representation of material to component to system level transition.

Then, using another set of assumptions (boundary conditions, interaction of components, damping model, numerical integration scheme) we reach the system level. Moreover, one should discriminate between quasi static and dynamic behavior. Contrary to blind prediction of system-level dynamic behavior, predicting the component-level cyclic behavior has been proven a more successful process [6-7-8]. Therefore, it is reasonable to assume that the main source of error is the assumptions that earthquake engineers do to scale up from component-level cyclic to system-level dynamic behavior.

This is in accordance with Bradley (2013) [9]: He claims that current uncertainty propagation methods usually focus on the first two levels of modelling, while it is often the transition from component to system level that induces the largest error (Figure 3). Apart from very insightfully

illustrating the above problem and identifying its solution "as a key research area in the coming years" Bradley (2013) [9] does not seem to offer a way of addressing it - and to our knowledge such a way has not been offered in the literature.

It is worth mentioning that there is currently no consensus on fundamental issues of structural modelling: Important figures of Earthquake Engineering disagree on conceptual issues like fiber vs lumped plasticity, or how damping should be modelled. This paper claims that this disagreement sources from the lack of a large database of full scale dynamic tests to serve as a validation benchmark.

3 THE CONCEPT OF STATISTICAL VALIDATION

Bachmann et al. (2018, 2019) [10-11] claimed that the conventional validation test of reproducing the experimentally obtained response to a particular ground motion with acceptable accuracy is too strict of a validation test for structural models. The Earthquake Engineering design problem involves predicting the statistics of the response to an ensemble of ground motions characterizing a given seismic hazard; not to a single ground motion. This is a weaker model validation test that requires that the structural model only be unbiased and introduce less uncertainty than the uncertainty of the excitation itself. Bachmann et al. (2018, 2019) [10-11] applied this weaker (but sufficient) validation procedure on the 1963 Housner dynamic response model of an uplifting structure (Figure 4, left). They performed 600 shaking table tests using a well-defined and repeatable uplifting structure as well as 600 numerical simulations of these tests, and compared both the individual test responses and the statistical aggregates of these responses focused on predicting limit states such as overturning or maximum tilt angle (Figure 4). They showed that the 1963 Housner model passes the weak validation test (Figure 4, right) even though it fails the strong validation test (Figure 4, middle). In other words, in this case the motion-to-motion variability is more important than the accuracy of the structural model. Therefore, the model is good enough for the scope of Earthquake Engineering.

It is worth noting that the concept of comparing seismic analysis methods in terms of the statistics of the response to sets of ground motions rather than in terms of individual responses is not something novel in Earthquake Engineering. It can be seen in Chapter 23 of the 4th edition of Chopra's Structural Dynamics textbook [12]. However, up to now it involved comparisons between different analysis methods (usually a more approximate against a more refined, taken as benchmark); not between an analysis method and experimental tests.

The optimal validation procedure question extends beyond Earthquake and Structural Engineering. Roy and Oberkampf (2011) [13] describe a comprehensive framework for verification, validation, and uncertainty quantification in scientific computing that resembles the method proposed herein.

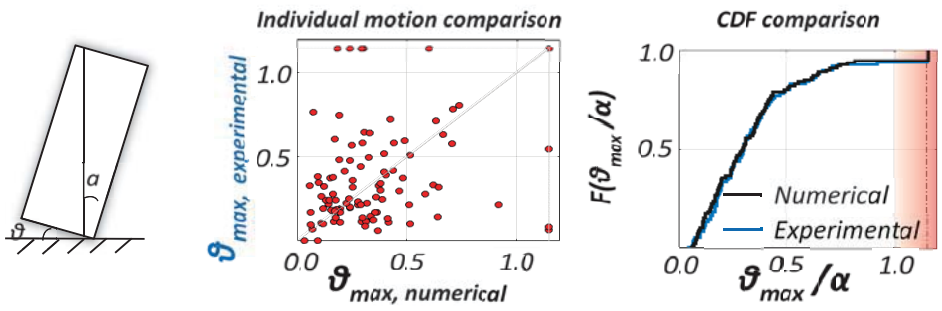

Figure 4. Left: Uplifting oscillator; Middle: Comparison of the maximum rotation obtained experimentally and numerically: Individual motion comparison; Right: CDF Comparison. Adapted from Bachmann et al. (2018).

Extending this statistical validation method to more realistic structures is not trivial: Since testing of RC specimens, involves damaging them, one would need multiple virgin specimens. This is cost- and time-wise not viable in full scale, and this is the reason why researchers only perform comparisons between individual excitations.

4 TESTING OF MICROSPECIMENS

To address the above contradiction, we restrict the problem from the statistical validation of the whole numerical modelling procedure (which is impossible) to the statistical validation of the assumptions to scale up from component-level to system level dynamic response. The latter can be performed with multiple virgin small-scale models (say 1:40 scale) in a centrifuge. Then constructing multiple specimens at such a scale becomes the constraint.

As geotechnical engineers often need to describe Soil Structure Interaction problems, they have used reduced-scale models of piles and walls, although using different materials. Knappett et al. (2011) [14] developed a micro-concrete (concrete with small-scale aggregates and gypsum instead of cement) for use in geotechnical centrifuge. They present experimental results on tests on 1:40 scaled RC beams and slabs made of microconcrete and steel wires as reinforcement. The modes of failure between model and prototype scales coincide, and the quantitative comparison of strength and ductility is relatively good, even if seen from the potentially stricter point of view of a structural engineer. Strength is better captured than the moment-curvature relationship and stiffness, but we have reasons to believe that the actual situation is better than described by Knappet et al. 2011 [14]: They compared the experimental M-κ relations they obtained, to analytical solutions using cracked cross section analysis. However, based on Panagiotakos and Fardis (2001) [15] and Priestley et al. (2007) [16] suggestions, such an analysis would be too stiff. Thus, the apparent extra flexibility is not a product of the scaled model, but of the equations that Knappet et al. 2011 [14] used to predict the prototype behavior. If one uses the stiffnesses provided by Priestley et al. (2007) [16] the curves match much better.

The micro-concrete that was developed was subsequently used to study a rocking isolated RC bridge pier at a 1:40 scale [17]. However there were three limitations: (a) The accuracy in positioning of the handmade micro-reinforcement, as well as the diameter of the stirrups (they were larger than what proper scaling would suggest). (b) The construction time: It took 8 hours of quasi-watchmaker's work and many failed specimens for a single column. (c) It was practically impossible to build frames, as there were difficulties in positioning the rebars in the joints at a 1:40 scale by hand.

This paper suggests that the problem of manufacturing and placing the reinforcement can be solved by using a metal 3D printer. Then, the construction of multiple specimens for a statistical validation of numerical models is time-wise feasible. Moreover, the method allows for the experimental study of a plethora of structural engineering problems that was impossible till now, namely SSI, pounding between adjacent buildings, or between a bridge and the abutment.

In order to avoid scale phenomena, it is necessary to perform the material and component level cyclic tests, at the model scale, namely 1:40. This paper presents some first experimental results of compression and tension strength of microconcrete, 3D printed steel reinforcement of 0.50 mm nominal diameter (without considering the ribs), and 4 point bending tests on microRC beams.

5 TESTING OF MICROCONCRETE IN TENSION AND COMPRESSION

Microconcrete comprises a mixture of plaster, sand and water. In this work, Saint-Gobain Hartform 1 gypsum based plaster was used. Perth silica sand with d50 = 0.23 mm was used as a model aggregate. Figure 5 compares a typical aggregate size distribution scaled down 40 times

to the distribution of the used sand. The ratio of the water/plaster/sand ratio of the mixture was 0.4/1/1.

Cylindrical specimens of size 50 by 112 mm were constructed and tested in compression (Figure 6, left) after 20 days. The deformation was applied at a rate of 0.5 mm/min. The results are shown in Figure 6, right. In the future, smaller models, as close to 1:40, will be constructed to study any scale effect and to take it into account in the numerical model validation procedure.

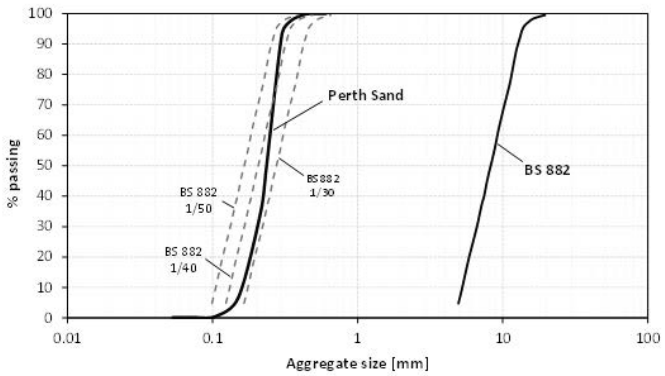

Figure 5. Scaling of typical aggregate size.

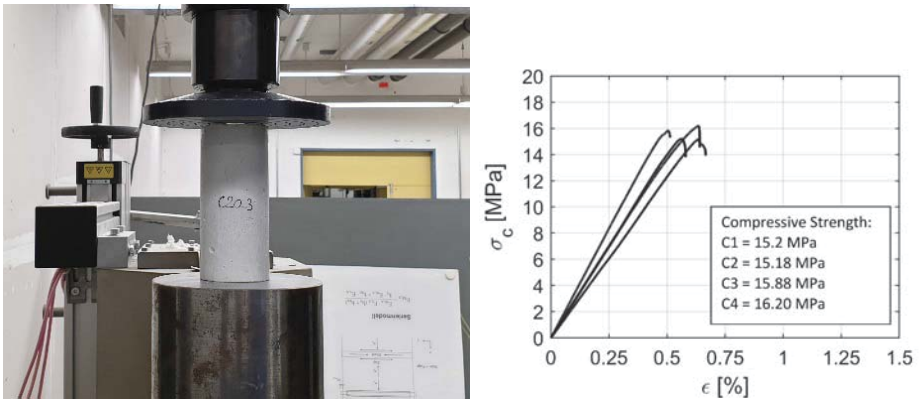

Figure 6. Left: Compression test setup. b) Stress-Strain curves.

Figure 7. Four point bending test setup.

Unreinforced 12.5x12.5x80 mm and 40x40x160 mm size rectangular beams were also constructed and tested in 4 point bending after 20 days (Figure 7). Figure 8 shows their force-deformation diagram as well as the tension strength of the unreinforced concrete. The maximum flexural strength is larger for the small specimens, this is in agreement with the well known size effect.

6 TESTING OF 3D PRINTED MICRO REINFORCEMENT IN TENSION

The 3D reinforcements were produced by Laser powder Bed Fusion (LPBF) technology using a Sisma Mysint100 equipped with a fiber laser of wavelength 1061 nm and a laser spot size 55 μm. The material used for manufacturing reinforcement was gas atomized 316l stainless steel powder provided by Oerlikon Metco. The tested reinforcement had a diameter of 0.35 mm for the stirrups and 0.50 mm for the rebars (1:40 scaled models of Φ14 and Φ20). Printing the rebars in a way that their bonding with concrete is similar to one of the prototype models is not trivial and will be a subject of future research. Due to some limitations in the size of the working chamber and appearance of high residual stress during the LPBF process, manufacturing the ribs of the reinforcement in 1:40 scale is problematic.

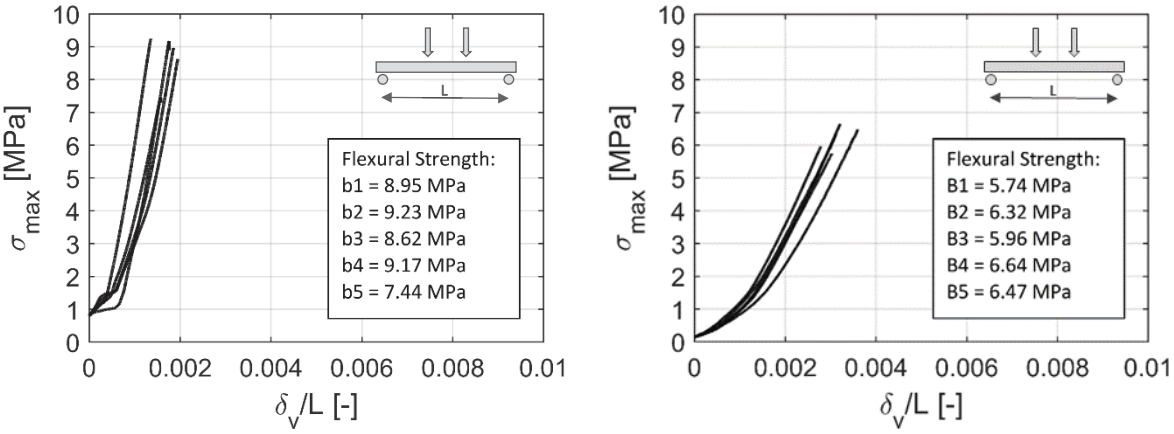

Figure 8. Maximum tension stress in the beam (σmax) vs normalized deflection in the middle (δv) normalized with respect to the beam spam between the supports (L) Left: Four point bending test results 12.5x12.5x80 mm beam. Right: b) Four point bending test results 40x40x160 mm beam.

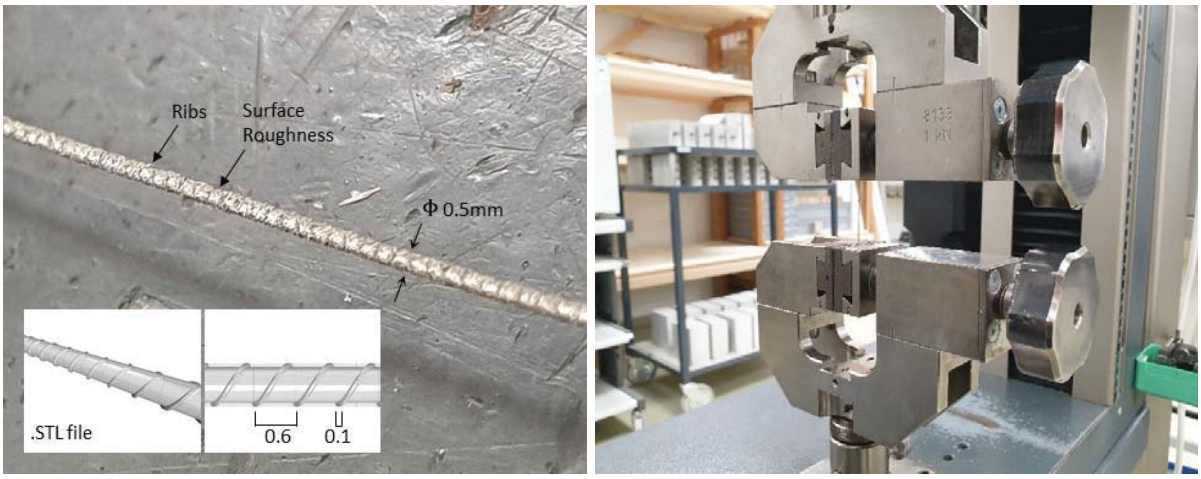

Figure 9. Left: .STL file and printed rebar. Right: Uniaxial tension test setup.

The minimum feature size of LPBF parts is around 200 μm (i.e. of 10 mm in the prototype scale). The ribs would have a size on the order of 1 mm in the prototype scale. However, the LPBF process results in a rough surface anyways with Ra values of 15-20 μm. For many technical applications, post processing steps reducing surface roughness (e.g. grinding, polishing) are required. In our case, we did not apply this process, as roughness is a target property. Moreover, an attempt to print ribs was made. Figure 9, left shows the STL file that was used for printing the parts as well as a photo of the rebar surface in the as-manufactured state.

Some of the rebars were tested in tension in order to assess the yielding and maximum strength of the printed rebars. The tests were performed with a Zwick Universal Testing Machine equipped with a 1 kN load cell. The initial gap between the clamping jaws was 30 mm which increased at a rate of 0.1 mm/min.

5 specimens were tested. Figure 10 left shows the results of the tension tests for all 5 tested specimens. The yield strength of the rebars was defined imposing a conventional 0.01 offset of the initial linear part of the curves. The average yield and maximum strength of the specimens were fy = 400.7 MPa and ft,max = 454.5 MPa. Casati et al. (2016) [18]on (10 mm × 10 mm × 75 mm) specimens had shown a yield strength of the 3D printed 316L stainless steel of 500-600 MPa meaning that the 0.5 mm diameter rebars were weaker: Any defects as well as the surface roughness will have a more pronounced effect in small-scale specimens. Hence there is a scale effect that needs further investigation. The Young modulus was 75 GPa, which is substantially lower than the 180 GPa value reported by Casati et al. (2016) [18], showing that more research is needed on the field to understand why.

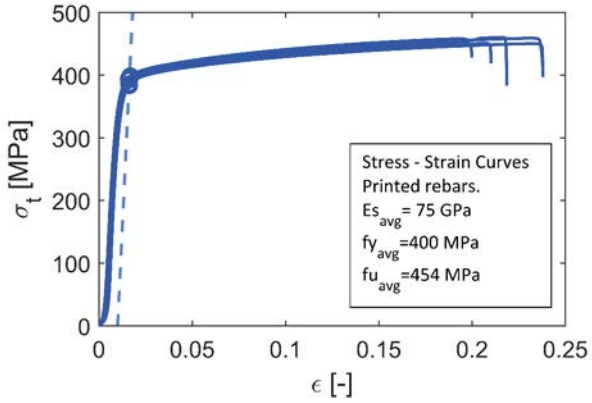

Figure 10. Tension tests of printed rebars.

7 FOUR POINT BENDING TESTS OF MICROREINFORCED CONCRETE BEAMS

Three model beams were manufactured and tested to determine their bending properties. The beams were designed to represent a 1/40 scale beam with 0.50 m by 0.50 m cross section and 3.2 m length, featuring 6 Φ20 longitudinal rebars and Φ14 shear reinforcement with 10cm spacing, all in the prototype scale. This translated in the model scale into 80 mm long beams with a cross section of 12.5 mm by 12.5 mm, Φ0.50 longitudinal rebars, and Φ0.35 stirrups spaced at 2.5 mm. The entire reinforcement cage, i.e. rebars and stirrups, was printed with the desired layout. Figure 11 shows the reinforcement cage detail, as well as the cross section layout.

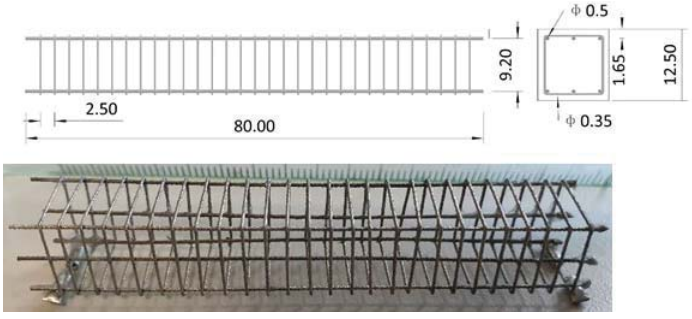

Figure 11. Reinforcement details and 3D printed cage.

The reinforcement was carefully placed into the mold, making sure that the 1.65 mm cover was respected. Subsequently the microconcrete was casted. The specimens were left for 2 days in the molds which were then removed. The unmolded specimens cured for other 18 days for a total of 20 curing days before testing.

The test setup consisted of a four point bending test with a support span of 60 mm and a loading span, i.e. the spacing of the loading pins, of 20 mm (Figure 12a). The applied loading rate was 0.1 mm/min to ensure static testing conditions. Figure 12 (b-d) shows the moment-vertical displacement plot, at the middle of the beams.

The average moment capacity was 3220 Nmm. Moreover, we noticed that after a first quasi-linear branch the curves become jagged at about 2'000 Nmm, this region corresponds to the crack onset within the loading span. A visual inspection during the tests has indeed shown that the first cracks appeared when the first peak of the curves were observed.

A visual inspection of the specimens after the tests has shown that the printed rebars fractured. Hence, the bonding strength created by the surface roughness and the printed details was enough to prevent debonding.

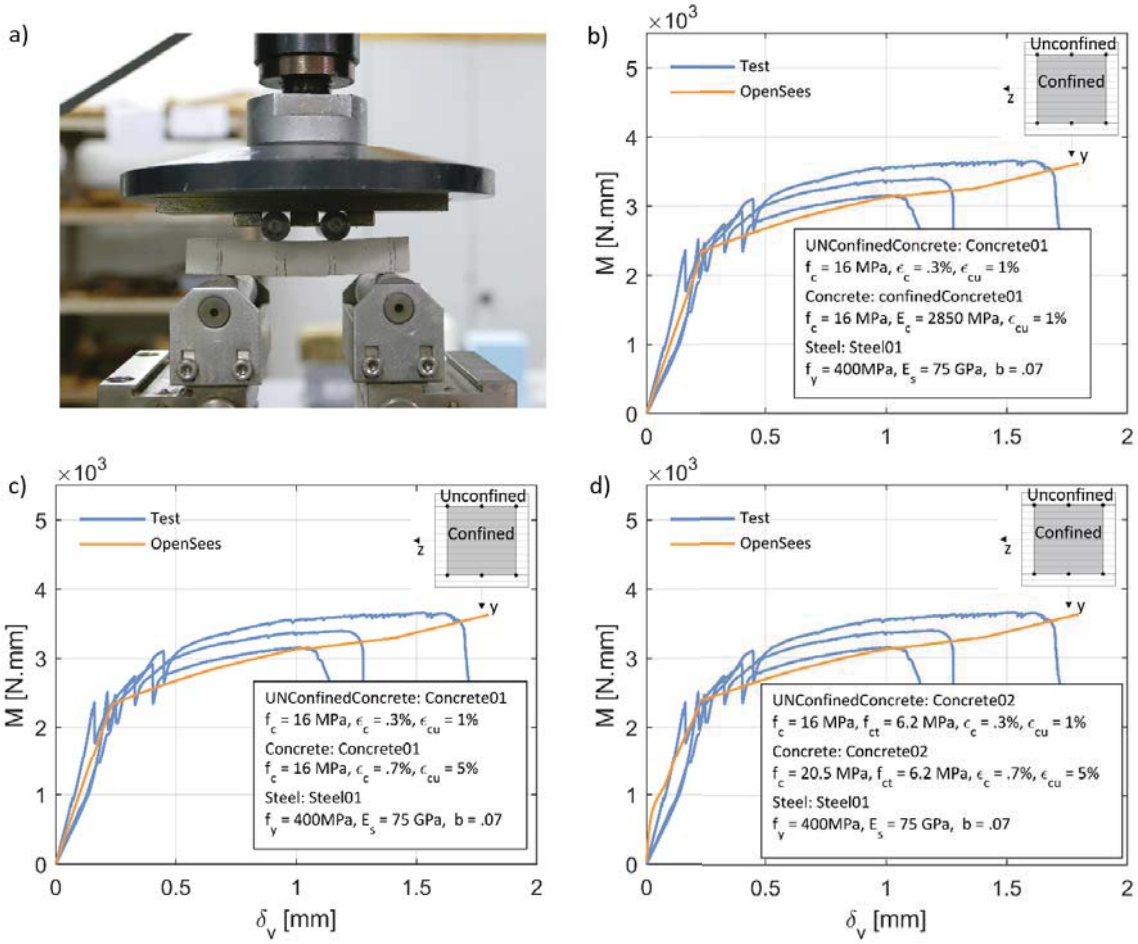

Figure 12. Comparison between experimental results and OpenSees simulation using fiber model.

Numerical models of the four point bending test were developed in OpenSees and the results compared against the experimental curves. The beam was modelled using a displacement-based element with non linear fiber section. The section was divided into three types of fibers, i.e. confined concrete (in the area enclosed by the rebars), unconfined concrete (concrete cover), and steel (longitudinal rebars). Steel was modelled with Steel01 material with fy=400 MPa,

Es=75 GPa, and 7% hardening. Different concrete modelling options were tried (Figure 12(b-d). Concrete01 has zero tension strength, while Concrete02 behaves linear-softening behavior in tension. ConfinedConcrete01 computes the confined concrete properties automatically based on the transverse reinforcement. In all cases, we used the results of the compression and bending tests to characterise the unconfined concrete. When confined properties were needed as an input, the Mander et al. (1988) [19] model was used. Figure 12 (b–d) shows the comparison between experimental results and the OpenSees analyses. The numerical results seem to be in good agreement with the experimental ones, which indicates that the fundamental assumptions valid for reinforced concrete elements, such as perfect bonding between steel and concrete and plane cross sections, apply for the micro-reinforced concrete beams.

8 CONCLUSIONS

Additive manufacturing is a promising technology for the automated construction of the reinforcement cages of small scale RC specimens. The tested members show a behavior, which is close to full scale RC structural members – with the exception of concrete tension strength, that needs to be reduced. Therefore, it seems feasible to use the proposed methodology to construct small scale models of full structures with the aim of testing them on a shake table inside a geotechnical centrifuge. The shake table tests datasets can be used by the Earthquake Engineering community to statistically validate the assumptions that it usually does to scale up from component-level cyclic to system-level dynamic behavior, namely boundary conditions, interaction of components, conceptual formulation of damping, and participation of slabs. Further investigations on materials and component at small scale are required.

Keywords: Soil strain, Direct measurement, New device, Centrifuge tests, Earthquake loading.

Abstract. *A new device has been developed for the direct measurement of soil strains under earthquake loading in centrifuge testing. The main body of the device is a potentiometer used to measure soil deformation directly. Two MEMS accelerometers are attached to either end of the device to obtain soil deformation as a semi-direct measurement method. Two different centrifuge models, a level sand bed and a slope, were prepared with dry sands to achieve small and large soil deformation, respectively. A series of model earthquake motions were applied to the centrifuge models. The strains obtained with the new devices are compared with the indirect measurement of Piezo-electric accelerometers. It is found that this new direct method to measure soil strain could be applicable for medium to large soil deformation, that is, in the case of relatively strong earthquakes.*

1 INTRODUCTION

Soil deformation induced by earthquakes can cause damage to structures and even pose a threat to human life. An important parameter in seismic analyses is soil strain. However, obtaining accurate measurements of strain remains challenging. Currently, the most widely-used measurement methods in geotechnics can be classified into two types, sensor-based and image-based methods.

Sensor-based methods generally involve two kinds of sensors, displacement measurement sensors (e.g., LVDTs, LDTs, laser displacement sensors and FBG sensors) and acceleration measurement sensors (e.g., MEMS and Piezo-electric accelerometers). However, most widely used displacement measurement sensors, such as LVDTs, LDTs and laser displacement sensors, are placed outside the soil mass and are used to measure the movement of the soil adjacent to the boundary [2, 4, 6], and thus their measurements are likely to suffer from boundary effects. To measure soil deformation within soil, FBG sensors came into use [13]. However, data processing for such sensors involves assumptions about parameters in calculation of displacements. Furthermore, these FBG sensors are costly and too delicate to be deployed widely under strong earthquake loading. In contrast, unlike displacement measurement sensors, acceleration measurement sensors can be placed within soil and indirectly provide displacements through double integration for strain calculation [14]. The problem of acceleration measurement sensors is that the numerical errors induced by integration in data processing may affect the accuracy of the results.

Image processing techniques comprise two methods, the Computerized X-ray tomography (CT) [10] and Particle Image Velocimetry (PIV) [11, 12]. Although the CT method can measure internal deformation, some intrusive marking may be required, disturbing the soil models that are being tested. In the PIV technique, soil deformations are defined across transparent surfaces, and thus the results suffer from boundary effects. Moreover, in dynamic tests costly high-speed cameras are necessary, making this technique expensive to apply.

This paper presents a new device developed to obtain soil strain within soil directly based on measurements of relative displacements of soil columns. The performance of this device is evaluated in comparison with a common method using dynamic centrifuge testing which is currently the most advanced experimental method available. The applicability of the new device is discussed based on the results in soil deformation analyses.

2 METHODOLOGY

A new device-based method and a common method used in this research are introduced. The detailed calculation process of soil characteristics, including shear stress, strain, shear moduli and damping, is demonstrated. Information on model preparation, testing programs, and signal processing is provided.

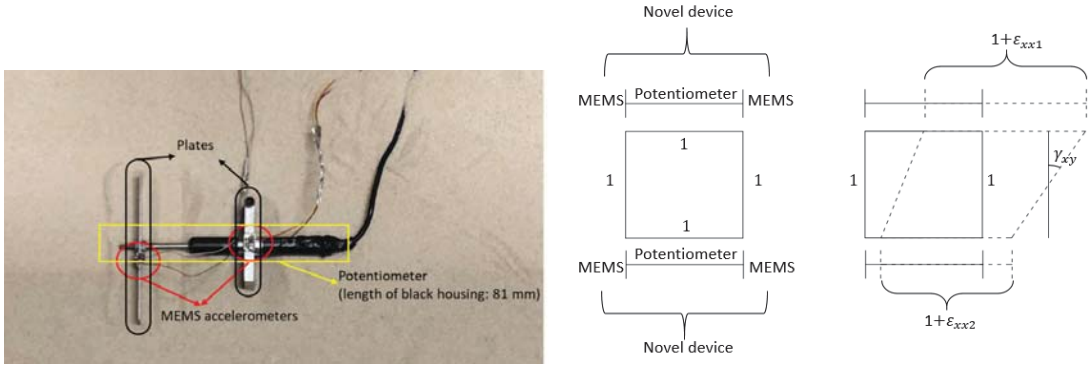
2.1 New device-based method

A new device (Figure1(a)) is used to obtain dynamic strains in this research. The device is comprised of two kinds of instruments, a potentiometer and two MEMS accelerometers. The potentiometer is used for direct measurement of displacements between the two aluminium plates. The two accelerometers are used for measurement of accelerations of either plate. With these accelerations, the displacements between the two plates can also be calculated via double integration. In this research, the displacements are caused by the horizontal and shear deformation of the small column confined by the two plates attached to the device during seismic

loading. In Figure 1(b), a unit volume is used to explain the principle of the calculation of strains. Since the measured or calculated relative displacements are applied to a soil column with realistic dimensions, those displacements should be normalised by their real lengths. Such normalised displacements also represent linear strains ε_{xx}. Thus, shear strains can be obtained from

$$\gamma = \varepsilon_{xx1} - \varepsilon_{xx2} \tag{1}$$

where ε_{xx1} and ε_{xx2} are the linear strains at the top and bottom surface of the soil block, respectively.



(a) A view of a new device. (b) Measurement principle.

Figure 1: New device for direct strain measurement.

2.2 Absolute acceleration-based method.

Two different equations are available for estimating shear strain. The shear strain at the mid-point between two adjacent accelerometers can be expressed as

$$\gamma = \frac{\Delta u}{\Delta z} \tag{2}$$

where Δu is the difference of displacements obtained from the records of the two accelerometers, and Δz is the difference of the two depths at which the two accelerometers are placed. For the case of a vertical array of accelerometers, Zeghal et al. [15] derived the shear strains γ_i at the depth of Δz_i, as

$$\gamma_i\left(z_i\right) = \frac{1}{\Delta z_{i-1} + \Delta z_i}\left[\left(u_{i+1} - u_i\right)\frac{\Delta z_{i-1}}{\Delta z_i} + \left(u_i - u_{i-1}\right)\frac{\Delta z_i}{\Delta z_{i-1}}\right]\left(i = 2, 3, 4\cdots\right) \tag{3}$$

where the subscript i is the number of the accelerometers.

Shear stress can be calculated based on absolute accelerations. Applying the classic beam theory, Brennan et al. [1] derived an equation to obtain the shear stress τ at the depth z_i, written as

$$\tau\left(z_i\right) = \frac{1}{2}\,\rho\,\frac{\left[\ddot{u}_i {z_i}^2 + \ddot{u}_i z_i\left(z_i - 2z_1\right)\right]}{\left(z_i - z_1\right)} \tag{4}$$

where ρ is the density of the sand.

2.3 Mohr's circle of strains

Mohr's circles of strains aim to present relationship between the normal strains and half of the shear strains of the unit volume. Two points, $(\varepsilon_{yy}, \gamma_{yx}/2)$ and $(\varepsilon_{xx}, -\gamma_{xy}/2)$, are needed to plot Mohr's circles. In this research, the normal strains perpendicular to the moving direction of the shaft of the potentiometer are assumed to be zero (i.e., $\varepsilon_{yy} = 0$ under plane strain condition). Thus, with the linear strains obtained from the new device and the shear strains obtained based on the absolute accelerations, the Mohr's circles of strains can be plotted.

2.4 Shear modulus and damping

Shear stress-strain loops are plotted with the calculated shear stress and strain from the absolute accelerations. The ratio of the magnitude of stress to the magnitude of strain is regarded as the shear modulus [1]. The obtained shear moduli G are normalised by small-strain moduli G_{max} which were obtained with an air hammer developed by Ghosh and Madabhushi [3], following the expression

$$G_{max} = \rho \, {v_s}^2 \tag{5}$$

where v_s is the velocity of the shear wave created by the air hammer. The equivalent damping ratios D can be obtained from these loops, following the equation

$$D = \frac{W}{2\pi \, W_e} \tag{6}$$

where W is the total energy dissipation during each loop and W_e is the energy dissipation in the equivalent elastic system. Specifically, W equals to area of each loop, while W_e equals to the area bounded by the representative line segment in the calculation of G and the strain axis.

2.5 Model preparation and test program

The preparation of a level sand bed model and a slope model at an angle of 30° were conducted with an automatic sand pouring machine [7], using dry Hostun sand. The maximum and minimum void ratios of the sand are 1.01 and 0.555 respectively, and the specific gravity of the sand grains is 2.65 [8]. Some 1-g shanking table tests were conducted under different seismic motions, but the new device was unable to capture the soil movement, indicating that the new device lacks high sensitivity. For this reason, the two models were both prepared with loose sand whose relative densities were 33% and 36% respectively. Both models were tested at 50-g level in the Turner Beam Centrifuge at Cambridge University. The instrumental layouts of the two models are illustrated in Figure 2. Table 1 shows the properties of the earthquakes for both tests. This research focuses on the single sinusoidal signals with the main driving frequencies ranging from 0.8 Hz to 1.2 Hz over 10 cycles.

2.6 Signal processing

The key to obtaining correct strain is appropriate signal filtering. Under-filtered signals, especially those involving low-frequency components, result in significant errors during integration of the accelerations. Such errors cause invalid shear stress-strain loops and as a result to inaccuracies in the determination of shear moduli and damping ratios. On the other hand, over-filtering, producing perfectly smooth stress-strain loops, damages part of the real signal. The signal filtering in this research is based on plots of fast Fourier transform (FFT). A band-pass filter with a frequency range of 0.4 Hz to 5 Hz was employed for EQ4 in Test-1.

3 DYNAMIC STRAINS IN THE LEVEL SAND BED

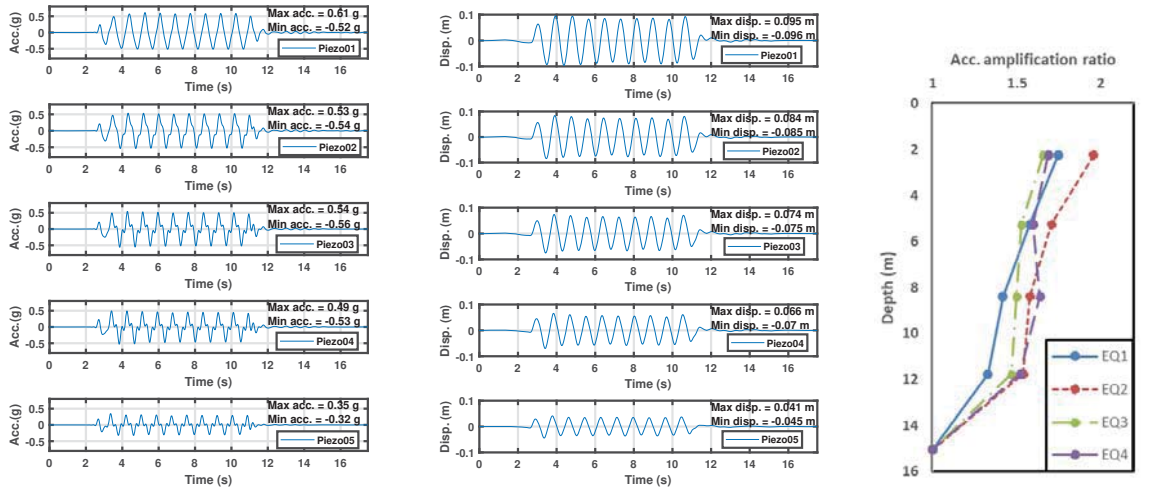
3.1 Absolute acceleration based results

The five Piezo-electric accelerometers recorded the absolute accelerations at different elevations in the sand, as shown in Figure 3(a). The amplitudes of accelerations increased with decreasing depth, i.e. amplification, indicating smaller stiffness at smaller depths. The acceleration amplification ratio is defined as the ratio of the average peak accelerations in two horizontal directions to the average peak acceleration of the input signal. Figure 3(c) displays the variation of the ratios with depth for four earthquakes, suggesting that the magnitudes of the earthquakes had marginal effect on the amplification ratios.

The corresponding absolute displacements (Figure 3(b)) were obtained by double integration of the absolute accelerations. Only the cyclic displacements are displayed, since Piezo-electric accelerometers do not respond to the low-frequency components well. The displacements became larger at smaller depths, that is, the larger soil deformation occurred in the shallower layers.

3.2 New device-based results

The accelerations measured by the MEMS accelerometers represent the movement of the two plates of the new device. The relative accelerations, that is, the difference between the two sets of the accelerations, are shown in Figure 4(a). Similar to the variation of the absolute accelerations, the relative accelerations increased towards the sand surface. The comparison between the measured and integrated relative displacements is presented in Figure 4(b). The accelerometers captured the soil movement, while the potentiometers failed to record useful movement, indicating that the potentiometers may lack sensitivity for small deformation measurement. Thus, the data obtained from MEMS accelerometers are focused on for the following

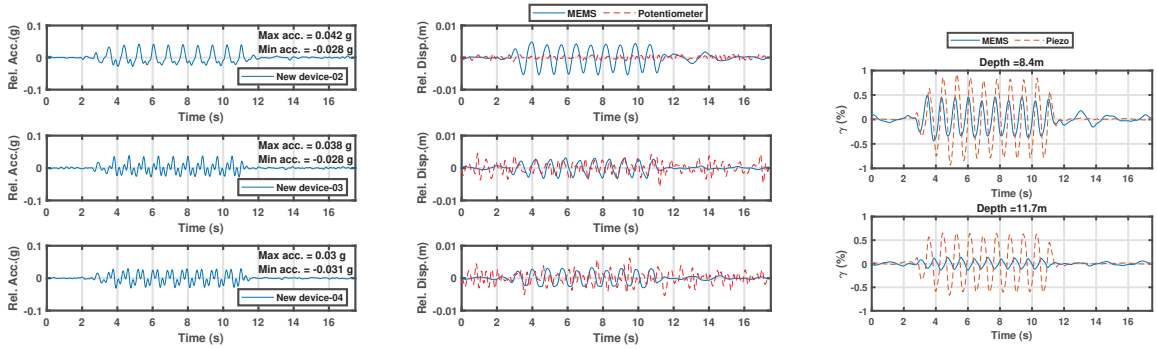


(a) Absolute acceleration records. (b) Absolute displacement records. (c) Amplification ratios.

Figure 3: Dynamic response of sand during EQ4 in Test-1.

analyses of Test-1.

A comparison between the absolute acceleration- and relative acceleration-based shear strains is shown in Figure 4(c). The dynamic shear strains from the MEMS accelerometers are generally smaller than those from the Piezo-electric accelerometers. Furthermore, the difference was larger at the larger depth (11.7 m). This is possibly because of the friction between the shaft and the housing, preventing the plates from moving freely with the soil.



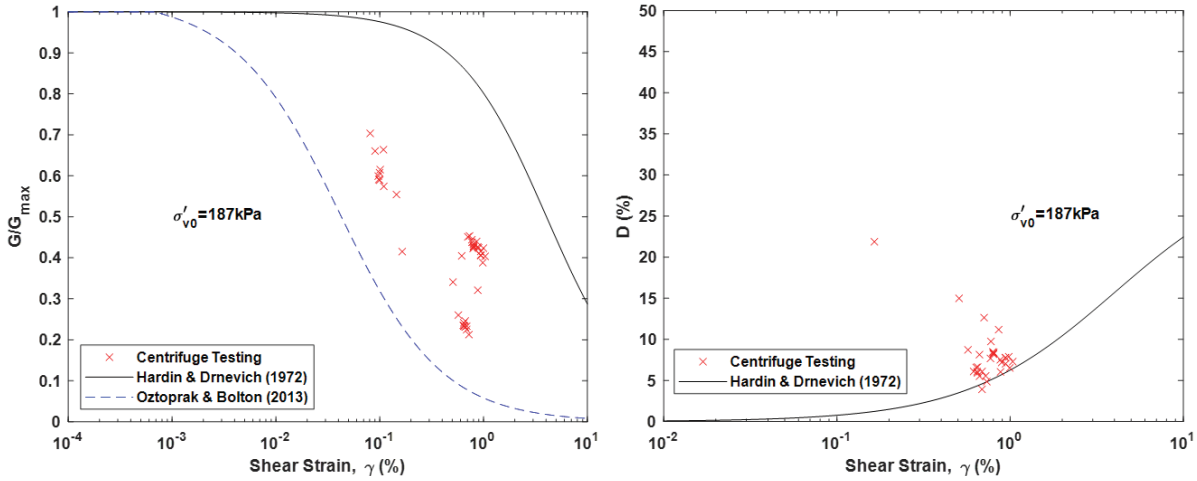
(a) (b) (c)

Figure 4: Results of dynamic analysis of the level sand bed subjected to EQ4: (a)relative acceleration histories from MEMS acceleometers (b)comparison between calculated displacements from MEMS accelerometers and measured displacements from potentiometers (c)comparison between shear strains from MEMS accelerometers and those from Piezo-electric accelerometers.

3.3 Shear modulus and damping

To plot normalised shear modulus degradation curve, an air hammer test at 50-g level was conducted to obtain G_{max} and the corresponding shear moduli in the test were obtained with the accelerations measured by the Piezo-electric accelerometers. The shear modulus curves based on two empirical equations proposed by Hardin and Drnevich [5], and Oztoprak and

Bolton [9] are presented for comparisons with the shear moduli obtained in this test. Figure 5(a) shows the experimental results are within the boundary of the two empirical curves and are generally closer to the curve of Oztoprak and Bolton [9]. These results seem to form a trend line, consistent with the empirical curves. Regarding the damping ratios, Figure 5(b) shows that the experimental results are generally above the empirical curve of Hardin and Drnevich [5], suggesting higher level of damping in the sand.



(a) Shear modulus degradation curve. (b) Damping curve.

Figure 5: Variation of shear modulus and damping with strain.

4 DYNAMIC STRAINS IN THE SLOPE MODEL

The dynamic response of a level soil bed subjected to the strong earthquake EQ4 has been analysed with the data obtained in Test-1, but the response of the potentiometers indicates low sensitivity. Therefore, a slope model, in which larger soil deformation tends to occur, was tested, and the results are presented and discussed.

4.1 Absolute acceleration based results

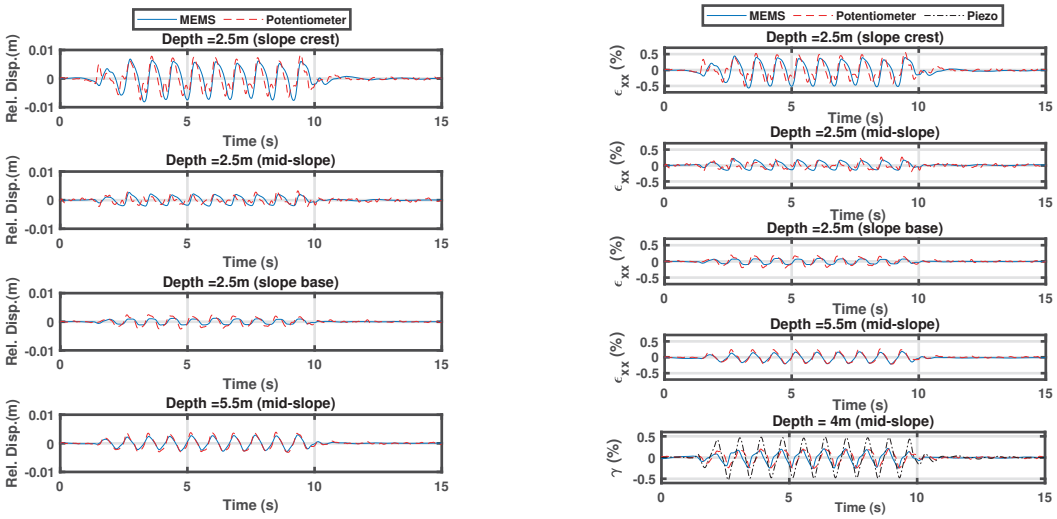
Table 2 shows that the accelerations at the slope crest (see Piezo-05 and -06) were larger than other locations around the slope. The difference between the peak +ve and –ve accelerations decreased, indicating soil sliding along the slope. Furthermore, the difference became smaller from the crest to the base.

Piezo no.	Depth in the slope (m)	Max. acc. (g)	Min. acc. (g)
05	1	0.41	-0.58
06	4	0.46	-0.59
07	1	0.28	-0.39
08	4	0.36	-0.42
10	1	0.38	-0.41

Table 2: Absolute accelerations around the slope during EQ4 in Test-2.

4.2 New device-based results

Following the same procedure of analyses of Test-1, the relative displacements measured by potentiometers and those calculated from accelerations are shown in Figure 6(a). The displacements agree with each other well. However, the relative displacements from accelerations are slightly different from those measured directly. Such a discrepancy could result from signal filtering, as the measured accelerations were filtered more than the measured displacements. Moreover, the noise may have different phases, that is, the calculated displacements can be larger or smaller than the measured ones. In addition, the linear strains were larger at the deeper layer than at the shallower layer of the mid-slope (Figure 6(b)). This could indicate the existence of slip plane.



(a) Comparison of relative displacements.

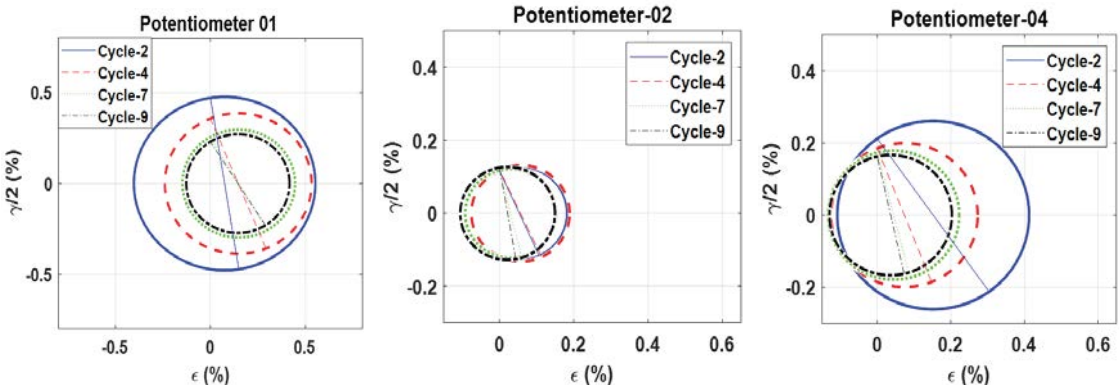
(b) Comparison of cyclic strains.

Figure 6: Result comparisons based on the various measurement methods during EQ4 in Test-2.

The potentiometers producing satisfactory relative displacement time-histories, the corresponding cyclic shear strains are compared with those calculated based on the absolute accelerations in Figure 6(b). As expected, the shear strains from relative accelerations and relative displacements show a good match. However, the cyclic strains based on the measurements of the Piezo-electric accelerometers are approximately 1.5 times larger than those based on the measurements of the new devices. The friction between the shaft and the housing of the potentiometer could be the primary reason. Additionally, the numerical errors could also cause the discrepancy.

4.3 Mohr's circles of strains

The maximum cyclic linear strains and maximum shear strains during the same cycle were used for Mohr's circles (Figure 7). Generally, the radii of circles at each location decreased with the number of cycles, indicating increasing soil stiffness. Additionally, the largest radii were seen at the slope crest (Figure 7(a)), while the smallest radii were observed at the mid-slope near the surface (Figure 7(b)). This indicates that larger soil deformation occurred at the crest, where confining pressures were relatively small.



(a) (b) (c)

Figure 7: Mohr's circles of strains.

5 CONCLUSIONS

This research has developed and tested a new device to measure soil deformation and verify the applicability of the new device. Two dynamic centrifuge tests were conducted on a level sand model and a slope model, respectively. Four new devices were used to measure soil strains directly based on a new principle. The results obtained with this new direct measurement method were compared with those obtained with a commonly-used indirect measurement method.

This research shows that the accelerations measured in the sand in both tests increased towards the sand surface, but the magnitudes of the earthquakes had a negligible impact on such acceleration amplification. This confirms that soil deformation is larger where confining stress is smaller. It was also found that the shear moduli calculated in the tests are generally within the boundary of the two empirical equations proposed by Hardin and Drnevich [5], and Oztoprak and Bolton [9], respectively. Specifically, those shear moduli fall closer to the curve presented by Oztoprak and Bolton [9]. For damping ratios, they fall generally above the empirical curve presented by Hardin and Drnevich [5]. This curve may be more applicable to the strain range from 0.15% to 1% under similar site conditions, as the experimental damping ratios are closer to it within this range. Another major finding is observed in the results obtained in Test-2 where the larger soil deformation was simulated, that is, the displacement records of the potentiometers show a good agreement with the calculated displacement histories based on the records of the MEMS accelerometers. It is, therefore, concluded that the new device could be applicable for large soil deformation.

However, it should be noted that the discrepancy between the results obtained from the new measurement methods and those obtained from the widely-employed method proposed by Brennan et al. [1] is still clear. As indicated by the experimental results in this research, the friction between the housing and shaft tends to affect the data significantly. Thus, more efforts should be made to reduce or even eliminate the friction in future research. Despite the discrepancy, this research undoubtedly provides some valuable evidence that this new measurement device can provide valid results with further improvement.

Abstract. *Non-structural unreinforced masonry (URM) walls are generally consisted of cement bricks and mortar used for joint material. Bricks in masonry works should be completely glued on bed and head-joints with sufficient thickness. In typical masonry construction, variation of thickness and recess of bed and head-joints is inevitable and they are important physical parameters that can be used in determining the construction quality of masonry works. Thus, it is necessarily required to investigate the influence of construction quality on the structural properties of an URM wall. As preliminary investigations, this study experimentally evaluates the effects of construction quality to the diagonal tension behavior of a masonry unit. The effects are discussed with selected test parameters, thicknesses and recesses of joints which can be considered to be critical quantities to erection time related to the construction quality of the test specimens. Test results present that the failure modes of the specimens are considerably dependent upon the construction qualities and their strength and elastic modulus increase in the specimen with better construction quality presenting the smaller recess and the larger thickness of the bed and head-joints.*

1 INTRODUCTION

Unreinforced masonry (URM) walls used as a non-structural element in building construction have been commonly implemented for architectural space zoning. The lessons learned from historical earthquakes have demonstrated that non-structural URM walls can be vulnerable to even low intensity of seismic attacks resulting in free structural damage to a building structure. Under cyclic loading, they suffer fatal failures classified into toe compression failure, rocking, bed-joint sliding, diagonal cracking and overturning failures. Thus, current seismic design codes, such as AIK [1] and ASCE [2], prescribe the design requirements for non-structural URM walls in order that their seismic performance improves and, in turn, the seismic damage is limited under even severe ground motion shaking.

A nonstructural URM wall consists of concrete bricks laminated by mortar without any reinforcements for structural integrity. Thin layer glue-mortar is applied to the perimeter sides of a brick to make bed and head-joints in the horizontal and vertical directions of a wall, respectively. Bricks in a masonry unit are manufactured with relatively excellent quality control. However, although construction specifications [3] for masonry works recommend that bed and head-joints of sufficient thickness (usually larger than 10 mm) be installed, the quality of in-situ mortar bed and head-joint works is still hardly controlled in a construction site. The construction quality of mortar joint works can be quantitively represented by their thickness and recess which will be chosen as test parameters for this study.

In order to assess the structural behavior of an URM wall resulting from such complicate material composition, the structural properties of a masonry unit first need to be precisely evaluated. This is carried out by compressive tests of prisms and diagonal tension tests of masonry units. This study investigates the influence of the thickness and recess of mortar joints on the structural properties which can be obtained from diagonal tension tests of a masonry unit. To do this, specimens for diagonal tension tests of masonry units were prepared with three construction qualities, "*Good*", "*Fair*" and "*Poor*" which can be classified by masonry piling time correlated with apparent physical test parameters, the thickness and recess of mortar joints. The testing parameters are statistically analyzed according to the construction qualities. Also, test results of the masonry unit specimens manufactured with different construction quality are discussed in terms of their strength and elastic modulus. This *pilot* test program intends to demonstrate the relation between the structural properties and the construction quality of masonry walls which can become basis information on the seismic evaluation of existing and new masonry building structures.

2 DESCRIPTION OF TEST SPECIMENS

The structural behavior of a non-structural URM wall mainly depends on the properties of masonry units affected by the construction quality which is influenced by a lot of factors including the workmanship of skilled laborers, working environments, working temperatures, working space, etc. All of factors related to construction quality of masonry works are closely represented by a masonry piling time. It was known throughout interview with skilled laborers that they are capable of piling only about 120 bricks in carrying out masonry works according to very strict working manual while they can pile more than 200 bricks under the allowance of poor construction quality. This study considers a masonry piling time as the main factor which can determine the construction qualities of masonry works.

Figure 1 shows the shapes and dimensions of specimens for diagonal tension test specimens according to ASTM [4]. The masonry unit specimens with 390 mm width, 392 mm height and 90 mm thickness were made with a total 12 cement bricks which were piled to 6 layers. The dimensions of each brick are 190 mm × 90 mm × 57 mm. According to general

construction specifications for masonry works, the thickness t_{bj} of both bed and head-joints is planned to be larger than 10 mm and straight head-joints are avoided. Note that during construction of the specimens, a value of t_{bj} for each specimen would be changed and would also have spatial variation within an individual specimen. A total of 30 specimens was prepared and 10 specimens were constructed with each construction quality classified into "*Good*", "*Fair*" and "*Poor*" which are dependent upon the masonry piling time *T*. Table 1 summaring the statistics of *T*s shows that mean values of *T*s increase for the specimens with better construction quality. Regardless of the construction qualities, the coefficients of variation COVs are similar. This means that all specimens categorized into the same construction quality maintain the similar degree of variation of masonry piling times.

Table 1: Statistical information for construction time of masonry unit specimens

Values of *T*s are considered as the main index of construction quality in manufacturing the specimens. More physical parameters are required to verify the relation between construction quality (represented by masonry piling time *T*) and the structural properties of the masonry unit specimens. This study considers the thickness t_{bj} of both bed and head-joints and their recess r_{bj} from the brick surface as the apparent testing parameters, shown in Figure 1. Values of t_{bj} and r_{bj} of all the specimen were examined after curing. For each specimen, a total of 37 measurements (12 at head joints and 25 at bed joints) was measured using a digital Vernier caliper.

The distributions of t_{bj} and r_{bj} values measured at the bed and head-joints in the specimens are found in Figures 2 and 3. Regardless of types of joints, the larger t_{bj} values and the smaller absolute values of r_{bj} are founded at the masonry unit specimens erected with better construc-

tion quality. A mean of t_{bj} values is the smallest at the head-joints for the *Poor* specimens while the corresponding mean values for the *Good* and *Fair* specimens are relatively close to 10 mm which is the planned joint thickness. Values of t_{bj} larger than 10 mm are found in the head-joint for some *Good* specimens. Mortar filling in bed-joints is better than in head-joints, which magnifies the variation of r_{bj} values measured in head-joints.

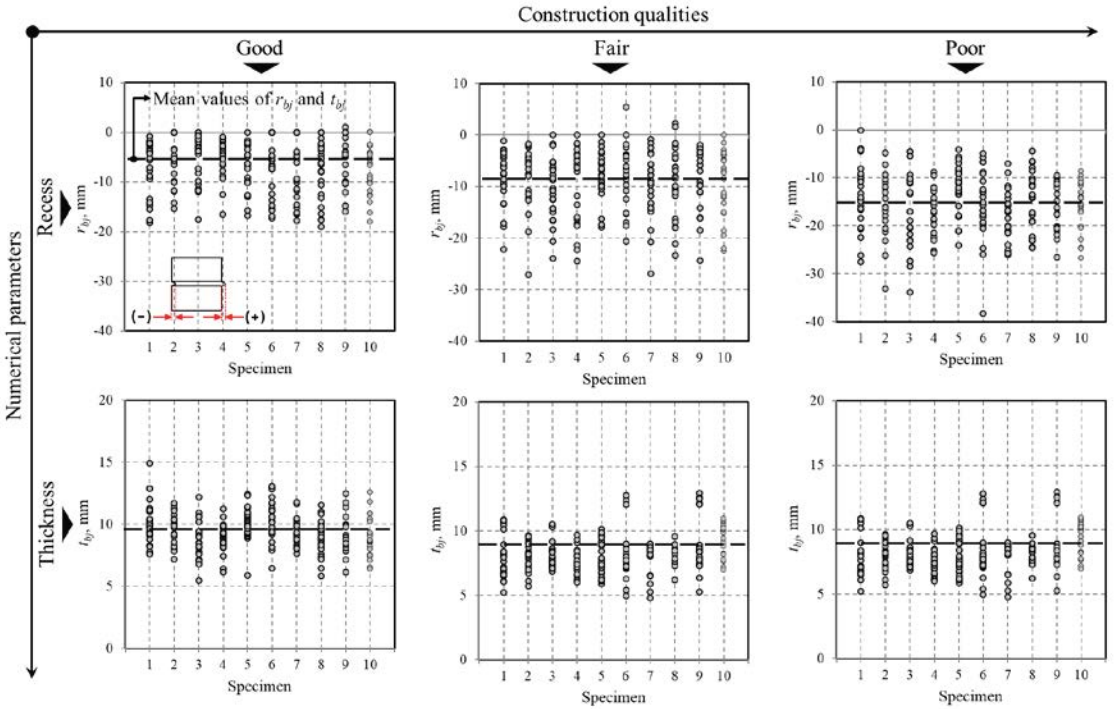

Figure 2: Distribution of numerical parameters measured at bed-joints in specimens

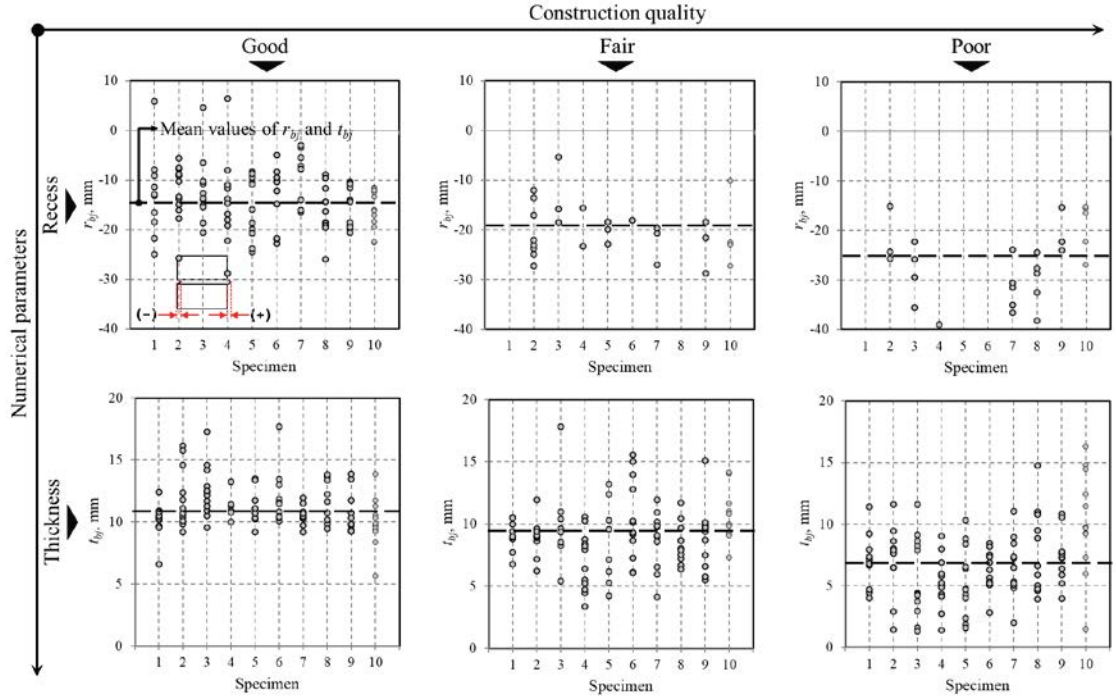

Figure 3: Distribution of numerical parameters measured at head-joints in specimens

Statistical spatial variations of t_{bj} and r_{bj} values measured at both of the bed and head-joints in the specimens were investigated and summarized in Figure 4. Expected values of r_{bj} measured at the bed-joints are the smallest at their center and are increased at the edges while those of t_{bj} are relatively constant along a joint line. Unlike the bed-joints, means of r_{bj} values measured at the head-joints of the *Good* specimens are the largest at their center. For the *Fair* and *Poor* specimens, means of r_{bj} values at the head-joints are smaller as the distance from the bottom bed-joint is increased. Again, the largest spatial variation of both t_{bj} and r_{bj} values is also observed at the *Poor* specimens even if there is still some degree of spatial distribution in the *Good* specimens.

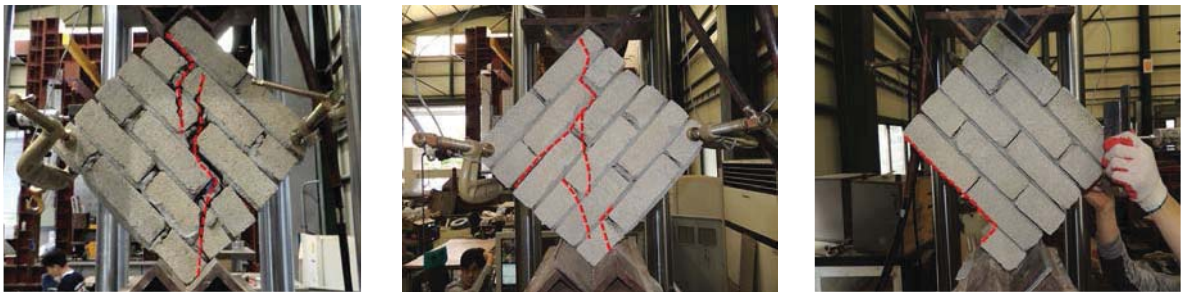
3 EFFECTS OF CONSTRUCTION QUALITY ON DIAGONAL TENSION BEHAVIOR OF TEST SPECIMENS

Diagonal tension tests were carried out with the Universal Testing Machine with 500 kN capacity. Figure 5 presents crack patterns observed at the end of each test. Also, the failure

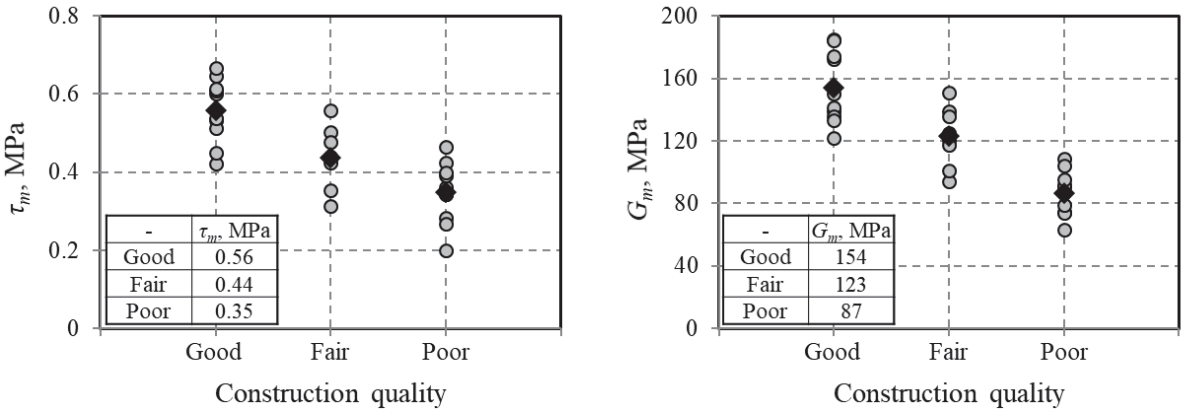
modes relied on the construction quality of the specimens are shown in the figure. In the *Good* specimens, cracks parallel to the loading direction developed along bed and head-joints alternately. A few cracks were also found in bricks. Similar crack pattern was observed in the *Fair* specimens. However, for the *Poor* specimens most of cracks were developed along one of bed-joints where is relatively short of filling mortar. Compared to the *Good* and *Fair* specimens, the total travelling length of cracks in the *Poor* specimens was shortened, which causes a brittle mode.



(a) *Good* specimen (b) *Fair* specimen (c) *Poor* specimen

Figure 5: Dominant failure modes of masonry unit specimens according to construction quality

Diagonal tension tests are typically performed to find out the direct shear stress and modulus which are important structural properties used for the seismic evaluation of a non-structural URM wall. Figure 6 contains measured shear stresses, τ_m at the maximum applied loads and shear modulus, G_m of the specimens. In this figure, solid parallelograms represent their mean values of the *Good*, *Fair*, and *Poor* specimens. The mean values of τ_m are, respectively, 0.56, 0.44 and 0.35 MPa for the *Good*, *Fair*, and *Poor* specimens, which demonstrates their dependence on the construction quality. The normalized means of τ_m values to that of the *Good* specimens, $\tau_{m(good)}$ are 0.79 and 0.63 for the *Fair* and *Poor* specimens, respectively. Note that even the mean of τ_m measured at the *Poor* specimens is still larger than the codified shear strength of 0.2 MPa [5] which is close to the smallest shear stress in the *Poor* specimen. The correlation of shear modulus with construction quality of masonry unit are similar to that of shear stress. The normalized means of G_m values to that of the *Good* specimens, $G_{m(good)}$ are *0.80* and *0.57* for the Fair and Poor specimens, respectively.



(a) Distribution of shear stress, τ_m (b) Distribution of shear modulus, G_m

Figure 6: Distributions of mechanical properties of masonry unit specimens

The normalized τ_m and G_m values are further analyzed to investigate effects of combination of the parameters, t_{bj} and r_{bj}, in detail. To do this, a normalized net mortar filling area factor, Λ defined as a ratio a net mortar filling area, $(A_{bj} - t_{bj} \times r_{bj})$ to the total joint area A_{bj} is introduced. Figure 7 shows the relations between the normalized τ_m and G_m, and Λ values for each type of joints in the all specimens. Linear correlation is clearly presented in the bed-joints rather than the head-joints. This is due to a factor that Λ values of the head-joints are not correlated with the construction quality, as shown in the figure where some of the *Poor* specimens have the head-joints with mortar-filling area that is larger than the corresponding of the *Good* and *Fair* specimens. In the bed-joints, Λ values increase for the specimens constructed with better quality. Most of the normalized τ_m and G_m values can be conservatively estimated using a linear equation established by considering one standard deviation from a trend line shown as a solid line in the figure.

4 CONCLUSIONS

This study is carried out diagonal tension tests of masonry units manufactured with construction qualities of "*Good*", "*Fair*" and "*Poor*" that can be differentiated by the thickness and recess of mortar joints. The effects of construction quality on the structural properties of the specimens are investigated. This *pilot* test program intends to provide basic information on the influence of construction qualities on the seismic capacities of nonstructural URM walls.

A total of 30 specimens with 390 mm width, 392 mm height and 90 mm thickness was prepared. Of them, 10 specimens were constructed with each construction quality classified into "*Good*", "*Fair*" and "*Poor*". This study considers the thickness t_{bj} and the depth of recess r_{bj} as parameters representing construction qualities. The largest t_{bj} values and the smallest absolute values of r_{bj} were founded in the *Good* specimens while a mean of t_{bj} values was the smallest at the head-joints for the *Poor* specimens. In statistical spatial variations of t_{bj} and r_{bj} values, the largest spatial variation of both t_{bj} and r_{bj} values was also observed at the *Poor* specimens.

The *Good* and *Fair* specimen's cracks developed into bed and head-joints alternately. In the *Poor* specimens, most of cracks were developed and propagated on a single bed-joint, which causes a brittle failure mode. The mean shear stresses are, respectively, 0.56, 0.44 and 0.35 MPa for the *Good*, *Fair*, and *Poor* specimens. Similar to the mean shear stresses, the correlation of shear modulus with construction quality is presented. There exists the linear correlation between normalized shear stress and modulus and a normalized net mortar filling area factor in the bed-joints. The normalized shear stress and modulus are increased with the increase in mortar filling area of the specimens.

Abstract: *A part of reinforced concrete structures are always subjected to dynamic repeated loading and simultaneously subjected to liquid water from an external source such as rains. These structures, especially the old ones, have numerous surface cracks that allow water to penetrate concrete and reach steel-concrete interface and subsequently affect the bond between concrete and steel bars. Against this issue, a fatigue pull-out test was carried out with supplying of water to investigate experimentally the bond behavior between the concrete and a deformed bar by using digital image correlation technique (DIC).A fatigue pull-out test was applied to a deformed steel bar which was embedded in a concrete specimen. The specimen had a trapezoidal "window," which allows full continues observation and measurements of concrete or cement paste displacements and subsequently strains by recording high-resolution digital video which was later analyzed by DIC software. The experiment focuses on the failure mechanism of the deformed bar from the concrete and the mechanism of the sludge's formation in the vicinity of the deformed bar. The results show that the actual deformations of concrete in case of fatigue test were captured well in both positive and negative direction of loading by using the DIC technique and they matched the past results. Also, the experimental results show that the pull-out failure of the deformed bar occurred due to the failure inside the concrete, not through the interface between the concrete and the deformed bar.*

1 INTRODUCTION

The combination of concrete, which has high durability in compression; and reinforcement that is ductile in tension, is used in civil engineering structures to ensure high strength with sufficient deformations to resist disaster. The load transform from the deck or slab in the superstructure to the foundations in substructure occurs due to the bond between the concrete and the embedded reinforcement bars. The mechanical behavior between the reinforcement lugs and the surrounding concrete at the steel-concrete interface is primarily responsible for acquiring high bond. Thus, several types of research have studied the global and local bond behavior between the concrete and the reinforcement bars for the static cases, and as a result, several bond models have been established [1, 2, 3, 4]. Also, local cracks at the reinforcement lugs scale and the influence of deformations patterns around the steel-concrete interface have been investigated experimentally [5, 6, 7].

Meanwhile, most of the civil engineering structures are subjected to dynamic loads, especially fatigue loads, resulting in severe localized bond damage and significant movement between the rebar and the surrounding concrete comparing to static loads. Extensive studies have been performed on both material and structural level to understand the bond behavior between the concrete and the rebar under fatigue loads [8, 9, 10, 11]. It was reported that fatigue loads always cause micro-cracks that affect stress distribution around the rebar, followed by cracks propagation, and finally leading to fracture of the rebar.

However, in real situations, civil engineering structures are also exposed to liquid water from an external source such as rains, and that case is considered being the worst scenario to affect the durability and thus the serviceability of the structures. Against this issue, recently, researches have been carried out on the fatigue properties of reinforced concrete elements, such as slab decks and beams, focusing on the effect of external liquid water. It was revealed that the fatigue life of RC beams in seawater is significantly reduced compared with that in the air [12, 13]. Also, it was found that the pull-out failure of deformed bars unaccompanied by macro cracking is produced by the complex action of external liquid water and fatigue by the conversion of the matrix in the vicinity of the deformed bar into sludge [14, 15].

Recently, some new techniques such as digital image correlation (hereafter referred to DIC) have been introduced to investigate deeply the material properties and analyze the surface deformations of concrete material [16, 17, 18]. Direct observation and clear measurements of the deformations near the concrete-steel interface at the local level became available by using that technique. Few studies on that technique have shown the applicability of using such a technique in standard pull-out tests in which one deformed bar is embedded centrally in concrete specimens [19]. Also, the DIC technique was used to investigate the local bond behavior and the local cracking phenomena in case of axial tension tests of reinforced concrete beams [20]. The results showed the high ability of the DIC technique to identify the shear transfer zone around the concrete-steel interface and clarify the local opening-sliding behavior between the concrete and the deformed bars.

Against this substance, there was a need to imply one of the most advanced methods to investigate the bond degradation behavior in reinforced concrete members, which are subjected to dynamic repeated loads. In this study, the fatigue pull-out test of a deformed bar from a massive concrete specimen was carried out with the presence of external liquid water. For the first time, in the case of fatigue experiments, a powerful experimental procedure for monitoring and examining local deformations between ribs of deformed bar and concrete has been proposed by using the DIC technique. This experiment improves our understanding regarding the local bond degradation behavior between the concrete and the deformed bars; and the mechanism, which governs that behavior.

2 EXPERIMENTAL PROGRAM

2.1 Material Properties

Ordinary Portland Cement (OPC) was used as the main binder for concrete. The water to cement ratio (w/c) was 60 % by weight, and the maximum size of the coarse aggregate was 20 mm. Also, fine aggregates and high-performance air entraining (AE) water reducing agents were used for the mixture. The concrete compressive strength was measured based on a standard cylinder with dimensions of 100 mm X 200 mm. Details of the concrete mix proportions and its strength are given in Table 1.

A deformed screw-shaped type of reinforcement rebar was used for this experiment. This type was used because of having a flat surface on its two sides, which is useful for attaching the steel strain gauges for local strain measurements. Also, this type was used to avert a possible reduction in the area of rebar at locations of strain gauges. The type of rebar was D25 in compliance with the JIS standard. The properties of the reinforcement are listed in Table 2.

W/C (%)	Water (kg/m^3)	Cement (kg/m^3)	Sand (kg/m^3)	Gravel (kg/m^3)	AE (gm)	Slump (cm)	Air content (%)	f_c (MPa)
60	190	315	810	1008	1.1	9.5	4.5	28

Table 1: Mix proportions and fresh properties of concrete

Type	Diameter (mm)	Area (cm^2)	Weight (kg/m)	Yield strength (MPa)	Modulus of Elasticity (MPa)
D25	25.4	5.067	3.98	490	190,000

Table 2: Material properties of reinforcement bar

2.2 Specimen

Figure 1 shows the set-up of the experiment that was arranged according to a typical fatigue pull-out test. The test specimen was almost a cuboidal concrete with dimensions of 300 mm x 300 mm x 250 mm. A single screw-shaped deformed bar was placed at the center of the concrete specimen. A single screw-shaped deformed bar was placed at the center of the concrete specimen. The dimensions of the specimen were selected to be small as much as possible; so that the specimen could be easily handled, but at the same time large enough to include an opening for the direct observation purpose. As the purpose of this study is to investigate the bond behavior between the deformed bar and the surrounding concrete, therefore, direct monitoring and observation of the interface between the deformed bar and the concrete were needed. Thus the formwork of the specimen was not filled with concrete material; instead, a cubic opening was formed during the set-up of the form by using a 'Polyurethane Foam' material, as shown in figure 2. This 'opening' may affect the stress distribution at the interface between the concrete and the rebar due to the unsymmetrical of the specimen. Meanwhile, the opening allows for close and continuous monitoring and observation of the deformations in the concrete. It was found that the height of the 'opening' should be around one-fifth of the total height of the specimen to reduce as much as possible the stress disturbance around the rebar while allowing appropriate lighting and subsequently monitoring of the desired area inside the opening [19]. Also, the formwork was designed to include four aluminum tubes to make four voids inside the concrete, as shown in figure 3. These voids were used later to fix the specimen to the base plate of the machine by PC rods and anchors. The setting was considered accurately to avoid any vibration or displacement of the specimen while applying the fatigue load to the deformed bar.

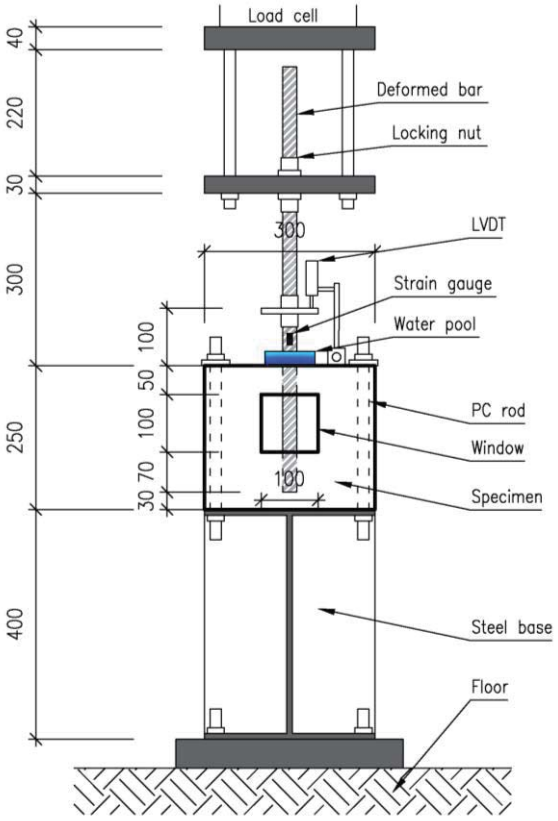

Figure 1: The set-up of the experiment (units: mm).

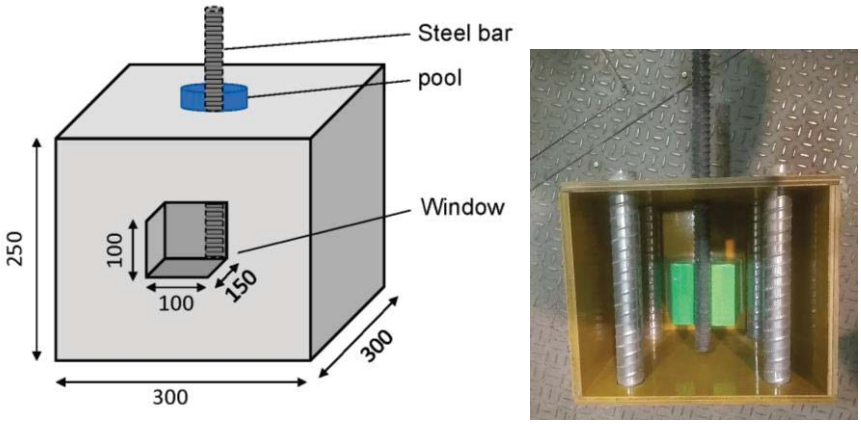

Figure 2: Lay-out of the test specimen (units: mm).

2.3 Mixing, casting and curing

The rebar was placed horizontally with arranging it at the center of the formwork, and it was settled above the foam piece. Lubricating oil was applied to all sides of the formwork for easy separation of the concrete from the formwork. Concrete was poured carefully from the top and segregation of the coarse aggregate was avoided. A needle vibrator was used to compact the concrete during the casting. After twenty-four hours of casting, the formwork was removed, and the specimen was cured by being covered with wet a cloth since formwork removing until the day before the test to avoid the drying shrinkage cracks.

2.4 Technical requirements

The purpose of this experiment is to study the local bond behavior between the concrete and the rebar in case of applying fatigue load with the supplying of liquid water. Therefore, there was a need to visualize and monitor the local bond interaction zone under the combined effect of fatigue load and water supply inside the concrete. Regarding that purpose, digital image correlation (DIC) analysis was used to obtain local deformations, such as displacements, from a high-resolution video that recorded during the experiments (GOM Correlate [20]). Before running the DIC analysis, images had to be extracted from the video with the same parameters; the software FFmpeg was used for that process [21]. GOM correlate can clearly identify areas of a measurement image which contains sufficient image information for analysis, and then identify the same areas in other images. These areas called "square facets," and the software recognizes them by their stochastic pattern structure, and the facets must have a unique gray level distribution which can be clearly identified by the software.

For the crack propagation purpose, and to investigate the contact surface between concrete and the deformed bar, the surface of the concrete was not sprayed before doing the test. Meanwhile, after the hardening of the concrete, the smooth outer layer of the concrete around the deformed bar inside the opening was removed and polished by using a handheld power tool called "disc grinder," as shown in figure 3. This step helps in achieving the required surface state similar to DIC analysis requirements. After removing this layer, aggregates could be seen, and this helps in tracking the crack propagation and observing how is the process of crack propagation through aggregates.

A high-resolution video camera (4k) was used for recording the loading process during the test. The resolution of the camera (i.e., the number of pixels per area in an image) is 3840 pixels × 2160 pixels, to catch very local deformations inside the opening.

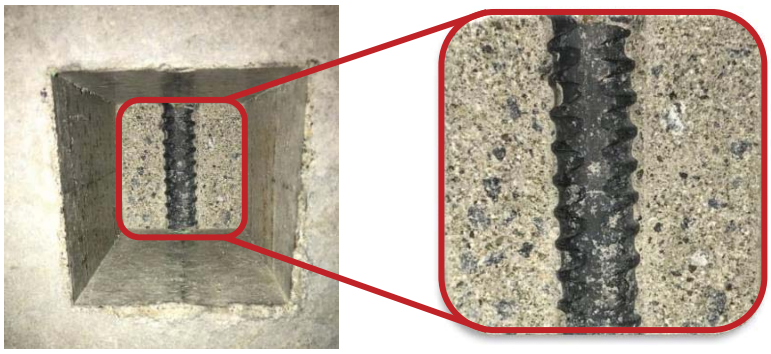

Figure 3: Removing surface layer of concrete inside the window

2.5 Test procedure

The testing apparatus for the fatigue pull-out test is shown in figure 4. Before testing, the specimen was arranged at the top of the steel base of the fatigue machine. The base of the steel frame was specially designed for that purpose and according to the dimensions of the specimen. The specimen was fixed with the steel base by using four steel anchors and four PC rods that were put inside the voids of the specimen. The deformed bar of the specimen was fixed with the jack load of the machine by steel nuts. To ensure the eccentricity of the rebar inside the specimen during the loading, two strain gauges were attached to both sides of the deformed bar outside the specimen. A liquid water pool was prepared at the top surface of the specimen by a circular plastic sheet that was attached to the specimen, as shown in figure 5. The specimen was tested vertically. A high-resolution video camera (4k) was used in front of the specimen window for recording during the test. To eliminate interruptions from surround-

ing light, a powerful LED light source was utilized to illuminate the sample and let only the reflected light go through the camera lens. The elongation and slip of the deformed bar were obtained from the relative displacement between the top surface of the specimen and the deformed rebar. For that purpose, linear variable displacement transducer (LVDT) was used at the top surface of the concrete, as shown in figure 4.

The dynamic load was applied automatically by the fatigue machine and monitored from load cell readings, which were displayed through the data logger. The capacity of the fatigue machine is 200 kN, and the magnitude of the applied load was about (± 50 kN), which was equivalent to 40 % of the rebar yield point, and low stress repeated reversal loading was used. The frequency of the loading was 1.0 Hz.

Figure 4: Testing apparatus of the experiment

Figure 5: Water pool at the top surface of the specimen

3 RESULTS AND DISCUSSIONS

Figure 6 shows the load versus pull-out displacement relationship for the concrete specimen with a deformed bar. The load was interrupted at (0 – 100 – 1000 – 3000 – 7000 and 10000) cycles during the loading process to check manually the pull-out behavior of the deformed bar and to check the cracks' status inside the window. These cracks were hard to be seen by naked eyes. The pull-out failure occurred after almost 10147 cycles. It was seen that air bubbles were generated from the beginning of the loading process, the water at the top surface of the specimen became cloudy, and then the pull-out of the deformed bar occurred. The failure occurred by the deformed bar being smoothly pulled out from the concrete specimen, unlike the failure of the static pull-out test in which the cone shape failure occurred at the surface of the concrete.

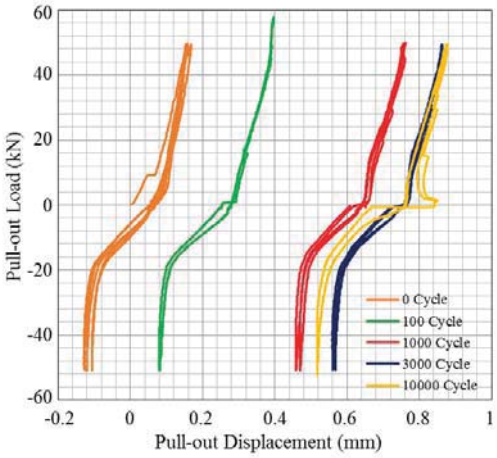

Figure 6: Pull-out load - pull-out displacement relationship

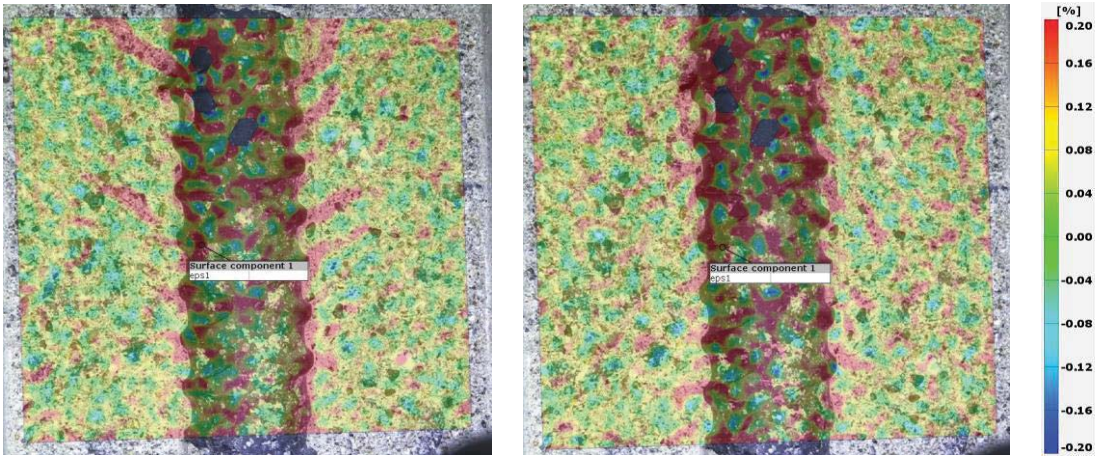
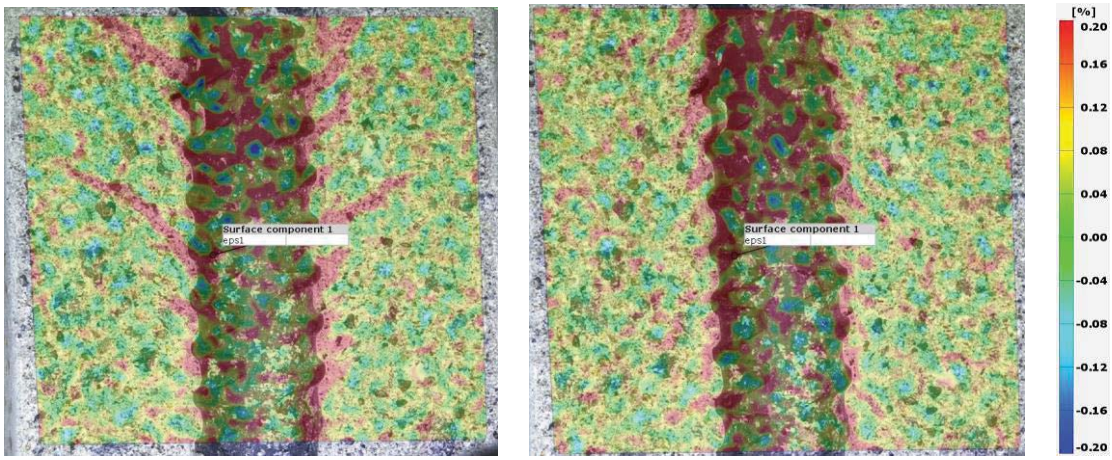
3.1 Deformations inside concrete by DIC

Image correlation software (GOM) was used to process the recorded data and derive the displacement and strain fields from the consecutive photographs that were extracted from video during the test. The local deformations, obtained from DIC analysis, were based on analysis of videos at (0 – 100 – 1000 – 3000 – 7000 and 10000) cycles. Figure 7 shows the contours of major principal strains (e1) at (0 – 100 – 1000 – 3000 – 7000 and 10000) cycles respectively. Each figure shows two deformation types in principal directions, one is at +50 kN, another one is at -50 kN. The local cracks, which were produced, have very tight widths which were hard to be seen by naked eyes. Therefore, calculated strains in the vicinity of the already formed crack have relatively large values (in the order of 1 %) because they are derived from displacements in the order of the crack width. It is clear that the local deformations are developed and increase gradually in both directions at each load level.

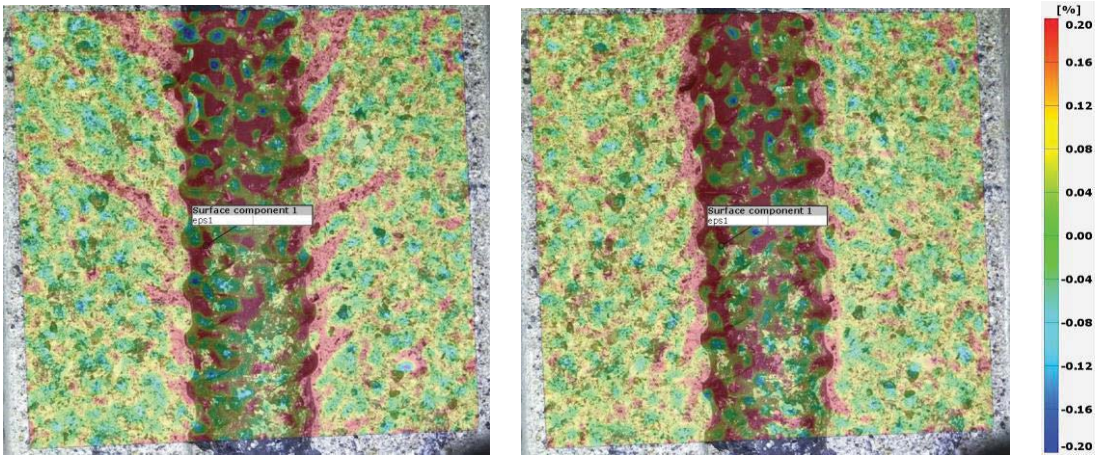
As explained before, a theoretically schematic diagram for deformations of concrete around the reinforcing bar, after the formation of internal cracks, was established by Goto [7] (as shown in Figure 8). According to his theory, as the tension in the steel bar increases, the concrete around the deformed bar presents the appearance of a comb. This complicated behavior of the concrete-steel interface was captured well by using the DIC technique in case of fatigue test in both positive and negative loading direction. Internal cracks form in concrete around the deformed bar at angle of about 60° to the bar axis. The actual deformations of concrete around the surface of the deformed bar were observed and measured during the loading process and they well matched the schematic diagram of Goto.



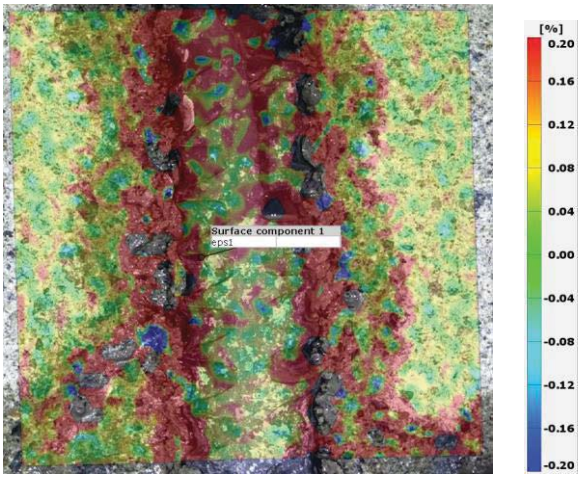
(a) Major principal strain e1 at 100 cycles (+50 & -50 kN)



(b) Major principal strain e1 at 1000 cycles (+50 & -50 kN)



(c) Major principal strain e1 at 3000 cycles (+50 & -50 kN)



(d) Major principal strain e1 at 10000 cycles

Figure 7: Major principal strain e1 at different loading cycles

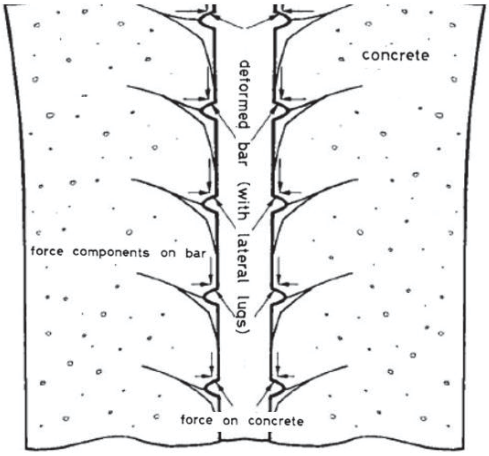


Figure 8: Schematic diagram of local deformation in concrete around the rebar (Goto, 1976)

3.2 Failure Mechanism and Sludge Formation

As mentioned above, the pull-out failure occurred after 10147 cycles. It was noticed that air bubbles were generated from the beginning of the loading process, the water at the top surface of the specimen became cloudy, and then the pull-out of the deformed bar occurred. Through continuous visual observation for the recorded video, it was found that the pull-out of the rebar occurred because the failure was developed inside the concrete surface (refer to Figure 9), not through the contact surface between the concrete and the deformed bar. Also, by visual observation at the top surface of the specimen and through the window inside the specimen, it was found that the concrete was converted to sludge around the ribs of the deformed bar, as shown in Figure 9 & 10. Also, the cone failure shape associated with macro cracks which are normally produced in the static pull-out test was not observed. The failure occurred by the deformed bar being smoothly pulled out from the concrete specimen. Therefore, it is thought that there is a convoluted interaction between the water ingress and the fatigue load that produced this type of failure.

Figure 9: Failure surface between the concrete and the rebar

From above visual observations, it is considered that when fatigue pull-out load is applied with external liquid water simultaneously, the pull-out failure of the deformed bar is occurred because of the conversion of the surrounding concrete to sludge, which is a different failure mechanism from the static test. Figure 11 shows the failure mechanism of the deformed bar associated with sludge formation. It is shown that in the vicinity of the deformed bar, the bearing force from the rib of the rebar is applied in one direction during a one-sided fatigue load, causing high stress in that direction in front of the rib. Meanwhile, with the repeated reversal load, the direction of the bearing force produced from the rib changes to the opposite direction causing high stress in opposite direction at the same zone within a distance almost (2-5 mm). Therefore, fine cracks are produced in opposite directions in the concrete in front of the ribs. As the ingress of liquid water increases, the pull-out strength becomes less than the applied load, and the granulation occurs around the deformed bar, then the formation of the sludge gradually progresses deeper. After that, significant pull-out failure occurs to the deformed bar from the concrete.

Figure 10: Sludge formation at the top surface of the specimen after dried

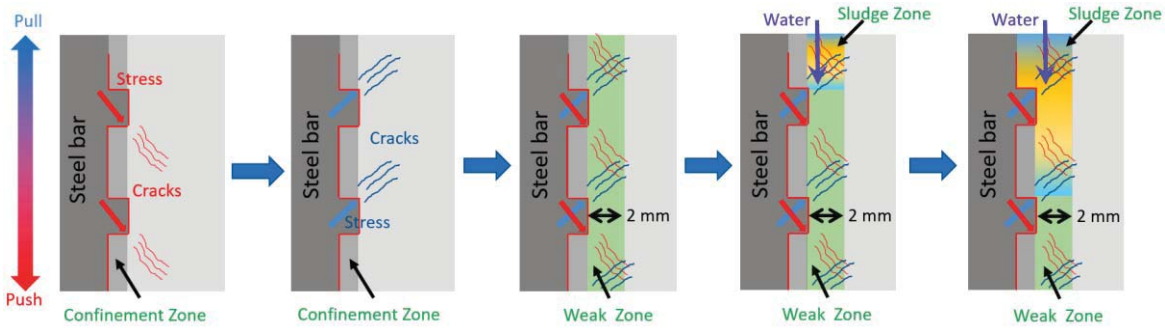

Figure 11: Failure mechanism of deformed bar with a conversion to sludge under pull-out

4 CONCLUSION

This paper presents an experimental study of the fatigue pull-out test of a deformed bar, which was embedded in a concrete specimen with the presence of external liquid water. For direct monitoring and observation purpose of the interface between the rebar and the concrete, the specimen had an opening, which was formed during casting. DIC analysis was used to visualize local deformations at the concrete-steel interface inside the window. The following conclusions have been drawn from this work:

1. The actual deformations of concrete in case of fatigue test are captured well in both positive and negative directions of loading by using the DIC technique, and they matched the past results. Internal cracks form in concrete around the deformed bar at an angle of about 60° to the bar axis.
2. The pull-out of the deformed bar occurs because the failure is developed inside the concrete surface, not through the contact surface between the concrete and the deformed bar.
3. When fatigue pull-out load is applied with external liquid water simultaneously, the pull-out failure of the deformed bar occurs due to the conversion of the surrounding concrete to sludge, which is a different failure mechanism from the static test.
4. A schematic diagram has been established to explain the failure mechanism of the deformed bar associated with sludge formation from the beginning of the load applying until the failure of the deformed bar.

Abstract. *In this study, the seismic performance evaluation is performed for the connection method each support elements and the anchoring interval of support elements panel system among several types of cladding system. The anchoring of the general support elements panel system is installed at intervals of 1,000mm. In order to grasp the problem, the concrete filled channel is installed in the test frame. It is implemented to realize the site situation. The specimens consist of 6 types according to the connection method and the anchoring method. In the experiment, the shake table test was carried out in the in-plane direction for 6 specimens, including the construction examples using the steel frame. Because the experiment considered in-plane direction displacement depending on the sensitivity of the cladding. After each seismic simulation test, damage is visually inspected, and used as a basis for evaluating seismic performance. The maximum response drift angle of test frame was measured at 4% rad. The damage type was defined by performance levels, in order to compare the observed damage by visual inspection according to the measured response drift angle. Finally, the fragility analysis of support elements panel system was conducted based on the previous seismic performance evaluation data.*

1 INTRODUCTION

1.1 Background

In the event of an earthquake, nonstructural components, directly or indirectly, cause damage to building and structures. This involves damage to equipment as well as damage to life and property caused by self-damage, that is falling of nonstructural components. Although the damage to these nonstructural components is considered secondary and tertiary damage, it is likely to develop into large-scale damage, and hence, must be secured against earthquakes. Some nonstructural components (ceilings, water tanks) have been used dynamic analysis. However, exterior materials such as curtain walls and masonry are difficult to secure by dynamic analysis. Therefore, in this study, shake table test are performed in the in-plane direction on six variables including construction cases using a test frame to evaluate the seismic performance and fragility of support elements.

1.2 Scope and purpose

To conduct the test on support elements, the system that attaches the external finishing materials such as metal and stone to the square steel pipe is mainly used. Vertical and horizontal members are welded together using 1.6mm thick square steel pipe. In this experiment, shake table tests were carried out on a total of six specimens using these connecting methods as variables. The experiment aims to compare the seismic performance of the support elements panel system according to the experimental variables for the same seismic wave. The experiment is carried out by calculating the acceleration spectrum of this experiment considering the domestic standard KDS 41 17 00 for RRS of ICC ES AC156, which is a shake table test method for nonstructural components. The experiment is conducted by generating an artificial earthquake wave according to the method presented in AC156. The seismic performance comparison based on the test results is estimated by conducting damage assessment through visual inspection. Performance level and damage items should be defined for visual inspection. In this study, damages to the support elements panel system are defined by referring to the transmission items based on the performance level and performance target level of the nonstructural components in ASCE 41-17, and the type of earthquake damage presented in FEMA E-74

1.3 Test specimens

The main experimental variables is the method of connecting the vertical and horizontal members of the support elements and the method of anchoring the structure of the support elements. In general, the support elements to be bonded by spot welding or line welding is set as the control group, and the support elements with a no welding connection is set as the experimental group. Each connecting method is shown in Figure 1. Chemical anchors and set anchors are used to anchor the support elements to the structure, and the difference between the two can be seen in Figure 2. To compare the behavior characteristics of each experimental variable under the same earthquake condition, six specimens were arranged in three rows using the front and rear elevations of the test frame, as shown in Figure 3. In this case, concrete-filled c-beams were pre-installed in the test frame before the test specimens were installed to fasten the anchorages of the support elements. Based on the anchorage-fastening conditions (chemical anchor construction or set anchor construction), each specimen was installed as close as possible to the actual construction. According to the installation conditions, all the specimens were set to resist horizontal external force in the in-plane direction.

2 EXPERIMENT INFORMATION

2.1 Test frame

The test frame is a single-story unit frame with a long span of 4.5m (in the direction of the weak axis of the column), short span of 4m (strong axis of the column), and a height of 3.5m. A concrete slab is installed on the upper and lower parts (upper: 200mm; lower: 150mm). In this experiment, the deformation capacity as well as the acceleration resistance capability of the exterior material are examined. Therefore, the frame is weakly placed in the excitation direction so that the frame can be deformed. The state of the test frame is as shown in Figure 4.

(a) Front of test frame (b) Inside of specimen

Figure 4: The state of test frame

2.2 Test method

The shake table test uses an artificial seismic wave that meets the conditions of the ICC ES AC156: 2010 response spectrum. The prepared Required Response Spectrum (RRS) is as shown in Figure 5 and the seismic parameters are as shown in Table 2. The prepared RRS is a response spectrum for nonstructural components corresponding to domestic design seismic force (recurrence period: about 1,000 years). The shake table test was carried out by increasing the artificial seismic wave by adjusting the scale factor based on the acceleration value of the response spectrum shown in Table 2.

Building Code	Test Criteria	S_{DS}*(g)	z/h*	Horizontal	
				A_{FLX-H}(g)	A_{RIG-H}(g)
KDS 41 17 00	ICC ES AC156	0.55	1.00	0.88	0.66

*S_{DS}: Spectral response acceleration at short period, z/h: Height factor ratio

When, $A_{FLX-H} = S_{DS}\left(1 + 2\frac{z}{h}\right)$, $A_{RIG-H} = 0.4S_{DS}\left(1 + 2\frac{z}{h}\right)$

2.3 Definitions of available damage

In the case of the domestic standard (KDS 41 17 00), it is difficult to objectively evaluate and compare the performance of nonstructural components by the experimental results because there is no example of damage according to the performance level of nonstructural components, including the support elements panel system. Therefore, this study defines the acceptable damage of cladding for each performance level by referring to the performance levels of the nonstructural components of the cladding presented in ASCE 41-17. To carry out objective damage assessment and performance comparison, damage to the enclosure system is defined as shown in Table 3.

Division		Acceptable damage			Unacceptable damage
		Operational	Position Retention	Life Safety	
Support elements panel system	Panels	- Cracks in sealant - Loosening - Slight damage to joint piece	- Partial breakage - Plastic deformation - Joint piece falling below 1/2 of the unit - Tearing of joint edge	- Joint separation (Do not dislodge) - Major plastic deformation - Joint piece falling above 1/2 of the unit	- Fall out - Dislodged
	Support elements	- creation of dust - slight damage	- Welding crack of fastener - Loosening of fastener's nut - Plastic deformation of fastener - Welding crack of support elements connection	- Partial break of anchor - Partial welding break of fastener - Major deformation of support elements - Deflection of support elements - Partial break of support elements connection	- Complete Breakage of anchor - Complete Breakage of fastener - Fall out of support elements

Table 3: Definition of acceptable damage of cladding

2.4 Sensor installation

To analyze the response of the specimen, accelerometer and wire LVDTs were installed at the main points of the specimen. The items to observe are the acceleration response and story drift of the upper and lower test frames. According to the test method of uniaxial excitation, the uniaxial accelerometer was attached to the upper and lower parts of the test frame, and the wire LVDTs were installed in four places of the upper and lower column members on one side of the test frame as shown in Figure 6. The relative displacement of the shake table and the test specimen was measured with wire LVDTs.

Figure 6: Sensor installation

3 SEISMIC PERFORMANCE EVALUATION

3.1 Test result

1) acceleration response

The AC156 used as a reference for this experiment requires that the output data satisfy the following two requirements for the input data after the shake table test is completed.

(1) Test Response Spectrum (TRS) should enclose the RRS.

(2) The peak in response acceleration-time history should satisfy more than 90% of ZPA (Zero Period Acceleration).

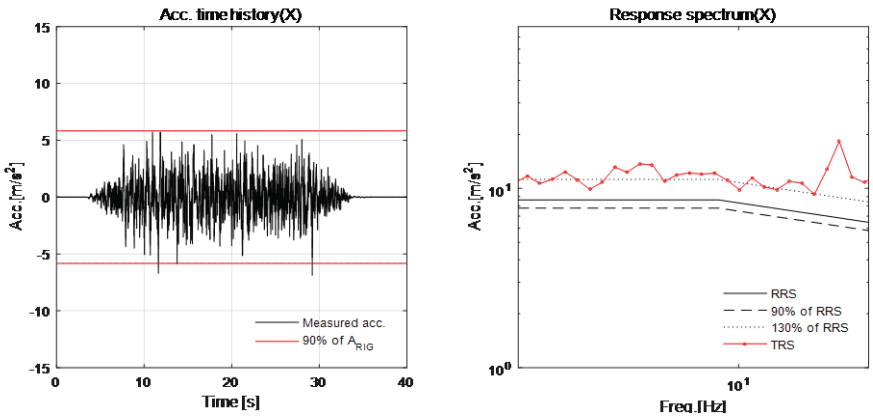

Figure 7: Acceleration time history, TRS and RRS (Step 3)

2) Story drift

To calculate the story drift, the displacement of the specimens was calculated using the average of the front displacement and the rear displacement, and each displacement was calculated using the displacement of the upper part of the test frame and the displacement of the lower part of the test frame. Table 4 shows the displacement of the front part and the rear part. The calculated maximum story drift angle of each test frame was more than 0.1%rad in step 2 (EQ 80%) and more than 0.2%rad in step 3 (EQ 100%). This means that the test frame in which the test specimens were installed underwent deformation above the maximum allowable story drift angle (0.2%rad, seismic level 2) of the structure specified in KDS 41 17 00.

Step	Peak relative displacement(mm)		Story drift (mm)	Story drift angle (radian)
	Front side column	Rear side column		
1	14.62	14.70	14.66	0.0042
2	41.18	40.68	40.93	0.0116
3	72.32	68.32	70.32	0.0201
4	96.66	86.12	91.39	0.0259
5	123.28	104.38	113.83	0.0325
6	140.54	119.80	130.17	0.0371
7	163.78	130.24	147.01	0.0412
8	164.80	129.04	146.92	0.0404

Table 4: Displacement response

3.2 Visual inspection

Visual inspection before the experiment confirmed that structural damage did not occur. The main types of damages that occurred after each test at each excitation stage are as follows.

1. Welding crack and plastic deformation of fastener
2. Complete breakage of fasteners

Table 5 shows the damage to the test specimens at each step according to the performance levels defined in Table 3. In addition, the symbols for each damage location are defined as shown in Figure 8, and the locations of the damages listed in Table 5 and Table 6 can be confirmed by referring to them.

In summary, the failure modes of all specimens were determined by anchoring forces at anchorage and fasteners, nut loosening, and fastener-welding break. After damage of the anchorage and the fastener, the damage of the support elements and the panels was slight as the horizontal external force was not sufficiently transmitted to the panel and the support elements. However, compared with the case where the support elements were connected by spot welding or line welding, the specimens with no welding method showed relatively little damage compared to the fastener, and no complete failure of the fastener was observed until the final step.

3.3 Fragility evaluation

In this study, the support elements panel system was analyzed for fragility by considering the story drift angle. The fragility function is the probability of exceeding the occurrence of damage corresponding to each performance level, depending on the influence factor. Figure 9 shows the seismic fragility curve for each specimen. This is the result of fragility curves using the mean of story drift angles and the natural logarithmic standard deviation. This fragility curve is a function of the fragility of the subject, and hence, if any of the variables do not match the subject, and hence, if any of the variables do not match the subject, there is an unreliable disadvantage.

4 CONCLUSION

In most cases, the anchoring interval of support elements is constructed in units of 1,000mm, and the anchorage is constructed by chemical anchor or set anchor. To understand this problem, concrete-filled c-beams were installed at intervals of 1,000mm, and the experiment was implemented to realize the site situation. In all six specimens classified in this experiment, the failure mode was determined by anchor fall-out, loosening of fastener, and fastener-welding failure. In the case of the support elements using the welding method, the support elements themselves could be damaged owing to the complete failure of the anchorage. On the contrary, in the case of the support elements not using the welding method, complete failure of the fastener was not observed until the final excitation caused by the plastic deformation of the fasteners. Therefore, dropping the support element was found to be a better method for ensuring safety.

Keywords: Shaking table test, Edge clearance, Glazing curtain wall system, Seismic performance, Damage assessment

Abstract. *In this paper, shaking table tests was conducted to evaluate the seismic performance according to the edge clearance of the glazing curtain wall system. Most tests on glazing curtain wall systems in Korea have been carried out by assessing airtightness and water-tightness to determine the stability in the out-plane direction. However, in the case of an earthquake, the stability in the in-plane direction is also important for glazing curtain wall systems. Therefore, the in-plane seismic performance of glazing curtain wall system is evaluated by calculating the edge clearance using the domestic seismic design standard (KDS 41 17 00:2019, 18.3.4) and applying the results as the experimental variables. The acceleration spectrum used in the experiment was derived by considering ICC ES AC-156, the foreign shaking table test method for non-structural elements, and KDS 41 17 00:2019. The excitation was gradually increased by adjusting the acceleration scale of the artificial seismic waves. The purpose of this experiment is to evaluate the seismic performance of glazing curtain wall systems in terms of the edge clearance for the same earthquake. To evaluate the seismic performance corresponding to the test results, a damage assessment was conducted through a visual inspection. After the experiment, the damage limits for each performance level of the glazing curtain wall were newly defined, and the requirements for the relative displacement of the glazing curtain wall systems Korea were verified.*

1. INTRODUCTION

The Po-hang earthquake damaged to nonstructural elements of buildings such as exteriors and glass, with three times more cost than for structural elements. Nonstructural elements are connected to the main structural members of buildings and perform specific functions within the building, but they do not support external loads. This results in a loss of function for the building and the damage of important facilities and equipment is linked to the 2nd and 3rd damages, so the possibility of large-scale damage is high[3]. Although glazing curtain walls are commonly used in modern buildings such as high-rises buildings due to their light weight and beauty, the seismic design criteria in Korea(KDS 41 17 00: 2019) do not clearly dictate seismic design. In addition, the relative displacement requirements for "18.3.4 curtain walls, stores and partition wall glass" are based on the those of ASCE 7-10 in the United States[1], but there are no shaking table test. Since studies that validate the domestic relative displacement criteria are needed.

Therefore, in this Study, based on the RRS of ICC ES AC-156, a foreign shaking table test method, the acceleration spectrum of this experiment considering the domestic standard (KDS 41 17 00: 2019) was derived first, and artificial seismic waves were generated and applied to the experiment according to the method proposed in AC-156[4]. By conducting shaking table tests in the in-plane direction, the glass standards (KDS 41 17 00 18.3.4) used in the current domestic curtain wall were verified, and the damage limit level is defined for the glazing curtain wall suitable for domestic use.

2. SEISMIC DESIGN CRITERIA FOR GLAZING CURTAIN WALL SYSYTEM

2.1 The current national standard

Curtain walls are classified as non-structural elements in building standards (KBC 2016) and they are designed to withstand the equivalent static loads and relative displacements. Glass is light in weight but is also brittle, and it is classified as a displacement-sensitive element rather than acceleration-sensitive. Domestic relative displacement criteria for nonstructural elements are based on the contents of ASCE 7-10 in the United States[1]. The relative displacement due to earthquakes, which nonstructural elements should accommodate, can be obtained as follows.

$$\begin{gathered} D_{pI} = D_p I_E \\ D_p = \delta_{xA} - \delta_{yA} \\ \text{only}, D_p \le (X - Y)\frac{\Delta_{aA}}{h_{sx}} \end{gathered} \tag{1}$$

In case of I_E is importance factor of the non-structural element. In the domestic standard, the importance factor of a curtain wall is not clearly defined. However, in the US, FEMA E-74 clearly defines ER (engineered required) requirements for exterior wall components such as glazed exterior wall systems[3]. It means I_E=1.5 that requires seismic design in domestic standard. In addition, h_{sx} is the height used to define the allowable story drift, δ_{xA} and δ_{yA} are displacement in x or y of A-phase vertical position on the floor displacement of x story. X and Y are respectively height from the underside of the structure to the upper attachment point x and the lower attachment point y. Δ_{aA} refers to the allowable story drift of the structure. The domestic standard (KDS 41 17 00 18.3.4) also sets out the relative displacement requirements for the glass used in the curtain wall, and also based on ASCE 7-10[1,6].

$$\Delta_{fallout} \ge 1.25 D_{pI} \;\; Only, \Delta_{fallout} \ge 13mm \tag{2}$$

Here, $\Delta_{fallout}$ refers to the relative displacement of the glass falling off the curtain wall, the front of the store, the partition wall through the experiment or analysis. However, if there is sufficient clearance between the glass and the frame and the contact between the glass and the frame does not occur at the required relative displacement, the following equation may be used.

$$D_{clear} \geq 1.25 D_{PI}$$
$$D_{clear} = 2c_1\left(1 + \frac{h_p c_2}{b_p c_1}\right) \quad (3)$$

In the case of a rectangular glazing frame

In this case, D_{clear} refers to the relative displacement of the frame in which the contact between the glass and the frame occurs, and it is defined for the height of the glass. $h_p$and $b_p$are the height and the width of rectangular glazing panels, respectively, and c_1 and c_2 mean average clearance values between glass and frame that of horizontal clearance on the left and right sides and vertical clearances on the upper and lower surfaces, respectively.

2.2 Staged damage assessment according to the performance level

In the case of non-structural elements that are subject to seismic design under current national standards, structural safety and functionality should be maintained even after an earthquake. In particular, glass installed in curtain walls should be able to sufficiently accommodate the relative displacement that occurs. For the evaluations, electrical, electronic and communication equipment can be evaluated quantitatively or qualitatively using standard methods, but most nonstructural elements are evaluated using qualitative assessments, such as visual inspections. Moreso, the criteria for damage according to the performance level of non-structural elements are not clear, so it is necessary to clarify the criteria and classification for seismic performance. For example, the international standard FEMA E-74 classifies damage types of non-structural elements caused by earthquakes into Functional Loss (FL), Property Loss (PL), and Life Safety (LS)[3]. In case of ASCE 41-13 damages of nonstructural elements are classified into four stages: Operational (N-A), Position Retention (N-B), Life Safety (N-C), and Not Considered (N-D)[2]. “A Shake Table Test for Seismic Performance Evaluation of Bolted Joint Panel Systems with External Finishing Materials,” was suggest definition of damage for paneling system according to performance level considering ASCE 41-13[5].

The purpose of this study is not just to identify the type of damage of nonstructural elements, but to derive the clear criteria for damage to glazing curtain walls that can be reflected into future seismic performance assessments. Therefore, to clearly define damages considering the performance level of the glazing curtain wall system, the definition of damage of nonstructural elements in ASCE 41-13 and “A Shake Table Test for Seismic Performance Evaluation of Bolted Joint Panel Systems with External Finishing Materials,” are referred to. Damage by performance level of nonstructural components presented in ASCE 41-13 and paper is shown in Table1 and Table 2.

Table 1 Nonstructural performance levels and illustrative damage-Glazing component

	Nonstructural Performance Levels		
Component Group	Operational(N-A)	Position Retention(N-B)	Life Safety(N-C)
Glazing	• No cracked or broken panes.	• Some cracked panes; none broken. • Limited loss of weather-tightness	• Extensively cracked glass with potential loss of weather-tightness and security. • Overhead panes do not shatter of fall

Table 2 Definition of damage for paneling systems according to the performance level

Performance target for a paneling system		
Operational (OP)	Position Retention (PR)	Life Safety (LS)
• Crack in the sealing • Damage of a joint piece	• Partial fracture of a stone panel • Minute weld crack in the truss • Plastic deformation of a metal panel • Silicone rubber tear • Minute deformation of a fastener	• Large deformation of the truss • Large crack or separation in the truss connection • Truss connection fracture • Large deformation or fall of a fastener • Panel fall

3. EXPERIMENTAL DESIGN AND METHOD

3.1 Experimental design

Tests of glazing curtain wall systems in Korea, have performed only static experiments on displacement and wind tunnel tests in the out-plane directions. Therefore, shaking table tests were conducted to evaluate the dynamic seismic performance of a glazing curtain wall by measuring the end clearance and to verify the relative displacement requirements of glass used for curtain wall in the current national standard. In addition, due to the characteristics of the non-structural elements called curtain walls, they cannot stand on the shaking table. So glazing curtain wall systems are installed on the test frame and Uniaxial excitation was performed only in in-plane direction.

The test frame is a one-story unit frame with a height of 3.5m, 4.5m long span and 4m short span and a concrete slab with a thickness of 200mm and 150mm on the upper and lower parts of the frame, respectively is installed. Flanges of girder and flanges of column are consist of full penetration welds, and girder webs and column flanges are bolted through shear tabs. In addition, the weld access holes shape at the end of the beam web is made up of a quarter circle. According to the test frame, all column members behave in a rigid or weak axis depending on the direction of excitation. Therefore, the structure in these experiments was set up a weak axis to occur sufficient deformation. In the case of the installation, the joining jig was first installed on the shaking table, and the test frame was mounted on the test jig. Detailed test frame drawings and weights of the test frame are shown in Table 3 and Figure 1.

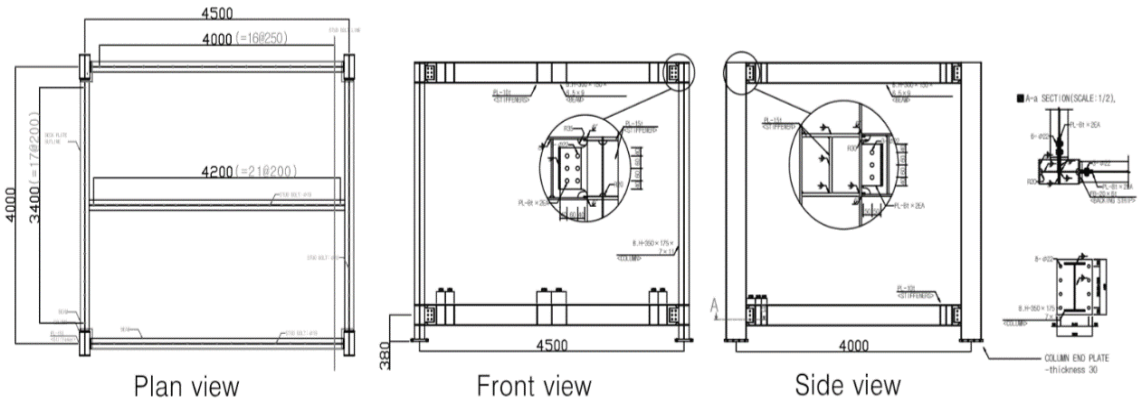

Figure 1 Test frame schematic

Table 3 Test frame specifications

Part of Test Frame		Dimension(mm)			Weight(kN·f)
		Width		Thickness	
		X-direction	Y-direction		
Slab	Upper part	4500	4000	200	86.4
	Lower part	4500	4000	150	64.8
Girder	Upper part	H-300x150x6.5x9 (SS400)			7.2
	Lower part	H-300x150x6.5x9 (SS400)			5.7
Column		H-350x175x7x11 (SS400)			7.2

The test subjects are glazing curtain wall system that composed of mullions, transoms and glass commonly used in Korea. Experimental variable is the edge clearance (b) and support depth (c) of the glazing panel shown in Fig. 1. Control specimen is satisfied requirement that specified in the Korean Architectural Structural Standards (KDS 41 17 00: 2019, 18.3.4). So edge clearance was set to 10mm (edge clearance + support depth = 25 mm). Because contact between the glass and the frame does not occur due to sufficient clearance between the glass and the frame. Comparison group is consisted of 5mm specimens with edge clearance that did not satisfy this condition and 15mm and 20mm specimens with deeper end clearance than the condition. Total subject included 4 specimens. Specification and the drawings of the control specimen are shown in Table 4 and Figure 2. In order to compare the behavior of each test variable under the same earthquake experience, four specimens were arranged in two rows using the front and rear of the test frame. According to the installation conditions, all specimens were set to resist the horizontal external force in the in-plane direction.

Table 4 Specimen specifications

Specimen Name	Clearance D_{clear}	Dimension(mm)			Location
		Width	Height	Thickness	
D05	5	2,000	3,650	150	Rear left
D10	10				Rear right
D15	15				Front left
D20	20				Front right

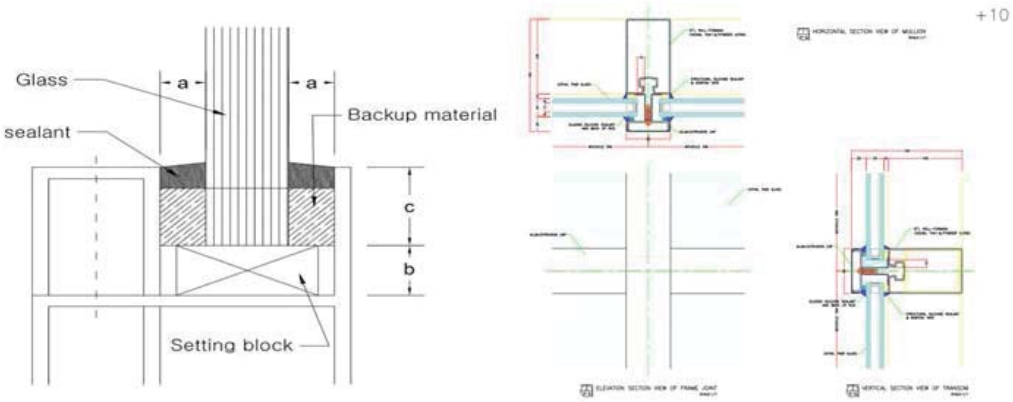

Figure 2 Detailed drawing of control specimen

3.2 Experimental method

The seismic performance evaluation of the glazing curtain wall can be carried out by conducting the shaking table test in AC-156 and the dynamic test in AAMA 501.6[4,7]. Therefore, in this study, the acceleration spectrum considering the national standard (KDS 41 17 00: 2019) is consulted for the RRS of ICC ES AC-156: 2010, and Artificial seismic waves generated according to the method proposed in AC-156 were used in the experiment. The excitation method was gradually increasing excited by adjusting the acceleration scale of the artificial seismic wave, and excites only in horizontal dimension (left and right directions). The required response spectrum (RRS) of the seismic wave used in the shaking table test is applied by a seismic parameter according to the set conditions (Effective ground acceleration(S): 0.22g, Ground condition: S_3) that is assumed according to the domestic building design standard. Therefore, the prepared RRS is the response spectrum for nonstructural elements corresponding to the design earthquake force that return period of 1000 year in domestic standard. The prepared RRS is shown in Figure3 and Seismic parameter is shown in Table 5.

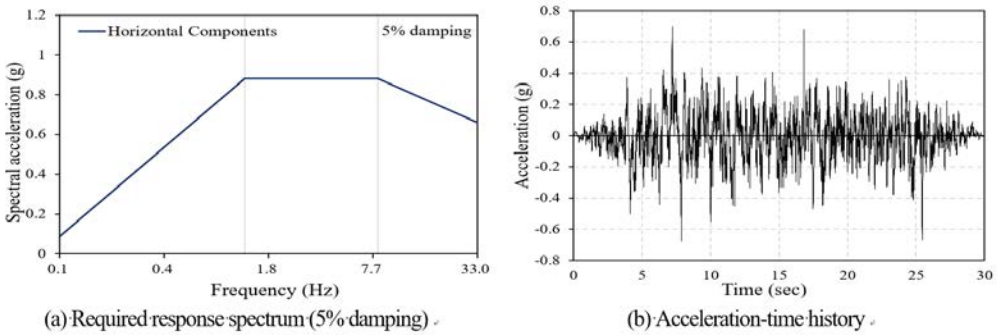

Figure 3 Input wave information

Table 5 Parameters for the required response spectrum

Building Code	Test Criteria	S_{DS}* (g)	z/h*	Horizontal	
				A_{FLX-H} (g)	A_{RIG-H} (g)
KDS 41 17 00	ICC-ES AC156	0.55	1.00	0.88	0.66

* S_{DS} : Spectral response acceleration for a short period, z/h : Height factor ratio

In here, $A_{FLX-H} = S_{DS}\left(1 + 2\frac{z}{h}\right)$, $A_{RIG-H} = 0.4S_{DS}\left(1 + 2\frac{z}{h}\right)$

3.3 Experimental procedure and sensor measurement plan

Shaking table test follows the sequence shown in Table 6. Pre-test inspection was performed with a visually inspection of the state of external deformation and damage, installation position and state of the accelerometer and displacement gauge measuring device, and etc. After the pre-test inspection, resonance search test is performed to evaluate the suitability of the test response spectrum or to analyze the test frame deformation. The maximum amplitude of the random wave for resonance detection was 0.05g and the frequency range was 1.0Hz ~ 50.0Hz. A seismic simulation test was performed by creating an acceleration time history using the defined response spectrum. The oscillation duration of the acceleration time history is 30 seconds and the amplitude of the seismic duration is 20 seconds. The experiment was carried out incrementally in the left and right (X) directions of the test frame by adjusting the acceleration scale using the prepared artificial earthquake wave. At this time, the acceleration scale was excited with 50%, 80%, and 100% of the reference earthquake wave (EQ), and then

the acceleration scale was increased by 20% intervals. Finally, after the seismic performance test at each stage as in the pre-experimental test, the structural deformation and damage state were visually inspected and recorded. The termination conditions are as follows.

1. When the next excitation level cannot be performed due to equipment limit
2. Hazardous structural damage occurs such as excessive plastic deformation of the test frame
3. Serious damage has occurred in specimen, and it is judged that next test would not be meaningful.

Table 6 Test procedure

Step	Test Name	Test Method	Remarks
1	Pre-test inspection	· Visual inspection	-
	Resonance search test	· Random wave (Dir. = X)	· Amp : 0.05 g · Freq. : 1.0Hz~50.0Hz

In order to analyze the response of the specimen, the accelerometer and the displacement gauge (wire LVDT) were installed at the main points of the specimen. The items to be observed are the acceleration of the table base and the upper and lower parts of the test frame, and the relative displacement of the test frame. A single-axis accelerometer was attached to the table base and the upper and lower parts of the test frame according to the uniaxial excitation test method, and the wire LVDT was installed at the top and the bottom of the post member on one side of the test frame. The location and orientation of the sensors are shown in Table 7 and Figure 5.

Table 7 Sensor location and orientation

Description	Location	Sensor Name	Dir.*	Sensor		
				Model	Serial	Cal. date
A1	Table base	acc 1	X	8315A030D0TA00	5039210	2019.04.22.

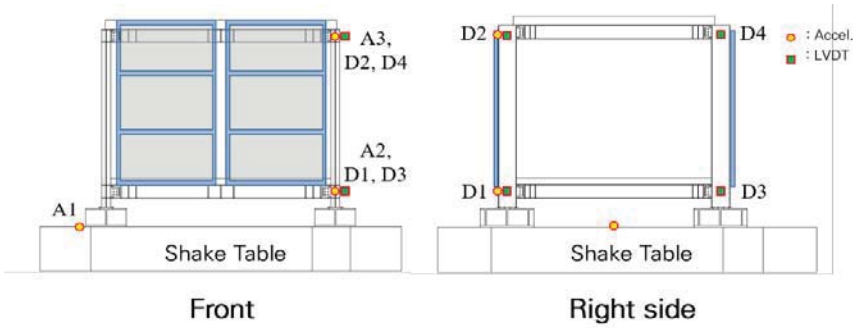

Figure 4 Sensor location

4. EXPERIMENTAL RESULTS

4.1 Resonant frequency

The resonance of the test frame was determined by calculating the transfer function of the response acceleration at the upper and lower positions of the test frame with respect to the acceleration input from the table base. The transfer function (T_{ab}) is calculated by the cross power spectral density (P_{aa}) of the input and output signals relative to the power spectral

density (P_{ba}) of the input signal. In order to improve the accuracy of the resonance analysis, each signal has applied a Symmetric Hamming Window.

$$T_{ab}(f) = \frac{P_{ba}(f)}{P_{aa}(f)} \quad (4)$$

Resonance test results are shown in Table 8, The natural frequency is expressed by the transfer function of the upper response acceleration (A3 / A1) of the test frame for each table base and the transfer function of the upper response acceleration (A3 / A2) of the lower test frame. The Table 8 shows that the resonant frequency of test frame decreased by 10% when going from step2 to step 3.

Table 8 Resonance search test summary

Step	Resonant Frequency(A3/A1) (Hz), df = 0.125 Hz	Resonant Frequency(A3/A2) (Hz), df = 0.125 Hz
1 (S_{DS} = 0.275 g)	2.50	2.50
2 (S_{DS} = 0.44 g)	2.50	2.50
3 (S_{DS} = 0.55 g)	2.25	2.25
4 (S_{DS} = 0.66 g)	2.25	2.25
5 (S_{DS} = 0.77 g)	2.25	2.25
6 (S_{DS} = 0.88 g)	2.25	2.25
7 (S_{DS} = 0.99 g)	2.25	2.25
8 (S_{DS} = 1.1 g)	2.25	2.25

4.2 Acceleration response

AC-156, the reference standard, requires that the output data of the seismic test based on the verification test result meet the following two conditions for the input data.

1. TRS (Test Response Spectrum) should enclose RRS (Required Response Spectrum)
2. Peak value in response acceleration-time history should satisfy more than 90% of ZPA.

The seismic test results of all stages planned in this experiment were found to satisfy the above conditions. Figures 5 and 6 shows the acceleration-time history graphs of Step 1 with the smallest magnitude and Step 8 with the largest magnitude.

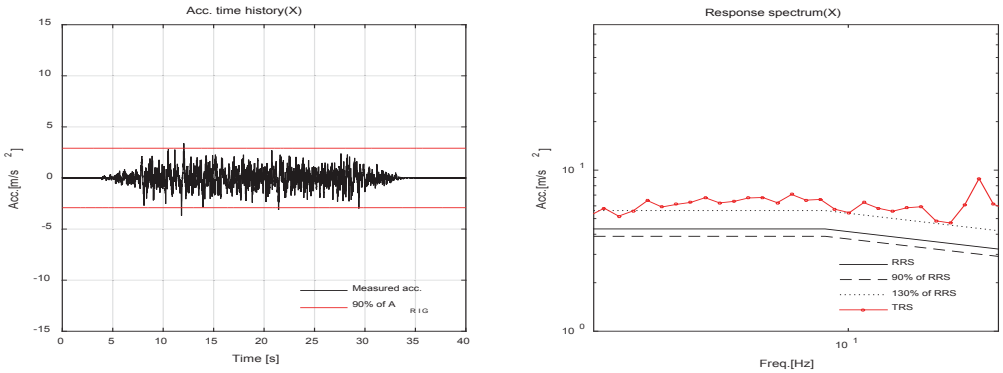

Figure 5 Acceleration time history, TRS and RRS (Step 1, SDS = 0.275 g)

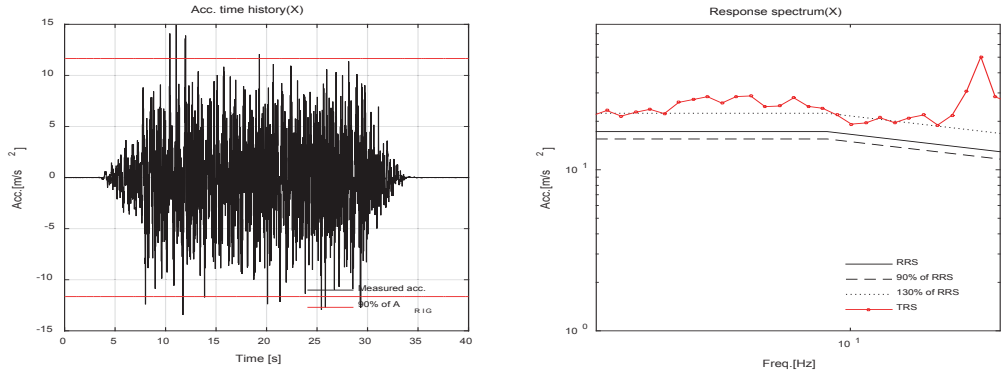

Figure 6 Acceleration time history, TRS and RRS (Step 8, SDS = 1.1 g)

4.3 Story drift angle

To calculate the Story drift angle, the measured front displacement (δ_{front}) and rear displacement (δ_{back}) of the test frame are used, as shown in the Figures 7 and 8. Each displacement was calculated using the displacement difference between the upper part of the experimental structure and the lower part of the test frame according to time history, and Table 9 shows displacement response of test frame. The maximum story drift angle of the test frame was 0.01 rad or more at Step 2(EQ 80%) and 0.02 rad or more at Step 3(EQ 100%). This means that the test frame on which the specimens was installed has been subjected to deformation exceeding seismic level 2 specified in the KDS 41 17 00: 2019.

$$\theta_{front} = \frac{\delta_{front}}{h} \qquad \theta_{back} = \frac{\delta_{back}}{h}$$

$$\theta_{frame} = \frac{\theta_{front} + \theta_{back}}{2}$$

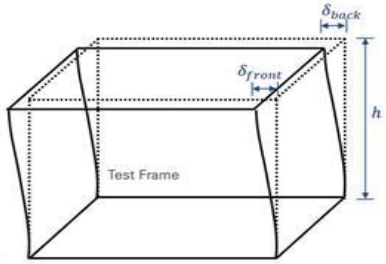

Figure 7 Method to calculate the drift angle

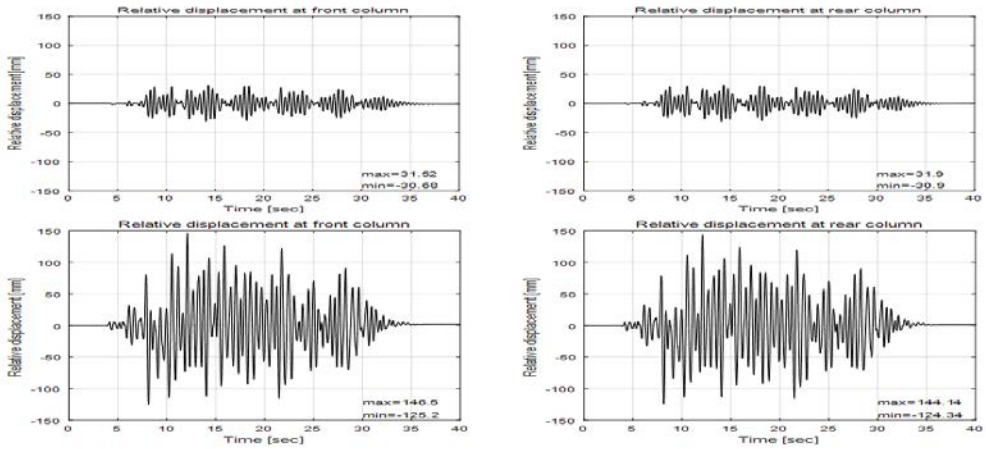

Figure. 8 Relative displacements between the upper and lower of the test frame over time history (Step 1 and 8)

Table 9 Displacement response

Step	Peak relative displacement (mm)		Story drift angle (radian)
	Front side column, δ_{front}	Rear side column, δ_{back}	
1 (EQ 50%)	31.52	31.90	0.0090
2 (EQ 80%)	62.38	61.46	0.0177
3 (EQ 100%)	80.14	78.08	0.0225
4 (EQ 120%)	96.14	95.58	0.0274
5 (EQ 140%)	112.58	110.80	0.0319
6 (EQ 160%)	129.54	127.18	0.0367
7 (EQ 180%)	142.12	139.14	0.0402
8 (EQ 200%)	146.50	144.14	0.0415

4.4 Damage assessment of specimens by excitation steps

The damage of the test specimen according to the story drift angle for each step is summarized in the table as follows.

Table 10 Damage condition according to the test steps

Step	Story drift Angle (radian)	D05	D10	D15	D20
Step 1 (EQ50%)	0.0090	No damage			
Step 2 (EQ80%)	0.0177	No damage			
Step 3 (EQ100%)	0.0225	 Slip of the fastener	No damage	 Minor crack in the silicone	 Minor crack in the silicone
Step 4 (EQ120%)	0.0274	 Minor crack in the silicone	 Minor crack in the silicone and minor slip of the fastener	 Expansion of the silicone crack	 Expansion the silicone crack

Step 5 (EQ140%)	0.0319	 Expansion the silicone crack and deformation of the fastener	 Expansion of silicone crack and slip of the fastener	 Expansion of silicone crack and minor slip of the fastener	 Expansion of the silicone crack
Step 6 (EQ160%)	0.0367	 Expansion of silicone crack	 Expansion of silicone crack	 Expansion of silicone crack	 Deformation of the fastener
Step 7 (EQ180%)	0.0402	 Partial cracking of the glass	 Partial cracking of the glass	 Partial cracking of the glass	 Partial cracking of the glass
Step 8 (EQ200%)	0.0415	 Plastic deformation of the grid elements	 Plastic deformation of the grid elements	 Joint separation of the fastener	 Joint separation of the fastener

In case of the specimen that do not satisfy edge clearance requirements of the domestic standard (KDS 41 17 00: 2019 18.3.4), damages such as cracks in the sealing material are occurred after deformation of the fastener. However in case of specimens that satisfying or excessively satisfying the criteria, the deformation and slip of the fastener appeared after cracking and expansion of the sealing material. Step 7 (EQ180%) showed partial breakage at the glass edges in all specimens. In particular, in the case of D05 specimens that do not satisfy the criteria and D15 specimens that were excessively satisfied, noticeable cracks appeared at the edges of the glazing panel. In Step 8 (EQ200%), joint fastener separation and plastic deformation of the grid elements were observed in all specimens, but there was no overall breakage or dropping of the glass in any of the specimens during the excitation step.

4.5 Definition of damage limit by performance level of glazing curtain wall

In order to compare the degree of damage in the glazing curtain wall, the damage limits for each performance level of the glazing curtain wall were defined considering ASCE 41-13 and domestic papers. The operational level is the level of damage that maintains the functionality of the curtain wall without replacement of the sub-parts, and the damage level of the Position Retention was defined as that of sub-parts needing replacement or repair, such as major cracking in the silicone, partial crack of the glass, or the damage that is clearly identified with the naked eye. In addition, damage requiring immediate evacuation of people, such as falling glass debris, overall cracks in the glazing panels, and excessive failure of the cover pieces, were defined as damages to safety levels. None of the three phases allowed damage that could cause serious hazard, such as falling of glazing panels, collapse of the grid elements.

Table 11 Definition of damage glazing curtain wall system by performance level

Classification		Acceptable damage states (Minor failure)		Acceptable damage states (Major Failure)
		Operational (OP)	Position Retention (PR)	Life Safety (LS)
Glazing Curtain Wall System	Glazing	- Minor Crack of the sealing material	- Major Expansion of silicone cracks - Partial cracks in the glazing panel	- Total cracks in the glazing panel - Falling of glass debris
	Grid element	- Loosening of the cover pieces	- a few cover pieces failed - Minor plastic deformation of the grid elements - Minor Plastic deformation of the fasteners and bolts	- Excessive failure of the cover piece - Excessive plastic deformation of the grid element - Excessive plastic deformation of the fasteners and bolts

5. CONCLUSIONS

In this study, shaking table test is conducted of glazing curtain wall system with reference to the RRS presented by ICC ES AC156. After conducting this experiment, the damages of each specimen was assessed through a visual inspection for each step, and the results are shown in the data above. In addition, in order to evaluate the results of this experiment, we suggested damages of the glazing curtain wall system that considered performance levels by referring domestic research and international standards such as ASCE 7-10 and ASCE 41-13. The types of damage occur alone or in combination and have been shown sealing material cracks, fastener and grid element movement, and glass breakage. Figure 9 shows the results of the damage assessment of glazing curtain wall system by performance level and also indicated acceptable story drift angle of domestic steel structure. The conclusions are as follows.

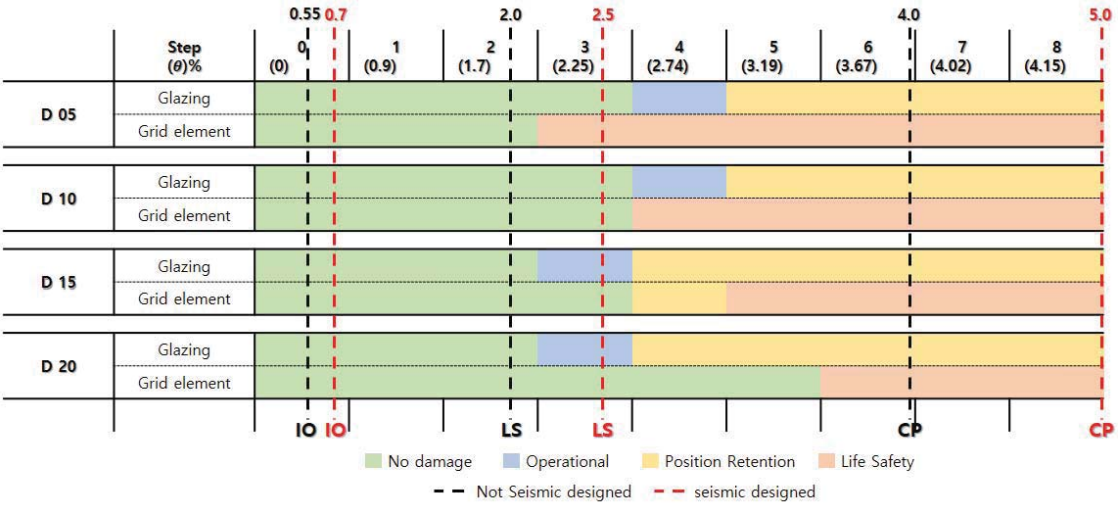

Figure 9 Damage assessment of glazing curtain wall system by performance level

1) Damage occurred simultaneously or individually on glazing and grid elements. In addition, as the end clearance widened, silicon material damage occurred from the initial step, whereas, damage to the grid element occurred at a larger story drift angle.

2) The damage occurred for the first time in all specimens in Step 3(2.25% of story drift angel) except for the D10 specimen. Specimen(D05), which failed to meet the domestic structural standard (KDS 41 17 00: 2019, 18.3.4), the damage pattern of Life Safety level, such as a slip or deformation of the fastener was shown before damages of Operational and Position Retention level. However, in the case of specimens satisfying the criteria(D15, D20), damages

including the slip of the fastener is occurred after the sealing material cracked

3) In the case of the D05 specimen with insufficient end clearance, damage to the life safety level occurred before reaching the life safety story drift angle of 2.5% of the steel structure designed as a seismic category 1 was shown. In addition all of the specimens which had sufficient end clearance were subject to damage that satisfied the criteria. Therefore, the current relative displacement requirement(KDS 41 17 00: 2019, 18.3.4) for curtain wall glass are suitable, but some research is required for 13mm, which is the minimum edge clearance in criteria.

4) The story drift angle at the final excitation stage(Step 8) was about 4% rad, and unacceptable damage such as a drop of the glazing panel and collapse of grid elements did not occur, but all specimens were showed partial breakage of the glazing panel at Step 7 (EQ180%). In last Step (EQ200%), excessive plastic deformation of the grid elements and separation of the fasteners are occurred.

5) Since all specimens had partial cracking in glazing panel at the edges, measures were expected to be needed to prevent the edges from colliding with the curtain wall structure and glazing. In addition, in the case of the hidden-bar type of curtain wall, failure in the structural sealing material is directly related to drop out of the glazing panel. Therefore, it is necessary to study the damage limit of hidden bar type curtain wall that considered the performance level.

ACKNOWLEDGMENTS

This research was supported by a grant(20AUDP-C146352-03) from the Architecture & Urban Development Research Program funded by Ministry of Land, Infrastructure and Transport of the Korean government.

Keywords: artefacts, museum, statues, busts, rocking, base isolation, shaking-table, shape memory alloy, seismic loading, earthquake

Abstract. *Earthquakes are a major threat to monuments and to museums and their valuable contents worldwide. The protection of cultural heritage structures and also of museums and their treasures against earthquakes is hence a top priority. The paper will present large scale shaking table tests on cultural heritage assets and will emphasize on the use computing models in tandem with experimental testing. More specifically, the paper will present an extensive*

experimental campaign on the seismic response of artefacts, with emphasis on statues and busts. The tests have been carried out in the framework of SEREME project (Seismic Resilience of Museum Contents) at the AZALEE seismic simulator of CEA in Saclay, Paris under the auspices of the EC funded SERA project. The aim is to understand the seismic response of statues and busts and then develop novel and cost-effective risk mitigation schemes for improving the seismic resilience of museum valuable contents. The study is focused on the investigation of the seismic response of two real-scale marble roman statues and three busts of three roman emperors standing on pedestals of different types and size. Both non-isolated and seismically isolated artefacts are considered, while two new and highly efficient base isolation systems, tailored to art objects, have been tested. The first isolator is a pendulum-based system, while the second utilizes Shape Memory Alloy wires. Specifically tailored, numerical models of varying complexity, for single and two-block rocking systems, were developed for the needs of this study and are also assessed against the experimental results.

1 INTRODUCTION

Earthquake actions pose an immense threat to museums and their contents. For example, during the recent earthquakes on 21 July 2017 and 24 March 2020, in the island of Kos (Greece) and in Zagreb (Croatia), respectively, severe and widespread damage were reported in the archaeological museums of the cities. The earthquakes extensively damaged the sculpture exhibition, where many artefacts were dislocated, leaned against the walls, or overturned. In the case of heavy and slender sculptures, the overturning mechanism, apart from damaging the sculptures themselves, poses a serious threat to other standing exhibits in the gallery and the visitors. It is, therefore, of paramount importance to rely on methods and tools for characterizing the seismic risk of museum artefacts and, where necessary, proposing cost-efficient protective measures.

The study of the seismic behaviour of museum assets and the investigation of novel and cost-effective risk mitigation schemes for improving the seismic resilience of European museums has received little attention in the past. The H2020-SERA project Seismic Resilience of Museum contEnts (SEREME) aims to fill this gap through extensive shake table tests on real-scale busts and statues. The aim of this large experimental campaign is to understand the seismic response of statues and busts and then develop novel and cost-effective risk mitigation schemes for improving the seismic resilience of museum valuable contents. The study focuses on the investigation of the seismic response of two real-scale marble roman statues and three busts of roman emperors standing on pedestals of different types and size. Both isolated and non-isolated artefacts are considered, while two new and highly efficient base isolation systems, tailored to art objects, are tested dynamically under seismic scenarios. The tested isolators include a pendulum-based system and devices with Shape Memory Alloy (SMA) wires. Furthermore, the importance of the hosting building is examined. Specifically tailored, numerical models of varying complexity, for single and two-block rocking systems, will developed for the needs of this study and will be assessed with the aid of the experimental results of the SEREME campaign.

The study of the seismic vulnerability of museum artefacts, especially of slender, human-formed statues, is related to the research on the dynamic response of rocking rigid blocks. The dynamic characteristics of the hosting structures are also important. This is evident from the fact that, on many occasions, damage to the structure was reported leaving the exhibits intact and vice-versa. Although the problem is coupled, it can be studied looking separately at the structure and its contents, provided that the contents are not attached to the building. The seismic response of building contents is a topic of growing interest, since it is directly related to seismic loss assessment and earthquake community resilience. Building contents can be

either attached to the structure, or may consist of objects that are simply standing. Museum exhibits belong generally to the latter category, while free-standing components are often studied as rocking objects. The response of the latter components is sensitive to acceleration and velocity-based quantities and also their geometry. Today, there is lack of standards, while the existing approaches in the literature are general in concept and do not sufficiently address the mechanisms of the variety of rocking objects. The reliability of such analytical approaches has also been scarcely validated with extensive testing, such as shake experiments.

Common structural analysis and design methods require the assessment of stress resultants and displacement-based quantities. Additionally, the three-dimensional rocking response has not received the interest it deserves. On the other hand, building contents, in most cases, consist of objects that are freestanding. There are recent works in which the seismic response of freestanding contents is investigated [1, 2, 3]. Museum exhibits belong to the latter category and the freestanding components are often studied as rocking objects, hence their response is sensitive to acceleration and velocity-based quantities. Geometrical properties of the artefacts also have significant effects on the dynamics and earthquake response of the components. Additionally, when freestanding components are placed on a pedestal, made either from marble or steel, their dynamic response is more difficult to be predicted with simplified methods.

The seminal analytical work carried out on the seismic response of rocking objects in the 60's [4] stimulated several quantitative studies that have focused primarily on numerical solutions [5, 6, 7, 8]. Recently, however, Purvance et al. [9] carried out extensive experimental and numerical studies in order to investigate the overturning response of symmetric and asymmetric blocks with both simple and complex basal contact conditions and also proposed block overturning fragilities. Similarly, ready-to-use fragility curves were proposed by Konstantinidis and Makris [10] through a comprehensive experimental program on full-scale freestanding laboratory equipment located on several floor levels. The latter studies, however, focused primarily on the behaviour of single blocks. Dual block systems were first studied numerically by Psycharis [11], while the recent experimental work of Wittich and Hutchinson [12] studied asymmetric free-standing component configurations. It is worth noting that, for rocking rigid objects, such as artefacts, the response, at least in terms of overturning motion, is size-dependent, thus the scaling of the specimens is not possible and the experimental tests should be based on full-scale specimens.

Nowadays, considering the huge earthquake losses registered in the recent earthquakes, especially in the Mediterranean region, it is also deemed imperative to propose viable and cost-effective seismic protection measures for free-standing statues and busts. Podany [13] discussed a range of retrofitting measures based on the best practice followed by the J. Paul Getty Museum in Los Angeles, in California, where a newly developed base isolation device has been employed. Past research on the seismic protection of art objects using isolators, includes primarily several analytical-numerical investigations (e.g. [14, 15]), while to our knowledge only few experimental studies can be found in literature. However, the effectiveness of the use of seismic isolators for light weight components should be further investigated to characterize thresholds for accelerations and horizontal displacements for an adequate seismic protection of the artefacts.

The H2020-SERA SEREME project aims to fill the experimental gaps highlighted above and to include comprehensive shake-table tests of several configuration of free-standing and base isolated statues and busts. The freestanding artefacts are installed either directly on the marble floor, or on a pedestal. The objective of the campaign was to give insight on the seismic behaviour of statues and busts as well as to evaluate the effectiveness of two different seismic risk mitigation systems. A total of 5 pairs of real scale marble artefacts were tested, 3 busts installed on marble pedestals and 2 statues. Seven different testing arrangements (also

termed “Configurations”) were considered during this experimental campaign and more than 400 seismic tests were performed. Two innovative base isolation devices were utilized as retrofitting remedies. The first system is a combination of friction pendulum isolators [16], a system designed for light components. The second system is a newly developed device utilizing shape memory alloy wires in the horizontal plane. The isolation devices tested are patented systems, namely ISOLART® PENDULUM &ISOLART® SMA, which are manufactured by the Italian company FIP Mec, a member of the User Team. In order to obtain a direct evaluation of the isolator effectiveness, for each test configuration, pairs of two similar artefacts were tested together in an isolated and a non-isolated arrangement. The shake-table tests were carried out considering uniaxial, biaxial and triaxial earthquake loadings at increasing amplitudes. In order to evaluate the influence of the frequency content and the directionality of the seismic excitation, 13 different waveforms were applied to the shake table (8 uni-directional motions, 3 bi-directional motions and 2 tri-directional motions). Regarding the instrumentation, the artefacts motions were recorded using accelerometers, gyroscopic and displacement sensors.

2 MUSEUM CONTENTS TESTED

The experimental campaign of SEREME focused on the investigation of the seismic behaviour of real-scale marble statues and busts standing on pedestals. The case study statues and busts were selected with different geometry and weights; they are replicas of ancient roman emperors. Five busts of roman emperors were utilized: two of emperor Traiano, two of Augusto and one of Tito. Furthermore, four statues were also purchased, two standing on a low height marble pedestal (quoted as “Figura Femminile”) and two simple female form statues (quoted as “Fanciulla”). Since all specimens are made from solid marble, the average weight of the busts is 250-300kg, while that of the statues was 500-600kg. The replicas of the same statue/bust have approximately the same geometry, but they are not perfectly identical (Figure 1). The seismic response of a display case was also examined.

(a) (b)

Figure 1. Components used for the shake table tests: (a) Busts and display case, (b) female statues.

The busts are placed on a pedestal which is used to bring the specimens to the eye-level of the visitor. Three different pedestal types were identified and then adopted for the experimental tests: (i) solid pedestal, with dimensions 45×45×100 cm, (ii) hollow pedestal, with dimensions 35×35×100 cm, and (iii) modern type metallic pedestals that were provided by the Italian manufacturer Fallani. The traditional, hollow and solid, pedestals were made of concrete which has a specific weight close to that of marble. To reproduce realistic conditions for

in-situ friction, on the upper and the lower face of the pedestals, 3 cm thick marble plates were installed. Solid pedestals have large weights (nearly 500kg) and they also employ large bases, thus these pedestals are not prone to uplift. On the other hand, hollow pedestals are slender with weight 226kg and have a base with smaller width equal to 35c. Furthermore, its centre of gravity is much higher compared to the solid case. The metallic pedestal has a large square base with side equal to 85 cm and it weighs only 85 kg.

In order to simulate the floor of museums, where typically busts and statues are hosted, the non-isolated specimens were placed on a marble floor surface. The marble has thickness equal to 3 cm and it is positioned on stiff wood also 3 cm thick. Both marble and wood were directly bolted on the shake table. All specimens are placed on top of the marble floor and pedestal without any connection material. In the case of isolated specimens, the isolator was bolted on the table with the aid of specific holders that adjusts the holes of the table to the holes of the device. For the SMA isolators, marble plates were glued on the upper surface of the isolator, while the specimens are simply standing.

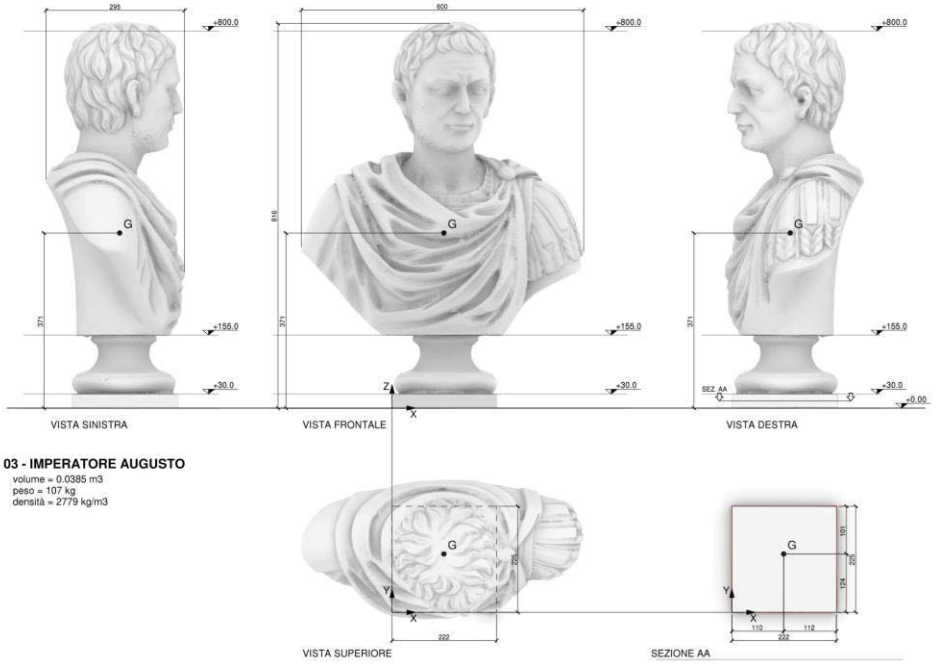

Figure 2. (a) Geometric properties of the Emperor August bust.

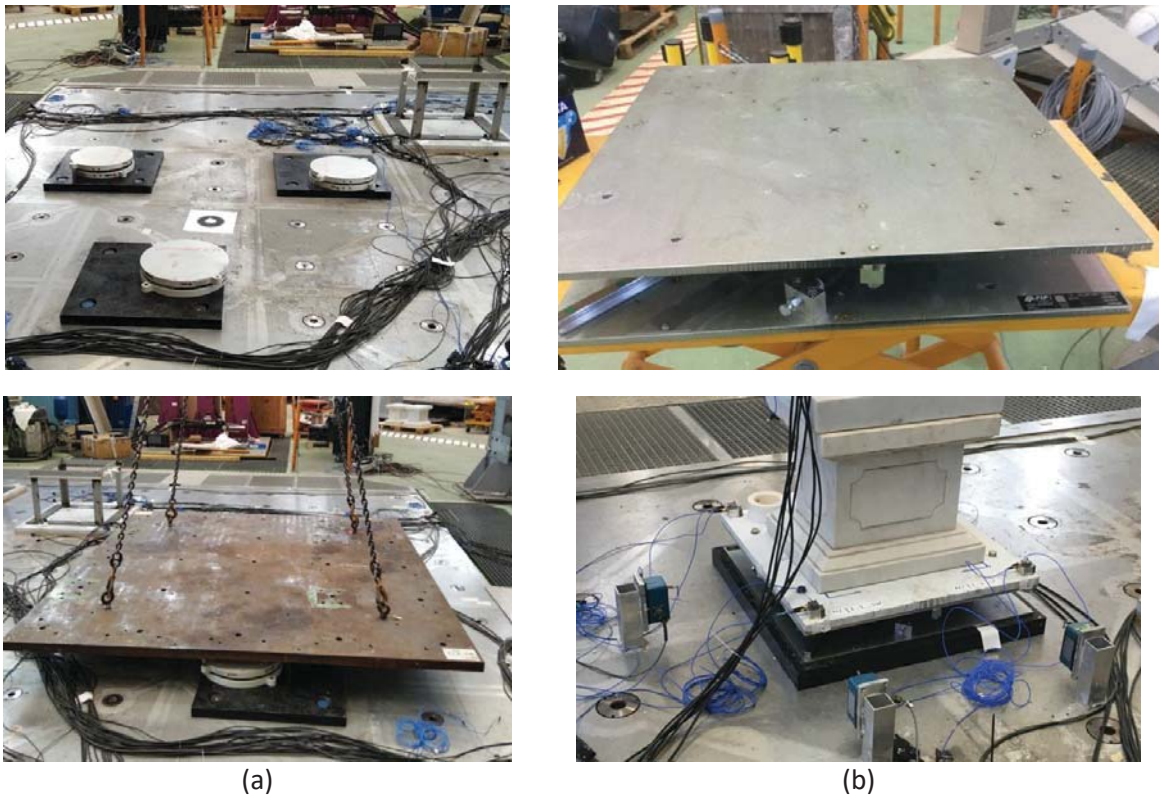
The static friction coefficient was measured for the marble-marble interface with inclined tests. The inclined tests were repeated 10 times in order to determine the mean friction angle. For the plate-plate marble interface the mean friction coefficient μ was found equal to 0.79, while for the bust-plate interface it was found equal to 0.39. The values of the friction coefficient for plate-plate interface that were derived experimentally comply with those provided in the literature. Conversely, the friction marble-plate interface was found unexpectedly low. However, both mean values were also verified during the shake table tests where sliding was observed approximately at peak ground acceleration (PGA) values close to the ones measured (the condition to have friction is PGA>μg). To increase the friction coefficient, where necessary, a thin layer of a rubber material was glued at the bottom of the busts. The friction coefficient at the interface of the marble floor and the bottom of the statues was found sufficiently high and thus no measures were required.

Laser scanning was carried out by a joint research team before moving them the artefacts from the vendor to CEA. Digitalization with laser scanning provides the geometrical properties of the specimens. The purpose of laser scanning is two-fold: (i) it provides a finite element (FE) mesh of the geometry of the artefacts that can be used to perform numerical simulations, and (ii) it allows the calculation of fundamental properties of the components, such as the centre of mass (CM), the total mass, the rotational moments of inertia and the distance of the CM from the pivot points. Furthermore, the laser scanning verified that the specimens are made from solid marble through calculating the ratio of the scanned volume over the measured weight of each specimen. Example of laser scanning information obtained are shown in Figure 2 for the bust of Emperor August.

Two different base isolator technologies were adopted (Figure 3): a friction pendulum isolator and an innovative device with shape memory alloy (SMA) wires. The tested seismic isolator systems were manufactured by the Italian company FIP Mec srl: the selected isolators are marketed as ISOLART® SMA and ISOLART® PENDULUM, respectively. ISOLART® PENDULUM, is similar to common pendulum isolators used for structures, but it consists of different materials and it has been designed specifically for low-mass structures such as objects of art. The main difference between the two isolation devices is the range of mass of the objects to seismically isolate. For ordinary friction pendulum bearings, the friction can be large because of low vertical pressure. To overcome the problem, an increase of the vertical force, or a decrease of the friction coefficient is required. For this purpose, the friction pendulum was used to isolate several artefacts together which are standing on a heavy steel plate, thus increasing the vertical force (Figure 3a). Therefore, three pendulum isolators were employed to isolate a floor on which a group of artefacts (2 or 3 artefacts) was installed. The installation of the ISOLART® PENDULUM devices is shown in Figure 3a.



(a) (b)

Figure 3 Tested isolation systems: (a) friction pendulum isolator, (b) SMA isolator.

ISOLART® SMA, i.e. the SMA-based isolator, is a novel isolator based on SMA wires that are effective in limiting the horizontal displacements of the device. ISOLART® SMA is a patented isolation system which takes advantage of the super-elastic properties of SMA wires, i.e. their capacity to have a stress-induced non-linear behaviour similar to elasto-plastic behaviour up to high deformations (about 7%) and unload to zero displacement. As shown Figure 3b, the SMA isolator can be used to isolate a single specimen each time, which is a significant advantage. Although all SMA isolators adopted have the same dimensions, the properties of the SMA may differ. Three different types of SMA isolators were tested.

Due to the large variety of specimens, pedestals and isolators, seven different Configurations were analysed experimentally using the 6-DOFs shake table AZALEE. The seven testing configurations were designed taking into consideration the limited testing time available and also the needs of the project. The tests of each configuration lasted approximately 2, or 3 days. Configuration 1, was sub-divided into five sub-configurations, shown in Figure 4 up to Figure 8 and considers only the SMA isolators. The caption of each figure explains the properties of the tested configuration. In order obtain a direct comparison between the isolated and the non-isolated case, the sub-configurations compare pairs of two similar artefacts tested side-by-side in an isolated and a non-isolated arrangement. Instead of testing simultaneously more than a pair of specimens, single pairs were considered every time. This practice offered speed during the tests, while it also allowed to focus on one tested pair every time. In configurations I.4 and I.5 a display case was tested, first isolated and then non-isolated.

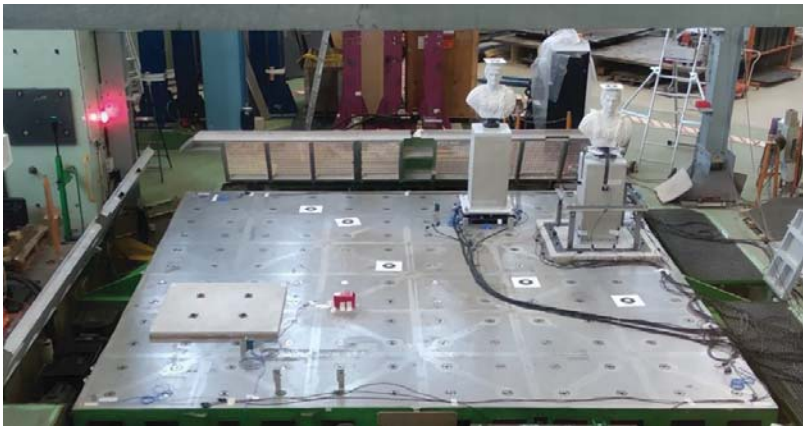


Figure 4. Configuration I-1: Traiano bust on solid pedestal; on marble and on SMA isolator

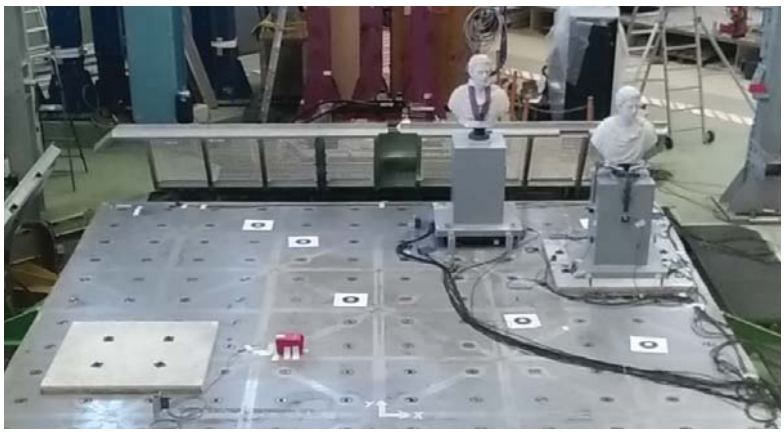

Figure 5: Configuration I-2: Traiano bust on steel metallic pedestal; on marble and on SMA isolator.

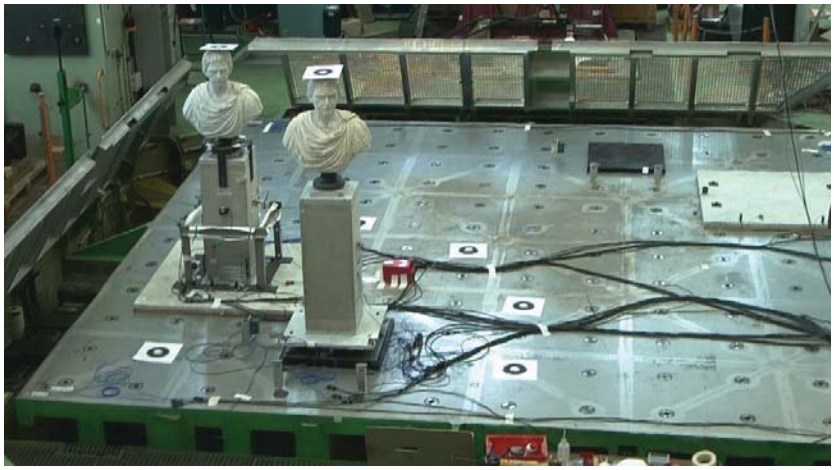

Figure 6: Configuration I-3: Augusto bust on hollow pedestal; on marble and on SMA isolator.

Figure 7: Configuration I-4: Female statue (Figura femminile) standing on the ground pedestal and non-isolated display case and isolated display case (SMA isolator)

Figure 8: Configuration I-5: Female statue (Fanciulla) standing on the ground pedestal and non-isolated display case and non-isolated display case

Figure 9: Configuration II: Non-isolated vs isolated statues (friction pendulum system). The pairs of specimens compared are: (i) Traiano bust on solid pedestal, (ii) Fanciulla and (iii) Figura femminile.

Figure 10: Configuration III: Non-isolated vs isolated statues (friction pendulum system). The pairs of specimens compared are: (i) Tito bust on metallic pedestal, (ii) Augusto bust on solid pedestal, and (iii) Traiano bust on hollow pedestal.

Configurations II and III are shown in Figure 9 and Figure 10, respectively. These two configurations test the friction pendulum as seismic isolator. In Figure 9, the two female statues and one bust were positioned on top of the friction pendulum isolators. The specimens were positioned on the steel plate in way that the centre of mass of the specimens approximately coincides with the centre of mass of the plate. Configuration III (Figure 10) compares simultaneously the three different types of pedestals. Since only five busts were available, for the metallic pedestals only the non-isolated case was considered. Furthermore, the upper face of the metallic pedestals was reinforced with an 8mm thick steel plate which considerable improved the performance of the system compared to Configuration I.2 (Figure 5).

3 NUMERICAL SIMULATIONS

Due to the complex geometry of museum exhibits and the uncertainties of the problem, the numerical simulation of artefacts and museum exhibit systems presents significant difficulties. Complex simulations should be repeated for each exhibit, or for groups of exhibits with similar geometrical characteristics. Moreover, despite the great value of museum exhibits, in practice all decisions about their safety are taken by museum curators, who have empirical knowledge, e.g. experience of past earthquakes, but no technical background to perform sophisticated computer simulations.

Specimen	Standing conditions	Rocking Acceleration (g)		Overturning (mm/s)	
		$a_{rock,B,x}$	$a_{rock,B,Y}$	$v_{cr,X}$	$v_{cr,Y}$
Figura Femminile with pedestal		0.244	0.207	0.446	0.344
Fanciulla		0.296	0.226	0.382	0.289
Emperor Traiano	Bust only	0.240	0.236	0.297	0.308
	Bust on solid pedestal	0.330	0.331	0.423	0.424
	Bust on hollow pedestal	0.207	0.208	0.280	0.281
	Bust on steel pedestal	0.293	0.292		
Emperor Tito	Bust only	0.283	0.254	0.262	0.309
Emperor Augusto	Bust on solid pedestal	0.283	0.253	0.257	0.304
	Bust on hollow pedestal	0.220	0.216	0.294	0.29
	Bust on steel pedestal	0.318	0.310		

Table 1 Peak ground acceleration that initiate rocking and overturning velocity estimates.

The possible methods of analysis are either simplified calculations based on first principles, or advanced methods of analysis, e.g. analyses using FE modelling, or the discrete element method (DEM). Simplifications are based on simplifying the geometry to one or two rectangular, rigid bodies. These are basic geometric calculations that do not require engineering knowledge, but give useful information such as the maximum ground acceleration for which the system will slide or will engage into a rocking motion. When laser scanning information is available, these calculations are more accurate and, despite their simplicity, they are very important and helpful. Table 1 shows the peak ground acceleration values that initiate rocking for each of the specimen considered. In the case of busts standing on a pedestal, the two bodies are, crudely, assumed to behave as a single body. Table 1 also shows the velocity that triggers overturning motion according to the relationship proposed by Ishiyama [17]. This is a conservative lower bound estimation, as opposed to the rocking initiation acceleration which is exact.

Laser scanning was adopted for determining the geometric characteristics of the busts and of the statues that were tested. The scanning provides FE models that allow to perform simulations, but with increased CPU requirements. Furthermore, the accuracy of the scanning is very high and results to very fine and detailed finite element models which do not offer more accuracy but they require excessive memory and CPU resources. It is, therefore, necessary to also have simple models for the seismic response prediction.

The FE method offers several advantages concerning the accuracy, but there are also difficulties in utilizing the analytical simulation approach. The surface-to-surface interaction between the upper surface of the pedestal and the lower surface of the bust requires knowledge of the friction coefficient and the damping ratio, while damping of the motion due to rocking impacts cannot be introduced in a straightforward manner. Also, the FE method is more realistic if the bodies have some flexibility. Introducing the flexibility and the real modulus of elasticity of the artefacts will increase the CPU time, thus making prohibitive a large number of simulations. On the other hand, the Discrete Element Method (DEM) assumes that the objects are rigid and consequently can be adopted with reduced computational costs. For the interaction between the surfaces, appropriately calibrated springs should be introduced in the model. Psycharis et al. [18] have described the numerical model for the simulation of a multi-drum ancient column which is subjected to natural ground motion records. The column consists of eight rigid bodies, the upper placed on the top of the lower. In this work the 3DEC software has been used for the simulation of a problem that has similarities to the problem at hand.

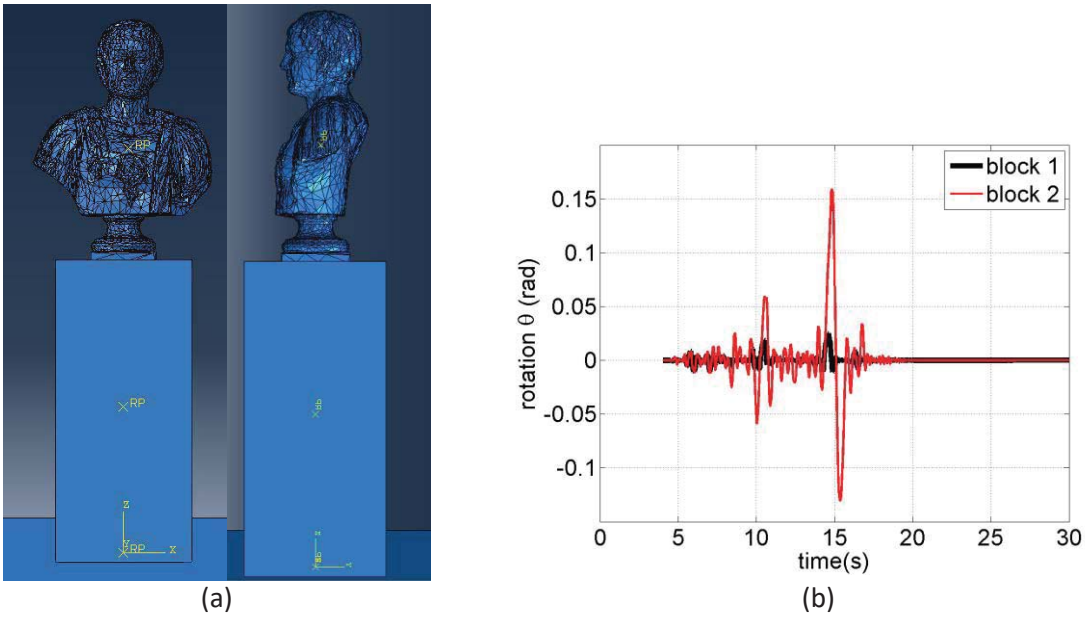

Figure 11. (a) Finite Element model (pedestal-bust), (b) response time history.

Models that consider either two-block assemblies (pedestal-bust) or freestanding, symmetric or asymmetric, rocking blocks (a freestanding statue or a bust that rocks on a pedestal in rest) are a possible alternative to the costly FEM and DEM simulations. Such simple models are typically limited to one-direction simulations and hence the procedure should be repeated for both the longitudinal and the transverse direction due to the asymmetry of the specimens. A simplified approach is offered by using the equation of motion proposed by Housner [4]. A possible way to handle the equations of Housner [4] has been proposed by Diamantopoulos and Fragiadakis [8]. For the two-block case and for simplicity reasons the work of Psycharis [11] can be adopted. Vlachos et al. [19] presented a first attempt to extend the two-block problem in case of asymmetric upper block when the pedestal is symmetric.

4 TEST SETUP

To evaluate the influence of frequency content of the excitation, as well as the directionality of the seismic input, five different earthquake ground motions were adopted in this experimental study. The ground motion records and their properties are shown in Table 2. The records were applied in different combinations every time, i.e. first the X-component was applied alone, the Y component afterwards and then the X and Y components were applied simultaneously.

Earthquake	Date	Mw	Station	Distance hypocentral	Soil category	PGA (g)
Emilia, Italy	29.05.2012	6.0	T0800	14.4	C* (EC8)	L: 0.33 T: 0.25 V: 0.33
Athens, Greece	07.09.1999	5,9	Syntagma Metro B	10.0	Stiff soil	L: 0.109, T: 0.086, V: 0.087
L'Aquila, Italy	06.04.2009	6.3	Aterno river-AQA	< 2km	Stiff soil	L: 0.45, T: 0.39, V: 0.37
Kalamata, Greece	09/13/1986	6.2	Nomarchia	5.0	Stiff soil	L: 0.22, T: 0.29

Kobe, Japan	1/16/1995	6.9	Takatori, Japan	22.2 (< 1.5 km)	C* (EC8)	L: 0.068
Emilia, Italy – first storey	29.05.2012	6.0	T0800	14.4	C* (EC8)	L: 0.37

Table 2 Ground motion records used for the testing campaign.

The record combinations adopted are listed in Table 3. For each record combination, the ground motion amplitude was gradually scaled up. In general, the target intensity levels considered were: 0.15g, 0.20g, 0.25g, 0.35g, 0.40g and 0.50g. For simulations where simultaneously two, or three, components were considered, a uniform scaling factor was adopted for all record components considered, while the target acceleration refers either to the X-, or the Y-component. When both X and Y are present, it refers to the X-component. For the Takatori and the Kalamata records, the maximum permissible scaling factor is controlled by the maximum allowable displacement of the shake table that cannot exceed 10cm. As expected, differences between target PGA and the PGA measured as input to the shake table were observed. On average 25-40 shake table runs were performed for each of the seven tested configurations.

ID	Record	Components	Target PGA
1	Emilia	X	0.15, 0.25, 0.35, 0.40, 0.50
2	Emilia	Y	0.15, 0.25, 0.35, 0.40, 0.50
3	Emilia	XYZ	0.15, 0.25, 0.35, 0.40, 0.50
4	Emilia	XY	0.15, 0.25, 0.35, 0.40, 0.50
5	Emilia	Y (first floor)	0.15, 0.25, 0.35, 0.40, 0.50
6	Emilia	YZ (first floor)	0.15, 0.25, 0.35, 0.40, 0.50
7	Syntagma	X	0.15, 0.25, 0.35, 0.40, 0.50
8	Takatori	Y applied on X	0.10, 0.15
9	Takatori	YZ applied on X	0.10, 0.13, 0.2, 0.24
10	Takatori	Y	0.10, 0.18, 0.2, 0.24
11	L'Aquila	X	0.15, 0.25, 0.35, 0.40, 0.50
12	L'Aquila	XYZ	0.15, 0.25, 0.35, 0.40, 0.50
13	Kalamata	X	0.15, 0.20, 0.25, 0.30

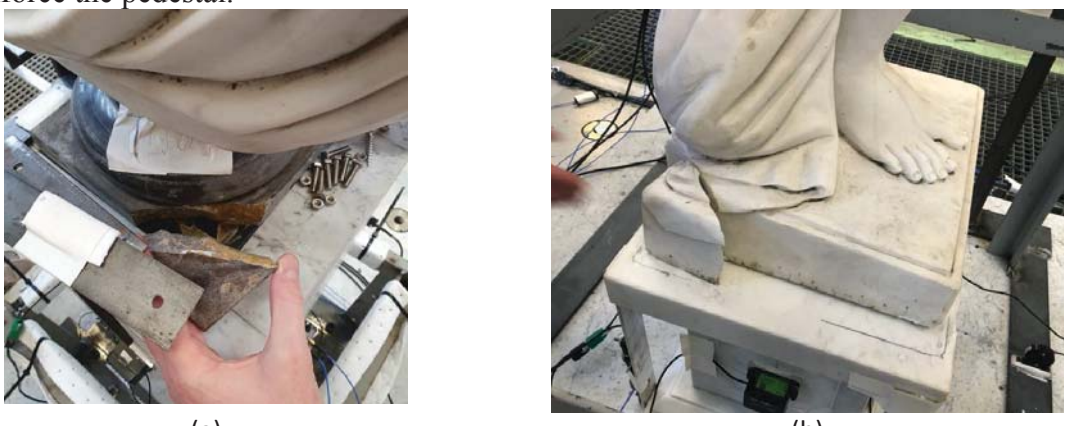
Table 3 Record combinations.

Apart from five naturally recorded ground motions, the acceleration response history of the first floor of the museum was considered. The museum is the Archaeological museum of Pella in Greece. This is a new reinforced concrete building. The building was modelled with OpenSees software and it was subjected to the five ground motion records of Table 2. Since it is a two storey RC building with many shear walls, it is a quite stiff structure (Tx =0.17s, Ty =0.14s) and hence large amplifications were observed at the stories. Among the various floor acceleration histories, the first storey of the Emilia 2012 (Italy) response acceleration was adopted for the tests.

5 OBSERVATIONS AND PRELIMINARY RESULTS

A vast amount of data was obtained during the experimental campaign that lasted approximately two months. The User Team is currently working on post-processing the experimental data. However, very interesting observations were made during the campaign. Due to the protection measures no major damage on the specimens occurred, while the most typical damage type observed is the failure at the corners of the specimens. This damage is shown in Figure 12 for both the bust and the statues. This type of damage happened practically to all busts of Configuration I.1-I.5, while the damage of statue show in Figure 12b happened once. Since a large number of tests had to be repeated, the marble bases of the busts were replaced, while

for the statue the failed wedge shown in Figure 12b was repaired by gluing it back and retesting the statue isolated. No damage occurred at the pedestals. The metallic modern pedestals when tested in Configuration I.2, exhibited some mild bending of their upper face, where the bust was standing. The lateral bending due to the selfweight of the bust affected the dynamic response. In order to mitigate this effect, in Configuration III, an 8mm thick plate was used to reinforce the pedestal.



(a) (b)

Figure 12. Typical damage at the base of the specimens: (a) bust, (b) base of the statue.

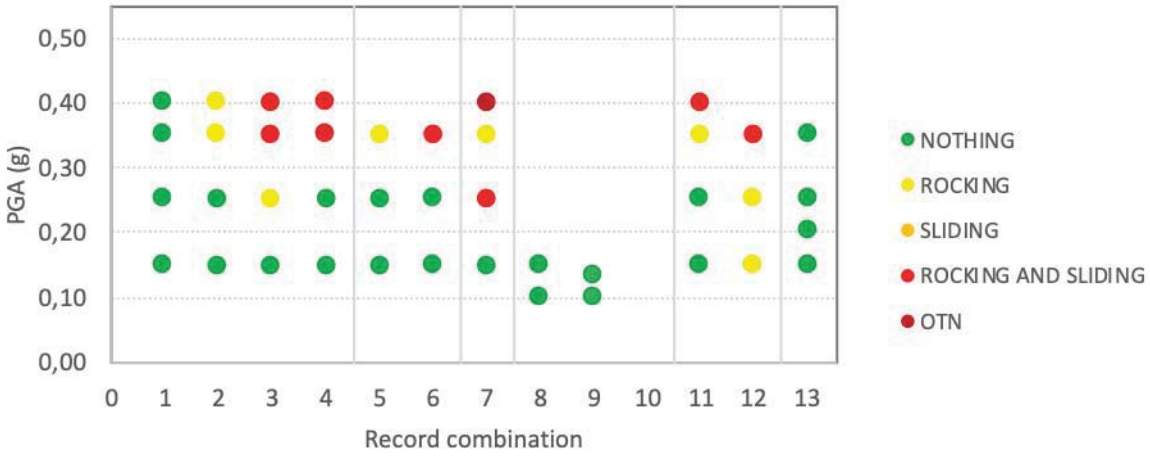


Figure 13. Response of the non-isolated bust of Configuration I.1.

Figure 13 summarizes the response of the non-isolated bust in Configuration I.1 where the bust of emperor Traiano was positioned on top of the solid pedestal. The solid pedestal, due to its massive geometry, never uplifted and hence only rocking of the bust was observed. As expected from the PGA values of Table 1, no uplift occurred for PGA values below 0.20g. Note that the accelerations of Figure 13 are the theoretical predictions; the latter differ, sometimes considerably, from the values recorded on the shake table. Comparing record combinations 1 and 2 to combinations 3 and 4, it is evident that the bidirectional ground shaking is more severe for the bust, since overturning was observed at much lower accelerations for the Emilia earthquake. This observation also holds for the L'Aquila record (combinations 11 and 12). The Takatori and Kalamata ground motions have a low recorded PGA and have a large frequency content. These records were scaled but they were not critical for the busts, as opposed to the Syntagma ground motion which was severe.

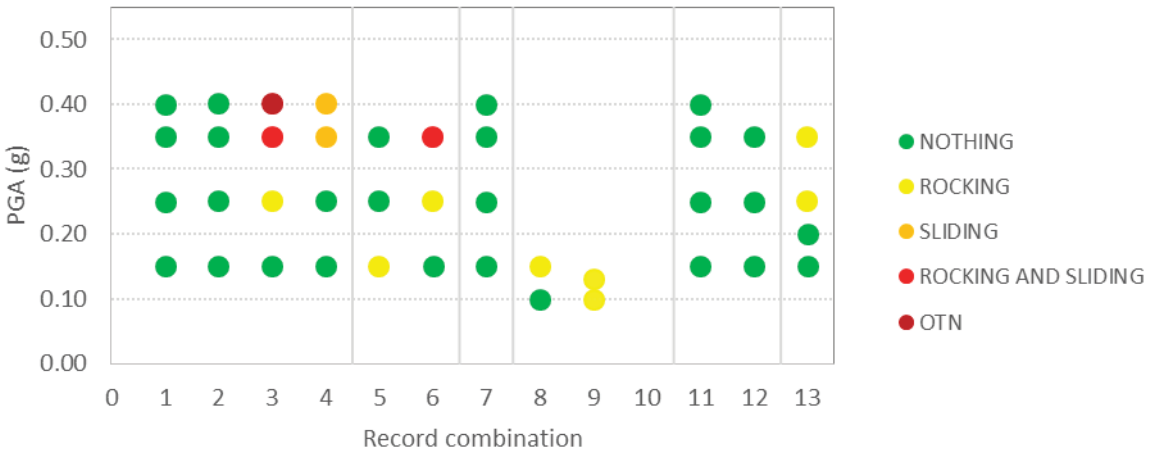

Figure 14. Response of the SMA-isolated bust of Configuration I.1.

Different observations hold also for the SMA isolated specimen. As show in Figure 14, the specimen was safe for most ground motion levels, practically for most ground motions. The Emilia XYZ ground motion produced sliding and rocking that threatened the bust for a PGA of 0.40g. This is attributed to the large vertical acceleration component. This was also seen for the first-floor response when a vertical component is present. Interestingly, rocking was observed also for the Takatori and the Kalamata ground motions.

Important findings were obtained from the experimental campaign and are briefly summarized as follows:

- For high excitation intensity tests, the non-isolated artefacts are prone to show a complex rocking and sliding behaviour. The impact induced by the rocking motion can be a source of damage to the base of the busts, especially at the corner points of the base of the bust.
- The response of the busts on the solid and the on the hollow pedestal is substantially different. The uplift of the hollow pedestal was always small and difficult to identify visually. However, it is clear that it considerably affected the seismic response. Whether the bust is safer on the solid, or on the hollow pedestal is a topic that deserves further research; the tests have shown that the safety depends also on the ground motion frequency content.
- Tests where the friction coefficient between the bust and the pedestal was low, i.e. when friction coefficients vary between 0.20 and 0.30, revealed that sliding is a beneficial response mode for the bust. If the sliding motion of the rigid object is controlled, then some sliding is desirable.
- In most of the cases, the considered mitigation methods have been effective in the prevention of the rocking/sliding behaviour of the artefacts. As a result, these mitigation methods improved significantly the seismic behaviour of the artefacts. Especially the friction-pendulum system was very efficient in practically all tests. Some attention is required in the case of high vertical component. Although the vertical earthquakes considered were very strong, some attention is required in this respect.
- The metallic pedestals, due to their geometry, did not uplift and hence they were equally efficient as the solid ones, provided that they can fully support the weight of the artwork.

- The response of the statues was well predicted and with no surprises. When the input acceleration was below the rocking initiation threshold, the statues performed some high frequency oscillation.
- The base of some of the statues was not fully flat, due to structural imperfections. This lack of planarity affected the response and threatened the safety of the statues. This issue has been also reported in previous research in the literature.
- The simplified calculations, summarized in Table 2, are very important and useful. Such information should be always advised when taking seismic protection measures for artefacts.

6 CONCLUSIONS

The project presents an extensive experimental campaign on the seismic response of artefacts, with emphasis on statues and busts. The tests took place in the framework of SEREME project (Seismic Resilience of Museum Contents) at the AZALEE seismic simulator of CEA in Saclay, Paris under the auspices of the SERA project. The campaign aims to help us understand the seismic behaviour of the selected statues and busts and then to develop novel and cost-effective risk mitigation schemes for improving the seismic resilience of valuable objects hosted in European museums. Two real-scale marble (replicas are usually made from gypsum) roman statues and three busts of three roman emperors standing on three pedestals of different types and size are investigated concerning their response under seismic loading. The artefacts are considered either isolated or non-isolated. In the latter case, two new and highly efficient base isolation systems, tailored to art objects, are tested. The efficiency and the effectiveness of the isolators are of the main interest for the authors. The first isolator is a pendulum-based system, while the second utilizes Shape Memory Alloy wires. Different configurations were considered for examining all cases. The importance of the hosting building is also examined, i.e. building type, stiffness and story that hosts the artefacts. Specifically tailored, numerical models of varying complexity and Finite Element models for single and two-block rocking systems were developed for the needs of this study and are also assessed against the experimental results.

Keywords: nonlinear response history analysis, machine learning

Abstract. *Nonlinear response history analysis (NRHA) is the most accurate seismic performance assessment method but it can be computationally intensive when it is applied to multi degree of freedom (DOF) structural systems. Machine learning techniques have gained increasing interest in engineering fields and can consist a powerful tool for reliable predictions with their ability to quickly and accurately identify trends or patterns through experimental or artificially generated data. In this study, we propose a robust machine learning pipeline to estimate the nonlinear response analysis of multi-DOF systems in terms of their maximum displacement/ductility aiming to eliminate the computational cost of the NRHA analysis. A pulse extraction process is used to quantify the wavelet parameters of a ground motion records which, along with the material parameters of the structural system consist the training data set. It is shown that adequate predictions were obtained through the validation of various benchmark structures which can act as a reference tool for an engineer in practice.*

1 INTRODUCTION

Nonlinear response history analysis (NRHA) is the most realistic seismic performance assessment tool of structures which requires the use of recorded acceleration time-histories as input into numerical simulations. Evidently, it can be computationally intensive when it is applied to multi degree-of-freedom (DOF) structural systems, particularly when dealing with parametric studies or/and incremental dynamic analyses. Different techniques have been proposed in the literature to reduce the computational cost of such analyses e.g. record simplification, record down-sampling, modified inverse Fourier transform, to name a few.

Machine learning (ML) techniques are constantly gaining increasing interest in engineering fields [1] and can consist a promising tool for reliable predictions with their ability to quickly and accurately identify trends or patterns through experimental or artificially generated data. In this study, we propose a robust machine learning pipeline to estimate the nonlinear response analysis of multi-DOF systems in terms of their maximum displacement/ductility aiming to eliminate the computational cost of the NRHA analysis. A pulse extraction process is used [2] to quantify the wavelet parameters of a ground motion records which, along with the material parameters of the structural system consist an adequate training data set. The applicability and efficiency of the proposed approach is demonstrated first in a single-DOF oscillator that is used as a benchmark example. A comparison study between various ML regression models, is followed by, in order to choose the efficient ML technique that will be used for the training process. It is shown that adequate predictions were obtained through the validation of various single-DOF benchmark structures which can act as a reference tool for an engineer in practice.

2 PULSE EXTRACTION OF NEAR-FIELD GROUND MOTIONS

Near-field ground motion records are characterized by dominant pulses in the ground velocity time histories, as well as high frequency content in acceleration time histories, especially at sites located in the forward direction of the fault rupture (directivity effects) [3]. The investigation of the ability to compose a near-field ground motion record with its pulse simulations [4] is a topic of great interest in the research community. Many researchers have proposed mathematical models for the representation of near-field ground motions mainly based on underlying wavelets. Among them, the model proposed by Mavroeidis and Papageorgiou (M&P) [2] introduced one of the most important pulse representation methods, that consists a mathematical representation of ground motion movements relying on designing a complex wavelet (based on Gabor wavelet). Gabor wavelet is characterized by four principal parameters (A, f_p, γ, ν), the most important of them is the pulse frequency f_p the calculation of which is based on the convolution spectrum. The analytical expression of the Gabor wavelet is given as follows:

$$f(t) = Ae^{-(2\pi\frac{f_p}{\gamma})^2 t^2} \cos(2\pi f_p t + \nu)$$

where:

A: is the amplitude
f_p: is the prevailing frequency
γ: is the oscillatory character ($\gamma > 1$)
ν: is the phase angle

However, this wavelet has a significant disadvantage, due to the existence of the exponential component that prevents the development of closed solutions for the response of single-stage

systems. To this end, M&P improved this model by allowing the development of closed solutions for estimating response spectra and determining spectral characteristics in Fourier form. This improved wavelet has the same parameters as the Gabor wavelet [5] and its analytical expression is given as follows:

$$f(t) = 0.5A\left[1 + \cos\left(2\pi\frac{f_p t}{\gamma}\right)\right]\cos(2\pi f_p t + \nu)$$

Natural ground motion records may consist of more than one discrete pulses. The pulse extraction process adopted in this study combines the use of the wavelet by M&P for the efficient representation of directional pulses along with the determination of each wavelet parameters. This process allows the identification and the output of all pulses located in the range of medium and high periods. If all extracted pulses are superimposed, a simulation of the entire ground motion can be produced (
Figure 1). The characteristics of the wavelets are determined by their optimal adjustment (maximum correlation) in the velocity response spectrum of each ground motion record.

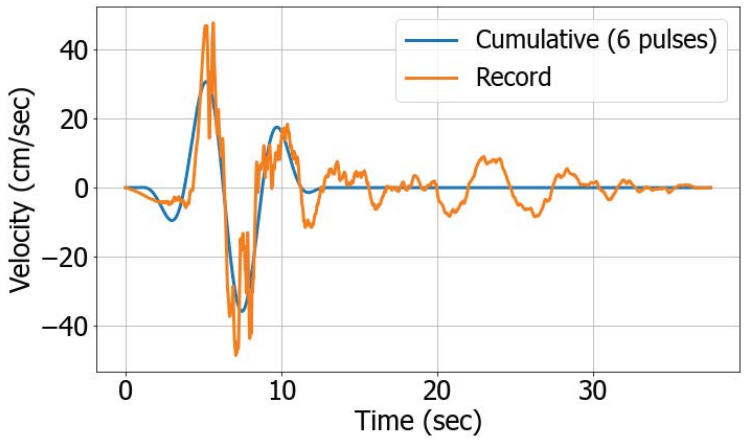

Figure 1: Cumulative velocity (6 pulses representation) of a ground motion record.

3 CASE STUDY: BILINEAR OSCILLATOR

The efficiency of the proposed approach is demonstrated in a single-DOF oscillator described by a hysteretic material model (uniaxial bilinear material with kinematic hardening) defined with four material parameters (fundamental period T, damping ratio ζ, yield force F_y and hardening ratio k). A database was generated consisting of 387 near-field ground motions records (distance from the rapture < 60 km), obtained from the Next Generation Attenuation for Western US (NGA-West2) (PEER 2017) [6]. The material parameters of the single-SDOF oscillator were adopted to artificially create a dataset using a range of values as shown in Table 1. For each ground motion of the database a total of 625 nonlinear history response analysis were conducted and the maximum displacement (u_{max}) along with maximum force ($F_{s,max}$) of the SDOF oscillator are obtained creating the dataset of outcomes.

Variable	Lower Bound	Upper Bound	Step
T [s]	0.1	0.9	0.1
ζ	0.01	0.1	0.01
F_y [% of SDOF mass]	0.1	0.9	0.1
k	0.1	0.9	0.1

Table 1: Lower, upper bound and step values for SDOF bilinear oscillator.

In order to avoid the nonlinear response analysis for a given ground motion record, two machine learning models are trained. The parameters of six pulses that represent each record along with the parameters of the bilinear material model consist the input data, while u_{max} and $F_{s,max}$ consist the output data of the two ML models, respectively. Each ML model is treated as a regression problem. A final subset of 337 records from the database with their corresponding pulse extraction parameters, were used for the training process of each ML model. The rest of 50 records were used to evaluate the performance of each ML model.

Choosing the proper machine learning algorithm for predicting purposes is not always a straightforward procedure, mainly depending on the inherent characteristics of the problem to solve. Thus, for each ML model a comparison study was elaborated between four regression ML algorithms (linear regression, extreme gradient boosting regressor – XGBoost, random forest regressor and bagging regressor). The root mean square error (RMSE), i.e. error between the tested (u_{max} / $F_{s,max}$) and predicted value ($\hat{u}_{max}$ / $\hat{F}_{s,max}$), as well as the mean absolute error (MAE) ware adopted as measures of performance of the machine learning algorithms. Table 2 shows the RMSE value of each of the four machine learning algorithms. It is shown that all of the four algorithms exhibit more or less the same performance with the random forest regressor to perform best in both cases. The tested vs predicted values of each machine learning algorithm are depicted in scatter plots of Figure 2.

	RMSE		MAE	
Model	u_{max}	$F_{s,max}$	u_{max}	$F_{s,max}$
Linear Regression	7.73E-04	8.93E-02	4.30E-04	5.80E-02
XGBoost	8.20E-04	5.66E-02	4.29E-04	4.46E-02
Random Forest	7.67E-04	5.63E-02	4.65E-04	4.22E-02
Bagging	8.55E-04	5.82E-02	5.12E-04	4.24E-02

Table 2: RMSE of the four machine learning algorithms.

The XGBoost regressor was selected as a compromise between the performance and the robustness of the algorithm, in order to further investigate the importance of each feature of the ML models. Figure 3 shows the ten most important features of the XGBoost regressor with its score. It is clearly shown the first three pulses amplitudes (A_1, A_2 and A_3), as well as F_y have an important role in the predictive performance of both ML models. The performance of each machine learning algorithm by fine tuning the number of the most important features is shown in Figure 4. It is shown that XGBoost outperforms the other three algorithms in all cases. In addition, it is worth noticed that the performance of linear regression model remains relatively stable even though the number of important features are high, because of the inability to represent the inherent nature of the problem due to its nonlinearity.

4 CONCLUSIONS

We propose a robust machine learning pipeline to estimate the nonlinear response analysis of multi-DOF systems in terms of their maximum displacement/ductility aiming to eliminate the computational cost of the NRHA analysis. A pulse extraction process is used to quantify the wavelet parameters of a ground motion records which, along with the material parameters of the structural system consist an adequate training data set. The applicability and efficiency of the proposed approach is demonstrated first in a single-DOF oscillator that is used as a benchmark example. A comparison study between various ML regression models shown that XGBoost regressor can be selected as a compromise between the performance and the robustness. It is shown that the performance of linear regression model remains relatively stable even though the number of important features of the ML regression models are high, due to the inability in representation of the nonlinear inherent nature of the problem.

Keywords: Stochastic modeling, Identification of stochastic processes, voice production, mechanical models, jitter

Abstract. *The aim of this paper is to use Artificial Neural Networks (ANNs) to solve a nonlinear inverse stochastic problem to identify a random process related to the stiffness of the vocal folds in a voice production model. The identification will be performed using the power spectral density function associated with the random process, which has two control parameters. For each pair of these parameters, realizations of the glottal signal are generated. This acoustic pressure signal is obtained just after the air passing through the vocal folds, which is filtered and amplified by the vocal tract generating the voice. As the stiffness of the vocal folds model is taken as a stochastic process, jitter phenomenon, characterized by the deviations of the glottal time interval in relation to a mean value, is present in each realization of the glottal signal. For each glottal signal obtained a set of measures can be extracted and this set is used as the input for an ANN constructed to solve the corresponding inverse problem.*

1 INTRODUCTION

The phonatory system is one of the most important sensory structures and, therefore, it is one of the main agents of the language. The voice has a fundamental importance in the transmission of knowledge, feelings and emotions. Over the years, researchers have had interests in some aspects of the human voice due to its peculiarities and actions in society

The phonation occurs when the glottis closes (adduction) and a column of air, expelled from the lungs, forces passing through the vocal folds. Then, pulses of air are produced forming a (quasi-)periodic acoustic pressure signal called the glottal signal, which goes into the vocal tract (portion that goes from the glottis up to the mouth), where it is filtered, amplified, and finally radiated by the mouth generating the sound we hear.

The glottal signal is not exactly periodic due to small deviations in relation to a mean value of the glottal time interval called jitter. This random phenomenon has practical applications as the identification of pathologies from the vocal folds, identification of voice aging, voice recognition, speaker recognition and other [1, 2, 3]. There are different objective ways to measure jitter as, for example, the absolute jitter and the local jitter. In general, values of local jitter between 0.1% and 1.04% indicate normal voice, that is, a voice that is not symptomatic of a pathology [4].

In this work, it is taken into account a simplified mechanical one-mass-spring-damper model for the generation of jitter, which considers the unification of two deterministic models named Qureshi model [5] and Gomes Model [6], and the stiffness is modelled as a stochastic process. Then, an artificial neural network (ANN) is trained to substitute the non-linear mapping from voice features to some control parameters of the numerical model. Random realizations of voice signals are obtained from the model and features are extracted from each realization. The features are used as inputs for the ANN and the corresponding inverse stochastic process is solved; that is, the stochastic model of the stiffness is identified using two control parameters of its power spectral density.

2 UNIFIED STOCHASTIC MODEL

The idea is to construct a stochastic model for the vocal folds based on the source-filter theory, where the source, the glottal signal, is obtained through a mathematical/mechanical model. However, before discussing the stochastic model, the corresponding deterministic model, also original, is constructed based on two other models from the literature, named: the Qureshi model [5] and the Gomes model [6]. Both models generate the glottal signal, the source, and the final idea is to consider the best characteristics of each model to construct the proposed unified deterministic model.

The sketch considered for the unified model is the one proposed by Qureshi and reproduced in Fig. 1: The movement of each vocal fold is given by a rotary motion about its support point

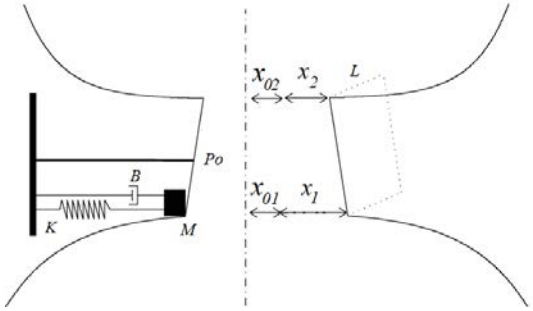

Figure 1: Sketch of the Qureshi model.

P_0. A single mass-spring system with mass M, spring constant K, and damper, with damping constant B, is attached to the glottis at its entrance. The model is assumed to be symmetric about its central line so that the left side of the vocal fold is the same as its right one. The glottal entry displacement is represented by $x_1(t)$, while $x_2(t)$ corresponds to the glottal exit displacement. The vertical component of the fulcrum point divides the glottis in two parts that are assumed to have the same length. The characteristic of a nonlinear damping is introduced in the model, according to the Gomes model, and the equation of the motion for a single vocal fold is described by

$$M\ddot{x_1}(t) + B(1 + \eta\, x_1^2(t))\, \dot{x}_1(t) + K(t)\, x_1(t) = P_g(t)\,. \tag{1}$$

The mean glottal pressure P_g is given by

$$P_g(t) = \frac{2\tau P_{sub}\dot{x}_1(t)}{K_t(x_0 + x_1(t))}\,, \tag{2}$$

where P_{sub} is the subglottal pressure, τ is the glottal time delay, x_0 is the mean position of oscillation of the vocal folds in the middle of the glottis, η is the nonlinear coefficient damping, and k_t is the coefficient of transglottal pressure.

Considering x_{01} and x_{02} the rest position, pre-phonation, of the vocal folds in the glottal input and output, respectively, L the width of the vocal folds, and $x_2(t) = -r(x_1(t) - x_0)$, according to [7], the glottal flow $u_g(t)$ is given by Eq. 3:

$$u_g(t) = \sqrt{\frac{2P_{sub}(t)}{k_t\,\rho}} A_{out}(t)\,, \tag{3}$$

where ρ is the air density and $A_{out}(t)$ is given by Eq. 4:

$$A_{out}(t) = \begin{cases} 2L(x_{02} + x_2(t))\,, & x_2(t) > -x_{02} \\ 2Lx_{02}\,, & \text{otherwise}\,. \end{cases} \tag{4}$$

After generating $u_g(t)$, the convolution with the filter (vocal tract) should be performed to produce the sound we hear. However, this work is concentrated in the glottal signal. The next step is the construction of the stochastic model of the vocal folds based upon the unified deterministic model proposed here.

The objective is to vary the frequency of the voice signal. As the mass is fixed, the stiffness is considered as a stochastic process following some ideas proposed by [8] with the corresponding changes, because the model created here does not consider the coupling between the vocal tract and the vocal folds.

Let E be the mathematical expectation. The stochastic process $K(t)$, indexed by $\mathbb{R}$, is constructed according to the properties defined as follows.

1. For all t, $0 < k_0 \leq K(t)$, where k_0 is a positive constant independent of t.

2. $K(t)$ is a non-Gaussian stationary stochastic process such that $E\{K(t)^2\} < +\infty$ for all t (second-order stochastic process), for which its mean function (that is independent of t) is written as $E\{K(t)\} = \underline{K} > k_0 > 0$, and which is assumed to be mean-square continuous in order to guaranty the existence of a power spectral measure.

A representation of the stochastic process K is chosen as described by

$$K(t) = K_0 + (\underline{K} - K_0)(\bar{z} + Z(t))^2, \tag{5}$$

where $\{Z(t), t \in \mathbb{R}\}$ is a second-order Gaussian stochastic process, centered, mean-square continuous, stationary and ergodic, physically realizable, and $\bar{z}$ is a constant such that for all real t, $E\{(\bar{z}+Z(t))^2\} = 1$, $E[K(t)] = \underline{K}$, and $E\{(\bar{z}+Z(t))^4\} < +\infty$, because $E\{K^2(t)\} < +\infty$. Then, $Z(t)$ can be seen as the response of a linear filter such that $Z(t) = (h * N_\infty)(t)$, where N_∞ is the centered Gaussian white noise with power spectral density $S_{N_\infty} = \frac{1}{2\pi}$ and where the frequency response function of the filter is the Fourier transform given by Eq. 6:

$$\widehat{h}(\omega) = (\mathcal{F}\{h\})(\omega) = a/(i\omega + b)\,. \tag{6}$$

The stochastic process $Z(t)$ can be obtained solving the linear Itô stochastic differential equation that is written as Eq. 7:

$$dY(t) = -b\,Y(t)\,dt + a\,dW(t)\ \ ,\ \ t > 0\,, \tag{7}$$

with initial condition $Y(0) = 0$ and where W is the normalized Wiener stochastic process with real value, indexed by $[0, +\infty]$. When $t_0 \to +\infty$, the stochastic process $\{Y(t), t > t_0\}$ goes asymptotically to the stationary stochastic process Z. Taking a sufficiently large value of t_0, Eq. (7) is used to generate realizations of the stochastic process $Z(t)$. Following Eq. (1), and considering the displacement of the vocal folds as a stochastic process, $x_1(t)$ becomes $X_1(t)$, and the dynamics of the vocal folds is then given by the stochastic differential equation Eq. 8:

$$M\ddot{X}_1(t) + B\,(1 + \eta\,X_1^2(t))\,\dot{X}_1(t) + K(t)\,X_1(t) = P_g(t)\ . \tag{8}$$

All the other equations related to the unified deterministic model should be rewritten substituting $x_1(t)$ and $x_2(t)$ by $X_1(t)$ and $X_2(t)$, respectively. With these modifications, the voice signals generated will indicate the presence of jitter and to quantify its level present in each voice signal, some measures are calculated.

2.1 MEASURES

For each glottal signal, measures will be extracted. They are: four jitter measures, HNR (harmonic richness fator), dH12 (difference between the first and second harmonics), mean and standard variation of the fundamental frequency, the 10 first hamonics and two time measures relating the opening time and the closing time of the vocal folds with the total glottal interval.

Jitter measures and frequency measures will be discriminated in the following.

2.1.1 Jitter measures

First of all, four jitter measures are considered: absolute jitter, relative jitter, jitter rap and jitter ppq5, defined in the following.

- Absolute Jitter (Jit_{abs}): it is the cycle-to-cycle variation of the fundamental frequency, i.e, the average absolute difference between consecutive periods, in seconds, given by

$$Jit_{abs} = \frac{\sum_{i=1}^{N-1} |T_{i+1} - T_i|}{N-1}, \tag{9}$$

  in which T_i is the time interval of each complete glottal cycle and where N is the number of intervals considered.

- Relative Jitter (Jit_{rel}): it is the average absolute difference between consecutive glottal intervals, divided by the average period, and given by

$$Jit_{rel} = \frac{Jit_{abs}}{\frac{\sum_{i=1}^{N} |T_i|}{N}}. \tag{10}$$

  In general, relative jitter values between 0.1% and 1.04% are considered as normal voices indicator, without pathological characteristics.

- Rap Jitter (Jit_{Rap}): is the three point period perturbation quotient jitter.It is computed as the average absolute difference between a period and the average of it and its two closest neighbors divided by the average period.

- PPQ5 Jitter (Jit_{PPPQ5}): is the five point period perturbation quotient jitter. It is computed as the average absolute difference between a period and the average of it and its four closest neighbors divided by the average period.

2.2 Frequency measures

First is $H1 - -H2$ or $dH12$ which is the difference of the first and second harmonics of the glottal frequency spectrum waveform in decibel. Another similar parameter is harmonic richness factor (HRF), which is defined as the ratio between the sums of the amplitudes of harmonics above the fundamental frequency and the magnitude of the fundamental frequency or the first harmonic in decibels. It is shown by the Eq. 11:

$$HRF = \frac{\sum_{r \geq 2} H_R}{H_1} \tag{11}$$

Here H_R represents the magnitude of the rth harmonic.
The third measure considered is the magnitude of the first 10 harmonics.

3 SIMULATIONS

In this section, simulations with the stochastic model proposed are performed. The variation of the parameter a, from Eq. 7, is considered. All the other parameters will be fixed and their values are given in Tab. 1.

Parameters	Values
M	$0.476\,g$
B	$100\,Nsm^{-1}$
η	5000
Pm	$800\,Pa$
Kt	1.1
τ	$0.001\,s$
x_0	$0.01\,cm$
x_{01}	$0.001\,cm$
x_{02}	$0.001\,cm$
ρ	$1.15 \times 10^{-2}\,kgm^{-3}$
L	$1.4\,cm$
b	1000000
k_0	$200\,Nm^{-1}$

Table 1: List of parameters and their values.

For the simulations, it is important to perform a convergence analysis, mainly for the solution of the Itô stochastic differential equation used to generate realizations of $K(t)$. Then, asymptotically stationary and ergodic solutions have been considered and, the mean value and the second moment of $K(t)$ have been estimated by

$$E\{K(n)\} = \lim_{n\to+\infty} \overline{K}(n) \quad , \quad \overline{K}(n) = \frac{1}{n}\sum_{i=0}^{n} K(i)\,; \tag{12}$$

$$E\{K^2(n)\} = \lim_{n\to+\infty} \overline{K}^2(n) \quad , \quad \overline{K}^2(n) = \frac{1}{n}\sum_{i=0}^{n} K^2(i)\,. \tag{13}$$

Figure 2 show three cases of glottal signals considering different levels of jitter, taking into account different values of a, showing that it is possible to generate the phenomenon with the model proposed.

Table 2 shows different values of jitter, and two corresponding measures, considering different values for a, in the the case of normal voices, without pathological characteristics (the first two values of a) and also three cases of voices with pathological characteristics (the last three values of a).

The glottal interval, that is, the total time of a complete glottal cycle, is a random variable and its inverse, $F_0 = \frac{1}{T}$, is the random variable called the fundamental frequency.

4 INVERSE PROBLEM WITH AN ARTIFICAL NEURAL NETWORK

The methodology proposed uses Artificial Neural Networks (ANN) to map from the features extracted of the glottal signal to the two parameters of the power spectral density.

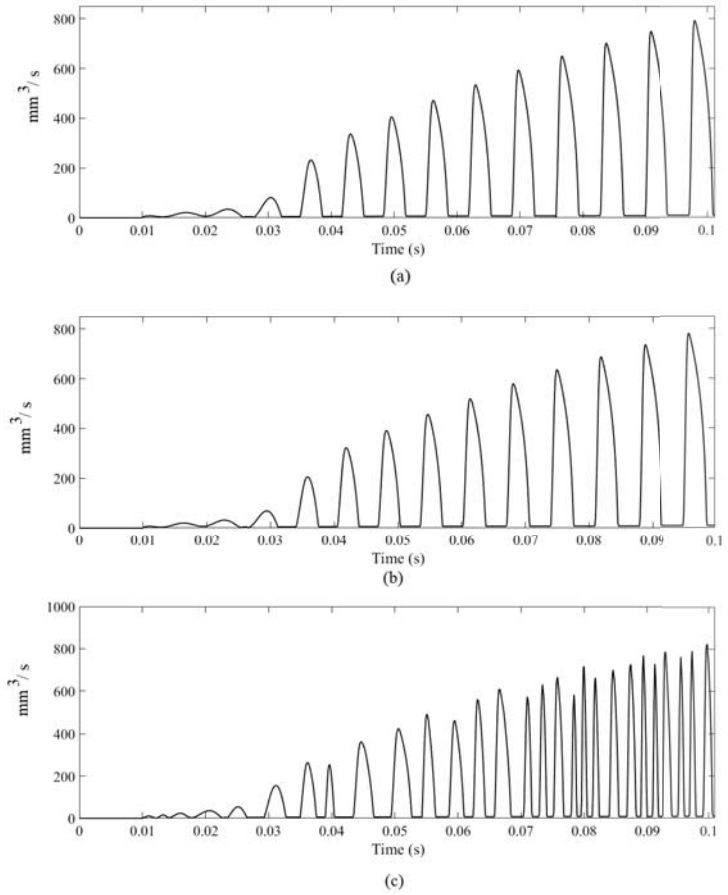

Figure 2: (a) Glottal signal without jitter $a = 0$, (b) Glottal signal with $Jit_{loc} = 0.5\%$ and (c) Glottal signal with $Jit_{loc} = 6.13\%$.

The stochastic process $U_g(t)$, the glottal signal, is represented in this work as a non-linear mapping of a vector $[a, b]$ through the stochastic model presented. To invert this mapping, using ANNs, it is required to extract a vector of features from $U_g(t)$ for which the ANN can learn to estimate the random vector $[a, b]$, according to Eq. 6.

The inputs of the constructed neural network, corresponding to the features extracted from the glottal signal, will then be: (i) the mean value of the fundamental frequency; (ii) the standard deviation of the fundamental frequency, (iii) dH_{12}, HRF, the four measures of Jitter (Absolute, Local, Rap and PPQ5), the values of the first **ten** harmonics and two time coefficients called $Open_1$, defined as the ratio between the opening time interval of the vocal folds and the total glottal interval, and $Open_2$ defined as the ratio between the closing time interval of the vocal folds and the total glottal interval. There are 22 parameters to be considered for the ANN. Clearly, some of these parameters give redundant information.

The methodology applied to solve the inverse problem can be divided in two parts: the first part consists in producing a training set for the ANN, by solving the direct problem; i.e, given a and b, parameters from the spectral density of the stochastic process related to the stiffness K, it is possible to generate realizations of the glottal signal and to extract all the parameters. The second part corresponds to the inverse problem; i.e, given the features extracted from the glottal signal, values from a and b are obtained.

The methodology is described in the following:

a	*Absolute Jitter*	*Local Jitter*
160	2.27×10^{-5}	0.34%
200	3.25×10^{-5}	0.50%
500	1.72×10^{-4}	2.70%
700	1.88×10^{-4}	3.00%
1000	3.78×10^{-4}	6.13%

Table 2: Absolute and local *jitter for voices without pathological characteristics and also with pathological characteristics.*

1. A set is created containing 10000 realizations of the pair (a, b) and the mathematical/mechanical model of the vocal folds is used to generate the glottal pulse; that is, 10000 realizations of the glottal pulse are obtained. For each realization, the set of features are extracted.

2. An artificial neural network is created, from the last item, in order to obtain more realizations of the glottal signal. The ANN created is a A feedforward multi-layer perceptron (MLP) network and the Levenberg-Marquardt optimization algorithm is used during learning phase. It solves the direct problem and uses 70% of the realizations for training, 15% for testing and 15% for validation. With the ANN created 30000 realizations are obtained and this is used for the extension of the results of the corresponding mechanical model. The inputs a and b are normalized because the scale of these values are very different. Considering $\mathbf{x}$ the vector containg the values x_i corresponding to the input (a or b).

3. It is important to normalize the inputs because the scale of their values are much different. The idea is to normalize all the values inside the interval $[-1, 1]$. Considering min_x and max_x the minimum and the maximum of the range of the parameter x, the values of x normalized, denoted by x_{norm} is given by Eq. 14:

$$\mathbf{x_{norm}} = \frac{(x - min_x)(2)}{max_x - min_x} - 1\,. \tag{14}$$

4. Then, an ANN is constructed for solving the corresponding inverse stochastic problema. Again, a feedforward multi-layer perceptron (MLP) network is constructed and the Levenberg-Marquardt optimization algorithm is used during learning phase. The training set of realizations is divided in three parts: 70% of the realizations are used for training, 15% for testing the network performance during training and 15% for the validation check. As the scale of the input/output parameters of the ANN are very different, a normalization is performed in all the inputs so that any realization of the training set lies between -1 and 1. The 30000 realizations of the vector of features were used as input to obtain 30000 realizations of the output; that is, realizations of pair (a, b).

   All the simulations were performed using the Matlab® Neural Networks Toolbox.

5 RESULTS

An example will be presented at first.

1. The values of a and b obtained were such that the variation of a was from 50 up to 4500, with step 10, and the variation of b was from 100000 to 1500000, with step 2000. These

values were considered as inputs for the ANN created to solve the direct problem; that is, after having been obtained values with the corresponding mechanical model. With this extension, more values of the features of the glottal signal could be obtained and it is very important to train the ANN.

2. Then, a new ANN was created to solve the corresponding inverse problema. The values obtained from the last item were used as inputs for this new ANN.

3. A confusion matriz was constructed and shown in Fig. 3:

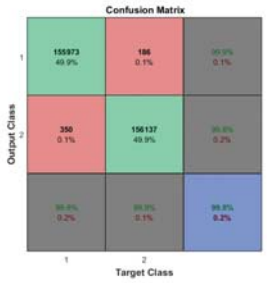

Figure 3: Confusion matrix.

4. Some tests were performed with specific values. The Tab. 3 shows some results:

position	$(\mathbf{a}, \mathbf{b})desired$	$(\mathbf{a}, \mathbf{b})obtained$
200	$(50, 498000)$	$(70, 498750)$
1000	$(50, 696000)$	$(70, 699900)$
5000	$(120, 284000)$	$(120, 277940)$
20000	$(330, 842000)$	$(330, 841890)$

Table 3: Absolute and local *jitter for voices without pathological characteristics and also with pathological characteristics.*

In the following, an experimental case is performed.

An audio produced by a woman, of a vowel /a/, is used. At first, using an inverse filtering method (the so-called IAIF) the corresponding glottal signal is obtained. Then, features of the glottal signal are obtained and submitted to the ANN created previously. And the results obtained are in the following: $a = 450$ and $b = 1500000$.

More examples are necessary and clearly there are still some limitations because the experimental signal can give parameters far from the ones trained by the ANN.

6 CONCLUSIONS

A stochastic model to generate voiced sounds with jitter has been proposed based on the unification of two deterministic models from the literature and considering one parameter as a stochastic process, the stiffness of the vocal folds. Two control parameters have been considered for the corresponding power spectral density and they were identified through an Artificial Neural Network created for solving the corresponding inverse stochastic problem.

Considering simulated data, the ANN solved the problem in a very satisfactory way and the challenge is to use this idea to experimental data. An example is presented with experimental data showing that it is possible to do it.

It is important to note that the features extracted from the experimental data should be near the range covered by the ANN and sometimes it can not be possible. Then, the next challenge is to upgrade the model and the ANN, and also the algorithm, to create conditions for identifying parameters corresponding to more general experimental data.

Keywords: Airship, Gust, Probabilistic surrogate, Karhunen Loeve.

Abstract. *In the context of random environment, time-domain simulation of structural responses is often necessary when the structure is nonlinear, but not only : when the structure is linear and the excitation modelled as a non-stationnary non-Gaussian process, Monte Carlo approaches are necessary to identify the probabilistic distribution of the output. In this paper we use a stochastic model developped for non-stationnary and non- Gaussian random processes. It is based on an empirical Karhunen-Loeve expansion of the process constructed from an available data basis. We study the particular case of linear structures: the Monte Carlo becomes particularely simple: one needs only to consider the construction of a low number of responses, corresponding to the deterministic eigen functions of the Karhunen-Loeve expansion, hence avoiding high number of calls to industrial codes. The KL expansion of the response is then obtained directly using these responses and the system output probabilistic characterization can be constructed through Monte Carlo simulation of the KL output model. This approach is used in order to quantify the effect of gusts on a future airship using a database obtained during a winter storm from which a model of vertical gusts isconstructed. Response comparisons for realistic and gusts and the one prescribed by national regulation requirements will be shown.*

1 INTRODUCTION

There exists today a new interest in airship exploitation as appears a need for a safe and sustainable solution that can deliver heavy cargo or personnel to remote communities that have no infrastructures. For instance the Flying Whales start-up has launched a 60 ton capacity airship project which size is unusual: 150 m long, 60 m large and 40 m height.

Figure 1: Flying Whale LCA60T airship project. Source: Flying Whales

New regulations had to be specified in order to certify such modern airships and among them was introduced one dedicated to gust. In the TAR (Transport Airship Regulation) the gust is modeled as an harmonic excitation and the question which arises is how will the airship response to real gusts, which exist within a turbulent wind field, compare to the regulation gust response. Real gusts are random phenomena which can be modeled as non-stationary and non-Gaussian processes. Therefore one needs to characterize the output of the airship to this random excitation. Airship is modeled as a coupled aerodynamic/structure system and due to the very low Mach number involved in airship flight the use of a linearized aerodynamic code is entirely justified. Nevertheless the response characterization goes through a complete Monte-Carlo approach since the input is non-stationary and non-Gaussian which can render the methodology numerically very expensive for high dimension structural models. We show that when the input process can be represented by its Karhunen Loeve expansion, the linearity of the numerical code allows to construct directly the Karhunen Loeve expansion of the response which can be used to generate samples used for constructing various estimators of the response. An illustration will be given on a simplified airship model which will be subject to real gusts identified in given wind measures.

2 PROBABILISTIC MODEL CONSTRUCTION OF OBSERVED SAMPLE PATHS

Three dimensional wind data are relatively scarce and existing gust databases contain insufficient samples in order to be relevant in a Monte Carlo procedure. An enrichment method will therefore be used in order to generate supplementary synthetic samples. This method, based on Karhunen Loeve expansion of stochastic process, is described in [10, 7]. We shall briefly recall the main ingredients.

Karhunen-Loève (KL) expansion provides a suitable framework for modeling a non-stationary scalar random process $X(t,\omega)$:

$$\forall t \in \mathcal{D},\ X(t) = \lim_{N\to+\infty} \sum_{\alpha=1}^{N} \sqrt{\lambda_\alpha}\, \xi_\alpha\, \phi_\alpha(t), \tag{1}$$

in which $\xi_1, \xi_2, \ldots, \xi_\alpha, \ldots$ are uncorrelated random variables given by

$$\xi_\alpha = \frac{1}{\sqrt{\lambda_\alpha}} \int_{\mathcal{D}} < X(t), \phi_\alpha(t) > dt, \tag{2}$$

where the λ_α and $\phi_\alpha(t)$ are the solutions of the integral equation

$$\int_{\mathcal{D}} R_X(t,t')\phi(t')dt' = \lambda\phi(t), \tag{3}$$

and where the limit in (1) is taken in the space $L^2(\Omega, \mathbb{R})$.

Let be given $\mathcal{N}$ measures $\{X^{(l)}(t_i)\ ;\ i = 1, ..., N\}\ ;\ l = 1, \mathcal{N}$ of a random phenomenon sample path. The first step to the KL expansion construction is to estimate the empirical autocorrelation of the underlying process X:

$$R(t_i, t_j) = \frac{1}{\mathcal{N}} \sum_{l=1}^{\mathcal{N}} X^{(l)}(t_i) X^{(l)}(t_j) \tag{4}$$

Solving the discretized eigenvalue problem (3) yields the λ_α and $\phi_\alpha(t_i)$, for $\alpha, i = 1, N$.

The second step is to construct the samples $\xi_\alpha^{(l)}$ using relation (2) which gives an explicit relation :

$$\xi_\alpha^{(l)} = \frac{1}{\sqrt{\lambda_\alpha}} \sum_{i=1}^{N} X^{(l)}(t_i)\phi_\alpha(t_i)\Delta t\ ;\ l = 1, \mathcal{N}\ ;\ \alpha = 1, N \tag{5}$$

where Δt is the sampling time step.

In order to be able to use the KL expansion for simulating the random process X, the last step is to identify the distribution of the random vector $\xi = (\xi_1, ..., \xi_N)$, which in the general case is not Gaussian. This multivariate distribution will be approximated by a Gaussian kernel density estimator :

$$\hat{f}_{\mathcal{N},h}(x) = \frac{1}{\mathcal{N} h^N (2\pi)^{N/2}} \sum_{\ell=1}^{\mathcal{N}} \exp \frac{(x - \xi^{(\ell)})^T (x - \xi^{(\ell)})}{2h^2} \tag{6}$$

where $\xi^{(\ell)}, \ell = 1, \mathcal{N}$ are the observed samples of random variable ξ.

Details on kernel density estimators construction can be found in the following references [3, 9, 8].

Simulation of a multivariate random variable ξ described by the kernel density (6) is straightforward:

- generate a random integer J uniformly distributed on $\{1, 2, ..., \mathcal{N}\}$
- generate a $\mathcal{N}$-dimensional normalized Gaussian random variable $\mathcal{G}$
- construct the sample $\xi = \xi^{(J)} + h \times \mathcal{G}$.

In practice, the approximation due to truncation of the KL expansion is evaluated considering the total energy $\int_{[0,T]} E(X(t)^2)dt$ of the process : $\int_{[0,T]} R_X(t,t)dt = \sum_\alpha \lambda_\alpha$, the relative error ϵ being then defined by:

$$\epsilon = \sum_{\alpha=1}^{N_T} \lambda_\alpha \; / \; \sum_{\alpha=1}^{\infty} \lambda_\alpha = \sum_{\alpha=1}^{N_T} \lambda_\alpha \; / \; \int_{[0,T]} R_X(t,t)dt \tag{7}$$

Numerically, the total energy can be determined from the empirical autocorrelation function of the N trajectories:

$$\int_{[0,T]} R_X(t,t)dt = \sum_{i=1}^{N} R_X(t_i,t_i)\Delta t_i$$

Finally one has to characterize the response of a system to a random excitation modeled as a KL expansion:

$$X(t,\omega) = \sum_{\alpha=1}^{M} \sqrt{\lambda_\alpha}\, \xi_\alpha(\omega)\, \phi_\alpha(t) \quad \rightarrow \quad H \quad \rightarrow \quad Y(t,\omega)$$

When the system is linear it is possible to use the input expression linearity to construct directly a probabilistic model of the system output.

3 RESPONSE OF A LINEAR DYNAMICAL SYSTEM TO KL EXCITATION

There exist many real-life systems which are described using industrial linear codes: in structures, aeronautics, etc. The use of such linear approximations of real structures and systems are still today mandatory in the conception phase or for optimization because high fidelity models are too CPU intensive. This is particularly true for probabilistic analysis based on Monte Carlo approaches. Even in the case of linear systems, there exist no analytic methods to characterize the system output when the excitation is modeled through a non-Gaussian non-stationary process. One has to go through numerical simulations in order to construct various statistical estimators.

Consider a linear system described through a differential equation

$$Y'(t) = A(t)Y(t) + X(t) \; ; \; Y(0) = Y_0 \; ; \; t \in [0,T]. \tag{8}$$

It is well known that its solution can be written

$$Y(t) = H(t,0)Y_0 + \int_0^t H(t,s)X(s)ds \tag{9}$$

where H is the resolvent matrix. Function H is the impulse response function and represents the linear system. It is generally obtained using an industrial code (Nastran, Marc, ...) and its derivation can be computationally expensive for high dimension models such as the ones encountered in aeronautics. When X is a general second order stochastic process defined on

a given probability space $(\Omega, \mathcal{T}, P)$, Monte Carlo approaches have to be used in order to construct statistical estimators of Y, and, even in a linear context, Monte Carlo based probabilistic analysis can become non practical for some applications. When X is approximated through a truncated KL expansion denoting $m_X(t)$ its expectation, relation (9) can be written,

$$Y(t,\omega) = H(t,0)Y_0 + \int_0^t H(t,s)m_X(s)ds + \sum_{\alpha=1}^{N} \sqrt{\lambda_\alpha}\xi_\alpha \int_0^t H(t,s)\phi_\alpha(s)ds, \ ; \ t \in [0,T] \quad (10)$$

The output characterization necessitates only $N+2$ calls of the linear codes, whith N generally less than 100 in order to construct the N deterministic response functions $\psi_\alpha(t) = \int_0^t H(t,s)\phi_\alpha(s)ds$, the initial condition and the mean excitation response. The probabilistic analysis is then achieved generating random linear combinations of these N functions.

4 AIRSHIP AEROELASTIC MODEL

The illustrations given in the following involve an airship model of dimensions $150 \times 60 \times 44$ meters and a weight of 60 tons. The cruise flight altitude is 1000 meter at a speed of 100 km/h. A crude finite element model, sufficiently meaningful for the aeroelastic illustration is used and is represented on figure 2.

The coupled system airship/aerodynamic forces is modeled using the code CAPRI [4, 5] which uses a linearized aerodynamic model based on the doublet lattice method [1]. The use of a linearized model is totally justified for an airship due to the very low Mach number involved: Mach 0.086. The aerodynamic force due to a gust is given in the frequency domain by the relation:

$$\hat{F}(\omega) = T(\omega) \times \frac{\hat{W}(M,\omega)}{V} \quad (11)$$

where V is the airship speed, $\hat{W}(M,\omega)$ the Fourier transform of a gust and $T(\omega)$ the transfer function calculated by the CAPRI code for a set of frequency values. Using a rational approximation of the transfer function allows to build a time domain representation of the force, solving a differential equation [6]. What is considered for certification is the charge factor defined by:

$$N(t) = \frac{F(t)}{Mg}, \quad (12)$$

where M is the airship mass and g the standard gravity.

5 GUST MODELS

The transportation airship requirements imply that the airship structure integrity should not be affected when the airship encounters an isolated gust defined by the following expression

$$v_g = \frac{V_g}{2}(1 + \cos(\pi \frac{x - x_g}{L_g})) \text{ for } |x - x_g| \leq L_g \quad (13)$$

where v_g is the gust speed at the point of coordinate x, x_g is the coordinate of the gust center, V_g is the maximal gust speed located at point x_g, L_g is the gust half length.

Such a gust is of course not representative of real gusts as it will be shown later on. Therefore it is interesting to compare the real gust and the regulation gust effects on the structure. First

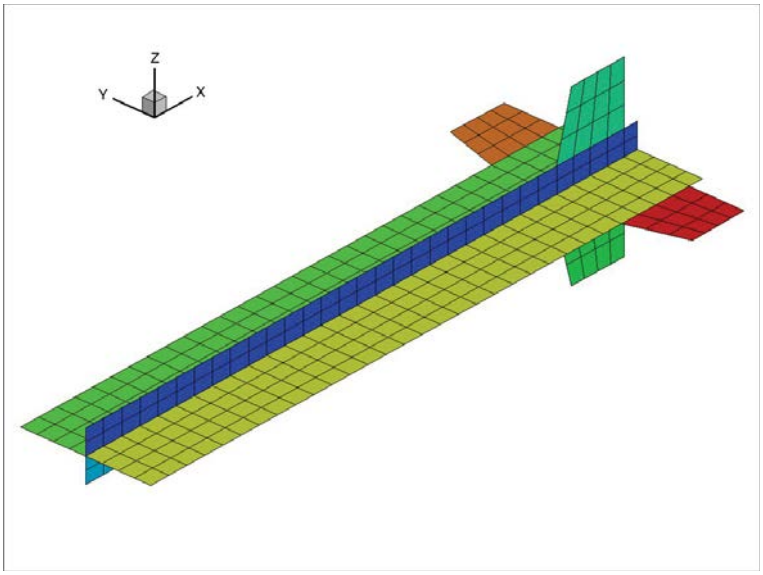

Figure 2: Airship finite element model

it is necessary to define what is a gust: a gust is a short-term wind speed variation within a turbulent wind field. There exist several methods to detect gusts in a wind time history [2], in this application we shall consider what is called the *velocity increment* method: a moving window of length T is shifted along the wind time history $W(t)$ and a gust of amplitude V_g is detected when $W(T) - W(0) = V_g$. There exist several public wind databases available, here

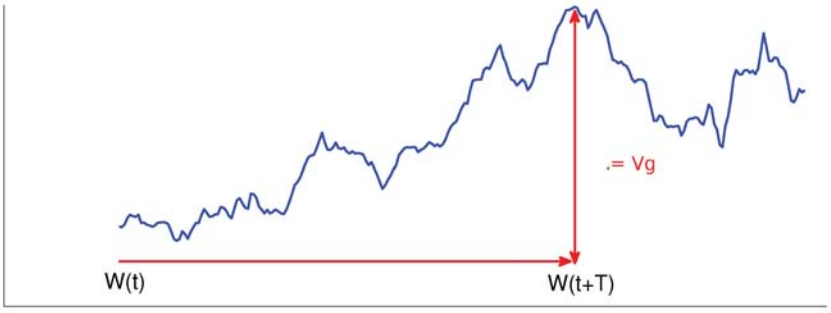

Figure 3: Velocity increment gust detection

we shall use a wind data obtained in a FINO offshore research platform [1] located in the North sea during a winter storm. The three components of the wind have been recorded during three days. Figure 4 shows the longitudinal and vertical component of the wind time history. This last component will be used in order to detect gusts.

6 NUMERICAL ILLUSTRATION

The transportation airship requirements fix the maximum gust speed V_g to 7.6 m/s for an airship speed equal to 100 km/h. The gust half length L_g is chosen equal to 75 m (the airship

[1]FINO: Research platforms in the North Sea and in the Baltic Sea, GL-Windenergie, Hamburg (http://www.fino-offshore.de)

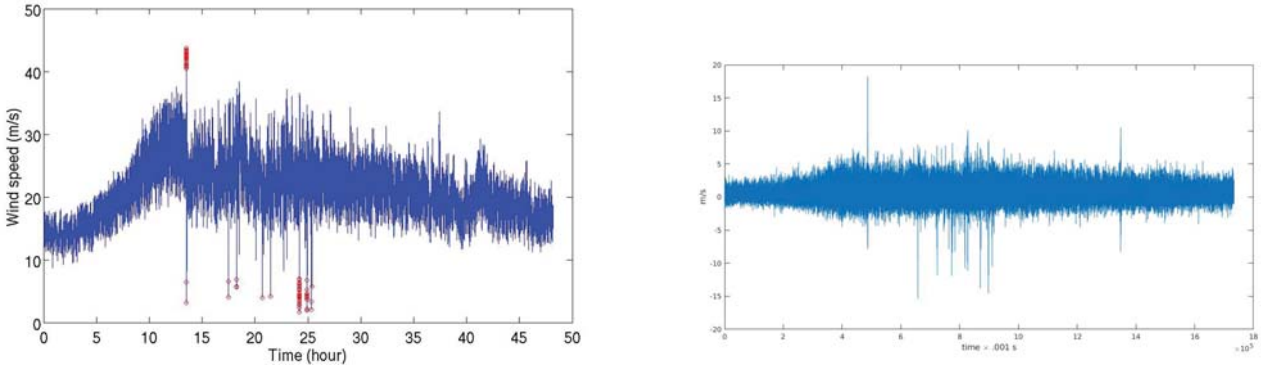

Figure 4: Horizontal and vertical wind time history

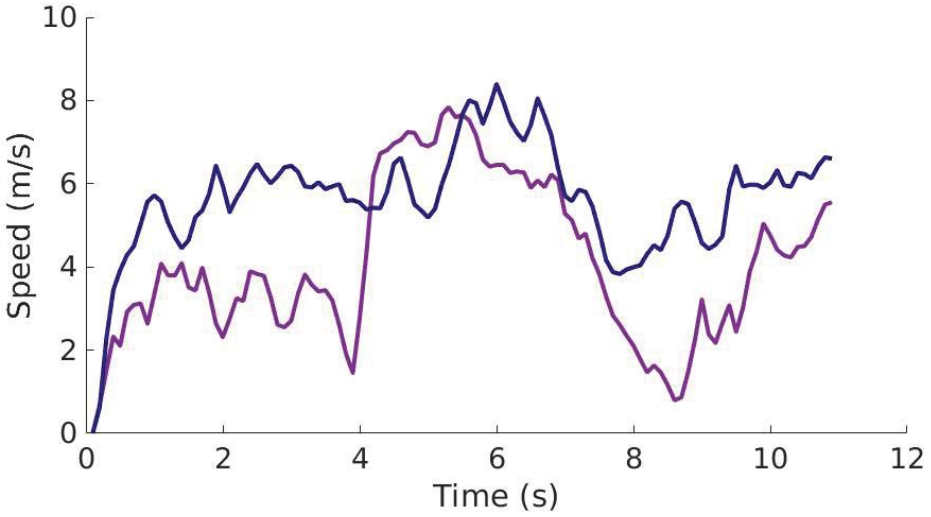

Figure 5: Two detected gusts

length being equal to 150 m). In a first stage we shall detect gusts characterized by the above values of V_g and L_g in the recorded vertical wind time history. Thirty nine gusts are detected and figure 5 shows two of them. Figure 6 compares the mean real gust and the TAR prescribed gust.

6.1 Input simulation

In a second stage the Karhunen Loeve stochastic model of the vertical gusts is constructed using the thirty nine gusts in the database. Thirty four terms are kept in the expansion. Using this model, 5000 gust sample paths are generated, each leading to the calculation of the corresponding charge factor. Figure 7 shows the mean charge factor as well the $\pm\sigma$ dispersion due to the generated gusts compared to the charge factor due to the TAR requirement gust, figure 8 gives the mean number of crossings of the charge factor for different levels.

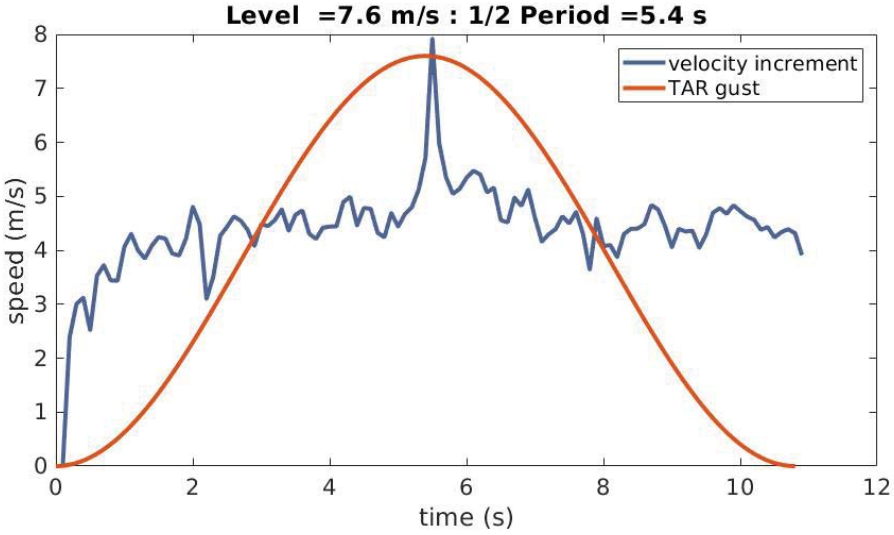

Figure 6: Mean gusts

6.2 Output simulation

We construct now the image of the gust Karhunen Loeve expansion by the linear aeroelastic operator: the input of the operator is the expansion eigen functions and the mean gust. The initial condition in equation 8 is 0. Relation 10 yields the Karhunen Loeve expansion of the random charge factor which can be used to generate additional responses in order to construct various statistical estimates. Again, 5000 simulated responses of the charge factor are generated using the KL image expansion and the same estimators as above are constructed. Figure 9 shows the mean charge factor as well the $\pm\sigma$ dispersion due to the simulated charge factor and, of course, the result is the same as the one shown on figure 7. Figure 10 shows the mean number of crossings of the charge factor for different levels calculated using the input stochastic model or the output stochastic model: the results are identical.

7 CONCLUSION

We have shown in this paper that when a linear system is excited by a stochastic process represented by its Karhunen Loeve expansion, one could directly construct the Karhunen Loeve expansion of any system output, allowing its use for direct Monte Carlo characterization. An illustration has been given related to the identification of an airship response to wind gusts. The gust are represented by a Karhunen Loeve expansion constructed from a database containing turbulent wind time history measures. Results haves shown in particular the important output (charge factor) scattering compared to the one obtained using the transport air requirements.

Keywords: Machine Learning, Earthquake Engineering, Geotechnical Engineering

Abstract. *In recent years there has been a proliferation in the availability of information generated across a range of engineering disciplines. Artificial intelligence techniques such as machine learning have found a wide range of applications as computationally efficient tools to reveal underlying trends in large and complex data sets. This state-of-the-art review discusses recent advances in the application of machine learning to geotechnical earthquake engineering problems. Such algorithms as Gaussian process regression, support vector machines, artificial neural networks, decision trees, random forests and their applications to this field are reviewed. Particular attention will be paid to machine learning applications for earthquake-induced soil liquefaction potential prediction, inelastic response spectra prediction, site-specific spectral acceleration prediction, dynamic soil-structure interaction, slope stability evaluation, shallow and deep foundation capacity prediction, soil and shear strength prediction. The training data set, the machine learning model configuration, the training, and the evaluation process, as well as the generalization capacity of each model, will be examined. The performance of different methods will be compared, and future research challenges will be discussed.*

1 INTRODUCTION

In recent years machine learning (ML) methods as computationally efficient tools to reveal underlying trends in complex problems have found a wide range of applications in many engineering fields. Since the late 1980s techniques like artificial neural networks (ANN) have been applied successfully to many civil engineering problems including geotechnical engineering. The applications of ANNs in civil engineering between 1989 and 2000 are discussed in Adeli's [1] literature review paper. Pre-2001 applications of ANNs to geotechnical engineering are reviewed in detail by Shahin et al. [2], while pre-2010 applications can be found in the review of Shahin et al. [3].

The purpose of this paper is to discuss recent advances in the application of machine learning techniques to geotechnical and geotechnical aspects of earthquake engineering fields. Among the many available ML algorithms in the literature, the ANNs and the support vector machines (SVM) were the most common in these fields. Besides these algorithms, applications of the Gaussian process regression (GPR), decision tree, and random forest algorithms are also included in this review. In order to facilitate the understanding of the ML applications, a brief description of the algorithms, as well as the ML model evaluation methods are given in the next section.

The geotechnical and geotechnical earthquake engineering problems are very complex in their nature and many assumptions are introduced in order to model them with traditional methods. The availability of experimental data, or even in some cases data from finite element analysis, has made the application of ML methods more and more popular in recent years enabling the use of these data as a tool. Many applications can be found in the literature, such as ANN based constitutive models, foundation capacity prediction, soil liquefaction potential prediction and applications to soil structure interaction. In this study, uniaxial compressive strength prediction using ANNs and SVMs, pile capacity prediction models using GPR, SVM and ANNs, shallow foundation capacity prediction using ANN and SVM, soil shear strength prediction, earthquake-induced soil liquefaction potential using SVM, decision tree and random forest, SVM and GPR applications for slope stability prediction, ANN and SVM applications to dynamic soil structure interaction, and applications of ANNs to site specific seismic analysis and inelastic response spectrum prediction are reviewed.

2 THEORETICAL BACKGROUND

Machine learning (ML) is the scientific study of algorithms and statistical models that computer systems use to perform a specific task without using explicit instructions, relying instead on patterns and inference. It is a subset of artificial intelligence. Machine learning algorithms build a mathematical model based on sample data, known as "training data", in order to make predictions or decisions without being explicitly programmed to perform the task [4],[5].

Machine learning algorithms are often categorized as *supervised* and *unsupervised*. In supervised learning, each training example is a pair consisting of an input feature and a desired output and the algorithm analyzes the training data and produces an inferred function, which can be used for mapping new examples [6]. In unsupervised learning, the training data has only the input values and the algorithm identifies commonalities in the data and reacts based on the presence or absence of such commonalities in each new piece of data.

The supervised learning method is used for *classification* and *regression* problems. In classification problems, the outputs are restricted to a limited set of values (a category or a group). Regression problems are named for their continuous outputs, meaning that they may have any value within a range.

There are plenty of algorithms for either task. In this section, the artificial neural networks, support vector machines, Gaussian process regression algorithm, decision trees and random forests, as well as their performance evaluation are briefly discussed.

2.1 Artificial neural networks

The artificial neural network is a computing technique designed to simulate the human brain's method of problem solving. The similarity between the ANNs and the human brain is that they both acquire skills in processing data and finding solutions through training [7]. Artificial neural networks consist of simple computing units "artificial neurons", and each unit is connected to the other units via weight connectors. These units calculate the weighted sum of the inputs and determine the output using an activation function. A schematic representation of an ANN with multiple inputs and a single neuron in the hidden layer (the layer between the input and output layer) is shown in Figure 1. The illustrated ANN has n input features X_1 to X_n and their connections with the unit in the hidden layer is the feature multiplied with its weight w_i and added bias b_i. The single unit in the hidden layer sums all the weighted inputs, applies an activation function f to the sum and passes the output α to the next layer. In this case, the next layer is the output unit Y and it provides the prediction of the ANN for the output value.

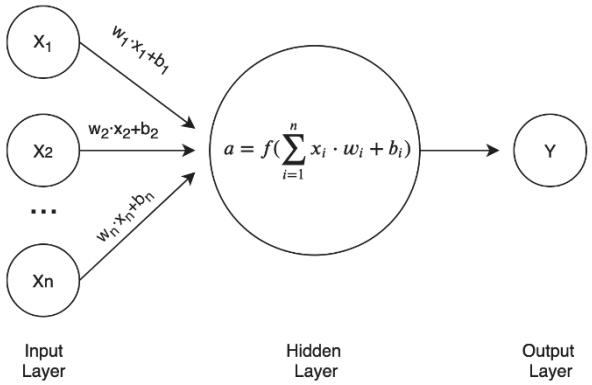

Figure 1: Artificial neural network with single neuron and multiple inputs.

The process of calibrating the values of the weights and biases of the ANN to predict the desired output correctly is called training. In the case of supervised learning, the learning algorithm will adapt the weights and biases depending on the error between the predicted output and the real output. The optimal ANN for a given training set is obtained by minimizing the loss function using an optimization algorithm.

2.2 Support vector machines

Support vector machines (SVM) are supervised learning models for classification and regression. For the binary classification case, the basic idea of a SVM is to find the optimal hyper-plane, i.e. decision surface, for linearly separable patterns, extend to linearly inseparable patterns by transforming the original data to map into new space with the kernel function and

use the SVM algorithm for pattern recognition. Support vectors are the data points that lie closest to the decision surface, and which have direct bearing on the optimal location of the decision surface.

Support vector machines maximize the margin around the separating hyperplane. The decision function is fully specified by the support vectors which are usually a small subset of the training samples. This becomes a quadratic programming problem that can be solved by standard methods. Similar to ANNs, the inputs of an SVM are input-output training pairs and the output is a set of weights *w*, one for each feature, whose linear combination predicts the value of the output. The important difference compared to ANNs is that SVMs use the optimization of maximizing the margin to reduce the number of weights that are non-zero to just a few that correspond to the support vectors.

The optimal separating hyper-plane of an SVM for a binary classification problem is illustrated in Figure 2. Anything on or above the hyper-plane $w \cdot x - b = 1$ is of one class with label 1. Accordingly, anything on or above the hyper-plane $w \cdot x - b = -1$ is of the other class with label -1. The data points on these hyper-planes are the support vectors, while the geometrical distance between them is $\frac{2}{\|w\|}$. The hyper-plane $w \cdot x - b = 0$ is the median of them and it is the optimal separating hyper-plane. The parameter $\frac{b}{\|w\|}$ determines the offset of the hyperplane from the origin.

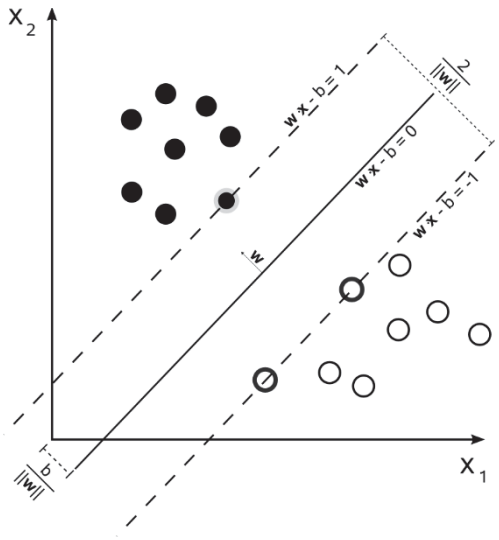

Figure 2: Optimal separating hyper-plane for binary classification.

Support vector machines for regression (SVR) use the same principles as the SVM for classification with only a few minor differences. In the case of regression, a margin of tolerance is set in approximation to the SVM which would have already requested it from the problem. The algorithm in this case is more complicated. However, the main idea is the same: to minimize the error, individualizing the hyperplane which maximizes the margin, keeping in mind that part of the error is tolerated. Details for the mathematical formulation of SVMs and SVRs are discussed by Christianini and Shawe-Taylor [8].

2.3 Gaussian process regression

In probability theory and statistics, a Gaussian process is a stochastic process (a collection of random variables indexed by time or space), such that every finite collection of those random variables has a multivariate normal distribution, i.e. every finite linear combination of them is normally distributed. The distribution of a Gaussian process is the joint distribution of all those random variables.

A machine learning algorithm that involves a Gaussian process uses lazy learning and a measure of similarity between points (the kernel function) to predict the value for an unseen point from training data. In a training set where x_i are the input features and y_i is the output, a Gaussian process regression model addresses the question of predicting the value of a response variable y_{new} given the new input vector x_{new} and the training data. The prediction is not just an estimation for that point but also has uncertainty information. It is a one-dimensional Gaussian distribution. The mathematical formulation of the GPR algorithm can be found in Rasmussen and Williams [9].

2.4 Decision trees and random forest

Decision trees build classification or regression models in the form of a tree structure. It breaks down a data set into smaller and smaller subsets while at the same time an associated decision tree is incrementally developed. The final result is a tree with decision nodes and leaf nodes. A decision node has two or more branches. Leaf nodes represent a classification or a decision. The topmost decision node in a tree, which corresponds to the best predictor, is called the root node. Decision trees can handle both categorical and numerical data.

The random forest is an algorithm consisting of many decision trees used for both classification and regression problems. It uses bagging and feature randomness when building each individual tree to try to create an uncorrelated forest of tree whose prediction by committee is more accurate than of an individual tree.

2.5 Bias and variance of machine learning models

How satisfactory the performance of an ML model depends on its predictions and how well it generalizes on an unseen data set. The bias variance trade-off is a way of analyzing the expected generalization error of a learning algorithm, with respect to a particular problem as a sum of three terms, the bias, the variance, and a quantity called the irreducible error, resulting from noise in the problem itself. It can be applied to all forms of supervised learning [10].

The bias is an error from erroneous assumptions in the learning algorithm. In other words, it is the difference between the average prediction of the model and the correct target value. Models with high bias pay very little attention to the training data and oversimplifies the model. It always leads to high error with training and test data. The variance is an error from sensitivity to small fluctuations in the training set. High variance can cause an algorithm to model random noise in the training data rather than the intended output. Models with high variance pay a lot of attention to training data and do not generalize with unseen data. As a result, such models perform very well on training data but have high error rates on test data.

In supervised learning underfitting happens when a model is unable to capture the underlying pattern in the data. Such models usually have high bias and low variance. Conversely,

overfitting happens when a model captures the noise along with the underlying pattern which occurs when trained with a noisy data set. These models have low bias and high variance.

2.6 Evaluation of machine learning models

To obtain a model that generalizes well on unseen data, there is a need to minimize the total error finding a good balance between bias and variance. Hence, there is a need to find a way to accurately measure the prediction error of the model. A common approach is using the data itself to estimate the prediction error.

The simplest technique for this approach is the holdout set method, splitting the data initially into two groups. One group is used to train the model and the second group is used to measure the model's error after training. Another commonly used approach is the cross-validation method which works by splitting the data into sets of *n* folds. The training and error estimation process is repeated *n* times. Each time *n-1* groups are combined and used to train the model. The group that was not used in the training is used to estimate the prediction error. The final error of the ML model is the average of the *n* calculated errors.

3 UNIAXIAL COMPRESSIVE STRENGTH PREDICTION

Cevik et al. [11] used the results of laboratory experiments as training data and developed an ANN model to estimate the uniaxial compressive strength of some clay-bearing rocks selected from Turkey, giving an emphasis on assessing the role of slake durability indices and clay contents. They performed X-ray diffraction analyses, slake durability index tests and the uniaxial compressive strength test on selected samples from Soma and Eskisehir regions. Then, they developed ANN based constitutive models for clay-bearing rocks based on the experimental data. The input features of the ANN model were the origin of the rocks, two/four cycle slake durability indices and the clay contents, while the output was the uniaxial compressive strength. They used 80% of the training data for training and 20% for testing. Their study showed that the ANN method had quite satisfying accuracy compared to other models.

Ceryan et al. [12] developed an ANN model to predict the uniaxial compressive strength of carbonate rocks. They collected 56 groups of block samples from the Tasonu Quarry in Trabzon, Turkey and performed X-ray diffraction analyses, and test such as, specific density, unit weight, porosity, P-wave velocity, slake durability, aggregate impact value and uniaxial compressive strength. They used all possible regression technique in order to select the input features for the ANN model. They used the total porosity and the P-wave velocity in the solid part of the sample as input features for the ANN, while the output was the uniaxial compressive strength. They used 80% of the training data for training and 20% for testing. They compared the results of the ANN model with multiple linear regression model and they concluded that the ANN model was capable of modeling the uniaxial compressive strength.

Tinoco et al. [13] proposed a SVM model to predict the uniaxial compressive strength of jet grouting columns. The training data set included 472 data points collected from different columns constructed in different places with different soil properties. The uniaxial compressive strength of each sample was obtained from an unconfined compression test with sample strain instrumentation. The proposed model had 9 input features, which were the relation between the mixture porosity and the volumetric content of cement, the age of mixture, the percentage of clay, the jet grouting method, inverse of the dry density of soil cement mixture, the void ratio, the cement content, the water content and the water cement ratio. To assess the generalization

capacity of their model they used 20-fold cross-validation method, which had an acceptable final error.

4 PILE CAPACITY PREDICTION

Pal and Deswal [14] developed a GPR model to predict the load-bearing capacity of piles and compared its results with an SVM model and empirically derived relationships. They used a data set which was derived from actual pile-driving records in cohesion less soil to train both models. Out of a total of 94 data points, they used 59 for training and 35 for testing. The results of this data set indicated that the GPR algorithm had improved performance compared with SVM and empirical relationships. Additionally, they used another data set consisting of 38 pieces of data to validate the performance of the GPR model.

Samui and Kim [15] developed a least square SVM and multivariate adaptive regression spline (MARS) to predict the lateral load capacity of pile foundations. They use the pile diameter, pile embedment depth, load eccentricity and undrained shear strength of the soil as input features for their models. Their data set had 41 data points, and they used 31 of them for training and the remaining data points for testing. They concluded that the developed models outperform the other available methods.

Kordjazi et al. [16] developed three SVM models with different kernel functions to predict the ultimate axial load-carrying capacity of piles based on cone penetration test (CPT) data. They used a data set consisting of 108 data points obtained from the literature. They used the type of static pile load test, pile material, method of installation, pile tip (closed or open), embedded length, pile-soil contact perimeter, cross sectional area of the pile tip, average cone tip resistance along the embedded length of the pile, average sleeve friction, and the average cone tip resistance beneath the pile tip as input features of the SVM model. The ultimate load bearing capacity of the pile was the single output variable. They used 83 data points for training and 25 for testing. They concluded that the SVM model with the radial basis kernel function and the Pearson VII kernel function had the best results. They compared the performance of the SVM model with CPT-based methods for determining the pile capacity. The comparison showed that the SVM models provide more accurate pile capacity prediction.

Momeni et al. [17] proposed an ANN model to estimate the axial load bearing capacity of piles. In order to create the training data, they performed 36 pile driving analyzer tests at various sites in Indonesia. The tested piles were reinforced and pre-stressed concrete piles with varying lengths and diameters and most of the tests were conducted in cohesionless soils. To represent the soil characteristics, the results of soil penetrations tests (SPT) were collected. The average SPT values along the pile shaft and tip, the pile length, the pile area and the pile set were used as input features. The output variables of the ANN were the shaft, tip and the ultimate bearing capacity of the pile. Their study indicated that the ANN model results were in a close agreement with those obtained from high strain dynamic pile testing.

Moayedi and Rezaei [18] developed an ANN model to predict the ultimate uplift capacity of under-reamed piles embedded in dry cohesionless soil. The training data, which had 432 data points, was obtained from small-scale laboratory work from a previous study. The input features of the ANN model were the base diameter, the angle of the enlarged base, the shaft diameter, and the embedment ratio, while the singe output of their model was the ultimate uplift resistance. The results of the ANN model they proposed showed that it can be applied to precisely predict the experimental results.

5 SHALLOW FOUNDATION CAPACITY PREDICTION

Ziaee et al. [19] proposed an ANN model to predict the bearing capacity of shallow foundations on rock masses using as training data a comprehensive database of rock socket, centrifuge rock socket, plate load, and large-scaled footing load test results. The database included the results of experiments on circular and square footings of different sizes on various types of rock masses. They used 85% of the data set for training and 15% for testing. The input features of the ANN model were the rock mass rating, the unconfined compressive strength of rock, the ratio of joint spacing to foundation width, and the angle of internal friction of the rock mass. The output was the ultimate bearing capacity of the foundation. Their study concluded that the ANN model had notably better performance than the traditional equations.

Moayedi and Hayati [20] used various ML algorithms such as feed forward neural network, radial basis neural network, SVM, tree regression fitting model and adaptive neuro-fuzzy inference system to predict the ultimate bearing capacity of strip footing near a slope. The training data were obtained from extensive finite element modeling of a shallow strip footing located near a homogenous sandy slope. The input features of the ML models were the soil type, the slope angle, the setback ratio and the applied load on the footing and the single output of the models was the settlement of the footing. The comparison of the models showed that the feed forward neural network had the most accurate results.

6 SOIL SHEAR STENGTH PREDICTION

Pham et al. [21] developed four ML methods to predict the shear strength of soft soils and compared their results. The methods they used were ANN, particle swarm optimization – adaptive neuro-fuzzy inference system, genetic algorithm - adaptive neuro-fuzzy inference system, and SVR. They used case studies of 188 plastic clay soil samples collected from Nhat Tan and Cua Dai bridge projects in Vietnam as training data. The input features of the models were the moisture content, clay content, liquid limit, and the plastic limit and the single output feature was the shear strength of the soil. They concluded that out of the four models the particle swarm optimization – adaptive neuro-fuzzy inference system performed best.

7 SOIL LIQUEFACTION POTENTIAL PREDICTION

Samui et al. [22] proposed two SVM models for classification based on actual shear wave velocity data in order to evaluate the seismic-liquefaction potential. The training data included information of soil characteristics and earthquake parameters. Out of 186 available data points, they used 130 for training and 56 for testing the SVM models. For the soil characteristics based SVM model the input features where the effective vertical stress, the soil type, the shear wave velocity, the peak horizontal acceleration, and the earthquake magnitude. For the shear wave velocity based model the input features were the shear wave velocity, the peak horizontal acceleration and the magnitude. For both cases the output of the models was whether liquefaction occurs or not. Their study indicated that the shear wave velocity based SVM model was sufficiently capable to predict the liquefaction potential.

Samui [23] developed a SVM model for classification in order to predict soil liquefaction based on actual CPT data from the 1999 Chi-Chi, Taiwan earthquake. He used the cone resistance, cyclic stress ratio, local friction, pore pressure, total stress, effective stress, peak ground surface acceleration and earthquake magnitude as input features. The proposed model had 100% prediction accuracy. Furthermore, he simplified the model using only two input

parameters, the cone resistance and the peak ground surface acceleration. The second model had 89% prediction accuracy. He concluded that the SVM model was a robust method for classifying liquefaction potential.

Lee and Chern [24] developed an SVM for classification using as input features the earthquake magnitude, total overburden pressure, effective overburden pressure, cone resistance from CPT, and peak ground acceleration. They trained the model with a data set which had 466 field liquefaction performance records and CPT measurement. They used the cross-validation method to evaluate the performance of the model. They compared the SVM with an ANN model and concluded the SVM model had more accurate results.

Ardakani and Kohestani [25] proposed a decision tree for classification based on CPT data to predict the seismic liquefaction potential. The training data they used consisted of a total of 109 cases, 78 of them used for training and 31 for testing. The input features of the decision tree were the cone resistance, total vertical stress, total effective stress, mean grain size, normalized peak ground surface acceleration, cyclic stress ratio, and the earthquake magnitude. The overall classification accuracy of the decision tree was 98%.

Kohestani et al. [26] developed two random forest models based on CPT data to evaluate the seismic liquefaction potential of soil. The random forest models were trained and validated using 226 field records of liquefaction performance and CPT measurements. The input features for the first model were the normalized cone tip resistance, soil type index, vertical effective stress, and the seismic cyclic stress ratio adjusted to an earthquake magnitude of 7.5, while for the second model inputs were the cone tip resistance, sleeve friction ratio, effective vertical stress, total vertical stress, maximum horizontal ground surface acceleration, and the earthquake magnitude. The models were compared to ANN and SVM models using the same input features found in the literature.

8 SLOPE STABILITY

Samui and Kothari [27] investigated the capability of a least square SVM (LSSVM) model to perform slope stability analysis. They developed two LSSVM models, one regression model to predict the factor of safety of the slope and one classification model to predict the stability status. Their training data consisted of 46 case studies of slopes, 32 used for training and 14 for testing. The input features of the models were the unit weight, cohesion, angle of internal friction, slope angle, height and the pore water pressure coefficient. They concluded that the proposed LSSVM was a robust model for slope stability analysis.

Kang et al [28] developed a probabilistic stability evaluation method for slopes based on GPR and Latin hypercube sampling. Their analysis was composed of three parts. Firstly, they used the Latin hypercube sampling technique to generate samples for constructing the response surface. Then, based on those samples they used the GPR model to establish the response surface to approximate the limit state function. Finally, they performed Monte Carlo simulation via the GPR response surface to estimate the system failure probability of slopes. They examined five case samples to verify the effectiveness of the methodology. The results of their study showed that the system reliability analysis they proposed could accurately setermine the system failure probability with a relatively small number of deterministic slope stability analyses.

9 SOIL STRUCTURE INTERACTION

Farfani et al. [29] proposed ANN and SVM models for dynamic analysis of soil-pile-structure (SPS) systems based on experimental data, which was produced by carrying out a series of centrifuge tests on SPS systems. The experiments included several configurations of SPS systems as well as a large number of real buildings with earthquake motions recorded inside them and at their nearby free-field ground surface. ANN and SVM models were developed to predict the maximum acceleration of the superstructure at the head of the column (SSA) and of the pile heads using as input parameters the peak base acceleration, amplitude factor of the earthquake record, length of column, mass on column and number of piles. The training data had a total of 70 data points, 45 of them used for training and the rest for testing the networks. Since the number of data points was relatively low, they created two ANN and two SVM models each having one output parameter (SSA or PHA). They performed finite element analysis to compare the ANN and SVM results. Furthermore, they extended their study creating ANN and SVM models in order to estimate the period of a structure based on recorded data taken from previous studies. The data included the soil-structure-interaction effects on 57 buildings, having various structural systems from different sites and under different earthquakes. The input features of these models were the maximum horizontal acceleration, the effective height of the building, embedment depth of the foundation, shear wave velocity of the soil, hysteretic damping of the soil and the radii of an equivalent circular foundation having a moment of inertia or a surface equal to the real foundation. The ratio of the fundamental periods of the building for fixed base and flexible base was the output. The results of their study showed that ML methods can be used for solving the complex problem of seismic response of structures in much less time compared to finite element modeling with acceptable accuracy if the necessary data is available.

10 SITE-SPECIFIC SEISMIC ANALYSIS

Kamatchi et al. [30] developed an ANN based methodology to predict site-specific acceleration values. In order to create the data for training they generated strong ground motions at bedrock level for a chosen site in Delhi, India due to earthquakes considered to originate from the central seismic gap of the Himalayan belt using necessary geological and geotechnical data and they performed one-dimensional equivalent linear site response analyses to calculate the surface level ground motions and response spectrums. Out of 49815 data points in their data set, 35000 data points were used for training and 14815 for testing. The input features of the ANN model were the moment magnitude of the earthquake, the shear wave velocity model of the soil, the depth of the soil stratum, the damping ratio and the vibration period of the SDOF oscillator. The output of the ANN was the average spectral acceleration at the surface. The trained ANN was validated using borehole log data of an actual soil site and two different buildings. The comparison showed that the ANN had a tolerable error.

11 INELASTIC RESPONSE SPECTRUM PREDICTION

Bojorquez et al. [31] proposed an ANN to estimate the inelastic response spectrum for earthquake acceleration records. Fifty earthquake ground motions taken from the NGA database and recorded at sites with different types of soils were used to train the proposed ANN model. They used 42 data points for training and 8 for testing the results of the trained network. In their study, they used the moment magnitude, fault mechanism, Joyner-Boore distance, the

shear-wave velocity above site depth of 30 m, the fundamental period of the structure, and the system ductility as input values of the ANN. The output of the ANN was the pseudo-spectral acceleration at first mode of acceleration. Even though they used a relatively small data set for the training, the results of the trained network had acceptable agreement with the actual response spectrum.

12 CONCLUSION REMARKS

In this study, the post-2010 applications of machine learning techniques to geotechnical earthquake engineering have been reviewed. Particular attention was given to uniaxial compressive strength prediction, pile and shallow foundation capacity prediction, soil shear strength prediction, prediction of the earthquake-induced soil liquefaction potential, slope stability prediction, dynamic soil structure interaction problems, site specific seismic analysis, and inelastic response spectrum prediction. It was observed that the artificial neural networks and support vector machines were the most commonly applied algorithms of the options available which shows their superior performance in complex problems compared to other algorithms. Also, the number of applications to soil constitutive models, to foundation capacity prediction, and soil liquefaction is greater than the applications to geotechnical earthquake engineering problems like dynamic soil structure interaction and site-specific seismic analysis. Future studies could include more applications to this field to consider not only the complex nature of soils, but also the complexity of earthquake characteristics.

Machine learning techniques have several advantages in simulating the complex behavior of most geotechnical and geotechnical earthquake engineering problems compared with the conventional methods. In most traditional mathematical models, the problem is simplified, or several assumptions are made, and the structure of the model is assumed in advance. Whereas, machine learning algorithms, as a data driven approach, rely on the training data to determine the structure and the parameters of the model without simplifying the problem or incorporating any assumptions. This requires the use of an adequate amount of data in order to develop a machine learning model which generalizes well. In most of the reviewed studies the training data was quite small, and the trained algorithm was able to make accurate predictions for specific input feature ranges. Hence, the already developed machine learning models could be updated to provide better results by adding new training examples in the data set and larger data sets could be used in future studies.

Despite the success of machine learning techniques in modeling complex geotechnical earthquake engineering problems, they suffer from some shortcomings, like model robustness, transparency and knowledge extraction, and uncertainties. The epistemic and aleatory uncertainties in machine learning models can be addressed by applying a probabilistic approach, such as Gaussian process regression algorithm or probabilistic deep learning methods. Furthermore, more robust models can be achieved by using larger data sets and deep learning techniques, like deep neural networks which use numerous hidden layers, each providing a different interpretation to the data it processes. In this way, critical features of the input data can be identified, and hidden patterns in highly complex problems can be found, providing better predictions. Improvements in these areas will greatly enhance the performance of machine learning applications to geotechnical earthquake engineering and other civil engineering problems.

Keywords: High-speed railway bridges, Bridge dynamics, Structural reliability, First order reliability methods, Running safety, Serviceability limit state.

Abstract. *The operational speed of the trains is intended to be significantly increased forthcoming; which consequently questions the safety level of the current design concepts concerning different performance limits. Thus, the reliability of the simply supported single-span bridges is assessed in the current article adopting the first-order reliability method (FORM) approach. In this regard, the dynamic response of the aimed bridges is investigated under the passage of a series of moving loads using available closed-form solutions in the literature. Hereof, axle load, car body/train configuration, flexural rigidity, damping, mass and model uncertainties are considered as random variables; while train-track-bridge interactions are neglected and the procedure is repeated for a wide range of span lengths and train velocities. Then, the safety index corresponding to each case is evaluated by considering running safety as the limit state function; where, the bridge deck vertical acceleration is taken as the capacity of the system. The outcomes are presented as average probability of exceeding the limit state versus train speed and categorized based on span lengths.*

1 INTRODUCTION

Former studies have shown that ballast instability is the dominant design criteria of high-speed railway bridges in comparison to the contact loss or excessive deflections. The latter statement is particularly validated for short to medium span bridges using numerical simulations [1, 2]. It was observed that this phenomenon may occur at high vertical accelerations leading the interlock between grains to be lost or the lateral resistance of sleeper to be reduced. Its possibility of occurrence significantly increases under resonance conditions; which may occur due to high speed and repeated action of the axle loads [3].

In this regard, Zacher and Baeßler [4] conducted a shaking table test; in which they observed that the lateral resistance of the sleeper was significantly reduced at vertical accelerations about 7 m/s^2. The obtained outcomes revealed that the proposed vertical acceleration limit in EN-1990-A2 [5], i.e. 3.5 m/s^2 for ballasted tracks comply with a safety factor of 2. Therefore, further researches particularly reliability assessments may be conducted to evaluate the achieved safety level by following current regulations. Those investigations may lead to more reliable design thresholds.

Generally, probability of failure/violation (p_f) of limit state (performance) function can be estimated by calculating reliability integral as follows [6]:

$$p_f = P[R - S \leq 0] = P[G(\mathbf{X}) \leq 0] = \int ... \int_{G(X)\leq 0} f_X(\mathbf{x}) d\mathbf{x} \tag{1}$$

Where, $G(\mathbf{X})$ is the limit state function (safety margin) representing capacity (resistance - R) minus demand (load effects - S) and $f_X(\mathbf{x})$ is the joint probability density function of all random (basic) variables.

The aforesaid integration cannot be calculated in real (complicated) problems; in which contributing random variables present an n-dimensional hyperspace. Thus, practical solutions have been developed to either numerically evaluate the integral (such as Monte Carlo simulations) or approximate it (e.g. First Order Reliability Method - FORM). The current article adopted FORM to evaluate the probability of ballast instability in simply supported bridges under the passage of high-speed trains.

Within the FORM method, the safety level is expressed as a *reliability index* (β); which is the shortest distance from the origin to the desired limit state function (see Figure 1). Then, the probability of failure can be estimated as Eq. 2:

$$p_f \approx \Phi(-\beta) \tag{2}$$

Where Φ is the standard Normal (Gaussian) distribution function.

Generally, FORM considers the linear approximation of the limit state function using Taylor series expansion around the most probable point (MPP) or checking point (shown as u^* in Figure 1); which its surrounding area has the highest contribution on the failure probability. Detailed information regarding FORM can be found in [6, 7]. Therefore, its outcome would depend on the used formulation defining failure surface; which is contrary to invariant problem. Thus, considered random variables and consequently, the limit state function should be transformed to standard Normal space using Hasofer-Lind transformation (Eq. 3).

$$U_i = \frac{X_i - \mu_{X_i}}{\sigma_{X_i}} \tag{3}$$

Where, X_i is the basic random variable with first two moments of μ_{X_i} and σ_{X_i} and U_i is the transformed random variable.

Furthermore, the obtained direction cosines ($\boldsymbol{\alpha}$) can be used as a sensitivity of the transformed limit state function to the random variables. In this study, the omission sensitivity factor (γ_i) is employed in addition to the direction cosines; which presents the relative importance of the random variable on reliability index if it was considered as deterministic. It is defined as the ratio of the reliability index when the i^{th} random variable is deterministic (β_i^f) to the reliability index when all variables are stochastic [8]. For independent random variables it would be as follows:

$$\gamma_i = \frac{\beta_i^f}{\beta} = \frac{1}{\sqrt{1-\alpha_i^2}} \tag{4}$$

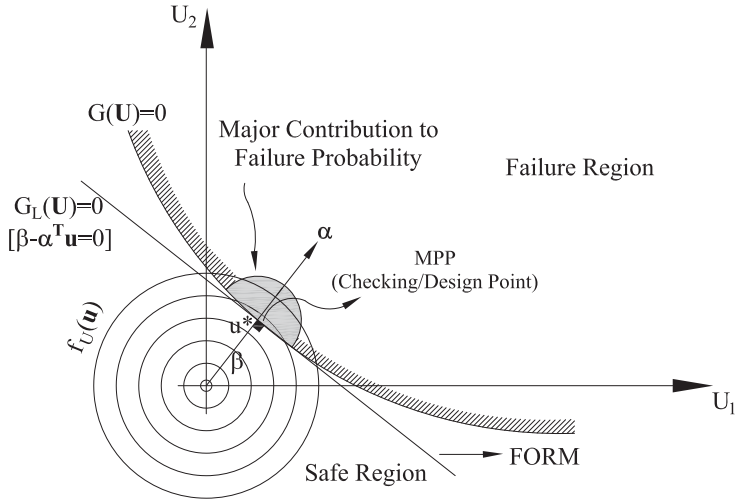

Figure 1: Schematic concept of the FORM [6, 7]

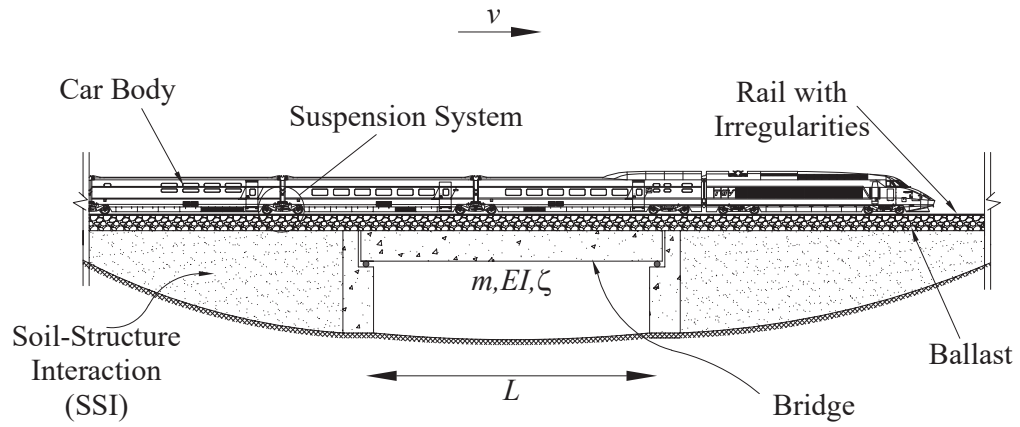
2 CONSIDERED ANALYTICAL SOLUTION

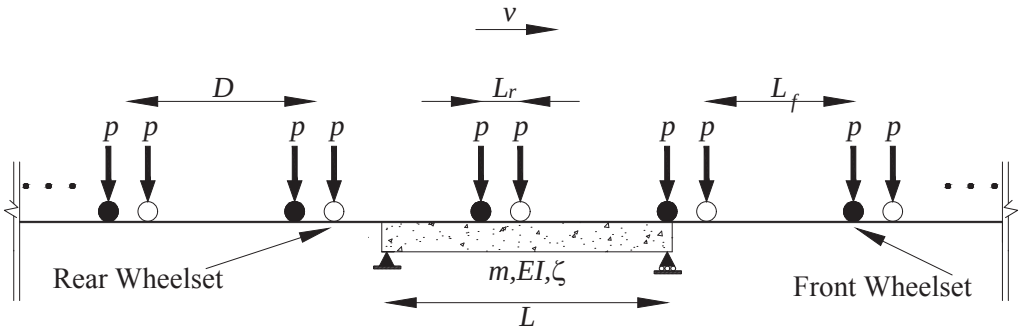
Detailed investigation of the dynamic behavior of railway bridges can be achieved by modeling bridge structure, boundary conditions (soil-structure interaction - SSI), ballast, track, rail, train and their interactions (train-track-bridge interaction - TTBI). Schematic view of such a general model is shown in Figure 2a. In spite of providing detailed insight regarding dynamic response, the general model requires considering many random variables; which significantly increases computational costs of reliability evaluations. Furthermore, the probability characteristics of interaction- and boundary condition related variables are not well exploited. Thus, a simplified model including passage of a series of moving loads along a simply supported beam is taken into account here (see Figure 2b).

A close-form solution has been previously presented by [9, 10] to calculate beam deflection under such loading scenario. Therefore, the second derivative of the proposed solution is derived here to estimate the vertical acceleration of the bridge. Those equations are presented in Eqs. (5) to (10).

$$\ddot{u}(t) = \sum_{n=1}^{\infty} \ddot{q}_n(t)\phi_n(x) = \sum_{n=1}^{\infty} \ddot{q}_n(t)\sin(\frac{n\pi x}{L}) \tag{5}$$



(a) General model with TTBI



(b) Simplified adopted model

Figure 2: General modeling of railway bridge under passage of trains versus simplified adopted load model

$$\ddot{q}_n(t) = \frac{2pL^3}{EI\pi^4}[P_n(v,t) + P_n(v,t - L_f/v)] \tag{6}$$

$$\begin{aligned} p_1 &= 1 - {S_n}^2, \quad p_2 = 2\xi_n S_n, \quad p_3 = -\xi_n \omega_n \\ p_4 &= \frac{S_n(2{\xi_n}^2 + {S_n}^2 - 1)}{\sqrt{1 - {\xi_n}^2}}, \quad t_k = \frac{(k-1)D}{v} \end{aligned} \tag{7}$$

$$P_n(v,t) = \frac{1}{n^4}\sum_{k=1}^{N}\frac{1}{{p_1}^2 + {p_2}^2}\left[A(t-t_k).H(t-t_k) + (-1)^{n+1}A(t-t_k-\frac{L}{v}).H(t-t_k-\frac{L}{v})\right] \tag{8}$$

$$\begin{aligned} \alpha_1 = -p_1{\Omega_n}^2, \quad \alpha_2 = p_2{\Omega_n}^2, \quad \alpha_3 &= p_2{p_3}^2 + 2p_3p_4\omega_{dn} - p_2{\omega_{dn}}^2 \\ \alpha_4 &= {p_3}^2p_4 - 2p_2p_3\omega_{dn} - p_4{\omega_{dn}}^2 \end{aligned} \tag{9}$$

$$A(t) = \alpha_1 \sin\Omega_n t + \alpha_2 \cos\Omega_n t + e^{p_3 t}\left[\alpha_3 \cos\omega_{dn} t + \alpha_4 \sin\omega_{dn} t\right] \tag{10}$$

Where, $\ddot{u}(t)$ is the deck acceleration, $\ddot{q}_n(t)$ is the generalized coordinate, $\phi_n(x)$ is the mode shape of the n^{th} mode of vibration, L is the span length of the beam, p is the axle load, EI is the flexural rigidity of the beam, v is the speed of the train, L_f is the distance between the front and rear wheelsets subsystems in each car body, $S_n = n\pi v/\omega_n L$ is the speed parameter corresponding to the n^{th} mode of vibration, ξ_n is the damping ratio of the n^{th} mode of vibration, D is the distance between front to front or rear to rear wheelsets in subsequent car bodies, N is the number of car bodies, $H(t)$ is the Heaviside function, $\Omega_n = S_n\omega_n$ is the exciting frequency implied by the moving load and $\omega_{dn} = \omega_n\sqrt{1-\xi_n^2}$ is the damped frequency of the n^{th} mode of vibration.

It is worthwhile noting that only the first mode of vibration is considered here for the sake of simplification. Such consideration imposes some errors particularly at off-resonance speeds; however, it results in accurate enough predictions for resonance speeds. Therefore, considering only one mode of vibration may not generally affect the safety of the bridge.

Additionally, it has been previously observed that spreading axle loads through the track structure (rails, sleepers and ballast) significantly reduces the bridge response particularly for the short span ones [11]. Therefore, a reduction coefficient is multiplied by the obtained response from the aforementioned analytical solution; which is obtained by fitting the presented relationship in Eq. 11 to the graphically proposed reduction factor in [12].

$$R(\lambda) = \begin{cases} 0.14 & ,\lambda \leq 1.5 \\ -0.00011\lambda^4 + 0.0053\lambda^3 - 0.083\lambda^2 + 0.57\lambda - 0.54 & ,1.5 < \lambda < 8.0 \\ 1.0 & ,\lambda \geq 8.0 \end{cases} \tag{11}$$

Where, $\lambda = v/f_1$ is the wavelength.

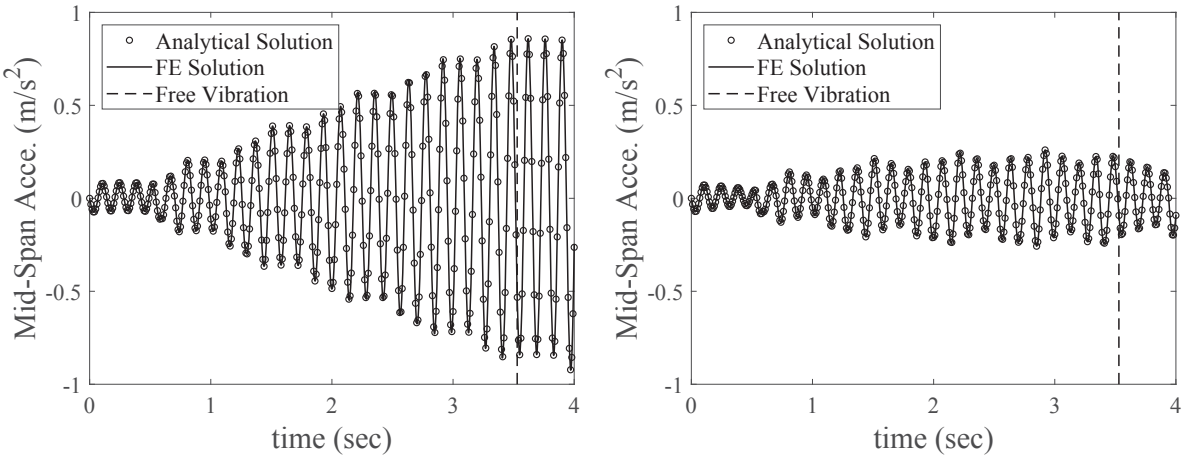
2.1 Verification of analytical solution

A previously presented example by Yang et al. [9] is taken into account to verify the adopted analytical solution. For this objective, mid-span acceleration of a simply supported beam with $L = 20$ m, $I = 2.81$ m^4, $E = 29.43$ GPa and $m = 34088$ kg/m under passage of a train with $N = 5$, $L_f = 18$ m, $L_r = 6$ m, $p = 215.6$ kN and $v = 122.4$ km/h is calculated. The considered speed corresponds to the resonance speed of the bridge. Additionally, two cases, i.e. without damping and $\xi = 2.5\%$ is taken into account. The obtained analytical accelerations are compared with those resulted from numerical evaluations in Figure 5; which, a promising agreement can be distinguished. It is worthwhile noting that the numerical calculations are conducted using Newmark's average acceleration method; however, reduction factor due to load distributions is neglected for the comparison objectives.

3 BASIC VARIABLES AND LIMIT STATE FUNCTION

As mentioned, the current article aims at evaluating the probability of ballast instability under passage of high-speed trains. Thus, the performance function regarding this limit state would be as follows:

$$G(\mathbf{X}) = a_{limit} - |a_{max}(\mathbf{X})|(1+\chi_m) \tag{12}$$
$$\mathbf{X} = (N, D, p, v, L, E, I, A_d, A_b, \rho_d, \rho_b, \xi, \chi_m)$$



(a) Without damping (b) $\xi = 2.5\%$

Figure 3: Verification of analytical solution with numerical method by comparing mid-span acceleration

Where, a_{limit} is the vertical acceleration initiating ballast instability, E is the modulus of elasticity of deck, I is the moment of inertia of deck, A_c is the deck area, A_b is the ballast area, ρ_d is the mass density of deck, ρ_b is the mass density of ballast, ξ is the damping ratio and χ_m is the model uncertainty. It is worthwhile noting that ballast has much lower modulus of elasticity than the deck [1]; which led its contribution in stiffness to be neglected.

As previously mentioned, only few shaking table tests have been conducted to determine the vertical acceleration leading ballast instability [4]. Thus, a triangular probability distribution is considered for a_{limit}; which its mode equals to experimentally captured value, i.e. 0.7g. Furthermore, a possible variation of 0.1g is taken into account based on authors' judgment to define its boundaries.

Regarding the applied loads, it is hardly possible to collect information corresponding to the variability of parameters in commercial trains. Thus, proposed load models in Annex E of Eurocode [13] are applied here. Hence, the uncertainty on moving loads would be a function of constant axle load (p_{axle}) and occupancy rate (α in %). By assuming the full passenger capacity of each car body as 65 and average weight of each passenger as 70 kg, the moving load can be calculated as Eq. 13; which is developed in kN units.

$$p = p_{axle} + 0.225\alpha \tag{13}$$

In order to select practically reasonable geometrical values (i.e. span length, moment of inertia and deck/ballast area) 62 single span and single track bridges in Sweden are surveyed. Detailed information about them can be found in [14]. The span length of the desired bridges varies between [5-30]m. Therefore, evaluations are conducted within this range for deterministic span lengths with a resolution of 5m.

The distribution of span length, moment of inertia, deck and ballast areas in addition to their linear correlations are depicted in Figure 4. A strong correlation between span length, moment of inertia and deck area is evident; while as expected, the ballast area seems to be independent on span length. Hence, a conditional probability for the moment of inertia and deck area is assigned (see Figures 5a and 5b); which, the parameters are extracted by regression analysis and fitting lower and upper boundaries. On the other

hand, the shown scatter plot of the ballast area (see Figure 5c) reveals that they mostly vary around mean value regardless of the span length. Due to extracting distributions from a limited database, a triangular probability distribution is adopted for the all geometrical random variables.

It is well-known that the response of the bridges is highly dependent on the damping ratio particularly around resonant speed. Additionally, the contribution of several factors makes damping measurement a tedious task; which may result in scattered outcomes. Therefore, the proposed lower bound in [12] is taken here as the mean value of the damping ratio.

Discussed simplifications and existing lack of knowledge on different aspects of the problem deviate the predicted responses by the adopted solution from corresponding real values. Thus, a model uncertainty (χ_m) is applied to the limit state function; which should be obtained from comparison of the experimentally captured values with those resulted from the numerical model. However, the lack of such information led to propose a model based on the authors' judgment. In this regard, a Gaussian probability density function with zero mean and a standard deviation of 20% is taken into account.

Considering all, the assigned parameters for the variables are reported in Table 1.

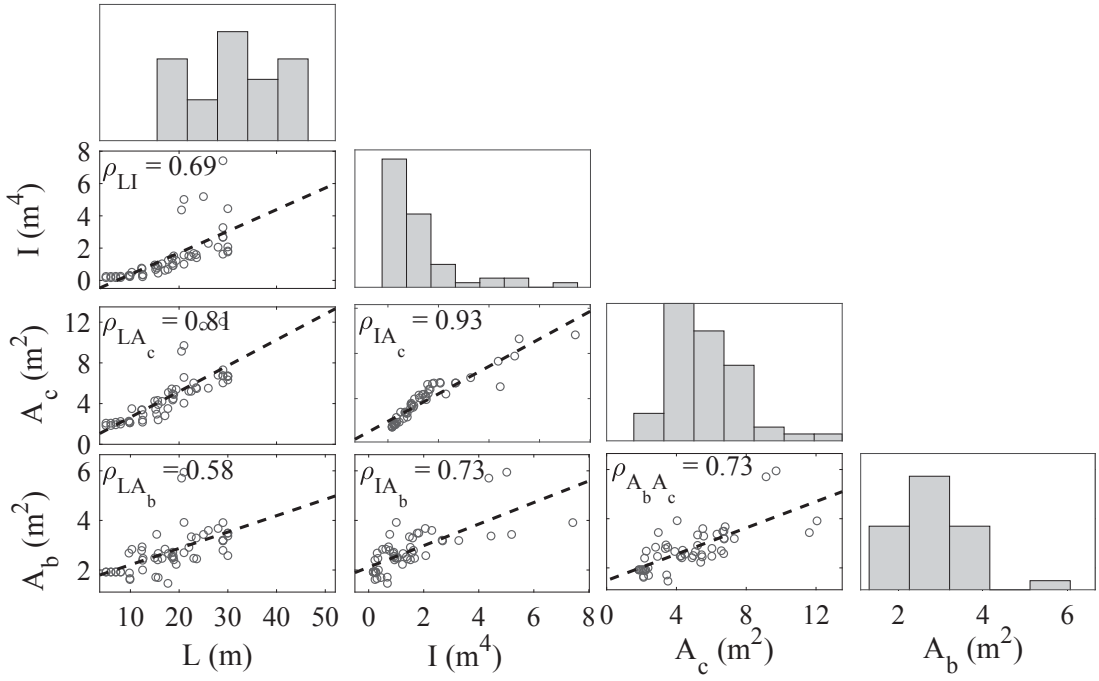


Figure 4: Correlation between span length, deck moment of inertia, deck area and ballast area

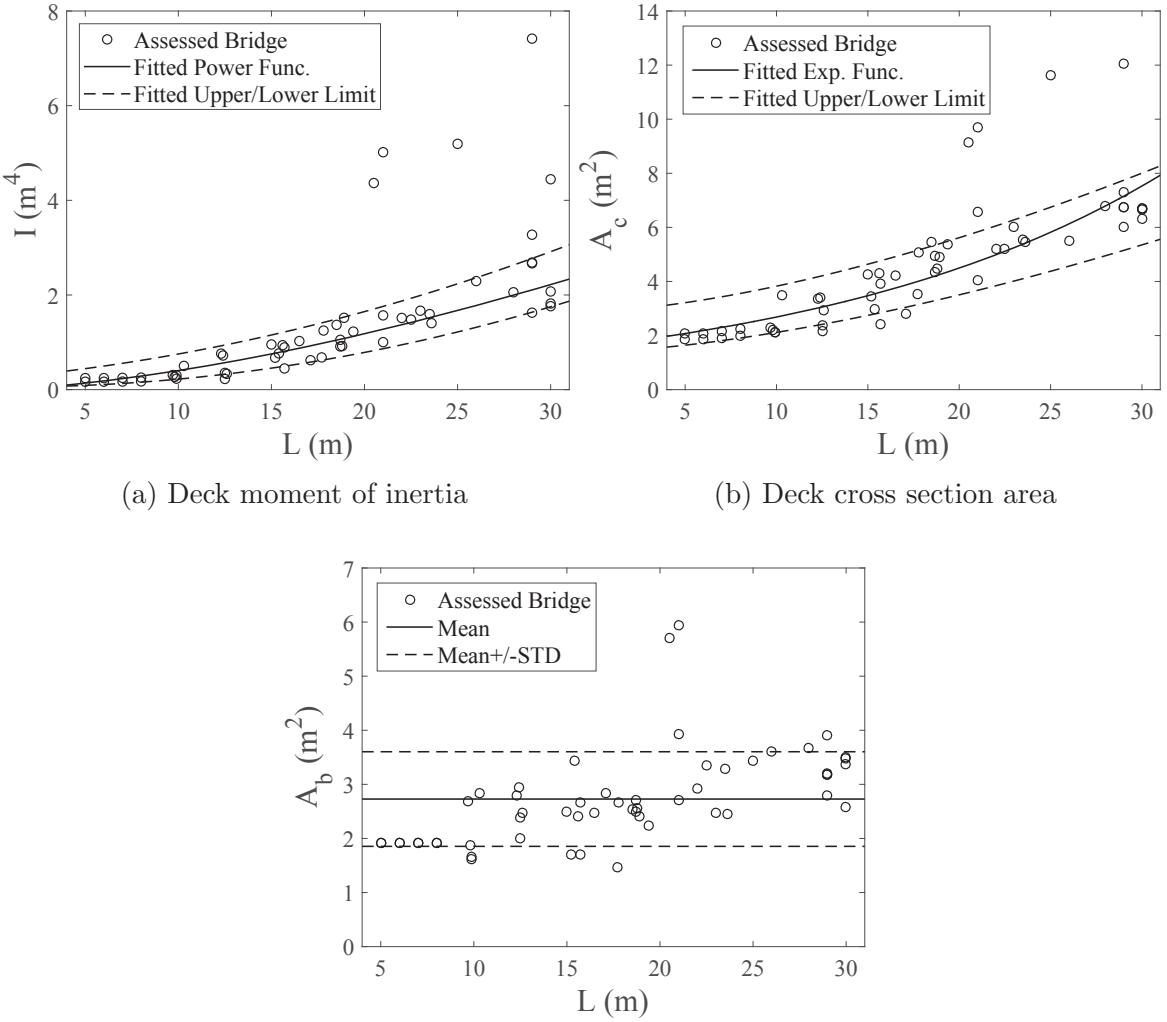
4 RESULTS AND DISCUSSION

Initially, the considered bridges are assessed following deterministic approaches. For this objective, the speed of passing trains swept between 100 km/h up to 400 km/h; while the average values are assigned for each variable. The analyses are repeated by changing each variable to mean plus/minus one standard deviation; while other variables remained constant. Hence, the train speed leading the vertical acceleration to surpass 3.5 m/s^2 is extracted (see for instance Figure 6). The obtained deterministic operating train speeds are reported in Table 2.



(a) Deck moment of inertia

(b) Deck cross section area

(c) Ballast area

Figure 5: Distribution function for deck moment of inertia, deck cross section area and ballast area as a function of span length

Then, the reliability of the developed limit state function is assessed using FORM. In this regard, UQLab toolbox [16] is employed to conduct the analyses and extract the corresponding probability of violence. For this objective, the span length of the bridge is assumed as a deterministic parameter varying in the desired range and properties of the other parameters are adopted as those tabulated in Table 1. Then, the reliability of each bridge is assessed for all considered trains with different configurations; while a speed resolution of 2 km/h is taken into account. Since the probability of violation is calculated at discrete points; then, the average exceeding (failure) probability ($p_{f,ave}$) can be calculated using Eq. 14 [18].

$$p_{f,ave} = \int_{v_l}^{v_u} P(a_{deck}(v) > a_{limit}) f_v(v) dv \approx \frac{1}{n} \sum_{i=1}^{n} P(a_{deck}(v_i) > a_{limit}) \tag{14}$$

Where, n is the number of discrete evaluations.

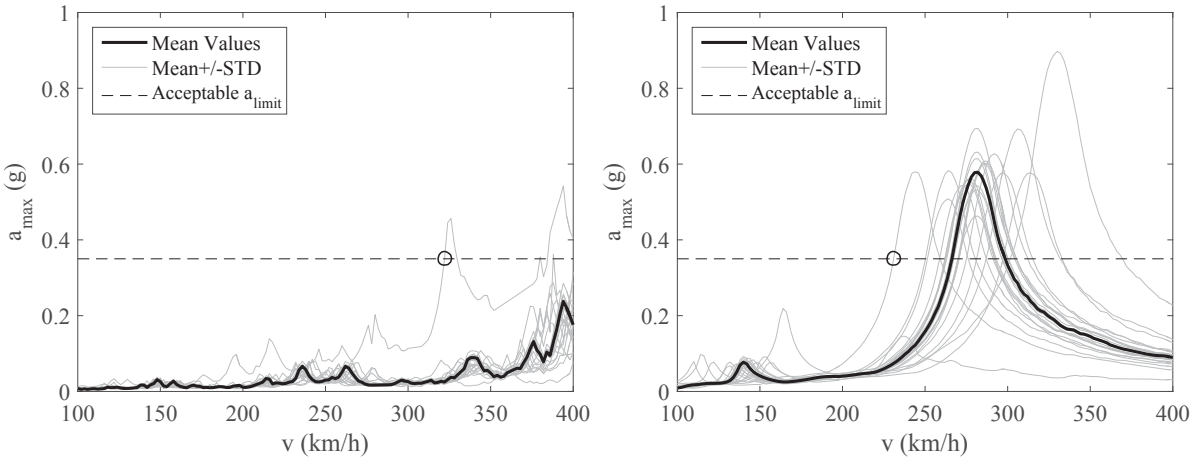
Variable	Unit	Dist.	Mean/Mode Min.	STD/Bound. Max.	Ref.
a_{limit}	m/s^2	Triangular	7.0	[6.0-8.0]	-
N	-	Uniform (Integer)	11	18	[13]
D	m	Uniform	18	27	[13]
L_r	m	Uniform	2.5	3.5	[13]
p_{axle}	kN	Deterministic	170	-	[13]
α	%	Uniform	0	100	-
v	km/h	Deterministic	100	400	-
L	m	Deterministic	5	30	-
E	GPa	Truncated Gaussian [a]	29.7	3.5	[15]
I	m^4	Triangular [b]	M_I	[LB_I-UB_I]	-
A_c	m^2	Triangular [c]	M_{A_c}	[LB_{A_c}-UB_{A_c}]	-
A_b	m^2	Triangular	2.7	[1.85-3.6]	-
ρ_c	kg/m^3	Lognormal [d]	7.82	0.04	[1]
ρ_b	kg/m^3	Uniform	1500	2100	[1]
ξ	%	Lognormal [e]	μ_ξ	σ_ξ	[1, 12]
χ_m	%	Gaussian	0	20	-

[a] The mean value is obtained from $5015\sqrt{f'_c}$ [MPa] and considering C35 as typical concrete class in bridges. A COV of equaling 12% is also considered. Due to controlled construction conditions of the railway bridges, the assigned probability distribution is truncated for values deviated more than two standard deviation from the mean value.
[b] The mode is obtained from regression analysis between span length and moment of inertia in the surveyed bridges; which equals as $M_I = 0.011(L^{1.55})$. Furthermore, the lower and upper bounds would obtain from $\mathrm{LB}_I = 0.002L^2 - 0.004L + 0.06$ and $\mathrm{UB}_I = 0.00185L^2 + 0.034L + 0.23$, respectively.
[c] The mode is obtained from regression analysis between span length and cross section area; which equals as $M_{A_c} = 1.6\exp(0.052L)$. Since cross section area is highly correlated to the moment of inertia; therefore, boundaries are obtained from $\mathrm{LB}_{A_c} = 1.781M_I + 1.4$ and $\mathrm{UB}_{A_c} = 2.3M_I + 2.9$, respectively.
[d] Reported mean and standard deviation correspond to 2500 kg/m^3 and 100 kg/m^3 mean and standard deviation in physical space, respectively.
[e] The mean value of the damping in normal space is obtained from $1.5 + 0.07(20 - L)$ [12] for bridges with less than 20 m span length and equals to 1.5% [12] for others. It is needed to be transformed to logarithmic space. Furthermore, the standard deviation of the lognormal distribution should be obtained by considering aforesaid mean and standard deviation of 0.3% in physical space.

Table 1: Considered variables and their stochastic/deterministic properties

The aforesaid probabilities are required to be compared by an appropriate target reliability index. Regarding the nature of the problem, it can be inferred both as serviceability (SLS) or ultimate (ULS) limit states. The former corresponds to the maintenance and tamping of the ballast; however, the later can be considered as severe cases in which ballast instability may lead to derailment. Hence, $\beta = 3.1$ ($p_f \approx 10^{-3}$) is considered as the target reliability [17, 18].

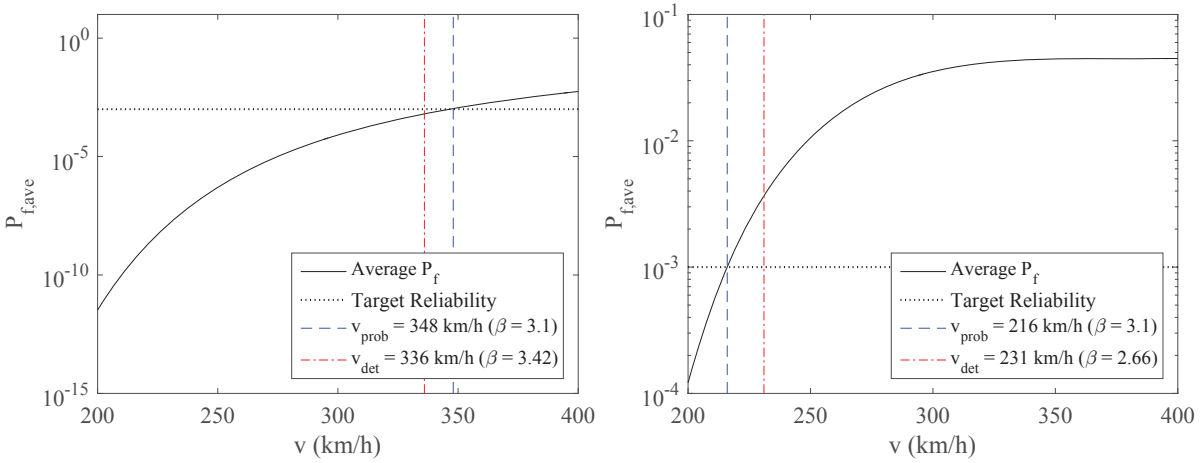
Then, the average probability of exceeding vertical limit acceleration versus train speed is illustrated in Figure 7. Only outcomes corresponding to 5m and 30m span lengths are presented here for the sake of brevity; while, the extracted operating speeds for all bridges



(a) L = 5m (b) L = 30m

Figure 6: Deterministic running safety assessment of the considered bridges

are reported in Table 2. As can be seen, the conventional deterministic approach does not lead at a constant safety level; which may result in designs with ambiguous capacity. Furthermore, it can be inferred from those safety indices that the conventional design method does not satisfy the desired safety level ($p_f = 10^{-3}$). The latter statement is particularly true for bridges with larger span lengths. Such lower safety may arise from several factors. Most importantly, shorter span bridges have generally higher frequencies. Thus, higher train speeds are required to observe the resonance phenomenon. In addition, the distribution of loads on track structure significantly reduces the response of bridges with shorter span lengths; while its influence would be negligible for larger span lengths.



(a) L = 5m (b) L = 30m

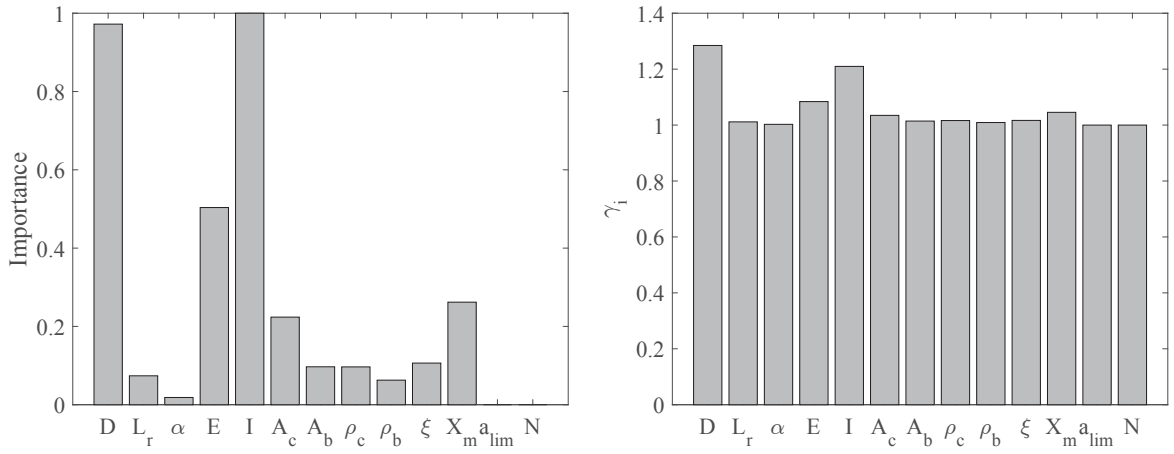
Figure 7: Reliability-based assessment of the considered bridges

Finally, the sensitivity of the reliability evaluations to the considered random variables is assessed using both direction cosines and omission sensitivity factor (see Figure 8). As can be seen, the response is most sensitive to variations on car-body length, modulus

L (m)	v_{prob} (km/h)	v_{det} (km/h)	β_{det}
5	348	322.0	3.42
10	230	315.5	1.97
15	250	284.0	2.37
20	170	215.0	2.01
25	148	186.0	2.27
30	216	231.0	2.66

Table 2: Comparison between reliability-based assessment versus deterministic evaluation

of elasticity and deck moment of inertia. It is worthwhile to note that deck/ballast cross section area and their mass densities are also relatively important; which leads the reliability level to be sensitive on their combination, i.e. mass of the bridge.



(a) Sensitivity from direction cosines

(b) Omission sensitivity

Figure 8: Sensitivity of the reliability evaluations to the considered random variables

5 CONCLUSIONS

- An existing closed-form solution is adopted to evaluate the reliability of simply supported single span high-speed railway bridges using FORM. It was noted that the conventional deterministic dynamic assessments result in bridges which do not satisfy desired target reliability level ($\beta = 3.1$).

- Despite applying a safety factor of 2.0 for the vertical acceleration limit, the conventional design method does not lead to a constant safety level on bridges with different span lengths.

- Reliability of the bridges are mostly sensitive to the car-body length, modulus of elasticity and deck moment of inertia. Moreover, the mass of the bridge would be a function of deck cross section area, ballast area, concrete mass density and ballast mass density. Thus, by considering their importance the assessed reliability would be considerably sensitive to their combination, i.e. mass of the bridge.

Keywords: Oscillator, Elasto-Plastic, Shock, White Noise, Energy Balance, Diffusion Process, Stochastic Variational Inequality

Abstract. *This paper deals with mechanical nonlinear oscillators, of mass-spring type, subjected to white noise excitation. First, a remarkable property is noted: the energy, per time unit, injected into the oscillator by the external force depends only on the white PSD level (directly), and the oscillator mass (inversely). So, different oscillators, whatever their nonlinearities and dissipation mechanisms, receive, and consequently dissipate, the same energy rate from the white noise provided they have the same mass. It is discussed how this simple energy balance, eventually connected to additional conjectures, gives information about the dynamics of oscillators of two classes, (i) the elastic shock oscillators (ESO), and (ii) the elasto-plastic oscillators (EPO), both including different subclasses (for the symmetry of stops or the type of plasticity). But relevant theories are needed to go further. The paper focuses on two items linked to stochastic diffusion processes. Concerning ESO with undamped stops, the theory leads, via the Fokker-Planck equation, to an analytical expression for the probability density function (PDF) of the oscillator in the phase space. Quantities of interest (like Rice frequency, impact frequency or distribution) may then be deduced under closed-form, even for totally asymmetric ESO. Concerning (perfectly) EPO, a completely new approach has appeared for a decade, based on stochastic variational inequality (SVI). The infinitesimal generator proper to the diffusion is degenerated and works in the special phase space defined from the EPO velocity and its elastic displacement. Joint PDF can be numerically determined through heavy computations, as illustrated by an example using finite differences. Finally, the paper comments the "white noise of engineers", the PSD of which is realizable since truncated in frequency, which justifies some assumptions and simplifies the plastic-elastic transitions for EPO, as well as the stop contact phases for ESO.*

1 INTRODUCTION

The starting point for apprehending mechanical vibration relies ordinarily on the single oscillator made of a lumped mass, a linear spring and a viscous dashpot. Indeed, this 1-DOF model evidences, without too much mathematics, basic physical concepts of linear vibration such as free or forced response, resonance, etc. Moreover, it even represents sometimes "reality" with sufficient accuracy, i.e. at the first order filter. At last, it gives birth to more advanced concepts, such as response spectrum or transfer function, that found many linear analyses of multi-DOF structures, in various fields: seismic, shock, random vibration, etc. Moving from linear to nonlinear vibration is never a straight forward extrapolation, but constitutes a *giant* step as the superposition principle is lost and no general theory exists. Consequently, the nonlinear vibration issues must be solved on a case-by-case basis. Nevertheless, the 1-DOF approach remains a good starting point, despite two major differences with the linear case: (i) the multiplication of 1-DOF models according to the nonlinearity; (ii) the dramatic challenging task for the multi-DOF extensions.

This paper deals with such 1-DOF approach. For keeping a certain degree of generality, it considers nonlinear single oscillators of two distinct classes, (i) the elastic shock oscillator (ESO), and (ii) the elasto-plastic oscillator (EPO), both subjected to white noise excitation.

Firstly, these cases, although a priori academic, are emblematic of real situations in mechanical or civil engineering. ESO under white noise might be associated to flow induced vibration (FIV) of components excited by turbulence, and whose supports have gaps, which is common in industrial facility to cope with thermal expansion. EPO under white noise might be associated to structures or components seismically shaken, that experience plastic excursions, the quantification of which is needed, notably in the margin studies with beyond design earthquakes.

Secondly, ESO and EPO present well-marked and very different nonlinearities that may be considered as two extreme cases, without and with "memory". But thirdly, the white noise excitation is rather universal; it does not depend on the oscillator response as any additive external force, but injects energy into the oscillator independently of its rigidity or damping, which is really a remarkable property.

Schematically, the paper aims at understanding and quantifying some features of the dynamics of ESO and EPO, whitely excited, by following two opposite ways. The first one, very simple, is based on the elementary energy balance mentioned above, eventually connected to additional conjectures. The second one, quite complicated in comparison and more mathematical, uses results produced by the theory of stochastic diffusion processes. The amount of information naturally grows with the degree of sophistication of analyses. But it is always interesting - and it is one of the paper's goals - to stress how very simple analyses can provide pertinent results, especially for extracting orders in magnitude.

2 ENERGY INJECTED BY A WHITE NOISE

The energy injected, per time unit, into the oscillator by the external force f(t) - in other words, the inserted mechanical power - may be heuristically calculated by considering an approximated or "truncated" white noise with time step Δt. In this modeling, the continuous force f(t) is a step piecewise function, build from the discretized values $f(t_k)$ of the force at time $t_k=k\times\Delta t$, $k\in\mathbb{Z}$: $f(t)=\sum_k f(t_k)\times\left(H(t-t_k)-H(t-t_{k+1})\right)$, where H is the Heaviside function and $f(t_k)$ a randomly distributed variable with zero mean and finite variance, all values being independent one from each other. By construction, the force value $f(t_k)$ and the oscillator velocity $\dot{x}(t_k)$ are independent variables, but $f(t_k)$ and the oscillator velocity

$\dot{x}(t_k + \Delta t)$ at the end of the time step are linked through the impulse generated by the force f(t) constant during the time step Δt. If this later is small enough for ensuring first order developments, we have (with m the oscillator lumped mass):

$$\Delta\dot{x}_k(\Delta t) = \dot{x}(t_k + \Delta t) - \dot{x}(t_k) = \frac{f(t_k).\Delta t}{m} \tag{1}$$

In fact, the impulse is linear on the time interval Δt: $\Delta\dot{x}_k(\tau) = f(t_k).\tau/m$, $\tau \in [0, \Delta t)$. The mathematical expectation of the instantaneous injected power is thus:

$$P_f = \langle p_f(t) \rangle = \frac{1}{\Delta t}\left\langle \int_0^{\Delta t} f(t_k).\Delta\dot{x}_k(\tau).d\tau \right\rangle = \frac{\Delta t}{2.m}\left\langle f(t_k)^2 \right\rangle \tag{2}$$

Let F_0 the level of the power spectral density (PSD) of the mathematical white noise expressed in negative and positive pulsations ω, ranging from -∞ to +∞ and, so, leading to an infinite variance. The "physical" white noise f(t), as build above, has a finite variance since Δt is finite: $\langle f(t)^2 \rangle = \langle f(t_k)^2 \rangle$. Its PSD can be easily deduced from the auto-correlation function, $R_{ff}(\tau) = \langle f(t).f(t+\tau) \rangle$; we have [3]: $S_{ff}(\omega) = \frac{\Delta t}{2\pi}.\langle f(t_k)^2 \rangle.\left(\frac{\sin(\omega\Delta t/2)}{\omega\Delta t/2}\right)^2$. By assimilating the mathematical PSD level to the zero-pulsation value of the physical PSD, $S_{ff}(0) = F_0$, we can get the following expression: $\int_{-\infty}^{+\infty} S_{ff}(\omega).d\omega = 2.F_0.\frac{2\pi}{2\Delta t} = \langle f(t)^2 \rangle = \langle f(t_k)^2 \rangle$, in which we recognize the Shannon cut-off pulsation: $\omega_c = 2\pi/2\Delta t$. So, Eq.(2) gives for the averaged power injected by f(t):

$$P_f = \langle p_f(t) \rangle = \frac{\Delta t}{2.m}\langle f(t_k)^2 \rangle = \frac{\pi.F_0}{m} \tag{3}$$

The energy rate injected by the white force f(t) is directly proportional to the PSD level and inversely proportional to the oscillator mass. No other characteristic acts in Eq.(3). Therefore, all the oscillators of the same mass, subjected to white noises of the same intensity, receive the same amount of energy, whatever their stiffnesses, dissipation mechanisms, and/or non-linearities of all kind (with or without a memory effect). Consequently, on the only condition that (at least) one dissipation mechanism exists, and works without any saturation, all the oscillators will dissipate the same energy rate and exhibit stationary responses (removing the initial transient part if the oscillator is at rest when the white noise applies).

3 DAMPED ELASTIC OSCILLATOR

Let us first consider a simple elastic oscillator made of the mass m, the elastic spring k_0, the viscous dashpot c_0 (always positive), submitted to a centered white noise force of intensity F_0 (PSD level). Thus, the mass motion satisfies the following time-history dynamic equation: $m.\ddot{x}(t) + c_0.\dot{x}(t) + k_0.x(t) = f(t)$. The differential energy dissipated by the dashpot at time t is: $dE_d(t) = c_0.\dot{x}(t).dx = c_0.\dot{x}(t)^2.dt$; hence the instantaneous dissipated power: $p_d(t) = c_0.\dot{x}(t)^2$; therefore, in average:

$$P_d = \langle p_d(t) \rangle = c_0.\langle \dot{x}(t)^2 \rangle = c_0.\sigma_{\dot{x}}^2 \tag{4}$$

Moreover, the injected power (precisely, its mathematical expectation) is strictly equal to the dissipated power (idem) for stationary processes since the vibratory energy (kinetic + potential elastic) is time independent: $\langle E_v(t)\rangle = \langle m.\dot{x}(t)^2/2 + k_0.x(t)^2/2\rangle = ct.$ Equalizing Eq.(4) to Eq.(3) produces the well-known formula for the velocity variance:

$$\sigma_{\dot{x}}^2 = \frac{\pi.F_0}{m.c_0} \tag{5}$$

Conjecturing the Rice pulsation, defined as: $\omega_{Ri} = \sigma_{\dot{x}} / \sigma_x$, is here equal to the oscillator eigen-pulsation, $\omega_0 = \sqrt{k_0 / m}$, we deduce from Eq.(5):

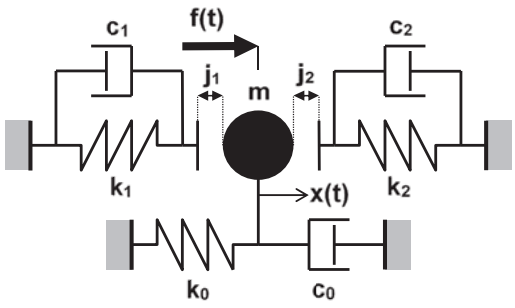
$$\sigma_x^2 = \frac{\pi.F_0}{m.c_0.\omega_{Ri}^2} = \frac{\pi.F_0}{k_0.c_0} \tag{6}$$

which is effectively the right expression for the displacement variance of an elastic oscillator whitely excited. In addition, it is recalled that the oscillator response is Gaussian.

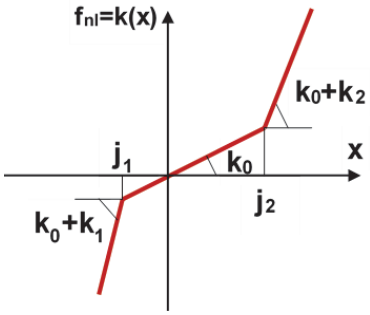
4 ELASTIC SHOCK OSCILLATOR (ESO)

ESO model is presented Figure 1-a. ESO are "without memory" in the sense that the current state of the oscillator in the phase space (displacement-velocity) is sufficient to determine the internal force that applies on the mass. A typical behavior law in terms of force-displacement relationship is shown Figure 1-b. We consider as ESO sub-classes:

- the elastic symmetric shock oscillator (ESSO), with two symmetrical stops in compression, and consequently an odd behavior law for positive and negative displacements of the mass;
- the elastic asymmetric shock oscillator (EASO), e.g. with one stop on only one side, the behavior remaining linear in the opposite direction.



(a) ESO Model



(b) Load-Displacement Law

Figure 1: Elastic Shock Oscillator (ESO)

4.1 ESO Response from Energy Balance

First, we consider ESSO, taking $j_1=j_2$ for the gap size, $k_1=k_2>>k_0$ for the stop stiffness, and $c_1=c_2=0$ for undamped stops (see Fig.1-a). So, the only dissipative component remains the viscous dashpot c_0 that is permanently acting; therefore, Eq.(5) still holds, which permits to get the *accurate* velocity variance that is independent of the stop characteristics (gap, rigidity).

The gap system is intuitively "bordered" by two extreme cases concerning the gap size: infinite (open gaps) or zero (closed gaps), that both produce a linear behavior. So, it can be conjectured that the actual Rice pulsation lies in the range: $\omega_0 \le \omega_{Ri} \le \omega_1 \simeq \sqrt{k_1 / m}$.

Let σ_{x0} the standard deviation in displacement obtained from Eq.(6), and attached to the associated linear oscillator (ALO) that corresponds to ESO with open gaps. The reduced gap, $j^*=j_1/\sigma_{x0}$, informs, at least qualitatively, about the occurrence of impacts knowing the ALO response is Gaussian. So, for "high" values of the reduced gap ($j^* \ge 3$), the impact frequency almost coincides with the ALO crossing rate [1-4]; for the right stop (idem for the left one): $f_j \simeq f_0.\exp(-j^{*2}/2)$; moreover, the Rice frequency is (quasi) the ALO one: $f_{Ri} \cong f_0 = \omega_0/2\pi$. But of course, the ALO predictions are no longer quantitative for lower reduced gaps.

Nevertheless, it appears that the impact peak values may be correctly estimated. The ESO joint PDF in the phase space is unknown (see § 4.2). But, we may conjecture: (i) the stationary PDF can be splitted according to the uncorrelated variables that are the displacement and velocity: $p(x,\dot{x}) = p_x(x).p_{\dot{x}}(\dot{x})$; (ii) the velocity part $p_{\dot{x}}(\dot{x})$, whose standard deviation is known via Eq.(5), is Gaussian. Common developments, e.g. [3,4], then permit to establish that the positive crossing velocity ($\dot{x}_a^+$) of any threshold (a) follows a Rayleigh distribution:

$$p_c(\dot{x}_a^+) = \frac{\dot{x}_a^+}{\sigma_{\dot{x}}^2}.\exp\left\{-\frac{\dot{x}_a^{+2}}{2.\sigma_{\dot{x}}^2}\right\} \quad ; \quad \left\langle \dot{x}_a^+ \right\rangle = \sqrt{\frac{\pi}{2}}.\sigma_{\dot{x}} \quad ; \quad \left\langle \dot{x}_a^{+2} \right\rangle = 2.\sigma_{\dot{x}}^2 \tag{7}$$

On the other hand, we can assume that, during each phase of stop contact, the impact peak value F_{max}, developed in the stop, depends at the 1st order on the impact velocity (velocity just at the contact start). This is equivalent to "forget" the white noise and dashpot, anticipating a quasi-zero mean effect. Hence the energy balance: $F_{max}^2 / 2.k_1 + k_0.j_1.(x_{max} - j_1) = m.\dot{x}_{j1}^{+2}/2$, with $F_{max} = k_1.(x_{max} - j_1)$. From Eq.(7), $\sigma_{\dot{x}0} = \omega_0.\sigma_{x0}$, $F_{max}^2 + 2.k_0.j_1.F_{max} \approx (F_{max} + k_0.j_1)^2$, we obtain the following approximation:

$$\frac{\langle F_{max} \rangle}{k_0.\sigma_{x0}} \simeq \sqrt{\frac{\pi}{2}}.\sqrt{\alpha} - j^* \quad \text{with} \quad \alpha = \frac{k_1}{k_0} \tag{8}$$

which will be proven to be excellent (see § 4.2).

4.2 ESO Response from Stochastic Diffusion Process

The ESO response to a white excitation constitutes a stochastic diffusion process (a class of Markov process) when described in the phase space displacement-velocity. Thus, the joint PDF, that is time dependent $p_t(x,\dot{x})$ given the initial conditions (e.g. ESO at rest when suddenly excited), satisfies a partial derivatives equation (PDE), the Fokker-Planck equation (also named forward Kolmogorov eq.), that is hereafter derived for ESO with undamped stops, k(x) being the nonlinear rigidity (see [1-5]):

$$\frac{\partial p_t(x,\dot{x})}{\partial t} = -\frac{\partial[\dot{x}.p_t(x,\dot{x})]}{\partial x} - \frac{\partial[(-k(x).m^{-1} - c_0.\dot{x}.m^{-1}).p_t(x,\dot{x})]}{\partial \dot{x}} + \pi F_0.m^{-2}.\frac{\partial^2 p_t(x,\dot{x})}{\partial \dot{x}^2} \tag{9}$$

The left term $\partial p/\partial t$ vanishes in stationary regime. Then, Eq.(9) has a "simple" analytical solution under the form, $p=C.\exp(-\gamma.E_v)$, where E_v is the ESO vibratory energy (elastic potential U(x) + kinetics $m.\dot{x}^2/2$), and C and γ two constants [5]:

$$p(x,\dot{x}) = \frac{1}{2\pi.\sigma_{x0}.\sigma_{\dot{x}0}.A}.\exp\left\{-\frac{1}{2.\sigma_{x0}^2}.\frac{2.U(x)}{k_0} - \frac{\dot{x}^2}{2.\sigma_{\dot{x}0}^2}\right\} \tag{10}$$

In Eq.(10), σ_{x0} and $\sigma_{\dot{x}0}$ represent the ALO standard deviations, respectively in displacement and velocity (see Eq.(6) & (5)). First, we note that the PDF properties, conjectured in the previous section, are verified. The constant A (or $C = 1/2\pi.\sigma_{x0}.\sigma_{\dot{x}0}.A$) is for the PDF normalization: $\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} p(x,\dot{x}).dx.d\dot{x} = 1$, and is given in Appendix A for ESSO and EASO. Trivial calculations using the above PDF give birth to closed-form formula for certain quantities of interest [5-6]. Let us quote:

Crossing Rate. By applying the well-known Rice formula, $\nu_a^+ = \int_0^{+\infty} \dot{x}.p(a,\dot{x}).d\dot{x}$, we obtain:

$$\nu_a^+ = \nu_0^+.\exp\left\{-\frac{1}{2.\sigma_{x0}^2}.\frac{2.U(a)}{k_0}\right\} \quad \text{with} \quad \nu_0^+ = \frac{f_0}{A} \tag{11}$$

Impact Frequency. Using Eq.(11), and distinguishing the left stop (subscript 1) and the right one (subscript 2), we have:

$$\nu_{j1} = \nu_0^+.\exp(-j_1^{*2}/2) \quad ; \quad \nu_{j2} = \nu_0^+.\exp(-j_2^{*2}/2) \tag{12}$$

Rice Frequency. For ESSO (see Appendix A for the G value and EASO).

$$f_{Ri} = \frac{1}{2\pi}.\sqrt{\frac{\sigma_{\dot{x}}^2}{\sigma_x^2}} = f_0.\sqrt{\frac{A}{G}} \tag{13}$$

The reduced frequencies (ν_0^+ / f_0) & (f_{Ri} / f_0) are shown Figure 2-a for ESSO having different ratios of rigidity $\alpha = k_1/k_0$.

Peak penetration PDF. Under a "narrow band assumption": one single peak of x(t) per stop contact, of amplitude (a), we get the conditional PDF: $p(a \mid a \geq j_2) = -(\partial\nu_a^+ / \partial a) / \nu_{j2}^+$. Noting, $\zeta_2^* = (a - j_2)/j_2$, the reduced penetration of the right stop, we then deduce the PDF:

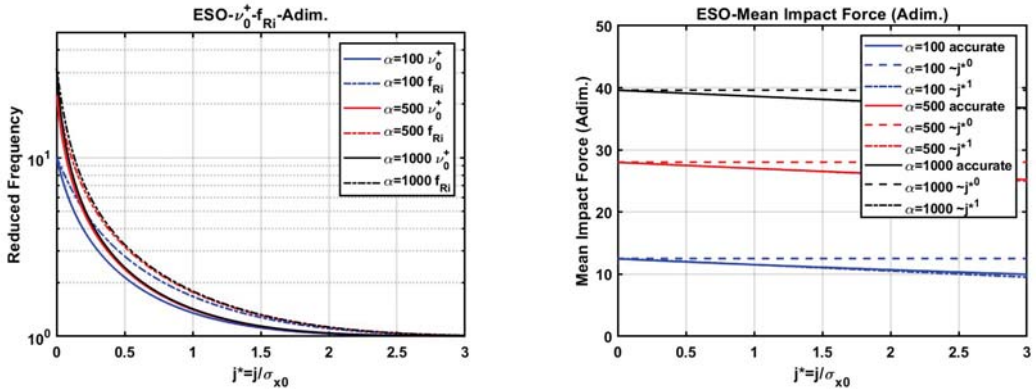
$$p(\zeta_2^*) = j_2^{*2}\left(\zeta_2^*.(1+\alpha_2)+1\right).\exp\left\{-\frac{j_2^{*2}}{2}\left(\zeta_2^{*2}.(1+\alpha_2)+2.\zeta_2^*\right)\right\} \tag{14}$$

This simplified expression agrees with more rigorous ones derived from filtered white noise, [5], see section 6. It stands also for the left stop with $\zeta_1^* = (|a| - j_1)/j_1$.

Impact Mean Force. This quantity may be derived from previous Eq.(14). We get for the right stop (similar formula for the left stop):

$$\frac{\langle F_{max,2}\rangle}{k_0.\sigma_{x0}} = \sqrt{\frac{\pi}{2}}.\frac{\alpha_2}{\sqrt{1+\alpha_2}}.\exp\left(\frac{j_2^{*2}}{2.(1+\alpha_2)}\right).\operatorname{erfc}\left(\frac{j_2^*}{\sqrt{2.(1+\alpha_2)}}\right) \tag{15}$$

Eq.(8), "made by hand", appears to be a first order development of Eq.(15) in j*. So, at the zero order, the (reduced) mean impact force does not depend on the gap size, but only on the stop rigidity (via α), and it slightly decreases by opening the gaps, as illustrated Figure 2-b.



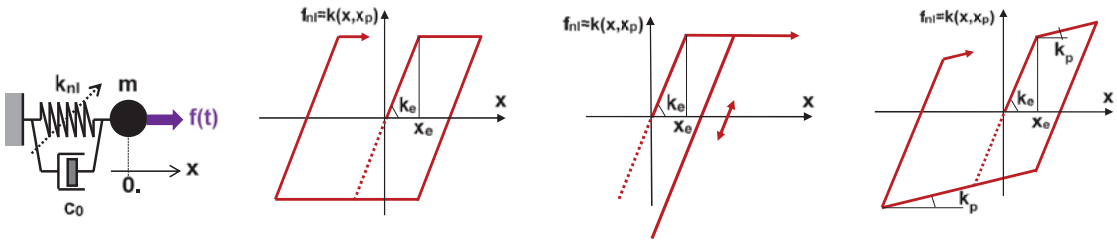
(a) Zero Crossing Rate & Rice Frequency (b) Mean Impact Force

Figure 2: Results for Elastic Shock Oscillator (ESO)

5 ELASTO-PLASTIC OSCILLATOR (EPO)

EPO model is schematized Figure 3-a where the dotted arrow stands for the elasto-plastic restoring force. EPO totally differ from ESO through the softening rigidity (ESO has hardening one) and the memory effect embedded in the plastic drift that may be viewed as a hidden internal variable. Indeed, at time t, the EPO displacement, $x(t)=x_p(t)+z(t)$, comprises a plastic part $x_p(t)$, and an elastic one, here named z(t), to avoid confusion with the elastic limit x_e present in the force-displacement relationship. Thus, the current displacement x(t) is not sufficient to determine the internal force that applies on the mass (the oscillator past response, via x_p, is required). The type of plasticity, encapsulated in the behavior law, pilots different subclasses (see Fig.3); we consider here:

- the elastic-perfectly-plastic oscillator (EPPO), with a zero plastic slope and a symmetrical plasticity in tension and compression (Fig. 3-b);
- the elastic-unilaterally-plastic oscillator (EUPO), with a plasticity only in tension (and a zero-plastic slope; Fig. 3-c);
- the elastic-kinematically-plastic oscillator (EKPO), with a non-zero plastic slope and a kinematic plasticity, i.e. the elastic range stays constant and equal to the initial one, whatever the plastic drift (Fig. 3-d).



(a) EPO Model (b) EPPO Law (c) EUPO Law (d) EKPO Law

Figure 3: Elasto-Plastic Oscillator (EPO)

5.1 EPO Response from Energy Balance

The elastic part of the EPO displacement is bounded, by construction, to the elastic limit(s). Consequently, it is often adequate to reduce the EPO dynamics to the quantification of the plastic drift which dramatically depends on the plasticity model that is operated.

EUPO. Considering, first, an EUPO with plasticity only in tension, zero plastic slope (Fig.3-c), and no viscous damping. The only dissipative mechanism in this system is the work made by the plastic force, $f_e = k_e.x_e$, during the plastic drift, $x_p(t)$, that is always growing in the positive direction. We get from the energy balance:

$$\frac{\pi.F_0}{m} = f_e.\left\langle \dot{x}_p^+ \right\rangle \tag{16}$$

where we recognize, in the last right term, the plastic growing average rate, including both the plastic phases, $z(t)=x_e$, and the elastic ones, $z(t)<x_e$, $dx_p(t)/dt=0$.

Let the EUPO at rest and virgin at time 0, $z(0)=0$, $x_p(0)=0$, when suddenly excited. The plastic growing rate, extracted from Eq.(16), gives a solid information about the oscillator displacement at time t: $x(t) \simeq x_p(t) \simeq \left\langle \dot{x}_p^+ \right\rangle.t$, provided the time t is large enough to count a lot of plastic events while erasing the initial elastic phase (before the 1st plasticity). Note that the plastic excursions are unavoidable, whatever the plastic force level (f_e), the detail of which (parameters x_e, k_e) doesn't matter. Now, if the EUPO is viscously damped, Eq.(16) is changed into (the decomposition of the plastic rate is explained hereafter):

$$\frac{\pi.F_0}{m} = c_0.\left\langle \dot{x}^2 \right\rangle + f_e.\left\langle \dot{x}_p^+ \right\rangle = c_0.\left\langle \dot{x}^2 \right\rangle + f_e.\nu_p^+.\left\langle \delta_p^+ \right\rangle \tag{17}$$

with two dissipation mechanisms in competition according to the reduced elastic limit, $x_e^*=x_e/\sigma_{x0}$, σ_{x0} being the standard deviation of the ALO that is equivalent to EPO with infinite elastic limit. Just like ESO, for "high" values, $x_e^* \geq 3$, the plasticity frequency almost coincides with the ALO crossing rate of the elastic limit: $\nu_p^+ \simeq f_0.\exp(-x_e^{*2}/2)$; moreover, the oscillator velocity, at the entry in plasticity, follows the Rayleigh distribution of Eq.(7), which permits to estimate the mean plastic drift through a crude energy balance:

$$\left\langle \dot{x}_e^{+2} \right\rangle = 2.\sigma_{\dot{x}0}^2 \Rightarrow k_e.x_e.\left\langle \delta_p^+ \right\rangle \simeq \frac{1}{2}m.\left\langle \dot{x}_e^{+2} \right\rangle \Rightarrow \left\langle \delta_p^+ \right\rangle \simeq \frac{\sigma_{\dot{x}0}^2}{\omega_0^2.x_e} = \frac{\sigma_{x0}}{x_e^*} \tag{18}$$

For lower values, $x_e^*<3$, more advanced analyses are necessary. Nevertheless, rough orders of magnitude might be conjectured from the oscillator conditions at each plasticity exit (at time τ_n): $z(\tau_n) = x_e$, $\dot{x}(\tau_n) = 0$. So,

$$\left\langle \dot{x}^2 \right\rangle = \left\langle \dot{x}_p^2 \right\rangle + \left\langle \dot{z}^2 \right\rangle \sim (\omega_0.x_e)^2/2 \tag{19}$$

to be inserted in Eq.(17). EUPO is a special case where the knowledge of the global plastic rate, through the energy balance, gives directly a pertinent information about the plastic drift which is constantly growing. This is no longer the case for EPPO and EKPO.

EPPO. In the elastic-perfectly-plastic oscillator (Fig.3-b), the plasticity occurs in tension or compression in a symmetrical way, with identical plastic parameters, except for the signs; for example, undamped EPPO leads to an energy balance similar to Eq.(16):

$$\begin{gathered} \frac{\pi.F_0}{m} = +f_e.\left\langle \dot{x}_p^+ \right\rangle - f_e.\left\langle \dot{x}_p^- \right\rangle = 2.f_e.\left\langle \dot{x}_p^+ \right\rangle \\ \text{with } \left\langle \dot{x}_p^+ \right\rangle = \nu_p^+.\left\langle \delta_p^+ \right\rangle;\ \left\langle \dot{x}_p^- \right\rangle = \nu_p^-.\left\langle \delta_p^- \right\rangle;\ \nu_p^- = \nu_p^+;\ \left\langle \delta_p^- \right\rangle = -\left\langle \delta_p^+ \right\rangle \end{gathered} \tag{20}$$

Consequently, the mathematical expectation of the plastic drift, viewed as a stochastic process, is always zero, whatever the time t. This is a correct, but poor information for people generally interested in the maximum displacement reached during the period of observation (0,T), or, in other words, in the demanded ductility: $\mu_T = \max_{0\le t\le T} |x(t)| / x_e$. In fact, the plastic drift is similar to a *Brownian motion*: its average is zero, but its variance linearly grows with the time. This has been demonstrated for damped EPPO, first heuristically (e.g. see [9]), then mathematically [13]. The knowledge of this growing rate permits, using the central limit theorem, to determine the demanded ductility in a probabilistic way [9]. Unfortunately, this requires additional ingredients out of the scope of the only Eq.(20), that can nevertheless be used as discussed in section 5.2.

EKPO. The introduction of a non-zero plastic slope k_p (Fig.3-d), even very weak, dramatically changes the plastic drift with respect to EPPO. Let the EKPO initially at rest (and virgin); the kinematic plasticity (with a constant elastic range) makes the oscillator to continuously experience plastic excursions, but the plastic drift will have a zero mean, and a finite variance, *time invariant* once the stationary regime reached (e.g. see [11]). Determining this variance, and more generally the EKPO dynamics, requires additional ingredients that only detailed analyses can provide. But analyses, "at the zero order" or "by hand", are always interesting for the understanding. Such a primitive analysis could be reduced to:

$$\frac{\pi.F_0}{m} \approx f_e.\left\langle\left|\dot{x}_p\right|\right\rangle;\ \left\langle\left|\dot{x}_p\right|\right\rangle = \nu_p.\left\langle\left|\delta_p\right|\right\rangle;\ \left\langle\delta_p^2\right\rangle \simeq 2.\left\langle\left|\delta_p\right|\right\rangle^2;\ \left\langle x_p^2(t)\right\rangle \sim \left\langle\delta_p^2\right\rangle / 2.A \qquad (21)$$

The 1st relation is the energy balance for an undamped EKPO with a moderate plastic slope, in such a way f_e is taken constant. The 2nd one is the decomposition of the average (absolute) plastic rate into the plastic frequency and the mean absolute plastic jump. The 3rd one supposes an exponential law for the plastic jumps, which is roughly verified in most cases, the velocity being Rayleigh distributed at the entry in plasticity [11]. The 4th one is specific to EKPO. Omitting the subscript p, we can write the nth plastic jump: $x_{n+1} = x_n + \delta_n$. By taking the mathematical expectation of this relation, squared, we obtain for the stationary regime, $\left\langle\delta_n^2\right\rangle + 2\left\langle x_n.\delta_n\right\rangle = 0$, where the 2nd term must be negative. At the 1st order, given the EKPO plastic law, and reinforced by time-history simulations, we have, in mean, $\delta_n = -A.x_n$, with A constant, which explains the 4th relation. Shortly, Eq.(21) says that the knowledge of ν_p and A suffices to get, in order of magnitude, the plastic variance from the energy balance, and consequently the demanded ductility, the plastic drift being Gaussian. How these two parameters, ν_p and A, could be conjectured cannot be detailed here.

5.2 EPPO Response from Stochastic Diffusion Process

Following the seminal paper [7] by Karnopp & Sharton, a lot of works (e.g. see [8-12]) has been made using the conditional probability devoted to the ALO, and exposed in Appendix B. Such use is clear: first, the EPPO behaves linearly and elastically between two plastic excursions, and, secondly, the initial conditions of *each* elastic phase are driven by the plasticity exit and are known: $z(0) = \pm x_e$; $\dot{z}(0) = 0$ (with a time reset). The joint PDF $p_t(z,\dot{z})$, whose expression is analytical, permits to obtain relevant statistics at the first ALO crossing of the elastic barriers ±xe, i.e. when the EPPO enters again in plasticity.

Among these statistics, a key factor is the probability P_1 that the next plasticity occurs immediately, on the opposite elastic barrier, after a half-cycle corresponding roughly to the ALO semi-period ($T_0/2$). Indeed, plasticity occurs by "clumps" in EPPO, made of a succession of

elementary plastic events, of alternate sign, spaced in time by about $T_0/2$. The probability P_1 directly pilots the clump size <N>, i.e. the average number of successive cascaded plastic excursions; it also takes place in the net plastic increment finally obtained at the end of the clump, after an algebraic summation of successive plastic shifts [9] (see after for α & β):

$$\langle N\rangle = \sum_{1}^{\infty} N.p(N) = \frac{1}{1-P_1}\ ;\ \left\langle \delta_p^c \right\rangle = 0\ ;\ \left\langle (\delta_p^c)^2 \right\rangle = 2.\left(\alpha^2 + \frac{P_1}{1-P_1^2}\beta^2 - \frac{P_1}{1+P_1}\alpha\beta \right) \qquad (22)$$

Time-history simulations, as well as the use of the joint PDF $p_t(z,\dot{z})$, show that the velocity distribution, at the entry in plasticity, follows rather well a Rayleigh distribution like Eq.(7) (but with unknown $\sigma_{\dot{x}}$). Consequently, from a crude energy balance (where the average effect of white noise and viscous damping would be zero), each elementary plastic jump follows an exponential law, the parameters of which are α for the *first* jump in the clump, and β for *all* the others *in* the clump; hence Eq.(22-right) that represents the variance of an *idealized* plastic jump modeling the "clump". Moreover, by construction, the plastic clump frequency is:

$$\nu_p^c = \frac{2.\nu_p^+}{\langle N\rangle} = 2.\nu_p^+.(1-P_1) \qquad (23)$$

By assuming the independency of two successive clumps, the growing rate of the *"Brownian"* plastic variance is $\nu_p^c.\left\langle (\delta_p^c)^2 \right\rangle$. Therefore, invoking the central limit theorem, the plastic displacement, at time t, of an EPPO initially virgin is normally distributed with zero mean and variance: $\sigma_{xp}^2(t) = \nu_p^c.t.\left\langle (\delta_p^c)^2 \right\rangle$. On the other hand, the EPPO is said "collapsed" if the demanded ductility, μ_T, exceeds the allowable one, μ, during the period (0,T). A simple development, based on the reflexion principle proper to the (true) Brownian motion, leads to estimate the EPPO collapse probability P_C as (see [9]):

$$P_C(\mu,T) = 1-\left(1-P(\mu,T)\right)^2 \text{ with } P(\mu,T) = 2.\int_{\mu.x_e}^{+\infty} \frac{1}{\sqrt{2\pi}.\sigma_{xp}(T)}.\exp\left(-x_p^2/2.\sigma_{xp}^2(T)\right).dx_p \qquad (24)$$

This *"Brownian"* approach, that requires the determination of four parameters: P_1, α, β, ν_p^c, may be simplified, using Eq.(20) and supposing $\alpha \approx \beta \approx \left\langle \delta_p^+ \right\rangle$:

$$\nu_p^c.\left\langle (\delta_p^c)^2 \right\rangle = \frac{4.\left\langle \dot{x}_p^+ \right\rangle.\beta}{1+P_1} \qquad (25)$$

This formula shows how the global plastic rate extracted from the energy balance must be married with the plastic parameters P_1 and β related to plasticity in the clump; (see also [17]).

5.3 EPPO from Stochastic Variational Inequality (SVI)

This section summarizes, without any mathematical rigor, the new ideas emerging for a decade to characterize the EPPO dynamics. Readers are invited to consult the references [13-15], for more details, especially for the mathematical foundations. For clarification, the previous notations are completed as follows: y(t) is the oscillator velocity, Z the elastic limit ($Z \equiv x_e$), w(t) a Wiener process, the time derivative of which produces the forcing white noise; in addition, all the force terms are referred to a unit mass (m=1).

SVI. EPPO satisfies the following usual equations in the time domain:

$$\begin{gathered}\text{elastic phase: } \ddot{z}+c_0.\dot{z}+k_0.z=\dot{w}(t) \;\; ; \text{ plastic phase: } \dot{y}+c_0.y\pm k_0.Z=\dot{w}(t)\\ \text{with: } \; z(t)=x(t)-x_p(t) \;\; ; \;\; y(t)=\dot{x}(t)\end{gathered} \tag{26}$$

In fact, the whole may be encapsulated into the stochastic variational inequality (SVI):

$$\forall t, \forall|\varphi|\le Z,\; dy(t)=-\big(c_0.y(t)+k_0.z(t)\big).dt+dw(t) \;\; ; \;\; \big(dz(t)-y(t).dt\big).\big(\varphi-z(t)\big)\ge 0 \tag{27}$$

in which x(t) no longer appears explicitly. This formulation permits, in a mathematically well-founded and rigorous way, to derive a PDE involving the couple (z(t),y(t)) with the non-standard boundary conditions attached to the plastic saturation: z(t)=±Z. Particularly, the infinitesimal generator, proper to the diffusion process, can be determined using Ito's lemma. This generator is given in Appendix C, while the concept, and its current use, are briefly reported hereafter.

Diffusion Generator. The pair made of the elastic displacement, $z(t)\equiv z_t$, and the oscillator velocity, $y(t)\equiv y_t$, constitutes a Markov process of diffusion in R^2. This process may be described thanks a set (Ω) of continuous functions, $\phi(z,y)$: $R^2\to R$, of sufficient regularity. The operator, $T_t(\phi):\Omega\to\Omega$, is thus defined as follows: $T_t\phi(z_s,y_s)=\big\langle\phi(z_{t+s},y_{t+s})\,|\,(z_s,y_s)\big\rangle$; in words, for each location z(s),y(s) in the phase space at time s, it gives the mathematical expectation of the function ϕ at time t+s, i.e. after a delay of t. This operator forms a semi-group; noting z for z_0, y for y_0: $T_{t+s}\phi(z,y)=T_t(T_s\phi(z,y))=(T_t\circ T_s)\phi(z,y)$; $T_0\phi(z,y)=\phi(z,y)$, from which the infinitesimal generator L is defined: $L\phi(z,y)=\lim_{t\to 0}(T_t\phi(z,y)-\phi(z,y))/t$. This concept is classic for Markov process, but the generator has here an unusual form (see App. C), and, moreover, it will be operated in an original way.

Generator Use. The derivation, $\partial(T_t\phi)/\partial t=T_tL\phi=LT_t\phi$, can be easily proved, at least heuristically. Noting for clarity, $T_t\phi(z,y)=v_\phi(t,z,y)$, so: $\partial v_\phi(t,z,y)/\partial t-Lv_\phi(t,z,y)=0$.

The Laplace transform of v_ϕ is: $u_{\lambda,\phi}(z,y)=\int_o^{+\infty}e^{-\lambda t}.v_\phi(t,z,y).dt$. Integrating by parts and using the previous relation, $\partial v_\phi/\partial t=Lv_\phi$, we get: $\lambda.u_{\lambda,\phi}(z,y)=\phi(z,y)+\int_o^{\infty}e^{-\lambda t}.Lv_\phi(t,z,y).dt$, that finally gives, as the generator L is time independent (in invariant model):

$$\lambda.u_{\lambda,\phi}(z,y)-Lu_{\lambda,\phi}(z,y)=\phi(z,y) \tag{28}$$

The final value theorem for the Laplace transform F(λ) of the function f(t) specifies that: $\int_0^{\infty}e^{-\lambda t}.\partial_t f(t).dt=\lambda.F(\lambda)-f(0^+)\;\Rightarrow\;\lim_{\lambda\to 0}\lambda.F(\lambda)=f(+\infty)$. Applying here this theorem:

$$\lim_{\lambda\to 0}\lambda.u_{\lambda,\phi}(z,y)=\lim_{t\to\infty}v_\phi(t,z,y)=\lim_{t\to\infty}\big\langle\phi\big(z(t),y(t)\big)\big\rangle=\int m(z,y).\phi(z,y).dz.dy \tag{29}$$

in which m(z,y) stands for the stationary probability density function (PDF) of the pair (z,y). It is worth noting that the initial conditions (z, y, at time 0) are "dissolved" in this formulation since: $\forall(z,y),\lim_{\lambda\to 0}\lambda.u_{\lambda,\phi}(z,y)=\int m(z,y).\phi(z,y).dz.dy=\text{constant}$.

PDF computation. For the computation, the PDF m(z,y) is approximated by a decomposition on a set of given basis functions, $g^i(z,y)$: $m(z,y)\simeq\sum_i m_i.g^i(z,y)$, where m_i are the unknown scalars to be determined. The computation process is thus clear:

(a) Choice of a "sufficient small" λ.

(b) For each i, resolution in $u_{i,\lambda}$ of Eq.(28): $\lambda u_{i,\lambda}(z,y) - L u_{i,\lambda}(z,y) = g^i(z,y)$, which provides according to Eq.(29): $\lambda.u_{i,\lambda} \simeq \int \sum_j m_j.g^j(z,y).g^i(z,y).dz,dy \simeq \sum_j m_j.G_{ij}$.

(c) Inversion of the system: $\left[G_{ij}\right]\left\{m_j\right\} = \left\{\lambda.u_{i,\lambda}\right\}$, where $G_{ij} = \int g^i(z,y).g^j(z,y).dz.dy$.

Finite Difference. The previous step (b) is solved by a finite difference method on a limited grid, from -Z to +Z for the elastic displacement z (which is self-obvious), from -Y to +Y for the oscillator velocity y (see Fig.4-a). Y is large enough to ensure a Neuman condition on the border $\partial u/\partial y=0$. The L operator (App. C) is discretized in a symmetrical, but very common way. For example, noting i and j the subscripts respectively attached to z and y, we have for the terms involving derivatives with respect to y:

$$(L_y u)_{i,j} \triangleq \frac{a_{22}}{2}\frac{u_{i,j+1} - 2u_{i,j} + u_{i,j-1}}{\Delta y^2} - \max(0, b_{i,j})\frac{u_{i,j+1} - u_{i,j}}{\Delta y} - \min(0, b_{i,j})\frac{u_{i,j} - u_{i,j-1}}{\Delta y} \qquad (30)$$

with $b_{i,j} = (c_0 y_j + k_0 z_i)$; see [16] for details. Figure 4-b shows an example of PDF, m(z,y), obtained with the grid of Fig.4-a (ξ_0=4%, x_e*=1). We particularly notice the PDF profile on the elastic barriers: z=+x_e, y≥0 ; z=-x_e, y≤0 . This PDF is coherent with Monte-Carlo results, but the precision and convergence rate cannot be discussed here.

6 "WHITE NOISE OF ENGINEER"

White noise is nowadays defined as the time derivative (in the sense of distribution) of Wiener process, which permits mathematically-well-founded developments. But degenerating the mathematical white noise F_0, the variance of which is infinite, into a physically-realizable process $S_{ff}(\omega)$ remains a necessity for engineers which face the real world. This transformation is generally without great consequence provided the cut-off frequency (~1/2.Δt) is large enough compared to the oscillator characteristic frequencies. Furthermore, engineers are most of the time interested in quantities at macro-or-meso-scale, by nature filtered or averaged. Nevertheless, we should be aware about the specificity of white noise, as well as the eventual impact of the cut-off frequency. Indeed, the convergence of certain quantities, as the time step Δt decreases, can be affected or "polluted" by micro-peaks-or-oscillations taking place in the oscillator trajectory. The purpose of this section is just to illustrate such phenomena.

Concerning ESO, Figure 5-a presents an example of peak penetration PDF obtained from Eq.(14), under "a narrow band assumption" (NBA). Analytical PDF got from filtered white noise (FWN) are also indicated, following [5] with a first order filter of eigen-pulsation, $\Omega=\Omega^*\times\omega_{j0}$ (ω_{j0} being the ESO pulsation with closed gaps). We see on Fig. 5-a how the PDF slightly differ as Ω^* increases, while producing very close mean values. The NBA assumption, "one single peak per stop contact", is so justified, as the more as it produces simple expressions such as Eq.(14) & (15).

Concerning EPO, Figure 5-b presents the crossing frequency $\nu_e(t)$ of the elastic limit x_e for an EUPO coming out of plasticity ($x=x_e$) at t=0. It has been obtained from the Rice formula: $\nu_e(t)=\int_0^{+\infty}\dot{x}.p_t(x_e,\dot{x}).d\dot{x}$, applied to the conditional probability reported in Appendix B. By definition, $\nu_e(t).dt$ is the probability of crossing during the differential time interval [t,t+dt). For short durations, this probability may be integrated [17]. We see on Fig. 5-b two contributions. The "bump", on the right part of the dotted blue line, corresponds to the crossing probability, roughly a period later (T_0=0.1 s). But we see also, on the left part, the asymptotic increase of the PDF towards t=0. Physically, it corresponds to a return in plasticity, just after the exit, due to a noise impulse, all the more possible as the elastic restoring force is weak and the noise intensity strong. The integral of this PDF portion tends to 1 (probability almost surely) for "true" white noise, for which the border between plasticity and elasticity becomes fuzzy in time. The plastic-elastic border is more and more net as the white noise is truncated in frequency. But this illustrates how simulations, especially in the time domain, may be delicate when involving white noises, and the necessity of "adequate" quantities to make comparisons or convergence tests.

7 CONCLUSION

This paper treated of the response of nonlinear single oscillators submitted to white noise excitations. The oscillators were, on the one hand, the elastic shock oscillators (ESO), with symmetrical or asymmetrical stops (resp. ESSO & EASO), and, on the other hand, the elasto-plastic oscillators (EPO), with different types of plasticity: perfect, unidirectional or kinematic (resp. EPPO, EUPO & EKPO). The subject is very broad, and the purpose of the paper was just to illustrate the following points:

- A white external force injects the same energy rate into all the oscillators having the same mass, whatever their non-linearities and dissipation mechanisms. Thus, a simple energy

balance provides a first level of information about the oscillators' dynamics, that can even be very quantitative in some cases (EUPO, ESO) with the help of additional conjectures.

- The next step is to build and feed the dynamics on nonlinear oscillators from the ones of the associated linear oscillators (ALO), the theory of which is well mastered. This "old" and common way is always source of improvements (e.g. [17] for EPO).
- The "ultimate" step is evidently to use relevant theories concerning the stochastic diffusion processes, such as Fokker-Planck equation (used here for ESO), or stochastic variational inequality (SVI, used here for EPPO). In most cases, these theories result in numerical computations (e.g. [6] for ESO with damped stops) that can serve of references, just like Monte-Carlo simulations. But special care must be done to the white noise specificity.
- Finally, analytical results devoted to nonlinear single oscillators, whitely excited, could appear of only academic interest, while Monte-Carlo simulations can now be easily operated. But the authors' opinion is that 1-DOF results, especially with closed-forms, exceed the academic sphere by providing tendencies that could be useful for engineers. Figure 2-b is such an example: it was not a priori evident that opening the gaps in ESO let quasi-unchanged the mean impact force. The change of plastic behavior, from "Brownian" for EPPO, to stationary for EKPO, is another example.

An engineer must have clear ideas. And this is the *set* of analyses, from the simplest (e.g. 1-DOF with energy balance) to the most complex (e.g. based on sophisticated finite-element models), that should forge his mind in the clarification and hierarchization of the involved physical phenomena he has to cope with.

APPENDIX A: RESULTS FOR ELASTIC SHOCK OSCILLATOR (ESO)

ESSO: elastic symmetric shock oscillator. EASO: elastic asymmetric shock oscillator.

Subscripts 1, 2 are respectively for the left and right stop (Fig.1-a); j is the gap size (j≥0); j* the reduced gap size, e.g. $j_1^* = j_1 / \sigma_{x0}$ (σ_{x0} is the ALO standard deviation); α the ratio of the stop stiffness over the permanent one, e.g. $\alpha_1 = k_1 / k_0$. The subscripts are omitted for ESSO : $j = j_1 = j_2$, $\alpha = \alpha_1 = \alpha_2$, except for the stop rigidity noted k_1.

Constant A: $A = \dfrac{A_1 + A_2}{2}$ for EASO, with (idem for A_2):

$$A_1 = \operatorname{erf}\left(\frac{j_1^*}{\sqrt{2}}\right) + \frac{1}{\sqrt{1+\alpha_1}}.\exp\left(\frac{-j_1^{*2}.\alpha_1}{2.(1+\alpha_1)}\right).\operatorname{erfc}\left(\frac{j_1^*}{\sqrt{2.(1+\alpha_1)}}\right) \qquad \text{(A-1)}$$

For ESSO: $A = A_1 = A_2$.

Mean displacement: for EASO, $E(x) = \dfrac{\sigma_{x0}}{\sqrt{2\pi}.A}.(H_1 - H_2)$, with (idem for H_2):

$$H_1(j_1^*, \alpha_1) = \left\{ \frac{\alpha_1}{1+\alpha_1}.\exp\left(\frac{-j_1^{*2}}{2}\right) - \frac{\alpha_1}{(1+\alpha_1)^{3/2}}.j_1^*.\sqrt{\frac{\pi}{2}}.\operatorname{erfc}\left(\frac{j_1^*}{\sqrt{2.(1+\alpha_1)}}\right).\exp\left(\frac{-j_1^{*2}}{2}\frac{\alpha_1}{1+\alpha_1}\right)\right\} \qquad \text{(A-2)}$$

For ESSO, E(x)=0 (the mean displacement is obviously zero).

Standard deviation: $\sigma_x^2 = \dfrac{\sigma_{x0}^2}{A}.\left\{\dfrac{g(j_1^*, \alpha_1) + g(j_2^*, \alpha_2)}{2}\right\} - \left[E(x)\right]^2$, with:

$$g(j^*,\alpha)=\left\{\begin{array}{l}\operatorname{erf}\left(\frac{j^*}{\sqrt{2}}\right)-\sqrt{\frac{2}{\pi}}.j^*.\frac{\alpha^2}{(1+\alpha)^2}.\exp\left(\frac{-j^{*2}}{2}\right)+\\ \operatorname{erfc}\left(\frac{j^*}{\sqrt{2.(1+\alpha)}}\right).\frac{1}{(1+\alpha)^{3/2}}.\left(1+j^{*2}.\frac{\alpha^2}{(1+\alpha)}\right).\exp\left(\frac{-j^{*2}}{2}\frac{\alpha}{1+\alpha}\right)\end{array}\right\} \qquad \text{(A-3)}$$

For ESSO: $\sigma_x^2=\sigma_{x0}^2\frac{G}{A}$, with $G=g(j^*,\alpha)$; G is noted in uppercase to distinguish ESSO.

APPENDIX B: CONDITIONAL PROBABILITY FOR A LINEAR OSCILLATOR [7,9]

$x_0,\dot{x}_0$: initial conditions at time t=0. F_0: white noise intensity (PSD for -∞<ω<+∞).

$$p(x,\dot{x},t\mid x_0,\dot{x}_0)=\frac{1}{2\pi.\sigma_{x(t)}.\sigma_{\dot{x}(t)}.\sqrt{1-\rho_t^2}}.$$
$$\exp\left\{\frac{-1}{2.(1-\rho_t^2)}.\left[\frac{(x-C_t)^2}{\sigma_{x(t)}^2}-\frac{2\rho_t(x-C_t)(\dot{x}-\dot{C}_t)}{\sigma_{x(t)}.\sigma_{\dot{x}(t)}}+\frac{(\dot{x}-\dot{C}_t)^2}{\sigma_{\dot{x}(t)}^2}\right]\right\} \qquad \text{(B-1)}$$

1st order terms: $C_t=x_0.g(t)+\dot{x}_0.h(t)$; $\dot{C}_t=x_0.\dot{g}(t)+\dot{x}_0.\dot{h}(t)$, with (B-2)

$$g(t)=e^{-\xi_0.\omega_0.t}.\left(\frac{\xi_0.\sin(\omega_d.t)}{\sqrt{1-\xi_0^2}}+\cos(\omega_d.t)\right);\ h(t)=e^{-\xi_0.\omega_0.t}.\frac{\sin(\omega_d.t)}{\omega_d}\ ;\ \omega_d^2=\omega_0^2.(1-\xi_0^2)$$

2st order terms: $\sigma_x^2(t)=\frac{2\pi.F_0}{m^2}.I_1(t)$; $\sigma_{\dot{x}}^2(t)=\frac{2\pi.F_0}{m^2}.I_2(t)$; $\rho_t=\frac{\pi.F_0.h^2(t)}{m^2.\sigma_{x(t)}.\sigma_{\dot{x}(t)}}$ (B-3)

$$I_1(t)=\frac{1}{\omega_d^2}.\left\{e^{-2.\xi_0.\omega_0.t}\left(-\frac{1}{4.\xi_0.\omega_0}+\frac{\xi_0}{4.\omega_0}.\cos(2\omega_d.t)-\frac{\sqrt{1-\xi_0^2}}{4.\omega_0}.\sin(2\omega_d.t)\right)+\frac{1-\xi_0^2}{4.\xi_0.\omega_0}\right\}$$

$$I_2(t)=\frac{e^{-2.\xi_0.\omega_0.t}}{\omega_d}\left\{-\frac{1}{4\xi_0.\sqrt{1-\xi_0^2}}+\frac{\xi_0}{4\sqrt{1-\xi_0^2}}\cos(2\omega_d.t)+\frac{1}{4}.\sin(2\omega_d.t)\right\}+\frac{1}{4\xi_0.\omega_0}$$

APPENDIX C: INFINITESIMAL GENERATOR FOR EPPO

$$L\phi=\lim_{t\to 0}\frac{\langle\phi(z_t,y_t)\rangle-\phi(z,y)}{t}=\left\{\begin{array}{l}L\phi\triangleq\frac{a_{22}}{2}\frac{\partial^2\phi}{\partial y^2}-(c_0y+k_0z)\frac{\partial\phi}{\partial y}+y\frac{\partial\phi}{\partial z},\ \text{if } |z|<Z\\ L_+\phi\triangleq\frac{a_{22}}{2}\frac{\partial^2\phi}{\partial y^2}-(c_0y+k_0Z)\frac{\partial\phi}{\partial y}+\min(0,y)\frac{\partial\phi}{\partial z},\ \text{if } z=+Z\\ L_-\phi\triangleq\frac{a_{22}}{2}\frac{\partial^2\phi}{\partial y^2}-(c_0y-k_0Z)\frac{\partial\phi}{\partial y}+\max(0,y)\frac{\partial\phi}{\partial z},\ \text{if } z=-Z\end{array}\right.$$

with $a_{22}=\frac{2\pi.F_0}{m^2}$; c_0 and k_0 stands here for $c_0.m^{-1}$ and $k_0.m^{-1}$. (C-1)

Keywords: multiple timescales, spectral analysis, inertial loading, skewness, variance, wave loading.

Abstract. *The Multiple Timescale Spectral Analysis is a framework relying on the existence of well-separated timescales in the dynamic response of structures to generalize for higher-order statistics the famous background/resonant decomposition, widely applied by the wind engineering community to compute the variance of the response of SDOF structures or of each modal response of MDOF structures. This fast spectral analysis method mainly concerns the statistics of the response of onshore structures subjected to a buffeting wind loading whose characteristic frequency is typically lower than the natural frequencies of the structures concerned. By contrast, when dealing with wave-loaded floating offshore structures, the roles of the slow and fast timescales are likely to be interchanged and the method is extended further in this paper to compute rapidly the variances and the skewnesses of modal responses of such structures responding in the inertial regime as well, since these statistics are necessary to consider the influence of the non-Gaussianity of the loading.*

1 INTRODUCTION

The stochastic surge response of a floating structure is governed by a nonlinear differential equation. The nature of this equation is such that the basic input of the problem, the water particle velocity which is commonly assumed to be a Gaussian random process, results in a non Gaussian surge response [10]. As a consequence, the extreme value response might substantially differ from the results predicted with a Gaussian model, which would be based on the variance of the response only [11, 8]. A typical model developed in marine engineering is based on the cubic translation and the evaluation of higher statistical moments [16]. There are two approaches to the solution of this type of problem.

The first approach relies on the generation of samples of the problem input (the wave velocity) and the numerical solution of the problem based on appropriate time marching algorithms. In order to reduce the influence of the sampling and because of the coexistence of several timescales in the problem, namely the slow dynamics of the oscillator and the fast inertial wave loading, it is necessary to model very long signals with very short time steps. This makes this first method computationally intense although straightforward as to its practical implementation.[1],[7],[9]

The second approach consists in a spectral analysis and its higher order extensions [17, 10]. Although the strict equivalence between time and frequency domains vanishes as soon as the problem at hand features some nonlinearities, it is still possible to find relatively accurate estimates of the solution of the problem when the nonlinearities are limited [12]. The use of Volterra and Wiener series is one such approach [15, 13]. In a spectral approach, the variance of the response is obtained as a result of the integral of the power spectral density, while the third (and higher) moments are obtained by integration of the bispectrum (and higher spectra, respectively). Because of the existence of the several timescales in the response, the numerical integration of these spectra might be intense too. However, it is possible to take advantage of the specific form of the spectra and proceed to their Multiple Timescale Spectral Analysis [5]. This method consists in taking advantage of the known local shape of either factor of the spectra (either related to the load, either to the structural filter) and provide approximations of the integral. This method is known to be approximately two orders of magnitude (100 times) faster than a standard numerical integration. It founds its roots in the small correlation expansion [14] and has been being applied in wind engineering since the introduction of the famous background/resonant decomposition [2]. The Multiple Timescale Spectral Analysis generalizes several other similar approximations which provide a simple and rapid evaluation of the statistics of the structural response (covariance [3], third moment [4]) in linear or slightly nonlinear systems [6].

In this paper, the Multiple Timescale Spectral Analysis is specialized to the case of a single-degree-of-freedom system subject to a stochastic loading distributed over its resonant and inertial regimes, i.e. with a main loading frequency band above the natural frequency of the structure. This configuration is typical of the surge response of floating structures and would be typically tackled by means of a numerical integration of the spectra. Instead, we suggest to decompose the response, at second and third orders, as a sum of a resonant and an inertial components. Numerical validations demonstrate the accuracy of the proposed approximate, while being significantly faster.

2 FORMULATION OF THE PROBLEM

2.1 Governing equations

The force exerted by random waves on an oscillating point-like structure, which is undoubtedly small compared to the wavelength of waves, can be expressed according to the Morison equation by the sum of an inertial loading component

$$f_m(t) = k_m \dot{u}(t) \tag{1}$$

resulting from a linear transformation, as the overhead dot denotes partial differentiation in time t, of $u(t)$, the fluctuations of the water velocity around the constant current speed u_c, and a drag, or viscous, loading component

$$f_d(t) = k_d \left|u_c + u(t)\right| \left(u_c + u(t)\right) \tag{2}$$

depending on a nonlinear function of the water velocity, i.e. the sum of the current and the waves speeds. For the sake of simplicity in this short paper, the influence of the movement of the structure itself on the loading is considered as negligible. The coefficients k_m and k_d are related to geometric and hydrodynamic properties through:

$$k_m = c_m \rho_w v_w \quad \text{and} \quad k_d = c_d \rho_w a_w / 2 \tag{3}$$

where ρ_w is the water density, c_m is the inertia coefficient, c_d is the drag coefficient and a_w is the cross-sectional area of v_w, the volume of the submerged part of the structure.

The surge response of a single degree-of-freedom structure subjected to such a one-dimensional Morison-type force is therefore governed by the nonlinear second order differential equation

$$m\ddot{x}(t) + c\dot{x}(t) + kx(t) = f_m(t) + f_d(t) \tag{4}$$

where $x(t)$ is the displacement, k is the stiffness, c is the viscosity and m is the effective mass of the structure, i.e. the mass of the structure plus the added mass of fluid accelerating with the structure, as represented in Figure 1. Because of the memoryless nonlinearity included in the drag loading component, the response of the structure is expected to be non-Gaussian, even if the only input of the dynamical system, the random process $u(t)$, is supposed to be zero-mean, Gaussian, stationary and thus fully defined by its power spectral density $S_u(\omega)$.

The developments presented next are valid no matter the analytical or experimental definition selected for this power spectral density (PSD) but, in order to illustrate the results in a simple manner, the structure is assumed to be located at the still-water level in deep water. In this specific case, the application of the Linear Airy Wave Theory gives

$$S_u(\omega) = \omega^2 S_h(\omega) \tag{5}$$

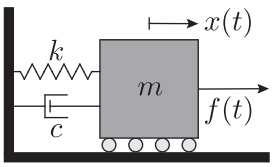

Figure 1: Typical single degree-of-freedom system

and it has been decided then to model the power spectral density $S_h(\omega)$ of the wave elevation process $h(t)$ by the two-sided Pierson-Moskovitz spectrum

$$S_h(\omega) = \frac{5}{32}\frac{\omega_h^4}{|\omega|^5} h_s^2 \mathrm{e}^{-\frac{5}{4}\left(\frac{\omega_h}{\omega}\right)^4} \tag{6}$$

with two parameters, h_s and ω_h, known as the significant wave height and the circular frequency corresponding to the peak of the spectrum of the wave elevation process. By cancelling the derivative of the PSD of the water velocity fluctuations, its own peak circular frequency, ω_u, is found to be equal to

$$\omega_u = \sqrt[4]{\frac{5}{3}}\omega_h \tag{7}$$

The power spectral densities employed in this paper are two-sided and their integration over the circular frequencies ω, from $-\infty$ to ∞, provides the variance of the associated process. Consequently, the variance of the water elevation process and the variance of the water velocity process are respectively given by

$$\sigma_h^2 = \left(\frac{h_s}{4}\right)^2 \quad \text{and} \quad \sigma_u^2 = \sqrt{\frac{3\pi}{4}}\omega_u^2\sigma_h^2 \tag{8}$$

2.2 Dimensionless formulation

A dimensionless formulation of this problem can be written by introducing a characteristic time t_r, a characteristic response x_r and a characteristic wave particle velocity u_r. Defining the dimensionless time $\tilde{t} = t/t_r$, the dimensionless displacement $\tilde{x}\left(\tilde{t}\right) = x\left[t\left(\tilde{t}\right)\right]/x_r$ and the dimensionless water velocity $\tilde{u}\left(\tilde{t}\right) = u\left[t\left(\tilde{t}\right)\right]/u_r$, Equation (4) becomes

$$\frac{m}{kt_r^2}\tilde{x}'' + \frac{c}{kt_r}\tilde{x}' + \tilde{x} = \frac{k_m u_r}{kx_r t_r}\tilde{u}' + \frac{k_d u_c^2}{kx_r}\left|1 + \frac{u_r}{u_c}\tilde{u}\right|\left(1 + \frac{u_r}{u_c}\tilde{u}\right) \tag{9}$$

after a divison by kx_r. The coefficient in front of the dimensionless drag loading component is set to unity by equalizing the characteristic elastic force kx_r to the force of the current $k_d u_c^2$. It is also chosen to define the reference time t_r as the inverse of $\omega_0 = \sqrt{k/m}$, the natural frequency of the system, in order to obtain a unitary coefficient in front of the highest order derivative. Lastly, the reference speed u_r is chosen as σ_u, the standard deviation of the water velocity process $u(t)$, and the presence of the turbulence intensity of waves, $\lambda_u = \sigma_u/u_c$, is hence revealed in the dimensionless formulation of the equation of motion

$$\tilde{x}'' + 2\xi_s\tilde{x}' + \tilde{x} = \kappa_u\lambda_u\tilde{u}' + |1 + \lambda_u\tilde{u}|\,(1 + \lambda_u\tilde{u}) \tag{10}$$

where the symbol $'$ denotes differentiation with respect to the new independent coordinate $\tilde{t}$. Besides,

$$\xi_s = \frac{c}{2m\omega_0} \quad \text{and} \quad \kappa_u = \frac{k_m\omega_0}{k_d u_c} \tag{11}$$

are respectively the structural damping ratio and the loading ratio. Similarly, Equation (5) is rewritten dimensionlessly as

$$S_{\tilde{u}}(\tilde{\omega}) = \sqrt{\frac{3}{\pi}}\frac{\varepsilon_u^2}{|\tilde{\omega}|^3}\mathrm{e}^{-\frac{3}{4}\left(\frac{\varepsilon_u}{\tilde{\omega}}\right)^4} \tag{12}$$

where $\tilde{\omega} = \omega t_r$ is the nondimensional circular frequency and $\varepsilon_u = \omega_u/\omega_0$ is the frequency ratio. The integration property of power spectral densities holds true for the nondimensional processes and can be applied to the rescaled water velocity process, $\tilde{u}(\tilde{t})$, to demonstrate that this input is now characterized by a unit variance, $\sigma^2_{\tilde{u}} = 1$, regardless the value of the frequency ratio ε_u. Interestingly enough, Equation (11) can be rearranged to introduce κ_c, the Keulegan-Carpenter number, that theoretically describes the relative importance of the drag loading component over the inertial loading component. It effectively plays this role in the equation of motion as it appears in the denominator of the loading ratio

$$\kappa_u = \frac{\varepsilon_u}{\kappa_c} \tag{13}$$

According to the Vashy-Buckingham theorem, the problem described in Equation (10) and Equation (12) is actually ruled by a set of four dimensionless numbers, $\{\xi_s, \lambda_u, \varepsilon_u, \kappa_u\}$. In wind engineering applications, where a very similar equation is encountered, these four parameters are typically all small and this property allows to simplify the governing equation. The inertial loading component is directly discarded and the absolute value is not needed anymore in the drag loading component since its argument is always positive. The expansion of the governing equation consequently yields

$$\tilde{x}'' + 2\xi_s\tilde{x}' + \tilde{x} = 1 + 2\lambda_u\tilde{u} + \lambda_u^2\tilde{u}^2 \tag{14}$$

in which the third term is at least one order of magnitude below the second because of the smallness of the turbulence intensity of wind, as detailed in [6]. In marine engineering applications, the structural damping ratio is usually still a small number, ranging between 10^{-3} and 10^{-1}, but the turbulence intensity of waves can reach values up to 2 or more. In addition, the loading ratio and the frequency ratio may take values above one, in the range $[10^0; 10^3]$, when wave-loaded structures are compliant in surge, as floating offshore wind turbines or floating bridges.

3 MULTIPLE TIMESCALE SPECTRAL ANALYSIS

Since the homogenous part of the dynamic system at hand (10) is linear, it is fully characterized by its frequency response function

$$H(\tilde{\omega}) = \frac{1}{1 - \tilde{\omega}^2 + 2i\xi\tilde{\omega}} \tag{15}$$

The PSD of the response thus takes the canonical form

$$S_{\tilde{x}}(\tilde{\omega}) = S_{\tilde{f}}(\tilde{\omega})\, K_s(\tilde{\omega}) \tag{16}$$

where the kernel function is, at second order,

$$K_s(\tilde{\omega}) \equiv |H(\tilde{\omega})|^2 = \frac{1}{\left(1 - \tilde{\omega}^2\right)^2 + 4\xi^2\tilde{\omega}^2}. \tag{17}$$

and, similarly, the bispectrum of the response is given by

$$B_{\tilde{x}}(\tilde{\omega}_1, \tilde{\omega}_2) = B_{\tilde{f}}(\tilde{\omega}_1, \tilde{\omega}_2)\, K_b(\tilde{\omega}_1, \tilde{\omega}_2) \tag{18}$$

where $B_{\tilde{f}}(\tilde{\omega}_1, \tilde{\omega}_2)$ represents the bispectrum of the loading. At third order, the kernel reads [4]

$$K_b(\tilde{\omega}_1, \tilde{\omega}_2) \equiv H(\tilde{\omega}_1)\, H(\tilde{\omega}_2)\, H(-\tilde{\omega}_1 - \tilde{\omega}_2) \tag{19}$$

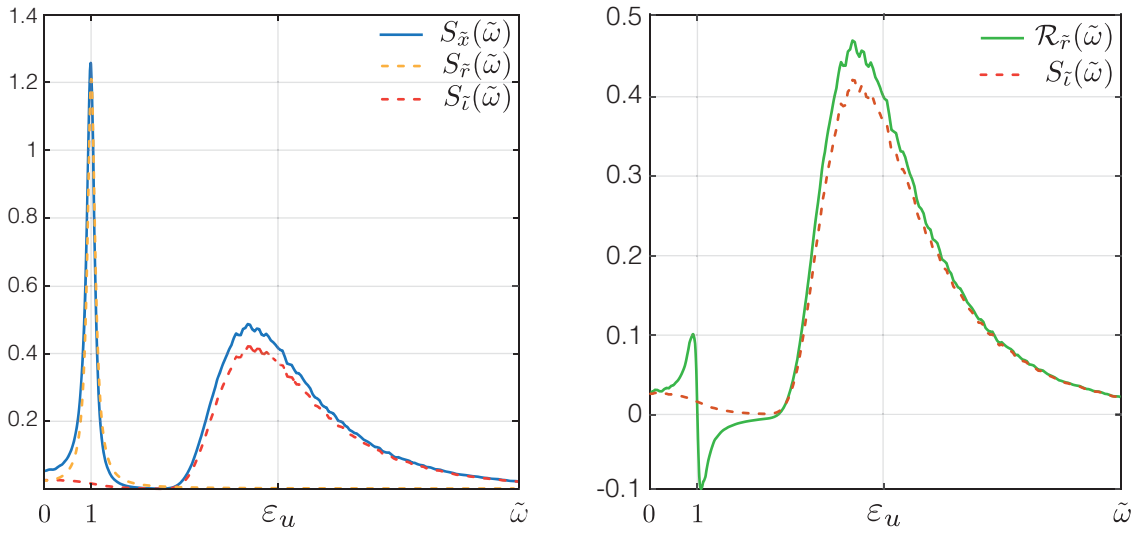

Figure 2: Typical shape of the PSD of the response (symmetrical, represented for $\tilde{\omega} \geq 0$) Numerical values: $\kappa_u = 10$; $\lambda_u = 1$; $\varepsilon_u = 5$ and $\xi = 10^{-1}$.

In a spectral approach, the statistical moments of the response are obtained by the (heavy) integration of the corresponding spectra, in particular

$$m_{2,\tilde{x}} = \int_{\mathbb{R}} S_{\tilde{x}}\left(\tilde{\omega}\right) \mathrm{d}\tilde{\omega} \qquad \text{and} \qquad m_{3,\tilde{x}} = \iint_{\mathbb{R}^2} B_{\tilde{x}}\left(\tilde{\omega}_1, \tilde{\omega}_2\right) \mathrm{d}\tilde{\omega}_1 \mathrm{d}\tilde{\omega}_2 \tag{20}$$

for the second and third moments. The Multiple Timescale Spectral Analysis aims at approximating these integrals with just a few operations [5], while providing at the same time a clear understanding of the different sources of contribution to the integral. Once statistical moments are determined, the skewness coefficient

$$\gamma_{\tilde{x}} = \frac{m_{3,\tilde{x}}}{m_{2,\tilde{x}}^{3/2}} \tag{21}$$

can be computed and used together with the peak factor model.

3.1 Second central moment of the response

As shown in Figure 2, when the frequency ratio ε_u is greater than one, the PSD of the response basically features:
- two resonant peaks having a width of ord (ξ) and being centered in $\tilde{\omega} = \pm 1$;
- two inertial peaks reaching their maximum value when $|\tilde{\omega}| = \text{ord}\left(\varepsilon_u\right)$ and spreading over the frequencies whose absolute value is above a given fraction ζ of the frequency ratio, $|\tilde{\omega}| > \zeta\varepsilon_u$;
- a flat background region in the vicinity of the origin.

As a first step, the introduction of the strained coordinates $\tilde{\omega} = \xi\tilde{\eta} \pm 1$, with $\tilde{\eta} = \text{ord}\left(1\right)$ at most, into Equation (16) allows to focus on the resonant peaks of the PSD of the response and the Taylor series expansion of the kernel function for small damping ratios yields

$$K_s\left(\xi\tilde{\eta} \pm 1\right) \simeq \frac{1}{4\xi^2}\left(\frac{1}{\left(\tilde{\eta}^2+1\right)} \mp \frac{\left(\tilde{\eta}^2+2\right)}{\left(\tilde{\eta}^2+1\right)^2}\xi\tilde{\eta} + \text{ord}\left(\xi^2\right)\right) \tag{22}$$

Likewise, the PSD of the loading is also expanded in Taylor series and reads

$$S_{\tilde{f}}\left(\xi\tilde{\eta}\pm 1\right) \;\simeq\; S_{\tilde{f}}\left(\pm 1\right) + S_{\tilde{f}}^{(1)}\left(\pm 1\right)\xi\tilde{\eta} + \text{ord}\left(\xi^2\right) \tag{23}$$

where the superscript (i) indicates the i-th derivative with respect to the dimensionless circular frequency $\tilde{\omega}$. While it seems reasonable to truncate Equation (22) at leading order on account that $\xi \ll 1$, it is necessary to check that the PSD of the loading is almost constant on the interval of interest, or more formally that

$$S_{\tilde{f}}^{(1)}\left(\pm 1\right) \;\leq\; \text{ord}\left(S_{\tilde{f}}\left(\pm 1\right)\right) \tag{24}$$

to be allowed to neglect higher order terms in Equation (23). If this condition is fulfilled, the PSD of the response is approximately equal to

$$S_{\tilde{r}}\left(\tilde{\omega}\right) \;=\; \frac{S_{\tilde{f}}\left(1\right)}{4\xi^2}\left(\frac{\xi^2}{\left(\left(\tilde{\omega}+1\right)^2+\xi^2\right)} + \frac{\xi^2}{\left(\left(\tilde{\omega}-1\right)^2+\xi^2\right)}\right) \tag{25}$$

in the regions spanned by the strained coordinates $\tilde{\omega} = \xi\tilde{\eta} \pm 1$, since the PSD of the loading is symmetric. This local approximation is represented by the yellow dashed line in Figure 2. The resonant component of the variance is eventually given by

$$m_{2,\tilde{r}} \;=\; \int_{\mathbb{R}} S_{\tilde{r}}\left(\tilde{\omega}\right)\mathrm{d}\tilde{\omega} = \frac{\pi}{2\xi}S_{\tilde{f}}\left(1\right). \tag{26}$$

Applying the procedure recommended in [5], the subtraction of $S_{\tilde{r}}\left(\tilde{\omega}\right)$ from the PSD of the response $S_{\tilde{x}}\left(\tilde{\omega}\right)$ provides a first residual with only two inertial peaks

$$\mathcal{R}_{\tilde{r}}\left(\tilde{\omega}\right) \;=\; S_{\tilde{x}}\left(\tilde{\omega}\right) - S_{\tilde{r}}\left(\tilde{\omega}\right) = S_{\tilde{f}}\left(\tilde{\omega}\right)\mathcal{K}_s\left(\tilde{\omega}\right) \tag{27}$$

in which

$$\mathcal{K}_s\left(\tilde{\omega}\right) \;=\; \left|H\left(\tilde{\omega}\right)\right|^2 - \frac{S_{\tilde{r}}\left(\tilde{\omega}\right)}{S_{\tilde{f}}\left(\tilde{\omega}\right)} \tag{28}$$

is the residual kernel function. A new coordinate stretching, $\tilde{\omega} = \left(\zeta\tilde{\eta}\pm 1\right)/\epsilon_u$ with $\epsilon_u = {}^1\!/_{\varepsilon_u} \ll 1$ and $\tilde{\eta} = \text{ord}\left(1\right)$ at most again, is then injected into Equation (27) to zoom on the inertial peaks. The Taylor series expansion of the residual kernel function for small values of ϵ_u yields

$$\mathcal{K}_s\left(\left(\zeta\tilde{\eta}\pm 1\right)/\epsilon_u\right) \;\simeq\; \frac{\epsilon_u^4}{\left(1\pm\zeta\tilde{\eta}\right)^4} - \frac{S_{\tilde{f}}\left(1\right)}{S_{\tilde{f}}\left(\left(\zeta\tilde{\eta}\pm 1\right)/\epsilon_u\right)}\frac{\epsilon_u^2}{\left(1\pm\zeta\tilde{\eta}\right)^2} \tag{29}$$

at leading order and the second term, coming from the approximations of the resonant peaks, can be discarded if

$$\frac{S_{\tilde{f}}\left(1\right)}{S_{\tilde{f}}\left(\left(\zeta\tilde{\eta}\pm 1\right)/\epsilon_u\right)} \;\leq\; \text{ord}\left(\epsilon_u^3\right) \tag{30}$$

in the interval of interest. However, even though the residual is correctly fitted by

$$S_{\tilde{\imath}}\left(\tilde{\omega}\right) \;=\; \frac{S_{\tilde{f}}\left(\tilde{\omega}\right)}{\tilde{\omega}^4} \tag{31}$$

in the regions spanned by the stretched coordinates $\tilde{\omega} = \xi\tilde{\eta} \pm 1$, this is not an appropriate local approximation, in the sense of the Multiple Timescale Spectral Analysis, because it is not always integrable near $\tilde{\omega} = 0$, regardless of the definition of the PSD of the loading. Considering, instead, the $(0, 4)$ Padé approximant

$$\mathcal{P}\,(0,4)\,[\mathcal{K}_s\,(\tilde{\omega})] = \frac{1}{1/\mathcal{K}_s\,(0) + \tilde{\omega}^4} \tag{32}$$

for the residual kernel, the local approximation

$$S_{\tilde{\imath}}\,(\tilde{\omega}) \;\; = \;\; \frac{S_{\tilde{f}}\,(\tilde{\omega})}{1/\mathcal{K}_s\,(0) + \tilde{\omega}^4} \tag{33}$$

of the residual is now integrable near $\tilde{\omega} = 0$ and matches the residual in the background region as well. The integrand is ultimately made totally independent from structural characteristics, such as the natural frequency of the system, by observing that $S_{\tilde{p}}\,(1) \simeq S_{\tilde{p}}\,(0)$, since $\varepsilon_u \gg 1$, and is represented by an orange dashed line in Figure 2. At the end, the mainly inertial, partly background, component of the variance of the response is given by

$$m_{2,\tilde{\imath}} \;\; = \;\; \int\limits_{\mathbb{R}} \frac{S_{\tilde{f}}\,(\tilde{\omega})}{2 + \tilde{\omega}^4} \mathrm{d}\tilde{\omega}. \tag{34}$$

and the variance of the response is approximated by the sum of the resonant and inertial contributions as

$$m_{2,\mathrm{mtsa}} \;\; = \;\; \frac{\pi}{2\xi} S_{\tilde{f}}\,(1) + \int\limits_{\mathbb{R}} \frac{S_{\tilde{f}}\,(\tilde{\omega})}{2 + \tilde{\omega}^4} \mathrm{d}\tilde{\omega}. \tag{35}$$

This approximation seems less advantageous, at first glance, than its equivalent background/resonant decomposition, since the inertial component is still expressed by means of an integral. Nevertheless, it is noticed that this integral only involves the loading and can be established, even maybe in closed-form, a priori, for a given PSD of loading.

3.2 Third central moment of the response

As shown in Figure 3, when the frequency ratio is greater than one, the bispectrum of the response exhibits essentially:
- six background bi-resonant peaks on an area of ord (ξ^2), centered in $(\pm 1, 0)$, $(\pm 1, 0)$ and $\pm\,(1, -1)$;
- six bi-resonant inertial peaks on an area of ord (ξ^2), centered in $\pm\,(1, -2)$, $\pm\,(2, -1)$ and $\pm\,(1, 1)$;
- six bi-background inertial triangular basins located between the background bi-resonant peaks and the bi-resonant inertial peaks;
- six resonant bi-inertial pairs of peaks, centered in $\pm\,(\varepsilon_u, 0)$, $\pm\,(0, \varepsilon_u)$ and $\pm\,(\varepsilon_u, -\varepsilon_u)$.

Focusing first on the region where $\tilde{\omega}_1$ and $\tilde{\omega}_2$ are both of ord (1), it appears quite clearly that the bispectrum of the response behaves locally as

$$B_{\tilde{r}}\,(\tilde{\omega}_1, \tilde{\omega}_2) \;\; = \;\; \Re\left[B_{\tilde{f}}\,(0,0)\right] K_b\,(\tilde{\omega}_1, \tilde{\omega}_2) \tag{36}$$

because the bispectrum of the loading is almost constant in this zone and its imaginary part is equal to zero. In addition, the third order kernel decreases fast enough along $\tilde{\omega}_1$ and $\tilde{\omega}_2$ for the

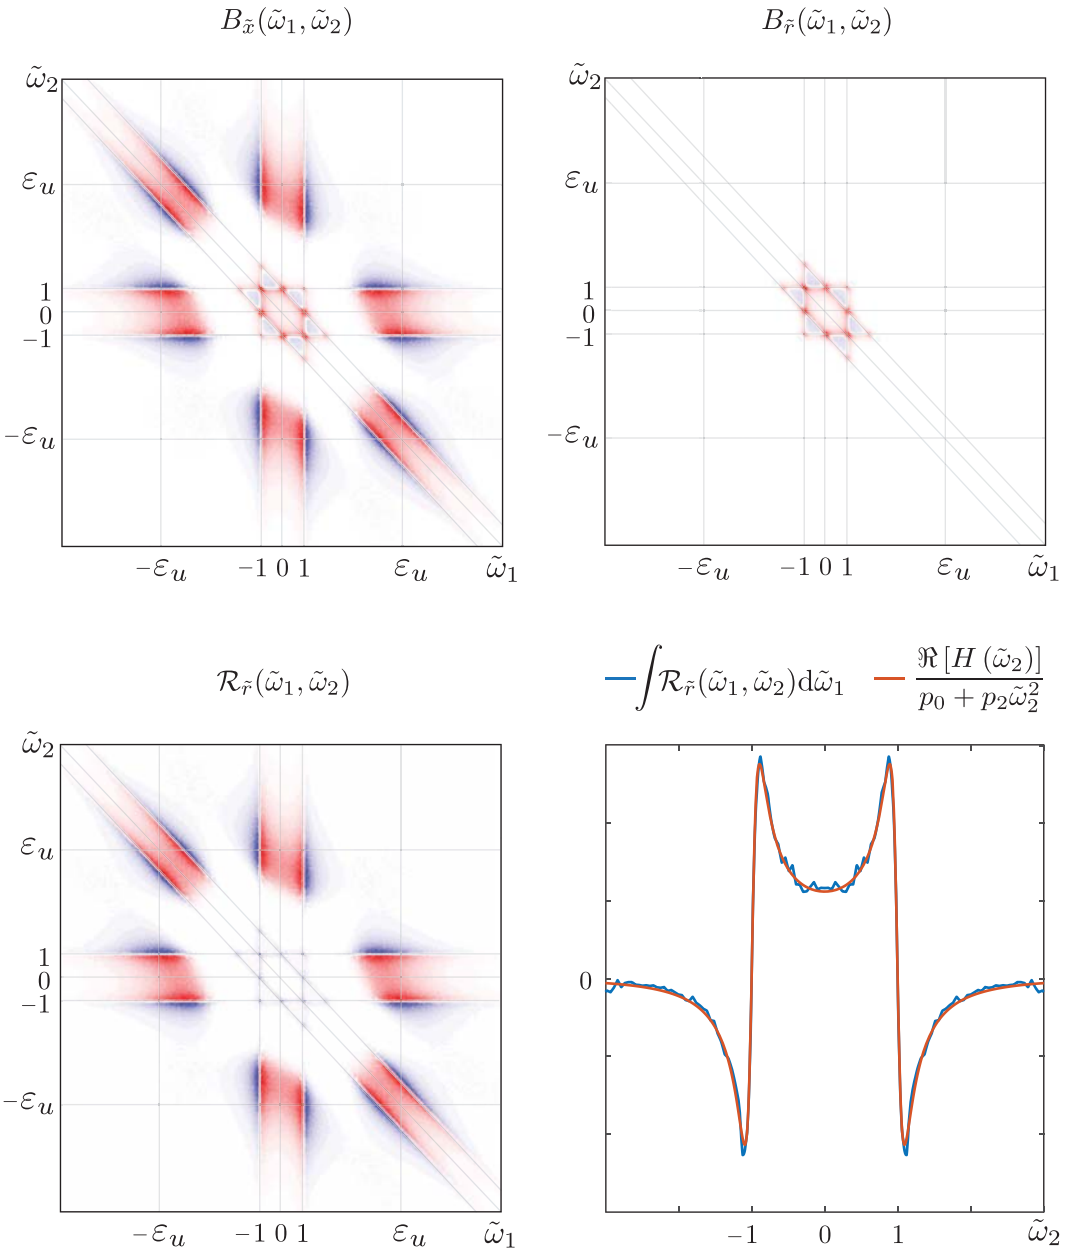

Figure 3: Typical shape of the bispectrum of the response $B_{\tilde{x}}(\tilde{\omega}_1, \tilde{\omega}_2)$. Numerical values: $\kappa_u = 10$; $\lambda_u = 1$; $\varepsilon_u = 5$ and $\xi = 10^{-1}$.

approximation presented in Equation (36) to be local and integrable, as required by the multiple timescale spectral analysis. Its double integration gives a simple and rapid estimation of the component of the third central moment of the response in the vicinity of the origin

$$m_{3,\tilde{o}} \quad = \quad \frac{8\pi^2}{3\left(1+8\xi^2\right)}\Re\left[B_{\tilde{f}}\left(0,0\right)\right] \tag{37}$$

which corresponds to the area under the six background bi-resonant peaks, the six bi-resonant inertial peaks and the six bi-background inertial triangular basins.

Then, the subtraction of $B_{\tilde{r}}\left(\tilde{\omega}_1,\tilde{\omega}_2\right)$ from the bispectrum of the response provides a first residual

$$\mathcal{R}_{\tilde{r}}\left(\tilde{\omega}_1,\tilde{\omega}_2\right) \quad = \quad \mathcal{B}_{\tilde{f}}\left(\tilde{\omega}_1,\tilde{\omega}_2\right)K_b\left(\tilde{\omega}_1,\tilde{\omega}_2\right) \tag{38}$$

where

$$\mathcal{B}_{\tilde{f}}\left(\tilde{\omega}_1,\tilde{\omega}_2\right) \quad = \quad B_{\tilde{f}}\left(\tilde{\omega}_1,\tilde{\omega}_2\right) - \Re\left[B_{\tilde{f}}\left(0,0\right)\right] \tag{39}$$

and a new coordinate stretching, $\tilde{\omega}_1 = \tilde{\eta}_1/\epsilon_u$ and $\tilde{\omega}_2 = \tilde{\eta}_2$ with $\tilde{\eta}_1$ and $\tilde{\eta}_2$ of ord (1), is injected into Equation (38) in order to zoom on one of the resonant bi-inertial pair of peaks. The leading order term of the Taylor series expansion of the third order kernel for small values of ϵ_u corresponds to

$$K_b\left(\tilde{\omega}_1,\tilde{\omega}_2\right) \quad \simeq \quad K_s\left(\tilde{\omega}_1\right)\Re\left[H\left(\tilde{\omega}_2\right)\right] \tag{40}$$

where we recover the second order kernel and the real part of the frequency response function. Interestingly enough, each of those two distinguished functions depends on only one coordinate in the intervals of interest. In order to ensure the integrability of the local approximation near $\tilde{\omega}_1 = 0$ and $\tilde{\omega}_2 = \pm 1$, respectively, the second order kernel is approximated by a $(0,4)$ Padé approximant, similarly to what was done before with the inertial component of the PSD of the response,

$$\mathcal{P}\left(0,4\right)\left[K_s\left(\tilde{\omega}_1\right)\right] \quad = \quad \frac{1}{1+\tilde{\omega_1}^4} \tag{41}$$

and the real part of the frequency response function, on the contrary, cannot be simplified on account that the damping ratio is a small number. In addition, the variations of the bispectrum of the loading along $\tilde{\omega}_1$ and along $\tilde{\omega}_2$ have both to be taken into account. The first ones are indeed required to get a local approximation that resembles the residual while the second ones are needed to obtain a non-zero result for the resonant bi-inertial component of the third central moment of the response, since

$$\int_{\mathbb{R}} \Re\left[H\left(\tilde{\omega}_2\right)\right]\mathrm{d}\tilde{\omega}_2 \quad = \quad 0 \tag{42}$$

However, the number of points where the bispectrum has to be evaluated is drastically reduced by using a $(0,2)$ Padé approximant to fit correctly the integral of the residual along $\tilde{\omega}_1$ when $\tilde{\omega}_2$ is of ord (1). It reads

$$\mathcal{P}\left(0,2\right)\left[\int_{\mathbb{R}} \frac{\mathcal{B}_{\tilde{f}}\left(\tilde{\omega}_1,\tilde{\omega}_2\right)}{1+\tilde{\omega_1}^4}\mathrm{d}\tilde{\omega}_1\right] \quad = \quad \frac{1}{p_0+p_2\tilde{\omega}_2^2} \tag{43}$$

in which

$$p_0 = \int_{\mathbb{R}} \frac{\mathcal{B}_{\tilde{f}}\left(\tilde{\omega}_1, 0\right)}{1+\tilde{\omega_1}^4} \mathrm{d}\tilde{\omega}_1 \quad \text{and} \quad p_2 = \int_{\mathbb{R}} \frac{\mathcal{B}_{\tilde{f}}^{(0,2)}\left(\tilde{\omega}_1, 0\right)}{1+\tilde{\omega_1}^4} \mathrm{d}\tilde{\omega}_1 \tag{44}$$

where the superscript (i,j) indicates the (i,j)-th derivative with respect to $\tilde{\omega}_1$ and $\tilde{\omega}_2$. It is worth to note that the Padé approximant is entirely independant from the structural characteristics again. The resonant bi-inertial component of the third central moment of the response is finally given by

$$m_{3,\tilde{\imath}} = \int_{\mathbb{R}} \frac{\Re\left[H\left(\tilde{\omega}_2\right)\right]}{p_0 + p_2 \tilde{\omega}_2^2} \mathrm{d}\tilde{\omega}_2$$

and the third moment of the response approximately corresponds to

$$m_{3,\mathrm{mtsa}} \;=\; m_{3,\tilde{o}} + m_{3,\tilde{\imath}} \tag{45}$$

3.3 Numerical validation

The mathematical developments presented in Sections 3.1 and 3.2 are now validated by comparing the results obtained with the multiple timescale spectral analysis to the results coming from Monte Carlo simulations.

First, the PSD of the dimensionless water velocity fluctuations, $S_{\tilde{u}}\left(\tilde{\omega}\right)$, is computed according to Equation (12) for a given set of dimensionless numbers. A time-history of wave velocity fluctuations, $\tilde{u}\left(\tilde{t}\right)$, is then generated by computing the inverse Fourier transform of

$$U\left(\tilde{\omega}_i\right) \;=\; \sqrt{S_{\tilde{u}}\left(\tilde{\omega}_i\right) N \tilde{\omega}_s} \mathrm{e}^{\mathrm{j}\,\theta_i} \tag{46}$$

where $N = 10^8$ is the number of elements, $\tilde{\omega}_s = 20\ \varepsilon_u$ is the sampling circular frequency and θ_i is a phase angle randomly drawn from a uniform distribution in the interval $[0, 2\pi[$. At this point, it is already possible to check that the frequency content of the wave velocity signal is correctly represented by superimposing its PSD on the theoretical one. Figure 4 shows the very good agreement between them. Then, a loading sample is obtained by calculating

$$\tilde{f} \;=\; \kappa_u \lambda_u \tilde{u}' + \left|1 + \lambda_u \tilde{u}\right| \left(1 + \lambda_u \tilde{u}\right). \tag{47}$$

It is used differently in the time domain analysis and in the Multiple Timescale Spectral Analysis.

In time domain, the loading sample enters into the equation of motion which is hence solved numerically to obtain the evolution of the displacement of the structure in time, $\tilde{x}\left(\tilde{t}\right)$. To do so, the finite difference method with an explicit scheme has been chosen here but any other time marching algorithm would obviously provide almost exactly the same results. At the end, the second and third central moments of the response are respectively given by

$$m_{2,\tilde{x}} \;=\; \mathbb{E}\left[\left(\tilde{x}\left(\tilde{t}\right) - \mathbb{E}\left[\tilde{x}\left(\tilde{t}\right)\right]\right)^2\right] \tag{48}$$

$$m_{3,\tilde{x}} \;=\; \mathbb{E}\left[\left(\tilde{x}\left(\tilde{t}\right) - \mathbb{E}\left[\tilde{x}\left(\tilde{t}\right)\right]\right)^3\right] \tag{49}$$

where the operator $\mathbb{E}\left[.\right]$ stands for the mathematical expectation, computed over the samples.

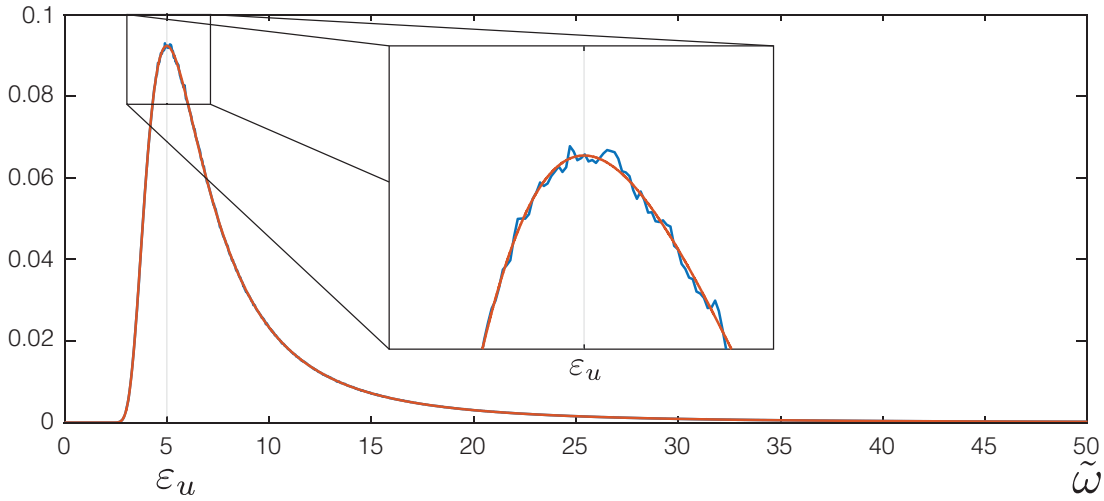

Figure 4: Typical shape of the power spectral density of the water velocity fluctuations.

In the spectral approach, we start by determining the power spectral density and the bispectrum associated to the loading sample. From there on, we just follow the steps detailed in Sections 3.1 and 3.2 to obtain the resonant and the inertial components of the second and third central moments of the response. Since we have kept the same set of dimensionless numbers throughout the whole paper, the local approximations and the first residual of the power spectral density and of the bispectrum of the response are respectively shown in Figure 2 and Figure 3.

The numerical results are summarized in Table 1 together with the computational time required in both cases. The second and third central moments of the response are computed much more rapidly with the Multiple Timescale Spectral Analysis and are very close to the references obtained with Monte Carlo simulations.

$S_{\tilde{f}}(1)$	$m_{2,\tilde{x}}$	$m_{2,\tilde{r}}$	$m_{2,\tilde{\imath}}$	$m_{2,\text{mtsa}}$	t_{time}	t_{mtsa}
0.05	3.58	0.76	2.60	3.36	5 s	0.1 s
$B_{\tilde{f}}(0,0)$	$m_{3,\tilde{x}}$	$m_{3,\tilde{o}}$	$m_{3,\tilde{\imath}}$	$m_{3,\text{mtsa}}$	$\gamma_{\tilde{x}}$	γ_{mtsa}
$8 \cdot 10^{-3}$	0.93	0.20	0.68	0.88	0.137	0.143

4 CONCLUSIONS

The background/resonant decomposition (which is widely applied in wind engineering) is a particular application of the Multiple Timescale Spectral Analysis where the natural frequency of the oscillator is larger than the frequency content of the loading. In this paper, we have specialized the concept to the companion problem, where the natural frequency of the oscillator is smaller than the characteristic frequency of the loading, as is typical in floating structures considered in marine engineering. Instead of the heavy numerical integration of the power spectral density and bispectrum of the structural response, the proposed methodology is able to determine the statistical moments of the response as a sum of two components. These two components correspond to a resonant contribution and an inertial contribution. The same decomposition is used for both the second and third orders. The resonant contribution takes a very similar shape as the well known existing approximations. Conversely to the companion problem though, the inertial contribution requires the evaluation of an integral, which is however

less cumbersome than in the formal numerical integration of the spectra since it involves the loading only.

The proposed methodology has been benchmarked against Monte Carlo simulations. It shows a significant CPU saving while offering a very competitive accuracy. It will certainly serve as a major cornerstone of a multi degree-of-freedom model, where the response of a structure in its modal basis will be computed as a linear combination of modal (single degree-of-freedom) responses.

Keywords: Inhomogeneous, Loads, Extreme, Response

Abstract. *For structures with large extensions in the horizontal plane (such as bridges with ultra-long spans), it is very likely that the characteristics of the environmental processes (such as wind, waves and earthquakes pressure) will exhibit inhomogeneous features across the structure. It is accordingly important to know how these features will affect the extreme dynamic response level of such bridges. In particular, the question arises whether application of simplified homogeneous load models will imply an under-prediction or an over-prediction of the extreme dynamic response. It will be also be of significant interest to identify the most "dangerous" load pattern for the case of inhomogeneous models and to compute the associated relative probability that this particular pattern may occur.*

These effects are investigated first by analysis of a simplified and "generic" case study of an extended line structure subjected to dynamic wave loading of the homogeneous versus the inhomogeneous type. A "forward calculation" is applied in order to study the extreme response level corresponding to these two load categories. It is next demonstrated how an inverse algorithm is able to identify the most critical inhomogeneous load pattern and the associated probability that this will occur (for given statistical models of the load parameters).

A numerical study of the hydroelastic response of a 4.6 km long fjord crossing floating bridge subjected to inhomogenous versus homogeneous stochastic wave loads is subsequently carried out. The bridge has a straight-line shape and is supported by 35 pontoons along its full length. To restrain the transverse motion in the horizontal plane, four clusters of deep water mooring lines are applied in order to strengthen the transverse stiffness of the bridge.

1 INTRODUCTION

The question arises whether inhomogeneous loading can lead to higher dynamic response levels than homogenous loading. Furthermore, there might be particular inhomogeneous load patterns that could possibly create significant amplification effects due to "modal resonance" phenomena. These features are presently illustrated in relation to a simplistic structural model and an "inverse" algorithm is applied in order to identify critical load patterns.

The effects of inhomogeneous wave loading are subsequently illustrated in connection with dynamic response of a floating bridge with an ultra-long span. Such and similar bridge concepts are presently being considered for crossing of extremely wide fjords along the West Coast of Norway, see e.g. [1, 2, 3, 4, 5, 6].

2 INHOMOGENEOUS LOADING: A GENERIC CASE STUDY

A simplified and "generic" case study of an extended line structure subjected to a deterministic dynamic wave loading of the homogeneous versus the inhomogeneous type is first considered. A "forward calculation" is applied in order to study the extreme response level corresponding to these two load categories. It is next demonstrated how an inverse algorithm is able to identify the most critical inhomogeneous load pattern and the associated probability that this will occur (for given statistical models of the load parameters). The findings from this simplified example are then summarized, and consequences for analysis and design of extended structures with more complex dynamic behaviour are discussed.

2.1 Forward modeling

A straight bridge structure of length L which is subjected to long-crested regular waves propagating at an angle θ is first analysed. Initially, the load pattern is uniformly distributed in space (with magnitudes q), see Figure 1 for an illustration. The line structure is taken to be simply supported at both ends, and the main bridge girder is supported by three pontoons at the three interior quarter points (i.e. at x = -L/4, 0 and +L/4). The bending stiffness of the bridge girder is EI, the cross-section area is A, the mass per unit length is m and the structural damping per unit length is c. The three pontoons all have the same mass (M_i = M for i = 1,2,3, which also includes hydrodynamic added mass in the direction transverse to the bridge axis), and with the same hydrodynamic damping (C_i = C for i = 1,2,3 also in the transverse direction)

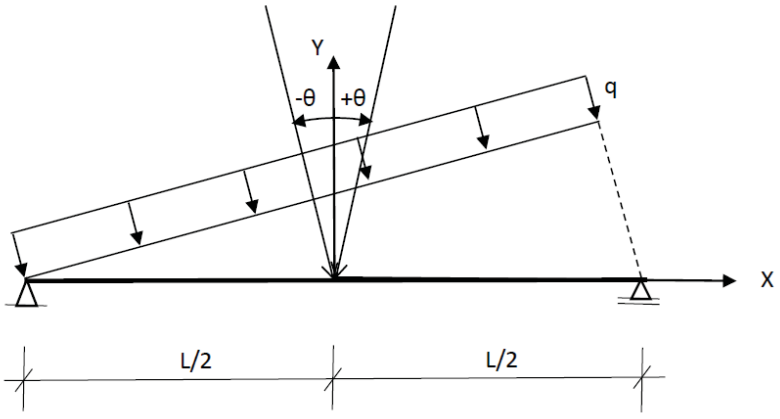

Figure 1. Line structure subjected to uniform load patterns with harmonic time variation.

The lateral dynamic response (strong-axis bending moment) of the line structure for the present loading is computed by application of the mechanical transfer functions for the relevant natural modes. Here, it is assumed that the first three horizontal modes are the relevant ones. These correspond respectively one, two and three sinusoidal half-waves. The lateral displacement is then expressed as follows:

$$\mathrm{v}(x,\theta,\omega,t)=\left[\sum_{j=1}^{3}\left[Q_j\cdot\cos(\theta\ )\right]\cdot\left|H_j(\omega)\right|\cdot\varphi_j(x)\right] \tag{1}$$

where $\varphi_j(x) = \sin(j\pi x/L+j\pi/2)$ is mode-shape number j (for j=1,2 and 3), $|H_j(\omega)|$ is the modulus of the frequency transfer function for mode number j. The modal load which corresponds to the distributed load q is expressed as:

$$Q_j=q\sum_{l=1}^{3}\cos\left(\omega t+k\cdot\sin(\theta_k)\cdot x_l\right)\cdot\varphi_j(x_l)\ \text{ for }\ \ \mathrm{j}=1,2,3;\ \text{and } l=1,2,3 \tag{2}$$

where the three x-coordinates of the pontoons are given as $x_1 = -L/4$, $x_2 = 0$ and $x_3 = +L/4$; $k = 2\pi/\lambda$ is the wave number corresponding to the frequency ω, as given by the wave length λ, which is obtained from the dispersion relationship for deep water (i.e. $\lambda = \omega^2/g$). The wave period is here taken as T = 10 seconds, implying a frequency of $2\pi/T=2\pi/10$.

The model mass, damping and stiffness properties of the line structure are expressed in terms of integrals involving the square of the mode shape functions and the corresponding curvatures:

$$\begin{aligned}
M_j &= M=\int_0^L m\cdot\varphi_j^2(x)\,dx+\sum_{l=1}^{3}M_P(\omega)\cdot\varphi_j^2(x_l)=\frac{mL}{2}+M_P(\omega)\cdot\sum_{l=1}^{3}\sin^2\left(\frac{j\pi\cdot x_l}{L}\right)=\frac{mL}{2}+2\cdot M_P(\omega)\\
C_j &= C=\int_0^L c\cdot\varphi^2(x)\,dx+\sum_{l=1}^{3}C_P(\omega)\cdot\varphi_j^2(x_l)=\frac{cL}{2}+C_P(\omega)\cdot\sum_{l=1}^{3}\sin^2\left(\frac{j\pi\cdot x_l}{L}\right)=\frac{cL}{2}+2\cdot C_P(\omega)\\
K_j &= \int_0^L EI\cdot\left(\frac{d^2\varphi_j(x)}{dx^2}\right)^2dx=\frac{EI\cdot L}{2}\cdot\left(\frac{j\pi}{L}\right)^4=\frac{(j\pi)^4\,EI}{2L^3}
\end{aligned} \tag{3}$$

where $M_P(\omega)$ is the pontoon mass (including hydrodynamic added mass) and $C_P(\omega)$ is the corresponding hydrodynamic damping in the lateral direction of the bridge.

Based on the model mass and stiffness, the corresponding natural frequencies for the three modes are obtained as:

$$\omega_j=\sqrt{\frac{K_j}{M_j}}=\left(\frac{j\pi}{L}\right)^2\cdot\sqrt{\frac{EI}{m+\dfrac{4\cdot M_P(\omega)}{L}}} \tag{4}$$

Furthermore, based on the modal properties, the modulus and phase angle for each of the three modes are then given as:

$$\left|H_j(\omega)\right| = \frac{1}{K_j\left[\left(1-\beta_j^2\right)^2 + \left(2\lambda_j\beta_j\right)^2\right]^{\frac{1}{2}}} \qquad \varepsilon_j(\omega) = \text{Arctan}\left[\frac{2\lambda_j\beta_j}{\left(1-\beta_j^2\right)}\right] \qquad (5)$$

where the frequency ratio for each mode is expressed as $\beta_j = \omega/\omega_j$ and the damping ratio is $\lambda_j = C_j/2M_j\omega_j$

The load frequency is next specialized to be $\omega = 0.9\cdot\omega_1$, and the three different load frequency ratios then become :

$$\beta_j = \left\lfloor \frac{0.9\omega_1}{\omega_j} \right\rfloor = \left\lfloor \frac{0.9}{j^2} \right\rfloor \qquad (6)$$

The damping ratios the three different modes are equal to $\lambda_1 = 1\%$, $\lambda_2 = 1.5\%$ and $\lambda_3 = 5\%$. The resulting simplified expression for the lateral displacement is then obtained as:

$$\text{v}(x,\theta,\omega,t) = \sum_{j=1}^{3}\left[Q_j\cdot\cos(\theta)\right]\cdot\left|H_j(\omega)\right|\cdot\varphi_j(x)\cdot\cos\left(\omega t-\varepsilon_j\right) \qquad (7)$$

The ratios between the values of the three mechanical transfer functions are approximately the following: $H_3(\omega)/H_1(\omega) = 19$ and $H_2(\omega)/H_1(\omega) = 500$. This implies that if the modal loads Q_j were identical, mode 2 would have a much higher influence on the displacement response than the other two mode shapes (and in particular mode 1).

The strong axis bending moment of the line structure is obtained from the curvature along the bridge accordingly and becomes:

$$M(x,\theta,\omega,t) = EI\cdot\sum_{j=1}^{3}\left[Q_j\cdot\cos(\theta)\right]\cdot\left|H_j(\omega)\right|\cdot\left(\frac{j\pi}{L}\right)^2\cdot\varphi_j(x)\cdot\cos\left(\omega t-\varepsilon_j\right) \qquad (8)$$

where EI is the corresponding bending stiffness of the bridge girder (for strong axis bending), The corresponding bending stresses are then obtained by dividing with the bending resistance of the girder.

Clearly, an important issue is at which cross-section along the line structure that the maximum bending moment will occur. This location will change for different combinations of the two direction parameters. However, the location can in all cases be seen to occur within the interval -L/3 to 0. Here, the quarter point (i.e. at x = –L/4) is selected for the purpose of illustration. The bending moment as a function of time and the direction angle of the incoming load is shown in Figure 2. It is seen that there are two positive maxima (both with magnitudes around 6.7) at times t slightly above t = 0 and slightly above t =10 sec. The corresponding value of the wave direction angle is around 0.7 radians in both cases. There is a single negative maximum (with the same magnitude as the positive maxima) at time t = 5 sec, which also occurs for a wave direction angle of around 0.7 radians.

The probability that the dynamic bending moment exceeds a given value (at a given cross-section, which preferably is the one with the highest bending moment along the line structure) can now be obtained by introducing a joint probability density function for the two basic variables t and θ. Denoting this density function by $f_{t,\theta}(t,\theta)$, the probability of exceeding a given

value of the bending moment can then be evaluated by integrating across the area in the (t,θ)-plane for which the given value of the bending moment is exceeded.

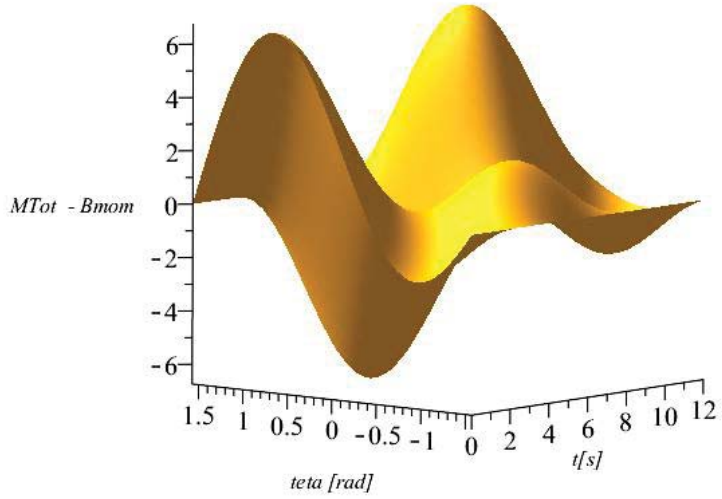

Figure 2. Normalized bending moment diagram of line structure for cross-section at x=-L/4, homogeneous loading. Normalization factor is EI/qL^3.

The subdomain which gives the maximum contribution to this integral will depend on the shape of the probability density function. For illustration purposes, we first apply a uniform joint density function with constant value in the rectangle bounded by the lines t=0., t=10 sec and $\theta = -\pi/2$, $\theta = +\pi/2$. The maximum contribution to the integral is then due to the regions close to the boundaries at t=0 and t=10 sec. In general, the probability of exceeding the specified bending moment value can then be evaluated by means of Monte Carlo simulation or FORM/SORM techniques, [7, 8]. The latter also provides direct information about the critical combination of time and wave direction. However, since time is strictly not a random variable as it runs sequentially through all the values from 0 to 10 seconds (and of course through subsequent load periods if such are given), calculation of this probability boils down to a one-dimensional formulation at the "critical" time, for which the load direction becomes the only remaining basic variable. This implies that the probability of being in the "exceedance region" can be calculated by application of the cumulative distribution function of the direction variable. For a uniform probability distribution in the range from $-\pi/2$ to $+\pi/2$, the cumulative distribution function for a given angle is just the cumulative angle divided by the length of the total interval (i.e. π).

The following probabilities are obtained for a selection of four different bending moment magnitudes: (i) a normalized bending moment value of 4 gives a probability of 0.35 (corresponding to the direction interval from around 0. rad to 1.1 rad) (ii) a normalized bending moment value of 5 gives a probability of 0.24 (corresponding to the direction interval from around 0.25 rad to 1.0 rad) (iii) a normalized bending moment value of 6 gives a probability of 0.17 (corresponding to the direction interval from around 0.4 rad to 0.9 rad) (iv) a normalized bending moment value of 6.7 gives a probability of 0.0068 (corresponding to the direction interval from around 0.64 rad to 0.67 rad). If the load direction is e.g. is instead parabolically distributed (i.e. $f_\theta = 1.9\cdot(0.5-\theta/\pi)*(0.5+\theta/\pi) = 1.9\cdot(0.25-(\theta/\pi)^2)$, the probabilities for the four cases instead become somewhat higher: (i)0.44 (ii)0.30 (iii)0.20 and (iv)0.012.

Subsequently, the case of *inhomogeneous loading* is addressed. A linear variation from zero to a maximum load intensity value is introduced for the load pattern. By requiring that the mean load intensity is the same as the constant value for the homogeneous case, the maximum intensity of the load components will be 2*q. This case is illustrated in Figure 3.

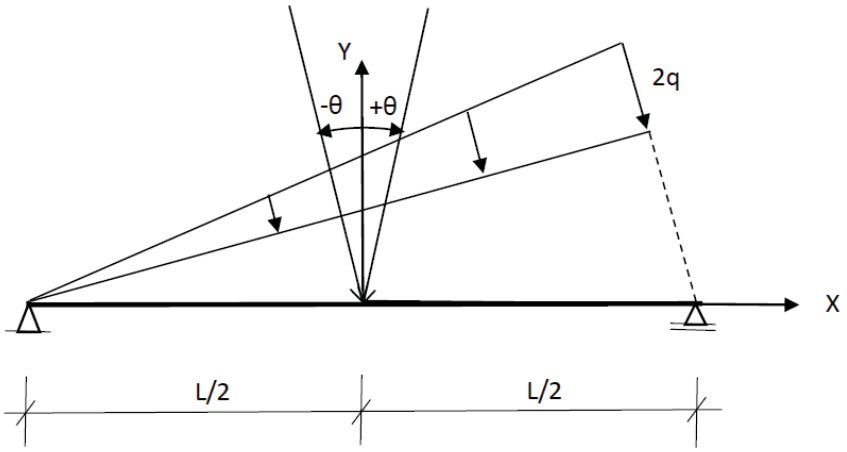

Figure 3. Line structure subjected to a non-homogeneous load pattern (linear variation) with harmonic time variation.

The modal loads for this case are obtained by introducing corresponding load factors, $f(x_l)$ at each pontoon:

$$Q_j = q\sum_{l=1}^{3}\cos\left(\omega t + k\cdot\sin\left(\theta_k\right)\cdot x_l - \varepsilon_j\right)\cdot f\left(x_l\right)\cdot\varphi_j\left(x_l\right) \qquad \text{for } j=1,2,3; \text{ and } l=1,2,3 \qquad (9)$$

where $f(x_1) = 0.25$, $f(x_2) = 0.5$ and $f(x_3) = 0.75$. For the present load pattern, the normalized bending moment for the cross-section at x = -L/4 is shown in Figure 4. It is seen that there is now a maximum negative peak at t = 0 and a maximum positive peak with a magnitude of 17 at around t=7.5 seconds.

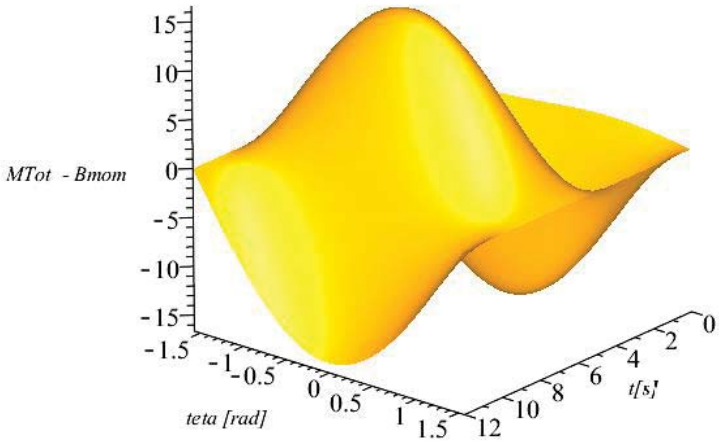

Figure 4. Normalized bending moment diagram of line structure for cross-section at x=-L/4, non-homogeneous loading. Normalization factor is EI/qL^3.

For the present case, five different magnitudes of the bending moment are considered and the corresponding direction intervals with associated probabilities are determined. These are as follows: (i) a normalized bending moment value of 12 gives a probability of 0.51(corresponding to the direction interval from around -0.8 rad to +0.8 rad) (ii) a normalized bending moment value of 14 gives a probability of 0.45 (corresponding to the direction interval from around -0.7 rad to 0.7 rad) (iii) a normalized bending moment value of 6 gives a probability of 0.32 (corresponding to the direction interval from around -0.5 rad to 0.5 rad) (iv) a normalized bending moment value of 16 gives a probability of 0.13 (corresponding to the direction interval from around -0.2 rad to 0.2 rad) (v) a value of 17 gives a probability of 0.0063 (corresponding to the direction interval from around -0.01 rad to 0.01 rad). If the load direction is e.g. parabolically distributed (i.e. $f_\theta = 1.9\cdot(\theta/\pi-0.5)*(\theta/\pi+0.5) = 1.9\cdot(\theta/\pi)2-0.25$), the probabilities for the five cases instead become: (i)0.70 (ii)0.62 (iii)0.46 (iv)0.19 and (v) 0.0096, i.e. somewhat higher than for the uniformly distributed case.

More complex load patterns (and also with different frequencies for different directions) could easily be constructed in order to represent various types of environmental loading. However, the main point to be made here is that non-homogenous loading may lead to amplification for some of the modal loads and accordingly give rise to higher dynamic response levels. Furthermore, for unidirectional loading the critical angle may change for different load patterns.

2.2 Inverse analysis

The question is next whether it is possible to find the most critical combination of the load parameters for a given cross-section along the line structure by a more efficient procedure without having to calculate the response for all combinations of time and direction values (or even more complex combinations for cases where more than two parameters are involved).

Here, it is considered whether this can be achieved by means of FORM/SORM techniques by application of uniform joint probability density function of the two parameters as input to the analysis. These techniques are usually based on the so-called Rosenblatt transformation which converts the uniformly distributed basic variables into normalized Gaussian variables (with zero mean values and unit variance). Subsequently, a search is performed in the normalized plane to identify the "critical" point on the failure surface (i.e. the surface for which the mechanical limit state function is zero, i.e. implying that the response bending moment is equal to the specified value of the bending moment). This is referred to as the "design point", see e.g. [7,8] for a more detailed description of the procedure.

This approach is here illustrated for both the homogenous and non-homogeneous load cases. For the former, the design point in the normalized Gaussian plane has the following coordinates for the four different cases: (i) (1.1,0.35) (ii) (1.25,0.41) (iii) (1.46,0.55) and (iv) (1.9,0.56). By transforming back to the physical parameter space, these point corresponds to the following time-direction angle combinations: (i) (8.6sec, 0.43rad) (ii) (8.9sec, 0.5rad) (iii) (9.3sec, 0.66rad) and (iv) (9.7sec, 0.67rad).

The main purpose of this analysis is to identify the most likely "parameter combination point", which here corresponds to a specific combination of time and direction. However, as a side product the probability of failure of the line structure (i.e. the probability that the bending moment will exceed the specified value) for the case of uniformly distributed load parameters can also be found based on the design point coordinates in the normalized plane. This is based on the relationship $\Phi(-\beta) = p_f$, where $\beta = u_2$, with u_2 denoting the design point coordinate for the normalized direction variable and with p_f denoting the probability of failure (i.e. the probability of exceeding the specified value of the bending moment).

By including only the load direction as a random variable, the design point for the corresponding "normalized variable" will change slightly. Essentially, it will be the point on the failure surface which is closest to the origin purely along the u_2 coordinate axis. Hence, the second point of the relevant direction interval is generally not identified. Accordingly, the estimated failure probabilities will be too high as compared to those obtained from the forward analysis. The following probabilities are now obtained for the four different cases: (i) p_f=0.36 (ii) p_f=0.34 (iii) p_f=0.29 (iv) p_f =0.28. It is seen that these probabilities are on the high side as compared to those obtained from the forward modeling, especially for the lowest probabilities. More correct probability values could be obtained as part of the inverse analysis by application of more refined methods such as Monte Carlo simulation techniques. For high dimensions, this would require that sufficiently accurate but numerically efficient response analysis methods are applied e.g. by application of surrogate models (response surface techniques).

For the non-homogenous load case, transformation of the design points in the normalized Gaussian line to the "physical load direction line" give the following coordinates for the five different cases: (i) (θ=-/+0.8) (ii) (θ=-/+0.7) (iii) (θ=-/+0.5) (iv) (θ=-/+0.2) and (v) (θ=-/+0.01). Here, the -/+ sign indicates that one of these points will be identified depending on whether the search algorithm starts at a positive or negative value. Again, it is seen that this is just one of the points that were identified based on the forward analysis. However, for this case the relevant points are symmetric around the origin. Applying only one of these points will imply an overestimation of the failure probabilities. The following values are obtained for the five different cases: (i) p_f=0.75 (ii) p_f=0.72 (iii) p_f=0.66 (iv) p_f =0.56 and (v) p_f =0.50. It is seen that these are on the high side compared to those from the forward analysis, especially for the smallest probabilities. If both of the "design points" are identified from the analysis, the correct values for the failure probabilities will be obtained.

Based on more exact information about the joint probability density function (pdf) of the load direction parameter, this will generally result in much more peaked shape than the uniform model. Accordingly, the most likely load parameter combination to result in failure of the structure will also change (relative to the case with uniformly distributed variables). This was also demonstrated in connection with the forward modelling by application of a parabolic density function for the load direction angle.

Furthermore, inclusion of additional random variables which represent physical properties of the structure and the environment are generally required in order to provide a more realistic description. By repeating the analysis for these cases, the coordinates of the most critical load combination point and the failure probability will change once more.

3 DYNAMIC RESPONSE TO INHOMOGENOUS WAVE LOAD FOR AN ULTRA-LONG FLOATING BRIDGE

In order to illustrate the effects of inhomogeneous loading on the dynamic response of a structure with an ultra-long span, the floating bridge shown in Figures 5 (graphical illustration) and Figure 6 (system layout) is considered. Such bridges are relevant e.g. for very wide lake or fjord crossings. The present structure is quite similar to a concept which is proposed for crossing of the Bjørnafjord at the west coast of Norway [3].

The hydroelastic responses of the 4.6 km long straight, side-anchored floating pontoon bridge subjected to wave loads is investigated. The vertical stiffness of the bridge is provided by 35 evenly spaced pontoons along the bridge girder. The transverse motion of the bridge is restrained by clusters of mooring lines tethered at four pontoons. Owing to the very large span and hydrological topology across the Bjørnafjord, inhomogeneity in the wave field exists. Various effects of inhomogeneous wave conditions on the hydroelastic responses of the float-

ing bridge are also examined. These include the inhomogeneity in wave direction, significant wave height, peak period as well as the coherence and correlation of waves at different locations along the entire length of the floating bridge. For the purpose of comparison, the bridge responses under homogeneous wave load cases are also studied. In addition, the effects of wave load components and short-crestedness are presented and discussed.

Figure 5. Graphical display of straight floating bridge design concept, [2]

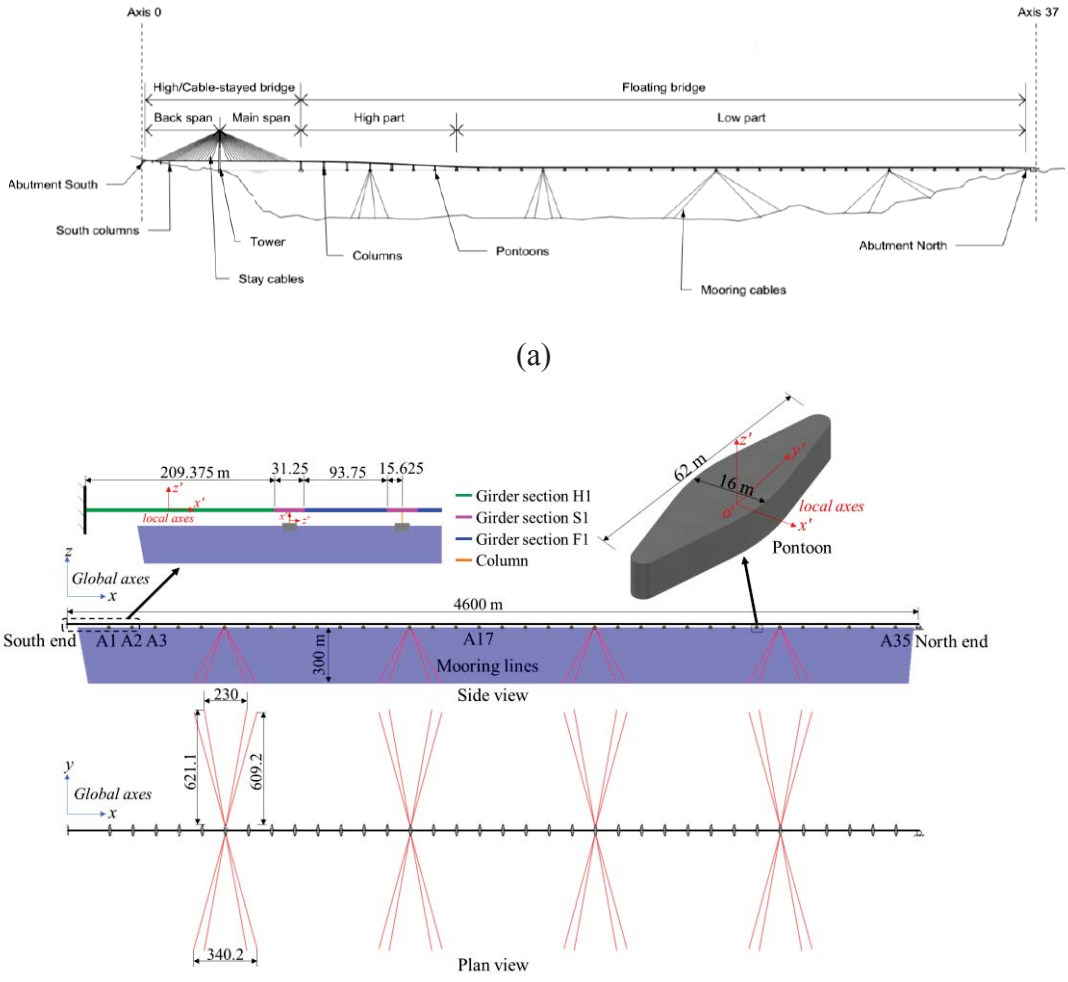

Figure 6. Straight floating bridge: (a) design concept and (b) idealised model, [3, 4, 6].

3.1 Structural model

The bridge structure is represented by beam elements with discrete pontoons, and the wave loading is of a stochastic nature such that spectral densities are applied in order to characterize the frequency distribution of the wave energy. Furthermore, directional spreading functions provide information about the directional distribution of the wave energy. For inhomogeneous loading, these quantities will generally vary as functions of the coordinates in the horizontal plane.

In order to focus on the wave load effect on the floating bridge section, this study employs an idealised, generic floating bridge model based on the low part of the design concept. As illustrated in Fig. 1(b), the simplified floating bridge, 4.6 km long and 18 m elevated above the water surface, is resting on 35 evenly spaced pontoons (which are referred to by their location as A1 to A35) and held in position by four mooring clusters. The water depth is set to 300 m and assumed to be constant across the entire bridge length. In view of the overall dimensions of the bridge, the girders and columns are reasonably modelled as Euler-Bernoulli beams and the mooring lines are represented by using bar elements submerged beneath the water surface. The pontoons are regarded as rigid bodies interacting with water. The connection between mooring lines and the pontoons in the conceptual design is provided on the side wall of the moored pontoon. The mooring line is terminated just above the chain stopper. The boundary conditions of the bridge model are given in Table 1.

Boundary	Translation			Rotation		
	x	y	z	R_x	R_y	R_z
South end	fixed	fixed	fixed	fixed	fixed	fixed
North end	free	fixed	fixed	fixed	fixed	free

Table 4. Boundary conditions

Note that the translational degree of freedom of the bridge girder along the x-axis at the North end is released to allow for axial deformation due to thermal effects. All the applied parameters are based on the independent feasibility studies of the straight floating bridge concept by Multiconsult and DNV GL [2, 3].

3.2 Load representation and load cases

A full stochastic wave load model is applied for the present dynamic response analysis. Accordingly, the basis for computation of random wave loads and associated dynamic response is provided by the wave spectral densities at the locations at the different pontoons. These spectral densities are generally parameterized by the significant wave height and the peak period. Phase information about wave elevation at the different pontoons is provided by the cross-spectral densities.

Table 2 lists the design wave load cases specified in the design basis [1] with a principal wave direction in the sector of 225°-315°. Note that a common practice in an engineering design is to apply the worst wave condition to the entire bridge structure. In view of this, inhomogeneous wave load cases may be reasonably established by scaling up the significant wave heights H_s and peak periods T_p measured at the three DWRs such that the highest inhomogeneous H_s and T_p are equal to the homogeneous wave characteristics listed in Table 2. Due to the lack of further information, the wave inhomogeneity between the DWRs is assumed to vary in a linear manner.

Return period	Wind waves			Swell		
	H_s	T_p	θ_p	H_s	T_p	θ_p
1-year	1.30 m	4.6 s	225°-315°	0.26 m	20 s	300°
100-year	2.40 m	5.9 s	225°-315°	0.40 m	20 s	300°

Table 2. Design homogeneous wave conditions [1]

Three inhomogeneous wave conditions are also considered, see [1]. The first two are the 1-year and 100-year inhomogeneous wave conditions established based on field measurement data. Due to availability of data, only wind waves are represented for these conditions. The waves corresponding to these two conditions exhibit a relatively large spatial variation in θ_p with a minor inhomogeneity in H_s and a constant T_p. Examining these two wave conditions is expected to reveal the effect of inhomogeneity in relation to wave direction on the bridge responses. The third condition describes a different pattern of 100-year inhomogeneous waves established based on wave conditions at another measurement site. A compared with the first two conditions, θ_p remains unchanged in condition 3. A much larger inhomogeneity in H_s and T_p is present and its effect may be revealed by comparing with the corresponding homogeneous conditions. Furthermore, inhomogeneous swell with a longer T_p that may give excitation to the lower order vibration modes of the floating bridge is also accounted for in condition 3.

Number	Description			
	Return period	Wind sea condition	Swell condition	Wave correlation
LC1.1a	1-year	H_s = 1.3 m, T_p = 4.6 s, θ_p = 288°	-	Fully correlated
LC1.1b		H_s = 1.23 m, T_p = 4.6 s, θ_p = 288°	-	Fully correlated
LC1.2		H_s = 1.3 m, T_p = 4.6 s, θ_p = 288°	-	Uncorrelated
LC1.3		condition 1	-	Fully correlated
LC1.4		condition 1	-	Uncorrelated
LC2.1a	100-year	H_s = 2.4 m, T_p = 5.9 s, θ_p = 288°	-	Fully correlated

*Load cases with grey shadow correspond to homogeneous wave conditions

Table 3. Load cases and descriptions

Table 3 summarises the wave load cases to be examined in this study. There are three main load cases (LCs), namely LC1, LC2 and LC3 that correspond to the wave conditions listed in Table 2. Each LC is comprised of three inhomogeneous wave load cases and one homogeneous wave load case that serves as a basis for comparison with the inhomogeneous wave load cases. The homogeneous wave load cases (LC1.1, LC2.1 and LC3.1) are further categorised into sub-cases a and b. Case a is defined by using the parameters listed in the design basis [1] and Table 5, whereas the H_s in case b is scaled down to match the average H_s in an inhomogeneous wave condition. The latter describes a sea state with the same wave energy as in the inhomogeneous wave load case provided that T_p remains unchanged.

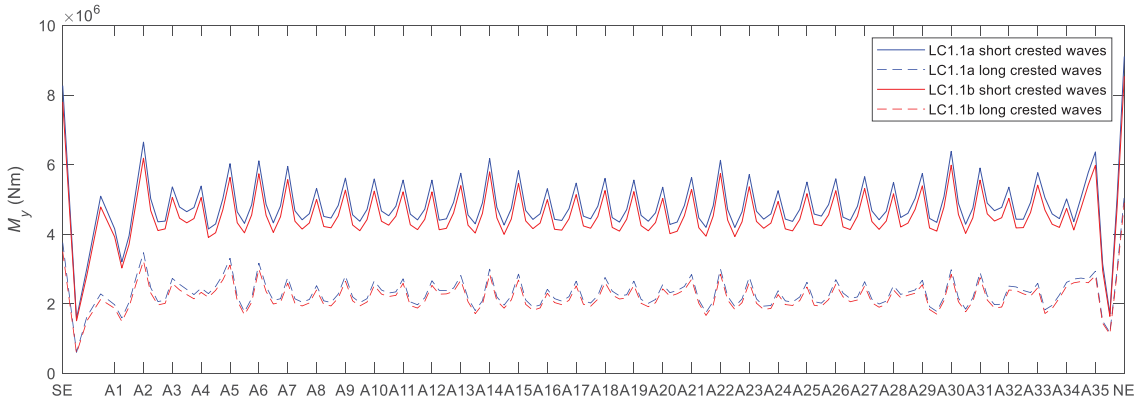
Time domain sample functions of the sea elevation are generated by summation of the various harmonic components and Monte Carlo simulation of the relevant random phase angles. If the unidirectional wave spectrum, directional distribution and random phase angles of the wave components are identical at all pontoons, the described wave conditions along the full length of the floating bridge are homogeneous. Otherwise, the wave conditions are inhomogeneous. Furthermore, if the phase angle in an inhomogeneous wave field for arbitrary pontoon numbers i and j are taken to be same, the wave conditions along the entire length of the bridge are fully coherent and correlated. On the other hand, if the phase angles are completely random at various pontoon locations, the corresponding wave conditions are incoherent as well as uncorrelated, i.e. they are statistically independent (in the case of Gaussian processes).

In all case studies, five independent wave realisations of each load case are used to reduce the variations in the stochastic results. In addition to the wave inhomogeneities described in Table 3, this study also investigates the effect of short-crestedness of wind waves.

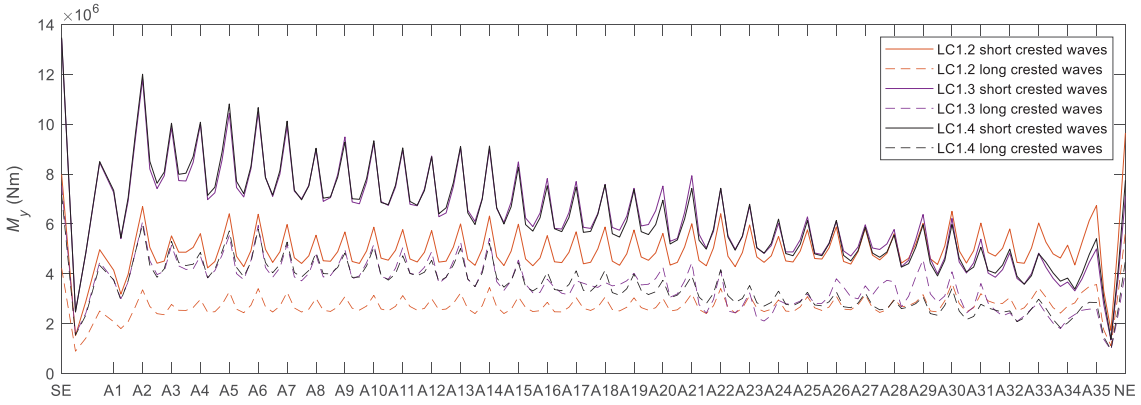
3.3 Dynamic response to inhomogeneous versus homogeneous loading

LC1: Load case with 1-year return period

To reveal the effect of wave short-crestedness on the bridge responses, Figure 7 plots the standard deviation of the weak axis bending moment M_y due to unidirectional long-crested waves for comparison with short-crested waves. As it can be seen, short-crested waves result in a much larger M_y along the full length of the bridge for both homogeneous and inhomogeneous wave load cases. The differences are up to 176% for homogeneous waves and 129% for inhomogeneous waves. This implies that oblique wave components in short-crested waves significantly augment the weak axis bending moment of the girder when compared with long-crested waves in a near beam sea condition.



(a)

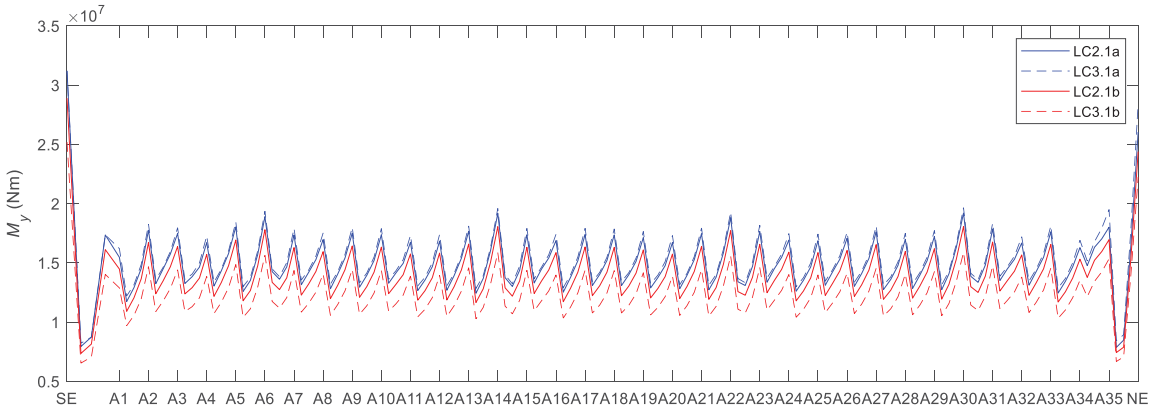


(b)

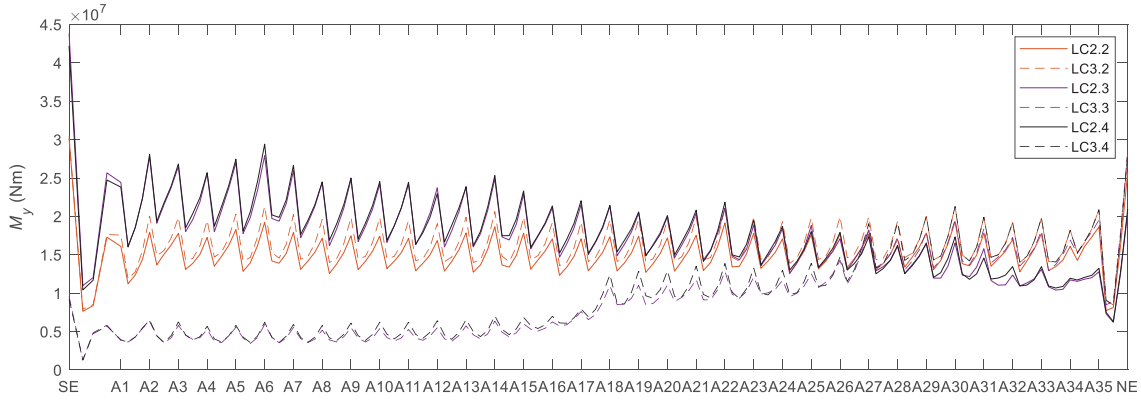
Figure 7. Effect of wave short-crestedness and wave inhomogeneity on standard deviation of weak axis bending moment under 1-year wave load cases (LC1): (a) homogeneous waves and (b) inhomogeneous waves.

LC2 and LC3: Load cases with 100-year return period

Figure 8 compares the standard deviation of M_y for LC2 and LC3. The comparison of homogeneous wave load cases shows that the results for LC2.1a and LC3.1a are very close to each other. This reveals that the inclusion of swell has a negligible effect on M_y. The comparison with inhomogeneous wave load cases (see Fig. 8(b)) shows that near the south end, more higher order vibration modes are excited by wind waves in LC3 than LC2 and the excitation level is lower. Moving from A10 to A27, the increase in T_p results in a change from higher order modes to lower order modes being excited by the wind waves. In addition, an increase in the extent of excitation of modes by wind waves is also observed, due to the combined effect of increasing T_p and H_s. The swell also excited M_y responses near the period of 20 s. However, no resonance is expected and thus swell has a limited effect on the dynamic M_y responses.



(a)



(b)

Figure 8. Standard deviation of weak axis bending moment under 100-year wave load cases (LC2 and LC3): (a) homogeneous waves and (b) inhomogeneous waves.

3.4 Extreme bridge response and accumulated fatigue damage

The extreme values of the bridge responses for a given (stationary) sea state are basically expressed as a product of the standard deviation and an amplification factor. The value of the amplification factor depends on the statistical nature of the response processes (i.e. Gaussian or non-Gaussian) and the length of the time period being considered. Accordingly, the ratios between the extreme values of the bending moments for the different load cases are also mainly the same as for the standard deviations. For fatigue damage accumulation, the effects are even stronger since the "standard deviation effect" is exponentiated to a power higher than one (and since the mean value essentially does not enter the picture). The effects of inhomogeneous versus homogeneous load representations in relation to design of the bridge structure are clearly of high importance.

4 CONCLUSIONS

The present paper has addressed the question of whether inhomogeneous load patterns can give rise to higher dynamic response levels than homogenous loading. This is shown to be the case, both for a simplistic model of a straight-line bridge, and subsequently for a more comprehensive and realistic model of a floating bridge with an ultra-long span. An important task will then clearly be to identify possible critical inhomogeneous load patterns and the corresponding probability associated with the event that this pattern will occur. This has been illustrated for the simplistic structural model. An ultra-long-span floating bridge structure is also analysed with to compare homogeneous and inhomogeneous load cases of different kinds.

As a general observation, it is found that the challenge associated with inhomogeneous load patterns is that they can easily can give rise to "modal resonance" phenomena, which occurs when the spatial load pattern more or less coincides with the mode shape. An inverse scheme for identification of such critical load patterns was outlined. The probability that such patterns may create critical extreme response levels is also quantified as part of the algorithm. As part of future developments, application of the outlined inverse scheme to large and complex bridge structural models is aimed at. It is anticipated that this may require utilization of reduced order models and surrogate models (also referred to as digital twins) in order to develop numerically efficient schemes.

Keywords: Environmental vibration tests, uncertainty, masonry vaults, modal parameters.

Abstract. *Environmental vibration tests are useful tools for the evaluation of real structures, since they can be carried out during the structure operating conditions. As drawback, the low intensity level of the vibrations makes it difficult to identify precisely the modal parameters of the structure. The objective of the work is to study the uncertainty related to the identification of modal parameters of masonry structures subjected to environmental vibrations. The work deals with experimental records derived from a masonry barrel vault that is conceived as a sequence of arches according to its cross sectional behavior. Two different structural configurations are considered: the vault in its original configuration and the vault in its retrofitted configuration according to current design concepts. Two symmetric arches for each vault configuration are analyzed and the relevant dynamic response monitored. The modal parameters (frequencies, mode shapes and damping ratios) are estimated using operational modal analysis techniques. Four different records, for each structural configurations, are processed to investigate the stationary of the estimates. The results indicate that even though the modal parameters are quite different between the two configurations the related uncertainty are similar in contrast to the common assumptions that the retrofitted configuration should be less dispersive than the original one. As concerns the individual modal parameters it is confirmed that the frequencies present the lower uncertainties whereas the damping ratios are endowed with the higher uncertainties. In any case the uncertainty level does not hide the general pattern of the damping ratios. The imprecision in the mode shapes identification, measured through the MAC index, shows unexpectedly stable and accurate estimates.*

1 INTRODUCTION

In the last decades the need for an effective seismic protection and vulnerability reduction of the cultural heritage determined a growing interest in structural monitoring as a knowledge-based assessment tool to quantify the uncertainties in the structural performances [1]. One of the main purposes of structural monitoring is to observe the structural response to loads and environmental influences over a period of time in order to reduce the uncertainties in the assessment of the actual structural conditions [2]. Different are the fields where uncertainty plays an important role and towards researchers turned their attention: variability of external actions, data dispersion due to measurement inaccuracies, modeling errors related to numerical approximations, changes in material properties [3, 4].

In this paper, the uncertainty related to the structural dynamic response in terms of modal parameters is analyzed. Environmental vibration tests were performed on purpose and Operational Modal Analysis (OMA) was used to identify frequencies, damping, and mode shapes [5]. OMA is a very powerful tool to estimate the modal parameters of a structure when subjected to environmental loads, that is when no measurement of the input is available [6, 7]; of course the quality of the estimates depends also on the choice of the parameters of the particular identification process adopted [8]. One disadvantage of OMA, is its inability in providing the modal masses. Therefore, in the estimation of modal parameters, the mode shapes cannot be mass normalized. Methods for the estimation of the mode shapes scaling factors were proposed and suggestions provided to overcome this limitation [9,10].

Environmental vibration tests are often resorted to in those cases in which the structure under investigation should remain in its full operational conditions. In this instance, because of the small amplitude of the vibrations, it is conceivable that the uncertainties in the modal parameters estimates could affect the stationary of the results. The paper aims at providing a contribution to this problem through the investigation of the peculiar case study of masonry arches. The entity by which uncertainty affects the results is assessed under different circumstances that involve the comparisons among different arches, different structural schemes and different field records.

2 THE ANALYZED STRUCTURE AND THE MONITORING SYSTEM

The analyzed structure is the barrel vault depicted in Figure 1. The vault is about 11.0 m long and 4.3 m large with an approximate circular shape of radius 2.5 m [11]. The vault cross section develops uniformly along the longitudinal axis and the two terminal gables are detached from the vault so that they do not affect significantly the vault behavior at the boundaries. The vault rests on squat thick walls that turn out to be very rigid as compared to the vault. The filling material is quite loose and act essentially as an added mass without providing further stiffness. This vault was damaged in occasion of the l'Aquila earthquake in 2009 and the described configuration pertains to this damaged vault in its original (*O*) state. In 2018 the same vault was subjected to important retrofitting works aimed at moving the fundamental frequencies towards less sensitive ranges to the seismic action. This was obtained by using a lighter filling material cemented with mortar; inserting fiberglass strips glued at the vault extrados; adding transversal masonry stiffeners and perimetral steel curbs. This vault configuration pertains to the vault in its retrofitted (*R*) state.

As concern the monitoring system, a large testing campaign was carried out. The paper reports only the part of the overall campaign functional to the present investigation.

Since the main vault deformation takes place in the transversal direction and in consideration of the uniform longitudinally behavior, it was decided to monitor the vault as it was con-

stituted by a sequence of arches. Two different arches were monitored and analyzed. For comparison purposes these arch sections were taken symmetrically placed with respect to the vault centerline and labelled arch *l* (left) and arch *r* (right), Figure 1.

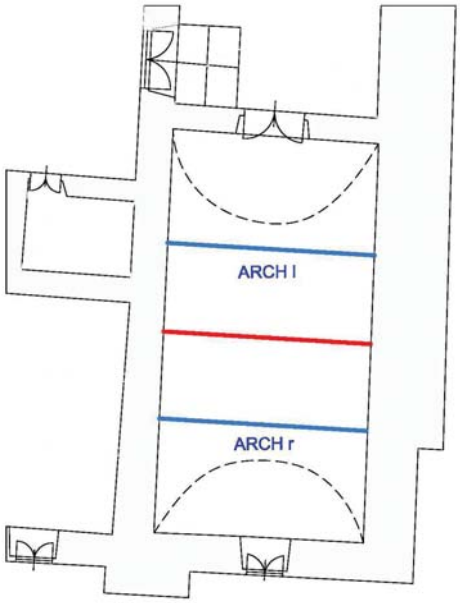

Figure 1. Plan view of the vault: centreline in red; arch *l* and arch r in blue.

Piezoelectric single axis accelerometers were employed (PCB 393A03 by Piezotronics) which are voltage mode output sensors characterized by a 1000 mV/g sensitivity, a ±5g full-scale and a frequency range from 0.5 to 2000Hz with a 5% error. Each accelerometer was connected, by means of shielded cables, to a 24-channels data logger (LMS-SCADAS) mobile hardware with a 24-bit A/D board for a dynamic range of 150 dB. The accelerometers were magnetically fixed to proper metal plates bolted at the intrados of the vault. All the measurement chain was managed by a notebook, Figure 2.

Five measurement points per arch were considered: one at key, two at the arches base and two at the kidneys. Each measurement point comprised a couple of sensors oriented in such a way to record tangential and radial accelerations, as shown in Figure 2, for a total of 10 accelerometers per arch.

Figure 2. Typical biaxial accelerometer and system management equipment.

3 MODAL PARAMETER IDENTIFICATION

In the ambient vibration tests, it is unfeasible to measure the ambient excitation so that the output response of the structure is the only information available to be processed for identification purposes. This circumstance is referred to as Operational Modal Analysis (OMA). A variety of commercial system identification packages exists. In the present case, the LMS TestLab software by Siemens was used since it is licensed together with the monitoring system adopted. TestLab embodies the PolyMAX algorithm [12] to estimate the modal parameters according to a frequency domain processing of the recorder signals.

In the case of OMA, the input spectra are replaced by the assumption that the input is a white noise, i.e. it has a constant power spectrum, independent on frequency. Under this hypothesis output spectra can be modelled with the same expression of the Frequency Response Functions (FRF). The theoretical formulation of the algorithm can be found in [12]. Hereafter, a brief description of the method, functional to the subject of the paper, is given. "PolyMAX", is a polyreference version of the least-squares complex frequency-domain (LSCF) method and makes use of the so-called right matrix-fraction model. One main benefit of the polyreference method is that very closely spaced poles can be effectively separated.

The PolyMAX method is based on two main steps each of which makes use of a least squares solution. In the first step, a stabilisation diagram is constructed via frequency response functions; in this step, frequency and damping ratios are estimated. In the second step, the mode shapes are found, starting from the user selection of the stable poles in the stabilization diagram. The stabilization diagram allows to distinguish the real structural modes from the numerical ones; a mode is defined "stable" if its frequency and damping do not vary as the model order increases.

Frequencies, damping ratios and modal shapes, identified with the above procedure, are used to discuss the uncertainty related to the modal properties of the masonry vault.

4 RESULTS

All the identification process was repeated twice according to the two different *O* and *R* structural configurations. In both cases, the data collected in a basic time window of 3600s were processed and modal parameters identified (frequencies, damping ratios and mode shapes).

In order to evaluate the stationarity of the results, 3 further time windows were processed. These time windows were obtained by segmentation of the basic one as reported in Table 1:

Time window label	Time window duration (s)	Time segment (s)
T - Total duration	3600	0 – 3600
I - Initial segment	1800	0 – 1800
C - Central segment	1800	900 – 2700
F - Final segment	1800	1800 – 3600

Table 1: Basic signal segmentation

In line with the concepts of interval arithmetic, numbers are expressed as intervals bounded by the minimum and maximum $I = [min, max]$ values attained by the set of the identified ordinary crisp quantities [14].

For the present purposes, an alternative more expressive representation is given by the use of the central value or midpoint C and of the radius Δ of the interval:

$$I = [C \pm \Delta] \qquad \text{where:} \quad C = (max + min)/2; \quad \Delta = (max - min)/2 \tag{1}$$

In equation (1) C can be intended as the "mean" value and Δ as the entity of "imprecision or uncertainty" of the estimates. As compared to Δ, that provides an absolute value, the relative uncertainty U can be evaluated by the ratio: $U = \Delta / C$.

In Figure 3 and 4 the identified frequencies are reported respectively for the O and the R configuration separately for the arch l, Figures 3a and 4a, and the arch r, Figures 3b and 4b. Each figure shows the identified frequencies subdivided per mode and per time window.

The inspection of the figures allows to state that the identified frequencies are highly stable regardless the time window or the mode considered. This feature is shared also by both configurations O or R and the relevant arches l or r. This result confirms that any arch of the vault can be used equivalently for monitoring purposes.

The above applies with the exception of mode 3 configuration O, arch l, time segments I and C. In this case it was not possible to identify any valid frequency. This aspect is nonetheless to be considered positive; in fact, or the frequencies are accurately identified or they are not at all. A further positive aspect is that this defect does not influence the remaining identification with special regard to the adjacent time segments.

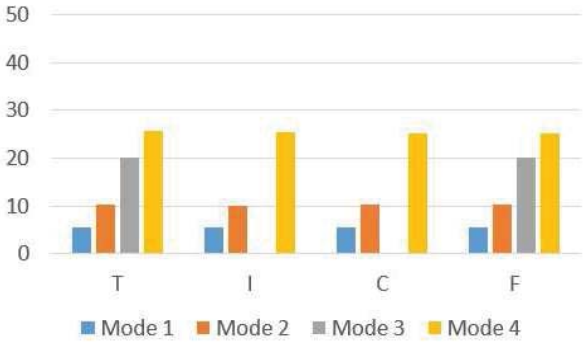

Figure 3a. Frequencies (Hz): config O, arch l

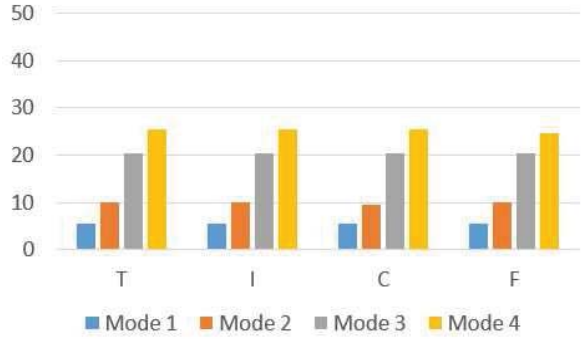

Figure 3b. Frequencies (Hz): config O, arch r

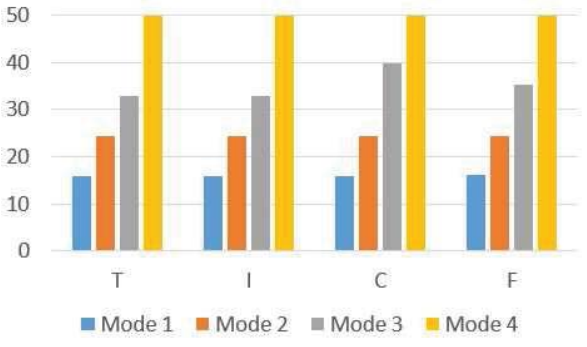

Figure 4a. Frequencies (Hz): config R, arch l

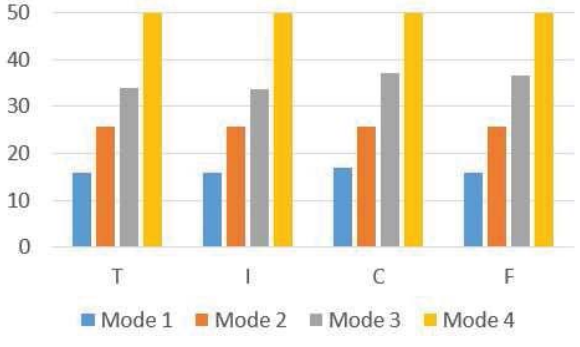

Figure 4b. Frequencies (Hz): config R, arch r

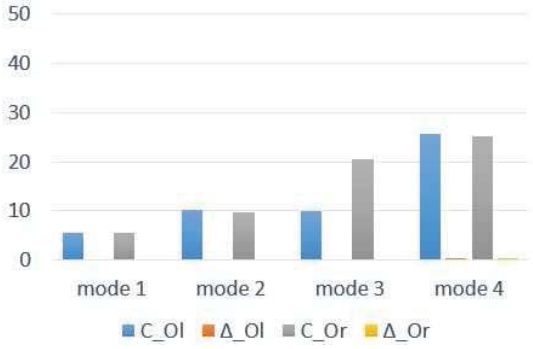

Figure 5. Frequency uncertainty: config O

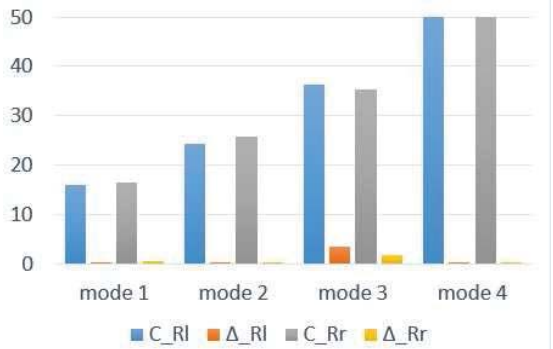

Figure 6. Frequency uncertainty: config R

The uncertainty level Δ against the central value C of the estimated frequencies is shown in Figures 5 and 6 where it is possible to appreciate the strong stationarity of the estimates.

As a conclusion, it is possible to substantiates the common assumption that frequencies can be identified with high accuracy and negligible uncertainties at least in the field of civil structures where the interested frequencies are usually the lower ones.

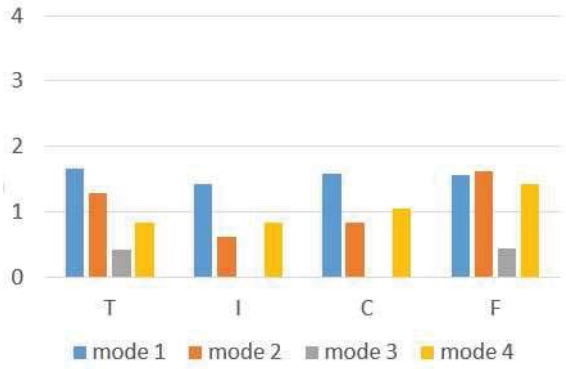

Figure 7a damping (%), config *O*, arch *l*

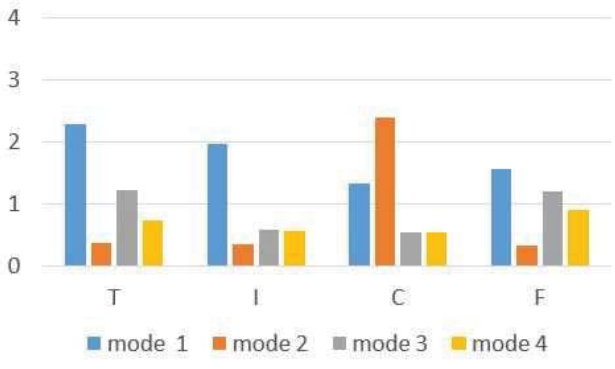

Figure 7b damping (%), config *O*, arch *r*

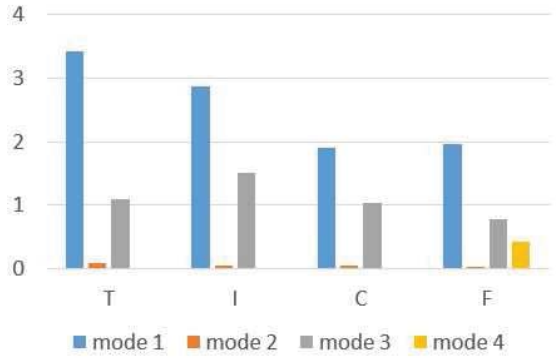

Figure 8a damping (%), config *R*, arch *l*

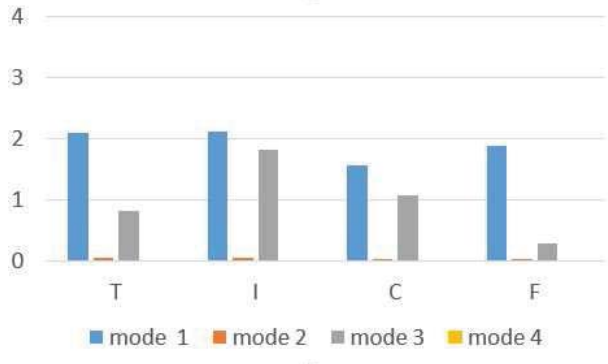

Figure 8b damping (%), config *R*, arch *r*

In general terms it can be stated that the fundamental damping model, i.e. the way in which the damping smears over the modes, is similar for the two arches, *l* and *r*, of the same *O* or *R* configuration with only small uncertainty. This similarity makes it possible to choose any arch as an equivalent candidate for monitoring.

It is observed a systematic prevalence of the damping values of mode 1 compared to the other modes for both configurations. This aspect is markedly evident for the *R* configuration. In addition to the above, it is also observed that the damping (energy dissipation) is distributed over all the modes for the *O* configuration, whereas it is concentrated in the first and third modes for the R configuration. As if it were all the modes of configuration *O* contribute on an equal level in energy dissipation; whereas for the configuration *R* as if it were modes 2 and 4 relate to a rigid body motion that does not produce (hysteretic) damping. This result is coherent with the hypothesis that the modes 2 and 4 would displace rigidly as a consequence of the deformation of the support walls of the vault.

The absolute value of the damping, referred to the first and third mode of both *R* and *O* configurations, happens to be greater for *R* than for *O*. This result is unexpected if one consider the common reasonable assumption that energy dissipation should be higher for "loose" structures (*O*) than for "tied" ones (*R*).

The Figures 9 and 10 refer to the configuration *O* and configuration *R* respectively. Each figure reports the central values *C* and the uncertainties *Δ* evaluated for arch *l* and arch *r* in correspondence with the four identified vibration modes. It is observed a good agreement between the trend of the *C* values in the two cases of arch *l* and arch *r*.

Both configurations *O* and *R* show negligible uncertainty with respect to the first fundamental mode shape. In the other cases, the uncertainty on damping does not show a defined trend. The uncertainties *Δ* remain always a relatively small fraction of *C*. In a couple of cases involving arch *r* of both configurations *Δ* attains values close to *C* displaying large dispersion of the identified values.

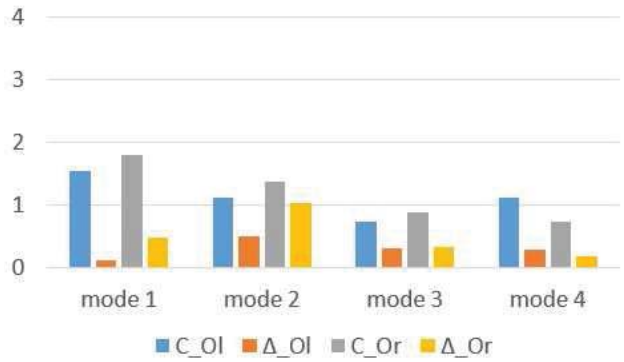

Figure 9 Damping uncertainty: config *O*

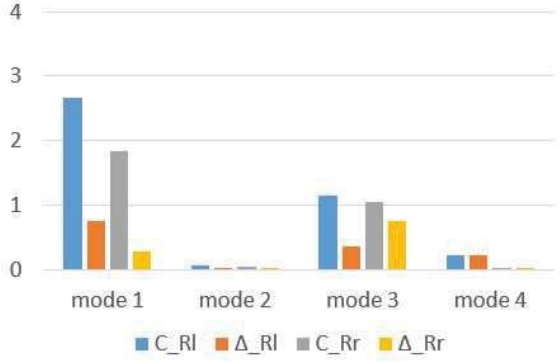

Figure 10 Damping uncertainty: config *R*

In order to get a homogeneous presentation of the results, the comparison among the mode shapes was carried out by means of the Modal Assurance Criterion (MAC) [14,15].

Presently, the advantage related to the use of the MAC index is that it allows to express the level of correlation between two mode shapes by just one number. In this way, it is possible to apply the equation (1) to quantify the uncertainty *Δ* also in the case of the mode shapes. The MAC is defined as (being $()^T$ the transpose operator):

$$MAC(\phi_{Sn}, \phi_{Sm}) = \frac{\left|\phi_{Sn}^T \cdot \phi_{Sm}\right|^2}{(\phi_{Sn}^T \cdot \phi_{Sn})(\phi_{Sm}^T \cdot \phi_{Sm})} \qquad (2)$$

and takes values in the range [0, 1] where 0 means no consistency and 1 means perfect matching. In equation (2) ϕ_{Sn} is the mode shape of order *S* identified using the time segment *n* and ϕ_{Sm} is the mode shape of the same order *S* but identified using the time segment *m*. So, for example, ϕ_{2C} is the mode shape *S* = *2* relative to the time segment *n* = C.

In the present case, the Modal Phase Collinearity (MPC) was used to quantify the degree of complexity of the identified mode shapes. It was found that in all examined cases MPC takes on values close to 100% that demonstrate perfect collinearity or monophase behavior. Consistently real evaluated mode shapes were used in the computations.

Ultimately, for each mode shape, the MAC indices were computed for the cases I, C and F against the common reference T as shown in Table 2.

T against all time segments	T-I	T-C	T-F

Table2: Couples of time segments for MAC computation.

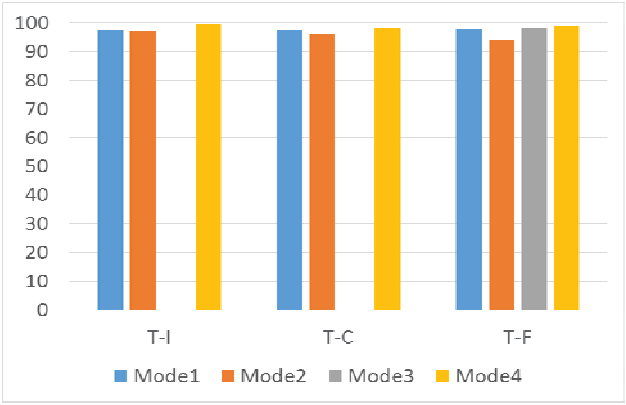

Figure 11a. MAC (%): Config *O*, Arch *l*.

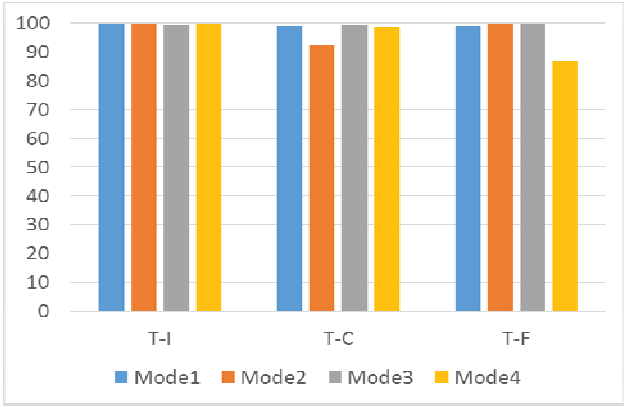

Figure 11b. MAC (%:) Config. *O*, Arch *r*.

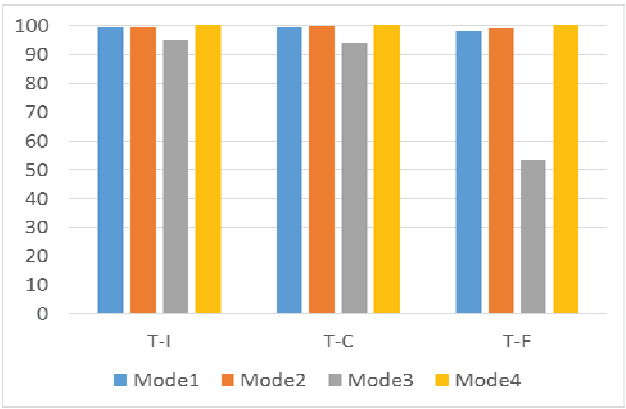

Figure 12a. MAC (%): Config. *R*; Arch *l*.

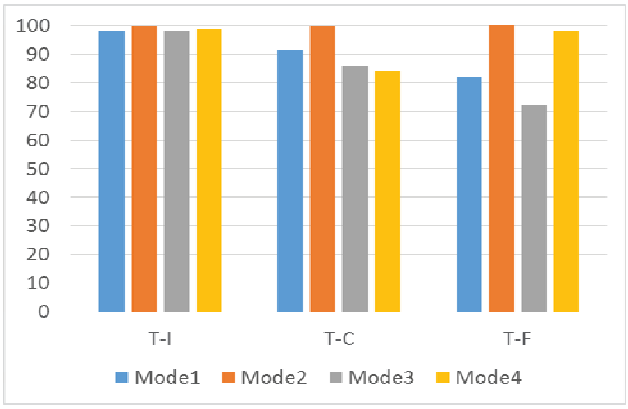

Figure 12b. MAC (%): Config. *R*; Arch *r*.

The results are illustrated in Figures 11 to 14 that are organized in the same format used to discuss the uncertainty relevant to frequencies and damping ratios. The histograms show the MAC values for the various combinations of the time segments, Table 2. The higher the MAC values are the lower the spread of the identified values is. That can be rephrased as: the more the similitude among the mode shapes is the lower the uncertainty is.

By the inspection of Figures 11 to 12 the following general comments can be dawn. The histograms are relatively similar; this statement applies whatever the structural configuration (*O* or *R*) and the measurement arch (*l* or *r*) are. The dispersion of the MAC values does not increase significantly as the mode shape order increases, except for the configuration *R* arch *r*. This was somewhat surprising considering that the *R* configuration should have a more regular behavior.

A more detailed inspection of the figures shows that the mode shape 3 is the hardest to be precisely identified. This happens especially in correspondence of the time segment F as clearly evidenced in Figure 12a; apart configuration *O*, arch *l*, time segments I and C where it is not detected at all (see also Figures 3a and 7a).

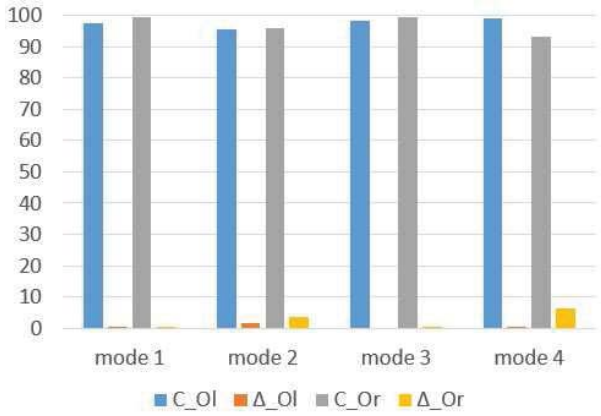

Figure 13. MAC uncertainty: Config *O*

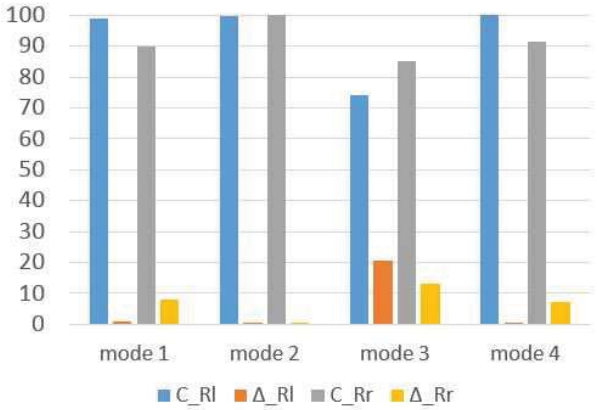

Figure 14. MAC uncertainty: Config *R*

The Figures 13 and 14 refer to the configuration *O* and configuration *R* respectively. Each figure reports the central values *C* and the uncertainties *Δ* evaluated for arch *l* and arch *r* in correspondence with the four identified vibration modes.

From the figures it is observed a *C* value greater than 90% for all the considered cases except for mode 3 where *C* is slightly below 80%. In any case a negligible uncertainty *Δ* lower than 10% with the only exception of mode shape 3 where *Δ* is of the order of 20%.

However, it is confirmed that any of the two arches *l* or *r* can be equivalently adopted for monitoring purposes even if with there exist some scatter of the results yet within acceptable uncertainty margins.

A summary of the relative uncertainty is given in Table 3 where the *U* values are listed, mode by mode, for frequencies, damping ratios and mode shapes.

Config	U_{freq}				U_{damp}				U_{MAC}			
/mode	O_l	O_r	R_l	R_r	O_l	O_r	R_l	R_r	O_l	O_r	R_l	R_r
1	0	1	1	3	7	27	29	15	0	0	1	9
2	1	3	0	0	45	76	46	29	2	4	0	0
3	-	0	1	5	-	38	32	72	-	7	28	15
4	1	1	0	0	27	25	97	54	1	0	0	8

Table 3: Relative uncertainty *U* (%) of the modal parameters: Config *O*, *R*, arches *l*, *r*.

In the inspection of the table it should be remembered that mode 3 was the hardest to identify as highlighted by the absence of any valid frequency in the O_l configuration and by the large scatter in the U_{MAC} case. Apart this aspect, the listed values show very low and negligible uncertainty in the U_{freq} case; the same can be said for the U_{MAC} case where the uncertainty is generally small, but not always entirely insignificant. The U_{damp} in turn is affected by high and dispersed uncertainty.

Whichever be the case, the dispersion of the *U* values does not show well defined trend and can be considered randomly distributed for all the modal parameters. This occurs for both configurations *O* and *R* and the arch *l* or *r* considered. The uncertainty level is roughly the same for the two configurations. This last finding contrasts the common assumption that a retrofitted "tied" structure should be less dispersive than the original "loose" one.

6 CONCLUSIONS

The work is devoted to the study of the uncertainty in the identification of the modal parameters of vaulted masonry structures. Only the transversal behavior of the vault was considered so that the dynamic response was monitored according to two arches symmetrically placed with respect to the central line of the vault.

Environmental tests were performed and the recorded signals processed to identify frequencies, damping ratios and mode shapes. To this end, the entire recorded signals was partitioned in sub time segments to control the stationarity of the identified quantities among the different time segments. The uncertainty was quantified in line with the concept of interval numbers characterized by the central value and the radius (uncertainty) of the interested range of values. The mode shapes needed to be processed to be represented by scalar quantities. To this end the MAC index of each mode shape obtained from the single sub time segment respect to the mode shape of the entire recorded signal was used. The measurements campaign and the identification process were repeated twice for two different vault configurations: the vault as it was in its original state and after retrofit interventions.

The results indicate that the uncertainty relevant to the two configurations is similar in contrast to the conventional assumption that the retrofitted "tied" configuration should be less dispersive than the original "loose" one. The results indicate also that the two arches, according to which the vault was monitored, showed very similar behavior so that any arch of the vault can be equivalently adopted for monitoring purposes within acceptable uncertainty margins. As concerns the individual modal parameters it is confirmed that the frequencies present negligible uncertainties whereas the damping ratios are endowed with the higher uncertainties. As a final result it can be said that the dispersion of the estimates of the modal parameters do not increase significantly as the mode order increases.

Keywords: Earthquake, Extreme events, Nonlinear secondary oscillator, Stochastic excitation.

Abstract. *The paper deals with the steady-state stationary response of single-degree-of-freedom nonlinear secondary oscillators in stochastically driven linear primary structures. Equations governing the primary-secondary dynamic interaction are presented, followed by a concise exposition of a two-degree-of-freedom system assembly with dimensionless coefficients. Stochastic forcing is successively modelled as monochromatic, white noise, and filtered white noise process, representing extreme forms of narrow-band and wide-band excitations, as well as an intermediate case, characterised by the Clough-Penzien stationary power spectrum, commonly adopted in earthquake engineering applications. A decomposition-synthesis approach is presented in order to analytically approximate the response of the secondary system in cascade, by quantifying the statistics to individual forcing components, and synthesising the results to obtain the response of an equivalent linear secondary system. Demonstrated to the case of a Duffing secondary oscillator, and compared with pertinent Monte-Carlo simulations, the derived formulas permit accurate and efficient quantification of the secondary system's response as a function of the design input parameters of the system assembly and the excitation.*

1 INTRODUCTION

For a plethora of structural systems encountered in engineering it is essential to specify their reliability under environmental loading conditions. Examples include missile and aircraft vibration due to atmospheric turbulence, the vibration of buildings and bridges due to earthquakes and wind, vehicle vibration due to ground and track surface irregularities, and the motion of ships and offshore structures due to wave excitation. Environmental loads are random by nature and comprise the dominant source of uncertainty for such systems. For this reason, numerous efforts have been devoted to the development of methods for the response quantification and analysis of dynamical systems subjected to random excitations.

Previous research endeavours mostly deal with primary systems, that is, load-bearing structures, modelled either as linear or weakly nonlinear, and driven by an excitation of idealised form, including broadband white noise and filtered white noise, characterised by various spectral shapes [1]. However, much research effort is still needed to provide efficient and accurate tools for estimating the response of nonlinear secondary systems subjected to random loads. Secondary structures, also referred to as subsystems, are defined as the auxiliary mechanical, electrical and electronic components and contents that are not part of the primary load-bearing structure, arising in modern engineering applications [2]. It is now well established that their reliability in the face of an extreme environmental event is essential as their damage can influence the operational continuity of the primary structure, leading to loss of life, injury, direct and indirect economic loss.

In this paper, the stochastic response of nonlinear single-degree-of-freedom secondary oscillators, in randomly excited linear primary building structures, is investigated. The full primary-secondary dynamic interaction is considered first and simplified equations are derived for a reduced two-degree-of-freedom system assembly with dimensionless coefficients. Stochastic forcing is then successively modelled as monochromatic, white noise and filtered white noise process. The first two, characterised by diametrically opposed spectral properties, represent extreme scenarios of a narrow-band and wide-band excitation, while the latter represents the intermediate case of the Clough-Penzien [3] stationary power spectrum, commonly adopted in earthquake engineering applications. A decomposition-synthesis approach is then presented in order to analytically approximate the stochastic response of the secondary system, with an application to a secondary Duffing oscillator. Based on the premise that the secondary structure is driven in a one-way interaction, the idea is to decouple the subsystems under the cascade analysis approximation [4], decompose the driving acceleration at the oscillator's position of attachment to individual components, separately quantify the response statistics, and synthesise the results to obtain the response of an equivalent linear secondary system. The resulting analytical approximation formulas fully characterise the response probability density functions under the excitation types considered, permit accurate and efficient quantification, and directly relate the statistical response parameters to the design input parameters of the primary-secondary system assembly and the excitation.

2 PRIMARY-SECONDARY SYSTEM VIBRATION

Consider the case of a dynamical system consisting of a single-degree-of-freedom (SDoF) secondary (S) oscillator attached to a multi-degree-of-freedom (MDoF) primary (P) structure. The P system represents herein a multi-storey building, while the S oscillator describes an attachment, whose performance is potentially critical to the overall resilience.

The differential equation governing the response of the combined system when subjected to

seismic excitation, assumed at rest for $t \leq 0$, reads:

$$\mathbf{M} \cdot \ddot{\mathbf{u}}(t) + \mathbf{C} \cdot \dot{\mathbf{u}}(t) + \mathbf{F}_r(\mathbf{u}(\mathbf{t})) = -\mathbf{M} \cdot \boldsymbol{\tau}\, \ddot{u}_{\mathrm{g}}(t)\,, \tag{1}$$

satisfying the initial conditions $\mathbf{u}(0) = \mathbf{0}_{n+1}$ and $\dot{\mathbf{u}}(0) = \mathbf{0}_{n+1}$, where $\mathbf{u}\,(t) = \left\{ \mathbf{u}_{\mathrm{p}}^{\top}\,(t) \,\middle|\, u_{\mathrm{s}}\,(t) \right\}^{\top}$ is the partitioned array collecting the $n+1$ DoFs relative to the ground, in which $\mathbf{u}_{\mathrm{p}}\,(t) = \{u_{\mathrm{p}1}\,(t), \ldots, u_{\mathrm{p}n}\,(t)\}^{\top}$ is the vector listing the n dynamically significant DoFs of the P structure, the superscripted $\top$ being the transpose operator; $u_{\mathrm{s}}(t)$ is the translational DoF of the S oscillator; $\boldsymbol{\tau} = \left\{ \boldsymbol{\tau}_{\mathrm{pg}}^{\top} \,\middle|\, 1 \right\}^{\top}$ is a partitioned array where $\boldsymbol{\tau}_{\mathrm{pg}}$ is the $(n \times 1)$ vector of seismic incidence; $\ddot{u}_g(t)$ is the unidirectional horizontal component of the ground acceleration, the overdot denoting differentiation with respect to the time t. Furthermore, $\mathbf{M}$ and $\mathbf{C}$ are the mass and damping matrices, partitioned as:

$$\mathbf{M} = \left[\begin{array}{c|c} \mathbf{M}_{\mathrm{p}} & \mathbf{0}_n \\ \hline \mathbf{0}_n^{\top} & m_{\mathrm{s}} \end{array}\right] \;; \quad \mathbf{C} = \left[\begin{array}{c|c} \mathbf{C}_{\mathrm{p}} + c_{\mathrm{s}}\, \boldsymbol{\tau}_{\mathrm{ps}} \boldsymbol{\tau}_{\mathrm{ps}}^{\top} & -c_{\mathrm{s}}\, \boldsymbol{\tau}_{\mathrm{ps}} \\ \hline -c_{\mathrm{s}}\, \boldsymbol{\tau}_{\mathrm{ps}}^{\top} & c_{\mathrm{s}} \end{array}\right], \tag{2}$$

where $\mathbf{M}_{\mathrm{p}}$ and $\mathbf{C}_{\mathrm{p}}$ are the mass and damping matrices of P, while m_{s} and c_{s} the associated coefficients for S; $\mathbf{0}_n$ being a zero vector of dimensions $(n \times 1)$; $\boldsymbol{\tau}_{\mathrm{ps}}$ is the $(n \times 1)$ incidence vector of the feedback action of S on P; and $\mathbf{F}_r(\mathbf{u})$ is a nonlinear restoring force that depends on the state of the system.

It has long been recognised that conventional methods can be cumbersome for the analysis of combined systems, owing to each subsystem's characteristics and dissimilarities between them, as well as impractical for design purposes, since, the P structure needs to be reanalysed for every change introduced on S. Even, if the combined system is linear,

$$\mathbf{F}_r(\mathbf{u}(t)) = \mathbf{F}_{r,lin}(\mathbf{u}(t)) = \left[\begin{array}{c|c} \mathbf{K}_{\mathrm{p}} + k_{\mathrm{s}}\, \boldsymbol{\tau}_{\mathrm{ps}} \boldsymbol{\tau}_{\mathrm{ps}}^{\top} & -k_{\mathrm{s}}\, \boldsymbol{\tau}_{\mathrm{ps}} \\ \hline -k_{\mathrm{s}}\, \boldsymbol{\tau}_{\mathrm{ps}}^{\top} & k_{\mathrm{s}} \end{array}\right] \cdot \left[\begin{array}{c} \mathbf{u}_{\mathrm{p}}(t) \\ \hline u_{\mathrm{s}}(t) \end{array}\right], \tag{3}$$

$\mathbf{K}_{\mathrm{p}}$ and k_{s} being the stiffness matrix and stiffness coefficient for P and S, the necessary and sufficient Caughey-O'Kelly condition $\mathbf{K} \cdot \mathbf{M}^{-1} \cdot \mathbf{C} = \mathbf{C} \cdot \mathbf{M}^{-1} \cdot \mathbf{K}$ [5] will, in general, not be satisfied and therefore classical modal analysis is inadmissible. However, recent advances on the decoupling of linear systems permit decoupling of Eq. (1) by the method of phase synchronisation through solution of the quadratic eigenvalue problem $(\mathbf{M} \cdot \lambda^2 + \mathbf{C} \cdot \lambda + \mathbf{K}) \cdot \mathbf{v} = 0$ [6–8].

2.1 Reduced primary-secondary system assembly

Let us now consider the case of a nonlinear S oscillator attached to a P system, as depicted in Figure 1, the latter assumed to be linear and classically damped. This assumption is not unduly restrictive, as critical infrastructure are often designed to respond within their linear-elastic regime and the survivability of internal equipment is in question. Furthermore, we separately consider P and therefore uniformly distributed energy dissipation is routinely assumed. The objective here is to formulate the system of differential equations in a simplified form, and pave the way for quantifying the S system's response under stochastic excitation in the next section.

Denoting $u_{\mathrm{s}}^{\mathrm{p}}(t)$ as the translational DoF of the S oscillator relative to the motion of the P structure, the equation of motion of P, can be conveniently expressed as:

$$\mathbf{M}_{\mathrm{p}} \cdot \ddot{\mathbf{u}}_{\mathrm{p}}(t) + \mathbf{C}_{\mathrm{p}} \cdot \dot{\mathbf{u}}_{\mathrm{p}}(t) + \mathbf{K}_{\mathrm{p}} \cdot \mathbf{u}_{\mathrm{p}}(t) = -\mathbf{M}_{\mathrm{p}} \cdot \boldsymbol{\tau}_{\mathrm{pg}} \ddot{u}_{\mathrm{g}}(t) - \boldsymbol{\tau}_{\mathrm{ps}}\, m_{\mathrm{s}} \left(\ddot{u}_{\mathrm{s}}^{\mathrm{p}}(t) + \boldsymbol{\tau}_{\mathrm{ps}}^{\top} \ddot{\mathbf{u}}_{\mathrm{p}}(t) + \ddot{u}_{\mathrm{g}}(t) \right) . \tag{4}$$

Furthermore, we denote $\ddot{\mathbf{u}}_{\mathrm{p}}^{(\mathrm{a})}(t) = \ddot{\mathbf{u}}_{\mathrm{p}}(t) + \boldsymbol{\tau}_{\mathrm{pg}} \cdot \ddot{u}_{\mathrm{g}}(t)$ as the vector listing the absolute accelerations of the P DoFs; $\ddot{u}_{\mathrm{ps}}^{(\mathrm{a})}(t) = \boldsymbol{\tau}_{\mathrm{ps}}^{\top} \cdot \ddot{\mathbf{u}}_{\mathrm{p}}^{(\mathrm{a})}(t)$ as the absolute acceleration of the P structure at the location of the S oscillator; and $\ddot{u}_{\mathrm{s}}^{(\mathrm{a})}(t) = \ddot{u}_{\mathrm{s}}^{\mathrm{p}}(t) + \ddot{u}_{\mathrm{ps}}^{(\mathrm{a})}(t)$ as the absolute acceleration of the S mass.

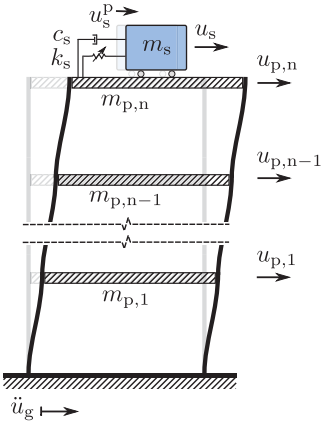

Figure 1: Combined linear P nonlinear S system.

2.1.1 Modal transformation

Aiming at reducing the dimensions of the P-S combined dynamic system, the equations of motion of the P structure are projected onto the reduced modal subspace. Accordingly, a solution to the real-valued eigenproblem $\mathbf{M}_{\mathrm{p}} \cdot \boldsymbol{\Phi}_{\mathrm{p}} \cdot \boldsymbol{\Omega}_{\mathrm{p}}^2 = \mathbf{K}_{\mathrm{p}} \cdot \boldsymbol{\Phi}_{\mathrm{p}}$ is sought, where $\boldsymbol{\Phi}_{\mathrm{p}} = \left[\boldsymbol{\phi}_{\mathrm{p1}}, \ldots \boldsymbol{\phi}_{\mathrm{p}n}\right]$ is the $(n \times n)$ modal matrix, whose columns are the n modal shapes of the P structure, and $\boldsymbol{\Omega}_{\mathrm{p}} = \mathrm{diag}\left\{\omega_{\mathrm{p1}}, \ldots, \omega_{\mathrm{p}n}\right\}$ is the diagonal spectral matrix listing the associated modal circular frequencies in ascending order. If the P-S dynamic interaction has its largest effects on the ith mode of vibration of the P structure, the following transformation can be adopted:

$$\mathbf{u}_{\mathrm{p}}(t) \approx \boldsymbol{\phi}_{\mathrm{p}i}\, q_{\mathrm{p}i}(t)\,, \tag{5}$$

where $q_{\mathrm{p}i}(t)$ is the ith modal coordinate of the P structure corresponding to the largest modal participation factor. Without loss of generality, the modal shape $\boldsymbol{\phi}_{\mathrm{p}i}$ can be normalised such that the largest horizontal displacement is set equal to 1.

Upon substitution of Eq. (5) in Eq. (4), pre-multiplication of the result by $\boldsymbol{\phi}_{\mathrm{p}i}^{\top}$ and further manipulations, one obtains:

$$\ddot{u}_{\mathrm{ps}i}(t) + 2\,\zeta_{\mathrm{p}i}\,\omega_{\mathrm{p}i}\,\dot{u}_{\mathrm{ps}i}(t) + \omega_{\mathrm{p}i}^2\,u_{\mathrm{ps}i}(t) = -\phi_{\mathrm{ps}i}\left(\beta_i\,\ddot{u}_{\mathrm{g}}(t) + \gamma_i\,\ddot{u}_{\mathrm{s}i}^{(\mathrm{a})}(t)\right)\,, \tag{6}$$

where $u_{\mathrm{ps}i}(0) = 0$ and $\dot{u}_{\mathrm{ps}i}(0) = 0$, and where $u_{\mathrm{ps}i}(t) = \phi_{\mathrm{ps}i}\,q_{\mathrm{p}i}(t)$ denotes the contribution of the ith mode of vibration to the seismic response of the P structure at the position of the S oscillator, $\phi_{\mathrm{ps}i} = \boldsymbol{\tau}_{\mathrm{ps}}^{\top} \cdot \boldsymbol{\phi}_{\mathrm{p}i}$ being the corresponding modal displacement; $\ddot{u}_{\mathrm{s}i}^{(\mathrm{a})}(t) = \ddot{u}_{\mathrm{s}}^{\mathrm{p}}(t) + \ddot{u}_{\mathrm{ps}i}(t) + \ddot{u}_{\mathrm{g}}(t)$ is the absolute acceleration of the S mass, considering for the P structure only the contribution of the ith mode of vibration; $\zeta_{\mathrm{p}i}$ and $\omega_{\mathrm{p}i}$ are the ith modal values of equivalent viscous damping ratio and circular frequency of the P modal oscillator, respectively; $\beta_i = \widetilde{m}_{\mathrm{p}i}^{-1}\,\boldsymbol{\phi}_{\mathrm{p}i}^{\top} \cdot \mathbf{M}_{\mathrm{p}} \cdot \boldsymbol{\tau}_{\mathrm{pg}}$ is the ith dimensionless modal factor for the seismic input, with $\widetilde{m}_{\mathrm{p}i} =$

$\boldsymbol{\phi}_{\mathrm{p}i}^{\top} \cdot \mathbf{M}_{\mathrm{p}} \cdot \boldsymbol{\phi}_{\mathrm{p}i}$ being the ith modal mass for the P structure; similarly, $\gamma_i = \widetilde{m}_{\mathrm{p}i}^{-1}\, \phi_{\mathrm{ps}i}\, m_{\mathrm{s}}$ is the ith dimensionless modal factor for the S feedback on the P structure.

In what follows, for the sake of simplifying the notation, the generalised P coordinate $u_{\mathrm{ps}i}(t)$ is replaced with $u_{\mathrm{p}}(t)$, and the modal index i is dropped in all the other quantities in Eq. (6) resulting to:

$$\ddot{u}_{\mathrm{p}}(t) + 2\,\zeta_{\mathrm{p}}\,\omega_{\mathrm{p}}\,\dot{u}_{\mathrm{p}}(t) + \omega_{\mathrm{p}}^2\,u_{\mathrm{p}}(t) = -\phi_{\mathrm{ps}}\left(\beta\,\ddot{u}_{\mathrm{g}}(t) + \gamma\left(\ddot{u}_{\mathrm{g}}(t) + \ddot{u}_{\mathrm{p}}(t) + \ddot{u}_{\mathrm{s}}^{\mathrm{p}}(t)\right)\right)\,. \tag{7}$$

It is clear that the contribution of higher modes can be included in the procedure, if needed. Notably, setting $\gamma = 0$ decouples Eq. (7) from the equation governing the seismic response of the S oscillator, leading to the so-called 'cascade approximation', where the P-S dynamic interaction is neglected. It is worth noting here that the condition $\gamma = 0$ does not imply a massless S system, but merely the fact that the feedback action of S on P is negligible. Furthermore, in the special case where P is a SDoF oscillator, i.e. $n = 1$, then, $\phi_{\mathrm{ps}} = \beta = 1$ and $\gamma = m_{\mathrm{s}}/m_{\mathrm{p}}$.

2.1.2 Duffing secondary oscillator

Without loss of generality, the simplest case of a SDoF S Duffing oscillator, extensively studied in the literature, is considered next. Dynamic equilibrium of the mass m_{s} in the horizontal direction gives:

$$\ddot{u}_{\mathrm{s}}^{\mathrm{p}}(t) + 2\,\zeta_{\mathrm{s}}\,\omega_{\mathrm{s}}\,\dot{u}_{\mathrm{s}}^{\mathrm{p}}(t) + \omega_{\mathrm{s}}^2\left(u_{\mathrm{s}}^{\mathrm{p}}(t) + \lambda\,\left(u_{\mathrm{s}}^{\mathrm{p}}(t)\right)^3\right) = -\ddot{u}_{\mathrm{p}}^{(\mathrm{a})}(t)\,, \tag{8}$$

where $u_{\mathrm{s}}^{\mathrm{p}}(0) = 0$ and $\dot{u}_{\mathrm{s}}^{\mathrm{p}}(0) = 0$, $u_{\mathrm{s}}^{\mathrm{p}}(t)$ being the displacement of the S oscillator relative to the P structure at its point of attachment; ζ_{s} and $\omega_{\mathrm{s}} = \sqrt{k_{\mathrm{s}}/m_{\mathrm{s}}}$ are the viscous damping ratio and natural circular frequency of S in its elastic range, k_{s} being its elastic stiffness; λ is a constant, for $\lambda = 0$ the restoring force reduces to the linear one, while $\lambda < 0$ and $\lambda > 0$ represent softening and hardening phases, respectively; $\ddot{u}_{\mathrm{p}}^{(\mathrm{a})}(t) = \ddot{u}_{\mathrm{p}}(t) + \ddot{u}_{\mathrm{g}}(t)$ is the absolute horizontal acceleration of P at the position of S, in which $\ddot{u}_{\mathrm{p}}(t)$ satisfies Eq. (7).

3 STOCHASTIC FORCING MODEL

Consider a ground acceleration $\ddot{u}_{\mathrm{g}}(t)$, successively modelled as monochromatic, white noise, and filtered white noise stationary Gaussian process. The monochromatic and white noise excitations, characterised by diametrically opposed properties, represent herein the extreme forms of narrow-band and wide-band processes, respectively, while the coloured noise represents an intermediate case, characterised by a modified Kanai-Tajimi (KT) power spectrum (Kanai [9]; Tajimi [10]) suggested by Clough and Penzien (CP) [3], commonly used in earthquake engineering applications. Their power spectral density (PSD) functions are, respectively, given by:

$$S_{\ddot{u}_{\mathrm{g}}}(\omega) = \alpha\,\delta\left(|\omega| - \omega_0\right)\,;\quad S_{\ddot{u}_{\mathrm{g}}}(\omega) = S_0\,;\quad S_{\ddot{u}_{\mathrm{g}}}(\omega) = S_0 \cdot H_k(\omega) \cdot H_c(\omega)\,, \tag{9}$$

for $-\infty < \omega < \infty$, where α is the strength of the unit impulse $\delta(\cdot)$ and ω_0 is the arrival frequency; S_0 represents a constant PSD level due to white noise; and $H_k(\omega)$ and $H_c(\omega)$ represent the KT and CP filters, respectively, given by:

$$H_k(\omega) = \frac{1 + 4\,\zeta_g^2\,(\omega/\omega_g)^2}{\left(1 - (\omega/\omega_g)^2\right)^2 + 4\,\zeta_g^2\,(\omega/\omega_g)^2}\,;\quad H_c(\omega) = \frac{(\omega/\omega_f)^4}{\left(1 - (\omega/\omega_f)^2\right)^2 + 4\,\zeta_f^2\,(\omega/\omega_f)^2}\,, \tag{10}$$

where ω_g and ζ_g are the frequency and damping ratio of the soil layer, respectively, and the parameters ω_f and ζ_f control the CP filter's characteristics.

In the CP model, $H_k(\omega)$ attenuates the frequency content for $\omega > \omega_g$ as $\omega \to \infty$, and amplifies the frequencies in the vicinity of $\omega = \omega_g$. $H_c(\omega)$ is then introduced to eliminate the low-frequency content, thus assuring finite power for the ground displacement.

4 RESPONSE QUANTIFICATION OF NONLINEAR SECONDARY OSCILLATOR

In §2 simplified equations were presented for the dynamic interaction of the P-S system. In this section a decomposition-synthesis (DS) approach is presented for the analysis of linear and equivalent linear S systems. The purpose is the quantification, through analytical approximations, of the response of the nonlinear S to stochastic excitation, with indicative application to an S Duffing oscillator subjected to the excitation considered in §3. The basic idea is to decouple P and S, separately quantify the response statistics to individual forcing components, and synthesise the results to obtain the response of an equivalent linear S oscillator.

4.1 Primary structure

To apply the DS method, we first assume that the S oscillator is essentially driven in a one-way interaction. On setting $\gamma = 0$, Eq. (7) and (8) decouple and can sequentially be considered. We emphasise that this is desirable as different S can be considered for the same P configuration.

Next, we proceed with quantification of the probabilistic structure of $\ddot{u}_{\mathrm{p}}^{(\mathrm{a})}$, which constitutes the driving acceleration of the S oscillator. We decompose this in two terms:

$$\ddot{u}_{\mathrm{p}}^{(\mathrm{a})}(t) = \ddot{u}_{\mathrm{p}}(t) + \ddot{u}_{\mathrm{g}}(t)\,, \tag{11}$$

and since both $\ddot{u}_{\mathrm{p}}(t)$ and $\ddot{u}_{\mathrm{g}}(t)$ are stationary and Gaussian distributed, $\ddot{u}_{\mathrm{p}}^{(\mathrm{a})}(t)$ will also be so. The autocorrelation function of the process $\ddot{u}_{\mathrm{p}}^{(\mathrm{a})}(t)$ may be expressed in terms of the autocorelation and cross-correlation functions of $\ddot{u}_{\mathrm{p}}(t)$ and $\ddot{u}_{\mathrm{g}}(t)$, and therefore one can obtain the PSD of $\ddot{u}_{\mathrm{p}}^{(\mathrm{a})}(t)$ as:

$$S_{\ddot{u}_{\mathrm{p}}^{(\mathrm{a})}}(\omega) = S_{\ddot{u}_{\mathrm{p}}}(\omega) + S_{\ddot{u}_{\mathrm{g}}}(\omega) + 2\,\mathbb{R}\mathrm{e}\{S_{\ddot{u}_{\mathrm{p}}\ddot{u}_{\mathrm{g}}}(\omega)\}\,, \tag{12}$$

where $S_{\ddot{u}_{\mathrm{p}}}(\omega)$, the response PSD of $\ddot{u}_{\mathrm{p}}(t)$, is related to the excitation through,

$$S_{\ddot{u}_{\mathrm{p}}}(\omega) = \omega^4 S_{u_{\mathrm{p}}}(\omega)\,; \quad S_{u_{\mathrm{p}}}(\omega) = |H_{\mathrm{p}}(\omega)|^2\, S_{\ddot{u}_{\mathrm{g}}}(\omega)\,, \tag{13}$$

in which $H_{\mathrm{p}}(\omega)$ is the frequency response function (FRF), given by:

$$H_{\mathrm{p}}(\omega) = \frac{\phi_{\mathrm{ps}}\,\beta}{\omega^2 - 2\,i\,\zeta_{\mathrm{p}}\omega_{\mathrm{p}}\,\omega - \omega_{\mathrm{p}}^2}\,. \tag{14}$$

Furthermore, the last term in Eq. (12) can be interpreted as the sum of the cross-spectral density functions $S_{\ddot{u}_{\mathrm{p}}\ddot{u}_{\mathrm{g}}}(\omega)$ and $S_{\ddot{u}_{\mathrm{g}}\ddot{u}_{\mathrm{p}}}(\omega)$, where $S_{\ddot{u}_{\mathrm{p}}\ddot{u}_{\mathrm{g}}}(\omega) = S^*_{\ddot{u}_{\mathrm{g}}\ddot{u}_{\mathrm{p}}}(\omega)$, in which $*$ denotes conjugation, and:

$$S_{\ddot{u}_{\mathrm{p}}\ddot{u}_{\mathrm{g}}}(\omega) = -\omega^2 S_{u_{\mathrm{p}}\ddot{u}_{\mathrm{g}}}(\omega)\,; \quad S_{u_{\mathrm{p}}\ddot{u}_{\mathrm{g}}}(\omega) = H_{\mathrm{p}}(\omega) S_{\ddot{u}_{\mathrm{g}}}(\omega)\,. \tag{15}$$

Notably, Eq. (12) expresses the PSD of the driving acceleration for S to individual components, simplifying manipulation. Furthermore, it permits the direct generation of floor acceleration time series ensembles corresponding to specified ground excitation spectral shapes,

through standard stochastic forcing simulation methods [11], for the numerical analysis of the nonlinear S.

The process variance of $\ddot{u}_{\mathrm{p}}^{(\mathrm{a})}(t)$, fully characterising the zero mean ($\mu_{\ddot{u}_{\mathrm{p}}^{(\mathrm{a})}} = \mu_{\ddot{u}_{\mathrm{p}}} + \mu_{\ddot{u}_{\mathrm{g}}} = 0$) Gaussian (absolute acceleration) response of P, can thus be readily obtained as:

$$\sigma^2_{\ddot{u}_{\mathrm{p}}^{(\mathrm{a})}} = \int_{-\infty}^{\infty} S_{\ddot{u}_{\mathrm{p}}^{(\mathrm{a})}}(\omega)\,\mathrm{d}\omega = \sigma^2_{\ddot{u}_{\mathrm{p}}} + \sigma^2_{\ddot{u}_{\mathrm{g}}} + 2\,\sigma_{\ddot{u}_{\mathrm{p}}\ddot{u}_{\mathrm{g}}}\,, \tag{16}$$

where $\sigma^2_{\ddot{u}_{\mathrm{p}}}$, $\sigma^2_{\ddot{u}_{\mathrm{g}}}$ and $\sigma_{\ddot{u}_{\mathrm{p}}\ddot{u}_{\mathrm{g}}}$ are the variances and covariance of the underlying processes, respectively, given by:

$$\sigma^2_{\ddot{u}_{\mathrm{p}}} = \int_{-\infty}^{\infty} S_{\ddot{u}_{\mathrm{p}}}(\omega)\,\mathrm{d}\omega\,; \quad \sigma^2_{\ddot{u}_{\mathrm{g}}} = \int_{-\infty}^{\infty} S_{\ddot{u}_{\mathrm{g}}}(\omega)\,\mathrm{d}\omega\,; \quad \sigma_{\ddot{u}_{\mathrm{p}}\ddot{u}_{\mathrm{g}}} = \int_{-\infty}^{\infty} \mathbb{R}\mathrm{e}\{S_{\ddot{u}_{\mathrm{p}}\ddot{u}_{\mathrm{g}}}(\omega)\}\,\mathrm{d}\omega\,. \tag{17}$$

4.2 Secondary oscillator

To estimate the response of the S oscillator, system nonlinearities can be important and to this end an appropriate quantification scheme needs to be employed. Herein the statistical linearisation approach [1] is adopted.

Accordingly, the nonlinear Duffing oscillator's Eq. (8) is replaced with a linear one:

$$\ddot{u}_{\mathrm{s}}^{\mathrm{p}}(t) + 2\,\zeta_{\mathrm{s}}\,\omega_{\mathrm{s}}\,\dot{u}_{\mathrm{s}}^{\mathrm{p}}(t) + \omega^2_{\mathrm{eq}} u_{\mathrm{s}}^{\mathrm{p}}(t) = -\ddot{u}_{\mathrm{p}}^{(\mathrm{a})}(t)\,, \tag{18}$$

where ω_{eq} represents the natural frequency of the equivalent linear system.

Minimising the mean square of the error $\varepsilon = \omega_{\mathrm{s}}^2\left(u_{\mathrm{s}}^{\mathrm{p}}(t) + \lambda\,\left(u_{\mathrm{s}}^{\mathrm{p}}(t)\right)^3\right) - \omega^2_{\mathrm{eq}} u_{\mathrm{s}}^{\mathrm{p}}(t)$ with respect to ω^2_{eq}, one obtains:

$$\omega^2_{\mathrm{eq}} = \omega_{\mathrm{s}}^2\left(1 + 3\,\lambda\,\sigma^2_{u_{\mathrm{s}}^{\mathrm{p}}}\right)\,. \tag{19}$$

The response statistics can then be obtained through the following spectral relationships:

$$\sigma^2_{u_{\mathrm{s}}^{\mathrm{p}}} = \int_{-\infty}^{\infty} S_{u_{\mathrm{s}}^{\mathrm{p}}}(\omega)\,\mathrm{d}\omega\,; \quad \sigma^2_{\dot{u}_{\mathrm{s}}^{\mathrm{p}}} = \int_{-\infty}^{\infty} S_{\dot{u}_{\mathrm{s}}^{\mathrm{p}}}(\omega)\,\mathrm{d}\omega\,; \quad \sigma^2_{\ddot{u}_{\mathrm{s}}^{\mathrm{p}}} = \int_{-\infty}^{\infty} S_{\ddot{u}_{\mathrm{s}}^{\mathrm{p}}}(\omega)\,\mathrm{d}\omega\,, \tag{20}$$

where the PSD functions $S_{u_{\mathrm{s}}^{\mathrm{p}}}(\omega)$, $S_{\dot{u}_{\mathrm{s}}^{\mathrm{p}}}(\omega)$ and $S_{\ddot{u}_{\mathrm{s}}^{\mathrm{p}}}(\omega)$ take the form:

$$S_{u_{\mathrm{s}}^{\mathrm{p}}}(\omega) = |H_{\mathrm{s}}(\omega)|^2\, S_{\ddot{u}_{\mathrm{p}}^{(\mathrm{a})}}(\omega)\,; \quad S_{\dot{u}_{\mathrm{s}}^{\mathrm{p}}}(\omega) = \omega^2 S_{u_{\mathrm{s}}^{\mathrm{p}}}(\omega)\,; \quad S_{\ddot{u}_{\mathrm{s}}^{\mathrm{p}}}(\omega) = \omega^4 S_{u_{\mathrm{s}}^{\mathrm{p}}}(\omega)\,, \tag{21}$$

in which $H_{\mathrm{s}}(\omega)$ is the FRF of the equivalent linear system in Eq. (18), given by:

$$H_{\mathrm{s}}(\omega) = \frac{1}{\omega^2 - 2\,i\,\zeta_{\mathrm{s}}\,\omega_{\mathrm{s}}\,\omega - \omega^2_{\mathrm{eq}}}\,. \tag{22}$$

We note that we deliberately avoid the matrix notation in the previous, emphasising the asynchronous response evaluation of the two subsystems, and enabling the adoption of alternative linearisation techniques for the S system such as, for instance, a higher order linearisation [12].

4.2.1 Monochromatic excitation

We next proceed with the evaluation of the random vibration integrals in Eq. (20). To this end the decomposed form of individual components, simplifies manipulation of the integrals which are conveniently computed analytically by utilising the general formula in [13], for the three

types of excitation considered. We note that solution of the integrals corresponding to the P structure's response falls beyond the scope of this work.

The monochromatic excitation is first considered. In this case, the response PSD retains similar form to the PSD of the excitation in Eq. (9), that is, an impulse whose strength depends on the parameters of the P-S system assembly. The displacement and velocity response variance then reads:

$$\sigma^2_{u^{\mathrm{p}}_{\mathrm{s}}} = \frac{2\,\alpha}{\mathcal{C}^m_1} + \frac{2\,\alpha\,\beta\,\omega_0^2\,\phi_{\mathrm{ps}}\,\mathcal{C}^m_2}{\mathcal{C}^m_1\,\mathcal{C}^m_3}\,; \quad \sigma^2_{\dot{u}^{\mathrm{p}}_{\mathrm{s}}} = \omega_0^2\,\sigma^2_{u^{\mathrm{p}}_{\mathrm{s}}}\,, \tag{23}$$

where $\mathcal{C}^m_1$ - $\mathcal{C}^m_3$ are a set of coefficients provided in Appendix A.

Notably, the same approach can be used for the acceleration response of the S oscillator although the analytical formulas will not be provided herein.

4.2.2 White noise excitation

For the white noise excitation, the response is given by:

$$\sigma^2_{u^{\mathrm{p}}_{\mathrm{s}}} = \frac{\pi S_0}{2\,\zeta_{\mathrm{s}}\,\omega^2_{\mathrm{eq}}\,\omega_{\mathrm{s}}} + \frac{\pi S_0\,\beta\,\phi_{\mathrm{ps}}\,\mathcal{C}^w_1}{2\,\zeta_{\mathrm{p}}\,\zeta_{\mathrm{s}}\,\omega_{\mathrm{s}}\,\mathcal{C}^w_2}\,; \quad \sigma^2_{\dot{u}^{\mathrm{p}}_{\mathrm{s}}} = \frac{\pi S_0}{2\,\zeta_{\mathrm{s}}\,\omega_{\mathrm{s}}} + \frac{\pi S_0\,\beta\,\phi_{\mathrm{ps}}\,(\mathcal{C}^w_3 + \mathcal{C}^w_4)}{2\,\zeta_{\mathrm{p}}\,\zeta_{\mathrm{s}}\,\omega_{\mathrm{s}}\,\mathcal{C}^w_2}\,, \tag{24}$$

where the associated coefficients $\mathcal{C}^w_1$ - $\mathcal{C}^w_4$ are likewise reported in Appendix A.

Evidently, the first term in Eq. (23) and (24) solely depends on the ground excitation while the second term also depends on the P system's parameters. On setting $\phi_{\mathrm{ps}} = 0$, the latter vanishes corresponding to an S oscillator mounted at ground level.

4.2.3 Filtered white noise excitation

The details of the analysis for the filtered white noise excitation characterised by the Clough-Penzien spectrum are lengthy, and therefore only the case where $\phi_{\mathrm{ps}} = 0$ will be provided herein. In this case the variance of the response reads:

$$\sigma^2_{u^{\mathrm{p}}_{\mathrm{s}}} = \frac{\pi S_0\,\omega_{\mathrm{g}}^2\,(\mathcal{C}^f_1 + \mathcal{C}^f_2 + \mathcal{C}^f_3 + \mathcal{C}^f_4)}{\mathcal{C}^f_5}\,; \quad \sigma^2_{\dot{u}^{\mathrm{p}}_{\mathrm{s}}} = \frac{\pi S_0\,\omega_{\mathrm{g}}^2\,(\mathcal{C}^f_6 + \mathcal{C}^f_7 + \mathcal{C}^f_8 + \mathcal{C}^f_9)}{\mathcal{C}^f_5}\,, \tag{25}$$

where the coefficients $\mathcal{C}^f_1$ - $\mathcal{C}^f_9$ are given in Appendix A.

On combining Eq. (19) with Eq. (23), (24) and (25), the resulting algebraic equations can be solved numerically for ω_{eq} and therefore $\sigma^2_{u^{\mathrm{p}}_{\mathrm{s}}}$ and $\sigma^2_{\dot{u}^{\mathrm{p}}_{\mathrm{s}}}$ can be evaluated from the above expressions.

4.3 Numerical investigations

Figure 2 presents spectra of the response variance of the Duffing S oscillator, for the three excitation types considered, as a function of the parameter $\lambda > 0$, and for $\phi_{\mathrm{ps}} = \{0, 0.5, 1\}$, the latter representing an oscillator mounted at ground level, at an intermediate height, and at roof level, respectively. The analytical derived expressions for the statistical linearisation procedure have been used for this purpose, and are compared with the stationary response value of the nonlinear system in Eq. (8), numerically computed via pertinent Monte Carlo simulations. The analysis has been carried out using the following reference values: $\alpha = 0.3$ and $\omega_0 = 10\,\mathrm{rad/s}$ (monochromatic excitation); $S_0 = 0.003\,\mathrm{m^2/s^3}$ (white noise); $S_0 = 0.003\,\mathrm{m^2/s^3}$, $\omega_g = 10\,\mathrm{rad/s}$, $\zeta_g = 0.4$, $\omega_f = 1\,\mathrm{rad/s}$ and $\zeta_f = 0.6$ (filtered white noise [11]); and $\beta = 1.3$,

$\omega_\mathrm{p} = 14.76$, $\omega_\mathrm{s} = 1.4\,\omega_\mathrm{p}$, $\zeta_\mathrm{p} = 0.05$ and $\zeta_\mathrm{s} = 0.02$ (for the P-S system assembly [4]). In this plot, $\sigma^{2*}_{u^\mathrm{p}_\mathrm{s}}$ and $\sigma^{2*}_{\dot{u}^\mathrm{p}_\mathrm{s}}$ denote the displacement and velocity response variances, normalised by the associated peak variances in the linear case, at roof level (i.e. $\lambda = 0$ and $\phi_\mathrm{ps} = 1$).

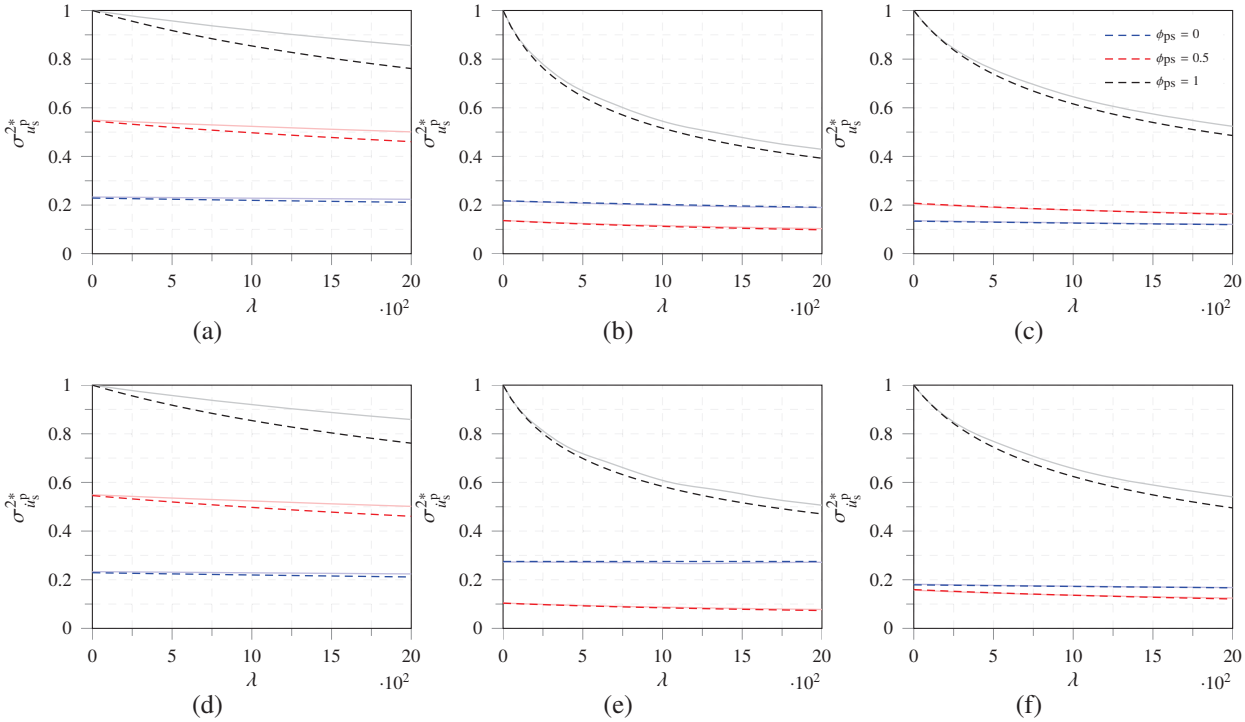

Figure 2: Variation of the secondary Duffing oscillator's mean square displacement (top) and velocity (bottom) response with λ and ϕ_ps. Comparison of statistical linearisation (dashed lines) and Monte Carlo simulation (solid lines) for: (a, d) monochromatic ($\alpha = 0.3$, $\omega_0 = 10\,\mathrm{rad/s}$); (b, e) white noise ($S_0 = 0.003\,\mathrm{m^2/s^3}$); and (c, f) filtered white noise ($S_0 = 0.003\,\mathrm{m^2/s^3}$, $\omega_g = 10\,\mathrm{rad/s}$, $\zeta_g = 0.4$, $\omega_f = 1\,\mathrm{rad/s}$, $\zeta_f = 0.6$) excitation. Reference parameters: $\beta = 1.3$, $\omega_\mathrm{p} = 14.76$, $\omega_\mathrm{s} = 1.4\,\omega_\mathrm{p}$, $\zeta_\mathrm{p} = 0.05$, $\zeta_\mathrm{s} = 0.02$.

Overall, the response variances (i.e. the areas under the associated PSD curves), are finite, and are smooth functions of the parameter λ. The statistical linearisation provides a good approximation of the nonlinear response for the cases considered. As expected, the effectiveness of the approximation deteriorates with λ, that is, at higher nonlinearity levels. We note that the validity of the derived expressions has been further confirmed through Monte Carlo simulations carried out directly on the equivalent linear system.

An interesting observation is that the response variance does not always increase with ϕ_ps (i.e. lower spectral ordinates are shown in Figures 2(b) and 2(e) for $\phi_\mathrm{ps} = 0.5$ when compared to $\phi_\mathrm{ps} = 0$). This is an important consequence of Eq. (16), which implies that even though $\sigma^2_{\ddot{u}_\mathrm{p}}$ will always increase with ϕ_ps (due to the amplified motions on the P structure), $\sigma^2_{\ddot{u}^{(\mathrm{a})}_\mathrm{p}}$ may or may not, as it also depends on the covariance of processes $\ddot{u}_\mathrm{p}$ and $\ddot{u}_\mathrm{g}$. Consequently, the response variance of S may or may not increase with ϕ_ps.

Finally, even though the application of the statistical linearisation procedure is straightforward, it cannot account for the existence of higher harmonics, such as the case of white noise and filtered white noise excitation, and therefore alternative quantification schemes need to be sought to achieve further improvements in accuracy.

5 CONCLUSIONS

The steady-state stationary response quantification and analysis of nonlinear secondary oscillators in randomly driven linear primary building structures, has been addressed. By utilising a modal coordinate transformation, simplified equations posed as a reduced two-degree-of-freedom system with dimensionless coefficients, have been derived for the primary-secondary system assembly.

Three different types of stochastic excitation spectra have been considered: monochromatic excitation, representative of the extreme scenario of a narrow-band process; white noise excitation, the extreme form of a wide-band process; and the intermediate case of filtered white noise characterised by the Clough-Penzien power spectrum, commonly used in earthquake engineering applications. A decomposition-synthesis approach has been presented for the analysis of linear and equivalent linear secondary systems, whereby the stochastic response of the nonlinear secondary system is analytically approximated, with an application to a secondary Duffing oscillator. In this approach, the secondary system is first decoupled from the primary structure under the cascade analysis approximation. The stochastic forcing delivered to the secondary system is decomposed as the sum of individual forcing components, the response statistics are separately quantified using spectral relationships, and are pieced-together to construct the overall response of an equivalent linear secondary system.

Decomposition of the power spectral density of the driving acceleration at the oscillator's position, simplifies the manipulation of the random vibration integrals and enhances the understanding on the physical meaning of the response. It further facilitates the direct generation of floor acceleration time series ensembles for the numerical analysis of nonlinear secondary systems. The resulting analytical expressions, derived herein for the secondary Duffing oscillator under the three types of excitation considered, approximate the response probability density functions and permit the accurate and efficient quantification, expressing the statistical parameters of the response as a function of the corresponding design input parameters of the system assembly and the excitation. Future work will involve the inclusion of the contribution of higher modes, and extensions to other types of nonlinear oscillators and multi-degree-of-freedom secondary systems using alternative statistical quantification schemes.

APPENDIX A. COEFFICIENTS

The coefficients $\mathcal{C}_1^m$ - $\mathcal{C}_3^m$ for the monochromatic excitation (§ 4.2.1) are:

$$\mathcal{C}_1^m = 4\,\zeta_\mathrm{s}^2\,\omega_0^2\,\omega_\mathrm{s}^2 + \left(\omega_0^2 - \omega_\mathrm{eq}^2\right)^2\,; \tag{26a}$$

$$\mathcal{C}_2^m = \omega_0^2\,(\beta\,\phi_\mathrm{ps} - 2) + 2\,\omega_\mathrm{p}^2\,; \tag{26b}$$

$$\mathcal{C}_3^m = \left(4\,\zeta_\mathrm{p}^2 - 2\right)\omega_0^2\,\omega_\mathrm{p}^2 + \omega_0^4 + \omega_\mathrm{p}^4\,. \tag{26c}$$

The coefficients $\mathcal{C}_1^w$ - $\mathcal{C}_4^w$ for the white noise excitation (§ 4.2.2) are:

$$\mathcal{C}_1^w = \zeta_\mathrm{p}\,\omega_\mathrm{eq}^2(\beta\,\phi_\mathrm{ps} - 2) + \beta\,\zeta_\mathrm{s}\,\omega_\mathrm{p}\,\omega_\mathrm{s}\,\phi_\mathrm{ps} + 2\,\zeta_\mathrm{p}\omega_\mathrm{p}^2\,; \tag{27a}$$

$$\mathcal{C}_2^w = 2\,\omega_\mathrm{eq}^2\,\omega_\mathrm{p}\left(\left(2\,\zeta_\mathrm{p}^2 - 1\right)\omega_\mathrm{p} + 2\,\zeta_\mathrm{p}\,\zeta_\mathrm{s}\,\omega_\mathrm{s}\right) + \omega_\mathrm{p}^2\left(4\,\zeta_\mathrm{p}\,\zeta_\mathrm{s}\,\omega_\mathrm{p}\,\omega_\mathrm{s} + 4\,\zeta_\mathrm{s}^2\omega_\mathrm{s}^2 + \omega_\mathrm{p}^2\right) + \omega_\mathrm{eq}^4\,; \tag{27b}$$

$$\mathcal{C}_3^w = \zeta_\mathrm{s}\,\omega_\mathrm{p}\,\omega_\mathrm{s}\left(4\,\zeta_\mathrm{p}^2\omega_\mathrm{eq}^2(\beta\,\phi_\mathrm{ps} - 2) + \beta\,\omega_\mathrm{p}^2\phi_\mathrm{ps}\right)\,; \tag{27c}$$

$$\mathcal{C}_4^w = \zeta_\mathrm{p}\left(4\,\zeta_\mathrm{s}^2\omega_\mathrm{p}^2\omega_\mathrm{s}^2(\beta\,\phi_\mathrm{ps} - 2) + \omega_\mathrm{eq}^4(\beta\,\phi_\mathrm{ps} - 2) + 2\,\omega_\mathrm{eq}^2\omega_\mathrm{p}^2\right)\,. \tag{27d}$$

The coefficients $\mathcal{C}_1^f$ - $\mathcal{C}_9^f$ for the filtered white noise excitation (§ 4.2.3) are:

$$\mathcal{C}_1^f = 4\,\zeta_\mathrm{f}^3\,\omega_\mathrm{eq}^2\,\omega_\mathrm{f}^2\,\omega_\mathrm{g}^2\left(4\,\zeta_\mathrm{g}^3\,\omega_\mathrm{eq}^2 + 4\,\zeta_\mathrm{g}^2\,\zeta_\mathrm{s}\,\omega_\mathrm{g}\,\omega_\mathrm{s} + \zeta_\mathrm{g}\,\omega_\mathrm{g}^2 + \zeta_\mathrm{s}\,\omega_\mathrm{g}\,\omega_\mathrm{s}\right)\,; \tag{28a}$$

$$\begin{aligned}\mathcal{C}_2^f =& 4\,\zeta_{\rm f}^2\,\omega_{\rm f}\,\omega_{\rm g}\left(4\,\zeta_{\rm g}^3\,\omega_{\rm eq}^2+4\,\zeta_{\rm g}^2\,\zeta_{\rm s}\,\omega_{\rm g}\,\omega_{\rm s}+\zeta_{\rm g}\,\omega_{\rm g}^2+\zeta_{\rm s}\,\omega_{\rm g}\,\omega_{\rm s}\right)\left(\zeta_{\rm g}\,\omega_{\rm eq}^2\left(\omega_{\rm f}^2+\omega_{\rm g}^2\right)\right.\\ &\left.+\,\zeta_{\rm s}\,\omega_{\rm g}\,\omega_{\rm s}\left(\omega_{\rm eq}^2+\omega_{\rm f}^2\right)\right);\end{aligned} \tag{28b}$$

$$\begin{aligned}\mathcal{C}_3^f =& \zeta_{\rm f}(16\,\zeta_{\rm g}^5\,\omega_{\rm eq}^4\,\omega_{\rm f}^2\,\omega_{\rm g}^2+16\,\zeta_{\rm g}^4\,\zeta_{\rm s}\,\omega_{\rm eq}^2\,\omega_{\rm f}^2\,\omega_{\rm g}(\omega_{\rm eq}^2+\omega_{\rm f}^2+2\,\omega_{\rm g}^2)\omega_{\rm s}\\ &+\zeta_{\rm s}\,\omega_{\rm g}^3\,\omega_{\rm s}((\,\omega_{\rm eq}^2-\omega_{\rm f}^2)^2+4\,\zeta_{\rm s}^2\,\omega_{\rm f}^2\,\omega_{\rm s}^2)+4\,\zeta_{\rm g}^3(\omega_{\rm eq}^2\,\omega_{\rm f}^2\,\omega_{\rm g}^4+\omega_{\rm eq}^4(\omega_{\rm f}^2-\omega_{\rm g}^2)^2\\ &+4\,\zeta_{\rm s}^2\,\omega_{\rm f}^2\,\omega_{\rm g}^2(2\,\omega_{\rm eq}^2+\,\omega_{\rm f}^2+\omega_{\rm g}^2)\omega_{\rm s}^2)+\zeta_{\rm g}\,\omega_{\rm g}^2(\,\omega_{\rm eq}^2(\omega_{\rm f}^2-\omega_{\rm g}^2)^2+\\ &4\,\zeta_{\rm s}^2(2\,\omega_{\rm f}^2\,\omega_{\rm g}^2+\omega_{\rm eq}^2\,(\omega_{\rm f}^2+\omega_{\rm g}^2))\omega_{\rm s}^2)+4\,\zeta_{\rm g}^2\,\zeta_{\rm s}\,\omega_{\rm g}^3\,\omega_{\rm s}(\omega_{\rm eq}^4+\omega_{\rm eq}^2\,\omega_{\rm g}^2\\ &+\omega_{\rm f}^2(\omega_{\rm f}^2+\omega_{\rm g}^2+4\,\zeta_{\rm s}^2\,\omega_{\rm s}^2)));\end{aligned} \tag{28c}$$

Keywords: CLT floors, Dynamic properties, Uncertainty quantification, Monte Carlo simulation, Finite element modeling

Abstract. *This paper investigates the effects of material properties (mass density, elastic and shear moduli) on dynamic properties of simply-supported CLT floors (natural frequencies, mode shapes and modal mass). Uncertainty quantification analysis has been carried out based on Monte Carlo simulations by varying material properties. Numerical modelling and analysis of the investigated CLT floors has been performed using finite element models in Abaqus CAE. The results show that uncertain mechanical parameters having significant influence on the dynamic properties are mass density, elastic modulus E_L, and shear moduli G_{LT} and G_{RT}, where L, T and R denote longitudinal, tangential and radial direction, respectively.*

1 INTRODUCTION

Recent technological advances and new construction techniques have led to the development of a natural composite material called cross-laminated timber (CLT). CLT is a multilayer composite, composed of several thin wooden layers bonded together in a crosswise manner. It has outstanding structural strength, stiffness and aesthetic properties, a high level of prefabrication, fire resistance and fast construction speed. Therefore, CLT is not only environmentally highly sustainable but also cost- and performance-competitive in comparison with the conventional mineral-based building materials (concrete and masonry) providing low carbon footprint and comfortable living conditions. This has been validated on many large-span residential, public and commercial floors in multistorey buildings in Europe and North America in the past decade [1-2]. An important aspect when designing CLT floors is the comfort criteria for vibrations. Due to low floor mass and high stiffness-to-weight ratio, human activities may cause vibration serviceability issues, such as annoyance to human occupants in buildings and malfunction of vibration sensitive equipment. Consequently, accurate and reliable prediction of dynamic properties of CLT floors is of great importance. However, there exists a limited research regarding vibration performance of CLT floors [3-6].

Main sources of uncertainties in timber floors related to their vibration performance are: (i) variability of mechanical properties of the wood as orthotropic material, (ii) pedestrian dynamic load and, (iii) boundary conditions. Item (i) is associated with a great variety of wood species used as a base material in civil engineering, leading to the variety of bulk material properties of wood [7]. In addition, the used material species may differ layer-wise, increasing the uncertainty related to the vibration performance of composite floor structure.

Effect of the variability of material properties on the modal and vibroacoustic properties of a conventional wooden floor have been studied by Persson et al. [8] and Persson & Floden [9]. They employed probabilistic analysis based on Monte Carlo (MC) simulations. Qian et al. [10] developed a stochastic finite element prediction tool to quantify the variability of mechanical properties of a CLT floor slab. The results of the performed studies indicate that the variability of mechanical properties of wood material can have a large impact on the natural frequencies and acoustic performance of the investigated wooden floors.

Mechanical material properties of CLT are differently regulated in technical approvals [11, 12], which might lead to significant differences between the actual mechanical properties and those defined in the design guidelines and recommendations. Material properties depend on the strength class of CLT as well as the strength class of the base material. For example, the values of shear moduli (G_{LT} and G_{LR}, see Fig. 1b) range from 600-690 N/mm^2, while the characteristic rolling shear modulus G_{RT} ranges from 50 to 60 N/mm^2, [11]. Poisson's ratios depend on the moisture level and they are usually adopted on the basis of experimental measurements for hardwoods and softwoods. Consequently, this can lead to inaccurate and unreliable prediction of the dynamic properties of CLT floors.

This paper aims to investigate the effects of the variability of material properties in terms of mass density, elastic/shear moduli and Poisson's ratios on dynamic properties of CLT floors (natural frequencies, mode shapes and modal mass). Uncertainty quantification analysis has been carried out using Monte Carlo simulations, by sampling selected material properties of CLT after the preliminary sensitivity analysis. Numerical modelling and analysis of the investigated CLT floors have been performed using finite element (FE) models in Abaqus CAE [12] and automated by making use of Python scripting. After this introductory section, Section 2 elaborates the computation of dynamic properties of selected CLT panel. In Section 3, preliminary sensitivity analysis, along with the uncertainty quantification analysis, has been carried out. Based on the performed analyses, conclusions have been derived in Section 4.

2 DYNAMIC PROPERTIES OF CLT FLOOR

2.1 Numerical model

Layout and dimensions of an analyzed 5-layer CLT floor panel are presented in Fig. 1a. FE-based numerical model of the CLT floor has been created by using Abaqus CAE software package [13]. The finite element mesh consists of 625 S4R shell elements (quadrilateral 4-node shell element with reduced integration and assigned composite section). Each layer (k) of CLT panel exhibits elastic orthotropic material behavior defined as:

$$\begin{Bmatrix} \varepsilon_L \\ \varepsilon_T \\ \varepsilon_R \\ \gamma_{TR} \\ \gamma_{LR} \\ \gamma_{LT} \end{Bmatrix}^{(k)} = \begin{bmatrix} 1/E_L & -\nu_{TL}/E_T & -\nu_{RL}/E_R & 0 & 0 & 0 \\ -\nu_{LT}/E_L & 1/E_T & -\nu_{RT}/E_R & 0 & 0 & 0 \\ -\nu_{LR}/E_L & -\nu_{TR}/E_T & 1/E_R & 0 & 0 & 0 \\ 0 & 0 & 0 & 1/G_{TR} & 0 & 0 \\ 0 & 0 & 0 & 0 & 1/G_{LR} & 0 \\ 0 & 0 & 0 & 0 & 0 & 1/G_{LT} \end{bmatrix}^{(k)} \begin{Bmatrix} \sigma_L \\ \sigma_T \\ \sigma_R \\ \tau_{TR} \\ \tau_{LR} \\ \tau_{LT} \end{Bmatrix}^{(k)} \quad (1)$$

In Eq. (1), E_L, E_T and E_R are elastic moduli in longitudinal (L), transverse (T) and radial direction (R), respectively, ν_{ij} are the Poisson's ratios, and G_{ij} are the shear moduli of the orthotropic material (Fig. 1b). The above are the 9 independent material coefficients for an orthotropic material. Assuming the same material behavior in the R and T direction, i.e. $E_R = E_T$, $G_{LR} = G_{LT}$, resulted in the total number of 7 elastic constants of a single layer of CLT panel. Material properties of the CLT layers for C24 timber class used as the initial (mean) values in the analysis are given in Table 1.

ρ (kg/m^3)	E_L (MPa)	$E_R = E_T$ (MPa)	$G_{LR} = G_{LT}$ (MPa)	G_{RT} (MPa)	ν_{LT}	ν_{LR}	ν_{RT}
450	11000	370	690	69	0.49	0.39	0.64

Table 1. Material properties for C24 timber class of CLT panels

Since the CLT panel is made of several orthotropic layers, which material axes are oriented by angles 0° and 90° with respect to the global (laminate) coordinates, the constitutive relations (1) must be transformed from the local (material) coordinate system to the global coordinate system using the well-known transformation matrix.

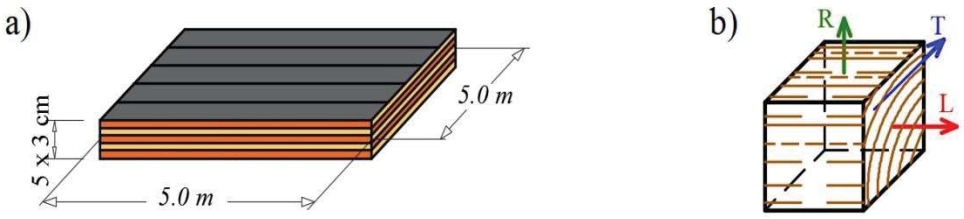

Figure 1. Layout of a 5-layer CLT floor

Simply supported boundary conditions have been assigned to the floor edges by constraining the displacements in X and Z direction (for the edges parallel to x-axis), and displacements in Y and Z direction (for the edges parallel to y-axis).

2.2 FE modal analysis

Dynamic properties of the first five bending and the first shear vibration modes have been calculated based on the material properties data given in Table 1. Natural frequencies and modal

masses that correspond to unity scaled mode shapes are presented in Table 2. The six vibration modes are shown in Fig. 2.

Mode No.	Mode type	Natural frequency f (Hz)	Modal mass m (kg)
1	1st bending	14.78	426.17
2	2nd bending	30.01	423.85
3	3rd bending	45.47	425.25
4	4th bending	54.66	419.62
5	5th bending	56.87	420.69
12	1st shear	123.99	844.46

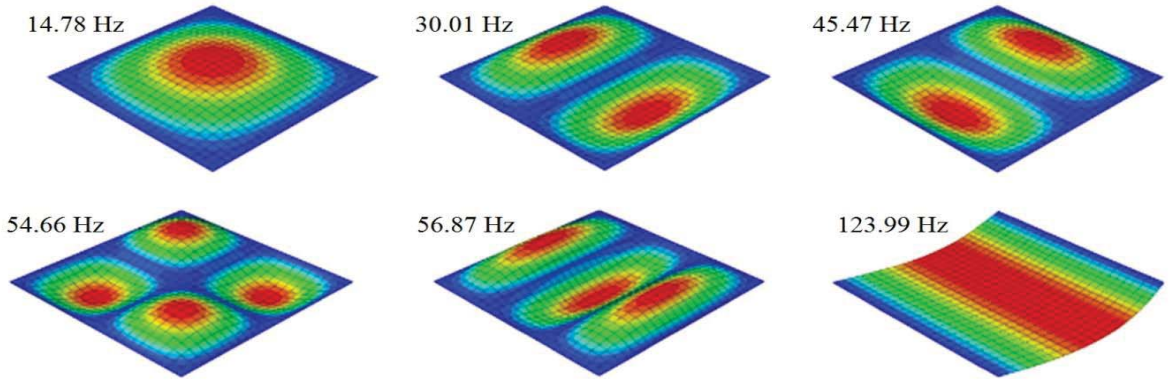

Figure 2. Mode shapes of the CLT floor

3 INFLUENCE OF MECHANICAL PROPERTIES

3.1 Preliminary sensitivity analysis

A preliminary sensitivity analysis has been carried out to ascertain the influence of the material parameters on the dynamic properties of CLT floor. For this purpose, elastic and shear moduli and mass density of the CLT panel have been increased and decreased by 20%, in comparison to the mean values given in Table 1. The results are presented in Figs. 3-6 in terms of relative change Δ with respect to the reference (mean) values. Natural frequencies and modal masses for all modes are found to be equally affected by the variability of the mass density ρ. Natural frequencies are most affected by the change of the longitudinal elastic modulus E_L, while the effect of elastic moduli E_R and E_T is found to be negligible. Shear modulus G_{LT} has the strongest impact on the dynamic properties of the first shear mode shape, while the first five bending modes are found to be less affected. Influence of the shear modulus G_{LR} and Poisson's ratios is negligible. Elastic and shear moduli, as well as the Poisson's ratios have insignificant influence on the modal masses of the first five bending modes. However, decrease of the shear modulus G_{LT} resulted in the change of the first shear mode shape and consequently the change of the corresponding modal mass for 75%, Fig. 7.

As a result of the sensitivity analysis, only four material parameters: mass density, elastic modulus E_L, and shear moduli G_{LT} and G_{RT} have been selected as uncertain parameters for further uncertainty quantification analysis.

As expected, 20% increase in CLT mass density resulted in the 20% increase in modal mass and around 9% decrease in frequency. The analogous trend was detected when mass density was reduced by 20% (see Fig. 3 for details).

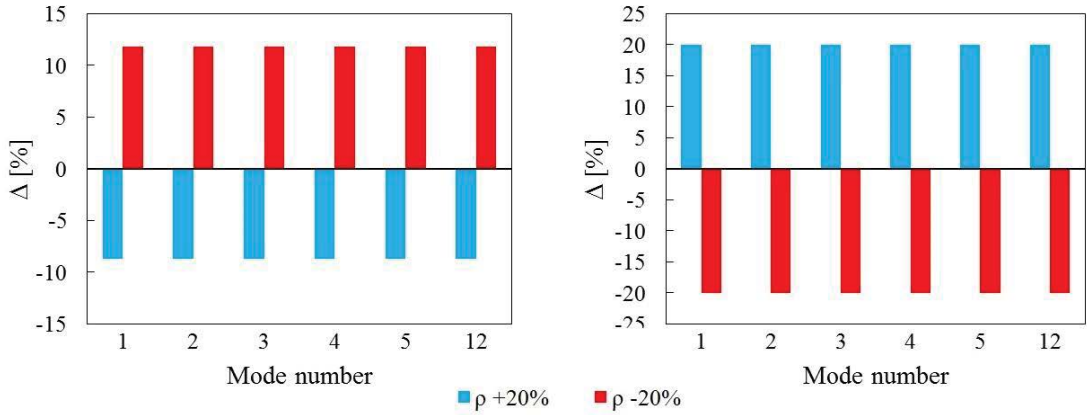

Figure 3. Influence of mass density on natural frequencies (left) and modal masses (right)

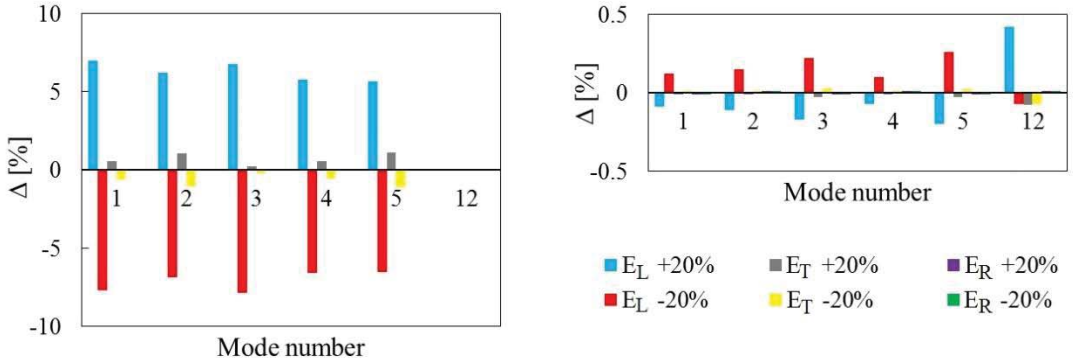

Figure 4. Influence of elastic moduli on natural frequencies (left) and modal masses (right)

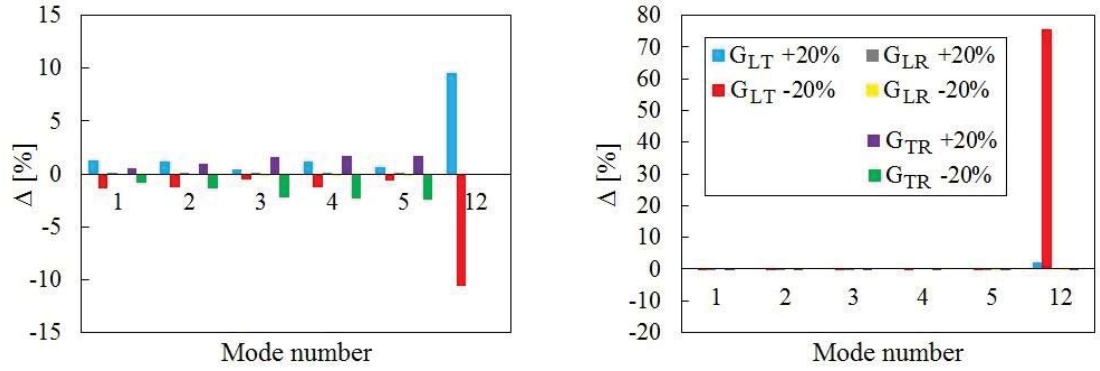

Figure 5. Influence of shear moduli on natural frequencies (left) and modal masses (right)

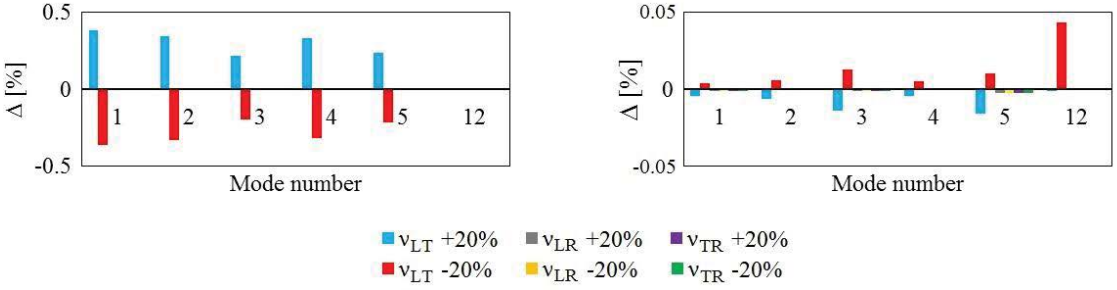

Figure 6. Influence of Poisson's ratios on natural frequencies (left) and modal masses (right)

3.2 Uncertainty quantification analysis

Properties of the four uncertain mechanical parameters of the CLT floor are given in Table 3. Mean values are those used in the initial FE analysis (Table 1). It is assumed that the parameters follow normal distribution, while the coefficient of variation (COV) is assumed to be 10%, based on the recommendations given in [9]. Latin hypercube sampling technique (ref?) has been applied first to generate samples for the four uncertain parameters used to perform 10,000 MC simulations.

Mechanical parameter	Distribution	Mean value	COV (%)
Elastic modulus E_L	Normal	11000	10
Shear modulus G_{LT}	Normal	690	10
Shear modulus G_{RT}	Normal	69	10
Mass density ρ	Normal	450	10

Table 3. Statistical properties of the four uncertain mechanical parameters

Generation of Abaqus input files with different set of mechanical parameters has been carried out using Python scripting. After completing modal analysis in the FE model, the natural frequencies, modal masses and unity scaled mode shapes have been automatically read from the output files created by Abaqus and statistically analyzed.

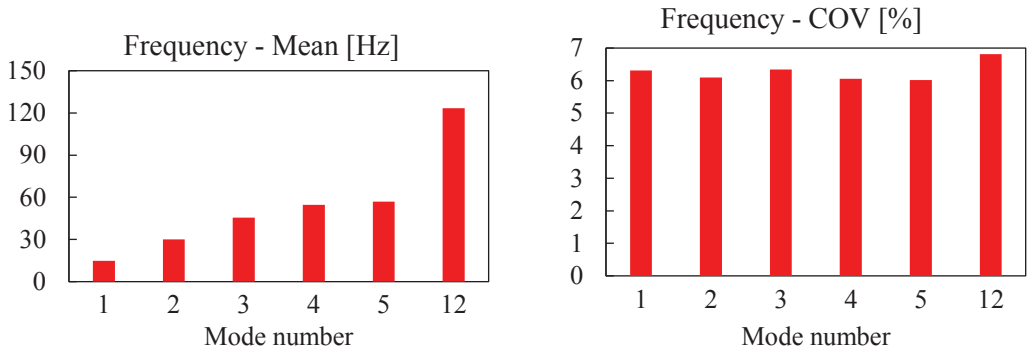

Figure 7. Statistical properties of natural frequencies

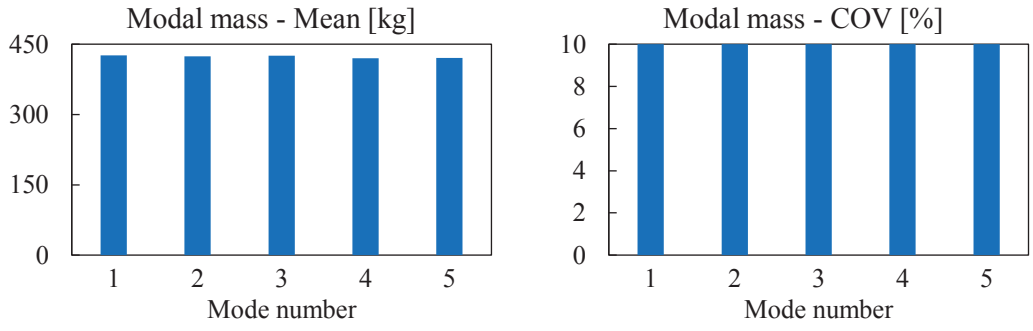

Figure 8. Statistical properties of modal masses

The results presented in Figs. 7-8 show that COV of 10% for the four input mechanical parameters resulted in the COVs of 6.31%, 6.10%, 6.34%, 6.06% and 6.02% for the natural frequencies of the first five bending modes, respectively, and 6.81% for the first shear mode. The results for natural frequencies follow lognormal distribution. Variations of input parameters resulted in the COV of 10% for modal masses of the first five bending modes, following

the normal distribution and maintaining the nature of the mode shapes. However, variation of input parameters qualitatively changed the first shear mode shape. Consequently, variation of the corresponding modal mass cannot be described either by normal or lognormal distribution, as shown in Fig. 9b.

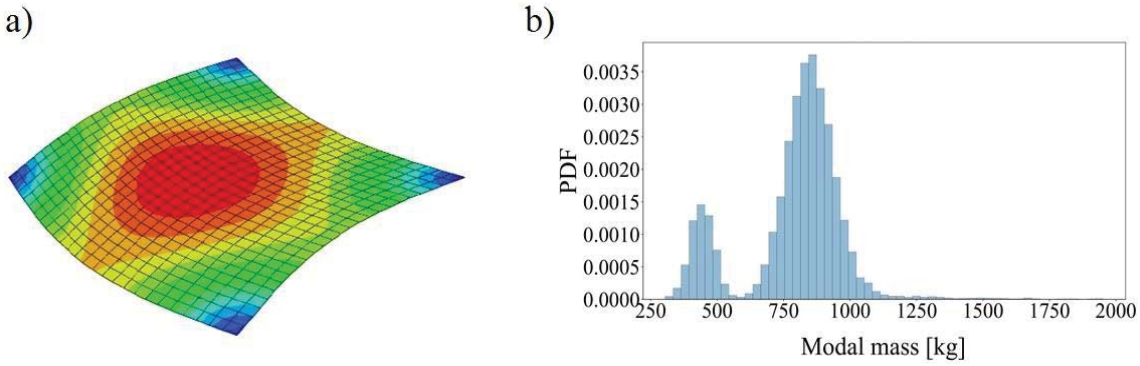

Figure 9. (a) First shear mode shape obtained when G_{LT} modulus is decreased by 20%; (b) variation of the modal mass of the first shear mode

4 CONCLUSIONS

MC-based uncertainty quantification analysis of simply supported CLT floor has been performed in the paper to ascertain the influence of mechanical properties on the dynamic properties (natural frequencies, modal masses and mode shapes) of CLT floor. The following conclusions have been derived:

- The preliminary sensitivity analysis demonstrated that uncertain mechanical parameters having significant influence on the dynamic properties are mass density, elastic modulus E_L, and shear moduli G_{LT} and G_{RT}. In addition, 20% decrease of shear modulus G_{LT} resulted in the decrease of natural frequency of the first shear mode by 10.56% and increase of the modal mass by 75.80% due to the change of corresponding mode shape.
- Uncertainty of mechanical parameters of CLT floor has a significant influence on the natural frequencies. COV of 10% resulted in the COVs of approximately 6% for the natural frequencies of the first five bending modes, and 10% for the corresponding modal masses. The results for natural frequencies follow lognormal distribution, while modal masses for the first five bending modes follow the normal distribution.
- COV of 10% in the input mechanical parameters resulted in the COV of 6.81% for the natural frequency of the first shear mode and the qualitative change of the shear mode shape. Consequently, corresponding modal mass could not be described by either Normal or lognormal distribution.

Keywords: NLFEAs; model uncertainties; reinforced concrete structures; cyclic loads

Abstract. *This work is focused on the resistance model uncertainties in non-linear finite element analyses (NLFEAs) for reinforced concrete structures under cyclic loading conditions. In detail, different walls experimentally tested are numerically reproduced by means of appropriate plane stress finite elements (FE) structural models within different assumptions and numerical codes. After that, the values of the global resistances computed through numerical simulations are compared to the experimental outcomes to evaluate the influence of the different assumptions on the mechanical behaviour of reinforced concrete members subjected to cyclic loads.*

1 INTRODUCTION

The adoption of non-linear finite element analyses (NLFEAs) for structural design and assessment of structures and infrastructures is one of the main innovation in civil engineering in the last decades. Such kind of instruments are able to reproduce with accuracy the mechanical behaviour of reinforced concrete (RC) structures. In order to allow the correct use of NLFEAs from designers and analysts, several guidelines and recommendations for NLFEAs have been developed [1]-[2] to assess the safety and resilience of infrastructure systems [3]-[4]. Moreover, several applications are reported in the literature with examples of appropriate procedures devoted to calibrate and interpret the outcomes from NLFE models [5]-[6]. Over the years, different methodologies denoted as "safety formats" for NLFEAs have been proposed by several researchers [7]-[8] and international codes [9]-[10] as well as their applications have been discussed by [11]-[13]. In the mentioned above methods, the aleatory uncertainties associated to material properties and the epistemic uncertainties related to the numerical definition of the structural model need to be properly treated in order to derive reliability-based values of the global structural responses [14]-[18]. Concerning the materials uncertainty, the corresponding variability is well known and reported in the scientific literature, whereas the resistance model uncertainty associated with NLFEAs needs to be investigated due to the possible different modelling hypotheses that can be assumed by engineers and analysts to model some physical phenomena without a perfect knowledge. For this reason and especially within seismic field, an appropriate evaluation of the resistance model uncertainties for NLFEAs of RC structures is still necessary with the aim to account for their influence in presence of cyclic loads. In detail, different assumptions can be performed regarding the parameters that govern the equilibrium, kinematic compatibility and constitutive equations in cyclic loading configurations according to scientific literature and numerical codes. In the present study, the cyclic responses of ten experimental tests on shear walls known from the literature [19]-[21] are compared to the related numerical outcomes derived from appropriate 2D NLFEAs. In detail, a multitude of NLFEAs are developed for each experimental test in order to investigate the effect of each assumption on the global resistance of each structural element. This comparison is herein based on the definition of different eighteen plausible structural models combing different types of numerical code with different mechanical constitutive laws for the reinforced concrete elements in cyclic loading configurations.

2 UNCERTAINTIES WITHIN SAFETY FORMATS FOR NLFEAS

Commonly, both epistemic and aleatory uncertainties influence structural engineering problems [14]. Focusing on the epistemic uncertainties, all the choices performed to define a specific numerical model (i.e., modelling hypotheses) as well as all the assumptions concerning auxiliary non-physical parameters [14] belong to this group of uncertainties.

The global safety formats for NLFEAs proposed by codes [9],[22] and [23]-[24], allow to evaluate the design structural resistance R_d as follows:

$$R_d = \frac{R_{rep}}{\gamma_R \gamma_{Rd}} \tag{1}$$

where

- R_{rep} = representative value of the global structural resistance (i.e., the peak resistance value with reference to cyclic analyses) estimated using NLFEAs;

- γ_R = global resistance partial safety factor which covers the inherent randomness of the material properties;
- γ_{Rd} = resistance model uncertainty partial safety factor that covers all the epistemic uncertainties related to the different assumptions within the model definition.

With specific reference to NLFEAs on RC structural systems under cyclic loads (e.g., the case of earthquake engineering), they may present significantly higher levels of modelling uncertainties if compared to the static loading configurations. In compliance with [14],[25] the resistance model uncertainty random variable ϑ can be expressed as:

$$\vartheta = \frac{R_{Exp}}{R_{NLFEA}} \tag{2}$$

where:

- R_{Exp} = global structural resistance from experimental investigation;
- R_{NLFEA} = global structural resistance from NLFEAs.

3 NLFE MODELLING ASSUMPTIONS AND OUTCOMES FROM NUMERICAL SIMULATIONS

3.1 Characterization and differentiation of the numerical models

As discussed in the previous sections, several modelling hypotheses may be adopted when plane stress NLFEAs are carried out to analyse the seismic response of reinforced concrete structural systems under cyclic loading. Two numerical codes [26]-[27], denoted as numerical code A and B anonymously, are employed to model numerically the experimental tests of [19]-[21] using four-nodes iso-parametric quadrilateral plane stress finite elements having linear interpolant shape functions and 2x2 Gauss integration points. A calibration process of the mesh size has been developed for each experimental test and numerical. The non-linear system of equation is solved by means of the standard Newton-Raphson method [2]. For each load step, the maximum number of iterations has been set equal to 200 adopting the displacement norm convergence criteria with a tolerance set equal to 2%.

A non-linear curve with compression softening and reduction of the compressive strength due to transversal cracking has been used for the concrete behaviour in compression. In detail, the law of [28] is adopted in order to model the mono-axial concrete compressive behaviour both in confined and unconfined zones.

The shear behaviour of concrete has been reproduced associating a constant value to the shear retention factor with the purpose to model the mechanism of aggregate interlock in cyclic response of the shear walls [29]. The un-loading/re-loading process is characterized by a linear relation secant to the origin with reference to both compressive and tensile concrete response [26]-[27]. The uniaxial model for concrete behaviour is extended to plane stress configuration in line with [30]. The smeared cracking with fixed crack direction model has been adopted in order reproduce cracked state concrete [31]. The reinforcement has been modelled by means of a tri-linear constitutive law with cyclic damaging process modelled in compliance to the suggestion of [32]. The reinforcements have been modelled by means of discrete reinforcement with the assumption of perfect bond.

The tensile concrete strength as well as the Young's modulus are derived from the experimental compressive strength in compliance with [33].

An additional discrimination between the modelling hypotheses has been specified with reference to both the concrete tensile response and the shear stiffness of concrete in cracked configuration. As regards the concrete tensile response, the "tension stiffening effect" cannot be neglected. In this way, in addition to the elastic-brittle and to the elastic-plastic model, a third law "LTS (i.e., linear tension softening)" is herein assumed [14]. The first two hypotheses are conceived as lower and upper bounds for tensile response of concrete. The LTS law has been calibrated through an iterative procedure with the aim to best fit each experimental test with the use of a specific numerical code.

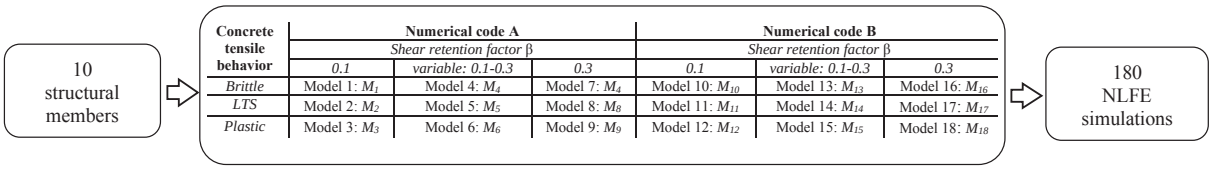

Figure 1: Summary of the 18 modelling hypotheses.

With reference to the shear stiffness, the shear retention factor β, that relates the shear stiffness of concrete after and before cracking, is assumed equal to 0.1 or to 0.3 [34]-[35] or properly calibrated for each numerical code and tensile behaviour and experimental test. In fact, in the third case, an iterative process is used to define the most appropriate value of β within the interval 0.1-0.3 [34]-[35]. Altogether, combining the the three different concrete tensile behaviours with the three different values of shear retention factor and the two numerical codes, 18 different modelling hypotheses (i.e., structural models M_j with $j=1,\ldots,18$ representative of the epistemic uncertainties) derive, as reported in Figure 1.

3.2 Experimental tests and numerical outcomes

The numerical and experimental results of [19]-[21], expressed in terms of lateral load vs displacement diagrams, are herein compared.

The experimental investigation of [19] focus on six reinforced concrete walls designed in pairs in order to have equal percentage of bending reinforcement but different percentage of shear reinforcement. In this study, only 3 walls are taken into consideration denoted respectively as SW4, SW6, SW8. In detail, they have the following geometrical characteristics: 1.20 m high, 0.6 m wide, 0.06 m thick and stiffened by a 0.2 m x 0.25 m inferior beam, and by a 0.2 m x 0.15 m superior beam useful to spread the applied horizontal load. All the walls are subjected to the same load history as showed in Figures 2-4. The tests have been performed in displacement control from 2 mm up to failure, performing two complete cycles with a 2 mm increment each time. The compressive strength of concrete is within the range 36.9 to 45.8 MPa in the different tests, whereas the flexural reinforcement remains constant in the web differently to the shear reinforcement and the vertical reinforcement that vary in the boundary elements. The numerical outcomes from the simulations expressed in terms of peak global structural resistance are presented in Table 1. The outcomes from NLFEAs are reported in Figures 2-4 (a)-(f) with reference to the several modeling hypotheses.

In general, the minimum values of the peak lateral loads are obtained adopting the elastic-brittle constitutive law for concrete tensile behavior, while the numerical models with plastic constitutive law always overestimate both the peak load and stiffness. It can also be observed that the best results are achieved with a shear retention factor equal or close to 0.1 for the tests SW6 and SW8. The simulations generally overestimate the global structural resistance, but underestimate the ductility because many simulations fail before if compared to the experimental results.

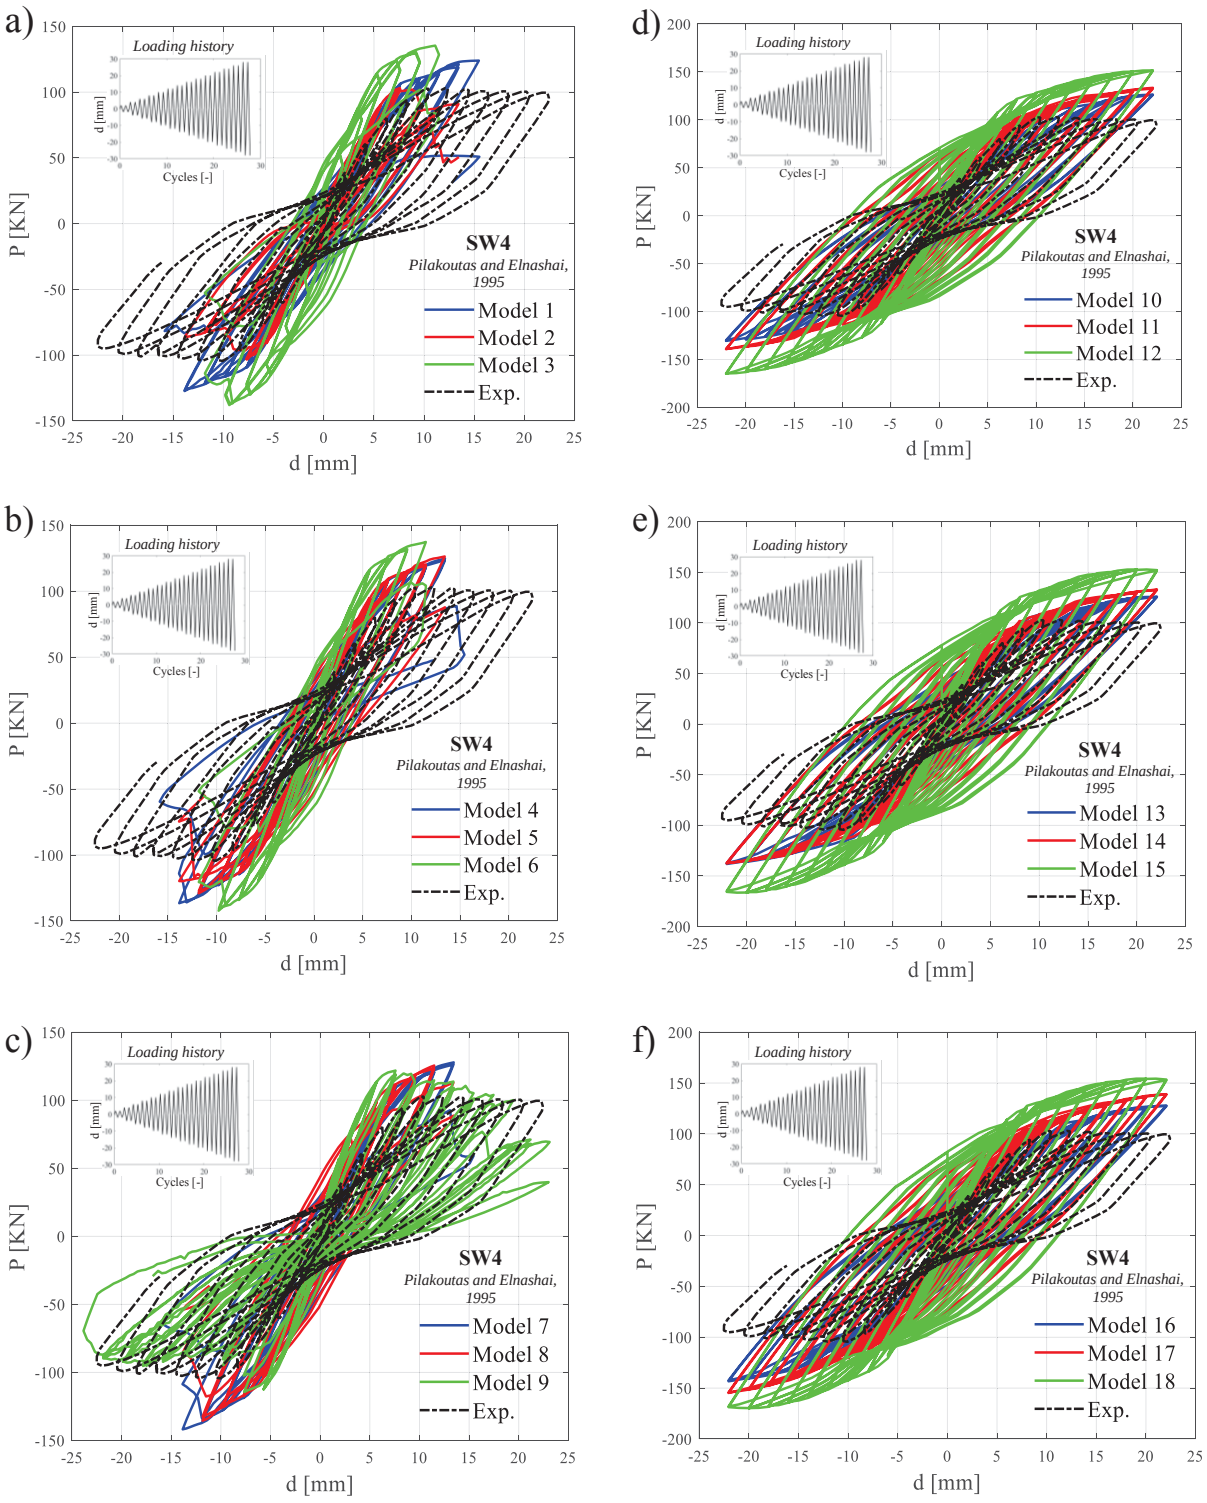

Figure 2: Comparison between NLFEAs and experimental tests expressed as load vs displacement curves - SW4 of [19]; (a-c) Numerical code A, (d-f) Numerical code B.

Figure 2-4 (a-c) and (d-f) show how the dependence of the results on the numerical code choice (numerical code A and B, respectively): in Figure 2-4 (a-c) the numerical models fail before the end of the experimental load history, while in Figure 2-4 (d-f) the simulations reach

the end of the analysis but overestimate the resistance, especially, for the Models 12, 15 and 18. The failure mode consists of the yielding of the main reinforcements and of the crushing of concrete in the boundary compressed element on the opposite side.

Table 1: Peak resistances from both the experimental tests R_{EXP} [19] and NLFEAs R_{NLFEA} for the different modelling hypotheses.

The experimental tests of [20] concern four identical walls of dimensions 1300x650x65mm, that are constrained inferiorly by a beam of section 200x300mm which simulates a stiff foundation. At the top there is a stiff beam to uniformly transmit the imposed displacement on the top of the wall. The flexural reinforcement is represented by ϕ8/100mm in the web, while the distance is reduced to 70mm in the boundary elements. The shear reinforcement is composed of ϕ6.25/260mm over the entire width of the wall and of additional stirrups of ϕ4/130mm in the boundary elements. The shear walls denoted as SW31, SW32 and SW33 are herein considered for the modelling uncertainty investigation. The experimental tests present a load history composed of four or five cycles with displacements of a few millimeters and then of a monotonic displacement increase up to failure. The compressive strength of concrete varies in the range 35-53 MPa in the different tests. The numerically computed peak global structural resistances are listed in Table 2. Figures 5-7 (a)-(f) show that the models related to elastic-plastic model for the tensile response of concrete (i.e., Models 3, 6, 9, 12, 15, 18) overestimate both the resistance and stiffness, while models having the assumption of elastic-brittle or linear tension softening in tension have more or less the same behavior with a stiffness similar to the actual one in the cyclic phase. In general, an underestimation of the resistance is recognized. It can be also noted that the more the shear retention factor increases (up to the value 0.3), the more the dissipated energy increases too.

Table 2: Peak resistances from both the experimental tests R_{EXP} [20] and NLFEAs R_{NLFEA} for the different modelling hypotheses.

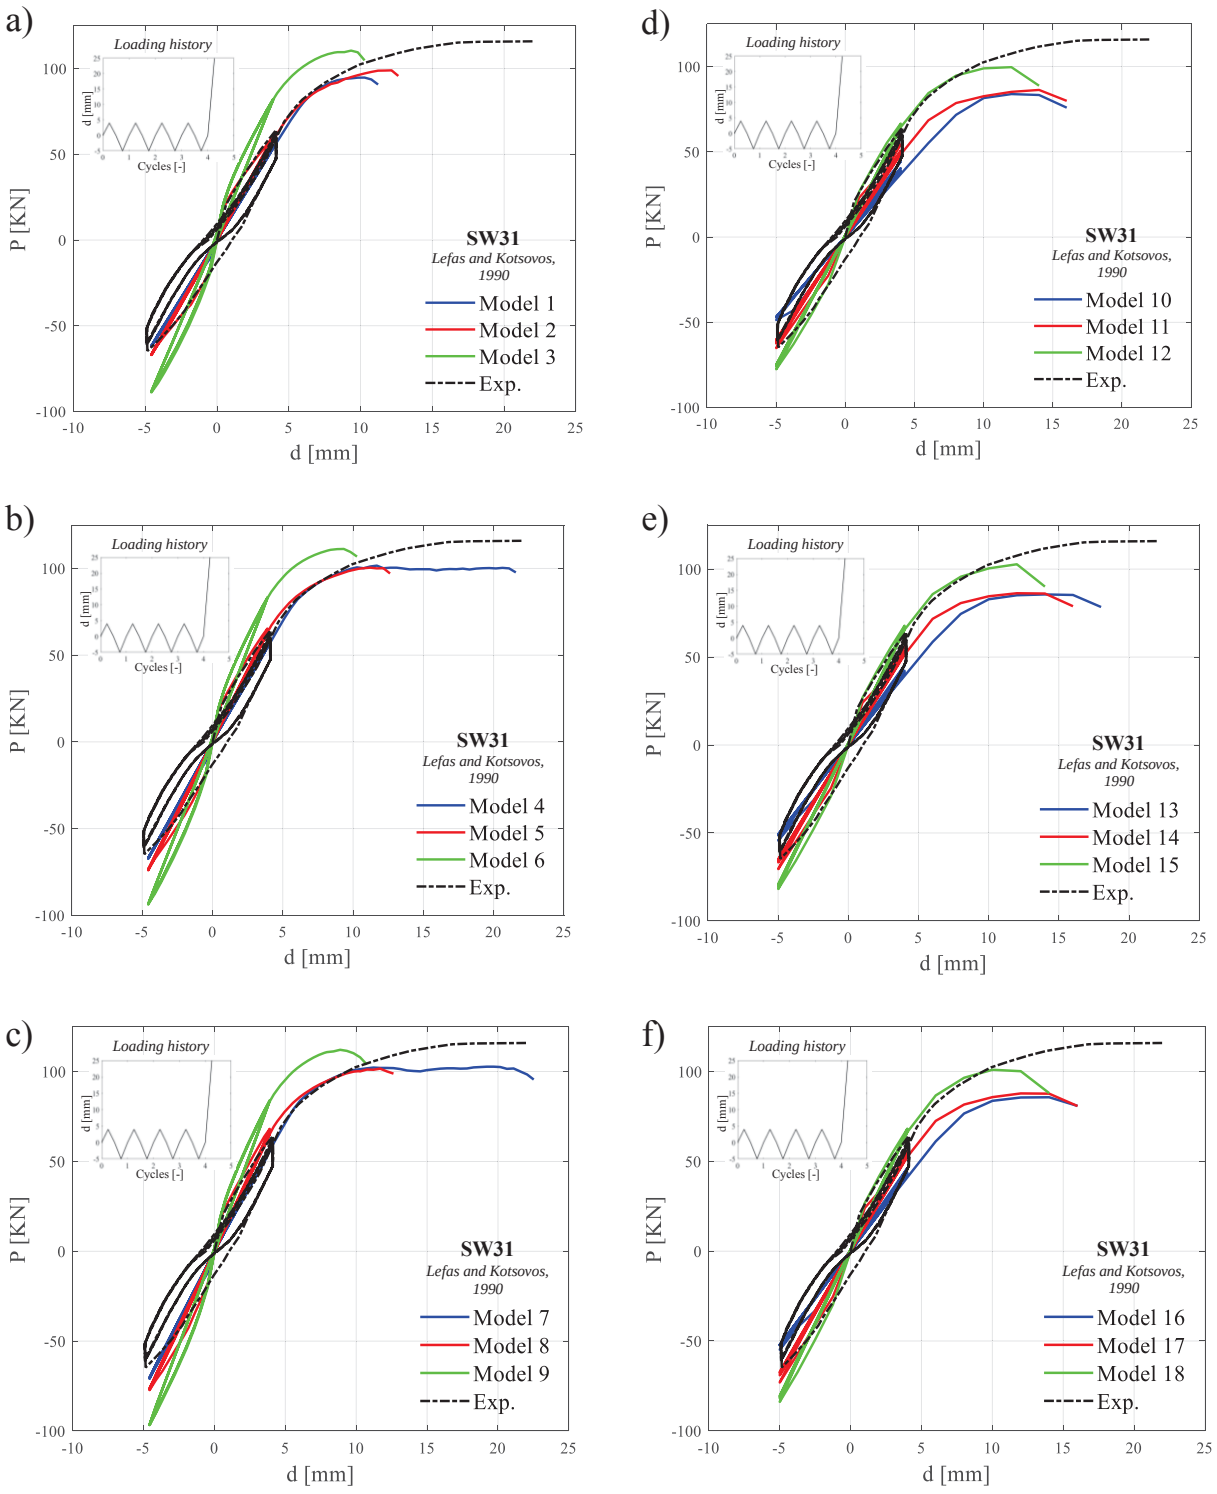

Figure 5: Comparison between NLFEAs and experimental tests expressed as load vs displacement curves – SW31 of [20]; (a-c) Numerical code A, (d-f) Numerical code B.

The failure mode is reached through the yielding of the tensile reinforcements and crushing of concrete located at the bottom of the boundary elements. Some simulations do not reach

the ultimate experimental displacement but fail upon reaching the maximum load or for a slightly greater displacement than the one achieved in the cyclic phase.

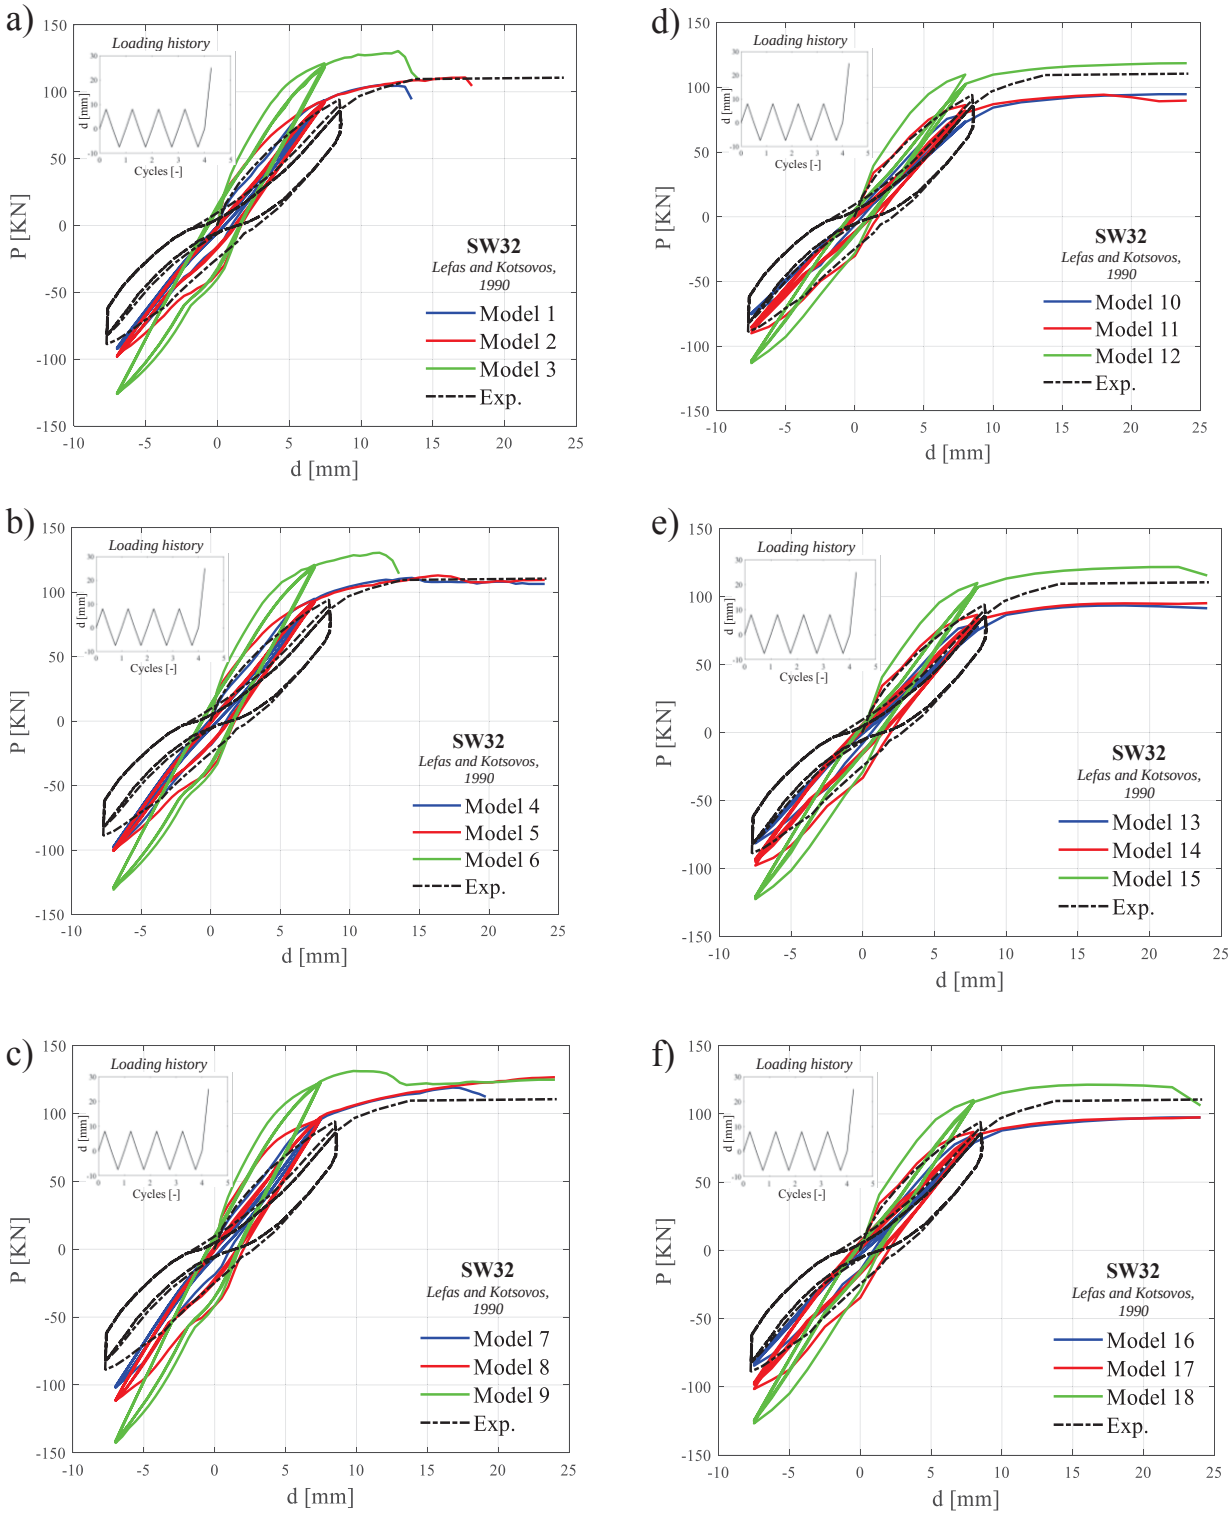

Figure 6: Comparison between NLFEAs and experimental tests expressed as load vs displacement curves – SW32 of [20]; (a-c) Numerical code A, (d-f) Numerical code B.

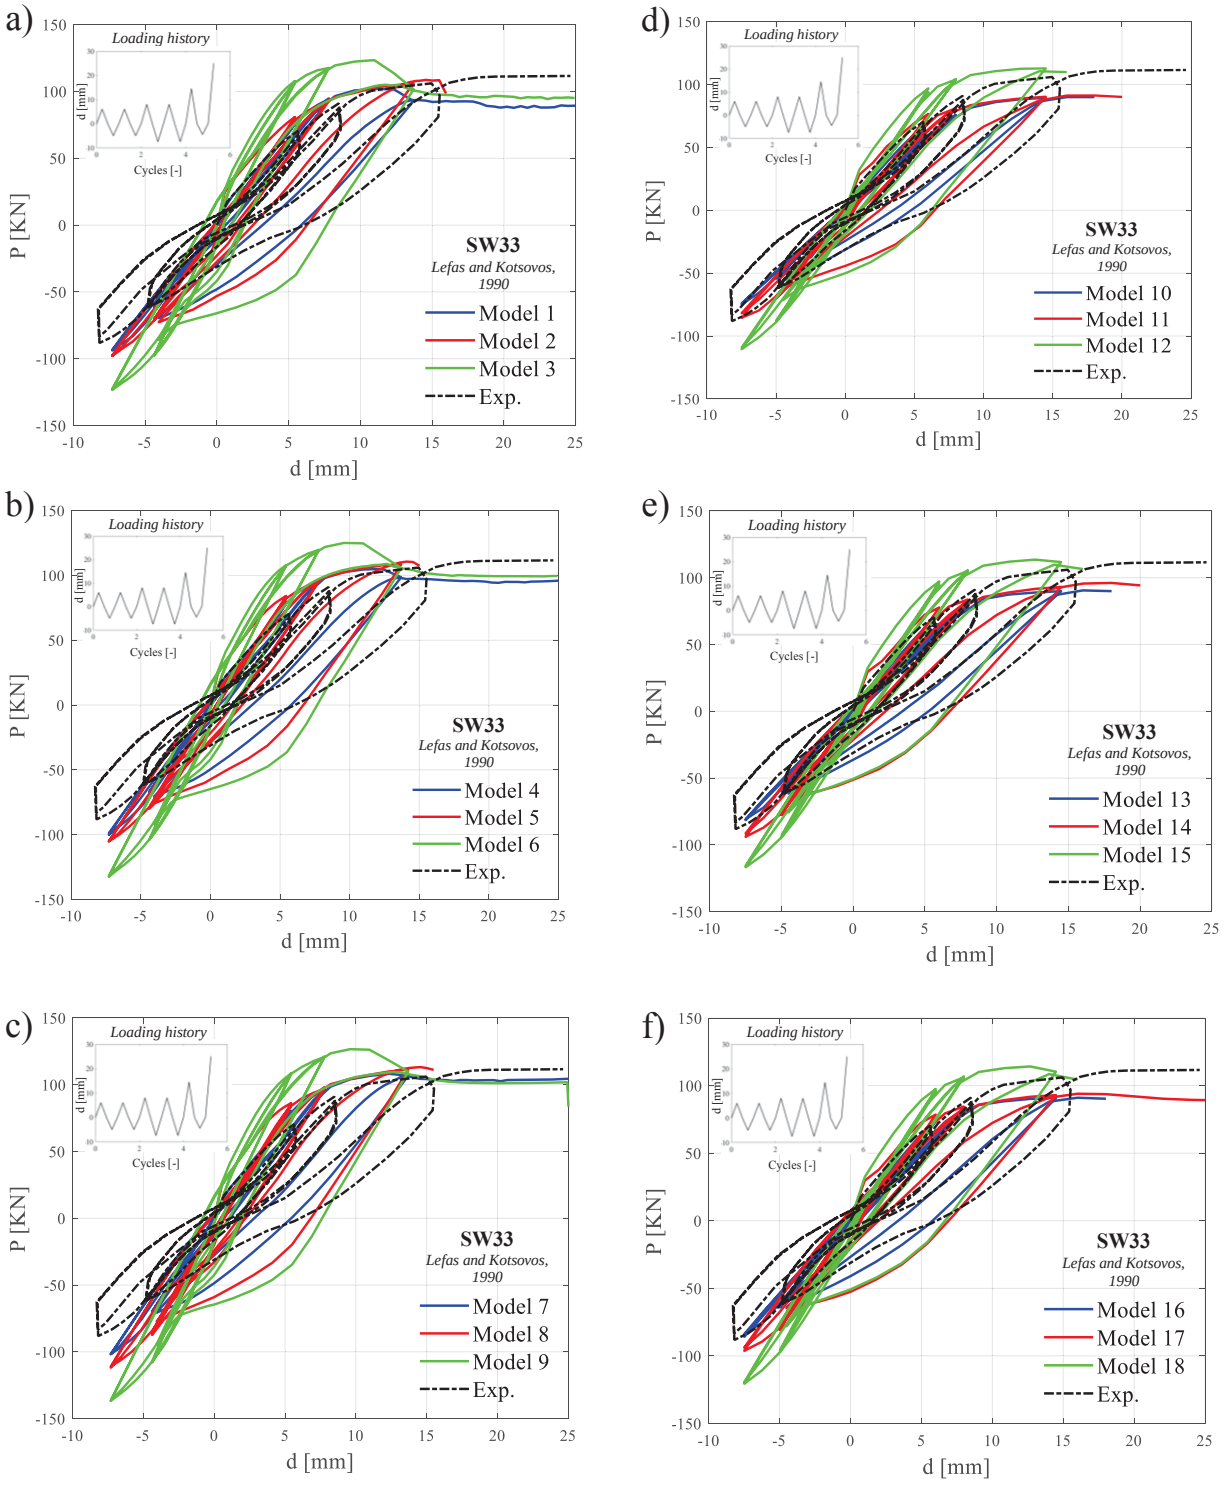

Figure 7: Comparison between NLFEAs and experimental tests expressed as load vs displacement curves – SW33 of [20]; (a-c) Numerical code A, (d-f) Numerical code B.

The laboratory tests of [21] investigate RC walls subjected to a in-plane quasi-static cyclic loading. In detail, four specimens (WSH2, WSH3, WHS4, WSH6) are considered and reproduced by means of numerical simulations. The walls have same geometry (i.e., 4.03 m high, 2 m wide and 0.15 m thick) and are fixed at the base through a beam integral with the support-

ing surface of section 0.6 m high and 0.7 wide and protruding 0.4 m from the two sides of the wall, while at the top there is a 0.4 m thick and 0.92 m high beam with a taper to favourite the connection with the wall. On this beam the axial load is provided and the cyclic loading history is applied by means of actuators located at a distance of 0.39 m from the upper edge. The walls are all reinforced with ϕ6/150 mm located horizontally along the entire width of the wall. They differs in the percentage of flexural reinforcement and in the percentage of shear reinforcement in the boundary element as well as for the value of the applied axial load. The WSH2 wall has flexural reinforcements of 6ϕ10, spaced at 75 mm in the boundary elements, and of 24ϕ6 in the web spaced at 125 mm (symmetrically starting from the outside to the center). The shear reinforcement consists of ϕ6/150 mm across the entire width, as mentioned above, and of stirrups ϕ6/75mm that enclose the ϕ10s and of a ϕ4.2 hoop that binds the two central ϕ10s. The specimen WSH3 is reinforced with 6ϕ12 on the boundary elements spaced at 100 mm, and with 22ϕ8 in the web spaced at 125 mm, and has a shear reinforcement identical to the WSH2. The wall WSH4 differs from the WSH3 concerning the shear reinforcement composed of ϕ6/150 mm across the entire width and of ϕ6/150 mm in the boundary element. The specimenWSH6 has the same bending reinforcement of the previous one with a higher reinforcement percentage in the boundary element. There are ϕ6/50 mm closed stirrups around the four lateral flexural bars, and another closed stirrup of 4.2/50 mm which encloses the four inners ϕ12. The compressive strength of concrete and axial load are similar for WSH2, WSH3 and WSH4 with values of 40.5, 39.2 and 40.9 MPa and 691, 686 and 695 kN, respectively. While WSH6 has a higher compressive strength equal to 45.6 MPa and an axial load of 1476 kN. The loading history is in line with the standard protocol by [36].

Table 3: Peak resistances from both the experimental tests R_{EXP} [21] and NLFEAs R_{NLFEA} for the different modelling hypotheses.

At each displacement level the wall has been subjected to two full cycles. The results of numerical simulations expressed as peak global structural resistance are presented in Table 3. Figures 8-11 (a)-(f) show that assuming the tensile behaviour of the concrete brittle or LTS reproduces efficiently the actual behaviour, while the models with concrete tensile behaviour perfectly plastic overestimate both the resistance and stiffness.

4 DISCUSSION

The results deriving from the abovementioned 180 non-linear FE simulations can be used in order to quantify the resistance model uncertainties in plane stress NLFEAs of RC structures under cyclic loads. These results show the several difficulties in reproducing the actual failure behaviour of structural members. The outcomes in terms of ratio $\vartheta = R_{Exp}/R_{NLFEA}$ reported in Table 4 demonstrate that the two extreme hypotheses regarding concrete tensile behaviour (i.e., elastic-brittle and elastic-plastic) do not represent in all the cases the bound limits concerning the experimental peak of resistance.

Table 4: $\vartheta = R_{Exp}/R_{NLFEA}$ for all the modelling hypotheses and related mean values and coefficient of variations (CoV).

These results highlight the effectiveness of the different assumptions to reproduce the cyclic response of the structural members. In fact, the differences between the experimental and the numerically predicted resistances may be significantly high: unsafe values up to 0.64 are obtained for the shear walls SW8 and WSH2. It means that the finite element models are not always able to reproduce the experimental behaviour accurately but sometimes overestimate the peak resistances of the walls under specific hypotheses leading to unsafe estimations. This issue is a crucial aspect in relation to safety verifications for seismic analyses. With reference

to each numerical model M_j, Table 4 also reports the mean value and coefficient of variation (CoV). The lowest unsafe bias is achieved for model M_6 and M_9 as well as concerning models M_{10} to M_{18} the highest dispersion are recognised. In particular, a substantial difference can be noted between Numerical code A and B. In fact, the numerical code A seems to provide slightly unsafe bias factors with respect to the numerical code B (in average, 0.85 against 0.90, respectively). Concerning the coefficient of variation, the numerical code A presents a lower level of dispersion of the data with respect to the numerical code B (in average, 9% against 14%, respectively). These results can be useful to develop statistical and probabilistic analyses [37]-[42] to interpret and treat the model uncertainty variable θ. Moreover, it is also highlighted that the choice of the type of software to solve a specific structural problem is relevant. More details may be found in [43].

5 CONCLUSIONS

The present investigation is devoted to quantify the resistance model uncertainties when the global structural resistance of RC structural systems under cyclic loads is estimated through plane non-linear finite element method analyses. A set of experimental tests concerning different walls subject of cyclic shear actions have been numerically simulated by means of 180 NLFEAs combining two different numerical codes, three different constitutive laws for the tension behaviour of concrete and three different shear retention factors. It can be observed that when the tensile behaviour for concrete is assumed perfectly plastic, a greater overestimation of the structural resistance always derives as well as the shear retention factor varies the amplitude of the cycle, and therefore influences the dissipated energy. However, in terms of resistance, a shear retention factor assumed close to 0.1 is the one that allows to obtain the best results with respect to the experimental outcomes. The average bias factor between the different modelling hypotheses is quantified as 0.88 with an average coefficient of variation of 11%.

UNCERTAINTIES IN WIND-INDUCED LOADS ON HYPERBOLIC PARABOLOID ROOFS: WIND-TUNNEL TESTS AND ANALYTICAL MODELS

Fabio Rizzo and Vincenzo Sepe

Department of Engineering and Geology, University "G. D'Annunzio"
Viale Pindaro 42, 65127 Pescara, Italy

Keywords: wind-tunnel tests, hyperbolic paraboloid roof, wind loads, pressure coefficients, experimental uncertainties.

Abstract. *The design coefficients provided by a wind-tunnel campaign on in-scale models, e.g. the pressure coefficients discussed in this paper, are always affected by physiological and unavoidable uncertainties. On the other hand, wind-induced loads at the real scale (e.g. peak pressure coefficients) may be provided, with a prescribed confidence level, by analytical models that include stochastic characteristics of the wind field (mean values, standard deviation, skewness, kurtosis) obtained by wind-tunnel tests. Based on aerodynamic tests on hyperbolic paraboloid models in the boundary layer wind-tunnel of the CRIACIV (Italy), this paper discusses a typical example of experimental uncertainties, i.e. the asymmetries measured for geometries and wind directions nominally symmetric, and investigates their effects on peak pressure coefficients provided by analytical models. To this aim, experimental peak pressure coefficients and their analytical prediction are compared for symmetrical geometries under wind flow direction parallel to the symmetry axis, and it is noted that asymmetries shown by experimental tests may be reduced by appropriate analytical models, that can therefore contribute to filter out the effects of experimental uncertainties for design purposes.*

1 INTRODUCTION

Although computational fluid dynamics (CFD) has become more and more accurate and reliable in the last years, and can therefore be an invaluable tool in the preliminary design stage, wind tunnel tests on in-scale models are still the more reliable way to get the wind-induced loads for structures with a complex shape.

Wind-tunnel tests, however, are always affected by several uncertainties, due to the measurements chain, to the scaling of the real building at the model size, to the geometrical details of the model and to its mechanical characteristics. The design coefficients provided by a wind-tunnel campaign, e.g. the pressure coefficients discussed in this paper, are therefore also affected by physiological and unavoidable uncertainties; this is the case, for example, of nominally symmetric and symmetrically loaded models for which wind-tunnel tests turn out instead asymmetric pressure fields.

As shown by the scientific literature, on the other hand, a sound prediction of wind-induced loads at the real scale may benefit of analytical models (e.g. [1][2][3]) able to provide, for example, average or peak pressure coefficients with a prescribed confidence level. To this aim, analytical models may use the stochastic characteristics of the wind field (mean values, standard deviation, skewness, kurtosis) obtained by wind-tunnel tests. This point has been addressed in a recent paper of the writers [4].

This paper is based on experimental results on hyperbolic paraboloid models tested in the boundary layer wind-tunnel of the CRIACIV (Italy) [4-9] and is part of a wider research that also deals with non-structural aspects of the design [10,11]. The paper discusses a typical example of experimental uncertainties, i.e. the asymmetries measured for geometries and wind directions nominally symmetric, and investigates their effects on peak pressure coefficients provided by two of the analytical models discussed in [4], i.e. the classical Davenport model and the modified Hermite model discussed in [1].

2 WIND-TUNNEL TESTS

Aerodynamic tests on a large set of hyperbolic paraboloid roofs were described in previous papers of the writers [5-9]. Wooden in-scale models with 16 different geometries and 16 different wind angles were tested in the boundary layer wind tunnel of CRIACIV (Interuniversity Research Center on Building Aerodynamics and Wind Engineering), in Italy.

In particular, this paper is focused on results obtained by wind tunnel test on roofs with square and rectangular plan and eight different geometries are discussed here.

The models represent closed buildings, e.g. as those of sports halls, and this paper discusses the aerodynamic pressure field recorded on the roof surfaces. Due to the stiffness of the models, that can be considered as rigid, roof displacements and therefore aeroelastic effects are not considered; this is an usual step in the preliminary design of this kind of structures.

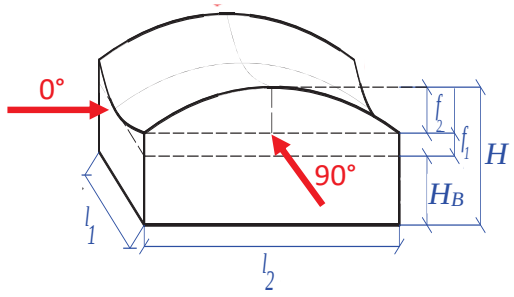
2.1 The sample square and rectangular models

Figure 1 describes the geometries discussed in Sect. 2.2 and Sect. 3.

The eight geometries considered here are denoted by three letters that refer to the model plan shape (square, S, or rectangular, R), to the model height (higher, H, or lower, L), and to the roof curvature (with smaller curvature or flatter, F, or higher curvature, C), respectively.

As reported in fig. 2, the roof surface consists of 89 and 95 elementary regions for the square and rectangular plan, respectively. Pressure time-histories were recorded (details in [6]) for about 30 seconds with an acquisition frequency of about 250 Hz for several angles of inci-

dence of wind. To explore situations nominally symmetric, only the wind directions 0° and 90° are discussed be' ›w, as shown in fig. 1.



model	l_1 [cm]	l_2 [cm]	f_1 [cm]	f_2 [cm]	H [cm]	H_B [cm]
SLF	80	80	2.67	5.33	21.33	13.33

Figure 1: The eight sample models

2.2 Pressure coefficients

For the pressure tap of each elementary region of the roof, the measured pressure time-history *p(t)* is described by non-dimensional pressure coefficients $c_p(t)$, defined as

$$c_p(t) = \frac{p(t) - p_0}{\frac{1}{2}\rho V_m^2} \tag{1}$$

where ρ denotes the air density and V_m and p_0 the mean speed at the roof level and the static pressure of undisturbed flow, respectively. Positive and negative values of c_p represent pressure larger than p_0 and suction, respectively.

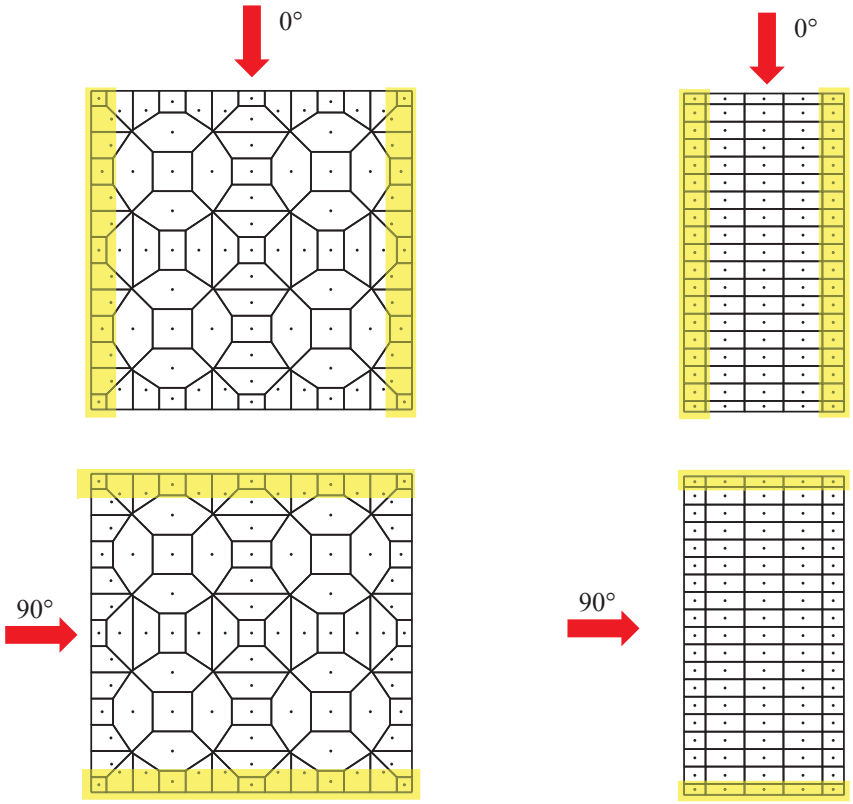

Figure 2: Map of the pressure taps for square and rectangular plans. The two alignments of pressure taps on the left and right edges of the roof with respect to the mean wind speed are highlighted in yellow

For each wind direction along a symmetry axis (angle 0° and 90°), Figure 2 reports the two alignments of pressure taps (highlighted in yellow) on the left and right edges of the roof with respect to wind direction, whose measured pressure coefficients will be compared to each other to discuss asymmetries shown by experimental tests.

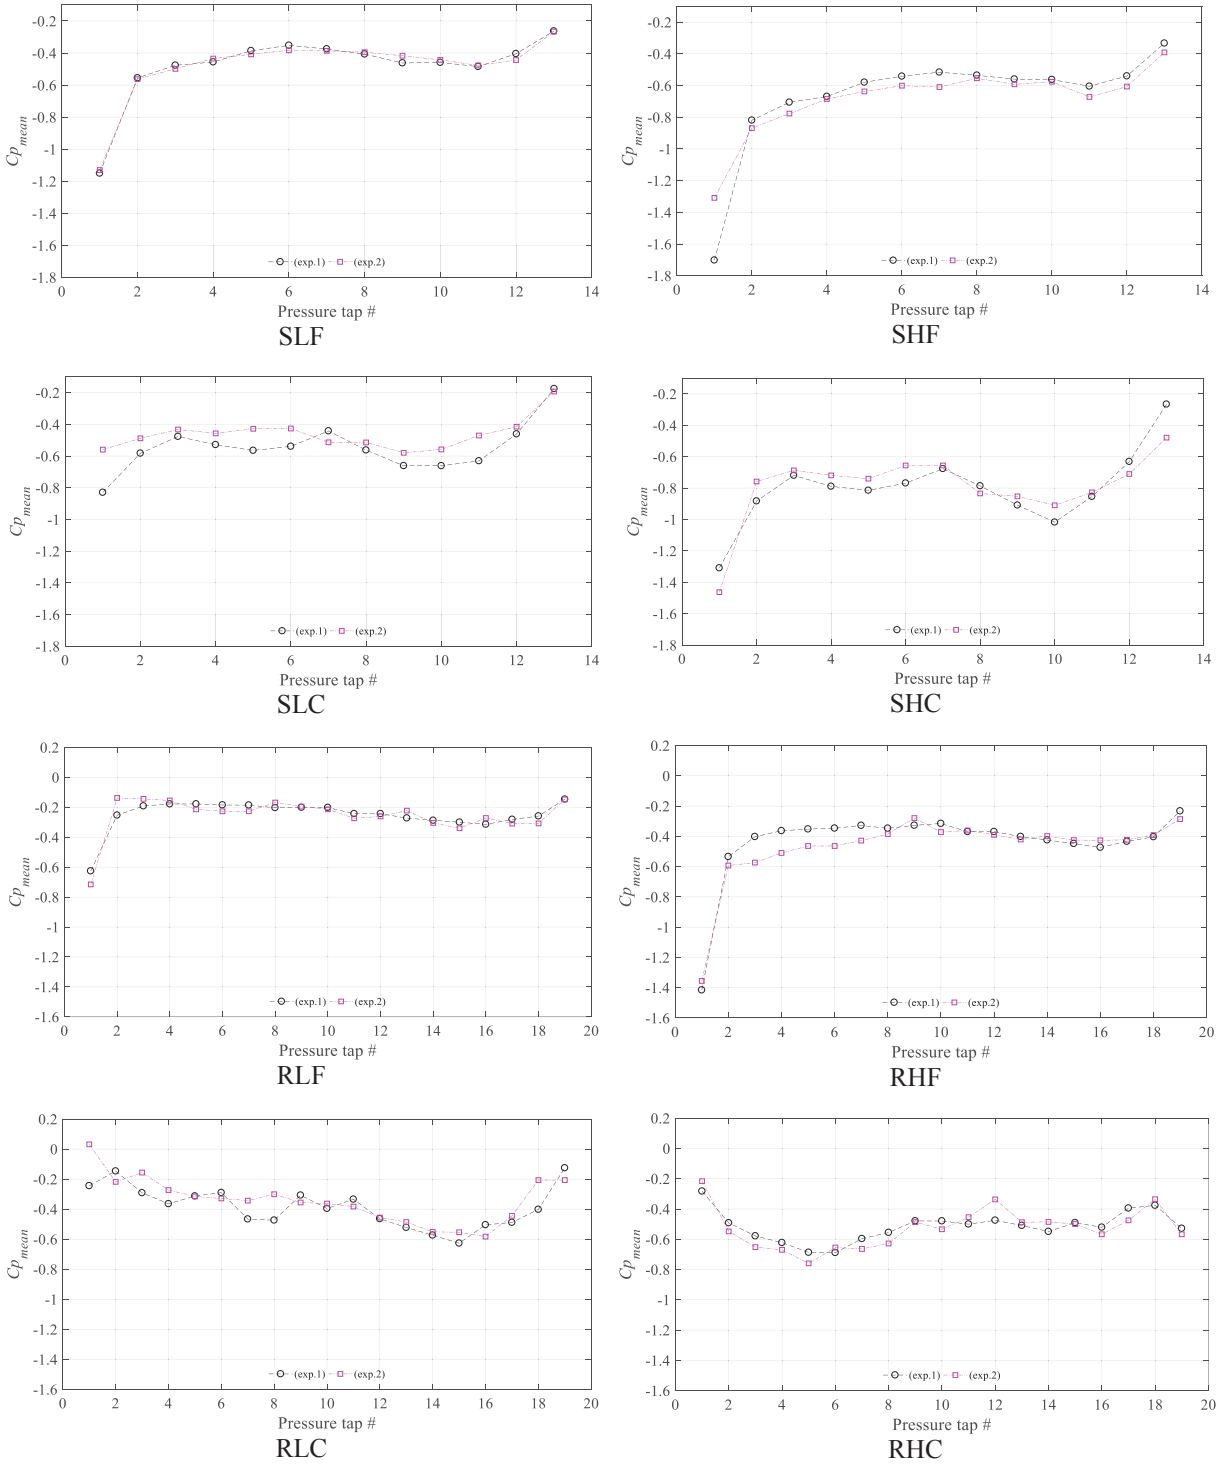

Figure 3: mean value $c_{p,mean}$ of the experimental c_p for the eight models in fig. 1 and $\theta = 0°$, measured by the pressure taps along the roof sides on the left (black curve) and on the right (red curve) of the wind direction.

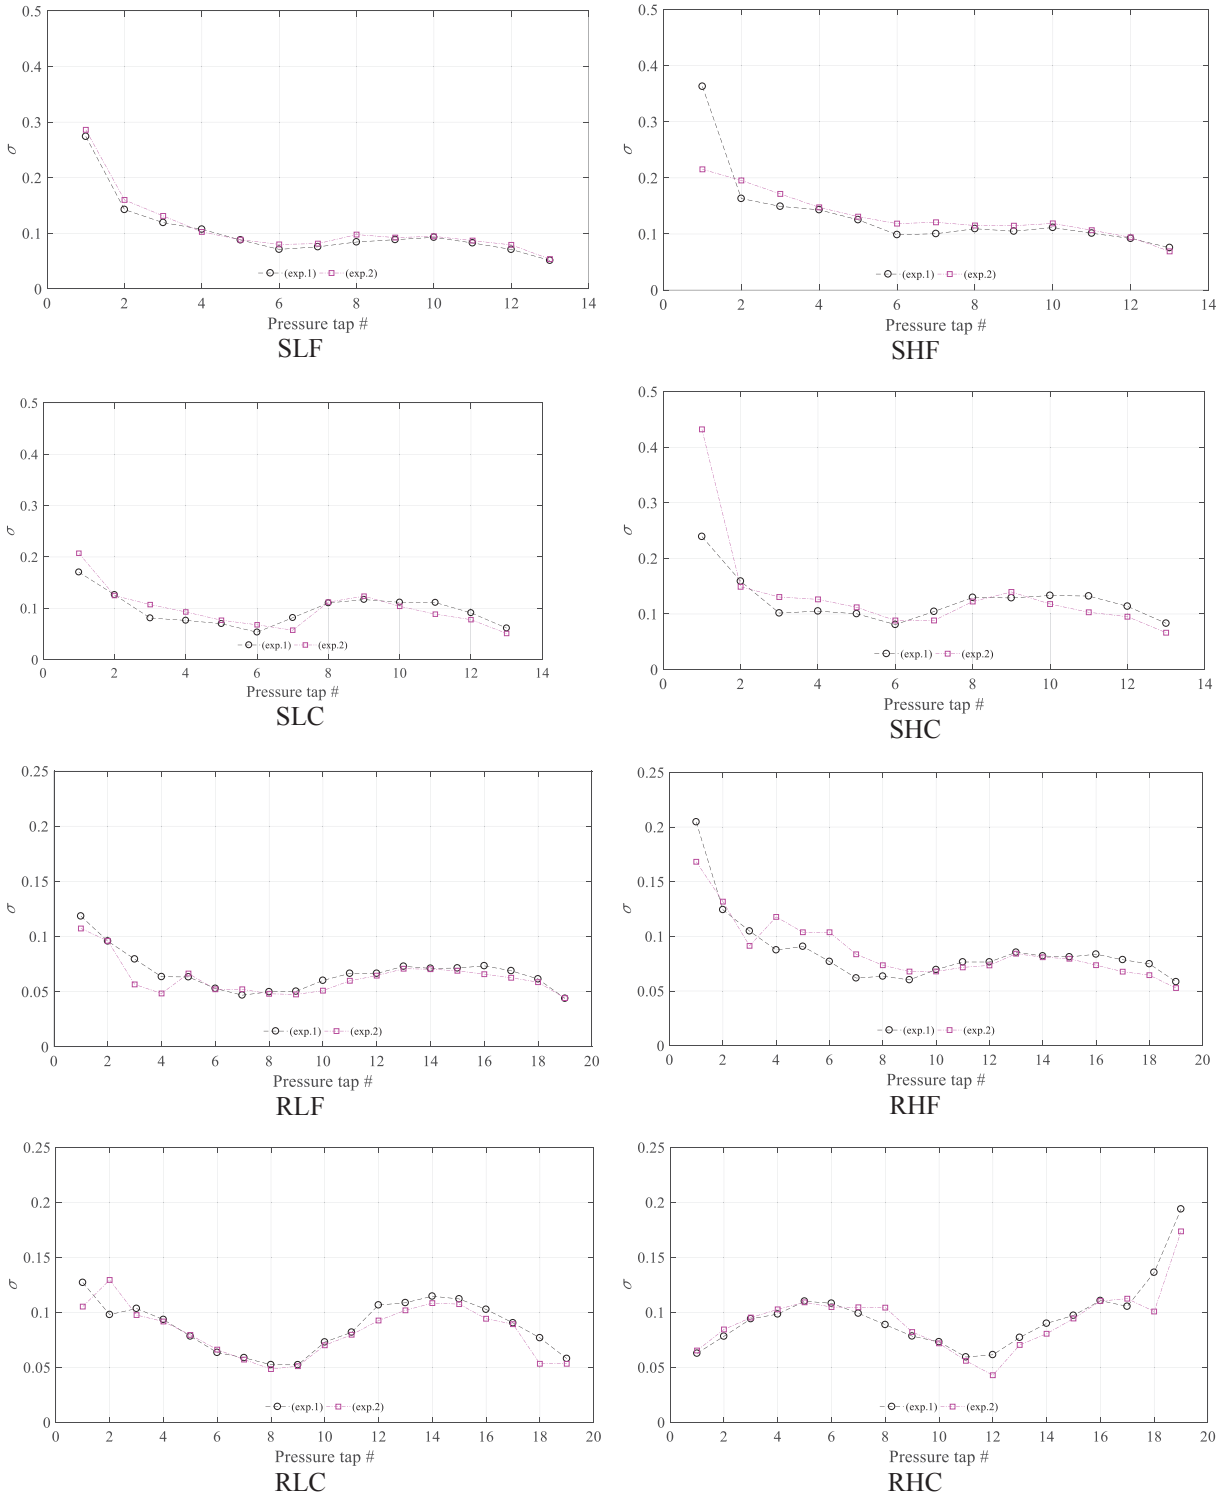

Figure 4: standard deviation σ_{cp} of the experimental c_p for the eight models in fig. 1 and $\theta = 0°$, measured by the pressure taps along the roof sides on the left (black curve) and on the right (red curve) of the wind direction.

3 EXPERIMENTAL AND ANALYTICAL PEAK PRESSURE COEFFICIENTS

Fig. 3 and 4 report the mean $c_{p,mean}$ and the standard deviation σ_{cp}, respectively, of the experimental c_p for the eight models in fig. 1 and $\theta = 0°$, measured by the pressure taps along the roof sides on the left and on the right of the wind direction.

It can be observed that for $\theta = 0°$ the differences between the mean $c_{p,mean}$ of the experimental pressure coefficients (fig. 3) measured by the pressure taps along the two sides of the roof are almost negligible for low curvature roofs (SLF, SHF, RLF, RHF). This can easily be explained once considered that for $\theta = 0°$ the wind flow impacts on the hogging curvature of the model and it is confined by the across-wind sagging curvature, and this implies small detachment regions. As also expected, on the other hand, for more curved models (SLC, SHC, RLC, RHC) the differences become more relevant, because of more pronounced detachment regions of the flow due to the larger curvature.

A similar trend has been observed for the standard deviations σ_{cp} of the experimental pressure coefficients (fig. 4).

The behavior becomes quite different for wind angle $\theta = 90°$, when the flow impacts the models on their highest wall, with a consequent detachment of the flow for a large part of the roof. In this case, as shown by results for square models reported in fig. 5 and 6 ($c_{p,mean}$ and σ_{cp}, respectively), the differences between the two alignments of pressure taps are still negligible for the lower model with smaller curvature (SLF). They are instead significantly larger for more curved ones, as shown by both $c_{p,mean}$ and σ_{cp} for SLC and SHC, and also for the highest model with smaller curvature (SHF), where significant differences of σ_{cp} have been found.

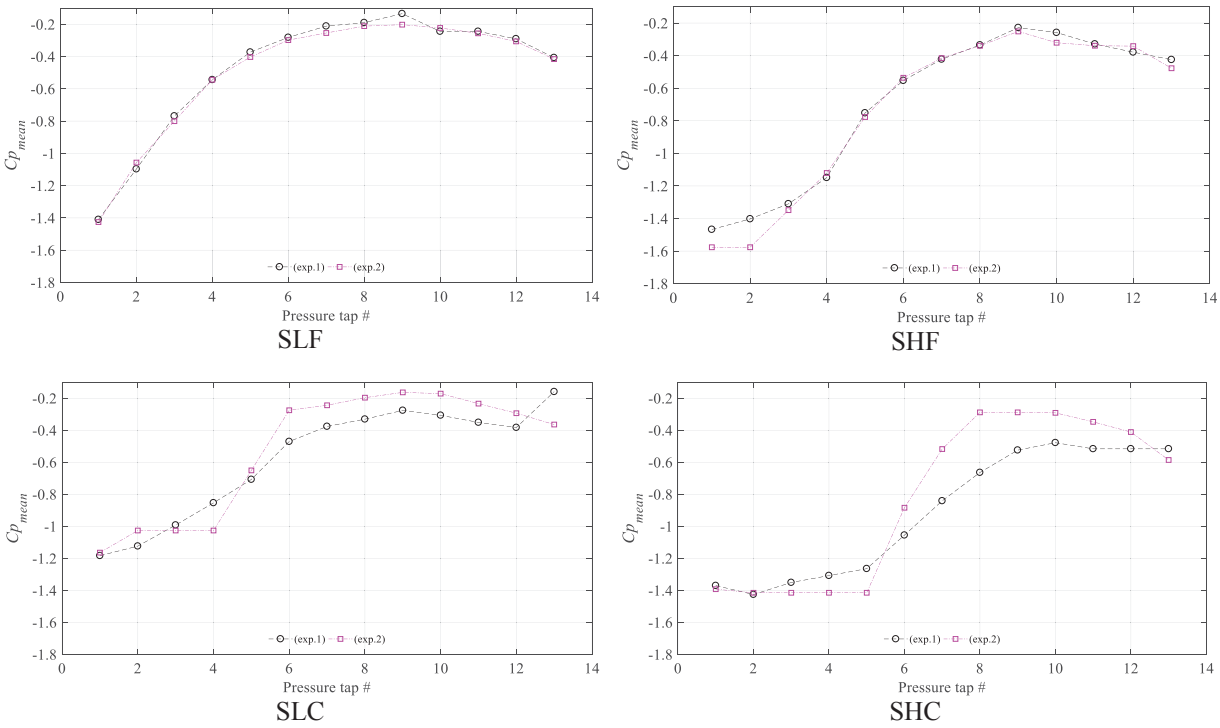

Figure 5: mean value $c_{p,mean}$ of the experimental c_p for the four square models in fig. 1 and $\theta = 90°$, measured by the pressure taps along the roof sides on the left (black curve) and on the right (red curve) of the wind direction.

Due to the experimentally observed non-symmetric behavior already discussed with reference to $c_{p,mean}$ and σ_{cp}, the differences between minimum (suction) values of c_p along the two alignments of pressure taps follow a similar trend or they are even more large, as shown for example by the extreme values in fig. 7 for square models and $\theta = 0°$.

The difference is even more evident for the experimental values of the peak factor g corresponding to the minimum values of c_p (i.e. suction), reported in fig. 8.

Peak factor g is defined as

$$c_p^{\min} = c_{p,\text{mean}} - g\ \sigma_{cp} \tag{2}$$

where for each pressure tap $c_{p,\text{mean}}$, σ_{cp} and $c_p^{\min}$ are the mean, the standard deviation and the minimum value of the c_p time history recorded in wind-tunnel tests, respectively.

On the other hand, for the sample cases discussed here also maximum values of c_p are almost always negative (suction) and smaller in absolute value than minima, and therefore they have no practical relevance to design purpose and are no further discussed below.

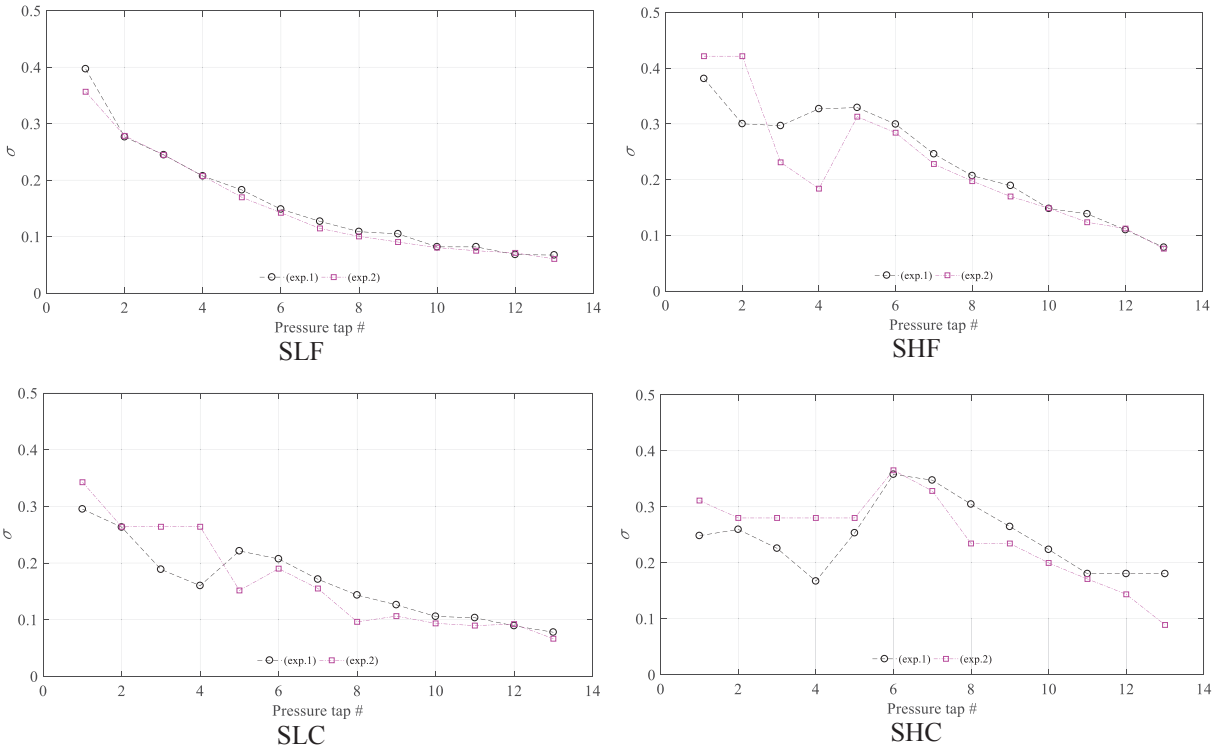

Figure 6: standard deviation σ_{cp} of the experimental c_p for the four square models in fig. 1 and $\theta = 90°$, measured by the pressure taps along the roof sides on the left (black curve) and on the right (red curve) of the wind direction.

Figures 7 also show for square models and $\theta = 0°$ the minimum values of c_p evaluated according to the classical Davenport model and to the analytical modified Hermite model [1]. Similarly, fig. 8 also show for square models and $\theta = 0°$ the peak factor g evaluated according to the classical Davenport model and to the modified Hermite model [1]. As expected, the Davenport peak factor assume almost constant values around 3.5.

It can be observed that, when compared to experimental results, the analytical models generally reduce the differences between the extreme values $c_p^{\min}$ of the two alignments of pressure taps. This is not true for the peak factor g evaluated according to the analytical modified Hermite model [1], which keeps maintaining significant differences between taps expected to have a symmetric behavior. In the authors' opinion, however, this difference should be reduced by evaluating g from the minimum expected values of c_p according to a soundly based statistical procedure (e.g. Cook and Mayne [12]), instead of assuming the minimum recorded values $c_p^{\min}$ as done here, and this will be investigated in future research.

Although differences between the two alignments are not negligible, however, the average value of $c_p^{\min}$ provided by the modified Hermite model [1] for pressure taps nominally symmetric is closer, with respect to the estimation provided by the Davenport model, to the aver-

age of their recorded extreme suction values. This can be explained by considering that in the Davenport model g turns out to be almost constant, while a recent research [4] shows that for this kind of geometries g may have quite large variations.

All in all, therefore, and according to these results for symmetrical geometries under wind flow direction parallel to the symmetry axis, asymmetries shown by experimental tests may be reduced by appropriate analytical models, that can therefore contribute to filter out the effects of these and others experimental uncertainties for design purposes.

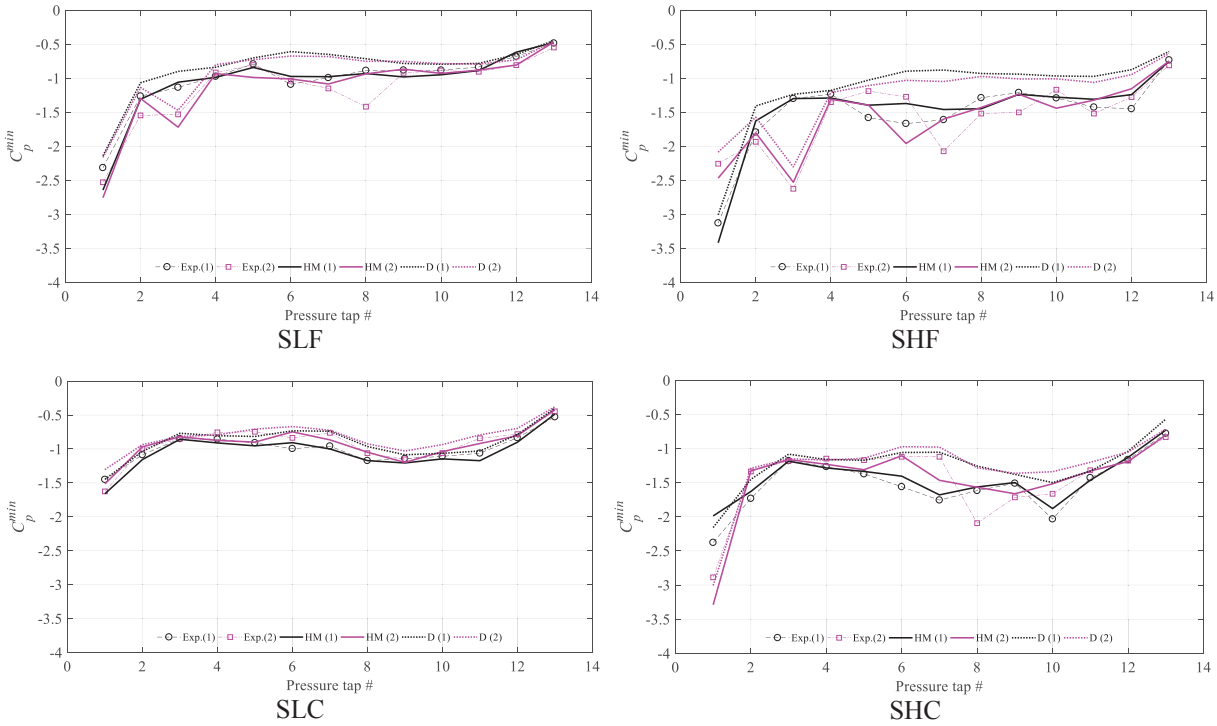

Figure 7: minimum value c_p^{min} of the experimental c_p for the four square models in fig. 1 and $\theta = 0°$, measured by the pressure taps on the left (broken black curve) and on the right (broken red curve) of the wind direction; peak values of c_p obtained with analytical models (Davenport and modified Hermite [1]) are also shown (dotted and continuous lines, respectively).

4 CONCLUSIONS

- Based on experimental results on hyperbolic paraboloid models tested in the boundary layer wind-tunnel of the CRIACIV (Italy) [4-9], this paper shows that experimental values of pressure coefficients are affected by physiological uncertainties, as the asymmetries measured for geometries and wind directions nominally symmetric.
- Although the results reported require further investigation, they suggest that technical codes should include asymmetrical load conditions also in case of nominally symmetric geometries and wind directions.
- Experimental peak pressure coefficients and their prediction given by two analytical models are compared for symmetrical geometries under wind flow direction parallel to the symmetry axis, and it is noted that asymmetries shown by experimental tests may be reduced by appropriate analytical models, that can therefore contribute to filter out the effects of experimental uncertainties for design purposes.

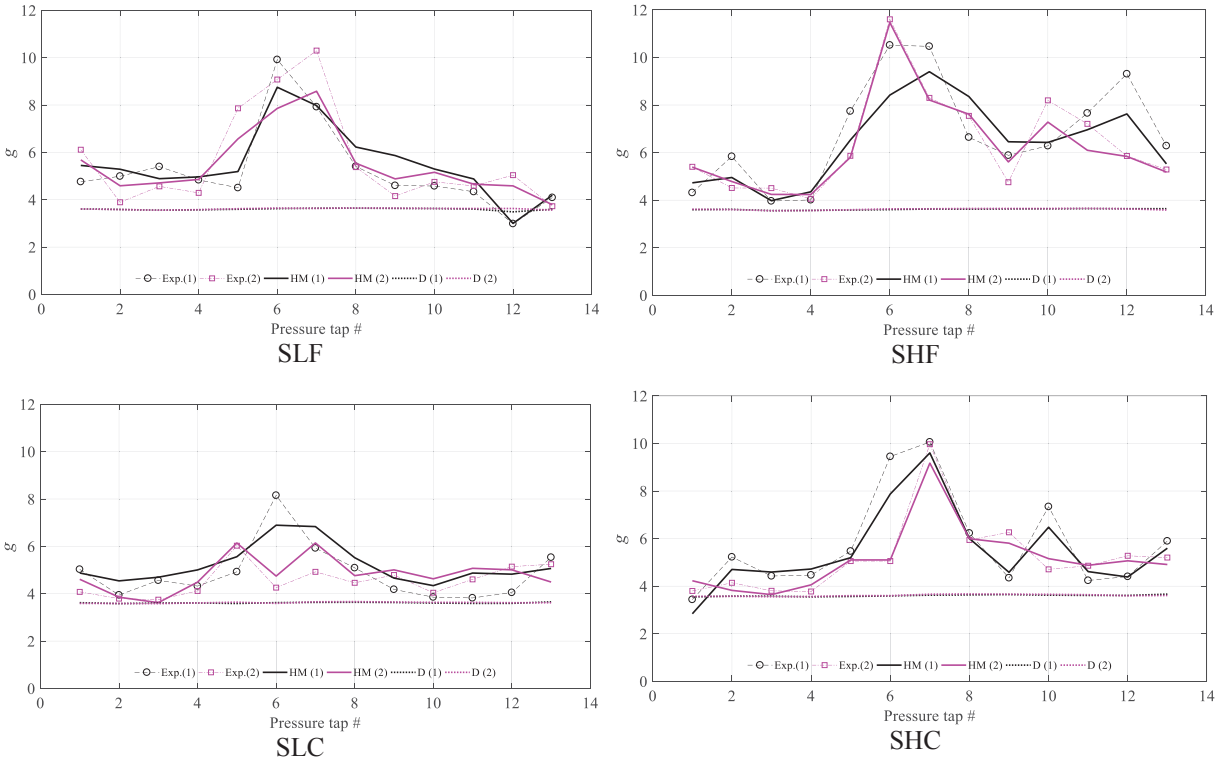

Figure 8: peak factor g for the minimum values (suction) of the experimental c_p for the four square models in fig. 1 and $\theta = 0°$, measured by the pressure taps along the roof sides on the left (broken black curve) and on the right (broken red curve) of the wind direction; peak factor g obtained with analytical models (Davenport and modified Hermite [1]) are also shown (dotted and continuous lines, respectively).

Keywords: Bayesian model updating, Bhattacharyya distance, uncertainty quantification, ageing existing bridge, time-series data

Abstract. *In ageing existing bridges, the deterioration of the members cannot be ignored and the model parameters should be carefully estimated in time through observation data from the structures. On seismic-isolated bridges, the post-yield stiffness of rubber bearings is a particularly critical parameter, since it affects the structural behavior against huge earthquakes. Additionally, its characteristic can be captured using available seismic response data. In this study, a seismic-isolated bridge pier is modelled as a two degree of freedom lumped mass system and its uncertain model parameters are estimated based on time-histories of the acceleration response through Bayesian model updating. The Bhattacharyya distance is used as a comprehensive uncertainty quantification (UQ) metric to capture multiple uncertainty sources from both model predictions and observation data. A sequential procedure is proposed to prevent the so-called "dimensional curse" due to very high dimensional time-series data in model updating. In this procedure, the Bhattacharyya distance is calculated for each predefined time segment and their root mean square is adopted as the UQ metric. The results demonstrate that the proposed framework can successfully update model parameters including the post-yield stiffness of the rubber bearing through seismic response data. Furthermore, the calibrated model can represent wholly the probability distribution of the target time-series observation.*

1 INTRODUCTION

Over the past decades, seismic isolation has been considered as an attractive technology to mitigate the risk of seismic damages on highway bridges [1-3]. Seismic isolation aims to shift the natural frequency of a structure away from the dominant frequency of earthquakes and to provide additional damping capacity in order to reduce seismic loadings on the structure. Among various types of isolation systems, rubber bearings have been widely used [3].

On the other hand, it is well known that the structural property of rubber bearings is varied due to aging deterioration. Long-term deterioration characteristics of natural rubber bearings were studied based on accelerated thermal oxidation tests [4], and decrease in the rupture strain and increase in the stiffness of bearings were also reported [5, 6]. Moreover, Onodera et al. [7] showed that deteriorated bearings increase the response of reinforced concrete (RC) piers at lower seismic intensity compared to bearings without deterioration based on incremental dynamic analysis. Hence, current model parameters of deteriorated bearings need to be carefully estimated through available seismic response data to compute seismic reliability of the bridges with deteriorated bearings in order to prevent their failure in future earthquakes.

Bayesian model updating [8, 9] is a powerful tool successfully employed to estimate model parameters through observation data. It has been widely accepted that uncertainties should be appropriately considered in model updating; thus, uncertainty quantification (UQ) metrics are significant to comprehensively and quantitatively measure the difference between model predictions and observation data. As an alternative to the classical Euclidian distance, the Bhattacharyya distance was proposed as a potential UQ metric capable of capturing a higher level of statistical information [10]. Bi et al. [11] developed an approximate Bayesian computation model updating framework, where the Bhattacharyya distance was fully embedded. The accuracy and efficiency of the framework were demonstrated through a three degree of freedom (DOF) spring-mass system example and a modal analysis of an airframe structure. Nevertheless, modal responses were used as the target output features in these examples and applicability for time-series responses, such as seismic responses, still needs to be investigated.

In this study, a sequential procedure is proposed to prevent the so-called "dimensional curse" due to very high dimensional time-series data in model updating. In this sequential procedure, the Bhattacharyya distance is calculated for each predefined time segment and their root mean square (RMS) is adopted as the UQ metric. In this context, the applicability and usefulness of the proposed method is examined updating model parameters of existing seismic-isolated bridges including the post-yield stiffness of rubber bearings through seismic response data.

2 MODEL DESCRIPTIONS

The target bridge, used in this study, is a seismic-isolated bridge designed based on the design specifications of highway bridges and manual on bearings for highway bridges by Japan Road Association [12, 13]. The seismic-isolated bridge pier is modelled as a 2-DOF lumped mass system, as shown in Figure 1(a), and descriptions of the bridge are also detailed in Table 1. Force-displacement relationships of the rubber bearing and RC pier are described by hysteresis loops using bi-linear model and stiffness degradation bi-linear model (so-called Takeda model) [14], respectively. The ultimate strength of the pier is idealized as same as its yield strength; thus, the pier has no post-yield stiffness. In addition, Rayleigh damping is assumed in which damping ratios of the bearings and pier are given as 0% and 2%, respectively.

Dynamic response analysis of the 2-DOF system is conducted by Newmark β method ($\gamma = 1/2$ and $\beta = 1/4$) with the time step $\Delta t = 0.001$sec. NS component of JR Takatori record during the 1995 Kobe earthquake is selected as the input ground motion and time-histories of the acceleration response at the superstructure is shown in Figure 1(b).

3 THEORIES AND METHODS

3.1 Bhattacharyya distance-based UQ metric

The numerical model with n input parameters and m output features can be expressed as:

$$\mathbf{y} = f(\mathbf{x}) \tag{1}$$

where $\mathbf{x} = [x_1, x_2, \cdots, x_n]^T$ and $\mathbf{y} = [y_1, y_2, \cdots, y_m]^T$ are the input and output vectors, respectively. The function can be either a structural analysis (e.g. dynamic response analysis of the target bridge, in which model parameters listed in Table 1 are the input parameters and time-histories of the acceleration response are the output features) or a meta-model.

In Bayesian model updating, some of the input parameters are considered as uncertain parameters while the remaining parameters are treated as deterministic parameters. Then, randomly sampled values of the parameters are used to calculate the corresponding output features. Suppose the sample size is N_{sim}, model predictions $\mathbf{Y}_{sim} \in \mathbb{R}^{N_{sim} \times m}$ are obtained as:

$$\mathbf{Y}_{sim} = [\mathbf{y}_1, \mathbf{y}_2, \cdots, \mathbf{y}_m], \ \ \mathbf{y}_i = \left[y_{1i}, y_{2i}, \cdots, y_{N_{sim}i}\right]^T, \ \forall i = 1, \cdots, m \tag{2}$$

In addition to model predictions, observed features are required as the target of model updating. Suppose the number of observations is N_{obs}, observation data $\mathbf{Y}_{obs} \in \mathbb{R}^{N_{obs} \times m}$ have a similar structure as Equation (1), where only the number of rows is changed.

After getting model predictions and observation data, the UQ metric can be defined to capture the discrepancy between them. The classical Euclidian distance metric is expressed as:

$$d_E(\mathbf{Y}_{obs}, \mathbf{Y}_{sim}) = \sqrt{(\overline{\mathbf{Y}}_{obs} - \overline{\mathbf{Y}}_{sim})(\overline{\mathbf{Y}}_{obs} - \overline{\mathbf{Y}}_{sim})^T} \tag{3}$$

where $\overline{\mathbf{Y}}_{\blacksquare}$ is the row vector of means of the features. The Euclidian distance only considers the effect of the mean, thus a more comprehensive distance accounting for a higher level of statistical information is required. The Mahalanobis distance can consider the effect of the variance and covariance, while it cannot take into account the difference in the distribution shapes.

The Bhattacharyya distance is hence proposed herein to measure the degree of overlap between distributions of two random variables and is expressed as:

$$d_B(\mathbf{Y}_{obs}, \mathbf{Y}_{sim}) = -\log\left[\int_{\mathbb{X}} \sqrt{p_{obs}(y)p_{sim}(y)}dy\right] \tag{4}$$

where $p_{\blacksquare}(x)$ is the probability density function (PDF) of the sample; $\mathbb{X}$ is the m-dimensional space, implying $\int_{\mathbb{X}} \blacksquare dx$ is the integration performed over the whole output space. Despite the advantage on uncertainty characterization, the direct calculation of Equation (4) is impractical because precise estimation of the PDF is generally unavailable, especially when the amount of observation data is limited. Hence, an approximate Bhattacharyya distance based on probability mass functions (PMFs) of discrete distributions is introduced as:

$$d_B(\mathbf{Y}_{obs}, \mathbf{Y}_{sim}) = -\log\left\{\sum_{i_m=1}^{n_{bin}} \cdots \sum_{i_1=1}^{n_{bin}} \sqrt{p_{obs}(b_{i_1,i_2,\cdots,i_m})p_{sim}(b_{i_1,i_2,\cdots,i_m})}\right\} \tag{5}$$

where $p_{\blacksquare}(b_{i_1,i_2,\cdots,i_m})$ is the PMF value of the bin $b_{i_1,i_2,\cdots,i_m}$. Bins are generated as a grid within the lower and upper bounds of all values of model predictions and observation data. More detailed information of the binning algorithm can be referred to Ref. [11].

More attention is paid that the grid is created in a m-dimensional space; thus, it is difficult to directly employ the Bhattacharyya distance using very high dimensional time-series data as the output features (due to so-called "curse of dimensionality"). To overcome this issue, a sequential procedure is proposed as following:

1) Define the common short time segment Δt_0 of both $\mathbf{Y}_{obs}$ and $\mathbf{Y}_{sim}$, and take RMS of them for each time segment.
2) Use the RMS of each time segment $\mathrm{RMS}_{\mathbf{Y}_{obs}i}$ and $\mathrm{RMS}_{\mathbf{Y}_{sim}i}$, $\forall i = 1, \cdots, k(= m \cdot \Delta t/\Delta t_0)$ independently to calculate the Bhattacharyya distance.
3) Again, take RMS of the set of the Bhattacharyya distance $\mathbf{d}_B = [d_{B1}, d_{B2}, \cdots, d_{Bk}]$ and employ it as an alternative UQ metric.

The principle of the time segment Δt_0 in step 1) is that a smaller Δt_0 leads to employing more detail information from the time-series data, while it leads to larger computational burden for the calculation of the UQ metric. Note that, an advantage to take RSM of $\mathbf{Y}_{obs}$ and $\mathbf{Y}_{sim}$ in step 1) is simplicity to address the different time resolutions in model predictions and observation data.

3.2 Bayesian model updating

The Bayesian model updating framework is based on the Bayes' theorem [8]:

$$P(\mathbf{X}|\mathbf{Y}_{obs}) = \frac{P_L(\mathbf{Y}_{obs}|\mathbf{X})P(\mathbf{X})}{P(\mathbf{Y}_{obs})} \tag{6}$$

where $P(\mathbf{X})$ is the prior distribution representing the initial knowledge about the input parameters, $P(\mathbf{X}|\mathbf{Y}_{obs})$ is the posterior distribution representing the updated knowledge based on observation data, $P(\mathbf{Y}_{obs})$ is the normalized factor ensuring the posterior distribution integrates to one, and $P_L(\mathbf{Y}_{obs}|\mathbf{X})$ is the likelihood function, theoretically defined as the probability of observation data conditional to each instance of the inputs.

The likelihood function is theoretically expressed as:

$$P_L(\mathbf{Y}_{obs}|\mathbf{X}) = \prod_{i=1}^{N_{obs}} P(\boldsymbol{y_i}|\mathbf{X}) \tag{7}$$

where $P(\boldsymbol{y_i}|\mathbf{X})$ is the probability distribution of ith observation data conditional to the corresponding instance of the inputs. However, the direct calculation of Equation (7) is generally unrealistic for practical applications because precise estimation of $P(\boldsymbol{y_i}|\mathbf{X})$ requires large number of simulated features. Hence, an approximate likelihood function based on the Bhattacharyya distance is defined as:

$$P_L(\mathbf{Y}_{obs}|\mathbf{X}) \propto exp\left\{-\frac{d_B(\mathbf{Y}_{obs}, \mathbf{Y}_{sim})^2}{\varepsilon^2}\right\} \tag{8}$$

where ε is the so-called width factor controlling the centralization of the posterior distribution. This likelihood function is based on the approximate Bayesian computation [15], in which any types of statistics can be used to measure the difference between model predictions and observation data in the kernel, and the Gaussian kernel is adopted in this study. Combining with the Bhattacharyya distance, the new likelihood function is capable of capturing comprehensive uncertainty information from both model predictions and observation data.

In addition, the normalized factor $P(\mathbf{Y}_{obs})$, also known as evidence, is also a non-trivial component as the direct integration of $P(\mathbf{X}|\mathbf{Y}_{obs})$ over the whole sample space. Thus, the TMCMC algorithm [16] is proposed in this study by introducing a series of intermediate PDFs of the inputs, which gradually converge to the posterior distribution, and thus avoiding the direct calculation of the integral.

4 CASE STUDY ON THE SEISMIC-ISOLATED BRIDGE PIER MODEL

4.1 Problem descriptions

The case study is performed on the 2-DOF system shown in Figure 1(a). The post-yield stiffness of the bearing K_{B2} as well as the initial stiffness of the bearing and pier K_{B1}, K_R are assigned as uncertain parameters while the remaining parameters are fixed constants with characteristic values listed in Table 1. Time-histories of the acceleration response at the superstructure against JR Takatori record are taken as the output features whose uncertainty are driven by the uncertain parameters. Both aleatory and epistemic uncertainties are included by modeling the uncertain parameters as independent Gaussian random variables, where distribution coefficients, which are multiplied by the characteristic values, are not fixed but unknowns lying within given intervals. The intervals of means μ and standard deviations σ associated to the uncertain parameters are detailed in Table 2.

Observation data $\mathbf{Y}_{obs}$ are simulated by assigning target values of the distribution coefficients, which are defined based on Adachi [17], shown in the last column of Table 2. Based on these target values, 100 random samples of the input parameters are generated and subsequently 100 observation samples are obtained by evaluating the model. The duration time of JR Takatori

record is 40sec and consequently the output features have 40,000 dimensions; thus, the direct calculation of the Bhattacharyya distance is apparently impossible and the proposed sequential procedure is required. In this study, the short time segment is set as $\Delta t_0 = 1$sec.

The purpose of the case study is to demonstrate the Bhattacharyya distance as a universal UQ metric in Bayesian model updating based on time-series data to calibrate the uncertainty distribution characteristics of the input parameters. In particular, the case study focuses on updating the post-yield stiffness of the bearing, which cannot be captured by modal responses, using seismic response data.

Parameter	Uncertainty characteristic	Target value of epistemic input
K_P	Gaussian, $\mu_1 \in [0.5, 1.5]$, $\sigma_1 \in [0.0, 0.15]$	$\mu_1 = 1.0$, $\sigma_1 = 0.07$
K_{B1}	Gaussian, $\mu_2 \in [0.5, 1.5]$, $\sigma_2 \in [0.0, 0.15]$	$\mu_2 = 1.0$, $\sigma_2 = 0.07$
K_{B2}	Gaussian, $\mu_3 \in [0.5, 1.5]$, $\sigma_3 \in [0.0, 0.15]$	$\mu_3 = 1.0$, $\sigma_3 = 0.07$

Table 2: Uncertainty properties of the input parameters.

4.2 Updating results

The Bayesian model updating is performed using the TMCMC algorithm [12]. Prior distributions of all uncertain parameters are set to be uniform distribution within the pre-defined intervals listed in Table 2.

The posterior distributions of the parameters calibrated by the Bhattacharyya distance metric are obtained, as shown in Figure 2. The diagonal subfigures illustrate the histograms of the posterior distributions and the other subfigures show the scatters of the posterior samples. It can be seen that all of the uncertain distribution parameters are significantly updated compared with their prior uniform distributions and accurately converge to their target values.

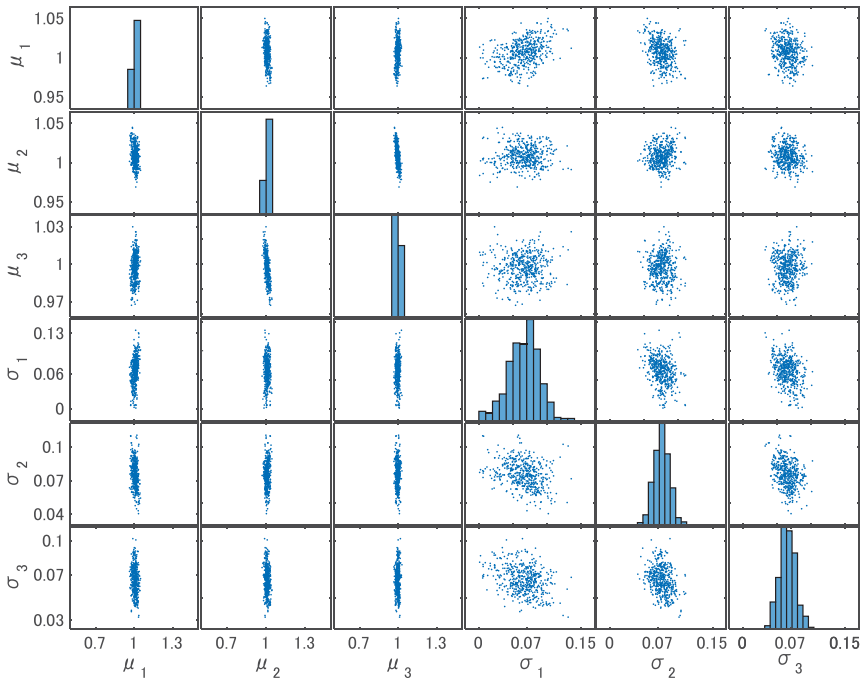

Figure 2: Posterior distributions of the uncertainty distribution characteristics.

Figure 3 illustrates the comparison between the target and updated scatters and histograms of the arbitrary selected RSM of the time-histories. Here, $\mathrm{ACC}_{\mathrm{RSMi}}$ denotes the RSM of the time-histories of the acceleration response corresponding to the ith time segment. Distribution properties of all RSMs of the time-histories are precisely updated to be identical with the target distributions, implying the proposed UQ metric, as the RSM of the set of the Bhattacharyya distance, has the capability to recreate wholly the distribution of the target time-histories.

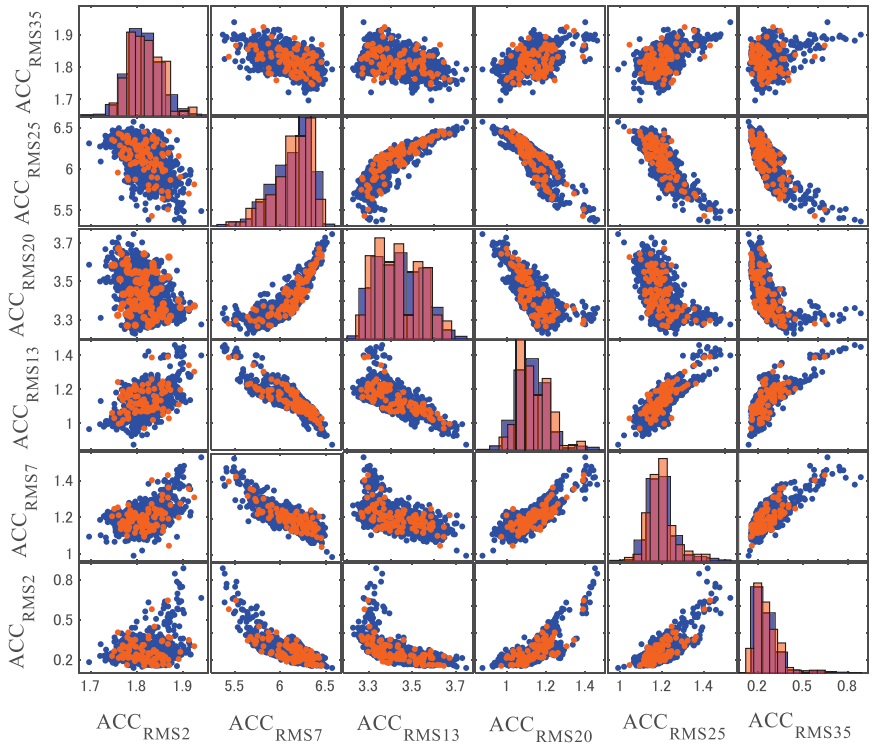

Figure 3: The target scatters (in orange) and updated output scatters (in blue).

Finally, updated values of the uncertain parameters are obtained by evaluating means of the posterior distributions, as detailed in Table 3. Percentage errors compared with the target values are also given in parentheses. The means have quite high updating precisions with errors less than 1%, while the standard deviations has relatively large errors more than 6%. Nevertheless, the final updated distributions of the outputs coincide well with the target distributions, as shown in Figure 3, demonstrating that the Bhattacharyya distance has successfully captured comprehensive uncertainty information from both model predictions and observation data.

Input	Target value	Updated value
μ_1	1.0	$1.0069(0.7\%)$
μ_2	1.0	$1.0081(0.8\%)$
μ_3	1.0	$0.9972(-0.3\%)$
σ_1	0.07	$0.0654(-6.6\%)$
σ_2	0.07	$0.0754(7.7\%)$
σ_3	0.07	$0.0654(-6.6\%)$

Table 3: Updated results of the uncertain parameters.

5 CONCLUSIONS

The Bhattacharyya distance is proposed as a comprehensive uncertainty quantification metric and a sequential procedure is introduced for its application for high dimensional time-series data. The proposed metric is utilized in Bayesian model updating and demonstrated through seismic-isolated bridge pier model example. Model parameters including the post-yield stiffness of the rubber bearing, which cannot be captured by modal responses, are successfully updated using seismic response data. Moreover, the proposed uncertainty quantification metric can handle rather than input parameters, but their uncertainty distribution characteristics, such as the calibrated model can represent the probability distribution of the time-series outputs as same as the multiple observations. As mentioned in Section 3.1, the selection of the predefined time segment Δt_0will affect the updating results and its computational burden, thus the investigation of the suitable value for the time segment should be addressed in the future work.

Keywords: Fiber Beam-Column Element with Bond-Slip, Steel corrosion, Unscented Kalman Filter, Model Updating

Abstract. *This paper proposes an innovative methodology to estimate the mechanical properties of corroded reinforced concrete (RC) structures based on recorded seismic response data. The essential idea of this approach is to combine the recursive Bayesian inference method with advanced finite element (FE) modeling strategies to estimate the corrosion-affected model parameters. Specifically, in the advanced FE model for corroded RC structures, the effect of corrosion in steel reinforcements (e.g., deteriorated bond-slip) are taken into account. The corrosion-affected model parameters are estimated by minimizing the model-predicted response and the measured response for an instrumented structure during an earthquake through recursive Bayesian inference (i.e., unscented Kalman filter). In this study, simulated seismic response data with additive noise is used for two application examples to demonstrate the proposed methodology with a focus on the deteriorated bond-slip only. The first application example considered consists of a statically tested column with real corrosion. An FE model is developed for this column with validation based on the static test and used to simulate seismic response data for demonstration purposes. The second application example considers an uncorroded bridge column which was tested on a shake-table. The FE model developed for this column is validated based on the shake-table test data and used to simulate the seismic response data for a corroded column where artificial corrosion is assumed. The successful estimation of the model parameters for corroded columns shows that the proposed methodology can potentially be used to identify the unknown mechanical properties of real-world corroded RC structures using recorded seismic response data.*

1 INTRODUCTION

Aging reinforced concrete (RC) structures are under high risk of deteriorations, such as corrosion in aggressive environments. Understanding the seismic performance of these corroded RC structures is one of the major requirements in the field of structural engineering, which assists the decision-making for aged RC structures. To this end, a twofold study is required: first, a computationally efficient finite element (FE) modeling approach, which is able to capture all the aspects of corrosion-induced structural properties; second, a nonlinear FE model updating (FEMU) methodology, which can automatically adjust the nonlinear behavior of the structure based on the measured response.

To quantify the effect of corrosion on the structural performance, several studies have focused on the corrosion-affected behavior of RC structures considering the steel mass loss ratio as a measure of corrosion level [1,2]. However, the common assumption in these studies is perfect bonding between reinforcing steel and the surrounding concrete (i.e., identical axial strain for rebars and concrete). In order to investigate the true performance of corroded RC structures, the corroded bond-slip behavior is required to be incorporated in nonlinear FE modeling, such as implied in [3–5]. In this study, the innovative fiber beam-column element with bond-slip that is developed by [6], enhanced and implemented recently in *OpenSees* [7] by the authors [5], is employed. This element introduces additional degrees of freedom for steel movement to account for the relative slip between steel rebars and the surrounding concrete, in which an explicit bond-slip relationship is considered. Hence, the effect of corrosion on bonding properties can be integrated into the bond-slip model used in the FE model for corroded structures. In this study, the corroded bond-slip behavior is implemented by combining the commonly used bond-slip model for uncorroded structures proposed by Eligehausen et al. [8] with the corrosion model for bonding properties per [3].

In order to develop a nonlinear FE model, which is able to predict accurately the measured structural response, a nonlinear FEMU approach is required. Several studies have proposed different techniques for nonlinear FEMU, including Bayesian inference or stochastic filtering methods, such as extended Kalman filter (EKF) and unscented Kalman filter (UKF). Some recent studies have applied EKF to nonlinear FEMU problems using simulated seismic response data (e.g., [9]); however, this approach has limited capability when applied to highly nonlinear problems because it is based on Taylor series expansion for linearization in first-order approximation of statistics. By contrast, the UKF, another stochastic filtering method based on the Kalman filter, uses the unscented transform for more accurate estimation of the first-order and second-order statistics (i.e., mean, covariance) [10]. The broad use of this method in the literature (e.g., [11–13]) indicates its robustness to solve nonlinear FEMU problems. However, to the best knowledge of the authors, the aforementioned stochastic filtering methods have not been utilized for system identification of corroded structures (e.g., health condition assessment of aged structures). The research work presented here consists of the first of its kind in the literature.

This study focuses on the identification of corroded bonding properties in RC columns using simulated seismic data with various noise levels. For this purpose, two experimental RC columns are considered: a statically tested RC column with real corrosion [14] and a shake-table tested RC bridge pier column with no corrosion [15]. The nonlinear FE model for these two columns are both validated and used to simulate seismic response data based on two columns with artificial corrosion for nonlinear FEMU. These two application examples demonstrate the capability of Bayesian inference to estimate the corroded bond-slip properties in aged RC structures after a brief description of stochastic inference method (i.e., UKF) used in this study.

2 CORROSION MODEL FOR BOND-SLIP

The rebar corrosion in aged RC structures influences the bond-slip behavior and reduces the contribution of steel rebars due to diminished composite action between steel and concrete. To account for such effect, this study proposes a corroded bond-slip model, which employs the bond-slip behavior for uncorroded RC structures developed by Eligehausen et al. [8] and the corrosion-induced modification factors for bonding properties [3], denoted as Kivell model. In this model, the maximum bonding stress, t_1^c, and the residual bonding, t_3^c, are both related to the corrosion level K, which is defined as the percentage of reinforcement mass loss ratio. The corroded properties t_1^c and t_3^c are defined according to Eq. (1) and Eq. (2), respectively.

$$\frac{t_1^c}{t_1^0} = \begin{cases} 1.2e^{-0.076K} \le 1.0 & K > 3\% \\ 1.0 & K \le 3\% \end{cases} \tag{1}$$

$$\frac{t_3^c}{t_1^c} = \begin{cases} 0.26 + 0.13K & 0 \le K < 3\% \\ 0.65 & 3\% \le K < 13\% \\ 0.65 - 0.06(K - 13) & 13\% \le K < 20\% \\ 0.23 & K \ge 20\% \end{cases} \tag{2}$$

In addition to the corrosion-induced reduction in the above properties for the bond-slip model, the cumulative damage factors are used in cyclic behavior to characterize the corrosion-affected degradation in the hysterical behavior. Readers of interest are referred to [3] for details. Such a corroded bond-slip model is implemented in *OpenSees* by the authors [5].

3 FE MODEL VALIDATION OF RC COLUMNS

The two RC columns considered in this study are both modeled through a newly developed fiber beam-column element with bond-slip in *OpenSees* by the authors [5] and validated based on the experimental data. Both validated nonlinear FE models will be used later in this study to simulate seismic response data after introducing artificial corrosion to the bonding.

3.1 Corroded RC column

The first RC column considered in this study is a corroded RC column tested under the static cyclic loading, denoted as Meda column [14], which is corroded so that the mass loss ratio of the longitudinal reinforcement (i.e., corrosion level) is equal to 20%. Figure 1(a) represents the geometry and section details for this column. The column is modeled with the newly developed fiber beam-column element with bond-slip in *OpenSees*, and the corroded bond-slip model mentioned earlier is used to consider the degraded bond-slip properties. Additionally, for the purpose of model validation, the other corrosion effects for the tested column are also taken into account, including the corresponding concrete cover spalling due to volumetric expansion of steel because of corrosion products, the reduced strength of concrete according to [16,17], rebar cross-section area reduction as well as the steel strength reduction caused by pitting corrosion [18]. The same loading protocol as the experiment is used to simulate the cyclic load-deflection curve of the corroded column in the experimental test. To emphasize the importance of corroded bond-slip, the case with perfect bonding but all other corrosion effects is also considered here for comparison. Figure 1(b) shows the resultant force-drift ratio hysteresis for the perfect bonding case by the gray solid curve, the corroded bonding case by the black solid curve, and experimental results by the dashed black curve. The FE model predictions with corroded bonding are in good agreement with the experi-

mental results until reaching the deformation level of about 2.0% drift ratio. It is worth mentioning that the pinching behavior (or less energy dissipation) is captured well comparing to the perfect bonding case, since this effect is dominated by bond-slip. However, the strength degradation at large deformation levels is not captured due to buckling of the reinforcement [14], while the effect of buckling are beyond the scope of this study.

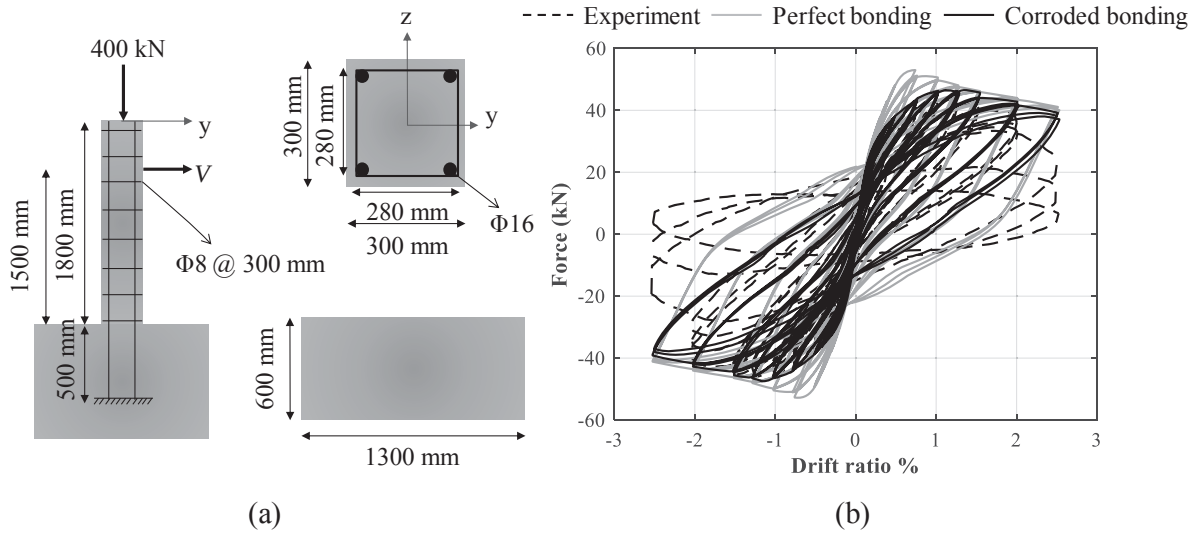

Figure 1: Meda column: (a) geometry and section details, and (b) force-drift ratio hysteresis comparison between FE and experimental prediction

3.2 Uncorroded RC column

The uncorroded RC column considered here is a RC bridge column tested under earthquake loading on the shake table at the University of California, San Diego in 2010, denoted as UCSD column [15]. Figure 2(a) describes the geometry and section details. This column is subjected to a sequence of 10 earthquake ground motions, and the first one: Loma Prieta ground motion recorded at Agnew State Hospital with a moment magnitude of 6.9, is considered. Similar to the previous column, it is modeled by the newly developed fiber beam-column element with bond-slip in *OpenSees*. The time-history of the top drift ratio is plotted in Figure 2(b) for the RC column with perfect bonding in comparison with the experimental results. Additionally, Figure 2(c) describes the top drift ratio time-history for the RC column with imperfect bonding (i.e., uncorroded normal bonding) compared to the experimental results. As indicated, the response of the model with imperfect bonding is in a proper correlation with the experiment compared to the model with perfect bonding, which implies the importance of bond-slip in the prediction accuracy of nonlinear FE models for RC columns.

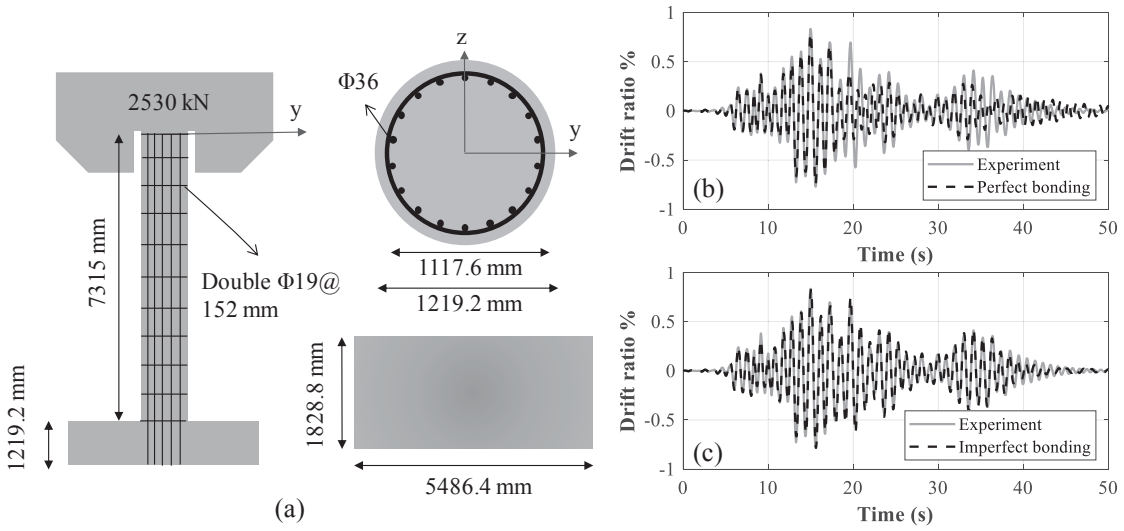

Figure 2: UCSD column: (a) geometry and section details, (b) top drift ratio time-history comparison between FE prediction with perfect bonding and experiment, and (c) top drift ratio time-history comparison between FE prediction with imperfect bonding and experiment

4 STOCHASTIC INFERENCE FOR PARAMETER ESTIMATION

Direct measurements of the corroded bonding properties are challenging and thus the accurate modeling parameters are not readily available. Such uncertainties in the FE modeling aspects can compromise the predictability of the model and in turn bias the residual performance evaluation of aged RC structures with corrosion. As such, reliable estimation of the parameters is needed for better simulation and for damage/condition assessment. Nonlinear parameter estimation using stochastic inference, such as UKF [10], can be integrated with nonlinear FE modeling to identify such uncertain modeling aspects by performing nonlinear FEMU, if other measurements are available. Such a strategy is briefly summarized as follows.

The unobservable time-invariant vector $\boldsymbol{x}$, containing unknown/uncertain FE model parameters, is represented as a random walk process in UKF (i.e., a linear state-transition equation); see Eq. (3):

$$\boldsymbol{x}_k = \boldsymbol{x}_{k-1} + \boldsymbol{w}_{k-1} \tag{3}$$

where the subscript k and $k-1$ denote the current and previous analysis steps, respectively; $\boldsymbol{w}$ is additive zero-mean white Gaussian noise (AWGN) with a diagonal covariance matrix $\boldsymbol{Q}$. The measurement (observation) vector of the system response, $\boldsymbol{y}$, is related to the unobservable vector, $\boldsymbol{x}$, through the nonlinear FE model prediction through the measurement equation, as shown in Eq. (4). In this equation, a prediction error vector $\boldsymbol{v}$, which is a zero-mean white Gaussian noise vector with a known covariance matrix $\boldsymbol{R}$, is used to model the inherent model uncertainty and the measurement noise in $\boldsymbol{y}$.

$$\boldsymbol{y}_k = \boldsymbol{h}_k(\boldsymbol{x}_k, \ddot{u}^g_{1:k}) + \boldsymbol{v}_k \tag{4}$$

Here, $\boldsymbol{h}_k(\boldsymbol{x}_k, \ddot{u}^g_{1:k})$ represents the simulated structure response at analysis step k. It is evaluated by analyzing the nonlinear FE model with the current model parameter vector $\boldsymbol{x}_k$, subjected to the earthquake ground motion acceleration series until the current time step.

By defining the state-transition and measurement equations, stochastic inference (e.g., UKF) can be utilized to estimate the posterior mean vector $\boldsymbol{\mu}_k^{\boldsymbol{xx}}$ and the corresponding covariance matrix $\boldsymbol{P}_k^{\boldsymbol{xx}}$ of $\boldsymbol{x}_k$ recursively when more observations are available as time evolves. This

is to incorporate the information obtained from experimental observations in a Bayesian framework at time step k. Compared with other Bayesian methodologies, Kalman filter-based approach allows efficient updating through the Kalman gain matrix, which is introduced as a weight measure based on the difference between the prediction ($\boldsymbol{h}_k(\boldsymbol{x}_k, \ddot{u}^g_{1:k})$) and observation (measurement) $\boldsymbol{y}_k$. The Kalman gain is calculated by the cross-covariance matrix between $\boldsymbol{x}_k$ and $\boldsymbol{y}_k$, $\boldsymbol{P}_k^{xy}$, and the covariance matrix of $\boldsymbol{y}_k$, $\boldsymbol{P}_k^{yy}$. By applying UKF, the values of $\boldsymbol{P}_k^{xy}$ and $\boldsymbol{P}_k^{yy}$ are estimated by unscented transform, in which a series of sigma points (SPs) are deterministically defined by $\boldsymbol{P}_k^{xx}$ and $\boldsymbol{\mu}_k^{xx}$ and the nonlinear FE model is evaluated as these SPs. Readers of interest are referred to [11,19] for details.

5 NONLINEAR FINITE ELEMENT MODEL UPDATING

The validated FE models for the two RC columns (i.e., Meda column and UCSD column) are used here to demonstrate the potential in estimating corrosion-affected parameters by a nonlinear FEMU strategy, integrating stochastic filtering and efficient FE modeling for corroded RC structures. For this purpose, the bonding properties of these two columns, t_1 and t_3, are assumed to be degraded due to artificial corrosion. Both of these columns are subjected to earthquake excitations, which are chosen purposely to have a short duration in order to save computational cost but without loss of generality. For the Meda column, the Loma Prieta earthquake recorded at Agnew State Hospital station is selected from the Next-Generation Attenuation ground motion database [20]. This ground motion is so scaled to reach the ductility demand (i.e., deformation demand with respect to the yield deformation) of 2.0 for the Meda column. The ground motion selected for the UCSD column is the Kobe earthquake (1995) recorded at the Takatori station [20]. This ground motion is scaled so that the ductility demand of 8.0 is reached for the UCSD column, where significant nonlinearity is involved in this column. The nonlinear FEMU strategy is employed to identify corroded t_1 and t_3 for these columns with different corrosion levels in the column and different noise levels in the measurements (e.g., the displacement at the top of the column used in this study).

5.1 FEMU of Meda column with different corrosion levels

To investigate the capability of the proposed methodology for identifying the corrosion-affected bonding properties, this study considers two levels of corrosion for the Meda column: 16% mass loss ratio as a medium level, and 24% mass loss ratio as a high level. The corrosion level corresponds to the age of the column and is dependent on the cover concrete, environmental conditions, etc. [1,18]. For the Meda column with a relatively small thickness in concrete cover, 16% and 24% corrosion levels represent the age of the column to be about 25 and 40 years in medium corrosion intensity situation, respectively. The effect of corrosion on the bonding properties (i.e., t_1 and t_3) is focused in this study. For 16% corrosion level, the ratios of the corroded to uncorroded values for t_1 and t_3 are equal to 0.33 and 0.48, respectively, per the Kivell model [3]. Similarly, the corroded to uncorroded ratios for t_1 and t_3 are 0.24 and 0.14 for the Meda column with 24% corrosion level.

Since no experimental observations are available, seismic simulation data, which are generated through the nonlinear FE model for the Meda column with corroded bond-slip, i.e., degraded t_1 and t_3 (denoted as the true parameters), are used. Note that in this section, accurate measurement from high precision sensors is assumed, and thus no noise is considered. In this study, only one observation is used, i.e., the time-history of the top drift ratio of the column subjected to the earthquake ground motion. Using the observations, the corroded bonding parameters considered here will be estimated through UKF.

In UKF, the initial guess for the bonding properties are assumed to be those for the uncorroded case. Figure 3(a) shows the time-history of the drift ratio of the Meda column with 16% corrosion level based on the initial set of parameters (i.e., before updating) with comparison to the observation. The observation is presented as true finite element analysis (FEA) and the initial response is denoted as initial FEA. By using the aforementioned UKF, the corroded bonding properties (t_1 and t_3) are updated. Figure 3(b) demonstrates the FE prediction of the same column after updating with comparison to the observation. Comparing Figure 3(a) and (b) indicates the FE prediction is improved significantly, and a near-perfect correlation is achieved using the updated model parameters. For more details, the updating histories for t_1 and t_3, are presented in Figure 4(a) and (b), respectively, in addition to their 95% confidence intervals (CI). The first parameter (t_1) is converged to the true value in the very beginning and the uncertainty in this parameter estimation decreases significantly since it is corresponding to the stiffness and yield stress of the bonding behavior. On the other hand, the second parameter (i.e., t_3) is converged later as expected but with only a slight reduction in the uncertainty. The reason lies in the fact that this parameter is to be influential after the bond yielding.

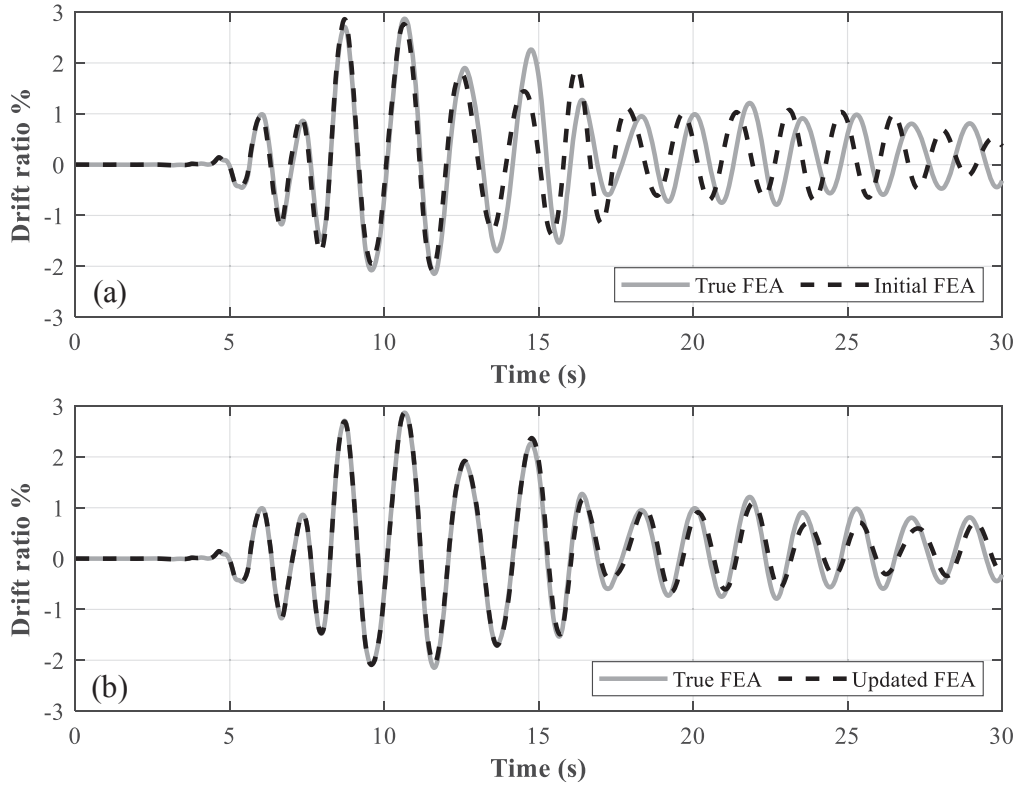

Figure 3: Time-history of drift ratio for Meda column with 16% corrosion level and zero noise in the observation: (a) before and (b) after updating

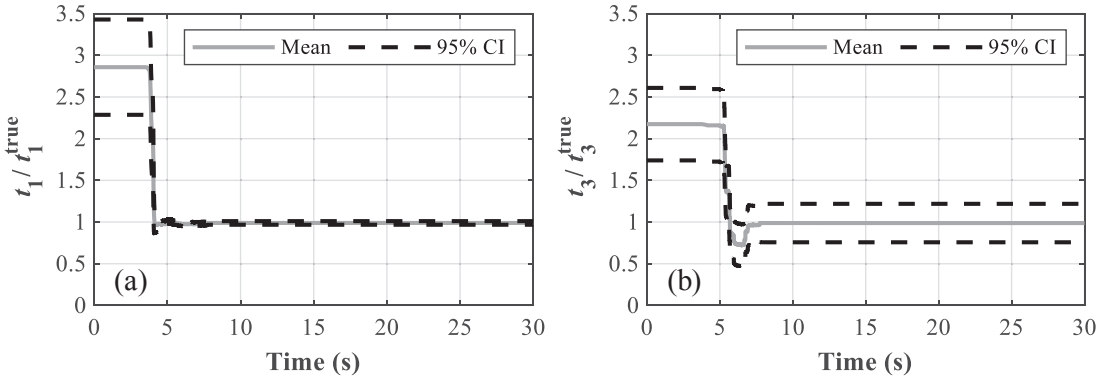

Figure 4: Updating history for (a) t_1 and (b) t_3 for Meda column with 16% corrosion level and zero noise in the observation

Similarly, the Meda column with a high-level corrosion is studied. Figure 5(a) and (b) show the time histories of the top drift ratio predicted from the FE model based on the bonding properties before and after updating in comparison with the observation (i.e., true FEA results). The comparison shows that nonlinear FEMU has led to a notable improvement in the FE prediction for this column with a high corrosion level as well. Therefore, it can be concluded that the proposed FEMU approach is also able to capture the effect of corrosion on the bonding properties in different levels. Similar to the previous case, the updating histories of t_1 and t_3 are presented in Figure 6(a) and (b), respectively. Note that in this case, due to the high level of corrosion, the bond yielding occurs at the earlier time step than the previous case and hence, t_3 would be updated earlier as well, and the associated uncertainty is reduced more.

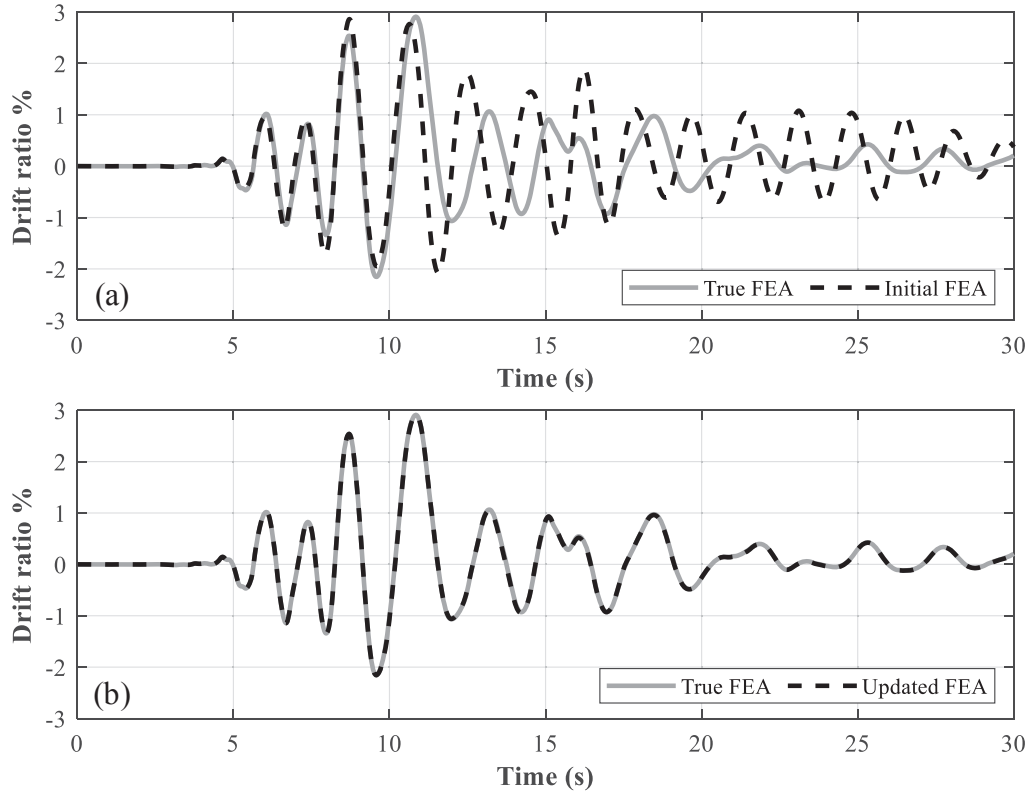

Figure 5: Time-history of drift ratio for Meda column with 24% corrosion level and zero noise in the observation: (a) before and (b) after updating

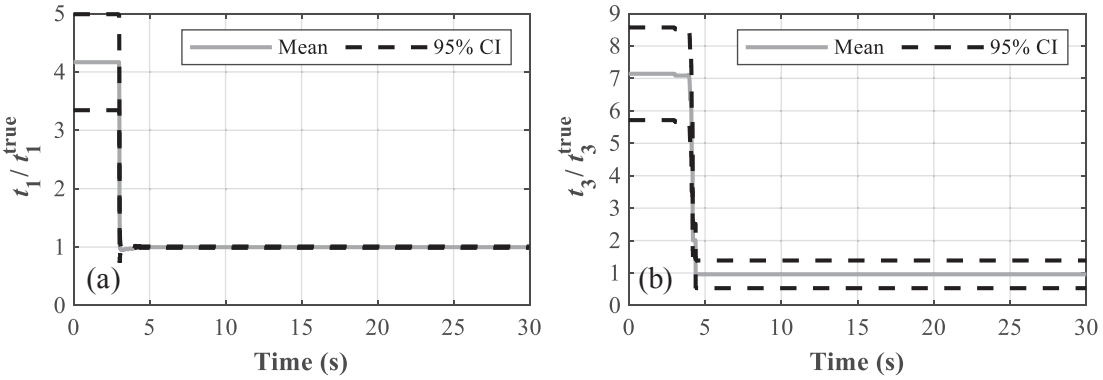

Figure 6: Updating history for (a) t_1 and (b) t_3 for Meda column with 24% corrosion level and zero noise in the observation

5.2 FEMU of Meda column with different noise levels

In the previous section, the observations are assumed to be noise-free. However, in reality, the observations are typically involved with various levels of noise, which may pollute the measurements and thus affect the updating process. To show the robustness of the proposed methodology for corrosion-affected parameter estimation in RC structures, this section considers the polluted observation with different levels of noise. As such, a medium and a high level of AWGN, with a standard deviation of 2% and 5% of the maximum response (i.e., maximum displacement), respectively, are considered here to contaminate the prediction from the true FE model defined earlier for the Meda column with 16% corrosion level. Figure 7(a) and (b) show the comparison between the time-histories of top drift ratio before and after updating based on the observation with 2% noise, for the Meda column under the effect of 16% corrosion level. In addition, Figure 8(a) and (b) present the updating histories of t_1 and t_3 corresponding to this case. The comparison reveals the employed methodology is able to update the parameters so that the FE prediction is in a good agreement with the observation, even though a low-level measurement noise (2%) exists. However, the estimation for t_3 is more challenging when noise comes into play.

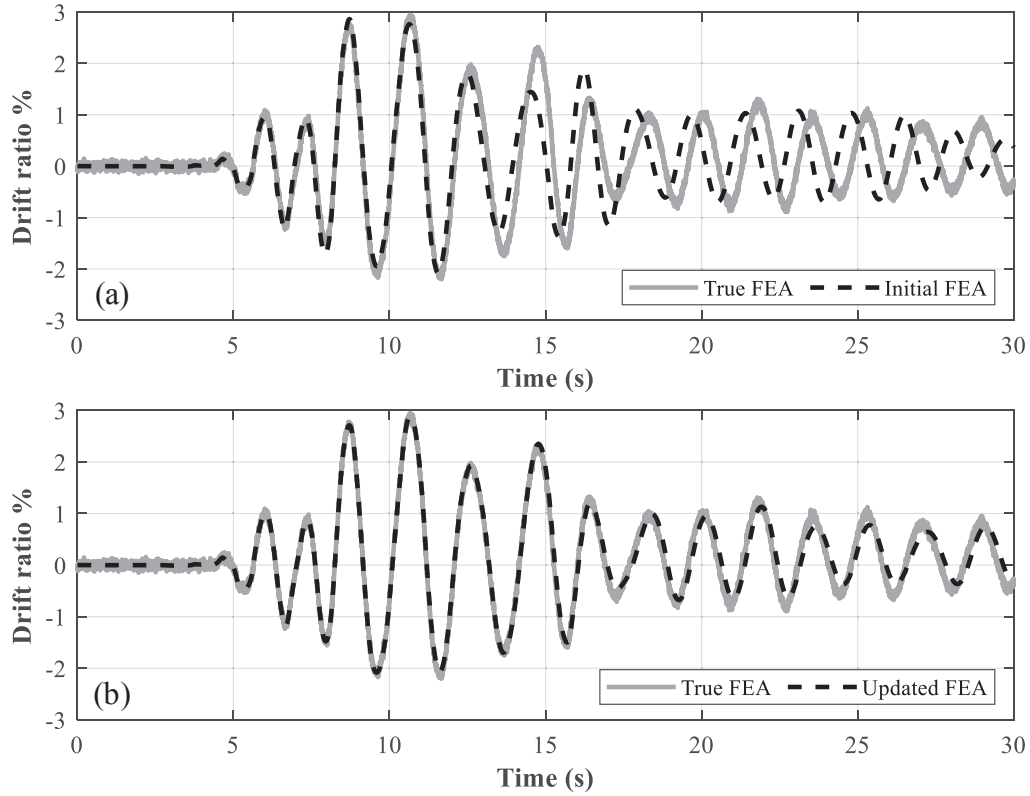

Figure 7: Time-history of drift ratio for Meda column with 16% corrosion level and 2% noise in the observation: (a) before and (b) after updating

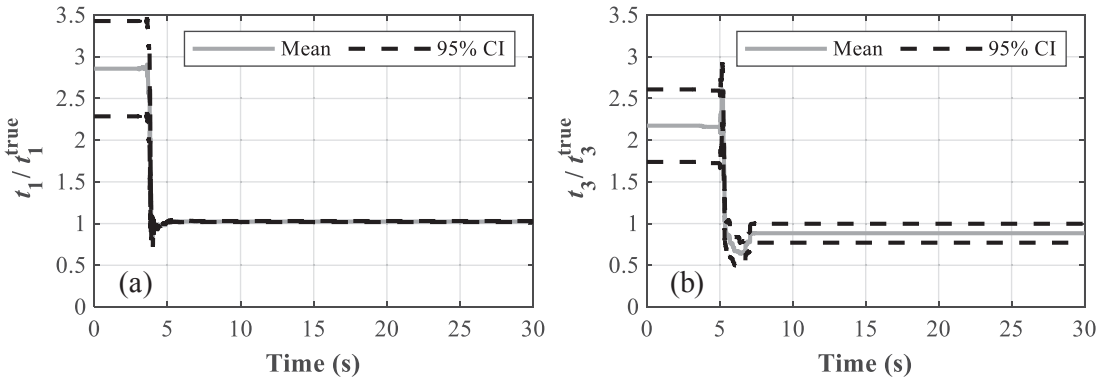

Figure 8: Updating history for (a) t_1 and (b) t_3 for Meda column with 16% corrosion level and 2% noise in the observation

The higher level of noise (i.e., 5% AWGN) is considered here. The nonlinear FE model is updated through UKF, and the predicted responses before and after updating are illustrated in Figure 9(a) and (b), respectively. Similar to the previous cases, the updating histories of t_1 and t_3 are displayed in Figure 10(a) and (b). The demonstrated results of this case reaffirm UKF is able to update the corroded bonding properties properly, even when a relatively high level of noise (5%) exists. Note that according to Figure 10(b), similar to Figure 8(b), the final values of t_3 are different from the true value. This difference mainly stems from the additive noise considered for these two cases, which affects the accuracy of the updating results. However, the global behavior of the column is not significantly sensitive to this parameter (i.e., t_3) and hence, the drift ratio time-history is still in a good agreement with the true FE results.

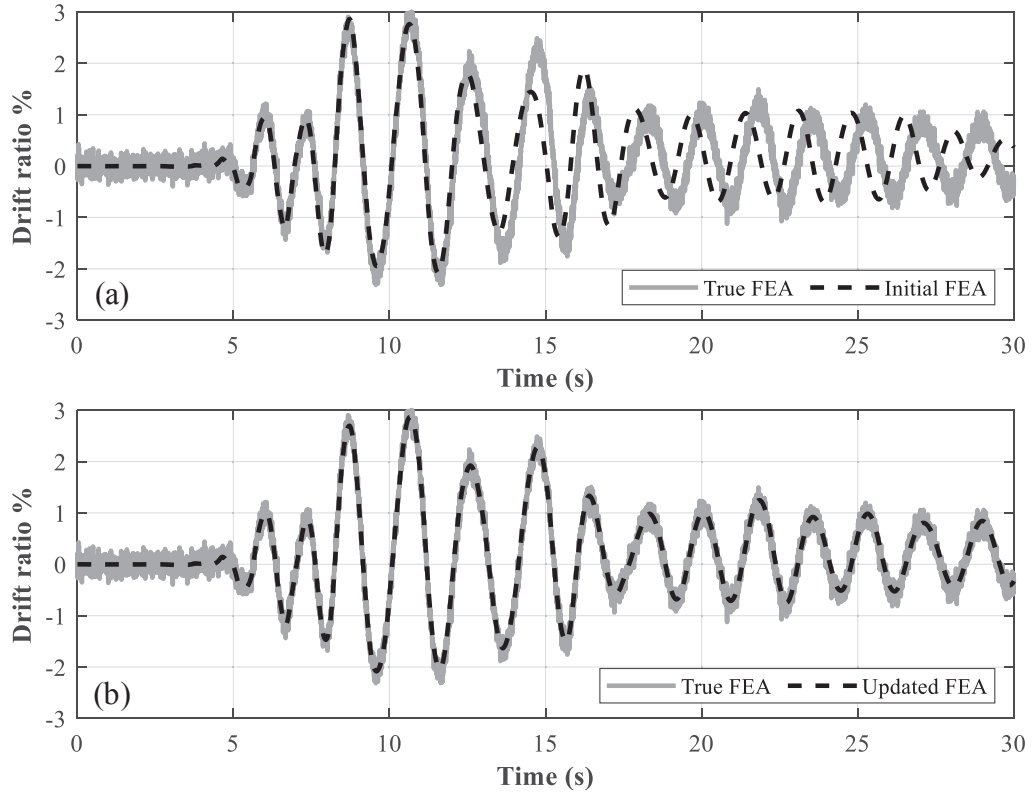

Figure 9: Time-history of drift ratio for Meda column with 16% corrosion level and 5% noise in the observation: (a) before and (b) after updating

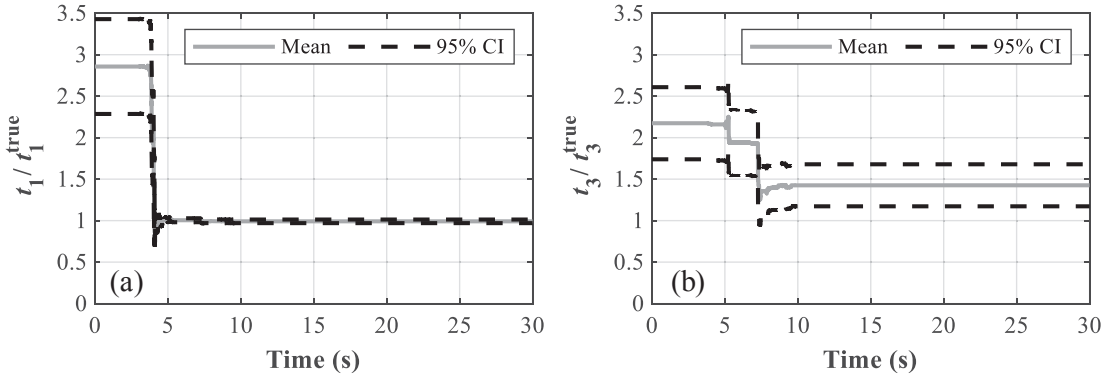

Figure 10: Updating history for (a) t_1 and (b) t_3 for Meda column with 16% corrosion level and 5% noise in the observation

5.3 FEMU of UCSD column under high-intensity excitation

In addition to the Meda column, UCSD column with artificial corrosion (16% corrosion level) is also considered. The ratio of corroded to uncorroded t_1 equals to 0.33, and the ratio of corroded to uncorroded t_3 equals to 0.63, per [3]. This developed RC column with these parameter values is assumed to be true FE and used to generate observations during the selected earthquake with a high seismic ductility demand. Figure 11(a) and (b) display the time-histories of the top drift ratio before and after updating with comparison to the observation, respectively. In addition, the updating histories for t_1 and t_3 are shown in Figure 12(a) and (b). According to Figure 11, the updated response is in a better correlation with the observation than the initial FEA responses. Note for the UCSD column with 16% of corrosion, the bond-

slip behavior stays in a range that the residual stress (i.e., t_3) does not play a significant role and then, the parameter is not altered in the updating process but the uncertainty is reduced due to the relative strong excitation.

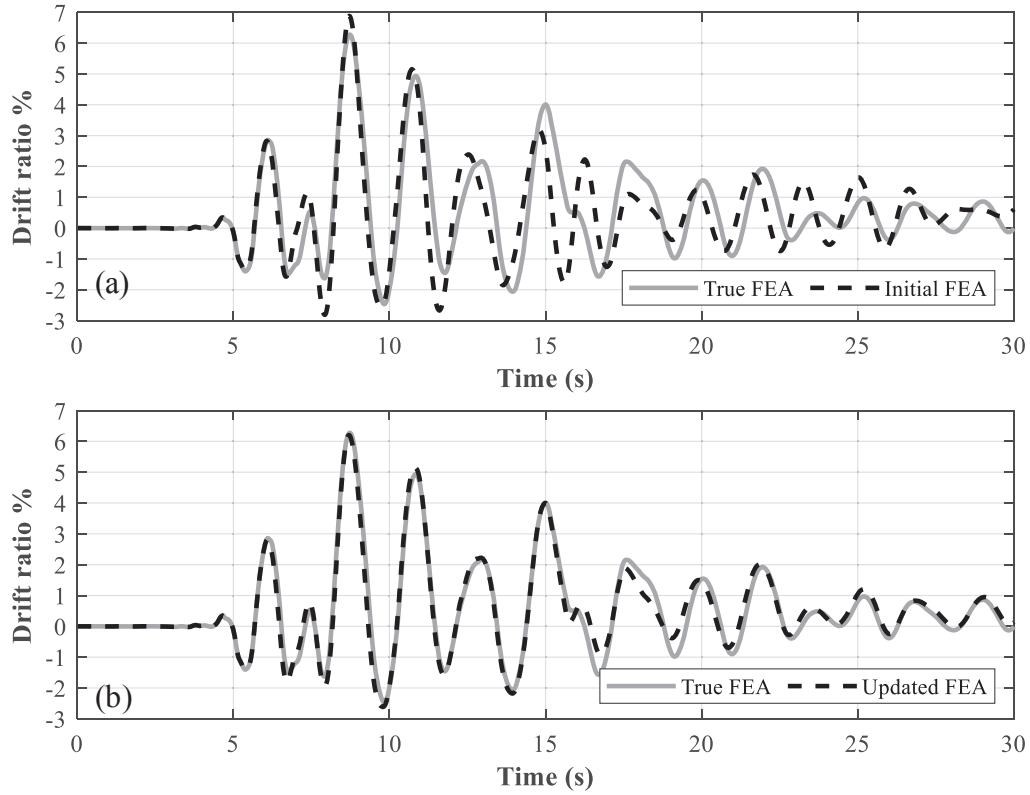

Figure 11: Time-history of drift ratio for UCSD column with 16% corrosion level and zero noise in the observation: (a) before and (b) after updating

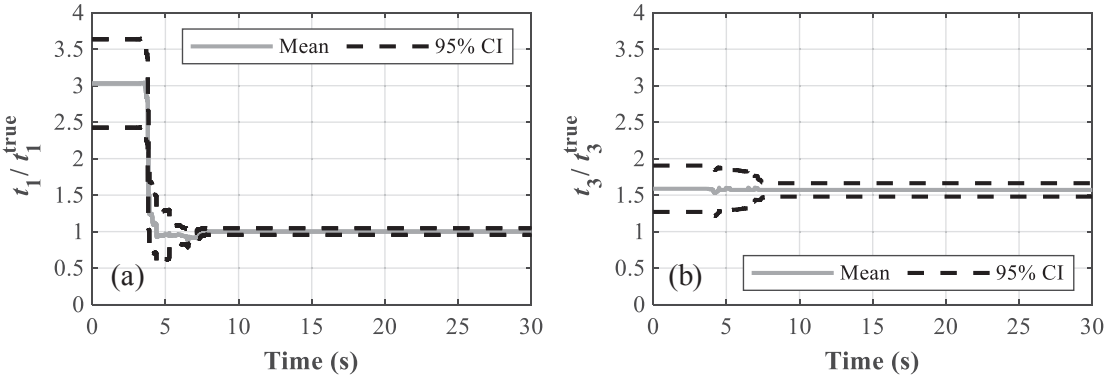

Figure 12: Updating history for (a) t_1 and (b) t_3 for UCSD column with 16% corrosion level and zero noise in the observation

6 CONCLUSIONS

This study proposes integrating stochastic filtering, such as the unscented Kalman filtering (UKF) strategy, with nonlinear FE model for corroded concrete structures, to estimate the corroded bond-slip properties based on global response observations (i.e., displacement history). To this end, a newly developed fiber beam-column element with bond-slip is used to model two RC columns. The FE models of the two considered RC columns are validated based on

the available experimental data. However, the measured responses utilized for parameter estimation in this study are simulated data from the nonlinear FE model of the RC columns with artificial corrosion. Different levels of corrosion and noise are considered. The presented study shows that the proposed methodology can successfully estimate the corroded bond-slip properties and significantly improve the model prediction accuracy. It indicates that the methodology adopted in this study is promising to be used for condition assessment of aged RC structures based on recorded seismic response data.

Abstract. *The reliable design of power electronics for automobiles is one of the major challenges in the advancing electrification of the powertrain. The printed controller boards (PCB) in particular are affected by the demanding operating conditions. The objective of this ongoing investigation is to analyze the effect of different joining technologies between the PCB and the casing on the reliability. Therefore, a structural health monitoring (SHM) concept is presented based on a Bayesian model updating framework that monitors changes in the stiffness of the joint connection. To cope with the computational challenges associated with the approach, parametric model order reduction is applied. The concept is validated by a generic use case where one of the joints has a sudden loss of stiffness.*

1 INTRODUCTION

The advancing electrification of the powertrain in automobiles introduces new components and hence new challenges for a reliable design. One of those components is the Power Electronical Unit (PEU) that transforms the direct current (DC) from the battery to an alternating current (AC) for the electric motor. The power electronic operates in demanding environments resulting in a challenging task for a reliable design. Depending on the component, different stressors come into play - e.g. high temperatures, temperature cycling, humidity, dust or vibration can endanger safe operation [1]. Due to their complex design and uneven mass distribution, vibrations are the main stressors for printed circuit boards (PCBs) [2]. The present work illustrates the current state of an ongoing investigation analyzing the effect on the reliability of different joining technologies connecting the PCB to the casing. The goal of the investigation is to replicate stresses on the PCB in an automobile on a test rig and analyze the effect of different joining technologies on the vibration behavior and derive the change in reliability from it. The power electronics and especially the PCB are crucial components where failure can lead to serve accidents. Therefore, a structural health monitoring (SHM) strategy for the experiment as well as later applications in the automobile is presented that monitors changes in the vibration behavior due to loosening of bolt connections between the PCB and the casing. SHM strategies have been used for a long time for monitoring structures like bridges [3, 4] or skyscrapers [5]. Due to the advancements in sensor technology and signal processing in recent years, those strategies are applied to other engineering structures like milling machines [6] and composite structures [7]. SHM methods can be divided into two groups: model based and feature based methodes [8]. *Model-based methods* correlate the observational signatures of abnormal structures with analytical or quantitative models to detect the damage parameters [8]. Common methods are autoregressive and moving average (ARMA) model [9], hidden Markov model (HMM) [10] or artifical neural network (ANN). In contrast to that, *Feature-based methods* are based on a two step process. The first step is the extraction of features (e.g. eigenfrequencies, mode shape, damping rations) and the second one is the interpretation of these features. The interpretation is usually performed by classical model updating algorithms [11–13]. Structural model updating methods are essentially a process of adjusting uncertain parameters of a finite element model by comparing it to measurement data. For the application of SHM classical deterministic gradient-based model updating methods have a disadvantage to probabilistic methods because of their tendency to converge into local minima. Probabilistic methods are based on stochastic simulation algorithms such as Markov Chain Monte Carlo (MCMC) [14] and Transitional MCMC [15, 16]. Model updating algorithms involve a moderate to very large number of FE reanalyses. For complex systems that easily involve hundreds of thousands of degree-of-freedom (DOF), the computational effort is too high for time-critical operations. Therefore, different approaches are used to reduce the analysis time ranging from the use of model order reduction techniques [17], surrogate models [18], and code parallelization [19,20]. Most often component mode synthesis (CMS) techniques [17], e.g. Craig-Bampton, are applied to carry out system analysis in a reduced space and to decrease the computational effort that arises from the variation of uncertain parameters [21, 22]. In the usual workflow, the structures under consideration are separated into substructures [3] and reassembled allowing the alteration linearly depended system parameters like stiffness, density or thickness of shell elements. To decrease the computational effort the reassembled system matrix can be further reduced [3, 23], avoiding the re-assembly of the reduced system matrices from the original matrices. This leads to solving the eigenproblem of the reduced-order model being the only time consuming analysis step.

Within this work, the development of the real-time capable parametric model of the test rig and a generic use case are presented. The use case includes the data acquisition from a time-domain simulation model, signal processing, modal parameter extraction by an operational modal analysis, data clustering and mode matching by a k-Means algorithm as well as the implementation of Bayesian SHM approach to monitor changes in the stiffness of the joint parameter.

2 STRUCTURAL HEALTH MONITORING USING MODAL CHARACTERISTICS

This paper presents details of the application of a Bayesian probabilistic framework that allows online SHM to monitor stiffness changes in the mounting of a PCB in an automobile by analyzing modal data (eigenfrequencies and modeshapes) from ambient vibration. The identified modal parameters are clustered by a k-Means algorithm [24] to enable a classification based on multiple previous measurements, therefore taking uncertainties into account and allowing a framework of inference in the presence of incomplete data [25]. The evaluation of the Bayesian framework is carried out by the so-called Transitional Markov Chain Monte Carlo (TMCMC) algorithm [15].

2.1 Bayesian formulation

The Bayesian model updating framework is based on the Bayes' Theorem, which is formulated in [26]. Adjusted to structural model updating, the Bayes' Theorem [12, 27] is described by

$$P(\theta|D,M) = \frac{P(D|\theta,M)P(\theta|M)}{p(D|M)}, \tag{1}$$

where M denotes the model class, D denotes the experimental data, which consists of the measured modal properties of the structure under consideration, and θ describes the parameter vector of the unknown, adjustable model parameters. The posterior distribution $P(\theta|D,M)$ expresses the conditional probability of θ on the prior probability $P(\theta|M)$ and the experimental data. The likelihood function $P(D|\theta,M)$ is a measure of agreement between the measured data D and the model out for a given data set θ.

The formulation of the likelihood function using modal data is derived in [25]. The experimental data obtain by an operational modal analyses algorithm is assumed to consist of N_s sets, $D = [\omega_{1,j}...\omega_{N_m,j}, \Phi_{1,j}\ ...\ \Phi_{1,N_m}]_{j=1}^{N_s}$ composed of N_m modal frequencies ω_r and N_m incomplete mode shape vectors $\Phi_r \in \Re_0^N$, where N_0 is the number of measured DOFs. The likelihood function can be written as

$$P(D|\theta,M) = c\,exp\left(-\frac{1}{2}\sum_{r=1}^{N_m} J_r(\theta)\right), \tag{2}$$

where $J_r(\theta)$ is given by

$$J_r(\theta) = \sum_{j=1}^{N_s}\left[\left(\frac{1-\omega_{r,j}^2/\hat{\omega}_r^2}{\epsilon}\right)^2 + (1-\frac{|\hat{\Phi}_r^T\Phi_{r,j}|^2}{(\hat{\Phi}_r^T\hat{\Phi}_r)^2})\Big/\delta_r^2\right]. \tag{3}$$

Here, $\hat{\omega}_r$ and $\hat{\Phi}_r$ denote the model eigenfrequenies and mode shapes respectively, while ϵ_r and δ_r denote the variance of the prediction error of the r-th eigenfrequency and mode shape.

2.2 Parametric model order reduction

One of the major drawbacks of the Bayesian model updating is the need for many iterations of solving the eigenvalue problem. For large FE-models, the computational effort might become infeasible. Therefore, a parametric model order reduction is performed. The mass and stiffness matrices of the substructures are exported individually and reassembled afterwards. The assembled system matrices here denoted as $\mathbf{M}_a$ and $\mathbf{K}_a$ can be represented by

$$\mathbf{M}_a = \sum_{i=1}^{N} \mathbf{M}_i^S \tag{4}$$

$$\mathbf{K}_a = \sum_{i=1}^{N} \mathbf{K}_i^S. \tag{5}$$

Calculating the transformation matrix (e.g. by modal model order reduction or Craig-Bampton reduction) of the assembled matrices the system can be reduced by

$$\mathbf{M}_{a,r} = \mathbf{T}^T \mathbf{M} \mathbf{T} = \mathbf{T}^T \left(\sum_{i=1}^{N} \mathbf{M}_i^S \right) \mathbf{T} \tag{6}$$

$$\mathbf{K}_{a,r} = \mathbf{T}^T \mathbf{K} \mathbf{T} = \mathbf{T}^T \left(\sum_{i=1}^{N} \mathbf{K}_i^S \right) \mathbf{T}$$

while maintaining the possibility of changing linearly dependent parameters of all subsystems. The parameterized system matrices can be describe as

$$\mathbf{M}_{a,r}(\theta) = \mathbf{M}_{a,r}^0 + \sum_{i=1}^{N_\theta} \mathbf{M}_{i,r}^S \theta_i \tag{7}$$

$$\mathbf{K}_{a,r}(\theta) = \mathbf{K}_{a,r}^0 + \sum_{i=1}^{N_\theta} \mathbf{K}_{i,r}^S \theta_i.$$

where $\mathbf{M}_{a,r}^0$, $\mathbf{K}_{a,r}^0$, $\mathbf{M}_{i,r}^S$, $\mathbf{K}_{i,r}^S$ are constant matrices independent of θ_i.

3 VIRTUAL PCB TEST RIG

The purpose of the virtual PCB test rig is to demonstrate the interaction between the different parts of the SHM concept and show the capabilities of the presented parametric model order reduction technique.

The FE simulation tool is used for developing the FE-model of the PCB. The model is constructed based on the design of the PCB that later will be used on the real test rig. For the PCB FR-4 material properties [28] are assumed. The capacitors are modeled as rigid mass points that are attached to the PCB by solder. The joint between the PCB and the casing is modeled by a spring element assuming the stiffness of a screw joint. For the simulation, three nodes are selected as sensors, highlighted in Fig. 1 by the red circles. The sensors are used for determining the modal parameters by an output only modal analyses algorithm.

The model is exported to the commercial numerical computing environment by an interface application. To test the capabilities of the presented model order reduction technique, the first 15 eigenfrequencies of the full and reduced model are compared for changing stiffness of one of the spring elements. The number of retained modes are 50, 70, 150, and 200 modes. Fig. 2 shows the fractional error for the first 15 eigenfrequencies for the case that the stiffness of one

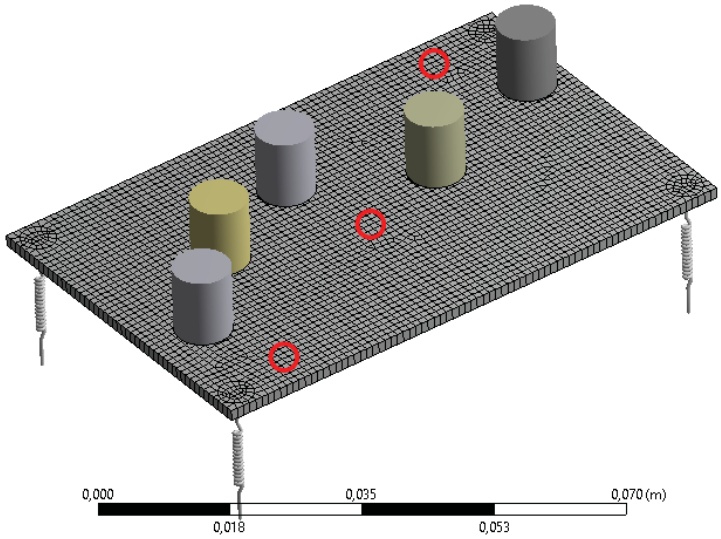

Figure 1: ANSYS model of the PCB with five capacitors. The joint to the casing is modeled by four spring elements. The sensor positions are highlighted by red circles.

spring element is multiplied by $\theta = 0.01$, hence showcasing a server change in stiffness of one of the screw joints. Even for a relatively small amount of retained modes the reduction shows only small errors. For the further analyses, 70 modes are used.

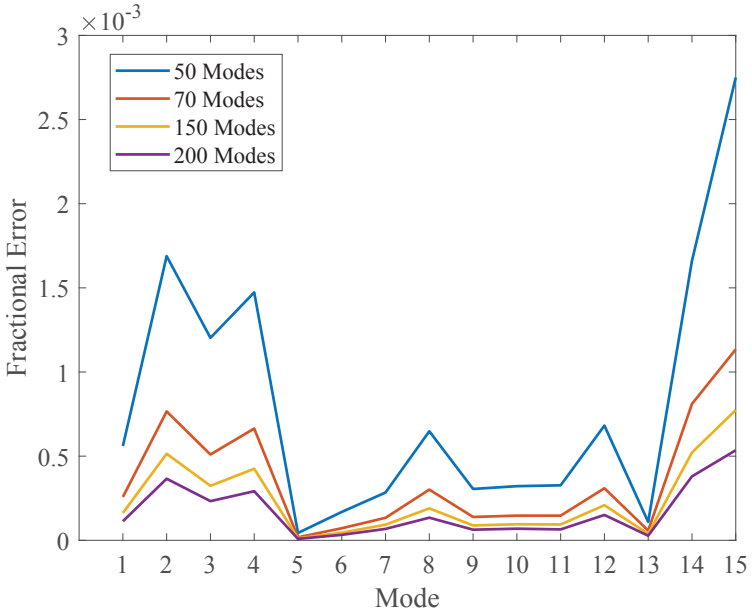

Figure 2: Fractional Error of the first 15 modes with different amount of retained modes for the model reduction.

The measurement data for the model updating and monitoring of the system is obtained by a Simulink model of the PCB that is excited by band limited white noise. The time signal of the three sensors is filtered by a 6th order Bessel filter with a cut-off frequency at 3 kHz to model the behavior of an analog acceleration sensor. The data acquisition is completed by rate transition block modeling the A/D converter. After each simulation (simulation time 50s), the digitized time data is analyzed by an automated operational modal analysis algorithm using k-Means clustering [24]. With the assumed sensor positioning the algorithm is able to consistently

identify 13 eigenfrequencies in the range from 20 Hz to 3 kHz. After each simulation, the new set of modal parameters is added to the data set used for model updating. To minimize the effect of uncertainties in the identification, the last 100 identified modal parameters are stored in the data set for model updating. A sudden loss of stiffness in one of the screws after five simulation steps is used to showcase the capabilities of the utilized Bayesian model updating framework. The starting values for the prior distribution are assumed to be normal distributed with $\mu(\theta) = 1$ and $\sigma(\theta) = 0.2$. The results in Fig. 3 show that the algorithm is capable of correctly identifying the damaged screw from the change in the vibration behavior. Due to of the data from previous measurements in the data set, a time delay in the identification is visible.

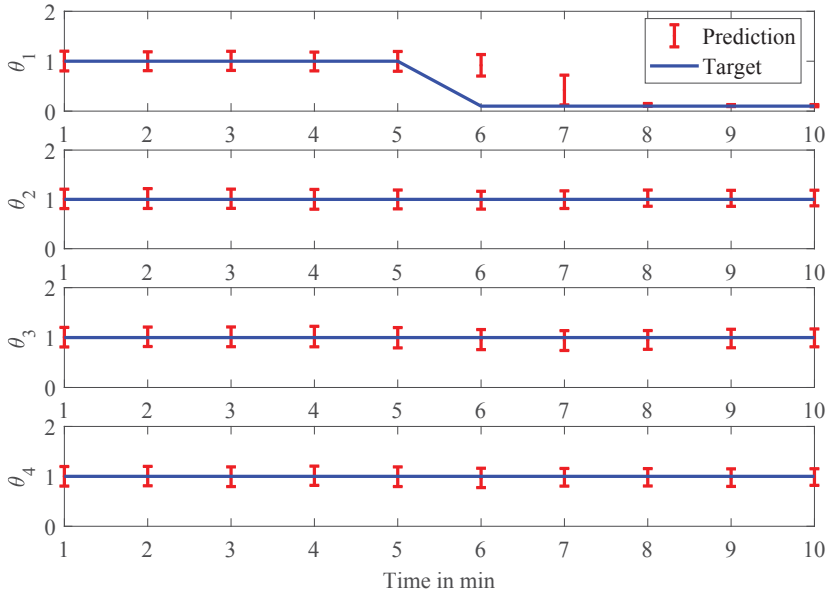

Figure 3: Test case to validate the used Bayesian model updating framework interacting with the SHM concept, showcasing a sudden stiffness loss in one of the screw joints after five time steps

Furthermore, the results show that the algorithm is only able to converge for the changed stiffness. This can be explained by the small sensitivity of the modal parameters due to the high stiffness of the joint connection.

4 Conclusion

In this paper, a SHM concept for a PCB test rig is presented and validated for a generic test case. The SHM is built around a Bayesian model updating framework that uses a parametric model order reduced model of the PCB test rig. The model reduction approach allows alteration of linear dependent parameters with high accuracy even for a small number of retained modes. The simulated test case shows that changes in stiffness of screw joints between the PCB and the casing can be correctly identified if the changes are big enough. The presented concept allows the efficient simulation of complex mechanical system and monitor changes in the model parameters. Further investigation have to be done towards the uncertainty in the measurement data and the model.

Abstract. *This paper presents a new sequential Bayesian method for the real-time estimation of state, input, parameters, and noise characteristics in dynamical systems using output-only measurements. It is an extension of the method developed by the authors for the joint input-state estimation in linear time-invariant systems* [1], [2]. *This method is built upon the Taylor series expansion of the state-space model and conjugate prior distributions, where the noise characteristics are described using Gaussian distributions and their covariance matrices are assumed to follow inverse Wishart distributions. When the Bayes rule is applied, explicit formulations for the posterior distributions are obtained, which allows efficient and real-time computations. The application of this method to a simple numerical example is demonstrated, which confirms its efficacy in handling this coupled estimation problem. It is observed that this method delivers accurate estimations for the state, input, model parameters, and noise covariance matrices when the results are compared with the actual values. Moreover, the proposed method has the potential to mitigate the low-frequency errors commonly produced in estimations of input forces and displacement responses when only acceleration responses are measured.*

1 INTRODUCTION

Kalman Filter (KF) is a well-established tool in the context of real-time estimation, which provides an efficient estimation of the dynamic response for linear time-invariant (LTI) systems. However, the performance of KF can be deteriorated in the absence of knowledge about the external input forces and system properties. Moreover, the KF is inapplicable when the system has nonlinearity in terms of material properties and geometric changes. This has motivated investigators to develop methods to estimate the system state, input forces, and dynamical parameters in real-time and simultaneously. However, the nonlinear nature of the joint

parameter-state estimation problems requires approximating the state-space formulations. Thus, Extended Kalman Filter (EKF) and Unscented Kalman Filter (UKF) have been developed to cope with this difficulty [3], [4]. While the EKF simplifies the formulation through the first-order Tylor series expansion, the UKF treats the nonlinearity in parameters through a numerical method offering exact solutions up to third order. However, this superior accuracy comes at the expense of additional computational cost. Furthermore, when the noise characteristics are non-Gaussian, these methods often appear to be inadequate, which has brought about the development of particle filters [5], [6]. However, using these filters is not desirable in practice mainly due to the high computational cost associated with the sampling over the parameters space.

The joint input-state estimation in LTI systems is another type of real-time estimation problem first addressed in [7]. Later, Hsieh [8] proposed the so-called two-stage recursive method, and Gillijns & De Moor [9] proved the optimality of this filter in the unbiased minimum variance (UMV) sense. Lourens et al. [10] implemented this filter for modally-reduced dynamical models, enhancing its computational efficiency. Another approach is Augmented Kalman Filter (AKF) introduced in [11], which applies the original KF to estimate an augmented vector of state and input. However, the displacement responses and input forces obtained using these filters are often observed to be contaminated with spurious low-frequency drift components arisen from the double integration over noisy acceleration response measurements. Eftekhar Azam et al. [12] developed Dual Kalman Filter (DKF) for the simultaneous estimation of state and input in LTI systems and have demonstrated the important role of the input covariance matrix in mitigating the drifts. Moreover, Naets et al. [13] prescribed using dummy displacement/strain measurements to reduce these drift in estimations. Nevertheless, these methods require the selection of regularization parameters, which is not always a trivial task. In the published literature, L-curve methods have been suggested for fine-tuning of the input and noise covariance matrices [12]. However, these methods hinder the capability of these methods to offer real-time and automated estimation, as they often require user interference and offline calibration.

In general, the performance of Kalman-type filters is reliant on the initial values of the parameters, and inappropriate choices of the noise covariance matrices can deteriorate the accuracy up to a great extent. Thus, several adaptive methods have been suggested for updating the process and measurement noise in real-time. These methods can be categorized into four groups, namely Bayesian, maximum likelihood, correlation, and covariance-matching methods [14], [15]. Recently, a sequential Bayesian method is developed for the real-time estimation of input, state, and noise covariance matrices [1], [2]. It is observed that this method can considerably mitigate the low-frequency drifts from the estimations of input and displacement responses [1], [2].

The simultaneous estimation of state, input, and parameters has led to an emerging type of real-time methods. Naets et al. [16] have developed a method for the coupled estimation of state, input, and parameters using a model reduction technique paired with the EKF. The UKF has been applied to this coupled estimation problem in Lei et al. [17]. The combination of UKF and DKF has appeared in Dertimanis et al. [18] as an efficient method to treat this joint estimation problem.

This paper aims to address the coupled estimation of the state, input, system parameters, as well as noise parameters using sparse output-only measurements. It follows the same line as the sequential Bayesian method presented in [1], [2] developing a new framework for the coupled estimation problems. It uses the first-order Taylor series expansion to simplify the formulations and proposes a new efficient algorithm. Details of this method will appear in the future, and in this paper, the proposed method is examined using a linear single-degree-of-

freedom (SDOF) system. The paper will continue with Section 2, briefly introducing the method. In Section 3, a numerical example is employed to test and verify the method, and in the end, conclusions are drawn.

2 PROBLEM STATEMENT

A state-space stochastic representation of dynamical systems can be obtained in discrete-time based on the second law of motion and the zero-order hold assumption for the input, which yield [1]:

$$\mathbf{z}_k = \mathbf{A}(\boldsymbol{\theta}_{k-1})\mathbf{z}_{k-1} + \mathbf{B}(\boldsymbol{\theta}_{k-1})\mathbf{p}_{k-1} + \mathbf{v}_k^z \quad , \quad \mathbf{v}_k^z \sim N(\mathbf{0}, \mathbf{Q}_k^z) \tag{1}$$

where $\mathbf{z}_k \in \mathbb{R}^{2N_{DOF}}$ is the state vector at discrete time $t_k = k\Delta t,\ k = \{0,1,2,...,n\}$, containing displacement and velocity responses at N_{DOF} degrees-of-freedom (DOF) sampled at Δt; $\mathbf{p}_k \in \mathbb{R}^{N_I}$ is a vector consisting of N_I unknown external forces; $\mathbf{v}_k^z \in \mathbb{R}^{2N_{DOF}}$ is the process noise considered to be white and Gaussian; $\mathbf{A}(\boldsymbol{\theta}_{k-1}) = \mathbf{e}^{\mathbf{A}_c(\boldsymbol{\theta}_{k-1})\Delta t}$ and $\mathbf{B}(\boldsymbol{\theta}_{k-1}) = \left(\mathbf{A}(\boldsymbol{\theta}_{k-1}) - \mathbf{I}\right)\mathbf{A}_c(\boldsymbol{\theta}_{k-1})^{-1}\mathbf{B}_c(\boldsymbol{\theta}_{k-1})$ are the system and input-to-state matrices for the discrete-time formulation and explained in terms of their continuous-time counterparts given as

$$\mathbf{A}_c(\boldsymbol{\theta}_{k-1}) = \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ -\mathbf{M}^{-1}\mathbf{K}(\boldsymbol{\theta}_{k-1}) & -\mathbf{M}^{-1}\mathbf{C}(\boldsymbol{\theta}_{k-1}) \end{bmatrix},\ \mathbf{B}_c(\boldsymbol{\theta}_{k-1}) = \begin{bmatrix} \mathbf{0} \\ \mathbf{M}^{-1}\mathbf{S}_p \end{bmatrix} \tag{2}$$

where $\mathbf{M} \in \mathbb{R}^{N_{DOF} \times N_{DOF}}$, $\mathbf{C}(\boldsymbol{\theta}_{k-1}) \in \mathbb{R}^{N_{DOF} \times N_{DOF}}$, and $\mathbf{K}(\boldsymbol{\theta}_{k-1}) \in \mathbb{R}^{N_{DOF} \times N_{DOF}}$ are the mass, damping, and stiffness matrices, respectively; $\boldsymbol{\theta}_k \in \mathbb{R}^{N_\theta}$ is a vector of unknown parameters; $\mathbf{S}_p \in \mathbb{R}^{N_{DOF} \times N_I}$ is a matrix specifying the spatial distribution of external forces acting on the system of interest. This state-space representation is nonlinear-in-parameters even if the stiffness and damping matrices are explained as a linear of function of the unknown parameters $\boldsymbol{\theta}_k$. Moreover, the parameters are regarded as time-variant whose variation between consecutive time instances can be described using the so-called random walk model:

$$\boldsymbol{\theta}_k = \boldsymbol{\theta}_{k-1} + \mathbf{v}_k^\theta \quad , \quad \mathbf{v}_k^\theta \sim N\left(\mathbf{0}, \mathbf{Q}_k^\theta\right) \tag{3}$$

where $\mathbf{v}_k^\theta \in \mathbb{R}^{N_\theta}$ characterizes the variation over each interval considered to be white, zero-mean, and Gaussian having the covariance matrix $\mathbf{Q}_k^\theta \in \mathbb{R}^{N_\theta \times N_\theta}$.

Let $\mathbf{d}_k \in \mathbb{R}^{N_0}$ be a vector of response quantities of interest observed at the discrete time t_k. It can be proved that this dynamical response can be written in terms of the system state, input, parameters, as well as the measurement noise leading to the following observation model [1]:

$$\mathbf{d}_k = \mathbf{G}(\boldsymbol{\theta}_k)\mathbf{z}_k + \mathbf{J}(\boldsymbol{\theta}_k)\mathbf{p}_k + \mathbf{w}_k \quad , \quad \mathbf{w}_k \sim N(\mathbf{0}, \mathbf{R}_k) \tag{4}$$

where $\mathbf{G}(\boldsymbol{\theta}_k) \in \mathbb{R}^{N_0 \times N_s}$ and $\mathbf{J}(\boldsymbol{\theta}_k) \in \mathbb{R}^{N_0 \times N_I}$ are the output influence and the direct transmission matrices, respectively, which can be found in [1]; $\mathbf{w}_k \in \mathbb{R}^{N_o}$ is the measurement noise vector modeled as Gaussian white processes with zero-mean and unknown covariance matrix $\mathbf{R}_k \in \mathbb{R}^{N_0 \times N_0}$, respectively.

We state that the problem lies in the real-time estimation of the state, input, parameters, as well as the noise characteristics based on sparse output-only measurements. We address this

problem using the foregoing state-space representation and through a novel sequential Bayesian approach. The presented approach is an extension of the method developed recently by the authors, particularly for the joint estimation of input and state in LTI systems [1], [2]. Of course, the mathematical formulation of this method is skipped in view of this paper's length. However, the method used here consists of five major steps, namely constructing prior distributions, jointly estimating parameters-input-state, estimating cross-covariance matrices, identifying noise characteristics, and making predictions for the next time step. In the derivation of this method, linear Taylor series expansions are employed to simplify both the observation and process models. Moreover, this method benefits from conjugate prior distributions, which allows producing closed-form expressions for the posterior distributions, which reduces the computational burden as well. This implementation includes using Gaussian distribution for the additive noise components as stated earlier, as well as adopting Inverse Wishart distributions for the noise covariance matrices. Further details about this method to be disclosed in the future, and in the remainder, we demonstrate this method by using a simple numerical example.

3 ILLUSTRATIVE EXAMPLE

Figure 1 shows a single degree-of-freedom (SDOF) spring-mass-damper system selected to demonstrate the proposed method. For ease of comparison, the system properties are set to be the same as the example presented in [18], wherein $M = 30\text{kg}$, $C = 700\text{N.s/m}$ and $K = 40\text{MN/m}$. The modal frequency and modal damping ratio for the SDOF system with the above-mentioned properties are 184 Hz and 0.01, respectively. The discrete-time acceleration response of this system is sampled at $\Delta t = 0.001s$ and considered as the measured quantity. This artificial response is generated when the system is subjected to zero-mean Gaussian white input process having 200N standard deviation. The measurement noise is modeled by a zero-mean Gaussian process with the standard deviation of 1% root-mean-square of the noise-free response and added on top of the acceleration response. Note that the zero-order hold assumption is employed when the discrete-time response is created.

The stiffness of the spring $K \equiv \theta$ and the applied force are considered to be unknown. The problem is to estimate and update the input, state, stiffness, and noise parameters in real-time using acceleration-only measurements.

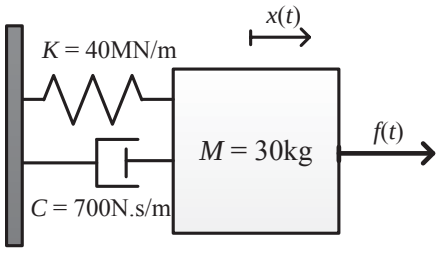

Figure 1: SDOF spring-mass-damper system considered for testing the method

The initial value for the parameters is selected to be $\theta_{0|0}$=0.8K=32MN/m. The input and parameter variances are both set to 100. The initial covariance matrix of the state is considered to be diagonal having elements of order 10^3. The estimation period is considered 200s, aiming to ensure the stability and accuracy of the method.

Figure 2 presents the estimation of stiffness. It is observed that within the first 10s, the estimation reaches to a satisfactory threshold varying around the actual value. The variation of the stiffness identified decreases as the time goes by, which is attributed to the convergence of

the noise covariance matrices. Moreover, the estimation of the applied force is displayed in Figure 3. For comparison, two windows each 1s long are enlarged, indicating the accuracy of the method in estimating the input. To shed light on the misfit between the actual and estimated input, the errors are plotted in Figure 4 in both time and frequency domains. In Figure 4(a), it is evident that the large errors appearing in the beginning swiftly decrease and reach to a stationary process with much smaller amplitude. This error process is transformed to the frequency-domain in Figure 4(b), showing that relatively large errors around the system's natural frequency. We believe this issue is attributed to the variation of identified stiffness. Another notable observation is the mitigation of low-frequency drifts up to a great extent.

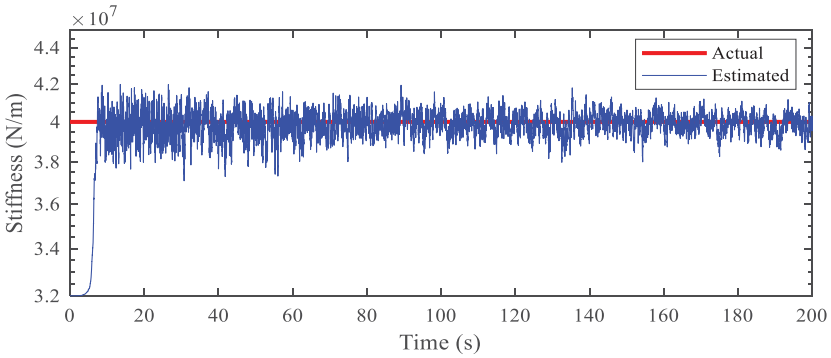

Figure 2: Identification of the stiffness using the proposed method

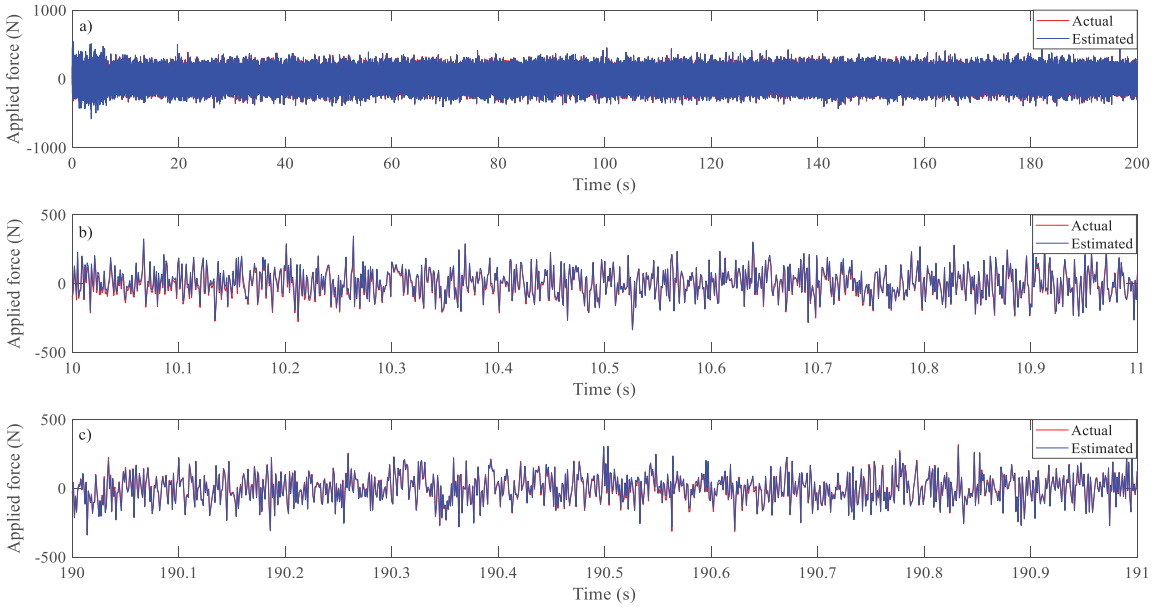

Figure 3: Estimation of input force over different intervals

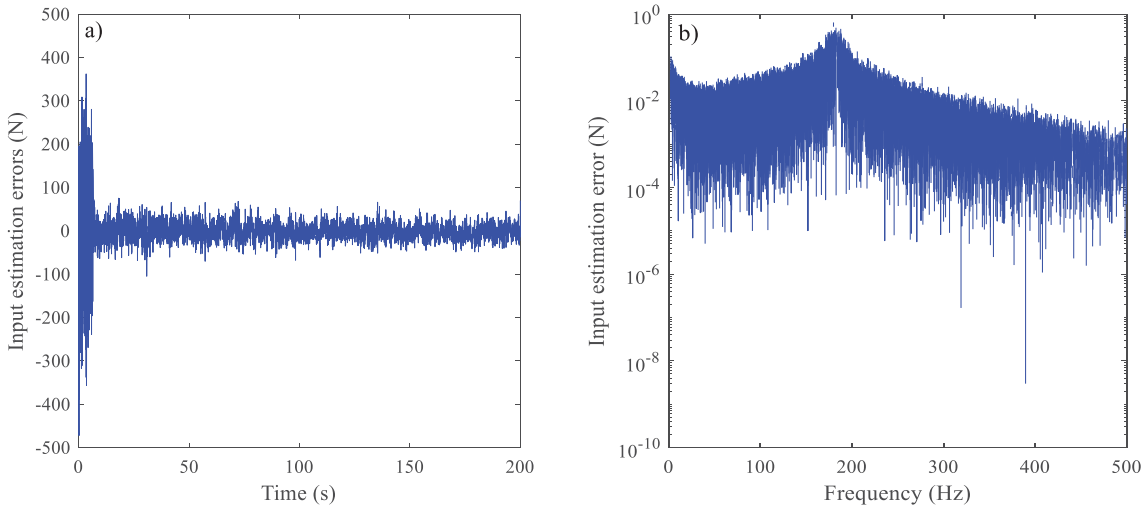

Figure 4: Input estimation errors presented in time and frequency domains

Figure 5 shows the time-history displacement response estimated using the proposed method. When these estimations are compared with the actual values, it is observed that the proposed method delivers accurate estimations and particularly free of significant low-frequency errors. This conclusion is reinforced when we zoom into different segments of the response, e.g. intervals [10-11s] and [190-191s]. It is to be noted that similar observations are made for the velocity and acceleration responses, which confirms the validity of the method. However, they are not presented here for brevity.

Figure 6 indicates the real-time estimation of the process noise covariance matrix and the stiffness variance. As shown, these variances converge and reach to stationary settings as time passes, putting emphasis on the stability of the estimators.

4 CONCLUSIONS

A new sequential Bayesian method is introduced for the coupled estimation of state, input, parameters, as well as noise covariance matrices using response-only measurements. This method is examined and tested using a simple numerical example. The convergence of the estimations to the actual values is demonstrated, and the stability of the estimations is verified using a basic numerical example. It is also observed that the proposed filter is capable of mitigating the adverse effect of using noisy acceleration responses, and corrects inappropriate choice of noise covariance made at the beginning, delivering highly accurate estimations. More examples to appear in the future aiming to lend further validity and verification to the method presented herein.

Abstract. *Updating dynamical models based on experimental modal information has become an important topic in structural health monitoring. This paper revisits this significant problem and develops a new two-stage hierarchical Bayesian framework, aiming to improve the quantification of uncertainty. This framework employs the Bayesian FFT approach to identify the modal parameters along with their identification uncertainty, and then, it utilizes this modal information to update the stiffness matrix. It can quantify the variability of both modal and structural parameters over multiple data sets while characterizing their identification uncertainty as well. This framework also proposes a new basis to assign optimal and appropriate weights for modal features. It weights different modal parameters based on the sum of identification uncertainty and the ensemble variability such that more uncertain parameters will be assigned smaller weights. As a result, a coherent quantification of uncertainty is attained by following Bayesian probability logic. Ultimately, experimental data from a shear building structure is used for demonstrating the proposed framework.*

1 INTRODUCTION

Bayesian statistical framework [1] has become central in structural health monitoring (SHM) since it provides a rigorous mathematical tool to quantify uncertainties. This framework has been developed further to tackle various problems visited in SHM, including the methods seasoned for updating dynamical models based on experimental modal information. Two decades ago, Vanik et al. [2] have first developed a Bayesian framework for updating stiffness parameters by comparing and matching experimental and analytical modal properties. Beck et al. [3] have used this framework to address damage detection in a probabilistic fashion. However, the original formulations [2] require matching the analytical and experimental dynamical modes. Yuen et al. [4] have introduced an efficient Bayesian formulation to handle

this problem without imposing any mode matching concept. This study establishes a Gaussian distribution to provide an explicit relationship between the structural and modal parameters and to avoid solving the eigenvalue problems. Christodoulou and Papadimitriou [5] have demonstrated that the weighting of modal features plays a crucial role in obtaining the most probable values of structural parameters accurately. They have also proposed a Bayesian method to calibrate the weights. Goller et al. [6] have introduced an evidence-based approach for the calibration of the weights. Au and Zhang [7] have developed a two-stage approach, which first identifies the modal parameters and their uncertainties using the Bayesian FFT approach [8], [9] and then updates the structural parameters accordingly. Behmanesh et al. [10] have proposed a hierarchical Bayesian method to account for the variability of structural parameters. The computing technique used in [10] is a Gibbs sampling method associated with the Metropolis-Hasting algorithm. However, this computational method appears to be inefficient as the number of parameters grows. For globally identifiable problems, an asymptotic approximation of the likelihood function can drastically reduce the computational cost and provides theoretical insights as to the separation of identification uncertainty and variability [11]. In the original framework, the data sets correspond to statistically independent experiments. However, this assumption can be relaxed by breaking a long time-history data set into multiple segments and capturing the variability through the same approach [12]. An extension of this framework to Bayesian operational modal analysis has recently appeared in [13]. These studies show that the hierarchical Bayesian framework provides robust uncertainties.

In this study, we develop a two-stage hierarchical Bayesian framework for model inference problems. In the first stage, the modal information is obtained from the Bayesian FFT method [8], [9], and in the second stage, this information is employed to update the stiffness parameters using a method similar to [4]. This development benefits from the hierarchical Bayesian framework presented in [11], [13].

2 HIERARCHICAL BAYESIAN FRAMEWORK

2.1 Problem statement

Let $M(\boldsymbol{\theta}) \in \boldsymbol{M}$ be a linear dynamical model, selected from a class of models $\boldsymbol{M}$ and described mathematically as a function of free parameters $\boldsymbol{\theta} \in \mathbb{R}^{N_\theta}$. These parameters are assumed herein to characterize the uncertainty associated with the stiffness matrix. The so-called substructure approach is convenient to express the stiffness and mass matrices in terms of the substructures' stiffness/mass matrices giving:

$$\mathbf{K}(\boldsymbol{\theta}) = \sum_{p=1}^{N_\theta} \theta_p \mathbf{K}_p \quad ; \quad \mathbf{M} = \sum_{p=1}^{N_\theta} \mathbf{M}_p \tag{1}$$

where $\mathbf{K}(\boldsymbol{\theta})$ and $\mathbf{M} \in \mathbb{R}^{N_{DOF} \times N_{DOF}}$ are the global stiffness and mass matrices, respectively; $\mathbf{K}_p$ and $\mathbf{M}_p \in \mathbb{R}^{N_{DOF} \times N_{DOF}}$ are the stiffness and mass matrices of the pth substructure. Note that the structural model is assumed to have N_{DOF} degrees-of-freedom (DOFs). This parameterization is advantageous since it provides a linear relationship between the global stiffness matrix and the unknown parameters. In this study, the mass matrix is considered to be known and computed from architectural and structural drawings. On the contrary, the parameters of the stiffness matrix should be updated based on the vibration measurements.

The primary goal is to calibrate the stiffness parameters and their uncertainty using N_D time-history data sets collected in the full data set $\mathbf{D} = \{D_s, s = 1,2,...,N_D\}$ while $D_s = \{\mathbf{y}_{j,s} \triangleq \mathbf{y}_s(j\Delta t) \in \mathbb{R}^{N_o}, j = 0,1,2,...,N-1\}$ is a particular sequence of response-only

measurement obtained at N_o DOFs and Δt intervals. Updating the model directly based on vibration responses, as proposed in [11], is non-trivial and difficult, mainly due to the fact that the input loading is not known. Consequently, it is preferred to identify the modal features first and then use them for inferring the stiffness parameters. This paper follows a similar approach by establishing a two-stage hierarchical Bayesian framework. In the first stage, the modal frequencies and mode shapes are inferred using the Bayesian FFT approach. In the second stage, the stiffness parameters are updated by comparing the identified and analytical modal parameters.

2.2 Hierarchical prior distribution

Let $\boldsymbol{\omega}^2=[\omega_1^2 \ ... \ \omega_{N_m}^2]^T$ and $\boldsymbol{\Phi}=[\boldsymbol{\phi}_1^T \ ... \ \boldsymbol{\phi}_{N_m}^T]^T$ be the experimental modal frequencies and mode shape vectors, respectively, where each pair $\{\omega_i^2 \in \mathbb{R}^1, \boldsymbol{\phi}_i \in \mathbb{R}^{N_0}\}$ corresponds to the ith dynamical mode when N_m modes are observed. Likewise, the modal parameters of the structural model $M(\boldsymbol{\theta}) \in \boldsymbol{M}$ can be expressed as $\boldsymbol{\varpi}^2=[\varpi_1^2 \ ... \ \varpi_{N_m}^2]^T$ and $\boldsymbol{\Psi}=[\boldsymbol{\psi}_1^T \ ... \ \boldsymbol{\psi}_{N_m}^T]^T$, where similarly the pair $\{\varpi_i^2 \in \mathbb{R}^1, \boldsymbol{\psi}_i \in \mathbb{R}^{N_{DOF}}\}$ is modal frequency and mode shape vector of the ith dynamic mode. Of course, the analytical modal parameters vary with stiffness parameters. The statistical relationship between the analytical modal parameters and the stiffness parameters is described as [4]:

$$p(\boldsymbol{\varpi}_s^2, \boldsymbol{\Psi}_s \,|\, \boldsymbol{\theta}_s, \sigma_\varepsilon^2) = \prod_{i=1}^{N_m} N\left(\mathbf{K}(\boldsymbol{\theta}_s)\boldsymbol{\psi}_{i,s} \,|\, \varpi_{i,s}^2 \mathbf{M}\boldsymbol{\psi}_{i,s}, \sigma_\varepsilon^2 \mathbf{I}_{N_{DOF}}\right) \tag{2}$$

where σ_ε^2 is the prediction error variance reflecting how accurate the Eigen equation is satisfied. Note that the subscript s represents that one parameter correspond to the data set D_s. Thus, the stiffness parameters are variable over different data sets. This variability is considered using a hyper Gaussian distribution imposed over the stiffness parameters giving:

$$p(\boldsymbol{\theta}_s \,|\, \boldsymbol{\mu}_{\boldsymbol{\theta}}, \boldsymbol{\Sigma}_{\boldsymbol{\theta}\boldsymbol{\theta}}) = N(\boldsymbol{\theta}_s \,|\, \boldsymbol{\mu}_{\boldsymbol{\theta}}, \boldsymbol{\Sigma}_{\boldsymbol{\theta}}) \tag{3}$$

where $\boldsymbol{\mu}_{\boldsymbol{\theta}} \in \mathbb{R}^{N_{\boldsymbol{\theta}}}$ and $\boldsymbol{\Sigma}_{\boldsymbol{\theta}} \in \mathbb{R}^{N_{\boldsymbol{\theta}} \times N_{\boldsymbol{\theta}}}$ are the hyper mean vector and covariance matrix, respectively. Likewise, the modal features $\{\boldsymbol{\omega}^2, \boldsymbol{\Phi}, \boldsymbol{\varpi}^2, \boldsymbol{\Psi}\}$ are specific to each experiment (data set) and modeled as statistically independent. The discrepancy between the experimental and analytical modal parameters describing each experiment can be written as

$$\begin{bmatrix} \boldsymbol{\omega}_s^2 \\ \boldsymbol{\Phi}_s \end{bmatrix} = \begin{bmatrix} \boldsymbol{\varpi}_s^2 \\ \boldsymbol{\Gamma}_s \boldsymbol{\Psi}_s \end{bmatrix} + \begin{bmatrix} \boldsymbol{\varepsilon}_{\boldsymbol{\omega}_s} \\ \boldsymbol{\varepsilon}_{\boldsymbol{\Phi}_s} \end{bmatrix} \tag{4}$$

where $\boldsymbol{\Gamma}_s \in \mathbb{R}^{N_m N_o \times N_m N_{DOF}}$ is a known selection matrix, which specifies the observed DOFs, and $[\boldsymbol{\varepsilon}_{\boldsymbol{\omega}_s}^T \quad \boldsymbol{\varepsilon}_{\boldsymbol{\Phi}_s}^T]^T$ is the prediction error vector described through a class of maximum-entropy probability distribution given as

$$\boldsymbol{\varepsilon}_{\boldsymbol{\omega}_s^2} \underset{i.i.d.}{\sim} N\left(\mathbf{0}, \boldsymbol{\Sigma}_{\boldsymbol{\omega}^2}\right) \quad ; \quad \boldsymbol{\varepsilon}_{\boldsymbol{\Phi}_s} \underset{i.i.d.}{\sim} N\left(\mathbf{0}, \boldsymbol{\Sigma}_{\boldsymbol{\Phi}}\right) \tag{5}$$

where $\boldsymbol{\Sigma}_{\boldsymbol{\omega}^2} \in \mathbb{R}^{N_m \times N_m}$ and $\boldsymbol{\Sigma}_{\boldsymbol{\Phi}} \in \mathbb{R}^{N_o N_m \times N_o N_m}$ are the covariance matrices of the modal frequencies and mode shape vectors, respectively. These parameters are to be inferred from the data as well. Having considered this statistical model, the probability distribution of the experimental modal parameters conditional on the analytical ones can be written as

$$p(\boldsymbol{\omega}_s^2, \boldsymbol{\Phi}_s \,|\, \boldsymbol{\varpi}_s, \boldsymbol{\Psi}_s, \boldsymbol{\Sigma}_{\boldsymbol{\omega}^2}, \boldsymbol{\Sigma}_{\boldsymbol{\Phi}}) = N\left(\boldsymbol{\omega}_s^2 \,|\, \boldsymbol{\varpi}_s^2, \boldsymbol{\Sigma}_{\boldsymbol{\omega}^2}\right) N\left(\boldsymbol{\Phi}_s \,|\, \boldsymbol{\Gamma}_s \boldsymbol{\Psi}_s, \boldsymbol{\Sigma}_{\boldsymbol{\Phi}}\right) \tag{6}$$

Figure 1 shows the hierarchical structure of the proposed probabilistic model. The conditional dependence of parameters is shown by the arrows, and the unknown parameters are

shown using the white circles. Each time-history data is shown by a gray circle. For brevity, the parameters having common realizations over data sets are collected into a hyper-parameters set $\varphi = \{\boldsymbol{\mu}_{\boldsymbol{\theta}}, \boldsymbol{\Sigma}_{\boldsymbol{\theta}}, \boldsymbol{\Sigma}_{\boldsymbol{\omega}^2}, \boldsymbol{\Sigma}_{\boldsymbol{\Phi}}, \sigma_{\varepsilon}^2\}$, and the data-set-specific parameters are collected into $\delta = \{\boldsymbol{\omega}_s^2, \boldsymbol{\Phi}_s, \boldsymbol{\varpi}_s^2, \boldsymbol{\Psi}_s, \boldsymbol{\theta}_s\}_{s=1}^{N_D}$. Therefore, the joint prior distribution of all parameters can be written as

$$p(\delta,\varphi) = p(\varphi)\prod_{s=1}^{N_D} p(\boldsymbol{\omega}_s^2, \boldsymbol{\Phi}_s \mid \boldsymbol{\varpi}_s^2, \boldsymbol{\Psi}_s, \boldsymbol{\Sigma}_{\boldsymbol{\omega}^2}, \boldsymbol{\Sigma}_{\boldsymbol{\Phi}})\, p(\boldsymbol{\varpi}_s, \boldsymbol{\Psi}_s \mid \boldsymbol{\theta}_s, \sigma_{\varepsilon}^2)\, p(\boldsymbol{\theta}_s \mid \boldsymbol{\mu}_{\boldsymbol{\theta}}, \boldsymbol{\Sigma}_{\boldsymbol{\theta}}) \tag{7}$$

where $p(\delta,\varphi)$ is the joint prior distribution and $p(\varphi)$ is the prior distribution of the hyper-parameters considered to uniform. It is notable that only the experimental modal parameters have a direct relationship with the measured responses. This relationship is described by the likelihood function, which will be discussed in the next section.

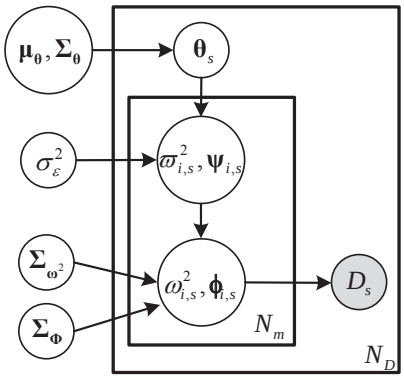

Figure 1: An overview of the hierarchical probabilistic model used for two-stage Bayesian model inference

2.3 Bayesian formulation

Given that the vibration responses are statistically independent, the Bayes' rule gives the joint posterior distribution of all parameters as

$$p(\delta,\varphi \mid \mathbf{D}) \propto \prod_{s=1}^{N_D} p(D_s \mid \boldsymbol{\omega}_s^2, \boldsymbol{\Phi}_s)\, p(\boldsymbol{\omega}_s^2, \boldsymbol{\Phi}_s \mid \boldsymbol{\varpi}_s^2, \boldsymbol{\Psi}_s, \boldsymbol{\Sigma}_{\boldsymbol{\omega}^2}, \boldsymbol{\Sigma}_{\boldsymbol{\Phi}})\, p(\boldsymbol{\varpi}_s, \boldsymbol{\Psi}_s \mid \boldsymbol{\theta}_s, \sigma_{\varepsilon}^2)\, p(\boldsymbol{\theta}_s \mid \boldsymbol{\mu}_{\boldsymbol{\theta}}, \boldsymbol{\Sigma}_{\boldsymbol{\theta}}) \tag{8}$$

where $p(\delta,\varphi \mid \mathbf{D})$ is the joint posterior distribution of all parameters, $p(D_s \mid \boldsymbol{\omega}_s^2, \boldsymbol{\Phi}_s)$ is the likelihood function of the data set D_s. It worth noting that, in derivation of this equation, the prior joint distribution is replaced from Eq. (7). The likelihood function connects the experimental modal parameters to the vibration responses. The Bayesian FFT approach [8], [9] provides a rigorous method to simplify the likelihood function by the following Gaussian distribution [13]:

$$p(D_s \mid \boldsymbol{\omega}_s^2, \boldsymbol{\Phi}_s) \propto N\left(\boldsymbol{\omega}_s^2 \middle| \hat{\boldsymbol{\omega}}_s^2, \hat{\boldsymbol{\Sigma}}_{\boldsymbol{\omega}_s^2}\right) N\left(\boldsymbol{\Phi}_s \middle| \hat{\boldsymbol{\Phi}}_s, \hat{\boldsymbol{\Sigma}}_{\boldsymbol{\Phi}_s}\right) \tag{9}$$

where $\hat{\boldsymbol{\Sigma}}_{\boldsymbol{\omega}_s^2}$ and $\hat{\boldsymbol{\Sigma}}_{\boldsymbol{\Phi}_s}$ are the covariance matrices showing how confident we are in the identified modal frequency and mode shapes, respectively. We refer to this data-driven uncertainty as identification uncertainty. The parameters $\hat{\boldsymbol{\omega}}_s^2$ and $\hat{\boldsymbol{\Phi}}_s$ are the most probable values (MPVs) of the modal parameters. The reader can refer to [13] for a detailed derivation of this approximate likelihood function. When this simplification is introduced into Eq. (8), it is possible to marginalize the experimental modal features explicitly. After simplification, we will arrive at

$$p(\{\boldsymbol{\varpi}_s^2,\boldsymbol{\Psi}_s,\boldsymbol{\theta}_s\}_{s=1}^{N_D},\varphi\,|\,\mathbf{D}) \propto \prod_{s=1}^{N_D} N\left(\boldsymbol{\varpi}_s^2\middle|\boldsymbol{\varpi}_s^2,\boldsymbol{\Sigma}_{\boldsymbol{\omega}^2}+\hat{\boldsymbol{\Sigma}}_{\boldsymbol{\omega}_s^2}\right) N\left(\boldsymbol{\Gamma}_s\boldsymbol{\Psi}_s\middle|\hat{\boldsymbol{\Phi}}_s,\boldsymbol{\Sigma}_{\boldsymbol{\Phi}}+\hat{\boldsymbol{\Sigma}}_{\boldsymbol{\Phi}_s}\right) \times \prod_{s=1}^{N_D}\left[N\left(\boldsymbol{\theta}_s\,|\,\boldsymbol{\mu}_{\boldsymbol{\theta}},\boldsymbol{\Sigma}_{\boldsymbol{\theta}}\right)\prod_{i=1}^{N_m} N\left(\mathbf{K}(\boldsymbol{\theta}_s)\boldsymbol{\psi}_{i,s}\,|\,\varpi_{i,s}^2\mathbf{M}\boldsymbol{\psi}_{i,s},\sigma_\varepsilon^2\mathbf{I}_{N_{DOF}}\right)\right] \tag{10}$$

where $p(\{\boldsymbol{\varpi}_s^2,\boldsymbol{\Psi}_s,\boldsymbol{\theta}_s\}_{s=1}^{N_D},\varphi\,|\,\mathbf{D})$ is the joint distribution of remaining parameters. Note that the procedure followed here for the marginalization is similar to the approach presented in [14]. This joint distribution can be used directly to compute the MPVs. Since the stiffness parameters are globally identifiable, it is however desirable to approximate the expressions relying on the stiffness parameters and the analytical modal features using another Laplace approximation. This set of parameters is essentially $\eta=\{\{\boldsymbol{\varpi}_s^2,\boldsymbol{\Psi}_s,\boldsymbol{\theta}_s\}_{s=1}^{N_D},\boldsymbol{\Sigma}_{\boldsymbol{\omega}^2},\boldsymbol{\Sigma}_{\boldsymbol{\Phi}},\sigma_\varepsilon^2\}$. For this purpose, we first explain that Eq. (10) can be rewritten as

$$p(\{\boldsymbol{\varpi}_s^2,\boldsymbol{\Psi}_s,\boldsymbol{\theta}_s\}_{s=1}^{N_D},\varphi\,|\,\mathbf{D}) \propto \prod_{s=1}^{N_D}\left[N\left(\boldsymbol{\theta}_s\,|\,\boldsymbol{\mu}_{\boldsymbol{\theta}},\boldsymbol{\Sigma}_{\boldsymbol{\theta}}\right)\exp\left(-J(\eta)\right)\right] \tag{11}$$

where $J(\eta)$ is the negative logarithm of the expressions summarized from the LHS of Eq. (10) given as

$$J(\eta)=\frac{1}{2}\sum_{s=1}^{N_D}\left[\ln\left|\boldsymbol{\Sigma}_{\boldsymbol{\omega}^2}+\hat{\boldsymbol{\Sigma}}_{\boldsymbol{\omega}_s^2}\right|+\ln\left|\boldsymbol{\Sigma}_{\boldsymbol{\Phi}}+\hat{\boldsymbol{\Sigma}}_{\boldsymbol{\Phi}_s}\right|+\left(\boldsymbol{\varpi}_s^2-\hat{\boldsymbol{\omega}}_s^2\right)^T\left(\boldsymbol{\Sigma}_{\boldsymbol{\omega}^2}+\hat{\boldsymbol{\Sigma}}_{\boldsymbol{\omega}_s^2}\right)^{-1}\left(\boldsymbol{\varpi}_s^2-\hat{\boldsymbol{\omega}}_s^2\right)\right] + \frac{1}{2}\sum_{s=1}^{N_D}\left[\left(\boldsymbol{\Gamma}_s\boldsymbol{\Psi}_s-\gamma_{i.s}\hat{\boldsymbol{\Phi}}_s\right)^T\left(\boldsymbol{\Sigma}_{\boldsymbol{\Phi}}+\hat{\boldsymbol{\Sigma}}_{\boldsymbol{\Phi}_s}\right)^{-1}\left(\boldsymbol{\Gamma}_s\boldsymbol{\Psi}_s-\gamma_{i.s}\hat{\boldsymbol{\Phi}}_s\right)+\sum_{i=1}^{N_m}\sigma_\varepsilon^{-2}\boldsymbol{\psi}_{i,s}^T\left(\mathbf{K}(\boldsymbol{\theta}_s)-\varpi_{i,s}^2\mathbf{M}\right)^2\boldsymbol{\psi}_{i,s}\right] \tag{12}$$

where |.| denotes the matrix determinant. This particular treatment of parameters allows separating the identification of η and $\{\boldsymbol{\mu}_{\boldsymbol{\theta}},\boldsymbol{\Sigma}_{\boldsymbol{\theta}}\}$. Later, it will be shown that this strategy is beneficial for separating different type of uncertainties.

It is worth to highlight that, when calculating the MPV, the mode shape vectors should be optimized subjected to the unit-norm constrain. This can be accomplished through the Lagrange multiplier approach using a method like [15]. Imposing this constraint requires the minimization of the following objective function:

$$J(\eta,\{\chi_{i,s},\lambda_{i,s}\}_{i=1\,s=1}^{N_m\,N_D})=J(\eta)+\frac{1}{2}\sum_{s=1}^{N_D}\sum_{i=1}^{N_m}\left[\chi_{i,s}\left(1-\boldsymbol{\psi}_{i,s}^T\boldsymbol{\psi}_{i,s}\right)+\lambda_{i,s}\left(\boldsymbol{\psi}_{i,s}^T\mathbf{T}_{i,s}^T\mathbf{T}_{i,s}\boldsymbol{\psi}_{i,s}-\gamma_{i,s}^2\right)\right] \tag{13}$$

where $\chi_{i,s}$ and $\lambda_{i,s}$ are the Lagrange multipliers should be identified as well. The minimization of this function yields the MPVs. Moreover, the exponential function in the RHS of Eq. (11) can be approximated by a Gaussian distribution centered at the MPVs. The covariance matrix of this distribution is equal to the inverse of the Hessian matrix of $J(\eta)$ evaluated at the MPVs. This approximation simplifies Eq. (11) into

$$p(\{\boldsymbol{\theta}_s\}_{s=1}^{N_D},\boldsymbol{\mu}_{\boldsymbol{\theta}},\boldsymbol{\Sigma}_{\boldsymbol{\theta}}\,|\,\mathbf{D}) \propto \prod_{s=1}^{N_D} N\left(\boldsymbol{\theta}_s\middle|\boldsymbol{\mu}_{\boldsymbol{\theta}},\boldsymbol{\Sigma}_{\boldsymbol{\theta}}\right)N\left(\boldsymbol{\theta}_s\middle|\hat{\boldsymbol{\theta}}_s,\hat{\boldsymbol{\Sigma}}_{\boldsymbol{\theta}_s}\right) \tag{14}$$

where $\hat{\boldsymbol{\theta}}_s$ and $\hat{\boldsymbol{\Sigma}}_{\boldsymbol{\theta}_s}$ are the MPV and identification uncertainty of the stiffness parameters obtained from data set D_s, respectively. In [11], it is proved that marginalization of $\boldsymbol{\theta}_s$'s provides:

$$p(\boldsymbol{\mu}_{\boldsymbol{\theta}},\boldsymbol{\Sigma}_{\boldsymbol{\theta}}\,|\,\mathbf{D}) \propto \prod_{s=1}^{N_D} N\left(\boldsymbol{\mu}_{\boldsymbol{\theta}}\middle|\hat{\boldsymbol{\theta}}_s,\boldsymbol{\Sigma}_{\boldsymbol{\theta}}+\hat{\boldsymbol{\Sigma}}_{\boldsymbol{\theta}_s}\right) \tag{15}$$

where $p(\boldsymbol{\mu}_{\boldsymbol{\theta}}, \boldsymbol{\Sigma}_{\boldsymbol{\theta}} \mid \mathbf{D})$ is the marginal posterior distribution of the hyper-parameters characterizing the stiffness parameters. In a special case when $\hat{\boldsymbol{\Sigma}}_{\boldsymbol{\theta}_s}$'s are fairly constant, the MPVs of the hyper-parameters are obtained [12]:

$$\hat{\boldsymbol{\mu}}_{\boldsymbol{\theta}} = \frac{1}{N_D}\sum_{s=1}^{N_D}\hat{\boldsymbol{\theta}}_s \tag{16}$$

$$\hat{\boldsymbol{\Sigma}}_{\boldsymbol{\theta}} = \frac{1}{N_D}\sum_{s=1}^{N_D}(\hat{\boldsymbol{\theta}}_s - \hat{\boldsymbol{\mu}}_{\boldsymbol{\theta}})(\hat{\boldsymbol{\theta}}_s - \hat{\boldsymbol{\mu}}_{\boldsymbol{\theta}})^T - \frac{1}{N_D}\sum_{s=1}^{N_D}\hat{\boldsymbol{\Sigma}}_{\boldsymbol{\theta}_s} \tag{17}$$

where $\hat{\boldsymbol{\mu}}_{\boldsymbol{\theta}}$ and $\hat{\boldsymbol{\Sigma}}_{\boldsymbol{\theta}}$ are the MPVs. These equations also reveal that the MPV of the hyper mean vector is the average of realizations obtained from different data sets. Moreover, the MPV of the hyper covariance matrix is determined as the difference of the ensemble covariance matrix computed from different realizations and the mean of identification uncertainties.

3 EXPERIMENTAL EXAMPLE

A three-story shear building small-scale structure is used for verifying the proposed framework shown in Figure 2(a). The acceleration time-history responses of the three floors were measured when subjected to N_D = 40 independent white Gaussian base excitations. The averaged singular value spectrum is plotted in Figure 2(b). Based on this figure, three resonant bands can be selected as [3.2–5.2 Hz], [12.0–14.0 Hz], and [17.5–19.5 Hz] for applying the Bayesian FFT approach. For each data set, the modal frequencies and mode shape vectors are thus obtained along with their identification uncertainty.

Figure 2(c) shows the dynamical model considered to describe the structure. It is a simple shear frame whose columns have unknown stiffness. The mass matrix is considered to be known and concentrated on each floor. Thus, there exist three unknown stiffness parameters to be identified from each data set, and their hyper-parameters should be inferred from multiple data sets. The modal statistical information obtained is then used for updating the modal and stiffness parameters. Table 1 presents the MPVs and the total uncertainty comprising both identification uncertainty and the variability. Table 2 presents both the identification uncertainty and the ensemble variability. These results demonstrate the proposed hierarchical framework in terms of the separation of the different sources of uncertainty and providing uncertainties robust to the variability induced by the modeling errors.

4 CONCLUSIONS

A hierarchical Bayesian modeling framework was developed to update dynamical models based on modal statistical information. This framework is coherent and consistent in terms of using Bayesian probability logic. It employs the Bayesian FFT approach for modal inference and updates the stiffness parameters based on the modal statistical information. This framework weights modal features based on their total uncertainty composed of the identification uncertainty and their variability across different data sets. It delivers the promise to quantify the variability induced due to modeling errors through efficient asymptotic approximations. This achievement is important since the variability often predominantly exceeds the identification uncertainty obtained using a Bayesian non-hierarchical probabilistic framework.

Keywords: seismic hazard, earthquake engineering, collapse probability, risk targeting, Alicante

Abstract. *The areas with higher seismic risks in Spain are located in the South and South-East of Spain. For instance, the recent seismic hazard analysis performed in the Alicante and Elche have obtained a PGA of 200 cm/sec^2 approximately in the region and indicated that the highest contribution to the seismic hazard comes from the seismicity due to the Crevillente and the Bajo Segura faults. Many studies have demonstrated that the design of structures in the region through the use of "uniform hazard" principle, does not guarantee that the collapse risk in the region is uniform as well, i.e., even in those regions with similar PGAs corresponding to the same mean return period, the seismic risk in terms of failure probability will be significantly different. A new approach called "risk targeting" has already been adopted by new generations of seismic codes and associated research, where the parameters are specified to ensure a tool for the design of buildings with a probability of collapse alike or at least harmonized throughout the area concerned. Consequently, in this study, we will focus on the evaluation of the collapse probability of the buildings and then developing the risk-targeted maps of the Alicante. Finally, the preliminary obtained results will be discussed.*

1 INTRODUCTION

Seismic assessment and structural designs are continually evolving, as evidenced by the rapid development of new procedures illustrated by the Pacific Earthquake Engineering Research Center (PEER); performance-based earthquake engineering framework [1]. Numerous studies aimed to integrate the principle of probability into seismic performance evaluation, taking into account the uncertainties related not only to seismic input but also to structural properties, capacity and model [2, 3, 4, and 5]. In order to estimate the seismic demand at a specific location, the vast majority of the Earthquake Design Codes rely on a seismically defined return period (for example, 10% in 50 years) of intensity measures. The decision to design the structure in accordance with a "uniform hazard" level is based on the idea that a process like this leads to the same annual probability of collapse as anywhere, in the buildings. Nevertheless, this fact happens only if the collapse probability of the structure will be a certain value that is infeasible in real cases. Recently, multiple studies have demonstrated that a design-based earthquake determined on a uniform hazard theory does not necessarily lead to the design of structures with a consistent risk of collapse in different areas. These inconsistencies are due to the different shape of the hazard curve for different regions and uncertainties in failure capacity of structures [6] arising from a set of factors, such as different material properties, differences in design, and among others. Hence, a structure can collapse for a different ground motion with what it was designed for. Moreover, as the shape of the hazard curve depends on the site location, even the buildings designed for the same ground motion will have different values of collapse probability.

Based on the work by [6], it would be more consistent to use "uniform risk" assumption in which the design ground motion is estimated to provide a constant level of risk. This algorithm was used to present the risk-targeted maximum considered earthquake (MCER) ground motion (ASCE7-10) [7]. Accordingly, using the proposed method, Douglas et al. [8] presented a risk-targeted seismic design map for France. In the study by [9], various parameters involved in developing risk-targeted design maps are analyzed and maps for Europe developed using SHARE seismic hazard results (www.share-eu.org). The risk-targeted map of Romania was developed by [10], using the hazard model of SHARE. [11] applied site- and structure specific fragility curves to estimate the risk-targeted design ground motion. [12] addressed some research results relating to the risk of failure in residential and industrial construction, in compliance with the Italian code. They showed that seismic structural reliability tends to decrease with increasing seismic hazard to the building site, despite the homogeneous return period of excess of seismic design ground motion. [13] presented a review of the state of the art of this technique, highlighting efforts to constrain better some of the input parameters. In addition, they discussed the problems in the practical implementation of this approach and the alternative forward paths. [14] have performed the probabilistic seismic hazard analysis and a risk-targeted map for Tehran provided based on the hazard curves achieved. [15] presented a risk-targeted seismic design map for Iran, considering the seismic hazard models from the EMME14 project [16] and STD-2800 [17]. Recently, [18] performed a review and comparison among the existing approaches with regard to the implementation of uniform-risk concepts in the performance-based design of structures. Among these, one based on the use of risk-targeted behavior factors (RTBFs) has been recently considered for the development of future versions of Eurocode 8 [19]. [20] demonstrated the effects of the RTBF approach being applied to the concept of risk-targeted maps for Italy.

In this study, using the updated seismic hazard in the regions of Alicante and Elche [21] and employment of generic fragility curves, the distribution of the risk-targeted ground motion has

been estimated for these areas. This study aims at evaluating the relevant peak ground accelerations for a given target annual collapse probability and different collapse probability for a given peak ground acceleration which corresponds to a specific mean return period of seismic action.

2 SEISMIC HAZARD MODEL

The seismic hazard map of Spain was recently updated after the events occurred in the Murcia region, such as the 1999 earthquake in Mula (Mw=4.7), 2002 in Bullas (Mw=5.0), 2005 in La Paca (Mw=4.8) or the destructive Lorca earthquake occurred in 2011 (Mw= 5.2) with catastrophic consequences in Lorca town despite being a relatively small event. None of those events were included in the seismic hazard map published under the framework of the current Spanish seismic code NCSE-02. For example, the PGA at rock for a 0.1 probability of exceedance in 50 years was 0.14 g and 0.15 g for Alicante and Elche respectively (according to NCSE-02) and it has been increased to 0.18 g and 0.20g with the updated of the seismic hazard map [21].

In this work, we have carried out a specific analysis of the seismic hazard map in both municipalities using the Spanish seismic catalog updated until 2018. The computation was done using the seismic zones proposed by IGN-UPM Working Group and updating the activity rate and beta values of the zone within the influence area of both cities (150 km). The software R-CRISIS [22, 23] was used to compute the seismic hazard map in terms of PGA for a probability of exceedance in 50 years (Figure 1).

As we can see, the seismic hazard results have slightly increased regarding previous studies.

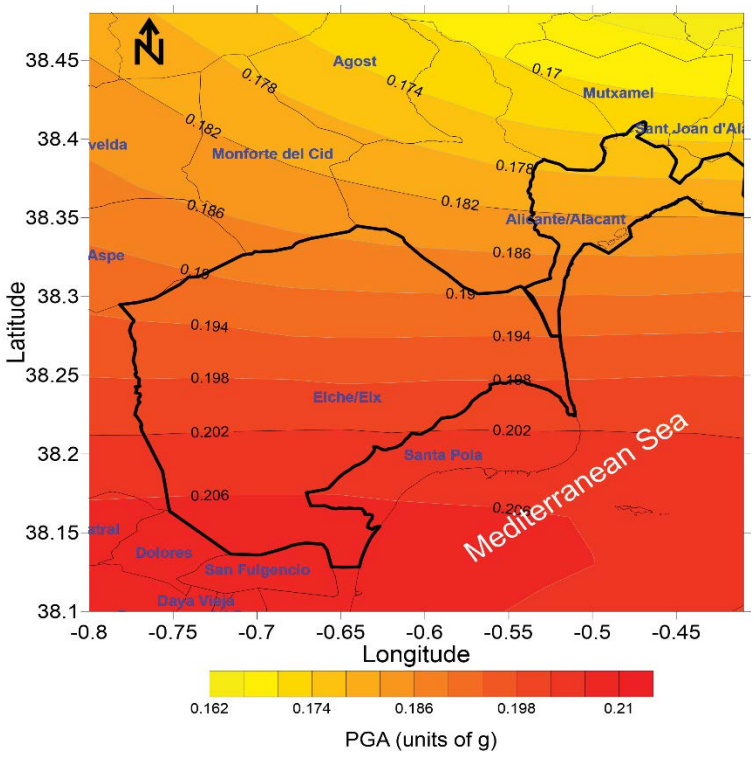

Figure 1: Seismic hazard map (PGA at rock) for the municipalities of Elche and Alicante for 0.1 exceedance probability in 50 years.

Therefore, we have chosen two sites (one in each municipality) as representatives of the PSHA values in the urban areas. Figure 2 represents the seismic hazard curves of PGA in terms of annual probability of exceedance and probability of exceedance in 50 years which will be used for the calculation of the risk-targeted hazard.

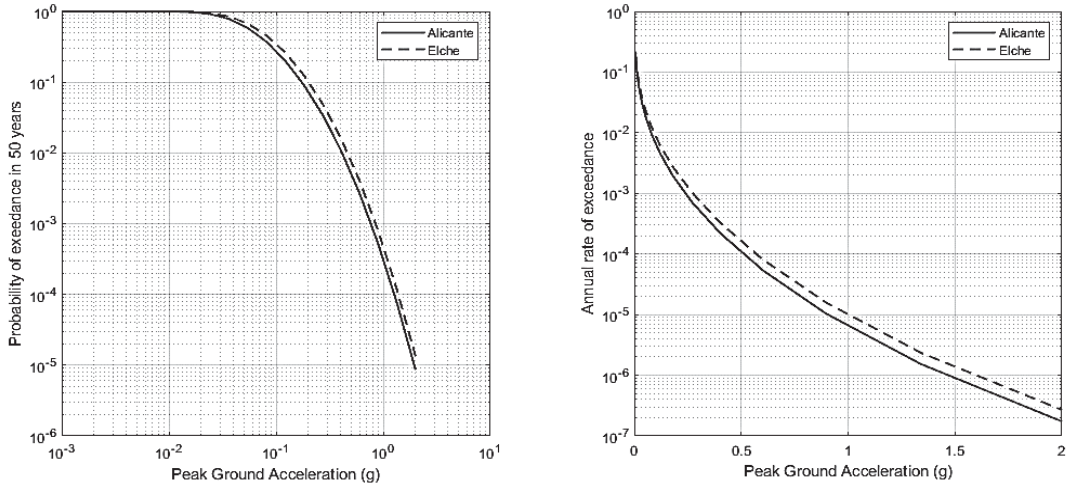

Figure 2: Seismic hazard curves for Alicante and Elche.

3 CALCULATION OF RISK-TARGETED MAP

In order to perform a risk-targeted analysis, it is necessary to develop the fragility curve corresponds to the structures under study. Considering that in this approach, the fragility curves should cover the vulnerability of a large range of different building typologies and on the other hand, developing these curves are too expensive for a specific building class and location, the generic collapse fragility curves will be used for all building classes in the desired area. It should be noted that the provided curve must be sufficiently generic to capture all possible vulnerabilities [8]. The fragility function is conditional upon the values of ground motion design and outlines the conditional probability of exceeding a limit state, which hereinafter is the collapse of a structure, for a given design ground motion with a specific mean return period (RP). In this study, the 475-year mean return period was implemented (i.e., 10% probability of exceedance in 50 years), since it is the most widely accepted value in Europe. The fragility functions are presented as lognormal distributions with two parameters: the median value of PGA and the logarithmic standard deviation of PGA (β). Hence, one can say, in order to develop a generic fragility curve for risk-targeted analysis, it is necessary to define the parameters of Pc|gm, and β. The latter (Pc|gm) is the conditional probability of collapse under the design ground motion with 475-year return period and the former (β) is taking into consideration several sources of uncertainty in the collapse capacity, such as the record-to-record variability, the uncertainty in the collapse definition, and, ideally other sources such as human error, that even the most advanced numerical models cannot accommodate [9].

Regarding with logarithmic standard deviation of the fragility functions, there are significant different values proposed by other researches. As an example, Luco et al. [6], used a β value of 0.8, while Douglas et al. [8] suggested value of 0.5. the β value of 0.6 was considered in the study by [9], while Vanzi et al. [24] used a value of 0.2. It is important to note that, using the higher values of β more than 0.8, provides a low probability of collapse even in highly seismic regions, which seems an unrealistic scenario. On the other hand, assuming low values of β (e.g.,

less than 0.2), leads to more steep collapse fragility curves that could provide 100% probability of collapse even at low ground motion levels. The estimation of Pc|gm, needs the design and evaluation of a large number of structures and a wide range of hazard levels. As stated earlier in this study, the probability of collapse corresponds to the peak ground acceleration of the hazard curve with a mean return period of 475 years. Several studies suggest different values of Pc|gm. For instance, Douglas et al. [8] suggested a Pc|gm value of 10^{-5}, while Silva et al. [9] used a value of 10^{-3}. Ulrich et al. [25] proposed a value of 10^{-7} for low, frequent design ground motion levels and 10^{-5} for higher and rarer design ground motion in their study. However, Silva et al. [9], believe this range of probability of collapse (i.e., 10^{-7} to 10^{-5}) is too extremely low for ordinary structures. Luco et al. [6], have selected 10% probability of collapse under MCE, which corresponds to the probability of collapse at 475-year ground motion ranging from 10^{-2} to 10^{-3} [9]. Fajfar and Dolšek [26] have computed the value of Pc|gm in the range of 10^{-4} to 10^{-5} and Vanzi et al. [24] used the value of 1.3×10^{-6} for the probability of collapse under gravity loads.

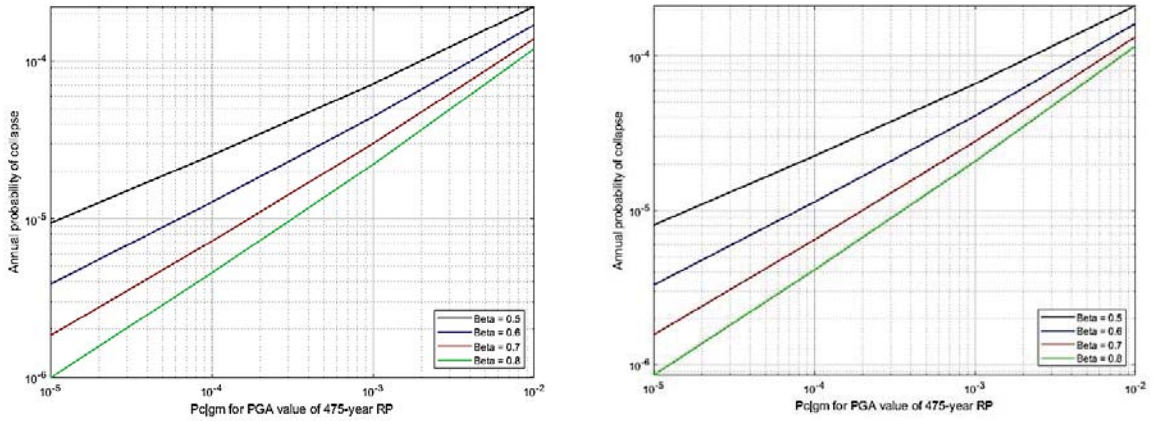
According to the PBEE method and using the seismic hazard curve and collapse fragility function the annual collapse rate of a structure, λ_c is determined using the following classic convolution products given by [27]:

$$\lambda_c = -\int_0^{+\infty} F(s).\frac{dG(s)}{ds}ds \tag{1}$$

Where F(s) is the fragility function (conditional probability of collapse for a given ground motion) and G(s) is the hazard curve. The integration in equation (1) does not have a closed-form solution [28], therefore an iterative process is required for calculation of annual collapse rate. As suggested by [9, 28] the annual failure probability will be computed by dividing both the fragility curve and the seismic hazard curve into a large number of segments and then numerically integration the distribution. Based on the Poisson assumption, the annual collapse rate is converted into the annual probability of collapse. It should be noted that since we are targeting the very low values, there is a negligible difference between the values of the annual probability of collapse P_c and the annual collapse rate (i.e., mean annual frequency of collapse, MAF). Since, the main objective of the risk-targeted analysis is the estimation of ground motion consistent with the target risk (i.e., accepted annual P_c), it is necessary to define an acceptable level of seismic risk, which can be expressed as annual collapse probability. Hence, in the iterative process, the value of design ground motion changes in each step until reaching the desired value of annual collapse probability. The obtained design ground motion at the final step will be the risk-targeted ground motion. Based on the study by [6], for each seismic site, the risk coefficient is calculated by dividing the obtained former value and the uniform hazard ground motion. Finally, the values of risk-targeted design ground motion are created by multiplying this coefficient to the current seismic design ground motion maps. Regarding with acceptable annual probability of collapse, there are different suggestions from other researches and seismic codes. For example, ASCE 2010 [7], proposed value of 2.0×10^{-4} for the United States. Douglas et al. [8], suggested using the value of 1.0×10^{-5} as a reasonable value. In the work by Silva et al. [9], the value of 5.0×10^{-5} established as an acceptable annual probability of collapse.

In order to investigate the effect of these parameters on the annual probability of collapse, a simple sensitivity analysis has been performed. In this analysis, different combinations of values for β and Pc|gm are considered (i.e., β = 0.5, 0.6, 0.7, and, 0.8 and Pc|gm = 10^{-2} … 10^{-5}). Then values of P_c (annual probability of collapse) will be calculated by developing the generic fragility curves and the computational approach described above. Figure 3a and 3b show the

relation of the annual probability of collapse with the parameters of Pc|gm, and β for Alicante and Elche, respectively.



(a) Alicante (b) Elche

Figure 3: Relation of annual probability of collapse with Pc|gm, and β

As shown in Figure 3, for both sites, the annual probability of collapse converges to a certain value when the conditional probability of collapse for a given design ground motion with a 475-year return period rises up to 10^{-2}. According to the analysis, in this study, we considered the values of 0.7, 10^{-2}, and 10^{-4} for β, Pc|gm, and P_c, respectively. Moreover, in the following sections for risk targeting analysis, the values proposed by other researches such as [6, 9] will be considered for a better comparison of the obtained results.

4 RESULTS FOR ALICANTE AND ELCHE

In this section, the risk-targeted maps for Alicante and Elche are built with the combination of target annual collapse probabilities and standard deviations suggested by [6, 9] as well as the ones assumed in this study. In order to evaluate the effect of two main input parameters, namely the standard deviation β and the probability of collapse for a given design ground motion with a 475-year mean return period (defining the fragility function) a series of maps were generated.

The first two tables (i.e., Table 1 and Table 2) show the annual probability of collapse for Alicante and Elche, Respectively. These values are corresponding to the PGA with a mean return period of 475 years. The standard deviation is considered as 0.6, 0.7, and 0.8 while the Pc|gm was taken as 0.1 and 0.001.

	β = 0.6	**β = 0.7**	**β = 0.8**
Pc|gm = 0.1	8.090×10^{-4}	8.054×10^{-4}	8.264×10^{-4}
Pc|gm = 0.001	4.421×10^{-5}	2.990×10^{-5}	2.207×10^{-5}

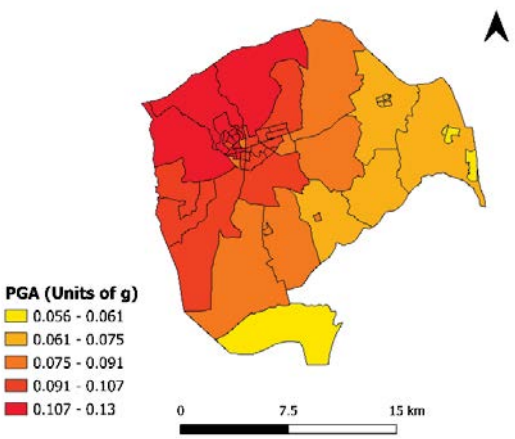
Table 1: Annual probability of collapse for the PGA corresponding to a mean return period of 475 years in Alicante

	β = 0.6	**β = 0.7**	**β = 0.8**
Pc|gm = 0.1	8.081×10^{-4}	8.077×10^{-4}	8.319×10^{-4}
Pc|gm = 0.001	4.089×10^{-5}	2.788×10^{-5}	2.071×10^{-5}

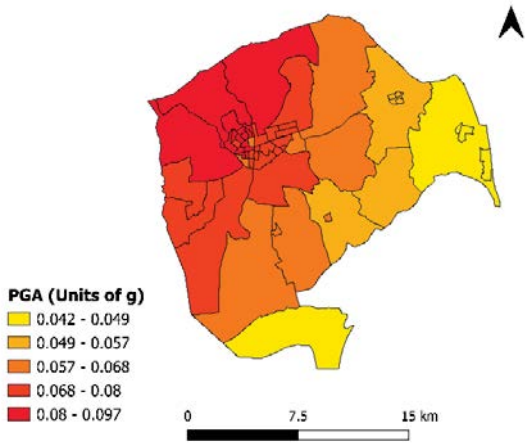
Table 2: Annual probability of collapse for the PGA corresponding to a mean return period of 475 years in Elche

Table 1 and Table 2 show the distinctive values of the annual probability of collapse. In the case of the Pc|gm = 0.001, Alicante has the highest probability of collapse, whereas in the case of Pc|gm = 0.1, the largest collapse probability is observed in Elche. Based on the seismic hazard map of the Alicante and Elche (Figure 1), it should be concluded that Elche has the highest collapse probability, but as it was observed above, using different values of Pc|gm in this approach, may lead to opposite results. A similar observation has been reported in the works by [9, 10] in which reveals some questions about this approach.

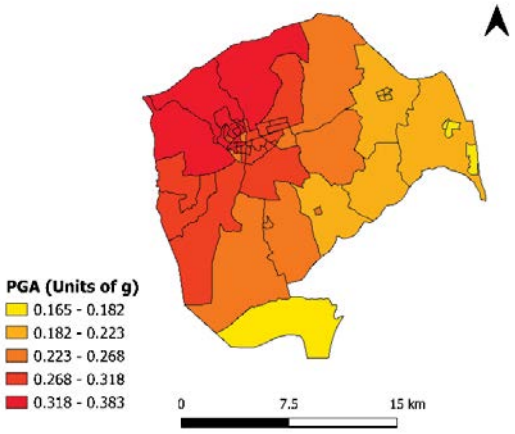
The four maps shown in Figure 4, represent the risk-targeted ground motions for the municipality of Elche corresponding to the annual collapse probability of 2×10^{-4}. The PGAs were calculated for $\beta = 0.6$ and 0.8 and using Pc|gm = 0.1 and 0.001.



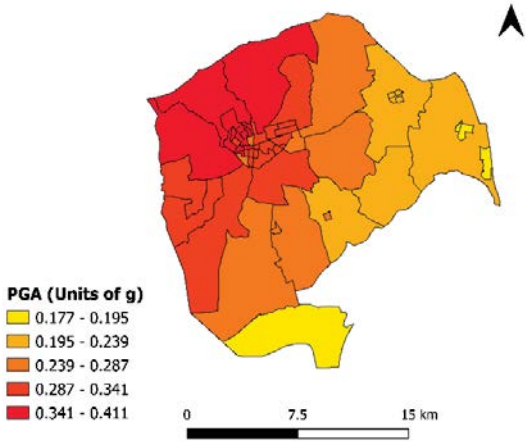
(a) Uniform risk-targeted map for target collapse probability 2×10^{-4}, $\beta = 0.6$, and Pc|gm = 10^{-3}



(b) Uniform risk-targeted map for target collapse probability 2×10^{-4}, $\beta = 0.8$, and Pc|gm = 10^{-3}



(c) Uniform risk-targeted map for target collapse probability 2×10^{-4}, $\beta = 0.6$, and Pc|gm = 10^{-1}



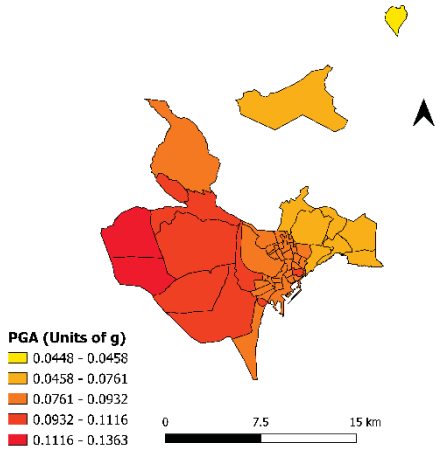
(d) Uniform risk-targeted map for target collapse probability 2×10^{-4}, $\beta = 0.8$, and Pc|gm = 10^{-1} (Elche)

Figure 4: Risk-targeted ground motion maps for Elche

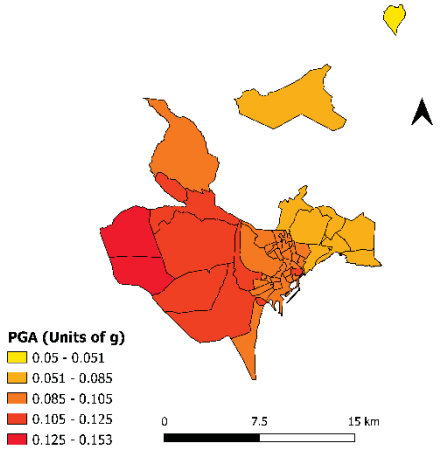
A comparison between Figure 4a and Figure 4b, indicates the larger values of β, results in the lower risk-targeted ground motion (almost 20% reduction). On the contrary, Figure 4c and Figure 4d show an increase of 7% by increasing the value of β. The risk-targeted ground motions in the Figure 4a and Figure 4c, show that for a given value of acceptable collapse probability and standard deviation, the ground motion level leads to larger values by increasing the

value of Pc|gm. A comparison between Figure 4b and Figure 4d displays the same trend as mentioned before.

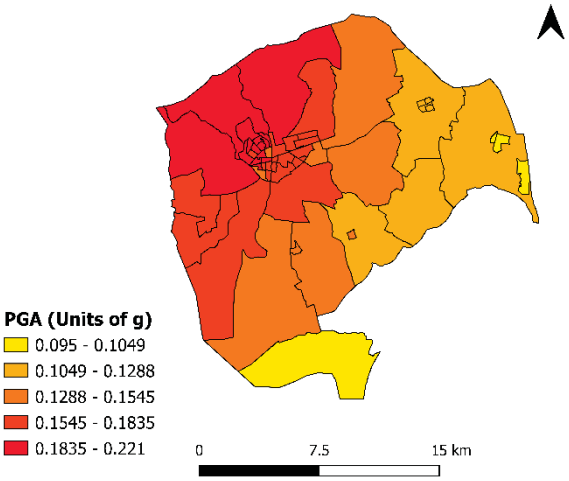
Finally, assuming $\beta = 0.7$ and $Pc|gm = 10^{-2}$ and target annual collapse probability of 10^{-4}, the risk-targeted ground motion maps for municipalities of Alicante and Elche are shown in Figure 5.



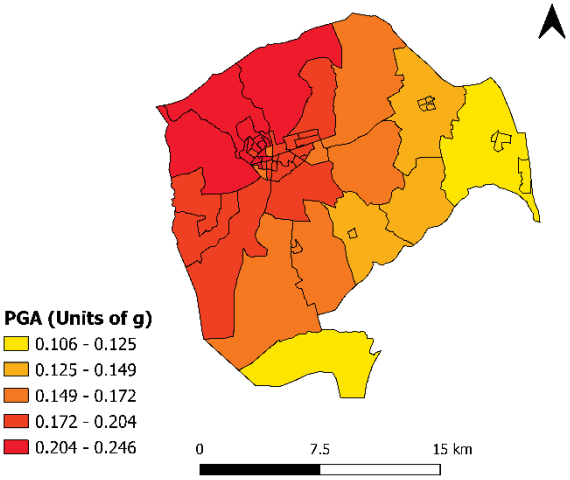
(a) Uniform hazard map for Alicante corresponding to 10% Probability of exceedance in 50 years



(b) Uniform risk-targeted map for target collapse probability 10^{-4}, $\beta = 0.7$, and $Pc|gm = 10^{-2}$ (Alicante)



(c) Uniform hazard map for Elche corresponding to 10% Probability of exceedance in 50 years



(d) Uniform risk-targeted map for target collapse probability 10^{-4}, $\beta = 0.7$, and $Pc|gm = 10^{-2}$ (Elche)

Figure 5: Uniform ground motion maps for Alicante (a and b) and Elche (c and d)

According to Figure 5a and Figure 5b, the risk-targeted ground motion in the municipality of Alicante varies between 0.05g and 0.153g with an average value of 0.098g indicating an almost 11% increase in the ground motion level. Figure 5c and Figure 5d show that the risk-targeted acceleration in the municipality of Elche changes from 0.106g to 0.246g with the average value of 0.162g representing 10% increase approximately. Clearly, the results of risk-targeted maps would be considerably different by variation of Pc|gm threshold in which considered in this study.

5 CONCLUSIONS

In this study, risk-targeted maps are developed for municipalities of Alicante and Elche based on the updated seismic hazard map of Spain [21]. The annual probability of collapse was calculated by using the convolution product between seismic hazard and fragility function. The relevant parameters suggested by [6, 9] and the results of the sensitivity analysis were also used to establish the generic fragility curves. Furthermore, by considering an acceptable collapse probability and the approach explained earlier in previous sections, the risk-targeted ground motion maps revealed. The results highlight the preliminary conclusions as follow:

- The influence of standard deviation on the annual probability of collapse is relevant, but no clear trends are observed.
- The influence of Pc|gm on annual collapse probability is significant.
- Given that these parameters (i.e., acceptable collapse probability, standard deviation, and distribution of collapse) can allocate different values proposed in the past works, different risk-targeted maps will be obtained for the considered regions in this study.
- Based on the assumed parameters and obtained results, it can be shown with some minor changes to the uniform hazard maps (up to 10%), the uniform risk of collapse will be achieved in the municipalities of Alicante and Elche.

Based on the obtained results, it is clear that risk-targeted seismic maps need to be created for the other municipalities and in the more extended work for Spain.

6 ACKNOWLEDGMENTS

The study has received funding from the European Union's Horizon 2020 research and innovation program under grant agreement No 821046, the Ministerio de Economía, Industria y Competitividad through research project CGL2016-77688-R, the Generalitat Valenciana through the research project AICO/2016/098 with the collaboration and funding provided by Elche and Alicante municipalities.

Abstract. *The increasing demand for housing in emerging countries has driven the construction of a significant number of buildings using thin reinforced concrete (RC) walls with a single layer of reinforcement. Studies in Latin America have found buildings using walls as thin as 80 mm and as height as 7 stories. The advantage of this structural system relies on its economy and its construction speed; however, different concerns emerge about the seismic performance of buildings using this system. These relate to the possible lack of ductility, the scarcity of information about their behavior during earthquakes, and the absence of design guidelines supported by experimental research. Contributing to these needs, researchers have conducted several studies, most of them focused on experimental campaigns to assess the seismic behavior of thin RC walls. Despite these efforts, there is still need of more information about buildings constructed with this structural system, particularly about their analytical modelling. This research investigated the effect that different modelling assumptions have on the seismic performance assessment of buildings with thin RC walls. A six-story building constructed in Bogotá, Colombia using 100 mm walls reinforced with welded-wire mesh (WWM), was modelled in OpenSees using the shear flexure interaction multiple line vertical element model, with different assumptions for damping and steel behavior. In terms of damping, two Rayleigh damping schemes were used, one considering the initial stiffness and other with the current stiffness. For steel modeling, the material properties obtained from experimental testing were used for two approaches, one that considered buckling and other where it was ignored. For further comparison, models with deformed bars instead of WWM were created. The seismic performance of the different models was evaluated through incremental dynamic analyses, using the FEMA P-695 ground motion suite. From these analyses, the interstory drift ratios, steel and concrete strains were recorded, which served as input for the development of seismic fragility functions. The results show that modelling parameters exert and influence at the different seismic performance levels, particularly on the collapse fragility of the WWM building. At the MCE level, the collapse probability observed for the WWM model with bar buckling was 14.8% higher than the model without buckling. This percentage was 7.4% for the model with damping proportional to the current stiffness compared to the model that used the initial stiffness. All things considered, the findings suggest that the modelling parameters have an influence on the analytical response of thin RC wall buildings.*

1 INTRODUCTION

In recent years, housing demand in Latin America has increased considerably. To supply this demand, an important number of low and mid-height buildings with thin reinforced concrete (RC) walls have been constructed in seismic prone countries like Venezuela, Mexico, Chile, Peru and Colombia [1–5]. The advantage of this structural system relies on its speed of construction and its economy. In Colombia, RC walls as thin as 80 mm have been used [6], using one layer of web reinforcement with welded-wire mesh (WWM) reinforcement or deformed bars (DB). The latter type of reinforcement has higher adoption because it allows a higher construction speed, and WWM with limited ductility capacity [7] are currently being using for projects in major cities like Medellín and Bogotá.

Several of the described buildings do not fulfill seismic requirements of major design codes like the ACI 318 [8], therefore local codes in some countries have included special provisions for buildings with thin RC walls to reflect on the awareness of housing demands. For instance, the Mexican Metropolitan Code [9] allows buildings of up to two stories with structural walls of 100 mm thickness. Similarly, the Chilean code [10] allows the use of ordinary RC walls for structures up to five stories if they are designed with a strength reduction factor equivalent to that of masonry structures. For such walls, a single or double layer of web reinforcement may be used, and the minimum wall thickness is 100 mm. In other countries like Colombia, whose local code shares many similarities with the ACI 318 [11], it does not include specific clauses for these type of buildings, and designers are following the RC wall building provisions.

Different concerns emerge about the seismic performance of buildings with thin RC walls, especially for those reinforced with WWM. These relate to the absence of design guidelines supported by experimental research, the scarcity of information about their behavior during earthquakes, and the possible lack of ductility. With these needs in mind, researchers have investigated the behavior of thin RC walls by both analytical and experimental means.

Some experimental campaigns have been carried to assess the seismic behavior of thin RC walls with different configurations, such as walls with different thickness and lap splicing [12], walls constructed with lightweight and low-strength concrete [13], and walls reinforced with welded-wire mesh [14]. Other tests have been conducted to compare the dynamic and quasi-static behavior of thin RC walls [15], to propose shear strength and hysteretic response rules [16], and to evaluate their out-of-plane behavior [17]. Moreover, equations have been proposed to estimate their shear strength [18] and numerical models have been proposed to simulate their seismic behavior [19,20]. Also, nonlinear three-dimensional analysis of typical Peruvian RC thin wall buildings have been conducted [18], and fragility function have been calculated for one-story houses reinforced with WWM in Perú [21] and for typical Chilean two-story houses [22].

Regardless of the described efforts, there is still need of more analytical information about the seismic behavior of thin RC walls that can provide guidance about the best practices for their usage as a structural system. In particular, there is need to understand the effect which different modelling assumptions have on the assessment of their seismic performance.

Contributing to these needs, this research investigates the seismic performance of a six-story thin RC wall building located in Bogotá, Colombia. This building was designed per the Colombian NSR-10 [23]. First, this article describes the building structural configuration and then, a section of the building is selected for developing nonlinear model in OpenSees [24], using the shear-flexure interaction multiple line vertical element (SFI-MVLEM) [25] model for the thin RC walls. The base model considers Rayleigh damping proportional to the building initial stiffness and does not include bar buckling. A second model was created that considers bar buckling.

A third model considers Rayleigh damping proportional to the current stiffness. These models are subjected to incremental dynamic analyses (IDA) [26] using the far field suite of the FEMA P-695 [27], which served as input information for the development of seismic fragility functions.

2 DESCRIPTION OF THE CASE STUDY BUILDING

A six-story building constructed in Bogotá, the capital city of Colombia, is taken as case study. This building was part of a survey conducted by the Colombian Earthquake Engineering Research network (CEER) in four major cities in Colombia.

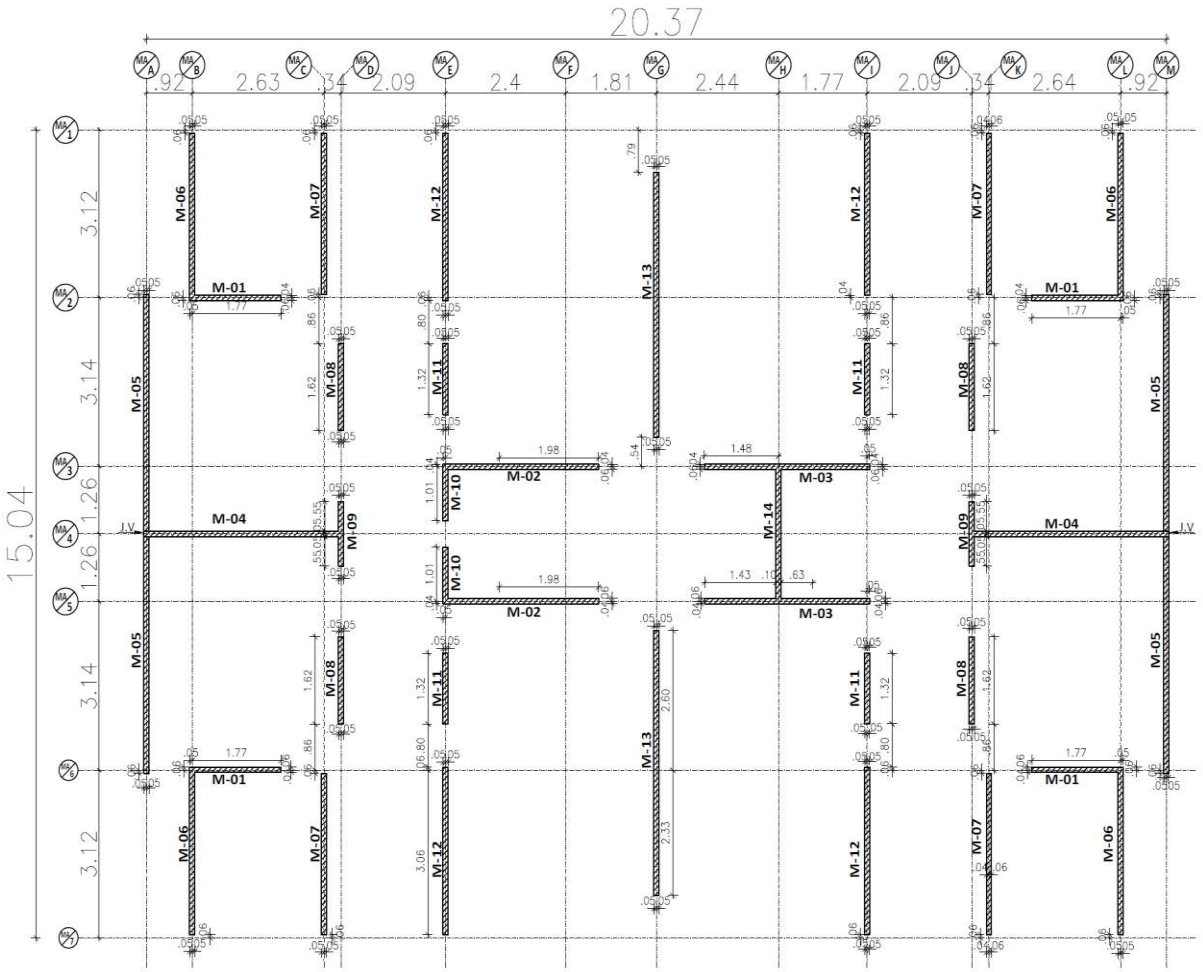

Figure 1: Plan configuration of a six-story building located in Bogotá, Colombia. Dimensions are in m.

The building has identical stories, which have a plan distribution (Figure 1) with a 4:3 aspect ratio and a free inter-story height of 2.45m. The building was designed according to the Colombian design code (NSR-10) for a design acceleration Sa = 0.5625g, with a structural system that uses 100 mm walls reinforced with a single steel mesh in the center of the wall. These walls are also used to separate habitational spaces. As stated by the structural drawings, the mesh used for wall reinforcement has 6.5 mm diameter bars with a separation of 150 mm in both directions, which are the equivalent of a vertical reinforcement ratio $\rho = 0.0023$ and a horizontal reinforcement ratio $\rho_h = 0.0023$. According to the ETABS model obtained by CEER, the fundamental period of the building is 0.36s, a value within the limits observed for this type of buildings. This elastic model was used to calculate the axial loads of each one of the building walls.

3 DESCRIPTION OF THE NONLINEAR MODELS

The seismic performance evaluation of this building is conducted considering a section in the X direction (Figure 2) of the building, which is comprised of four walls. This direction was selected because it represents the weakest building direction, as the larger number of walls have their main orientation in the Y direction. The four selected walls are a major part of the building lateral force resisting system in the X direction used for this study.

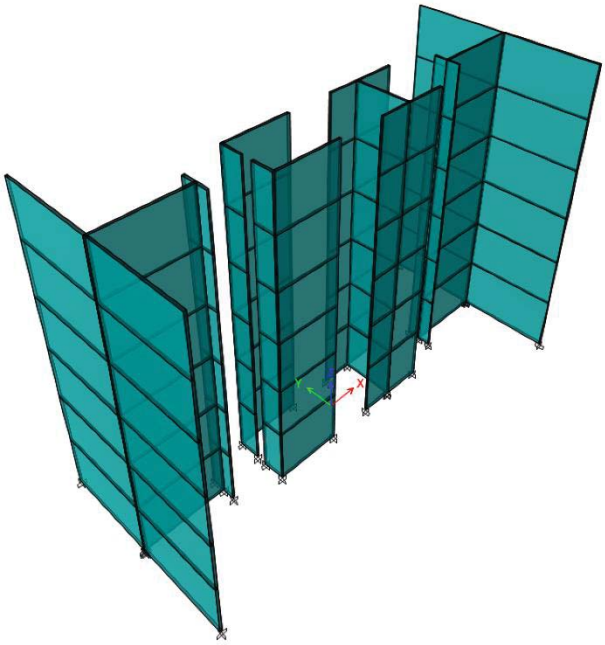

Figure 2: Building section used for nonlinear analyses.

The nonlinear response of this section is assessed using an OpenSees model. The shear-flexure interaction multiple vertical line element (SFI-MVLEM) [25] is used to model the behavior of the walls, using six panels for the inner walls and eight panels for the outer walls. As the walls are reinforced with a single layer of reinforcement without confinement, the concrete is modeled as unconfined using the ConcreteCM material, with $f'_c = 21$ MPa, and a strain at peak concrete strength $e_c = 0.002$. For the model with welded-wire mesh, the steel properties are obtained from the tests by Carrillo et al. [7], which report an elastic modulus $E = 210GPa$, a yielding stress $f_y = 621MPa$, an ultimate stress $f_u = 687MPa$ and an ultimate strain $e_u = 0.0155$. This last property is the cause of major concerns about the potential lack of ductility of these walls, as well as their seismic performance [7]. For the model with deformed bars, material properties $E_s = 210GPa$, $f_y = 420MPa$, $f_u = 630MPa$ and an ultimate strain $e_u = 0.15$. Both steel types are modelled using the Hysteretic material in OpenSees, in combination with the MinMax material to account for the fracture after exceeding the ultimate strain. For both models, the foundation is modeled as rigid, and the gravity loads for the model are calculated based on the expected loads and using the combination 1.05 D + 0.25 L. Rayleigh damping was applied to the model, with 2.5% damping to the first and third mode of the structure.

A base model considers damping proportional to the building initial stiffness and does not include bar buckling. A second model was created that considers bar buckling and a third model considers Rayleigh damping proportional to the current stiffness. Hereinafter these models will be referred as the Damping1, Buckling and DampingC models.

These models were subjected to incremental dynamic analysis using the 44 ground motions of the FEMA P-695 suite [27]. For the models with WWM, the ground motions were scaled to 0.25, 0.5, 1.0, 1.5 and 2.0 times the design acceleration of the building. For the model with DB, two additional factors of 3.0 and 3.5 were included. The concrete stress, inter-story drifts, roof drifts and steel strain were recorded during the dynamic analyses. Several failure modes were considered based on these results. Crushing of the unconfined concrete was assumed to occur at an e = 0.004 strain. Steel failure was considered due to fracture when the recorded strain exceeded the ultimate strain.

Four damage levels were defined for the DB and WWM based on the inter-story drifts. The limits for the slight, moderate and extensive damage were set based on the recommendations by Carrillo and Alcocer [28]. For the collapse limit, it was defined at 0.4% based on the findings reported by the same authors. This limit was set to 5% for the model with DB (Table 1).

Damage level	Deformed bars	Welded-wire mesh
Slight	0.15%	0.10%
Moderate	0.40%	0.25%
Extensive	0.65%	0.35%
Collapse	1.00%	0.40%

Table 1: Limits for the drifts in the DB and WWM models

4 SEISMIC PERFORMANCE RESULTS

The results of the incremental dynamic analyses were used to calculate the fragility functions at the four damage levels described in table 1. For each damage level the probability of exceeding a given damage level was computed as the number of times that the observed drift was higher than the limit, divided by the number of ground motions (44). The results were fitted to a log normal distribution. The distribution parameters for the WWM and DB models are reported in Tables 2 and 3, and the corresponding functions for the buildings are shown in Figures 3 and 4.

Slight	0.300	0.087	0.334	0.278	0.358	0.264
Moderate	0.565	0.376	0.569	0.412	0.617	0.288
Extensive	0.647	0.468	0.637	0.452	0.731	0.339
Collapse	0.694	0.506	0.692	0.491	0.763	0.349

Table 2: Fitted lognormal parameters for the buildings with WWM

The results from Figure 3 show that the modelling assumptions exert an influence on the observed seismic response during the analyses of the buildings. At the maximum credible earthquake (Sa = 0.84g) level, the collapse probability observed for the Damping1, Buckling and DampingC models were 61.4%, 70.4% and 65.9%, respectively. Compared to the Damping1 model, the Buckling and DampingC models are 14.8% and 7.4% higher; however, the three values are significantly higher than the 10% limit that is expected for buildings designed according to modern design codes. Steel fracture was the dominant failure mode observed for the three models, demonstrating that despite the modelling scheme used for damping and steel, the use of WWM for thin RC results in buildings with seismic performance that falls below what is expected for code compliant buildings.

Table 2 allows several observations. The comparison between the Damping1 and Buckling model shows that both modelling hypothesis lead to similar median values for the moderate, extensive and collapse levels. In contrast, the median for the slight level is 10% higher for the Buckling model, suggesting that including buckling exerts an influence at lower performance states. The comparison of β values shows that these are larger for the Buckling model at the slight and moderate levels and similar for the extensive and collapse levels. A possible explanation for this behavior is that the drift limits for the extensive and collapse levels are similar for the buildings with WWM, and in the case of collapse, the fracture and not the buckling of steel control this limit.

The results of for the DampingC model show that this modelling assumption leads to less variability in the seismic response, as evidenced by the β values, which are smaller for at the

moderate, extensive and collapse levels. In contrast, the Θ values are higher when this scheme is used to simulate the seismic response. Figure 4 shows the fitted fragility functions for the three modelling assumptions at the collapse level, showing that the DampingC model has smaller probabilities than the Damping1 and Buckling models for smaller intensity earthquakes.

On the other hand, for earthquakes with larger intensities, this model has higher collapse probabilities. Although there may be several reasons that contribute, it is likely that at these earthquakes the stiffness matrix may have reduced significantly, causing a reduction in the overall damping. This consequence of using the damping proportional to the current matrix stiffness has been discussed before by Charney [29].

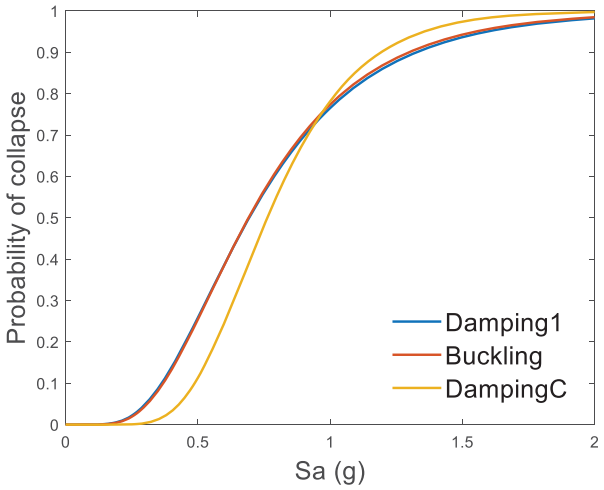

Figure 4: Collapse fragility of the WWM buildings for the three modelling assumptions

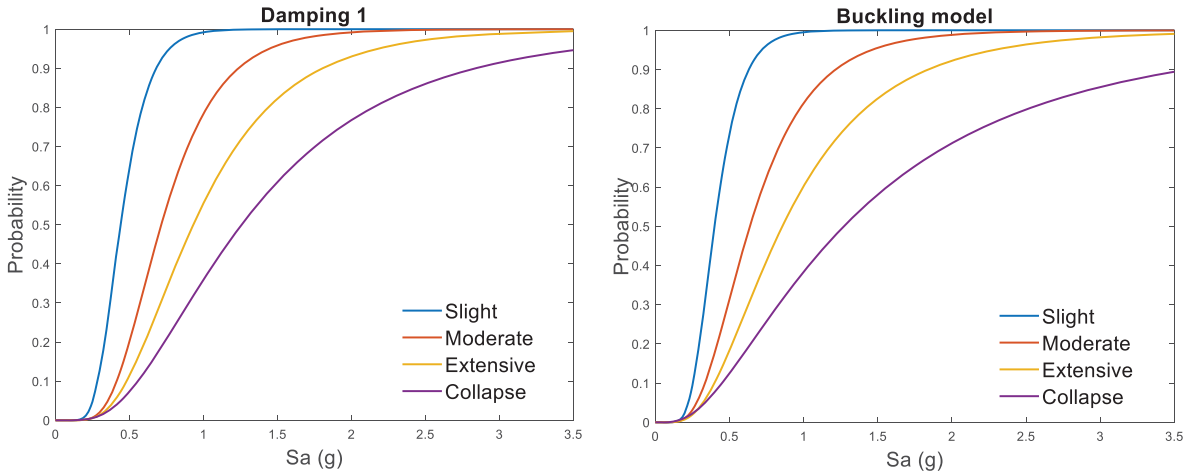

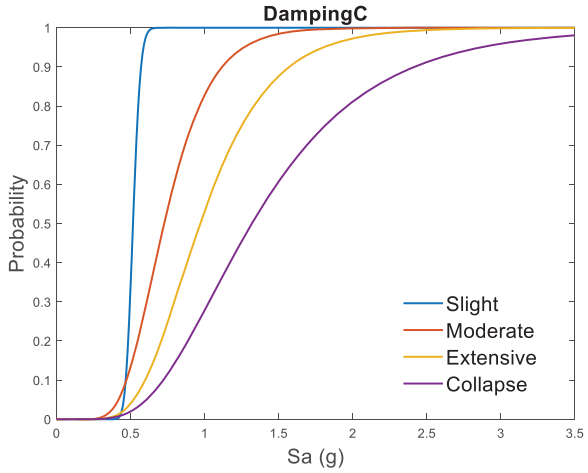

(c)

Figure 5: Fragility functions for the building with deformed bars considering the (a) Damping1, (b) Buckling and (c) DampingC models

Damage level	Damping 1		Buckling		DampingC	
	Θ	β	Θ	β	Θ	β
Slight	0.441	0.340	0.400	0.356	0.516	0.078
Moderate	0.715	0.427	0.638	0.503	0.727	0.337
Extensive	0.932	0.516	0.857	0.597	0.970	0.377
Collapse	1.258	0.635	1.272	0.811	1.319	0.472

Table 3: Fitted lognormal parameters for the buildings with DB

The results for the models with deformed bars show that the modelling assumption also exert an influence for this type of building, particularly in the variability parameters. At the slight damage level, the Θ parameter varies from 0.4g for the Buckling model to 0.516g for the DampingC model, a 29% difference. However, the coefficients of variations at this level are 77%, 89% and 15% for the Damping1, Buckling and DampingC models. This smaller variation of the DampingC model is evidenced by the steep function in Figure 5c.

At the moderate and extensive damage levels, the Damping1 and DampingC models had similar Θ parameters, although the DampingC model had lesser variability in the response, as evidence by the smaller value for β (Table 3). At these performance levels, the Buckling model had significantly higher variability than the Damping1 and DampingC model, with β values that are up to 49% and 58% for the moderate and extensive levels.

The comparison of the three modelling assumptions at the collapse level (Figure 6) shows that the DampingC model exhibits a similar trend to the one observed for the buildings with WWM. Compared to the Damping1 and Buckling models, this modelling scheme produces smaller probabilities at lower acceleration levels, and bigger probabilities for higher acceleration values. In contrast with the models with WWM, where the Damping1 and Buckling models showed identical performance, Figure 6 also shows that the inclusion of bar buckling with deformed bars has an impact on the collapse of the building. This model showed the opposite behavior of the DampingC model, with higher probabilities for lower accelerations and smaller ones for higher accelerations.

At the maximum credible earthquake, the models with Damping1 and Buckling showed a 20.4% probability of collapse and the DampingC model an 18.2% probability, which double the 10% target value of modern design codes. Although unacceptable, these probabilities are significantly smaller than those observed for the buildings with WWM, further supporting the fact that the lack of ductility of the WWM severely hinders the seismic performance, and that this type of structural system should be limited in seismic prone regions.

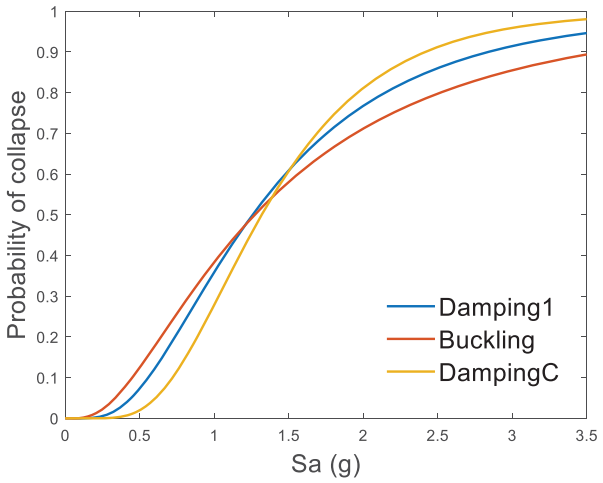

Figure 6: Collapse fragility of the DB buildings for the three modelling assumptions

6 Conclusions

This paper investigated the effect that different modelling assumptions have on the seismic assessment of thin RC wall buildings reinforced with a single layer of reinforcement. For this purpose, a six-story building constructed using this system was modelled in OpenSees considering two Rayleigh damping schemes, one proportional to the initial stiffness matrix and other proportional to the current stiffness matrix. Two approaches were used to model the behavior of the reinforcing steel, one that ignores the bar buckling and other that includes it. Although this building was constructed using welded-wire mesh (WWM) as reinforcement, a model with deformed bars (DB) was also created for the sake of further comparisons. All models were subjected to incremental dynamic analyses and the results were used to calculate the seismic fragility functions at four different damage levels. The findings of this paper support several conclusions:

The use of the current stiffness matrix for the damping produces seismic fragility functions with the smallest level of variation. At the collapse level, when compared to the models with damping proportional to the initial stiffness and bar buckling, this modelling scheme produced smaller probabilities for lower acceleration levels, and bigger probabilities for higher accelerations. This behavior occurred for both type of steel reinforcement (WWM and DB) and it was result of the reduction in damping for larger accelerations, where the building damage reduces the stiffness component of the damping.

For the buildings with WWM, the models with stiffness proportional to initial stiffness and with bar buckling showed similar results at the slight and moderate damage levels, and identical behavior at the extensive and collapse performance levels. This suggests that the inclusion of bar buckling affects the behavior for small to medium accelerations, but for larger ones, the lack of ductility of the WWM becomes a governing factor and these performance limits are

controlled by the steel fracture and not its buckling. In contrast, for the buildings with DB, the additional ductility of the steel allows bar buckling to exert an influence and this modelling scheme produces smaller probabilities for larger accelerations.

In terms of seismic performance at the maximum credible earthquake, the building with WWM had collapse probabilities of 61.4%, 70.4% and 65.9% for the models with initial damping, bar buckling and current damping. For the building with DB, the corresponding values were 20.4%, 20.4% and 18.2%. For both types of reinforcement, these probabilities are higher than the 10% limit that is expected for buildings designed according to modern design codes, particularly those of the WWM buildings. These findings support the idea that the use of RC thin walls for mid-rise buildings should be limited for seismic prone areas, regardless of the type of reinforcement used.

Keywords: Steel Moment Frame, Probability of Collapse, Base Connections, Gravity Framing

Abstract. *Special Steel Moment Frames (SMFs) are one of the most common lateral-load resisting systems. Hysteretic energy in these systems is dissipated by the development of plastic hinges at the end of the beams. In order to guarantee the desired collapse mechanism, columns, beam-column, and column base connections are sized employing the capacity design-criteria. Recent research on column base plates indicates that these connections pose high deformation capacity and may be used as part of the dissipative energy system. These findings have motivated studies to evaluate a possible strong-column weak-base connection criterion, implying a reduction on the base demands and, consequently, a nonlinear incursion of these connections. The implication is a potential reduction of connection costs at similar building performance. However, these studies have neglected the influence of the gravity system on the seismic performance of the SMFs analyzed. Consequently, a study that includes the profound influence of gravity system while investigates the consequences of seismic demands reduction of base plates has not been conducted. Against this backdrop, this research presents a parametric study conducted on an 8-story SMF, which evaluates the probability of collapse considering three different levels of base connection strength while including the gravity system. Results indicate that gravity systems tend to enforce the building to deform on the first mode of shape even at large floor displacements while base rotations are increased significantly. The design implication is that base-connections should be kept designed to carry the plastic capacity of the column.*

1 INTRODUCTION

Steel Moment Frames (SMFs) are one of the preferred lateral-load resisting systems by the construction industry due to their high deformation capacity as well as architectural versatility. Because of this, these systems have been extensively studied over the last decades. Early studies on the topic started to understand their modes of response under gravity loads. Formal requirements for lateral forces started officially after the 1906 San Francisco earthquake, although seismic provisions were not mandated until 1948. Before the 1994 Northridge earthquake, it was assumed that SMFs are ductile without special detailing. However, this assumption was challenged by the way how the buildings performed during this earthquake. In a post-earthquake evaluation, brittle failure was observed in the connections. Extensively experimental programs were conducted after that aimed to develop ductile behavior in the connections. These investigations ended up in notably design guidelines for new and existing SMFs (e.g., FEMA 355 [1]).

Typically, the SMFs consist of an assembly of beams and column elements rigidly connected between them. Because of this, the main components are beams, columns, beam-column connections, and column base connections. As mentioned before, special attention has been given to beam-column connections. Although, in a less degree compared to beam-column connections, column base connections have been studied during the last years through experimental and numerical investigations. Two types of base connections have been used in the context of US construction practice: i) for low-to-midrise buildings exposed base plates are preferred. These connections consist of a steel column welded to a base plate, which is anchor to the foundation; ii) on the other hand, for high-rise buildings, embedded base connections are the norm. This detail consists of a steel column embedded in a concrete foundation.

Recent experimental studies conducted on column base connections (i.e., exposed and embedded type) indicate that these connections have high deformation capacity with desirable hysteretic properties [2–5]. Furthermore, other experimental programs conducted on columns [6,7] suggest that these members, especially when subjected to axial load, may have limited ductility due to local phenomena such as local and lateral-torsional buckling. This background suggests that the current design criteria for column base connections (i.e., design them to remain elastic) may be unjustified, considering that this approach is protecting the more ductile component (i.e., base connection over column member). This criterion of strong base connection – weak column may be attributed to the sparse information about the dissipative properties of column base connections, and to the intuitive idea that connections are less ductile than component members. Besides, the construction of strong base connections implies a significant extra cost. For instance, when an exposed base plate is specified, thicker base plates and a large number of anchor bolts are required to satisfy the demands (based on capacity design principles). If an embedded base connection is detailed (e.g., in the case of mid-rise or tall buildings), the embedded depth may be significant.

Falborski et al., 2020 [8] conducted a parametric study to investigate the effect of base connection strength, flexibility, and deformation capacity on the probability of collapse of four SMFs (i.e., 4-story, 8-story, 12-story, and 20-story). Four levels of column base connection strength were considered in this study. The first level (the lowest one in terms of strength) corresponds to a base connection designed for reduced seismic loads (i.e., R=8). Two intermediate levels of strength include designing the base connection for R=3 and Ω_o=3. Finally, the strong base criteria, which implies designing the connection for the fully plastified and strained hardened attached column. Each of these strength levels is associated with a rotational stiffness calculated by methods developed by Kanvinde et al., 2012 [9] for the exposed base plates and Torres-Rodas et al., 2017 [10] for the embedded details. The hysteretic characteristics of the

connections were considered based on the recommendations of Torres-Rodas et al., 2016 [11] (for exposed base plates), and Torres-Rodas et al., 2018 [12] (for embedded base connections). The main finding of this investigation was that similar performance (i.e., acceptable probability of collapse) for all the SMFs might be obtained by designing the base connections for the strength level corresponding to demands computed with over-strength seismic loads (i.e., Ω_o =3) rather than for $1.1R_yM_p$ of the attached column. The key design implication was that the base connections must be detailed to accommodate rotations of 0.05 rad in order to use over-strength seismic load combinations. However, it is important to mention that this study did not include the effect of the gravity framing system on the response of the SMFs which were analyzed.

The influence of gravity framing system on the seismic performance of SMFs have been reported in the past. Gupta and Krawinkler [13] addressed the response of SMFs at different seismic hazard levels using four models. Two of them included the gravity system. The results of this study indicate that significant improvement in the response of the SMFs may be achieved at large inter-story drifts when the gravity system is included. These authors defined gravity connections with a simple rotational spring in which the peak strength was reached at 0.02 rad and 0.01 rad for the positive and the negative moments, respectively. Other studies [14] predicted the influence of gravity system on the seismic performance of SMFs through the definition of a confidence factor, which indicates whether the structure satisfies the collapse prevention criteria at the Maximum Considered Earthquake (MCE). Flores et al. 2014 [15] investigated the effect of the gravity framing system on the probability of collapse of SMFs with the use of FEMAp695 methodology. These authors analyzed three SMFs (2-story, 4-story, and 8-story) in their study. The influence of two main parameters was investigated, i.e., the stiffness of the gravity columns and the strength of gravity-beam connections. Results indicate that gravity framing system deeply influences the seismic performance by reducing the probability of collapse. The reviewed studies consider idealized boundary conditions, i.e., either pinned or fixed-bases in their analyses.

In summary, studies conducted on SMFs to examine the influence of gravity framing systems typically have been carried out considering idealized boundary conditions (i.e., fixed or pinned bases), neglecting the potential benefit of base-connections as energy dissipative mechanisms. On the other hand, studies (e.g. [8,16]) carried out on the topic to assess the influence hysteretic behavior of column base connections on the seismic response of SMFs neglected the beneficial effect of the gravity system. This backdrop motives the present investigation to examine the interrelation between the column base connection strength, stiffness, and deformation capacity with the seismic performance of SMFs (by using FEMAp695 methodology) incorporating the beneficial effect of gravity columns and gravity beam-column connections, seeking to explore the consequences of using a strong-column weak-base connection criterion that leverages the hysteretic properties of these connections.

This paper starts by describing in this introductory section the studies conducted on the topic in the past. Subsequently, the methodology employed in the current investigation is described, detailing the 8-story SMF model used herein. Sophisticated nonlinear time history analysis was conducted on the 8-story SMF model to investigate the effect of column base connection strength, flexibility and deformation capacity accompanied by gravity framing system on its seismic performance expressed in terms of its probability of collapse at MCE level. Results from the simulations are discussed, and potential implications for design are presented.

2 METHODOLOGY OF ANALYSIS

The scientific basis of this research consists of a series of Nonlinear Time History (NTH) analysis conducted on an 8-story archetype frame complemented by Nonlinear Static Pushover

(NSP) analysis. The 8-story SMF analyzed herein belongs to the NEHRP project [17] and was designed assuming a Response Coefficient Factor $R=C_d=8$ and site class "D" conditions under the seismic design category D_{max}. Fig. 1 illustrates its characteristics (plan view, elevation, and member size). The height of the frame is 31.8m and consists of three-bay frames located at the perimeter of the building plan. The bay width is 6.00m. The height of the first story is 4.50m, while the height of the rest of the stories is 3.90m. A dead load of 4.78 kN/m^2 was applied on all the floors, while an unreduced live load of 2.38 kN/m^2 was applied on all floors except on the roof, where a live load of 0.95 kN /m^2 was applied. A perimeter load of 1.20 kN/m^2 was assigned to simulated cladding. Beam-column connections were detailed as Reduced Beam Section (RBS) connections based on AISC 341 [18] recommendations.

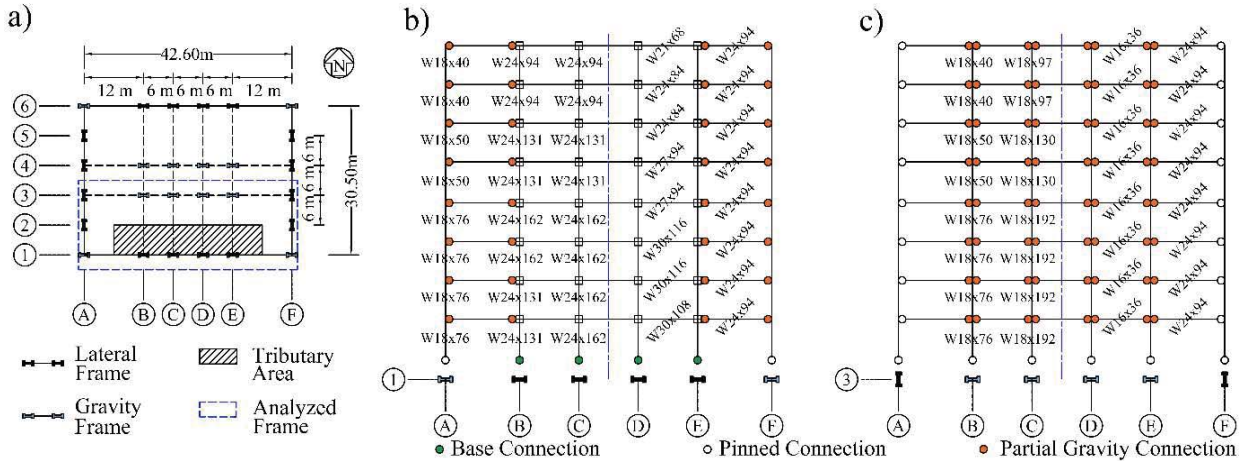

Figure 1: 8-story SMF. a) Plan view. b) Elevation view axis 1. c) Elevation view axis 3.

The beams and columns are modeled as linear-elastic elements with the plasticity concentrated at their ends. For beam elements, nonlinear rotational springs are placed at the RBS locations, while in the columns, rotational springs are located at their ends. These nonlinear rotational springs are aimed to capture the hysteretic response of the connections. The hysteretic model employed is the well-known Ibarra-Medina-Krawinkler (IMK) model, which consists of a tri-linear backbone curve with kinematic strain hardening and monotonic deterioration, supplemented with rules to capture cyclic strength and stiffness deterioration [19]. This model inherits an important limitation from uniaxial plasticity formulations, i.e., it cannot capture moment-axial load interaction. Because of it, this phenomenon is represented in an approximate manner. First, the gravity load is considered as an average value of the axial load to be presented in the NTH analysis [20,21]. Next, a reduced bending strength may be calculated with the interaction equations from AISC [22]. This reduced strength is used in the rotational springs at the end of the columns. Panel zone is modeled as a hinged parallelogram assembly by rigid elements with a nonlinear spring at one of the corners to represent shear distortions in the panel zone. The properties of these springs (i.e., for beam-column connections and panel zone) are computed based on the recommendations [13,21].

The column base connection for this SMF was detailed as an embedded base connection. Its hysteretic response was capture by the model proposed by [12] for embedded base connections. This model has a trilinear backbone curve similar to the IMK models, supplemented by rules aimed to capture the hysteretic response as well as modes of deterioration found in column base connections. The backbone curve of the models is defined by the following parameters: the moment at first yield, initial rotational stiffness, maximum moment (i.e., peak strength), and

rotation of the connection associated with its peak strength. These parameters were estimated from analytical models available in the literature. For instance, the maximum connection strength (i.e., M_{peak}) was calculated by Grilli and Kanvinde 2016 [23]. Besides, these authors showed that the moment at first yield might be considered as 70% of M_{peak}, which is the criteria considered herein. The rotational stiffness of these connections was calculated by the method proposed by Torres-Rodas et al. (2017) [10], which consists of calculating the flexibility of the connection by aggregating the deformations within the components (Fig. 2a).

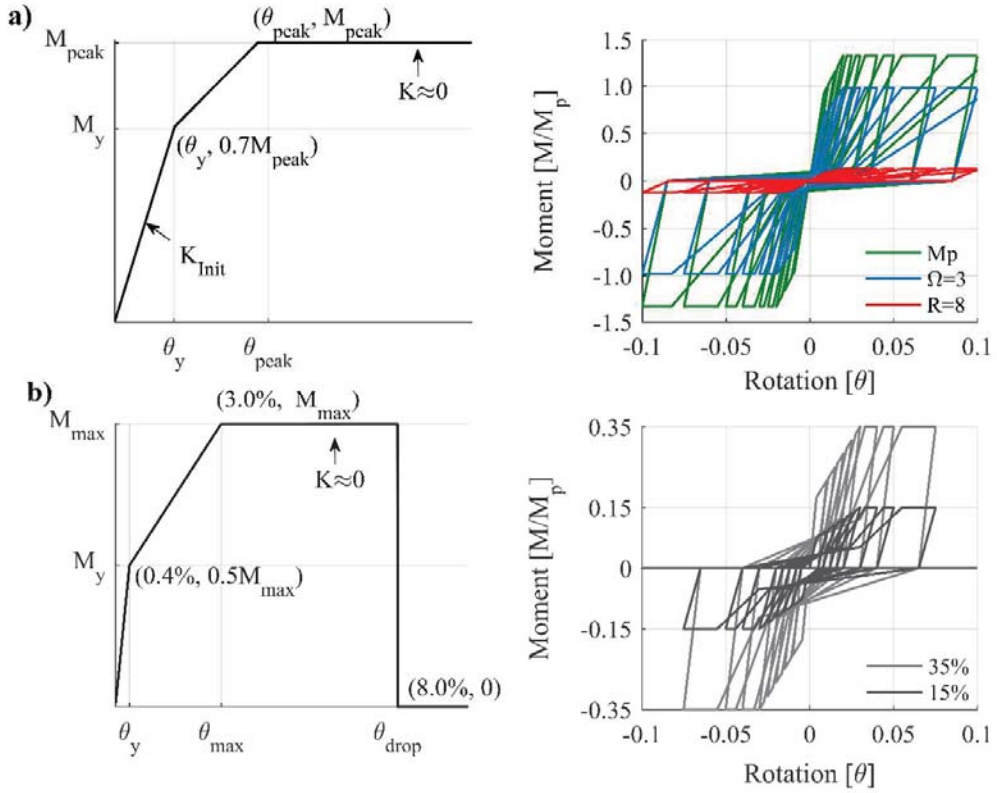

Figure 2: Hysteretic models for a) Base base connection. b) PR gravity connection.

As per Falborski et al., 2020 [8], three different levels of column base connection strength are considered in this paper (for the parametric analysis) which consist of a connection design to resist: i) $1.1R_yM_p$ of the attached column which corresponds to the capacity design criteria; ii) Over-strength seismic loads, i.e., Ω_o =3; and iii) Reduced seismic loads, i.e., R=8. It is anticipated based on previous work ([24,25]) that the first level of strength (i.e., capacity design criteria) will not allow the development of inelastic rotations while the last one will imply large inelastic rotations for which the connections must be properly detailed. The flexural capacity of each base connection strength level is provided in Table 1.

Strength Level	**Moment Strength**	
	Int (kN.m)	**Ext** (kN.m)
$R=8$	309.04	292.35
$\Omega=3$	1167.36	2309.99
$1.1R_yM_p$	2612.09	3276.38
Fixed-Base	-	-

Table 1: Base Connection Strength Levels

The gravity framing system is included as part of the lateral-load resisting system in the simulations, as shown in Fig. 1c. Gravity beam and column sizes were obtained through a typical design based on ASCE 7 [26] and AISC 360 [22]. The gravity connections are considered as partially restrained (PR) connections [15,27]. The main characteristic of these connections is that their capacity is lower than the plastic capacity (i.e., M_p) of the beam, which ranges from 15-35% of M_p [28]. The model developed by Elkady and Lignos 2015 [27] is used to capture the influence of PR connections in the seismic performance of SMFs. The effects of column base hysteretic behavior and the gravity framing system on the seismic performance of SMFs are considered parametrically, while four cases are presented for all the archetype frames. The first case corresponds to the models without any gravity framing. The second case consists of analyzing only the influence of gravity columns, neglecting the effect of gravity connections. This is performed by an approach proposed by Flores et a., 2015 [15] by concentrating all the gravity columns in a lumped elastic column pinned at the base and attached to the SMFs, as illustrated in Fig. 1. The last two cases include the effect of gravity system beams using a rotational spring aimed to capture the hysteretic response of PR connections. Two main parameters defined this spring, i.e., the strength and initial stiffness (Fig. 2b). In this paper, two values of PR strength are considered. The first value represents 15% of the beam M_p, while the second one a 35% of M_p of the beam. Table 2 summarizes the details and define an appropriate notation for all models analyzed herein.

Notation	**Column Base Strength Level**
$R = 8$	$R = 8$
$\Omega = 3$	$\Omega = 3$
Mp	$1.1R_yM_p$
Fix	Fixed-Base
Notation	**Gravity System Strength Level**
Non	No gravity system
00%	Only gravity columns (or partial connections 00%)
15%	15%Mp
35%	30%Mp

Table 2: Models Analyzed in this study

Two types of analyses are carried out in this paper. These analyses are 1) Nonlinear Time History (NTH) analysis, and 2) Nonlinear Static Pushover (NSP) analysis. The NTH analysis is conducted on the archetype frame to parametrically investigate the effects of column base strength, rotational stiffness, and ductility accompanied by the beneficial influence of gravity columns, and PR connections strength on 1) the probability of collapse of SMFs at MCE level, and 2) the seismic performance (i.e., inter-story drift ratios) at the Maximum Considered Earthquake (i.e., 2 % probability of exceedance in 50 years). The SMF analyzed herein is first simulated with idealized boundary conditions (i.e., fixed base) without considering the influence of the gravity framing following current design practice. Next, it is analyzed considering three different levels of base connection strength (i.e., R=8, Ω_o=3, and $1.1R_yM_p$), and three different values of PR connection strength (i.e., 0%, 15%, and 30% of M_p) in the presence of gravity columns.

The software OpenSees is used for all the simulations since it has been extensively verified for NTH simulations [29]. A collapse assessment relative to each of the models simulated was conducted following the FEMAp695 methodology. Sideways collapse is defined by FEMAp695 (2010) when the IDA curves become flat (or typically with a slope less than 20%), or when the inter-story drift ratios reach a value of 10% from which the structure is extremely unlikely (if not impossible) to recover [30,31]. In this manner, the median collapse capacity of each of the simulations may be obtained once 22 out of 44 ground motions produce sideways collapse. This median collapse capacity is compared with the site-hazard (i.e., probability of exceedance of 2% in 50 years) to compute the collapse margin ratio (CMR). This CMR is adjusted with the spectral shape factor (which considers the spectral shape of rare earthquakes in California) to obtain the adjusted collapse margin ratio (ACMR). Finally, the probability of collapse can be computed with the ACMR. This metric of performance is used to evaluate the safety of the archetype frame and to understand their sensitivity to variations in column base connection strength with the inclusion of the gravity framing system (varying PR connections strength).

In addition to IDA simulations, this study presents the results of the NTH analysis conducted on the archetype frame to assess the effect of column base strength, and stiffness accompanied by gravity framing in the inter-story drift ratios at MCE level of shaking (i.e., probability of exceedance of 2% in 50 years). For this purpose, the suite of ground motions from FEMAp695 methodology is considered too severe [32]. A suite of 40 ground motions selected by Medina and Krawinkler [33] is scaled up to MCE-level of shaking, assuming soil type D, which is representative of the Los Angeles basin.

Apart from the NTH analysis, a Nonlinear Static Pushover (NSP) analysis is conducted on the models to supplement the information obtained from the NTH analysis. The NSP analysis generates "pushover curves," which provides general insights on frame response (e.g., collapse mechanism) and structural properties. Two structural properties may be obtained from NSP analysis; 1) system overstrength, 2) period-based ductility. The next section discusses the results of the NTH and NSP analysis on the models conducted in this investigation and possible implications in design.

3 DISCUSSION OF RESULTS

This section summarizes the results obtained from the NTH and NSP analysis described in the previous section conducted on the 8-story SMF with possible implications in design. Fig. 3 summarizes the results from NSP analysis. Fig. 3a illustrates the effect of base connection strength and gravity framing on the pushover curve. Each color of Fig. 3a represents the results of a model analyzed for different connection strength levels while each inset contains different curves that highlight the influence of PR gravity beam-column connections for a specific base connection strength. Fig. 3a indicates that an increase in base connection strength entails an increase in the system overstrength as well as in the period-base ductility. The same trend is observed when the strength of PR beam-column gravity connections is increased. In general, the overall frame behavior is improved with the inclusion of gravity framing while increasing base connection strength.

Fig. 3b illustrates the building deformed shape under different base connections and PR beam-column connections strength. Similar to Fig. 3a each color represents a different base connection strength level. As a general trend, a decrease in base connection strength tends to concentrate deformations on the first floor. The more impacting case is the one corresponding to R=8, where a soft story is formed when gravity framing is not included. Even though base flexibility tends to concentrate deformations at first-floor gravity framing counteracts this effect by linearizing the inter-story drift ratios along with the height of the frame.

The yielding mechanisms are presented for two cases of analysis: 1) R=8–Non and 2) R=8–35% and shown in Fig. 3c. In the first case, the point P1 represent the RBS connection yielding on the second floor. Then the point P2 represents the yielding on the base connection. P3 shows that RBS connections reach the deterioration on a drift of 0.75%, and P4 represents the top column yielding of the second floor, causing the highest deterioration on the structure's capacity. The addition of the gravity system keeps constant the P1 and P2 yielding events but increases the ductility of the system. The deterioration on RBS connection is reached on point P3' on a drift of 1.45%, which duplicates the drift reached without the gravity system. The next yielding point P4' occurs when the partial connection of the gravity system reaches the threshold of $0.8V_{max}$. Moreover, this model, which includes gravity framing, does not present the weak-story mechanism that led the R=8–Non model to the fragile behavior.

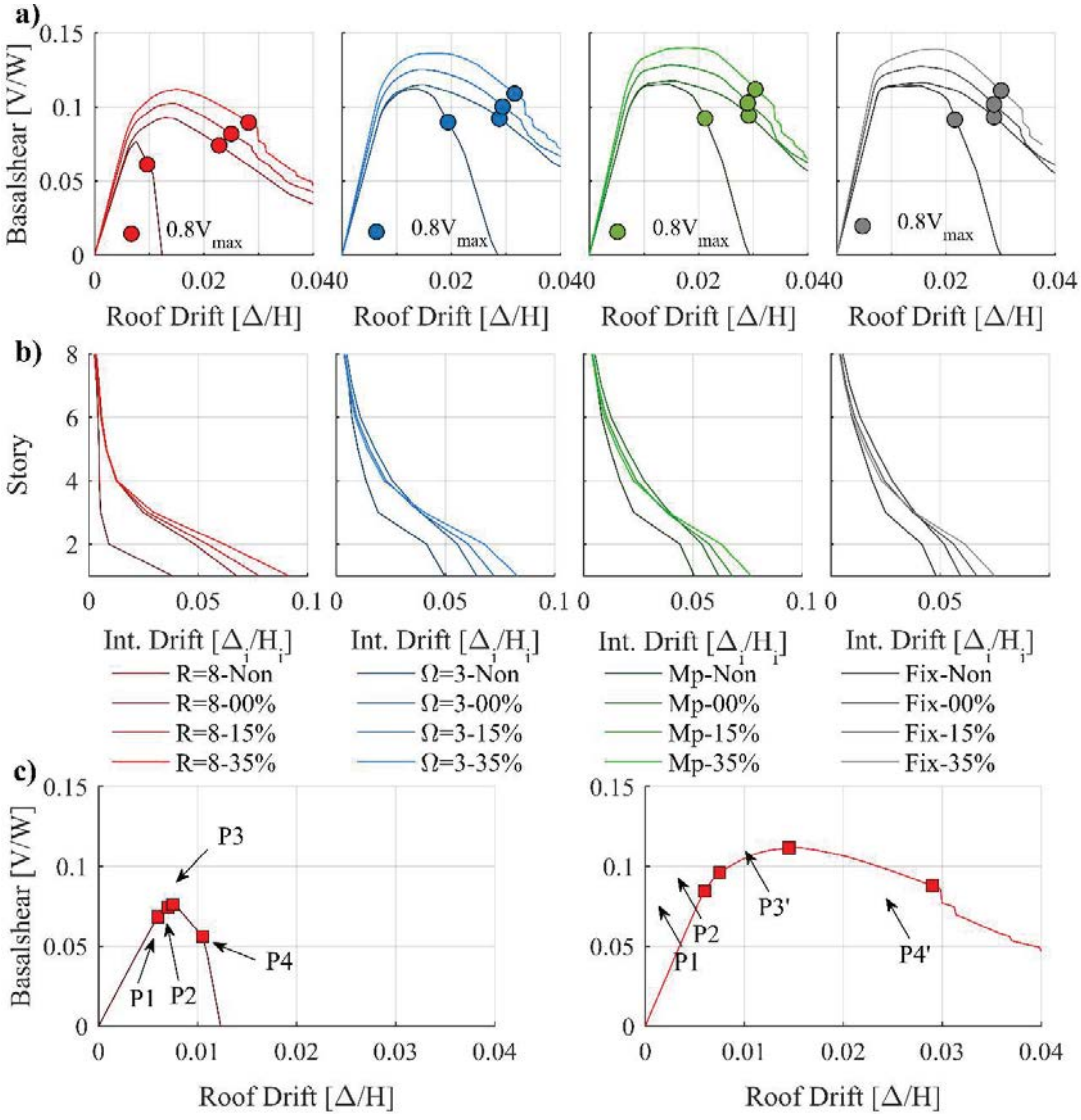

Figure 3: Results from static analysis. a) Pushover: R=8, Ω_o=3, $1.1R_yM_p$, and Fixed-Base. b) Inter-story drift profile: R=8, Ω_o=3, $1.1R_yM_p$, and Fixed-Base. c) Yielding Mechanism for two models: R=8-Non, and R=8-35%.

Fig. 4 summarizes the NTH results conducted on the 8-story SMF. Fig. 4a presents the Collapse Margin Ratio (CMR) for each connection strength level while in each inner inset, the influence of PR connections is illustrated. In other words, each color set corresponds to a

connection strength level (i.e., R=8, Ω_o=3, 1.1R_yM_p, Fixed-Base.) while each tone color represents a PR connection strength. As per Fig. 4a and 4b, there are no significant differences between the collapse probability or the CMR value between the models Ω_o=3, 1.1R_yM_p, and Fixed-base. However, the case R=8 presents an unacceptable performance in terms of collapse probability when the gravity system is not included. As a general trend, a decrease in base connection strength entails an increase of probability of collapse while the inclusion of the gravity system always improves the system behavior even if only the gravity columns continuum stiffness (i.e., Col.) is included. The former may be attributed to the fact that a decrease of base connection strength entails an increase of base flexibility, which drops the inflection point of first story columns moment diagrams. This results in an increment of stresses at the top of the fist story columns, which may give rise to a soft story.

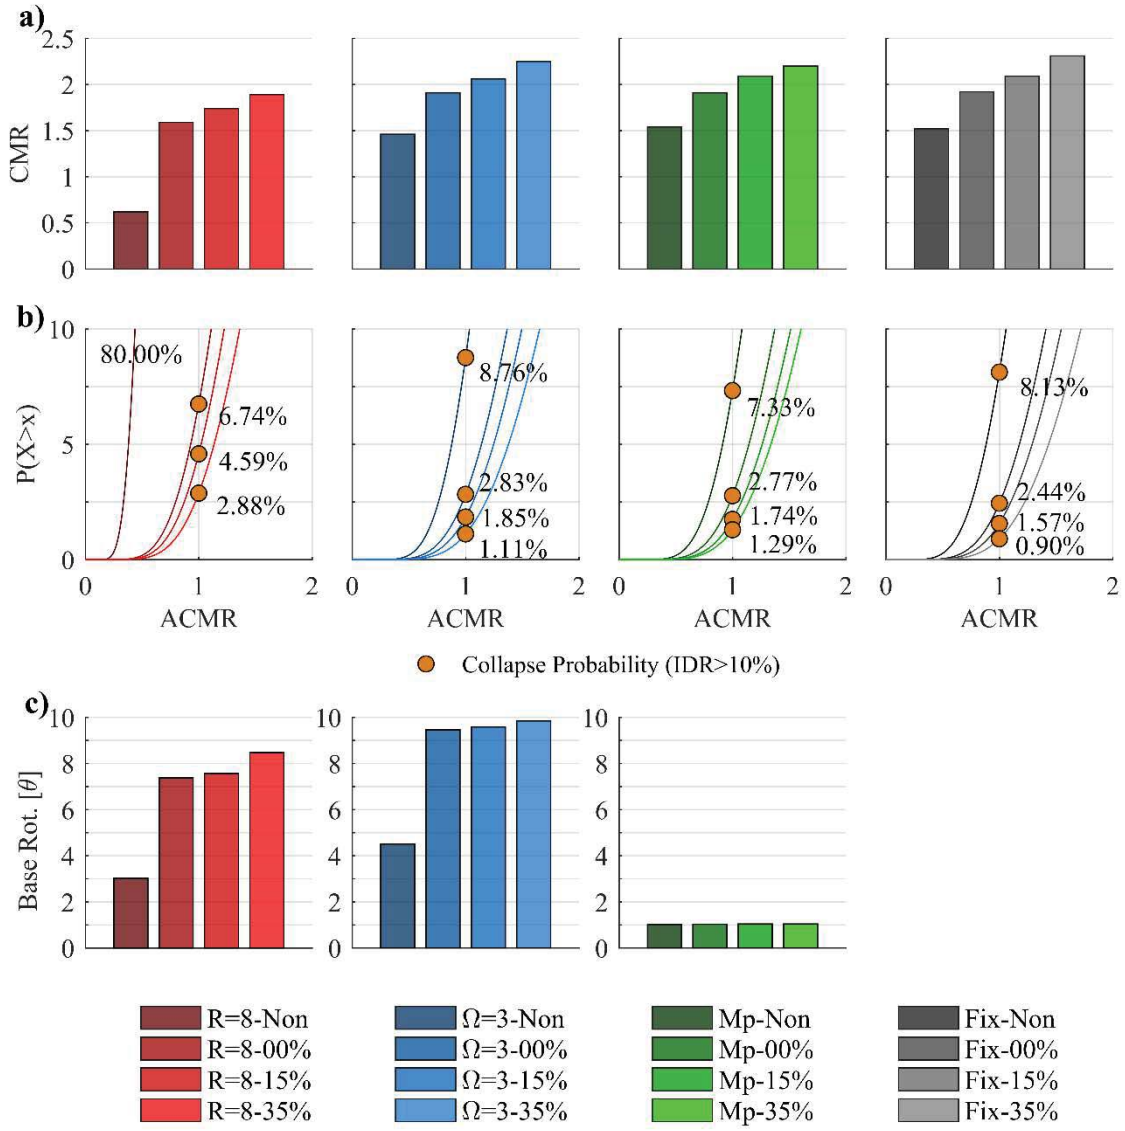

Figure 4: Collapse analysis. a) Collapse margin ratio: R=8, Ω_o=3, M_p, and Fixed-Base. b) Probability of collapse: R=8, Ω_o=3, 1.1R_yMp, and Fixed-Base. c) Median base rotation: R=8, Ω_o=3, and 1.1R_yMp.

Fig.4c presents the median of the base connection rotations obtained from NTH analysis on the verge of structural collapse for each column base connection strength varying PR beam-column connection strength. As expected, when the connection is designed for carrying a moment corresponding to $1.1R_yM_p$, rotations are less than 1% implying elastic behavior. In general, rotations are increased when base connection strength is reduced. A closer inspection of Fig. 4c reveals interesting results. The addition of the gravity system presents a singular effect in the base connection rotations, which are significantly increased. This may be explained due to the fact that the gravity system tends to enforce the building to deform in the first shape mode. Consequently, this phenomenon avoids the formation of soft-story mechanisms decreasing the system probability of collapse while implying a significant increment in base rotation demands. These results imply that although the gravity system counteracts the detrimental effect of base flexibility (in the probability of collapse of the 8-story SMF), it would require connections detailed to hold rotations in the order of 10%.

At first glance, results from IDA (Fig. 4b) indicate that base connection strength could be reduced (even for the case R=8), and similar performance can be achieved compared with the strong base criteria when the gravity system is included. However, an inspection of base rotations indicates that this conclusion cannot be stated unless base connections are properly detailed to hold rotations in the order of 10%.

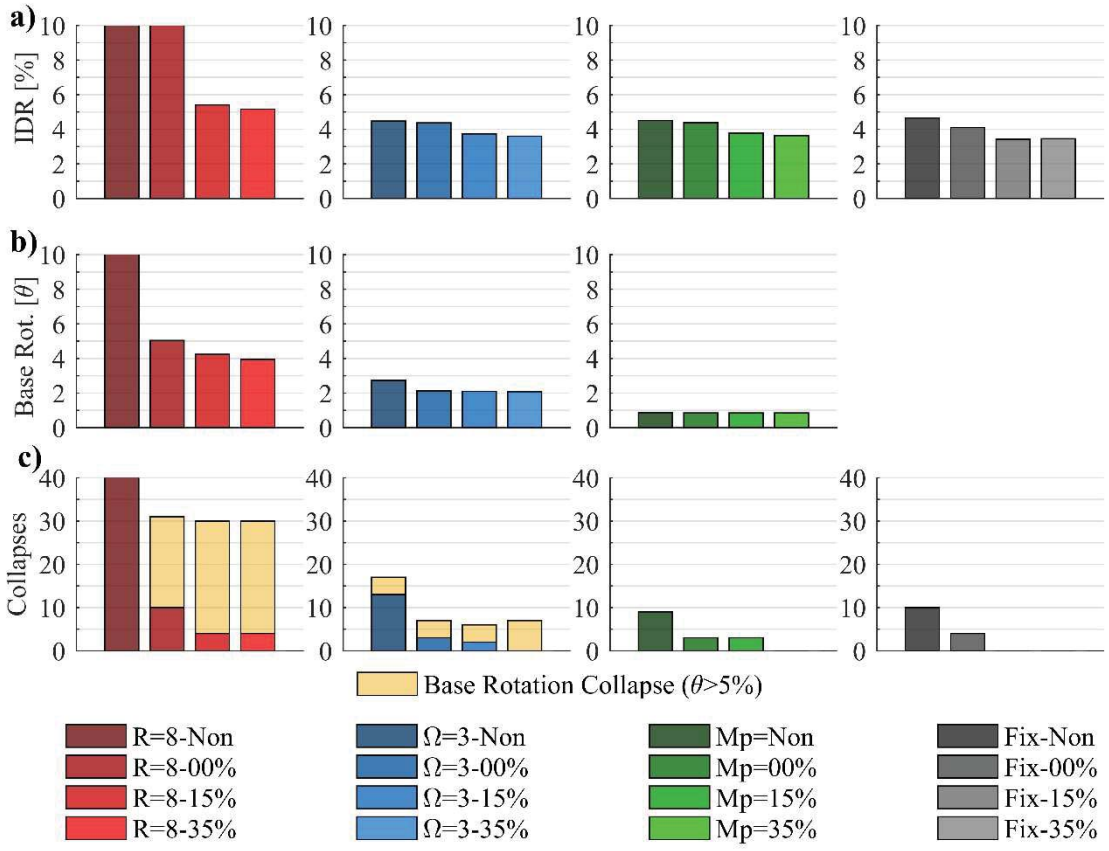

Figure 5: NTH analysis at MCE level of shaking. a) Inter-story drift ratios: R=8, Ω_o=3, $1.1R_yM_p$, and Fixed-Base. b) Median column base rotations: R=8, Ω_o=3, and $1.1R_yM_p$. c) The number of Sidesway Collapses in the SMF: R=8, Ω_o=3, $1.1R_yM_p$, and Fixed-Base.

The seismic performance of the SMF at MCE level of shaking was conducted in order to explore the effect of base connection behavior in the presence of gravity framing on the inter-story drift ratios. As per Fig. 5a, the cases Ω_o=3, $1.1R_yM_p$, and Fixed-Base leads to similar results even for different values of PR connection strength except for the case R=8 that presents the highest drifts. Specifically, the simulations conducted on the case R=8 presents drifts superior to 10% when gravity framing was neglected and when only the stiffness of gravity columns was included. On the other hand, considering the hysteresis of PR gravity connections entails a significant reduction of drifts, which highlights the effect of these gravity-connections in the overall system behavior. Fig. 5b shows the median base rotations for each simulation. Base rotations ranging from 1% for the strongest base to 10% for the weakest one are reported. In contrast to collapse assessment, at the MCE level of shaking, the gravity framing tends to reduce these rotations. This is explained because the effect of gravity framing is maximum at large deformations (at the verge of collapse), while its influence is minor at smaller deformations. Finally, Fig. 5c presents the number of sidesway collapses in the analyzed frame versus the number of connection failures. It is defined that a connection will fail beyond a 5% base rotation threshold [2-5]. As expected, the inclusion of the gravity system reduces the number of building collapses significantly. However, it is important to indicate that for all the cases corresponding to R=8, although the gravity system reduces the number of collapses, the number of base connection failures (i.e., rotations exceeding 5%) is high. From a design point of view, this will imply detailing column base connections for significant rotation capacity. On the other hand, base connections designed for Ω_o=3 and $1.1R_yM_p$ show a similar number of sidesway collapses even though the gravity system is excluded from the analysis. However, a closer inspection of the cases corresponding to Ω_o=3 strength level reveals a high number of connection failures (i.e., rotations beyond 5%), implying that connections need to be detailed to hold these significant levels of base rotations.

4 CONCLUSIONS

This paper investigates parametrically the effect of base connection strength, rotational stiffness, and deformation capacity incorporating the effect of gravity framing system on the seismic performance of an 8-story SMF. The scientific basis of this research consists of a series of NTH simulations conducted on the frame. Three levels of base connection strength are considered in this study (i.e., R=8, Ωo=3, and $1.1R_yM_p$), while the influence of gravity framing and PR gravity connections strength is included in each case analyzed giving a total of 16 mathematical models. In all models, sophisticated NTH analysis is conducted, which is supplemented by NSP. The NTH analysis is aimed to investigate the influence of base connection behavior accompanied by gravity framing on 1) probability of collapse of the SMF following the methodology described at FEMAp695; 2) inter-story drift ratios at MCE level.

Results from NTH analysis indicate that a reduction of base connection strength is accompanied by an increment on base-connection flexibility. This phenomenon tends to drop the inflection point of the moment diagram from the first story columns leading to a soft story mechanism. Specifically, when the gravity system is neglected, the model corresponding to base strength level R=8 presents unacceptable performance (i.e., probability of collapse in the order of 80%) while stronger base connections are on the verge of the 10% threshold. Inclusion of gravity framing in general decreases the probability of collapse to values less than 5%. Even the cases analyzed for the weak base connection criteria (i.e., R=8) present acceptable performance when the effect of the gravity system is considered. This may be attributed to the fact that gravity columns tend to enforce the SMF to deform on the first mode of shape, reducing stress concentrations on the first story.

Interestingly, when the gravity system is included, the median rotations at the base increase significantly except for the case where base connections are detailed by the capacity designed criterion. For this latter case, base rotations are less than 1% implying purely linear elastic behavior. On the other hand, a reduction in base connection strength entails a significant increase in base rotations. The implications might be important. If base connection strength is reduced, it must be detailed to hold rotations close to 10%. Up to this point, there are no guidelines to achieve this ductile behavior. Therefore, from the author's analysis base connections must be kept design based on capacity design principles or another collapse criteria should be proposed to consider a base connection failure limite state (i.e., base connection rotation < 5.0%).

This study is subjected to several limitations. First, only one archetype frame is analyzed. It is recommended to investigate further the effect of base connection behavior accompanied by gravity framing with different frames varying in height and plan view. Other limitations from this study that might be described are the bias due to ground motion effects, including the effects of vertical acceleration components, and assumptions related to the models such as concentrated plasticity models vs. distributed plasticity models. However, the results of this study must be understood as the first parametric investigation aimed to evaluate the impact of base connection behavior in the presence of the gravity framing system on the seismic performance of SMFs.

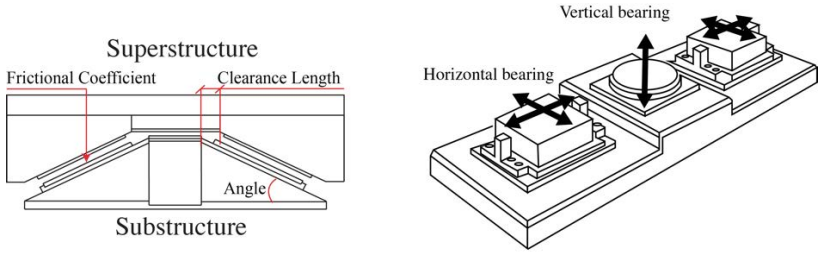
Keywords: Slide bridge bearings, Multi-objective optimization, Seismic excitations, Stochastic-deterministic approach, Seismic performance assessment

Abstract. *In the process of seismic performance-based design of bridges with slide bearings, there exist intrinsic tradeoffs between minimization of bearing displacement and that of the pier response in selecting bearing parameters for strong earthquake events. However, difficulty in determining the optimal parameters of the bearings that satisfy the two objectives arises, in conjunction with considerable computational resource requirement for nonlinear time-history analysis. In order to find the solutions of the multi-objective optimization problem that reduce the computational cost, a procedure that utilizes the stochastic structural response of equivalent linear systems is proposed. To obtain the performance indices, seismic load is modeled as a stationary random process, whose characteristics are determined for the standard design ground motions specified by the Japanese design code, and the nonlinear behavior of the slide bearings is modeled as equivalent-linear elements using the stochastic linearization technique. As the result, a set of optimal parameter candidates is obtained as the Pareto-front solutions in the multi-objective function space. As the next step, the search of the optimal parameters is conducted by performing nonlinear time-history analysis only for the Pareto-front solution parameter sets to save the computational requirement. As a numerical example, the proposed method is applied to bridges with two types of slide bearings: the uplifting sliding shoe (UPSS) consisting of multiple sliding surfaces, and functionally discrete bearings (FDB) in which friction bearings and elastomeric bearings set in parallel are combined. It is demonstrated that the seismic performance of the bridge for the case of the design parameters obtained by the proposed procedure is almost equivalent to the one with the optimal parameters found by the conventional exhaustive search approach.*

1 INTRODUCTION

The bridge bearing with seismic functionality is recognized as a key component to facilitate the required seismic performance. With the use of these devices, elongation of the natural period and providing supplementary energy dissipation capability are achieved so that both the bearing and pier responses are minimized under strong earthquakes. In addition, a better serviceability that includes the control of ambient vibration and the thermal elongation problem of the girders can be achieved in regular maintenance and management.

Recently, some unconventional bridge bearings have been proposed to provide more flexible and feasible options for seismic performance enhancement of bridges. The uplifting slide shoe (UPSS) bearing [1, 2] is a new type of bearing consisting of multiple sliding surfaces, as shown in Fig. 1(a). The mechanism of UPSS is characterized by sliding actions on different sliding surfaces. The horizontal sliding surface of UPSS is to accommodate the thermal effects and small vibration of continuous girders, while the inclined sliding surface is to provide extra restoring force to effectively mitigate the excessive horizontal displacement response of the girders under strong earthquake events. The functionally discrete bearing (FDB) system [3] is a combination of elastomeric bearings and sliding bearings to separately provide restoring force and energy dissipation ability, as shown in Fig. 1(b). Unlike the conventional rubber bearings, this system allows required period elongation of the structural systems and the energy dissipation performance.



(a) UPSS (b) FDB

Figure 1: Schematics of UPSS and FDB.

In the process of the seismic performance-based design of bridges with either of these types of bearings, there exist intrinsic tradeoffs between minimization of bearing displacement and that of pier response in selecting bearing parameters for strong earthquake events. However, difficulty in determining the optimal parameters of these devices arises. Conventional exhaustive search method requires numerous computational resources to perform the nonlinear time-history analysis for many cases of the slide bearing parameters to determine the corresponding optimal design, since all of the possible parameter combinations are of a large number, whereas only a small number of the parameter combinations satisfy the optimal design criteria. On the other hand, the objective function of the optimization problem is usually unknown due to the complexity of nonlinear time-history analysis. Therefore, a fast search algorithm to determine the optimal parameter selection is required.

The optimal design of structures can be achieved by different approaches according to previous studies. Feng et al. [4] derived the optimal parameters for the tall building with mega substructure configuration under white-noise excitations by minimizing the mean square of the responses of interest. A series solution of the H_∞ optimization problem and a closed-form algebraic solution of the H_2 optimization problem for the dynamic vibration absorber attached to linear systems were given by Asami et al. [5]. The optimal design of the unconventional tuned mass damper to individually minimize the response quantity of interest was investigated in Refs. [6, 7]. Specifically, Hoang and Fujino [6] investigated the optimal parameter design of rubber

bearings for seismic response mitigation of a long-span truss bridge in Japan. Under the consideration of nonlinear structural elements, optimal parameter design of nonlinear base isolation systems was investigated by Reggio [8] and De Domenico [9] based on stochastic dynamic analysis. In addition, a performance-based optimization procedure for nonlinear structures subjected to random seismic excitation is proposed by Xu and Spencer [10] to deal with optimal parameter design for competing performance objectives.

In this study, a deterministic-stochastic approach is proposed to achieve the multi-objective design of slide bearings under seismic excitation. To obtain the performance indices, seismic load is modeled as a stationary random process and the nonlinear behavior of the slide bearings is modeled as equivalent-linear elements using the stochastic linearization technique. As the result, a set of optimal parameter candidates is obtained as the Pareto-front solutions in the multi-objective function space. As the next step, the search of the optimal parameters is conducted by performing nonlinear time-history analysis only for the set of the Pareto-front solution parameter sets to save the computational requirement. As a numerical example, the proposed method is applied to optimal parameter selection of UPSS and FDB in a girder bridge. It is demonstrated that the seismic performance of the bridge for the case of the design parameters obtained by the proposed procedure is almost equivalent to the one with the optimal parameters found by the conventional exhaustive search approach.

2 MODELING

A bridge with a straight girder supported by single columns with UPSS or FDB is studied. The dynamic behavior of the bridge in the longitudinal direction is simplified as a lumped-mass model with two horizontal degrees of freedom (DOF), as shown in Fig. 2.

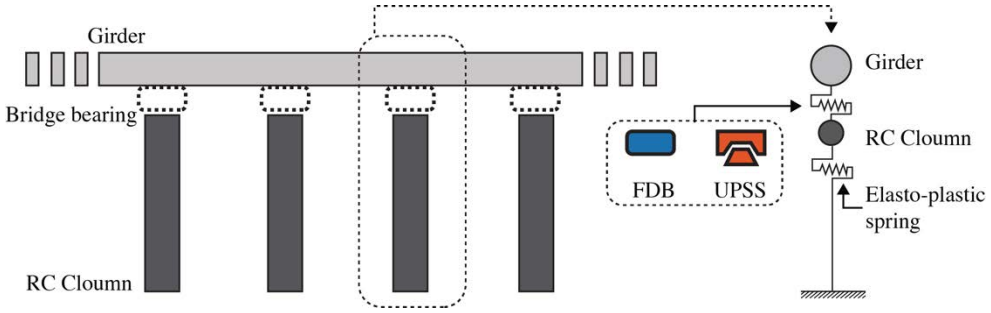


Figure 2: Bridge model with application of UPSS or FDB

2.1 Equation of motion

The governing equation of the system is given as:

$$\boldsymbol{M}\ddot{\boldsymbol{u}} + \boldsymbol{g}(\boldsymbol{u}, \dot{\boldsymbol{u}}) = -\boldsymbol{\tau}\ddot{u}_g \tag{1}$$

where $\boldsymbol{M} = \mathrm{diag}(m_1, m_2)$, m_1 and m_2 are the masses of the pier and girder, respectively; $\boldsymbol{u} = [u_1 \quad u_2]^T$ is the vector of the nodal displacements and $\dot{\boldsymbol{u}} = [\dot{u}_1 \quad \dot{u}_2]^T$ is the vector of the nodal velocities; $\boldsymbol{g}(\boldsymbol{u}, \dot{\boldsymbol{u}})$ is the reaction force vector, which can be linear or nonlinear; $\ddot{u}_g$ is the ground acceleration; $\boldsymbol{\tau} = [1 \quad 1]^T$ is the excitation vector to couple the input and the structural DOFs.

The mechanical behavior of UPSS and the superstructure can be simplified as a point mass sliding on three sliding surfaces, as shown in Fig. 3. Based on the dynamic equilibrium condition, the restoring force of UPSS is expressed as:

$$f_2 = \begin{cases} \mu m_2 g \ \mathrm{sgn}(\dot{u}_b), & -L < u_b < L \\ N \sin\theta \ \mathrm{sgn}(u_b) + \mu N \cos\theta \ \mathrm{sgn}(\dot{u}_b), & (u_b < -L) \text{ or } (u_b > L) \end{cases} \quad (2)$$

where $N = m_2 g \cos\theta$ is the resistant force of the inclined sliding surface, and g is the gravitational acceleration; μ is the friction coefficient of sliding interface; θ is the inclined angle of the inclined sliding surfaces from the horizontal direction; L is the distance of the clearance length from the neutral position of the horizontal sliding surface to the beginning of the inclined sliding surface; u_b is the relative displacement of the bearing with respect to the pier; and $\mathrm{sgn}(\cdot)$ is the signum function.

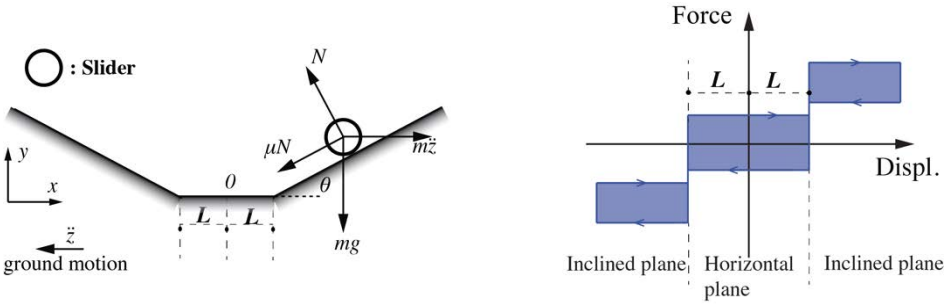

Figure 3: Mechanism of UPSS

Since FDB is a combination of rubber bearings and slide bearings, the mechanical behavior of FDB is expressed as the sum of that of the two types of bearings, as shown in Fig. 4. The sliding bearing is represented by the Coulomb friction model, and the rubber bearing is represented by an elastic linear spring. The restoring force of FDB is expressed as:

$$f_b = k_b u_b + \mu m_2 g \ \mathrm{sgn}(\dot{u}_b) \quad (3)$$

where $k_b = m_2(2\pi/T_b)^2$ is the stiffness of the rubber bearing, and T_b is the specified natural period when the superstructure is in the fixed bearing condition.

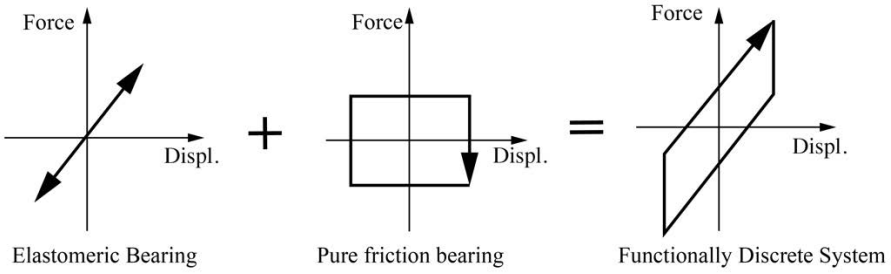

Figure 4: Mechanism of FDB

The behavior of the RC pier supporting the bridge bearing is represented by the Clough's degrading stiffness model in the nonlinear time-history analysis. The initial stiffness of the RC pier is specified so that the elastic period for the fixed bearing condition is 0.5 sec, and the yielding strength is 0.66g lateral force.

2.2 Stochastic representation of seismic excitations

The ground motion is assumed to be represented by the modified Kanai-Tajimi model [11, 12]. In the time domain, this model can be expressed in a state-space form as Eq. (4).

$$\dot{\boldsymbol{x}}_f = \boldsymbol{A}_f \boldsymbol{x}_f + \boldsymbol{B}_f w(t) \quad (4)$$

$$p(t) = \boldsymbol{C}_f \boldsymbol{x}_f$$

where,

$$\boldsymbol{x}_f = \begin{bmatrix} u_f \\ \dot{u}_f \\ u_g \\ \dot{u}_g \end{bmatrix};\ \boldsymbol{A}_f = \begin{bmatrix} 0 & 1 & 0 & 0 \\ -\omega_f^2 & -2\zeta_f\omega_f & \omega_g^2 & 2\zeta_g\omega_g \\ 0 & 0 & 0 & 1 \\ 0 & 0 & -\omega_g^2 & -2\zeta_g\omega_g \end{bmatrix};\ \boldsymbol{B}_f = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \end{bmatrix};\ \boldsymbol{C}_f^T = \begin{bmatrix} -\omega_f^2 \\ -2\zeta_f\omega_f \\ \omega_g^2 \\ 2\zeta_g\omega_g \end{bmatrix}$$

in which $w(t)$ is the bedrock Gaussian white-noise process; ω_g and ζ_g are the fundamental circular frequency and damping ratio, respectively, of the surface soil layer in the Kanai-Tajimi model; ω_f and ζ_f are the parameters of the second filter suggested by Clough and Penzien.

The peak ground acceleration (PGA) is related to the spectral intensity of the white-noise [9] as Eq. (5):

$$S_w = \frac{0.141\zeta_g \ddot{u}_{g0}^2}{\omega_g\sqrt{1+4\zeta_g^2}} \tag{5}$$

The parameters of the modified K-T model are determined by the PSD of the standard design ground motions in the Japanese design code through the least-square method.

2.3 Stochastic response of MDOF structures

The above equation of motion can be substituted into an equivalent linearized form, if $\boldsymbol{g}(\boldsymbol{u}, \dot{\boldsymbol{u}})$ satisfies some smoothness requirement and the input is a zero-mean stationary Gaussian process so as to minimize the mean square error between the linearized counterpart and the original nonlinear system [13], as shown in Eq. (6):

$$\boldsymbol{M}\ddot{\boldsymbol{u}} + \left(\boldsymbol{C} + \boldsymbol{C}_{eq}\right)\dot{\boldsymbol{u}} + \left(\boldsymbol{K} + \boldsymbol{K}_{eq}\right)\boldsymbol{u} = -\boldsymbol{\tau}\ddot{u}_g \tag{6}$$

where $\boldsymbol{C}$ and $\boldsymbol{K}$ are the damping matrix and stiffness matrix for linear elements, respectively; $\boldsymbol{C}_{eq}$ and $\boldsymbol{K}_{eq}$ are the equivalent linearized damping and stiffness matrices for nonlinear elements, respectively.

Then the governing equation can be rewritten into a state-space form as:

$$\begin{aligned} \dot{\boldsymbol{x}}_s &= \boldsymbol{A}_s\boldsymbol{x}_s + \boldsymbol{B}_s w(t) \\ \boldsymbol{y}_s &= \boldsymbol{C}_s\boldsymbol{x}_s + \boldsymbol{D}_s w(t) \end{aligned} \tag{7}$$

where $\boldsymbol{x}_s = [\boldsymbol{u}^T \quad \dot{\boldsymbol{u}}^T]^T$ is the state vector, $\boldsymbol{y}_s$ is the response vector, and

$$\boldsymbol{A}_s = \begin{bmatrix} \boldsymbol{0}_{N\times N} & \boldsymbol{I}_{N\times N} \\ -\boldsymbol{M}^{-1}\left(\boldsymbol{K} + \boldsymbol{K}_{eq}\right) & -\boldsymbol{M}^{-1}\left(\boldsymbol{C} + \boldsymbol{C}_{eq}\right) \end{bmatrix}, \qquad \boldsymbol{B}_s = \begin{bmatrix} \boldsymbol{0}_{N\times 1} \\ \boldsymbol{M}^{-1}\boldsymbol{\tau} \end{bmatrix}$$

the matrices $\boldsymbol{C}_s$ and $\boldsymbol{D}_s$ are the response matrices, which are determined by the specified outputs.

Combined with the ground motion model, the state of the combined system can be expressed as Eq. (8):

$$\begin{aligned} \dot{\boldsymbol{x}}_a &= \boldsymbol{A}_a\boldsymbol{x}_a + \boldsymbol{B}_a w(t) \\ \boldsymbol{y}_s &= \boldsymbol{C}_a\boldsymbol{x}_a \end{aligned} \tag{8}$$

where $\boldsymbol{x}_a = \left[\boldsymbol{x}_s^T \quad \boldsymbol{x}_f^T\right]^T$ is the augmented state-space vector collecting displacement and velocities of both the system and the filter variables, and

$$\boldsymbol{A}_a = \begin{bmatrix} \boldsymbol{A}_s & \boldsymbol{B}_s\boldsymbol{C}_f \\ \boldsymbol{0}_{r\times 2N} & \boldsymbol{A}_f \end{bmatrix}, \qquad \boldsymbol{B}_a = \begin{bmatrix} \boldsymbol{0}_{2N\times 1} \\ \boldsymbol{B}_f \end{bmatrix}, \qquad \boldsymbol{C}_a = \begin{bmatrix} \boldsymbol{C}_s & \boldsymbol{D}_s\boldsymbol{C}_f \end{bmatrix}$$

in which $r = 4$ is the size of the filter equation describing the modified K-T model.

The second order moment of the stochastic structural response is considered as the performance objective, which is defined as $\boldsymbol{\Gamma}_{\boldsymbol{x}_a} = E[(\boldsymbol{x}_a - \boldsymbol{\mu}_a)(\boldsymbol{x}_a - \boldsymbol{\mu}_a)^T]$, where $\boldsymbol{\mu}_a$ is the expected value vector and $E[\cdot]$ denotes the expectation operator. In stationary cases, the covariance matrix is a constant matrix. With the assumption of a zero-mean Gaussian process as input and zero-mean initial conditions, the covariance of the structural response $\boldsymbol{\Gamma}_{\boldsymbol{x}_a} = E[\boldsymbol{x}_a\boldsymbol{x}_a^T]$ is governed by the following Lyapunov equation: $\boldsymbol{A}_a\boldsymbol{\Gamma}_{\boldsymbol{x}_a} + \boldsymbol{\Gamma}_{\boldsymbol{x}_a}\boldsymbol{A}_a^T + 2\pi\boldsymbol{B}_a S_w \boldsymbol{B}_a^T = 0$. Note that the solution of the above equation is implicit, since the determination of linearized coefficients is dependent on the corresponding second-order moment responses which are unknown. Hence, an iterative procedure should be performed until the convergence is reached by initializing the procedure with a linear system.

2.4 Stochastic linearization

If the structural responses are assumed to be stationary random processes, the equivalent linearized damping and stiffness can be determined through the stochastic linearization technique [13] as Eq. (9).

$$K_{eq}^{(i,j)} = E\left[\frac{\partial g_i}{\partial u_j}\right], \qquad C_{eq}^{(i,j)} = E\left[\frac{\partial g_i}{\partial \dot{u}_j}\right] \tag{9}$$

Since the inclined surfaces of UPSS are responsible for controlling the excessive horizontal response under strong earthquakes, only the action of UPSS sliding on the inclined surfaces is considered here. The restoring force of UPSS in the horizontal direction can be simplified as Eq. (10).

$$f_b = N\sin\theta\,\mathrm{sgn}(u_b) + \mu N\cos\theta\,\mathrm{sgn}(\dot{u}_b) \tag{10}$$

where the same definition applies to the symbols as mentioned above.

Hence, the stochastic linearization coefficients for UPSS can be solved by Eq. (11).

$$\begin{aligned} K_{eq}^{(b,b)} &= E\left[\frac{\partial f_b}{\partial u_b}\right] = N\sin\theta\,E\left[\frac{\partial \mathrm{sgn}(u_b)}{\partial u_b}\right] = N\sin\theta\,E[2\delta(u_b)] = N\sin\theta\sqrt{\frac{2}{\pi}}\frac{1}{\sigma_{u_b}} \\ C_{eq}^{(b,b)} &= E\left[\frac{\partial f_b}{\partial \dot{u}_b}\right] = \mu N\cos\theta\,E\left[\frac{\partial \mathrm{sgn}(\dot{u}_b)}{\partial \dot{u}_b}\right] = \mu N\cos\theta\sqrt{\frac{2}{\pi}}\frac{1}{\sigma_{\dot{u}_b}} \end{aligned} \tag{11}$$

where $\delta(\cdot)$ denotes Dirac delta function.

Similarly, the stochastic linearization coefficients for FDB can be solved by Eq. (12).

$$K_{eq}^{(b,b)} = k_b, \qquad C_{eq}^{(b,b)} = \mu m_2 g\sqrt{\frac{2}{\pi}}\frac{1}{\sigma_{\dot{u}_b}} \tag{12}$$

2.5 Stochastic and deterministic modeling analysis

The constraint conditions for parameter selection and the structural information for the stochastic analysis are listed in the Table I. Since minimization of the pier response is considered

to be one of the optimization objectives, the stiffness and damping properties of the bridge pier are assumed to be constant in the stochastic analysis. On the other hand, the structural information for the nonlinear time-history analysis (NTHA) is presented in the Table II.

Mass ratio m_2/m_1		3.0
Pier	Natural period T_1	0.5 (sec)
	Damping ratio ξ_1	0.02
Elastomeric bearing	Natural period T_b	1.0~2.0 (sec)
	Damping ratio ξ_b	0.03
Friction coefficient μ		0.05~0.15
UPSS inclined angle θ		5 ~30 (°)

Table I: Design variables and structural parameters for stochastic analysis

Mass of girder m_2	900 (ton)
Mass of RC bridge pier m_1	300 (ton)
Initial natural period of RC pier $T_{0,1}$	0.5 (sec)
Yield strength of RC pier	0.66g
Clearance of UPSS L	0.03 (m)

Table II: Structural parameters for NTHA

3 MULTI-OBJECTIVE DESIGN

3.1 Pareto-front solutions

Since minimization of both the bearing and bridge pier responses is a multi-objective optimization problem, the Pareto-front solution is introduced in the form of the ε-Constraint method. This method is to minimize the pier response for a given bearing displacement demand as expressed by Eq. (13).

$$\begin{aligned} &\min J_I(\boldsymbol{x}) \\ \text{Subjected to:} \quad &J_{II}(\boldsymbol{x}) < \varepsilon_m, \qquad m = 1,2,3,\dots,M \\ &\boldsymbol{x}_{lb} < \boldsymbol{x} < \boldsymbol{x}_{ub} \end{aligned} \tag{13}$$

where the performance objectives J_I and J_{II} are the second-order moment of the displacement response of the bridge pier and that of the bearing, respectively; ε_m is the constraint condition in terms of the bearing response; $\boldsymbol{x}_{lb}$ and $\boldsymbol{x}_{ub}$ are the lower and upper bounds of the design variable vector, as shown in Table I.

3.2 Procedure for optimal parameter selection

The procedure to determine the optimal design is given as follows and as Fig. 5:

I. Determine the parameters of the modified K-T model for a given standard ground motion accelerogram of the design code. The PSD corresponding to the ground motion accelerogram is firstly determined by the Welch's method, and then the paramters of the modified K-T model are determined by the least square method.
II. Compute the second-order moment of the structural responses for all possible parameter combinations through the stochastic dynamic analysis.
III. Select a set of optimal parameter candidates through the Pareto solutions of the all stochastic responses. The constraint condition (ε_m) of the Pareto-front is ranging from the minimum bearing displacement to the maximum bearing displacment responses (σ_{u_b}).
IV. Search the optimal design for the given bearing displacement demand by performing nonlinear time-history analysis only using the set of the optimal parameter candidates obtained in the previous step.

Since the selected optimal parameter candidates are a subset of all possible parameter combinations, the computational resources are considerably reduced in comparison with the conventional exhaustive search approach.

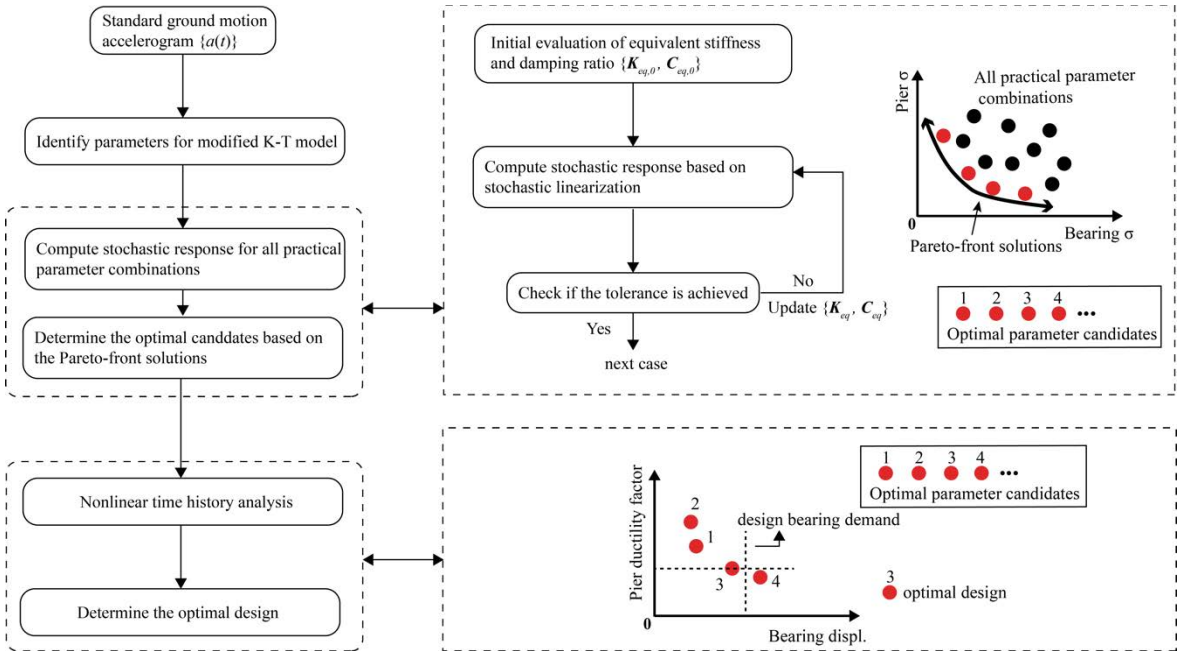

Figure 5: Flowchart of the proposed procedure

3.3 Numerical example

An example of determination of the optimal parameters for UPSS and FDB is presented. The corresponding structural parameters are given in section 2.

The standard ground motion II-I-2 provided in the Japanese Highway Bridges Design Specification [14] is used in this example. The corresponding accelerogram and PSD of the standard ground motion are shown in Fig. 6. As indicated by this figure, PSD of the modified K-T model determined by the least-square method shows a good agreement with that of the standard ground motion.

Then, the optimal parameter candidates of the bearings are determined based on the Pareto solutions of the stochastic dynamic response of all possible parameter combinations, as shown in Fig. 7.

Finally, the optimal design is searched by performing the nonlinear time-history analysis using the limited set of the Pareto solution parameters (optimal parameter candidates). For all possible bearing displacement demands, the maximum pier response ductility factors obtained by the proposed procedure are plotted in the Fig. 8 with red dots. As indicated by this figure, the seismic performance of the bridge for the case of the optimal design shown by red dots are close to that obtained by the conventional exhaustive search approach indicated by black dots.

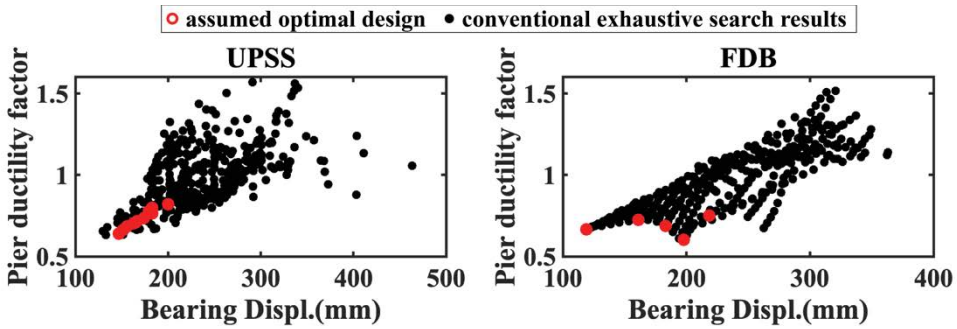
Figure 7: Pareto solutions of stochastic analysis



(a) Cases of UPSS (b) Cases of FDB

Figure 8: Comparison with conventional exhaustive search

More specifically, for a given bearing displacement demand (200mm), the optimal design for UPSS is determined as $\mu = 0.11$, $\theta = 5°$ and that for FDB is $\mu = 0.15$, $T_b = 1.45$ sec. The corresponding seismic responses of the bridge are shown in Fig. 9.

Figure 9: Bridge response for the optimal parameters

4 EFFECTIVENESS

To validate the effectiveness of the proposed procedure compared with the conventional exhaustive search approach, the definition of assessment error is firstly given. In the ideal situation, the assumed Pareto solutions perfectly match with the exact Pareto solutions obtained by the conventional exhaustive search. However, errors appear, if the minimum pier response obtained from the proposed procedure is higher than the minimum value obtained by the conventional exhaustive search, for a given bearing displacement demand, as shown in Fig. 10. Thus, the amount of assessment error is defined as:

$$\text{error} = \frac{\Delta d}{D} \times 100\% \tag{14}$$

where Δd is the difference between the two minimum pier responses obtained from the two approaches, and D denotes the difference between the maximum and minimum pier responses obtained by the conventional exhaustive search for the given bearing displacement demand.

The results for UPSS and FDB under 18 standard ground motions covering three different soil conditions and two earthquake source types are shown in Fig. 11, where the horizontal axis is normalized by the maximum and minimum bearing displacements of each case. As indicated by this figure, error of each ground motion case shows different precision depending on the characteristics of the ground motion. The mean error over most of the bearing displacement range is lower than 4% for UPSS and is approximately 11.5% for FDB, while the mean error tends to rise when the bearing displacement demand is in lower level.

5 CONCLUSIONS

For the seismic design of bridges with unconventional slide bridge bearings, a stochastic-deterministic approach to determine bearing parameters is proposed to achieve the multi-objective optimal design that minimizes the bearing displacement as well as the pier response to save the computational requirement. A numerical example is given for the optimal design of slide bearings of two types, namely UPSS and FDB, under strong ground motions. It is demonstrated that the seismic performance of the bridge for the case of the design parameters obtained by the proposed procedure is almost equivalent to the one with the optimal parameters found by the conventional exhaustive search approach.

Abstract. *Performance-based seismic engineering has been gaining acceptance in the last decade. This philosophy seeks to ensure that a structure satisfies specific behavioral requirements for a given event. There are different guides and methodologies to evaluate structural performance, but conceptually they do not keep much difference. In order to perform an evaluation a mathematical model is required; however. However, the idealizations to represent the behavior of structural elements can vary significantly, giving rise to models with different degrees of complexity in their implementation or computational costs. Furthermore, the wide range of approaches, such as lumped or distributed plasticity and their calibration, can generate different results. To this, it must be added that not always a robust model is the best option for a performance analysis since it would not be practical to implement.*

This paper compares the pertinence of different modeling approaches to conduct a performance analysis on an 8-story building with Steel Special Moment Frames under different seismic intensity levels. Moreover, this article establishes the influence of various parameters (i.e., hysteretic detailing, Rayleigh damping, axial-moment interaction) within mathematical models on the overall response of the structure. For the purpose, FEMA P-695 methodology, as well as the ASCE 7-16 maximum-drifts requirements were used to run a sensitivity analysis between models aiming to warn of inappropriate practices.

Within the findings, it can be emphasized that the secondary stiffness (in-cycle deterioration) of the element is the parameters that influence the most in the collapse response as opposed to cyclic degradation. Also, it must be noted that adding a smother yielding transition causes a higher seismic performance, which could be unconservative within an evaluation. Furthermore, the analyses illustrate how misusing an initial-stiffness proportional Rayleigh damping produces unrealistic performance values. Additional comments are made on the methodologies used to account for axial-moment interaction in lumped-plasticity models.

1 INTRODUCTION

Performance-based seismic engineering has been gaining acceptance in the last decade. This philosophy seeks to ensure that a structure can satisfy certain behavioral requirements established for a given event. In the case of the design basis earthquake intensity (DBE) and maximum considered earthquake (MCE), the event corresponds to an earthquake with 10% and 2% probability of exceedance in 50 years, respectively. There are different guides and methodologies to evaluate the performance of the structure, but conceptually they do differ from each other.

FEMA P695 [1] allows calculating the probability of collapse depending on the intensity of the earthquake, but this implies carrying out more complex analyses and assuming that the modeling of the elements is appropriate up to collapse levels. The FEMA P695 methodology is consistent with the objectives of collapse prevention by establishing a probability of collapse less than 10% for an earthquake with a return period of 2475 years (i.e. MCE). On the other hand, there are simpler procedures that establish the performance acceptance criteria for an assigned earthquake intensity. For example, ASCE7-16 [2] establishes that, at the global level, the average inter-story drift should not exceed 2% for DBE and 4% for MCE intensity. Also, ASCE7-16 states that for MCE there should not be more than one unacceptable result (e.g. collapse) in a set of 11 earthquakes.

For the evaluation of the structure's performance, it is needed a mathematical model that can simulate its behavior. However, the idealizations to represent the behavior of structural elements can vary significantly giving rise to models with different degrees of complexity in their implementation or computational costs and even generate diverse results. The NIST modeling guides [3] differentiate three main modeling approaches: 1) concentrated plasticity, 2) distributed plasticity and 3) continuous models with finite elements. Similarly, there are different damping idealizations with variations in their implementation (e.g. Rayleigh damping). It is also important to consider that not always a robust model is the best option for a performance analysis since its use would not be practical for complex methodologies. Thus, selecting the appropriate mathematical model becomes relevant, as well as knowing the sensitivity of the performance response to the selection of a certain modeling approach and the calibration of its parameters.

Some investigations compare the effect of different modeling approaches at the element level [4] but not the structure's performance at a global level. The purpose of this research is to compare the relevance of different models to accomplish performance analysis of an 8-story building with Steel Special Moment Frames (SSMF) as the lateral system. In addition, this article establishes the influence of various parameters within mathematical models on the overall response of the structure. This research analyzes three main modeling parameters. The first one is related to the constitutive law used on concentrated and distributed plasticity models. The second is related to the damping assignation on distributed plasticity models. And finally, the coupled axial-flexural moment modeling is assessed for concentrated plasticity models.

1.1 Background

The concentrated plasticity technique is currently the most used approach for modeling SSMF. This approach calibrates the element's behavior with phenomenological criteria. Therefore, based on experimental results [5,6] the response of a structural element (e.g. beams and columns) subjected to static or dynamic loads can be simulated. One of the first approaches to perform nonlinear analysis was introduced decades ago assuming an elastic perfectly plastic hysteretic behavior for beams and columns [7,8]. With the advances in

computational resources, further studies had implemented more features such as hardening, deterioration, and cyclic degradation. A more detailed review of articles is presented in appendix A of FEMA P-440A [9]. It should be noted that models with abrupt transitions are oriented to mark each stage of the behavior of the element (cracking, yielding, etc.) and it can be more practical. However, there are models with a smooth transition of stiffness which is meant to 1) to represent the progressive yielding of the element and 2) to alleviate the numerical procedures near the yielding points. Previous research has shown that for floor accelerations, these models with smoother transitions of stiffness shown slightly lower acceleration demands than models with abrupt transitions [10]. The Ibarra-Medina-Krawinkler model (IMK) [11] and their later modifications (ModIMK) [5,12] are the reference hysteretic model that includes strength and stiffness deterioration properties to simulate the response of SSMF.

The limitation of the lumped plasticity approach is that very specific zones are assigned for the element's yielding. Furthermore, given its formulation, it does not allow to consider the interaction of the axial-moment (P-M) load and, therefore the calibration is performed for a given axial force. To take into consideration the effect of the axial load on the capacity of the section, the flexural capacity has to be reduced based on an imposed axial load before the dynamic analyses are executed. The moment capacity under an axial load follows the interaction equations presented in AISC 360 [13]; however, there are different strategies to calculate the axial load to be considered in the equations.

On the other hand, the distributed-plasticity approach requires to define the behavior of the section at each integration point. This is achieved by 1) explicit modeling the section using fibers that have been assigned a stress-strain relationship (material constitutive) or 2) with the calibration of the moment-curvature response of a predetermined section. The advantage of fiber modeling is that it does not require an extensive process of calibration based on experimentation because the response is integrated throughout the section itself. This approach also allows capturing the axial-moment interaction automatically during the analysis. In general, the main problem of the distributed plasticity approach are the concentration of deformations, the loss of objectivity and the difficulty to represent material softening. To deal with this problem, solutions have been proposed from several authors, ranging from modifying the behavior at the section level, applying the material-regularization technique [14,15] up to variations of the formulations [16–18].

There are two main formulations for distributed plasticity, 1) force-based and 2) displacement-based. The main difference is that the first one determines the forces of the sections performing static equilibrium. This results in a constant axial force and a linear distribution of moments in the absence of distributed forces [19]. The second approach interpolates the deformations of the sections, resulting in constant axial-deformation and the linear distribution of the curvature along with the element [20]. The last requires a greater discretization of the element than the force-based formulation to obtain the same level of accuracy [21]. The force-controlled formulation using fibers will be used in this study to simulate distributed-plasticity.

In addition to the simulation of elements' behavior, damping can also influence a seismic response of a building. Rayleigh damping is the most common technique to simulate damping. It is a type of equivalent viscous damping that facilitates the resolution of the differential equation of motion in the linear range by making the damping matrix classic or diagonalizable as well as the mass and rigidity matrix. Some complications come once the structure has entered the non-linear range [22]. This happens because the proportionality coefficients become time-variant as well as the stiffness matrix. In the case of concentrated plasticity models, Rayleigh damping is considered with a time-invariant stiffness matrix by excluding damping in the rotational springs that contained the nonlinear properties [23]. This solution prevents the generation of unreal damping forces that cause underestimation of displacements, overestima-

tion of efforts and underestimation of the collapse potential of the building. However, in distributed plasticity models, damping assignment considering a stiffness matrix proportional only to the elastic elements is not possible because all elements are able to capture inelastic behavior to their constitutive law.

2 METHODOLOGY

The building to be analyzed was taken from the ATC 76-1 project [24] within the 2RSA group. This 8-story and 3-bay building was designed for a D_{max} category (maximum spectral acceleration of 1.0, and a one-second acceleration of 0.6) [1]. The height of the first floor is 15ft and 13ft for the rest of the floors, and the length of each span is 20ft. The lateral system consists of steel special moment frames (SSMF). The beams have RBS pre-qualified connections type defined by parameters a, b and c (0.625bf, 0.750db and 0.25bf respectively). The element sections are shown in Table 1.

Story	Elevation [in.]	Beam	Exterior Col.	Interior Col.	Doubler Plate Size [in]	
					Exterior Col.	Interior Col.
1	166.55	W30X108	W24X131	W24X162	1/16	9/16
2	322.55	W30X116	W24X131	W24X162	1/16	3/8
3	478.55	W30X116	W24X131	W24X162	1/16	11/16
4	634.55	W27X94	W24X131	W24X162	0	3/8
5	790.55	W27X94	W24X131	W24X131	0	9/16
6	946.55	W24X84	W24X131	W24X131	0	7/16
7	1102.55	W24X84	W24X94	W24X94	0	9/16
8	1258.55	W21X68	W24X94	W24X94	0	5/16

Table 1: Sections and geometry

Initially, FEMA P-695 methodology was used for the performance evaluation of the structure using different modeling approaches. It is a tool to determine the performance factors of earthquake-resistant systems. However, this methodology specifies that it can also be used to demonstrate the correct performance to the collapse of structures designed under the requirements of ASCE 7. For these analyses, it was considered that the structure collapsed once it reached an inter-story drift of 10%. At this drift deformation, it is assumed that the elements are no longer able to resist gravity loads due to P-Δ effects and the results of modeling are no longer reliable.

The nonlinear models were developed with the specifications provided in the next section. Their behavior was validated through a series of checks [25]. Among them, the verification of the hysteretic behavior, modal analysis, yielding sequence, ductility and over-resistance, damping assignment.

The earthquakes selected for the evaluation have been obtained from the Far-Field set corresponding to the methodology and scaled to the period C_uT_a according to the design spectrum. Finally, a dynamic incremental analysis (IDA) was performed for each model until a 50% of collapses is obtained in order to calculate the Collapse Margin Ratio (CMR). This CMR value is adjusted by a spectral shape factor (SSF) that is a function of the period ductility and design category, resulting in the Adjusted Collapse Margin Ratio (ACMR). This SSF modification takes into account the effect of the frequency content of the series of earthquakes.

To obtain the probability of collapse at other intensity levels, a logarithmic adjustment was made according to the methodology. The uncertainty parameter (β_{TOT}) that represents the ad-

justment deviation is defined in terms of four sources of uncertainty due to 1) the variability between records (β_{RTR}) as a function of ductility, 2) design requirements (β_{DR}), 3) experimental data (β_{TD}) and 4) model quality (β_{MDL}). β_{DR} and β_{TD} are not dependent on the model, while β_{MDL} is subjective to the qualitative criterion proposed by the designer. Once the adjustment is made, the probability of collapse of the structure for the MCE is calculated, contrasting with the design objective (probability of collapse less than 10% under this intensity).

On the other hand, a comparison was made with simpler analyses to perform the evaluation, which do not imply subjecting the models to intensities of collapse. This evaluated the global performance of the structure under DBE and MCE with maximum inter-story drifts of 2% and 4% respectively as the limit criteria as described in ASCE 7-16. It should be emphasized that under MCE intensity, according to this criterion, it is not allowed more than one collapse for a set of 11 earthquakes.

3 MATHEMATICAL MODELS

The two-dimension models were developed in OpenSees [26]. To include the effects of geometric nonlinearity, all the gravity system loads were concentrated in a leaning column that does not add rigidity to the structure. Masses and loads are shown in Table 2. The splices of the columns were not modeled and the contribution of slab and gravity columns were neglected. The behavior of the beam-column connection was simulated using the theory developed by Krawinkler [27] which consists of simulating the shear through a rotational spring with trilinear behavior. In effect, the panel-zone is modeled by eight rigid elements connected in three corners by pinned joints and with the rotational spring calibrated to represent the shear at the fourth corner. Hysteretic material within OpenSees was used for this spring.

Story	Mass	Load over the tributary area [ksi]	Load over leaning column [ksi]
1	2.16779	250.8	586.5
2-7	2.15148	248.1	582.8
8	1.90950	216.1	521.4

Table 2: Masses and loads

The behavior of beams and columns was represented trough the concentrated and distributed plasticity approaches with different modeling assumptions. To evaluate the importance of detailing the hysteretic behavior, a concentrated-plasticity model was chosen and it was subjected to changes in the uniaxial material of the plastic hinges. The evaluated behaviors are 1) elastoplastic behavior with hardening (PM-BM) using uniaxial material Steel01, 2) hardening with a smooth transition (PM-SBM) using Steel02, 3) hardening, deterioration and cyclic degradation of stiffness (PM-DM) and 4) hardening and deterioration post hardening, but without cyclic degradation (PM-HM) using uniaxial material Bilin. The calibration of the springs used in the concentrated plasticity models was based on the experimentation and regressions proposed in [5,12]. Likewise, Steel01 and Steel 02 were used in the steel constitutive curve (Steel ASTM A992) for the fibers of the distributed plasticity models with the force-controlled formulation giving raise to the models described later. In the case of fibers, calibration was done at the material level (not the element).

Additionally, Rayleigh damping was used. It was proportional to the mass and proportional to the stiffness (initial or tangential, depending on the model) with a target damping of 2.5% and constant coefficients based on the fundamental period of the structure (T_1), and $0.2T_1$. The influence of damping was analyzed in the distributed plasticity models (as nonlinear ele-

ments can not be excluded). The models that were used presented 1) elastoplastic behavior with hardening and damping proportional to the initial stiffness (FM-BM-I), 2) hardening with smoothed transition and damping proportional to the initial stiffness (FM-SBM-I) and variations of damping proportional to the tangential stiffness giving 3) FM-BM-T and 4) FM-SBM-T.

The models used to compare the moment-axial force interactions are one model with distributed plasticity in the columns (PM-FM), which implicitly accounts for P-M interaction, and two models of concentrated plasticity, which do not include the interaction. Thus, for the concentrated-plasticity models, each uses a different technique to reduce the moment capacity to deal with this disadvantage. In the evaluation guide of the FEMA P695 [24], they suggest that the axial load for each element is calculated considering the gravity loads plus half the maximum load due to lateral forces. More recent studies show that the constant gravity load has a greater influence than the transitory loads resulting from the dynamic effects [28]; therefore, the behavior of the element can be predicted by the relationship between the gravity load and the effective yield stress P_g/P_{ye} only [3,6]. These two techniques give rise to models PM-BM-F and PM-BM respectively.

In addition to the already mentioned models, a simpler model was developed that includes nonlinearities at the beams and the base of the columns only. In summary, for the parametric study, 11 models were developed as shown in Table 3.

Plasticity	Model	Hyst. Behavior	Damping	P-M interaction
Concentrated	PM-BM-F	Steel01	Only elastic elements (rotational springs were excluded)	FEMA
	PM-DM	Bilin		NIST
	PM-HM	Bilin w/o degrad.		
	PM-BM	Steel01		
	PM-SBM	Steel02		
	SM	Steel01		
Distributed	FM-BM-I	Steel01	β proportional to K_{ini}	Implicit
	FM-SBM-I	Steel02		
	FM-BM-T	Steel01	β proportional to K_{tg}	
	FM-SBM-T	Steel02		
Mixed	PM-FM	Steel01	β proportional to K_{tg} excluding springs.	Implicit

Table 3: Model summary

4 RESULTS AND DISCUSSIONS

First, the influence of the hysteretic behavior, damping and forces interaction is compared in nonlinear static and dynamic analysis to point out certain characteristics. In the case of dynamic analysis, the 1st story drift is shown because it presented the greatest differences. Similarly, the models are compared in the calculation of the CMR, which allows quantifying the collapse performance of the structure. Then, models are evaluated using the FEMA P-695 adjusted fragility curves and collapse probability. Finally, the global performance-based on inter-story drifts is compared with the intensities of DBE and MCE among all models.

It should be noted that all models have similar initial stiffness as expected, giving fundamental periods close to the reference value of 2.29 seconds.

4.1 Influence of hysteretic behavior

In Figure 1 the behavior of a beam hinge under the compared assumptions is shown. In terms of energy, it could be inferred that the PM-DM model will limit the dissipation by hysteresis of the structural element more than the other models, which would cause a more premature collapse in the structure. Likewise, among the models that only show hardening, the model with smoothed transition would also cause a lower dissipation capacity compared to the model with abrupt transitions, however, the responses show that this softened transition model makes the structure to have a better performance.

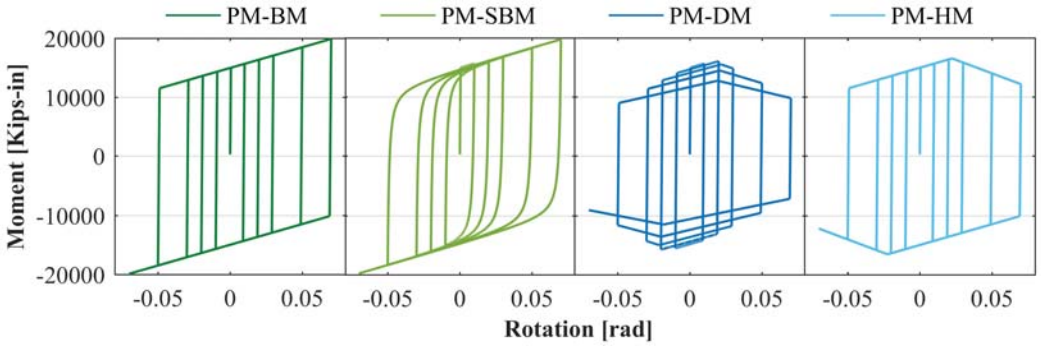

Figure 1 Hysteretic behavior of a beam under the compared assumptions

It is observed in Figure 2 that the smoothed transition has no major influence on the static analysis, however, the inclusion deterioration does cause a decrease in the ductility of the structure due to the drop in stiffness. In this figure, it can also be noticed the influence of the P-Delta effect, since, without it, the model with hardening would never have shown a decrease of the basal shear as seen after the roof drift is approximately 2%. The degradation characteristics are not observable in the analysis performed since a monotonic load analysis was carried out.

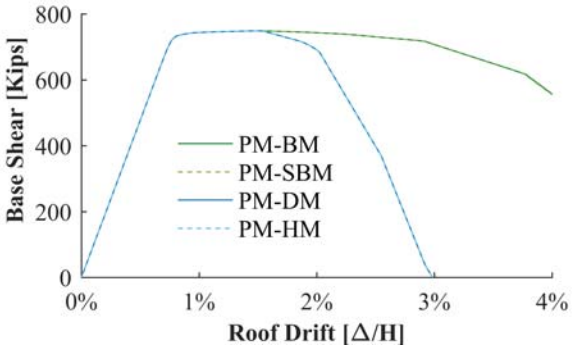

Figure 2 Non-linear static analysis for models with different hysteretic behavior

On the other hand, in the dynamic analysis (Figure 3a) the smoothing effect causes smaller residual drifts than the PM-BM model due to the Bauschinger effect on the reload-rigidity. Also, it is observed that the parameter that has the greatest effect is deterioration causing the structure to have the maximum drifts. Regarding the inclusion of the cyclic degradation of the

element, it increases, even more, the drifts that the structure reaches. However, this last parameter has less impact than deterioration.

The CMR values (Figure 3b) are congruent with the analysis of the dynamic response presented above. With these values, it can be established that the use of a smoother hysteretic curve improves the seismic performance which could be non-conservative from the design point of view. Similarly, the inclusion of cyclic degradation does not have a great effect on the building performance because CMRs among the models that include the backbone curve is very close. Again, it can be observed that the parameter that significantly decreases the performance of the structure is the in-cycle deterioration of the elements.

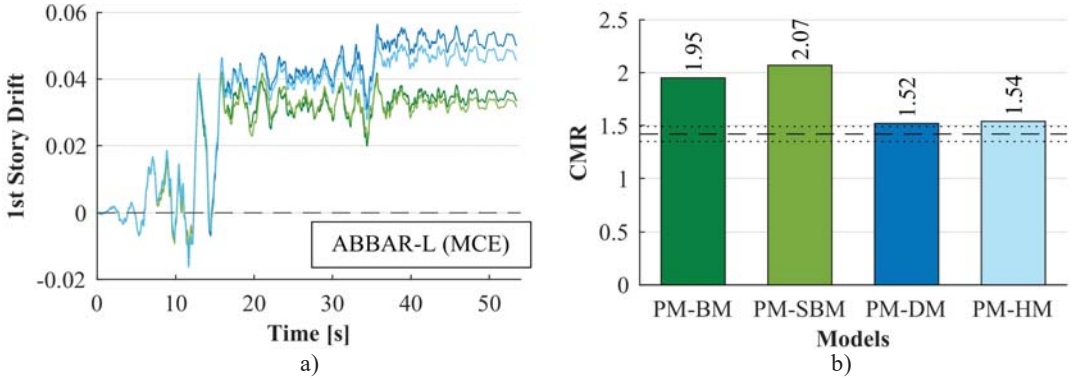

Figure 3 a) Non-linear dynamic analysis and b) CMR for models with different hysteretic behavior

4.2 Influence of material constitutive and damping in distributed-plasticity models

Figure 4a shows the material constitutive law assigned to each fiber of the distributed-plasticity elements. This represents the steel properties, with the difference in the stress-strain yielding transition.

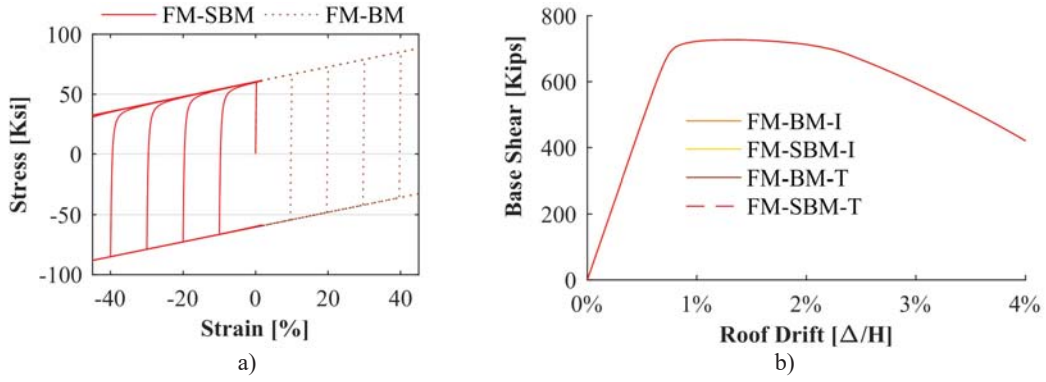

Figure 4 a) Stress-Strain relationship of steel and b) Non-linear static analysis in distributed models

As in the models of concentrated plasticity, the effect of the stiffness transition (transition of the stress-strain curve in this case) does not influence the response of the building in the nonlinear static analysis presented in Figure 4b.

In the nonlinear dynamic analysis presented in Figure 5a, it is observed that models with softened transition produce lower drifts, just as in the concentrated-plasticity case. Now for the same hysteretic behavior, comparing the damping assignment, it is observed that the damping proportional to the initial stiffness causes smaller drifts. This is because the structures is over-damped because the stiffness of the structure decreases when yielding occurs. From this analysis, it can be said that the least conservative approach of the cases presented is to use a model with hardening and smoothed transition and apply Rayleigh damping proportional to the initial rigidity. It should also be pointed out that applying Rayleigh damping proportional to tangential stiffness causes the analyses to have greater convergence problems. At this point, for more complex prototypes, the implementation of this feature in the model should be evaluated whether it is worth or not to increase the computational cost of the analysis depending on the errors this will cause.

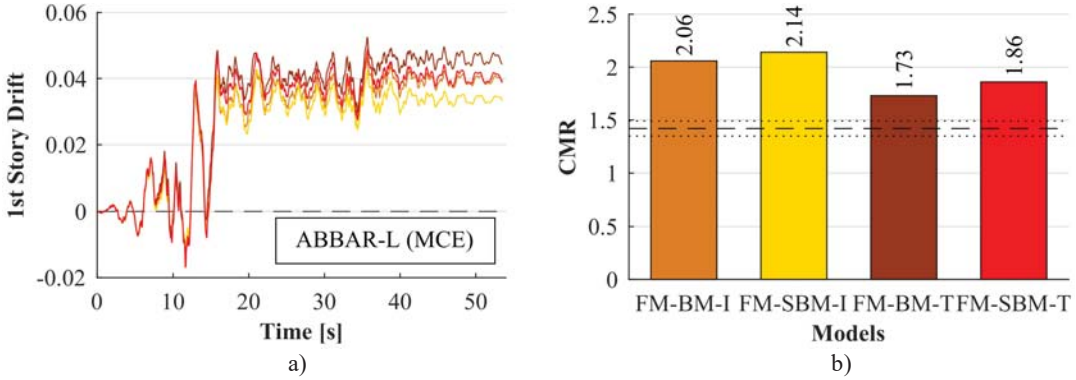

Figure 5 a) Non-linear dynamic analysis and b) CMR for models with different damping assumptions

The collapse analysis presented in Figure 5b confirms that the most conservative case (out of the four cases) is the FM-BM-T model, however, the CMR value is still far from the reference value (PM-DM). This higher CMR value is interpreted as a better performance of the building, however, this is because none of these models of distributed plasticity considers the deterioration of the elements due to the incompatibility in their force-based formulation using fibers as covered in [29].

4.3 Influence of P-M interaction

For this comparison, all models were chosen to have an elastoplastic hysteretic behavior with hardening as shown in Figure 6. In this figure, it is also shown the reductions that have been made to one of the columns.

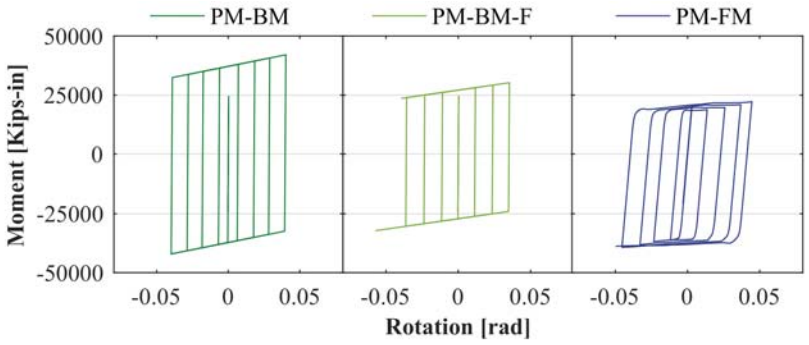

Figure 6 Hysteretic behavior of a base column under different P-M interaction considerations

The methodologies adopted for concentrated plasticity do not consider the asymmetric behavior of the element (i.e. compression or tension) neither the variation of axial forces along the time. It is also observed that PM-FM response shows a lower flexural capacity when the column is under compression loads.

For the non-linear static analysis (Figure 7), it is observed that the FEMA-type reduction method (based on gravity and lateral loads) underestimates the structure's ductility due to its more conservative reductions. In contrast, the NIST-type reduction (based only on gravity loads) slightly overestimates the over-strength and ductility to the model that does consider the interaction automatically.

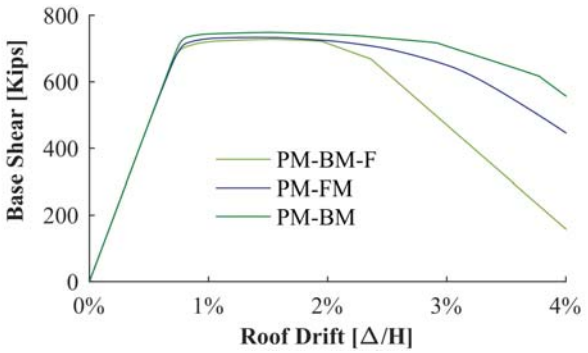

Figure 7 Non-linear static analysis under different P-M interaction considerations

This same trend can be observed in the dynamic analysis presented in Figure 8a where the FEMA type reduction causes greater drifts than the mixed plasticity model while the NIST type reduction can give non-conservative values. The CMR values are presented in Figure 8b, where it is seen that the response of the structure, even at collapse intensities, falls between the two methodologies when the axial-moment interaction is included by the fiber model.

Figure 8 a) Non-linear dynamic analysis and b) CMR values under different P-M interaction considerations

4.4 Collapse performance evaluation according to FEMA P-695

Results of the fundamental period and ductility of each model are presented in Table 4. It can be seen that the periods are similar to the value of the reference model (2.29sec). Concerning to ductility, the model with deterioration is the one that represents lower ductility and agrees with the original reference model. Also, the corresponding SSF and β_{TOT} values according to FEMA methodology P695 are shown. Uncertainty, $\beta_{TOT,}$ remains similar for all models due to their high ductility.

Model	Period	Ductility	SSF	β_{TOT}
PM-BM-F	2.284	3.74	1.38	0.5
PM-DM	2.283	2.99	1.32	0.4992
PM-HM	2.283	2.99	1.32	0.4992
PM-BM	2.283	5.30	1.47	0.5
PM-SBM	2.280	5.29	1.47	0.5
SM	2.281	-	1.61	0.5
FM-BM-I	2. 282	4.39	1.42	0.5
FM-SBM-I	2. 282	4.39	1.42	0.5
FM-BM-T	2. 282	4.39	1.42	0.5
FM-SBM-T	2.282	4.39	1.42	0.5
PM-FM-B	2.284	4.75	1.44	0.5

Table 4: Fundamental period, ductility, SSF, and β_{TOT} summary

One of the differences in performing the analysis of collapses following the FEMA P695 methodology is the use of the SSF factor. This factor modifies the CMR leading to a better performance of the structure. In Figure 9a the fragility curve for the most complex model (PM-DM) and the effect of the SSF is observed. The solid line represents the fragility curve considering the modification of the CMR while the dashed line represents the adjustment with the original CMR.

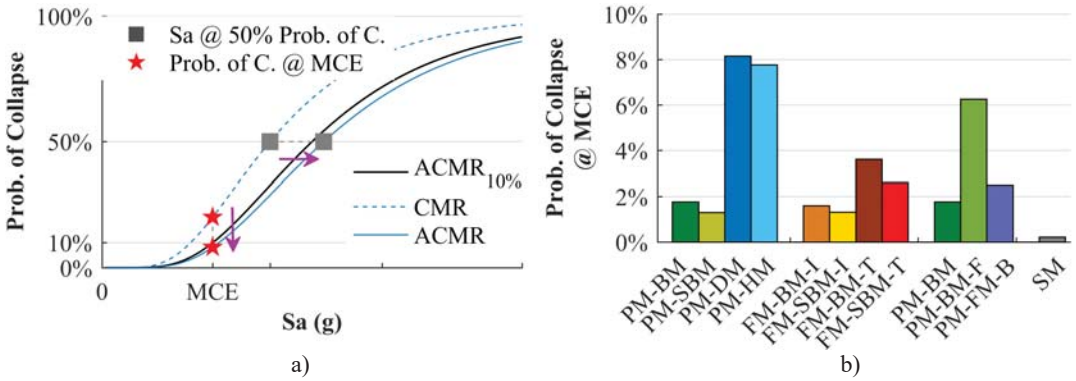

Figure 9 a) Fragility curve for PM-DM and b) Summary of collapse probabilities for all models

It is observed that when displacing the acceleration necessary to produce 50% of collapses, the probability of collapse for the acceleration corresponding to the MCE decreases. The black line represents the reference curve with the values presented in FEMA P695 for collapse evaluation; in other words, for an uncertainty value of 0.5, the fragility curve that generates a probability of collapse of 10% at the MCE. Given this reference, it is observed that the adjustment parameter of the CMR can cause a model to go from not fulfilling the collapse objective to satisfactorily fulfill. For example, the PM-DM goes from a probability of collapse of 20.12% to 8.15%.

Figure 9b shows a summary of the collapse probabilities obtained for each model. It is observed that models with high values of probability of collapse are those that consider the in-cycle deterioration (backbone curve) of the elements (i.e. PM-DM and PM-HM). Also, it is seen that for this structure, excluding the strength and stiffness cyclic degradation will cause an error of less than 5% to evaluate the probability of collapse. Additionally, comparing the models with different stiffness transition, it is seen that the smooth transition cause to reduce the probability of collapse around 20%, for concentrated plasticity as for distributed plasticity approaches.

Analyzing damping assignation in the models with distributed plasticity, it is seen that using the initial stiffness may cause a reduction of up to 50% in the collapse probability in comparison with tangent stiffness. Thus, more caution should be taken to the assumptions regarding damping.

About the techniques to account for P-M interaction in lumped plasticity models, by using the momentum capacity reduction in columns based on gravity loads, the model overestimates the building performance in relation to the mixed plasticity model. In contrast, it can be seen that reducing the capacity in accordance with axial forces including gravity and lateral forces, almost duplicates the probability of collapse, which could be very conservative. Congruently, the probability of collapse of the distributed plasticity model, FM-BM-T, relies on between the lumped plasticity models that had the same assumptions.

Also, the probability of collapse was calculated for the simplified model. It produced negligible values of collapse probability, so its use in this methodology is not recommended in contrast to what research has shown in the evaluation of floor acceleration [10].

4.5 Performance evaluation according to ASCE 7-16.

In ASCE 7-16, the SSF factor is not considered which causes more conservative results. This is consistent with the lower complexity of the process. For MCE-level analyses, the ref-

erence inter-story drift may not exceed 4% drifts. Additionally, no more than one out of 11 earthquakes might give an unacceptable result (i.e. collapse). For the prototype used, all the models generate at least one collapse to the MCE, so 1.2 times the median drift was used as a reference value for the evaluation.

It can be observed in Figure 10a that, for the MCE intensity, the median values of the maximum inter-story drifts are similar between the models; however, they present a different distribution of drifts in the upper quartiles. For example, concentrated plasticity models with deterioration and distributed plasticity models with tangential damping do not satisfy the maximum number collapses that are allowed despite satisfying the limiting condition of inter-story drifts of 4%. This shows that conducting performance analysis without including these modeling characteristics can lead to erroneous decisions, overestimating the performance of the structure. In the case of the model with FEMA reduction, it also exceeds the maximum limit of allowed collapses, however, this is only due to the excessive reduction of the moment-capacity of the columns. Regarding the simplified model, this has a decent prediction of the median drift, which could serve as a rapid approach for the iterative design of the building to meet performance limits.

Similarly, Figure 10b shows the distribution of the maximum inter-story drifts under the DBE level. In this case, the models, besides having similar medians, inter-story drifts present a similar distribution. The analyzed parameters do not present major influence to this intensity, even the simplest model can simulate the behavior as the other models do. One of the characteristics that should be noted in the models is that they all show a collapse, except for those that use softened hysteretic behavior with damping proportional to the initial stiffness. Furthermore, all models agree that the building does not meet the performance objectives at the design level by exceeding the 2% target-drift in more than half of the analyses.

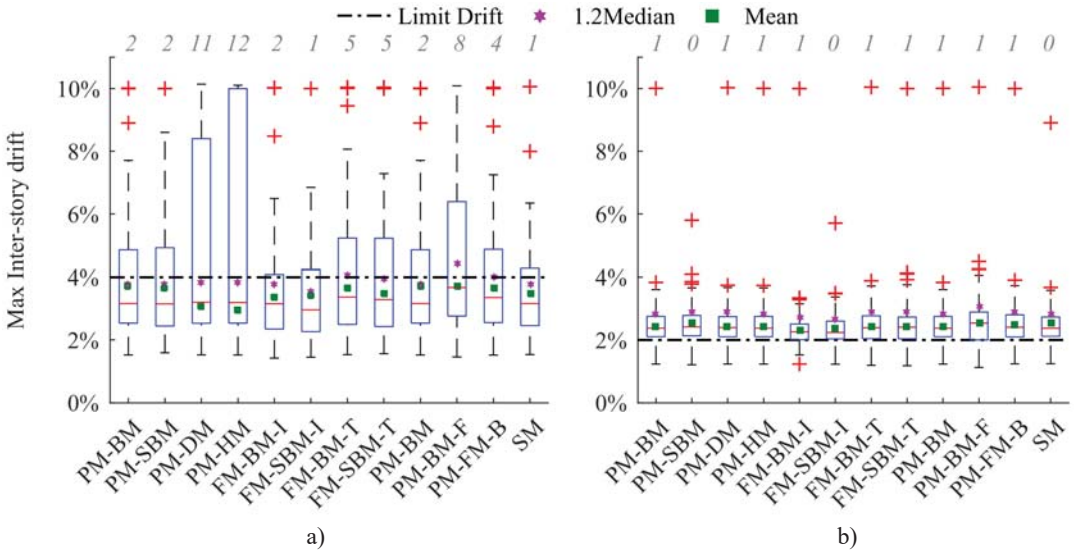

Figure 10 Maximum inter-story drifts distribution under a) MCE level and b) DBE

5 CONCLUSIONS

- In the models with concentrated and distributed plasticity, it was observed that using non-smoothed curves for the collapse analysis can be reflected in a lower seismic performance of the structure, which would be conservative.
- The inclusion of the cyclic degradation of the structural elements does not cause greater variations in the performance of the structure, so not considering them in the analyzes would avoid the complexity of the calibration without losing greater objectivity in the study. In fact, the main characteristic of the hysteretic curves for collapse prediction is the inclusion of in-cycle deterioration. Not including this behavior could overestimate the performance of the structure, which would not be a good practice.
- Assigning proportional damping to the initial stiffness generates a false better performance of the structure under collapse; however, this is due to the overdamping that is generated when the structure enters the non-linear range. Therefore, caution should be used in the assignation of damping, especially in distributed plasticity where nonlinear elements can not be excluded.
- The probability of collapse in lumped-plasticity models showed to be sensitive to the method used to reduce the flexural capacity. Reduction based on gravity loads underestimates the collapse probability in comparison with models that accounted for the P-M interaction. In contrast, the reduction based on gravity and lateral loads overestimate the collapse probability. Thus, future research should be made to recommend using a weighted average between the two techniques or some other method to include the axial-moment interaction in the concentrated plasticity models to evaluate the performance of the structure.
- The spectral form factor has a great influence on the probability of a structure collapse. Using this value to adjust the CMR can cause a model to go from not meeting performance objectives to fully satisfying them.
- For the performance evaluation under MCE, it is recommended to use the models that include deterioration, since, although models without this characteristic can give similar results in terms of the median drift, the number of collapses produced can be underestimated.
- Despite the influences of the parameters in the CMR values, it must be pointed out that, to evaluate the behavior of the structure under design performance levels, these have no greater impact. For design intensities, even a simplified model can approximate the performance evaluation response at maximum inter-story drifts. It should also be evaluated in terms of residual drifts.
- The results and conclusions correspond specifically to the presented 8-story building; however, it is necessary to carry out the same study on more prototypes to generalize the influence of modeling in the performance evaluation of structures.

Keywords: Existing steel frames, Masonry infills, Multiple earthquakes, Dynamic analysis

Abstract. *Existing steel moment-resisting frames in several seismic regions worldwide are often characterised by high vulnerability to earthquakes due to insufficient local and/or global ductility. Therefore, it is of paramount importance to assess their response under strong motions and provide cost-effective retrofitting remedies. However, the current code-based assessment framework utilized in Europe for assessing existing structures is inadequate and requires improvement, especially to account for the contribution of masonry infills as they significantly influence the seismic response of steel buildings. To this end, the H2020-INFRAIA-SERA project HITFRAMES (i.e., HybrId Testing of an Existing Steel Frame with Infills under Multiple EarthquakeS) aims at experimental evaluation of a case study building representative of non-seismically designed European steel frames. This paper presents the dynamic response analyses of the case study building and serves as a theoretical prediction of the experimental results*

for HITFRAMES. The case study building is analysed as a bare, an infilled and a retrofitted frame with buckling restrained braces (BRBs), respectively. It is subjected to the natural seismic sequence recorded during the 2016-2017 Central Italy earthquakes. The modal properties of the case study building are determined first, followed by the investigation of its non-linear dynamic response. The dynamic tests are performed with the earthquake records scaled to different intensity levels to simulate the structural performance under different limit states according to Eurocode 8-Part 3. The impact of masonry infills and BRB-retrofit is also investigated by comparing the response of models with different configurations. It can be concluded that appropriately-designed BRBs are effective in protecting steel frames from experiencing critical damage during earthquakes and reducing significantly the transient and residual drift.

1 INTRODUCTION

It has now been widely recognised in modern seismic codes that the inelastic behaviour of structural systems plays an important role in their seismic response during earthquakes. However, numerous existing buildings in current earthquake-prone areas in Europe were constructed before the seismic provisions of Eurocode 8 or complied with low seismic resistance. Such buildings are often characterised by insufficient ductile design and low energy dissipation capacity, hence high vulnerability to earthquakes. Therefore, it is necessary to develop an advanced framework of the assessment of existing buildings, which further leads to an optimised retrofit solution.

Previous research has been done on the seismic performance of existing steel frames [1][2][3], which is a popular topic in the context of assessing existing buildings. Typical damage on existing steel frames after strong ground motions include significant yielding on columns, especially at beam-column connections, cracks or partial collapse of cladding and masonry infills, and large residual drifts that leave the building little residual strength to carry vertical loading. It is also found that the seismic performance of the steel building was greatly affected by the presence of the infill walls. Existing research in literature shows that masonry infills considerably increase the lateral stiffness and strength of buildings and at the same time cause much higher localised stress at the contact areas between the corners of infills and the framed system, normally the beam-column connections [4][5][6]. Moreover, the presence of infills may lead to even higher vulnerability of existing building to collapse in moderate and strong earthquakes, as it increases the possibility of soft storey mechanisms at lower floors, eventually resulting in the collapse of the entire building.

However, despite large effort has been put into the study of seismic behaviour of infilled structures, most research was carried out on reinforced concrete buildings and there is a lack of studies on steel building with infills. Besides, most of the popular numerical models of masonry infill walls (e.g. single strut model) were developed and calibrated for reinforced concrete buildings, which naturally leads to the question that whether those models of infills are appropriate in the case of steel buildings, which are usually more flexible compared to reinforced concrete buildings. To this end, the H2020-SERA project 'Hybrid Testing of an Existing Steel Frame with Infills under Multiple Earthquakes' (HITFRAMES) aims at performing pseudo-dynamic tests on a typical existing steel frame model and providing insights on the seismic behaviour of existing steel building with infills. The project also involves assessment of the retrofit technique that uses buckling restrained braces (BRBs), which are efficient energy dissipation devices that are capable of withstanding both tension and compression in an almost symmetrical way [7][8][9].

This paper presents the theoretical estimation of the structural response of a two-storey steel moment-resisting frame under multiple earthquakes. The steel frame was designed to sustain only gravity loads with similar deficiencies found in the previously-mentioned steel building in Amatrice, hence is considered not safe under moderate and strong earthquakes and requires retrofit. The steel frame was modelled in OpenSees [10] as a bare, an infilled and a retrofitted frame with BRBs, respectively, so that the response with different configurations of the steel frame model can be compared. Firstly, the seismic response of the steel frame under the unscaled record of selected earthquake sequence will be investigated, so that some moderate damage are expected without global collapse. Then a scaling factor of 3.0 will be applied to the record of earthquake sequence in order to cause more significant damage on the structure. This paper also presents comparison of the peak and residual inter-storey drifts of different models to investigate the effects of infills and effectiveness of the BRBs. Besides, to predict the performance of the steel frame during laboratory tests and to assess the capability of the designed

BRB system, i.e. to what extent it can protect the steel frame and masonry infills and improve the overall resistance of the steel building to strong earthquakes, the behaviour of columns, masonry infills and BRBs will be examined individually.

Apart from the time history analysis, pushover analysis has already been performed according to the procedure in Eurocode 8-Part 3 [11] as a preliminary assessment of the steel frame and the results are provided in two previous papers [12][13].

2 THE 'HITFRAMES' PROJECT

A brief description of the HITFRAMES project will be provided here; the main aims of the project include:

- Develop reliable methods for assessing seismic performance of existing steel frames with infills under multiple earthquakes;
- Develop appropriate design procedures of BRBs that account for the contribution of masonry infills;
- Perform fragility analysis of existing steel frames with infills and retrofitted with BRBs under multiple earthquakes.

To achieve the above goals, a case study steel frame, which consists of three bays and two storeys and is referred to as the *prototype* frame hereafter, was designed to be a representative of existing steel buildings. The steel frame was designed for gravity loadings only and is characterised by weak column-strong beam seismic behaviour and soft storey mechanism. Then a two-storey one-bay sub-structure of the prototype frame was scaled down by a factor of 0.75 and was tested in the Structures Lab of University of Patras, Greece. The scaled sub-structure is referred to as the *test* frame hereafter.

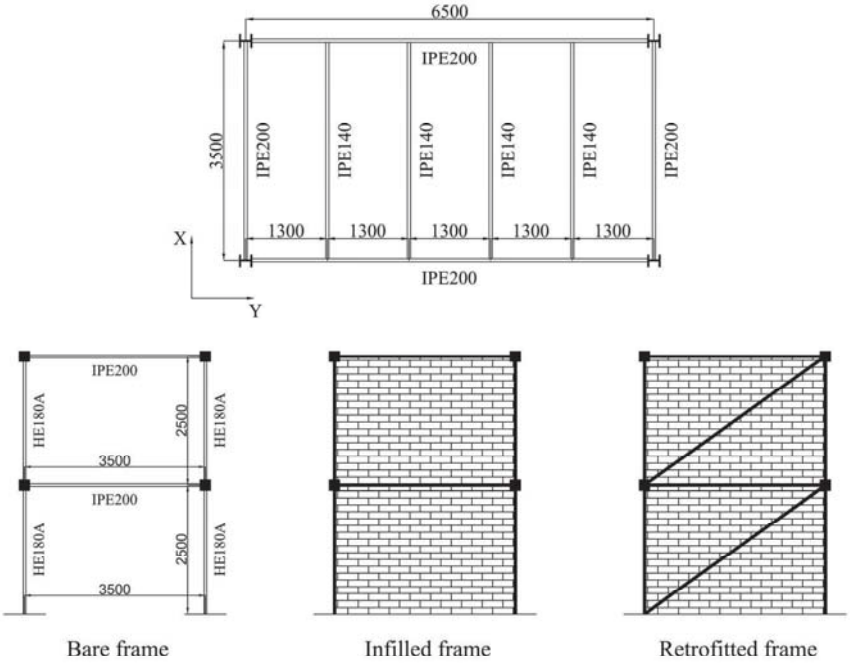

Figure 1: Plan view (top) and side view (bottom) of the test frame with different configurations (unit: mm).

The geometric properties of the test frame are provided in Figure 1. The steel profiles after scaling are IPE200, IPE140 and HE180A respectively for external beams, internal beams and columns. The steel grade is S355 (f_y = 355MPa) for all beams and columns. Besides, the

composite slab consists of 250mm-thick concrete slab poured on 1.25mm-thick corrugated steel sheet (SYMDECK 73). Furthermore, all external beams are connected to columns through full penetration welding, and fully rigid beam column connections are considered in this study. It is worth noting that stiffeners were placed at all beam-column connections and column base connections. Figure 2 demonstrates the position of stiffeners. Finally, the BRB consists of a BRAD damper and an elastic steel bracing, which are connected in series to each other. The BRAD damper has a hysteretic behaviour with an ultimate strength of 210kN at 20mm displacement. The BRB will be installed externally to the framed structure and attached to the flange of columns with specially designed connection systems.

Figure 2: Stiffeners at beam column connection and column base.

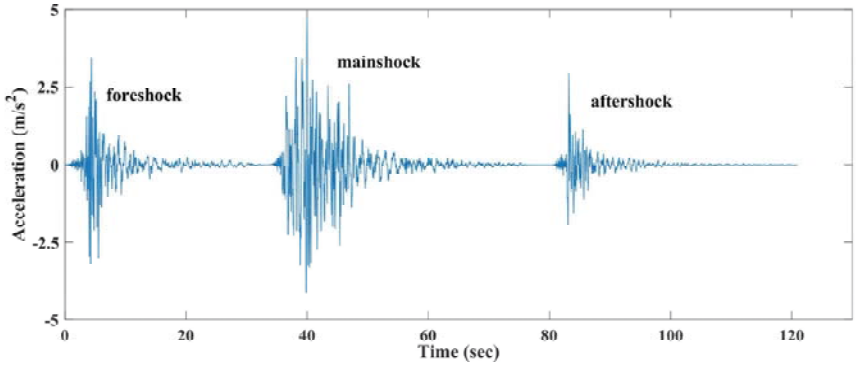

Figure 3: Acceleration history of the selected ground motion sequence.

Event	Date	M_w	R_{epi} (km)	PGA
foreshock	24/08/2016	6.0	15.3	0.35
mainshock	30/10/2016	6.5	4.6	0.48
aftershock	26/10/2016	5.4	9.4	0.30

Table 1: Summary of records of the selected earthquake sequence used in this study.

To facilitate the tests in laboratory, a series of earthquakes records have been selected to form an earthquake sequence. Figure 3 shows the acceleration history of the earthquake sequence, which includes a foreshock with peak ground acceleration (PGA) of 0.35g, a mainshock with PGA of 0.48g and an aftershock with PGA of 0.30g. Their information is also summarised

in Table 1. Those records are able to reflect the moderate-to-high seismicity in some areas of the Southern Europe based on their PGAs.

3 NUMERICAL MODELLING IN OPENSEES

Similar to what has been done in [13], the test steel frame was built in the finite element software OpenSees [7] considering three different configurations:

- Case A: bare frame (only beams and columns are included)
- Case B: infilled frame (bare frame + masonry infills)
- Case C: retrofitted frame (bare frame + masonry infills + BRBs)

For finite element modelling of the test frame, beams and columns are modelled with lumped and distributed plasticity, respectively. Each beam consists of an elastic element with modulus of elasticity 210GPa, plus two end plastic hinges to represent the lumped plasticity. The property of the plastic hinges is determined based on the moment-rotation relationship suggested in [14]. The plastic hinges are further modified based on the proposal in [15] to ensure more accurate overall lateral stiffness. The property of beam plastic hinges is shown in Figure 4. It should be noted that only the beam plastic hinges in X direction (test direction) are considered in the model. On the other hand, all columns are modelled using fibre-elements with ten integration points. The columns have the same modulus of elasticity as the elastic elements in beams and with 2% post-yield strain hardening.

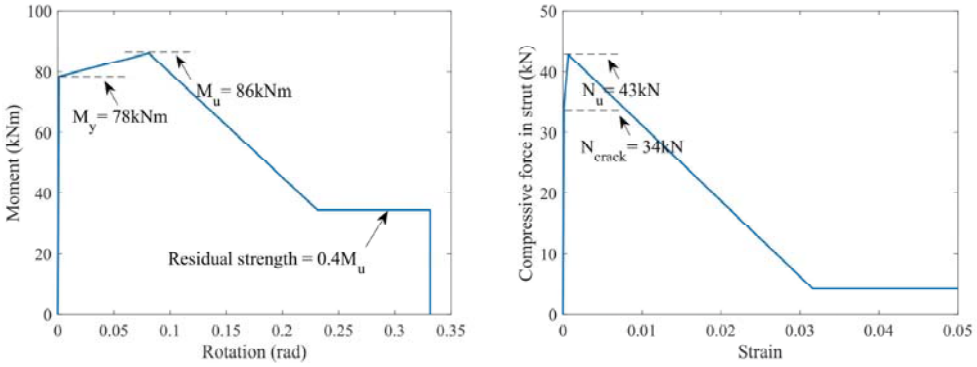

Figure 4: Backbone curve of the beam plastic hinges (left) and the infill struts (right).

In terms of the modelling of masonry infills, there are several alternatives available in literature ([4][5][16][17][18] among others), however, most of the widely-used models were developed for reinforced concrete buildings and their reliability of being applied in steel frames, which are normally more flexible than concrete buildings, is not examined. In this case study, the single-strut model adapted from the one used by Mohammad [16] and Liberatore and Decanini [18] is temporally adopted, and its property will be adjusted in the future according to the test results. A detailed discussion on the modelling of infills is provided in [13]. Figure 4 shows the backbone curve of infill struts in the compressive range, while in the tensile range, zero-strength is assumed.

4 MODAL ANALYSIS

Modal analyses are firstly performed on all the three cases in the X direction (see Figure 1). Table 2 summarises the periods and associated mode shapes and modal masses of the first and second mode. By comparing the results from Case A and B, it is clear that both the fundamental and second periods are decreased by more than 80% due to the presence of infills, which

considerably reduces the natural periods by contributing significantly to the lateral stiffness. In terms of the effective mass in each mode, the infills slightly increase the modal mass of the first mode and consequently decrease the mass participated in the second mode.

Case	1st mode			2nd mode		
	period (sec)	mode shape	modal mass	period (sec)	mode shape	modal mass
Case A	0.71	0.4552 1.000	87.1%	0.25	-1.8674 1.0000	12.9%
Case B	0.12 (-83%)	0.5644 1.000	92.5% (+6%)	0.05 (-82%)	-1.5043 1.000	7.5% (-42%)
Case C	0.12 (-83%)	0.5585 1.000	92.3% (+6%)	0.05 (-82%)	-1.5224 1.000	7.7% (-40%)

Table 2: Modal properties of the case study steel frame in the test direction.

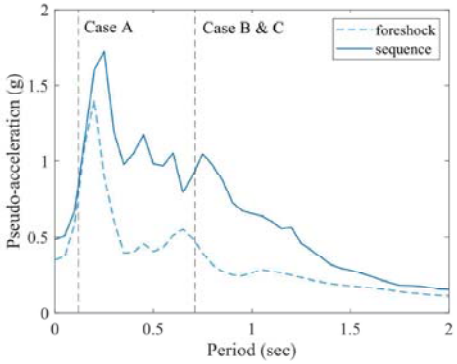

Figure 5: Elastic response spectrum of the foreshock and entire sequence in Table 1.

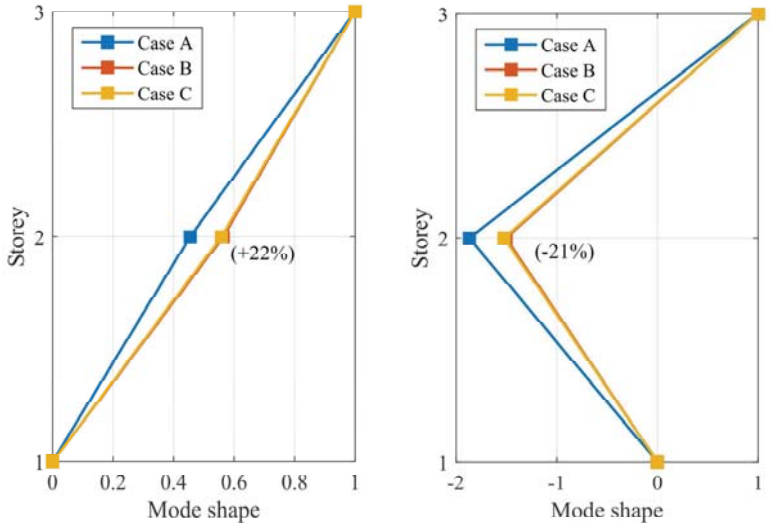

Figure 6: Normalised mode shape for the first mode (left) and the second mode (right).

Figure 5 shows the elastic response spectrum of the foreshock and entire sequence selected in Table 1. It is found that the spectral acceleration with respect to the entire sequence is much higher than the one associated with the foreshock, except in the range of period from 0.1 to 0.15 sec, where small differences between the two spectra are observed. It should be noted that the fundamental periods of the infilled and retrofitted frame are within the above range. However, when the infilled frame is damaged, its natural periods will be longer, hence will experience higher seismic loading during the whole sequence than during the foreshock only.

Figure 6 shows the normalised mode shape of the first and second mode from all three cases. Since in all cases the fundamental mode dominates the structural behaviour, it is evident that the infilled frame is more likely to possess the soft storey mechanism as the infills will concentrate the deformation to the lower storey in this case. By comparing Case B and C, it is found that attaching BRBs to the test frame barely affects its modal properties at the initial state. However, as found in [13], the infilled frame in Case B may not able to maintain its initial modal properties during earthquakes and its natural periods and mode shapes may experience great changes due to the failure of masonry infills.

5 TIME HISTORY ANALYSIS

This section presents the results of time history analysis performed on the finite element model of the test frame. The inter-storey drifts and residual drifts of different models will be compared to investigate the effects of infills and effectiveness of the BRBs. The behaviour of columns, masonry infills and BRBs will also be presented individually in the following sections. The assessment of the test frame will be carried out with the help of inter-storey drift limits in Table 3 proposed by ASCE41-06 [19], which are adapted to comply to the limit states in EC8-3 [11], i.e. Damage Limitation (DL), Significant Damage (SD) and Near Collapse (NC) limit state.

DL	SD	NC
0.7%	2.5%	5.0%

Table 3: Inter-storey drift ratio limits adapted to the limit states in EC8-3.

5.1 Structural response under unscaled earthquake sequence

The response of the test frame with the three different configurations are compared in Figure 7 in terms of their first and second storey drift. The effects of infills is evident as the amplitudes in Figure 7 are reduced by more than 50% when the infills are present. It is also found that the current zero-acceleration periods, which were introduced to simulate the time interval between two earthquakes, are not long enough for the bare frame to rest due to the large vibration amplitudes and relatively low damping ratio of steel frames (3% damping assumed for the test frame). However, it is adequate to calm down the infilled and retrofitted frame, therefore, quite long periods of low-amplitude vibration are expected when the infilled frame is tested in the laboratory.

By comparing the first and second floor drifts, it can be concluded from Figure 7 that for the bare frame, the roof displacement are equally distributed to the first and second storey, which is consistent with its first mode shape in Figure 6. For the infilled and retrofitted frame, the drift of the second floor is considerably smaller than that of the first floor, indicating concentration of lateral displacement on the first floor (soft-storey mechanism), where more evident damage may be observed. Besides, Figure 7 also shows that the bare frame experienced large residual drift on both floors after the second earthquake, which has the largest PGA as indicated in Table

1. On the other hand, the residual drifts of the infilled and retrofitted frame are very small and can be neglected. The peak and residual drifts are summarised in Table 4. Finally, it seems that the BRBs do not have significant effects on the overall structural behaviour when they are installed on the infilled frame, although it tends to slightly reduce the storey drift. Since it is found from previous discussion that the first-floor slab (also the top of ground floor) suffers the critical lateral displacement in Case B and C, the response of columns, infills and BRBs on the ground floor will be presented hereafter.

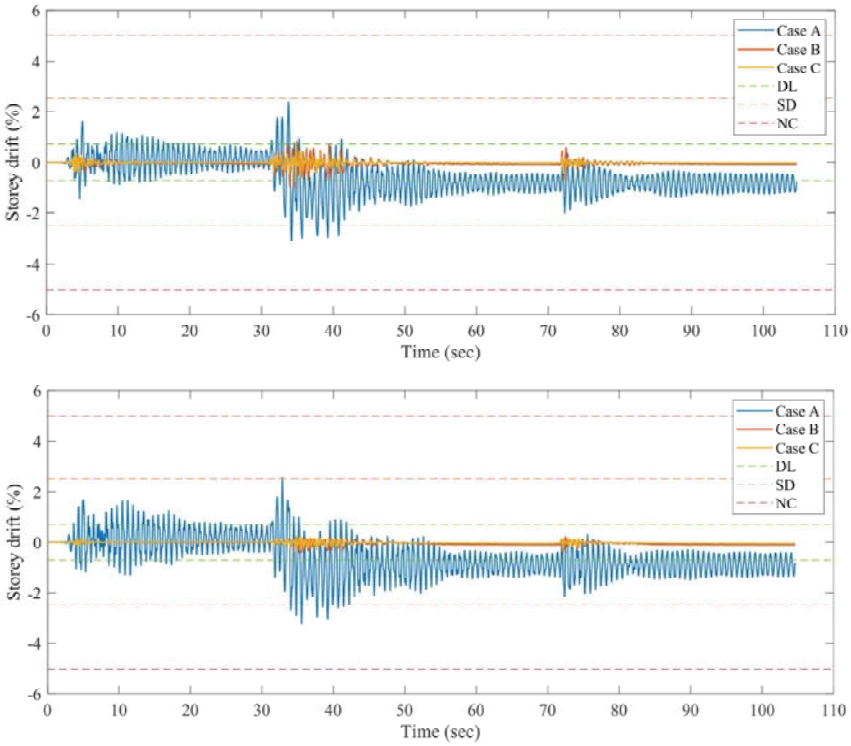

Figure 7: Response of the case study frame in terms of the first (top) and second (bottom) floor drift under unscaled earthquake sequence.

		GM1		GM2		GM3	
		Peak	Residual	Peak	Residual	Peak	Residual
Case A	1F	1.6	0.13	3.1	0.83	2.0	0.84
	2F	1.7	0.15	3.2	0.89	2.1	0.88
Case B	1F	0.5	0.05	1.1	0.08	0.8	0.07

Table 4 Peak and residual drifts (%) of the case study frame under unscaled earthquake sequence.

Figure 8 presents the moment-rotation behaviour at the base of columns on the two sides of the test frame. It is found that the columns in the bare frame reached a maximum rotation of more than twice the yield rotation θ_y, while in the infilled and retrofitted frame, the maximum column base rotation was around θ_y and $0.5\theta_y$, respectively. It is also noticed that the BRB

caused slight differences between the behaviour of columns on its two sides, probably due to the higher axial load in the left-side column in Figure 1 as a result of the orientation of the BRB. Furthermore, the response of masonry infills with and without BRBs is presented in Figure 9, which shows the axial force-displacement diagram of the two struts forming the same masonry wall but in opposite directions. As expected, the designed BRBs reduced the displacement of masonry infills both in tension and in compression, however, it failed to protect the infills from cracking and experiencing degrading of stiffness. Figure 10 shows the behaviour of the BRBs adopted for the retrofit of the case study frame. It is clearly demonstrated that the BRBs are only slightly yield and have not fully developed their full post-yield strength and displacement capacity.

It can be concluded that in the case of unscaled earthquake sequence, the BRBs were barely activated, therefore, they only contributed to the lateral stiffness and strength of the structure and hardly improved the overall energy dissipation capability. The columns were well protected from yielding by infills and BRBs, and the structure were verified safe at significant damage limit state according to Table 3, and the retrofitted frame was close to satisfying the damage limitation limit state.

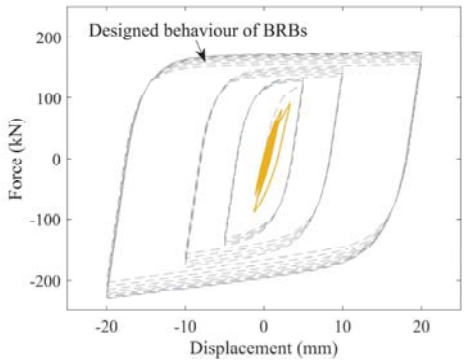

Figure 10: Cyclic behaviour of BRB in Case C.

5.2 Structural response under scaled earthquake sequence

The results obtained with the scaled earthquake sequence are presented in this section in a similar manner to what have been done for the unscaled earthquake sequence. It should be noted that the bare frame in Case A were not involved in this part of assessment as it is by nature not able to survive such strong earthquakes. Generally speaking, the test frame experienced much more severe damage when it was under the scaled earthquake sequence, which meets the expectation of significantly damaging the infilled frame in the lab so that more information of the seismic behaviour of the steel frame can be collected for further study. Figure 11 shows the inter-storey drift of the frame in Case B and C. It is clear that the infilled frame experienced increasing residual drifts up to 2.4% after each earthquake on both storey when there was no protection from BRBs, and the first storey suffered a peak drift of nearly 6% during the second earthquake. Besides, it is also clearly demonstrated in Figure 11 that the BRBs in Case C effectively reduced both the peak drift of the steel frame by around 50% and in most cases reduced the residual drift by a large amount as well, as indicated in Table 5.

Figure 12 shows the response of columns. It is found that under the strong earthquakes, the columns in the infilled frame were significantly yielded and suffered large deformation at the column bases (approximately $5\theta_y$). However, the rotation of column in the retrofitted frame was reduced to around $2\theta_y$. Figure 13 and 14 shows the cyclic response of infill struts and BRBs, respectively. It can be anticipated from Figure 13 that severe damage or even partial collapse may occur on the infill walls without BRBs' protection, as one of the struts is approaching its residual strength, which is around 4kN. However, when the BRBs were included, the infills experienced 50% smaller peak displacement in both tension and compression, although cracks and stiffness degradation were still observed. This is not a surprise as the BRBs adopted failed to prevent the infills from cracking under the previous unscaled earthquake sequence. The behaviour of BRB in Figure 14 suggests that the BRB was activated during the earthquake sequence with a shift of equilibrium position to around 0.01mm. It also experienced a larger displacement than its ultimate limit, which occurred during the second earthquake component, indicating that in reality the BRB was probably unable to dissipate energy anymore after it was broken.

In conclusion, when a scaling factor of 3 was applied to the previous earthquake sequence, the BRBs on the ground floor were clearly activated and contributed to the energy dissipation capability through its cyclic behaviour. The columns were protected with maximum base rotation being reduced by more than 50%, and the retrofitted frame were eventually verified safe at the near collapse limit state according to Table 3.

6 CONCLUSIONS

This paper presented the results of preliminary dynamic analysis carried out on a 2-storey case study steel frame designed for the experimental tests of the HITFRAMES project. The steel frame was designed to be a representative of existing steel frames in Southern Europe. Dynamic analysis was performed on the steel frame in different configurations, including the bare frame, the infilled frame and the infilled frame retrofitted with BRBs. The analysis was done as a preparatory work for the experimental tests.

Three earthquakes were selected in this study to form an earthquake sequence. The unscaled record of the entire sequence was applied to the steel frame in the first part of analysis. In the second part, the record was scaled by a factor 3.0 and then applied to the steel frame. The inter-storey drifts of both floors were examined as well as the response of column, masonry infills and BRBs, in order to assess the capability of the designed BRB system of protecting the steel frame and masonry infills. It is found that under the unscaled earthquake sequence record, the BRB were barely activated, although it helped reduce the deformation of both columns and masonry infills by around 50% and eliminated yielding in columns. When the intensity of input earthquake record was increased by a factor of 3.0, it is concluded that the BRBs were significantly damaged and exceeded its maximum deformation capacity. The column base rotation was reduced by nearly 50% due to the protection of BRBs and yielding in column was considered to be minimised. This protection is also reflected by the dramatic reduction in the transient and residual drift, where the former was decreased by around 50% and the latter was reduced to a negligible level.

A major limitation in this study is that the flexibility of beam-column connections were not accounted for in either the strong or weak axis of columns, although the column panel zones (along the strong axis) do not play an important role in this study, since the tests will be performed along the weak axis of columns. The column base connections were not considered, either. These limitations may significantly affect the results of the real tests, which will be updated in the model calibration based on the test results.

7 ACKNOWLEDGEMENTS

The financial support from Seismic Engineering Research Infrastructure for HITFRAMES (SERA) Project, funded within the H2020-INFRAIA-2016-2017 Framework Program of the European Commission under grant agreement No.730900 is greatly appreciated. Keywords: resilience assessment, road infrastructure, seismic risk assessment, bridges

Abstract. *The seismic risk is assessed for two twin bridges, one per direction, forming the G7 branch of the Egnatia Odos highway in Greece. These are structurally independent horizontally-curved cantilevered-deck three-span reinforced concrete structures with a monolithic pier-to-deck connection that have been designed circa 2004 according to Greek and European standards. The aim is to develop a tool for pre-event risk assessment and rapid post-event inspection of critical road infrastructure by combining hazard, vulnerability and sensor information (where available) to predict the resulting consequences. To enhance the assessment resolution, a component-based approach is followed, allowing us to evaluate damage scenarios for individual critical components (i.e., piers and bearings) and propagate them to the system-level performance. Consequences are quantified in terms of repair losses, downtime, and traffic capacity losses, the latter identified as the number of closed lanes and the allowable speed limit for the open ones. This allows tracing back the consequences after an event to individual bridge components to help road operators establish bridge inspection prioritization protocols and manage associated incidents, facilitating the rapid assessment of the state of the bridge and optimal recovery to full functionality.*

1 INTRODUCTION

Road operators nowadays face the challenge of efficient maintenance and operation of road infrastructure networks as well as the rapid inspection in case of natural hazard events. To this effect, significant effort has been invested in quantifying risk and resilience for interdependent road networks. Risk assessment focuses on estimating the probability of undesirable/extreme event occurrence and on the quantification of the associated consequences, such as monetary loss, downtime etc. (e.g., Kappos et al. [1]). Resilience goes a step further to assess the follow-up to a failure, attempting to quantify the system's ability to recover after a catastrophic event. Thus, resilience incorporates the dimension of time to measure the ability of the entire system to retain and recover functionality after a potential event, considering either a single or multiple hazards. For example, conceptual views of infrastructure resilience have been discussed by Cimellaro et al. [2], Argyroudis at al. [3], and Ouyang et al. [4], while Kilanitis and Sextos [5] and Costa [6] have offered focus on road networks under seismic hazard. Still, the definition and application of a practical multi-hazard approach on any realistic infrastructure system remains a challenge.

In response, the PANOPTIS project integrates multi-hazard resilience assessment of highway networks with real-time sensor information to offer a holistic tool for pre-event assessment and rapid post-event inspection of critical road infrastructure under multiple hazards. It is a decision support tool that helps road operators efficiently inspect, maintain and safely operate existing road networks and mitigate the risks. In PANOPTIS two types of sensors are employed, namely (i) sensors providing information on the hazard, such as seismographs, and (ii) sensors providing information on the response of the structure, such as accelerometers. The near-real-time sensor integration has formed the basis of our approach, necessitating focusing on multiple hazard and damage/loss scenarios to accommodate rapid damage and consequence identification. To this extent, an enhanced resolution is adopted for the highway assets, allowing tracing back potential consequences to individual components with more ease, facilitating the rapid inspection after a potentially damaging natural hazard event. This paper presents the framework for resilience assessment of highway assets within the PANOPTIS project, using the G7 bridge of Egnatia Odos in Greece as the case study that is subjected to the seismic hazard.

2 RISK AND RESILIENCE ASSESSMENT FRAMEWORK FOR THE HIGHWAY BRIDGE

Seismic risk assessment according to the PBEE framework [7] requires convolving the seismic hazard with the vulnerability to quantify risk. Vulnerability functions are probabilistic distributions of losses given the Intensity Measure (IM) of interest. They translate the physical damage into monetary loss, repair time, downtime, traffic capacity reduction etc. Vulnerability functions can either be derived empirically based on data from past catastrophic events or they can be analytically computed by combining fragility with the associated consequence functions. The consequence functions are probabilistic distributions of losses given a level of damage that are usually derived empirically. In PANOPTIS two approaches can be followed for vulnerability assessment, termed system-only and component-based. System-only approaches are the norm and employ classic system-level fragility curves, such as the ones of HAZUS-MH [8], which are combined with the corresponding cumulative consequences to the asset for the given damage state. On the contrary, the component-based approach of FEMA P-58 [9] involves employing component-based fragility curves that provide the probability of a component violating the limit states of interest given the component's Engineering Demand

Parameter(s) EDP(s). These are convolved with the losses/consequences implied by each component to generate high-resolution vulnerability functions. Herein the component-based approach is followed as it allows identifying potential consequences of individual bridge components with more ease, since a general rating of "moderate damage" on the bridge would be quite vague in contrast to "moderate damage state on the bearings", which would more efficiently help road operators to establish prioritization protocols and facilitate rapid inspection.

Resilience assessment requires also the definition of the system's recovery function. For instance, Cimellaro et al. [10] proposed adopting a linear, trigonometric or exponential recovery function depending on the response of the system and the stakeholder/owner/operator. Even more complicated shapes have been proposed, such as by Miles and Chang [11] or Zhang et al. [12]. In our case, functionality is quantified in terms of the traffic capacity of the system. Starting at 100% capacity, the event causes a drop to a lower capacity level (fewer cars allowed through) due to reduction in the allowable speed limit and/or potential lane closure that is required for inspection and damage fixing. All such restrictions are lifted and the full traffic capacity of the bridge is assumed to be restored only when all damages are fixed, thus he "bathtub" recovery function of Figure 1 is adopted.

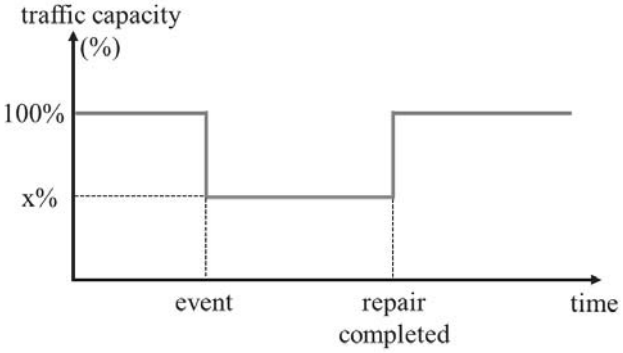

Figure 1: "Bathtub" recovery function, showing that the traffic capacity is reduced in a catastrophic event and is restored to 100% when the repair actions are completed.

3 CASE-STUDY BRIDGE

The G7 bridge is located at the Metsovo-Panagia section of Egnatia Odos in Greece (Figure 2a and b). It consists of two structurally independent twin bridges, each of them carrying one traffic direction of two lanes resulting in four lanes for both directions. The bridge was designed circa 2004 and built in 2009 following the cantilever method of construction with in-situ concreting. Each of the twin bridges has three spans of 75+120+75m resulting in 270m total length. The longitudinal axis of the bridges is curved in both horizontal and vertical plane. The deck is a prestressed single-cell concrete box girder with its depth varying from 2.75m close to the abutments to 7.25m at the piers, that is monolithically connected to the two piers (M1 and M2) of 41.70m and 49.50 height, respectively. The cross section of both piers is hollow rectangular of in-situ cast concrete with 7.35x4.0m external dimensions and 0.75m width. The piers are appropriately oriented so that deformation in the transverse bridge direction leads to bending around their strong-axis, while deformation in the longitudinal bridge direction leads to weak-axis bending for the piers. They are founded within the rock via concrete shafts of 10m diameter and 15m height. The deck is supported via two pot-bearings at each abutment that allow the horizontal deck movements in both longitudinal and transverse bridge directions while a third bearing is added in the middle, having a transverse shear key to eventually restrict transverse bridge displacement.

Figure 2: G7 bridge of the Egnatia Odos highway in Greece.

4 UNDERSTANDING THE BRIDGE BEHAVIOR

The bridge may displace longitudinally, transversally or even vertically. Due to the monolithic deck-to-pier connections such displacements become of importance at the abutments, where the deck rests on bearings.

4.1 Bridge behavior in the longitudinal direction

In the longitudinal bridge direction, the expansion joint shown by green color in Figure 3 prevents the deck from hitting the abutment. Potential deck movement during normal bridge operation can be attributed to expansion/contraction caused by temperature changes, concrete creep, or as a result of braking especially of heavy vehicles, such as trucks. During earthquakes the expansion joint is expected to prevent the deck hitting the ballast wall. Its opening is 0.53m and is composed of steel beams. If bridge-to-deck deformation exceeds the value of approximately 0.5·0.53m, the steel longitudinal "beams" that form the structure of the joint are expected to sustain considerable damage thus requiring repair or even replacement. For higher relative deformations exceeding the gap of 0.53m, the deck is expected to hit the upper part of the ballast wall (indicated by mustard color in Figure 3) thus causing significant damage. It should be noted that the continuity of the backwall is interrupted at the sacrificial joint (shown by cyan color in Figure 3), thus in this case potential damages are limited to the upper part of the ballast wall and to the approach slab (also shown in mustard color) that is monolithically connected to it. In this case, steel plates are typically placed as a temporary measure to bridge the damaged parts until they are repaired. In case of extensive deck-to-abutment deformation, which is not expected to occur for the design level earthquake, the deck can further move up to a limit of approximately ±1.50m when it might either hit the ballast wall (see the distance indicated in red in Figure 3) or fall from the pedestal, which results in deck unseating (see distance indicated in magenta color in Figure 3). Of course, in this case the bearings will also be damaged due to extensive deformations beyond their capacity. It should be noted that even if deck unseating happens, this would not result in collapse since the deck is monolithically connected to the piers. Still it is an unlikely situation that would require considerable

repair actions. The abutments are founded on solid rock thus they are not assumed to be vulnerable to the seismic action.

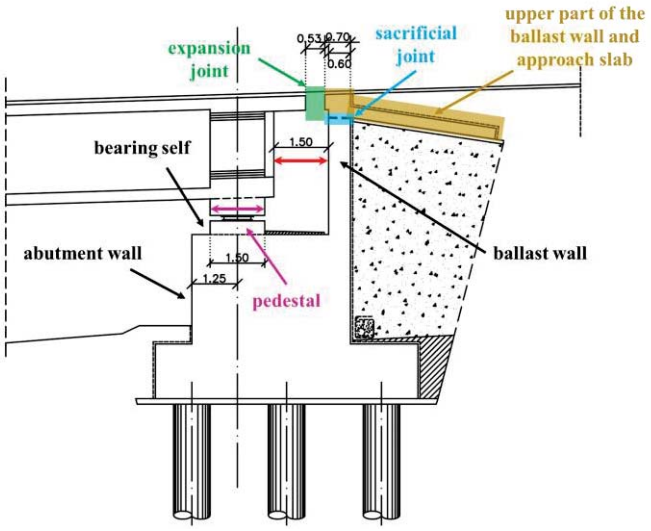

Figure 3: Support conditions of the deck in the longitudinal bridge direction, showing the expansion joint in green, the sacrificial joint in cyan, the upper part of the ballast wall, the pedestal in magenta and the approach plate in mustard color and the deck-to-abutment displacement thresholds that indicate deck hitting the ballast wall in red or deck unseating in magenta.

4.2 Bridge behavior in the transverse direction

The structural system of the bridge is designed and constructed so that the bridge mainly deforms in the longitudinal direction during earthquakes. However, it is also important to identify potential damages caused by transverse deck-to-abutment deformations. As presented in Figure 4, the shear key of the middle bearing (indicated in red color) restricts the transverse deck displacement up to the load of 250tn. If this load is exceeded, the shear key is expected to break thus letting the deck to move freely since pot bearings (shown in blue) enable such movements. If the deck-to-abutment deformation exceeds ±0.05m the deck is expected to hit the elastomeric bearings placed at the safety walls (shown in green color in Figure 4) which restrict further movements and partially alleviate impact. The safety walls of the G7 case act as transverse stoppers, hence they have an increased width of 0.75m. Overall, the bridge is designed so that in the design earthquake the shear key does not break, while in stronger earthquakes it can break thus in this case safety walls restrain further movement, until their eventual shear failure.

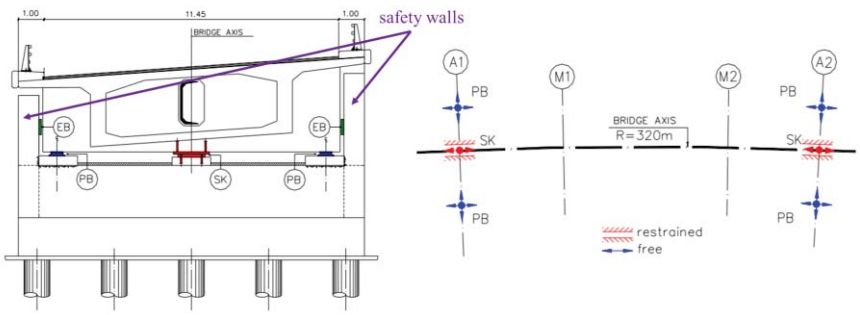

Figure 4: Support conditions of the deck in transverse bridge direction showing the elastomeric bearing (EB, green color), pot bearings (PB, blue color) and the bearing with the shear key acting in transverse bridge direction (SK, red color) (adapted from [13]).

4.3 Vertical bride displacements

Overall the deck is designed not to uplift during the design earthquake, however higher intensity events can very well cause uplift, immediately resulting to damage in the bearings.

5 DEFINITION OF CRITICAL BRIDGE COMPONENTS

After having elaborated on the bridge behavior in potential longitudinal, transverse and vertical displacements, the critical bridge components that might sustain damage during earthquakes can be identified along with the associated limit states and consequences. The critical components considered for the G7 bridge of Egnatia Odos are the piers, bearings, abutments, ballast walls, safety walls, pedestals, the deck and the expansion joints. Regarding the piers, they are critical components that may experience damage due to longitudinal or transverse bridge displacements. The response of the piers is discretized in the four limit-states of Stefanidou [14], thus associated thresholds are calculated based on the proposed closed-form equations. For the other components of the bridge, the limit states are derived based on the manufacturer's data as well as discussions with professional bridge engineers.

The consequences associated to each damage state are quantified based on expert opinion in terms of repair cost, repair time and the standard procedures the road operators follow until damages are repaired. These relate to the number of lanes that should be closed and/or the maximum allowable speed of the vehicles in remaining open ones.

6 RISK AND RESILIENCE ASSESSMENT

6.1 Non-linear modeling

A three-dimensional (3D) reduced-order model of the bridge was developed by [15] on the OpenSees platform [16], as shown in Figure 5. Due to its computational efficiency, it is also employed for our purposes. The deck is assumed to remain elastic thus it is modeled using linear elastic beam-column elements following the central axis of the deck. Rigid elements are added on both sides to carefully capture the double curvature of the bridge. Force-based beam-column elements discretized into longitudinal steel and concrete fibers are used for modeling the piers, with appropriate stress-strain laws to represent the confined core concrete, the unconfined concrete of the cover and the steel rebars. The effect of confinement is calculated on the basis of the Mander et al. model [17]. Rigid elements of zero mass are used for connecting the deck with the bearings, the latter being modeled via a set of one-dimensional springs to model the restraints imposed upon the deck ends by the bearings, the backwalls and the sidewalls. They allow a longitudinal deck-abutment gap-opening displacement of up to 1.50m, until unseating occurs, while they also simulate the sequential failure of the deck and backwall top and eventual contact of deck and backwall after a gap closing displacement of 1.5m. The shear key of the middle bearings is introduced via a hysteretic spring fracturing at the load of 250tn, also accounting for contact with the side walls of the abutment if the shear key collapses. The bridge is founded on the bedrock via deep foundations thus the piers are assumed to be fixed. The fundamental period of the bridge vibrates at T_1 = 1.65sec and is the longitudinal-direction-dominant one, while the second eigen-period is the transverse-direction-dominant one with T_2 = 1.54sec.

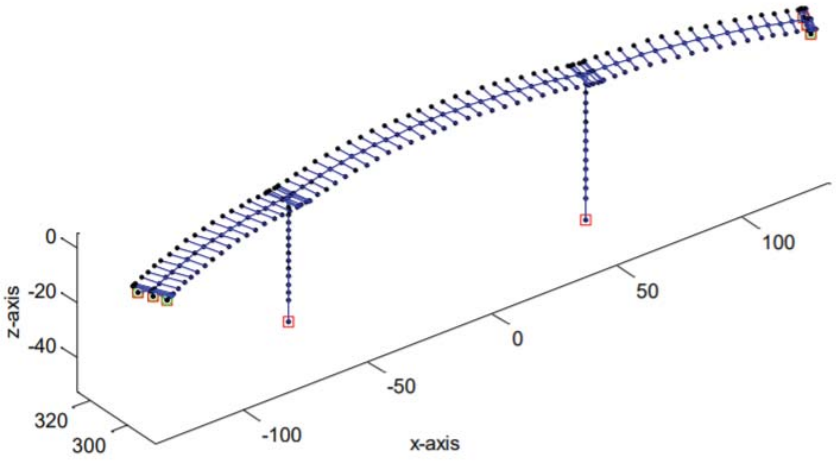

Figure 5: 3D reduced-order model of the G7 bridge [15].

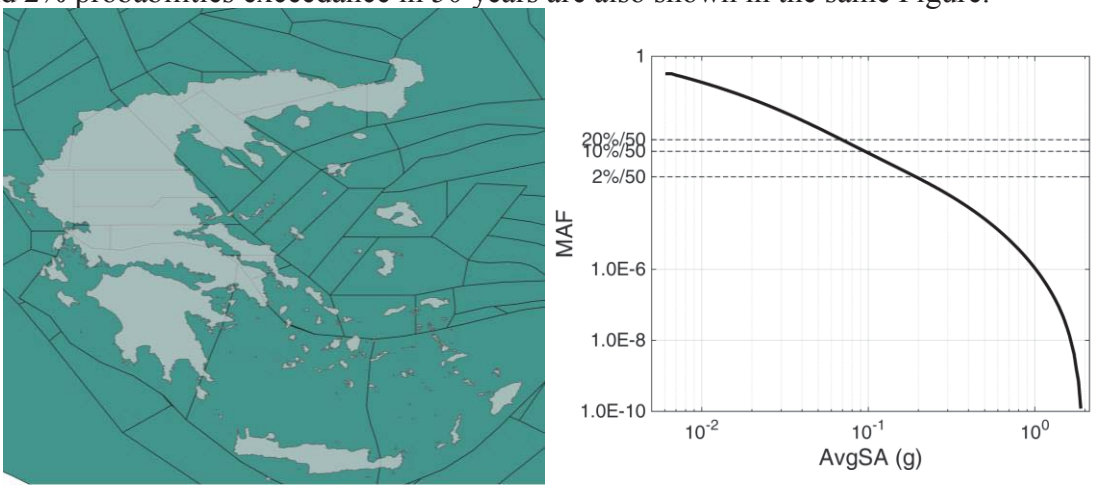
6.2 Site-specific seismic hazard assessment

The G7 bridge is located in an earthquake prone area thus it is important to consider the site-specific seismic hazard during the analysis. The state-of-the-art average spectral acceleration, *AvgSa*, ([18]-[20]) is adopted as the IM:

$$AvgSa(T_{Ri}) = \left(\prod_{i=1}^{n} Sa(T_{Ri}) \right)^{1/n} \tag{1}$$

It is the geometric mean of *n* spectral acceleration ordinates, *Sa*, at periods T_{Ri}. Each *Sa* ordinate is the geometric mean of the 5%-damped spectral acceleration from the two horizontal components of each ground motion. The periods, T_{Ri}, are equally spaced in [0.3s, 3.0s] with an increment of 0.1s. The seismic hazard is assessed on the basis of probabilistic seismic hazard analysis (PSHA), using the OpenQuake software [21], by employing the area source model of the SHARE project [22] and the ground motion prediction equation proposed by Boore and Atkinson [23]. The resulting seismic hazard curve is presented in Figure 6b in terms of the *AvgSa* and the mean annual frequency, *MAF*, of exceeding it. The *AvgSa* with 20%, 10% and 2% probabilities exceedance in 50 years are also shown in the same Figure.



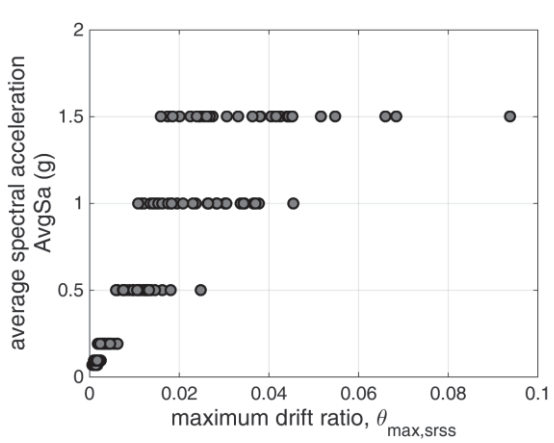
(a) (b)

Figure 6: Site-specific seismic hazard assessment using the area source model of the SHARE project that is presented in (a). The resulting seismic hazard curve is shown in (b).

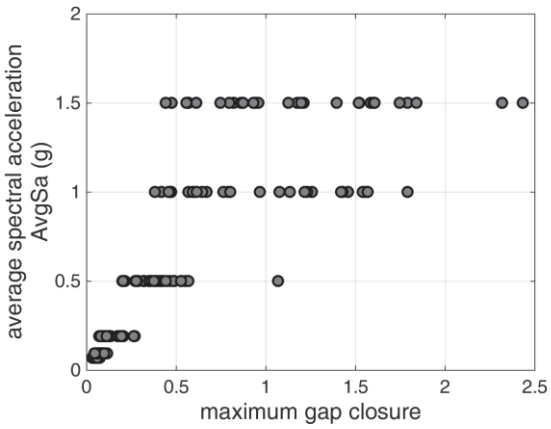
For each hazard level, a set of 30 ground motion records is selected that is compatible to the site-specific seismic hazard based on the Conditional Spectrum ([24], [25]). This bridge is not expected to sustain considerable damage under the design level earthquake, thus three additional set of records are selected for *AvgSa* equal to 0.5, 1.0 and 1.5g.

6.3 Non-linear dynamic analyses

The non-linear model of the bridge is subjected to nonlinear dynamic analyses using the 6 sets of CS-compatible ground motion records. Both horizontal components of each ground motion are applied on the 3D model of the bridge, after being appropriately scaled to match the level of *AvgSa* for the given set. Therefore, the analysis results are grouped in the six stripes of Figure 7 (multi-stripe analysis, MSA), where each point represents an AvgSa-EDP pair, the latter being the response parameter of interest. The EDPs are appropriately selected to adequately characterize the response of the critical bridge components that may sustain damage and whose performance defines damage states. For instance, in Figure 7a the maximum drift ratio of the M1 pier is presented, that is the square root of sum of squares (srss) of pier drifts in the longitudinal and transverse directions, while in Figure 7b the maximum gap closure of the left abutment is shown.



(c) *AvgSa* versus maximum srss drift ratio for the M1 pier



(d) *AvgSa* versus maximum gap closure for the left abutment

Figure 7: Multi-stripe analysis results. For each of the six stripes, the bridge is subjected to a set of 30 hazard-consistent CS-compatible ground motion records.

6.4 RESILIENCE ASSESSMENT OUTPUTS

For each level of the IM, multiple damage and associated consequence scenarios are defined by randomly sampling the corresponding distributions in the pre-event phase of PANOPTIS based on the MSA results. In each case, the time-to-recover is computed by adding the time needed for repairing the damages associated with each individual component, assuming that they are tackled in series. For simplification purposes, we assume perfect correlation in the demand and the capacities of the two twin bridges. This means that both of them are expected to sustain the exact same damage level, thus for example in both bridges we might close one out of the two lanes if needed. Of course, this simplification is not exactly the case and a non-perfect correlation in the seismic capacities should be taken into account.

Our main metric of functionality is the theoretical traffic capacity, without regard to the actual traffic loads. This is a demand-agnostic view of the system functionality, as obviously the full capacity of the road is not necessarily used at all times of the day, or all days of a year. Still, it remains a useful metric that does not require traffic load estimates for current and fu-

ture use, allowing us to offer an objective "timeless" comparison of the damaged and undamaged states of the bridge. Specifically, the traffic capacity of any bridge state is estimated as $TC = MaxSpeed \cdot NOL$, i.e., as the product of the speed limit, *MaxSpeed*, multiplied by the number of open lanes, *NOL*. Consequently, the traffic capacity reduction, *R*, can be quantified as

$$R = \left(TC_{pre} - TC_{post}\right) / TC_{pre} \tag{2}$$

where TC_{pre} and TC_{post} are the pre- and post-even capacities, respectively. For the former, the undamaged state of the bridge stipulates a 90km/h speed limit with 2 lanes of traffic for each twin bridge. The mean annual frequency of exceeding each value of *R* is presented in Figure 8a), while the 16, 50 and 84% quantiles given the intensity in terms of are presented in Figure 8b). Evidently, no loss of functionality is observed for intensities lower than 0.2g, or mean annual frequencies higher than $2 \cdot 10^{-4}$. In other words, loss of even the lowest possible value of functionality happen with a return period larger than $1/(2 \cdot 10^{-4}) = 5000$yrs. On the other hand, when such an event occurs, the capacity loss is steep, with functionality losses of up to 30% occurring with only slightly higher return periods, typically owing to bearing and/or expansion joint damages.

7 CONCLUSIONS

A methodology is presented for modeling the structure and data dependencies for the resilience assessment of a highway bridge within the PANOPTIS project. This approach can be applied for each individual highway/road infrastructure asset and the combined results can be used for the resilience assessment of the entire interconnected system. The proposed framework is quite straightforward, still the toughest part is the definition of the limit states on a component basis and the quantification of the associated consequences in a consistent way for all components. This challenge requires the assistance of engineers specialized in the design and construction of similar structures as well as of road operators experienced in road maintenance, repair and rehabilitation after potential damaging events. Once the required limit states and consequences are defined, the proposed methodology can be implemented for the resilience assessment of a given highway asset.

Keywords: Eurocode 8, ductility class, high-rise buildings, shear force

Abstract. *The paper contains a discussion of limitations of dual ductility class approach in seismic design of reinforced concrete (RC) high-rise buildings designed according to Eurocode 8. An extensive study is performed in order to examine the applicability of Eurocode 8 provisions related to ductility classes for seismic design of RC walls in high-rise buildings. As representative buildings, 20-storey, 30-storey and 40-storey RC high-rise buildings with core wall structural system are selected. For the purposes of the conducted study, nonlinear time-history analyses are performed for 60 ground motion records with a wide range of magnitudes, distances to source and various soil types. Design seismic shear forces obtained by Eurocode 8 for medium and high ductility classes are analyzed and compared with the real shear forces obtained by nonlinear time-history analyses. The current Eurocode 8 provisions for calculating seismic design shear forces in RC walls yields significantly incorrect results when it is applied to RC walls of high-rise buildings. The results derived in this study indicate that RC high-rise buildings should be designed according Eurocode 8 provisions specified for medium ductility class, taking into consideration the weakness of the existing procedure for calculating design shear force. The need of introducing a single ductility class for RC high-rise buildings is pointed out.*

1 INTRODUCTION

Over the past decades, the construction of high-rise buildings in seismically active areas has become an everyday design trend, which is mainly due to growing urbanisation, rapid growth of cities, and concentration of material resources in urban environments. This is why comprehensive seismic studies of RC high-rise buildings have to be conducted for earthquake-prone areas. Given the sensitivity of high-rise buildings to horizontal loads (earthquake and wind loads), special attention should be paid to seismic analysis of RC high-rise buildings. Even in conditions where the horizontal wind load is relevant for design, which typically occurs for higher RC buildings, approximately 250 m in height, it is not entirely adequate to neglect seismic analysis [1]. High-rise buildings have frequency response range that is much wider than in the case of lower buildings. The wide frequency range of actual earthquake records can induce very complex seismic responses of high-rise RC buildings [2]. Due to the specific behavior of high-rise buildings exposed to seismic effects, the provisions of existing seismic design codes (such as Eurocode 8 EN1998-1 [3]) are usually not sufficient to design seismically resistant RC high-rise buildings. EN1998-1[3] does not define restrictions in terms of number of storeys, but it is the fact that number of storeys has the influence on seismic behavior, and so most commonly existing provisions of EN1998-1 [3] are inadequate and need to be revised for RC high-rise buildings. The most recent studies have shown that modifications and improvements to Eurocode 8 procedures are required [4]–[7]. Rutenberg and Nsieri [4] has shown that the Eurocode 8 procedure for calculating design shear force is conservative for DCH walls and gives lower value of magnification factor ε for DCM walls. Kappos and Antoniadis [5] proposed modified shear force design Eurocode 8 envelope for dual system of walls. Antoniou et al. [6] in their research concluded that Eurocode 8 overestimates the post-elastic amplification of shear walls. Antoniou et al. [7] have shown that actual moments exceed the linear design Eurocode 8 envelope over most of the wall height for mid-rise wall-frame structures.

In the literature, there is a lack of research on this topic with regard to the RC high-rise buildings. In this study, RC high-rise buildings with core wall structural system and three characteristic heights: 20-storey, 30-storey and 40-storey are analysed in order to examine the limitations of EN1998-1 [3] dual ductility class approach in seismic design of RC high-rise buildings

2 DESCRIPTION OF SELECTED REPRESENTATIVE RC HIGH-RISE BUILDINGS

A three representative RC high-rise buildings with core wall structural system, 20-storey, 30-storey and 40-storey high, designed according to Eurocode 8 provisions for two different ductility class (high and medium) are examined. The considered structures are 36x32m in size at the base, with spans in the X direction of 10x8x8x10m and spans in the Y direction of 10x6x6x10m (Figure 1). RC core is 16 x 12 m in size at the base and is located in the central part of the buildings. It consists of three characteristic complex cross section walls (U and I cross-sectional shapes) connected in the X direction of structure by coupling beams. In the area between the central RC core and the perimeter of the structure there is no structural elements. RC frames were formed in the circumferential planes. Vertical structural members are connected with a floor flat slab. The dimensions of the individual structural elements differ for different storey numbers and they are determined in accordance with the requirements defined in Eurocode 2 EN1992-1-1 [8] and EN1998-1 [3]. The main characteristic of the considered RC high-rise structures are shown in the Table 1.

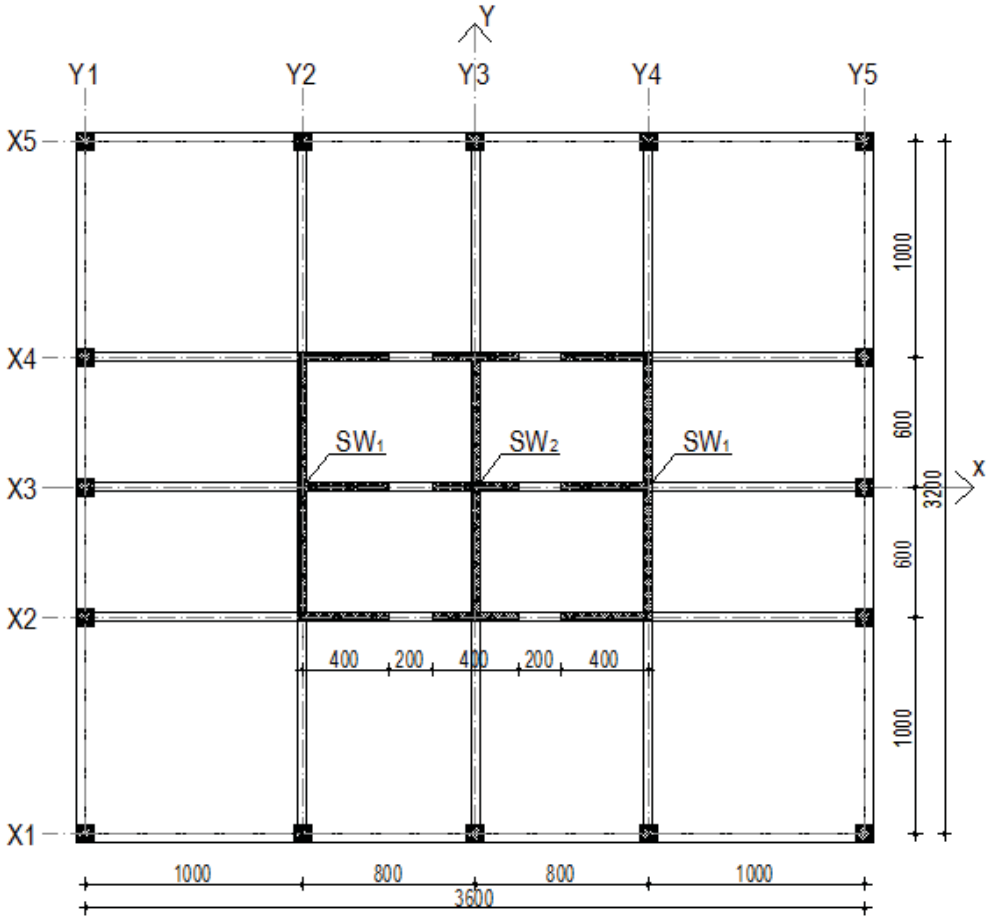

Figure 1: Base plan view of the representative buildings.

Features	20-storey	30-storey	40-storey
Total height (m)	60	90	120
Storey height (m)	3	3	3
Storey RC slab thickness (m)	0.20m	0.20m	0.20m
RC beams (m)	0.40x0.65	0.40x0.65	0.40x0.65
RC columns (m)	0.80x0.80	0.80x0.80	0.90x0.90
Core walls thickness (m)	1-5 storey: 0.30 6-20 storey: 0.20	1-5 storey: 0.40 6-30 storey: 0.30	1-10 storey: 0.55 11-40 storey: 0.45
Coupling beams in X direction (m)	1-5 storey: 0.3x0.8 6-20 storey: 0.2x0.8	1-5 storey: 0.4x0.8 6-30 storey: 0.3x0.8	1-10 storey: 0.55x0.8 11-40 storey: 0.45x0.8
Concrete f_{ck} (f_{cm}) (MPa)	35(43)	45(53)	55(63)
Reinforcement f_{yk}(f_{ym}) (MPa)	500(575)	500(575)	500(575)
Modulus of elasticity E_{cm} (MPa)	34000	36000	38000

3 SEISMIC DESIGN OF REPRESENTATIVE BUILDINGS ACCORDING TO EN1998-1

Seismic design of the representative RC high-rise buildings is done according to Eurocode 2 EN1992-1-1 [8] and Eurocode 8 EN1998-1 [3]. The considered buildings are designed for two ductility classes defined in EN 1998-1: high ductility class (DCH) and medium ductility

class (DCM). For defining seismic load, the design response spectrum type 1 (magnitude of surface wave M_S>5.5) with adopted value of design peak horizontal acceleration 0.37g is used. The structural system of the considered buildings is a ductile wall system in both horizontal directions according to the classification in EN1998-1 [3]. Considering the structural system and the regularity achieved, the adopted values of the behavior factors for the DCM ductility class is 3.6, and for the DCH class is 5.4.

The ETABS2013 [9] was used for linear seismic analysis of considered buildings. 3D linear models are constructed in ETABS2013 [9]. 50% of the uncracked flexural and shear stiffness is considered in linear analysis according to EN1998-1 [3]. The storey slabs are modeled as rigid diaphragms in the horizontal plane. The vertical structural system is modeled with absolute supports at the foundation level. The structures of the selected buildings are regular in base and over the height. In addition to lateral stability and rigidity, the structures of the buildings under consideration also have adequate torsional resistance and rigidity. On the each storey and in the both considered X and Y directions, the structural eccentricity e_o and the torsional radius r satisfy the conditions defined in EN1998-1 [3].

The total seismic forces for the two horizontal orthogonal directions were calculated by multi-modal response spectrum analysis, which is quite appropriate given the influence of higher modes on RC high-rise buildings. The results from linear multi-modal response spectrum analysis are shown in Table 2.

Number of storeys			20	30	40
Total base shear force for in Y direction for DCM (kN)			18503	24331	32454
Total base shear force for in X direction for DCM (kN)			16348	23266	32340
Total base shear force for in Y direction for DCH (kN)			15376	21322	29441
Total base shear force for in X direction for DCH (kN)			14946	21385	29989
Periods in Y direction (sec)	Mode	1	1.652	2.880	4.097
		2	0.389	0.623	0.858
		3	0.181	0.270	0.355
Periods in X direction (sec)	Mode	1	1.641	2.597	3.511
		2	0.480	0.702	0.880
		3	0.250	0.347	0.423
Mass participation factors in Y direction (%)	Mode	1	64.26	63.53	63.24
		2	20.32	19.43	18.94
		3	7.04	7.05	7.05
Sum of mass part.factors in Y direction (%)			94.85	93.58	92.88
Mass participation factors in X direction (%)	Mode	1	69.36	67.70	66.08
		2	15.96	17.40	18.78
		3	5.49	5.23	5.68
Sum of mass part.factors in X direction (%)			93.64	93.11	93.18

Table 2: The linear multi-modal response spectrum analysis results.

The analysis of the calculated seismic and gravitational effects obtained in the structural elements revealed that the total seismic force is dominantly accepted by RC walls of the core. For this reason, RC core was subjected to further detailed calculations and designing according to the relevant EN1998-1 [3] provisions and subsequently RC core walls were also analysed using nonlinear time-history analyses. The serviceability limit state according to EN1998-1 [3] has been checked and it was found that it provisions are satisfied. All the provisions of the EN1998-1 [3] regulations regarding the dimensioning and reinforcement detailing

of ductile walls of the ductility classes DCM and DCH were applied. Certain walls of RC core, since they represent complex sections of walls, composed of connected rectangular segments, were treated as integral parts consisting of webs in the direction in which the seismic shear force acts, with flanges normal to them. This is also in accordance with the rules defined in EN1998-1 [3]. The considered positions of integral shear walls (complex cross sections of U and I, SW1 and SW2) are shown in Figure 1.

The design values of the walls bending moments were obtained from the EN1998-1 [3] bending moments envelope for a seismic design situation. The design shear force along the height of the walls were determined using the corresponding values of the shear force magnification factor ε for the individual ductility classes. All requirements related to dimension acquisition (height of critical zone, minimum wall thickness, thickness and length of boundary elements) and reinforcement detailing for vertical and horizontal reinforcement (stirrups) of the boundary elements in critical zones and areas outside critical zones, as well as requirements related to vertical and horizontal web reinforcement are fulfilled.

4 NONLINEAR TIME-HISTORY ANALYSIS

The nonlinear spatial model of the RC core walls was made. The PERFORM-3D software [10] was used for the nonlinear time-history analysis. The core walls are modeled using nonlinear vertical fiber elements representing the expected behavior of the concrete and reinforcing steel [11]. The area and location of reinforcement within the cross-section, as well as concrete properties, were defined using individual fibers forming the cross-section of the wall. The shear behavior is modeled as elastic. Stress-strain relationship for unconfined concrete, confined concrete, and reinforcement, compliant with recommendations given in Eurocode 8 [3], were adopted. The data of the European strong-motion database [12] were used as database of ground motions. Sixty seismic records were selected. Out of these records 25 were recorded in rock, which corresponds to the type A soil according to EN1998-1 [3]. The remaining thirty-five records were recorded on stiff soil, which corresponds to the type B soil according to EN1998-1 [3]. Magnitude values for selected records range between 5.1 and 7.0, while distances to source vary from 5 to 70 km. The basic criterion used in this paper for the selection of ground motions is that the mean value of their response spectra be compatible with the corresponding target spectrum in a wider range of periods. The elastic spectrum from EN1998-1 [3] was selected as the target spectrum for the return period of 475 years, with the design ground acceleration amounting to 0.37g. The mean squared error method (MSE) is selected for ground motions scaling [13]. Figures 2 and 3 show: response spectra of selected ground motions scaled by MSE method for the intensity level of 10%/50, the mean spectrum and relevant target spectra (Eurocodes 8 elastic spectra) for the intensity level of 10%/50 and the mean spectrum for the intensity level of 2%/50, for certain soil types.

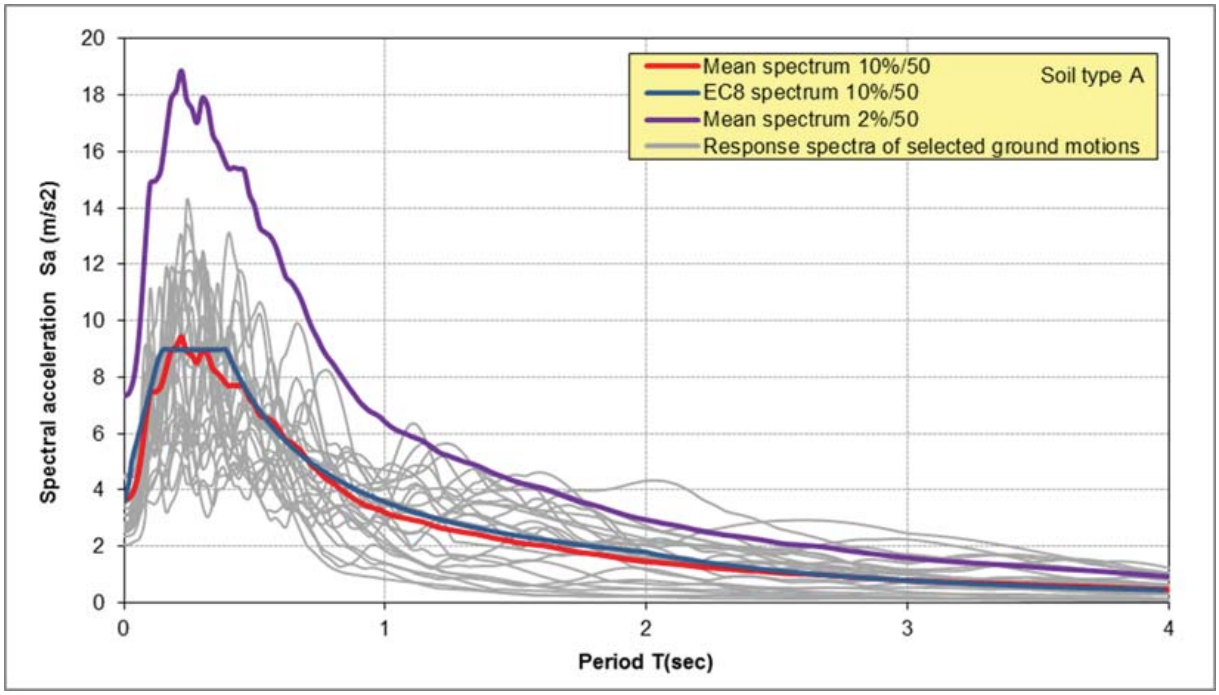

Figure 2: Characteristic response spectra of the selected ground motions for soil type A.

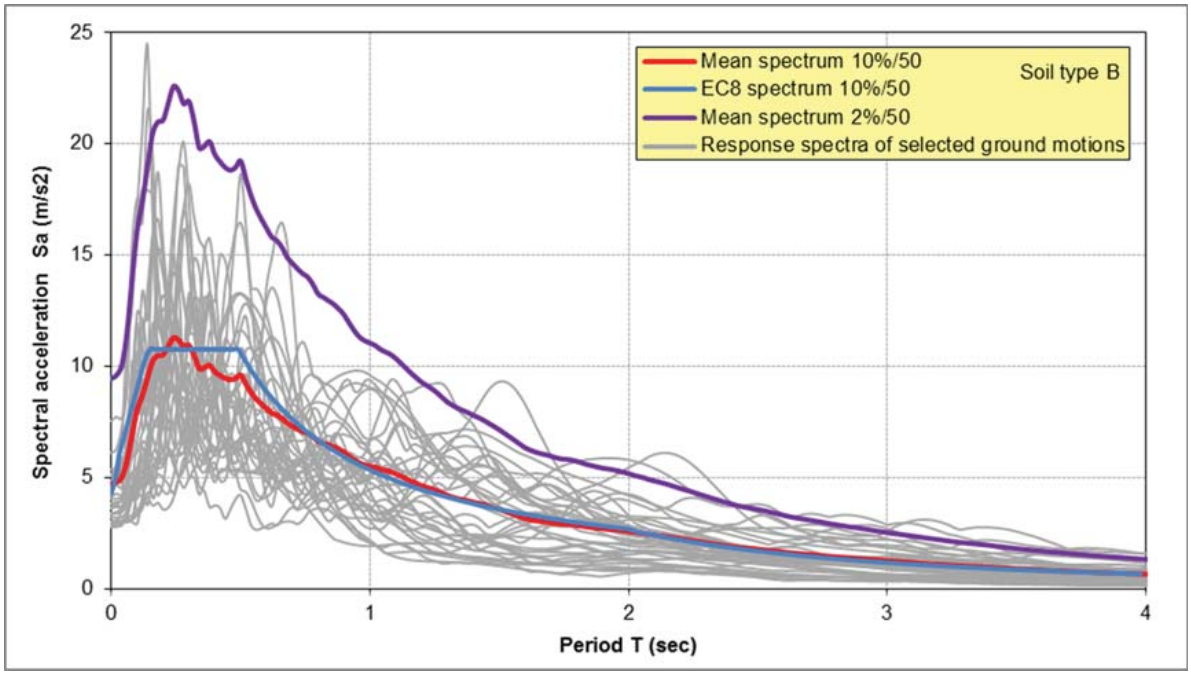

Figure 3: Characteristic response spectra of the selected ground motions for soil type B.

5 ANALYSIS RESULTS

The considered buildings are designed for two ductility classes defined in EN 1998-1: high ductility class (DCH) and medium ductility class (DCM). During the design of representative RC high-rise buildings for specific ductility classes in accordance with EN1998-1 [3], certain specificities were observed. Firstly, it has been observed that for RC high-rise buildings, characterized by higher values of the fundamental periods, the values of design spectrum for fun-

damental mode $S_d(T_1)$ are very low (less then the lower boundary of the horizontal project spectrum β defined in EN1998-1 [3]). For this reason, the total seismic forces in linear analysis for DCH and DCM buildings do not differ much (see Table 2). It is interesting to notice that for lateral force method of analysis, which is not advisable for RC high-rise buildings due to the influence of higher modes, the values of the total seismic forces for the individual ductility classes would be identical.

Further, due to the high values of the design shear forces in DCH walls, obtained by existing EN1998-1 [3] procedure, it is practically impossible to satisfy demand regarding diagonal compression failure of the web due to shear in the web $V_{Rd,max}$ [3]. The design shear force V_{Ed}, according to rules from EN1998-1 [3], must be less than shear resistance controlled by diagonal compression in the web $V_{Rd,max}$ [3]. Outside the critical region, this shear resistance is calculated as in EN 1992-1 [8] for monotone loads, while in the critical region, 40% of the value outside of critical region is proposed by EN1998-1 [3]. This EN1998-1 [3] rule is based on experimental research done by Biskinis et al. [14]. Biskinis et al. [14] has shown that the cyclic load significantly reduces this resistance and that the shear resistance $V_{Rd,max}$, is averages 40% of the value defined in EN 1992-1 [8]. These differences are very large and for this reason stated reduction of $V_{Rd,max}$ is included in EN 1998-1 only for DCH walls in the critical area. This large reduction of the design shear resistance $V_{Rd,max}$, applied together with the shear magnification, might be prohibitive for the usage of DCH RC ductile walls. Fulfillment of shear control would only be possible with unrealistically large wall thicknesses. This limitation is noted by previous studies even for lower buildings and for this reason, the DCM walls are not included in EN1998-1 [3] by this provision, while the above-mentioned experimental findings are not confirmed with the more experimental tests [15]. Due to the inability to the fulfilment of this EN1998-1 [3] provision for DCH RC walls with the realistic wall thickness, the considered representative RC high-rise buildings are designed to fulfil all the EN1998-1 [3] provisions except demand regarding diagonal compression failure.

In Figure 4, characteristic seismic shear force diagrams in wall (SW_1) in Y direction for three representative buildings are shown: V'_{Ed} – seismic shear forces obtained by multi-modal response spectrum analysis according to EN1998-1 [3], V_{Ed} – design seismic shear forces obtained by EN1998-1 [3], and $V_{Rd,max}$ - the shear resistance controlled by diagonal compression in the web. It is easy to notice that in critical regions of the wall for the DCH ductility class, the shear resistance $V_{Rd,\,max}$ is significantly less than the design shear force V_{Ed}, while for the ductility class DCM the design shear forces satisfy the condition that they are less than shear resistance.

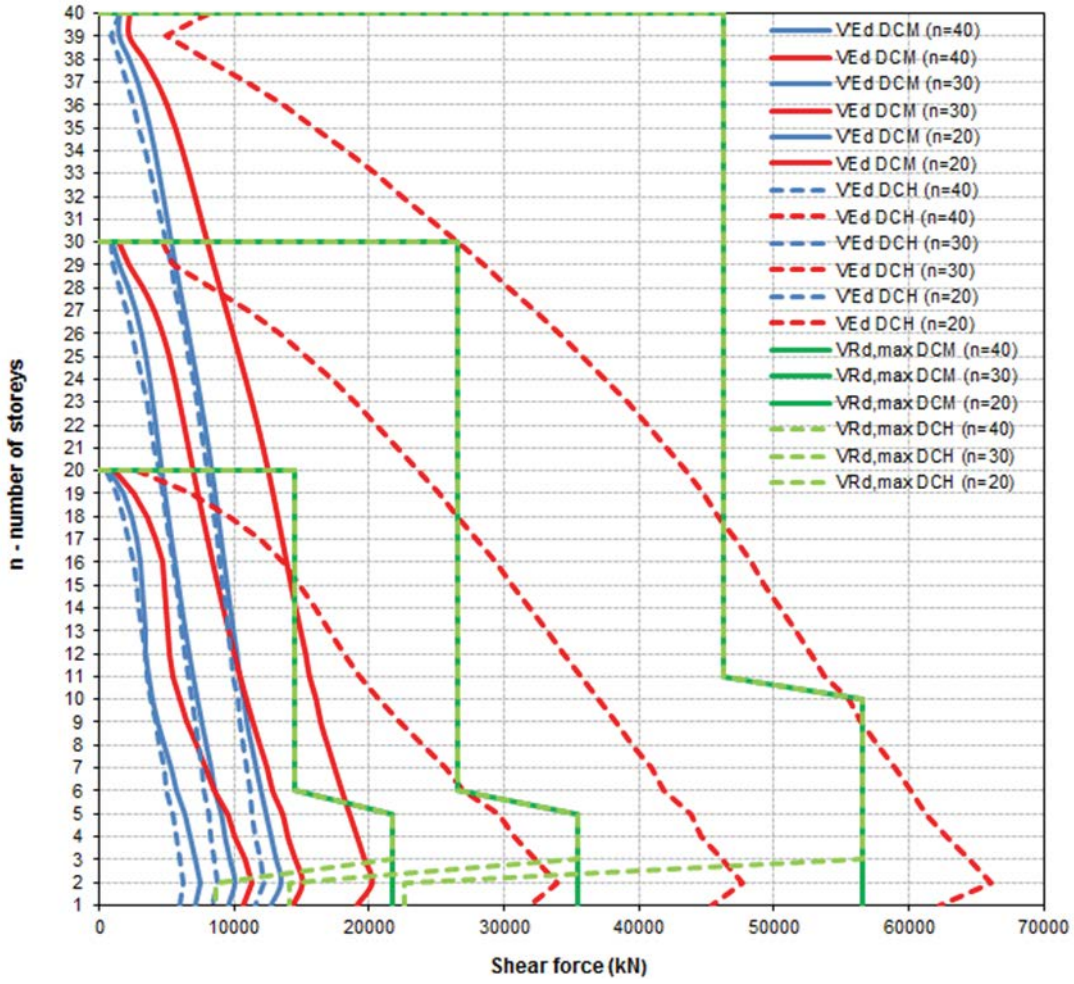

Figure 4: The characteristic seismic shear force diagrams in wall SW_1.

Figure 4 also shows that the shear forces along the wall height obtained by linear analysis V'_{Ed} do not differ much for the ductility classes DCM and DCH. These two facts, i.e. similar values of shear forces from linear analysis for individual ductility classes and inability to meet shear control in the case of DCH class, clearly indicate that RC high-rise buildings should be designed for DCM ductility class for the current state of EN1998-1 [3].

Furthermore, Figure 5 shows the characteristic values of the base shear forces of wall SW1 for the Y direction for DCM and DCH buildings. In addition to the shear forces V'_{Ed}, V_{Ed} i $V_{Rd,max}$ at the base of the wall, the values of the shear forces obtained from nonlinear time-historey analysis V_{na} are shown. V_{na} is the mean value of seismic shear forces obtained by using the 60 selected ground motions.

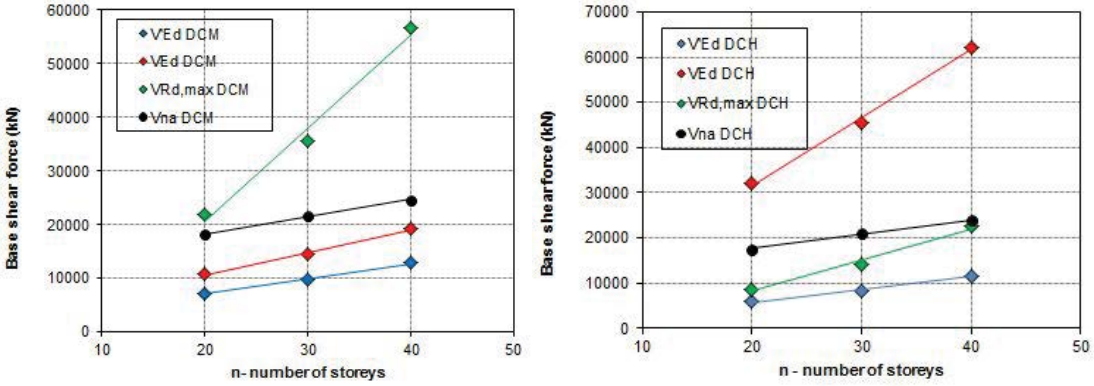

Figure 5: The characteristic base seismic shear forces in wall SW_1.

From the Figure 5, it can be seen that for the DCM ductility class, the shear forces obtained from the nonlinear time-history analysis V_{na} are higher than the designed ones, indicating that it is not appropriate to use a constant value of the magnification factor of 1.5 for the DCM ductility class. This imposes the need to calculate the increase factor ε in the same way as in the case of the DCH ductility class. On the other hand, for the DCH ductility class, the shear force values V_{na} differ significantly from the design values, which, unlike DCM shear forces, are overestimated or much larger than the actual forces that occur in the walls during an earthquake. It can be concluded that the correction of seismic design forces calculation for RC high-rise buildings in EN1998-1 [3] is required.

Also the high level of normal compressive force in the walls of high-rise RC buildings can be a limiting factor when designing high ductility class. For this reason, an analysis of the feasibility of achieving the required displacement ductility was performed for the three representative buildings designed for the DCM and DCH ductility classes. Given that for high-rise RC buildings characterized by values of fundamental vibration periods greater than 0.7s, the principle of equal displacements applies, the behavior factor is equal to displacement ductility factor [16]. The results of nonlinear time-history analyzes in buildings with a fundamental period greater than about 0.7s, showed that the maximum displacements in the elasto-plastic system are approximately equal to those in an elastic system that has the same initial stiffness but has no limited bearing capacity [17]. For the purposes of this analysis, the calculation of displacement ductility factors was done using the recommendations given by [16]. Paulay and Priestley [16] derived displacement ductility factors for RC vertical cantilever elements. The displacement ductility factor depending on the curvature ductility factor is calculated using the equation 1:

$$\mu_\Delta = 1 + 3 \cdot (\mu_\varphi - 1) \cdot \frac{L_p}{L} \cdot \left(1 - 0.5 \cdot \frac{L_p}{L}\right) \tag{1}$$

Where: μ_φ is curvature ductility factor, L_p plastic hinge length, L wall height. The theoretical background for derivation of the expression for the displacement ductility factor has been discussed in the literature [16]. The length of the plastic hinge is also determined by [16] as follows (equation 2):

$$L_p = 0.2 \cdot D_w + 0.044 \cdot h_e \tag{2}$$

Where: D_w wall cross-section thickness and h_e effective wall height equal to the height of the cantilever wall with the horizontal force at the top of the wall and the same value of moment and shear force at the fixed end as in the case of the actual wall.

For the three considered representative RC high-rise buildings using the XTRACT [18] software, cross-sections of the walls at the location of the plastic hinge were analyzed and moment-curvature dependencies for the plastic hinge were derived. The curvature ductility factors were determined using the derived dependencies. Based on derived curvature ductility factors for individual representative RC high-rise buildings, designed for both ductility classes, displacement ductility factors were calculated, which at the same time represent behavior factors q. Figure 6 shows the derived behavior factors for individual representative RC high-rise buildings.

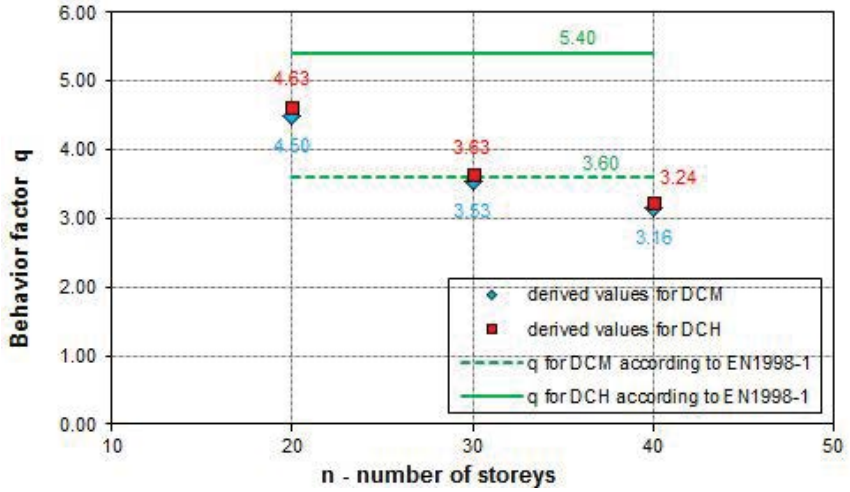

Figure 6: The derived behavior factors.

From the Figure 6, the limitations in terms of the behavior factors values for RC high-rise buildings can be noticed. The highest behavior factor is obtained for the case of a 20-story representative building due to the least normal compression force in the wall and therefore the highest curvature ductility in plastic hinge cross section and the corresponding displacement ductility. For reasons of maximum values of normal compression force in wall of 40-storey building, the smallest behavior factor is obtained. For all three buildings designed for the DCH ductility class, smaller behavior factors, than the value defined by EN1998-1 [3], were derived. Buildings designed for DCM have satisfactory values of derived behavior factors, that is, greater or approximately the same value as those for the DCM class according to EN1998-1 [3]. Exception is a 40-story building that has a slightly lower value. These results also indicate the limitation of the application of the DCH ductility class to the design of RC high-rise buildings in accordance with EN1998-1 [3]. The presence of higher normal compression forces in the RC walls of high-rise buildings is a limiting factor when considering the DCH ductility classes. With the increase in number of storeys, the possibility of achieving an appropriate value of displacement ductility, characteristic for the DCH ductility class, decreases. Therefore RC high-rise buildings should be designed with DCM ductility class, wherein there are wider possibilities for defining the behavior factor q for the DCM ductility class. This range can be defined depending on different parameters (for example: number of storeys, structural system, etc.).

6 CONCLUSIONS

In analysis of seismic design of representative high-rise buildings for DCM and DCH ductility classes, in accordance with Eurocode 8, the following conclusions were pointed out:

- The conducted analysis has shown that total seismic base shear forces for considered ductility classes (DCM and DCH) differs only 5-15%. This occurs because the values of design spectrum for fundamental mode $S_d(T_1)$ of high-rise buildings are very low, less than values related to lower bound factor for the horizontal design spectrum β (defined in Eurocode 8). Therefore, the influence of behaviour factor q on design spectrum for fundamental mode is negligible. The seismic base shear forces of the first mode for DCM and DCH ductility class have the same value while shear forces for higher modes differ slightly. There is a need to introduce a unique ductility class for RC high-rise buildings.
- Due to the high design shear forces in DCH walls, it is practically impossible to satisfy demand regarding diagonal compression failure of the web due to shear in the web. Large reduction of the shear resistance of DCH wall controlled by diagonal compression, applied together with magnification of shear forces with current Eurocode 8 procedure, limits the design of DCH ductile walls. Fulfillment of shear control would only be possible with unrealistically large wall thicknesses.
- From the analysis of the possibility of achieving the required displacement ductility for the DCH class, it is concluded that the presence of higher normal compression forces is a limiting factor when applying the DCH ductility class. With increasing number of stories, the ability to achieve the appropriate value of displacement ductility, characteristic for the DCH ductility class, decreases. Such results indicate the limitation of the application of the DCH ductility class to the design of RC high-rise buildings in accordance with Eurocode 8.
- All these facts clearly indicate that RC high-rise buildings should be designed according Eurocode 8 provisions specified for medium ductility class, taking into consideration the weakness of the existing procedure for calculating design shear force. The need of introducing a single medium ductility class for RC high-rise buildings is pointed out.

Keywords: rocking, analytical dynamics, fragility, seismic loss, resilience.

Abstract. *Conventionally designed bridges, i.e. when the column is monolithically connected with the ground (fixed-base), sustain considerable damage at the column ends after severe earthquakes. Seismic damage often determines whether or not the bridge remains functional after an earthquake event. Rocking isolation, on the other hand, allows structural components to uplift and pivot; thus, in principle, it relieves the structure from excessive deformations and damage. However, rocking isolation is still rarely applied in engineering practice, mainly due to the lack of thorough understanding of its dynamic (seismic) performance and its post-earthquake financial benefits. This paper redirects our attention to the main benefits of rocking design, and conducts a thorough seismic loss assessment adopting two different rocking bridge configurations in terms of their post-earthquake economic losses and resilience. In particular, this work extends the well-established performance-based earthquake engineering framework to evaluate the seismic losses of the examined rocking structures accumulated following severe seismic events and quantify their post-earthquake resilience. The analysis reveals the considerably mitigated seismic losses and the remarkable post-earthquake resilience that a rocking bridge offers when carefully designed. In particular, even a slight modification of the slenderness of the structure leads to a substantial enhancement of its seismic performance; reinforcing its potential as an alternative seismic design paradigm for bridges. The above findings illustrate the considerable financial benefits of such innovative seismic-resistant structural systems, which can serve as an efficient seismic design paradigm for future bridge engineering applications.*

1 INTRODUCTION

Conventional bridge seismic design provides the necessary strength and ductility to the structure to withstand seismic forces and avoid collapse. Such a design concept, though, accepts the "*prize*" of sustainable seismic damage after severe earthquakes. Seismic damage is an important measure that often determines whether or not a bridge remains operational following a seismic event. Rocking design, on the other hand, relieves the structure from seismic damage by allowing structural components to uplift and pivot during an earthquake. After the Chilean earthquake in 1960, the seminal work of Housner [1] revealed the benefits of rocking design and triggered a thorough investigation on the seismic performance [2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12] of various rocking structural systems [13, 14, 15, 16, 17, 18].

The mechanical configuration of the single-column frame of Fig. 1, where the column is monolithically connected with the footing (or base) while the column-base system can detach from the ground when subjected to a ground motion, is particularly attractive for bridge design. Various studies have experimentally and/or numerically investigated its seismic performance highlighting: (i) the mitigated seismic forces that are transmitted to the column of the structure; and (ii) the negligible seismic damage and small residual displacements that the rocking structure sustains [19, 20, 21, 22, 23, 24]. On the other hand, the analytical studies that focus on the potential post-earthquake financial benefits of rocking structures still remain scarce. Modelling the structural system of Fig. 1 as a two degree-of-freedom oscillator, Giouvanidis and Dong [25] compared the seismic performance of a (single-column) rocking versus a conventionally designed (fixed-base) bridge. That study revealed the remarkable post-earthquake financial benefits that a rocking bridge offers when carefully designed.

This research is motivated by the lack of analytical studies that thoroughly quantify the post-earthquake financial benefits of a rocking bridge. In particular, it extends the well-established performance-based earthquake engineering framework to investigate the seismic performance of two rocking bridge configurations and to unveil the influence of design parameters (i.e. slenderness) on their functionality and resilience in the aftermath of severe seismic hazard scenarios. In this context, this research study: (i) redirects our attention to the main benefits of rocking design (e.g. seismic loss, post-earthquake resilience); and (ii) paves the way for a more holistic seismic assessment framework of single-column rocking bridges.

2 ANALYTICAL MODELLING OF A ROCKING BRIDGE FRAME

Fig. 1 illustrates the examined single-column rocking bridge frame. Assuming rigid ground conditions and no sliding at the rocking interface allow the structure to uplift and pivot during an earthquake exhibiting planar rocking motion. When the rocking structure of Fig. 1 remains in full contact with the ground, it behaves as a single degree-of-freedom system. Thus, its motion is captured by the deformation of the column u. After rocking commences, the motion of the rocking structure is captured by both the deformation of the column u and the rocking rotation ϕ of the base [26, 27].

Consider the rocking oscillator of Fig. 1 with a concentrated mass m at height h. The column has a total mass of m_c and elastic stiffness of EI uniformly distributed along its length. The rigid base has mass m_b and width $2b$. For simplicity, assume the lumped mass m creates no moment of inertia, while the rigid base creates moment of inertia with respect to its center of mass equal to $I_{m_b} = (1/3)\, m_b b^2$. The equations of motion of the rocking oscillator

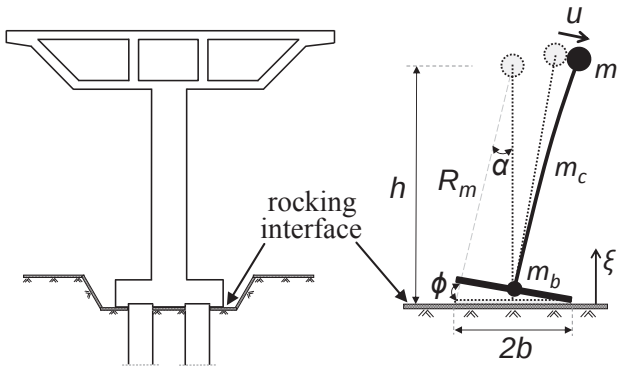

Figure 1: Typical single-column rocking bridge frame (left) modelled as a two degree-of-freedom oscillator (right)

can be derived using the general form of the Lagrange's equation:

$$\frac{d}{dt}\left(\frac{\partial L}{\partial \dot{u}}\right) - \frac{\partial L}{\partial u} = Q, \qquad \frac{d}{dt}\left(\frac{\partial L}{\partial \dot{\phi}}\right) - \frac{\partial L}{\partial \phi} = 0 \tag{1}$$

where $L = T - V$, with T the kinetic energy, V the potential energy and Q the generalized force, whose mathematical derivations are for brevity omitted herein (see [25] for more details). While the oscillator of Fig. 1 exhibits planar rocking, the equations that describe its motion become [25]:

$$\begin{array}{l} \left(m+\frac{33}{140}m_c\right)\ddot{u} + \left(m+\frac{11}{40}m_c\right)h\ddot{\phi} = \\ -C\dot{u} - \frac{3EI}{h^3}u + \left[\left(m+\frac{33}{140}m_c\right)u - sgn\left(\phi\right)\left(m+\frac{3}{8}m_c\right)b\right]\dot{\phi}^2 \\ -\ddot{u}_g\left(m+\frac{3}{8}m_c\right)\cos\phi + g\left(m+\frac{3}{8}m_c\right)\sin\phi \end{array} \tag{2}$$

$$\begin{array}{l} \left(m+\frac{11}{40}m_c\right)h\ddot{u} + \left[\begin{array}{l}\left(I_{m_b}+m_b b^2\right)+m\left(h^2+b^2\right)+mu^2 - sgn\left(\phi\right)2mbu \\ +m_c\left(\frac{1}{3}h^2+b^2\right)+\frac{33}{140}m_c u^2 - sgn\left(\phi\right)\frac{3}{4}m_c bu\end{array}\right]\ddot{\phi} = \\ \quad -\left(2m+\frac{33}{70}m_c\right)u\dot{u}\dot{\phi} + sgn\left(\phi\right)\left(2m+\frac{3}{4}m_c\right)b\dot{u}\dot{\phi} \\ \quad +\ddot{u}_g\left[\begin{array}{l}-sgn\left(\phi\right)\left(m+m_b+m_c\right)b\sin\phi \\ -\left(m+\frac{1}{2}m_c\right)h\cos\phi + \left(m+\frac{3}{8}m_c\right)u\sin\phi\end{array}\right] \\ \quad +g\left[\begin{array}{l}-sgn\left(\phi\right)\left(m+m_b+m_c\right)b\cos\phi \\ +\left(m+\frac{1}{2}m_c\right)h\sin\phi + \left(m+\frac{3}{8}m_c\right)u\cos\phi\end{array}\right] \end{array} \tag{3}$$

whereas when it remains in full contact with the ground, the pertinent equation of motion becomes:

$$\left(m+\frac{33}{140}m_c\right)\ddot{u} = -C\dot{u} - \frac{3EI}{h^3}u - \ddot{u}_g\left(m+\frac{3}{8}m_c\right) \tag{4}$$

where C is the damping coefficient responsible for the energy loss while the structure vibrates, $sgn\left(\phi\right)$ is the signum function of the rocking rotation ϕ and $\ddot{u}_g\left(t\right)$, g denote the ground and the gravitational acceleration, respectively.

Rocking initiates when the overturning moment due to the external forces exceeds the restoring moment of the structural system. Hence, uplift occurs when [25]:

$$\pm h\frac{m+\frac{11}{40}m_c}{m+\frac{33}{140}m_c}\left[\begin{array}{l}C\dot{u}+\frac{3EI}{h^3}u \\ +\ddot{u}_g\left(m+\frac{3}{8}m_c\right)\end{array}\right] \mp \ddot{u}_g\left(m+\frac{1}{2}m_c\right)h - g\left[\begin{array}{l}\left(m+m_b+m_c\right)b \\ \mp\left(m+\frac{3}{8}m_c\right)u\end{array}\right] > 0 \tag{5}$$

where the upper sign denotes clockwise rotations and the lower sign counter-clockwise rotations.

During rocking, the smooth motion of the structure is interrupted by nonsmooth events (i.e. impacts) when $\phi = 0$ and kinetic energy is lost. Following [28, 29], this study assumes totally inelastic impacts, where the rocking oscillator remains in full contact with the ground after each impact and uplifts when the condition of Eq. (5) is met. Under these assumptions, the sole post-impact unknown is the flexural velocity $\dot{u}^+$. Conservation of angular momentum gives [25]:

$$\dot{u}^+ = \dot{u}^- + \frac{I_{m_b} - m_b b^2 + m_c\left(-b^2 + \frac{1}{3}h^2 + \frac{33}{140}u^2\right) + m\left(-b^2 + h^2 + u^2\right)}{\left(m + \frac{11}{40}m_c\right)h}\dot{\phi}^- \tag{6}$$

where $\dot{u}^-$ and $\dot{\phi}^-$ denote the pre-impact flexural and angular velocity, respectively.

3 RESILIENCE-BASED EARTHQUAKE ENGINEERING ASSESSMENT OF THE EXAMINED ROCKING BRIDGE FRAMES

To evaluate the seismic performance of a structural system, the Pacific Earthquake Engineering Research (PEER) Center proposed the *performance-based earthquake engineering* (PBEE) framework [30, 31]. The PBEE analysis allows for a quantitative assessement of the seismic performance of a structural system in terms of engineering parameters, such as the expected seismic loss accumulated in the aftermath of an earthquake. The PBEE framework encompasses four steps: hazard analysis, structural analysis, damage analysis and loss analysis. The

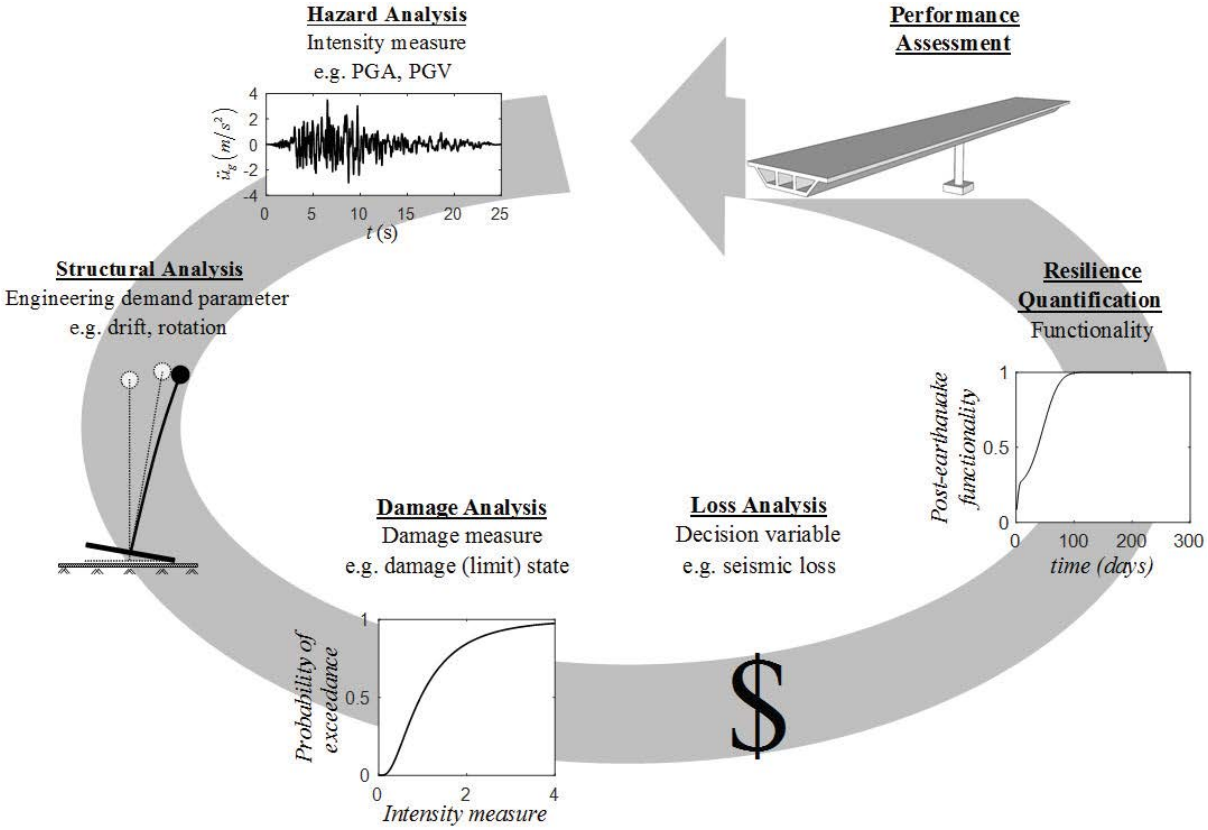

Figure 2: Resilience-based earthquake engineering framework

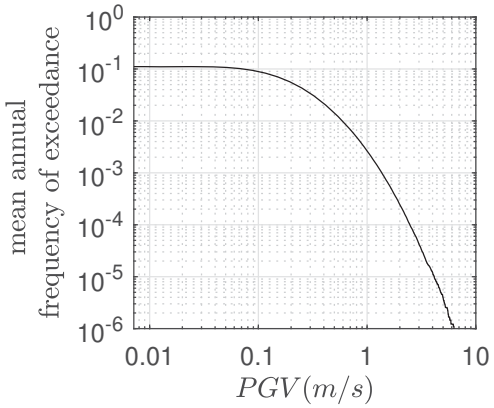

Figure 3: Hazard curve (in logarithmic scale) for the area of focus after conducting the probabilistic seismic hazard analysis

PBEE framework, though, does not incorporate the post-earthquake functionality and resilience of the structure, which are also important indicators of its seismic performance. On the other hand, the *resilience-based earthquake engineering* (RBEE) framework of Fig. 2 focuses on mitigating the earthquake-induced risks to enable rapid recovery of the structure in the aftermath of severe earthquakes [32]. Therefore, the RBEE appears to be a more holistic approach and it is considered as an extension of the PBEE in the design process (Fig. 2).

3.1 Hazard Analysis

To perform the probabilistic seismic hazard analysis (PSHA), this section assumes that the examined rocking bridge frames are located in California laying on a strike-slip fault. The minimum and maximum moment magnitudes M_w are taken as 5.5 and 8, respectively, while the shear wave velocity is $V_{s,30} = 480$ m/s. The Joyner-Boore distance is $R_{JB} = 5$ km. The intensity measure (IM) considered herein is the peak ground velocity (PGV) as it was shown to be the most critical for overturning various rocking configurations [33, 34]. To connect the earthquake events that are likely to appear in the examined area (i.e. California) with their annual frequency of exceedance, the Gutenberg-Richter recurrence law is adopted [35, 36]:

$$\log_{10}\lambda_M = 3.94 - 0.89 \cdot M \tag{7}$$

where λ_M is the frequency of the earthquakes with magnitudes greater than M. Fig. 3 plots the hazard curve (in logarithmic scale) that provides the mean annual frequency of exceedance λ_M of every earthquake that is likely to occur in the area of focus.

3.2 Structural Analysis

This section investigates the seismic response of two single-column rocking bridge frames (Fig. 1). Each frame is part of a two-span (box-girder) bridge of total length L = 60 m and width W = 10 m. Assume the lumped mass m is located at height h = 8 m, while the total mass of the column and of the base is $m_c = 0.25m$ and $m_b = 0.15m$, respectively. The two rocking bridge frames have different slenderness α and subsequently different base-width $2b$, while they have the same height h. Consider one rocking frame with base-width $2b$ = 3 m and slenderness $\alpha = 0.18$ rad $= \pi/17$ (i.e. $\alpha < \pi/15$ [37]), and another with base-width $2b$ = 4.6 m and slenderness $\alpha = 0.28$ rad $= \pi/11$ (i.e. $\pi/15 < \alpha < \pi/10$ [37]). Both structural

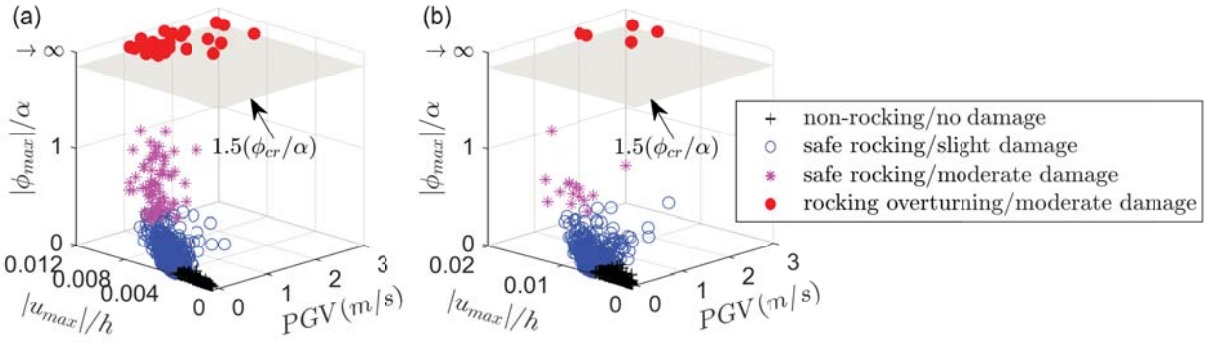

Figure 4: Seismic response analysis of a rocking bridge frame with slenderness (a) α = 0.18 rad and (b) α = 0.28 rad (Fig. 1)

configurations have identical natural frequency $\omega_n = 8p$, where $p = \sqrt{g/R_m} \simeq 1.1$ rad/sec is the frequency parameter of both rocking oscillators, and R_m is the diagonal distance of the lumped mass from the pivot points (Fig. 1). In addition, the analysis assumes a constant damping ratio $\zeta = 5\%$ when the examined rocking bridge frames exhibit rocking motion and a reduced damping ratio when they remain in full contact with the ground (see e.g. [27] for further details).

To perform the structural analysis, appropriate engineering demand parameters (EDPs) which describe the motion of the two examined structural systems need first to be defined. This work adopts as EDPs: (i) the absolute maximum flexural deformation $|u_{max}|$ normalized with respect to the height h; and (ii) the absolute peak rocking rotation $|\phi_{\max}|$ normalized with respect to the slenderness α (Fig. 1).

$$EDP_1 = \frac{|u_{\max}|}{h}, \qquad EDP_2 = \frac{|\phi_{\max}|}{\alpha} \tag{8}$$

For consistency, each rocking bridge frame is subjected to a series of strong ground motions adopted from the Pacific Earthquake Engineering Research (PEER) Center [38]. The adopted ground motions consist of two horizontal components and one vertical. Both horizontal components are used separately, while the vertical component is ignored. To induce higher levels of demand, a scale factor of 1, 1.25 and 1.5 is, respectively, assigned to the accelerograms of the adopted database. Therefore, 960 response-history analyses are conducted for each of the examined structural systems.

Fig. 4 illustrates the structural response of both rocking bridge frames with respect to the adopted IM. Fig. 4 reveals that increasing the slenderness of the structure considerably mitigates the rocking response $|\phi_{\max}|/\alpha$. However, note that, increase of the slenderness leads also to an increase of the structural deformation $|u_{max}|/h$ and, subsequently, potentially higher levels of damage. In addition, Fig. 4 shows that when the rotation $|\phi_{\max}|/\alpha$ exceeds 1.5 times the critical rotation ϕ_{cr}/α [27], the structure becomes dynamically unstable and overturns.

3.3 Damage Analysis

The seismic response of the rocking bridge frame of Fig. 1 is related to the damage occurred at the structure through appropriate damage measures. This work assumes that damage is occurred only at the column of the structure due to seismic forces [39]; all other kinds of damage are ignored. When excessive damage occurs, the structure collapses and subsequently

Damage limit state	Capacity limit	Response mode	Damage description
LS1	$\frac{\lvert u_{\max}\rvert}{h} = \frac{u_{cr}}{h}$	Rocking initiation	*Slight* concrete cracking and spalling at the column. Onset of yielding of the reinforcing bars. Column in operational condition (damage requires no more than cosmetic repair)
LS2	$\frac{\lvert \phi_{\max}\rvert}{\alpha} = 0.35$	Safe rocking	*Moderate* concrete cracking and spalling at the column. Damage to the exposed reinforcing bars. Minimal residual displacements. Column is still operational. Damage at the pivot points and the abutments due to rocking motion (column is structurally sound, damage is repairable)
LS3	$\frac{\lvert \phi_{\max}\rvert}{\alpha} = 1.5\left(\frac{\phi_{cr}}{\alpha}\right)$	Rocking overturning	*Moderate* concrete cracking and spalling at the column. Damage to the exposed reinforcing bars. Minimal residual displacements. Column is still operational. Damage at the pivot points and the abutments due to rocking motion (column is structurally sound, damage is repairable, the column-base system can be reused after the applied repair methods, the whole bridge needs to be reconstructed)

Table 1: Damage limit states of the rocking bridge frame of Fig. 1 [25].

the bridge needs to be reconstructed. In addition, when excessive rocking rotation occurs, the rocking bridge might overturn, thus, reconstruction of the the bridge is again required. To define the levels of the expected damage accumulated at the examined rocking bridge frames, this work adopts the pertinent damage limits states proposed in Giouvanidis and Dong [25]. Table 1 illustrates the adopted damage limit states, where u_{cr}/h is the critical deformation of the column when rocking initiates (i.e. when the condition of Eq. (5) is met).

This section employs the fragility function fitting method [40] to calculate the probability of the examined structures to exceed the certain limit values that correspond to each damage limit state. The fitting methodology to calculate the probability of exceedance can be estimated following the *maximum likelihood estimation* (MLE) approach [40]. In general, the MLE method calculates the fragility function parameters for which the assumed lognormal distribution attains the highest likelihood of producing the observed data. Fig. 5 plots the fragility curves for both rocking bridge frames (i.e. with slenderness $\alpha = 0.18$ rad and $\alpha = 0.28$ rad respectively). Note from Fig. 5 that, indeed, increase of the slenderness of the structure considerably decreases its probability of exceeding the certain damage limit states of Table 1.

3.4 Loss Analysis

The structural damage of the rocking bridge frames accumulated in the aftermath of a seismic event, investigated in Section 3.3, is related to the seismic loss through decision variables, e.g. the seismic (repair) loss. The seismic loss is defined as the sum of the seismic consequences

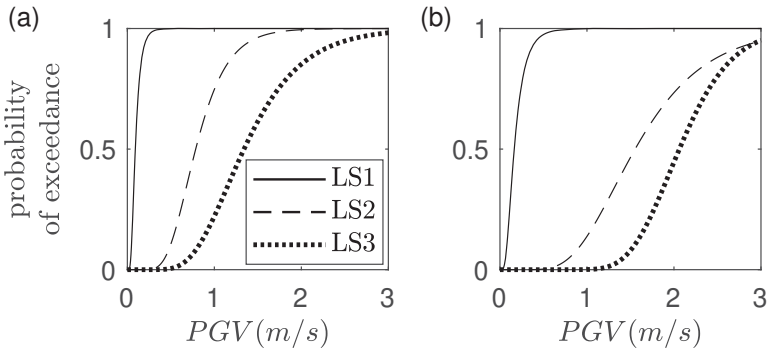

Figure 5: Fragility curves of a rocking bridge frame with slenderness (a) α = 0.18 rad, (b) α = 0.28 rad (Fig. 1) with respect to the adopted intensity measure

(e.g. damage and subsequently repair cost) weighted with their probability of occurrence. The expected seismic loss under the given IM can be expressed as [41]:

$$E\left(l\right) = \sum_{i=1}^{n} C_i \cdot P_{LSi|IM} \tag{9}$$

where C_i represents the seismic consequences, e.g. the repair costs associated with the given damage limit state i, and $P_{LSi|IM}$ is the conditional probability of the structure to be at the given damage limit state. The consequences of a seismic event C_i are quantified in monetary values and expressed as the summation of the direct and indirect costs accumulated after an earthquake event. This work considers only the direct costs, which are associated with the reconstruction expenses and are directly related to the level of structural damage. Therefore, the seismic consequence C_i associated with a given damage limit state is assumed proportional to the reconstruction cost of the rocking bridge [42, 43, 41]:

$$C_i = RCR_i \cdot c_{rec} \cdot W \cdot L \tag{10}$$

where W and L are the bridge width and length respectively. c_{rec} is the reconstruction cost (per square meter), which is translated into 2,306 $\$/m^2$ in present monetary values [44]. RCR_i is the repair cost ratio that corresponds to each damage limit state. The repair cost ratios are expressed as a percentage of the reconstruction cost of the bridge, and they differ from damage limit state to damage limit state; the more severe the damage, the larger the repair cost ratio. Table 2 presents the pertinent repair cost ratio values for each damage limit state of the rocking bridge frame of Fig. 1 [45, 25].

To assess the expected seismic losses of the examined rocking structures, this study considers nine different seismic hazard scenarios. These scenarios correspond to seismic events with T_R = 40, 72, 125, 225, 475, 975, 1,485, 2,475 and 4,975-year return period, which translate into a probability of 71%, 50%, 33%, 20%, 10%, 5%, 3%, 2% and 1%, respectively, that at least one such event will occur in the next 50 years in the area of focus. The hazard curve of Fig. 3 provides the intensities in terms of PGV values that correspond to the adopted seismic hazard scenarios, i.e. 0.37, 0.51, 0.65, 0.83, 1.08, 1.36, 1.53, 1.76 and 2.11 m/s, respectively.

Fig. 6 presents a comparison of the two rocking bridge structures in terms of the expected seismic loss accumulated after the considered seismic hazard scenarios normalized with respect to their construction cost. Note that, even though the two rocking structures have slightly different geometry (i.e. due to the different base-width $2b$), for simplicity, this work assumes that

Damage limit state	Repair cost ratio [45]	Repair methods description	Downtime (days) [45, 46]	
			Mean	Standard deviation
LS1	0.03	Repair slight concrete cracking/spalling at the column (epoxy injection, patch with concrete, etc.)	0.6	0.6
LS2	0.08	Repair moderate concrete cracking/spalling at the column, repair damaged reiforcing bars (patch with concrete, reinforce and recast, etc.). Repair damage at the pivot points and the abutments	2.5	2.7
LS3	1	Repair moderate concrete cracking/spalling at the column, repair damaged reiforcing bars (patch with concrete, reinforce and recast, etc.). Repair damage at the pivot points and the abutments. Reuse the column-base system after the applied repair methods. Reconstruction of the whole bridge	46	22

Table 2: Repair cost ratio and downtime values for each damage limit state of the rocking bridge frame of Fig. 1 [25].

they have the same construction cost (i.e. 2,306 $\$/m^2$ [44]). Fig. 6 unveils that even a slight modification of the slenderness of the rocking frame can lead to a drastic decrease of the seismic losses. Note that, even under a severe seismic event (i.e. with $T_R = 4{,}975$-year return period and 1% probability of occurrence in the next 50 years), the rocking bridge with larger slenderness yields seismic losses equivalent to 50% of the construction cost of the bridge; a considerable post-earthquake financial benefit. For all the remaining seismic hazard scenarios examined herein, the pertinent seismic losses are less than 25% of the construction cost of the bridge. A further decrease on the expected seismic losses can be achieved by enhancing further its seismic performance, thus, decreasing its seismic fragility (Fig. 5), via the use of e.g. additional re-centering and/or energy dissipation capacity; increasing in that way, though, its construction cost. However, such an analysis is beyond the scope of the present study.

3.5 Resilience quantification

Resilience, as a performance indicator, quantifies the recovery (or restoration) functions of a structural system following a seismic event. In general, after an earthquake, repair methods are applied to the damaged structure and its functionality starts enhancing. The expected (dimensionless) time-variant functionality $Q(t)$ can be expressed as [47]:

$$Q(t) = \sum_{i=1}^{n} FR_i(t) \cdot P_{LSi|IM} \tag{11}$$

where $P_{LSi|IM}$ is the conditional probability of the structure to be at the given damage limit state, and $FR_i(t)$ denotes the functionality restoration process of the structure for each damage limit state. This study models the functionality restoration process of the examined rocking

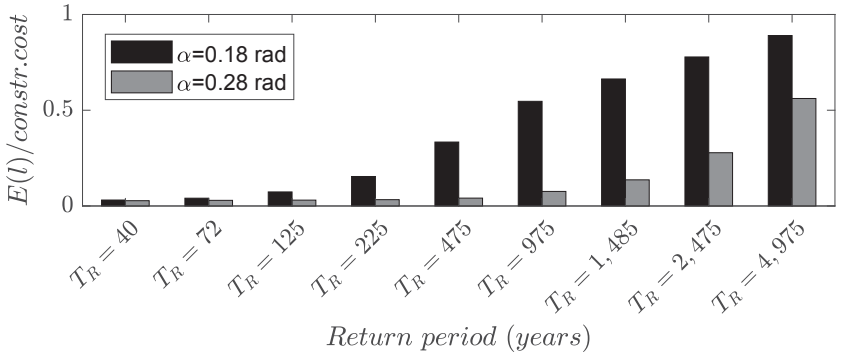

Figure 6: Expected seismic loss normalized with respect to the construction cost of the examined rocking bridges in the aftermath of various seismic hazard scenarios

structures as a normal cumulative distribution function corresponding to each damage limit state i [48, 45]:

$$FR_i(t) = \frac{1}{2}\left[1 + erf\left(\frac{t-\mu_{d_i}}{\sqrt{2}\sigma_{d_i}}\right)\right] \tag{12}$$

where μ_{d_i} and σ_{d_i} represent the mean and standard deviation, respectively, of the time during which the bridge is under restoration (i.e. downtime). HAZUS [45] proposed appropriate mean and standard deviation values of downtime (in days) for conventionally designed (fixed-base) bridges. To estimate the downtime values for rocking bridges, Mantawy et al. [46] experimentally compared the seismic performance of a rocking versus a conventionally designed (fixed-base) bridge. That study showed that the construction time of the rocking bridge is (on average) 5 times lower than the construction time of the fixed-base bridge. In other words, the downtime of the rocking structure is considered as 1/5 of the downtime of the fixed-base structure. Following [46], Table 2 presents the pertinent mean and standard deviation values of downtime for the rocking structures of Fig. 1 [25]. The resilience of the rocking structure of Fig. 1 under the investigated time-interval (i.e. Δt = 365 days) can be expressed as [49]:

$$R = \frac{1}{\Delta t}\int_{t_0}^{t_0+\Delta t} Q(t)\,dt \tag{13}$$

where t_0 indicates the time-instant the seismic event occurs.

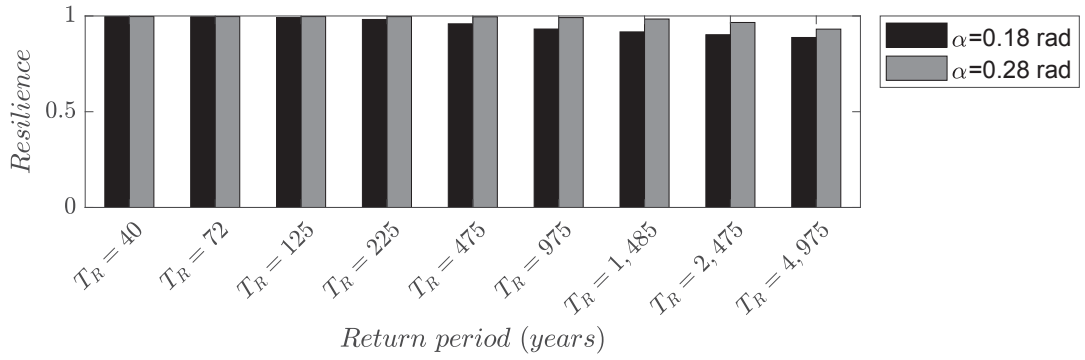

Figure 7: Resilience of the examined rocking bridges when subjected to different seismic hazard scenarios under the investigated time-interval of Δt = 365 days

Fig. 7 quantifies the resilience of the examined rocking bridge structures; the closer to unity the more resilient the structure. Specifically, Fig. 7 illustrates that both rocking bridges show remarkable resilience in the aftermath of severe earthquake events under the investigated time-interval Δt. However, the rocking bridge with larger slenderness exhibits (slightly) enhanced resilience after all the examined seismic hazard scenarios. Note that, its resilience starts deteriorating only when a maximum considered earthquake occurs (i.e. with $T_R = 2{,}475$-year return period and 2% probability of occurrence in the next 50 years). In sum, Figs 6, 7 reveal the remarkable post-earthquake financial benefits (i.e. decreased seismic losses and increased resilience) that a rocking bridge offers when carefully designed.

4 CONCLUSIONS

This work investigates the seismic performance of two rocking bridge frames, which are particularly attractive for bridge design. For the purposes of the present analysis, this work extends the well-established performance-based earthquake engineering (PBEE) framework to compare the two rocking structures in terms of their seismic fragility and the accumulated seismic losses in the aftermath of extreme hazard scenarios. In addition, it extends the PBEE approach to quantify their post-earthquake resilience adopting a more holistic resilience-based earthquake engineering framework.

The analysis reveals the considerably mitigated seismic losses that a rocking bridge offers when carefully designed. In particular, this study shows that a slight modification of the slenderness of the structure can lead to a drastic decrease of its post-earthquake financial losses. Further, results show that even under an extreme seismic hazard event, i.e. with 1% probability of occurrence in the next 50 years and $T_R = 4{,}975$-year return period, the rocking bridge frame with larger slenderness yields financial losses equivalent to 50% of the construction cost of the bridge; a considerable post-earthquake financial benefit. Importantly, this paper also unveils the remarkable post-earthquake resilience of the examined rocking bridge structures. Specifically, modifying the slenderness of a rocking bridge enhances its resilience against various seismic hazard scenarios. Importantly, when a rocking bridge is carefully designed, it sustains its resilience at the highest level till a maximum considered earthquake occurs (i.e. with $T_R = 2{,}475$-year return period and 2% probability of occurrence in the next 50 years). The above findings redirect our attention to the considerable post-earthquake financial benefits of rocking isolation, which can serve as an efficient seismic isolation technique for future bridge engineering applications.

Abstract. *Seismic performance of structural systems is assessed by performing fragility analysis. Generally, downstream of this analysis, fragility curves are estimated in order to obtain the structural system performance. Seismic fragilities are the probability that the structural response of a system overcomes specified limit states for given seismic intensity measure. The most widespread procedure to estimate seismic fragility curves is based on scaling seismic accelerograms by a reference intensity measure (e.g. single/multiple ordinates of the pseudo-acceleration response spectrum or peak ground acceleration). Recently, it was shown that this methodology gives limited if any information on the structural seismic performance when the dependence between the intensity measure and the system demand parameter of interest (e.g. max inter-story displacement) is weak. This paper presents a general algorithm to improve the accuracy in fragilities estimation when the dependence between the intensity measure and the demand parameter is weak and the widely used method in Performance-Based Earthquake Engineering does not give accurate results. The proposed algorithm is based on a linear transformation of samples of a given intensity measure, which improves the correlation with a set of demand parameters. Fragility curves are obtained using the transformed intensity measure samples and compared with those estimated with the standard approach. The effectiveness of the proposed algorithm is demonstrated for an actual multi-degree of freedom structural system.*

1 INTRODUCTION

Seismic fragilities are the probability that the structural response of a system overcomes specified limit states for given seismic intensity measure (IMs). Performance-Based Earthquake Engineering (PBEE) ambition is to evaluate structural efficiency by fragility analysis. The Federal Emergency Management Agency (FEMA) recommends to estimate the seismic fragility curve by an approach based on scaling the seismic accelerograms with a reference intensity measure IM [1]. This method is widely applied because it is simple and, together with Monte Carlo simulation, it overcomes the problem of the limited number of natural recorded ground motions available for fragility analysis.

Two groups of IMs are usually used to define the seismic fragilities: (i) functional of samples of seismic ground acceleration process $A(t)$, such as peak ground acceleration (PGA); (ii) functional of filtered version of samples of $A(t)$, e.g. single/multiple ordinates of pseudo-acceleration response spectrum $S_a(T)$ for different structural system periods T [2, 3, 4]. In particular, the IMs in the second group, that are widely used to define the fragilities, depend on the system demand parameter D (e.g. max inter-story displacement) on which the analysis is based [5, 6, 7, 8].

The usefulness of this procedures [1] based on scaled seismic ground motion acceleration is indisputable, but it was shown that this methodology gives limited if any information on the structural seismic performance when the dependence between the IM and D is weak [9]. Moreover, the dependence between these two variables (i.e. IM and D) depends on the seismic direction, the intensity measure and the demand parameter considered [10, 11]. In particular, assumed an IM, the dependence can vary significantly with different seismic directions. For example, the fragilities defined as function of $S_a(T)$ for nonlinear single degree of freedom (SDOF) system to a seismic acceleration process $A(t)$ have large uncertainties when D and $S_a(T)$ are weakly correlated. Furthermore, the fragilities defined as function of multiple ordinates of $S_a(T)$ experience poor improvements if compared to the case of single ordinate of $S_a(T)$. It was demonstrated that the dependence between IMs and various system demand parameters, D, is weak for nonlinear system and also for complex multi-degree of freedom (MDOF) linear structures [9, 10, 11]. This issue can be avoided by defining the fragilities as functions of parameters of the law of $A(t)$. This approach was first introduced in [12] and used in [13, 14, 15] to estimate fragility surfaces. However, this approach requires a high computational cost.

This paper presents a general approach to improve the accuracy in fragilities estimation when the dependence between the intensity measure IM and the demand parameter D is weak and the widely used method in Performance-Based Earthquake Engineering [1] does not give accurate results. This general method is based on a modified version of the current intensity measure approach. In particular, once an IM is chosen it is mapped in a suitable space where D and the IM are correlated. The proposed algorithm is based on a linear transformation of samples of a given IM, which improves the correlation with a set of demand parameters. Fragility curves are obtained using the transformed IM samples and compared with those estimated with the standard approach. An actual multi-degree of freedom structural system, a school building in Norcia, Italy, is considered as case study.

Finally, the effectiveness of the proposed approach is demonstrated by comparing the fragility estimates obtained with a chosen seismic intensity measure and the its modified version.

2 BACKGROUND

Let I be the set of demand parameters which yield a structural failure. The fragility can be defined as

$$\begin{aligned} P_f(\xi) &= P(D \in I \subset \mathbb{R} | IM = \xi) \\ &= E[1(D \in I | IM = \xi)] = \int_I f_{D|IM}(x|\xi)\, dx \end{aligned} \tag{1}$$

i.e. the probability that a structural system enters a damage state given a ground motion with scalar/vector intensity measure $IM = \xi$, where $1(\cdot)$ and $f_{D|IM}(\cdot|\xi)$ are the indicator function and probability density function (PDF) of the conditional variable $D|(IM = \xi)$, respectively. The fragility in (1) is usually estimated from the structural response to scaled seismic time histories, $a(t)$ of the stochastic process $A(t)$ [16], and its accuracy depends on the scaling procedure, the sample size and the IMs properties.

When D and IM are strongly dependent, the random variable $D|IM$ has small variance, i.e. $f_{D|IM}(\cdot|\xi)$ is concentrated about its mean value. On the contrary, when D and IM are weakly dependent the random variable $D|IM$ has large variance. In the limit, $f_{D|IM}(\cdot|\xi)$ becomes a δ-function or D and $D|IM$ have the same PDF when D and $D|IM$ are perfectly correlated or independent, respectively [9]. In the latter case, the fragility in (1) does not depend on ξ. Within this context, especially if (1) is estimated by the commonly used method [1], it is crucial to quantify the dependence between the demand parameter D and various IM definitions to implicitly determine whether or not fragilities, defined as function of the commonly used IMs, can provide useful information for PBEE of actual complex multi-degree of freedom (MDOF) linear and nonlinear structural systems. If the dependence between D and IM is strong, the fragility $P_f(\xi)$ gives accurate information [10, 11]. The opposite holds when the dependence between D and IM is weak. Several statistical tools can be used to investigate the dependence between the random variables D and IM, which includes correlation coefficients, copula models and multivariate extreme value theory [9]. In this work the correlation coefficient is used to quantify the dependence between D and IM.

The IMs used in PBEE to scale seismic acceleration ground motion are divided into three broad categories: (i) non-structures-specific scalar IMs; (ii) structures-specific scalar IMs; (iii) vector-valued IMs. A complete classification of the most known IMs in literature is reported in [6]. In this work, two version of IMs are considered to estimate the fragilities

$$IM_1 = PGA \tag{2}$$

$$IM_2 = S_a(T_1, \zeta_1) \tag{3}$$

where T_1 is the first period of the MDOF structural system with associated damping ratios ζ_1. It is worth noting that the two IMs in Equations (2) and (3) are the most widely used in literature [6].

3 THE MODIFIED INTENSITY MEASURE (IM^*)

Let $X(t)$ be the response vector-valued process of an arbitrary MDOF structural system to the ground acceleration $A(t)$. The demand parameter is defined as

$$D^{(j)} = \max_{0 \le t \le \tau} |h(X(t))|, \quad j = 1, \ldots, m \tag{4}$$

where τ is the time length of $A(t)$, while $h(\cdot)$ is a function mapping the response $X(t)$ into the j-th system demand parameter (e.g. maximum displacement/acceleration) and m is the number of demand parameters of interest. The dependence between the random variables $D^{(j)}$, $j = 1, \dots, m$, and IM is a measure to quantify the accuracy in the estimation of $P_f(\xi)$ [11]. When this dependence is weak the widely used method in PBEE [1] does not give accurate results. To overcome this issue it is proposed to replace samples of a chosen standard intensity measure IM with a suitable linear transformation that modifies the dependence with the selected demand parameters samples. In particular, for each n_s samples, $a_i(t)$, $i = 1, \dots, n_s$, of the random process $A(t)$ the corrisponding IM and $D^{(j)}$ are evaluated, i.e. im_i and $d_i^{(j)}$, $i = 1, \dots, n_s$. For each of these samples, the z-scores $z(d_i^{(j)})$ and $z(im_i)$, $i = 1, \dots, n_s$, of the standardized random variables

$$z(D^{(j)}) = \frac{D^{(j)} - E[D^{(j)}]}{\sigma(D^{(j)})}\,, \quad j = 1, \dots, m \tag{5}$$

$$z(IM) = \frac{IM - E[IM]}{\sigma(IM)} \tag{6}$$

are computed, respectively. It is worth noting that if the random variables defined in Equations (5) and (6) are linearly dependent, the correlation coefficient is equal to one and the scatter plots of pairs of samples $z(d_i^{(j)})$ and $z(im_i)$ describe straight line. Given the demand parameter $D^{(j)}$, for each pair of samples $z(d_i^{(j)})$ and $z(im_i)$ it is possible to evaluate the distance from perfect correlation

$$e_i^{(j)} = |z(d_i^{(j)}) - z(im_i)|\,, \quad i = 1, \dots, n_s, \quad j = 1, \dots, m \tag{7}$$

and estimate the average distance of the j demand parameters

$$\bar{e}_i = \frac{1}{m} \sum_{j=1}^{m} e_i^{(j)}\,, \quad i = 1, \dots, n_s\,. \tag{8}$$

The samples obtained with Equation (8) can be considered as realizations of a random variable $\bar{E}$. The linear transformation

$$im_i^* = [z(im_i) + \bar{e}_i]\sigma(IM) + E[IM]\,, \quad i = 1, \dots, n_s \tag{9}$$

gives samples that can be considered the realizations of a new intensity measure IM^*.

The procedure reported above describes a general algorithm that can be used to transform any intensity measure IM (e.g. Eqs (2) and (3)) into samples of its modified version, IM^*. It is worth noting that for $m = 1$ (i.e. one demand parameter), the correlation estimated from the n_s samples of D and IM^* is exactly one. When $m > 1$ it is not possible to have perfect correlation, but the correlation between $D^{(j)}$ and IM^* is significantly higher than the one estimated from samples of $D^{(j)}$ and IM.

It follows that the IM^* samples obtained with Equation (9) can be used to scale the ground acceleration records to build fragility curves that give more accurate information on the structural system performance when compared with the standard intensity measures.

4 CASE STUDY

The procedure described in the previous Section is used to build fragility curves of a structural system of a school in Norcia (Italy) that was affected by the 2016 earthquake sequence.

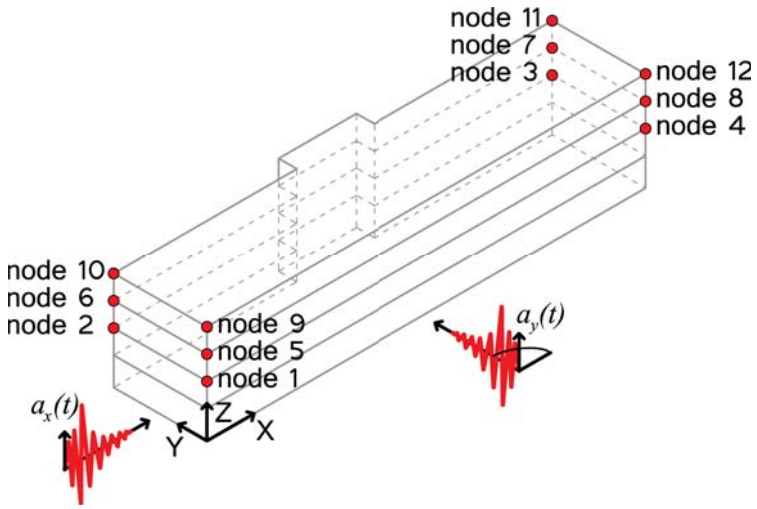

Figure 1: Seismic directions used in the analyses and reference node locations.

The structural system consists of a reinforced concrete frame (RCF) on four floors with a dissipative bracing system, made of Buckling-Restrained Axial Dampers (BRAD), and inverse beams foundation. The RCF and foundation are modeled with classical beam elements, while the BRAD elements are modeled with the constitutive law described in [17]. The obtained numerical model details on the school building and the model modal parameters are reported in [10].

Linear analyses are performed to evaluate the structural response. In this work the maximum absolute inter-story displacement in the y-direction D_{dy} (Fig. 1) is considered as demand parameter in the fragility analysis. It is well known that the maximum inter-story drift is correlated with different damage states [18] and, in general, it gives information for the performance-based seismic assessment.

The strong event recorded in Norcia on October 30th, 2016 is used to calibrate the stochastic non-stationary process $\boldsymbol{A}(t)$. Structural analyses are developed for each samples of the process $\boldsymbol{A}(t) = \{A_x(t); A_y(t)\}$, i.e. $\boldsymbol{A}(t)$ is a two-varied stochastic process, that acts in x and y global-directions of the finite element numerical model (FEM) (Figure 1). The non-stationary model described in [19, 20] is used to generate samples $a_x(t)$ and $a_y(t)$ of $A_x(t)$ and $A_y(t)$, respectively. The probabilistic model used for $\boldsymbol{A}(t)$ is calibrated with actual time histories recorded at the school base during the October 30th, 2016 earthquake.

The demand parameter D_{dy} is obtained by a three-step Monte Carlo algorithm: (i) n_s ground motion acceleration time series $a_n(t)$ of the process $A_n(t)$, $n = x, y$, are generated using the method proposed in [19]; (ii) linear time domain numerical dynamic structural analyses are used to obtain response samples $\boldsymbol{x}(t)$ of $\boldsymbol{X}(t)$ assuming proportional damping ratio $\zeta = 5\%$; (iii) n_s samples of the random vector $D_{dy} = \{D_y^{(1)}, D_y^{(2)}, \ldots, D_y^{(m)}\}$ are computed using Equation (4). In this case study the interstorey drifts in y-direction at the $m = 12$ node positions shown in Figure 1 are selected as demand parameters.

4.1 Improving dependence between D and IM

In this section, first scatter plots and the correlation between the random variables $D_y^{(j)}$ and the two IMs in Equations (2) and (3) are investigated. Second the dependence is improved

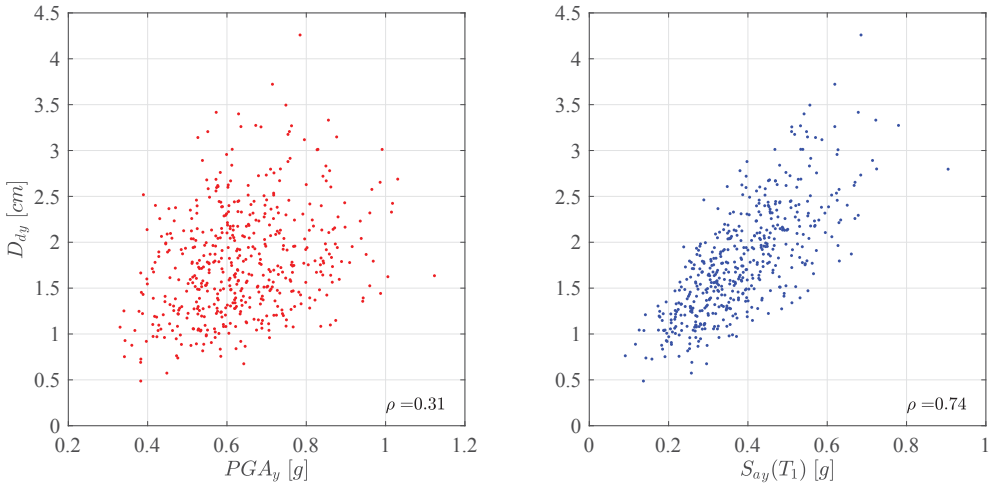

Figure 2: Scatter plots of $n_s = 500$ samples of (PGA_y, D_{dy}) and $(S_{ay}(T_1), D_{dy})$ at node #12.

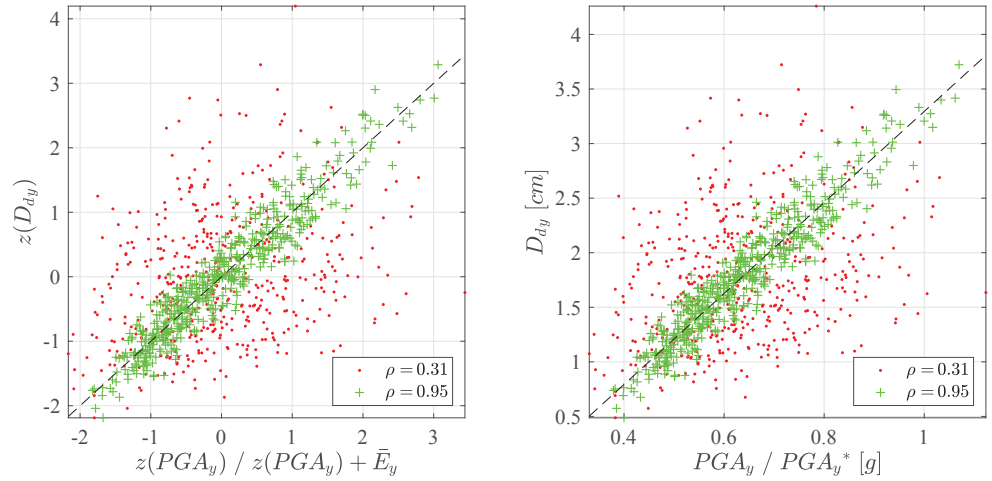

Figure 3: Scatter plots of $n_s = 500$ samples at node #12: $(z(PGA_y), z(D_{dy}))$ red dots, $(z(PGA_y)+\bar{E}_y, z(D_{dy}))$ green crosses (left panel); (PGA_y, D_{dy}) red dots, $(PGA_y{}^*, D_{dy})$ green crosses (right panel).

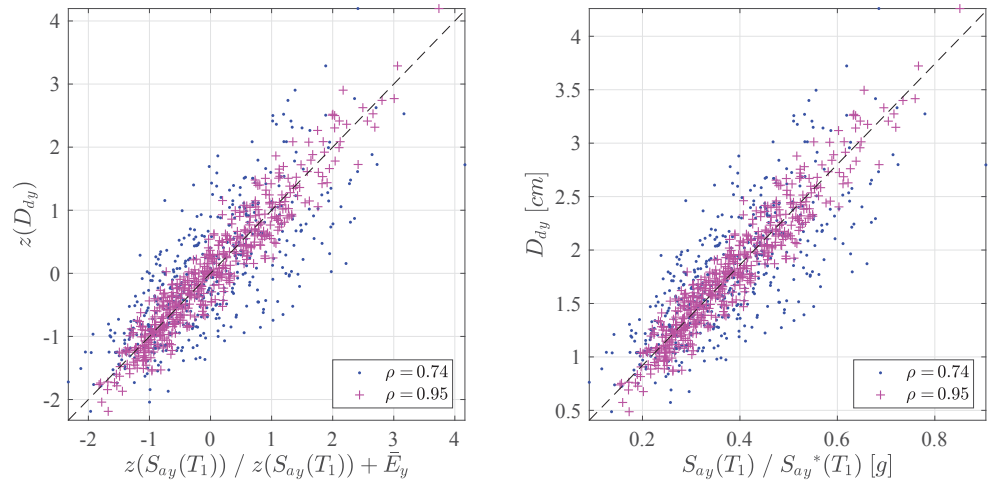

Figure 4: Scatter plots of $n_s = 500$ samples at node #12: $(z(S_{ay}(T_1)), z(D_{dy}))$ blue dots, $(z(S_{ay}(T_1)) + \bar{E}_y, z(D_{dy}))$ magenta crosses (left panel); $(S_{ay}(T_1), D_{dy})$ blue dots, $(S_{ay}{}^*(T_1), D_{dy})$ magenta crosses (right panel).

with the procedure described in Section 3.

Figure 2 shows scatter plots of $ns = 500$ samples of the seismic drift in y-direction $D_{dy} = D_y^{(j)}$, $j = 12$, (Fig. 1), against the two intensity measures IM_{ly}, $l = 1, 2$ (Eq. (2)-((3)) estimated from samples of $A_y(t)$ from left to right, respectively, together with the estimated correlation coefficient ρ. Damping ratio $\zeta_1 = 5\%$ is assumed for IM_{2y}. The results presented in the left panel of Figure 2 demonstrate that the peak ground acceleration in the y-direction, $PGA_y = IM_{1y}$, represents an unsatisfactory intensity measure given the low value of the correlation coefficient, $\rho = 0.31$, between D_{dy} and IM_{1y}. The fragility estimated using this IM would provide poor information on the seismic structural performance. In the present case, the same holds for $IM_{2y} = S_{ay}(T_1)$ since the conditional random variable $D_{dy}|IM_{2y}$ has large variance (i.e. D_{dy} and IM_{2y} are low correlated). In general, when using the intensity measure in Equation (3), it was demonstrated that IM_{2n}, $n = x, y$, can be both strongly and weakly correlated with the demand parameter depending on the selected structural response of interest and the earthquake direction [11].

The initial correlation between the chosen m demand parameters and the IMs described above can be improved using the procedure presented in Section 3. Samples of the demand parameters and the two intensity measures in Figure 2 are first transformed into their standardized versions using Equations (5) and (6) and the distance from perfect correlation is evaluated by Equation (7) for each of the m demand parameters. Then, the n_s average distances are evaluated using Equation (8) and collected in the vector $\bar{E}_y$ that is used to correct the samples of $z(IM_{ly})$, $l = 1, 2$. The last step is to evaluate samples of the modified intensity measure IM^* using Equation (9).

Figures 3 and 4 show the obtained results for the intensity measures $IM_{1y} = PGA_y$ and $IM_{2y} = S_{ay}(T_1)$, respectively. In particular the left panels report the scatter plots and the correlation coefficients before and after the correction in the standardized space, i.e. ($z(IM_{ly})$, $z(D_{dy})$), and ($z(IM_{ly}) + \bar{E}_y$, $z(D_{dy})$), $l = 1, 2$, respectively. The right panels report the scatter plots of the same samples (before and after the correction) linearly transformed back into their original space by Equation (9), i.e. (IM_{ly}, D_{dy}), and ($IM_{ly}{}^*$, D_{dy}), $l = 1, 2$, respectively. In these figures the scatter plots with $IM_{1y} = PGA_y$ are red dots and green crosses, before and after the correction, respectively, while those with $IM_{2y} = S_{ay}(T_1)$ are blue dots (before) and magenta crosses (after).

The two figures demonstrate the ability of the proposed algorithm to improve the correlation between the selected demand parameters and intensity measures. This will result into an improved accuracy in the fragility curves.

Is interesting to note that the linear transformation of the intensity measure samples obtained in this case study does not significantly change the intensity measures first four statistical moments. Figures 5-6 show the probability density functions (PDFs) and the first four statistical moments estimated from samples of the original intensity measures IM_{ly}, $l = 1, 2$ (left panels) and their modified versions $IM_{ly}{}^*$ (right panels). In particular, Figure 5 shows the results for $IM_{1y} = PGA_y$, while Figure 6 refers to $IM_{2y} = S_{ay}(T_1)$.

4.2 Estimation of fragility curves

The seismic fragility analysis, as also recommended by FEMA, is commonly based on a four-steps algorithm consisting of scaling seismic accelerograms by a reference IM. In particular, in this paper the following steps are considered

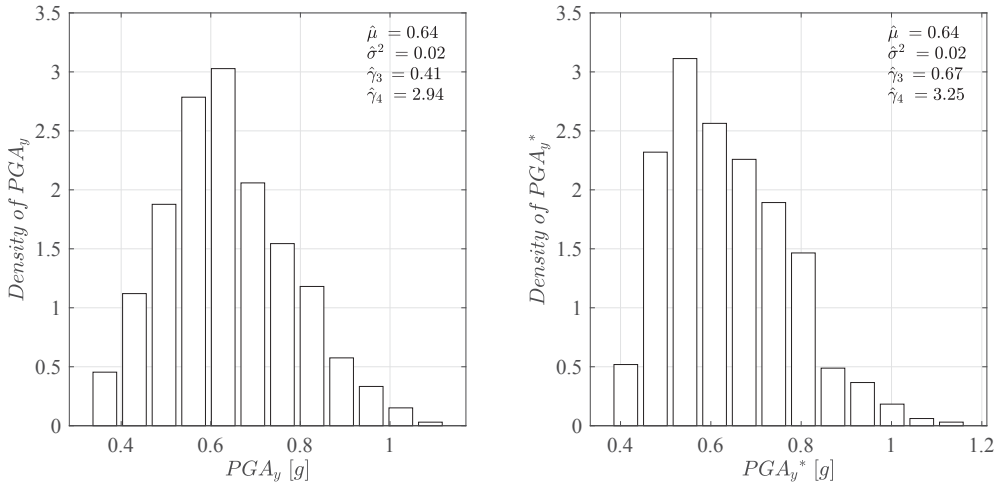

Figure 5: Estimated PDF for $n_s = 500$ samples of PGA_y (left panel) and $PGA_y{}^*$ (right panel).

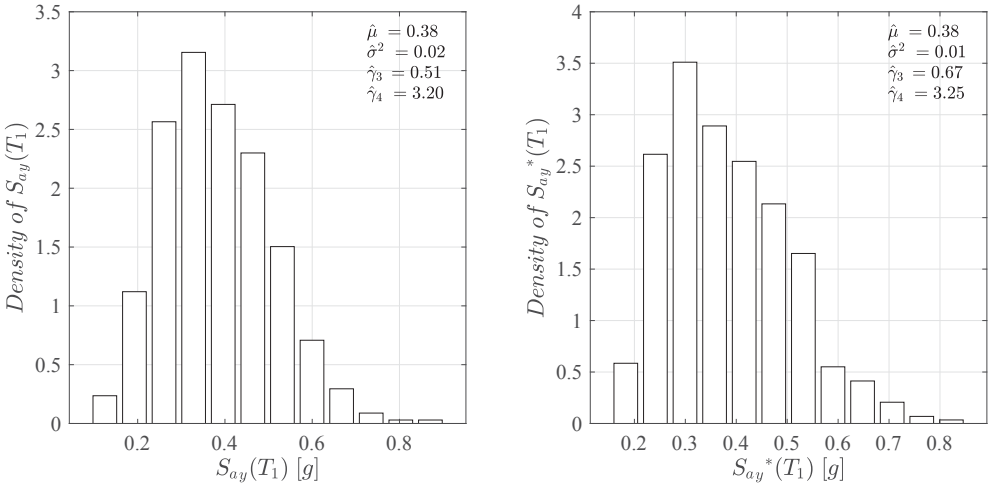

Figure 6: Estimated PDF for $n_s = 500$ samples of $S_{ay}(T_1)$ (left panel) and $S_{ay}{}^*(T_1)$ (right panel).

1. selection of a finite set of intensity measures $\{\xi_k\}$, $k = 1, \ldots, N$;
2. generation of $n_s = 500$ independent samples $a_{n,i}(t)$, $i = 1, \ldots, n_s$ of $A_n(t)$, $n = x, y$ using the method reported in [19];
3. for each of the values $\{\xi_k\}$ scale the n_s acceleration records, $a_{n,i}(t)$, in order to have the intensity level $IM_{ly} = \xi_k$, $\xi_k > 0$, $l = 1, 2$;
4. for each of the values $\{\xi_k\}$ estimate fragility as

$$\hat{P}_f(\xi_k) = \sum_{i=1}^{n_s} 1(d_{k,i} \in I)/n_s \tag{10}$$

where $1(\cdot)$ is the indicator function and $d_{k,i}$, $i = 1, \ldots, n_s$, are samples of the demand parameters computed for each intensity level ξ_k by linear dynamic analysis. The previous four-steps

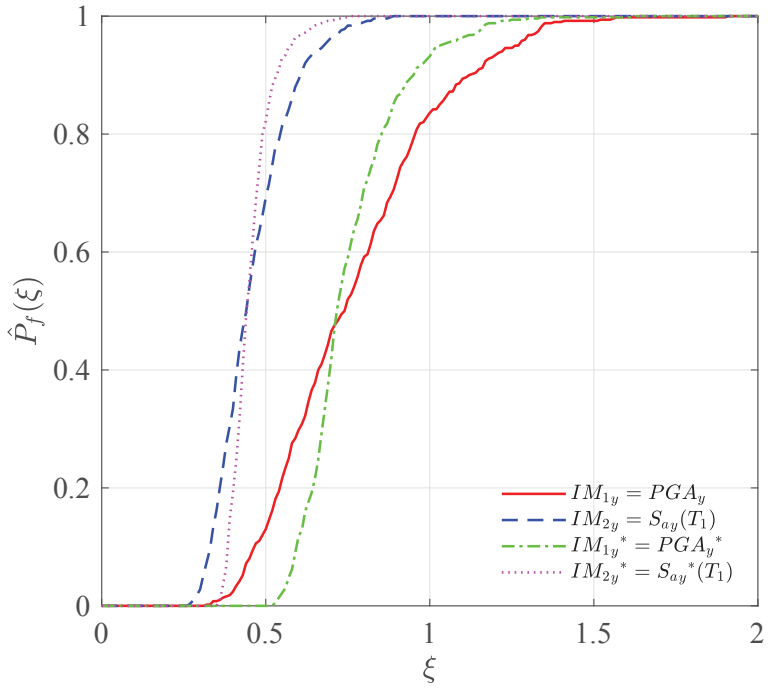

Figure 7: Fragilities against intensity level ξ for different definitions of IMs and its modified version IMs^* at node $\#12$, seismic drifts D_{dy} for limit state $\bar{D}_{d_y} = 2cm$.

algorithm is used to estimate fragility curves using both samples of the original and the transformed intensity measures.

Figure 7 reports the obtained fragility curves of the inter-storey drift at node $\#12$ for limit state $\bar{D}_{d_y} = 2cm$. It is worth noting that the fragility curves obtained with the modified intensity measures (dash-dotted green and dotted magenta lines) are steeper than those estimated using the original intensity measures (continuous red and dashed blue lines). This is consistent with the lower variability (i.e. lower variance) of the conditional random variable $D|IM^*$.

5 CONCLUSION

In Performance-Based Earthquake Engineering the seismic fragilities are commonly estimated by the classical approach based on scaling the seismic accelerograms with a reference intensity measure (IM). For this method, a strong dependence is required between the demand parameter D of the structural system, on which the fragility analysis is based, and the IM used for scaling, in order to have accurate fragility curves. The approach provides limited if any information on the seismic performance of the structural system for weak dependence between D and IM.

The work presented in this paper proposed a general approach to improve the accuracy in fragilities estimation when the dependence between the intensity measure IM and the demand parameter D is weak and the widely used method in Performance-Based Earthquake Engineering does not give accurate results. In particular, samples of any chosen intensity measure IM are linearly transformed in order to improve the correlation with a set of selected demand parameters. The new samples can be considered as realizations of a modified intensity measure IM^* and used to scale the ground acceleration records to build fragility curves that give more

accurate information on the structural system performance when compared with the standard intensity measures.

The effectiveness of the proposed method in improving the fragility curves accuracy was demonstrated on an actual multi-degree of freedom structural system of a school building in Norcia (central Italy). The results demonstrate the effectiveness of the modified seismic intensity measure in fragility analysis. Work is in progress to investigate the accuracy of fragilities based on modified intensity measures in nonlinear structural systems.

Keywords: Pounding, optimal dampers, adjacent buildings, viscous dampers, seismic effects.

Abstract. *Structural pounding is prevalent in general during earthquake shaking for adjacent structures in earthquake prone cities. In this study, the prevention of pounding effect is targeted by the optimal placement of viscous damping elements within the adjacent buildings. One of the important reasons of the pounding phenomenon is the out of phase vibrations of adjacent structures. A couple of adjacent structures which have different heights are modeled as shear buildings to set the proposed method. The relative displacement, defined as the extraction of horizontal displacements of adjacent structures at the top level of the shorter building, are chosen as the objective function to be minimized. In addition, reduction of relative displacement of the buildings and the effects of various vibration characteristics of each building is investigated based on transfer functions. Equations of motion of a structure, which are uncoupled when each structure is considered alone, become coupled when damping elements are placed in between the adjacent structures. The first mode response of the structures is considered while the transfer function response is derived. Optimal designs are determined for different total damping levels and different vibration characteristics of adjacent structures. The results of numerical analyses reveal that optimal designs effectively decrease the relative displacements between adjacent structures. Optimal designs are compared with the uniform design and without damper cases. The numerical analyses show that the proposed optimal damper design method in this study is vigorously effective for the prevention of pounding of adjacent buildings.*

1 INTRODUCTION

In this study, the prevention of pounding effect is targeted by the optimal placement of viscous damping elements within the adjacent buildings. If the viscous damper's (VDs) phase of relative acceleration is the same with the phase of the main structure's velocity, maximum energy dissipation is executed by damping forces. Therefore, VDs manufacture damping forces proportional to damping coefficient and relative velocity between neighboring stories at the same elevation level [1-3]. Analytical models of different impacts have been developed to define the structural response of adjacent structures during an earthquake [4-7]. Stavroulakis and Abdalla [8] derived optimality conditions by minimizing potential energy of adjacent structures. Jeng et al. [9] proposed a method called Spectral Difference Method and Double Difference Combination rule based on random vibration theory. In order to prevent pounding, Lin [10] developed a statistical method of the mean and standard deviation of the separation distance of adjacent buildings based on the random vibration theory. Valles and Reinhorn [11] studied pounding problem based on the radius of pseudo energy. Zhang and Xu [12] calculated optimal values of viscoelastic dampers to reduce the maximum seismic response under random seismic response. Zhu and Xu [13] and Zhu et al.[14] derived analytical formulas to find optimal parameters of Maxwell model defined for fluid dampers used to link two adjacent structures. Aldemir and Aydin [15] proposed an active control algorithm for adjacent structures. Kasai et al. [16] proposed a method, called the "spectral difference (SPD) method" based on spectral approach. Previous studies have shown that VDs placed between adjacent buildings are very effective in reduction of pounding cases.

The most important reason for pounding of adjacent buildings is their motions at different phases. In this study, to counterwork the pounding of two adjacent buildings, the allocation of VDs which are optimally placed between them is suggested. In this optimal design, one of the gradian based optimization algorithms, which is called Steepest Direction Search Algorithm (SDSA) [17], is applied considering the optimal condition to find optimum viscous damper quantities and their settlement to adjoining shear buildings. The relative displacement of top floor of the shorter building and middle floor of the taller building is considered as an objective function to be minimized in frequency domain. The behaviors of two adjacent buildings having different heights are evaluated with and without viscous dampers. Therefore, the reduction of relative transfer function displacement (U_R) between the top floor of shorter building and middle floor of taller building is monitored to detect the effectiveness of optimally designed VDs for prevention and reduction of pounding of adjacent shear buildings. This proposed design method is tested under El Centro (NS) ground motion record as well.

2 FORMULATION OF THE PROBLEM

As shown in Figure 1, s number of stories for shorter shear building A on the left side and n number of stories for taller shear building B on the right side are considered. In Figure 1, k_{As} and k_{Bn} are stiffnesses of the i^{th} floor of the buildings A and B. In the same way, m_{As} and m_{Bn} are the floor masses, respectively. The c_{As} and c_{Bn} , which are at the i^{th} floor for the buildings A and B, represent the structural damping coefficients proportional to floor masses. The c_{ads}^{A} and c_{adn}^{B} denote the added viscous dampers for prevention of pounding between the adjacent buildings A and B.

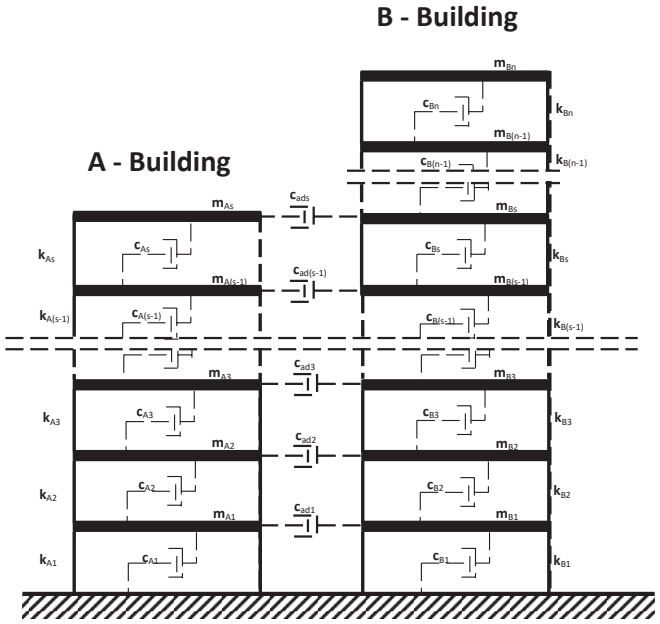

Figure 1: Adjacent buildings A and B with added viscous dampers.

The equation of motion of the shear buildings A and B can be separately expressed as follows.

$$\boldsymbol{M}_A\ddot{\boldsymbol{y}}_A(t) + \boldsymbol{C}_A\dot{\boldsymbol{y}}_A(t) + \boldsymbol{K}_A\boldsymbol{y}_A(t) = \boldsymbol{M}_A\boldsymbol{r}_A\ddot{y}_g(t) \tag{1}$$

$$\boldsymbol{M}_B\ddot{\boldsymbol{y}}_B(t) + \boldsymbol{C}_B\dot{\boldsymbol{y}}_B(t) + \boldsymbol{K}_B\boldsymbol{u}_B(t) = \boldsymbol{M}_B\boldsymbol{r}_B\ddot{y}_g(t) \tag{2}$$

In these equations, $\boldsymbol{M}_A$, $\boldsymbol{M}_B$, $\boldsymbol{C}_A$, $\boldsymbol{C}_B$, $\boldsymbol{K}_A$, $\boldsymbol{K}_B$ represent mass, structural damping and stiffness coefficient matrices of the buildings A and B, respectively. $\boldsymbol{y}_A(t)$ and $\boldsymbol{y}_B(t)$ denote displacement vectors of the buildings A and B, and over-dots show the derivatives according to time. $\ddot{y}_g(t)$ is the horizontal ground acceleration. $\boldsymbol{r}_A$ and $\boldsymbol{r}_B$ are influence vectors which consist of ones and zeros for the buildings A and B. The adjacent shear buildings A and B are modeled with added viscous dampers which are located between them. The equation of motion of the combined system can be written as follows.

$$\boldsymbol{M}\ddot{\boldsymbol{y}}(t) + \boldsymbol{C}\dot{\boldsymbol{y}}(t) + \boldsymbol{K}\boldsymbol{y}(t) = \boldsymbol{M}\boldsymbol{r}\ddot{y}_g(t) \tag{3}$$

$\boldsymbol{M}$, $\boldsymbol{C}$, $\boldsymbol{K}$ indicate mass, damping and stiffness matrices of the system composed of adjacent buildings A and B. $\boldsymbol{y}(t)$ is the system displacement vector. The system influence vector can be defined as $\boldsymbol{r}$ ={1,1,..,1}. $\boldsymbol{M}$, $\boldsymbol{C}$, $\boldsymbol{K}$ can be detailed further as follows.

$$\boldsymbol{M} = \begin{bmatrix} \boldsymbol{M}_A & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{M}_B \end{bmatrix} \tag{4}$$

$$\boldsymbol{K} = \begin{bmatrix} \boldsymbol{K}_A & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{K}_B \end{bmatrix} \tag{5}$$

$$\boldsymbol{C} = \begin{bmatrix} \boldsymbol{C}_A & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{C}_B \end{bmatrix} + \boldsymbol{C}_{ad} \tag{6}$$

in which $\boldsymbol{0}$ is the null vector and the added matrix $\boldsymbol{C}_{ad}$ placed between adjacent buildings A and B can be defined as follows.

$$\boldsymbol{C}_{ad} = \begin{bmatrix} \boldsymbol{C}_{ad}^{A} & \boldsymbol{C}_{ad}^{B} \\ \boldsymbol{C}_{ad}^{B} & \boldsymbol{C}_{ad}^{A} \end{bmatrix} \tag{7}$$

where, $\boldsymbol{C}_{ad}^{A} = -\boldsymbol{C}_{ad}^{B}$.

The Fourier transform of system equation for the adjacent buildings can be expressed as follows.

$$(\boldsymbol{K} + i\omega\boldsymbol{C} - \omega^2\boldsymbol{M})\boldsymbol{Y}(\omega) = -\boldsymbol{M}\,\boldsymbol{r}\,\ddot{Y}_g(\omega) \tag{8}$$

In this equation, $\boldsymbol{Y}(\omega)$ is the Fourier transform of displacement vector $(\boldsymbol{t})$, and $\ddot{Y}_g(\omega)$ is the Fourier transform of horizontal ground acceleration $\ddot{y}_g(t)$. $i = \sqrt{-1}$ denotes the imaginary unit.

The floor displacement transfer function $\boldsymbol{U}_D(\omega)$ of the adjacent buildings can be expressed as follows.

$$\boldsymbol{U}_D(\omega) = -(\boldsymbol{K} + i\omega\boldsymbol{C} - \omega^2\boldsymbol{M})^{-1}\boldsymbol{M}\boldsymbol{r} \tag{9}$$

3 DEFINITION OF THE OPTIMIZATION PROBLEM

The k^{th} value of relative displacement transfer function of the s^{th} floor level, which is also the objective function to be minimized, can be defined as,

$$U_{Rk}(\omega) = |U_{Ds}(\omega)| - |U_{Dn}(\omega)| \tag{10}$$

The objective function of the problem can be minimized using the SDSA method [17] considering optimal conditions. It gives the optimum damping distribution and the transfer function gives the value of the peak displacement. There are an active total of dampers and one passive constraint as many as the number of design variables in each damper. Active and passive restrictions on the total of the dampers added can be written as follows.

$$\sum_{i=1}^{n} \bar{c}_{adi} = W \tag{11}$$

$$0 < c_{adi} < \bar{c}_{adi} \qquad (i=1,\ldots,n) \tag{12}$$

W, $\bar{c}_{ad}$ are an upper limit value given for the sum of the damping coefficients of the dampers and the given upper limit value for the damping coefficient of each damper, respectively. Lagrangian (L) functional under the selected objective function and constraints is given as,

$$L(\bar{c}_{ad}, \lambda, \mu, \nu) = U_{Rk}(\omega) + \lambda(\sum_i^n \bar{c}_{ad} - W) + \sum_{i=1}^n \mu_i(0 - c_{adi}) + \sum_{i=1}^n \nu_i(c_{adi} - \bar{c}_{ad}) \quad (13)$$

In this equation, n is the number of design variables, and $\mu = \mu_i$ and $\nu = \nu_i$ are the Lagrange multipliers.

Taking into consideration the optimum damping criteria for relative displacement at the top of the structures, the damping coefficients of Lagrangian functional L ($\mu = 0$, $\nu = 0$) are taken according to c_{adi} (i = 1, ..., n) and λ without the upper and lower constraints in order to minimize the objective function of the problem,

$$U_{R,j} + \lambda = 0 \quad (j = 1, \dots, n) \; 0 < c_{adj} < \bar{c}_{adj} \quad (14)$$

Here, the expression $(.)_{,j}$ shows the partial derivatives with respect to c_{adj}. It should be considered that the damping coefficients cannot be negative in the dampers added. There is no physical significance of the damping coefficients to be zero. If the upper and lower constraints of the damping coefficients are active, the equation above should be corrected as follows,

$$U_{R,j} + \lambda \geq 0 \qquad c_{adj} = 0 \quad (15)$$

$$U_{R,j} + \lambda \leq 0 \qquad c_{adj} = \bar{c}_{adj} \quad (16)$$

4 NUMERICAL EXAMPLE

In order to understand the efficiency of the proposed method, four story and eight story adjacent buildings system with and without VDs, which is shown in Figure 2, is considered as an example. The floor masses and stiffness for building A are $m_{As} = 3.2 \times 10^4$kg and $k_{As} = 1 \times 10^7$kg for *s*=1,…,4. The floor masses and stiffness for building B are $m_{Bn} = 3.2 \times 10^4$kg and $k_{Bn} = 10 \times 10^7$kg for *n*=1, 2…, 8. The natural damping ratios of the first modes of shear buildings A and B are $\xi_{A1} = \xi_{B1} = 0.02$. The natural frequencies for the first modes of buildings A and B are $\omega_{A1} = 6.1$ rad/s and $\omega_{B1} = 30.60$ rad/s, respectively. Figure 3 depicts variation of the 4th floor absolute displacement transfer function $|U_{D4}|$ with respect to excitation frequency for the buildings A and B in the case of without control. The structural damping is taken as proportional to mass matrix. The ratio of periods of buildings A and B for the first modes is $\frac{T_{A1}}{T_{B1}} = 1.68$. Total quantity of the VDs inserted to adjacent buildings is $\bar{c}_{ad} = 20x\ 10^4$ Ns/m.

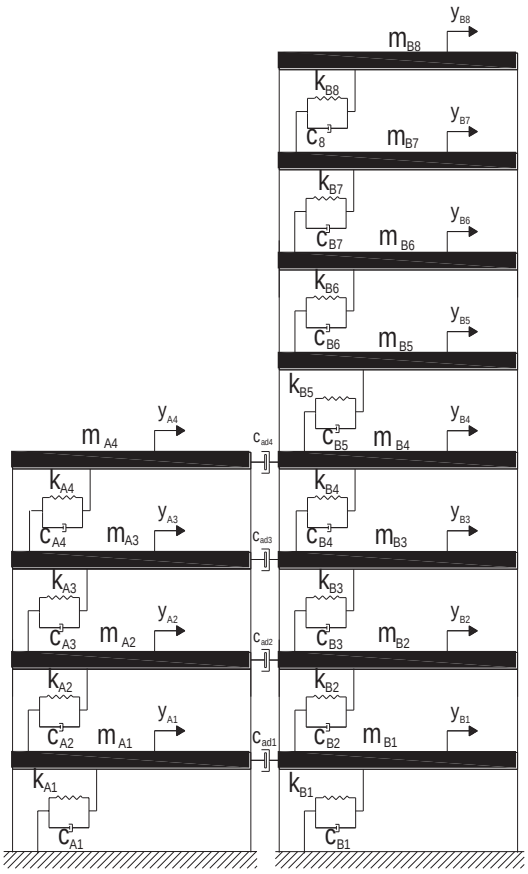

Figure 2: Four story and eight story adjacent buildings with viscous dampers.

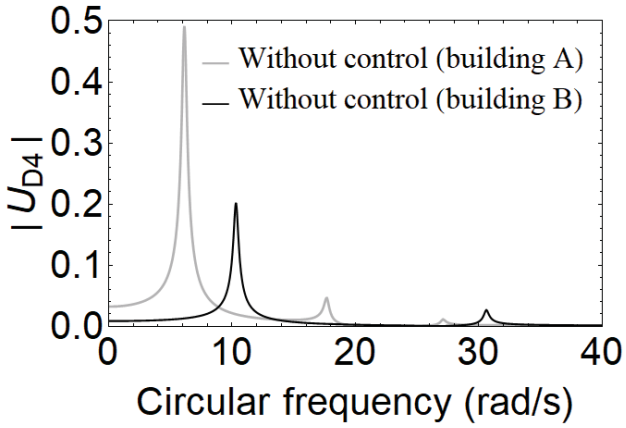

Figure 3: Variation of the 4th floor absolute displacement transfer function $|U_{D4}|$ with respect to excitation frequency for the buildings A and B in the case of without control.

The optimum distribution of damping is calculated in 300 steps by using the Steepest Direction Search Algorithm (SDSA) with respect to the 4th floor relative displacement transfer function $U_{R4}(\omega)$. Figure 4 shows the distribution of VD between adjacent buildings. As shown in Figure 4, VD is totally focused on the top floor of the four-story building A in the adjacent building system. Figure 5 demonstrates the reduction of the objective function $U_{R4}(\omega)$ according to redesign step number. After execution of optimum VD distribution, the variation of the objective function $U_{R4}(\omega)$ considering the excitation frequency and time his-

tory of the 4th floor relative displacement (RD) between the adjacent buildings are shown in Figures 6 and 7, respectively. It can be observed that the proposed method is very effective in descending the relative response between adjacent buildings A and B.

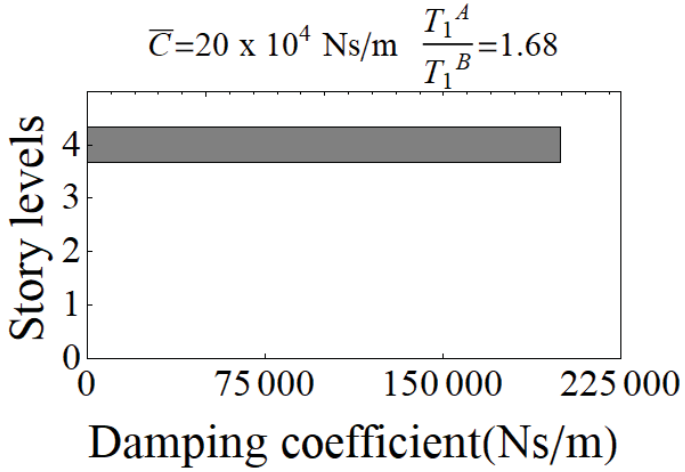

Figure 4: Optimal distribution of the VD with respect to relative displacement between the adjacent buildings

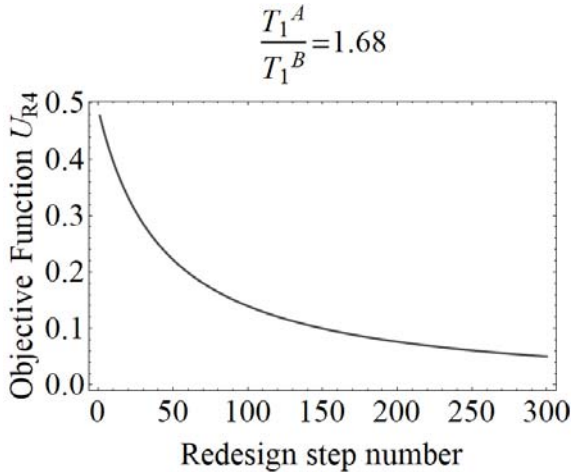

Figure 5: Reduction of the objective function $U_{R4}(\omega)$ according to redesign step number.

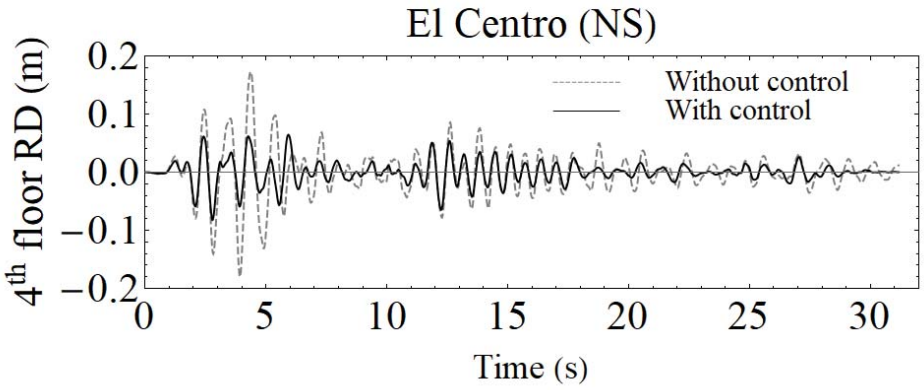

Figure 7: Time history of the 4th floor relative displacement (RD) between the adjacent buildings

5 CONCLUSION

In this study, the following conclusions can be obtained.

(1) In order to overcome pounding between the adjacent buildings, the optimal distribution of VDs has been studied using the SDSA. Optimization results have shown that the most suitable VD location in between the adjacent buildings A and B is at the top floor of building A.

(2) Comparison of the structural behavior of adjacent buildings with and without VDs is provided. It is shown that enhancing the VD capacity is very effective in decreasing the amplitude of relative displacement of the adjacent buildings and dissipating the energy of the system as well. In this study, VD location focused on the top floor of shorter building A.

(3) Considering the decrease in pounding of the adjacent buildings, the proposed method is quite effective. The objective function $\boldsymbol{U_{R4}(\omega)}$, which relies on the excitation frequency, is reduced. It is also effective in the mitigation of relative displacement between the adjacent buildings which can be observed in time history analysis.

Keywords: seismic isolation, double friction pendulum bearing, seismic reliability-based design, ductility demand, behaviour factor, post-yield hardening/softening stiffness.

Abstract. *This work deals with seismic reliability-based design (SRBD) for softening and hardening structures equipped with double friction pendulum system (DFPS) isolators. The isolated system is represented by means of an equivalent 3dof model having a softening/hardening post-yield slope for the superstructure and velocity-dependent rules for the two surfaces of the DFP devices. The yielding characteristics of the superstructures are defined in compliance with the seismic hazard of L'Aquila site (Italy) and with NTC18 assuming ordinary characteristics. Considering several natural seismic records and the relevant random variables, incremental dynamic analyses are carried out for assessing the seismic fragility and the seismic reliability of these systems. Finally, seismic reliability-based design (SRBD) curves for these systems are proposed.*

1 INTRODUCTION

Sliding pendulum bearings are more and more used to isolate buildings and infrastructures in seismic zone [1]-[3] and have been studied by many researchers (e.g., [4]-[5]) in order to ensure appropriate safety and resilience levels to infrastructure systems [6]-[7]. Probabilistic analyses together with reliability-based investigations have also been developed by [8]-[9] as well as reliability and reliability-based optimization analyses for base-isolated systems have been discussed in [10]-[11]. Adopting the friction coefficient in addition to the earthquake characteristics as the main aleatory uncertainties, seismic reliability and life-cycle cost analyses of 3D base-isolated reinforced concrete (RC) structures have been commented in [12]-[13]. Referring to elastic systems isolated through single FPS, the seismic reliability-based design (SRBD) approach in general terms has been presented in [14]. In the literature articles [15] and [16], two different optimization approaches are proposed for systems equipped with FPS: in [15], with the purpose to minimize the superstructure displacement demand, the influence of the system properties and of the soil conditions on the optimal friction coefficients is examined; in [16], the ratio peak ground acceleration/velocity is assumed as the relevant parameter to determine the optimal friction coefficients. The studies [17]-[19] investigated the seismic performance of bridges or structures equipped with DFPS (doubleFPS) or FPS providing [19] useful relationships to assess the seismic response of structures isolated by frictional isolators and highlighting that the principal benefit of the DFPS bearing in comparison to the singleFP is the capacity to accommodate larger displacements.

With regard to the design of base-isolated systems when they respond inelastically, seismic code provisions [20]-[24] prescribe low values for the strength reduction factor [20],[24] or behavior factor [21]-[22] to avoid non linear dynamic amplification phenomena (e.g., partial resonance) [25]. In detail, NTC18 [22], the Japanese building code [23] and Eurocode 8 [21] state 1.5 as maximum value, without specifying a distinction between the ductility and overstrength factor term. A behavior factor equal to 0.375 times the value for corresponding fixed-base structures and no larger than 2 is prescribed in ASCE 7 [20].

This study describes the seismic reliability-based design (SRBD) for softening and hardening structural systems equipped with DFPS devices and located in L'Aquila (Italy). The isolated system is represented by means of an equivalent 3-degree-of-freedom (3dof) model having a softening/hardening post-yield slope for the superstructure and velocity-dependent rules for the two surfaces of the DFP devices [4]. In this way, a wide parametric analysis is developed investigating the influence of different elastic and inelastic structural system properties of the superstructure and of the DFPS for increasing behavior factors [20]-[23]. In addition, the investigation is carried out assuming the both friction coefficients of the two surfaces of the DFPS and the characteristics of the ground motions as the main aleatory uncertainties. In detail, the both friction coefficients are modelled by means of appropriate Gaussian probability density functions (PDFs) and, the Latin Hypercube Sampling (LHS) method [26]-[27] is employed to generate the input data. After that, several incremental dynamic analyses (IDAs) are developed for increasing seismic intensity levels in compliance with the site seismic hazard to assess the seismic fragility curves and, successively, the seismic reliability curves. Finally, SRBD curves for the two surfaces of the DFPS devices are provided as design relationships. The results herein presented allow a comparison with the outcomes when single-FPS are employed [28],[29] in order to highlight the potential advantages of the DFPS and recommend reliable values of the displacement demands to the DFPS bearings.

2 EQUATIONS OF MOTION FOR NON-LINEAR STRCTURAL SYSTEMS WITH DFPS

The equivalent system depicted in Figure 1 is a 3dof system presents a dof for the superstructure behaviour and two dofs for the responses of the two surfaces of the DFPS. This equivalent system has been adopted to model the mechanical nonlinearities of the superstructure and of the DFPS [30].

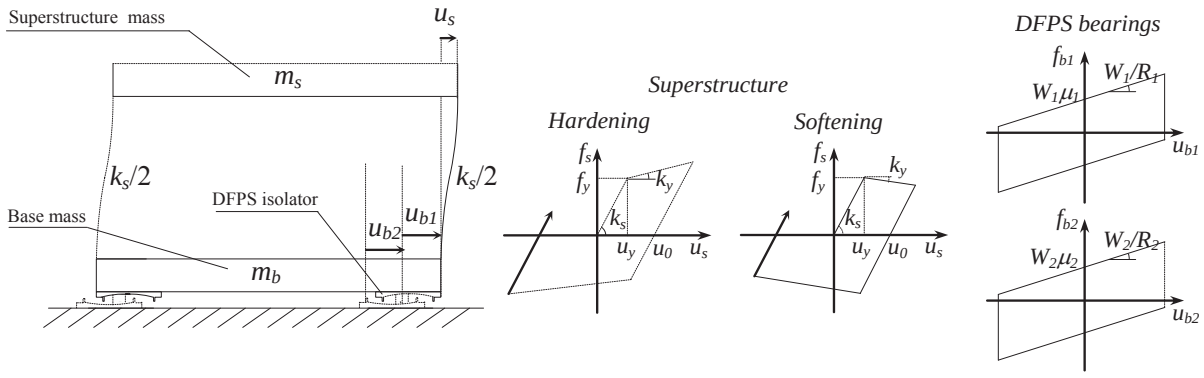

Figure 1: 3dof model with the constitutive laws.

Regarding the free body diagram of the DFPS, the bearing restoring forces of the DFPS apply:

$$f_{b,1} = \frac{W_1}{R_1} u_{b,1} + \mu_{d,1} W_1 \operatorname{sgn}\left(\dot{u}_{b,1}\right) \tag{1a}$$

$$f_{b,2} = \frac{W_2}{R_2} u_{b,2} + \mu_{d,2} W_2 \operatorname{sgn}\left(\dot{u}_{b,2}\right) \tag{1b}$$

where $W_1 = \left(m_b + m_s\right) g$ denotes the weight on the upper surface (surface 1) of the isolator, $W_2 = \left(m_b + m_s + m_d\right) g$ is the weight on the lower surface (surface 2) of the isolator, g is the gravity constant, R_1 and R_2 are the curvature radii of the two surfaces of the isolator, $u_{b,1}$ represents the displacement of the surface 1 with respect to the slider, $u_{b,2}$ is the slider displacement with respect to the ground, $\mu_{d,1}$ and $\mu_{d,2}$ denote the sliding friction coefficients of the two surfaces and sgn is the signum function of the sliding velocity for each surface. In this work, the surface 1 presents higher values of both the friction coefficient and the radius of curvature. Precisely, $\mu_{d,1}$ is chosen as $4\mu_{d,2}$ and $R_1=2R_2$ [30].

Along each surface, the friction coefficient applies [4]-[5]:

$$\mu_{d,i} = f_{\max,i} - \left(f_{\max,i} - f_{\min,i}\right) \exp\left(-\alpha \dot{u}_{b,i}\right) \quad \text{for } i = 1,2 \tag{2}$$

where $f_{\max,i}$ and $f_{\min,i}$ are, respectively, the friction coefficients at high and very low sliding velocities of the i-th surface. The values of 30 and 3 are assumed, respectively, for α and $f_{\max,i} / f_{\min,i}$ for each sliding surface [15],[28].

The hardening or softening behaviour of the superstructure is modelled herein through a bilinear constitutive law. In this way, the response is elastic if Eqn.(3) is verified and the restoring force $f_{s,i}$ is expressed according to Eqn.(4):

$$\left|u_{s,i}-u_{0,i-1}\right|<y\left(u_{s,i}\right) \tag{3}$$

$$f_{s,i}\left(u_{s,i}\right)=k_s\left(u_{s,i}-u_{0,i-1}\right) \tag{4}$$

where $f_{s,i}$ denotes the restoring force at time instant i, $u_{s,i}$ represents the superstructure deformation at the same instant, $u_{0,i-1}$ is the maximum inelastic response at time instant $(i-1)$ and k_s is the superstructure elastic stiffness. The term $y(u_{s,i})$ is the yielding function depending on the displacement as explained in [31]. Defining u_y as the yield displacement, whose yield force is f_y, H or S denotes the ratio of the hardening or softening post-yield stiffness over the elastic stiffness [32]-[33], evaluated as:

$$H=S=\frac{k_y}{k_s} \tag{5}$$

The superstructure response is in plastic phase if Eqn.(6) is verified and the restoring force can be calculated through Eqn.(7):

$$\left|u_{s,i}-u_{0,i-1}\right|\geq y(u_{s,i}) \tag{6}$$

$$f_{s,i}\left(u_s\right)=k_s(u_{s,i}-y(u_{s,i}))\,\mathrm{sgn}(u_{s,i}-u_{0,i-1}) \tag{7}$$

Therefore, the equations of motion that govern the inelastic response of the equivalent 3dof system to the seismic input $\ddot{u}_g(t)$, without any viscous dissipative capacities for the DFPS, are:

$$m_s\ddot{u}_s+(m_s+m_b)\ddot{u}_{b,1}+(m_s+m_b+m_d)\ddot{u}_{b,2}+\frac{W_2}{R_2}u_{b,2}+W_2\mu_2\,\mathrm{sgn}\left(\dot{u}_{b,2}\right)=-(m_s+m_b+m_d)\ddot{u}_g$$

$$m_s\ddot{u}_s+(m_s+m_b)\ddot{u}_{b,1}+(m_s+m_b)\ddot{u}_{b,2}+(m_s+m_b)\frac{g}{R_1}u_{b,1}+(m_s+m_b)g\mu_1\,\mathrm{sgn}\left(\dot{u}_{b,1}\right)=-(m_s+m_b)\ddot{u}_g$$

$$m_s\ddot{u}_s+m_s\ddot{u}_{b,1}+m_s\ddot{u}_{b,2}+c_s\dot{u}_s+f_{s,i}(u_s)=-m_s\ddot{u}_g \tag{8a,b,c}$$

where m_s, m_b and m_d represent respectively the mass of the superstructure, of the isolation level and of the slider, c_s is the superstructure viscous damping factor. Dividing Eqn.(8a) by $m_s+m_b+m_d$ as well as Eqn.(8b) by m_b+m_s and Eqn.(8c) by m_s, defining the mass ratios as $\gamma_s=m_s/(m_s+m_b+m_d)$, $\gamma_b=m_b/(m_s+m_b+m_d)$ and $\gamma_d=m_d/(m_s+m_b+m_d)$ [34], the isolation $\omega_{b,i}=\sqrt{g/R_i}$ and structural $\omega_s=\sqrt{k_s/m_s}$ circular frequency, the structural damping ratio $\xi_s=c_s/2m_s\omega_s$, the non-dimensional equations become as follows:

$$\gamma_s \ddot{u}_s + (\gamma_s + \gamma_b)\ddot{u}_{b,1} + \ddot{u}_{b,2} + \omega_{b,2}^2 u_{b,2} + g\mu_2 \operatorname{sgn}\left(\dot{u}_{b,2}\right) = -\ddot{u}_g$$
$$\gamma_s \ddot{u}_s + (\gamma_s + \gamma_b)\ddot{u}_{b,1} + (\gamma_s + \gamma_b)\ddot{u}_{b,2} + (\gamma_s + \gamma_b)\omega_{b,1}^2 u_{b,1} + (\gamma_s + \gamma_b) g\mu_1 \operatorname{sgn}\left(\dot{u}_{b,1}\right) = -(\gamma_s + \gamma_b)\ddot{u}_g$$
$$\ddot{u}_s + \ddot{u}_{b,1} + \ddot{u}_{b,2} + 2\omega_s \xi_s \dot{u}_s + a_s(u_s) = -\ddot{u}_g \tag{9a,b,c}$$

where $a_s\left(u_s\right) = f_s\left(u_s\right)/m_s$ denotes the dimensionless superstructure force proportional to the elastic stiffness k_s if the response is elastic or depends on the yielding condition if the system responds inelastically. Note that the elastic vibration period of the isolation system provided by the DFPS devices depends on which surfaces are moving during the earthquake [19]. In detail, if only one surface slides, the isolation period depends only on the radius of curvature of that surface R_i and the bearing behaves like a simple FPS [14], whereas when the both surfaces slide, the isolation effective period applies [19]:

$$T_b = 2\pi\sqrt{\frac{R_1 + R_2}{g}} \tag{10}$$

It follows that the seismic isolation degree [35], expressed as the variable isolation period over the structural period of vibration, is not a constant during an earthquake event. Moreover, when the both surfaces slide simultaneously the restoring force of the DFPS isolator can be evaluated as $\mu_e W_1$ neglecting the mass of the slider [30], where μ_e is the effective sliding coefficient given by:

$$\mu_e = \frac{\mu_{d,1}R_1 + \mu_{d,2}R_2}{R_1 + R_2} \tag{11}$$

Regards the inelastic behavior of the superstructure [36]-[37], Eqn.s (12)-(13) define, respectively, the inelastic capacities in terms of behavior factor, q, and displacement ductility, μ, defined, respectively, as:

$$q = \frac{f_{s,el}}{f_y} = \frac{u_{s,el}}{u_y} \tag{12}$$

$$\mu = \frac{u_{\mathrm{s,max}}}{u_y} \tag{13}$$

where $f_{s,el}$ and $u_{s,el}$ represent the peak response values, respectively, in terms of strength and displacement when the superstructure responds elastically during a ground motion, whereas $u_{\mathrm{s,max}} = \left|u_s(t)\right|_{\max}$ denotes the peak inelastic response in terms of displacement. The terms u_y and f_y are, respectively, the yielding displacement and strength. More details may be found in [30].

3 INCREMENTAL DYNAMIC ANALYSES

This section describes the results achieved from the incremental dynamic analyses (IDAs) of the system in Figure 1 within a wide parametric analysis, considering several structural parameters and as Italian site: L'Aquila (42°38'49''N and 13°42'25''E and a soil class B). In detail, the responses of the superstructure, of the DFPS are investigated for increasing intensity measure (*IM*) levels and shown in the following figures adopting 30 real ground motions,

which have also been used in previous studies by the authors [28],[29],[30], to describe the aleatory uncertainty on the seismic input denoted as record-to-record variability. The *IM* is herein chosen as the spectral displacement at the effective isolated period $S_D(T_b)$.

Elastic and inelastic properties of the isolated superstructure

Within the parametric analysis, the following deterministic parameters are taken into account: the isolation degree I_d with respect to the equivalent effective isolated period of Eq.(10) = 2, 4, 6 and 8; the equivalent effective isolation period T_b of Eq.(10) = 3s, 4s, 5s and 6s; the mass ratios: γ_s = 0.6 and 0.8, γ_d = 0.001, and so γ_b = 0.399 and 0.199; the behaviour factor q = 1.1, 1.2, 1.3, 1.4, 1.5, 1.6, 1.7, 1.8, 1.9 and 2, according to [20]-[23], and the post-yield softening or hardening stiffness ratio S or H = 0.03 [38]-[39]. Combing all these properties, 768 equivalent inelastic 3dof systems derive. The isolation damping ratio ξ_b is assumed equal to 0% whereas, superstructure damping ratio ξ_s equal to 2%.

Neglected the inelastic properties and considering only the elastic ones, 32 different 3dof systems derive (with the different values of I_d, of T_b and of the mass ratios). Assuming $\mu_{d,1}$ and $\mu_{d,2}$ equal to 4% and 1%, respectively, and a ratio equal to 2 between R_1 and R_2 [30], for 32 elastic 3dof elastic systems, it has been possible to evaluate the average elastic responses, in Matlab-Simulink [40], to the 30 records scaled to the *IM* value of the life safety limit state for L'Aquila: the $IM = S_D(T_b)$ applies 0.311 m for T_b=3, 4, 5 s and 0.26 m for T_b =6 s [22]. In this way, the yielding characteristics of the 768 inelastic 3dof systems have been computed in terms of the average values of both yield strength and yield displacement (i.e., $f_{y,\text{average}}$ and $u_{y,\text{average}}$) divided by the increasing values of q, as expressed by Eqn.(14):

$$u_{y,average} = \frac{f_{y,average}}{k_s} = \frac{f_{s,el,average}}{k_s q} = \frac{u_{s,el,average}}{q} \tag{14}$$

Incremental dynamic analysis (IDA) curves

This sub-section deals with the responses of the 768 equivalent 3dof hardening and softening systems, considering the aleatory uncertainties of the sliding friction coefficients through 15 sampled couples, to the 30 seismic inputs scaled to the increasing $IM = S_D(T_b)$, varying in the range from 0 m to 0.45 m. Specifically, for each *IM* level and parameter combination, 450 numerical non-linear analyses have been developed. The isolated non-linear hardening and softening systems are modelled in Matlab-Simulink [40], by employing the Runge-Kutta-Fehlberg integration algorithm to solve Eqn.(9) and determine the responses of the superstructure and of the DFPS bearings.

For each softening structural system, the collapse condition assumed within the numerical analyses is reached when the response of the superstructure is equal to zero. For the other systems as well as for the isolation devices any limitation is not considered.

Form the results of the non-linear incremental dynamic analyses, it has been possible to estimate the collapsed system cases together with the displacement ductility demand μ for the superstructure and the displacements for the DFPS (i.e., peak value for each one of the two surfaces "$u_{b,1}$ and $u_{b,2}$" and peak value of their sum computed at each time instant "u_b"). These response parameters are denoted as the engineering demand parameters (EDPs) and their peak

values have been fitted by means of lognormal distributions [12]-[15],[28],[41],[42] at each *IM* level. In detail, for each lognormal distribution, through the maximum likelihood estimation (MLE) technique [43]-[47], the mean, $\mu_{\ln}(EDP)$, and the standard deviation, $\sigma_{\ln}(EDP)$, have been computed as well as the 50th, 84th and 16th percentile.

It is also important to specify that neither other aleatory uncertainties not epistemic uncertainties have been herein considered [48]-[49].

Figures 2-3 depict the IDA curves for hardening structures. The results related to I_d =2 and 8, T_b =3s and 6s and γ_s equal to 0.6 are herein illustrated.

Fig. 2 depicts the IDA curves of the isolation level EDP $u_{b,\max}$, which is the peak value of the sum of $u_{b,1}$ and $u_{b,2}$ in each time instant. The lognormal mean of $u_{b,\max}$ is higher by increasing T_b and I_d. Moreover, the increase of q causes a slight decrease of $u_{b,\max}$, especially for higher values of I_d. The results are consistent with the ones achieved in [29] considering a single concave sliding device.

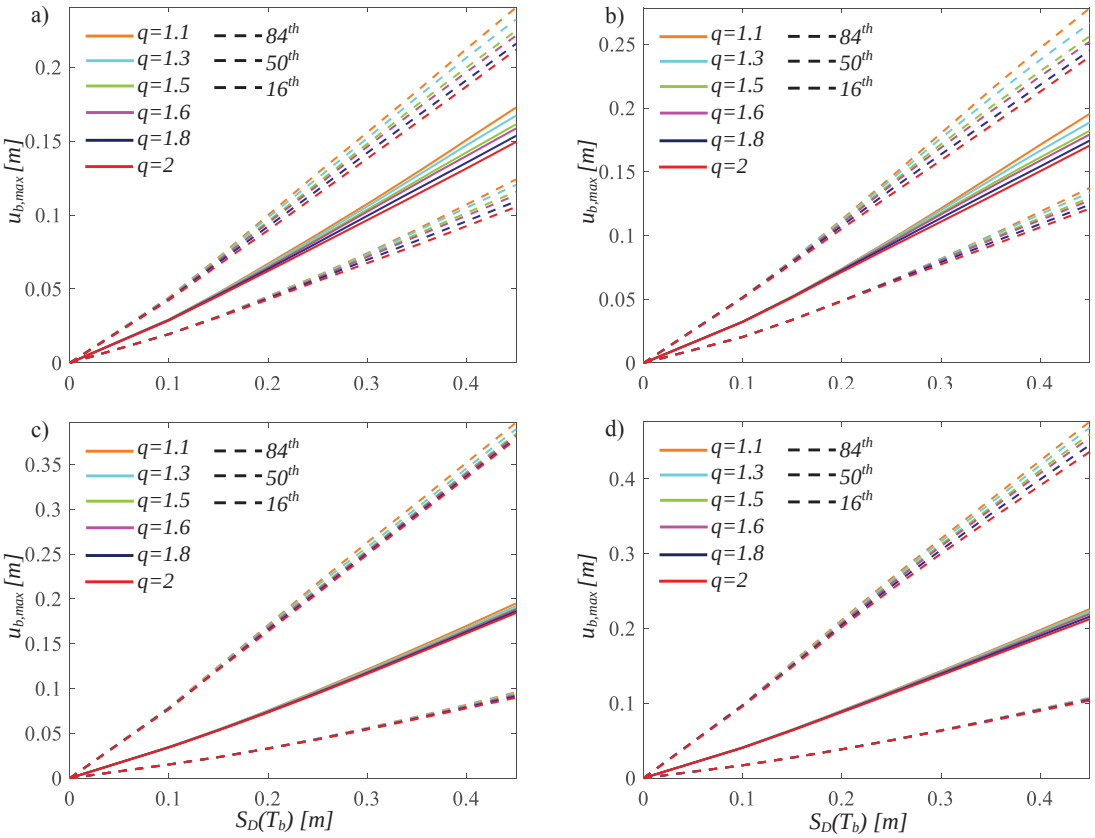

Figure 2: IDA curves of the isolation level with γ_s =0.6 for I_d=2, T_b=3 s, H=0.03 (a), I_d=2, T_b=6 s, H=0.03 (b), I_d=8, T_b=3 s, H=0.03 (c), I_d=8, T_b=6 s, H=0.03 (d).

Fig. 3 depicts the IDA results for the EDP μ. The corresponding statistical parameters are strongly influenced by the variation of q. In fact, an its increase leads to a very high displacement ductility demand μ. In addition, $\mu_{\ln}(\mu)$ highly decreases by decreasing T_b but is higher for lower values of I_d, especially for high values of T_b.

The IDA results of the isolation level and of the superstructure for the softening behavior are not reported because the influence of the data related to the dynamic collapses has been taken

into account within the assessment of the seismic fragility, as discussed in the next section, together with the description of the influence of the other structural properties (i.e., γ_s, q and S) on both the DFPS and the softening superstructures.

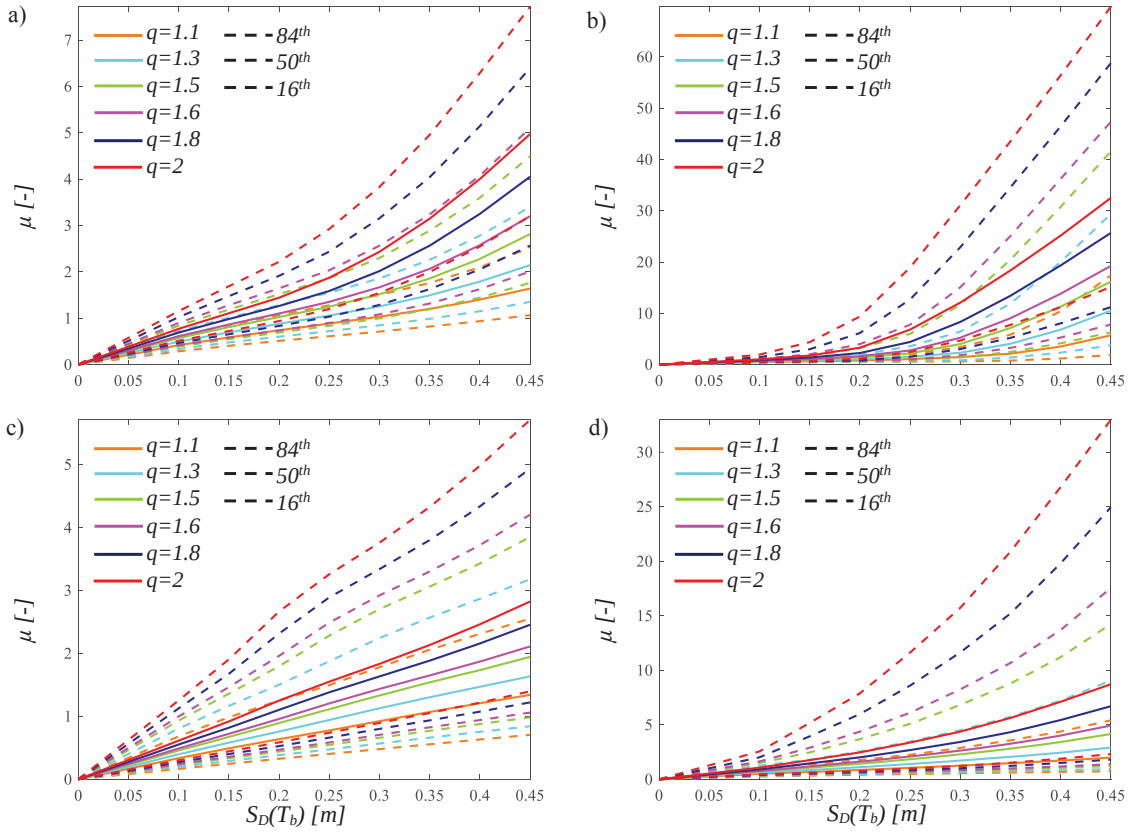

Figure 3: IDA curves of the superstructure with γ_s=0.6 for I_d=2, T_b=3 s, H=0.03 (a), I_d=2, T_b=6 s, H=0.03 (b), I_d=8, T_b=3 s, H=0.03 (c), I_d=8, T_b=6 s, H=0.03 (d).

4 SEISMIC FRAGILITY CURVES

The definition of the limit states with respect to the EDP is necessary to reach the fragility assessment. In detail, different thresholds, respectively, in terms of the radius in plan for each surface of the DFPS isolator, $r_1[m]$ and $r_2[m]$, and of the displacement ductility for the superstructure, $\mu[-]$, have been selected. In this way, the probabilities P_f exceeding the different limit states at each *IM* level, have been numerically computed. Tables 1-2 report, respectively, the failure probabilities in 50 years [50] and the corresponding thresholds, related to the *LS*s provided by the codes [21]-[22]: the failure probability in 50 years [13],[50] associated to the collapse limit state [22] for the DFPS; whereas, the failure probability in 50 years [13],[50] associated to the life safety *LS* [22] for the superstructure in compliance with the design.

For each structural system of the 768 equivalent 3dof systems, the probabilities P_f exceeding the different limit states at each *IM* level, are numerically computed and successively fitted through lognormal distributions [14] with a R-square value higher than 0.8. For the softening systems, the number of both the collapse cases has been considered to estimate the seismic fragility through the total probability theorem [29],[51], as follows:

$$P_{SL}(IM = im) = (1 - F_{EDP|IM=im}(LS_{EDP})) \cdot \frac{N_{not-collapse}}{N} + 1 \cdot \left(1 - \frac{N_{not-collapse}}{N}\right) \quad (15)$$

where N is the overall number of analyses at each IM level, and $N_{not-collapse}$ is the number of numerical simulations without any collapse.

Figures 6-8 depict the fragility curves for increasing IM regarding both softening and hardening structures. Precisely, the curves related to the different structural properties and only to some limit state thresholds ($LS_{r,4}$ and $LS_{\mu,3}$) and to I_d=8 and T_b=3s, are illustrated.

Generally, the seismic fragility is lower for increasing the corresponding limit state threshold and is the highest for the post-yield softening behavior.

Figure 4 illustrates the fragility curves regarding the overall response of isolation level for hardening models.

Figures 6-7 depict the fragility curves of the two surfaces of DFPS for the softening systems.

For the all limit states, P_f decreases slightly for increasing γ_s. Then, especially for high limit state thresholds, the fragility increases by increasing T_b, I_d and decreasing q. Note that the probability exceeding a limit state is quite low for the single surface, with a lower probability for the surface 2 characterized by a lower friction coefficient with a lower radius of curvature, in compliance with the IDA results. Obviously, higher values are achieved for the softening behaviour.

The fragility curves for the nonlinear superstructures are shown in Figures 5 (hardening) and 8 (softening). The exceeding probabilities are slightly lower as γ_s decreases but highly increase for increasing values of q. Conversely, lower values of T_b for fixed I_d lead to an increase of the seismic fragility because a decrease of the period T_s means a decrease of the correlated yielding displacement as well as lower values of T_b for fixed I_d lead to higher values of the seismic fragility. In fact, the coupling between I_d and T_b influences T_s and the associated yielding displacement and so, as also discussed in [28]-[29], with reference to systems with low T_s, the ensuing dynamic amplification can negatively affect the superstructure responses increasing the seismic fragility.

5 SEISMIC RELIABILITY-BASED DESIGN CURVES FOR DFPS

This section illustrates the results of the seismic reliability assessment for all the equivalent softening or hardening structures isolated by DFPS within their lifetime of 50 years. This assessment is composed of the following two steps: (i) computation of the convolution integral between the seismic fragility curves and the seismic hazard curves, expressed in terms of the same $IM=S_D(T_b)$ [22],[29], to assess the mean annual rates exceeding the limit states; (ii) assessment of the probabilities exceeding the limit states in 50 years through the homogenous Poisson model.

As regards the DFPS isolators, the seismic reliability curves can be seen as the SRBD curves to design the dimensions in plan of each surface and the overall dimension of these devices depending on the expected reliability target and of the structural properties. Figures 9-10 show, respectively, the linear regressions, representative of the seismic reliability of the overall dimension of the isolation level, in the semi-logarithmic space for hardening and softening structures. The R-square value is higher than 0.8. The figures demonstrate that the seismic reliability of the isolation level decreases for the softening behavior in comparison to the hardening case. The increasing direction of the structural parameter q is denoted by means of the arrow in the figures. As for hardening models, these curves demonstrate that an exceeding probability of $P_f=1.5\cdot10^{-3}$ (corresponding to the collapse limit state in 50 years) [50]-[52] requires a global dimension ranging from about 0.3 m to about 1 m depending on the structural characteristics. Instead, for softening superstructures, higher values are required.

Figures 11-22 show the seismic reliability curves for the hardening and softening superstructures highlighting the great influence of the behavior factor as well as the great contribution of the hardening properties in comparison to the softening ones.

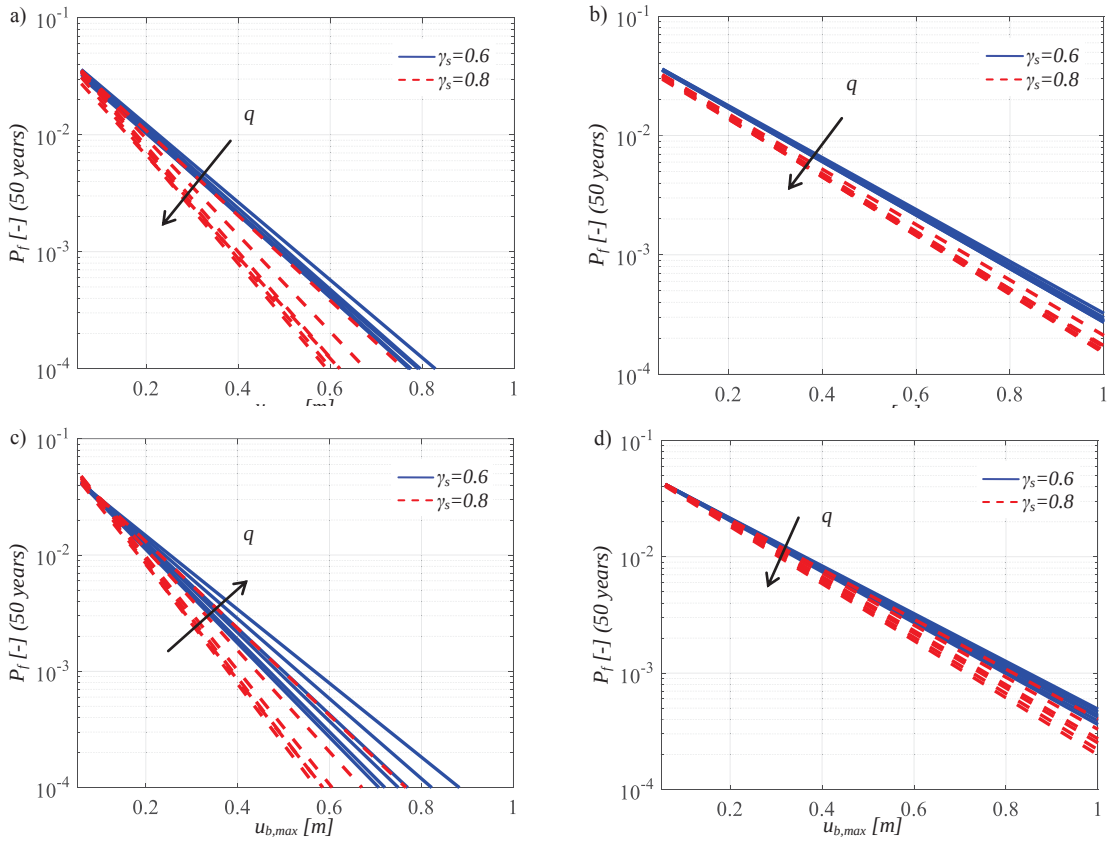

Figure 9: Seismic reliability of the isolation level related to I_d=2, T_b=3 s, H=0.03 (a), I_d=2 and T_b=6 s, H=0.03 (b), I_d=8 and T_b=3 s, H=0.03 (c), I_d=8 and T_b=6 s, H=0.03 (d).

6 CONCLUSIONS

This study focuses on the seismic reliability-based response of hardening and softening structures isolated with double concave sliding isolators. A wide investigation is presented considering different elastic and inelastic mechanical properties and assuming the friction coefficients together with the characteristics of the seismic ground motions as random variables. Adopting an equivalent 3dof system with non-linear velocity-dependent rules for the two surfaces of the DFPS, incremental dynamic analyses are carried out for several natural seismic records, different behavior factors and post-yield stiffness ratios. Then, the seismic fragility curves are derived for each engineering demand parameters of interest for these systems: peak values of the response of the superstructure, of the upper surface and of the lower surface of the DFPS. Successively, assuming a lifetime of 50 years and the seismic hazard of L'Aquila (Italian site), seismic reliability-based design curves are derived for the DFPS. The results have highlighted the great influence of the behavior factor as well as the negative effects of the post-yield stiffness also regarding the seismic reliability of the superstructure.

Abstract. *In this study the seismic performance of a real multistory RC frame structure against pounding with an adjacent shorter and stiffer structure is evaluated based on probabilistic assessment methods. The examined pounding case is between an 8-story RC frame and a 3-story rigid barrier (very stiff structure) with equal story heights (floor-to-floor interaction). Three different initial gap distances (d_g) between the adjacent structures are considered. The seismic performance of the 8-story structure without the pounding effect is also included for comparison reasons. The probabilistic evaluation of the pounding effect is performed through fragility curves in terms of global and local engineering demand parameters (EDPs) as a function of the intensity measure (IM). For this purpose, linear and bilinear regression models in log-log space have been considered to define the relationship between the examined EDPs and IMs. The commonly used intensity measures (IMs) of peak ground acceleration, PGA and that of spectral acceleration corresponding to the fundamental period of the examined structure, Sa($T_{1,8\text{-story}}$) are adopted. Displacement and rotation EDPs that could control the global state of the structure are examined at different performance levels. However, the most critical issue in earthquake-induced interaction between adjacent structures is the local responses of the columns at the pounding side. Thus, three local performance levels in terms of ductility capacity of the external columns at each story level of the 8-story frame have also been incorporated in the probabilistic assessment of the pounding problem. The results of this study indicate that the probability of pounding between the examined structures is increased as the separation gap distance d_g decreases. The fragility curves of the 8-story frame are significantly influenced due to the structural pounding effect. The probability of damage at columns seems to be an important parameter that has to be further investigated. Different types of global and local performance levels altered the intensity values for the seismic hazard of the structural pounding.*

1 INTRODUCTION

Field observations after numerous destructive earthquakes all over the world indicate that pounding is frequently observed when strong earthquakes strike big cities and densely populated urban areas. In these events it has been proved that the interaction between adjacent buildings results in local damages at the pounding area of the structures while there are cases where the seismic pounding has been identified as a primary cause for the initiation of collapses. In this view, the problem of earthquake induced pounding between adjacent buildings has received substantial attention over the last two to three decades [e.g. 1-14]. In the beginning these studies were based on the response of pairs or sets of colliding single degree of freedom systems in earthquake excitations [1]. However, results about the influence of the structural pounding on the seismic response of real multistory reinforced concrete structures based on inelastic time-history analyses have also been reported (e.g. [4], [5], [8], [9], [13], [14]). It is noted here that Karayannis and Favvata [4] for the first time, examined the influence of the structural pounding problem on the ductility requirements and the overall seismic response of reinforced concrete structures with unequal heights designed according to the Eurocodes 2 and 8. Since then an extensive work in this field, revealed that the local ductility demands of the columns in the pounding area of the tall structure are critically increased due to the interaction with an adjacent shorter and stiffer structure, at the floors above the highest contact story level. Furthermore, results have clearly shown that in situations of potential pounding, neglecting its possible local effects leads to non-conservative building design or assessment that may become critical in some cases [11, 13].

On the other hand, the typical measure that modern codes specify against structural pounding is the provision for sufficient separation between the adjacent buildings [15-17]. However, the estimation of the separation gap distances between the structures is not directly incorporated with the seismic hazard level and the local capacities of the structural members that may suffer the pounding effect. As properly pointed out by Barbato and Tubaldi [18] the minimum gap distance prescribed by the current seismic design codes is based on a uniform-hazard response spectrum that corresponds to an ultimate design limit state. In this way the structural pounding is related only with the ultimate design seismic performance of the building and thus the evaluated gap separation is not appropriately correlated with other levels of seismic demand. Abdel Raheem [10] studied the pounding effect on the global response of structures at different levels of seismic hazard in order to establish mitigation solution using rubber shock absorber devices. In this study [10], the design codes limitations for the evaluation of the gap size between adjacent structures are presented and the need for adequate characterization of the correlation between displacement responses of nonlinear systems is stressed. In this research direction, a deterministic seismic assessment of the inter-story pounding effect at different levels of seismic demand is presented by Favvata [13]. For the examined interaction cases, the minimum required gap distances between adjacent RC structures have been evaluated taking also into account the local capacities of the columns that suffer the inter-story pounding effect.

Nevertheless, this study is focused on the probabilistic seismic assessment procedures that have been used so far for the evaluation of the pounding risk between adjacent structures [18-30]. Penzien [19] presented an analytical procedure to evaluate the separation distance that is required between two buildings to avoid seismic pounding. The procedure is based on equivalent linearization of non-linear hysteretic behavior. Based on the reliability methods and random vibration theory, Hong et al. [20] presented a procedure to evaluate the required separation distance with or without considering possible uncertainty in structural properties. Another numerical simulation approach to estimate the seismic pounding risk of adjacent buildings separated by a minimum code-specified separation distance during a certain period

has been presented by Lin and Weng [21]. The overall pounding probability of adjacent buildings was evaluated by combining the results of the seismic hazard analyses and the relations of peak ground acceleration and the conditional pounding probability. Lopez-Garcia and Soong [22] examined the accuracy of the Double Difference Combination (DDC) rule in predicting the separation necessary to prevent seismic pounding between linear structural systems. Furthermore, in 2009 the same authors [23] evaluated the accuracy of four different criteria to calculate the necessary separation against seismic pounding between nonlinear hysteretic structural systems. Tubaldi and Barbato [25], proposed a reliability-based procedure to evaluate the level of safety corresponding to a given value of the separation distance between adjacent buildings. The proposed procedure is used to estimate a) the probability of pounding between linear single-degree-of-freedom systems and b) the reliability of the design code's formula to define building separation distances.

In 2013, Tubaldi et al. [26] presented a probabilistic seismic demand model (PSDM) for pounding risk assessment suitable for use within modern performance-based design frameworks. For the purposes of their study, the case of two adjacent buildings modeled as single-degree-of-freedom systems with linear and nonlinear hysteretic behavior was considered and parametrically evaluated. An innovative reliability-based methodology for the design of the separation distance between adjacent buildings is proposed by Barbato and Tubaldi [18]. Several different buildings modeled as linear elastic single-degree-of-freedom (SDOF) and multi-degree-of-freedom systems, as well as SDOF nonlinear hysteretic systems are examined. The proposed methodology provides consistent safety levels for different building properties and different seismic hazard conditions.

Another probabilistic investigation of the structural pounding using a simplified two degree-of-freedom structural model was recently presented by Chase et al. [27]. In this study an attempt to include the column’s nonlinear behavior was presented. In Tubaldi et al [28, 29] linear and bilinear probabilistic seismic demand models PSDMs are proposed for the assessment of the pounding risk. Parameters such as, the seismic intensity measure IM and the model describing the EDP statistics given the IM are discussed and evaluated. Linear single-degree-of-freedom (SDOF) systems and nonlinear hysteretic multi-degree-of-freedom (MDOF) systems are considered. Finally, Naeej et al [30] presented a probabilistic evaluation of the separation distance between adjacent structures with equal heights by using bilinear elastoplastic SDOF systems. For this purpose, numerical models with varying structural models have been generated using a robust Monte-Carlo simulation.

The above review of the literature indicates that the probabilistic evaluation of the pounding problem is still in an early state of knowledge. Lack of relation attempts between the seismic performances of a real structure with the probabilistic assessment of the pounding effect still exists and more limitations are identified. So far, SDOF and/or MDOF linear elastic systems, as well SDOF nonlinear systems have been used. In most of the cases, the peak relative displacement between the adjacent structures has been examined as key parameter of the pounding risk, while the case of floor-to-floor pounding type has been considered.

Based on the above discussion, in this study a probabilistic assessment of the seismic pounding between adjacent structures at different global and local performance levels is attempted. The IDA method [31] has been employed to estimate the seismic global and local demand parameters of a multistory RC frame structure due to the pounding effect. The computer program Drain-2dx and the Matlab programming tool are used for the needs of this study.

2 EXAMINED POUNDING CASE

In this study the seismic performance of a real RC frame structure against pounding with an adjacent shorter and stiff structure is evaluated based on probabilistic assessment methods. The examined pounding case is an interaction case between an 8-story RC frame and a 3-story rigid barrier (very stiff structure). The story levels of the two adjacent structures have the same height so that collisions may occur between the story diaphragms and consequently between the story masses (floor-to-floor pounding type). The top level of the potential contact point of the adjacent structures is located at the 4th floor level of the 8-story frame. The assumption of using a rigid 3-story structure has been adopted in order the overall assessment of the pounding effect to be engaged only on the global and local responses of the 8-story frame. In a future study the characteristics of both adjacent structures could be the main topic under concern. In Eurocode 8 the minimum gap distance separation is defined at the top level of the potential contact point of the adjacent structures based on either the maximum relative displacement of both structures (using the Square Root of Sum of Squares – SRSS rule) or the maximum plastic displacement of the one building. For the examined interaction case according to the Eurocode 8 a minimum gap distance of 9.0 cm between the 8-story frame structure and the 3-story rigid barrier is required in order to prevent the pounding at the 4th floor level. In order to incorporate the separation gap distance between the two structures, as a key parameter of this study three different initial gap distances (d_g) are considered, namely $d_g = 0.0$ cm (structures in contact from the beginning), $d_g = 4.5$ cm and $d_g = 9.0$ cm (Eurocode's requirement). The seismic performance of the 8-story structure without the pounding effect is also included for comparison reasons.

3 DESIGN OF 8-STORY RC FRAME STRUCTURE

The 8-story frame structure was designed according to Eurocodes 2 and 8, meeting the Ductility Capacity Medium (DCM) criteria of the codes. The seismic behavior factor for the frame was q=3.75. The mass was taken equal to M=(G+0.3Q)/g (where G gravity loads and Q live loads) and the design base shear force was equal to V=(0.3g/q)M. Reduced values of member moments of inertia (I_{ef}) were considered in the design to account for the cracking; for beams $I_{ef}=0.5I_g$ (where I_g the moment of inertia of the gross section) and for the columns $I_{ef}=0.9I_g$. Critical for the dimensioning of the columns proved to be in most cases the code provision, regarding the axial load ratio limitation $v_d \leq 0.65$ and in a few cases (columns of the upper stories) the code minimum dimensions requirements. Structure geometry and reinforcement of the columns of the 8-story RC frame structure are shown in Figure 1.

4 STRUCTURAL MODELLING

In this work, the computer program package Drain-2dx is used. The finite element mesh for the 8-story RC frame structure utilizes an one-dimensional element for each structural member, while two types of one-dimensional beam-column elements were used. For the simulation of the beams the common lumped plasticity model has been employed. This element considers the inelastic behavior concentrated in zero-length "plastic hinges" at the element's ends. For the columns of the structure a special purpose element of "distributed plasticity" type accounting for the spread of inelastic behavior both over the cross-sections and along the deformable region of the member length is adopted. More details can be found in Favvata [13]. Collisions are simulated using contact elements that become active when the corresponding nodes come into contact. The response of the contact element is described by: a) the negative direction of the X-axis that represents the condition that the buildings move away from each other and b) the positive direction of the X-axis that simulates the actual behavior of the structures in case there is a small gap distance (d_g) between them. It is possible that the structures move one towards the

other, but the displacements are small, and the existing gap is not covered. In this case the contact element remains non-active and the buildings continue to vibrate independently. In the case that the structures move one towards the other and the displacements bridge the existing gap or the structures are in contact from the beginning then the contact element responds as a spring with almost infinite stiffness [13].

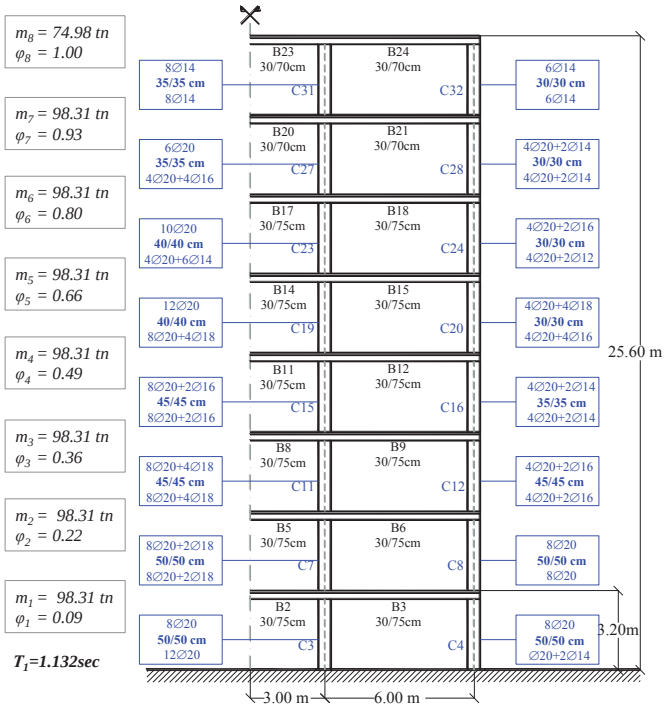

Figure 1: Examined 8-story RC frame structure.

5 KEY ASSUMPTIONS FOR THE PROBABILISTIC ASSESMENT OF THE POUNDING EFFECT

5.1 Probabilistic seismic demand model

A probabilistic seismic demand model is a mathematical relation between the structural response and the earthquake intensity measure (IM) [32]. The structural response is described through engineer demand parameters (EDPs) representing the global or the local responses of a structural system such as maximum interstory drift, moments, curvature, e.tc. On the other hand, the intensity measures (IMs) refer to ground motion characteristics that may be structural independed (PGA, PGV e.tc.) or structural depended ($Sa(T_1)$, $Sv(T_1)$ e.tc.). In order to develop the probabilistic seismic demand model (PSDM), EDP|IM pairs should be generated through nonlinear dynamic analysis. Statistical process of EDP|IM pairs synthesizes the PSDM. The mathematical representation of median structural demand response $\widehat{EDP}$ and the IM can be approximated by a two parameters power law model [33, 34]:

$$\widehat{EDP}|IM = a\, IM^b \tag{1}$$

The coefficients α and b are calculated through linear regression analysis of logarithm of IM and EDP, so the equation (1) is transformed to the following expression:

$$ln\,\widehat{EDP}|IM = b\, ln\, IM + ln\, a + \varepsilon|IM \tag{2}$$

where, ε|IM is the random error with mean zero and variance σ^2.

The structural response demand is assumed to follow lognormal distribution [33] with logarithm standard deviation $\beta_{EDP|IM}$ which is calculated by the following equation:

$$\beta_{EDP|IM} = \sqrt{\frac{\sum_{i=1}^{n}\left(ln\, EDP_i|IM - ln\,\widehat{EDP}|IM\right)^2}{n-2}} \quad (3)$$

The mathematical representation of the PSDM leads to a closed form solution that permits the definition of the fragility curves [34]. Each fragility curve describes, the probability a EDP to exceed the capacity $\hat{C}$ for a given IM and can be calculated as:

$$G_{EDP|IM}(C|IM) = P[EDP|IM \geq C|IM] = \Phi\left(\frac{ln\,\widehat{EDP}|IM - ln\,\hat{C}}{\beta_{EDP|IM}}\right) \quad (4)$$

$\Phi(.)$ denotes the standard normal cumulative function, $\hat{C}$ the median value of the capacity and $\beta_{EDP|IM}$ the logarithm standard deviation (eq. 3).

Nevertheless, it has also been shown that linear representation of PSDM is not always accurate to describe the structural response for entire range of IM [35-37]. Therefore, the adoption of a bilinear regression model especially for local EDPs seems to be more valid to capture the nonlinear behaviour of the structural members. The bilinear regression model can be described by the following expression:

$$ln\,\widehat{EDP}|IM = (a_1 + b_1\, ln\, IM)(1 - H_1) + [ln\, EDP|IM^* + b_2(ln\, IM - ln\, IM^*)]H_1 + \varepsilon|IM \quad (5)$$

The coefficients α_1, b_1 and b_2 are defined through linear regression analysis and determine the slope of the two linear branches. H_1 is a dummy variable which is equal to $H_1 = 0$ for $IM \leq IM^*$ and $H_1 = 1$ for $IM > IM^*$. Finally, the parameter IM^* is the intersection of two linear branches, while $ln\, EDP|IM^*$ is the value of the EDP at the intersection point.

5.2 Examined EDPs and IMs

The incremental dynamic analysis (IDA) method [31] has been used to define the seismic demands of the 8-story structure due to the pounding effect. In this way the necessary EDPs sample are accomplished as a function of the intensity measure (IM) that has been selected for the assessment. For this purpose, four different EDPs are evaluated: a) maximum interstory drift (IDR_{max}), b) maximum top drift (TDR_{max}), c) rotational demands θ of the columns of the 8-story frame and d) maximum curvature ductility demands $\mu_{\varphi,max}$ of the external columns at the pounding side of the frame.

The commonly used intensity measures (IMs) of peak ground acceleration (PGA) and that of spectral acceleration corresponding to the fundamental period of the 8-story frame Sa ($T_{1,8\text{-story}}$) are considered in this study. Both components of seven different seismic excitations (totally 14 records) extracted from the PEER's database [40] are used with each IM to be scaled in the range of 0.005g to 1.4g. Thus, a total number of 1348 inelastic dynamic analyses have been performed. The characteristics of the seismic excitations are presented in Table 1.

In this study, the global EDPs of IDR_{max} and TDR_{max} seem to conform better with the linear regression model. Figure 2 shows the median structural response of the RC frame in terms of IDR_{max} and TDR_{max} for linear PSDM and for the examined cases of "without pounding effect" and "d_g = 0.0 cm". On the other hand the local demand of maximum curvature ductility $\mu_{\varphi,max}$ seems to be expressed more accurate through a bilinear model. In Figure 3 the PSDMs of the external column C20 as a function of the two IMs by using linear and bilinear regression model are presented for all the examined pounding cases. As breakpoint of the bilinear demand models

is considered the $\mu_{\varphi,max} = 1.0$ that represents the transition from linear ($\mu_\varphi \leq 1.0$) to nonlinear behaviour ($\mu_\varphi > 1.0$).

Furthermore, in the probabilistic methods the selection of the IM should verify the criteria of efficiency and sufficiency [38]. An efficienct IM reduces the variation in estimation of the

structural demand for a give IM. The efficiency can be quantified by using the logarithm standard deviation $\beta_{EDP|IM}$. A sufficient IM indicates that it is conditionally independed of ground motion characteristic such as Magnitude (M_w) and source-to-source distance (R) [38], [39]. Adopting a sufficient IM avoids potentially biased in the calculation of the fragility curves. The sufficient of an IM is quantified through linear regression analysis of the residuals $\varepsilon|IM$ from PSDM and M_w or R through corresponding p-value. A small p-value (less than a cut-off value of 0.05) indicates that regression is statistically significant and the IM is insufficient. The IMs of this study have also been evaluated in terms of sufficiency and efficiency and indicative results are presented in Table 2, for global EDPs. For all the examined cases of this study, it has been observed that the dispersion of the regression models is lower in the case of Sa than in the case of the PGA. Figure 4 displays the variation of dispersion of the examined IMs for linear PSDM (LPSDM) and bilinear regression PSDM (BPSDM) for the local EDP of $\mu_{\varphi,max}$ of column C20. It is observed that the dispersion in the elastic range is significant lower than the inelastic one. Both IMs exhibite lower dispersion at the first branch of BPSDM while the nonlinear behaviour of the structural member tends to reduce the efficiency of the model.

On the other hand, Figure 5 shows p-values of bilinear PSDMs of PGA and Sa for the examined pounding cases. The results show that the null hypothesis for the significance of the regression cannot be rejected in the case of Sa. The p-values corresponding to PGA are lower than the cut-off value of 0.05 indicating that is statistically depended of ground morion characteristics.

5.3 Examined performance levels - PLs

The probabilistic evaluation of the pounding effect is performed through fragility curves in terms of EDP|IM. Each fragility curve represents the probability of exceeding a particular performance level (PL) that corresponds to a specific value of EDP as a function of the IM. Thus, the fragility curves of this study are developed based on different structural global and local performance levels. In this direction, the next four global performance levels are chosen to be examined for the IDR_{max} and TDR_{max} demand parameters [41]:

(i) the level of immediate occupancy (IO) that corresponds to a maximum interstory drift equal to 1% of the story height (h_{st}) (ATC-40: IO level; 1% drift),
(ii) the level of life safety (LS) that corresponds to a maximum interstory drift equal to 1.5% of the story height (h_{st}) (ATC-40: LS level; 1.5% drift),
(iii) the level of collapse prevention (CP) that corresponds to a maximum interstory drift equal to 2.5% of the story height (h_{st}) (ATC-40: CP level; 2.5% drift) and
(iv) top drift equal to 1% of the total height of the structure (H_{tot}).

Assuming that the most critical column controls the global state of the structure two more structural performance levels in terms of rotational criteria are also examined: (a) Significant Damage (SD) level when the rotation at any column exceeds the 75% of the ultimate rotation θ_u , and (b) Near Collapse (NC) level when the rotation at any column exceeds the ultimate rotation θ_u . The ultimate rotation (θ_u) of the critical each time column of the structure is evaluated based on the recommendations of Eurocode 8 - part3 [42].

Finally, the local curvature ductility capacities ($\mu_{\varphi\text{-}PL}$) of the external columns of the 8-story RC frame have been estimated for three different performance levels (PL) of near collapse (NC), significant damage (SD) and damage limitation (DL) (Eurocode 8-part3, [42]).

6 RESULTS

In Figure 6, the probability of exceeding a pre-defined displacement the floor level of the 8-story building that layes at the top level of the contact point with the 3-story rigid structure is evaluated. As pre-defined displacement limit is considered the initial gap distance d_g between the adjacent structures. The examined interaction cases are: $d_g = 0.0$ cm, $d_g = 4.5$ cm, $d_g = 9.0$cm and $d_g = 50$ cm (without pounding). It can be observed that the 8-story frame is more vulnerable

to pounding with the adjacent shorter and stiffer structure as smaller the initial separation gap distance between them is. Thus, considering a probability of pounding between the examined structures equal to 60%, an earthquake intensity of 0.25g is critical when $d_g = 4.5$ cm, while in case of $d_g = 9.0$ cm the critical IM value is 0.55g.

A different approach provides that for an earthquake intensity of Sa=0.3g the probability of pounding between the examined structures is about 80% for $d_g = 4.5$ cm while in case of d_g=9.0cm this probability is less than 10%.

In Figure 7 the fragility curves of the 8-story frame in terms of maximum interstory drift (IDR_{max}) are presented for all the examined interaction cases: (a) without pounding effect, (b) initial gap distance $d_g = 0.0$ cm, (c) initial gap distance $d_g = 4.5$ cm, (d) initial gap distance d_g=9.0 cm. Each fragility curve represents the probability that a particular performance level (PL) of IDR_{max} is exceeded as a function of the IM (PGA or Sa). In this study, three global performance levels have been chosen to be examined for the IDR_{max} demand parameter (section-5.3). It can be observed that the more exigent the performance level (PL) is, the fragility curves move towards greater values of IM. Moreover, in all the examined cases, the dispersion of the $IDR_{max}|IM$ values is reduced when the intensity measure Sa is used instead of the PGA. Similar observations also hold when the probability of exceeding a particular performance level (PL) of the maximum top drift (TDR_{max}) in the 8-story frame as a function of the IM, is estimated. Thus, in Figures 8 and 9 the effect of the pounding on the fragility curves of $IDR_{max}|Sa$, and $TDR_{max}|Sa$, are presented and discussed.

Figure 8 shows that in the case of earthquake-induced pounding, the 8-story frame has exhibited the same probability of exceeding a particular performance level (PL) of the maximum interstory drift (IDR_{max} - $\%h_{st}$), at a lower value of Sa in comparison to the case without the pounding effect. The probability for the 8-story frame to exceed a specific PL of IDR_{max} at the same Sa value is increased due to the pounding effect as the initial gap distance between the adjacent structure is decreased. Indicative results for Sa = 0.3g and Sa = 0.6g are pointed in Figure 8d. Moreover, the results of this study show that even in low values of earthquake intensity measures (e.g. Sa < 0.2g) the effect of the pounding between the two adjacent structures is depicted on the fragility curves of the 8-story frame in terms of $IDR_{max}|IM$.

On the other hand, the pounding effect is depicted on the fragility curves of the 8-story frame in terms of $TDR_{max}|IM$ when the value of the IM is greater than 0.6g (see Fig. 9).

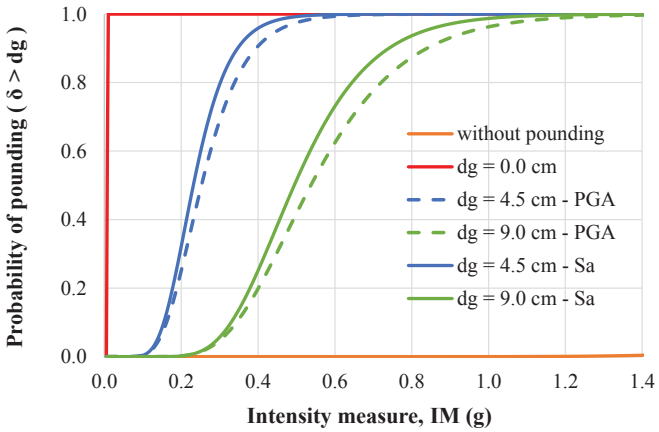

Figure 6: Probability of pounding the 8-story frame with the 3-story rigid barrier structure for initial gap distance (d_g) equal to: $d_g = 0.0$ cm, $d_g = 4.5$ cm, $d_g = 9.0$ cm and $d_g = 50.0$ cm (without pounding).

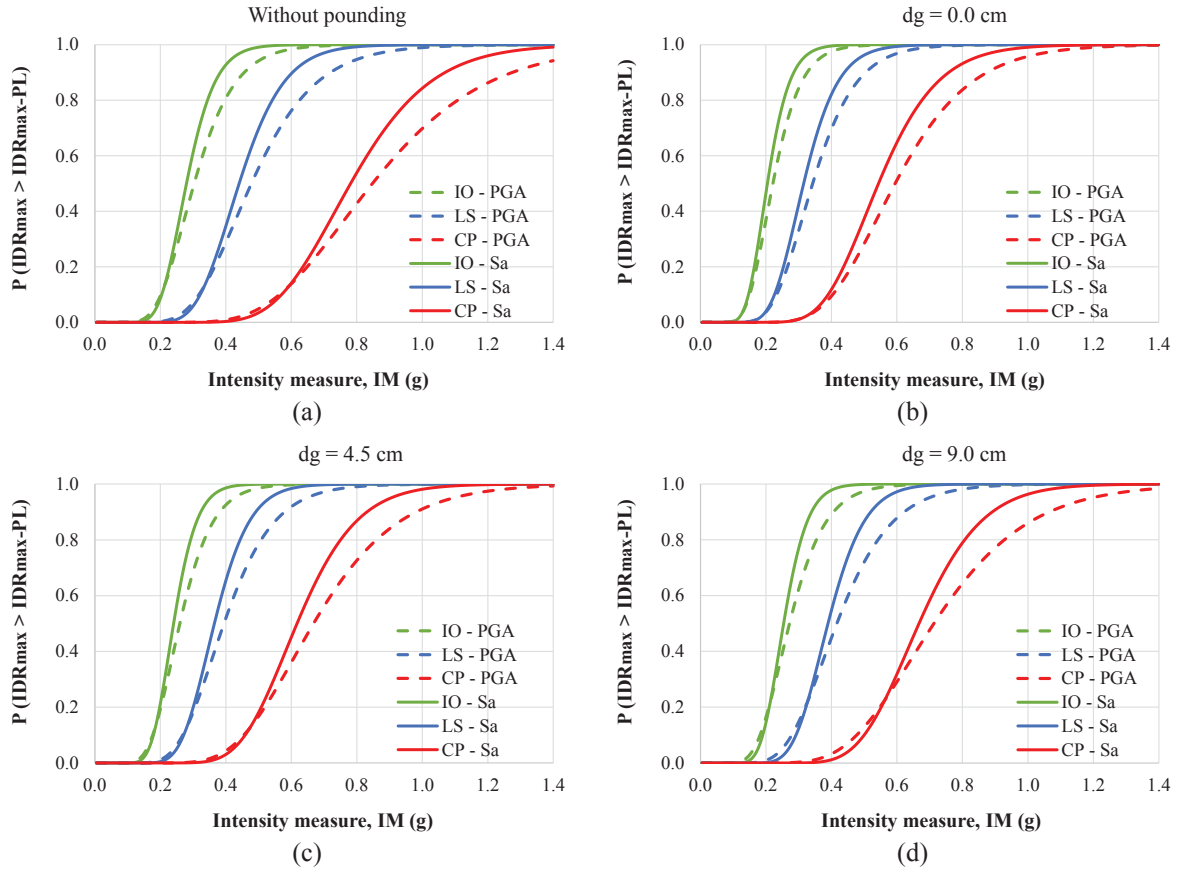

Figure 7: Probability of exceeding a particular performance level (PL) of the maximum interstory drift (IDR_{max} -%h_{st}) the 8-story frame as a function of the IM. Influence of the PL. Results are taken for intensity measure PGA and Sa. Fragility curves: (a) without pounding effect, (b) initial gap distance d_g = 0.0 cm, (c) initial gap distance d_g = 4.5 cm, (d) initial gap distance d_g = 9.0 cm.

Beneficial seems to be the influence of the pounding between the adjacent structures on the fragility curves of the 8-story frame in terms of $TDR_{max}|Sa$, when the two structures are in contact from the beginning d_g = 0.0 cm and Sa > 0.6g. As it can be observed in Figure 9, the 8-story frame has exhibited the same probability of exceeding the 1% of TDR_{max}, at a greater value of Sa due to the pounding effect (d_g = 0.0 cm).

The fragility curves of the 8-story frame that describe the probability of exceeding two different performance levels in terms of rotation at any column of the structure as a function of PGA and Sa, are presented in Figure 10. The examined performance levels are: (a) Significant Damage (SD) when the rotation θ at any column exceeds the 75% of the ultimate rotation θ_u, and (b) Near Collapse (NC) when the rotation at any column exceeds the ultimate rotation θ_u. The ultimate rotation (θ_u) of the critical each time column of the structure is evaluated based on the recommendations of Eurocode 8-part3. It can be observed that, the fragility curves of the 8-story frame in terms of θ|IM move towards a lower value of IM due to the interaction with the adjacent shorter and stiffer structure when compared with the fragility curves without pounding effect. Furthermore, the results in Figure 10 show that in the case of considering the two adjacent structures in contact from the beginning (d_g = 0.0 cm) the probability of exceeding the rotation limit that corresponds to a particular PL any column of the frame is significantly

increased due to the pounding, under the same value of IM, in comparison to the case of free vibration.

Fragility curves: (i) without pounding effect, (ii) d_g = 0.0 cm, (iii) d_g = 4.5 cm, (iv) d_g = 9.0 cm.

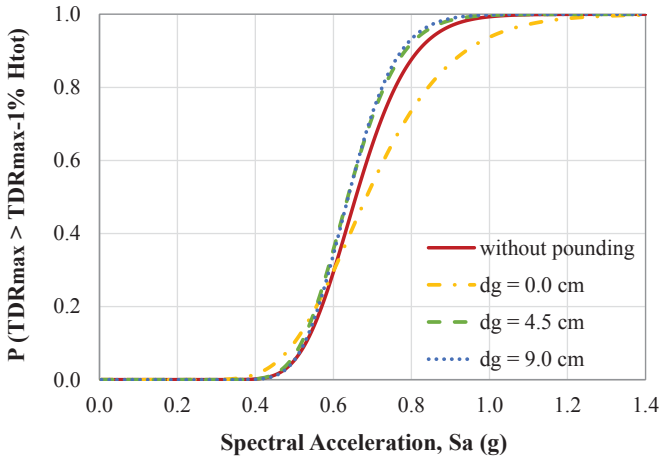

Figure 9: Influence of the pounding effect on the probability of exceeding the performance level (PL) of 1% maximum top drift (TDR$_{max}$- % H$_{tot}$) the 8-story frame as a function of the Sa. Fragility curves: (i) without pounding effect, (ii) d_g = 0.0 cm, (iii) d_g = 4.5 cm, (iv) d_g = 9.0 cm.

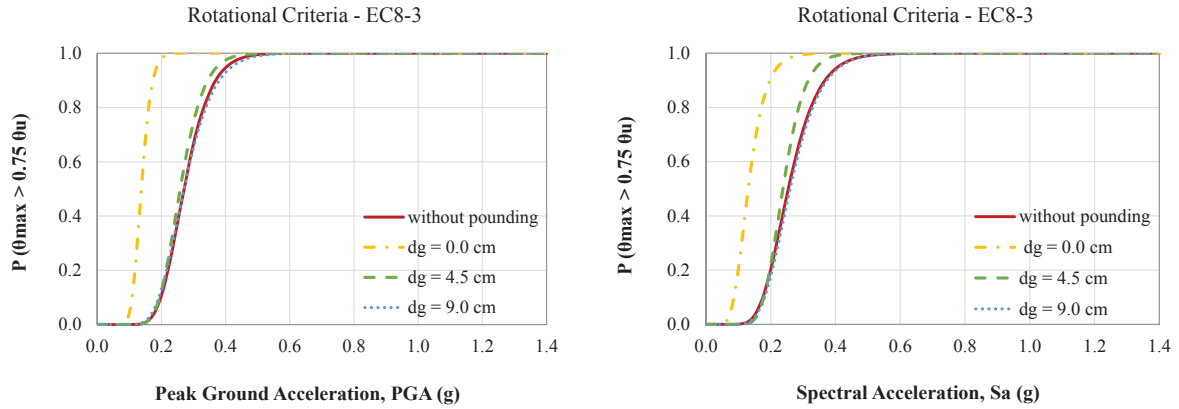
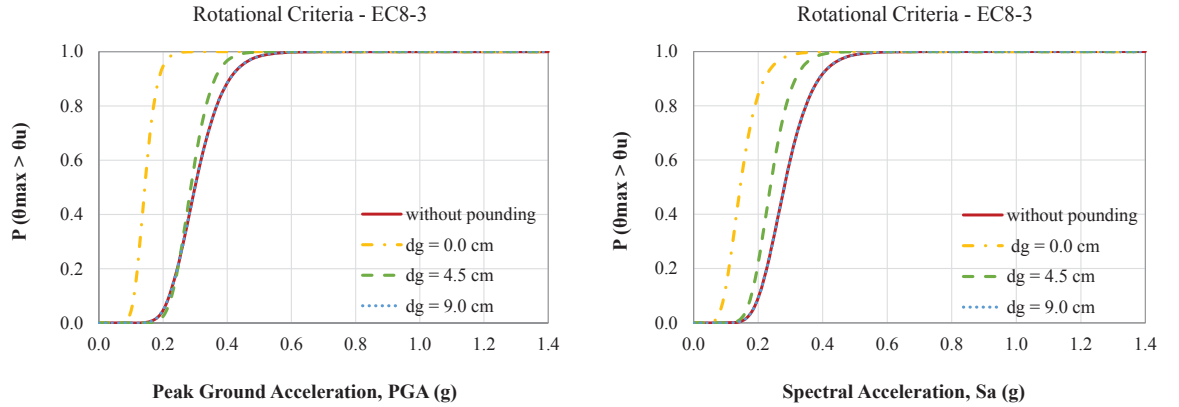


(a) Performance level of Significant Damage (SD)



(b) Performance level of Near Collapse (NC)

Figure 10: Influence of the pounding effect on the fragility curves of the 8-story frame at two different performance levels (PL) in terms of rotation θ requirements at any column of the frame as a function of the PGA and Sa. Fragility curves: (i) without pounding effect, (ii) d_g = 0.0 cm, (iii) d_g = 4.5 cm, (iv) d_g = 9.0 cm.

For example, in Figure 10b, for Sa = 0.2g the corresponding fragility curve indicates a probability value of 84% to exceed the rotation limit state of NC any column of the 8-story frame structure when d_g = 0.0 cm, while in the case without the pounding effect the corresponding probability is less than 10%. Also, the results in Figure 10 show that, for IM values greater than 0.4g the vulnerability of the frame is critical in terms of rotational demands of columns, since the examined performance levels have been exceeded, while the study of the pounding effect seems meaningless. Nevertheless, the results in Figure 11, indicate that this observation may lead to conservative solutions, as it is discussed below.

In this study, the local ductility requirements of the columns of the 8-story structure have also been incorporated in the probabilistic assessment of the pounding effect. For this purpose, fragility curves at each floor level of the 8-story frame in terms of maximum curvature ductility $\mu_{\varphi,max}$ of the external columns at the pounding side have been developed as a function of PGA and Sa. For each column the probability of exceeding the limit states of Near Collapse (NC), Significant Damage (SD) and Damage Limitation (DL) (Eurocode 8 - part3) is evaluated. Therefore, in Figure 11, indicative results about the influence of the pounding effect on the fragility curves in terms of $\mu_{\varphi,max}|Sa$ are presented. Based on these results it can be observed that for the examined 8-story RC frame structure with and without pounding problems critical is the local response of the columns at the top floor levels (C28 and C32). The fragility curves of these columns (C28 and C32) shift towards lower values of IM due to the pounding effect.

Vital seems to be the effect of the pounding on the local responses of the columns of the 5th and 6th floor level (C20 and C24) as it is demonstrated in Figure 11a. These columns are just above the top level of the contact point of the adjacent structures. The effect of the pounding on the fragility curves $\mu_{\varphi,max}|Sa$ of these columns at the performance level of DL can be evaluated within an earthquake intensity range of 0.2g to 1.0g. Similarly, in the cases of SD and NC performance levels the corresponding critical range is 0.2g to 1.4g. Moreover, when the separation gap distance between the structures is decreased the fragility curves shift towards to a lower value of IM. These observations contrast with the comments that have been deduced based on the results of Figure 10. Figure 11 illustrates that the pounding effect can be evaluated for intensity values greater than the 0.4g when the local ductility demands of the columns are considered.

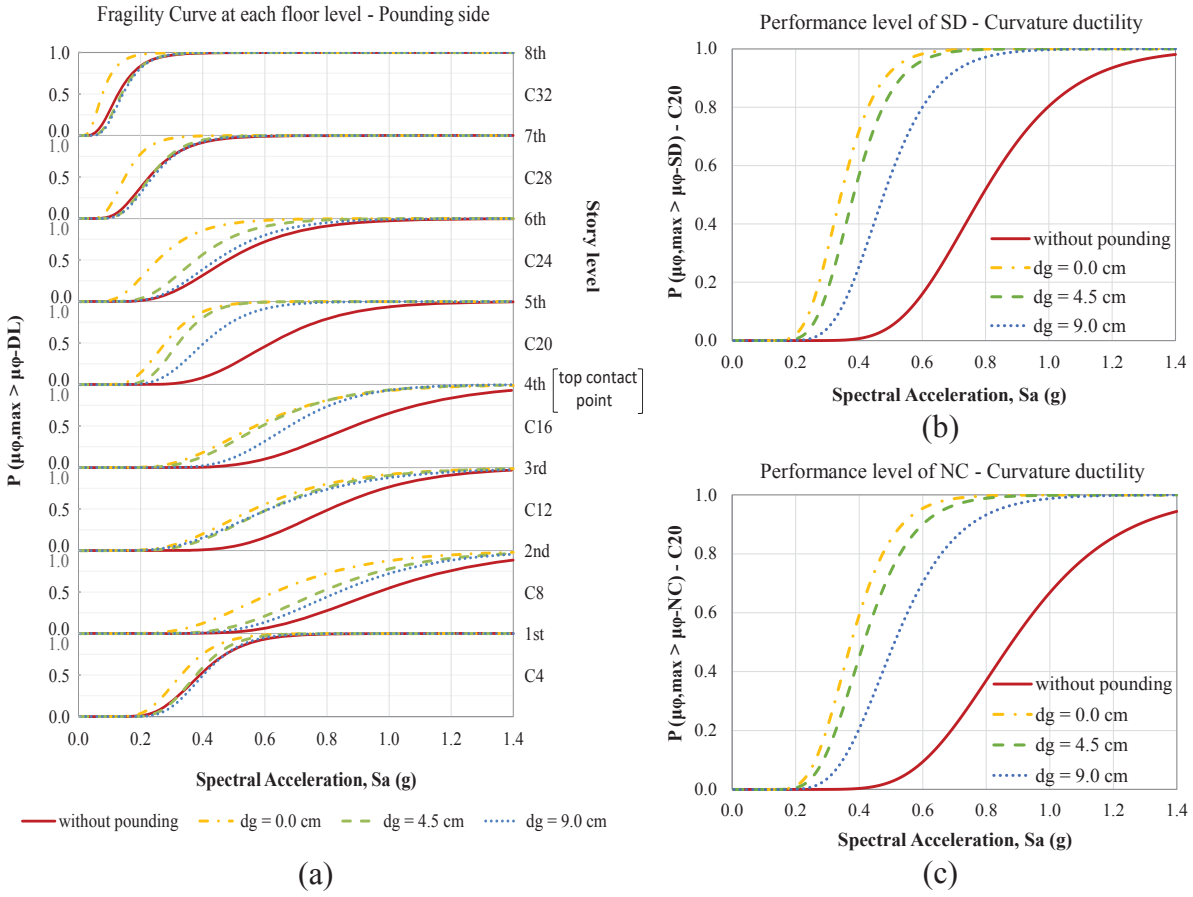


Figure 11: Influence of the pounding effect on the probability to exceed a particular performance level (PL) in terms of maximum curvature ductility $\mu_{\varphi,max}$, the external columns of the 8-story frame at the pounding side as a function of the Sa. Fragility curves: (i) without pounding effect, (ii) d_g = 0cm, (iii) d_g = 4.5cm, (iv) d_g = 9.0 cm.

Furthermore, it can be observed that for an earthquake intensity equal to 0.4g the probability of the external column C20 to exceed the curvature capacity at the performance level of DL is 48% when d_g = 9.0 cm. This probability is increased to 80 % for initial gap distance between the adjacent structures equal to 4.5 cm and to 88% for d_g = 0.0 cm. Similarly, for Sa=0.4g the probabilities of exceeding the rotation capacity at the level of SD the column C20 is 25%, 56% and 72% for d_g = 9.0 cm, d_g = 4.5 cm and d_g = 0.0 cm, respectively. In the case of NC these probabilities are decreased to the values of 20%, 45%, 59% for d_g = 9.0 cm, d_g = 4.5 cm and

d_g=0.0 cm, respectively. In all the examined cases of "without pounding effect" the column's response is elastic one (probability equal to zero) for Sa = 0.4g.

7 CONCLUSIONS

Based on the results of this study the following concluding remarks are noted:

- The 8-story frame is more vulnerable to pounding with the adjacent 3-story rigid structure as smaller the initial separation distance (d_g) between them is.
- The probability for the 8-story frame to exceed a specific global or local performance level at the same value of intensity measure (IM) is increased due to the pounding effect.
- The more exigent the performance level is, the fragility curves move towards greater values of intensity measure (IM).
- For the 8-story frame, the probability of damage due to the pounding effect can be gauged through the fragility curves at different global performance levels of IDR_{max} even for values of earthquake intensity less than 0.2g.
- For the examined global performance level of TDR_{max} the probability of damage due to the pounding effect can be evaluated only for values of earthquake intensity greater than 0.6g and only for d_g = 0.0 cm.
- The probability of damage due to the pounding effect for the global performance levels in terms of the local EDP rotation θ can also be assessed even for values of earthquake intensity less than 0.2g. Nevertheless, in this study for IM values greater than 0.4g the vulnerability of the frame is critical due to the increased rotational demands of columns.
- Finally, in case of incorporating the local performance levels of curvature ductility, the probability of damage due to the pounding effect is depicted in a wide range of earthquake intensity values and for all the examined d_g.

Keywords: Earthquake-induced landslides, RC framed buildings, Cumulative damage, Fragility analysis.

Abstract. *Earthquake-induced landslides are strongly dangerous secondary events of earthquakes, which every year cause huge losses around the world. In this paper, the structures at the toe of slopes subjected to the impact of landslides were considered. A probabilistic procedure developed in another paper is applied to two-story reinforced concrete building without infill walls. A method to evaluate cumulative damage to structures due to earthquake shaking and landslide impact was implemented through MATLAB. The variability in landslide-related loading, in terms of extension in plan and impact angle, was considered. A 2D frame was taken out from a 3D model and sequential response analysis was carried out on both models through OpenSees. Uncertainties were modelled through probability distributions of primary variables that mostly influence structural response, allowing the derivation of fragility curves via simulation. The probability of collapse was investigated under varying peak ground acceleration and impact velocity, which were considered as intensity measures for earthquake shaking and landslide impact, respectively.*

1 INTRODUCTION

Earthquake shaking can produce a number of secondary events such as tsunamis, fires, explosions, and landslides. The latter events are characterized by high destructive potential and can be distinguished in two categories according to their velocity: slow-moving landslides and flow-type landslides. The former mostly affect buildings located upstream of the slopes, as their structural response is influenced by differential settlements induced at the base of the structure [2]–[5]. By contrast, flow-type landslides are characterized by very high velocities and the damages to the structures are caused by their impact on building façades. Therefore, most of damage affects buildings located downstream of the slopes. Recent studies investigated the fragility of 2D structures impacted by flow-type landslides [6], associating structural damage with the velocity of the flow (v) that was assumed as intensity measure (IM) [7].

In this paper, the fragility of a reinforced concrete (RC) framed building located downstream of the slope and subjected to earthquake-induced landslide is discussed. Cumulative damage due to the seismic action and landslide impact was assessed through the proposed methodology. Furthermore, a 2D frame taken out from a 3D model was taken into account in order to compare its fragility curves to those obtained for the entire 3D model.

2 MODELING ASSUMPTIONS

The case study considered herein concerns a structure designed for gravity loads only, according to design criteria in force in Italy before 1971 [8]. The structural model adopted consists of two spans of equal length and two storeys with same height. A rigid diaphragm was assumed at each floor level, whereas the structure was considered fixed at the base. All columns have a square section, whereas the beams are characterized by a rectangular cross section. Infill walls were not considered in the capacity model, so the structure is totally bare, as shown in Figure 1 and 2. The 2D frame is located on the perimeter of the building, as highlighted by the red box in Figure 1.

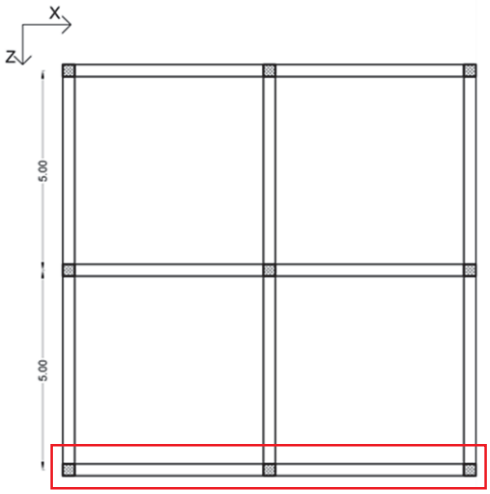

Figure 1. Building plan (dimensions in meters).

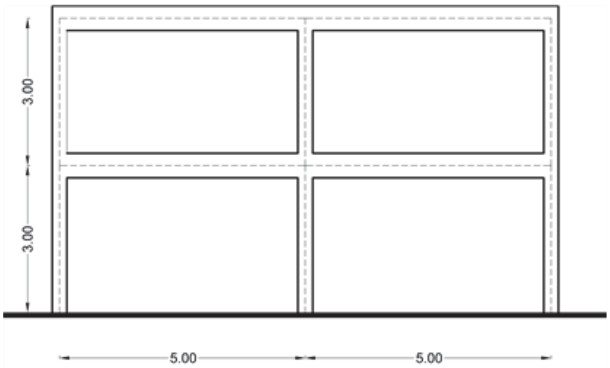

Figure 2. Building elevation (dimensions in meters).

Modelling criteria for seismic actions, landslide load and structural system, as well as the methodology adopted, are described in detail in the papers by Miluccio et al. [9] and Parisi et al. [6]. Figure 3 shows the landslide loads assumed, whereas Figure 4 represents the sequential analysis adopted to account for cumulative damage due to earthquake shaking and landslide impact. All analyses were carried out through OpenSees software [10].

The intensity of seismic shaking was measured through the peak ground motion (PGA), which is an IM well correlated with both damage to low-period structures and occurrence of earthquake-induced landslides (see e.g. [1], [11]).

It was assumed that the landslide velocity has a constant maximum value over a time span sufficiently long to cause the out-of-plane collapse of infill walls and subsequent impact on columns along both X and Z global axes.

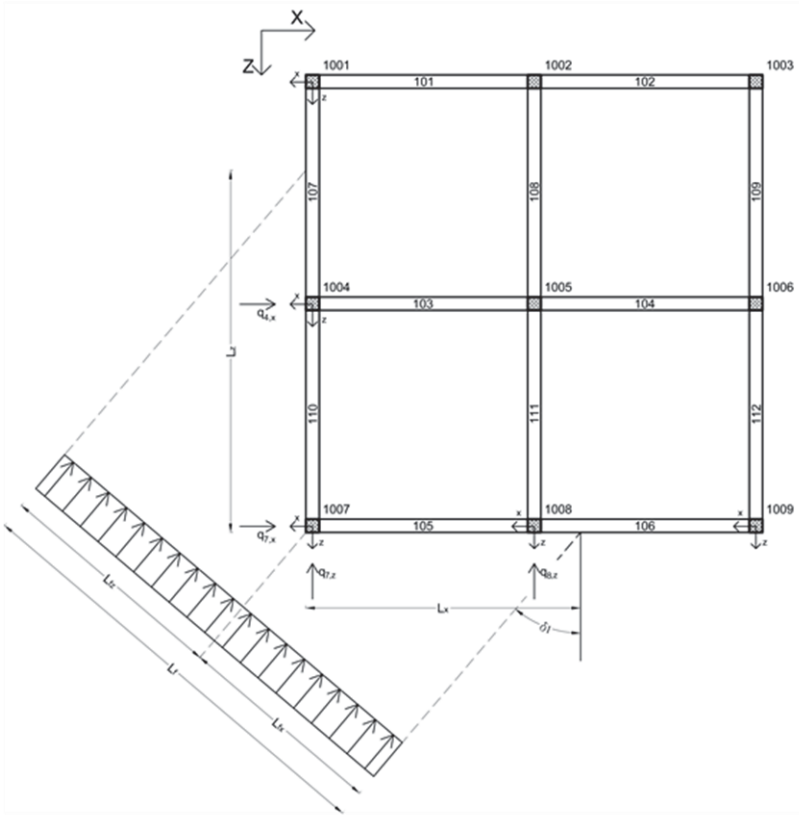

Figure 3. General scheme for diagonal landslide impact.

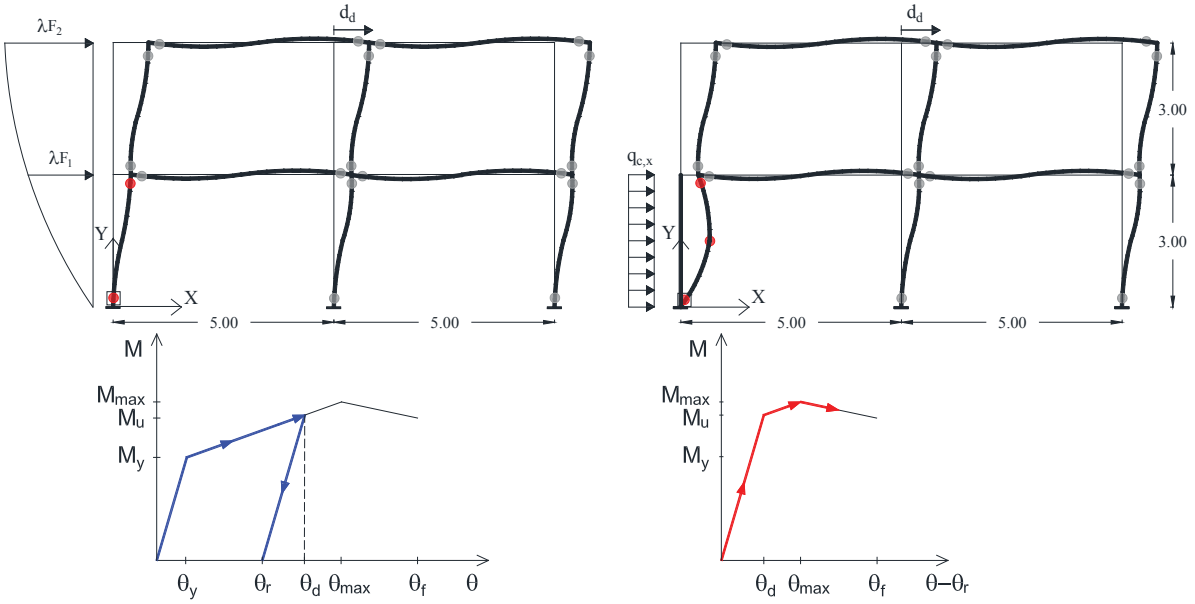

Figure 4. Sequential nonlinear modelling and analysis: (a) earthquake ground shaking; (b) landslide impact.

3 SENSITIVITY ANALYSIS

Sensitivity analysis was carried out in order to evaluate the influence of the earthquake parameters (PGA and ϑ) and landslide parameters (L_f and δ) on the structural response. A PGA equal to $0.1g$, $0.2g$ and $0.3g$ with an angle ϑ equal to 0°, 30° and 45° was assumed for the 3D model, whereas, in order to define landslide, three values of extension on plan L_f and angle δ were assumed. The L_f was defined equal to: d_b, $\sqrt{2}L$ and H_{col}, whereas the angle δ is equal to 0°, 30° and 45°. Where H_{col} is the section width of columns; L stands for the on-centre distance between consecutive columns (along either the X-axis or Z-axis of the building plan) and d_b is the diagonal of building plan. As regards the 2D frame, a value of ϑ equal to 0° and δ equal to 45° was assumed, considering different valued of PGA and L_f in order to define the level of damage linked to the seismic shaking and the different structural response linked to the involvement of a variable number of columns impacted by the landslide. Therefore, 81 loading scenarios were obtained for the 3D model and 9 scenarios for the two-dimensional model.

$PGA = 0.1g, 0.2g, 0.3g$ $\vartheta = 0°, 30°, 45°$		
	L_f [m]	δ
1	$\sqrt{2}H_{col}$	30°
2	$\sqrt{2}H_{col}$	45°
3	$\sqrt{2}H_{col}$	0°
4	$\sqrt{2}L$	30°
5	$\sqrt{2}L$	45°
6	$\sqrt{2}L$	0°
7	d_b	30°
8	d_b	45°
9	d_b	0°

Table 1. Loading scenarios for sensitivity analysis.

Due to the large amount of results, the scenario that underlines the difference in structural response in the case of 3D or 2D modelling was chosen.

Figure 3 shows the deformed shape of structure in the collapse condition and is characterized by a PGA equal to 0.2*g*. In both models, the plastic rotation demand in the plastic hinges is about 40% of total capacity. A soft-storey mechanism was developed and light red colour in Figure 3a represents the damage in the plastic hinges at the head and toe of the columns on the first level. That damage is typical of buildings designed for gravity loads only subjected to seismic shaking. Following the seismic action, the response of the structure impacted by the landslide was assessed, considering the cumulated damage. An extension of the landslide equal to d_b was defined, determining, in the 2D model, an impact of the landslide on the all columns of the first level. In the 3D model, the elements that does not impacted by the landslide help the entire structure to undergo much smaller displacements when load increases. That aspect is underlined in Figures 3a and 3b, by the difference between the deformation of the structure due to the seismic shaking (black dashed line) and landslide impact (blue solid line). In the 3D model the displacements induced by landslide are very small, with a shear collapse of the elements involved into landslide impact, whereas, the 2D structure exhibits much larger displacements, leading the elements to express a flexural type behaviour, with a collapse of the plastic hinges and reaching their ultimate rotation.

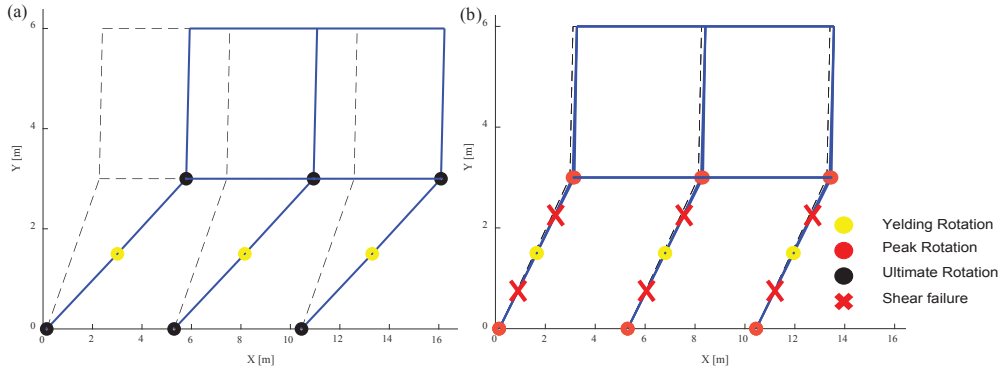

Figure 5. Near-collapse deformed shapes along X-axis considering cumulative damage under PGA = 0.2g, $\vartheta = 0°$, $\delta = 45°$ and $L_f = d_b$: (a) 2D Model; (b) 3D Model.

4 FRAGILITY ANALYSIS

The Monte Carlo procedure was implemented in the MATLAB® software [12] in order to carry out the fragility analysis. A number of 10^3 models was defined, assuming appropriate probability distributions regarding loads, geometries and materials [6]. For each realization, the procedure described in [9] was adopted for both 3D and 2D models.

The IMs defined, PGA and *v*, were assumed to range from: 0 to 0.6*g* with a step of 0.025*g* and 0 to 10 m/s with step of 1 m/s, respectively. The probability of collapse P_f was defined as the probability of reaching the ultimate rotation in the first plastic hinge of the columns at the first level, given a fixed value of PGA and *v*. P_f was assessed as the ratio between the number of cases that collapse to the number of total cases ($N_{sim} = 10^3$). Finally, the probability points obtained were fitted by a log-normal distribution [13].

The results obtained for the two models (3D and 2D) were showed in Figure 6 and in table 2, where the median values of the PGA (μ), the logarithmic standard deviation (β) and the distribution coefficient (R^2) are indicated. The fragility curves were extrapolated from the two sets of curves described above. It can be noted that for low speeds, the fragility of the 2D

model is slightly less than fragility of 3D model. As the speed increases, i.e. the damage linked to the landslide impact increases, the 2D structure has a much higher fragility than the three-dimensional model. In that case (i.e. medium-high value of v), PGA median values of 2D and 3D model are about 0.06g and 0.13g, respectively, for v = 7 m/s, whereas when v is equal to 10 m/s the median value of PGA for 2D model is 10 times smaller than 3D model. For v = 7 m/s there is an intersection between the curves of 2D and 3D models. When PGA has lower values, the damages linked to the landslide impact are higher and the two-dimensional model has a bigger fragility than the 3D one, whereas, with increasing PGA, the 3D model has a higher curve than the two-dimensional model, presenting a greater fragility towards the seismic shaking.

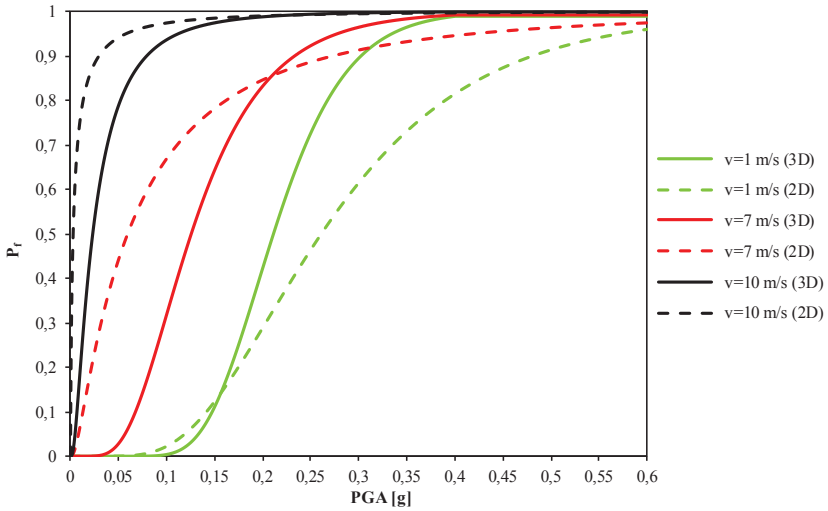

Figure 6. Fragility curves considering cumulative damage due to earthquake ground shaking and landslide impact: 3D Model (solid lines) and 2D Model (dash lines).

	3D Model			2D Model		
v [m/s]	μ [g]	β	R^2	μ [g]	β	R^2
1	0.21	0.28	0.98	0.26	0.48	0.98
7	0.13	0.48	0.79	0.06	1.19	0.89
10	0.02	0.96	0.92	0.003	1,85	0.71

5 CONCLUSIONS

The main goal of this study was the fragility assessment of RC framed buildings subjected to seismically-induced landslides, comparing the response of a 3D model with respect to a two-dimensional one. A sequential nonlinear analysis was implemented in order to consider the cumulated damage induced by seismic shaking and subsequently by the impact of the landslide. The rotation of the plastic hinges was considered as an engineering demand parameter.

The sensitivity analysis showed a totally different behaviour with regards to the two different models. By adopting a 3D model of the structure, the failure of columns was related with their shear collapse and appears to be concentrated in the elements impacted by the landslide.

In the case of a 2D model, the flexural collapse of the elements was reached, with a more distributed damage and the triggering of a soft storey mechanism for the global structure.

The fragility analysis showed a significant increasing in the vulnerability for the 2D structure in the case of medium-high velocities, whereas, for lower velocities, where the damage by earthquake shaking is predominant, the 3D structure has a greater vulnerability.

The study, whether the structure is taken through a three-dimensional model or through a simplified 2D model, shows a significant increase in the fragility considering the cumulative damage when landslide with medium-high velocities occurs.

ACKNOWLEDGEMENTS

This study was carried out in the framework of GRISIS research project (Gestione dei Rischi e Sicurezza delle Infrastrutture a Scala regionale) funded by Regione Campania.

Keywords: Earthquake-induced landslides, RC framed buildings, Cumulative damage, Fragility analysis.

Abstract. *Numerical studies and field missions have shown that seismically-induced slides and rock falls are secondary events of earthquakes with very high destructive potential. In many cases, the loss induced by the landslide phenomenon has significantly exceeded the impact of earthquake shaking. Recent studies proposed fragility models for 2D reinforced concrete (RC) framed buildings on the crest of the slope subjected to slow-moving landslide. In this paper, a new fragility model is proposed for RC framed buildings located downstream of the slope, and hence subjected to landslide impact loading. A two-storey structure, which was designed only to gravity loads, was selected as case study. According to Monte Carlo simulation method, one thousand realizations of the structure were randomly generated by considering uncertainties on both landslide parameters and structural properties. The peak ground acceleration was chosen as intensity measure (IM) for earthquake ground shaking, whereas the landslide impact velocity was selected as landslide IM. The novelty of this paper includes the consideration of (i) the uncertainty on landslide width and impact angle, and (ii) damage accumulation due to earthquake shaking and landslide impact. Both the generation of random load-capacity models and post-processing of analysis results were performed in Matlab, whereas sequential structural analyses were carried out with OpenSees. The inter-storey drift ratio was assumed as engineering demand parameter and two limit states were assumed, producing as many fragility curves of the structure.*

1 INTRODUCTION

Many secondary events are induced by ground shaking: fires, explosion, tsunami and landslides. In the literature, studies about damages due to earthquake-induced events were studied. Wang et al. [1] outlined huge damages to structural systems due to landslides produced by the 2008 Wenchuan earthquake in China. Many studies were carried out to develop fragility models for 2D reinforced concrete (RC) framed buildings on the crest of the slope (e.g. [2]–[5][3]). Damages were related to vertical and horizontal differential displacements of foundation soil. In the case of slow-moving earthquake-induced landslides, the peak ground displacement can be considered as intensity measure (IM), which can be correlated with peak ground acceleration (PGA) [6]. Actually, landslide-related settlements at base of the structure are the main cause of building collapse. More recent studies investigated the fragility of 2D structural models located downstream of the slope [7], in order to evaluate the behaviour of the structure impacted by landslide. In that case, flow-type landslides were considered, so structural damage was associated with impact velocity of the debris flow, which was then assumed as IM of fragility models.

In this study, a 3D structural model at the base of the slope was considered in order to define the fragility of RC framed buildings to fast-moving earthquake-induced landslides. Accordingly, ground shaking intensity was measured through PGA, whereas the impact velocity was chosen as IM for the landslide. Cumulative damage due to the sequence of earthquake shaking and landslide impact is simulated, considering the variability of both width and direction of the landslide in the building plan.

2 MODELLING OF LOADS AND STRUCTURE

2.1 Assumptions

The case-study building was assumed to be designed for gravity loads only, according to past Italian codes in force before 1971 [8][5]. The structural system is composed of two storeys and two bays per storey, with the same height and span respectively. Each floor system was modelled as a rigid diaphragm. Columns and beams were modelled with squared and rectangular cross sections. A rigid basement was considered at the base of buildings and soil-structure interaction was not taken into account. Infill walls were not considered in the capacity model of the structure, resulting in a bare framed system as shown in Figures 1 and 2.

The inelastic behaviour of frame elements was modelled in accordance to the lumped plasticity approach. Flexural-shear interaction and axial load-biaxial bending moment interaction were defined in line with Eurocode 8 (EC8) – Part 3 [10] and models available in the literature [11]–[12]. In addition to plastic hinges at element ends, a third plastic hinge was assigned to mid cross sections of first-storey columns, hence accounting for potential damage induced by the landslide impact.

Gravity loads were uniformly distributed over beams according to their tributary floor areas. PGA was chosen as IM for ground shaking, also because of its potential use in modelling the landslide occurrence conditioned upon earthquake intensity (e.g. [1] and [13][13]). Seismic performance assessment was carried out in terms of displacements according to EC8 [10]. The displacement capacity was derived through a nonlinear static (pushover) analysis of the structure, under varying incidence angle (ϑ) of seismic actions with respect to the global X-axis of building plan.

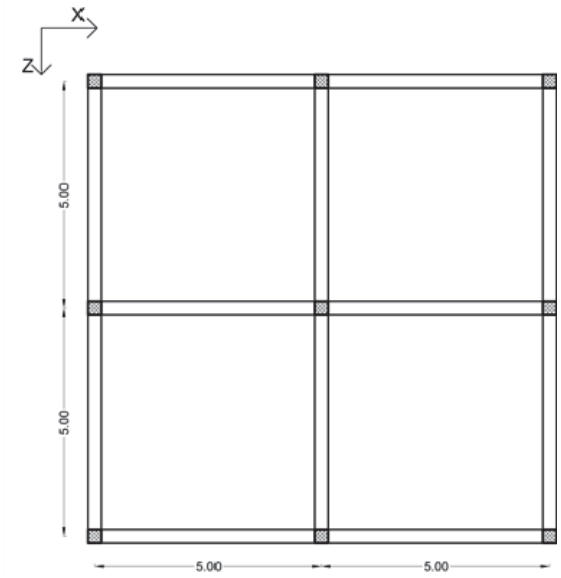

Figure 1. Building plan (dimensions in meters).

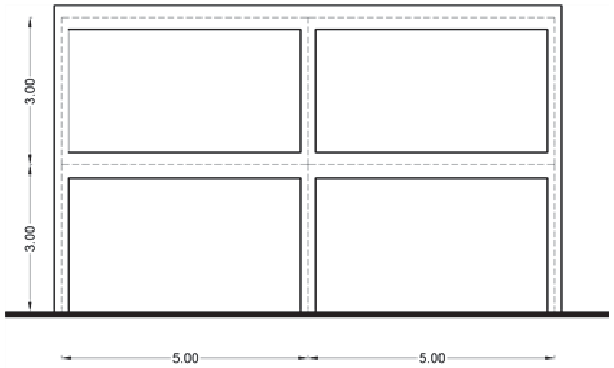

Figure 2. Building elevation (dimensions in meters).

The impact velocity of soil mass was chosen as IM for the landslide, according to many studies in the literature that define a relationship between structural damages and intensity of rapid landslides [14]. Impact loading was simulated through lateral pressures defined as sum of hydrostatic pressures and kinetic pressures, which are linearly and uniformly distributed over the height of columns, respectively. The earth-flow height was assumed between 0.5 and 1.5 times the inter-story eight. Therefore, the components of pressure along the axis of building plan were defined as follows:

$$p_{dx}(z_s) = \rho g(D - z_s) + \rho v^2 \cos^2 \delta \tag{1}$$

$$p_{dz}(z_s) = \rho g(D - z_s) + \rho v^2 \sin^2 \delta \tag{2}$$

where g = acceleration of gravity; D = flow depth; ρ = flow density; z_s = height of generic soil layer from the sliding surface of the flow; v = impact flow velocity; δ = angle between flow direction and perpendicular axis of impacted building façade ($\delta = 0$ in case of perpendicular impact). A variable size of the landslide in plan was considered. According to Parisi et al. [7], a uniform pressure distribution per unit length (p_{eq}) was defined to be applied on columns:

$$q_x = p_{eq} b_c \cos\delta \tag{3}$$

$$q_z = p_{eq} b_c \sin\delta \tag{4}$$

where b_c and h_c indicate the dimensions of column cross section along the X- and Z-axis of the building plan. Thus, landslide-related loading was modelled as uniformly distributed pressures both in plan and over the height of columns (Fig. 3).

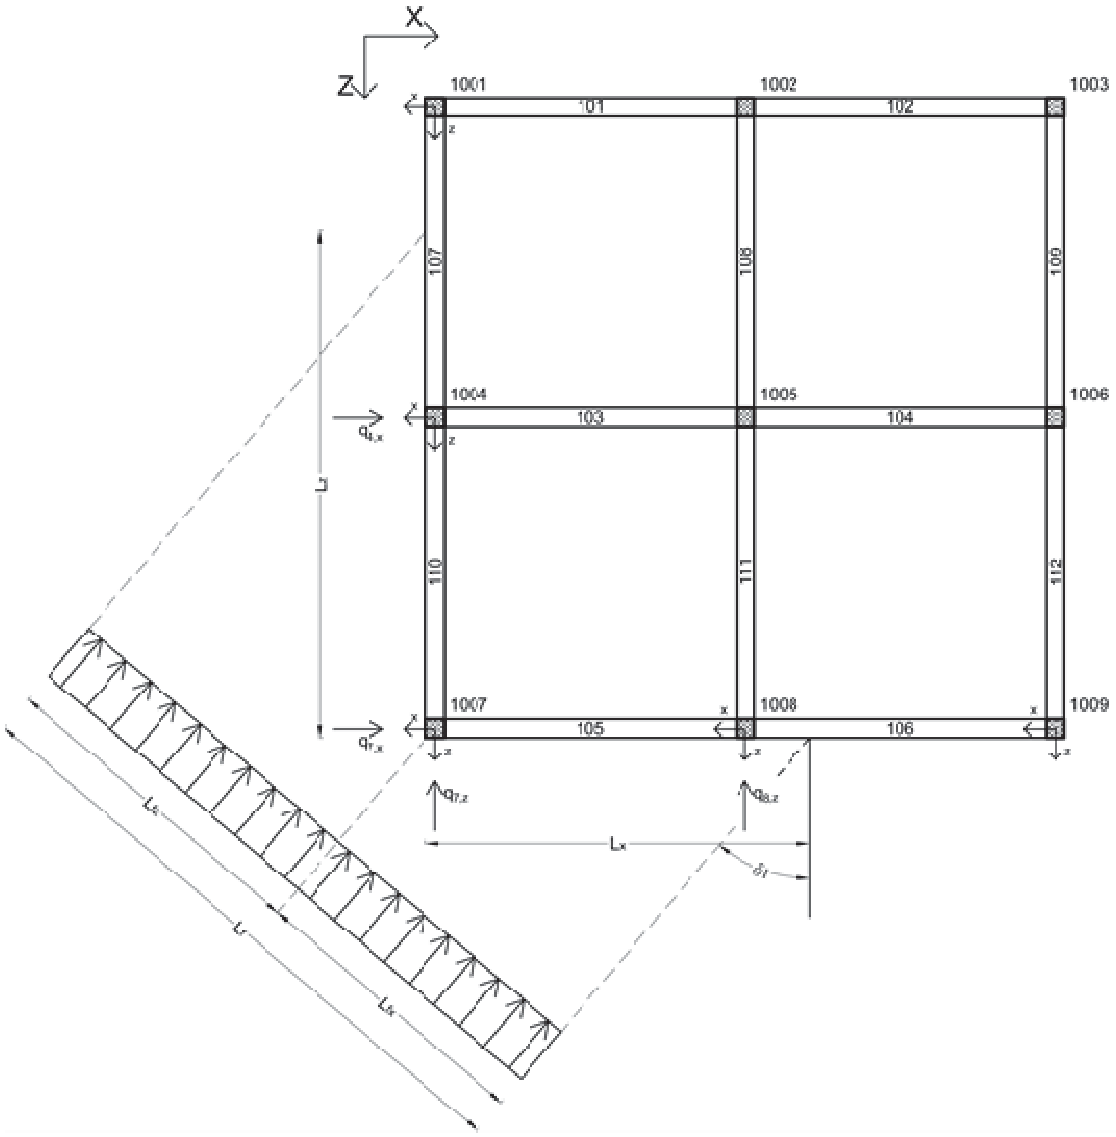

Figure 3. General scheme for diagonal landslide impact.

2.2 Procedure

An eigenvalue analysis was carried out with OpenSees® [15] to evaluate modal shapes and vibration periods of the elastic structure. The building symmetry produces the same first two modal shapes and periods along global axes. An inelastic model was developed in OpenSees® [15] according to the lumped plasticity approach and pushover analysis with displacement control was carried out to assess the effects of earthquake ground shaking on the building

structure. The N2 method was used to evaluate seismic displacement demand, considering the worst lateral force profile among those provided by EC8 - Part 3 [10][9]. Accordingly, the inelastic capacity of building was defined in terms of displacements, assuming structural collapse to be associated with the first occurrence of maximum chord rotation in a plastic hinge. In case displacement demand did not reach capacity, a degraded capacity model was defined to consider cumulative damage due to subsequent landslide impact. This was consistent with the assumption that landslide impact follows seismic shaking, hence allowing a sequential analysis. To that aim, a non-degrading stiffness model was adopted to define the unloading branch of moment-rotation diagrams of plastic hinges. A nonlinear static analysis with force control was then carried out to simulate landslide impact on the building façade. Figures 4a and 4b show the sequence of structural analyses performed for earthquake shaking and landslide impact.

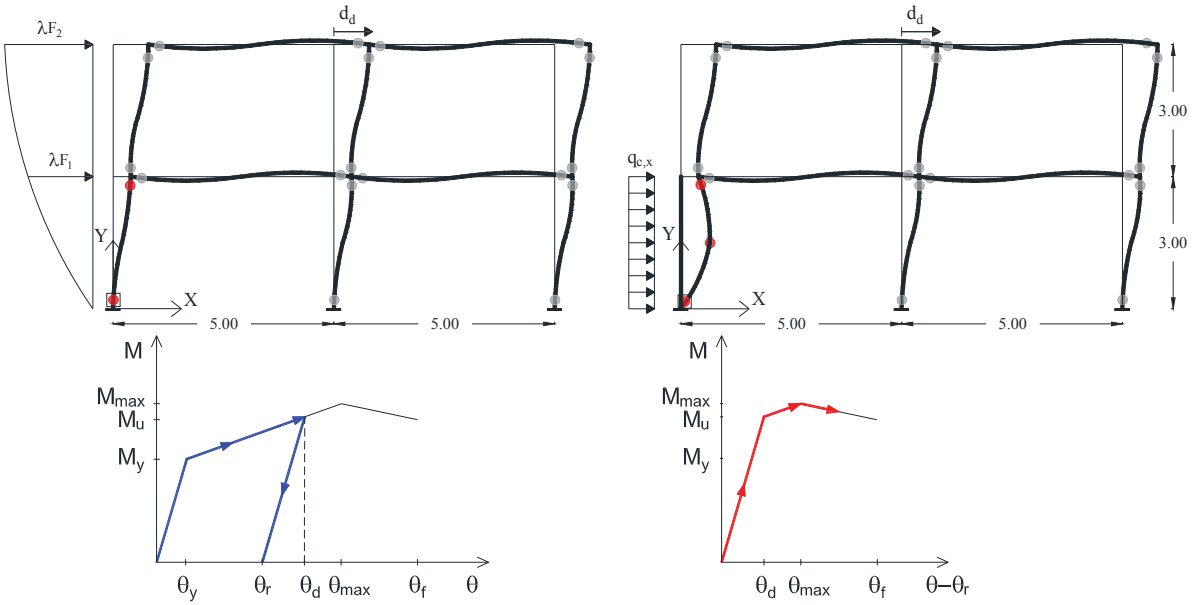

Figure 4. Sequential nonlinear modelling and analysis: (a) earthquake ground shaking; (b) landslide impact.

3 SENSITIVITY ANALYSIS

3.1 Methodology

The case-study building was parametrically analysed to investigate the influence of earthquake and landslide parameters on structural response. PGA was set to 0.1g, 0.2g and 0.3g, whereas the incidence angle of seismic action (ϑ) was assumed to be 0°, 30°and 45°. In terms of landslide parameters, three values of landslide width (L_f) and three values of landslide impact angle (δ) were considered. L_f was set to $\sqrt{2}H_{col}$, $\sqrt{2}L$ and d_b, where: H_{col} is the sectional width of columns; L stands for the on-centre distance between consecutive columns (along either the X-axis or Z-axis of the building plan); and d_b is the diagonal of building plan. δ was assumed to be 0°, 30° and 45°. By contrast, the height of landslide mass was set constant and equal to 3 m, i.e. the inter-storey height of the structure. Considering the variability of parameters indicate above, 81 scenarios were defined as shown in Table 1.

$PGA = 0.1g, 0.2g, 0.3g$ $\vartheta = 0°, 30°, 45°$		
	L_f [m]	δ
1	$\sqrt{2}H_{col}$	30°
2	$\sqrt{2}H_{col}$	45°
3	$\sqrt{2}H_{col}$	0°
4	$\sqrt{2}L$	30°
5	$\sqrt{2}L$	45°
6	$\sqrt{2}L$	0°
7	d_b	30°
8	d_b	45°
9	d_b	0°

Table 1. Definition of loading scenarios for sensitivity analysis.

For each scenario, the procedure described in Section 2.2 was adopted. Analysis results in terms of demand-capacity ratio (DCR), collapse velocity (i.e. the landslide velocity that leads the structure to collapse), and near-collapse deformed shape of the structure, are discussed below.

3.2 Discussion of results

The first set of sensitivity analyses were carried out to evaluate the variability of collapse velocity (v_c). Due to the huge number of scenarios and analysis results, only the output for scenarios with $\vartheta = 30°$ are described later on.

As the case-study building was designed only to gravity loads, its collapse mechanism can be governed by brittle shear failure of columns under lateral loading. Therefore, the influence of shear failure was investigated by assuming two different capacity models: (i) model with consideration of shear failure in columns of pre-damaged structure, namely the structure previously damaged under seismic ground motion; (ii) model without consideration of shear failure. In model (ii), the elements can suffer only a flexural failure, which was assumed to occur when chord rotation demand reached the maximum rotation capacity of plastic hinges.

Figures 5a and5b show the collapse velocity versus the landslide width under varying scenario in terms of landslide angle and PGA, for models (i) and (ii) respectively. In Figure 5a, the collapse velocity ranges between 7 and 8 m/s, showing a minor influence of damage due to earthquake shaking. The ground motion intensity causing structural collapse was $PGA_c = 0.3g$, as outlined by a horizontal line with $v_c = 0$ m/s. The collapse velocity drops when the landslide width is equal to the diagonal size of building plan, because more elements are involved in the collapse mechanism. Moreover, the scenario with frontal landslide impact (i.e. $\delta = 0°$) is characterized by the lowest values of collapse velocity.

Focusing on Figure 5b, the maximum velocity that the structure was able to withstand (with the smallest landslide width) is approximately equal to 15 m/s. In that case, if shear failure is not considered in the capacity model of the structure, columns develops a flexural behaviour up to the maximum chord rotation capacity (θ_{max}).

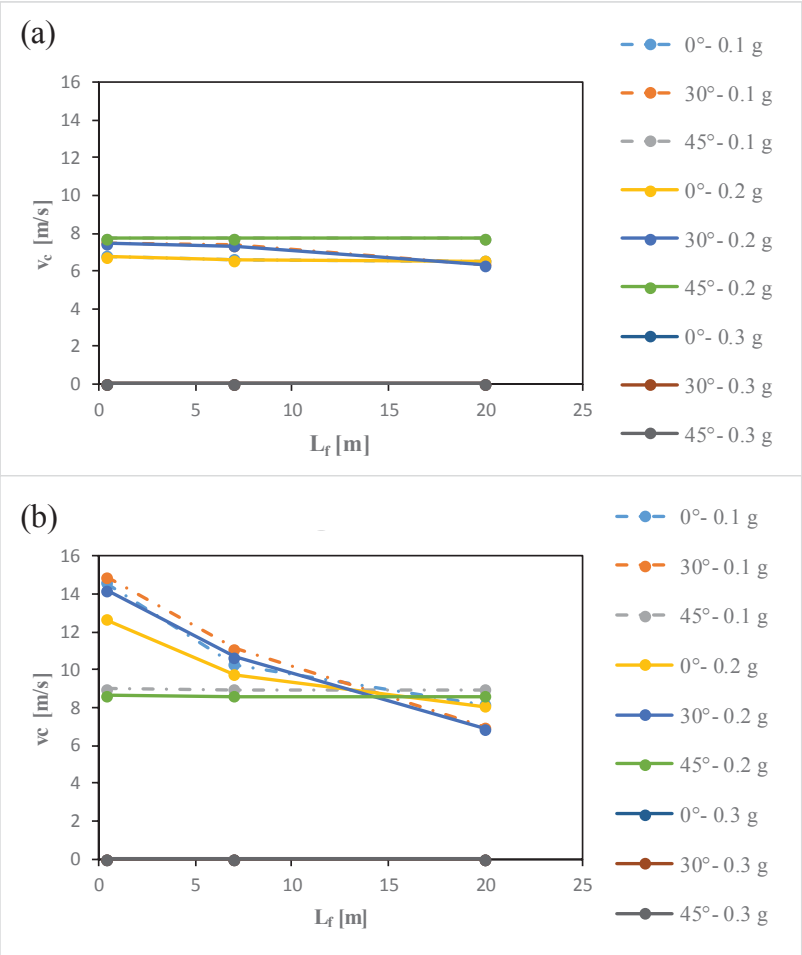

Figure 5. Influence of landslide width and impact angle on collapse velocity: (a) model with consideration of shear failure; (b) model without consideration of shear failure.

Moreover, the influence of damage due to earthquake shaking is more significant than that observed in Figure 5a. If shear failure of columns is considered, a limited number of columns are involved in the collapse mechanism, showing very low values of chord rotation. Conversely, if columns are assumed to develop their full flexural capacity and hence larger chord rotations (Fig. 5b), the influence of shaking-related damage increases.

Figures 6a–f show DCRs in first-floor columns under varying PGA and ϑ. Figures 6a, 6c and 6e are related to PGA = 0.1g, whereas the others to PGA = 0.2g. This motivates DCRs approximately equal to 50% in case of PGA = 0.2g, which are very higher than those predicted under the lowest PGA level. Scenarios with PGA = 0.2g produced very high levels of plastic rotation demand in columns, resulting in evenly distributed damage throughout the structure. This played a key role in nonlinear response of pre-damaged structure to subsequent landslide impact on perimeter columns.

Structural response to earthquake shaking is graphically represented by near-collapse deformed shapes in Figures 7a–f. Red-tagged plastic hinges outline the attainment of ultimate chord rotation, and hence element failure. The direction of seismic shaking has major influence, as evidenced by comparison between Figures 7a–b, 7c–d and 7e–f, which are respectively related to ϑ = 0°, ϑ = 30° and ϑ = 45°. Figures 6b, 6d and 6f show that DCRs increase by 10% when the earthquake shaking angle increases from 0° to 30° and 45°. In all cases, the structure suffered a soft-story mechanism as typical collapse mechanism of structure designed for gravity loads only without seismic detailing.

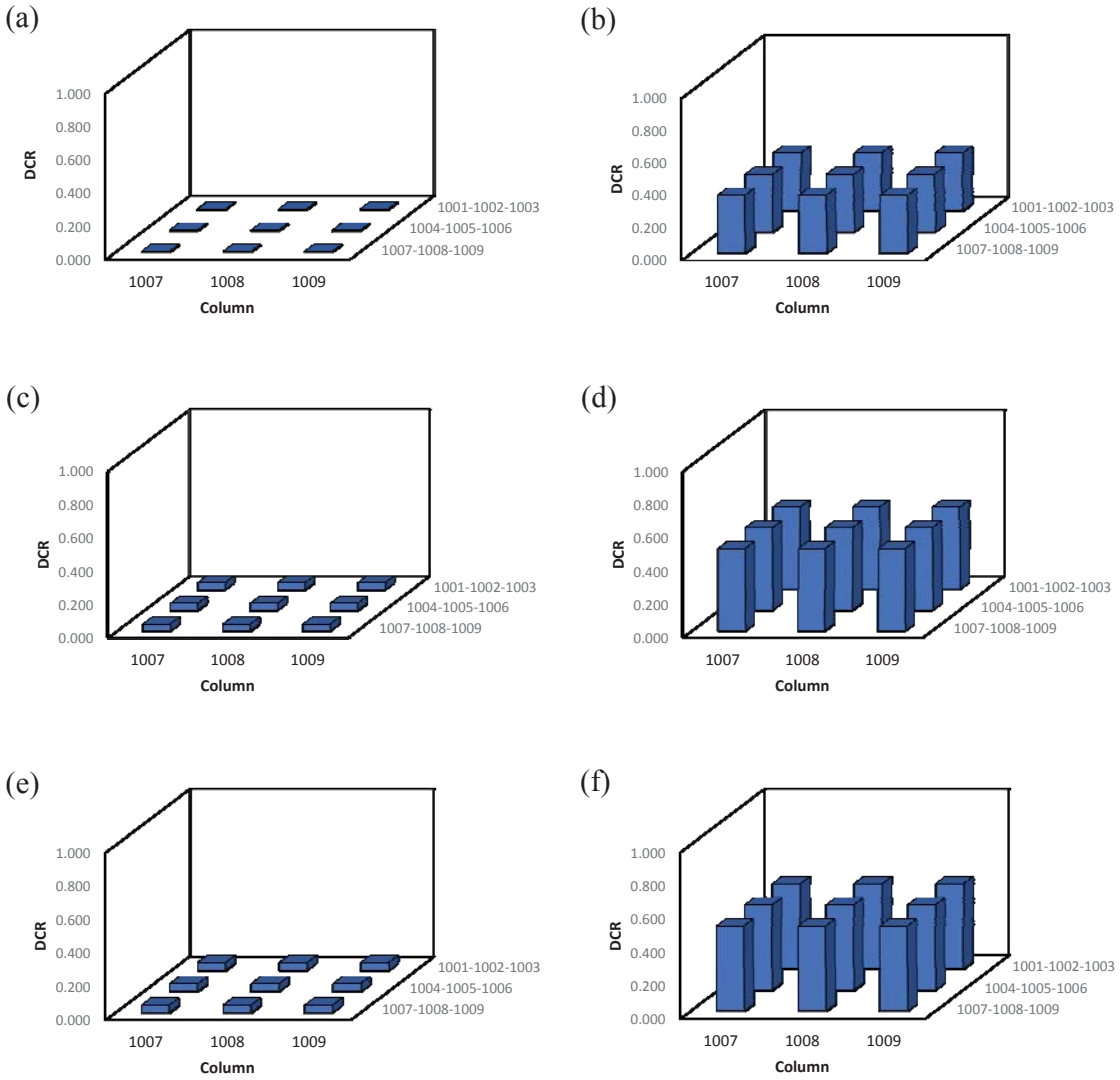

Figure 6. DCR for first-floor columns under varying PGA and ϑ: (a) PGA = 0.1g – ϑ = 0°; (b) PGA = 0.2g – ϑ = 0°; (c) PGA = 0.1g – ϑ = 30°; (d) PGA = 0.2g – ϑ = 30°; (e) PGA = 0.1g – ϑ = 45°; (f) PGA = 0.2g – ϑ = 45°.

It is noted that lateral displacements were amplified to better show collapse mechanisms. According to the procedure described in Section 2.2, a nonlinear static analysis with force control was run to simulate landslide impact on building façade considering shaking pre-damage predicted through seismic pushover analysis. DCRs are depicted in Figures 8a and 8b for capacity models neglecting and considering shear column failure, respectively. For the sake of brevity, analysis results shown in those figures are related to a selected scenario, i.e. the loading case defined by $\vartheta = 30°$, $\delta = 30°$ and $L_f = d_b$.

If Figure 8a is considered, the huge value of landslide width (L_f equal to the diagonal of the building plan) and the angle of landslide flow produced a collapse mechanism involving all columns located at the first floor level. Thus, plastic hinges reached the maximum chord rotation capacity and a soft-storey mechanism developed. By contrast, the inclusion of shear column failure in the capacity model induced a strongly different collapse mechanism, which mostly involved only the perimeter columns impacted by the landslide. In that case, structural collapse was reached under low levels of plastic rotation demand as a consequence of high shear force levels. Moreover, when PGA = 0.1g, damage due to earthquake shaking was very slight, with no influence on structural behaviour.

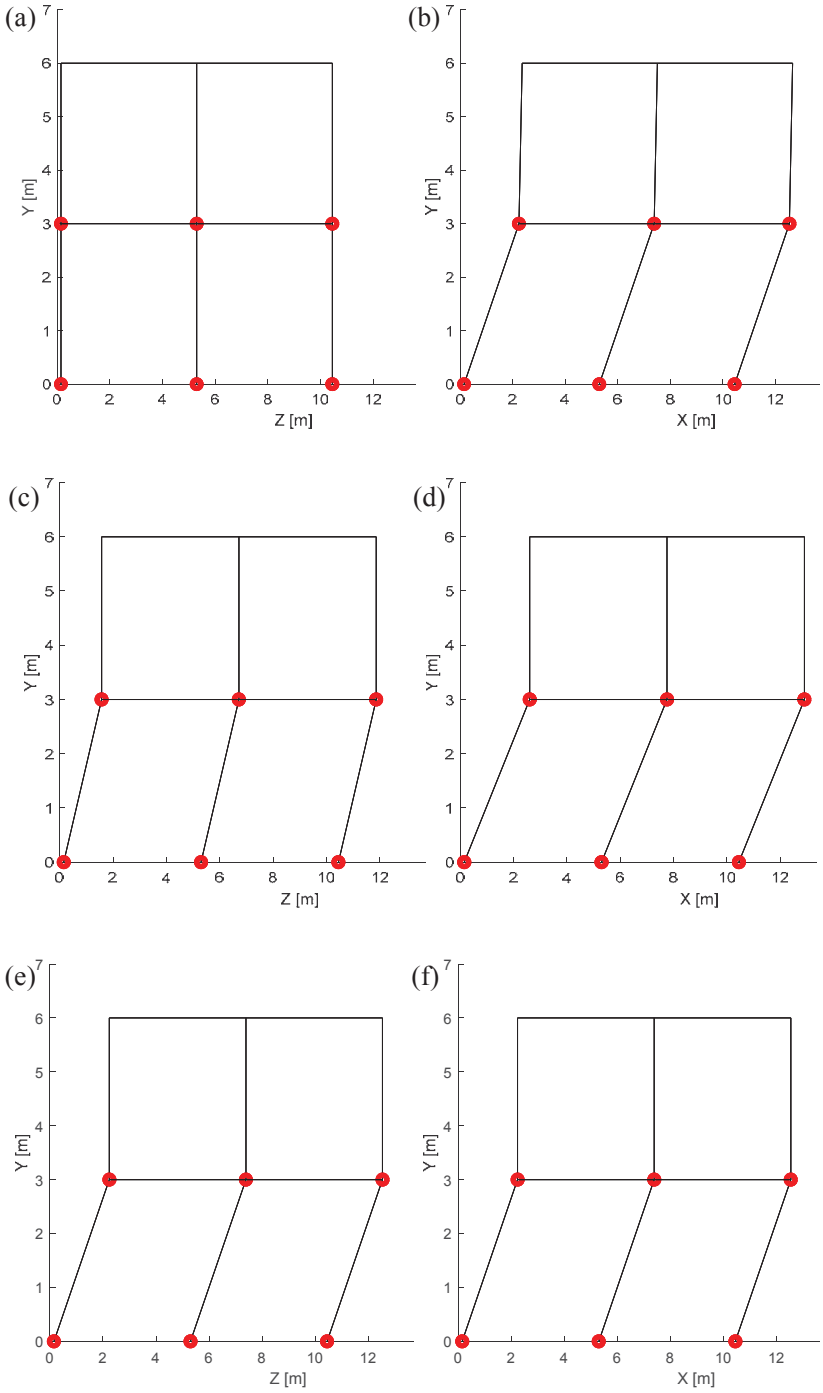

Figure 7. Near-collapse deformed shapes along Z- and X-axis due to earthquake shaking under PGA = 0.2g and different ϑ values: (a) Z-axis – $\vartheta = 0°$; (b) X-axis – $\vartheta = 0°$; (c) Z-axis – $\vartheta = 30°$; (d) X-axis – $\vartheta = 30°$; (e) Z-axis – $\vartheta = 45°$; (f) X-axis – $\vartheta = 45°$.

The DCR distribution in Figure 8b is described by near-collapse deformed shapes in Figure 9a–d, which schematically represent near-collapse deformed shapes due to cumulative damage after seismic shaking and landslide impact under PGA ranging from 0.1g to 0.2g. Dashed black lines indicate displacements due to earthquake shaking only, whereas solid blue lines represent final displacements after landslide impact. The latter produced the achievement of shear failure in columns, resulting in a soft-storey mechanism.

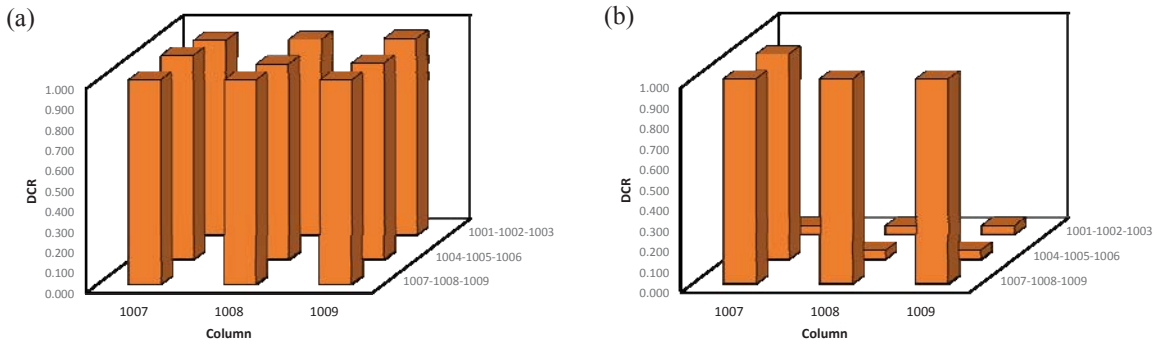

Figure 8. Cumulative DCR for first-floor columns under PGA = 0.1g, $\vartheta = 30°$, $\delta = 30°$ and $L_f = d_b$: model without consideration of shear column failure; (b) model with consideration of shear column failure.

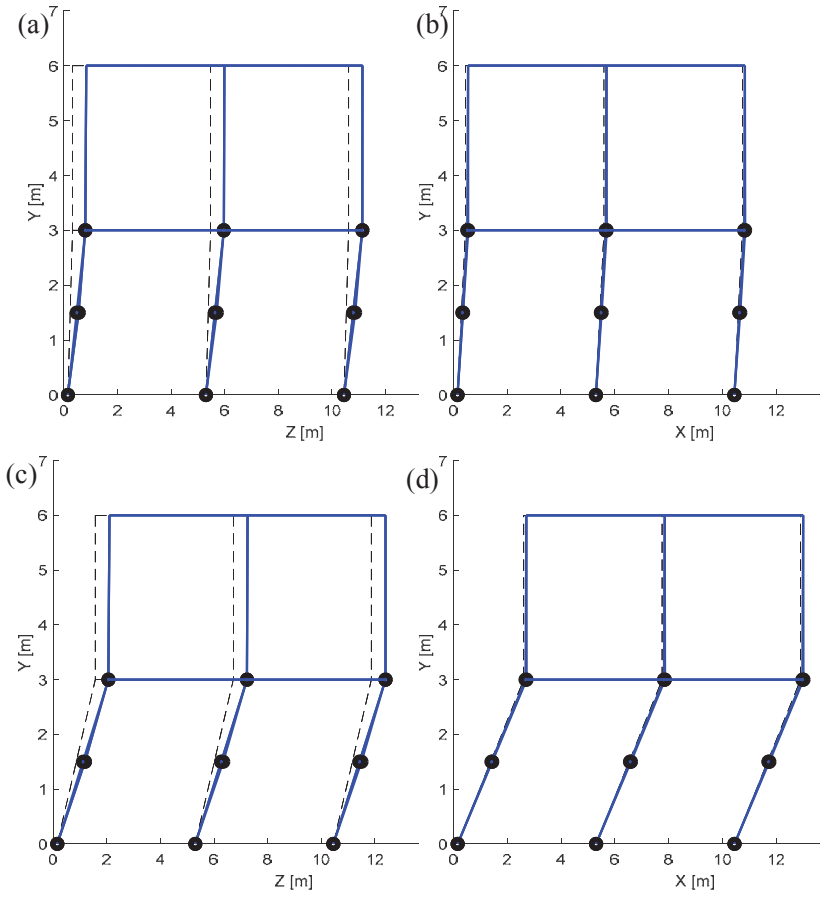

Figure 9. Near-collapse deformed shapes along Z- and X-axis considering shear column failure and cumulative damage under $\vartheta = 30°$, $\delta = 30°$, $L_f = d_b$: (a,b) PGA = 0.1g; (c,d) PGA = 0.2g (dashed black lines indicate displacements due to earthquake shaking; solid blue lines indicate total displacements after landslide impact).

4 FRAGILITY ANALYSIS

4.1 Methodology

The fragility analysis of the case-study building was carried out following the procedure summarised in Figure 10. Uncertainties in materials, geometry, loads and capacity model were defined through random variables with continuous probability distributions used in a previous study [7].

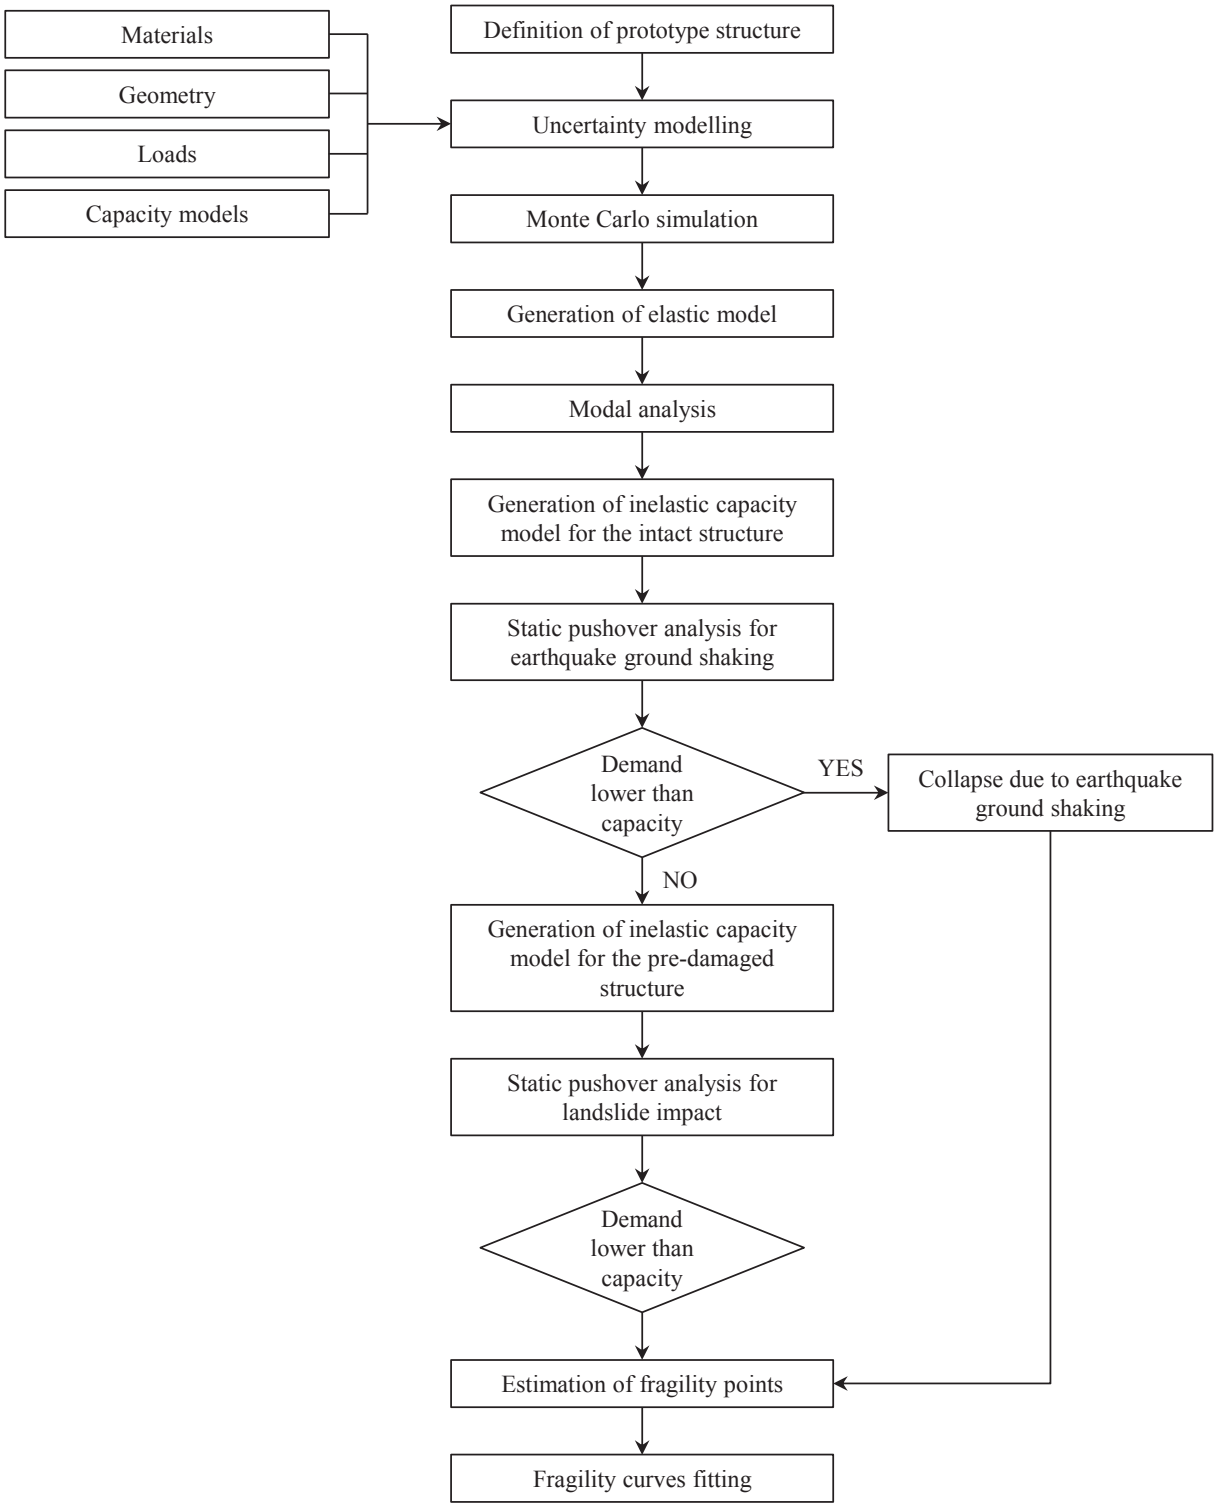

Figure 10. Flowchart of earthquake-induced landslide fragility analysis.

OpenSees® [15] and MATLAB® [16] software packages were used to automatically perform 10^3 random generations of load-capacity models and nonlinear sequential analyses. The fragility procedure was implemented through the Monte Carlo simulation method, considering the uncertainty modelling discussed above. For each realization, the sequential nonlinear analysis described in Section 2.2 was applied, assuming PGA ranging from 0.05g to 0.4g with step equal to 0.025g.

The impact velocity v of landslide was assumed to range from 0 to 10 m/s with step equal to 1 m/s. Damage associated only with earthquake shaking is related to the case of $v = 0$, whereas landslide impact with the maximum selected velocity always caused collapse of columns.

A biaxial interaction model [12][12] was used considering a degraded behaviour of plastic hinges in each direction to account for pre-damage due to earthquake shaking. A corner column was considered as the element in the worst condition of loading (impact in all cases) and capacity (lowest axial load).

The collapse fragility P_f (i.e. the conditional probability of exceeding the ultimate rotation in a plastic hinge of a first-floor column given PGA and v) was evaluated as the ratio between the number of collapse cases and the total number of simulations ($N_{sim} = 10^3$). A lognormal distribution function was fitted to fragility points in order to derive fragility curves for each velocity and PGA level [17].

In line with previous sensitivity analysis, fragility curves were derived for both capacity models considered in this study, highlighting the role of shear column failure on the vulnerability of the case-study building structure.

4.2 Discussion of results

The two sets of fragility curves are shown in Figures 11a and 11b, considering or not the shear failure of columns, respectively. Table 2 outlines the median PGA (μ), logarithmic standard deviation (β) and coefficient of determination (R^2) of fragility curves. Over all cases, R^2 reached very high values ranging between 0.85 and 0.99.

If shear failure of columns is considered (Fig. 11a), fragility curves can be grouped according to three ranges of impact velocity:

(i) v = 1–5 m/s, which are low velocity levels where structural vulnerability is mostly associated with earthquake shaking; in that case, the median PGA causing collapse is approximately 0.2g.

(ii) v = 6–7 m/s, which are medium velocity levels where structural vulnerability depends on both earthquake shaking and landslide impact, reducing the median collapse PGA to approximately 0.15g.

(iii) v = 8–10 m/s, which are high velocity levels where structural vulnerability is mostly associated with landslide impact on building façade, resulting in a median PGA equal to about 0.04g.

Dealing with the second set of fragility curves related to capacity models neglecting shear column failure (Fig. 11b), the vulnerability depends on two ranges of impact velocity as follows:

(i) v = 1–7 m/s, which are low-medium velocity levels where structural vulnerability is mostly associated with earthquake shaking, highlighting a median PGA approximately equal to 0.2g;

(ii) v = 8–10 m/s, which are high velocity levels where structural vulnerability depends on both earthquake shaking and landslide impact, resulting in a median PGA equal to 0.17g.

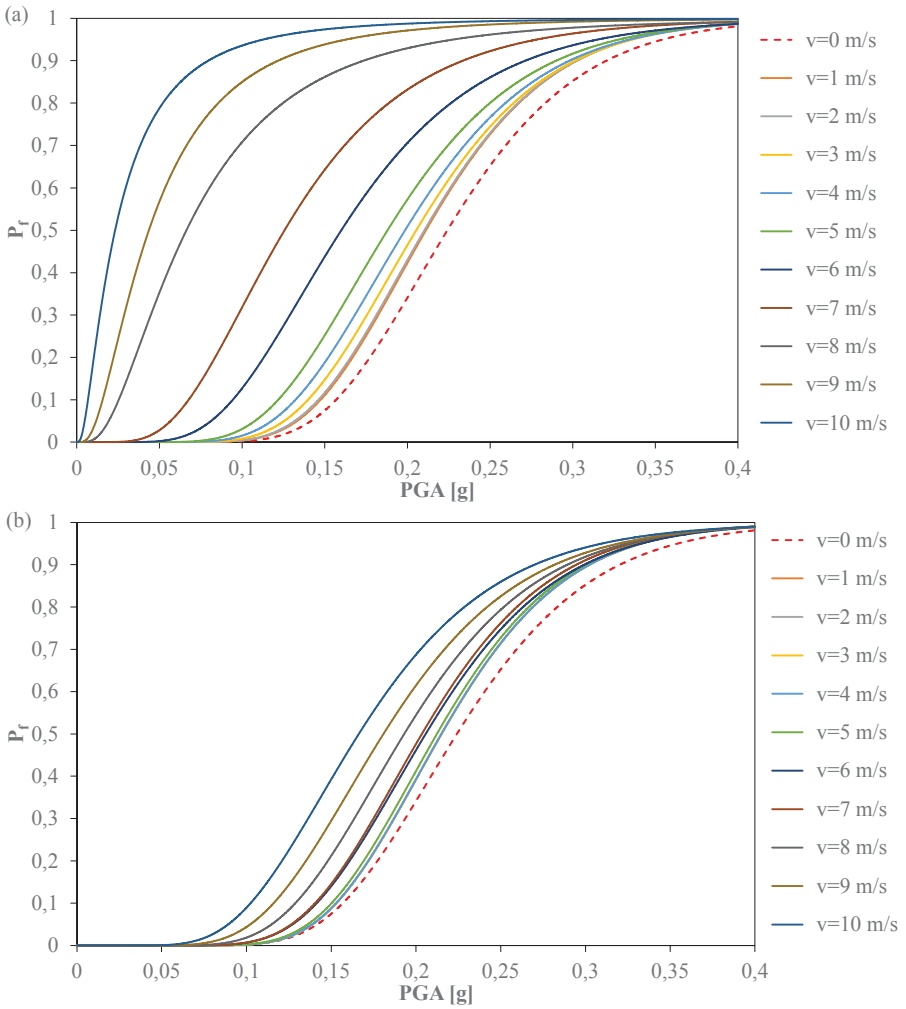

Figure 11. Fragility curves considering cumulative damage due to earthquake ground shaking and landslide impact: (a) model considering shear column failure; (b) model neglecting shear column failur.

	Model with shear failure			Model w/o shear failure

5 CONCLUSIONS

The primary goal of this study was the fragility assessment of RC framed buildings subjected to earthquake-induced landslide hazard. To assess the effects of ground shaking and subsequent landslide impact, a computational strategy based on sequential nonlinear analysis of structural response was set up and implemented. The chord rotation of plastic hinges was assumed as engineering demand parameter measuring the structural response to sequential loading. This allowed the evaluation of cumulative damage due to earthquake actions and lateral pressures acting at the ground floor of the building. Uncertainties were modelled and propagated according to standard Monte Carlo simulation, accounting for diagonal impact and variable size of the landslide in plan.

Sensitivity analysis results underline the influence of width and impact angle of the landslide on structural response under varying ground shaking intensity. As landslide width increases, a growing number of columns are involved in the collapse mechanism of the structure. For the case-study building, sensitivity analysis evidenced upper bound capacity levels for ground shaking and landslide impact, which were respectively associated with $PGA_{max} = 0.4g$ and $v_{max} = 10$ m/s. Those limit values were then considered later in fragility analysis. Sensitivity analysis highlighted a totally different behaviour modes of the structure, depending on whether shear failure of columns is considered or not. In the former case, the structure experienced local collapse of columns, whereas in the other a soft-story mechanism was observed. As far as collapse velocity is concerned, the capacity model including shear failure reached collapse at $v_c = 6–7$ m/s, whereas collapse velocities $v_c > 14$ m/s were found when shear failure was not taken in due consideration.

Fragility analysis highlighted a significant vulnerability increase when landslide impact with medium-high velocity is expected. Therefore, the seismic risk of structures located in landslide-prone areas should be assessed with a multi-hazard approach to account for cumulative damage due to earthquake shaking and subsequent landslide movements.

Future developments of this study will include the analysis of 3D structural models with masonry infill walls, considering potential benefits from seismic design rules and detailing.

ACKNOWLEDGEMENTS

This study was carried out in the framework of GRISIS research project (Gestione dei Rischi e Sicurezza delle Infrastrutture a Scala regionale) funded by Regione Campania.

Abstract. In structural dynamics the considerations of statistical uncertainties are imperative to ensure a realistic modelling of loading and material parameter setup. It is well known that any deterministic analysis only constitutes a narrow result for the given input parameters. Because of aleatoric or epistemic uncertainties, many factors must be considered either in certain interval margins or with subjective probabilities. Especially in the case of seismic ground motion, due to significant uncertainties, a reliable prediction of future event characteristics is important in designing safe structures.

This work attends to the well known statistical procedure of simulating time histories of a mechanical model under an artificially generated earthquake loading, which is modelled by a stochastic process. The stochastic processes in this work are throughout synthesized using the Spectral Representation Method (SRM). A key aspect of this procedure is the estimation of the Power Spectrum Density (PSD). The PSD determines dominant frequencies and their magnitude of influence on the stochastic process and in nature on the earthquake signals. There are numerous methods to estimate the PSD from source data, however, the amount of data available is seldom enough to do this accurately and reliably. To address this issue, the authors suggest that the PSD model itself could be defined as a random vector in the frequency domain, thereby encompassing a range of possible valid PSD models for a given data set. For a stationary process, the random dimension of said model would be dependent upon its frequency discretisation.

On a simple mechanical system, artificially generated stochastic processes with the novel described underlying power spectra are analysed utilizing a Monte Carlo simulation. A reliability statement of the mechanical system in the form of a first-passage problem is defined to acquire a probability of failure which is used alongside first- and second-order moments of the system's output as reasonable benchmark values.

1 INTRODUCTION

Many problems in engineering sciences are subject to random vibrations and thus lead to stochastic dynamic problems, for example, where environmental processes have an influence. These examples could be high-rise buildings, bridges or critical infrastructure subjected to earthquake, wind loads, or offshore platforms excited by waves. Because of the structural complexity, incomplete information of the system as well as hardly predictable natural processes, aleatory and epistemic uncertainties exist. Therefore, for these aforementioned facilities often a direct application of safety codes of civil engineering practice is not possible, which demands detailed time analyses and simulations to ensure a robust design [1]. To determine the influence of environmental processes on structures by running simulations, it is necessary to record these influences and apply them to a model with a system excitation/response process [2]. For this purpose, e.g. different earthquake ground motions are recorded and utilised for system analysis. However, these real data records are often already subjected to uncertainties. These uncertainties can arise due to various reasons, such as a limited amount of samples, damaged sensors, device failure, perhaps due to the environmental process itself, sensor threshold limitations and measurement errors. Additionally, the sensor could capture the data incorrectly, e.g. extreme features or other causes such as sensor maintenance, bandwidth limitation or data acquisition restrictions could lead to poor quality of the data records. For this reason, the real data records must be represented in an appropriate manner and the uncertainties mitigated as much as possible [3].

Since stochastic dynamics have been studied very efficiently in recent decades, different models have been developed to describe seismic ground motion. One of these tools to capture information of phenomena involving random fluctuations in time and space is the Power Spectral Density (PSD), which is widely used in the modelling of stochastic processes, especially in applications such as earthquake, wind and ocean engineering [4, 5, 6]. In earthquake engineering, for example, the use of the PSD dates back to Housner [7] or Kanai [8]. At least in the linear case considered in this work, a relationship between the system response can be derived with an elegant relationship between the power spectra of the input data and that of the output data [9]. Nonetheless, the available information of the probabilistic models for the input is often not enough to directly assess the resulting randomness of a structural response. For seismic ground motions with critical peaks, the structural response is generally non-linear and a direct relation of the probabilistic input models to the probabilistic output is not available. For this purpose the Monte Carlo simulation (MC) will be applied. It has been shown that for complex non-linear relations MC can compute probabilistic characteristics of the response. [10]

For the development of a load model that uses such a random excitation process, the following applies: The more real data sets are available, the better, since the numerical results are statistically more accurate for a large amount of data. In addition, it is useful if the underlying physics is understood well in order to make further assumptions. Because both cases are often not satisfied, other approaches must be found to develop a load model that represents the data in the best possible way [3]. In the context of a First-Passage reliability statement that requires for assessment the actual excitation of a mechanical model, the main focus of the method to mimic the seismic ground motion is to accurately represent the underlying stochastic information of the process. For the purpose of this work, the Spectral Representation Method (SRM) seems to be the most suited. In this

procedure, different processes with a specified PSD are generated. For standard cases this method generates a stationary homogeneous process, see e.g. [11, 12].

When estimating the PSD from multiple real data records by averaging their periodograms, it is assumed that the process defined by the records may be represented by a single PSD. When dealing with real data, the uncertainty introduced by this assumption could be significant and at the very least, an attempt should be made to quantify it. In this work, an approach is pursued where the single discrete frequencies are treated as probability density functions, which leads to a subjective probabilistic model. Therefore meaningful statistical variables of the ensemble are extracted. Based on these variables a probability density function for each single frequency is calculated.

This work is organised as follows: An explanation in which form the environmental processes are available and how a power spectrum density is estimated from a stochastic process is presented in section 2. Section 3 describes how the novel relaxed power spectral density is developed using subjective probabilities. In section 4 the First-Passage reliability measure is introduced. To validate the model a numerical example and a comparison of different approaches is given in 5. The final conclusion is given in section 6.

2 STOCHASTIC PROCESSES REPRESENTATION AND POWER SPECTRUM ESTIMATION

Given a real-valued stationary process $X(t)$. For each of these processes exist a corresponding orthogonal process $Z(\omega)$. Thus, $X(t)$ can than be written in the form

$$X(t) = \int_0^\infty e^{i\omega t} dZ(\omega), \tag{1}$$

where $Z(\omega)$ has the following properties:

$$\begin{aligned} E(\left|dZ^2(\omega)\right|) &= 4S_X(\omega)d\omega \\ E(dZ(\omega)) &= 0. \end{aligned} \tag{2}$$

In Eq. 2, $S_X(\omega)$ describes the two-sided power spectrum of the stationary process $X(t)$, see [13]. To generate a stationary stochastic process, the following model, first formulated by Shinozuka, is considered in this work [12]:

$$X(t) = \sum_{n=0}^{N-1} \sqrt{4S_X(\omega_n)\Delta\omega}\cos(\omega_n t + \varphi_n(\theta)), \tag{3}$$

where

$$\begin{aligned} \omega_n &= n\Delta\omega, \quad n = 0, 1, 2, \ldots, N-1 \\ \Delta\omega &= \frac{\omega_u}{N} \end{aligned} \tag{4}$$

with $N \to \infty$ and $\varphi_n(\theta)$ as $n_\varphi = N$ uniform distributed phase angles in the range $[0, 2\pi]$. This method is commonly referred to as the Spectral Representation Method (SRM). For the power spectrum density $S_X(\omega)$ the filtered noise power spectrum

$$S_X(\omega) = \frac{1 + a\omega^2}{(\omega_p^2 - \omega^2)^2 + (2\zeta\omega\omega_p)^2} \tag{5}$$

is used with $a = 5$ and $\zeta = 0.25$ as shape parameters and $\omega_p = 10$ rad/s as peak frequency [14]. The power spectrum S_X with the given parameters is depicted in Fig. 1.

To transform a stochastic process from time domain to frequency domain, the discrete Fourier transform is applied. A frequently used estimator of the power spectrum is the periodogram [15] which can be understood as the squared absolute value of the discrete Fourier transform of the time signal $x(t)$:

$$\hat{S}_X(\omega_k) = \lim_{T\to\infty} \frac{2\Delta T}{T} \left| \sum_{t=0}^{T-1} x_t e^{-2\pi i k t/T} \right|^2 \tag{6}$$

In this equation, T is the number of data points, t describes the data point index in the record, k is the integer frequency for $\omega_k = \frac{2\pi k}{T_0}$ and T_0 is the total length of the record. In Fig. 1, the power spectrum is given and the corresponding generated stochastic process is depicted.

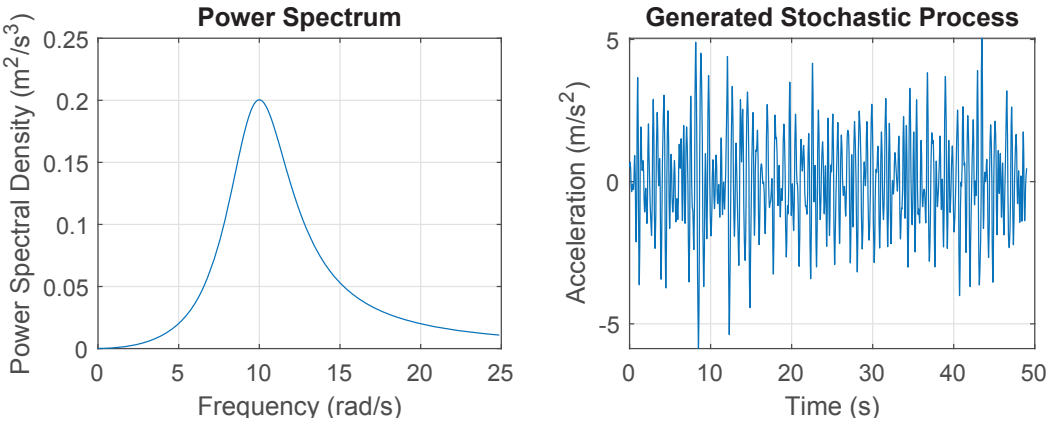

Figure 1: Example for the filtered noise power spectrum (left) and a generated stochastic process (right)

3 RELAXED POWER SPECTRUM

Uncertainties occur in the data records and in the estimation process. To account for these uncertainties, a relaxed model of a power spectrum is developed. The term "relaxed" means, that instead of a single power spectrum an ensemble of power spectra is utilised to determine a probability density function for each frequency. Although the individual power spectra in the ensemble show the same characteristics and shape, there is still variance among them, see Fig. 2. In order to determine a representative power spectrum for the ensemble, a relaxed spectrum represented by a uniform distribution or truncated normal distribution can be utilised.

For both approaches, first the ensemble of power spectra has to be estimated from an ensemble of simulated stochastic processes or real data records from seismic ground motions. Therefore, the periodogram (Eq. 6) is utilised. The ensemble can be seen as a set of different power spectra with cardinality R, i.e. ensemble $= \{\hat{S}_{X_i}\}, i = 1, 2, ..., R$. Here, R is determined by the number of available power spectra estimated either from real seismic ground motions or from artificially created stochastic processes. Each PSD in the set can be evaluated and yield a value $s_{i,\omega_n} = \hat{S}_{X_i}(\omega_n)$.

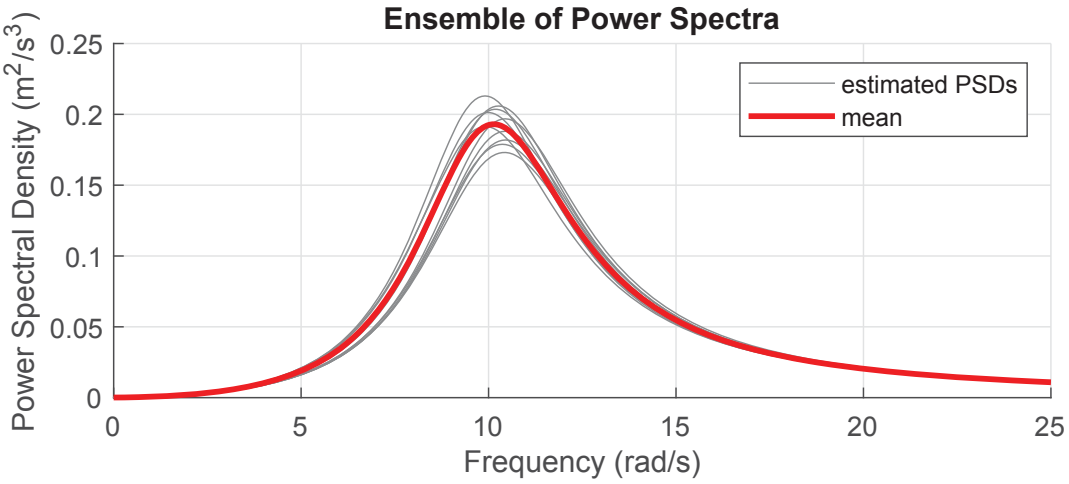

Figure 2: Ensemble of power spectra

3.1 Relaxed power spectrum utilising a uniform distribution

For the development of the relaxed power spectrum with a uniform distribution, the maximum and minimum for the power spectral density s_{i,ω_n} for each frequency ω_n of the ensemble is determined. These values are then used as the upper and lower bound for the uniform distribution.

$$f_{U,\omega_n}(s; a_{\omega_n}, b_{\omega_n}) = \begin{cases} \frac{1}{b_{\omega_n} - a_{\omega_n}} & \text{for } a_{\omega_n} \leq s \leq b_{\omega_n}, \\ 0 & \text{for } s \notin [a_{\omega_n}; b_{\omega_n}] \end{cases} \tag{7}$$

where a_{ω_n} and b_{ω_n} describe the minimum and maximum value of the power spectral density for each frequency:

$$a_{\omega_n} = \min[s_{\omega_n}], \quad b_{\omega_n} = \max[s_{\omega_n}] \tag{8}$$

For instance, the resulting relaxed power spectrum is depicted in Fig. 3 (left).

3.2 Relaxed power spectrum utilising a truncated normal distribution

Based on the ensemble of power spectra, given in the preceding section, mean (Eq. 9) and standard deviation (Eq. 10) are calculated for each frequency.

$$\mu_{\omega_n} = \frac{1}{R} \sum_{i=1}^{R} s_{i,\omega_n} \tag{9}$$

$$\sigma_{\omega_n} = \sqrt{\frac{1}{R} \sum_{i=1}^{R} \left(s_{i,\omega_n} - \mu_{\omega_n} \right)^2} \tag{10}$$

with $\omega_n = n\Delta\omega, n = 0, 1, 2, \ldots, N-1$ and R the ensemble's cardinality. By extracting these statistical information from the ensemble, a truncated normal distribution (Eq. 11) is used to calculate the relaxed power spectrum. The probability density function is given by

$$f_{TN,\omega_n}(s; \mu_{\omega_n}, \sigma_{\omega_n}, a = 0, b = \infty) = \frac{1}{\sigma_{\omega_n}} \frac{\phi(\frac{s-\mu_{\omega_n}}{\sigma_{\omega_n}})}{\Phi(\frac{b-\mu_{\omega_n}}{\sigma_{\omega_n}}) - \Phi(\frac{a-\mu_{\omega_n}}{\sigma_{\omega_n}})}, \tag{11}$$

where $a = 0$ and $b = \infty$ defines the interval, $\phi(\xi) = \frac{1}{\sqrt{2\pi}} \exp\left(-\frac{1}{2}\xi^2\right)$ is the standard normal distribution and $\Phi(s) = \frac{1}{2}\left(1 + \mathrm{erf}(s/\sqrt{2})\right)$ is the corresponding cumulative distribution function. As negative values are not possible in terms of power spectra, the interval $[0; \infty]$ is defined beforehand.

The resulting relaxed power spectrum for the ensemble using a truncated normal distribution is depicted in Fig. 3 (right).

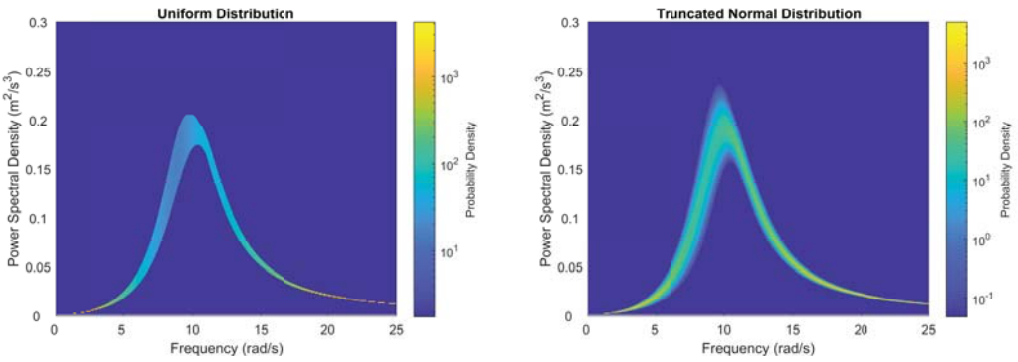

Figure 3: Relaxed power spectrum with probability density functions for each frequency derived from the ensemble given in Fig. 2; Uniform distribution (left); Truncated normal distribution (right)

3.3 Relaxed Spectral Representation Method

With the previous definitions in Eq. 7 and Eq. 11 a new formulation for the SRM in Eq. 3 can be given. This shall be called the Relaxed Spectral Representation Method (RSRM):

$$X(t,\theta) = \sum_{n=0}^{N-1} \sqrt{4 S_{X,\omega_n}(\theta)\Delta\omega}\, \cos(\omega_n t + \varphi_n(\theta)), \tag{12}$$

where $S_{X,\omega_n}(\theta)$ denotes that corresponding to each ω_n a distribution function according to either Eq. 7 or Eq. 11 is defined, which using a sample technique, such as inverse sampling, yields the PSD value. This leads likewise as for $\varphi_n(\theta), n_\varphi$ to a number of n_S new random distributions, which are now distinctively for each ω_n defined, i.e. $S_{X,\omega_n}(\theta), n_S$. The extension is not ideal due to the large number of random variables. However, for a first accurate approximation this approach was chosen. For instance, the probability density functions for the frequencies 5 rad/s, 10 rad/s and 15 rad/s for both, uniform and truncated normal distributed relaxed power spectrum, are depicted in Fig. 4.

4 FIRST-PASSAGE RELIABILITY PROBLEM

In the introduction, a referral to the safety of critical infrastructure and high-rise buildings under the influence of environmental processes such as earthquakes has been given. In practice, this safety of structures is approached by defining the structure's reliability. An application-specific problem related to seismic reliability could be: "Under a particular earthquake loading, does the structure exceed a certain critical displacement?" To tackle this problem a well defined mechanical model is proposed with which simulations are carried out. The simulation outputs are analysed to identify the first exceedances of a pre-defined critical displacement. These first time exceedances can be counted as

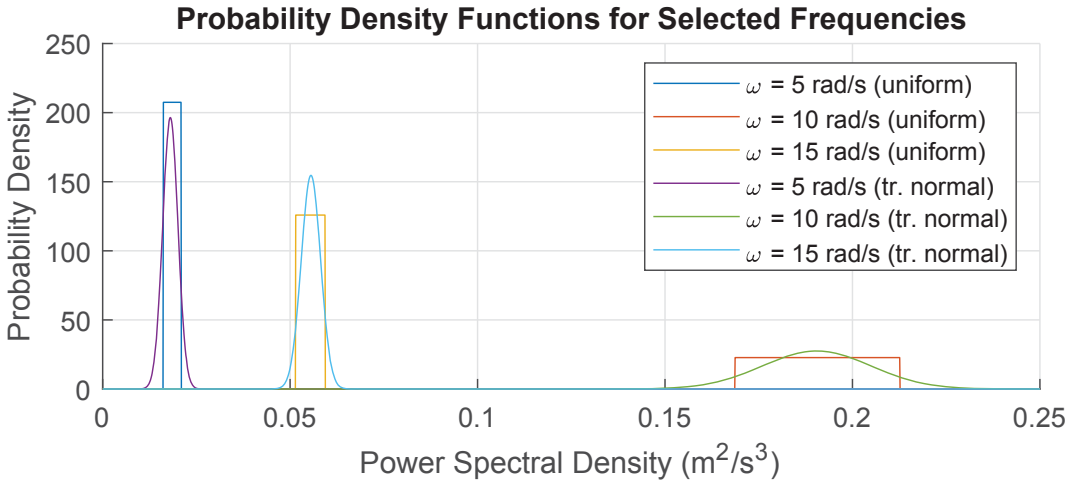

Figure 4: Probability density functions for selected frequencies

failure events. Such an approach is common for hysteretic structures subjected to seismic excitation where a failure can occur due to e.g. cumulative plastic deformations. All these assumptions regarding the occurrence of a failure can be gathered under the term First-Passage Reliability Problem [16]. Note that the exact time of exceedance is not of interest in the analysis of this work.

Since seismic excitation is a natural phenomenon that inhibits a stochastic nature, no exact statement about the occurrence of these failures can be given. To estimate the probability of an exceedance a Monte Carlo simulation can be applied. The estimated probability of exceedance is then called the probability of failure and denoted by p_f.

4.1 Probability of failure

First a relation between a critical value and the systems response is defined. Let

$$g(\boldsymbol{\theta}) = C_{crit} - D(\boldsymbol{\theta}) \tag{13}$$

be the performance function, sometimes also referred to as limit state function, where C_{crit} is a pre-defined capacity value that may or may not be exceeded by a systems demand $D(\boldsymbol{\theta})$. The vector $\boldsymbol{\theta} = (\theta_1, \theta_2, ..., \theta_{n_\theta})$ is composed of all random parameters affecting the system. This may include physical properties as well as random modelling parameters used to simulate e.g. a forced excitation. All probability density functions (PDFs) in $\boldsymbol{\theta}$ are known and the random dimension is n_θ (i.e. the total number of Random Variables). With this mathematical threshold description of a failure the performance function Eq. 13 can be used to describe a corresponding failure region F by a relational description for the value of $g(\boldsymbol{\theta})$:

$$\begin{aligned} g(\boldsymbol{\theta}) \leq 0 \rightarrow \boldsymbol{\theta} \in F \\ g(\boldsymbol{\theta}) > 0 \rightarrow \boldsymbol{\theta} \notin F. \end{aligned} \tag{14}$$

The probability of failure for any arbitrary multivariate probability distribution function $f_{\boldsymbol{\Theta}}(\boldsymbol{\theta})$ is then calculated by following integral over the whole failure domain F

$$p_f = \int_F f_{\boldsymbol{\Theta}}(\boldsymbol{\theta}) d\boldsymbol{\theta}, \tag{15}$$

since the exact failure domain is usually unknown, by using the indicator function $\mathcal{I}(\boldsymbol{\theta})$ with $\mathcal{I}(\boldsymbol{\theta}) = 1$ if $\boldsymbol{\theta} \in F$ and 0 otherwise, the above integral can be expanded on the whole domain and rewritten to

$$p_f = \int_{-\infty}^{+\infty} \mathcal{I}(\boldsymbol{\theta}) f_{\boldsymbol{\Theta}}(\boldsymbol{\theta}) d\boldsymbol{\theta} = E[\mathcal{I}(\boldsymbol{\theta})]. \tag{16}$$

4.2 Monte Carlo simulation

The expression in Eq. 16 allows the Monte Carlo (MC) estimation of p_f to be

$$\hat{p}_f = \frac{1}{N_{MC}} \sum_{i=1}^{N_{MC}} \mathcal{I}(\theta_{i,n_\theta}) \tag{17}$$

where N_{MC} indicates the number of Monte Carlo samples used. For each $\boldsymbol{\theta}_i$ a deterministic analysis with n_θ random inputs is carried out. This estimators variance and the corresponding coefficient of variation are

$$\mathrm{Var}[\hat{p_f}] = \frac{\hat{p_f} - \hat{p_f}^2}{N_{MC}}, \quad \nu_{p_f} = \frac{\sqrt{\mathrm{Var}[\hat{p_f}]}}{\hat{p_f}}. \tag{18}$$

All derivations in this section, with a focus on a high dimensional random space, can be revisited in [17].

5 NUMERICAL EXAMPLE

With the two novel descriptions of the underlying PSDs, several Monte Carlo simulations (MCS) are carried out to investigate the effect of the now different stochastic processes and their influence on a specific exemplary reliability problem by comparing the MCS estimated probability of failure. Variance and coefficient of variation are tracked for different numbers of MC samples.

5.1 Model

A simple Single Degree-of-Freedom (SDOF) linear oscillator in the form

$$m\ddot{\boldsymbol{x}}(t) + c\dot{\boldsymbol{x}}(t) + k\boldsymbol{x}(t) = \boldsymbol{F}(\boldsymbol{\theta}, t), \tag{19}$$

with mass $m = 50$ kg, spring constant $k = 1922$ N/m and damping coefficient $c = 37.2$ kg/s is introduced. $\boldsymbol{x}, \dot{\boldsymbol{x}}, \ddot{\boldsymbol{x}}$ are displacements, velocities and accelerations of the system. The forcing term on the right hand side $\boldsymbol{F}(\boldsymbol{\theta}, t)$ is modelled by the stochastic process as introduced in section 2 utilizing the novel random relaxed spectra as given in section 3. Above equation is solved using an explicit Runge-Kutta scheme according to [18]. The capacity within the performance function C_{crit} is chosen to be 0.0055 m. The demand D is the maximum absolute displacement of the system through the whole time domain and given as

$$g(\boldsymbol{\theta}) = 0.0055 - \max_{t \in [0, T_E]} \left[|\boldsymbol{x}(\boldsymbol{\theta}, t)| \right]. \tag{20}$$

Note that since the right hand side of Eq. 19 contains a random input, the systems output $\boldsymbol{x}(\boldsymbol{\theta})$ becomes random as well. The exact time t of an exceedance is not of interest here but an exceedance is only counted once in a certain time interval $[0, T_E]$. All values and

parameters were chosen in order to generate a relatively small probability of failure which is $p_f < 0.01$.

The random dimension n_θ present in the model (Eq. 19) highly affects the MCS efficiency and therefore needs a careful consideration. In Eq. 3 random phase angles are introduced to create shifted harmonics. In order to prevent repeating behaviour of the stochastic process due to the restricted number of harmonic terms N a sufficiently large number n_φ of summands, containing random phase angles, corresponding to the simulation time need to be chosen. This relationship was chosen to be

$$n_\varphi \geq \lceil \frac{T_E \omega_u}{2\pi} \rceil \tag{21}$$

where $\omega_u = 25$ rad/s is the so called cut-off frequency in Eq. 4 and T_E is the total simulation time given to be 49 s. This results in $n_\varphi = 195$ uniform distributed phase angles.

5.2 Random distributions and random dimension

Because of the summation of the SRM and RSRM in e.g. Eq. 12 for each random phase angle a random PSD value according to $S_{X,\omega_n}(\theta)$ is sampled. This results in $n_\varphi = n_S$ and $n_\theta = n_\varphi + n_S = 390$ random distributions. For the further analysis three different cases will be explored.

- Case 1: SRM with $\varphi_{1,2,\dots,n_\varphi} \sim U([0, 2\pi])$
- Case 2: RSRM-U with $\varphi_{1,2,\dots,n_\varphi} \sim U([0, 2\pi])$ and $S_{X,\omega_{1,2,\dots,n_S}} \sim f_U(s, a_{\omega_n}, b_{\omega_n})$
- Case 3: RSRM-TN with $\varphi_{1,2,\dots,n_\varphi} \sim U([0, 2\pi])$ and $S_{X,\omega_{1,2,\dots,n_S}} \sim f_{TN,\omega_n}(s; \mu_{\omega_n}, \sigma_{\omega_n}, a = 0, b = \infty)$

Note that for all three cases the same set $\{\varphi_n(\theta)\}$ of random phase angles has been used. The increase of the total random dimension n_θ is not the ultimate goal of this work, on the contrary with further experiments the total number of used random distributions in this model shall be reduced. But as for now to mimic the given crisp PSD function this approach has been used.
Exemplary results for the stochastic process of Eq. 12 and the underlying PSD, $S_{X,\omega_n}(\theta)$ in Case 2 and Case 3 can be seen in Fig. 5. Since the bounds are chosen reasonably small, only a 5 s stochastic process is shown to make differences visible.

5.3 Results & discussion

For all cases different number of MC samples N_{MC} are sampled to estimate p_f. For instance, the results of one MC simulation solving Eq. 19 in each case are shown in Fig. 6. For the full-time history of the system's response, the difference between the three cases is not directly visible. It is obvious that no forcing signal $\boldsymbol{F}(\boldsymbol{\theta}, t)$ for this simulation is able to deflect the system into reaching the capacity C_{crit}. Further analyses with large numbers of MC samples have been carried out and p_f was estimated. These results are gathered in Tab. 1 and calculated according to Eq. 18. Case 1 is the classic SRM - Spectral Representation Method, Case 2 the RSRM-U, Relaxed Spectral Representation Method using uniform distributions for the PSD and Case 3 RSRM-TN using the truncated normal distributions. From these results in Tab. 1 the assumption could be made that p_f and

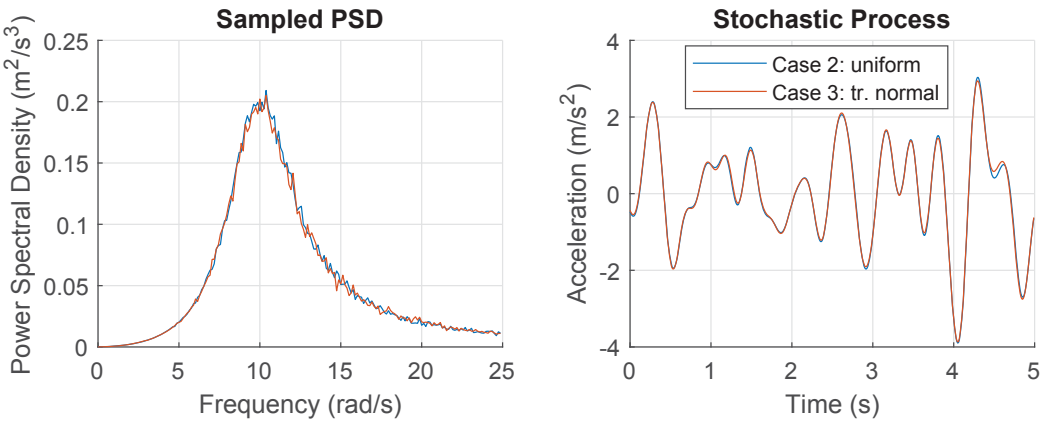

Figure 5: Example for two generated power spectral densities (left) and the corresponding stochastic processes in a time window of 5 s (right)

ν_{p_f} are independent from the case and therefore of the underlying presented random PSD function. Evidence could be that the differences between all results have a magnitude smaller than 10^{-3}. Though, when a detailed relation is shown as in Fig. 7 differences especially in the amplitude can be spotted. The results given in Tab. 1 and Fig. 6 are to be explained due to a considerate definition of the random PSD values. Boundaries and model parameters were carefully chosen.

In Tab. 1 it can be seen that the p_f does not change significantly when using the RSRM instead of SRM. The goal of this paper was to establish a random definition of the stochastic processes underlying PSD function. The reliability measure as well as first- and second-order moments were chosen to be measured in order to prove that no significant model changes were imposed from the RSRM towards the model versus the SRM influence on the model. This would mean that the induced aleatoric uncertainty by adding new random distributions to describe the PSD is not unnecessarily increased. However, if a few model parameters are changed, e.g. the simulation time T_E or the random dimensions

	$7.5 \cdot 10^5$	$1.9 \cdot 10^{-7}$	$6.0 \cdot 10^{-9}$	0.0074	0.0119	0.0093
	$1.0 \cdot 10^6$	$1.9 \cdot 10^{-7}$	$1.6 \cdot 10^{-10}$	0.0075	0.0102	0.0095

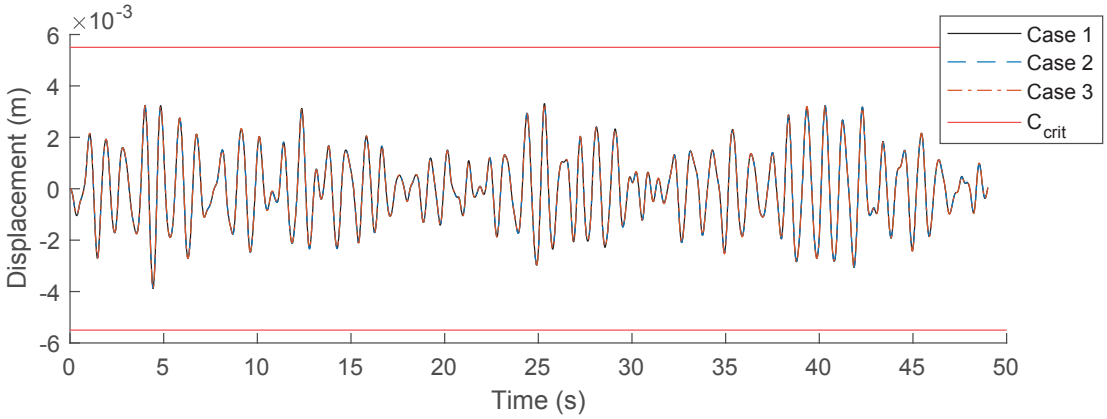

Figure 6: One MC full system response for all cases.

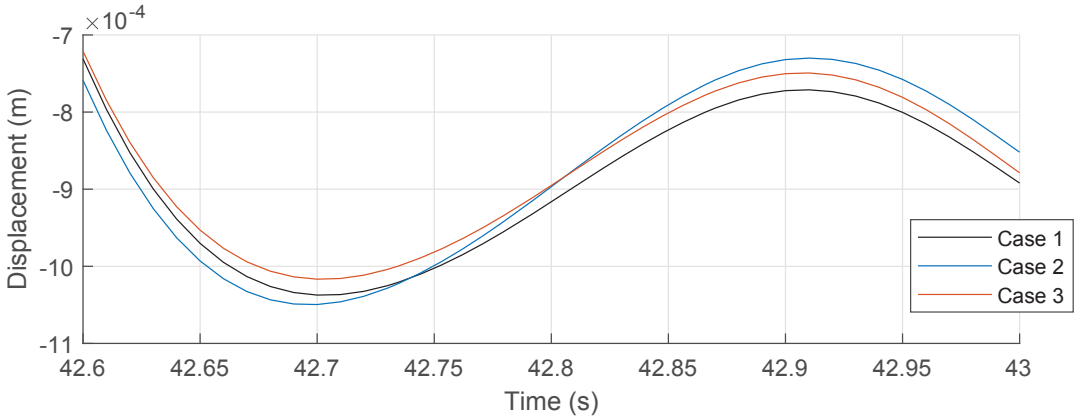

Figure 7: System response for all cases in $t \in [42.6s, 43.0s]$

n_φ, n_S that affect the number of summands, as in Eq. 21 or Eq. 12 a huge variation in results can be observed. This leaves the task open to diminish the epistemic uncertainty of the RSRM in combination with a mechanical system.
For all MC simulations the calculation time was monitored. As measured a respective number $t_{sim} = \frac{\text{simT}}{N_{MC}}$, where simT is the machine's needed calculation time, of how long the calculation took per single sample was calculated. As average over all different MC simulations this delivered following results: SRM= 3.896 ms/sample, RSRM-U= 4.172 ms/sample, RSRM-TN= 4.119 ms/sample. Since from the formulation of the SRM a summation needs to be carried out, which is realised in a for loop an additional sampling for each summand does not significant increase the calculation time.

6 CONCLUSION

In this work, a novel representation of the power spectral density function was presented. Instead of using discrete values for the power spectral density for each frequency, statistical information from an ensemble of power spectra can be extracted and a corresponding probability distribution function can be calculated. In this way, the power spectral density is "relaxed" as the previous discrete values are now treated as probability functions. Therefore, not only one value for a specific frequency is possible, but a range of values with different probabilities. It has been shown, that the developed relaxed power

spectra are usable for producing non-ergodic process realisations immediately applicable for Monte Carlo simulation analyses.

The relaxed power spectrum offers several advantages compared to the traditional power spectral density. Due to the sensor limitations mentioned in section 1 and the estimation of power spectra, the excitation and response of simulations are subject to uncertainties. Therefore, a single discrete value as solution is unlikely to be true and reliable. The relaxed spectrum is more robust as it is able to capture these uncertainties. A range of possible excitations with different probabilities are then known, yielding various plausible solutions. Especially in the case that a high amount of real data records are available, an approach with subjective probabilities is useful to calculate a relaxed power spectrum, since it is possible to obtain reliable statistical informations of the ensemble. The same holds for artificially generated stochastic processes as an unlimited number can be generated.

For the development of the proposed relaxed power spectrum a crucial point is the choice of the utilised probability density function. Here, a uniform distribution and a truncated normal distribution are used, for comparison purposes. It has been shown, that the selection of the PDF has not a big influence to the simulated displacement of a single Degree-of-Freedom model with a First-Passage problem. The two models show very similar results, also in comparison with the traditional spectral representation method. It can be deduced that the relaxation of the models is a valid method to take uncertainties into account. In order to confirm these results other investigations with more complex structures, e.g. non-linear finite element simulations, must be carried out.

Furthermore, there is also a need to understand the influence of the model parameters and how they affect the underlying system. Since it was observed that even small changes in these parameters caused a large variation in the results, this must be investigated in order to make the relaxed models applicable to any structure with a different set of parameters.

Finally the ultimate goal is to reduce the total number of used random distributions. In this work an approach has been chosen to simulate stochastic processes as close to a target precise PSD as possible. This took a careful parameter setting. In future work the possibilities of decreasing the random dimension will be targeted. Additionally, synergies with the Stochastic Harmonic Function representation will be explored.

Keywords: Structural health monitoring, machine learning, neural networks, generative adversarial networks, GANs

Abstract. *In the current work, the use of generative adversarial networks (GANs) in a simulated structural health monitoring (SHM) application is studied. A specific type of GAN is considered, aiming at a disentangled representation of underlying features and clusters of data through some latent variables. This idea could prove useful in SHM, since explanation of how damage mechanisms or environmental conditions affect a structure may be exploited in order to monitor structures more effectively. In a simulated mass-spring example, different damage cases are introduced by reducing the stiffness of specific springs and different damage levels by applying different extents of stiffness reduction. The GAN implementation proves able to capture different damage cases through its categorical latent variables, as well as the damage extent within its continuous latent variables. The results demonstrate that the latent variables are indeed capturing the effect of damage in the structure and can be exploited for the purpose of condition assessment.*

1 Introduction

Modern societies extensively rely on structural elements. Everyday activities depend on structures like bridges, engines, power generators etc. Malfunction or damage of these critical systems may lead to delays in transportation, power shutdowns or even injury or death of individuals. Avoiding such failures and guaranteeing safe operation and efficient performance is therefore a matter of critical importance. *Structural Health Monitoring* (SHM) offers a tool to this end. SHM is employed to ensure operability and safety of structures and to avoid consequences of failure. Many different approaches have been proposed in the context of SHM, but all of them can be categorised according to the hierarchical structure proposed by Rytter [1] and extended in [2]:

1. Is there damage (*existence*)?
2. Where is the damage in the system (*location*)?
3. What kind of damage is present (*type/classification*)?
4. How severe is the damage (*extent/severity*)?
5. How much useful (safe) life remains (*prognosis*)?

Ascending in Rytter's hierarchy makes the task at hand more difficult than the one in the previous step. Detecting if damage exists requires definition of the normal condition of a structure and divergence from that is an indication of damage and has to be examined. The second step of localising damage, requires further knowledge about the behaviour of a structure and how damage in various areas may affect the structural response. Moreover, defining the type of damage is a task that requires further understanding of the structural behaviour and of the manner in which different types of damage affect observed features of the structure. Finally, the two last steps in the hierarchy, demand understanding of the damage mechanism in order to define its severity and to further predict the useful life of the structure under the specific damage case. Although some data driven methods would promise to do this without really understanding the mechanism as long as sufficient instances of failure are recorded.

It is straightforward that dealing with these tasks involves acquiring and processing data in order to infer results about the condition of a structure. Taking into account the progress made in the disciplines of data analysis and *machine learning* (ML), diverse methods from these fields have been exploited for the purposes of SHM [2]. Regarding the first step in the aforementioned hierarchy, ML has been used to perform outlier detection using autoencoders to explain data corresponding to the normal condition of a structure [3]. Autoencoders were chosen because they are able to explain data belonging to an arbitrary manifold. For damage classification or localisation, ML classifiers have been used [4], yielding quite good accuracy. The main drawback of these methods is that data from damage states is required to perform their tasks. Oftentimes however, data from damaged states are absent, or only limited samples are available. Furthermore, to perform tasks further up in Rytter's hierarchy, understanding of the underlying physics of structures and damage mechanisms is needed.

Trying to understand the underlying physics within such a context, one may attempt to study a black box model that is performing well on a task related to the underlying mechanism of the problem. A representative example of such a case is a model trained on patient data [5] that was able to predict schizophrenia with adequate precision. It is clear then that it may be worth

spending some time studying the model in an attempt to understand better how schizophrenia works and which symptoms indicate its existence. The same scheme may be applied on structures with models trained on identifying damage location/type. A black-box model like a neural network [6] may be exploited to understand the way some type of damage affects a structure.

A specific type of black-box model that is targeted to capturing the physics of a specific problem, is the generative model. More specifically, Generative Adversarial Networks (GANs) [7] and Variational Autoencoders (VAEs) [8] are neural networks that learn how to generate data that look like reality. It is believed that, by studying these types of neural networks and the way they produce data, further understanding of the underlying problems may be achieved. In the current work, a specific type of GAN is used, the infoGAN [9]. This specific type of network achieves a disentanglement in the latent feature space of the data which may have great benefits in an SHM application. The use of such networks is considered in the task of classifying data from structures and also in defining latent variables that explain the extent of damage in the data or the variation of a parameter affecting the behaviour of the structure.

2 Generative Adversarial Networks (GANs)

2.1 Vanilla GANs

The traditional scheme followed in ML is the training of a model to perform classification [6] or regression [10]. To extend this to images, convolutional neural networks were developed [11] yielding superior performance in the two mentioned tasks. Recently, a new type of neural network has emerged, the *Generative Adversarial Network* [7]. The goal of this new scheme is to generate images that resemble reality, which is achieved via use of *two* neural networks. The first one is termed the *generator* and produces "fake" images given a latent vector. The second network is the *discriminator*, which tries to identify whether an image is fake (generated by the generator) or real (coming from the available dataset). Through training both of these networks, improve in reaching their objective and finally, the generator, provided with some latent vector, can generate images that appear to be real. More intuitively, this means that the generator maps a latent vector distribution into a distribution or a manifold of the real data. The layout of the basic (vanilla) GAN can be seen in Figure 1.

The generator is a multi-layer perceptron (MLP) that takes as input a latent noise vector $\mathbf{z}$ coming from a probability distribution $p_z(\mathbf{z})$ and maps it into a vector (or an image) $G(\mathbf{z})$ of dimension equal to the dimension of the training samples. The discriminator is another MLP that takes as inputs, vectors (or images) $\mathbf{x}$, and outputs the probability of the sample being real, $P(\mathbf{x} = real) = D(\mathbf{x})$. The training of D is carried out by maximising the probability that it assigns the correct label ("real" or "fake") to the samples. At the same time, the training of the generator, G, is accomplished by trying to minimise the probability that the discriminator classifies the generated samples as fake, i.e. minimisation of $log(1 - D(G(z)))$. Following from [7], the objective function can be interpreted as a two player minmax game given by,

$$\min_G \max_D V(D,G) = \mathbb{E}_{\mathbf{x}\sim p_{data}(\mathbf{x})}[\log D(\mathbf{x})] + \mathbb{E}_{\mathbf{z}\sim p_z(\mathbf{z})}[\log 1 - D(G(\mathbf{z}))] \tag{1}$$

Training of such a network is performed in two steps per epoch. During the first step, random samples are created by the generator and they are concatenated with a batch of real samples from the dataset. The resulting training batch is used to train the discriminator for one epoch by

back-propagating the error of the output. The target label for the real samples is 1 and for the generated ones is 0. The right-hand side of equation (1) is set in this step as the objective function and its **maximisation** is attempted. Consequently, the two networks are clipped together, as in Fig 1, and random samples of the latent vector are generated in order to create random generated samples. These samples are fed into the whole GAN and the target outputs are labels of 1. The weights of the discriminator's connections are considered as constants during the second training phase and the error is back-propagated in order to train the generator. This latter time, the objective function is comprised exclusively from the second term of the right-hand side of equation (1) and its **minimisation** is sought. Following this training scheme, during the first step the discriminator learns to distinguish between real and generated images and the generator to generate images that the discriminator classifies as real.

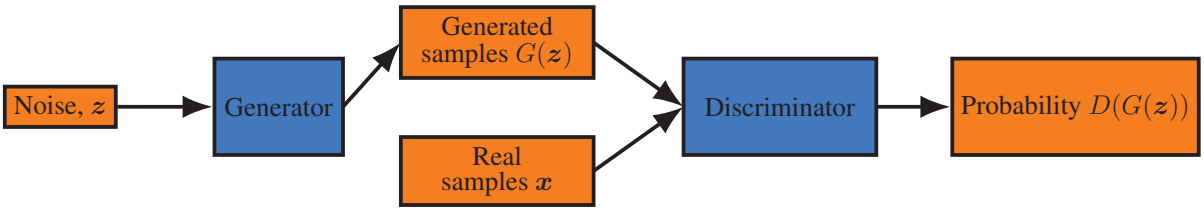

Figure 1: Vanilla GAN layout.

The most straightforward application of GANs is to generate artificial data to augment a dataset. Training neural networks is highly dependent on the size of the available dataset. The rule-of-thumb for training neural networks that generalise well [12], specifies that for each trainable weight of the neural network, 10 training samples are needed. Acquiring data is difficult and some times even expensive. Labelled images are hard to be obtained and their manual labeling costs. In cases of image datasets, augmentation can also be achieved by rotation of the pictures or colour change etc. In SHM though, the securing of data from structures in different damage cases or under different environmental conditions is expensive or even impossible; the samples are usually limited and augmentation is not that easy. For this purpose, GANs can be used to increase the size of a dataset and may even serve as interpolators. Especially for deep networks and even more for deep convolutional neural networks, where the number of trainable parameters is huge, augmentation of available dataset size could yield an efficient way to increase the generalisation performance of models [13].

Another use of GANs is found in filling gaps in pictures [14, 15]. In this case, GANs trained on a dataset are able to use pictures with missing pixels and generate a complete picture by replacing missing pixels with something that fits well in the gap. This is a great example of how this type of model may assist in repairing corrupted datasets. At the same time, these results are encouraging the perspective that GANs achieve a better linkage of data to the driving physics (or semantics) than traditional neural networks, since they are able repair corrupted data that they have never seen before.

Furthermore, GANs are applied in image processing [16, 17, 18]. This application is also an impressive usage of GANs, since they are able to capture through their latent variables, specific features of the data. Afterwards, the users are able to manipulate the latent vectors and use the generator to produce images, whose characteristics fit custom needs. A similar approach in the current work is followed and an attempt is performed to capture in the latent code the extent and type of damage in a structure. The ability to describe such features through a latent vector

and generate data corresponding to specific damage cases or to the extent of damage would be beneficial for the purposes of SHM, since further progress related to the fourth and fifth steps in Rytter's hierarchy could be achieved.

2.2 Information Maximising Generative Adversarial Nets

According to the classic formulation of GANs described, the latent variables used as inputs in the generator do not encapsulate any specific features from the data. This is because no restriction is imposed during training that every variable would describe a specific feature, resulting in latent noise variables that correspond to entangled features or combinations of features. In order to improve performance regarding the representation of disentangled features by the latent variables, a slightly different architecture and training scheme is followed in [9], called *Information Maximising Generative Adversarial Nets* (InfoGAN).

The procedure followed to enforce this disentanglement will be described below. At first, the latent vector is divided into two parts, the latent noise $\mathbf{z}$ and the latent code $\mathbf{c}$. The noise part $\mathbf{z}$ is used to model noise that may be present in the data, while the latent code $\mathbf{c}$ is used to represent interpretable features of the data. Following [9], the output of the generator becomes $G(\mathbf{z}, \mathbf{c})$. In order for the latent code $\mathbf{c}$ to have a meaning, there should be high mutual information between the code $\mathbf{c}$ and the generator distribution $G(\mathbf{z}, \mathbf{c})$, i.e. $I(\mathbf{c}; G(\mathbf{z}, \mathbf{c}))$. The term $I(c; G(\mathbf{z}, \mathbf{c}))$ represents the amount of information learnt from knowledge of $G(\mathbf{z}, \mathbf{c})$ about $\mathbf{c}$ and can be calculated using two entropy terms from,

$$I(\mathbf{c}; G(\mathbf{z}, \mathbf{c})) = H(\mathbf{c}) - H(\mathbf{c}|G(\mathbf{z}, \mathbf{c})) = H(G(\mathbf{z}, \mathbf{c})) - H(G(\mathbf{z}, \mathbf{c})|\mathbf{c}) \tag{2}$$

where $H(\mathbf{x})$ and $H(\mathbf{x}|\mathbf{y})$ are the entropy of the random variable $\mathbf{x}$ and the conditional entropy of $\mathbf{x}$ given $\mathbf{y}$, respectively.

Trying to get further insight into equation (2), one realizes the reduction of uncertainty about $\mathbf{c}$ when $G(\mathbf{z}, \mathbf{c})$ is observed. If the two variables are completely independent, then the term is equal to zero. So for the maximisation of (2), given $\mathbf{x} \sim P_G(x)$, $P_G(\mathbf{c}|\mathbf{x})$ should have small entropy. Trying to maximise this term, enforces a deterministic relationship between the two variables. To include this quantity in the optimisation process, the following modification is made in the cost functions from equation (1),

$$\min_G \max_D V_1(D, G) = \min_G \max_D V(D, G) - \lambda I(\mathbf{c}; G(\mathbf{z}, \mathbf{c})) \tag{3}$$

In practice though, maximisation of $I(\mathbf{c}; G(\mathbf{z}, \mathbf{c}))$ is non-trivial, as one has no access to the

posterior $P_G(\mathbf{c}|\mathbf{x})$. To avoid maximising it directly, an auxiliary distribution $Q(\mathbf{c}|\mathbf{x})$ is defined,

$$
\begin{aligned}
I(\mathbf{c}; G(\mathbf{z}, \mathbf{c})) &= H(\mathbf{c}) - H(\mathbf{c}|G(\mathbf{z}, \mathbf{c})) = \\
&\mathbb{E}_{\mathbf{x}\sim G(\mathbf{z},\mathbf{c})}[\mathbb{E}_{\mathbf{c}\sim P(\mathbf{c}|\mathbf{x})}[\log P(\mathbf{c}|\mathbf{x})]] + H(\mathbf{c}) = \\
&\mathbb{E}_{\mathbf{x}\sim G(\mathbf{z},\mathbf{c})}[\mathbb{E}_{\mathbf{c}\sim P(\mathbf{c}|\mathbf{x})}[\log \frac{P(\mathbf{c}|\mathbf{x})}{Q(\mathbf{c}|\mathbf{x})} Q(\mathbf{c}|\mathbf{x}))]] + H(\mathbf{c}) = \\
&\mathbb{E}_{\mathbf{x}\sim G(\mathbf{z},\mathbf{c})}[\mathbb{E}_{\mathbf{c}\sim P(\mathbf{c}|\mathbf{x})}[\log \frac{P(\mathbf{c}|\mathbf{x})}{Q(\mathbf{c}|\mathbf{x})}] - \mathbb{E}_{\mathbf{c}\sim P(\mathbf{c}|\mathbf{x})}[\log Q(\mathbf{c}|\mathbf{x}))]] \\
&+ H(\mathbf{c}) = \\
&\mathbb{E}_{\mathbf{x}\sim G(\mathbf{z},\mathbf{c})}[\underbrace{D_{KL}(P(\cdot|\mathbf{x})||Q(\cdot|\mathbf{c}))}_{\geq 0} - \mathbb{E}_{\mathbf{c}\sim P(\mathbf{c}|\mathbf{x})}[\log Q(\mathbf{c}|\mathbf{x}))]] \\
&+ H(\mathbf{c}) \\
&\geq \mathbb{E}_{\mathbf{x}\sim G(\mathbf{z},\mathbf{c})}[\mathbb{E}_{\mathbf{c}\sim P(\mathbf{c}|\mathbf{x})}[\log Q(\mathbf{c}|\mathbf{x})]] + H(\mathbf{c})
\end{aligned}
\tag{4}
$$

The technique of maximising the lower bound of the mutual information is called Variational Information Maximisation [19]. In equation (4) the quantity to be maximised is the first term of the final formula, since $H(\mathbf{c})$ is a constant and has an analytical form and a common distribution is chosen for $\mathbf{c}$. To avoid sampling from the posterior in the inner expectation of the expression in equation (4), the **Lemma 5.1** of [9] is used; according to which, for random variables X, Y and functions $f(x, y)$ under suitable regularity conditions it applies that: $\mathbb{E}_{x\sim X, y\sim Y|x}[f(x,y)] = \mathbb{E}_{x\sim X, y\sim Y|x, x\sim X|y}[f(x,y)]$. Following this result a variational lower bound, $L_1(G, Q)$, of the mutual information $I(\mathbf{c}; G(\mathbf{z}, \mathbf{c}))$ is defined,

$$
\begin{aligned}
L_1(G, Q) &= \mathbb{E}_{\mathbf{x}\sim G(\mathbf{z},\mathbf{c})}[\mathbb{E}_{\mathbf{c}\sim P(\mathbf{c}|\mathbf{x})}[\log Q(\mathbf{c}|\mathbf{x})]] = \\
&\mathbb{E}_{\mathbf{c}\sim P(\mathbf{c}), \mathbf{x}\sim G(\mathbf{z},\mathbf{c})}[\log Q(\mathbf{c}|\mathbf{x})] + H(\mathbf{c}) \leq I(\mathbf{c}; G(\mathbf{z}, \mathbf{c}))
\end{aligned}
\tag{5}
$$

In equation (5), the quantity to be maximised is the log-probability of the auxiliary distribution Q. In practice Q is modeled using a neural network. The newly-defined neural network is part of the discriminator network of the vanilla GAN. By defining the neural network Q, maximisation of the quantity in equation (5) is performed by back-propagating its error.

In the categorical case, in order to maximise $\log Q(\mathbf{c}|\mathbf{x})$ by training Q, the output is given by a softmax function and the categorical-crossentropy loss function gives the desired results. In the case of a continuous code $\mathbf{c}$, a maximum likelihood estimation (MLE) scheme has to be followed. The outputs of the neural network are two for each continuous code c_i; one for the mean value of the code and one for the variance. Afterwards, the loss function to be maximised is the mean log probability of all the outputs corresponding to the continuous code inputs. Assuming that $\mathbf{c}$ comes from a Gaussian distribution and that the variables c_i are independent, the loss function is

given by,

$$\log[Q(\mathbf{c}|\mathbf{x})] = \log[\prod_{i=1}^{n_c} P(c_i)] = \sum_{i=1}^{n_c} \log P(c_i) = \\ \sum_{i=1}^{n_c} [-\frac{1}{2}\log(2\pi\sigma_i^2) - \frac{(c_i-\mu_i)^2}{\sigma_i^2}] \propto \sum_{i=1}^{n_c} [-\log(\sigma_i) - \frac{(c_i-\mu_i)^2}{\sigma_i^2}] \tag{6}$$

In equation (6), c_i corresponds to the input value in the neural network and μ_i, σ_i are the mean and variance of each distribution of the code c_i. An overview of the network architecture of the infoGAN is shown in Fig 2. It becomes clear that the logic behind this architecture is that a sample is generated by the generator; it should look real, so that the discriminator classifies it as real and the parameters of the code **c** that were used to generate it should be as distinguishable as possible by the auxiliary neural network Q. Following this scheme, the infoGAN is expected to generate samples belonging to different classes (or manifolds) using different categorical codes $\mathbf{c}_{cat}$ and to explain the variability of features within the classes, using the continuous code $\mathbf{c}_{cont}$. Also, some random noise is added via **z** because as usual, noise in the data exists and should be modelled.

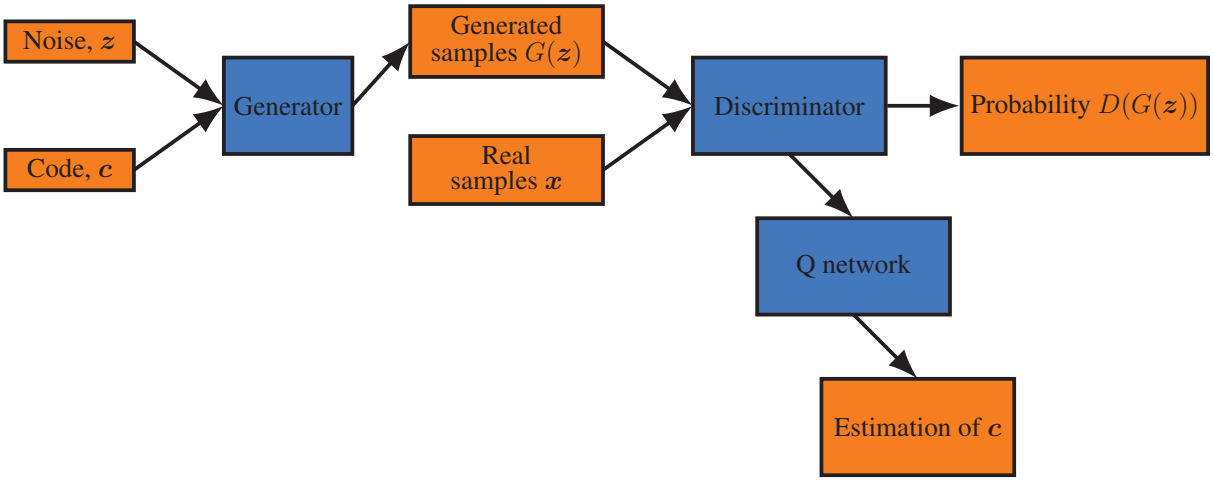

Figure 2: InfoGAN layout.

3 Application on simulated data

3.1 Simulation description

For the application of GANs to structural data, a simple simulated linear six-degree-of-freedom lumped mass system is examined. The masses of the system were all equal to one, the stifness of the undamaged states of the springs equal to 10^4 and a diagonal damping matrix was assumed with its elements equal to 25. The system was simulated using a fourth-order Runge-Kutta integration scheme. The excitation was a white noise signal applied on the first mass. In order to introduce different levels of damage in the structure, stiffness reductions were applied on springs 1-2, 2-3, 3-4 and 4-5. The reducted stifnesses came from normal distributions with mean values of 80% of the initial values of the system and variance equal to 4.5% of the initial stiffness of each spring.

In each simulation the *transmissibilities* between masses 1-2, 2-3, 3-4 and 4-5 were calculated, concatenated and considered as the samples representing each simulation. The normal condition concatenated transmissibilities are shown in Figure 4. Transmissibilities are a useful tool in monitoring real structures, where one has no knowledge about the input excitation to a dynamical system, in order to calculate the *frequency response function* (FRF). The sampling frequency of the simulation was $200Hz$; each transmissibility consists of 512 spectral lines and noise with variance equal to 5% of the transmissibility's variance was added to each one of them. In order to visualise the data, a *principal component analysis* (PCA) [20] was performed on the data and the first three principal components were plotted. In Figure 5 each batch/manifold of points corresponds to a different damage case. Moreover, through the gradual colour transition, the different damage levels are shown. A yellow colour represents points with low damage level (5-7.5% stiffness reduction) and dark red points correspond to higher damage levels (32-35%).

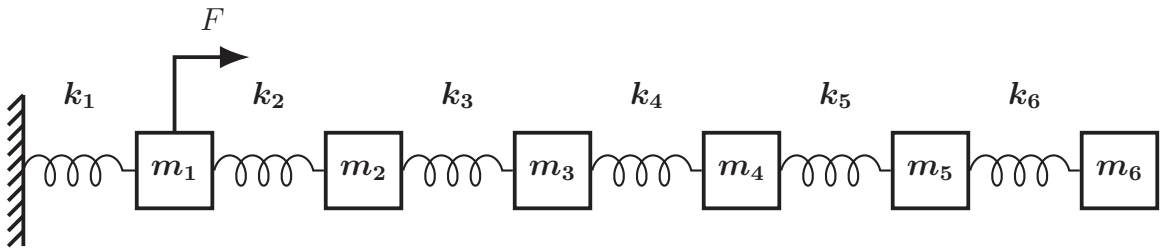

Figure 3: Mass-spring system.

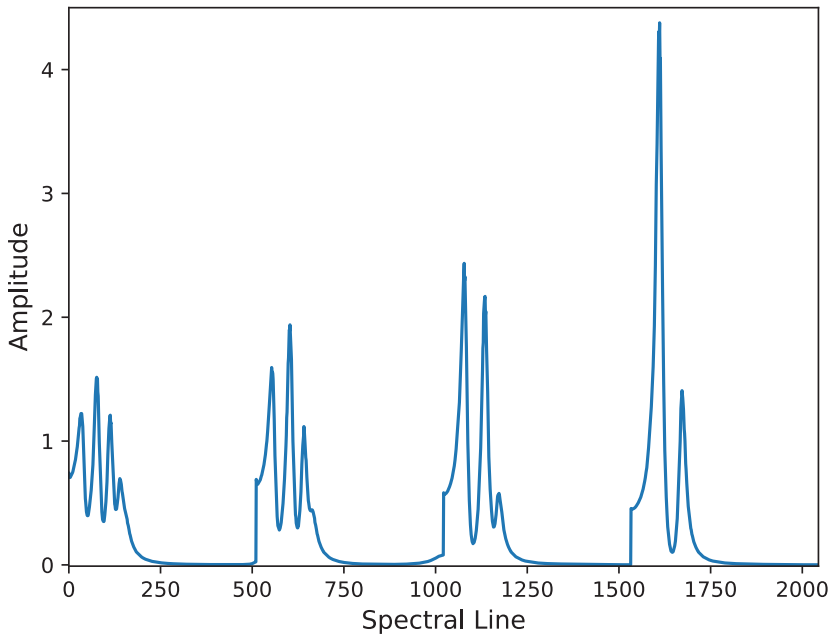

Figure 4: Normal condition concatenated transmissibilities.

Each damage case affects the transmissibilities in a different way. To be able to judge the results of the GANs to be trained consequently, an illustration of influence of that stiffness reduction on the transmissibilities is offered in Figure 6. Each different colour line corresponds to different

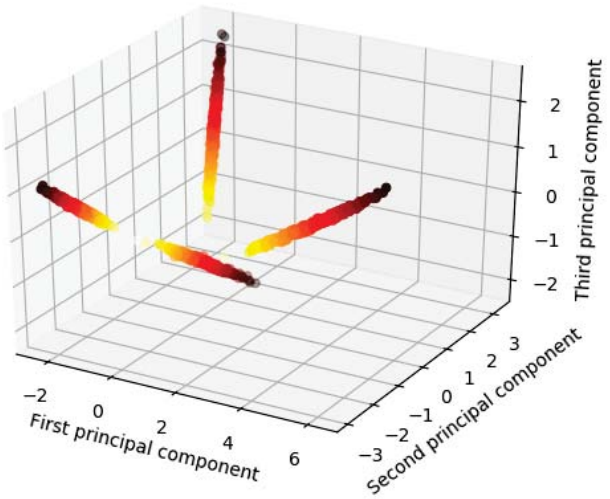

Figure 5: First three principal components of simulated transmissibilities. Gradual colour change from yellow to dark red represents lower to higher damage levels respectively.

damage level and the "movement" of the diagram as the damage extent increases is depicted. Damage induced in different springs causes similar effects to the one shown in Figure 6, but in different areas of the diagram.

3.2 InfoGAN training

The infoGAN was trained on the five first principal components of the data (explaining 99% of the variance) in order to reduce both training time and trainable parameters of the networks. Since the PCA transformation is linear, the infoGAN training is not considered to be assisted by it in any way other than the dimensionality reduction. In the input layer of the generator, two latent variables z_i sampled from a Gaussian distribution $z \sim N(0, 1)$ were used because noise is present in the data. Four categorical variables $c_{i,cat}$ sampled with equal probability were also used, since there are four different damage cases and one continuous c_{cont}, sampled also from a Gaussian distribution similar to the previous one. The expected result is that the generator should be able to generate samples corresponding to the different damage cases by altering the categorical variables and also corresponding to the damage extent by varying the continuous latent variable.

The discriminator was chosen to be a neural network with two hidden layers comprising 60 and 30 nodes and an output layer. The generator was also defined as a neural network with two hidden layers of 100 and 15 nodes and an output layer with five nodes. The ideal size of the networks is not considered to be the object of the current work, therefore, choosing the best architecture is not examined and was simply performed by trying different architectures manually and selecting the ones that had satisfying results in terms of the value of the loss function. The networks were initialised several times and the one with the lowest value for the loss function was kept. In contrast to vanilla GANs, where the value of the objective function oscillates during training, the value of the regularisation term in the loss function of infoGANs (4) gets lower by training and selection of the network with the lowest value of the cost function is a legitimate

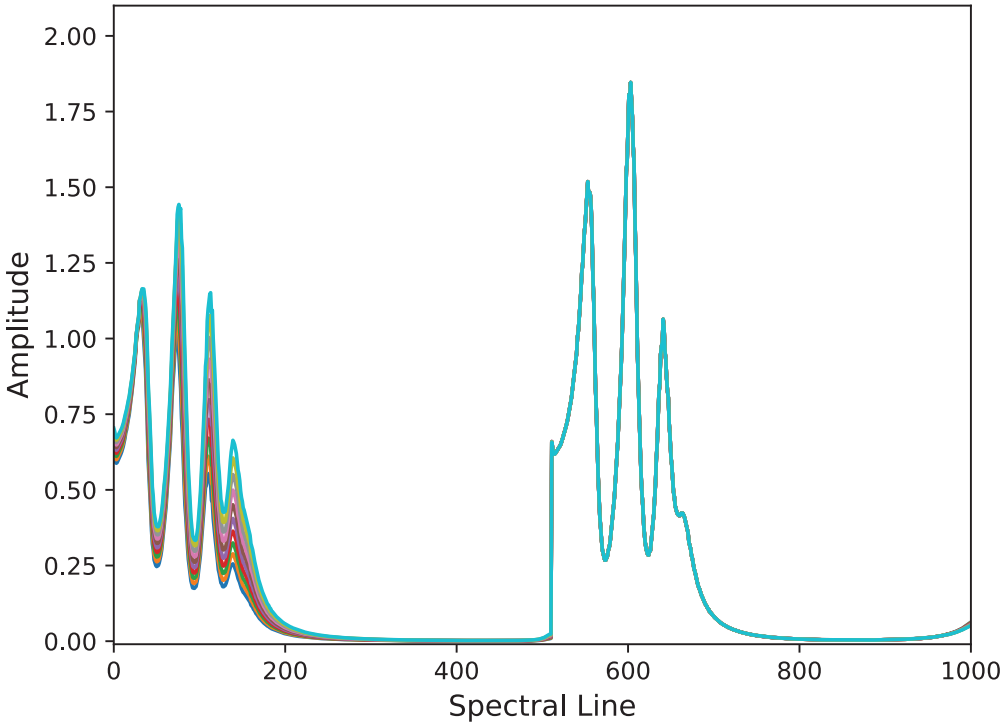

Figure 6: First damage case samples, focused on the first transmissibility, which is affected by the damage. Different colours reflect gradually increasing damage level, from cyan (no damage) to blue (highest damage level).

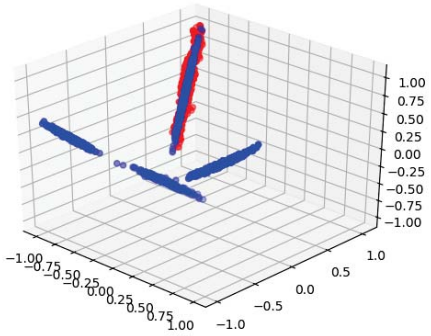
strategy.

Having trained the generator, random samples are generated and studied. For each categorical variable, 1000 samples were generated varying the continuous c_{cont} in the interval $[-2.0, 2.0]$ and generating random values for the latent noise vector $\mathbf{z}$. In Figure 7. It is clear that the generated points are quite close to the areas of the original points. It is also clear that each categorical variable forces the generated points to belong to different clusters of the data, as long as the manifolds of these clusters are not connected.

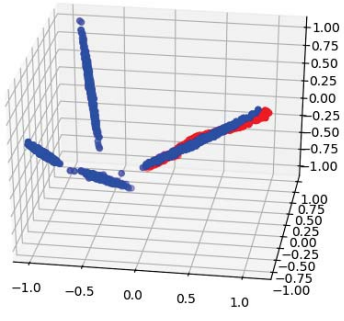
3.3 Classification and regression using GANs

In order to exploit the results of training a GAN, apart from generating artificial data, two more use cases are examined. The first one is classification of the data and the second one is a regression scheme; both in an unsupervised manner. The algorithm so far required minimal supervision for the results above. The only supervised part of the algorithm was the definition of the number of noise, categorical and continuous variables in the latent space.

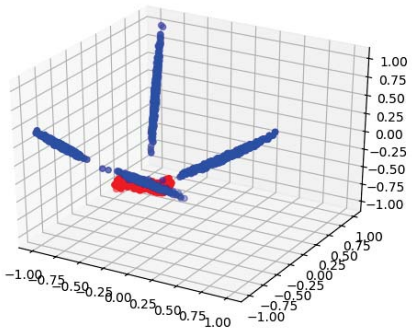
For the classification process, random samples are generated in the principal component space for each categorical variable separately. Subsequently, for each sample in the original dataset the closest generated point is sought in terms of the Euclidean distance between the points. The class assigned to the sample from the dataset is the class of the categorical variable that was used to generate the closest point to the sample. Following this procedure for every point in



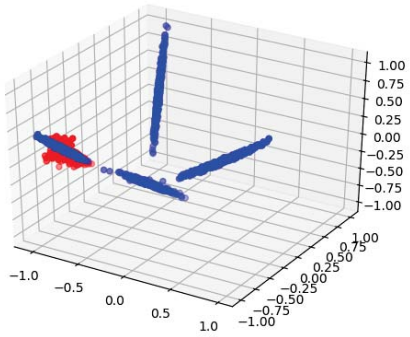
(a) First categorical variable.



(b) Second categorical variable.



(c) Third categorical variable.

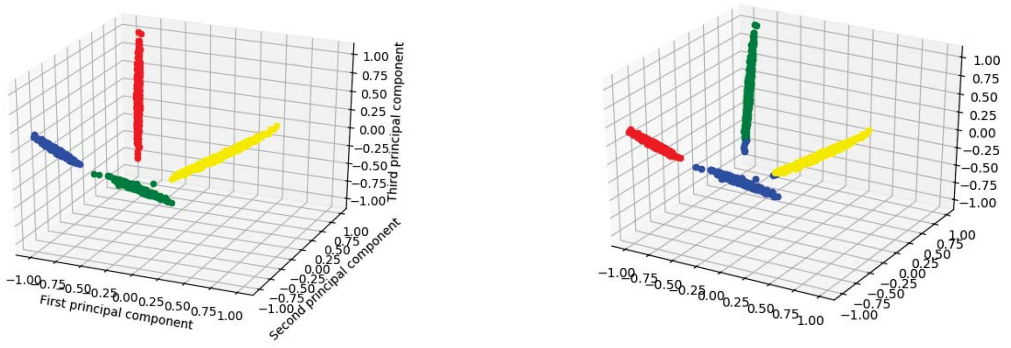


(d) Fourth categorical variable.

Figure 7: Generated points (red) and original points (blue) using different categorical variables.

the dataset, the result of the classification is shown in Figure 8a. Each colour corresponds to a different cluster assigned by the algorithm. The classification is perfect, as each point is classified correctly. In order to contrast performance against a more trivial unsupervised classification algorithm, a K-means clustering algorithm [21] is also applied on the same dataset and the results are shown in Figure 8b. It is clear that there are some misclassified points using the K-means algorithm.

Regarding the regression scheme, the captured variance from the continuous variable is examined. In order to illustrate what the continuous variable has captured, more samples were generated this time with the noise latent variables z considered constant and equal to zero. Again for each categorical variable, several samples were generated by using different values for the continuous variable in the interval $[-3.0, 3.0]$. The results are shown in Figure 10. The variable has captured some of the physics, explaining how the extent of damage affects the transmissibilities but the fit is not perfect. By generating samples in the principal component space and transforming them back to the original space, the effect of varying the continuous and the categorical code can be illustrated. In Figure 9 the transmissibilities generated the way mentioned above are shown for the categorical variable that corresponds to the first damage case. It is clear that the continuous variable has the same effect on the diagram as the same "movement" occurs as in the one with



(a) (b)

Figure 8: Results of the classification procedure using the GAN generator (left) and a K-means algorithm (right).

different damage extents in Figure 6. Similar behaviour is observed with the rest of the damage cases.

4 Conclusions

Summarising, this work demonstrates that there exist certain benefits in using GANs, and more specifically infoGANs, in SHM. Using simulated data, it was illustrated that an infoGAN with only prior knowledge of the number of different states of the structure is able to fit latent variables in the distribution of the real data. Being trained on the data, the algorithm could be used to classify the samples according to the categorical variables defined and at the same time to produce artificial samples in a desired class. Furthermore, the continuous variable was able to capture an underlying varying feature of the data, that of the extent of damage. As before, samples could be generated by altering the continuous variable, while keeping the categorical variable constant. This way, the effect of the level of damage was observed on the generated *transmissibilities*. It could be stated that the infoGAN is imitating the damage mechanism through the continuous code variables and such a scheme could be followed with a view to understanding how damage mechanisms affect specific structures.

Since the GAN is an artificial intelligence algorithm, the results it yields should be evaluated in this context. In artificial intelligence, the goal is for algorithms to perform as good as human intelligence would and if possible, outperform it. In the case of classifying points in a feature space, human-like behaviour is quite similar to the way infoGANs cluster data. A human examining this data, in order for two batches of points to belong in different clusters, their manifolds should be disjoint. The infoGAN exhibits a similar behaviour, as for it to generate points using different categorical variables, the real points should belong in two unconnected manifolds. Under this assumption, the algorithm's performance is quite good, since it classifies points the same way a human would and can moreover perform it in multidimensional spaces, which humans usually are not able to perceive and process.

Focusing on SHM and damage detection, if damage occurs gradually, the points representing the status of the structure smoothly moves in space as a function of the damage extent. In this case the infoGAN algorithm should be able to capture this change through a continuous latent

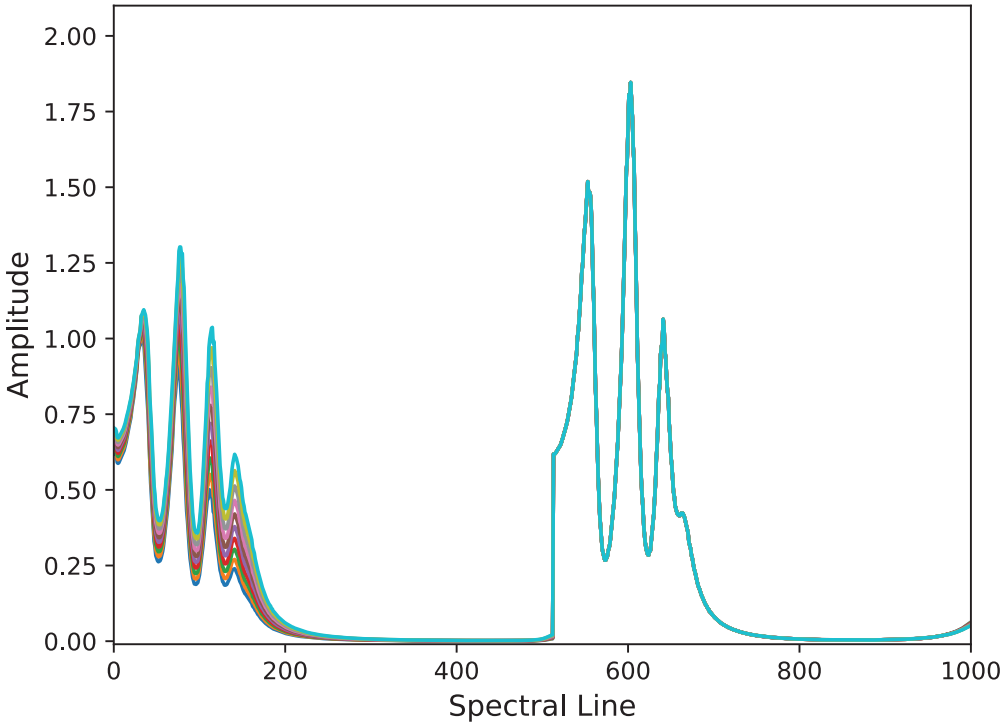


Figure 9: Generated samples, using a single categorical variable, corresponding to the first damage case and varying the continuous variable, focused on the first transmissibility, which is affected by the damage. Different colours reflect gradually increasing damage level, from cyan (lower damage level) to blue (higher damage level).

variable. If damage occurs suddenly, the infoGAN might be able to capture it as a different cluster through its categorical variables. At the same time, generation of artificial data for different clusters or values of underlying variables as damage extent is possible. In cases of continuous monitoring of structures, some varying environmental conditions in the acquired data may be captured. In this case, the infoGAN should also be able to capture the variation of the parameters in its continuous variables. This observation points out a potential use of infoGANs in large databases in order to define trends and different clusters of data caused either by damage or benign changing environmental conditions.

Keywords: Structural health monitoring, machine learning, neural networks, neuroevolution of augmenting topologies (NEAT).

Abstract. *In the current paper, an application of the neuroevolution of augmenting topologies (NEAT) algorithm is considered in a structural health monitoring (SHM) application. The algorithm is a variation of genetic algorithms, applied in neural networks, and has the goal of optimising both the topology and the weights and biases of a neural network model. The algorithm is applied here to an SHM problem instead of using feedforward neural networks. The algorithm is called to search for the best-fitting topology in the task, which would otherwise be sought through experimenting with the size and number of the layers of the neural network. Having used the algorithm, the accuracy is found to be close to the one achieved using classically trained neural networks. Another aspect of the application is that subnetworks were defined for every damage case of the problem, whose topologies are much simpler than a fully-connected feedforward neural network. These subnetworks define classification submodels that may be used in different combinations, building models for a subset of damage cases and input features.*

1 Introduction

Structures are essential elements of human everyday life. From living in houses to moving from one place to another, structures play a key role in activities that are vital for everyone and monitoring them is required in order to make sure that they operate in the way in which they were designed. A malfunctioning structure could cause various problems. A building that has been damaged endangers the lives of those that live within it. Malfunctioning wind turbines may produce reduced electrical energy or even collapse, having as a result huge economic costs. A damaged bridge that requires stopping traffic on it, results in huge delays and even bigger financial damage to people who need to cross the bridge as part of their business. Taking into account the potential consequences of failure of structures, the need to monitor them emerges.

The discipline of acquiring data from structures through sensors, processing them and inferring results about the health state of the structure is called *structural health monitoring* (SHM). There are several approaches to monitoring structures but the most dominant use *data-driven* or *machine learning* (ML) methods [1], in order to infer results about the data. The models created are, in general, black-box models that rely on existing data acquired from a structure. There are several tasks that such a model may be called on to perform; a hierarchical way of classifying these tasks is given by Rytter in [2]:

1. Is there damage (*existence*)?
2. Where is the damage in the system (*location*)?
3. What kind of damage is present (*type/classification*)?
4. How severe is the damage (*extent/severity*)?
5. How much useful (safe) life remains (*prognosis*)?

The first two tasks are the most simple ones and in the context of machine learning, they have been dealt with using quite simple approaches. In [3], Mahalanobis distances were calculated between the baseline condition of a structure and the condition that is tested for the existence of damage. More complicated and more robust approaches for detecting the existence of damage are given in [4]. Another novelty measure that indicates existence of damage is given in [5]; it is defined using autoencoders in order to describe the manifold to which the data of the normal condition of the structure belong. If some testing data belong to the same manifold, the samples are considered as healthy; otherwise, it is considered that damage exists in the structure and it should be examined. Regarding the second level of Rytter's hierarchy; in [6], neural networks have been used to localise damage in an aircraft wing. The neural network was trained to classify damage into nine location different classes, according to features that were extracted from sensors placed on the wing.

Neural networks are machine learning algorithms that can approximate any arbitrary function [7], that explains the relationship between some input and some output values. For this reason, they have been widely used in the context of SHM and in many other disciplines including natural language processing, computer vision, etc. A major drawback of neural networks is that they require large training datasets in order to generalise well on unseen data. Moreover, selecting their architecture involves hyperparameters that have to be tuned by the user with a view to creating a model that fits the training data and generalises well on testing data.

In the current work, an approach to avoid selecting the exact architecture of a neural network for

an SHM problem is studied. This approach is called *neuroevolution of augmenting topologies* (NEAT) [8]. According to this approach, a genetic algorithm scheme is followed to train the neural network weights and at the same time create its topology from scratch [9]. The mainstream approach of training a feed-forward neural network requires trying different numbers and sizes for the hidden layers. In the end, the neural network that performs best on the task that they were trained for is used. This may be considered a brute force search for the best architecture and sometimes may take a lot of time. In addition, the architectures that are tested through this approach follow a specific pattern and more complicated approaches are not considered. The algorithm is tested here on experimental data with the task of localising/classifying damage on a structure.

2 Training neural networks using genetic algorithms

2.1 Genetic algorithms

Genetic algorithms are widely used in many scientific disciplines; they are a means of optimisation of given objective functions, as explained in [10]. In engineering, such algorithms have been used in order to optimise the design of whole structures [11], according to a quantity of interest, or even to select the model that best describes some acquired data [12].

Genetic algorithms draw inspiration from the natural selection scheme that exists in nature; individuals - structures, models or whichever entity is set to be optimised - are initially born with random characteristics. Afterwards, their strength is calculated through a fitness function that reflects the quantity whose optimisation is sought. In every generation, individuals that do better according to the fitness function, survive, while the rest die. One of the most important aspects of a genetic algorithm is the creation of offspring. Couples of individuals that have survived, create offspring that inherit characteristics from both their parents and have a probability of a mutation in their characteristics. Following this framework, the population moves towards the areas in the parameter space that generate more appropriate values regarding the fitness function and through creation of offspring through mutation, the space is further explored. The individuals may be points in an n-dimensional space representing parameters of a model, or even whole structures. There are many variations on the described genetic algorithm but they all, more or less, follow this scheme.

One of the main reasons that genetic algorithms are chosen as an optimisation tool is that the quantities that are being optimised or minimised may be a function without a specific formula. A quite common way of optimising function parameter values is using gradient descent [13], a requirement of which is having a formula that needs to be minimised or maximised and also, the formula should be differentiable. Quite often, the quantity that needs to be optimised may be a discrete one, such as the accuracy of a model in terms of number of correct decisions.

Another aspect that makes genetic algorithms powerful, is that they are thought to be exploring the parameter space to a greater extent than other methods, including gradient descent. An ideal solution to the problem of finding the optimal value for some quantities of interest, would be an exhaustive search in the whole parameter space. Through this kind of search, finding the optimal solution/global minimum or maximum is ensured, but in most cases it is computationally intractable. In contrast, a gradient-descent search, will follow a single path in the parameter space that depends on the initial value of the parameters and on the gradient of the objective function on each point during search and may hit a local minimum. Using a genetic algorithm, discrete points in the parameter space are chosen and the ones that do better in optimising the

objective function survive. The population slowly moves towards the areas in space that optimise the objective function, but at the same time explores a bigger part of the space than the gradient descent, since mutations create many different points in space rather than following a single path. This property is also the reason that a genetic algorithm is less likely to get stuck in local minima/maxima.

In the context of neural networks, where gradient descent through backpropagation is the most common way of training, tuning the trainable parameters may be alternatively performed using a genetic algorithm [14]. Using this approach, local minima may be avoided and also the loss function does not need to be differentiable. According to this framework of training, the neural network still has a fixed architecture. This idea may not allow finding the optimal solution, since the optimal network architectures vary according to the task for which they are used. Since the topology/architecture of the network also affects its functionality, exploring the space of topologies along with the space of parameters would be convenient and so a different scheme is proposed in [8] -the neuroevolution of augmenting topologies.

2.2 Neuroevolution of augmenting topologies (NEAT)

Following the aforementioned approach, the architecture of the network is not predefined. To avoid a predefined topology and force the algorithm to search for the one that performs best in some task, an augmenting topology scheme is followed. Again, the general genetic algorithm is used, as random individual neural networks are generated. The initial state of networks is considered to be a totally unconnected network with some input and output nodes. The first population is formed by creating random connections between these nodes. A fitness function is defined and performance of each network is evaluated in every generation. Consequently, the procedures of genetic encoding, mutation and crossover between networks have to be defined.

2.2.1 Genetic encoding

In order to perform the operations needed for the evolution of the population, an encoding of each individual neural network is needed. This encoding is referred to as the *genome* or *genotype*, and the network it corresponds to is the *phenotype*, in parallel with human DNA being an encoding and the phenotype being the way this encoding is translated into human characteristics. For the purposes of the algorithm, the genome will be a list with the connections, called *genes*, that have been defined in the network with a chronological order. The list will increase in length as generations pass, since new connections will be defined due to mutations or crossover.

By defining a chronological order or *historical marking* as mentioned in [8], a global naming for every mutation that has happened is achieved. Since mutations will be happening at random within the population, it is plausible that the same mutation may occur more than once. In such a case, the genes that correspond to the same connection in the networks, should be identified as so. During crossover, if a historical marking exists in both parents, it should be inherited to the offspring. An example of a genome and its phenotype is shown in Figure 1, where the encoding of a network is shown. Using the historical markings, encoding of the same connection in many different genes, is avoided.

In: 1 Out: 5 Weight: 0.7 Bias: 0.3 Enabled Hist. marking: 1	In: 2 Out: 5 Weight: -0.5 Bias: 0.12 Enabled Hist. marking: 3	In: 3 Out: 4 Weight: -0.17 Bias: 0.92 Enabled Hist. marking: 5	In: 5 Out: 4 Weight: 1.22 Bias: 0.83 Enabled Hist. marking: 6

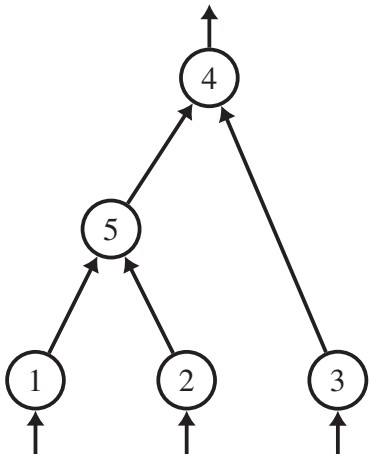

Figure 1: Example of a genome and the corresponding *phenotype* [8].

2.2.2 Mutation

One of the basic operations of a genetic algorithm is the mutation of individuals; this allows further exploration of the parameter space. In the case of NEAT, mutations should be able to explore both the network topology space and the parameter space of the networks. In order to explore the parameter space of the networks, mutations are allowed in the weights and biases of the connections and the activation and aggregative functions of nodes.

Mutations of the weights and biases are quite trivial. At the end of every generation, offspring have a probability of mutating a weight or a bias term from their connections. The mutations are simply changes in the values of the variables. The most common way of defining the new value is through sampling from a normal distribution with mean value μ equal to the current value of the parameter and a variance σ^2 that is defined by the user. This scheme introduces four hyper-parameters in the algorithm that the user has to define; the probabilities of a weight (p_w) or a bias mutation (p_b) and the power of the mutations or the variances (σ_w^2 and σ_b^2) of the distributions used to define the mutated value. Small values assigned to these hyper-parameters will result in a more thorough search in the parameter space, but also probably in a slower convergence of the algorithm.

The first mutation that applies to the topology of the networks is the *add connection* mutation; a connection is added between two nodes that so far have not been connected. Nodes and their IDs are shared amongst every individual in the population. Every network though has different connections defined in between the nodes and through this mutation type, new connections are defined within the mutated individual. The weight of the new connection is sampled from a random distribution and a historical marking is assigned to it. The opposite mutation should also be considered, the *disable connection*. This type of mutation, straightforwardly disables an existing connection in an individual. An example of how an add connection mutation is encoded

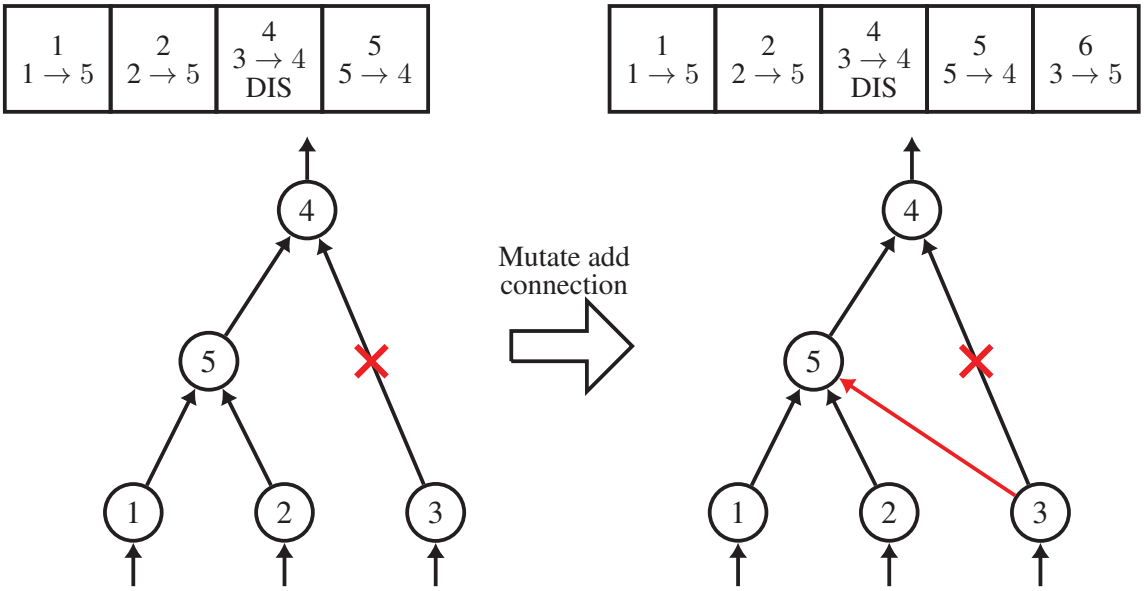

Figure 2: Example of an *add connection* mutation and the corresponding genome change [8].

is shown in Figure 2, where also a disabled connection is shown.

The second mutation regarding the topology is the *add node*, where a new node that did not exist so far is introduced. The way that such a node is added is by splitting an existing connection into two and placing a node between the two new ones. The old connection is disabled and the two new ones are added to the genome of the individual. The connection leading to the new node has a weight of 1 and the second one has weight equal to the weight of the old connection. The new node has a new ID and it is available in every individual to be connected through *add connection* mutations with other nodes. An example of the *add node* mutation is shown in Figure 3.

2.2.3 Crossover

Finally, the crossover operation is needed to completely define the genetic algorithm procedure. The crossover is performed using the genetic encoding of the networks. The genomes of the parents are placed in parallel according to the historical marking of each gene in the genomes. If a gene with a specific historical marking exists only within the genome of one parent, it is directly inherited to the offspring. If a gene with the same historical marking exists in both parents, it is inherited to the child by the most fit parent. An example is shown in Figure 4.

3 Application on experimental data

3.1 Experiment description

In order to test the algorithm, an experimental setup is considered [6]. The experiment is that of simulating damage on an aircraft wing. The wing was set in the laboratory and was excited with white noise using a shaker attached to its bottom surface. Sensors were placed on it as shown in Figure 5. The experiments were performed using the wing in both damaged and undamaged states. The damaged states were simulated by removal of one out of nine different wing panels. The panels that correspond to a different damage case are each shown in Figure 6.

The quantities that were recorded during the experiments with the damaged wing, were the

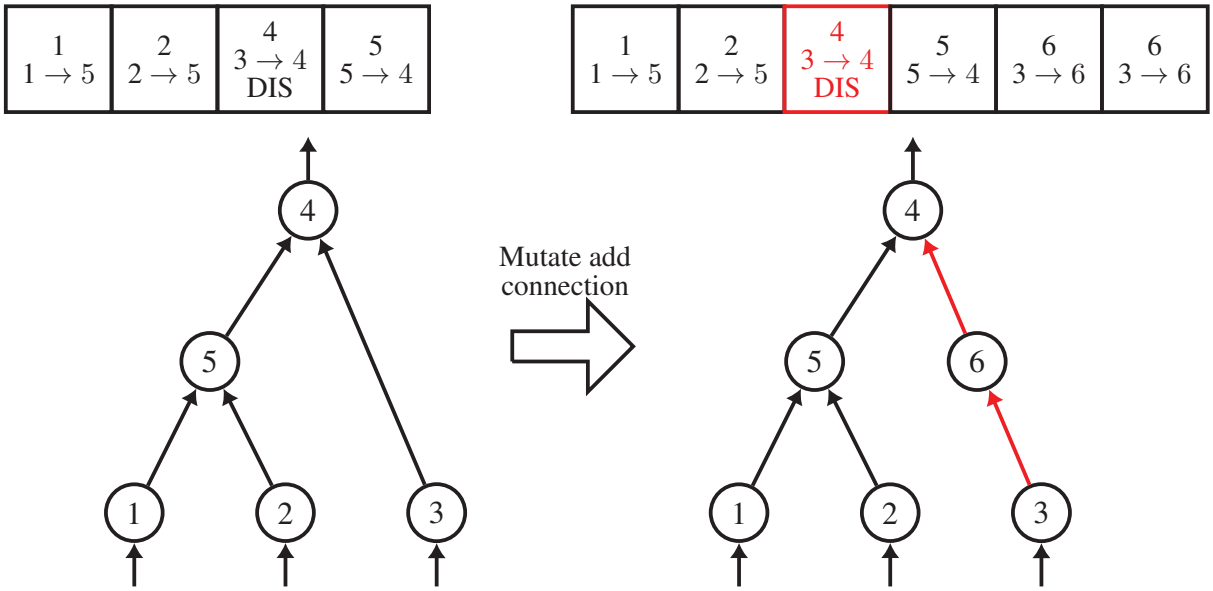

Figure 3: Example of an *add node* mutation and the corresponding genome change [8].

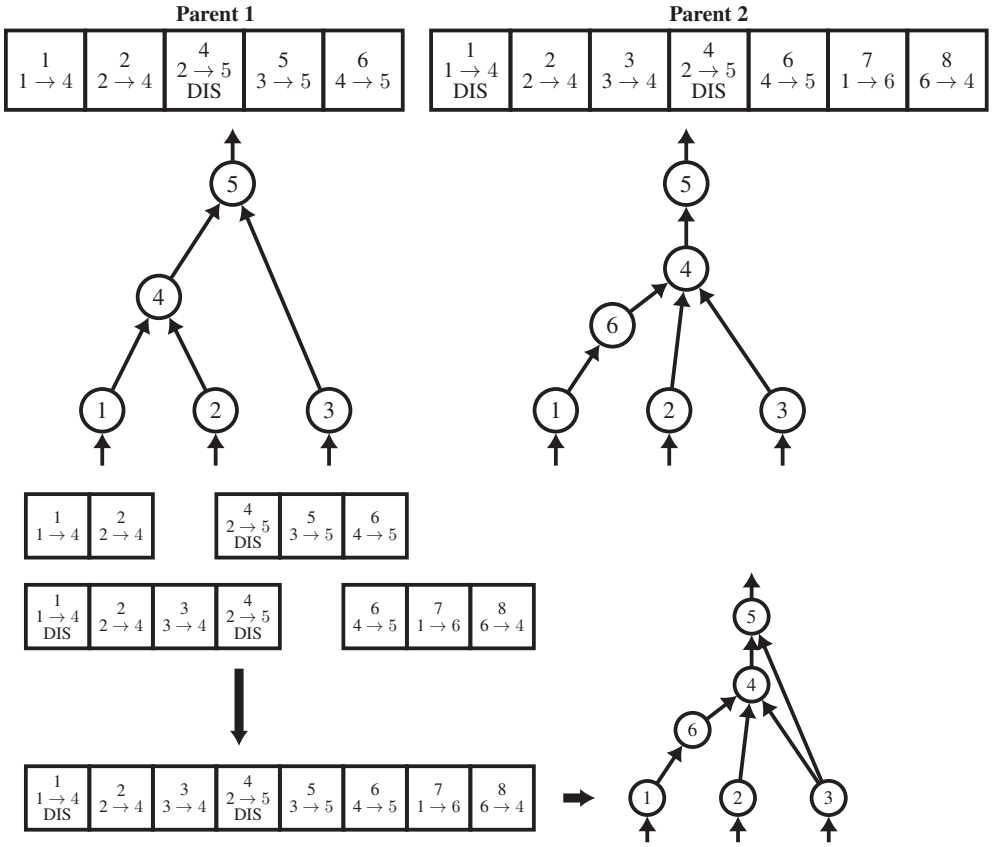

Figure 4: Crossover process given two parents and their genomes [8].

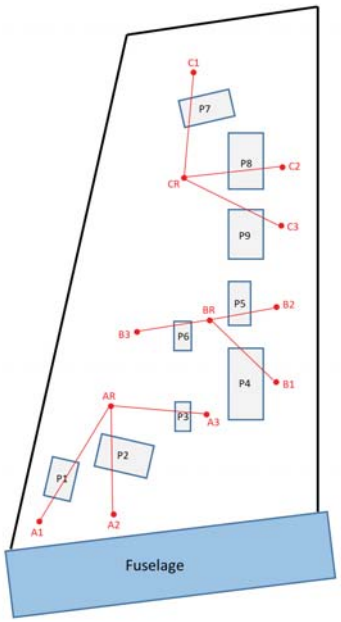

Figure 5: Configuration of sensors placed on the GNAT wing [6].

transmissibilities between two sensors. Transmissibilities are a quite useful feature, since knowledge about the excitation force is not required, in contrast to the case of a *frequency response function* (FRF). The transmissibilities were recorded between sensors AR and A1, A2 and A3 and similarly between the rest of the sets shown in Figure 5. This procedure resulted in nine different transmissibilities that were available for both the undamaged and the damaged states. Subsequently, intervals within the transmissibilities that were more sensitive to damage were identified "by eye"; this resulted in 72 different intervals and for each one of them, novelty indices were calculated between the normal condition transmissibilities and the testing cases. The novelty indices were calculated using the Mahalanobis distance,

$$D_{\zeta}^2 = (\mathbf{x}_{\imath} - \overline{\mathbf{x}})^T S^{-1} (\mathbf{x}_{\imath} - \overline{\mathbf{x}}) \tag{1}$$

where $\mathbf{x}_{\imath}$ is the sample whose Mahalanobis distance is calculated, $\overline{\mathbf{x}}$ is the mean vector of the observations and S^{-1} is the covariance matrix of the observations.

The type of model that was selected to classify the data was a neural network taking as inputs the values of the novelty indices and as output one out of nine classes of damage. In order to further reduce the feature space, a genetic algorithm was used to select the best subset of features out of the 72 novelty indices [15]; this resulted in nine novelty indices. The neural network was selected to be a feedforward neural network with one input layer, a hidden layer and a decision/output layer. The best size for the hidden layer was selected according to the performance of the networks in the validation set after having tried different sizes. The optimal network had nine nodes in the hidden layer and the its accuracy is shown in the confusion matrix in Table 1. The total accuracy was 98.14% on the testing set.

Table 2: Confusion Matrix of fittest NEAT individual, test set, total accuracy: 95.79%.

3.2 NEAT training

Taking into account the time needed to select the optimal size for the hidden layer, as well as the fact that the neural network selected had a restricted architecture since it was a feedforward one, application of NEAT was attempted on the same problem. By applying NEAT in this problem, a different topology for the network is expected and maybe a more interpretable model. The exact datasets were used in order to facilitate comparison between the two algorithms.

The population for NEAT was chosen to be a 500-neural network population with a *rectifier* or *relu* activation function on their nodes. The probabilities of mutating a weight or a bias term were both 0.7 and the mutate power was 0.1 in both cases. Moreover, the probabilities of adding a new connection or a new node were both 0.5 and the probability of deleting a connection was 0.05. The fitness function was set to be the accuracy of predictions given by a softmax function σ,

$$\sigma(\mathbf{x})_i = \frac{\exp(x_i)}{\sum_j \exp(x_j)} \tag{2}$$

applied on the values of the output nodes of each network, using this function on the output of the networks, the algorithm allows their interpretation as probabilities.

3.3 Results and splitting into subnetworks

Having trained the population, after 3216 generations and about a day of training, the fitness of the "strongest" individual had been stable for many generations and so it was considered to have converged. The confusion matrix for the fittest individual on the testing set is shown in Table 2. The accuracy is slightly lower than the accuracy of the original work where feedforward networks were used.

It is worth isolating the sub-networks that describe how each output node is activated. This is done by looking for paths from every input node to each output node separately. Doing so, the subnetworks that are found for every damage class are shown in Figure 7. Connections with green colour represent positive weights while the ones in red correspond to negative weights. It is particularly interesting that subnetworks whose structure is quite simple have been created. For example the subnetwork corresponding to panel 9, is affected only by input features 3, 7 and

Predicted panel	1	2
Missing panel 1	64	2
Missing panel 2	0	66

Table 3: Confusion Matrix regarding classifying cases of missing panels 1 and 2 using the respective subnetworks, accuracy = 98.48%.

8. This separation could result in further insight into the physics of the problem, as it is more interpretable than a fully connected neural network.

Another aspect of this approach is that these subnetworks could be combined and used as a modular classification model for a subset of damage cases. For example, one may be interested in creating a classifier that would be able to distinguish between the classes of missing panel 1 or missing panel 2. The procedure to be followed is to use the subnetworks of the two cases and assign a label to the sample according to which subnetwork generated a greater value on its output node. By applying this algorithm for the case of damage cases 1 and 2, the confusion matrix for the testing data is shown in Table 3. It is also worth noting that using this approach, the values of the input features that are needed are those of features 1, 2, 3, 4, 5, 6, 8, since they are the subset of input features that are used by the two subnetworks.

4 Conclusions

An alternative approach to training neural networks for SHM was presented, that of augmenting topologies. The algorithm used does not have a specific topology for the neural network that is going to be trained, but is searching for an optimal one using a genetic algorithm. Following this approach, the size and architecture of the network to be used does not have to be predefined. Even though selection of a topology is avoided, new training hyperparameters have to be defined, for example the probabilities of the creation of a new node or a new connection in the population of neural networks.

The results of the classification task in the SHM example described, reveal that the accuracy of the fittest individual was close to the accuracy of a feedforward neural network trained using backpropagation. The training time, taking into account recent advances in hardware used in applying backpropagation in neural networks, is much larger for the NEAT algorithm. The training time for NEAT could be lower if a parallelisation scheme was followed, which was not used in the current work.

Although there are some disadvantages in applying such an algorithm, some advantages emerged; the first is that the fitness function may be a discrete quantity that could not be used as a cost function in a feedforward neural network. Furthermore, the isolation of subnetworks presented, generated quite simple sub-models for each damage case, whose extraction is not applicable in a feedforward neural network. The use of such subnetworks for classification of a subset of damage cases was also shown to be possible. These modular models used a subset of features which may prove useful in cases that some features may not available. In such cases, inference may still be made for subsets of damage cases.

Finally, more simple or more complex architectures that are not achievable by using a mainstream feedforward network are considered. The approach of augmenting topologies allows a greater variety of networks to be tested for the task at hand. In many problems, this may result in models that achieve greater accuracy compared to other neural networks. The algorithm has also the

potential of allowing recurrent connections that may also fit the underlying physics of a problem and approximate better the real relationship between inputs and outputs.

Keywords: Joints, connections, structural dynamics, validation, calibration, uncertainty, probabilistic methods.

Abstract. *Computer models are inevitable in the present world, and the past few years have witnessed significant improvements in modelling capabilities. Most of the critical engineering structures in the real world exhibit complex behaviour and are often made up of constitutive subsystems or components. In most of the cases, performance or test data at system level might not be adequately available to perform a full-scale validation and hence the predictions from such a model cannot be relied upon in taking crucial decisions. A straightforward approach is to validate the individual subsystems or components and establish confidence in those respective models. Although various components can be modelled reasonably accurately, the prediction of the overall response of a structure also depends on the interaction between various components; developing and validating such a full-scale model is not an easy job. In this regard, it could be narrated that the connections or joints between the components are equally important as the components themselves and need to be modelled as accurately as needed, and the respective models validated. This paper discusses an approach to deal with system-level responses, where the components, as well as the joints between them are treated as separate subsystems. An isolated model has been employed to validate the model for the joint separately and a probabilistic approach is adopted to propagate various parameters and associated uncertainties through the respective models to predict the overall response. This approach is demonstrated through a generic problem, where two different subsystems are connected together to form a full system.*

1 INTRODUCTION

The process of developing any computational model starts with a concept. The concept depends on the understanding of the underlying physics of the process, which paves the way to fit a mathematical model to the concept. This mathematical model defines how different parameters affect the process. In order to solve this mathematical model, a numerical strategy is adopted (e.g. a computer code) and it is this computer code that usually predicts the required response. It is an important step to make sure that the model is good enough for purpose, and that is where verification, calibration and validation come into the picture. Figure 1 shows various stages in the development of a numerical model and where verification, calibration and validation come in.

It is through verification that one confirms the ability of the numerical strategy to accurately represent the underlying mathematical equation. There are different methods of verification that exist depending on the type of the code, and this is still an active topic of research [1, 2, 3]. Even when the code is verified and is proven to give accurate results based on the mathematical model, the parameters of the mathematical model might require calibration or fine tuning. It is through calibration that one can update the parameters so that the mathematical model predicts the responses with accuracy. This process involves comparing the output from the model with real or experimental data to confirm that the parameters are tuned well [4, 5]. Calibration updates the mathematical model based on the experimental results, but the ability of the model to perform well in different settings can be realised only if the concept in the beginning was right; this is established through validation. Model validation refers to the process of determining the degree to which a model (and its associated data) is an accurate representation of the real world from the perspective of the intended use of the model [3].

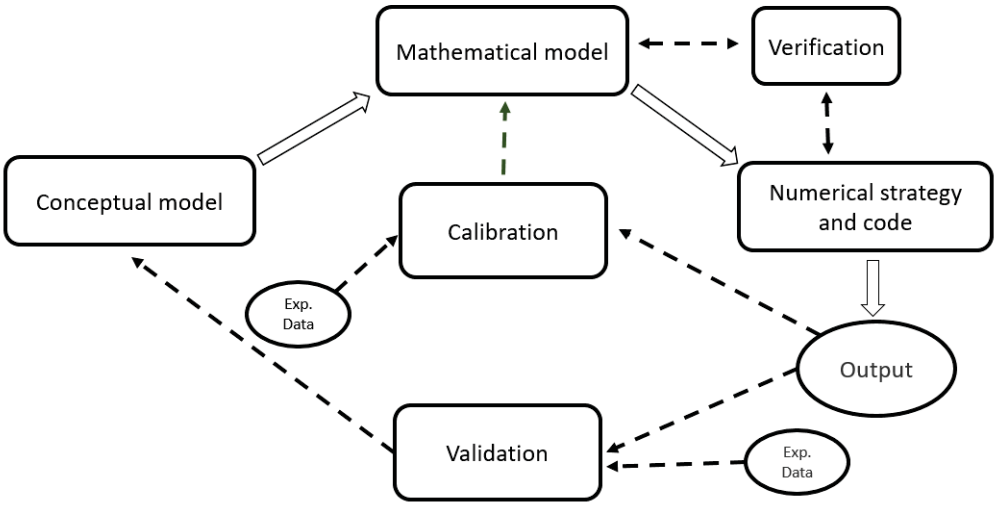

Figure 1: Stages in development of a numerical model.

Both validation and calibration require performance or test data. In practice, many engineering structures are impractical to test to obtain these data and in such situations, it may not be possible to calibrate or validate a model. This paper discusses such situations were a structure cannot be tested, but the substructures or components can be tested. In such cases where the component or subsystem-level models can be calibrated and validated, these can be used to have

better predictions at the system level. This situation also depends on the interaction between the components and in the physical sense, these interactions are determined by the joints. This fact makes it important to know more about joints, and the way joints influence structural responses.

The initial part of the paper reviews methods to apply calibration of parameters through subsystem-level models before focusing on joints. The primary aim is to present an approach to deal with connected systems and on how to address the joints in such systems. The interaction of a joint, and ways of addressing the joints in a system are also discussed. The paper adheres to a probabilistic framework, and hence applications of Bayesian statistics can be found linked to some key concepts. An example problem on a simple connected setup is employed to discus the key concepts and methodologies presented.

2 SUBSYSTEM-LEVEL MODELS

2.1 Concept

Due to the practical difficulties in testing entire structures, calibration and validation data cannot always be obtained for models (system-level models) representing many engineering structures. Nevertheless, simpler parts of the same structure (subsystems) or individual components may be tested independently and the data thus obtained can be used to calibrate and validate the respective subsystem-level or component-level models. A component-level model is a subsystem-level model where the subsystem is reduced to just one component. This process of validating the subsystem-level models does not directly validate the system-level models, but the inferences from the validation exercises at such lower levels, can be used to improve the system-level model and thus to obtain better predictions of the behaviour of the overall structure through these improved system-level models. One way to improve the system-level model is through updating the parameters in the system-level models through observations of the subsystem-level models which employ the same parameters. Integrating the calibration and validation process in the subsystem-level models facilitates the use of better-calibrated parameters in the system-level models, which results in better predictions [6].

This process of obtaining better-calibrated parameters is realised through a probabilistic approach where updated parameters from individual subsystem-level models are further updated according to the respective validation results. This process improves the results and is particularly applicable in situations where there are multiple subsystem-level models to calibrate for the same parameter. To better understand the process, let a system-level model, H, be assumed for a system S such that the model predicts a response Y_S, from an input X_S. It can be expressed as

$$Y_S = H(X_S, \theta_S) \tag{1}$$

where θ_S represents the parameters that define the model. Furthermore, assume that this system is formed of two subsystems. Let G_1 and G_2 be subsystem-level models that represent subsystems S_1 and S_2 of the structure being represented by H,

$$Y_{S_1} = G_1(X_{S_1}, \theta_1, \theta_2) \tag{2}$$

$$Y_{S_2} = G_2(X_{S_2}, \theta_2) \tag{3}$$

Here, θ_1 and θ_2 are subsets of θ_S and θ_S may have other parameters which are not addressed by either of the subsystems,

$$\theta_S = \{\theta_1, \theta_2, \theta_3, ...\theta_n\} \tag{4}$$

This vector may be represented as,

$$\theta_S = \{\theta_1, \theta_2, \theta_{extra}\} \tag{5}$$

where the additional parameters are represented as $\theta_{extra} = \{\theta_3, \ldots \theta_n\}$.

If data for calibration (D_1^c and D_2^c) and validation (D_1^v and D_2^v) are available at the subsystem levels S_1 and S_2 respectively, models G_1 and G_2 can be calibrated for the parameters and validated. Once the calibrated distributions of the parameters, θ_1 and θ_2, are obtained from both the models, the result of validation can be applied to and propagated through the system-level model H to obtain a better prediction Y_s. This process is explained below and a graphical representation of the problem is illustrated in Figure 2. A probabilistic graphical modelling framework [7, 8] enables better control over the process and the changes in response predictions can be updated in real time through additional calibration and validation data. In this paper, graphical models are not employed, but graphical representations are illustrated for better understanding of the model interactions.

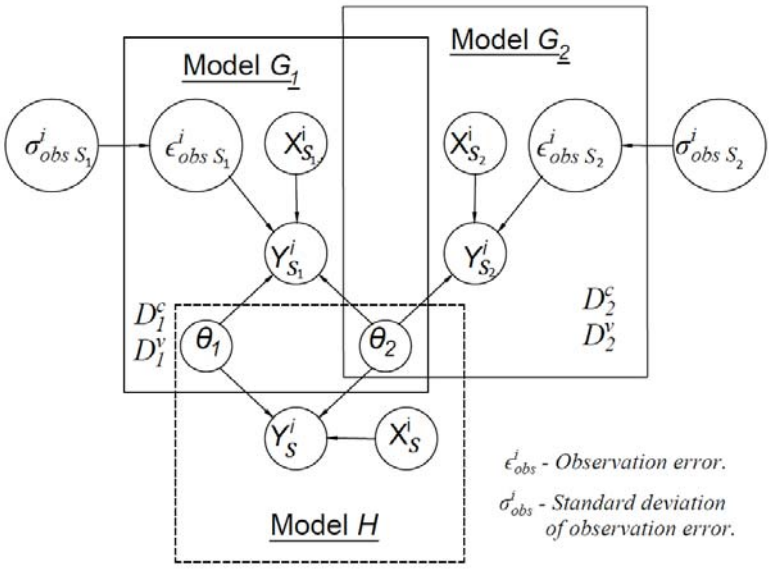

Figure 2: Graphical representation of the system and subsystem-level model interaction.

2.2 Calibration

Let $p(\theta_1)$ and $p(\theta_2)$ be the prior distributions of the parameters θ_1 and θ_2 respectively. D_1^c and D_2^c refer to the calibration data for the models G_1 and G_2 respectively. From the calibration data, posterior distributions of θ_1 and θ_2, $p(\theta_1|D_1^c)$, $p(\theta_2|D_1^c)$ and $p(\theta_2|D_2^c)$ can be obtained through a Bayesian approach [4]. The posterior of a parameter θ of a model G with calibration data D^c and a prior $p(\theta)$ can be obtained using the following relation,

$$p(\theta|D^c, G) = \frac{P(D^c|\theta, G)p(\theta)}{\int P(D^c|\theta, G)p(\theta)d\theta} \tag{6}$$

$P(D^c|\theta, G)$ is the likelihood function of θ and can be expressed as,

$$P(D^c|\theta, G) \propto \prod_{i=1}^{n} \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(Y_i - G(X_i, \theta_i)^2)}{2\sigma^2}} \tag{7}$$

where σ is the standard deviation of the observation errors. Here, θ_1 can be calibrated through G_1 and θ_2 through either G_1 or G_2 or through both G_1 and G_2 together at once. In situations where both the subsystem-level models G_1 and G_2 are considered together, the likelihood function $P(D_1^c, D_2^c|\theta_2, G_1, G_2)$ is given by (assuming independence between the models),

$$P(D_1^c, D_2^c|\theta_2, G_1, G_2) \propto (\prod_{i=1}^{n} \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(Y_i - G_1(X_i,\theta_i)^2)}{2\sigma^2}})(\prod_{j=1}^{n} \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(Y_j - G_2(X_j,\theta_j)^2)}{2\sigma^2}}) \tag{8}$$

2.3 Validation

Once the process of calibration is completed, the individual subsystem-level models can be validated from the available validation data D_1^v and D_2^v corresponding to G_1 and G_2 respectively [9, 10, 11]. An integral aspect of any validation process lies in having a validation metric. Different validation metrics are discussed in various parts of literature [2, 12]. The use of a Bayes factor B [11] as a validation metric finds application in such problems. The Bayes factor represents the likelihood ratio, and in cases where there is only a single model $G(\theta)$, it can be used to represent the ratio of likelihood of observing the data with null (G) and alternate hypotheses ($G^{'}$),

$$B = \frac{P(D^v|G)}{P(D^v|G^{'})} = \frac{\frac{P(G|D^v p(D^v)}{P(G)}}{\frac{P(G^{'}|D^v p(D^v)}{P(G^{'})}} = \frac{P(G|D^v)P(P(G^{'})}{P(G^{'}|D^v)P(G)} \tag{9}$$

The Bayes factor gives a measure on the probability of a model to be validated. The probability of a model G being valid based on available validation data D^v, represented as $P(G|D^v)$ can be obtained from the equation,

$$P(G|D^v) = \frac{B}{B+1} \tag{10}$$

It is obvious from the equation that a Bayes factor equal to one ($B = 1$) corresponds to equal probabilities for the model to be valid and not to be valid. In a generic approach, the model which corresponds to the highest Bayes factor might be more probable and be selected, but [6] proposes a method where all models are selected based on their respective probabilities of being valid, to update the already calibrated parameters. Once the probabilities of subsystem-level models G_1 and G_2 being valid ($P(G|D_1^v)$ and $P(G|D_2^v)$) are determined as above, the probabilities corresponding to the respective models not being valid ($P(G^{'}|D_1^v)$ and $P(G^{'}|D_2^v)$) can also be obtained. Assuming independence between the models, $P(G^{'}|D_1^v) = 1 - P(G|D_1^v)$ and $P(G^{'}|D_2^v) = 1 - P(G|D_2^v)$.

This approach can also be used to find the probabilities that both the models are valid, only one of the models is valid or both the models are not valid [6]. The literature [6] also proposes to include the prior distribution weighted accordingly with the probability of both the models being invalid. This strategy makes complete sense, as no posteriors can be relied on in cases where the models are invalid. For example, here, θ_1 exists only in the subsystem-level model G_1 and hence the only applicable factors would be $P(G_1|D_1^v)$ and its compliment $P(G_1^{'}|D_1^v)$; the prior $p(\theta_1)$ shall be weighted according to $P(G_1^{'}|D_1^v)$.

2.4 Isolated models

In the current discussion, the number of subsystem-level models is limited to two in which one can obtain calibration and validation data. Through these models, G_1 and G_2, and the

associated test data, one could propagate updated and probabilistically-weighted parameters through the model H to facilitate better predictions. But still, the model H, involves other parameters that were not addressed with the subsystem-level models. These situations also arise in real life situations where all the subsystems or components of a structure cannot be tested thus compromising the reliability of the predictions. It is in this context that the importance of isolated models shall be discussed. In order to calibrate a parameter associated to a system or subsystem-level model, an isolated model, specifically designed to address the case can be used. These isolated models shall represent structures which are feasible for testing, and more importantly shall involve the parameters which need to be updated. In this case, one can employ an isolated model G_3 representing a simple structure which can be tested. Let the model be mathematically represented as,

$$Y_3 = G_3(X_3, \theta_3) \tag{11}$$

where X_3 and Y_3 refer to input and output respectively. This model and the associated calibration and validation data D_3^c and D_3^v can be used to obtain a reliable distribution for θ_3, represented as $p(\theta_3|D_3^c, D_3^v)$ using the methods described before.

While the approach discussed above remains a good way of propagating parameters through the system-level models, the validation at the system level still remains a problem. This approach considers the system-level model as an independent model from the subsystem-level models and the focus lies on calibrating the parameters that define the model through subsystem-level models or isolated models. The advantage of such isolated models is that the models and associated structures need not be a part of the structure under consideration. While considering the subsystem-level models as representing real parts of the structure is advisable, isolated models can be used to fill the gap in missing parameters through subsystem-models. A proper metric [2, 12] to evaluate the degree of validation that can be achieved through validating subsystem-level models of different degrees of similarity and assessing the similarity in the role of the subsystems in the full system itself remains a hurdle at present, which demands expert knowledge and critical engineering judgements in proceeding with such assumptions.

2.5 Interaction function

It is important to approach the problem in a way that directs one towards a validated model at the system level. Apart from calibration and validation of the subsystem-level models as a means of obtaining calibrated parameters, it has to be such that these models directly form a part of the overall system or the system-level model and interact within the model towards obtaining target quantities. This interaction between different subsystem-level models in a structural engineering scenario is not easy to generalise and can be specific to a particular problem. These interactions can be defined using an interaction function which governs how the different subsystem-level models compile to a system-level model.

Looking back at the previously-defined system S represented by system-level model H, formed of two subsystems S_1 and S_2 represented by subsystem-level models G_1 and G_2, the interaction function f_H shall determine the interaction between models G_1 and G_2,

$$H = f_H(G_1(\theta_1, \theta_2), G_2(\theta_2), \theta_{extra}) \tag{12}$$

Here, once G_1 and G_2 are validated, they contribute towards more reliable predictions with the model H. The extra parameters may not be calibrated and the part of the system-level model H which is not validated is limited to the interaction function. Calibration of some or all of the additional parameters θ_{extra} may be performed through isolated models (such as G_3)

as described above, and propagated through this system-level model. There could be situations where the subsystems are represented by more than one model; in such a case, multiple models can be used for updating the same parameters, but the most valid model representing the subsystem's role in the model shall be the one selected. A Bayesian hypothesis selection approach [11] can be adopted to select the best model in these situations. Again, a Bayes factor can be used to select between models. To select between two models G_3 and G_4, with respective validation data D_3^v and D_4^v, the Bayes factor between G_3 and G_4 can be obtained as in equation (13). A Bayes factor greater than one favours the model G_3, and less than one favours the model G_4, where,

$$B = \frac{P(D_3^v|G_3)}{P(D_4^v|G_4)} = \frac{\frac{P(G_3|D_3^v p(D_3^v)}{P(G_3)}}{\frac{P(G_4|D_4^v p(D_4^v)}{P(G_4)}} = \frac{P(G_3|D_3^v)P(P(G_4)}{P(G_4|D_4^v)P(G_3)} \tag{13}$$

3 JOINTS

Any structure (system level) could be divided into subsystem-level components and an approach to predict system-level responses through subsystem-level inferences is described above. However, real structures are more complex. Although the components form the structure, the interaction between the components is as important as the components. These interactions between the connected components within a structure are governed by the joints. In a system-level model representing a full structure, it is an obvious need to find parameters that define any joints involved; however, these joint specific parameters may not be existent in the subsystem-level models that could be validated. Moreover, any possibility to validate the modelling concepts related to the joints are also lost. It is in this context that it becomes a necessity to calibrate for the joint-specific parameters and to validate the joint-specific models through an appropriate method. An effective approach to deal with the above aspects of joints is through treating joints as a separate subsystem. The role of this subsystem in a full system is to connect components or other subsystems together in the required configuration, and a model representing this subsystem - the joint model - shall be good enough to address this role. Thus, the system-level model will be a combination of the subsystem-level models and the joint models that determines how the subsystems shall interact within the full structure.

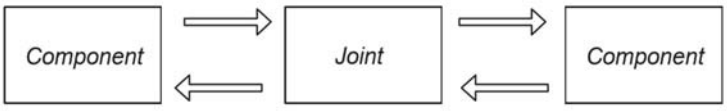

Figure 3: Interaction of a joint with components.

In many cases, as it might not be practical enough to test the components in connection, joint models will often be isolated models of simpler test structures (connected structures) with the same type of joint, which could be tested. It is also an obvious fact that a joint does not exist on its own, but only co-exists with the components it connects together. Therefore, in any exercise to calibrate or validate a joint model in a structure through isolated structures, care must be taken to select or design the test-joint, so that it should effectively address major parameters that define the joint and in a way that it closely matches the purpose of the joint in the full structure.

A joint, apart from having its own general properties (such as the Young's modulus and Poisson's ratio of weld material in case of the welded joint), might also possess properties that

are dependent on the components it connects, and even properties specific for the particular combination of the components being connected (such as thickness of a component). With an isolated model as described above, most of the physics, which are general for a particular type of a joint, can be characterised and the associated parameters updated and propagated through any system level models as in the previous sections. While the calibration and validation of isolated models enhances the results, the system-level model shall also be capable of including the uncertainties arising from any properties which were not validated through the joint model or either of the subsystem models. These parameters come into the system-level model as new elements - additional parameters θ_{extra} as explained in the previous sections.

A well-selected isolated model for the joint which can closely represent the functioning of the joint in the structure, can be integrated into the system-level model through the interaction function. The joint model has a significant role in determining the interaction between the components and it is very important to include such validated models of joints in the interaction function. The primary function of any joint model is to address how the joint influences various degrees of freedom between the components and the effect of various physical and geometrical parameters on this influence. An isolated joint model which can address this effects on a similar, simpler structure can be projected on to a different scenario of connecting different structures (the actual components or subsystems) thorough a proper interaction function and with help of any extra parameters that might be necessary to define the specific interaction. Suppose the joint model is represented by J,

$$Y_J = J(X_J, \theta_J) \tag{14}$$

where Y_J is the response to an input X_J and θ_J represent the parameters that define the joint model. If this joint model can be calibrated for the parameters θ_J and also validated, it could then be used to in the interaction function together with the other subsystem-level models to obtain the system-level model H,

$$H = f_H(G_1(\theta_1, \theta_2), G_2(\theta_2), J(\theta_J), \theta_{extra}) \tag{15}$$

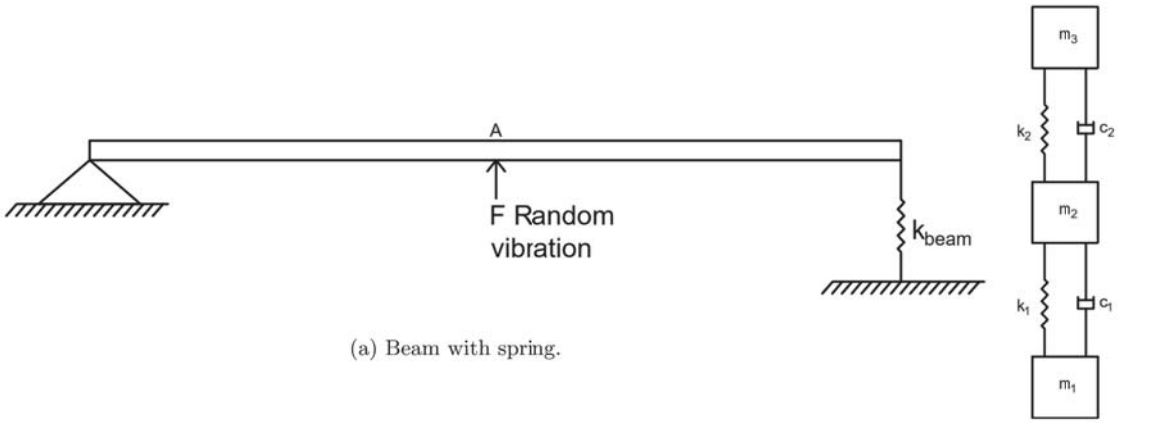
Here, θ_{extra} includes additional parameters required to define the joint in the full-structure, as well as any other parameters that may be required to define the full-structure through the system-level model. If all subsystems and joints in a full structure are considered such that there are no additional parameters involved in defining a system-level model, the system responses and uncertainties can be quantified with better accuracy; however, in a real structure where tests are not possible in the connected configuration, such scenarios of not requiring any additional parameters are unlikely.

4 EXAMPLE CONNECTED SYSTEM

4.1 Problem description

In order to demonstrate the approach to deal with a connected system, an example problem is introduced. In this setting, the full structure is a 3-DOF spring-mass-damper system fixed onto a beam. The beam is hinged at one end and supported at the other end through a spring as shown in Figure 4a. The 3-DOF spring-mass-damper system is shown in Figure 4b.

The target quantity here is the acceleration of the top mass of the 3-DOF system, in the connected configuration when the beam is subjected to a random vibration at point A (midpoint of the beam) as shown in Figure 4a. It has to be assumed here that one cannot test the full



(a) Beam with spring.

(b) 3-DOF system.

Figure 4: Subsystems to be connected.

structure and hence no calibration or validation data are available at the system level. The 3-DOF spring-mass-damper system shown in Figure 4b forms one of the subsystems, S_1 and the Beam with spring in Figure 4a forms the second subsystem S_2.This example problem has been inspired by a similar model and validation exercise presented in [13]. Test data are assumed to be available at the subsystems levels, which make it possible to carry out the calibration and validation operations at the subsystem levels for individual subsystem-level models. These exercises can be carried out using the methods described before using a Bayesian approach [4, 11, 6]. In order to predict reliably the response quantity of interest - the acceleration at the top mass - one has to use the validation and calibration results from the subsystem level. As described in the previous section, this also involves having a reliable joint model, so that the interaction between the two subsystems can be realised. The following sections explain how this could be realised in the context of this example.A similar problem is discussed in

Tables 1 and 2 show various parameter values considered in this example. The parameters related to the beam were assumed deterministic to reduce the computational costs associated, while the parameters associated with the 3-DOF system are assumed random. The role of these parameters will be more evident in the following sections.

Parameter	Value
E - Modulus of Elasticity	210 Gpa
ν - Poissons ratio	0.3
ρ - Density	2700 kg/m^3
L - Length	0.5 m
b - cross sectional breadth	0.01 m
h - cross sectional height	0.01 m
k_{beam} - stiffness of spring	$10^5 N/m$

Table 1: Parameters governing the beam in Figure 4.

4.2 Joint as a subsystem

Here, apart from considering the 3-DOF system and the beam-with-spring as subsystems, one needs to address the joint as a separate subsystem. In this particular example, it is assumed

Parameter	Mean	Standard deviation
$k_1 = k_2$	10000 N/m	200 N/m
$c_1 = c_2$	0.3 Ns/m	0.03 Ns/m
k_j - prior	8000 N/m	800 N/m
c_j	0.3 Ns/m	0.03 Ns/m
α	350 mm	4 mm
k_s	$10^6 N/m$	$10^4 N/m$
k_p	3000 N/m	150 N/m

Table 2: Parameters governing 3-DOF system and joint.

that the 3-DOF system is being connected to the beam, but to simplify the problem the connection is being represented with a spring and a damper. This might be a debatable and simplest representation of a connection by itself, but as the focus is not on modelling, this simplicity helps a lot in highlighting the specific approach that is being demonstrated. Even in this simplest representation, one needs an isolated system to calibrate for the parameters of the joint; as mentioned earlier, the joint cannot exists on its own. Therefore, any tests can only be performed on a connected system and by reducing the complexity of this isolated connected system, the joint-model can be validated more reliably. This test can be achieved through isolated connected systems where the connected components have well-validated models by themselves and the calibration and validation operations limit specifically to the introduced joint. Here in this example, an isolated model with the same joint as used in the full structure (represented by a spring and damper) connecting two sample masses - which are perfectly calibrated - is used. The parameters of the joint (k_j and c_j) can be calibrated and also this model, which predicts the dynamic behaviour of systems connected by the particular joint can also be validated. Figure 5 illustrates the isolated connected system used for calibration and validation (of the isolated model) of the joint model.

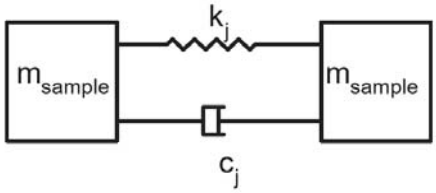


Figure 5: Isolated setup for validating joint model.

Since calibration and validation operations are possible on the subsystem models S_1 and S_2, three different validated and calibrated models will be available in this case. The calibration and validation of these models is not exercised here, as the paper focuses on a different aspect. However, interested readers are referred to [4, 11, 6, 9] to strengthen their knowledge in Bayesian calibration and validation procedures. Here, it is assumed that perfectly-validated models exist for both S_1 and S_2 and all the associated parameters in those subsystem-level models are calibrated. Furthermore, the isolated model for the joint is also calibrated for the respective parameters k_j and c_j, and this model is validated.

4.3 Subsystem-level models

Adhering to the convention adopted in the earlier sections, let the subsystem level models be G_1 and G_2 respectively for the subsystems S_1 and S_2. The model representing the isolated joint model is denoted J. The model G_1 predicts the acceleration of the mass m_3 when a force F_1 excites the mass m_1; is represented mathematically using the dynamic equation (16). $[m]$, $[c]$, $[k]$, and $[F]$ in the following equations represents the mass, damping, stiffness and force matrices respectively,

$$[m]_{S_1}[\ddot{X}] + [c]_{S_1}[\dot{X}] + [k]_{S_1}[X] = [F]_{S_1} \tag{16}$$

The force F_1 being a time series, the acceleration, velocity and displacement of all the masses at any point in time can be calculated from the above model described in (16) through a valid time integration scheme [14, 15]. Similarly regarding the model for the beam with spring, S_2, it is a finite element model with beam elements and does not consider any out of the plane degrees of freedom. This model is also realised using the dynamic equation, where the mass and stiffness matrix of the beam are developed [16] with a damping of 2% assumed. This subsystem model G_2, predicts the responses (acceleration, velocity and displacement) at every node in the finite element model on application of a force, which here is random,

$$[m]_{S_2}[\ddot{X}] + [c]_{S_2}[\dot{X}] + [k]_{S_2}[X] = [F]_{S_2} \tag{17}$$

The isolated joint model, which is also calibrated and validated, connects two masses and is capable of representing the interaction between them in a dynamic context. The joint itself is composed of the spring and damper, but it determines how the masses interact with each other. Further-more, in the system-level model, the same joint determines how S_1 (3-DOF system) and S_2 (beam with spring) interact,

$$[m]_J[\ddot{X}] + [c]_J[\dot{X}] + [k]_J[X] = [F]_J \tag{18}$$

4.4 Integrating subsystem-level models

Having validated models of the two subsystems, and also a validated model representing a similar joint, it is required to predict the response at the system level through the system-level model. As explained in the previous sections, the system level model H can be realised through an interaction function as described before,

$$H = f_H(G_1(\theta_{S_1}), G_2(\theta_{S_2}), J(\theta_J), \theta_{extra}) \tag{19}$$

This interaction function here is a code or scheme that decides how the 3-DOF system S_1, is joined to the Beam S_2, through the joint J. It is easy to imagine in this simpler example, on what the interaction function is intended to do. There exists a validated joint model which can represent the interaction between two connected components. In the isolated condition, the components it connects are purposefully limited to a simpler entity (two calibrated masses here) to make the calibration and validation process feasible. However, it is the same joint that exists in the full structure, connecting more complex subsystems (S_1 and S_2 in this example). When the same isolated joint model is modified by replacing one of the sample masses with S_1 and the other with S_2, the full structure shall be defined. The interaction function is intended to do exactly the same task of integrating these models together in the required configuration demanded by the specific problem.

While the above described process seems trivial, it must be noted that the model-integration process may not be completed without extra parameters that define many specific criteria and properties of the joint. Although the isolated joint model represented the interaction between the two sample masses perfectly, when joining S_1 and S_2, it needs additional parameters that define further specifications of the joint. This is often the case in real engineering where a particular joint may not be fully replicated using simpler connected systems. Although a good part of the joint can be represented through the simpler isolated connections, there exist certain aspects which are to be addressed in the real connection which were not present in such isolated models.

In this isolated joint model, it represents the connecting of two nodal masses, and it does not have any parameters that define any point of connection, simply because it was not needed. But when the same joint connects the beam and the 3-DOF systems together, there exists a need to define where and how they are connected together, which mass is being connected together with the beam and at what point in the beam is it going to be connected. Therefore, the interaction function shall address these qualities of the joint and this demands more parameters that can define such qualities.

In this particular example, a new parameter α, which defines the distance from the hinged end of the beam to where the 3-DOF system (S_1) is connected is introduced as an additional parameter. Another parameter β which can take values 1, 2 or 3 defines the index of mass to be connected. Furthermore, an effect on stiffness and damping values is also considered. This latter takes into account the effect of the substructures on the joint. In the real world, the connection is influenced also by the components being connected and as the components change, the effect will be witnessed in the interaction due to their influence on joint characteristics. The additional stiffness and damping parameters are represented as k_p and k_s. Figure 6 gives a pictorial representation of how the subsystem-level models get integrated with the isolated joint model through extra parameters. Note that additional parameters, which were absent in the isolated model are required to define the connection.

The interaction function f_H, generates the system-level model from the subsystem-level models, in this case by generating new mass, stiffness and damping matrices. The parameters of the joint, the parameter α which define the location of the joint in the beam, β which defines the location of joint in the 3-DOF system, the additional stiffness parameters k_p and k_s, all influence the formation of the new matrices. Here, β is a constant, assuming the mass being connected is always the bottom mass m_1, but the other parameters are expected to be uncertain and a Gaussian distribution is assumed. The interaction function determines the indices of various elements in the matrices in the system-level model, according to the parameters. Equation (20) represents the stiffness matrix in the system level model, by concatenating the stiffness matrix of the 3-DOF system to the stiffness matrix of the beam through the joint in generic form,

$$[m]_S[\ddot{X}] + [c]_S[\dot{X}] + [k]_S[X] = [F]_S \tag{20}$$

In a system-level model thus obtained, a good part of it is validated as all the subsystem-level models are validated. A model for the same joint is also validated fully in an isolated connection set-up. Employing the same validated models in the system-level models improves the reliability of the predicted responses and the part of the system not validated is limited to the function which defines how the different models interact. Although this aspect of the system relies on expert knowledge, the possibility to validate the constituent subsystem-level models is a decent achievement in most engineering problems. It is also very important to make

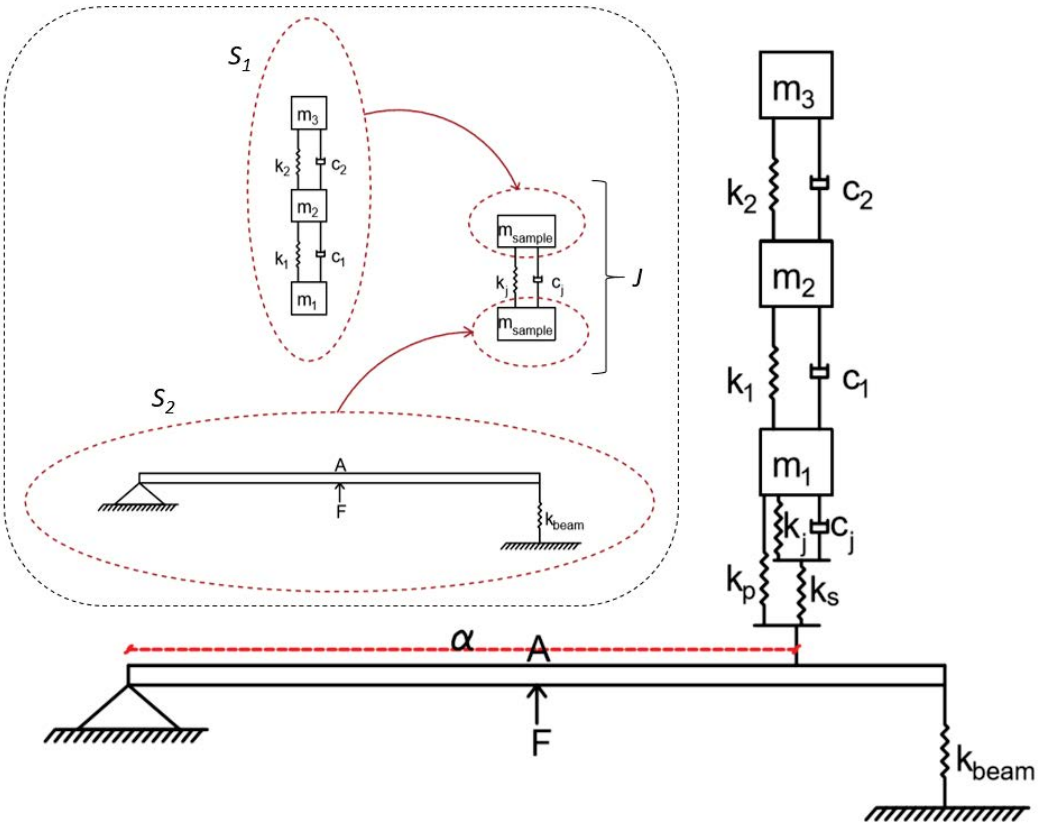

Figure 6: Interaction between subsystem level models.

sure that the additional parameters are addressed properly and the uncertainties related to these parameters are considered while predicting the target quantities.

4.5 System-level model

Figure 7 shows the graphical representation of the current problem. As one can clearly interpret, the system-level model share most of the parameters from the subsystem-level models G_1 and G_2, and the isolated joint model J. Furthermore, the system-level model H itself was developed through integrating the subsystem-level models G_1, G_2 and J with the additional parameters. The models G_1, G_2 and J have associated calibration data through which the parameters can be updated, and also these subsystem-level models can be validated.

The validation results from the subsystem-level model, apart from influencing the updating of parameters, will also play a major role in improving the reliability of predictions at the system level. A good part of the interaction is defined through the isolated joint model, which when validated, improves the confidence further. As discussed before in the paper, if there are more subsystem-level models, which might not be used in the formation of the system level model, but help in calibrating the parameters, they can be included in the graph network so that the parameters can be better calibrated.

4.6 Calibration of the joint model

Once again stressing that the point of this paper is not intended to demonstrate the calibration and validation exercises, but to propose an approach to deal with the joints, the subsystem

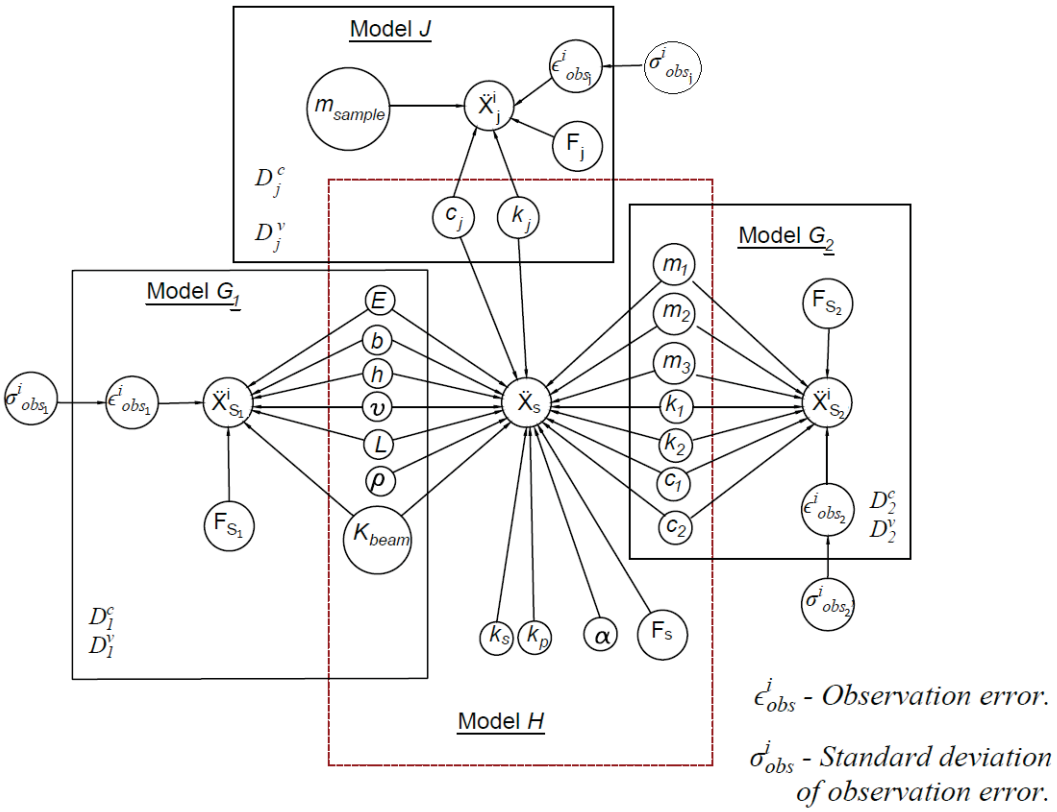

Figure 7: Graphical representation of the problem.

models, as well as the isolated joint models are assumed to be validated. Furthermore, all the parameters defining both subsystems are assumed calibrated. However, to demonstrate the purpose of considering the joint as a separate subsystem, the stiffness at the joint k_J is assumed not to be calibrated. This parameter needs to be calibrated through the isolated joint model.

The prior value of k_J is given in Table 2. In a scheme where the joints are not considered, it will be this prior value that would be propagated through the system-level model. Since the joint is being treated as a separate subsystem, the model for the joint can be calibrated (and validated - for this problem it is assumed that the model is validated). Here, the model J is calibrated for k_J from the calibration data D^c_j which in this case is the natural frequency of the the isolated connected system.

The posterior of the joint parameter $p(k_j|D^c_j, J)$ is given by,

$$p(k_j|D^c_j, J) = \frac{p(D^c_j|k_j, J)p(k_j)}{\int p(D^c_j|k_j, J)p(k_j)dk_j} \tag{21}$$

and as in equation (7), the likelihood function can be expressed as,

$$p(D^c_j|k_j, J) \propto \prod_{i=1}^{n} \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(\omega^i - J(m,k^i_j)^2)}{2\sigma^2}} \tag{22}$$

The posterior of k_j was obtained through a Metropolis-Hastings MCMC algorithm and the updated k_J values are shown in Figure 8. The red dashed line corresponds to the prior and the blue one corresponds to the posterior distribution of k_J.

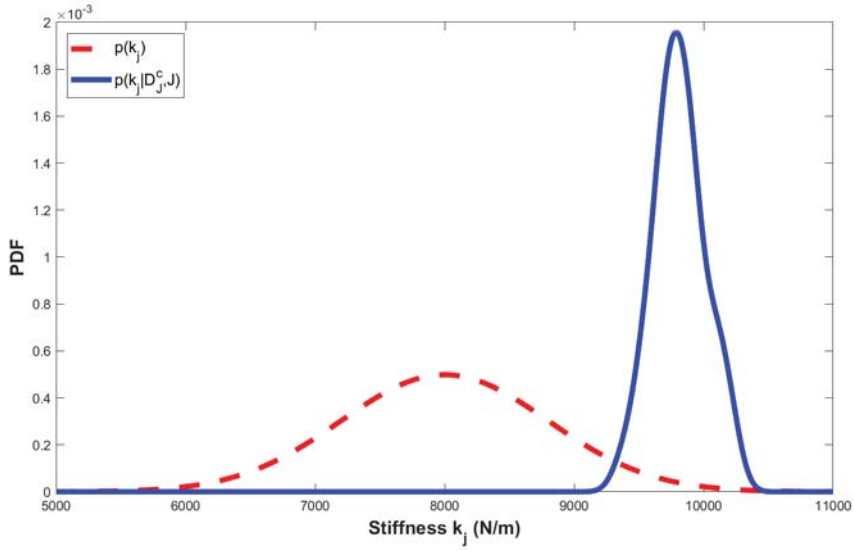

Figure 8: Joint parameter k_j before and after calibration (by considering an isolated joint model).

4.7 System-level responses: some numerical results

In this particular example, three different cases of the system-level models are considered to demonstrate the approach of considering joints as separate sub-systems and in considering extra parameters that might be needed to define a connected system. In the first case, it is assumed that no extra parameters are required to define the connected system, or all the parameters were identified and calibrated through the isolated joint model. The case is realised through system-level model H_1. In the second case, it is assumed that the extra parameters k_p and k_s are considered, while α is assumed to be constant. Model H_2 represents the second case. In the third case, all the three extra parameters and associated uncertainties are considered and the model H represents this case. The models H_1 and H_2 in terms of the interaction function is represented below.

$$H_1 = f_{H1}(G_1(\theta_{S1}), G_2(\theta_{S2}), J(\theta_J)) \tag{23}$$

$$H_2 = f_{H2}(G_1(\theta_{S1}), G_2(\theta_{S2}), J(\theta_J), k_p, k_s) \tag{24}$$

The results (the maximum acceleration at the third mass) shown in Figure 9 are obtained by considering the system level model H_1 corresponding to Case 1. The black line corresponds to the value of acceleration considering the posterior distribution of k_j, $p(k_j|D_j^c, J)$ and the red dotted line corresponds to the same acceleration when k_j is not calibrated through an isolated model. Figure 10 compares the results when the joint parameter k_j is calibrated through an isolated model and when it is not, in case of considering all the additional parameters and the associated uncertainties, i.e. through the model H. Both these figures show the importance of calibrating the joint parameters. In the absence of an isolated model to calibrate for the parameter k_j, one could only go with the prior assumptions and hence affect the predictions.

It also needs to be noted that the system-level models might require additional parameters to define the connection properly, represented in this example through k_p, k_s and α. Here k_p and k_s are the additional stiffness parameters representing the complexity at the connection, and α is assumed so as to account for the uncertainty in the location of the connection. Although these

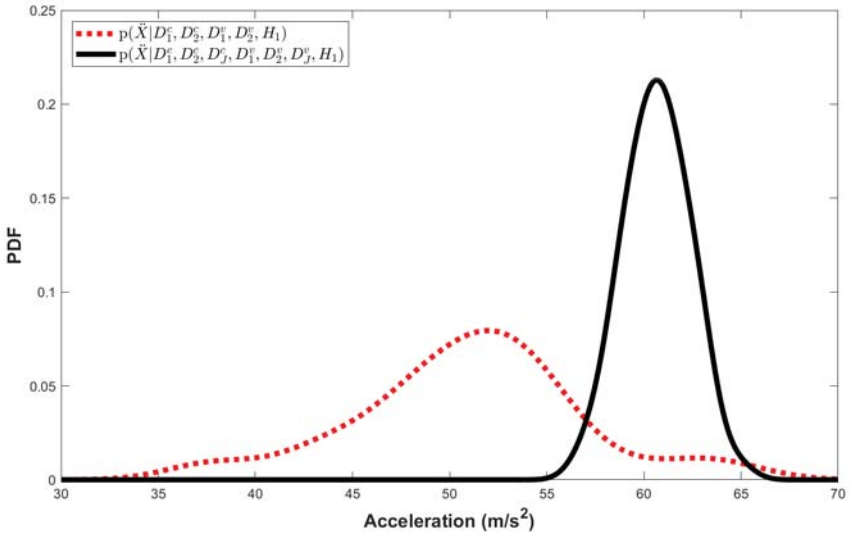

Figure 9: Acceleration of 3^{rd} mass before and after calibration of joint parameter k_j (Additional joint parameters k_p, k_s and α not considered : System-level model H_1).

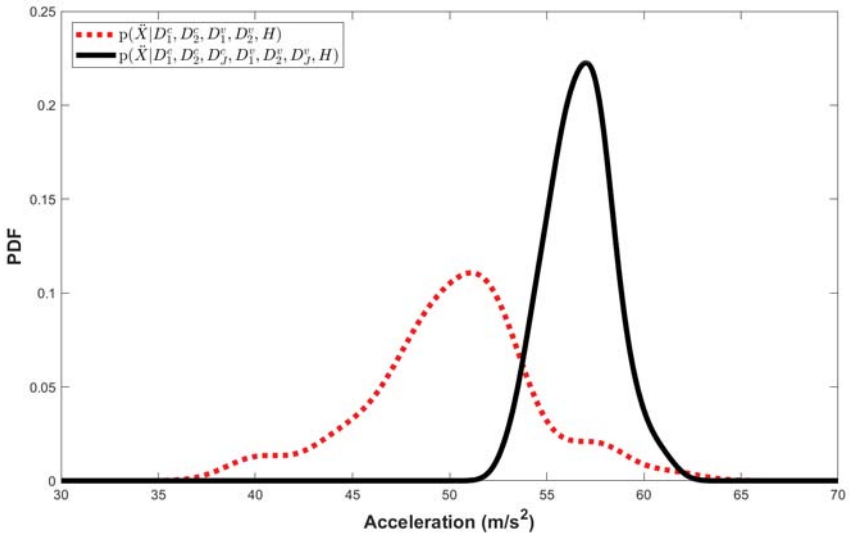

Figure 10: Acceleration of 3^{rd} mass before and after calibration of joint parameter k_j (Additional joint parameters k_p, k_s and α considered) : System-level model H).

parameters were not able to be calibrated through any subsystem-level models, they need to be considered with due importance; any models should have provisions to take this into account. Figure 11 illustrates the comparison between responses (maximum acceleration at the third mass) under various considerations, 1) Through model H_1, when no additional parameters are considered, 2) through model H_2, when no the extra parameters k_p and k_s are considered while α is assumed to be constant and 3) through model H where k_p and k_s are considered as well as the uncertainty in exact location is considered through α.

The red dotted line corresponds to the case when no additional parameters are considered while the blue dashed line represents the response when k_p and k_s are considered. The black line corresponds to the system-level model H where all extra parameters and uncertainties assumed

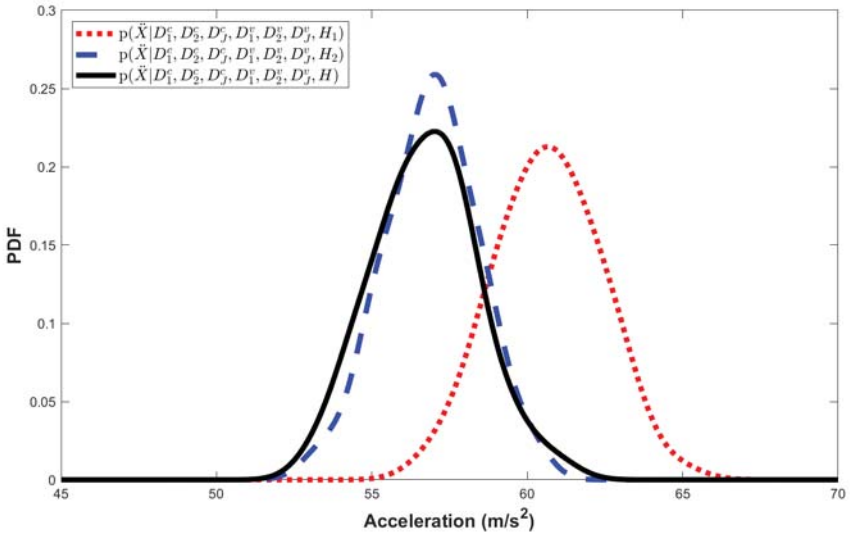

Figure 11: Acceleration of 3^{rd} mass : sensitivity to additional parameters k_p, k_s and α.

in this example are considered. The effect of additional parameters can be evidently noticed from these. In a real engineering problem, the magnitudes of different additional parameters might be different but might play very important roles in determining the total responses and should be considered with due importance.

5 SUMMARY

As this approach to deal with connected systems focuses on uncertainties related to the underlying mathematical model, the process of verification at full system level is not discussed. It has to be specifically noted that any numerical code shall be subjected to a suitable verification methodology that aligns well with the particular problem. To summarise the overall approach, the steps involved in predicting the response of a full structure can be listed as follows; this assumes that the full structure cannot be tested or performance data cannot be collected, while the constituent subsystems can be tested.

1. Identify and select the relevant subsystem-level models. More than one model can be selected if they increase reliability in calibrated results at a later stage.
2. Obtain calibration and validation data for all the considered subsystem-level models.
3. Identify the types of joints that connect various subsystems in the full structure.
4. Select isolated connected specimens with the same type of joints, which can be tested.
5. Develop suitable joint models to represent the joint interaction in the isolated set-ups.
6. Obtain calibration and validation data for the joint models.
7. Perform calibration exercises on all available models.
8. Validate the subsystem and joint models.
9. Update the calibrated parameters in each model with the result of validation.

10. Select the most valid subsystem-level models (in case of multiple models) for use in the system-level model.

11. Select the most valid joint models to be used in the system-level model.

12. Formulate the interaction function that can integrate the subsystem-level models to form the system-level model. (Expert knowledge and engineering judgments are demanded at this stage.)

13. Identify the additional parameters required to define the system-level model. (Those parameters that were not addressed at subsystem level.)

14. Use expert knowledge to address the uncertainties in these parameters.

15. Propagate all the parameters through the developed system-level model to predict the results.

6 CONCLUSION

A general approach to deal with predicting responses of connected structures, more reliably through inferences from testing their parts or components, was discussed in this paper. This approach helps in calibrating the parameters through subsystem-level models and validating the subsystem-level models including the joints. Considering the joints in a system as a separate subsystem enables one to calibrate and validate the joints through isolated models; this was found to be promising in situations where system-level data are not available for calibration and validation. The interactions of the validated subsystem-level models are defined through interaction functions to obtain the system-level model. This approach ensures that the constituent models and their interactions (defined by joints) are validated. The fact that an isolated model may not be able to address all the parameters that define a particular connection between particular components and the necessity to include these additional parameters in the system-level model was also dealt with in the paper. Such an approach enables better prediction and better quantification of uncertainties in the predicted responses.

In future, the authors are aligned to work on these approach in real structural engineering problems and to quantify the improvements in reliability of results with respect to other existing methods. The future works are expected to develop and demonstrate more clearly, various strategies regarding validation of joint models.

Abstract. *In many areas of engineering, nonlinear numerical analysis is playing an increasingly important role in supporting the design and monitoring of structures. Whilst increasing computer resources have made such formerly prohibitive analyses possible, certain use cases such as uncertainty quantification and real time high-precision simulation remain computationally challenging. This motivates the development of reduced order modelling methods, which can reduce the computational toll of simulations relying on mechanistic principles. The majority of existing reduced order modelling techniques involve projection onto linear bases. Such methods are well established for linear systems but when considering nonlinear systems their application becomes more difficult. Targeted schemes for nonlinear systems are available, which involve the use of multiple linear reduction bases or the enrichment of traditional bases. These methods are however generally limited to weakly nonlinear systems. In this work, nonlinear normal modes (NNMs) are demonstrated as a possible invertible reduction basis for nonlinear systems. The extraction of NNMs from output only data using machine learning methods is demonstrated and a novel NNM-based reduced order modelling scheme introduced. The method is demonstrated on a simulated example of a nonlinear 20 degree-of-freedom (DOF) system.*

1 INTRODUCTION

The utilisation of nonlinear finite element simulations for dynamic problems has become more common in recent years as a result of increasing computational power rendering possible analyses that were previously prohibitively expensive. However, increasing interest in uncertainty quantification and digital twins once again raises the issue of computational resources. As such, the development of efficient metamodelling schemes for nonlinear dynamical systems is necessary. Meta-models are models which approximate a full-order or high-resolution model to some degree of accuracy, whilst greatly decreasing the cost of evaluation.

Reduction of FE models was initially considered with regards to the reduction of linear elastic models in the 1960s and techniques such as the Craig-Bampton and MacNeal-Rubin methods [1][2], are well developed and widely used for the reduction of linear FE models. These methods largely make use of linear normal modes as a reduced basis on which the systems' equations of motion are projected. Normal modes form a very efficient reduction basis for linear systems due to their orthogonality and the ability to target certain frequency regions of interest. When considering nonlinear systems however, these linear methods are not appropriate, as the concept of linear normal modes no longer holds. The most common method for the reduction of weakly nonlinear FE models adopts Proper Orthogonal Decomposition (POD), wherein a dynamic simulation of the system is carried out with "snapshots" of the response field extracted at various time intervals. These snapshots are used to construct an optimal linear reduction basis using singular value decomposition [3]. Related recent work explores the extension of the traditional reduction approach by inclusion of higher order enrichments, such as mode shape derivatives [4].

An alternative to this reduction approach is offered by a theory which extends the concept of normal modes to nonlinear systems, the so-called nonlinear normal modes (NNMs). Several different formulations of NNMs exist with the Shaw-Pierre modes being considered in this work, which build on the fundamental work of Rosenberg [5]. As a result of their ability to form a nonlinear manifold, these NNMs can provide a very efficient reduction basis for nonlinear systems [6]. Furthermore, they should be generally valid over the whole phase space of a system and not require multiple, energy dependent reduction bases as in the case of linear methods. In the following work, NNMs are used as basis to construct a reduced order model of a nonlinear system. Autoencoder neural networks are used to extract these NNMs, a recurrent neural network (RNN) is then used to create a regression approximating the overall system, making use of the extracted NNMs as a basis.

The layout of this paper is as follows. Section 2 introduces the theoretical background of nonlinear normal modes along with the process of their extraction. Section 3 describes autoencoder neural networks, their architecture and common usage. Section 4 then discusses the conceptual framework of the reduced order modelling procedure used herein. Section 5 discusses the regression problem in the reduced order model and briefly introduces the long short term memory (LSTM) neural network used. Section 6 gives a demonstration of the reduced order modelling method in practice, the nonlinear MDOF system approximated is described along with greater details on the implementation of the ROM on this system. Finally section 7 contains the conclusions and further work considerations.

2 Nonlinear Normal Modes

2.1 Shaw-Pierre Manifolds

Shaw and Pierre first proposed their theory of non-linear normal modes in 1993. They defined a NNM as being a "a motion which takes place on a two dimensional invariant manifold in phase space". More simply put, this means that in a Shaw-Pierre NNM the motion of each point in the system could be given as a function of the displacement and velocity of a single point in the system. This function if plotted in phase space, would form a surface which is the manifold they refer to. In the case of the linear system, the manifold would be a flat plane. Nonlinearities in a system cause curvature of this manifold. This curvature results in the amplitude dependence of mode shapes observed in nonlinear systems [7].

The calculation of these NNMs however is rather challenging, the assumption of the normal mode forming an invariant manifold is represented in equation 1. In this equation x_i and $\dot{x}_i$ are the displacement and velocity of the ith coordinate in the response whilst u_i and v_i represent the displacement and velocity of the ith transformed coordinate in the NNM. It can be seen that velocity and displacement of each of the coordinates in the NNM's can be described as a function of a displacement velocity pair of a single coordinate. These are linked by the functions f_i and g_i. This relationship is then substituted into the equation of motion which results in a new formulation of the equations of motion, which are unfortunately at least as difficult to solve as the original case. The solution here is to assume a power series solution for the functions $f_1 \cdots f_n$ and $g_1 \cdots g_n$. This then allows for analytical solution for some cases and numerical solutions for the general case.

$$\begin{bmatrix} x_1 \\ \dot{x}_1 \\ x_2 \\ \dot{x}_2 \\ \vdots \\ x_n \\ \dot{x}_n \end{bmatrix} = \begin{bmatrix} u_1 \\ v_1 \\ u_2 \\ v_2 \\ \vdots \\ u_n \\ v_n \end{bmatrix} = \begin{bmatrix} u_1 \\ v_1 \\ f_2(u_1, v_1) \\ g_2(u_1, v_1) \\ \vdots \\ f_n(u_1, v_1) \\ g_n(u_1, v_1) \end{bmatrix} \tag{1}$$

2.2 Output Only Extraction

Some previous work examined the use of machine learning methods to extract NNMs from output only data of nonlinear systems in a manner similar to how singular value decomposition can be used for principal orthogonal decomposition. The work of Worden and Green [8] made use of the representation of NNMs as truncated polynomial series as defined in the Shaw-Pierre paper. Having assumed the form of these polynomials, the coefficients were inferred through an optimisation procedure wherein statistical independence up to a given order of correlation was also maximised. In addition, in the work of Dervilis et al, [9], various machine learning methods drawn from the field of manifold learning were demonstrated for the extraction of NNMs. Both these methods were illustrated on systems of few degrees of freedom for both simulated datasets and an experimental 4 DOF nonlinear dataset from Los Alamos national laboratory [10].

3 Autoencoder Neural Networks

Autoencoder neural networks are a specialised type of neural network often used for dimensionality reduction or de-noising problems [11]. They are constructed, as illustrated in Figure 1,

as a deep neural network architecture with a so-called "bottleneck" layer in which the number of nodes is reduced; in the case of this example to one. The key concept of their operation involves setting the cost function of the network such that the output attempts to re-create the inputs as closely as possible. By the inclusion of the bottleneck layer which forces the data through a lower dimensional feature space, a near optimal reduction of the data onto the feature space dimension can be achieved. The hidden layers in the network allow for a nonlinear transform of the input coordinates before the bottleneck layer. The nature of an autoencoder is such that it simultaneously learns both the encoding operation to transform from the physical to latent space, and the decoding operation whereby the latent variables are returned to the physical space.

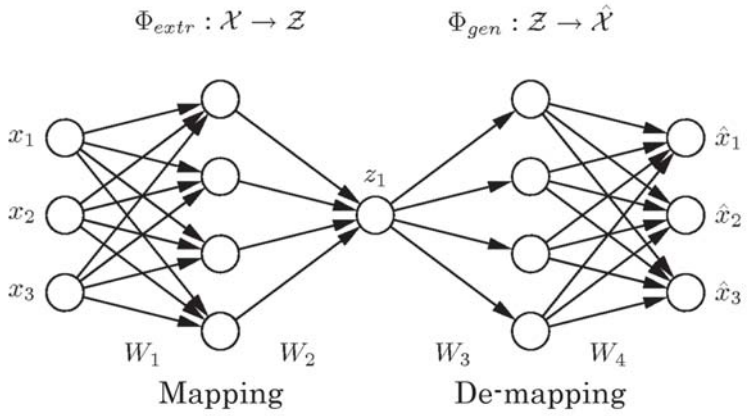

Figure 1: Architecture of an AANN with input/output dimension of 3 and a bottleneck dimension of 2.

Autoencoders have previously been used in similar applications in which it is desired that a model for a system be constructed on a lower dimensional "manifold", whereby it is believed that high dimensional data can be well described as existing on a lower dimensional space [12]. In the case of nonlinear structural dynamics it is thought that the NNMs could correspond to this lower dimensional manifold on which the majority of the high dimensional data can be represented. The same way that a high dimensional linear finite element model can often be represented on a far lower number of mode shapes. The encoding of an autoencoder is the function through which the high dimensional input data can be transformed to the lower dimensional manifold or NNM space, whilst the decoder can provide the inverse operation.

4 Model Order Reduction with Autoencoders

The first step of the model order reduction method used herein involves generating training data from the system of interest. This pertains to creating simulation time histories for the model of both the forcing and response of the system at all DOFs. Having generated time histories, the autoencoder can be used to compress the dimensionality down to a reduced number of latent variables or NNMs. These are extracted from the displacement time histories of the data with a number of NNMs retained, which balances reduction in the dimensionality of the system with accuracy of reconstruction of the full field response, as shown in Figure 2. In this process the cost function used is described by Equation 2, which can be seen as the mean squared error of

reconstruction between the original time series and those after compression.

$$\ell(\hat{x}) = \frac{1}{N}\sum_{i=1}^{N}(x_i - \hat{x_i})^2 \tag{2}$$

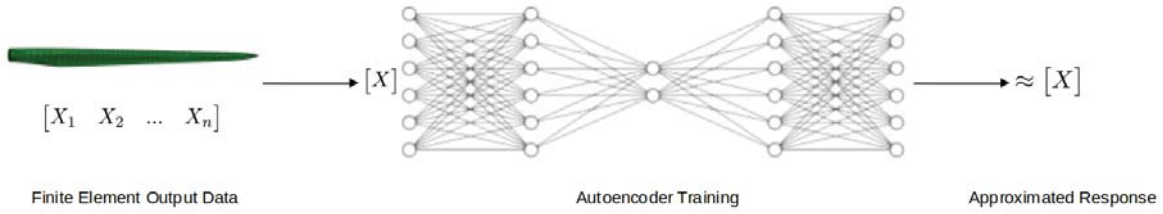

Figure 2: 1st step of ROM; a reduced number of NNMs are extracted from output only dataset

As opposed to projection based reduction methods, whereby the original equations of motion can be projected on to the reduced coordinate set and solved through conventional means, the method developed herein uses a statistical regression to allow for future simulations of the system. The regression model is trained which predicts the response of the system within the NNMs based on a given forcing time history, as illustrated in Figure 3. The regression model is trained based on the forcing time histories used for the simulation, F, and the corresponding NNMs are extracted by the encoder, Y.

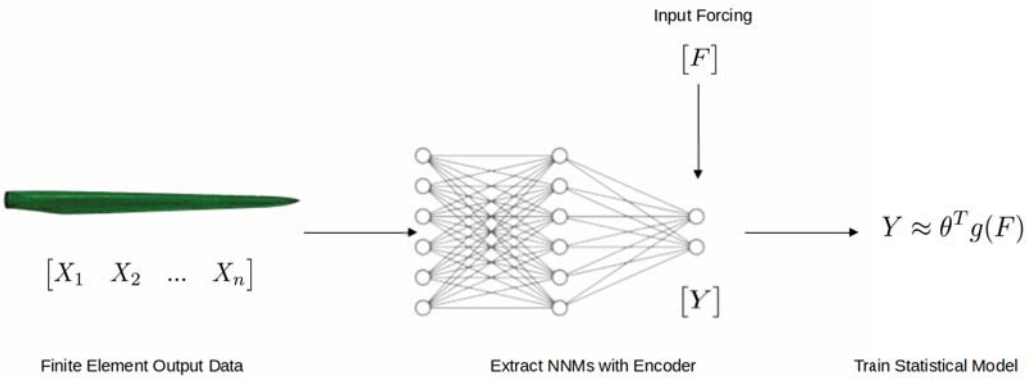

Figure 3: 2nd step of the ROM; a regression model is trained which predicts response in the retained NNMs based on forcing histories.

The final step in the metamodelling process is to predict the system response to a new forcing time history. As illustrated in Figure 4, the trained regression model is used to predict the response of the system within the NNMs, having predicted this response, Y_{pred}, the full field response, X_{pred}, can be recovered by using the decoding portion of the autoencoder.

5 LSTM Neural Networks

In constructing the meta-model, a statistical regression model must be used which can predict new time histories of the latent variables based on forcing time histories. The time series nature of the data would encourage the use of a method including an auto-regressive element. The nonlinear nature of the system would further require a nonlinear regression method to accurately

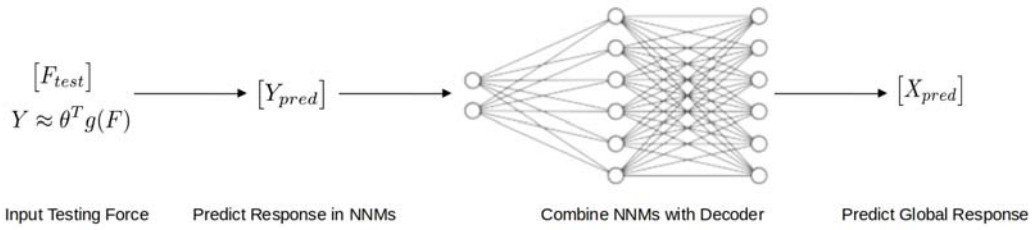

Figure 4: 3rd step of the ROM; the response in the NNMs is predicted for new forcing histories and the full response is reconstructed through the decoder

represent the nonlinear dynamics. In this case it was decided to use a neural network regression architecture, the advantages of neural networks being the scalability and ability to perform MIMO regression.

Recurrent neural networks (RNNs) are a class of networks developed specifically for dealing with sequence data such as time series [13]. The core of an RNN is not dissimilar from that of an ARX model. A basic RNN consists of a unit which receives as input exogenous variables along with a hidden state value which is propagated from the previous time step. Based on these inputs a new value of the hidden state is calculated using a conventional neural network layer, i.e. through multiplication with a weight matrix and then application of an activation function. The output at each time step can then be calculated through an additional layer or layers which act upon the hidden state of the RNN. The hidden state of the RNN can preserve some context information about the previous states and inputs. In contrast to an ARX method however, it is not necessary to state apriori, how many previous values of input and outputs should be considered. This means that theoretically, RNNs can be very powerful at learning relationships between time series with long term dependencies, however, in practice it was found that when training an RNN using back propagation through time, the process suffered from vanishing gradients. As a result of this, a conventional RNN struggles to propagate errors back through many time steps and hence fails to learn long term dependencies [14]. This motivated the development of more advanced RNN cells, such as the long short term (LSTM) cell [15].

Much of the significant work with RNNs has been achieved making use of LSTM cells. These have found very wide use in the field of natural language processing (NLP) [16] as well as time series forecasting [17]. In the area of mechanical systems however, the use of LSTM networks is less prevalent with a limited amount of work applying them to traditional system identification problems [18]. They have proven themselves however, to be capable of learning long term nonlinear relationships in NLP tasks and hence have significant potential as a useful regression framework for nonlinear time series.

6 Case Study

We verify applicability of the proposed method on a 20 degree-of-freedom mass, spring, damping system. The system was considered to be comprised of 20 masses in a chain, with linear spring, linear damping and nonlinear spring elements between each mass, as demonstrated in Figure 5. The nonlinearity of the non-linear spring elements is of the cubic type. Forcing was applied to this system in two locations, at the first and final masses in the chain. All the parameters are assumed uniform across all degrees of freedom and the underlying linear system is proportionally damped; the parameters are defined as follows: $M_i = 0.1\,kg$, $K_l = 100\,N/m$, $C_l = 0.1\,kg/s$, $K_{nl} = 2500\,N/m^3$.

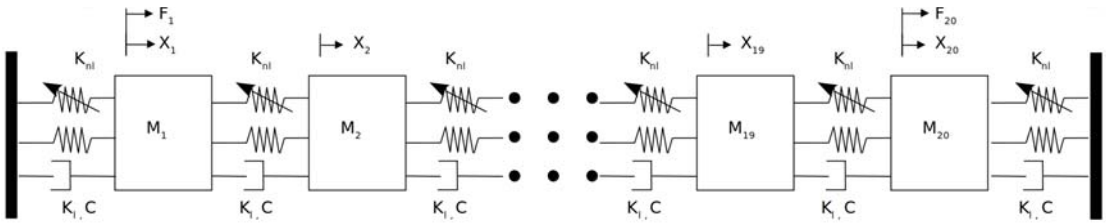

Figure 5: The simulated 20 DOF system including cubic nonlinear spring elements between each mass.

Time series simulations of this system were carried out using a 4th order Runge-Kutta fixed step integration scheme. A sampling frequency of 100 Hz was used for the simulation with a total time series length of 1000s. The forcing applied at masses 1 and 20 comprises realisations of a constant amplitude Gaussian white noise input, which had been low pass filtered with a cut-off frequency of 8 Hz. Figure 6 shows the multicoherence between the input forcing and the outputs of the system both for the underlying linear system and the nonlinear system tested. The nonlinear system shows considerably more incoherence with the input than the linear system, this demonstrates the considerable nonlinearity of the response. For both systems the region of interest is principally at frequencies below 8 Hz. In both cases the response begins to become completely incoherent at higher frequencies it is thought that this is largely an artifact of the processing, since the forcing contains very little energy at higher frequencies both the input and output in this region is very small making the coherence value very sensitive to numerical and processing errors.

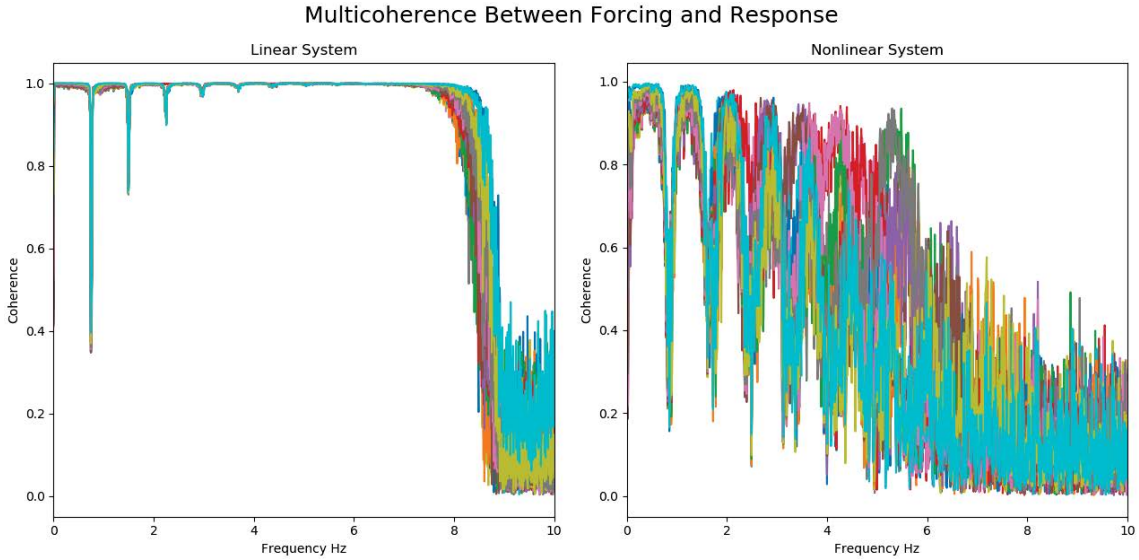

Figure 6: Multicoherence of the signal

Figure 7 demonstrates the comparative magnitude of the restoring force in the linear and nonlinear spring elements of the system a the 10^{th} DOF. The magnitude of the nonlinear restoring force can be seen to be considerable regularly exceeding that of the linear elements. As such it can be considered that the system considered differs significantly from the underlying linear system. The remaining DOFs also demonstrated similar behaviour.

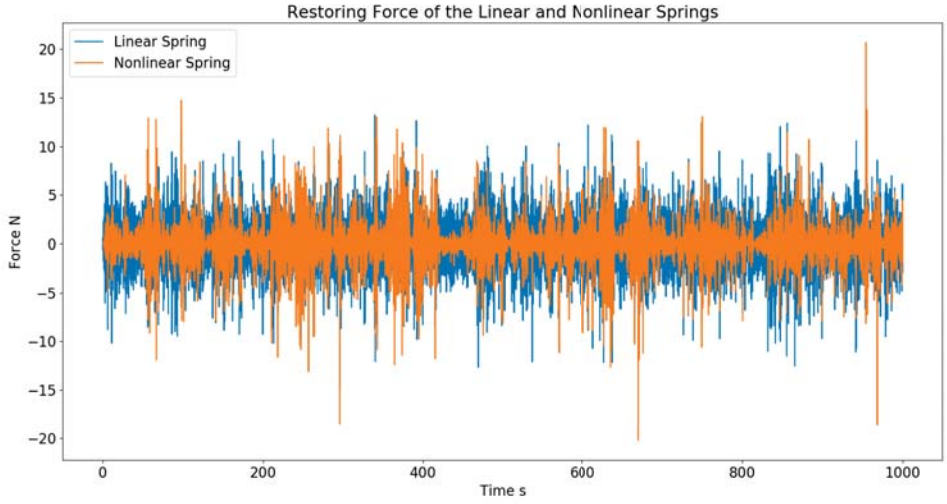

Figure 7: Restoring Force time History of the Linear and Nonlinear Spring Elements at the 10^{th} DOF

6.1 NNM Extraction

A 5 layer autoencoder is used for the extraction of NNMs from the output data. The encoder receives as input the 20 dimensional data corresponding to the displacement time histories at each of the 20 masses. The encoder portion consists of a hidden layer containing 20 nodes with a linear activation function, followed by a second 20-node layer with a hyperbolic tangent activation function. These layers were followed by the bottleneck layer consisting of 10 nodes. The decoder portion of the autoencoder mirrors the encoder in reverse, passing through a 20 node hidden layer with a hyperbolic tangent activation to a 20 node layer with a linear activation to the 20 dimensional output layer.

For the training of the autoencoder, a training dataset consisting of the first 50 % of the time histories was used corresponding to the first 500 s. The second 50 % of the time histories were used as a testing dataset. It is noteworthy that the resulting training and testing loss values were similar, indicating that the NNMs captured were generalisable over the whole dataset. Figure 8 shows the full order response along with the response reconstructed with 10 retained NNMs for the 1st DOF in the model.

It is worth noting, that in previous studies involving output only extraction of NNMs using machine learning, that a key justification in referring to the extracted components as NNMs, is that the components be statistically independent. This statistical independence is considered to be analogous to the modal invariance property of theoretical NNMs [8][7] and the orthogonality property of linear modes. Figure 9 presents the correlation matrix of the NNMs extracted by the autoencoder used herein. The non-zero off diagonal elements of this matrix imply significant correlation between the extracted components which implies that these are rather NNM-like quantities and do not comply with the strict definition of NNMs.

6.2 Response Prediction in the Latent Space

The response prediction in the NNMs involves a non-linear multivariate time series forecasting problem. This problem proved to be the most challenging aspect of the ROM process. Various regression architectures were attempted including polynomial NARX, Gaussian pro-

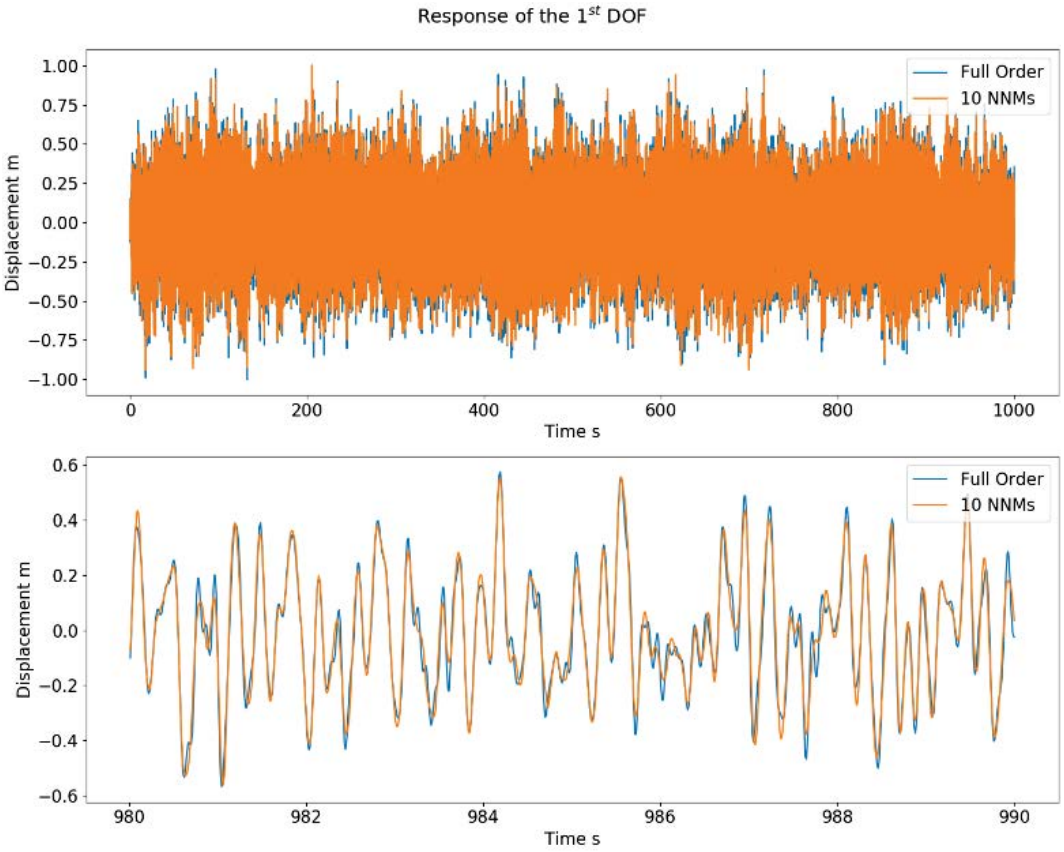

Figure 8: Reconstruction of the response at the 1st DOF with 10 retained NNMs

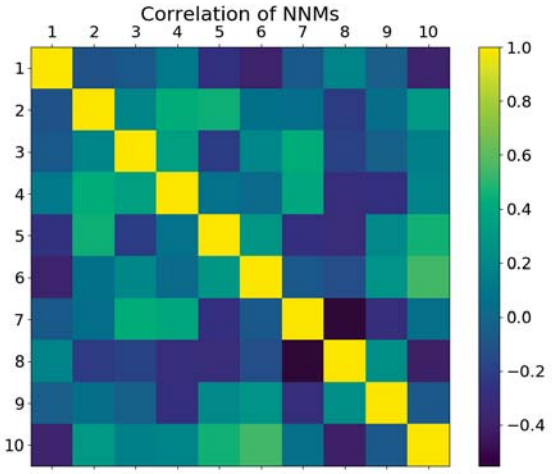

Figure 9: Correlation between the 10 extracted NNMs

cess NARX and recurrent neural net-works (RNN). Finally, a long short term (LSTM) neural network [15], a type of RNN with improved long term memory characteristics, was used for this process. The regression was setup as an autoregressive process. This implies that the input for the prediction model at each time step includes not only the current and previous values of the forcing, but also previous values of the output. In training a prediction error was used,

meaning that for each time step the ground truth values of the previous system outputs were given. During the testing stage however, a simulation error was used, meaning that the outputs predicted by the model at previous steps were subsequently fed to the model as inputs at a next time instant. The LSTM network used 64 hidden cells with 100 previous input and output values also fed as inputs to the network. The training data was assumed as the first 60% of the time histories with predictions made on the next 1000 points corresponding to 10s, the exogenous inputs for this prediction were taken as the next 1000 points of forcing time history, which were not used in the training process. Initial states used for the first model prediction, were taken from the final "true" values in the training dataset.

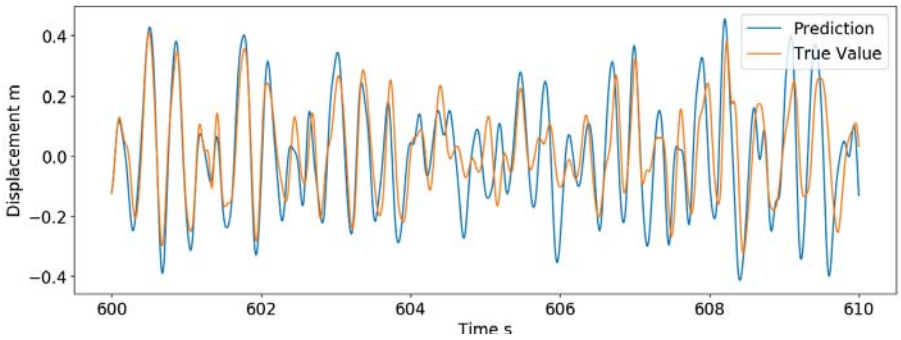

Figure 10: The respone prediction in the latent space for the 1st NNM

Figure 10 compares the prediction of the response in one of the NNMs using the LSTM regression to the "true value". The latter is the value obtained when the physical coordinate time series is passed through the encoder section of the autoencoder. The prediction performs well initially but diverges somewhat over time, it is noteworthy however that the prediction does not become unstable. Similar performance was obtained for all of the 10 NNMs predicted.

6.3 Response Prediction in the Physical Space

Upon availability of the response predictions of the system in the NNM variables, the full response prediction can be determined by simply passing the predicted NNM time histories through the decoder portion of the autoencoder. The decoder combines the NNMs so as to recreate the response in the physical space and is hence analogous to the nonlinear super-position discussed by Shaw and Pierre.

Figure 7 compares the true and predicted values of the response simulated for 1000 timesteps between the ground truth and the model predicted values. For these predictions, the testing dataset lies outside of the training dataset both in the case of the autoencoder training and the regression model training. The predictions shown include both the 1st and 10th DOF predictions, in both cases, the prediction performance is initially quite good with performance decreasing with in-creasing simulation time. Whilst the performance does degrade over time, the predictions still remain stable and of a similar magnitude and frequency as the true values. The mean squared error values for each of the predictions shown below were 0.025 and 0.048 respectively. These two examples are indicative of the performance of the method across all 20 degrees of freedom of the system.

(b)

Figure 11: The final response prediction for both the 1st (a) and 10th (b) DOF for a new force history input

7 Conclusions

A novel reduced order modelling method was demonstrated, which relies exclusively on input and output data from nonlinear structural systems to allow for time series predictions under arbitrary dynamic forcing. The method makes use of nonlinear normal modes as an efficient reduction basis for nonlinear dynamical systems. It was discussed how these NNMs can be extracted using machine learning methods in an invertible manner and a predictive model was created using an LSTM neural network. The modelling procedure was demonstrated on a 20 DOF nonlinear system featuring cubic nonlinearities. Despite shortcomings in the reconstruction accuracy, which is understandable for this high order of nonlinearity, the proposed method shows considerable promise.

The demonstrated method does offer numerous advantages. It does not assume any a priori form of the nonlinearity considered and hence may be generally applicable to multiple systems. Secondly, due to the nonlinear nature of the NNMs, they should, if sufficient training data is used, be generally valid over the whole state trajectory of a system, as opposed to previous methods based on linear projections.

Future development will concentrate on improving the performance of the regression problem in order to increase the accuracy of the model predictions. In addition, it will be investigated how the amplitude range of the forcing affects the modelling technique and to whether the model can generalise well to broad ranges of input amplitude. Further to this, the method will be tested on larger scale problems, such as finite element simulations of nonlinear elements

or jointed systems. It is also thought that the method may demonstrate greater advantages when applied to larger models, due to a greater number of redundant degrees of freedom. Finally, it is worth noting that variational autoencoders [19] can be considered to enforce statistical independence of the extracted components, hence improving predictive capability.

Keywords: Virtual Sensing, Kalman Filter, Response Estimation, Environmental Testing, Boundary Condition Challenge.

Abstract. *Environmental tests are conventional procedures conducted to verify whether a spacecraft and all its components can stand the random excitations to which they are subjected throughout their operational life. In this framework, the Boundary Condition Challenge (BCC) aims at the establishment of new testing practices that allow to improve the poor operational environment representation currently achieved during environmental tests. The challenge focuses on the Box Assembly with Removable Component (BARC), a mock-up which is currently studied by several research institutes. The BARC has been subject to a measurement campaign carried-out at Siemens Industry Software, during which it has been placed on a modal shaker of comparable size and excited along its vertical axis. In order to improve service response replication during these tests, Virtual Sensing (VS) techniques, such as Kalman-type filters, can be used for estimating the complete response field from a limited number of measured responses. Moreover, by jointly estimating states and inputs, the unmeasured loads applied to the system can also be inferred. This work proposes the use of a combination of strain and acceleration observations to enhance the estimation of the mentioned unmeasured inputs.*

1 INTRODUCTION

Environmental testing is a standard procedure in spacecraft engineering used for verifying the resistance of the system and all its components to the random excitations to which they are subjected throughout their operational life. During these tests, the spacecraft is mounted on a shaker testing facility of comparable size and excited with the purpose of replicating its in-service structural response. Limitations in the adopted vibration control strategies and difficulties in reproducing realistic boundary conditions, can give rise to a poor operational environment representation, leading to undesired issues, e.g. over- or under testing, errors in failure modes and time to failure estimation or even damage.

In this framework, a collaboration between Kansas City National Security Campus (managed by Honeywell Federal Manufacturing & Tecnology) and Sandia National Laboratories introduced the Boundary Condition Challenge (BCC) [1], [2] [3]. The goal of the BCC is to improve the in-service environment replication at a component level during environmental tests. The challenge makes use of a simple demonstrator known as the "Box Assembly with Removable Component" (BARC).

Virtual Sensing (VS) techniques such as Kalman-type filters [4], can be used for environmental testing applications to combine information from simulated models and test data with the purpose of estimating the quantities of interest, e.g. the complete strain field on the tested component or/and the inputs provided to the structure by the shaker [5] [6]. In this view, the Augmented Kalman Filter (AKF) [7] has been employed in [8], on strain data acquired during a measurement campaign performed by exciting the BARC via a monoaxial electrodynamic shaker. The mentioned work shows that a good response reconstruction can be achieved. At the same time, the absence of acceleration data among the observations used in the AKF [9] [10] and the test boundary conditions uncertainties, strongly affect the input estimation results.

This work proposes the use of a combined set of strain and acceleration observations to be employed in the AKF. A comparison with results obtained by using strain observations only is hereby provided. It is shown how the addition of acceleration measurements contributes to enhance the input estimation results. Boundary conditions uncertainties, which still influence the estimation outcome, will be object of future investigations.

2 VIRTUAL SENSING FOR ENVIRONMENTAL TESTS ON THE BARC

In order to improve the currently adopted environmental testing procedures, a full comparison between operational and test component responses, both when the sole component or the entire assembly are tested, must be available. In this sense, VS techniques can be used to expand the information pertaining to the system's response, i.e., to infer response at locations that are hard to instrument or even to yield the full field response of the tested structure. Additionally, joint input-state estimation techniques can be used for estimating inputs applied to the system, given that they are not usually measured during environmental tests.

2.1 Test campaign

Virtual Sensing techniques have been employed on data acquired during the test campaign described in detail in [8]. The BARC, object of the mentioned tests and shown in Figure 1, is made up of two units: the upper one plays the role of the component under test, while the lower one, addressed as "subassembly", represents a general fixture used to attach the component on the shaker during tests.

Figure 2a shows the complete setup adopted during the mentioned test campaign, while

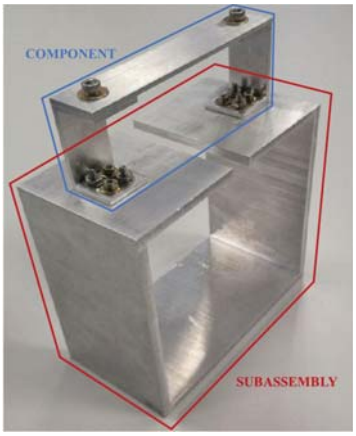

Figure 1: The Box Assembly with Removable Component

detailed focus on the sensors and BARC's connection to the shaker is provided in Figure 2b. Several excitation signals with different amplitude levels have been used during tests, such as single sines, sine sweeps and random signals.

Figure 2: Test setup

2.2 Virtual Sensing: objectives and adopted procedures

Kalman-based strategies are well known tools for input-state-response estimation and can be therefore adopted for environmental testing applications, such as the BARC case study. Their working principle consists in combining a discrete-time state space representation of the system with observations measured at a limited number of locations on the structure with the purpose of inferring the states of the system at each time step, as well as the unknown input. From the estimated states, the responses at unmeasured locations can be derived.

In [8], the estimation of the quantities of interest via the AKF during a test run performed using a pseudo random signal (0.3 V RMS level) was proposed. Indeed, random signals repre-

sent the type of excitation adopted during environmental tests.
The state-space matrices of the system are usually retrieved by making use of a validated simulation model which can well represent the physical system and the boundary conditions to which it is subjected during tests. A Reduced Order Model (ROM) is usually built in order to reduce the computational effort derived by models large dimensions. For the hereby described application, a Model Order Reduction (MOR) technique, as described in [11], has been applied. According to this method, the dynamic behavior of the BARC can be formulated as a superposition of modal contributions and the adopted reduction basis includes the normal modes of the system in the frequency range of interests and a set of Residual Inertia-Relief Attachment (RIRA) modes, one for each unknown input to be estimated. More details about how this procedure has been implemented for the BARC case can be found in [8].

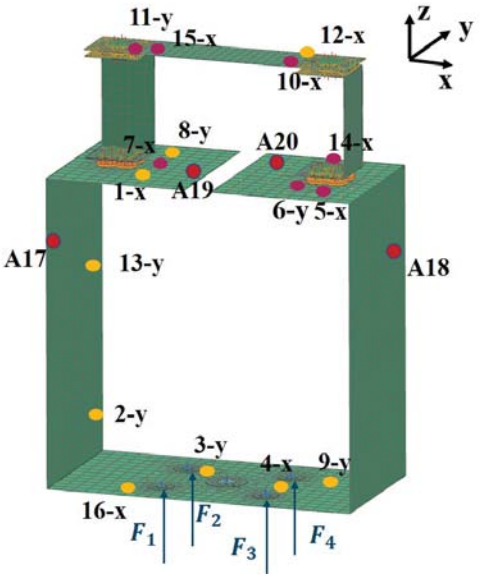

Figure 3: Sensors map: accelerometers (red), measured (yellow) and unmeasured (magenta) strain sensors locations

Figure 3 shows the test sensors (sixteen monoaxial strain gages and four triaxial accelerometers) locations and directions obtained by applying an existing Optimal Sensor Placement (OSP) strategy [12] [13]. Moreover, the four inputs to be estimated are reported. Figure 2b shows that a monoaxial force cell has been placed between the BARC and the shaker at each bolted connection, i.e., at each input location, in order to measure the applied forces in Z direction. These quantities were indeed used as references for the estimation.
Only a reduced subset of nine strains has been included in the set of observations used in the AKF, the remaining ones have been used as reference quantities to check the validity of the response estimation. The measured locations have been chosen in order to focus on response estimation at the component level and to guarantee that measurements collocated with the applied forces could be included. Indeed, collocated measurements allow for a more accurate reconstruction of the inputs [14].
The observability requirements for the reduced sensor set have been checked by ensuring that the condition number of the observability matrix [8] for the reduced set is of the same order of magnitude as the one obtained in the full sensor set, which is guaranteed by the OSP adopted

stategy.

3 INPUT-STATE-RESPONSE ESTIMATION USING THE AKF

3.1 Strain-based Virtual Sensing for environmental testing: results and limitations

As pointed out in [8], the AKF provides a good response estimation, except for the poor reconstruction of high frequency components magnitude on the sensor measuring in y direction. This model gap is well compensated for measured signals in x direction, such as sensor 10, because higher measured response levels were detected for all the sensors measuring in x direction with respect to the ones measuring in y direction.
On the contrary, as shown in Figure 5, input estimation fails to provide good results. The imprecise estimation of the four vertical forces can be explained by the presence of strong boundary conditions uncertainties. As reported in Figure 5 (right), the measured forces are not characterized by flat PSDs. The BARC was indeed exhibiting modal deformations at its several natural frequencies during tests, thus affecting the quantities measured by the force cells. Moreover, according to the natural frequency and the corresponding mode shape, the four force cells were differently influenced, thus resulting in four different PSD shapes. Additionally, the boundary conditions used in the model introduce a strong approximation of the test configuration. In this respect, including the shaker in the model and modeling its interaction with the BARC represents another additional development.

3.2 Virtual Sensing using a fusion of strain and acceleration sensors

This Section reports on the results obtained by applying the AKF for jointly estimating inputs and responses using an observations set that contains both strain and acceleration measurements. Figure 4 illustrates the response estimation of strain sensors 10 and 11 when acceleration sensors A17, A18, A19, A20 shown in Figure 3 are included in the measured quantities. A comparison with the results obtained in the case of strains-only observations is also offered. Moreover, Table 1 reports the RMSE values of the estimated responses with respect to their measured time histories. It is possible to conclude that a good agreement is obtained between the two resulting estimated quantities for both sensors 10 and 11.

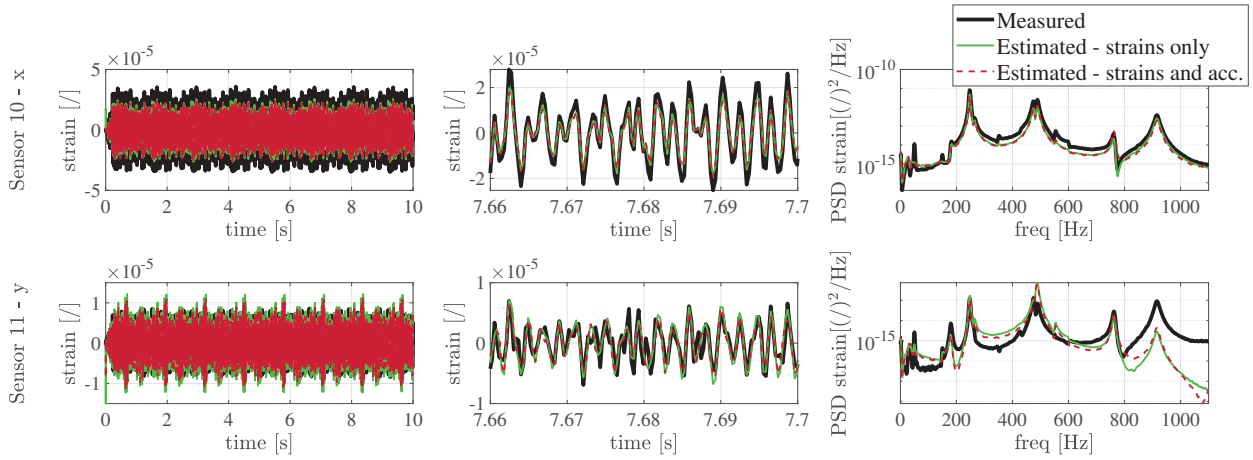

Figure 4: Time history (left), detailed time history (middle) and PSD (right) of strain responses of sensors 10 and 11.

	Sensor 10 - x	Sensor 11 - y
Strains only	3.98×10^{-6}	2.83×10^{-6}
Strains and accelerations	4.11×10^{-6}	2.81×10^{-6}

Table 1: RMSE values of the estimated responses of sensors 10 and 11 with respect to their measured time histories.

Figure 5 proposes a comparison between the input estimation results obtained in the strains-only case and the ones achieved in case the combined set of strains and accelerations is used. This plot indicates that the introduction of a direct feedthrough, i.e., a non-zero output-input matrix in the observation equation of the state-space model, allows for an overall better force estimation. In particular, Figure 5 (right) shows that including accelerations allows to detect PSDs peaks, e.g. at around 250, 550 and 760 Hz, that are not identified when using only strains. Moreover, from Figure 5 (left) it is possible to notice that the force amplitude better matches the actually measured one, with the exception of input 1, which is overestimated.

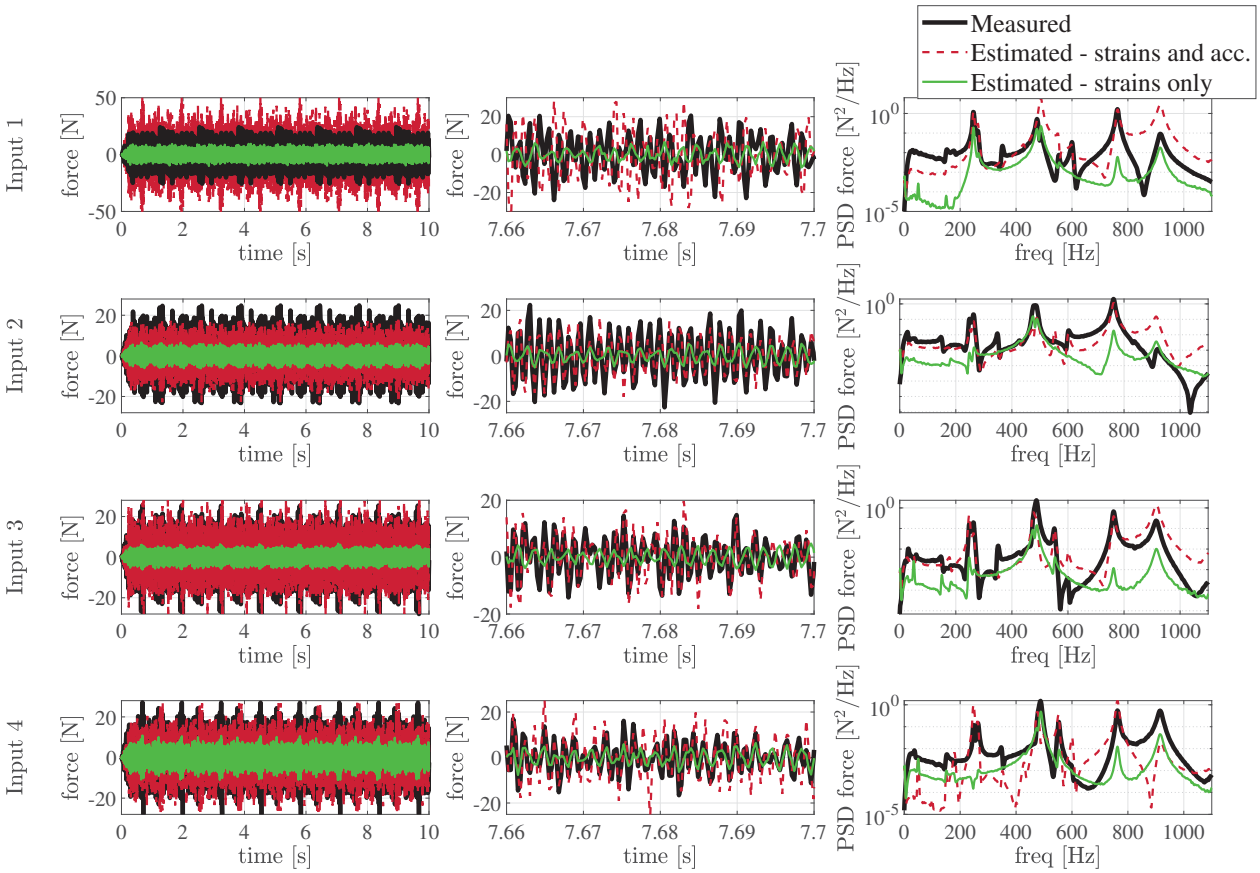

Figure 5: Time history (left), detailed time history (middle) and PSD (right) of input 1, input 2, input 3 and input 4.

Table 2 shows the RMSE values of the four estimated inputs with respect to their measured time histories. The RMSEs comparison for inputs 2 and 3 demonstrates the enhancement achieved by introducing acceleration observations. On the contrary, the RMSE values associated with inputs 1 and 4 show an increase with respect to the values obtained in the strains-only

case. The RMSE related to input 1 is indeed effect of the previously mentioned overestimation, which can be explained by the poor reproduction of the test boundary conditions in the model. Indeed, this issue can negatively influence the terms relating input 1 and the acceleration observations in the output-input matrix of the system's state-space model. Likewise, also the RMSE increase for input 4, visible in some overestimated peaks in Figure 5 (input 4, center), can be attributed to the boundary conditions uncertainties.

	Input 1	Input 2	Input 3	Input 4
Strains only	8.1	7.1	8.7	4.8
Strains and accelerations	17.7	6.9	8.2	8.9

Table 2: RMSE values of the estimated inputs with respect to their measured time histories.

4 CONCLUSIONS

An enhancement of the AKF application to environmental tests on the BARC has been proposed in this paper. A previously presented work [8] already discussed the potential of the AKF for both input and state estimation on this simple hardware demonstrator. Limitations of the application of the algorithm to strains-only data have been pointed out. The present work has reported the results obtained by employing the AKF on an observations set including strain and acceleration measurements. It is shown that the introduction of accelerations, even if non-collocated with the unknown inputs, improves the global result in terms of input estimation. On the contrary, no differences are detected in terms of component response estimation. However, uncertainties affecting the test boundary conditions and their approximated representation in the simulation model still influence the estimation results. In this sense, a further improvement could consist in including the shaker in the simulation model in order to take into account its interaction with the BARC.

Keywords: Hierarchical Bayesian modeling; uncertainty propagation; model updating; structural dynamics; structural reliability; model reduction.

Abstract. *A hierarchical Bayesian modeling (HBM) framework has recently been developed for estimating the uncertainties in the parameters of physics-based models of systems, as well as propagating these uncertainties to estimate the uncertainty in output quantities of interest. According to the framework, uncertainties due to model error are embedded into the model parameters by assigning a parameterized probability distribution and inferring the hyper-parameters of this distribution using multiple sets of experimental data. Herein the framework is extended to properly account for the uncertainty in the prediction error model. The error term is modeled by a Normal distribution with hyper parameters to be estimated by the multiple sets of data. This generalization allow making consistent uncertainty propagation for response quantities of interest. New asymptotic approximations for estimating the uncertainties in the hyper-parameters, as well as propagating these uncertainties to model parameters and observed and unobserved output quantities of interest are developed. The proposed framework provide realistic account of model uncertainties that are insensitive to large number of data sets, avoiding severe underestimation of uncertainty arising from conventional Bayesian learning techniques. Problems drawn from structural dynamics applications are used to demonstrate the effectiveness of the proposed framework.*

1 INTRODUCTION

Bayesian tools can rationally integrate data and physics-based models in order to select the most appropriate models among alternative competing ones, estimate the parameters of these models and their uncertainties, as well as propagating uncertainties to predict important quantities of interest in operation and safety of structural systems [1]. Despite significant advances in the development of Bayesian inference tools for uncertainty quantification and propagation (UQP) in structural dynamics, some challenges still exist and need to be resolved. For example, due to the redundant information carried in the data, the classical Bayesian framework often underestimates the uncertainty, resulting in an inherent reduction of the parameter uncertainty as the number of data increases. More importantly, standard Bayesian procedures do not properly take into account the uncertainty in the parameters due to variability in experimental data, environmental conditions, material properties, manufacturing process, assembling process, and nonlinear mechanisms activated under different loading conditions. Therefore, a better account of the uncertainty is to embed uncertainties within the model by introducing a hierarchy in the model parameters [2].

In this work, a computational efficient HBM framework [3, 4] is further developed and applied to model updating, uncertainty calibration and propagation for linear structural dynamics models using multiple modal data sets. Novel computing tools, based on asymptotic approximations [5] and sampling algorithms [6], are incorporated for parameter inference and uncertainty propagation within the HBM framework. A remarkable feature of this framework lies in the capability to account for identification precision, prediction error, as well as model error, environmental and operational variabilities, offering realistic uncertainties as evidenced in the application. A spring-mass chain model with simulated, noise contaminated, multiple measured modal data sets is used to demonstrate the effectiveness of the proposed approach.

The presentation in this paper is organized as follows. In Section 2, the comprehensive HBM framework based on modal data is proposed. The effectiveness of the proposed method is demonstrated using a 10 degrees of freedom (DoF) spring-mass chain system in Section 3. Section 4 reports the conclusions of this study.

2 PROPOSED COMPUTATIONAL EFFICIENT HBM FRAMEWORK

Let $D=\{D_i,\ i=1,2,\ldots,N_D\}$ be the measured full data sets from the structure comprising N_D independent experiments. Each data set $D_i=\left\{\hat{\lambda}_{r,i},\phi_{r,i}\in R^{N_0},r=1,2,\ldots,m\right\}$ denotes the *i-th* experiment and consists of the square of modal frequencies $\hat{\lambda}_{r,i}$ and mode shapes $\phi_{r,i}$ at N_0 measured degrees of freedoms (DOFs), where m is the number of the observed modes [7]. For each experiment, the modal properties have been obtained by modal estimation techniques using available input-output or output-only vibration measurements. Consider a parameterized class of structural models *M* that is used to predict the squares of the modal frequencies $\lambda_r(\boldsymbol{\theta})$ and mode shapes $\phi_r(\boldsymbol{\theta})$, where $\boldsymbol{\theta}$ is the model parameter set. Herein, uncertainties are embedded into the model parameters by assigning the Gaussian prior probability density function (PDF)

$$p(\boldsymbol{\theta})=N(\boldsymbol{\theta}|\mu_{\boldsymbol{\theta}},\Sigma_{\boldsymbol{\theta\theta}}) \tag{1}$$

for $\boldsymbol{\theta}$ with hyper mean $\mu_{\boldsymbol{\theta}}$ and hyper covariance matrix $\Sigma_{\boldsymbol{\theta\theta}}$ to be estimated using the multiple datasets..

The discrepancy between the *i*-th predicted modal properties and the *i*-th measured data set is quantified based on the prediction error equations, given as follows:

$$\begin{aligned}
&\hat{\lambda}_{r,i} = \lambda_{r,i}(\boldsymbol{\theta}_i) + \hat{\lambda}_{r,i}\ e_r, \\
&\underline{\hat{\phi}}_{r,i} = \beta_{r,i}(\boldsymbol{\theta}_i)\underline{\phi}_{r,i}(\boldsymbol{\theta}_i) + \left\|\underline{\hat{\phi}}_{r,i}\right\|\ \underline{\varepsilon}_r, \\
&\beta_{r,i}(\boldsymbol{\theta}_i) = \frac{\underline{\hat{\phi}}_{r,i}^T \underline{\phi}_{r,i}(\boldsymbol{\theta}_i)}{\underline{\phi}_{r,i}^T(\boldsymbol{\theta}_i)\underline{\phi}_{r,i}(\boldsymbol{\theta}_i)}
\end{aligned} \tag{2}$$

where e_r and $\underline{\varepsilon}_r$ are respectively the prediction errors for the modal frequency and the mode shape components of the *r*-th mode. The prediction errors are then modeled by zero-mean Gaussian variables $e_r \sim N(e_r \mid 0, \sigma^2)$ and $\underline{\varepsilon}_r \sim N(\underline{\varepsilon}_r \mid \underline{0}, \Sigma)$, with covariance matrix $\Sigma = \sigma^2 I$. The standard deviation σ is the hyperparameter to be estimated using the multiple datasets.

According to Bayes rules, the joint posterior distribution of all parameters is built as follows [3]:

$$p(\{\boldsymbol{\theta}_i\}_{i=1}^{N_D}, \Sigma, \boldsymbol{\mu}_{\boldsymbol{\theta}}, \boldsymbol{\Sigma}_{\boldsymbol{\theta}\boldsymbol{\theta}} \mid D) \propto p(\boldsymbol{\mu}_{\boldsymbol{\theta}}, \boldsymbol{\Sigma}_{\boldsymbol{\theta}\boldsymbol{\theta}}) \prod_{i=1}^{N_D} \left[p(\mathrm{D}_i \mid \boldsymbol{\theta}_i, \Sigma)\, \mathrm{N}(\boldsymbol{\theta}_i \mid \boldsymbol{\mu}_{\boldsymbol{\theta}}, \boldsymbol{\Sigma}_{\boldsymbol{\theta}\boldsymbol{\theta}}) \right] \tag{3}$$

where the individual likelihood function $p(\mathrm{D}_i \mid \boldsymbol{\theta}_i, \boldsymbol{\Sigma}_i)$ can be derived based on Eq. (2) as:

$$p(D_i \mid \boldsymbol{\theta}_i, \boldsymbol{\Sigma}) \propto \frac{1}{(\sigma)^{(N_0+1)m}} \exp\left[-\frac{1}{2\sigma^2}\left(J_1(\boldsymbol{\theta}_i) + J_2(\boldsymbol{\theta}_i) \right) \right] \tag{4}$$

where

$$\begin{aligned}
J_1(\boldsymbol{\theta}_i) &= \sum_{r=1}^{m} \frac{\left(\hat{\lambda}_{r,i} - \lambda_{r,i}(\boldsymbol{\theta}_i) \right)^2}{\left(\hat{\lambda}_{r,i} \right)^2} \\
J_2(\boldsymbol{\theta}_i) &= \sum_{r=1}^{m} \frac{\left\| \underline{\hat{\phi}}_{r,i} - \beta_{r,i}(\boldsymbol{\theta}_i)\underline{\phi}_{r,i}(\boldsymbol{\theta}_i) \right\|^2}{\left\| \underline{\hat{\phi}}_{r,i} \right\|^2}
\end{aligned} \tag{5}$$

By using the Taylor expansion for $L\left(\boldsymbol{\theta}_i, \sigma^2\right) = -\ln p(\mathrm{D}_i \mid \boldsymbol{\theta}_i, \Sigma)$, it can be shown that the likelihood function can be approximated by a normal distribution (valid for large number of data) as:

$$p(\mathrm{D}_i \mid \boldsymbol{\theta}_i, \Sigma) \propto N\left(\sigma^2 \mid \hat{\sigma}^2, \frac{2\hat{\sigma}^4}{m\left(N_0 + 1\right)} \right) N\left(\boldsymbol{\theta}_i \mid \hat{\boldsymbol{\theta}}_i, 2\hat{\sigma}^2 \left[H\left(\hat{\boldsymbol{\theta}}_i\right) \right]^{-1} \right) \tag{6}$$

where $\hat{\boldsymbol{\theta}}_i$ and $\hat{\sigma}^2$ are computed by minimizing $L\left(\boldsymbol{\theta}_i, \sigma^2\right)$, and $H\left(\hat{\boldsymbol{\theta}}_i\right) = \dfrac{\partial^2 \left(J_1(\boldsymbol{\theta}_i) + J_2(\boldsymbol{\theta}_i) \right)}{\partial \boldsymbol{\theta}_i \partial \boldsymbol{\theta}_i^T}$ is the hessian matrix evaluated at $\hat{\boldsymbol{\theta}}_i$. By solving the marginalization integrals over the model parameters, one can derive the marginal distribution of the hyper-parameters $\boldsymbol{\theta}_i$ as:

$$p(\Sigma,\boldsymbol{\mu}_{\boldsymbol{\theta}},\boldsymbol{\Sigma}_{\boldsymbol{\theta\theta}}\,|\,\mathrm{D}) \propto p(\boldsymbol{\mu}_{\boldsymbol{\theta}},\boldsymbol{\Sigma}_{\boldsymbol{\theta\theta}})\,p(\Sigma)$$
$$\prod_{i=1}^{N_D}\left[N\left(\sigma^2\,|\,\hat{\sigma}^2,\frac{2\hat{\sigma}^4}{m(N_0+1)}\right)N(\boldsymbol{\mu}_{\boldsymbol{\theta}}\,|\,\hat{\boldsymbol{\theta}}_i,\boldsymbol{\Sigma}_{\boldsymbol{\theta\theta}}+2\hat{\sigma}^2*\left[H\left(\hat{\boldsymbol{\theta}}_i\right)\right]^{-1})\right] \tag{7}$$

Then the posterior PDF of model parameters can be computed as:

$$p(\boldsymbol{\theta}\,|\,\mathrm{D}) = \int_{\boldsymbol{\mu}_{\boldsymbol{\theta}}}\int_{\boldsymbol{\Sigma}_{\boldsymbol{\theta\theta}}}\int_{\Sigma} p(\boldsymbol{\theta}\,|\,\Sigma,\boldsymbol{\mu}_{\boldsymbol{\theta}},\boldsymbol{\Sigma}_{\boldsymbol{\theta\theta}})\,p(\Sigma,\boldsymbol{\mu}_{\boldsymbol{\theta}},\boldsymbol{\Sigma}_{\boldsymbol{\theta\theta}}\,|\,\mathrm{D})\;d\boldsymbol{\mu}_{\boldsymbol{\theta}}d\boldsymbol{\Sigma}_{\boldsymbol{\theta\theta}}d\Sigma$$
$$\approx \frac{1}{N_s}\sum_{i=1}^{N_s} N(\boldsymbol{\theta}\,|\,\boldsymbol{\mu}_{\boldsymbol{\theta}}{}^{(i)},\boldsymbol{\Sigma}_{\boldsymbol{\theta\theta}}{}^{(i)}) \tag{8}$$

where N_s is the number of the samples. The TMCMC algorithm [8] is used in this work to generate samples from the PDF in Eq. (7). Samples of the modal parameters are generated from Eq. (8) by noting that the PDF is a mixture of normal distributions. It should be noted that the sampling approaches no longer involve model runs. The model parameter uncertainty can be propagated for predicting the quantity of interest (QoI) W (modal properties, displacements, acceleration, etc) as:

$$p(W\,|\,D) \approx \frac{1}{N_s}\sum_{m=1}^{N_s} p\left(W\,|\,\boldsymbol{\theta}^{(m)},\Sigma^{(m)}\right) \tag{9}$$

3 APPLICATION

A 10-DoF spring-mass chain system fixed at one end (base) and free at the other end. The system can be used to simulate the response of a 10-story shear building. The system is excited at the base. The nominal spring stiffness and mass values for each link are 1.8kN/m and 1kg, respectively. The damping ratio for each mode is assumed to be 0.02. Three (3) model parameters are introduced for the stiffness. The first parameter multiplies the nominal stiffness values of the stories 1-3, the second parameters multiplies the stiffness values of stories 4-6, and the third parameter multiplies the stiffness values of the stories 7-10. 40 data sets based on modal data (modal frequencies and modal shapes) are simulated, which represent the measured data. Simulated datasets for the modal properties are generated by from the prior model for the model parameters using as mean the nominal values of the model parameters and as covariance matrix a diagonal one with standard deviation equal to 2% of the mean. A 2% modeling error is also added to the simulated square root of the modal frequencies and the modeshapes to account for measurement noise.

The proposed HBM is then applied for parameter estimations and model predictions. BASIS [9] is used to draw the posterior distribution of the parameters. Only the first five modes are identified, and 5 sensors located in the stories 1, 3, 5, 7, 9 are considered. The posterior distribution of hyper parameters is shown in Fig. 1. It can be seen that a non-zero peak value is obtained of the hyper variance, this is due to the existence of the variability over the multiple data sets. The PDF of the prediction error calculated based on Eq. (7) is shown in Fig. 2, which is essential for further predicting output QoI. Fig. 3 shows the uncertainty bounds of the model parameters along with the error bars obtained from individual data set. It is noted that the uncertainty bounds decrease as the number of data sets increases. However, it will tend to a non-zero value which represents the variability of the data sets. Therefore, the HBM framework can consider the variability of the multiple data sets, and also give a reason-

able uncertainty bounds unlike the classical Bayesian approach.

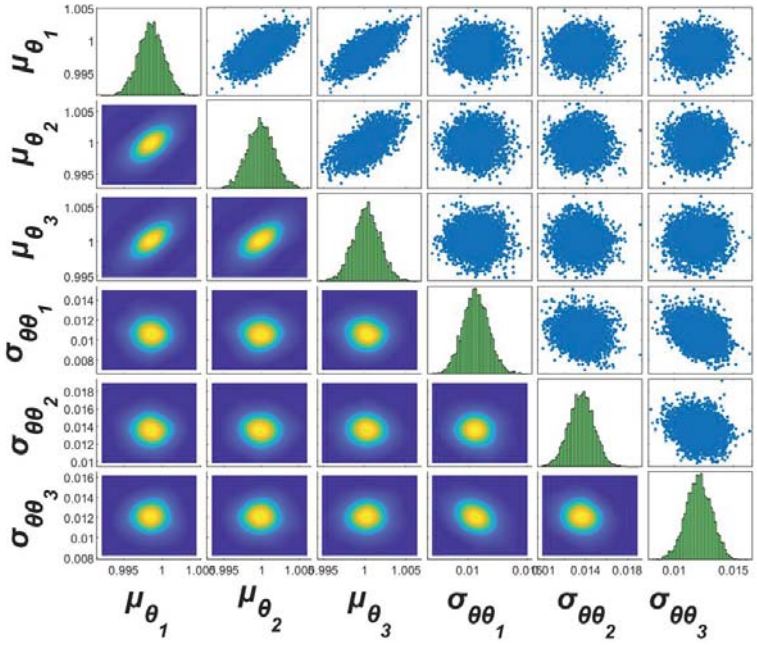

Fig. 1 Posterior distribution of hyper parameters

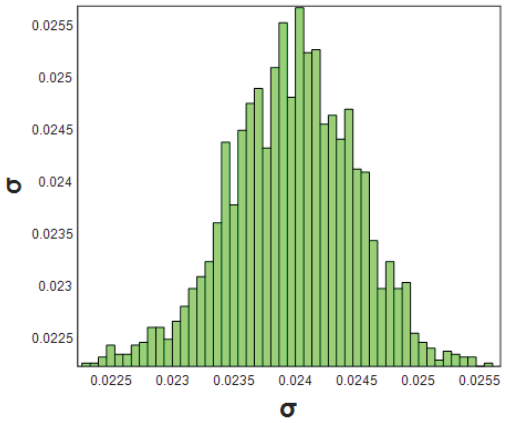

Fig. 2 PDF of prediction error

The uncertainty estimated for the model parameters is then propagated for predicting the uncertainty in the acceleration. Two cases are considered. In the first one the prediction error in the modal properties is not taken into account and the uncertainty is due to the structural model parameter uncertainty. In the second case, the prediction error uncertainty in the modal properties is also considered. As shown in Fig. 4(a), the uncertainty bound of the acceleration is non-zero when the prediction error is not included in the uncertainty propagation. Due to a larger variability over the data sets, one can get a larger uncertainty bound of the estimated model parameters such that a realistic uncertainty bound of the acceleration is obtained even if the prediction error is not considered. Fig. 4(b) shows the propagated acceleration by considering the prediction error. It can be observed that a much larger uncertainty is obtained compared to the case for which the prediction error is not considered.

4 CONCLUSIONS

A computational efficient HBM based on multiple modal data sets is proposed in this paper to estimate the structural model parameters and the prediction error parameters. Uncertainties are embedded into the model parameters and also the prediction errors by assigning normal distributions to these parameters and model errors with hyper parameters, the mean and covariance matrices of the normal distributions. Asymptotic approximations are used to estimate the hyper parameters and propagate uncertainty in output QoI. The effectiveness of the proposed formulation has been demonstrated by a spring-mass chain model. The proposed HBM framework properly accounts for the uncertainty due to variability in experimental data, environmental conditions, modeling assumptions and nonlinear mechanisms activated under different loading conditions. The HBM framework can predict the output QoI with reasonable accuracy, producing reliable uncertainty bounds.

The framework can be integrated with sampling methods for computing system reliability using the identified model uncertainties. For complex large-scale models, the excessive computational cost involved in the framework can be substantially alleviated using model reduction or surrogate techniques[10]. The proposed HBM framework applied herein to linear structural systems and multiple sets of modal properties measurements can also be extended to non-linear structural systems given multiple sets of response time histories measurements.

Abstract. *The potential of real-time hybrid simulation (RTHS) has been increasingly explored over the last twenty years, bringing numerous methods into focus, both from a scientific and a technological perspective. In contrast to other forms of hybrid simulation, such as pseudo-dynamic substructuring, RTHS poses significant challenges in both its numerical and experimental counterparts, mainly due to the hard real-time constraints that must be met during each execution of the associated control loop.*

As far as the numerical substructure is concerned, the time step of the numerical integration scheme should conform to the step of the real time control loop. This is quite demanding for substructures of increasing complexity and usually necessitates the introduction of a reduced order model [1]. The numerical substructure is linked to the physical one through a transfer system, which brings additional complexity into the loop, as it is characterized by its own dynamics. Here, issues involving the accurate reproduction of the control signal, the elimination of the inherited time delay, the control-structure interaction and the rejection of all disturbance sources, are still subject to intensive research.

Among other considerations, the application of adaptive inverse control (AIC) methods [2] has shown quite good performance in terms of accurate time-series reproduction. In this study, we explore further the effectiveness of AIC via its implementation to a recently published virtual RTHS benchmark problem [3]. In specific, we adopt a filtered-X AIC framework and we report on its effectiveness in modelling the control plant (e.g. transfer system and physical substructure) under representative input signals, partitioning schemes and parametric uncertainties. Our assessment shows a high degree of efficacy and robustness for the proposed AIC architecture and suggests further investigation, mainly in actual RTHS tests.

1 INTRODUCTION

The Digital Twin is a concept of considerable interest in a multitude of industries currently. The essence of the concept is the assimilation of models with data to create an overall system model. This model should, within an operational range of interest, be able to predict system behaviour sufficiently accurately to inform key decisions in both design, operation and maintenance [4]. Digital Twins have arisen as more and more engineering components are designed and monitored through computational models. However, several instances still exist whereby numerical models are insufficient; notably in highly nonlinear regions such as joints between components [5]. Hence the need for the incorporation of physical models in the Digital Twin framework. Hybrid simulation provides a method through which physical models can be dynamically coupled with numerical models and can hence be seen as an important addition to achieve the required fidelity of a Digital Twin.

Hybrid simulation involves the creation of coupled dynamic tests in which a computer is coupled to a physical component in a dynamic testing rig. The system is then solved as a whole by intergrating the numerical system, calculating predicted forces at the interface between the structures and applying this to the physical system. The response of the physical system is then measured and fed back into the equations in the numerical system [6]. The "gold standard" of hybrid simulation is real time hybrid simulation (RTHS) wherein real time implies that the time scales of the numerical and physical system are the same; this allows for tests which incorporate rate dependent nonlinearities in the physical component and are hence more representative of the true system.

When considering the real time aspect, the issue of actuator control becomes very important in hybrid simulation. The dynamics of the actuation system can have very significant effects on the reproduction of the reference signal from the equations of motion, and that which is actually applied by the actuator. This results in two key control issues when implementing a RTHS scheme, namely, (i) the accurate reproduction (through the transfer system) of the reference signal that corresponds to the common boundaries between the experimental and the numerical substructure; and (ii) the suppression of the time delay, which is inevitably introduced by the transfer system (actuators, A/D-D/A converters, etc.). The first issue is a typical control problem, while the second is a problem of prediction.

In this work, a benchmark virtual RTHS is considered, as developed by Silva et al. [3] for the purpose of comparing various control schemes, this benchmark system virtually models both the numerical and physical substructures along with the dynamics of the actuation system. The problem of then developing a controller for the reduction of actuator delay and error can then be considered in isolation. This study discusses such a control strategy and introduces an alternative framework for the effective reproduction of reference signals, which is based exclusively on adaptive signal processing and requires no prior knowledge about the dynamics of the transfer system, the specimen and their interaction. The controller used is based on the filtered-X algorithm [7] for adaptive tracking control which has been widely used in signal processing [8] and previously applied to the problem of control in hybrid simulation [2].

2 THE vRTHS BENCHMARK PROBLEM

The RTHS case study considered herein pertains to the recently published virtual benchmark problem of Silva *et. al* [3]. In specific, we focus on the control plant part of the vRTHS paradigm, a layout of which is displayed in Fig. 1. Table 2 shows the numerical values of the parameters, some of which are considered as uncertain that follow the Gaussian distribution

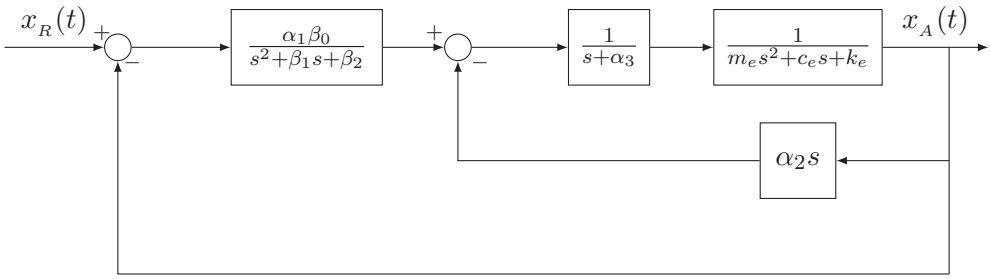

Figure 1: Layout of the control plant (transfer system plus experimental substructure). From left to right, the transfer functions on the upper correspond to the valve, actuator and experimental substructure dynamics, respectively, while the transfer function on the inner feedback loop corresponds to the control-structure interaction dynamics. The signals $x_{_R}(t)$ and $x_{_A}(t)$ refer to the reference and the achieved response of the experimental substructure, respectively. Adapted from [3].

with the indicated mean and standard deviation.

Parameter	**Component**	**Nominal value**	**St. dev.**	**Units**
$\alpha_1\beta_0$	Servo-valve	2.13×10^{13}	-	m Pa/s
α_2	Actuator	4.23×10^{6}	-	m Pa
α_3	Actuator	3.3	1.3	1/s
β_1	Servo-valve	425	3.3	-
β_2	Servo-valve	10×10^{4}	3.31×10^{3}	1/s
m_e	Exp. sub.	29.1	-	kg
c_e	Exp. sub.	114.6	-	kg/s
k_e	Exp. sub.	1.19×10^{6}	5×10^{4}	N/m

Table 1: Parameter values for the control plant of Fig. 1. From [3].

By applying block diagram algebra on the closed loops of Fig. 1, the transfer function between the reference and the achieved signals, $x_R(t)$ and $x_A(t)$, respectively, is given by [3]

$$G(s) = \frac{B_0}{A_5 s^5 + A_4 s^4 + A_3 s^3 + A_2 s^2 + A_1 s + A_0} \tag{1}$$

for

$$\begin{aligned}
B_0 &= \alpha_1\beta_0 A_0 = k_e\alpha_3\beta_2 + \alpha_1\beta_0 \\
A_1 &= k_e\alpha_3\beta_1 + (k_e + c_3\alpha_3 + \alpha_2)\beta_2 \\
A_2 &= k_e\alpha_3 + (k_e + c_3\alpha_3 + \alpha_2)\beta_1 + (c_e + m_e\alpha_3)\beta_2 \\
A_3 &= (k_e + c_3\alpha_3 + \alpha_2) + (c_e + m_e\alpha_3)\beta_1 + m_e\beta_2 \\
A_4 &= c_e + m_e\alpha_3 + m_e\beta_1 \\
A_5 &= m_e
\end{aligned} \tag{2}$$

In discretizing Eq. 1 the zero-order hold scheme is applied for $T_s = 1$ ms, leading to a nominal digital transfer function of the form

$$G(z) = \frac{C_1 z^{-1} + C_2 z^{-2} + C_3 z^{-3} + C_4 z^{-4} + C_5 z^{-5}}{1 + D_1 z^{-1} + D_2 z^{-2} + D_3 z^{-3} + D_4 z^{-4} + D_5 z^{-5}} \tag{3}$$

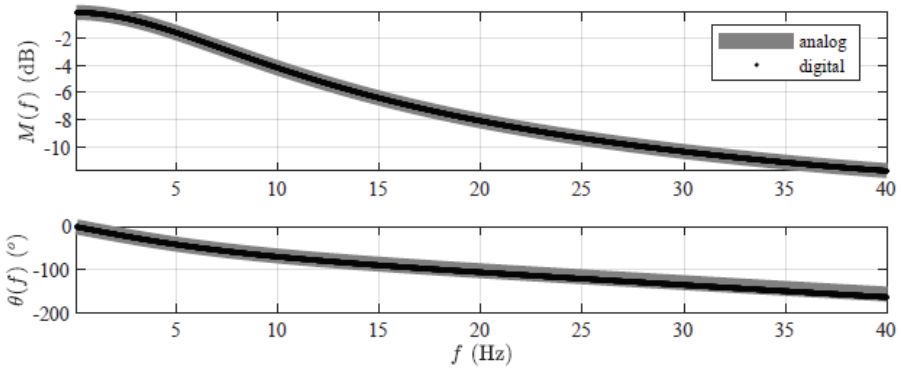

Figure 2: Frequency response of the analog ($G(s)$) and digital ($G(z)$) nominal transfer functions.

with parameters shown in Tab. 2. Notice that $G(z)$ is characterized by unit delay: this is attributed to the fact that the transfer function of the experimental substructure (see Fig. 1) has displacement as output. In the case of velocity, or acceleration control, this transfer function has to be modified accordingly, leading to corresponding zero-delay digital equivalents. In the case of the displacement, the close resemblance between $G(s)$ and $G(z)$ is confirmed in Figure 2, where the frequency response of both transfer functions is plotted.

Numerator		**Denominator**	
Coefficients	**Roots**	**Coefficients**	**Roots**
$C_1 = 5.637 \times 10^{-6}$	-21.347	$D_1 = -4.383$	0.953
$C_2 = 1.349 \times 10^{-4}$	-2.149	$D_2 = \ \ 7.878$	$0.905 \pm 0.406j$
$C_3 = 3.174 \times 10^{-4}$	-0.403	$D_3 = -7.239$	$0.810 \pm 0.190j$
$C_4 = 1.169 \times 10^{-4}$	-0.041	$D_4 = \ \ 3.394$	
$C_5 = 4.226 \times 10^{-6}$	0	$D_5 = -0.649$	

Table 2: Numerator and denominator coefficients for the nominal digital control plant.

Table 2 shows further the roots of the numerator and denominator polynomials, from where it is deduced that the control plant is of nonminimum phase. By applying the theory of two-sided $\mathcal{Z}$-transform, $G^{-1}(z)$ can be expanded to either a causal, but unstable series, or to a noncausual, but stable one. The former expansion is obviously unacceptable, as it would lead to control plant instability. The latter is acceptable, yet this would mean that the inverse controller would be a predictor. This behaviour is typical for plants having nonminimum phase features [7]. In such cases, the best practice is to attempt adapting the controller (see next section) to delayed responses of the control plant. To demonstrate how this is accomplished, assume that $G^{-1}(z)$ can be expanded to a convergent (i.e., stable) series as

$$G^{-1}(z) = \cdots + g_2 z^{-2} + g_1 z^{-1} + g_0 + g_{-1} z^1 + g_{-2} z^2 + g_{-3} z^3 + \ldots \tag{4}$$

If the g_{-i} terms are negligible, then one can discard the noncasual part of the expansion and obtain a casual, stable inverse transfer function. Since, however, this is usually not the case, a delay term is added to the signal path, and an inverse filter of the form

$$z^{-\Delta} G^{-1}(z) = z^{-\Delta}\big(\cdots + g_2 z^{-2} + g_1 z^{-1} + g_0 + g_{-1} z^1 + g_{-2} z^2 + g_{-3} z^3 + \ldots\big) \tag{5}$$

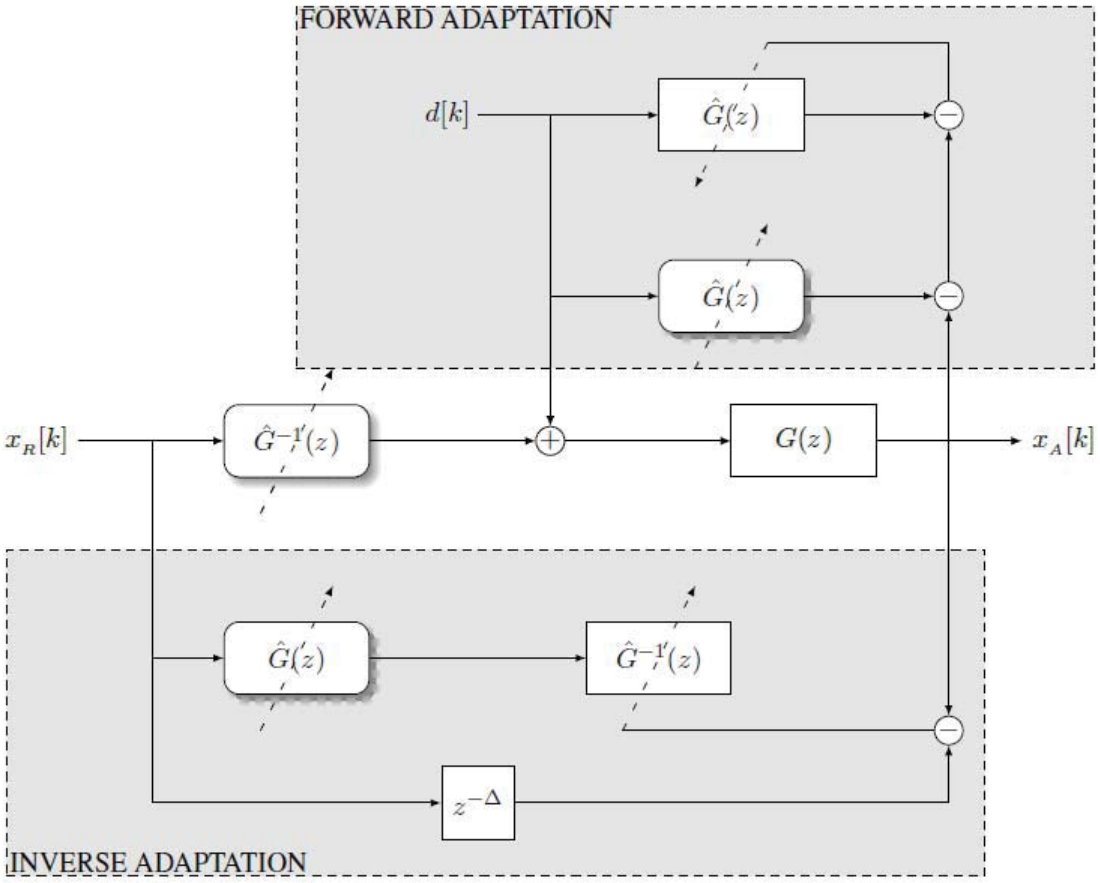

Figure 3: Graphical representation of the adaptive inverse control process. The hat symbol denotes estimate and the shadowed boxes indicate copies of the respective forward/inverse adaptive filters. $d[k]$ is the dither signal.

is estimated online, allowing for more terms of the expansion to be included, using the adaptive scheme that is outlined next.

3 ADAPTIVE INVERSE CONTROL

Our strategy for adapting an inverse controller to the control plant of Fig. 1 is based on the work of Dertimanis *et. al* [2] and it is sketched in Fig. 3. It consists of two successive stages that are implemented in real-time:

- The *forward adaptation* stage, where a finite impulse response (FIR) estimate of the $G(z)$, $\hat{G}(z)$, is estimated.

- The *inverse adaptation* stage, where a FIR estimate of $G^{-1}(z)$, $\hat{G}^{-1}(z)$, is made.

When both stages have been successfully executed and convergence has been achieved, the controller can immediately accept any reference signal for reproduction through the transfer system.

3.1 Forward adaptation

In view of Fig. 3, the adaptive identification of the control plant is achieved though the use of a "dither" signal, $d[k]$. Notice that in this stage the weights of the FIR filter that pertain to the inverse controller are zero, thus, the reference signal $x_R[k]$ does not reach the control plant.

If simultaneous estimation of forward and inverse filters is selected, then, as Fig. 3 illustrates, the plant is excited by both the reference and the dither signals, while forward adaptation is performed using only the dither one. In any case, the dither signal is usually a realization of a zero-mean Gaussian white noise process (see the discussion on the effects of training signals in Dertimanis *et. al* [9], in order to excite all modes of the control plant up to the Nyquist rate.

The adaptation is carried out using the decorrelated LMS method [10], which combines improved convergence properties and low computational complexity. At each step, the adaptive filter's output is calculated as

$$\hat{x}_{_A}[k] = \mathbf{g}^T[k]\mathbf{d}[k] \tag{6}$$

where $\mathbf{g}^T[k]$ are the filter coefficients, $\mathbf{g}^T[k] = \begin{bmatrix} g[k,0] & c[k,1] & \dots & c[k,n_g] \end{bmatrix}^T$, $\mathbf{x}[k] = \begin{bmatrix} d[k] & d[k-1] & \dots & d[k-n_g] \end{bmatrix}$ and n_g is the order of the filter. The coefficients are updated by

$$\mathbf{g}[k+1] = \mathbf{g}[k] + \mu[k]\mathbf{g}[k] \tag{7}$$

for a step size $\mu[k]$

$$\mu[k] = \frac{\rho e[k]}{\mathbf{d}^T[k]\mathbf{s}[k]} \tag{8}$$

In Eq. 8, ρ is a trimming factor, $e[k] = x_{_A}[k] - \hat{x}_{_A}[k]$ is the error between the measured and the predicted signal and $\mathbf{s}[k]$ is the filter gradient, updated by

$$\mathbf{s}[k] = \mathbf{d}[k] - \alpha[k]\mathbf{d}[k-1] \tag{9}$$

with $a[k]$ denoting the decorrelation coefficient

$$a[k] = \frac{\mathbf{d}^T[k]\mathbf{d}[k-1]}{\mathbf{d}^T[k-1]\mathbf{d}[k-1]} \tag{10}$$

3.2 Inverse adaptation

The inverse adaptation process, which can be initiated before full convergence of the forward adaptation has been achieved, is shown at the lower part of Fig. 3. It utilizes a copy of $\hat{G}(z)$ just before the inverse adaption process and attempts to minimize the overall system error, e.g. the difference between a delayed version of the reference signal and the response of the control plant. Adaptation is succeeded using the discrete cosine transform-least mean square (DCT-LMS) filter [11], which consists of the orthogonalization, the power normalization and the filtering steps. In the former, the input vector is transformed by the DCT as

$$w[k,i] = \sum_{\ell=0}^{n_{g_I}-1} Q_{n_{g_I}}(k,\ell)u[k-\ell], \;\; i = 0,1,\dots,n_{g_I}-1 \tag{11}$$

with n_{g_I} being the order of the inverse filter and $Q_{n_{g_I}}(k,\ell)$ the DCT coefficients, which can be calculated a priori offline from

$$Q_{n_{g_I}}(k,\ell) = \sqrt{\frac{2}{n_{g_I}}} K_k cos\left(\frac{k(\ell+1/2)\pi}{n_{g_I}}\right), \;\; k,\ell = 0,1,\dots,n_{g_I}-1 \tag{12}$$

for

$$K_k = \begin{cases} \frac{1}{\sqrt{2}}, & k = 0 \\ 1, & k \neq 0 \end{cases} \tag{13}$$

The transformed values are accordingly normalized by the square root of their power via

$$v[k,i] = \frac{w[k,i]}{\sqrt{P[k,i]+\epsilon}}, \;\; i = 0,1,\ldots,n_{g_I} \tag{14}$$

where ϵ is a small constant and

$$P[k,i] = P[k-1,i] + (1-\gamma)w^2[k,i], \;\; i = 0,1,\ldots,n_{g_I} \tag{15}$$

and the power update factor $\gamma \in (0,1]$. The inverse filter weights are updated according to

$$g_I[k+1,i] = g_I[k,i] + \mu e[k] v[k,i], \;\; i = 0,1,\ldots,n_{g_I} \tag{16}$$

where $e[k]$ is the overall system error.

4 IMPLEMENTATION

To validate and assess our control framework, we adopt a realization of the vRTHS problem that pertains to the first partitioning case explained in Silva *et. al* [3, Tab. 01]. To reduce high demands on the discretization process and the associated sampling rates, our simulations are performed at a sampling period $T_s = 1$ ms, and thus Eq. 1 is sampled at this rate. The reference signal corresponds to the displacement at the boundary between the numerical and the "experimental" substructure. During the training phase, it is selected as a zero-mean Gaussian white noise of variance 10^{-7}, modulated through a low-pass filter with a cut–of frequency at 250 Hz, while the dither signal is also zero-mean Gaussian white noise of the same variance.

Our implementation proceeds via the following steps:

- Assign values for the standard parameters and obtain realizations of the uncertain ones [3, Tab. 02].
- Perform forward adaptation for extracting a FIR estimate of the control plant.
- Upon successful convergence of the forward adaptation path, we lock the weights and we switch to the inverse adaptation path.
- Finally, when the inverse adaptation path has converged to a FIR estimate of the control plant's inverse, we again lock the weights of the inverse and we switch the reference signal to the one intended for RTHS. The time-series of this signal are obtained from conducting simulations via the original distributed software code of Silva *et. al* [3]

It is further mentioned that, after initial investigations, the orders for the forward and inverse FIR models are kept constant and equal to $n_g = 300$ and $n_{g_I} = 200$, respectively, while the reference signal's delay is set to $\Delta = 100$.

Indicative results for one occurrence of the aforementioned steps are expanded over Figs 4–7. Focusing on the top plot of the first, one can clearly observe the underlying adaptation procedure. The adaptive modeling step of the control plant evolves over the first 15–20 s (although convergence has been achieved already from the first 1-3 s), in which the reference signal (in black) is significantly larger than the achieved one (in red): this is due to the fact that herein only the dither signal is involved to the adaptation process. Accordingly, the inverse adaptation does not show any chattering and/or instabilities, while again convergence is achieved relatively

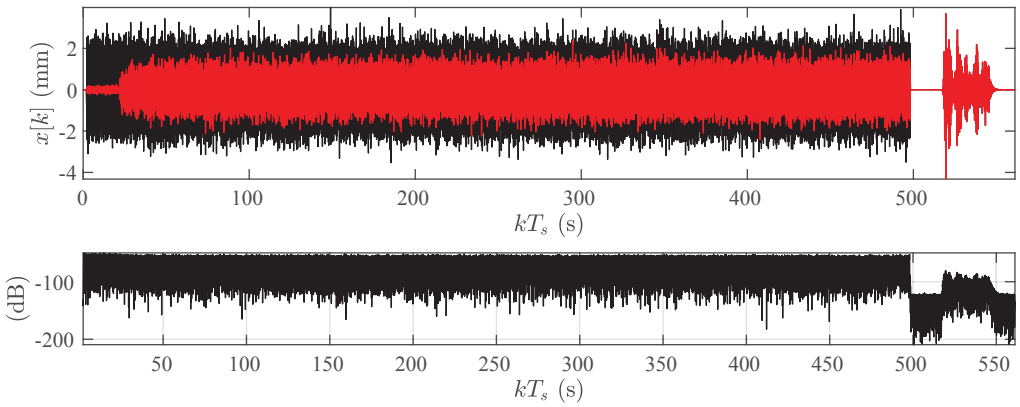

Figure 4: Top: evolution of the adaptive inverse control process for a single realization of the uncertain parameters. Bottom: overall adaptation error.

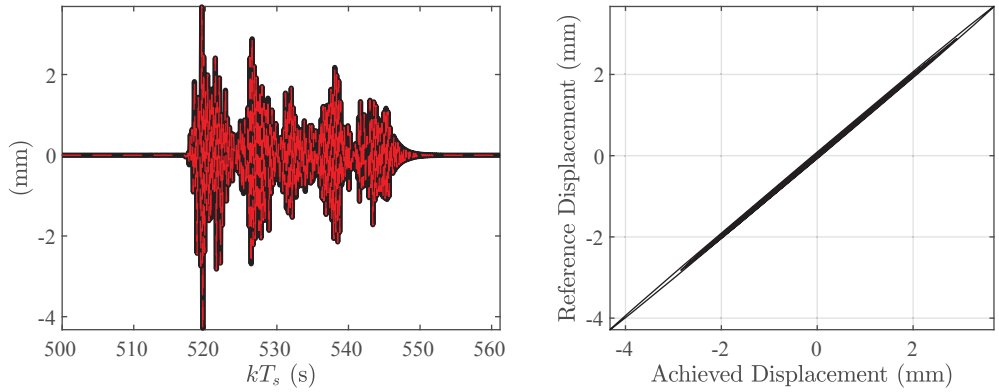

Figure 5: Left: zoom of Fig. 4 at the part of the simulation where the RTHS displacement is applied. Right: Synchonization plot between the reference and the achieved signals.

early (around 50 s the overall error does not essentially reduce anymore. Perhaps a proper adjustment of the DCT-LMS parameters can speed up convergence). When the adaptive inverse controller is properly adapted to the control plant, the execution of the desired reference signal follows after a short pause. The quality in the reproduction of the desired displacement is depicted in Fig. 5, from where an excellent synchronization plot between the (delayed) reference and achieved signals can be observed.

In terms of FIR models, Fig. 6 displays the resulted forward and inverse filters. The former succeeds in accurately reproducing the digital impulse response of the control plant (e.g. the inverse $\mathcal{Z}$-transform of Eq. 3) at the selected order, rendering the adopted deconvolution algorithm quite successful. Regarding the resulted shape of the inverse filter, with low-valued leading weights, significant ones at the middle and negligible trailing values, essentially explains the effects of Eq. 5 to the process. The convolution of the two resembles a digital impulse, as illustrated in Fig. 7, where the impulse response of the cascaded forward and inverse FIR models is plotted. Notice that, while the digital impulse does not reach unity, the reproduction of the reference signal is almost perfect. This is merely due to the flat amplitude of the corresponding frequency response function at 0 db, over a wide frequency range that reaches up to 100 Hz (the effective band of most hydraulic actuators used in structural testing).

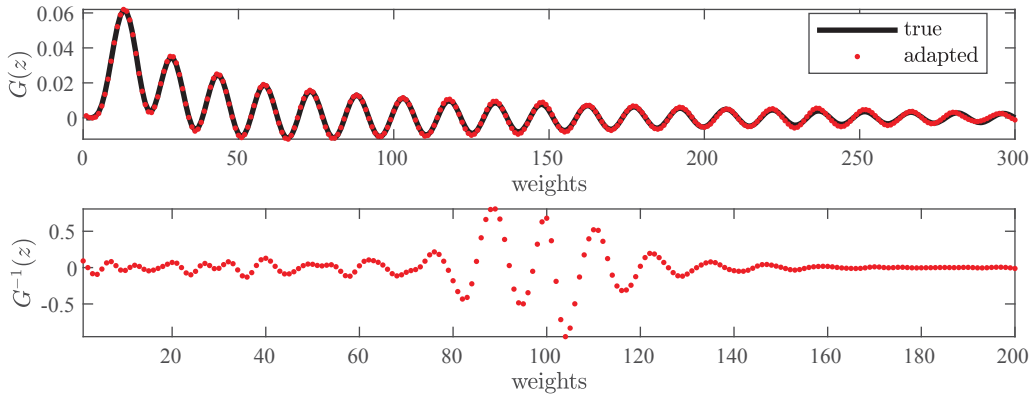

Figure 6: Top: true digital impulse response (continuous black curve) of the control plant and adapted FIR model (red dotted curve). Bottom: adapted FIR model for the inverse of the control plant.

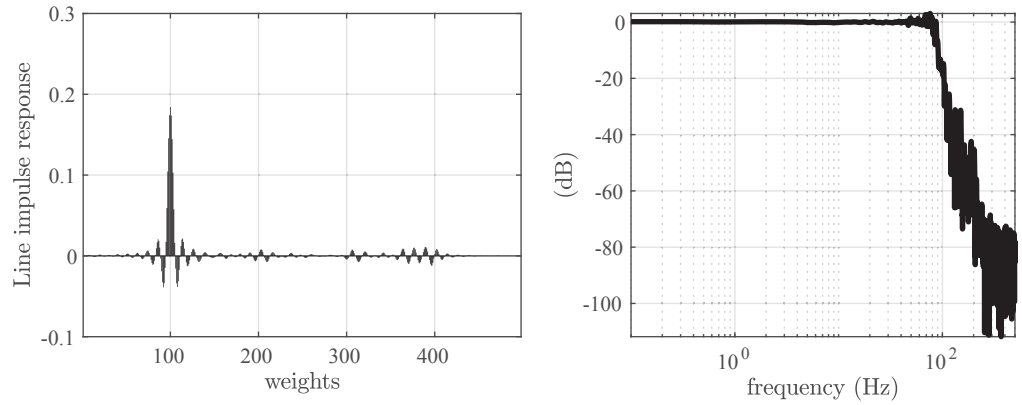

Figure 7: Left: Impulse response of the cascaded forward and inverse FIR models. Right: amplitude of the associated frequency response function.

5 CONCLUSIONS

Adaptive inverse control offers many advantages, compared to conventional control methodologies. Among others, it requires no prior model for the control plant, it is exclusively based on digital signal processing (thus it is fast), while it retains certain stability and robustness features, due to the FIR filters involved. This comes at the cost of somehow increased model orders, the computational cost of which is, nevertheless very small (in the orders of μs in processors with typical specifications). In this respect, our methodology showed quite satisfactory results and we aim at further investigating its capabilities, by testing its efficacy within the RTHS loop.

Abstract. *Optimal sensor placement (OSP) in complex systems implies a configuration that maximizes the information gain by the sensors. This configuration is identified by maximizing, with respect to the location of the sensors, an expected utility function on information-based measures. The resulting multi-dimensional integrals are estimated using asymptotic approximations and sampling techniques. Herein we extend such formulations to be robust to uncertainties in nuisance parameters associated with system and prediction error model conditions, and environmental variabilities. The nuisance parameters are not inferred from the collected data but they affect the learning or prediction processes. Robust designs are achieved by maximizing the expected amount of information in the data and minimizing its fluctuation due to uncertainties in the nuisance parameters. We demonstrate, through a number of examples in structural dynamics, the capabilities of the proposed OSP framework for model parameter estimation and model response predictions.*

1 INTRODUCTION

Optimal sensor placement (OSP) is an important component for numerous structural engineering applications. OSP aims to maximize the quality of the experimental or observational data in order to improve models and narrow the uncertainties in their parameters and their predictions for quantities of interest (QoI). Eventually such improved models are used to update the state of the structure, trace structural deterioration, update structural reliability and safety, prognose the remaining lifetime of structural components (e.g. fatigue lifetime) and design cost-effective maintenance actions. Bayesian OSP framework enables to select the design variables (type, number and location of sensors) to obtain most informative data to update posterior probability density function (PDFs) of model parameters for the purposes of parameter estimation, model selection and response prediction.

In this study, we outline a robust Bayesian OSP framework, based on information theory for parameter estimation and response reconstruction of linear systems. The information gain is quantified using the Kullback-Leibler divergence (KL-div) between the posterior and prior distribution of the model parameters or the response QoI. The Optimal Experimental Design (OED) framework is expanded to consider the uncertainties in the nuisance parameters arising from the variability in structural model parameters, environmental loads or prediction error model parameters. The nuisance parameters are not included in the parameters inferred by the Bayesian methodology. The utility function, chosen as the expected KL-div over all possible data, becomes a function of the design variables and the uncertain nuisance parameters. Thus robust design optimization techniques can be applied to find optimal sensor configurations that maximize the expected information gain and minimize the variability of the information gain over all possible values of the nuisance parameters. To demonstrate the efficiency of the proposed method, a simple spring mass chain system is selected.

2 BAYESIAN OPTIMAL EXPERIMENTAL DESIGN

2.1 Bayesian Parameter Estimation and Prediction of Output QoI

We consider a model of a structural system subjected to external loads. We define as $\underline{\theta} \in R^{N_\theta}$ the model parameters that will be estimated using a set of measured data $\underline{y} \equiv \underline{y}(\underline{\delta}) \in R^N$ of output quantities that depend on experimental design variables $\underline{\delta}$. The design variables $\underline{\delta}$ are related to the sensor configuration (number, type and location of sensors).We define as $\underline{\varphi}$ a set of nuisance parameters of the system model and/or the external loads that affect the output quantities of interest but they are not inferred from the available data. These parameters are related to factors that may be uncertain during the operation of the structure including environmental conditions and modeling assumptions. The values of the output QoI ($\underline{g}(\underline{\theta};\underline{\delta},\underline{\varphi}) \in R^N$) are predicted by the structural model at the measured locations, for specific values of the parameter set $\underline{\theta}$. These predictions depend on the model structure and the excitations, the sensor configuration $\underline{\delta}$ and the nuisance parameters $\underline{\varphi}$.

The discrepancy between the measurements and the model predictions is expressed as:

$$\underline{y} = \underline{g}(\underline{\theta};\underline{\delta},\underline{\varphi}) + \underline{e} \tag{1}$$

where $\underline{e}$ is due to the model and measurement error. The error $\underline{e}$ is modeled as a zero-mean Gaussian vector with covariance $\Sigma_e(\underline{\sigma}) \in R^{N\times N}$, where $\underline{\sigma}$ contains the parameters that define

the correlation structure of $\Sigma_e(\underline{\sigma})$. Herein the parameter set $\underline{\sigma}$ is included in the nuisance parameter set $\underline{\varphi}$. The Bayesian theorem is applied to estimate the posterior PDF $p(\underline{\theta} \mid \underline{y}, \underline{\delta}, \underline{\varphi})$ of the model parameters $\underline{\theta}$, with a prior $\pi(\underline{\theta})$, given the measured data $\underline{y}$ and the values of the nuisance parameters $\underline{\varphi}$.

We introduce an output vector QoI $\underline{z}$ given by

$$\underline{z} = \Psi(\underline{\delta}, \underline{\varphi})\underline{\theta} + \underline{\eta} \tag{2}$$

where $\Psi(\underline{\delta},\underline{\varphi}) \in R^{n \times N_\theta}$ has a known structure that depends on $\underline{\delta}$ and $\underline{\varphi}$, and $\underline{\eta}$ is the modeling error. Herein, for simplicity, a linear relation between the response QoI and the model parameters $\underline{\theta}$ is assumed. Also, the error is taken to be zero-mean Gaussian distribution with covariance matrix $\Sigma_\eta(\underline{s}) \in R^{n \times n}$. Using the posterior distribution of the model parameters, one can readily obtain the posterior distribution of the output QoI $\underline{z}$ as a function of $\Psi(\underline{\delta},\underline{\varphi})$ and $\Sigma_\eta(\underline{s})$.

2.2 Bayesian OSP for Parameter Estimation

One of the objectives of an experiment is to maximize the information contained in the data in order to estimate reliably the parameters of the model or for reliably predicting an output QoI. The information content of the data is quantified through the utility function chosen as the information gained by the experiment. The utility function is related to the relative entropy or the KL-divergence [1] between the prior and posterior PDF of the model parameters or the output QoI given an outcome $\underline{y}$ obtained from an experimental design $\underline{\delta}$. In the experimental design phase the data are not available and the expected utility function over all possible outcomes of the experimental data $\underline{y}$, is introduced to reflect the usefulness of the experiment in estimating the model parameters [1] or estimating an output QoI.

Using an asymptotic approximation for large numbers of data and assuming small prediction error, the expected utility function for model parameter estimation takes the form [2]:

$$U\left(\underline{\delta}, \underline{\varphi}\right) = -\int_{\Theta} H\left(\underline{\delta}; \underline{\theta}, \underline{\varphi}\right)\, \pi\left(\underline{\theta}\right) d\underline{\theta} + c_1 \tag{3}$$

where c_1 is constant,

$$H\left(\underline{\delta}; \underline{\theta}, \underline{\varphi}\right) = \frac{1}{2} N_\theta \ln\left(2\pi\right) - \frac{1}{2} \ln \det\left[Q\left(\underline{\delta}; \underline{\theta}, \underline{\varphi}\right) + \Sigma_\pi^{-1}\left(\underline{\theta}\right)\right] \tag{4}$$

is the posterior information entropy,

$$Q\left(\underline{\delta}; \underline{\theta}, \underline{\varphi}\right) = \nabla_{\underline{\theta}} g\left(\underline{\theta}; \underline{\delta}, \underline{\varphi}\right)^T \Sigma_e^{-1}\left(\underline{\theta}; \underline{\delta}, \underline{\varphi}\right) \nabla_{\underline{\theta}} g\left(\underline{\theta}; \underline{\delta}, \underline{\varphi}\right) \tag{5}$$

is the posterior covariance matrix approximated by the Fisher information matrix, and $\Sigma_\pi(\underline{\theta})$ is the covariance of the prior PDF of the model parameters $\underline{\theta}$, with $\nabla_{\underline{\theta}} = \left[\partial / \partial\theta_1, ..., \partial / \partial\theta_{N_\theta}\right]$. The prior PDF provides the necessary information to optimize the sensor configuration in the case where the Fisher information matrix is ill-conditioned due to insufficient information contained in the data.

2.3 Bayesian OSP for Response Prediction

The sensor configuration can be optimally designed to provide the highest information gain for predicting a set of output QoI. Using asymptotic approximation, assuming large number of data and small prediction error, the expected utility function for predicting output QoI is given in terms of the covariance matrix $P^z\left(\underline{\delta},\underline{\theta}\right)$ of the posterior uncertainty in the output QoI, in the form [3]:

$$U\left(\underline{\delta},\underline{\varphi}\right)=-\frac{1}{2}\int_{\Theta}\ln\det\left(P^z\left(\underline{\delta},\underline{\theta},\underline{\varphi}\right)\right)\pi\left(\underline{\theta}\right)d\underline{\theta}+c_2 \tag{6}$$

where c_2 is constant, $P^z(\underline{\delta},\underline{\theta},\underline{\varphi})$ depends on the sensor location $\underline{\delta}$, the model parameters $\underline{\theta}$ to be inferred from the data, and the values of the nuisance parameters $\underline{\varphi}$. The integral is over the uncertain parameter space associated with the model parameters $\underline{\theta}$. Using (2), the covariance matrix $P^z(\underline{\delta},\underline{\theta},\underline{\varphi})$ of the posterior PDF is expressed as

$$P^z\left(\underline{\delta},\underline{\theta},\underline{\varphi}\right)=\Psi(\underline{\delta},\underline{\varphi})\left[Q\left(\underline{\delta};\underline{\theta},\underline{\varphi}\right)+\Sigma_\pi^{-1}\left(\underline{\theta}\right)\right]^{-1}\Psi^T(\underline{\delta},\underline{\varphi})+\Sigma_\eta\left(\underline{\varphi}\right) \tag{7}$$

where $\Psi(\underline{\delta},\underline{\varphi})$ relate to the sensitivity of the output QoI with respect to the model parameters $\underline{\theta}$.

3 ROBUST OPTIMAL SENSOR PLACEMENT (ROSP)

The OSP should be designed to be robust to uncertainties arising from manufacturing variability, structural conditions not accounted into the modelling, environmental variabilities and modelling errors. To account for the uncertainties in the nuisance parameters, a robust design optimization technique is used to find the optimal values of the design variables. This optimal design is selected to maximize the expected amount of information in the data over all possible values of the nuisance parameters and also minimize the variability in this information due to the uncertainty in the values of the nuisance parameters.

The expected utility function $U(\underline{\delta},\underline{\varphi})$ depends on the uncertain nuisance parameters $\underline{\varphi}$. The respective minimization problem is expressed as

$$\underline{\delta}_{opt}=\arg\min_{\underline{\delta}}J(\underline{\delta})=\arg\min_{\underline{\delta}}[-\mu(\underline{\delta})+\alpha\sigma(\underline{\delta})] \tag{8}$$

where $\mu(\underline{\delta})$ is the expected utility

$$\mu(\underline{\delta})=E_{\underline{\varphi}}[U(\underline{\delta},\underline{\varphi})]=\int_{\Phi}U(\underline{\delta},\underline{\varphi})\ \pi(\underline{\varphi})\ d\underline{\varphi} \tag{9}$$

and $\sigma(\underline{\delta})$ is the standard deviation of the utility

$$\sigma^2(\underline{\delta})=E[(U(\underline{\delta},\underline{\varphi})-\mu(\underline{\delta}))^2]=\int_{\Phi}[U(\underline{\delta},\underline{\varphi})-\mu(\underline{\delta})]^2\ \pi(\underline{\varphi})\ d\underline{\varphi} \tag{10}$$

In this study the value of α in Equation (8) is equal to 1. Equation (8) is equivalent to minimizing the expected information entropy and its variability over all possible values considered for the nuisance parameters.

The multi-dimensional integrals in Equations (3) and (6) over the parameter space Θ and in Equations (9) and (10) over the uncertain parameter space Φ can be estimated using Monte Carlo or Sparse Grid [4] techniques. The optimization of (8) is performed using heuristic sequential sensor placement algorithms to overcome the large computational expense without sacrificing accuracy [5].

4 NUMERICAL EXAMPLES

We first demonstrate the effectiveness of the proposed ROSP methodology, on a 20 DOFs spring-mass chain system. The nominal mass and stiffness of each link in the chain are identical with $m = 0.085$ and $k = 600$ respectively. ROSP results are compared with the deterministic case.

In the first example, ROSP is performed to estimate the first three stiffness parameters of the system. Uniform prior PDF for the three stiffness parameters is assumed with lower and upper bounds taken to be 0.8 and 1.2 times the nominal stiffness values. The analysis is performed considering the uncertainty in the mass of the system. An uncertain nuisance parameter is assumed for the first mass of the system. The nuisance parameter follows a Gaussian distribution with mean equal the nominal mass value and standard deviation equal to 10% of the nominal mass value. Rayleigh damping is assumed with the mass and stiffness coefficients selected so that they correspond to 2% damping ratio for the first and the fifth mode of the system. The equations of motion are solved using the state space method for the system subjected to white noise input at the 20th DOF with 0.05 sec time step. It is assumed that the sensors measure acceleration time histories.

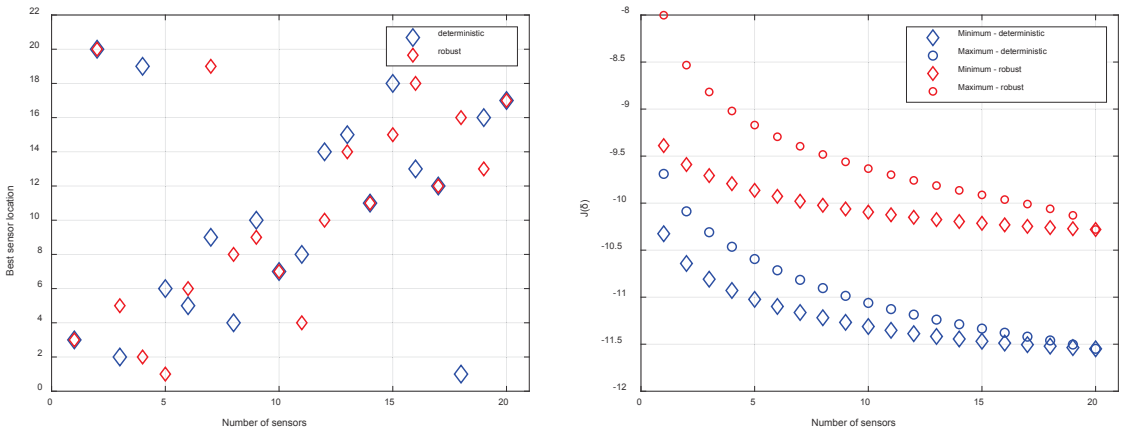

Figure 1: Comparison between the robust and deterministic OSP results (left) and the best and worst expected information entropy values (right) for parameter estimation.

In Figure 1, the optimal sensor locations and the corresponding best and worst (minimum and maximum) expected information entropy values for the robust and the deterministic cases are compared. Results are given as a function of the number of sensors. It can be seen that the expected utilities decrease as the number of sensors increases. The distance between maximum and minimum expected utility values quantify the information gain that can be achieved using the ROSP methodology. According to the comparison of deterministic and robust cases, the optimal sensor configurations and utility values are affected significantly when considering the uncertainty in the nuisance parameters. The difference in the optimal sensor configuration appears for configurations involving more than two sensors.

In the second example, OSP is performed for response prediction using a modal expansion technique [5]. Acceleration sensors at optimal locations are used to reconstruct the acceleration responses at all DOF of the system. Modal damping is used assuming that only four modes are contributing to the system dynamic. Robust analysis takes into consideration uncertain boundary conditions. Specifically, the fixity condition of the first link in the chain is assumed to be uncertain. The degree of fixity is simulated by replacing the base support by a spring. The stiffness of the added spring is assumed $k_0 = \varphi\, k$, where φ represents the uncertainty nuisance parameter taken as uniform distribution with lower bound 1 (simulating a flexible support) and upper bound 10 (simulating a fixed support).

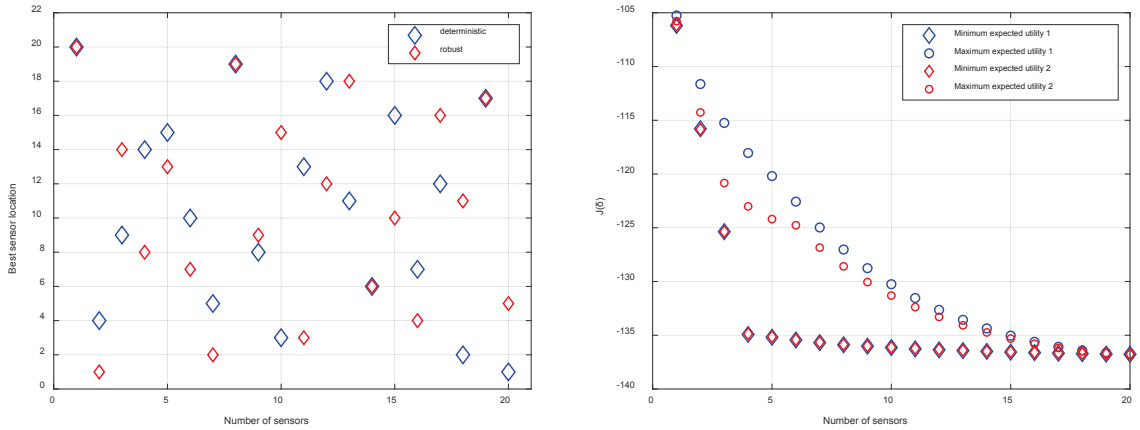

Figure 2: Comparison of the deterministic and robust OSP results throughout the best sensor locations (left) and the –utility values (right) for response prediction.

Figure 2 compares the deterministic and ROSP results for response prediction. Similar to the previous example, the information gain is a decreasing function of the number of sensors placed at their optimal position. The information gain for up to four sensors is significant for both deterministic and robust cases as the problem is ill-conditioned for less than four sensors. As observed by the small reduction in the information entropy values as a function of the number of sensors for more than four sensors, there is no significant information gained for accurate response prediction purposes from these additional sensors. This result holds for both robust and deterministic cases. It is also clear from the optimal sensor placement results that the optimal sensor configurations are affected significantly as a result of the uncertainty in the boundary condition.

5 CONCLUSIONS

We present a novel formulation for robust optimal sensor placement (ROSP) in structural dynamics by combining utility theory and information-based measures. The optimal sensor configuration maximizes the expected information gain computed by the KL divergence between prior and posterior distribution of the model parameters or the model predictions of an output QoI. Robust optimal configuration designs are proposed that take into account uncertainties in nuisance parameters that are not inferred from the data. Such parameters are associated with uncertain model conditions (e.g. boundary conditions), environmental variabilities, manufacturing variabilities as well as parameters of the prediction error models. The framework employs asymptotic approximations to simplify the computation of the integrals involved in the utility function. However, it is readily applicable to estimates of the expected utility functions that are based on full sampling techniques [7-9]. The multi-dimensional integrals involved

in the robust design optimization technique were estimated using Monte Carlo or sparse grid methods. The optimization is performed using heuristic sequential sensor placement algorithms to provide computationally efficient solutions. The effectiveness of the method was demonstrated for a multi-DOF linear spring-mass chain system. The proposed ROSP framework is general and can be extended to handle nonlinear structural dynamics models. It is also applicable to optimize the experimental design for a wide variety of systems encountered in engineering and applied sciences.

Keywords: Wind Turbine Blade, Uncertainty quantification, Sensitivity Analysis, Gaussian Process.

Abstract. *Wind energy is in the forefront of the renewable energy sources and it is expected to show continuous expansion demanding more efficient design, simulation and production procedures. Nevertheless, with the rise of power ratings and the steep increase in size of the blades, there is a considerable need for the development of more reliable simulation predictions with quantified uncertainties and deeper understanding of the randomness that affects the system. The effect of structural uncertainties and imperfections on the properties of the composite material used for blades has long been confirmed. Many uncertainties in a wind turbine blade design relate directly to the uncertainties of material properties. Wind turbine blade models can rely on tens of thousands of parameters, including geometric, material and layup information. Some of these parameters can show diverse stochastic behaviours, which may impact prediction capacity, but are not easily included in an uncertainty study. Requirements for simulation accuracy and precision continue to intensify, together with the performance requirements. Uncertainty quantification is an important step towards an optimised structural design, i.e. it is important to analyse both data and model results to understand limitations of current modelling and data variability making informed decisions. This article shows the application of a non-intrusive uncertainty quantification framework to the structural model of a wind turbine blade, considering the main material property parameters as randomly-distributed inputs. The effects of these uncertainties and sensitivities of these parameters are investigated for stiffness distribution, mass and center of gravity (CG) of the blade and for their effect on the static deflection test. The numerical results are compared with experimental test data for validation.*

1 INTRODUCTION

The blades of a wind turbine are constructed by combining different composite materials - including glass and carbon fibre reinforced polymers with different fibre orientation - and a core material (typically wood or foam). The blades are required to withstand a diverse range of loads, while maintaining their aerodynamic profile and have a useful life of 20 years or more. These requirements mean that every aspect of their design, installation, operation and maintenance must be optimised.

Structural performance can be directly affected by uncertainties associated with models, making it harder to specify resistance and loadings. The conventional design approach has been to adopt characteristic values and safety factors to compensate for structural variations resulting from the production process. However, probabilistic analysis permits a more rigorous quantification of the various uncertainties, and ultimately will facilitate a more efficient design. Quantifying the confidence and predictive accuracy of model calculations is a necessary step toward model verification and validation (V&V); this is an enabling methodology for the development of computational models that can be used to make predictions with quantified confidence [1].

Uncertainty quantification (UQ) in wind applications (turbine models, wind forecasting, energy production) is still a young research theme, but the presence of uncertainties in wind turbine outputs, lifetimes, and failure probabilities leads to a conservative philosophy with high safety factors. Blades can be improved by using a probabilistic approach to design in which the effects of uncertainties are understood and quantified [2].

This paper describes the application of a UQ framework based on Monte Carlo simulation of a structural model of a wind turbine blade. The quantities of interest are the blade stiffness distribution, mass and centre of gravity (CG) location and static deflection under a specific loading. The material properties of the three main types of laminates used in the blade have been characterised as random inputs whose uncertainties are propagated to the QoIs (quantity of interest). A Gaussian process emulator is used to conduct sensitivity analysis on the parameters. Monte Carlo simulation with Latin Hypercube (MC-LHS) sampling is used for UQ. Results are validated against experimental data.

2 MODEL

2.1 Blade structural model

The cross-sectional model used in this study is based on the formulations of Krenk and Jeppesen [3]; utilising a line mesh in the calculation of the structural features, the torsion and shear properties of the cross-sections are formulated within a finite element method (FEM) with the warping function as unknown. The cross section is divided into straight elements with uniform trapezoidal thickness. Every component is simplified and lumped into a thin-walled shell structure with the help of so-called superelements. The Crs (cross-sectional) model also calculates the sectional mass by summing the contribution of each layer of the laminate. The calculation is repeated for each cross section throughout the blade (Fig.1) along the blade span. The blade's stiffness can be seen in Fig.2, normalised by the maximum value.

The QoIs for this study are the distributions of stiffness in flapwise (EI_Y), edgewise (EI_X) and torsional (GI_Z) directions, based on the blade reference frame shown in Fig. 1A. The model combines information from geometry, ply definition, layup and materials properties to calculate geometric and structural properties, mass and stiffness distributions. Elastic moduli are termed in accordance with a material coordinate system seen in Fig. 1B, where the 1-

direction corresponds to the 0° fibre direction.

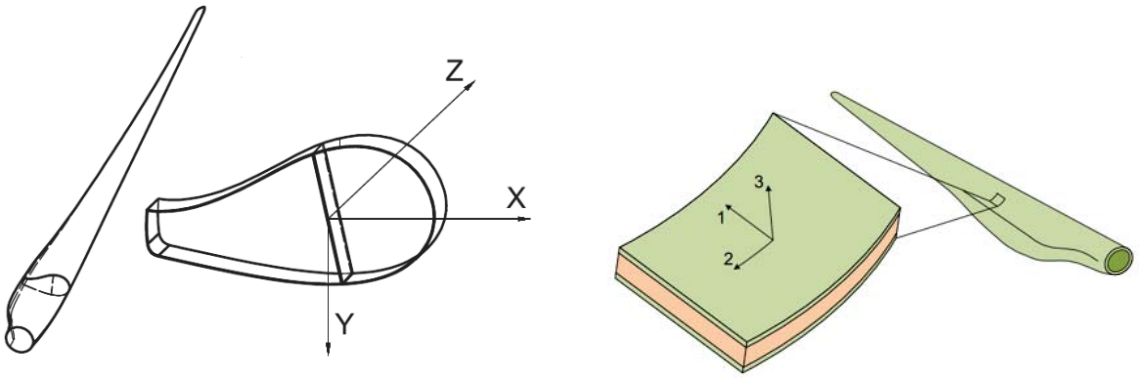

Figure 1: Reference system for wind turbine blade and material properties.

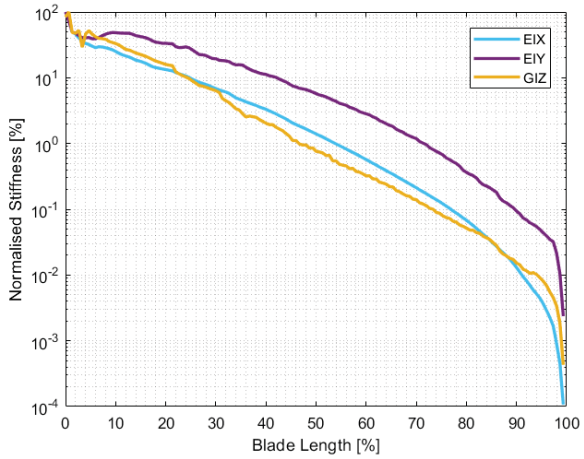

Figure 2: Wind Turbine Blade stiffness distribution - Deterministic results.

The blade layup is important information because, as can be seen in Fig.3 where it is plotted for normalised blade length X [%], there are substantial differences of composition along the blade. The blade studied in this paper has two main laminate types:

- UD: Unidirectional laminate
- BIAX: Bi-directional laminate

Results will show that the type and quantity of laminate used for specific regions of the blade have different impacts on the responses, meaning also that a few material properties have a much bigger influence in some model outputs than others.

2.2 Blade static deflection test

The blades are often considered the most critical structural component of the turbine. Therefore, safety standards require full-scale testing for every prototype and after major design changes. Overall, full-scale tests are seen as a final design verification with the following objectives:

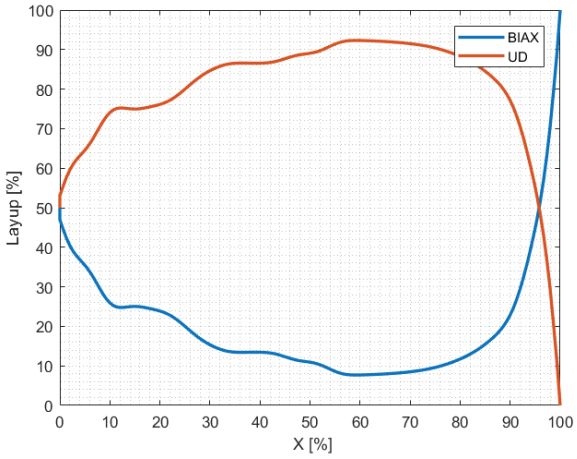

Figure 3: Wind turbine blade layup.

- validate assumptions;
- identify relevant failure modes;
- identify manufacturing details prone to damage initiation.

Requirements for blade testing are part of international standards (e.g. IEC-61400-23 and DNV GL-ST-0376) which manufacturers are required to comply with. The scope for certification static bending test (section 4.9 on [4]) involves (but is not limited to) testing in:

- positive flapwise direction (from pressure side to suction side);
- negative flapwise direction (from suction side to pressure side);
- positive edgewise direction (from trailing edge to leading edge);
- negative edgewise direction (from leading edge to trailing edge).

The blade static deflection test described in this section is not part of a certification campaign; it is a quality control test whose goal is to check whether the blade can withstand extreme load cases and gives evidence that the blade is neither too stiff nor too flexible. It is a way to evaluate blades per tolerance thresholds. The test setup consists of the blade supported at the root section and at midspan subjected to a negative flapwise load close to the tip. The blade is essentially kept in rigid-body statics due to its own weight pushing it on the supports.

The setup is illustrated by a 3D model in Fig. 4 together with the finite element model used to simulate the test. This model is based on the lengthwise stiffness distribution of the blade (which is characterised by the Crs model). Data from static deflection tests of 34 blades of the same type subjected to the same load will be compared in the UQ results.

3 RANDOM INPUT CHARACTERISATION

The characterisation of the uncertain inputs of an UQ problem is of utmost importance because poor input models will have a large effect on the interpretation of the uncertainty behaviour of the system. Bigoni [5] defines three main approaches to the *probability distribution estimation* of inputs:

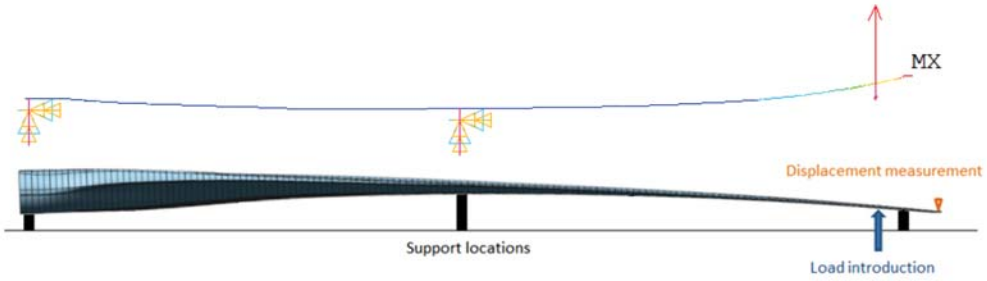

Figure 4: Wind Turbine Blade static test: Setup and finite element model.

- Assumption: probability distributions for the parameters are defined relying on experience and wisdom.
- Inference: the probability distributions are reconstructed using measurements of the quantity of interest.
- Measurement: measurements of the parameters are carried out, and probability distributions are fitted to these experiments.

The last approach is always preferred, but it is seldom available. The costs, effort and time necessary to characterise random parameters by experiments (that have to be repeated, generating enough samples to have a good fit) are usually too high.

The access to Siemens Gamesa Renewable Energy's material test database allowed this study to be conducted with experimental data for the estimation of material property probability distributions.

In this study the random variables are the material properties (Table 1) of the two main types of glass-fibre reinforcements (BIAX and UD) used in the blades. Fig. 3 shows the evolution of composition of the blade along its length.

Property	Description
E_{11}	Modulus of elasticity in direction 1 [Pa]
E_{22}	Modulus of elasticity in direction 2 [Pa]
E_{33}	Modulus of elasticity in direction 3 [Pa]
G_{12}	In-plane shear modulus of elasticity [Pa]
G_{13}	Out-of-plane shear modulus of elasticity [Pa]
G_{23}	Out-of-plane shear modulus of elasticity [Pa]
ρ	Laminate density [Kg m^3]
t	Laminate thickness [m]

Table 1: Laminate main material properties.

The material stiffness and strength for the glass-fibre laminates are determined from material testing of actual fibre-resin and core materials that are representative of the production blade laminates and sandwich configurations. Testing for each material property is carried out according to the relevant standard [6]. For each type of laminate, the main material properties were considered as random input parameters (Table 1). The nominal values and coefficient of variation were used to fit pdf to these inputs. The number of samples and coefficient of variation for each property, are presented at Table 2. The Gaussian distribution was used for all variables

so that the differential entropy is maximized for a given variance [7], which means this is the distribution with least assumptions and can be fitted only with information of variance and mean values.

E_{33}	5	15	G_{23}	3	15
ρ	0.6	9	t	3	9

Table 2: Materials properties experimental CoV.

Latin Hypercube Sampling (LHS) is widely used in Monte Carlo simulations as a way to improve accuracy and computational cost. LHS is a method to generate controlled random samples, the idea is to take the sampling point distribution close to the probability density function (pdf). It involves dividing the cumulative density function (cdf) into *n* equal partitions and then sampling a specified number of random data points in each partition. A MC-LHS (Monte Carlo with Latin Hypercube Sampling) was implemented for the materials properties previously defined by fitting pdfs to the coupon testing data and LHS from these pdfs. The fitted pdfs and the histogram of the LHS UD properties realisations can be seen in Fig. 5.

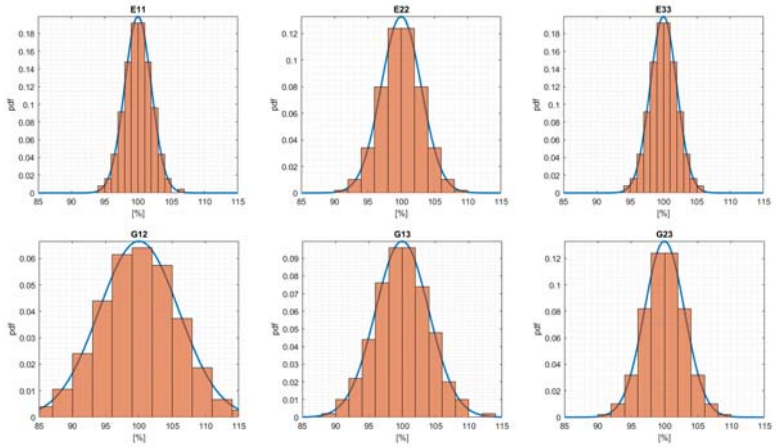

Figure 5: pdfs and histogram of UD random properties realisations from MC-LHS.

4 SENSITIVITY ANALYSIS

The software GEM-SA (Gaussian Emulator Machine - Sensitivity Analysis [8]), was used to calculate the main effects and total effects for each parameter. The emulator can be seen as a model of the model. The physics based model is treated as an unknown function, with the

possible ranges of the input parameters specified by probability distributions. Assuming this model is a smooth function of its inputs, then a response surface can be fitted to the training data using a least squares regression and the output can be estimated for any set of inputs, faster than using the physics based simulation. Details for this procedure are found in [9].

The emulator was trained using an LHS with 100 realisations of the deterministic code. This study relies on the following assumptions:

- No correlation between random variables (i.e. all properties were considered to be independent).
- No uncertainties in the geometry of the blade were considered.
- The CG and mass were assumed to be dependent exclusively on the density and thickness of the laminate.
- The static deflection was assumed to be dependent exclusively on the laminate's moduli.

Figs.6A and B show the contribution of the input parameters on the blade mass and CoG, respectively. As shown, the thickness of the UD is the most influential parameter both in the blade mass and in the blade CG.

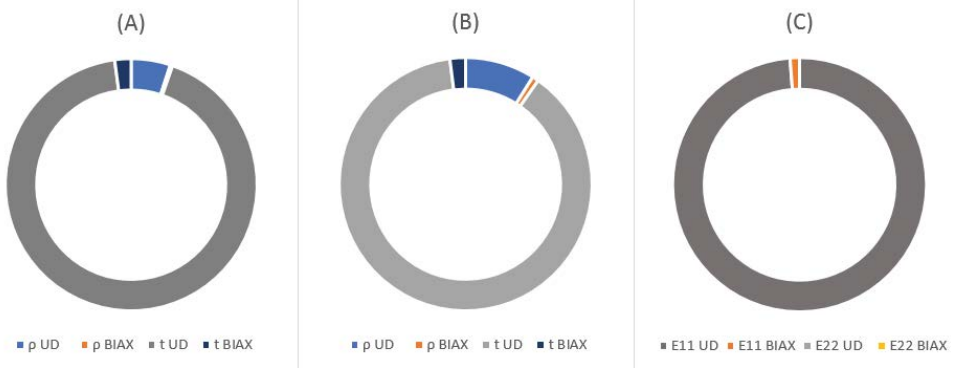

Figure 6: Blade mass, CG and static deflection sensitivity analysis - main effect.

Fig.6C shows the contribution of the material stiffness in the blade static deflection. The E_{11} of the UD dominates the variance of the static deflection test. This is coherent since the UD is the major laminate type in the spar cap, which is the substructure responsible for the flapwise blade stiffness. It is worth highlighting that the variation of the input parameters is limited (around 3 to 5%, shown in Table 2). In Table 3, the contributions can be seen for the main properties in each case: CG, mass and static deflection. The other parameters would need bigger variations to have a significant effect in the blade deflection.

5 UNCERTAINTY QUANTIFICATION

Monte Carlo (MC) simulation is the most applied methodology for uncertainty propagation, due to its straight forward implementation and non-intrusiveness to the deterministic model. It can be summarised in three steps:

1. construct probability density function (pdfs) for all random inputs independently
2. randomly sample from all the pdfs

Variance contribution (%)				
Property	CG	Mass	Property	Static Def
ρ UD	5.04	8.93	E11 UD	98.8
ρ BIAX	0.3	0.8	E11 BIAX	1.2
t UD	92.6	88.3	E22 UD	0.0
t BIAX	2.1	2.0	E22 BIAX	0.0

Table 3: Variance contribution - Sensitivity analysis.

3. evaluate the deterministic model

4. use the collection of realisations to compute relevant statistics of the quantity of interest

Even though the sensitivity analysis was dominated by few parameters, the MC simulation for CG, mass and static deflection were performed with the whole set of material properties of the laminates. The reason is because there could be cross-over effects between different parameters that could bring them to more relevance that might not be captured by the emulator.

MC results and fitted pdfs for experimental data can be seen in Figs. 7A, 7B and 8 for mass, CG, stiffness distribution and static deflection, respectively.

A total of 3000 realisations of the deterministic model were used on the MC simulation. The results are normalised by the experimental mean value. Table 4 shows the statistical moments for MC and experimental data.

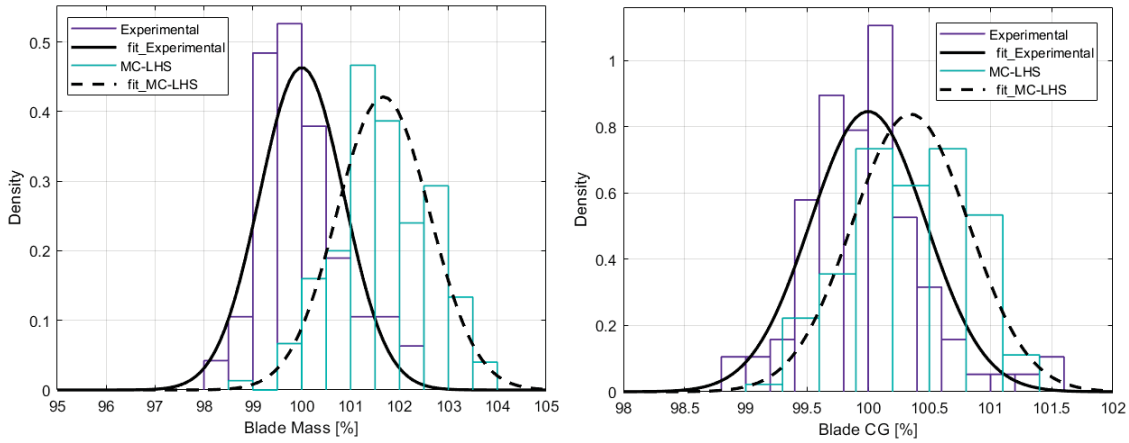

Figure 7: Blade mass and CG: Experimental and MC-LHS.

	Experimental		MC-LHS	
	μ (%)	σ (%)	μ (%)	σ (%)
Deflec.	100.0	2.2	99.9	3.0
Mass	100.0	0.9	101.7	0.9
CG	100.0	0.5	100.3	0.5

Table 4: Results summary: Mean values and standard deviation for experimental data and MC-LHS.

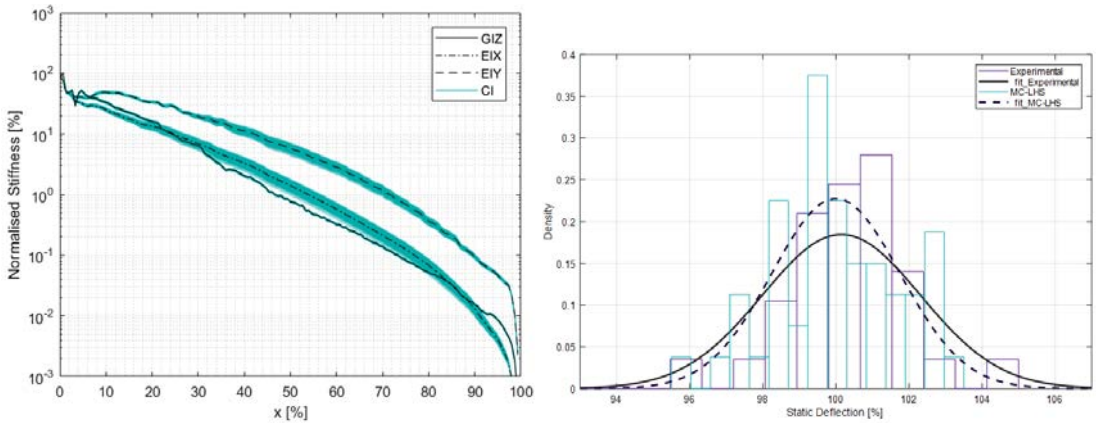

Figure 8: Blade stiffness distribution C.I. for normalised blade length and static deflection pdf .

6 DISCUSSION

The results for the UQ in the static deflection test can be given a high confidence as the deterministic model is accurate and the pdfs for both UQ and experimental data are in good agreement. Probabilistic simulations are heavily reliant of random input characterisation. Even though material properties are not highly uncertain (CoV of 3 - 5$\%$) there is still a considerable effect on the blade, which can be mostly seen in the flapwise stiffness (whilst the torsional stiffness is the least affected).

Comparison of the UQ results with experimental data test, showed the resulting variation of mass, CG location and static deflection can be reasonably explained by the uncertainties in the material properties of the 2 most used laminate types in the blade. The same order of variation is seen both in simulation and test data. The fact that the uncertainty in the E_{11} of the UD laminate (CoV 3 $\%$) is of the same order of the CoV in the static deflection test supports the Gaussian process sensitivity analysis results that it dominates the uncertainty (98.8$\%$ of variance contribution) and that the static deflection test can be accurately simulated by a beam model based on the blade stiffness distribution.

Mass and CG location present the same CoV for test data and MC simulations, although there is a small bias on the mean values. Under the current assumptions (section 4), this is a strong evidence that the uncertainty characterisation of the inputs (section 3) is representative of the blade production. Furthermore, this information is useful to update the model and have an even better numerical representation of the structure.

7 CONCLUSIONS

The present paper has investigated the effect of material properties uncertainties on the stiffness, mass and CG location as well as on static deflection of a wind turbine blade. The material properties were characterised by coupon testing statistical data. It is assumed that the uncertainty of these parameters can be modelled with a fitted normal distribution. In order to investigate combined effects on the stiffness and mass distribution, the parameters are simultaneously varied by means of LHS and the sensitivity described by means of a Gaussian emulator.

The material properties are not the only source of uncertainty in the characterisation of a wind turbine blade model. Still, the present study of propagating uncertainties in the materials properties of the blade is important because it shows that small uncertainties in these parameters have actually measurable effect on the characteristics of the blade.

It is also important to extend the uncertainties sources considered because blade stiffness, mass and CG can directly influence turbine loads and operation. Therefore, it is a natural step to extend the UQ framework to the turbine simulation, in order to have a best estimate of the impact uncertainties can have in the turbine in addition to other types of uncertainties (e.g. uncertainty in environmental parameters).

Abstract. *In order to analyze the influence of surface soil loading on the safety performance of buried pipelines, based on the non-linear contact model, the pipe-soil interaction model under the action of surface soil loading is established by using the finite element software ANSYS. Then, based on the PDS module of ANSYS probability design, the sensitivity values of the four parameters of surcharge height H, soil density ρ, elastic modulus E and Poisson's ratio μ to the maximum Von Mises stress σ_{max} and horizontal maximum displacement x_{max} of the pipeline are analyzed. The results show that for σ_{max}, with the increase of ρ, σ_{max} increases significantly; with the increase of H, σ_{max} increases; with the increase of μ and E, σ_{max} decreases. For x_{max}, increasing ρ, x_{max} decreases significantly; increasing μ, x_{max} increases; increasing E and H, x_{max} decreases. It shows that the soil density has a great influence on the stress and displacement of the buried pipeline. The research results have certain engineering significance for the safety protection during the construction of buried pipelines.*

1 INTRODUCTION

Pipeline transportation is a safe and convenient way to transport resources. After the pipeline has been completed and put into operation, due to the influence of natural and human factors in the pipeline area, the external conditions will inevitably change, such as the surcharge phenomenon near the pipeline is very common. Surface surcharge causes pipeline deformation and stress change. When the stress and deformation exceed the pipeline's bearing range, the pipeline will fail and cause disastrous damage and accidents. Therefore, the study of the effect of surcharge on buried pipelines has an important guiding role and engineering value for ensuring the safe operation of pipeline engineering.

Because the model test is limited by the field conditions, more and more experts and scholars around the world use analytical method and finite element method to study the influence of surface surcharge on the mechanical properties of buried pipelines. Trichey [1] used finite element method to study the dynamic response of buried pipelines under the circular uniform load. Han et al [2] studied the effect of surface load on the mechanical properties of buried pipelines in hard rock area by establishing a three-dimensional numerical model of pipe-soil coupling. Li and Ding [3] established the calculation theory of pipe shear, bending moment and deformation, and obtained the quantitative evaluation method for the influence degree of the adjacent building load on underground pipelines. Li et al [4] established a three-dimensional pipe-soil interaction model to study the influence of the location and size of surface surcharge on the displacement, stress and ellipticity of pipelines. Shuai et al [5] analyzed the effect of loads on stress and strain of buried pipelines by establishing three-dimensional finite element model. Wang et al [6] comprehensively analyzed the mechanical parameters of buried pipelines through theoretical calculation and test, and studied the safety performance of buried natural gas pipelines under the heavy vehicle load.

For the analysis of the safety performance of buried pipelines under surcharge loading, previous studies have adopted deterministic analysis method, and a large number of trial calculations have been carried out to analyze the variation of displacement and stress of buried pipelines by changing the influencing factors several times. It is difficult for this method to consider the influence degree on the pipeline safety performance when a factor changes continuously, and when the influence factors increase, it cannot distinguish the contribution of each factor to the influence degree on the pipeline safety performance, so there is blindness in the analysis. In view of this, this paper chooses the surcharge height and characteristics (including the soil density, elasticity modulus and Poisson's ratio) as random variables, calculates the sensitivity of random parameters to pipeline safety performance by using ANSYS-PDS random analysis module, and obtains the correlation between parameters and the pipeline safety performance.

2 MECHANICAL MODEL AND CALCULATION PARAMETERS

The normal buried depth of the raw water steel pipe is about 2 meters, and the surface slag heaped load is about 2 meters high. The pipe is covered along the axis of the pipe, and its transverse width is about 12 meters, which is symmetrical to the center of the pipe. Steel tube diameter D=2.4m, wall thickness d=18mm, material elastic modulus E=2.1×10^{11}Pa, Poisson's ratio u=0.3, mass density ρ=7800kg/m^3.

3 FAILURE CRITERION OF BURIED PIPELINE

3.1 Strength checking standard

Because of the complex stress state of pipelines, Von Mises yield condition is often used to check the strength of pipelines. That is, when the maximum deformation ratio of pipelines reaches a certain value, the yield occurs [7]. The expression is as follows:

$$\sigma_{VonMises} = \sqrt{\frac{1}{2}\left[\left(\sigma_1 - \sigma_2\right)^2 + \left(\sigma_2 - \sigma_3\right)^2 + \left(\sigma_3 - \sigma_1\right)^2\right]} < \varphi\sigma_s \tag{1}$$

where σ_1, σ_2, σ_3 are the first, second and third principal stresses, φ is the design factor and σ_s is the yield stress of the pipe.

3.2 Stability check standard

The ratio of the maximum horizontal deformation Δx to the diameter D of the pipeline is defined as ellipticity Δ_θ. When the Δ_θ is greater than 3%, the section of the pipeline will lose stability [8].

$$\Delta_\theta = \frac{\Delta x}{D} \tag{2}$$

In this paper, the maximum Von Mises stress and horizontal maximum displacement of the pipeline are taken as the output variables to measure the safety performance of the buried pipeline.

4 ESTABLISHMENT AND SOLUTION OF FINITE ELEMENT MODEL

4.1 Constitutive model

The material nonlinearity should be considered in the analysis of the pipeline limit state. In this paper, the stress-strain relationship curve of three-fold line is chosen as the constitutive model of the pipeline. For soil constitutive model, Drucker-Prager material is used to simulate soil medium in ANSYS geotechnical finite element analysis.

4.2 Pipe-soil interaction model

In the modeling process of pipe, the commonly used models of pipe-soil interaction are elastic foundation beam model, soil spring model and non-linear contact model [9]. Compared with the non-linear contact model, the elastic foundation beam model and the soil spring model are simpler in calculation, but there are a lot of simplifications, which cannot better simulate the contact non-linear and non-linear friction between pipe and soil. Therefore, based on the non-linear contact model and the finite element software ANSYS, the pipe is regarded as a rigid body and the soil is regarded as a flexible body. A two-dimensional rigid-flexible surface contact is established to simulate the interaction between pipe and soil. The finite element model is shown in Figure 1.

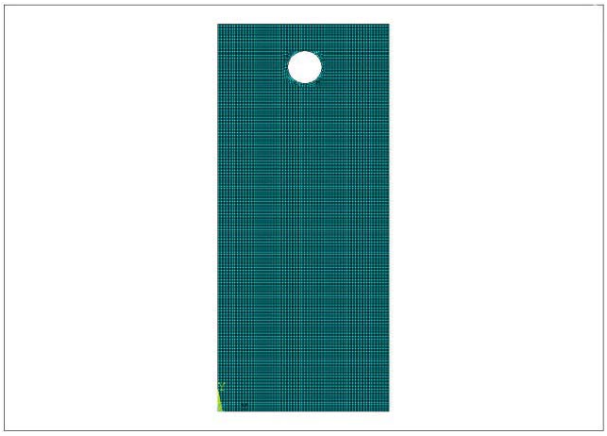

Figure 1: Schematic diagram of the finite element model.

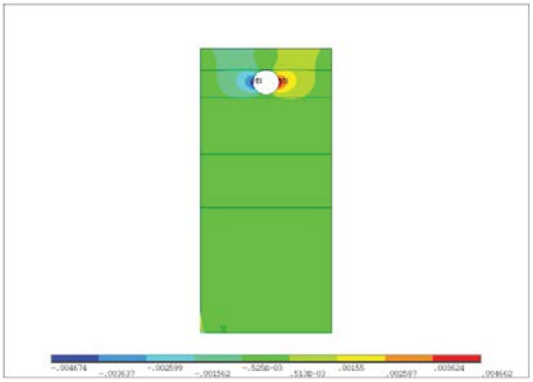
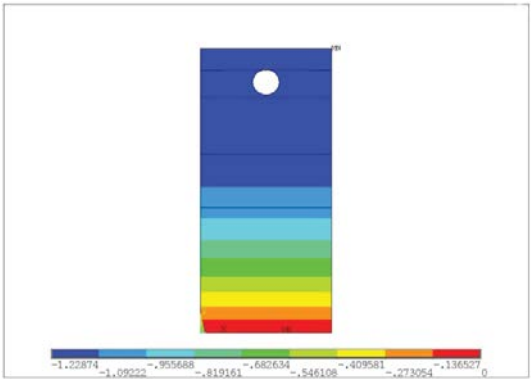
4.3 Solution of finite element model

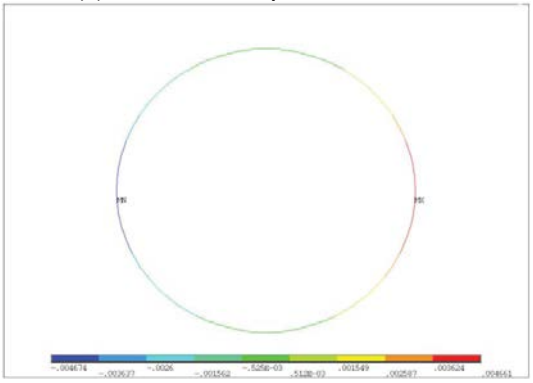
The displacement nephograms and equivalent stress nephograms of soil and pipeline can be obtained by solving the above finite element model, as shown in Figure 2.



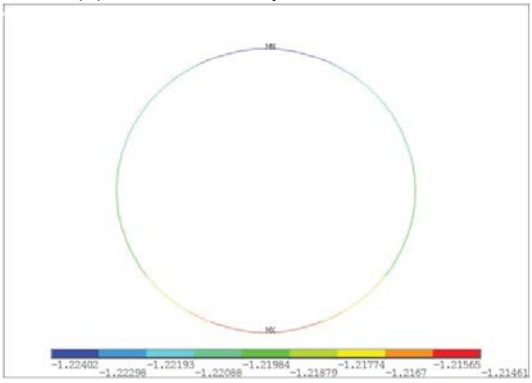
(a) X direction displacement of soil



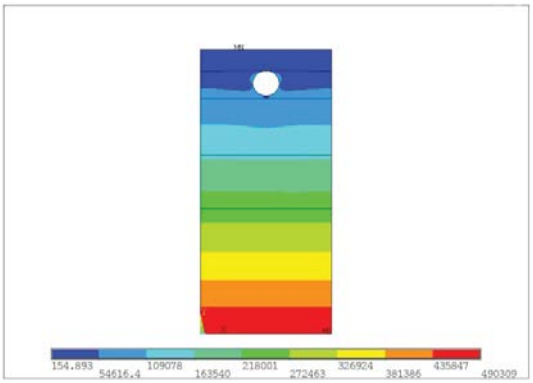
(b) Y direction displacement of soil



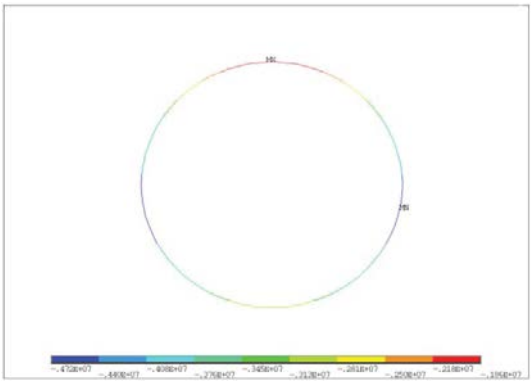
(c) X direction displacement of pipe



(d) Y direction displacement of pipe



(e) Equivalent stress of soil



(f) Equivalent stress of pipe

Figure 2: Displacement and stress nephograms of soil and pipeline.

Based on the finite element model of pipe-soil interaction, the sensitivity analysis of the pipeline safety performance is carried out below.

5 SENSITIVITY ANALYSIS OF SAFETY PERFORMANCE

ANSYS PDS module [10] is designed based on the probability of finite element method, which can be used to study the influence of uncertain factors on the pipeline safety performance. In this module, Monte-Carlo method is used to simulate random parameters [11]. In the analysis, the random variables are parameterized, so that the random parameters can be randomly selected according to their probability distribution in a limited range. Finally, the response values of stress and displacement of pipelines can be obtained by calculation.

In this paper, four parameters of surcharge height H and characteristics of surcharge soil (including soil density ρ, elastic modulus E and Poisson's ratio μ) are taken as random input variables, without considering the correlation among variables, and all variables obey truncated normal distribution. The random distribution and eigenvalues are shown in Table 1.

Variable	Mean	Standard deviation	Minimum limit	Maximum limit
H/m	2	0.01	1.97	2.03
$\rho/10^3$ kg/m^3	1.80	0.09	1.53	2.07
E/ MPa	12.24	0.612	10.404	14.076
μ	0.3	0.015	0.255	0.345

Table 1: Statistical characteristics of random input variables.

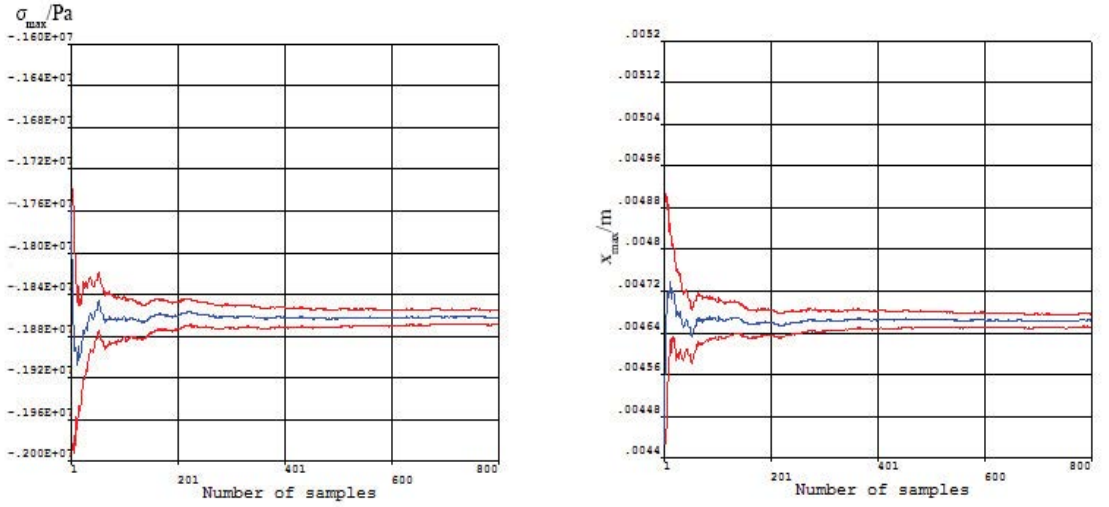
5.1 Sensitivity analysis based on Spearman rank correlation coefficient

Sensitivity analysis is a method to evaluate the variation rate of structural response characteristics due to random parameter changing. It can be used to analyse the influence degree of random factors on structural response values [12-15]. Refer to literatures [16-18] for more cases related to this method.

The Spearman rank correlation coefficient is an important method for studying the correlation between test variables in nonparametric statistics and its sensitivity is expressed by the rank correlation coefficient. If the coefficient is close to -1 or 1, the input variable is considered to have a large influence on the output variable. If the calculated coefficient approaches 0, the effect is considered to be small. At the same time, if the coefficient is positive, it means that the output variable value increases with the increase of the input variable value; if the coefficient is negative, it means that the output variable value decreases with the increase of the input variable value.

5.2 Sensitivity calculation results

ANSYS-PDS module is used for sensitivity analysis. Monte-Carlo method and Latin hypercube method are adopted as probability analysis methods. The number n of cycles is set as 800, and the mean trend charts of σ_{max} and x_{max} are obtained as shown in Figure 3. With the increase of sampling times, the width of the confidence interval decreases, and the sampling mean approaches to the level, which indicate that 800 sampling times are enough.



(a) The maximum Von Mises stress σ_{max} (b) The horizontal maximum displacement x_{max}

Figure 3: Average trend charts of σ_{max} and $x_{max.}$

The sensitivity values of σ_{max} and x_{max} to each random variable are shown in Table 2. According to the analysis data, the most significant influence on the maximum Von Mises stress σ_{max} of the pipeline is the density ρ of surcharge soil, which is 0.993, followed by the height H of surcharge soil, Poisson's ratio μ, and elastic modulus E of soil, which are 0.063, -0.021 and -0.017. The most significant influence on the maximum horizontal displacement x_{max} of the pipeline is the soil density ρ as well, which is -0.976, followed by elastic modulus E, height H and Poisson's ratio μ, which are -0.140, -0.073 and 0.025. Further analysis of the scatter plots shown in Figures 4 and 5 shows that with the increase of ρ, σ_{max} increases significantly; with the increase of H, σ_{max} increases; with the increase of μ and E, σ_{max} decreases; for the maximum horizontal displacement x_{max} of the pipeline, with the increase of ρ, x_{max} decreases significantly, with the increase of μ , x_{max} increases, with the increase of E and H, x_{max} decreases. It shows that the soil density has a great influence on the stress and displacement of the buried pipeline.

	H	ρ	E	μ
σ_{max}	0.063	0.993	-0.017	-0.021
x_{max}	-0.073	-0.976	-0.140	0.025

6 CONCLUSIONS

Based on the non-linear contact model, the pipe-soil interaction model of the buried pipeline under soil surcharge is established by using the finite element software ANSYS. Then, based on the ANSYS PDS module, the sensitivity values of the four parameters of surcharge height H and the characteristics of surcharge soil (including soil density ρ, elastic modulus E and Poisson's ratio μ) to the maximum Von Mises stress σ_{max} and the maximum horizontal displacement x_{max} of the pipeline are analyzed. The results show that the effect of soil surcharge on buried pipelines cannot be ignored.

(1) According to the sensitivity calculation results, for the maximum Von Mises stress σ_{max} of the pipeline, with the increase of ρ, σ_{max} increases significantly; with the increase of H, σ_{max} increases; with the increase of E and μ, σ_{max} decreases. The results show that the density of surcharge soil has the greatest influence on the stress of pipelines, while the elastic modulus of soil has the least influence on that.

(2) For the maximum horizontal displacement x_{max} of the pipeline, with the increase of ρ, x_{max} decreases significantly, with the increase of μ, x_{max} increases, with the increase of E and H, x_{max} decreases. It shows that the density of soil has the greatest influence on the horizontal displacement of the pipeline, while the Poisson's ratio of soil has less influence than other parameters.

(3) By the stochastic finite element analysis of the corresponding parameters of surcharge soil, it is easy to know which parameters are most sensitive to the pipeline stress and displacement, so that these parameters can be applied or prevented purposefully in engineering practice. The research results can provide some references for the construction and safety protection of buried pipelines.

CONFLICT OF INTEREST

The authors declare no conflict of interest.

Keywords: Increments, Differentials, Itô Calculus, Fractional Differential Equations.

Abstract. *A clear definition of increments and differentials in the case of fractional differential equations enforced by white noise processes is of fundamental importance for the probabilistic characterization of the response process. In this paper it is shown that the increments for equations of the kind* $\left(D^{\alpha}X\right)(t)=W(t)$ *where* α *is the order of fractional derivative and* $W(t)$ *is a white noise process, strictly depend on the order of the fractional derivative at hand. It is shown that increments may be of order* $dt^{(\alpha-1/2)}$ *and thus range from* ∞ *up to* $dt^{1.5}$ *as* $\alpha=2$ *and so on.*

1 INTRODUCTION

In the stochastic dynamics of classical nonlinear systems, the Ito calculus is usually adopted [1-6]. In particular, dealing with the differential equation of systems enforced by normal white noise processes, the differential of the response in Ito form is $dX(t) = f(X,t)dt + dB(t)$, where $B(t)$ is the Brownian motion process whose formal derivative is the white noise. The r.h.s. of the previous equation is composed by two terms: the first one ($f(X,t)dt$) is an infinitesimal of order dt, while the second ($dB(t)$) is an infinitesimal of order $dt^{1/2}$ [7-16]. This vision opens the way to the Ito calculus and gives a whole scenario for the complete characterization of the response process $X(t)$ in probabilistic setting. Such a clear vision disappears for nonlinear fractional differential equations of the kind $\left(D^{\alpha}X\right)(t) = f(X,t) + W(t)$, where the symbol $\left(D^{\alpha}X\right)(t)$ is the fractional derivative of order α of the response process $X(t)$ and $W(t)$ is the white noise. For such an equation, the present state in the generic time *t* depends on the entire past history and thus the Ito form of the latter equation has not been defined in the past. This paper aims to give an insight on this fundamental matter. The question will be posed by making a distinction between increments and differentials in evaluating the response in presence of very irregular processes like white noise or, equivalently, Brownian motion processes.

2 PRELIMINARIES

In this section some concepts of Itô stochastic differential calculus [17] and of fractional differential equations [18] are reported for clarity's sake as well as for introducing the fundamental concepts to explain the difficulty involved in extending Itô calculus for fractional differential equations.

2.1 Itô calculus

Let the differential equation of a nonlinear system under normal white noise $W(t)$ be given as:

$$\dot{X}(t) + f(X,t) = W(t) \tag{1}$$

where $X(t)$ is the response process and $f(X,t)$ is a nonlinear function of $X(t)$. As $W(t)$ is a normal white noise, eq.(1) may be rewritten in Itô form as follows:

$$dX(t) + f(X,t) = dB(t) \tag{2}$$

where $B(t)$ is the so called Brownian motion process having independent increments and characterized in probabilistic settings by:

$$\begin{aligned} &E[dB(t)] = 0; \\ &E[dB(t_1)dB(t_2)] = 0; \quad \forall t_1 \neq t_2 \end{aligned} \tag{3}$$

$$\begin{aligned} &E[dB(t)^k] = qdt^{\frac{k}{2}} \\ &E[dB(t)^2] = qdt \end{aligned} \tag{4}$$

where $E[\bullet]$ means ensemble average.

The process $B(t)$ is nowhere differentiable, *q* is the strength of the white noise process. From eq. (4) it may be stated that $dB(t)$ is an infinitesimal of order $dt^{1/2}$. This produces in the clas-

sical rule of differentiation of a composite function $\Psi(X,t)$ twice differentiable on X and continuously differentiable on t, the following rule

$$d\Psi(X,t)=\frac{\partial\Psi(X,t)}{\partial t}dt+\frac{\partial\Psi(X,t)}{\partial x}dX+\frac{1}{2}\frac{\partial^2\Psi(X,t)}{\partial x^2}\left(dX\right)^2 \tag{5}$$

where the extra term involving the second order derivative of $\Psi(X,t)$ is present since $\left(dX\right)^2$ is of order *dt* and thus it may be not neglected. Eq. (5) is known as the Itô differential rule, and by properly selecting the trial function $\Psi(X,t)$ the various equations ruling the evolution of $X(t)$ in probabilistic setting may be readily found. An example of this is given by selecting that $\Psi(X,t)=X^k$, the equations in terms of statistical moments can be obtained; by selecting that $\Psi(X,t)=\exp\left(i\theta X\right)$ where θ is a real parameter, the equation of the characteristic function is readily found, the inverse Fourier transform of this equation returns the renowned Fokker-Plank (FPK) equation. Now the question is; if in eq. (1) the first order derivative is substituted by a fractional derivative of order $\alpha\in\mathbb{R}^+$ how can the stochastic analysis be performed? In the authors' opinion the main key to correctly answering this question is found by coming back to eq. (1), and by considering the various sample functions of $W(t)$ as an approximation by subdividing the time axis into small intervals of equal length Δt as shown in fig. (1a). The sample functions of $W(t)$ are considered as a step wise function, and in the k-th interval the amplitude is $N_k\sqrt{q/\Delta t}$ where N_k is a normal random variable with zero mean and unitary variance. The random variables N_k are independent of each another and thus $E[N_rN_s]=\delta_{rs}\,q/\Delta t$ where δ_{rs} is the Kronecker delta. In fig. (1.a) the j-th sample function is labeled as $W^{(j)}(t)$.

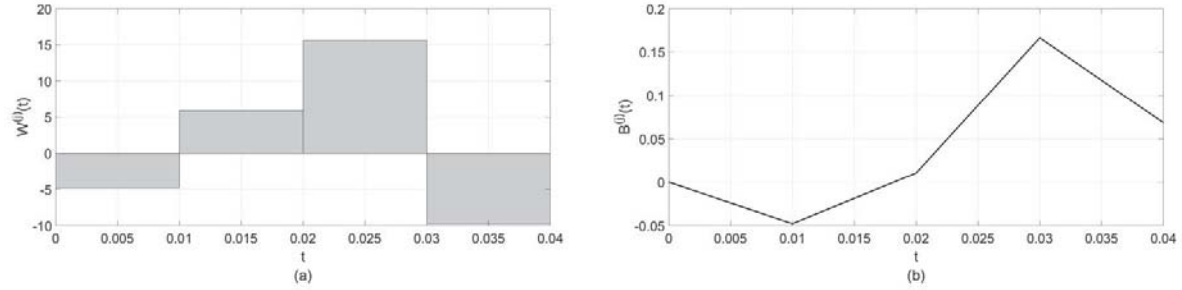

Figure 1 : j-th sample function of white noise (Fig.1a) and the correspondent Brownian motion (Fig.1b)

The correspondent sample function of the Brownian motion labeled as $B^{(j)}(t)$, is depicted in fig. (1b). As $t_k-t_{k-1}=\Delta t\to 0$ the approximations of $W^{(j)}(t)$ and $B^{(j)}(t)$ revert to the true j-th sample function of the white noise process and the correspondent j-th sample function of the Brownian motion process respectively.

3 FRACTIONAL DIFFERENTIAL EQUATION

Let us now suppose that the first order derivative is substituted by $\left(D^\alpha X\right)(t)$, that is:

$$\left(D^\alpha X\right)(t)=-f(X,t)+W(t) \tag{6}$$

where the symbol $\left(D^{\alpha}X\right)(t)$ stands for Riemann-Liouville fractional derivative defined as:

$$\left(D^{\alpha}X\right)(t)=\frac{1}{\Gamma(n-\alpha)}\left(\frac{d}{dt}\right)^{n}\int_{0}^{t}(t-\tau)^{n-\alpha-1}X(\tau)d\tau \tag{7}$$

where $n-1$ is the integer part of α. The inverse operator of the fractional derivative is the so called Riemann-Liouville fractional integral defined as:

$$\left(I^{\alpha}X\right)(t)=\frac{1}{\Gamma(\alpha)}\int_{0}^{t}(t-\tau)^{\alpha-1}X(\tau)d\tau;\quad \alpha\in\mathbb{R}^{+} \tag{8}$$

where $\Gamma(\bullet)$ is the Euler Gamma function ($\Gamma(\alpha)=\int_{0}^{\infty}e^{-t}t^{\alpha-1}dt$) that is the interpolating of the factorial.

In order to understand the problem at hand, namely, finding the characterization of $X(t)$ in a probabilistic setting we suppose that $f(X,t)=0$.

Eq. (6) is rewritten as:

$$\begin{cases}\left(D^{\alpha}X\right)(t)=W(t)\\ \quad X(0)=0\end{cases} \tag{9}$$

In particular, the above equation for $0\le\alpha\le 1$ rules the evolution of a quiescent viscoelastic bar under a white noise process. We start by assuming that the sample functions of $W(t)$ are approximated as in fig. (1a). In this figure an approximation of the white noise is depicted. The j-th sample function is represented as a stepwise function. As aforementioned, the amplitude of each step is $N_k^{(j)}\sqrt{q/\Delta t}$ where $N_k^{(j)}$ is the j-th realization of a normal standard variable (zero mean and unit variance). As $\Delta t\to 0$ the band limited white noise reverts into a true white noise. Then by assuming that the system is quiescent at $t=0$, the j-th sample function of $X(t)$ labelled as $X^{(j)}(t)$, correspondent to the j-th sample function of $W^{(j)}(t)$, is the Riemann-Liouville integral of the white noise is given as [19]

$$\underline{X}_m^{(j)}=\frac{\Delta t^{\alpha}}{\Gamma(1+\alpha)}\underline{V}_m(\alpha)\underline{W}_m^{(j)};\quad \alpha\in\mathbb{R}^{+} \tag{10}$$

where $\underline{X}_m^{(j)}$ is the vector collecting $X^{(j)}(t_k)=X_k^{(j)};\quad k=1,2,...,m$

$$\underline{X}_m^{(j)T}=[X_1^{(j)}\quad X_2^{(j)}\quad\dots\quad X_m^{(j)}]. \tag{11}$$

$\underline{W}_m^{(j)}$ is the m - vector of the amplitudes of the white noise represented in fig. (1a), namely:

$$\underline{W}_m^{(j)T}=\left(\frac{q}{\Delta t}\right)^{\frac{1}{2}}\left[N_1^{(j)}\quad N_2^{(j)}\quad\dots\quad N_m^{(j)}\right] \tag{12}$$

and $\underline{V}_m(\alpha)$ is a lower band triangular strip matrix defined [19]

$$\underline{V}_m(\alpha)=\begin{bmatrix}\omega_1(\alpha) & 0 & \cdots & 0\\ \omega_2(\alpha) & \ddots & \ddots & \vdots\\ \vdots & \ddots & \ddots & 0\\ \omega_m(\alpha) & \cdots & \omega_2(\alpha) & \omega_1(\alpha)\end{bmatrix} \tag{13}$$

where $\omega_k(\alpha)=k^\alpha-\left(k-1\right)^\alpha$. Eq. (10) gives the exact solution for the step wise representation of the white noise process.

It is worth noting at this point that a very similar representation of the Riemann-Liouville fractional integral is proposed by Grünwald-Letnikov [18], this representation implicitly assumes that the function at hand is continuous and differentiable up to the order $\left(n-1\right)$. Since this condition for $W(t)$ is violated owing to it's totally discontinuous the use of eq. (10) with $\underline{V}_m(\alpha)$ defined in eq. (13) and of $W(t)$ depicted in fig. (1a) is mandatory. Eq. (10) remains valid for $\alpha\in\mathbb{R}^+$, however the response $X_k^{(j)}$ to the step wise representation of the white noise depends upon the order of the fractional derivative. In fig. (2) a representative number of instants of the trajectories of the j-th sample function of $W(t)$ are plotted for different values of α.

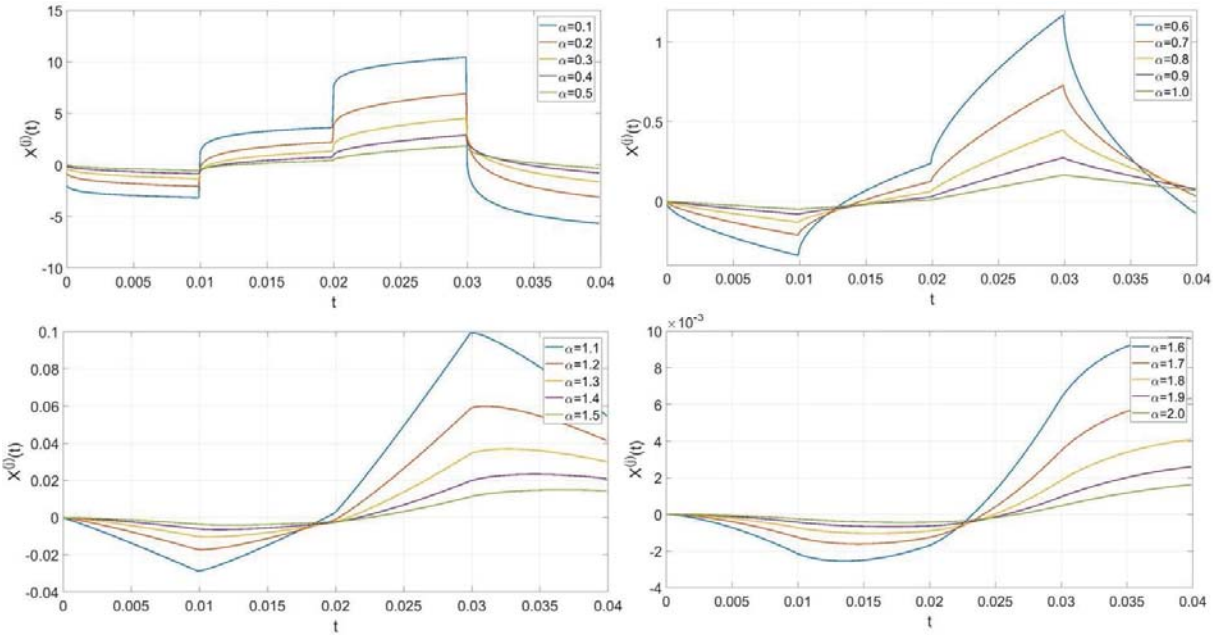

Figure 2: Few time instants of the response $X^{(j)}(t)$ for different values of α

As shown in fig.(2) we have very different scenarios for different values of α. In particular for $\alpha=0.5$ we have a continuous function with a vertical slope at the time t_k^+ (the apex + means immediately after t_k), and this behaviour does not change for $0<\alpha<1$; for $\alpha=1$ (Brownian motion) the response is a piece-wise function; for $\alpha=1.5$, $X^{(j)}(t)$ remains continuous with a discontinuity of first kind in t_k and this situation does not change for $1<\alpha<2$. For $\alpha>2$ the response is continuous with all the derivatives up to the integer part of α.

On the basis of these results we observe that an increment of $X^{(j)}(t)$ in passing from $X^{(j)}(t_{k-1})$ in $X^{(j)}(t_k)$, according to eq.(10) is given as:

$$X^{(j)}(t_k) - X^{(j)}(t_{k-1}) = \Delta X^{(j)}(t_k) = \frac{\sqrt{q}\Delta t^{\alpha-\frac{1}{2}}}{\Gamma(1+\alpha)} P_k^{(j)}(\alpha) \tag{14}$$

where $P_k^{(j)}(\alpha)$ is the j-th realization of a normal random variable (RV) $P_k(\alpha)$ defined as:

$$P_k^{(j)}(\alpha) = \left(\omega_k(\alpha) - \omega_{k-1}(\alpha)\right) N_1^{(j)} + \left(\omega_{k-1}(\alpha) - \omega_{k-2}(\alpha)\right) N_2^{(j)} + \ldots + \omega_1 N_k \tag{15}$$

and since it is a linear combination of independent normal random variables, the variance of $P_k(\alpha)$ is $\sum_{s=1}^{k}\left(\omega_s(\alpha) - \omega_{s-1}(\alpha)\right)^2 = \sigma_{P_k}^2$, and thus the variance is a finite quantity and the order of variance of $\Delta X(t_k)$ depends upon the order $\Delta t^{\alpha-1/2}$.

Now we turn out interest to the order of magnitude of the increments of the RV $\Delta X(t_k)$. As we have seen, the sample functions of $X^{(j)}(t)$ drastically depend upon the value of $\Delta X^{(j)}(t_k)$ therefore, we will consider the following different situations:

• $0 < \alpha < 1/2$. In this case $\Delta X^{(j)}(t_k)$ experiences a jump whose order of magnitude is $1/\Delta t^{1/2-\alpha}$ and thus as $\Delta t \to 0$ the RV $\Delta X(t_k)$ experiences an ∞ jump (like an instantaneous instability).

• $\alpha = 1/2$. In this case the RV experiences a jump of a finite quantity $\left(\sqrt{q}/\Gamma(1+\alpha)\right) P_k^{(j)}(\alpha)$ that is independent on the Δt selected.

• $1/2 < \alpha < 1$. In this case the RV $\Delta X(t_k)$ experiences an infinitesimal increment $\left(\sqrt{q}/\Gamma(1+\alpha)\right)\Delta t^{\alpha-1/2} P_k^{(j)}(\alpha)$ and thus the order of the RV is $\Delta t^{\alpha-1/2} > \Delta t$; to give an example, for $\alpha = 0.6$ the increment of $\Delta X(t_k)$ is $\frac{\sqrt{q}\Delta t^{0.1}}{0.894} P_k^{(j)}(\alpha)$.

• $\alpha = 1$. In this case $\Delta X(t_k) = B(t_k) - B(t_{k-1}) = \left(q\Delta t\right)^{1/2} P_k(1) = \left(q\Delta t\right)^{1/2} N_k$ and thus the increment is of order $\Delta t^{1/2} > \Delta t$ and $\Delta X(t_k)^2$ is of order Δt (increment of Brownian motion). It should be remarked that the increment only depends on the random variable N_k and not on the past history (the order of Markovianity is zero).

• $1 < \alpha < 1.5$. In this case the increment is $\left(\sqrt{q}/\Gamma(1+\alpha)\right)\Delta t^{\alpha-1/2} P_k^{(j)}(\alpha)$ with $0.5 < \alpha - 1/2 < 1$ and thus $\Delta X(t_k)$ is an infinitesimal quantity of order $\Delta t^{\alpha-1/2} > \Delta t$.

• $\alpha = 1.5$. In this case the increment coalesces with the differential order Δt and thus as $\Delta t \to 0$ the increment $\Delta X^{(j)}(t_k)$ is of order *dt*, and thus the increment and the differentials coalesce with each another.

• $1.5 < \alpha < 2$. In this case the increment is of order $1 < \alpha - 0.5 < 1.5$ and thus is a higher order infinitesimal than *dt*.

• $\alpha = 2$. This is a case of particular interest since $\omega_k(2) - \omega_{k-1}(2) = 2 \;\; \forall k \neq 1$ and $\omega_1(2) - \omega_0(2) = 1$ and the increment of RV $X(t_k)$ according to eq. (14) is given as:

$$\Delta X(t_k) = \frac{\sqrt{q}\Delta t^{1.5}}{2}\left(2\sum_{s=1}^{k-1} N_s + N_k\right) \tag{16}$$

and then $\left(2\sum_{s=1}^{k-1} N_s + N_k\right)$ is a normal zero mean RV, having variance $4(k-1)+1$ and thus $\Delta X(t_k)$ is a normal zero mean RV having a variance:

$$\sigma^2_{\Delta X}(t_k) = \frac{q\Delta t^3}{4}(4k+3) \tag{17}$$

From all of these observations, it is clear that in any case the order of the increments strictly depend on the value of α.

It must be stressed that the classical Brownian motion ($\alpha = 1$ in eq.9) is self-similar [20] that is the finite dimensional distribution for $a > 0$ $\{X(at); t \in T\} = \{a^H X(t); t \in T\}$, where H is the Hurst exponent. For $B(t)$ the Hurst exponent is 1/2, for the Lévy process, where the derivative is the stable white noise the Hurst exponent is the inverse of the instability index. These processes are called "fractional" but in the authors' opinion this is a misnomer introduced by Mandelbrot [21] but it may create confusion since one imagines that some fractional operator will appear, but this is not the case. In any case the fractional integral of the white noise is not in general self similar and hence, a deeper insight on this matter is necessary.

4 CONCLUSIONS

The extension of Itô calculus to the case in which some fractional operators appear is not currently available. In the authors opinion this is mainly due to the fact that the order of magnitude of the increments of the response process has to be defined in a correct way.

In this paper it is shown that for fractional differential equations of the kind $\left(D^\alpha X\right)(t) = W(t)$ the order of increments are $\Delta t^{\alpha-1/2}$ and thus, depending on the value of α it may experience jumps of order ∞ up to order dt^∞ for $\alpha = \infty$. This explains the difficulty for the extension of Itô calculus to fractional differential equations.

Abstract. *Multi-layer elastomeric bearings (EB) are used in civil engineering in many applications such as vibration control and base isolation in bridges and infrastructures. During strong seismic actions, EB can be subjected to both axial and shear loads. The recent theoretical model [1] considers the effects of both loads to study large deformation stability of EB. The present paper investigates the accuracy of this theory by comparing the proposed results with numerical findings, aiming to extend the current linear elastic model with a more accurate non-linear advanced formulation that can consider the behaviour of elastomeric bearings captured by numerical findings. In particular, such improvement is necessary in designing strategic structures, such as bridges or nuclear power plants. The developed model may be implemented in existing Finite Element Model (FEM) platforms and be widely used by the practitioners.*

1 INTRODUCTION

Base isolation and vibration control systems are the most common applications of EB towards the protection of structures and infrastructure assets from the effects of dynamic loads, such as earthquakes and vibrations. Isolation allows the decoupling of the structure from the ground by intentionally concentrating dynamic/seismic energy dissipation in a unique element with low horizontal stiffness between the substructure and the superstructure. In the past 20 years, extensive contributions developed models that can consider the complex mechanism of such systems. In particular, experimental tests that have been conducted [2-13] showed how the vertical and horizontal stiffness are related with the increase of the lateral displacement. Furthermore, numerical simulations were performed during the last decades [14-18], in order to model the non-linearity of EB and to predict the critical and post-critical mechanisms. More recently, Kumar et al. [19] investigated the effect of lateral displacement on vertical stiffness and the critical buckling load capacity of EB. In this background, Forcellini [20], Kalfas *et al.* [21-23], Kalfas and Mitoulis [24], and Rahnavard and Thomas [25] conducted numerical studies on EB with several platforms, such as Abaqus/ CAE and Opensees. In particular, Forcellini *et al.* [26] compared the numerical findings with the theoretical ones [1]. In this regard, numerical simulations apply isolators as finite elements inside structural models.

Other researchers studied simplified models that describe the behaviour of EB with the aim to be directly implemented in structural models. In particular, Forcellini and Kelly [1] described the stability of EB extending the original two-spring model of the bearing, developed by Kelly [27] and Kelly and Takhirov [28] to large deformations. The model is used to illustrate the influence of large deformations on the interaction between horizontal and vertical loads and assessing the post-buckling behaviour of EB.

The present paper investigates the accuracy of the theoretical model, particularly regarding the non-linear modelling of shear force – shear deflection and study its effects shown both by laboratory tests [29] and numerical studies [21-24]. The paper aims to extend the current linear elastic model with a more accurate non-linear advanced formulation. In this regard, the developed relationship can be implemented inside a finite element that reproduces the combined axial-shear behaviour. As shown by Forcellini *et al.* [26], Forcellini[30,31], and Canini and Forcellini [32,33] the role of non-linearity is fundamental in order to understand the cases where potentially EB becomes crucial for important structures such as bridges and nuclear power plants. In this regard, the paper first compares the numerical findings with the linear elastic theory. Subsequently, the procedure that was carried out in order to calibrate the most significant parameters is presented.

2 NUMERICAL SIMULATIONS IN SUPPORT OF THE ANALYTICAL MODEL

Abaqus/ CAE and Straus7 have been used here to perform numerical simulations (Fig. 1). The finite element (FE) models have been reproduced with layered systems that represent the alternating steel and rubber layers and the bolted connections. In particular, the models were performed in order to reproduce the experimental results by Ohsaki *et al.* [29].

The numerical models consist of two anchor plates at the upper and lower levels of the model (diameter: 1000 mm and thickness: 28 mm) and 30 rubber layers and 29 steel plates alternating each other. Each rubber layer had a thickness of 4 mm and the individual steel plate thickness was 3.1 mm, with a total thickness of 2x28 mm+30x4 mm+29x3.1 mm= 265.9 mm. The diameter of the intermediate layers was 700 mm and there was a hollow core, which run along the whole thickness of the bearing (internal diameter: 15 mm). The mesh consisted of 62,672 3D solid elements: 1,008 for each rubber layer and steel plate and 1,600 elements

for the anchor plates. Full integration elements were chosen in order to obtain more accurate results, especially in correspondence with the hourglass effect [34]. Boundary conditions are depicted in Fig. 1b (where X-, Y- and Z-axes can be seen). The bottom anchor plate was fixed (i.e. $UX=UY=UZ=URX=URY=URZ=0$). The axial load (along the *Z*-axis) and the horizontal displacement (along the *Y*-axis) were applied at the top anchor plate (where $UZ\neq0$ and $UY\neq0$). The remaining boundary conditions at the top anchor plate were: $UX=URY=URZ=0$, with $URX\neq0$. The elastic properties of the rubber layer and steel plates are shown in Table 1.

Two platforms were used to perform non-linear analyses with hyperelastic behaviour for the rubber layers. In Abaqus/ CAE, the Ogden material was used [35] and the hyperelastic properties were: $\mu_1= 0.41$ MPa, $\alpha_1= 1.6$, $\mu_2= 0.0012$ MPa and $\alpha_2= 6.2$ (as in [21]). These parameters led to a shear modulus of $G= 0.66344$ MPa and a Poisson's Ratio of $\nu= 0.49989$. Other parameters were: the stress scaling factor $S_{SF}= 1.6$, the creep parameter $A= 0.56$, the effective stress exponent $m= 4$ and the creep strain exponent $C= -1$. In Straus7, the rubber material was modelled with the Mooney and Rivlin model [36, 37] and the main parameters *C1* and *C2* (both equal to 0.16586 MPa) were calibrated with a parametric study. The compressibility modulus was set equal to 2,000 MPa.

3 ANALYTICAL, LINEAR ELASTIC MODEL

The theory of stability of EB was firstly developed by Haringx [38] and later applied by Gent [39] that can be considered the basis for the theory of stability. In particular, EBs can be susceptible to a type of instability similar to that of an ordinary column but dominated by the low shear stiffness of a bearing, as described by the simplified two-spring linear elastic model that can be seen in Fig. 2 [27] and the developed theory [1].

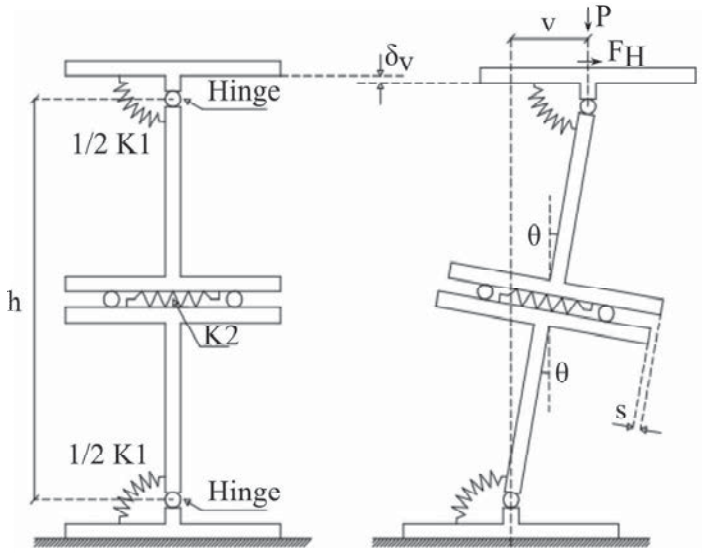

Figure 2. Linear elastic model

The formulation of the original model of the EB is based on three kinematic variables: the rotation θ, the vertical displacement δ_v and the horizontal displacement v. The equations can be condensed in the following:

$$[p \cdot \cos\theta + \lambda] \cdot [p \cdot \sin\theta + f \cdot \cos\theta] = \theta \tag{1}$$

where

$$p = \frac{P}{\sqrt{P_E P_S}} \tag{2}$$

$$f = \frac{F}{\sqrt{P_E P_S}} \tag{3}$$

$$\lambda^2 = \frac{P_S}{P_E} \tag{4}$$

$$P_E = \frac{\pi^2 \cdot E \cdot I_S}{h^2} \tag{5}$$

$$P_S = G \cdot A_s \tag{6}$$

EI_s is the bending stiffness, GA_s is the effective shear stiffness and λ^2 is the ratio between the Euler load (P_E) and the shear load (P_S), which generally tends to be a very small constant, usually of the order of 0.001 – 0.05 [1]. Since this model applies a linear isotropic material, the value of λ^2 does not depend on the shear modulus (G) and can be calculated as (by considering the Poisson's coefficient almost 0.5, for the rubber):

$$\lambda^2 = \frac{P_S}{P_E} = \frac{G \cdot A_S}{\frac{\pi^2 \cdot E \cdot I_S}{h^2}} = \frac{G \cdot A_S}{\frac{\pi^2 \cdot 2G \cdot (1+\nu) \cdot I_S}{h^2}} = \frac{A_S \cdot h^2}{\pi^2 \cdot 2(1+\nu) \cdot I_S} \cong 0.3377 \frac{A_S \cdot h^2}{I_S} \tag{5}$$

The above mathematical model is here compared with the results obtained from the numerical simulations where materials are set as linear elastic. Figure 3 compares the results for increasing vertical pressure p (i.e. 2 MPa, 5 MPa, 10 MPa and 14 MPa). It is possible to see that the linear elastic theoretical model is in close proximity to the results from the numerical simulations performed in Abaqus/ CAE and Straus7.

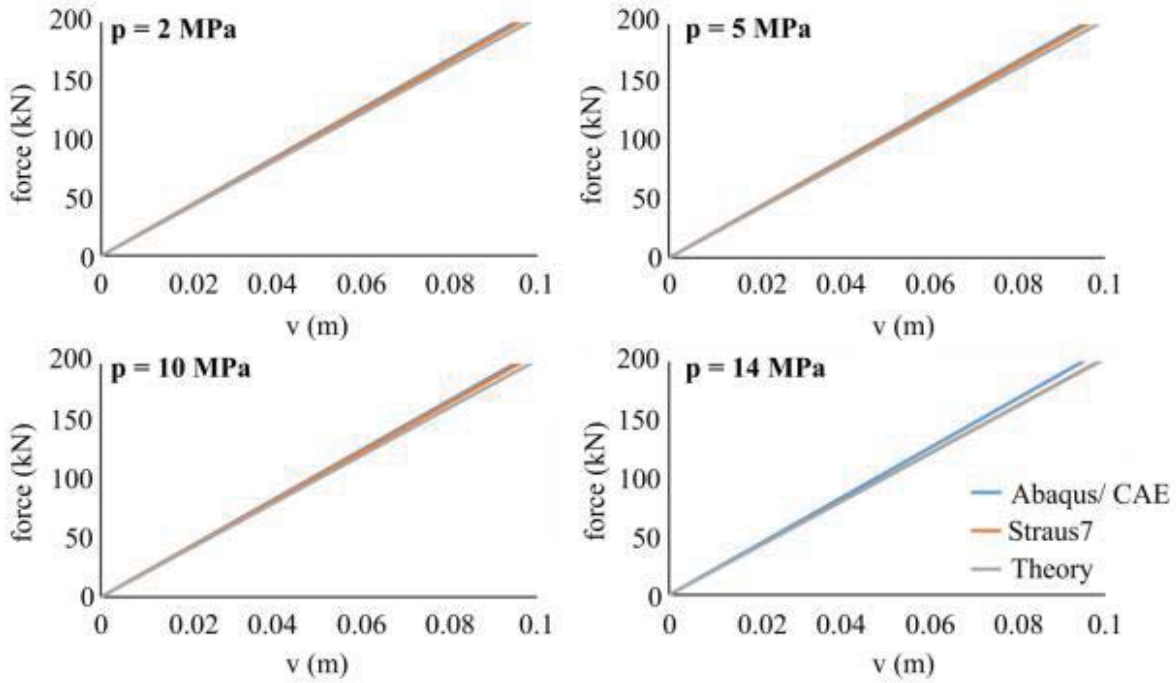

Figure 3. Comparison between linear assumptions (Abaqus/ CAE, Straus7 and Theory)

4 DEVELOPMENT OF THE NON-LINEAR ELASTOMERIC BEARING MODEL

In this section, the assumptions of the linear elastic material are neglected. Therefore, it is not possible to assume a linear relationship between G and E, as in Equation (7). In particular, λ^2 depends on the ratio between G and E and the assumption that it remains constant during the deformation needs to be removed. There are studies that describe the source of non-linearities of EB, such as the Mullin's effect [40, 41], which causes the reduction of the bulk modulus (volumetric elasticity). This paper aims to extend the linear theory by concentrating all the sources of non-linearity inside λ^2 and a new formulation of such parameter is proposed here. The formulation describes the behaviour of the EB by taking the horizontal displacement as the main kinematic variable. A non-linear relationship between such variable and λ^2 was built up with this form:

$$\lambda^2 = \lambda^2(v) = \alpha \cdot v^{\beta} \tag{8}$$

The power relationship was shown to be the best correlation between v and λ^2 and it was obtained adopting the least square regression technique. The correlation parameters α and β were calibrated considering R^2 value to be the measure of the correlation. Table 2 shows the parameters for the considered loading conditions.

	α	β	R^2
2 MPa	0.0014278	-0.0001	0.9991
5 MPa	0.00142	-0.026	0.9987
10 MPa	0.0106	-0.395	0.9976
14 MPa	0.0233	-0.576	0.9856

Table 2: Correlation parameters.

In order to implement formula (8) inside (1), an incremental solution was needed due to non-linearity. The Newton-Rapson algorithm was chosen as one of the most credited methods for solving non-linear problems. The new formulation was finally solved for the increasing vertical pressure p (2 MPa, 5 MPa, 10 MPa and 14 MPa) and compared with numerical simulations performed by Abaqus/ CAE and Strauss 7 (Fig. 4). It is worth noticing that for 2 MPa and 5 MPa the proposed formulation leads to a fairly linear relationship between the horizontal displacement and the horizontal force (λ^2 is fairly constant). For bigger values of p (10 MPa and 14 MPa), non-linearity behaviour becomes significant.

Figure 5 shows the proposed formulation (8) for the considered EB and it is possible to assess the relationship of λ^2 and the displacement. It is worth noticing that the variation is more significant for bigger values of vertical loads (10 MPa and 14 MPa), where non-linear behaviour needs to be considered.

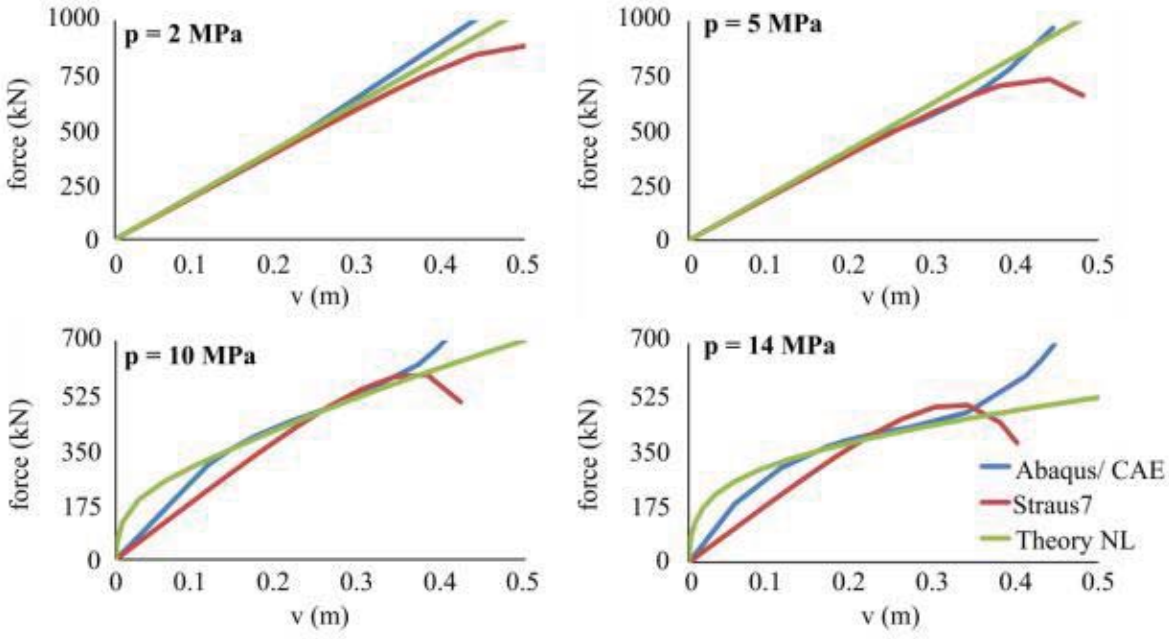

Figure 4. Comparison between non-linear results (Abaqus/ CAE, Straus 7 and the modified NL model)

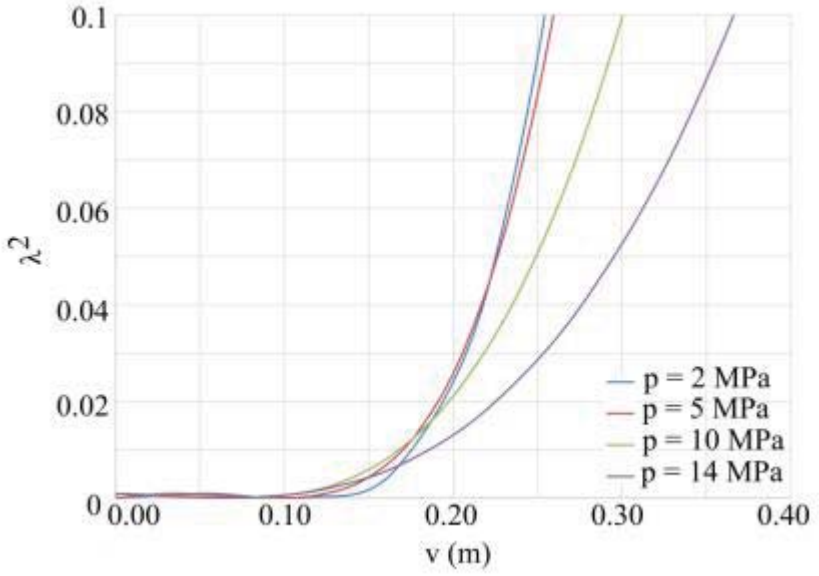

Figure 5. The proposed formulation (8)

5 CONCLUSIONS

The study conducted in this paper may be viewed as an original contribution to study the modelling of stability of EB with analytical models. In particular, the paper shows the credibility of the two-spring model by Forcellini and Kelly [1] in representing the linear behaviour of EB. The comparison between the theory and the numerical simulations performed with Abaqus/CAE and Straus7 showed good agreement under linear assumptions. The paper proposes the development of the original two-spring model by introducing a non-linear relationship between the λ^2 and the horizontal displacement. The proposed formulation can consider a more realistic non-linear behaviour of the EB and can be implemented in numerical codes. Overall, this study can be considered as a first step towards proposing a new easy-to-use approach that will assess the non-linear response of EB.

Abstract. *Elastomeric bearings may be applied as passive energy devices for seismic protection of structures and vibration control of systems and machinery. Their main loading state is compression combined with horizontal displacements and thus compressive behavior requires particular attention. In this study, three approaches (theoretical, experimental and numerical) are taken into account to study several scaled bearings with relative low shape factors. Compressive tests to scaled elastomeric bearings were performed and used to validate the large-displacement theory proposed by Forcellini and Kelly (2012). Relative large values of material variations, geometrical dimensions, and fabrication imperfections were taken into account in the validation of the theoretical model. Finite element modeling was performed using OpenSees, which is able to reproduce alternating rubber and steel layers subjected to vertical load conditions.*

1 INTRODUCTION

Elastomeric bearings have being used in applications such as bridges, buildings, and power generation plants due to their damping capacity, long life span, moderate cost since the 70s [1]. In addition, elastomeric bearings have been applied to control deformations in bridges and buildings due to vehicular traffic, wind, seismic activity, and thermal expansion, which generate cyclic loads in compression, shear, and torsion. Besides fulfilling the role of connectors between structural parts, they support relative large static loads in compression due to the weight of the structure [2, 3].

Bearings vertical behavior has been studied by experimental tests [4–8] using the results for design purposes. In [5], the authors studied the behavior of bearings used as seismic isolation systems under compression. Mechanical properties such as stiffness and damping ratio under axial loading were investigated [9–11]. Different rubber compounds were experimentally studied by [12] that evaluated physical and mechanical properties. Uniaxial compressive tests were performed by [13] on anisotropic laminated rubber bearings using v-shaped steel reinforcement shims with a predefined angle during the manufacturing process. Other authors [14] developed a failure model for rubber used in bearings by measuring local strains at failure using an image analysis approach. Recent studies [15, 16] obtained experimental results on high-damping rubber to validate constitutive models of elastomeric bearings.

Theoretical models have been proposed to consider the stability of bearings, which is controlled by the reduction of shear stiffness due to increasing axial load or increasing lateral displacements [8, 17–22]. There are contributions that propose mechanical models such as [23, 24]. Recently, [25] studied the stability of bearings subjected to large deformations, [26] presented a nonlinear analytical model based on [24] and capable of predicting the dynamic behavior at all displacement ranges. In addition, [27] developed an analytical model for the coupled horizontal-vertical behavior of bearings subjected to dynamic loads. Other theoretical models include [28–32].

Several finite element models (FEM) where proposed [33-37] and studies to predict critical loads, vertical and horizontal stiffness have been carried out [21, 38–40]. Recently, [41] studied and proposed several models by applying OpenSees, while [42] performed numerical simulations in LS-DYNA. Recently, [43] compared the large deformation response theory proposed in [25] with test results of [24] performing FEM using OpenSees. Other researchers [44] used different axial displacements to study the stress distribution within the rubber and steel reinforcing shims using ABAQUS, that was applied also by [45] that compared the three models proposed by [24, 28, 29]. Other studies focused on modeling civil structures to assess their dynamic response in order to design effective isolation systems [46–54].

Therefore, this paper aims at applying the experimental, theoretical, and FEM approaches to assess the behavior of elastomeric bearings under compressive loading states.

2 EXPERIMENTAL

Scaled bearings were manufactured using two natural rubber-based compounds typically used in elastomeric bearings with 15 and 45 phr (parts per hundred of rubber by mass) of carbon black as reinforcing filler, and nominal Shore A hardness of 55 and 70, respectively. Rubber compounds evaluated in this study have been analyzed previously in [55]. Shear properties of both rubber compounds we characterized for the FEM analysis using pure shear specimens following the recommendations of [56]. A displacement-controlled method was used at a deformation rate of 12 mm/min to approximately 40 % of shear strain. Three loading cycles were recorded, and from the stress-strain curves, shear modules were calculated from

the third loading cycle as the initial slope of the curves. Mean values of the shear modules of the 55 and 70 Shore A hardness compounds were 0.63 MPa and 1.13 MPa, respectively.

For the scaled bearings, different individual rubber thickness were chosen as shown in Table 1. The study analyzed two different shape factors, the geometrical parameter that characterizes a single rubber layer and defined as the ratio of the load area to the bulge area [57] (calculated using equation 1). Plan dimensions of all scaled bearings were fixed to 140x140 mm with a 5 mm edge cover, and 1 mm-thick steel reinforcement shims. Compression tests were performed using a SHIMADZU unidirectional testing machine with a load cell of 300 kN and a deformation rate of 5 mm/min.

$$S = \frac{(length)(width)}{2t(length + width)} \tag{1}$$

Name	Number of rubber layers (n)	Thickness of individual rubber layer (t, mm)	Shape factor (S)
B55-4	3	4	8.75
B55-6	3	6	5.83
B70-4	3	4	8.75
B70-6	3	6	5.83

Table 1: Characteristics of the bearings.

3 THEORETICAL MODEL

The large-displacement theory proposed by [25] uses the mechanical model shown in Figure 1 to assess the stability of elastomeric bearings due to vertical and horizontal loads (P and F_H respectively).

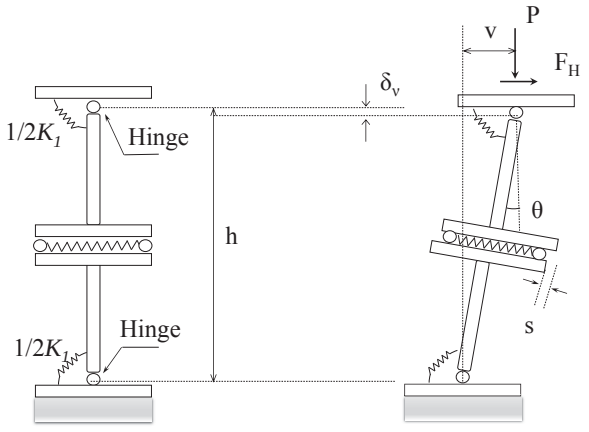

Figure 1: Two-spring model used by Forcellini and Kelly [25].

Where h is the total height of the bearing, δ_v and v the vertical and horizontal displacements respectively, s the shear displacement, and θ the relative rotation.

For compressive loads, $F_H = 0$ and P can be calculated as:

$$P = -\frac{P_S}{2\cos\theta} + \sqrt{\frac{P_S^2}{4\cos^2\theta} + \frac{P_E P_S(\theta - \theta_0)}{\sin\theta\cos\theta}} \tag{2}$$

Material variations, geometric, and fabrication imperfections are considered into the θ_0 angle expressed in radians [25]. P_E is the Euler load for a standard column defined as

$$P_E = \frac{\pi^2 EI_S}{h^2} \tag{3}$$

where EI_S the bending stiffness of the square section of the bearing calculated as

$$EI_S = E_c\left(\frac{1}{12}l^4\right) \tag{4}$$

where l is the length of a square section, and E_c the compressive modulus was calculated according to equation 5 taking into account the compression spring rate [56] and calculated as a function of the compressive force and compressive displacement from the force-displacement curve of the compressive test.

$$E_c = \frac{F_c tn}{Ad_c} \tag{5}$$

The compressive force F_c is obtained from the experimental test, A the loading area of the bearing, d_c the experimental vertical displacement, and h the total height of the bearing including steel shims. P_S from equation 2 is the shear stiffness of a unit element defined as

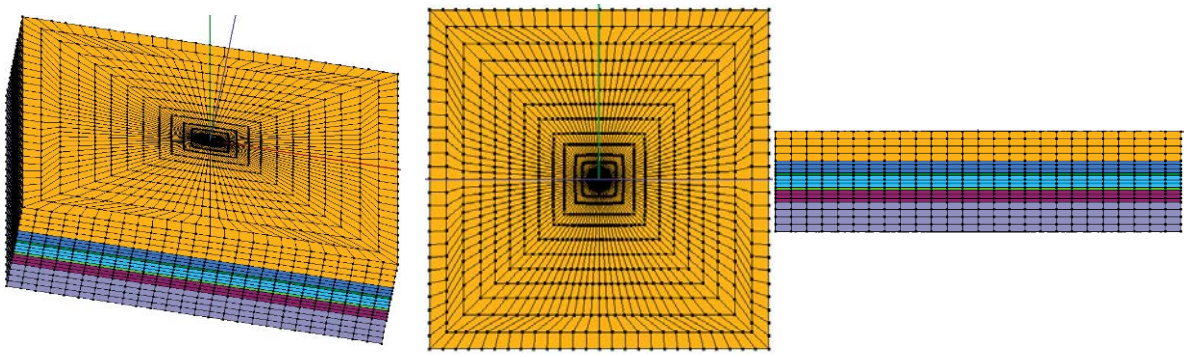
$$P_S = GA_S = GA\frac{h}{t_r} \tag{6}$$

where A is the plan area, and t_r the total rubber thickness. Finally, the vertical displacement δ_v can be calculated as

$$\delta_v = \frac{P}{P_S}h\sin^2\theta + (1-\cos\theta)h \tag{7}$$

4 NUMERICAL SIMULATIONS

Opensees (Open System for Earthquake Engineering Simulations), developed by the Pacific Earthquake Engineering Center (PEER), was applied to perform 3D FEM [58]. OpenSeesPL interface originally designed for soil analyzes was here applied by selecting shear-beam boundary conditions with side boundary nodes fixed vertically at gravity runs [59]. Figure 2 shows the mesh used for the 3D models, which contains 22464 elements and 24769 nodes. Furthermore, 10 mm-thick top and bottom steel plates are considered rigid ensuring that deformation concentrates only within the elastomer layers. Furthermore, a linear behavior in shear of the rubber compounds was assumed (shear modules of 0.63 MPa and 1.13 MPa for the 55 and 70 Shore A hardness compounds respectively). For the steel reinforcing shims, and both top and bottom steel plates, a shear modulus of 74.93 MPa and a density of 7850 kg/m^3 were considered.



Isometric view Top view Front view

Figure 2: 3D model for the scaled elastomeric bearings.

A monotonic pushover analysis was carried out using the displacement-based method to simulate the conditions of a compressive load. Using this method, numerous displacements were applied to the 3D models with a total number of 10 steps. Several numerical simulations were performed for each bearing with increasing the vertical displacement. For each numerical simulation, the compressive force values were calculated from the maximum normal stress as the mean stress value at the center of each model.

5 DISCUSSION

Figure 3 shows the comparison of the experimental, theoretical, and numerical simulation approaches results for the different bearings. Regarding the comparison between the experimental and theoretical approaches, the large-displacement theory accounts for typical bearings with shape factors between 10 and 30 [25]. Since the shape factors considered in this study are smaller than those applied in the theory, relative large values of θ_0 (material variations and fabrication imperfections) were used, which are larger than those obtained in [25]. Among the bearings tested, higher values of θ_0 are observed for bearings with the lower shape factor, that is, bearings with 6 mm-thick individual rubber layers indicating that the number of rubber layers plays an important role besides the shape factor.

It is observed that the results of the numerical simulations showed an increased force-displacement response (Figure 3) because the model assumes an ideal bonding between rubber layers and steel reinforcing shims. In addition, the shape factor S seems not to affect significantly the comparison between the different approaches. And since the compressive stiffness of a rubber layer depends on the steel-rubber bond, a perfectly bonded surface yields in additional stiffness due to the kinematic constraint [60]. Furthermore, the numerical simulations assumed perfect bonding between the top and bottom outer rubber layers with the steel plates, while in the experimental tests surfaces in contact rely only on the friction between rubber and steel.

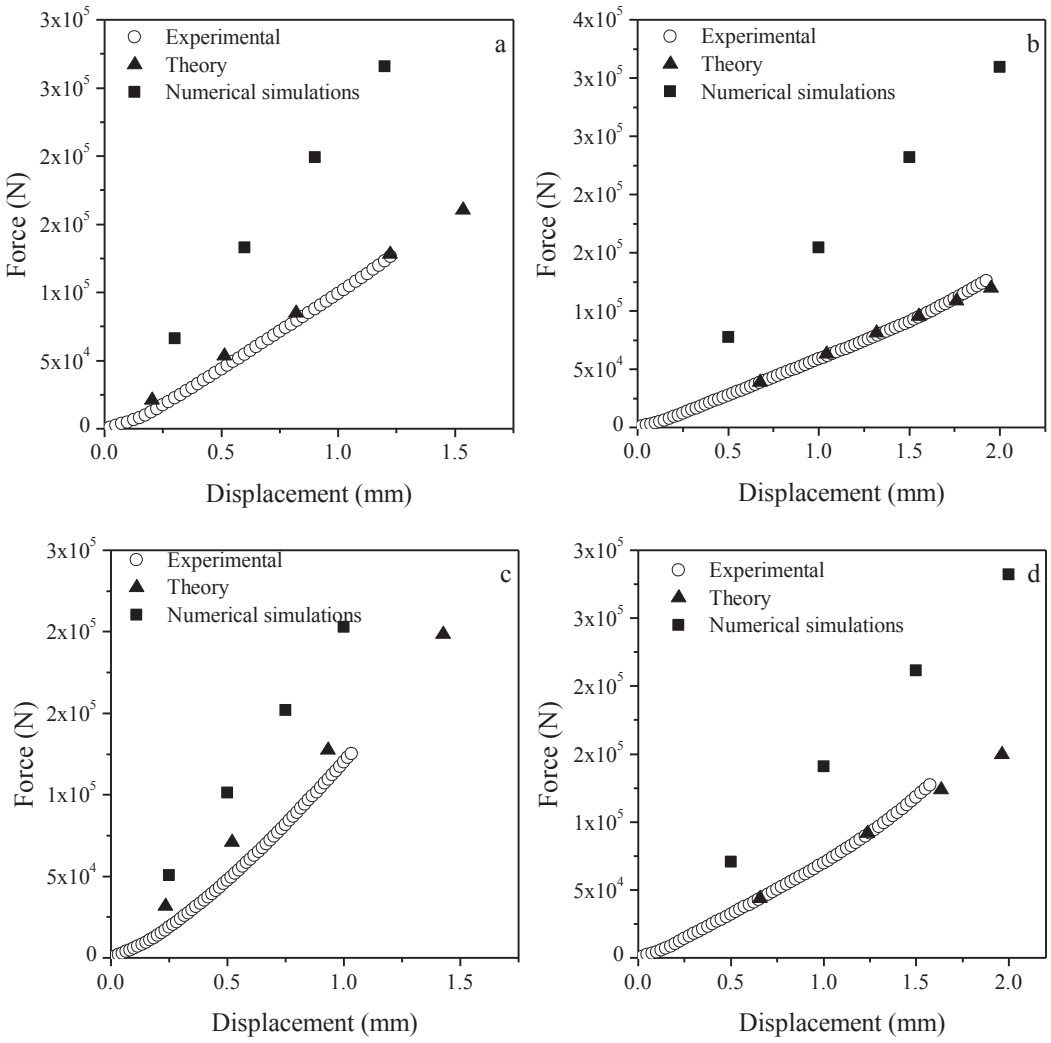


Figure 3: (a) B55-4, (b) B55-6, (c) B70-4, and (d) B70-6.

6 CONCLUSIONS

This study considered experimental, theoretical and numerical simulation approaches to assess the uniaxial compressive behavior of elastomeric bearings. The theoretical approach proposed by [25] was compared with experimental tests and numerical simulations using OpenSeesPL. Scaled bearings tested in this study had shape factors of 5.83 and 8.75, which are typical shape factors applied for viaducts but that are lower than the typical values used in the large-displacement theory. Calibration of θ_0 values was used to set the agreement between theoretical and experimental results. Although relative large values of θ_0 were taken into account due to material variations and manufacture imperfections, a good agreement between theoretical and experimental approaches was found for all the specimens. Relative errors (less than 6 %) were observed between experimental and theoretical results except for the bearings with the least total height (*i.e.*, bearings with $t = 4$ mm).Validation of the model using experimental data obtained in this study is considered of great importance and the model can be used in the design process of laminated elastomeric bearings. Linear properties of the materials were assumed for the numerical simulations in accordance with the characteristic shear curves of both compounds. Discrepancies can be addressed to linear assumptions and ideal bonding between internal steel shims and rubber layers and between the outer top and bottom

rubber covers and steel plates. Future studies will consider bearings with lower shape factors and an increased number of rubber layers.

THE ROLE OF NON-LINEARITY IN THE SEISMIC ASSESSMENT OF A BASE ISOLATED BENCHMARK BUILDING WITH SOIL STRUCTURE INTERACTION EFFECTS

Andrea Canini[1]

[1] Head of Project Department in Slovakia and Poland at Dominion Steelcon A/S

Keywords: Soil non-linearity, Non-linear isolation, Numerical Simulations, OpenSees, Soil Structure Interaction, Base Isolation, Ordinary buildings.

Abstract. *Advanced 3D numerical simulations of a soil-structure systems aim to assess non-linear behaviors of soil and structure and ultimately to describe realistic scenarios. The paper purpose is to simulate the effects of Soil Structure Interaction (SSI) on an ordinary base-isolated shear type building (BI), driving the assessment of the isolators by evaluating both their linear and non-linear behaviour. Non-linearity is also considered in the description of the soil which is modelled with hysteretic materials and advanced plasticity models that enable to reproduce soil hysteretic elasto-plastic shear response (including permanent deformations) and damping foundation impedances. Credited non-linear theories are applied in order to take into account appropriate flow rules as to reproduce the observed strong dilation tendency and resulting increase in cyclic shear stiffness and strength. The paper applies the open-source computational interface OpenSeesPL, implemented within the FE code OpenSees. The interface performs the 3D spatial soil domain, boundary conditions and input seismic excitation definition with convenient post-processing and graphical visualization of analysis results including deformed ground response time histories. Reproduce wave propagation adopting realistic boundaries is of crucial importance and significance in order to realistically reproduce SSI effects. The ultimate goal of the paper is the assessment of cases where BI becomes detrimental with particular attention to the structural performance by considering accelerations and displacements at various heights.*

1 INTRODUCTION

Base isolation (BI) is one of the most convincing solutions in order to protect structures from the destroying effects of earthquakes. This technique allows to decouple the structure from the ground by intentionally concentrating seismic energy dissipation in a unique element with low horizontal stiffness placed between the foundation and the structure. Many researchers have been carried on this issue, but few contributions have been focused on the effects of the soil structure interaction (SSI) on isolated buildings. Thanks to its benefits, BI has been spread all over the world in the last decades. For example, [1] showed that in Japan after the 1995 Kobe earthquake, the number of base-isolated buildings significantly increased from ten buildings to more than 150 buildings. In particular, [2] remarked that there was a significant increase in the application of base isolation to residential buildings after 1995. In Italy, the number of isolated buildings increased after L'Aquila earthquake to more than 400 [3], with many applications to residential buildings.

Extensive research has been conducted in the past 30 years regarding the effects of soil–structure interaction (SSI) on the seismic response of civil engineering structures. Even if many codes suggest to neglect SSI [4], [5], there are some researches where SSI is shown to be non-conservative for safety and cost reduction. In such cases, it is fundamental to take into account SSI in design procedures in order to predict its effects as detailed as possible [6], and [7].

The majority of publications study SSI simply by introducing springs, dashpots and artificial masses in the interface between the structure and the soil. This approach is generally accepted since modelling SSI is a challenging problem for numerical simulations. However, it could be insufficiently detailed in order to model the complexity of the problem. In particular, system response is directly connected with the mutual dynamic characteristics (natural frequencies) and thus with structural mass and stiffness, soil shear velocity and layer depth [8]. For this reason, the beneficial effects of BI can be strongly modified by soil deformability and energy dissipation in the ground [9], [10], [11] and [12].

This study aims at overcoming all previous simplifications considering a 3D numerical simulation of a soil-structure system applied to a shear type building isolated at the base. In particular, the soil has been performed with nonlinear hysteretic materials and advanced plasticity models. The proposed approach enables to drive the assessment of BI technique with evaluation of soil non-linear response into a unique twist. In this regard, the paper aims at assessing the cases where BI becomes detrimental. In particular, the study shows how considering the structure fixed at the base is non conservative and underestimates dynamic effects.

The study aims at considering the effects of SSI on a residential building, by taking into account the previous contributions such as [13], [14] and [15]. In particular, numerical simulations have been widely performed ([6],[16], [17], [18], [19], [20], [21], [22], [23], [24], [25], [26]), in order to study the dynamic interaction of a structure placed on a deformable soil. Taking into account these relevant contributions, the present study wants to consider a 3D soil-structure system that applies nonlinear hysteretic materials with plasticity models for the soil and a detail description of the structural system (building and foundation). The proposed model is able to reproduce soil hysteretic elasto-plastic shear response (including permanent deformations), damping foundation impedances and realistic boundary conditions at the base of soils and in correspondence with the interface between the soil and the structure.

The study allows to perform the behavior of a realistic base isolated building consisting of four stories shear type concrete structure. Its response at the base of the structure (foundation level) and along its height has been assessed. In this regard, with the development of the performance-based earthquake engineering methodology ([26], [27], [29] and [30]), there has

been an increasing attention to the floor acceleration, as one of the most useful engineering demand parameters to assess structural performance of buildings. In particular, many codes ([31] and [32]) are implementing new provisions based on floor performance [33]. In this regard, the paper aims to move in the direction of this new approach by calculating top floor accelerations and displacements and not just the peak values of such engineering demand parameters (EDP). The final goal is to provide valuable element-specific seismic assessment or design evaluations with a particular focus on the cases where BI technique can become detrimental due to SSI effects.

2 CASE STUDY

The paper must be written in English within a printing box of 16 cm x 24 cm, centered in the page. The paper goal is to perform a case study of a benchmark concrete structure (Figure 1) on different deformable soil conditions and adopting two typologies of isolators at the base.

The soil has been performed with nonlinear hysteretic materials and advanced plasticity models. This approach enables to assess SSI effects by reproducing soil hysteretic elasto-plastic shear response (including permanent deformations) and damping foundation impedances by applying the open-source computational interface OpenSeesPL [34] implemented within the FE code OpenSees [35].

It consists of a framework for saturated soil response as a two-phase material following the u-p (where u is displacement of the soil skeleton and p is pore pressure) formulation. This interface, implemented within the FE code OpenSees [35], has been originally calibrated for pile analysis. Here it has been modified in order to consider the presence of the system structure – foundation.

The study has been divided into several steps. The first step aims at calibrating the mesh and consist of eigenvalue analysis. In particular, the effects of the soil have been neglected by considering a hard soil (named soil A and with shear wave velocity equal to 1000 m/s) which reproduce rigid base conditions (see section 4.a). In the second step, soil is applied and the dynamic characteristics (in terms of natural periods) of the system (soil and structure) have been calculated. The third step consists of performing dynamic analysis.

Seven input motions (shown in Figure 3 and Table 1) were applied along the longitudinal direction (x-axis). These records were selected by following EC8 provisions [32], at section 4.3.3.4.3, Part 1 that allows to consider at least seven nonlinear time-history analyses, in accordance with 3.2.3.1, as described in [36]. Figure 3 shows the comparison between the mean response spectra of the selected ground motions (named MEAN in the figure) and the design spectra. They were chosen in order to significantly affect the dynamic behaviour of the structures in a wide range of periods: 0 - 2.5 s. The system performance has been assessed by considering accelerations and displacements as the main parameters. For all analysis, the Newmark transient integrator is used with $\gamma = 0.6$ and $\beta = 0.3$.

3 COMPUTATIONAL MODEL

The finite element model (FEM) has been built with OpenSees [35] that allows high level of advanced capabilities for modelling and analyzing non-linear responses of systems using a wide range of material models, elements and solution algorithms. In particular, numerical simulations follow the previous contributions [9], [14], [15], [16], [17], [37], [38], [39] [40], [41] and applies OpenSees PL [34] which consists of a framework for saturated soil response as a two-phase material following the u-p (where u is displacement of the soil skeleton and p is pore pressure) formulation and has been here modified in order to consider the presence of the system structure – foundation. Due to the high-level of non-linearity, some assumptions were important, for example, numerical damping was introduced in order to avoid the generation of high frequency noises that can cause instability of the computation process. Rayleigh numerical damping has been applied and equal to 2% and proportional to stiffness and mass (at 1 and 6 Hz) and it corresponds to mass-proportional and stiffness proportional coefficients respectively equal to 0.12542 and 0.00090946, as described in [39] and [40]. In additions, dynamic analyses were divided into four subsequent sub-steps in order to separate the various sources of numerical instabilities. In steps 1 and 2, linear properties (weight, Shear and Bulk modulus) were considered for the soil (without the structure) in order to reach the convergence. In step 3 the structure was added and all the properties have been changes from elastic to plastic by applying 25 load steps to reach convergence, then dynamic analysis were carried out in step 4 (for more details, see [39] and [40]. NewtonLineSearch algorithm [35] was used to speed of the solution.

The structure has been modelled with an equivalent 4-story concrete building (Figure 1 and Figure 2) and some approximations were assumed as a compromise between representativeness and computational time. A shear type behavior was considered for the building and a schematic geometry, based on 2 columns (15 m spaced) in the longitudinal direction and 4 in the transversal direction (10 m spaced), has been chosen as to maintain a plan and vertical regularity. The structure is assumed to be capacity designed and the presence of the isolation allows to remain in the elastic range and thus to model the columns with sixteen elasticBeamColumn elements, with a total height of 13.6 m (3.4 m for each floor). Seismic masses were assigned to each floor by calculating the structural self-weights of various elements (beams, columns, slabs, balconies, stairs). A rigid foundation has been assumed and modelled with a 28.4 m x 34.4 m 0.5-m thick concrete slab designed to maintain the stresses (induced by the seismic and vertical loads) inside the foundations in a range of acceptable values. In this regard, the foundation has been verified by calculating the eccentricity (the ratio between the overturning bending moment at the foundation level and the vertical forces) in the more detrimental condition of minimum vertical loads (gravity and seismic loads) and maximum

bending moments. For the fixed cases, the columns have been embedded inside the foundation material for 0.50 m, corresponding to the foundation thickness. The nodes at the base of the columns were linked together with equalDOF [35] in order to model rigid foundations. The interface between the columns and the foundations has been modelled with rigid beam-column links normal to the column longitudinal axis, as shown in [9], [13], [14], [15], [16], [17], [37], [38], [39], [40] and [41]. In particular, the elements of the foundation and the column elements are linked by connecting the outer nodes of these rigid links using the equalDOF (constraint in OpenSees for translations only) that connects two separate points (one belonging to the structure and the second to the soil) and imposes the displacements to be the same between the structure and the soil nodes [34] and [35]. Therefore, the system is able to capture the interaction between the columns and the foundation, including the potential settlement into the surrounding soil. Isolation devices at the base of the building have been modelled by applying the so called elastomericBearing element, [35] in order to overcome the previous publications where the structure was modelled with a single degree of freedom [14], [42] and [43]. (see Section 5). The slab is surrounded by a weak soil (named in the following with soil W), representing the infill layer of soil surrounding the foundation. Both the foundation and W soil have been modelled with the implemented material named Pressure Independent Multiyield [35].

Table 2 shows the values used for these two materials. The soil has been modelled with a 68.4m x 74.4m x 20.5m 3D mesh (Figure 1 and Figure 2), composed of 8228 brickUP linear isoparametric 8-nodes elements with 9660 nodes, [44] and with one-layer homogenous cohesive material (see also [14] and [45]) that was discretized in ten layers (0.5 m thickness for the first and 20 m for the others). Mesh dimensions have been determined following the suggestions indicated in [46] and [47] already applied in [9],[14], [15], [16], [17], [37], [38], [39], [40] and [41]. Discretization is built up with relatively small elements around the structure and gradually larger toward the outer mesh boundaries. The model applies hysteretic elasto-plastic materials in order to take into account realistic behavior of the soil, modified by the degradation of soil stiffness and energy dissipation [43]. Soil damping is directly computed by the implemented materials ([48] and [49]) that enable to consider many non-linear dynamic effects, such as permanent deformations, damping foundation impedances, hysteretic response and radiation damping). In particular, a Von Mises multi-surface ([44], [50]) kinematic plasticity model has been applied within the framework of multi-yield-surface plasticity [51] with an appropriate non-associative flow rule [52], [53], [54] and [55] that allows to control the magnitude of cycle-by-cycle permanent shear strain accumulation [48] and [56], with an associative flow rule deviatoric component, while non-associativity is restricted to the volumetric component. The adopted non-linear shear stress strain back-bone curves, represented by hyperbolic relation [57] and defined by two material constants (low-strain shear modulus and ultimate shear strength) are shown in Fig. 4 in correspondence with the considered soils (named Soil A, Soil B, Soil C and Soil D) which were modelled with four clay materials called Pressure Independent Multiyield [44], as shown in Table 3. Characteristic site periods have been calculated by assuming a uniform and damped soil and the linear formulation: $T = 4 H / Vs$, by [8]. H is the height of the soil layer and Vs the shear wave velocity of each layer. Base and lateral boundaries have been modelled to represent a small section of a presumably infinite (or at least very large) soil domain and allowing the seismic energy to be removed from the site itself ([9], [13], [14], [15], [16], [17], [37], [38], [39], [40] and [41]) and by modelling the real wave propagation with realistic boundaries at the base (at 20.5 m depth) and laterally located as far as possible from the structure as to decrease their effects on the response. In order to verify that they worked correctly, the response near the boundary where compared with the one resulted for free field conditions. In particular, at any special location,

symmetry conditions can be adopted and periodic boundaries [58] have been considered together with the penalty method to tie together the degrees of freedom of the left and right boundary nodes both longitudinally and vertically.

Paraments	Concrete	Soil W

4 CALIBRATION

Calibration is the preliminary step in order to test OpenSees [35] potentialities in reproducing the non-linear problem. The soil non-linearity is tested, by considering the original configuration (without isolation) in two steps. The first step aims at assessing periods of the structure and a hard soil (shear velocity equal to 1600 m/s) has been calibrated in order to be stiffer than the structure to neglect SSI effects (simulating fixed based conditions), Figure 5, in the following named as FIX. In order to verify the consistency of the model accelerations time histories at the base of the mesh (the input motion) and at the top of the layer (and prop-

agating to the foundation) were considered were compared and found to be identical. Then the first four shape modes were compared with those obtained by SAP2000 [59] 3D numerical simulation and a simplified 1D scheme (Table 4).

The second step aims to consider the soil deformability, by calculating the period elongation of the soil-structure system due to the presence of the soil (Table 5) and it is worth to see that for example, the fundamental period of the structure (0.67 s) and the first period of the system increases with soil deformability (the ratio varies from 3.20% for soil B, to 7.08% for soil C and 19.7% for soil D). Then, transfer functions have been calculated as the ratio between the time histories of longitudinal accelerations at the base of the mesh (denoted as I in the figure) and the ones at the top of the soil layer (denoted as O) for the most severe input motion (input n. 2) in correspondence with the considered soils. Then, the characteristic soil periods of the layer have been calculated by assuming a linear layer of soil and following the linear formulation T = 4 H / Vs [8], where H is the height of the soil layer (20 m) and Vs the shear wave velocity of each layer. The transfer function peak values are shown to be close to the characteristic site periods (named with "linear" and represented with vertical lines in the figure).

5 BASE ISOLATION IMPLEMENTATION

The study performs the behavior of base isolation technique and it considers the effect of non-linearity by comparing two typologies of isolator models: a linear base isolation (BI-L) and a bilinear isolation (BI-NL), Figure 7. Isolators are consider in the longitudinal direction, by modelling significant high stiffness in the other directions (vertical and transversal) and applying the elastomericBearing element, (as shown in [9], [14], [15], [16], [17], [37], [38], [39], [40], [41] and [45]) which needs the calibration of 3 parameters: the initial elastic stiffness (named K), the yield strength (named Fy) and the post-yield stiffness ratio (alpha). Eigenvalue analysis were carried out in order to assess the effect of soil deformability and it was shown that the fundamental period increases for all the soil conditions to 3.35 s (Table 6), demonstrating that isolators perform their function to decouple the soil and the structure. It is worth to notice that comparing with the non-isolated cases (Table 5), the increases are more significant for soil A than in case of soil D, confirming that the efficiency of base isolation technique increases with rigid soils, as shown in [9].

6 DYNAMIC ANALYSES

This paragraph discusses the results of dynamic analyses, by considering the parameters that represent the performance of structures, following the new provisions included in many codes ([31] and [32]), as indicated [33] for multi freedom structures. The floor accelerations and displacements at each floor were chosen as engineering demand parameters (EDP), since in order to provide valuable element-specific seismic assessment or design evaluations. In particular, Figure 9 and Figure 10 show a comparison between time histories obtained with FIX and BI models, in terms of accelerations and displacements on top of the structure (z = 13.6 m) for input motion 2 (chosen because the most severe). In particular, the benefit of non-linear isolator is shown to significantly reduce the displacements after the first peak (at around 2.7 s) in correspondence with every considered soil. It is worth to notice that the largest displacements occur in correspondence of soil C, where the site fundamental period is relatively close to the second structural period (T2) both in FIX and BI configurations. In particular, for the FIX structure, T2 plays a significant role (modal participations mass ratio around 10%). When the isolation system is implemented (BI), T2 does not contribute to the seismic response of the structure (modal participations mass ratio almost 0%), since the mass of the structure is completely activated by T1 that has been shifted away from the period affected by the majority of ground motions.

Figure 11 shows that the most significant improvement of applying non-linear devices can be seen in by comparing the base shear time histories at the base of structure (z = 0.00 m) for the FIX case and at the top of the isolator for BI models. It is possible to assess how the isolation system performs its function by decoupling the structure from the soil. In addition, the results show also that in correspondence with soil D, the shear forces are bigger for the BI configurations that those calculated by the FIX case, demonstrating that high soil deformability can induce great damping in the system that reduces the forces more than what base isolation is able to do. This behaviour (already described by [9]) depends on the dissipation of seismic energy in the soil, that is shown to act as a natural base isolation.

As stated in [60] and [61], the first period of the isolated model become that of the isolation system and the second that of the structure. Table 7 shows the best reductions of the accelerations at the top of the structure occur with BI-L system. The average reductions are about 80%, 76% and 63% respectively for soil A, B and C. In correspondence of soil D have been observed reductions of about 53%, 15% and 60% for input n.2, n.4 and n.7, respectively. For input n.1, n.5 and n.6 small increments (of about 4%, 9% and 26%, respectively) and a significant increment for input n.3 (86%). For BI-NL case accelerations reductions are around 79%, 71% and 61% for soil A, B and C, while for soil D have been observed increments with all ground motions except for input n.1 and n.2 (where reductions are about 22% and 34%). The highest increment has been observed for BI-NL with input n.3 (107%).

Figure 9 shows the time histories of base shear forces in correspondence with input 3 that is shown to be the most severe. It is worth to see that soil deformability reduces base shear only for the case of FIX configurations. For BI models, it is confirmed that the response does not depend on soil deformability, since isolators decouple the structure from the soil. Non-linear models are shown to be more efficient than BI-L in reducing the peak values and in some cases modelling the isolator with linear assumptions can become more conservative and not realistic of the real behaviour of the structure. Table 9 shows the ratio between the results obtained in correspondence with BI-L and BI-NL respect the case of FIX configuration, respectively in column 4 and 5. The reduction operated between the BI-L and the FIX configuration is significantly high for soil A (between 60.4% and 87.3%), but when high soil deformability is considered (soil D), the linear bearings are not working properly and an increment of 151.1% occurs in correspondence with input 3. Similar trend can be seen for BI-NL cases and the reduction in correspondence with soil A are bigger that those resulted for BI-L (maximum: 91.1%). Their behaviour is shown to be more efficient even when soil deformability is applied and they perform properly in correspondence with soil D for all the input motions except for input 3, where there is an increment of 23.7% respect the FIX case. Last column of the table shows the ratio between BI-NL and BI-L results in terms of shear forces and it allows to assess the general benefit of NL over L models in correspondence with every soil condition. There is an exception for input motion, where linear isolations seem to perform better that what non-linear isolation does.

Overall, the results show that considering both soil and isolation non-linearity is significantly challenging because many parameters play important role and the assessment of the effects of non-linearity over linearity need to be related to the particular input motion considered.

7 CONCLUSION

The study conducted in this paper may be viewed as an original contribution to seismic assessment of a residential benchmark BI building with SSI effects that considers the mutual effects of non-linearity both in the soil and in isolators. The FE computational model of the soil is based on an advanced constitutive formulation that enables to drive the assessment of structural behavior with the evaluation of soil non-linear response, by capturing the effects of accumulation of deformation in the ground. At the same time, the model of the structure allows to assess the structural performance by considering accelerations and displacements at various floors. Thanks to these potentialities, it was possible to demonstrate that isolation systems perform their functions consisting in decoupling the structure and the soil, by concentrating the deformations at the base of the buildings and by reducing the damage to the structure and thus to its contents. In particular, the paper shows that the effects of non-linear isolation are fundamental to be considered as well as soil deformability that can significantly modify the efficiency of base isolation technique. In this regard, the paper can be seen as a first attempt to propose new design considerations for engineers and consultants. Further analyses will be performed in order to consider advanced models of isolators and to extend the presented results.

8 END CREDITS

A special thanks goes to the company Dominion Global and especially Dominion Engineering and Construction division which sponsored the participation of the present paper to the EURODYN 2020 conference and least but not last my Employer Dominion Steelcon A/S that allowed me to attend the conference. Without this support this won't happened.

Another important contribution that allowed me publishing this job was given by the Dr. Davide Forcellini which supported me along the way.

Abstract.

Performance-based design principles rely heavily on the estimation of engineering demand parameters through nonlinear static or dynamic analysis. The increased focus on nonlinear analysis in recent and upcoming building codes calls for a detailed investigation into the limitations of these procedures. This is especially true for nonlinear dynamic analysis, which is often referred to as "exact" or "benchmark" solution. This article examines the sensitivity of nonlinear analysis results to the assumptions made in the modeling of nonlinear element behavior. To this end, a four-story reinforced concrete building designed according to the recent European standards is modeled in OpenSEES computational environment. Nonlinear element behavior is modeled using several approaches from lumped plasticity models to force-based and displacement-based elements with fiber sections using complex stress-strain curves. The results of nonlinear static and dynamic analysis reveal that the modeling assumptions have a significant effect on both displacement demands at the story and global level. More specifically, the curvature demands at the bottom of the ground story columns are very significantly affected by the modeling assumptions, particularly for diplacement- and force-based elements.

1 INTRODUCTION

Current seismic design procedures rely on elastic analysis where earthquake ground motions are simulated using equivalent lateral forces. On the other hand, ordinary structures that are designed using elastic analysis procedures are expected to be forced well beyond their elastic limit. The safety of these structures is ensured by prescriptive measures without actually evaluating their real performance. Performance based design procedures aim to provide a more transparent approach by evaluating the performance of the structure under different hazard levels. These methods rely heavily on estimation of engineering demand parameters such as total or plastic deformations through nonlinear static and dynamic analysis. As performance based design procedures are used more and more in seismic design, the numerical models become more complex. The assumptions used in the numerical modeling phase such as inelastic material behaviour, cyclic degradation and geometric nonlineareties can have severe implications for the results of an analysis [1–4]. For example, plastic rotations and curvatures of structural elements such as columns and beams are widely used for the assessment of the structural state in seismic design [2] and have been shown to be sensitive to the numerical parameters used in the analysis [5]. Although some studies [3, 5] have commented on the sensitivity of the engineering demand parameters to the numerical modeling assumptions, a quantitative documentation of this sensitivity is vital as the performance based design methods begin to find their way into seismic design codes.

The objective of this study is to investigate the effects of numerical modeling assumptions on the engineering demand parameters (EDPs) obtained from nonlinear static and dynamic analyses. Section curvatures, roof drifts and interstory drift ratios are chosen as the EDPs as these parameters have been documented to be well-correlated with structural damage. This will be done by conducting nonlinear static analyses (SPO) and nonlinear response history analyses (NRHA) on a reinforced concrete moment resisting frame (MRF) designed according to EN-1998-1 [6]. The analyses are performed using the open system for earthquake engineering simulation (OpenSees), which is an advanced computational tool frequently used in research.

2 THE ANALYZED STRUCTURE AND NUMERICAL MODELS

The analyzed structure is a four-story reinforced-concrete frame. It is symmetric about both horizontal axes with five bays in both directions. Due to the regularity of the building in plan, only one of the inner frames was modeled and used in the analysis. Figure 1 shows the elevation view of the of this frame. The structure was designed according to EN-1998:2004 [6] assuming moderate ductility level (DCM). All structural elements were designed for exposure class XC3, M60. The concrete quality was chosen as C30/37 and the thickness of cover concrete is 35mm for all elements. The reinforcement is of quality B500C with a modulus of elasticity of 200 GPa. The cross sections of the structural elements are summarized in Table 1.

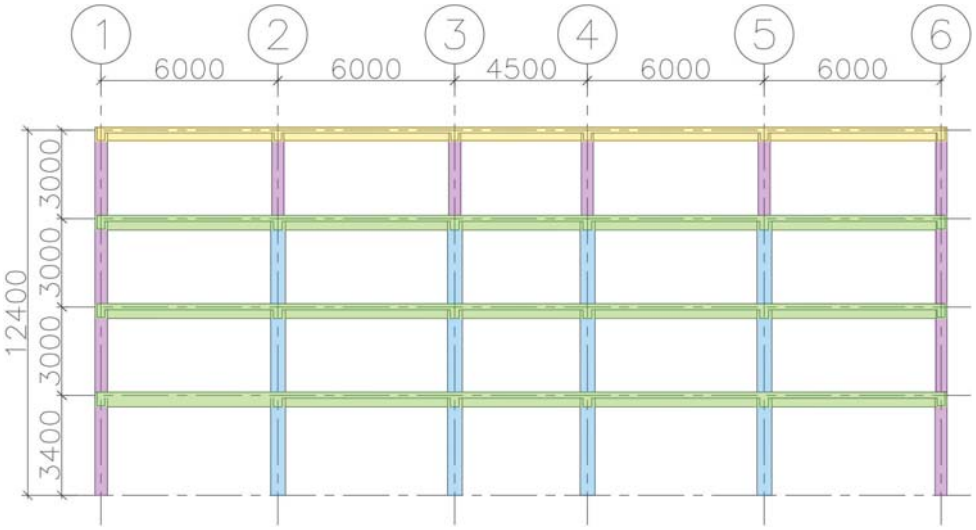

Figure 1: Elevation view of the analyzed frame (all measurements in mm)

Name	B [mm]	H [mm]	Color in Elevation View
Column 1	450	450	Pink
Column 2	500	500	Blue
Beam 1	300	500	Green
Beam 2	250	450	Yellow

Table 1: Cross sections of the structural elements of the frame shown in Figure 1.

The mass of the entire structure is 2 024 tons. The masses are lumped in their respective vertical level in nodes along axis 3. The natural periods for the first three modes were found to be 0.53, 0.17, and 0.10 seconds, respectively. Details of the structure can be found in [7]. For nonlinear response history analysis, damping of the system is modeled using 5% Rayleigh damping anchored at the $\omega_i = 0.707\omega_1$ (ω_1: the vibration frequency of the first mode) and $\omega_j = 31.4$ rad/s [8].

2.1 Structural Models

2.1.1 Element Models

All nonlinear analysis were carried out in the OpenSEES computational environment. Three types of structural element models were used in the analyses. The first element is a *force-based beam-column element* (FBE) that is based on the flexibility formulation and uses force interpolation functions for the variation of internal forces over the element length which represent the exact solution to the governing equations [9, 10]. The force-based approach relies on the equilibrium solution and, as such, even for nonlinear material response, FBE always satisfies the equilibrium conditions [11]. The inelastic properties are defined at integration points (IP) along the element, each contributing to the global inelasticity of the element [5]. The cross-sections of the elements have been modeled using fiber sections. Figure 2 illustrates a sample element with five integration points together with a sample fiber section where reinforcement, unconfined concrete and confined concrete fibers are depicted.

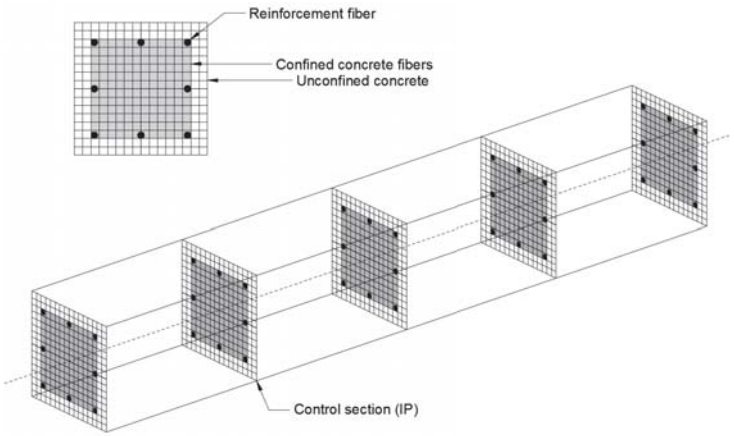

Figure 2: Illustration of the distributed plasticity model. One FE with five integration sections.

With regards to modeling softening behaviour, the stresses tend to localize in the most strained integration point (IP) of the most strained element [5]. As the number of integrations points are increased and the length of integration reduces, larger and larger rotations are required in the most strained IP for an element to produce same values of displacement, making the response nonobjective. Four to six IPs are necessary to accurately represent nonlinear material response and obtain an objective response [9].

The second element that was used in the analysis is the *displacement-based beam-column element* (DBE). This model is very similar to its force-based counterpart but uses the displacement formulation instead of the flexibility formulation. Despite their similarities, FBE and DBE cannot be modeled following the same approach. Most significantly, while the accuracy of the FBE can be improved by increasing either the number of integration points or the number of elements, the accuracy of the DBE can only be improved by increasing the number of elements.

The final element used in the present study is the *beam with hinges element* (BwH) which is also based on the flexibility formulation but the location and the weight of the integration points are predefined and based on the plastic-hinge formulation. This allows the users to specify plastic hinge lengths at the element ends. Two-point Gauss integration is used on the element interior while two-point Gauss-Radau integration is applied over lengths of $4Lp_I$ and $4Lp_J$ at the element ends [2, 12]. Figure 3 shows the underlying principles of the element together with the location of the integration points. The behaviour of the interior section can be modeled as linear elastic or inelastic; *e.g.* by using the fiber section shown in Figure 2. One of the most important parameters of BwH element is the plastic hinge length, l_p, which designates the part of the element where the nonlinear behavior is expected to occur, as the nonlinear behavior of the element depends, to a greater extent, to this parameter, especially if the interior of the element is modeled as linear elastic. There are different approaches to determine l_p, one of which is using empirical equations. One example can be found where Paulay and Priestly [13] provide an empirical formulation, and suggest that, for frame elements with normal proportions, this equation will lead to an approximate plastic hinge length of l_p = 0.5 h, where h is the depth of the cross section.

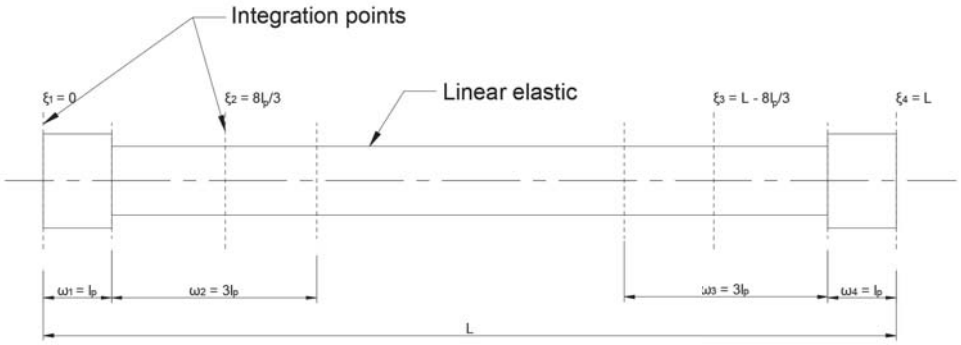

Figure 3: Beam with hinges element using the modified Gauss-Radeu integration rule.

2.1.2 Section and Material Models

All the cross-sections in the analysis were modeled using a fiber section as depicted in Figure 2. The material behavior at each fiber of the section is defined using a uniaxial stress-strain relationship. In order for a reliable nonlinear analysis, the concrete material model should be able to describe all material behaviours expected to occur before collapse during static and dynamic analyses. This includes, among other phenomena, strain softening and hardening, the effects of strain rates and confinement. To achieve this, the stress-straing model by Mander, Priestley and Park [14], which was based on Popovics model [15] and used extensively in literature (e.g. [2, 5, 16]), was used.

Two sets of parameters that were used for unconfined and confined concrete are presented in Table 2. The strain rate used in the calculations was 0.013 s^{-1}. The parameters shown in Table 2 were used as the input parameters for the CONCRETE04 material model in OpenSees. The reinforcement steel was modeled using the simplest model provided in OpenSees for steel, i.e STEEL01. The input parameters for this model were f_{yk} = 500 MPa, E_s = 200 GPa with a strain hardening ratio of b = 0.005.

Name	f_c	ϵ_c	ϵ_{cu}	E_c	ϵ_{ct}	ϵ_t
Unconfined concrete	-38.6	-0.00199	-0.0060	33.916	2.9	0.0855
Confined concrete nr.1	-47.9	-0.00420	-0.0142	-	-	-

Table 2: Concrete material parameters.

3 NUMERICAL ANALYSES

3.1 General

Nonlinear static analyses (NSA) and response history analyses (NRHA) were conducted using the elements described previously with different configurations. For the models using the DBE, each structural element was modeled using a different number of finite elements with two integration points. For the model using FBE such refinement is not necessary; instead the number of IPs per element has an effect and was thus varied. Similarly, only one finite element was used per structural element for the BwH elements. For the BwH element, the hinge length varied as well as the behavior of the interior section (elastic or inelastic). The different model configurations used in the analyses are summarized in Table 3. No NRHAs were performed using the DBE due to extremely long computational time and convergence issues.

Model	Configurations	Analyses
DBE	4, 8, 18 or 24 finite elements each using 2 IPs	NSA
FBE	One finite element using 2, 3, 4, 5, 6, 7 or 8 IPs	NSA and NRHA
BwH	$l_p = \{1.0\text{h} , 1.5\text{h} , 2.0\text{h}\}$ with elastic interior	NSA and NRHA
BwH	$l_p = \{1.0\text{h} , 1.5\text{h} , 2.0\text{h}\}$ with inelastic interior	NSA and NRHA

Table 3: Different model configurations

3.2 Nonlinear Static Analysis

NSA were performed to assess the behaviour of the structure and the different element formulations. The static pushover loads were applied at the nodes along axis 3 in a vertical pattern based on the eigenvectors of the first mode, making this a first-mode pushover analysis. P-δ effects were included in all analyses.

3.3 Nonlinear Response History Analysis

Nonlinear response history analyses were performed for a set of seven ground motion records for the different numerical models; in total 84 NRHAs. The ground motions records were selected for ground type C in EN 1998-1:2004 [6]. The ground motion records are listed in Table 4 with the corresponding parameters.

RSN	Name	Year	M_w	Rrap (km)	V_{s30} (m/sec)	PGA	SF
282	Trinidad	1980	7.2	76	312	0.22	2.32
720	Superstition Hills-02	1987	6.5	27	206	0.33	1.88
1003	Northridge-01	1994	6.7	27	309	0.64	0.76
1110	Kobe Japan	1995	6.9	25	256	0.25	1.67
4889	Chuetsu-Oki Japan	2007	6.8	33	315	0.37	1.29
5832	Iwate Japan	2010	6.9	31	248	0.40	1,121
6923	Darfield New Zealand	2010	7	31	255	0.47	0.99

Table 4: Ground motion records used for the analyses with the corresponding scale factors (SF).

The ground motions were scaled so that the spectral acceleration at the first natural period of the structure matches the elastic response spectrum defined in EN 1998 [6]. The scale factors used are also shown in Table 4. The scaled response spectra are plotted in Figure 4. The response of the structure is dominated by the first natural mode, hence scaling in this way is justified.

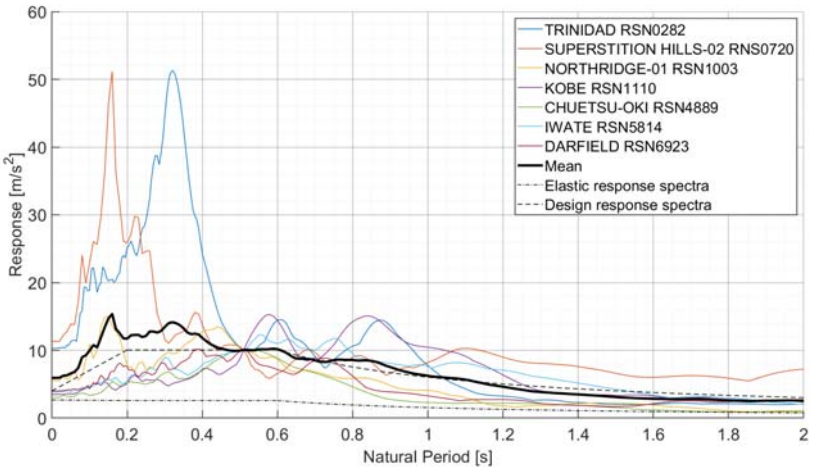

Figure 4: Response spectra scaled to match the elastic spectrum in EN-1998:2004 [6] at T_1.

4 RESULTS

4.1 Nonlinear Static Analysis

The capacity curves resulting from NSA for the different DBE models are shown in Figure 5. The results appear to converge to a stable solution as the number of FEs per member increases. As expected from the coarsely meshed models using DB elements, the base shear capacity of the structure is overestimated significantly for four- and eight-element models.

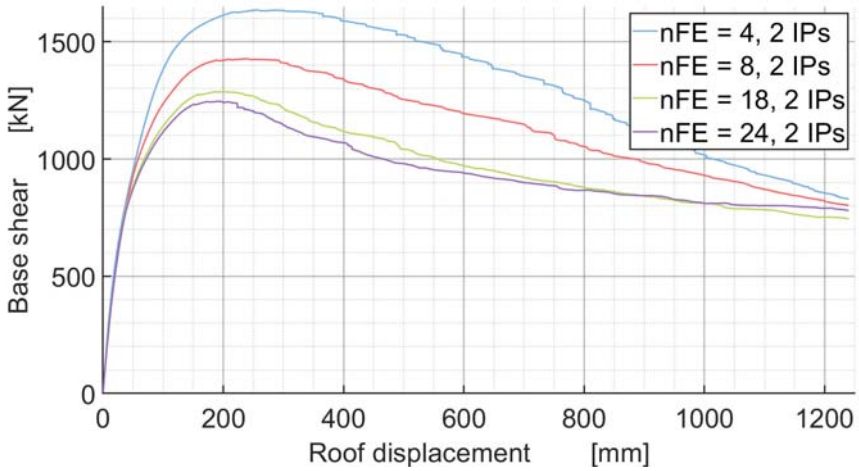

Figure 5: Base shear plotted against roof drift for different configurations of the DB model.

The response of the FBE model is nonobjective, i.e. as the number of IPs increases, the different curves do not converge towards a stable solution. Figure 6 presents capacity curves obtained from NSA using FBE. Figure 6 shows that increasing the number of IPs does not necessarily lead to a unique solution. Although the estimated maximum base shear load converges with increasing IP, the overall response, particularly, the immediate post-peak response shows discrepancies as the number of IPs increases. This can be attributed to the spread of nonlinearity over a larger part of the element as the number of integration points increases.

Comparing the computation time of NSA using DBE and FBE shows one of the significant disadvantages of DBE compared to the other elements, namely its poor efficiency. NSA using DBE with 18 FEs for each member provides a capacity curve quite similar to the one using FBE with 5 IPs per member. However, the computational time of the analysis with DBE is approximately five times that of the analysis with FBE.

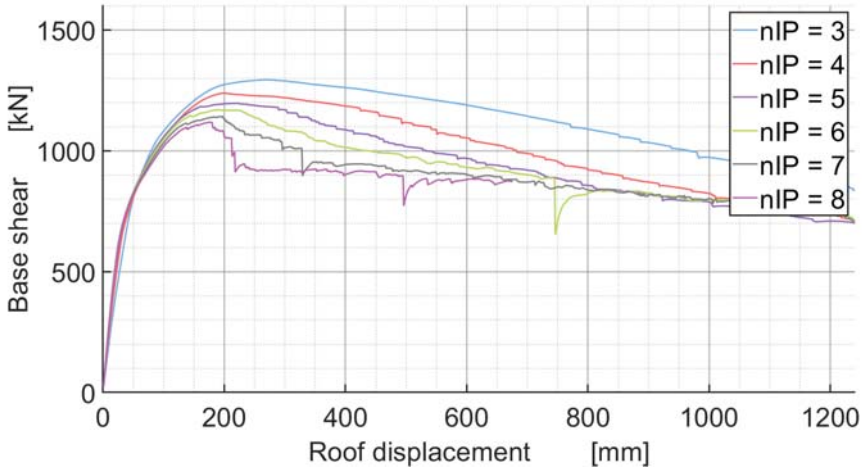

Figure 6: Base shear plotted against roof drift for different configurations of the FB model.

Using the BwH model, the models show similar responses for different plastic hinge lengths; see Figure 7. The stiffness of the structure immediately between first yielding (i.e. base shear around 500 kN) and the overall yielding is affected by the plastic hinge length if the element interior is modeled as elastic. When the element interior is inelastic, the capacity curves become virtually identical for different plastic hinge lengths. For the models where elements were defined with the inelastic fiber section in the interior, the response is generally softer. Note also that the model that used a hinge length of l_p = 2.0 h with an inelastic interior failed to converge at around 50 mm roof drift.

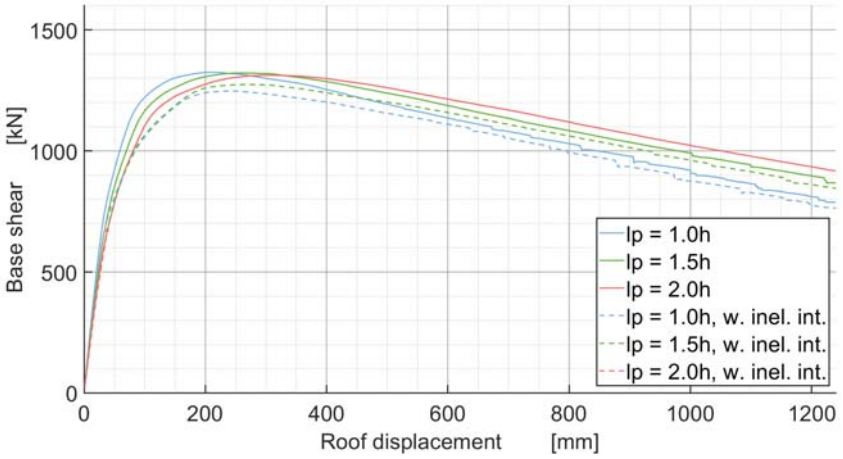

Figure 7: Base shear plotted against roof drift for different configurations of the BwH model.

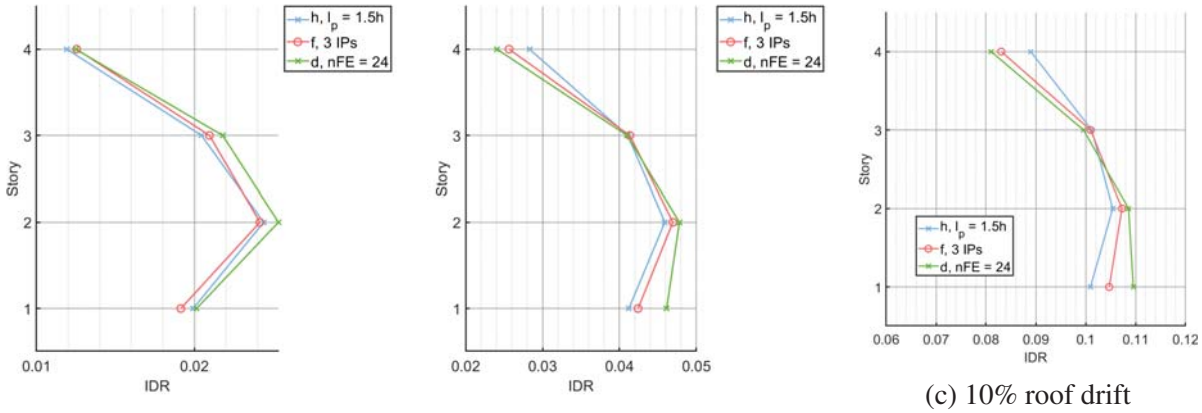
One of the demand parameters that is strongly correlated with structural damage is the interstory drift ratio (IDR). Therefore, the effect of modeling assumptions on the IDR estimates

from NSA has been investigated. Figure 8 shows the IDRs for three different models at various roof drifts. From the IDR profiles at 2 and 4% roof drift, it can be seen that the three different models lead to very similar IDR estimates. As the roof drift increases, the DBE model starts displaying higher IDRs at the lower stories while the BwH leads to a higher estimate at the upper stories; Figure 8 (c).



(a) 2% roof drift (b) 4% roof drift (c) 10% roof drift

Figure 8: IDRs for different element configurations at various roof drifts.

Curvature and curvature ductility at the element ends are often used as an indicator of damage at the element level. As such, variation of curvature estimates for different models can lead to a variation in the damage estimates. The curvature estimates at the bottom section of the ground story column in axis 3 from NSA is plotted against the roof drift in Figure 9. This plot illustrates how some of the model configurations give significantly different curvature estimates for a given roof drift even if the global demand estimates such as capacity curves and IDR estimates are rather similar. The most drastic variation is observed for FBE and DBE elements when the distance between the two integration points become rather short, either through increased number of IPs for FBE or through finer mesh for DBE.

Evaluating Figures 5 and 9 together presents a potential dilemma for use of displacement-based elements for nonlinear static analysis. More specifically, Figure 5 shows that in order to achieve a satisfactory capacity curve using DBEs, a fine mesh of 18 to 24 elements per member is necessary. However, using such a fine mesh leads to a potential problem that can have significant consequences as far as local behavior and damage estimates is concerned. As illustrated in Figure 9, using a very fine mesh, which is necessary to capture the global behavior satisfactorily, can lead to very high ductility demands for a given roof drift ratio compared to other models. These results are consistent with those found by Calabrese et al. [5] and others [17]; for softening behaviour, increasing the number of DB elements leads to nonobjective curvatures. The same issue can also be encountered for force-based elements when a high number of integration points is used as shown in Figure 9 and also reported by Calabrese et al. [5]. However, in case of FBE, the issue can be resolved by using less IPs, e.g. four or five, as these models produce very similar capacity curves compared to the model with 8 IPs.

With regards to the BwH model, Figure 9 shows results consistent with expectations. Since the characteristic length of the plastic hinge gets shorter, it must give higher values of curvature to produce the same displacements. As a result, the differences between the BwH model configurations are significant, although not as dramatic as FBE and DBEs with fine mesh.

The differences seen in curvature responses of these models can have direct implications for the estimated damage in the structural elements. It shows that when using a shorter hinge length or a finer mesh than the "correct" value, the level of damage may be greatly overestimated. Also, if a larger hinge length or a coarser mesh is used, the assessment may be unconservative.

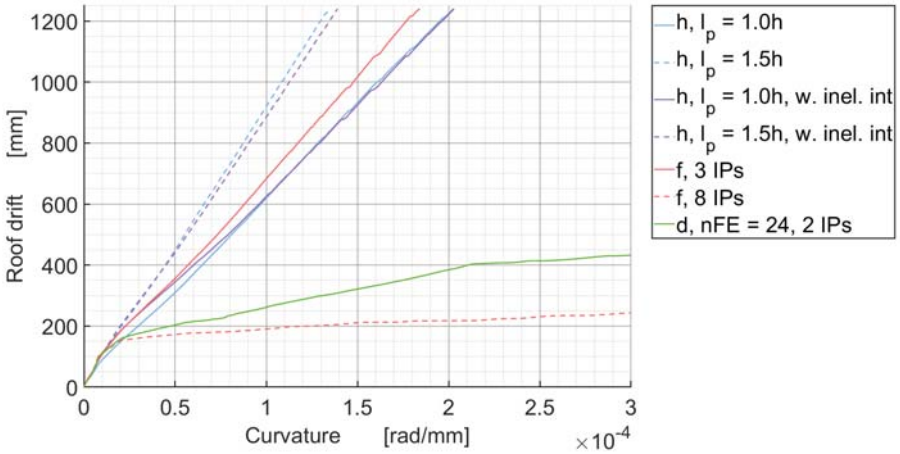


Figure 9: Roof drift plotted against the curvature in the monitored section.

4.2 Nonlinear Response History Analysis

The maximum interstory drift ratios obtained through NRHA for FBE, using different element configurations, are summarized in Figure 10. Here, it is seen that increasing the number of IPs beyond five appears to have little effect on the maximum IDR demands. Figures 11 and 12 shows the maximum IDRs for the BwH model, using elastic and inelastic interior, respectively. Both figures show that increasing the plastic hinge length for BwH elements lead to an increase in the maximum IDR demands for all ground motions.

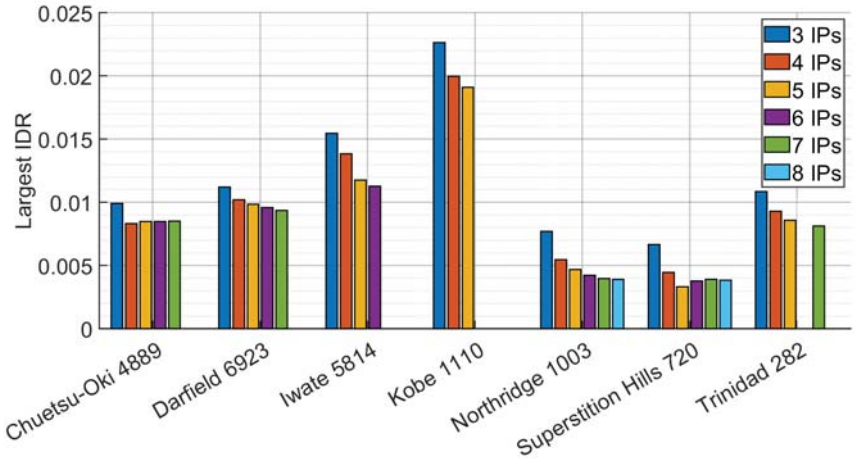

Figure 10: Maximum IDRs for the FB model.

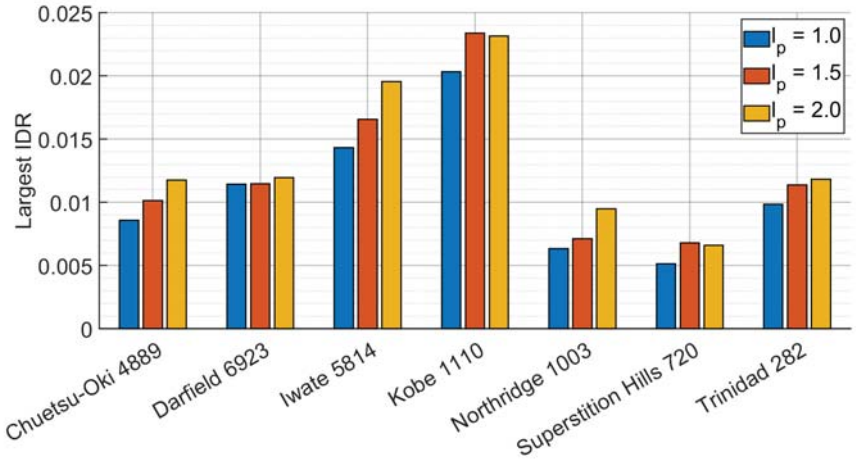

Figure 11: Maximum IDR for the BwH model using elastic interior.

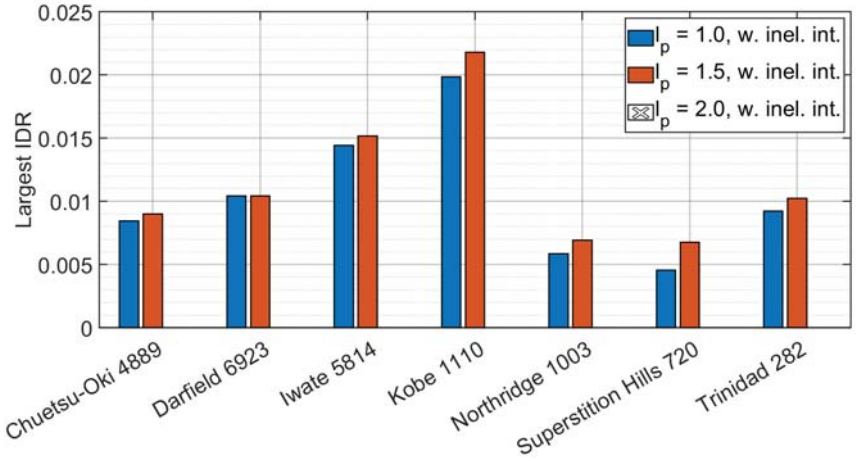

Figure 12: Maximum IDR for the BwH model using inelastic interior.

Figure 13 shows an overview of the mean value of the maximum roof drift ratios (RDR) and IDRs for the different model configurations. Across the various configurations, the trends shown for the RDRs and IDRs are very similar. For both parameters, it is evident that the peak responses decrease as the number of IPs increases for the FB model. For the BwH element, longer hinge lengths leads to larger peak values for both RDRs and IDRs. For elastic interiors, the peaks are somewhat larger when compared to the results from models using inelastic interiors.

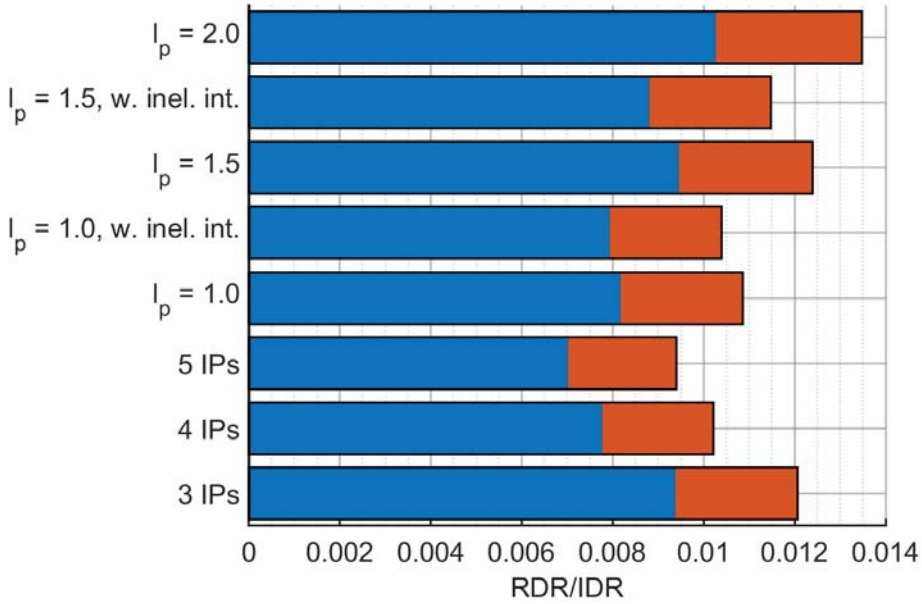

Figure 13: Mean values of RDRs and IDRs for the different numerical models. Blue bars represent RDRs while the values of the IDRs are represented by blue plus orange bars.

5 CONCLUSIONS

The objective of this study was to investigate the effect of modeling assumptions on deformation demand estimates of nonlinear static and dynamic analysis. This has been achieved through nonlinear static and dynamic analyses of a four-story reinforced concrete moment resisting frame using different model configurations. As a result of the analyses conducted, the following conclusions can be drawn:

- Use of displacement-based elements in nonlinear static analysis requires a fine mesh for a reliable capacity curve. Specifically, the base shear capacity of the structure can be significantly overestimated if less than 18 elements per member is used.
- Due to this requirement for a finer mesh, models created using displacement-based are computationally much more expensive compared to the models that use force-based elements.
- The modeling assumptions such as the number of integration points for forced-based element and the plastic hinge length for beam-with-hinges elements can have a significant effect on displacement demands such as interstory and roof drift ratios.
- The most significant impact of modeling assumptions have been observed for ductility estimates. For a given roof drift ratio, the ductility estimates can vary significantly from one model to another.
- The curvature estimates at the bottom of the ground story column from a displacement-based model with 24 elements per member are much higher compared to the other models. This is because, as the distance between the two element get smaller with finer mesh, very high curvatures at the exterior section can be required to achive the same roof displacement compared to other models with coarser mesh.

- Considering that a fine mesh is required in order to achieve a reliable capacity curve using displacement-based elements and the high curvature estimates for the same fine mesh, caution should be exercised when using this type of elements for nonlinear analysis.

- Force-based elements can also be susceptible to very high curvature estimates when a high number of integration points is chosen. To avoid this, the number of integration points has to be chosen carefully. The recommendation of using four to six IPs by Neuenhofer and Filippou [9] seems to provide satisfactory results at both global and local levels.

- The different types of elements available to an analyst, be it displacement-based, force-based or beam-with-hinges elements, have each their benefits as well as limitations and potential pitfalls. The different results show that an analyst must be able to assess what kind of phenomena are occurring in the numerical model in order to assess the objectivity of the results.

- More research that include a variety of structures and evaluate the sensitivity of more engineering demand parameters such as plastic rotations and hysteretic energy demands is necessary to enable the practitioners and researchers make informed decisions while developing nonlinear models.

EFFECT OF THE JOINT STRENGTH ON THE PERFORMANCE OF ORDINARY MOMENT-RESISTING FRAMES UNDER A PROGRESSIVE COLLAPSE SITUATION

Keywords: Progressive collapse, Panelzone, Column removal, Ductile fracture.

Abstract. *In standard design procedures of steel structures, buildings are usually designed for gravity and seismic load rather than a progressive collapse situation. When a structure is located in a low seismic zone, the codes have dictated fewer requirements regarding the beam-to-column strength ratio and the panelzone strength. In this study, a frame subassembly from an 8-story ordinary steel moment-resisting structure with different strength of exterior joints was investigated by numerical models under a column removal situation. The results revealed that although the beam-to-column strength ratio and the panelzone strength are generally less critical parameters in the seismic design of ordinary moment-resisting frames, they can have a notable effect on the fracture pattern and the capacity of the structure under a progressive collapse. Hence a special consideration about the joints strength is needed when a structure is aimed to be designed for a progressive collapse situation.*

1 INTRODUCTION

Progressive collapse is known as a rapid dynamic process that usually initiates from a local failure and propagates element-by-element to a global or partial collapse of the structure [1-4]. When a column is removed within a story of a steel structure, several sequential mechanisms act against the unbalanced vertical load. At very early stages, the beams and connections are under shear actions. In a subsequent stage as vertical displacement increases, the flexural moment at the beams becomes the dominant resisting mechanism in the frame. Finally, if the connections are ductile enough to undergo large deformations and adapt to a new configuration, the catenary action will be activated as the last resisting mechanism [1-3]. Since catenary action plays the main role in the frame resistance in progressive collapse, enough ductility of steel joints is required to develop catenary forces in the beams; otherwise, the premature global collapse of a multi-story steel structure might occur.

On the other hand, the standard design procedures of steel structures have been developed mostly for other dynamic loads like seismic load rather than a progressive collapse situation. Although the design methodology for seismic load and the progressive collapse is different, the seismic details in the steel structures would influence the performance of the connections and structures under a progressive collapse situation.

Two critical parameters of the seismic design of moment-resisting frames are the beam-to-column strength ratio and the panelzone strength. The codes [5, 6] have determined a maximum level of beam-to-column strength ratio to prevent plastic hinge formation in the columns and reduce the potential of the column-sway collapse. This limit is not obligatory for low-dissipative structures (ordinary moment frames) that are usually designed in a low-seismic zone [5, 6].

So far, the progressive collapse of steel structures has been investigated in many experimental and numerical studies [3, 7-16]; however, there are a few research studies to focus on the effect of the beam-to-column strength ratio and the panelzone strength, especially in ordinary moment frames that the strong-column-weak-beam criterion is usually neglected.

Kim and Kim [17] studied moment-resisting structures with both weak and strong panelzones by using macro-scale numerical models. The results of the nonlinear dynamic analyses showed that the influence of panelzone is dependent on the location of the removed column. The panelzone deformation could be notable if an exterior joint is engaged in the progressive collapse mechanism, while when all joints are interior, the effect of the panelzone deformation on the performance of the frame is not significant. For structures designed for high seismic load, it was also indicated that the panelzone consideration had little effect on the overall performance of the structure. In contrast, the performance of low-rise structures designed only for gravity loads could significantly be affected by the deformation of the panelzones, especially at the exterior bays. It was also reported that excessive panelzone distortion decreased the ductility demand of the beams in some cases.

In a similar study, Kordbagh and Mohammadi [18] investigated special moment-resisting frames under corner and middle column removal scenarios. The results revealed that considering panelzone in the structure with I-section columns notably increased the maximum and permanent vertical displacement of the frame, especially when the removed column was an exterior one. As a general conclusion, the panelzone effect must be considered for progressive collapse evaluation of moment-resisting structures if the panelzones were designed only for minimum requirements recommended by building codes.

Most of the previous studies used macro-level models to evaluate the effect of the beam-to-column strength ratio and the panelzone strength. Such models are not able to provide details about other level phenomena like the joints fracture mode and local plastic deformations.

2 OBJECTIVE AND SCOPE

In this paper, a frame subassembly from an exterior bay of an 8-story moment-resisting structure located in a low-seismic zone was studied under a column removal situation. In such structures, the beam-to-column strength ratio limit is usually ignored due to low seismic hazard. Therefore, two configurations of the selected subassembly with different beam-to-column strength ratios (and different panelzone strength) were investigated by nonlinear finite element simulations. A calibrated plasticity model in conjunction with a ductile damage initiation criterion was used to predict the performance of the subassemblies. These two subassemblies were compared in terms of the capacity and the pattern of ductile fracture.

3 DESCRIPTION OF THE FRAME SUBASSEMBLIES

An 8-story building with a steel moment-resisting system designed for a low-seismic area (e.g., Norway) with 0.1g design ground acceleration was selected as a case study. In terms of geometry, the structure was considered with four equal bays of 5 m (see Fig. 1(a)). Also, each story was assumed to be 3m in height. Besides seismic loads, the structure was designed for 30 kN/m and 12 kN/m uniformly distributed dead and live loads, respectively. The frame was designed according to EC8 [6] for a low ductility class with a behavior factor (q) equal to 2. In this ductility class controlling the strong-column-weak-beam criterion is not obligatory. It is worth mentioning that in the design process of this frame, strength criteria were dominant in the design of the sections, and the size of the beams was constant over the height of the building. All elements were selected from S355J2 structural steel with 355 MPa nominal yield strength. Welded Unreinforced Flange-Welded web (WUF-W) connections described in Fig. 1(c) were employed as the moment-resisting connections to resist lateral seismic loads. The weld access holes with the geometry adapted from AWS D1.8, 2016 [19] was implemented in the web of the beams to provide enough space for the flange Complete Joint Penetration welds (CJPs).

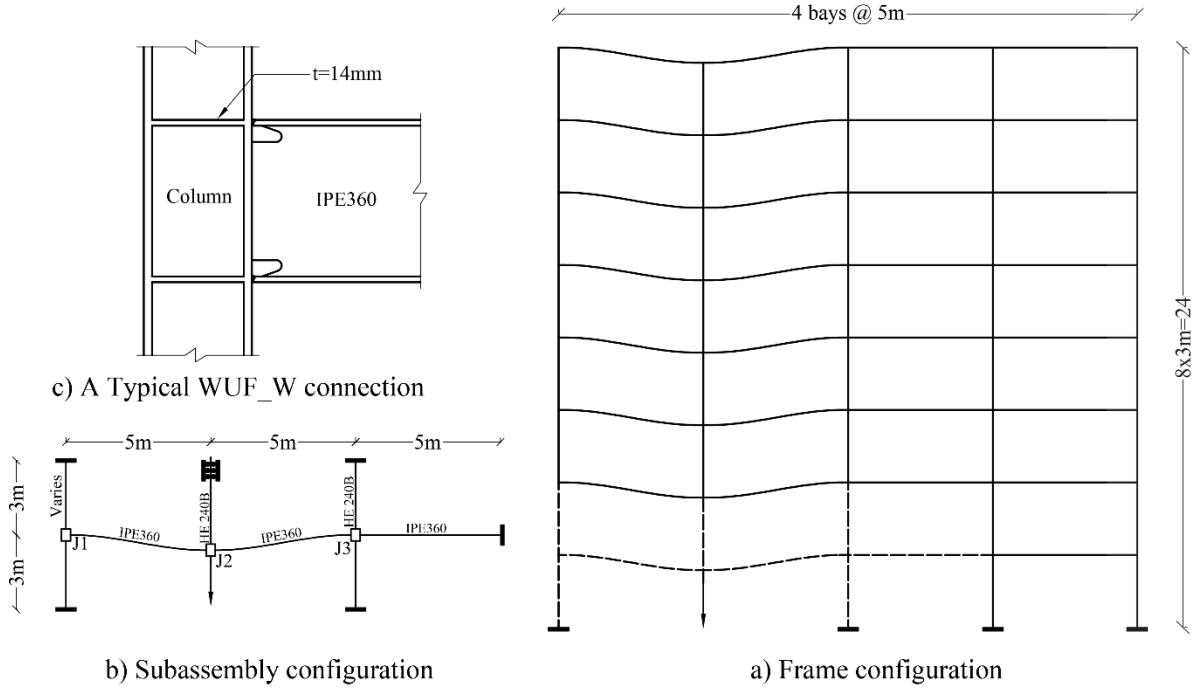

Figure 1: Configuration of a) the studied 8-story moment-resisting frame b) the subassembly c) Welded Unreinforced Flange-Welded web (WUF-W) connections.

Since analyzing the whole of the structure at the micro-level is challenging in terms of computational time and effort, a subassembly of the frame located at the first story as shown in Fig.1(b) was chosen for the finite element analyses. As it is apparent in this figure, this subassembly included three joints (J1, J2, and J3) connected by beams and columns with boundary conditions applied at the interface points between the subassembly and the rest of the frame. This subassembly was selected because the asymmetric strength of the joint J1 and J3 can also provide more detailed information regarding the effects of the beam-to-column joint strength. The previous studies also indicated that in this scenario, the panelzones have the most influence [17].

All design sections were the same in two subassemblies except the left column cross section that varies between HE180B and HE240B to study the effect of the beam-to-column strength ratio and the panelzone strength of the exterior joint. It should be noted that Subassembly-1 is from the original design of the frame that HE180B section was adequate as the left column for applied loads. On the other hand, in Subassembly-2, HE240B as the left column is a conservative design compared to the original frame.

4 NUMERICAL MODELS

4.1 Material model

Ductile fracture is known as a continuous process in which nucleation, growth, and coalescence of microvoids in ductile metals lead to form a new free surface in the material. Based on the prior studies [20-24], ductile fracture initiation is a function of equivalent plastic strain, stress triaxiality, strain rate, and Lode angle; however, the later one is less important when the structure is under tension load (positive triaxiality) [24, 25]. So far, several fracture models have been developed and utilized for predicting and evaluating the ductile fracture in steel structures. Some of these models are more complicated to be implemented (e.g., the Gurson-Tvergaard-Needleman model has over ten parameters for a single material [26]). Some other models (e.g., Johnson-Cook [20] and Bai-Wierzbicki [25]) are more appropriate for engineering applications where the uniaxial test is a standard test.

In this study, a phenomenological ductile damage model for predicting the onset of ductile fracture [27, 28] was used to investigate the fracture pattern of the studied subassemblies. In this model, it is assumed that the equivalent plastic strain at the onset of damage (ε_D^{pl}), is a function of stress triaxiality and strain rate [27]:

$$\varepsilon_D^{pl}(\eta, \dot{\varepsilon}^{pl}) \tag{1}$$

Where $\eta = {}^{\sigma_m}/_{\sigma_{eq}}$ is the stress triaxiality, σ_m is hydrostatic pressure and σ_{eq} is Mises equivalent stress. $\dot{\varepsilon}^{pl}$ also denotes the strain rate. Based on this definition, the damage variable can be defined as follows [7]:

$$D = \int \frac{d\varepsilon^{pl}}{\varepsilon_D^{pl}(\eta, \dot{\varepsilon}^{pl})} \tag{2}$$

This damage variable is an incremental state variable that increases monotonically with plastic deformations (ε^{pl}) to reach D=1 which indicates the fracture initiation. To use this model, a fracture strain curve in the space of ε^{pl}-η is needed. This curve was obtained by performing uniaxial tests under different triaxiality states for steel grade S355J2, as shown in Fig. 2. The described ductile fracture criterion was used in conjunction with the Mises plasticity and a linear isotropic hardening rule as the material model. To calibrate the stress-strain behavior of the

S355J2 material, five round smooth samples were tested under the uniaxial tensile test. Fig.3 shows the geometry of the samples.

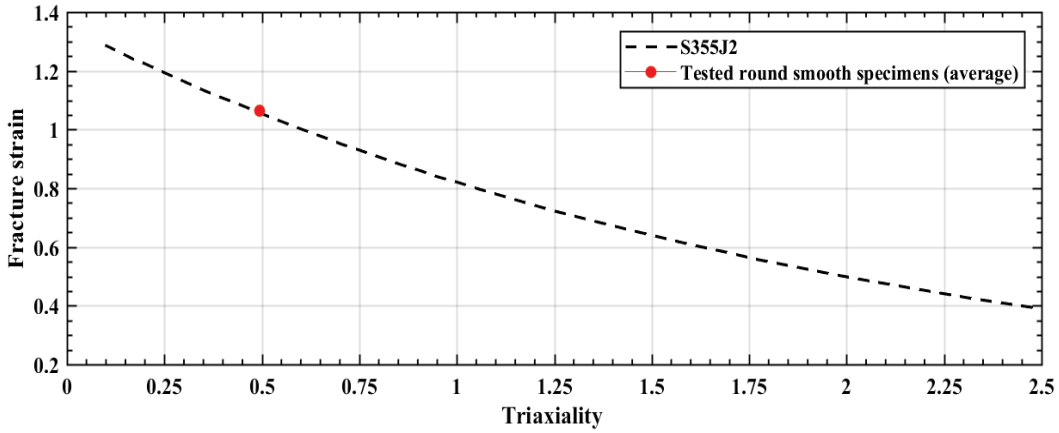

Figure 2: Fracture strain curve for S355J2 at different triaxiality.The curve adapted from [29].

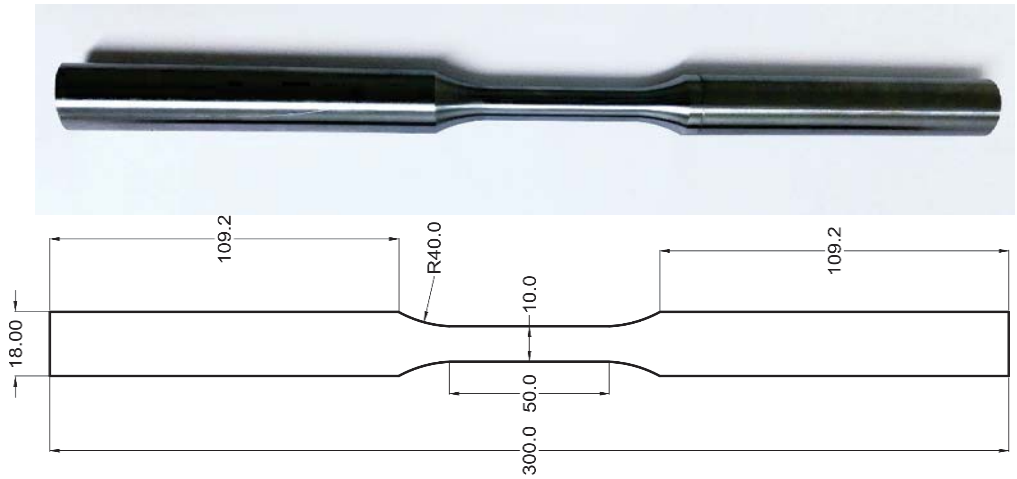

Figure 3: The geometry of round smooth tensile specimens.

All specimens were taken from a flat plate with 25mm thickness in the rolling direction. It should be noted that the effect of the strain rate was outside of the scope so that all tests were conducted at a strain rate of 0.002 mm/mm/s.

A 50mm axial extensometer and a digital image correlation system (DIC) were used to measure the elongation of the gage length. Using DIC can provide the fracture strain of each sample precisely. For example, as shown in Fig. 4, the fracture strain was 1.047 and 1.075 in sample MU1 and MU4, respectively. The engineering stress-strain curves for all tested samples are illustrated in Fig. 5.

To calibrate the ductile damage model an average fracture strain of all five samples ($\bar{\varepsilon}_f = 1.064$) was used. The point corresponding to the average fracture strain and triaxiality of the samples is plotted in Fig. 2 to validate the curve at least at one point. Since the stress triaxiality is varying after the necking of the samples, an average value was obtained ($\bar{\eta} = 0.49$) from the numerical simulation. Fig. 2 indicates a good agreement between the curve and experimental results for round smooth bar samples (plotted by a red circle).

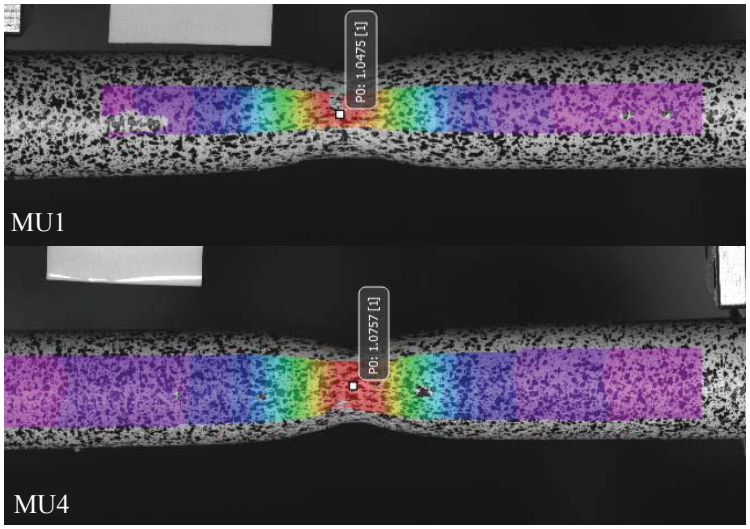

Figure 4: Fracture strain of samples MU1 and MU4 extracted from DIC.

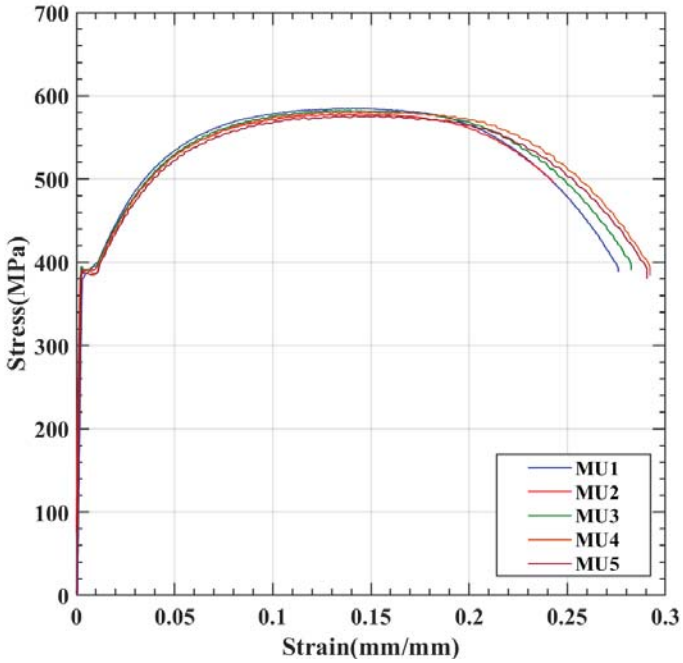

Figure 5: Engineering stress-strain curves for tested round smooth bar samples.

To use the test data in the material plasticity model, true stress-strain curves are required. Before the necking that the uniaxial state is governed, the true strain and stress can be obtained as follows:

$$\varepsilon_t = \ln(\varepsilon_e + 1)$$
$$\sigma_t = (1 + \varepsilon_e)\sigma_e \tag{3}$$

Where ε_t and σ_t are true strain and stress respectively, while ε_e and σ_e denote engineering values.

After necking, these relations are invalid due to stress triaxiality and strain localization. Therefore, a linear transition was assumed between the ultimate and the fracture point. The fracture strain could be obtained by DIC; however, the equivalent true fracture stress also

should be calculated to consider the triaxial stress state. Bridgman proposed an approximate conversion from a triaxial stress state into an equivalent stress σ_{eff} by using the geometry of the samples as follows [30]:

$$\sigma_{eff} = \frac{\sigma_t}{(1 + \frac{4R}{D}) \times ln(1 + \frac{D}{4R})} \tag{4}$$

Where D is the diameter of the sample, and R is the radius of curvature at the fracture point. These two parameters can be measured at the fracture point by image processing (e.g., See Fig. 6 for sample MU1).

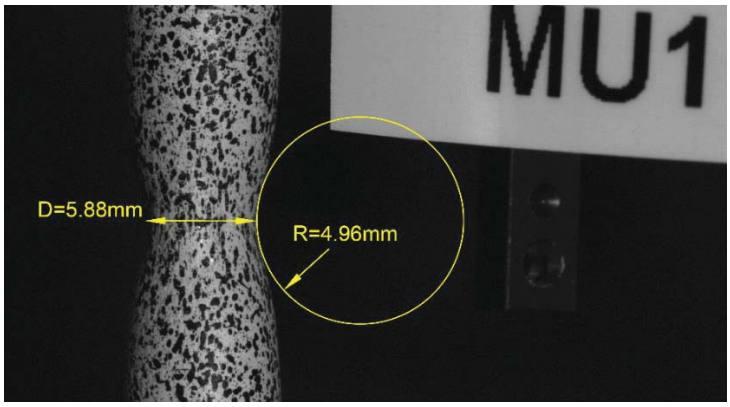

Figure 6: The diameter of the sample and the radius of curvature at the fracture point for sample MU1.

The calibrated material plasticity and damage model verified by numerical models. For instance, Fig. 7 compares the experimental and numerical force-displacement curves for the MU1 specimen. As this figure shows, there is a good agreement between numerical and experimental curves.

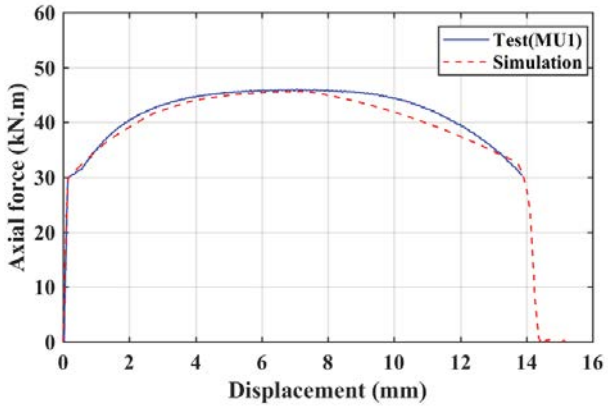

Figure 7: Ductile damage model verification for sample MU1.

4.2 Finite element models of the subassemblies

To predict the ductile fracture of two pre-described subassemblies, nonlinear finite element models were created in Abaqus/CAE. The explicit solver was employed due to its efficiency in conducting and converging extreme nonlinear behavior, particularly when a fracture and material separation are simulated. The simulations were implemented as a quasi-static to find the

capacity of the subassemblies and track the fracture behavior of the components under incremental displacement imposed at the point of the removed column.

For all nonlinear parts around the beam-to-column joints, the eight-node solid brick elements with reduced integration points (C3D8R) with a fine mesh were applied for the discretization of the models (see Fig. 8). These fine-meshed domains were assumed to have a length at least equal to the depth of beam or column that is known as the most probable place for plastic hinges formation. In these areas, the thickness of beams flanges and webs divided into at least four layers of element.

On the other hand, the middle parts of the beams and columns were modeled by a coarse mesh to reduce the time of analyses. To make an appropriate transition between the fine-meshed and the coarse-meshed areas a combination of C3D8R and six-node wedge element (C3D6) was used as shown in Fig. 8. It is worth mentioning that in numerical models, the properties of the welds were ignored.

An incremental displacement was applied to the removed column at joint J2, and the boundary conditions were defined as shown in Fig. 1(b). Also, it was supposed that beams flanges and columns at the joint level are laterally braced due to the slab system and secondary beams.

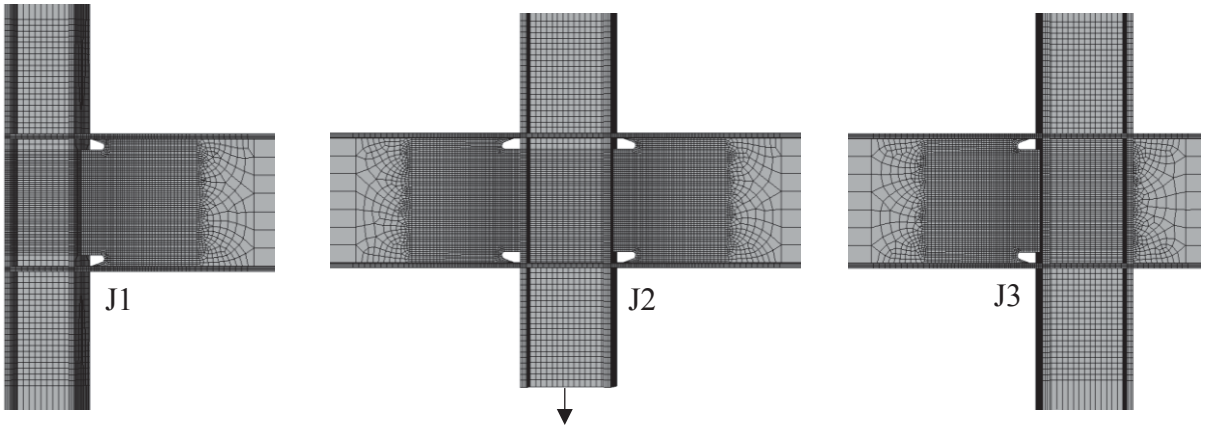

Figure 8: Finite element discretization of subassemblies with a fine mesh around the joints.

5 RESULTS

Fig. 9 compares the force-vertical displacement of two described subassemblies. Comparing of the subassemblies can be done in different aspects and parameters. In terms of yielding strength, both subassemblies provided approximately similar global yielding strength; however, due to the panelzone distortion in the Subassembly-1 with HE180B column, the panelzone in J1 was the first component that experienced plastic deformations, while the beam in this joint had a limited plastic strain even at the last step of the analysis. Moreover, this panelzone distortion imposed the maximum equivalent plastic strain (PEEQ) in the upper column of the joint J1. Forming plastic hinge and excessive lateral deformation of the column can increase the potential of post-yield buckling of the column under axial loads. In contrast, in the other subassembly (with HE240B column) the panelzone yielded after some plastification in the beam so that in the last step of the analysis, the maximum PEEQ occurred in the beam area while the upper column exhibited a low amount of plastic deformations.

Before any fracture initiation in the subassemblies, the Subassembly-2 with stronger joint J1 provided significantly more vertical strength. For example, in the vertical displacement of 877mm that is corresponding to the onset of fracture in the bottom flange of the joint J2 in the

Subassembly-2, the vertical strength of this subassembly was about 44% more than Subassembly-1.

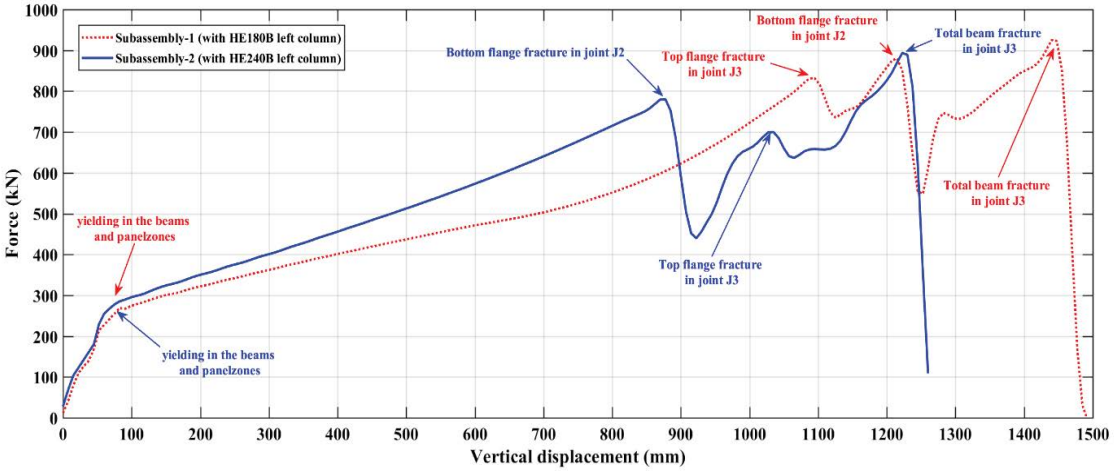

Figure 9: Vertical force-displacement curves for two studied frame subassemblies.

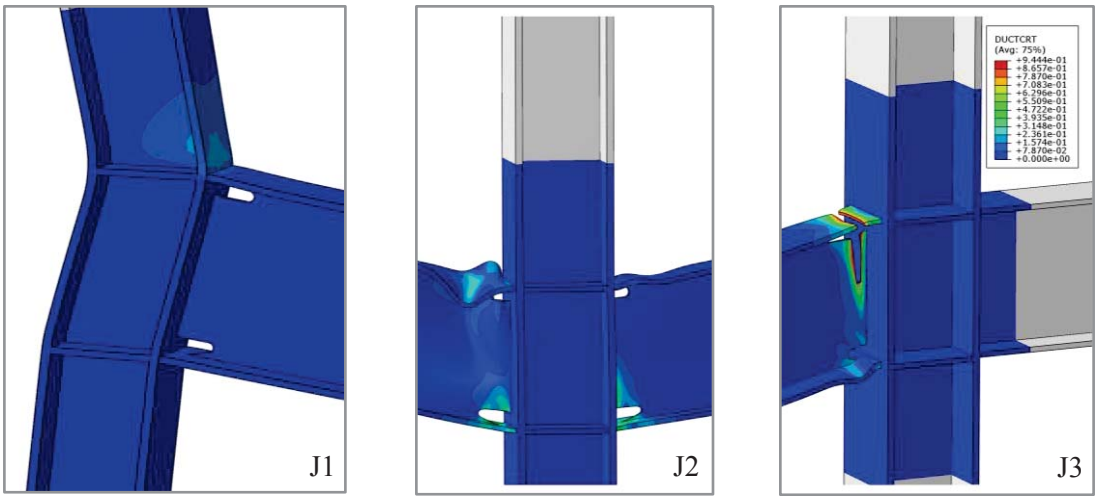

Figure 10: Distribution of ductile damage variable (D) at different joints in Subassembly-1 (ductile fracture initiated and developed firstly in J3)

In terms of ductile fracture initiation pattern, as shown in Fig.10 for the Subassembly-1, due to unbalanced stiffness and catenary action in the two sides beams, the fracture firstly initiated at the top flange of the beam in J3 joint and then developed to the web of the beam. When the right beam lost some amount of its stiffness, the fracture also initiated at the bottom flange in the other side beam in the joint J2.

On the other hand, the Subassembly-2 exhibited a vice-versa fracture initiation pattern. In other words, due to the stronger J1 joint, the stiffness and catenary action is more balanced than the Subassembly-1. As Fig.11 indicates the fracture initiated at the left beam of the joint J2. By developing the crack in the beam web and decreasing the beam stiffness, the J3 joint finally experienced the fracture at the top flange of the beam.

An interesting trend can be drawn from Fig.9 although the complete fracture of beams for both subassemblies happened in joint J3 and the cap vertical forces of both subassemblies are approximately similar, the Subassembly-1 exhibited larger vertical displacement than the Subassembly-2. This extra displacement caused by the excessive distortion of joint J1 (less stiffness) that delayed the activation of the catenary action in the beams. As a result, a weak panelzone

can significantly increase the vertical displacement demand of the frames and have to be considered in the frame analysis.

In addition, if the maximum vertical displacement demand obtained from the nonlinear dynamic analysis of the frame under similar column removal scenario was less than vertical displacement corresponding to ductile fracture initiation of subassemblies (in the capacity curves), using a simplified material model like a bilinear model can provide valid results in nonlinear dynamic analysis of the frame.

All these conclusions were made based on the assumption that welds material possesses higher toughness than base metal and the welds are without defects and significant stress and strain concentration.

6 CONCLUSIONS

A frame subassembly from an 8-story ordinary steel moment-resisting structure was studied for a column removal situation. The capacity and the fracture pattern of the subassembly obtained for different exterior joint strength. Based on the results from numerical models, the following conclusions can be drawn:

- The strength of the exterior joints in outer bays of such structures can significantly affect the fracture pattern and the capacity of the frame under a column removal situation.
- When an exterior weak joint was used, excessive plastic deformation of the panelzone led to an unbalanced state in catenary action so that the asymmetric force induced the fracture at the end of the right beam near to the interior joint. In contrast, when a stronger exterior joint was used, the rigidity of the panelzone led to make a balanced state in catenary action so that the fracture occurred at the left beam near to the middle joint that the column was removed.
- Before any fracture initiation, the vertical strength of the specimen with a stronger exterior joint showed about 44% more strength than the model with a weaker exterior joint; however, the maximum resisted vertical force for both models was approximately similar.

- In general, although the beam-to-column strength ratio and the panelzone strength usually are less critical in the standard procedure of design of moment-resisting structures in a low seismic zone, special consideration is needed when such structures are also designed for a progressive collapse situation.

Keywords: numerical simulations, lateral buckling, seismic scenarios, HP/HT subsea pipelines

Abstract. *Vulnerability of subsea high pressure/high temperature (HP/HT) pipelines to seismic actions is studied numerically. This study focuses on the response of an unburied pipeline, laid on the seabed and resting on a sleeper. Two different scenarios are considered: (1) earthquake imposed on a laterally buckled pipeline and (2) earthquake imposed at temperatures lower than the lateral buckling temperature. The onset of yield and development of compressive local wrinkles in the wall thickness are calculated as the failure modes.*

1 INTRODUCTION

Resilience of pipelines during catastrophic events is a strategic issue that has a great impact on both society and the environment [1], being particularly vulnerable to high-intensity earthquakes as demonstrated during the 1989 Loma Prieta earthquake [2], the 1995 Kobe earthquake [3], and the Chi-Chi earthquake in 1999 [4]. Consequences of seismic events can potentially worsen in hazardous areas subjected to other risks, such as slope instability, landslide, soil liquefaction and fault movements [5]. International codes such as ALA [6] provide specifications for the seismic design of buried pipelines.
